Contents

Preface
Anne Benoit, Haim Kaplan, Sebastian Wild, and Grzegorz Herman 0:xv

Program Committees
..... 0:xvii

External Reviewers
..... 0:xix

Invited Talks

Graph Decompositions and Length-Constrained Expanders
Bernhard Haeupler 1:1–1:2

Securing Dynamic Data: A Primer on Differentially Private Data Structures
Monika Henzinger and Roodabeh Safavi 2:1–2:14

Regular Papers

Generalized Graph Packing Problems Parameterized by Treewidth
Barış Can Esmer and Dániel Marx 3:1–3:15

Optimal Quantum Algorithm for Estimating Fidelity to a Pure State
Wang Fang and Qisheng Wang 4:1–4:12

External-Memory Priority Queues with Optimal Insertions
Gerth Stølting Brodal, Michael T. Goodrich, John Iacono, Jared Lo, Ulrich Meyer, Victor Pagan, Nodari Sitchinava, and Rolf Svenning 5:1–5:14

On the Complexity of Knapsack Under Explorable Uncertainty: Hardness and Algorithms
Jens Schlöter 6:1–6:15

Graph Modification of Bounded Size to Minor-Closed Classes as Fast as Vertex Deletion
Laure Morelle, Ignasi Sau, and Dimitrios M. Thilikos 7:1–7:18

Fast Computation of k-Runs, Parameterized Squares, and Other Generalised Squares
Yuto Nakashima, Jakub Radoszewski, and Tomasz Waleń 8:1–8:18

MorphisHash: Improving Space Efficiency of ShockHash for Minimal Perfect Hashing
Stefan Hermann 9:1–9:16

Connected Partitions via Connected Dominating Sets
Aikaterini Niklanovits, Kirill Simonov, Shaily Verma, and Ziena Zeif 10:1–10:14

Courcelle's Theorem for Lipschitz Continuity
Tatsuya Gima, Soh Kumabe, and Yuichi Yoshida 11:1–11:14

33rd Annual European Symposium on Algorithms (ESA 2025).
Editors: Anne Benoit, Haim Kaplan, Sebastian Wild, and Grzegorz Herman
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Subtrajectory Clustering and Coverage Maximization in Cubic Time, or Better
Jacobus Conradi and Anne Driemel 12:1–12:18

Tight Bounds for Some Classical Problems Parameterized by Cutwidth
Narek Bojikian, Vera Chekan, and Stefan Kratsch 13:1–13:17

Testing Sumsets Is Hard
Xi Chen, Shivam Nadimpalli, Tim Randolph, Rocco A. Servedio, and Or Zamir .. 14:1–14:16

Linear Layouts Revisited: Stacks, Queues, and Exact Algorithms
Thomas Depian, Simon D. Fink, Robert Ganian, and Vaishali Surianarayanan ... 15:1–15:18

On Algorithmic Applications of $\mathcal{F}$-Branchwidth
Benjamin Bergougnoux, Thekla Hamm, Lars Jaffke, and Paloma T. Lima 16:1–16:17

Weighted Matching in a Poly-Streaming Model
Ahammed Ullah, S M Ferdous, and Alex Pothen 17:1–17:18

Efficiency of Learned Indexes on Genome Spectra
Md. Hasin Abrar, Paul Medvedev, and Giorgio Vinciguerra 18:1–18:18

On Finding ℓ-Th Smallest Perfect Matchings
Nicolas El Maalouly, Sebastian Haslebacher, Adrian Taubner, and Lasse Wulf 19:1–19:15

Beeping Deterministic CONGEST Algorithms in Graphs
Pawel Garncarek, Dariusz R. Kowalski, Shay Kutten, and Miguel A. Mosteiro 20:1–20:17

A Unified FPT Framework for Crossing Number Problems
Éric Colin de Verdière and Petr Hliněný 21:1–21:18

Constructing Long Paths in Graph Streams
Christian Konrad and Chhaya Trehan 22:1–22:19

Computing Largest Subsets of Points Whose Convex Hulls Have Bounded Area and Diameter
Gianmarco Picarella, Marc van Kreveld, Frank Staals, and Sjoerd de Vries 23:1–23:16

Fréchet Distance in Unweighted Planar Graphs
Ivor van der Hoog, Thijs van der Horst, Eva Rotenberg, and Lasse Wulf 24:1–24:16

Instance-Optimal Imprecise Convex Hull
Sarita de Berg, Ivor van der Hoog, Eva Rotenberg, Daniel Rutschmann, and Sampson Wong 25:1–25:15

Faster Dynamic 2-Edge Connectivity in Directed Graphs
Loukas Georgiadis, Konstantinos Giannis, and Giuseppe F. Italiano 26:1–26:16

Online Makespan Scheduling Under Scenarios
Ekin Ergen 27:1–27:16

Sliding Squares in Parallel
Hugo A. Akitaya, Sándor P. Fekete, Peter Kramer, Saba Molaei, Christian Rieck, Frederick Stock, and Tobias Wallner 28:1–28:17

The Tape Reconfiguration Problem and Its Consequences for Dominating Set Reconfiguration
Nicolas Bousquet, Quentin Deschamps, Arnaud Mary, Amer E. Mouawad, and Théo Pierron 29:1–29:15

Reconstructing Random Graphs from Distance Queries
Michael Krivelevich and Maksim Zhukovskii 30:1–30:17

An Optimal Algorithm for Shortest Paths in Unweighted Disk Graphs
Bruce W. Brewer and Haitao Wang 31:1–31:8

Linear-Time Multilevel Graph Partitioning via Edge Sparsification
Lars Gottesbüren, Nikolai Maas, Dominik Rosch, Peter Sanders, and Daniel Seemaier 32:1–32:20

Better Indexing for Rectangular Pattern Matching
Paweł Gawrychowski and Adam Górkiewicz 33:1–33:7

On the Approximability of Train Routing and the Min-Max Disjoint Paths Problem
Umang Bhaskar, Katharina Eickhoff, Lennart Kauther, Jannik Matuschke, Britta Peis, and Laura Vargas Koch 34:1–34:15

The Geodesic Fréchet Distance Between Two Curves Bounding a Simple Polygon
Thijs van der Horst, Marc van Kreveld, Tim Ophelders, and Bettina Speckmann . 35:1–35:16

Efficient Contractions of Dynamic Graphs – With Applications
Monika Henzinger, Evangelos Kosinas, Robin Münk, and Harald Räcke 36:1–36:14

Hardness of Computation of Quantum Invariants on 3-Manifolds with Restricted Topology
Henrique Ennes and Clément Maria 37:1–37:16

Tight Guarantees for Cut-Relative Survivable Network Design via a Decomposition Technique
Nikhil Kumar, J. J. Nan, and Chaitanya Swamy 38:1–38:18

Going Beyond Surfaces in Diameter Approximation
Michał Włodarczyk 39:1–39:19

Maximum List r-Colorable Induced Subgraphs in kP_3-Free Graphs
Esther Galby, Paloma T. Lima, Andrea Munaro, and Amir Nikabadi 40:1–40:13

Min-Max Correlation Clustering via Neighborhood Similarity
Nairen Cao, Steven Roche, and Hsin-Hao Su 41:1–41:18

(Multivariate) k-SUM as Barrier to Succinct Computation
Geri Gokaj, Marvin Künnemann, Sabine Storandt, and Carina Truschel 42:1–42:19

Edge Clique Partition and Cover Beyond Independence
Fedor V. Fomin, Petr A. Golovach, Danil Sagunov, and Kirill Simonov 43:1–43:16

Near-Optimal Vertex Fault-Tolerant Labels for Steiner Connectivity
Koustav Bhanja and Asaf Petruschka 44:1–44:13

Bounded Weighted Edit Distance: Dynamic Algorithms and Matching Lower Bounds
Itai Boneh, Egor Gorbachev, and Tomasz Kociumaka 45:1–45:16

Max-Distance Sparsification for Diversification and Clustering
Soh Kumabe 46:1–46:14

Fast and Lightweight Distributed Suffix Array Construction
Manuel Haag, Florian Kurpicz, Peter Sanders, and Matthias Schimek 47:1–47:18

The Support of Bin Packing Is Exponential
Klaus Jansen, Lis Pirotton, and Malte Tutas 48:1–48:16

Efficient Top-Down Updates in AVL Trees
Vincent Jugé 49:1–49:15

Online Hitting Sets for Disks of Bounded Radii
Minati De, Satyam Singh, and Csaba D. Tóth 50:1–50:16

Quantum Approximate k-Minimum Finding
Minbo Gao, Zhengfeng Ji, and Qisheng Wang 51:1–51:15

Beating Competitive Ratio 4 for Graphic Matroid Secretary
Kiarash Banihashem, MohammadTaghi Hajiaghayi, Dariusz R. Kowalski, Piotr Krysta, Danny Mittal, and Jan Olkowski 52:1–52:16

When Is String Reconstruction Using de Bruijn Graphs Hard?
Ben Bals, Sebastiaan van Krieken, Solon P. Pissis, Leen Stougie, and Hilde Verbeek 53:1–53:16

Non-Boolean OMv: One More Reason to Believe Lower Bounds for Dynamic Problems
Bingbing Hu and Adam Polak 54:1–54:16

Safe Sequences via Dominators in DAGs for Path-Covering Problems
Francisco Sena, Romeo Rizzi, and Alexandru I. Tomescu 55:1–55:17

PLS-Completeness of String Permutations
Dominik Scheder and Johannes Tantow 56:1–56:14

Improved Hardness-Of-Approximation for Token-Swapping
Sam Hiken and Nicole Wein 57:1–57:16

Streaming Diameter of High-Dimensional Points
Magnús M. Halldórsson, Nicolaos Matsakis, and Pavel Veselý 58:1–58:10

Improved Dominance Filtering for Unions and Minkowski Sums of Pareto Sets
Konstantinos Karathanasis, Spyros Kontogiannis, and Christos Zaroliagis 59:1–59:17

Fast and Memory-Efficient BWT Construction of Repetitive Texts Using Lyndon Grammars
Jannik Olbrich 60:1–60:19

ε-Net Algorithm Implementation on Hyperbolic Surfaces
Vincent Despré, Camille Lanuel, Marc Pouget, and Monique Teillaud 61:1–61:18

Polynomial-Time Constant-Approximation for Fair Sum-Of-Radii Clustering
Sina Bagheri Nezhad, Sayan Bandyapadhyay, and Tianzhi Chen 62:1–62:16

Connected $\boldsymbol{k}$-Median with Disjoint and Non-Disjoint Clusters
Jan Eube, Kelin Luo, Dorian Reineccius, Heiko Röglin, and Melanie Schmidt 63:1–63:14

A Dynamic Piecewise-Linear Geometric Index with Worst-Case Guarantees
Emil Toftegaard Gæde, Ivor van der Hoog, Eva Rotenberg, and Tord Stordalen ... 64:1–64:18

From Theory to Practice: Engineering Approximation Algorithms for Dynamic Orientation
Ernestine Grossmann, Henrik Reinstädtler, Eva Rotenberg, Christian Schulz, Ivor van der Hoog, and Juliette Vlieghe 65:1–65:18

Bicriteria Approximation for k-Edge-Connectivity
Zeev Nutov and Reut Cohen 66:1–66:17

Compact Representation of Semilinear and Terrain-Like Graphs
Jean Cardinal and Yelena Yuditsky 67:1–67:19

Faster Algorithm for Second (s,t)-Mincut and Breaking Quadratic Barrier for Dual Edge Sensitivity for (s,t)-Mincut
Surender Baswana, Koustav Bhanja, and Anupam Roy 68:1–68:19

Bandwidth vs BFS Width in Matrix Reordering, Graph Reconstruction, and Graph Drawing
David Eppstein, Michael T. Goodrich, and Songyu (Alfred) Liu 69:1–69:17

Improved Parallel Derandomization via Finite Automata with Applications
Jeff Giliberti and David G. Harris 70:1–70:17

Simpler Universally Optimal Dijkstra
Ivor van der Hoog, Eva Rotenberg, and Daniel Rutschmann 71:1–71:9

Color Distance Oracles and Snippets: Separation Between Exact and Approximate Solutions
Noam Horowicz and Tsvi Kopelowitz 72:1–72:17

Classical Algorithms for Constant Approximation of the Ground State Energy of Local Hamiltonians
François Le Gall 73:1–73:19

Core-Sparse Monge Matrix Multiplication: Improved Algorithm and Applications
Paweł Gawrychowski, Egor Gorbachev, and Tomasz Kociumaka 74:1–74:17

An Improved Bound for Plane Covering Paths
Hugo A. Akitaya, Greg Aloupis, Ahmad Biniaz, Prosenjit Bose, Jean-Lou De Carufel, Cyril Gavoille, John Iacono, Linda Kleist, Michiel Smid, Diane Souvaine, and Leonidas Theocharous 75:1–75:10

A 3.3904-Competitive Online Algorithm for List Update with Uniform Costs
Mateusz Basiak, Marcin Bienkowski, Martin Böhm, Marek Chrobak, Łukasz Jeż, Jiří Sgall, and Agnieszka Tatarczuk 76:1–76:15

Tolerant Testers for Subgraph-Freeness
Reut Levi and Jonathan Meiri 77:1–77:15

Testing Depth First Search Numbering
Artur Czumaj, Christian Sohler, and Stefan Walzer 78:1–78:16

Semi-Streaming Algorithms for Hypergraph Matching
Henrik Reinstädtler, S M Ferdous, Alex Pothen, Bora Uçar, and Christian Schulz 79:1–79:19

Online Metric TSP
Christian Bertram 80:1–80:9

An $O(n \log n)$ Algorithm for Single-Source Shortest Paths in Disk Graphs
Mark de Berg and Sergio Cabello 81:1–81:15

Buffered Partially-Persistent External-Memory Search Trees
Gerth Stølting Brodal, Casper Moldrup Rysgaard, and Rolf Svenning 82:1–82:18

Fault-Tolerant Matroid Bases
Matthias Bentert, Fedor V. Fomin, Petr A. Golovach, and Laure Morelle 83:1–83:14

Property Testing of Curve Similarity
Peyman Afshani, Maike Buchin, Anne Driemel, Marena Richter, and Sampson Wong 84:1–84:16

A Simple yet Exact Analysis of the MultiQueue
Stefan Walzer and Marvin Williams 85:1–85:14

New Algorithms for Pigeonhole Equal Subset Sum
Ce Jin, Ryan Williams, and Stan Zhang 86:1–86:12

Multicut Problems in Almost-Planar Graphs: the Dependency of Complexity on the Demand Pattern
Florian Hörsch and Dániel Marx 87:1–87:13

Parameterized Approximability for Modular Linear Equations
Konrad K. Dabrowski, Peter Jonsson, Sebastian Ordyniak, George Osipov, and Magnus Wahlström 88:1–88:15

A Simple Algorithm for Trimmed Multipoint Evaluation
Nick Fischer, Melvin Kallmayer, and Leo Wennmann 89:1–89:11

Separating Two Points with Obstacles in the Plane: Improved Upper and Lower Bounds
Jack Spalding-Jamieson and Anurag Murty Naredla 90:1–90:18

Near-Optimal Differentially Private Graph Algorithms via the Multidimensional AboveThreshold Mechanism
Laxman Dhulipala, Monika Henzinger, George Z. Li, Quanquan C. Liu, A. R. Sricharan, and Leqi Zhu 91:1–91:20

Incremental Maximization for a Broad Class of Objectives
Yann Disser and David Weckbecker 92:1–92:13

Recognizing and Realizing Temporal Reachability Graphs
Thomas Erlebach, Othon Michail, and Nils Morawietz 93:1–93:18

Faster Algorithm for Bounded Tree Edit Distance in the Low-Distance Regime
Tomasz Kociumaka and Ali Shahali 94:1–94:16

The Planted Orthogonal Vectors Problem
David Kühnemann, Adam Polak, and Alon Rosen 95:1–95:17

Counting Small Induced Subgraphs: Scorpions Are Easy but Not Trivial
Radu Curticapean, Simon Döring, and Daniel Neuen 96:1–96:16

A Fast and Simple Algorithm for the Resource Constrained Shortest Path Problem
Saman Ahmadi, Andrea Raith, and Mahdi Jalili 97:1–97:15

Fine-Grained Classification of Detecting Dominating Patterns
Jonathan Dransfeld, Marvin Künnemann, and Mirza Redzic 98:1–98:15

Engineering Minimal k-Perfect Hash Functions
Stefan Hermann, Sebastian Kirmayer, Hans-Peter Lehmann, Peter Sanders, and Stefan Walzer 99:1–99:18

Cut-Query Algorithms with Few Rounds
Yotam Kenneth-Mordoch and Robert Krauthgamer 100:1–100:14

Improved Algorithms for Quantum MaxCut via Partially Entangled Matchings
Anuj Apte, Eunou Lee, Kunal Marwaha, Ojas Parekh, and James Sud 101:1–101:14

A Combinatorial Proof of Universal Optimality for Computing a Planar Convex Hull
Ivor van der Hoog, Eva Rotenberg, and Daniel Rutschmann 102:1–102:13

On the Satisfiability of Random 3-SAT Formulas with k-Wise Independent Clauses
Ioannis Caragiannis, Nick Gravin, and Zhile Jiang 103:1–103:17

Optimal Antimatroid Sorting
Benjamin Aram Berendsohn 104:1–104:14

Parameterized Algorithms for Computing Pareto Sets
Joshua Marc Könen, Heiko Röglin, and Tarek Stuck 105:1–105:15

On Estimating the Quantum ℓ_α Distance
Yupan Liu and Qisheng Wang 106:1–106:19

Length-Constrained Directed Expander Decomposition and Length-Constrained Vertex-Capacitated Flow Shortcuts
Bernhard Haeupler, Yaowei Long, Thatchaphol Saranurak, and Shengzhe Wang 107:1–107:17

Deterministic Approximation Algorithm for Graph Burning
Matej Lieskovský 108:1–108:7

Combined Search and Encoding for Seeds, with an Application to Minimal Perfect Hashing
Hans-Peter Lehmann, Peter Sanders, Stefan Walzer, and Jonatan Ziegler 109:1–109:18

Faster Exponential Algorithms for Cut Problems via Geometric Data Structures
László Kozma and Junqi Tan 110:1–110:12

Hardness of Median and Center in the Ulam Metric
Nick Fischer, Elazar Goldenberg, Mursalin Habib, and Karthik C. S. 111:1–111:17

A Faster Parametric Search for the Integral Quickest Transshipment Problem
Mariia Anapolska, Dario van den Boom, Christina Büsing, and Timo Gersing 112:1–112:15

Bootstrapping Dynamic APSP via Sparsification
Rasmus Kyng, Simon Meierhans, and Gernot Zöcklein 113:1–113:15

A Deterministic Partition Tree and Applications
Haitao Wang 114:1–114:17

Smoothed Analysis of Online Metric Problems
Christian Coester and Jack Umenberger 115:1–115:14

Fast Gaussian Elimination for Low Treewidth Matrices
Martin Fürer, Carlos Hoppen, and Vilmar Trevisan 116:1–116:15

Preface

This volume contains the extended abstracts selected for presentation at ESA 2025, the 33rd European Symposium on Algorithms. The event was organized by the University of Warsaw, Poland, as a part of ALGO 2025, on September 15–17, 2025.

The scope of ESA includes original, high-quality, theoretical and applied research on algorithms and data structures. Since 2002, it has had two tracks: the Design and Analysis Track (Track A), for papers with a strong emphasis on the theoretical analysis of algorithms, and the Engineering and Applications Track (Track B), for papers reporting on the results of extensive experimental evaluations and/or providing original contributions to the engineering of algorithms for practical applications. In 2022, a Simplicity Track (Track S) was added, inviting submissions that prove or explain results, possibly already known, in a particularly clear, simple or elegant way.

In response to the call for papers for ESA 2025, 372 papers were submitted, 261 for Track A, 54 for Track B, and 57 for Track S (these numbers exclude 5 submissions that were later withdrawn). Paper selection was based on originality, technical quality, exposition quality, and relevance. Each paper received at least three reviews (apart from two exceptional cases).

Due to a substantial increase (+11% compared to last year) in the number of submissions and the strong quality of submitted results, the program committees selected 115 papers for inclusion in the program (also +11%): 83 from Track A, 16 from Track B, and 16 from Track S, yielding an overall acceptance rate of about 31%. The presentations of the accepted papers, together with two invited talks by Bernhard Haeupler (INSAIT, University of Sofia "St Kliment Ohridski" and ETH Zurich) and Monika Henzinger (Institute of Science and Technology Austria) promise to make up an exciting program.

The European Association for Theoretical Computer Science (EATCS) sponsored best paper awards. For Track A, the best paper award was given to Hans-Peter Lehmann, Peter Sanders, Stefan Walzer and Jonatan Ziegler for the paper *Combined Search and Encoding for Seeds, with an Application to Minimal Perfect Hashing*. For Track B, the best paper award was given to Ahammed Ullah, SM Ferdous and Alex Pothen for the paper *Weighted Matching in a Poly-Streaming Model*. For Track S, the best paper award was given to Ivor van der Hoog, Eva Rotenberg and Daniel Rutschmann for the paper *Simpler Universally Optimal Dijkstra*.

As a typical convention in the field is to list authors in alphabetical order, we randomized the order of papers in these proceedings to avoid biases.

We wish to thank all the authors who submitted papers for consideration, the invited speakers, the members of the program committees for their hard work, and the (exactly!) 600 external reviewers who assisted the program committees in the evaluation process. Special thanks go to the organizing committee, who helped us with the organization of the conference.

Information on past ESA symposia, including locations and proceedings, is maintained at `https://algo-conference.org/`.

33rd Annual European Symposium on Algorithms (ESA 2025).

Graph Decompositions and Length-Constrained Expanders

Bernhard Haeupler
INSAIT, Sofia University "St. Kliment Ohridski", Bulgaria
ETH Zürich, Switzerland

Abstract

Graph decompositions are powerful algorithmic tools with wide applications to graph structures (e.g., spanners, hopsets, sparsifiers, oblivious routings, etc.) and network optimization algorithms, including parallel, distributed and dynamic algorithms for flow and distance problems.

Classical graph decompositions include

- low-diameter decomposition, which captures ℓ_1-quantities like lengths and costs, and
- expander decomposition, which captures ℓ_∞-quantities like flows and congestion.

This keynote starts with a brief survey of these classical decompositions, then presents length-constrained expanders and length-constrained expander decompositions – a recent and technically rich generalization that simultaneously controls length and congestion (ℓ_1 & ℓ_∞). Length-constrained expander decompositions significantly broaden and extend the range of applications for graph decompositions, and this talk will discuss several examples and ways to leverage their power.

Securing Dynamic Data: A Primer on Differentially Private Data Structures

Monika Henzinger
Institute of Science and Technology, Klosterneuburg, Austria

Roodabeh Safavi
Institute of Science and Technology, Klosterneuburg, Austria

Abstract

We give an introduction into differential privacy in the dynamic setting, called the continual observation setting.

2012 ACM Subject Classification Security and privacy; Theory of computation

Keywords and phrases Differential privacy, continual observation

1 Introduction

In 2006, Netflix released an anonymized dataset of movie ratings for a public competition. Although names were removed, it was later shown that users could be re-identified by linking the data with publicly available IMDb ratings [39]. This so-called (privacy) attack demonstrated the failure of traditional anonymization techniques, especially when different anonymized datasets are combined. It also highlighted the need for stronger privacy definitions that provide rigorous guarantees even when multiple analyses (or synthetic datasets) based on the same individual's secret data are published.

This motivated the definition of differential privacy (DP), a privacy requirement for mechanisms introduced by Dwork, McSherry, Nissim, and Smith [17]. A differentially private mechanism[1] adds randomness to the output in such a way that, for any two "neighboring" datasets, the resulting output distributions are "close". Formally, the notion of neighboring datasets is defined as a binary relation on the family of datasets, and closeness of output distributions is defined by the following definition of indistinguishability:

▶ **Definition 1** ((ϵ, δ)-indistinguishability). *For $\epsilon \geq 0$ and $0 \leq \delta \leq 1$, two random variables X_0 and X_1 over a domain $\mathcal{Y}$ are (ϵ, δ)-indistinguishable if, for every subset $Y \subseteq \mathcal{Y}$,*

$$Pr[X_0 \in Y] \leq e^{\epsilon} Pr[X_1 \in Y] + \delta.$$

X_0 and X_1 are ϵ-indistinguishable if $\delta = 0$.

Two datasets are typically considered to be neighboring if they differ by the presence or absence of a single data record. With this definition of neighboring, after observing the output of a differentially private mechanism, an attacker cannot confidently determine

[1] In theory, a common way to achieve differential privacy is by adding noise drawn from continuous distributions, such as the Gaussian distribution, when computing data analysis. However, exact sampling from continuous distributions is computationally infeasible. For this reason, the differential privacy literature typically avoids the term "differentially private algorithm" and uses the term "mechanism" instead. In practice, discrete approximations of these continuous distributions – implemented with finite precision – are used instead.

whether any specific data record was included in the input dataset. Let $\mathcal{X}$ denote the family of data records, and $\mathrm{MS}(\mathcal{X})$ denote the set of all multisets over $\mathcal{X}$. A differentially private mechanism is formally defined as follows:

▶ **Definition 2** ((ϵ, δ)-Differential Privacy [17]). *For $\epsilon \geq 0$ and $0 \leq \delta \leq 1$, a randomized mechanism $\mathcal{M} : MS(\mathcal{X}) \to \mathcal{Y}$ is (ϵ, δ)-differentially private (or (ϵ, δ)-DP for short) if, for every two neighboring datasets $D_0, D_1 \in MS(\mathcal{X})$, the random variables $\mathcal{M}(D_0)$ and $\mathcal{M}(D_1)$ are (ϵ, δ)-indistinguishable. $\mathcal{M}$ is ϵ-differentially private (or ϵ-DP for short) if $\delta = 0$.*

Note that there exist problems that can be solved efficiently and with high accuracy in the non-private setting, but for which no differentially private solution exists. The interior point problem is an instance of this: Suppose the data universe $\mathcal{X}$ is totally ordered and datasets are multisets of size $n \in N$ over $\mathcal{X}$. An interior point mechanism takes a dataset D as input and its goal is to return an element $y \in \mathcal{X}$ such that y is an interior point in D, i.e., $\min_{x \in D} x \leq y \leq \max_{x \in D} x$. An interior point mechanism is said to be accurate if for every input dataset, it returns an interior point of the dataset with probability at least 3/4. Differential privacy for this mechanism is defined with respect to neighboring datasets that differ in exactly one element. Bun, Nissim, Stemmer, and Vadhan [6] showed that for any $0 < \epsilon < 1/4$ and $\delta < 1/(50n^2)$, there exists no accurate interior point mechanism that satisfies (ϵ, δ)-DP.

Fundamental properties of differential privacy. Differential privacy is carefully designed to satisfy the following two crucial properties: (i) It is preserved under post-processing, and (ii) executing multiple differentially private mechanisms on the same private dataset remains differentially private, with the privacy parameters determined by those of the executed mechanisms. The first property ensures that any computation applied to the output of a differentially private mechanism does not incur additional privacy loss. For example, a privatized statistic released by a hospital can be safely reused in multiple research studies to derive new results, without further compromising the privacy of the patients. The second property, known as *composition*, provides a bound on the total privacy loss when an individual's data is used in multiple differentially private analyses. The goal of this property is to prevent attacks similar to the Netflix attack discussed before.

In *post-processing*, a subsequent mechanism that does *not* have access to the sensitive dataset uses the output of a DP mechanism as input. The so-called *post-processing lemma* states that this does not affect the differential privacy properties; informally speaking, no more privacy is lost.

▶ **Lemma 3** (Post-Processing [20]). *Let $\mathcal{M} : MS(\mathcal{X}) \to \mathcal{Y}$ be an (ϵ, δ)-DP mechanism, and $f : \mathcal{Y} \to \mathcal{Z}$ be a function. Then, the mechanism $f(\mathcal{M})$, which applies $\mathcal{M}$ to the input and then applies f to its output, is also (ϵ, δ)-DP.*

A different situation arises if the second mechanism has access to the sensitive data as well. In this case, for every output of the first mechanism, the second mechanism must also satisfy differentially private. The following two so-called *composition theorems* analyze the total privacy loss for the combination of the output of multiple mechanisms.

▶ **Theorem 4** (Basic Composition [20]). *Let $\mathcal{M}_1 : MS(\mathcal{X}) \to \mathcal{Y}_1$ and $\mathcal{M}_2 : MS(\mathcal{X}) \to \mathcal{Y}_2$ be mechanisms that satisfy (ϵ_1, δ_1)-DP and (ϵ_2, δ_2)-DP, respectively. Then, the mechanism $\mathcal{M}$, defined as $\mathcal{M}(D) = (\mathcal{M}_1(D), \mathcal{M}_2(D))$ for each $D \in MS(\mathcal{X})$, is $(\epsilon_1 + \epsilon_2, \delta_1 + \delta_2)$-DP.*

By applying basic composition inductively, we obtain that the composition of $k \in \mathbb{N}$ mechanisms, each satisfying (ϵ_0, δ_0)-DP, ensures $(k\epsilon_0, k\delta_0)$-DP. The next theorem, known as *advanced composition theorem*, shows that when ϵ_0 is small, composition also satisfies $(\sqrt{k}\sqrt{\log(1/\delta)}\epsilon_0, \delta + k\delta_0)$-DP for every $\delta \in (0, 1]$, where the first privacy parameter scales with $\sqrt{k}$ rather than k. However, unlike basic composition, advanced composition introduces a nonzero δ even if each individual mechanism is purely differentially private (i.e., $\delta_0 = 0$). This additive term can be interpreted as a small probability of privacy failure. Thus, in applications where any such failure is unacceptable and composition must satisfy pure differential privacy, basic composition must be applied.

▶ **Theorem 5** (Advanced Composition [21]). *Let $k \in \mathbb{N}$, and for each $i \in [k]$, let $\mathcal{M}_i : MS(\mathcal{X}) \to \mathcal{Y}_i$ be an (ϵ_i, δ_i)-DP mechanism. Then, for every $0 \le \delta \le 1$, the mechanism $\mathcal{M}$, defined as $\mathcal{M}(D) = (\mathcal{M}_1(D), \ldots, \mathcal{M}_k(D))$ for each $D \in MS(\mathcal{X})$, is (ϵ, δ)-DP, where*

$$\epsilon = \sum_{i=1}^{k} \epsilon_i \cdot (e^{\epsilon_i} - 1) + \sqrt{2\log(\frac{1}{\delta'}) \sum_{i=1}^{k} \epsilon_i^2} \qquad \text{and} \qquad \delta = \delta' + \sum_{i=1}^{k} \delta_i.$$

The next composition theorem guarantees differential privacy when multiple differentially private analyses are performed on disjoint subsets of a dataset. In this composition, known as the *parallel composition*, the overall privacy loss is determined by the *maximum* privacy loss of the individual mechanisms, rather than the sum. For example, consider multiple elementary schools, each with a distinct set of students. Suppose each school applies an (ϵ, δ)-differentially private mechanism to analyze its own student data. If the government later aggregates the privatized outputs from all schools for policy decisions, the overall process remains (ϵ, δ)-differentially private.

▶ **Definition 6** (Parallel Composition [38]). *Let $k \in \mathbb{N}$, and for each $i \in [k]$, let $\mathcal{M}_i : MS(\mathcal{X}) \to \mathcal{Y}_i$ be an (ϵ_i, δ_i)-DP mechanism with respect to a neighbor relation $\sim_i$. Define $\mathcal{M} : MS(\mathcal{X})^k \to \mathcal{Y}_1 \times \cdots \times \mathcal{Y}_k$ as $\mathcal{M}(D) = (\mathcal{M}_1(D_1), \ldots, \mathcal{M}_k(D_k))$ for each $D = (D_1, \ldots, D_k) \in MS(\mathcal{X})^k$. Two sequences of datasets $D = (D_1, \ldots, D_k) \in MS(\mathcal{X})^k$ and $D' = (D'_1, \ldots, D'_k) \in MS(\mathcal{X})^k$ are considered to be neighboring if and only if there exists $i \in [k]$ such that $D_i \sim_i D'_i$ and $D_j = D'_j$ for all $j \neq i$. Then, the mechanism $\mathcal{M}$ satisfies (ϵ, δ)-DP, where $\epsilon = \max_{1 \le i \le k} \epsilon_i$ and $\delta = \max_{1 \le i \le k} \delta_i$.*

The Laplace Mechanism. One of the most fundamental differentially private mechanisms is the *Laplace Mechanism*. This mechanism computes a "simple" statistic f on the input dataset, adds Laplace noise to it, and outputs the noisy result. Here, "simple" refers to functions with low *sensitivity*, where the sensitivity of a function measures how much its output can differ over neighboring datasets:

▶ **Definition 7** (ℓ_k-Sensitivity). *Let $f : MS(\mathcal{X}) \to \mathbb{R}^d$ be a function mapping a dataset to a real number. For each $k \in \mathbb{N}$, the ℓ_k-*sensitivity of f, *denoted $\Delta_{k,f}$, is defined as*

$$\Delta_{k,f} = \max_{D, D' \in MS(\mathcal{X})} \|f(D) - f(D')\|_k ,$$

where $\|\cdot\|_k$ is the k-norm.

▶ **Definition 8** (Laplace Distribution). *The Laplace distribution with mean 0 and scale parameter b has the probability density function*

$$f_{Lap(b)}(x) = \frac{1}{2b} \exp\left(\frac{-|x|}{b}\right), \quad x \in \mathbb{R}.$$

A random variable following this distribution is denoted by $Y \sim Lap(b)$ or simply $Lap(b)$.

The following Lemma formally defines the Laplace mechanism and states a trade-off between its privacy and accuracy guarantees:

▶ **Lemma 9** (Laplace Mechanism [17]). *Let $f : MS(\mathcal{X}) \to \mathbb{R}$ be a function with ℓ_1-sensitivity $\Delta_{1,f}$. For $\epsilon \geq 0$, the Laplace mechanism $\mathcal{M}^{f,\epsilon}_{Lap}$ takes a dataset $D \in MS(\mathcal{X})$ as input and outputs $f(D) + Lap(\Delta_{1,f}/\epsilon)$. The mechanism $\mathcal{M}^{f,\epsilon}_{Lap}$ satisfies ϵ-DP. Furthermore, for every $D \in MS(\mathcal{U})$ and $t \geq 0$,*

$$\Pr\left[|\mathcal{M}^{f,\epsilon}_{Lap}(D) - f(D)| \geq t \cdot \Delta_{1,f}/\epsilon\right] \leq e^{-t}.$$

We note that the definition of accuracy depends on the application and may be different in each context. Therefore, we do not provide a general definition and instead define accuracy for each concrete application in the subsequent sections.

Differential privacy in the continual and interactive setting. The mechanisms discussed so far are referred to as *non-interactive mechanisms (NIMs)* or *batch* mechanisms, as they take a single input dataset and produce a single output. In the rest of this paper, we define settings where either multiple different queries are asked to the mechanism, resulting in an *interactive mechanism (IM)*, or the dataset is changed through update operation, resulting in a *continual mechanism (CM)*.

Note that these mechanisms are differential privacy analogues of randomized algorithms and data structures in the non-private setting: A non-interactive mechanism corresponds to a *static* (or *batch*) *algorithm*, while an interactive mechanism corresponds to *static data structure*. A continual mechanism allows both queries and updates and corresponds to *dynamic data structures*. While the adaptivity of the sequence of operations is a common concern for the correctness and running time of randomized data structures, in differential privacy, adaptivity is additionally a concern for privacy. Concretely, note that the above definitions and composition theorems only hold for non-interactive mechanisms. In the following sections, we will discuss how to define and analyze the privacy properties of interactive and continual mechanisms.

2 The Continual Setting

In many real-world applications, data is not available in a single static batch but is collected incrementally over time or the dataset is changing over time. In such settings, it is often necessary to update the output continually in order to provide timely and relevant analysis of the dataset. For example, an online movie platform may collect user interactions, such as who watches which movie, and update its recommendation model accordingly. In this scenario, the platform must ensure that the sequence of recommendations over time does not reveal sensitive information, such as whether a user has watched a specific movie. The problem of dynamically receiving data and updating the output while protecting the privacy of each data point is studied in the *continual observation model* of differential privacy [18, 10], which has recently become a popular research topic (see e.g. [8, 9, 26, 32, 33, 2, 1, 16, 31, 4, 23] for CMs for various problems on sequences of numbers, [34, 29, 46] for CMs for set cardinality, [11, 40, 14] for CMs for problems in databases, [7, 30] for CMs for various histogram queries, [42, 25, 26, 41, 22] for CMs for various graph problems, [15] for CMs for clustering problems in the Euclidean space, and [45, 5] for CMs for releasing synthetic data).

In the non-private setting, the goal is to design dynamic algorithms that are accurate, memory-efficient, and time-efficient. In the private setting, however, one must additionally ensure the privacy of the input data, which is always in conflict with accuracy. Nonetheless, with the emergence of new algorithmic techniques, several continual mechanisms have

been developed that provide meaningful trade-offs between privacy and accuracy. These mechanisms have been shown to be practical and are already deployed in real-world systems [24, 3, 12, 13, 47, 48].

Formally, a mechanism $\mathcal{M}$ in the continual observation model is defined by a randomized function $f_{\mathcal{M}}$ that maps a current state and an incoming update to a new state and an output. The state represents the internal memory of the mechanism and may, for example, include the current dataset or relevant summary statistics. For simplicity, we assume the mechanism starts from an initial state corresponding to an empty dataset, though this assumption can be relaxed.

The mechanism $\mathcal{M}$ processes a sequence of update instructions $\sigma = (x_1, x_2, \dots)$ as follows[2]: Starting from the (empty) initial state, at each step t, the mechanism applies $f_{\mathcal{M}}$ to its current state and the incoming update x_t, yielding a new internal state and an output value y_t. $\mathcal{M}$ then returns y_t. We denote the sequence of outputs $(y_1, y_2, \dots)$ generated in response to the update sequence σ by the random variable $\mathcal{M}(\sigma)$. We also refer to such a mechanism as a *continual mechanism*.

Depending on the problem definition, each update x_i can be a data record in $\mathcal{X}$ to be inserted into the dataset or an instruction that arbitrarily modifies the current dataset (e.g., it deletes certain records). For simplicity, in the remainder of this section, we assume that each update x_t is a data record in $\mathcal{X}$ to be inserted in the dataset. We note that all the definitions can naturally be extended to non-empty initial datasets and to general update operations.

Recall that in the non-interactive model, the differential privacy guarantee is defined over pairs of neighboring datasets. In the continual setting, on the other hand, the notion of neighboring is defined over sequences of data records. For example, if $\mathcal{X} = \{0, 1\}$, we can define two sequences of data records $\sigma = (x_1, \dots, x_T)$ and $\sigma' = (x'_1, \dots, x'_T)$ of equal length $T \in \mathbb{N}$ to be neighboring if they differ at exactly one position, i.e., there exists $i \in [T]$ such that $x_j = x'_j$ for all $j \neq i$. Using this definition of neighboring in the definition of DP leads to so-called *event-level privacy*.

▶ **Definition 10** ((ϵ, δ)-Differential Privacy for Continual Mechanisms [18, 10])**.** *Let $\mathcal{M}$ be a continual mechanism, and let $\mathcal{Y}$ denote the output space of $\mathcal{M}$ at each step. For $\epsilon \geq 0$ and $0 \leq \delta \leq 1$, $\mathcal{M}$ is said to be (ϵ, δ)-differentially private (or (ϵ, δ)-DP for short) until time step $T \in \mathbb{N}$ if, for every pair of neighboring sequences $\sigma, \sigma' \in \mathcal{X}^T$ and every set of output sequences $V \subseteq \mathcal{Y}^T$, we have*

$$Pr[\mathcal{M}(\sigma) \in V] \leq e^{\epsilon} Pr[\mathcal{M}(\sigma') \in V] + \delta.$$

$\mathcal{M}$ is ϵ-differentially private (or ϵ-DP for short) if $\delta = 0$.

In the above definition, the continual mechanism is differentially private against an *oblivious* adversary. In the *adaptive* setting, however, an *adversary* generates neighboring sequences over time, adaptively, based on the previous outputs of the mechanism. Specifically, given a continual mechanism $\mathcal{M}$, an adversary $\mathcal{A}$ interacts with an *oracle* holding a secret bit $b \in \{0, 1\}$. An oracle is a very limited algorithm that behaves as follows: At each time step, $\mathcal{A}$ issues a pair of updates (u_0, u_1), and the oracle forwards u_b to $\mathcal{M}$. Observing the corresponding output of $\mathcal{M}$, the adversary then adaptively generates the next pair of updates. If, at any time step, the sequences of u_0s and u_1s does not satisfy the required neighboring relation, the oracle halts the interaction.

[2] More generally, $\mathcal{M}$ can be an interleaved sequence of updates and (parametrized) queries, but for simplicity we just assume that one unparametrized query is fixed, and $\mathcal{M}$ answers that query after receiving each update.

We say that the mechanism $\mathcal{M}$ is (ϵ, δ)-differentially private against adaptive adversaries if, for every adversary $\mathcal{A}$, the distributions of output sequences induced by oracle bits $b = 0$ and $b = 1$ are (ϵ, δ)-indistinguishable.

3 Example: Continual Binary Counting

The first and most foundational problem studied in the continual observation model is the *continual binary counting problem*. In this problem, the continual mechanism $\mathcal{M}$ receives a bit x_t at each step $t \in \mathbb{N}$ and returns an estimate y_t of the cumulative sum $s_t = \sum_{i=1}^{t} x_t$. If x_t is an arbitrary real number, the problem is called *continual counting problem*. Two input sequences of the same length are considered to be neighboring if they are identical except for a single time step. The goal is to guarantee differential privacy while providing accuracy, where accuracy is measured as follows:

▶ **Definition 11** ((α, β)-Accuracy for Continual Counter). *For $T \in \mathbb{N}$, $0 < \alpha$ and $0 < \beta \leq 1$, a continual counting mechanism $\mathcal{M}$ is said to be* (α, β)-accurate for T steps *if, for every input sequence $\sigma = (x_1, \ldots, x_T) \in \mathcal{X}^T$,*

$$\Pr[\max_{t \in [T]} |y_t - s_t| \leq \alpha] \geq 1 - \beta,$$

where $s_t = \sum_{i=1}^{t} x_t$ and y_t is the output of $\mathcal{M}$ at step t. We say that $\mathcal{M}$ has additive error α *over the first T steps* with high probability *if it is (α, β)-accurate for T steps, where $\beta = 1/T^c$ for some constant $c > 0$.*

First simple mechanism (Laplace mechanism on each output): A trivial design of a continual counting mechanism $\mathcal{M}$ is to run $T \in \mathbb{N}$ instances of the static Laplace mechanism to privatize the sums s_t for $t \in [T]$. Specifically, at each step $t \in [T]$, the mechanism $\mathcal{M}$ computes s_t and outputs $y_t = s_t + \mathrm{Lap}(1/\epsilon')$, where $\mathrm{Lap}(1/\epsilon')$ is a fresh sample of Laplace noise with scale $1/\epsilon'$. Since changing a single input bit affects each s_t by at most 1, by Lemma 9, the output at each individual step is ϵ'-DP. Thus, applying basic composition (Lemma 4), the sequence of the first T outputs is $T \cdot \epsilon'$-DP. To guarantee $\mathcal{M}$ is ϵ-DP, we must therefore set $\epsilon' = \epsilon/T$. This implies that for each step $t \in [T]$, with a constant probability, $|y_t - s_t| = |\mathrm{Lap}(T/\epsilon)|$ is $\Omega(T/\epsilon)$.

Second simple mechanism (Laplace mechanism on each input) Another trivial approach is to run T instances of Laplace mechanism on the input bits x_t instead of s_t. That is, at each step $t \in [T]$, the continual counting mechanism $\mathcal{M}$ sets $\hat{x}_t = x_t + \mathrm{Lap}(1/\epsilon)$. Since two neighboring input sequences (of length $T \in \mathbb{N}$) differ on at most one coordinate, all but one Laplace mechanism receive the same input for both sequences. Thus, by Lemma 9 and Lemma 4, the sequence $(\hat{x}_1, \ldots, \hat{x}_T)$ is ϵ-DP. Since the output sequence of $\mathcal{M}$ is computed as a post-processing of $(\hat{x}_1, \ldots, \hat{x}_T)$, by Lemma 3, it is distinguishable for two neighboring input sequences. Thus, $\mathcal{M}$ is ϵ-DP. At step T, $|y_T - s_T|$ equals the sum of T i.i.d. samples from $\mathrm{Lap}(1/\epsilon)$. By a standard Chernoff bound, this implies that with high probability, $|y_T - s_T|$ is $\Omega(\sqrt{T})$.

The two naive designs for continual counting illustrate a fundamental trade-off between privacy and accuracy. In the first approach, independent Laplace noise is added to each cumulative sum $s_t = \sum_{i=1}^{t} x_i$. Since each input bit x_i contributes to up to T such sums, satisfying ϵ-differential privacy requires the Laplace scale to be T/ϵ. This, however, results in an additive error that grows linearly with T. In contrast, the second approach adds Laplace noise to each input bit x_t individually and then sums the noisy inputs in a post-processing

step. Here, each input only affects the output of a single Laplace mechanism, allowing for a smaller Laplace scale of $1/\epsilon$. However, because the output at step $t \in [T]$ includes t independent noise, the additive error grows polynomially in t.

To overcome this, Dwork, Naor, Pitassi and Rothblum [19] and Chan, Li, Shi, and Xu [10] proposed a new approach, the so-called *binary (tree) mechanism*, where each input bit is used in the input of $O(\log T)$ Laplace mechanisms, and each output is computed by summing $O(\log T)$ noisy values: Instead of adding noise to each individual bit or to every prefix sum, they add noise to sums of subsequences of the form $(x_{(k-1)\cdot 2^i+1}, \dots, x_{k\cdot 2^i})$ for every $0 \le i \le \log(T)$ and $1 \le k \le T/2^i$. More precisely, at time step $k \cdot 2^i$ (i.e., when the complete subsequence is available), they calculate and store the noisy sum $\sum_{j=(k-1)\cdot 2^i+1}^{k\cdot 2^i} x_j + \text{Lap}(\frac{\log(T)+1}{\epsilon})$. Then, to output the noisy cumulative sum at step $t \in [T]$, they partition the input sequence $(x_1, \dots, x_t)$ into at most $\log(T)$ disjoint subsequences of the above form and return the sum of their noisy values.

Another way to view this dynamic data structure is through a binary tree over time steps 1 to T, where each node stores the noisy sum of the corresponding bits in its subtree, i.e., runs the Laplace mechanism on this partial sum. At each level of the tree, the input bits are partitioned between the nodes. Thus, the (parallel) composition of Laplace mechanisms at each level is $\frac{\epsilon}{\log(T)+1}$-DP. Composing the $\log(T)+1$ levels and applying the basic composition theorem, we conclude that the joint output of all Laplace mechanisms is ϵ-DP. Since the noisy cumulative sum at every step is a post-processing of these noisy partial sums, this implies that the continual counter is ϵ-DP.

For the accuracy analysis, note that each output equals the true cumulative sum plus at most $\log(T)$ i.i.d. noise drawn from $\text{Lap}\left(\frac{\log(T)+1}{\epsilon}\right)$. Chan et al. [10] showed that the sum of these $\log(T)$ Laplace random variables is $O(\sqrt{\log(T)}\frac{\log(T)+1}{\epsilon}\sqrt{\log(1/\beta)})$ with probability at least $1-\beta$. Applying a union bound over all T time steps, the maximum additive error across all steps is $O(\log(T)^{3/2}\sqrt{\log(T/\beta)}/\epsilon)$ with probability at least $1-\beta$.

4 Interactive Setting

Consider a hospital that collected patient records during the Covid-19 pandemic, i.e., it has a static dataset. Over time, researchers may issue a sequence of statistical queries to investigate long-term effects of Covid and its potential correlation with current medical conditions. These queries are *parametrized*, meaning that they are given one or multiple parameters determining which query is asked, and these parameters are often chosen *adaptively*, meaning that the parameters for each new query may be chosen based on the responses to previous ones. To protect each patient record, queries must satisfy certain properties, e.g., an analyst cannot ask whether Mr. X had Covid or not.

In the DP literature, a mechanism that holds a static dataset and answers multiple adaptive queries is usually referred to as an *interactive mechanism*. To formally define differential privacy for the interactive setting, we need to define a *view* random variable: Let $\mathcal{M}$ be an interactive mechanism, and let $\mathcal{A}$ be an analyst (or adversary) that adaptively asks queries from $\mathcal{M}$. We denote the mechanism $\mathcal{M}$ holding dataset D by $\mathcal{M}(D)$. The *view* of the analyst $\mathcal{A}$ interacting with $\mathcal{M}(D)$, denoted $\text{View}(\mathcal{A}, \mathcal{M}(D))$, is the sequence $(r_{\mathcal{A}}, q_1, a_1, q_2, a_2, \dots)$ consisting of the analyst's internal randomness $r_{\mathcal{A}}$ and the sequence of queries q_i and corresponding answers a_i returned by $\mathcal{M}$.

▶ **Definition 12.** *An interactive mechanism $\mathcal{M}$ is said to be (ϵ, δ)-differentially private (or (ϵ, δ)-DP for short) if for every adversary $\mathcal{A}$ and every pair of neighboring datasets D_0 and D_1, the random variables View$(\mathcal{A}, \mathcal{M}(D_0))$ and View$(\mathcal{A}, \mathcal{M}(D_1))$ are (ϵ, δ)-indistinguishable. We say that $\mathcal{M}$ is ϵ-differentially private (or ϵ-DP for short) if $\delta = 0$.*

A fundamental problem in the interactive setting is *threshold testing*, where the mechanism holds a static dataset $D \in \mathrm{MS}(\{0,1\})$ consisting of binary values, and receives a sequence of integer thresholds over time. Specifically, at each time step $t \in \mathbb{N}$, the analyst sends a threshold query $\texttt{thresh}_t \in \mathbb{N}$, asking whether the sum $\sum_{x \in D} x$ exceeds the given threshold $\texttt{thresh}_t$. The mechanism responds with either $\top$ (yes) or $\bot$ (no). Once the mechanism returns $\top$, it is required to halt. For simplicity, we assume the mechanism continues to return $\top$ indefinitely after it outputs $\top$ for the first time.

Two datasets $D_0, D_1 \in \mathrm{MS}(\{0,1\})$ are considered *neighboring* if they differ in the presence or absence of one element. The goal is to provide accurate answers to threshold queries while preserving privacy, where accuracy is defined as follows:

▶ **Definition 13.** *A threshold testing mechanism $\mathcal{M}$ is said to be (α, β)-accurate until step $T \in \mathbb{N}$ if, for every input dataset $D \in MS(\{0,1\})$, with probability at least $1-\beta$, the following conditions hold for every $t \in [T]$:*

1. ***(Above threshold).*** *If $\sum_{x \in D} x \geq \texttt{thresh}_t + \alpha$, then $\mathcal{M}(D)$ returns $\top$ at step t.*
2. ***(Below threshold).*** *If for every $i \leq t$, $\sum_{x \in D} x \leq \texttt{thresh}_i - \alpha$, then $\mathcal{M}(D)$ returns $\bot$ at all steps $i \leq t$.*

A well-known continual threshold-testing mechanism is the sparse vector technique (SVT) mechanism [19, 36]. The SVT mechanism allows an analyst to issue adaptive threshold queries on a static dataset while preserving differential privacy. This mechanism is described in Algorithms 1 and 2.

In Algorithm 1, the mechanism is initialized with a dataset D and a privacy parameter ϵ. It first computes the true count $s = \sum_{x \in D} x$ and then draws a sample Z_0 from $\mathrm{Lap}(2/\epsilon)$. This sample will be repeatedly used in all future comparisons. Upon receiving a threshold query $\texttt{thresh}_t$, the mechanism proceeds as follows (see Algorithm 2): If it has already returned $\top$ in any prior step, it returns $\top$. Otherwise, using the old noise Z_0 and a fresh noise $Z_t \sim \mathrm{Lap}(4/\epsilon)$, it compares $s + Z_0 \geq \texttt{thresh}_t + Z_t$. If the inequality holds, then the mechanism returns $\top$ and sets a flag to indicate that it has exceeded a threshold; otherwise, it returns $\bot$.

▶ **Lemma 14** (Privacy [19] and Accuracy [35] of SVT)**.** *For every $\epsilon \geq 0$, the SVT mechanism described in Algorithms 1 and 2 satisfies ϵ-DP. Moreover, for every $0 < \beta \leq 1$ and $T \in \mathbb{N}$, this mechanism is $(\alpha = O(\log(T/\beta)/\epsilon), \beta)$-accurate until step T.*

Algorithm 1 $\texttt{svt}_\epsilon$ (initialization).

Input: privacy parameter $\epsilon > 0$; dataset $D \in \mathrm{MS}(\{0,1\})$.

1: $\epsilon_1 = \epsilon_2 = \epsilon/2$
2: $s = \sum_{x \in D} x$
3: $\texttt{varflag} = 0$
4: Draw $Z_0 \sim \mathrm{Lap}(1/\epsilon_1)$

Algorithm 2 $\texttt{svt}_\epsilon$ (update).

Input: threshold $\texttt{thresh}_t$
Output: an element of $\{\top, \bot\}$.
if $\texttt{varflag} = 1$ **then**
  return $\top$
end if
Draw $Z_t \sim \text{Lap}(2/\epsilon_2)$
if $s + Z_0 \geq \texttt{thresh}_t + Z_t$ **then**
  $\texttt{varflag} = 1$
  return $\top$
else
  return $\bot$
end if

5 Designing New Continual Mechanisms

In this section, we introduce new composition tools that enable a modular construction of complex continual mechanisms executing not only non-interactive mechanisms (NIMs) but also continual and interactive mechanisms as sub-mechanisms. As we mentioned before, the composition theorems presented in Section 1 only apply to NIMs. This raises a question: can interactive or continual sub-mechanisms always be decomposed into NIMs followed by post-processing, thereby enabling privacy analysis of the complex mechanism using composition theorems for NIMs and the post-processing lemma? We will first show that such a decomposition is not always possible and then present composition tools that simplify the privacy analysis of the mechanism with modular design. Due to complicated dependencies between the outputs and inputs of the sub-mechanisms and their potential influence on each other, analyzing the privacy of these mechanisms from scratch can be challenging.

Roughly speaking, interactive mechanisms can be viewed as a special case of continual mechanisms, where the first input update is a dataset and all subsequent updates are adaptively chosen queries with no effect on the dataset. When modeling an interactive mechanism as a continual mechanism, two input sequences are considered neighboring if their first element (i.e., the dataset) are neighboring, and all subsequent elements (i.e., the queries) are identical. This perspective allows us to unify continual and interactive mechanisms and refer to both of them as *continual mechanisms (CMs)*.

Continual mechanisms are not necessarily compositions of non-interactive mechanisms. We begin by demonstrating that an (ϵ, δ)-DP continual mechanism cannot, in general, be expressed as the post-processing of a composition of NIMs, each using independent random coins, such that the composition satisfies (ϵ, δ)-DP. To illustrate this, we compare the privacy analysis of the binary-tree mechanism (Section 3) and of the Sparse Vector Technique (SVT) mechanism (Section 4).

Let $T \in \mathbb{N}$ and $\epsilon \geq 0$. The binary-tree mechanism draws $2T - 1$ independent Laplace noises from $\text{Lap}((\log T + 1)/\epsilon)$, one for each node of the binary tree. Each noise is then used individually to privatize a partial sum of the input sequence, and the output at each time step is computed by combining a subset of these privatized values. This structure enables a clean decomposition of the mechanism into NIMs with independent randomness, followed by a post-processing.

In contrast, the privacy analysis of the SVT mechanism is different: given a dataset D, this mechanism samples $T+1$ independent Laplace noises: $Z_0 \sim \text{Lap}(2/\epsilon)$ and $Z_i \sim \text{Lap}(4/\epsilon)$ for each $i \in [T]$. At time step $t \in [T]$, given a threshold $\texttt{thresh}_t$, the mechanism determines the output based on the comparison $\sum_{x \in D} x + Z_t \geq \texttt{thresh}_t + Z_0$. Each noisy sum $\sum_{x \in D} x + Z_t$ can be considered as an instance of the Laplace mechanism with the privacy parameter $\epsilon/4$, and the comparison can be interpreted as a post-processing of this $\epsilon/4$-DP mechanism. However, since each data record in D contributes to the input of all T Laplace mechanisms, the composition of these mechanisms would be $\frac{T}{4\epsilon}$-DP.

To avoid this undesirable polynomial privacy parameter, the SVT mechanism is analyzed directly by comparing the view of any adversary interacting with this mechanism for any two neighboring datasets. This analysis yields an ϵ-DP guarantee. Notably, this proof crucially exploits a shared source of randomness, i.e., the random variable Z_0, to get a better privacy guarantee, something that the privacy analysis by composition cannot capture as it requires the composed mechanisms to use independent random coins.

Composition theorems for continual mechanisms. This limitation implies that, in general, when analyzing a mechanisms executing multiple continual sub-mechanisms, we cannot simply decompose each continual sub-mechanism into NIMs and then apply standard composition theorems for NIMs to derive overall privacy guarantees. This challenge has led to a line of research on extending the composition theorems for NIMs to *concurrent composition* theorems for CMs [43, 37, 44, 27, 28]. Here, the term *concurrent* captures the fact that the inputs to the composed CMs are generated concurrently: Specifically, the input to one mechanism may depend on the outputs of *all* other mechanisms up to that point.

Although we do not formally define concurrent composition in this paper, we highlight a recent work by Henzinger, Safavi, and Vadhan [28] showing that composition theorems for NIMs, such as Theorem 4 and Theorem 5, still hold in the more general setting of the concurrent composition of CMs, provided that the composed mechanisms are differentially private against *adaptive* adversaries.

Moreover, they show a separation between parallel composition in the non-interactive model (Theorem 6) and the concurrent parallel composition of CMs, where an adversary adaptively selects which mechanism receives non-identical input sequences. To address this, they develop new concurrent parallel composition theorems.

Assume a mechanism $\mathcal{M}$ uses multiple CMs as subroutines. Henzinger et al. [28] also formalize which types of *post-processing* on the outputs of these sub-mechanisms are permissible in order to preserve the privacy guarantee of the concurrent composition of the sub-mechanisms: They present a general framework for combining the given inputs and the previous outputs of sub-mechanisms to generate new inputs for the sub-mechanisms and then generate the final output based on the outcomes of the sub-mechanisms. This formalism results in a simple privacy analysis for complex mechanisms executing continual sub-mechanisms.

6 Conclusions

Continual mechanisms are the analogue of dynamic data structures in the differentially private setting. Apart from analyzing their accuracy, time, and space requirements, their privacy properties need to be proven, which can be challenging. New composition theorems for continual mechanisms simplify this task and will hopefully support the design of continual mechanisms for various applications with improved tradeoffs between privacy and accuracy.

Abstract

H-Packing is the problem of finding a maximum number of vertex-disjoint copies of H in a given graph G. H-Partition is the special case of finding a set of vertex-disjoint copies that cover each vertex of G exactly once. Our goal is to study these problems and some generalizations on bounded-treewidth graphs. The case of H being a triangle is well understood: given a tree decomposition of G having treewidth tw, the K_3-Packing problem can be solved in time $2^{\mathrm{tw}} \cdot n^{O(1)}$, while Lokshtanov et al. [*ACM Transactions on Algorithms* 2018] showed, under the Strong Exponential-Time Hypothesis (SETH), that there is no $(2-\epsilon)^{\mathrm{tw}} \cdot n^{O(1)}$ algorithm for any $\epsilon > 0$ even for K_3-Partition. Similar results can be obtained for any other clique K_d for $d \geq 3$. We provide generalizations in two directions:

- We consider a generalization of the problem where every vertex can be used at most c times for some $c \geq 1$. When H is any clique K_d with $d \geq 3$, then we give upper and lower bounds showing that the optimal running time increases to $(c+1)^{\mathrm{tw}} \cdot n^{O(1)}$. We consider two variants depending on whether a copy of H can be used multiple times in the packing.
- If H is not a clique, then the dependence of the running time on treewidth may not be even single exponential. Specifically, we show that if H is any fixed graph where not every 2-connected component is a clique, then there is no $2^{o(\mathrm{tw} \log \mathrm{tw})} \cdot n^{O(1)}$ algorithm for H-Partition, assuming the Exponential-Time Hypothesis (ETH).

1 Introduction

Parameterized complexity theory has proven instrumental in systematically understanding the computational complexity of various combinatorial problems under different parameterizations. Parameterization by treewidth implies tractability for a large number of fundamental algorithmic problems. A prominent line of research has emerged around classifying the complexity of classical NP-hard graph problems under this parameterization framework [8, 7].

In their influential work, Lokshtanov et al. [8] studied six classical combinatorial problems for which parameterized algorithms are known where the running-time dependence on treewidth is single exponential. They showed that, under Strong Exponential Time Hypothesis (SETH), the running times are optimal in the base of the exponent. Following this work, significant efforts have been devoted to generalizing and extending these results. In particular, five out of six problems in [8] have been put into a wider context and generalized to an infinite family of problems: q-Coloring was generalized into H-homomorphism problems [1, 10, 9], Independent Set (equivalent to Vertex Cover), MaxCut and Odd Cycle Transversal [2] into H-homomorphism deletion problem, and Dominating Set into general (σ, ρ)-dominating set problems [5]. Curticapean and Marx [3] showed tight lower bounds for the problem of

counting perfect matchings, which was later extended into general factor problems. However, from the initial six problems studied by Lokshtanov et al. [8], the triangle packing problem has remained unaddressed by prior generalization efforts.

The $2^{tw} \cdot n^{\mathcal{O}(1)}$ running time for triangle packing stated in [8] is actually valid for any clique packing problem, instead of triangle with just three vertices. In this paper, we investigate further generalizations of the triangle packing problem. This line of research naturally gives rise to two conceptually distinct directions:

1. **Allowing vertices to be covered multiple times:** The motivation for this generalization stems naturally from closely related problems such as fractional packing, where vertices can inherently contribute fractionally or multiple times to different packings. To illustrate, Figure 1.1 shows a graph that does not admit a triangle partition, yet allows a collection of triangles that cover each vertex exactly twice. Motivated by this observation, we formally define and explore a generalized packing problem, where each vertex of G can be covered at most c times, for any fixed integer $c \geq 1$. Unlike $c = 1$ case, this generalization demands careful consideration of the definition, specifically on whether a copy of H may appear multiple times in the solution.
2. **Considering packings of arbitrary graphs:** The second natural direction involves generalizing triangle packing by replacing triangles with an arbitrary fixed graph H. This problem has already been studied in the literature under the name of H-partition in [6]. Specifically, in [6] the authors prove the NP-Hardness of the H-partition problem where H has a connected component with at least three vertices. In this paper we let H be a connected graph with at least three vertices and study the complexity of the H-partition problem parameterized by treewidth.

(a) The graph under consideration.

(b) Each color represents a triangle in the collection. Observe that each vertex is covered exactly twice.

Figure 1.1 A graph that does not admit a triangle partition, but allows a collection of triangles such that each vertex is covered exactly twice.

1.1 Our Results

Let H be a fixed graph and $c \geq 1$ be an integer. Given a graph G, a subgraph Z of G is called a copy of H if Z is isomorphic to H. Moreover, if Z is a copy of H in G, we say that Z covers v if $v \in V(Z)$.

▶ **Definition 1.** *We say that a multiset (respectively, set)* $\mathcal{S} = \{(V_1, E_1), \ldots, (V_k, E_k)\}$ *of subgraphs of* G *is a* (c, H)*-multi-packing (respectively,* (c, H)*-single-packing) in* G *if*

1. *each* (V_i, E_i) *is isomorphic to* H *for* $1 \leq i \leq k$
2. *each vertex* v *of* G *is covered at most* c *times by the subgraphs in* $\mathcal{S}$*.*

The collection $\mathcal{S}$ *is called a* (c, H)*-multi-partition (respectively,* (c, H)*-single-partition) of* G *if each vertex* $v \in V(G)$ *is covered exactly* c *times.*

Observe that when c is equal to 1, two copies of H are not allowed to have any common vertices. Therefore, in this case, the notions of (c, H)-single-packing and $\big(c, H\big)$-multi-packing coincide, and we write H-packing to simpify the notation. We define H-partition in a similar way. The first problem we introduce, `Generalized Graph Packing`(H), asks the maximum size of an H-packing in G.

`Generalized Graph Packing`(H)
Input: A graph G
Output: The size of a largest H-packing in G.

For a fixed H, we show that `Generalized Graph Packing`(H) can be solved in time $2^{\mathcal{O}(w \cdot \log w)} \cdot n^{\mathcal{O}(1)}$ for graphs of treewidth w.

▶ **Theorem 2.** *Let H be an arbitrary graph such that it contains at least 3 vertices. Then,* `Generalized Graph Packing`(H) *can be solved in time $2^{\mathcal{O}(w \cdot \log(w))} \cdot n^{\mathcal{O}(1)}$ for all n-vertex graphs G where w is the treewidth of G.*

Then, we define partitioning problems in which each vertex of G must be covered the same number of times. For an arbitrary graph H, we let $c = 1$ which results in vertex disjoint copies of H.

`Generalized Graph Partitioning`(H)
Input: A graph G
Question: Is there an H-packing of G such that each vertex is covered exactly once?

Observe that `Generalized Graph Partitioning`(H) is a special case of the problem `Generalized Graph Packing`(H), which implies an algorithm with running time $2^{\mathcal{O}(w \cdot \log w)} \cdot n^{\mathcal{O}(1)}$ for the `Generalized Graph Partitioning`(H) problem on graphs of treewidth w. We show that this running time cannot be improved for many choices of H.

▶ **Theorem 3.** *Let H be an arbitrary graph with at least 3 vertices such that H is not a block graph. Then, there is no algorithm for* `Generalized Graph Partitioning`(H) *problem, that solves all instances G in time $2^{o(w \cdot \log w)} \cdot n^{\mathcal{O}(1)}$ where w is the treewidth of G, unless ETH fails.*

When H is a clique, we consider the more general problem in which a vertex $v \in V(G)$ can be covered more than once, at most c times for some $c \geq 1$. Therefore, we distinguish between two variants of the problem: one where each clique can be selected at most once, and another without restriction. The `Multi-Clique Packing`(c, d) problem asks the maximum size of a $\big(c, K_d\big)$-multi-packing in G.

`Multi-Clique Packing`(c, d)
Input: A graph G
Output: The size of a largest $\big(c, K_d\big)$-multi-packing in G.

Similar to the `Multi-Clique Packing`(c, d) problem, the `Single-Clique Packing`(c, d) problem asks the maximum size of a (c, K_d)-single-packing in G.

`Single-Clique Packing`(c, d)
Input: A graph G
Output: The size of a largest (c, K_d)-single-packing in G.

In the full version of the paper we show that `Single-Clique Packing`(c, d) admits a single-exponential time algorithm where the same algorithmic result also applies to `Multi-Clique Packing`(c, d) with slight modifications.

▶ **Theorem 4.** *Let $c \geq 1$ and $d \geq 3$ be integers. Then,* `Single-Clique Packing`(c, d) *can be solved in time $(c+1)^w \cdot n^{\mathcal{O}(1)}$ for all n-vertex graphs G given together with a tree decomposition of width at most w.*

Moreover, we define partitioning problems where H is a clique.

`Multi-Clique Partitioning`(c, d)
Input: A graph G
Question: Is there a $\big(c, K_d\big)$-multi-partition of G?

`Single-Clique Partitioning`(c, d)
Input: A graph G
Question: Is there a (c, K_d)-single-partition of G?

Similarly, we prove that this running time is optimal up to polynomial factors in the size of the input graph.

▶ **Theorem 5.** *Let $c \geq 1$ and $d \geq 3$ be integers. If there exists an $\varepsilon > 0$ such that* `Multi-Clique Partitioning`(c, d) *can be solved in time $(c+1-\varepsilon)^w \cdot n^{\mathcal{O}(1)}$ for all n-vertex graphs G given together with a path decomposition of width at most w, then the* **pw**-*SETH fails.*

Finally, we show that the lower bound result in Theorem 5 can also be transferred similarly.

▶ **Theorem 6.** *Let $c \geq 1$ and $d \geq 3$ be integers. If there exists an $\varepsilon > 0$ such that* `Single-Clique Partitioning`(c, d) *can be solved in time $(c+1-\varepsilon)^w \cdot n^{\mathcal{O}(1)}$ for all n-vertex graphs G given together with a path decomposition of width at most w, then the* **pw**-*SETH fails.*

2 Technical Overview

In this section, we will give an overview of the techniques and ideas presented in the paper.

2.1 Preliminaries

A graph H is k-connected if for each $A \subseteq V(H)$ such that $|A| = k-1$ it holds that $H \setminus A$ is connected. A graph is also called biconnected if it is 2-connected, and a block is a maximal 2-connected component of H. Similarly, a graph H is called a block graph if every block of H is a clique.

A vertex v of a connected graph H is a cutvertex if $G \setminus v$ is disconnected. In this paper, we refer to both the blocks of a graph and the nodes of the corresponding block tree interchangeably, with a slight abuse of notation. While formally distinct, we find it convenient to treat them as equivalent entities for the sake of clarity and brevity. For a vertex $h \in V(H)$ and a block $B \in \mathcal{B}_H$, we write $h \in B$ if $h \in V(B)$.

▶ **Definition 7.** *For a function f and a set X, we let $f\restriction_X$ denote the restriction of f to $X \cap \operatorname{dom}(f)$. Similarly, we let $f\restriction_{-X}$ denote the restriction of f to $\operatorname{dom}(f) \setminus X$. Finally, for $v \notin \operatorname{dom}(f)$ and a value y, we let $f\restriction_{[v\to y]}$ denote a function g which is defined as*

$$g(x) = \begin{cases} f(x) & \text{if } x \in \operatorname{dom}(f), \\ y & \text{if } x = v. \end{cases}$$

We use the Iverson bracket $[\![P]\!]$, which is defined to be 1 if the proposition P is true and 0 otherwise.

2.2 Gadgets

In this paper, we derive our lower bounds via reductions from well-studied base problems whose intractability is established under standard complexity hypotheses. Each reduction makes use of compact, purpose-built gadgets – small graphs whose behavior can be precisely engineered. Embedding these gadgets into our constructions yields intuitive, transparent proofs that highlight the underlying ideas without excessive technical overhead.

More formally, we define a gadget G as a graph with designated portal vertices $\{p_1, \ldots, p_\ell\} \subseteq V(G)$, where the vertices $\operatorname{int}(G) := (G \setminus \{p_1, \ldots, p_\ell\})$ are called internal vertices. We say that a graph E is an extension of a gadget G if E contains G as an induced subgraph, where each internal vertex v of G satisfies

$$N_E(v) \subseteq V(G).$$

In other words, in an extension E, only the portal vertices of G can have neighbors outside of G.

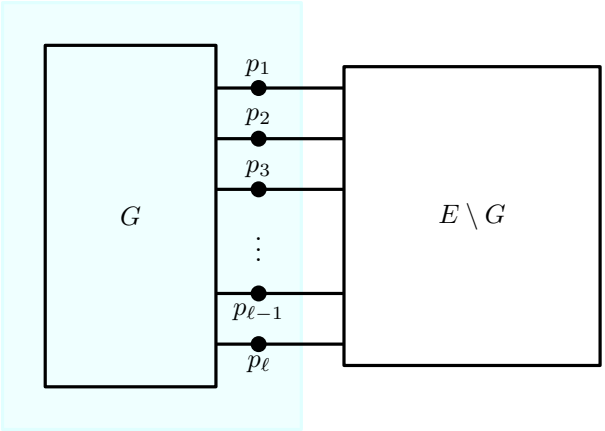

Figure 2.1 Illustration of an extension of gadget G with ℓ portal vertices: the blue region on the left highlights G along with its portals, while the rectangle on the right depicts the remainder $E \setminus G$.

We also require gadgets to behave in a structured way. Whenever a copy of H intersects the gadget, it must lie entirely within the gadget when connected to a larger graph. We formalize this in the following definition.

▶ **Definition 8.** *Let G be a gadget and P_G be the set of its portal vertices. For a graph H and $c \geq 1$, we say that G is (c, H)-internally coherent if, for any extension E of G and any (c, H)-multi-partition / (c, H)-single-partition $\mathcal{Z}$ of E, the following holds: If there exists $Z \in \mathcal{Z}$ that contains an internal vertex of G, then all vertices in Z must belong to G. Formally,*

$$\Big(V(Z) \cap \big(V(G) \setminus P_G\big)\Big) \neq \emptyset \implies V(Z) \subseteq V(G).$$

Next, we define the relation realized by a gadget.

▶ **Definition 9.** *Let H be a graph, $c \geq 1$ and G be a gadget with portal vertices $P_G = \{p_1, \ldots, p_\ell\}$. We say G dist-(c, H)-realizes (respectively, arb-(c, H)-realizes) a relation $R \subseteq \{0, \ldots, c\}^\ell$ if the following holds:*

$r \in R \iff$ *There exists a (c, H)-single-packing (respectively, $\big(c, H\big)$-multi-packing) $\mathcal{Z}$ of G such that $\mathcal{Z}$ covers each internal vertex of G exactly c times, and each portal vertex p_i exactly r_i times for $1 \leq i \leq \ell$.*

We say that G strict-(c, H)-realizes R if it both dist-(c, H) and arb-(c, H)-realizes R.

▶ Remark 10. When $c = 1$, the notions of dist-(c, H)-realization and arb-(c, H)-realization coincide. In this case, we simply say that the relation R is H-realized by G, instead of using the term "strict-$(1, H)$".

We say a relation $R \subseteq \{0, \ldots, c\}^\ell$ is (x, d)-regular for $d \geq 1$ and $0 \leq x \leq d - 1$ if for each $r \in R$, the weight of r is equivalent to $x \mod d$, i.e. $\mathbf{w}(r) \coloneqq \left(\sum_{i \in [\ell]} r_i\right) = x \mod d$. Moreover, a relation R has weight X if $\left(\max_{r \in R} \mathbf{w}(r)\right) = X$. Recall that a gadget is a small, engineered graph used to enforce specific behaviors in a reduction. We streamline the lower bound constructions by building general-purpose gadgets that can realize any relation. The descriptions of the gadgets are deferred to the full version of the paper. This way, we avoid repetitive constructions and keep the focus on the core ideas.

▶ **Lemma 11.** *Let H be an arbitrary graph, $\ell \geq 1$ be an integer and $R \subseteq \{0, 1\}^\ell$ be a relation that is $(x, |H|)$-regular for some $0 \leq x \leq |H| - 1$. Then, there exists a $(1, H)$-internally coherent gadget G that H-realizes the relation R and the size of G is bounded by some function of ℓ. Moreover, for relations with constant weight, it holds that $\mathbf{pw}(G) = \mathcal{O}(\ell)$.*

When $c \geq 1$, we require the relation to have more structure, i.e., the relation should be $(0, |H|)$-regular. However, this restriction can be easily handled in our lower bound constructions.

▶ **Lemma 12.** *Let $c \geq 1$, H be a clique, $\ell \geq 1$ be a constant and $R \subseteq \{0, \ldots, c\}^\ell$ be a $(0, |H|)$-regular relation. Then, there exists a (c, H)-internally coherent gadget G that strict-(c, H)-realizes the relation R. Moreover, the size of G is bounded by some function of ℓ.*

2.3 Single-Exponential Lower Bound

In this section, we give an overview of how the above-described gadgets are used to prove Theorem 6. Classically, when proving conditional lower bounds based on SETH, one needs to find a reduction from SAT. However, this usually involves carrying out repetitive, unnecessary work that is not specific to the problem one is working on. One of the strengths of the framework introduced by Lampis [7] is removing the need for such repetitive constructions.

The primal graph of a CSP instance ψ is a graph G that has a vertex for each variable of ψ, and there is an edge between $x, y \in V(G)$ if x and y appear together in a constraint. The pathwidth of the CSP instance ψ is defined to be the pathwidth of its primal graph. Similarly, by path decomposition of ψ, we mean a path decomposition of the primal graph of ψ. The following lemma from [7] implies that we can assume the path decomposition to be nice.

▶ **Lemma 13** (Lemma 2.1 in [7], restated for CSPs). *There is a linear-time algorithm that takes as input a CSP formula ψ with n variables and m constraints and a path decomposition of its primal graph of width p and outputs a nice path decomposition $B_1, \ldots, B_t$ of ψ containing at most $t = \mathcal{O}(p \cdot m)$ bags, as well as an injective function b from the set of constraints of ψ to $[t]$ such that for each constraint c, $B_{b(c)}$ contains all the variables of c.*

The following conjecture from [7], called **pw**-SETH, will form the basis of our hardness results.

▶ **Conjecture 14** (Conjecture 1.1 from [7].). *For all $\epsilon > 0$ we have the following: there exists no algorithm which takes as input a $3-SAT$ instance ϕ on n variables and a path decomposition of its primal graph of width* **pw** *and correctly decides if ϕ is satisfiable in time $(2-\epsilon)^{\mathbf{pw}} n^{O(1)}$.*

Moreover, we have the following result from [7], which proves the equivalence of falsifying **pw**-SETH and finding a faster algorithm for 2-CSP.

▶ **Theorem 15** (Theorem 3.2 from [7], shortened). *For each $B \geq 3$ the following statements are equivalent:*

1. *The* **pw**-*SETH is false.*
2. *There exist $\epsilon > 0, b > 0$ and an algorithm that takes as input a 2-CSP instance ψ on alphabet $[B]$, together with a path decomposition of ψ, and decides if ψ is satisfiable in time $(B-\epsilon)^{\mathbf{pw}} \cdot |\psi|^b$.*

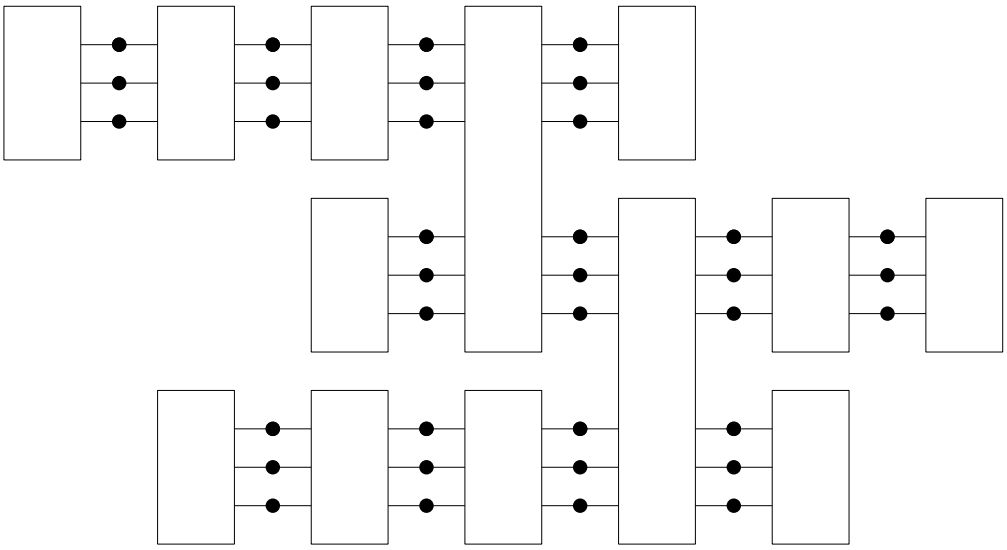

Figure 2.2 A high-level description of the lower bound construction used to prove Theorem 5. The coverage counts of all vertices in a column represent an assignment to the variables of the 2-CSP instance. The rectangles depict the gadgets that enforce the constraints; observe that they interact locally with the vertices, which allows us to bound the pathwidth of the constructed instance.

Motivated by Theorem 15, Section 3 presents a reduction from the 2-CSP problem to the `Single-Clique Partitioning`(c,d) problem. The core idea is to encode each variable's B possible assignments using a set of vertices whose coverage count in a (c, K_d)-single-packing represents the chosen value. We then introduce gadgets each enforcing a single constraint

of the 2-CSP instance via carefully specified relations so that only coverage patterns corresponding to satisfying assignments are possible. By designing these gadgets to interact locally, we ensure the pathwidth of the resulting instance increases by at most a constant, completing the reduction.

2.4 Slightly Superexponential Lower Bound

We now give a high-level description of the proof of Theorem 3. Let H be a graph with at least 3 vertices that is not a block graph. Next, we will describe the lower bound for the `Generalized Graph Partitioning`(H) problem which is stated in Theorem 3. Recall that `Generalized Graph Partitioning`(H) is solvable in slightly super-exponential time for any fixed graph H, i.e., there is an algorithm with running time $\mathcal{O}^*\left(2^{O(tw\cdot\log tw)}\right)$.[1] We show that this running time is optimal under ETH, i.e. there exists no algorithm for `Generalized Graph Partitioning`(H) with running time $\mathcal{O}^*\left(2^{o(tw\cdot\log(tw))}\right)$. To that end, we use an auxiliary problem for which such a lower bound was presented in [4]. Specifically, we define the $k \times k$ Permutation Independent Set problem where given a graph G on a vertex set $[k] \times [k]$, we ask whether there exists an independent set X in G that contains exactly one vertex from each row and each column.

$k \times k$ Permutation Independent Set
Input: A graph G on the vertex set $[k] \times [k]$
Question: Is there an independent set X of G such that X induces a permutation on $[k] \times [k]$?

The following hardness result was presented for the analogous $k \times k$ Permutation Clique problem in [4] which translates easily to $k \times k$ Permutation Independent Set. Below we state it for $k \times k$ Permutation Independent Set.

▶ **Theorem 16** (Theorem 14.14 in [4]). *Unless ETH fails, $k \times k$ Permutation Independent Set cannot be solved in time $2^{o(k\cdot\log k)}$.*

To prove Theorem 3, we reduce the $k \times k$ Permutation Independent Set problem to `Generalized Graph Partitioning`(H). The construction relies on structural properties of H. Let B be a block in H with a minimum separator S such that $B \setminus S$ has at least two connected components. Since H contains a non-clique block, such B and S exist. We partition S into two subsets, U and D, and create k copies of each. The construction in the proof of Theorem 3 ensures that any $|H|$-packing includes k copies of H, each covering exactly one copy of U and one of D. This yields $k! = 2^{\mathcal{O}(k\cdot\log k)}$ configurations, corresponding to all permutations of a set of size k. Additionally, for each edge e in the $k \times k$ Permutation Independent Set instance, we introduce a gadget to prevent e from being included in the set of vertices induced by this permutation. Moreover, these gadgets are designed to preserve pathwidth by interacting only locally. The detailed proof of Theorem 3 is deferred to the full version of the paper.

[1] The $O^*(f(k))$ notation suppresses polynomial factors in the input size n; that is, $O^*(f(k)) = O(f(k)\cdot n^c)$ for some constant c.

2.5 Algorithmic Results

Recall that a tree decomposition of a graph $G = (V, E)$ is a pair $(T, \{X_t\}_{t \in T})$, where T is a tree whose every node t is assigned a bag $X_t \subseteq V(G)$, satisfying the following properties:

1. For every vertex $v \in V$, there exists at least one bag X_t such that $v \in X_t$.
2. For every edge $(u, v) \in E$, there exists a bag X_t such that $\{u, v\} \subseteq X_t$.
3. For every vertex $v \in V$, the set of nodes $\{t \in V(T) \mid v \in X_t\}$ induces a connected subtree of T.

The *width* of a tree decomposition is the size of its largest bag minus one, and the *treewidth* of G is the minimum width over all possible tree decompositions of G. A nice tree decomposition is a rooted tree decomposition in which each node is one of the four types: leaf, introduce, forget or join. We refer the reader to [4] for more details.

The algorithmic results in Theorems 2 and 4 follow a fairly standard dynamic programming framework over tree decompositions. We define a suitable set of states for each bag in the decomposition, capturing the essential information needed to extend partial solutions. The main challenge of the approach lies in carefully designing these states and proving the correctness of the update rules that determine how states transition from one bag to the next. Usually what determines the running time is the state representation and transitions to the specific structural constraints of our problem.

In particular, the single-exponential algorithm for the `Single-Clique Packing`(c, d) problem defines the state of a bag based on how many times each vertex in the bag is covered by a partial solution. This yields $(c+1)^\ell$ states for a bag of size ℓ, naturally leading to a running time of $(c+1)^{tw} \cdot n^{\mathcal{O}(1)}$.

In contrast, the slightly superexponential algorithm for the `Generalized Graph Packing`(H) problem requires keeping track of a partition of the bag, in which each part corresponds to a partial copy of H. This results in $\mathcal{O}(\ell^\ell)$ possible states for a bag of size ℓ, leading to an overall running time of $2^{\mathcal{O}(tw \cdot \log tw)} \cdot n^{\mathcal{O}(1)}$. The algorithms are presented in detail in the full version of the paper.

3 Lower Bounds for Clique Partitioning Problems

In this section we prove Theorems 5 and 6. Theorem 15 says that in order to prove a conditional lower bound based on **pw**-SETH, one can start the reduction from the 2-CSP problem. In the following, we will present a reduction from the 2-CSP problem to the `Multi-Clique Partitioning`(c, d). Subsequently, we will describe another reduction from `Multi-Clique Partitioning`(c, d) to `Single-Clique Partitioning`(c, d) problem, and prove Theorems 5 and 6.

3.1 Lower Bounds

We first prove Theorem 5. To that end, intuitively, we show that a fast algorithm for the `Multi-Clique Partitioning`(c, d) problem implies a fast algorithm for the 2-CSP problem.

▶ **Lemma 17.** *Let $c \geq 1$ and $d \geq 3$ be integers. Suppose there exists an $\varepsilon > 0$ such that* `Multi-Clique Partitioning`(c, d) *can be solved in time $(c + 1 - \varepsilon)^{\mathbf{pw}(G)} \cdot n^{\mathcal{O}(1)}$ for all n-vertex graphs G given together with a path decomposition of width at most $\mathbf{pw}(G)$. Then, there exist $\epsilon', b' > 0$, an integer $B \geq 1$ and an algorithm that takes as input a 2-CSP instance ψ on alphabet $[B]$, together with a path decomposition of ψ, and decides if ψ is satisfiable in time $(B - \epsilon')^{\mathbf{pw}} \cdot |\psi|^{b'}$.*

Proof. Let ε, b be as in the lemma statement and let $\mathcal{A}$ be the hypothetical algorithm for `Multi-Clique Partitioning`(c, d). Moreover, we let H denote the clique K_d and let ℓ be the smallest integer that is a multiple of $|H|$ such that

$$(1-\varepsilon)\cdot|H| < \frac{\varepsilon}{2}\cdot(\ell-|H|)\,. \tag{3.1}$$

Observe that ℓ is a constant that only depends on ε and H.

Let $B = (c+1)^{\ell-|H|}$ and $\varepsilon' = \frac{\varepsilon}{2}$. We will now present a reduction from 2-CSP with alphabet size B to `Multi-Clique Partitioning`(c, d). The idea is as follows: in order to make use of regular relations, we will represent each variable of the 2-CSP instance by ℓ vertices. Note that each of the ℓ vertices can be covered between 0 and c times, which can be thought of as the state of a vertex. In total, ℓ vertices combined give rise to $(c+1)^\ell$ states. These states can also be visualized as vectors $r \in \{0,\ldots,c\}^\ell$. Next, we consider the following subset of vectors

$$Z \coloneqq \{x \in (c+1)^\ell \mid w(x) = 0 \mod |H|\}.$$

Observe that we have $|Z| \geq (c+1)^{\ell-|H|} = B$, because we can append to each vector in $r' \in \{0,\ldots,c\}^{\ell-|H|}$ at most $|H|$ many 1's so that the new vector $r \in \{0,\ldots,c\}^\ell$ constructed this way satisfies $w(r) = 0 \mod |H|$. Hence there exists an injective map $\Phi\colon [B] \to Z$ where we define $W \coloneqq \operatorname{im}(\Phi)$. We use the set W to simulate B many assignments to a variable of the 2-CSP instance. Observe that W, as a relation, is $(0, |H|)$-regular.

Construction of the `Multi-Clique Partitioning`(c, d) instance. Let ψ be a 2-CSP instance with variables $x_1,\ldots,x_n$, contraints $C_1,\ldots,C_m$ and alphabet $[D]$. Let $\mathcal{P} = (B_1,\ldots,B_t)$ be a nice path decomposition of width p. Finally, let $b\colon [m] \to [t]$ be a function that maps each constraint C_i of ψ to a bag such that $B_{b(i)}$ contains the variables occurring in C_i. We will construct an instance of the `Multi-Clique Partitioning`(c, d) problem as follows:

1. For each $1 \leq i \leq n$, define $l(i) \in [t]$ to be the smallest integer such that $x_i \in B_{l(i)}$. Similarly, let $r(i)$ be the largest integer such that $x_i \in B_{r(i)}$. For each $i \in [n]$ and $l(i) \leq j \leq r(i)+1$, introduce ℓ vertices $\{a_1^{i,j},\ldots,a_\ell^{i,j}\}$.
2. Define the relation

   $$W^C \coloneqq \operatorname{Compl}_c\big(W\big).$$

   Observe that W is $(0, |H|)$-regular by construction. The same also holds for W^C, because for each $x \in W^C$ such that $x = \operatorname{Compl}_c\big(s\big)$ for $s \in W$, we have

   $$w(x) = \Big(\ell\cdot c - w(s)\Big) = 0 \mod |H|,$$

   where the last equivalence holds because ℓ and $w(s)$ are both equivalent to $0 \mod |H|$. Introduce two gadgets L^i and R^i that arb-(c, H)-realize the relation W^C and W, respectively, which exist by Lemma 12. Then, identify the portal vertices of L^i with $(a_1^{i,l(i)},\ldots,a_\ell^{i,l(i)})$, and similarly, identify the portal vertices of R^i with the vertices $\{a_1^{i,r(i)+1},\ldots,a_\ell^{i,r(i)+1}\}$.
3. Let $j \in [t]$. We say that j represents s for $s \in [m]$ if $b(s) = j$. In that case, we define S_j to be the relation, and i_1 and i_2 to be the indices of the variables associated with the constraint C_s. We define the new relation

   $$R_j \coloneqq \left\{\Phi(u_1)\odot\Phi(u_2)\odot\operatorname{Compl}_c\big(\Phi(u_1)\big)\odot\operatorname{Compl}_c\big(\Phi(u_2)\big) \;\middle|\; (u_1,u_2)\in S_j\right\}.$$

Observe that R_j is $(0, |H|)$-regular because for each $x \in R_j$ we have

$$w(x) = (2 \cdot \ell \cdot c) = 0 \mod |H|$$

since ℓ is a multiple of $|H|$. Hence, we can introduce a gadget $N^j_{i_1,i_2}$ by Lemma 12 that arb-(c, H)-realizes R_j. Then, we identify the portal vertices of $N^j_{i_1,i_2}$ with the vertices

$$\left(a_1^{i_1,j}, \ldots, a_\ell^{i_1,j}\right) \odot \left(a_1^{i_2,j}, \ldots, a_\ell^{i_2,j}\right) \odot \left(a_1^{i_1,j+1}, \ldots, a_\ell^{i_1,j+1}\right) \odot \left(a_1^{i_2,j+1}, \ldots, a_\ell^{i_2,j+1}\right). \quad (3.2)$$

Next, we define the relation COPY $\subseteq \{0, \ldots, c\}^{2\cdot\ell}$ where

$$\text{COPY} \coloneqq \{\boldsymbol{u} \odot \text{Compl}_c(\boldsymbol{u}) \mid \boldsymbol{u} \in W\} \quad (3.3)$$

and let

$$\Gamma_j \coloneqq \begin{cases} \{i_1, i_2\} & \text{if } j \text{ represents } s, \\ \emptyset & \text{otherwise.} \end{cases}$$

Observe that COPY is $(0, |H|)$-regular because for each $x \in$ COPY we have

$$w(x) = \ell \cdot c = 0 \mod |H|.$$

By Lemma 12, there exists a gadget that arb-(c, H)-realizes COPY. Next, for each $i \in \left([n] \setminus \Gamma_j\right)$ such that $l(i) \leq j \leq r(i)$, we introduce a gadget F_i^j that arb-(c, H)-realizes the relation COPY and identifies the portal vertices of F_i^j with

$$\left(a_1^{i,j}, \ldots, a_\ell^{i,j}\right) \odot \left(a_1^{i,j+1}, \ldots, a_\ell^{i,j+1}\right). \quad (3.4)$$

Finally, for each $i \in [n]$ and $j \in [t]$ such that $l(i) \leq j \leq r(i)$, we define the gadget that covers i at step j as

$$K_i^j \coloneqq \begin{cases} N^j_{i_1,i_2} & \text{if } j \text{ represents } s \in [m] \text{ and } i \in \{i_1, i_2\} \\ F_i^j & \text{otherwise.} \end{cases}$$

This is the whole construction of the `Multi-Clique Partitioning`(c, d) instance which we call G.

Equivalence of the instances. We now prove that ψ is satisfiable if and only if G admits a $\left(c, K_d\right)$-multi-partition, by establishing each direction separately.

Suppose that there exists an assignment $(\alpha_1, \ldots, \alpha_n)$ to $(x_1, \ldots, x_n)$ such that ψ is satisfied. In the following, we will describe a $\left(c, K_d\right)$-multi-partition $\mathcal{K}$ of G. For each $i \in [n]$, define $\boldsymbol{a}_i \coloneqq \Phi(\alpha_i) \in W$. Now let $j \in [t]$. Observe that since $\boldsymbol{a}_i \in W$ for each $i \in [n]$, it holds that there exists a $\left(c, K_d\right)$-multi-packing of L^i that covers $(a_1^{i,l(i)}, \ldots, a_\ell^{i,l(i)})$ according to $\text{Compl}_c(\boldsymbol{a}_i)$. Moreover, there exists a $\left(c, K_d\right)$-multi-packing of R^i that covers $(a_1^{i,r(i)+1}, \ldots, a_\ell^{i,l(i)+1})$ according to $\boldsymbol{a}_i$. In both cases, the internal vertices of the gadgets are covered exactly c times.

Now let $j \in [t]$. For all $i \in \left([n] \setminus \Gamma_j\right)$, there exists a $\left(c, K_d\right)$-multi-packing of F_i^j that covers

$$\left(a_1^{i,j}, \ldots, a_\ell^{i,j}\right) \odot \left(a_1^{i,j+1}, \ldots, a_\ell^{i,j+1}\right) \quad (3.5)$$

according to $\boldsymbol{a}_i \odot \mathrm{Compl}_c(\boldsymbol{a}_i)$, because $\boldsymbol{a}_i \in W$. Moreover, if j represents s for some $s \in [m]$, and x_{i_1}, x_{i_2} are the variables corresponding to C_s, then there exists a (c, K_d)-multi-packing that covers

$$\left(a_1^{i_1,j}, \ldots, a_\ell^{i_1,j}\right) \odot \left(a_1^{i_2,j}, \ldots, a_\ell^{i_2,j}\right) \odot \left(a_1^{i_1,j+1}, \ldots, a_\ell^{i_1,j+1}\right) \odot \left(a_1^{i_2,j+1}, \ldots, a_\ell^{i_2,j+1}\right) \quad (3.6)$$

according to $\boldsymbol{a}_{i_1} \odot \boldsymbol{a}_{i_2} \odot \mathrm{Compl}_c(\boldsymbol{a}_{i_1}) \odot \mathrm{Compl}_c(\boldsymbol{a}_{i_2})$. Again, in both cases, the internal vertices of the gadgets are covered exactly c times. Next, we prove that the remaining vertices are covered c times as well.

▷ Claim 18. It holds that for each $i \in [n]$, $j \in [t]$ such that $l(i) \leq j \leq r(i) + 1$ and $x \in [\ell]$, $a_x^{i,j}$ is covered exactly c times by $\mathcal{K}$.

Proof. We prove the claim by induction on j. Let $j = 1$, $i \in [n]$ and suppose that $l(i) \leq j \leq r(i) + 1$. Since $1 \leq l(i) \leq j = 1$, we have that $l(i) = 1 = j$. Consider the vertices $\left(a_1^{i,1}, \ldots, a_\ell^{i,1}\right)$, which are covered according to $\mathrm{Compl}_c(\boldsymbol{a}_i)$ by L^i. Moreover, $\left(a_1^{i,1}, \ldots, a_\ell^{i,1}\right)$ is covered according to $\boldsymbol{a}_i$ by K_i^1 which follows from (3.5) or (3.6), depending on whether $i \in \Gamma_1$ or not, respectively. All in all, $a_x^{i,1}$ is covered exactly c times for $x \in [\ell]$.

Now suppose that the claim holds for $1 < j \leq t$, and we will prove the claim for $j + 1$. Let $i \in [n]$ such that $l(i) \leq j + 1 \leq r(i) + 1$. Consider the vertices $\left(a_1^{i,j+1}, \ldots, a_\ell^{i,j+1}\right)$, which are covered according to $\mathrm{Compl}_c(\boldsymbol{a}_i)$ by K_i^j. This follows from (3.5) and (3.6). Now, observe that we have either $j < r(i)$ or $j = r(i)$. In both cases, by using the arguments in the $j = 1$ case, one can conclude that $\left(a_1^{i,j+1}, \ldots, a_\ell^{i,j+1}\right)$ is covered according to $\boldsymbol{a}_i$ by K_i^{j+1}. Therefore, all in all, it holds that each vertex $a_x^{i,j}$ is covered exactly c times for $x \in [\ell]$. ◁

Now for the reverse implication, suppose that G has a (c, K_d)-multi-partition. Since each gadget used in the construction of G is (c, K_d)-internally coherent, this implies that for each gadget there is a (c, K_d)-multi-packing that covers its interval vertices exactly c times, and its portal vertices according to the relation associated with it. In particular, for each $i \in [n]$, let $\boldsymbol{b}_i \in W^C$ denote the vector such that L^i covers the vertices $\{a_1^{i,l(i)}, \ldots, a_\ell^{i,l(i)}\}$ according to $\boldsymbol{b}_i$.

By induction, one can show that for each $j \in [t]$ and $i \in [n]$ such that $l(i) \leq j \leq r(i)$, the tuple $(a_1^{i,j}, \ldots, a_\ell^{i,j})$ is covered by K_i^j according to $\boldsymbol{z}_i$ where $\boldsymbol{z}_i = \mathrm{Compl}_c(\boldsymbol{b}_i)$. Hence, we let $\alpha_i \coloneqq \Phi^{-1}(\boldsymbol{z}_i) \in B$. Next, we will prove that $A \coloneqq (\alpha_1, \ldots, \alpha_n)$ is a satisfying assignment for ψ. To that end, let $s \in [m]$ and $j = b(s)$. To show that C_s is satisfied by A, let x_{i_1} and x_{i_2} be the variables associated with C_s. By the above discussion, we know that $\left(a_1^{i_1,j}, \ldots, a_\ell^{i_1,l}\right)$ and $\left(a_1^{i_2,j}, \ldots, a_\ell^{i_2,j}\right)$ is covered according to $\boldsymbol{z}_{i_1}$ and $\boldsymbol{z}_{i_2}$, respectively. By the definition of R_j, $a_{i_1} = \Phi^{-1}(\boldsymbol{z}_{i_1})$ and $a_{i_2} = \Phi^{-1}(\boldsymbol{z}_{i_2})$ satisfy C_s. Therefore, the assignment A satisfies all constraints of ψ, and ψ is satisfied if and only if G has a (c, K_d)-multi-partition.

Pathwidth and size of the constructed instance. To bound the pathwidth of G, we will create a path decomposition by following $\{B_j\}_{j \in [t]}$. Specifically, for each $j \in [t]$, we first create a new path decomposition $\mathcal{X} = (X_1, \ldots, X_t)$ where each X_j is a copy of B_j and we replace each $x_i \in B$ with the vertices $a_1^{i,j}, \ldots, a_\ell^{i,j}$. Note that the size of each X_j is at most $p \cdot \ell$ for $j \in [t]$.

In the following, we will add the remaining vertices of G to the bags in $\mathcal{X}$ such that $\mathcal{X}$ is a valid path decomposition of G. Let $j \in [t]$. For each $i \in [n] \setminus \Gamma_j$ such that $l(i) \leq j \leq r(i)$, we replace the vertices $\{a_x^{i,j}\}_{x \in [\ell]}$ with $\{a_x^{i,j+1}\}_{x \in [\ell]}$ as follows. After the bag X_j ,we first insert the bag $X'_{j,i} \coloneqq \left(X_j \cup V\left(F_i^j\right)\right)$, and then add another bag $X''_{j,i}$ where we replace

$\{a_x^{i,j}\}_{x\in[\ell]}$ in $X'_{j,i}$ with $\{a_x^{i,j+1}\}_{x\in[\ell]}$, and finally, another bag $X'''_{j,i}$ where we remove the vertices $V\left(F_i^j\right)$ from $X''_{j,i}$. For a fixed $j \in [t]$, we keep adding the bags iteratively for each $i \in [n] \setminus \Gamma_j$ such that $l(i) \leq j \leq r(i)$, until all vertices in all the gadgets are contained in the bag decomposition. Note that, by our construction, edges that are adjacent to a vertex in F_i^j are also covered by either $X'_{j,i}$ or $X''_{j,i}$.

Finally, for each $s \in [m]$ and $j = b(s)$, we add the gadgets $N^j_{i_1,i_2}$ to the tree decomposition in a similar way. Since the size of each $N^j_{i_1,i_2}$ and F_i^j is a function of ℓ, it is bounded by a constant. All in all, the pathwidth of G increases at most by a constant. We have

$$\mathbf{pw}(G) = l \cdot p + \mathcal{O}(1).$$

Finally, since t and m are bounded by a polynomial of n, it follows from the construction that

$$V(G) = n^{\mathcal{O}(1)}.$$

Running Time. Constructing the graph G from ψ takes time polynomial in n. By our assumption on $\mathcal{A}$, the whole reduction takes time

$$\begin{aligned}
(c+1)^{(1-\varepsilon)\cdot\mathbf{pw}(G)} \cdot V(G)^b &= (c+1)^{(1-\varepsilon)\cdot\ell\cdot p} \cdot n^{\mathcal{O}(1)} \\
&= (c+1)^{(1-\varepsilon)\cdot(\ell-|H|)\cdot p} \cdot (c+1)^{(1-\varepsilon)\cdot|H|\cdot p} \cdot n^{\mathcal{O}(1)} \\
&= B^{(1-\varepsilon)\cdot p} \cdot (c+1)^{(1-\varepsilon)\cdot|H|\cdot p} \cdot n^{\mathcal{O}(1)} \\
&< B^{(1-\varepsilon)\cdot p} \cdot (c+1)^{\frac{\varepsilon}{2}\cdot(\ell-|H|)\cdot p} \cdot n^{\mathcal{O}(1)} \\
&= B^{(1-\varepsilon)\cdot p} \cdot B^{\frac{\varepsilon}{2}\cdot p} \cdot n^{\mathcal{O}(1)} \\
&= B^{(1-\varepsilon')\cdot p} \cdot |\psi|^{b'}
\end{aligned}$$

where the inequality follows from (3.1) and b' is a constant. ◀

The proof of Theorem 5 follows from Theorem 15 and Lemma 17. We note here that the same construction can be used to prove Theorem 6, because the gadgets used in Lemma 17 strict-(c, K_d)-realize their relations (see Definition 9 and Lemma 12). However, by presenting a simple reduction, we demonstrate that a fast algorithm for `Single-Clique Partitioning`(c, d) implies a fast algorithm for `Multi-Clique Partitioning`(c, d), which is used to prove Theorem 6 in a more formal way.

▶ **Lemma 19.** *Let $c \geq 1$ and $d \geq 3$ be integers. Suppose there exists an $\varepsilon > 0$ such that* `Single-Clique Partitioning`(c, d) *can be solved in time $(c + 1 - \varepsilon)^{\mathbf{pw}(G)} \cdot n^{\mathcal{O}(1)}$ for all n-vertex graphs G given together with a path decomposition of width at most $\mathbf{pw}(G)$. Then, there exist $\epsilon' > 0$ and $b' > 0$ such that* `Multi-Clique Partitioning`(c, d) *can be solved in time $(c+1-\varepsilon')^{\mathbf{pw}(G)} \cdot n^{b'}$ for all n-vertex graphs G given together with a path decomposition of width at most $\mathbf{pw}(G)$.*

Proof. Let ε and b be as in the statement of the lemma. Moreover, let $\mathcal{A}$ be the hypothetical algorithm for `Single-Clique Partitioning`(c, d).

Construction of the `Single-Clique Partitioning`(c, d) instance. Let G be an instance of `Multi-Clique Partitioning`(c, d). Moreover, we let H denote the clique K_d and construct a `Single-Clique Partitioning`(c, d) instance G' as follows. Let G' have the same vertex set as G. We call these vertices the original vertices of G'. Moreover, for each clique X in G of size d, we add a gadget E_X that dist-(c, H)-realizes the relation $\mathrm{EQ}_d^{[0,c]}$. We identify the portal vertices of E_X with $V(X)$. This is the whole construction.

Equivalence of Instances. We will now prove that G admits a $\big(c, K_d\big)$-multi-partition if and only if G' admits a (c, K_d)-single-partition.

Suppose that G has a $\big(c, K_d\big)$-multi-partition which is denoted by $\mathcal{Z}$. For each clique X in G, let a_x denote the number of occurences of X in $\mathcal{Z}$. We construct a (c, K_d)-single-partition $\mathcal{K}$ for G' as follows. For each clique X in G, consider a (c, K_d)-single-packing of E_X such that the portal vertices of E_X are covered a_X times. Add this (c, K_d)-single-packing to $\mathcal{K}$. Since the gadgets are disjoint, the copies of K_d are also disjoint. The internal vertices of the gadgets are covered exactly c times. Moreover, the original vertices of G' are also covered c times, since each equality gadget simulates a clique. Hence $\mathcal{K}$ is a valid (c, K_d)-single-partition and therefore G' is a yes instance.

Now suppose that G' has a (c, K_d)-single-partition $\mathcal{K}$. Then, for each clique X in G, let a_X denote the number of times E_X covers its portal vertices. We construct a $\big(c, K_d\big)$-multi-packing $\mathcal{Z}$ by including each X exactly a_X times in $\mathcal{Z}$. Moreover, $\mathcal{Z}$ covers each vertex exactly c times, hence it is a valid $\big(c, K_d\big)$-multi-partition. Therefore, G is a yes-instance.

Running Time. First, we show that the pathwidth of G' is $p + \mathcal{O}(1)$. Take the path decomposition of G and for each clique X, let B_X denote the bag that contains the vertices of X. Note that since X is a clique, there exists such a bag. Moreover, we may assume each bag B_X is unique for each clique X, duplicating bags if necessary. Then, we simply add the vertices of E_X to the bag B_X, increasing its size at most by a constant. Therefore, we get a new path decomposition for G' where the size of a bag is at most $p + \mathcal{O}(1)$. Hence, it holds that $\mathbf{pw}(G') = p + \mathcal{O}(1)$.

Constructing the graph takes time polynomial in $n = V(G)$, and we also have $V(G') = n^{\mathcal{O}(1)}$. Therefore, the whole reduction takes time

$$\begin{aligned}(c+1-\varepsilon)^{\mathbf{pw}(G')} \cdot V(G')^b &= (c+1-\varepsilon)^{p+\mathcal{O}(1)} \cdot n^{\mathcal{O}(1)} \\ &= (c+1-\varepsilon)^{p} \cdot n^{\mathcal{O}(1)} \\ &= (c+1-\varepsilon)^{\mathbf{pw}(G)} \cdot n^{b'}\end{aligned}$$

where b' is a constant. ◀

The proof of Theorem 6 follows from Theorem 5 and Lemma 19.

Optimal Quantum Algorithm for Estimating Fidelity to a Pure State

Wang Fang
School of Informatics, University of Edinburgh, UK

Qisheng Wang

Abstract

We present an *optimal* quantum algorithm for fidelity estimation between two quantum states when one of them is pure. In particular, the (square root) fidelity of a mixed state to a pure state can be estimated to within additive error ε by using $\Theta(1/\varepsilon)$ queries to their state-preparation circuits, achieving a quadratic speedup over the folklore $O(1/\varepsilon^2)$. Our approach is technically simple, and can moreover estimate the quantity $\sqrt{\mathrm{tr}(\rho\sigma^2)}$ that is not common in the literature. To the best of our knowledge, this is the *first* query-optimal approach to fidelity estimation involving mixed states.

1 Introduction

The fidelity between quantum states [24, 13] is a closeness measure that is commonly used in quantum physics and quantum computing [20, 34, 12, 33]. Formally, for two (mixed) quantum states ρ and σ, their (square root) fidelity is defined by (see [20, Equation (9.53)])

$$\mathrm{F}(\rho,\sigma) = \mathrm{tr}\left(\sqrt{\sqrt{\sigma}\rho\sqrt{\sigma}}\right).$$

The fidelity is generally bounded by $0 \leq \mathrm{F}(\rho,\sigma) \leq 1$. In particular, when $\mathrm{F}(\rho,\sigma) = 1$, the two states ρ and σ are identical; and when $\mathrm{F}(\rho,\sigma) = 0$, the two states are orthogonal.

The estimation of fidelity turns out to be central in quantum property testing (cf. [18]). The earliest approach is now known as the SWAP test [5], allowing us to estimate to within additive error ε the squared fidelity $\mathrm{F}^2(\rho,\sigma) = \mathrm{tr}(\rho\sigma)$ when ρ and σ are pure states, using $O(1/\varepsilon^2)$ samples of ρ and σ. Moreover, the squared fidelity $\mathrm{F}^2(\rho,\sigma)$ for pure states ρ and σ can be estimated using $O(1/\varepsilon)$ queries to their state-preparation circuits through the SWAP test [5] equipped with quantum amplitude estimation [4]. The approach based on the SWAP test has been found to have various applications [21]. Fidelity estimation for pure states was also considered in some restricted models: a direct fidelity estimation [7] was proposed when only Pauli measurements are allowed and a distributed approach was developed in [1]. Recently, query-optimal and sample-optimal quantum algorithms for estimating the fidelity $\mathrm{F}(\rho,\sigma) = \sqrt{\mathrm{tr}(\rho\sigma)}$ for pure states ρ and σ have been found in [25] and [28], respectively.

		$\mathrm{poly}(\kappa,1/\varepsilon)$ samples	/

Although fidelity estimation is known to be BQP-complete when one of the quantum states is pure [22], fidelity estimation for mixed states is QSZK-hard in general [31, 32], which means that there is no polynomial-time quantum algorithm for fidelity estimation unless BQP = QSZK. Nevertheless, efficient quantum algorithms for fidelity estimation for low-rank states were recently discovered [29] and later improved [26, 10] with time complexity $\mathrm{poly}(r,1/\varepsilon)$, where r is the rank of the states. Quantum algorithms for fidelity estimation for well-conditioned states was recently proposed with query complexity $\mathrm{poly}(\kappa)\cdot\widetilde{O}(1/\varepsilon)$ [15], achieving almost optimal dependence on the precision ε, where κ is the condition number such that $\rho,\sigma \geq I/\kappa$.

In this paper, we present an optimal quantum algorithm for estimating the fidelity of a mixed state ρ to a pure state $\sigma = |\psi\rangle\langle\psi|$, using queries to the state-preparation circuits of both states. The input model is known as the "*purified quantum query access*" model, where we assume query access to (the controlled version of) a quantum unitary oracle that prepares the purification of the input quantum state, and its inverse. This input model is commonly employed in quantum computational complexity [31] and quantum algorithms [8]. Our main result is stated in the following theorem.

▶ **Theorem 1** (Estimating fidelity to a pure state, Theorem 6 simplified)**.** *Given purified quantum query access to a mixed state ρ and a pure state $\sigma = |\psi\rangle\langle\psi|$, the fidelity $\mathrm{F}(\rho,\sigma) = \sqrt{\langle\psi|\rho|\psi\rangle}$ can be estimated to within additive error ε with query complexity $O(1/\varepsilon)$.*

Prior to the result of Theorem 1, we are only aware of a folklore quantum algorithm based on the SWAP test (which was mentioned above and will be explained in detail in Section 3.1). This folklore approach computes $\mathrm{F}^2(\rho,\sigma) = \langle\psi|\rho|\psi\rangle$ to within additive error ε with query complexity $O(1/\varepsilon)$, thereby resulting in a query complexity of $O(1/\varepsilon^2)$ for estimating $\mathrm{F}(|\psi\rangle,\rho)$ to within additive error ε. By comparison, Theorem 1 exhibits a quadratic improvement.

The quantum query algorithm given in Theorem 1 generalizes the pure-state fidelity estimation in [25] where unitary oracles are required to directly prepare the pure states. In comparison, our result in Theorem 1 allows the unitary oracles to have redundant output qubits (see Section 5 for more details).

Our approach is actually optimal, as it can be used to estimate the fidelity between two pure states and the quantum query lower bound $\Omega(1/\varepsilon)$ is due to [2, 19] (noted in [25]). In Section 6, we further show that the optimality holds even if ρ is of an arbitrary rank.

We compare fidelity estimations for pure states in Table 1.

As a bonus, our approach in Theorem 1 can further estimate the quantity $\sqrt{\mathrm{tr}(\rho\sigma^2)}$ with optimal query complexity (see Section 4.2), which is of independent interest as this quantity is not common in the literature.

Organization of this paper. We give a formal definition of the purified quantum query access model and the problem statement of fidelity estimation in Section 2. Then, we review previous approaches in Section 3 with their subroutines. In Section 4, we present our approach and its generalization. An implication of our results is discussed in Section 5. Lower bounds for fidelity estimation are given in Section 6. Finally, a brief discussion is drawn in Section 7.

2 Problem Settings

In this paper, we assume purified quantum query access to the input quantum states. This input model is widely used in the literature, e.g., [8, 23, 11, 10, 30, 27, 16].

▶ **Definition 2** (Purified quantum query access). *For a mixed quantum state ρ, purified quantum query access to ρ means query access to a unitary oracle U that prepares a purification of ρ. Specifically, suppose U_{AB} acts on two subsystems A and B, then $\rho_{\mathsf{A}} = \mathrm{tr}_{\mathsf{B}}(|\rho\rangle\langle\rho|_{\mathsf{AB}})$, where $|\rho\rangle_{\mathsf{AB}} = U_{\mathsf{AB}}|0\rangle_{\mathsf{AB}}$. Moreover, we are allowed to use queries to (controlled-)U and its inverse.*

We consider the problem of fidelity estimation, formally stated as follows.

▶ **Problem 1** (Fidelity estimation). *Given purified quantum query access to two mixed quantum states ρ and σ, the task is to compute $\mathrm{F}(\rho,\sigma)$ to within additive error ε.*

In particular, this paper focuses on the case of Problem 1 where $\sigma = |\psi\rangle\langle\psi|$ is pure.

3 Warm-Ups

As a warm-up, we review the previous approaches to fidelity estimation involving pure states, together with their useful subroutines.

3.1 SWAP Test

It is well known that the SWAP test [5] can be used to estimate the fidelity $\mathrm{F}(\rho,\sigma)$ when one of ρ and σ is pure. In particular, if $\sigma = |\psi\rangle\langle\psi|$ is pure, the SWAP test on input ρ and σ (see Figure 1) outputs a bit $x \in \{0,1\}$ such that (adapted from [14, Proposition 9])

$$\Pr[x=0] = \frac{1+\mathrm{F}^2(\rho,|\psi\rangle)}{2}. \tag{1}$$

With this, we can estimate $\mathrm{F}(\rho,|\psi\rangle)$. Specifically, suppose that $\tilde{p}$ is an estimate of $\Pr[x=0]$ such that $|\tilde{p}-\Pr[x=0]| \le \delta$. Then, it can be shown that $\sqrt{2\tilde{p}-1}$ is an estimate of $\mathrm{F}(\rho,|\psi\rangle)$ with $|\sqrt{2\tilde{p}-1} - \mathrm{F}(\rho,|\psi\rangle)| \le \Theta(\sqrt{\delta})$. An estimate of $\mathrm{F}(\rho,|\psi\rangle)$ to within additive error ε can be obtained by setting $\delta = \Theta(\varepsilon^2)$.

To estimate $\mathrm{F}(\rho,|\psi\rangle)$ when given purified quantum query access to ρ and $|\psi\rangle$, we need the quantum subroutine for amplitude estimation [4].

▶ **Theorem 3** (Quantum amplitude estimation, [4]). *Suppose that U is a unitary operator such that $U|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}} = \sqrt{p}|0\rangle_{\mathsf{A}}|\varphi_0\rangle_{\mathsf{B}} + \sqrt{1-p}|1\rangle_{\mathsf{A}}|\varphi_1\rangle_{\mathsf{B}}$, where $p \in [0,1]$ and $|\varphi_0\rangle, |\varphi_1\rangle$ are normalized pure states. Then, we can estimate p to within additive error δ using $O(1/\delta)$ queries to (controlled-)U and its inverse.*

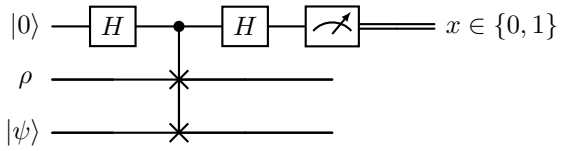

Figure 1 The SWAP test for estimating $\mathrm{F}(\rho, |\psi\rangle)$.

By Theorem 3, we can therefore obtain an estimate of $\mathrm{F}(\rho, |\psi\rangle)$ to within additive error ε using $O(1/\varepsilon^2)$ queries to the state-preparation circuits of ρ and $|\psi\rangle$, based on the SWAP test in Figure 1.

3.2 Pure-State Fidelity Estimation

Recently, a new approach was proposed in [25] for estimating the fidelity $\mathrm{F}(|\varphi\rangle, |\psi\rangle)$ between two pure quantum states $|\varphi\rangle$ and $|\psi\rangle$, improving the folklore approach in Section 3.1. However, the approach in [25] assumes a slightly more restricted input model, where U_φ and U_ψ are two unitary quantum circuits that respectively prepare $|\varphi\rangle$ and $|\psi\rangle$, i.e., $U_\varphi|0\rangle = |\varphi\rangle$ and $U_\psi|0\rangle = |\psi\rangle$.

The key idea of [25] is to *encode* the value of $\mathrm{F}(|\varphi\rangle, |\psi\rangle)$ in the amplitudes of a quantum state, rather than the $\sqrt{(1+\mathrm{F}^2(|\varphi\rangle, |\psi\rangle))/2}$ (in Equation (1)). Specifically, $\mathrm{F}(|\varphi\rangle, |\psi\rangle)$ can be encoded by the unitary operator $W = U_\varphi^\dagger U_\psi$ such that

$$W|0\rangle = \mathrm{F}(|\varphi\rangle, |\psi\rangle)|0\rangle + |\perp\rangle, \tag{2}$$

where $|\perp\rangle$ is an (unnormalized) pure state that is orthogonal to $|0\rangle$. The circuit W is depicted in Figure 2 and it outputs a bit $x \in \{0,1\}$ such that

$$\Pr[x = 0] = \mathrm{F}^2(|\varphi\rangle, |\psi\rangle). \tag{3}$$

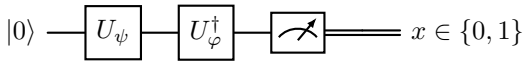

Figure 2 The quantum circuit for estimating $\mathrm{F}(|\varphi\rangle, |\psi\rangle)$.

Finally, the value of $\mathrm{F}(|\varphi\rangle, |\psi\rangle)$ can be estimated by the square root amplitude estimation provided in [25].

▶ **Theorem 4** (Quantum square root amplitude estimation, [25, Theorem I.5]). *Suppose that U is a unitary operator such that $U|0\rangle_\mathsf{A}|0\rangle_\mathsf{B} = \sqrt{p}|0\rangle_\mathsf{A}|\varphi_0\rangle_\mathsf{B} + \sqrt{1-p}|1\rangle_\mathsf{A}|\varphi_1\rangle_\mathsf{B}$, where $p \in [0,1]$ and $|\varphi_0\rangle, |\varphi_1\rangle$ are normalized pure states. Then, we can estimate $\sqrt{p}$ to within additive error δ using $O(1/\delta)$ queries to (controlled-)U and its inverse.*

For convenience, throughout this paper, we use $\mathsf{SqrtAmpEst}(U, \varepsilon)$ *to denote (the returned value of) the square root amplitude estimation process.*

Compared to Theorem 3, Theorem 4 gives an estimate of $\sqrt{p}$ (instead of p), thereby allowing us to skip taking square roots. By Theorem 4, we can therefore obtain an estimate of $\mathrm{F}(|\varphi\rangle, |\psi\rangle)$ to within additive error ε using $O(1/\varepsilon)$ queries to the state-preparation circuits of $|\varphi\rangle$ and $|\psi\rangle$, based on the construction of W in Equation (2).

4 Our Approach

For the task of estimating the fidelity $\mathrm{F}(\rho, |\psi\rangle)$ of a mixed state to a pure state, the approach in Section 3.1 only gives a query complexity of $O(1/\varepsilon^2)$, while the approach in Section 3.2, however, turns out not to be applicable (as a more restricted input model is assumed). In this section, we present a simple quantum algorithm that estimates $\mathrm{F}(\rho, |\psi\rangle)$ to within additive error ε using $O(1/\varepsilon)$ queries to the state-preparation circuits of ρ and $|\psi\rangle$.

Suppose that the purified quantum query access to ρ and $|\psi\rangle$ is given by two quantum circuits U and V, respectively:

$$U_{\mathsf{AB}}|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}} = |\rho\rangle_{\mathsf{AB}}, \tag{4}$$

$$V_{\mathsf{A'B'}}|0\rangle_{\mathsf{A'}}|0\rangle_{\mathsf{B'}} = |\psi\rangle_{\mathsf{A'}}|\psi'\rangle_{\mathsf{B'}}, \tag{5}$$

where $\rho_{\mathsf{A}} = \mathrm{tr}_{\mathsf{B}}(|\rho\rangle\langle\rho|_{\mathsf{AB}})$ and $|\psi'\rangle_{\mathsf{B'}}$ is any pure state. Here, A, B, $\mathsf{A'}$, and $\mathsf{B'}$ are subscripts of subsystems for clarity, where the subsystems A and $\mathsf{A'}$ have the same dimension. Without loss of generality, we can also assume that the subsystems B and $\mathsf{B'}$ have the same dimension.[1]

4.1 Fidelity to a Pure State

Our idea is to encode $\mathrm{F}(\rho, |\psi\rangle)$ in the amplitudes of an efficiently preparable quantum state, and then take use of the square root amplitude estimation in Theorem 4. To this end, we present a quantum circuit

$$W = (V_{\mathsf{AB}}^{\dagger} \otimes I_{\mathsf{A'B'}}) \cdot \mathsf{SWAP}_{\mathsf{BB'}} \cdot (U_{\mathsf{AB}} \otimes V_{\mathsf{A'B'}}). \tag{6}$$

This circuit is depicted in Figure 3 and it outputs two bits $x_{\mathsf{A}}, x_{\mathsf{B}} \in \{0, 1\}$ such that

$$\Pr[x_{\mathsf{A}} = x_{\mathsf{B}} = 0] = \mathrm{F}^2(\rho, |\psi\rangle). \tag{7}$$

Equation (7) is comparable to Equation (1) for the SWAP test and Equation (3) for the pure-state fidelity estimation, and it can be verified by the following proposition.

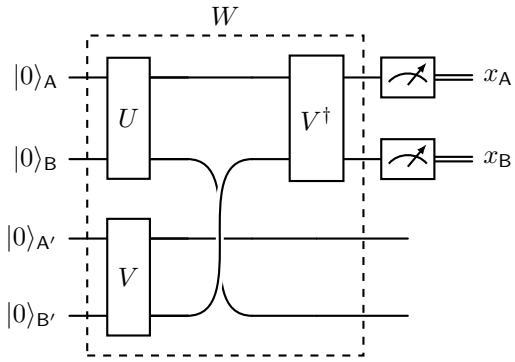

Figure 3 The encoding unitary operator W for $\mathrm{F}(\rho, |\psi\rangle)$.

▶ **Proposition 5.** *$\|(\langle 0|_{\mathsf{A}}\langle 0|_{\mathsf{B}} \otimes I_{\mathsf{A'B'}})W|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}|0\rangle_{\mathsf{A'}}|0\rangle_{\mathsf{B'}}\|^2 = \mathrm{F}^2(\rho, |\psi\rangle)$, where W is defined by Equation (6), U_{AB} is defined by Equation (4), and $V_{\mathsf{A'B'}}$ is defined by Equation (5).*

[1] If the subsystem B has a larger dimension than $\mathsf{B'}$, then $V_{\mathsf{A'B'}} \otimes I_{\mathsf{C}}$ (for certain subsystem C) can be a purified quantum query oracle for $|\psi\rangle$ with the ancilla system $\mathsf{B'C}$ having the same dimension as B. A similar construction also applies to the case that the subsystem $\mathsf{B'}$ has a larger dimension than B.

Proof. This can be shown by direct calculations.

$$
\begin{aligned}
&\|(\langle 0|_{\mathsf{A}}\langle 0|_{\mathsf{B}} \otimes I_{\mathsf{A}'\mathsf{B}'})W|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}|0\rangle_{\mathsf{A}'}|0\rangle_{\mathsf{B}'}\|^2 \\
&= \left\|(\langle 0|_{\mathsf{A}}\langle 0|_{\mathsf{B}} \otimes I_{\mathsf{A}'\mathsf{B}'})(V_{\mathsf{AB}}^{\dagger} \otimes I_{\mathsf{A}'\mathsf{B}'}) \cdot \mathsf{SWAP}_{\mathsf{BB}'} \cdot (U_{\mathsf{AB}} \otimes V_{\mathsf{A}'\mathsf{B}'})|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}|0\rangle_{\mathsf{A}'}|0\rangle_{\mathsf{B}'}\right\|^2 \\
&= \|(\langle \psi|_{\mathsf{A}}\langle \psi'|_{\mathsf{B}} \otimes I_{\mathsf{A}'\mathsf{B}'}) \cdot \mathsf{SWAP}_{\mathsf{BB}'} \cdot |\rho\rangle_{\mathsf{AB}}|\psi\rangle_{\mathsf{A}'}|\psi'\rangle_{\mathsf{B}'}\|^2 \\
&= \|(\langle \psi|_{\mathsf{A}} \otimes I_{\mathsf{BA}'} \otimes \langle \psi'|_{\mathsf{B}'}) \cdot |\rho\rangle_{\mathsf{AB}}|\psi\rangle_{\mathsf{A}'}|\psi'\rangle_{\mathsf{B}'}\|^2 \\
&= \|(\langle \psi|_{\mathsf{A}} \otimes I_{\mathsf{BA}'}) \cdot |\rho\rangle_{\mathsf{AB}}|\psi\rangle_{\mathsf{A}'}\|^2 \\
&= \langle \rho|_{\mathsf{AB}}\langle \psi|_{\mathsf{A}'} \cdot (|\psi\rangle\langle\psi|_{\mathsf{A}} \otimes I_{\mathsf{BA}'}) \cdot |\rho\rangle_{\mathsf{AB}}|\psi\rangle_{\mathsf{A}'} \\
&= \langle \rho|_{\mathsf{AB}} \cdot (|\psi\rangle\langle\psi|_{\mathsf{A}} \otimes I_{\mathsf{B}}) \cdot |\rho\rangle_{\mathsf{AB}} \\
&= \operatorname{tr}\big((|\psi\rangle\langle\psi|_{\mathsf{A}} \otimes I_{\mathsf{B}}) \cdot |\rho\rangle\langle\rho|_{\mathsf{AB}}\big) \\
&= \operatorname{tr}\Big(\operatorname{tr}_{\mathsf{B}}\big((|\psi\rangle\langle\psi|_{\mathsf{A}} \otimes I_{\mathsf{B}}) \cdot |\rho\rangle\langle\rho|_{\mathsf{AB}}\big)\Big) \\
&= \operatorname{tr}\big(|\psi\rangle\langle\psi|_{\mathsf{A}} \cdot \operatorname{tr}_{\mathsf{B}}(|\rho\rangle\langle\rho|_{\mathsf{AB}})\big) \\
&= \operatorname{tr}(|\psi\rangle\langle\psi|_{\mathsf{A}} \cdot \rho_{\mathsf{A}}) \\
&= \mathrm{F}^2(\rho, |\psi\rangle).
\end{aligned}
$$

◀

According to Proposition 5, we can write

$$
W|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}|0\rangle_{\mathsf{A}'}|0\rangle_{\mathsf{B}'} = \mathrm{F}(\rho, |\psi\rangle)|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}|\phi\rangle_{\mathsf{A}'\mathsf{B}'} + \sqrt{1 - \mathrm{F}^2(\rho, |\psi\rangle)}|\phi^{\perp}\rangle_{\mathsf{ABA}'\mathsf{B}'} \tag{8}
$$

for some normalized pure states $|\phi\rangle$ and $|\phi^{\perp}\rangle$ such that $(|0\rangle\langle 0|_{\mathsf{A}} \otimes |0\rangle\langle 0|_{\mathsf{B}} \otimes I_{\mathsf{A}'\mathsf{B}'})|\phi^{\perp}\rangle = 0$. With this, we can therefore estimate $\mathrm{F}(\rho, |\psi\rangle)$ using the square root amplitude estimation (Theorem 4). We formally state the result and give its rigorous proof as follows.

Algorithm 1 Quantum query algorithm for estimating fidelity to a pure state.

Input: Quantum oracles U and V that prepare n-qubit purifications of a k-qubit mixed state ρ and a k-qubit pure state $|\psi\rangle\langle\psi|$, respectively (as well as $U^{\dagger}$, $V^{\dagger}$, and their controlled versions); the desired additive error $\varepsilon \in (0, 1)$.

Output: An estimate of $\mathrm{F}(|\psi\rangle, \rho)$ to within additive error ε with probability at least $2/3$.

1: Let unitary operator

$$
\begin{aligned}
W' = (I_{\mathsf{C}} \otimes |0\rangle\langle 0|_{\mathsf{A}} \otimes |0\rangle\langle 0|_{\mathsf{B}} \otimes I_{\mathsf{A}'\mathsf{B}'} + X_{\mathsf{C}} \otimes (I_{\mathsf{AB}} - |0\rangle\langle 0|_{\mathsf{A}} \otimes |0\rangle\langle 0|_{\mathsf{B}}) \otimes I_{\mathsf{A}'\mathsf{B}'}) \\
\cdot (V_{\mathsf{AB}}^{\dagger} \otimes I_{\mathsf{A}'\mathsf{B}'}) \cdot \mathsf{SWAP}_{\mathsf{BB}'} \cdot (U_{\mathsf{AB}} \otimes V_{\mathsf{A}'\mathsf{B}'}).
\end{aligned}
$$

2: **return** $\mathsf{SqrtAmpEst}(W', \varepsilon)$ by Theorem 4.

▶ **Theorem 6** (Estimating fidelity to a pure state)**.** *Suppose that U and V are quantum unitary operators that prepare n-qubit purifications of a k-qubit mixed state $\rho = \operatorname{tr}_{\mathsf{B}}(|\rho\rangle\langle\rho|_{\mathsf{AB}})$ and a k-qubit pure state $|\psi\rangle\langle\psi| = |\psi\rangle\langle\psi|_{\mathsf{A}'}$, respectively, as in Equations (4) and (5). For $\varepsilon \in (0, 1)$, there is a quantum query algorithm that estimates $\mathrm{F}(\rho, |\psi\rangle)$ to within additive error ε with probability at least $2/3$ using $O(1/\varepsilon)$ queries to (controlled-)U, (controlled-)V, and their inverses.*

Proof. The formal algorithm is given in Algorithm 1. To make the proof rigorous, we introduce an auxiliary system C that consists of one qubit. Let

$$
W' = \big((I_{\mathsf{C}} \otimes |0\rangle\langle 0|_{\mathsf{A}} \otimes |0\rangle\langle 0|_{\mathsf{B}} + X_{\mathsf{C}} \otimes (I_{\mathsf{AB}} - |0\rangle\langle 0|_{\mathsf{A}} \otimes |0\rangle\langle 0|_{\mathsf{B}})) \otimes I_{\mathsf{A}'\mathsf{B}'}\big)W, \tag{9}
$$

where W is defined by Equation (6). According to Equation (8), we have

$$W'|0\rangle_{\mathsf{C}}|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}|0\rangle_{\mathsf{A}'}|0\rangle_{\mathsf{B}'} = \mathrm{F}(|\psi\rangle,\rho)|0\rangle_{\mathsf{C}}|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}|\phi\rangle_{\mathsf{A}'\mathsf{B}'} + \sqrt{1-\mathrm{F}(|\psi\rangle,\rho)^2}|1\rangle_{\mathsf{C}}|\phi^{\perp}\rangle_{\mathsf{ABA}'\mathsf{B}'}.$$

Finally, we can obtain an estimate $\tilde{x} = \mathsf{SqrtAmpEst}(W',\varepsilon)$ of $\mathrm{F}(|\psi\rangle,\rho)$ to within additive error ε (i.e., $|\tilde{x} - \mathrm{F}(|\psi\rangle,\rho)| < \varepsilon$) with probability at least $2/3$ using $O(1/\varepsilon)$ queries to W'. According to Equations (6) and (9), one query to W' consists of one query to U and two queries to V. Therefore, the way we obtain $\tilde{x}$ uses $O(1/\varepsilon)$ queries to both U and V. ◀

4.2 Generalization to Two Mixed States

In this subsection, we naturally extend the unitary operator in Figure 3 to the scenario where V prepares a purification of an arbitrary mixed state σ. That is, we replace Equation (5) with

$$V_{\mathsf{A}'\mathsf{B}'}|0\rangle_{\mathsf{A}'}|0\rangle_{\mathsf{B}'} = |\sigma\rangle_{\mathsf{A}'\mathsf{B}'}, \tag{10}$$

where $\sigma_{\mathsf{A}'} = \mathrm{tr}_{\mathsf{B}'}(|\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})$. In this case, it turns out that $\sqrt{\mathrm{tr}(\rho\sigma^2)}$ is encoded in the amplitude. Note that when σ is pure, $\sigma^2 = \sigma$, the quantity $\sqrt{\mathrm{tr}(\rho\sigma^2)}$ equals the fidelity $\mathrm{F}(\rho,\sigma)$. Specifically, the circuit in Figure 3 outputs two bits $x_{\mathsf{A}}, x_{\mathsf{B}} \in \{0,1\}$ such that

$$\Pr[x_{\mathsf{A}} = x_{\mathsf{B}} = 0] = \mathrm{tr}(\rho\sigma^2), \tag{11}$$

which generalizes Equation (7). This can be verified by the following proposition.

▶ **Proposition 7.** *$\|(\langle 0|_{\mathsf{A}}\langle 0|_{\mathsf{B}} \otimes I_{\mathsf{A}'\mathsf{B}'})W|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}|0\rangle_{\mathsf{A}'}|0\rangle_{\mathsf{B}'}\|^2 = \mathrm{tr}(\rho\sigma^2)$, where W is defined by Equation (6), U_{AB} is defined by Equation (4), and $V_{\mathsf{A}'\mathsf{B}'}$ is defined by Equation (10).*

Proof. This can be shown by direct calculations generalizing the proof of Proposition 5.

$$\begin{aligned}
&\|(\langle 0|_{\mathsf{A}}\langle 0|_{\mathsf{B}} \otimes I_{\mathsf{A}'\mathsf{B}'})W|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}|0\rangle_{\mathsf{A}'}|0\rangle_{\mathsf{B}'}\|^2 \\
&= \|(\langle\sigma|_{\mathsf{AB}} \otimes I_{\mathsf{A}'\mathsf{B}'}) \cdot \mathsf{SWAP}_{\mathsf{BB}'} \cdot |\rho\rangle_{\mathsf{AB}}|\sigma\rangle_{\mathsf{A}'\mathsf{B}'}\|^2 \\
&= \langle\rho|_{\mathsf{AB}}\langle\sigma|_{\mathsf{A}'\mathsf{B}'} \cdot \mathsf{SWAP}_{\mathsf{BB}'} \cdot (|\sigma\rangle\langle\sigma|_{\mathsf{AB}} \otimes I_{\mathsf{A}'\mathsf{B}'}) \cdot \mathsf{SWAP}_{\mathsf{BB}'} \cdot |\rho\rangle_{\mathsf{AB}}|\sigma\rangle_{\mathsf{A}'\mathsf{B}'} \\
&= \mathrm{tr}\big(\mathsf{SWAP}_{\mathsf{BB}'}(|\sigma\rangle\langle\sigma|_{\mathsf{AB}} \otimes I_{\mathsf{A}'\mathsf{B}'})\mathsf{SWAP}_{\mathsf{BB}'} \cdot (|\rho\rangle\langle\rho|_{\mathsf{AB}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\big) \\
&= \mathrm{tr}\big(\mathsf{SWAP}_{\mathsf{AA}'}(I_{\mathsf{AB}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\mathsf{SWAP}_{\mathsf{AA}'} \cdot (|\rho\rangle\langle\rho|_{\mathsf{AB}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\big) \\
&= \mathrm{tr}\Big(\mathrm{tr}_{\mathsf{B}}\big(\mathsf{SWAP}_{\mathsf{AA}'}(I_{\mathsf{AB}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\mathsf{SWAP}_{\mathsf{AA}'} \cdot (|\rho\rangle\langle\rho|_{\mathsf{AB}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\big)\Big) \\
&= \mathrm{tr}\big(\mathsf{SWAP}_{\mathsf{AA}'}(I_{\mathsf{A}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\mathsf{SWAP}_{\mathsf{AA}'} \cdot (\mathrm{tr}_{\mathsf{B}}(|\rho\rangle\langle\rho|_{\mathsf{AB}}) \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\big) \\
&= \mathrm{tr}\big(\mathsf{SWAP}_{\mathsf{AA}'}(I_{\mathsf{A}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\mathsf{SWAP}_{\mathsf{AA}'} \cdot (\rho_{\mathsf{A}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\big) \\
&= \mathrm{tr}\big((I_{\mathsf{A}} \otimes \langle\sigma|_{\mathsf{A}'\mathsf{B}'}) \cdot \mathsf{SWAP}_{\mathsf{AA}'}(I_{\mathsf{A}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\mathsf{SWAP}_{\mathsf{AA}'} \cdot (\rho_{\mathsf{A}} \otimes |\sigma\rangle_{\mathsf{A}'\mathsf{B}'})\big) \\
&= \mathrm{tr}\Big(\big((I_{\mathsf{A}} \otimes \langle\sigma|_{\mathsf{A}'\mathsf{B}'})\mathsf{SWAP}_{\mathsf{AA}'}(I_{\mathsf{A}} \otimes |\sigma\rangle_{\mathsf{A}'\mathsf{B}'})\big)^2 \cdot \rho_{\mathsf{A}}\Big).
\end{aligned}$$

The proof is completed by showing that $(I_{\mathsf{A}} \otimes \langle\sigma|_{\mathsf{A}'\mathsf{B}'})\mathsf{SWAP}_{\mathsf{AA}'}(I_{\mathsf{A}} \otimes |\sigma\rangle_{\mathsf{A}'\mathsf{B}'}) = \sigma_{\mathsf{A}}$. To see this, note that

$$
\begin{aligned}
&(I_{\mathsf{A}} \otimes \langle\sigma|_{\mathsf{A}'\mathsf{B}'})\mathsf{SWAP}_{\mathsf{A}\mathsf{A}'}(I_{\mathsf{A}} \otimes |\sigma\rangle_{\mathsf{A}'\mathsf{B}'}) \\
=\ & \mathrm{tr}_{\mathsf{A}'\mathsf{B}'}\big(\mathsf{SWAP}_{\mathsf{A}\mathsf{A}'} \cdot (I_{\mathsf{A}} \otimes |\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\big) \\
=\ & \mathrm{tr}_{\mathsf{A}'}\Big(\mathsf{SWAP}_{\mathsf{A}\mathsf{A}'} \cdot \big(I_{\mathsf{A}} \otimes \mathrm{tr}_{\mathsf{B}'}(|\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})\big)\Big) \\
=\ & \mathrm{tr}_{\mathsf{A}'}\big(\mathsf{SWAP}_{\mathsf{A}\mathsf{A}'} \cdot (I_{\mathsf{A}} \otimes \sigma_{\mathsf{A}'})\big) \\
=\ & \mathrm{tr}_{\mathsf{A}'}\big((\sigma_{\mathsf{A}} \otimes I_{\mathsf{A}'}) \cdot \mathsf{SWAP}_{\mathsf{A}\mathsf{A}'}\big) \\
=\ & \sigma_{\mathsf{A}} \cdot \mathrm{tr}_{\mathsf{A}'}(\mathsf{SWAP}_{\mathsf{A}\mathsf{A}'}) \\
=\ & \sigma_{\mathsf{A}} \cdot I_{\mathsf{A}} \\
=\ & \sigma_{\mathsf{A}}. \qquad \blacktriangleleft
\end{aligned}
$$

Therefore, with a similar analysis, we can estimate the quantity $\sqrt{\mathrm{tr}(\rho\sigma^2)}$ by Proposition 7 with the same complexity as Theorem 6, stated as follows.

▶ **Theorem 8.** *Suppose that U and V are quantum unitary operators that prepare n-qubit purifications of a k-qubit mixed states $\rho = \mathrm{tr}_{\mathsf{B}}(|\rho\rangle\langle\rho|_{\mathsf{A}\mathsf{B}})$ and $\sigma = \mathrm{tr}_{\mathsf{B}'}(|\sigma\rangle\langle\sigma|_{\mathsf{A}'\mathsf{B}'})$, respectively, as in Equations (4) and (10). For $\varepsilon \in (0,1)$, there is a quantum query algorithm that estimates $\sqrt{\mathrm{tr}(\rho\sigma^2)}$ to within additive error ε with probability at least $2/3$ using $O(1/\varepsilon)$ queries to (controlled-)U, (controlled-)V, and their inverses.*

To provide an intuitive understanding of our encoding scheme, we restructure the circuit in Figure 3 into the form shown in Figure 4. This revised visualization explicitly reveals the

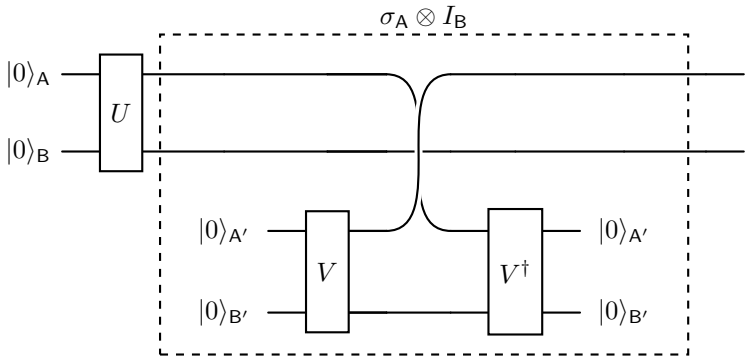

Figure 4 Restructured circuit of Figure 3, illustrating the operator $\sigma_{\mathsf{A}} \otimes I_{\mathsf{B}}$ and its action on the purification $|\rho\rangle_{\mathsf{A}\mathsf{B}}$.

construction of an operator $\sigma_{\mathsf{A}} \otimes I_{\mathsf{B}}$ acting on the purification $|\rho\rangle_{\mathsf{A}\mathsf{B}}$ of ρ_{A}. Since

$$\|(\sigma_{\mathsf{A}} \otimes I_{\mathsf{B}})|\rho\rangle_{\mathsf{A}\mathsf{B}}\|^2 = \mathrm{tr}\big(\rho\sigma^2\big),$$

we clearly see that $\sqrt{\mathrm{tr}(\rho\sigma^2)}$ is encoded into the amplitude of an efficiently preparable quantum state. While the encoding pattern for σ in Figure 4 had previously appeared in [17], people mainly focused on operator properties without explicitly deriving the amplitude structure of the resulting pure state.

5 An Implication: Generalized Pure-State Fidelity Estimation

Our quantum algorithm provided in Theorem 1 suggests a new approach to estimating the fidelity between pure states, where the pure states are given through purified quantum query access, or equivalently prepared by (purified) quantum channels. The purified quantum query

access to a (mixed) quantum state can be understood as a purified version of the quantum channel that prepares the quantum state (cf. [9]). Formally, a quantum channel $\mathcal{E}$ is said to prepare a quantum state ρ, if $\rho = \mathcal{E}(|0\rangle\langle 0|)$. A purified version of $\mathcal{E}$ is a unitary operator U acting on two subsystems A and B such that $\mathcal{E}(\sigma) = \mathrm{tr}_{\mathsf{B}}(U(\sigma_{\mathsf{A}} \otimes |0\rangle\langle 0|_{\mathsf{B}})U^{\dagger})$ for every mixed quantum state σ. Then, ρ can be prepared by the unitary operator U in the way that its purification is prepared by $|\rho\rangle_{\mathsf{AB}} = U|0\rangle_{\mathsf{A}}|0\rangle_{\mathsf{B}}$ and ρ is obtained by tracing out the subsystem B, i.e., $\rho = \mathrm{tr}_{\mathsf{B}}(|\rho\rangle\langle\rho|_{\mathsf{AB}})$. In the following, we state the special case of Theorem 1 for pure-state fidelity estimation.

▶ **Corollary 9** (Pure-state fidelity estimation). *Given purified quantum query access to two pure states $|\varphi\rangle$ and $|\psi\rangle$, the fidelity $\mathrm{F}(|\varphi\rangle, |\psi\rangle) = |\langle\varphi|\psi\rangle|$ can be estimated to within additive error ε with query complexity $O(1/\varepsilon)$.*

Corollary 9 generalizes the pure-state fidelity estimation in [25, Theorem IV.2] to a more general input model. By comparison, the prior approach for pure-state fidelity estimation [25] requires that the pure states should be prepared by a unitary quantum channel. Specifically, Ref. [25] assumes two unitary oracles U_{φ} and U_{ψ} such that $U_{\varphi}|0\rangle = |\varphi\rangle$ and $U_{\psi}|0\rangle = |\psi\rangle$ (see Section 3.2 for details). The input model employed in [25] is more restricted than the purified quantum query access model. For example, $U_{\varphi} \otimes I$ always provides purified quantum query access to $|\varphi\rangle$, where I is the identity operator; however, it is unlikely that U_{φ} could be implemented by purified quantum query access to $|\varphi\rangle$.

In addition to adopting a more general input model than [25], Corollary 9 attains the same optimal query complexity of $O(1/\varepsilon)$, where the lower bound (noted in [25]) is implied in [2, 19] (see Theorem 10).

6 Lower Bounds

For completeness, we discuss the lower bounds for estimating the fidelity. In fact, a lower bound of $\Omega(1/\varepsilon)$ is implied in [2, 19] when both quantum states are pure (as noted in [25]).

▶ **Theorem 10** (Adapted from [2, 19]). *Given purified quantum query access to quantum states ρ and $|\psi\rangle$, any quantum query algorithm that estimates $\mathrm{F}(\rho, |\psi\rangle)$ to within additive error ε requires query complexity $\Omega(1/\varepsilon)$, even if ρ is pure.*

We strengthen this lower bound so that it applies to the case where ρ is a mixed quantum state of an arbitrary rank.

▶ **Theorem 11.** *Given purified quantum query access to quantum states ρ and $|\psi\rangle$, any quantum query algorithm that estimates $\mathrm{F}(\rho, |\psi\rangle)$ to within additive error ε requires query complexity $\Omega(1/\varepsilon)$, even if ρ is of an arbitrary rank.*

To prove Theorem 11, we need the following tool.

▶ **Theorem 12** ([3, Theorem 4]). *Let p and q be probability distributions over n elements. Then, any quantum algorithm that determines whether an unknown unitary oracle U is*

$$U_p = \sum_{j=1}^{n} \sqrt{p_j}|j\rangle \text{ or } U_q = \sum_{j=1}^{n} \sqrt{q_j}|j\rangle$$

requires $\Omega(1/d_{\mathrm{H}}(p,q))$ queries to U, where

$$d_{\mathrm{H}}(p,q) = \sqrt{\frac{1}{2}\sum_{j=1}^{n}\left(\sqrt{p_j} - \sqrt{q_j}\right)^2}$$

is the Hellinger distance.

Now we are ready to prove the lower bounds.

Proof of Theorem 11. Let $r = \mathrm{rank}(\rho) \geq 2$ be an arbitrary rank parameter. Now we reduce the distinguishing problem in Theorem 12 to the estimation of $\mathrm{F}(\rho, |\psi\rangle)$. Consider the two probability distributions $p^{\pm}$ such that

$$p_1^{\pm} = p \pm \varepsilon,\ p_j^{\pm} = \frac{1 - p \mp \varepsilon}{r - 1} \text{ for } 2 \leq j \leq r, \text{ and } p_j^{\pm} = 0 \text{ for } r < j \leq n,$$

where $p \in (0, 1)$ is an arbitrary constant. It can be verified that

$$d_{\mathrm{H}}(p^+, p^-) = \sqrt{1 - \sqrt{p^2 - \varepsilon^2} - \sqrt{(1-p)^2 - \varepsilon^2}} \leq O(\varepsilon).$$

To distinguish whether an unknown unitary oracle U is U_{p^+} or U_{p^-}, we can prepare a mixed state ρ that is either of the following two mixed states

$$\rho_{\pm} = (p \pm \varepsilon)|0\rangle\langle 0| + \sum_{j=2}^{r} \frac{1 - p \mp \varepsilon}{r - 1} |j\rangle\langle j|,$$

using one query to U. By taking $|\psi\rangle = |0\rangle$, we can distinguish which the case is by noting that the fidelity $\mathrm{F}(\rho_{\pm}, |0\rangle) = \sqrt{p \pm \varepsilon} = \sqrt{p} \pm \Theta(\varepsilon)$. Therefore, any quantum algorithm for estimating $\mathrm{F}(\rho, |\psi\rangle)$ to within additive error $\Theta(\varepsilon)$ requires query complexity $\Omega(1/d_{\mathrm{H}}(p^+, p^-)) = \Omega(1/\varepsilon)$, even if ρ is of rank r. ◀

7 Discussion

In this paper, we present an optimal quantum algorithm for estimating the fidelity of a mixed state to a pure state, given purified quantum query access. Our approach is simple, which moreover estimates the quantity $\sqrt{\mathrm{tr}(\rho\sigma^2)}$ that has not been commonly considered in the literature. Here, we raise some questions for future research.

1. Can we encode $\sqrt{\mathrm{tr}(\rho\sigma)}$ rather than $\sqrt{\mathrm{tr}(\rho\sigma^2)}$ in the amplitudes? In addition to its relationship with fidelity estimation, this may also estimate the *Frobenius norm* of a quantum state, $\|\rho\|_F = \sqrt{\mathrm{tr}(\rho^2)}$, which is also the square root of purity.
2. Can we estimate the fidelity $\mathrm{F}(\rho, |\psi\rangle)$ with *optimal* sample complexity, generalizing the result of [28]?

Abstract

We present an external-memory priority queue structure supporting Insert and DeleteMin with amortized $\mathcal{O}(1)$ and $\mathcal{O}(\lg N)$ comparisons, respectively, and amortized $\mathcal{O}\left(\frac{1}{B}\right)$ and $\mathcal{O}\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$ I/Os, respectively. Here, M is the size of the internal memory, B is the block size of I/Os between internal and external memory, and N is the number of elements in the priority queue just before an operation is performed. Previous external-memory priority queues required amortized $\mathcal{O}(\lg N)$ comparisons and $\mathcal{O}\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$ I/Os for both Insert and DeleteMin. The construction requires the minimal assumption $M \geq 2B$.

1 Introduction

Priority queues are fundamental data structures with a host of applications. For example, algorithmic applications for priority queues range from classic results for sorting (such as heapsort) [13, 31, 32] and network optimization [19] to recent instance-optimal results for graph algorithms [22, 23]. In addition, priority queues have been developed for external-memory models [3, 6, 12, 18, 25, 26], ideal-cache models [4, 9], concurrent models [29], and RAM models [30]. Thus, it is desirable to design efficient priority queue data structures.

Throughout the paper, we assume a priority queue stores a multi-set of elements, where each element is a $\langle key, value \rangle$ pair, and the keys are from some totally ordered universe. In the following, a comparison between two elements refers to the comparison of the two elements' keys.

Part of the reason priority queues are so broadly applicable is that they are defined in terms of two simple and useful operations:

- Insert(e) inserts an element e.
- DeleteMin() extracts and returns an element from the priority queue with minimum key. If several elements have equal keys, an arbitrary one of those is returned. This operation requires the priority queue to be non-empty before the operation.

Moreover, in internal memory, it is possible to design priority queues that hold N elements and achieve $\mathcal{O}(1)$ time for Insert and $\mathcal{O}(\lg N)$ time for DeleteMin, either in the worst case [14] or amortized [13, 31][1]. Unfortunately, prior to this work, we are not aware of any efficient data structures in external-memory models [1, 20, 21] that can match the performance of these classic internal-memory data structures.

Internal-memory priority queues

Williams introduced the binary heap in 1964 [32], which supports Insert and DeleteMin with $\mathcal{O}(\lg N)$ comparisons. Since then, many priority queues have been proposed; see, e.g., the survey by Brodal [7]. Vuillemin [31] introduced the binomial queue and demonstrated that it supports a sequence of N Insert and DeleteMin operations using a total of $\mathcal{O}(N \lg N)$ comparisons. Shortly after, Brown [13] gave a detailed analysis of binomial queues. Binomial queues support a sequence of I Insert and D DeleteMin operations in total $\mathcal{O}(I + D \lg I)$ comparisons. Carlson, Munro, and Poblete [14] showed how to achieve binomial queues supporting Insert with worst-case $\mathcal{O}(1)$ comparisons and DeleteMin with worst-case $\mathcal{O}(\lg N)$ comparisons. Fibonacci heaps, introduced by Fredman and Tarjan [19], achieve the same amortized performance as binomial queues for Insert and DeleteMin operations. Additionally, they support the DecreaseKey operation in amortized $\mathcal{O}(1)$ time and comparisons, allowing the key of an element to be replaced with a smaller key. Relaxed heaps, proposed by Driscoll, Gabow, Shrairman, and Tarjan [16], matched these bounds in the worst case.

External-memory model and priority queues

Aggarwal and Vitter [1] introduced the external-memory model as a model of computation focusing on the communication between two levels of memory: an *internal memory* of size M and an infinite *external memory*, where an *I/O* transfers a block of B consecutive memory cells between the two levels of memory. The *I/O cost* of an algorithm is the number of I/Os the algorithm performs. The minimal assumption is that $B \geq 1$ and $M \geq 2B$.

Aggarwal and Vitter proved that comparison-based sorting of N elements in the external-memory model can be done with $\mathcal{O}\left(\frac{N}{B} \log_{M/B} \frac{N}{B}\right)$ I/Os, and proved a matching lower bound for comparison-based sorting. Since sorting can be performed using a priority queue by performing N Insert operations followed by N DeleteMin operations, the amortized I/O cost of either Insert or DeleteMin must be $\Omega\left(\frac{1}{B} \log_{M/B} \frac{N}{B}\right)$ I/Os. Arge [3], Kumar

[1] $\lg x$ denotes the binary logarithm of x.

and Schwabe [27], and Fadel, Jakobsen, Katajainen, and Teuhola [18] presented external-memory priority queues supporting Insert and DeleteMin in amortized $\mathcal{O}\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$ I/Os, assuming $M \geq 2B$. Brengel, Crauser, Ferragina and Meyer [6] presented a simple external-memory priority queue denoted an *array heap* with matching I/O bounds, assuming $B\log_{M/B}\frac{N}{B} \leq M$. Brodal and Katajainen [12] achieved a matching worst-case I/O cost. Since the number of DeleteMin operations is always no more than the number of Insert operation, we can charge the deletion cost to the insertions, i.e., we can restate the amortized costs to be $\mathcal{O}\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$ I/Os for Insert and $\mathcal{O}(1/B)$ I/Os for DeleteMin (or even zero). The question we address in this paper is whether we can swap the two I/O costs, i.e., achieve amortized $\mathcal{O}(1/B)$ I/Os for Insert and $\mathcal{O}\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$ I/Os for DeleteMin, which is relevant when the number of Insert operations is asymptotically larger than the number of DeleteMin operations, i.e., not all elements inserted into the priority queue are eventually also extracted. Table 1 summarizes previous results, where we let $\mathrm{Sort}(N) = \frac{N}{B}\log_{M/B}\frac{N}{B}$; hence, $\frac{1}{N}\mathrm{Sort}(N) = \frac{1}{B}\log_{M/B}\frac{N}{B}$.

Frigo, Leiserson, Prokop, and Ramachandran [20, 21] introduced the *ideal-cache* model by augmenting the external-memory model with an optimal offline paging mechanism. In this model, instead of having each algorithm explicitly transfer data between the two levels of memory, the data transfers are assumed to be performed by an optimal offline paging mechanism. While this might seem like a strong assumption, they demonstrated that under reasonable resource augmentation assumptions, a more realistic paging mechanism, e.g., the one implementing *least recently used (LRU)* replacement policy, is competitive with an optimal one. Consequently, ideal-cache model allows the design of so-called *cache-oblivious* algorithms – algorithms that are oblivious to the parameters M and B. Frigo et al. [20, 21] presented cache-oblivious sorting algorithms achieving optimal I/O cost, provided a *tall-cache assumption* of $M \geq B^2$. Brodal and Fagerberg [8] proved that the same bounds can be achieved under the weaker tall cache assumption $M \geq B^{1+\varepsilon}$ for any constant $\varepsilon > 0$, with a constant overhead of $\frac{1}{\varepsilon}$ in the I/O bounds. Brodal and Fagerberg [10] proved that this trade-off between the tall-cache assumption and the I/O cost is inherent to cache-oblivious algorithms. Cache-oblivious priority queues were presented by Arge, Bender, Demaine, Holland-Minkley, and Munro [4] and Brodal and Fagerberg [9] achieving $\mathcal{O}\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$ I/Os for Insert and DeleteMin, under the tall cache assumptions $M \geq B^2$ and $M \geq B^{1+\varepsilon}$, respectively.

In internal memory, several priority queues support Insert and DeleteMin in amortized $\mathcal{O}(\lg N)$ time, and additionally a DecreaseKey operation in amortized $\mathcal{O}(1)$ time (some also in the worst-case and Insert in $\mathcal{O}(1)$ time). A natural question is if it is possible to achieve similar results in external memory, i.e., N Insert and DeleteMin operations with $\mathcal{O}\left(\frac{N}{B}\log_{M/B}\frac{N}{B}\right)$ I/Os and DecreaseKey with $\mathcal{O}\left(\frac{1}{B}\right)$ I/Os. Eenberg, Larsen, and Yu [17] proved a lower bound that this is not possible. An external-memory priority queue structure by Kumar and Schwabe [27] supports each of the three operations with amortized $\mathcal{O}\left(\frac{1}{B}\lg\frac{N}{B}\right)$ I/Os. Similar bounds were achieved cache-obliviously by Brodal, Fagerberg, Meyer, and Zeh [11] and Chowdhury and Ramachandran [15]. External-memory priority queues with improved DecreaseKey operations were presented by Iacono, Jacob, and Tsakalidis [25], who support Update (a combination of Insert and DecreaseKey) and DeleteMin in amortized $\mathcal{O}\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$ and $\mathcal{O}\left(\left\lceil\frac{M^\varepsilon}{B}\log_{M/B}\frac{N}{B}\right\rceil\log_{M/B}\frac{N}{B}\right)$ I/Os, respectively, and by Jiang and Larsen [26], who support Insert, DeleteMin and DecreaseKey in expected amortized time $\mathcal{O}\left(\frac{1}{B}\lg\frac{N}{B}/\lg\lg N\right)$ I/Os, assuming $M > B\lg^{0.01} N$.

Table 1 Selected previous and new comparison and I/O bounds for priority queues. $\mathcal{O}_A$ denotes amortized bounds, whereas $\mathcal{O}$ denotes worst-case bounds.

Result

In this paper, we present an external-memory priority queue that is optimal both with respect to the amortized I/Os and comparisons performed, achieving the following result.

▶ **Theorem 1.** *There exists an external-memory priority queue supporting* Insert *with amortized* $\mathcal{O}(1)$ *comparisons and* $\mathcal{O}\left(\frac{1}{B}\right)$ *I/Os, and* DeleteMin *with amortized* $\mathcal{O}(\lg N)$ *comparisons and* $\mathcal{O}\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$ *I/Os, where* N *is the current number of elements in the priority queue. The space usage is* $\mathcal{O}\left(\frac{N}{B}\right)$ *blocks. The memory size only needs to satisfy the minimal requirement* $M \geq 2B$.

We achieve this result using what can intuitively be considered an element "juggling" scheme, where we maintain three types of data structures – two in internal memory and one in external memory, transferring elements between them as needed. In a nutshell, our result is obtained by maintaining an internal-memory priority queue with the $\mathcal{O}(M)$ smallest elements supporting Insert and DeleteMin with $\mathcal{O}(1)$ and $\mathcal{O}(\lg M)$ comparisons. We also maintain an insert-buffer in internal memory as a buffer between the internal-memory priority queue and an external-memory structure comprising a forest of multi-way heaps. Specifically, in external memory, we store multi-way heap structures with buffers at the nodes, somewhat similar to an approach by Fadel, Jakobsen, Katajainen, and Teuhola [18] but adapted to support the insertion of batches of $\mathcal{O}(M)$ elements using $\mathcal{O}\left(\frac{M}{B}\right)$ I/Os. Whereas nodes in this previous construction store sorted buffers, in our construction, we maintain the forest of heaps in external memory to use partially sorted buffers (*semi-sorted* at internal nodes and *lazy semi-sorted* at the leaves) to avoid insertions requiring amortized $\Omega(\lg M)$ comparisons.

2 External-memory priority queue

In Sections 3–7, we describe the details of an external-memory priority queue achieving Lemma 2 below, where we bound the total number of comparisons and I/Os performed by a sequence of priority queue operations in terms of the total numbers of Insert and DeleteMin operations performed, denoted I and D, respectively. In Section 8, we then apply global rebuilding to make the bounds depend on the current number of elements in the priority queue, achieving the amortized bounds in Theorem 1.

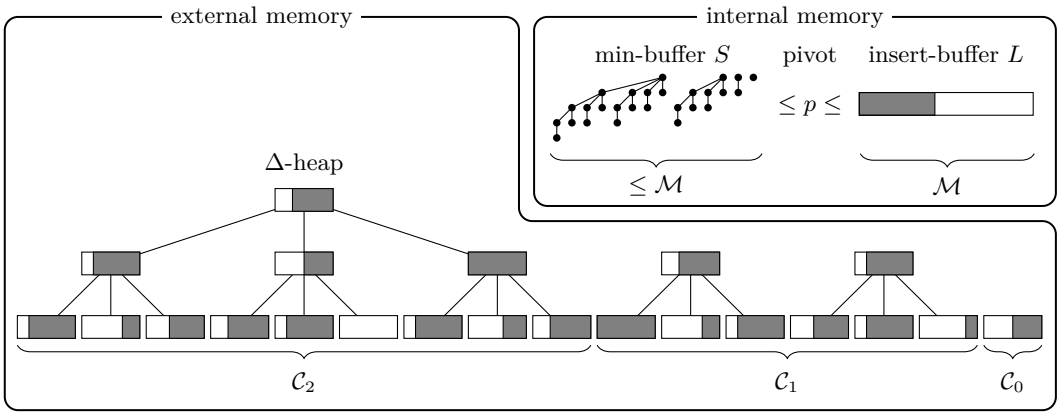

Figure 1 External-memory priority queue. All rectangles are buffers of capacity $\mathcal{M}$, where the gray area illustrates elements in buffers.

▶ **Lemma 2.** *There exists an external-memory priority queue supporting a sequence of I* Insert *and D* DeleteMin *operations, using a total of $\mathcal{O}(I + D \lg I)$ comparisons and $\mathcal{O}\left(\frac{1}{B}\left(I + D \log_{M/B} \frac{I}{B}\right)\right)$ I/Os, assuming $M \geq 2B$.*

Our priority queue consists of an internal-memory part and an external-memory part; see Figure 1 for an overview. Each element is stored exactly once in our data structure. In internal memory we store a *min-buffer*, a *pivot* element, and an *insert-buffer*, where the elements in the min-buffer are all smaller than or equal to the pivot, and the elements in the insert-buffer and external memory are all larger than or equal to the pivot element. By default, Insert and DeleteMin are performed in internal memory without performing any I/Os. If internal memory contains too many elements, $\Theta(M)$ elements are moved from the insert-buffer to the external part. To perform DeleteMin when the min-buffer is empty, $\Theta(M)$ smallest elements from external memory are moved to internal memory. We call moving $\Theta(M)$ elements between internal and external memory a *transfer*. In the subsequent sections, we describe the two parts in detail. We let $\mathcal{M}$ be a parameter for our construction, such that $\mathcal{M}$ is even, $\mathcal{M}$ is divisible by B, and $\mathcal{M} = \Theta(M)$. We choose $\mathcal{M}$ such that the $\mathcal{O}(\mathcal{M})$ space internal-memory data structure in Section 3 fits into internal memory. To be able to choose $\mathcal{M}$, M is required to be sufficiently large and the internal memory to be able to hold a sufficiently large number of blocks of size B. If $M = \mathcal{O}(1)$, then an internal-memory data structure like a binomial queue already achieves the result of Lemma 2, and if the number of blocks fitting in internal memory is too small we can simulate a smaller block size with a constant blow up in the I/O complexity. I.e., in the following we w.l.o.g. can assume that M and M/B are sufficiently large to be able to choose $\mathcal{M}$.

3 The internal-memory part

The internal-memory part consists of a *min-buffer* S, a *pivot* element p, and an *insert-buffer* L. The pivot is larger than or equal to any element in the min-buffer, and smaller than or equal to any element in the insert-buffer and external memory. The insert-buffer is an unordered array of at most $\mathcal{M}$ elements. The min-buffer stores the overall at most $\mathcal{M}$ smallest elements in the priority queue, and is implemented using an internal-memory linear-space priority queue supporting Insert in amortized $\mathcal{O}(1)$ time and DeleteMin in amortized $\mathcal{O}(\lg n)$

time, where n is the number of elements in the min-buffer. The min-buffer can, e.g., be implemented using a binomial queue [31] or the implicit post-order heap by Harvey and Zatloukal [24]. The total space for the internal part is $\mathcal{O}(\mathcal{M})$.

INSERT(e) first compares e to the pivot p. If $e \leq p$, e is inserted in the min-buffer using the min-buffer's INSERT operation. Otherwise, e is appended to the insert-buffer. If the min-buffer overflows, i.e., gets size $\mathcal{M}+1$, we find a new pivot p' by applying the linear-time internal-memory median finding algorithm by Blum, Floyd, Pratt, Rivest, and Tarjan [5] to the elements in the min-buffer. The median, i.e., the $\left(\frac{\mathcal{M}}{2}+1\right)$th smallest element, becomes the new pivot p', the $\frac{\mathcal{M}}{2}$ larger elements and the old pivot p are appended to the insert-buffer, and the $\frac{\mathcal{M}}{2}$ smaller elements are inserted into a new empty min-buffer structure using its INSERT operations. If the insert-buffer overflows, i.e., gets size $> \mathcal{M}$ (due to the insertion of a single element or the old pivot p and $\frac{\mathcal{M}}{2}$ elements being moved from the min-buffer to the insert-buffer), we transfer $\mathcal{M}$ elements from the insert-buffer to the external part (see Section 4).

For DELETEMIN, if the min-buffer is non-empty, the smallest element is extracted from the min-buffer using the min-buffer's DELETEMIN operation and returned. Otherwise, the min-buffer is empty and the pivot p is the smallest element to be returned. To establish a new pivot p' and min-buffer, the $\frac{\mathcal{M}}{2}$ smallest elements are extracted from external memory (see Section 4) and transferred to the insert-buffer (except when the external part is empty). This ensures that the $\frac{\mathcal{M}}{2}$ smallest elements in the insert-buffer are now smaller than or equal to all elements in the external part. The $\frac{\mathcal{M}}{2}$th smallest element in the insert-buffer is selected as the new pivot p' in linear time using the internal-memory selection algorithm [5]. If the insert-buffer contains $< \frac{\mathcal{M}}{2}$ elements, we set the pivot p to be $+\infty$. The at most $\frac{\mathcal{M}}{2}-1$ elements smaller than or equal to the new pivot p' in the insert-buffer are deleted from the insert-buffer and inserted into the min-buffer structure using its INSERT operation. The old pivot p is returned as the extracted minimum.

Note that a transfer either moves $\mathcal{M}$ elements from the internal to the external part, or $\frac{\mathcal{M}}{2}$ elements from the external to the internal part, i.e., the external memory always contains a multiple of $\frac{\mathcal{M}}{2}$ elements. Note also that the size of the insert-buffer is unchanged during DELETEMIN, provided that there are elements in external memory. Otherwise, the number of elements in the insert-buffer decreases by $\frac{\mathcal{M}}{2}$.

Initially, the pivot $p = +\infty$, such that all elements are inserted into the min-buffer until the priority queue contains $\mathcal{M}+1$ elements, where a real element is selected as the pivot and $\frac{\mathcal{M}}{2}$ elements are moved to the insertion-buffer and a new min-buffer is created for the $\frac{\mathcal{M}}{2}$ smallest elements using repeated insertions.

4 The external-memory part

The external-memory part supports the insertion of a batch of $\mathcal{M}$ elements and the extraction of the $\mathcal{M}/2$ smallest elements. It consists of a set of Δ-*heaps*, where $\Delta = \frac{\mathcal{M}}{B} \geq 2$. A Δ-heap with height h is a tree where all leaves have depth h (the root having depth zero), and all non-leaves have exactly Δ children. Each node contains a buffer storing up to $\mathcal{M}$ elements. The elements must satisfy *extended heap order*, i.e., the elements in the buffer of a node u are smaller than or equal to any element in the buffers of the children of u. A Δ-heap is a generalization of a binary heap [32] and is very similar to the external-memory priority queue of Fadel, Jakobsen, Katajainen and Teuhola [18], except that we do not require buffers to be sorted (this would not be possible when insertions only perform amortized $\mathcal{O}(1)$ comparisons.) The buffers in a Δ-heap store elements in various degrees of sortedness to be able to achieve the stated insertion cost: non-leaves are *semi-sorted*, whereas leaves are *lazy semi-sorted* as discussed in Sections 5 and 6, respectively.

The Δ-heaps are maintained as a sequence of collections $\mathcal{C}_0, \ldots, \mathcal{C}_H$, where $\mathcal{C}_h$ contains all Δ-heaps with height h. We maintain the invariant (**I1**) that $|\mathcal{C}_h| < \Delta$ and that the total number of leaves in the Δ-heaps is $\leq \frac{I}{\mathcal{M}}$ (Lemma 7), where I is the total number of insertions. This invariant ensures that the maximum height H of a Δ-heap is $\leq \lfloor \log_\Delta \frac{I}{\mathcal{M}} \rfloor$. The buffers of all nodes must satisfy the following invariant (**I2**): The buffer of a node u stores at most $\mathcal{M}$ elements. If no descendant of u stores elements, there is no lower bound on the buffer size of u. Otherwise, the buffer of u contains at least $\frac{\mathcal{M}}{2}$ elements. Together with the extended heap order, this invariant implies that the $\frac{\mathcal{M}}{2}$ smallest elements in a Δ-heap are stored in the root buffer, except if the Δ-heap contains fewer than $\frac{\mathcal{M}}{2}$ elements, in which case all elements are stored in the root buffer.

When $\mathcal{M}$ elements are transferred from the internal to the external part, the $\mathcal{M}$ elements become a single node Δ-heap with height zero that is added to collection $\mathcal{C}_0$. If the collection is full, that is, $|\mathcal{C}_0| = \Delta$, then a new root r is created for a Δ-heap of height one with each leaf of $\mathcal{C}_0$ as its children. Invariant **I2** is established for r by recursively *pulling* the $\frac{\mathcal{M}}{2}$ smallest elements from its children and inserting them in the buffer (the pull operation is described below). This leaves $\mathcal{C}_0$ empty, and r is promoted to $\mathcal{C}_1$. As in a Δ-ary number system, this promotion may propagate up through the collections, repeatedly combining Δ Δ-heaps with height h to a Δ-heap with height $h+1$.

For a node with $< \frac{\mathcal{M}}{2}$ elements in its buffer, a *pull* operation moves $\frac{\mathcal{M}}{2}$ elements from its children to the buffer of the node while preserving extended heap order, using Lemma 5 in Section 5. Note that this will make the buffer contain at least $\frac{\mathcal{M}}{2}$ elements and less than $\mathcal{M}$. If a child buffer gets size $< \frac{\mathcal{M}}{2}$, we recursively apply the pull operation to the child, provided that not all subtrees below the child are exhausted.

To extract the $\frac{\mathcal{M}}{2}$ smallest elements from the external part, first, for each collection $\mathcal{C}_i$, the $\frac{\mathcal{M}}{2}$ smallest elements are found by considering the elements in the buffers of the roots by applying Lemma 5 to the roots of the collection. As the elements are just identified but not pulled from the roots, we call this a *virtual pull*. Second, the $\frac{\mathcal{M}}{2}$ smallest elements among the $(H+1)\frac{\mathcal{M}}{2}$ candidates from the virtual pulls are found by applying a linear-time selection algorithm, Corollary 3 below. These elements are removed from their respective roots and transferred to the internal part. For each root buffer now containing $< \frac{\mathcal{M}}{2}$ elements, we recursively pull $\frac{\mathcal{M}}{2}$ elements from its children, to the extent possible.

Note that the total number of elements in external memory is always a multiple of $\frac{\mathcal{M}}{2}$, but this is not necessarily true for each Δ-heap due to the extractions of the smallest $\frac{\mathcal{M}}{2}$ elements across all Δ-heaps.

5 Semi-sorted lists

Given two sequences X and Y, we say $X \preceq Y$, if for every $x \in X$ and $y \in Y$: $x \leq y$. Note that $X \preceq Y$ implies no specific order within each individual sequence X or Y.

A buffer in external memory is a linked list of blocks $b_1, b_2, \ldots, b_\delta$, where each block contains B elements, except possibly the first and last blocks, which contain $\leq B$ elements. In the following, we simply denote such a linked list as a *list*. We define a list to be *semi-sorted* if $b_i \preceq b_{i+1}$ for every $1 \leq i < \delta$. All buffers of non-leaf nodes in a Δ-heap are stored as semi-sorted lists. The following are useful tools for working with semi-sorted buffers.

Blum, Floyd, Pratt, Rivest, and Tarjan [5] proved that the kth smallest element in a list with N elements can be found using $\mathcal{O}(N)$ comparisons using a double recursion making repeated use of scanning lists. Analyzed in the external-memory model, this immediately implies that selection can be performed in a linear number of I/Os, and we have the following corollary.

▶ **Corollary 3** (Blum et al. [5]). *Given a list of N elements and an integer $1 \leq k \leq N$, the list can be partitioned into two lists X and Y, with $|X| = k$ and $X \preceq Y$, using $\mathcal{O}(N)$ comparisons and $\mathcal{O}\left(\frac{N}{B}\right)$ I/Os.*

▶ **Lemma 4** (Constructing semi-sorted buffer). *An unsorted list of $B\delta \leq \mathcal{M}$ elements can be converted into a semi-sorted list using $\mathcal{O}(B\delta \lg \delta)$ comparisons and $\mathcal{O}(\delta)$ I/Os.*

Proof. Recursively apply [5] to partition an unsorted list with δB elements into two subproblems with $\lceil \delta/2 \rceil B$ and $\lfloor \delta/2 \rfloor B$ elements, until the subproblems are of size exactly B. The result follows since there are $\lceil \lg \delta \rceil$ levels of recursion with a linear number of comparisons per level, and we only perform I/Os to read the initial list into internal memory and to write the final list to external memory, since the problem fits in internal memory. ◀

▶ **Lemma 5** (Pulling from semi-sorted lists). *Given at most $\Delta = \frac{\mathcal{M}}{B}$ semi-sorted lists, a semi-sorted list of the $\frac{\mathcal{M}}{2}$ smallest elements of their union can be computed in $\mathcal{O}(\mathcal{M} \lg \Delta)$ comparisons and $\mathcal{O}\left(\frac{\mathcal{M}}{B}\right)$ I/Os.*

Proof. Read the first block from each semi-sorted list into internal memory and insert the largest element of each block into a binary min-heap Q [32]. Then, delete the smallest element from Q, read the next block from the corresponding semi-sorted list, and insert the largest element of this block into Q. Let X denote the elements in blocks whose maximums have been deleted from Q, and Y the elements in blocks whose maximums are in Q. Repeat this process of reading blocks until $|X| \geq \frac{\mathcal{M}}{2}$. In total, $\Theta\left(\frac{\mathcal{M}}{B}\right)$ blocks are read, where the maximum is computed of each block and each block requires $\mathcal{O}(1)$ heap operations on Q, where $|Q| \leq \Delta$. This initial phase requires a total of $\mathcal{O}\left(\mathcal{M} + \frac{\mathcal{M}}{B} \cdot \lg \Delta\right)$ comparisons and $\Theta\left(\frac{\mathcal{M}}{B}\right)$ I/Os.

Let x be the last element deleted from Q. We have $\max(X) \leq x$, since when the lists are semi-sorted, elements will be extracted in non-decreasing order from Q. From each list, we have a block represented in Q with maximum $\geq x$, so all remaining unread elements in the lists are also $\geq x$. Thus, the $\frac{\mathcal{M}}{2}$ smallest elements can be found by a single partition of $X \cup Y$ using $\mathcal{O}(\mathcal{M})$ comparisons and $\mathcal{O}\left(\frac{\mathcal{M}}{B}\right)$ I/Os per Corollary 3. They can then be converted to a semi-sorted list using additional $\mathcal{O}(\mathcal{M} \lg \Delta)$ comparisons per Lemma 4. ◀

6 Lazy semi-sorted lists

Since I insertions can create $\Theta(I/\mathcal{M})$ leaf buffers of size $\mathcal{M}$, they cannot all be semi-sorted, as that would require $\Theta(I \lg \Delta)$ comparisons. The lower bound of $\Omega(\mathcal{M} \lg \Delta)$ comparisons for the multiple selection problem for each buffer is due to Dobkin and Munro [2, Theorem 1]. Instead, a leaf buffer with $\mathcal{M}$ elements is stored as a *lazy semi-sorted* list, see Figure 2. A lazy semi-sorted list stores the $\mathcal{M}$ elements as a sequence of *chunks* $c_1 \preceq c_2 \preceq \cdots \preceq c_d$, where $d = \left\lceil \lg \frac{\mathcal{M}}{B} \right\rceil + 1$ and, initially, the elements inside a chunk are stored in arbitrary order. Chunk c_1 stores B elements, c_i stores $B2^{i-2}$ elements for $2 \leq i < d$, and c_d stores the largest $\mathcal{M} - B2^{d-2}$ elements. If each chunk is converted into a semi-sorted list, and all chunks are concatenated, we have a semi-sorted list for the buffer. The basic idea is to exploit that a Δ-heap always accesses the blocks of a semi-sorted buffer left-to-right, implying that we can delay expanding a chunk into a semi-sorted sequence of blocks using Lemma 4 until the first block of the (semi-sorted version of the) chunk is accessed, hence the name lazy semi-sorted. The initial partitioning of a buffer into chunks is done by recursively partitioning the half with the smaller elements using Corollary 3.

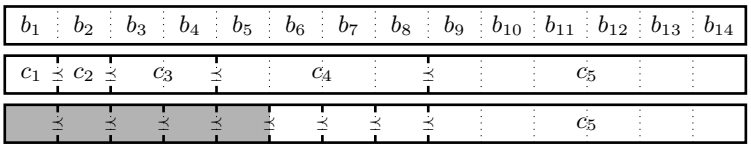

Figure 2 A lazy semi-sorted list. Top: Initial unsorted list of blocks $b_1, \ldots, b_{\mathcal{M}/B}$. Middle: Initial chunks $c_1 \preceq \cdots \preceq c_5$. Bottom: The state after the first five blocks $b_1, \ldots, b_5$ in the semi-sorted list have been accessed, i.e., the chunks $c_1, \ldots, c_4$ have been made into semi-sorted sublists.

▶ **Lemma 6** (Lazy access cost). *Initializing a lazy semi-sorted list of $\mathcal{M}$ elements requires $\mathcal{O}(\mathcal{M})$ comparisons and $\mathcal{O}(\frac{\mathcal{M}}{B})$ I/Os. The cost of accessing the first $k \leq \frac{\mathcal{M}}{B}$ blocks of the lazy semi-sorted list requires $\mathcal{O}(Bk \lg k)$ comparisons and $\mathcal{O}(k)$ I/Os.*

Proof. To initialize the lazy semi-sorted list, all $\mathcal{M}$ elements are first read into internal memory using $\mathcal{O}(\frac{\mathcal{M}}{B})$ I/Os. No further I/Os are performed, except for eventually writing the output to external memory. The initial chunks, with elements in arbitrary order, are constructed one at a time by repeatedly applying Corollary 3 to find the appropriate number of largest elements. By constructing the chunks in the order $c_d, c_{d-1}, \ldots c_0$ from the largest to the smallest, the number of remaining elements decreases geometrically, leading to a total of $\mathcal{O}(\mathcal{M})$ comparisons.

If the k first blocks of elements have been accessed, then chunks $c_1, \ldots, c_{\lceil \lg k \rceil + 1}$ have been semi-sorted, i.e., fewer than $2k$ blocks. Note that c_1 and c_2 only consist of a single block, i.e., they are already semi-sorted at initialization. By applying Lemma 4, semi-sorting the remaining $\lceil \lg k \rceil - 1$ accessed chunks requires $\mathcal{O}\left(\sum_{i=1}^{\lceil \lg k \rceil - 1} B2^i \lg 2^i\right) = \mathcal{O}(Bk \lg k)$ comparisons and $\mathcal{O}\left(\sum_{i=1}^{\lceil \lg k \rceil - 1} 2^i\right) = \mathcal{O}(k)$ I/Os. ◀

The idea of lazy semi-sorted buffers is that they allow us to charge the non-linear comparison cost of constructing a semi-sorted buffer to the pull operations on the buffer, in particular, the pull operations triggered by deletions.

7 Analysis

When Insert and DeleteMin can be performed entirely within the internal part, no I/Os are performed. The number of comparisons is $\mathcal{O}(1)$ for Insert and $\mathcal{O}(\lg \min(\mathcal{M}, I))$ for DeleteMin, plus the cost of moving elements from the min-buffer to the insert-buffer. If an insertion causes the min-buffer to overflow, we spend $\mathcal{O}(\mathcal{M})$ comparisons moving elements to the insert-buffer and building a new min-buffer. This can only happen once every $\frac{\mathcal{M}}{2}$ insertion, so the total cost for this is $\mathcal{O}(I)$ comparisons and no I/Os.

A transfer either moves $\mathcal{M}$ elements from the internal to the external part, or $\frac{\mathcal{M}}{2}$ elements from the external to the internal part. The following lemma bounds the number of transfers in each direction in terms of I and D.

▶ **Lemma 7** (Bounding transfers). *The number of transfers from the internal to the external part is $\leq \frac{I}{\mathcal{M}}$. The number of transfers from the external to the internal part is $\leq \frac{2D}{\mathcal{M}}$.*

Proof. We first consider the number of transfers from the internal to the external part. Let $\phi \geq 0$ be the number of elements in the min-buffer beyond the first $\frac{\mathcal{M}}{2}$ elements plus the number of elements in the insert-buffer. Insertions cause ϕ to increase by at most one, and deletions do not cause ϕ to increase. A transfer to the external part decreases ϕ by $\mathcal{M}$, whereas a transfer to the internal part of $\frac{\mathcal{M}}{2}$ elements leaves ϕ unchanged, since the min-buffer gets size $\frac{\mathcal{M}}{2} - 1$ and the size of the insert-buffer does not change. It follows that ϕ only

increases during the I insertions, where the total increase is $\leq I$, and each transfer to the external part decreases ϕ by $\mathcal{M}$, i.e., the number of transfers to the external part is at most $\frac{I}{\mathcal{M}}$.

The size of the min-buffer can only decrease below $\frac{\mathcal{M}}{2}$ due to a deletion, where it decreases by one. (When the size of the min-buffer decreases because half of the elements are moved to the insert-buffer, the min-buffer changes size from $\mathcal{M}+1$ to $\frac{\mathcal{M}}{2}$.) A transfer to the internal part occurs when the size of the min-buffer is zero before the deletion, but then the min-buffer has size $\frac{\mathcal{M}}{2}-1$ after the deletion and the next $\frac{\mathcal{M}}{2}-1$ deletions do not cause a transfer to the internal part. It follows that at most every $\frac{\mathcal{M}}{2}$ deletion can cause a transfer to the internal part. The first transfer to the internal part can only happen after a transfer to the external part has occurred, which first can happen after the pivot $p \neq +\infty$, where the size of the min-buffer is $\frac{\mathcal{M}}{2}$, i.e., there must have been at least $\frac{\mathcal{M}}{2}$ deletions before the first transfer to the internal part. It follows that the number of transfers to the internal part is at most $\frac{2D}{\mathcal{M}}$. ◀

The key part of the analysis is threefold. First, we bound the cost to restore invariants **I1** and **I2** whenever elements are removed from the internal nodes of the external part. Second, we bound the cost of *accessing* the lazy semi-sorted leaves. The access cost of a leaf refers to the cost of semi-sorting its chunks. Third, we bound the cost involved with transfers between internal and external memory. We define the *height* of a node in a Δ-heap to be the height of the subtree rooted at the node (leaves have height zero).

▶ **Lemma 8** (Total pull cost excluding leaf access). *The total number of pulls is $\mathcal{O}\big(\frac{I}{\mathcal{M}\Delta}+\frac{DH}{\mathcal{M}}\big)$ and their total cost is $\mathcal{O}\Big(I\frac{\lg\Delta}{\Delta}+D\lg\frac{I}{\mathcal{M}}\Big)$ comparisons and $\mathcal{O}\big(\frac{I}{\mathcal{M}}+\frac{DH}{B}\big)$ I/Os, excluding the cost of accessing the leaves.*

Proof. A pull at a node increases the height of $\frac{\mathcal{M}}{2}$ elements from the buffers of the children by one, except the last pull at a node that exhausts all subtrees at the children, where at most $\frac{\mathcal{M}}{2}$ elements have their height increased by one. By Lemma 7, at most $\frac{I}{\mathcal{M}}$ leaves are created, i.e., the maximum height of a Δ-heap is $H \leq \log_\Delta \frac{I}{\mathcal{M}}$. For a height h, $1 \leq h \leq H$, we bound the number of pulls P_h to nodes with height h by bounding the number of elements that could have been moved to a height $\geq h$ or transferred to the internal memory, the latter being bounded by D by Lemma 7. Since there are $\leq \frac{I}{\mathcal{M}}$ leaves, the number of nodes at height h is $\leq \frac{I}{\mathcal{M}\Delta^h}$, implying that the number of elements that could ever have been pulled to height h (and possibly further up) is at most $D+\mathcal{M}\sum_{j=h}^{H}\frac{I}{\mathcal{M}\Delta^j}$. Since each non-exhausting pull moves $\frac{\mathcal{M}}{2}$ elements one level up, and each node with height h can have one final pull exhausting all children, we get that the final number of pulls to height h is $P_h \leq \Big(D+\mathcal{M}\sum_{j=h}^{H}\frac{I}{\mathcal{M}\Delta^j}\Big) / \frac{\mathcal{M}}{2}+\frac{I}{\mathcal{M}\Delta^h} = \mathcal{O}\big(\frac{I}{\mathcal{M}\Delta^h}+\frac{D}{\mathcal{M}}\big)$, as $\Delta \geq 2$.

The total number of pulls is then $\sum_{h=1}^{H} P_h = \mathcal{O}\big(\frac{I}{\mathcal{M}\Delta}+\frac{DH}{\mathcal{M}}\big)$. Excluding the cost of accessing the leaves, we may treat each pull as being from semi-sorted lists. Applying Lemma 5, the total number of comparisons is $\mathcal{O}\big(\big(\frac{I}{\mathcal{M}\Delta}+\frac{D}{\mathcal{M}}\log_\Delta\frac{I}{\mathcal{M}}\big)\mathcal{M}\lg\Delta\big) = \mathcal{O}\Big(I\frac{\lg\Delta}{\Delta}+D\lg\frac{I}{\mathcal{M}}\Big)$ and the number of I/Os is $\mathcal{O}\big(\big(\frac{I}{\mathcal{M}\Delta}+\frac{DH}{\mathcal{M}}\big)\frac{\mathcal{M}}{B}\big) = \mathcal{O}\big(\frac{I}{\mathcal{M}}+\frac{DH}{B}\big)$ I/Os. ◀

▶ **Lemma 9** (Total leaf access cost). *The total cost of constructing the lazy semi-sorted leaves and accessing them is $\mathcal{O}(I+D\lg\Delta)$ comparisons and $\mathcal{O}\big(\frac{I}{B}+\frac{D}{B}\big)$ I/Os.*

Proof. As described in the proof of Lemma 8, the number of pulls from the leaves is $P_1 = \mathcal{O}\big(\frac{I}{\mathcal{M}\Delta}+\frac{D}{\mathcal{M}}\big)$. Virtual pulls may, however, also access elements in the leaves. Since each transfer to the internal part causes one virtual pull from $\mathcal{C}_0$, the number of virtual pulls from the leaves is bounded by $\frac{2D}{\mathcal{M}}$ by Lemma 7. The total number of pulls and virtual pulls from the leaves is $\mathcal{O}\big(\frac{I}{\mathcal{M}\Delta}+\frac{D}{\mathcal{M}}\big)$.

By Lemma 6, the cost for the initial construction of the at most $\frac{I}{\mathcal{M}}$ leaves as lazy semi-sorted lists is $\mathcal{O}(I)$ comparisons and $\mathcal{O}\left(\frac{I}{B}\right)$ I/Os. Since, by Lemma 5, each pull and virtual pull performs $\mathcal{O}(\mathcal{M}\lg\Delta)$ comparisons and accesses $\mathcal{O}\left(\frac{\mathcal{M}}{B}\right)$ blocks, we have, by Lemma 6, that at the leaves, the total number of comparisons is $\mathcal{O}\left(I+\left(\frac{I}{\mathcal{M}\Delta}+\frac{D}{\mathcal{M}}\right)\mathcal{M}\lg\Delta\right)=\mathcal{O}(I+D\lg\Delta)$ comparisons and the total number of I/Os is $\mathcal{O}\left(\frac{I}{B}+\left(\frac{I}{\mathcal{M}\Delta}+\frac{D}{\mathcal{M}}\right)\frac{\mathcal{M}}{B}\right)=\mathcal{O}\left(\frac{I}{B}+\frac{D}{B}\right)$ I/Os. ◀

▶ **Lemma 10** (Cost of transfers excluding pulls and leaf accessing). *The total cost of transfers between the internal and external part is $\mathcal{O}\left(D\lg\frac{I}{\mathcal{M}}\right)$ comparisons and $\mathcal{O}\left(\frac{I}{B}+\frac{D}{B}\log_\Delta\frac{I}{\mathcal{M}}\right)$ I/Os, excluding the cost of pulling to restore the invariants and to access the leaves.*

Proof. By Lemma 7, there are at most $\frac{I}{\mathcal{M}}$ transfers to the external part, each moving $\mathcal{M}$ elements from the input-buffer to a new leaf, with no comparisons and $\mathcal{O}\left(\frac{\mathcal{M}}{B}\right)$ I/Os.

By Lemma 7, there are at most $\frac{2D}{\mathcal{M}}$ transfers to the internal part. Each transfer involves finding the $\mathcal{M}$ smallest elements among the elements in the buffers of all roots in all collections. First, for each collection, we perform a virtual pull from the semi-sorted roots. We exclude the access cost for the leaves and treat them as semi-sorted. Applying Lemma 5 for each of the $\mathcal{O}(H)=\mathcal{O}\left(\log_\Delta\frac{I}{\mathcal{M}}\right)$ collections leads to a cost of $\mathcal{O}\left(\mathcal{M}\lg\Delta\log_\Delta\frac{I}{\mathcal{M}}\right)=\mathcal{O}\left(\mathcal{M}\lg\frac{I}{\mathcal{M}}\right)$ comparisons and $\mathcal{O}\left(\frac{\mathcal{M}}{B}\log_\Delta\frac{I}{\mathcal{M}}\right)$ I/Os. Then among these $\mathcal{O}\left(\mathcal{M}\log_\Delta\frac{I}{\mathcal{M}}\right)$ elements, we find the $\frac{\mathcal{M}}{2}$ smallest elements by applying Corollary 3. These elements are then transferred to the insert-buffer and removed from their respective roots. This may trigger pulls to restore the invariants, the cost of which we exclude here and is accounted for in Lemma 8. These operations do not asymptotically increase the total cost, which is $\mathcal{O}\left(D\lg\frac{I}{\mathcal{M}}\right)$ comparisons and $\mathcal{O}\left(\frac{D}{B}\log_\Delta\frac{I}{\mathcal{M}}\right)$ I/Os. Finally, a transfer to the internal part causes $\mathcal{O}(\mathcal{M})$ comparisons to build the new min-buffer and insert-buffer, which sums up to $\mathcal{O}(D)$ comparisons for all transfers to the internal part. ◀

Proof of Lemma 2. Summarizing the number of comparisons and I/Os performed, the total number of comparisons is

$$\mathcal{O}\Bigg(\underbrace{(I+D\lg\mathcal{M})}_{\text{internal memory}}+\underbrace{\left(I\frac{\lg\Delta}{\Delta}+D\lg\frac{I}{\mathcal{M}}\right)}_{\text{pulls}}+\underbrace{(I+D\lg\Delta)}_{\text{leaves}}+\underbrace{\left(D\lg\frac{I}{\mathcal{M}}\right)}_{\text{transfers}}\Bigg)=\mathcal{O}(I+D\lg I)\ ,$$

and the total number of I/Os is

$$\mathcal{O}\Bigg(\underbrace{\left(\frac{I}{\mathcal{M}}+\frac{DH}{B}\right)}_{\text{pulls}}+\underbrace{\left(\frac{I}{B}+\frac{D}{B}\right)}_{\text{leaves}}+\underbrace{\left(\frac{I}{B}+\frac{D}{B}\log_\Delta\frac{I}{\mathcal{M}}\right)}_{\text{transfers}}\Bigg)=\mathcal{O}\left(\frac{I}{B}+\frac{D}{B}\log_\Delta\frac{I}{\mathcal{M}}\right)\ .$$

Lemma 2 follows from $\mathcal{M}=\Theta(M)$ and $\Delta=\frac{\mathcal{M}}{B}$. ◀

8 Dependence on current priority queue size

In Sections 3–7, I denotes the total number of insertions performed, allowing the current size N to be arbitrarily smaller than I. Since the comparison and I/O bounds of Lemma 2 are dependent on I, the bounds are not a function of the current number of elements N in the priority queue. To achieve this, we apply the standard technique of *global rebuilding* [28, Chapter 5].

Proof of Theorem 1. Let N_0 denote the size of the priority queue at the last global rebuilding of the priority queue, and let I_0 and D_0 denote the number of insertions and deletions since the last global rebuilding, respectively. We rebuild the priority queue whenever $I_0+D_0>\frac{N_0}{2}$.

Rebuilding a priority queue containing N elements is performed by scanning over the structure, collecting the N elements into a list, and then repeatedly inserting these into a new empty priority queue using Insert. By Lemma 2, the resulting priority queue is constructed using $\mathcal{O}(N)$ comparisons and $\mathcal{O}\left(\frac{N}{B}\right)$ I/Os (the previous structure can be scanned in $\mathcal{O}\left(\frac{N}{B}\right)$ I/Os, since we argue below that $N = \Theta(N_0)$ and at most $2\frac{N_0+I_0}{\mathcal{M}} = \mathcal{O}\left(\frac{N}{\mathcal{M}}\right)$ buffers have been created in external memory since the last global rebuilding).

Together with Lemma 2, the previous rebuilding and the subsequent I_0 insertions and D_0 deletions, causing a total of $N_0 + I_0$ insertions and D_0 deletions, imply a total comparison cost of $\mathcal{O}(N_0 + I_0 + D_0 \lg(N_0 + I_0)) = \mathcal{O}(N_0 + D_0 \lg N_0)$ and a total I/O cost of $\mathcal{O}\left(\frac{N_0}{B} + \frac{1}{B}\left((N_0 + I_0) + D_0 \log_{M/B} \frac{N_0+I_0}{B}\right)\right) = \mathcal{O}\left(\frac{N_0}{B} + \frac{D_0}{B} \log_{M/B} \frac{N_0}{B}\right)$, since $I_0 \leq \frac{N_0}{2}$. We charge the linear cost to the at least $\frac{N_0}{3}$ priority queue operations between the last two global rebuildings, and the remaining cost to the deletions since the last global rebuilding. While no global rebuilding is triggered, we have $\frac{1}{2}N_0 \leq N \leq \frac{3}{2}N_0$, i.e., we have $N = \Theta(N_0)$ between two global rebuildings. Theorem 1 follows. ◀

9 Conclusion and open problems

The external-memory priority queue presented in this paper supports insertions with asymptotically fewer comparisons and I/Os than previous results. This is particularly beneficial in settings such as event-driven simulations or other incremental computations where execution may terminate before all elements have been extracted from the queue and the cost of insertions dominates. It should be noted that the amortized internal computation time required by our construction is asymptotically the same as the number of comparisons performed (which also holds for the black boxes used by the construction [5, 24, 31]).

The presented data structure is inherently cache-aware. This raises a natural question: does there exist a cache-oblivious priority queue that achieves the same amortized bounds on comparisons and I/Os?

The structure is also highly amortized (e.g., due to global rebuilding, transfers between internal and external memory, recursive pulling, lazy semi-sorted buffers), and a single Insert or DeleteMin operation might require $\Theta(N/B)$ I/Os in the worst-case. Another natural question, is whether it is possible to achieve a solution with worst-case guarantees, e.g., such that a window of B priority queue operations requires worst-case $\mathcal{O}(B \lg N)$ comparisons and $\mathcal{O}\left(\log_{M/B} \frac{N}{B}\right)$ I/Os, while maintaining the improved amortized bounds for Insert.

On the Complexity of Knapsack Under Explorable Uncertainty: Hardness and Algorithms

Jens Schlöter
Centrum Wiskunde & Informatica (CWI), Amsterdam, The Netherlands

Abstract

In the *knapsack problem under explorable uncertainty*, we are given a knapsack instance with uncertain item profits. Instead of having access to the precise profits, we are only given *uncertainty intervals* that are guaranteed to contain the corresponding profits. The actual item profit can be obtained via a *query*. The goal of the problem is to adaptively query item profits until the revealed information suffices to compute an optimal (or approximate) solution to the underlying knapsack instance. Since queries are costly, the objective is to minimize the number of queries.

In the offline variant of this problem, we assume knowledge of the precise profits and the task is to compute a query set of minimum cardinality that a third party without access to the profits could use to identify an optimal (or approximate) knapsack solution. We show that this offline variant is complete for the second-level of the polynomial hierarchy, i.e., Σ_2^p-complete, and cannot be approximated within a non-trivial factor unless $\Sigma_2^p = \Delta_2^p$. Motivated by these strong hardness results, we consider a "resource-augmented" variant of the problem where the requirements on the query set computed by an algorithm are less strict than the requirements on the optimal solution we compare against. More precisely, a query set computed by the algorithm must reveal sufficient information to identify an approximate knapsack solution, while the optimal query set we compare against has to reveal sufficient information to identify an optimal solution. We show that this resource-augmented setting allows interesting non-trivial algorithmic results.

1 Introduction

The field of *explorable uncertainty* considers optimization problems with uncertainty in the numeric input parameters. Initially, the precise values of the uncertain parameters are unknown. Instead, for each uncertain parameter, we are given an *uncertainty interval* that contains the precise value of that parameter. Each uncertain parameter can be queried to reveal its precise value. The goal is to adaptively query uncertain parameters until we have sufficient information to solve the underlying optimization problem.

In this paper, we consider *knapsack under explorable uncertainty* (KnapExp) with uncertain item profits. That is, we are given a set of items $\mathcal{I}$ and a knapsack capacity $B \in \mathbb{N}$. Each item $i \in \mathcal{I}$ has a known weight $w_i \in \mathbb{N}$ and an uncertain profit $p_i \in \mathbb{R}$ that is initially hidden within the known uncertainty interval I_i, i.e., $p_i \in I_i$. A *query* of an item i reveals the profit p_i. Our goal is to compute a set $P \subseteq \mathcal{I}$ of items with $w(P) := \sum_{i \in P} w_i \leq B$ that

maximizes the profit $p(P) := \sum_{i \in P} p_i$. We refer to this problem as the *underlying knapsack problem*. Since the profits are initially hidden within their uncertainty intervals, we do not always have sufficient information to compute an optimal or even approximate solution for the underlying knapsack problem. Instead, an algorithm for KnapExp can adaptively query items to reveal their profits until the revealed information suffices to compute an optimal solution for the underlying knapsack instance. As queries are costly, the goal is to minimize the number of queries.

The *offline version*, sometimes also called *verification problem*, of knapsack under explorable uncertainty (OfflineKnapExp) assumes full initial access to the profits p_i and asks for a *query set* $Q \subseteq \mathcal{I}$ of minimum cardinality such that access to the profits of the items in Q and access to the uncertainty intervals of the items in $\mathcal{I} \setminus Q$ suffices to compute an optimal solution to the underlying knapsack instance, independent of what the precise profits of the items in $\mathcal{I} \setminus Q$ are. In this work, we mainly focus on studying the offline version of knapsack under explorable uncertainty. Most commonly, problems under explorable uncertainy are studied in an *adversarial online setting*, where the uncertain values are unknown, query outcomes are returned in a worst-case manner, and algorithms are compared against the optimal solution for the corresponding offline version by using competitive analysis. The complexity of the offline version is a natural barrier for efficiently solving the online version.

So far, most problems that have been studied under explorable uncertainty have an underlying problem that belongs to the complexity class P, i.e., can be solved in polynomial time. The seminal work by Kahan [20] on computing the minimum in a set of uncertain values was followed by works on computing the k-th smallest uncertain value [16, 20], computing a minimum spanning tree with uncertain edge weights [10, 12, 14, 24, 25, 28], sorting [13, 19], shortest path [15], finding the cheapest set in a given family of sets [11, 26], simple geometric problems [7], stable matchings [2], and other selection problems [3, 13]. If we remove the explorable uncertainty aspect, then all of these problems can be solved in polynomial time.

Even tough these underlying problems are in P, the offline versions of the corresponding problems under explorable uncertainty are often NP-hard. For instance, the offline version of identifying the set of maximal points under explorable uncertainty is NP-hard [8], the offline version of the selection problem in [3, 13] is NP-hard, and the offline version of the minimum-spanning tree problem under vertex uncertainty is NP-hard [10]. The offline version of selecting the cheapest set is NP-hard [11] and even hard to approximate within a factor of $o(\log m)$, where m is the number of sets [26]. Similarly, the offline version of stable matching under uncertainty is NP-hard to approximate [2]. For all of these problems, adding the layer of explorable uncertainty increases the complexity from polynomial-time solvable to NP-hard and leads to interesting algorithmic challenges even tough the underlying problems are easy. However, this observation also raises the following question:

> If the underlying problem is already NP-hard, does adding the layer of explorable uncertainty still increase the complexity?

As a first main result, we answer this question in the affirmative for the offline version of knapsack under explorable uncertainty. More precisely, we show that OfflineKnapExp is complete for the second level of the polynomial hierarchy, i.e., Σ_2^p-complete. We even show that, under a certain conjecture ($\Sigma_2^p \neq \Delta_2^p$), no $n^{1-\epsilon}$-approximation is possible for any $\epsilon > 0$, where n is the number of items. The latter can be seen as a natural next step from the inapproximability result given in [26]: They show that approximating the offline version of the cheapest set problem is hard to approximate within a factor of $o(\log m)$ by exploiting that it is equivalent to solving a covering integer linear program (ILP) with m constraints,

whereas we show our inapproximability result by exploiting that offline KnapExp can be represented as a covering ILP with an exponential number of constraints. Unfortunately, these extremely strong hardness results pose further challenges:

> If the hardness of the offline version prevents any non-trivial approximation, is there any hope for interesting algorithmic results in the offline, online or stochastic version?

Our approach for answering this question is to consider a form of *resource augmentation*. More precisely, we relax the requirements on a solution Q for OfflineKnapExp: Instead of requiring that querying Q reveals sufficient information to identify an optimal solution for the underlying knapsack problem, we only require sufficient information to identify an α-approximate solution. Unfortunately, we can show that, unless P=NP, there is no non-trivial approximation for this relaxed problem variant if we compare against an optimal solution for the relaxed problem variant. However, as a second main result, we show that non-trivial algorithmic results are possible if the requirements on the algorithm's solution are less strict than the requirements on the optimal solution we compare against; we make this more precise in the next section.

1.1 Problem Definition

An *instance* $\mathcal{K}$ of KnapExp and OfflineKnapExp is a quintuple $\mathcal{K} = (\mathcal{I}, B, w, p, \mathcal{A})$, where $\mathcal{I} = \{1, \dots, n\}$ is a set of n items, $B \in \mathbb{N}$ is the knapsack capacity, w is the weight vector with $w_i \in \mathbb{N}_{\leq B}$ for all items $i \in \mathcal{I}$, p is the profit vector with $p_i \in \mathbb{R}_{\geq 0}$ for all $i \in \mathcal{I}$, and $\mathcal{A} = \{I_1, \dots, I_n\}$ is the set of uncertainty intervals such that $p_i \in I_i$ for all $i \in \mathcal{I}$. The quadruple $(\mathcal{I}, B, w, p)$ characterizes the underlying knapsack problem.

As is common in the area of explorable uncertainty, we assume that each uncertainty interval I_i is either open or *trivial*. That is, we either have $I_i = (L_i, U_i)$ for a *lower limit* L_i and an *upper limit* U_i, or $I_i = \{p_i\}$. In the latter case, we call both the item i and the uncertainty interval I_i *trivial* and define $U_i = L_i = p_i$. All items that are not trivial are called *non-trivial*. We use $\mathcal{I}_T$ to refer to the set of trivial items. A *query* of an item i reveals the profit p_i and can be seen as replacing the uncertainty interval $I_i = (L_i, U_i)$ with $I_i = \{p_i\}$.

In OfflineKnapExp, all input parameters are known to the algorithm, while in KnapExp the profits p_i are initially uncertain. Both problems ask for a *feasible query set* $Q \subseteq \mathcal{I}$ of minimum cardinality. Intuitively, a query set $Q \subseteq \mathcal{I}$ is feasible if the revealed information suffices to identify an optimal solution to the underlying knapsack problem *and* to determine the profit of such a solution. We proceed by making this definition more formal.

Packings and Feasible Query Sets. To formally define feasible query sets, we first define *packings*. A subset of items $P \subseteq \mathcal{I}$ is a *packing* if $\sum_{i \in P} w_i \leq B$. That is, packings are feasible solutions to the underlying knapsack problem. For $P \subseteq \mathcal{I}$ let $p(P) = \sum_{i \in P} p_i$ denote the profit of P. We call a packing *optimal* if it maximizes the profit over all packings. We usually use P^* to refer to an optimal packing and $p^* := p(P^*)$ to refer to the *optimal profit*.

For each packing $P \subseteq \mathcal{I}$ define $U_P := \sum_{i \in P} U_i$, i.e., the term U_P describes an upper limit on the maximum possible profit the packing could potentially have. Note that U_p can be computed even without access to the profits. By querying items in P, the upper limit U_P decreases as we gain more information and can replace the non-trivial uncertainty interval $I_i = (L_i, U_i)$ with $I_i = \{p_i\}$ after we query i and learn the profit p_i. For $Q \subseteq \mathcal{I}$, we use $U_i(Q)$ to denote the upper limit of i after querying Q, i.e., $U_i(Q) = p_i$ if $i \in Q$ and $U_i(Q) = U_i$ otherwise. The upper limit $U_P(Q)$ of packing P after querying a set $Q \subseteq \mathcal{I}$, is

$$U_P(Q) := \sum_{i \in P} U_i(Q) = \sum_{i \in P \setminus Q} U_i + \sum_{i \in P \cap Q} p_i = \sum_{i \in P} U_i - \sum_{i \in P \cap Q} (U_i - p_i) = U_P - \sum_{i \in P \cap Q} (U_i - p_i).$$

▶ **Definition 1.** *A query set $Q \subseteq \mathcal{I}$ is* feasible *if the following two conditions hold:*
1. *There is a packing $P \subseteq Q \cup \mathcal{I}_T$ with $p(P) = p^*$.*
2. *$U_P(Q) \leq p^*$ holds for every packing $P \subseteq \mathcal{I}$.*

The first condition of Definition 1 ensures that querying Q reveals sufficient information to verify that there exists a packing with the optimal profit p^*, while the second condition ensures that querying Q reveals sufficient information to verify that no packing can possibly have a larger profit than p^*, no matter what the profits of items $i \in \mathcal{I} \setminus Q$ actually are.

Since any packing P^* with $p(P^*) = p^*$ can only satisfy $U_{P^*}(Q) \leq p^*$ if $P^* \subseteq Q \cup \mathcal{I}_T$, the second condition of the definition actually implies the first one. In particular, this means that a query set is feasible if and only if it satisfies the constraints of the following ILP. Note that a similar covering point of view was first observed in [26] for the cheapest set problem.

$$\begin{array}{lll} \min & \sum_{i\in\mathcal{I}} x_i & \\ \text{s.t.} & \sum_{i\in P} x_i \cdot (U_i - p_i) \geq U_P - p^* & \forall P \subseteq \mathcal{I}\colon \sum_{i\in P} w_i \leq B \\ & x_i \in \{0,1\} & \forall i \in \mathcal{I} \end{array} \tag{K-ILP}$$

The offline problem. In the offline problem OfflineKnapExp, we are given an instance $\mathcal{K} = (\mathcal{I}, B, w, p, \mathcal{A})$ with full knowledge of all parameters and our goal is to compute a feasible queryset of minimum cardinality, which is equivalent to solving (K-ILP) with full knowledge of all coefficients. We use Q^* to refer to an optimal solution of OfflineKnapExp.

The online problem. In the online problem KnapExp, we are also given an instance $\mathcal{K} = (\mathcal{I}, B, w, p, \mathcal{A})$ but the profits p_i are initially unknown. The goal is to iteratively and adaptively query items i to reveal their profit p_i until the set of queried items is a feasibile query set. This problem can be seen as solving (K-ILP) with uncertain coefficients $U_i - p_i$ and right-hand side values $U_P - p^*$: Querying an item i corresponds to irrevocably setting $x_i = 1$, incurs a cost that cannot be reverted, and reveals the coefficient $(U_i - p_i)$.

Relaxations. As OfflineKnapExp turns out to admit strong inapproximability results, we introduce the following relaxed notion of feasible query sets. We use (α, β)-OfflineKnapExp to refer to the offline problem of computing a (α, β)-feasible query set of minimum cardinality.

▶ **Definition 2** ((α, β)-feasibility). *Let $\alpha, \beta \geq 1$. We say that a query set $Q \subseteq \mathcal{I}$ is (α, β)-feasible if the following two conditions hold:*
1. *There is a packing P such that $P \subseteq Q \cup \mathcal{I}_T$ and $p(P) \geq \frac{1}{\alpha} \cdot p^*$.*
2. *$U_P(Q) \leq \beta \cdot p^*$ for every packing P.*

The first condition of the definition ensures that we can find an α-approximation for the underlying knapsack instance by using only queried and trivial items. The second condition ensures that, after querying Q, no feasible packing can have profit greater than $\beta \cdot p^*$, no matter what the profits of the items in $\mathcal{I} \setminus Q$ are. Thus, querying Q reveals sufficient information to verify that the set P of the first condition is a $\frac{1}{\alpha\beta}$-approximation for the underlying knapsack instance. We use $Q^*_{\alpha,\beta}$ to refer to a minimum-cardinality (α, β)-feasible query set. Note that $Q^* = Q^*_{1,1}$, Q^* is (α, β)-feasible for every $\alpha, \beta \geq 1$ and $|Q^*| = \max_{\alpha\geq 1, \beta \geq 1} |Q^*_{\alpha,\beta}|$.

In contrast to Definition 1, the second condition of Definition 2 does not imply the first one. As a consequence, each (α, β)-feasible query set is a feasible solution for a variant of (K-ILP) in which we replace p^* with $\beta \cdot p^*$, but the inverse is not necessarily true.

1.2 Our Results and Outline

In Section 2, we give several hardness results for OfflineKnapExp. First, we show that deciding whether $Q = \emptyset$ is an (α, β)-feasible query set is weakly NP-hard for any $\alpha, \beta \geq 1$, which immediately implies that it is weakly NP-hard to approximate (α, β)-OfflineKnapExp within any bounded multiplicative factor. This hardness result mainly exploits that the optimal solution p^* to the weakly NP-hard [21] underlying knapsack problem appears on the right-hand sides of (K-ILP). Then, we move on to show that OfflineKnapExp is Σ_2^p-complete, which intuitively means that the problem remains hard even if we are given an oracle for deciding problems in NP. Since such an oracle allows us to compute p^*, the reason for the Σ_2^p-hardness is not the appearance of p^* in the right-hand sides but the exponential number of constraints in (K-ILP). In fact, we prove this hardness result via reduction from *succinct set cover* [31, 32], which is a set cover variant where the elements and sets are only given implicitly, i.e., the number of set cover constraints is exponential in the encoding size of the problem. Exploiting a result by [30], our reduction also shows that there is no $n_0^{1-\epsilon}$-approximation for any $\epsilon > 0$ unless $\Sigma_2^p = \Delta_2^p$, where $n_0 := |\mathcal{I} \setminus \mathcal{I}_T|$.

In Section 3, we design algorithms for (α, β)-OfflineKnapExp for different values of α and β. Since the hardness results prevent any non-trivial results when comparing against $|Q^*_{\alpha,\beta}|$, we analyze our algorithms by comparing their solutions to $|Q^*|$ instead. This can be seen as a form of resource augmentation as the requirements on the algorithms's solution are less strict than the requirements on the optimal solution we compare against. To achieve our algorithmic results, we treat the two conditions for (α, β)-feasible query sets (cf. Definition 2) as separate subproblems: (i) Compute a query set Q_1 such that there exists a packing $P \subseteq Q_1 \cup \mathcal{I}_T$ with $p(P) \geq \frac{1}{\alpha} p^*$, and (ii) Compute a query set Q_2 such that $U_P(Q_2) \leq \beta p^*$ holds for all packings P. First, we show how to solve subproblem (i) in polynomial-time for $\alpha = \frac{1}{1-\epsilon}$ with a set Q_1 such that $|Q_1| \leq |Q^*|$. Our algorithm for this subproblem exploits existing results for the two-dimensional knapsack problem. For (ii), we first show how to solve the problem in pseudopolynomial time for $\beta = 2 + \epsilon$ with the guarantee $|Q_2| \leq |Q^*|$. The algorithm is based on solving an OfflineKnapExp variant that only considers packings that correspond to certain greedy solutions. We justify the pseudopolynomial running-time by showing weak NP-hardness for this OfflineKnapExp variant. By considering a relaxed version of that problem, we manage to solve problem (ii) for $\beta = 4 + \epsilon$ with $|Q_2| \leq |Q^*|$ in polynomial time. Combining the results for both subproblems yields a pseudopolynomial algorithm that computes a $(\frac{1}{1-\epsilon}, 2+2\epsilon)$-feasible query set Q and a polynomial time algorithm that computes a $(\frac{1}{1-\epsilon}, 4 + 4\epsilon)$-feasible query set Q. In both cases, $|Q| \leq 2 \cdot |Q^*|$.

1.3 Further Related Work

Meißner [27] gives an adversarial lower bound of n for KnapExp that holds even if the instance only has two different weights, preventing any non-trivial adversarial results. However, Megow and Schlöter [26] show that this lower bound does not hold in a stochastic setting where the profits p_i are drawn from their intervals I_i according to an unknown distribution that satisfies $\Pr[p_i \leq \frac{U_i + L_i}{2}] \leq \tau$ for a threshold parameter τ. However, their result only breaks that particular lower bound instance and does not imply general stochastic results for KnapExp.

Goerigk et al. [18] consider a knapsack problem under uncertainty in a different query setting. In their problem, the profits are known and the weights are uncertain. Furthermore, there is a budget on the queries that an algorithm is allowed to make. These differences lead to a problem fundamentally different from KnapExp.

Maehara and Yamaguchi [23] consider packing ILPs with uncertainty in the cost coefficients. The cost coefficients can be queried. The key difference to the setting of explorable uncertainty is that they are interested in bounding the absolute number of queries instead of comparing against the optimal feasible query set. We remark that this is an important distinction between explorable uncertainty and many other query models. For example, the same distinction applies to a line of research that studies queries that reveal the *existence* of entities instead of numeric values, e.g., the existence of edges in a graph, c.f. [4–6, 9, 17, 33]. For instance, Behnezhad et al. [4] considered vertex cover in a stochastic setting and showed that it can be approximated within a factor of $(2+\epsilon)$ with only a constant number of queried edges per vertex.

2 Hardness of Approximation

We start by showing our hardness results for (α, β)-OfflineKnapExp. Not surprisingly, the appearance of p^* in the right-hand sides of (K-ILP) suffices to render (α, β)-OfflineKnapExp weakly NP-hard. The following proposition shows that even deciding whether a given set Q is (α, β)-feasible is already weakly NP-hard (cf. the full version [29] for a formal proof).

▶ **Proposition 3.** *Deciding if $Q = \emptyset$ is (α, β)-feasible is weakly NP-hard for any $\alpha, \beta \geq 1$.*

This means that distinguishing between instances that can be solved without any query and instances that need at least one query is weakly NP-hard, which implies the following:

▶ **Corollary 4.** *It is weakly NP-hard to approximate (α, β)-OfflineKnapExp within any bounded multiplicative factor.*

Proposition 3 is also an indicator that (α, β)-OfflineKnapExp might not be in NP, as verifying whether a query set is (α, β)-feasible is already NP-hard. For $\alpha, \beta = 1$, we make this observation more formal by proving that OfflineKnapExp is complete for the second level of the polynomial hierarchy, i.e., Σ_2^p-complete. Intuitively, the class Σ_2^p contains problems that, given an oracle for deciding problems in NP, can be solved in non-deterministic polynomial time. Similarly, the class Δ_2^p contains problems that, given the same type of oracle, can be solved in deterministic polynomial time. Hardness and completeness for the class Σ_2^p are defined in the same way as for the class NP. For a more formal introduction, we refer to [1]. Under the conjecture that $\sum_2^p \neq$ NP, the $\sum_2^p$-completeness implies that OfflineKnapExp is not in NP, and under the conjecture $\sum_2^p \neq \Delta_2^p$ it cannot be solved optimally in polynomial time even when given an oracle for deciding problems in NP.

▶ **Theorem 5.** OfflineKnapExp *is Σ_2^p-complete.*

Proof. We show Σ_2^p-membership in the full version [29] and focus here on proving Σ_2^p-hardness. Our proof is via reduction from *succinct set cover*, which is known to be $\sum_2^p$-complete [31, 32]. In the same way as for NP-hardness proofs, we need to give a polynomial time reduction to the decision problem variant of OfflineKnapExp such that the constructed instance is a YES-instance if and only if the given succinct set cover instance is a YES-instance.

Succinct set cover. We are given n decision variables $x_1, \ldots, x_n$, m propositional logic formulas $\phi_1, \ldots, \phi_m$ over these variables and an integer parameter k. Each formula ϕ_j is in 3-DNF form[1] and we use S_j to denote the set of 0-1-vectors (variable assignments) that

[1] *Disjunctive normal form (DNF)* refers to a disjunction of conjunctions, i.e., $\phi_j = C_{j,1} \vee \ldots \vee C_{j,k_j}$, where each clause $C_{j,k}$ is a conjunction of literals. In 3-DNF, each $C_{j,k}$ contains exactly three literals. A formula in DNF is satisfied by a variable assignment if at least one clause is satisfied by the assignment.

satisfy ϕ_j. The formulas ϕ_j have to satisfy $\bigcup_{j\in\{1,\dots,m\}} S_j = \{0,1\}^n$, i.e., each variable assignment satisfies at least one formula ϕ_j. The goal is to find a subset $S \subseteq \{1,\dots,m\}$ such that $\bigcup_{j\in S} S_j = \{0,1\}^n$ and $|S| \leq k$. We assume that each variable occurs as a literal in at least one formula. If not, we can just remove the variable and obtain a smaller instance. Succinct set cover can be interpreted as a set cover variant where the elements and sets are only given *implicitly* and not as an explicit part of the input.

Main reduction idea. Before we give the technical details of the reduction, we first sketch the basic idea. In particular, we describe the properties that we want the constructed instance to have. In the technical part, we then describe how to actually achieve these properties. At its core, the reduction will use the knapsack weights to encode structural information of the input instance into the constructed instance. The idea to use numerical weights to encode constraints is quite natural in hardness proofs for weakly NP-hard problems, see e.g. the NP-hardness proof for the subset sum problem given in [22]. The usage of the knapsack weights in our reduction is on some level inspired by such classical reductions, but requires several new ideas to handle the implicit representation of the input problem and the covering nature of OfflineKnapExp.

First, we introduce a single trivial item i^* with $w_{i^*} = p_{i^*} = B$. This item alone fills up the complete knapsack capacity B, which we define later, and the instance will be constructed in such a way that $p^* = p_{i^*} = B$ is the maximum profit of any packing. Thus, only packings P with $U_P > p^*$ induce non-trivial constraints in (K-ILP). We design the instance such that $U_P \geq p^*$ only holds for packings that use the full capacity.

▶ **Property 1.** A packing P of the constructed instance satisfies $U_P \geq p^*$ only if $w(P) = B$.

Next, we want each packing P with $w(P) = B$ and $U_P > p^*$ to represent a distinct variable assignment in $\{0,1\}^n$. To this end, we introduce a set X of $2n$ items, two items v_i and $\bar{v}_i$ for each variable x_i with $i \in \{1,\dots,n\}$. Intuitively, v_i represents the positive literal x_i and $\bar{v}_i$ represents the negative literal $\neg x_i$. We say that a subset $X' \subseteq X$ *represents* a variable assignment if $|X' \cap \{v_i, \bar{v}_i\}| = 1$ for all $i \in \{1,\dots,n\}$. We design our instance such that the packings P with $w(P) = B$ and $U_P > p^*$ exactly correspond to the variable assignments in $\{0,1\}^n$. Note that this excludes the packing $P = \{i^*\}$ as this packing has $w(P) = B$ and $p(P) = p^*$.

▶ **Property 2.** If $w(P) = B$ and $U_P > p^*$, then $P \cap X$ represents a variable assignment. Each variable assignment is represented by at least one P with $w(P) = B$ and $U_P > p^*$.

If the first two properties hold, then all non-trivial constraints in the ILP (K-ILP) for the constructed instance correspond to a packing P with $w(P) = B$ and $U_P > p^*$ and, thus, to a variable assignment of the given succinct set cover instance. Furthermore, each variable assignment is represented by at least one active constraint. With the next property, we want to ensure that each possible query, i.e., each non-trivial item, corresponds to a succinct set cover formula ϕ_j. To this end, we introduce the set of items $Y = \{y_1,\dots,y_m\}$. These items will be the only non-trivial items in the constructed instance, so each possible query is to an element of Y. Next, we want to achieve that querying an item y_j suffices to satisfy all constraints of (K-ILP) for packings P with $w(P) = B$ and $U_P > p^*$ that represent a variable assignment which satisfies formula ϕ_j, and does not impact any other constraints. Formally, we would like to design our instance such that the following property holds.

▶ **Property 3.** For each packing P with $U_P > p^*$ and each $y_j \in Y$: $y_j \in P$ if and only if $X \cap P$ represents a variable assignment that satisfies ϕ_j. If $y_j \in P$, then $U_P - p^* \leq U_{y_j} - p_{y_j}$.

If we manage to define our reduction in such a way that the three properties are satisfied, it is not hard to show correctness (see the full version [29] for the second direction):

First Direction. If there is an index set S with $|S| \leq k$ that is a feasible solution to the succinct set cover instance, then each possible variable assignment must satisfy at least one formula ϕ_j with $j \in S$. We claim that $Q = \{y_j \mid j \in S\}$ is a feasible query set for the constructed OfflineKnapExp instance. To this end, consider an arbitrary packing P with $U_P > p^*$, which are the only packings that induce non-trivial constraints in the corresponding (K-ILP). By Property 1, we have $w(P) = B$. Property 2 implies that $X \cap P$ represents some variable assignment φ and Property 3 implies that $y_j \in P$ for all ϕ_j that are satisfied by φ. By assumption that S is a feasible succinct set cover solution, we get $Q \cap P \neq \emptyset$. Property 3 implies $U_P(Q) \leq U_P(\{y_j\}) \leq p^*$ for each $y_j \in Q \cap P$. Thus, Q satisfies the constraint of P in the (K-ILP) for the constructed instance. As this holds for all P with $U_P > p^*$, the set Q is a feasible solution for the constructed OfflineKnapExp instance.

Technical reduction. It remains to show how to actually construct an OfflineKnapExp instance that satisfies the three properties. Given an instance of succinct set cover, we construct an instance of OfflineKnapExp consisting of four sets X, Φ, A and L of items such that $\mathcal{I} = X \cup \Phi \cup A \cup L$. The set X is defined exactly as sketched above, the set Φ contains the set $Y = \{y_j, \dots, y_m\}$ as introduced above, and $L := \{i^*\}$ for the item i^* with $w_{i^*} = p_{i^*} = B$. All further items will be used to ensure the three properties.

Conceptionally, we construct *several* partial weights for each item i that will later be combined into a single weight. For each item i, we construct two weights w_{i,ϕ_j} and w_{i,ρ_j} for each formula ϕ_j, and a single weight $w_{i,x}$. Similarly, we break down the knapsack capacity into multiple partial knapsack capacities B_x, and B_{ϕ_j}, B_{ρ_j} for each ϕ_j. Intuitively, the full weight w_i of an item i will be the concatenation of the decimal representations of the partial weights, i.e., $w_i = w_{i,x} w_{i,\rho_m} \cdots w_{i,\rho_1} w_{i,\phi_m} \cdots w_{i,\phi_1}$, and B will be the concatenation of the partial capacities. We make this more precise in the full version [29] after defining all partial weights in such a way that the following property holds.

▶ **Property 4.** For each packing P with $P \neq \{i^*\}$, it holds $\sum_{i \in P} w_i = B$ if and only if $\sum_{i \in P} w_{i,x} = B_x$, and $\sum_{i \in P} w_{i,\phi_j} = B_{\phi_j}$ and $\sum_{i \in P} w_{i,\rho_j} = B_{\rho_j}$ for all $j \in \{1, \dots, m\}$.

For now, we operate under the assumption that Property 4 holds and focus on the partial weights and capacities, and proceed by defining the remaining parts of the construction.

Definition of the w_x-weights. As formulated in Property 2, we would like each packing P with $w(P) = B$ and $U_P > p^*$ to represent a variable assignment. To this end, we need such a packing to contain exactly one item of $\{v_i, \bar{v}_i\}$ for each $i \in \{1, \dots, n\}$. To enforce this, we use the partial w_x-weights and the partial capacity B_x. In particular, we define $w_{v_i,x} = w_{\bar{v}_i,x} = 10^i$ for each $i \in \{1, \dots, n\}$, and $B_x = \sum_{i=1}^{n} 10^i$. For all items $j \in \mathcal{I} \setminus X$, we define $w_{j,x} = 0$, which immediately implies the following property:

▶ **Property 5.** P satisfies $\sum_{i \in P} w_{i,x} = B_x$ iff $P \cap X$ represents a variable assignment.

Definition of the set A and the w_{ϕ_j}-weights. Define $A = \bigcup_{j \in \{1,\dots,m\}} A_{\phi_j}$ for sets A_{ϕ_j} to be defined below. For formula ϕ_j, let k_j denote the number of clauses in ϕ_j and let $C_{j,1}, \dots, C_{j,k_j}$ denote these clauses. For each $C_{j,k}$, we add four items $a_{j,k,0}, a_{j,k,1}, a_{j,k,2}, a_{j,k,3}$ to set A_{ϕ_j}. The idea is to define the partial w_{ϕ_j}-weights and the partial B_{ϕ_j} capacity in such a way that the following property holds.

▶ **Property 6.** For each ϕ_j, a packing P satisfies $\sum_{i\in P} w_{i,\phi_j} = B_{\phi_j}$ and $\sum_{i\in P} w_{i,x} = B_x$ iff $a_{j,k,0} \in P$ for each clause $C_{j,k}$ that is satisfied by the assignment represented by $X \cap P$.

To achieve the property, we first define the partial w_{ϕ_j}-weights for the items X. For a literal x_i, let $\mathcal{C}_{x_i,j} := \{k \mid x_i \text{ occurs in } C_{j,k}\}$ and define $\mathcal{C}_{\neg x_i,j}$ in the same way. We define the weights w_{v_i,ϕ_j} and $w_{\bar{v}_i,\phi_j}$ as $\sum_{k\in\mathcal{C}_{x_i,j}} 10^{k_j+k-1}$ and $\sum_{k\in\mathcal{C}_{\neg x_i,j}} 10^{k_j+k-1}$, respectively. Intuitively, digit $k_j + k$ of the sum $\sum_{h\in X\cap P} w_{h,\phi_j}$ of a packing P with $\sum_{i\in P} w_{i,x} = B_x$ indicates whether the assignment represented by $X \cap P$ satisfies clause $C_{j,k}$ or not: If the clause is satisfied, then $X \cap P$ contains the items that represent the three literals of $C_{j,k}$ and the digit has value 3. Otherwise, $X \cap P$ contains at most two of the items that represent the literals of $C_{j,k}$ and the digit has value at most 2.

Finally, for each for $i \in \{0, 1, 2, 3\}$, we define the w_{ϕ_j}-weight of item $a_{j,k,i}$ as $w_{\phi_j,a_{j,k,i}} = i\cdot 10^{k_j+k-1} + 10^{k-1}$. For all remaining items $i \in \mathcal{I}\setminus(X \cup A_{\phi_j})$, we define the partial w_{ϕ_j}-weight to be zero. Furthermore, we define the partial capacity $B_{\phi_j} = \sum_{k=0}^{k_j-1} 10^k + \sum_{k=k_j}^{2k_j-1} 3 \cdot 10^k$. We claim that these definitions enforce Property 6.

Intuitively, the fact that the k_j decimal digits of lowest magnitude in B_{ϕ_j} have value 1 forces a packing P with $\sum_{i\in P} w_{i,\phi_j} = B_{\phi_j}$ to contain exactly one item of $\{a_{j,k,0}, \ldots, a_{j,k,3}\}$ for each $k \in \{1, \ldots, k_j\}$ as each such item increases the corresponding digit $k - 1$ by one. Similarly, the value of each digit $k_j + k - 1$ in B_{ϕ_j} is three. Since the elements of X that occur in clause $C_{j,k}$ increase the value of digit $k_j + k - 1$ in $w_{\phi_j}(P)$ by one and item $a_{j,k,i}$ increases the digit by i, a packing P with value three in digit $k_j + k - 1$ of $w_{\phi_j}(P)$ can contain item $a_{j,k,0}$ if and only if $X \cap P$ contains the three items that correspond to the literals in $C_{j,k}$. This implies Property 6. We give a more formal argumentation in the full version [29].

Definition of set Φ and the w_{ρ_j}-weight. Define $\Phi = \bigcup_{j\in\{1,\ldots,m\}} \Phi_j$ such that $\Phi_j = \{y_j, u_j, f_{j,0}, \ldots, f_{j,k_j-1}\}$. Note that y_j is the item that has already been introduced for Property 3. As a step toward enforcing this property, we define the w_{ρ_j}-weights such that:

▶ **Property 7.** For each ϕ_j, a packing P with $\sum_{i\in P} w_{i,\rho_j} = B_{\rho_j}$ has $y_j \in P$ if and only if $a_{j,k,0} \in P$ for some clause $C_{j,k}$ in ϕ_j.

To enforce this property, we define the following partial capacity $B_{\rho_j} = k_j + 10^{k_j^2} + 10^{k_j^2+1}$. Next, we define the w_{ρ_j}-weight of the elements $a_{j,k,0}$, $k \in \{1, \ldots, k_j\}$, as $w_{a_{j,k,0},\rho_j} = 1$. Furthermore, we define $w_{u_j,\rho_j} = 10^{k_j^2+1} + 10^{k_j^2} + k_j$, $w_{y_j,\rho_j} = 10^{k_j^2+1}$ and $w_{f_{j,k},\rho_j} = 10^{k_j^2} + k$, for all $k \in \{0, \ldots, k_j - 1\}$. For all other items, define the w_{ρ_j}-weight to be zero. We show in the full version [29] that these definitions imply Property 7.

Definition of the uncertainty intervals and precise profits. To finish the reduction, we define the profits and uncertainty intervals of all introduced items:

- For the items y_j, $j \in \{1, \ldots, m\}$, we define the uncertainty interval $I_{y_j} = (w_{y_j} - 2, w_{y_j} + \epsilon)$ for a fixed $0 < \epsilon < \frac{1}{m}$. We define the profits as $p_{y_j} = w_{y_j} - 1$.
- For all items $i \in \mathcal{I} \setminus \{y_j \mid j \in \{1, \ldots, m\}\}$, we use trivial uncertainty intervals $I_i = \{w_i\}$.

Proof of the three main properties. With the full construction in place, we are ready to prove the three main properties from the beginning of the proof:

1. **Property 1:** By definition of the profits, we have $p(P) \leq w(P)$ for each packing P, which implies that the maximum profit is $p^* \leq B$. Since the packing $P = L = \{i^*\}$ has a profit of exactly B, we get $p^* = B$. On the other hand, the upper limit U_P of a packing P is $w(P) + \epsilon|P \cap \{y_j \mid j \in \{1, \ldots, m\}\}|$ as only the items in $\{y_j \mid j \in \{1, \ldots, m\}\}$ have

a non-trivial uncertainty interval with upper limits of $w_{y_j} + \epsilon$. By choice of ϵ, this gives $U_P = w(P) + \epsilon|P \cap \{y_j \mid j \in \{1, \dots, m\}\}| < w(P) + 1$. Since all weights are integer, this implies that $U_P \geq p^* = B$ only holds if $w(P) = B$.

2. **Property 2:** The property, in particular the first part, is essentially implied by Property 4 and Property 5. We give the formal argumentation in the full version [29].
3. **Property 3:** By Property 1 and definition of the uncertainty intervals, a packing P has $U_P > p^*$ if and only if $w(P) = B$ and $P \neq \{i^*\}$. By Property 4, the latter holds if and only if $w_x(P) = B_x$, $w_{\phi_j}(P) = B_{\phi_j}$ and $w_{\rho_j}(P) = B_{\rho_j}$ for all $j \in \{1, \dots, m\}$. Fix a packing P with $y_j \in P$ for some $j \in \{1, \dots, m\}$. By Property 7, $y_j \in P$ holds if and only if $a_{j,k,0} \in P$ for some clause $C_{j,k}$ in ϕ_j. By Property 6, $a_{j,k,0} \in P$ if and only if $C_{j,k}$ is satisfied by the assignment represented by $X \cap P$. This gives the first part of Property 3. For the final part, observe that $U_{y_j} - p_{y_j} > 1$. On the other hand, $U_p - p^* < 1$. Hence, the second part of Property 3 holds.

To finish the proof of the reduction, it remains to argue about the running time and space complexity of the reduction. We do so in the full version [29]. The main argument is that, while the numerical values of the constructed weights are exponential, the number of digits in their decimal representations (and, thus, their encoding size) is polynomial. ◀

The previous theorem proves $\sum_2^p$-hardness for OfflineKnapExp. Exploiting the inapproximability result on the succinct set cover problem given in [30, Theorem 7.2], we can show the following stronger statement by using the same reduction (cf. the full version [29] for a formal proof).

▶ **Theorem 6.** *Unless $\Sigma_2^p = \Delta_2^p$, there exists no $n_0^{1-\epsilon}$-approximation (given access to an oracle for problems in NP) for* OfflineKnapExp *for any $\epsilon > 0$, where $n_0 := |\mathcal{I} \setminus \mathcal{I}_T|$.*

▶ Remark 7. We remark that all results given in this section require large numerical input parameters. Hence, they do not prohibit the existence of pseudopolynomial algorithms.

3 Algorithmic Results

In this section, we give algorithms for (α, β)-OfflineKnapExp for different values of α and β. Motivated by the hardness results of the previous section, we show bounds on the size of the computed query sets in comparison to $|Q^*|$ instead of $|Q^*_{\alpha,\beta}|$. All our algorithms treat the two conditions on (α, β)-feasible query sets (cf. Definition 2) as two separate subproblems:

1. Compute a query set Q_1 such that there exists a packing $P \subseteq Q_1 \cup \mathcal{I}_T$ with $p(P) \geq \frac{1}{\alpha} p^*$.
2. Compute a query set Q_2 such that $U_P(Q_2) \leq \beta \cdot p^*$ for all packings P.

In the following, we show how to solve these two problems and give bounds on $|Q_1 \cup Q_2|$ in terms of $|Q^*|$.

3.1 The First Subproblem

The following lemma solves the first subproblem for $\alpha = \frac{1}{1-\epsilon}$ by computing a packing P with $p(P) \geq (1 - \epsilon) \cdot p^*$ and $|P \setminus \mathcal{I}_T| \leq |Q^*|$. The set $Q_1 = P \setminus \mathcal{I}_T$ satisfies the requirement of the subproblem and has $|Q_1| \leq |Q^*|$. In the full version [29], we prove the lemma by exploiting existing algorithms for two-dimensional knapsack.

▶ **Lemma 8.** *Fix an $\epsilon > 0$. Given an instance of* OfflineKnapExp*, there exists a polynomial time algorithm that computes a packing P with $p(P) \geq (1 - \epsilon) \cdot p^*$ and $|P \setminus \mathcal{I}_T| \leq |Q^*|$.*

3.2 The Second Subprobem: Prefix Problems

For the second subproblem, we consider special packings that correspond to greedy solutions for the underlying knapsack problem. For an item $i \in \mathcal{I}$, define the *density* $d_i = \frac{p_i}{w_i}$ and the *optimistic density* $\bar{d}_i = \frac{U_i}{w_i}$. For a query set $Q \subseteq \mathcal{I}$, define the optimistic density of an item i *after* querying Q as $\bar{d}_i(Q) = \bar{d}_i$ if $i \notin Q$ and $\bar{d}_i(Q) = d_i$ if $i \in Q$. We use $\bar{\prec}_Q$ to denote the *optimistic density order* after querying Q, that is, for $i, j \in \mathcal{I}$ we use $i \bar{\prec}_Q j$ to denote that $\bar{d}_i(Q) \geq \bar{d}_j(Q)$. We assume an arbitrary but fixed tiebreaking rule between the items to treat $\bar{\prec}_Q$ as a total order. This allows us to define *optimistic prefixes* and the *prefix problem*.

▶ **Definition 9** (Optimistic prefixes). *For a set $Q \subseteq \mathcal{I}$ and a parameter $0 \leq C \leq B$, define the* optimistic prefix $\bar{F}_C(Q)$ *to be the maximal prefix S of order $\bar{\prec}_Q$ such that $w(S) \leq C$. To shorten the notation, we define $\bar{F}(Q) := \bar{F}_B(Q)$*

From the analysis of the knapsack greedy algorithm, it is well-known that the following holds for all packings P:

$$U_P(Q) \leq U_{\bar{F}(Q)}(Q) + \max_{i \in \mathcal{I}} U_i(Q). \tag{1}$$

If we compute a set Q, such that $U_{\bar{F}(Q)} \leq \beta' p^*$ and $\max_{i \in \mathcal{I}} U_i(Q) \leq \beta' \cdot p^*$, then Q solves the second subproblem for $\beta = 2 \cdot \beta'$, which motivates the following problem.

▶ **Definition 10** (Prefix problem). *Given an instance of* OfflineKnapExp *and a threshold parameter $D \geq p^*$, where p^* is the optimal profit of the underlying knapsack instance, the* prefix problem *asks for the set $Q \subseteq \mathcal{I}$ of minimum cardinality such that $U_{\bar{F}(Q)}(Q) \leq D$.*

Unfortunately, the prefix problem preserves the hardness of knapsack, even if the given threshold is larger than p^* by a constant factor. We show this in the full version [29].

▶ **Theorem 11.** *The prefix problem is weakly NP-hard for every $D = c \cdot p^*$ with $c \geq 1$.*

On the positive side, the problem can be solved to optimality in pseudopolynomial time.

▶ **Theorem 12.** *The prefix problem can be solved in pseudopolynomial time.*

We give the full proof of Theorem 12 in the full version [29], but highlight the main ideas here. In the following, we use Q^*_F to refer to an optimal solution for the prefix problem.

Assume for now, that the algorithm knows the last item i_1 in the prefix $\bar{F}(Q^*_F)$ and the first item i_2 outside of $\bar{F}(Q^*_F)$ in the order $\bar{\prec}_{Q^*_F}$ (Figure 1 (a)) and, for the sake of simplicity, assume that $i_1, i_2 \notin Q^*_F$. We design our algorithm to reconstruct the optimal solution $\bar{F}(Q^*_F)$ (or a similar solution) using just the knowledge of i_1 and i_2.

If we look at the same two items i_1, i_2 in the initial optimistic density order $\bar{\prec}_\emptyset$, then there can be a subset of items S before i_1, a subset of items A between i_1 and i_2 and a subset of items R after i_2 (Figure 1 (b)). Based on i_1 and i_2 being next to each other in order $\bar{\prec}_{Q^*_F}$, we can immediately deduce that $A \subseteq Q^*_F$ as items in $A \setminus Q^*_F$ would still be between i_1 and i_2 in $\bar{\prec}_{Q^*_F}$. Thus, the algorithm can safely add A to its solution as the optimal solution does the same. Similarly, from i_2 being the first item outside of $\bar{F}(Q^*_F)$, it is clear that $R \cap Q^*_F = \emptyset$ as the items in R stay outside the prefix $\bar{F}(Q^*_F)$ whether they are queried or not. Hence, the algorithm can safely ignore such items.

In the order $\bar{\prec}_A$, i.e., in the order after adding A to the solution, the items i_1 and i_2 must already be next to each other. However, we still can have $i_1 \notin \bar{F}(A)$, that is, i_1 might not yet be part of the prefix (Figure 1 (c)). To fix this, the algorithms needs to query items from the

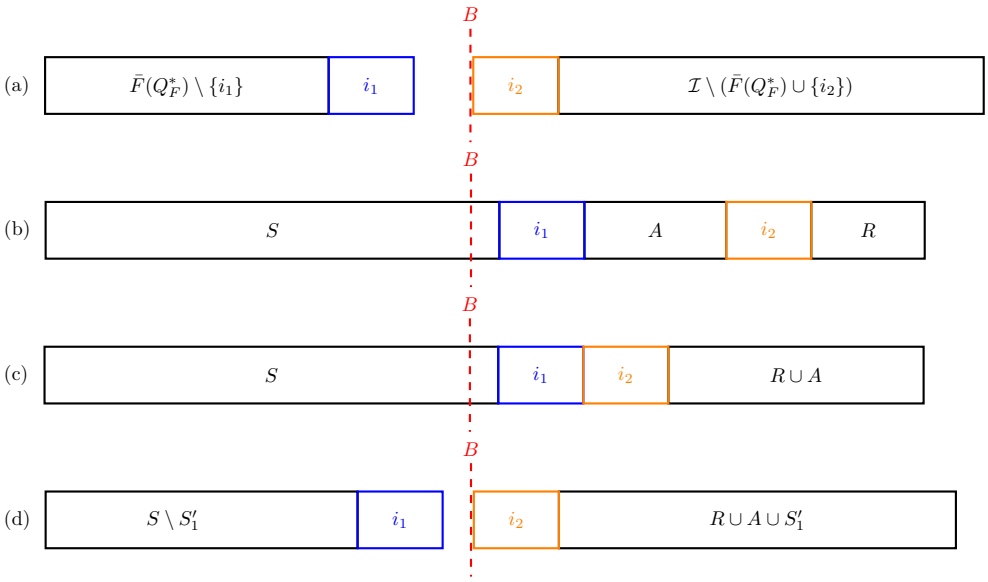

Figure 1 Illustration of the algorithmic ideas used to prove Theorem 12.

set $S_1 \subseteq S$, which contains items that are before i_1 in the order $\bar{\prec}_A$ but would move behind i_2 if they are added to the solution. To reconstruct the optimal solution, the algorithm has to query these items in such a way that i_1 enters the prefix but i_2 does not. On the one hand, the algorithm should select items $i \in S_1$ with high U_i as the items will leave the prefix and the goal of the prefix problem is to decrease the upper limit of the prefix below the threshold D. On the other hand, the algorithm needs to make sure not to query too many items in S_1, so the cardinality of the solution does not grow too large. If K is the minimum amount of weight that needs to be queried for i_1 to enter the prefix, D is the maximum amount of weight that can be queried before i_2 enters the prefix, and n_1 is the number of queries that the algorithm can afford, then the algorithm should select its queries from S_1 according to the following ILP, which we show to be solvable in pseudopolynomial time:

$$\begin{aligned} \max \quad & \textstyle\sum_{i \in S_1} x_i \cdot U_i \\ \text{s.t.} \quad & \textstyle\sum_{i \in S_1} x_i \cdot w_i \geq K \\ & \textstyle\sum_{i \in S_1} x_i \cdot w_i \leq H \\ & \textstyle\sum_{i \in S_1} x_i = n_1 \\ & x_i \in \{0,1\} \qquad \forall i \in S_1 \end{aligned} \tag{$\mathcal{P}_{S_1}$}$$

After adding the solution S_1' of $(\mathcal{P}_{S_1})$ to the solution, the prefix $\bar{F}(A \cup S_1')$ of the algorithm has reached roughly the same configuration as $\bar{F}(Q_F^*)$: i_1 is last in the prefix and i_2 is first outside the prefix (Figure 1 (d)). However, we still might have $U_{\bar{F}(A \cup S_1')}(A \cup S_1') > D$. To fix this, the algorithm has to query items of $S \setminus S_1'$ that stay in front of i_1 in the optimistic density order even after being queried. Since these items are part of the prefix $\bar{F}(A \cup S_1')$ *and* will stay part of the prefix even after being queried, the algorithm should greedily query such items i with large $U_i - p_i = U_{\bar{F}(A \cup S_1')}(A \cup S_1') - U_{\bar{F}(A \cup S_1' \cup \{i\})}(A \cup S_1' \cup \{i\})$ until the solution becomes feasible for the prefix problem instance. Our algorithm for Theorem 12 is based on exactly this approach. We show in the full version [29] how to formalize this and get rid of all assumptions that were used in the description above.

To achieve polynomial running time, we use the same approach but instead of $(\mathcal{P}_{S_1})$ we solve a certain LP-relaxation with the property that an optimal basic feasible solution has at most two fractional variables. Omitting the fractional items leads to the following corollary.

▶ **Corollary 13.** *Given an instance of the prefix problem with threshold parameter D, let Q_F^* denote an optimal solution to the instance. There exists a polynomial time algorithm that computes a set Q with $|Q| \leq |Q_F^*|$ such that $U_{\bar{F}(Q)}(Q) \leq D + 2 \cdot \max_{i \in \mathcal{I}} U_i$.*

3.3 Combining the Subproblems

By combining Lemma 8 and Theorem 12, we can show the following theorem. The idea is to use Lemma 8 to compute a packing P with $p(P) \geq (1-\epsilon')p^*$ for a carefully chosen $\epsilon' > 0$ and then use Theorem 12 with threshold $D = \frac{p(P)}{(1-\epsilon')}$ to compute a solution Q' to the prefix problem. Exploiting (1), we return the solution $Q = (P \setminus \mathcal{I}_T) \cup Q' \cup \{i \in \mathcal{I} \mid U_i > D\}$ and observe that Q satisfies the theorem. A formal proof is given in the full version [29].

▶ **Theorem 14.** *Fix $\epsilon > 0$. There exists a pseudopolynomial algorithm that given an instance of* OfflineKnapExp *computes a $(\frac{1}{1-\epsilon}, (1+\epsilon) \cdot 2)$-feasible query set Q with $|Q| \leq 2|Q^*|$.*

Replacing the usage of Theorem 12 with Corollary 13 in the approach above yields:

▶ **Theorem 15.** *Fix $\epsilon > 0$. There exists a polynomial time algorithm that given an instance of* OfflineKnapExp *computes a $(\frac{1}{1-\epsilon}, (1+\epsilon) \cdot 4)$-feasible query set Q with $|Q| \leq 2|Q^*|$.*

4 Conclusion

We hope that our results on OfflineKnapExp improve the understanding of NP-hard problems under explorable uncertainty. In particular, our algorithmic insights on the resource augmentation setting give hope for tackling such problems even if the corresponding offline versions have strong impossibility results. For knapsack specifically, studying a stochastic version of the prefix problem of Section 3, for example in the stochastic setting of [26], seems like a logical next step towards algorithmic results for the non-offline KnapExp. For OfflineKnapExp, our results of Section 3 show that non-trivial algorithmic results with theoretical guarantees are possible, opening the door for more research on finding the best-possible guarantees.

Abstract

A *replacement action* is a function $\mathcal{L}$ that maps each graph H to a collection of graphs of size at most $|V(H)|$. Given a graph class $\mathcal{H}$, we consider a general family of graph modification problems, called $\mathcal{L}$-Replacement to $\mathcal{H}$, where the input is a graph G and the question is whether it is possible to replace some induced subgraph H_1 of G on at most k vertices by a graph H_2 in $\mathcal{L}(H_1)$ so that the resulting graph belongs to $\mathcal{H}$. $\mathcal{L}$-Replacement to $\mathcal{H}$ can simulate many graph modification problems including vertex deletion, edge deletion/addition/edition/contraction, vertex identification, subgraph complementation, independent set deletion, (induced) matching deletion/contraction, etc. We present two algorithms. The first one solves $\mathcal{L}$-Replacement to $\mathcal{H}$ in time $2^{\mathsf{poly}(k)} \cdot |V(G)|^2$ for every minor-closed graph class $\mathcal{H}$, where poly is a polynomial whose degree depends on $\mathcal{H}$, under a mild technical condition on $\mathcal{L}$. This generalizes the results of Morelle, Sau, Stamoulis, and Thilikos [ICALP 2020, ICALP 2023] for the particular case of Vertex Deletion to $\mathcal{H}$ within the same running time. Our second algorithm is an improvement of the first one when $\mathcal{H}$ is the class of graphs embeddable in a surface of Euler genus at most g and runs in time $2^{\mathcal{O}(k^9)} \cdot |V(G)|^2$, where the $\mathcal{O}(\cdot)$ notation depends on g. To the best of our knowledge, these are the first parameterized algorithms with a reasonable parametric dependence for such a general family of graph modification problems to minor-closed classes.

1 Introduction

A graph modification problem is typically determined by a target graph class $\mathcal{H}$ and a prescribed set of allowed local modifications $\mathcal{M}$, such as vertex/edge removal or edge addition/contraction or combinations of them, and the question is, given a graph G and an integer k, whether it is possible to transform G to a graph in $\mathcal{H}$ by applying at most k modification operations from $\mathcal{M}$. Graph modification problems are fundamental in algorithmic graph theory, as can be seen from the span of applications in domains as diverse

as computational biology, computer vision, machine learning, networking, or sociology; see [19] and the references therein. Unfortunately, most of these problems are NP-complete [32, 49], and this justifies, among other approaches, to study them from the parameterized complexity viewpoint (see the monographs [10, 12, 15, 40] for an introduction to the field), where the number k of allowed modifications is taken as the parameter.

In the recent years, there has been a very active line of research about algorithmic meta-theorems for graph modification problems where the target class $\mathcal{H}$ is *minor-closed*, that is, closed under vertex deletion, edge deletion, and edge contraction. By Robertson and Seymour's seminal result [43], a minor-closed graph class $\mathcal{H}$ has a finite number of minor-obstructions, that is, graphs that are not in $\mathcal{H}$ but whose all proper minors are. Combined with a minor containment algorithm [30] (see also [26, 42]) running in almost-linear time, this implies that checking membership in a minor-closed graph class can be done in almost-linear time. For some modification problems where the target class $\mathcal{H}$ is minor-closed, such as vertex deletion, edge deletion, or vertex identification, the graphs G such that (G, k) is a yes-instance of the problem for a fixed k form a minor-closed graph class, which immediately implies an FPT-algorithm in almost-linear time for these problems. However, not all graph modification problems define a minor-closed graph class. For instance, edge contraction to planar graphs does not. Indeed, consider the graph $K_{3,4}^{+}$ obtained from $K_{3,4}$ by adding one edge e on the side with three vertices. Contracting e gives the planar graph $K_{2,4}$, but $K_{3,4}$ cannot be made planar by contracting one edge. Hence, some other algorithmic meta-theorems for graph modification problems to minor-closed graph classes were later introduced. Some of them are ad-hoc meta-theorems such as the one of Fomin, Golovach, and Thilikos [17] that gives quadratic FPT-algorithms for graph modification problems where $\mathcal{H}$ is the class of planar graphs and the modification is any combination of edge addition and edge deletion. Much more generally, there has been a recent line of research on model-checking on minor-closed graph classes [16, 47], which in particular implies quadratic FPT-algorithms for an extremely wide family of graph modification problems where the target class $\mathcal{H}$ is minor-closed. Unfortunately, all these algorithmic meta-theorems have a major drawback: the parametric dependence on the "amount of modification" is humongous; in fact, even a rough upper bound is not known.

On the other hand, another line of research has focused on optimizing the parametric dependence for some particular graph modification problems when the parameter is the solution size. When the target class $\mathcal{H}$ is minor-closed, such study usually does not go much beyond $\mathcal{H}$ being the class of forests and the class of union of paths [7, 9, 22, 23, 33, 39, 48]. To the best of our knowledge, only the case of vertex deletion has been studied in a a series of papers [18, 24, 25, 28, 29, 37, 38, 44, 45], focusing on optimizing the running time (both the dependence on k and n). In particular, when the minor-obstructions of $\mathcal{H}$ are connected and that one of them is planar, the currently fastest algorithm runs in time $2^{\mathcal{O}(k)} \cdot n \log^2 n$ [18], when $\mathcal{H}$ excludes a planar graph, in time $2^{\mathcal{O}(k)} \cdot n^2$ [28], when $\mathcal{H}$ is the class of planar graphs, in time $2^{\mathcal{O}(k \log k)} \cdot n$ [24], when $\mathcal{H}$ is the class of graphs embeddable in a surface of bounded genus, in time $2^{\mathcal{O}(k^2 \log k)} \cdot n^{\mathcal{O}(1)}$ [29], and when $\mathcal{H}$ is any minor-closed graph class, in time $2^{\mathsf{poly}(k)} \cdot n^2$ [38].

This article places itself in-between these two lines of research: we consider generic "meta-modification" operations (of course, much less generic than those of the currently most general algorithmic meta-theorem in [47], but still quite versatile), and we manage to achieve the same (very reasonable) parametric dependence as the currently best one for vertex deletion [38] when the target $\mathcal{H}$ is any minor-closed graph class. We hope that our work will trigger further research about *efficient* algorithmic meta-theorems for graph modification problems to minor-closed graph classes.

Our results. We define a graph modification problem, called $\mathcal{L}$-Replacement to $\mathcal{H}$ ($\mathcal{L}$-R-$\mathcal{H}$ for short), which, depending on the choice of the function $\mathcal{L}$, called a *replacement action*, can simulate vertex deletion, edge deletion, edge completion, edge edition, edge contraction, vertex identification, independent set deletion, matching deletion, matching contraction, star deletion, and subgraph complementation, to name a few (see section 3 for an exposition of some problems encompassed by our result). When $\mathcal{H}$ is minor-closed, we solve $\mathcal{L}$-R-$\mathcal{H}$ in time $2^{\mathsf{poly}(k)} \cdot n^2$ (Theorem 2), where the degree of the polynomial poly depends on the maximum size $s_{\mathcal{H}}$ of the minor-obstructions of $\mathcal{H}$. This is the same running time as the one achieved by the currently best algorithm for vertex deletion [38] (the degree of k in poly is the same as in [38] up to an extra additive constant of one that is absolutely negligible compared to the total degree that depends (wildly) on $s_{\mathcal{H}}$). For the other graph modification problems encompassed within $\mathcal{L}$-R-$\mathcal{H}$, to the authors' knowledge, the only minor-closed classes for which a good parametric dependence was previously known, if any, were the class of forests and the class of union of paths [9, 22, 33, 39, 48].

As it is usually the case concerning meta-theorems, the degree d of the polynomial poly in Theorem 2 is unfortunately huge. While we did not compute its exact value, we know that $d \geq 2^{2^{s_{\mathcal{H}}^{24}}}$. Nevertheless, d can improved for some specific target classes $\mathcal{H}$. The *Euler genus* of a surface Σ that is obtained from the sphere by adding h handles and c crosscaps is defined to be $c + 2h$. In particular, when $\mathcal{H}$ is the class of graphs embeddable in a surface of Euler genus at most g, we provide another algorithm solving $\mathcal{L}$-R-$\mathcal{H}$ in time $2^{\mathcal{O}(k^9)} \cdot n^2$ (Theorem 3), where the $\mathcal{O}(\cdot)$ notation depends on g. Note that, as opposed to Theorem 2, in Theorem 3 the contribution of the genus (that is, of the target graph class $\mathcal{H}$) does *not* affect the degree of the parameter k in the exponent.

Organization. In section 2 we give basic definitions and conventions, and we formally define the problem and state our results. In section 3 we provide a non-exhaustive list of problems generated by different instantiations of the replacement action $\mathcal{L}$, and hence encompassed by our results. In section 4 we present an overview of our techniques. Due to space limitations, all proofs have been deferred to the full version of this article. In section 5 we present some directions for further research.

2 Definition of the problem and formal statement of the results

In this section we formally define the $\mathcal{L}$-R-$\mathcal{H}$ problem and state our results, already informally discussed in the introduction. We use standard graph-theoretic notation, and complete preliminaries about graphs (including tree decompositions and minors) can be found in the full version. We define here the non-standard notions that are needed in order to state our results.

Minor-closed graph classes. A graph class $\mathcal{H}$ is *minor-closed* if, for each graph G and each minor H of G, the fact that $G \in \mathcal{H}$ implies that $H \in \mathcal{H}$. Given a collection of graphs $\mathcal{F}$, we denote by $\mathsf{exc}(\mathcal{F})$ the class of graphs that do not contain a graph in $\mathcal{F}$ as a minor. Obviously, $\mathsf{exc}(\mathcal{F})$ is minor-closed. A *(minor-)obstruction* of a graph class $\mathcal{H}$ is a graph F that is not in $\mathcal{H}$, but whose minors are all in $\mathcal{H}$. The set of all the obstructions of $\mathcal{H}$ is denoted by $\mathsf{obs}(\mathcal{H})$. By the seminal work of Robertson and Seymour [43], if $\mathcal{H}$ is a minor-closed graph class, then $\mathsf{obs}(\mathcal{H})$ is finite. Note that, if $\mathcal{F} = \mathsf{obs}(\mathcal{H})$, then $\mathsf{exc}(\mathcal{F}) = \mathcal{H}$. The *detail* of a graph G is $\max\{|V(G)|, |E(G)|\}$.

Ordered graphs. For the definitions of the next two paragraphs to be correct, we actually need to consider ordered graphs instead of graphs (see the "Graph modifications" paragraph). An *ordered graph* is a graph G equipped with a strict total order on $V(G)$, denoted by $<_G$. In other words, there exists an indexation $v_1, \ldots, v_n$ of the vertices of $V(G)$ such that $v_1 <_G v_2 <_G \cdots <_G v_n$. A subgraph H of an ordered graph G naturally comes equipped with the strict order $<_H$ such that, for each distinct $u, v \in V(H)$, $u <_H v$ if and only if $u <_G v$.

Replacement actions. The *any-replacement action* is the function $\mathcal{M}$ that maps each ordered graph H_1 to the collection $\mathcal{M}(H_1)$ of all the pairs (H_2, ϕ), where H_2 is an ordered graph and $\phi : V(H_1) \to V(H_2) \cup \{\emptyset\}$ is a function such that:

- $|V(H_2)| \leq |V(H_1)|$,
- for each $v \in V(H_2)$, $\phi^{-1}(v) \neq \emptyset$, and
- $<_{H_2}$ is the strict total order such that, for each distinct $v_1, v_2 \in V(H_2)$, we have $v_1 <_{H_2} v_2$ if and only if $u_1 <_{H_1} u_2$ where, for $i \in [2]$, u_i is the smallest vertex (according to $<_G$) in $\phi^{-1}(v_i)$.

A *replacement action* (abbreviated as *R-action*) is any function $\mathcal{L}$ that maps an ordered graph (called a *pattern*) H_1 to a non-empty collection $\mathcal{L}(H_1) \subseteq \mathcal{M}(H_1)$ of its possible *pattern transformations*. See Figure 1 for an illustration. The vertices of H_1 mapped by ϕ to the empty set are said to be *deleted*, and two vertices of H_1 mapped by ϕ to the same vertex of H_2 are said to be *identified*. Given $S \subseteq V(H_1)$, we set $\phi^+(S) = \phi(S) \setminus \{\emptyset\}$. Note that, if $\phi(S) = \{\emptyset\}$, then $\phi^+(S) = \{\emptyset\} \setminus \{\emptyset\} = \emptyset$.

Graph modifications. Let $\mathcal{L}$ be an R-action, let G be an ordered graph, and $S \subseteq V(G)$. Let $(H_2, \phi) \in \mathcal{L}(G[S])$. We denote by $G^S_{(H_2,\phi)}$ the graph obtained from the disjoint union of $G - S$ and H_2 by adding an edge $u\phi(v)$ for each $u \in V(G) \setminus S$ and each $v \in \phi^{-1}(V(H_2))$ such that $uv \in E(G)$. We equip $G' := G^S_{(H_2,\phi)}$ with the strict total order $<_{G'}$ such that $v_1 <_{G'} v_2$ if and only if $u_1 <_G u_2$ where, for $i \in [2]$, $u_i := v_i$ if $v_i \in V(G) \setminus S$, and u_i is the smallest vertex in $\phi^{-1}(v_i)$ if $v_i \in V(H_2)$. We also set $\mathcal{L}_S(G) = \{G^S_{(H_2,\phi)} \mid (H_2, \phi) \in \mathcal{L}(G[S])\}$. See Figure 1 for an illustration.

Note that we consider ordered graphs merely so that the correspondence between the vertices in S and the vertices in $V(H_2)$ is well-defined. We actually omit the order from the statements, but it will be implicitly assumed that vertices have a label that allows us to keep track of them during the modification procedure.

Let $\mathcal{L}$ be an R-action and $\mathcal{H}$ be a graph class. We define the following problem.

$\mathcal{L}$-Replacement to $\mathcal{H}$ ($\mathcal{L}$-R-$\mathcal{H}$)

Input:	A graph G and $k \in \mathbb{N}$.
Question:	Is there a set $S \subseteq V(G)$ of size at most k such that $\mathcal{L}_S(G) \cap \mathcal{H} \neq \emptyset$?

Such a set S is called *solution* of $\mathcal{L}$-R-$\mathcal{H}$ for the instance (G, k).

We will use the following observation, which implies that a no-instance for Vertex Deletion to $\mathcal{H}$ is also a no-instance for $\mathcal{L}$-R-$\mathcal{H}$.

▶ **Observation 1.** *Let $\mathcal{H}$ be a hereditary graph class, let $\mathcal{L}$ be an R-action, let G be a graph, and let $S \subseteq V(G)$. If $\mathcal{L}_S(G) \cap \mathcal{H} \neq \emptyset$, then $G - S \in \mathcal{H}$.*

Proof. Indeed, suppose that there is $(H_2, \phi) \in \mathcal{L}(G[S])$ such that $G^S_{(H_2,\phi)} \in \mathcal{H}$. Then, because $\mathcal{H}$ is hereditary, $G^S_{(H_2,\phi)} - \phi^+(S) = G - S \in \mathcal{H}$. ◀

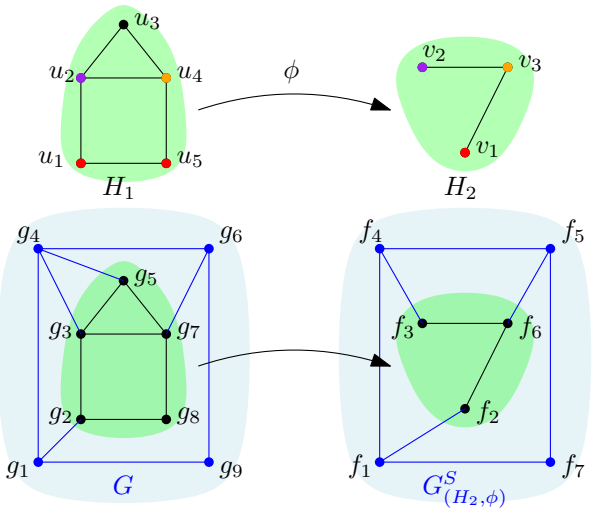

Figure 1 Example of $(H_2, \phi) \in \mathcal{L}(H_1)$ and of the graph modification $G^S_{(H,\phi)}$ where S is the set of black vertices of G. ϕ is represented by the colors, that is, $\phi(u_1) = \phi(u_5) = v_1$, $\phi(u_2) = \phi(v_2)$, $\phi(u_3) = \emptyset$, and $\phi(u_4) = v_3$. The order on the vertex sets of the depicted graphs is given by the corresponding labels.

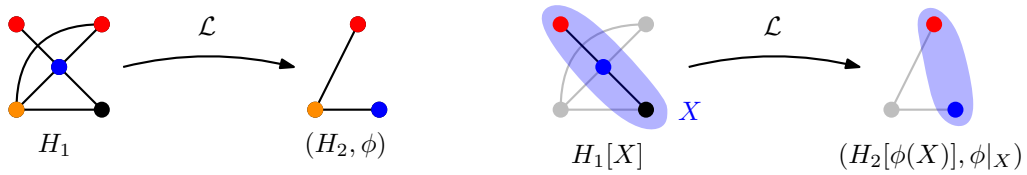

Figure 2 If $\mathcal{L}$ is hereditary, then a restriction of an allowed modification is also allowed.

Hereditary R-actions. An R-action is said to be *hereditary* if, for each ordered graph H_1, for each non-empty $X \subseteq V(H_1)$, and for each $(H_2, \phi) \in \mathcal{L}(H_1)$, we have $(H_2[\phi^+(X)], \phi|_X) \in \mathcal{L}(H_1[X])$. We say that $(H_2[\phi^+(X)], \phi|_X)$ is the *restriction* of (H_2, ϕ) to X. See Figure 2 for an illustration. Informally, an R-action is hereditary if, when a modification is allowed, then modifying "less" is allowed as well. For instance, if $\mathcal{L}$ allows us to delete *exactly* k vertices, then $\mathcal{L}$ also allows us to delete *at most* k vertices.

Some conventions. By convention, when there is no confusion, we set $n := |V(G)|$ and $m := |E(G)|$. In the rest of the paper, instead of considering a minor-closed graph class $\mathcal{H}$, we consider its obstruction set $\mathcal{F}$, and thus the minor-closed graph class $\mathsf{exc}(\mathcal{F})$. We define three constants depending on $\mathcal{F}$ that will be used throughout the paper whenever we consider such a collection $\mathcal{F}$. We define $a_{\mathcal{F}}$ as the minimum apex number of a graph in $\mathcal{F}$, we set $s_{\mathcal{F}} := \max\{|V(F)| \mid F \in \mathcal{F}\}$, and we define $\ell_{\mathcal{F}}$ to be the maximum detail of a graph in $\mathcal{F}$. Given a tuple $\mathbf{t} = (x_1, \ldots, x_\ell) \in \mathbb{N}^\ell$ and two functions $\chi, \psi : \mathbb{N} \to \mathbb{N}$, we write $\chi(n) = \mathcal{O}_{\mathbf{t}}(\psi(n))$ in order to denote that there exists a computable function $\phi : \mathbb{N}^\ell \to \mathbb{N}$ such that $\chi(n) = \mathcal{O}(\phi(\mathbf{t}) \cdot \psi(n))$. Notice that $s_{\mathcal{F}} \leq \ell_{\mathcal{F}} \leq s_{\mathcal{F}}(s_{\mathcal{F}} - 1)/2$, and thus $\mathcal{O}_{\ell_{\mathcal{F}}}(\cdot) = \mathcal{O}_{s_{\mathcal{F}}}(\cdot)$.

Our main result is the following.

▶ **Theorem 2.** *Let $\mathcal{F}$ be a finite collection of graphs and let $\mathcal{L}$ be a hereditary R-action. There is an algorithm that, given a graph G and $k \in \mathbb{N}$, runs in time $2^{\mathsf{poly}_{\mathcal{F}}(k)} \cdot n^2$ and either outputs a solution of $\mathcal{L}$-R-$\mathsf{exc}(\mathcal{F})$ for the instance (G, k) or reports a* no*-instance. Moreover, $\mathsf{poly}_{\mathcal{F}}$ is a polynomial whose degree depends on the maximum detail of a graph in $\mathcal{F}$.*

As mentioned in the introduction, the main result in [47] already implies that $\mathcal{L}$-R-$\mathcal{H}$ is solvable in time $f(k) \cdot n^2$ when $\mathcal{H}$ is minor-closed for some huge function f that is not even estimated. Our main contribution is an explicit and single-exponential dependence on k.

The degree of $\mathsf{poly}_{\mathcal{F}}(k)$ is quite big, but we can reduce it in some specific cases.

▶ **Theorem 3.** *Let $\mathcal{L}$ be a hereditary R-action and $\mathcal{H}$ be the class of graphs embeddable in a surface Σ of Euler genus at most g. There is an algorithm that, given a graph G and $k \in \mathbb{N}$, runs in time $2^{\mathcal{O}_g(k^9)} \cdot n^2$ and either outputs a solution of $\mathcal{L}$-R-$\mathcal{H}$ for the instance (G, k) or reports a* no*-instance.*

More generally, we study the annotated version of $\mathcal{L}$-R-$\mathcal{H}$. Let $\mathcal{L}$ be a hereditary R-action and $\mathcal{H}$ be a graph class. We define the following problem.

$\mathcal{L}$-Annotated Replacement to $\mathcal{H}$ ($\mathcal{L}$-AR-$\mathcal{H}$)

Input:	A graph G, a set of annotated vertices $S' \subseteq V(G)$, $(H_2', \phi') \in \mathcal{L}(G[S'])$, and $k \in \mathbb{N}$.
Question:	Is there a set $S \subseteq V(G)$ of size at most k and $(H_2, \phi) \in \mathcal{L}(G[S])$ such that (H_2', ϕ') is the restriction of (H_2, ϕ) to S' and $G^S_{(H_2,\phi)} \in \mathcal{H}$?

Obviously, we must have $S' \subseteq S$. Such a triple (S, H_2, ϕ) is called a *solution* of $\mathcal{L}$-AR-$\mathcal{H}$ for the instance (G, S', H_2', ϕ', k). An instance of $\mathcal{L}$-AR-$\mathcal{H}$ where $S' = \emptyset$ is an instance of $\mathcal{L}$-R-$\mathcal{H}$, so $\mathcal{L}$-AR-$\mathcal{H}$ generalizes $\mathcal{L}$-R-$\mathcal{H}$. Two instances $\mathcal{I}_1$ and $\mathcal{I}_2$ are *equivalent* instances of $\mathcal{L}$-AR-$\mathcal{H}$ if $\mathcal{I}_1$ is a yes-instance of $\mathcal{L}$-AR-$\mathcal{H}$ if and only if $\mathcal{I}_2$ is a yes-instance of $\mathcal{L}$-AR-$\mathcal{H}$.

In fact, we prove stronger statements of Theorem 2 and Theorem 3 that apply to their respective annotated versions.

3 Problems generated by different instantiations of $\mathcal{L}$

Many graph modification problems correspond to $\mathcal{L}$-R-$\mathcal{H}$ for a specific R-action $\mathcal{L}$ and a specific target graph class $\mathcal{H}$. We give a few examples below. Let $\mathcal{H}$ be a minor-closed graph class. For instance, $\mathcal{H}$ could be the class of edgeless graphs, of forests, of graphs whose connected components have size at most k, of planar graphs, or of graphs embeddable in a surface Σ. Note that we do not mention Edge Addition to $\mathcal{H}$ (nor Edge Edition to $\mathcal{H}$) here, because when $\mathcal{H}$ is a minor-closed graph class, adding edges is "unnecessary", in the sense that the edge deletion variant has the same expressive power, and we can solve it. Note also that $\mathcal{L}$-R-$\mathcal{H}$, and thus in particular all problems of this section, was already known to be solvable in FPT-time (when $\mathcal{H}$ is minor-closed) by the result of [47]. However, as mentioned before, the parametric dependence is huge and not even explicit in [47].

Given a set A, we denote the identity function mapping each $a \in A$ to itself by id_A.

Vertex Deletion to $\mathcal{H}$

Input:	A graph G and $k \in \mathbb{N}$.
Question:	Is there a set $S \subseteq V(G)$ of size at most k such that $G - S \in \mathcal{H}$?

Vertex Deletion to $\mathcal{H}$ reduces to $\mathcal{L}_{\mathsf{vDel}}$-R-$\mathcal{H}$, where $\mathcal{L}_{\mathsf{vDel}}$ is the function that maps any graph H_1 to the singleton containing the empty graph and the constant function $\phi : V(H_1) \to \{\emptyset\}$. Vertex Deletion to $\mathcal{H}$ is already known [38] to be solvable within the same running time as the one of Theorem 2. Hence, the result of Theorem 2 is not an improvement for this specific problem, but it shows that our result is tight compared to the currently best known result for Vertex Deletion to $\mathcal{H}$.

Edge Deletion to $\mathcal{H}$

Input: A graph G and $k \in \mathbb{N}$.
Question: Is there a set $F \subseteq E(G)$ of size at most k such that $G - F \in \mathcal{H}$?

(G, k) is a yes-instance of Edge Deletion to $\mathcal{H}$ if and only if $(G, 2k)$ is a yes-instance of $\mathcal{L}_{\mathsf{eDel},k}$-R-$\mathcal{H}$, where $\mathcal{L}_{\mathsf{eDel},k}$ is the function that maps each graph H_1 to the set of pairs $(H_1 - F, \mathsf{id}_{V(H_1)})$ over all $F \subseteq E(G)$ of size at most k. Algorithms with a nice parametric dependence are only known for specific target classes $\mathcal{H}$. Namely, when $\mathcal{H}$ is the class of forests, Edge Deletion to $\mathcal{H}$ corresponds to Feedback Edge Set, which can be solved in constant time given that the size of a minimum feedback edge set is $m - n + 1$ (assuming the graph is connected). When $\mathcal{H}$ is the class of graphs that are a union of paths, then there is a linear kernel for the problem [34], as well as a FPT algorithm with parametric dependence on k at most 2^k [48]. We refer the reader to the survey of [9], as well as [13], for other results with explicit dependence on k when $\mathcal{H}$ is not a minor-closed graph class.

Given a graph G and a set of edges $F \subseteq E(G)$, we denote by G/F the graph obtained from G after contracting the edges in F.

Edge Contraction to $\mathcal{H}$

Input: A graph G and $k \in \mathbb{N}$.
Question: Is there a set $F \subseteq E(G)$ of size at most k such that $G/F \in \mathcal{H}$?

(G, k) is a yes-instance of Edge Contraction to $\mathcal{H}$ if and only if $(G, 2k)$ is a yes-instance of $\mathcal{L}_{\mathsf{Con},k}$-R-$\mathcal{H}$, where $\mathcal{L}_{\mathsf{Con},k}$ is the function that maps each graph H_1 to the set of pairs $(H_1/F, \phi)$ over all $F \subseteq E(G)$ of size at most k, where ϕ maps $v \in V(H_1)$ to the corresponding vertex of H_1/F. An explicit parametric dependence was given in [22] when $\mathcal{H}$ is a class of paths (running time $2^{k+o(k)} + n^{\mathcal{O}(1)}$) or the class of trees (running time $4.98^k \cdot n^{\mathcal{O}(1)}$). Though these classes are not minor-closed, we can easily extend these results to the case when $\mathcal{H}$ is the class of unions of paths or the class of forests (up to a 2^k factor). FPT-algorithms with an explicit parametric dependence were also studied when $\mathcal{H}$ is a collection of generalization and restriction of trees [2,3], or when $\mathcal{H}$ is the class of cactus graphs [31]. We refer the reader to [21] for more results when the target class is not minor-closed.

Vertex Identification to $\mathcal{H}$

Input: A graph G and $k \in \mathbb{N}$.
Question: Is there a set $S \subseteq V(G)$ of size at most k and a partition $(X_1, \ldots, X_p)$ of S such that the graph obtained after identifying the vertices in X_i to a single vertex x_i, for $i \in [p]$, belongs to $\mathcal{H}$?

Vertex Identification to $\mathcal{H}$ reduces to $\mathcal{L}_{\mathsf{Id}}$-R-$\mathcal{H}$, where $\mathcal{L}_{\mathsf{Id}}$ is the function that maps each graph H_1 to the set of pairs (H_2, ϕ), where H_2 can be obtained from H_1 after identifying each X_i of a partition $(X_1, \ldots, X_p)$ of some set $S \subseteq V(H_1)$ to a single vertex x_i, and ϕ maps vertices of X_i to x_i and is the identity on $V(H_1) \setminus S$. Vertex Identification to $\mathcal{H}$ is known to admit a kernel of size $2k + 1$ when $\mathcal{H}$ is the class of forests [39]. To the authors' knowledge, this is the only known result for this problem.

Independent Set Deletion to $\mathcal{H}$

Input: A graph G and $k \in \mathbb{N}$.
Question: Is there an independent set $I \subseteq V(G)$ of size at most k such that $G - I \in \mathcal{H}$?

Independent Set Deletion to $\mathcal{H}$ reduces to $\mathcal{L}_{\mathsf{ISDel}}$-R-$\mathcal{H}$, where $\mathcal{L}_{\mathsf{ISDel}}$ is the function that maps any graph H_1 to the set of pairs $(H_1 - I, \phi)$ over all independent sets $I \subseteq V(H_1)$, where ϕ maps vertices of I to the empty set and is the identity on $V(H_1) \setminus I$.

When $\mathcal{H}$ is the class of forests, the problem is known to be solvable in time $3.62^k \cdot n^{\mathcal{O}(1)}$ [33]. Concerning other target classes that are not minor-closed, mainly bipartite graphs, let us mention [1, 6, 20].

To illustrate the versatility of $\mathcal{L}$-R-$\mathcal{H}$, let us present some other problems that can be defined by particular hereditary R-actions, though they do not seem to have been studied when parameterized by the solution size.

(Induced) Matching Deletion to $\mathcal{H}$

Input:	A graph G and $k \in \mathbb{N}$.
Question:	Is there an (induced) matching $M \subseteq E(G)$ of size at most k such that $G - M \in \mathcal{H}$?

(G, k) is a yes-instance of (Induced) Matching Deletion to $\mathcal{H}$ if and only if $(G, 2k)$ is a yes-instance of $\mathcal{L}_{\mathsf{mDel},k}$-R-$\mathcal{H}$, where $\mathcal{L}_{\mathsf{mDel},k}$ is defined similarly to $\mathcal{L}_{\mathsf{eDel},k}$ above, but for (induced) matchings. There are some results on Matching Deletion to $\mathcal{H}$ when $k = n$ and $\mathcal{H}$ is the class of forests [36, 41] or bipartite graphs (see [35] for a small survey).

(Induced) Matching Contraction to $\mathcal{H}$

Input:	A graph G and $k \in \mathbb{N}$.
Question:	Is there an (induced) matching $M \subseteq E(G)$ of size at most k such that $G/M \in \mathcal{H}$?

(G, k) is a yes-instance of (Induced) Matching Contraction to $\mathcal{H}$ if and only if $(G, 2k)$ is a yes-instance of $\mathcal{L}_{\mathsf{mCon},k}$-R-$\mathcal{H}$, where $\mathcal{L}_{\mathsf{mCon},k}$ is defined similarly to $\mathcal{L}_{\mathsf{Con},k}$ above, but for (induced) matchings.

Induced Star Deletion to $\mathcal{H}$

Input:	A graph G and $k \in \mathbb{N}$.
Question:	Is there a set $F \subseteq E(G)$ inducing a star $K_{1,k'}$ with $k' \leq k$ such that $G - F \in \mathcal{H}$?

(G, k) is a yes-instance of Star Deletion to $\mathcal{H}$ if and only if $(G, k+1)$ is a yes-instance of $\mathcal{L}_{\mathsf{StarDel},k}$-R-$\mathcal{H}$, where $\mathcal{L}_{\mathsf{StarDel},k}$ is the function that maps any graph H_1 to the set of pairs $(H_1 - F, \mathsf{id}_{V(H_1)})$ over all sets $F \subseteq E(G)$ inducing a subgraph of $K_{1,k}$.

Given a graph G, the *complement* of G, denoted by $\overline{G}$, is graph with vertex set $V(G)$ and edge set the edges that do not belong to $E(G)$.

Subgraph Complementation to $\mathcal{H}$

Input:	A graph G and $k \in \mathbb{N}$.
Question:	Is there a set $S \subseteq V(G)$ of size at most k such that the graph obtained after replacing $G[S]$ with its complement $\overline{G[S]}$ belongs to $\mathcal{H}$?

Subgraph Complementation to $\mathcal{H}$ reduces to $\mathcal{L}_{\mathsf{Comp}}$-R-$\mathcal{H}$, where $\mathcal{L}_{\mathsf{Comp}}$ is the function that maps any graph H_1 to the singleton containing the pair $(\overline{H_1}, \mathsf{id}_{V(H_1)})$. The problem was recently studied when $k = n$ for various target classes; we refer the reader to [4].

4 Overview of our techniques

To handle several modification problems at once, we adapt the vocabulary of Fomin, Golovach, and Thilikos [17], who introduced the notion of replacement action. Intuitively (see section 2 for the formal definition), a *replacement action* is a function $\mathcal{L}$ that maps a graph H_1 to a collection $\mathcal{L}(H_1)$ of pairs (H_2, ϕ) where H_2 is a graph with at most $|V(H_1)|$ vertices and ϕ maps each vertex of H_1 to either a vertex of H_2 or the empty set. Mapping a vertex of H_1 to the empty set corresponds to a deletion, while mapping several vertices to the same vertex of H_2 corresponds to an identification. Replacement actions were originally defined in [17] to solve a collection of graph modification problems where only edges are modified and where the target class is the class of planar graphs. Compared to [17], however, the size of H_2 may here be smaller than the size of H_1, which happens when deleting or identifying vertices, while in [17] it is required that $|V(H_1)| = |V(H_2)|$. Let us fix a replacement action $\mathcal{L}$ and a target graph class $\mathcal{H}$. Recall that the $\mathcal{L}$-Replacement to $\mathcal{H}$ ($\mathcal{L}$-R-$\mathcal{H}$) problem asks, given a graph G and $k \in \mathbb{N}$, whether there is an induced subgraph H_1 of size at most k in G and a pair $(H_2, \phi) \in \mathcal{L}(H_1)$ such that H_1 can be replaced by H_2 such that the resulting graph G' belongs to $\mathcal{H}$ (for $u \in V(G) \setminus V(H_1)$ and $v \in V(H_2)$, $uv \in E(G')$ if and only if there is $v' \in \phi^{-1}(v)$ such that $uv' \in E(G)$). For our techniques to work (see the "irrelevant vertex technique" paragraph below for more precision), we require our function $\mathcal{L}$ to be *hereditary*, which essentially means if H_2 is in $\mathcal{L}(H_1)$, then for any induced subgraph H_1' of H_1, the corresponding induced subgraph of H_2 is in $\mathcal{L}(H_1')$ (cf. section 2 for the formal definition and Figure 2 for an illustration). For instance, this implies that we can ask whether it is possible to do *at most* k edge editions to get a graph in $\mathcal{H}$, but we cannot ask whether it is possible to do *exactly* k edge editions to get a graph in $\mathcal{H}$.

High-level description of our algorithms. The techniques that we employ for our first algorithm (that is, when $\mathcal{H}$ is any minor-closed graph class) are strongly inspired by those used by Morelle, Sau, Stamoulis, Thilikos [38] for the particular case of vertex deletion (see also [44]), namely Vertex Deletion to $\mathcal{H}$, achieving the same running time. Nevertheless, in order to deal with our "meta-modification" operations, we need several new technical insights compared to the approach of [44], which we proceed to sketch. In a nutshell, the algorithm of [38] employs a win/win strategy that proceeds as follows:

- If the treewidth of the input graph is small (as a function of the parameter k), then solve the problem via a dynamic programming approach.
- If the treewidth of the input graph is big, then either
  - (*irrelevant vertex*) find a vertex v such that (G, k) and $(G - v, k)$ are equivalent instances, or
  - (*branching case*) find a set $A \subseteq V(G)$ of small size such that there exists $v \in A$ such that (G, k) and $(G - v, k - 1)$ are equivalent instances,

  and recurse.

Hence, we require three ingredients: one to solve the problem parameterized by treewidth, one to find an irrelevant vertex, and one to find an "obligatory set" A, all with a "reasonable" parametric dependence on k. Then, we need to construct an algorithm so that one of these three cases always applies and such that the overall running time is still within the desired bound, which is one of the most convoluted parts of the proof. In what follows we provide further insights about these steps, by first saying a few words about flat walls.

The need for annotation. Let S' be the set of vertices recursively guessed to be modified in the branching step. An advantage when the modification consists in vertex deletion is that we can simply recurse on $(G - S', k - |S'|)$. For the more general case of $\mathcal{L}$-R-$\mathcal{H}$, we cannot simply delete S', as the considered modification may be different from vertex deletion. We need 1) to guess how $G[S']$ is modified, that is, to guess $(H'_2, \phi') \in \mathcal{L}(G[S'])$ and 2) to remember S' and (H'_2, ϕ') in order to check that we eventually find a set $S \supseteq S'$ and an allowed modification $(H_2, \phi) \in \mathcal{L}(G[S])$ whose restriction to S' is (H'_2, ϕ') such that the modified graph is in $\mathcal{H}$. This is why we need to solve the *annotated version of the problem*, denoted by $\mathcal{L}$-AR-$\mathcal{H}$, where we add to the input a subset S' of vertices of G that are required to be part of H_1, as well as the modification (H'_2, ϕ') made on S'.

Dynamic programming algorithm in the case of bounded treewidth. Note that we cannot just use Courcelle's theorem [8], since we require a nice parametric dependence on k. Hence, we need to design our own dynamic programming algorithm to solve $\mathcal{L}$-AR-$\mathcal{H}$ parameterized by the treewidth and k. Essentially, the idea is to guess, in each bag $\beta(t)$ of the decomposition, the set S_t of vertices that are modified as well as how they are modified, and to reduce the size of the graph G_t induced by the bag t and its children using the representative-based technique of [5]. This technique is essentially based on the property that, given a graph G in a minor-closed graph class $\mathcal{H}$ with a boundary B, there is a graph R of *bounded size* with same boundary B, called the *representative of* G, such that, for any graph H glued on B to get $G \oplus H$ and $R \oplus H$, $G \oplus H \in \mathcal{H}$ if and only if $R \oplus H \in \mathcal{H}$. G_t does not belong to $\mathcal{H}$, so we cannot find a representative of G_t, but we find instead a representative of the graph $G'_t \in \mathcal{H}$ modified from G_t according to the guessed modification on S_t and the previously guessed modification on the children of t. Given that we may need to identify together vertices that are far apart in the tree decomposition, we need to remember throughout the algorithm the vertices that are guessed to be part of the solution. The fact that we keep information about these at most k vertices explains the dependence on k of the dynamic programming algorithm. More precisely, we prove the following result.

▶ **Theorem 4.** *Let $\mathcal{F}$ be a finite collection of graphs and $\mathcal{L}$ be an R-action. There is an algorithm that, given $k \in \mathbb{N}$, a graph G of treewidth at most w, a set $S' \subseteq V(G)$ of size at most k, and $(H'_2, \phi') \in \mathcal{L}(G[S'])$, in time $2^{\mathcal{O}_{\ell_{\mathcal{F}}}(k^2+(k+w)\log(k+w))} \cdot n$ either outputs a solution of $\mathcal{L}$-AR-exc($\mathcal{F}$) for the instance (G, S', H'_2, ϕ', k), or reports a* no*-instance.*

The above result parameterized by treewidth and k may be of independent interest, given that it implies an algorithm with a good parametric dependence on the treewidth and k for a number of graph modification problems. Note that the question of whether $\mathcal{L}$-R-$\mathcal{H}$ is FPT parameterized by only treewidth is open. Even Courcelle's theorem only implies a running time of $f(\mathsf{tw}, k) \cdot n$, given that the size of the CMSO formula expressing yes-instances of $\mathcal{L}$-R-$\mathcal{H}$ depends on k. Note that, in [38], the bounded treewidth part consists just in a black-box application of the algorithm of Baste, Sau, and Thilikos [5].

Flat walls. An essential tool of our approach is the notion of *flat wall*, originating in the work of Robertson and Seymour [42]. Informally speaking, a flat wall is a structure made up of (non-necessarily planar) pieces, called *flaps*, that are glued together in a bidimensional grid-like way defining the so-called *bricks* of the wall. While such a structure may not be planar, it enjoys topological properties similar to those of planar graphs, in the sense that two paths that are not routed entirely inside a flap cannot "cross", except at a constant-sized vertex set A whose vertices are called *apices*. Hence, flat walls are only "locally non-planar",

and after removing apices we can apply useful locality arguments, in the sense that two vertices that are in "distant" flaps should also be "distant" in the whole graph without the apices. In this article we apply some variants of one of the most celebrated results in the theory of Graph Minors by Robertson and Seymour [42,43], known as the *Flat Wall theorem* (see also [27,46] for recently proved variants), which informally states that graphs of large treewidth contain either a large clique minor or a large flat wall.

In order for our formal statements to be mathematically correct, we would need to introduce a number of notions originating in [46]. Unfortunately, in the attached full version several pages are required to provide all these technical notions. Due to space limitations, in this extended abstract we only provide intuitive descriptions of the main notions required to read the statement of the results, but we skip a number of technical terms (such as renditions, tilts, influence, regular flatness pairs, etc.) that are not the main focus of this sketch. All details can be found in the attached full version, and we refer the reader to [46] for a more detailed exposition of these definitions and the reasons for which they were introduced.

An *r-wall* is any graph W obtained from a so-called *elementary* r-wall $\bar{W}$ after subdividing edges: see Figure 3 for self-explanatory illustration of a 5-wall.

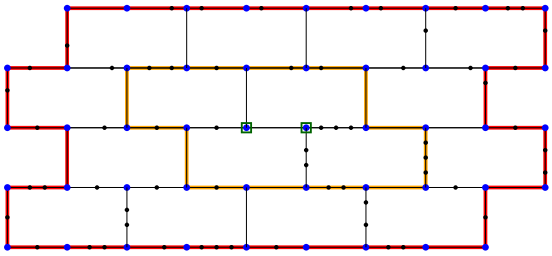

Figure 3 A 5-wall.

A flat wall is illustrated in Figure 4, where the flaps mentioned above correspond to the orange cells. The perimeter of a flat wall in a graph G separates $V(G)$ into two sets X and Y with Y containing the wall. The *compass* of a flat wall is $G[Y]$. For example, in Figure 4, X is the set of vertices in the green part, and Y the set of vertices in the orange part.

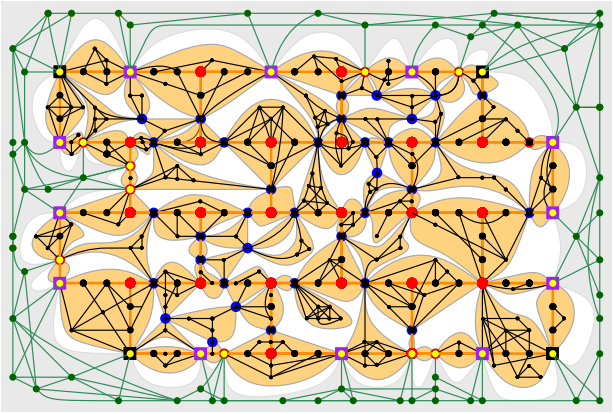

Figure 4 Illustration of flat wall, adapted from [5, Figure 4]). The edges of the subjacent wall are depicted in orange, defining the corresponding bricks.

In order to find an irrelevant vertex, we need to deal with *homogeneous* flat walls. Intuitively, homogeneous flat walls are flat walls that allow the routing of the same set of (topological) minors in the augmented flaps (i.e., the flaps together with the apex set)

"cropped" by each one of their bricks. Such a homogeneous wall can be detected in a big enough flat wall and this "homogeneity" property implies that some central part of a big enough homogeneous wall can be declared irrelevant.

Another very useful notion is that of a *canonical partition* of a graph G with respect to some wall W of G. Informally, this refers to a partition of the vertex set of G into bags that follow the grid-like structure of W; see Figure 5. Essentially, the goal is to be able to contract each of these bags to obtain a grid that is a minor of W, and thus of G. In particular, we prove (see Theorem 5 below) that if G contains as a minor a grid Γ along with a set A whose vertices have sufficiently many neighbors in the grid, then some vertex in A is obligatory. We use canonical partitions here to easily find such a structure given a wall of G.

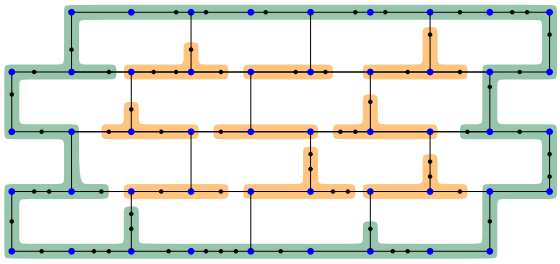

Figure 5 A 5-wall and its canonical partition $\mathcal{Q}$. The green bag is the external bag Q_{ext} and the orange bags are the internal bags of $\mathcal{Q}$. Contracting each internal bag of $\mathcal{Q}$ we obtain a (3×3)-grid.

Branching step. The branching case is not much different from what is done in [38] (originally from [45]): essentially, if there is a big enough wall W (cf. Figure 3) and a set A of vertices having many disjoint paths to W (cf. Figure 6), then some modification (H_A, ϕ_A) must happen in A and we can branch. Here, we however need to additionally prove that we must have $|\phi_A(A) \setminus \{\emptyset\}| < |A|$. We stress that it is important here to guess some modification in A that strictly decreases the size of A, so that, after applying this partial modification to G at the next step in the recursion, we will not find the exact same obligatory set A. Hence, in the algorithm with input (G, S', H_2', ϕ', k), at each step, either we find an irrelevant vertex and strictly decrease the size of G, or we branch and strictly increase the size of S'.

More precisely, the next result is the main technical ingredient in this part of the proof, essentially stating that a part of the solution S can be found in a set A of size $a_{\mathcal{F}}$ in which every vertex is adjacent to many vertices of a big enough wall. This is our "obligatory vertex" method. See Figure 6 for an illustration and Section 6 of the full version for the details.

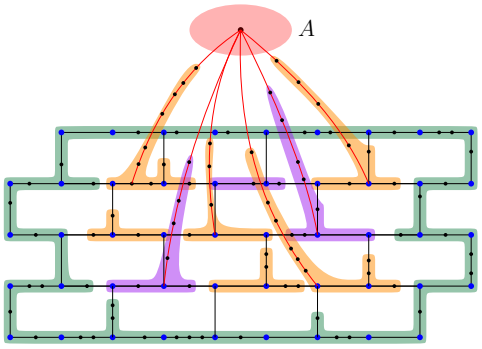

Figure 6 Illustration of Theorem 5.

▶ **Lemma 5.** *Let $\mathcal{F}$ be a finite collection of graphs and $\mathcal{L}$ be a hereditary R-action. There exist three functions $f_1, f_2, f_3 : \mathbb{N} \to \mathbb{N}$ such that the following holds. Let $k \in \mathbb{N}$. Let G be a graph, $S' \subseteq V(G)$ be a set of size at most k, and $(H_2', \phi') \in \mathcal{L}(G[S'])$. Suppose that $G' := G^{S'}_{(H_2', \phi')}$ contains a set $A \subseteq V(G')$ of size at least $a_{\mathcal{F}}$ and that there is a wall W in $G' - A$ of height $f_1(k)$. Suppose also that there is a W-canonical partition $\tilde{\mathcal{Q}}$ of $G' - A$ such that each vertex of A is adjacent to at least $f_2(k)$ many $f_3(k)$-internal bags of $\tilde{\mathcal{Q}}$. Then, for every solution (S, H_2, ϕ) of $\mathcal{L}$-AR-exc($\mathcal{F}$) for (G, S', H_2', ϕ'), it holds that $A' \neq \emptyset$, where $A' := (S \setminus S') \cap A$, and that $|\phi^+(A')| < |A'|$. Moreover $f_1(k) = \mathcal{O}_{s_{\mathcal{F}}}(k^2)$, $f_2(k) = \mathcal{O}_{s_{\mathcal{F}}}(k^3)$, and $f_3(k) = \mathcal{O}_{s_{\mathcal{F}}}(k^2)$.*

Finding an irrelevant vertex. As expected, we use the irrelevant vertex technique of Robertson and Seymour [42]. More specifically, we generalize the irrelevant vertex technique used in [38] (actually proved in [45]). This technique is based on the (intuitive but surprisingly hard to prove) fact that the central vertex of a homogeneous flat wall is always irrelevant. While our irrelevant vertex technique for $\mathcal{L}$-AR-$\mathcal{H}$ takes inspiration from [45], it is far more involved due to the annotation and the fact that we allow a wide variety of modifications. In particular, we need to redefine what it means to be homogeneous for a flat wall, to adapt it to our new setting. The previous definition was made to handle the case when we had to remove a small vertex set, called *apex set*, to find a flat wall, and more specifically to handle the fact that some vertices are possibly deleted from the apex set. Now, we also need to handle any other way the apex set may be modified, hence the new definition. The fact that we ask the replacement action $\mathcal{L}$ to be hereditary comes from the irrelevant vertex technique. Indeed, in order to prove that the central vertex v of a homogeneous flat wall W is irrelevant, we essentially prove that, for any solution (S, H_2, ϕ), we can delete a small part X of W containing v, and that the restriction of (S, H_2, ϕ) to $G - X$ is still a solution.

The following is the main technical result that we prove in this part, stating that an irrelevant vertex can be found in a big enough flat wall whose compass has bounded treewidth.

▶ **Theorem 6.** *Let $\mathcal{F}$ be a finite collection of graphs and $\mathcal{L}$ be a hereditary R-action. There exist a function $f_4 : \mathbb{N}^2 \to \mathbb{N}$, whose images are odd integers, and an algorithm with the following specifications:*

`Irrelevant-Vertex`$(G, S', H_2', \phi', k, A, a, W, \mathfrak{R}, t)$

Input: *Integers $k, a, t \in \mathbb{N}$, a graph G, a set $S' \subseteq V(G)$ of size at most k, $(H_2', \phi') \in \mathcal{L}(G[S'])$, a set $A \subseteq V(G')$ of size at most a, where $G' := G^{S'}_{(H_2, \phi)}$, and a regular flatness pair $(W, \mathfrak{R})$ of $G' - A$ of height at least $f_{??}(k, a)$ whose $\mathfrak{R}$-compass has treewidth at most t and does not intersect $\phi'(S')$.*

Output: *A vertex $v \in V(G) \setminus S'$ such that (G, S', H_2', ϕ', k) and $(G - v, S', H_2', \phi', k)$ are equivalent instances of $\mathcal{L}$-AR-exc($\mathcal{F}$). Moreover, $f_{??}(k, a) = \mathcal{O}_{a, \ell_{\mathcal{F}}}(k^c)$, where $c = \mathcal{O}_{a, \ell_{\mathcal{F}}}(1)$, and the algorithm runs in time $2^{\mathcal{O}_{a, \ell_{\mathcal{F}}}(k \log k + t \log t)} \cdot (n + m)$.*

We also prove the following result for the bounded genus case with a better dependence on k and a better running time. In this case, we do not ask for our flat wall to have bounded treewidth, but to have a planar embedding instead. Note that here, instead of a single vertex v, we might sometimes find an entire planar block of vertices V that is irrelevant.

▶ **Theorem 7.** *Let $\mathcal{L}$ be a hereditary R-action and $\mathcal{F}$ be the collection of obstructions of the graphs embeddable in a surface of genus at most g. There exist a function $f_5 : \mathbb{N} \to \mathbb{N}$, whose images are odd integers, and an algorithm with the following specifications:*

`Planar-Irrelevant-Vertex`$(G, S', H_2', \phi', k, W, \mathfrak{R})$

Input: *An integer $k \in \mathbb{N}$, a graph G, a set $S' \subseteq V(G)$ of size at most k, $(H_2', \phi') \in \mathcal{L}(G[S'])$, and a flatness pair $(W, \mathfrak{R} = (X, Y, P, C, \Gamma, \sigma, \pi))$ of $G^{S'}_{(H_2', \phi')}$ of height at least $f_{??}(k)$ whose $\mathfrak{R}$-compass does not intersect $\phi'(S')$ and is embeddable in a disk with $X \cap Y$ on the boundary.*

Output: *A non-empty set $Y \subseteq V(G) \setminus S'$ such that (G, S', H_2', ϕ', k) and $(G - Y, S', H_2', \phi', k)$ are equivalent instances of $\mathcal{L}$-AR-exc$(\mathcal{F})$.*

Moreover, $f_5(k) = \mathcal{O}(k)$ and the above algorithm runs in time $\mathcal{O}(n + m)$.

Piecing everything together. Finally, we combine the three ingredients discussed above to find an algorithm for $\mathcal{L}$-AR-$\mathcal{H}$. We essentially proceed as follows. Let (G, S', H_2', ϕ', k) be the instance we want to solve, and G' be obtained by doing the modification (H_2', ϕ') of S'. In the first steps, we either find that G has small treewidth, where we can use our dynamic programming algorithm to conclude, or that G' contains a wall W. Given W, we first try to find a flat wall W' inside, with all the necessary conditions to find an irrelevant vertex. If we manage to do so, we remove the irrelevant vertex and recurse. Otherwise, through a greedy procedure, we try to find an obligatory vertex set A with many disjoint paths to W in G'. If we find such a set, we branch and recurse. If not, we manage to argue that we must have a no-instance, and conclude.

The special case of bounded genus. Our second algorithm (Theorem 3), when $\mathcal{H}$ is a class of graphs embeddable in a surface of bounded Euler genus, uses two additional ideas to get an improved running time. The first one is that here, the obligatory set A is a singleton. Indeed, the size of A is the size of the minimum number of vertices one can remove from an obstruction of $\mathcal{H}$ to make it planar. It is well known that, when $\mathcal{H}$ is such a class, there is some integer t depending on the Euler genus such that $K_{3,t} \notin \mathcal{H}$, and thus, $|A| = 1$. In particular, this implies that we do not need to branch on A, but that we instead immediately find an obligatory vertex. The second idea is about homogeneous flat walls. In the running time $2^{\mathsf{poly}(k)} \cdot n^2$ of the first algorithm, the degree of poly essentially corresponds to the size of the required flat wall to find a big enough homogeneous flat wall, and hence an irrelevant vertex, inside of it. In the case where $\mathcal{H}$ is the class of graphs embeddable in a surface of Euler genus at most g, we prove that we can find a homogeneous flat wall inside a flat wall of smaller size, hence the improved running time. To do so, we prove that, after some preliminary processing, a flat wall that is furthermore embeddable in a disk with the perimeter on its boundary is already homogeneous. Hence, our second algorithm proceeds similarly to the first one, but if we find a flat wall W' in G', we divide W' into $k + 1$ disjoint smaller flat walls and check whether they belong to $\mathcal{H}$. By the pigeonhole principle, one of them, W_i, does not contain a modified vertex and must thus be in $\mathcal{H}$, otherwise we return a no-instance. Then, we argue, using a result from [11] to guarantee additional properties of the planar embedding that are needed for technical reasons, that we can find a smaller flat wall W_i' in W_i with a *planar embedding* (even if the genus of the target graph class is strictly positive). Hence, we find an irrelevant vertex in W_i' and conclude.

5 Conclusion

For a large family of graph modification problems involving a bounded number of vertices, if the target class $\mathcal{H}$ is minor-closed, we provided an algorithm solving the problem in time $2^{\mathsf{poly}(k)} \cdot n^2$. This is actually the same running time as the best known running time for Vertex Deletion to $\mathcal{H}$ [38]. For the other graph modification problems encompassed by our result, such as Edge Deletion to $\mathcal{H}$, Edge Contraction to $\mathcal{H}$, Vertex Identification to $\mathcal{H}$, or Independent Set Deletion to $\mathcal{H}$, the only minor-closed $\mathcal{H}$ for which an algorithm with an explicit parametric dependence in the solution size was known, to the authors' knowledge, were the class of forests and the class of union of paths. Other problems, such as Matching Deletion to $\mathcal{H}$, Matching Contraction to $\mathcal{H}$, Induced Star Deletion to $\mathcal{H}$, or Subgraph Complementation to $\mathcal{H}$, were not even considered yet from the parameterized complexity viewpoint, other than in the meta-theorem of [47].

The degree of $\mathsf{poly}(k)$ in the running time comes from the irrelevant vertex technique and is quite huge. In the bounded genus case, we reduce the running time to $2^{\mathcal{O}(k^9)} \cdot n^2$ thanks to some improvement on the irrelevant vertex technique. This does not match the parametric dependence in the running time of $2^{\mathcal{O}(k^2 \log k)} \cdot n^{\mathcal{O}(1)}$ for Vertex Deletion to $\mathcal{H}$ [29] for $\mathcal{H}$ of bounded genus, though we possibly have a better dependence on n. To the authors' knowledge, this is the first bounded genus result with an explicit parametric dependence in the solution size for the other graph modification problems encompassed by our result.

Improving more the parametric dependence in the general case would certainly require coming up with new techniques. On the other hand, given the recent results of [30] for minor containment, it is worth studying whether the quadratic dependence on n could be improved to an almost-linear dependence while maintaining a good dependence on k. Note that the approach of [30] heavily uses Courcelle's theorem [8], which would require to be translated to a plausibly very involved dynamic programming algorithm to keep a good parametric dependence on k.

Given that we require the replacement action $\mathcal{L}$ to be hereditary for our irrelevant vertex technique to work, we unfortunately restrict the graph modification problems that we solve. For instance, Planar Subgraph Isomorphism can be expressed as an $\mathcal{L}$-R-Planar problem for a specific $\mathcal{L}$, which is not hereditary. Hence, we do not encompass this problem in our general algorithm, while such an algorithm is provided in [17], where the constraint about $\mathcal{L}$ being hereditary is not required. While most of the "reasonable" modification problems correspond to a hereditary replacement action, it is worth investigating whether our result can be extended to non-hereditary replacement actions.

Here, we only consider modifications that affect a bounded number of vertices of the input graph. This is necessary as we want k to decrease by one each time we find an obligatory vertex (or, more precisely, as we want the size of the increasingly guessed partial solution to be bounded by k), so that the depth of the branching tree is bounded. Some relevant graph modification problems, however, such as Elimination Distance to $\mathcal{H}$ [38] or $\mathcal{H}$-Treewidth [14] (where we want to delete a vertex set X whose "torso" has bounded treedepth or treewidth, respectively, such that $G - X \in \mathcal{H}$), consider a modification that affects a set of vertices that may have *unbounded* size. In this case, the branching method does not seem applicable. However, the irrelevant vertex technique still works, and provided that we have a dynamic programming for graphs of bounded treewidth, an algorithm can still be designed in some cases, but with a worse parametric dependence on k. This is what is done, for instance, in [38] for Elimination Distance to $\mathcal{H}$. Therefore, we could consider extending the results of this paper to (some kinds of) modifications involving sets of vertices or edges of unbounded size.

Abstract

A k-mismatch square is a string of the form XY where X and Y are two equal-length strings that have at most k mismatches. Kolpakov and Kucherov [*Theor. Comput. Sci.*, 2003] defined two notions of k-mismatch repeats, called k-repetitions and k-runs, each representing a sequence of consecutive k-mismatch squares of equal length. They proposed algorithms for computing k-repetitions and k-runs working in $\mathcal{O}(nk \log k + \mathsf{output})$ time for a string of length n over an integer alphabet, where output is the number of the reported repeats. We show that $\mathsf{output} = \mathcal{O}(nk \log k)$, both in case of k-repetitions and k-runs, which implies that the complexity of their algorithms is actually $\mathcal{O}(nk \log k)$. We apply this result to computing parameterized squares.

A parameterized square is a string of the form XY such that X and Y parameterized-match, i.e., there exists a bijection f on the alphabet such that $f(X) = Y$. Two parameterized squares XY and $X'Y'$ are equivalent if they parameterized match. Recently Hamai et al. [SPIRE 2024] showed that a string of length n over an alphabet of size σ contains less than $n\sigma$ non-equivalent parameterized squares, improving an earlier bound by Kociumaka et al. [*Theor. Comput. Sci.*, 2016]. We apply our bound for k-mismatch repeats to propose an algorithm that reports all non-equivalent parameterized squares in $\mathcal{O}(n\sigma \log \sigma)$ time. We also show that the number of non-equivalent parameterized squares can be computed in $\mathcal{O}(n \log n)$ time. This last algorithm applies to squares under any substring compatible equivalence relation and also to counting squares that are distinct as strings. In particular, this improves upon the $\mathcal{O}(n\sigma)$-time algorithm of Gawrychowski et al. [CPM 2023] for counting order-preserving squares that are distinct as strings if $\sigma = \omega(\log n)$.

1 Introduction

A string of the form XX, for any string X, is called a *square* (or a *tandem repeat*). Squares are a classic notion in combinatorics on words (see, e.g., the early works of Thue [53] on avoidability of square substrings), text algorithms (starting from an algorithm for computing square substrings by Main and Lorentz [40]), and bioinformatics (see Gusfield's book [22]). A string of length n contains at most n distinct square substrings [8] and all of them can be computed in $\mathcal{O}(n)$ time [4, 9, 14, 23] or even $\mathcal{O}(n/\log_\sigma n)$ time [10] assuming that the string is over an integer alphabet of size σ. A maximal sequence of consecutive squares in a string

is called a run (or a generalised run; cf. Section 2); see [33]. A string of length n contains at most n runs [3] and they can all be computed in $\mathcal{O}(n)$ time [3, 17]. Our work is devoted to efficient algorithms for computing known generalizations of squares and runs: k-mismatch squares represented as k-runs or k-repetitions, parameterized squares, and generalised squares that include parameterized squares, order-preserving squares, and Cartesian-tree squares.

We assume that positions in a string X are numbered from 1 to $|X|$, so that $X[i]$ is the ith character of X. For integers i, j such that $1 \le i \le j \le |X|$, by $X[i\,..\,j] = X[i\,..\,j+1)$ we denote the substring composed of characters $X[i], X[i+1], \ldots, X[j]$. We use similar notation for integer intervals: $[i\,..\,j] = [i\,..\,j+1) = \{i, i+1, \ldots, j\}$.

We say that a length-n string is over an integer alphabet if its letters belong to $[0\,..\,n^{\mathcal{O}(1)}]$. We use the word-RAM model of computation.

1.1 k-Mismatch Squares and k-Runs

For two equal-length strings X and Y, their Hamming distance is defined as $d_H(X,Y) = |\{i \in [1\,..\,|X|] : X[i] \neq Y[i]\}|$. A *$k$-mismatch square* (also known under the name of k-mismatch tandem repeat) is a string XY such that $|X| = |Y|$ and $d_H(X,Y) \le k$. Let T be a string of length n. A *k-run of period ℓ* in T (cf. [38]) is a maximal substring $T[a\,..\,b)$ such that $T[i\,..\,i+2\ell)$ is a k-mismatch square for every $i \in [a\,..\,b-2\ell]$; see Figure 1. Maximality means that the k-run is extended to the right and left as much as possible provided that the definition is still satisfied.

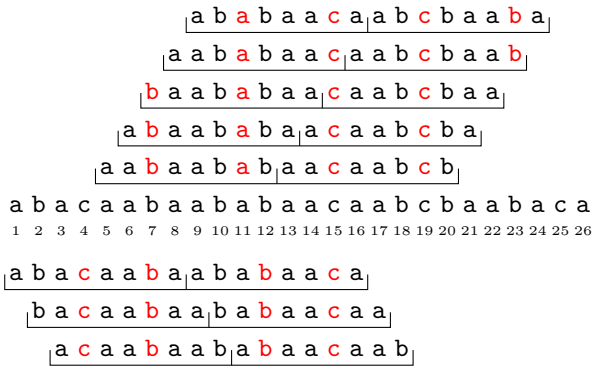

Figure 1 String $T[1\,..\,26]$ contains two 2-runs with period 8, $T[1\,..\,18]$ and $T[5\,..\,24]$. The two 2-runs represent three 2-mismatch squares (below) and five 2-mismatch squares (above), respectively; mismatches are shown in red. Strings $T[x\,..\,x+16)$ for $x \in \{4, 10, 11\}$ are not 2-mismatch squares.

Landau, Schmidt and Sokol [39] showed an algorithm for computing k-runs in a string of length n that works in $\mathcal{O}(nk\log(n/k))$ time; hence, the total number of k-runs reported is $\mathcal{O}(nk\log(n/k))$. Kolpakov and Kucherov [34, 35] showed that all k-runs (called there runs of k-mismatch tandem repeats) in a string of length n can be computed in $\mathcal{O}(nk\log k + \mathsf{output})$ time, where output is the number of k-runs. Many other algorithms for computing approximate tandem repeats under various metrics, in the context of computational biology and with the aid of statistical methods and heuristics, were proposed [6, 7, 15, 16, 28, 31, 36, 43, 45, 46, 47, 48, 49, 50, 51, 52, 55, 56]. In Section 2 we show the following theorem.

▶ **Theorem 1.** *A string of length n contains $\mathcal{O}(nk\log k)$ k-runs.*

Theorem 1 provides the first $\mathcal{O}(n)$ upper bound on the number of k-runs for $k = \mathcal{O}(1)$ and implies that the algorithm of Kolpakov and Kucherov computing k-runs actually works in $\mathcal{O}(nk\log k)$ time. Actually, we show a stronger condition that a string T of length n

contains $\mathcal{O}(nk \log k)$ *uniform* k-runs. Intuitively, a uniform k-run is a maximal sequence of consecutive k-mismatch squares of the same length in which the mismatches of all squares are at the same positions. (See Section 2 for a formal definition.) Our bound on the number of uniform k-runs implies the bound for k-runs as well as an $\mathcal{O}(nk \log k)$ upper bound on the number of k-repetitions as defined in [34, 35] (called there k-mismatch globally defined repetitions).

To prove Theorem 1, we explore a combinatorial relation between k-runs and maximum gapped repeats [32] and apply the optimal $\mathcal{O}(n\alpha)$ bound on the number of maximal α-gapped repeats in a length-n string [20, 27].

1.2 Parameterized Squares

For a string X, by $\mathsf{Alph}(X)$ we denote the set of characters of X. Two strings X, Y *parameterized match* if $|X| = |Y|$ and there is a bijection $f : \mathsf{Alph}(X) \mapsto \mathsf{Alph}(Y)$ such that $f(X) = Y$ (i.e., $|X| = |Y|$ and $f(X[i]) = Y[i]$ for all $i \in [1\,..\,|X|]$). A *parameterized square* (*p-square*, in short) is a string XY such that X parameterized matches Y (see Figure 2). Two p-squares XY and $X'Y'$ are called *equivalent* if they parameterized match.

Parameterized matching was introduced by Baker [2] motivated by applications in code refactoring and plagiarism detection. The notion of p-squares was introduced by Kociumaka, Radoszewski, Rytter, and Waleń [30] who showed that a string of length n over alphabet of size σ contains at most $2\sigma!n$ non-equivalent p-squares. They also considered avoidability of parameterized cubes. The bounds from [30] were recently improved by Hamai, Taketsugu, Nakashima, Inenaga, and Bannai [24]; they showed that a length-n string over alphabet of size σ contains less than σn non-equivalent p-squares. This bound automatically implies that such a string contains at most $\sigma! \cdot \sigma \cdot n$ p-squares that are distinct as strings (improving the $2(\sigma!)^2 n$ upper bound from [30]). We show that all non-equivalent p-squares can be computed efficiently; our approach also extends to p-squares that are distinct as strings. See Section 4.

▶ **Theorem 2.** *All non-equivalent p-square substrings in a string of length n over alphabet of size σ can be computed in $\mathcal{O}(n\sigma \log \sigma)$ time.*

All p-square substrings that are distinct as strings can be computed in $\mathcal{O}(n\sigma \log \sigma + \mathsf{output})$ time, where output is the number of p-squares reported.

By the above discussion, all p-square substrings that are distinct as strings can be computed in $\mathcal{O}(n(\sigma+1)!)$ time. The key ingredient in the algorithm behind Theorem 2 is a relation between p-squares and σ-mismatch squares (and uniform σ-runs).

1.3 Generalised Squares under Substring Consistent Equivalence Relations

We then show an alternative algorithm for counting p-squares whose complexity does not depend on the alphabet size σ. The algorithm is stated for squares under any *substring consistent equivalence relation* (*SCER* in short). An SCER is a relation $\approx$ on strings such that $X \approx Y$ implies that (1) $|X| = |Y|$ and (2) $X[i\,..\,j] \approx Y[i\,..\,j]$ for all $1 \le i \le j \le |X|$; see [42]. Known examples of SCERs include parameterized matching, order-preserving matching [29, 37], Cartesian tree matching [44], and palindrome pattern matching [26]. Two strings X and Y *order-preserving match* if $|X| = |Y|$, sets $\mathsf{Alph}(X)$ and $\mathsf{Alph}(Y)$ are totally ordered, and there is a bijection $f : \mathsf{Alph}(X) \mapsto \mathsf{Alph}(Y)$ that is increasing (i.e., if $x < y$ then $f(x) < f(y)$) such that $f(X) = Y$. Strings X, Y *Cartesian-tree match* if they have the same shape of a Cartesian tree (cf. [54]). Finally, strings X and Y *palindrome match* if for all $1 \le i \le j \le |X|$, $X[i\,..\,j]$ is a palindrome if and only if $Y[i\,..\,j]$ is a palindrome.

An $\approx$-*square* is a string XY such that $X \approx Y$ under SCER $\approx$. Thus p-squares and order-preserving squares [30] (op-squares, in short) as well as Cartesian-tree squares [44] (CT-squares) and squares in the sense of palindrome matching (palindrome-squares) are $\approx$-squares for the respective SCERs $\approx$. See Figure 2 for an example.

$$S = \underbrace{1\ 3\ \overbrace{2\ 2\ 4\ 3}^{Y}}_{X}\ \underbrace{4\ 4\ 1\ 2\ \overbrace{3\ 2\ 3}^{Y}}_{Z}$$

Figure 2 For string $S = 1322434412323$, $X = 132\ 243$ is an op-square (hence, automatically, a p-square and a CT-square), $Y = 2243\ 4412$ is a p-square, and $Z = 412\ 323$ is a CT-square. Among the three substrings, only Z is *not* a palindrome-square, as its second half is a palindrome whereas its first half is not.

In a prefix consistent equivalence relation (PCER), condition (2) of an SCER only needs to hold for $i = 1$. An SCER is a PCER. We say that $\mathcal{E} : \Sigma^* \to \mathbb{Z}$ is an *encoding function* if

$$X \approx Y \quad \Leftrightarrow \quad (\,|X| = |Y| \ \wedge\ \forall_{i \in [1\,..\,|X|]}\, \mathcal{E}(X[1\,..\,i]) = \mathcal{E}(Y[1\,..\,i])\,). \tag{1}$$

▶ **Observation 3.** *For every PCER $\approx$ on strings over integer alphabet there exists an encoding function.*

Proof. Let $\mathcal{E}(X)$ be defined as the number of the equivalence class under $\approx$ of X among all strings of length $|X|$. Let us verify that $\mathcal{E}$ satisfies equivalence (1). ($\Rightarrow$) If $X \approx Y$, then, by definition, $|X| = |Y|$ and $X[1\,..\,i] \approx Y[1\,..\,i]$ for all $i \in [1\,..\,|X|]$. Then indeed $\mathcal{E}(X[1\,..\,i]) = \mathcal{E}(Y[1\,..\,i])$. ($\Leftarrow$) Taking $i = |X| = |Y|$, we obtain $\mathcal{E}(X) = \mathcal{E}(Y)$. As $|X| = |Y|$, we have $X \approx Y$. ◀

The encoding function defined in the proof of Observation 3 could be hard to compute efficiently for a particular PCER $\approx$. It is also stronger, as it satisfies $X \approx Y \ \Leftrightarrow\ (\,|X| = |Y| \ \wedge\ \mathcal{E}(X) = \mathcal{E}(Y))$. Luckily, for the aforementioned known SCERs efficient encoding functions are known, as shown in the following Example 4.

For an encoding function $\mathcal{E}$, let $\pi^{\mathcal{E}}(n)$, $\rho^{\mathcal{E}}(n)$ be integer sequences such that for a string T of length n over integer alphabet, after $\pi^{\mathcal{E}}(n)$ preprocessing time, $\mathcal{E}(T[i\,..\,j])$ for any i, j can be computed in $\rho^{\mathcal{E}}(n)$ time.

▶ **Example 4.** For parameterized matching, there exists a classic *prev*-encoding, see [2], that is an encoding function:

$$\mathit{prev}(X) = \begin{cases} |X| - i & X[i] = X[|X|] \text{ and } X[j] \neq X[|X|] \text{ for all } j \in [i+1\,..\,|X|) \\ 0 & \text{otherwise} \end{cases}$$

The *prev*-encodings of all prefixes of a string T can be computed by sorting all pairs $(T[i], i)$. If T is over an integer alphabet, this is performed in $\pi^{prev}(n) = \mathcal{O}(n)$ time. Then $\mathit{prev}(T[i\,..\,j])$ can be computed from $\mathit{prev}(T[1\,..\,j])$ in $\rho^{prev}(n) = \mathcal{O}(1)$ time.

For order-preserving matching, one can use an encoding as pairs $(\alpha(X), \beta(X))$. Here

$$\alpha(X) \text{ is the largest } j < |X| \text{ such that } X[j] = \max\{X[k] \ :\ k \in [1\,..\,|X|),\ X[k] \leq X[|X|]\},$$

and if there is no such j, then $\alpha(X) = 0$. Similarly,

$$\beta(X) \text{ is the largest } j < |X| \text{ such that } X[j] = \min\{X[k] \ :\ k \in [1\,..\,|X|),\ X[k] \geq X[|X|]\},$$

and $\beta(X) = 0$ if no such j exists; see [13, 29, 37]. As we require the encoding function to return integers, we can set $\mathcal{E}(X) = \alpha(X) \cdot |X| + \beta(X)$, since $\alpha(X), \beta(X) \in [0\,..\,|X|)$. Then [13, Lemma 4] implies that $\mathcal{E}$ is an encoding function for order-preserving matching and [13, Lemma 24] gives $\pi^{\mathcal{E}}(n) = \mathcal{O}(n\sqrt{\log n})$, $\rho^{\mathcal{E}}(n) = \mathcal{O}(\log n / \log\log n)$.

For Cartesian-tree matching, [44, Theorem 1] shows that the following *parent-distance* representation:

$$PD(X) = \begin{cases} |X| - \max_{1 \le j < |X|}\{j \,:\, X[j] \le X[|X|]\} & \text{if such } j \text{ exists} \\ 0 & \text{otherwise} \end{cases}$$

is an encoding function. Encodings of all prefixes of a string T can be computed in $\pi^{PD}(n) = \mathcal{O}(n)$ time using a folklore nearest smaller value algorithm. In [44, Section 5.2] it is noted that $PD(T[i\,..\,j])$ can be computed from $PD(T[1\,..\,j])$ in $\rho^{PD}(n) = \mathcal{O}(1)$ time.

By X^R we denote the reverse of string X. In [26, Lemma 2] it is shown that the length of the longest suffix palindrome of X, formally:

$$Lpal(X) = \max\{|X| - k + 1 \,:\, X[k\,..\,|X|] = X[k\,..\,|X|]^R\},$$

is an encoding function for palindrome matching.

Computing encodings of substrings $Lpal(T[i\,..\,j])$ can be reduced in linear time to 2D range successor queries as follows.

In the 2D range successor problem we are given n points in an $n \times n$ grid and we are to answer queries that, given a rectangle in the grid, report a point in the rectangle with the smallest first coordinate, if any. Such queries can be answered in $\mathcal{O}(\log\log n)$ time after $\mathcal{O}(n\sqrt{\log n})$ preprocessing [18].

In the reduction, we compute all maximal palindromes in T in $\mathcal{O}(n)$ time using Manacher's algorithm [41]. Let us show how we deal with odd-length palindromes; the approach for even-length palindromes is analogous. For a maximal palindrome $T[c - r\,..\,c + r]$ with $c \in [1\,..\,n]$ and $r \ge 0$, we create a point $(c, c + r)$. To compute $Lpal(T[i\,..\,j])$, it suffices to find the point in the rectangle $[\lceil (i + j)/2 \rceil\,..\,j] \times [j\,..\,\infty)$ with the smallest first coordinate. If x is the sought coordinate, the longest odd-length suffix palindrome of $T[i\,..\,j]$ has length $2(j - x) + 1$.

By [18], we get $\pi^{Lpal}(n) = \mathcal{O}(n\sqrt{\log n})$ and $\rho^{Lpal}(n) = \mathcal{O}(\log\log n)$.

In Section 5 we show the next theorem on efficient counting of $\approx$-squares.

▶ **Theorem 5.** *Let $\approx$ be an SCER and $\mathcal{E}$ be its encoding function. The number of non-equivalent $\approx$-square substrings in a length-n string can be computed in $\mathcal{O}(\pi^{\mathcal{E}}(n) + n\rho^{\mathcal{E}}(n) + n\log n)$ time.*

The number of $\approx$-square substrings in a length-n string that are distinct as strings can be computed in the same time complexity.

Consequently, in a length-n string, the numbers of non-equivalent p-squares, op-squares, CT-squares, and palindrome-squares, as well as the numbers of the respective squares that are distinct as strings can be computed in $\mathcal{O}(n\log n)$ time, as the respective SCERs enjoy encoding functions with $\pi^{\mathcal{E}}(n) = \mathcal{O}(n\log n)$ and $\rho^{\mathcal{E}}(n) = \mathcal{O}(\log n)$ as shown in Example 4. In particular, the algorithm of Theorem 5 in the case that $\sigma = \omega(\log n)$ improves upon the $\mathcal{O}(n\sigma)$-time algorithm of Gawrychowski, Ghazawi, and Landau [19] for reporting (thus, counting) op-squares that are distinct as strings. Moreover, the obtained complexity for counting non-equivalent p-squares (p-squares that are distinct as strings, respectively) is better than the one in Theorem 2 if $\sigma = \omega(\log n / \log\log n)$ ($\sigma = \Omega(\log\log n)$, respectively).

Theorem 5 involves constructing a $\approx$-suffix tree data structure (see Section 3 for a definition).

2 Upper Bound on the Number of k-Runs

This section introduces an upper bound on the number of k-runs (proof of Theorem 1) which implies their efficient computation by the algorithm of Kolpakov and Kucherov [34, 35]. A position i in string T is called an *ℓ-mismatching position* if $i \in [1\,..\,n-\ell]$ and $T[i] \neq T[i+\ell]$. In particular, $T[i\,..\,i+2\ell)$ is a k-mismatch square if and only if $T[i\,..\,i+\ell)$ contains at most k ℓ-mismatching positions. Let us formally define a uniform k-run.

▶ **Definition 6.** *A substring $T[a\,..\,b)$ is called a* uniform k-run of period ℓ *if $b-a \geq 2\ell$ and the sets $\{j \in [i\,..\,i+\ell) : T[j] \neq T[j+\ell]\}$ of ℓ-mismatching positions for all $i \in [a\,..\,b-2\ell]$ have cardinality at most k and are all the same. We are interested in maximal uniform k-runs.*

A *gapped repeat* in a string T is a fragment of the form UVU, for $|U| > 0$. Fragments denoted by U are called *arms* of the gapped repeat (left and right arm). The *period* of the gapped repeat is defined as $|UV|$. An α-gapped repeat (for $\alpha \geq 1$) in T is a gapped repeat UVU such that $|UV| \leq \alpha|U|$. An (α-)gapped repeat is called *maximal* if its arms cannot be extended simultaneously with the same character to the right or to the left. A maximal (α-)gapped repeat will be called an (α-)MGR, for short. Gawrychowski, I, Inenaga, Köppl, and Manea [20] showed that, for a real $\alpha \geq 1$, a string of length n contains $\mathcal{O}(n\alpha)$ α-MGRs.

A *generalised run* is a pair $(T[x\,..\,y), p)$ such that p satisfies $2p \leq y-x$ and (1) $x = 1$ or $T[x-1\,..\,y)$ does not have period p, and (2) $y = |T|+1$ or $T[x\,..\,y]$ does not have period p. That is, a generalised run is a 0-run. A run is a generalised run in which p is the smallest period of $T[x\,..\,y)$. A string of length n contains less than n runs and $\mathcal{O}(n)$ generalised runs [3].

▶ **Definition 7.** *We say that an MGR $UVU = T[x\,..\,y)$ with period $\ell = |UV|$ in T* induces *a uniform k-run $T[a\,..\,b)$ of period ℓ if $[x\,..\,y-\ell) \cap [a\,..\,b-\ell) \neq \emptyset$.*

We further say that a generalised run $(T[x\,..\,y), \ell)$ induces *a uniform k-run $T[a\,..\,b)$ of period ℓ if $[x\,..\,y-\ell) \cap [a\,..\,b-\ell) \neq \emptyset$.*

Let us emphasize that the uniform k-run does not need to be a substring of the MGR or generalised run. Intuitively, an MGR induces a uniform k-run if the left half of at least one k-mismatch square of the k-run contains a position of the left arm of the MGR; see Figure 3. If an MGR or a generalised run induces a uniform k-run, we say that the k-run is *induced* by the MGR or run, respectively. We also say that the MGR or generalised run induces all k-mismatch squares in the uniform k-run that it induces.

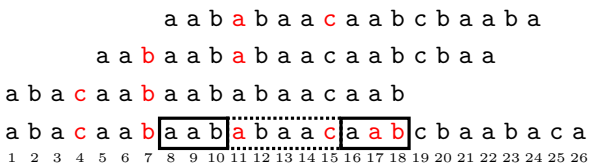

Figure 3 String $T[1\,..\,26]$ from Figure 1 with 8-mismatching positions shown in red. The string contains three uniform 2-runs with period 8, $T[1\,..\,18]$, $T[5\,..\,22]$, and $T[8\,..\,24]$ (in Figure 1, the last two form a single 2-run). They are all induced by a 3-MGR UVU for $U = T[8\,..\,10] = T[16\,..\,18]$ and $V = T[11\,..\,15]$. In the proof of Lemma 8 for this MGR, we have $L = \{7, 4, 0\}$ and $R = \{11, 15, 17\}$.

▶ **Lemma 8.** *An MGR induces at most $2k+1$ uniform k-runs.*

Proof. Consider an MGR $T[x\,..\,y)$ with period ℓ. Let R be the set of $k+1$ smallest ℓ-mismatching positions in $[y-\ell\,..\,y)$ in T; if there are no such $k+1$ positions, we select all ℓ-mismatching positions in $[y-\ell\,..\,y)$ in T to the set R. Similarly, let L be the set of $k+1$ largest ℓ-mismatching positions in $[x-\ell+1\,..\,x)$ in T; if there are no $k+1$ such positions, we select all ℓ-mismatching positions in $[x-\ell+1\,..\,x)$. If $|R|\leq k$, we insert y to R. If $|L|\leq k$, we insert $x-\ell$ to L. This way, if a k-mismatch square $T[i\,..\,i+2\ell)$ is induced by the MGR $T[x\,..\,y)$, then $i\in I$ for $I=[\min L+1\,..\,\max R-\ell]$ (as otherwise the left half of the square would contain more than k ℓ-mismatching positions or would not touch $T[x\,..\,y-\ell)$).

Let us consider a window of length ℓ sliding left-to-right over T with the left end point of the window located in interval I. There are at most $2k$ moments when the number of ℓ-mismatching positions in the window changes. Between them, we obtain uniform k-runs if the number of ℓ-mismatching positions in the window is at most k. ◀

An analogous lemma for generalised runs is obtained with the same proof (replacing "MGR" by "generalised run"); see Figure 4.

Figure 4 String $T[1\,..\,26]$ with its 6-mismatching positions shown in red. A generalised run $T[6\,..\,21]$ with period 6 (rectangle) induces five uniform 2-runs with period 6 shown above. In this example, the generalised run corresponds to a run with period 3.

▶ **Lemma 9.** *A generalised run induces at most $2k+1$ uniform k-runs.*

A uniform k-run can be induced by several MGRs and generalised runs.

▶ **Example 10.** The middle uniform 2-run $T[5\,..\,22]$ in Figure 3 is induced also by two other MGRs with period 8, $T[5\,..\,14]$ (with arms $T[5\,..\,6]=T[13\,..\,14]=\mathtt{aa}$) and $T[12\,..\,22]$ (with arms $T[12\,..\,14]=T[20\,..\,22]=\mathtt{baa}$).

For a gapped repeat UVU, the fraction $\frac{|UV|}{|U|}$ is called the *gap ratio*. That is, the gap ratio is the minimum α such that UVU is an α-gapped repeat. We assign to each gapped repeat UVU in T a *weight* equal to the reciprocal of its gap ratio, that is, $\frac{|U|}{|UV|}$.

▶ **Lemma 11.** *If $\ell\geq 4k$ and $T[a\,..\,b)$ is a uniform k-run of period ℓ, then it is induced by a generalised run or by some number of $(2k+2)$-MGRs of total weight at least $\frac{1}{4}$.*

Proof. Let $p_1,\ldots,p_t$ be all ℓ-mismatching positions among $[a\,..\,b-\ell)$, listed in an increasing order. We define sentinel p_0 being the maximum ℓ-mismatching position that is smaller than a; if there is no such position, we set $p_0=0$. Similarly, we define sentinel p_{t+1} as the minimum ℓ-mismatching position that is at least $b-\ell$; if no such position exists, we set $p_{t+1}=n+1-\ell$.

Let us fix $s\in[0\,..\,t]$. We have $U_s:=T[p_s+1\,..\,p_{s+1})=T[p_s+\ell+1\,..\,p_{s+1}+\ell)$, so $W_s:=T[p_s+1\,..\,p_{s+1}+\ell)$ has period ℓ. Moreover, we have (1) $p_s=0$ or $T[p_s]\neq T[p_s+\ell]$ and (2) $p_{s+1}+\ell=n+1$ or $T[p_{s+1}]\neq T[p_{s+1}+\ell]$. If $0<|U_s|<\ell$, then W_s is an MGR with arms equal to U_s. If $|U_s|\geq\ell$, W_s is a generalised run. The MGR or generalised run induces $T[a\,..\,b)$ unless $p_{s+1}=a$ or $p_s=b-\ell-1$.

Assume that the uniform k-run $T[a\,..\,b)$ is not induced by a generalised run. If a string W_s, for $s \in [0\,..\,t]$, is not a $(2k+2)$-MGR of period ℓ, the length of its left arm U_s is smaller than $\frac{\ell}{2k+2}$. Hence, for strings W_s that are not $(2k+2)$-MGRs, the total length of their left arms U_s is at most $\frac{\ell}{2}$. The remaining $(2k+2)$-MGRs among W_s have total length of left arms at least $(b-a-\ell)-\frac{\ell}{2}-k \geq \frac{\ell}{2}-k$ (accounting for the at most k ℓ-mismatching positions $p_1,\ldots,p_t$) which is at least $\frac{\ell}{4}$ by the assumption of the lemma. This means that the total weight of $(2k+2)$-MGRs that induce the k-run, defined as the sum of the lengths of their left arms divided by their periods, all equal to ℓ, is at least $\frac{1}{4}$. ◀

We show a theorem that implies Theorem 1.

▶ **Theorem 12.** *A string of length n contains $\mathcal{O}(nk\log k)$ uniform k-runs.*

Proof. Let T be a string of length n. Let us consider a bipartite graph $G=(V_1\cup V_2,E)$ such that vertices in V_1 are uniform k-runs in T, vertices in V_2 are $(2k+2)$-MGRs and generalised runs in T, and there is an edge $uw\in E$, for $u\in V_1$ and $w\in V_2$, if k-run u is induced by the MGR or generalised run w. Our goal is to bound $|V_1|$ from above.

Let us remove from G all vertices in V_1 that are uniform k-runs with period at most $4k$. There are at most $4kn$ such k-runs (as there are at most $4kn$ substrings of T of length at most $4k$). Let us also remove from G all vertices in V_2 that are generalised runs and all vertices in V_1 that are adjacent to at least one of the removed vertices in V_2. By [3], this way at most $1.5n$ vertices are removed from V_2, so by Lemma 9, $\mathcal{O}(nk)$ vertices are removed from V_1. Let $G'=(V_1'\cup V_2',E')$ be the remaining graph. We assume that each edge has a weight equal to the weight of the MGR in V_2' it is incident to. In order to bound $|V_1'|$, we will consider the *total weight of edges* in E'.

For each $\alpha\in[2\,..\,2k+2]$, let x_α be the number of α-MGRs in T that are not $(\alpha-1)$-MGRs. Each such MGR has weight at most $\frac{1}{\alpha-1}$ and $2k+1\leq 3k$ edges incident to it (cf. Lemma 8). Thus the sum of weights of edges in E' is bounded from above by

$$\sum_{\alpha=2}^{2k+2}\frac{3kx_\alpha}{\alpha-1} \tag{2}$$

The improved upper bound on the number of α-MGRs of I and Köppl [27] implies that

$$\sum_{i=2}^{\alpha} x_i < 13n\alpha \quad \text{for every } \alpha\in[2\,..\,2k+2] \tag{3}$$

We show how to bound the number (2) in general.

▷ Claim 13. For every sequence $(x_2,\ldots,x_{2k+2})$ of non-negative integers that satisfies the condition (3), the value (2) is $\mathcal{O}(nk\log k)$.

Proof. As long as there exists $\alpha\in[3\,..\,2k+2]$ such that $x_\alpha>13n$, we select $i\in[2\,..\,\alpha)$ such that $x_i<13n$ or $i=2$ and $x_i<26n$, decrement x_α and increment x_i. Such i exists by (3) and the pigeonhole principle. The operation does not change any lhs in (3) and increases (2).

In the end, we have $x_2\leq 26n$ and $x_\alpha\leq 13n$ for all $\alpha\in[3\,..\,2k+2]$. Hence, (2) is bounded as:

$$\sum_{\alpha=2}^{2k+2}\frac{3kx_\alpha}{\alpha-1} \;\leq\; 78k+39nk\sum_{\alpha=2}^{2k+1}\frac{1}{\alpha} \;\leq\; 78k+39nk(\ln(2k+1)+1) \;=\; \mathcal{O}(nk\log k). \qquad \triangleleft$$

By the claim, the sum of weights of edges in G' is $\mathcal{O}(nk \log k)$. By Lemma 11, for each uniform k-run with period $\ell \geq 4k$ that is not induced by a generalised run, the total weight of edges incident to it is at least $\frac{1}{4}$. This concludes that $|V_1'| = \mathcal{O}(nk \log k)$, so the total number of uniform k-runs (across all periods $\ell \in [1\,..\,\lfloor n/2 \rfloor]$) is $|V_1| = \mathcal{O}(nk \log k)$. ◀

A k-run of period ℓ contains a prefix being a uniform k-run of period ℓ, constructed by taking k-mismatch squares of length 2ℓ at subsequent positions as long as their sets of ℓ-mismatching positions are the same. By maximality, no two k-runs with equal period start at the same position, so this way each k-run produces a different uniform k-run. Thus the number of k-runs in T does not exceed the number of uniform k-runs, which proves Theorem 1. By the same argument, each k-repetition implies a unique uniform k-run and so the number of k-repetitions is $\mathcal{O}(nk \log k)$. (We refer the reader to the definition of k-repetition in [34, 35, 38] as this notion is not used below.)

3 ≈-Suffix Trees and Their Applications

We introduce useful tools for the next two sections. Cole and Hariharan [11] defined a *quasi-suffix collection* as a collection of strings $S_1, S_2, \ldots, S_n$ that satisfies the following conditions:

1. $|S_1| = n$ and $|S_i| = |S_{i-1}| - 1$.
2. No S_i is a prefix of another S_j.
3. Suppose strings S_i and S_j have a common prefix of length $\ell > 0$. Then S_{i+1} and S_{j+1} have a common prefix of length at least $\ell - 1$.

A quasi-suffix collection is specified implicitly by a character oracle that given i, j returns $S_i[j]$. They obtain the following result.

▶ **Theorem 14** ([11]). *The compacted trie of a quasi-suffix collection of n strings can be constructed in $\mathcal{O}(n)$ expected time assuming that the character oracle works in $\mathcal{O}(1)$ time.*

For a string T of length n, the *≈-suffix tree* of T is a compacted trie of strings $\mathit{Code}(T[i\,..\,n])\#$, $i \in [1\,..\,n+1]$, where $\mathit{Code}(X) = \mathcal{E}(X[1])\mathcal{E}(X[1\,..\,2]) \cdots \mathcal{E}(X)$ for a string X and $\#$ is an end-marker that is not an encoding of any string. We extend the sequences π, ρ so that for any string $T \in [0\,..\,\sigma)^n$, after $\pi^{\mathcal{E}}(n, \sigma)$ preprocessing time, $\mathcal{E}(T[i\,..\,j])$ for any i, j can be computed in $\rho^{\mathcal{E}}(n, \sigma)$ time. By $\gamma^{\mathcal{E}}(n, \sigma)$ we denote an upper bound on the total number of distinct characters in the strings stored in the ≈-suffix tree of a string in $[0\,..\,\sigma)^n$. Theorem 14 implies the following corollary. (A similar result, but only for order-preserving equivalence, was shown in [19, Lemma 16].)

▶ **Corollary 15.** *Let ≈ be an SCER and $\mathcal{E}$ be its encoding function. The ≈-suffix tree of a string in $[0\,..\,\sigma)^n$ can be constructed in worst case time:*

$$\mathcal{O}(\pi^{\mathcal{E}}(n, \sigma) + n\rho^{\mathcal{E}}(n, \sigma) + \min\{n \log^2 \log n / \log \log \log n,\ n\gamma^{\mathcal{E}}(n, \sigma)\}).$$

Proof. Let us verify that strings $\mathit{Code}(T[i\,..\,n])\#$ satisfy the conditions 1-3 of a quasi-suffix collection. Condition 1 for $n+1$ is obvious. Condition 2 follows due to the end-marker. As for condition 3, assume $\mathsf{LCP}(S_i, S_j) = \ell > 0$ and let $i \neq j$ as otherwise the conclusion is trivial. Then $\ell < |S_i|, |S_j|$ because of the end-marker. By equivalence (1), we have $T[i\,..\,i+\ell) \approx T[j\,..\,j+\ell)$. Because ≈ is an SCER, we have $T[i+1\,..\,i+\ell) \approx T[j+1\,..\,j+\ell)$. Hence, $\mathsf{LCP}(S_{i+1}, S_{j+1}) \geq \ell - 1$ by equivalence (1).

An oracle for the quasi-suffix collection S_i answers queries in $\mathcal{O}(\rho^{\mathcal{E}}(n, \sigma))$ time after $\mathcal{O}(\pi^{\mathcal{E}}(n, \sigma))$ preprocessing. The only source of randomness in the algorithm behind Theorem 14 is the need to maintain, for each explicit node of the current tree, a dictionary

indexed by the next character on an outgoing edge. If we store the respective characters per each node in a dynamic predecessor data structure of Andersson and Thorup [1], the total space remains $\mathcal{O}(n)$ and each predecessor query is answered in $\mathcal{O}(\log^2 \log n / \log\log\log n)$ time in the worst case. Alternatively, one can store all the children of a node in a list, to achieve $\mathcal{O}(\gamma^{\mathcal{E}}(n,\sigma))$ space per an explicit node and $\mathcal{O}(\gamma^{\mathcal{E}}(n,\sigma))$ time for a predecessor query. The complexity follows. ◀

▶ Remark 16. For SCERs mentioned in Example 4, we obtain the following time complexities for constructing $\approx$-suffix trees in the respective settings: $\mathcal{O}(n \log^2 \log n / \log\log\log n)$ for parameterized matching and Cartesian tree matching, $\mathcal{O}(n\sqrt{\log n})$ for palindrome matching (that matches the complexity from [26]), and $\mathcal{O}(n \log n / \log\log n)$ for order-preserving matching (a faster, $\mathcal{O}(n\sqrt{\log n})$-time construction was proposed in [13]).

For two strings X and Y, by $\mathsf{LCP}^{\approx}(X,Y)$ we denote $\max\{\ell \geq 0 : X[1\,..\,\ell] \approx Y[1\,..\,\ell]\}$. As in the case of standard suffix trees, by equivalence (1), having an $\approx$-suffix tree of T and the data structure answering lowest common ancestor queries for nodes in $\mathcal{O}(1)$ time after $\mathcal{O}(n)$ preprocessing [25, 5], we can answer $\mathsf{LCP}^{\approx}$ queries about pairs of substrings of T in $\mathcal{O}(1)$ time.

The longest previous $\approx$-factor array $\mathsf{LPF}^{\approx}$ for a string T is an array such that

$$\mathsf{LPF}^{\approx}[i] = \max\{\ell \geq 0 : T[i\,..\,i+\ell) \approx T[j\,..\,j+\ell) \text{ for some } j \in [1\,..\,i)\}.$$

Computing this array can be stated in terms of the $\approx$-suffix tree: for a leaf with index i of the tree we are to find a leaf with index $j < i$ such that the lowest common ancestor of the two leaves is as low as possible. The actual value $\mathsf{LPF}^{\approx}[i]$ is then the (weighted) depth of this ancestor. In [13, Theorem 16] it was shown that this problem, stated for an arbitrary rooted (weighted) tree with n leaves, can be solved in $\mathcal{O}(n)$ time. Thus, the $\mathsf{LPF}^{\approx}$ array for a length-n string can be computed in $\mathcal{O}(n)$ time if the $\approx$-suffix tree is available.

4 Counting p-Squares in $\mathcal{O}(n\sigma \log \sigma)$ Time

In this section we consider $T \in [0\,..\,\sigma)^n$ and $\approx$ denotes the relation of parameterized matching. We use the following function $\mathbf{E}$ for $\approx$ (see Example 17):

$$\mathbf{E}(X) = |\mathsf{Alph}(U)| \text{ where } U \text{ is the longest suffix of } X[1\,..\,|X|) \text{ without letter } X[|X|].$$

▶ **Example 17.** $\mathbf{E}(X)$ for $X = [1,2,1,1,2,3,2,1,4]$ is as follows:

i	1	2	3	4	5	6	7	8	9
$X[i]$	1	2	1	1	2	3	2	1	4
$\mathbf{E}(X[1\,..\,i])$	0	1	1	0	1	2	1	2	3

A similar function was used in the context of parameterized matching in [30]. Lemma 18 below shows that $\mathbf{E}$ is an encoding function for parameterized matching and Lemma 19 shows that it can be computed efficiently.

The ($\Leftarrow$) part of the proof of Lemma 18 is similar to the proof of [30, Lemma 5.4]. A proof of the lemma can be found in the full version.

▶ **Lemma 18.** *$\mathbf{E}$ is an encoding function for parameterized matching.*

▶ **Lemma 19.** *We have $\pi^{\mathbf{E}}(n,\sigma) = \mathcal{O}(n\sigma)$, $\rho^{\mathbf{E}}(n,\sigma) = \mathcal{O}(\sigma)$, and $\gamma^{\mathbf{E}}(n,\sigma) = \sigma + 1$.*

Proof. Let $T \in [0\,..\,\sigma)^n$. By definition, $\mathbf{E}(T[i\,..\,j]) \in [0\,..\,\sigma)$ for any indices i, j. Hence, $\gamma^{\mathbf{E}}(n,\sigma) = \sigma + 1$ (including the sentinel). In order to compute encodings of substrings of T, we can store for every $c \in [0\,..\,\sigma)$, the numbers of characters c in respective prefixes of T. Moreover, for every index i, we store the position $prev[i] \in [0\,..\,i)$ of the last occurrence of character $T[i]$ in $T[1\,..\,i)$; $prev[i] = 0$ if there is no such occurrence. The array $prev$ can be computed from left to right in $\mathcal{O}(n+\sigma)$ time by storing an array of size σ of rightmost occurrences of each character. Then indeed $\pi^{\mathbf{E}}(n,\sigma) = \mathcal{O}(n\sigma)$. When computing $\mathbf{E}(T[i\,..\,j])$, we can compare the counts of every character c at prefixes $T[1\,..\,j)$ and $T[1\,..\,i')$ where $i' = \max(prev[j]+1, i)$. Hence, $\rho^{\mathbf{E}}(n,\sigma) = \mathcal{O}(\sigma)$. ◀

We define strings $\overrightarrow{T}$, $\overleftarrow{T}$ of length n such that

$$\overrightarrow{T}[i] = \mathbf{E}(T[1\,..\,i]), \quad \overleftarrow{T}[i] = \mathbf{E}((T[i\,..\,n])^R).$$

Our goal is to reduce reporting non-equivalent p-squares to computing uniform k-runs. We use two auxiliary lemmas.

▶ **Lemma 20.** *If $T[i\,..\,i+2\ell)$ is a p-square, then $\overrightarrow{T}[i\,..\,i+2\ell)$ and $\overleftarrow{T}[i\,..\,i+2\ell)$ are σ-mismatch squares.*

Proof. We show a proof that $\overrightarrow{T}[i\,..\,i+2\ell)$ is a σ-mismatch square; the proof that $\overleftarrow{T}[i\,..\,i+2\ell)$ is a σ-mismatch square is symmetric.

Let $i_1, \ldots, i_t \in [0\,..\,\ell)$, for $t \in [1\,..\,\sigma]$, be the positions of leftmost occurrences of characters from $[0\,..\,\sigma)$ in $T[i\,..\,i+\ell)$; if some character is not present in $T[i\,..\,i+\ell)$, it is not included in the sequence. Let $j \in [0\,..\,\ell) \setminus \{i_1, \ldots, i_t\}$. Let $j' \in [0\,..\,j)$ be the maximum index such that $T[i+j'] = T[i+j]$, so $T[i+\ell+j'] = T[i+\ell+j]$ and $T[i+\ell+j''] \neq T[i+\ell+j]$ for all $j'' \in [j'+1\,..\,j)$ because $T[i\,..\,i+\ell) \approx T[i+\ell\,..\,i+2\ell)$. Then

$$\overrightarrow{T}[i+j] \;=\; |\mathsf{Alph}(T[i+j'+1\,..\,i+j))| \;=\; |\mathsf{Alph}(T[i+\ell+j'+1\,..\,i+\ell+j))| \;=\; \overrightarrow{T}[i+\ell+j]$$

by the fact that $\approx$ is an SCER. Hence, $\overrightarrow{T}[i\,..\,i+\ell)$ and $\overrightarrow{T}[i+\ell\,..\,i+2\ell)$ have at most $t \le \sigma$ mismatches, as required. ◀

▶ **Lemma 21.** *If $T[i\,..\,i+2\ell)$ is a p-square and $\overrightarrow{T}[i+\ell] = \overrightarrow{T}[i+2\ell]$, then $T[i+1\,..\,i+2\ell]$ is a p-square. Similarly, if $T[i\,..\,i+2\ell)$ is a p-square and $\overleftarrow{T}[i-1] = \overleftarrow{T}[i+\ell-1]$, then $T[i-1\,..\,i+2\ell-1)$ is a p-square.*

Proof. Again, we only prove the first part of the lemma. We have $T[i\,..\,i+\ell) \approx T[i+\ell\,..\,i+2\ell)$, so $T[i+1\,..\,i+\ell) \approx T[i+1+\ell\,..\,i+2\ell)$ since $\approx$ is an SCER. If

$$\overrightarrow{T}[i+2\ell] = \overrightarrow{T}[i+\ell] < |\mathsf{Alph}(T[i+1\,..\,i+\ell))| = |\mathsf{Alph}(T[i+1+\ell\,..\,i+2\ell))|,$$

then $\overrightarrow{T}[i+\ell] = \mathbf{E}(T[i+1\,..\,i+\ell])$, $\overrightarrow{T}[i+2\ell] = \mathbf{E}(T[i+1+\ell\,..\,i+2\ell])$, and $T[i+1\,..\,i+\ell] \approx T[i+1+\ell\,..\,i+2\ell]$ by the fact that $\mathbf{E}$ is an encoding function for parameterized matching (Lemma 18). Otherwise,

$$T[i+\ell] \notin \mathsf{Alph}(T[i+1\,..\,i+\ell)) \quad \text{and} \quad T[i+2\ell] \notin \mathsf{Alph}(T[i+1+\ell\,..\,i+2\ell)),$$

so we immediately obtain $T[i+1\,..\,i+\ell] \approx T[i+1+\ell\,..\,i+2\ell]$. In both cases, $T[i+1\,..\,i+2\ell]$ is a p-square. ◀

If $T[a\,..\,b)$ is a uniform k-run with period ℓ, then there is no ℓ-mismatching position in $T[a+\ell\,..\,b-\ell)$, i.e., $T[a+\ell\,..\,b-\ell) = T[a+2\ell\,..\,b)$. Hence, if $\overrightarrow{T}[a\,..\,b)$ is a uniform k-run with period ℓ and $T[a\,..\,a+2\ell)$ is a p-square, then by Lemma 21, each string $T[i\,..\,i+2\ell)$ for $i \in [a\,..\,b-2\ell]$ is a p-square. With this intuition, we are ready to obtain the reduction.

▶ **Lemma 22.** *Let $T \in [0\,..\,\sigma)^n$. Reporting non-equivalent p-squares in T reduces in $\mathcal{O}(n\sigma+r)$ time to computing uniform σ-runs in $\overrightarrow{T}$ and $\overleftarrow{T}$, where r is the number of these σ-runs.*

Reporting p-squares in T that are distinct as strings reduces to the same problem in $\mathcal{O}(n\sigma + r + \mathsf{output})$ time, where output is the number of p-squares reported.

Proof. For a uniform k-run $T[a\,..\,b)$ of period ℓ, we define its *interval* as $[a\,..\,b-2\ell]$. For each $\ell \in [1\,..\,\lfloor n/2 \rfloor]$, let $\overrightarrow{\mathcal{P}}_\ell$ and $\overleftarrow{\mathcal{P}}_\ell$ be sets of intervals of uniform σ-runs of period ℓ in $\overrightarrow{T}$ and $(\overleftarrow{T})^R$, respectively. Let $\overleftarrow{\mathcal{P}}'_\ell = \{[n-b-2\ell\,..\,n-a-2\ell] \,:\, [a\,..\,b] \in \overleftarrow{\mathcal{P}}_\ell\}$. Finally, let $\mathcal{P}_\ell = \left(\bigcup \overrightarrow{\mathcal{P}}_\ell\right) \cap \left(\bigcup \overleftarrow{\mathcal{P}}'_\ell\right)$.

▷ Claim 23. If $T[i\,..\,i+2\ell)$ is a p-square in T, then $i \in \mathcal{P}_\ell$.

Proof. By Lemma 20, if $T[i\,..\,i+2\ell)$ is a p-square in T, then $\overrightarrow{T}[i\,..\,i+2\ell)$ and $\overleftarrow{T}[i\,..\,i+2\ell) = (\overleftarrow{T})^R[n-i-2\ell\,..\,n-i)$ are σ-mismatch squares. Therefore, there exist intervals $[a\,..\,b] \in \overrightarrow{\mathcal{P}}_\ell$ and $[a'\,..\,b'] \in \overleftarrow{\mathcal{P}}_\ell$ such that $i \in [a\,..\,b]$ and $n-i-2\ell \in [a'\,..\,b']$. In particular, $i \in \bigcup \overrightarrow{\mathcal{P}}_\ell$. We have $[n-b'-2\ell\,..\,n-a'-2\ell] \in \overleftarrow{\mathcal{P}}'_\ell$ and $i \in [n-b'-2\ell\,..\,n-a'-2\ell]$, so $i \in \bigcup \overleftarrow{\mathcal{P}}'_\ell$. ◁

We store $\mathcal{P}_\ell$ as a union of non-empty intervals of the form $\{I \cap J \,:\, I \in \overrightarrow{\mathcal{P}}_\ell,\, J \in \overleftarrow{\mathcal{P}}'_\ell\}$. Let this representation be denoted as $\mathcal{R}_\ell$.

All the representations $\mathcal{R}_\ell$ can be computed from $\overrightarrow{\mathcal{P}}_\ell$ and $\overleftarrow{\mathcal{P}}'_\ell$ in $\mathcal{O}(n + \sum_\ell(|\overrightarrow{\mathcal{P}}_\ell| + |\overleftarrow{\mathcal{P}}_\ell|))$ total time. Let us bucket sort all endpoints of intervals in $\overrightarrow{\mathcal{P}}_\ell$ and $\overleftarrow{\mathcal{P}}'_\ell$, for each ℓ. When processing the endpoints for a given ℓ, we keep track of the number of intervals containing a given position. This counter never exceeds 2 as intervals in each of $\overrightarrow{\mathcal{P}}_\ell$ and $\overleftarrow{\mathcal{P}}'_\ell$ are pairwise disjoint. Whenever the counter reaches 2, for some endpoint a, it will drop at the next endpoint encountered, say b. Then $[a\,..\,b)$ is inserted into $\mathcal{R}_\ell$.

The next claim shows that, for each interval in $\mathcal{R}_\ell$, all positions correspond to p-squares of length 2ℓ or none of them does.

▷ Claim 24. Let $[a\,..\,b] \in \mathcal{R}_\ell$. For each $i \in [a\,..\,b]$, $T[i\,..\,i+2\ell)$ is a p-square if and only if $T[a\,..\,a+2\ell)$ is a p-square.

Proof. Let us fix $i \in [a\,..\,b]$. Let $[a'\,..\,b'] \in \overrightarrow{\mathcal{P}}_\ell$ and $[a''\,..\,b''] \in \overleftarrow{\mathcal{P}}'_\ell$ be intervals such that $[a\,..\,b] = [a'\,..\,b'] \cap [a''\,..\,b'']$.

Assume first that $T[a\,..\,a+2\ell)$ is a p-square. As $\overrightarrow{\mathcal{P}}_\ell$ was computed from uniform σ-runs, we have $\overrightarrow{T}[a'+2\ell\,..\,b'+2\ell) = \overrightarrow{T}[a'+\ell\,..\,b'+\ell)$, so $\overrightarrow{T}[a+2\ell\,..\,i+2\ell) = \overrightarrow{T}[a+\ell\,..\,i+\ell)$. By Lemma 21 applied for each subsequent position in $[a\,..\,i)$, $T[i\,..\,i+2\ell)$ is a p-square.

Now assume that $T[i\,..\,i+2\ell)$ is a p-square. As $[a''\,..\,b''] \in \overleftarrow{\mathcal{P}}'_\ell$, $[n-b''-2\ell\,..\,n-a''-2\ell] \in \overleftarrow{\mathcal{P}}_\ell$. By definition, we have $(\overleftarrow{T})^R[n-b''\,..\,n-a'') = (\overleftarrow{T})^R[n-b''-\ell\,..\,n-a''-\ell)$, i.e., $\overleftarrow{T}[a''\,..\,b'') = \overleftarrow{T}[a''+\ell\,..\,b''+\ell)$. In particular, $\overleftarrow{T}[a\,..\,i) = \overleftarrow{T}[a+\ell\,..\,i+\ell)$. By Lemma 21 applied for each position in $[a+1\,..\,i]$ in decreasing order, $T[a\,..\,a+2\ell)$ is a p-square. ◁

By Corollary 15 and Lemmas 18 and 19, after $\mathcal{O}(n\sigma)$ preprocessing we can check if a given even-length substring of T is a p-square in $\mathcal{O}(1)$ time using an $\mathsf{LCP}^{\approx}$ query. For each $\ell \in [1\,..\,\lfloor n/2 \rfloor]$ and each interval $[a\,..\,b] \in \mathcal{R}_\ell$, we check if $T[a\,..\,a+2\ell)$ is a p-square. By Claim 24, if so, we obtain an interval of occurrences of p-squares, and if not, then none of the positions in $[a\,..\,b]$ is the start of a p-square of length 2ℓ in T. The total number of intervals in $\mathcal{R}_\ell$ is linear in the number of uniform σ-runs in $\overrightarrow{T}$ and $\overleftarrow{T}$, so we obtain $\mathcal{O}(r)$ intervals of occurrences of p-squares. By Claim 23, we do not miss any p-squares.

The final step of reporting non-equivalent p-squares mimics an analogous algorithm for standard squares of Bannai, Inenaga, and Köppl [4]. We report non-equivalent p-squares at their leftmost occurrence in T and use the $\mathsf{LPF}^{\approx}$ array to identify them in intervals of

occurrences. More precisely, we compute the $\mathsf{LPF}^{\approx}$ array in $\mathcal{O}(n\sigma)$ time and construct in $\mathcal{O}(n)$ time a data structure for answering Range Minimum Queries (RmQs) over $\mathsf{LPF}^{\approx}$ in $\mathcal{O}(1)$ time per query; see [5, 25]. For each of the $\mathcal{O}(r)$ intervals $[a\,..\,b]$ of starting positions of p-squares of length 2ℓ, we want to list all positions $i \in [a\,..\,b]$ such that $\mathsf{LPF}^{\approx}[i] < 2\ell$ and report corresponding leftmost occurrences of p-squares $T[i\,..\,i+2\ell)$. We ask an RmQ on $\mathsf{LPF}^{\approx}$ on the interval $[a\,..\,b]$; let the minimum be attained for $i \in [a\,..\,b]$. If $\mathsf{LPF}^{\approx}[i] \geq 2\ell$, the algorithm is finished. Otherwise, we report $T[i\,..\,i+2\ell)$ and run the algorithm recursively on intervals $[a\,..\,i-1]$ and $[i+1\,..\,b]$. The total time complexity is proportional to the number of reported p-squares plus 1. By [24], T contains $\mathcal{O}(n\sigma)$ non-equivalent p-squares. This completes an $\mathcal{O}(n\sigma + r)$-time reduction to computing uniform σ-runs.

When reporting all p-squares that are distinct as strings, it suffices to replace the $\mathsf{LPF}^{\approx}$ array with the standard $\mathsf{LPF} = \mathsf{LPF}^{=}$ array. Such an array can be computed in $\mathcal{O}(n)$ time after the letters of the string have been sorted [12]. Then the computations take $\mathcal{O}(n\sigma + r + \mathsf{output})$ time. ◀

By Theorem 12, string $\overrightarrow{T}$ (and $\overleftarrow{T}$) contains $\mathcal{O}(n\sigma \log \sigma)$ uniform σ-runs. They can be computed in $\mathcal{O}(n\sigma \log \sigma)$ time; we use the algorithm of Kolpakov and Kucherov [34, 35] to compute all σ-runs in $\overrightarrow{T}$ and then partition each σ-run to uniform σ-runs using kangaroo jumps. That is, let $\overrightarrow{T}[a\,..\,b)$ be a σ-run with period. We compute two values:

$$d_1 = 1 + \mathsf{LCP}(\overrightarrow{T}[a\,..\,b-2\ell), \overrightarrow{T}[a+\ell\,..\,b-\ell))$$
$$d_2 = 1 + \mathsf{LCP}(\overrightarrow{T}[a+\ell\,..\,b-\ell), \overrightarrow{T}[a+2\ell\,..\,b))$$

that, intuitively, find the first ℓ-mismatching position in the σ-run, if any (d_1), and the first ℓ-mismatching position after position $a+\ell-1$, if any (d_2). Let $d = \min(d_1, d_2)$. We then report a uniform σ-run $\overrightarrow{T}[a\,..\,a+d+2\ell)$ and continue processing the (non-maximal) σ-run $\overrightarrow{T}[a+d\,..\,b)$ until its length drops below 2ℓ. The LCP-queries in $(\overrightarrow{T})^R$ are answered in $\mathcal{O}(1)$ time [5, 25]. Thus Lemma 22 implies Theorem 2.

5 Counting Generalised Squares in $\mathcal{O}(n \log n)$ Time

In this section we show an algorithm that counts non-equivalent $\approx$-squares, for an SCER $\approx$ with encoding function $\mathcal{E}$, in $\mathcal{O}(\pi^{\mathcal{E}}(n) + n\rho^{\mathcal{E}}(n) + n \log n)$ time.

For a string T of length n and positive integer $p \leq n/2$, we denote

$$\mathsf{Squares}_p^{\approx} = \{i \in [1\,..\,n-2p+1] : T[i\,..\,i+2p) \text{ is an } \approx\text{-square}\}.$$

An *interval representation* of a set X of integers is $X = [i_1\,..\,j_1] \cup [i_2\,..\,j_2] \cup \cdots \cup [i_t\,..\,j_t]$, where $j_1 + 1 < i_2, \ldots, j_{t-1} + 1 < i_t$; t is called the *size* of the representation.

Counterparts of the following lemma corresponding to order-preserving squares and Cartesian-tree squares were shown in [21] and [44], respectively. Our proof generalises these proofs; it can be found in the full version.

▶ **Lemma 25.** *Let $\approx$ be an SCER and $\mathcal{E}$ be its encoding function. Given a string T of length n, the interval representations of the sets $\mathsf{Squares}_p^{\approx}$ for all $1 \leq p \leq n/2$ have total size $\mathcal{O}(n \log n)$ and can be computed in $\mathcal{O}(\pi^{\mathcal{E}}(n) + n\rho^{\mathcal{E}}(n) + n \log n)$ time.*

We count non-equivalent $\approx$-squares using the $\mathsf{LPF}^{\approx}$ array. We would like to count an $\approx$-square at the position of its leftmost occurrence. For an integer array $A[1\,..\,n]$, we denote a range count query for $i, j \in [1\,..\,n]$, $x \in \mathbb{Z}$ as $\mathsf{RangeCount}_A(i, j, x) = |\{k \in [i\,..\,j] : A[k] < x\}|$.

Then our problem reduces to computing the sum

$$\sum_{p=1}^{\lfloor n/2 \rfloor} \sum_{[i..j] \in \mathsf{Squares}_p} \mathsf{RangeCount}_{\mathsf{LPF}^{\approx}}(i, j, 2p). \tag{4}$$

We say that an array $A[1..n]$ is a *linear oscillation array* if $\sum_{i=1}^{n-1} |A[i+1] - A[i]| = \mathcal{O}(n)$. The following fact is folklore for the LPF array; we prove it for $\mathsf{LPF}^{\approx}$ in the full version.

▶ **Lemma 26.** *For any SCER $\approx$, $\mathsf{LPF}^{\approx}$ is a linear oscillation array.*

We will now show that the sum from Equation (4) can be computed in $\mathcal{O}(n \log n)$ time. We use a very simple abstract problem.

Counting Problem
Input: A set $Y \subseteq [1..n]$, initially empty, and an integer ℓ, initially $\ell = 0$.
Operation: One of: (1) insert an element $x \in [1..n]$ to Z; (2) delete an element $x \in Y$ from Y; (3) increment ℓ by 1; (4) decrement ℓ by 1. After each operation, output $|Y \cap [\ell+1..n]|$.

The Counting Problem can be solved with a basic indicator array for Y.

▶ **Lemma 27.** *After $\mathcal{O}(n)$-time preprocessing, each operation in the Counting Problem can be answered in $\mathcal{O}(1)$ time.*

Proof. We store an indicator array of bits $C[1..n]$ such that $C[i] = 1$ if and only if $i \in Y$. Initially, $C \equiv 0$. We also store a value $a = |Y \cap [\ell + 1..n]|$; initially $a = 0$. After each operation, the current value of a is returned.

When we insert an element $x \in [1..n]$ to Y, we set $C[x]$ to 1 and increment a if $x > \ell$. Symmetrically, when we delete $x \in Y$ from Y, we set $C[x]$ to 0 and decrement a if $x < \ell$. When we increment ℓ, we subtract $C[\ell]$ from a. When we decrement ℓ, we add $C[\ell]$ to a. ◀

We are ready to obtain the final main result.

Proof of Theorem 5. First we show how to compute the number of non-equivalent $\approx$-squares in a length-n string. The $\mathsf{LPF}^{\approx}$ array can be computed in $\mathcal{O}(\pi^{\mathcal{E}}(n) + n\rho^{\mathcal{E}}(n) + n \log^2 \log n / \log \log \log n)$ time (Corollary 15). We compute the interval representations of the sets $\mathsf{Squares}_p^{\approx}$ using Lemma 25 in $\mathcal{O}(\pi^{\mathcal{E}}(n) + n\rho^{\mathcal{E}}(n) + n \log n)$ time. The interval representations have total size $\mathcal{O}(n \log n)$. We need to compute the sum of results of $\mathcal{O}(n \log n)$ $\mathsf{RangeCount}$ queries as in Equation (4). We will do it using the Counting Problem.

Let us bucket sort all start and end points of intervals across all sets $\mathsf{Squares}_p^{\approx}$ in $\mathcal{O}(n \log n)$ total time. We create an instance of the Counting Problem. For each position k from 1 to n, we proceed as follows. First, for each interval $[k..j] \in \mathsf{Squares}_p^{\approx}$, for any p, we insert $2p$ to the set Y. Then, we change the current value ℓ in the problem to $\mathsf{LPF}^{\approx}[k]$ by performing increments or decrements, as appropriate. Afterwards, we add the returned value of the Counting Problem to the final result. Finally, for each interval $[i..k] \in \mathsf{Squares}_p^{\approx}$, for any p, we delete $2p$ from the set Y.

For each $p \in [1..\lfloor n/2 \rfloor]$, the intervals in $\mathsf{Squares}_p$ are pairwise disjoint. By Lemma 25, $\mathcal{O}(n \log n)$ insertions and deletions are performed in the Counting Problem. The total number of increments and decrements is bounded by $\mathcal{O}(n)$ by Lemma 26 (and the fact that the values in this array are in $[0..n)$). In total, the sum (4) is computed in $\mathcal{O}(n \log n)$ time. We obtain the first part of Theorem 5.

As before, if one wishes to compute all $\approx$-squares that are distinct as substrings, it suffices to replace the $\mathsf{LPF}^{\approx}$ array in the algorithm by the standard $\mathsf{LPF} = \mathsf{LPF}^{=}$ array. We obtain the second part of Theorem 5. ◀

MorphisHash: Improving Space Efficiency of ShockHash for Minimal Perfect Hashing

Stefan Hermann
Karlsruhe Institute of Technology, Germany

Abstract

A minimal perfect hash function (MPHF) maps a set of n keys to unique positions $\{1, \ldots, n\}$. Representing an MPHF requires at least $\log_2(e) \approx 1.443$ bits per key. ShockHash is a technique to construct an MPHF and requires just slightly more space. It gives each key two random candidate positions. If each key can be mapped to one of its two candidate positions such that there is exactly one key mapped to each position, then an MPHF is found. If not, ShockHash repeats the process with a new set of random candidate positions. ShockHash has to store how many repetitions were required and for each key to which of the two candidate positions it is mapped. However, when a given set of candidate positions can be used as MPHF then there is not only one but multiple ways of mapping the keys to one of their candidate positions such that the mapping results in an MPHF. This redundancy makes up for the majority of the remaining space overhead in ShockHash. In this paper, we present MorphisHash which almost completely eliminates this redundancy. Our theoretical result is that MorphisHash saves $\Theta(\ln(n))$ bits in expectation compared to ShockHash. This corresponds to a factor of 20 less space overhead in practice. Just like ShockHash, MorphisHash can be used as a building block within RecSplit to obtain MorphisHash-RS. When compared for same space consumption, MorphisHash-RS can be constructed up to 21 times faster than ShockHash-RS. The technique to accomplish this might be of a more general interest to compress data structures.

1 Introduction

Given a set S of n keys, a minimal perfect hash function (MPHF) maps each key to a unique position in $[n] := \{1, \ldots, n\}$. MPHFs have a wide range of applications including compressed full-text indexes [2], computer networks [18], databases [6], prefix-search data structures [1], language models [24], bioinformatics [7, 23], and Bloom filters [5]. Different techniques exist for constructing an MPHF. They offer a variety of trade-offs between construction time, space consumption and query time. The space lower bound of an MPHF is $\log_2(e) \approx 1.443$ bits per key [19].

ShockHash. Our technique builds on ShockHash [15, 16]. Similar to Cuckoo hashing [22], each key is given two candidate positions using respective hash functions $h_{s,0} : S \to [n]$ and $h_{s,1} : S \to [n]$ with seed s. ShockHash finds a seed s such that all keys can be mapped to one of their candidate positions and there is exactly one key mapped to each position. ShockHash needs to store the seed s, once found. Additionally, it needs to store for each key $k \in S$ if the candidate position $h_{s,0}(k)$ or $h_{s,1}(k)$ is used. This can be represented using a function $f : S \to \{0, 1\}$. Such a mapping can be stored efficiently using a retrieval data structure [8] which requires about 1 bit per key. A key $k \in S$ is queried using $h_{s,f(k)}(k)$.

A different perspective on ShockHash is that with each seed s it samples a random graph. The $[n]$ possible output positions are the nodes of that graph. The keys are the edges, connecting the nodes of their respective candidate positions. A seed is accepted if the graph can be oriented, i.e. each edge is given a direction, such that the indegree of each node is 1. This is possible if and only if the graph is a *pseudoforest* – a graph where each component is a cycle with trees branching from it. The edges of the cycle of each component are oriented either all "clockwise" or "counterclockwise". The edges in the trees are uniquely oriented away from their cycle. Hence, the indegree of each node is 1. ShockHash arbitrarily chooses one of two possible orientations of each cycle and stores the according orientation of each edge in a retrieval structure. Hence, for each cycle there is one bit of redundancy.

Contribution. In this paper we introduce MorphisHash which exhausts this remaining redundancy. MorphisHash is a recursive acronym: **M**orphisHash is an **o**verloaded **r**etrieval structure for **p**erfect **h**ash**i**ng using **S**hock**Hash**. Our key observation is that the possible orientations of a pseudoforest can be described as the solution of a linear equation system. A retrieval structure that stores the edge orientations can also be described as the solution of a linear equation system. This allows us to concatenate the equation systems using matrix multiplication. We achieve compression by reducing the dimensionality of the solution space of the combined equation system. Our theoretical insight is that a random pseudoforest has $\Theta(\ln(n))$ components in expectation and MorphisHash can convert this into $\Theta(\ln(n))$ bits of expected space savings compared to ShockHash by utilizing the freedom of choosing the orientation of each component's cycle. Our experiments show that MorphisHash has about a factor of 20 less space overhead than ShockHash at the cost of roughly 4 times more construction time.

Partitioning. Note that within this paper, n denotes the input size for one instance of MorphisHash. In Section 5, an MPHF is obtained by splitting a large input key set into a linear number of MorphisHash instances, each of size n, and concatenating them afterwards. Partitioning is required mainly for keeping construction times feasible. Furthermore, our per instance space savings translate to linear space savings in terms of the large input.

Outline. We begin in Section 2 with related space efficient PHF construction techniques. We present MorphisHash in Section 3 and analyze it in Section 4. We explain implementation details in Section 5. Finally, Section 6 discusses experiments and the paper is concluded with Section 7. Our compression technique might be of a more general interest and we give further examples in the full version of this paper [11].

2 Related Work

We provide a brief overview of other space efficient PHF techniques. For a detailed survey of state-of-the-art techniques we refer to [14].

RecSplit. RecSplit [9, 3] first hashes the keys into partitions of about 2000 keys. RecSplit then finds a seed of a hash function that splits the partition into smaller subsets of equal size. This is applied recursively resulting in a tree-like structure. Once sufficiently small subsets are obtained, RecSplit uses brute-force search to find an MPHF within each leaf. Very recently a significant improvement to RecSplit has been made with the introduction of CONSENSUS [17]. Instead of allowing arbitrarily large seeds, CONSENSUS-RecSplit uses a fixed number of bits for each seed and backtracks in the splitting tree if a seed cannot be found within the allowed space. CONSENSUS-RecSplit is currently the most space efficient technique with just 0.001 bits per key overhead.

PHOBIC. Another PHF construction technique is PHOBIC [12]. Again, the keys are hashed into partitions of about 2000 keys. Within each partition the keys are hashed to buckets which have an average size of about 10. For each bucket, PHOBIC uses brute force search to find a seed of a hash function such that all keys of that bucket are hashed to positions in $[n]$ to which no keys of previous buckets are hashed to. The buckets are inserted in non-increasing order of size because it is much easier to insert the larger buckets when the output domain is almost empty. This effect is utilized further by intentionally making some of the buckets larger. PHOBIC has fast queries at the cost of more space overhead.

3 MorphisHash

ShockHash samples random graphs until stumbling on a pseudoforest. The only remaining degree of freedom when orienting the pseudoforest is that each component contains a cycle and there are two ways to orient each cycle. We address this remaining redundancy with MorphisHash.

The first ingredient of MorphisHash is the insight that all allowed orientations of a graph can be expressed as an affine subspace of $\mathbb{F}_2^S$, where S is the set of n keys. To show this, we define $y \in \mathbb{F}_2^S$ as the vector representing the orientation of each edge such that an edge $j \in S$ is oriented to node $h_{s,y_j}(j)$. We now consider a given pseudoforest and one possible orientation y. We can flip the orientation of a cycle by adding a vector $v \in \mathbb{F}_2^S$ to y where $v_j = 1$ if and only if j is part of that cycle. This can be done for each cycle independently. Clearly, the dimension of this subspace is equal to the number of components. Part of this section is to describe the linear equation system of which the solution space is our desired affine subspace.

The second ingredient is a 1-bit retrieval data structure. The retrieval structure works by storing a bit vector $x \in \mathbb{F}_2^b$, where the parameter $b \in \mathbb{N}_0$ is discussed in detail later. The orientation of an edge $j \in S$ is described using $h'_s(j)x$, where $h'_s : S \to \mathbb{F}_2^{1\times b}$ is a hash function and s is the ShockHash seed. Using linear equations that involve hash functions is a common technique for retrieval data structures [8].

The beauty of MorphisHash is that we can concatenate both linear equation systems using a simple matrix multiplication to find a retrieval structure which directly orients the edges correctly. We can then decrease the number of bits b that the retrieval structure is allowed to use which reduces the dimension of the solution space and therefore extracts the remaining redundancy.

We now show the equation system that describes the allowed edge orientations. As a first step we show that the constraints of an MPHF can be weakened in the following sense:

▶ **Lemma 1.** *A function $f : S \to [n]$ with $|S| = n$ is an MPHF (i.e. a bijection) if and only if for all $i \in [n]$ we have that $|\{f^{-1}(i)\}|$ is uneven.*

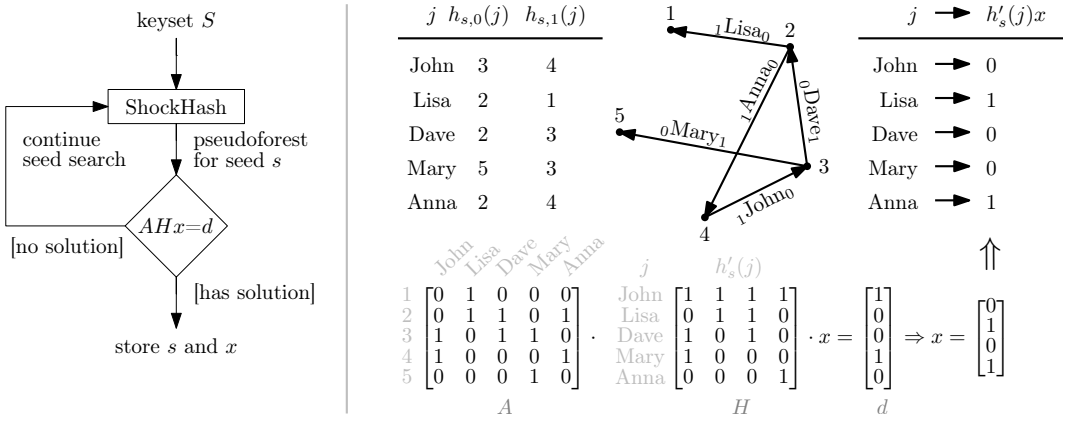

Figure 1 Left: MorphisHash uses ShockHash as a black box. Right: An example. ShockHash has found a pseudoforest using the candidate positions $h_{s,0}$ and $h_{s,1}$ as shown in the table and also illustrated as a graph. The description ${}_1\text{Lisa}_0$ indicates that $h_{s,1}$ is the left candidate and $h_{s,0}$ the right. This can be used to find d. For example, $d_3 = 0^{\text{Dave}} + 0^{\text{Mary}} + 1^{\text{John}} + 1^{\text{offset}} = 0$. The incidence matrix A and some random matrix H is shown. A solution x is found resulting in the orientations as shown both in the right table and using arrows in the graph. The solution x describes the orientation of 5 edges but only requires 4 bits to store. The figure is derived from [16, Fig. 1].

Proof. Clearly, if f is bijective then $|\{f^{-1}(i)\}| = 1$ is uneven. If f is not bijective then there is at least one i such that $|\{f^{-1}(i)\}| = 0$ which is even. ◀

Linear Equations in Graphs. This allows us to count the indegree of each node using $\mathbb{F}_2$: If the indegree of all nodes is $1_{\mathbb{F}_2}$ then the orientations result in a valid MPHF. Recall the definition of $y \in \mathbb{F}_2^S$ as the vector representing the orientation of each edge such that an edge $j \in S$ is oriented to node $h_{s,y_j}(j)$. A different perspective is that an edge j is oriented towards a node i if and only if $(h_{s,1}(j) = i \wedge y_j = 1) \vee (h_{s,0}(j) = i \wedge y_j + 1 = 1)$, which will be useful in the following equation. We define $A \in \mathbb{F}_2^{n \times S}$ as the incidence matrix of the graph. We also define $d \in \mathbb{F}_2^n$ where $d_i = |\{j \mid h_{s,0}(j) = i\}| + 1$ counts the number of edges $(+1)$ that are mapped to position i using the $h_{s,0}$ candidate function. Finally, this allows us to count the indegree of a node i as

$$\sum_{h_{s,1}(j)=i} y_j + \sum_{h_{s,0}(j)=i} (1 + y_j) = \Big(\sum_{\substack{h_{s,0}(j)=i \\ \oplus h_{s,1}(j)=i}} y_j \Big) + d_i + 1 = A_i y + d_i + 1$$

The $\oplus$ operator is logical XOR. According to Lemma 1 setting $A_i y + d_i + 1 = 1$ such that the indegree of each node i is uneven results in a valid orientation of all edges. The complete equation system therefore simplifies to $Ay = d$, which has a solution if and only if the graph is a pseudoforest. Note that in case of a loop, the respective column in the incidence matrix is a zero column.

The Retrieval Data Structure. To store the orientation of the edges we cannot use y directly because we do not know the index of a key during query time. We therefore employ the idea of a retrieval structure. Our retrieval structure consists of a bit vector $x \in \mathbb{F}_2^b$, where b is a tuning parameter. The orientation of edge j is then described using a scalar product $y_j = h'_s(j)x$ where $h'_s : S \to \mathbb{F}_2^{1 \times b}$ is a hash function and s is the ShockHash seed. MorphisHash needs to find x such that all edges are properly oriented. The above linear

equation is given for each key and can therefore be written using a matrix H. Each row H_j is the hash $h'_s(j)$ of the respective key j. We have $y = Hx$ and substitute it into $Ay = d$ resulting in $AHx = d$. If a solution x for $AHx = d$ exists then the graph is a pseudoforest, $y = Hx$ is a valid orientation and x requires exactly b bits to store using a bit string. We discuss the selection of b both in theory (Section 4) and practice (Section 6). Querying our MPHF for a key j is now straightforward $h_{s,h'_s(j)x}(j)$.

If the system $AHx = d$ does not have a solution for a sampled graph this can have two reasons. (1) The graph is no pseudoforest (2) A possible orientation of the pseudoforest is not within the solution space of the retrieval structure. If there is no solution we reject the seed and ShockHash continues with searching for a new seed.

The already existing step in ShockHash of checking whether a seed is a pseudoforest is therefore redundant. However, solving an equation system is computationally more expensive than using the original ShockHash pseudoforest check. We therefore leave the original pseudoforest check as a filter and only need to solve $AHx = d$ a few times in practice. MorphisHash is illustrated using an example in Figure 1.

Bipartite MorphisHash. A variant of ShockHash is bipartite ShockHash. Assume that n is even, the extension for uneven numbers can be found in the original paper [15]. In bipartite ShockHash, the ranges of the two hash functions are made disjoint using $h_{s_0,0} : S \to \{1, \ldots, \frac{n}{2}\}$ and $h_{s_1,1} : S \to \{\frac{n}{2} + 1, \ldots, n\}$. The seed is also split in two independent parts s_0 and s_1. Seeds where not all positions are hit by at least one candidate position are filtered out. Bipartite ShockHash only checks if pairs of s_0 and s_1 that passed the filter result in a pseudoforest. MorphisHash uses ShockHash as a black box and can be applied on the bipartite case just as well as on the non-bipartite case. In an obvious manner, we refer to bipartite MorphisHash if bipartite ShockHash is used.

4 Analysis

In this section we analyze non-bipartite MorphisHash for large n. Our analysis is split in two parts. First, we analyze the number of components of a random pseudoforest. We use this in the second part, to show the space efficiency of MorphisHash compared to ShockHash. Note that we employ the common simple uniform hashing assumption [21], which assumes that hash functions behave like truly random functions.

4.1 The Number of Components in a Random Pseudoforest

In a pseudoforest each component is a tree with one additional edge. An equivalent view is that each component of the pseudoforest is a cycle with trees branching from it.

Our first result uses the following graph model. Let $R = [n]^{[n]}$ be the set of all functions from $[n]$ to $[n]$. Every $r \in R$ corresponds to a directed graph $G_r = ([n], \{(v, r(v)) \mid v \in [n]\})$. All G_r are pseudoforests, because if we start from any node and follow its edges we will eventually end up in a cycle. Furthermore, there can only be one cycle in each component because each node has an out-degree of one. In the following we refer to all G_r as *maximal directed pseudoforests*. All edges of the pseudoforest which are not part of the cycle are pointed towards the cycle and all edges in the cycle are all directed in the same direction. We will first need the following results.

▶ **Lemma 2** ([25]). *Let $T(n, i)$ be the number of undirected forests having node set $[n]$ with i components where nodes $1, 2, \ldots, i$ belong to different trees. We have $T(n, i) = in^{n-i-1}$.*

▶ **Lemma 3.** $|\{r \in R \mid \text{all components in } G_r \text{ are cycles}\}| = n!$

Proof. If each node in G_r is part of a cycle then the indegree of each node is 1. Hence, r is a bijection and there are $n!$ possible bijections. ◀

We can now combine the previous results to analyze how the number of nodes in cycles is distributed in maximal directed pseudoforests.

▶ **Lemma 4.** $|\{r \in R \mid G_r \text{ is pseudoforest and has } i \text{ nodes in cycles}\}| = \frac{in^{n-1-i}n!}{(n-i)!}$.

Proof. There are $\binom{n}{i}$ ways of partitioning the nodes into (1) cycles with a total of i nodes and (2) trees that are attached to the cycles. According to Lemma 3 there are $i!$ ways to create cycles with i nodes. The i nodes in the cycles are the roots of trees. According to Lemma 2 the number of labeled rooted trees with n nodes and i roots is in^{n-i-1} . This number holds for graphs where each node has one outgoing edge, because all edges are uniquely oriented towards their parent node. We therefore have

$$\binom{n}{i} i! i n^{n-i-1} = \frac{n!}{i!(n-i)!} i! i n^{n-i-1} = \frac{i n^{n-1-i} n!}{(n-i)!}$$ ◀

The previous result is based on maximal directed pseudoforests. However, in MorphisHash we sample graphs in a different manner. Let $Q = [n]^{S \times \{0,1\}}$ be the set of functions from $S \times \{0,1\}$ to $[n]$. Each $q \in Q$ corresponds to a graph $G_q = ([n], \{\{q(x,0), q(x,1)\} \mid x \in S\})$. We refer to the set of all G_q as the *hashed* graph model. Graphs in this model may have multiple edges and loops. MorphisHash uniformly samples functions $q \in Q$. We are interested in the distribution of G_q conditioned on the event that G_q is a pseudoforest. In the following, we transfer our result of maximal directed pseudoforests to the hashed graph model.

▶ **Lemma 5.** *Let $c(G)$ be the number of components of G, C_n an appropriate normalization constant, $q \sim \mathcal{U}(Q)$ and $r \sim \mathcal{U}(R)$ then*

$$\begin{aligned} p_n(i) :=& \mathbb{P}[G_q \text{ has } i \text{ nodes in cycles} \mid G_q \text{ is pseudoforest}] \\ =& C_n \mathbb{E}[2^{-c(G_r)} \mid G_r \text{ has } i \text{ nodes in cycles}] \frac{i}{n^i (n-i)!} \end{aligned}$$

Proof. We begin with a relation between maximal directed pseudoforests G_r and hashed pseudoforests G_q. A hashed pseudoforest G_q is related to a maximal directed pseudoforest G_r if we can obtain G_r by orienting the edges of G_q. Let $a_{k,d,l}$ be the number of maximal directed pseudoforests and $b_{k,d,l}$ the number of hashed pseudoforest with i nodes in cycles, k components, d double edges and l loops. Within this subset, each cycle of the hashed graph can be oriented in two possible ways to obtain a maximal directed pseudoforest. However, changing the orientation of cycles that are a loop or double edge does not result in different maximal directed pseudoforests. Hence, we have $\frac{a_{k,d,l}}{b_{k,d,l}} = 2^{k-d-l}$ orientations which result in different maximal directed pseudoforest.

Let $c_{k,d,l}$ be the number of elements $q \in Q$ such that G_q is a pseudoforest with i nodes in cycles, k components, d double edges and l loops. We show that $\frac{c_{k,d,l}}{b_{k,d,l}} = n! 2^{n-d-l}$. We have to consider the number of functions in Q that result in the same hashed pseudoforest. The order of the edges can be permuted in $n!$ ways without changing the underlying pseudoforest, except for double edges. The number of possible permutations decreases by a factor of two for each double edge (2^{-d}). Analogously, the nodes within the n edges can be switched without changing the underlying graph in 2^n ways, except for loops (2^{-l}).

By definition we have $|Q_i| = \sum_{k,d,l} c_{k,d,l}$ and $|R_i| = \sum_{k,d,l} a_{k,d,l}$, where $Q_i \subset Q$ and $R_i \subset R$ are the pseudoforests with i nodes in cycles. For brevity let

$$p_{k,d,l} := \frac{a_{k,d,l}}{|R_i|} = \mathbb{P}[G_r \text{ has } k \text{ components, } d \text{ double edges and } l \text{ loops} \mid G_r \text{ has } i \text{ nodes cycles}]$$

We have

$$\begin{aligned}
p_n(i) &= \frac{|Q_i|}{\sum_j |Q_j|} = \frac{|R_i|}{\sum_j |Q_j|} \frac{\sum_{k,d,l} c_{k,d,l}}{|R_i|} = \frac{|R_i|}{\sum_j |Q_j|} \sum_{k,d,l} \frac{a_{k,d,l} c_{k,d,l}}{a_{k,d,l}|R_i|} \\
&= \frac{|R_i|}{\sum_j |Q_j|} \sum_{k,d,l} p_{k,d,l} \frac{c_{k,d,l}}{a_{k,d,l}} = \frac{|R_i|}{\sum_j |Q_j|} \sum_{k,d,l} p_{k,d,l} \frac{c_{k,d,l}}{b_{k,d,l}} \frac{b_{k,d,l}}{a_{k,d,l}} \\
&= \frac{|R_i|}{\sum_j |Q_j|} \sum_{k,d,l} p_{k,d,l} n! 2^{n-d-l} 2^{-k+d+l} = \frac{|R_i| n! 2^n}{\sum_j |Q_j|} \sum_{k,d,l} p_{k,d,l} 2^{-k} \\
&= \frac{|R_i| n! 2^n}{\sum_j |Q_j|} \mathbb{E}[2^{-c(G_r)} \mid G_r \text{ has } i \text{ nodes in cycles}] \\
&= C_n \mathbb{E}[2^{-c(G_r)} \mid G_r \text{ has } i \text{ nodes in cycles}] \frac{i}{n^i (n-i)!}
\end{aligned}$$

Where we used Lemma 4 for $|R_i|$. $\sum_j |Q_j|$ is the number of all hashed pseudoforests and thus only depends on n. C_n is chosen such that the probabilities add up to 1. ◀

The next step is to analyze $\mathbb{E}[2^{-c(G_r)} \mid G_r \text{ has } i \text{ nodes in cycles}]$. To this end, we first require some definitions and more general results.

▶ **Lemma 6.** *The number of components of a pseudoforest with n nodes and i nodes in cycles follows the same distribution as the number of components of a graph of i nodes where each component is a cycle.*

Note that this refers to both graph models G_r and G_q.

Proof. The order in which the edges of a graph are sampled does not change the distribution of the graph. Given a graph of n nodes and i edges such that all edges are part of cycles, the probability that the remaining $n - i$ edges form trees with the root being part of the existing cycles is independent of how the nodes of the cycles are connected to form any number of components. ◀

Configuration Model. The *configuration model* [20] can be used to describe distributions of random graphs. In the model, each node is given a fixed number of half-edges. The graph is obtained by repeatedly connecting half-edges by uniformly sampling from the set of all remaining half-edges.

▶ **Lemma 7.** *The distribution of the hashed graph G_q with $q \sim \mathcal{U}(Q)$ is equal to the distribution of the following graph.*

The graph is obtained in two steps. First, the degree of each node is revealed by distributing $2n$ half-edges. In a second step, the edges of the graph are obtained in a sequence of n rounds. In each round an unmatched half-edge $i \in [2n]$ is chosen arbitrarily and matched to a distinct unmatched half-edge $j \in [2n]$, chosen uniformly at random. The choice of i may depend on the set of half-edges matched previously.

We refer to ShockHash [15, Lemma 5] for a proof. We require an analogous result for G_r

▶ **Lemma 8.** *The distribution of the maximal directed pseudoforest G_r with $r \sim \mathcal{U}(R)$ is equal to the distribution of the following directed graph.*

The number of outgoing edges of each node is fixed to 1. The graph is obtained in two steps. First, the indegree of each node is revealed by distributing n incoming half-edges. In a second step, the edges of the graph are obtained in a sequence of n rounds. In each round an unmatched outgoing half-edge at node $i \in [n]$ is chosen arbitrarily and matched to a distinct unmatched incoming half-edge $j \in [n]$, chosen uniformly at random. The choice of i may depend on the set of half-edges matched previously.

Again, the proof is analogous to ShockHash [15, Lemma 5].

▶ **Lemma 9.** *For $i \in \mathbb{N}$: $\prod_{k=2}^{i}(1-\frac{1}{k}) = \frac{1}{i}$*

Proof. By induction $\prod_{k=2}^{1}(1-\frac{1}{k}) = 1$ and

$$\prod_{k=2}^{i+1}(1-\frac{1}{k}) = (1-\frac{1}{i+1})\prod_{k=2}^{i}(1-\frac{1}{k}) = (1-\frac{1}{i+1})\frac{1}{i} = \frac{1}{i+1}$$ ◀

We now have the available tools to analyze the number of components conditioned on the number of nodes in cycles.

▶ **Lemma 10.** $\frac{1}{4}i^{-1/2} \leq \mathbb{E}[2^{-c(G_r)} \mid G_r \text{ has } i \text{ nodes in cycles}] \leq i^{-1/2}$, *where $r \sim \mathcal{U}(R)$ and $c(G_r)$ is the number of components of G_r.*

Note that the following proof has similarities to ShockHash [15, Lemma 6].

Proof. We consider the number of components of a maximal directed pseudoforest G_r^i with i nodes, $R = [i]^{[i]}$, $r \sim \mathcal{U}(R)$, conditioned on the event that each component of G_r^i is a cycle. According to Lemma 6 the number of components of G_r^i follows the same distribution as the number of components of a maximal directed pseudoforest with n nodes and i nodes in cycles. We proceed as described in Lemma 8 by revealing the graph in a sequence of rounds. First, the indegree of each node is revealed. Each component is a circle and therefore each node has indegree one. We choose the outgoing half-edge at an arbitrary node x. The outgoing half-edge is matched with one of the i incoming half-edges. Let y be the node at the incoming half-edge. There are two cases.

1. With probability $\frac{1}{i}$ we have $x = y$. In this case, a loop is created, a cycle is closed and the next outgoing half-edge to match is chosen arbitrarily.
2. Otherwise we merge the nodes to a single one which does not change the number of components. The outgoing half-edge at node y is matched next.

In both cases, the distribution of the remaining graph is that of G_r^{i-1}. Because of this independence, we can multiply the expectation values to obtain the recurrence

$$\mathbb{E}[2^{-c(G_r^i)}] = \frac{1}{2}\frac{1}{i}\mathbb{E}[2^{-c(G_r^{i-1})}] + \left(1-\frac{1}{i}\right)\mathbb{E}[2^{-c(G_r^{i-1})}] = \left(1-\frac{1}{2i}\right)\mathbb{E}[2^{-c(G_r^{i-1})}]$$

With the base case $\mathbb{E}[2^{-c_0}] = 1$ the recurrence is solved and upper bounded by

$$\begin{aligned}\mathbb{E}[2^{-c(G_r^i)}] &= \prod_{k=1}^{i} 1-\frac{1}{2k} = \sqrt{\prod_{k=1}^{i}\left(1-\frac{1}{2k}\right)^2} \leq \sqrt{\prod_{k=1}^{i}\left(1-\frac{1}{2k}\right)\left(1-\frac{1}{2k+1}\right)} \\ &= \sqrt{\prod_{k=2}^{2i+1}\left(1-\frac{1}{k}\right)} = \sqrt{\frac{1}{2i+1}} \leq i^{-1/2}\end{aligned}$$

Where we used Lemma 9. Analogously, a lower bound is

$$\begin{aligned}\mathbb{E}[2^{-c(G_r^i)}] &= \sqrt{\left(1-\frac{1}{2}\right)^2 \prod_{k=2}^{i}\left(1-\frac{1}{2k}\right)^2} = \frac{1}{2}\sqrt{\prod_{k=2}^{i}\left(1-\frac{1}{2k}\right)^2} \\ &\geq \frac{1}{2}\sqrt{\prod_{k=2}^{i}\left(1-\frac{1}{2k-1}\right)\left(1-\frac{1}{2k-2}\right)} \geq \frac{1}{2}\sqrt{\prod_{k=2}^{2i}\left(1-\frac{1}{k}\right)} \\ &= \frac{1}{2}\sqrt{\frac{1}{2i}} \geq \frac{1}{4}i^{-1/2}\end{aligned}$$

◀

A similar result for hashed pseudoforests instead of maximal directed pseudoforests is the following.

▶ **Lemma 11.** *$\mathbb{P}[c(G_q) \geq \frac{1}{4}\ln(i) \mid G_q$ is pseudoforest with i nodes in cycles$] \in \Omega_{i\to\infty}(1)$, where $q \sim \mathcal{U}(Q)$ and $c(G_q)$ is the number of components of G_q.*

Proof. The proof is analogous to the previous one. We use Lemma 7 to match a half-edge to one of the remaining $2i-1$ half-edges. In each round the number of components increases by one with probability $\frac{1}{2i-1}$. Resolving the respective recurrence results in

$$\begin{aligned}&\mathbb{E}[c(G_q) \mid G_q \text{ is pseudoforest with } i \text{ nodes in cycles}] \\ =\ & (\frac{1}{2i-1}+\frac{1}{2i-3}+\frac{1}{2i-5}+\frac{1}{2i-7}+\ldots+\frac{1}{3}+1) \\ =&\frac{1}{2}(\frac{1}{2i-1}+\frac{1}{2i-1}+\frac{1}{2i-3}+\frac{1}{2i-3}+\ldots+1+1) \\ >&\frac{1}{2}(\frac{1}{2i-0}+\frac{1}{2i-1}+\frac{1}{2i-2}+\frac{1}{2i-3}+\ldots+\frac{1}{2}+1) \\ =&\frac{1}{2}H_{2i} > \frac{1}{2}\ln(i)\end{aligned}$$

Where H_k is the k-th harmonic number. We are interested in a lower bound for the probability that the number of components is at least $\frac{1}{4}\ln(i)$. We can use the variance to find such a bound. The probability distribution of the number of components can be described in terms of a Poisson binomial distribution. The variance of a Poisson binomial distribution can be bounded above by the expected value. Clearly, $H_{2r} < \ln(3i)$ is an upper bound for the variance. Using Cantelli's inequality ($\mathbb{P}[X \geq \mathbb{E}[X]+x] \geq \frac{x^2}{x^2+\sigma^2}$) we find with $x = -\frac{1}{4}\ln(i)$ that with probability $\frac{(\frac{1}{4}\ln(i))^2}{(\frac{1}{4}\ln(i))^2+\ln(3i)} \in \Omega(1)$ the pseudoforest has at least $\frac{1}{4}\ln(i)$ components. ◀

The previous result shows that the number of components increases logarithmically in the number of nodes in cycles. The next step is therefore to show that the cycles are sufficiently large.

▶ **Lemma 12.** *$\mathbb{P}[G_q$ has at least $\sqrt{n}$ nodes in cycles $\mid G_q$ is pseudoforest$] \in \Omega_{n\to\infty}(1)$, where $q \sim \mathcal{U}(Q)$.*

Proof. Let $p_n(i)$ be the probability of sampling a hashed pseudoforest with i nodes in cycles as determined in Lemma 5. We need to show that the probability of sampling a pseudoforest with at least $\sqrt{n}$ nodes in cycles is at least a constant factor larger than sampling a pseudoforest with less than $\sqrt{n}$ nodes in cycles, i.e. $\left(\sum_{i=\sqrt{n}}^{n} p_n(i)\right) / \left(\sum_{i=1}^{\sqrt{n}} p_n(i)\right) \in \Omega(1)$.

A stronger statement is $\left(\sum_{i=\sqrt{n}}^{2\sqrt{n}} p_n(i)\right) / \left(\sum_{i=1}^{\sqrt{n}} p_n(i)\right) \in \Omega(1)$. In the following we show $\frac{p_n(\sqrt{n}+x)}{p_n(\sqrt{n}-x)} \in \Omega(1)$ for all $0 \leq x \leq \sqrt{n}$. This pointwise comparison is an even stronger statement. For brevity, we omit rounding of $\sqrt{n}$. Using the bounds of Lemma 10 and Stirling's approximation we have:

$$
\begin{aligned}
&\frac{p_n(\sqrt{n}+x)}{p_n(\sqrt{n}-x)} \geq \frac{1}{4}\frac{(\sqrt{n}-x)^{1/2}}{(\sqrt{n}+x)^{1/2}} \cdot \frac{\sqrt{n}+x}{\sqrt{n}-x} \cdot \frac{n^{\sqrt{n}-x}}{n^{\sqrt{n}+x}} \cdot \frac{(n-\sqrt{n}+x)!}{(n-\sqrt{n}-x)!} \\
&= \frac{1}{4}\left(\frac{\sqrt{n}+x}{\sqrt{n}-x}\right)^{1/2} \cdot n^{-2x} \cdot \sqrt{\frac{n-\sqrt{n}+x}{n-\sqrt{n}-x}} \cdot \frac{e^{n-\sqrt{n}-x}}{e^{n-\sqrt{n}+x}} \cdot \frac{(n-\sqrt{n}+x)^{n-\sqrt{n}+x}}{(n-\sqrt{n}-x)^{n-\sqrt{n}-x}} \\
&> \frac{1}{4}n^{-2x} \cdot e^{-2x} \cdot \left(\frac{n-\sqrt{n}+x}{n-\sqrt{n}-x}\right)^{n-\sqrt{n}} \cdot \big((n-\sqrt{n}+x)(n-\sqrt{n}-x)\big)^{x} \\
&= \frac{1}{4}e^{-2x} \cdot \left(\frac{1+\frac{x}{n-\sqrt{n}}}{1-\frac{x}{n-\sqrt{n}}}\right)^{n-\sqrt{n}} \cdot \left(\frac{(n-\sqrt{n}+x)(n-\sqrt{n}-x)}{n^2}\right)^{x} \\
&> \frac{1}{4}e^{-2x} \cdot \frac{e^{x}}{e^{-x}} \cdot \left(\frac{(n-\sqrt{n}+\sqrt{n})(n-\sqrt{n}-\sqrt{n})}{n^2}\right)^{\sqrt{n}} \\
&= \frac{1}{4}\left(\frac{n(n-2\sqrt{n})}{n^2}\right)^{\sqrt{n}} = \frac{1}{4}\left(1-\frac{2}{\sqrt{n}}\right)^{\sqrt{n}} = \frac{1}{4}\frac{1}{e^2}
\end{aligned}
$$

◀

Combining the results gives us the following.

▶ **Theorem 13.** *$\mathbb{P}[c(G_q) \geq \frac{1}{8}\ln(n) \mid G_q$ is pseudoforest$] \in \Omega_{n\to\infty}(1)$, where $c(G_q)$ is the number of components of G_q and $q \sim \mathcal{U}(Q)$.*

Proof. According to Lemma 12 at least $\sqrt{n}$ nodes are in cycles with constant probability. Using Lemma 11 this results in $\frac{1}{4}\ln(\sqrt{n}) = \frac{1}{8}\ln(n)$ components with constant probability. ◀

▶ **Corollary 14.** *$\mathbb{E}[c(G_q) \mid G_q$ is pseudoforest$] \in \Theta_{n\to\infty}(\ln(n))$, where $c(G_q)$ is the number of components of G_q and $q \sim \mathcal{U}(Q)$.*

Proof. Use Theorem 13 for the lower bound. There can be at most all n nodes in cycles of the pseudoforest and we can apply Lemma 11 for the upper bound. ◀

4.2 Space Savings of MorphisHash

We now show that MorphisHash can convert each component into space savings compared to ShockHash. As a first step we transition the previous graph results into the world of matrices.

▶ **Lemma 15.** *The defect of the incidence matrix A of a pseudoforest is at least the number of the pseudoforests components.*

Proof. For each component C, summing up the rows A_j of the respective nodes $j \in C$ results in zero rows because for each component, the two endpoints of each edge are included in the summed up rows. The rows summed up for each zero row are disjoint and therefore in particular linearly independent combinations. ◀

▶ **Lemma 16** ([4])**.** *The probability that a random square matrix (of any field) with n rows and columns has full rank approaches 1 for large n.*

▶ **Lemma 17.** *The probability that a random rectangular matrix (of any field) with n rows and $m \in o(n)$ columns has full rank approaches 1 for large n.*

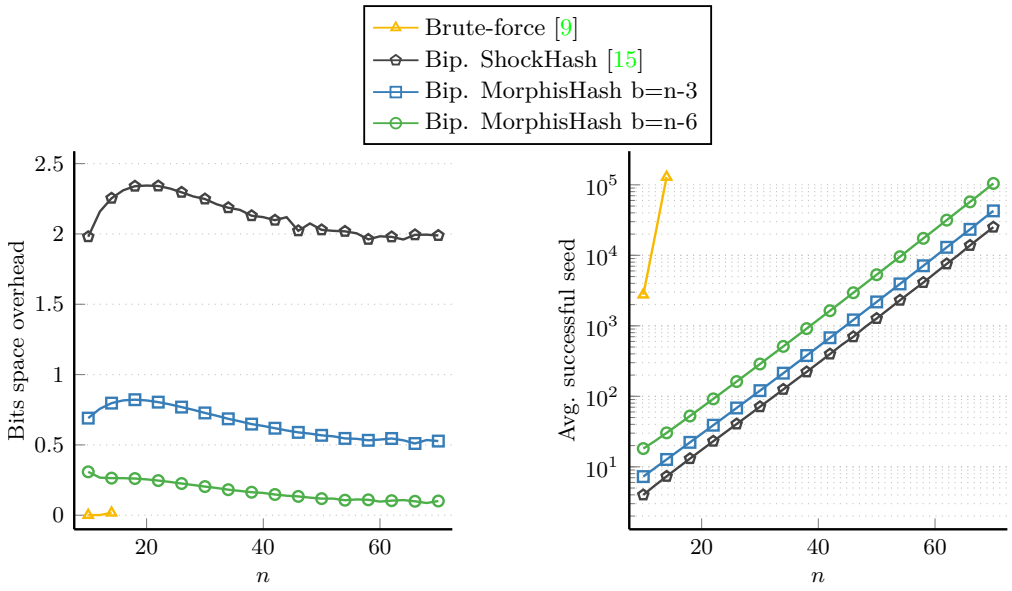
Proof. A necessary condition that a square matrix with n rows has full rank is that the first m columns have full rank. The probability that this rectangular submatrix has full rank is therefore bounded below by Lemma 16. ◀

We now show our main result.

▶ **Theorem 18.** *$\mathbb{P}[\exists x : AHx = d \mid G_q$ is pseudoforest$] \in \Omega_{n\to\infty}(1)$, where $q \sim \mathcal{U}(Q)$, incidence matrix A and vector d of G_q are as described in the algorithm, $b = n - \frac{1}{9}\ln(n)$ and $H \sim \mathcal{U}(\mathbb{F}_2^{n\times b})$.*

Proof. In Theorem 13 we showed that a hashed pseudoforest has at least $\frac{1}{8}\ln(n)$ components with constant probability. According to Lemma 15 a direct consequence is that the incidence matrix A of a random pseudoforest has a defect of at least $\frac{1}{8}\ln(n)$ with constant probability. According to Lemma 17, the probability that H has full rank is at least constant. The system $AHx = d$ has a solution if there is a vector y which solves $Ay = d$ and simultaneously $Hx = y$. Such a vector y exists if the two solution spaces have to intersect, which happens once $\mathrm{def}(A) + \mathrm{rank}(H) - n > 0$. Since A and H are uncorrelated we have with constant probability that both H has full rank b and simultaneously A has at least a defect of $\frac{1}{8}\ln(n)$. With $b = n - \frac{1}{9}\ln(n)$ we have $\mathrm{def}(A) + \mathrm{rank}(H) - n \geq \frac{1}{8}\ln(n) + (n - \frac{1}{9}\ln(n)) - n > 0$ with constant probability. ◀

We use the above result to measure the space savings compared to ShockHash.



▶ **Corollary 19.** *Compared to ShockHash, MorphisHash is at least $\frac{1}{9}\ln(n) - \mathcal{O}(1)$ bits more space efficient in expectation while requiring a constant factor more time.*

Proof. ShockHash requires at least n bits to store the orientation of all keys in a retrieval structure. MorphisHash has to store the solution vector x instead, requiring exactly b bits. According to Theorem 18 we can choose $b = n - \frac{1}{9}\ln(n)$ to obtain the desired space savings. However, there is a constant probability that a seed pair has to be rejected because there is no solution for x. MorphisHash therefore has to check a constant factor more seeds in expectation, consequently increasing the expected space required to store the seed by a constant number of bits. Analogously, the construction time grows by a constant factor in expectation. The time required to solve an expected constant number of equation systems is dominated by the seed search. ◀

5 Partitioning

The time required to find a seed in MorphisHash and ShockHash grows exponentially with n. To keep construction feasible for a large number of keys, we first partition the input into equally sized subsets of manageable size. For consistency, we use n for the size of those subsets, and refer to them as *base cases* in the following. MorphisHash is then applied on those base cases. Note that the following two partitioning schemes are also applied on ShockHash and we refer to their paper for more details [15, Section 7].

MorphisHash-RS. We use RecSplit [9] to recursively split the input into smaller subsets. Once sufficiently small subsets are obtained we apply MorphisHash on those subsets as a base case. RecSplit is space efficient but has significant query time overheads caused by traversing the tree. In MorphisHash-RS we store the solution vector x of the retrieval structure directly next to the corresponding seed to improve locality.

(a) Idealized space overhead over the lower bound $\log_2(n^n/n!)$. For an average successful seed s we charge $\log_2(s)$ bits plus the bits required for retrieval i.e. n for ShockHash and b for MorphisHash.

(b) Average successful seed. Note that we use Bip. ShockHash and Bip. MorphisHash without the quad split technique (see [15, Section 8.3]).

Figure 2 Space and avg. successful seed for ShockHash, MorphisHash and brute force search.

MorphisHash-Flat. The input keys are first hashed into buckets. Using thresholds, some keys are bumped such that the bucket does not exceed the desired base case size n. The bumped keys are then used to fill up buckets which did not reach the desired size. We apply MorphisHash on each bucket.

6 Experiments

In this section we experimentally evaluate MorphisHash. We show the effect of the new parameter b introduced by MorphisHash. We then compare MorphisHash-Flat and MorphisHash-RS with state-of-the-art competitors. Our source code is public under the General Public License [10]. We integrate MorphisHash into an existing benchmark framework [13], which was used for the comparison with competitors. The benchmark framework is described in detail in [14]. We perform all experiments on a Core i7-11700 CPU which has 48 KiB L1 and 512 KiB L2 data cache per core. The CPU has a total of 16 MiB L3 cache. The machine has 64 GiB of dual-channel DDR4-3200 RAM. Note that our experiments are at a scale where variances are relatively small, we therefore omit them for better readability.

6.1 MorphisHash vs ShockHash without partitioning

In the following we compare Bipartite MorphisHash with Bip. ShockHash. MorphisHash has the additional parameter b, which determines the size of the retrieval structure. Smaller b values result in less space overhead at the cost of more seed tests. Note that in theory we choose $b = n - \frac{1}{9}\ln(n)$ but in practice where n is small it is more intuitive to work with n minus a small constant. Figure 2 shows that Bip. MorphisHash has to check roughly a constant factor more seeds than Bip. ShockHash when b is fixed to n minus a constant. For

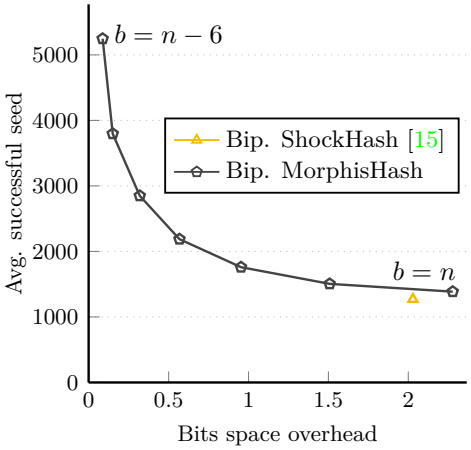


Figure 3 Comparing ShockHash with the MorphisHash trade-off between time and space for fixed $n = 50$ and $b = \{n-6, \ldots, n\}$.

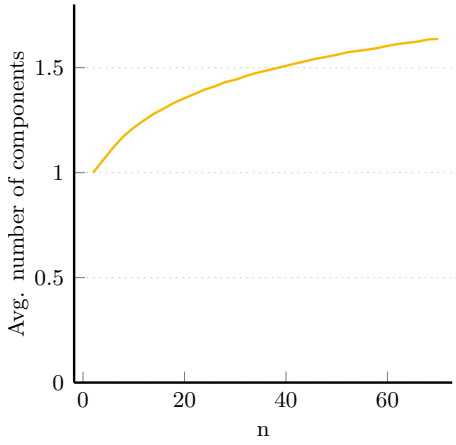

Figure 4 Experimentally measured average number of components when sampling bipartite pseudoforests.

$b = n - 6$ this factor is ≈ 4. At the same time, MorphisHash almost completely eliminates the remaining space overhead. MorphisHash comes below 0.1 bits of space overhead when using $b = n - 6$ while ShockHash has about 2 bits of space overhead. Thus, MorphisHash has roughly 20 times less space overhead. For $n = 54$, MorphisHash has $\frac{0.11}{54} \approx 0.002$ bits per key space overhead.

Figure 3 gives another perspective. In this plot, we fix n and vary b. Interestingly, ShockHash even outperforms MorphisHash for $b = n$. This is because MorphisHash requires n bits for the retrieval structure in this case just like ShockHash. However, there is still the chance that the equation system of MorphisHash has no solution resulting in more retries and therefore in a higher space consumption of the seed and a higher construction time. For smaller b the space overhead approaches 0. In the extreme case of $b = 0$ and respective zero dimensional retrieval vector, MorphisHash is equivalent to simple brute force search because all keys can only use the h_0 candidate function. The average successful seed grows rapidly with smaller b as it is increasingly less likely to stumble upon a pseudoforest which has at least $n - b$ many components. A pseudoforest with less than $n - b$ components may still result in a solvable (overdetermined) equation system, but this becomes exponentially less likely with every component below $n - b$. Figure 3 uses $n = 50$. The expected number of components for $n = 50$ is 1.56 as shown in Figure 4.

6.2 Choosing b in MorphisHash-RS and MorphisHash-Flat

Space improvements in MorphisHash-RS and MorphisHash-Flat can be made either by (1) increasing the base case size n which reduces the space overhead of the partitioning technique or (2) decreasing b which reduces the space overhead of MorphisHash. In both cases the construction time increases. We experimented with different values of b to identify the configurations which dominate the construction time and space trade-off. We determined that $b = n - 4$ is a good choice for MorphisHash-RS and $b = n - 2$ for MorphisHash-Flat. MorphisHash-Flat is a less space efficient partitioning technique compared to MorphisHash-RS. Space savings can be made more easily by increasing n instead of decreasing b.

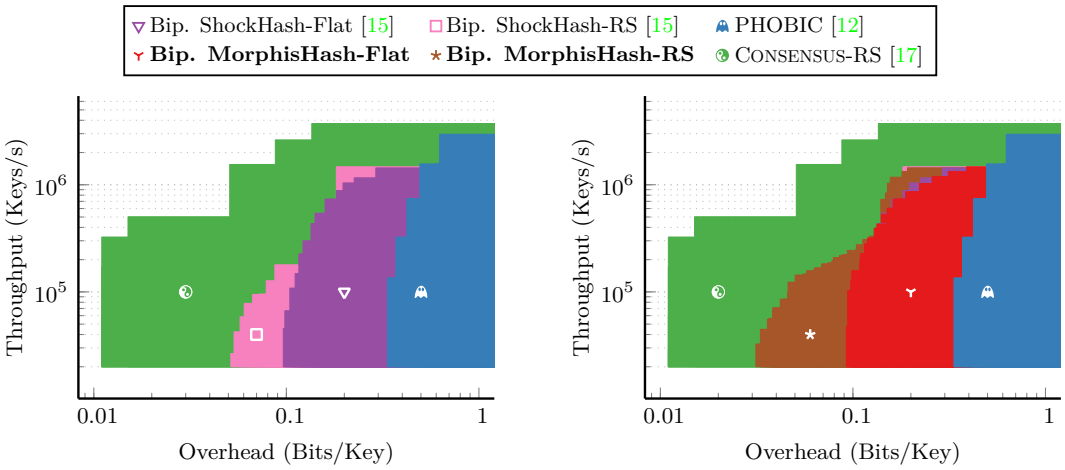

Figure 5 Dominance maps indicating the approach with the fastest queries, given a specific trade-off between space and construction time with (right) and without (left) MorphisHash on 100 M keys. Space overhead in bits per key over the lower bound of 1.44.

Table 1 Performance of various methods on 100 M keys. In the first part, configurations are chosen such that the construction times are about equal (sorted by space efficiency). In the second part, configurations are chosen such that space consumption is almost equal.

Method	Space (bits/key)	Query (ns/query)	Construction (ns/key)
Consensus-RS, k=32768, o=0.0025	1.447	222	6 733
Bip. MorphisHash-RS, base case size n=52, b=n-4	1.501	137	6 669
Bip. ShockHash-RS, base case size n=66	1.523	147	7 186
Bip. MorphisHash-Flat, base case size n=88, b=n-2	1.541	75	6 330

6.3 Comparison to Competitors

We compare MorphisHash-RS and MorphisHash-Flat with state-of-the-art competitors. We select the following space efficient competitors based on a recent survey [14]: Consensus-RS[17], ShockHash-Flat, ShockHash-RS and PHOBIC [12]. We test a wide range of configurations for each competitor and compare them in Figure 5. A selection of configurations is shown in Table 1. As can be seen in the plot and the table, MorphisHash-RS is about 0.02 bits per key more space efficient than ShockHash-RS when compared for equal construction time. This corresponds to a reduction of 27% in space overhead. When compared for equal space consumption of 1.489 bits per key, MorphisHash-RS is $\frac{172\,738}{8085} \approx 21$ times faster to construct (see Table 1). For MorphisHash-Flat we select b less aggressively compared to MorphisHash-RS (Section 6.2) and obtain a space improvement of about 0.01 bits per key. According to Figure 5 MorphisHash dominates ShockHash in the overall space, construction and query time trade-off. The next best competitor in terms of space efficiency is PHOBIC which is a clear winner in terms of query throughput. In the other direction, we have the

recently published CONSENSUS-RS, which can reach space overheads as low as 0.001 bits per key at the cost of additional query time. A negative result regarding non-minimal PHFs can be found in the full version of this paper [11].

7 Conclusion and Future Work

MorphisHash almost completely eliminates the remaining redundancy in ShockHash. This is particularly effective when combined with a space efficient partitioning technique. Our compression scheme might be of a more general interest, further examples can be found in the full version of this paper [11].

In future work we plan to improve the space efficiency of partitioning techniques as those are a major source of space overhead. We are hopeful that a partitioning technique that involves the novel CONSENSUS technique puts further trade-offs for MorphisHash into reach.

Abstract

The classical theorem due to Győri and Lovász states that any k-connected graph G admits a partition into k connected subgraphs, where each subgraph has a prescribed size and contains a prescribed vertex, as long as the total size of target subgraphs is equal to the size of G. However, this result is notoriously evasive in terms of efficient constructions, and it is still unknown whether such a partition can be computed in polynomial time, even for $k = 5$.

We make progress towards an efficient constructive version of the Győri–Lovász theorem by considering a natural strengthening of the k-connectivity requirement. Specifically, we show that the desired connected partition can be found in polynomial time, if G contains k disjoint connected dominating sets. As a consequence of this result, we give several efficient approximate and exact constructive versions of the original Győri–Lovász theorem:

- On general graphs, a Győri–Lovász partition with k parts can be computed in polynomial time when the input graph has connectivity $\Omega(k \cdot \log^2 n)$;
- On convex bipartite graphs, connectivity of $4k$ is sufficient;
- On biconvex graphs and interval graphs, connectivity of k is sufficient, meaning that our algorithm gives a "true" constructive version of the theorem on these graph classes.

1 Introduction

Partitioning a graph into connected subgraphs is a problem that naturally arises in various application areas such as image processing, road network decomposition and parallel graph systems for supporting computations on large-scale graphs [30, 31, 18, 21]. Usually in such applications, there is a certain number of parts k that the partition should have, as well as certain constraints on the size of each part. In particular, a prominent objective is for the size of the parts to be as equal as possible and, therefore, for the partition to be as balanced as possible, known as Balanced Connected Partition problem (BCP_k). This problem is proven to be NP-complete [19] and even hard to approximate [14] and, hence, it has been studied in restricted graph classes such as grid graphs for which it was again proven to be NP-hard [3].

From a theoretical point of view, partitioning a graph into connected components each of a certain, chosen in advance, size is of independent interest as it gives us an insight into the structure of the graph. With the simple example of a star graph, one can observe that it

© Aikaterini Niklanovits, Kirill Simonov, Shaily Verma, and Ziena Zeif;
licensed under Creative Commons License CC-BY 4.0

is not possible to partition it into connected sets where more than one of them has size 2 or more. In general, if there exists a set of t vertices whose removal disconnects the graph (called a *separator*), and if the number of parts k is greater than t, then the k parts of a connected partition might not necessarily be of arbitrary size. Graphs that do not contain a separator of size strictly less than t are called *t-connected*.

The essence of this observation was captured in 1976 by Győri [22] and Lovász [29] who independently proved that the k-connectivity of a graph is a necessary and sufficient condition for any partition of a specific size to be possible, even when each part is additionally required to contain a specified vertex called a *terminal*. This was later generalized to weighted graphs by Chandran et al. [12], Chen et al. [13] and Hoyer [24]. Formally, we define the following computational problem.

▶ **Definition 1.** *In the GL-Partition problem, the input is a graph $G = (V, E)$, an integer $k \geq 1$, a set of k distinct vertices $C = \{c_1, \ldots, c_k\}$ of G, and k integers $N = \{n_1, \ldots, n_k\}$ such that $\sum_{i=1}^{k} n_i = |V|$, in short denoted as (G, k, C, N). The task is to compute a partition of V into k disjoint subsets $V_1, \ldots, V_k$ such that $|V_i| = n_i$, $c_i \in V_i$, and the induced subgraph $G[V_i]$ on V_i is connected, for all $i \in [k]$.*

We call the partition satisfying the property above a *Győri–Lovász partition*, or a *GL-partition* for short. The result of Győri and Lovász can then be stated as follows.

▶ **Theorem** (Győri–Lovász Theorem)**.** *Given an instance of GL-Partition where the graph is k-connected, a GL-partition always exists.*

Although the proof of Győri [22] is constructive, the resulting algorithm runs in exponential time. To this day, it remains open whether finding a GL-partition of a given k-connected graph could be done in polynomial time in general. On the other hand, a few polynomial algorithms have been developed for special cases. The original research direction is concerned with smaller values of k. Specifically, in 1990, Suzuki et al. [37, 38] provided a polynomial algorithm for the cases $k = 2$ and $k = 3$. Later, in 1993, Wada et al. [39] extended the result for $k = 3$, and, in 1997, Nakano et al. [32] showed a linear-time algorithm for the case where $k = 4$ and the graph is planar with all the terminals located on the same face of the planar embedding. More recently, in 2016, Hoyer and Thomas [24] presented a polynomial-time algorithm for the case $k = 4$ without additional restrictions on the graph structure. It is still open whether a polynomial-time algorithm exists for any fixed value of k starting from 5. Another research direction focuses on polynomial-time constructions for the Győri–Lovász theorem on specific graph classes, for all values of k. Recently, Casel et al. [9] developed a polynomial-time algorithm for chordal graphs and (with a small additive violation of the size constraint) for HHI_4^2-free graphs. Additionally, Borndörfer et al. [6] have shown an approximate version of the Győri–Lovász theorem on general graphs, where the size of each part is within a factor of 3 from the given target.

In the light of the challenges above, it is natural to ask whether efficient constructions exist for more restrictive versions of the Győri–Lovász theorem. Censor-Hillel, Ghaffari, and Kuhn [11] pioneered the notion of a connected dominating set (CDS) partition as a proxy for vertex connectivity of the graph. Formally, a graph admits a CDS partition of size k, if there exists a partition of the vertices into k sets, such that each set forms a dominating set of the graph, and induces a connected subgraph. It is easy to see that any graph that admits a CDS partition of size k, is also k-connected. The converse, unfortunately, does not hold; however, Censor-Hillel, Ghaffari, and Kuhn show that there is only a polylogarithmic gap between the connectivity and the size of the maximum CDS partition. Moreover, a suitable CDS partition can be efficiently computed. The bound was later improved by Censor-Hillel et al. [10].

▶ **Theorem 2** (Corollary 1.6, [10]). *Every k-connected n-vertex graph has a CDS partition of size $\Omega(\frac{k}{\log^2 n})$, and such a partition can be computed in polynomial time.*

On the other hand, Censor-Hillel, Ghaffari, and Kuhn [11] show that a logarithmic gap between the connectivity and the size of a CDS partition is necessary.

▶ **Theorem 3** (Theorem 1.3, [11]). *For any sufficiently large n, and any $k \geq 1$, there exist k-connected n-vertex graphs, where the maximum CDS partition size is $O(\frac{k}{\log n})$.*

More recently, Draganić and Krivelevich [17] obtained a tighter bound of $(1 + o(1))d/\ln d$ for CDS partitions in d-regular pseudorandom graphs.

Our contribution

The core result of our work is an efficient version of the Győri–Lovász theorem that is based on the existence of a CDS partition of size k in the given graph, which strengthens the original requirement of k-connectivity.

▶ **Theorem 4.** *There is an algorithm that, given an instance of GL-Partition together with a CDS partition of the graph of size k, computes a GL-partition in polynomial time.*

However, on its own Theorem 4 would have a notable limitation, that computing an adequate CDS partition may in itself be an obstacle – as opposed to connectivity, which can always be computed exactly in polynomial time. Fortunately, it turns out that a sufficiently large CDS partition can be found efficiently in a range of scenarios. As the first example, Theorem 2 due to Censor-Hillel et al. [10] provides such a construction for general graphs. Combining it with our algorithm, we obtain the following efficient version of the Győri–Lovász theorem, which requires higher connectivity, but puts no additional restrictions on the graph.

▶ **Corollary 5.** *GL-Partition is poly-time solvable on $\Omega(k \cdot \log^2 n)$-connected graphs.*

Furthermore, we investigate the cases where Theorem 4 can be applied to obtain a tighter connectivity gap. Following the results of Censor-Hillel, Ghaffari, and Kuhn [11], the case of general graphs cannot be improved beyond a logarithmic factor, as there exist $\Omega(k \cdot \log n)$-connected graphs that do not admit CDS partitions of size k, see Theorem 3. Therefore, putting additional restrictions on the input graph is necessary.

The first natural target here would be efficient constructions for the Győri–Lovász theorem on certain graph classes in its exact version, that is, requiring connectivity exactly k. In the light of Theorem 4, it is sufficient to show a statement of the following form, that any k-connected graph in the class $\mathcal{G}$ admits a CDS partition of size k. This would imply that the Győri–Lovász theorem admits an efficient construction on graphs in $\mathcal{G}$. We identify two such cases, biconvex graphs and interval graphs.

▶ **Theorem 6.** *Let G be a k-connected biconvex graph. A CDS partition of G of size k exists, and can be computed in polynomial time.*

▶ **Theorem 7.** *Let G be a k-connected interval graph. A CDS partition of G of size k exists, and can be computed in polynomial time.*

Coupled with the algorithm of Theorem 4, this gives an efficient construction for the Győri–Lovász theorem on biconvex graphs and interval graphs.

▶ **Corollary 8.** *GL-Partition is poly-time solvable on k-connected biconvex graphs.*

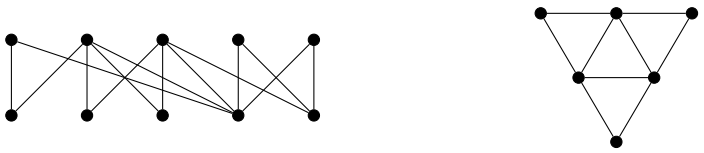

Figure 1 Examples of a 2-connected convex bipartite graph and a 2-connected chordal graph that do not admit a CDS partition of size 2.

We note that the efficient construction for chordal graphs was identified by Casel et al. [9], implying the same result for interval graphs, since interval graphs form a subclass of chordal graphs. Nonetheless, we state the algorithmic consequence of Theorem 7 next for completeness.

▶ **Corollary 9.** *GL-Partition is poly-time solvable on k-connected interval graphs.*

Unfortunately, there is a limit to the results of the form above, as already graph classes such as chordal graphs and convex bipartite graphs do not possess the property that k-connectivity implies the existence of a CDS partition of size k (see Figure 1 for examples). On the positive side, we are able to retain the productivity of Theorem 4 even in such cases. We focus on the class of convex bipartite graphs and show that $4k$-connected convex bipartite graphs always admit a CDS partition of size k.

▶ **Theorem 10.** *Let G be a $4k$-connected convex bipartite graph. A CDS partition of G of size k exists, and can be computed in polynomial time.*

This allows us to explore a trade-off between efficiency of the construction and the connectivity requirement for the class of convex bipartite graphs. As before, combined with the algorithm of Theorem 4, Theorem 10 gives us a "4-approximate" (in terms of connectivity) efficient version of the Győri–Lovász theorem on this graph class, considerably improving the connectivity requirement of the general case.

▶ **Corollary 11.** *GL-Partition is solvable in polynomial time on $4k$-connected convex bipartite graphs.*

Related work

The problem of computing the largest CDS partition of a graph was first introduced by Hedetniemi and Laskar [23], where the maximum size of a CDS partition is referred to as the connected domatic number of the graph. A number of bounds on the size of a CDS partition are due to Zelinka [41], including the fact that it is upper-bounded by the connectivity of the graph. Connected dominating sets have many practical applications for tasks such as routing and load-balancing in networks, for a detailed overview we refer to a survey due to Yu et al. [40]. Connections between CDS partitions and graph rigidity were explored by Krivelevich, Lew and Michaeli [26].

Chordal graphs are graphs that do not admit induced cycles of length more than 3. The class of chordal graphs is well-studied, and is known to possess many useful properties; in particular, many problems that are NP-hard on general graphs turn out to be polynomial-time solvable on chordal graphs, such as computing chromatic number, independence number, treewidth [34]. Interval graphs are intersection graphs of intervals on a real line, and form a subclass of chordal graphs [27].

Convex bipartite graphs[1] were introduced in 1967 by Glover [20] as they naturally arise in various industrial and scheduling applications. Formally, a bipartite graph $G = (A \cup B, E)$ is called *convex* if there exists an ordering σ of the vertices in A such that the neighborhood of any vertex of B is consecutive under σ. Restricting to the class of convex bipartite graphs has been proven fruitful for many problems such as maximum independent set, minimum feedback set, (dynamic) maximum matching and independent dominating set [35, 8, 28, 25, 36, 15]. On the other hand, several natural problems are known to be NP-complete on convex bipartite graphs. Most relevant to our work is the example of the k-path partition problem, proven to be NP-complete on convex bipartite graphs by Asdre and Nikolopoulos [2]. Belmonte and Vatshelle [4] show that convex bipartite graphs have bounded mim-width, which provides a unified perspective on polynomial-time algorithms for various classes. Bonomo-Braberman et al. [5] generalize this perspective further to extended notions of convexity.

Bipartite graphs with an ordering satisfying the convexity condition for both parts, are called biconvex. Biconvex graphs are thus a subclass of convex bipartite graphs. Abbas and Stewart studied properties of vertex orderings in biconvex graphs, yielding in particular that the vertex ranking problem is polynomial-time solvable on biconvex graphs [1]. Apart from their structural and algorithmic interest, biconvex graphs and convex bipartite graphs have been proven useful in practice, as they model well situations such as task allocation problems [20, 25]. In terms of other well-studied graph classes, convex bipartite graphs and biconvex graphs form a subclass of chordal bipartite graphs, which have a natural analogue of the chordal property among the bipartite graphs. For a more detailed introduction to the graph classes, their properties and relations between the classes, we refer to a survey by Brandstädt, Bang Le and Spinrad [7].

Paper organization. In Section 2, we introduce preliminaries that we use throughout the paper. Section 3 is dedicated to the main case of the algorithm constructing a Győri–Lovász partition on the basis of a CDS partition, and Section 4 completes the algorithm. We conclude with an overview and selected open problems in Section 5. Due to space restrictions, the results for biconvex, interval, and convex bipartite graphs, as well as details from Section 4 and selected proofs from Section 3 are omitted and we refer the reader to the full version of the paper [33]. Such results are marked by ($\star$).

2 Preliminaries

All graphs mentioned in this paper are finite, undirected and simple. We use standard graph theory notation, for reference see the full version of the paper [33] and the book of Diestel [16]. We call a graph $G = (V, E)$ a *path* if $V = \{v_1, \dots, v_n\}$ and $E = \{v_i v_{i+1} | \text{for } i \in [n-1]\}$. We usually denote a path by P and we call its order, the *length* of P. We call a graph $G = (V, E)$ a *cycle* if $V = \{v_1, \dots, v_n\}$ and $E = \{v_i v_{i+1}, v_1 v_n | \text{for } i \in [n-1]\}$. We call a graph $G = (V, E)$ a *tree* if it does not contain any cycle as a subgraph. Throughout this paper a vertex set of a tree is usually denoted by T, while its edge set is denoted by $E(T)$. Given two graphs H, G we say that G is *H-free* if G does not contain H as an induced subgraph. Given two graphs G and T, we say that T is a *spanning tree* of G if $V(G) = V(T)$ and $G[V(T)]$ induces a tree.

Given two vertex sets $A, B \in V(G)$ we say that A is *dominating* to B if every vertex in B is adjacent to some vertex in A. Also, when we say that a vertex set is dominating to some graph G, we mean that it is dominating to its vertex set $V(G)$. A vertex set A is called

[1] Often referred to simply as *convex graphs* in the literature.

a *connected dominating set* (CDS) if and only if it is a dominating set and $G[A]$ is connected. Given a graph G, a collection of vertex sets $\mathcal{V} = \{V_1, \ldots, V_l\}$ such that $V_i \subseteq V(G)$ is called a *connected dominating set partition* (CDS partition) if and only if the sets in $\mathcal{V}$ are pairwise disjoint and $\cup_{U \in \mathcal{V}} U = V(G)$, and each of them is a connected dominating set of G. We call $|\mathcal{V}|$ the *size* of the CDS partition $\mathcal{V}$. Throughout the paper, we also use an equivalent notion of vertex-disjoint dominating trees. Given a CDS partition of a graph it is immediate to get a set of vertex-disjoint dominating trees of the same size by considering the spanning tree of each set in the CDS partition. Moreover, given k disjoint dominating trees, one may obtain a CDS partition of size k by simply adding the remaining vertices arbitrarily to those trees.

3 From Simple CDS Partition to GL-partition

Before we move on to the general algorithm of Theorem 4 that computes a GL-partition from a CDS partition of size k, we cover in this section the main subroutine of this algorithm. Specifically, we present an algorithm (Algorithm 3) that, given as input an instance of GL-Partition and k dominating trees such that all terminals are contained in the same dominating tree, returns a partial GL-partition with l sets, for some $l \in [k]$, such that the remaining vertices admit a CDS partition of size $k - l$. The general algorithm, described in the next section, then uses this result as a subprocedure. We first describe the intuition behind the main steps of Algorithm 3, then provide a more detailed description of these steps, and finally define a formal procedure for each step and show its correctness.

Intuition of Algorithm 3. Let T_1 be the dominating tree that contains k terminal vertices. First we add all the vertices of T_1 to one of the k vertex sets while maintaining the connectivity of each set. There exist $k - 1$ dominating trees that have no terminal vertex. Now, we map these k vertex sets to one of these $k - 1$ dominating trees. We aim to fulfill the vertex set to its demand while using the corresponding dominating tree.

We use an iterative procedure that first assigns (but does not add) neighbors for each vertex set to these $k - 1$ dominating trees, and then we add assigned vertices to each vertex set whose demand is not met by the assignment. Now, to fulfill the demand of each such vertex set, we use its corresponding dominating tree while preserving the connectivity of the vertex set. At the end of this procedure, each part is either full or contains a whole dominating tree (apart from the one that was not assigned to any tree). The remaining vertices are arbitrarily added to the non-full sets, as each contains a dominating tree, apart from the one that has not been assigned a tree, for which we have ensured that there are enough adjacent vertices left.

Description of Algorithm 3. The algorithm receives an instance of GL-Partition, (G, k, C, N), where $C = \{c_1, \ldots, c_k\}$, $N = \{n_1, \ldots, n_k\}$ and a set of dominating trees $\mathcal{T} = \{T_1, \ldots, T_k\}$ as an input such that such that G is k-connected graph and $C \subseteq T_1$.

It is important to note that during this description of the algorithm, every time we add a vertex to a vertex set, it is implied that we also check whether the condition of having l full sets say $V_1, \ldots, V_l$, intersecting exactly l of the dominating trees, say $T_1, \ldots, T_l$ is met. If yes, then we output those l full sets and return an instance of the original problem, $G - \cup_{i=1}^{l} V_i$ and $k - l$, $\mathcal{T} = \mathcal{T} \setminus \{T_{k-l}, \ldots, T_k\}$, $C = C \setminus \{c_{k-l}, \ldots, c_k\}$ and $N = N \setminus \{n_{k-l}, \ldots, n_k\}$. We moreover assume that every time we add a vertex we also check if a set meets its size demand and if so we add it to the set Full that includes all the connected vertex sets that satisfy their size demands. We denote this procedure of adding a vertex u to set V by Add(V, u)

(similarly Add(V, U) when we have a vertex set U instead of singleton $\{u\}$). Similarly every time we remove a vertex from some set we check if it is in Full and if yes, we remove the set from Full. We denote this procedure of removing vertex u from the set V by Remove(V, u).

Step 1 We initialize each set V_i to contain the corresponding terminal vertex c_i for all $i \in [k]$ and then add the vertices of $T_1 \setminus C$ one by one to a vertex set that it is adjacent to (based only on the adjacencies occurring by T_1). Next, we add the vertices of $V(G) \setminus V(\mathcal{T})$ to an adjacent set one by one.

Step 2 Each vertex of $\mathcal{T} \setminus T_1$ is assigned through a function Vlabel to an adjacent vertex set. Depending on whether the amount of vertices assigned to some vertex set is less than the vertices needed to be added for the set to satisfy its demand or not, the set is categorized in the set Under or Over respectively (Algorithm 1).

Step 3 Through the function Tlabel each set in Under is assigned one of the trees in $\mathcal{T} \setminus T_1$. Then, one vertex of each such tree adjacent to the corresponding set is added. Priority is given to the vertices assigned to this set through the function Vlabel. However, if no such vertex exists, another adjacent vertex is arbitrarily chosen to be added, and we change the value of this vertex in the function Vlabel accordingly. If this results in a set moving from Over to Under, we again assign a tree to this set (that has not been assigned to any other set) through the function Tlabel (Algorithm 1).

Step 4 For each tree assigned to some set, we consider its vertices not belonging in that set one by one and add them to that set as long as the set connectivity is preserved. Again, if, during this procedure, a set moves from Over to Under, go to the previous Step. Repeat this procedure until each set in Under is either full or contains a whole tree (Algorithm 2).

Step 5 Add each of the remaining vertices, the ones not added to any set, to an adjacent non full set one by one (Algorithm 2).

Step 6 Output the k sets created.

As Step 1 works in a straightforward way, we do not provide a pseudocode for it. We describe in the proof of the lemma below how this can be done in polynomial time. In the main algorithm, we refer to this procedure as AddTrees$(G, C, \mathcal{T})$ that returns the sets $V_1, \ldots, V_k$.

▶ **Lemma 12** ($\star$). *Given an instance of GL-Partition (G, k, C, N) and k vertex disjoint dominating trees $T_1, \ldots, T_k$ such that $C \subseteq T_1$, we construct k vertex connected sets $V_1, \ldots, V_k$ such that $c_i \in V_i$ for all $i \in [k]$ and $T_1 \subseteq \cup_{i=1}^{k} V_i$, in polynomial time.*

Algorithm 1 realizes the two next steps of Algorithm 3. In particular, first each remaining vertex of the graph is assigned to some set through Vlabel and then each set is categorized in Over or Under depending on the number of vertices assigned to it. Then, for each set in Under the assigned vertices are added and through Tlabel we assign a distinct tree each such set. Afterwards we ensure that each set in Under contains a vertex from its assigned tree.

It is easy to notice that Step 2 runs in polynomial time. In order to prove the correctness of Step 3 in Lemma 13, it suffices to show that there are at most $k - 1$ sets in Under and this property is not affected while ensuring that each vertex set contains a vertex from the corresponding through Tlabel tree. This part of the algorithm also runs in polynomial time because each set in Under is considered at most once and a set from Over might move to Under but once a set is in Under it will never move to Over.

▶ **Lemma 13.** *Let (G, k, C, N) be an instance of GL-Partition, where $C = \{c_1, \ldots, c_k\}$, $\{V_1, \ldots, V_k\}$ are k connected vertex sets such that $c_i \in V_i$ for all $i \in [k]$, and a set of k vertex disjoint dominating trees $\mathcal{T} = \{T_1, \ldots, T_k\}$ such that $C \subseteq T_1$, are given as input to Algorithm 1. Then, after the loop in line 17 (Step 3) each vertex set is either in* Over*, or is assigned to a tree through* Tlabel *and contains a vertex from that tree. Moreover, $G[V_i \cup \text{Vlabel}(V_i)]$ is connected for each $i \in [k]$ and at least one set is in* Over*.*

Proof. First notice that $G[V_i \cup \mathsf{Vlabel}(V_i)]$ is connected for all $i \in [k]$, by the definition of the function Vlabel. We now show that there is at least one vertex set in Over. Assume that there is no set in Over and hence $n_i - |V_i| > |\mathsf{Vlabel}(V_i)|$ for all $i \in [k]$. Then $\sum_{i=1}^{k} n_i - |V_i| > \sum_{i=1}^{k} |\mathsf{Vlabel}(V_i)| \Rightarrow n > \sum_{i=1}^{k} |\mathsf{Vlabel}(V_i)| + \sum_{i=1}^{k} |V_i| = n$ which is a contradiction. This implies that regardless of whether a set moves from Over to Under, as long as all vertices of G are assigned to the sets $V_1, \ldots, V_k$, one of these sets will be in Over.

In the loop in line 17, we consider each tree assigned to some vertex set and first check whether this vertex set already contains some vertex of the tree. If yes, our lemma is satisfied. Otherwise, since the tree is dominating, there exists at least one vertex adjacent to the part of the vertex set intersecting T_1. This vertex is already added to some vertex set in Under or assigned to one in Over. If it belongs in some set in Over, then we simply add it to the vertex set. Then we remove this vertex from the set that occurs from the assignment Vlabel for the set previously in Over, and we check to see if it now meets the condition for this set belonging to Under. If yes, we go to line 12 to deal with this set similarly. Repeating this procedure for the other sets in Under does not affect them as every vertex set currently in Under already contains all the vertices assigned to it through the function Vlabel. Moreover, since in this step, we add a vertex to a vertex set, we also check if this set becomes full and intersects exactly one dominating tree. If that is true, we restart the algorithm for the adjusted values of k, G, $\mathcal{T}$, and $\mathcal{C}$.

Otherwise, if the adjacent vertex is part of some other set in Under, we add it to our current set and remove it from the previous one (again checking if the condition for restarting the algorithm is met). Moreover, we remove it from the set created through the function Vlabel to avoid this vertex from existing in two sets (in case we go to line 12) in some other iteration of this loop. Note that sets initially in Under might be added in Full or removed from it depending on whether we add or remove vertices from them, but they will never go from Under to Over as we need to maintain the property that each set in Over contains no vertices from $T_2, \ldots, T_k$. ◀

Algorithm 2 realizes essentially the last two steps of the algorithm and either returns the desired partition of size k or a smaller instance of a more general problem. First we ensure that each set in Under is either full or contains the dominating tree assigned to it through Tlabel. This is done by considering each set in *Under* separately and then adding the neighboring vertices of the corresponding tree one by one. If during this procedure we "steal" a vertex assigned in some set in Over and this causes it to move to Under we run Algorithm 1 starting from line 13 (only running the loop of line 12 once, for the set that moved to Under). This happens at most once for each set hence this part of Algorithm 2 runs in polynomial time. In the last part of this algorithm we simply add the remaining vertices to some adjacent non full set, first based on their assignment through Vlabel and then based on the adjacencies in G.

▶ **Lemma 14.** *Let an instance of GL-Partition $(G, k, C = \{c_1, \ldots, c_k\}, N)$, k connected vertex sets $\{V_1, \ldots, V_k\}$ such that $|V_i| < n_i$ and $c_i \in V_i$ for all $i \in [k]$, k dominating to G trees $\{T_1, \ldots, T_k\}$ and a function* Vlabel $: \{V_1, \ldots, V_k\} \to P(V(G))$*, are given as an input to Algorithm 2. Then, after the loop in line 1 (Step 5), each vertex set is connected and is either full or completely contains a dominating tree or is assigned through* Vlabel *to at least as many vertices as its remaining size demand that do not belong in any other vertex set.*

Proof. In order to see that the loop in line 1 terminates, it suffices to notice that it only considers sets in Under and the value of $\sum_{i=2}^{k} |T_i' \cap \mathsf{Tlabel}^{-1}(T_1)|$.

Algorithm 1 Labeling (Step 2, Step 3).

Require: An instance of GL-Partition $(G, k, C = \{c_1, \ldots, c_k\}, N = \{n_1, \ldots, n_k\})$, a set of k vertex disjoint dominating trees $\mathcal{T} = \{T_1, \ldots, T_k\}$ such that $C \subseteq T_1$, and k connected vertex sets $\{V_1, \ldots, V_k\}$ such that $c_i \in V_i$ for all $i \in [k]$

1: Initialize $\mathsf{Vlabel} : \{V_1, \ldots, V_k\} \to P(V(G))$ and $\mathsf{Tlabel} : \{V_1 \ldots, V_k\} \to \mathcal{T}$ such that $\mathsf{Vlabel}(V_i) \leftarrow \emptyset$, $\mathsf{Tlabel}(V_i) \leftarrow \emptyset$, $\forall i \in [k]$.
2: $\mathsf{Over} \leftarrow \emptyset$, $\mathsf{Under} \leftarrow \emptyset$
3: **for** $i \leftarrow 2$ to k **do**
4: **for** every vertex $v \in T_i$ **do** ▷ Step 2
5: Let $V_j \in \{V_1, \ldots, V_k\}$ such that $v \in N_G(V_j \cap T_1)$
6: $\mathsf{Vlabel}(V_j) \leftarrow \mathsf{Vlabel}(V_j) \cup v$
7: **for** $i \leftarrow 2$ to k **do**
8: **if** $n_i - |V_i| \leq |\mathsf{Vlabel}(V_i)|$ **then**
9: $\mathsf{Over} \leftarrow \mathsf{Over} \cup V_i$
10: **else**
11: $\mathsf{Under} \leftarrow \mathsf{Under} \cup V_i$
12: **for** every $V_i \in \mathsf{Under}$ **do** ▷ Step 3
13: $V_i \leftarrow \mathrm{Add}(V_i, \mathsf{Vlabel}(V_i))$
14: **if** $\mathsf{Tlabel}(V_i) = \emptyset$ **then**
15: Let T_j be a tree such that $T_j \notin \cup_{s=1}^{k} \mathsf{Tlabel}(V_s)$
16: $\mathsf{Tlabel}(V_i) \leftarrow T_j$
17: **for** every tree $T_i \in \mathcal{T} \setminus T_1$ such that $\mathsf{Tlabel}^{-1}(T_i) \neq \emptyset$ **do**
18: Let V_j be the vertex set such that $\mathsf{Tlabel}(V_j) = T_i$.
19: **if** $V_j \cap T_i = \emptyset$ **then**
20: Let $u \in T_i$ such that $u \in N(V_j \cap T_1)$ and V_s such that $u \in \mathsf{Vlabel}(V_s)$
21: **if** $V_s \in \mathsf{Over}$ **then**
22: $V_j \leftarrow \mathrm{Add}(V_j, u)$, $\mathsf{Vlabel}(V_s) \leftarrow \mathrm{Remove}(\mathsf{Vlabel}(V_s), u)$.
23: **if** $n_s - |V_s| > |\mathsf{Vlabel}(V_s)|$ **then**
24: $\mathsf{Over} \leftarrow \mathsf{Over} \setminus V_s$, $\mathsf{Under} \leftarrow \mathsf{Under} \cup V_s$
25: Go to line 12
26: **else**
27: $V_s \leftarrow \mathrm{Remove}(V_s, u)$, $\mathsf{Vlabel}(V_s) \leftarrow \mathsf{Vlabel}(V_s) \setminus u$, $V_j \leftarrow \mathrm{Add}(V_j, u)$
28: **return** $\mathsf{Over}, \mathsf{Under}, \mathsf{Vlabel}, \mathsf{Tlabel}$

We start by considering the vertex set V_j such that $\mathsf{Tlabel}(V_j) = T_i$ for some value of i. Due to Lemma 13, we know that T_i is either completely contained in V_j, in which case we do nothing and we proceed to consider the next tree, or it has a vertex of T_i that is adjacent to $V_j \cap T_1$ and not in V_j. We then add that vertex to V_j in the same manner as in the loop in line 17 of Algorithm 1 depending on whether this vertex belongs already in some set or not.

Notice that this action preserves the connectivity of the set V_j due to the way the vertex is chosen and also does not affect the connectivity of other sets as this is based only on the adjacencies of the parts of each vertex set intersecting T_1, which is not affected. Moreover it increases the value of $\sum_{i=2}^{k} |T_i \cap \mathsf{Tlabel}^{-1}(T_1)|$ by 1, which ensures that this loop terminates. Again, every time we add a vertex to a vertex set, it is implied that we also check if that set should meets its size demand and should be added to Full and also if the condition to terminate and output l full sets and a smaller instance of the general problem is met. ◀

Algorithm 2 Add Vertices (Step 4, Step 5).

Require: An instance of GL-Partition $(G, k, C = \{c_1, \ldots, c_k\}, N = \{n_1, \ldots, n_k\})$, a set of k vertex disjoint dominating trees $\mathcal{T} = \{T_1, \ldots, T_k\}$ such that $C \subseteq T_1$, k connected vertex sets $\{V_1, \ldots, V_k\}$ such that $c_i \in V_i$ for all $i \in [k]$, sets Under, Over, Full, and functions Vlabel, Tlabel.

1: **while** $\exists V_j \in$ Under such that $V_j \notin$ Full and $T_i \not\subseteq V_j$ $\forall i \in \{2, \ldots, k\}$ **do** ▷ Step 4
2: Let T_i be the tree such that Tlabel$(V_j) = T_i$
3: **while** V_j doesn't contain vertices only from T_i and $T_i \not\subseteq V_j$ and $V_j \notin$ Full **do**
4: Let $v \in T_i$ such that $v \in N(V_j \cap (T_1 \cup T_i))$
5: **if** v is assigned through the function Vlabel to some set $V_s \in$ Over **then**
6: $V_j \leftarrow$ Add(V_j, v), Vlabel$(V_s) \leftarrow$ Vlabel$(V_s) \setminus v$
7: **if** $n_s - |V_s| >$ |Vlabel(V_s)| **then**
8: Over $\leftarrow$ Over $\setminus V_s$, Under $\leftarrow$ Under $\cup V_s$
9: Run Algorithm 1 with input $(G, \{T_1, \ldots, T_k\}, C,$ Under, Over, Vlabel, $N)$ starting from line 13.
10: **else**
11: $V_s \leftarrow$ Remove(V_s, v), Vlabel$(V_s) \leftarrow$ Vlabel$(V_s) \setminus v$, $V_j \leftarrow$ Add(V_j, v)
12: **for** every $V \in$ Over and $V \notin$ Full **do** ▷ Step 5
13: Let u be a vertex in Vlabel(V) and not in V
14: $V \leftarrow$ Add(V, u)
15: **for** every $v \in \cup_{i=2}^{k} T_i \setminus \cup_{i=1}^{k} V_i$ **do**
16: Let V be a set such that $V \notin$ Full and $v \in N(V)$
17: $V \leftarrow$ Add(V, v)
18: **return** $\{V_1, \ldots, V_k\}$

Now that we have proved the correctness of Step 4, notice that in the last part of Algorithm 2 each non full set either contains a whole dominating tree or is adjacent to at least as many available vertices as it needs for its size demand to be met. We first start by the second case in which we add the assigned vertices to the set one by one until it is full. Then we are left with the case where each non full set contains a dominating tree, in which we can greedily add adjacent vertices to each such set one by one until all of them meet their size demands.

We now put everything together and provide the main algorithm of this section.

Algorithm 3 Győri–Lovász theorem for special case of graphs with k dominating trees.

Require: An instance of GL-Partition (G, k, C, N) and a set of k vertex disjoint dominating trees $\mathcal{T} = \{T_1, \ldots, T_k\}$ such that $C \subseteq T_1$.

1: $(V_1, \ldots, V_k) \leftarrow$ AddTrees$(G, C, \mathcal{T})$
2: (Over, Under, Vlabel, Tlabel) $\leftarrow$ Labeling$(G, C, \mathcal{T}, N, V_1, \ldots, V_k)$
3: $(V_1, \ldots, V_k) \leftarrow$ Add Vertices$(G, C, \mathcal{T}, N,$ Over, Under, Vlabel, Tlabel, Full)
4: Output $V_1, \ldots, V_k$

▶ **Lemma 15** (⋆). *Let an instance of GL-Partition $(G, k, C = \{c_1, \ldots, c_k\}, N = \{n_1, \ldots, n_k\})$ and k vertex disjoint dominating trees $T_1, \ldots, T_k$ such that $C \subseteq T_1$ are given as an input to Algorithm 3. Then Algorithm 3 returns l full sets $V_1, \ldots, V_l$ and a reduced instance, $(G - \cup_{i=1}^{l} V_i, k - l, C \setminus \{c_{k-l}, \ldots, c_k\}, N \setminus \{n_{k-l}, \ldots, n_k\})$ of GL-Partition with a set of vertex-disjoint dominating trees of reduced graph $\mathcal{T} \setminus \{T_{k-l}, \ldots, T_k\}$, for some $l \in [k]$, in polynomial time.*

In the next section we tackle the more general instance in which there is a dominating tree that contains strictly less than k terminals and some other contains at least one by showing that we are able to iteratively find a smaller instance in which all the terminals are contained in some dominating tree and then employ the algorithm developed in this section.

4 From General CDS Partition to GL-partition

In this section we provide the algorithm from Theorem 4. The algorithm receives an instance of GL-Partition (G, k, C, N) and k vertex disjoint dominating trees $T_1, \ldots, T_k$ as input and it outputs a GL-partition $V_1, \ldots, V_k$ of $V(G)$.

If all terminal vertices are contained in one dominating tree then we can directly use Algorithm 3 of the previous section. Notice that if a terminal is not contained in any tree we can simply add it to one since each tree is dominating. Hence, we assume without loss of generality that every terminal vertex is contained in some tree. Moreover, we assume that the dominating trees are separated into three sets $\mathcal{T}_0, \mathcal{T}_1$ and $\mathcal{T}_{>1}$ depending on whether they contain 0, 1 or more than 1 terminal vertices, respectively. This categorization can be done in polynomial time so for simplicity we assume that this is also part of the input. As in the previous section we first provide an intuitive description of Algorithm 4. The formal descriptions of the steps and the proof of correctness is deferred to the appendix.

Description of Algorithm 4. The Algorithm receives as input a GL-Partition instance (G, k, C, N), where $C = \{c_1, \ldots, c_k\}$, $N = \{n_1, \ldots, n_k\}$, and a set of k vertex-disjoint dominating trees $\mathcal{T} = \{T_1, \ldots, T_k\}$ separated into three sets $\mathcal{T}_0, \mathcal{T}_1, \mathcal{T}_{>1}$ depending on how many terminal vertices they contain. It is important to note that, like in the previous section, during this description of the algorithm, every time we add a vertex to a vertex set, it is implied that we also check if the condition of having l full sets say $V_1, \ldots, V_l$, intersecting exactly l of the dominating trees, say $T_1, \ldots, T_l$ is met. If yes, then we output those l full sets and restart the algorithm for $G - \cup_{i=1}^{l} V_i$ and $k - l$, $\mathcal{T} = \mathcal{T} \setminus \{T_{k-l}, \ldots, T_k\}$, $C = \{c_{k-l}, \ldots, c_l\}$ and $N = \{n_{k-l}, \ldots, n_k\}$. For simplicity and space constraints, we do not include this in every step of this description nor in the pseudocodes provided in this section. We moreover assume both in pseudocodes of this section and in this description that every time we add a vertex we also check if a set meets its size demand and if so we add it to the set Full that includes all the connected vertex sets that satisfy their size demands. Similarly every time we remove a vertex from some set we check if it is in Full and if yes, we remove it from Full.

Step 1 We first initialize each vertex set V_i to contain the corresponding terminal vertex c_i, where $i \in [k]$. Then, for each tree in $\mathcal{T}_1 \cup \mathcal{T}_{>1}$, we add its vertices one by one to a vertex set that it is adjacent to (based only on the adjacencies occurring only by the tree considered). Next, we add the vertices of $V(G) \setminus V(\mathcal{T})$ to an adjacent set one by one.

Step 2 For each tree $T \in \mathcal{T}_{>1}$ that contains l terminals, we create a tree set $\mathcal{T}'$ containing T and $l - 1$ trees from $\mathcal{T}_0$, which we then remove from $\mathcal{T}_{>1}$ and $\mathcal{T}_0$ respectively. Among those sets, we choose one that has enough vertices available to satisfy the size demands of all of the l vertex sets intersecting T. (Algorithm Choose a Tree Set)

Step 3 Call Algorithm 3 that has as input those l dominating trees, the corresponding vertex sets and terminal vertices, while the graph we work on is the one that occurs from the union of those sets and trees. Notice that the sum of the demands of those sets might be less than the size of the graph but this does not affect the correctness of the algorithm.

Algorithm 4 Győri–Lovász theorem for graphs with k dominating trees.

Require: A graph G, three sets of dominating trees $\mathcal{T}_0, \mathcal{T}_1, \mathcal{T}_{>1}$, a set of k vertices $C = \{c_1, \ldots, c_k\}$, a set of k natural numbers $N = \{n_1, \ldots, n_k\}$ and k connected vertex sets $\{V_1, \ldots, V_k\}$ such that $c_i \in V_i$ for all $i \in [k]$

1: $(V_1, \ldots, V_k) \leftarrow$ Add Vertices$(\mathcal{T}_0, \mathcal{T}_1, \mathcal{T}_{>1}, V_1 \ldots, V_k, C, N, U)$
2: $(T, T_1, \ldots, T_{l-1}) \leftarrow$ Choose a Tree Set$(\mathcal{T}_0, \mathcal{T}_1, \mathcal{T}_{>1}, C, N, V_1, \ldots, V_k)$
3: Algorithm 3$(\cup_{i=1}^{l} V_i \cup_{i=1}^{l-1} T'_i \cup T, T, T'_1, \ldots, T'_{l-1}, c_1, \ldots, c_l, n_1, \ldots, n_l)$.

5 Conclusion

As we showcase in this work, the algorithm of Theorem 4 opens up a new avenue for efficiently computing connected partitions, in the settings where sufficiently large CDS partitions are available. This motivates further research into improving bounds for CDS partitions beyond the worst-case instances, as well as into parameterized and approximation algorithms for computing a CDS partition of the largest size.

To the best of our knowledge, Corollaries 5 and 11 are the first examples of a Győri–Lovász type of results that allow for a trade-off between efficiency of the construction and the connectivity requirement. It would be interesting to investigate whether a more refined trade-off is possible, interpolating smoothly between the polynomial time for higher connectivity and exponential time for extremal connectivity.

Our work also initiates the study of the gap between connectivity and the size of a CDS packing in structured graph classes. It remains a curious open question to characterize the class of graphs, for which k-connectivity implies the existence of a k-CDS partition. So far, our results show that this class contains interval and biconvex graphs (Theorems 7 and 6), but does not contain chordal and convex bipartite graphs.

Courcelle's Theorem for Lipschitz Continuity

Tatsuya Gima

Yuichi Yoshida
National Institute of Informatics, Tokyo, Japan

Abstract

Lipschitz continuity of algorithms, introduced by Kumabe and Yoshida (FOCS'23), measures the stability of an algorithm against small input perturbations. Algorithms with small Lipschitz continuity are desirable, as they ensure reliable decision-making and reproducible scientific research. Several studies have proposed Lipschitz continuous algorithms for various combinatorial optimization problems, but these algorithms are problem-specific, requiring a separate design for each problem.

To address this issue, we provide the first algorithmic meta-theorem in the field of Lipschitz continuous algorithms. Our result can be seen as a Lipschitz continuous analogue of Courcelle's theorem, which offers Lipschitz continuous algorithms for problems on bounded-treewidth graphs. Specifically, we consider the problem of finding a vertex set in a graph that maximizes or minimizes the total weight, subject to constraints expressed in monadic second-order logic (MSO_2). We show that for any $\varepsilon > 0$, there exists a $(1 \pm \varepsilon)$-approximation algorithm for the problem with a polylogarithmic Lipschitz constant on bounded treewidth graphs. On such graphs, our result outperforms most existing Lipschitz continuous algorithms in terms of approximability and/or Lipschitz continuity. Further, we provide similar results for problems on bounded-clique-width graphs subject to constraints expressed in MSO_1. Additionally, we construct a Lipschitz continuous version of Baker's decomposition using our meta-theorem as a subroutine.

1 Introduction

Lipschitz continuity of algorithms, introduced by Kumabe and Yoshida [14], is a measure of an algorithm's stability in response to errors or small perturbations in the input for weighted optimization problems. Roughly speaking, it is the maximum ratio of the (weighted) Hamming distance between the outputs of an algorithm for two different weights to the ℓ_1 distance between those weights (see Section 2.4 for the precise definition). It is desirable for algorithms to have small Lipschitz constants, as large constants can undermine the reliability of decision-making and the reproducibility of scientific research.

Since its introduction, Lipschitz continuous algorithms have been proposed for various optimization problems [14, 16]. However, we need to design a different algorithm and analyze its Lipschitz continuity for each problem, which can be impractical. To address this limitation, we present an algorithmic meta-theorem for Lipschitz continuous algorithms, which can be seen as Lipschitz continuity analogue of celebrated Courcelle's theorem [3].

To present our results, we first introduce some notation. Let $G = (V, E)$ be a graph of n vertices with treewidth tw, $\varphi(X)$ be an MSO_2 formula with a free vertex set variable X (see Section 2.3 for details about logic), and $w \in \mathbb{R}_{\geq 0}^V$ be a weight vector. We consider the problem of finding a vertex subset $X \subseteq V$ such that $G \models \varphi(X)$ and $w(X)$ is maximized, which we call the *MSO_2 maximization problem*. We also consider the problem of finding X such that $w(X)$ is minimized, which we call the *MSO_2 minimization problem*. Our main results are the following.

▶ **Theorem 1.** *For any $\varepsilon \in (0, 1]$, there is a $(1-\varepsilon)$-approximation algorithm for the MSO_2 maximization problem with Lipschitz constant $O\left((f(\mathrm{tw}, |\varphi|) + \log \varepsilon^{-1} + \log\log n)\varepsilon^{-1}\log^2 n\right)$, where f is some computable function. The time complexity is bounded by $O\left(f(\mathrm{tw}, |\varphi|)n\right)$.*

▶ **Theorem 2.** *For any $\varepsilon \in (0, 1]$, there is a $(1+\varepsilon)$-approximation algorithm for the MSO_2 minimization problem with Lipschitz constant $O\left((f(\mathrm{tw}, |\varphi|) + \log \varepsilon^{-1} + \log\log n)\varepsilon^{-1}\log^2 n\right)$, where f is some computable function. The time complexity is bounded by $O\left(f(\mathrm{tw}, |\varphi|)n\right)$.*

We note that the trivial upper bound on Lipschitz constant is n [16]; therefore the bounds in the theorems above are significantly smaller for fixed tw and φ. We also remark that our meta-theorems yield randomized approximation algorithms. This is necessary since, for most problems, it is known that exact or deterministic algorithms cannot be Lipschitz continuous [14].

When the treewidth of the input graph is bounded by a constant, Theorems 1 and 2 provide algorithms that outperform existing algorithms in terms of approximability and/or Lipschitz continuity:

- For the minimum weight vertex cover problem, Theorem 2 yields an algorithm with a better approximation ratio than the previous 2-approximation algorithm with Lipschitz constant 4 [16], at the polylogarithmic sacrifice of the Lipschitz constant.
- For the minimum weight feedback vertex set problem, Theorem 2 outperforms the previous $O(\log n)$-approximation algorithm with Lipschitz constant $O(\sqrt{n}\log^{3/2} n)$ [16] in terms of both approximability and Lipschitz continuity.
- For the maximum weight matching problem[1], Theorem 1 yields an algorithm with a better approximation ratio than the previous $\left(\frac{1}{8} - \varepsilon\right)$-approximation algorithm with Lipschitz constant $O(\varepsilon^{-1})$ [14], at the polylogarithmic sacrifice of the Lipschitz constant.
- For the shortest path problem, Theorem 2 slightly improves the Lipschitz continuity compared to the previous $(1-\varepsilon)$-approximation algorithm with Lipschitz constant $O(\varepsilon^{-1}\log^3 n)$ [14], without losing approximability.

For a fixed φ, by explicitly specifying the transitions in the dynamic programming within the algorithm, we can provide more precise bounds on the function f that appears in Theorems 1 and 2. In particular, considering the case that φ is an MSO_2 formula representing the independent set constraint, we have the following.

▶ **Theorem 3.** *For any $\varepsilon \in (0, 1]$, there is a $(1-\varepsilon)$-approximation algorithm for the maximum weight independent set problem with Lipschitz constant $O\left((\mathrm{tw} + \log \varepsilon^{-1} + \log\log n)\varepsilon^{-1}\log^2 n\right)$. The time complexity is bounded by $2^{O(\mathrm{tw})}n$.*

This result is surprising as the dependence of tw on the Lipschitz constant is subexponential and, even more remarkably, linear. We note that through similar arguments, analogous results hold for several other problems, such as the minimum weight vertex cover problem and the minimum weight dominating set problem.

[1] Although the output of this problem is an edge set rather than a vertex set, this problem can be expressed by an MSO_2 formula on a new graph $G' = (V \cup E, \{(v, e) \colon e \text{ is incident to } v\})$

We further demonstrate that Theorems 1 and 2 lead to Lipschitz continuous version of Baker's technique [1]. As a representative example, we consider the maximum weight independent set problem on planar graphs, where a vertex subset X is an *independent set* of a graph G if no two vertices in X are adjacent in G. We prove the following.

▶ **Theorem 4.** *For any $\varepsilon \in (0,1]$, there is a $(1-\varepsilon)$-approximation algorithm for the maximum weight independent set problem on planar graphs with Lipschitz constant $O\left((\varepsilon^{-1}+\log\log n)\varepsilon^{-1}\log^2 n\right)$. The time complexity is bounded by $2^{O(\varepsilon^{-1})}n$.*

Using similar algorithms, Lipschitz continuous PTASes can be obtained for many problems, including the minimum weight vertex cover problem and the minimum weight dominating set problem.

As a lower bound result, we prove that the Lipschitz constant of any $(1-\varepsilon)$-approximation algorithm for some MSO_2 maximization problem is large on general graphs, which justifies considering the MSO_2 maximization problem on a restricted graph class. Specifically, we consider the *max ones problem* [6, 9], where the instance is a 3CNF formula over a variable set X and a weight function $w : X \to \mathbb{R}_{\geq 0}$, and the goal is to find a satisfying assignment $\sigma : X \to \{0,1\}$ that maximizes the weight $\sum_{x\in\sigma^{-1}(1)} w(x)$. It is easy to see that there exists a fixed MSO_2 formula $\varphi(X)$ such that the max ones problem can be reduced to a problem on bipartite graphs, where the task is to find a vertex set X that maximizes the weight $\sum_{x\in X} w(x)$ subject to φ. We show the following.

▶ **Theorem 5.** *There exist $\varepsilon, \delta > 0$ such that any $(1-\varepsilon)$-approximation algorithm for the max ones problem has Lipschitz constant $\Omega(n^{\delta})$, where n is the number of variables.*

We note that it is possible to construct an algorithm for the max ones problem with a Lipschitz constant similar to that in Theorem 3, where tw denotes the treewidth of the "incidence graph" of the 3CNF instance (see Section 4.2 for details). Since tw is upper bounded by n for any instance, Theorem 5 implies that the dependency of the Lipschitz constant on tw cannot be improved to $\mathrm{tw}^{o(1)}$.

We also prove analogous meta-theorems when parameterizing by clique-width. Let an *MSO_1 maximization (resp., minimization) problem* be the variant of an MSO_2 problem in which the formula φ is restricted to MSO_1. Denote by cw the clique-width of the graph G. We then obtain the following.

▶ **Theorem 6.** *For any $\varepsilon \in (0,1]$, there is a $(1-\varepsilon)$-approximation algorithm for the MSO_1 maximization problem with Lipschitz constant $O\left((f(\mathrm{cw},|\varphi|)+\log\varepsilon^{-1}+\log\log n)\varepsilon^{-1}\log^2 n\right)$, where f is some computable function. The time complexity is bounded by $O\left(f(\mathrm{cw},|\varphi|)n\right)$.*

▶ **Theorem 7.** *For any $\varepsilon \in (0,1]$, there is a $(1+\varepsilon)$-approximation algorithm for the MSO_1 minimization problem with Lipschitz constant $O\left((f(\mathrm{cw},|\varphi|)+\log\varepsilon^{-1}+\log\log n)\varepsilon^{-1}\log^2 n\right)$, where f is some computable function. The time complexity is bounded by $O\left(f(\mathrm{cw},|\varphi|)n\right)$.*

We note that the functions f in Theorems 6 and 7 are much larger than those in Theorems 1 and 2. In particular, the bounds for Theorems 3 and 4 do not follow from Theorem 6.

1.1 Technical Overview

Now we provide a technical overview of our framework. Since the arguments for clique-width are similar, we focus here on the treewidth results and omit the clique-width case.

For simplicity, here we consider the maximum weight independent set problem on a full binary tree (a rooted tree in which every vertex has exactly 0 or 2 children). This corresponds to the case where $\varphi(X) = \forall x \forall y((x \in X \wedge y \in X) \to \neg\mathsf{adj}(x,y))$. Let $w \in \mathbb{R}^V_{\geq 0}$ be the weight vector.

If we do not care about Lipschitzness, this problem can exactly be solved by the following algorithm. For each vertex $v \in V$, define $\mathsf{DP}[v][0]$ to be an independent set in the subtree rooted at v that does not include v with the maximum weight. Similarly, define $\mathsf{DP}[v][1]$ to be an independent set in the subtree rooted at v with the maximum weight. If v is a leaf, then $\mathsf{DP}[v][0] = \emptyset$ and $\mathsf{DP}[v][1] = \{v\}$. Otherwise, let u_1 and u_2 be the two children of v. We have $\mathsf{DP}[v][0] = \mathsf{DP}[u_1][1] \cup \mathsf{DP}[u_2][1]$, and $\mathsf{DP}[v][1]$ is the one with the larger weight of $X_{v,0} := \mathsf{DP}[u_1][0] \cup \mathsf{DP}[u_2][0] \cup \{v\}$ and $X_{v,1} := \mathsf{DP}[u_1][1] \cup \mathsf{DP}[u_2][1]$. By performing this dynamic programming in a bottom-up manner, the problem can be solved exactly.

However, this algorithm is not Lipschitz continuous. This is because when we compute $\mathsf{DP}[v][1]$, which of $X_{v,0}$ or $X_{v,1}$ has a larger weight is affected by small changes in the weights. To address this issue, we use the exponential mechanism [7]. Specifically, for some constant $c > 0$, we select $X_{v,i}$ with probability proportional to $\exp(c \cdot w(X_{v,i}))$. This approach makes the algorithm Lipschitz continuous, with only a slight sacrifice in the approximation ratio. Specifically, we can prove that by appropriately choosing c for a given $\varepsilon' \in (0, 1]$, the increase in the Lipschitz constant can be bounded by $\tilde{O}(\varepsilon'^{-1})$ by reducing the approximation guarantee by a factor of $1 - \varepsilon'$ at each vertex where the exponential mechanism is applied.

While this approach makes the algorithm Lipschitz continuous, the Lipschitz constant is still too large when the height h of the tree is large. Specifically, to achieve an approximation guarantee of $1 - \varepsilon$, we need to set $\varepsilon' = \frac{\varepsilon}{h}$, leading to a Lipschitz constant of $h \cdot \tilde{O}(\varepsilon'^{-1}) = \tilde{O}(\varepsilon^{-1}h^2)$. This is larger than the trivial bound n when $h = O(n)$. We resolve this issue by using the fact that any tree has a tree decomposition of width 5 and height $O(\log n)$ [2]. By performing dynamic programming with the exponential mechanism on this tree decomposition, we can obtain $(1-\varepsilon)$-approximation algorithm with Lipschitz constant $\tilde{O}(\varepsilon^{-1})$. This argument can be naturally extended to the case where G is a bounded treewidth graph. By following the proof of Courcelle's Theorem [3, 5], we further extend this argument to the case where φ is a general MSO_2 formula with a free vertex variable.

We prove Theorem 5 by leveraging a lower bound on a related notion of sensitivity for the maximum cut problem [8], where sensitivity measures the change in the output with respect to the Hamming distance under edge deletions [21]. Specifically, we reduce the maximum cut problem, where stability is defined with respect to edge deletions, to the max ones problem, where stability is measured with respect to weight changes.

1.2 Related Work

Lipschitz continuity of discrete algorithms is defined by Kumabe and Yoshida [14], and they provided Lipschitz continuous approximation algorithms for the minimum spanning tree, shortest path, and maximum weight matching problems. In a subsequent work [16], they further provided such algorithms for the minimum weight vertex cover, minimum weight set cover, and minimum weight feedback vertex set problems. In another work [15], they defined Lipschitz continuity for allocations in cooperative games and provided Lipschitz continuous allocation schemes for the matching game and the minimum spanning tree game.

A variant known as *pointwise Lipschitz continuity* has also been studied, which is defined using the unweighted Hamming distance instead of the weighted Hamming distance. Kumabe and Yoshida [14] defined pointwise Lipschitz continuity and provided pointwise Lipschitz continuous algorithms for the minimum spanning tree and maximum weight bipartite matching problems. Liu et al. [18] proposed the *proximal gradient method* as a general technique for solving LP relaxations stably. Using this, they provided pointwise Lipschitz continuous approximation algorithms for the minimum vertex (S, T)-cut, densest subgraph, maximum weight (b-)matching, and packing integer programming problems.

(Average) sensitivity, introduced by Varma and Yoshida [21] with preliminary ideas by Murai and Yoshida [19], is a notion similar to Lipschitz continuity. While Lipschitz continuity evaluates an algorithm's stability against unit changes in the input weights, (average) sensitivity evaluates an algorithm's stability against (random) deletions of elements from the input. Algorithms with small (average) sensitivity have been studied for several problems, such as maximum matching [21, 23], minimum cut [21], knapsack problem [13], Euclidean k-means [22], spectral clustering [20], and dynamic programming problems [12]. Recently, Fleming and Yoshida [8] constructed a PCP framework to prove the sensitivity lower bound for the constraint satisfaction problem.

1.3 Organization

The rest of this paper is organized as follows. In Section 2, we describe the necessary preliminaries on tree decomposition (Sections 2.1 and 2.2), logic (Section 2.3), and Lipschitz continuity (Section 2.4). In Section 3, we prove Theorem 1 by providing a Lipschitz continuous algorithm for the MSO_2 maximization problem. Since the algorithm and analysis for MSO_2 minimization are similar, we defer the proof of Theorem 2 to the full version. In Section 4, we give a more precise Lipschitzness analysis for specific formulas φ, which includes the proof of Theorem 3. Proofs of Theorems 4, 5, 6, and 7 are given in the full version.

2 Preliminaries

2.1 Tree Decomposition

Let G be a graph with n vertices. A pair $(\mathcal{B}, \mathcal{T})$ consisting of a family $\mathcal{B}$ of subsets (called *bags*) of $V(G)$ and a rooted tree $\mathcal{T}$ whose vertex set is $\mathcal{B}$ is a *(rooted) tree decomposition* of G if it satisfies the following three conditions.

- $\bigcup_{B\in\mathcal{B}} B = V(G)$.
- For each edge $e \in E(G)$, there is a bag $B \in \mathcal{B}$ such that $e \subseteq B$.
- For each vertex $v \in V(G)$, the set of bags $\{B \in \mathcal{B} \colon v \in B\}$ induces connected subgraph in T.

For a tree decomposition $(\mathcal{B}, \mathcal{T})$, we may refer to the *root node*, *leaf nodes*, and the *height* of $\mathcal{T}$ as those of $(\mathcal{B}, \mathcal{T})$, respectively. Moreover, $(\mathcal{B}, \mathcal{T})$ is binary if $\mathcal{T}$ is a binary tree. The *width* of a tree decomposition $(\mathcal{B}, \mathcal{T})$ is the maximum size of a bag in $\mathcal{B}$ minus one. The *treewidth* of G is the minimum possible width among all possible tree decompositions of G. It is known that the tree decomposition of G of width at most $2k+1$ can be computed in $2^{O(k)}n$ time [10], where k is the treewidth of G. Moreover, any tree decomposition of G of width k can be transformed into a binary tree decomposition of width at most $3k+2$ and height at most $O(\log n)$ [2]. Thus, we obtain the following lemma.

▶ **Lemma 8** ([2, 10]). *Let G be a graph with n vertices and k be the treewidth of G. Then, a binary tree decomposition of G with width $O(k)$ and height $O(\log n)$ can be computed in $2^{O(k)}n$ time.*

2.2 HR-algebra

We introduce the notions of HR-algebra[2], which is one of the algebraic definitions of tree decomposition. A *k-graph* is a tuple $G = \langle V, E, \mathsf{src}\rangle$ of a set of vertices V, a set of edges E, and a k-vector $\mathsf{src} \in (V \cup \{\mathtt{nil}\})^k$. We write the i-th element of a vector src by $\mathsf{src}(i)$. If $\mathsf{src}(i) = u$, we say that u is a *i-source*. We write the set $\{\mathsf{src}(i) : i \in [k]\} \setminus \{\mathtt{nil}\}$ by $\mathsf{src}(G)$.

Let G and H be k-graphs. The *parallel-composition* of G and H, denoted by $G /\!\!/ H$, is the graph generated by the following procedure. First, create the disjoint union of G and H, and identify the (non-$\mathtt{nil}$) vertices $\mathsf{src}_G(i)$ and $\mathsf{src}_H(i)$ for each $i \in [k]$. Finally, remove all the self-loops and multi-edges. Let B be a non-empty subset of $[k]$. The *source forgetting operation* fg_B is the function that maps a k-graph G to a k-graph G' such that $V_G = V_{G'}$, $E_G = E_{G'}$, and $\mathsf{src}_{G'}(i) = \mathtt{nil}$ if $i \in B$, and $\mathsf{src}_{G'}(i) = \mathsf{src}_G(i)$ otherwise.

▶ **Definition 9** (HR-algebra)**.** *A* term *of a HR-algebra over k-graphs is either*

- *a constant symbol* $\mathtt{i}$, $\mathtt{ij}$, *or* $\emptyset$ *denoting a k-graph* $\langle\{v\}, \emptyset, \mathsf{src}\rangle$ *with* $\mathsf{src}(i) = v$, *a k-graph* $\langle\{u, v\}, \{\{u, v\}\}, \mathsf{src}\rangle$ *with* $\mathsf{src}(i) = u$ *and* $\mathsf{src}(j) = v$, *or the empty graph, respectively;*
- $t /\!\!/ s$ *for any terms t and s;*
- $\mathsf{fg}_B(t)$ *for any term t and any $B \subseteq [k]$.*

We may associate a term with the graphs represented by it. A term of an HR-algebra t can be decomposed into the parse tree in the usual way, called the *(rooted) HR-parse tree* of t. The *height* of a HR-parse tree is the maximum distance from the root to a leaf. It is known that tree decompositions are equivalent to HR-parse trees in the following sense.

▶ **Proposition 10** (see e.g. [4])**.** *The treewidth of a graph is at most k if and only if the graph can be denoted by a term of a HR-algebra over $(k+1)$-graphs.*

Moreover, binary tree decomposition can be transformed into an HR-parse tree with approximately the same height.

▶ **Proposition 11** ($\star$)**.** *Given a rooted binary tree decomposition $(\mathcal{B}, \mathcal{T})$ of G with width k and height h, we can compute a HR-parse tree over $(k+1)$-graph denoting G with height $O(\log k + h)$.*

The proof of Proposition 11 is essentially the same as the proof of Proposition 10 but we give in the full version.

2.3 Monadic Second-Order Logic

We provide a slightly less formal definition of *monadic second-order (MSO) logic* over k-graphs for accessibility (see, e.g., [17] for more formal definition). An *atomic formula* is a formula of the form $s = t$, $\mathsf{adj}(s, t)$, $t \in X$, and Boolean constants $\mathtt{True}$ and $\mathtt{False}$. Here, $\mathsf{adj}(s, t)$ is the predicate that represents whether s and t are adjacent. A *monadic second-order formula* over k-graphs is a formula built from atomic formulas, the usual Boolean connectives $\wedge, \vee, \neg, \to$, first-order quantifications $\exists x$ and $\forall x$ (quantifications over vertices), and second-order quantifications $\exists X$ and $\forall X$ (quantification over sets of vertices). The notation $\varphi(X)$ indicates that φ has exactly one free variable X. The *quantifier height* (or *quantifier rank*) of a formula φ, denoted by $|\varphi|$, is the maximum depth of quantifier nesting in φ (see e.g. [17] for a formal definition). The *counting monadic second-order (CMSO) logic*

[2] The acronym HR stands for hyperedge replacement [4].

is an expansion of MSO logic that have additional predicates $\mathsf{Card}_{m,r}(X)$ for a second-order variable X, meaning $|X| \equiv m \pmod r$. A $\mathsf{C}_r\mathsf{MSO}^q$-formula is a CMSO formula φ such that the quantifier height of φ is at most q and $r' \leq r$ holds for any predicate $\mathsf{Card}_{m,r'}$ in φ. For a logical formula φ and a graph G, we write $G \models \varphi$ when graph G satisfies the property expressed by φ.

There are two variants of MSO logic: MSO_1 (or simply MSO), which is described above, allows quantification over vertices and sets of vertices only, and MSO_2 which allows quantification over edges and sets of edges as well. It is well known that, for any graph G and MSO_2-formula φ, there exists an MSO_1 formula φ' such that $G \models \varphi \iff G' \models \varphi'$, where G' is the *incidence graph*, obtained by subdividing each edge of G (with two colors meaning the original and the subdivision vertices) (see e.g. [11]). It is easy to see that the treewidth of the incidence graph is at most the treewidth of the original graph. Thus, since this paper focuses on graphs with bounded treewidth, we mainly consider MSO_1. However, all the theorems are held for MSO_2 and graphs of bounded treewidth.

We introduce some more notations. For a set V, two families $\mathcal{A} \subseteq 2^V$ and $\mathcal{B} \subseteq 2^V$ are *separated* if $A \cap B = \varnothing$ for all $A \in \mathcal{A}$, and $B \in \mathcal{B}$. We write $A \cup B$ by $A \uplus B$ if $A \cap B = \varnothing$, and $\mathcal{A} \boxtimes \mathcal{B} \coloneqq \{A \cup B : A \in \mathcal{A}, B \in \mathcal{B}\}$ if $\mathcal{A}$ and $\mathcal{B}$ are separated. For a formula $\varphi(X)$ and a graph G, the set of vertex sets satisfying φ is denoted by $\mathsf{sat}(G, \varphi)$, that is, $\mathsf{sat}(G, \varphi) = \{A : G \models \varphi(A)\}$.

The following theorem is a key of the MSO model-checking algorithm [3, 4].

▶ **Theorem 12** ([4]). *Let r, q, k be positive integers. Let $\varphi(X)$ be a $\mathsf{C}_r\mathsf{MSO}^q$-formula over k-graphs with a second-order free variable X. Then, the following hold.*

1. *For any $B \subseteq [k]$, there exists a $\mathsf{C}_r\mathsf{MSO}^q$-formula $\psi(X)$ such that for any k-graph G, we have*

$$\mathsf{sat}(\mathsf{fg}_B(G), \varphi) = \mathsf{sat}(G, \psi).$$

2. *There exists a family of tuples $\{\theta_i(X), \psi_i(X)\}_{i \in [p]}$ of $\mathsf{C}_r\mathsf{MSO}^q$-formulas with a free variable X such that, for any k-graphs G and H,*

$$\mathsf{sat}(G /\!\!/ H, \varphi) = \biguplus_{i \in [p]} \{S \cup P : S \in \mathsf{sat}(G, \theta_i), P \in \mathsf{sat}(H, \psi_i)\}.$$

It is known that, for any r, q, k, up to logical equivalence, there are only finitely many different $\mathsf{C}_r\mathsf{MSO}^q$-formulas $\varphi(X)$ over k-graphs (see e.g., [17]). Thus, we can obtain a linear-time algorithm, based on dynamic programming over trees, for $\mathsf{C}_r\mathsf{MSO}^q$ model checking over bounded treewidth. Courcelle and Mosbah [5] adjusted Theorem 12 to address optimization, counting, and other problems. We use a slightly modified version of the theorem of Courcelle and Mosbah.

Let $\mathsf{nosrc}(X) \equiv \bigwedge_{i \in [k]} (\mathsf{src}(i) \notin X)$, and $\varphi\restriction_S(X)$ denote $\varphi(X \cup S) \wedge \mathsf{nosrc}(X)$ for a set $S \subseteq \mathsf{src}(G)$.

▶ **Observation 13.** *Let G be a k-graph, and $\varphi(X)$ be a formula with a free set variable X. Then, we have $\mathsf{sat}(G, \varphi) = \biguplus_{S \subseteq \mathsf{src}(G)} \mathsf{sat}(G, \varphi\restriction_S) \boxtimes \{S\}$.*

The proof of Corollary 14 is given in the full version.

▶ **Corollary 14** (⋆). *Let r, q, k be positive integers. Let $\varphi(X)$ be a $\mathsf{C}_r\mathsf{MSO}^q$-formula over k-graphs with a second-order free variables X. Then, for all $S \subseteq \mathsf{src}(G)$, the following hold.*

1. *For any $B \subseteq [k]$, there exists a $\mathsf{C}_r\mathsf{MSO}^q$-formula $\psi(X)$ such that for any k-graph G, we have*

$$\mathsf{sat}(\mathsf{fg}_B(G), \varphi\restriction_S) = \biguplus_{S' \subseteq B} \mathsf{sat}(G, \psi\restriction_{S \cup S'}) \boxtimes \{S'\}.$$

2. *There exists a family of tuples* $\{\theta_i\restriction_{S_i}(X), \psi_i\restriction_{S'_i}(X)\}_{i\in[p]}$ *of* $\mathsf{C}_r\mathsf{MSO}^q$*-formulas with a free variable* X *such that, for any* k*-graphs* G *and* H*,*

$$\mathsf{sat}(G /\!\!/ H, \varphi\restriction_S) = \biguplus_{i\in[p]} \mathsf{sat}(G, \theta_i\restriction_{S_i}) \boxtimes \mathsf{sat}(H, \psi_i\restriction_{S'_i}).$$

Moreover, $S_i \cup S'_i = S$ *for all* $i \in [p]$*.*

Then, we can design an algorithm for an (C)MSO maximization (minimization) problem over graphs of bounded treewidth. For simplicity, we assume that the given graph G has no sources, that is, $\mathsf{src}(G) = \varnothing$. Let t be a term denoting G_t and $\varphi(X)$ be the (C)MSO-formula describing the constraint of the problem. We recursively compute the value $\mathsf{opt}(t', \varphi'\restriction_S) = \max\{w(A) : G \models \varphi'\restriction_S(A)\}$ for any subterm t' of t and MSO-formula $\varphi'\restriction_S$ as follows, where $w \in \mathbb{R}^V_{\geq 0}$ is the given weight vector and $w(X) = \sum_{x\in X} w_x$ for any $X \subseteq V(G)$. If t' is of the form $\mathsf{fg}_B(t'')$, then $\mathsf{opt}(\mathsf{fg}_B(t''), \varphi'\restriction_S) = \max_{S'\subseteq B}\{\mathsf{opt}(t'', \psi\restriction_{S\cup S'}) + w(S')\}$, where, ψ is the formula obtained from Corollary 14. If t' is of the form $t_1 /\!\!/ t_2$, then $\mathsf{opt}(t', \varphi'\restriction_S) = \max_{i\in[p]}\{\mathsf{opt}(t_1, \theta\restriction_{S_i}) + \mathsf{opt}(t_2, \psi\restriction_{S'_i})\}$, where, $\{\theta_i\restriction_{S_i}(X), \psi_i\restriction_{S'_i}(X)\}_{i\in[p]}$ are the formulas obtained from Corollary 14. Then, $\mathsf{opt}(t, \varphi\restriction_\varnothing)$ is the maximum value for the problem since t has no sources. In the following, for simplicity, we may omit the $\restriction_S$ notation and consider only formulas φ such that $\mathsf{sat}(G, \varphi)$ does not contain any sources.

In the above setting, the graphs are considered without any special vertex sets (called as colors) or special vertices (called as labels). However, for k-graphs with a constant number of colors and/or labels, an appropriate HR-algebra and logics can be defined, and the similar results for Corollary 14 hold (see e.g. [4, 17]).

2.4 Lipschitz Continuity

We formally define Lipschitz continuity of algorithms. As this is sufficient for this work, we only consider algorithms for vertex-weighted graph problems. The definition can be naturally extended to other settings, such as edge-weighted problems. Let $G = (V, E)$ be a graph. For vertex sets $X, X' \subseteq V$ and weight vectors $w, w' \in \mathbb{R}^V_{\geq 0}$, we define the *weighted Hamming distance* between (X, w) and (X', w') by

$$d_{\mathrm{w}}((X, w), (X', w')) := \left\| \sum_{v\in X} \mathbf{1}_v w_v - \sum_{v\in X'} \mathbf{1}_v w'_v \right\|_1 = \sum_{v\in X\cap X'} |w_v - w'_v| + \sum_{v\in X\setminus X'} w_v + \sum_{v\in X'\setminus X} w'_v,$$

where $\mathbf{1}_v \in \{0,1\}^V$ denotes the *characteristic vector* of v, that is, the vector $\mathbf{1}_{v,u} = 1$ holds if and only if $u = v$. For two probability distributions $\mathcal{X}$ and $\mathcal{X}'$ over subsets of V, we define

$$\mathsf{EM}\left((\mathcal{X}, w), (\mathcal{X}', w')\right) := \inf_{\mathcal{D}} \mathbb{E}_{(X,X')\sim\mathcal{D}}\left[d_{\mathrm{w}}((X, w), (X', w'))\right],$$

where the minimum is taken over *couplings* of $\mathcal{X}$ and $\mathcal{X}'$, that is, distributions over pairs of sets such that its marginal distributions on the first and second coordinates are equal to $\mathcal{X}$ and $\mathcal{X}'$, respectively. Consider an algorithm $\mathcal{A}$, that takes a graph $G = (V, E)$ and a weight vector $w \in \mathbb{R}^V_{\geq 0}$ as an input and outputs a vertex subset $X \subseteq V$. We denote the output distribution of $\mathcal{A}$ for weight w as $\mathcal{A}(w)$. The *Lipschitz constant* of $\mathcal{A}$ is defined by

$$\sup_{\substack{w,w'\in\mathbb{R}_{\geq 0},\\ w\neq w'}} \frac{\mathsf{EM}\left((\mathcal{A}(w), w), (\mathcal{A}(w'), w')\right)}{\|w - w'\|_1}.$$

For two random variables $\boldsymbol{X}$ and $\boldsymbol{X}'$, the *total variation distance* between them is given as:

$$\mathsf{TV}\left(\boldsymbol{X}, \boldsymbol{X}'\right) := \inf_{\mathcal{D}} \Pr_{(X,X')\sim\mathcal{D}}\left[X \neq X'\right],$$

where the minimum is taken over couplings between $\boldsymbol{X}$ and $\boldsymbol{X}'$, that is, distributions over pairs such that its marginal distributions on the first and the second coordinates are equal to $\boldsymbol{X}$ and $\boldsymbol{X}'$, respectively. For an element $u \in V$, we use $\mathbf{1}_u \in \mathbb{R}^V_{\geq 0}$ to denote the *characteristic vector* of u, that is, $\mathbf{1}_u(u) = 1$ and $\mathbf{1}_u(v) = 0$ for $v \in V \setminus \{u\}$. The following lemma indicates that, to bound the Lipschitz constant, it suffices to consider pairs of weight vectors that differ by one coordinate.

▶ **Lemma 15** ([14]). *Suppose that there exist some $c > 0$ and $L > 0$ such that*

$$\mathsf{EM}\left((\mathcal{A}(G,w),w),(\mathcal{A}(G,w+\delta\mathbf{1}_u),w+\delta\mathbf{1}_u)\right) \leq \delta L$$

holds for all $w \in \mathbb{R}^V_{\geq 0}$, $u \in V$ and $0 < \delta \leq c$. Then, $\mathcal{A}$ is L-Lipschitz.

In our algorithm, we use the following procedures *softmax* and *softmin*. These procedures are derived from the *exponential mechanism* in the literature of *differential privacy* [7] and frequently appear in the literature on Lipschitz continuity [14, 16]. Here, we organize them into a more convenient form for our use. Let $p \in \mathbb{Z}_{\geq 1}$, $x_1, \ldots, x_p \in \mathbb{R}_{\geq 0}$, and $\epsilon \in (0, 1]$. The *softmax* of $x_1, \ldots, x_p$ is taken as follows. If $\max_{i\in[p]} x_i = 0$, we set $\mathsf{softargmax}^{\epsilon}_{i\in[p]} x_i$ to be an arbitrary index i with $x_i = 0$ and $\mathsf{softmax}^{\epsilon}_{i\in[p]} x_i = 0$. Assume otherwise. First, we sample $\boldsymbol{c}$ uniformly from $\left[\frac{2\epsilon^{-1}\log(2p\epsilon^{-1})}{\max_{i\in[p]} x_i}, \frac{4\epsilon^{-1}\log(2p\epsilon^{-1})}{\max_{i\in[p]} x_i}\right]$. Let $\boldsymbol{i}^*$ be a probability distribution over $[p]$ such that

$$\Pr\left[\boldsymbol{i}^* = i\right] = \frac{\exp(\boldsymbol{c}x_i)}{\sum_{i'\in[p]}\exp(\boldsymbol{c}x_{i'})}.$$

holds for all $i \in [p]$. Then, we define $\mathsf{softargmax}^{\epsilon}_{i\in[p]} x_i := \boldsymbol{i}^*$ and $\mathsf{softmax}^{\epsilon}_{i\in[p]} x_i := x_{\boldsymbol{i}^*}$. We have the following. The proofs of Lemmas 16 and 17 are given in the full version.

▶ **Lemma 16.** *We have $\mathbb{E}\left[\mathsf{softmax}^{\epsilon}_{i\in[p]} x_i\right] \geq (1-\epsilon)\max_{i\in[p]} x_i$.*

▶ **Lemma 17.** *Let $\delta > 0$ and assume $\delta \leq \frac{\max_{i\in[p]} x_i}{4\epsilon^{-1}\log(2p\epsilon^{-1})}$. Let $x'_1, \ldots, x'_p \in \mathbb{R}_{\geq 0}$ be numbers such that $x_i \leq x'_i \leq x_i + \delta$ holds for all $i \in [p]$. Then, $\mathsf{TV}\left(\mathsf{softargmax}^{\epsilon}_{i\in[p]} x_i, \mathsf{softargmax}^{\epsilon}_{i\in[p]} x'_i\right) \leq \frac{10\epsilon^{-1}\log(2p\epsilon^{-1})\delta}{\max_{i\in[p]} x_i}$.*

Similarly, the *softmin* of $x_1, \ldots, x_p$ is taken as follows. If $\min_{i\in[p]} x_i = 0$, we set $\mathsf{softargmin}^{\epsilon}_{i\in[p]} x_i$ be an arbitrary index i with $x_i = 0$ and $\mathsf{softmin}^{\epsilon}_{i\in[p]} x_i = 0$. Assume otherwise. First, we sample $\boldsymbol{c}$ uniformly from $\left[\frac{2\epsilon^{-1}\log(2p\epsilon^{-1})}{\min_{i\in[p]} x_i}, \frac{4\epsilon^{-1}\log(2p\epsilon^{-1})}{\min_{i\in[p]} x_i}\right]$. Let $\boldsymbol{i}^*$ be a probability distribution over $[p]$ such that

$$\Pr\left[\boldsymbol{i}^* = i\right] = \frac{\exp(-\boldsymbol{c}x_i)}{\sum_{i'\in[p]}\exp(-\boldsymbol{c}x_{i'})}.$$

holds for all $i \in [p]$. Then, we define $\mathsf{softargmin}^{\epsilon}_{i\in[p]} x_i := \boldsymbol{i}^*$ and $\mathsf{softmin}^{\epsilon}_{i\in[p]} x_i := x_{\boldsymbol{i}^*}$. We have the following. The proofs of Lemmas 18 and 19 are given in the full version.

▶ **Lemma 18.** *We have $\mathbb{E}\left[\mathsf{softmin}^{\epsilon}_{i\in[p]} x_i\right] \leq (1+\epsilon)\min_{i\in[p]} x_i$.*

▶ **Lemma 19.** *Let $\delta > 0$ and assume $\delta \leq \frac{\min_{i\in[p]} x_i}{4\epsilon^{-1}\log(2p\epsilon^{-1})}$. Let $x'_1, \ldots, x'_p \in \mathbb{R}_{\geq 0}$ be numbers such that $x_i \leq x'_i \leq x_i + \delta$ holds for all $i \in [p]$. Then, $\mathsf{TV}\left(\mathsf{softargmin}^{\epsilon}_{i\in[p]} x_i, \mathsf{softargmin}^{\epsilon}_{i\in[p]} x'_i\right) \leq \frac{10\epsilon^{-1}\log(2p\epsilon^{-1})\delta}{\min_{i\in[p]} x_i}$.*

3 Lipschitz Continuous Algorithms for MSO_2 Optimization Problems

In this section, we prove Theorems 1–3. Since the proofs are similar to that for Theorem 1, we provide most of the proof of Theorem 2 in the full version. In Section 3.1, we define the notations and give a brief overview of the algorithm. Section 3.2 handles the base case, where the graph consists of a single vertex. Sections 3.3 and 3.4 analyze the impact of the parallel composition and the forget operations, respectively, on approximability and the Lipschitz constant. In Section 3.5, we put everything together to prove Theorem 1. Finally, in Section 4.1, we provide a more refined analysis for the special case of the maximum weight independent set problem to prove Theorem 3.

3.1 Definitions

For a graph G, a weight vector w, and an MSO_2 formula φ, we define

$$\mathsf{opt}_w[G,\varphi] = \max_{S\subseteq V(G), G\models\varphi(S)} w(S). \tag{1}$$

for maximization problems and

$$\mathsf{opt}_w[G,\varphi] = \min_{S\subseteq V(G), G\models\varphi(S)} w(S). \tag{2}$$

for minimization problems. If $\mathsf{sat}(G,\varphi)=\emptyset$, we define $\mathsf{opt}_w[G,\varphi] = \mathtt{nil}$. For graphs G and MSO_2 formulas φ with $\mathsf{sat}(G,\varphi)\neq\emptyset$, our algorithm recursively computes the vertex set $\mathsf{DP}_w[G,\varphi]$ that approximately achieves the maximum in Equation (1) or minimum in Equation (2). When it is clear from the context, we omit the subscript w and simply write $\mathsf{opt}[G,\varphi]$ and $\mathsf{DP}[G,\varphi]$. We perform the dynamic programming algorithm using the formulas defined in Corollary 14 over the parse tree of a term obtained from Lemma 8 and Proposition 11. Specifically, at every stage of the algorithm, it is guaranteed that each $X\in\mathsf{sat}(G,\varphi)$ satisfies $X\subseteq V(G)\setminus\mathsf{src}(G)$. Furthermore, our algorithm is randomized. Thus, $\mathsf{DP}[G,\varphi]$ can be considered as a probability distribution over vertex sets in $\mathsf{sat}(G,\varphi)$.

To bound the approximation ratio, for a weight vector $w\in\mathbb{R}^V_{\geq 0}$, we bound the ratio between $\mathbb{E}\left[w(\mathsf{DP}[G,\varphi])\right]$ and $\mathsf{opt}[G,\varphi]$. To bound the Lipschitz constant, for a weight vector $w\in\mathbb{R}^V_{\geq 0}$, $u\in V$, and $\delta>0$, we bound $\mathsf{EM}\left(\mathsf{DP}_w[G,\varphi],\mathsf{DP}_{w+\delta\mathbf{1}_u}[G,\varphi]\right)$. From now on, we will concentrate on maximizing problems. The algorithm for minimization problems is similar to that for maximization problems, while the detail of the analysis is slightly differ. We discuss the minimization version in the full version.

3.2 Base Case

Here we consider the base case. Let G be a graph with a single vertex v and no edges, where v is a source of G, and φ be an MSO_2 formula such that $\mathsf{sat}(G,\varphi)$ is nonempty and contains no set containing v. In particular, we have $\mathsf{sat}(G,\varphi)=\{\emptyset\}$. We set $\mathsf{DP}[G,\varphi]:=\emptyset$. Since $w(\emptyset)=0$, it is clear that $w\left(\mathsf{DP}[G,\varphi]\right)=\mathsf{opt}[G,\varphi]=0$. Furthermore, it is obvious that

$$\mathsf{EM}\left(\mathsf{DP}_w[G,\varphi],\mathsf{DP}_{w+\delta\mathbf{1}_u}[G,\varphi]\right)=\mathsf{EM}(\emptyset,\emptyset)=0.$$

3.3 Parallel Composition

Next, we consider the parallel composition. Let

$$\mathsf{sat}(G /\!\!/ H,\varphi) = \biguplus_{i\in[p]} \mathsf{sat}(G,\theta_i)\boxtimes\mathsf{sat}(H,\psi_i). \tag{3}$$

Assume we have already computed $\mathsf{DP}[G, \theta_i]$ and $\mathsf{DP}[H, \psi_i]$ for each $i \in [p]$. We compute $\mathsf{DP}[G /\!\!/ H, \varphi]$. For each $i \in [p]$, we denote $\mathsf{opt}_i := \mathsf{opt}[G, \theta_i] + \mathsf{opt}[H, \psi_i]$. By definition, we have $\max_{i \in [p]} \mathsf{opt}_i = \mathsf{opt}[G /\!\!/ H, \varphi]$. Then, we take $\boldsymbol{i}^* = \mathsf{softargmax}^{\varepsilon}_{i \in [p]} \mathsf{opt}_i$ and define $\mathsf{DP}[G /\!\!/ H, \varphi] := \mathsf{DP}[G, \theta_{\boldsymbol{i}^*}] \cup \mathsf{DP}[H, \psi_{\boldsymbol{i}^*}]$. First we analyze the approximation ratio.

▶ **Lemma 20.** *Let $0 < \alpha \leq 1$ and suppose $\mathbb{E}[w(\mathsf{DP}[G, \theta_i])] \geq \alpha \mathsf{opt}[G, \theta_i]$ and $\mathbb{E}[w(\mathsf{DP}[H, \psi_i])] \geq \alpha \mathsf{opt}[H, \psi_i]$ hold for all $i \in [p]$. Then, we have $\mathbb{E}[w(\mathsf{DP}[G /\!\!/ H, \varphi])] \geq (1 - \varepsilon)\alpha \mathsf{opt}[G /\!\!/ H, \varphi]$.*

Proof. We have

$$\begin{aligned}
&\mathbb{E}[w(\mathsf{DP}[G /\!\!/ H, \varphi])] = \mathbb{E}[w(\mathsf{DP}[G, \theta_{\boldsymbol{i}^*}] \cup \mathsf{DP}[H, \psi_{\boldsymbol{i}^*}])] \geq \alpha \mathbb{E}[\mathsf{opt}[G, \theta_{\boldsymbol{i}^*}] + \mathsf{opt}[H, \psi_{\boldsymbol{i}^*}]] \\
&= \alpha \mathbb{E}\left[\mathsf{softmax}^{\varepsilon}_{i \in [p]} \mathsf{opt}_i\right] \geq (1 - \varepsilon)\alpha \max_{i \in [p]} \mathsf{opt}_i = (1 - \varepsilon)\alpha \mathsf{opt}[G /\!\!/ H, \varphi].
\end{aligned}$$

◀

Now we analyze the Lipschitz constant. We denote the variable $\boldsymbol{i}^*$ corresponding to the weight w and $w + \delta \mathbf{1}_u$ by $\boldsymbol{i}^*_w$ and $\boldsymbol{i}^*_{w+\delta \mathbf{1}_u}$, respectively. We note that $\mathsf{DP}_w[G, \theta_i]$ and $\mathsf{DP}_{w+\delta \mathbf{1}_u}[G, \theta_i]$ are the same as a distribution unless $u \in V(G) \setminus \mathsf{src}_G$. The same also holds for H. Since $V(G) \setminus \mathsf{src}_G$ and $V(H) \setminus \mathsf{src}_H$ are disjoint, without loss of generality, we can assume the $\mathsf{DP}_w[H, \psi_i]$ and $\mathsf{DP}_{w+\delta \mathbf{1}_u}[H, \psi_i]$ are the same as a distribution. We have the following.

▶ **Lemma 21.** *Let $\beta \in \mathbb{R}_{\geq 0}$ and suppose $\mathsf{EM}(\mathsf{DP}_w[G, \theta_i], \mathsf{DP}_{w+\delta \mathbf{1}_u}[G, \theta_i]) \leq \beta$ holds for all $i \in [p]$. Then, we have $\mathsf{EM}(\mathsf{DP}_w[G /\!\!/ H, \varphi], \mathsf{DP}_{w+\delta \mathbf{1}_u}[G /\!\!/ H, \varphi]) \leq 30\varepsilon^{-1} \log(2p\varepsilon^{-1})\delta + \beta$.*

Proof. We have

$$\begin{aligned}
&\mathsf{EM}(\mathsf{DP}_w[G /\!\!/ H, \varphi], \mathsf{DP}_{w+\delta \mathbf{1}_u}[G /\!\!/ H, \varphi]) \\
&\leq \mathsf{TV}\left(\boldsymbol{i}^*_w, \boldsymbol{i}^*_{w+\delta \mathbf{1}_u}\right)\left(\mathsf{opt}_w[G /\!\!/ H, \varphi] + \mathsf{opt}_{w+\delta \mathbf{1}_u}[G /\!\!/ H, \varphi]\right) + \max_{i \in [p]}\left(\mathsf{EM}(\mathsf{DP}_w[G, \theta_i], \mathsf{DP}_{w+\delta \mathbf{1}_u}[G, \theta_i])\right) \\
&\leq \frac{10\varepsilon^{-1} \log(2p\varepsilon^{-1})\delta}{\mathsf{opt}_w[G /\!\!/ H, \varphi]}\left(\mathsf{opt}_w[G /\!\!/ H, \varphi] + \mathsf{opt}_{w+\delta \mathbf{1}_u}[G /\!\!/ H, \varphi]\right) + \beta \leq 30\varepsilon^{-1} \log(2p\varepsilon^{-1})\delta + \beta,
\end{aligned}$$

where the last inequality is from $\varepsilon \leq 1$ and $\delta \leq \mathsf{opt}_w[G /\!\!/ H, \varphi]$. ◀

3.4 Forget

Here we consider forget operation. Let $B \subseteq \mathsf{src}_G$ and

$$\mathsf{sat}(\mathsf{fg}_B(G), \varphi) = \biguplus_{i \in [p]} \mathsf{sat}(G, \varphi_i) \boxtimes \{S_i\}. \tag{4}$$

Assume we have already computed $\mathsf{DP}[G, \varphi_i]$ for each $i \in [p]$. We compute $\mathsf{DP}[\mathsf{fg}_B(G), \varphi]$.

We first sample $\boldsymbol{c} \in \mathbb{R}_{>0}$ uniformly from $\left[\frac{2\log(2p\varepsilon^{-1})}{\varepsilon \mathsf{opt}[G, \varphi, S]}, \frac{4\log(2p\varepsilon^{-1})}{\varepsilon \mathsf{opt}[G, \varphi, S]}\right]$. For each $i \in [p]$, we denote $\mathsf{opt}_i = \mathsf{opt}[G, \varphi_i] + w(S_i)$. By definition, we have $\max_{i \in [p]} \mathsf{opt}_i = \mathsf{opt}[\mathsf{fg}_B(G), \varphi]$. Then, we take $\boldsymbol{i}^* = \mathsf{softargmax}^{\varepsilon}_{i \in [p]} \mathsf{opt}_i$ and define $\mathsf{DP}[\mathsf{fg}_B(G), \varphi] := \mathsf{DP}[G, \varphi_{\boldsymbol{i}^*}] \cup S_{\boldsymbol{i}^*}$. First we analyze the approximation ratio.

▶ **Lemma 22.** *Let $0 < \alpha \leq 1$ and suppose $\mathbb{E}[w(\mathsf{DP}[G, \varphi_i])] \geq \alpha \mathsf{opt}[G, \varphi_i]$ holds for all $i \in [p]$. Then, we have $\mathsf{DP}[\mathsf{fg}_B(G), \varphi] \geq (1 - \varepsilon)\alpha \mathsf{opt}[\mathsf{fg}_B(S), \varphi]$.*

Proof. We have

$$\begin{aligned}
\mathbb{E}[w(\mathsf{DP}[G, \varphi])] &= \mathbb{E}[w(\mathsf{DP}[G, \varphi_{\boldsymbol{i}^*}] \cup S_{\boldsymbol{i}^*})] \geq \mathbb{E}[\alpha \mathsf{opt}[G, \varphi_{\boldsymbol{i}^*}] + w(S_{\boldsymbol{i}^*})] \geq \alpha \mathbb{E}[\mathsf{opt}[G, \varphi_{\boldsymbol{i}^*}] + w(S_{\boldsymbol{i}^*})] \\
&= \alpha \mathbb{E}\left[\mathsf{softmax}^{\varepsilon}_{i \in [p]} \mathsf{opt}_i\right] \geq (1 - \varepsilon)\alpha \max_{i \in [p]} \mathsf{opt}_i = (1 - \varepsilon)\alpha \mathsf{opt}[\mathsf{fg}_B(G), \varphi].
\end{aligned}$$

◀

Now we analyze the Lipschitz constant.

▶ **Lemma 23.** *Let $\beta \in \mathbb{R}_{\geq 0}$ and suppose $\mathsf{EM}(\mathsf{DP}_w[G, \varphi_i], \mathsf{DP}_{w+\delta \mathbf{1}_u}[G, \varphi_i]) \leq \beta$ holds for all $i \in [p]$. Then, we have $\mathsf{EM}(\mathsf{DP}_w[\mathsf{fg}_B(G), \varphi], \mathsf{DP}_{w+\delta \mathbf{1}_u}[\mathsf{fg}_B(G), \varphi]) \leq 31\varepsilon^{-1} \log(2p\varepsilon^{-1})\delta + \beta$.*

Proof. We have

$$
\begin{aligned}
&\mathsf{EM}(\mathsf{DP}_w[\mathsf{fg}_B(G), \varphi], \mathsf{DP}_{w+\delta \mathbf{1}_u}[\mathsf{fg}_B(G), \varphi]) \\
&\quad \leq \mathsf{TV}\left(\boldsymbol{i}^*_w, \boldsymbol{i}^*_{w+\delta \mathbf{1}_u}\right)\left(\mathsf{opt}_w[\mathsf{fg}_B(G), \varphi] + \mathsf{opt}_{w+\delta \mathbf{1}_u}[\mathsf{fg}_B(G), \varphi]\right) \\
&\qquad + \max_{i \in [p]} \left(\mathsf{EM}\left(\mathsf{DP}_w[G, \varphi_i] \cup S_i, \mathsf{DP}_{w+\delta \mathbf{1}_u}[G, \varphi_i] \cup S_i\right)\right) \\
&\quad \leq \frac{10\varepsilon^{-1} \log(2p\varepsilon^{-1})\delta}{\mathsf{opt}_w[\mathsf{fg}_B(G), \varphi]}\left(\mathsf{opt}_w[\mathsf{fg}_B(G), \varphi] + \mathsf{opt}_{w+\delta \mathbf{1}_u}[\mathsf{fg}_B(G), \varphi]\right) \\
&\qquad + \max_{i \in [p]} \left(\mathsf{EM}\left(\mathsf{DP}_w[G, \varphi_i], \mathsf{DP}_{w+\delta \mathbf{1}_u}[G, \varphi_i]\right)\right) + \max_{i \in [p]} \left[d_{\mathrm{w}}((S_i, w), (S_i, w + \delta \mathbf{1}_u))\right] \\

\end{aligned}
$$

◀

3.5 Putting Together

Let $G = (V, E)$ be a graph with treewidth k. From Lemma 8 and Proposition 11, we can compute a HR-parse tree t over $(k+1)$-graph denoting G with height $O(\log k + \log n) \leq O(\log n)$. We perform the dynamic programming algorithm on this parse tree. We have the following.

▶ **Lemma 24.** *Let $\varepsilon \in (0, 1]$ and h be the height of t. Our algorithm outputs a solution $X \in \mathsf{sat}(G, \varphi)$ such that $\mathbb{E}[w(X)] \geq (1 - h\varepsilon)\mathsf{opt}[G, \varphi]$. The Lipschitz constant is bounded by $31h\varepsilon^{-1} \log(2p_{\max}\varepsilon^{-1})$, where $p_{\max}$ is the maximum of p among all update formulas (3) or (4) that the algorithm uses.*

Proof. The approximability bound is obtained by repeatedly applying Lemmas 20 and 22 and $(1-\varepsilon)^h \geq 1 - h\varepsilon$. The Lipschitzness bound is obtained by repeatedly applying Lemmas 21 and 23. ◀

Since $p_{\max}$ is bounded by a function of k and $|\varphi|$, we have the following.

Proof of Theorem 1. The claim follows by substituting ε, h, and k in Lemma 24 with $\frac{\varepsilon}{\Theta(\log n)}$, $O(\log n)$, and $3k + 2$, respectively. ◀

4 Special Cases

4.1 Independent Set

From the proof of Theorem 1, $f(k, \varphi)$ in Theorem 1 is bounded by $\log(2p_{\max})$. Particularly, if $p_{\max}$ is bounded by $2^{O(k)}$, the Lipschitz constant depends linearly on k. Here, we prove Theorem 3 for the maximum weight independent set problem by showing that $p_{\max} \leq 2^{O(k)}$. Similar arguments can be applied to several other problems, such as the minimum weight vertex cover problem and the minimum weight dominating set problem. For a k-graph G and $S \subseteq \mathsf{src}(G)$, let

$$
\varphi_S(X) \equiv \forall x(x \in \mathsf{src}(G) \to \neg x \in X) \wedge \forall x \forall y(((x \in X \vee x \in S) \wedge (y \in X \vee y \in S)) \to \neg \mathsf{adj}(x, y)).
$$

In words, $\mathsf{sat}(G, \varphi_S)$ is the family of subsets X of V such that X is disjoint from $\mathsf{src}(G)$ and $X \cup S$ is an independent set of G. Then, we have

$$\mathsf{sat}(\mathsf{fg}_B(G), \varphi_S) = \biguplus_{S' \subseteq B} \mathsf{sat}(G, \varphi_{S \cup S'}) \boxtimes \{S'\}, \quad \mathsf{sat}(G /\!\!/ H, \varphi_S) = \mathsf{sat}(G, \varphi_S) \boxtimes \mathsf{sat}(H, \varphi_S).$$

Particularly, we have $p_{\max} \leq 2^{O(k)}$ and therefore Theorem 3 is proved.

4.2 Max Ones

Recall that in *max ones problem*, we given a 3CNF formula Φ over a variable set X and a weight function $w : X \to \mathbb{R}_{\geq 0}$, the goal is to find a satisfying assignment $\sigma : X \to \{0, 1\}$ that maximizes the weight $\sum_{x \in \sigma^{-1}(1)} w(x)$. We reduce the problem to a graph problem. Let $G_\Phi = (X \cup \bar{X} \cup \mathcal{C}, E)$ be the graph such that X is the variable set of Φ, $\bar{X} = \{\bar{x}_i : x_i \in X\}$, $\mathcal{C}$ is the clause set of Φ, $\{x_i, \bar{x}_i\} \in E$ for all $x_i \in X$, $\{C_j, x_i\} \in E$ iff clause C_j contains x_i as a positive literal, and $\{C_j, \bar{x}_i\} \in E$ iff clause C_j contains x_i as a negative literal. Let $w'(x) = w(x)$ if $x \in X$, and otherwise $w'(x) = 0$. Note that the treewidth of G_Φ is at most $2|X|$.

Here, the notations $a \in A \cup B$, $a \in A \cap B$, $a \in A \setminus B$, $\forall a \in A\ \psi$, and $\exists a \in A\ \psi$ are syntactic sugar defined in the usual sense. For a k-graph G and $S, D \subseteq \mathsf{src}(G)$, let

$$\varphi_{S,D}(A) \equiv \exists B \begin{bmatrix} & \forall a \in A \cup S\ \forall b \in B\ (a \in X \wedge b \in \bar{X} \wedge \neg \mathsf{adj}(a, b)) \\ \wedge & \forall x \in X \cup \bar{X}\ \forall y \in X \cup \bar{X}\ (\mathsf{adj}(x, y) \to (x \in A \cup S \cup B \vee y \in A \cup S \cup B)) \\ \wedge & \forall s \in \mathsf{src}(G)\ (\neg s \in A) \wedge \forall c \in \mathcal{C} \setminus D\ \exists x \in A \cup S \cup B\ (\mathsf{adj}(x, c)) \end{bmatrix}.$$

The first and the second rows says that $A \cup S$ and B represent the sets $\sigma^{-1}(1)$ and $\sigma^{-1}(0)$ of an assignment σ, respectively. The third row says that A has no sources, and all clauses except in D are satisfied by the σ defined by $A \cup S$ and B. Then, the max ones problem is equivalent to find a vertex set Y maximizes the weight $\sum_{x \in Y} w'(x)$ and satisfies $G_\Phi \models \varphi_{\emptyset,\emptyset}(Y)$. Here, we have

$$\mathsf{sat}(\mathsf{fg}_B(G), \varphi_{S,D}) = \begin{cases} \biguplus_{S' \subseteq B} \mathsf{sat}(G, \varphi_{S \cup S', D}) \boxtimes \{S'\} & \text{if } D \cap B = \emptyset, \\ \emptyset & \text{otherwise} \end{cases}$$

$$\mathsf{sat}(G /\!\!/ H, \varphi_{S,D}) = \biguplus_{\substack{D_1 \cap D_2 = D \\ D_1, D_2 \subseteq \mathsf{src}(G)}} \mathsf{sat}(G, \varphi_{S,D_1}) \boxtimes \mathsf{sat}(H, \varphi_{S,D_2}).$$

Particularly, we have $p_{\max} \leq 2^{O(k)}$.

Subtrajectory Clustering and Coverage Maximization in Cubic Time, or Better

Anne Driemel
University of Bonn, Germany

Abstract

Many application areas collect unstructured trajectory data. In subtrajectory clustering, one is interested to find patterns in this data using a hybrid combination of segmentation and clustering. We analyze two variants of this problem based on the well-known SetCover and CoverageMaximization problems. In both variants the set system is induced by metric balls under the Fréchet distance centered at polygonal curves. Our algorithms focus on improving the running time of the update step of the generic greedy algorithm by means of a careful combination of sweeps through a candidate space. In the first variant, we are given a polygonal curve P of complexity n, distance threshold Δ and complexity bound ℓ and the goal is to identify a minimum-size set of center curves $\mathcal{C}$, where each center curve is of complexity at most ℓ and every point p on P is covered. A point p on P is covered if it is part of a subtrajectory π_p of P such that there is a center $c \in \mathcal{C}$ whose Fréchet distance to π_p is at most Δ. We present an approximation algorithm for this problem with a running time of $\mathcal{O}((n^2\ell + \sqrt{k_\Delta}n^{5/2}) \log^2 n)$, where k_Δ is the size of an optimal solution. The algorithm gives a bicriterial approximation guarantee that relaxes the Fréchet distance threshold by a constant factor and the size of the solution by a factor of $\mathcal{O}(\log n)$. The second problem variant asks for the maximum fraction of the input curve P that can be covered using k center curves, where $k \leq n$ is a parameter to the algorithm. For the second problem variant, our techniques lead to an algorithm with a running time of $\mathcal{O}((k+\ell)n^2 \log^2 n)$ and similar approximation guarantees. Note that in both algorithms $k, k_\Delta \in O(n)$ and hence the running time is cubic, or better if $k \ll n$.

1 Introduction

Trajectory analysis is a broad field ranging from gait analysis of full-body motion trajectories [16, 20, 13], via traffic analysis [21] and epidemiological hotspot detection [25] to Lagrangian analysis of particle simulations [24]. Using the current availability of cheap tracking technology, vast amounts of unstructured spatio-temporal data are collected. Clustering is a fundamental problem in this area and can be formulated under various similarity metrics, among them the Fréchet distance. However, the unstructured nature of trajectory data poses the additional challenge that the data first needs to be segmented before the trajectory segments, which we call subtrajectories, can be clustered in a metric space. Subtrajectory clustering aims to find clusters of subtrajectories that represent complex patterns that reoccur along the trajectories [1, 8, 17], such as commuting patterns in traffic data.

We study two variants of a problem posed by Akitaya, Brüning, Chambers, and Driemel [3], which are based on the well-known set cover and coverage maximization problems. Both rely on the definition of a geometric set system built using metric balls under the Fréchet distance. Given a polygonal curve, we are asked to produce a set of "center" curves that either

1. has minimum cardinality and covers the entirety of the input curve, or
2. covers as much as possible of the input curve under cardinality constraints.

In either setting a point p of the input-curve is considered as "covered", if there is a subcurve π_p of the input curve that contains p and has small Fréchet distance to some center curve. Note that a point p may be covered by multiple center curves. For the precise formulation refer to Section 2. This formulation extends immediately to a set of input curves – instead of one – where one is now tasked to cover the entirety (respectively as much as possible) of all points on all input curves combined.

In this paper we study the continuous variant of the problem where we need to cover the continuous set of points given by the input polygonal curve. It is instructive, however, to first consider a discrete variant of the set cover instance as follows. Given a discrete point sequence $A = a_1, \ldots, a_n$, consider the set of contiguous subsequences of the form $A_{ij} = a_i, \ldots, a_j$. We say a_k is contained in the set defined by A_{ij} if there exist $i' \leq k \leq j'$ such that $A_{i'j'}$ is similar to A_{ij}. Note that a full specification of this set system has size $\Theta(n^3)$ in the worst case. This phenomenon is shared with the continuous setting where all known discretizations lead to a cubic-size set system. In this paper, we examine the question of whether we can obtain subcubic-time algorithms by internally representing the set system implicitly.

2 Preliminaries

An **edge** is a map $e : [0,1] \to \mathbb{R}^d$ defined by two points $p, q \in \mathbb{R}^d$ as the linear interpolation $t \mapsto p + t(q-p)$. A **polygonal curve** is a map $P : [0,1] \to \mathbb{R}^d$ defined by an ordered set $(p_1, \ldots, p_n) \subset \mathbb{R}^d$ as the result of concatenating the edges $(e_1, \ldots, e_{n-1})$, where e_i is the edge from p_i to p_{i+1}. Any point $P(t)$ is said to lie on the edge e_i if t lies in the preimage of e_i. Any point $P(t)$ lies on at most two edges, exactly if it defines the endpoint of edge e_i which coincides with the start point of e_{i+1}. The number of points n defining the polygonal curve P is its **complexity**, and we denote it by $|P|$. The set of all polygonal curves in $\mathbb{R}^d$ of complexity at most ℓ we denote by $\mathbb{X}_\ell^d$. For any polygonal curve P and values $0 \leq s \leq t \leq 1$ we define $P[s,t]$ to be the subcurve of P from s to t, which itself is a polygonal curve of complexity at most $|P|$. For two polygonal curves P and Q we define the **continuous Fréchet distance** to be $\mathrm{d}_{\mathcal{F}}(P,Q) = \inf_{f,g} \max_{t\in[0,1]} \|P(f(t)) - Q(g(t))\|$ where f and g range over all non-decreasing surjective functions from $[0,1]$ to $[0,1]$.

▶ **Definition 1** (Δ-coverage [3]). *Let P be a polygonal curve in $\mathbb{R}^d$, and let $\Delta \in \mathbb{R}_{>0}$ and $\ell \in \mathbb{N}_{\geq 2}$ be given. For any $\mathcal{Q} \subset \mathbb{X}_\ell^d$, define the Δ-coverage of $\mathcal{Q}$ on P (refer to Figure 1) as*

$$\mathrm{Cov}_P(\mathcal{Q}, \Delta) = \bigcup_{Q\in\mathcal{Q}} \left(\bigcup_{0\leq s\leq t\leq 1,\, \mathrm{d}_{\mathcal{F}}(P[s,t],Q)\leq\Delta} [s,t] \right) \subset [0,1].$$

For a curve $Q \in \mathbb{X}_\ell^d$ we denote the Δ-coverage $\mathrm{Cov}_P(\{Q\}, \Delta)$ by $\mathrm{Cov}_P(Q, \Delta)$.

Problem 1: Subtrajectory Covering (SC). Let P be a polygonal curve in $\mathbb{R}^d$, and let $\Delta \in \mathbb{R}_{>0}$ and $\ell \in \mathbb{N}_{\geq 2}$ be given. The task is to identify a set $\mathcal{Q}$ of curves in $\mathbb{X}_\ell^d$ minimizing $|\mathcal{Q}|$ such that $\mathrm{Cov}_P(\mathcal{Q}, \Delta) = [0,1]$.

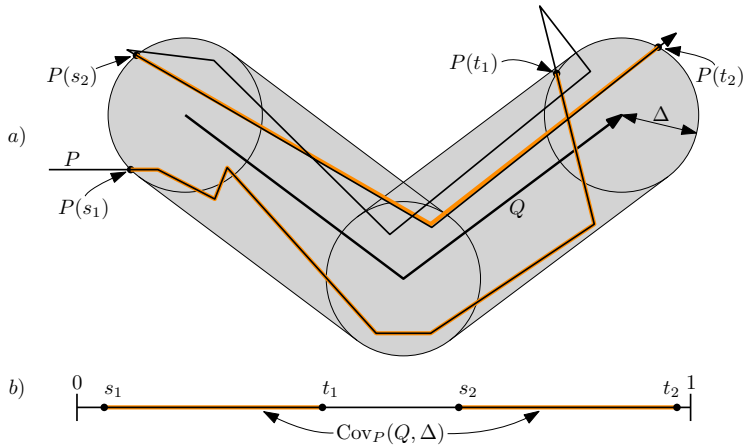

Figure 1 *a*): Example of all points on P that lie on subcurve of P that have Fréchet distance at most Δ to a curve Q of complexity 3. *b*): The set $\mathrm{Cov}_P(Q,\Delta) \subset [0,1]$.

▶ **Definition 2** (Bicriteria approximation for SC). *Let P be a polygonal curve in $\mathbb{R}^d$, and let $\Delta \in \mathbb{R}_{>0}$ and $\ell \in \mathbb{N}_{\geq 2}$ be given. Let $C^* \subset \mathbb{X}_\ell^d$ be a set of minimum cardinality such that $\mathrm{Cov}_P(C^*,\Delta) = [0,1]$. Let $\alpha, \beta \geq 1$ be given. An algorithm that outputs a set $C \subset \mathbb{X}_\ell^d$ of size $\alpha|C^*|$ such that $\mathrm{Cov}_P(C,\beta\Delta) = [0,1]$ is called an (α,β)-approximation for SC.*

Problem 2: Subtrajectory Coverage Maximization (SCM). Let P be a polygonal curve in $\mathbb{R}^d$, and let $\Delta \in \mathbb{R}_{>0}$, $\ell \in \mathbb{N}_{\geq 2}$ and $k \in \mathbb{N}_{\geq 1}$ be given. The task is to identify a set $\mathcal{Q}$ of k curves in $\mathbb{X}_\ell^d$ maximizing the Lebesgue measure $\|\mathrm{Cov}_P(\mathcal{Q},\Delta)\|$.

▶ **Definition 3** (Bicriteria approximation for SCM). *Let P be a polygonal curve in $\mathbb{R}^d$, and let $\Delta \in \mathbb{R}_{>0}$ and $\ell \in \mathbb{N}_{\geq 2}$ be given. Let $C^* \subset \mathbb{X}_\ell^d$ be a set of size k such that $\|\mathrm{Cov}_P(C^*,\Delta)\|$ is maximum. Let $\alpha \geq 0$ and $\beta \geq 1$ be given. An algorithm that outputs a set $C \subset \mathbb{X}_\ell^d$ of size k such that $\|\mathrm{Cov}_P(C,\beta\Delta)\| \geq \alpha \|\mathrm{Cov}_P(C^*,\Delta)\|$ is called an (α,β)-approximation for SCM.*

2.1 Prior work on Subtrajectory Covering and Coverage Maximization

We first discuss prior work on the SC problem. The SC problem was introduced by Akitaya, Brüning, Chambers, and Driemel [3]. Their results were later improved by Brüning, Conradi, and Driemel [4]. Both works identified a curve S that approximates the input P, such that any solution to the problem induces an approximate solution of similar size consisting of only subcurves of S. This set of subcurves defines a set system which turns out to have low VC-dimension. This enables randomized set cover algorithms with improved approximation factors and expected running time in $\mathcal{O}(n(k_\Delta)^3(\log^4(\Lambda/\Delta) + \log^3(n/k_\Delta)) + n\log^2 n)$, where Λ corresponds to the arc length of the curve P. While the complexity of the main algorithm in [3] depends on the relative arclength of the input curve, the latter [4] also identified a set of points on S that define $\mathcal{O}(n^3)$ subcurves of complexity 2 which induce the set-system of the SetCover instance resulting in an expected running time of $\tilde{\mathcal{O}}(k_\Delta n^3)$, where $\tilde{\mathcal{O}}(\cdot)$ hides polylogarithmic factors. The approximation quality of both approaches depends on ℓ, k_Δ as well as on the VC-dimension of the set system. A drawback of these algorithms is that they generate cluster centers that are line segments only and that the algorithm is randomized with large constants in the approximation factors. Conradi and Driemel [9] took a different approach by focusing on the greedy set cover algorithm, which successively adds the candidate

curve maximizing the added coverage to a partial solution until the entirety of $[0,1]$ is covered. Their algorithm computes $\mathcal{O}(n^3\ell)$ candidate curves that have complexity up to ℓ instead of 2. Applying the greedy algorithm, this results in a deterministic $(\mathcal{O}(\log n), 11)$-approximation algorithm with running time $\tilde{\mathcal{O}}(k_\Delta n^4\ell + n^4\ell^2)$. Recently, van der Hoog, van der Horst and Ophelders showed [23] that the cardinality of the candidate curve set can be further reduced to a size of $\mathcal{O}(n^2 \log n)$. They improve the quality of the approximating curve S resulting in a $(\mathcal{O}(\log n), 4)$-approximation with running time in $\tilde{\mathcal{O}}(k_\Delta n^3)$.

As for the SCM problem, by standard sub-modular function maximization arguments [19, 15], the greedy algorithm used in all these approaches [3, 4, 9, 23] yields an $(\mathcal{O}(1), \mathcal{O}(1))$-approximation. Using this reduction, the candidate curve set identified in [23] yields a $(\mathcal{O}(1), 4)$-approximation to the SCM problem with a running time of $\tilde{\mathcal{O}}(kn^3)$.

2.2 Structure and contributions

In Section 3 we describe how to obtain a set of $\tilde{\mathcal{O}}(n^2)$ candidate center curves $\mathcal{C}$ based on known transformations [23]. Unlike the recent line of work discussed above [3, 4, 9, 23], we do not improve any further on the size of the set $\mathcal{C}$. Instead, our focus lies on the update step of the greedy set cover algorithm. In this step, we have to find the element $c \in \mathcal{C}$ that maximizes the coverage that is added to a partial solution. In Section 4 we describe our first contribution: a partition of the set $\mathcal{C}$ into few ordered lists, called **sweep-sequences**, which we each process via a sweep algorithm computing their coverage reusing prior computations. Unfortunately, the coverage does not immediately allow efficient maintenance along a sweep-sequence. Here, we introduce our second contribution: a candidate-specific approximation of the coverage, called the **proxy coverage**. In Section 5, we describe how sweep-sequences allow efficient maintenance of the proxy coverage and with Theorem 26 describe the culmination of our techniques enabling our algorithm: for a weighted set $A \subset [0,1]$ of points we are able to compute the total weight of points that lie inside the proxy coverage of every element in the sweep-sequence in logarithmic time per element.

In Section 6 we present two $(\mathcal{O}(\log n), 4)$-approximation algorithms for Subtrajectory Covering. The algorithms discretize the ground-set $[0,1]$ by the arrangement (of size $\tilde{\mathcal{O}}(n^3)$) of the intervals representing the coverage of each element in $\mathcal{C}$. Computing the arrangement together with standard greedy set cover techniques and the subroutine from Theorem 26 results in a first approximation algorithm for SC with running time in $\tilde{\mathcal{O}}(|\mathcal{C}|n + k_\Delta|\mathcal{C}|) = \tilde{\mathcal{O}}(n^3)$ (see Corollary 30). Our third contribution is a sampling technique improving the running time: we identify a representative subset (comparable to a sampling) of size roughly $\mathcal{O}(\sqrt{k_\Delta} n^{3/2})$ of the arrangement. This enables a faster algorithm by first covering the representative subset and with it almost the entire arrangement in an initial pass. The remaining $\mathcal{O}(\sqrt{k_\Delta} n^{5/2})$ elements of the arrangement are then identified and covered resulting in the following theorem.

▶ **Theorem 4.** *There is a* $(96\ln(n) + 128, 4)$*-approximation for SC. Given a polygonal curve* P *of complexity* n*,* $\Delta > 0$ *and* $\ell \leq n$*, its running time is in* $\mathcal{O}\left(\left(n^2\ell + \sqrt{k_\Delta} n^{\frac{5}{2}}\right)\log^2 n\right)$*, where* k_Δ *is the size of the smallest subset* $C^* \subset \mathbb{X}_\ell^d$ *such that* $\mathrm{Cov}_P(C^*, \Delta) = [0,1]$.

As trivially $k_\Delta \leq \lceil \frac{n}{\ell} \rceil$, Theorem 4 yields an algorithm with (near-)cubic running time. Further, in the case that $k_\Delta \in \mathcal{O}(n^{1-\varepsilon})$, it yields an algorithm with subcubic running time. This compares favorably to the best known algorithm with running time $\tilde{\mathcal{O}}(k_\Delta n^3)$ [23].

In Section 7, we sketch how our techniques can be applied to obtain faster algorithms for the SCM problem which compares favorably to the best known algorithm with running time $\tilde{\mathcal{O}}(kn^3)$ [23]. All omitted proofs and discussions can be found in the full version.

▶ **Theorem 5.** *Let $\varepsilon \in \left(0, \frac{1}{5}\right]$. There is a $(\frac{e-1}{16e}, 4+\varepsilon)$-approximation algorithm for SCM, where e is the base of the natural logarithm. Given a polygonal curve P of complexity n, $\Delta > 0$, $\ell \leq n$ and $k > 0$, its running time is in $\mathcal{O}((k+\ell)n^2\varepsilon^{-2}\log^2 n \log \varepsilon^{-1})$.*

2.3 Related work

Prior to the line of work on the SC and SCM problem discussed in Section 2.1, Buchin et al. [7] presented one of the earlier works on subtrajectory clustering for both the discrete and continuous Fréchet distance. Their work focuses on finding the largest subtrajectory cluster, where different variants of "largest" are considered. They present hardness results for $(2-\varepsilon)$-approximations for any ε and a matching polynomial time 2-approximation algorithm. Gudmundsson and Wong [12] present a cubic lower bound conditioned on SETH for the same problem and show that this lower bound is tight. In subsequent experimental work [11, 5, 6, 8] the formulation from [7] was studied, but these works do not offer any theoretical guarantees.

Agarwal et al. [1] base their formulation of the subtrajectory clustering problem on FacilityLocation. In this formulation there is an opening cost associated with every center curve, a cost for every point on the input that is assigned to a cluster, and a cost for points that are not assigned. They present conditional NP-hardness results and an $O(\log^2 n)$-approximation for well-behaved classes of curves under the discrete Fréchet distance.

3 Set system discretization

In this section we show that, given a curve P of complexity n, there is a curve S of complexity n and a set $\mathcal{C}_S(P)$ of at most $\mathcal{O}(n^2 \log n)$ subcurves of S, each of complexity at most ℓ, such that for any set of curves $C \subset \mathbb{X}_\ell^d$ there is a subset $\hat{C} \subset \mathcal{C}_S(P)$ of size $\mathcal{O}(|C|)$ such that $\mathrm{Cov}_P(C, \Delta) \subset \mathrm{Cov}_P(\hat{C}, 4\Delta)$. This result is known and follows the line of research in [4, 9, 23]. All of these approaches compute a "maximally simplified" version S of P, see also [10]. Our definition of a simplification follows the notion of *pathlet-preserving simplifications* from [23], as it yields the best constants.

▶ **Definition 6.** *Let a polygonal curve P, $\Delta \geq 0$, and $\ell \geq 1$ be given. A curve S is a simplification of P if $\mathrm{d}_{\mathcal{F}}(S, P) \leq 2\Delta$, and for any curve $Q \in \mathbb{X}_\ell^d$ and $P[s,t]$ with $\mathrm{d}_{\mathcal{F}}(Q, P[s,t]) \leq \Delta$ there is a subcurve $S[s',t']$ with $\mathrm{d}_{\mathcal{F}}(P[s,t], S[s',t']) \leq 2\Delta$ and $|S[s',t']| \leq \ell + 2$.*

▶ **Theorem 7** ([23])**.** *For any curve P of complexity n a simplification S of P of complexity $\mathcal{O}(n)$ can be computed in $\mathcal{O}(n \log n)$ time.*

By definition of the simplification S of P and the triangle inequality for any curve $\pi \in \mathbb{X}_\ell^d$ there is a subcurve $\hat{\pi}$ of S of complexity at most $\ell + 2$ such that $\mathrm{Cov}_P(\pi, \Delta) \subset \mathrm{Cov}_P(\hat{\pi}, 4\Delta)$.

▶ **Definition 8** (Free space diagram)**.** *Let S and P be two polygonal curves parametrized over $[0,1]$. The free space diagram of S and P is defined as the joint parametric space $[0,1]^2$ together with a not necessarily uniform grid, where each vertical grid line corresponds to a vertex of P and each horizontal grid line to a vertex of S. The Δ-**free space** (refer to Figure 2) of S and P is defined as*

$$\mathcal{D}_\Delta(S, P) = \left\{(x, y) \in [0,1]^2 \mid \|P(x) - S(y)\| \leq \Delta\right\}.$$

*This is the set of points in the parametric space, whose corresponding points on S and P are at a distance at most Δ. The edges of S and P segment the free space diagram into cells. We call the intersection of $\mathcal{D}_\Delta(S, P)$ with the boundary of cells the **free space intervals**.*

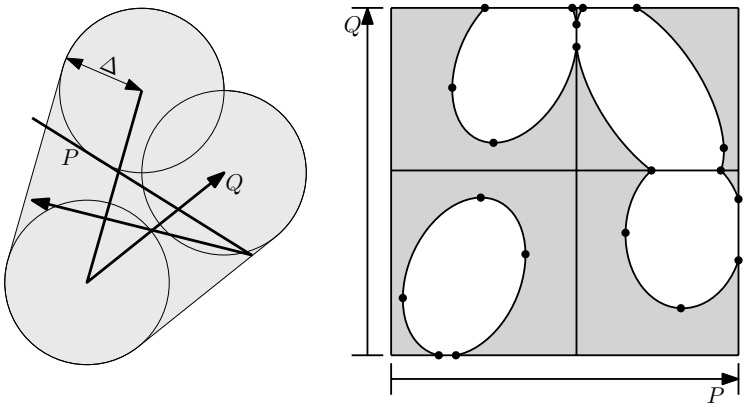

Figure 2 Illustration of the Δ-free space of two curves P and Q as well as their extremal points.

As was noted by Alt and Godau [2], the Fréchet distance of S and P is at most Δ if and only if there is a monotone (in both x- and y-direction) path from $(0,0)$ to $(1,1)$ in Δ-free space of S and P. They further observed that the free space inside any cell is described by an ellipse intersected with the cell and thus is convex and has constant complexity. Observe that two subcurves $P[a,c]$ and $S[b,d]$ have Fréchet distance at most Δ if and only if there is a monotone (in both x- and y-direction) path from (a,b) to (c,d) in Δ-free space of S and P.

▶ **Definition 9** (Extremal points [4]). *As the Δ-free space of two curves S and P is convex in any cell C, the set of points of $\mathcal{D}_\Delta(S,P)$ minimizing the x-coordinate in C are described by either a single point or a vertical line segment. We call either the single point or the start and end point of the line segment the leftmost points of $\mathcal{D}_\Delta(S,P)$ in C. Similarly C has at most two bottommost, rightmost and topmost points. The set of all these at most eight points of $\mathcal{D}_\Delta(S,P)$ in every cell defines the set of extremal points of $\mathcal{D}_\Delta(S,P)$.*

Similar to [23], we define specific subcurves via the extremal points of the 4Δ-free space.

▶ **Definition 10** ((I)-, (II)- and (III)-subcurves). *Let P be a polygonal curve and let S be a simplification of P. Let Δ and ℓ be given. Define the following three types of subcurves of S via the (sorted) set $\mathcal{E}(S,P)$ of y-coordinates of extremal points in $\mathcal{D}_\Delta(S,P)$. For every edge e let $\mathcal{E}(e,P)$ be the subset of $\mathcal{E}(S,P)$ corresponding to the extremal points in $\mathcal{D}_\Delta(e,P)$ (refer to Figure 3).*

- **(I):** *A (I)-subcurve of S is a subcurve of S that starts at some ith vertex of S and ends at the $(i+j)$th vertex for $j \in \{2^m \mid 0 \le m \le \lfloor \log_2(\ell) \rfloor\}$.*
- **(II):** *A (II)-subcurve of S is either a subcurve $e[0,\varepsilon_i]$ or $e[\varepsilon_i,1]$ of an edge e of S defined by a vertex of e and a value $\varepsilon_i \in \mathcal{E}(e,P)$ or its reversal* $\mathrm{rev}(e[0,\varepsilon_i])$ *or* $\mathrm{rev}(e[\varepsilon_i,1])$.
- **(III):** *A (III)-subcurve of S is either a subcurve $e[\varepsilon_i,\varepsilon_{i+j}]$ of an edge e of S defined by two values $\varepsilon_i,\varepsilon_{i+j} \in \mathcal{E}(e,P)$ such that $j \in \{2^m \mid 0 \le m \le \lfloor \log_2(|\mathcal{E}(e,P)|) \rfloor\}$, or its reversal* $\mathrm{rev}(e[\varepsilon_i,\varepsilon_{i+j}])$.

The set containing all Type (I)-, (II)- and (III)-subcurves which we denote by $\mathcal{C}_S(P)$ describes the set of candidate curves similar to the candidate set from [23].

▶ **Theorem 11** (adapted from [23]). *Let P be a polygonal curve, and let S be a simplification of P. Then for any curve $\pi \in \mathbb{X}_\ell^d$ there is a set $S_\pi \subset \mathcal{C}_S(P)$ of size at most 8 such that*

$$\mathrm{Cov}_P(\pi,\Delta) \subset \bigcup_{s \in S_\pi} \mathrm{Cov}_P(s,4\Delta).$$

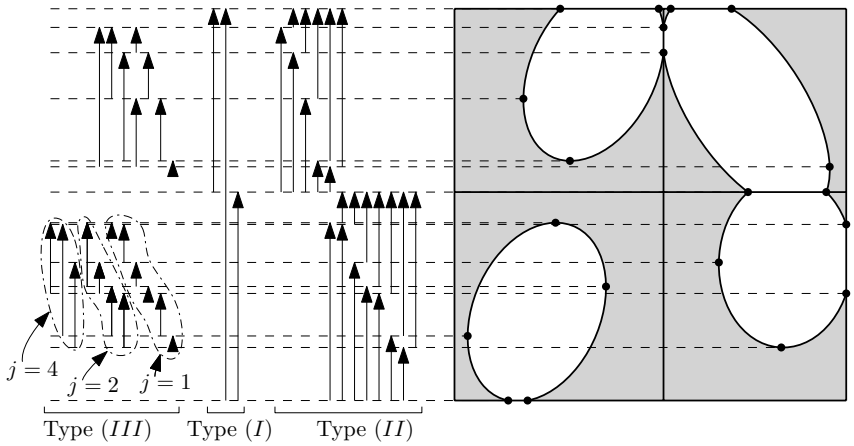

Figure 3 Illustration of all Type (I)-, (II)- and (III)-subcurves of Q (as vertical lines) that are not reversals, induced by the 4Δ-free space of Q and P from Figure 2. Further denoted are the values j, which induced the set of Type (III)-subcurves on the first edge of Q.

4 Sweep-sequences and the proxy coverage

In this section we define an ordering of Type (II) and Type (III) subcurves in the set $\mathcal{C}_S(P)$ and introduce an approximate Δ-coverage called the **proxy coverage**. Later on, we show that a coarse representation of the proxy coverage can be maintained along the ordering.

Throughout this section we are given a polygonal curve P of complexity n, values $\Delta > 0$ and $\ell \leq n$, as well as a simplification S of P. As $|\mathcal{E}(e, P)| = \mathcal{O}(n)$ for any edge e, there are $\mathcal{O}(n \log \ell)$ Type (I)-, $\mathcal{O}(n^2)$ Type (II)- and $\mathcal{O}(n^2 \log n)$ Type (III)-subcurves in $\mathcal{C}_S(P)$.

▶ **Definition 12** (Sweep-sequence). *Let $E = (e_1, \ldots)$ be a sorted list of values in $\mathbb{R}$. We say $\mathfrak{s}$ is a sweep-sequence of E if $\mathfrak{s}$ is a list of tuples of E such that either for all consecutive tuples (e_a, e_b) and (e_c, e_d) it holds that $a \leq b$, $c \leq d$, $0 \leq a - c \leq 1$ and $0 \leq b - d \leq 1$ or for all consecutive tuples it holds that $a \geq b$, $c \geq d$, $0 \leq c - a \leq 1$ and $0 \leq d - b \leq 1$.*

We are able to construct few sweep-sequences that already capture the entirety of $\mathcal{C}_S(P)$.

▶ **Lemma 13.** *Let e be an edge of S. In time $\mathcal{O}(n \log n)$, one can compute a set $\mathfrak{S}_e$ of $\mathcal{O}(\log n)$ sweep-sequences of $\mathcal{E}(e, P)$, each of length $\mathcal{O}(n)$, such that for any Type (II)- or Type (III)-subcurve $\pi \in \mathcal{C}_S(P)$ on the edge e there is a tuple $(\varepsilon_i, \varepsilon_j)$ in one of the sweep-sequences in $\mathfrak{S}_e$ such that $\pi = e[\varepsilon_i, \varepsilon_j]$ if $\varepsilon_i \leq \varepsilon_j$ (refer to Figure 4), and $\pi = \mathrm{rev}(e[\varepsilon_j, \varepsilon_i])$ if $\varepsilon_i > \varepsilon_j$. Further, for the first and last pair (e_a, e_b) in every sweep-sequence it holds that $a = b$.*

We focus our analysis on sweep-sequences of $\mathcal{E}(e, P)$ where for every tuple $(\varepsilon_a, \varepsilon_b)$ it holds that $a \leq b$ (refer to Figure 4). This analysis carries over to all sweep-sequences of $\mathcal{E}(e, P)$ by setting $e \leftarrow \mathrm{rev}(e)$, and thus to all sweep-sequences in $\mathfrak{S}_e$.

We now turn to defining the proxy coverage on P which approximates the 4Δ-coverage.

▶ **Definition 14.** *Let e be an edge of S. Define $l_i(\cdot)$ to be the function mapping any y to the x-coordinate of the leftmost point of the ith cell in $\mathcal{D}_{4\Delta}(e, P)$ at height y. If this point does not exist, $l_i(y) = \infty$. Similarly define $r_j(y)$ to be the x-coordinate of the rightmost point at height y, and ∞ otherwise.*

We assume that for every edge e and every $i < n$ the functions $l_i(\cdot)$ and $r_i(\cdot)$ of the free space $\mathcal{D}_\Delta(e, P)$ can be evaluated in $\mathcal{O}(1)$ time.

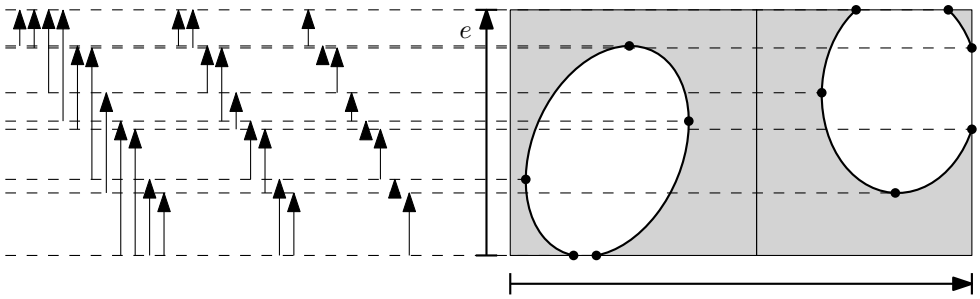

Figure 4 Illustration of three of the eight sweep-sequences in $\mathfrak{S}_e$ of the edge e that are constructed for Type (III)-subcurves. From left to right one for $j = 4$, one for $j = 2$ and one for $j = 1$.

▶ **Definition 15** (Combinatorial representation). *Let e be an edge of S and let $0 \leq s \leq t \leq 1$ be given. The combinatorial representation $\mathcal{R}(e[s,t])$ of the 4Δ-coverage $\mathrm{Cov}_P(e[s,t], 4\Delta)$ of $e[s,t]$ is the set of all inclusionwise-maximal pairs of indices (i,j) such that there are points s' and t' on the ith and jth edge of P respectively such that there is a monotone path from (s',s) to (t',t) in $\mathcal{D}_\Delta(e,P)$. An index pair (i,j) includes (i',j') if $i \leq i'$ and $j' \leq j$.*

The combinatorial representation can be partitioned into two sets, the global group $\mathcal{G}(e[s,t])$ consisting of all index-pairs $(i,j) \in \mathcal{R}(e[s,t])$ such that $i < j$ and the local group $\mathcal{L}(e[s,t])$ consisting of all index-pairs $(i,i) \in \mathcal{R}(e[s,t])$.

▶ **Observation 16.** *Let $e[s,t]$ be a subcurve of an edge e of S. Then (refer to Figure 5)*

$$\mathrm{Cov}_P(e[s,t], 4\Delta) = \bigcup_{(i,j)\in\mathcal{R}(e[s,t])} [l_i(s), r_j(t)] = \bigcup_{(i,j)\in\mathcal{L}(e[s,t])\cup\mathcal{G}(e[s,t])} [l_i(s), r_j(t)]$$

Let an edge e of S together with $0 \leq s \leq t \leq 1$ be given. We say an index i is bad for $e[s,t]$, if all topmost points in cell i of the free space of e and P are to the left of both $l_i(s)$ and $r_i(t)$, and both $l_i(s)$ and $r_i(t)$ are to the left of all bottom most points in cell i. Call this set of bad indices $\mathcal{B}(e[s,t])$. If $i \notin \mathcal{B}(e[s,t])$, i is said to be good for $e[s,t]$. Intuitively, an index is bad if the free-space inside the cell is a diagonal from the top left to the bottom right. For Lemma 21 to hold, the definition a bad index is stronger and depends on s and t.

▶ **Observation 17.** *Let i be good for $e[s,t]$ and P. If $l_i(s) \neq \infty \neq r_i(t)$ then $l_i(s) \leq r_i(t)$.*

We now turn to defining our central tool, the proxy coverage, which approximates the Δ-coverage and is easy to maintain. It is defined via a reduced combinatorial representation.

▶ **Definition 18** (Reduced global group). *Let e be an edge of S and let $0 \leq s \leq t \leq 1$ be given. Based on the global group $\mathcal{G}(e[s,t])$ we define the reduced global group $\widetilde{\mathcal{G}}(e[s,t])$ which results from $\mathcal{G}(e[s,t])$ after merging all pairs of index pairs (a,b) and (c,d) if either $a < c < b < d$, or $b = c$ and $b = c$ is good for e (see Figure 5).*

▶ **Definition 19** (Proxy coverage). *For edge e of S, $0 \leq s \leq t \leq 1$ and $1 \leq i,j < n$ define*

$$\hat{l}_{i,e[s,t]}(s) = \begin{cases} l_i(s), & \text{if } i \text{ is good for } e[s,t] \\ r_i(s), & \text{if } i \text{ is bad for } e[s,t] \end{cases} \qquad \hat{r}_{j,e[s,t]}(t) = \begin{cases} l_j(t), & \text{if } j \text{ is good for } e[s,t] \\ r_j(t), & \text{if } j \text{ is bad for } e[s,t]. \end{cases}$$

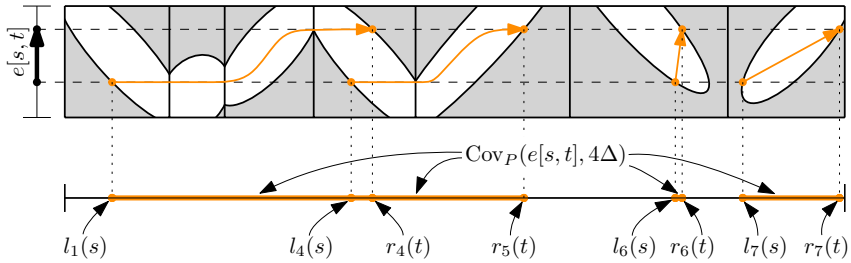

Figure 5 Illustration of the 4Δ-coverage of $e[s,t]$. The global group of $e[s,t]$ is $\{(1,4),(4,5)\}$. The reduced global group of $e[s,t]$ is $\{(1,4),(4,5)\}$ also, as 4 is bad for $e[s,t]$.

With these at hand, define the ***proxy coverage*** *of subedges of S as the union*

$$\widehat{\mathrm{Cov}}_P(e[s,t]) = \left(\bigcup_{(i,i)\in\mathcal{L}(e[s,t])\setminus\mathcal{B}(e[s,t])} [l_i(s), r_i(t)] \right) \cup \left(\bigcup_{(i,j)\in\widetilde{\mathcal{G}}(e[s,t])} [\hat{l}_{i,e[s,t]}(s), \hat{r}_{j,e[s,t]}(t)] \right),$$

where by a slight abuse of notation let $\mathcal{L}(e[s,t]) \setminus \mathcal{B}(e[s,t])$ be all index-pairs (i,i) in $\mathcal{L}(e[s,t])$ such that i is not in $\mathcal{B}(e[s,t])$.

We observe that the proxy coverage can be expressed as a disjoint union via $\widetilde{\mathcal{G}}(e[s,t])$.

▶ **Lemma 20.** *Let e be an edge and let $0 \le s \le t \le 1$. Then $\widehat{\mathrm{Cov}}_P(e[s,t])$ is the disjoint union (refer to Figure 6)*

$$\widehat{\mathrm{Cov}}_P(e[s,t]) = \left(\bigsqcup_{i\in\mathcal{L}(e[s,t])\setminus\mathcal{B}(e[s,t])} [l_i(s), r_i(t)] \right) \sqcup \left(\bigsqcup_{(i,j)\in\widetilde{\mathcal{G}}(e[s,t])} [\hat{l}_{i,e[s,t]}(s), \hat{r}_{j,e[s,t]}(t)] \right).$$

▶ **Lemma 21.** *If i is bad for $e[s,t]$, then i is good for $\mathrm{rev}(e[s,t])$ and $l_i(s), r_i(t) \in [l_i(t), r_i(s)]$.*

▶ **Lemma 22.** *Let e be an edge of S and let $0 \le s \le t \le 1$ be given. Then (refer to Figure 6)*

$$\mathrm{Cov}_P(e[s,t], 4\Delta) \subset \widehat{\mathrm{Cov}}_P(e[s,t]) \cup \widehat{\mathrm{Cov}}_P(\mathrm{rev}(e[s,t])) \subset \mathrm{Cov}_P(\{e[s,t], \mathrm{rev}(e[s,t])\}, 4\Delta).$$

We extend the proxy coverage $\widehat{\mathrm{Cov}}$ to also be defined for Type (I)-subcurves of S, where we set $\widehat{\mathrm{Cov}}_P(S[s,t]) = \mathrm{Cov}_P(S[s,t], 4\Delta)$. Overall, we see that for any $\pi \in \mathcal{C}_S(P)$ – not just Type (II)- and (III)-subcurves of S – there are at most two elements $\pi_1, \pi_2 \in \mathcal{C}_S(P)$ with

$$\mathrm{Cov}_P(\pi, 4\Delta) \subset \widehat{\mathrm{Cov}}_P(\pi_1) \cup \widehat{\mathrm{Cov}}_P(\pi_2) \subset \mathrm{Cov}_P(\{\pi_1, \pi_2\}, 4\Delta).$$

▶ **Theorem 23.** *Let P be a polygonal curve, and let S be a simplification of P. Then for any curve $\pi \in \mathbb{X}_\ell^d$ there is a set $S_\pi \subset \mathcal{C}_S(P)$ of size at most 16 such that*

$$\mathrm{Cov}_P(\pi, \Delta) \subset \bigcup_{s\in S_\pi} \widehat{\mathrm{Cov}}_P(s).$$

Proof. This follows from the definition of the proxy coverage, Lemma 22 and Theorem 11. ◀

5 Maintaining the proxy coverage along a sweep-sequence

In this section we present an algorithm that given $\mathfrak{s} \in \mathfrak{S}_e$ maintains a symbolic representation of $\widehat{\mathrm{Cov}}_P(e[s,t])$ in (roughly) logarithmic time per element in $\mathfrak{s}$. To this end we maintain the set $\mathcal{U}(e[s,t])$ of inclusion-wise maximal index-pairs (i,j) such that there is a path from cell i at height s to cell j at some height $\hat{t} \leq t$, which helps maintain $\widetilde{\mathcal{G}}(e[s,t])$ and $\mathcal{L}(e[s,t]) \setminus \mathcal{B}(e[s,t])$. We want to highlight that maintaining $\mathcal{G}(e[s,t])$ and $\mathcal{L}(e[s,t])$ as a symbolic representation of the 4Δ-Coverage can take total time in $\Theta(n|\mathfrak{S}_e|)$ (Figure 7) motivating our techniques.

▶ **Theorem 24.** *At the beginning and end of the loop in Lines 7 – 15 of* MAINTAIN *of Algorithm 1, the set of index-pairs $\widetilde{\mathcal{G}}$ coincides with $\widetilde{\mathcal{G}}(e[s,t])$, $\mathcal{L}$ coincides with $\mathcal{L}(e[s,t]) \setminus \mathcal{B}(e[s,t])$ and $\mathcal{U}$ coincides with $\mathcal{U}(e[s,t])$. Further, executing* MAINTAIN *takes $\mathcal{O}(n \log n)$ time.*

▶ **Corollary 25.** *Let $\mathfrak{s} \in \mathfrak{S}_e$ be a sweep-sequence. There are $m = \mathcal{O}(n)$ (not necessarily distinct) index-pairs $p_1 = (i_1, j_1), \ldots, p_m = (i_m, j_m)$ together with m contiguous subsets $I_i = \{(s_{a_i}, t_{a_i}), \ldots, (s_{b_i}, t_{b_i})\} \subset \mathfrak{s}$ such that for every $(s,t) \in \mathfrak{s}$ it holds that*

$$\widetilde{\mathcal{G}}(e[s,t]) \cup (\mathcal{L}(e[s,t]) \setminus \mathcal{B}(e[s,t])) = \bigcup_{1 \leq i \leq m, (s,t) \in I_i} \{p_i\}.$$

Further for $p_k = (i_k, j_k)$ the index i_k is either always good or always bad for $e[s,t]$ for $(s,t) \in I_k$, and the index j_k is either always good or always bad for $e[s,t]$ for $(s,t) \in I_k$. The index-pair p_i as well as the values a_i and b_i can be computed for all i in total time $\mathcal{O}(n \log n)$.

Overall, we can maintain a symbolic representation of $\widehat{\mathrm{Cov}}_P(\cdot)$ during a sweep-sequence in total time $\mathcal{O}(n \log n)$ which enables the use of the maintained sets for batch point-queries.

▶ **Theorem 26.** *Let $\mathfrak{s} \in \mathfrak{S}_e$, and let $Q \subset [0,1]$ together with $w_Q : Q \to \mathbb{N}$ be a weighted point-set. For any $Q' \subset Q$ let $w_Q(Q') = \sum_{q \in Q'} w_q(q)$ denote its weight. There is an algorithm which computes $w_Q(Q \cap \widehat{\mathrm{Cov}}_{A_S}(e[s,t]))$ for every $(s,t) \in \mathfrak{s}$ in $\mathcal{O}(|Q| \log |Q| + n \log n)$ time.*

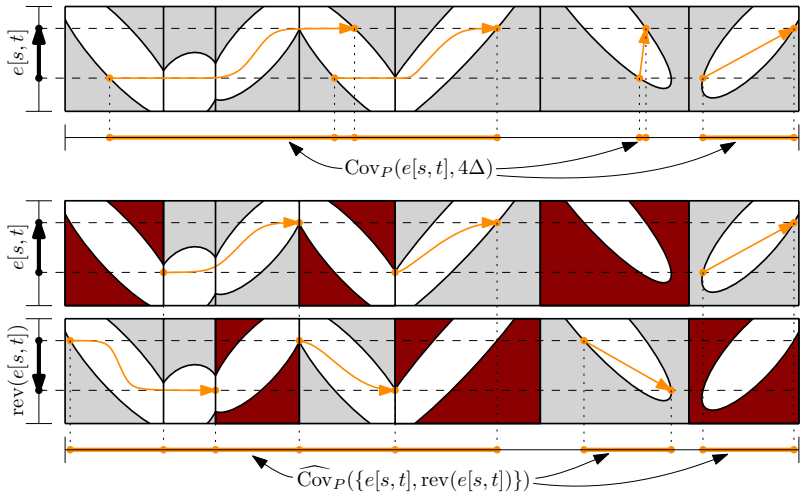

Figure 6 Illustration of the proxy coverage of $e[s,t]$ and $\mathrm{rev}(e[s,t])$ compared to the 4Δ-coverage of $e[s,t]$. Cells with bad index for $e[s,t]$ and $\mathrm{rev}(e[s,t])$ are highlighted in red.

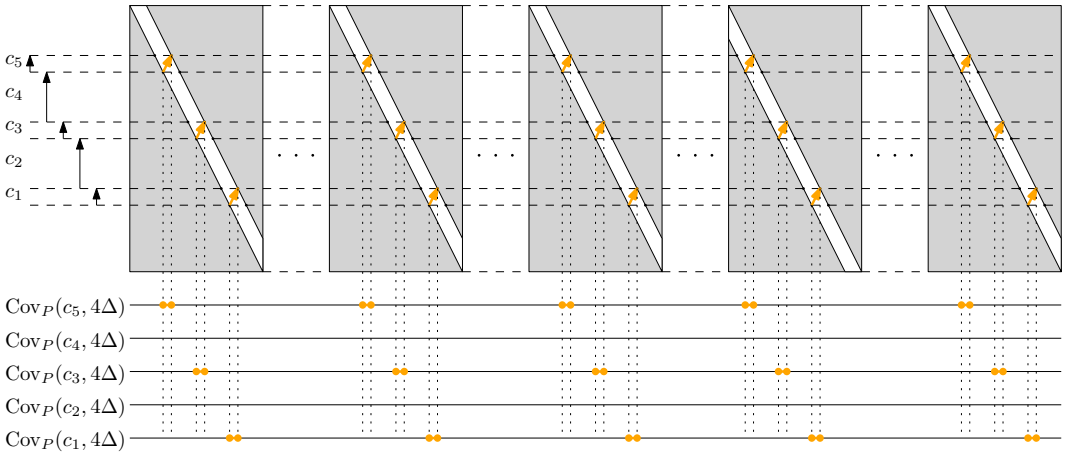

Figure 7 Illustration of how the combinatorial description of the 4Δ-coverage of two neighbouring elements in a sweep-sequence may differ by up to n index-pairs. Instead, $\widehat{\mathrm{Cov}}(c_i) = \emptyset$ for all i.

Algorithm 1 Maintenance of the reduced global group.

procedure MAINTAIN($\mathcal{D}_{4\Delta}(e, P)$, sweep-sequence $\mathfrak{s} = \{(s_1, t_1), \ldots, (s_m, t_m)\}$ of $\mathcal{E}(e, P)$)
  for $i < n$ **do** compute the contiguous sets $B_i = \{(s, t) \in \mathfrak{s} \mid i \text{ is bad for } e[s, t]\}$
  Compute coverage $\mathrm{Cov}_P(e[s_m, t_m], 4\Delta)$ represented as $\mathcal{O}(n)$ disjoint intervals
  Compute $\mathcal{L}(e[s_m, t_m])$ and $\mathcal{G}(e[s_m, t_m])$ from $\mathrm{Cov}_P(e[s_m, t_m], 4\Delta)$
  $\mathcal{U}, \mathcal{L}, \mathcal{G}, (s, t) \leftarrow \mathcal{L}(e[s_m, t_m]) \cup \mathcal{G}(e[s_m, t_m]), \mathcal{L}(e[s_m, t_m]), \mathcal{G}(e[s_m, t_m]), (s_m, t_m)$
  Compute $\mathcal{B}(e[s, t])$ from B_i and with it $\widetilde{\mathcal{G}} \leftarrow \widetilde{\mathcal{G}}(e[s_m, t_m])$
  for (s', t') in REVERSED(S) **do** ▷ sweeping window events
    if $s' \neq s$ **then** ▷ $s' = s - 1$
      Compute $\mathcal{B}(e[s', t]) \setminus \mathcal{B}(e[s, t])$ and $\mathcal{B}(e[s, t]) \setminus \mathcal{B}(e[s', t])$ via the sets B_i
      Update $\mathcal{U}, \mathcal{L}, \mathcal{G}$ and $\widetilde{\mathcal{G}}$ via ADVANCESTART(s, s', t) from Algorithm 2
      Update $\mathcal{B}(e[s, t])$ to $\mathcal{B}(e[s', t])$ via the sets B_i, and $s \leftarrow s'$
    if $t' \neq t$ **then** ▷ $t' = t - 1$
      Compute $\mathcal{B}(e[s, t']) \setminus \mathcal{B}(e[s, t])$ and $\mathcal{B}(e[s, t]) \setminus \mathcal{B}(e[s, t'])$ via the sets B_i
      Update $\mathcal{U}, \mathcal{L}, \mathcal{G}$ and $\widetilde{\mathcal{G}}$ via ADVANCEEND(s, t, t') from Algorithm 2
      Update $\mathcal{B}(e[s, t])$ to $\mathcal{B}(e[s', t])$ via the sets B_i, and $t \leftarrow t'$

Proof. Define following values for all i, j along the sweep-sequence $\mathfrak{s}$ where for $(s, t) \in \mathfrak{s}$:

$$L_i((s,t)) = \sum_{\substack{q \in Q,\ q \text{ in cell } i \\ \hat{l}_{i,e[s,t]}(s) \neq \infty,\ \hat{l}_{i,e[s,t]}(s) \leq q}} w_Q(q), \qquad R_j((s,t)) = \sum_{\substack{q \in Q,\ q \text{ in cell } j \\ \hat{r}_{j,e[s,t]}(t) \neq \infty,\ q \leq \hat{r}_{j,e[s,t]}(t)}} w_Q(q),$$

$$M_i((s,t)) = \sum_{\substack{q \in Q,\ i \notin \mathcal{B}(e[s,t]),\ q \text{ in cell } i \\ l_i(s) \neq \infty,\ r_i(t) \neq \infty,\ l_i(s) \leq q \leq r_i(t)}} w_Q(q), \qquad D(i,j) = \sum_{\substack{q \in Q,\ q \text{ in cell } m \\ i \leq m \leq j}} w_Q(q).$$

The value $L_i((s, t))$ corresponds to the weight of points in cell i that lie right of $\hat{l}_{i,e[s,t]}(s)$. Similarly, $R_i((s, t))$ corresponds to the weight of points in cell i that lie left of $\hat{r}_{i,e[s,t]}(t)$. The value $M_i((s, t))$ corresponds to the weight of points in cell i that lie in between $\hat{l}_{i,e[s,t]}(s)$ and $\hat{r}_{i,e[s,t]}(t)$ if i is good for $e[s, t]$. Lastly $D(i, j)$ corresponds to the total weight of points that lie on edge $i, \ldots, j$. Then for any $(s, t) \in \mathfrak{s}$ and any $(i, i) \in \mathcal{L}(e[s, t]) \setminus \mathcal{B}(e[s, t])$ it holds that $M_i((s, t)) = w_Q(Q \cap [l_i(s), r_i(t)])$. Similarly, for any $(i, j) \in \widetilde{\mathcal{G}}(e[s, t])$ it holds that

Algorithm 2 Advancing the start/end point of the sweeping window.

procedure AdvanceStart(s,s',t)
  Get $\mathcal{U}$, $\mathcal{L}$, $\mathcal{G}$, $\widetilde{\mathcal{G}}$, $\mathcal{B}(e[s,t])$, $\mathcal{B}(e[s',t]) \setminus \mathcal{B}(e[s,t])$, $\mathcal{B}(e[s,t]) \setminus \mathcal{B}(e[s',t])$ and $\mathcal{D}_{4\Delta}(e,P)$
  if s is induced by a lowest point in cell i of $\mathcal{D}_{4\Delta}(e,P)$ **then**
    Identify smallest $j > i$ such that $l_j(s) \neq \infty$
    Update index-pairs in $\mathcal{U}$ and in $\mathcal{G}$ starting at i to start at j
  if s' is induced by a upper boundary of free space interval of cell i of $\mathcal{D}_{4\Delta}(e,P)$ **then**
    Identify largest $j < i$ such that $l_j(s)$ is in the interior of cell j
    Update index-pairs in $\mathcal{U}$ and in $\mathcal{G}$ starting at i to start at j
  if s' is induced by a highest point in cell i of $\mathcal{D}_{4\Delta}(e,P)$ **then** add (i,i) to $\mathcal{U}$
  for changed index-pair (i,j) in $\mathcal{U}$ and $\mathcal{G}$ **do**
    if $i \neq j$ and $r_j(t) \neq \infty$ **then** move index-pair to $\mathcal{G}$, else move it to $\mathcal{U}$
    Remove any dominated index-pairs involving (i,j) from $\mathcal{G}$ and $\mathcal{U}$
  Update $\widetilde{\mathcal{G}}$ from $\mathcal{G}$ after merging overlapping intervals via $\mathcal{B}(e[s,t])$ and $\mathcal{B}(e[s',t])$
  Update $\mathcal{L}$ via the changes to $\mathcal{U}$, $\mathcal{B}(e[s,t])$ and $\mathcal{B}(e[s,t'])$
procedure AdvanceEnd(s,t,t')
  dual to AdvanceStart; refer to full version in appendix

$L_i((s,t)) + D(i+1,j-1) + R_j((s,t)) = w_Q(Q \cap [\hat{l}_{i,e[s,t]}(s), \hat{r}_{i,e[s,t]}(t)])$. Then, by Lemma 20

$$
\begin{aligned}
&w_Q(Q \cap \widehat{\mathrm{Cov}}_{A_S}(e[s,t])) = \\
&= \left(\sum_{i \in \mathcal{L}(e[s,t]) \setminus \mathcal{B}(e[s,t])} w_Q(Q \cap [l_i(s), r_i(t)]) \right) + \left(\sum_{(i,j) \in \widetilde{\mathcal{G}}(e[s,t])} w_Q(Q \cap [\hat{l}_{i,e[s,t]}(s), \hat{r}_{j,e[s,t]}(t)]) \right) \\
&= \left(\sum_{i \in \mathcal{L}(e[s,t]) \setminus \mathcal{B}(e[s,t])} M_i((s,t)) \right) + \left(\sum_{(i,j) \in \widetilde{\mathcal{G}}(e[s,t])} L_i((s,t)) + D(i+1,j-1) + R_j((s,t)) \right).
\end{aligned}
$$

Observe that $D(i,j)$ can be provided via a data-structure that first computes $d_i = \sum_{q \in Q, q \text{ in cell } i} w_Q(q)$ for every i in total time $\mathcal{O}(|Q| \log n)$ and stores them in a balanced binary tree as leaves, where every inner node stores the sum of the values of its children. For every $i \leq j$ the value $D(i,j) = \sum_{i \leq m \leq j} d_m$ can then be returned in $\mathcal{O}(\log n)$ time by identifying in $\mathcal{O}(\log n)$ time all $\mathcal{O}(\log n)$ maximal subtrees whose children lie in the interval $[i,j]$ and then returning the sum of the stored values in the root of each maximal subtree.

Next we show that $L_i(\cdot)$ (resp. $R_j(\cdot)$ and $M_i(\cdot)$) can correctly be maintained when performing the sweep of $\mathfrak{s}$. To this end let

$$I_q = \{(s,t) \in \mathfrak{s} \mid q \text{ is in cell } i \text{ and } \hat{l}_{i,e[s,t]}(s) \neq \infty, \hat{l}_{i,e[s,t]} \leq q\}.$$

Refer to Figure 8. As the free space in every cell is convex, throughout $\mathfrak{s}$ the first indices are monotone and the y-coordinates of the left-most and right-most points are stored in $\mathcal{E}(A_e)$, for every $q \in Q$ the contiguous subsets

$$L_q = \{(s,t) \in \mathfrak{s} \mid q \text{ is in cell } i \text{ and } l_i(s) \neq \infty, l_i(s) \leq q\} \text{ and}$$
$$R_q = \{(s,t) \in \mathfrak{s} \mid q \text{ is in cell } i \text{ and } l_i(s) \neq \infty, r_i(s) \geq q\}$$

can be computed in $\mathcal{O}(\log n)$ time. Similarly the set $B_i = \{(s,t) \in \mathfrak{s} \mid i \text{ is bad for } e[s,t]\}$ is also a contiguous subset of $\mathfrak{s}$ and can be computed in $\mathcal{O}(\log n)$ time. Let Q_i denote all $q \in Q$ that lie on the ith edge of P. Then for any $q \in Q_i$

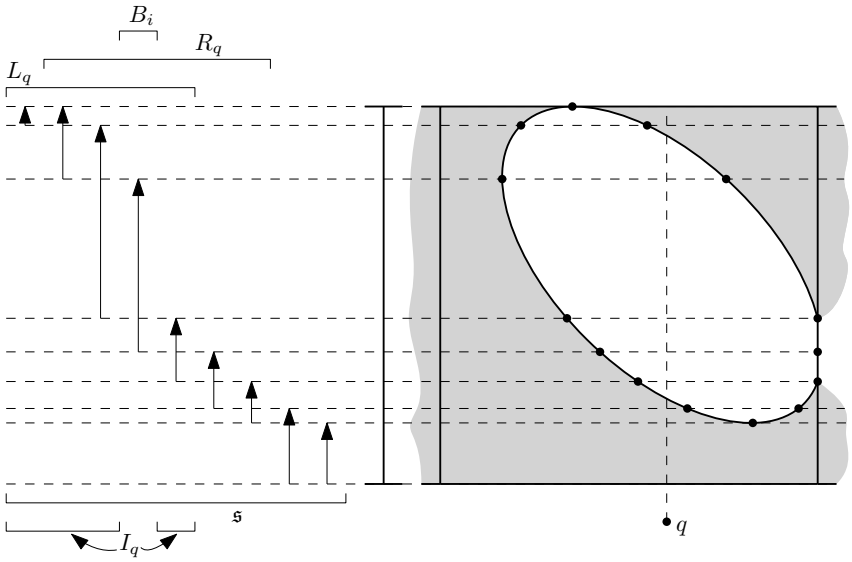

Figure 8 Construction of the set I_q encoding when $\hat{l}_{i,e[s,t]}(s) \leq q$ from Proof of Theorem 26 via the sets L_q and R_q encoding when $l_i(s) \leq q$ and $r_i(s) \geq q$ and the set B_i for all $(s,t) \in \mathfrak{s}$.

$$I_q = (L_q \cap (\mathfrak{s} \setminus B_i)) \cup ((\mathfrak{s} \setminus R_q) \cap B_i),$$

and thus I_q consists of $\mathcal{O}(1)$ contiguous disjoint subsets of $\mathfrak{s}$. Thus all sets I_q (represented as $\mathcal{O}(1)$ contiguous subsets of $\mathfrak{s}$) can be computed in time $\mathcal{O}(|Q| \log n + n \log n)$. Further,

$$L_i((s,t)) = \sum_{q \in Q_i} \mathbb{1}_{q \in I_q} w_Q(q),$$

and hence $L_i(\cdot)$ can be maintained in total time $\mathcal{O}(|Q| + n \log n)$ after one initial computation of all I_q, by adding $w_Q(q)$ for $q \in Q_i$ whenever (s,t) enters the $\mathcal{O}(1)$ contiguous disjoint subsets of I_q, and subtracting $w_Q(q)$ for $q \in Q_i$ whenever (s,t) exits the $\mathcal{O}(1)$ contiguous disjoint subsets of I_q. Sorting the boundaries of all I_q preparing them for the maintenance of $L_i(\cdot)$ takes $\mathcal{O}(|Q| \log |Q|)$ time. Similarly $M_i(\cdot)$ and $R_j(\cdot)$ can be maintained.

Overall, the values $L_i(\cdot)$, $R_j(\cdot)$, $M_i(\cdot)$ and $D(i,j)$ are correctly maintained in total time $\mathcal{O}(|Q| \log |Q|)$ time such that they can be evaluated in $\mathcal{O}(\log n)$. By Corollary 25 there are only $\mathcal{O}(n)$ total updates to $\widetilde{\mathcal{G}}(\cdot)$ and $\mathcal{L}(\cdot) \setminus \mathcal{B}(\cdot)$. Hence, $w_Q(\cdot)$ can be correctly maintained along $\mathfrak{s}$ by updating it whenever $L_i(\cdot)$, $R_j(\cdot)$, $M_i(\cdot)$, $\widetilde{\mathcal{G}}(\cdot)$, $\mathcal{L}(\cdot) \setminus \mathcal{B}(\cdot)$ or $\mathcal{B}(\cdot)$ change. Thus computing $w_Q(e[s,t])$ for all $(s,t) \in S$ takes $\mathcal{O}(|Q| \log |Q| + n \log n)$ time. ◀

6 Ground-set discretization and sampling

We now present two $(\mathcal{O}(\log n), 4)$-approximation algorithm for SC that uses the efficient batch point queries from Theorem 26.

▶ **Definition 27** (Atomic intervals). *Let P be a polygonal curve, and let $\Delta > 0$ and ℓ be given. Let S be a simplification of P. Let G be the set of all intersection-points of horizontal lines at height h for y-coordinates $h \in \mathcal{E}(S,P)$ of extremal points of $\mathcal{D}_{4\Delta}(S,P)$ with the boundary of the free space $\mathcal{D}_{4\Delta}(S,P)$. From this, define the set of atomic intervals $\mathcal{A}(S,P)$ as the set of intervals describing the arrangement of $[0,1]$ defined by the set $\{x \in [0,1] \mid \exists y \in [0,1] : (x,y) \in G\}$ (Figure 9).*

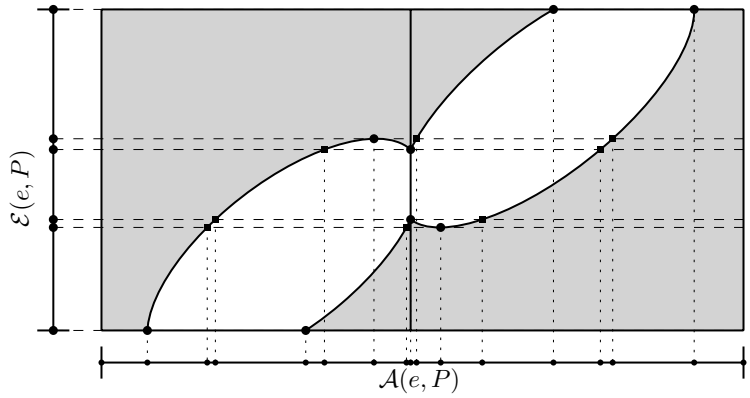

Figure 9 Illustration of atomic intervals $\mathcal{A}(e,P)$ induced by $\mathcal{E}(e,P)$.

▶ **Observation 28.** *As $|\mathcal{E}(S,P)| \leq 8n^2$, and each horizontal line intersects at most n cells, and the free space in every cell is convex it follows, the set of all midpoints of atomic intervals $\mathcal{A}(S,P)$ is a point set $A \subset [0,1]$ of size $16n^3$ such that for any $C \subset \mathcal{C}_S(P)$ it holds that*

$$\widehat{\mathrm{Cov}}_P(C) = [0,1] \iff A \subset \widehat{\mathrm{Cov}}_P(C).$$

▶ **Lemma 29.** *Let P be a polygonal curve of complexity n and let $\Delta > 0$ and $\ell \leq n$ be given. Let S be a simplification of P. Let $\mathcal{E}(S,P)$ be the extremal points of $\mathcal{D}_{4\Delta}(S,P)$. Let $A \subset [0,1]$ be a given set of size at most cn^3 points. For every edge e of S let W_e be the set of atomic intervals a in $\mathcal{A}(e,P)$ such that $w_A(a) = |A \cap a| \neq 0$. Let k_Δ be the size of the smallest set $\mathcal{C}^* \subset \mathbb{X}_\ell^d$ such that $\mathrm{Cov}_P(\mathcal{C}^*, \Delta) = [0,1]$. There is an algorithm that computes a set $\mathcal{C} \subset \mathcal{C}_S(P)$ of size $16(3\ln(n) + \ln c + 1)k_\Delta$ such that $A \subset \widehat{\mathrm{Cov}}_{A_S}(\mathcal{C})$ in time*

$$\mathcal{O}\left(n^2 \ell \log^2 n + |A| \log n + k_\Delta n^2 \log^3 n + \log n \sum_e |W_e|\right).$$

Proof Sketch. The algorithm operates in rounds. In every round we start with a subset A' of A, where initially $A' = A$, and in every round for the partial solution R of the greedy algorithm it holds that $A' = A \setminus \widehat{\mathrm{Cov}}_P(R)$. Further in every round and for every edge e of S we maintain the set W'_e of atomic intervals a in $\mathcal{A}(e,P)$ such that $w_{A'}(a) = |A' \cap a| \neq 0$. These weights in combination with Theorem 26 allow us to identify the Type (II)- or (III)-subedge r of S maximizing $|A' \cap \widehat{\mathrm{Cov}}_P(r)| = |(A \setminus \widehat{\mathrm{Cov}}_P(R)) \cap \widehat{\mathrm{Cov}}_P(r)|$. We similarly identify the Type (I)-curve r maximizing $|A' \cap \widehat{\mathrm{Cov}}_P(r)|$ by initially computing $\widehat{\mathrm{Cov}}_P(r)$ for every Type (I)-curve and then in every round recomputing $|A' \cap \widehat{\mathrm{Cov}}_P(r)|$. Afterwards we add the subcurve maximizing $|A' \cap \widehat{\mathrm{Cov}}_P(r)|$ to R. Lastly we update $A' \leftarrow A' \setminus \widehat{\mathrm{Cov}}_P(r)$. This results in almost all intervals in W'_e whose weights are updated, to have their weights set to zero and are thus removed from W'_e. The number of updates setting such a weight to zero, together with the initial application of Theorem 26 dominate the running time. Lastly, by standard greedy SetCover arguments [14, 22, 18] and Theorem 23 the number of rounds until the algorithm terminates ($A' = \emptyset$) is bounded by $16(\ln(|A|) + 1)$. ◀

▶ **Corollary 30.** *There is an $(48\ln(n) + 64, 4)$-approximation algorithm for SC. Given a polygonal curve P of complexity n, $\Delta > 0$ and $\ell \leq n$, its running time is in $\mathcal{O}\left(n^3 \log^3 n\right)$.*

Proof. Lemma 29 together with Observation 28 and Theorem 23 yields the claim. ◀

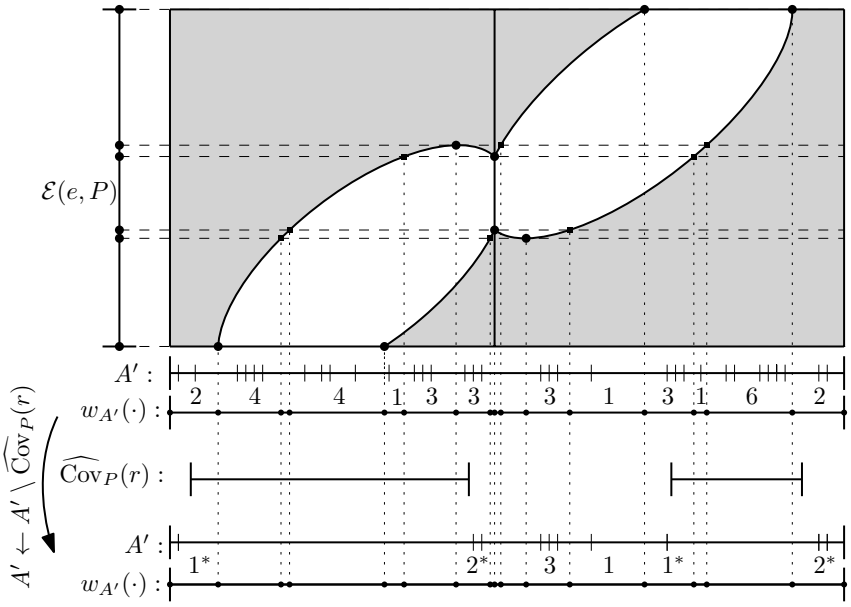

Figure 10 Illustration to Proof Sketch of Lemma 29. Modification of non-zero weights when adding r to R. All weights that are updated but not necessarily set to 0 are highlighted with a *.

The running time of Corollary 30 is dominated by the size of $\mathcal{A}(S,P)$. We now present techniques enabling identification of a representative subset of $\mathcal{A}(S,P)$.

▶ **Theorem 31.** *Let n lists L_i be given, each containing m_i sorted values such that all values are distinct and in every list L_i and for every $j \leq m_i$ identifying the item at position j takes $\mathcal{O}(\log m_i)$ time and also for given v determining the maximal index j such that the jth item is less than v takes $\mathcal{O}(\log m_i)$ time. Then for every $K \leq \sum_i m_i$ in $\mathcal{O}(Kn \log \max_i m_i)$ time one can determine K values $v_1 < \ldots < v_K$ such that*

1. *for every $x \in \bigcup_i L_i$ there is an i such that $x \in [v_i, v_{i+1}]$ and*
2. $|[v_i, v_{i+1}] \cap \bigcup_i L_i| = O\left(\frac{\sum_i m_i}{K}\right)$ *for all i.*

Proof Sketch. We recursively compute a value m such that both a constant fraction of values among all lists is smaller than m and a constant fraction of values among all lists is bigger than m. To find m we compute the middle element of every list in $\mathcal{O}(n \log \max_i m_i)$ time. Then m is (roughly) the middle element of these middle elements. ◀

▶ **Lemma 32.** *For every $\alpha \in [0,3]$ in $\mathcal{O}(n^{1+\alpha} \log n)$ time one can determine $\mathcal{O}(n^\alpha)$ so called α-**coarse** intervals partitioning $[0,1]$, each containing at most $\mathcal{O}(n^{3-\alpha})$ intervals of $\mathcal{A}(S,P)$.*

Proof Sketch. By the structure of $\mathcal{D}_{4\Delta}(e,P)$ we can compute how many atomic intervals of $\mathcal{A}(e,P)$ are contained on any edge of P in $\mathcal{O}(\log n)$ time. Similarly, on any edge of P we can compute the ith atomic interval boundary via $\mathcal{O}(1)$ binary searches of $\mathcal{E}(e,P)$. Hence after $\mathcal{O}(n \log n)$ precomputation time per edge e of S, we can output the ith interval boundary of $\mathcal{A}(e,P)$ in $\mathcal{O}(\log n)$ time for any i. Hence Theorem 31 implies the claim. ◀

We now use Lemma 32 together with Lemma 29 to obtain the following lemma and theorem. The overarching approach for the algorithm is as follows: First use Lemma 32 to compute roughly $\mathcal{O}(n^{3/2})$ points from $\mathcal{A}(S,P)$. These points we cover with a set R_1 of

$\tilde{\mathcal{O}}(k_\Delta)$ elements from $\mathcal{C}_S(P)$ in time $\tilde{\mathcal{O}}(k_\Delta n^{5/2})$ via Lemma 29. Between any two consecutive points of the $\mathcal{O}(n^{3/2})$ points there are at most $\mathcal{O}(n^{3/2})$ other points from $\mathcal{A}(S,P)$, and at most $\tilde{\mathcal{O}}(k_\Delta n)$ of these sets are **not** covered by R_1. This leaves us with $\tilde{\mathcal{O}}(k_\Delta n^{5/2})$ uncovered points in $\mathcal{A}(S,P)$. We again invoke Lemma 29, covering these remaining points with a set R_2 of $\tilde{\mathcal{O}}(k_\Delta)$ elements from $\mathcal{C}_S(P)$ in time $\tilde{\mathcal{O}}(k_\Delta n^{5/2})$.

▶ **Lemma 33.** *Let $\alpha \in [0,3]$ and $K > 0$ be given. Let $C \subset \mathcal{C}_S(P)$ be a set covering all midpoints of α-coarse intervals of size $\mathcal{O}(K \log n)$. Then there are $\mathcal{O}(Kn^{4-\alpha} \log n)$ atomic intervals in $\mathcal{A}(S,P)$ and $\mathcal{O}(Kn^{4-\alpha} \log n + Kn^2 \log n)$ atomic intervals in $\bigcup_e \mathcal{A}(e,P)$ that are not contained in $\widehat{\mathrm{Cov}}_{A_S}(C)$. They can be computed in $\mathcal{O}(Kn^{4-\alpha} \log^2 n + Kn^2 \log^2 n)$ time.*

▶ **Theorem 4.** *There is a $(96\ln(n)+128, 4)$-approximation for SC. Given a polygonal curve P of complexity n, $\Delta > 0$ and $\ell \leq n$, its running time is in $\mathcal{O}\left(\left(n^2\ell + \sqrt{k_\Delta} n^{\frac{5}{2}}\right) \log^2 n\right)$, where k_Δ is the size of the smallest subset $C^* \subset \mathbb{X}_\ell^d$ such that $\mathrm{Cov}_P(C^*, \Delta) = [0,1]$.*

Proof Sketch. The algorithm maintains an internal guess K of k_Δ, which initially is 1. We describe a subroutine that decides, whether $K < k_\Delta$ or outputs a solution of size $\mathcal{O}(K \log n)$. If the subroutine outputs that $K < k_\Delta$ we set $K \leftarrow 2K$, which then implies the claim.

First set $\alpha = \frac{3}{2} + \frac{\log K}{2 \log n} + \frac{\log \log n}{\log n}$. Next compute a set of α-coarse intervals via Lemma 32. From them compute their midpoints M and for every edge e of S compute the subset W_e of $\mathcal{A}(e,P)$ containing such a midpoint. Then W_e is the set of atomic intervals in $\mathcal{A}(e,P)$ with $w_M(\cdot) \neq 0$. The algorithm then attempts to cover the mid-points of these intervals via $\mathcal{O}(K \log n)$ rounds of the algorithm from Lemma 29. If the algorithm does not terminate after $\mathcal{O}(K \log n)$ rounds we return that $K < k_\Delta$. Otherwise we compute the set of atomic intervals $A \subset \mathcal{A}(S,P)$ and for every e the set of atomic intervals in $W'_e \subset \mathcal{A}(e,P)$ that are not fully contained in the solution returned from the first call of the algorithm from Lemma 29 via Lemma 33. We then invoke the algorithm from Lemma 29 on the midpoints M' of A and W'_e which is precisely the set of atomic intervals in $\mathcal{A}(e,P)$ with $w_{M'}(\cdot) \neq 0$. As $K \in \mathcal{O}(k_\Delta)$ and thus $K \in \mathcal{O}(n)$, the running time of the subroutine is

$$\mathcal{O}(n^{1+\alpha} \log n + Kn^{4-\alpha} \log^3 n + Kn^2 \log^2 n) = \mathcal{O}(K^{\frac{1}{2}} n^{\frac{5}{2}} \log^2 n).$$

And thus overall the running time of the algorithm is

$$\mathcal{O}\left(n^2 \ell \log^2 n + \sum_{K=1}^{\log(k_\Delta)} \left(\left(2^K\right)^{\frac{1}{2}} n^{\frac{5}{2}} \log^2 n\right)\right) = \mathcal{O}\left(n^2 \ell \log^2 n + \sqrt{k_\Delta} n^{\frac{5}{2}} \log^2 n\right). \quad \blacktriangleleft$$

7 Subtrajectory Coverage Maximization

The techniques discussed in this paper can also be used to obtain the following result.

▶ **Theorem 5.** *Let $\varepsilon \in \left(0, \frac{1}{5}\right]$. There is a $(\frac{e-1}{16e}, 4+\varepsilon)$-approximation algorithm for SCM, where e is the base of the natural logarithm. Given a polygonal curve P of complexity n, $\Delta > 0$, $\ell \leq n$ and $k > 0$, its running time is in $\mathcal{O}((k+\ell) n^2 \varepsilon^{-2} \log^2 n \log \varepsilon^{-1})$.*

Proof Sketch. We first compute an ε-approximation of the 4Δ-free space, which allows describing $\|\widehat{\mathrm{Cov}}_P(\cdot)\|$ as a sum of linear functions. A sum of linear functions is a linear function itself. As we can maintain a combinatorial description of the proxy coverage we are able to parsimoniously maintain this linear function during a scan of a sweep-sequence in $\mathfrak{S}_e$, which allows evaluating $\|\widehat{\mathrm{Cov}}_P(\cdot)\|$ for all elements in a single sweep-sequence in time roughly $\mathcal{O}(n \log n)$. Using this subroutine once per round and sweep-sequence results in a running time of $\mathcal{O}(kn^2 \log^2 n)$. $\blacktriangleleft$

Tight Bounds for Some Classical Problems Parameterized by Cutwidth

Narek Bojikian
Humboldt-Universität zu Berlin, Germany

Vera Chekan
Humboldt-Universität zu Berlin, Germany

Stefan Kratsch
Humboldt-Universität zu Berlin, Germany

Abstract

Cutwidth is a widely studied parameter and it quantifies how well a graph can be decomposed along small edge-cuts. It complements pathwidth, which captures decomposition by small vertex separators, and it is well-known that cutwidth upper-bounds pathwidth. The SETH-tight parameterized complexity of problems on graphs of bounded pathwidth (and treewidth) has been actively studied over the past decade while for cutwidth the complexity of many classical problems remained open.

For Hamiltonian Cycle, it is known that a $(2+\sqrt{2})^{\mathrm{pw}} n^{\mathcal{O}(1)}$ algorithm is optimal for pathwidth under SETH [Cygan et al. JACM 2018]. Van Geffen et al. [J. Graph Algorithms Appl. 2020] and Bojikian et al. [STACS 2023] asked which running time is optimal for this problem parameterized by cutwidth. We answer this question with $(1+\sqrt{2})^{\mathrm{ctw}} n^{\mathcal{O}(1)}$ by providing matching upper and lower bounds. Second, as our main technical contribution, we close the gap left by van Heck [2018] for Partition Into Triangles (and Triangle Packing) by improving both upper and lower bound and getting a tight bound of $\sqrt[3]{3}^{\mathrm{ctw}} n^{\mathcal{O}(1)}$, which to our knowledge exhibits the only known tight non-integral basis apart from Hamiltonian Cycle [Cygan et al. JACM 2018] and C_4-Hitting Set [SODA 2025]. We show that the cuts inducing a disjoint union of paths of length three (unions of so-called Z-cuts) lie at the core of the complexity of the problem – usually lower-bound constructions use simpler cuts inducing either a matching or a disjoint union of bicliques. Finally, we determine the optimal running times for Max Cut ($2^{\mathrm{ctw}} n^{\mathcal{O}(1)}$) and Induced Matching ($3^{\mathrm{ctw}} n^{\mathcal{O}(1)}$) by providing matching lower bounds for the existing algorithms – the latter result also answers an open question for treewidth by Chaudhary and Zehavi [WG 2023].

1 Introduction

In parameterized complexity the (worst-case) complexity of problems is expressed in terms of input size n and one or more parameters, often denoted k. The parameter can, for example, be the size of the sought solution or some measure of the structure of the input. The goal is to understand the influence of solution size or structure on the complexity. A problem is said to be fixed-parameter tractable with parameter k if it admits an algorithm with running time of $f(k) \cdot n^{\mathcal{O}(1)}$ (also denoted by $\mathcal{O}^*(f(k))$) for some computable function f. For NP-hard problems, this function f is usually exponential and it may be doubly exponential or worse.

Due to space constraints, we defer full proofs and technical details to the full version [8].

This motivates a line of research devoted to the study of the smallest possible functions f for various problem-parameter combinations. In this context, one is often interested in NP-hard problems and hence, conjectures stronger than $\mathsf{P} \neq \mathsf{NP}$ are assumed for conditional lower bounds. For example, it has been shown that unless the Exponential Time Hypothesis (ETH) fails, some problems do not admit algorithms with running time $\mathcal{O}^*(c^k)$ for any constant c (e.g., [38]) – algorithms with such a running time are called *single-exponential*. For problems admitting single-exponential algorithms, it is natural to search for the smallest value of c for which such an algorithm exists. An even stronger conjecture called the Strong Exponential Time Hypothesis (SETH) has been assumed to prove for many problems that existing algorithms with some running time $\mathcal{O}^*(c^k)$ are essentially optimal, i.e., for any $\varepsilon > 0$, there is no algorithm for this problem running in time $\mathcal{O}^*((c-\varepsilon)^k)$. This conjecture states, informally speaking, that the SAT problem cannot be solved much more efficiently than brute-forcing all truth-value assignments.

SETH-tight complexity of problems parameterized by treewidth has been actively studied over the last decade. This was initiated by Lokshtanov et al. [37] who showed that for many classical graph problems (e.g., Independent Set or Max Cut) the folklore dynamic-programming (DP) algorithms are essentially optimal under SETH. In parallel, there is also a line of research devoted to accelerating the existing DP algorithms by employing more careful analysis and advanced tools like fast subset convolution (e.g., [4, 48, 5]), Discrete Fourier Transform (e.g., [47]), rank-based approach (e.g., [6]), isolation lemma ([40]), and Cut&Count (e.g., [17]), we refer to the survey by Nederlof [41] for more details.

Such dynamic-programming algorithms on graphs of bounded treewidth employ the fact that those graphs can be decomposed along small vertex separators and therefore, when processing this decomposition in a bottom-up way, one only needs to remember how a partial solution interacts with the current small separator, also called a bag. Thus it is also natural to study parameters based on small edge-cuts (as edge-counterparts of vertex separators). A linear arrangement of a graph places its vertices on a horizontal line so that no two vertices have the same x-coordinate. Now suppose every edge is drawn as an x-monotone curve, then the cutwidth of this linear arrangement is the maximum number of edges crossing any vertical line – observe that the edges crossing such a line separate the vertices on the left side of the vertical line from the vertices on the right side so they form an edge-cut. The cutwidth of the graph, denoted ctw, is then the minimum over all of its linear arrangements. It is well-known that pathwidth, denoted pw, can be defined similarly but instead of the edges crossing the vertical line, one counts its end-vertices on, say, the right side of the cut. In particular, this implies that the cutwidth of a graph upper-bounds its pathwidth.

Due to this relation, every $\mathcal{O}^*(f(\mathrm{pw}))$-time algorithm is also a $\mathcal{O}^*(f(\mathrm{ctw}))$-time algorithm. However, it is possible that a problem admits a more efficient algorithm when parameterized by cutwidth than when parameterized by pathwidth. For example, Edge Disjoint Paths is paraNP-hard for pathwidth [20] but becomes FPT for cutwidth [24]. This difference sparked deeper interest in studying the cutwidth parameter, and in distinguishing problems whose complexity differ between these two parameterizations. On a finer level, for some of the problems for which the SETH-tight complexity parameterized by treewidth is known, the study continued for the parameterization by cutwidth. The SETH-tight bounds parameterized by cutwidth are known for Independent Set and Dominating Set [45], Odd Cycle Transversal [7], Chromatic Number [30], #q-Coloring [26], as well as a list of connectivity problems (e.g., Feedback Vertex Set and Steiner Tree) [7]. The Chromatic Number problem exposes again a particularly interesting behavior: for treewidth, it is known that for any $q \geq 3$, the folklore $\mathcal{O}^*(q^{\mathrm{tw}})$ algorithm is optimal under SETH [37], but for

cutwidth Jansen and Nederlof [30] proved that there is a (randomized) algorithm computing the chromatic number of the graph in time $\mathcal{O}^*(2^{\mathrm{ctw}})$, i.e., independent of the number of colors in question. Recently, a notable progress was also made for H-Homomorphism: Groenland et al. [25] provided a non-algorithmic proof of the existence of so-called representative sets of certain small size on which a dynamic-programming algorithm can rely, and they also provided a lower-bound construction matching the size of these representative sets. They leave it open, though, whether representative sets of small size can also be found efficiently.

The above-mentioned paper by Lokshtanov et al. [37] provided SETH-tight lower bounds for six classical graph problems, namely Independent Set, Dominating Set, Partition Into Triangles, Odd Cycle Transversal, q-Coloring (for any fixed $q \geq 3$), and Max Cut when parameterized by treewidth [37]. The SETH-tight complexity of these problems parameterized by cutwidth was only partially known till now.

Our results. As a first contribution, we resolve the complexity of the two remaining problems from [37], namely Partition Into Triangles (and also Triangle Packing) as well as Max Cut when parameterized by cutwidth. The study of Partition into Triangles parameterized by cutwidth was initiated by van Heck [46]: it was shown that the problem admits a $\mathcal{O}^*(\sqrt[4]{8}^{\mathrm{ctw}})$ algorithm and no $\mathcal{O}^*((\sqrt{2}-\varepsilon)^{\mathrm{ctw}})$ algorithm exists for any $\varepsilon > 0$ unless SETH fails. In this work, we close this gap by providing an algorithm that solves Triangle Packing in time $\mathcal{O}^*(\sqrt[3]{3}^{\mathrm{ctw}})$, together with a matching SETH-based lower bound for the Partition Into Triangles. There is a trivial reduction from Partition Into Triangles to Triangle Packing and hence, $\mathcal{O}^*(\sqrt[3]{3}^{\mathrm{ctw}})$ is the SETH-optimal running time for both problems. Our algorithm is a straightforward dynamic programming over a path decomposition. While a simple analysis yields running time $\mathcal{O}^*(2^k)$ over a path decomposition of width k, we show that given a linear arrangement ℓ of cutwidth ctw, one can construct a specific path decomposition form ℓ, where a careful analysis shows that the number of states in the dynamic programming is bounded by $\mathcal{O}^*(\sqrt[3]{3}^{\mathrm{ctw}})$, resulting in the desired running time. A bottleneck for the running time are the so-called Z-cuts, i.e., bipartite graphs consisting of a disjoint paths of length three. We show that these cuts inherently determine the complexity of this problem, as the lower bound construction also relies on them. For Max Cut we provide a lower bound showing that no $\mathcal{O}^*((2-\varepsilon)^{\mathrm{ctw}})$ algorithm can solve this problem for any $\varepsilon > 0$ implying that the folklore algorithm for tree decompositions is optimal for cutwidth as well.

Apart from these two problems, we resolve two further open questions. We show that SETH-tight complexity of Hamiltonian Cycle is $\mathcal{O}^*((1+\sqrt{2})^{\mathrm{ctw}})$ when parameterized by cutwidth – this was asked by van Geffen et al. [45] and Bojikian et al. [7]. Let us remark, that although for pathwidth it is known that the $\mathcal{O}^*((2+\sqrt{2})^{\mathrm{pw}})$ algorithm is optimal for Hamiltonian Cycle, the complexity relative to treewidth remains a challenging open problem. Finally, Chaudhary and Zehavi [13] developed a $\mathcal{O}^*(3^{\mathrm{tw}})$ algorithm for Induced Matching problem and an SETH-based lower bound excluding $\mathcal{O}^*((\sqrt{6}-\varepsilon)^{\mathrm{ctw}})$ algorithms for any $\varepsilon > 0$. They conjectured that their algorithm is optimal and asked for a matching lower bound. We confirm their conjecture and provide a stronger result, namely that Induced Matching cannot be solved in $\mathcal{O}^*((3-\varepsilon)^{\mathrm{ctw}})$ for any $\varepsilon > 0$ when parameterized by cutwidth – this resolves the complexity of the problem for both treewidth and cutwidth. [1]

[1] Recently, the conjecture was also independently confirmed by Vasilakis and Lampis [36] by providing a matching lower bound for the parameterization by pathwidth. We remark that our lower bound for cutwidth is a stronger result.

Table 1 Tight bounds for parameterizations by treewidth / pathwidth, and cutwidth. For all problems but Hamiltonian Cycle the tight bounds are known to be equal for treewidth and pathwidth. And the tight complexity of Hamiltonian Cycle parameterized by treewidth remains open. The results of this paper are in the right column.

Triangle Packing (TP)	2^{tw}	$\sqrt[3]{3}^{\mathrm{ctw}}$
Partition into Trianlges (PT)	2^{tw}	$\sqrt[3]{3}^{\mathrm{ctw}}$
Hamiltonian Cycle (HC)	$(2+\sqrt{2})^{\mathrm{pw}}$	$(1+\sqrt{2})^{\mathrm{ctw}}$
Max Cut (MC)	2^{tw}	2^{ctw}
Induced Matching (IM)	3^{tw}	3^{ctw}

Related Work. The (S)ETH tight complexity of problems parameterized by structural parameters has been widely studied. Apart from the already mentioned results, there is a long list of papers related to such algorithms on graphs of bounded treewidth (e.g., [10, 14, 15, 18, 19, 21, 22, 32, 43, 44]), treedepth (e.g., [27, 31, 32, 42]), clique-width (e.g., [1, 2, 9, 23, 28, 31, 33]), rank-width (e.g., [3, 11]), and cutwidth (e.g., [7, 39]). There is also a line of work devoted to conjectures weaker than SETH and yielding the same lower bounds for structural parameterizations (e.g., [12, 35, 34]).

Organization. We start by providing a short summary of the used notation. Section 3 is devoted to Triangle Packing, there we provide our algorithm together with the main steps required to justify its running time. We also sketch the lower-bound construction. After that in Section 4 we present the main idea behind the lower bound state the lower bound for Hamiltonian Cycle. In Section 5 we state our lower bounds for Induced Matching and Max Cut. We conclude in Section 6 by providing some open questions.

2 Preliminaries

We use $\mathcal{O}^*$ notation to suppress factors polynomial in the input size. For an integer $i \in \mathbb{N}_0$ by $[i]$ we denote the set $\{1, \ldots, i\}$ (in particular, we have $[0] = \emptyset$) and by $[i]_0$ we denote the set $[i] \cup \{0\}$. For a vector $a = (a_1, \ldots, a_n)$ over a ground set U and a mapping $f : U \to V$ for some set V, we denote by $\big(f(v)\big)_{v \in a}$ the vector $(f(a_1), \ldots, f(a_n))$.

Given a graph $G = (V, E)$ and a vertex $v \in V$, the neighborhood of v in G is defined as $N_G(v) = \{w \in V(G) \colon \{v, w\} \in E(G)\}$. We omit the index G when clear from the context. For an edge set $F \subseteq E$, we define $G[F] = (V, F)$ and we define $V(F)$ as the set of end-points of F. For a vertex set $S \subseteq V$ and a vertex $v \in V$ we define $N_S(v) = N_G(v) \cap S$ and $\deg_S(v) = |N_S(v)|$. We define $\mathrm{cc}(G)$ as the set of all connected components of G, where a connected component of G is a maximal connected subgraph of G.

We base our lower bounds on the Strong Exponential Time Hypothesis (SETH) [29]:

▶ **Conjecture 1** (SETH). *For every $\varepsilon > 0$, there exists a constant $d > 0$ such that d-SAT cannot be solved in time $\mathcal{O}^*((2-\varepsilon)^n)$, where n is the number of variables.*

Cutwidth. A linear arrangement $\ell = v_1, \ldots, v_n$ of a graph $G = (V, E)$ is a linear ordering of V. We define $V_0 = \emptyset$, $V_i = \{v_1, \ldots, v_i\}$ and $\overline{V}_i = V \setminus V_i$ for $i \in [n]_0$. We define the *cut-graph* at $i \in [n]_0$ as the bipartite graph $H_i = G[V_i, \overline{V}_i]$. The set E_i denotes the edge set of H_i. The cutwidth of ℓ is defined as $\mathrm{ctw}(\ell) = \max_{i \in [n]} |E(H_i)|$. The cutwidth of G is defined as $\mathrm{ctw}(G) = \min_\ell \mathrm{ctw}(\ell)$, where the minimum is taken over all linear arrangements of G. We define L_i and R_i as the set of the left and right endpoints of edges in E_i, respectively. Finally, for $i \in [n]$, we define $Y_i = L_{i-1} \cup \{v_i\}$, i.e., Y_i contains all left end-points of the edges of E_{i-1} together with v_i.

Path decompositions. A *path decomposition* of a graph G is a pair $(P, \mathcal{B} : V(P) \to 2^V)$, where P is a simple path and the following properties hold:

1. For every vertex $v \in V(G)$, the set $\{x \in V(P) \colon v \in \mathcal{B}(x)\}$ induces a non-empty connected subgraph of P.
2. For every edge $\{u, v\} \in E(G)$, there exists a node $x \in V(P)$ with $\{u, v\} \subseteq \mathcal{B}(x)$.

Let $x_1, \ldots, x_r$ be the *nodes* of P in the order they occur on P. The sets $\mathcal{B}(x_1), \ldots, \mathcal{B}(x_r)$ are called *bags*. For every $x_i \in V(P)$, we define $B_{x_i} = \mathcal{B}(x_i)$, $V_{x_i} = \cup_{j \leq i} \mathcal{B}(x_i)$, and $G_{x_i} = G[V_{x_i}]$. A path decomposition $(P, \mathcal{B})$ is *nice*, if we have $\mathcal{B}(x_1) = \mathcal{B}(x_r) = \emptyset$ and for any two consecutive nodes x, x' on P, we have $|\mathcal{B}(x) \Delta \mathcal{B}(x')| \leq 1$. Hence, one can define a nice path decomposition by a sequence of introduce- and forget-vertex operations. It is sometimes useful to have designated *introduce-edge* operations as well, in this case, we call the path decomposition *very nice*. For a node x of a very nice path decomposition, by $G_x = (V_x, E_x)$ we denote the (not necessarily induced) subgraph of G whose vertex resp. edge set consists of the vertices resp. edges of G introduced in this decomposition up to the node x.

3 Triangle Packing

A *triangle packing* of a graph $G = (V, E)$ is a subgraph T of G such that each connected component of T is a cycle of length three, the *size* of T is the number of its connected components. In the Triangle Packing problem, given a graph G and a positive integer b^*, we are asked whether there exists a triangle packing of size b^* in G. In the Partition into Triangles problem, we are asked whether a triangle packing of size $|V|/3$ exists in G. We obtain the following result:

▶ **Theorem 2.** *There exists an algorithm that given an instance (G, b^*) of* Triangle Packing *together with a linear arrangement of G of width at most* ctw*, runs in time $\mathcal{O}^*(\sqrt[3]{3}^{\text{ctw}})$ and outputs whether G admits a triangle packing of size b^*.*

We emphasize that in what follows we only provide a sketch of the proof of this theorem and we refer to the full version for all details.

Let $(G = (V, E), b^*)$ be an instance of Triangle Packing and let $\ell = v_1, \ldots, v_n$ be a linear arrangement of G of cutwidth at most ctw. First, we describe a dynamic-programming algorithm over a nice path decomposition $(P, \mathcal{B})$ of G. After that, we construct a nice path decomposition of G from ℓ and show that it has certain useful properties, namely, the number of possible states of our dynamic-programming algorithm is bounded for each bag.

Algorithm over a path decomposition

Let $(P, \mathcal{B})$ be a nice path decomposition of G. For every node x of P, every set $S \subseteq B_x$, and every integer b, we define the family $\mathcal{H}_x^b[S]$ of all triangle packings of G_x of size b whose intersection with B_x is precisely S and furthermore, each triangle in this packing contains at least one vertex of $V_x \setminus B_x$ (i.e., forgotten already). We define the set $\mathcal{S}_x^b$ consisting of all subsets $S \subseteq B_x$ such that $\mathcal{H}_x^b[S]$ is non-empty. We call $\mathcal{S}_x = \bigcup_{b \in \mathbb{N}} \mathcal{S}_x^b$ the set of *realizable states* at x. For a set $Y \subseteq B_x$, let $\mathcal{S}_x[Y] = \{S \cap Y \mid S \in \mathcal{S}_x\}$ be the set of states "induced" by the set Y.

A straightforward algorithm computing all sets $\mathcal{S}_x^b$ can be informally summarized as follows. Let x' be the node preceding x. At every node x forgetting a vertex, say v, we iterate over all triangles containing the vertex v whose other end-points are still in the bag, iterate over all sets in $\mathcal{S}_{x'}^{b-1}$, and "combine" the two if they are vertex-disjoint. For every $S \in \mathcal{S}_{x'}^b$, we also add $S \setminus \{v\}$ to $\mathcal{S}_x^b$ as the corresponding triangle packing of $G_{x'}$ remains "valid" in G_x.

At every introduce-node x we just keep the family $\mathcal{S}^b_{x'}$. Recall that the root-node, say r, of the nice path decomposition $(P, \mathcal{B})$ is an empty bag. Then the graph G admits a triangle packing of size b if and only if $\emptyset \in \mathcal{S}^b_r$ holds. We can show that if α denotes the maximum size of a family $\mathcal{S}^b_x$ over all nodes x and all integers $b \in [\lfloor \frac{n}{3} \rfloor]_0$, then all families $\mathcal{S}^b_x$ can be computed in time $\mathcal{O}^*(\alpha)$. In order to achieve this, we describe a data structure that allows the insertion of a single "state" in time polynomial in n as well as the iteration over all states present in the data structure in time $\mathcal{O}^*(\alpha)$. In the remainder of the proof, we show how to get a nice path decomposition of G from its linear arrangement ℓ so that the value of α is sufficiently small.

From linear arrangement to path decomposition

To obtain the desired path decomposition $(P, \mathcal{B})$ we will proceed as follows. We will first define a set of the so-called *checkpoint* bags $X_0, \ldots, X_n$ corresponding to the cut graphs $H_0, \ldots, H_n$ of ℓ. Later we will show how to add so-called *transition* bags to turn this sequence into a nice path decomposition, while still keeping the number of possible states bounded.

First, for a bipartite graph H (think of $H = H_0, \ldots, H_n$), we define the sets F_H and I_H by an iterative process formally defined next. The set F_H is intended to represent the set of vertices from the left side of the cut that are forgotten already, while the set I_H corresponds to the vertices on the right side of the cut that are introduced already. To ensure that the corresponding "ordering" of the forget- and introduce-operations even yields a valid path decomposition, i.e., no vertex is forgotten before one of its neighbors is introduced, we will ensure that I_H contains all neighbors of F_H.

Clearly, one can safely forget a vertex if all of its neighbors have already been introduced. We additionally apply the following non-trivial rule. We forget a vertex v if (1) it has a single neighbor w in H that is not introduced yet, and (2) the vertex v has degree at most two in H. In this case we introduce the unique missing neighbor of v before forgetting v. We define Q_H as the vertices on the right side that have not been introduced yet, i.e., do not belong to I_H. We provide formal definitions of these sets (see Figure 1 for an illustration):

▶ **Definition 3.** *Let $H = (L, R, E)$ be a bipartite graph. First, we define $F^{(0)} = \emptyset$. For $j \geq 0$, let $I^{(j)} = N_H(F^{(j)})$, and let $Q^{(j)} = R \setminus I^{(j)}$. We define the sets $F^{(j+1)}$ recursively as follows:*

$$F^{(j+1)} = \left\{ v \in L \colon \deg_{Q^{(j)}}(v) = 0 \vee \left(\deg_{Q^{(j)}}(v) = 1 \wedge \deg(v) \leq 2 \right) \right\}.$$

In the full version we show, that there exists an integer k such that $F^{(k')} = F^{(k)}$ for all $k' \geq k$. Let k be the smallest such value. We define $F_H = F^{(k)}$, $I_H = I^{(k)}$, and $Q_H = Q^{(k)}$. We also define the sets L^1_H and L^2_H as the vertices of $L_H \setminus F_H$ that have exactly one or at least two neighbors in Q_H, respectively. Finally, we define the *bag* at H as $X_H = L^1_H \cup L^2_H \cup I_H$.

For every $i \in [n]_0$, we define $L^2_i = L^2_{H_i}$, $L^1_i = L^1_{H_i}$, $F_i = F_{H_i}$, $I_i = I_{H_i}, Q_i = Q_{H_i}$, and $X_i = X_{H_i}$. We call F_i the set of *forgotten vertices* at i, I_i the set of *introduced vertices*, and Q_i the set of *unintroduced vertices*.

It can be shown that X_i is a vertex separator for every $i \in [n]$: this follows from the fact that I_i is the neighborhood of F_i. Furthermore, we show in the full version that if in Definition 3 instead of $F^{(0)} = \emptyset$, we start with the set $F^{(0)} = F_{i-1}$ of the vertices already forgotten at the previous cut, then we obtain the same set F_i of vertices forgotten at the current cut. From this we can then conclude that a nice path decomposition of G can be constructed by using $X_1, \ldots, X_n$ as the main building blocks. We emphasize that the sequence of vertex separators $X_1, \ldots, X_n$ itself does not even necessarily contain every vertex of G. To resolve this, we will turn it into a nice path decomposition by adding the so-called *transition bags*. The bags $X_1, \ldots, X_n$ are called the *checkpoint bags*, and $x_1, \ldots, x_n$ denote the corresponding nodes in the arising path decomposition.

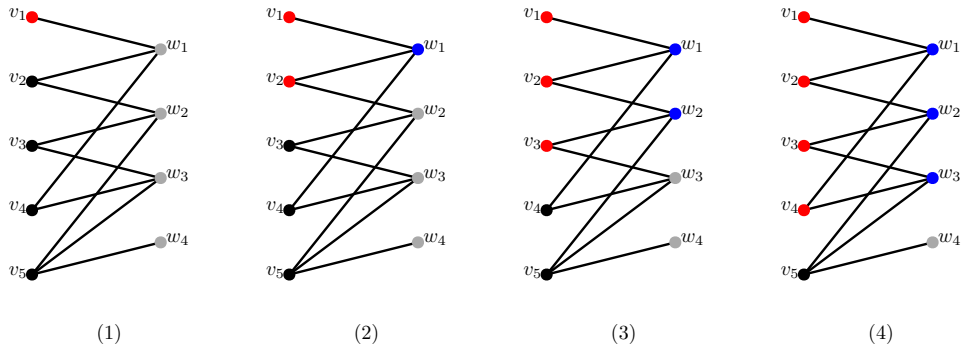

Figure 1 For $i = 1, 2, 3, 4$, the family $F^{(i)}$ is red on the left-hand side of the cut while the families $I^{(i-1)}$ and $Q^{(i-1)}$ are blue and gray, respectively, on the right-hand side. The sets F_H, I_H, Q_H are the red, blue, and gray vertices, respectively, in (4). The black vertex in (4) belongs to L_H^1 as it has a single gray neighbor. The bag X_H is the set of all black and blue vertices in (4).

The reason why we distinguish the sets L_i^1 and L_i^2 is two-fold. First, to bound the number of states in terms of cutwidth, we will "assign" the edges of the cut H_i to certain sets of vertices in the bag, these sets are then called *components*. Since every vertex in L_i^2 has at least two neighbors in Q_i, and since no vertex of Q_i belongs to the bag X_i by definition, we can assign at least two cut-edges to every vertex of L_i^2. Based on this, we show that for some components of a specific structure, enough edges of the cut can be assigned to these components to "allow" all possible state combinations of the vertices of these components. Let us elaborate a bit more on what we mean by this. Our goal is to bound the number of states of the bag X_i in terms of the number of edges in the cut H_i. To prove the desired bound, it suffices to partition the bag into the components, partition the edges of the cut to be assigned to these components, and then show that the bound holds for each component with respect to the number of assigned edges. We will show that if a component contains a vertex from L_i^2, then for the number s of vertices of this component and the number q of edges assigned to it, we have $2^s \leq \sqrt[3]{3}^q$, i.e., the desired bound holds even without a further careful analysis. We will provide more details later. Second, we also need to ensure that along the way between the checkpoint bags, i.e., in transition bags, we do not have too many possible states. This will be achieved by a careful choice of the ordering in which the vertices are forgotten and introduced. The sets L_i^1 and L_i^2 will be used to determine this ordering.

Bounding the number of realizable states

We define the graph $\hat{H}_i$ as $\hat{H}_i = H_i[V_i, I_i]$ to represent the part of the cut restricted to the vertices introduced so far (i.e., we discard the not yet introduced vertices of Q_i from H_i). For a set $S_0 \subseteq R_i$ of vertices on the right side of the cut-graph H_i, we also define the graph $H_i^{S_0} = H_i[V_i, I_i \setminus S_0]$ that additionally removes the vertices S_0 from the right side of the cut. This graph will be crucial to bound the number of the possible states for the transition bags: for example, the graph $H_{i-1}^{\{v_i\}}$ will be useful to analyze the first step of the transition from the cut H_{i-1} to the cut H_i, i.e., removing v_i from the right side of the cut.

▶ **Definition 4.** *For every $i \in [n]$ and $S \subseteq V(H_i)$, we define the set E_i^S of all edges of H_i incident with S and we define $m_i(S) = |E_i^S|$.*

By definition of the bipartite graph $\hat{H}_i$, each edge of H_i either has both end-points in some connected component of $\hat{H}_i$, or it has its left end-point in some connected component of $\hat{H}_i$ and its right end-point in Q_i. First, this implies that we have $E_i^{V(C)} = E(C) \dot{\cup} E_{H_i}(C, Q_i)$ for

every connected component C of $\hat{H}_i$. And second, it shows that every edge of H_i is incident with the vertices of exactly one connected component of $\hat{H}_i$. Therefore, the sets $E_i^{V(C)}$ for $C \in \mathrm{cc}(\hat{H}_i)$ partition $E(H_i)$. This will be crucial to bound the number of states in the checkpoint bags. An analogous argument shows that for any choice of $S_0 \subseteq R_i$, the sets $E_i^{V(C)}$ for $C \in \mathrm{cc}(H_i^{S_0})$ partition the set $E(H_i)$ as well.

Now we aim at showing that for each connected component $C \in \mathrm{cc}(\hat{H}_i)$, the number of possible states of $\mathcal{S}_{x_i}[V(C)]$ is upper-bounded by $\sqrt[3]{3}^{m_i(V(C))}$. The bound on $\mathcal{S}_{x_i}$ then follows by the fact that the sets $E_i^{V(C)}$ are pairwise disjoint. This will actually be the part where it becomes evident, as we shall see in the following proof, that the so-called Z-cuts form the bottleneck of the algorithm: We will distinguish different types of components C of $\hat{H}_i$ and the tight upper bound on the number of possible states is achieved by the Z-cuts.

We actually prove a more general statement. First, we prove that the claimed bound holds not only for $C \in \mathrm{cc}(\hat{H}_i)$, but for any connected component C of $H_i^{S_0}$ where $S_0 \subseteq R_i$ is arbitrary. Here it is important to remember that S_0 only contains vertices from the right side of the cut. Second, we will show that the bound holds even if we allow to add any subset of $L_i \setminus F_i$ to every realizable state. This motivates the next definition of the set $\mathcal{T}_i^b[S]$ which can be considered as a robust generalization of the set of possible states: intuitively, this permits us to say that even if we allow, instead of $G[V_i]$, an arbitrary graph on the left-hand side of the cut (i.e., a triangle packing is allowed to use an arbitrary subset of vertices on the left-hand side), the number of states is still bounded. This will later allow us to prove the bound for the transition bags as well, given that the transitions are carried out in the correct order. For every $i \in [n]$ and every $b \in [\lfloor \frac{n}{3} \rfloor]_0$, we will use $\mathcal{S}_i^b$ as a shorthand for $\mathcal{S}_{x_i}^b$.

▶ **Definition 5.** *For $b \in [\lfloor \frac{n}{3} \rfloor]_0$, $i \in [n]$, and $S \subseteq V(H_i)$, we define*

$$\mathcal{T}_i^b[S] = \{S' \cup T \colon S' \in \mathcal{S}_i^b[S], T \subseteq S \cap (L_i^1 \cup L_i^2)\} \text{ and } \mathcal{T}_i[S] = \cup_{b \in [\lfloor \frac{n}{3} \rfloor]_0} \mathcal{T}_i^b[S].$$

For a connected component C of a subgraph of H_i, we use $\mathcal{T}_i[C]$ and $m_i(C)$ as shorthands for $\mathcal{T}_i[V(C)]$ and $m_i(V(C))$, respectively. Now we prove the main technical lemma.

▶ **Lemma 6.** *For all $i \in [n]$, all $S_0 \subseteq R_i$, and all $C \in \mathrm{cc}(H_i^{S_0})$ it holds that $|\mathcal{T}_i[C]| \leq \sqrt[3]{3}^{m_i(C)}$.*

Sketch. Let $F = F_i \cap V(C)$, $I = I_i \cap V(C)$, $L^1 = L_i^1 \cap V(C)$, $L^2 = L_i^2 \cap V(C)$, and $X = X_i \cap V(C)$. By definition of these sets we thus get $|X| = |L^1| + |L^2| + |I|$. First of all, it can be argued that the claim is true whenever $m_i(C) \leq 2$ so we assume $m_i(C) \geq 3$ in the remainder. The proof is based on two main inequalities. The first follows directly from the definition of the $\mathcal{T}_i^b$: as every element of $\mathcal{T}_i$ is a subset of $V(C) \cap X_i = X$, we have:

$$|\mathcal{T}_i[C]| \leq 2^{|X|}. \tag{1}$$

For the second inequality, recall that $E_i^C = E(C) \dot{\cup} E_{H_i}(C, Q_i)$ holds, i.e., we have $m_i(C) = |E(C)| + |E_{H_i}(C, Q_i)|$. Since C is a connected component of $H_i^{S_0}$, its edge set $E(C)$ contains at least $|V(C)| - 1 = |L^2| + |L^1| + |F| + |I| - 1$ edges. Moreover, we claim that $|F| \geq |I|$ holds. Recall that by definition of the sets $F^{(j)}$ and $I^{(j)}$ for $j \geq 0$ (see Definition 3), we have that $|F^{(j)}| \geq |I^{(j)}|$: this is because a vertex can only be added to I_i (i.e., introduced) if at least one of its neighbors is added to F_i (i.e., forgotten). Furthermore, for any vertex v in $I^{(j)} \cap V(C)$, the unique vertex in $F^{(j)}$ due to which v was introduced belongs to the same connected component C. Thus we have $|E(C)| \geq |L^2| + |L^1| + 2|I| - 1$. Finally, recall that by definition, each vertex of L^1 has exactly one neighbor in Q_i while each vertex of L^2 has at least two neighbors in Q_i. Hence, it holds that $|E_{H_i}(C, Q_i)| \geq |L^1| + 2|L^2|$. It follows that $m_i(C) \geq (|L^2| + |L^1| + 2|I| - 1) + (|L^1| + 2|L^2|) = 2|X| + |L^2| - 1$, and hence we get:

$$|X| \leq \frac{m_i(C) + 1}{2}. \tag{2}$$

First, assume that at least one of the following hold: C contains a cycle, or L^2 is not empty, or $|F| > |I|$, or $V(C) \cap L_i$ has a neighbor in $S_0 \cap I_i$. It is not hard to verify that in this case $m_i(C) \geq 2|X|$ holds and therefore, $|\mathcal{T}_i[C]| \leq 2^{|X|} \leq \sqrt{2}^{m_i(C)} \leq \sqrt[3]{3}^{m_i(C)}$.

In the remainder of the proof we may thus assume that C is a tree, L^2 is empty, $|F| = |I|$, and each neighbor of $V(C) \cap L_i$ in S_0 belongs to Q_i. We can show that in this case, each vertex of F has degree at most 2 in H_i. After that we carry out an extensive case distinction and show that in each case, there exists a constant fraction of all subsets of X that are certainly not elements of $\mathcal{T}[C]$. The main idea behind each of the cases is to find a vertex, say v, in I with certain nice properties, namely there exists a constant-sized subset, say U, of X such that any triangle packing using v has to use at least one of the vertices in X. Thus, every subset of X that contains v and has an empty intersection with U is not a possible state – let us remark that this intuition reflects the proof in an overly simplified manner for space reasons.

The simplest of these cases is when C contains a leaf v in I. Then let w be the unique neighbor of v in L_i. As v was introduced due to forgetting one of its neighbors, this neighbor has to be w, i.e., we have $w \in F$. As $m_i(C) \geq 3$, there exists a vertex $v' \neq v \in I$ adjacent to w. Since every vertex in F has degree at most 2 in H_i, the vertex w does not have neighbors other than v and v'. Recall that the dynamic-programming algorithm only considers triangles where at least one vertex is forgotten already. Since w is the unique forgotten neighbor of v, every such triangle packing containing the vertex v, uses the triangle v, w, v'. Recall that we have $v, v' \in I \subseteq X$. Hence, for every $S \in \mathcal{T}_i[C]$, the property $v \in S$ implies $v' \in S$. This way we exclude one fourth of all subsets of X from $\mathcal{T}_i[C]$ and get:

$$|\mathcal{T}_i[C]| \leq \frac{3}{4}2^{|X|} \leq \frac{3}{4}2^{\frac{m_i(C)+1}{2}} \leq \sqrt[3]{3}^{m_i(C)},$$

where the last inequality holds due to $m_i(C) \geq 3$.

This is the spot where a Z-cut occurs: If C contains exactly three edges, then it consists of the vertices v, v', w as well as a vertex, say $w' \in F$, adjacent to v' only, and C induces a Z-cut. Recall that by definition we have $X = \{v, v'\}$ (i.e., the bag contains v and v') since the vertices w and w' are forgotten, i.e., belong to F. One can verify that in this case all states other than $\{v\}$ are possible and therefore, the above inequality is tight and the equality is achieved by a Z-cut.

If C contains no leaves in I, we can show that $m_i(C) \geq 5$ holds. Analyzing the structure of the cut, we then show the inequality $|\mathcal{T}_i[C]| \leq \frac{49}{64}2^{|X|}$ implying the desired bound. ◀

By applying the above lemma with $S_0 = \emptyset$, we can show that the number of states at each checkpoint bag is upper-bounded by $\sqrt[3]{3}^{\mathrm{ctw}}$:

▶ **Corollary 7.** *For all $i \in [n]$ and $b \in [\lfloor \frac{n}{3} \rfloor]_0$, it holds that $|\mathcal{S}_i^b| \leq \sqrt[3]{3}^{|E_i|}$.*

Due to space constraints, we omit the proof of the following bound for transition bags. It relies on a careful choice of the ordering of the forget- and introduce-operations together with an involved analysis of the relation between the connected components of the graphs $\hat{H}_{i-1}$ and $\hat{H}_i$ as well as the states of these components:

▶ **Lemma 8.** *For every transition node x_i^j and every $b \in [\lfloor \frac{n}{3} \rfloor]_0$, it holds that $|\mathcal{S}_{x_i^j}^b| \leq 4 \cdot \sqrt[3]{3}^{\mathrm{ctw}}$.*

In Figure 2 we sketch the idea behind our lower-bound construction matching the running time of our algorithm from the previous subsection and refer to the full version for a formal description. We prove the following result for Partition into Triangles:

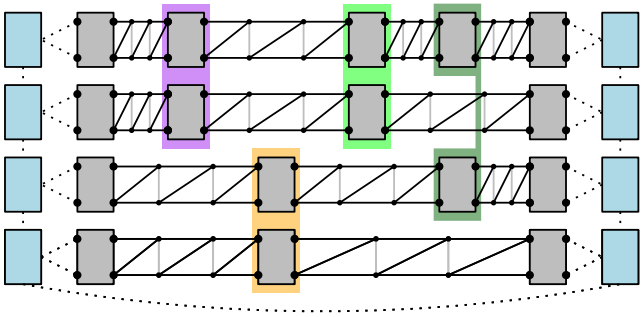

Figure 2 Sketch of the lower-bound construction for $n = 4$ variables and $m = 4$ clauses in an instance of d-CSP-3. Each of the gray boxes is a path gadget which may have one of the three states. Blue boxes are small cliques. Dotted lines reflect that there exist all possible edges between the sets. Every colored box is a constraint gadget. The cutwidth of the construction is essentially upper-bounded by $3n$ as each of the n Z-cuts contributes three edges to the size of a cut.

▶ **Theorem 9.** *Assuming SETH, there exists no algorithm that solves* Partition into Triangles *on graphs given with linear arrangements of cutwidth k in time $\mathcal{O}^*\big((\sqrt[3]{3}-\varepsilon)^k\big)$ for any $\varepsilon > 0$.*

Since there is a trivial reduction from Partition into Triangles to Triangle Packing, this lower bound then also holds for Triangle Packing and so the running time of $\mathcal{O}^*(\sqrt[3]{3}^{\mathrm{ctw}})$ is optimal for both problems under SETH.

4 Hamiltonian Cycle

For a graph $G = (V, E)$, a set $C \subseteq E$ of edges is called a *Hamiltonian cycle* of G if C induces a single cycle visiting all vertices of G. In the Hamiltonian Cycle problem, we are given a graph G and asked if there is a Hamiltonian cycle in G.

Here we provide a randomized algorithm solving Hamiltonian Cycle in time $\mathcal{O}^*((1+\sqrt{2})^k)$ on graphs provided with a linear arrangement of cutwidth k. For this we adapt the $\mathcal{O}^*((2+\sqrt{2})^p)$ algorithm by Cygan et al. [16] working on graphs provided with a path decomposition of pathwidth p. We will transform a linear arrangement of cutwidth k into a path decomposition having a useful algorithmic property, namely, the dynamic-programming table as defined by Cygan et al. has only $\mathcal{O}^*((1+\sqrt{2})^k)$ non-zero entries and there is an efficient way to determine the "certainly zero" entries. Now we provide some details. The algorithm by Cygan et al. [16] strongly relies on their algebraic result about the $\mathbb{F}_2$-rank of a certain "compatibility" matrix reflecting, for each pair of perfect matchings, whether their union is a Hamiltonian cycle. We summarize the necessary parts of this result:

▶ **Theorem 10** ([16])**.** *Let $t \in \mathbb{N}$ be even. Then there exists a set $\mathcal{X}_t$ of perfect matchings of the complete graph K_t with the following properties: (1) $|\mathcal{X}_t| = 2^{t/2-1}$, (2) $\mathcal{X}_t$ can be computed in time $\sqrt{2}^t t^{\mathcal{O}(1)}$, and (3) for every matching $M \in \mathcal{X}_t$, there exists a unique matching $M' \in \mathcal{X}_t$ such that $M \cup M'$ forms a Hamiltonian cycle of K_t.*

Observe that the third property implies that one can partition the set $\mathcal{X}_t$ into pairs of matchings such that the union of two perfect matchings forms a Hamiltonian cycle, if and only if the two matchings are paired in this partition. In other words, the family $\mathcal{X}_t$ induces a permutation submatrix of the compatibility matrix mentioned above. Like Cygan et al., we will sometimes identify some ordered set, say S, of even cardinality t with the vertex set $[t]$ of K_t. Then by $\mathcal{X}(S)$ we denote the set obtained from $\mathcal{X}_t$ by identifying the elements of S with $[t]$. In particular, every element of $\mathcal{X}(S)$ is a perfect matching on the vertex set S.

In the following, we assume that the graph G is provided with a weight function $\omega\colon E(G) \to \mathbb{N}$. As many other algorithms for connectivity problems, the algorithm of Cygan et al. [16] makes use of the classic isolation lemma (see [40]) and samples ω in a certain probabilistic way. Their algorithm works on a very nice path decomposition of the input graph G. Essentially, it processes such a path decomposition and for every bag, counts, modulo 2, the number of subgraphs of the already processed graph such that every vertex in this subgraph has degree 2, except for vertices in the current bag which may have lower degree. The dynamic-programming table refines these counts depending on the weight of the subgraph, its degree sequence on the bag, and whether this subgraph forms a single cycle with a certain matching defined on the vertex set of the bag. A crucial implication of Theorem 10 (as proven in their paper) is that instead of taking all such matchings into account, it suffices to consider only the "base matchings" from $\mathcal{X}_t$ to solve the problem. Now we summarize this more formally:

▶ **Definition 11** ([16]). *A* partial cycle cover *of a graph is a set of edges such that every vertex has at most two incident edges in this set. For every node x of the provided very nice path decomposition, every $s\colon B_x \to \{0,1,2\}$ where $s^{-1}(1)$ has even cardinality, every $M \in \mathcal{X}(s^{-1}(1))$, and every $w \in \mathbb{N}$, the value $T_x[s,M,w]$ is defined as the number, modulo 2, of partial cycle covers C of the graph G_x with the following properties:*

1. *the set $C \cup M$ of edges induces a single cycle,*
2. *the total weight (with respect to ω) of the edges in C is w,*
3. *every vertex $v \in B_x$ has precisely $s(v)$ incident edges in C,*
4. *every vertex $v \in V(G_x) \setminus B_x$ has precisely two incident edges in C.*

We say that a partial cycle cover C of G_x has *footprint* s on x if it satisfies the last two items.

▶ **Theorem 12** ([16]). *Let x be a non-first node of a very nice path decomposition of a graph G and let y denote its predecessor. For any fixed $s\colon B_x \to \{0,1,2\}$ where $s^{-1}(1)$ has even cardinality, every $M \in \mathcal{X}(s^{-1}(1))$, and every $w \in \mathbb{N}$, given the table T_y, the value $T_x[s,M,w]$ can be computed in time $\mathcal{O}^*(1)$ by querying $\mathcal{O}(1)$ entries of T_y.*

Let G be a graph and let $\ell = v_1, \ldots, v_n$ be a linear arrangement of G of cutwidth at most k. The aim now is to compute from ℓ a path decomposition of G with certain nice properties to which we will later apply the algorithm from Theorem 12. We recall that by definition for every $i \in [n]$, the set Y_i consists of all left end-points of the edges in the $(i-1)$st cut E_{i-1} of ℓ together with the vertex v_i. Thus, we have $|E_{i-1}| \leq k$ and $|Y_i| \leq k+1$ for all $i \in [n]$. It is well-known that the sequence $Y_1, \ldots, Y_n$ of bags is a path decomposition of G (see e.g., [26] for the idea and [7] for a formal proof). To reverse the ordering in which these bags are traversed, for every $i \in [n]$, we define the set $X_i = Y_{n+1-i}$.

▶ **Definition 13.** *For a node x of a path decomposition we define the sets*

$$B_1(x) = \{u \in B_x \mid \deg_{G_x}(u) = 1\} \text{ and } B_2(x) = \{u \in B_x \mid \deg_{G_x}(u) \geq 2\}.$$

We call a mapping $s\colon B_x \to \{0,1,2\}$ relevant *if all of the following hold: (1) $|s^{-1}(1)|$ is even, (2) $s^{-1}(2) \subseteq B_2(x)$, and (3) $s^{-1}(1) \subseteq B_1(x) \cup B_2(x)$.*

▶ **Lemma 14.** *Let x be a node of a very nice path decomposition of G and P be a partial cycle cover of G_x. Let $s\colon B_x \to \{0,1,2\}$ be such that P has footprint s. Then s is relevant.*

Furthermore, if $|B_1(x)| + 2 \cdot |B_2(x)| \leq k + \mathcal{O}(1)$ holds, then the number of pairs (s,M) such that $s\colon B_x \to \{0,1,2\}$ is relevant and $M \in \mathcal{X}(s^{-1}(1))$ is upper-bounded by $\mathcal{O}((1+\sqrt{2})^k)$.

Sketch. Let P be a partial cycle cover of G_x and let $s\colon B_x \to \{0,1,2\}$ be such that P has footprint s. By definition of a footprint, all end-vertices of P belong to B_x. Furthermore, every vertex of degree 1 resp. 2 in P has the degree of at least 1 resp. 2 in G_x so the first claim holds. Now let $\ell_1 = |B_1(x)|$ and $\ell_2 = |B_2(x)|$. The number of pairs (s, M) such that $s\colon B_x \to \{0,1,2\}$ is relevant and $M \in \mathcal{X}(s^{-1}(1))$ is at most

$$\sum_{0 \le i_2 \le \ell_2} \binom{\ell_2}{i_2} \sum_{0 \le i_1 \le (\ell_2 - i_2) + \ell_1} \binom{(\ell_2 - i_2) + \ell_1}{i_1} 2^{i_1/2-1}.$$

A careful analysis upper-bounds this by $\mathcal{O}((1+\sqrt{2})^k)$ if $\ell_1 + 2 \cdot \ell_2 \le k + \mathcal{O}(1)$ holds. ◀

▶ **Lemma 15.** *From the linear arrangement $v_1, \ldots, v_n$ of the graph G, in polynomial time we can construct a very nice path decomposition of G in which each node x satisfies $|B_1(x)| + 2 \cdot |B_2(x)| \le k + \mathcal{O}(1)$.*

Sketch. The desired path decomposition is obtained by starting with the nodes $x_1, \ldots, x_n$ corresponding to the bags $X_1, \ldots X_n$, respectively, and making the decomposition very nice by a careful choice of the ordering of introduce-vertex-, introduce-edge-, and forget-vertex-operations. This ordering, in particular, ensures that the graph G_{x_i} contains no edges with both end-points in $X_i \setminus \{v_{n+1-i}\}$. We recall that for every $i \in [n]$, all vertices in the bag X_i (apart from v_{n+1-i}) are left end-points of edges in the cut E_{n-i} (whose size is bounded by k). So every vertex in $B_1(x_i) \setminus \{v_{n+1-i}\}$ resp. $B_2(x_i) \setminus \{v_{n+1-i}\}$ contributes 1 resp. at least 2 to the size of E_{n-i}. And therefore $|B_1(x_i)| + 2 \cdot |B_2(x_i)|$ is upper-bounded by $k+2$. We also show that the intermediate bags added to make the decomposition very nice also have this property as they can be upper-bounded using x_i for some $i \in [n]$. ◀

We can then run the dynamic-programming algorithm from Theorem 12 restricted to relevant footprints only to compute the values $T_r[\emptyset, \emptyset, w]$ for every "reasonable" integer w where r denotes the root of a path decomposition satisfying the above lemma. Cygan et al. [16] show that this information suffices to find out, with high probability, if the graph G admits a Hamiltonian cycle. We refer to the full version for all details.

▶ **Theorem 16.** *There exists a one-sided error Monte-Carlo algorithm that takes a graph G together with a linear arrangement of G of cutwidth at most* ctw*, runs in time $\mathcal{O}^*((1+\sqrt{2})^{\mathrm{ctw}})$, and solves the* Hamiltonian Cycle *problem. The algorithm cannot give false positives and may give false negatives with probability at most $1/2$.*

Cygan et al. [16] showed that unless SETH fails, no algorithm working on path decompositions of pathwidth pw can solve the problem in time $\mathcal{O}^*((2+\sqrt{2}-\varepsilon)^{\mathrm{pw}})$ for any $\varepsilon > 0$. We show that their ideas are also useful to exclude the $\mathcal{O}^*((1+\sqrt{2}-\varepsilon)^{\mathrm{ctw}})$ algorithms for any $\varepsilon > 0$. To ensure that the construction has bounded cutwidth (and not only pathwidth), we modify the connections between path gadgets and employ new clause gadgets:

▶ **Theorem 17.** *Assuming SETH, there is no algorithm that solves* Hamiltonian Cycle *on graphs given with linear arrangements of cutwidth k in time $\mathcal{O}^*((1+\sqrt{2}-\varepsilon)^k)$ for any $\varepsilon > 0$.*

5 Max Cut and Induced Matching

In Induced Matching, given a graph G and an integer b, we are asked whether G contains a matching M of cardinality b such that $(V(M), M)$ is an induced subgraph of G, i.e., there are no edges other than M with both endpoints in $V(M)$. We prove the following result:

▶ **Theorem 18.** *Assuming SETH, there is no algorithm that solves* Induced Matching *on graphs given with linear arrangements of cutwidth k in time $\mathcal{O}^*\big((3-\varepsilon)^k\big)$ for any $\varepsilon > 0$.*

We recall that the treewidth of a graph is upper-bounded by its cutwidth. This shows that the $\mathcal{O}^*\big(3^k\big)$ algorithm by Chaudhary and Zehavi [13] working on graphs provided with tree decompositions of treewidth at most k is optimal for both treewidth and cutwidth and thus answers their open question. In Max Cut we are given a graph and asked to partition its vertex set into two sets to maximize the number of edges between these sets. We prove that the folklore $\mathcal{O}^*\big(2^k\big)$ algorithm working on graphs provided with tree decompositions of treewidth at most k is optimal for both treewidth and cutwidth:

▶ **Theorem 19.** *Assuming SETH, there is no algorithm that solves* Max Cut *on graphs given with linear arrangements of cutwidth k in time $\mathcal{O}^*\big((2-\varepsilon)^k\big)$ for any $\varepsilon > 0$.*

6 Conclusion and Future Work

Our results together with previous work [7, 30] show an interesting variety of behaviors for the complexity of problems relative to treewidth/pathwidth vs. relative to cutwidth: We may get the same tight bound, a small decrease in complexity, or a substantial decrease. We also discovered two more rare examples of tight exponential bounds with non-integral bases, especially Triangle Packing, which has an integral base relative to treewidth. In our opinion, this makes parameterization by cutwidth a very good test bed for deepening the understanding of dynamic programming and width parameters.

There are several avenues for future work: (i) Some edge-disjoint packing problems are intractable for treewidth but we may be able to dertermine tight bounds for cutwidth. (ii) Going beyond classical problems, it would be interesting to determine the tight complexity of (σ, ρ)-domination problems for cutwidth which is known for treewidth [21]. (iii) Closing the gap for H-Homomorphism left by Groenland et al. [25] is a challenging open question.

Abstract

A subset S of the Boolean hypercube $\mathbb{F}_2^n$ is a *sumset* if $S = \{a + b : a, b \in A\}$ for some $A \subseteq \mathbb{F}_2^n$. Sumsets are central objects of study in additive combinatorics, where they play a role in several of the field's most important results. We prove a lower bound of $\Omega(2^{n/2})$ for the number of queries needed to test whether a Boolean function $f : \mathbb{F}_2^n \to \{0, 1\}$ is the indicator function of a sumset, ruling out an efficient testing algorithm for sumsets.

Our lower bound for testing sumsets follows from sharp bounds on the related problem of *shift testing*, which may be of independent interest. We also give a near-optimal $2^{n/2} \cdot \mathrm{poly}(n)$-query algorithm for a smoothed analysis formulation of the sumset *refutation* problem. Finally, we include a simple proof that the number of different sumsets in $\mathbb{F}_2^n$ is $2^{(1\pm o(1))2^{n-1}}$.

1 Introduction

In recent years, theoretical computer science has increasingly been influenced by ideas and techniques from *additive combinatorics*, a field sitting at the intersection of combinatorics, number theory, Fourier analysis, and ergodic theory. Notable examples of this connection include communication complexity [16, 9, 14], constructions of randomness extractors [13, 7, 31, 21], and property testing [27, 32]; we also refer the reader to various surveys on additive combinatorics from the vantage point of theoretical computer science [8, 35, 36, 10, 30].

Among the simplest objects of study in additive combinatorics are *sumsets*: A subset S of an abelian group G (with group operation "+") is said to be a *sumset* if $S = A + A$ for some $A \subseteq G$, where for sets $A, B \subseteq G$ we write $A + B$ to denote the set $\{a + b : a \in A, b \in B\}$. Sumsets play a major role in additive combinatorics, where their study has led to many

questions and insights about the additive structure of subsets of abelian groups. They are the subject of touchstone results in the field such as Freiman's theorem [23], which (roughly speaking) says that if $|A+A|$ is "not too much larger" than $|A|$ then A must be contained in a generalized arithmetic progression which is "not too large."

Our main interest in this paper is in *algorithmic* questions related to sumsets. In [22] Fagnot, Fertin, and Vialette considered the 2-Sumset Cover problem: given a set S of integers, does there exist a set A of cardinality at most k such that $S \subseteq A+A$? They proved APX-hardness for this problem and presented a $\text{poly}(k) \cdot 5^{k^2(k+3)/2}$-time algorithm. The latter was improved to $\text{poly}(k) \cdot 2^{(3\log k - 1.4)k}$ by Bulteau, Fertin, Rizzi, and Vialette [15]. 2-Sumset Cover itself specializes Generating Set, in which the goal is to find a minimal set A such that $S \subseteq \{\sum_{i \in I} i \; ; \; I \subseteq A\}$ and which was studied in [17]. Given S and k, finding a set A of size $|A| \geq k$ with $A+A \subseteq S$ is equivalent to finding a k-Clique on the Cayley sum graph of S; this problem remains NP-hard, but can be solved with existing algorithms for k-clique [25]. Recently, Abboud, Fischer, Safier, and Wallheimer proved that recognizing sumsets is NP-complete [1], settling a question raised by Granville [18].

1.1 This Work

In this paper we restrict our attention to the case in which the ambient abelian group G is $\mathbb{F}_2^n$. We do this for several reasons: first, given that our focus is on algorithmic problems, $\mathbb{F}_2^n$ is a very natural domain to consider from a theoretical computer science perspective. Another motivation is that $\mathbb{F}_2^n$ is in some sense the simplest setting for many problems involving sumsets; as Green stated in [27], "the reason that finite field models are nice to work with is that one has the tools of linear algebra, including such notions as subspace and linear independence, which are unavailable in general abelian groups." Indeed, several of our arguments use these linear-algebraic tools.

Since $\mathbb{F}_2^n$ is an exponentially large domain, it is natural to approach the study of sumsets over $\mathbb{F}_2^n$ from the vantage point of *sublinear* algorithms. Thus, we will be interested in algorithms for which either the running time or the number of calls to an oracle for the input set S (i.e. queries of the form "does element x belong to the set S?" is less than 2^n. The recent work [19] took such a sublinear-algorithms perspective; it studied a problem which was closely related to the problem of approximating the size of the sumset $A+A$, given access to an oracle for the unknown set $A \subseteq \mathbb{F}_2^n$. The main result of [19] was that in fact $O_\varepsilon(1)$ queries – in particular, with no dependence on the dimension parameter n – are sufficient for a $\pm\varepsilon \cdot 2^n$-accurate approximation of the quantity that they consider. This naturally motivates the following broad question: What other algorithmic problems involving sumsets may be solvable with "constant" (depending only on ε) or very low query complexity?

Motivated by this general question, in the current work we study a number of algorithmic questions related to sumsets. The main problems we consider are described below:

1. We study (approximate) sumset recognition from a property testing perspective. In more detail, given access to a membership oracle for an unknown set $S \subseteq \mathbb{F}_2^n$, in the *sumset testing problem* the goal is to output "yes" with high probability (say, at least 9/10) if S is a sumset and "no" with high probability if S is ε-far from every sumset (i.e. $|S \triangle (A+A)| \geq \varepsilon 2^n$ for every set $A \subseteq \mathbb{F}_2^n$), while making as few queries to the oracle as possible.
2. The above-described sumset testing problem turns out to be closely related to the problem of *shift testing*, which is defined as follows: A shift testing algorithm is given black-box access to two oracles $\mathcal{O}_A, \mathcal{O}_B : \mathbb{F}_2^n \to \{0,1\}$, which should be viewed as membership oracles for two subsets $A, B \subseteq \mathbb{F}_2^n$. The algorithm must output "yes" with probability at

least 9/10 if $B = A + \{z\}$ for some string $z \in \mathbb{F}_2^n$ and must output "no" with probability at least 9/10 if the symmetric difference $B \triangle (A + \{z\})$ has size at least $\varepsilon 2^n$ for every $z \in \mathbb{F}_2^n$.

3. For $S \subseteq \mathbb{F}_2^n$, let $\boldsymbol{N}_\varepsilon(S)$ denote a random set which is an "ε-noisy" version of S, obtained by flipping the membership / non-membership of each $x \in \mathbb{F}_2^n$ in S with probability ε. It can be shown that for every $S \subseteq \mathbb{F}_2^n$ and every constant $0 < \varepsilon < 1$, the noisy set $\boldsymbol{N}_\varepsilon(S)$ is with high probability not a sumset. We study the problem of algorithmically *certifying* that $\boldsymbol{N}_\varepsilon(S)$ is not a sumset; i.e. we are given access to a membership oracle for $\boldsymbol{N}_\varepsilon(S)$, where S is an arbitrary and unknown subset of $\mathbb{F}_2^n$, and the goal is to output a set $C \subseteq \mathbb{F}_2^n$ of points such that there is no sumset $A + A$ for which $(A + A) \cap C = \boldsymbol{N}_\varepsilon(S) \cap C$. We refer to this problem as the *smoothed sumset refutation problem,* since it aligns with the well-studied framework of smoothed analysis [34] in which an arbitrary worst-case instance is subjected to a mild perturbation.

The latter is also of non-algorithmic interest, and for completeness we also present (in Section 3) a short proof that the number of different sumsets in $\mathbb{F}_2^n$ is between $2^{2^{n-1}}$ and $2^{2^{n-1}+O(n^2)}$. While an upper bound on the number of such sumsets could have been previously deduced from Theorem 3 in [33], our proof is simpler and gives tighter bounds. Following this work, Alon and Zamir recently further improved these bounds [6].

Our main results are as follows.

Sumset Testing Lower Bound

We give an $\Omega(2^{n/2})$ lower bound on the query complexity of sumset testing:

▶ **Theorem 1.** *There is a constant $\varepsilon > 0$ (independent of n) such that any algorithm $\mathcal{A}$ for the ε-sumset testing problem must make $\Omega(2^{n/2})$ oracle calls.*

Theorem 1 holds even for adaptive testers which may make two-sided error. In particular, note that Theorem 1 rules out the possibility of an efficient tester for the property of being a sumset. Recall that in the property testing literature, "efficient" testers are often defined as algorithms that make a number of queries that depend only on the distance parameter ϵ, or occasionally also polylogarithmic in the problem size. For example, the seminal Blum-Luby-Rubinfeld linearity tester [12] determines if a function $f : \mathbb{F}_2^n \to \mathbb{F}_2$ is linear or ε-far from all linear functions by making $O_\varepsilon(1)$ queries to the function. Other examples include testing for juntas [11], low-degree functions [20], and testing monotonicity [29].

Tight Bounds for Shift Testing

We show that the query complexity of shift testing is $\Theta^*(2^{n/2})$.

▶ **Theorem 2.** *(1) There is an algorithm for the shift testing problem which makes $O(n2^{n/2}/\varepsilon)$ oracle calls and runs in time $\mathrm{poly}(n) \cdot 2^n/\varepsilon$. Moreover, (2) For any constant $0 < c < 1/2$, any algorithm for the shift testing problem must make $\Omega(2^{n/2})$ oracle calls, even for $\varepsilon = (1/2 - 1/2^{cn})$. This lower bound holds even for distinguishing the following two cases: (i) A is a uniform random subset of $\mathbb{F}_2^n$ and $B = A + \{z\}$ for a uniform random $z \in \mathbb{F}_2^n$; versus (ii) A and B are independent uniform random subsets of $\mathbb{F}_2^n$.*

Like Theorem 1, the lower bound, i.e. Part (2), of Theorem 2 holds even for adaptive testers which may make two-sided error.

A Near-Optimal Algorithm for "Smoothed" Sumset Refutation

Our final result is a near-optimal algorithm which certifies that any noisy set $\boldsymbol{N}_\varepsilon(S)$ is not a sumset:

▶ **Theorem 3.** *(1) There is an algorithm for the ε-smoothed sumset refutation problem that makes $2^{n/2} \cdot O(n^{1.5}/\epsilon^{1.5})$ oracle calls and succeeds in certifying that $\boldsymbol{N}_\epsilon(S)$ is not a sumset with probability $1 - o_n(1)$. Moreover, (2) for any constant $\varepsilon > 0$, any algorithm that certifies that $\boldsymbol{N}_\epsilon(S)$ is not a sumset must make $\Omega(2^{n/2}/\sqrt{n})$ many oracle calls.*

1.2 Technical Overview

The $\mathbb{F}_2^n$ testing setting allows us to employ algorithms that are conceptually straightforward, even if proving correctness requires some care.

The main idea of our algorithm for shift testing (Part (1) of Theorem 2) is to query one oracle with all shifts of a random point r by a subspace V, and query the other oracle by all shifts of the same point r by the orthogonal complement $V^\perp$. This requires only $O(2^{n/2})$ queries, while providing information about the relationship between the two oracles vis-a-vis any possible shift $z \in \mathbb{F}_2^n$, since every possible shift has a decomposition into $z = z_1 + z_2$ for some $z_1 \in V, z_2 \in V^\perp$.

The optimality of this general approach is witnessed by the lower bound in Part (2) of Theorem 2. The proof is by a "deferred decisions" argument which analyzes the knowledge transcript of a query algorithm which may be interacting either with the "yes"-pair of oracles or the "no"-pair of oracles. We describe a coupling of the knowledge transcripts between these two cases, and use it to argue that if fewer than $0.1 \cdot 2^{n/2}$ queries have been made, then with high probability the transcripts are identically distributed across these two cases. (See [26] for a similar high-level argument, though in an entirely different technical setting.)

The $\Omega(2^{n/2})$ lower bound of Theorem 1 for sumset testing is by a reduction to the lower bound for shift testing. We give a straightforward embedding of the "A is random, $B = A + \{z\}$"-versus-"A, B are independent random" shift testing problem over $\mathbb{F}_2^n$ into the problem of sumset testing over $\mathbb{F}_2^{n+2}$. The most challenging part of the argument is to prove that in fact the "no" instances of shift testing (when A, B are independent random sets) give rise to instances which are far from sumsets over $\mathbb{F}_2^{n+2}$. This requires us to argue that a subset of $\mathbb{F}_2^{n+2}$ which is constant on two n-dimensional cosets and is uniform random on the other two n-dimensional cosets, is likely to be far from every sumset, which we prove using a linear algebraic argument.

For Theorem 3, a result due to Alon establishes that every subset of the Boolean cube of size $2^n - c2^{n/2}/\sqrt{n}$ is a sumset for a small constant c, which implies that any sumset "0-certificate" has size $\Omega^*(2^{n/2})$ [3]. To find such a certificate, we show that few noisy sumsets are likely to be consistent with an arbitrarily chosen subspace of dimension $n/2$, and then use a small random sample to rule out these sumsets with high probability.

1.3 Discussion

Our results suggest many questions and goals for future work; we record two such directions here.

The first direction is to obtain stronger results on sumset refutation. Is it possible to strengthen our sumset refutation result by eliminating the "smoothed analysis" aspect, i.e. is it the case that any $S \subseteq \mathbb{F}_2^n$ that is ε-far from every sumset has a "0-certificate" of size $2^{n/2} \cdot \mathrm{poly}\left(n, \frac{1}{\varepsilon}\right)$? If so, can such certificates be found efficiently given query access to S?

The second, and perhaps most compelling, direction is to either strengthen our $\Omega(2^{n/2})$-query lower bound, or prove an upper bound, for the sumset testing problem. We are cautiously optimistic that the true query complexity of sumset testing may be closer to $2^{n/2}$ queries than to 2^n queries, but any nontrivial ($o(2^n)$-query) algorithm would be an interesting result. One potentially relevant intermediate problem towards sumset testing is the problem of *k-shift testing*, in which the goal is to determine whether oracles $\mathcal{O}_A, \mathcal{O}_B : \mathbb{F}_2^n \to \{0,1\}$ correspond to $B = A + \{s_1, \dots, s_k\}$ for some k "shift" vectors $(s_i)_{i\in[k]}$ versus B being ε-far from every union of k shifts of A.

2 Preliminaries

All probabilities and expectations will be with respect to the uniform distribution, unless otherwise indicated. We use boldfaced characters such as $\boldsymbol{x}, \boldsymbol{f}$, and $\boldsymbol{A}$ to denote random variables (which may be real-valued, vector-valued, function-valued, or set-valued; the intended type will be clear from the context). We write $\boldsymbol{x} \sim \mathcal{D}$ to indicate that the random variable $\boldsymbol{x}$ is distributed according to the probability distribution $\mathcal{D}$. We write $\mathrm{dist}_{\mathrm{TV}}(\mathcal{D}_1, \mathcal{D}_2)$ to denote the *total variation distance* or *statistical distance* between the distributions $\mathcal{D}_1$ and $\mathcal{D}_2$.

For $\epsilon \in [0,1]$, we write $\boldsymbol{R}_\varepsilon$ to denote a random subset of $\mathbb{F}_2^n$ obtained by selecting each element with probability ϵ, so the "ε-noisy version" of a set $S \subseteq \mathbb{F}_2^n$, denoted $\boldsymbol{N}_\varepsilon(S)$, is equivalent to $S \triangle \boldsymbol{R}_\varepsilon$, where $A \triangle B := (A \setminus B) \cup (B \setminus A)$ denotes the symmetric difference of A and B.

Given a set $A \subseteq \mathbb{F}_2^n$, we will write $\mathcal{O}_A : \mathbb{F}_2^n \to \{0,1\}$ to denote the membership oracle for A, i.e.

$$\mathcal{O}_A(x) = \begin{cases} 1 & x \in A \\ 0 & x \notin A \end{cases}$$

for $x \in \mathbb{F}_2^n$. Given $A, B \subseteq \mathbb{F}_2^n$, we write $\mathrm{dist}(A,B)$ for the normalized Hamming distance between the sets A and B, i.e.

$$\mathrm{dist}(A,B) := \frac{|A \triangle B|}{2^n} = \mathop{\mathbf{Pr}}_{\boldsymbol{x} \sim \mathbb{F}_2^n}[\mathcal{O}_A(\boldsymbol{x}) \neq \mathcal{O}_B(\boldsymbol{x})].$$

We will also write $A + B := \{a + b : a \in A, b \in B\}$. If one of the sets is a singleton, e.g. if $A = \{a\}$, we will sometimes write $a + B := \{a\} + B$ instead.

We write $H(x)$ to denote the binary entropy function $-x \log_2 x - (1-x)\log_2(1-x)$. Stirling's approximation gives us the following helpful identity:

$$\binom{n}{\alpha n} = \Theta^*(2^{H(\alpha)n}); \text{ or, equivalently, } \binom{2^n}{\alpha 2^n} = 2^{H(\alpha)2^n} \cdot 2^{\Theta(n)}. \tag{1}$$

Given a subset D of an Abelian group G, we write $\Gamma_G(D)$ to denote the *Cayley sum graph* of G with respect to the generator set D; that is, the graph on the vertex set G that contains the edge (x,y) if and only if $x + y \in D$. (Since the group we consider is $\mathbb{F}_2^n$, for us this is the same as the regular Cayley graph of G with respect to generator set D.) When $D = \{x\}$ is a singleton for some $x \in G$, we abuse notation slightly and write $\Gamma_G(x)$ for $\Gamma_G(\{x\})$.

3 The Number of Sumsets in $\mathbb{F}_2^n$

▶ **Proposition 4.** *The number of sumsets in $\mathbb{F}_2^n$ is at most*

$2^{2^{n-1}+O(n^2)}$.

Proof. Consider a sumset $S = A + A$; we consider two cases depending on the linear rank of the set $\mathbb{F}_2^n \setminus S$.

Case 1: $\mathbb{F}_2^n \setminus S$ does not have full rank. In other words, there exists a vector $v \in \mathbb{F}_2^n$ such that

$$\langle x, v\rangle = 1 \qquad \text{implies that} \qquad x \in S.$$

In particular, we have that $S = S' \cup \left(\mathbb{F}_2^n \setminus v^\perp\right)$ for some $S' \subseteq v^\perp = \{x \in \mathbb{F}_2^n : \langle x, v\rangle = 0\}$. As there are at most 2^n choices for v, and for each choice of v there are at most $2^{2^{n-1}}$ choices for S', we have that there are at most $2^{2^{n-1}+n}$ many sumsets of this form.

Case 2: $\mathbb{F}_2^n \setminus S$ has full rank. In particular, there are n linearly independent vectors *not* in S. For $v \in \mathbb{F}_2^n$, observe that the Cayley graph $\Gamma_{\mathbb{F}_2^n}(v)$ is a perfect matching. Next, note that if $v \notin S = A + A$, then A must be an independent set in $\Gamma_{\mathbb{F}_2^n}(v)$. This is because, if $x, y \in A$ with $x + v = y$ then

$$A + A \ni x + y = x + x + v = v \notin A + A,$$

which is a contradiction. As we have n linearly independent vectors not in S, it follows that there exists an orthogonal transformation of $\mathbb{F}_2^n$ such that A must be an independent set in the hypercube (where edges are incident to elements of $\mathbb{F}_2^n$ that differ in a single coordinate). As the number of independent sets in the hypercube Q_n is at most $2^{2^{n-1}+O(1)}$ (see for example [24]), and as the number of orthogonal transformations of the hypercube is at most 2^{n^2}, it follows that the total number of sumsets of this form is at most

$$2^{2^{n-1}+n^2+O(1)}.$$

Both cases together complete the proof. ◀

▶ **Proposition 5.** *The number of sumsets in $\mathbb{F}_2^n$ is at least $2^{2^{n-1}}$.*

Proof. For any subset $A \subseteq \mathbb{F}_2^{n-1}$ of the $(n-1)$-th dimensional hypercube, we define a subset $A' \subseteq \mathbb{F}_2^n$ as

$$A' := \{\vec{0}\} \cup \{(1, a) \mid a \in A\},$$

where for a $(n-1)$-dimensional vector a, the concatenation $(1, a)$ is defined as the n-dimensional vector where the first coordinate is 1 and the other $(n-1)$ coordinates are equal to a. We observe that $(A' + A') \cap \left(\mathbb{F}_2^n \setminus e_1^\perp\right) = \{(1, a) \mid a \in A\}$. That is, in the sumset $(A' + A')$ all vectors in which the first coordinate is 1 exactly correspond to the set A. In particular, for any $A_1 \neq A_2 \in \mathbb{F}_2^{n-1}$, we have $(A_1' + A_1') \neq (A_2' + A_2')$. ◀

4 Optimally Testing Shifts

Given $A, B \subseteq \mathbb{F}_2^n$, we say that B is a *shift* of A if there exists $z \in \mathbb{F}_2^n$ such that $A + z = B$. We obtain the following upper and lower bounds for the *shift testing* problem:

▶ **Theorem 6.** *Let $\mathcal{O}_A, \mathcal{O}_B : \mathbb{F}_2^n \to \{0,1\}$ be membership oracles for $A, B \subseteq \mathbb{F}_2^n$. Then:*

1. *The algorithm* Shift-Tester *(Algorithm 1) makes $O(n2^{n/2}/\varepsilon)$ oracle calls, runs in time $\mathrm{poly}(n) \cdot 2^n/\varepsilon$, and guarantees that:*
   - **a.** *If $B = A + z$ for some $z \in \mathbb{F}_2^n$, the algorithm outputs "shift" with probability $9/10$;*
   - **b.** *If for every $z \in \mathbb{F}_2^n$ we have $\mathrm{dist}(A + z, B) \geq \varepsilon$, the algorithm outputs "ε-far from shift" with probability $9/10$.*

2. *Fix c to be a constant that is less than $1/2$. Any (adaptive, randomized) algorithm with the performance guarantee in the previous item makes $\Omega(2^{n/2})$ oracle calls, even for $\varepsilon = 1/2 - 1/2^{cn}$.*

In fact, the lower bound holds even for distinguishing the following two cases: (i) A is a uniform random subset of $\mathbb{F}_2^n$ and $B = A + s$ for a uniform random $s \in \mathbb{F}_2^n$; versus (ii) A and B are independent uniform random subsets of $\mathbb{F}_2^n$.

4.1 Upper Bound

In this section, we prove Item 1 of Theorem 6. Note that since

$$\operatorname{dist}(B, A + z) = \mathop{\mathbf{Pr}}_{\boldsymbol{x}}\left[\mathcal{O}_A(\boldsymbol{x}) \neq \mathcal{O}_B(\boldsymbol{x} + z)\right],$$

if B is a shift of A (i.e. $B = A + z_*$ for some z_*), we then have for that z_* that

$$\mathop{\mathbf{Pr}}_{\boldsymbol{x}}\left[\mathcal{O}_B(\boldsymbol{x}) = \mathcal{O}_A(\boldsymbol{x} + z_*)\right] = 1.$$

On the other hand, if $\operatorname{dist}(B, A + z) \geq \varepsilon$ for every z, then for every z we have

$$\mathop{\mathbf{Pr}}_{\boldsymbol{x}}\left[\mathcal{O}_B(\boldsymbol{x}) = \mathcal{O}_A(\boldsymbol{x} + z)\right] \leq 1 - \varepsilon.$$

These simple observations suggest that in order to estimate $\Pr[\mathcal{O}_B(\boldsymbol{x}) = \mathcal{O}_A(\boldsymbol{x} + z)]$ for a particular z, we would like to make queries $\mathcal{O}_B(\boldsymbol{x}), \mathcal{O}_A(\boldsymbol{x} + z)$ for uniform random $\boldsymbol{x}$. The fact that we need to do this for all z motivates the following approach; before proceeding, we introduce some notation.

▶ **Notation 7.** *We define the subsets $D_1, D_2 \subset \mathbb{F}_2^n$, where D_1 is the set of all $2^{\lfloor n/2 \rfloor}$ vectors whose last $\lfloor n/2 \rfloor$ coordinates are all-0 and $D_2 \subset \mathbb{F}_2^n$ is the set of $2^{\lceil n/2 \rceil}$ vectors whose first $\lceil n/2 \rceil$ coordinates are all-0. Note that every $z \in \mathbb{F}_2^n$ has a unique expression as*

$$z := z^{(1)} + z^{(2)}, \qquad \text{for } z^{(1)} \in D_1 \text{ and } z^{(2)} \in D_2.$$

Fix a particular string $z = z^{(1)} + z^{(2)}$ as above. We write $\boldsymbol{x} = \boldsymbol{r} + z^{(1)}$, and we observe that if $\boldsymbol{r}$ is uniform random then so is $\boldsymbol{x}$. As alluded to earlier we would like to query B on $\boldsymbol{x}$ and A on $\boldsymbol{x} + z = \boldsymbol{r} + z^{(1)} + z = \boldsymbol{r} + z^{(2)}$. The main observation is that if we query B on all strings in $D_1 + \boldsymbol{r}$ and query A on all strings in $D_2 + \boldsymbol{r}$, then no matter what z is we will have made the queries $\mathcal{O}_B(\boldsymbol{x}) = \mathcal{O}_B(\boldsymbol{r} + z^{(1)})$ and $\mathcal{O}_A(\boldsymbol{x} + z) = \mathcal{O}_A(\boldsymbol{r} + z^{(2)})$, so we will have obtained a sample towards estimating $\Pr_{\boldsymbol{x}}[\mathcal{O}_B(\boldsymbol{x}) = \mathcal{O}_A(\boldsymbol{x} + z)]$. Since this is true for every z, we can reuse the above queries towards all possibilities for z. (Of course one sample is not enough to estimate a probability, so we will repeat the above with n/ε different choices of $\boldsymbol{r}$.)

Proof of Item 1 of Theorem 6. Our algorithm, Shift-Tester, is presented in Algorithm 1. Note that if B is a shift of A, i.e. if there exists a $z_* \in \mathbb{F}_2^n$ for which $B = A + z_*$ then

$$\boldsymbol{r} + z_*^{(1)} \in A \qquad \text{if and only if} \qquad \boldsymbol{r} + z_*^{(1)} + z_* = \boldsymbol{r} + z_*^{(2)} \in B,$$

where we used the fact that $z_*^{(1)} + z_* = z_*^{(1)} + z_*^{(1)} + z_*^{(2)} = z_*^{(2)}$. In particular, we will have $p_{z_*} = 1$ and so the algorithm will return "shift" with probability 1. On the other hand, suppose B is ε-far from $A + z$ for every $z \in \mathbb{F}_2^n$; fix any such z. Then the probability that all n/ε repetitions in Algorithm 1 will have $\mathcal{O}_A(\boldsymbol{r} + z^{(1)}) = \mathcal{O}_B(\boldsymbol{r} + z^{(2)})$ is at most

$$(1 - \varepsilon)^{n/\varepsilon} \leq e^{-n}.$$

Taking a union bound over all $z \in \mathbb{F}_2^n$ implies that the probability that Algorithm 1 will output "ε-far from shift" is at least $1 - (2/e)^n$, completing the proof. ◀

Algorithm 1 An algorithm for shift testing.

Input: Oracles $\mathcal{O}_A, \mathcal{O}_B : \mathbb{F}_2^n \to \{0,1\}$ and $\epsilon > 0$
Output: "Shift" or "ε-far from shift"

SHIFT-TESTER$(\mathcal{O}_A, \mathcal{O}_B, \epsilon)$:

1. Repeat the following n/ϵ times:
   a. Draw a uniformly random $\boldsymbol{r} \in \mathbb{F}_2^n$.
   b. Query $\mathcal{O}_A$ on all $x \in D_1 + \boldsymbol{r}$, and query $\mathcal{O}_B$ on all $y \in D_2 + \boldsymbol{r}$.
2. For each $z = z^{(1)} + z^{(2)} \in \mathbb{F}_2^n$, let p_z be the fraction of the n/ε iterations for which

$$\mathcal{O}_A(\boldsymbol{r} + z^{(1)}) = \mathcal{O}_B(\boldsymbol{r} + z^{(2)}).$$

3. If $p_z = 1$ for some $z \in \mathbb{F}_2^n$, output "shift"; otherwise output "ε-far from shift".

Note that Algorithm 1 in fact guarantees 1-sided error, stronger than what is required by Theorem 6: The algorithm never outputs "ε-far from shift" if B is a shift of A, and if B is ε-far from every shift of A then the algorithm outputs "shift" with probability at most $(2/e)^n$.

4.2 Lower Bound

To prove Item 2 of Theorem 6 we define two probability distributions, $\mathcal{D}_{\text{yes}}$ and $\mathcal{D}_{\text{no}}$, over instances of the shift testing problem.

▶ **Definition 8.** *A draw $(\boldsymbol{A}, \boldsymbol{B})$ from $\mathcal{D}_{\text{yes}}$ is obtained as follows:*
- *$\boldsymbol{A} \subseteq \mathbb{F}_2^n$ includes each element of $\mathbb{F}_2^n$ independently with probability 1/2.*
- *$\boldsymbol{B} \subseteq \mathbb{F}_2^n$ equals $\boldsymbol{A} + \boldsymbol{s}$ for $\boldsymbol{s}$ sampled uniformly at random from $\mathbb{F}_2^n$.*

Note that for $(\boldsymbol{A}, \boldsymbol{B}) \sim \mathcal{D}_{\text{yes}}$, $\boldsymbol{B}$ is a shift of $\boldsymbol{A}$.

▶ **Definition 9.** *A draw $(\boldsymbol{A}, \boldsymbol{B})$ from $\mathcal{D}_{\text{no}}$ is obtained as follows:*
- *$\boldsymbol{A} \subseteq \mathbb{F}_2^n$ includes each element of $\mathbb{F}_2^n$ independently with probability 1/2.*
- *$\boldsymbol{B} \subseteq \mathbb{F}_2^n$ also includes each element of $\mathbb{F}_2^n$ with probability 1/2 (independently of $\boldsymbol{A}$).*

A straightforward application of the Chernoff bound, combined with a union bound over the 2^n possible shifts, shows that with probability at least 19/20 a draw of $(\boldsymbol{A}, \boldsymbol{B}) \sim \mathcal{D}_{\text{no}}$ is such that $\boldsymbol{B}$ is $(1/2 - 1/2^{cn})$-far from every shift of $\boldsymbol{A}$ (for any constant $c < 1/2$). So to prove Item 2 of Theorem 2, it is enough to establish the following claim for deterministic algorithms. (By Yao's minimax principle, this is sufficient to prove a lower bound for randomized algorithms as well.)

▷ Claim 10. Let `Test` be any deterministic, adaptive algorithm that makes $N := 0.1 \cdot 2^{n/2}$ oracle calls to $\mathcal{O}_A$ and $\mathcal{O}_B$. Let $T_{\texttt{test}}(A, B)$ be the "transcript" of its queries to the oracles and received responses, i.e. $T_{\texttt{test}}(A, B)$ consists of

$$\begin{gathered}(\text{first query to one of the oracles, response received})\\ \vdots\\ (N\text{-th query to one of the oracles, response received}).\end{gathered}$$

Then we have

$$\text{dist}_{\text{TV}}\left(T_{\texttt{test}}(\boldsymbol{A}_{\text{yes}}, \boldsymbol{B}_{\text{yes}}), T_{\texttt{test}}(\boldsymbol{A}_{\text{no}}, \boldsymbol{B}_{\text{no}})\right) \leq 0.02,$$

where $(\boldsymbol{A}_{\text{yes}}, \boldsymbol{B}_{\text{yes}}) \sim \mathcal{D}_{\text{yes}}$ and $(\boldsymbol{A}_{\text{no}}, \boldsymbol{B}_{\text{no}}) \sim \mathcal{D}_{\text{no}}$.

The claim follows by analyzing the behavior of the algorithm on an oracle constructed over the course of answering the queries posed by algorithm `Test`, i.e., "deferring" the decision of whether the oracle $(\boldsymbol{A}, \boldsymbol{B})$ is drawn from $\mathcal{D}_{\text{yes}}$ or $\mathcal{D}_{\text{no}}$. See for example Section 7.1 of [26].

Proof. For simplicity, we assume that in each round, `Test` queries one point q and receives *both* $\mathcal{O}_A(q)$ and $\mathcal{O}_B(q)$; this can only make `Test` more powerful.

Consider the following approach to answering queries posed by `Test`: before any queries are made, draw a uniform random $\boldsymbol{s} \sim \mathbb{F}_2^n$. Let $q_1, \ldots, q_{t-1} \in \mathbb{F}_2^n$ be the first $t-1$ queries made by `Test` (we may suppose without loss of generality that all these $t-1$ query strings are different from each other, since any algorithm that repeats a query string can easily be modified so as not to do so). When the t-th query string q_t is provided by `Test`, the answer is generated as follows:

1. If $\boldsymbol{s} \neq q_t + q_{t'}$ for all $t' \leq t$, then two independent uniform random bits $\boldsymbol{b_A}, \boldsymbol{b_B} \in \{0,1\}$ are drawn and returned as $\mathcal{O}_{\boldsymbol{A}}(q_t)$ and $\mathcal{O}_{\boldsymbol{B}}(q_t)$. (It may be helpful to think of this outcome as being "recorded", i.e. when this happens the process "decides" that $\boldsymbol{b_A}, \boldsymbol{b_B}$ are the values of $\boldsymbol{A}$ and $\boldsymbol{B}$ on the point q_t.)
2. If $\boldsymbol{s} = q_t + q_{t'}$ for some $t' \leq t$, then the process halts and outputs "failure."

The key observation is that conditioned on the above process proceeding through t queries without an output of "failure", the length-t transcript is distributed exactly according to the pair of oracles $(\boldsymbol{A}, \boldsymbol{B})$ being $(\boldsymbol{A}_{\text{yes}}, \boldsymbol{B}_{\text{yes}}) \sim \mathcal{D}_{\text{yes}}$, and also exactly according to the pair of oracles being $(\boldsymbol{A}_{\text{no}}, \boldsymbol{B}_{\text{no}}) \sim \mathcal{D}_{\text{no}}$. This is because in either case, as long as no pair of queries $q_t, q_{t'}$ sum to the "hidden" random string $\boldsymbol{s} \in \mathbb{F}_2^n$, every response to every oracle call is distributed as an independent uniform random bit.

We finish the proof by showing that the probability that the process above outputs "failure" is at most 0.02. We emphasize that the probability here is taken over the entire random process which includes the initial uniform random draw of $\boldsymbol{s} \sim \mathbb{F}_2^n$.

To this end, we note that conditioning on no "failure" during the first $t-1$ rounds $q_1, \ldots, q_{t-1}$, $\boldsymbol{s}$ is distributed uniformly among all points in $\mathbb{F}_2^n$ that are not equal to $q_i + q_j$ for some $i, j \in [t-1]$. The number of such points is at least $2^n - N^2/2 > 0.99 \cdot 2^n$. On the other hand, the process outputs "failure" in round t if one of $q_1 + q_t, \ldots, q_{t-1} + q_t$ is $\boldsymbol{s}$, which happens with probability at most $N/(0.99 \cdot 2^n) < 0.2 \cdot 2^{-n/2}$. It follows from a union bound on the N rounds that the process outputs "failure" with probability at most 0.02. This finishes the proof of the claim. ◁

5 Lower Bound for Testing Sumsets

In this section, we show that the lower bound for shift testing established in Section 4.2 implies a lower bound for the problem of testing sumsets. More formally, we prove the following:

▶ **Theorem 11.** *Let $\mathcal{O}_S : \mathbb{F}_2^n \to \{0,1\}$ be a membership oracle for $S \subseteq \mathbb{F}_2^n$. There is an absolute constant $\varepsilon > 0.0125$ such that the following holds: Let $\mathcal{A}$ be any (adaptive, randomized) algorithm with the following performance guarantee:*

1. *If $S = A + A$ for some $A \subseteq \mathbb{F}_2^n$, $\mathcal{A}$ outputs "sumset" with probability $9/10$; and*
2. *If $\operatorname{dist}(S, A+A) \geq \epsilon$ for all $A \subseteq \mathbb{F}_2^n$, $\mathcal{A}$ outputs "ε-far from sumset" with probability $9/10$.*

Then $\mathcal{A}$ must make $\Omega(2^{n/2})$ calls to $\mathcal{O}_S$.

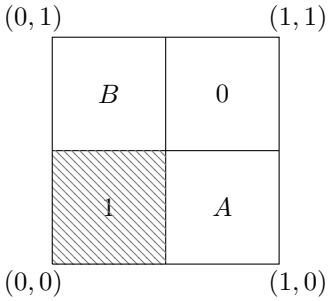

Figure 1 The set $\mathcal{S}(A, B) \subseteq \mathbb{F}_2^{n+2}$. By Proposition 12, for a typical $(\boldsymbol{A}_{\text{yes}}, \boldsymbol{B}_{\text{yes}})$ drawn from $\mathcal{D}_{\text{yes}}$, adding a single point $(1, 1, \boldsymbol{s})$ in the top right cell makes $S(\boldsymbol{A}_{\text{yes}}, \boldsymbol{B}_{\text{yes}})$ into a sumset.

The distributions we use to prove Theorem 11 are based on the distributions $\mathcal{D}_{\text{yes}}$ and $\mathcal{D}_{\text{no}}$ defined in Definitions 8 and 9 for shift testing. Given $A, B \subseteq \mathbb{F}_2^n$, we define $\mathcal{S}(A, B) \subseteq \mathbb{F}_2^{n+2}$ as

$$\mathcal{S}(A, B) := \{x : x_1 = x_2 = 0\} \sqcup \{(1, 0, a) : a \in A\} \sqcup \{(0, 1, b) : b \in B\}, \tag{2}$$

where the notation (b_1, b_2, v) indicates that the bits b_1 and b_2 are concatenated with $v \in \mathbb{F}_2^n$ to create an element in $\mathbb{F}_2^{n+2}$. Figure 1 illustrates the set $\mathcal{S}(A, B)$.

We use $\mathcal{D}_{\text{no}}$ to define $\mathcal{S}_{\text{no}}$, a distribution over subsets of $\mathbb{F}_2^{n+2}$ as follows: To draw $\boldsymbol{S}_{\text{no}} \sim \mathcal{S}_{\text{no}}$, we draw $(\boldsymbol{A}_{\text{no}}, \boldsymbol{B}_{\text{no}}) \sim \mathcal{D}_{\text{no}}$ and set $\boldsymbol{S}_{\text{no}} = \mathcal{S}(\boldsymbol{A}_{\text{no}}, \boldsymbol{B}_{\text{no}})$. On the other hand, we use $\mathcal{D}_{\text{yes}}$ to define $\mathcal{S}_{\text{yes}}$ as follows: To draw $\boldsymbol{S}_{\text{yes}} \sim \mathcal{S}_{\text{yes}}$, we draw $(\boldsymbol{A}_{\text{yes}}, \boldsymbol{B}_{\text{yes}} = \boldsymbol{A}_{\text{yes}} + \boldsymbol{s}) \sim \mathcal{D}_{\text{yes}}$ but add one "extra" point to $\boldsymbol{S}_{\text{yes}}$, defining it as: $\boldsymbol{S}_{\text{yes}} = \mathcal{S}(\boldsymbol{A}_{\text{yes}}, \boldsymbol{B}_{\text{yes}}) \sqcup \{(1, 1, \boldsymbol{s})\}$. This will ensure that $\boldsymbol{S}_{\text{yes}} \sim \mathcal{S}_{\text{yes}}$ is likely to be a sumset (see Proposition 12 below).

At a high level, the proof of Theorem 11 contains three steps: we show (1) that $\boldsymbol{S}_{\text{yes}} \sim \mathcal{S}_{\text{yes}}$ is a sumset with high probability (Proposition 12), (2) that $\boldsymbol{S}_{\text{no}} \sim \mathcal{S}_{\text{no}}$ is ϵ-far from being a sumset with high probability (Proposition 13), and (3) that oracles to $\boldsymbol{S}_{\text{yes}} \sim \mathcal{S}_{\text{yes}}$ and $\boldsymbol{S}_{\text{no}} \sim \mathcal{S}_{\text{no}}$ are too similar for an algorithm that makes few queries to tell the difference, where "similarity" is measured in terms of the total variation distance between distributions over transcripts (proof of Theorem 11). The theorem then follows quickly from these three facts.

▶ **Proposition 12.** *With probability at least* $1 - 2^{-\Omega(2^n)}$, $\boldsymbol{S}_{\text{yes}} \sim \mathcal{S}_{\text{yes}}$ *is a sumset over* $\mathbb{F}_2^{n+2}$.

Proof. Let $(A_{\text{yes}}, B_{\text{yes}})$ be a pair of sets in the support of $\mathcal{D}_{\text{yes}}$ with $B_{\text{yes}} = A_{\text{yes}} + s$. It is easy to verify that $\mathcal{S}(A_{\text{yes}}, B_{\text{yes}}) \sqcup \{(1, 1, s)\}$ is equal to $C + C$ with

$$C := \{0^n\} \sqcup \{(1, 0, a) : a \in A_{\text{yes}}\} \sqcup \{(1, 1, s)\}.$$

as long as $A_{\text{yes}} + A_{\text{yes}}$ covers all of $\mathbb{F}_2^n$. So it suffices to show that this holds with extremely high probability with a uniformly random set $\boldsymbol{A}_{\text{yes}}$.

To see this, consider any fixed, nonzero element $z \in \mathbb{F}_2^n$. Without loss of generality, suppose that the first coordinate of z is 1. We have

$$\Pr\left[z \notin \boldsymbol{A}_{\text{yes}} + \boldsymbol{A}_{\text{yes}}\right] = \Pr\left[\text{for all } y \in \mathbb{F}_2^n, \text{ either } y \notin \boldsymbol{A}_{\text{yes}} \text{ or } z + y \notin \boldsymbol{A}_{\text{yes}}\right] = (3/4)^{2^{n-1}},$$

where the second equality holds because $\boldsymbol{A}_{\text{yes}}$ is a uniform random subset of $\mathbb{F}_2^n$ and $y, z + y$ are distinct elements (observe that the first coordinate of y is 0 while the first coordinate of $z + y$ is 1). Since $\Pr[0^n \notin \boldsymbol{A}_{\text{yes}} + \boldsymbol{A}_{\text{yes}}] = \Pr[\boldsymbol{A}_{\text{yes}} \text{ is empty}] = (1/2)^{2^n} < (3/4)^{2^{n-1}}$, we get that each fixed element $z \in \mathbb{F}_2^n$ is missing from $\boldsymbol{A}_{\text{yes}} + \boldsymbol{A}_{\text{yes}}$ with probability at most $(3/4)^{2^{n-1}}$. The claim follows from a union bound over the 2^n elements of $\mathbb{F}_2^n$. ◀

▶ **Proposition 13.** *With probability at least* $1 - o_n(1)$, $\boldsymbol{S}_{\text{no}} \sim \mathcal{S}_{\text{no}}$ *is* 0.0125*-far from every sumset.*

We now complete the proof of Theorem 11 using Propositions 12 and 13. The proof of Proposition 13 is deferred to Section 5.1.

Proof of Theorem 11. Let $\mathcal{A}$ be an algorithm for sumset testing on $\mathbb{F}_2^{n+2}$ that makes at most $N = 0.1 \cdot 2^{n/2}$ queries. As in the proof of Theorem 6, we let $T_{\mathcal{A}}(S)$ denote the N-element transcript of $\mathcal{A}$ given the oracle $\mathcal{O}_S$ and take a "deferred decision" approach to prove that $\mathcal{A}$ cannot distinguish between $\mathcal{S}_{\text{yes}}$ and $\mathcal{S}_{\text{no}}$ with high probability.

By Propositions 12 and 13, the probability that $\boldsymbol{S}_{\text{yes}} \sim \mathcal{S}_{\text{yes}}$ is not a sumset is $o_n(1)$, and the probability that $\boldsymbol{S} \sim \mathcal{S}_{\text{no}}$ is 0.0125-close to any sumset is $o_n(1)$. As a result, to prove Theorem 11 it suffices to show that

$$\text{dist}_{\text{TV}}\left(T_{\mathcal{A}}(\boldsymbol{S}_{\text{yes}}), T_{\mathcal{A}}(\boldsymbol{S}_{\text{no}})\right) < 0.1 - o_n(1),$$

where $\boldsymbol{S}_{\text{yes}} \sim \mathcal{S}_{\text{yes}}$ and $\boldsymbol{S}_{\text{no}} \sim \mathcal{S}_{\text{no}}$.

Consider the sham oracle $\mathcal{O}_{\text{sham}}$ that samples a point $\boldsymbol{s} \in \mathbb{F}_2^n$ uniformly at random, then responds to queries as follows:

1. If the query is a point q_t for which $q_{t,1} = q_{t,2} = 0$, the oracle returns 1.
2. If the query is $(1, 1, \boldsymbol{s})$, the oracle outputs "failure". Otherwise, if $q_{t,1} = q_{t,2} = 1$, it returns 0.
3. If the query is a point q_t such that $q_t + q_{t'} = (1, 1, \boldsymbol{s})$ for some previously queried point $q_{t'}$, the oracle outputs "failure". Otherwise, it returns a random bit.

We proceed to consider the behavior of $\mathcal{A}$ given $\mathcal{O}_{\text{sham}}$, $\mathcal{O}_{\boldsymbol{S}_{\text{yes}}}$, and $\mathcal{O}_{\boldsymbol{S}_{\text{no}}}$. Conditioned on the event that $\mathcal{O}_{sham}$ does not output "failure", $\mathcal{A}$ always receives the answer '1' when querying a point with initial coordinates $(0, 0)$, always receives the answer '0' when querying a point with initial coordinates $(1, 1)$, and receives a random bit when querying a point with the initial coordinates $(0, 1)$ or $(1, 0)$. If, after the point of "failure", our oracle subsequently responds to queries consistently with the distribution $\mathcal{S}(\boldsymbol{A}_{\text{yes}}, \boldsymbol{A}_{\text{yes}} + \boldsymbol{s})$, randomly determining membership in $\boldsymbol{A}_{\text{yes}}$ via deferred decision as necessary, the resulting distribution over transcripts is identical to that given oracle access to $\boldsymbol{S}_{\text{yes}}$. Likewise, if the oracle responds '0' on $(1, 1, s)$ and continues to return random bits on queries whose initial coordinates begin with $(0, 1)$ or $(1, 0)$, the resulting distribution over transcripts is identical to that given oracle access to $\boldsymbol{S}_{\text{no}}$. We conclude that the distribution of $T_{\mathcal{A}}(\text{sham})$, the transcript of $\mathcal{A}$ given $\mathcal{O}_{\text{sham}}$, is identical to the distribution of transcripts given $\mathcal{O}_{\boldsymbol{S}_{\text{yes}}}$ and $\mathcal{O}_{\boldsymbol{S}_{\text{no}}}$ unless failure occurs.

Failure is unlikely for any algorithm $\mathcal{A}$ that makes at most N queries: With N queries, the algorithm can rule out at most $N = O(2^{n/2})$ candidates for $\boldsymbol{s}$ by querying points with the initial coordinates $(1, 1)$, and at most $N^2 = 0.01 \cdot 2^n$ candidates for $\boldsymbol{s}$ by querying points with the initial coordinates $(0, 1)$ and $(1, 0)$. Conditioned on no failure, the posterior distribution of $\boldsymbol{s}$ is thus uniform over at least $(0.99 - o_n(1))2^n$ points. Thus subsequently querying a point discovers s with probability at most

$$\frac{N}{(0.99 - o_n(1))2^n} \leq \frac{0.2}{2^{n/2}}.$$

Union-bounding over all N rounds gives a failure probability of at most 0.02.

We conclude that

$$\text{dist}_{\text{TV}}(T_{\mathcal{A}}(\boldsymbol{S}_{\text{yes}}), T_{\mathcal{A}}(\boldsymbol{S}_{\text{no}})) \leq 0.02 + o_n(1),$$

and thus any algorithm that makes at most $N = 0.1 \cdot 2^{n/2}$ queries cannot answer correctly with probability 9/10. ◀

5.1 Proof of Proposition 13

We prove Proposition 13 via a counting argument. The distribution $\mathcal{S}_{\text{no}}$ produces subsets of $\mathbb{F}_2^{n+2}$ of a specific form: these subsets contain every point in the subspace $\{x : x_1 = x_2 = 0\}$, no points in the coset $\{x : x_1 = x_2 = 1\}$, and have density roughly 0.5 on the cosets $\{x : x_1 = 0, x_2 = 1\}$ and $\{x : x_1 = 1, x_2 = 0\}$. We first bound the number of sumsets that are ϵ-*eligible* (roughly, "close") to any subset of this form (Proposition 16). Since there are relatively few subsets of $\mathbb{F}_2^{n+2}$ near any ϵ-eligible sumset, we conclude that most subsets drawn from $\mathcal{S}_{\text{no}}$ are far from any sumset (Proposition 13).

▶ Remark 14. It can be shown that the number of sumsets in $\mathbb{F}_2^{n+2}$ is at most $2^{2^{n+1}+O(n^2)}$ (this bound is implicit in the work [33], and for completeness we give a proof in Section 3). However, this upper bound is not enough for us per se since the support of $\mathcal{S}_{\text{no}}$ is also of size $2^{2^{n+1}}$; hence we need to use the more refined notion of "ε-eligible" sumsets mentioned above.

In the remainder of this section, we make frequent reference to the volume of sets within the subspace $\{x : x_1 = x_2 = 0\}$ of $\mathbb{F}_2^{n+2}$ and its three cosets. Given a set $S \subseteq \mathbb{F}_2^{n+2}$ and a pair of bits $(b_1, b_2) \in \{0,1\}^2$, we define

$$\text{Vol}_{b_1 b_2}(S) := \frac{|S \cap \{x \in \mathbb{F}_2^{n+2} : x_1 = b_1, x_2 = b_2\}|}{2^n}.$$

in order to simplify notation.

▶ **Definition 15.** *Given $\varepsilon > 0$, we say that a set $S \subseteq \mathbb{F}_2^{n+2}$ is an* ε-eligible sumset *if $S = A + A$ for some $A \subseteq \mathbb{F}_2^{n+2}$ and if the following holds:*

$$\text{Vol}_{00}(S) \geq 1 - \varepsilon \qquad \textit{and} \qquad \text{Vol}_{11}(S) \leq \varepsilon.$$

Roughly, the ϵ-eligible sumsets are all those that might be close to $\boldsymbol{S}_{\text{no}} \sim \mathcal{S}_{\text{no}}$.

▶ **Proposition 16.** *For any ε, the number of ε-eligible sumsets in $\mathbb{F}_2^{n+2}$ is at most*

$$\max\left\{2^{4H(\epsilon)\cdot 2^n}, 2^{(1+2H(\epsilon))2^n}\right\} \cdot 2^{O(n)}.$$

We defer the proof of Proposition 16 to Appendix A. We conclude with the proof of Proposition 13.

Proof of Proposition 13. By Proposition 16, the number of ϵ-eligible sumsets is $2^{(1+2H(\epsilon))2^n} \cdot 2^{O(n)}$ when $\epsilon < 0.1$. By Equation (1), the number of *subsets* of $\mathbb{F}_2^{n+2}$ that are γ-close to a given sumset is

$$\binom{2^{n+2}}{\gamma 2^{n+2}} = 2^{H(\gamma)2^{n+2}} \cdot 2^{O(n)}.$$

Thus, by union-bounding over all ϵ-eligible sumsets, we conclude that the number of subsets of $\mathbb{F}_2^{n+2}$ that are γ-close to any ϵ-eligible sumset is at most

$$2^{(1+2H(\epsilon))2^n + H(\gamma)2^{n+2}} \cdot 2^{O(n)}.$$

Choosing $\epsilon = 0.05$ and $\gamma = \epsilon/4$ gives an upper bound of $2^{1.96\cdot 2^n}$ subsets of $\mathbb{F}_2^{n+2}$ that are $\epsilon/4$-close to any ϵ-eligible sumset. Since $\mathcal{S}_{\text{no}}$ is distributed uniformly over $2^{2^{n+1}}$ subsets, the probability that $\boldsymbol{S}_{\text{no}} \sim \mathcal{S}_{\text{no}}$ is $(\epsilon/4)$-close to any ϵ-eligible sumset is $2^{-\Omega(2^n)}$.

We further claim that $\boldsymbol{S}_{\text{no}} \sim \mathcal{S}_{\text{no}}$ is always $(\varepsilon/4)$-far from any sumset that is not ε-eligible. This is just because that we always have $\text{Vol}_{11}(\boldsymbol{S}_{\text{no}}) = 0$ and $\text{Vol}_{00}(\boldsymbol{S}_{\text{no}}) = 1$. On the other hand, any non-ϵ-eligible sumset S has either $\text{Vol}_{00}(S) < 1 - \epsilon$ or $\text{Vol}_{11}(S) > \epsilon$ by definition and thus, must be at least $(\epsilon/4)$-far from $\boldsymbol{S}_{\text{no}}$.

Thus with probability at least $1 - o_n(1)$, $\boldsymbol{S}_{\text{no}} \sim \mathcal{S}_{\text{no}}$ is $\epsilon/4 = 0.0125$-far from any sumset. ◀

6 Refuting Sumsets in the Smoothed Analysis Setting

In this section we study the smallest size of a *certificate* that a set is *not* a sumset. Informally, for a set $S \subseteq \mathbb{F}_2^n$ a sumset 0-certificate is a set $D \subseteq \mathbb{F}_2^n$ of points such that querying the oracle $\mathcal{O}_S$ on every point in D suffices to prove that S is not a sumset. More formally:

▶ **Definition 17.** *A set $D \subseteq \mathbb{F}_2^n$ is a* sumset 0-certificate for $S \subseteq \mathbb{F}_2^n$ *if there is no sumset $S' = A + A \subseteq \mathbb{F}_2^n$ for which $S \cap D = S' \cap D$.*

Small 0-certificates are important objects of study for many property testing problems; for example, consider the classic problem of linearity testing. Since a function $f : \mathbb{F}_2^n \to \mathbb{F}_2$ is linear if and only if $f(x+y) = f(x) + f(y)$ for all $x, y \in \mathbb{F}_2^n$, the property of linearity is characterized by the non-existence of a "linearity 0-certificate" of size three. As is well known, in the seminal work [12] Blum et al. showed that this is a *robust* characterization, in the sense that a simple sampling procedure which queries random triples $x, y, x+y$ and checks whether they constitute a linearity 0-certificate suffices to distinguish linear functions from functions which are far from being linear. A similar framework of sampling 0-certificates is at the heart of many other important property testing results such as low degree testing (see e.g. [5, 28] and many other works) and testing triangle-freeness (see e.g. [4, 2] and many other works). Of course, testing results of this sort rely on, and motivate the discovery of, structural results showing that functions which are far from having the property in question must have "many" "small" 0-certificates.

With this motivation, it is natural to study the size of sumset 0-certificates. Our sumset testing lower bound from Section 5 suggests that there are sets which are far from being sumsets but which do not have "many" "small" sumset 0-certificates. In fact, known results imply that for every non-sumset the smallest 0-certificate is of size $\Omega(2^{n/2}/\sqrt{n})$:

▶ **Lemma 18.** *Let $S \subseteq \mathbb{F}_2^n$ be any non-sumset. Then any sumset 0-certificate D for S must have $|D| \geq \Omega(2^{n/2}/\sqrt{n})$.*

Proof. This is an immediate corollary of a result due to Alon (Section 4 of [3]), which shows that any subset $T \subseteq \mathbb{F}_2^n$ of size $|T| \geq 2^n - \frac{1}{4000}\frac{2^{n/2}}{\sqrt{n}}$ is a sumset. It follows that if $|D| < \frac{1}{4000}\frac{2^{n/2}}{\sqrt{n}}$, then any 0/1 labeling of the points in D is consistent with a sumset (by labeling all points in $\mathbb{F}_2^n \setminus D$ as belonging to the set). ◀

The previous lemma, which establishes that any 0-certificate for sumset testing must have size $\Omega(2^{n/2}/\sqrt{n})$, establishes Part (2) of Theorem 3. In the full version of our paper, we prove a matching upper bound (up to a factor of $\mathrm{poly}(n, 1/\epsilon)$) for any set perturbed by a small amount of random noise, thereby establishing Part (1) of Theorem 3:

▶ **Theorem 19.** *For any set $S \subseteq \mathbb{F}_2^n$ and any $\varepsilon \in (0, \frac{1}{2}]$, there exists a sumset 0-certificate for $\boldsymbol{N}_\varepsilon(S) = S \triangle \boldsymbol{R}_\varepsilon$ of size $2^{n/2} \cdot O(n^{1.5}/\epsilon^{1.5})$, with probability $1 - o_n(1)$ over the random draw of $\boldsymbol{R}_\varepsilon$. Moreover, such a 0-certificate can be found efficiently and non-adaptively (by querying $2^{n/2} \cdot O(n^{1.5}/\epsilon^{1.5})$ points) given oracle access to $\boldsymbol{N}_\varepsilon(S)$.*

A Proof of Proposition 16

Proof. Let S be any ϵ-eligible sumset, and let A satisfying $A + A = S$ be an additive root of S. We bound the number of ϵ-eligible sumsets by considering possibilities for A.

We begin with the observation that if $\mathrm{Vol}_{00}(A), \mathrm{Vol}_{11}(A) > 0$, then it must be true that $\mathrm{Vol}_{00}(A), \mathrm{Vol}_{11}(A) \leq \epsilon$. Otherwise, we would have $\mathrm{Vol}_{11}(A+A) = \mathrm{Vol}_{11}(S) > \epsilon$, contradicting our assumption that S is ϵ-eligible. Likewise, we have that if $\mathrm{Vol}_{01}(A), \mathrm{Vol}_{10}(A) > 0$, then $\mathrm{Vol}_{01}(A), \mathrm{Vol}_{10}(A) \leq \epsilon$. We split into cases accordingly.

1. All four cosets of $\{x : x_1 = x_2 = 0\}$ are nonempty:
   $\mathrm{Vol}_{00}(A), \mathrm{Vol}_{11}(A), \mathrm{Vol}_{01}(A), \mathrm{Vol}_{10}(A) > 0$.
   In this case, we have that $\mathrm{Vol}_{00}(A), \mathrm{Vol}_{11}(A), \mathrm{Vol}_{01}(A), \mathrm{Vol}_{01}(A) \leq \epsilon$. Using Equation (1), we can then bound the number of possibilities for A (and S) by

   $$\binom{2^n}{\varepsilon 2^n}^4 \leq 2^{4H(\varepsilon)\cdot 2^n} \cdot 2^{O(n)}.$$

2. Either $\mathrm{Vol}_{00}(A)$ and $\mathrm{Vol}_{11}(A) > 0$, or $\mathrm{Vol}_{01}(A)$ and $\mathrm{Vol}_{10}(A) > 0$, but not both.
   Here the volume of A on two of the four cosets is at most ϵ, in one other coset it is 0, and in the final coset it may be as large as 1. In this case, again using Equation (1), the number of possibilities for A (and S) is bounded by

   $$2^{2^n} \cdot \binom{2^n}{\varepsilon 2^n}^2 \leq 2^{(1+2H(\varepsilon))\cdot 2^n} \cdot 2^{O(n)}.$$

3. Either $\mathrm{Vol}_{00}(A)$ or $\mathrm{Vol}_{11}(A) = 0$, and either $\mathrm{Vol}_{01}(A)$ or $\mathrm{Vol}_{10}(A) = 0$, hence at least two of the four cosets contain no points in A.
   Assume without loss of generality that $\mathrm{Vol}_{11}(A) = \mathrm{Vol}_{01}(A) = 0$. This immediately implies that $\mathrm{Vol}_{01}(S) = \mathrm{Vol}_{11}(S) = 0$, as $A + A$ cannot contain points in either coset. (Note that, whichever pair of cosets we choose to zero out, this implies that $\mathrm{Vol}_{11}(S) = 0$ and either that $\mathrm{Vol}_{01}(S) = 0$ or $\mathrm{Vol}_{10}(S) = 0$.) Using the fact that $\mathrm{Vol}_{00}(S) \geq 1 - \epsilon$, the number of possibilities for S is bounded by

   $$2^{2^n} \cdot \binom{2^n}{\varepsilon 2^n} \leq 2^{(1+H(\varepsilon))\cdot 2^n} \cdot 2^{O(n)}.$$

Summing the number of ϵ-eligible sumsets covered by each case completes the proof. ◀

Linear Layouts Revisited: Stacks, Queues, and Exact Algorithms

Abstract

In spite of the extensive study of stack and queue layouts, many fundamental questions remain open concerning the complexity-theoretic frontiers for computing stack and queue layouts. A stack (resp. queue) layout places vertices along a line and assigns edges to pages so that no two edges on the same page are crossing (resp. nested). We provide three new algorithms which together substantially expand our understanding of these problems:

1. A fixed-parameter algorithm for computing minimum-page stack and queue layouts w.r.t. the vertex integrity of an n-vertex graph G. This result is motivated by an open question in the literature and generalizes the previous algorithms parameterizing by the vertex cover number of G. The proof relies on a newly developed Ramsey pruning technique. Vertex integrity intuitively measures the vertex deletion distance to a subgraph with only small connected components.
2. An $n^{\mathcal{O}(q\ell)}$ algorithm for computing ℓ-page stack and queue layouts of page width at most q. This is the first algorithm avoiding a double-exponential dependency on the parameters. The page width of a layout measures the maximum number of edges one needs to cross on any page to reach the outer face.
3. A $2^{\mathcal{O}(n)}$ algorithm for computing 1-page queue layouts. This improves upon the previously fastest $n^{\mathcal{O}(n)}$ algorithm and can be seen as a counterpart to the recent subexponential algorithm for computing 2-page stack layouts [ICALP'24], but relies on an entirely different technique.

1 Introduction

A linear layout $\langle \prec, \sigma \rangle$ of a graph G is a total ordering $\prec$ of its vertices and a partitioning σ of its edges into k *pages* such that each page satisfies certain conditions. The two by far most commonly studied types of linear layouts are *stack layouts* and *queue layouts*; in the

licensed under Creative Commons License CC-BY 4.0

former, we require that no four vertices $a \prec b \prec c \prec d$ have the edges ac and bd placed on the same page, while for the latter we forbid any page from containing the edges ad and bc. Intuitively, this corresponds to forbidding edges crossing and edges nesting (in a rainbow pattern), respectively – see Figure 1.

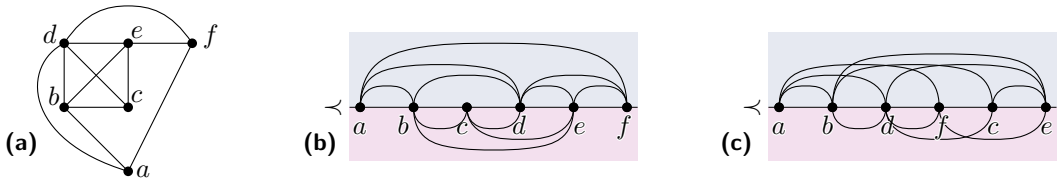

Figure 1 A graph G **(a)** together with a 2-page stack layout **(b)** and 2-page queue layout **(c)**. The two pages are colored blue and lilac, respectively.

Originally motivated from applications in VLSI [10, 41] and bioinformatics [31], stack and queue layouts have become the focus of extensive research. While there are many classical works studying the structural properties of the two notions [17–21, 32, 34, 46], several more recent studies have targeted exact and parameterized algorithms for computing stack and queue layouts that minimize the number of used pages. These results are inherently aimed at circumventing the long-known intractability of these problems: the NP-hardness of determining whether an input graph admits a 2-page stack layout or a 1-page queue layout has been established over thirty years ago [34, 46].

To that end, recent works have pursued the use of structural graph parameters to establish tractability on graphs which are "well-structured". Computing ℓ-page stack layouts is now known to be fixed-parameter tractable w.r.t. the vertex cover number [7] or, alternatively, the feedback edge number of the input graph G [26]. Computing ℓ-page queue layouts is likewise known to admit a fixed-parameter algorithm w.r.t. the vertex cover number of G [8]. One drawback of these results is that they only yield tractability under highly restrictive graph parameters, in the sense of achieving low values only on very "simple" graphs. While computing 1-page queue layouts is also known to be fixed-parameter tractable when parameterized by the treedepth of G [8], for general ℓ it was repeatedly posed as an open question whether the aforementioned vertex-cover based algorithms can be lifted to less restrictive structural graph parameters [7, 8, 21, 25, 26]. Another recent direction is the establishment of tighter algorithmic upper bounds for special cases: while ℓ-page stack and queue layouts can both be computed in time $n^{\mathcal{O}(n)}$ via trivial brute-force algorithms, 2-page stack layouts are now known to admit a subexponential algorithm [26].

Contributions. As our **first contribution**, we lift the aforementioned fixed-parameter tractability of computing linear layouts to a less restrictive structural graph parameter:

▶ **Theorem 1.** *Computing a minimum-page stack layout and minimum-page queue layout is fixed-parameter tractable w.r.t. the* vertex integrity *of the input graph.*

The vertex integrity $\mathsf{vi}(G)$ of a graph G measures, roughly speaking, how many vertex deletions are required to decompose G into small connected components, and has been used in the design of parameterized algorithms for a variety of challenging problems [9, 22–24, 27, 29, 30, 39].[1] More precisely, $\mathsf{vi}(G)$ is the minimum integer k satisfying the following:

Due to space constraints, we defer full proofs of statements marked with ★ to the full version [14].

[1] Some prior works use the *fracture number*, which is parametrically equivalent to vertex integrity.

there exists a vertex set $X \subseteq V(G)$ such that for each connected component C of $G - X$, $|V(C) \cup X| \leq k$. As vertex integrity is upper-bounded by the vertex cover number plus one, Theorem 1 generalizes the fixed-parameter tractable algorithms for computing stack and queue layouts w.r.t. the vertex cover number by Bhore, Ganian, Montecchiani, and Nöllenburg [7, 8]. Moreover, since the vertex integrity is sandwiched between the vertex cover number and treedepth, our result can be seen as a stepping stone towards solving the problem on more general parameterizations.

To establish Theorem 1, we introduce a novel proof technique we call *Ramsey pruning*. On a high level, the algorithm underlying the computation is very simple: assuming $|G|$ is larger than some pre-designated function k, it recursively identifies a connected component C of $G - X$ such that $G - X$ contains sufficiently many copies of C, and deletes C from the instance. The difficulty lies in proving that this operation is safe, i.e., that $G - C$ does not admit a layout with fewer pages than G. The "usual" approach for such a proof would be to show that C can be reinserted into any hypothetical linear layout $\langle \prec, \sigma \rangle$ of $G - C$ without increasing the number of pages; however, this not only seems excruciatingly difficult to prove, but we also believe it to be false for certain choices for $\langle \prec, \sigma \rangle$. Ramsey pruning avoids this issue by using Ramsey-type arguments to argue that $\langle \prec, \sigma \rangle$ must contain a *guiding sub-layout* $\langle \prec', \sigma' \rangle$ – a linear layout of some carefully selected subgraph of $G - C$ – with certain well-defined properties. We then use the well-formedness of $\langle \prec', \sigma' \rangle$ to build a brand new linear layout $\langle \prec^*, \sigma^* \rangle$ of G, thus establishing that G and $G - C$ indeed require the same number of pages. We believe this new technique to be generic and applicable to other problems under the same parameterization, as suggested by the fact that unlike the previous vertex-cover based algorithms our approach works for both stack and queue layouts with almost no problem-specific changes required.

While Theorem 1 pushes the frontiers of tractability for our two problems of interest in a complexity-theoretic sense, our use of Ramsey-type arguments means that the obtained running time bound has an entirely impractical dependency on the parameter (see Lemma 5). In fact, up to now none of the known parameterized algorithms for computing ℓ-page stack or queue layouts have a runtime parameter dependency that would be better than double-exponential – the parameterized algorithms w.r.t. the vertex cover [7, 8] and feedback edge numbers [26] all preprocess the graph to obtain an equivalent instance (a *kernel*) whose size is exponential in the parameter, and then solve that equivalent bounded-size instance via brute force. As our **second contribution**, we provide the first single-exponential algorithms (in the parameters) capable of solving these problems for arbitrary fixed choices of ℓ:

▶ **Theorem 2 (★).** *Given integers ℓ and q along with an n-vertex graph G, we can compute an ℓ-page stack or queue layout with page width at most q of G (if one exists) in time $n^{\mathcal{O}(q \cdot \ell)}$.*

Here, the page width measures the maximum number of edges one needs to cross to reach any vertex from the outer face (see also Section 2). The page width of linear layouts[2] has been studied in several early works [10, 32, 43, 44] and it is generally desirable to obtain layouts not only using few pages, but also with low page width – in fact, the original papers introducing stack layouts explicitly targeted algorithms optimizing both measures. However, the algorithmic applications of page width as a parameter have only been investigated in a recent paper on extending incomplete linear layouts [12]. We remark that while Theorem 2 merely provides a so-called XP *algorithm* in a complexity-theoretic sense, it may still be more efficient in practice than known fixed-parameter algorithms for the problem – especially if the aim is to compute layouts with low pagewidth.

[2] The term *cutwidth* has been used interchangeably with page width in the past [10]; here, we use the latter in order to disambiguate from the related graph parameter cutwidth.

A natural approach towards establishing Theorem 2 would be to use dynamic programming in order to construct the sought-after linear layout in a "left-to-right" fashion; however, the issue is that doing this directly would require us to store roughly 2^n possible subsets of previously processed vertices. To circumvent this, we obtain new insights into the decomposability of layouts with bounded page width, allowing us to construct an $n^{\mathcal{O}(q \cdot \ell)}$-size auxiliary *state graph* H, where we show that the dynamic computation of a sought-after layout can be represented as an easily computable path in H.

As our final **third contribution**, we take a step back from the multivariate analysis of these problems and recall that the trivial $n^{\mathcal{O}(n)}$ barrier was only recently overcome for computing 2-page stack layouts [26], i.e., the lowest-page stack layouts giving rise to an NP-complete problem. Here, we show that the trivial $n^{\mathcal{O}(n)}$ barrier can also be overcome when aiming for the lowest-page queue layouts which still give rise to NP-completeness:

▶ **Theorem 3 (★).** *Given an n-vertex graph G, we can compute a 1-page queue layout of G (if one exists) in time $2^{\mathcal{O}(n)}$.*

We remark that the running time bound provided by Theorem 3 is worse than the $2^{\mathcal{O}(\sqrt{n})}$ bound previously obtained for 2-page stack layouts [26]. The reason for this is that the latter result relied on the equivalence of 2-page stack layouts with the existence of *subhamiltonian paths*; the authors of that previous work then essentially obtained a single-exponential fixed-parameter algorithm for finding such paths w.r.t. the graph parameter treewidth, improving on the previously established fixed-parameter tractability of the problem [4].

However, emulating the same approach seems difficult in the queue layout setting: 1-page queue layouts also have an equivalent formulation in terms of so-called *arched-level planar* drawings [34], but it is not at all clear whether computing such drawings is fixed-parameter tractable w.r.t. treewidth (not to mention the fact that one would need a single-exponential algorithm). Instead, our proof of Theorem 3 relies on a Turing reduction from computing arched-level planar drawings to $2^{\mathcal{O}(n)}$ many instances of a well-studied problem called Level Planarity, which is known to be solvable in polynomial time [33, 37].

Related Work. We refer to the dedicated survey for an overview of many earlier structural results concerning linear layouts [19]. Key structural results in the area include the existence of 4-page stack layouts [46] and 42-page queue layouts [5,17] for all planar graphs. Researchers have also studied the notion of *mixed layouts*, which are linear layouts with some pages behaving like stack and some like queue layouts [3, 38]. We note that due to the techniques used in their proofs, it seems very likely that Theorems 1 and 2 could be adapted to the mixed layout setting with minimum changes required. Finally, we remark that parameterized algorithms for stack and/or queue layouts have additionally been considered in the extension setting (where the task is to complete a provided partial layout) [12, 13], in the upward-planarity setting (where the graph is directed and edges must be oriented in a left-to-right fashion along the layout) [6] and when the vertex ordering in the layout is fixed [1, 40].

2 Preliminaries

For an integer $\ell \geq 1$ we let $[\ell]$ denote the set $\{1, 2, \ldots, \ell\}$. We assume the reader to be familiar with standard graph terminology [15]. Without loss of generality, we assume all input graphs to be connected, have n vertices and m edges. For a set of vertices $V' \in V(G)$, we let $G[V']$ denote the graph induced on V'. Furthermore, for a set of edges $E' \in E(G)$, we let $V(E')$ denote the set of its endpoints and $G[E'] = (V(E'), E')$. A *cut* (A, B) of G is a partition of

the vertices in $A \subseteq V(G)$ and $B = V(G) \setminus A$. We call $F = \{uv \in E(G) \mid u \in A, v \in B\}$ a *cut-set* of *size* $|F|$ that *induces* the cut (A, B). Throughout the paper, we omit an explicit reference to G if it is clear from the context, e.g., we write V and E instead of $V(G)$ and $E(G)$.

Given a linear order $\prec$ of a graph G and two vertices $u, v \in V$, we say that u is *left* of v if $u \prec v$ and *right* of v if $v \prec u$. The vertices u and v are *consecutive on the spine* if they occur consecutively in $\prec$, i.e., there is no vertex $w \in V$ such that $u \prec w \prec v$ or $v \prec w \prec u$ holds. We address with $\text{Left}_v^{\prec} := \{u \in V \mid u \prec v\}$ all vertices $u \in V$ left of v with respect to $\prec$ and define $\text{Right}_v^{\prec} := V \setminus (\text{Left}_v^{\prec} \cup \{v\})$. Finally, we let $X_v^{\prec} := \{uw \in E \mid u \in \text{Left}_v \cup \{v\}, w \in \text{Right}_v\}$ denote the set of edges that *span* the spine between v and its right neighbor, i.e., all edges with one endpoint left of (or at) v and one right of v.

We assume familiarity with the basic foundations of parameterized complexity theory [11]. All algorithms obtained in this work are exact, deterministic, constructive and rely exclusively on computable functions. To express some of our bounds, we will occasionally use the Knuth notation $\uparrow\uparrow$ where for an integer z, $2 \uparrow\uparrow z$ represents an exponential tower of 2's of height z.

Linear Layouts. Let u_1v_1 and u_2v_2 be two edges of G. We say that they *cross* under a linear order $\prec$ if $u_1 \prec u_2 \prec v_1 \prec v_2$ holds, and they *nest* if $u_1 \prec u_2 \prec v_2 \prec v_1$ holds. For an integer $\ell \geq 1$, let $\sigma_G \colon E(G) \to [\ell]$ be a function that assigns each edge to a *page* $p \in [\ell]$. The *linear layout* $\langle \prec_G, \sigma_G \rangle$ is a *stack* (*queue*) *layout* if no two edges $e_1, e_2 \in E$ with $\sigma_G(e_1) = \sigma_G(e_2)$ cross (nest). We call $\prec_G$ the *spine order* and σ_G the *page assignment*. For the remainder of the paper, we write $\prec$ and σ if the graph G is clear from context.

The *page width* $\omega(\langle \prec, \sigma \rangle)$ of an ℓ-page linear layout $\langle \prec, \sigma \rangle$ corresponds to the maximum number of edges on a single page that span the spine between a vertex and its right neighbor, i.e., $\omega(\langle \prec, \sigma \rangle) := \max_{p \in [\ell]} \max_{v \in V(G)} \left| X_v \cap \sigma^{-1}(p) \right|$. We call an ℓ-page linear layout with page width q an *ℓ-page q-width linear layout*, or simply a *solution* when the ℓ and q are clear from context. In line with the literature, we assume no explicit bound on the page width when q is not specified.

Vertex Integrity. A graph G has *vertex integrity* $\mathsf{vi}(G) = p$ if p is the smallest integer with the following property: G contains a vertex set S such that for each connected component H of $G - S$, $|V(H) \cup S| \leq p$. One may observe that the vertex integrity is upper-bounded by the size of a minimum vertex cover in the graph (i.e., the vertex cover number) plus one. The vertex integrity of an n-vertex graph along with a corresponding partition into S and $\mathcal{C} = G - S$ can be computed in time $\mathcal{O}(p^{p+1} \cdot n)$ [16].

3 A Fixed-Parameter Algorithm Parameterized by Vertex Integrity

In this section, we obtain a fixed-parameter algorithm that takes as input a positive integer ℓ and a graph G, is parameterized by $\ell + \mathsf{vi}(G)$ and computes an ℓ-page stack and/or queue layout of G (or both), if such layouts exist. We begin by noting that using well-known relationships between vertex integrity, minimum-page stack and queue layouts and the graph parameter *treewidth* (tw), we can assume ℓ to be upper-bounded by a function of $\mathsf{vi}(G)$ thanks to the well-known relation $\mathsf{tw}(G) \leq \mathsf{vi}(G)$:

▶ **Proposition 4** ([20, 45]). *The number of pages in a minimum stack and queue layout of a graph G is upper-bounded by $\mathsf{tw}(G) + 1 \leq \mathsf{vi}(G) + 1$ and $2^{\mathsf{tw}(G)} + 1 \leq 2^{\mathsf{vi}(G)} + 1$, respectively.*

The algorithm operates by obtaining a problem kernel, as formalized below; recall $p = \mathsf{vi}(G)$.

▶ **Lemma 5.** *There is an $\mathcal{O}(p^{p+1} \cdot n)$ time algorithm that takes a graph G with an integer ℓ and outputs a subgraph G' of G (a* kernel*) of size at most $\left(2 \uparrow\uparrow (p \cdot 2^{2p^2}) \cdot 2 + 6\right)^{\ell \cdot p}$ with the following property: G' admits an ℓ-page stack (or queue) layout $\langle \prec_{G'}, \sigma_{G'} \rangle$ if and only if so does G. Moreover, such a layout for G can be computed from $\langle \prec_{G'}, \sigma_{G'} \rangle$ in polynomial time.*

Lemma 5 directly implies Theorem 1, and the rest of this section is dedicated to proving this lemma. For the following, let us fix a graph G, positive integers ℓ and p, and a choice of $S \subseteq V(G)$ witnessing $\mathsf{vi}(G) = p$ as in Section 2. Further let $\mathcal{C}$ be the set of connected components of $G - S$. First, we define a notion of "component-types" which groups components in $\mathcal{C}$ that exhibit the same outside connections and internal structure.

▶ **Definition 6.** *We say two graphs $H_0, H_1 \in \mathcal{C}$ are* twins*, denoted $H_0 \sim H_1$, if there exists a canonical isomorphism α from H_0 to H_1 such that for each vertex $u \in V(H_0)$ and each $v \in S$, $uv \in E(G)$ if and only if $\alpha(u)v \in E(G)$.*

▶ **Lemma 7 (★).** *Each graph $H \in \mathcal{C}$ has at most p vertices, $\sim$ is an equivalence relation and the number of equivalence classes in $[\sim]$ is upper-bounded by $p \cdot 2^{2p^2}$. Moreover, a partition of connected components into $[\sim]$ can be computed in time at most $\mathcal{O}(p \cdot 2^{2p^2} \cdot n)$.*

We now introduce the notion of large equivalence classes based on their size. We then use this to define what we call a large group of vertices – one that contains exactly one representative from each large equivalence class. Our kernel will keep a bounded number of these large groups.

▶ **Definition 8.** *Let k be a positive integer, an equivalence class $[H]$ of $\sim$ is said to be k-*large *if $|[H]| \geq k$. Further a vertex set $L \subseteq V(G)$ is called a k-*large group *if the induced subgraph $G[L]$ is a disjoint union of exactly one graph from each k-large equivalence class of $\sim$.*

Next we define a special induced subgraph that will serve as our kernel. The definition is based on carefully choosing a k that is bounded by a computable function of p and ℓ so that keeping only k many k-large groups along with the small parts of the graph suffices to capture the necessary structure. Towards this, let us first fix $f(\ell, p, x) := 2^{2^{\ell \cdot x^2 \cdot 2^{12p^2}}}$ to be a computable function that is large enough to apply our Ramsey-type arguments later on; here, x will be an integer that represents the size of a deletion set (initially S, but this will be updated iteratively in the proof of Lemma 11). Moreover, let $g(\ell, p)$ be a computable function of ℓ and p that will upper-bound our nested application of the function f in that same proof; to provide a concrete bound, we set $g(\ell, p) := \left(2 \uparrow\uparrow (p \cdot 2^{2p^2}) \cdot 2 + 4\right)^{\ell \cdot p}$.

▶ **Definition 9.** *An induced subgraph G' of G is said to be a* reduced graph *of G if there exists a positive integer $x \leq g(\ell, p)$ and a partition of $V(G') = S \uplus S' \uplus Y$ satisfying:*

1. *$|S \cup S'| = x$ and S' is the set of all vertices in graphs in $\mathcal{C}$ that do not belong to an $f(\ell, p, x)$-large equivalence class of $\sim$.*
2. *If there are no $f(\ell, p, x)$-large equivalence classes of $\sim$, $Y = \emptyset$ and $V(G') = S \uplus S' = V(G)$. Otherwise, it holds that $Y = L_1 \uplus \cdots \uplus L_{f(\ell,p,x)}$ where L_i is an $f(\ell, p, x)$-large group for each $i \in \{1, \cdots, f(\ell, p, x)\}$, and each pair of L_i and L_j, $i \neq j$, is vertex-disjoint.*

Intuitively, the reduced graphs we will be dealing with will consist of S, a set S' of all equivalence classes of $\sim$ which are too small to fully saturate our large groups (these will later be treated essentially in the same way as S), and a sufficient number of large groups; equivalence classes of size larger than $f(\ell, p, x)$ are "pruned" to have size exactly $f(\ell, p, x)$. A schematic overview of this intuition can be found in Figures 2b and c later on.

The core of our result is the following lemma, which we prove separately in Section 3.1.

▶ **Lemma 10.** *If G' is a reduced graph of G then G has an ℓ-page stack (queue) layout if and only if G' has an ℓ-page stack (queue) layout.*

Before proceeding to that proof, we show how to construct a reduced graph having size bounded by a computable function of p and ℓ in polynomial time.

▶ **Lemma 11 (★).** *There exists a reduced graph G' of G, and given S and $\sim$ such a graph can be computed in polynomial time. Further, the number of vertices in G' is upper-bounded by $\left(2 \uparrow\uparrow (p \cdot 2^{2p^2}) \cdot 2 + 6\right)^{\ell \cdot p}$.*

Lemma 11 combined with Lemma 10 establishes Lemma 5 by constructing a reduced graph which is a kernel of the desired size. Thus, what remains is to establish Lemma 10; this is where the core ideas of Ramsey pruning will come into play.

3.1 Proof of Lemma 10

For this proof, we fix G' to be a reduced graph of G. Since G' is an induced subgraph of G, it is clear that if G has an ℓ-page stack (queue) layout then G' also has an ℓ-page stack (queue) layout. To complete the proof we show that the reverse is true: If G' has an ℓ-page stack (queue) layout, then G also has an ℓ-page stack (queue) layout.

Recall that $f(\ell, p, x) := 2^{2^{\ell \cdot x^2} \cdot 2^{12p^2}}$. Let $\langle \prec, \sigma \rangle$ be a fixed (but hypothetical) ℓ-page stack (queue) layout of G'; throughout this section, for $H \subseteq G'$ we will use $\langle \prec_H, \sigma_H \rangle$ to refer to the sublayout of $\langle \prec, \sigma \rangle$ induced on the subgraph H of G'. If $V(G') = V(G)$ we are done. So let $V(G') = S \uplus S' \uplus L_1 \uplus \cdots \uplus L_{f(\ell,p,|S \cup S'|)}$ be a partition witnessing that G' is a reduced graph. Here each L_i is a $f(\ell, p, |S \cup S'|)$-large group and S' is the set of all vertices in graphs that do not belong to an $f(\ell, p, |S \cup S'|)$-large equivalence class in $\sim$. For brevity, we will hereinafter use *large* as shorthand for $f(\ell, p, |S \cup S'|)$-large.

Let $\mathcal{L} = \{L_1, \cdots, L_{f(\ell,p,|S \cup S'|)}\}$. Our key idea is to identify three large groups $X, Y, Z \in \mathcal{L}$ with a special structure (a "guiding sublayout") in the solution $\langle \prec, \sigma \rangle$ using Ramsey theory. We will then use this pattern to insert the remaining parts of the graph. Before proceeding, we define some notations to be able to identify these groups, starting with a "template" R.

▶ **Definition 12.** *Let k be the number of large equivalence classes in $\sim$ and let $R_i \in \mathcal{C}$ be a canonical representative of the i^{th} large equivalence class $[R_i]$. Let $R := V(R_1) \uplus \cdots \uplus V(R_k)$.*

Recall that by Definition 8, if X is a large group then $G[X]$ is a disjoint union of exactly one graph from each large equivalence class of $\sim$. We now define a natural isomorphism from $G[X]$ to $G[R]$. This will allow us to map consistently between different large groups via R.

▶ **Definition 13.** *For a large group X with $G[X] = H_1 \uplus \cdots \uplus H_k$, $H_i \in [R_i]$ for each $i \in [k]$, let α_X be an isomorphism from $G[X]$ to $G[R] = R_1 \uplus \cdots \uplus R_k$ such that for each $i \in [k]$ and vertex $u \in H_i$, $\alpha_X(u) \in V(R_i)$, and for each $v \in S$, $uv \in E(G)$ if and only if $\alpha_X(u)v \in E(G)$.*

For any large group A and for each $u \in R$ we will sometimes use u_A as shorthand for $\alpha_A^{-1}(u)$. From now we fix two distinct large groups L and L' in $\mathcal{L}$. Further, for distinct large groups $X, Y \in \mathcal{L}$, we say $X \prec Y$ if in $\prec$, the first vertex in $X \cup Y$ is from X.

▶ **Definition 14.** *For $X \prec Y \in \mathcal{L} \setminus \{L, L'\}$, we define $\phi_{X,Y} : S \cup S' \cup X \cup Y \to S \cup S' \cup L \cup L'$*

- *$\phi_{X,Y}(s) = s$ for each $s \in S \cup S'$*
- *$\phi_{X,Y}(x) = \alpha_L^{-1}(\alpha_X(x))$ for each $x \in X$*
- *$\phi_{X,Y}(y) = \alpha_{L'}^{-1}(\alpha_Y(y))$ for each $y \in Y$*

Note that $\phi_{X,Y}$ is an isomorphism from $G[S \cup S' \cup X \cup Y]$ to $G[S \cup S' \cup L \cup L']$.

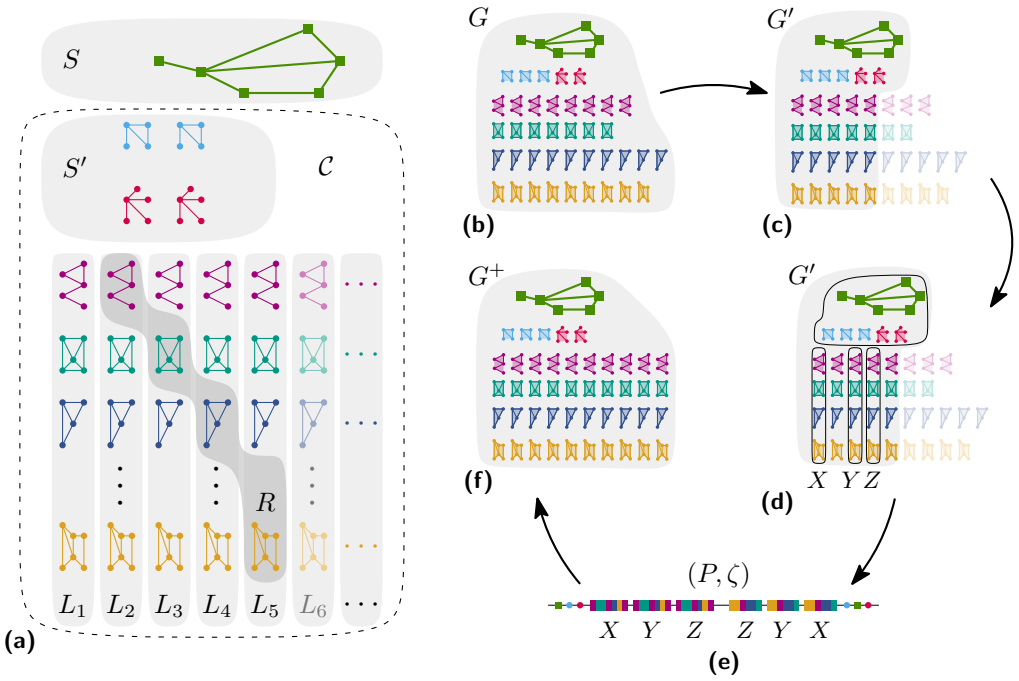

Figure 2 A schematized overview of **(a)** the used notation and **(b)**–**(f)** proof of Theorem 1. In the latter, G is the original input graph, G' the reduced graph obtained after applying Lemma 11, and $S \cup S' \cup X \cup Y \cup Z$ form the guiding sublayout that is used to construct an ℓ-page layout for a graph G^+ which is a supergraph of G – hence establishing that G' admits an ℓ-page stack (or queue) layout if and only if so does G.

▶ **Definition 15.** *For $X \prec Y \in \mathcal{L} \setminus \{L, L'\}$, $\mathit{info}_{\langle \prec, \sigma \rangle}(X, Y)$ is the stack (queue) layout of $G[S \cup S' \cup L \cup L']$ obtained from $\langle \prec_{G[S \cup S' \cup X \cup Y]}, \sigma_{G[S \cup S' \cup X \cup Y]} \rangle$ using the isomorphism $\phi_{X,Y}$.*

We are now ready to show the existence of three distinct large groups X, Y, Z with a useful consistent pattern between them and $S \cup S'$ based on info. Essentially, these three groups will form the aforementioned guiding sublayout used to argue the correctness of the pruning step, i.e., establish Lemma 10 by showing that we can reinsert all the removed vertices by building on $\langle \prec_{G[S \cup S' \cup X \cup Y \cup Z]}, \sigma_{G[S \cup S' \cup X \cup Y \cup Z]} \rangle$. Note that – perhaps counterintuitively – we will do so by discarding all other information about $\langle \prec, \sigma \rangle$. We refer to Figure 2 for an overview of the entire approach and to Figure 4 for a visualization of info.

▶ **Lemma 16.** *There exists distinct large groups $X, Y, Z \in \mathcal{L} \setminus \{L, L'\}$ with $X \prec Y \prec Z$ such that $\mathit{info}_{\langle \prec, \sigma \rangle}(X, Y) = \mathit{info}_{\langle \prec, \sigma \rangle}(Y, Z) = \mathit{info}_{\langle \prec, \sigma \rangle}(X, Z)$.*

Proof. Construct a complete edge colored auxiliary graph $\mathcal{H}$ with $V(\mathcal{H}) = \mathcal{L} \setminus \{L, L'\}$. For $X, Y \in \mathcal{L} \setminus \{L, L'\}$ with $X \prec Y$, we set $\mathit{color}((X, Y)) = \mathsf{info}_{\langle \prec, \sigma \rangle}(X, Y)$. Let $x := |S \cup S'|$.

▷ Claim 17 (★). The number of possible distinct edge colors of $\mathcal{H}$ is at most $2^{\ell \cdot x^2 \cdot 2^{9p^2}}$.

We now use a well-known fact (from Ramsey theory [2]) that any edge-colored clique on n vertices colored with t colors has a monochromatic clique of size at least $\log_t(n)/t$.

We have $|V(\mathcal{H})| = |\mathcal{L}| - 2 = f(\ell, p, x) - 2 \geq 2^{2^{\ell \cdot x^2 \cdot 2^{11p^2}}}$. Thus $n \geq 2^{2^{\ell \cdot x^2 \cdot 2^{11p^2}}}$ and $t \leq 2^{\ell \cdot x^2 \cdot 2^{9p^2}}$ and therefore there is a monochromatic clique of size at least $\log_t(n)/t \geq 2^{2^2} \geq 3$. A monochromatic clique of size 3 in $\mathcal{H}$ corresponds to distinct large groups $X, Y, Z \in \mathcal{L} \setminus \{L, L'\}$ with $X \prec Y \prec Z$ such that $\mathsf{info}_{\langle \prec, \sigma \rangle}(X, Y) = \mathsf{info}_{\langle \prec, \sigma \rangle}(Y, Z) = \mathsf{info}_{\langle \prec, \sigma \rangle}(X, Z)$. ◀

Let $X, Y, Z \in \mathcal{L}$ be three large groups witnessing the previous lemma. We now show that we can partition the vertices of X, Y, and Z in a nice way that will guide us on how to insert the remaining parts of the graph. Towards this, we first note that the $\mathsf{info}_{\langle \prec, \sigma \rangle}$ forces (1) edges incident to X, Y and Z to have the same page assignment, and moreover (2) forces the individual vertex orderings of $X \cup S \cup S'$, $Y \cup S \cup S'$, $Z \cup S \cup S'$ to be exactly the same as some ordering $\prec'$ of $R \cup S \cup S'$; see also the full version [14, Observations 18 and 19]. However, this does not yet fix how the vertices of X, Y and Z are ordered with respect to each other.

For the following, let us set $\Upsilon = S \cup S' \cup X \cup Y \cup Z$. Let a *block* be a consecutive subsequence of vertices from R w.r.t. $\prec'$, and a *solution-block* of $\langle \prec_{G[\Upsilon]}, \sigma_{G[\Upsilon]} \rangle$ be a consecutive subsequence of vertices from Υ; see also Figure 3.

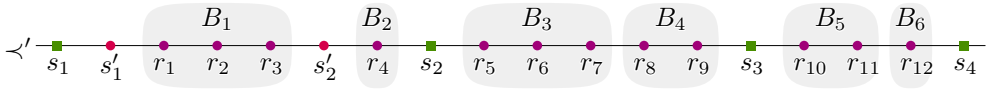

Figure 3 An ordering $\prec'$ of $R \cup S \cup S'$ and a partition of R into the blocks B_1 to B_6, indicated in gray. Note that vertices of $S \cup S'$, colored green and red, respectively, always separate two blocks. However, not every pair of blocks is separated by such a vertex, see, for example, blocks B_3 and B_4.

We are now ready to prove the structural result which provides strong guardrails on $\langle \prec_{G[\Upsilon]}, \sigma_{G[\Upsilon]} \rangle$; in particular, it guarantees that all vertices from X, Y and Z must occur in consecutive solution-blocks and following a strict "ascending" or "descending" order. We remark that this structural result is only made possible by the extraction of three copies of large groups via Lemma 16; see also Figure 4 for an illustration.

▶ **Lemma 18 (★).** *There exists a pair (P, ζ), where P is a partitioning of R into blocks and $\zeta \colon P \to \{\nearrow, \searrow\}$ satisfying the following. For every block $B \in P$ with $\zeta(B) = \nearrow$, the sequence $\alpha_X^{-1}(B)\alpha_Y^{-1}(B)\alpha_Z^{-1}(B)$ is a solution-block of $\langle \prec_{G[\Upsilon]}, \sigma_{G[\Upsilon]} \rangle$. Moreover, for every block $B \in P$ with $\zeta(B) = \searrow$, the sequence $\alpha_Z^{-1}(B)\alpha_Y^{-1}(B)\alpha_X^{-1}(B)$ is a solution-block of $\langle \prec_{G[\Upsilon]}, \sigma_{G[\Upsilon]} \rangle$.*

Crucially, we can now use Lemma 18 to safely insert an arbitrary number of large groups into $G[\Upsilon]$ without increasing the number of required pages.

▶ **Lemma 19 (★).** *Let G^+ be the supergraph of G with each large equivalence class having equal size, then G^+ has an ℓ-page stack (queue) layout.*

Proof sketch. Let $t \geq 3$ be the maximum size of a large equivalence class of $\sim$. Note that G^+ can be expressed as $G^+ = G^+[S \cup S' \cup X_1 \cup \cdots \cup X_t]$ where each $X_i, i \in [t]$ is a large group. We construct a stack (or queue, as desired) layout $\langle \prec^+, \sigma^+ \rangle$ of G^+ as follows.

Construction of σ^+. For each edge $(u, v) \in G^+$,

- If $u, v \in S \cup S'$, we set $\sigma^+(u, v) := \sigma(u, v)$.
- If $u \in X_i$ for some $i \in [t]$ and $v \in S$, we set $\sigma^+(u, v) := \sigma(r_Y, v)$ where $r = \alpha_{X_i}(u)$.
- If $u, v \in X_i$ for some $i \in [t]$, we set $\sigma^+(u, v) := \sigma(r_Y, r'_Y)$ where $r = \alpha_{X_i}(u)$, $r' = \alpha_{X_i}(v)$.

Construction of $\prec^+$. In $\prec'$, replace each block $B \in P$ with $\alpha_{X_1}^{-1}(B)\alpha_{X_2}^{-1}(B) \cdots \alpha_{X_t}^{-1}(B)$ if $\zeta(B) = \nearrow$ and with $\alpha_{X_t}^{-1}(B)\alpha_{X_{t-1}}^{-1}(B) \cdots \alpha_{X_1}^{-1}(B)$ if $\zeta(B) = \searrow$.

To show that $\langle \prec^+, \sigma^+ \rangle$ is indeed an ℓ-page stack (queue) layout of G^+, we show that any conflict in $\langle \prec^+, \sigma^+ \rangle$ would also imply a conflict in $\langle \prec_{G[\Upsilon]}, \sigma_{G[\Upsilon]} \rangle$ in the full proof [14]. ◀

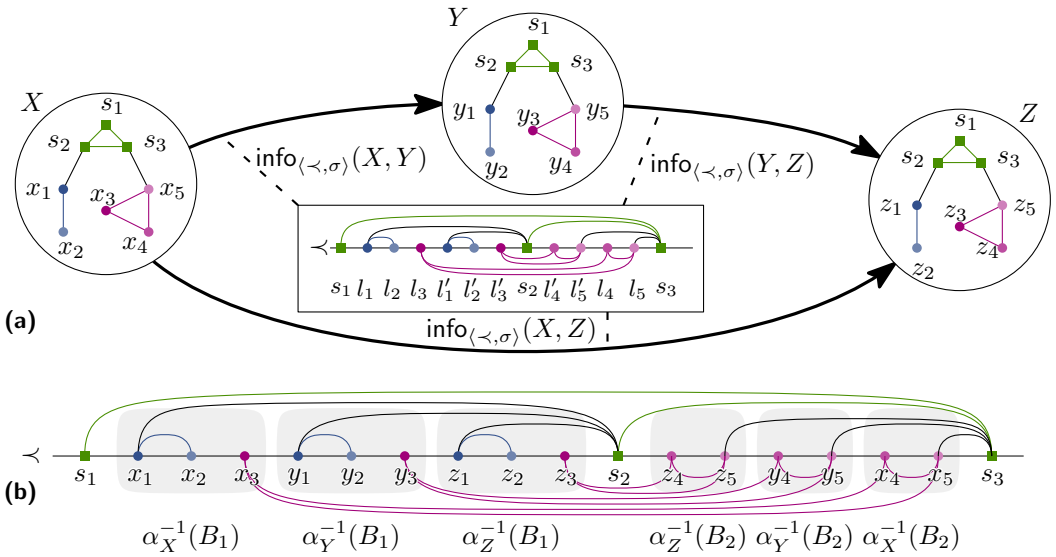

Figure 4 (a) The three large groups $X \prec Y \prec Z \in \mathcal{L} \setminus \{L, L'\}$ form a monochromatic clique in the auxiliary graph $\mathcal{H}$, i.e., we have $\mathsf{info}(X,Y) = \mathsf{info}(Y,Z) = \mathsf{info}(X,Z)$. The tuple (P,ζ), where P partitions R into two blocks $B_1 = \{r_1, r_2, r_3\}$ and $B_2 = \{r_4, r_5\}$ with $\zeta(B_1) = \nearrow$ and $\zeta(B_2) = \searrow$ fulfills the properties from Lemma 18. As X, Y, Z form a monochromatic clique, the solution blocks from **(b)** must occur in $\langle \prec_{G[\Upsilon]}, \sigma_{G[\Upsilon]} \rangle$.

4 An XP-Algorithm For Bounded-Width Linear Layouts

In this section, we present an algorithm to decide if a given graph G has a stack (or queue) layout on ℓ pages and with page width q, i.e., an ℓ-page q-width linear layout, in $n^{\mathcal{O}(q\cdot\ell)}$ time. In the affirmative case, it can also output such a layout. Since only little adaption is required between stack and queue layouts, we only discuss problem specific changes where necessary. We will first give an intuitive overview over our approach and the core ideas to showing its correctness, details can be found in Sections 4.1 and 4.2 and the full version.

Bounded-size Interfaces. Observe that, for each vertex $v \in V$ in a stack (or queue) layout $\langle \prec, \sigma \rangle$ of G, the edges $X_v^{\prec}$ that span the spine right next to v, induce the cut $(\mathrm{Left}_v^{\prec} \cup \{v\}, \mathrm{Right}_v^{\prec})$ in G; see Figure 5a. The size of the cut-set $F = X_v^{\prec}$ only depends on the number of the pages and their width. Our algorithm is centered around the insight that, through limiting these parameters and thus the size of any such cut, we limit the size of the "interface" (a notion we will define more precisely in a second) between a drawing on its left side and a drawing on its right side (Lemma 22). We note that this insight parallels to the approach used by Saxe [42] to test if a graph has bandwidth at most k. In our setting, replacing the left side of such cut in any solution drawing with one that provides the same interface will yield another solution. This is because having the same interface will imply inducing the same decompositions into left and right vertices (Lemma 24), the statement then follows by simply gluing the two drawings together along the cut.

Our bounded-size interface consists of the set of edges F that intersect the cut right next to v, their vertical order along the cut, and the information which edge endpoint lies on which side of the cut, together with a page assignment for the edges in F. We will encapsulate this information in what we call a (nicely) *oriented cut-set*; see Definition 21.

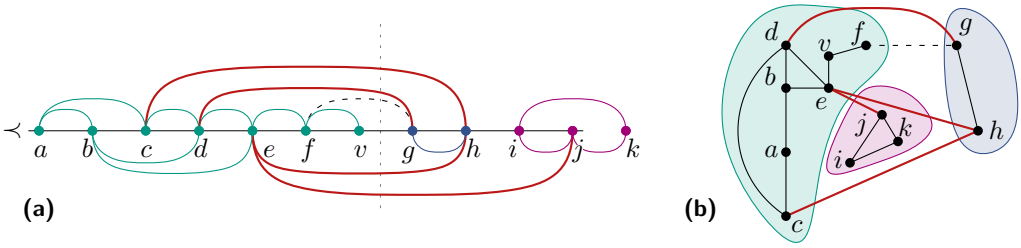

Figure 5 The two-page width-five stack layout in **(a)** induces the cut-set $F = X_v^{\prec}$ indicated with the red edges. **(b)** The three connected components in $G \setminus F$ are indicated with color. Observe that $(F, c \prec d \prec e \prec g \prec h \prec j)$ is nicely oriented. The source e and sink g cannot be in the same connected component, as every path between them contains at least one edge of F; e.g., the edge fg cannot exist.

Our Dynamic Programming Solution. Given only an arbitrary oriented cut-set F for an instance G, we are able to infer which connected components and thus which vertices of the graph lie on the left (or also right) side of the cut (Lemma 23; see also Figure 5b). This now allows us to solve this problem via dynamic programming. We build a directed acyclic state graph where each state corresponds to one configuration of our interface, i.e. one (nicely) oriented cut-set together with a page assignment for its edges (formalized as $\mathcal{N}$C 1 and 2 in the full version [14]). We add an arc between two states if we can move from one oriented cut-set to the other by moving exactly one vertex (which we inferred to be on the right side via Lemma 23) to the (end of a linear order used on the) left without directly violating a necessary stack or queue layout property (i.e., no crossing or nesting of edges) with regard to only the edges in the current cut-set; the exact conditions are again formalized as $\mathcal{A}$C 1–4 in the full version [14]. In Lemma 25, we will show that this means that we can extend any partial solution represented by the current state with the further vertex when moving along such an arc to obtain a solution for the new state. Then, we have a yes-instance if and only if there exists a directed path between the (artificially-distinguished) empty beginning and end states. As finding such path takes linear time, Theorem 2 then follows from the insight that the state graph has a size bounded by $n^{\mathcal{O}(q \cdot \ell)}$ and can be computed in this time.

4.1 Decomposing Linear Layouts Using Oriented Cut-Sets

As already hinted above, our algorithm uses at its core cut-sets of G to compute the desired stack (or queue) layout $\langle \prec_G, \sigma_G \rangle$. Before we discuss their usage in detail, let us first take a closer look at them and define their desired properties.

▶ **Observation 20.** *Given a connected graph G and a cut-set $F \subseteq E$ that separates the graph into $k \geq 2$ connected components $C_1, \ldots, C_k$. For all $i \in [k]$, component C_i contains at least one vertex that is an endpoint of an edge in F.*

We consider in addition to a cut-set F a total order $\prec_F$ on the endpoints of its edges and call this the *oriented cut-set*, denoted as $(F, \prec_F)$. While a single cut-set F has $\mathcal{O}((2\,|F|)!)$ different oriented cut-sets, we are only interested in "nicely oriented" cut-sets. Let F be a cut-set and $\prec_F$ a linear order on the endpoints of edges in F. A vertex $v \in V(F)$ is a *source* (or *sink*) in $(F, \prec_F)$ if for every edge $uv \in F$ we have $v \prec_F u$ ($u \prec_F v$, respectively).

▶ **Definition 21.** *For a cut-set F, $(F, \prec_F)$ is* nicely oriented *if and only if each vertex $v \in V(F)$ is either a source or sink, each connected component of $G - F$ contains either only sources or only sinks, and all sources are left of every sink in $\prec_F$.*

To ease presentation, we use a slight abuse of notation and allow the linear order $\prec_F$ of an oriented cut-set $(F, \prec_F)$ to be a total order of a super-set of $V(F)$. We consider $(F, \prec)$ and $(F, \prec')$ identical if $\prec$ and $\prec'$ agree on $V(F)$. We now establish a crucial connection between linear layouts and nicely oriented cut-sets of G; see also Figure 5.

▶ **Lemma 22 (★).** *Let G be a graph and $\langle \prec, \sigma \rangle$ be an ℓ-page q-width linear layout of G. For every vertex $v \in V$ that is not the rightmost in $\prec$, the edges $X_v^{\prec}$ form a cut-set of size at most $q \cdot \ell$ that induces the cut $(Left_v^{\prec} \cup \{v\}, Right_v^{\prec})$ in G. Furthermore, $(X_v^{\prec}, \prec)$ is nicely oriented.*

A liner order $\prec$ *induces* an oriented cut-set $(F, \prec')$ if there exists a vertex v that witnesses $(X_v^{\prec}, \prec) = (F, \prec')$. Note that the same oriented cut-set can be induced by different linear orders. From Lemma 22, we can deduce that all cuts (A, B) of an ℓ-page q-width stack (and queue) layout of G can be constructed using at most $\binom{m}{\ell \cdot \omega} = \mathcal{O}(m^{\ell \cdot \omega})$ different cut-sets. We aim to use their oriented counterparts to obtain the spine order $\prec$ of the desired stack (or queue) layout. We next show that we can efficiently compute for a given oriented cut-set $(F, \prec_F)$ a witnessing linear order that induces $(F, \prec_F)$.

▶ **Lemma 23 (★).** *Given a graph G and a nicely oriented cut-set $(F, \prec_F)$ of G, we can compute a linear order $\prec$ of V that induces $(F, \prec_F)$ in $\mathcal{O}(n + m)$ time.*

Lemma 23 only shows that we can compute *some* linear order $\prec$ of V that induces $(F, \prec_F)$. However, to efficiently use oriented cut-sets in our state graph, we must be able to precisely determine which vertices have already been placed on the spine without storing them explicitly. The following lemma lays the foundation for this, as it shows that no matter which linear order $\prec$ we choose to induce an oriented cut-set $(F, \prec_F)$, we obtain the same partition into left and right vertices.

▶ **Lemma 24 (★).** *Let $(F, \prec_F)$ be a nicely oriented cut-set. Furthermore, let $\prec$ and $\prec'$ be two linear orders such that $(X_v^{\prec}, \prec) = (X_u^{\prec'}, \prec') = (F, \prec_F)$ for some $u, v \in V$, i.e., they induce $(F, \prec_F)$. Then we have $Left_v^{\prec} \cup \{v\} = Left_u^{\prec'} \cup \{u\}$.*

4.2 Using Nicely Oriented Cut-Sets to Show Theorem 2

The state graph H contains a node for each possible nicely-oriented cut-set of G, together with the corresponding page assignment. The arcs in H represent possible transitions from one nicely oriented cut-set to another that can occur when traversing a hypothetical solution from left to right (see Figure 6), i.e., that are obtained by moving exactly one vertex from the right to the left. A state $S = (F, \prec_{F_X}, \sigma_{F_X})$ is *feasible* if and only if there exists an ℓ-page q-width stack layout $\langle \prec_S, \sigma_S \rangle$ of $G[L(S) \cup V(F)]$ such that for all $u, v \in V(F)$ we have $u \prec_F v \Leftrightarrow u \prec_S v$ and $\sigma_F = \sigma_S|_F$. For queue layouts, the definition is analogous. In the full version, we show that, essentially, having arcs only between state pairs where both induce valid stack (or queue) layouts on their respective cut-sets is enough to preserve feasibilty along arcs.

▶ **Lemma 25 (★).** *Let $H = (N, A)$ be a state graph and $S_X S_Y \in A$ one of its arcs. If S_X is feasible for stack (queue) layouts then so is S_Y.*

We now have all tools at hand to present our algorithm. Since the arcs of H preserve existence of a (partial) ℓ-page q-width stack (or queue) layout of G, we have reduced the problem of finding such a layout to the problem of finding a path in H between the two special nodes $S_\emptyset$ and S_V. In the full version, we show that H can be computed in polynomial time and use this to summarize the main result of this section in the following theorem.

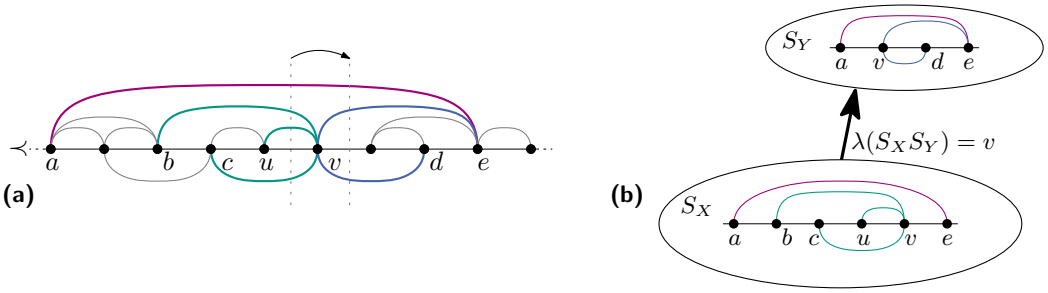

Figure 6 (a) Parts of a stack layout of G with the two cut-sets $X_u^{\prec}$ and $X_v^{\prec}$. **(b)** The corresponding nodes in the state graph. The arc in (b) corresponds to the transition from $X_u^{\prec}$ to $X_v^{\prec}$ in (a). Edges appearing in at least one cut-set are colored.

▶ **Theorem 2 (★).** *Given integers ℓ and q along with an n-vertex graph G, we can compute an ℓ-page stack or queue layout with page width at most q of G (if one exists) in time $n^{\mathcal{O}(q \cdot \ell)}$.*

The algorithm from Theorem 2 runs in polynomial time for constant ℓ and q. Furthermore, recall that deciding if a graph has a 2-page stack layout or 1-page queue layout is NP-complete [34, 46]. An ℓ-page 1-width stack or queue layout witnesses that G has cutwidth at most ℓ, which is in general NP-complete to decide [28]. This means that under well-established complexity assumptions, it is not possible to preserve XP-tractability if either of the two parameters is dropped.

5 Single-Exponential Algorithm for 1-Page Queue Layouts

In this section, we show that we can find a one-page queue layout, if it exists, in $2^{\mathcal{O}(n)}$ time, which improves on the trivial algorithm that exhaustively considers all $n!$ possible spine orders. Our algorithm exploits the equivalence between one-page queue layouts and arched leveled planar embeddings established by Heath and Rosenberg [34]. We first show that we can reduce the problem of deciding whether a graph admits a one-page queue layout to deciding whether at least one of $2^{\mathcal{O}(n)}$ *labeled* instances of Arched Leveled Planarity admits a solution. While Arched Leveled Planarity is NP-complete [34], our labeled instances can be solved in linear time thanks to a reduction to the well-studied problem Level Planarity [35, 36]. We will assume that G is connected (as each component can be treated separated) and, as G must be planar [34], we assume $|E| = \mathcal{O}(n)$.

We translate the definition of Heath and Rosenberg [34] into moderns terms as follows. Graph G has a *leveled planar embedding* if there exists a *level assignment* function $\gamma \colon V \to [h]$ that maps each $v \in V$ to one of $h \geq 1$ *levels*, and a straight-line planar drawing Γ of G such that each vertex v has y-coordinate $\gamma(v)$ and all edges are *proper*, i.e., for all $uv \in E$ we have $|\gamma(u) - \gamma(v)| = 1$. The latter property allows us to express the drawing as a collection of total orders $\prec_i$, one for each level $i \in [h]$, that specifies the left-to-right order of the vertices on level i [36]. For each level i, let s_i be the rightmost vertex on level i in Γ such that we have $s_i w \in E$ for some $w \in V$ with $\gamma(w) = i+1$, or if there is no such vertex, let s_i be the leftmost vertex on level i. *Arched leveled planar embeddings* extend leveled planar embeddings by also allowing non-monotone *arching* edges $t_i w$ between the leftmost vertex t_i on level i and vertices $w \in V$ with $\gamma(w) = i$ and $s_i \preceq_i w$ [34]. These edges can be drawn crossing-free below the lowest level; see Figure 7b. The problem Arched Leveled Planarity asks whether G has a level assignment that admits an arched leveled planar embedding. Heath

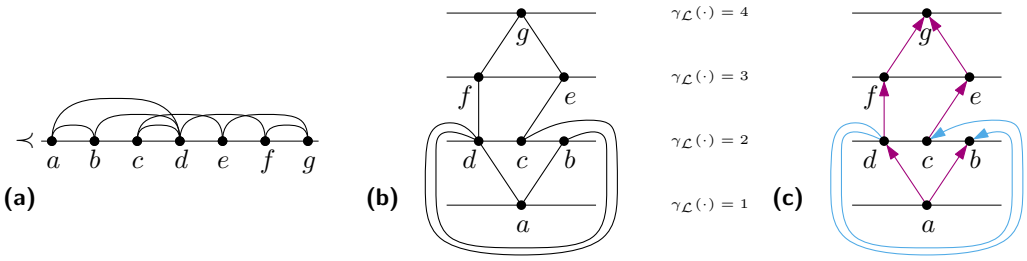

Figure 7 (a) A one-page queue layout of G and **(b)** the corresponding arched leveled planar embedding obtained by the equivalence established by Heath and Rosenberg [34]. **(c)** The labeling induced by the embedding from **(b)**: Arcs labeled $\uparrow$ and $\smile$ are colored lilac and blue, respectively.

and Rosenberg [34] showed that the spine order of a one-page queue layout of a graph G induces a level assignment together with a vertex order on each level that together yield an arched leveled planar embedding of G and vice versa; see Figure 7.

We show that, when seeking a one-page queue layout of G, one can branch over the information needed to infer the level assignment for a corresponding arched leveled planar embedding. Consider an arbitrary orientation of the edge set E as an oriented arc set A and let $\delta\colon A \to \{\uparrow, \smile\}$ be a function that determines if an arc $uv \in A$ should be *ordinary* ($\uparrow$) or *arching* ($\smile$). The tuple $\mathcal{L} = (A, \delta)$ is called a *labeling* of G; see also Figure 7c. A level assignment γ is said to be *consistent* with $\mathcal{L}$ if and only if, for every $uv \in A$, it holds $\gamma(u) = \gamma(v) - 1$ if $\delta(uv) = \uparrow$ and $\gamma(u) = \gamma(v)$ if $\delta(uv) = \smile$. Similarly, an embedding Γ is consistent with $\mathcal{L}$ if its level assignment is consistent and we have $u \prec_{\gamma(u)} v$ for every $uv \in \delta^{-1}(\smile)$. Clearly, every arched leveled planar embedding Γ of G induces a labeling $(A_\Gamma, \delta_\Gamma)$ that is consistent with Γ. Conversely, we can reobtain Γ from this $(A_\Gamma, \delta_\Gamma)$ by fixing an arbitrary vertex to level 0, performing a BFS from v using the direction information in A_Γ to determine levels for all other vertices above and below, and potentially shifting all assigned levels such that their numbers span the same range as those in Γ. This is formalized by the following lemma.

▶ **Lemma 26 (★).** *Let $\mathcal{L} = (A, \delta)$ be a labeling of G. In linear time we can compute a level assignment $\gamma_{\mathcal{L}}\colon V \to [h]$ that is consistent with the labeling or report that no such assignment exists. If there exists an arched leveled planar embedding Γ that induces $\mathcal{L}$, then there also exists one that induces $\mathcal{L}$ and uses the level assignment $\gamma_{\mathcal{L}}$.*

To now decide if a given graph G has an arched leveled planar embedding Γ, we can branch over all $\mathcal{O}(4^n) = 2^{\mathcal{O}(n)}$ different labelings $\mathcal{L} = (A, \delta)$ of G. In each branch, we use Lemma 26 to compute a level assignment $\gamma_{\mathcal{L}}$ or immediately reject the branch. Thus, it remains to check in each branch, i.e., for each level assignment, if G admits a corresponding arched leveled planar embedding. We do so using a linear-time reduction to the problem Level Planarity, which requires a level assignment as part of its input but does not allow arching edges. We emulate arching edges in Level Planarity as follows (see also Figure 8). First, we enclose the whole graph in a *frame*, which is a cycle spanning from below its lowest level to above its highest that will have a unique embedding (up to reflection) and for which we ensure that the remaining graph is drawn inside of it. Between each pair of levels $i, i+1$, we add a level $i + 0.5$ and subdivide all edges to ensure properness. We use l_i and r_i to refer to the two vertices of the frame cycle that are on level $i + 0.5$. Replace each arching arc $uv \in A$ with $\delta(uv) = \smile$ on level i with the edges ul_{i-1}, ul_i, and vr_i to G'; see Figure 8. Observe that this forces u to become the leftmost vertex on level i and v to be right of any

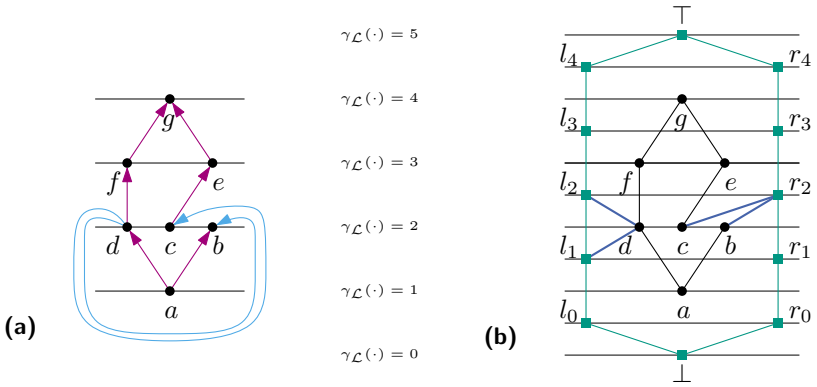

Figure 8 (a) An instance of Labeled Arched Level Planarity and **(b)** the obtained instance of Level Planarity. We also visualize a drawing and color the frame and edges that simulate the arching edges from **(a)** in green and blue, respectively. Only relevant subdivision vertices are shown.

vertex adjacent to one on level $i+1$. We provide a formal construction and show equivalence in the full version [14]. Using the known algorithm for testing Level Planarity in linear time [35, 36], we finally obtain our third contribution.

▶ **Theorem 3 (★).** *Given an n-vertex graph G, we can compute a 1-page queue layout of G (if one exists) in time $2^{\mathcal{O}(n)}$.*

6 Concluding Remarks

While our results improve the state of the art on computing linear layouts in several directions, they also highlight the prominent open questions in this area. In particular, Theorem 1 moves us closer to settling the long-standing open questions of whether treewidth or treedepth can be used to facilitate the computation of linear layouts [7, 8, 21, 25, 26]. At the same time, Theorems 2 and 3 yield the question of whether these classical problems can be solved in single-exponential time.

Abstract

$\mathcal{F}$-branchwidth is a framework for width measures of graphs, recently introduced by Eiben et al. [ITCS 2022], that captures tree-width, co-tree-width, clique-width, and mim-width, and several of their generalizations and interpolations. In this work, we search for algorithmic applications of $\mathcal{F}$-branchwidth measures that do not have an equivalent counterpart in the literature so far. Our first contribution is a minimal set of eleven $\mathcal{F}$-branchwidth measures such that each of the infinitely many $\mathcal{F}$-branchwidth measures is equivalent to one of the eleven. We observe that for the FO Model Checking problem, each $\mathcal{F}$-branchwidth is either equivalent to clique-width (and therefore has an FPT-algorithm by formula length plus the width) or the problem remains as hard as on general graphs even on graphs of constant width. Next, we study the number of equivalence classes of the neighborhood equivalence in a decomposition, which upper bounds the run time of the model checking algorithm for A&C DN logic recently introduced by Bergougnoux et al. [SODA 2023]. We give structural lower bounds that show that for each $\mathcal{F}$-branchwidth, an efficient model checking algorithm was already known or cannot be obtained via this method. Lastly, we classify the complexity of Independent Set parameterized by any $\mathcal{F}$-branchwidth except for one open case. Also here, our contributions are lower bounds. In this context, we also prove that Independent Set on graphs of mim-width w cannot be solved in time $n^{o(w)}$ unless the Exponential Time Hypothesis fails, answering an open question in the literature.

1 Introduction

Eiben et al. [12] recently introduced *$\mathcal{F}$-branchwidth*, a framework of graph width measures that allows for an infinite number of instantiations. Among them are width measures that are asymptotically equivalent to treewidth, clique-width, and mim-width. These three have wide algorithmic applications which immediately begs the following question:

Are there any *unknown* $\mathcal{F}$-branchwidth measures that have interesting algorithmic applications?

The goal of this paper is to address this question – to which we provide negative answers in several contexts.

For a family of bipartite graphs $\mathcal{F}$, the $\mathcal{F}$-branchwidth of a graph G bounds the size of any member of $\mathcal{F}$ that appears as a semi-induced subgraph in a recursive partitioning of the vertex set of G. Therefore, any family of bipartite graphs $\mathcal{F}$ gives rise to a new $\mathcal{F}$-branchwidth measure. To avoid chaotic definitions, some technical restrictions are imposed on $\mathcal{F}$, but there is still an infinite number of families $\mathcal{F}$ satisfying them. However, as already observed in [12], there is a finite number of classes of $\mathcal{F}$-branchwidth measures that are bounded on different families of graphs. This means that we can restrict the search for new algorithmically useful width measures to the representatives of these classes. These are obtained as any combination of the six families shown in Figure 1.

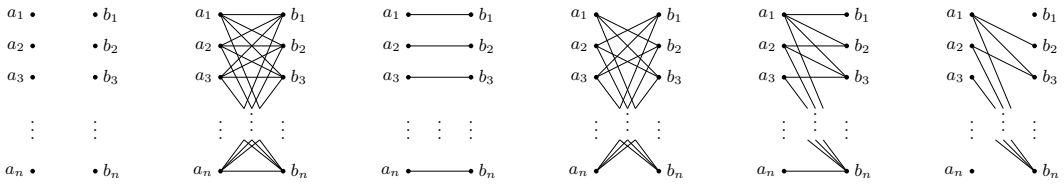

Figure 1 The six canonical families usable as building blocks for $\mathcal{F}$-branchwidth. From left to right: edgeless (⁝ ⁝), complete (⨉), matchings (=), antimatchings (⋈), chains (⧅), and skewed chains (⧅).

This brings down the number of cases to consider from infinite to constant, if one wants to determine the complexity of a problem parameterized by *any* of the possible $\mathcal{F}$-branchwidth measures. However, a priori there are still 2^6 cases to consider. Our first contribution is to provide a family of eleven $\mathcal{F}$-branchwidth, called *The Eleven*, that captures the modeling power of every possible $\mathcal{F}$-branchwidth in the following sense. For an illustration see Figure 2.

▶ **Theorem 1.** *For each $\mathcal{F}$-branchwidth, one of the following holds.*

(i) *There is a computable function f such that for each graph G with $\mathcal{F}$-$\mathsf{bw}(G) \leq k$, $|V(G)| \leq f(k)$.*

(ii) *$\mathcal{F}$-branchwidth is asymptotically equivalent to $\mathcal{F}^*$-branchwidth, where $\mathcal{F}^*$ is one of the Eleven branchwidths (presented in Figure 2 and formally defined in Table 1).*

We provide families of obstructions to bounded width that show that the classification in Theorem 1 is in fact minimal, in the sense that no pair of width measures can be asymptotically equivalent to each other.

▶ **Theorem 2.** *For each pair of distinct $\mathcal{F}_1, \mathcal{F}_2 \in \mathfrak{F}$ there is some $i \in [2]$ such that there is a graph class of bounded $\mathcal{F}_i$-width but unbounded $\mathcal{F}_{3-i}$-width.*

Throughout the following, we refer to the $\mathcal{F}$-branchwidth measures based on the families in $\mathfrak{F}$ as the *canonical* ones. Notice that the second item of Theorem 1 says that $\mathcal{F}$-branchwidth and $\mathcal{F}^*$-branchwidth are bounded on the same graph classes, but the exact bounds may differ. Theorem 1, along with the hierarchy among the eleven relevant width measures, allows us to determine the complexity of a problem parameterized by any $\mathcal{F}$-branchwidth by considering these cases alone.

A common way to classify the algorithmic power of a width measure is to determine for which logic L, the L-Model Checking problem can be solved efficiently whenever the input graph is given together with a decomposition of constant width. For instance, an

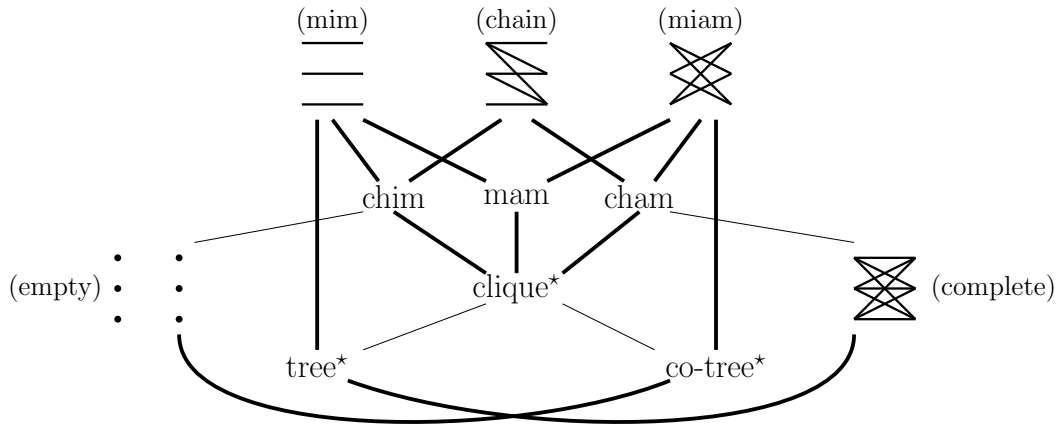

Figure 2 The Eleven canonical $\mathcal{F}$-branchwidth measures, ordered according to expressive power from top (high) to bottom (low). The five base cases show the singleton classes, and bold edges show combinations. For instance, chim-width is ($\equiv \cup \lessapprox$)-branchwidth, clique*-width is ($\equiv \cup \lessapprox \cup \approx$)-branchwidth, and tree*-width is ($\equiv \cup \approx$)-branchwidth. The remaining edges show some relationships given by the structures of the families. As one may expect, tree*-width is asymptotically equivalent to tree-width, clique*-width is asymptotically equivalent to clique-width, and co-tree*-width is asymptotically equivalent to co-tree-width.

L-formula ϕ may express that a graph has an independent set of size k. Then, the evaluation of ϕ at a graph G is true, in symbols $G \models \phi$ (read: "G models ϕ"), if and only if G has an independent set of size k. Typically, one aims for efficient parameterized algorithms in the parameterization formula length plus width.

L-Model Checking parameterized by $|\phi| + w$

Input:	Graph G given together with a decomposition of width w, L-formula ϕ.
Question:	Does $G \models \phi$?

Classical examples of such meta-theorems are Courcelle's Theorem [8] which gives an FPT-algorithm when L is MSO_2 logic and the width is tree-width and its extension to the more general clique-width while restricting the logic to MSO_1 [9]. More recent examples include an FPT-algorithm for FO logic and twin-width [6], and an XP-algorithm for A&C DN logic and mim-width [3]. The following hierarchy holds for the first three logics: $\mathsf{FO} \subsetneq \mathsf{MSO}_1 \subsetneq \mathsf{MSO}_2$.

We consider the Model Checking problem for any of these logics parameterized by any of the $\mathcal{F}$-branchwidth measures. Our first result is that for MSO/FO, we cannot expect any new tractability islands via $\mathcal{F}$-branchwidth, so in fact, our current understanding of the complexity of MSO/FO Model Checking is tight for any $\mathcal{F}$-branchwidth. We illustrate the following theorem for the canonical $\mathcal{F}$-branchwidth measures in Figure 3.

▶ **Theorem 3.** *For each $\mathcal{F}$-branchwidth, one of the following holds.*

1. *There is a computable function f such that each graph of $\mathcal{F}$-branchwidth k has clique-width at most $f(k)$, implying that* FO *Model Checking is* FPT *parameterized by formula length plus k.*
2. *There is a constant c such that* FO *Model Checking parameterized by formula length is* AW[$*$]*-hard even when the input graph is given with one of its decompositions of $\mathcal{F}$-branchwidth c.*

Next, we move on to A&C DN logic which was recently introduced by Bergougnoux et al. [3] as a logic to capture the problems that are solvable in XP time parameterized by the mim-width of a given decomposition of the input graph. This logic is a good target to study under the lens of $\mathcal{F}$-branchwidth. It is the right fit for mim-width which is Ξ-branchwidth where Ξ is the family of matchings – one of the base families of $\mathcal{F}$-branchwidth. A&C DN logic is essentially[1] based on existential MSO_1 and a *neighborhood operator* which, for a given set variable X, returns the set $\bigcup_{v \in X} N(v)$, and predicates checking acyclicity and connectivity. The runtime of the algorithm for A&C DN Model Checking is bounded by the index of the *neighborhood equivalence relation* (nec), first studied by Bui-Xuan et al. [7].To get efficient algorithms, it therefore suffices to show, for graphs of width k, that the index of the neighborhood equivalence grows relatively slowly in terms of n and k. For instance, a bound of $f(k) \cdot n^{\mathcal{O}(1)}$ implies an $f(k) \cdot n^{\mathcal{O}(1)}$ time algorithm for A&C DN Model Checking, while a bound of $n^{g(k)}$ implies an $n^{\mathcal{O}(g(k))}$ time algorithm, using the meta-theorem of [3].

Several such bounds on the index of this equivalence relation are already known in the literature. First, mim-width k implies that there are at most n^k equivalence classes [2]. Furthermore, there are bounds of the form $2^{\mathcal{O}(k)}$ when k is either the tree-width, clique-width, or co-tree-width (see, for instance, [3]). Next, we cannot hope to obtain any meaningful bound for any $\mathcal{F}$-branchwidth that generalizes complete-width. When a cut consists of matching with n vertices on each side, the complete-width is just 1, while the number of neighborhoods across the cut is 2^n. Indeed, for each subset of vertices contained in one side of the cut, there is a different subset across the cut whose neighborhood is exactly that subset.

The cases that remain are the ones asymptotically equivalent to empty-width, chim-width, and mam-width. As mim-width generalizes all of them, we immediately have XP-algorithms parameterized by each of them. Also here, we provide a number of negative results. For chim-width and mam-width, not much improvement can be made over the bound given by mim-width. We show that there are graphs of chim-width (or mam-width) k such that each of their decompositions induces a cut with at least $(n/(k^2 \log n))^{\Omega(k)}$ neighborhoods. By a probabilistic argument, we show that there are graphs whose decompositions have cuts of empty-width k that have $n^{\Omega(k)}$ neighborhoods. We conclude that the technology from [3] cannot be applied directly to any $\mathcal{F}$-branchwidth measure to extend the range of tractability of A&C DN Model Checking, see Figure 3 for an illustration.

▶ **Theorem 4.** *For each $\mathcal{F}$-branchwidth, one of the following holds.*

1. *There is a computable function f such that each graph of $\mathcal{F}$-branchwidth k has clique-width at most $f(k)$, implying that* A&C DN *Model Checking is* FPT *parameterized by formula length plus the width of a given decomposition of the input graph.*
2. *Each graph of $\mathcal{F}$-branchwidth k has mim-width at most k, implying that* A&C DN *Model Checking is* XP *parameterized by formula length plus the width of a given decomposition of the input graph. On the other hand, there are cuts of $\mathcal{F}$-branchwidth k with $n^{\Omega(k)}$ neighborhood equivalence classes.*
3. *There is a computable function f such that each graph of complete-width at most k has $\mathcal{F}$-branchwidth at most $f(k)$, implying that there are cuts on n vertices of constant $\mathcal{F}$-branchwidth with $2^{\Omega(n)}$ neighborhood equivalence classes.*

[1] The neighborhood operator in [3] is somewhat more general, but for the sake of this introduction it suffices to think of simple neighborhoods.

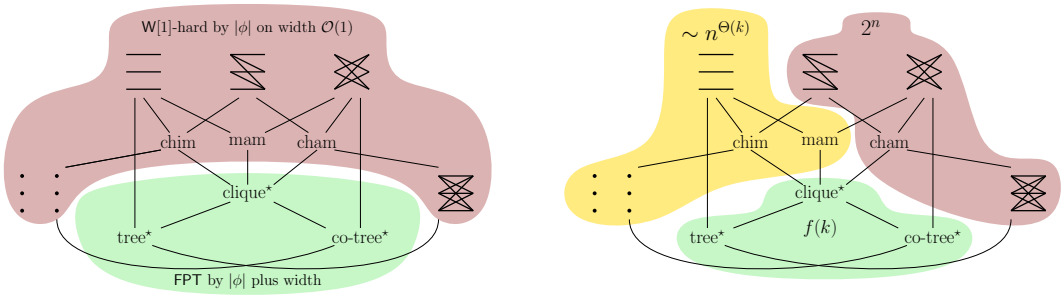

Figure 3 Results about the complexity of model checking problems on graphs of bounded $\mathcal{F}$-branchwidth. Left: Complexity of FO Model Checking. Right: Number of neighborhoods in cuts of bounded width.

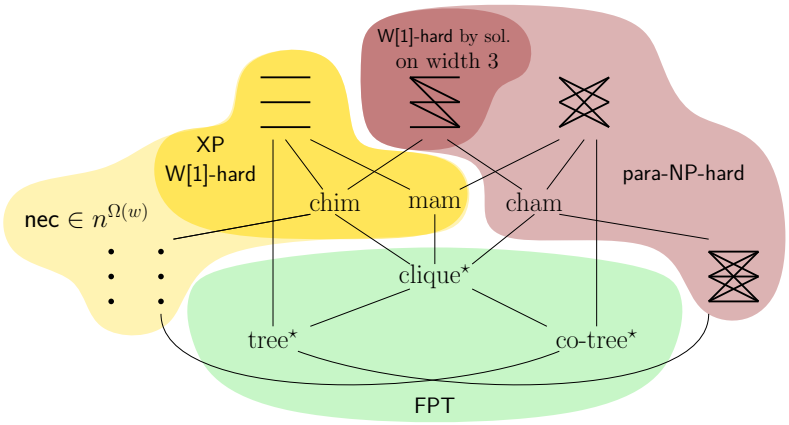

Figure 4 The complexity of Independent Set parameterized by any $\mathcal{F}$-branchwidth measure. Note that the complexity of Independent Set parameterized by empty-width is still open, but the XP lower bound on the number of equivalence classes in the neighborhood equivalence implies that known techniques are not applicable to show fixed-parameter tractability in this case. Moreover, it is worth looking into the complexity of IS parameterized by solution size on graphs of constant miam-width, cham-width, or complete-width.

For the canonical $\mathcal{F}$-branchwidth measures, we also take a more fine-grained look at the index of the neighborhood equivalence. The upper bounds on the number of equivalence classes in terms of clique*-width and tree*-width follow from known bounds [3] together with Ramsey-theory based arguments from [12]. This results in upper bounds that are double-exponential in the width k, i.e., bounds of the form $2^{2^{\mathsf{poly}(k)}}$. For tree*-width and co-tree*-width k, we give improved, single-exponential, bounds of $2^{\mathcal{O}(k^3 \log k)}$ each, and a lower bound of $2^{\Omega(k \log k)}$ for tree*-width k.

For the lower bound statements of Theorem 4, observe two things. First, for chim-width and mam-width, the bounds in fact hold for *any* decomposition of graphs within a family we construct. Second, lower bounds on the number of equivalence classes of the neighborhood equivalence only rule out direct applications of the meta-theorem from [3], and are not hardness results per se.

Due to that, we explicitly consider the Independent Set and Dominating Set problems as two of the most fundamental problems expressible in A&C DN logic. Here, we provide several new hardness results. First, we show W[1]-hardness parameterized by chim-width and mam-width, and we show that under the Exponential Time Hypothesis, no $n^{o(k)}$ time

algorithm can exist. The latter gives a negative answer to the question explicitly asked for instance in [1, 4] whether the linear dependence on the mim-width in the exponent of the algorithms from [7] can be lowered significantly.

▶ **Theorem 5.** *Unless the Exponential Time Hypothesis fails, neither* Independent Set *nor* Dominating Set *can be solved in $f(k)n^{o(k)}$ time for any computable function f, where k is either the chim-width, the mam-width, or the mim-width of a given decomposition of the n-vertex input graph. Moreover, both problems parameterized by either the chim-width or the mam-width are* W[1]*-hard.*

Since Independent Set is NP-complete on cubic graphs, it is para-NP-hard when parameterized by any width measure in whose obstructions the degree increases proportionally to the size. This is the case for complete bipartite graphs, anti-matchings, and chains. However, one might hope for efficient algorithms for Independent Set parameterized by solution size on graphs of constant width. For chain-width, we rule out this possibility by proving that the graphs from a reduction due to Fomin, Golovach, and Raymond [13] have bounded chain-width.

▶ **Theorem 6.** *Independent Set parameterized by solution size is* W[1]*-hard even when the input graph is provided with a linear decomposition of chain-width* 3*.*

We summarize the results for the Independent Set problem in Figure 4.

This paper is organized as follows. In the next section, we introduce our notations and the $\mathcal{F}$-branchwidths framework, as wells as some basics facts on these parameters. Theorem 2 is proved in Section 3. Theorem 3 is proved in Section 4. Theorem 4 is proved in Section 5. Finally, Theorem 5 is proved in Section 5. Missing proofs are in the full version.

2 Preliminaries

For an integer i, we let $[i] = \{1, 2, \ldots, i\}$.

We use standard graph terminology and notation [11], some of which we briefly recall in the following. In every notation with a graph subscript, we may omit it if the graph is clear from the context.

A *cut* of a graph G is a partition of $V(G)$ into two sets A, B. We denote by $G[A, B]$ the subgraph of G with edge set $\{uv \in E(G) \mid u \in A, v \in B\}$. A graph G is *bipartite* if it can be written as $G[A, B]$ for some cut A, B. In this case we also use (A, B, E) to denote G. If $|A| = |B|$, then we call $|V(G)/2|(= |A| = |B|)$ the *half-order* of G.

For a graph G, its *(edge) complement* $\overline{G}$ is given by $(V(G), \{uv \mid u, v \in V(G) \wedge vw \notin E(G)\})$. Given a set $A \subseteq V(G)$, we use $\overline{A}$ as shorthand for $V(G) \setminus A$. For a bipartite graph $G = (A, B, E)$, its *bipartite (edge) complement* is given by $(A, B, \{uv \mid u \in A \wedge v \in B \wedge uv \notin E\})$.

Branch decomposition. A *branch decomposition* or *tree layout* (or simply *layout*) of a graph G is a pair (T, λ) where T is a ternary tree (i.e., every internal node of T has degree 3) and λ is a bijection from $V(G)$ to the leaves of T. An edge e of T *induces* or *defines* a cut (X_e, Y_e) of G, where X_e and Y_e are the preimages by λ of the leaves in the two components of $T - e$. For a symmetric function $\mathsf{f}_G \colon 2^{V(G)} \to \mathbb{Z}$ which we refer to as a *cut function* of G, the f*-width* of e is $\mathsf{f}_G(X_e)$, the f-width of the branch decomposition T is the maximum width over all edges of T, and the f-branchwidth of G, denoted by $\mathsf{f}\text{-}\mathsf{width}(G)$, is the minimum width of a branch decomposition of G.

The following lemma encapsulates a standard argument on branch decompositions that we need to obtain some of our lower bound results.

▶ **Lemma 7.** *Let G be a graph and $X \subseteq V(G)$ such that $|X| \geq 2$. Any branch decomposition of G has an edge that displays a bipartition (L, R) of $V(G)$ so that $|L \cap X| \geq |X|/3$ and $|R \cap X| \geq |X|/3$.*

Corresponding *linear branchwidth* constrains T to be a path with a pendant for each internal node. The linear f-branchwidth of G is denoted by $\mathsf{lin\text{-}f\text{-}width}(G)$. It is equivalent to view the layout given by such a tree as a permutation of $V(G)$ where the considered cuts for linear branchwidth are between vertices before and vertices after each point in the permutation.

Besides $\mathcal{F}$-branchwidth, we will also use the cut function nec_G (and its associated branchwidth) defined as follows. Given $A \subseteq V(G)$, two subsets X and Y of A are neighborhood-equivalent over A if $N(X) \setminus A = N(Y) \setminus A$, we define $\mathsf{nec}_G(A)$ as the number of equivalence relation over A.

We focus on the branchwidths proposed in [12] that arise as follows. Let $\mathcal{F}$ be an infinite family of bipartite graphs where each graph in $\mathcal{F}$ has bipartition $(A = (a_1, \ldots, a_n), B = (b_1, \ldots, b_n))$ such that for each $2n$-vertex graph in $\mathcal{F}$ and each subset L of $[n]$, the graph induced on $\{a_i, b_i | i \in L\}$ is isomorphic to a graph in $\mathcal{F}$. Given a graph G, we define the *$\mathcal{F}$-cut function* f_G of G such that $\mathsf{f}_G(X)$ is the the largest k such that a $2k$-vertex graph in $\mathcal{F}$ is isomorphic to an induced subgraph of $G[X, V(G) \setminus X]$. It is known that for any such choice of $\mathcal{F}$, $\mathcal{F}$-branchwidth is asymptotically equivalent to $\mathcal{F}'$-branchwidth where $\mathcal{F}'$ is a union of any of the following six graph classes which are called *si ph* (short for *size identifiable partner hereditary*): $\equiv$ the class of all bipartite induced matchings, $\bigtimes$ the class of all bipartite complements of induced matchings, also called *antimatchings* (or co-matchings), $\boxtimes$ the class of all complete bipartite graphs with an equal number of vertices on each side of the bipartition, $\vdots\ \vdots$ the class of all bipartite edgeless graphs with an equal number of vertices on each side of the bipartition, which we simply refer to as *bipartite edgeless graphs*, $\leqslant$ the class of all bipartite graphs with an equal number of vertices on each side of the bipartition such that the vertices on each side permit an indexing under which each vertex u on one side has an edge to a vertex v other the index of u is at most the index of v, which we refer to as *chains*, and $\diagdown\!\!\!\leqslant$ the class of all bipartite graphs with an equal number of vertices on each side of the bipartition such that the vertices on each side permit an indexing under which each vertex u on one side has an edge to a vertex v other the index of u is less than the index of v, which we refer to as *skewed chains*.

It will be useful to introduce the following notation for some bipartite graphs:

- $\vdots\ \vdots_k = ((a_1, \ldots, a_k), (b_1, \ldots, b_k), E)$, where $E = \emptyset$.
- $\boxtimes_k = ((a_1, \ldots, a_k), (b_1, \ldots, b_k), E)$, where $E = \{a_i b_j \mid i, j \in [k]\}$.
- $\equiv_k = ((a_1, \ldots, a_k), (b_1, \ldots, b_k), E)$, where $E = \{a_i b_i \mid i \in [k]\}$.
- $\bigtimes_k = ((a_1, \ldots, a_k), (b_1, \ldots, b_k), E)$, where $E = \{a_i b_j \mid i, j \in [k], i \neq j\}$.
- $\leqslant_k = ((a_1, \ldots, a_k), (b_1, \ldots, b_k), E)$, where $E = \{a_i b_j \mid 1 \leq i \leq j \leq k\}$.
- $\diagdown\!\!\!\leqslant_k = ((a_1, \ldots, a_k), (b_1, \ldots, b_k), E)$, where $E = \{a_i b_j \mid 1 \leq i < j \leq k\}$.

2.1 Co-/degeneracy, empty-width/complete-width, and subdivisions

In this subsection, we explore the relations between degeneracy [16], subdivisions, complete-width and empty-width. All the corollary of this subsection follows from the fact that the (linear) complete-width of a graph is exactly the (linear) empty-width of its complement. This will be useful to establish relationships between $\mathcal{F}$-branchwidths in the next section.

▶ **Proposition 8.** *Let G be a graph with degeneracy at most k. Then, G has linear complete-width at most k.*

▶ **Corollary 9.** *Let G be a graph with co-degeneracy at most k. Then, G has linear empty-width at most k.*

On the other hand, hypercubes have unbounded degeneracy but complete-width at most 2.

▶ **Proposition 10.** *For each $d \in \mathbb{N}$, the hypercube of dimension d has minimum degree d and linear complete-width at most two.*

▶ **Corollary 11.** *For each $d \in \mathbb{N}$, the hypercube of dimension d has minimum co-degree d and linear empty-width at most two.*

For a graph G and a positive integer q, the *q-subdivision of G* is the graph obtained from G by subdividing each edge q times.

▶ **Observation 12.** *Let G be a simple graph, and let G' be obtained from G by subdividing each edge at least once. Then, any linear ordering of G' has complete-width at most one.*

▶ **Corollary 13.** *Let G be a simple graph and let $\overline{G'}$ be the complement of a graph obtained from G by subdividing each edge at least once. Then, any linear ordering of G' has empty-width at most one.*

3 The Eleven

In this section we show that we can restrict ourselves further to eleven different $\mathcal{F}$-branchwidth measures, called *the Eleven* (shown in Figure 2) and still obtain complete classifications. We begin by restating a lemma from [12] to justify that we do not need to consider the family of skewed chains.

▶ **Lemma 14** (Lemma 4.9 in [12])**.** *Let $\mathcal{F}$ be a union of si ph classes. If $\diagup\!\!\!\!\diagup \subseteq \mathcal{F}$, then for every graph G it holds that $|\mathcal{F}\text{-bw}(G) - \mathcal{F}'\text{-bw}(G)| \leq 1$, where $\mathcal{F}' = (\mathcal{F} \setminus \diagup\!\!\!\!\diagup) \cup \boxplus$.*

The remaining five singleton-classes that we restrict our attention to from now on are each interesting in their own right. The following observation will come in useful.

▶ **Observation 15.** *Let $H = ((a_1, \ldots, a_k), (b_1, \ldots, b_k), E)$ be an ordered bipartite graph.*
1. *If $H = \equiv_k$, then H contains an edgeless bipartite graph of half-order $\lfloor k/2 \rfloor$.*
2. *If $H = \boxplus_k$ or $H = \diagup\!\!\!\!\diagup_k$, then H contains an edgeless bipartite graph of half-order $\lfloor k/2 \rfloor$.*
3. *If $H = \boxtimes_k$, or $H = \boxplus_k$, or $H = \diagup\!\!\!\!\diagup_k$, then H contains a complete bipartite graph of half-order $\lfloor k/2 \rfloor$.*

We move on to pairs, first observing that we can restrict ourselves to the case when at most one of $\vdots\ \vdots$ or $\boxtimes$ is contained in $\mathcal{F}$.

▶ **Lemma 16.** *Let $\mathcal{F}$ be a union of si ph classes such that $\vdots\ \vdots \cup \boxtimes \subseteq \mathcal{F}$. There is a computable function f such that for each graph G with $\mathcal{F}\text{-bw}(G) \leq k$, $|V(G)| < f(k)$.*

When $\vdots\ \vdots \subseteq \mathcal{F}$, the presence or absence of $\equiv$ or $\boxplus$ in $\mathcal{F}$ does not matter asymptotically either.

▶ **Lemma 17.** *Let $\mathcal{F}$ be a union of si ph classes such that $\vdots\ \vdots \subseteq \mathcal{F}$. Let $\mathcal{F}^*$ be any (possibly empty) combination of $\{\equiv, \boxplus\}$, and let $\mathcal{F}' = \mathcal{F} \cup \mathcal{F}^*$. Then, for any graph G, $\mathcal{F}\text{-bw}(G) \leq \mathcal{F}'\text{-bw}(G) \leq 2 \cdot \mathcal{F}\text{-bw}(G) + 1$.*

Similarly, we have the following.

▶ **Lemma 18.** *Let $\mathcal{F}$ be a union of si ph classes such that $\boxtimes \subseteq \mathcal{F}$. Let $\mathcal{F}^*$ be any (possibly empty) combination of $\{\boxtimes, \boxplus\}$, and let $\mathcal{F}' = \mathcal{F} \cup \mathcal{F}^*$. Then, for any graph G, $\mathcal{F}$-bw$(G) \leq \mathcal{F}'$-bw$(G) \leq 2 \cdot \mathcal{F}$-bw$(G) + 1$.*

We are now ready to define the Eleven– see Table 1 – and prove Theorem 1.

Table 1 Definitions of *the Eleven* $\mathcal{F}$-branchwidth and introduction of the notations for their associated $\mathcal{F}$-cut functions.

$\mathcal{F}$	Name	$\mathcal{F}$-cut function	$\mathcal{F}$	Name	$\mathcal{F}$-cut function
$\boxtimes$	complete-width	complete$_G$	$\boxtimes \cup \boxplus$	tree*-width	t$^\star{}_G$
$\vdots\ \vdots$	empty-width	empty$_G$	$\vdots\ \vdots \cup \boxtimes$	co-tree*-width	co-t$^\star{}_G$
$\boxplus$	mim-width	mim$_G$	$\boxplus \cup \boxtimes$	mam-width	mam$_G$
$\boxtimes$	miam-width	miam$_G$	$\boxtimes \cup \boxplus$	chim-width	chim$_G$
$\boxplus$	chain-width	chain$_G$	$\boxplus \cup \boxplus$	cham-width	cham$_G$
			$\boxplus \cup \boxtimes \cup \boxplus$	clique*-width	c$^\star{}_G$

Observe that tree*-width is asymptotically equivalent to tree-width and clique*-width is asymptotically equivalent [12, Section 4].

▶ **Theorem 1.** *For each $\mathcal{F}$-branchwidth, one of the following holds.*

- **(i)** *There is a computable function f such that for each graph G with $\mathcal{F}$-bw$(G) \leq k$, $|V(G)| \leq f(k)$.*
- **(ii)** *$\mathcal{F}$-branchwidth is asymptotically equivalent to $\mathcal{F}^*$-branchwidth, where $\mathcal{F}^*$ is one of the Eleven branchwidths (presented in Figure 2 and formally defined in Table 1).*

Next, we argue that the relationships between the Eleven as shown in Figure 2 indeed faithfully represent their hierarchy. That is, whenever two width measures are connected, then the one on top *strictly* generalizes the one the bottom, and whenever there is no connection (in terms of paths) between two, then they are incomparable. The fact that the depicted generalizations hold up follows directly from the definition and in some cases Observation 15.

For the lower bounds on width measures, we need the following canonical classes of graphs of unbounded width. For each $n \in \mathbb{N}$, we consider the following graphs on vertex set $[n] \times [n]$.

- The $n \times n$ *grid*, denoted by $\boxplus_n$, has edges $\{(i,j),(i',j')\}$ where $|i-i'| + |j-j'| = 1$.
- The *complement of the $n \times n$ grid* is denoted by $\overline{\boxplus}_n$.
- The $n \times n$ *comparability grid*, denoted by $\boxtimes_n$, has edges $\{(i,j),(i',j')\}$ where $i \leq i'$ and $j \leq j'$. For an illustration see Figure 5. Note that comparability grids appear in the study of rank-width naturally [15].

Grids have unbounded mim-width [17], which in the language of $\mathcal{F}$-branchwidth can be expressed in a more general form as follows.

▶ **Proposition 19.** *Let $\mathcal{F}$ be a union of si ph families. If $(\boxplus \cup \vdots\ \vdots) \cap \mathcal{F} \neq \emptyset$, then for each $n \in \mathbb{N}$, $\mathcal{F}$-bw$(\boxplus_n) \in \Omega(n)$.*

By complementation, we have the following consequence.

▶ **Corollary 20.** *Let $\mathcal{F}$ be a union of si ph families. If $(\boxtimes \cup \boxtimes) \cap \mathcal{F} \neq \emptyset$, then for each $n \in \mathbb{N}$, $\mathcal{F}$-bw$(\overline{\boxplus}_n) \in \Omega(n)$.*

Lastly, we show that comparability grids are a family of unbounded chain-width, while their mam-width is bounded by a constant.

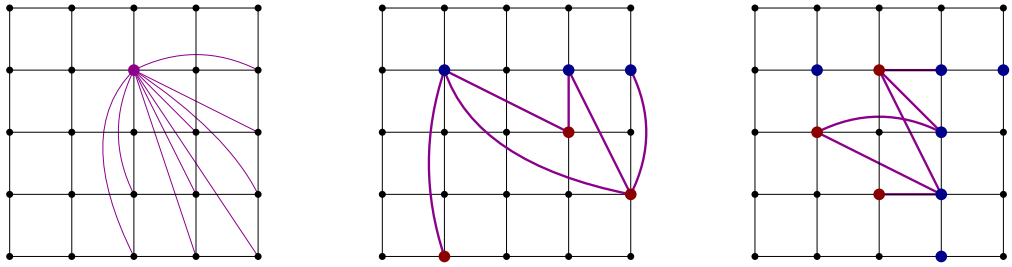

Figure 5 Illustration of comparability grids by the example of $\boxtimes_5$. On the left, the grid structure plus the additional edges incident with one highlighted vertex. In the middle and on the right, some chains that appear in cuts of a branch decomposition.

Table 2 Each cell shows families of graphs whose width is bounded by a constant by the width measure whose cut-function indexes the row and unbounded by the width measure whose cut-function indexes the column. Here, $\boxplus$ stands for the family of grids, $\overline{\boxplus}$ for the complements of grids, and $\boxplus$ for the comparability grids. For instance, the entry $\boxplus$ in row "chain" and column "mim" indicates that the family of grids has constant chain-width but unbounded mim-width. Furthermore, K_n denotes the family of complete graphs, and $\emptyset_n$ the family of edgeless graphs.

	chain	mim	miam	chim	mam	cham	empty	complete	c*/t*/co-t*
chain		$\boxplus$	$\overline{\boxplus}$	$\boxplus$	$\boxplus$ $\overline{\boxplus}$	$\overline{\boxplus}$	$\boxtimes$	$\overline{\boxplus}$	$\boxtimes$ $\overline{\boxplus}$
mim	$\boxtimes$		$\overline{\boxplus}$	$\boxtimes$	$\overline{\boxplus}$	$\boxtimes$ $\overline{\boxplus}$	$\boxtimes$	$\overline{\boxplus}$	$\boxplus$ $\overline{\boxtimes}$
miam	$\boxplus$	$\boxtimes$		$\boxplus$ $\boxtimes$	$\boxtimes$	$\boxplus$	$\boxtimes$ $\boxplus$	$\boxplus$	$\boxplus$ $\boxplus$
chim			$\overline{\boxplus}$		$\overline{\boxtimes}$	$\overline{\boxtimes}$	$\emptyset_n$	$\overline{\boxtimes}$	$\overline{\boxtimes}$
mam	$\boxtimes$			$\boxtimes$		$\boxplus$	$\boxplus$	$\boxplus$	$\boxplus$
cham		$\boxplus$		$\boxplus$	$\boxplus$		$\boxplus$	K_n	$\boxplus$
empty			$\overline{\boxplus}$		$\overline{\boxplus}$	$\overline{\boxplus}$		$\overline{\boxplus}$	$\overline{\boxplus}$
complete		$\boxplus$		$\boxplus$	$\boxplus$		$\boxtimes$		$\boxplus$
c*							$\emptyset_n$	K_n	/ K_n / $\emptyset_n$
t*							$\emptyset_n$		/ / $\emptyset_n$
co-t*								K_n	/ K_n /

▶ **Proposition 21.** *For each $n \in \mathbb{N}$,* lin-mam-width($\boxtimes_n$) $= 1$ *and* chain-width($\boxtimes_n$) $\geq n/4$.

Next, we observe upper bounds on $\mathcal{F}$-branchwidth of grids, their complements, and comparability grids.

▶ **Proposition 22.** *Let $\mathcal{F}$ be a union of si ph families. If $\mathcal{F} \subseteq \boxplus \cup \boxtimes \cup \overline{\boxplus}$, then, for each $n \in \mathbb{N}$, $\mathcal{F}$-bw($\boxplus_n$) $\in \mathcal{O}(1)$.*

By complementation and Corollary 9, we get the following.

▶ **Corollary 23.** *Let $\mathcal{F}$ be a union of si ph families. If $\mathcal{F} \subseteq \vdots \cup \equiv \cup \overline{\boxtimes}$, then, for each $n \in \mathbb{N}$, $\mathcal{F}$-bw($\overline{\boxplus}_n$) $\in \mathcal{O}(1)$.*

Using Propositions 19, 21, and 22 and Corollaries 20 and 23, we can argue almost all of the desired relationships, see Table 2. The remainder is discussed in the full version which concludes the proof of Theorem 2.

4 FO logic

It is known that FO Model Checking is AW[∗]-hard on interval graphs [14]. Furthermore, interval graphs are known to have linear mim-width 1, witnessed by a linear order that can be computed in polynomial time [2]. Next, we can observe that for any graph G and $A \subseteq V(G)$,

$$\mathsf{mim}_G(A) \leq 1 \Leftrightarrow \mathsf{miam}_G(A) \leq 1.$$

This is because a matching of half-order 2 and an anti-matching of half-order 2 are isomorphic. Therefore, we have the following consequence.

▶ **Corollary 24** (of [2, 14]). FO-*Model Checking parameterized by the length of the formula is* AW[∗]*-hard on graphs of linear mam-width one, even if a width-*1 *linear order of the input graph is given.*

Due to Corollary 24, the only remaining cases where we could hope for FPT-algorithms for FO-Model Checking are complete-width and empty-width. However, we show by two trivial reductions that the problem remains W[1]-hard parameterized by formula length on graphs of width 1 as well. Note that the following reduction is folklore, but we state it here for completeness.

▶ **Proposition 25.** FO-*Model Checking parameterized by the length of the formula is* AW[∗]*-hard on graphs of linear complete-width one, even if a width-*1 *linear order of the input graph is given.*

Let (G, ϕ) be an instance of FO-Model Checking such that G has linear complete-width one. Observe that $\overline{G}$ has linear empty-width one. We replace each occurrence of $x_i \sim x_j$ in ϕ with $\neg x_i \sim x_j$ to obtain a formula ϕ'. Then, $\overline{G} \models \phi'$ if and only if $G \models \phi$ and we obtain the following.

▶ **Corollary 26.** FO-*Model Checking parameterized by the length of the formula is* AW[∗]*-hard on graphs of linear empty-width one, even if a width-*1 *linear order of the input graph is given.*

5 Bounds on nec in terms of $\mathcal{F}$-branchwidth

The run time of the algorithm for A&C DN Model Checking from [3] is polynomial in the number of equivalence classes of the neighborhood equivalence relation. Therefore, any bound on this quantity immediately translates to an efficient algorithm for A&C DN Model Checking.

5.1 Upper Bounds

We first give some upper bounds. For tree-width, co-tree-width, and clique-width, single-exponential upper bounds on nec are known (e.g., [3]). Pipelined through the arguments from [12], this gives bounds for the equivalent $\mathcal{F}$-branchwidth parameters, but they might end up double-exponential due to the Ramsey arguments in [12]. Here, we give single-exponential upper bounds in terms of these width parameters by giving more direct arguments.

▶ **Lemma 27.** *Let G be a graph and $A \subseteq V(G)$ such that $\mathsf{t}^\star_G(A) \leq k$. Let M be a matching in $G[A, \overline{A}]$. Then, $|M| < (k+1)^{k+2}$.*

▶ **Lemma 28.** *Let G be a graph, $A \subseteq V(G)$ with $\mathsf{t}^\star{}_G(A) \leq k$. There is a set $\Omega \subseteq A$ of size at most $2^{\mathcal{O}(k^2 \log k)}$ such that $\{N(v) \cap \overline{A} \mid v \in A\} = \{N(v) \cap \overline{A} \mid v \in \Omega\}$.*

▶ **Proposition 29.** *Let G be a graph and $A \subseteq V(G)$ with $\mathsf{t}^\star{}_G(A) \leq k$. Then, $\mathsf{nec}_G(A) \in 2^{\mathcal{O}(k^3 \log k)}$.*

▶ **Proposition 30.** *Let G be a graph and $A \subseteq V(G)$ with $\mathsf{co\text{-}t}^\star{}_G(A) \leq k$. Then, $\mathsf{nec}_G(A) \leq 2^{\mathcal{O}(k^3 \log k)}$.*

5.2 Lower bounds

We first exhibit some cuts with high nec in terms of the respective width parameters. Later, we then prove that there are families of graphs where each of their branch decompositions has to have a cut with large nec.

▶ **Observation 31.** *Let G be obtained by taking the disjoint union of an antimatching with $2n$ vertices and a matching with $2k$ vertices and completely connecting the sides A and $\overline{A}$ of the resulting bipartite graph. It holds that $\mathsf{empty\text{-}width}(G) \leq k$, and $\mathsf{nec}_G(A) \geq 2^k \cdot n$.*

For the following observation, take the disjoint union of k chains of half-order k.

▶ **Observation 32.** *There is a bipartite graph $G = (A, B, E)$ with $\mathsf{t}^\star{}_G(A) = k$ and $\mathsf{nec}_G(A) \in 2^{\Omega(k \log k)}$.*

▶ **Observation 33.** *Let $H = H_{=\!=}^n$ with bipartition (A, B). Then, $\mathsf{nec}_H(A) = 2^n$.*

▶ **Observation 34.** *For each $n \in \mathbb{N}$ there is a graph G on $2n$ vertices and $A \subseteq V(G)$ such that $\mathsf{complete}_G(A) = 1$ and $\mathsf{nec}_G(A) = 2^n$.*

▶ **Proposition 35.** *There is an infinite family of graphs G with $\mathsf{complete\text{-}width}(G) = 1$ and such that each branch decomposition of G induces a cut $(A, \overline{A})$ with $\mathsf{nec}_G(A) \in 2^{\Omega(\sqrt{|V(G)|})}$.*

▶ **Proposition 36.** *For each $n, k \in \mathbb{N}$ with $n \geq k$ there is a bipartite graph $G = (A, B, E)$ on $2n$ vertices such that $\mathsf{mam}_G(A) = k$ and $\mathsf{nec}_G(A) = \lfloor n/k \rfloor^k$.*

By taking a disjoint union of k antimatchings of half-order n/k in the previous proof, we get the following corollary.

▶ **Corollary 37.** *For each $n, k \in \mathbb{N}$ with $n \geq k$ there is a bipartite graph $G = (A, B, E)$ on $2n$ vertices such that $\mathsf{chim}_G(A) = k$ and $\mathsf{nec}_G(A) = \lfloor n/k \rfloor^k$.*

In the following, we provide several lower bounds on the nec-width of graphs of low chim-width, mam-width, tree*-width, or co-tree*-width. The proofs strategy are based on the proof of [5, Theorem 1.3] stating that there exists arbitrary large graphs of rank-width k with Boolean-width $\Omega(k^2)$.

We start by proving a lower bound on nec-width in terms of chim-width. The following construction is based on the reduction used to prove Theorem 5 for chim-width.

▶ **Lemma 38.** *For each $k \in \mathbb{N}$ with $k > 0$, there exist arbitrary large graphs G of linear chim-width at most $2k$ and with $\mathsf{nec\text{-}width}(G) \in (n/(k^2 \log n))^{\Omega(k)}$.*

It is easy to obtain the same result as Lemma 38 for mam-width by replacing anti-matchings by chains in the construction of the graph G.

▶ **Lemma 39.** *For each $k \in \mathbb{N}$ with $k > 0$, there exist arbitrary large graphs G of linear mam-width at most $k + 1$ and with $\mathsf{nec\text{-}width}(G) \in (n/(k^2 \log n))^{\Omega(k)}$.*

▶ **Lemma 40.** *For each $k \in \mathbb{N}$ with $k > 0$, there exist arbitrary large graphs G of linear tree*-width at most $2k$ and with* nec-width$(G) \in k^{\Omega(k)}$.

▶ **Lemma 41.** *For each $n, k \in \mathbb{N}$ with n sufficiently large, there is a graph $G = (A, B, E)$ on $2n$ vertices such that* empty-width$(G) \leq k$ *and with* nec-width$(G) \in |V(G)|^{\Omega(k)}$.

6 Independent Set parameterized by $\mathcal{F}$-Branchwidth

In this section, we discuss the complexity of Independent Set parameterized by any $\mathcal{F}$-branchwidth measure. On top of that, we strengthen known hardness results for Independent Set and Dominating Set (full version) on graphs of bounded mim-width under the ETH. Concretely, we show the following.

▶ **Theorem 5.** *Unless the Exponential Time Hypothesis fails, neither Independent Set nor Dominating Set can be solved in $f(k)n^{o(k)}$ time for any computable function f, where k is either the chim-width, the mam-width, or the mim-width of a given decomposition of the n-vertex input graph. Moreover, both problems parameterized by either the chim-width or the mam-width are* W[1]*-hard.*

These lower bounds are tight because the algorithm – based on the d-neighbor equivalence – from [7] solves Independent Set and Dominating Set in time $n^{O(w)}$ where w is the mim-width of a given decomposition which is always smaller than its chim-width and mam-width.

It is well-known that Independent Set is FPT parameterized by clique-width, and therefore clique*-width, so for all $\mathcal{F}$-branchwidth measures that are at most as general as clique*-width, Independent Set is FPT.

6.1 Independent Set on graphs of bounded complete-width and chain-width

Since Independent Set is NP-complete on cubic graphs, it is paraNP-hard when parameterized by any width measure in whose obstructions the degree increases proportionally to the size. This is the case for complete bipartite graphs, anti-matchings, and chains.

▶ **Observation 42.** *Independent Set is* NP*-hard on graphs with complete-width at most* 3.

Nevertheless, the previous result does not rule out efficient parameterized algorithms for Independent Set when the solution size is an additional part of the parameter. Note that here, the bounded-degree argument does not apply, since Independent Set parameterized by solution size plus maximum degree can easily be shown to be FPT [10]. However, we show that Independent Set remains W[1]-hard parameterized by solution size on graphs of (the more general) chain-width at most 3. (The same reduction in fact shows W[1]-hardness parameterized by solution size plus chim-width.)

This can be shown by observing that the graphs obtained in the reduction that proved W[1]-hardness for Independent Set parameterized by mim-width plus solution size [13] in fact have a linear order whose mim-width is bounded by a function of the parameter and whose chim-width is at most three.

▶ **Corollary 43.** *Independent Set is W[1]-hard parameterized by*

- *the solution size (plus the linear mim-width) on graphs of linear chain-width* 3*, or*
- *the solution size plus the linear chim-width*

of the input graph, even if a linear order of bounded width is provided with the input.

6.2 Independent Set on graphs of bounded chim-width

To prove Theorem 5 for chim-width and Independent Set, we provide a reduction from Multicolored Independent Set in general graphs to Independent Set in graphs of low chim-width. Briefly, an instance of Multicolored Independent Set consists of a graph whose vertex set is the disjoint union of k sets $V_1, \ldots, V_k$ and the problem asks for a *multicolored* independent set which is an independent set with exactly one vertex in each V_i. Let H a graph with $V(H) = V_1 \uplus \cdots \uplus V_k$ be an instance of Multicolored Independent Set. We denote by N the number of vertices of H and by M the number of edges of H. In the following, we show how to construct in polynomial time a graph G with at most $n = NM$ vertices and a linear order of chim-width at most $2k$ such that H admits a multicolored independent set iff G admits an independent set of size at least kM. This is sufficient to prove Theorem 5 for chim-width. Indeed, with a $f(w)n^{o(w)}$ time algorithm for Independent Set for some computable function f, we would be able to solve Multicolored Independent Set in time $f(k)N^{o(k)}$ which is not possible under the ETH [10]. Futhermore, the W[1]-hardness of Independent Set parameterized by chim-width follows from the W[1]-hardness of Multicolored Independent Set parameterized by k [10].

Intuitively, we start by creating a *selection gadget* S_{uv} for each edge uv of H such that the maximum independent sets of $G[S_{uv}]$ are bijectively mapped to the *potential solution* of H – set of vertices with exactly one vertex in each V_i – which do not contains both u and v. Then we glue the selection gadgets together in such a way that the maximum independent sets in two glued gadgets are non-adjacent if and only if they are associated with the same potential solution of H. See Figure 6 for an illustration of the following construction.

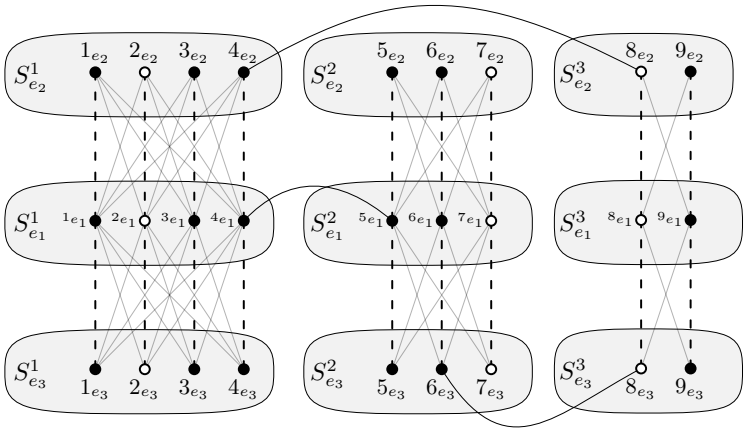

Figure 6 Illustration of the reduction for chim-width with $k = 3$, $V_1 = \{1, 2, 3, 4\}$, $V_2 = \{5, 6, 7\}$ and $V_3 = \{8, 9\}$. Here $M = 3$ and the edges of H consists of $e_1 = 45$, $e_2 = 48$ and $e_3 = 68$. Dashed lines represent the non-edges of the anti-matchings between the selection gadgets. To improve the legibility, we omit the edges of the cliques $S^j_{e_i}$: $i, j \in [3]$. The independent set I consisting of the white filled vertices have size kM and $I_H = \{2, 7, 8\}$ is a multicolored independent set of H.

Selection gadgets. For each edge $e \in E(H)$, we create the selection gadget S_e which consists of the disjoint union of k cliques $S^1_e, \ldots, S^k_e$ such that for each $j \in [k]$, $S^i_e := \{x_e \mid x \in V_i\}$. We finish the construction of S_e by adding the edge between u_e and v_e where u and v are the endpoints of e. Given a set $X \subseteq S_e$, we denote by X_H the set $\{x \in V(H) \mid x_e \in X\}$.

▶ **Observation 44.** *For every edge e of H, X is a maximum independent set I of $G[S_e]$ if and only if X_H has exactly one vertex in each V_i and does not contain both endpoints of e.*

Propagation. The final step of this construction is to add edges between the selection gadgets such that if H admits a multicolored independent sets then every maximum independent set I of G intersects the selections gadgets in the same way, i.e. for every pair of edges (e_1, e_2) of H, we have $(I \cap S_{e_1})_H = (I \cap S_{e_2})_H$. We achieve this without blowing up the chim-width of G as follows. We fix an edge e_1 of H and for every edge $e \neq e_1$ of H and $i \in [k]$, we first add all the edges between $S^i_{e_1}$ and S^i_e and then for each vertex $x \in V_i$, we remove the edge $x_{e_1}x_e$. Consequently, the bipartite graph $G[S^i_{e_1}S^i_e]$ is an anti-matching of half-order $|V_i|$. As $S^i_{e_1}$ and S^i_e are cliques in G, the maximum independent sets of $G[S^i_{e_1} \cup S^i_e]$ are exactly the pairs $\{x_{e_1}, x_e\}$ with $x \in V_i$. This leads to the following observation.

▶ **Observation 45.** *For every edge $e \neq e_1$ of H and subsets X, Y of size k of respectively S_{e_1} and S_e, there is no edge between X and Y in G if and only if we have $X_H = Y_H$.*

We deduce from Observations 44 and 45 the correctness of our reduction.

▶ **Lemma 46.** *The graph G admits an independent set of size at least kM if and only if H admits a multicolored independent set.*

Finally, we prove that we can construct in polynomial time a linear order of G of chim-width at most $2k + 2$. The following proof relies on the fact that induced matchings and chains in anti-matchings have size at most 2, which implies that the chim-width of the cut $(S_{e_1}, V(G) \setminus S_{e_1})$ is at most $2k$.

▶ **Lemma 47.** *We can compute in polynomial time a linear order of G of chim-width at most $2k + 2$.*

6.3 Independent Set on graphs of bounded mam-width

The proof of Theorem 5 for mam-width is similar to the one for chim-width, we start from the same instance of Multicolored Independent Set and construct a graph G. Compared to chim-width, the following construction is a bit more involved and uses skewed chains instead of anti-matchings to glue the selection gadgets together. See Figure 7 for an illustration of the following construction.

Selection gadgets. We reuse the selection gadget $S_{e_1}, S_{e_2} \ldots, S_{e_M}$ from the reduction for chim-width where $e_1, \ldots, e_M$ are the edges of H.

Propagation. First, we add anti-matchings between S_{e_1} and S_{e_2} just as we did in the reduction of chim-width. That is for every $i \in [k]$, we do the following. We add all the edges between $S^i_{e_1}$ and $S^i_{e_2}$. Finally, for every vertex $v \in V_i$, we remove the edge $v_{e_1}v_{e_2}$. Note that $G[S^i_{e_1}, S^i_{e_2}]$ is big anti-matching, but this does not blow-up the mam-width. Indeed, we can insert in the permutation of Lemma 47 each vertex of $S^i_{e_2}$ next to its non-neighbor in $S^i_{e_1}$, this way every cut of the resulting permutation contains at most one non-edge of $G[S^i_{e_1}, S^i_{e_2}]$ and the mam-width stays low. Note that Observation 45 holds for $e = e_2$.

Finally, we add skewed chains between $S_{e_1} \cup S_{e_2}$ and the other selection gadgets, by doing the following. We take a arbitrary strict linear order $<_H$ on the vertices of H such that for each $i, j \in [k]$ with $i < j$, we have $u <_H v$ for each $u \in V_i$ and $v \in V_j$. For every $i \in [M]$ with $i > 2$, $j \in [k]$, and $x, y \in V_j$ such that $x <_H y$, we make x_{e_1} adjacent to y_{e_i} and y_{e_2} adjacent to x_{e_i}.

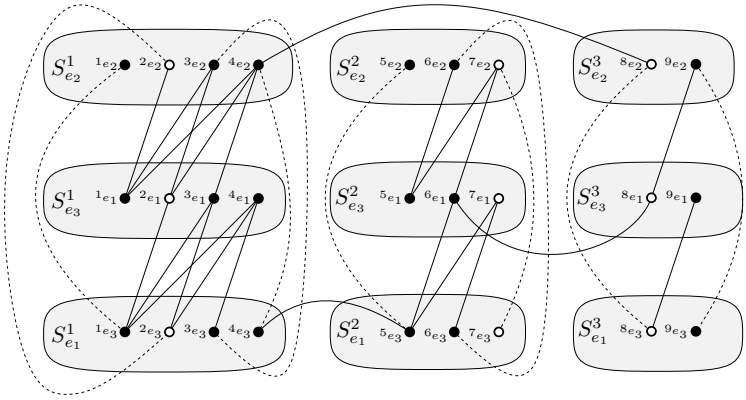

Figure 7 Illustration of the reduction for mam-width with $k = 3$, $V_1 = \{1, 2, 3, 4\}$, $V_2 = \{5, 6, 7\}$ and $V_3 = \{8, 9\}$. Here $M = 3$ and the edges of H consists of $e_1 = 45$, $e_2 = 48$ and $e_3 = 68$. To improve the legibility, we omit the edges of the cliques $S^j_{e_i}$: $i, j \in [3]$. Moreover, we represent only the non-edges (with dashed lines) of the anti-matchings between S_{e_1} and S_{e_2}. The independent set I consisting of the white filled vertices have size kM and $I_H = \{2, 7, 8\}$ is a multicolored independent set of H.

Observe that, for every $i \in [M]$, $j \in [t]$ and $X \in \{R, S\}$, the graphs $G[S^j_{e_1}, S^j_{e_i}]$ and $G[S^j_{e_2}, S^j_{e_i}]$ are skewed chain graphs of half-order $|V_i|$. Moreover, the maximum independent sets of $G[S^j_{e_1} \cup S^j_{e_2} \cup S^j_{e_i}]$ are exactly the sets $\{v_{e_1}, v_{e_2}, v_{e_i}\}$ with $v \in V_i$.

▶ **Observation 48.** *For every $i \in [M]$ and subsets X, Y and Z of respectively S_{e_1}, S_{e_2} and S_{e_i}, each of size k, there is no edge between any two of these subsets in G if and only if $X_H = Y_H = Z_H$.*

Weighted Matching in a Poly-Streaming Model

Abstract

We introduce the *poly-streaming model*, a generalization of streaming models of computation in which k processors process k data streams containing a total of N items. The algorithm is allowed $\mathcal{O}(f(k) \cdot M_1)$ space, where M_1 is either $o(N)$ or the space bound for a sequential streaming algorithm. Processors may communicate as needed. Algorithms are assessed by the number of passes, per-item processing time, total runtime, space usage, communication cost, and solution quality.

We design a *single-pass* algorithm in this model for approximating the *maximum weight matching* (MWM) problem. Given k edge streams and a parameter $\varepsilon > 0$, the algorithm computes a $(2+\varepsilon)$-approximate MWM. We analyze its performance in a shared-memory parallel setting: for any constant $\varepsilon > 0$, it runs in time $\widetilde{\mathcal{O}}(L_{max} + n)$, where n is the number of vertices and L_{max} is the maximum stream length. It supports $\mathcal{O}(1)$ per-edge processing time using $\widetilde{\mathcal{O}}(k \cdot n)$ space. We further generalize the design to hierarchical architectures, in which k processors are partitioned into r groups, each with its own shared local memory. The total intergroup communication is $\widetilde{\mathcal{O}}(r \cdot n)$ bits, while all other performance guarantees are preserved.

We evaluate the algorithm on a shared-memory system using graphs with trillions of edges. It achieves substantial speedups as k increases and produces matchings with weights significantly exceeding the theoretical guarantee. On our largest test graph, it reduces runtime by nearly two orders of magnitude and memory usage by five orders of magnitude compared to an offline algorithm.

1 Introduction

Data-intensive computations arise in data science, machine learning, and science and engineering disciplines. These datasets are often massive, generated dynamically, and, when stored, kept in distributed formats on disks, making them amenable to processing as multiple data streams. The modular feature of these datasets can be exploited by streaming algorithms designed for tightly-coupled shared-memory and distributed-memory multiprocessors to efficiently solve large problem instances that offline algorithms cannot handle due to their high memory requirements. However, the design of parallel algorithms that process multiple data streams concurrently has not yet received much attention.

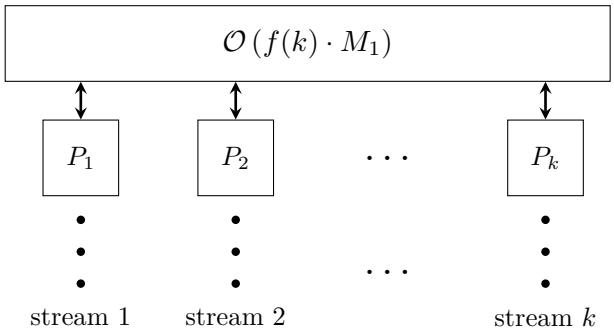

Figure 1 A schematic diagram of the *poly-streaming model* for shared-memory parallel computers. Processors $\{P_l\}_{l \in [k]}$ have access to $\mathcal{O}(f(k) \cdot M_1)$ memory collectively, depicted with the rectangle connected to the processors.

Current multicore shared-memory processors consist of up to a few hundred cores, organized hierarchically to share caches and memory controllers. These cores compute in parallel to achieve speedups over serial execution. With multiple memory controllers, I/O operations can also proceed in parallel, and this feature can be used to process multiple data streams concurrently. These I/O capabilities and the limitations of offline algorithms motivate a model of computation, illustrated in Figure 1 and discussed next.

The streaming model of computation allows $o(N)$ space for a data stream of size N [2, 13]. For graphs, the *semi-streaming model* permits $\mathcal{O}(n \cdot \text{polylog } n)$ space for a graph with n vertices and an edge stream of arbitrary length [8]. Building on these space-constrained models, we introduce the *poly-streaming model*. The key aspects of our model are as follows.

We consider k data streams that collectively contain N items. An algorithm has access to k (abstract) processors, and is allowed $\mathcal{O}(f(k) \cdot M_1)$ total space, where M_1 is either $o(N)$ or the space permitted to a single-stream algorithm. In each pass, each stream is assigned to one of the processors, and each processor independently reads one item at a time from its stream and processes it. Processors may communicate as needed, either via shared or remote memory access. Algorithms are assessed on several metrics: space complexity, number of passes, per-item processing time, total runtime, communication cost, and solution quality.

In the poly-streaming model, we address the problem of approximating a *maximum weight matching* (MWM) in an edge-weighted graph, where the goal is to find a set of vertex-disjoint edges with maximum total weight. We design an algorithm for approximating an MWM when the graph is presented as multiple edge streams. Our design builds on the algorithm of [20] and adds support for handling multiple streams concurrently. We also generalize the design to NUMA (non-uniform memory access) multiprocessor architectures.

We summarize our contributions to the MWM problem as follows. Let L_{max} and L_{min} denote the maximum and minimum lengths of the input streams, respectively, and let n denote the number of vertices in a graph G. For any realization of the CREW PRAM model (such as in Figure 1), we have the following result.

▶ **Theorem 1.** *For any constant $\varepsilon > 0$, there exists a* single-pass *poly-streaming algorithm for the maximum weight matching problem that achieves a $(2+\varepsilon)$-approximation. It admits a CREW PRAM implementation with $\widetilde{\mathcal{O}}(L_{max} + n)$ runtime.*[1] *If $L_{min} = \Omega(n)$, the algorithm*

[1] $\widetilde{\mathcal{O}}(\cdot)$ hides polylogarithmic factors.

achieves $\mathcal{O}(\log n)$ *amortized per-edge processing time using* $\widetilde{\mathcal{O}}(k+n)$ *space. For arbitrarily balanced streams, it uses either* $\widetilde{\mathcal{O}}(k+n)$ *space and* $\widetilde{\mathcal{O}}(n)$ *per-edge processing time, or* $\widetilde{\mathcal{O}}(k \cdot n)$ *space and* $\mathcal{O}(1)$ *per-edge processing time.*

In NUMA architectures, memory access costs depend on a processor's proximity to the target memory. We generalize the algorithm in Theorem 1 to account for these cost differences. In particular, we show that when k processors are partitioned into r groups, each with its own shared local memory, the total number of global memory accesses across all groups is $\widetilde{\mathcal{O}}(r \cdot n)$. This generalization preserves all other performance guarantees from Theorem 1, except that the $\widetilde{\mathcal{O}}(k+n)$ space bound becomes $\widetilde{\mathcal{O}}(k+r \cdot n)$. These results are formalized in Theorem 18 in Section 4. This design gives a memory-efficient algorithm for the NUMA shared memory multiprocessors, on which we report empirical results.

We have evaluated our algorithm on a NUMA machine using graphs with billions to trillions of edges. For most of these graphs, our algorithm uses space that is orders of magnitude smaller than that required by offline algorithms. For example, storing the largest graph in our evaluation would require more than 91,600 GB (≈ 90 TB), whereas our algorithm used less than 1 GB. Offline matching algorithms typically require even more memory to accommodate their auxiliary data structures.

We employ approximate dual variables that correspond to a linear programming relaxation of MWM to obtain *a posteriori* upper bounds on the weights of optimal matchings. These bounds allow us to compare the weight of a matching produced by our algorithm with the optimal weight. Thus, we show that our algorithm produces matchings whose weights significantly exceed the approximation guarantee.

For $k = 128$, our algorithm achieves runtime speedups of 16–83 across all graphs in our evaluation, on a NUMA machine with only 8 memory controllers. This is significant scaling for a poly-streaming algorithm, given that 8 memory controllers are not sufficient to serve the concurrent and random access requests of 128 processors without delays. Nevertheless, these speedups demonstrate the effectiveness of our design, which accounts for a processor's proximity to the target memory. A metric less influenced by memory latency suggests that the algorithm would achieve even better speedups on architectures with more efficient memory access.

Note that Theorem 1 and Theorem 18 both guarantee $\widetilde{\mathcal{O}}(L_{max}+n)$ runtime. For $L_{max} = \Omega(n)$, this is tight up to polylogarithmic factors. However, by using $\widetilde{\mathcal{O}}(k \cdot n)$ space and $\mathcal{O}(1)$ per-edge processing time, we can even achieve $\widetilde{\mathcal{O}}(L_{max}+n/k)$ runtime, which becomes polylogarithmic for large values of k (see the arXiv version).

Organization. Section 2 introduces necessary background. Section 3 presents the design and analyses of our algorithm in Theorem 1. In Section 4, we extend the design to NUMA architectures. Section 5 summarizes the evaluation results. We conclude in Section 6 with a discussion of future research directions.

2 Preliminaries

For a graph $G = (V, E)$, let $n := |V|$ and $m := |E|$ denote the number of vertices and edges, respectively. We denote an edge $e := \{u, v\}$ by the unordered pair of its endpoints. For a weighted graph, let w_e denote the weight of edge e, and for any subset $A \subseteq E$, define $w(A) := \sum_{e \in A} w_e$. For $\ell \in [k]$, let E^ℓ be the set of edges received in the ℓth stream. Define $L_{max} := \max_{\ell \in [k]} |E^\ell|$ and $L_{min} := \min_{\ell \in [k]} |E^\ell|$.

Primal LP

$$\begin{aligned} \text{maximize} \quad & \sum_{e \in E} w_e x_e \\ \text{subject to} \quad & \sum_{e \in \delta(u)} x_e \leq 1, \quad \text{for all } u \in V \\ & x_e \geq 0, \quad \text{for all } e \in E \end{aligned}$$

Dual LP

$$\begin{aligned} \text{minimize} \quad & \sum_{u \in V} y_u \\ \text{subject to} \quad & \sum_{u \in e} y_u \geq w_e, \quad \text{for all } e \in E \\ & y_u \geq 0, \quad \text{for all } u \in V \end{aligned}$$

Figure 2 The linear programming (LP) relaxations of the MWM problem and its dual.

A *matching* $\mathcal{M}$ in a graph is a set of edges that do not share endpoints. A *maximum weight matching* (MWM) $\mathcal{M}^*$ is a matching with maximum total weight; that is, $w(\mathcal{M}^*) \geq w(\mathcal{M})$ for all matchings $\mathcal{M} \subseteq E$.

A ρ-approximation algorithm computes a solution whose value is within a factor ρ of optimal. The factor ρ is called the (worst-case) *approximation ratio*. We assume $\rho \geq 1$ for both maximization and minimization problems. Thus, for maximization, a ρ-approximation guarantees a solution whose value is at least $\frac{1}{\rho}$ times the optimal.

We use the linear programming (LP) relaxation of the MWM problem, and its dual, shown in Figure 2. In the primal LP, each variable x_e is 1 if edge e is in the matching and 0 otherwise. Each y_u is a dual variable, and $\delta(u)$ denotes the set of edges incident on a vertex u. Let $\{x_e\}_{e \in E}$ and $\{y_u\}_{u \in V}$ be feasible solutions to the primal and dual LPs, respectively. By weak LP duality, we have $\sum_{e \in E} w_e x_e \leq \sum_{u \in V} y_u$. If $\{x_e\}_{e \in E}$ is an optimal solution to the primal LP, then $w(\mathcal{M}^*) \leq \sum_{e \in E} w_e x_e \leq \sum_{u \in V} y_u$. The first inequality holds because the primal LP is a relaxation of the MWM problem.

3 Algorithms for Uniform Memory Access Cost

In this section, we present the design and analyses of our algorithm in Theorem 1 that assumes a uniform memory access cost.

3.1 The Algorithm

Several semi-streaming algorithms have been designed for the MWM problem [3, 4, 6, 8, 10, 11, 18, 20, 23] (see the arXiv version for brief descriptions of these algorithms). In this paper, we focus exclusively on the single-pass setting in the *poly-streaming* model. Our starting point is the algorithm of Paz and Schwartzman [20], which computes a $(2+\varepsilon)$-approximation of MWM. This is currently the best known guarantee in the single-pass setting under arbitrary or adversarial ordering of edges.[2] We extend a primal-dual analysis by Ghaffari and Wajc [11] to analyze our algorithm.

The algorithm of Paz and Schwartzman [20] proceeds as follows. Initialize an empty stack S and set $\alpha_u = 0$ for each vertex $u \in V$. For each edge $e = \{u, v\}$ in the edge stream, skip e if $w_e < (1+\varepsilon)(\alpha_u + \alpha_v)$. Otherwise, compute $g_e = w_e - (\alpha_u + \alpha_v)$, push e onto the stack S, and increase both α_u and α_v by g_e. After processing all edges, compute a matching $\mathcal{M}$ greedily by popping edges from S.

[2] No single-pass algorithm can achieve an approximation ratio better than $1 + \ln 2 \approx 1.7$; see [15].

PS-MWM(V, ℓ, ε)**:**

/* each processor executes this algorithm concurrently */
1. In parallel initialize $lock_u$, and set α_u and $mark_u$ to 0 for all $u \in V$
   /* processor ℓ initializes or sets $\Theta(n/k)$ locks/variables */
2. $S^\ell \leftarrow \varnothing$ /* initialize an empty stack */
3. for each edge $e = \{u, v\}$ in ℓth stream do
   a. Process-Edge(e, S^ℓ, ε)
4. wait for all processors to complete execution of Step 3 /* a barrier */
5. $\mathcal{M}^\ell \leftarrow$ Process-Stack(S^ℓ)
6. return $\mathcal{M}^\ell$

Figure 3 A poly-streaming matching algorithm.

Note that for each edge pushed onto the stack, the increment $g_e = w_e - (\alpha_u + \alpha_v)$ satisfies $g_e \geq \varepsilon(\alpha_u + \alpha_v)$. This ensures that both α_u and α_v increase by a factor of $1 + \varepsilon$. Hence, the number of edges in the stack incident to any vertex is at most $\log_{1+\varepsilon}(W) = \mathcal{O}\left(\frac{\log W}{\varepsilon}\right)$, where W is the (normalized) maximum edge weight. Therefore, the total number of edges in the stack is $\mathcal{O}\left(\frac{n \log W}{\varepsilon}\right) = \mathcal{O}\left(\frac{n \log n}{\varepsilon}\right)$.[3]

To design a poly-streaming algorithm, we begin with a simple version and then refine it. All k processors share a global stack and a set of variables $\{\alpha_u\}_{u \in V}$, and each processor runs the above sequential streaming algorithm on its respective stream. To complete and adapt this setup for efficient execution across multiple streams, we must address two interrelated issues: (1) concurrent edge arrivals across streams may lead to contention for the shared stack or variables, and (2) concurrent updates to the shared variables may lead to inconsistencies in their observed values.

A natural approach to addressing these issues is to enforce a fair sequential strategy, where processors access shared resources in a round-robin order. While this ensures progress, it incurs $\mathcal{O}(k)$ per-edge processing time, which scales poorly with increasing k. Instead, we adopt fine-grained contention resolution that avoids global coordination by allowing processors to operate asynchronously. However, under the initial setup, this leads to $\widetilde{\mathcal{O}}(n/\varepsilon)$ per-edge processing time: a processor may be blocked from accessing shared resources until the stack has accumulated its $\widetilde{\mathcal{O}}(n/\varepsilon)$ potential edges. We address these limitations with the following design choices.

For the first issue, we observe that a global ordering of edges, as used in the single-stack solution, is not necessary; local orderings within multiple stacks suffice. In particular, we can identify a subset of edges (later referred to as *tight edges*) for which maintaining local orderings is sufficient to compute a $(2 + \varepsilon)$-approximate MWM. Hence, we can localize computation using k stacks, assigning one stack to each processor exclusively during the streaming phase. This design eliminates the $\widetilde{\mathcal{O}}(n/\varepsilon)$ contention associated with a shared stack.

[3] Throughout the paper, we assume $W = \mathcal{O}(poly(n))$. For arbitrary weights on edges, we can skip any edge whose weight is less than $\frac{\varepsilon W_{max}}{2(1+\varepsilon)n^2}$, where W_{max} denotes the maximum edge weight observed so far in the stream. This ensures that the (normalized) maximum weight the algorithm sees is $\mathcal{O}\left(n^2/\varepsilon\right)$, while maintaining a $2(1 + \mathcal{O}(\varepsilon))$ approximation ratio (see [11] for details).

Process-Edge$(e = \{u, v\}, S^\ell, \varepsilon)$**:**

/* Assumes access to global variables $\{\alpha_u\}_{u \in V}$ and locks $\{lock_u\}_{u \in V}$ */

1. if $w_e \leq (1+\varepsilon)(\alpha_u + \alpha_v)$ then return
2. repeatedly try to acquire $lock_u$ and $lock_v$ in lexicographic order of u and v as long as $w_e > (1+\varepsilon)(\alpha_u + \alpha_v)$
3. if $w_e > (1+\varepsilon)(\alpha_u + \alpha_v)$ then
   a. $g_e \leftarrow w_e - (\alpha_u + \alpha_v)$
   b. increment α_u and α_v by g_e
   c. add e to the top of S^ℓ along with g_e
4. release $lock_u$ and $lock_v$, and return

Figure 4 A subroutine used in algorithms PS-MWM and PS-MWM-LD.

However, contention still arises when updating the variables $\{\alpha_u\}_{u \in V}$. It is unclear how to resolve this contention without using additional space. Hence, we consider two strategies for processing edge streams that illustrate the trade-off between space and per-edge processing time. In the first, which we call the *non-deferrable strategy*, the decision to include an edge in a stack is made immediately during streaming. In the second, which we call the *deferrable strategy*, this decision may be deferred to post-processing. The latter strategy requires more space but achieves $\mathcal{O}(1)$ per-edge processing time.

To address the second issue, which concerns the potential for inconsistencies due to concurrent updates to the variables $\{\alpha_u\}_{u \in V}$, we observe that the variables are monotonically increasing and collectively require only $\widetilde{\mathcal{O}}(n/\varepsilon)$ updates. Thus, for most edges that are not eligible for the stacks, decisions can be made by simply reading the current values of the relevant variables. However, for the $\widetilde{\mathcal{O}}(n/\varepsilon)$ edges that are included in the stacks, we must update the corresponding variables. To ensure consistency of these updates, we associate a lock with each variable in $\{\alpha_u\}_{u \in V}$. We maintain $|V|$ exclusive locks and allow a variable to be updated only after acquiring its corresponding lock.[4]

We now outline the non-deferrable strategy of our poly-streaming algorithm for the MWM problem (for the deferrable strategy see the arXiv version). For simplicity, we assume that if a processor attempts to release a lock it did not acquire, the operation has no effect. We also assume that any algorithmic step described with the "in parallel" construct includes an implicit barrier (or synchronization primitive) at the end, synchronizing the processors participating in that step.

The non-deferrable strategy is presented in Algorithm PS-MWM, with two subroutines used by PS-MWM described in Process-Edge (Figure 4) and Process-Stack (Figure 5). In PS-MWM, Steps 1–2 form the preprocessing phase, Steps 3–4 the streaming phase, and Step 5 the post-processing phase. Each processor $\ell \in [k]$ executes PS-MWM asynchronously, except that all processors begin the post-processing phase simultaneously (due to Step 4) and then resume asynchronous execution.

In the subroutine Process-Edge, Step 2 ensures that all edges are processed using the non-deferrable strategy: a processor repeatedly attempts to acquire the locks corresponding to the endpoints of an edge $e = \{u, v\}$ until it succeeds, or the edge becomes ineligible for

[4] This corresponds to the concurrent-read exclusive-write (CREW) paradigm of the PRAM model.

Process-Stack(S^ℓ)**:**

/* Assumes access to global variables $\{\alpha_u\}_{u \in V}$; and $\{mark_u\}_{u \in V}$, initialized in Algorithm PS-MWM (or PS-MWM-LD). */

1. $\mathcal{M}^\ell \leftarrow \varnothing$
2. while $S^\ell \neq \varnothing$ do
   a. remove the top edge $e = \{u, v\}$ of S^ℓ
   b. if $w_e + g_e < \alpha_u + \alpha_v$ then wait for e to be a tight edge
      /* e is a *tight edge* if $w_e + g_e = \alpha_u + \alpha_v$ */
   c. if both $mark_u$ and $mark_v$ are set to 0 then
      /* no locking is needed since e is a tight edge */
      i. $\mathcal{M}^\ell \leftarrow \mathcal{M}^\ell \cup \{e\}$
      ii. set $mark_u$ and $mark_v$ to 1
   d. decrement α_u and α_v by g_e
3. return $\mathcal{M}^\ell$

Figure 5 A subroutine used in algorithms PS-MWM and PS-MWM-LD.

inclusion in a stack. As a result, a processor executing Step 3, has a consistent view of the variables α_u and α_v. In Step 3(c), we store the *gain* g_e of an edge e along with the edge itself for use in the post-processing phase.

When all k processors are ready to execute Step 5 of PS-MWM, the k stacks collectively contain all the edges needed to construct a $(2+\varepsilon)$-approximate MWM, which can be obtained in several ways. In the subroutine Process-Stack, we outline a simple approach based on local edge orderings. We define an edge $e = \{u, v\}$ in a stack to be a *tight edge* if $w_e + g_e = \alpha_u + \alpha_v$. Equivalently, an edge is tight if and only if all of its neighboring edges that were included after it in any stack have already been removed. Any set of tight edges can be processed concurrently, regardless of their positions in the stacks. In Process-Stack, we simultaneously process the tight edges that appear at the tops of the stacks.

3.2 Analyses

We now formally characterize several correctness properties of the algorithm and analyze its performance. These correctness properties include the absence of deadlock, livelock, and starvation. The performance metrics are space usage, approximation ratio, per-edge processing time, and total runtime.

To simplify the analysis, we assume that processors operate in a quasi-synchronous manner. In particular, to analyze Step 3 of Algorithm PS-MWM, we define an algorithmic *superstep* as a unit comprising a constant number of elementary operations.

▶ **Definition 2** (Superstep). *A processor takes one* superstep *for an edge if it executes Process-Edge with at most one iteration of the loop in Step 2 (i.e., without contention), requiring $\mathcal{O}(1)$ elementary operations. Each additional iteration of Step 2 due to contention adds one superstep, with each such iteration also requiring $\mathcal{O}(1)$ operations.*

▶ **Definition 3** (Effective Iterations). Effective iterations *is the maximum number of supersteps taken by any processor during the execution of Step 3 of Algorithm PS-MWM.*

Note that for $k = 1$, the effective iterations is equal to the number of edges in the stream. Using this notion, we align the supersteps of different processors and define the following directed graph.

▶ **Definition 4** ($G^{(t)}$). *For the* tth *effective iteration, consider the set of edges processed across all* k *streams. Let* $e_\ell = (u_\ell, v_\ell)$ *denote an edge processed in* ℓ*th stream, where* u_ℓ *precedes* v_ℓ *in the lexicographic ordering of the vertices. If processor* ℓ *is idle in the* tth *iteration, then* $e_\ell = \varnothing$. *Define* $G^{(t)} := \left(V^{(t)}, E^{(t)}\right)$, *where* $E^{(t)} := \{e_\ell \mid \ell \in [k]\}$ *and* $V^{(t)} := \bigcup_{(u_\ell, v_\ell) \in E^{(t)}} \{u_\ell, v_\ell\}$.

The following property of $G^{(t)}$ is straightforward to verify.

▶ **Proposition 5.** *$G^{(t)}$ is a directed acyclic graph.*

We show that Algorithm PS-MWM is free from deadlock, livelock, and starvation. *Deadlock* occurs when a set of processors forms a cyclic dependency, with each processor waiting for a resource held by another. *Livelock* occurs when a set of processors repeatedly form such a cycle, where each processor continually acquires and releases resources without making progress. *Starvation* occurs when a processor waits indefinitely for a resource because other processors repeatedly acquire it first. The following lemma shows that the streaming phase of Algorithm PS-MWM is free from deadlock, livelock, and starvation.

▶ **Lemma 6.** *The concurrent executions of the subroutine Process-Edge are free from deadlock, livelock, and starvation.*

Proof. Since the variables $\{\alpha_u\}_{u \in V}$ are updated only while holding their corresponding locks, we treat the locks $\{lock_u\}_{u \in V}$ as the only shared resources in Process-Edge.

Let $G^{(t)}$ be the graph defined in Definition 4. By Proposition 5, $G^{(t)}$ is a directed acyclic graph (DAG), and hence each of its components is also a DAG.

To reason about cyclic dependencies, we focus on components of $G^{(t)}$ involving processors executing Step 2 of Process-Edge. Every DAG contains at least one vertex with no outgoing edges. Thus, each such component includes an edge $e_\ell = (u_\ell, v_\ell)$ such that only processor ℓ requests $lock_{v_\ell}$. This precludes the possibility of cyclic dependencies; that is, the concurrent executions of Process-Edge is free from deadlock and livelock.

To show that starvation does not occur, suppose an edge appears in every effective iteration $t \in [a, b]$, that is, $e_\ell = (u_\ell, v_\ell) \in \bigcap_{t \in [a,b]} E^{(t)}$. We show that $b - a = \widetilde{\mathcal{O}}(n/\varepsilon)$, which bounds the number of supersteps that processor ℓ may spend attempting to acquire locks for e_ℓ. Step 2 requires one superstep per iteration, while all other steps collectively require at most one. For each $t \in (a, b]$, the component of $G^{(t-1)}$ containing e_ℓ has at least one vertex with no outgoing edge. This guarantees that at least one edge in that component acquires its locks and completes Step 3 during the $(t-1)$th effective iteration. Since Step 3 can increment the values in $\{\alpha_u\}_{u \in V}$ for at most $\mathcal{O}\left(n \log_{1+\varepsilon} W\right) = \widetilde{\mathcal{O}}(n/\varepsilon)$ edges over the entire execution, the number of iterations for which e_ℓ may remain blocked is also bounded by $\widetilde{\mathcal{O}}(n/\varepsilon)$. ◀

To analyze Step 5 of Algorithm PS-MWM, we adopt the same simplification: processors are assumed to operate in a quasi-synchronous manner. Accordingly, we define $\mathcal{U}^{(t)}$ as the set of edges present in the stacks $\bigcup_{\ell \in [k]} S^\ell$ at the beginning of iteration t of Step 2 in Process-Stack. The following definition is useful for characterizing tight edges via an equivalent notion.

▶ **Definition 7** (Follower). *An edge $e_j \in \mathcal{U}^{(t)}$ is a* follower *of an edge $e_i \in \mathcal{U}^{(t)}$ if $e_i \cap e_j \neq \varnothing$ and e_j is added to some stack S^j after e_i is added to some stack S^i. We denote the set of followers of an edge e by $\mathcal{F}(e)$.*

The proofs of the following four lemmas are included in the arXiv version. The fourth lemma establishes that the post-processing phase of PS-MWM is free from deadlock, livelock, and starvation.

▶ **Lemma 8.** *An edge e is a tight edge if and only if $\mathcal{F}(e) = \varnothing$.*

▶ **Lemma 9.** *Let $\mathcal{T}^{(t)}$ be the set of top edges in the stacks at the beginning of iteration t of Step 2 of Process-Stack. Then $\mathcal{T}^{(t)}$ contains at least one tight edge.*

▶ **Lemma 10.** *The set of tight edges in $\mathcal{U}^{(t)}$ is vertex-disjoint.*

▶ **Lemma 11.** *The concurrent executions of the subroutine Process-Stack are free from deadlock, livelock, and starvation.*

We now analyze the performance metrics of the algorithm.

▶ **Lemma 12.** *For any constant $\varepsilon > 0$, the space complexity and per-edge processing time of Algorithm PS-MWM are $\mathcal{O}(k + n \log n)$ and $\mathcal{O}(n \log n)$, respectively. Furthermore, for $L_{min} = \Omega(n)$, the amortized per-edge processing time of the algorithm is $\mathcal{O}(\log n)$.*

Proof. The claimed space bound follows from three components: $\mathcal{O}(n)$ space for the variables and locks, $\mathcal{O}(n \log n)$ space for the stacked edges, and $\mathcal{O}(1)$ space per processor.

The worst-case per-edge processing time follows from the second part of the proof of Lemma 6.

Processor ℓ processes $|E^\ell|$ edges, each requiring at least one distinct effective iteration (see Definition 3). Additional iterations may arise when it repeatedly attempts to acquire locks in Step 2 of Process-Edge. From the second part of the proof of Lemma 6, the total number of such additional iterations is bounded by $\mathcal{O}(n \log n)$. This implies that to process $|E^\ell|$ edges, a processor ℓ uses $\mathcal{O}\left(|E^\ell| + n \log n\right)$ supersteps. Therefore, the amortized per-edge processing time is

$$\mathcal{O}\left(\frac{|E^\ell| + n \log n}{|E^\ell|}\right) = \mathcal{O}\left(\frac{n \log n}{|E^\ell|}\right) = \mathcal{O}\left(\frac{n \log n}{L_{min}}\right) = \mathcal{O}(\log n). \quad \blacktriangleleft$$

Note that the amortized per-edge processing time is computed over the edges of an individual stream, not over the total number of edges across all streams. While both forms of amortization are meaningful for poly-streaming algorithms, our analysis is more practically relevant, as it reflects the cost incurred per edge arrival within a single stream.

▶ **Lemma 13.** *For any constant $\varepsilon > 0$, Algorithm PS-MWM takes $\mathcal{O}(L_{max} + n \log n)$ time.*

Proof. The preprocessing phase (Steps 1–2) takes $\Theta(n/k)$ time.

To process $|E^\ell|$ edges, processor ℓ takes $\mathcal{O}\left(|E^\ell| + n \log n\right)$ supersteps (see the proof of Lemma 12). Since $|E^\ell| \leq L_{max}$ for all $\ell \in [k]$, the time required for Step 3 is $\mathcal{O}(L_{max} + n \log n)$.

At the beginning of Step 5, the total number of edges in the stacks is $\mathcal{U}^{(1)} = \mathcal{O}(n \log n)$. By Lemma 9, iteration t of Process-Stack removes at least one edge from $\mathcal{U}^{(t)}$. Hence, the time required for Step 5 is $\mathcal{O}(n \log n)$.

The claim now follows by summing the time spent across all three phases. ◀

Now, using the characterizations of tight edges, we extend the duality-based analysis of [11] to our algorithm. Let Δ_α^e denote the change in $\sum_{u\in V}\alpha_u$ resulting from processing an edge $e \in E^\ell$ in Step 3 of Process-Edge. If an edge $e \in E^\ell$ is not included in a stack S^ℓ, then $\Delta_\alpha^e = 0$, either because it fails the condition in Step 1 or Step 3 of Process-Edge. It follows that $\sum_{e\in\bigcup_{\ell\in L} E^\ell}\Delta_\alpha^e = \sum_{u\in V}\alpha_u$. For an edge e that is included in some stack S^i, let $\mathcal{P}(e)$ denote the set of edges that share an endpoint with e and are included in some stack S^j no later than e including e itself. The following two results are immediate from Observation 3.2 and Lemma 3.4 of [11].

▶ **Proposition 14.** *Any edge e added to some stack S^ℓ satisfies the inequality*

$$w_e \geq \sum_{e'\in\mathcal{P}(e)} g_{e'} = \frac{1}{2}\left(\sum_{e'\in\mathcal{P}(e)}\Delta_\alpha^{e'}\right).$$

▶ **Proposition 15.** *After all processors complete Step 3 of Algorithm PS-MWM, the variables $\{\alpha_u\}_{u\in V}$, scaled by a factor of $(1+\varepsilon)$, form a feasible solution to the dual LP in Figure 2.*

▶ **Lemma 16.** *Let $\mathcal{M}^*$ be a maximum weight matching in G. The matching $\mathcal{M} := \bigcup_{l\in[k]}\mathcal{M}^\ell$ returned by Algorithm PS-MWM satisfies $w(\mathcal{M}) \geq \frac{1}{2(1+\varepsilon)}w(\mathcal{M}^*)$.*

Proof. We only process tight edges in Process-Stack. By Lemma 10 tight edges are vertex disjoint, and hence their independent processing does not interfere with their inclusion in $\mathcal{M}$.

By Lemma 8, an edge e included in $\mathcal{M}$ must satisfy $\mathcal{F}(e) = \varnothing$. Consider any edge $e' \in \mathcal{P}(e)\backslash\{e\}$. Since $e \in \mathcal{F}(e')$, we have $\mathcal{F}(e') \neq \varnothing$, which means e' is not a tight edge before e is processed. Thus, when e is selected for inclusion in $\mathcal{M}$, none of the edges in $\mathcal{P}(e)\backslash\{e\}$ is tight. Hence, all edges of $\mathcal{P}(e)$ are in the stacks when we are about to process e. Therefore, the total gain contributed by edges of $\mathcal{P}(e)$ can be attributed to the weight of e, and by Proposition 14, we have

$$\begin{aligned} w(\mathcal{M}) = \sum_{e\in\mathcal{M}} w_e &\geq \frac{1}{2}\left(\sum_{e\in\mathcal{M}}\sum_{e'\in\mathcal{P}(e)}\Delta_\alpha^{e'}\right) \geq \frac{1}{2}\left(\sum_{e\in\bigcup_{\ell\in[k]} S^\ell}\Delta_\alpha^e\right) \\ &= \frac{1}{2}\left(\sum_{e\in\bigcup_{\ell\in[k]} E^\ell}\Delta_\alpha^e\right) = \frac{1}{2}\left(\sum_{u\in V}\alpha_u\right). \end{aligned}$$

Let $\{x_e^*\}_{e\in E}$ be an optimal solution to the primal LP in Figure 2. By Proposition 15 and LP duality we have

$$w(\mathcal{M}^*) \leq \sum_{e\in E} w_e x_e^* \leq (1+\varepsilon)\left(\sum_{u\in V}\alpha_u\right) \leq 2(1+\varepsilon)w(\mathcal{M}). \qquad \blacktriangleleft$$

Algorithm PS-MWM uses only one pass over the streams. Theorem 1 now follows by combining the results in Lemma 12, Lemma 13, Lemma 16, and the analysis of the *deferrable strategy* sketched in the arXiv version.

4 Algorithms for Non-Uniform Memory Access Costs

In this section, we extend the algorithm from Section 3 to account for the non-uniform memory access (NUMA) costs present in real-world machines.

PS-MWM-LD(V, l, j, ε)**:**

1. In parallel initialize $lock_u$, and set α_u and $mark_u$ to 0 for all $u \in V$
   /* processor ℓ initializes or sets $\Theta(n/k)$ locks/variables */
2. In parallel initialize $lock_u^j$, and set α_u^j to 0 for all $u \in V$
   /* processor ℓ initializes or sets $\Theta(n/(k/r))$ locks / variables */
3. In parallel initialize $glock^j$ /* one processor initializes for group j */
4. $S^\ell \leftarrow \varnothing$ /* initialize an empty stack */
5. for each edge $e = \{u, v\}$ in ℓth stream do
   a. Process-Edge-LD(e, S^ℓ, ε)
6. wait for all processors to complete execution of Step 4 /* a barrier */
7. $\mathcal{M}^\ell \leftarrow$ Process-Stack(S^ℓ)
8. return $\mathcal{M}^\ell$

Figure 6 A generalization of Algorithm PS-MWM using local dual variables.

In a poly-streaming algorithm, each processor may receive an arbitrary subset of the input, making it difficult to maintain memory access locality. Modern shared-memory machines, as illustrated in Figure 1, have non-uniform memory access costs and far fewer memory controllers than processors [12]. As a result, memory systems with such limitations would struggle to handle the high volume of concurrent, random memory access requests generated by poly-streaming algorithms, leading to significant delays.

We now describe a generalization of the algorithm from Section 3 that localizes a significant portion of each processor's memory access to its near memory. This generalization applies to both edge-processing strategies introduced in Section 3.1. We focus on the *non-deferrable strategy*. (The deferrable strategy generalizes in the same way, following the same relationship between the two strategies as in the specialized case.)

The runtime of Process-Edge is dominated by the time to access the dual variables $\{\alpha_u\}_{u \in V}$. By assigning a dedicated stack to each processor, we have substantially localized accesses associated with edges in that stack. However, since a large fraction of edges is typically not included in the stacks, the runtime remains dominated by accesses to dual variables associated with these discarded edges. We therefore describe an algorithm that localizes these accesses to memory near the processor.

To localize accesses to the dual variables $\{\alpha_u\}_{u \in V}$, we observe that these variables increase monotonically during the streaming phase. This observation motivates a design in which a subset of processors maintains local copies of the variables and can discard a substantial number of edges without synchronizing with the global copy. When a processor includes an edge in its stack, it increments the corresponding dual variables in the global copy by the gain of the edge and synchronizes its local copy accordingly. As a result, some local copies may lag behind the global copy, but they can be synchronized when needed.

A general scheme for allocating dual variables is as follows. The set of k processors is partitioned into r groups. For simplicity, we assume that k is a multiple of r, so each group contains exactly k/r processors. For $r > 1$, in addition to a global copy of dual variables, we maintain r *local copies* $\{\alpha_u^j\}_{u \in V}$, one for each $j \in [r]$. Group j consists of the processors $\{\ell \in [k] \mid \lfloor \ell/(k/r) \rfloor = j\}$, and uses $\{\alpha_u^j\}_{u \in V}$ as its local copy of the dual variables. Algorithm PS-MWM is the special case $r = 1$, where all processors operate using only the global copy of the dual variables.

Process-Edge-LD$(e = \{u, v\}, S^{\ell}, \varepsilon)$**:**

/* Assumes access to $\{\alpha_u\}_{u \in V}$, $\{lock_u\}_{u \in V}$, $\{\alpha_u^j\}_{u \in V}$, $\{lock_u^j\}_{u \in V}$, and $glock^j$ */

1. if $w_e \leq (1+\varepsilon)(\alpha_u^j + \alpha_v^j)$ then return
2. repeatedly try to acquire $lock_u^j$ and $lock_v^j$ in lexicographic order of u and v as long as $w_e > (1+\varepsilon)(\alpha_u^j + \alpha_v^j)$
3. if $w_e \leq (1+\varepsilon)(\alpha_u^j + \alpha_v^j)$ then release $lock_u^j$ and $lock_v^j$, and return
4. repeatedly try to acquire $glock^j$
5. Process-Edge$(e, S^{\ell}, \varepsilon)$
6. $\alpha_u^j \leftarrow \alpha_u$ and $\alpha_v^j \leftarrow \alpha_v$ /* synchronization of local and global dual variables */
7. release $lock_u^j$, $lock_v^j$, $glock^j$ and return

Figure 7 A subroutine used in Algorithm PS-MWM-LD.

Algorithm PS-MWM-LD, along with its subroutine Process-Edge-LD, incorporates local dual variables in addition to global ones. In Step 2, processors in each group $j \in [r]$ collectively initialize their group's local copies of dual variables and locks, followed by initializing a group lock in Step 3. All other steps of the algorithm are identical to those in PS-MWM.

In the subroutine Process-Edge-LD, Step 5 implements the non-deferable strategy. Steps 1–3 and Step 6 enforce the localization of access to dual variables. Steps 2–3 ensure that, at any given time, each global dual variable is accessed by at most one processor per group; we refer to this processor as the *delegate* of the group for that variable. Thus, a processor executing Steps 4–6 serves as a delegate of its group for that time. In Step 6, after completing updates to the global variables, the delegate synchronizes its group's local copy in $\mathcal{O}(1)$ time. As a result, the waiting time on a local variable in Step 2 is bounded by the total time spent by the corresponding delegates, up to constant factors.

The delegates in each group handle vertex-disjoint edges, so concurrent executions of Step 6 would have been safe. However, the lock in Step 4 ensures that at most one delegate per group executes Step 5. Regardless of these design choices, the behavior of the delegates executing Step 5 concurrently mirrors that of processors competing for exclusive access to global dual variables in PS-MWM.

The following lemma highlights the benefit of using Algorithm PS-MWM-LD.

▶ **Lemma 17.** *For any constant $\varepsilon > 0$, in the streaming phase of Algorithm PS-MWM-LD, processors in all r groups collectively access global variables a total of $\mathcal{O}(r \cdot n \log n)$ times.*

In contrast to the result in Lemma 17, the streaming phase of Algorithm PS-MWM accesses global variables $\Omega(m)$ times or up to $\mathcal{O}(m + k \cdot n \log n)$ times.

Algorithm PS-MWM-LD, together with the generalization of the deferrable strategy, leads to the following result (a proof is included in the arXiv version).

▶ **Theorem 18.** *Let k processors be partitioned into r groups, each with its own shared local memory. For any constant $\varepsilon > 0$, there exists a* single-pass *poly-streaming algorithm for the maximum weight matching problem that achieves a $(2+\varepsilon)$-approximation. It admits a CREW PRAM implementation with $\widetilde{\mathcal{O}}(L_{max} + n)$ runtime. If $L_{min} = \Omega(n)$, the algorithm achieves $\mathcal{O}(\log n)$ amortized per-edge processing time using $\widetilde{\mathcal{O}}(k + r \cdot n)$ space. For arbitrarily balanced streams, it uses either $\widetilde{\mathcal{O}}(k + r \cdot n)$ space and $\widetilde{\mathcal{O}}(n)$ per-edge processing time, or $\widetilde{\mathcal{O}}(k \cdot n)$ space and $\mathcal{O}(1)$ per-edge processing time. The processors collectively access the global memory $\widetilde{\mathcal{O}}(r \cdot n)$ times.*

Table 1 Summary of datasets. Each collection contains eight graphs.

Graph Collection	# of Edges (in billions)
The *SSW graphs*	1.36 – 127.4
The *BA graphs*	4.64 – 550.1
The *ER graphs*	256 – 4096
The *UA-dv graphs*	275.2 – 550.1
The *UA graphs*	8.93 – 1100
The *ER-dv graphs*	32 – 4096

5 Empirical Evaluation

This section summarizes our evaluation results for Algorithm PS-MWM-LD. Detailed datasets, experimental setup, and additional comparisons (including with PS-MWM) are provided in the arXiv version.

5.1 Datasets

Table 1 summarizes our datasets. Each collection consists of eight graphs, with edge counts ranging from one billion to four trillion. To the best of our knowledge, these represent some of the largest graphs for which matchings have been reported in the literature. Exact and approximate offline MWM algorithms (see [22]) would exceed available memory on the larger graphs. The first class (SSW) consists of six of the largest graphs from the SuiteSparse Matrix collection [5] and two from the Web Data Commons [19], which includes the largest publicly available graph dataset. Other classes include synthetic graphs generated from the Barabási–Albert (BA), Uniform Attachment (UA), and Erdős–Rényi (ER) models [1, 7, 21].

5.2 Experimental Setup

We ran all experiments on a community cluster called Negishi [17], where each node has an AMD Milan processor with 128 cores running at 2.2 GHz, 256–1024 GB of memory, and the Rocky Linux 8 operating system version 8.8. The cores are organized in a hierarchy: groups of eight cores constitute a core complex that share an L3 cache. Eight core complexes form a socket, and they share four dual-channel memory controllers; two sockets constitute a Milan node [12]. Memory access within a socket is approximately three times faster than across sockets.

We implemented the algorithms in `C++` and compiled the code using the *gcc* compiler (version 12.2.0) with the `-O3` optimization flag. For shared-memory parallelism, we used the OpenMP library (version 4.5). All experiments used $\varepsilon = 1e - 6$. Reported values are the average over five runs.

5.3 Space

Figure 8 summarizes the space usage of our algorithm. For $k = 1$, the algorithm of Paz and Schwartzman [20], we store one copy of the dual variables, stack, and matching. For $k > 1$, our algorithm stores $r + 1$ copies of the dual variables (global and local), stacks, matching, and locks. We choose the values of r based on the number of memory controllers and the number of streams.

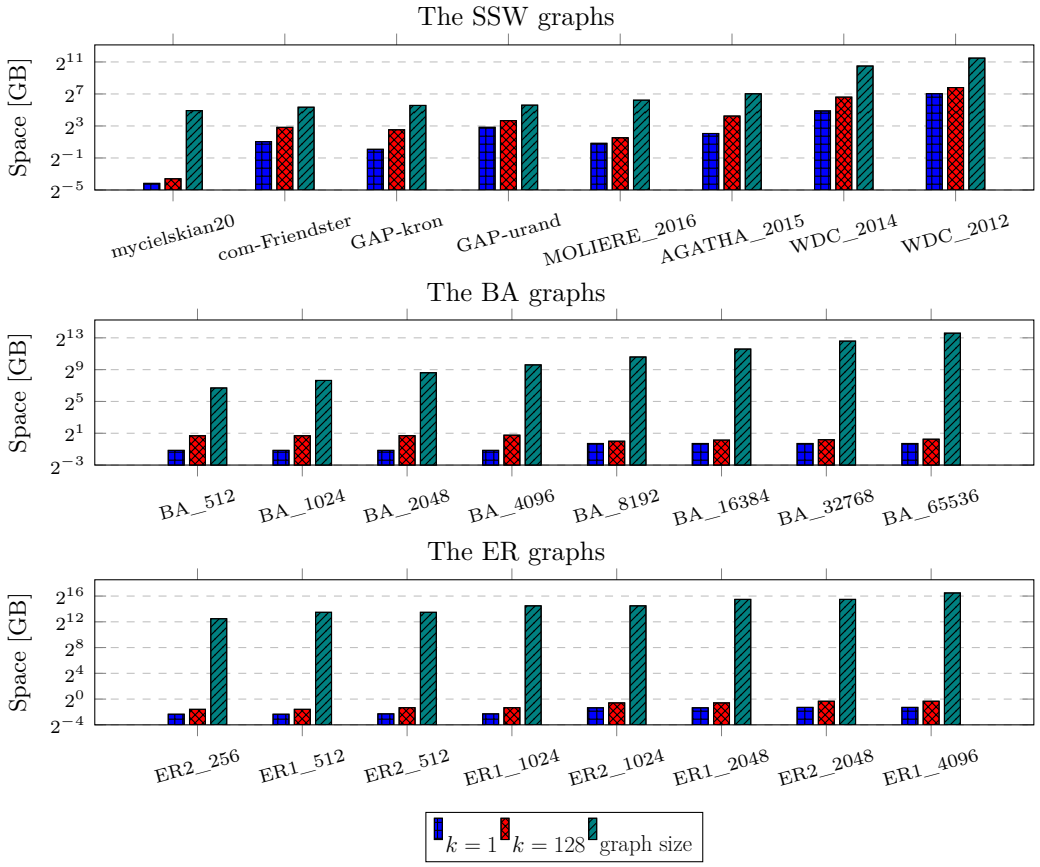

Figure 8 Memory used by the algorithm and the corresponding *graph size* (space needed to store the entire graph in CSR format). Note that the y-axes are in a logarithmic scale.

The maximum space used by our algorithm is 223 GB, for the web graph WDC_2012. In comparison, storing this graph in compressed sparse row (CSR) format would require over 2800 GB. Storing the largest graph in our datasets (ER1_4096) in CSR would require more than 91,600 GB (89.45 TB), for which our algorithm used less than 0.8 GB.

5.4 Solution Quality

min-OPT percent. In the arXiv version, we describe different ways to get *a posteriori* upper bounds on the weight of a MWM $w(M^*)$, using the values of the dual variables. Let Y_{min} denote the minimum value of these upper bounds. If $\mathcal{M}$ is a matching in the graph returned by any algorithm, then we have $\frac{w(\mathcal{M})}{w(\mathcal{M}^*)} \geq \frac{w(\mathcal{M})}{Y_{min}}$. Hence, $\frac{w(\mathcal{M})}{Y_{min}} \times 100$ gives a lower bound on the percentage of the maximum weight $w(\mathcal{M}^*)$ obtained by $\mathcal{M}$. We use *min-OPT percent* to denote the fraction $\frac{w(\mathcal{M})}{Y_{min}} \times 100$.

Figure 9 shows min-OPT percent obtained by different algorithms. In the arXiv version, we describe four dual update rules as alternatives to the default rule used in Steps 3(a)–(b) of Process-Edge. The values under $k = 1$ and $k = 128$ use the default rule, and the values under *ALG-d* use the best result among the four new dual update rules. For perspective, we include min-OPT percent obtained by the sequential 6-approximate streaming algorithm of Feigenbaum et al. [8], denoted *ALG-s*.

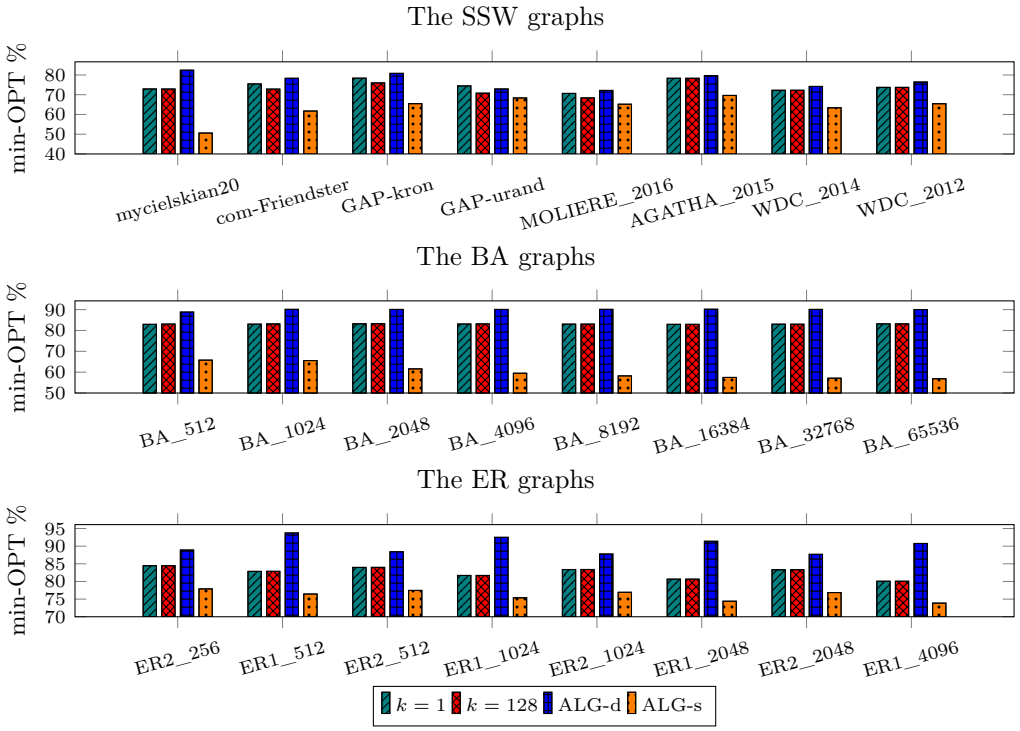

Figure 9 Comparisons of *min-OPT percent* obtained by different algorithms. *ALG-d* denotes the best results from four dual update rules, and *ALG-s* denotes the algorithm of Feigenbaum et al. [8].

The results under $k = 1$ and $k = 128$ show that, in terms of solution quality, our poly-streaming algorithm is on par with the single-stream algorithm of [20]. The values under *ALG-d* indicate further potential improvements using alternative dual update rules. The comparison with *ALG-s* supports our choice of the algorithm from [20] over other simple algorithms, such as that of [8]. The arXiv version contains comparisons with an offline algorithm and details on the dual update rules.

5.5 Runtime

We report runtime-based speedups, computed as the total time across all three phases of PS-MWM-LD (preprocessing, streaming, and post-processing). Figure 10 shows these speedups. For $k = 128$, we have speedups of $16 - 60$, $37 - 73$, and $68 - 83$ for the SSW graphs, the BA graphs, and the ER graphs, respectively.

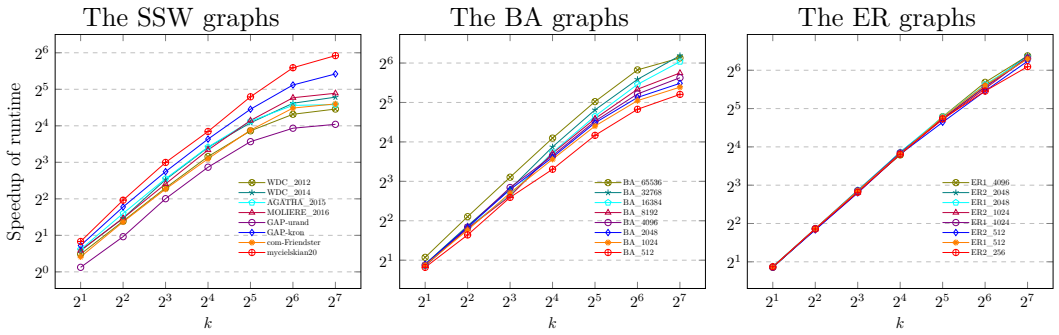

Figure 10 Speedup in runtime vs. k. Note that both axes are in a logarithmic scale.

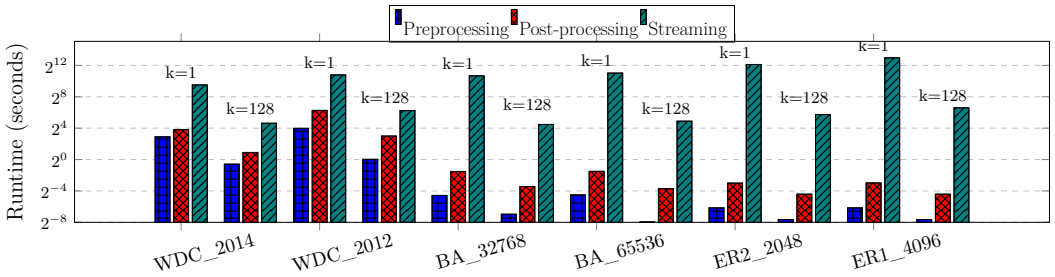

Figure 11 Breakdown of runtime into three phases for $k = 1$ and $k = 128$. Note that the y-axis is in a logarithmic scale.

Due to the significant memory bottlenecks (discussed in Section 4), we also report speedups w.r.t. *effective iterations* (Definition 3), which are less affected by such bottlenecks. The speedup w.r.t. effective iterations is the ratio of the metric for one stream to that for k streams. Now for $k = 128$, we obtain speedups of $112 - 127$, $121 - 127$, and $124 - 128$ for the SSW graphs, the BA graphs, and the ER graphs, respectively. These results indicate that shared variable access incurs no noticeable contention among processors. As a result, we expect even better runtime improvements on systems with more memory controllers or better support for remote memory access.

Figure 11 shows the runtimes for different graphs, decomposed into three phases, for $k = 1$ and $k = 128$. The plots report the absolute time savings achieved by processing multiple streams concurrently. For $k = 1$ and $k = 128$, the geometric means of the runtimes for these graphs are over 2350 seconds and under 45 seconds, respectively. For the largest graph (ER1_4096), single-stream processing took over 8000 seconds, whereas poly-stream processing reduced the time to under 100 seconds.

6 Conclusion

While numerous studies have focused on optimizing time (in parallel computing) or space (in streaming algorithms) in isolation, the poly-streaming model offers a *practically relevant paradigm* for exploring how time and space can be jointly optimized. It fills a gap by providing a formal framework for analyzing algorithmic design choices and their associated time-space trade-offs. Our study of matchings illustrates both the benefits of this paradigm and its practical relevance.

The simplicity of our matching algorithm and its generalization reflect our choice to adopt the design of [20]. We believe this principle will inspire the development of other poly-streaming algorithms. To this end, we note that [20] has also motivated simple algorithms for related problems, such as matchings with submodular objectives [16], b-matchings [14], and collections of disjoint matchings [9].

Abstract

Data structures on a multiset of genomic k-mers are at the heart of many bioinformatic tools. As genomic datasets grow in scale, the efficiency of these data structures increasingly depends on how well they leverage the inherent patterns in the data. One recent and effective approach is the use of learned indexes that approximate the rank function of a multiset using a piecewise linear function with very few segments. However, theoretical worst-case analysis struggles to predict the practical performance of these indexes.

We address this limitation by developing a novel measure of piecewise-linear approximability of the data, called CaPLa (Canonical Piecewise Linear approximability). CaPLa builds on the empirical observation that a power-law model often serves as a reasonable proxy for piecewise linear-approximability, while explicitly accounting for deviations from a true power-law fit. We prove basic properties of CaPLa and present an efficient algorithm to compute it. We then demonstrate that CaPLa can accurately predict space bounds for data structures on real data. Empirically, we analyze over 500 genomes through the lens of CaPLa, revealing that it varies widely across the tree of life and even within individual genomes. Finally, we study the robustness of CaPLa as a measure and the factors that make genomic k-mer multisets different from random ones.

1 Introduction

Data structures on k-mers (fixed-length strings) originating from genomes form a crucial component of many bioinformatics tools [22]. Their space usage is now a major bottleneck at the forefront of biological discovery. For example, the Logan project needed two petabytes to index the 31-mers from the Sequence Read Archive [7]. Existing data structures often meet the space challenge by exploiting the non-uniform structure of genomic k-mer sets [6]. In doing so, they circumvent [2, 17, 23, 28] the theoretical worst- and average-case lower bounds, which offer a more pessimistic perspective [25].

A popular approach is based on learned indexes, a recent research direction that takes advantage of the internal patterns in the rank curve of a dataset [5, 10, 18, 32]. The rank of an element x in a multiset S is defined as the position of the first occurrence of x in the sorted list of S. A learned index is constructed from S and, given a query k-mer, returns an error-bounded prediction for its rank. Initial approaches used machine learning to construct the index [13, 14, 15], but it later turned out that in this setting, it is more effective to model the rank curve using a piecewise linear approximation [2, 4, 17], as depicted in Figure 1.

Learned indexes based on piecewise linear approximations (PLAs) of the rank curve have resulted in practically groundbreaking time/space tradeoffs, both on genomic [2, 8, 17] and other kinds of data [8, 11, 12, 16, 19, 20, 21, 31]. However, existing theoretical worst-case analyses only show improved performance under assumptions that are unrealistic for genomic datasets, such as the independence and identical distribution of gaps between k-mers [9]. This leaves a gap between the theoretical analysis of k-mer-based learned indexes and their much better performance on real data [2, 17]. By better understanding and characterizing the structural properties of genomic k-mer sets, we can not only better predict the performance of learned indexes but also drive the development of new PLA-based tools that maximally exploit the properties of real data.

Our approach in this paper is to develop a measure of piecewise linear (PL) approximability which can be used to parameterize the theoretical analysis of PLA-based methods. Parameterizing string complexity is an active area of research [26], but none of the existing measures capture the PL-approximability of a genome's rank curve. Previous papers have proposed modeling the PL-approximability of S using a power-law [9, 11], and have implicitly used the two parameters of a power-law fit as proxies for the PL-approximability of S. However, the interpretation of such parameters is limited when the rank curve strays from a power-law, as (we will show) occurs in real genomic data.

We develop a novel measure of PL-approximability, which we call CaPLa (Canonical PL-approximability) (Section 2). It builds on the idea of a power-law fit but adds the uncertainty of the fit as part of the measure. We prove basic properties of CaPLa, including its existence, and give an algorithm to compute it (Section 3). The algorithm is exact under certain conditions of the data, which we empirically show are nearly always met in practice. We demonstrate how CaPLa can be applied to derive space bounds that accurately reflect properties of real data (Section 4).

Finally, we apply CaPLa to analyze genome spectra, where a spectrum is the multiset of all k-mers appearing in a string.[1] We use a dataset of more than 500 genomes and find that CaPLa varies greatly across the tree of life and even within individual genomes (Section 5). We also show that CaPLa is a good predictor of the space usage of a learned index data structure (the PLA-index [2]). We use controlled experiments to elucidate what

[1] Our tool for computing CaPLa is available at `https://github.com/medvedevgroup/CaPLa`.

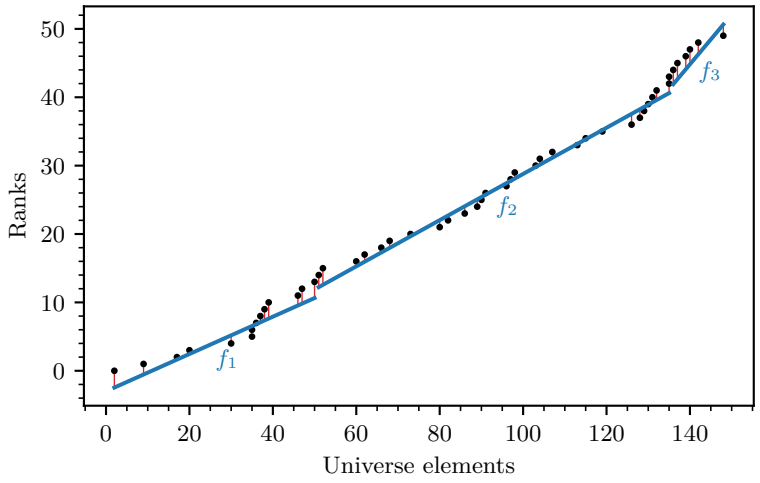

Figure 1 An example multiset S of size $N = 50$ with $n = 48$ distinct elements drawn from a universe of size $u = 150$, plotted as points $\{(x, \text{RANK}_S(x)\}_{x \in S}$ on the plane. The points are approximated using a PLA with error bound $\varepsilon = 2$, where the vertical orange lines show the error. The PLA uses 3 segments, which is the smallest possible for S at $\varepsilon = 2$, so $b(\varepsilon) = 3$.

makes genome spectra different from random k-mer multisets. Finally, we verify that CaPLa has some of the desired properties of a measure of genome complexity, namely robustness to variation in genome or k-mer size. Our work helps reduce the gap between theory and practice and aims to deepen our understanding of when and how to best apply PLA-based indexes to real genomic data.

2 PL-approximability definitions and motivation

In this section, we present the key definitions of PL-approximability and the motivation behind them. We start with a multiset S of elements from an integer universe $[u] = \{0, 1, \ldots, u-1\}$. In the case of k-mers, $u = 4^k$, though our definitions work for any u. We will use the notation that n is the number distinct and N is the total number of elements in S. The function we will be approximating is defined as $\text{RANK}_S(x) = |\{y \in S \mid y \leq x\}|$, for all $x \in [u]$. The key tool in designing PLA-based learned data structures [2, 8, 11, 12, 17] is the following:

▶ **Definition 1** (Piecewise linear ε-approximation). *For a given positive integer ε, a* piecewise linear ε-approximation (PLA) *of S is a partition of $[u]$ into subintervals such that, for each subinterval $[a_i, b_i]$, there exists a segment (i.e., a linear function) f_i such that $|f_i(x) - \text{RANK}_S(x)| \leq \varepsilon$ for all $x \in [a_i, b_i]$.*

Figure 1 shows an example of a PLA. The usefulness of a PLA comes from the fact that a data structure can avoid storing the full rank function and instead just store the PLA, as long as it has a way to handle the uncertainty due to the error of the approximation. To this end, the PLA with the smallest number of segments is the most space-efficient representation. Such a PLA can also be computed efficiently [27]. As a result, minimum-sized PLAs have formed the basis of several data structures [2, 8, 11, 19, 21, 31]. We formalize it with the following definition.

▶ **Definition 2** (PLA-size). *The* PLA-size *of S is the function $b\colon \mathbb{Z}^+ \to \mathbb{Z}^+$ mapping a positive integer ε to the smallest integer $b(\varepsilon)$ such that there exists a piecewise linear ε-approximation of S using exactly $b(\varepsilon)$ segments.*

In this paper, we introduce a closely related measure, but one that factors out the effect of the data size.

▶ **Definition 3** (PL-approximability). *The* PL-approximability *of S is the function mapping a positive integer ε to $\frac{n}{b(\varepsilon)}$, where $b(\varepsilon)$ is the PLA-size of S.*

The PL-approximability of S can be interpreted as the longest average number of elements spanned by a segment in a PLA of S, so it directly quantifies the efficiency of a PLA in capturing the structure and distribution of the underlying data.

The space and time performance of learned data structures based on PLAs are often bounded in terms of the PLA-size [2, 8, 11]. Typically, smaller values of ε lead to faster query times, but require a larger number of segments $b(\varepsilon)$ and thus increased space. The PLA-size and PL-approximability can then be tabulated for a given dataset and plugged into these space- and time-bounds to assess the resulting space-time trade-off. However, this approach provides little insight into broader trends and differences among data distributions. Ideally, the PL-approximability could be modeled as a parametrized family of functions, such that fitting this family to S yields parameters that fully capture the PL-approximability of S.

A key difficulty is that the shape of the PLA-size function varies significantly depending on the structure and distribution of the underlying data. In general, the PLA-size is bounded between $b(\varepsilon) = 1$ and $b(\varepsilon) = N/(2\varepsilon)$ for all ε [11]. For sets where the gaps between elements are random and independently drawn, the PLA-size has been shown to be $b(\varepsilon) = \mathcal{O}(N/\varepsilon^2)$ [9]. For real data, the PLA-size rarely admits a closed-form expression, but power-law relations of the form $b(\varepsilon) = n/(\beta\varepsilon^\alpha)$ have been empirically observed [9, 11]. Here, β and α are dataset-specific constants found through fitting to the tabulated PLA-size. This power-law modeling provides a degree of generality, but when the PLA-size does not exactly follow a power-law, it has several drawbacks. Figure 2 demonstrates that this type of modeling 1) has a high variability in the error, 2) is not robust to the choice of fitting algorithm, and 3) is unpredictable in whether it over- or under-estimates the true PLA-size. Such drawbacks make it challenging to incorporate this type of model into downstream analyses of data structures, especially since its predictions are neither worst- nor average-case bounds.

To address this challenge, we propose bounding the PLA-size using two power laws instead of relying on a single fitted curve. We first fix a finite set $\mathcal{E} \subset \mathbb{Z}^+$ of ε values for which the PL-approximability is evaluated. This reflects practical applications, where ε is chosen from a set of values according to the desired space-time trade-off.

▶ **Definition 4** (Bounded PL-approximability). *The PL-approximability of S is power-law bounded over $\mathcal{E}$ with parameters $(\alpha, \beta_{\text{low}}, \beta_{\text{high}})$ if*

$$\beta_{\text{low}}\varepsilon^\alpha \leq \frac{n}{b(\varepsilon)} \leq \beta_{\text{high}}\varepsilon^\alpha \quad \text{for all } \varepsilon \in \mathcal{E}. \tag{1}$$

When $\beta_{\text{low}} = \beta_{\text{high}}$, this is equivalent to a perfect power-law fit. The role of α is to capture the rate of segment growth as a function of ε. If $\beta_{\text{low}} = \beta_{\text{high}}$, then when ε doubles, the average segment length increases by a factor of 2^α. There is similarly an intuitive interpretation of β_{low} and β_{high}: when $\varepsilon = 1$, the average segment length is between β_{low} and β_{high}.

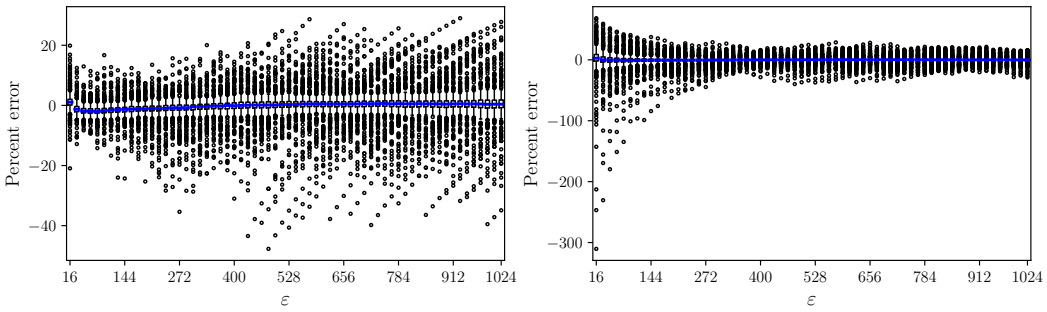

Figure 2 Errors due to fitting a single power-law curve to the PLA-size of a set of 513 genomes (dataset details are in Section 5.1). The left panel models the relationship as $n/b(\varepsilon) = \beta\varepsilon^{\alpha}$ and uses Python's *scipy.optimize.curve_fit* with the Levenberg–Marquardt algorithm to estimate α and β. The right panel uses the model $\log(n/b(\varepsilon)) = \alpha \log \varepsilon + \log \beta$ and applies Python's *scipy.stats.linregress* to estimate α and β. For each $\varepsilon \in \{16, 32, 48, 64, \ldots, 1024\}$, we calculate the percent error between $b(\varepsilon)$ and the prediction $n/(\beta\varepsilon^{\alpha})$ and show a box plot of the distribution aggregated over the 513 genomes (with the median line colored in blue).

Definition 4 captures a full spectrum of data distributions and their PLA-size, from the best case $b(\varepsilon) = 1$ (with $\alpha = 0$ and $\beta_{\text{low}} = \beta_{\text{high}} = n$), to the worst case $b(\varepsilon) = N/(2\varepsilon)$ from [11] (with $\alpha = 1$ and $\beta_{\text{low}} = \beta_{\text{high}} = 2n/N$), to the case of random gaps from [9] (with $\alpha = 2$ and $\beta_{\text{low}} = \beta_{\text{high}} = cn/N$ for a constant $c > 0$). More importantly, it enables bounding the PL-approximability of real datasets where an exact power-law fitting is not possible.

The PL-approximability of a single dataset can be power-law bounded for infinitely many values of $\alpha, \beta_{\text{low}}$, and β_{high}. To capture a single parameterization that can be used as a proxy for the PL-approximability of a dataset, we introduce the following notion of *canonical PL-approximability*.

▶ **Definition 5** (CaPLa). *A pinch point of S is any α^* that satisfies*

$$\alpha^* = \operatorname*{argmin}_{\alpha \geq 0} \big(H(\alpha) - L(\alpha)\big), \quad \textit{where} \quad L(\alpha) = \min_{\varepsilon \in \mathcal{E}} \frac{n}{\varepsilon^{\alpha} b(\varepsilon)}, \quad H(\alpha) = \max_{\varepsilon \in \mathcal{E}} \frac{n}{\varepsilon^{\alpha} b(\varepsilon)}. \tag{2}$$

If a unique pinch point α^* exists, then we let $\beta^*_{\text{low}} = L(\alpha^*)$ and $\beta^*_{\text{high}} = H(\alpha^*)$ and say that S has a canonical PL-approximability (CaPLa) of $(\alpha^*, \beta^*_{\text{low}}, \beta^*_{\text{high}})$. Otherwise, we say that the CaPLa of S is undefined.

We note that if S has CaPLa $(\alpha^*, \beta^*_{\text{low}}, \beta^*_{\text{high}})$, then Equation 1 immediately implies that S is power-law bounded with parameters $(\alpha^*, \beta^*_{\text{low}}, \beta^*_{\text{high}})$.

3 Existence and computation of the canonical PL-approximability

In this section, we show under which conditions the canonical PL-approximability exists and how it can be efficiently computed. We do so by introducing a geometric object, the *twisted ribbon*, which captures the entire family of valid power-law bounds for S. We then study the structural properties of this ribbon to identify a *pinch point*, which yields the canonical PL-approximability (Definition 5). Finally, we describe a two-phase algorithm that efficiently locates a pinch point based on the twisted ribbon's geometry.

We first observe that, for any given α, the tightest possible power-law bound on the PL-approximability of S is given by choosing β_{low} and β_{high} as $L(\alpha)$ and $H(\alpha)$, respectively. The proof follows easily from the definitions of L and H.

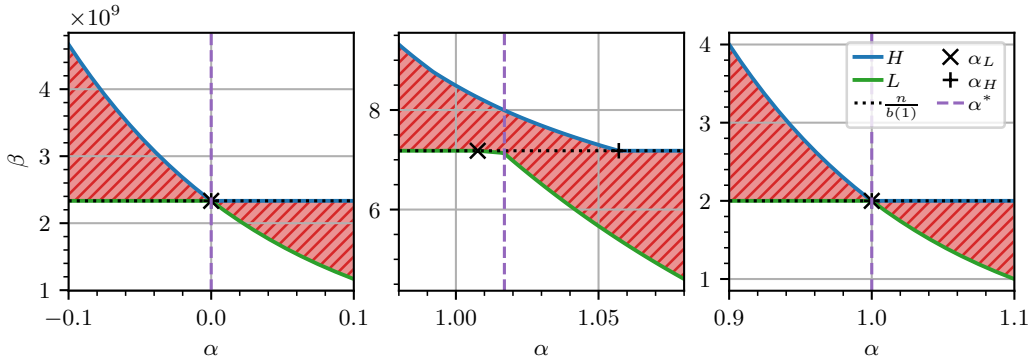

Figure 3 On the left, a twisted ribbon corresponding to a set S giving the best case $b(\varepsilon) = 1$ for any $\varepsilon \in \{1, \ldots, 1024\}$. On the center, a twisted ribbon derived from the human genome (T2TCHM13v2.0). On the right, a twisted ribbon corresponding to a set S giving the worst case $b(\varepsilon) = N/(2\varepsilon)$ for any ε. For symmetry with the other plots, the left plot extends to values of $\alpha < 0$ despite the ribbon being formally defined for $\alpha \geq 0$.

▶ **Lemma 6.** *For any $\alpha \geq 0$ and $\delta > 0$, we have that (i) S is power-law bounded over $\mathcal{E}$ with parameters $(\alpha, L(\alpha), H(\alpha))$, and (ii) S is not power-law bounded over $\mathcal{E}$ with parameters $(\alpha, L(\alpha) + \delta, H(\alpha) - \delta)$.*

We can plot the functions H and L on a Cartesian plane with α along the horizontal axis and β along the vertical axis. The region enclosed between these two curves forms the aforementioned twisted ribbon, depicted in Figure 3 and formally defined as follows.

▶ **Definition 7** (Twisted ribbon)**.** *The twisted ribbon of S is the region in the α-β space enclosed between the curves $L(\alpha)$ and $H(\alpha)$ for any $\alpha > 0$. Formally, the twisted ribbon of S is the set $\mathcal{R}_S = \{(\alpha, \beta) \in \mathbb{R}^2_{\geq 0} \mid L(\alpha) < \beta < H(\alpha), \alpha \geq 0\}$.*

Observe that choosing β_{low} or β_{high} inside of the twisted ribbon (that is, setting $\beta_{\text{low}} > L(\alpha)$ or $\beta_{\text{high}} < H(\alpha)$ for some α) would violate Equation 1, and therefore would not yield a valid bound on the PL-approximability of S. This reduces the space of relevant power-law bounds to that of $\{(\alpha, L(\alpha), H(\alpha))\}_{\alpha \geq 0}$.

We further aim to summarize this entire family of bounds into a single representative instance. Intuitively, this means identifying a value of α that yields the tightest bound. This corresponds to a value α^* that minimizes the twisted ribbon width $W(\alpha) = H(\alpha) - L(\alpha)$, i.e., what we call a pinch point (Definition 5).

To study the existence and computation of a pinch point, we first show some structural properties of the twisted ribbon. For technical convenience, we assume that the (nonincreasing integer) function $b(\varepsilon)$ has been extended to a continuous, nonincreasing, and differentiable function on the reals, e.g., via monotone cubic interpolation.

▶ **Lemma 8.** *If $1 \in \mathcal{E}$ and $|\mathcal{E}| > 1$, then:*

- **(i)** *H and L are continuous functions.*
- **(ii)** *For any $\alpha \geq 0$, it holds $0 \leq L(\alpha) \leq \frac{n}{b(1)} \leq H(\alpha) \leq \frac{n}{b(\varepsilon_{\max})}$, where $\varepsilon_{\max} = \max \mathcal{E}$.*
- **(iii)** *There exists a value α_L such that $L(\alpha) = \frac{n}{b(1)}$ for $\alpha \leq \alpha_L$, and $L(\alpha_L + \delta)$ decreases as $\delta > 0$ increases. We call α_L a flattening point of S.*
- **(iv)** *There exists a value α_H such that $H(\alpha) = \frac{n}{b(1)}$ for $\alpha \geq \alpha_H$, and $H(\alpha_H - \delta)$ increases as $\delta > 0$ increases. We also call α_H a flattening point of S.*
- **(v)** *The flattening points satisfy $\alpha_L \leq \alpha_H$.*

Note that the lemma holds for any dataset, as its conditions are related to a parameter ($\mathcal{E}$) chosen by the user. The following result shows that a pinch point exists and is confined between (or at) the flattening points mentioned in Lemma 8 and depicted in Figure 3.

▶ **Theorem 9.** *If $1 \in \mathcal{E}$ and $|\mathcal{E}| > 1$, then a pinch point α^* of S exists and is guaranteed to lie in the interval $[\alpha_L, \alpha_H]$, where α_L and α_H are the flattening points of S.*

We now focus on finding a pinch point, that is, on solving the problem $\operatorname{argmin}_{\alpha \geq 0} W(\alpha)$. Observe W is non-differentiable due to the presence of min and max operations. Moreover, we assume that W is *unimodal*, namely, it has a unique minimum α^*, is strictly decreasing for all $\alpha < \alpha^*$, and strictly increasing for $\alpha > \alpha^*$. While we do not have any general theoretical guarantee on the unimodality of W (except in simple cases such as those shown in the left and right plots of Figure 3), our empirical observation suggests that unimodality often holds in practice (see Section 5.5). If this is not the case, our algorithm finds a local minimum instead. We also assume $b(\varepsilon)$ has been precomputed for all $\varepsilon \in \mathcal{E}$, allowing $W(\alpha)$ to be evaluated in $\mathcal{O}(|\mathcal{E}|)$ time via a direct computation based on Equation 2. This precomputation can be done in $\mathcal{O}(N|\mathcal{E}|)$ time [27].

The algorithm works in two phases. In the first phase, we identify the flattening points α_L and α_H by observing from Lemma 8 that α_L is the smallest value of α such that $\frac{n}{\varepsilon^\alpha b(\varepsilon)} = \frac{n}{b(1)}$ for some $\varepsilon \in \mathcal{E} \setminus \{1\}$. This equality simplifies to $\alpha = \log_\varepsilon \frac{b(1)}{b(\varepsilon)}$, so we obtain $\alpha_L = \min_{\varepsilon \in \mathcal{E} \setminus \{1\}} \log_\varepsilon \frac{b(1)}{b(\varepsilon)}$, which can be computed in $\mathcal{O}(|\mathcal{E}|)$ time. A similar derivation with max instead of min yields α_H.

In the second phase, we run a derivative-free minimization algorithm (golden-section search) within the interval $[\alpha_L, \alpha_H]$, which is guaranteed to contain α^* due to Theorem 9. It converges in $\lceil \log_\phi \frac{\alpha_H - \alpha_L}{\tau} \rceil$ iterations, where τ is the desired tolerance, and $\phi \approx 1.618$ is the golden ratio [29]. Since the cost of each iteration is dominated by the evaluation of $W(\alpha)$, the overall time complexity of finding the pinch point is $\mathcal{O}(|\mathcal{E}| \log \frac{\alpha_H - \alpha_L}{\tau})$. This gives the following theorem.

▶ **Theorem 10.** *Suppose the ribbon width $W(\alpha) = H(\alpha) - L(\alpha)$ is unimodal, $1 \in \mathcal{E}$, and $|\mathcal{E}| > 1$. Suppose the value $b(\varepsilon)$ has been precomputed for all $\varepsilon \in \mathcal{E}$ in $\mathcal{O}(N|\mathcal{E}|)$ time. Then, there exists an algorithm that finds the pinch point α^* in $\mathcal{O}(|\mathcal{E}| \log \frac{\alpha_H - \alpha_L}{\tau})$ time, where τ is the desired tolerance.*

Section 5.1 will show that the runtime of this algorithm is on the order of a few milliseconds in practice.

4 Using PL-approximability bounds in downstream applications

There are a number of PLA-based learned data structures whose space-time performance is bounded in terms of the PLA-size, such as the PGM-index [11, Theorem 1], LeMonHash [8, Theorem 2], and the PLA-index [2, Theorem 1]. In this section, we showcase how our PL-approximability framework can be used to reinterpret such bounds, focusing on the PLA-index as a concrete example particularly relevant in genomic applications. The PLA-index has been applied to substantially improve the run time of suffix array search and decrease the space of a read aligner and direct-access lookup tables [2].

The PLA-index uses a piecewise linear ε-approximation to a multiset of k-mers S to estimate the rank of a query k-mer in S [2]. The tuning parameter ε represents a time/space trade-off, with smaller ε values resulting in faster index query times but more segments.

Theorem 1 in [2] describes the size of the PLA-index as a function of the number of segments used by the PLA index (denoted by s_ε), N, and ε:

$$s_\varepsilon(2k - \lg \frac{s_\varepsilon^{31/16}}{N(1+4\varepsilon)} + \mathcal{O}(1)). \tag{3}$$

As s_ε can be high in the worst case, Equation 3 does not capture the fact that the space is very low in practice.

Here, we show that if S has a power-law bounded PL-approximability, then Equation 3 can be turned into a useful predictor of PLA-index space usage. One of the technical difficulties is that PL-approximability gives bounds on the PLA size $b(\varepsilon)$, whereas Equation 3 is stated in terms of s_ε. Though the PLA-index uses a segmentation based on the optimal one, it requires consecutive segments to share an endpoint and in some rare cases breaks segments. This dependence of s_ε on $b(\varepsilon)$ is difficult to quantify in terms of S. Instead, we isolate the dependence by expressing our results in terms of $\gamma_\varepsilon \triangleq \frac{s_\varepsilon}{b(\varepsilon)}$. Though γ_ε is theoretically unknown (except that $\gamma_\varepsilon \geq 1$), empirical results show that it is close to one on genome spectra. For example, for the 21-spectrum of chromosome 1 of the human genome, γ_ε values are below 1.21 for all tested ε up to $\varepsilon = 1023$.

▶ **Theorem 11.** *Let S be a multiset of k-mers, with n distinct elements, N total elements. Suppose the PL-approximability of S is $(\alpha, \beta_{\text{low}}, \beta_{\text{high}})$ power-law bounded over $\mathcal{E}$. Let B_ε be the number of bits used by the PLA-index on S with tuning parameter ε. Then, for all $\varepsilon \in \mathcal{E}$, we have that*

$$f(\beta_{\text{high}}, \beta_{\text{low}}) \leq B_\varepsilon \leq f(\beta_{\text{low}}, \beta_{\text{high}}),$$

where

$$f(\beta_1, \beta_2) = \frac{n\gamma_\varepsilon}{\beta_1 \varepsilon^\alpha}\left(2k - \frac{15 \lg n}{16} + \left(\frac{31 \log_\varepsilon(\beta_2 \varepsilon^\alpha)}{16} + 1\right)\lg \varepsilon + C\right), \tag{4}$$

and $C = c - \frac{31 \lg \gamma_\varepsilon}{16} + \lg N/n$ and, for large enough $\frac{n}{\beta_{\text{high}}\varepsilon^\alpha}$, c is a number between 5 and 7.

We have isolated and combined some terms into a variable C, in order to convey that they can be thought of as constants in practice. First, N/n is in practice smaller than 2 when avoiding small values of k, for which a suffix array would not make sense as an application anyway. Second, as we mentioned earlier, γ_ε is in practice a number close to 1.

Interpreting Eq. 4 is helped by the observation that given the type of values we see in practice, the dominating term is the leading one, i.e. $1/(\beta_1 \varepsilon^\alpha)$. This intuition is confirmed by Figure 4AB, which plots Eq. 4 using real numbers from human chromosome 1. As suggested by the leading term, increasing the α value of a dataset by δ results in the leading term decreasing by a factor of ε^δ, with the plots confirming this type of exponential decay for Eq. 4 overall. Note that for $\varepsilon = 63$ (Panel A), the decay is slower than for $\varepsilon = 1023$ (Panel B), as expected from the leading term. Figure 4CD shows how the gap between β_{low} and β_{high} affects the gap between the upper and lower bounds of Theorem 11 and gives the scale of the gap at which our bounds become meaningless.

5 Experimental results

The goal of our experiments is threefold. First, we want to understand how much PL-approximability varies among the tree of life. Second, we want to understand the properties of genome spectra that make them different from random k-mer multisets. Finally, we want to evaluate the suitability of CaPLa as a measure of PL-approximability. Our tool for computing CaPLa, as well as reproducibility information, is available through GitHub at `https://github.com/medvedevgroup/CaPLa`.

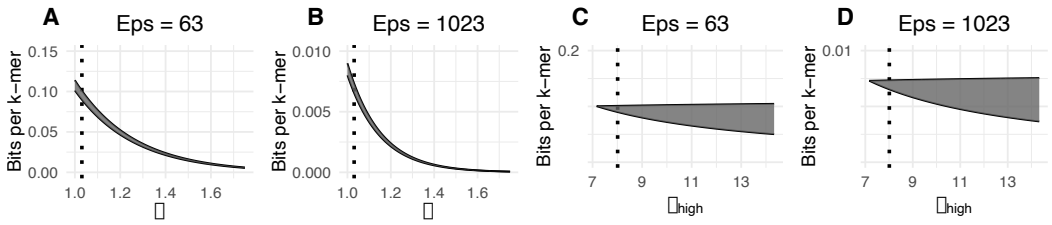

Figure 4 Analysis of space usage of PLA index, as predicted by Theorem 11, plugging in $C = 6$. In each panel, the shaded area is bounded from above by the upper bound curve and below by the lower bound curve. We use values corresponding to human chromosome 1 with $k = 21$: $n = 195,735,278$, $\alpha^* = 1.03$, $\beta^*_{\text{low}} = 7.2$, and $\beta^*_{\text{high}} = 8.0$, $\gamma_{63} = 1.13$ and $\gamma_{1023} = 1.15$. In panels A and B, we fix $\beta_{\text{low}} = \beta^*_{\text{low}}$ and $\beta_{\text{high}} = \beta^*_{\text{high}}$ while varying α. The vertical dotted line corresponds to $\alpha = \alpha^*$. In panels C and D, we fix the values of $\alpha = \alpha^*$ and $\beta_{\text{low}} = \beta^*_{\text{low}}$ and vary β_{high}. The vertical dotted line corresponds to $\beta_{\text{high}} = \beta^*_{\text{high}}$.

5.1 Experimental setup

Data. We downloaded a sample of RefSeq genomes that are complete and full, do not have any missing bases, and are longer than 10,000nt. We further filtered out any genomes for which the number of segments at $\varepsilon = 1024$ was 1 (i.e. $b(1024) = 1$). This excludes genomes that are too trivial to offer meaningful insight and for which the PL-approximability becomes trivially dominated by n. We process the genomes to make everything uppercase, remove any letters that are not A, C, G, or T, and concatenate all contigs into a single string. The resulting dataset contains 513 genomes, representing the kingdoms of virus (91 genomes), bacteria (200 genomes), archaea (200 genomes), and fungi (22 genomes). The median genome length was 2.98 mil and the maximum was 63 mil . We also downloaded six other larger genomes: *C. elegans*, *P. yoelii*, *M. commoda*, *O. lucimarinus*, and the latest high-quality assemblies of the human (T2TCHM13v2.0) and Gorilla genomes .

Tool. Our tool to compute CaPLa takes a genome, a k-mer size, and $\mathcal{E}$, builds a suffix array of the genome using libdivsufsort [24], computes the values $\{b(\varepsilon)\}_{\varepsilon\in\mathcal{E}}$ using O'Rourke's algorithm [27] on the genome's k-mers (extracted in sorted order using the suffix array), and then computes CaPLa using the algorithm of Theorem 10 with tolerance $\tau = 1.49 \times 10^{-8}$ (i.e., the square root of the machine epsilon). We use $\mathcal{E}$ as the set of all integers from 1 to 1024, and $k = 21$ by default. We also construct the PLA-index [2] for $\varepsilon \in \{32, 64\}$ for all genomes, using $k = 21$ as in previous works [2, 17]. Full details, including the accession number of the genomes, their CaPLa values, PLA-index sizes, and other associated information are available at our GitHub repository.

Runtime. For runtime analysis, we used a machine with a 2.10 GHz Intel Xeon CPU E5-2683 v4 processor with 512 GB of memory. To give a sense of the execution time of our pipeline, for a RefSeq genome of median length (GCF_001870125, 2.98M bases), it takes 0.318 s to construct the suffix array, 730.979 s to compute the values $\{b(\varepsilon)\}_{\varepsilon\in\mathcal{E}}$, and 0.006 seconds to run the algorithm of Theorem 10. Thus, the runtime of the algorithm of Theorem 10 is negligible and we do not investigate it further. A more detailed analysis of the runtime of computing $b(\varepsilon)$ values is covered in other papers (e.g. [2]); since it is not a contribution of our work, we do not expand on those studies here.

CaPLa comparison. At first glance, comparing CaPLa values across genomes may seem challenging, as α^* has a larger impact on the PL-approximability than β^*_{low} or β^*_{high}, due to its presence in the exponent of ε in Equation 1. However, the values are easier to compare when the user has a desired query time, i.e. when we think of ε as being fixed. In this case, we define the *ε-mapped CaPLa* as the following two values: $\rho_{\text{low}} = \alpha + \log_\varepsilon \beta_{\text{low}}$ and $\rho_{\text{high}} = \alpha + \log_\varepsilon \beta_{\text{high}}$. The PL-approximability power-law bound (Equation 1) can then be rewritten in terms of ρ_{low} and ρ_{high}, i.e. $\varepsilon^{\rho_{\text{low}}} \leq n/b(\varepsilon) \leq \varepsilon^{\rho_{\text{high}}}$. This replaces the three variables of CaPLa with two variables which, moreover, are now directly comparable between genomes. We can further average ρ_{low} and ρ_{high} to get the *averaged ε-mapped CaPLa*, which becomes useful for looking at CaPLa distributions across large datasets.

Table 1 CaPLa of the RefSeq dataset and of six additional genomes. The first row corresponds to all of the RefSeq dataset, while the later four rows separate the dataset into Kingdoms. Note that percentiles are not reported for the last six rows because each row corresponds to a single genome.

	α^*			β^*_{low}			β^*_{high}		
Category	5th%	Mean	95th%	5th%	Mean	95th%	5th%	Mean	95th%
RefSeq dataset	1.03	1.09	1.16	4.8	7.4	8.6	7.1	9.0	11.1
Virus	1.06	1.12	1.19	3.4	5.6	7.9	7.1	8.6	10.8
Bacteria	1.03	1.08	1.12	6.4	7.8	8.6	7.0	9.1	11.2
Archaea	1.03	1.07	1.12	6.7	7.8	8.6	7.2	8.9	10.7
Fungi	1.08	1.12	1.17	6.5	8.2	9.0	7.3	10.3	12.5
C. elegans		1.06			7.4			8.2	
P. yoelii		1.00			5.5			6.1	
M. commoda		1.06			7.4			8.2	
O. lucimarinus		1.06			7.4			8.1	
Human		1.02			7.1			8.0	
Gorilla		1.00			7.1			7.9	

5.2 Understanding the scale of CaPLa

Table 1 shows the CaPLa values for our data. But, to make sense of the variability, we need to first understand how variations in CaPLa values translate into variations in the space of downstream data structures. The theoretical predictions of Theorem 11 allow such an analysis for the case of the PLA-index. To simplify the analysis, we consider the case that PL-approximability follows a perfect power law, i.e. there is a β^* such that $\beta^* = \beta^*_{\text{low}} = \beta^*_{\text{high}}$. As Theorem 11 and Figure 4 indicated, the total bits per k-mer is approximately $\frac{\gamma_\varepsilon}{\beta^* \varepsilon^{\alpha^*}}$. When α^* increases by an additive factor of δ, then the approximate space decreases by a multiplicative factor of $1 - \varepsilon^{-\delta}$; when β^* increases by a multiplicative factor of δ, then the approximate space decreases by a multiplicative factor of $\frac{\delta}{\delta+1}$. Table 2 shows these numbers for some concrete values that we encounter in our data. For example, in the bacterial genomes, the α^* values increase by 0.1 from the 5th and 95th percentiles (Table 1); Table 2 shows that this corresponds to a decrease in space of 32% for the PLA index with $\varepsilon = 64$. Thus the variability in CaPLa across RefSeq corresponds to a substantial variability in predicted bits per k-mer of the associated PLA-index.

5.3 Variation of CaPLa among the tree of life

To better understand the distributions of CaPLa among different kingdoms, Figure 5AC shows the distributions of the averaged ε-mapped CaPLa. The fungi kingdom has a noticeably higher CaPLa. The difference is substantial, as is reflected in the lower PLA-index space

Table 2 The effect of CaPLa on PLA-index space. We show the decrease in bits per distinct k-mer when adding δ to α (left columns) and multiplying β by $(1+\delta)$ (right columns). The numbers without parenthesis indicate the predicted decrease using $\frac{\gamma_\varepsilon}{\beta^* \varepsilon \alpha^*}$, the leading term of Equation 4. The numbers in parenthesis indicate the change predicted by the full form of Theorem 11, using $C = 6$ and the real values from human chromosome 1 with $k = 21$ ($n = 195,735,278$, $\alpha^* = 1.0309$, $\beta^*_{\text{low}} = 7.1645$, and $\beta^*_{\text{high}} = 8.0119$, $\gamma_{63} = 1.13$ and $\gamma_{32} = 1.13$).

	$\alpha \leftarrow \alpha + \delta$			$\beta \leftarrow \beta(1+\delta)$	
	$\delta = 0.01$	$\delta = 0.05$	$\delta = 0.1$	$\delta = 0.1$	$\delta = 0.5$
$\varepsilon = 32$	3% (3%)	16% (15%)	29% (28%)	9% (9%)	33% (32%)
$\varepsilon = 64$	4% (4%)	19% (18%)	34% (32%)	9% (9%)	33% (32%)
$\varepsilon = 1024$	7% (6%)	29% (28%)	50% (48%)	9% (9%)	33% (32%)

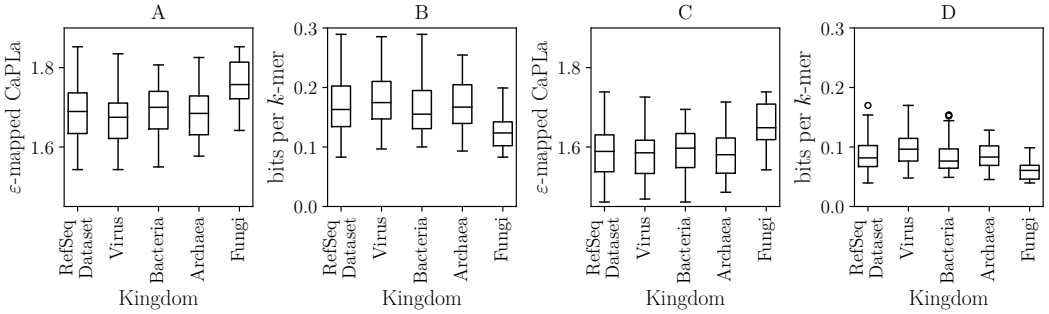

Figure 5 Distribution of averaged ε-mapped CaPLa across RefSeq. Panels A and C show the values for $\varepsilon = 32$ and $\varepsilon = 64$, respectively. Panels B and D show the distribution of bits per distinct k-mer in the constructed PLA indexes. In each panel, the left box plot is for our whole RefSeq dataset, while the remaining four box plots correspond to subsets according to Kingdoms.

usage of fungi genomes compared to the other kingdoms (Figure 5BD). The reasons for this could be due to biological factors but could also be due to biases in the type of genomes that have been sequenced and/or deposited into RefSeq.

Figure 6 shows the space usage of the PLA index and breaks down the relationship between bits per distinct k-mer and the CaPLa separately for each genome. The variation is substantial, with space differences as big as threefold between different RefSeq genomes. Furthermore, the figure shows a strong correlation between CaPLa and bits per distinct k-mer of the PLA-index.

We also split the human genome into its 24 constituent chromosome sequences. Figure 7 shows that CaPLa varies substantially across the chromosomes, indicating that PL-approximability varies not only between different species but also within the genome of a single species. Figure 7 also shows a similar pattern for the chromosomes of the Gorilla genome. Chromosome Y, which is known for being highly repetitive, is an outlier in both species, with substantially lower CaPLa than other chromosomes.

In spite of the CaPLa variability, our results give a general range of CaPLa for genomes that are not part of our dataset. This gives a user with a new genome sequence a robust estimate of the expected efficiency of a PLA-based learned index. This is in contrast with datasets from other domains that have been shown to roughly fit a power-law curve with significantly different α values, such as $\alpha = 1.8$ on book popularity data, $\alpha = 1.4$ on Facebook user IDs, and $\alpha = 2$ on random gaps [9].

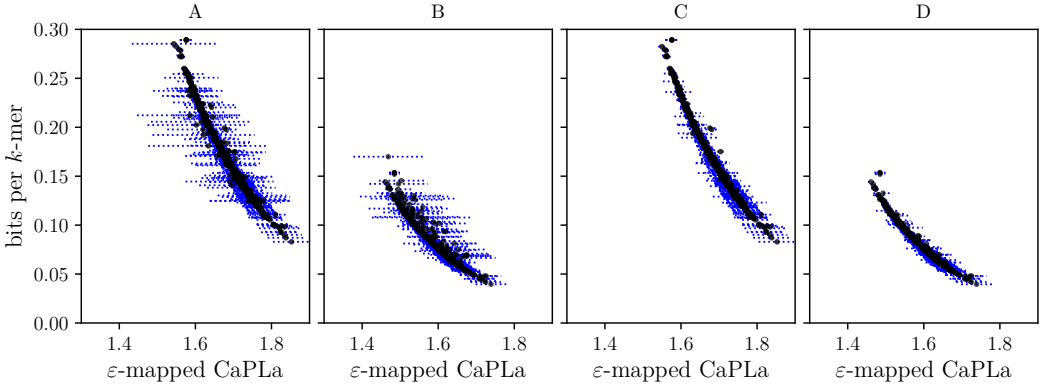

Figure 6 Relation between the bits per distinct k-mer of the PLA-index to the ε-mapped CaPLa for the RefSeq dataset. Panel A shows the result for $\varepsilon = 32$ and Panel B for $\varepsilon = 64$. Each dashed horizontal line represents the range of the ε-mapped CaPLa for a single genome and each black dot represents an averaged ε-mapped CaPLa for a single genome. Panels C and D show the same information as panels A and B, but we additionally filter out all genomes that are shorter than $80,000$nt. For such shorter genomes, the constant overhead of the PLA-index data structures starts to dominate the part that makes use of the PL-approximation; as the plot shows, most of the widest horizontal lines in panels A and B are gone after filtering out the shorter genomes.

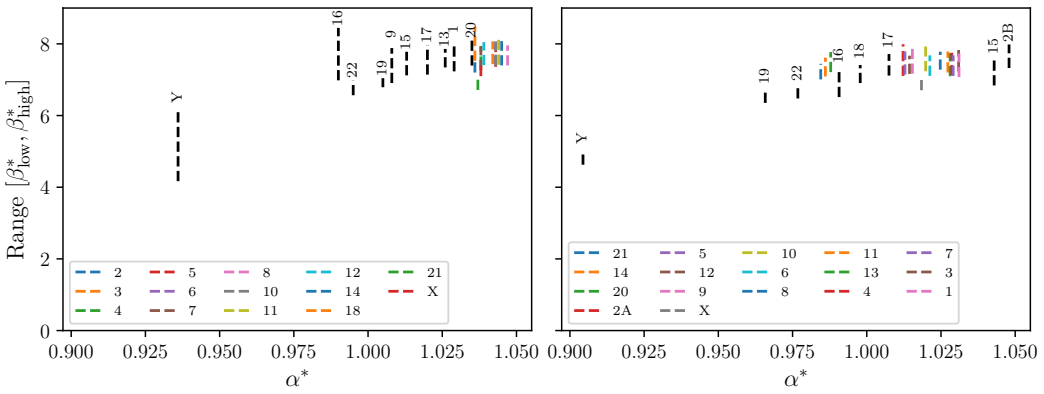

Figure 7 CaPLa of Human (left) and Gorilla (right) chromosomes. Each vertical segment is labeled with the corresponding chromosome, either in the legend or directly above the segment.

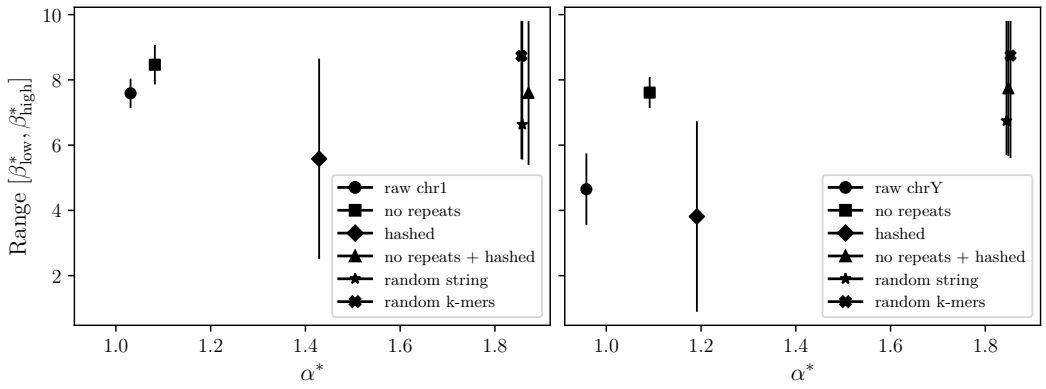

Figure 8 PL-approximability of a genome spectrum versus a random k-mer multisets. The left and right panels show human chromosomes 1 and Y, respectively, for $k = 21$. The y-axis shows the range from β^*_{low} to β^*_{high}. The random string and the random k-mers are generated so as to match the number of k-mers in the raw sequence.

5.4 What makes a genome spectrum special?

Figure 8 shows a huge difference between the CaPLa of human chromosome 1 ($\alpha^* = 1.03$) and a random multiset of k-mers of the same size ($\alpha^* = 1.86$). Theorem 11 predicts a 26-fold difference in the size of the corresponding PLA indexes, at $\varepsilon = 64$. We therefore wanted to tease out the effect of several factors which distinguish a genome spectrum from a random multiset. The first factor is that the k-mers of a genome spectrum must be overlapping, i.e. not all multisets of k-mers can be put together into a continuous genome sequence, even allowing for chromosome breaks. To test the effect of this, we create a random string with the same length as chr1 and find that it also had $\alpha^* = 1.86$. Thus, this factor does not seem to play a role, at least in isolation.

A second effect is that chr1 is not random but is evolved to have a biological function. One consequence is that the genome has k-mers which appear more than once, which is rare in a random string of the same length (for $k = 21$). To test the effect of this, we make a linear scan of chr1 and clip out any encountered k-mer which we have previously seen. In this way, we create a genome-like string which is nearly repeat-free. We found $\alpha^* = 1.08$ for this low-repeat string, suggesting that repeats do negatively affect the PL-approximability.

Another consequence of having a biological function is that the spectrum of a genome has a non-uniform distribution. To test the effect of this, we process the k-mers of chr1 with a hash function and use the hashed value as the basis for the rank function. This has the effect of making the distribution uniform. The resulting $\alpha^* = 1.43$ shows that the non-uniform distribution of the k-mers in a spectrum substantially decreases the PL-approximability.

Finally, we combined the two effects by removing repeats and then hashing the k-mers, getting an $\alpha^* = 1.87$, the same as a random multiset. This indicates that the two factors have an interplay which drives down the PL-approximability a lot when combined.

We repeated the same experiments on the Y chromosome (Figure 8). The effects were similar, though the effect of removing repeats was more pronounced (α^* rose from 0.96 to 1.09). This was expected, as the Y is known to be more repetitive than chromosome 1 [30].

5.5 Stability of CaPLa as a measure

Uniqueness of pinch point. We conducted brute-force tests to investigate whether in our data the pinch point is unique (i.e. CaPLa is well defined), and to verify whether the unimodality assumption required by our algorithm in Theorem 10 holds in practice. Specifically, for each genome in the RefSeq dataset, we sampled the twisted ribbon width $W(\alpha)$ at uniformly spaced α-values within the interval $[\alpha_L, \alpha_H]$ containing a pinch point (Theorem 9), using a step size of 10^{-6}. We then checked for the presence of multiple minima within a numerical tolerance of $\tau = 1.49 \times 10^{-8}$, and verified unimodality by looking for a decreasing and increasing trend before and after the minimum, respectively.

We found that the pinch point was unique in all of the 513 RefSeq genomes. Furthermore, the unimodality assumption was not met in only 11 datasets. Even in those 11 cases, the algorithm of Theorem 10 avoided local minima and matched the brute-force pinch point in all but one instance, where the actual pinch point was nonetheless close (within 3.23×10^{-2}). In summary, up to the tested step size, CaPLa was defined for all genomes and our efficient algorithm returned the correct value in all but one case.

Genome length. A desirable property of a measure of PL-approximability is that it is not causally dependent on genome length and is only an intrinsic property of a genome's rank curve. To verify this, we compare the lengths of our RefSeq genomes with their α^*, β^*_{low}, and β^*_{high} values, respectively, as well as to the ε-mapped CaPLa, for $\varepsilon \in \{2, 4, 8, \ldots, 1024\}$. The Pearson correlation coefficient (R^2) is less than 0.02 for all comparisons, providing evidence that the relationship between CaPLa and genome length is negligible.

***k*-mer size.** The structure of the rank curve is unavoidably dependent on k, because for small k, the number of repeats and the density of S with respect to the universe gets high. Ideally, when k is above the threshold where spurious repeats are rare, CaPLa should stabilize. To validate this, we looked at the behavior of CaPLa with respect to k for the RefSeq dataset and for bigger mammalian genomes. Figure 9 shows six genomes, which we manually selected to capture the phylogenetic diversity of the data. We measure the averaged ε-mapped CaPLa for $\varepsilon = 64$. The plots show that indeed CaPLa plateaus at some point between $k = 16$ and $k = 21$, depending on the genome. The difference between the averaged ε-mapped CaPLa values at $k = 26$ and $k = 31$ was less than 0.01 for all six genomes, both for $\varepsilon = 64$ (Figure 9) and $\varepsilon = 32$ (data not shown). Similarly, between $k = 21$ and $k = 26$, the differences in α^* values were less than 0.4% and the difference in the β^*_{low} and β^*_{high} values were less than 4%. These results provide strong evidence that the CaPLa is relatively stable for large enough values of k, and, in particular, for values of $k \geq 21$.

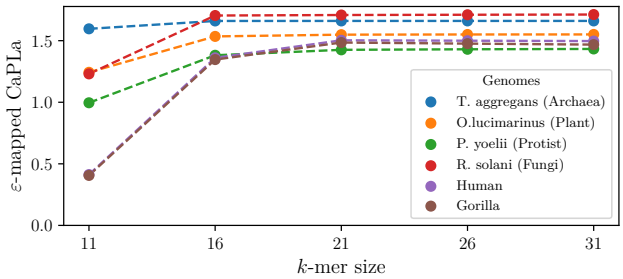

Figure 9 Effect of k-mer size on CaPLa, for $\varepsilon = 64$, using averaged ε-mapped CaPLa

Accuracy of prediction. We compare the space range predicted by plugging in CaPLa into Theorem 11 with the true space taken by the PLA-index (Figure 10). In the majority of cases, the true space falls within the predicted range, as expected. However, for most cases of $\varepsilon = 1024$ and one case of $\varepsilon = 16$, the true space is higher than the predicted range. This is likely due to one of two reasons: 1) the PLA-index uses an implementation of Elias-Fano encoding that has a constant overhead per character, which is not the theoretically optimal data structure used for theoretical analysis, and 2) the results of Theorem 11 hold only asymptotically and do not account for constant factors that contribute to the space, especially for higher ε where the total space is small.

We also compare the true space with the space predicted by fitting a single power-law model to the tabulated PLA-sizes (as we previously discussed in Figure 2) and plugging the fitted parameters into Theorem 1 from [2], with $c = 4$. As Figure 10 shows, the fit-based predictions are often significantly under-predicting the true space, especially at $\varepsilon = 16$.

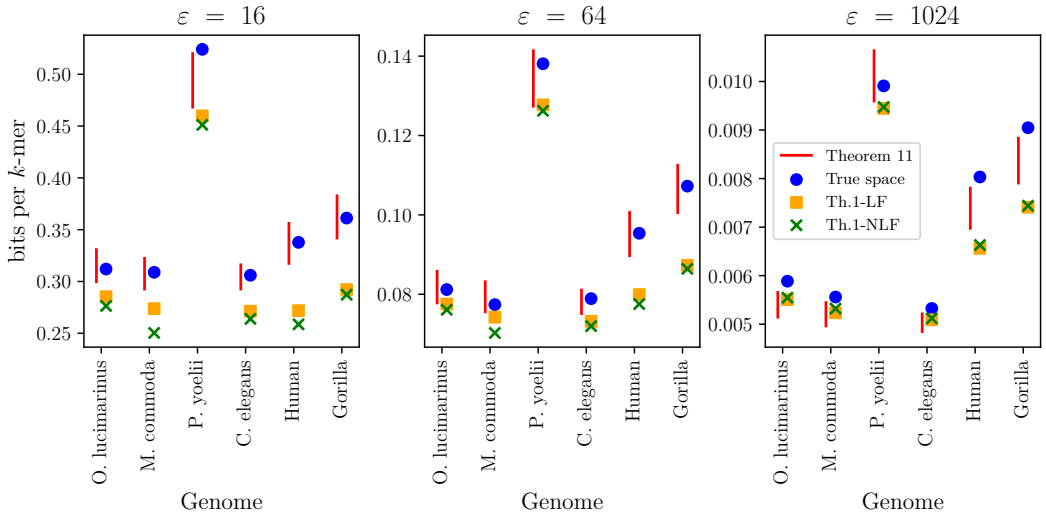

Figure 10 The true space of the PLA-index compared with various forms of predictions, for $\varepsilon \in \{16, 64, 1024\}$. The true space is measured using a version of the PLA-index implementation which encodes the X-array using Elias-Fano, which is the version that is theoretically analyzed in [2] and in Theorem 11. The predicted range (red) corresponds to plugging in the CaPLa into Theorem 11, using $c = 7$. The Th.1-LF and Th.1-NLF correspond to fitting a power-law model with a linear and non-linear fit, respectively, and plugging in the fitted parameters into Theorem 1 in [2] (with $c = 4$). The fitted and non-fitted models are described in the caption of Figure 2.

6 Conclusion

In this paper, we introduced the notion of PL-approximability of a multiset and a corresponding measure called CaPLa (Section 2). Our theoretical results show that CaPLa is well-defined and can be computed efficiently, under reasonable assumptions which we demonstrate hold in almost all tested data (Section 3). Our experimental results show that CaPLa varies substantially not only across genomes and kingdoms, but also within individual genomes, and this variability can lead to differences of up to 50% in the space required by a PLA-based data structure (Sections 5.2 and 5.3). Within our CaPLa framework, the key factors distinguishing a genome spectrum from a random k-mer multiset are the presence of

repeats and the non-uniform distribution of k-mers. The combined effect of these two factors substantially reduces PL-approximability (Section 5.4). CaPLa has several desirable properties, namely, it is well-defined and efficient to compute across our experimented genomes, it is not trivially correlated with genome length thus indicating it captures the intrinsic properties of the genome, and it is robust with respect to k-mer size when $k \geq 21$ (Section 5.5).

Our result has a concrete application to parameter selection in PLA-based indexes such as the PLA-index. When a target space is specified, an approximate estimate of the dataset's CaPLa can be used with Theorem 11 to compute a suitable value for the tuning parameter ε. This is particularly advantageous when the CaPLa is known for a similar dataset (e.g., from another individual of the same species), as it avoids the need to recompute the full set of $(\varepsilon, b(\varepsilon))$ pairs. In the absence of prior CaPLa information, future work could also explore efficient estimation of CaPLa over a small sample of the dataset itself (e.g., a contiguous region of the suffix array).

Our paper presents several future directions. From an application perspective, it will be interesting to connect the variability of PL-approximability to biological properties. Our preliminary results show that PL-approximability is higher in fungi and lower in repeat-rich chromosomes like the Y, but this raises more questions than it answers. From a theory perspective, it would be interesting to find the conditions under which the pinch point is unique. In our experiments, we could not find any instances of non-unique pinch points, suggesting that a theoretical proof may be possible. Finally, Theorem 9 requires that $1 \in \mathcal{E}$ in order to guarantee the existence of a pinch point. This condition is necessary, as in fact one can prove that a pinch point does not exist if $1 \notin \mathcal{E}$. This raises an interesting open question if there is some alternative notion of CaPLa that can be used when $1 \notin \mathcal{E}$.

Abstract

Given an undirected weighted graph G and an integer k, Exact-Weight Perfect Matching (EWPM) is the problem of finding a perfect matching of weight exactly k in G. In this paper, we study EWPM and its variants. The EWPM problem is famous, since in the case of unary encoded weights, Mulmuley, Vazirani, and Vazirani showed almost 40 years ago that the problem can be solved in randomized polynomial time. However, up to this date no derandomization is known.

Our first result is a simple deterministic algorithm for EWPM that runs in time $n^{\mathcal{O}(\ell)}$, where ℓ is the number of distinct weights that perfect matchings in G can take. In fact, we show how to find an ℓ-th smallest perfect matching in any weighted graph (even if the weights are encoded in binary, in which case EWPM in general is known to be NP-complete) in time $n^{\mathcal{O}(\ell)}$ for any integer ℓ. Similar next-to-optimal variants have also been studied recently for the shortest path problem.

For our second result, we extend the list of problems that are known to be equivalent to EWPM. We show that EWPM is equivalent under a weight-preserving reduction to the Exact Cycle Sum problem (ECS) in undirected graphs with a conservative (i.e. no negative cycles) weight function. To the best of our knowledge, we are the first to study this problem. As a consequence, the latter problem is contained in RP if the weights are encoded in unary. Finally, we identify a special case of EWPM, called BCPM, which was recently studied by El Maalouly, Steiner and Wulf. We show that BCPM is equivalent under a weight-preserving transformation to another problem recently studied by Schlotter and Sebő as well as Geelen and Kapadia: the Shortest Odd Cycle problem (SOC) in undirected graphs with conservative weights. Finally, our $n^{\mathcal{O}(\ell)}$ algorithm works in this setting as well, identifying a tractable special case of SOC, BCPM, and ECS.

1 Introduction

A big open question in complexity theory concerns the role of randomness in devising polynomial-time algorithms. While it is conjectured that every problem in RP (and even BPP) should also lie in P (see e.g. Chapter 20 in [1] for more details), there exist several

natural problems for which efficient randomized algorithms, but no efficient deterministic algorithms, are known. Thus, instead of attacking the conjecture RP = P directly, it might be more reasonable to first try to devise efficient deterministic algorithms for those problems.

A famous example of a problem in RP, that is not known to lie in P, is the unary version of Exact-Weight Perfect Matching (EWPM): Given an undirected weighted graph G and an integer k, EWPM is the problem of deciding whether G admits a perfect matching of weight exactly k. Note that this problem is often called Exact Matching (EM) if we allow only weights 0 and 1, and it is not hard to see (by replacing single edges by paths corresponding to their weight) that unary EWPM is equivalent to EM.

EWPM was introduced by Papadimitriou and Yannakakis [27] in 1982, and it is known to be NP-hard in general (for a short proof, see [14]). Papadimitriou and Yannakakis also conjectured that EWPM remains NP-hard if weights are encoded in unary. However, Mulmuley, Vazirani and Vazirani [24] proved in 1987 that unary EWPM is in RP. This makes it very unlikely for the problem to be NP-hard. Hence, the question became whether one could also find an efficient deterministic algorithm for unary EWPM.

This question has been open for almost 40 years now. In fact, despite considerable effort, no deterministic algorithm is known that runs in time that is subexponential in the number of vertices of the graph. Instead, progress has been made mostly by focusing on restricted graph classes, approximation variants of EWPM, and finding other natural problems that are equivalent to unary EWPM (see Section 1.3 for more details).

Our main result is a new parameterized algorithm for EWPM that works on general graphs, even if weights are encoded in binary: Assume that $k_1 < k_2 < \cdots < k_\ell$ are all the distinct weights up to k_ℓ that perfect matchings in G take. We prove that it is possible to find a perfect matching of weight k_ℓ in time $n^{\mathcal{O}(\ell)}$. Our algorithm is very simple and relies on our main theorem (Theorem 9), which says that there must exist $2(\ell-1)$ edges such that any minimum-weight perfect matching that includes all of these $2(\ell-1)$ edges must have weight k_ℓ. The obtained bound of $2(\ell-1)$ is tight.

1.1 Next-to-Optimal Problems

Our main result can be equivalently stated in a different way: Consider the following problem, which we call ℓ-th Smallest Perfect Matching (SPM_ℓ): Given a weighted graph G, an integer k, and a natural number ℓ, decide whether G contains an ℓ-th smallest perfect matching of weight exactly k. Here, the notion of ℓ-th smallest perfect matchings is defined recursively: 1st-smallest perfect matchings are exactly the minimum-weight perfect matchings, and for $\ell \geq 2$, ℓ-th smallest perfect matchings are the perfect matchings of minimum weight among all perfect matchings that are not ℓ'-th smallest for any $\ell' < \ell$. In this language, our result is an algorithm that solves SPM_ℓ in time $n^{\mathcal{O}(\ell)}$.

Similar next-to-optimal problems have been studied in the literature before. In particular, there is a line of work on finding next-to-shortest paths in directed or undirected graphs. In these problems, we want to find a next-to-shortest (s,t)-path in a weighted graph G, i.e. the path should have minimum weight among all (s,t)-paths that are not shortest paths. This problem is NP-hard on directed graphs [22], but admits polynomial-time algorithms on undirected graphs [18, 21, 23, 31, 33]. Note that the NP-hardness result in [22] heavily relies on allowing edges to have weight zero. Indeed, the so-called detour problem – decide whether all (s,t)-shortest paths in a given unweighted directed graph have the same length or not – is very similar but does not allow for zero-weight edges, and its complexity status is still unresolved [15].

Instead of asking for a perfect matching of ℓ-th smallest weight, one could instead ask for ℓ distinct perfect matchings while minimizing their combined weight. This is a conceptually different problem which is equivalent to repeatedly (ℓ times) finding the best solution distinct from previously obtained solutions. Such k-best enumeration problems have been studied for a number of combinatorial optimization problems: Murty [26] first showed a polynomial-time algorithm for the k-best bipartite perfect matching problem. Later, the time complexity was improved by Chegireddy and Hamacher [2]. For more information, we refer the reader to the survey by Eppstein [11].

1.2 Related Cycle Problems

Our second contribution in this paper is to strengthen the connection between EWPM and related cycle problems, as we will outline here.

Consider the following problem, which we call Exact Cycle Sum (ECS): Given an undirected graph G with conservative (i.e. no negative cycles) edge-weights and an integer k, decide whether G contains a set of disjoint cycles of weight exactly k. A directed version of ECS with general weights has been studied e.g. by Papadimitriou and Yannakakis [27]. Concretely, they proved that the directed version of ECS is equivalent to EWPM on bipartite graphs. We extend this result by proving that the undirected problem ECS as defined above is equivalent to EWPM on general graphs. Our reductions preserve the encoding of the weights. Hence, we obtain as a result that ECS is in RP if weights are encoded in unary, and NP-complete if weights are encoded in binary.

Another interesting problem on cycles in graphs is the so-called Shortest Odd Cycle problem (SOC): Given an undirected graph G with conservative edge-weights and an integer k, decide whether G contains a cycle of odd weight at most k. SOC was recently studied by Schlotter and Sebő [28] (they use slightly different but equivalent definition, see Section 2.3 for more details), who proved that it is equivalent to finding minimum-weight odd T-joins. They also point out that SOC is contained in RP for unary weights, due to a result by Geelen and Kapadia [13], and therefore conjecture that the problem should be contained in P as well. Interestingly, the algorithm in [13] follows from a reduction to a problem on perfect matchings that can then be solved using the techniques of Mulmuley, Vazirani, and Vazirani [24]. In fact, this problem on perfect matchings has independently been studied by El Maalouly, Steiner, and Wulf [8] who called it Bounded Correct-Parity Perfect Matching (BCPM): Given a weighted graph G and an integer k, decide whether G contains a perfect matching M of weight $w(M)$ at most k and with $w(M) \equiv_2 k$ (where $\equiv_2$ is used to denote mod 2 equivalence). El Maalouly, Steiner, and Wulf use BCPM on bipartite graphs as a subroutine for a parameterized algorithm for EM on bipartite graphs. To this end, they prove that BCPM on bipartite graphs is in P, by reducing it to the directed version of SOC (which can be solved via dynamic programming). In this paper, we extend this set of results by proving that BCPM on general graphs is equivalent to SOC as defined above. Unfortunately, we are not able to give deterministic polynomial-time algorithms for either problem, but any such deterministic polynomial-time algorithm for SOC or BCPM would immediately imply that the parameterized algorithm from [8] also works on general graphs. Furthermore, our results highlight that the two equivalent problems SOC and BCPM can be seen as a stepping stone for solving unary EWPM, and that it might be reasonable to tackle them first.

Concretely, some interesting further questions that remain unresolved are: Can we solve SOC and BCPM in deterministic polynomial time? The conjecture RP = P suggests that for unary weights, one should be able to do it. Interestingly, we know very little about the case of weights encoded in binary: If the weights are encoded in binary, it is not known whether SOC or BCPM are in RP or NP-hard (since the randomized algorithm in [13] works only for unary weights). Note that the same questions were also asked by Schlotter and Sebő [28].

While in the general case, derandomization of unary SOC and BCPM remains open, combining our algorithm for EWPM with our reductions also implies that BCPM, SOC, and ECS can be deterministically solved in time $n^{O(\ell)}$ if at most ℓ many different possible weights of perfect matchings (cycle sums, respectively) appear in the instance.

1.3 Further Related Work on EM

As mentioned before, EWPM with weights restricted to 0 and 1 is called the Exact Matching Problem (EM). Derandomizing the known randomized algorithm is an important open problem. Solution approaches have mainly been focused on three directions: Finding deterministic approximation algorithms, finding deterministic algorithms on restricted graph classes, and identifying other polynomial-time equivalent problems.

- In terms of approximation algorithms for EM, Yuster [32] proved that one can find an almost exact matching (a matching of weight exactly k that may fail to cover two vertices of the graph) in deterministic polynomial time if an exact matching exists in the graph. One could interpret this as an approximation result that relaxes the perfect matching constraint. If we relax the exactness constraint instead, recent progress includes a two-sided 2-approximation algorithm on bipartite graphs by El Maalouly [5], and a one-sided 3-approximation algorithm on bipartite graphs by Dürr, El Maalouly, and Wulf [3].
- EM has been studied on various restricted graph classes. In fact, Karzanov [19] proved already in 1987 that EM can be solved in deterministic polynomial time on complete and complete bipartite graphs. This has been generalized in different ways: El Maalouly and Steiner [7] gave deterministic polynomial-time algorithms on graphs with bounded independence number (and bipartite graphs of bounded bipartite independence number). In the case of bipartite graphs, this was improved to an FPT-algorithm by El Maalouly, Steiner, and Wulf [8]. In the general case, Murakami and Yamaguchi [25] gave an FPT-algorithm that is paramatrized by the independence number and the minimum size of an odd cycle transversal.

  El Maalouly, Haslebacher, and Wulf [6] used Karzanov's original techniques to prove that EM restricted to chain graphs, unit-interval graphs, and complete r-partite graphs is in P. They also showed that a local search algorithm works in deterministic polynomial time on complete r-partite graphs, graphs of bounded neighborhood diversity, and graphs without complete bipartite t-holes.

  Finally, it is also possible to derandomize the randomized algorithm on some graph classes, e.g. by finding so-called Pfaffian orientations. Concretely, Vazirani [30] showed how to do this for $K_{3,3}$-free graphs, and Galluccio and Loebl [12] obtained Pfaffian orientations for graphs of bounded genus.
- Previously, some effort has also been made to identify other natural problems that are polynomial-time equivalent to EM. We already mentioned some of these results in Section 1.2. Besides the mentioned cycle problems, EM is also known to be equivalent to a problem called Top-k Perfect Matching [9].
- Finally, Jia, Svensson, and Yuan [16] recently proved that the bipartite exact matching polytope has exponential extension complexity. This stands in contrast to the bipartite perfect matching polytope, which is known to be integral.

We remark that many of these algorithmic results only hold for 0-1-weighted EWPM, and do not even translate to unary EWPM since they often involve very specific graph structures or parameters. In contrast, our parameterized algorithm works even for binary encoding of weights in EWPM.

1.4 Outline

We formally define EWPM and related problems in Section 2, where we also recall some of the most important concepts from the literature. In Section 3, we introduce the ℓ-th Smallest Perfect Matching (SPM$_\ell$) problem, and we prove that it can be solved deterministically in time $n^{\mathcal{O}(\ell)}$. In Section 4, we explain our reductions between cycle and matching problems. Full proofs of all statements in Section 4 can be found in the Appendix of the full version.

2 Preliminaries

We start by introducing notation and afterwards recall important facts from the literature. First of all, all our graphs are considered to be simple, i.e. they do not contain self-loops or parallel edges. If not specified, graphs are also considered to be undirected. Now, given a graph $G = (V, E)$, we will frequently use the standard notions of paths, cycles, and matchings, and we usually think of those objects as subsets of edges. In particular, a perfect matching M of G is a subset of edges $M \subseteq E$ such that every vertex of G is covered exactly once by M. We denote by $\mathcal{M}_G$ the set of all perfect matchings of G.

Occasionally, we will explicitly use directed graphs. In particular, we will write $(u, v) \in E$ (instead of $\{u, v\} \in E$) for directed edges in a directed graph $G = (V, E)$ with $u, v \in V$.

In some problems, edge-weights are given for a graph $G = (V, E)$ in terms of a function $w : E \to \mathbb{Z}$ or $w : E \to \mathbb{N}$. We use the convention that $w(X)$ denotes the sum of all weights of edges in $X \subseteq E$.

For two decision problems A and B, we use $A \leq_p B$ to denote that there exists a polynomial-time many-one reduction from A to B. We also write $A \equiv_p B$ to say that both $A \leq_p B$ and $B \leq_p A$ are true.

2.1 Symmetric Difference and Alternating Cycles

An important and common tool for working with perfect matchings is the *symmetric difference*. The symmetric difference of two sets X, Y is defined as $X \Delta Y \coloneqq (X \cup Y) \setminus (X \cap Y)$. It is a well-known fact that the symmetric difference $M \Delta M'$ of two perfect matchings M, M' in a graph $G = (V, E)$ always consists of a set of vertex-disjoint even cycles. In other words, there exist vertex-disjoint even cycles $C_1, \dots, C_p \subseteq E$ such that $M \Delta M' = \bigsqcup_{i=1}^{p} C_i$. We say that C_i is a cycle from $M \Delta M'$, and we sometimes use the letter p to refer to the number of cycles in $M \Delta M'$. Further, we recall that every cycle C in $M \Delta M'$ is alternating in both M and M' (an even cycle C of G is called *M-alternating* if and only if it alternates between edges in M and edges not in M). The set $M \Delta C$ is again a matching of the same cardinality as M. We often refer to this property by saying that we *switch* M along C to obtain the new matching $M \Delta C$. Naturally, the matchings $M \Delta C$ and M differ exactly in C, i.e. $(M \Delta C) \Delta M = C$.

Recall again that $M \Delta M'$ is a collection of vertex-disjoint even cycles $C_1, \dots, C_p \subseteq E$, and that each of the cycles $C_1, \dots, C_p$ is both M-alternating and M'-alternating. Hence, given both M, M', some new perfect matchings of G can be obtained by switching either M or M' along a subset of the cycles $C_1, \dots, C_p$. In particular, we can perform the switching operations independently of each other because the cycles are vertex-disjoint.

2.2 Minimum-Weight and Exact-Weight Perfect Matching

Finding a minimum-weight perfect matching is a classical problem that has been studied extensively. We will define it as follows.

▶ **Definition 1** (MWPM). *Given a graph $G = (V, E)$, edge-weights $w : E \to \mathbb{Z}$, and an integer k, Minimum-Weight Perfect Matching (MWPM) is the problem of deciding whether G admits a perfect matching of total weight at most k.*

It is well-known that MWPM is in P (even if weights are encoded in binary, see e.g. [20]). Moreover, finding a maximum-weight perfect matching is analogous to finding a minimum-weight perfect matching, and hence that can also be done in deterministic polynomial time. Since both of these problems are in P, it then seems natural to ask whether we can also test for a perfect matching of weight exactly k in polynomial time.

▶ **Definition 2** (EWPM). *Given a graph $G = (V, E)$, edge-weights $w : E \to \mathbb{Z}$, and an integer k, Exact-Weight Perfect Matching (EWPM) is the problem of deciding whether G admits a perfect matching of weight exactly k.*

As mentioned in Section 1, the variant of EWPM with weights from $\{0, 1\}$ is also known as Exact Matching (EM), and it is contained in RP [24]. Moreover, this also implies that EWPM with weights encoded in unary is contained in RP. In contrast, EWPM with weights encoded in binary is NP-complete [27, 14]. Note that this constitutes a major difference to MWPM, where both the unary and binary variant admit efficient algorithms.

The following problem BCPM is at most as hard as EWPM, and it was used in [8] as part of an algorithm for EM.

▶ **Definition 3** (BCPM). *Given a graph $G = (V, E)$, edge-weights $w : E \to \mathbb{Z}$, and an integer k, Bounded Correct-Parity Perfect Matching (BCPM) is the problem of deciding whether G admits a perfect matching M of weight $w(M)$ at most k satisfying $k \equiv_2 w(M)$.*

The randomized algorithm for unary EWPM also implies a randomized algorithm for unary BCPM. Interestingly, the complexity of binary BCPM remains open. In particular, it is not known whether binary BCPM is NP-hard or not.

2.3 Conservative Weights and Cycle Problems

Many problems on finding shortest paths and cycles in graphs with non-negative edge-weights can be solved efficiently. On the other hand, allowing for negative weights usually makes those problems NP-hard as they now include problems such as finding Hamiltonian paths or cycles. An interesting compromise is provided by conservative edge-weights.

▶ **Definition 4** (Conservative Weights). *Edge-weights $w : E \to \mathbb{Z}$ of a (possibly directed) graph $G = (V, E)$ are conservative if and only if there are no negative (directed) cycles in G with respect to w.*

Using established techniques (see e.g. Johnson's algorithm [17] or Suurballe's algorithm [29]), conservative weights on directed graphs can be turned into non-negative weights while maintaining the total weight of each cycle. Hence, cycle problems in directed graphs with conservative edge-weights are usually not harder than their non-negative variants. However, in the case of undirected graphs, the same technique is not applicable, and it turns out that there are interesting cycle problems on undirected graphs with conservative edge-weights that relate to EWPM and BCPM. Concretely, we will work with the two problems Exact Cycle Sum (ECS) and Shortest Odd Cycle (SOC), defined on graphs with conservative weights.

▶ **Definition 5** (ECS). *Given a graph $G = (V, E)$ with conservative edge-weights $w : E \to \mathbb{Z}$ and an integer k, Exact Cycle Sum (ECS) is the problem of deciding whether there exists a set of vertex-disjoint cycles of total weight exactly k in G.*

▶ **Definition 6** (SOC). *Given a graph $G = (V, E)$ with conservative edge-weights $w : E \to \mathbb{Z}$ and an integer k, Shortest Odd Cycle (SOC) is the problem of deciding whether there exists a cycle of odd weight at most k in G.*

Note that the definition of SOC by Schlotter and Sebő [28] as well as Geelen and Kapadia [13] slightly differs from ours: They require the cycle to have odd length (i.e. an odd number of edges) instead of odd weight. However, it is not hard to see that the two versions are polynomial-time equivalent. Indeed, by splitting even-weight edges, we can ensure to get a graph with only odd-weight edges, yielding a reduction from our odd-weight version to the odd-length version. To reduce the odd-length version to the odd-weight version, it suffices to manipulate the weights, replacing the weight $w(e)$ of each edge e with $2|V|w(e) + 1$.

As mentioned in Section 1.2, El Maalouly et al. [8] gave a polynomial-time algorithm for BCPM on bipartite graphs by reducing it to a directed version of SOC. An analogous connection between EWPM on bipartite graphs and the directed version of ECS has been observed by Papadimitriou and Yannakakis [27] already in 1982. In Section 4, we will extend these connections between cycle and matching problems by proving equivalence of ECS (undirected) and EWPM (on general graphs), and SOC (undirected) and BCPM (on general graphs), respectively.

3 ℓ-th Smallest Perfect Matchings

As discussed in Section 1, the problem of finding a deterministic polynomial-time algorithm for unary EWPM has been attacked from various directions in recent years. We attack it from yet another direction that involves so-called ℓ-th smallest perfect matchings.

▶ **Definition 7.** *Let $G = (V, E)$ be a graph with edge-weights $w : E \to \mathbb{Z}$. We define ℓ-th smallest perfect matchings for all $\ell \in \mathbb{N}$ recursively. The 1st-smallest perfect matchings of G are exactly the minimum-weight perfect matchings. Moreover, for fixed $\ell \geq 2$, a perfect matching M is ℓ-th smallest if and only if it has minimum weight among all perfect matchings that are not ℓ'-th smallest for any $\ell' < \ell$.*

▶ **Definition 8** (SPM_ℓ). *Given a graph $G = (V, E)$, edge-weights $w : E \to \mathbb{Z}$, an integer k, and a natural number ℓ, ℓ-th Smallest Perfect Matching (SPM_ℓ) is the problem of deciding whether G admits an ℓ-th smallest perfect matching of weight exactly k.*

The goal of this section is to give a deterministic algorithm that can decide SPM_ℓ in time $n^{\mathcal{O}(\ell)}$, where n is the size of the instance. Naturally, this has interesting consequences for EWPM: Assume that we are given an instance of EWPM where k is such that any perfect matching M with $w(M) = k$ is an ℓ'-th smallest perfect matching. Then we can verify existence of such a matching in time $n^{\mathcal{O}(\ell')}$ by simply calling the SPM_ℓ-algorithm repeatedly for $\ell = 1, \ldots, \ell'$.

To the best of our knowledge, we are the first to observe a result of this kind. Our algorithm is very simple and follows a natural approach: For a given ℓ and for every set $F \subseteq E$ of size at most $2(\ell - 1)$, compute a minimum-weight perfect matching that includes all of F. We prove in Theorem 9 that there is always a 1st-smallest, a 2nd-smallest, …, an ℓ-th smallest perfect matching among the set of perfect matchings that were computed. The proof of Theorem 9 is less straight-forward. It relies on the complementary slackness theorem (compare e.g. [20]) and the perfect matching polytope.

▶ **Theorem 9** (ℓ-th Smallest PM in General Graphs). *Let $G = (V, E)$ be a graph with edge-weights $w : E \to \mathbb{Z}$. Let $\ell \in \mathbb{N}$ be arbitrary. Assume that G contains an ℓ-th smallest perfect matching M. Then there exists a subset of edges $F \subseteq E$ of size at most $2(\ell - 1)$ such that*

$$w(M) = \min_{M' \in \mathcal{M}_G : F \subseteq M'} w(M').$$

It turns out that one can slightly improve the above theorem in the case of bipartite graphs.

▶ **Theorem 10** (ℓ-th Smallest PM in Bipartite Graphs). *The ℓ-th smallest perfect matching in a weighted bipartite graph can be obtained the same way as in Theorem 9, except that F ranges only over edge sets of size at most $\ell - 1$.*

In this paper, we omit the proof of Theorem 10, since its proof is identical to that of Theorem 9, except that the general matching polytope is swapped with the bipartite matching polytope.

One might ask whether the number of edges one needs to "fix" in these two theorems is tight. Indeed, this is the case, i.e. in order to find the ℓ-th smallest perfect matching, one needs to fix $\ell - 1$ edges in a bipartite graph and $2(\ell - 1)$ edges in a general graph. To see this, consider Figure 1, where dashed edges have a weight of 1 while solid edges have a weight of 0. Consider first the bipartite four-cycle on the left. It has exactly two perfect matchings, one of weight 0 and one of weight 2. Fixing one edge is necessary and sufficient to find the 2nd-smallest perfect matching. Taking multiple disjoint copies of this four-cycle generalizes this to show that it is sometimes necessary to fix $\ell - 1$ edges to find the ℓ-th smallest perfect matching in a bipartite graph. Analogously, the graph on the right has perfect matchings of weight 1 and 3, but fixing a single edge does not suffice to find the perfect matching of weight 3. In other words, we need to fix 2 edges to find the second-smallest perfect matching here. Again, generalizing this argument by taking multiple copies of this graph proves that the bound $2(\ell - 1)$ is best possible in general graphs.

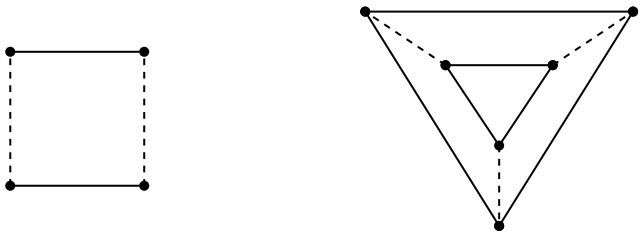

Figure 1 Example that Theorems 9 and 10 are tight in terms of the number of fixed edges. Dashed edges have a weight of 1 and solid edges have a weight of 0.

3.1 Proof of Theorem 9

The goal of this section is to prove Theorem 9. We start by recalling some useful facts about the perfect matching polytope from Chapter 11 of the standard textbook by Korte and Vygen [20]. For this, it will be convenient to use the notation $\delta(v)$ to denote the set of edges incident to a vertex $v \in V$. Similarly, for all $A \subseteq V$, we use $\delta(A)$ to denote the set of edges with one endpoint in A and the other in $V \setminus A$. Moreover, we denote by $\mathcal{A}$ the set of all odd-cardinality sets $A \subseteq V$, i.e. $\mathcal{A} := \{A \subseteq V : |A| \equiv_2 1\}$.

For the remainder of this section, let $G = (V, E)$ be a graph with edge-weights $w : E \to \mathbb{Z}$. The integer linear program

$$\begin{aligned} &\min \sum_{e \in E} x_e w(e) && \\ \text{s.t.} \quad &\sum_{e \in \delta(v)} x_e = 1 && \forall v \in V \\ \text{and } &x_e \in \{0, 1\} && \forall e \in E \end{aligned}$$

with variables $\{x_e \mid e \in E\}$ captures the problem of finding a minimum-weight perfect matching in G. Now consider the following LP relaxation

$$\begin{aligned} &\min \sum_{e \in E} x_e w(e) && \\ \text{s.t.} \quad &\sum_{e \in \delta(v)} x_e = 1 && \forall v \in V \\ &\sum_{e \in \delta(A)} x_e \geq 1 && \forall A \in \mathcal{A} \text{ with } |A| > 1 \\ &x_e \geq 0 && \forall e \in E \end{aligned}$$

where additional odd-set constraints were added. By the famous result of Edmonds [4], adding these additional odd-set constraints is necessary and sufficient to make the LP integral. In other words, the basic feasible solutions to the LP are exactly the perfect matchings of G. The dual LP is now given by

$$\begin{aligned} &\max \sum_{A \in \mathcal{A}} z_A && \\ \text{s.t.} \quad &\sum_{A \in \mathcal{A} \,:\, e \in \delta(A)} z_A \leq w(e) && \forall e \in E \\ &z_A \geq 0 && \forall A \in \mathcal{A} \text{ with } |A| > 1 \end{aligned}$$

where we introduced a variable z_A for all $A \in \mathcal{A}$. By strong duality, the optimal value of the primal and the dual coincide.

▶ **Definition 11** (Residual Graph). *Let $G = (V, E)$ be a graph with edge-weights $w : E \to \mathbb{Z}$. Let z be an optimal solution to the dual LP associated with G. The graph $G_z := (V, E_z)$ with*

$$e \in E_z \iff w(e) = \sum_{A \in \mathcal{A} \,:\, e \in \delta(A)} z_A$$

is called residual graph with respect to z.

Unsurprisingly, it turns out that all minimum-weight perfect matchings are contained in the residual graph with respect to a given optimal solution z. However, there might exist perfect matchings in the residual graph that are not minimum-weight perfect matchings of G. Hence, we need an extra condition to exactly characterize which perfect matchings in the residual graph are minimum-weight in G. Eppstein [10] shows such a result for bipartite graphs. We present here the natural generalization to all graphs. This essentially follows from the complementary slackness theorem [20].

▶ **Lemma 12.** *Let $G = (V, E)$ be a graph with edge-weights $w : E \to \mathbb{Z}$. Let z be an optimal solution to the dual LP associated with G, and let $G_z = (V, E_z)$ be its residual graph. A perfect matching M of G has minimum weight if and only if $M \subseteq E_z$ and $|M \cap \delta(A)| = 1$ holds for all $A \in \mathcal{A}$ with $z_A > 0$.*

Proof. For the sake of clarity, we prove both directions individually.
(⇒) We provide an indirect proof. Assume first that there exists $f \in M$ such that

$$\sum_{A \in \mathcal{A} \colon f \in \delta(A)} z_A < w(f)$$

holds and hence $f \notin E_z$. Observe that, by feasibility of z, we have

$$\sum_{A \in \mathcal{A} \colon e \in \delta(A)} z_A \leq w(e)$$

for all $e \in E$. Moreover, we have $z_A \geq 0$ for all $A \in \mathcal{A}$ with $|A| > 1$. Thus, we get

$$w(M) - \sum_{A \in \mathcal{A}} z_A \geq \sum_{e \in M} \left(w(e) - \sum_{A \in \mathcal{A} \colon e \in \delta(A)} z_A \right) > 0$$

since every set $A \in \mathcal{A}$ with $|A| = 1$ is associated with exactly one edge in M, and every other set $A \in \mathcal{A}$ (with $|A| > 1$) satisfies $z_A \geq 0$. In other words, we have

$$w(M) > \sum_{A \in \mathcal{A}} z_A$$

which, by strong duality, implies that M does not have minimum weight. Thus, assume now that $M \subseteq E_z$, but there exists $A \in \mathcal{A}$ such that $z_A > 0$ and $|M \cap A| > 1$. Again, we calculate

$$w(M) - \sum_{A \in \mathcal{A}} z_A > \sum_{e \in M} \left(w(e) - \sum_{A \in \mathcal{A} \colon e \in \delta(A)} z_A \right) = 0$$

where the strict inequality now comes from the fact that we needed to duplicate the variable z_A in the first step. Again, by strong duality, we conclude that M does not have minimum weight.
(⇐) Assume now that we have $M \subseteq E_z$ and $|M \cap A| = 1$ for all $A \in \mathcal{A}$ with $z_A > 0$. In this case, we get

$$w(M) - \sum_{A \in \mathcal{A}} z_A = \sum_{e \in M} \left(w(e) - \sum_{A \in \mathcal{A} \colon e \in \delta(A)} z_A \right) = 0$$

as every set $A \in \mathcal{A}$ with $z_A > 0$ is associated with exactly one edge in M. By strong duality, we can use the fact that z is optimal to conclude that M has minimum weight. ◀

Using Lemma 12, we can prove the following lemma, which captures the special case $\ell = 2$ of Theorem 9.

▶ **Lemma 13.** *Let $G = (V, E)$ be a graph with edge-weights $w : E \to \mathbb{Z}$. Assume that G contains a 2nd-smallest perfect matching M. Then there exist edges $e, f \in E$ such that*

$$w(M) = \min_{M' \in \mathcal{M}_G \colon \{e,f\} \subseteq M'} w(M').$$

Proof. Let z be a fixed optimal dual solution. Since M is not a minimum-weight perfect matching, by Lemma 12, there are two cases: Either there exists an edge $e \in M$ with $e \notin E_z$ (in this case, take as f any edge from M and we are done), or there exists some odd set $A \in \mathcal{A}$ with $z_A > 0$, distinct edges $e, f \in M$, and both $e, f \in \delta(A)$. In the latter case, by the same lemma, no minimum-weight perfect matching contains both e and f. Hence, we get

$$\text{OPT} < \min_{M' \in \mathcal{M}_G : \{e,f\} \subseteq M'} w(M') = w(M)$$

where OPT denotes the weight of a minimum-weight perfect matching in G. ◀

It remains to use Lemma 13 repeatedly to obtain Theorem 9.

Proof of Theorem 9. We proceed by induction over ℓ. The case $\ell = 1$ is trivial and Lemma 13 already proves the case $\ell = 2$. Thus, let now $\ell \geq 3$ be arbitrary, and assume as induction hypothesis that the statement holds for all $\ell' < \ell$. Recall that M is an ℓ-th smallest perfect matching. We want to prove that there is a subset $F \subseteq E$ of edges of size at most $2(\ell - 1)$ such that

$$w(M) = \min_{M' \in \mathcal{M}_G : F \subseteq M'} w(M').$$

Let $M_{\min}$ be an arbitrary minimum-weight perfect matching of G. From the argument in Lemma 13, we know that there exist edges $e, f \in M$ such that

$$w(M_{\min}) < \min_{M' \in \mathcal{M}_G : \{e,f\} \subseteq M'} w(M') \leq w(M).$$

Consider now the graph G' obtained from G by removing e and f, their incident vertices, and all their incident edges. Observe that $M \setminus \{e, f\}$ is an ℓ'-th smallest perfect matching in G' for some $\ell' < \ell$. By the induction hypothesis, this means that there is a set $F' \subseteq E \setminus \{e, f\}$ of size at most $2(\ell' - 1)$ such that

$$w(M \setminus \{e, f\}) = \min_{M' \in \mathcal{M}_{G'} : F' \subseteq M'} w(M').$$

Define $F := F' \cup \{e, f\}$ and observe that

$$w(M) = w(\{e, f\}) + \min_{M' \in \mathcal{M}_{G'} : F' \subseteq M'} w(M') = \min_{M' \in \mathcal{M}_G : F \subseteq M'} w(M')$$

and that the set F has size at most $2(\ell - 1)$. ◀

4 Related Cycle Problems

In this section, we present the ideas behind Theorem 14 below. The full proof of Theorem 14 and the involved lemmata can be found in the Appendix of the full version.

▶ **Theorem 14** (EWPM $\equiv_p$ ECS & BCPM $\equiv_p$ SOC)**.** *EWPM is polynomial-time equivalent to ECS. BCPM is polynomial-time equivalent to SOC.*

As we will see, both equivalences use the same base construction and only differ in some minor configurations. The encoding of the weights is preserved in all reductions and hence ECS is equivalent to EM for weights encoded in unary, and NP-complete for weights encoded in binary.

From Matchings to Cycles

We start with the direction of EWPM $\leq_p$ ECS and BCPM $\leq_p$ SOC, i.e. we give reductions starting from matching-type problems going to cycle-type problems. We use roughly the same construction for both reductions. We remark that in the case of matching-type problems in *bipartite graphs*, a similar reduction already exists, and it goes to cycle-type problems in *directed* graphs [27, 8]. In these existing reductions, the bipartition of the graph was used to define some edge orientation, which in turn ensured that cycles in the new graph would correspond to M-alternating cycles (where M is an arbitrary minimum-weight perfect matching) in the old graph (see [27] and [8] for more details). The same trick does not apply in general graphs, which is why we need to reduce to undirected cycle problems instead. In particular, the new trick will be to manipulate the weights such that the weight of any non-alternating cycle exceeds some threshold. The following lemma captures the key properties of this construction.

▶ **Lemma 15.** *Let $G = (V, E)$ be a graph with non-negative edge-weights $w : E \to \mathbb{N}$ that admits a minimum-weight perfect matching M. Consider the new edge-weights $w' : E \to \mathbb{Z}$ defined as*

$$w'(e) := \begin{cases} -w(e) - r - 1, & e \in M \\ w(e) + r + 1, & e \notin M \end{cases}$$

for some integer $r \geq w(M)$. Then every cycle C with $w'(C) \leq r - w(M)$ is M-alternating and w' is conservative.

Using Lemma 15, we can now informally describe the reductions: Assume first that we are given an EWPM-instance I consisting of $G = (V, E)$, $w : E \to \mathbb{Z}$, and $k \in \mathbb{Z}$. Without loss of generality, we can assume that the weights w are non-negative. We first compute a minimum-weight perfect matching M in G. Note that if no such matching exists or its weight exceeds k, I is a NO-instance and we can produce a simple NO-instance of ECS. Otherwise, we construct w' as in Lemma 15 (setting $r = k$) and return the ECS-instance I' consisting of G, w' and $k' := k - w(M)$. By Lemma 15, w' is conservative. Setting $r = k$ crucially guarantees that solutions to the ECS-instance can be translated back to solutions to the EWPM-instance I.

The only difference in the reduction from BCPM to SOC is that we need to manually check the parity of M and use a trivial construction if it already has correct parity.

From Cycles to Matchings

We will now turn our attention to the reverse reductions ECS $\leq_p$ EWPM and SOC $\leq_p$ BCPM. The general idea is again inspired by the existing reductions between bipartite matching and directed cycle problems ([27, 8]): We want to duplicate every vertex and add edges between duplicates in order to ensure the existence of a canonical perfect matching M. Additionally, we want to ensure that the existence of any other perfect matching M' in the new graph implies existence of cycles in the original graph by looking at the symmetric difference $M \Delta M'$. Unfortunately, since our original graph is not directed anymore, we cannot use the ideas from [27, 8] to achieve this. Instead, we use the construction described in Lemma 16 and Figure 2.

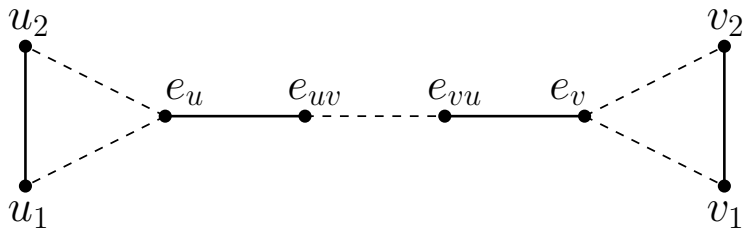

Figure 2 This figure shows the construction from Lemma 16 for a single edge $e = \{u, v\}$. Solid edges indicate the perfect matching M from Lemma 16. The edge $\{e_{uv}, e_{vu}\}$ receives the weight of e while all other edges get a weight of zero.

▶ **Lemma 16.** *Let $G = (V, E)$ be a graph with conservative edge-weights $w : E \to \mathbb{Z}$. We define*

$$\begin{aligned}
V' \coloneqq& \{v_1, v_2 \mid v \in V\} \cup \{e_u, e_{uv}, e_{vu}, e_v \mid e = \{u, v\} \in E\} \\
E' \coloneqq& \{\{v_1, v_2\} \mid v \in V\} \\
&\cup \{\{u_1, e_u\}, \{u_2, e_u\}, \{e_u, e_{uv}\}, \{e_{uv}, e_{vu}\}, \\
&\quad \{e_{vu}, e_v\}, \{e_v, v_1\}, \{e_v, v_2\} \mid e = \{u, v\} \in E\} \\
w' \coloneqq& e' \in E' \mapsto \begin{cases} w(e) & \text{if } e' = \{e_{uv}, e_{vu}\} \text{ for some } e = \{u, v\} \in E \\ 0 & \text{otherwise} \end{cases} \\
M \coloneqq& \{\{v_1, v_2\} \mid v \in V\} \cup \{\{e_u, e_{uv}\}, \{e_{vu}, e_v\} \mid e = \{u, v\} \in E\}
\end{aligned}$$

and consider the graph $G' = (V', E')$ with edge-weights w' and perfect matching M. Then there exist vertex-disjoint cycles $C_1, \ldots, C_p$ of total weight k (w.r.t. w) in G if and only if there exist vertex-disjoint M-alternating cycles $C'_1, \ldots, C'_p$ of total weight k (w.r.t. w') in G'.

Let us now briefly explain how this yields the desired reductions. Assume that we are given an ECS-instance I consisting of $G = (V, E)$, $w : E \to \mathbb{Z}$, and $k \in \mathbb{Z}$. We use the construction from Lemma 16 to obtain a graph G' with edge-weights w' and return the EWPM-instance I' consisting of $G' = (V', E')$, w', and $k' \coloneqq k$. The symmetric difference $M \Delta M'$ of M with any perfect matching M' in G' yields a set of vertex disjoint cycles that can be translated back to G using Lemma 16. The reduction from SOC to BCPM uses the same construction, but we need to additionally observe that we can get a single odd-weight cycle that translates through Lemma 16.

5 Final Remarks

In Section 3, we proved that we can deterministically find an ℓ-th smallest perfect matching in time $n^{\mathcal{O}(\ell)}$. This also allows us to solve certain instances of EWPM efficiently: Assume e.g. that we are given an EWPM instance with k such that $k_1 < k_2 < \cdots < k_\ell = k$ are all the distinct weights up to k that perfect matchings in G can take. Then our algorithm can find a perfect matching of weight $k = k_\ell$ efficiently if ℓ is small.

Clearly, this also works in the case of BCPM. Moreover, our reductions from Section 4 also allow us to get similar guarantees for ECS and SOC, respectively. Indeed, assume that we are given an instance of ECS or SOC with k such that $k_1 < k_2 < \cdots < k_\ell = k$ are all the distinct weights up to k that cycle sums in G can take. We apply our reduction to build a corresponding EWPM or BCPM instance. By Lemma 16, our reductions have a one-to-one correspondence between ℓ-th smallest perfect matchings and ℓ-th smallest cycle sums. Hence, the parameterized runtime guarantees of the SPM$_\ell$-algorithm carry through the reduction.

▶ **Corollary 17.** *BCPM can be solved in time $n^{\mathcal{O}(\ell)}$ if $k_1 < k_2 < \cdots < k_\ell = k$ are all the distinct weights up to k that perfect matchings in G can take. ECS and SOC can be solved in time $n^{\mathcal{O}(\ell)}$ if $k_1 < k_2 < \cdots < k_\ell = k$ are all the distinct weights up to k that cycle sums in G can take.*

Abstract

Beeping Network (BN) is a popular graph-based model of wireless computation, which applies the OR operation to one-bit messages sent simultaneously by neighbors. It admits fast (polylogarithmic in the number of nodes n) randomized solutions to many graph problems, but all known deterministic algorithms for non-trivial graph problems are at least polynomial in the maximum node degree Δ.

We improve known results for deterministic algorithms by showing that this polynomial can be as low as $\widetilde{O}(\Delta^2)$. More precisely, we show how to simulate a single round of any CONGEST algorithm in any network in $O(\Delta^2 \ polylog\ n)$ beeping rounds, each accommodating at most one beep per node, even if the nodes intend to send different messages to different neighbors. This upper bound reduces polynomially the time for a *deterministic* simulation of CONGEST in a Beeping Network, comparing to the best known algorithms, and nearly matches the time obtained recently using *randomization* (up to a poly-logarithmic factor) as well as the lower bound. Specifically, any algorithm designed for the CONGEST networks can be run in BNs with $O(\Delta^2 \ polylog\ n)$ multiplicative overhead, e.g., we can now deterministically compute an MIS in any BN in $O(\Delta^2 \ polylog\ n)$ beeping rounds, improving the previous best $\Theta(\Delta^3)$-round solution. For h-hop simulations, we prove a lower bound $\Omega(\Delta^{h+1})$, and we design a nearly matching algorithm that is able to "pipeline" the node-to-node information in a faster way than beeping layer-by-layer.

1 Introduction

The study of the Beeping Networks (BN) model [10] is simultaneously interesting, challenging, and useful in several respects. Even some less-restrictive ad-hoc networks (e.g., wireless) are frequently the algorithmist delight: a seemingly simple computational problem that

© Pawel Garncarek, Dariusz R. Kowalski, Shay Kutten, and Miguel A. Mosteiro;

becomes challenging under harsh yet realistic conditions. In terms of communication, BN may be the harshest model: network nodes can only *beep* (emit a signal) or *listen* (detect if a signal is emitted in its vicinity). A listening node may distinguish between *silence* (no beeps) and *noise* (at least one beep), but it cannot distinguish between single and multiple beeps. Theoretically, the BN model is important since it enables one to study whether distributed tasks can be performed efficiently under minimal conditions. It is a fundamental model to study communication complexity on channels where signals are superimposed (by applying the OR operator), which makes it more challenging than the basic model in which transmissions on links are independent. Moreover, in a one-hop network,[1] non-adaptive communication schedules in the BN model are equivalent to superimposed codes, which have been widely applied not only to communication problems, but also to text alignments, bio-computing, data pooling, dimensionality reduction, and other areas.

In addition to its theoretical importance, this model is recognized as useful for studying natural communication in biological networks [30, 2] (e.g., cells). A better understanding of the power of biological communication processes may lead to better nature-inspired algorithms [28]. It has been argued that the model is also a practical tool because algorithms designed for BNs can be implemented on non-expensive devices with low energy consumption. For example, nodes deployed (in ad-hoc topologies) for monitoring in Internet of Things (IoT) applications such as Sensor Networks. It should be noted that a mechanism similar in properties to beeping, called "busy tone," has been in wide use in wireless networks but for very limited purposes in channel access algorithms (as opposed to the Beeping model that is intended for general-purpose distributed algorithms). See e.g., [32, 22].

A wealth of successful research on computational problems in Beeping Networks has appeared in the literature (see, for instance [5, 15] and the references therein). Nevertheless, fundamental distributed computing questions remain open in the context of Beeping Networks, especially for deterministic algorithms. On the other hand, the CONGEST [31] model has been profusely studied. A natural question that follows is how to efficiently transform CONGEST Network algorithms into Beepping Network algorithms.

1.1 Our Contributions

The main results are detailed and compared to previous work in Table 1. Our main contributions are the near optimal[2] deterministic implementations of two simulators.

The main simulator, see Section 3 and Theorem 8, efficiently translates any CONGEST algorithms (deterministic or randomized) to the Beeping model. Each CONGEST round is simulated using $O(\Delta^2 \; polylog \; n)$ rounds, improving the previous result of $O(\Delta^4 \log n)$ of [5] and recent $O(\Delta^3 \log n)$ of [12] [3] (for $\Delta \in \omega(\; polylog \; n)$), and matches the lower bound $\Omega(\Delta^2 \log n)$ in [12] (that lower bound holds even for randomized simulations, hence combined with our algorithm they imply that the randomization can not help more than, possibly, a polylogarithmic factor).

Our approach differs substantially from previous ones based on superimposed codes. Our algorithm is adaptive, but using *a family of codes*, called avoiding selectors, that are parts of nodes' beeping schedules. These codes combined assure that, gradually, more and more

[1] For any given path of links connecting two nodes, the number of *hops* is the number of links in such path.
[2] Optimal up to a polylogarithmic factor.
[3] The latter result was not explicitly stated in [12], but one could use its randomized $O(\Delta^2 \log n)$-round solution designed for broadcasting $O(\Delta \log n)$ input bits stored in each node (this is the number of bits in our case, as messages to individual Δ neighbors could be different), and then derandomize it by using the suggested superimposed codes (with additional factor $O(\Delta)$, hence $O(\Delta^3 \log n)$ in total).

Table 1 Summary of our main results and related work for Beeping Networks with n nodes and maximum degree Δ. All protocols are distributed. Highlighted pairs of cells show direct comparison of our main results with previous work. B denotes the maximum number of input bits at a node.

links will "successfully beep" the information between their two end nodes, by "avoiding" interfering beeps from other nodes. The main challenge is that each node may have some incident links already successful and other links that are not – hence, it has to beep anyways and may interfere with other neighbors but, thanks to our avoiding selectors, not all the time. In this process, once a node recognizes that a neighbor is a unique beeper (so called "announcer"), it decodes its ID and message, and then it competes with other nodes to respond in subsequent rounds, and after that – it gets confirmation from the announcer.

Simulations of some CONGEST algorithms, relying on sending *the same message to all neighbors in a round* such as Network Decomposition in [20], could be further improved by a polylogarithmic factor by applying a deterministic version of local broadcast algorithm (i.e., same message to all neighbors) proposed in [12] (see the full version of this work [19]).

Our second main result is an extension of the notion of neighborhood to $h \geq 1$ hops and pipelining of the one-hop simulation. We call this problem a *B-bit h-hop simulation*, and show bounds $O(h \cdot B\Delta^{h+2} \ \textit{polylog}\ n)$ and $\Omega(B\Delta^{h+1})$, where the lower bound holds also for randomized solutions. See Section 4, and Theorems 11 and 10, respectively. Our algorithm efficiently "pipelines" point-to-point messages, and achieves substantially better complexity (for $h > 3$) than a straightforward application of 1-hop simulator h times (which would need $O(\Delta^{2h} \ \textit{polylog}\ n)$ time). For the simpler problem when each node has to deliver the same message to all nodes in its h-hop neighborhood, which we call *B-bit h-hop Local Broadcast*, we show a lower bound of $\Omega(B\Delta^h)$ even with randomization (see the full version of this work [19]).

1.2 Related Work

The Beeping Network model was defined by Cornejo and Kuhn in [10] in 2010, inspired by continuous beeping studied by Degesys et al. [13] and Motskin et al. [29], and by the implementation of coordination by carrier sensing given by Flury and Wattenhofer in [17]. Since then, the literature has included studies on MIS and Coloring [2, 1, 27, 23, 5, 7], Naming [8], Leader Election [21, 18, 14], Broadcast [21, 25, 26, 11, 4], and Shortest Paths [15].

Techniques to implement CONGEST algorithms in BNs were studied. In [5], the approach is to schedule transmissions according to a 2-hop c-coloring to avoid collisions. The multiplicative overhead introduced by the simulation is $O(c^2 \log n)$. A constant c is enough for the simulation, but the only coloring algorithm provided in the same paper takes time $O(a^2\Delta^2 \log^2 n + a^3\Delta^3 \log n)$ for a (Δ^2+1)-coloring. Thus, the multiplicative overhead is $O(\Delta^4 \log n)$, which our simulation improves by a factor of $\Delta^2/$ *polylog* n.

On the side of randomized protocols, in a recent work by Davies [12], a protocol that simulates a CONGEST round in a Beeping Network with $O(\Delta^2 \log n)$ overhead is presented. The protocol works even in the presence of random noise in the communication channel. Still, it is correct only with high probability (whp),[4] and requires a polynomial number of CONGEST rounds in the simulated algorithm. More relevant for comparison with our work, in the same paper, a lower bound of $\Omega(\Delta^2 \log n)$ on the overhead to simulate a CONGEST round is shown. The lower bound applies even in a noiseless environment and regardless of randomization. Thus, our simulation is optimal modulo some poly-logarithmic factor. [12] also proposed using superimposed codes instead of randomness, resulting in $\Theta(\Delta)$ multiplicative overhead, i.e., $O(\Delta^3 \log n)$ rounds in total. Another randomized simulation was previously presented in [3] with overhead of $O(\Delta \min(n, \Delta^2) \log n)$ whp.

Regarding the MIS problem, the closest work is the deterministic protocol in [5], which runs in $O(\Delta^2 \log n + \Delta^3)$. Thus, our results improve by a factor of $\Delta/$ *polylog* n for any $\Delta \in \omega(\log n)$, and match the running time (modulo poly-logarithmic factor) for $\Delta \in O(\log n)$.

On the side of randomized MIS protocols, an upper bound of $O(\log^3 n)$ has been shown in [1] for the same beeping model, and faster with some additional assumptions.

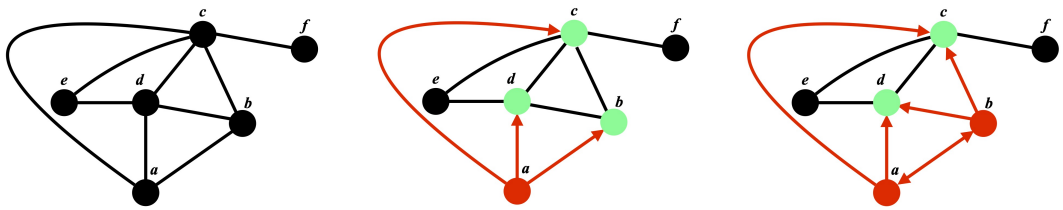
Our network decomposition algorithm for BNs is based on the protocol for the CONGEST model [20] that shows a $(\log n, \log^2 n)$ network decomposition in $O(\log^5 n)$ CONGEST rounds. We get the same network decomposition in $O(\Delta^2 \log^7 n)$ beeping rounds. Other graph problems and (restricted) local broadcast of *same message* are discussed in the full version of this work [19].

Non-synchronized BNs pose even more challenges to graph algorithms, cf. [1, 18, 14, 24].

2 Model, Notation, and Problems

We specify first the communication network notation used throughout, and we define the communication models studied in the section that follows. We consider a communication network formed by n devices with communication and computation capabilities, called **nodes**. Each node has a unique **ID** from the range $[1, n^c]$ for some constant $c \geq 1$.[5] Nodes communicate by sending **messages** among them. A message is composed of a binary sequence containing the source node ID, the destination node ID (if applicable), and the specific information to be sent. If the destination node receives the message from the source node,

[4] An event E occurs *with high probability* if $Prob(E) \geq 1 - 1/n^c$ for some $c > 0$.



[5] The availability of identifiers is essential in order to break symmetry in deterministic protocols, as pointed out in previous works on deterministic protocols in the Beeping model [5, 14].

we say that the message was **delivered**. Each pair of nodes that are able to communicate directly (i.e., without relaying communication through other nodes) are said to be connected by a communication **link** and are called **neighbors**. We assume that links are **symmetric**, i.e., messages can be sent in both directions (delivery is restricted to the communication models specified below). The network topology defined by the communication links is modeled with an undirected graph $G = (V, E)$ where V is the set of nodes and E is the set of links. If E is such that for every pair of nodes $u, v \in V$ there is a path of links connecting u and v we say that the network is **connected**. For each node $v \in V$, the set of neighbors of v is called its **neighborhood**, denoted as $N(v)$. We assume that time is slotted in **rounds** of communication. All nodes start running protocols simultaneously, i.e., the network is **synchronous**. We assume that computations take negligible time with respect to communication. Thus, we measure algorithm performance in rounds.

2.1 Communication Models

Beeping Networks (BNs) [10]. In this model, in each round each node can either **beep** (send a signal) or **listen** (do not send any signal). By doing so, nodes obtain the following **communication channel feedback**. In any given round, a listening node **hears** either **silence** (no neighbor beeps) or **noise** (one or more neighbors beep). A listening node that hears noise cannot distinguish between a single beep and multiple beeps.

Network protocols may use the channel feedback (i.e. the temporal sequence of strings from {“silence”,“noise”}) to make decisions adaptively. However, delivering messages is not straightforward because it requires sending (and receiving) the whole binary sequence of the message (according to some beeping schedule, possibly changing adaptively during the communication), somehow encoded with beeps. In that sense, protocols for Beeping Networks can be seen as radio network coding to cope with the communication restrictions (as in [16] to cope with noise).

(a) All nodes listen. All nodes hear silence.

(b) Node a beeps, $\{b, c, d, e, f\}$ listen. $\{b, c, d\}$ hear noise. $\{e, f\}$ hear silence.

(c) Nodes $\{a, b\}$ beep, $\{c, d, e, f\}$ listen. $\{c, d\}$ hear noise. $\{e, f\}$ hear silence.

Figure 1 Beeping Network communication model example.

CONGEST Networks [31]. In this model, in each round each node can send a (possibly different) message of $O(\log n)$ bits to each neighbor independently. All nodes receive the messages sent by their neighbors. That is, there are no collisions. In the **CONGEST Broadcast** version of this model, each node can only broadcast the same message to all its neighbors in each round.

2.2 Problems Studied

Our main research question in this work is how to efficiently simulate a round of communication of a CONGEST Network protocol in a Beeping Network, and how to improve MIS in BNs.

CONGEST Simulation. Given a Beeping Network with topology graph $G = (V, E)$, where each node $u \in V$ may hold a message $m_{u,v}$ of $O(\log n)$ bits that must be delivered to node $v \in N(u)$, the CONGEST simulation problem is solved once for every $u \in V$ and $v \in N(u)$, $m_{u,v}$ and the ID of u has been delivered to v.

Maximal Independent Set (MIS). Given a Beeping Network with topology graph $G = (V, E)$, The Maximal Independent Set problem is solved when, for some such set, $S \subseteq V$, every node $v \in S$, v knows that it is in S.

Our second main problem – generalized **h-hop simulations** – are defined and studied in Section 4 and in the full version of this work [19]. We also study several distributed computing problems of independent interest (see their definition in the full version of this work [19]) in the context of Beeping Networks and applications of our simulator that improve efficiency with respect to known solutions for BNs.

3 Simulation of a CONGEST Round in Beeping Networks

We present a deterministic distributed algorithm that efficiently simulates a round of *any algorithm designed for the CONGEST model* in the Beeping Networks model, even if the algorithm sends different messages to neighbors. It is only somewhat (polylogarithmically) slower than the existing more restricted local broadcast algorithms, which require a node to send *the same message* to all its neighbors), e.g., the local broadcast solution mentioned in [12] (see also more details in the full version of this work [19]) and faster nearly by factor Δ than the full deterministic simulation also mentioned in [12]. Unlike the superimposed-codes-based deterministic algorithms in [12], our simulator is adaptive and uses heavier machinery. It is built hierarchically using the known family of codes called "avoiding selectors". The codes, intuitively, say "when to beep". However, it is still possible that when two neighbors of some node v send their messages (by beeping in subsequent rounds), node v will receive a "message" that is a logical OR of the two. Our simulator resolves such collision problems and assures fast progress by:

- coding messages (cf. extended-IDs) such that OR of more than one message is identified;
- beeping according to specific avoiding selectors, assuring that a fraction of links that have not yet "delivered" the beeped messages will now succeed in one direction (i.e., one end node of such link "announces" itself to the other one through successful beeping of its ID);
- allowing those who received such announcements, the responders, to compete in successful delivery of their IDs to the corresponding announcers; this competition sets up bi-directional matching between the announcers and the corresponding responders, which allows bi-directional message exchange via beeping (3-stage parallel handshaking); this competition also uses avoiding selectors, but differently parameterized than the ones used for announcing (as announcing and responding are different processes).

The announcing, followed by responders' competition, continues until all links end up in some of the successfully realized matchings (as described in the above bullet points).

Avoiding selectors for n nodes use two parameters, k, ℓ, corresponding to the number of competing neighbors/responders versus the other (potentially interrupting) neighbors:

Algorithm 1 C2B algorithm for each node u. $E(u)$ is a global variable.

$E(u) \leftarrow \{\{u,v\} | \{u,v\} \in E \text{ for some } v \in V\}$

Algorithm `C2B()`

```
1  for each epoch i = 1, 2, ..., log Δ do                    // iterating epochs
2      k_i ← Δ/2^i
3      for each phase j = 1, 2, ..., |F_{Δ,k_i}| do
4          if u ∈ F_{Δ,k_i}(j) then
5              announcer(u, k_i)
6          else
7              responder(u, k_i)
```

▶ **Definition 1** (Avoiding selectors). *A family $\mathcal{F}$ of subsets of $[n]$ is called an (n,k,ℓ)-*avoiding selector*, where $1 \leq \ell < k \leq n$, if for every non-empty subset $S \subseteq [n]$ such that $|S| \leq k$ and for any subset $R \subseteq S$ of size at most ℓ, there is an element $a \in S \setminus R$ for which there exists a set $F \in \mathcal{F}$ such that $|F \cap S| = \{a\}$.*

The following fact follows directly from Definition 1, see also [6, 9].

▶ **Fact 1.** *Suppose we are given an (n,k,ℓ)-avoiding selector $\mathcal{F}$ and a set S of size at most k. Then, the number of elements in S not "selected" by selector $\mathcal{F}$ (i.e., for which there is no set in the selector that intersects S on such singleton element) is smaller than $k-\ell$.*

▶ **Theorem 2** ([6, 9]). *There exists an (n,k,ℓ)-avoiding selector of size $O\left(\frac{k^2}{k-\ell}\log n\right)$, and moreover, an (n,k,ℓ)-avoiding selector of size $O\left(\frac{k^2}{k-\ell}\operatorname{polylog} n\right)$ can be efficiently deterministically constructed (in polynomial time of n) for some polylogarithmic function* polylog n*, locally by each node.*

3.1 The C2B Algorithm

The pseudocode of our main C2B algorithm is in Algorithm 1, and its subroutines in Algorithms 2 and 3. The algorithm proceeds in epochs $i = 1, \ldots \log\Delta$. In the beginning, each node has all its links not successfully realized – here by a link $\{v,w\}$ being realized we understand that up to the current round, an input message/ID sent by v has been successfully encoded by w (using a sequence of beeps) and vice versa (note that these are two different messages and were sent/encoded each in different rounds); the formal definition of link realization will be given later. The goal of the algorithm is to preserve the following invariant for epoch $i \geq 1$:

> At the end of epoch $i = 1, \ldots, \log\Delta$, each vertex has less than $\kappa_i = \Delta/2^i$ incident links not realized.

We set an auxiliary value $\kappa_0 = \Delta$, which corresponds to the maximum number of adjacent links per node at the beginning of the computation. For ease of presentation, we assume that node IDs come from the range $[1,n]$. Note that in all the formulas, the number of possible IDs appears only under logarithms, so the algorithm and analysis for range $[1,n^c]$ are the same.

Algorithm for epoch i: Preliminaries and main concepts

Epoch i proceeds in subsequent batches of $2\log n$ rounds, each batch is called a **super-round**. In a single super-round, a node can constantly listen or keep beeping according to some 0-1 sequence of length $2\log n$, where 1 corresponds to beeping in the related round and 0 means staying silent. The sequences that the nodes use during the algorithm are **extended-IDs**, defined as follows: the first $\log n$ positions contain an ID of some node in $\{1,\ldots,n\}$, while the next $\log n$ positions contain the same ID with the bits flipped, that is, with ones swapped to zeros and vice versa. Note that extended-IDs are pairwise different, and each of them contains exactly $\log n$ ones and $\log n$ zeros. We say that a node v *beeps an extended-ID of node w in a super-round s* if, within super-round s, node v beeps only in rounds corresponding to positions with 1's in the extended ID of w (w could be a different node id than v). We say that a node w *receives an extended-ID of a node v in a super-round s* if:

- w does not beep in super-round s,
- the sequence of noise/silence heard by w in super-round s form an extended-ID of v.

From the perspective of receiving information in a super-round, all other cases not falling under the above definition of receiving an extended-ID, i.e., when a node is not silent in the super-round or receives a sequence of beeps that does not form any extended-ID, are ignored by the algorithm, in the sense that it could be treated as meaningless information noise.

Analogously to extended-ID's, nodes create an **extended-message** by taking the binary representation of the message of logarithmic length and transforming it to a $2\log n$ binary sequence in the same way as an extended-ID is created from the binary ID of a node. An extended-message, as well as an extended-ID, is easily decodable after being received without interruptions from other neighbors.

A specification of the conditions to achieve one-to-one communication, which is given "for free" in the CONGEST model, is crucial. An illustration of the following handshake communication procedure is shown in the full version of this work [19]. We say that our algorithm **realizes link** $\{v,w\}$ if the following are satisfied:

(a) there are three consecutive super-rounds (called "responding") in which v beeps an extended-ID of itself followed by an extended-ID of w and then by extended-message of v addressed to w, and w receives them in these super-rounds; intuitively, it corresponds to the situation when v "tells" w that it dedicates these three super-rounds for communication from itself to w, and w receives this information;

(b) there are three consecutive super-rounds (called "confirming") in which w beeps an extended-ID of itself followed by an extended-ID of v and by its extended-message addressed to v, and v receives them in these super-rounds; intuitively, it corresponds to the situation when w "tells" v that it dedicates these three super-rounds for communication from itself to v, and v receives this information;

(c) there is a super-round, not earlier than the one specified in point (a), at the end of which node w locally marks link $\{v,w\}$ as realized, and analogously, there is a super-round, not earlier than the one specified in point (b), at the end of which node v locally marks link $\{v,w\}$ as realized.

It is straightforward to see that in super-rounds specified in points (a) and (b), a multi-directional communication between v and w takes place – by sending and receiving both "directed pairs" of extended-IDs of these two nodes, each of them commits that the super-rounds specified in points (a) and (b) are dedicated for sending a message dedicated to the other node, and vice versa. Additionally, in some super-round(s) both nodes commit that it has happened (c.f., point (c) above).

Algorithm 2 C2B algorithm for announcer node v.

```
Procedure announcer(v, k_i)
    // announcing super-round
1   for each round r = 1, 2, ..., 2 log n do
2       if ⟨v⟩(r) = 1 then beep else listen
3   for each sub-phase a = 1, 2, ..., log k_i do
4       for b = 1, 2, ..., |F_{k_i/2^{a-2}, k_i/2^{a-1}}| do
            // responding 3 super-rounds
5           for 6 log n rounds do listen // announcer only listens
6           if some ⟨w⟩⟨v⟩⟨m_{w,v}⟩ was heard and {w, v} ∈ E(v) then
                // confirming 3 super-rounds
7               for each round r = 1, 2, ..., 2 log n do
8                   if ⟨v⟩(r) = 1 then beep else listen
9               for each round r = 1, 2, ..., 2 log n do
10                  if ⟨w⟩(r) = 1 then beep else listen
11              for each round r = 1, 2, ..., 2 log n do
12                  if ⟨m_{v,w}⟩(r) = 1 then beep else listen
13              E(v) ← E(v) \ {w, v} // link realized
14              if E(v) = ∅ then v stops executing
15          else
16              for 6 log n rounds do listen // wait to synchronize
```

Algorithm for epoch i: Structure

An epoch i is split into $|\mathcal{F}_{\Delta,k_i}|$ *phases*, for a given $(n, \Delta, \Delta - k_i)$-avoiding selector $\mathcal{F}_{\Delta,k_i}$ and parameter $k_i = \Delta/2^i$, parameterized by a variable j. Each phase starts with one *announcing super-round*, in which nodes in set $\mathcal{F}_{\Delta,k_i}(j)$ beep in pursuit to be received by some of their neighbors. This super-round is followed by $\log k_i$ *sub-phases*, parameterized by $a = 1, \ldots, \log k_i$. A sub-phase a uses sets from an $(n, k_i/2^{a-2}, k_i/2^{a-1})$-avoiding selector $\mathcal{F}_{k_i/2^{a-2},k_i/2^{a-1}}$ to determine who beeps in which super-round (together with additional rules to decide what extended-ID and extended-message to beep and how to confirm receiving them), and consists of $|\mathcal{F}_{k_i/2^{a-2},k_i/2^{a-1}}|$ 6-tuples of super-rounds (3 responding super-rounds and 3 confirming super-rounds). The goal of a phase is to realize links that were successfully received ("announced") in the first (announcing) super-round of this phase. This is particularly challenging in a distributed setting since many neighbors could receive such an announcement, but the links between them and the announcing node must be confirmed so that one-to-one communication between the announcer and responders could take place in different super-rounds (in one super-round, a node can receive only logarithmic-size information).

Definitions and notation. $\mathcal{F}_{\Delta,k_i}$ is a locally computed $(n, \Delta, \Delta - k_i)$-avoiding selector, and for any $a = 1, \ldots, \log k_i$, $\mathcal{F}_{k_i/2^{a-2},k_i/2^{a-1}}$ is a (locally computed) $(n, k_i/2^{a-2}, k_i/2^{a-1})$-avoiding selector, as in Theorem 2. We denote the extended-ID of node x as $\langle x \rangle$, and the extended-message of node x for node y as $\langle m_{x,y} \rangle$, both given as a sequence of bits. For any sequence of bits s, $s(i)$ is the i^{th} bit of s.

Algorithm 3 C2B algorithm for responder node w.

```
Procedure responder(w, k_i)
1   status(u) ← nil
    // announcing super-round
2   for 2 log n rounds do listen // responder only listens
3   if some ⟨v⟩ was heard and {v, w} ∈ E(w) then
4       status(w) ← v-responsive
5   for each sub-phase a = 1, 2, ..., log k_i do

```

3.2 Analysis of the C2B Algorithm

Recall that the algorithm proceeds in synchronized super-rounds, each containing a subsequent $2 \log n$ rounds. Therefore, our analysis assumes that the computation is partitioned into consecutive super-rounds and, unless stated otherwise, it focuses on correctness and progress in super-rounds. Recall also that each node either stays silent (no beeping at all) or beeps an extended ID of some node or an extended message of one node addressed to one of its neighbors in a super-round. The missing proofs are deferred to the full version of this work [19].

In the next two technical results, we state and prove the facts that receiving an extended-ID by a node w in a super-round can happen if and only if there is *exactly one neighbor* of w has been beeping *the same extended-ID* during the considered super-round.

▶ **Fact 2** (Single beeping). *If during a super-round, exactly one neighbor of a node w beeps an extended-ID of some z, then w receives this extended-ID in this super-round.*

Proof. Directly from the definition of receiving an extended-ID. ◀

▶ **Lemma 3** (Correct receiving). *During the algorithm, if a node w receives some extended-ID of z in a super-round, then some unique neighbor v of w has been beeping an extended-ID of z in this super-round while all other neighbors of w have been silent. The above holds except, possibly, some second responding super-rounds, in which a node can receive an extended-ID of z that has been beeped by more than one neighbor.*

We now prove that link realization implemented by our algorithm is consistent with the definition – it allocates in a distributed way super-rounds for bi-directional communication of distinct messages.

▶ **Lemma 4** (Correct realization). *If a node v (locally) marks some link $\{v, w\}$ as realized, which may happen only at the end of a second confirming super-round, the link has been realized by then.*

As mentioned earlier in the description of the phase, the goal of a phase j (of epoch i) is to assure that any node v that was received by some other nodes w in the announcing super-round, gets all such links $\{v, w\}$ realized by the end of the phase (and vice versa, because the condition on the realization by this algorithm is symmetric). The next step is conditional progress in a sub-phase a of a phase j.

▶ **Lemma 5** (Sub-phase progress). *Consider any node v and suppose that in the beginning of sub-phase a of phase j, there are at most $\Delta/2^{i+a-2}$ nodes w such that w is (j, v)-responsive and it does not mark link $\{v, w\}$ as realized. Then, by the end of the sub-phase, the number of such nodes is reduced to less than $\Delta/2^{i+a-1}$.*

▶ **Lemma 6** (Phase progress). *Consider a phase j of epoch i and assume that in the beginning, there are at most $2k_i$ non-realized incident links to any node. Every node w that becomes (j, v)-responsive in the first (announcing) super-round of the phase, for some v, mark locally the link $\{v, w\}$ as realized during this phase. And vice versa, also node v marks locally that link as realized.*

The next lemma proves the invariant for epoch i, assuming that it holds in the previous epochs.

▶ **Lemma 7** (Epoch invariant). *The invariant for epoch $i \geq 1$ holds.*

▶ **Theorem 8.** *The* C2B *algorithm deterministically and distributedly simulates any round of any algorithm designed for the CONGEST networks in $O(\Delta^2 \operatorname{polylog} n \log \Delta)$ beeping rounds, where the $\operatorname{polylog} n$ is the square of the (poly-)logarithm in the construction of avoiding-selectors in Theorem 2 multiplied by $\log n$.*

Proof. By Lemma 7, each epoch i reduces by at least half the number of non-realized incident links. We next count the number of rounds in each epoch by counting the number of super-rounds and multiplying the result by the $O(\log n)$ length of each super-round. Recall that link realization means that some triples of responding and confirming super rounds were not interrupted by other neighbors of both end nodes of that link; therefore, the attached extended messages (in the third super-rounds in a row) were correctly received. Thus, the local exchange of messages addressed to specific neighbors took place successfully.

Each sub-phase a has $O(\Delta^2 \operatorname{polylog} n)$ super-rounds, because for each set in of the $(n, k_i/2^{a-1}, k_i/2^a)$-avoiding selector $\mathcal{F}_{k_i/2^{a-1}, k_i/2^a}$, there are four super-rounds and the selector itself has $O((k_i/2^a) \operatorname{polylog} n)$ set, by Theorem 2.

Therefore, the total number of super-rounds in all sub-phases executed within the loops in Line 3 of Algorithm 2 and Line 5 of Algorithm 3 is

$$O(\sum_{a=1}^{\log k_i} (k_i/2^a)\ \textit{polylog}\ n) \leq O(k_i\ \textit{polylog}\ n)\ .$$

Within one phase, they are executed as many times as the number of announcing super-rounds. The number of such super-rounds in a phase is $|\mathcal{F}_{\Delta,k_i}|$, which is $O((\Delta^2/k_i)\ \textit{polylog}\ n)$ by Thm. 2. Thus, the total number of super-rounds in a phase is $O((\Delta^2/k_i)\ \textit{polylog}\ n \cdot k_i\ \textit{polylog}\ n) \leq O(\Delta^2\ \textit{polylog}\ n)$, where the final *polylog* n is a square of the (poly-)log in Thm. 2.

Since there are $\log \Delta$ epochs, the total number of super-rounds is $O(\Delta^2\ \textit{polylog}\ n \log \Delta)$, which is additionally multiplied by $O(\log n)$ – the length of each super-round – if we want to refer the total number of beeping rounds. ◀

Maximal Independent Set (MIS). To demonstrate that the above efficient simulator can yield efficient results for many graph problems, we apply it to the $O(\log^5 n)$ MIS algorithm in [20] to improve polynomially (with respect to Δ) the best-known solutions for MIS (c.f. [5]):

▶ **Corollary 9.** *MIS can be solved deterministically on any network of maximum node-degree Δ in $O(\Delta^2$ polylog $n)$ beeping rounds.*

4 Multi-hop Simulation

We generalize the simulation at distance 1 to the following *B-bit h-hop simulation* problem: each node has messages, potentially different, of size at most B bits addressed to any other node, and it needs to deliver them to all destination nodes within distance at most h hops. If each node has only a single message of size at most B bits to be delivered to all nodes within distance at most h hops, then we call this restricted version *B-bit h-hop Local Broadcast*. Note also that we do not require messages addressed to nodes of distance larger than h to be delivered. Below we generalize the lower bound for single-hop simulation in [12] to multi-hop simulation and multi-hop local broadcast.

▶ **Theorem 10.** *There is an adversarial network of size $\Theta(\Delta^h)$ such that any B-bit h-hop simulation algorithm requires $\Omega(B\Delta^{h+1})$ beeping rounds to succeed with probability more than $2^{-\frac{1}{2}\cdot B(\Delta-1)^{h-2}(\Delta/2)^3} = 2^{-\Theta\left(B\Delta^{h+1}\right)}$.*

Proof. Problem instance. We describe the construction of the adversarial network and input set of messages used to prove our lower bound as follows (refer to Figures 2 and 3). Consider a full bipartite graph $K_{\Delta/2,\Delta/2}$, with one part called T and the other R. We focus on transmissions going towards nodes in R, hence nodes in R will be called receivers, while nodes in $T = T_1$ will be called the first of h layers of transmitters.

Each node in T_1 will be a root of an $(h-1)$-depth tree of transmitters. We create a second layer of transmitters T_2 composed of $(\Delta/2)^2$ nodes. Each node in T_1 (already connected to each node in R) will also be connected to different $\Delta/2$ nodes in T_2. For subsequent layers of transmitters, that is each layer T_i, for $3 \leq i \leq h$, will be composed of $(\Delta/2)^2(\Delta-1)^{i-2}$ nodes. Each node in layer T_{i-1}, for $3 \leq i \leq h$, will be connected to different $\Delta - 1$ nodes in layer T_i. Note that each node in the defined network has at most Δ neighbors.

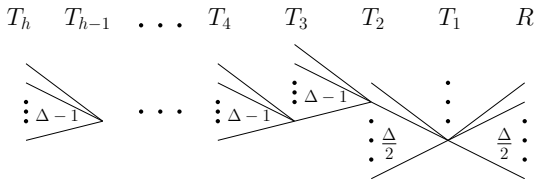

Figure 2 An illustration of the structure of the graph. The graph is partitioned into vertical layers $T_h, \ldots, T_1, R$. The graph is branching out heavily, so we show only a path from an arbitrary node in T_1 layer to an arbitrary node in T_h layer, with all the edges incident to the path. The numbers between the layers denote the number of edges between the layers that are incident to the path or on the path. Recall that layers T_1 and R have $\Delta/2$ nodes each, while the other layers have significantly more nodes, but we only show nodes that are adjacent to the considered path.

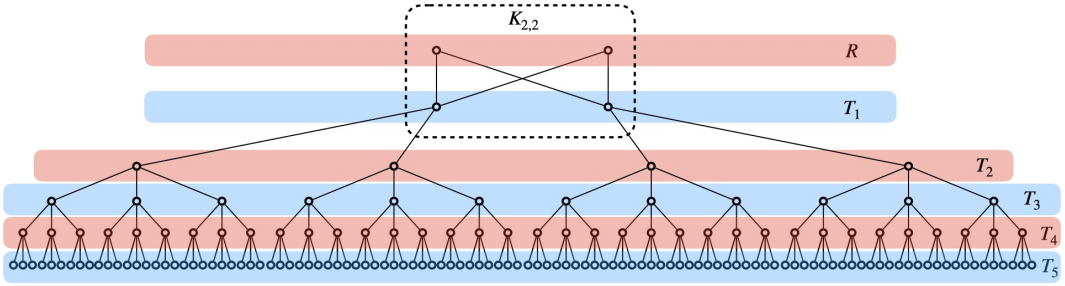

Figure 3 Illustration for Theorem 10. Example of adversarial graph for $\Delta = 4$ and $h = 5$.

We define now the input set of messages as follows. Let each node $v \in T_h$ have a B-bit message $m_{v \to u}$ to each node $u \in R$. We choose those messages uniformly at random. We will show that just these messages cannot be relayed efficiently and we do not need any other messages in our problem instance.[6]

Multihop Simulation. Here we analyze the multihop simulation algorithms.

There are $(\Delta/2)^2(\Delta-1)^{h-2}$ nodes in T_h, and each of them has $\Delta/2$ (possibly different) messages, one for each node in R. Therefore, there are $(\Delta/2)^3(\Delta-1)^{h-2} = \Theta(\Delta^{h+1})$ messages to nodes in R that are passing through nodes in T_1.

Let $\mathcal{R}$ be the concatenated string of local randomness in all the nodes in R. The output of any receiver $u \in R$ must depend only on $\mathcal{R}$, node IDs and the pattern of beeps and silences of nodes in T_1.

There are 2^t possible patterns of beeps and silences in t rounds. Therefore, the output of nodes in R must be one of the 2^t possible distributions, where a distribution is over the randomness of $\mathcal{R}$. The correct output of nodes in R is a string $\{0,1\}^{B(\Delta-1)^{h-2}(\Delta/2)^3} = \{0,1\}^{\Theta(B\Delta^{h+1})}$ chosen uniformly at random (since the input messages of nodes in T_h were chosen uniformly at random). Therefore, the probability of picking the correct result is at most $2^{t-B(\Delta-1)^{h-2}(\Delta/2)^3}$, and any algorithm that finishes within $t \leq \frac{1}{2} \cdot B(\Delta-1)^{h-2}(\Delta/2)^3$ rounds has at most $2^{-\frac{1}{2} \cdot B(\Delta-1)^{h-2}(\Delta/2)^3}$ probability of outputting the correct answer. ◀

[6] Alternatively we can make all other messages known to the optimal algorithm, e.g., by setting them to 0^B.

Algorithm

A simple algorithm would repeatedly use a 1-hop Local Broadcast routine to flood the network with the messages until nodes at a distance h received the messages. This, however, can take $\Omega(\Delta^{2h})$ rounds. Instead, we limit the flooding by only sending messages along the shortest paths to their destinations using a 1-hop simulation algorithm. The details of the algorithm as well as its analysis are presented next.

In the beginning, nodes use a standard protocol to disseminate their IDs up to distance h. They do it in h subsequent epochs, each epoch i of t_i rounds sufficient to run our Local Broadcast (see full version of this work [19]) for messages of size $\Delta^i \log n$. These messages contain different IDs learned by the node at the beginning of the current epoch. A direct inductive argument, also using the property that there are at most Δ^i nodes at a distance at most i, shows that at the end of epoch i, each node knows the IDs of all nodes at a distance at most i from it. Additionally, each node records in which epoch i it learned each known ID v for the first time and from which of its neighbors w – and stores this information as a triple (v, w, i). The invariant for $i = h$ proves that at the end of epoch h, each node knows IDs of all nodes of distance at most h from it. The round complexity is $\sum_{i=1}^{h} \Delta^i \log n \cdot \Delta^2 \log n = O(\Delta^{h+2} \log^2 n)$, and as will be seen later, it is subsumed by the round complexity of the second part of our algorithm (as the *polylog* n function in Theorem 8 is asymptotically bigger than $\log^2 n$).

Note that a sequence of triples $(v, w_1 = v, 1), \ldots, (v, w_\ell, \ell)$, stored at nodes $w_2, w_3, \ldots, w_\ell, w_{\ell+1} = u$ respectively, represents a shortest path to node v starting from the node u; the length of that path is ℓ.

In the second part, nodes also proceed in epochs, but this time each epoch i takes t_i^* rounds sufficient to execute 1-hop simulation algorithm from Section 3 (see Theorem 8) for point-to-point messages of size $(B + \log n)\Delta^h$. Here B denotes the known upper bound on the size of any input message. In epoch i, every node u transmits a (possibly different) message of size $(B + \log n)\Delta^h$ to each neighbor w. Such a message contains all the input messages of nodes within $i - 1$ distance and the recipients of these messages such that w is the next node on the saved shortest path to the recipient. The messages have already traveled $i - 1$ hops, so their destination is at most $h - (i - 1)$ hops away. More specifically, the message from node u addressed to a neighbor w in epoch i contains pairs $(v, m_{z \to v})$, where v is such that (v, w, i') is stored at the node for some $i' \leq h - (i - 1)$ and $m_{z \to v}$ is a message received by the node u in epoch $i - 1$ (in case of $i - 1 = 0$, it is the original message of the node addressed to v). A direct inductive argument shows that at the end of each epoch i a node knows at most Δ^i messages addressed to any node v of distance $\ell \leq h - i$ from the node. This invariant is based on the following arguments:

- Because there is a unique neighbor w of the node u such that a triple (v, w, ℓ) is stored at the node, the number of such nodes v of distance at most $h - i + 1$ from the node u is at most Δ^{h-i+1},
- by the end of epoch $i - 1$, node u could receive messages to be relayed to v from Δ^{i-1} different nodes at distance $i - 1$,
- each message contains up to B-bit long original message and an ID of length $\log n$,
- hence, messages of size at most $(B + \log n)\Delta^{i-1} \cdot \Delta^{h-i+1} = (B + \log n)\Delta^h$ are being sent to each neighbor in epoch i, and by definition – epoch i has sufficient number of rounds to deliver them.

The invariant for $i = h$ proves the desired property of B-bit h-hop simulation. The total number of rounds is $O(h \cdot (B + \log n)\Delta^h \cdot \Delta^2 \textit{ polylog } n) \subseteq O(h \cdot B\Delta^{h+2} \textit{ polylog } n)$, where factor h comes from the number of epochs, each sending at most Δ point-to-point messages of size at most $(B + \log n)\Delta^h$ to neighbors (by the invariant) using the 1-hop simulation protocol with overhead $O(\Delta^2 \textit{ polylog } n)$ (by Theorem 8). Hence we proved the following.

▶ **Theorem 11.** *There is a distributed deterministic algorithm solving the B-bit h-hop simulation problem in a beeping network in $O(h \cdot B\Delta^{h+2}$ polylog $n)$ rounds.*

5 Conclusions

We provided deterministic distributed algorithms to efficiently simulate a round of algorithms designed for the CONGEST model on the Beeping Networks. This allowed us to improve polynomially the time complexity of several (also graph) problems on Beeping Networks. The first simulation by the Local Broadcast algorithm is shorter by a polylogarithmic factor than the other, more general one – yet still powerful enough to implement some algorithms, including the prominent solution to Network Decomposition [20]. The more general one could be used for solving problems such as MIS. We also considered efficient pipelining of messages via several layers of BN. Two important lines of research arise from our work. First, whether some (graph) problems do not need local broadcast to be solved deterministically, and whether their time complexity could be asymptotically below Δ^2. Second, could a lower bound on any deterministic local broadcast algorithm, better than $\Omega(\Delta \log n)$, be proved?

A Unified FPT Framework for Crossing Number Problems

Éric Colin de Verdière

Petr Hliněný
Faculty of Informatics, Masaryk University, Brno, Czech Republic

Abstract

The basic (and traditional) *crossing number problem* is to determine the minimum number of crossings in a topological drawing of an input graph in the plane. We develop a unified framework that smoothly captures many generalized crossing number problems, and that yields fixed-parameter tractable (FPT) algorithms for them not only in the plane but also on surfaces.

Our framework takes the following form. We fix a surface $\mathcal{S}$, an integer r, and a map κ from the set of topological drawings of graphs in $\mathcal{S}$ to $\mathbb{Z}_+ \cup \{\infty\}$, satisfying some natural monotonicity conditions, but essentially describing the allowed drawings and how we want to count the crossings in them. Then deciding whether an input graph G has an allowed drawing D on $\mathcal{S}$ with $\kappa(D) \leq r$ can be done in time quadratic in the size of G (and exponential in other parameters). More generally, we may take as input an edge-colored graph, and distinguish crossings by the colors of the involved edges; and we may allow to perform a bounded number of edge removals and vertex splits to G before drawing it. The proof is a reduction to the embeddability of a graph on a two-dimensional simplicial complex.

This framework implies, in a unified way, quadratic FPT algorithms for many topological crossing number variants established in the graph drawing community. Some of these variants already had previously published FPT algorithms, mostly relying on Courcelle's metatheorem, but for many of those, we obtain an algorithm with a better runtime. Moreover, our framework extends, at no cost, to these crossing number variants in any fixed surface.

1 Introduction

The (traditional) *crossing number* problem, minimizing the number of pairwise edge crossings in topological drawings of an input graph in the plane, is a long-standing and central task in graph drawing and visualization that comes in many established flavors; see the extensive dynamic survey by Schaefer [45]. In this paper, we give a framework that smoothly captures many of the variants of crossing numbers, and in a unified way provide efficient algorithms for them when parameterized by the solution value (i.e., the respective crossing number).

Many flavors of crossing numbers. There is currently a surge of crossing number variants. A motivation for such variations is that, in practical drawing applications, not every crossing or crossing pattern of edges may be "equal" to other ones. One may, e.g., want to avoid

mutual crossings of important edges. Or, to allow crossings only within specific parts of a graph, and not between unrelated parts. Or, to exclude crossings of edges of some type. Or, to allow only certain "comprehensible" crossing patterns in order to help visualize the graph. This is the main focus of the recent research direction called "beyond planarity" [15].

Paraphrasing Schaefer [45, Chapter 2], a crossing number variant minimizes, over all *allowed drawings* D of an input graph G in some specified *host surface*, an *objective function* related to the crossings in D. The *allowed drawings* may, e.g., restrict the crossings on one edge or in a local pattern of crossing edges, or prescribe or forbid certain local properties of the drawing (also depending on types or colors of edges). The *host surface* is usually the plane, but can be any fixed surface, orientable or not. The *objective function* is often the number of crossings between edges, but other possibilities include, e.g., the number of edges involved in crossings, or the number of pairs of edges that cross an odd number of times.

Existing algorithms for the traditional version. One usually considers the decision version of the (traditional) crossing number problem: Given an input graph G of size n, and an integer r, does G have a crossing number at most r? This problem is already NP-hard in the plane, as proved by Garey and Johnson in 1983 [18], and even in very specific cases [8, 24, 26]. Moreover, the problem is APX-hard [7], and the best known polynomial-time approximation algorithm [10] gives an approximation factor that is subpolynomial in n only for bounded-degree graphs.

Thus, the main current focus is on algorithms that are fixed-parameter tractable (FPT) in r – the runtime has the form $f(r) \cdot \mathsf{poly}(n)$, where f is a computable function of the *parameter* r. For fixed r, Grohe [20] has described an $O(n^2)$-time algorithm, and Kawarabayashi and Reed [32] have announced an $O(n)$-time algorithm. Both rely on Courcelle's metatheorem [14], which automatically entails a huge dependence in the parameter r.

Two recent approaches avoid resorting to Courcelle's theorem. First, Colin de Verdière, Magnard, and Mohar [13] have studied the problem of embedding a graph in a *two-dimensional simplicial complex* (2-complex for short), a topological space obtained from a surface by adding isolated edges and identifying vertices. Among other motivations for this problem, they observe [13, Introduction] that the crossing number problem reduces to the embeddability of the input graph in a certain 2-complex depending only on r. Then Colin de Verdière and Magnard [12] have shown that the embeddability of a graph of size n in a 2-complex of size C can be tested in $2^{\mathsf{poly}(C)} \cdot n^2$ time. Hence, this results in a $2^{\mathsf{poly}(r)} \cdot n^2$-time algorithm for the crossing number problem, which, moreover, extends to any fixed surface.

Second, even more recently, Lokshtanov, Panolan, Saurabh, Sharma, Xue, and Zehavi [35] have given a $2^{\mathcal{O}(r \log r)} \cdot n$-time algorithm for the traditional crossing number problem in the plane, by a reduction to bounded treewidth and dynamic programming, all in time linear in n.

Existing algorithms for other variants. For other flavors of crossing numbers, which are (typically) also NP-hard, the literature on FPT algorithms is scarce; besides Pelsmajer, Schaefer, and Štefankovič [41] giving FPT algorithms for the odd and pair crossing numbers, we are only aware of two very recent papers, which bring a general approach to multiple crossing number flavors and which we now detail. (The various flavors of crossing numbers are defined in Section 5.)

First, Münch and Rutter [37], extending Grohe's approach [20], provide a framework for quadratic FPT algorithms for the crossing number of several types of beyond-planar drawings of graphs in the plane, characterized by forbidden combinatorial crossing patterns. This includes the crossing number of k-planar, k-quasi-planar, min-k-planar, fan-crossing, and fan-crossing free drawings of a graph for any constant k.

Second, Hamm, Klute, and Parada [22], in a very recent preprint, have announced a generalization of the previous framework [37], also handling forbidden topological crossing patterns in drawing types in the plane and, more importantly, bringing the possibility of handling predrawn parts of the input graph (as already known for the traditional crossing number [21]). The dependence in the size n of the input graph is an unspecified polynomial.

The above results all rely on Courcelle's theorem. Apart from that, we are only aware of sporadic results for isolated variants. Kawarabayashi and Reed [32] and Jansen, Lokshtanov, and Saurabh [30] both claim, without details, a linear FPT algorithm to compute the skewness of a graph, and Nöllenburg et al. [39] give a non-uniform FPT algorithm for the splitting number in surfaces. All mentioned papers except Nöllenburg et al. are restricted to the plane.

Our contributions. Our general framework takes the following form. We fix a surface $\mathcal{S}$ and an objective function κ from the set $\mathcal{D}$ of (possibly edge-colored) topological drawings of graphs on $\mathcal{S}$ to the set $\mathbb{Z}_+ \cup \{\infty\}$; the allowed drawings D are those that satisfy $\kappa(D) < \infty$. The map κ has to satisfy some natural monotonicity conditions, defined later. Given an integer r, we prove that deciding whether an input graph G has a drawing D on $\mathcal{S}$ with $\kappa(D) \leq r$ can be done in quadratic time in the size n of G, and exponential in a polynomial of the other parameters, namely the genus of $\mathcal{S}$, the maximum size of a "fully crossing" drawing $D^\times$ satisfying $\kappa(D^\times) \leq r$, and the integer r. This remains true if one allows a bounded number of (possibly color-restricted) edge removals and vertex splits to G before drawing it; these numbers are also parameters. The proof is a reduction to the already mentioned problem of deciding the embeddability of a graph on a 2-complex [12]; while the general strategy is intuitive, many subtle technical details need to be overcome to make it all work.

We deduce FPT algorithms with runtime quadratic in the size n of the input graph, and exponential in a polynomial of the other parameters, for many established crossing number variants; we now survey some of them. First, we can restrict ourselves to many established drawing styles, such as k-planar, k-quasi-planar, min-k-planar, fan-crossing, weakly and strongly fan-planar, k-gap, and fixed-rotation drawings (k being an additional fixed parameter). For the k-gap and fixed rotation cases, no FPT algorithms were known. Second, we may assign colors to the edges of the input graph and count the crossings differently depending on the colors of the edges involved, leading to the first FPT algorithms on the joint crossing number on surfaces and its generalizations. Third, assuming suitable additional properties, we can handle problems that do not count the crossings, but rather the number of edges, or pairs of edges, involved in crossings, such as the edge, pair, and odd crossing numbers (no FPT algorithm was known for the edge crossing number). And fourth, since we allow for prior edge removals and vertex splits, our framework encompasses, e.g., the skewness, for which FPT algorithms were only sketched [30, 32] in the plane, and the splitting number, which was only known to admit a nonuniform FPT algorithm [39].

Last but not least, all these four aspects that define flavors of crossing numbers can be combined arbitrarily, and our main results are valid not only in the plane, but for arbitrary surfaces. For most flavors of crossing number, the arguments are direct, though they really differ according to the flavor; they essentially boil down to checking some technical conditions (see Definition 3.1), and to giving an algorithm (not necessarily polynomial) to check a given drawing of bounded size and to count its crossings (see Theorem 3.2). However, for a couple of crossing number flavors (in particular, when fixing the rotation scheme), additional ingredients are needed.

Comparison with the state of the art. Our main contribution is a convenient, versatile, and unified framework capturing a very general class of crossing number variants while giving FPT algorithms. In particular, as listed above, we get new FPT results for several established variants and their generalizations (to surfaces, or by combining the features of multiple variants). It is conceivable that some of the variants newly covered by our framework could be proved FPT using other techniques, perhaps the (very powerful) metatheorem of Courcelle, as already used in [20–22, 37]. However, such developments are extremely delicate even in isolated variants and lead to hard-to-describe algorithms. Indeed, first, checking a given drawing and counting its crossings must be formalized in the MSO_2 logic of graphs, which usually needs heavy tricks tailored to the specific case; second, there remains the specific and often highly nontrivial treewidth reduction step to be done. So far, such approaches have been successful only in the case of the plane.

Moreover, all approaches using Courcelle's theorem inherently come with a high computational cost. Indeed, they result in algorithms with a huge multi-level exponential dependence in the parameter r; for instance, it is an exponential tower of height at least four in the case of [20] and three in the case of [32], see the discussion in [35]. In contrast, our algorithms are singly exponential in a polynomial in r. Also, while Courcelle's theorem itself runs in linear time in the size n of the input graph, the necessary treewidth reduction step requires quadratic time, if not more, in the known approaches for the non-traditional crossing numbers. Our algorithms have a quadratic dependence in n, and the only bottleneck to a linear-time dependence is the quadratic runtime of the current best embeddability algorithm [12].

The frameworks used in the two very recent works mentioned above [22, 37], which both use treewidth reduction and Courcelle's theorem, can handle some of the drawing styles that we encompass, but different counting functions, edge removals and vertex splits, and nonplanar surfaces are out of their reach. However, it should not be difficult to extend their framework to handle edge-colored graphs, thanks to the MSO_2 logic being able to handle arbitrary sets of edges. On the other hand, the recent breakthrough of Lokshtanov et al. [35] for the traditional crossing number problem may fuel hope for more $2^{\mathcal{O}(r \log r)} \cdot n$-time algorithms, but tweaking all ingredients of that highly technical paper seems hard, even for isolated crossing number variants, and moreover this approach is inapplicable to surfaces other than the plane, due to the use of several inherently planar techniques (3-connectivity arguments and dependence on [30]).

Organization of the paper. After the preliminaries (Section 2), we describe our general framework and state our main result (Section 3), which is then proved (Section 4). We then list the numerous applications to crossing number variants (Section 5).

2 Preliminaries

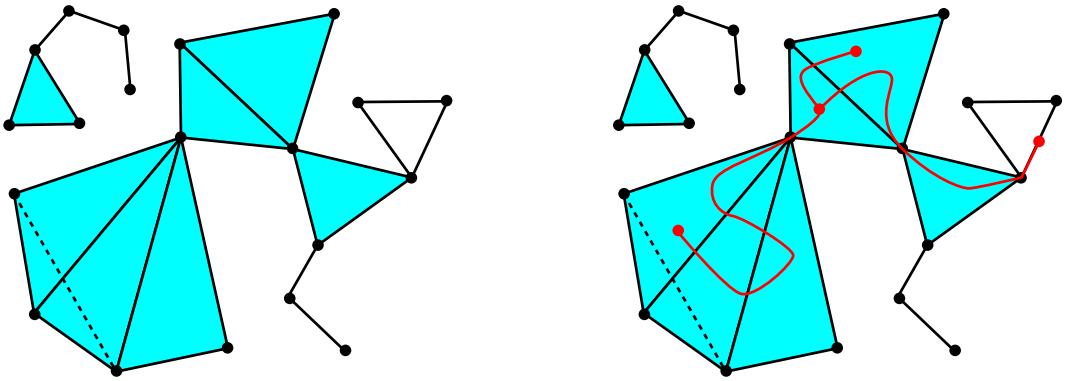
Graphs and surfaces. In this paper, graphs are finite and undirected, but not necessarily simple unless specifically noted. The *size* of a graph G is the number of vertices plus the number of edges of G. A *vertex split* of a graph G at vertex v creates a new vertex v' and replaces some of the edges incident to v by making them incident to v' instead of v.

We follow [2, 36] for surface topology. A *surface* $\mathcal{S}$ is a topological space obtained from finitely many disjoint solid, two-dimensional triangles by identifying some of their edges in pairs. Surfaces are not necessarily connected. The *boundary* of $\mathcal{S}$ is the closure of the union of the unidentified edges. The *(Euler) genus* of a connected surface is twice its number of "handles", if it is orientable, and is its number of "crosscaps", otherwise. The *topological size*

of $\mathcal{S}$ equals $s := d+b+g$, where d is the number of connected components of $\mathcal{S}$, g is the sum of the (Euler) genera of its connected components, and b is the number of boundary components. The plane is not a surface according to our definition, but in this paper it can always be substituted with a disk, which is (homeomorphic to) a surface. A *self-homeomorphism* of $\mathcal{S}$ is just a homeomorphism from $\mathcal{S}$ to $\mathcal{S}$.

(Topological) drawings of graphs. A *curve* c in a topological space $\mathcal{X}$ is a continuous map from the closed interval $[0,1]$ into $\mathcal{X}$. The *relative interior* of c is the image, under c, of the open interval $(0,1)$. In a *drawing* D of a graph G in a topological space $\mathcal{X}$, vertices are represented by points of $\mathcal{X}$ and edges by curves in $\mathcal{X}$ such that the *endpoints* $c(0)$ and $c(1)$ of a curve c are the images of the end vertices of the corresponding edge. Moreover, we assume that distinct vertices are mapped to distinct points and that the relative interiors of the edges avoid the images of the vertices. Given a point $x \in \mathcal{X}$, its *multiplicity* in D is the number of pairs (c,t) such that $c(t) = x$, where c is a curve representing an edge of G in D, and $t \in (0,1)$. An *intersection point* (shortly an *intersection*) of D is a point with multiplicity at least two. We only consider drawings D with finitely many intersection points.

When considering a drawing D of a graph G on a *surface* $\mathcal{S}$, we *always* implicitly assume that G has no isolated vertex and that the image of D avoids the boundary of $\mathcal{S}$; these conditions are actually benign in a graph drawing context. In D, each edge e is subdivided into (finitely many) *pieces* by the intersection points along e. A point of multiplicity two corresponds to a *crossing* if no local perturbation of the curves can remove this intersection, or to a *tangency*, otherwise. D is *normal* [44] if every intersection point has multiplicity two and is a crossing (not a tangency). Moreover, D is *simple* if it is normal, no edge self-crosses, no two adjacent edges cross, and no two edges cross more than once.[1]



The (traditional) *crossing number* of a graph G in a surface $\mathcal{S}$ is the least number of crossings over all normal drawings of G in $\mathcal{S}$. Many variations exist [45], see Section 5.

We need to represent drawings of graphs on a surface $\mathcal{S}$ combinatorially, up to self-homeomorphisms of $\mathcal{S}$. Cellular embeddings can be represented by combinatorial maps [16], but we need to allow crossings, and moreover faces need not be disks. We can achieve this, ultimately relying on combinatorial maps. Details can be found in the full version.

2-complexes. In this paper, a 2-*complex* $\mathcal{C}$ (or two-dimensional simplicial complex) is a topological space obtained from a simple graph (without loops or multiple edges) by attaching solid, two-dimensional triangles to some of its cycles of length three; see Figure 1.[2] The *simplices* of $\mathcal{C}$ are its vertices, edges, and triangles. We can easily represent 2-complexes algorithmically, by storing the vertices, edges, and triangles, and the incidences between them. In general, many such representations correspond to the same topological space, and the choice of the representation only impacts the complexity analysis of our algorithms. The class of 2-complexes is quite general; it contains all graphs, all surfaces, and any space obtained from a surface by identifying finitely many finite subsets of points and by adding finitely many edges between any two points.

[1] Note that many authors do not consider a drawing D *simple* if D contains two parallel edges (even uncrossed), as two parallel edges necessarily intersect at their two endpoints. Likewise, uncrossed loops are usually not allowed in simple drawings. We do not make these additional restrictions here for technical reasons connected to Definition 3.1; see also Proposition 5.2.

[2] Our definition of 2-complex slightly departs from the standard one; it is the same as a geometric simplicial complex of dimension at most two, realized in some ambient space of dimension large enough.

(a) (b)

Figure 1 (a): An example of a two-dimensional simplicial complex, or 2-complex for short. (b): An embedding of some graph with four vertices and three edges on the same 2-complex.

An *isolated edge* of a 2-complex $\mathcal{C}$ is an edge incident to no triangle. The *surface part* of $\mathcal{C}$ is the union of all its triangles, together with their incident vertices and edges. A *singular point* of $\mathcal{C}$ is a point that has no open neighborhood homeomorphic to an open disk, a closed half-disk, or an open segment.

Our above definition of drawings in topological spaces applies to drawings in 2-complexes. In particular, vertices of G may lie anywhere on $\mathcal{C}$, and edges of G as curves may traverse several vertices, edges, and triangles of $\mathcal{C}$. An *embedding* of G into $\mathcal{C}$ is a drawing without any intersection point.

Embeddability of graphs on 2-complexes. The *embeddability problem* takes as input a graph G and a 2-complex $\mathcal{C}$, and the task is to decide whether G has an embedding in $\mathcal{C}$. This problem is fixed-parameter tractable in the size of the input 2-complex:

▶ **Theorem 2.1** (Colin de Verdière and Magnard [12, arXiv version, Theorem 1.1][3])**.** *One can solve the embeddability problem (of graphs in 2-complexes) in* $2^{\mathsf{poly}(C)} \cdot n^2$ *time, where* C *is the number of simplices of the input* 2*-complex and* n *is the size of the input graph.*

3 The framework: description and results

We consider *colored graphs*, in which each *edge* is labeled with a positive integer. A *colored drawing* in a surface $\mathcal{S}$ is a drawing of a colored graph G in $\mathcal{S}$ in which each edge of the drawing inherits the color of the corresponding edge of G. Throughout this paper, let $\mathcal{S}$ be a surface, and let $\mathcal{D}$ be the set of colored drawings of graphs on $\mathcal{S}$.

The general formulation of our result is based on the following definition, in which the function κ of a drawing should be thought of as a generalization of the (traditional) crossing number – "counting the crossings", or indicating (with value ∞) that "a drawing is invalid". More precisely, κ is a quality function that does not increase upon changes that add no new crossings, and λ bounds the number of pieces into which edges are split in valid drawings:

[3] The conference proceedings version of [12] gives a slightly worse bound on the running time, cubic in n. The theorems that we state take into account the improvement in the latest arXiv version.

▶ **Definition 3.1** (Crossing-counting pair). *Let $\kappa : \mathcal{D} \to \mathbb{Z}_+ \cup \{\infty\}$ be a function, and let $\lambda : \mathbb{Z}_+ \to \mathbb{Z}_+$ be a non-decreasing function. We say that (κ, λ) is a* crossing-counting pair *if:*

1. *for any $D, D' \in \mathcal{D}$, we have $\kappa(D') \leq \kappa(D)$ whenever D' results from D by one of the following operations:* (a) *the removal of a vertex or an edge;* (b) *the addition of a vertex whose image is disjoint from the image of D (and from the boundary of $\mathcal{S}$);* (c) *the addition of an edge, of an arbitrary color, connecting two vertices in D, and otherwise disjoint from the image of D (and from the boundary of $\mathcal{S}$);* (d) *a self-homeomorphism of $\mathcal{S}$;*
2. *for any drawing $D^\times \in \mathcal{D}$ such that each edge carries at least one intersection point in $D^\times$ (either a self-intersection or an intersection with another edge, but common endpoints do not count) and $\kappa(D^\times) < \infty$, the number of pieces of $D^\times$ is at most $\lambda(\kappa(D^\times))$;*
3. *one can compute $\lambda(i)$ in $2^{\mathcal{O}(i)}$ time.*

Note that Definition 3.1, Item 1, implies that κ is not affected by any of the operations (b), (c), and (d), since such operations can be reversed by an operation of type (a) or (d).

As an important special case, if $\kappa(D)$ is the number of crossings in D, or is ∞ if D is not a normal drawing, and $\lambda(i) = 4i$, then (κ, λ) satisfies the conditions of Definition 3.1 (indeed, note that each piece of an edge of $D^\times$ is incident to at least one crossing point, and each crossing point involves at most four pieces). This motivates the term "crossing-counting pair".

We now introduce the following problem (the reader may wish to focus on the simplified case of $p = q_1 = \ldots = q_c = 0$, which implies $G = G'$):

(κ, λ)-Crossing Number (for the class $\mathcal{D}$ of c-colored drawings, in surface $\mathcal{S}$)
Input: A colored graph G with colors in $\{1, \ldots, c\}$ for some integer c, with at most n vertices and edges, a non-negative integer r, and non-negative integers p and $q_1, q_2, \ldots, q_c$.
Question: Is there a colored drawing $D' \in \mathcal{D}$ in $\mathcal{S}$, with $\kappa(D') \leq r$, of a colored graph G', such that G' is obtained from G by performing at most p successive vertex splits and by removing, for $i = 1, \ldots, c$, at most q_i edges of color i?

Our main result is that, assuming κ is computable, the (κ, λ)-Crossing Number problem is fixed-parameter tractable in the topology of the surface, the number c of colors, the number $p + \sum_i q_i$ of allowed vertex splits and edge removals, and the value of r:

▶ **Theorem 3.2.** *Let $\mathcal{S}$ be a surface of topological size s, let $\mathcal{D}$ be the set of colored drawings of graphs in $\mathcal{S}$, and let (κ, λ) be a crossing-counting pair.*

Let δ be a non-decreasing function such that, given a representation of size i of a (colored) drawing $D \in \mathcal{D}$, one can compute $\kappa(D)$ in time $\delta(i)$.

Then the (κ, λ)-Crossing Number problem, on input instance $(G, r, p, q_1, \ldots, q_c)$, can be solved in time $2^{\mathsf{poly}(s+c+p+q+\lambda(r))} \cdot \delta(\mathcal{O}(s + \lambda(r))) \cdot n^2$, where n is the size of G and $q = \sum_i q_i$.

In all our applications, the factor $\delta(\cdot)$ in the runtime will be at most exponential in the parameters, and can thus be ignored. Moreover, for positive instances, we can compute an actual representation of the corresponding drawing; see the full version.

4 Sketch of proof of Theorem 3.2

Due to space restrictions, we only informally describe the reduction here; details are in the full version. Recall that $\mathcal{D}$ denotes the set of drawings of graphs on the surface $\mathcal{S}$. Let (κ, λ) be a crossing-counting pair for drawings in $\mathcal{D}$.

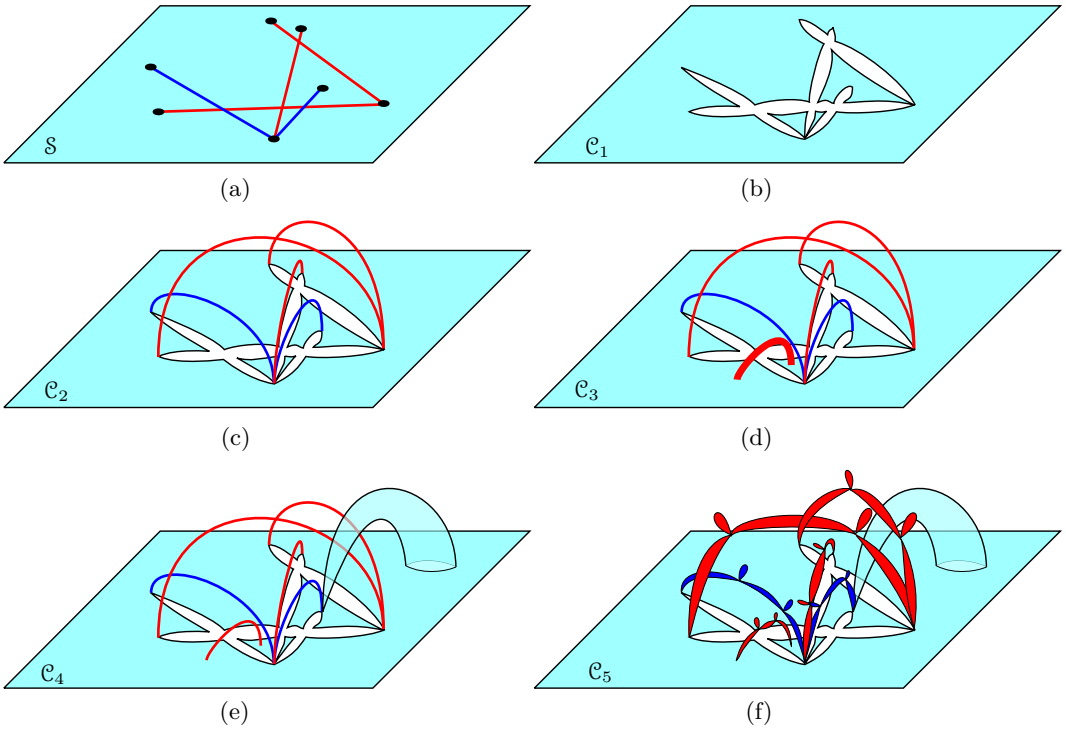


Figure 2 The construction of a 2-complex $\mathcal{C}_5$ in our reduction. (a): The surface $\mathcal{S}$ and the colored drawing $D^\times$. (b): $\mathcal{C}_1$ is obtained by cutting $\mathcal{S}$ along $D^\times$. Note that each vertex of G (in particular, the one in the bottom of the image) on $\mathcal{S}$ corresponds to a single point in $\mathcal{C}_1$, while, in this particular example, each intersection point in D of multiplicity i corresponds to $4i$ points in $\mathcal{C}_1$. (c) $\mathcal{C}_2$ is obtained by adding isolated edges corresponding to the edges of $D^\times$; we define the color of each isolated edge to be that of the corresponding edge in $D^\times$. (d) $\mathcal{C}_3$ is obtained by adding q_i isolated edges of color i for each color i. Here color 1 is represented in red, color 2 is represented in blue, and $q_1 = 1$, $q_2 = 0$. (e) $\mathcal{C}_4$ is obtained by iteratively identifying p pairs of points of $\mathcal{C}_3$ (here $p = 1$). (f) $\mathcal{C}_5$ is obtained by replacing each isolated edge of color i with a necklace (represented figuratively here) of thickness $p + 2q + 2\lambda(r) + i$ and beads of size $c - i + 2$.

The proof of Theorem 3.2 is a parameterized Turing reduction to the embeddability problem on 2-complexes. Consider an instance $(G, r, p, q_1, \ldots, q_c)$ of the (κ, λ)-Crossing Number problem. We define an uncolored graph $G_2 = G_2(G, r, p, q_1, \ldots, q_c)$ and a set of 2-complexes $\Gamma = \Gamma(r, p, q_1, \ldots, q_c)$ such that our (κ, λ)-Crossing Number instance is positive if and only if G_2 embeds in at least one of the 2-complexes in Γ (see a sketch in Figure 2). The set Γ is built by branching over a (small enough) set of properties for the hypothetical drawing of a graph G' (obtained from G by edge removals and vertex splits as in the problem definition) or, equivalently, by *guessing* some properties of that drawing.

Assume that G' has a colored drawing D' in $\mathcal{S}$ with $\kappa(D') \leq r$. Let $D^\times$ be the subdrawing of the subgraph of G' made of the edges that are involved in at least one intersection in D'; the definition of a crossing-counting pair implies that $\kappa(D^\times) \leq r$, so $D^\times$ is made of at most $\lambda(\kappa(D^\times)) \leq \lambda(r)$ pieces. Viewing $D^\times$ as an abstract drawing, without its correspondence with the vertices and edges of G', this implies that we can enumerate all such colored drawings up to self-homeomorphism of $\mathcal{S}$ in time $(s + c + \lambda(r))^{\mathcal{O}(s+\lambda(r))}$. In other words, we can *guess* the appropriate colored drawing $D^\times$.

Subsequently, we cut $\mathcal{S}$ along the relative interior of the edges of $D^\times$ (Figure 2(b); details are in the full version) and add isolated edges connecting the endpoints of the edges in $D^\times$ (Figure 2(c)), obtaining a 2-complex $\mathcal{C}_2$ in which G' embeds. If G' is allowed to result from G by edge removals and vertex splits, we modify the 2-complex appropriately, by guessing where the endpoints of the additional isolated edges must be inserted (Figure 2(d)) and which points of the 2-complex must be identified back (doing an inverse of the vertex split, Figure 2(e)). Note that these guessed points may be picked from the surface part of $\mathcal{C}_2$, as well as among the vertices of the edges of $D^\times$ in $\mathcal{C}_2$. We obtain a 2-complex $\mathcal{C}_4$ in which G embeds. Each isolated edge of $\mathcal{C}_4$ naturally bears the color of the edge of G it carries.

It remains to ensure that, conversely, the embeddability of G into one of the resulting 2-complexes implies a positive (κ, λ)-Crossing Number instance. For this purpose, we do the following. First (Figure 3(b)), as a minor technical detail, we apply a preprocessing step – attaching a 4-clique to each vertex of G, to ensure that all vertices of G have degree at least three. Let G_1 be this new graph. Second, and more importantly (Figure 2(f) and Figure 3), we need to encode the colors of the edges. We turn each edge of G_1 and each isolated edge of the 2-complex $\mathcal{C}_4$ (in which G_1 embeds, see above) into a *necklace* encoding the color, such that a necklace of a certain encoding type in the resulting graph can only use a necklace of the same type in the resulting 2-complex. This results in an (uncolored) graph G_2 embedded in a 2-complex $\mathcal{C}_5$. Finally, the set Γ of 2-complexes in which we try to embed G_2 is made of all 2-complexes $\mathcal{C}_5$, over all possible choices (guesses) described above.

In more detail, we define a *necklace of thickness h and beads of size k* to be the graph obtained from a path of length three by (1) replacing each edge with h parallel edges, and (2) attaching k loops to each of the two internal vertices of the path (Figure 3(c)). The intuition is that, by the minimum-degree condition on G_1, the internal vertices of necklaces of our 2-complex can essentially only be used by internal vertices of the necklaces of G_2. So, if edges of color i are encoded with necklaces of, say, thickness i and beads of size $c - i$, we effectively prevent graph necklaces from using 2-complex necklaces of different types. (We will actually use slightly refined formulas for the thickness and the size of the beads.)

5 Applications: FPT algorithms for diverse crossing number variants

In this section, we demonstrate the wide applicability of our framework to crossing number problems. First, as a toy example, we reprove that we can compute the traditional crossing number in quadratic FPT time on surfaces [12]:

▶ **Proposition 5.1.** *Let $r \geq 0$ be an integer, and $\mathcal{S}$ a surface with topological size s. Deciding whether an input graph G of size n has crossing number at most r in $\mathcal{S}$ can be solved in time $2^{\mathsf{poly}(s+r)} \cdot n^2$.*

Proof. We apply our framework with a single color ($c = 1$), no vertex splits or edge removals ($p = q_1 = 0$), and in the case where $\mathcal{D}$ is the set of drawings of graphs on $\mathcal{S}$. For any drawing D, let $\kappa(D)$ be the number of crossings in D, or ∞ if D is not a normal drawing. Moreover, let $\lambda(i) = 4i$. Since $\kappa(D) < \infty$ only if D is normal, (κ, λ) is a crossing-counting pair. Theorem 3.2 implies the result. ◀

We now turn to the promised applications. We survey, in order, specific drawing styles, colored crossing number problems, various counting methods, and problems where prior edge removals and vertex splits are allowed. Throughout this section, again, let $\mathcal{S}$ be a surface and $\mathcal{D}$ the set of colored drawings of graphs on $\mathcal{S}$. In our reductions to the (κ, λ)-Crossing Number problem, we always set $p = q_1 = \ldots = q_c = 0$ except in Section 5.4. In nearly all

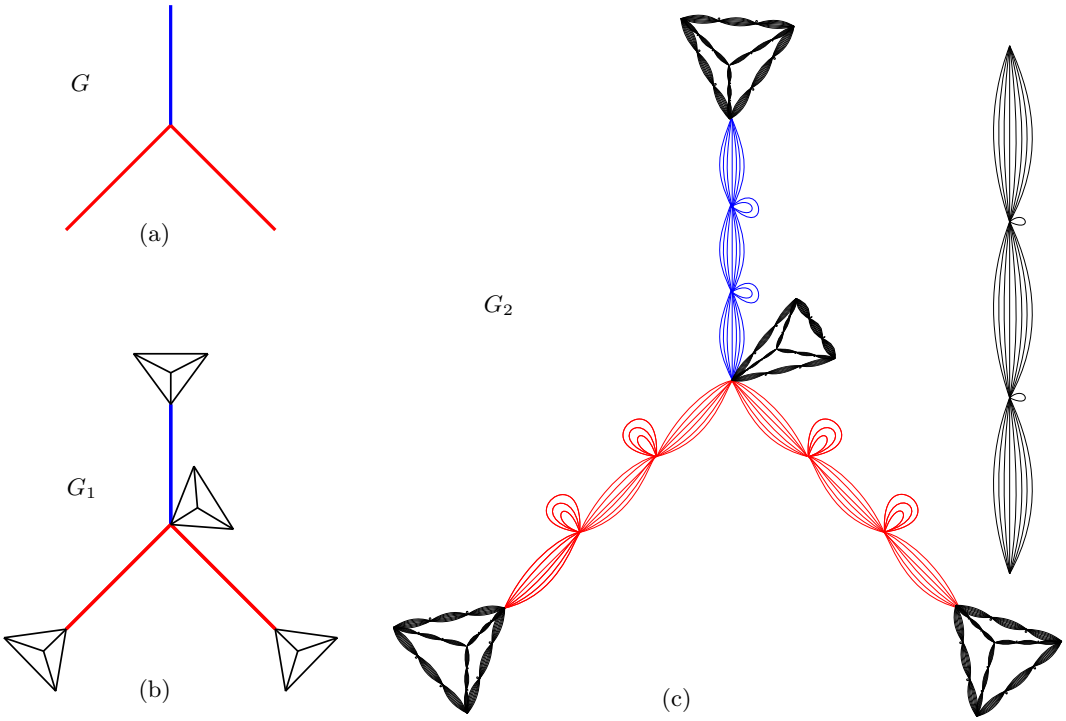

Figure 3 The construction of the graph G_2. (a): The graph G; the red edges have color 1 and the blue edge has color 2. (b): The graph G_1. The new edges, in black, have color 3. (c): The graph G_2 in the case $c = 2$, $\lambda(r) = p = q = 1$. Each edge of color i is replaced with a necklace of thickness $p + 2q + 2\lambda(r) + i = 5 + i$ and beads of size $c - i + 2 = 4 - i$. On the right, a close-up on the replacement for a black edge in G_1, which is a necklace of thickness eight and beads of size one.

cases, only normal drawings of graphs are considered. Note that in all cases, for positive instances, we can compute a corresponding drawing; see the full version. Statements marked with * are proved in the full version.

5.1 Variations on the traditional crossing number

k-planar drawings. Introduced by Pach and Tóth [40], *k-planar drawings* (for $k \geq 0$) are normal drawings in the plane such that every edge is involved in at most k crossings. For any drawing D, let $\kappa(D)$ be the number of crossings in D, if D is a normal k-planar drawing, and $\kappa(D) = \infty$ otherwise. The *k-planar crossing number* is then the smallest value of $\kappa(D)$ over all normal drawings D of G (which may equal ∞). Already for $k = 1$, deciding the existence of a 1-planar drawing is NP-hard even for very restricted inputs [8, 19]. This definition naturally extends to an arbitrary surface $\mathbb{S}$, which we call the *k-surface crossing number* in $\mathbb{S}$.

k-quasi-planar and min-k-planar drawings. There are similar concepts of *k-quasi-planar* [1] (no k edges pairwise cross) and of *min-k-planar* [6] (for every two edges with a common crossing, one carries at most k crossings) normal drawings in the plane, which give rise to the corresponding crossing number flavors in the plane, and we may likewise generalize them to the *k-quasi-surface* and *min-k-surface crossing numbers* in a surface $\mathbb{S}$.

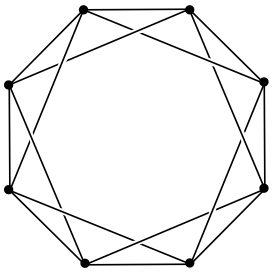

Figure 4 A drawing of some graph that is a 1-gap drawing, as certified by the casing.

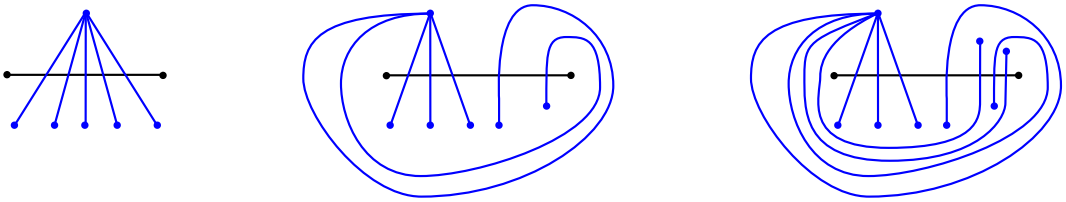
Many authors restrict the problems to simple graphs and require the admissible drawings to be simple; this restriction defines the *simple-drawing k-surface* (*k-quasi-surface*, *min-k-surface*) crossing number(s). These simple-drawing variants can be very different from the non-simple ones, see, e.g., [44, Chapter 7] and [27], but we will show that they also smoothly fit into our framework.

k-gap drawings. Another known concept is that of *k-gap crossing number* [3,46], minimizing the number of crossings over *k-gap drawings* in the plane (Figure 4), namely, normal drawings D of a graph G admitting a mapping from each crossing in D to one of the two involved edges such that at most k crossings are mapped to each edge of G. This problem is NP-hard for $k = 1$ [3]. Again, the k-gap crossing number is naturally generalized to any surface $\mathcal{S}$.



Applying our framework. Given $r \geq 0$, deciding whether a graph G has k-planar (k-quasi-planar, or min-k-planar) crossing number at most r can be done in quadratic FPT-time [37] using Courcelle's theorem. The parameterized complexity of these three problems in other surfaces, and of the k-gap crossing problem altogether, has not been studied prior to us. Even in the known planar cases, we largely improve the dependence in r in the runtime:

▶ **Proposition 5.2.** *Let $k \geq 1$ and $r \geq 0$ be integers, $\mathcal{S}$ a surface with topological size s, and let $\Pi \in \{$"k-surface", "k-quasi-surface", "min-k-surface", "k-gap"$\}$. Deciding whether an input graph G of size n has Π-crossing number at most r in $\mathcal{S}$ can be solved in time $2^{\mathsf{poly}(s+r)} \cdot n^2$. The same conclusion holds for the simple-drawing Π-crossing number of a simple input graph G.*

Proof. The proof relies on Theorem 3.2 with a single color ($c = 1$) and no splits or removals ($p = q_1 = 0$). For each Π, we must give an appropriate crossing-counting pair (κ, λ) such that κ is efficiently computable. Let $\kappa = \kappa_\Pi$ map a drawing D to ∞ if it is not a normal drawing or if it violates the property Π, and to the number of crossings of D otherwise. In particular, if k is greater than the number of crossings in D, then D always satisfies Π.

Given a drawing D, one may in time polynomial in the size of a representation of D verify that D is a normal drawing satisfying Π, and so compute $\kappa_\Pi(D)$. This is an easy routine in all cases of Π except when $\Pi =$ 'k-gap'; in the latter case we additionally employ a standard maximum flow algorithm to decide the existence of a mapping from the crossings to their incident edges respecting "capacities" of edges to accept at most k crossings each.

Since we only consider normal drawings, $\lambda(i) = 4i$ satisfies the assumption of Definition 3.1. Likewise, it is easy to see that κ_Π is non-increasing under the operations listed in Definition 3.1. Hence, our conclusion follows by an application of Theorem 3.2 to (κ_Π, λ) and the graph G.

(a) (b) (c)

Figure 5 (a) A strongly fan-planar drawing. (b) A weakly fan-planar drawing that is not strongly fan-planar. (c) A fan-crossing drawing that is not weakly fan-planar.

Next, we consider the simple-drawing Π-crossing number, assuming G is simple. We now, additionally, set $\kappa_\Pi(D) = \infty$ if D is a non-simple drawing. For this case, it is important that our definition of a simple drawing does not immediately exclude drawings of non-simple graphs; while this is irrelevant for our simple graph G, fulfillment of Definition 3.1, Item 1(c), depends on this technical twist. The rest of the argument is identical. ◀

Fan-crossing and fan-planar drawings. A normal drawing is *fan-crossing* [31] if all edges crossing the same edge are incident to a common vertex. One can restrict this notion to *strongly* or *weakly fan-planar* drawings, which not necessarily lead to the same crossing number problems, see Figure 5 and [9]. The *fan-crossing*, *strongly fan-planar*, and *weakly fan-planar crossing numbers* are the minimum number of crossings over all strongly fan-planar, weakly fan-planar, and fan-crossing drawings in the plane, respectively.

FPT algorithms, all using Courcelle's theorem, exist for the fan-crossing crossing number, by Münch and Rutter [37], and for the weakly fan-planar crossing number, by Hamm, Klute, and Parada [22], and it seems that with further adjustments they ([22]) could also handle the strongly fan-planar version. We solve all three variants, again with a better runtime. For the strongly fan-planar version, we use the fact that our framework allows for surfaces with boundary, and thus can easily capture the "infinite face" of the drawing; indeed, strong fan-planarity is invariant under self-homeomorphisms of the plane, but not of the sphere (e.g., the drawings in Figure 5(a) and (b) are homeomorphic when seen on the sphere).

▶ **Proposition 5.3.*** *Let $r \geq 0$ be an integer. The problem to decide whether an input graph G of size n has strongly fan-planar, weakly fan-planar, or fan-crossing crossing number at most r in the plane can be solved in time $2^{\mathsf{poly}(r)} \cdot n^2$.*

The proof is very similar to that of Proposition 5.2 and extends to arbitrary surfaces.

Drawings that may not be normal. To illustrate the applicability of our framework to non-normal drawings, we introduce the following example. For an integer $k \geq 2$, we define the *k-intersecting crossing number* of a graph G to be the minimum value r such that there is a drawing of G with at most r intersection points in which the multiplicity of every intersection point is at most k. For every graph G, the traditional crossing number of G is at most $\binom{k}{2}$ times its k-intersecting crossing number, and this bound can be tight. We prove:

▶ **Proposition 5.4.*** *Let $k \geq 2$ and $r \geq 0$ be integers, $\mathbb{S}$ a surface with topological size s. The problem to decide whether an input graph G of size n has k-intersecting crossing number at most r in $\mathbb{S}$ can be solved in time $2^{\mathsf{poly}(s+k+r)} \cdot n^2$.*

We refer to Section 5.3 for more examples of different methods for counting crossings.

5.2 Crossing problems with colored edges

We now turn our attention to problems in which the colors of intersecting edges play a role.

Joint crossing number and generalizations. In the *joint crossing number* problem [38], the goal is to embed two input graphs simultaneously on the same surface while minimizing the number of crossings between them. It is NP-hard for any fixed Euler genus $g \geq 6$ [25,28], and the complexity parameterized by the solution value has not been studied prior to our work. We actually solve the following new problem generalizing the joint crossing number:

Color-Constrained Crossing Problem (in surface $\mathcal{S}$)
Input: A colored graph G with colors in $\{1,\dots,c\}$, and a symmetric matrix M of size $c \times c$ with nonnegative integer values.
Question: Is there a normal colored drawing D of G in $\mathcal{S}$ such that, for each $i,j \in \{1,\dots,c\}$, the number of crossings involving two edges, one colored i and the other j, is at most $M_{i,j}$?

▶ **Proposition 5.5.*** *Let $\mathcal{S}$ be a surface of with topological size s. The Color-Constrained Crossing Problem in $\mathcal{S}$ of the input graph G of size n and matrix M can be solved in time $2^{\mathsf{poly}(s+r)} \cdot n^2$, where $r = \sum_{1 \leq i \leq j \leq c} M_{i,j}$.*

Proposition 5.5 solves the joint crossing number in $\mathcal{S}$ simply by giving the edges of one graph color red and the edges of the other color blue, and allowing only red–blue crossings.

Our approach can also be applied (see the full version) to the *homeomorphic joint crossing number* [28] of two graphs G_1 and G_2, in which G_1 and G_2 are given as cellularly embedded in $\mathcal{S}$, and the task is to minimize the number of crossings of $G_1 \cup G_2$ under an additional condition that the subdrawings of G_1 and G_2 are homeomorphic to the given embeddings.

Fixing the rotation system. More generally, a natural restriction on crossing number problems is to fix the clockwise cyclic order of edges around each vertex (the *rotation system*). The traditional crossing number with a fixed rotation system remains NP-hard [43], and its parameterized complexity has not been considered so far. We solve the variant of the Color-Constrained Crossing Problem where the input also prescribes the cyclic permutation of the edges around each vertex of G, and give a solution in the plane. (We remark that the problem naturally generalizes to orientable surfaces, but the proof is more complicated then, so in this version we only formulate it in the plane.)

▶ **Theorem 5.6.*** *The Color-Constrained Crossing Problem with Rotation System (in the plane) of the input connected graph G of size n, matrix M, and rotation system $\big(\pi_v : v \in V(G)\big)$ can be solved in time $2^{\mathsf{poly}(r)} \cdot n^2$, where $r = \sum_{1 \leq i \leq j \leq c} M_{i,j}$.*

The proof reduces to the Color-Constrained Crossing Problem. The main delicate task in it is to "transfer the sense of orientation" from one vertex to another, which is achieved with suitably crafted tri-colored rigid "chains" as sketched in Figure 6.

5.3 Non-traditional methods of counting crossings

We now look at different problems which do not count the crossings simply "one by one".

Edge crossing number. The *edge crossing number* of a graph G is the smallest r such that G has a normal drawing having at most r edges with at least one crossing. Computing the edge crossing number is NP-hard [4], and according to Schaefer [45, Section 3.2: Edge crossing number], no FPT algorithm parameterized by the solution size r is known even in the plane.

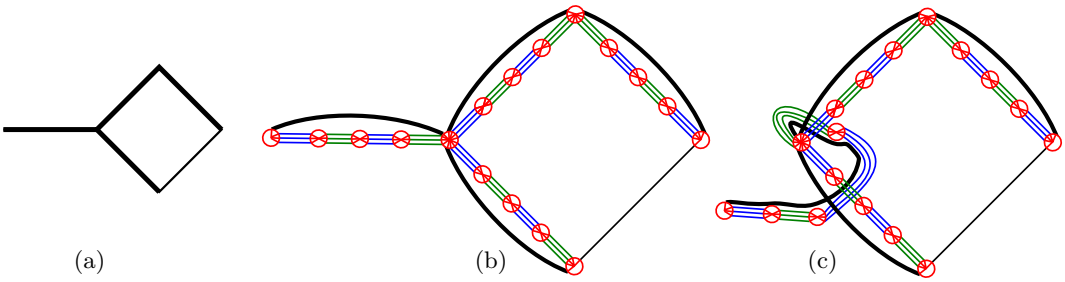


Figure 6 The construction of the graph G_1 for the proof of Theorem 5.6.(a) The graph G, with the spanning tree T in thick lines, shown with the desired rotation system. (b) The graph G_1; its original edges are black, and the new colors red, blue, and green are as pictured. Red edges cannot carry any crossing, and blue-blue and green-green crossings are forbidden. (c) A valid drawing of the graph G_1 with crossings. In general, we must allow crossings between the chains, and these are made possible with the alternating green-blue paths; forbidding blue-blue and green-green crossings forces the consistency of the rotation systems of the wheels.

▶ **Proposition 5.7.** *Let $r \geq 0$ be an integer and $\mathbb{S}$ be a surface with topological size s. The problem to decide whether an input graph G of size n has edge crossing number at most r in $\mathbb{S}$ can be solved in time $2^{\mathsf{poly}(s+r)} \cdot n^2$.*

Proof. For a drawing D in $\mathbb{S}$, let $\kappa(D)$ be equal to the number ℓ of edges of D carrying an intersection point if the total number of intersection points in D is at most $\binom{\ell}{2}$, and let $\kappa(D) = \infty$ otherwise. We also set $\lambda(i) = 4\binom{i}{2}$. It is again routine to check that (κ, λ) is a crossing-counting pair and that $\kappa(D)$ is computable in polynomial time.

It is well known, see, e.g., Schaefer [44], that any drawing D with ℓ edges carrying an intersection point can be turned into a normal drawing D in which no two edges cross twice, without introducing new crossed edges, and thus having at most $\binom{\ell}{2}$ crossings. Thus, the edge crossing number of G indeed equals the minimum value of $\kappa(D)$ over all drawings D of G. Hence, Theorem 3.2 implies an algorithm running in time $2^{\mathsf{poly}(s+r)} \cdot n^2$. ◀

A natural edge-colored generalization can be solved by a straightforward combination of the ideas in the proof of Proposition 5.5 and of the previous proof.

Odd and pair crossing numbers. The *pair (resp. odd) crossing number* of a graph G is the minimum r such that there exists a normal drawing of G in which at most r pairs of edges mutually cross (resp. cross an odd number of times). While the question whether the pair crossing number coincides with the traditional crossing number is one of the biggest open problems in crossing numbers, Pelsmajer, Schaefer, and Štefankovič [42] proved that the odd crossing number can be lower than the traditional crossing number. FPT algorithms for the pair and odd crossing numbers were given by Pelsmajer, Schaefer, and Štefankovič [41], with an unspecified dependence on r; however, because these algorithms are based on an adaptation of Grohe's algorithm [20], they are quadratic in the size n of the input and the dependence on r is at least an exponential tower of height four. We improve over their algorithms by providing algorithms also quadratic in n but with a better dependence in the parameter r:

▶ **Proposition 5.8.*** *Let $r \geq 0$ be an integer, and let $\Pi \in \{$'pair', 'odd'$\}$. The problems to decide whether an input graph G of size n has Π-crossing number at most r in the* plane *can be solved in time $2^{2^{\mathcal{O}(r)}} \cdot n^2$.*

5.4 Allowing edge removals and vertex splits before drawing

Finally, we consider crossing number variants that allow graph simplifications before drawing.

Skewness. The *skewness* of a graph G is the smallest number of edges whose removal from G leaves a planar graph. Deciding whether the skewness of G is at most q is NP-complete [34], and linear-time FPT algorithms are claimed, without details, by Kawarabayashi and Reed [32] and Jansen, Lokshtanov, and Saurabh [30]. We generalize the problem as follows.

Color-Constrained $\mathcal{S}$-Skewness with Crossings
Input: A colored graph G with colors in $\{1,\dots,c\}$, non-negative integers $q_1,\dots,q_c$ and r.
Question: Can we remove, for each $i=1,\dots,c$, at most q_i edges of color i from G, such that the resulting graph has crossing number at most r in $\mathcal{S}$?

▶ **Proposition 5.9.*** *Let $\mathcal{S}$ be a surface with topological size s. The* Color-Constrained $\mathcal{S}$-Skewness with Crossings *problem for an input graph G of size n and parameter r can be solved in time $2^{\mathsf{poly}(s+q+r)}\cdot n^2$, where $q=\sum_i q_i$.*

Splitting number. The smallest integer p such that a graph obtained from the given graph G by p successive vertex splits is embeddable in $\mathcal{S}$ is called the *splitting number* of G in $\mathcal{S}$ [23,29]. This problem is NP-hard [17], already in the plane. Nöllenburg et al. [39] proved that the $\mathcal{S}$-splitting number has a nonuniform FPT algorithm parameterized by p using the theory of graph minors. We generalize and improve the latter result to a uniform FPT algorithm:

▶ **Proposition 5.10.*** *Let $p,r\geq 0$ be integers and $\mathcal{S}$ be a surface with topological size s. The problem to decide whether an input graph G of size n has, after at most p vertex splits, a crossing number at most r in $\mathcal{S}$ can be solved in time $2^{\mathsf{poly}(s+p+r)}\cdot n^2$.*

6 Conclusions

More applications. Theorem 3.2 allows for almost endless combinations for crossing number variants, in terms of drawing styles, ways to count crossings, allowed vertex splits and edge removals, all possibly taking edge colors into account, all on an arbitrary surface.

Limitations. Nonetheless, in our definition of crossing-counting pair, $\kappa(D)$ must functionally bound the total number of intersection points in the drawing D, and the value of κ cannot grow upon deletion of vertices and edges. The first requirement immediately excludes, e.g., the local crossing number (the minimum r such that a given graph has an r-planar drawing, which is NP-complete to compute already for $r=1$ [8,19]), and the second requirement excludes some recently introduced drawing styles such as, for instance, 1^+ and 2^+-real face drawings [5]. It is conceivable that Courcelle-based approaches would be able to handle 1^+ and 2^+-real face drawings, albeit not easily.

Another weakness, in particular compared to the very recent preprint by Hamm, Klute, and Parada [22], is our quite restricted ability to handle predrawn parts of the input graph, essentially limited to fixing *uncrossable* parts of the graph via rigid subembeddings, and to special restrictions like the fixed rotation system in Theorem 5.6. In contrast, [21] and [22] are very general in this respect and, in particular, allow crossings of fixed parts with the unfixed rest of the graph.

Remarks and possible extensions. Beyond their use for strongly fan-planar drawings, surfaces with boundaries can be useful for other problems, because they allow to pinpoint specific regions of the surface. One could actually consider a version with colored boundaries, restricting Item 1(d) of the definition of a crossing-counting pair to color-preserving self-homeomorphisms; all our arguments carry through. Finally, a possible extension of the (κ, λ)-Crossing Number problem would be to replace the surface $\mathcal{S}$ with an arbitrary 2-complex. We leave open whether such an extension is possible, and also potential applications.

Constructing Long Paths in Graph Streams

Christian Konrad

Abstract

In the *graph stream model of computation*, an algorithm processes the edges of an n-vertex input graph in one or more sequential passes while using a memory that is sublinear in the input size. The streaming model poses significant challenges for algorithmically constructing long paths. Many known algorithms that are tasked with extending an existing path as a subroutine require an entire pass over the input to add a single additional edge. This raises a fundamental question: Are multiple passes inherently necessary to construct paths of non-trivial lengths, or can a single pass suffice? To address this question, we systematically study the Longest Path problem in the one-pass streaming model. In this problem, given a desired approximation factor α, the objective is to compute a path of length at least $\mathrm{lp}(G)/\alpha$, where $\mathrm{lp}(G)$ is the length of a longest path in the input graph G.

We study the problem in the insertion-only and the insertion-deletion streaming models, and we give algorithms as well as space lower bounds for both undirected and directed graphs. Our results are:

1. We show that for undirected graphs, in both the insertion-only and the insertion-deletion models, there are *semi-streaming algorithms*, i.e., algorithms that use space $O(n \operatorname{poly} \log n)$, that compute a path of length at least $d/3$ with high probability, where d is the average degree of the input graph. These algorithms can also yield an α-approximation to Longest Path using space $\tilde{O}(n^2/\alpha)$.
2. Next, we show that such a result cannot be achieved for directed graphs, even in the insertion-only model. We show that computing a $(n^{1-o(1)})$-approximation to Longest Path in directed graphs in the insertion-only model requires space $\Omega(n^2)$. This result is in line with recent results that demonstrate that processing directed graphs is often significantly harder than undirected graphs in the streaming model.
3. We further complement our results with two additional lower bounds. First, we show that semi-streaming space is insufficient for small constant factor approximations to Longest Path for undirected graphs in the insertion-only model. Last, in undirected graphs in the insertion-deletion model, we show that computing an α-approximation requires space $\Omega(n^2/\alpha^3)$.

1 Introduction

In the *graph stream model of computation*, an algorithm processes a stream of edge insertions and deletions that make up an n-vertex input graph $G = (V, E)$ via one or multiple sequential passes. The primary objective is to design algorithms that use as little space as possible. The most studied and best-understood setting is the one-pass insertion-only setting, where

only a single pass is allowed and the input stream does not contain any edge deletions. It is known that many fundamental problems can be solved well in this setting, e.g., there are *semi-streaming algorithms*, i.e., algorithms that use space $\tilde{O}(n) = O(n \operatorname{poly} \log n)$[1], for computing a spanning tree and a maximal matching [16], while no $o(n^2)$ space algorithms exist for other problems such as computing a maximal independent set or a BFS/DFS tree [14, 6]. For such problems, algorithms that make multiple passes over the input data are typically considered [24, 13, 1, 9, 4].

Our work is motivated by the observation that streaming algorithms that construct long paths, often as a subroutine, require a large number of passes. For example, many streaming algorithms for computing large matchings construct augmenting paths as a subroutine (e.g., [29, 28, 30]), and these algorithms typically only add a single edge or a few edges per pass to a not-yet-completed augmenting path. Another example is streaming algorithms for computing BFS/DFS trees that extend partial trees/paths by adding only a single edge per pass [24, 13]. This raises a fundamental question: Is the one/few-edges-per-pass strategy best possible and multiple passes are inherently necessary to construct paths of non-trivial lengths, or can a single pass suffice?

The Longest Path Problem. We address this question by systematically studying the Longest Path (LP) problem in the one-pass streaming setting. In this problem, the objective is to compute a path of length $\operatorname{lp}(G)/\alpha$, where $\operatorname{lp}(G)$ denotes the length of a longest path in the input graph G, and $\alpha \geq 1$ is the approximation factor.

In the offline setting, in undirected graphs, it is known that it is NP-hard to compute a constant factor approximation to Longest Path [23] (see the same paper for stronger impossibility results that are based on other hardness conjectures). In directed graphs, a much stronger hardness result is known. Björklund, Husfeldt and Khanna [11] showed that it is NP-hard to approximate LP in directed graphs within a factor of $n^{1-\epsilon}$, for any $\epsilon > 0$. Regarding upper bounds, it is known that a path of length $d_{\min}$ can be constructed greedily in polynomial time, where $d_{\min}$ is the min-degree of the input graph [23]. There are also FPT algorithms with runtime polynomial in n but exponential in the length of the path constructed (see, for example, [10] and the references therein). We note that streaming algorithms for the LP problem have also previously received attention, however, only from a practical perspective. Kliemann et al. [25] studied practical multi-pass algorithms without providing any theoretical guarantees.

1.1 Our Results

In this work, we give one-pass streaming algorithms and space lower bounds for undirected graphs as well as a strong space lower bound for directed graphs. We consider both the insertion-only model (no deletions) and the insertion-deletion model (deletions allowed).

As our first result, we show that, in undirected graphs, if we sample $O(n \log n)$ random edges from the input graph, then this sample contains a path of length $\Omega(d)$ with high probability, where d is the average degree of the input graph. Since this sampling task can be implemented in both the insertion-only and the insertion-deletion streaming models using standard techniques, we obtain the following theorem:

[1] We write $\tilde{O}(.)$ to mean the usual Big-O notation with poly-logarithmic dependencies suppressed. $\tilde{\Theta}(.)$ and $\tilde{\Omega}(.)$ are defined similarly.

▶ **Theorem 1.** *In both the insertion-only and the insertion-deletion models, for undirected graphs, there are $O(n \operatorname{poly} \log n)$ space algorithms that compute a path of length at least $d/3$ with high probability, where d is the average degree of the input graph.*

We remark that our algorithm can be used to obtain an α-approximation to LP using $\tilde{O}(n^2/\alpha)$ space, for any $\alpha \geq 1$. This is achieved by running our algorithm in parallel with the trivial algorithm that stores $\tilde{\Theta}(n^2/\alpha)$ edges. Then, if the space constraint of $\tilde{\Theta}(n^2/\alpha)$ is large enough to store the entire graph then we can find an exact solution in exponential time. If not, then we are guaranteed that the average degree of the input graph is $\Omega(n/\alpha)$, which implies that the algorithm of Theorem 1 yields the desired result. We thus obtain the following corollary:

▶ **Corollary 2.** *In both insertion-only and insertion-deletion models, for undirected graphs, there are $\tilde{O}(n^2/\alpha)$-space streaming algorithms for an α-approximation to Longest Path.*

Next, we ask whether a similar algorithmic result is possible in directed graphs. As our main and most technical result, we show that this is not the case in a strong sense:

▶ **Theorem 3.** *Every one-pass streaming algorithm for Longest Path in the insertion-only model in directed graphs with approximation factor $n^{1-o(1)}$ requires space $\Omega(n^2)$.*

Theorem 3 together with Corollary 2 establishes a separation in the space complexity between algorithms for undirected and directed graphs for LP in the insertion-only model. This lower bound is also in line with recent results for directed graphs that demonstrate that problems on general directed graphs are often hard to solve in the streaming model [12].

Finally, we complement our results with two additional lower bounds. First, we give a lower bound for insertion-only streams and undirected graphs, ruling out the existence of semi-streaming algorithms with constant approximation factor close to 1.

▶ **Theorem 4.** *Every one-pass insertion-only streaming algorithm for Longest Path on undirected graphs with approximation factor $1 + \frac{1}{25} - \gamma$, for any $\gamma > 0$, requires space $n^{1+\Omega(\frac{1}{\log \log n})}$.*

We note that this lower bound result is significantly weaker than our lower bound for directed graphs, both in terms of approximation factor and space. This, however, is in line with the status of the problem in the offline setting, where a very strong impossibility result for directed graphs is known, but only significantly weaker impossibility results for undirected graphs exist. While the offline setting is orthogonal to the streaming setting, one cannot help but wonder whether similar mechanisms are at work that prevent us from obtaining stronger NP-hardness results for LP approximation in undirected graphs and from obtaining stronger space lower bounds in the streaming setting.

Last, we show that, in insertion-deletion streams, space $\Omega(n^2/\alpha^3)$ is required for an α-approximation of LP.

▶ **Theorem 5.** *Every one-pass insertion-deletion streaming algorithm for Longest Path on undirected graphs with approximation factor $\alpha \geq 1$ requires space $\Omega(n^2/\alpha^3)$.*

This lower bound together with our algorithm show that the optimal dependency of the space complexity on α in insertion-deletion streams is between $1/\alpha$ and $1/\alpha^3$.

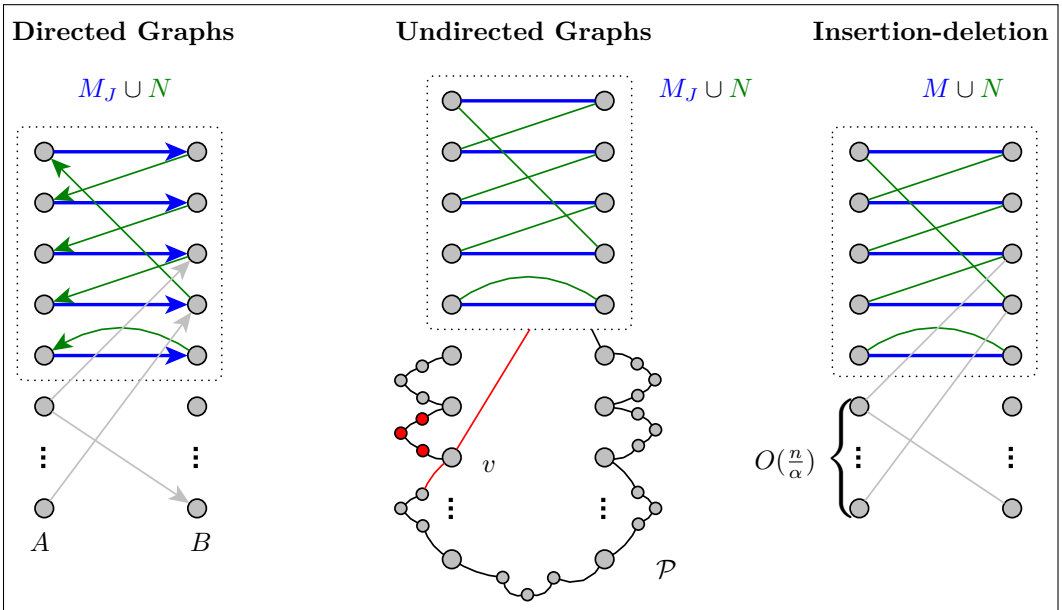
1.2 Our Techniques

Algorithm. We will first explain the key ideas behind our algorithm. As observed by Karger et al. [23], a path of length $d_{\min}$, where $d_{\min}$ is the minimum degree of the input graph G, can be computed as follows: Start at any vertex v_0 and visit an arbitrary neighbor that we denote by v_1. In a general step i, we have already constructed the path $v_0, \ldots, v_i$. We then visit a neighbor v_{i+1} of v_i that has not previously been visited. Then, as long as $i < d_{\min}$, we can always find a yet unvisited neighbor, and, hence, we obtain a path of length $d_{\min}$. We first see that this argument can also be applied to the average degree d of the graph G. It is well known that, by repeatedly removing vertices of degree at most $d/2$ from G until no such vertex remains, we are left with a non-empty graph G' with min-degree at least $d/2$. We can now apply the same argument as above to G' and thus find a path of length at least $d/2$.

The approach outlined above, however, does not yield a small space streaming algorithm since a) we do not know which vertices are contained in G', and b) we cannot afford to store $\Theta(d)$ incident edges on each vertex. To overcome these obstacles, we resort to randomization. Our algorithm solely samples $O(n \log n)$ random edges F from the input graph and outputs a longest path among the edges F. To see that a long path in F exists, we argue that the subset of edges $F' \subseteq F$ that are also contained in G' contains a path of length at least $d/3$ with high probability. Such a path can be constructed greedily. Suppose we have already constructed a partial path of length $\ell < d/3$ solely using the edges F', and let $v_{\ell+1} \in V(G')$ denote its current endpoint. Then, since $v_{\ell+1}$ has a degree of at least $d/2$ in G', there are at least $d/2 - d/3 = d/6$ neighbors of $v_{\ell+1}$ in G' that have not yet been visited in the path. Since we sample $\Theta(n \log n)$ edges overall, the probability that any one of these edges incident to $v_{\ell+1}$ that connect to these $d/6$ vertices is sampled is $\Omega(\frac{n \cdot \log n}{n \cdot d}) = \Omega(\frac{\log n}{d})$, which implies that at least one of these edges is sampled with high probability and we can extend the path.

Space Lower Bounds. All our space lower bounds are proved in the one-way two-party communication setting. In this setting, two parties that we denote by Alice and Bob each hold a subset of the edges of the input graph $G = (V, E = E_A \cup E_B)$, with E_A being Alice's edges, and E_B being Bob's edges. Alice sends a single messages Π to Bob, and Bob computes the output of the protocol. Then, it is well-known that a lower bound on the size of the message Π also constitutes a lower bound on the space of any one-pass streaming algorithm.

We work with *induced matchings* in all our lower bound constructions. In a graph $G = (V, E)$, a matching $M \subseteq E$ is *induced* if the edges of the vertex-induced subgraph $G[V(M)]$ are precisely the edges of M. Suppose now that G is bipartite, and we denote it by $G = (A, B, E = E_A \cup E_B)$. Furthermore, we suppose that Alice's subgraph, i.e., the graph spanned by the edges E_A, contains a matching M that is induced in the final graph. We say that M is the *special* matching. We complete our lower bound constructions so that:



1. Every long path in the graph must contain many edges of the special matching M;
2. The special matching M is *hidden* among the edge set E_A so that Alice cannot identify M, and, given a limited communication budget, Alice therefore cannot forward many of M's edges to Bob.

The two properties then imply a lower bound since, if Bob knows only few edges of M, but every long path contains many such edges, then Bob cannot output a long path.

To achieve property 2, in our insertion-deletion lower bound, we make use of edge deletions as part of Bob's input to turn a large matching in E_A into an induced matching, and in our insertion-only lower bounds, we work with *Rusza-Szemerédi graphs* (RS-graphs in short), which have been extensively used for proving lower bounds for matching problems in the streaming setting (e.g., [18, 8, 26, 27]). An (r, t)-RS-graph is a balanced bipartite graph on $2n$

vertices such that its edge set can be partitioned into t induced matchings $M_1, \ldots, M_t$, each of size r. Our insertion-only constructions are such that each of these t matchings can take the role of the special matching M, which will allow us to argue that Alice essentially has to send many edges of each induced matching to Bob if Bob is to report a long path. We note that the framework of working with RS-graphs and a special hidden matching among Alice's edges is well-established and has previously been used, for example, in [18, 7, 3, 27, 5, 4].

Regarding establishing property 1, we pursue different strategies that depend on the specific streaming setting, and on whether we work with directed or undirected graphs. These strategies are described below and illustrated in Figure 1.

Directed Graphs: Since N constitutes the only edges directed from right to left, and M_J is an induced matching, up to potentially the first and last edge, every long path alternates between edges of M_J and N and thus contains many edges of M_J.

Undirected Graphs: (Insertion-Only) The path $\mathcal{P}$ is connected to a longest path in $V(M_J)$. Our argument is based on the fact that it is detrimental to the length of the output path to include many edges between $V \setminus V(M_J)$ and $V(M_J)$. Indeed, suppose that the output path contains the two red edges incident on vertex v. Then, the vertices highlighted in red cannot be visited by the output path. This allows us to argue that, for each edge going across the cut $(V \setminus V(M_J), V(M_J))$, multiple vertices on the path $\mathcal{P}$ are not visited. This in turn implies that every long path must contain many edges of M_J in order to visit the vertices in $V(M_J)$.

Insertion-Deletion Streams: (Undirected Graphs) Our construction is such that there are only $O(\frac{n}{\alpha})$ vertices outside $V(M)$. Hence, if Bob does not know many edges of M then there are at most $O(\frac{n}{\alpha})$ vertices of $V \setminus V(M)$ available to connect to vertices within $V(M)$. Since this number is small, Bob is required to learn many edges of M in order to output a long path.

Figure 1 Illustrations of our three lower bound constructions.

Directed Graphs in the Insertion-only Model. The cleanest case is our lower bound for directed graphs. In this setting, Alice holds the edges of an RS-graph $G' = (A, B, E)$, and we assume that all edges are directed from A to B. We then pick a matching M_J, for a uniform random $J \in [t]$, and Bob inserts a random matching N that matches $B(M_J)$ to $A(M_J)$ so that all edges in N are directed from B to A. We then leverage the well-known result that the expected length of a longest cycle in a random permutation of the set $[r]$ is of length $\Theta(r)$ [20, 19] in order to argue that $M_J \cup N$ contains a path of expected length $\Theta(|M_J|)$. It then remains to argue that every path of length ℓ, for any ℓ, in the input graph $G = G' \cup N$ must contain $\Omega(\ell)$ edges of M_J, which uses the fact that the matching M_J is induced. Since, however, Alice did not know that M_J is the special matching, Alice is required to send a large number of edges of each induced matching to Bob so that Bob can output a long path.

For technical reasons, our graph construction is slightly more involved than described above since we need to turn Alice's RS-graph into an input distribution, see Section 4 for details. While it is easy to argue that if Alice sends k edges of M_J to Bob then Bob can compute a path of length at most $O(k)$ in $M_J \cup N$, we need to argue a much stronger bound. We show that, even if Alice sends as many as $r/100$ M_J edges to Bob then Bob can still only find a path of size $O(\log r)$ in $M_J \cup N$. We implement our approach using the information complexity paradigm, including direct sum and message compression arguments.

Undirected Graphs in the Insertion-only Model. In our construction for undirected graphs, Alice holds an RS-graph $G' = (A, B, E)$, and, given a random index $J \in [t]$, Bob holds a random matching N matching $A(M_J)$ to $B(M_J)$. Similar as above, the matchings $M_J \cup N$ contain a path of length $\Omega(|M_J|)$. However, it is no longer true that any long path in $G' \cup N$ must contain many edges of M_J as, for example, the vertices in $V \setminus V(M_J)$ can now be used to visit the vertices within $V(M_J)$ as their incident edges are undirected.

Our aim is to ensure that it is detrimental for constructing long paths to include many edges across the cut $(V \setminus V(M_J), V(M_J))$ in the path. Once this property is established, we will argue that, if Bob only knows few of the M_J edges then many vertices of $V(M_J)$ will remain unvisited in the output path, which implies that the path is bounded in length as not all vertices are visited. To argue that only few edges across the cut $(V \setminus V(M_J), V(M_J))$ are included in the output path, we ensure that all the vertices $v \in V \setminus V(M_J)$ serve as *gateways* to other parts of the graph that are introduced by Bob. The construction is so that these other parts cannot be visited if v connects to a vertex in $V(M_J)$ in the output path, which will then be detrimental for the construction of a long path. To achieve this, Bob introduces additional edges as follows. First, let $\mathcal{P}'$ be a path consisting of novel edges that visits every vertex in $V \setminus V(M_J)$, and let $\mathcal{P}$ be the path obtained from $\mathcal{P}'$ by subdividing every edge in $\mathcal{P}'$, ℓ times, for some integer ℓ. Furthermore, this path is connected to the longest path within $M_J \cup N$. Then, the path $\mathcal{P}$ significantly contributes to the longest path in the input graph. Observe, however, if a vertex $v \in V \setminus V(M_J)$ connects to a vertex in $V(M_J)$ then the vertices on the subdivision on one of the edges of $\mathcal{P}$ incident on v cannot be visited anymore. By setting ℓ large enough, we show that it is detrimental for the algorithm to use such vertices to connect to $V(M_J)$, which renders the edges of M_J indispensable for a long path. As above, the actual lower bound construction is more involved since we need to turn Alice's RS-graph into an input distribution. On a technical level, we give a reduction to the two-party communication problem Index using ideas similar to those introduced by Dark and Konrad [15].

Undirected Graphs in the Insertion-deletion Model. The key advantage that allows us to prove a much stronger lower bound for insertion-deletion streams than for insertion-only streams is that Bob can insert edge deletions that turn a large matching contained in Alice's edges E_A into an induced matching. We see that it is possible to achieve this so that:

1. The special (induced) matching M is of size $n - O(n/\alpha)$; and
2. The special matching M is hidden among Alice's edges.

Furthermore, we make sure that there exists a second matching N such that $N \cup M$ forms a path of length $\Omega(n)$. Property 1 significantly helps in proving our lower bound since, as opposed to our lower bound for undirected graphs in insertion-only streams, there are only $O(n/\alpha)$ vertices outside the set $V(M)$, and, hence, these vertices only allow us to visit $O(n/\alpha)$ vertices of $V(M)$. We can then argue that, for the remaining $n - O(n/\alpha)$ vertices of $V(M)$, Bob is required to know the edges of M for those to be visited. This however requires Alice to send these edges to Bob. Then, Property 2 ensures that Alice cannot identify these edges and would therefore have to send most edges of the input graph to Bob, which exceeds the allowed communication budget. On a technical level, we give a reduction to the Augmented-Index two-party communication problem, again, reusing many of the ideas given in the lower bound by Dark and Konrad [15].

1.3 Outline

We provide notation, state RS-graph constructions, introduce the information complexity framework, state important inequalities involving mutual information, and give a message compression theorem in our preliminaries section, Section 2. Then, we present our algorithm in Section 3, and our lower bound for directed graphs in insertion-only streams is given in Section 4. Due to space restrictions, our lower bound for undirected graphs in insertion-only streams and our lower bound for undirected graphs in insertion-deletion streams are deferred to the full version of this paper. We conclude in Section 5 with open problems.

2 Preliminaries

Given a graph $G = (V, E)$, for vertices $u, v \in V$, we denote an undirected edge between u and v by $\{u, v\}$, and a directed edge with tail u and head v by (u, v).

2.1 Rusza-Szemerédi Graphs

In our lower bounds, we make use of Rusza-Szemerédi graphs.

▶ **Definition 6** (Rusza-Szemerédi Graph). *A bipartite graph $G = (A, B, E)$ is an (r, t)-*Ruzsa-Szemerédi graph*, (r, t)-RS graph for short, if its edge set can be partitioned into t induced matchings, each of size r.*

We will use the RS-graph constructions of Alon et al. [2] and Goel et al. [18], the latter is based on the construction by Fischer et al. [17].

▶ **Theorem 7** (Ruzsa-Szemerédi Graph Constructions). *There are bipartite RS-graphs $G = (A, B, E)$ with $|A| = |B| = n$ with the following parameters:*

1. *$r = n^{1-o(1)}$, and $t \cdot r = \Omega(n^2)$ [2]; and*
2. *$r = (\frac{1}{2} - \epsilon)n$, for any constant $\epsilon > 0$, and $t = n^{\Omega(\frac{1}{\log \log n})}$ [18].*

2.2 Streaming Models

Given an input graph $G = (V, E)$, an *insertion-only* stream describing G is an arbitrarily ordered sequence of the edge set E. An *insertion-deletion* stream is a sequence of edge insertions and deletions so that, at the end of the stream, the surviving edges constitute the edge set E. Furthermore, the stream is such that only edges that have previously been

inserted are deleted, i.e., the multiplicity of an edge is never negative. We also assume that at any moment the multiplicity of any edge is polynomially bounded. This standard assumption ensures that sampling methods such as ℓ_0-sampling require only $\operatorname{poly}\log(n)$ space.

2.3 Communication Complexity

We consider the one-way two-party model of communication for proving our space lower bounds. In this setting, two parties, denoted Alice and Bob, share the input data $X = (X_A, X_B)$ so that Alice holds X_A and Bob holds X_B. They operate as specified in a protocol Π in order to solve a problem $\mathcal{P}$. Alice and Bob can make use of both private and public randomness. Randomness is provided via infinite sequences of uniform random bits. Private randomness can only be accessed by one party. The sequence of public randomness can be accessed by both Alice and Bob, and we denote this sequence by R.

The protocol Π instructs the parties to operate as follows. First, Alice computes a message that we (ambiguously) also denote by Π as a function of X_A, R, and her private randomness, sends the message Π to Bob, who then computes the output of the protocol as a function of X_B, Π, R and his private randomness. The *communication cost* of a protocol Π is the maximum length of the message sent by Alice in any execution of Π. The *communication complexity* of a problem $\mathcal{P}$ is the minimum communication cost of any protocol that solves $\mathcal{P}$.

2.4 Information Complexity and Message Compression

We prove lower bounds using the *information complexity paradigm*, which is a framework that is based on information theory. Let $(A, B, C) \sim \mathcal{D}$ be jointly distributed random variables according to distribution $\mathcal{D}$. We denote the *Shannon entropy* of A by $H_{\mathcal{D}}(A)$, the entropy of A conditioned on B by $H_{\mathcal{D}}(A \mid B)$, the *mutual information* of A and B by $I_{\mathcal{D}}(A \ : \ B)$, and the conditional mutual information between A and B conditioned on C by $I_{\mathcal{D}}(A \ : \ B \mid C)$. We may drop the subscript $\mathcal{D}$ in $H_{\mathcal{D}}(.)$ and $I_{\mathcal{D}}(.)$ if it is clear from the context.

We will use the following standard facts about entropy and mutual information: (let $(A, B, C, D) \sim \mathcal{D}$ be jointly distributed random variables.)

P1: If A and C are independent conditioned on D then: $I(A \ : \ B \mid D) \leq I(A \ : \ B \mid C, D)$
P2: $I(A \ : \ B \mid C, D) = \mathbb{E}_{d \leftarrow D} I(A \ : \ B \mid C, D = d)$
P3: Let E be an event independent of A, B, C. Then: $I(A \ : B \mid C, E) = I(A \ : B \mid C)$
P4: $I(A, B \ : C \mid D) = I(A \ : C \mid D) + I(B \ : C \mid D, A)$

Given a one-way two-party communication protocol Π and an input distribution $(X_A, X_B) \sim \mathcal{D}$, we will measure the amount of information that the message Π reveals about Alice's input under distribution $\mathcal{D}$. The following quantity is denoted the *external information cost* of Π:

▶ **Definition 8.** *The (external) information cost* $\mathrm{ICost}_{\mathcal{D}}(\Pi)$ *of the one-way two-party communication protocol* Π *under input distribution* $\mathcal{D}$ *is defined as:*

$$\mathrm{ICost}_{\mathcal{D}}(\Pi) = I_{\mathcal{D}}(X_A \ : \ \Pi \mid R) \ .$$

Then, for a given problem $\mathcal{P}$, we denote the *information complexity* $\mathrm{IC}_{\mathcal{D}}(\mathcal{P})$ of $\mathcal{P}$ under distribution $\mathcal{D}$ as the minimum information cost of a protocol that solves $\mathcal{P}$.

It is well-known that information cost of a protocol lower bounds its communication cost.

We will also use a *message compression* result, which is due to Harsha et al. [21]. We follow the presentation of this result given in [31].

▶ **Theorem 9** (Message Compression). *Let Π be a protocol in the one-way two-party communication setting. Then, the protocol can be simulated with a different protocol that sends a message of expected size at most*

$$I_{\mathcal{D}}(X_A \ : \ \Pi) + 2 \cdot \log\left(1 + I_{\mathcal{D}}(X_A \ : \ \Pi)\right) + O(1) \ .$$

3 Algorithm

We will first describe and analyze our sampling-based algorithm in Subsection 3.1, and then discuss implementations of this algorithm in streaming models in Subsection 3.2.

3.1 Sampling-based Algorithm

Let $G = (V, E)$ be the input graph with $n = |V|$, $m = |E|$, and average degree $d = 2\frac{m}{n}$. Consider the following algorithm:

Algorithm 1 Sampling-based algorithm for constructing a path of length $\Omega(d)$.

Require: $G = (V, E)$
Sample $10 \cdot n \cdot \ln n$ random edges from E and denote this set by F
return Longest path in $G[F]$

We show that Algorithm 1 constructs a path of length at least $d/3$ with high probability.

▶ **Theorem 10.** *Algorithm 1 constructs a path of length $d/3$ with probability at least $1 - \frac{1}{n^2}$. It can also be regarded as an $O(\frac{n}{d})$-approximation algorithm for Longest Path.*

Proof. Given the input graph $G = (V, E)$, let $U \subseteq V$ denote a subset of vertices of V such that $G[U]$ has minimum degree at least $d/2$. It is well-known that such a subset of vertices exists (see Lemma 19 for completeness).

Let $u_0 \in U$ be any vertex, and let $P_0 = \{u_0\}$ be the path of length 0 with start and end point u_0. We will extend P_0 using the edges in F that are also contained in $G[U]$, as follows:

In step $i = 1, 2, \ldots, d/3$, we add the edge (u_{i-1}, u_i) to P_{i-1} and obtain the path P_i. The edge (u_{i-1}, u_i) is an arbitrary edge in F incident on u_{i-1} that connects to a vertex $u_i \in U$ that has not yet been visited on the path P_{i-1}. We will now prove that such a vertex exists.

First, recall that, by definition of U, the vertex u_{i-1} has at least $d/2$ neighbors in $G[U]$. Since $i \leq d/3$, at least $d/2 - d/3 = d/6$ of these neighbors are not visited by the path P_{i-1}. Denote by $E(u_{i-1})$ this set of at least $d/6$ edges connecting u_{i-1} to not yet visited neighbors in $G[U]$. We now claim that at least one of the edges of $E(u_{i-1})$ is contained in F with high probability. Observe that at stage $i-1$, we have only learnt so far that the sample F contains the $i-1$ edges of the path P_{i-1}. Hence,

$$\begin{aligned}
&\Pr\left[F \cap E(u_{i-1}) = \varnothing \mid P_{i-1} \subseteq F\right] = \frac{\binom{m-(i-1)-|E(u_{i-1})|}{|F|-(i-1)}}{\binom{m-(i-1)}{|F|-(i-1)}} \\
&\leq \exp\left(-\frac{|E(u_{i-1})|(|F| - (i-1))}{m-(i-1)}\right) \leq \exp\left(-\frac{\frac{d}{6}(10n\ln(n) - n\ln(n))}{m}\right) \\
&= \exp(-\frac{\frac{m}{3n}(9n\log n)}{m}) = \frac{1}{n^3} \ ,
\end{aligned}$$

where we used the inequality $\frac{\binom{a-c}{b}}{\binom{a}{b}} \leq \exp\left(-\frac{bc}{a}\right)$ (see Lemma 18) to obtain the first inequality and the bound $(i-1) \leq n\ln(n)$ to obtain the second.

We can therefore extend the path with probability $1 - \frac{1}{n^3}$ at any step i. Since we run $d/3 \leq n$ steps overall to create the final path $P_{d/3}$ of length $d/3$, by the union bound, we succeed with probability at least $1 - \frac{1}{n^2}$. Last, since a longest path in G is of length at most n, the algorithm also constitutes an $O(n/d)$-approximation algorithm to Longest Path. ◀

3.2 Implementation in Streaming Models

Algorithm 1 can easily be implemented in both the insertion-only and the insertion-deletion streaming models. In the insertion-only model, a uniform sample of the edges in the stream can be obtained using *reservoir sampling* [32], and, in the insertion-deletion model, this can be achieved using ℓ_0-samplers [22] and rejection sampling. We obtain our main theorem:

▶ **Theorem 1.** *In both the insertion-only and the insertion-deletion models, for undirected graphs, there are semi-streaming algorithms that compute a path of length at least $d/3$ with high probability, where d is the average degree of the input graph.*

4 Insertion-only Lower Bound for Directed Graphs

In this section, we prove an $\Omega(n^2)$ space lower bound for one-pass streaming algorithms for LP on directed graphs that compute an $(n^{1-o(1)})$-approximation. To this end, we work with two input distributions $\mathcal{D}_{\text{SLP}}$ (**S**imple **L**ongest **P**ath) and $\mathcal{D}_{\text{LP}}$ (**L**ongest **P**ath). In Subsection 4.1, we give a lower bound on the information cost of protocols that solve $\mathcal{D}_{\text{SLP}}$ well. We achieve this by, first, proving a lower bound on the communication cost of any protocol that solves $\mathcal{D}_{\text{SLP}}$ directly via combinatorial arguments, and then employ a message compression argument that allows us to conclude that the information cost of such protocols must also be large. Then, in Subsection 4.2, we present the distribution $\mathcal{D}_{\text{LP}}$, which makes use of an (r, t)-RS-graph, and we establish a direct sum argument, showing that the information cost of protocols that solve $\mathcal{D}_{\text{LP}}$ is at least t times the information cost of protocols that solve $\mathcal{D}_{\text{SLP}}$, which bounds the information cost of protocols that solve $\mathcal{D}_{\text{LP}}$ from below. Then, since information cost is a lower bound on communication cost, we obtain our result.

4.1 A Simple Distribution

We will first work with the distribution denoted $\mathcal{D}_{\text{SLP}}(r)$, see Figure 2.

We first argue that the expected length of a longest path in $H \sim \mathcal{D}_{\text{SLP}}(r)$ is $\Omega(r)$.

▶ **Lemma 11.** *The expected length of a longest path in $H \sim \mathcal{D}_{SLP}(r)$ is bounded as follows:*

$$\mathop{\mathbb{E}}_{H \leftarrow \mathcal{D}_{SLP}(r)} \text{lp}(H) \geq 2\lambda r \geq 1.24r \ ,$$

where $\lambda = 0.62432\ldots$ is the Golomb-Dickman constant.

Proof. For an input graph $H = (A, B_1 \cup B_2, E) \sim \mathcal{D}_{\text{SLP}}(r)$ with $B_1 = \{b_1^1, \ldots, b_r^1\}$ and $B_2 = \{b_1^2, \ldots, b_r^2\}$, let H' be the graph obtained from H by *contracting* the vertex pairs b_i^1 and b_i^2, for all i, and by treating parallel edges in the resulting graph as single edges, see Figure 3 for an illustration. It is easy to see that $\text{lp}(H') = \text{lp}(H)$. Furthermore, denote by $\mathcal{D}'_{\text{SLP}}(r)$ the distribution of H'. Observe that $\mathcal{D}_{\text{SLP}}(r)$ and $\mathcal{D}'_{\text{SLP}}(r)$ are uniform distributions over their respective supports.

Next, consider the set Σ_r of permutations of the set $\{1, 2, \ldots, r\}$. Consider now the bijection $f : \Sigma_r \to \text{range}(\mathcal{D}'_{\text{SLP}}(r))$, where a permutation $\sigma \in \Sigma_r$ is mapped to the graph that contains the edges $(b_i, a_{\sigma(i)})$, for all i. Then, we observe that, for a permutation $\sigma \in \Sigma_r$, the length of the longest cycle $\text{lc}(\sigma)$ is related to $\text{lp}(f(\sigma))$ as follows:

$$2 \cdot \text{lc}(\sigma) - 1 = \text{lp}(f(\sigma)) \ .$$

Input Distribution $\mathcal{D}_{\text{SLP}}(r)$:

The directed graph $G = (A, B = B_1 \cup B_2, E)$ with $|A| = |B_1| = |B_2| = r$, $A = \{a_1, \ldots, a_r\}$, $B_1 = \{b_1^1, \ldots, b_r^1\}$, $B_2 = \{b_1^2, \ldots, b_r^2\}$, and $E = E_A \cup E_B$, where E_A are Alice's edges and E_B are Bob's edges, is obtained as follows:

Alice's Input: Edge set E_A

For each $i \in [r]$, flip an unbiased coin $X_i \in \{0, 1\}$ and if it comes out heads then insert the directed edge (a_i, b_i^1) into the graph. If it comes out tail then insert the edge (a_i, b_i^2). Observe that this constitutes a directed matching M that matches all A-vertices and exactly one of b_i^1, b_i^2, for all i.

Alice holds the edges $E_A = M$.

Bob's Input: Edge set E_B

Let N^1 be a uniform random matching between A and B_1, directed from B_1 towards A. Let N^2 be a copy of N^1, but every B_1-vertex is replaced by the corresponding B_2-vertex.

Bob holds the edges $E_B = N^1 \cup N^2$.

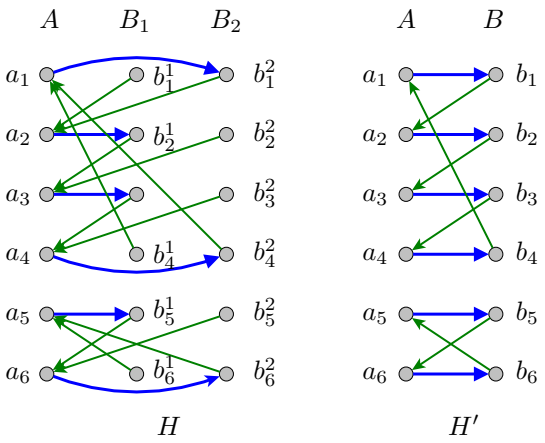
Figure 2 Input Distribution $\mathcal{D}_{\text{SLP}}(r)$.

It is known that the expected length of a longest cycle in a random permutation $\sigma \in \Sigma_r$ is at least $\lambda \cdot r$, where $\lambda = 0.624\ldots$ is the Golomb-Dickman constant [20, 19]. Hence, we obtain

$$\mathop{\mathbb{E}}_{\mathcal{H}' \sim \mathcal{D}'_{\text{SLP}}(r)} \text{lp}(H') \geq 2 \cdot \lambda \cdot r - 1 \geq 1.24 \cdot r \ ,$$

using the assumption that r is large enough. Since the longest paths in H and H' are identical, the result follows. ◀

Next, we show that any deterministic protocol on distribution $\mathcal{D}_{\text{SLP}}(r)$ that communicates at most $\frac{1}{100}r$ bits outputs a path of length $O(\log r)$ with high probability over $\mathcal{D}_{\text{SLP}}(r)$.



▶ **Lemma 12.** *Let Π_{SLP} be a deterministic one-way communication protocol for Longest Path on distribution $\mathcal{D}_{SLP}(r)$ that communicates at most $\frac{r}{100}$ bits. Then, the probability over the input distribution $\mathcal{D}_{SLP}(r)$ that Π_{SLP} outputs a path of length $O(\log r)$ is at least $1 - \frac{1}{500}$.*

Proof. Denote by $\mathcal{M}$ the set of possible directed input matchings M for Alice in $\mathcal{D}_{\text{SLP}}(r)$. Then, $|\mathcal{M}| = 2^r$. Next, since every message sent by protocol Π_{SLP} is of length at most $s := r/100$, there are at most 2^s different messages. On average, a message therefore corresponds to 2^{r-s} inputs, and, at most $\frac{1}{1000} \cdot 2^r$ inputs yield messages that in turn only correspond to at most $\frac{1}{1000}2^{r-s}$ inputs. Hence, at least $\frac{999}{1000}2^r$ inputs yield messages that each correspond to at least $\frac{1}{1000}2^{r-s}$ inputs. Consider now one of these messages π, and let $M_1, M_2, \ldots$ be the matchings M that correspond to π. Given π, the protocol can only output an edge if it is contained in all matchings M_i. Suppose that there are k such edges. Then, there are at most 2^{r-k} input graphs that contain these edges. We then have:

$$2^{r-k} \geq \frac{1}{1000}2^{r-s} \ ,$$

which implies $k \leq s + 10$.

Denote by K this set of at most $k \leq s + 10$ edges. We will now prove that the longest path in $K \cup E_B$ is of length $O(\log r)$ with high probability.

$$\sigma = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 2 & 3 & 4 & 1 & 6 & 5 \end{pmatrix}$$

Figure 3 Illustration of the proof of Lemma 11. The vertices b_i are obtained by contracting b_i^1 and b_i^2. We observe that the permutation σ has a longest cycle of length 4 $(1-2-3-4)$, while H' (and H) have longest paths of lengths 7 $(a_1, b_1, a_2, b_2, \ldots, a_4, b_4)$.

Denote by A' the A-endpoints of the edges K, and let $a'_0 \in A'$ be any vertex. We bound the length of the path with starting point a'_0. This path first uses the edge in K incident on a'_0, and denote by b'_0 the other endpoint of this edge. Then, the path uses the edge of N_1 or N_2 incident on b'_0 to return to an A-vertex that we denote by a'_1. Observe that we can only continue on this path if $a'_1 \in A'$. If this is the case then we can continue in the same fashion, visit a B-vertex b'_1, and return to another A-vertex a'_2. Again, we can only continue if $a'_2 \in A'$, and so on. For any $i \geq 1$, the following holds:

$$\Pr[a'_i \in A' \mid a'_0, \ldots, a'_{i-1} \in A'] \leq \frac{s+10-i}{r-i} \leq \frac{s+10}{r} = \frac{1}{100} + \frac{10}{r} \leq \frac{1}{50} ,$$

assuming that r is large enough. Hence, the probability that the path contains $p+2$ A'-vertices and is thus of length $2(p+1)$ is at most $\frac{1}{50^p}$. This further implies that, with probability at least $1 - \frac{1}{r^2}$, the path is of length $O(\log r)$.

Observe that the argument above applies when considering any start vertex in A'. Hence, by a union bound over all possible start vertices in A', all paths starting at an A' vertex are of length $O(\log r)$ with probability at least $1 - \frac{1}{r}$. Last, observe that a longest path that may be able to form could also start at a B-vertex. Such a path however is only by one edge longer than a path starting at an A-vertex. The $O(\log r)$ length bound therefore still holds.

So far, we proved that for a message that corresponds to at least $\frac{1}{1000}2^{r-s}$ inputs, Bob can only output a path of length at most $O(\log r)$ with high probability, where the probability is over Bob's input. Hence, overall, for a uniform input from $\mathcal{D}_{\mathrm{SLP}}(r)$, the probability that Bob will output a path of length $O(\log r)$ is at least $\frac{999}{1000} \cdot (1 - \frac{1}{r}) \geq \frac{998}{1000}$ for r large enough. ◀

We use the notation $\mathsf{LP}_{\epsilon}^{\alpha}$ to denote LP with approximation factor α and error probability ϵ.

▶ **Theorem 13.** *The randomized one-way communication complexity of* $\mathsf{LP}_{1/4}^{O(r/\log r)}$ *on inputs from* $\mathcal{D}_{SLP}(r)$ *is* $\Omega(r)$.

Proof. Towards a contradiction, let Π_{r} be a randomized protocol for Longest Path on inputs from $\mathcal{D}_{\mathrm{SLP}}(r)$ with approximation factor $o(r/\log r)$ that errs with probability at most $1/4$. Given Π_{r}, by Yao's Lemma, there exists a deterministic protocol Π_{d} on distribution $\mathcal{D}_{\mathrm{SLP}}(r)$ with distributional error $1/4$ and approximation factor $o(r/\log r)$, i.e., on at least $3/4$ of the inputs, the protocol achieves a $o(r/\log r)$-approximation.

Lemma 11 states that $\mathbb{E}_{H \leftarrow \mathcal{D}_{\mathrm{SLP}}(r)} \mathrm{lp}(H) \geq 1.24r$. This allows us to bound the quantity $\Pr_{H \leftarrow \mathcal{D}_{\mathrm{SLP}}(r)}[\mathrm{lp}(H) \geq \frac{1}{2}r]$, as follows:

$$1.24r \leq \mathop{\mathbb{E}}_{H \leftarrow \mathcal{D}_{\mathrm{SLP}}(r)} \mathrm{lp}(H) \leq \Pr_{H \leftarrow \mathcal{D}_{\mathrm{SLP}}(r)}[\mathrm{lp}(H) \geq \frac{1}{2}r] \cdot 2r + (1 - \Pr_{H \leftarrow \mathcal{D}_{\mathrm{SLP}}(r)}[\mathrm{lp}(H) \geq \frac{1}{2}r])\frac{1}{2}r$$
$$= r \cdot \left(1.5 \cdot \Pr_{H \leftarrow \mathcal{D}_{\mathrm{SLP}}(r)}[\mathrm{lp}(H) \geq \frac{1}{2}r] + \frac{1}{2}\right) ,$$

where we used the fact that the longest path in H is at most the number of vertices in H, i.e., $2r$. The previous inequality then implies that $\Pr_{H \leftarrow \mathcal{D}_{\mathrm{SLP}}(r)}[\mathrm{lp}(H) \geq \frac{1}{2}r] \geq \frac{1.24-0.5}{1.5} \geq \frac{1}{3}$.

Next, Lemma 12 states that, with probability at least $1 - \frac{1}{500}$, Π_{d} outputs a path of length at most $O(\log r)$. Hence, with probability at least $1/3 - 1/500 > 1/4$, there simultaneously exists a longest path of length at least $\frac{1}{2}r$ and Π_{d} outputs one of length $(O \log r)$. The approximation factor of Π_{d} is therefore $\Omega(r/\log r)$, contradicting the fact that Π_d achieves an approximation factor of $o(r/\log r)$ on at least $3/4$ of the instances. Protocols Π_d and Π_r therefore do not exist, which completes the proof. ◀

▶ **Lemma 14.** *Let Π be a randomized protocol for $\mathsf{LP}^{O(r/\log r)}_{1/4-\frac{1}{100}}$ on inputs from $\mathcal{D}_{SLP}(r)$. Then:*

$$\mathrm{ICost}_{\mathcal{D}_{SLP}(r)}(\Pi) = \Omega(r) .$$

Proof. Denote by Π a randomized one-way two-party communication protocol for $\mathsf{LP}^{O(r/\log r)}_{1/4-\frac{1}{100}}$ on inputs from $\mathcal{D}_{\mathrm{SLP}}(r)$. Given Π, using the message compression technique stated in Theorem 9, we obtain a protocol Π' for $\mathsf{LP}^{O(r/\log r)}_{1/4-\frac{1}{100}}$ that sends a message of expected size (recall that M is Alice's input matching)

$$s := I_{\mathcal{D}_{\mathrm{SLP}}(r)}(M \ : \ \Pi) + 2 \cdot \log\left(1 + I_{\mathcal{D}_{\mathrm{SLP}}(r)}(M \ : \ \Pi)\right) + O(1) , \tag{1}$$

where the expectation is taken over the randomness used by the protocol. Then, by the Markov inequality, the probability that the message is of size at least $100 \cdot s$ is at most $\frac{1}{100}$.

Given Π', we now construct a protocol Π'' with maximum message size $100 \cdot s$ that solves LP with slightly increased error: Whenever Π' sends a message of size at most $100 \cdot s$, Π'' also sends this message and the protocol behaves exactly the same as Π'. However, when Π' sends a message of size at least $100 \cdot s$, Π'' aborts and thus fails. Since the probability of sending a message of size larger than $100 \cdot s$ is $1/100$, the error probability of Π'' is $(\frac{1}{4} - \frac{1}{100}) + \frac{1}{100} = \frac{1}{4}$. From Theorem 13, we obtain that the communication cost of Π'' is $\Omega(r)$, which implies that $100 \cdot s = \Omega(r)$. Hence, combined with Inequality 1, we conclude that

$$\Omega(r) = I_{\mathcal{D}_{\mathrm{SLP}}(r)}(M \ : \ \Pi) \leq I_{\mathcal{D}_{\mathrm{SLP}}(r)}(M \ : \ \Pi \mid R) = \mathrm{ICost}_{\mathcal{D}_{\mathrm{SLP}}(r)}(\Pi) ,$$

where the inequality follows from property **P1** stated in the preliminaries. ◀

4.2 Hard Input Distribution and Direct Sum Argument

The input distribution $\mathcal{D}_{\mathrm{LP}}(n)$ used to obtain our main lower bound is stated in Figure 4.

We now argue that a protocol $\Pi_{\mathrm{LP}}(n)$ that solves LP under distribution $\mathcal{D}_{\mathrm{LP}}(n)$ can be used to obtain a protocol $\Pi_{\mathrm{SLP}}(r)$ that solves LP under $\mathcal{D}_{\mathrm{SLP}}(r)$, where r is the size of the induced matchings of the RS-graph used in $\mathcal{D}_{\mathrm{LP}}(n)$. This establishes a connection between the information costs of $\Pi_{\mathrm{LP}}(n)$ and $\Pi_{\mathrm{SLP}}(r)$. We use the reduction stated in Algorithm 2.

This reduction has the following properties:

Input Distribution $\mathcal{D}_{\text{LP}}(n)$:

Let $H = (A^H, B^H, E^H)$ be an (r,t)-RS graphs with $|A^H| = |B^H| = n$ and induced matchings $M_1^H, M_2^H, \ldots, M_t^H$.

Alice's Input: Edge set E_A

Given $H = (A^H, B^H, E^H)$, we construct the directed bipartite graph $G = (A, B = B_1 \dot\cup B_2, E)$, where:

- A is a copy of A^H, and B_1 and B_2 are copies of B^H.
- For every edge $e = \{a, b\} \in E^H$, we flip an unbiased coin $X_{a,b}$. If it comes out heads then the directed edge (a, b) between the sets A and B_1 is introduced, and if it comes out tail then the directed edge (a, b) between the sets A and B_2 is introduced.

We denote the edges in E that originated from the matching M_i^H, for any i, by M_i. Alice holds the edges $E_A = \cup_i M_i$.

Bob's Input: Edge set E_B

- Let $J \in [t]$ be a uniform random index.
- Consider the matching $M_J^H \in E_H$ and let $A'_H = A(M_J^H)$ and $B'_H = B(M_J^H)$. Let N_J be a uniform random matching between A' and B'.
- Bob introduces two copies of N_J into G: To this end, let $A' \subseteq A$ be the copy of A'_H in G, let $B'_1 \subseteq B_1$ be the copy of B' in B_1, and let $B'_2 \subseteq B_2$ be the copy of B' in B_2. The first copy N_J^1 is introduced between A' and B'_1, and the second copy N_J^2 is introduced between A' and B'_2. The edges in N_J^1 and N_J^2 are directed such that the A-vertex constitutes the head and the B-vertex the tail of the directed edge.

Bob holds the edges $E_B = N_J^1 \cup N_J^2$.

Figure 4 Input Distribution $\mathcal{D}_{\text{LP}}(n)$.

Algorithm 2 Construction of protocol $\Pi_{\text{SLP}}(r)$.

Require:

1. Protocol $\Pi_{\text{LP}}(n)$ that solves $\mathsf{LP}^{\alpha}_{1/4}$ under distribution $\mathcal{D}_{\text{LP}}(n)$
2. Input $(M, N^1, N^2) \sim \mathcal{D}_{\text{SLP}}(r)$, Alice holds matching M, Bob holds matchings N^1, N^2

1: Alice and Bob use public randomness to generate a uniform random index $J \in [t]$
2: Alice samples graph $G \sim \mathcal{D}_{\text{LP}}(n)$ and updates matching M_J in G such that $M_J = M$
3: Bob set $N_J^1 = N^1$ and $N_J^2 = N^2$ and adds these to G
4: Alice and Bob run the protocol $\Pi_{\text{LP}}(n)$ on G, denote by $\mathcal{P}$ the output of $\Pi_{\text{LP}}(n)$
5: **return** Longest sub-path of $\mathcal{P}$ that solely uses edges in $M_J \cup N_J^1 \cup N_J^2$

▶ **Lemma 15.** *Consider the reduction in Algorithm 2. Given any path $\mathcal{P}$ in G of length at least 2, the path $\mathcal{P}'$ with the first and last edge removed only uses edges from $M_J \cup N_J^1 \cup N_J^2$.*

Proof. Let $\mathcal{P}$ be a path of length at least 2 in G. Since G is bipartite, every other edge in $\mathcal{P}$ must be an edge from $N_J^1 \cup N_J^2$ since these are the only edges with head in A. Observe that the edges M_J are the only edges with both endpoints in $A(N_J^1 \cup N_J^2)$ and $B(N_J^1 \cup N_J^2)$. Hence, for any three consecutive edges e, f, g in path $\mathcal{P}$, if e and g are edges from $N_J^1 \cup N_J^2$, then f must be an edge from M_J. It follows that if an edge that is not contained in $M_J \cup N_J^1 \cup N_J^2$ is included in $\mathcal{P}$ then this edge must be the first or the last edge of $\mathcal{P}$. ◀

Given our reduction, we now relate the information costs of $\Pi_{\text{SLP}}(r)$ and $\Pi_{\text{LP}}(n)$:

▶ **Lemma 16.** *Let $\Pi_{LP}(n)$ be a protocol for LP^{α}_{ϵ}, for some parameters α and ϵ, and let $\Pi_{SLP}(r)$ be the protocol obtained from $\Pi_{LP}(n)$ via the reduction given in Algorithm 2. Then, $\Pi_{SLP}(r)$ has approximation factor $O(\alpha)$, errs with the same probability ϵ, and:*

$$\mathrm{ICost}_{\mathcal{D}_{LP}(n)}(\Pi_{LP}(n)) = t \cdot \mathrm{ICost}_{\mathcal{D}_{SLP}(r)}(\Pi_{SLP}(r)) \ .$$

Proof. We denote by R_{SLP} and R_{LP} the public randomness used in $\Pi_{\mathrm{SLP}}(r)$ and in $\Pi_{\mathrm{LP}}(n)$, respectively. Then (see the rules **P1**, ..., **P4** in the preliminaries):

$$\begin{aligned}
\mathrm{ICost}_{\mathcal{D}_{\mathrm{SLP}}(r)}(\Pi_{\mathrm{SLP}}(r)) &= I_{\mathcal{D}_{\mathrm{SLP}}(r)}(M \ : \ \Pi_{\mathrm{SLP}}(r) \mid R_{\mathrm{SLP}}) \\
&= I_{\mathcal{D}_{\mathrm{SLP}}(r)}(M_J \ : \ \Pi_{\mathrm{LP}(n)} \mid R_{\mathrm{LP}}, J) \\
&= \mathbb{E}_{j \leftarrow J} \, I_{\mathcal{D}_{\mathrm{LP}}(n)}(M_J \ : \ \Pi_{\mathrm{LP}(n)} \mid R_{\mathrm{LP}}, J = j) && \textbf{P2} \\
&= \frac{1}{t} \cdot \sum_{j \in [t]} I_{\mathcal{D}_{\mathrm{LP}}(n)}(M_j \ : \ \Pi_{\mathrm{LP}(n)} \mid R_{\mathrm{LP}}, J = j) \\
&= \frac{1}{t} \cdot \sum_{j \in [t]} I_{\mathcal{D}_{\mathrm{LP}}(n)}(M_j \ : \ \Pi_{\mathrm{LP}(n)} \mid R_{\mathrm{LP}}) && \textbf{P3} \\
&\leq \frac{1}{t} \cdot \sum_{j \in [t]} I_{\mathcal{D}_{\mathrm{LP}}(n)}(M_j \ : \ \Pi_{\mathrm{LP}(n)} \mid M_1, \ldots, M_{j-1}, R_{\mathrm{LP}}) && \textbf{P1} \\
&= \frac{1}{t} \cdot I_{\mathcal{D}_{\mathrm{LP}}(n)}(M_1, \ldots, M_t \ : \ \Pi_{\mathrm{LP}(n)} \mid R_{\mathrm{LP}}) && \textbf{P4} \\
&= \mathrm{ICost}_{\mathcal{D}_{\mathrm{LP}}(n)}(\Pi_{\mathrm{LP}}(n)) \ .
\end{aligned}$$

Regarding the approximation factor, observe that $\mathrm{lp}(H) \leq \mathrm{lp}(G)$. Furthermore, by Lemma 15, the path found by $\Pi_{\mathrm{SLP}}(r)$ is at most by 2 shorter than the path found by $\Pi_{\mathrm{LP}}(n)$, which in turn is of length at least $\mathrm{lp}(G)/\alpha$. Hence, the approximation factor of $\Pi_{\mathrm{SLP}}(r)$ is bounded by $\frac{\mathrm{lp}(H)}{\mathrm{lp}(G)/\alpha - 2} \leq \frac{\mathrm{lp}(G)}{\mathrm{lp}(G)/\alpha - 2} = O(\alpha)$. ◀

We are now ready to state our main lower bound result for directed graphs.

▶ **Theorem 17.** *The randomized one-way communication complexity of $LP^{O(r/\log r)}_{1/4-\frac{1}{500}}(n)$ is $\Omega(r \cdot t)$.*

Proof. Let $\Pi_{\mathrm{LP}}(n)$ be a protocol for $\mathsf{LP}^{O(r/\log r)}_{1/4-\frac{1}{500}}(n)$. Then, from Lemmas 16 and 14, we obtain

$$\mathrm{ICost}_{\mathcal{D}_{\mathrm{LP}}(n)}(\Pi_{\mathrm{LP}}(n)) = \Omega(r \cdot t) \ .$$

Since the choice of $\Pi_{\mathrm{LP}}(n)$ was arbitrary, and information complexity is a lower bound on communication complexity, the result follows. ◀

Finally using the well-known connection between streaming algorithms and one-way two-party communication protocols as well as the RS-graph construction by Alon et al. as stated in Theorem 7, we obtain the following theorem:

▶ **Theorem 3.** *Any one-pass algorithm for $LP^{O(n^{1-o(1)}/\log(n^{1-o(1)})}_{1/4-\frac{1}{500}}(n) = LP^{O(n^{1-o(1)})}_{1/4-\frac{1}{500}}(n)$ requires space $\Omega(n^2)$.*

5 Conclusion

We studied one-pass streaming algorithms for LP and showed that, in both insertion-only and insertion-deletion streams, for undirected graphs, there are semi-streaming algorithms that find paths of lengths at least $\frac{d}{3}$ with high probability, where d is the average degree of the input graph. The algorithm can also give an α-approximation algorithm that uses space $\tilde{O}(n^2/\alpha)$. We then showed that no such result can be obtained for directed graphs in that a $n^{1-o(1)}$-approximation requires space $\Omega(n^2)$, even in insertion-only streams. We also showed that semi-streaming algorithms in the insertion-only model for undirected graphs cannot yield an arbitrarily small constant factor approximation, and, in insertion-deletion streams, space $\Omega(n^2/\alpha^3)$ is necessary to obtain an α-approximation in undirected graphs.

We conclude with two open questions: First, while we resolved the space complexity of one-pass algorithms for directed graphs in both the insertion-only and the insertion-deletion models, the space complexity for undirected graphs, in particular, in the insertion-only model, remains wide open. Can we close this gap? Second, for undirected graphs, are there multi-pass semi-streaming algorithms that compute paths longer than $\Theta(d)$, where d is the average degree of the input graph?

A Technical Lemmas

▶ **Lemma 18.** *Let a, b, c be positive with $a - c \geq b$. Then:* $\frac{\binom{a-c}{b}}{\binom{a}{b}} \leq \exp(-\frac{b \cdot c}{a})$.

Proof. We compute as follows:

$$\frac{\binom{a-c}{b}}{\binom{a}{b}} = \frac{\frac{(a-c)!}{(a-b-c)!b!}}{\frac{a!}{(a-b)!b!}} = \frac{(a-c)\cdot(a-c-1)\cdot\ldots\cdot(a-b-c+1)}{a\cdot(a-1)\cdot\ldots\cdot(a-b+1)} \leq (1-\frac{c}{a})^b \leq \exp(-\frac{bc}{a}) ,$$

where we used the inequality $1 + x \leq \exp(x)$, which holds for all x. ◀

▶ **Lemma 19.** *Let $G = (V, E)$ be a graph with $|V| = n$, $|E| = m$, and average degree $d = 2\frac{m}{n}$. Then, there exists a subset of vertices $U \subseteq V$ such that the vertex-induced subgraph $G[U]$ has minimum degree greater than $\frac{d}{2}$.*

Proof. We iteratively remove vertices of degree at most $d/2$ from G until no such vertex is left. Let G_i be the graph with the first i vertices removed, and let $G_0 = G$. We denote m_i the number of edges in G_i, and $n_i = n - i$ the number of vertices in G_i. It can then be seen by induction that the average degree d_i of every graph G_i is still at least $d_0 = d$. Indeed, observe that removing a vertex of degree at most $d/2$ removes at most $d/2$ edges from the graph. Then, the average degree of graph G_{i+1} is:

$$2 \cdot \frac{m_{i+1}}{n_{i+1}} \geq 2 \cdot \frac{m_i - \frac{d}{2}}{n-(i+1)} = 2 \cdot \frac{\frac{d}{2}(n-i) - \frac{d}{2}}{n-(i+1)} = d .$$

Then, since the average degree remains as high as d throughout, and we only ever remove vertices of degree at most $d/2$, the process must leave a non-empty graph with minimum degree at least $\lfloor d/2 + 1 \rfloor$ behind. The set U then is the set of vertices that are not removed by this process. ◀

Computing Largest Subsets of Points Whose Convex Hulls Have Bounded Area and Diameter

Abstract

We study the problem of computing a convex region with bounded area and diameter that contains the maximum number of points from a given point set P. We show that this problem can be solved in $O(n^6k)$ time and $O(n^3k)$ space, where n is the size of P and k is the maximum number of points in the found region. We experimentally compare this new algorithm with an existing algorithm that does the same but without the diameter constraint, which runs in $O(n^3k)$ time. For the new algorithm, we use different diameters. We use both synthetic data and data from an application in cancer detection, which motivated our research.

1 Introduction

Medical image data is examined by specialists to detect anomalies. For example, human tissue may contain mitotic cells, where dense areas are indicative of the presence of breast cancer. Therefore, pathologists used to count mitotic cells in small areas to establish a risk and treatment regime. To automate this process, mitotic cells are nowadays identified from images and converted to (planar) point sets. Dense areas are regions of a certain size and shape that contain many points, which need to be found and inspected.

According to medical specialists, a region of interest is convex, has an area of 2–4 mm^2, a bounded aspect ratio, and has the maximum number of points [9]. More generally, the identification of well-shaped, small, dense areas in point sets is a common data analysis task.

In this paper we address the problem of computing – for a point set P – a convex region with the largest number of points from P, given an upper bound on the area and on the diameter. We present both algorithmic and experimental results. Earlier research showed that a convex region with at least k points and the minimum area can be computed using dynamic programming in $O(n^3k)$ time and $O(n^2k)$ space. This algorithm can be used to compute the maximum number of points in a convex region of at most a given area, but the diameter constraint is not taken into account. Alternatively, computing a convex region with bounded diameter and the maximum number of points can be done using furthest-site

Voronoi diagrams in $O(nk^{2.5} \log k + n \log n)$ time and $O(nk)$ space [1]. We show that with a dynamic programming method, we can ensure both a maximum area *and* a maximum diameter in $O(n^6 k)$ time and $O(n^3 k)$ space. A previous solution to this problem [9] takes exponential time, which made it applicable only to very small point sets. Hence, that paper also presented a heuristic to find good but not necessarily optimal solutions more efficiently.

Experimentally, we investigate three types of point set: (i) uniformly distributed in a fixed square, where we consider different numbers of points (and hence densities); (ii) normally distributed in a fixed square, with different standard deviations; (iii) real-world medical data that was also used in [9].

We investigate different maximal diameters and compare our new algorithm to the existing algorithm by Eppstein, Overmars, Rote, and Woeginger [5] that does not use the diameter constraint. In theory, their algorithm has a much better worst-case running time, and it is possible that the found area satisfies the diameter condition without explicitly enforcing it. This would be the case if densest areas by our definition typically yield roundish regions rather than elongated ones. The experiments show that this is not the case, and we do not get the diameter constraint "for free". The solutions are elongated; they have a larger diameter than expected and than is allowed in the application.

The new algorithm, which enforces a bounded diameter, has a high worst-case running time. Fortunately, the bound on the diameter allows us to perform significant pruning, making the algorithm often faster in practice for not too dense point sets when compared to the algorithm that bounds the area only, despite being a factor n^3 slower in theory. Our experiments analyze this for different data sets and different settings of the diameter with respect to the area.

Related work. The identification of dense areas – clusters – in point sets is a common task in many data analysis applications, as witnessed by the immensely popular DBSCAN method [6]. It is impossible to review the complete literature; we concentrate on algorithmic results related to this paper. These are 2-dimensional, use a clear definition of a dense area, compute exact results, and admit a running time analysis in the standard algorithmic sense.

Previous research has considered smallest area, perimeter, or diameter convex polygons that contain at least k points. The mentioned paper [5] addresses area or perimeter, and can find smallest polygons with k points on the boundary, or k points on the boundary while having no points inside, or k points in total. In all cases, an $O(n^3 k)$ time and $O(n^2 k)$ space algorithm solves the problem. More generally, the method works whenever the optimization concerns a "monotone decomposable weight function": any function where the value for a convex polygon can be obtained from the values of two parts (and possibly the chord used to split in those parts). Eppstein [4] later presented an alternative method for the problem of computing a minimum area convex polygon with k points inside that is more efficient when k is sufficiently small. It runs in $O(n^2 \log n + n^2 k^3)$ time and $O(n \log n + k^3)$ space.

Around the same time, Arkin, Khuller and Mitchell considered geometric knapsack problems [2], which include computing a minimum area convex polygon containing k points. They obtain essentially the same $O(n^3 k)$ time dynamic programming algorithm, but include some other generalizations than the ones in [5].

The problem of computing a convex polygon that contains k points and has minimum diameter uses a different approach. Note that the diameter is not a monotone decomposable weight function, and hence the approach in [5] does not work directly. Aggarwal, Imai, Katoh and Suri [1] propose an $O(k^{2.5} n \log k + n \log n)$ time and $O(kn)$ space algorithm for this problem using higher-order Voronoi diagrams.

For smallest k-point enclosing rectangle or circle algorithms, see [3, 7].

Our research was motivated by [9], where the problem of computing a convex region with bounded area and bounded aspect ratio that contains most points was mentioned. The aspect ratio is the diameter-to-width ratio. The paper describes an automated mitosis detection pipeline that includes an algorithm for the problem mentioned. The algorithm first cover the region with points into square patches that partially overlap, and then finds solutions in these patches by one of two methods, a brute-force method and a heuristic.

Note that bounding the aspect ratio is not the same as bounding the diameter, but in combination with a bounded area they realize the same goal of finding not too elongated areas. A constant upper bound on the aspect ratio guarantees a constant upper bound on the diameter, but the reverse is not true. If all points are (nearly) collinear, an upper-bounded aspect ratio cannot be attained by a convex hull of any subset (or perhaps only by a singleton point), whereas an upper-bounded diameter solution always exists, and might be desired.

Organization. This paper is organized as follows. In Section 2 we review the algorithm from [5] that computes a smallest area convex set with k points inside. We also present our new algorithm that computes a smallest area convex set with bounded diameter and k points inside, and prove its correctness and running time. In Section 3 we describe the experimental set-up, including the data used and implementation aspects. In Section 4 we present the results of the experiments and discuss them. These results concern running time, memory used, number of points inside, and realized area and diameter of the solution.

2 Algorithms

In this section we present two dynamic programming algorithms to compute minimum area polygons containing k points. The former algorithm appeared in [5]; we repeat it since our new algorithm can be seen as an extension of it. The latter is the new algorithm, which incorporates a given diameter bound. Both algorithms are used in our experiments.

We start with some notation that is used in both algorithms. Let P be a set of n points in the plane, and assume we are searching for a solution containing $2 \leq k \leq n$ points. Assume, for ease of description, that no three points in P are collinear. Observe that a minimum area solution with at least k points will always be a minimum area solution with exactly k points, because if the solution had more than k points from P, we can always exclude a corner of the convex solution and reduce its area, while reducing the number of points by one only.

For three points a, b, c, let $A(a, b, c)$ denote the area of the triangle $\triangle abc$ whose corners are a, b, c, and let $K(a, b, c)$ denote the number of points from P in this triangle. Points of P on the boundary of $\triangle abc$ are not counted.

For a convex polygon C, the diameter is the distance between the two points of C that realize the largest distance. Two points that realize the diameter are called a diametral pair. In our context, points will always be points that are in the set P, because C is always the convex hull of some subset of the points in P. A pair of points a, b of C is antipodal if two parallel lines exist, one through a and one through b, such that the interior of polygon C lies between these lines (inside the slab). When the vertices of C are in general position (no two sides are parallel), a convex polygon with m vertices has m antipodal pairs. If there are parallel sides, the number of antipodal pairs can be larger but is still $O(m)$. It is well-known that for a convex polygon C, its diameter is realized by an antipodal pair of vertices of C.

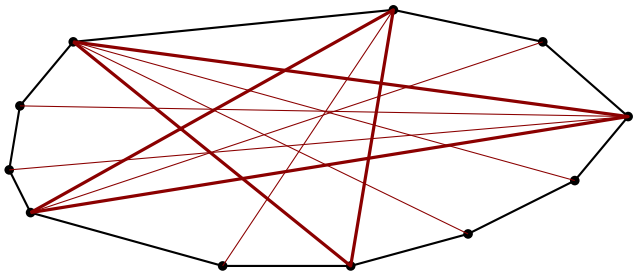

Figure 1 The antipodal structure of a convex polygon. Bold chords form a five-pointed star in brown, the six thin brown edges connect to leafs and split star angles.

If we assume that no two sides of C are parallel, the antipodal pairs have a clear structure. If we draw them as chords in C, then we get one odd-sided star plus zero or more edges that end in leaves, which always split an angle of a star vertex opposite the leaf, see Figure 1. This is true because any two chords have an endpoint in common or they intersect properly. Note that an antipodal pair may be the endpoints of an edge that bounds C.

The standard method to find all antipodal pairs of a convex polygon in linear time is referred to as rotating calipers [10]. It comes down to a traversal of the boundary of C on opposite sides in parallel, using the slopes of the edges to decide on which side we make the next step and find a new antipodal pair. This general idea will be integrated into the dynamic programming algorithm for the bounded-diameter case.

2.1 Computing a minimum area convex polygon containing k points

We describe the algorithm of Eppstein, Overmars, Rote and Woeginger [5].

Take any point $p \in P$ and choose it to be the bottommost vertex of a set of candidate solutions. In other words, we search for the optimal solution among all convex polygons with k points inside that have p as the bottommost vertex. By iterating over all points $p \in P$, we will find the global optimum with a linear factor extra in the time bound.

Given the bottommost point p in the solution, we can use a recursive structure when setting up the dynamic program by considering a bottom-vertex triangulation. This is a triangulation where all vertices on the boundary connect to p. A convex polygon C is now partitioned into a fan of triangles around p and above it.

Assume the vertices are listed in clockwise order around C as $p, p_1, \ldots, p_m$. Then the last (most clockwise) triangle in the fan around p is $\triangle p p_{m-1} p_m$.

If C is an optimal solution with k points from P, then the convex polygon $p, p_1, \ldots, p_{m-1}$ is an optimal solution with $k - K(p, p_{m-1}, p_m) - 1$ points among the solutions that have p_{m-1} as the counterclockwise neighbor of p and where p_{m-2}, p_{m-1}, p_m makes a right turn (is convex at p_{m-1} in C). This suggests a 3-dimensional table $T[q, r, k]$, defined as: the minimum area of a convex polygon with p as the bottommost vertex, q as its ccw (counterclockwise) neighbor, and r as the ccw neighbor of q. See Figure 2. This leads to a standard dynamic program with the recurrence:

$$T[q,\, r,\, k] = A(p, q, r) + \min_s\, T[r,\, s,\, k - K(p, q, r) - 1]\,,$$

where s is chosen over the points above the horizontal line through p, left of the directed line from p to r, and that leads to convexity at r. Since $K(p, q, r)$ counts only points strictly inside $\triangle pqr$, we subtract one more for point q. As the base case we let $T[q,\, r,\, k] = A(p, q, r)$ if triangle $\triangle pqr$ has exactly k points, p, q, and r included.

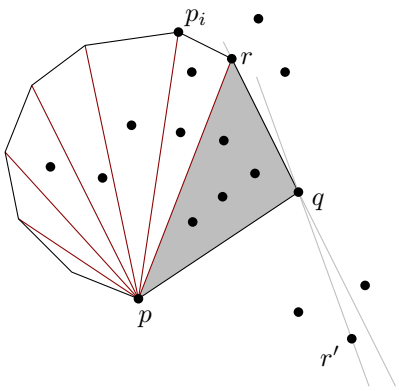

Figure 2 An optimal solution can be decomposed in $\triangle pqr$ and an optimal convex polygon with area $T[r, p_i, k - K(p, q, r) - 1]$. Table entries can be computed in $O(1)$ time by rotating around q.

It is easy to see that filling an entry takes $O(n)$ time, and the whole dynamic program requires $O(n^3k)$ time. Together with the fact that we try all n points as the bottommost point p, the whole algorithm takes $O(n^4k)$ time.

In [5] a technique is described that reduces the running time by a linear factor. A similar table is used, assuming a given point p as bottommost point, but with a subtly different definition: $T[q, r, k]$ is the smallest area convex polygon with k points inside where p is the bottommost vertex, q is its ccw neighbor, and the convex polygon lies on the same side of the line through q and r as p does. Note that r might not be part of the convex polygon itself. With a rotational sweep around q, entries are filled in only $O(1)$ time per point r. We consider all points r above a horizontal line through p, not just the ones left of the directed line through p and q. We consider the full lines through r and q and order them by angle around q, starting clockwise from the line through p and q.

The rotational sweep maintains a value T_q^* that is the minimum area encountered so far with k points. The sweep has two cases: (i) Point r lies left of the directed line through p and q (in that order), in which case we may use $T[q, r, k - K(p, q, r) - 1]$ to potentially find a smaller T_q^*, in which case we update T_q^* and fill $T[q, r, k]$; (ii) Point r lies to the right of the directed line, in which case we fill $T[q, r, k]$ with T_q^*. This leads to an $O(n^3k)$ time algorithm. Details can be found in [5].

2.2 Computing a minimum area convex polygon with bounded diameter containing k points

In this section we show how to compute a minimum area convex polygon with bounded diameter and k points inside. We do this by trying all pairs of points $p, q, \in P$, assuming they form the diameter, and then computing an optimal convex polygon under this assumption. The algorithm is an extension of the basic, $O(n^4k)$ time algorithm from [5]. At the end of this section we show how to use this algorithm to find a convex polygon with bounded diameter and area and the maximum number of points inside. The full version [8] contains omitted proofs.

After choosing a pair p, q, we first select all points of P that are at most $|pq|$ from both p and from q. They are the points in a lune formed by the intersection of two disks with radius $|pq|$, centered at p and at q, see Figure 3. For ease of description and without loss of generality, we let pq be vertical with p below q. We now need to form the right chain of a convex polygon, clockwise (cw) from q to p, and the left chain, clockwise from p to q. While

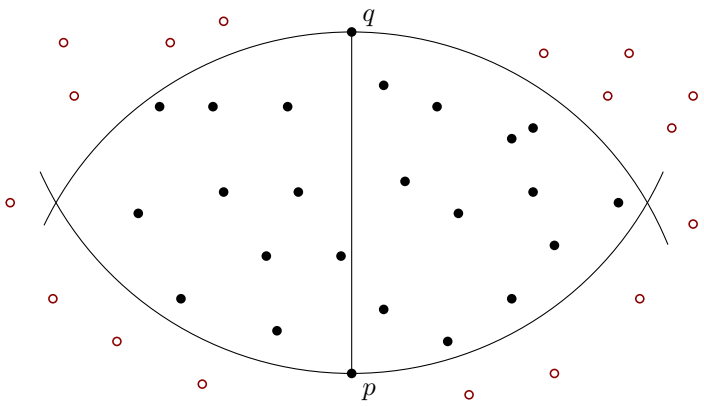

Figure 3 The black points lie inside the lune, whereas the red points do not. The latter are ignored in the dynamic program that assumes p, q is the diameter.

doing so, we must make sure that we do not consider solutions that use a point ℓ on the left chain that is too far from a point r on the right chain. Note that two points on the right chain can never be too far from each other, and the same is true for the left chain (since we restricted our points to the ones inside the lune).

To solve the problem for a given p, q we combine the dynamic programming solution from [5] with a rotating calipers algorithm to make sure that all antipodal pairs (one from the left chain and one from the right chain) have distance no more than $|pq|$.

Let $R[r, r', \ell, k]$ be the minimum area of a convex polygon with pq as a diameter, where r is the ccw neighbor of p, r' is the ccw neighbor of r, ℓ is the ccw neighbor of q, that has exactly k points inside, and where ℓ is antipodal to r and to r'. Analogously, let $L[\ell, \ell', r, k]$ be the minimum area of a convex polygon with pq as a diameter, where ℓ is the ccw neighbor of q, ℓ' is the ccw neighbor of ℓ, r is the ccw neighbor of p, that has exactly k points inside, and where r is antipodal to ℓ and to ℓ'. We allow r' to be q and ℓ' to be p. Note that p and q are antipodal: there is a pair of horizontal lines through p and through q that have any convex polygon with p, q as diameter in between. We study antipodality more closely in the following lemma.

▶ **Lemma 1.** *Let C be a convex polygon with p, q as diameter, with r as ccw neighbor of p and ℓ as ccw neighbor of q. Furthermore, assume that C has no two sides that are parallel. Then we have at least one of the following cases:*

- *r is antipodal to only q, to only ℓ, or to both but no other points.*
- *ℓ is antipodal to only p, to only r, or to both but no other points.*

From the lemma above, it follows that ℓ is not antipodal to r' or r is not antipodal to ℓ'. Now consider an optimal solution C_{opt} with a given diameter pq, and let ℓ, r, ℓ' and r' be as in the proof. If ℓ is not antipodal to r', then we can see C_{opt} as being composed of a triangle $\triangle \ell \ell' q$ and an optimal subsolution C'_{opt} where ℓ' is the ccw neighbor of q. Since ℓ is antipodal to no more than r and possibly p, by induction we can assume that C'_{opt} has all antipodal pairs no larger than the diameter $|pq|$, we need to test only the distance $|\ell r|$ to conclude that C_{opt} also has all antipodal pairs close enough. If r is not antipodal to ℓ', the argument is symmetric.

If $|r\ell| > |pq|$ then $R[r, ., \ell, .] = \infty$. Similarly, if $|r'\ell| > |pq|$ then $R[., r', \ell, .] = \infty$.

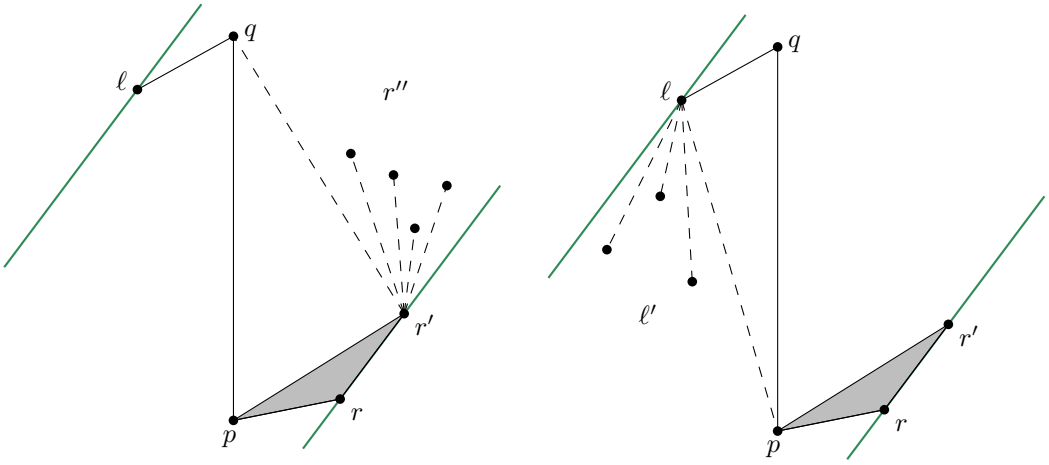

Figure 4 The two cases in the recurrence that defines $R[r, r', \ell, k]$. The grey triangle is left out when using the optimal substructure.

The recurrence optimizes over two options: use a subproblem of the R-type or use a subproblem of the L-type. The optimization of the R-type using a step on the right side is:

$$R[r,\, r',\, \ell,\, k] = A(p, r, r') + \min_{r''} R[r',\, r'',\, \ell,\, k - K(p, r, r') - 1]\,.$$

Here the r'' must be such that $r''r'r$ is a right turn at r', vertex r'' is right of the line through r' and q, and $|r''\ell| \leq |pq|$. In such a case, r' is antipodal to only ℓ. We can choose r'' to be q. If $r' = q$, then this option cannot be chosen because the right boundary is finished. Finally, ℓ can be p to capture the case that the left side is empty.

The optimization of the R-type using a step on the left side is:

$$R[r,\, r',\, \ell,\, k] = A(p, r, r') + \min_{\ell'} L[\ell,\, \ell',\, r',\, k - K(p, r, r') - 1]\,.$$

Here, ℓ' must be such that $q\ell\ell'$ is a left turn at ℓ, vertex ℓ' is to the left of the line through ℓ and p and right of the line through ℓ that is parallel to the line through r and r' (showing that ℓ' and r are not antipodal), and $|\ell' r'| \leq |pq|$. We can choose ℓ' to be p, which would complete the left boundary. Also here, r' might be q.

As base case of the recursion, we take all triangles including the points p and q. In particular, we define $R[r_1, q, p, k] = A(p, r_1, q)$ if $k = 3 + K(p, r_1, q)$, and ∞ otherwise.

The definition of $L[\ell, \ell', r, k]$ is symmetric, having analogous options. Note that since q is the unique highest point and p the unique lowest point, "left" and "right" of any line through p (or q) and another point is well-defined.

Intuitively, the algorithm constructs an optimal solution as follows, see Figure 5. Consider a *triangulation* of the solution C for a given diameter p, q where p has chords to all vertices on the right and q has chords to all vertices on the left. Let $p = r_0, r_1, \ldots, r_j = q$ be the vertices incident to edges on the right boundary. Then the edges $r_1r_2, \ldots, r_{j-1}r_j$ are the sequences of edges of the triangles in the right half that are opposite to p in these triangles. Let $q = \ell_0, \ldots, \ell_h = p$ be defined analogously for the left half.

Consider the sorted sequence (by positive turn angle from the positive x-axis vector) of edges $\vec{e}_1, \ldots, \vec{e}_{j+h-2}$ from $\overrightarrow{r_1r_2}, \ldots, \overrightarrow{r_{j-1}r_j}$ and $\overrightarrow{\ell_2\ell_1}, \overrightarrow{\ell_3\ell_2}, \ldots, \overrightarrow{\ell_h\ell_{h-1}}$. This sorted sequence defines an order on the triangles in the left and right halves of C that is a merge of the two sequences. The solution C can be deconstructed by peeling off the triangles according to

that ordered sequence. If triangle $\triangle pr_1r_2$ is first in the sequence, then C is composed of this triangle and the convex polygon C where that triangle is removed. As we argue next, this solution is found when computing $R[r_1, r_2, \ell_1, k]$, where k is the number of points of P in C.

▶ **Lemma 2.** *Let C be an optimal solution, and let $t_1 = \triangle pr_1r_2$ be the first triangle in the triangulation as described above. Vertex ℓ_1 is antipodal to r_1 and r_2.*

As a consequence of this lemma, r_1 is not antipodal to ℓ_2, so removing r_1 from consideration the recursive problem does not remove any antipodal pairs in C that must be checked.

▶ **Lemma 3.** *An optimal solution with pq as diameter is considered during the algorithm.*

Proof. Let C be an optimal solution, and let its triangulation be as described above. Also assume (by symmetry) that the first triangle in the sequence $t_1 = \triangle pr_1r_2$. Observe that C thus has: (i) pq as a diameter, (ii) r_1 as the ccw neighbor of p, (iii) r_2 as the ccw neighbor of r_1, (iv) ℓ_1 as the ccw neighbor of q, (v) k points inside it (for some $k \in \mathbb{N}$), and (vi) ℓ_1 antipodal with both r_1 and r_2 (by Lemma 2). Therefore, by definition of R, the area of C is $R[r_1, r_2, \ell_1, k]$. Symmetrically, it follows that if t_1 lies on the left it is a solution to an L subproblem. We now establish by induction that our definitions of R and L are correct.

If t_1 is the only triangle in C, it thus follows that we are in a base case, and $C = t_1$ indeed has area $R[r_1, r_2, \ell_1, k] = A(p, r_1, r_2) = A(p, r_1, q)$ and contains $k = 3 + K(p, r_1, r_2)$ points.

If there exists a triangle t_2, and this triangle also lies on the right, then it directly follows from the induction hypothesis that the area of C without triangle t_1 is $R[r_2, r_3, \ell_1, k - K(p, r_1, r_2) - 1]$, and thus our definition of $R[r_1, r_2, \ell_1, k]$ correctly computes the area of C. Symmetrically, if t_2 lies on the left, the induction hypothesis gives us that the area of C without triangle t_1 is $L[\ell_1, \ell_2, r_2, k - K(p, r_1, r_2) - 1]$. It again follows that our definition of $R[r_1, r_2, \ell_1, k]$ is correct. ◀

▶ **Lemma 4.** *No solution is determined that is not convex or where p, q is not a diameter.*

The two tables R and L require $O(n^3k)$ storage, each entry is filled in $O(n)$ time if we know the point count in each triangle, and there are $O(n^2)$ choices for p, q. Hence we obtain:

▶ **Theorem 5.** *Given a set of n points in the plane, a diameter bound D, and an integer $k \geq 3$, a smallest convex polygon that has diameter at most D and contains k points inside or on the boundary can be computed in $O(n^6k)$ time and $O(n^3k)$ space.*

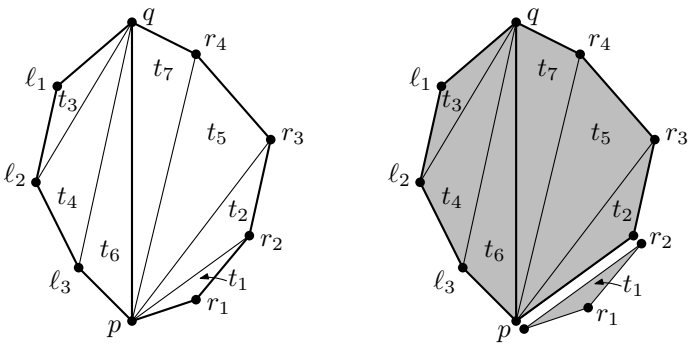

Figure 5 A solution C seen as a decomposition into triangles that are consecutively removed.

Proof. The algorithm that attains this bound has already been described, except for determining how many points of P lie in any triangle, as used in the recursion. We can do an easy preprocessing step where we determine for each of the $O(n^2)$ edges how many points of P lie vertically below that edge. This allows us to retrieve the point count inside a triangle in constant time by using the three edges of the triangle, and adding or subtracting these counts. This takes $O(n^3)$ time, which is clearly dominated by the time to run the dynamic programming steps. ◀

The final algorithm from [5] can fill in table entries in constant time. Unfortunately, we were unable to use a similar approach (e.g. rotating around r filling in the R-entries for every point r') as the table entry depends on a second point ℓ' on the left to guarantee the bound on the diameter. It seems hard to maintain the appropriate point ℓ' as r' varies. Also, rotating around r and ℓ simultaneously did not seem to work.

By running the algorithm with some value k, we also determine the smallest solutions for all values $3, \ldots, k$. This allows us to assume an maximum diameter D and maximum area A, and determine the convex polygon with most points inside within the same time bound. Start with $k = 4$, run the algorithm above, and if the area is smaller than A, double k and repeat. If the area is larger than A for the current k, we can look up the largest point count for which the area is at most A.

▶ **Corollary 6.** *Given a set P of n points in the plane, a diameter bound D and an area bound A, a convex polygon with diameter at most D and area at most A that contains the maximum number of points of P can be computed in $O(n^6k)$ time and $O(n^3k)$ space, where k is the number of points in the optimal solution.*

3 Experimental setup

The second part of this paper contains the experimental part of the research. We answer a few questions relating to the resources used by the algorithm from [5], referred to as the area-only (A) algorithm, and the new version that also enforces an upper bound on the diameter, referred to as the area-diameter (AD) algorithm. We use AD_d to refer to the AD algorithm with maximum diameter set to d. When testing on data from the application itself, we also compare with the algorithm from [9], referred to as the area selection (AS) algorithm like in their paper. We are interested in answering the following questions:

- How efficient in terms of running time and storage requirements are the A and AD_d algorithms? How does the AD_d algorithm's efficiency depend on the diameter?
- What diameters are realized by the A algorithm in the optimal solutions?
- How do the number of enclosed points compare in the optimal solutions of the A and AD_d algorithms?
- What are the found results in terms of area, diameter, and point count, of the three algorithms, now including the AS algorithm [9], on real-world data of the application that motivated this research?

Note that the first question relates to the resources used by the algorithms, whereas the other three questions relate to the output features. To answer these questions, we implemented the algorithms and selected data to be used. In the next subsections we discuss the data and the implementation aspects. The next section discusses the results and answers the research questions.

Table 1 The ten real-world point sets used in our experiments. We report the data set index (I), number of points n, and Average Nearest Neighbor distance (ANN) in mm with standard deviation.

I	n	ANN	I	n	ANN
0	699	0.21 ± 0.14	5	474	0.30 ± 0.23
1	623	0.32 ± 0.22	6	412	0.35 ± 0.23
2	594	0.28 ± 0.19	7	382	0.34 ± 0.23
3	526	0.29 ± 0.21	8	377	0.33 ± 0.27
4	492	0.32 ± 0.25	9	362	0.48 ± 0.34

3.1 Data and settings

We use three types of data for the experiments:

- Uniformly distributed point sets inside a square of size 20×20 mm^2 of increasing cardinalities $100, 110, \ldots, 200$.
- Normally distributed point sets of 100 points centered inside a square of size 20×20 mm^2 of increasing standard deviations ranging from $\sigma = 0.5, 1.0, 1.5, \ldots, 6.5$ mm. Points outside the square are discarded and re-generated.
- Medical data used in [9]. We selected ten data sets with up to 700 points, in particular the ten most populated sets.

We will always search for an area of at most 4 mm^2.[1] For the AD algorithm, we examine maximum diameters of 2, 3, 4, 5, and 6 mm. Note that for a diameter of 2 mm, the maximum area possible is π mm^2, so in this setting, we cannot "use" the full allowed area of 4 mm^2.

Since the first two types of data are randomly generated, we generated 100 point sets in each setting and report averages over these 100 runs.

The real-world data is obtained by preprocessing the data set provided by the Department of Digital Pathology at UMC Utrecht, containing 1982 point sets representing the mitotic figures identified in Whole-Slide-Images (WSIs) from actual patients [9]. The identification was carried out by the classification model introduced in [11], which produced 2-dimensional points with detection accuracies, since the points have a different likeliness of being a mitotic cell. We apply a preprocessing step to filter out any point with detection accuracy below 0.86 and convert the coordinates from pixels to millimeters. We consider the top 10 most populated point sets for our experiments. Table 1 provides an overview of this data. The average nearest neighbor distances provide an indication of how clustered the points are.

Both the synthetic generation and preprocessing of real-world data are fully automated in a Python script which we provide in a repository.

3.2 Implementation

We implemented the A algorithm from [5] and the AD algorithm in C++[2]. We implemented all other necessary data structures and algorithms that are not already in the std ourselves. The implementations do not use parallelism and run in a single thread. The experiments were run on a MacBook Pro using an Apple M1 Pro (3228 MHz) and 16GB (6400 MT/s

[1] While [9] lists 2 mm^2 as the desired area of the region, personal communication with the authors of the paper showed that they use 4 mm^2 currently in the application.

[2] Our code is available at `https://github.com/gianmarcopicarella/area-diameter-algorithm`.

LPDDR5) RAM. It runs macOS Sonoma 14.2.1, and we compiled it for 64 bits using clang 19.1.6 with the -O3 option. We used the Google Benchmark library to set up our experiments and perform data collection. The data is then post-processed in Python with several scripts that we provide in our repository. Regarding the Area Selection method (AS), we used the Python implementation made available by [9]. We use this implementation mostly to compare output, not to compare resources, although we report times.

The AS algorithm from [9] first partitions the data in patches of 3×3 mm, allowing overlap so that solutions across the boundary of a patch are not missed. For each patch, if it contains at most 25 points, a brute-force method determines the optimum. Otherwise, a heuristic is used that takes the convex hull of a patch and incrementally discards points from the convex hull, until the criteria are met. More precisely, it considers each convex hull point p, analyzes the decrease in area and cardinality if it were discarded, but also if it were replaced by any point inside the triangle formed by p and its two neighbors (details in [9]).

The A and AD algorithms use a few optimizations. First, we preprocess for quickly determining the point count in triangles, so that the dynamic program can avoid spending more than constant time. We use only $O(n^2)$ time for preprocessing and storage by computing the number of points below each of the $\binom{n}{2}$ possible edges. To represent all table entries of the AD algorithm, we used hashing, since many table entries are not used. In particular, we use an array with k hash tables for R and for L: to retrieve $R[r, r', \ell, k']$ we inspect the k'-th hash table and use the indices of r, r' and ℓ as the key, and similar for L. In the A algorithm, most table entries are used, so the A algorithm does not benefit as much from hashing. Hence it is not used. Finally, both the A and AD algorithms use an early exit strategy. For the AD algorithm point pairs are treated in decreasing order of number of points in the lune. If a solution of cardinality k is known, then all point pairs whose lune contains fewer points can be skipped. For the A algorithm, the early exit strategy is much less strong, but we can still skip processing points p as bottommost point if there are not enough points above it to improve the current best solution. Any preprocessing time is included in the timings. The implementations handle degenerate cases like collinear points properly.

4 Experimental results

We first present and discuss the results on synthetic data, starting with the resources needed by the A and AD algorithms. We then discuss the output results. Finally, we discuss the results on real-world data.

Resources. In Figure 6, the running time for synthetic point sets generated with uniform and normal (Gaussian) distributions is displayed. We see the AD algorithm makes very good use of the bounded diameter when compared with the A algorithm. Despite requiring $O(n^6k)$ time worst case, the pruning possible by bounding the diameter in the AD algorithm easily outweighs the much better $O(n^3k)$ running time of the A algorithm. This is true for the point set sizes tested. The situation is different for the normal distribution. When $\sigma \leq 1.5$, the 100 points are clustered around the center and the AD algorithm must try many more options, leading to a worse performance than the A algorithm. Both for the uniform and the Gaussian distribution, we can clearly see that the AD algorithm is more efficient for smaller diameters than for larger diameters, which is expected. In the full version [8] we also show test results on larger point sets, up to 500 points for the uniform distribution, but due to computational demands we averaged over only 5 repetitions. The patterns appear the same; the AD algorithms are still more efficient.

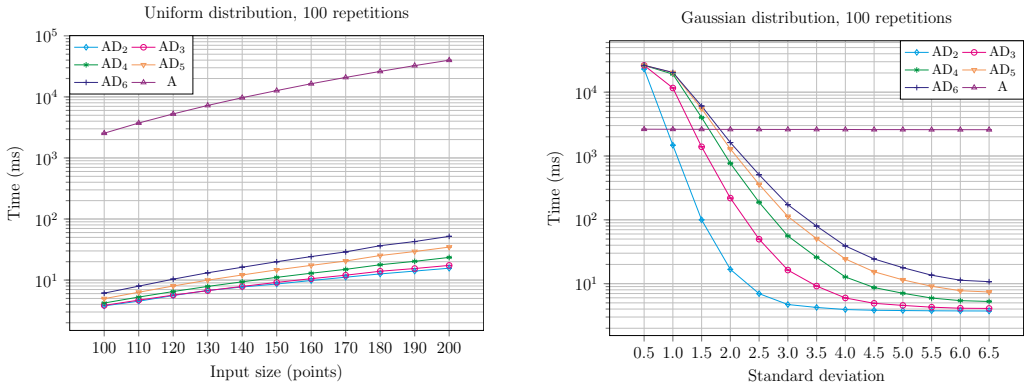

Figure 6 Left: average running time over 100 uniformly distributed data sets of sizes 100 to 200. Right: average running time over 100 normally distributed data sets of 100 points with varying standard deviations.

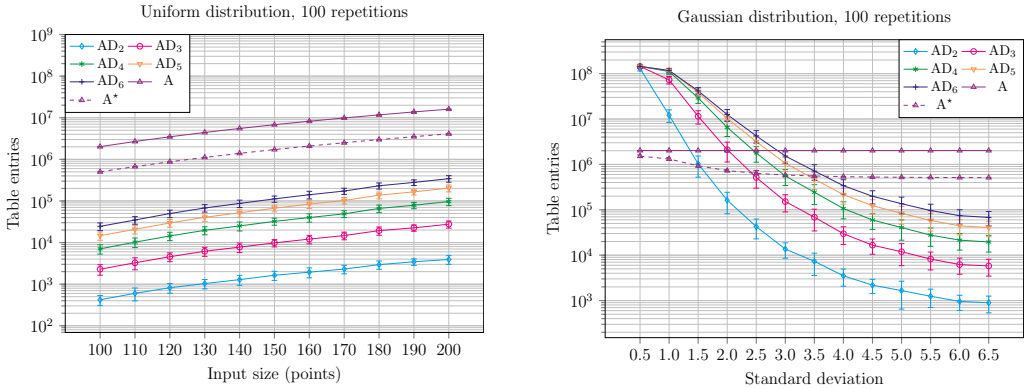

Figure 7 Left: average number of entries over 100 uniformly distributed data sets of sizes 100 to 200. Right: average number of entries over 100 normally distributed data sets of 100 points with varying standard deviations.

To measure the memory usage of the algorithms we consider the number of table entries that are used by the algorithms. See Figure 7. The results are similar to those of the running times. In the basic implementation of the A algorithm, a fixed size table is allocated, and the number of entries does not depend on the specific point set, only on its size. To also let the A algorithm benefit from fewer entries, we consider a version of the A algorithm that stores repeated entries found during the rotational sweep around q just once. Whenever we use the same T_q^* to fill $T[q, r, k]$, we can store it as a sequence of values that are all T_q^*, at the expense of extra query time for table entries. This is shown by the dashed purple curve. We would use a factor 3–4 fewer entries, except for the Gaussian distribution with lower values of σ. We also studied the memory usage instead of the number of entries in the tables, but since this showed the same patterns, we left out these graphs.

Output. We can compare the results of running the algorithms on cardinality (point count), area, and diameter. Since all algorithms are optimal for their settings, it is clear that the cardinality for the A algorithm is highest, followed by the cardinalities of the AD algorithm by decreasing diameter.

The output numbers cardinality, area, and diameter, averaged, are shown in Figures 8–10 for the uniform and normal distributions.

Indeed the A algorithm finds larger cardinality solutions; the differences between different diameter bounds are also clear. It is perhaps surprising that the highest cardinality solutions are typically not compact, but rather elongated. This is confirmed in Figure 10, where the A algorithm always finds solutions with diameters 8–18 mm. With an area close to 4 mm^2, these regions must be elongated. Further experiments [8] confirm these findings up to 500 points, albeit based on just 5 repetitions.

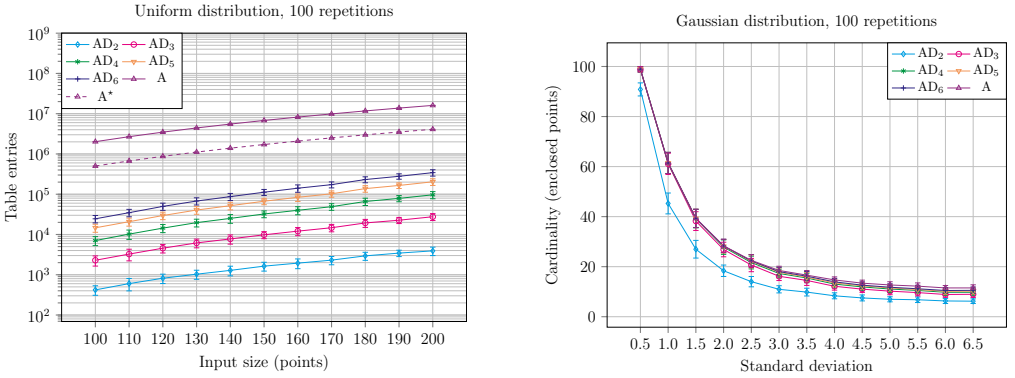

Figure 8 Left: average cardinality over 100 uniformly distributed data sets of sizes 100 to 200. Right: average cardinality over 100 normally distributed data sets of 100 points with varying standard deviations.

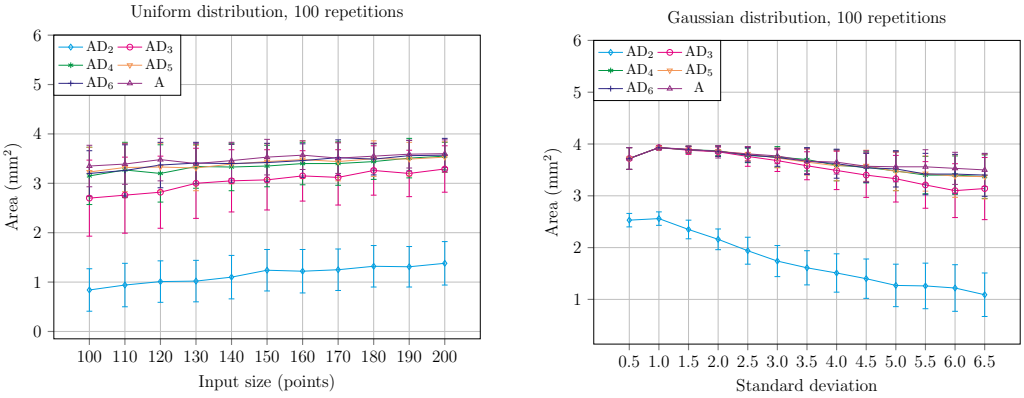

Figure 9 Left: average area over 100 uniformly distributed data sets of sizes 100 to 200. Right: average area over 100 normally distributed data sets of 100 points with varying standard deviations.

Real-world data. We consider the output of the algorithms on the data that inspired this research, where we include the area selection (AS) algorithm from [9]. That algorithm uses patches for efficiency reasons, and to be able to run an exact, exponential-time algorithm on patches that contain few points. Interestingly, patches are also a way to limit the diameter that can be found by the A algorithm, namely at most the diameter of a patch. Since patches are 3×3 mm, the A algorithm and the AS algorithm may find regions with diameter up to 4.24 mm. We use a diameter of 4 mm in the AD algorithm, which does not use patches.

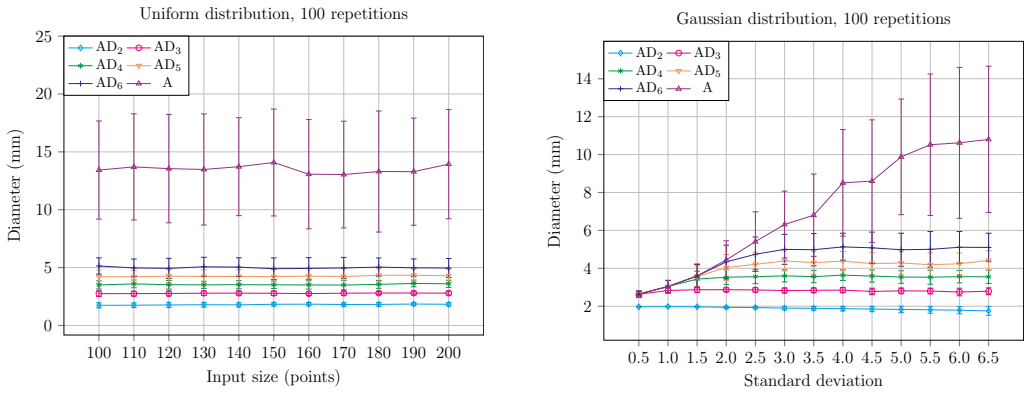

Figure 10 Left: average diameter over 100 uniformly distributed data sets of sizes 100 to 200. Right: average diameter over 100 normally distributed data sets of 100 points with varying standard deviations.

Table 2 The runtime (seconds) of the Area-Diameter (AD) algorithm, the area selection (AS) algorithm and the A algorithm applied to the real-world data summarized in Table 1. AS is run for step sizes $s = 1.98$ and $s = 0.5$; A is run within each patch generated with step size $s = 0.5$.

I	AD_4	AS ($s = 1.98$)	AS ($s = 0.5$)	A ($s = 0.5$)
0	494.19	**5.24**	72.83	13.7
1	14.7	17.15	274.82	**2.84**
2	29.38	19.89	218.36	**3.66**
3	24.43	19.12	263.07	**3.17**
4	8.83	13.83	229.33	**2.08**
5	21.76	9.16	141.13	**4.51**
6	2.08	9.32	161.07	**1.63**
7	6.19	13.66	174.71	**1.82**
8	37.18	9.66	77.41	**2.58**
9	**0.19**	4.83	52.02	1.47

Patches are shifted with overlap to cover the whole region. We show results of the AS algorithm with a rather large step size of 1.98 mm, and results of the A and AS algorithms with a step size of 0.5 mm.[3]

The results are shown in Tables 2 and 3. In the ten examples, the four algorithms usually find the same rough region, but seldom the exact same convex solution. One example is shown in Figure 11; the full version [8] shows all ten data sets. In two cases, the AS algorithm with $s = 1.98$ finds a very different region, confirming that that step size of a moving window matters and must be set small enough. The results of the two AS methods show how many more points can be enclosed by using a smaller step size. The results of AS and A with step size $s = 0.5$ show how well the AS heuristic works compared to the optimal algorithm A (optimal per patch). The timings show that A is faster than AS, while being optimal per patch as well. While AD_4 finds better solutions without patches, it is clearly slower.

[3] The step size of 1.98 mm is based on the actual usage of the algorithm currently by the authors of [9].

Table 3 Comparison of the results obtained by applying the area-diameter algorithm (AD), the area selection method (AS) and the A algorithm to all patches of the point sets summarized in Table 1. AS is run for step sizes $s = 1.98$ and $s = 0.5$; A is run for step size $s = 0.5$. All the values for area and diameter are expressed in mm^2 and mm respectively. Best counts are shown bold; values k and $\hat{k}$ use different diameter bounds and are not directly comparable.

5 Conclusions and further research

We have shown that maximum cardinality convex subsets with bounded area and diameter can be computed in polynomial time by a dynamic programming method that embeds rotating calipers. The algorithm runs in $O(n^6k)$ time, a cubic factor higher than the algorithm that does not consider the diameter.

The original application worked with a bounded area and aspect ratio, which is similar but not quite the same as area and diameter. It is unclear whether a polynomial-time algorithm exists that computes maximum cardinality subsets with bounded area and aspect ratio, or bounded area and perimeter. These are open theoretical questions for future research.

We have also shown that the new algorithm may well be faster than the algorithm that ignores diameter in practical situations, because optimal solutions without a diameter constraint are often very elongated. With a bounded diameter, we can often prune significantly. Of course this depends heavily on the specific data set. We have analyzed this experimentally for uniformly distributed data and Gaussian distributed data.

For the data from the application, we have shown that we can compute an optimal solution in the practical situation within a reasonable amount of time, where the problem is phrased as a well-defined optimization problem and the solution need not use patches.

Abstract

The Fréchet distance is a distance measure between trajectories in $\mathbb{R}^d$ or walks in a graph G. Given constant-time shortest path queries, the Discrete Fréchet distance $\mathrm{D_G}(P, Q)$ between two walks P and Q can be computed in $O(|P| \cdot |Q|)$ time using a dynamic program. Driemel, van der Hoog, and Rotenberg [SoCG'22] show that for weighted planar graphs this approach is likely tight, as there can be no strongly-subquadratic algorithm to compute a 1.01-approximation of $\mathrm{D_G}(P, Q)$ unless the Orthogonal Vector Hypothesis (OVH) fails.

Such quadratic-time conditional lower bounds are common to many Fréchet distance variants. However, they can be circumvented by assuming that the input comes from some well-behaved class: There exist $(1+\varepsilon)$-approximations, both in weighted graphs and in $\mathbb{R}^d$, that take near-linear time for c-packed or κ-straight walks in the graph. In $\mathbb{R}^d$ there also exists a near-linear time algorithm to compute the Fréchet distance whenever all input edges are long compared to the distance.

We consider computing the Fréchet distance in unweighted planar graphs. We show that there exist no strongly-subquadratic 1.25-approximations of the discrete Fréchet distance between two disjoint simple paths in an unweighted planar graph in strongly subquadratic time, unless OVH fails. This improves the previous lower bound, both in terms of generality and approximation factor. We subsequently show that adding graph structure circumvents this lower bound: If the graph is a regular tiling with unit-weighted edges, then there exists an $\tilde{O}((|P| + |Q|)^{1.5})$-time algorithm to compute $\mathrm{D_G}(P, Q)$. Our result has natural implications in the plane, as it allows us to define a new class of well-behaved curves that facilitate $(1+\varepsilon)$-approximations of their discrete Fréchet distance in subquadratic time.

1 Introduction

The Fréchet distance is a widely used metric for measuring the similarity between trajectories. It is often illustrated through a metaphor: imagine a person walking along one trajectory and their dog following another, connected by a leash. The Fréchet distance is the minimum possible leash length over all synchronized traversals of both trajectories.

This metric has numerous applications, particularly in movement data analysis [10, 18, 24, 15, 5, 13, 25, 33]. It is versatile, having been applied to handwriting recognition [29], coastlines [26], geometric shapes in geographic information systems [16], and trajectories of moving objects such as vehicles, animals, and athletes [28, 30, 6, 13]. We consider the *discrete* Fréchet distance, where trajectories are modeled as sequences of discrete points.

Alt and Godau [2] were the first to analyse the Fréchet distance from a computational perspective. They considered trajectories as polygonal curves in $\mathbb{R}^d$ with n and m vertices, and compute the continuous Fréchet distance in $O(mn \log(n+m))$ time. Later, Buchin, Buchin, Meulemans and Mulzer [11] introduced a faster randomized algorithm, achieving a running time of $O(n^2\sqrt{\log n}(\log\log n)^{3/2})$ on a real-valued pointer machine and $O(n^2 \log\log n)$ on a word RAM. For the discrete Fréchet distance, Eiter and Mannila [20] presented an $O(nm)$ time algorithm under constant-time distance computations. Agarwal, Avraham, Kaplan, and Sharir [1] later improved this to $O(nm(\log\log nm)/\log nm)$ in the word RAM.

Driemel, van der Hoog, and Rotenberg [19] initiate the study of Fréchet distance in graphs. They consider as input a (weighted) graph G where a trajectory is a walk in the graph. The distance between two vertices is the length of their shortest path. Given a constant-time distance oracle, the discrete Fréchet distance $\mathrm{D_G}(P, Q)$ between any two walks in G can then be computed in $O(nm)$ time using the algorithm by Eiter and Mannila [20].

Conditional Lower Bounds. Several conditional lower bounds exist for computing the Fréchet distance or its constant-factor approximations. These results rely on complexity assumptions such as the Orthogonal Vector Hypothesis (OVH) and the Strong Exponential Time Hypothesis (SETH) [32]. Bringmann [7] established that no algorithm can compute the (discrete or continuous) Fréchet distance between two polygonal curves of n vertices in $O(n^{2-\delta})$ time for any $\delta > 0$, unless OVH fails. The same lower bound holds for small constant-factor approximations. Bringmann's proof originally involved self-intersecting curves in the plane, but later work by Bringmann and Mulzer [9] extended the result to intersecting curves in $\mathbb{R}^1$. Buchin, Ophelders, and Speckmann [12] further demonstrated that the same lower bound applies for any better-than-3-approximation algorithm for pairwise disjoint planar curves in $\mathbb{R}^2$, or intersecting curves in $\mathbb{R}^1$.

Bringmann's lower bound [7] holds also for unbalanced inputs: given two curves with n and m vertices in the plane, no algorithm can compute the Fréchet distance in $O((nm)^{1-\delta})$ time assuming OVH. Driemel, van der Hoog and Rotenberg [19] give a similar lower bound for paths in a weighted planar graph. They prove that, unless OVH fails, no $O((nm)^{1-\delta})$-time algorithm can 1.01-approximate the discrete Fréchet distance between arbitrary paths in a weighted planar graph – even if the ratio between smallest and highest weight is bounded by a constant. This lower bound applies only to weighted graphs and does therefore not exclude the existence of a fast algorithm on unweighted planar graphs. A closer inspection of their argument reveals that their proof cannot simply be adapted to the unweighted case by subdividing long edges often enough. In this case, new vertices get introduced to the graph and their arguments break down.

Avoiding lower bounds through well-behaved curves. These lower bounds can be circumvented if the input is well-behaved. Driemel, Har-peled and Wenk [17] consider three classes of curves in $\mathbb{R}^d$ which are well-behaved as long as their corresponding behavioural parameter is low. These are c-packed curves [17, 8], ϕ-low density curves [17], and κ-bounded curves [3, 4, 17]. They show algorithms to compute a $(1+\varepsilon)$-approximation between two well-behaved curves whose running time is near-linear in n and m. Gudmundsson, Mirzanezhad, Mohades, and Wenk consider the special case where all edges of the input curves are long with respect to their Fréchet distance [23]. In this case, the Fréchet distance can be computed in $O((n+m)\log(n+m))$ time [23]. Driemel, van der Hoog, and Rotenberg [19] show that if the input are walks in a graph G and one of the walks is restricted to a c-packed or κ-straight path, then there exists $(1+\varepsilon)$-approximations that take near-linear time.

Contribution. Driemel, van der Hoog, and Rotenberg [19] ruled out a strongly subquadratic algorithm for a 1.01-approximation between paths in a weighted graph, while the construction by Buchin, Ophelders, and Speckmann [12] rules out a strongly subquadratic algorithm for a 3-approximation between walks in an unweighted planar graph. We consider the discrete Fréchet distance between paths in an unweighted planar graph. We prove (Theorem 5) that no strongly-subquadratic 1.25-approximation algorithm exists unless OVH fails, thereby improving both the generality (and also the approximation factor for planar graphs).

Next, we prove that adding graph structure circumvents this lower bound. If G is an unweighted regular tiling of the plane, then there exists an $\tilde{O}((n+m)^{1.5})$-time algorithm to compute the Fréchet distance $\mathrm{D_G}(P,Q)$, between curves of length n and m. Our results have natural implications in the plane, for a special class of well-behaved curves ((ε,δ)-curves, to be defined). For those, we can compute the Fréchet distance under the L_1 metric (respectively, approximate it for any L_c metric) in $\tilde{O}(\frac{\sqrt{\delta}}{\varepsilon}(n+m)^{1.5})$ time (respectively, $\tilde{O}(\frac{\delta}{\varepsilon^2}(n+m)^{1.5})$ time). For completeness, we explain the continuous analogy to (ε,δ)-curves in the full version of this paper. We also compare this new curve class to existing well-behaved curve classes in the full version.

2 Preliminaries

Let G be an unweighted graph where $V(G)$ is its vertex set. We define $P=(p_1,\ldots,p_n)$ and $Q=(q_1,\ldots,q_m)$ as two paths in G. A path cannot visit a vertex twice. For integers $i,i'\in[n]$ with $i\leq i'$ we denote by $P[i:i']$ the subpath of P from p_i to $p_{i'}$. We define the discrete Fréchet distance $\mathrm{D_G}(P,Q)$ between P and Q as follows [19]: A sequence $(a_i,b_i)_{i\in[k]}$ of pairs of indices is a *monotone walk* if for all $i\in[k-1]$ we have $a_{i+1}\in\{a_i,a_i+1\}$ and $b_{i+1}\in\{b_i,b_i+1\}$. Let $\mathbb{F}_{n,m}$ be the set of all monotone walks from $(1,1)$ to (n,m). The cost of $F\in\mathbb{F}_{n,m}$ is the maximum of $\mathrm{dist}(p_i,q_j)$ over $(i,j)\in F$, where dist() denotes the length of the shortest path between vertices. $\mathrm{D_G}(P,Q)$ is the minimum cost of a walk in $\mathbb{F}_{n,m}$.

$$\mathrm{D_G}(P,Q)=\min_{F\in\mathbb{F}_{n,m}}\mathrm{cost}(F)=\min_{F\in\mathbb{F}_{n,m}}\max_{(i,j)\in F}\mathrm{dist}(p_i,q_j).$$

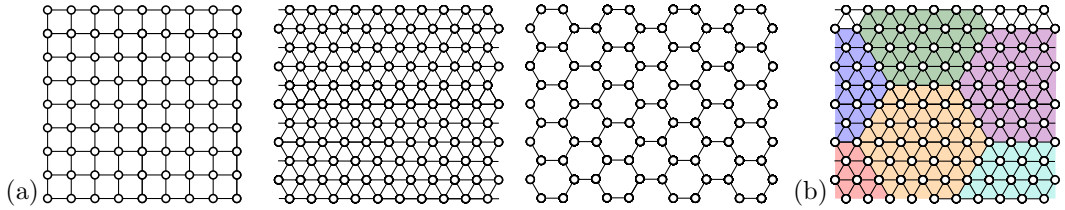

Figure 1 (a) The three regular plane tilings. (b) A hexagonal super-tiling of a triangular tiling.

Decision variant. We focus on the decision variant where the input includes some $\Delta \geq 0$ and the goal is to output whether $\mathrm{D_G}(P, Q) \leq \Delta$. The Δ-*free space matrix* M_Δ is the n by m matrix where $M_\Delta[i, j]$ is 0 if $\mathrm{dist}(p_i, q_j) \leq \Delta$ and 1 otherwise. We follow geometric convention, where i denotes the column of M_Δ (column i corresponds to some $p_i \in P$. Column entries with value 0 correspond to $q_j \in Q$ with $\mathrm{dist}(p_i, q_j) \leq \Delta$). Eiter and Mannila [20] define a directed graph over M_Δ where there is an edge from $M_\Delta[a, b]$ to $M_\Delta[c, d]$ if and only if $c \in \{a, a+1\}$, $d \in \{b, b+1\}$ and $M_\Delta[a, b] = M_\Delta[c, d] = 0$. They prove that $\mathrm{D_G}(P, Q) \leq \Delta$ if and only if there exists a directed path from $(1, 1)$ to (n, m) in this graph.

Orthogonal vectors. Our conditional lower bound reduces from the Orthogonal Vector Hypothesis. The input consists of two ordered sets of d-dimensional Boolean vectors U, W of sizes $|U| = n$ and $|W| = m$. We denote for $u \in U$ by $u_i \in \{0, 1\}$ its i'th component. The *OV problem* is to find out if some vector of U is orthogonal to some vector of W.

▶ **Definition 1** (Williams [32]). *The orthogonal vector hypothesis (OVH) states that for all $\delta > 0$, there exists constants ω and $1 > \gamma > 0$ such that the OV problem for vectors of dimension $d = \omega \log n$ and $m = n^\gamma$ cannot be solved in $O((nm)^{1-\delta})$ time.*

We consider each vector in U (or W) as a string of d bits. We denote by $\mathrm{str}(U)$ and $\mathrm{str}(W)$ the concatenation of all strings in U and W, respectively. A *substring* of some string $s_1 s_2 \ldots s_k$ is the sequence $s_a s_{a+1} \ldots s_{b-1} s_b$ for some $1 \leq a \leq b \leq k$.

Regular tilings. A *regular tiling* T is an infinite plane graph where each face is a regular polygon and each face has the same degree. There exist exactly three regular tilings [22]: the triangular, square, and hexagonal tiling (Figure 1). Without loss of generality, we assume that our tilings are axis-aligned. A face F of T is an open region bounded by the edges of T, we denote by $\overline{F}$ its closure. The *edge length* of T is the length of any edge. A tiling is *unit* if its edges have unit length. A path in T is a path in its corresponding graph. We always denote by T a unit tiling where $(0, 0)$ is a vertex of T. For any pair of vertices p, q of T, the term $\mathrm{dist}(p, q)$ denotes the distance in the graph T. We assume that we can compute $\mathrm{dist}(p, q)$ in constant time. Our algorithm considers what we will call a *super-tiling* of T and a natural partition of the edges of P and Q into subpaths.

▶ **Definition 2** (Figure 1 (b)). *Given a regular tiling T of the plane, a* super-tiling $\mathbb{T}$ *of T is a regular tiling of the plane whose vertex set is a subset of the vertex set $V(T)$. The* boundary vertices $B(\mathbb{T})$ *are the vertices of T that lie on the boundary of some face of $\mathbb{T}$.*

▶ **Definition 3.** *Consider a regular tiling T, some super-tiling $\mathbb{T}$ and a path P in T, we define the* breakpoints $B(P, \mathbb{T})$ *as all vertices in $P \cap B(\mathbb{T})$.*

Given a path P in a tiling T and a super-tiling $\mathbb{T}$ of T, we want to consider how $\mathbb{T}$ splits P into smaller snippets, each snippet "belonging" to a face of $\mathbb{T}$. More formally:

▶ **Definition 4** (Figure 2). *Consider a regular tiling T and a super-tiling $\mathbb{T}$ of T. Given a path $P = (p_1, p_2, \ldots, p_n)$ in T, let $\mathbb{I} := \{i \in [n] \mid p_i \in B(P, \mathbb{T}) \text{ or } i \in \{1, n\}\}$. We define the* induced subpaths $S(P, \mathbb{T})$ *as all subpaths $P[x : y]$, for consecutive $x, y \in \mathbb{I}$. Note that for each induced subpath, there exists a (not necessarily unique) face F in $\mathbb{T}$ whose closure $\bar{F}$ contains it; we say the induced subpath is* assigned *to one such face (breaking ties arbitrarily).*

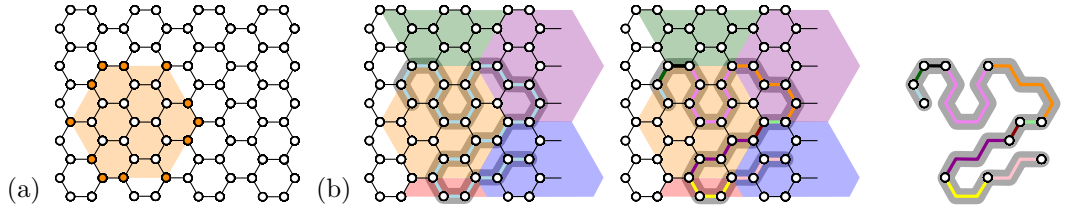

Figure 2 (a) For a face F in the super-tiling $\mathbb{T}$, we show the set $B(\mathbb{T}) \cap \overline{F}$. (b) Given a path P, we create a sequence of subpaths of P where consecutive subpaths overlap in a single vertex.

Submatrices of M_Δ. We show a subquadratic algorithm to decide whether $\mathrm{D_T}(P,Q) \leq \Delta$ if P and Q are paths in a tiling T. We compute a monotone walk from $(1,1)$ to (n,m) in M_Δ by efficiently propagating reachability information across *submatrices* of M_Δ. For integers $i, i' \in [n]$ and $j, j' \in [m]$ with $i \leq i'$ and $j \leq j'$ we denote by $M_\Delta[i:i', j:j']$ the submatrix of M_Δ that consist of all entries $M_\Delta[x,y]$ for $(x,y) \in [i,i'] \times [j,j']$. We define the *bottom-left* facets of $M_\Delta[i:i', j:j']$ as all entries $\{M_\Delta[i,y] \mid y \in [j,j']\}$ and $\{M_\Delta[x,j] \mid x \in [i,i']\}$. The *top-right* facets are defined as the entries $\{M_\Delta[i',y] \mid y \in [j,j']\}$ and $\{M_\Delta[x,j'] \mid x \in [i,i']\}$.

(ε, δ)-curves. Finally, we introduce a new class of well-behaved curves in the plane. Intuitively, an (ε,δ)-curve, for small δ, is a curve composed of short edges that does not revisit the same region of the plane too frequently. Formally, fix a universal constant $\gamma \in O(1)$. Let P be a curve in the plane, and let B_ε denote the set of all balls (in Euclidean metric) of radius ε centred at the vertices of P. We say that P is an (ε,δ)-curve if all its edges have length at most γ, and any point in the plane lies in at most δ balls from B_ε.

For any given pair (P,ε), δ is determined. As ε decreases, so may δ. If δ remains large for small ε, then many vertices of P are densely clustered – i.e., effectively, the curve frequently revisits the same locations. We present an exact algorithm for the Discrete Fréchet distance under the L_1 metric with a linear dependency on $\frac{\sqrt{\delta}}{\varepsilon}$. We assume that the input specifies a desirable value of ε, and that this yields a favourable corresponding δ. Imposing that δ is constant amounts to requiring that the curve does not revisit any ε-ball more than a constant number of times – a restriction that somewhat resembles the well-studied c-packed curves [17, 19, 8]. In the full version of this paper, we discuss in detail how our new class relates to the prior well-behaved curve classes.

3 A lower bound for paths in an unweighted planar graph

Let G be an unweighted planar graph and P and Q be paths in G. We show a lower bound, conditioned on OVH, that excludes any strongly subquadratic algorithm to compute a 1.25-approximation of $\mathrm{D_G}(P,Q)$. Since we are space-restricted, we present our argument only in the full version of this paper. Here, we assume that the reader is familiar with how these lower bounds are typically constructed [7, 12, 19, 9] and only mention how our construction differs from prior works. We start with some OV instance (U,W). We build an unweighted planar graph G and two paths P and Q in G such that $\mathrm{D_G}(P,Q) \leq 4$ if and only if the OV instance is a yes-instance and $\mathrm{D_G}(P,Q) \geq 5$ otherwise. One novelty of our approach is a preprocessing step, where we transform (U,W) into an equivalent instance with additional properties:

▶ **Lemma 1.** *An instance $U', W' \subseteq \{0,1\}^{d'}$ of OV can be preprocessed in $O(d'(n+m))$ time, resulting in a new instance $U, W \subseteq \{0,1\}^d$ with $d \in O(d')$ such that:*

- *a yes-instance stays a yes-instance and a no-instance stays a no-instance,*

- *for all* $u \in U$, $u_1 = u_d = 0$ *and for all* $w \in W$, $w_1 = w_d = 1$,
- *if the instance is a no-instance, then* $\forall u \in U$ *the vector* u *is not only non-orthogonal to every* $w \in W$*, but even non-orthogonal to all consecutive length-*d *substrings of* $\mathrm{str}(W)$.

This preprocessing significantly simplifies our proofs and may be of independent interest. Previous lower bound constructions [7, 19, 12, 9] fix some $\Delta \in \mathbb{R}$. Given an OV-instance (U, W), they construct curves (P, Q) by constructing for each $u \in U$ a subcurve $f(u)$ and each $w \in W$ a subcurve $g(w)$ (see Figure 3). The construction has a very strong property: Consider a traversal of P and Q where the person and the dog remain within distance Δ of one another. If the person is in $f(u)$ for some $u \in U$ and the dog is in $g(w)$ for some $w \in W$ then neither the person or the dog can stand still if the other moves.

Requiring the planar graph to be unweighted significantly restricts the freedom we have in engineering the pairwise distance between vertices. We are unable to recreate an equally strong property and instead obtain a much weaker statement: If the person is traversing the subpath $f(u)$ for some $u \in U$ and the dog is traversing $g(w)$ for some $w \in W$ and the person moves at least two steps then the dog has to move at least one. We rely upon our preprocessing to then still argue that there exists a traversal of P and Q such that the leash length is at most 4 if and only if there is an orthogonal pair $(u, w) \in U \times W$.

▶ **Theorem 5.** *Let* P *and* Q *be paths in an unweighted planar graph. Let* $|P| = n$ *and* $|Q| = m = n^\gamma$ *for some constant* $\gamma > 0$*. Then for all* $\delta \in (0, 1)$*, one cannot approximate* $\mathrm{D_G}(P, Q)$ *by a factor better than* 1.25 *in* $O((nm)^{1-\delta})$ *time unless OVH fails.*

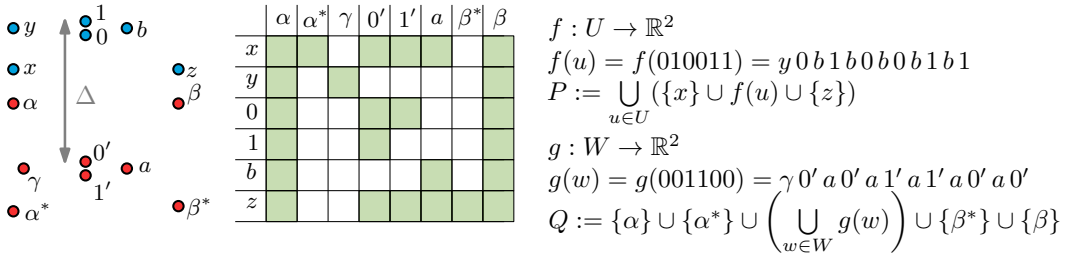

Figure 3 We illustrate the construction for planar curves by Bringmann [7]. Each $u \in U$ becomes a subcurve $f(u)$ of P and each $w \in W$ becomes a subcurve $g(w)$ of Q. Our table shows a green cell if the distance between the vertices is less than Δ. If the person is in a subcurve $f(u)$ and the dog is in $g(w)$ and the person moves from its vertex then the dog *must* also move.

4 Upper bound

We show that subquadratic algorithms *do* exist for unweighted planar graphs that exhibit additional structure. Specifically, our main result is as follows:

▶ **Theorem 6.** *Let* T *be a regular unit tiling and* (P, Q) *be paths in* T *with* $|P| = n$ *and* $|Q| = m$*. Given* $\Delta \in \mathbb{R}$*, we can output whether* $\mathrm{D_T}(P, Q) \leq \Delta$ *in* $O((n+m)^{1.5} \log(n+m))$ *time.*

We compute $\mathrm{D_T}(P, Q)$ as follows. Given (P, Q), we compute the smallest axis-aligned rectangles R_P and R_Q that contain P and Q, respectively, in $O(n + m)$ time. Let d_0 be the Euclidean length of the shortest segment (p, q) with $p \in R_P$ and $q \in R_Q$, and let d_1 be the Euclidean length of the longest such segment. Observe that $\mathrm{D_T}(P, Q) \in [\frac{d_0}{2}, 2d_1]$, that this range contains $O(n + m)$ integers, and that $\mathrm{D_T}(P, Q)$ is always integral. By performing a binary search over $[\frac{d_0}{2}, 2d_1] \cap \mathbb{Z}$, applying Theorem 6 at each step, we obtain:

▶ **Corollary 7.** *Let T be a regular unit tiling, and let P and Q be paths in T with $|P| = n$ and $|Q| = m$. Then $\mathrm{D}_{\mathrm{T}}(P, Q)$ can be computed in $O((n+m)^{1.5} \log^2(n+m))$ time.*

Additional definitions. To prove Theorem 6, we first introduce a few new concepts. Let T be a regular, unit, axis-aligned tiling. Based on T, we construct a super-tiling $\mathbb{T}$ of the same type as T, that is, if T is a square/triangular/hexagonal tiling, then $\mathbb{T}$ is also a square/triangular/hexagonal tiling. We state our results in general terms, but for ease of reading, the reader may assume T is a square tiling. For a (super) tiling $\mathbb{T}$, we define the *halfslabs* of any face F of $\mathbb{T}$ by picture (Figure 4).

▶ **Definition 8.** *Let T be a regular tiling, and let $\mathbb{T}$ be a super-tiling of T. We say that two faces F and F' of $\mathbb{T}$ are* well-separated *by a vertex $v \in V(T)$ if, for all $p \in V(T) \cap \overline{F}$ and $q \in V(T) \cap \overline{F'}$, there exists a shortest path from p to q in T that passes through v.*

Having faces F, F' be well-separated proves to be very useful, since in such a pair the distance between some vertex $p \in V(T) \cap \overline{F}$ and $q \in V(T) \cap \overline{F'}$ can be well-understood. We provide an efficient algorithm to compute the pairwise Fréchet distance between subpaths of P and Q whenever their corresponding faces in $\mathbb{T}$ are well-separated. We identify a sufficient condition that ensures that some pair F, F' is well-separated, based on the *alignment* of the two:

▶ **Definition 9.** *Let T be a regular tiling. Two faces F and F' of T are* aligned *if F' intersects a halfslab of F (or F intersects a halfslab of F').*

▶ **Lemma 10.** *Let T be an axis-aligned regular unit tiling, and let $\mathbb{T}$ be a super-tiling of T of the same type as T. Any two faces F, F' of $\mathbb{T}$ that are not aligned are well-separated by a vertex $v \in V(T)$.*

Proof. Consider first the case where T is a square tiling (and so $\mathbb{T}$ is too). The situation is depicted in Figure 5 (a). If the faces F, F' are not aligned, then F' is contained in one of the four regions (R_1, R_2, R_3, R_4) of the plane formed by the halfslabs of F. Let v be the vertex at the apex of the region which contains F'. We claim that for any vertices $p \in V(T) \cap \overline{F}$ and $q \in V(T) \cap \overline{F'}$, there exists a shortest path between p and q that passes through v. Hence F and F' are well-separated. The claim is easy to see from the properties of shortest paths in grid graphs. We provide an alternative proof of the claim, with the advantage that it can be more easily generalized to the triangular and hexagonal grid. See Figure 5 (b) and consider for $i = 1, 2, \ldots$ the circles of radius i in the plane graph T centred around p, and q.

$$h_i := \{x \in V(T) : \mathrm{dist}(p, x) = i\}, \quad h'_i := \{x \in V(T) : \mathrm{dist}(q, x) = i\}.$$

We can see that h_i, h'_i can be described as diamonds with four sides. Let us among the four sides of h_i denote by X_i the side that is facing towards F'. Likewise, let us among the

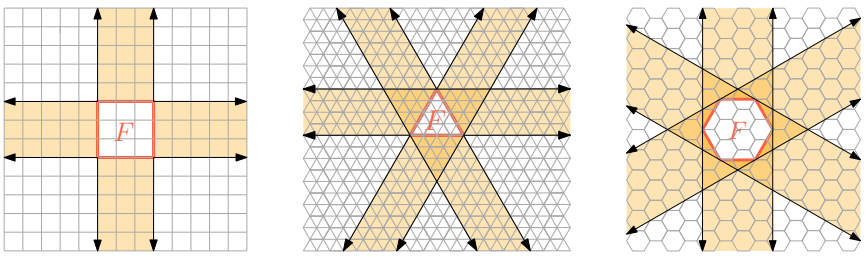

Figure 4 For a face F in a square/triangular/hexagonal (super-)tiling, its halfslabs are the infinite slabs enclosing F along the directions depicted here (orange).

four sides of h'_i denote by X'_i the side that is facing towards F. Note that all of X_i, X'_i are parallel for $i \in \mathbb{N}$. Let ℓ denote the line through vertex v parallel to the X_i. Let $a \in \mathbb{N}$ be minimal such that h_a touches ℓ. Since X_a is parallel to ℓ, we have $X_a \subseteq \ell$. Furthermore, no matter which $p \in V(T) \cap \overline{F}$ was chosen as the centre of the circles h_i, we always have $v \in X_a$. This follows due to the way and the angle in which the circles h_i expand. Analogously, let $b \in \mathbb{N}$ be minimal such that h'_b touches ℓ. Due to the way the h'_i expand and since F and F' are not aligned, we have $v \in X'_b$. Now, the circle h_a is entirely on one side of ℓ, the circle h'_b is entirely on the other side, and $v \in h_a \cap h'_b$. By definition of h_a, h'_b, this implies $\text{dist}(p, q) = a + b$ and there is a shortest path between p, q that passes through v.

For the case of triangular and hexagonal grids, the situation is depicted in Figures 6 and 7. Here the halfslabs divide the plane into 6 cone-shaped regions $R_1, \ldots, R_6$. Let v_j be the point at the apex of R_j for $j = 1, \ldots, 6$. Note that v_j is also a vertex of $V(T)$. For both the triangular and hexagonal grid, the definitions of $h_i, h'_i, X_i, X'_i, \ell, a, b$ can be made in an analogous matter. Analogously, it follows that $v_j \in h_a \cap h'_b$ which concludes the lemma. ◀

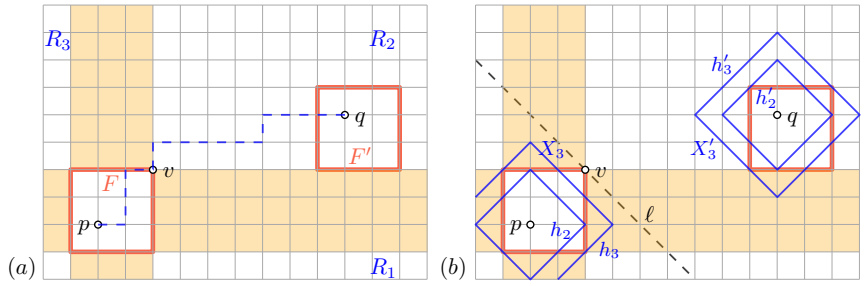

Figure 5 (a) The two faces F, F' of the square super-tiling $\mathbb{T}$ are non-aligned.

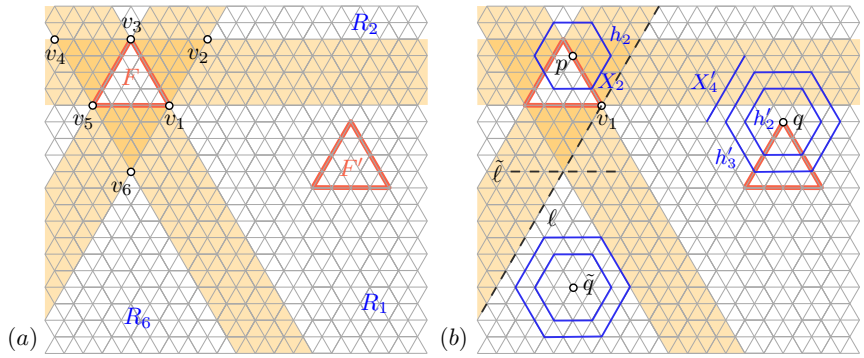

Figure 6 (a) Vertex v_1 well-separates non-aligned faces in a triangular grid. (b) Proof.

Algorithm overview. Given T and paths P and Q, we first compute a suitable super-tiling:

▶ **Lemma 11.** *Let T be a regular unit tiling, and let P and Q be two paths in T of lengths n and m. In $O((n+m)^{1.5})$ time, we can compute a super-tiling $\mathbb{T}$ such that:*

- *the edges of $\mathbb{T}$ have a length in $\Theta(\sqrt{n+m})$, and*
- *the total number of induced subpaths in $S(P, \mathbb{T}) \cup S(Q, \mathbb{T})$ (see Definition 4) is $O(\sqrt{n+m})$.*

Proof. Our proof is inspired by that of Chan and Rahmati [14, Lemma 1], who prove an analogous statement for grids and curves in higher-dimensional real space (without graphs). For the proof, we assume without loss of generality that T is axis-aligned.

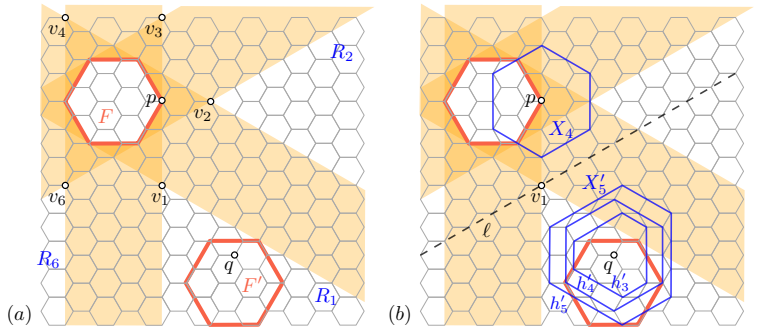

Figure 7 (a) Vertex v_1 well-separates non-aligned faces in a hexagonal grid. (b) Proof.

Let $f = \lceil \sqrt{n+m} \rceil$, and let $\mathbb{T}_0$ be any axis-aligned super-tiling of T with an edge length in $\Theta(f)$. For each $i \in [f-1]$, define $\mathbb{T}_i$ to be the super-tiling obtained by shifting $\mathbb{T}_0$ by the vector (i, i) if T is square, or by $(0, i\sqrt{3})$ if T is triangular or hexagonal. These shifted super-tilings remain axis-aligned super-tilings of T, as all their vertices align with those of T.

Since we shift in a direction not aligned with any edge of T, and since $i \leq f-1$, each edge or vertex of T lies on the boundary of $O(1)$ faces across the family $\{\mathbb{T}_i\}_{i=0}^{f-1}$. It follows that for any discrete vertex set $V \subseteq V(T)$ with $|V| = k$, there exists some $\mathbb{T}_i$ such that only $O(k/f)$ vertices lie on boundaries of faces in $\mathbb{T}_i$. Therefore, there exists a super-tiling $\mathbb{T} \in \{\mathbb{T}_0, \ldots, \mathbb{T}_{f-1}\}$ such that the total number of boundary vertices from P and Q is $O((n+m)/f)$, which implies $O((n+m)/f) = O(\sqrt{n+m})$ induced subpaths. To compute $\mathbb{T}$, we iterate over all vertices v of P and Q and, for each, determine the $O(1)$ super-tilings $\mathbb{T}_i$ with $v \in B(\mathbb{T}_i)$ by iterating over all $\mathbb{T} \in \{\mathbb{T}_0, \ldots, \mathbb{T}_{f-1}\}$. This takes $O((n+m)f)$ total time. We then select the super-tiling $\mathbb{T}_i$ that minimizes $|(P \cup Q) \cap B(\mathbb{T}_i)|$. ◀

Let $\mathbb{T}$ be the computed super-tiling of T. We partition P and Q into induced subpaths, denoted by $S(P, \mathbb{T})$ and $S(Q, \mathbb{T})$. These $O(\sqrt{n+m})$ subpaths naturally induce a subdivision of the free-space diagram M_Δ into $O(n+m)$ rectangular submatrices $M_\Delta[i\colon i', j : j']$, where $P[i : i'] \in S(P, \mathbb{T})$ and $Q[j : j'] \in S(Q, \mathbb{T})$ (see Figure 8(a)).

Our algorithm makes use of a wave-front method. We define a wave-front W as a monotone walk through the grid $[1, n] \times [1, m]$ that separates $(1, 1)$ from (n, m). At each grid point $(i, j) \in W$, we store a Boolean value indicating whether there exists a monotone walk F from $(1, 1)$ to (i, j) such that all points on F lie in free space: that is, $M_\Delta[x, y] = 0$ for all $(x, y) \in F$ (Figure 8(b)).

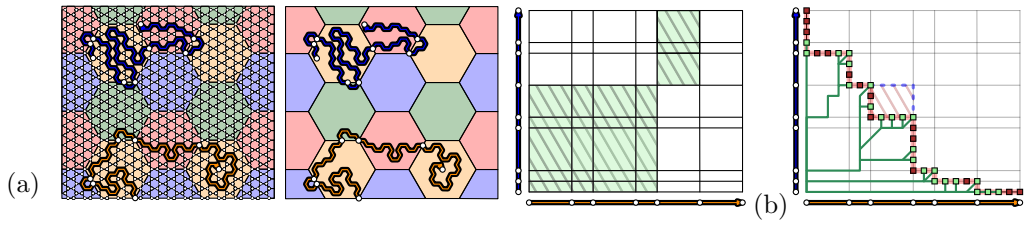

Figure 8 (a) For a given tiling T, we first compute a super-tiling $\mathbb{T}$ which partitions the edges of P and Q. These subpaths divide the Δ-free space matrix M_Δ into submatrices that correspond to aligned and non-aligned curve pairs (green dashed versus neutral). (b) We maintain a wave-front W which is a monotone curve through M_Δ that has a Boolean value at each entry. An *update* selects a submatrix $M_\Delta[i : i', j : j']$ and removes from W its bottom-left facets (adding its top-right facets).

An *update* to the wave-front W selects a pair of subpaths $(P[i:i'], Q[j:j']) \in S(P,\mathbb{T}) \times S(Q,\mathbb{T})$ such that the bottom and left facets of the submatrix $M_\Delta[i:i', j:j']$ lie on the current wave-front. The update removes these facets from W and inserts the top and right facets instead. To perform the update, we consider the faces F_P and F_Q of $\mathbb{T}$ that $P[i:i']$, respectively $Q[j:j']$, are assigned to, and proceed via a case distinction:

1. If F_P and F_Q are not aligned, then they are well-separated by a vertex v (by Lemma 10), and we show how to perform a fast update using v.
2. If F_P and F_Q are aligned, we perform a brute-force update and use a counting argument to bound the total running time of these updates.

We analyse both cases separately, observing that while some instances may involve only Case 1 or only Case 2 submatrices, we can independently bound the total cost for each case.

Case 1: Updating with $(P[i:i'], Q[j:j'])$ where F_P and F_Q are not aligned. We show an update algorithm that is near-linear in the perimeter of the submatrix $M_\Delta[i:i', j:j']$.

▶ **Lemma 12.** *Let $P[i:i'] \in S(P,\mathbb{T})$ and $Q[j:j'] \in S(Q,\mathbb{T})$ be subpaths whose faces F_P and F_Q in $\mathbb{T}$ are not aligned. Then the corresponding wave-front update can be performed in $O(k \log k)$ time, where $k = |P[i:i']| + |Q[j:j']|$.*

Proof. By Lemma 10, the subcurves $P[i:i']$ and $Q[j:j']$ are well-separated by some vertex $v \in V(T)$, which we can identify in constant time. Given v, we compute two curves in $\mathbb{R}$ whose Δ-free space matrix equals $M_\Delta[i:i', j:j']$. We define these curves as follows.

For a point $p \in P[i:i']$ we let $\bar{p} = \operatorname{dist}(p,v)$. Likewise, for a point $q \in Q[j:j']$, we let $\bar{q} = -\operatorname{dist}(q,v)$. Note the difference in sign. Because $P[i:i']$ and $Q[j:j']$ are well-separated by v, we have $\operatorname{dist}(p,q) = \operatorname{dist}(p,v) + \operatorname{dist}(v,q) = |\bar{p} - \bar{q}|$ for any $p \in P[i:i']$ and $q \in Q[j:j']$. We let $\bar{P} = (\bar{p}_i, \ldots, \bar{p}_{i'})$ and $\bar{Q} = (\bar{q}_j, \ldots, \bar{q}_{j'})$.

The Δ-free-space matrix $M_\Delta[i:i', j:j']$ is equal to the Δ-free space matrix of the sequences $\bar{P}$ and $\bar{Q}$ over the real line under the absolute value metric. Let $\bar{M}_\Delta$ be this matrix. We compute the top and right facets of $\bar{M}_\Delta$ in $O(k \log k)$ time with existing fast algorithms for 1D separated sequences [8, 31]. ◀

Case 2: Updating with $(P[i:i'], Q[j:j'])$ where F_P and F_Q are aligned. For aligned face pairs, we fall back on a brute-force update strategy based on *switching cells*, a concept introduced by Har-Peled, Knauer, Wang and Wenk. [4].

▶ **Definition 13** (Switching cells). *A cell (i,j) in M_Δ is a* switching cell *if $M_\Delta[i,j] = 0$, but either $M_\Delta[i,j-1] = 1$ or $M_\Delta[i,j+1] = 1$ (or both).*

The switching cells in a submatrix $M_\Delta[i:i', j:j']$ allow for a direct update of the wave-front:

▶ **Lemma 14** ([4]). *Let $P[i:i']$ and $Q[j:j']$ be two subpaths. Given all s switching cells in $M_\Delta[i:i', j:j']$, a brute-force wave-front update takes $O(|P[i:i']| + |Q[j:j']| + s)$ time.*

We apply the brute-force update algorithm to all subpath pairs $(P[i:i'], Q[j:j']) \in S(P,\mathbb{T}) \times S(Q,\mathbb{T})$ whose associated faces F_P and F_Q in $\mathbb{T}$ are aligned. We now show that the total number of switching cells encountered in these submatrices is not too large:

▶ **Lemma 15.** *Let T be a regular unit tiling, and let P and Q be two paths in T. Let $\mathbb{T}$ be any super-tiling of T with edge length $\Theta(\sqrt{n+m})$. Then there are at most $O(n\sqrt{n+m})$ pairs (p_i, q_j) such that $M_\Delta[i,j]$ is a switching cell and p_i and q_j lie on aligned faces of $\mathbb{T}$. We can compute these pairs in $O(n\sqrt{n+m}\log m)$ time.*

Proof. Fix a vertex p_i and let F_p be a face of $\mathbb{T}$ such that $p_i \in \overline{F_p}$. Since P and Q are paths in a unit tiling, a switching cell $M_\Delta[i,j]$ occurs only if q_j lies at distance exactly Δ from p_i.

Let $B_i(\Delta) \subseteq V(T)$ denote the set of all vertices at distance exactly Δ from p_i. This set lies on the boundary of a shape whose geometry depends on the tiling type:

- $B_i(\Delta)$ is the boundary of a diamond if T is a square tiling.
- $B_i(\Delta)$ is the boundary of a regular hexagon if T is a triangular tiling.
- $B_i(\Delta)$ is the boundary of a (non-regular) hexagon if T is a hexagonal tiling.

These regions are convex. Consider a face F' of $\mathbb{T}$ that is aligned with F_p. The intersection of $B_i(\Delta)$ with $\overline{F'}$ contains at most $O(\sqrt{n+m})$ vertices. Each of these vertices could correspond to at most one vertex $q_j \in Q$ where (i,j) is a switching cell. There are only $O(1)$ faces of $\mathbb{T}$ that are aligned with F_p, whose closures intersect $B_i(\Delta)$. Hence, there are at most $O(\sqrt{n+m})$ such q_j values per p_i. Summing over all n vertices of P gives the desired $O(n\sqrt{n+m})$ bound.

What remains is to compute these pairs (p_i, q_j). We preprocess Q in a membership query data structure. For each $p_i \in P$, we select its assigned face F_p in constant time and we identify the $O(1)$ faces F' of $\mathbb{T}$ that are aligned with F_p and intersect $B_i(\Delta)$ in constant time. For every such face F', we iterate over the vertices v in $\overline{F'} \cap B_i(\Delta)$. We find if there exists a $q_j \in Q$ with $v = q_j$ in $O(\log m)$ time through a membership query. If so, then we compute $\text{dist}(p_i, q_{j+1})$ and $\text{dist}(p_i, q_{j-1})$ to determine whether $M_\Delta[i,j]$ is a switching cell. ◀

We are now ready to prove our main theorem:

▶ **Theorem 6.** *Let T be a regular unit tiling and (P,Q) be paths in T with $|P| = n$ and $|Q| = m$. Given $\Delta \in \mathbb{R}$, we can output whether $\mathrm{D}_{\mathrm{T}}(P,Q) \leq \Delta$ in $O((n+m)^{1.5}\log(n+m))$ time.*

Proof. Given T, P, and Q, we begin by applying Lemma 11 to compute in $O((n+m)^{1.5})$ time a super-tiling $\mathbb{T}$ and the corresponding subpaths $S(P,\mathbb{T})$ and $S(Q,\mathbb{T})$. The number of subpath pairs $(P[i:i'], Q[j:j']) \in S(P,\mathbb{T}) \times S(Q,\mathbb{T})$ is $O(n+m)$. For each pair, we determine if the corresponding faces F_P and F_Q in $\mathbb{T}$ are aligned, which takes $O(n+m)$ total time.

The product set $S(P,\mathbb{T}) \times S(Q,\mathbb{T})$ induces a grid of $O(n+m)$ rectangular submatrices of M_Δ with $O(\sqrt{n+m})$ rows and columns. Thus:

$$\sum_{\text{submatrices } M' \text{ of } M_\Delta} |\text{facets}(M')| = \sum_{(P[i:i'],Q[j:j']) \in S(P,\mathbb{T}) \times S(Q,\mathbb{T})} (i'-i+j'-j) \qquad \in O((n+m)^{1.5}). \quad (1)$$

Next, we initialize the wave-front W by computing the first row and first column of M_Δ, i.e., all entries $M_\Delta[i,1]$ for $i \in [n]$ and $M_\Delta[1,j]$ for $j \in [m]$, in $O(n+m)$ time. We then iterate diagonally through all pairs $(P[i:i'], Q[j:j'])$ in $S(P,\mathbb{T}) \times S(Q,\mathbb{T})$ and perform a wave-front update for each pair.

If the two faces F_P and F_Q of $\mathbb{T}$ assigned to $P[i:i']$ and $Q[j:j']$ are *not aligned* then we apply Lemma 12. The total time spent in this case equals:

$$\sum_{(P[i:i'],Q[j:j']) \text{ where } (F_P,F_Q) \text{ are not aligned}} O((i'-i+j'-j))\log(i'-i+j'-j)$$

By Equation 1, this sum is upper bound by $O((n+m)^{1.5}\log(n+m))$.

If the two faces F_P and F_Q of $\mathbb{T}$ assigned to $P[i:i']$ and $Q[j:j']$ are aligned then we apply Lemma 14 instead. The total time spent is:

$$\sum_{P[i:i'],Q[j:j']) \text{ where } (F_P,F_Q) \text{ are aligned}} O((i'-i+j'-j) + \text{switching cells}(M_\Delta[i:i', j:j']))$$

The first term and second term are bounded by $O((n+m)^{1.5}\log(n+m))$ by Equation 1 and Lemmas 14+15, respectively. Once the wave-front W reaches the entry (n,m), we have determined whether $\mathrm{D_T}(P,Q) \leq \Delta$, proving the theorem. ◀

5 The discrete Fréchet distance under the L_1 metric

We extend our techniques for paths in tilings to curves in the plane. Fix some universal constant $\gamma > 0$ and fix some value $\varepsilon \in (0,1)$. We consider $\mathbb{R}^2$ under the L_1 metric, and two polygonal curves P and Q with n and m vertices, respectively. In full generality, we only require that all edges in P have length at most γ and that Q is an (ε,δ)-curve. Denote their discrete Fréchet distance under the L_1 metric by $D_F(P,Q)$. We show that we can compute $D_F(P,Q)$ in $\tilde{O}\left(\frac{\sqrt{\delta}}{\varepsilon}(n+m)^{1.5}\right)$ time. We adapt this algorithm in the full version of this paper, to make it work for any L_c metric, by allowing some inaccuracy.

Our approach. Given some $\Delta \in \mathbb{R}$, we first show how to decide whether $D_F(P,Q) \leq \Delta$ using the wave-front propagation technique from Section 4, with suitable modifications for curves in the plane. Let $t > 1$ be a parameter to be determined later. We define an axis-aligned square tiling $\mathbb{T}$ of the plane where each square has edge length t.

▶ **Definition 16.** *We define the* breakpoints $B(P,\mathbb{T})$ *of P as the set of vertices $p \in V(P)$ such that some edge of P incident to p intersects an edge of $\mathbb{T}$.*

Note that $B(P,\mathbb{T})$ may contain overlapping but distinct vertices of P (since an (ε,δ)-curve may visit the same point up to δ times). If we remove all edges from P which intersect some edge of $\mathbb{T}$, we see that the breakpoints induce a partition of the vertices of P into pairwise vertex-disjoint subcurves $P[i:i']$, each fully contained in the closure $\overline{F}$ of a face $F \in \mathbb{T}$. We refer to these subcurves as the *induced subcurves* $S(P,\mathbb{T})$ and we assign each induced subcurve to a face in $\mathbb{T}$. We prove that for a suitable choice of $\mathbb{T}$, the total number of induced subcurves satisfies $|S(P,\mathbb{T}) \cup S(Q,\mathbb{T})| = O((n+m)/t)$.

We then apply our wave-front algorithm over the product set $S(P,\mathbb{T}) \times S(Q,\mathbb{T})$. For a pair of subcurves $(P[i:i'],Q[j:j'])$, let F_P and F_Q denote their respective containing faces in $\mathbb{T}$. We distinguish two cases:

- If F_P and F_Q are not aligned, we show that $(P[i:i'],Q[j:j'])$ is well-separated by a corner of either F_P or F_Q. We then apply Lemma 12 to perform a wave-front update in $O((i'-i+j'-j)\log(n+m))$ time.
- If F_P and F_Q are aligned, we apply the brute-force algorithm of Lemma 14, but with a more careful analysis of the number of switching cells.

Balancing the choice of t is critical: a larger t reduces the number of wave-front updates, while a smaller t reduces the number of switching cells encountered. We choose t to optimize the overall running time.

Choosing a tiling. We construct a tiling $\mathbb{T}$ such that it creates few induced subcurves.

▶ **Lemma 17.** *Given $t \geq 1$, we can compute in $O((n+m)t)$ time a square tiling $\mathbb{T}$ of edge length t such that the number of induced subcurves satisfies $|S(P,\mathbb{T}) \cup S(Q,\mathbb{T})| = O((n+m)/t)$.*

Proof. The proof mirrors that of Lemma 11. Let $\mathbb{T}_0$ be an axis-aligned square tiling with edge length t, and let $\mathbb{T}_i$ denote the tiling obtained by shifting $\mathbb{T}_0$ by (i,i) for $i \in [t-1]$. We required that each edge e of P or Q has length at most $\gamma \in O(1)$. Thus each edge intersects the boundary of at most $O(1)$ of the shifted tilings. It follows that there exists an index i such that $\mathbb{T}_i$ induces only $O((n+m)/t)$ breakpoints across P and Q.

To find $\mathbb{T}_i$, we iterate over all $O(n+m)$ edges of P and Q. For each edge, we test for intersection with each of the t candidate tilings in constant time. This gives an overall running time of $O((n+m)t)$ to find the tiling $\mathbb{T}_i$ that minimizes $|B(P,\mathbb{T}_i) \cup B(Q,\mathbb{T}_i)|$. ◀

Wave-front updates. Unlike in Section 4, the subcurves in $S(P,\mathbb{T})$ are vertex-disjoint. Thus, we never have a submatrix $M_\Delta[i:i', j:j']$ whose bottom-left facet coincides with the current wave-front W. However, we can always find a submatrix $M' := M_\Delta[i:i', j:j']$ where each of the cells on the bottom-left facet of M' is adjacent to a cell in W. We extend W to cover it in $O(i'-i+j'-j)$ time via brute force and thereby define wave-front updates analogously.

Case 1: Updating with $(P[i:i'], Q[j:j'])$ where F_P and F_Q are not aligned. Our key observation is that, even though the edges of $P[i:i']$ and $Q[j:j']$ do not coincide with $\mathbb{T}$, a pair of faces (F_P, F_Q) of $\mathbb{T}$ are still well-separated whenever they are not aligned:

▶ **Lemma 18.** *Let $P[i:i'] \in S(P,\mathbb{T})$ and $Q[j:j'] \in S(Q,\mathbb{T})$ be subcurves whose faces F_P and F_Q in $\mathbb{T}$ are not aligned. Then the corresponding wave-front update can be performed in $O(k \log k)$ time, where $k = |P[i:i']| + |Q[j:j']|$.*

Proof. Assume, without loss of generality, that the bottom-left corner of F_P lies above and to the right of the top-right corner of F_Q. Then any shortest L_1 path from a point in $\overline{F_P}$ to one in $\overline{F_Q}$ may be rerouted through that corner. The rest follows from Lemma 12. ◀

Case 2: Updating with $(P[i:i'], Q[j:j'])$ where F_P and F_Q are aligned. We upper bound the number of switching cells $M_\delta[i,j]$ where p_i and q_j lie in aligned faces of $\mathbb{T}$:

▶ **Lemma 19.** *Let $\mathbb{T}$ be the tiling from Lemma 17. Then there are at most $O(\frac{\delta n(t+1)}{\varepsilon^2})$ pairs (p_i, q_j) such that $M_\Delta[i,j]$ is a switching cell and p_i and q_j lie in aligned faces of $\mathbb{T}$. We can compute these pairs in $O(\frac{\delta n(t+1)}{\varepsilon^2} \log m)$ time.*

Proof. We preprocess Q by snapping its vertices to a square grid G of edge length ε^{-1}, forming Q'. Each vertex in Q' corresponds to $O(\delta)$ original vertices since Q is an (ε,δ)-curve. We store Q' in a spatial data structure (e.g., a lexicographically sorted balanced binary tree), where a query point z returns all $q_j \in Q$ corresponding to z in $O(\delta + \log n)$ time.

Recall that all edges of Q have length at most $\gamma \in O(1)$. Fix a vertex p_i and let F_p be a face of $\mathbb{T}$ that contains p_i. Let $B_i(\Delta)$ be the metric circle (under the L_1 metric) of radius Δ centred at p_i. Let Γ denote a ball with radius 2γ and $B_i^*(\Delta)$ be the metric annulus that is the Minkowski-sum $\Gamma \oplus B_i(\Delta)$. Observe that an edge (q_j, q_{j+1}) of Q intersects $B_i(\Delta)$ only if one of its corresponding vertices q'_j and q'_{j+1} of Q' lies in $B_i^*(\Delta)$.

There are $O(1)$ faces F' of $\mathbb{T}$ that are aligned with F_p and that intersect $B_i^*(\Delta)$. Let $A := B_i^*(\Delta) \cap F'$. Distinguishing between $\Delta > 1$ and $\Delta \leq 1$, we see that A has an area of $O(\max\{1,t\}\gamma)$ and therefore A contains at most $O(\frac{\gamma \max\{1,t\}}{\varepsilon^2}) = O(\frac{t+1}{\varepsilon^2})$ vertices of G. We iterate over the vertices in $B_i^*(\Delta) \cap \overline{F'} \cap V(G)$ and for each we perform a membership query on Q'. This returns $O(\frac{\delta(t+1)}{\varepsilon^2})$ vertices of Q'. For each reported vertex q'_j we test if $M_\Delta[i,j]$ is a switching cell in constant time. Thus, for any $p_i \in P$, we compute all switching cells $M_\Delta[i,j]$ that correspond to the lemma statement in $O(\frac{\delta(t+1)}{\varepsilon^2} \log m)$ time. ◀

▶ **Theorem 20.** *Let P and Q be two curves in $\mathbb{R}^2$ under the L_1 metric with $|P| = n$ and $|Q| = m$. Fix a universal constant $\gamma \in O(1)$. For $\varepsilon > 0$ (with $\varepsilon \in \omega(\sqrt{\frac{\delta}{n}})$) and $\Delta \in \mathbb{R}$, if P has edge length at most γ and Q is an (ε,δ)-curve, then we can compute whether $D_F(P,Q) \leq \Delta$ in $O(\frac{\sqrt{\delta}}{\varepsilon}(n+m)^{1.5} \log(n+m))$ time.*

Proof. Let $t \geq 1$ be a value that we set later. Given P and Q, we apply Lemma 17 to compute in $O((n+m)t)$ time our tiling $\mathbb{T}$ and the $O((n+m)/t)$ induced subcurves $S(P,\mathbb{T})$ and $S(Q,\mathbb{T})$. The product set $S(P,\mathbb{T}) \times S(Q,\mathbb{T})$ induces a grid over M_Δ with $O((n+m)/t)$ rows and columns. Thus:

$$\sum_{\text{submatrices } M' \text{ of } M_\Delta} |\text{facets}(M')| = \sum_{(P[i:i'],Q[j:j']) \in S(P,\mathbb{T}) \times S(Q,\mathbb{T})} (i'-i+j'-j) \qquad \in O((n+m)^2/t). \quad (2)$$

We iteratively perform wave-front updates with the input $(P[i:i'], Q[j:j'])$. Let F_P and F_Q denote the corresponding two faces of $\mathbb{T}$. If F_P and F_Q are *not aligned* then we apply Lemma 14. The total time spent in this case equals:

$$\sum_{(P[i:i'],Q[j:j']) \text{ where } (F_P,F_Q) \text{ are not aligned}} O((i'-i+j'-j)) \log(n+m)$$

By Equation 2, this sum is upper bound by $O(\frac{(n+m)^2}{t} \log(n+m))$.

If F_P and F_Q are aligned then we apply Lemma 15 instead. The total time spent is:

$$\sum_{P[i:i'],Q[j:j']) \text{ where } (F_P,F_Q) \text{ are aligned}} O((i'-i+j'-j) + \text{switching cells}(M_\Delta[i:i', j:j']))$$

The first term is upper bounded by $O(\frac{(n+m)^2}{t})$ by Equation 2. The second term is upper bounded by $O(\frac{\delta n(t+1)}{\varepsilon^2} \log m)$ by combining Lemma 14 and 19. It follows, assuming that $\frac{\varepsilon}{\sqrt{\delta}}\sqrt{n}$ goes to infinity, that if we choose $t \in \Theta(\frac{\varepsilon \cdot (n+m)}{\sqrt{\delta n}})$ the total running time is upper bounded by $O(\frac{\sqrt{\delta}}{\varepsilon}(n+m)^{1.5} \log(n+m))$. ◀

Computing $D_F(P,Q)$. Given P and Q, there is a set of $O(nm)$ values S, which can be computed in $O(nm)$ time, such that $D_F(P,Q) \in S$. The classical algorithm to compute $D_F(P,Q)$ performs binary search over S. Since we want to use subquadratic time, we cannot compute the set S explicitly. Instead, we represent S as the *Cartesian sum* $X \oplus Y$ of two sets of $O(n+m)$ values. The Cartesian sum of X and Y is the multiset $X \oplus Y = \{\{x+y \mid x \in X, y \in Y\}\}$. We can use existing techniques [21, 27] for selection in Cartesian sums to binary search over the Cartesian sum $X \oplus Y$ without explicitly computing its $O(|X| \cdot |Y|)$ elements.

Specifically, we define X and Y as follows. The set X contains, for each point $(x,y) \in P$, the four values $x+y$, $-x+y$, $x-y$ and $-x-y$. The set Y is defined analogously for points in Q. For all $(p,q) \in P \times Q$, the distance between p and q is the sum of an element in X and an element in Y. That is, their distance is an element of $X \oplus Y$. Hence, $D_F(P,Q) \in X \oplus Y$.

After sorting X and Y, we can compute the i^{th} smallest value in $X \oplus Y$, for any given i, in $O(|X|+|Y|) = O(n+m)$ time [21, 27]. We binary search over the integers $1, \ldots, |X| \cdot |Y|$, and for each considered integer i, we compute the i^{th} smallest value Δ in $X \oplus Y$. Then we use our decision algorithm (Theorem 20) to decide whether $D_F(P,Q) \leq \Delta$ to guide the search to $D_F(P,Q)$. Thus, we obtain the following result:

▶ **Corollary 21.** *Given $\gamma > 0$, let P and Q be curves in $\mathbb{R}^2$ under L_1 with $|P|+|Q| = n+m$. For any $\varepsilon > 0$, if P has edge length at most γ and Q is an (ε,δ)-curve, then $D_F(P,Q)$ can be computed in $O(\frac{\sqrt{\delta}}{\varepsilon}(n+m)^{1.5} \log^2(n+m))$ time.*

Abstract

Imprecise measurements of a point set $P = (p_1, \ldots, p_n)$ can be modelled by a family of regions $F = (R_1, \ldots, R_n)$, where each imprecise region $R_i \in F$ contains a unique point $p_i \in P$. A *retrieval* models an accurate measurement by replacing an imprecise region R_i with its corresponding point p_i.

We construct the convex hull of an imprecise point set in the plane, by determining the cyclic ordering of the convex hull vertices of P as efficiently as possible. Efficiency is interpreted in two ways: (i) minimising the number of retrievals, and (ii) the computation time to determine the set of regions that must be retrieved.

Previous works focused on only one of these two aspects: either minimising retrievals or optimising algorithmic runtime. Our contribution is the first to simultaneously achieve both. Let $r(F, P)$ denote the minimal number of retrievals required by any algorithm to determine the convex hull of P for a given instance (F, P). For a family F of n constant-complexity polygons, our main result is a reconstruction algorithm that performs $\Theta(r(F, P))$ retrievals in $O(r(F, P) \log^3 n)$ time.

Compared to previous approaches that achieve optimal retrieval counts, we improve the runtime per retrieval from polynomial to polylogarithmic. We extend the generality of previous results to simple k-gons, to pairwise disjoint disks with radii in $[1, k]$, and to unit disks where at most k disks overlap in a single point. Our runtime scales linearly with k.

1 Introduction

Imprecision is inherent in real-world data. It arises from rounding errors in floating-point computations, inaccuracies in measurement, and delayed sampling in GPS devices. In many scenarios, imprecise data can be refined at a cost by computing exact values or by taking additional samples. This is formalised in the model of *imprecise geometry* introduced by Held and Mitchell [13], and studied further in [8–10, 13, 17, 19, 25].

Imprecise geometry. An imprecise point set [13] is defined as a family of regions $F = (R_1, \ldots, R_n)$, where each region R_i contains a unique but unknown point p_i. A *realisation* $P \sim F$ is a sequence $P = (p_1, \ldots, p_n)$ where $p_i \in R_i$. An input instance is a pair (F, P). A *retrieval* operation reveals the precise location of a point p_i, replacing R_i with p_i.

Let $F \odot_P B$ denote the family F after retrieving all $R_i \in B$, where $B \subset F$. The aim of a *reconstruction algorithm* is to identify a subset $B \subset F$ such that for all realisations $P_1, P_2 \sim F \odot_P B$, the algorithm's output (e.g., the cyclic order of the region indices of the points around the convex hull) is identical for P_1 and P_2. Figure 1 illustrates an example. After retrieving the subset $B = \{R_3, R_4\}$, the cycling ordering of the convex hull vertices is identically (p_1, p_3, p_2, p_4) for all realisations of $F \odot_P B$.

We evaluate reconstruction algorithms by three criteria: the preprocessing time, the total number of retrievals, and the running time per retrieval. Next, we consider instance-optimal algorithms, which minimise the total number of retrievals in the strictest sense.

Worst-case results. Many geometric problems have been studied in imprecise geometry, including Delaunay triangulations [8, 13, 19, 25], convex hulls [9, 10], Gabriel graphs [19], and onion decompositions [17]. For these geometric problems, it is known that any reconstruction algorithm must, in the worst case, use $\Omega(n)$ retrievals. Most of the existing algorithms assume that the regions in F are pairwise disjoint unit disks [8, 9, 13, 17, 19, 25]. Under these assumptions, deterministic worst-case optimal algorithms exist with $O(n \log n)$ preprocessing time, $O(n)$ retrievals, and $O(n)$ reconstruction time. Ezra and Mulzer [10] allow F to consist of arbitrary lines and reconstruct the convex hull using $O(n)$ retrievals and $O(n \cdot \alpha(n))$ expected time where $\alpha(n)$ denotes the inverse Ackermann function. Buchin, Löffler, Morin and Mulzer [3] permit overlapping unit disks of *ply* k (i.e., at most k disks intersect each point in the plane). We summarize these results in the top three rows of Table 1.

Instance-optimality. In many instances, worst case bounds are overly pessimistic. Intuitively, an algorithm is instance-optimal if, for every input (F, P), no other algorithm performs better on that instance. Constructing instance-optimal algorithms is challenging, as they must match every alternative algorithm, including those tailored for specific instances.

Afshani, Barbay, and Chan [1] proved that, for many geometric problems including constructing the convex hull, instance-optimal reconstruction time is unachievable. Likewise, it is easy to see that instance-optimality in the number of retrievals cannot be guaranteed in general: E.g., let F consist of two overlapping intervals R_1 and R_2 in $\mathbb{R}$, with $R_1 \setminus R_2 \neq \emptyset$ and $R_2 \setminus R_1 \neq \emptyset$. Define P_1 with $p_1 \in R_1 \setminus R_2$ and $p_2 \in R_1 \cap R_2$, and P_2 with $p_1 \in R_1 \cap R_2$

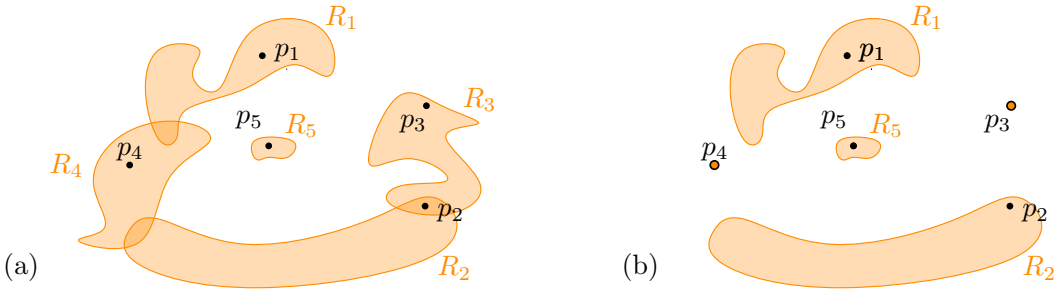

Figure 1 (a) A family of regions $F = R_1, \ldots, R_5$ and a sequence $P = (p_1, \ldots, p_5)$ with $P \sim F$. (b) If we retrieve R_3 and R_4 to obtain F' then for all $P' \sim F'$ the convex hull equals (p_1, p_3, p_2, p_4). Note that if p_3 would lie in $R_2 \cap R_3$ instead, then retrieving only R_3 and R_4 does not suffice.

and $p_2 \in R_2 \setminus R_1$. In (F, P_1), retrieving R_1 suffices; in (F, P_2), retrieving R_2 suffices. No algorithm can distinguish between the two instances without making a retrieval, and hence must use two retrievals on one of the instances. Since exact instance-optimality cannot be obtained, we instead aim for *asymptotic* instance-optimality.

Formally, we denote for any input instance by $r(F, P)$ the minimum integer such that there exists a subset $B \subset F$ of size $r(F, P)$ where all realizations $P' \sim (F \odot_P B)$ have the same vertex-ordering along the convex hull of P'. We note that $r(F, P)$ is, equivalently, the optimal number of retrievals. We say that an algorithm is *instance-optimal* if for all inputs (F, P) it uses $\Theta(r(F, P))$ retrievals. We highlight that $r(F, P)$ depends on both the region family F and the specific realisation P. To illustrate, suppose F consists of nested rectangles $R_n \subset R_{n-1} \subset \ldots \subset R_1$. If $P \sim F$ is such that the convex hull of (p_1, p_2, p_3, p_4) contains all of R_5, then retrieving just those four suffices: $r(F, P) = 4$. But if all p_i coincide then $r(F, P) = n$.

Prior instance-optimal work. Only a few instance-optimal reconstruction algorithms are known (see Table 1). Bruce, Hoffmann, Krizanc, and Raman [2] presented the first such algorithm for the convex hull. Their approach is computationally expensive, using an unspecified but superlinear time per retrieval (we discuss this in detail in the full version). Subsequent works show that polylogarithmic time per retrieval is achievable, albeit on geometric structures that are much simpler than the convex hull.

Van der Hoog, Kostitsyna, Löffler, and Speckmann [21] introduced the first near-linear instance-optimal algorithm, solving the sorting problem for one-dimensional intervals. Their algorithm preprocesses the intervals in $O(n \log n)$ time and uses $\Theta(r(F, P))$ retrievals, with at most logarithmic time per retrieval. Later, Van der Hoog, Kostitsyna, Löffler, and Speckmann [22] extended this approach to two-dimensional inputs for Pareto front reconstruction, under the assumption that F consists of pairwise disjoint axis-aligned rectangles. Their method also guarantees at most logarithmic time per retrieval.

Here, we show that polylogarithmic time per retrieval is achievable for reconstructing the convex hull with an instance-optimal number of retrievals. Moreover, our work generalises previous works in that we can handle overlapping regions in two dimensions, whereas previous works could only support one-dimensional inputs or disjoint two dimensional inputs.

Simultaneous work. Simultaneously and independently of this paper, Löffler and Raichel [18] developed an algorithm for reconstructing the convex hull when F is a set of unit disks of ply k. Their number of retrievals (Table 1) is not instance-optimal but rather worst-case optimal for every instance F. Formally, they use $O(w(F))$ retrievals for some region-dependent value $w(F)$ with $r(F, P) \leq w(F) \leq n$. We discuss their result in more detail in the full version.

Instance optimality in other fields. The study of instance-optimal algorithms extends beyond computational geometry. A prime example is sorting under partial information. Given a partial order O over a set X and an unknown linear extension L, the goal is to sort X using a minimum number of comparisons, where a comparison queries the order of a pair $(x, y) \in X$ under L. This is directly analogous to retrievals. Kahn and Saks [16] introduced an exponential-time algorithm that is instance-optimal in the number of comparisons. Since then, significant progress has been made on improving the runtime of such algorithms [5, 15], culminating in near-linear time algorithms that are instance-optimal in both runtime and comparisons [12,23,24]. Another example is the bidirectional shortest path problem. Haeupler, Hladík, Rozhoň, Tarjan, and Tětek [11] show an algorithm that finds the shortest path between two nodes s and t using an instance-optimal number of edge-weight comparisons.

Table 1 Previous results that compute a *sorting*, Pareto *front*, convex *hull*, or *Delaunay* triangulation. The bottommost result is simultaneous and independent work from ours.

Our contributions. We present the first algorithm for convex hull reconstruction that is instance-optimal while only requiring polylogarithmic time per retrieval. If F is a family of n constant-complexity simple polygons, we preprocess F in $O(n \log^3 n)$ time and reconstruct the convex hull of any $P \sim F$ using $\Theta(r(F,P))$ retrievals and $O(r(F,P) \log^3 n)$ total time. Our approach applies to simple k-gons with a linear factor in k in space and time, to pairwise disjoint disks with radii in $[1,k]$, and to unit disks of ply k (see Table 1). Compared to previous approaches for convex hulls that achieve optimal retrieval counts [2], we exponentially improve the runtime per retrieval from polynomial to polylogarithmic. Compared to near-linear time algorithms for convex hulls (or, Delaunay triangulations) [8–10, 13, 18, 19, 25], we significantly reduce the number of retrievals used and broaden the generality of input families. The latter comes at a cost of a polylogarithmic slowdown if $r(F,P)$ is linear in n.

Organisation. In Section 2, we provide some preliminaries. Then, in Section 3, we present our general algorithm for reconstructing the convex hull and prove its optimality (Theorem 18). In Section 4, we present a data structure for simple k-gons and give an instance-optimal algorithm that uses $O(kn)$ space and $O(r(F,P) \cdot k^2 \log^3(kn))$ time (Theorem 33). In the full version we improve the dependency on k to near-linear (Theorem 34). In the full version, we study pairwise disjoint disks with a radius in $[1,k]$, or, unit disks with ply k.

2 Preliminaries

Recall that an imprecise point set is defined as a family of geometric regions $F = (R_1, \ldots, R_n)$, and a realisation $P \sim F$ is defined as a sequence P of n points with $p_i \in R_i$. We explicitly allow for duplicate points in P and do not assume general position. The algorithm has two phases [13]: a *preprocessing phase*, where only F is available, and a *reconstruction phase*, in which we may perform a *retrieval* on any $R_i \in F$, replacing R_i with the point p_i. To maintain generality, we require only that each R_i is a point or a closed, connected, bounded region whose boundary is a simple closed piecewise-C^1 curve. Non-point regions must have connected interiors and coincide with the closure of their interiors; see Figure 2. Next, we define retrievals, convex hulls, vertices, edges, reconstruction strategies, and instance-optimality.

Retrievals. Given a family of regions F, a *retrieval* operation on a non-point region R_i replaces R_i with its associated point p_i (thereby updating F). We write $F \odot_P A$ for the family resulting from retrieving all regions in $A \subseteq F$. We denote by $F - A$ the family obtained by removing all regions in A from F. This removal is used in our analysis when we identify regions whose corresponding points cannot appear on the convex hull.

Critical assumptions. Since all regions in F are closed, we claim that we must assume P may contain duplicates and require that the convex hull of a point sequence includes all collinear and duplicate points. To illustrate, let F consist of n identical unit squares, and suppose $P \sim F$ includes four points forming the corners of one square. A lucky algorithm might retrieve these four points first and construct the convex hull [14]. If we assumed general position or excluded duplicates from the convex hull, this algorithm could then conclude that all remaining points cannot lie on the convex hull and terminate early. However, such behaviour cannot be guaranteed against an adversary. Since all regions are indistinguishable, an adversary may simply give these four points last. Alternatively, if F consisted of open regions, we could assume general position and exclude duplicates.

Upper quarter convex hull. We focus on the *upper quarter convex hull* of P. The other three quarters can be constructed analogously, and the full convex hull results from combining them. Let $\mathrm{CH}(P)$ denote the upper quarter convex hull: the boundary of the smallest convex set containing $P \cup \{(-\infty, -\infty), (+\infty, -\infty)\}$. We assume that $(R_{n+1}, R_{n+2}) = (\{(-\infty, -\infty)\}, \{(+\infty, -\infty)\})$, with corresponding points (p_{n+1}, p_{n+2}). These are always included in F and P. For any family of regions F, we denote by $\mathrm{OCH}(F)$ the *upper quarter outer convex hull*: the boundary of the smallest convex area enclosing all regions in F. Thus, $\mathrm{CH}(P)$ and $\mathrm{OCH}(F)$ represent convex hulls over point sequences and region families, respectively. As convex hulls define boundary curves, we may say that a point $p \in \mathbb{R}^2$ lies *on*, *inside*, or *outside* $\mathrm{CH}(P)$ or $\mathrm{OCH}(F)$.

Vertices and edges. We define convex hull vertices and edges of $\mathrm{OCH}(F)$. Although intuitive in simpler settings, these concepts require care due to the generality of F.

▶ **Definition 1.** *A point $p \in R$ is a* vertex *of a region R if p lies on the boundary of R and every open line segment through p contains a point not on the boundary of R. For any $R \in F$, $V(R)$ is the (infinite) set of vertices of R.*

Intuitively, the edges of $\mathrm{OCH}(F)$ connect successive vertices lying on its boundary. Due to potential overlaps between regions, vertices may coincide. As illustrated in Figure 2(c), a single edge may therefore be considered to connect different pairs of overlapping vertices. To avoid such degeneracy, we define $V(F) = \bigcup_{R \in F} V(R)$ as a set, and define edges robustly:

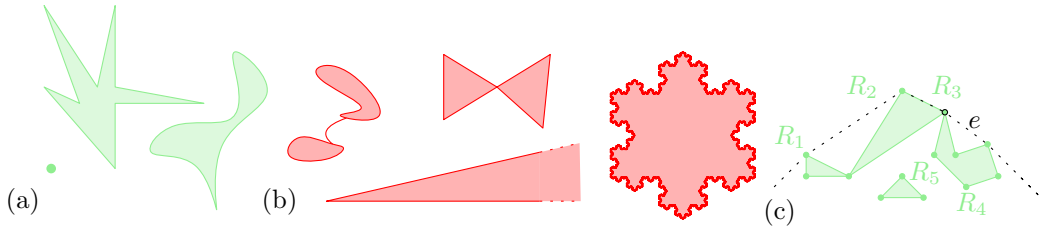

Figure 2 (a) Regions may have bends and sharp corners, and, be points. (b) Regions may not be unbounded, non-simple, connected by a line, or have infinitely many sharp corners. (c) Vertices between regions may coincide, and point regions (R_3) may coincide with vertices of other regions.

▶ **Definition 2.** *We define an* edge (s,t) *of* $\mathrm{OCH}(F)$ *to be a pair of distinct vertices in* $V(F)$ *where the subcurve of* $\mathrm{OCH}(F)$ *from* s *to* t *contains no vertices in* $V(F)$ *other than* s *and* t*.*

Note that a disk has infinitely many vertices but no edges under these definitions. We also define when a region appears on the outer convex hull:

▶ **Definition 3.** *We say a region* R appears on $\mathrm{OCH}(F)$ *if there is a point* p *on* $\mathrm{OCH}(F)$ *with* $p \in R$*. (Observe that we may always pick* p *to be a vertex of* R*.)*

Reconstruction algorithms. We will retrieve regions until all realisations $P' \sim F$ yield the same ordering of points along their convex hull. We formalise this via a partial order:

▶ **Definition 4.** *Given* $P \sim F$*, let* $\preceq(\mathrm{CH}(P))$ *be the partial order on* $[n]$ *induced by the left-to-right traversal of* $\mathrm{CH}(P)$*, i.e. for* $p_a, p_b \in P$*, we have* $a \prec b$ *if and only if* p_a *and* p_b *both lie on* $\mathrm{CH}(P)$ *and* p_a *lies strictly to the left of* p_b*.*

We say a family F is *finished* if all realisations $P_1, P_2 \sim F$ satisfy $\preceq(\mathrm{CH}(P_1)) = \preceq(\mathrm{CH}(P_2))$. A *reconstruction algorithm* retrieves some $B \subseteq F$ such that $F \odot_P B$ is finished. Let $r(F,P)$ denote the minimum number of retrievals needed by any such algorithm.

▶ **Observation 5.** *For any fixed* $P \sim F$*, let* $A \subset F$ *be a smallest subset of* F *such that* $F \odot_P A$ *is finished. Then* $|A|$ *is a tight lower bound for* $r(F,P)$*.*

A reconstruction algorithm is *instance-optimal* if for all inputs (F,P) it retrieves $\Theta(r(F,P))$ regions before F is finished. We distinguish two types of reconstruction algorithms:

- A *reconstruction strategy* is any such algorithm, analysed only by the number of retrievals.
- A *reconstruction program* is a reconstruction algorithm executed on a pointer machine or RAM, and is analysed by both retrievals and instructions.

The previous instance-optimal reconstruction strategy. Bruce, Hoffmann, Krizanc, and Raman [2] present an instance-optimal reconstruction strategy for region families F consisting of points and closed piecewise-C^1 regions. They do not present a corresponding reconstruction program. When F consists of disks or polygons, a reconstruction program may be derived, albeit with unspecified polynomial-time costs per retrieval. We further discuss their algorithm in the full version. We rely on a key concept of their paper, i.e. a witness.

▶ **Definition 6.** *Let* F *be a family of regions and let* $A \subseteq F$*. Any* $A \subset F$ *is a* witness *if for all* $P' \sim (F - A)$*, the family* $A \cup P'$ *is not finished.*

We observe that a reconstruction strategy is instance-optimal if, at each step, it retrieves all regions from a constant-size witness set of F.

2.1 Explicit dynamic planar convex hull

We rely on a data structure to maintain the upper quarter convex hull of a dynamic point set. Overmars and van Leeuwen [20] provide the best-known solution, achieving deterministic update time $O(\log^2 n)$. Their data structure, known as the *Partial Hull Tree* (PHT), is now textbook material. We follow their terminology:

▶ **Definition 7** (PHT from [20])**.** *Given a two-dimensional point set* S*, the* Partial Hull Tree *stores* S *in a leaf-based balanced binary tree* T *(sorted by* x*-coordinates). For each interior node* $\nu \in T$*, denote by* $\mathrm{CH}(\nu)$ *the (upper quarter) convex hull of all points in the leaves of the subtree rooted at* v*. For each* $\nu \in T$*, with children* (x,y) *and parent* w*, the PHT stores:*

- *The* bridge $e(\nu)$ *(the unique edge in* $\mathrm{CH}(\nu)$ *that is not in* $\mathrm{CH}(x)$ *and* $\mathrm{CH}(y)$*), and*
- *a* concatenable queue $\mathbb{E}^*(\nu)$ *(a balanced tree of the edges in* $CH(\nu) - CH(w)$*).*

We denote by $\mathbb{E}(\nu)$ *a balanced tree over* $CH(\nu)$ *and by* $V[\nu]$ *the vertices in the subtree of* ν*.*

Note that for the root ρ of T, $\mathbb{E}(\rho) = \mathbb{E}^*(\rho)$.

3 Witnesses and an instance-optimal reconstruction strategy

We introduce a new geometric classification over the edges of $\mathrm{OCH}(F)$. This leads to an alternative instance-optimal reconstruction strategy, detailed in Algorithm 1. Our results hold in full generality for any family F of points and closed regions whose boundaries are simple, closed, piecewise-C^1 curves. In particular, each region is connected and bounded, and any non-point region has a connected interior equal to its closure; see Figure 2. We define a classification over vertex pairs (s,t), which we apply to edges of $\mathrm{OCH}(F)$. However, we formulate the classification for arbitrary vertex pairs, as this generality will be useful for our data structures. We say that two regions $R_a, R_b \in F$ are *strictly vertically separated* if there exists a vertical line ℓ where R_a and R_b lie in opposite open half-planes defined by ℓ.

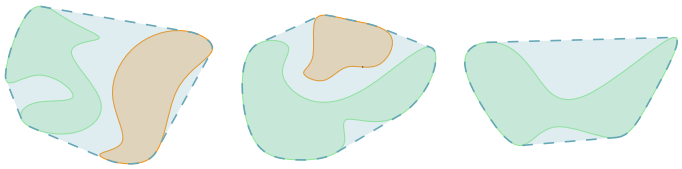

Figure 3 Three examples of a band (blue) between regions (green, brown).

▶ **Definition 8** (Band. Fig. 3)**.** *For any pair of regions* (R_a, R_b) *(where* $a = b$ *is allowed) we define* $\mathrm{band}(R_a, R_b)$ *as the area enclosed by the (full) outer convex hull of* $\{R_a, R_b\}$*.*

▶ **Definition 9** (Fig. 4)**.** *We say* $(s,t) \in V(R_a) \times V(R_b)$ *with* $s \neq t$ *and* $R_a, R_b \in F$*, is:*

- canonical *in* F *if the following holds for all* $x \in \{s,t\}$*. Either:*
  - x *is exclusively a vertex of point regions, or*
  - x *is a vertex of a unique region that is not a point region.*
- dividing *in* F *if* (s,t) *is canonical and either:*
  - $a = b$*, or*
  - R_a, R_b *are strictly vertically separated.*
- occupied *in* F *if* (s,t) *is dividing and:*
  - $\mathrm{band}(R_a, R_b)$ *contains a vertex in* $V(F - R_a - R_b) - \{s\} - \{t\}$*.*

In our reconstruction strategy, we retrieve regions until no non-canonical, non-dividing, or occupied edges remain. This alone does not guarantee that F is finished, so we introduce a final characterisation based on convex chains.

▶ **Definition 10** (Spanning chain. Fig. 5)**.** *A convex chain* $C = (q, r, \ldots, s, t)$ *is* spanning *in* F *if the following three conditions hold:*

- *all edges on* C *are dividing in* F*,*
- $q \in V(R_a)$*,* $r, s \in V(R_b)$*,* $t \in V(R_c)$ *where* R_b *intersects the inside of* $\mathrm{OCH}(\{R_a, R_c\})$*,*
- *all vertices of* C *between and including* r *and* s *are in* $V(R_b)$*.*

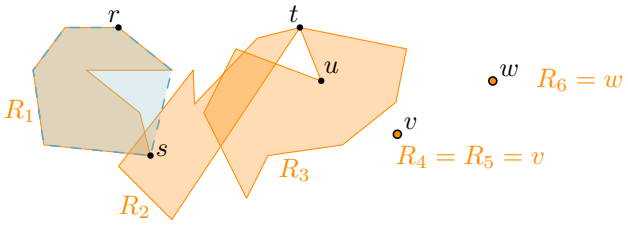

Figure 4 We illustrate all (sub) cases of vertex pairs corresponding to Definition 9:

- All pairs that include t are non-canonical, as t is a vertex of more than one non-point region.
- All pairs in $\{r, s, u, v, w\}^2$ are all canonical, as v is exclusively a vertex of two point regions.
- The pair (u, v) is non-dividing, as R_3 and R_4 are not vertically separated.
- The pairs (s, u), (r, u), (r, v), (s, v), and any pair in $\{r, s, u, v\} \times \{w\}$ are dividing because their regions are vertically separated. (r, s) is dividing because they are vertices of the same region.
- The pair (r, s) is not occupied since $\text{band}(R_1, R_1)$ only contains vertices of R_1. The pair (v, w) is not occupied since $\text{band}(R_4, R_6)$ only contains vertices v and w.
- The pair (u, w) is occupied as $V(F - R_3 - R_6)$ contains the vertex $t \in R_2$. The pairs (s, u), (r, u), (r, v), (s, v), (r, w), and (s, w) are also occupied.

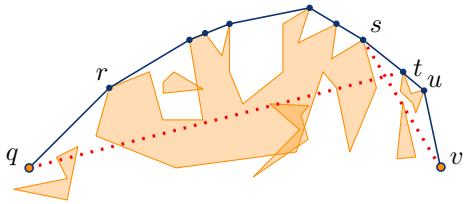

Figure 5 The convex chain from q to t is spanning. The chain from r to v is not spanning.

We use $\text{OCH}(\{R_a, R_c\})$ rather than $\text{band}(R_a, R_c)$ in Definition 10 to ensure meaningful behaviour even when R_a and R_c are point regions (since $\text{band}(R_a, R_c)$ would then be empty). Algorithm 1 processes edges of $\text{OCH}(F)$ by a priority based on Definitions 9 and 10:

$$\text{non-canonical} \gg \text{canonical but non-dividing} \gg \text{occupied} \gg \text{in spanning chain.}$$

In the following two subsections, we first show that each case in Algorithm 1 retrieves a witness. Then, we prove that if Algorithm 1 is instance-optimal.

3.1 Proving that Algorithm 1 retrieves only witnesses

The first case of Algorithm 1 considers a non-canonical edge, which implies that there is a point on $\text{OCH}(F)$ that lies in two regions that are not both point regions.

▶ **Lemma 11** (Proof in the full version). *Let $s \in \text{OCH}(F)$ be a point that lies in two regions R_a, R_b that are not both point regions. Then $\{R_a, R_b\}$ is a witness.*

The second case of Algorithm 1 considers an edge (s, t) of $\text{OCH}(F)$ that is canonical but not dividing in F. Let $s \in V(R_a)$ and $t \in V(R_b)$. Because (s, t) is canonical but not dividing it holds that $a \neq b$ and R_a and R_b are distinct regions that are not strictly vertically separated. The following lemma implies that $\{R_a, R_b\}$ is indeed a witness.

▶ **Lemma 12** (Proof omitted). *Let $R_a, R_b \in F$ with $R_a \neq R_b$ appear on $\text{OCH}(F)$. If R_a and R_b are not strictly vertically separated, then $\{R_a, R_b\}$ is a witness.*

Algorithm 1 A data structure friendly reconstruction strategy: Reconstruct(F).

if $\exists$ an edge (s,t) of OCH(F) that is non-canonical in F **then**
  Let $s \in V(R_a)$ and $s \in V(R_b)$ (or t) where R_a is not a point region
  Reconstruct($F \odot_P \{R_a, R_b\}$)
else if $\exists$ an edge (s,t) of OCH(F) that is canonical but not dividing in F **then**
  Let $s \in V(R_a)$ and $t \in V(R_b)$ for $a \neq b$
  Reconstruct($F \odot_P \{R_a, R_b\}$)
else if $\exists$ an edge (s,t) of OCH(F) that is occupied in F **then**
  Let $s \in V(R_a)$ and $t \in V(R_b)$ for $a \neq b$
  Let R_i with $R_i \neq R_a$ and $R_i \neq R_b$ be a region with $V(R_i) \cap \text{band}(R_a, R_b) \neq \emptyset$
  Reconstruct($F \odot_P \{R_a, R_b, R_i\}$)
else if $\exists$ a contiguous subchain $C = (q, r, \ldots, s, t)$ of OCH(F) spanning in F **then**
  Let R_a, R_b, R_c be as in the definition of spanning chains
  Reconstruct($F \odot_P \{R_a, R_b, R_c\}$)
else
  Return OCH(F)
end if

The third case of Algorithm 1 considers an occupied edge. The next lemma shows that any choice of region that has a vertex in the occupied band gives rise to a witness.

▶ **Lemma 13** (Proof omitted). *Let (s,t) be an edge of* OCH(F) *that is occupied in F. Let $s \in V(R_a)$ and $t \in V(R_b)$ for $a \neq b$. Let R_i be a region not equal to R_a or R_b with a vertex $q \in V(R_i) \cap \text{band}(R_a, R_b)$. Then $\{R_a, R_b, R_i\}$ is a witness.*

The final case of Algorithm 1 considers any remaining spanning subchains of OCH(F).

▶ **Lemma 14** (Proof omitted). *Let $(q, r, \ldots, s, t)$ be a contiguous subchain of* OCH(F) *that is spanning in F. Let R_a, R_b, R_c be as in Definition 10. Then $\{R_a, R_b, R_c\}$ is a witness.*

3.2 Proving that Algorithm 1 is instance-optimal

We now prove that Algorithm 1 is instance-optimal. That is, the algorithm retrieves the minimal number of regions (up to constant factors) necessary to determine the ordering of points on the convex hull, for any realisation $P \sim F$. We first observe that Algorithm 1 only terminates when F is *terminal*, meaning: every edge of OCH(F) is dividing, no edge of OCH(F) is occupied, and no contiguous subchain of OCH(F) is spanning.

For the remainder of this section, let A denote the multiset of regions that appear on OCH(F). If F is terminal, the regions in A satisfy the following structure:

▶ **Lemma 15.** *If F is terminal, then all regions in A are strictly vertically separated from each other, with the exception of pairs of regions that are duplicates of the same point.*

Proof. Walk along OCH(F) from left to right, considering edges (s,t) with $s \in R_a$, $t \in R_b$, $a \neq b$. As F is terminal, this edge is dividing, hence R_a lies strictly to the left of R_b. All previously encountered regions lie strictly left of R_a, hence also strictly to the left of R_b. Moreover, this edge is not occupied, so R_b is disjoint from all regions not equal to R_b. ◀

With Lemma 15, we define for each region R that appears on OCH(F) its left (or right) neighbour as the first region on OCH(F) that lies *strictly* left (or right) of R. Note that two duplicate point regions on OCH(F) have the same neighbours. Next, we show that the points corresponding to regions in A always appear on the convex hull (Lemma 16), and that no points corresponding to regions in $F - A$ appear on the convex hull (Lemma 17).

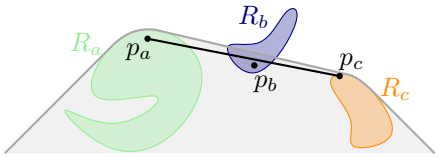

Figure 6 p_b must be above $p_a p_c$, as otherwise there is a spanning contiguous subchain of $\mathrm{OCH}(F)$.

▶ **Lemma 16.** *If F is terminal, then for any $P' \sim A$ each point in P' lies on* $\mathrm{CH}(P')$.

Proof. Let $P' \sim A$ and $R_b \in A - \{(-\infty,-\infty),(\infty,-\infty)\}$ be arbitrary. Let R_a and R_c be the left and right neighbour of R_b on $\mathrm{OCH}(F)$. Observe that these neighbours are well-defined as $(-\infty,-\infty)$ and $(\infty,-\infty)$ lie on $\mathrm{OCH}(F)$. Suppose by contradiction that p_b lies below the segment $p_a p_c$. Then R_b intersects the inside of $\mathrm{OCH}(\{R_a, R_c\})$, see Figure 6, so there is a contiguous subchain of $\mathrm{OCH}(F)$ that is spanning in F. This contradicts F being terminal. Since R_b was arbitrary, this shows that any three consecutive points in P' form a convex-down angle. Hence, P' spans a convex polygon, so all points in P' appear on $\mathrm{CH}(P')$. ◀

▶ **Lemma 17.** *If F is terminal, then for any $P \sim F$ only points of regions in A lie on* $\mathrm{CH}(P)$.

Proof. Let $P' \sim A$ be arbitrary. Suppose by contradiction that there is a region $R_i \in F - A$ with a point $p_i \in R_i$ on or outside of $\mathrm{CH}(P')$. Since the inside of $\mathrm{CH}(P')$ is convex, we may require p_i to be an extreme point of R_i, so $p_i \in V(R_i)$. By Lemma 15 and Lemma 16, there exist consecutive regions $R_a, R_b \in A$ for which p_i lies on or above $p_a p_b$. As $p_a p_b$ lies fully inside $\mathrm{band}(R_a, R_b)$, the point p_i lies in or directly above $\mathrm{band}(R_a, R_b)$. We make a case distinction, where p_i lies directly above R_b (or R_a), or, on the upper tangent of R_a, R_b.

Suppose first that p_i lies directly above a point $q \in R_b$. Let R_a, R_c be the left and right neighbour of R_b on $\mathrm{OCH}(F)$, respectively. Let r be the point on $\mathrm{OCH}(F)$ directly above p_i. Then $r \in \mathrm{band}(R_b, R_c)$ (or $r \in \mathrm{band}(R_a, R_b)$), hence also $p_i \in \mathrm{band}(R_b, R_c)$ as bands are convex and p_i lies on qr. Hence, F is not terminal. Similarly, p_i being directly above a point in R_a implies that F is not terminal. Furthermore, p_i cannot lie above the upper tangent of R_a, R_b since $R_i \notin A$. This shows that p_i does not lie above $\mathrm{band}(R_a, R_b)$, hence $p_i \in \mathrm{band}(R_a, R_b)$, so F is not terminal. ◀

▶ **Theorem 18.** *Algorithm 1 is an instance-optimal reconstruction strategy.*

Proof. First, we show that when Algorithm 1 terminates, the set F is finished. Let F be terminal. Let $A \subseteq F$ be the multiset of regions that appear on $\mathrm{OCH}(F)$. Let $P' \sim A$ and $Q' \sim F - A$ be arbitrary. By Lemma 17, no points in Q' are on $\mathrm{CH}(P' \cup Q')$. By Lemma 16, the points in P' all appear on $\mathrm{CH}(P' \cup Q')$. Moreover, together with Lemma 15, this implies that for all $P_1 \sim A$ and $P_2 \sim A$, $\preceq(\mathrm{CH}(P_1)) = \preceq(\mathrm{CH}(P_2))$. So, F is finished. Hence, Algorithm 1 is a correct reconstruction strategy.

We now show instance-optimality. By Lemmas 11, 12, 13 and 14, the algorithm retrieves a constant-size witness in each iteration. Let $X_1, \ldots, X_k$ be the sets of non-point regions of these witnesses. Since the witnesses have constant size, Algorithm 1 does $O(k)$ retrievals. A retrieval turns a region into a point region, hence the X_i are pairwise disjoint. On the other hand, if $(F \odot_P A)$ is finished for some $A \subseteq F$, then A needs to contain at least one element from each X_i (by the definition of witness). As the X_i are disjoint, this forces $|A| \geq k$. Hence, Algorithm 1 is instance optimal by Observation 5. ◀

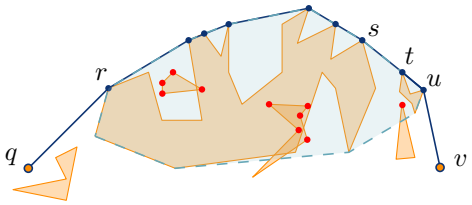

Figure 7 The convex chain from q to v is hit in F since (s,t) is occupied due to the red vertices.

4 Regions that are simple k-gons

We present a reconstruction program that executes our strategy from Algorithm 1 in polylogarithmic time per retrieval. To this end, we restrict F to a family of n (possibly overlapping) simple polygons, each with at most k vertices. Recall that $V(F) = (v_1, \ldots, v_m)$ denotes the set of all $m \in O(kn)$ *distinct* vertices in F. After each retrieval, we update F by replacing R_i with p_i, and update V by deleting $O(k)$ vertices from V and adding p_i to V.

▶ **Observation 19.** *For any family of regions F,* $\mathrm{OCH}(F)$ *has the same edges as* $\mathrm{CH}(V(F))$.

Consider a PHT T of $V(F)$ (Definition 7). After one retrieval, let T' be the updated PHT. We define the *recourse set* as the set symmetric difference of all bridges in T and all bridges in T'. *Recourse* is defined as the maximum size, across all possible retrievals, of any recourse set. A PHT has $O(\log m)$ recourse per update, and hence $O(k \log m)$ recourse per retrieval.

Augmenting the Partial Hull Tree. Within each leaf of T, corresponding to a vertex $v \in V(F)$, we maintain two doubly linked lists. The *point region list* stores all point regions that are v. The *non-point region list* stores the other regions $R \in F$ where $v \in V(R)$. Recall that Algorithm 1 retrieves regions corresponding to the endpoint of edges that are:

$$\text{non-canonical} \gg \text{canonical but non-dividing} \gg \text{occupied} \gg \text{in spanning chain.}$$

For every node $\nu \in T$ with bridge $e(\nu) = (s,t)$, we maintain pointers to the leaves containing s and t, along with Boolean flags indicating whether $e(\nu)$ is canonical or dividing. An update to F may make $O(n)$ edges occupied. So instead, we maintain a different property (Fig. 7):

▶ **Definition 20.** *A convex chain $C = (q, r, \ldots, s, t, \ldots, u, v)$ of vertices is* hit *in F if:*

- *all edges of C are dividing,*
- *the edge (s,t) is occupied in F,*
- *$s \in V(R_a), t \in V(R_b)$ and $a \neq b$, and*
- *$q \notin V(R_a)$, $r, \ldots, s \in V(R_a)$, $t, \ldots, u \in V(R_b)$ and $v \notin V(R_b)$.*

Recall Definition 7, where for $\nu \in T$, $\mathbb{E}(\nu)$ denotes a balanced binary tree on $\mathrm{CH}(\nu)$. The PHT stores in ν a *concatenable queue* $\mathbb{E}^*(\nu)$ which is $\mathbb{E}(\nu)$ minus all edges that are in $\mathbb{E}(w)$ where w is the parent of ν. We further augment the data structure by maintaining four balanced trees associated with $\mathbb{E}^*(\nu)$, where edges are ordered by their appearance in $\mathbb{E}^*(\nu)$:

1. a tree $\Lambda^*(\nu)$ storing all edges $(s,t) \in \mathbb{E}^*(\nu)$ that are non-canonical in F,
2. a tree storing all edges $(s,t) \in \mathbb{E}^*(\nu)$ that are canonical and non-dividing in F,
3. a tree storing all contiguous subchains of $\mathbb{E}^*(\nu)$ that are spanning in F,
4. a tree storing all contiguous subchains of $\mathbb{E}^*(\nu)$ that are hit in F.

We only give the first tree a name since all others are maintained in similar fashion. We denote by Λ_ν a balanced tree on all non-canonical edges in $\mathbb{E}(\nu)$.

▶ **Observation 21** (by Definition 9). *For any canonical bridge (s,t) in T, there exists a unique area $R(s)$ that contains s. $R(s)$ is either a point, or a unique region in F and can be found in $O(1)$ time by checking the regions lists stored at one of the leaves that (s,t) points to.*

We store for every region in F their maximum and minimum x-coordinate, this way we can test if a pair of regions is vertically separated in constant time.

Candidate chains. Our data structure maintains for each $\nu \in T$, a collection of special edges and special chains. We observe that these chains have a special structure:

▶ **Definition 22.** *Let $\nu \in T$ and consider $\mathbb{E}(\nu)$ (not $\mathbb{E}^*(\nu)$). Any contiguous subchain $C = (q, s, \ldots, r)$ of $\mathbb{E}(\nu)$ is a* candidate chain *if all edges of C are dividing in F and:*
- *$C = (q, s, r)$ with $q \in V(R_a)$, $s \in V(R_b)$, $r \in V(R_c)$, and $q, r \notin V(R_b)$, or,*
- *all interior vertices of C are in $V(R_b)$ and $q, r \notin V(R_b)$,*
  (note that this implies that all interior vertices are not in $V(R_x)$ for $x \neq b$).

▶ **Observation 23.** *Any subchain of $\mathbb{E}(\nu)$ that is* spanning *in F is also a candidate chain.*

▶ **Observation 24.** *Any subchain $(q, r, \ldots, s, t, \ldots, u, v)$ of $\mathbb{E}(\nu)$ is* hit *in ν only if $(q, r, \ldots, s, t)$ and $(s, t, \ldots, u, v)$ are candidate chains.*

▶ **Lemma 25.** *Let $\nu \in T$. There are at most two candidate chains that contain an edge (s,t) of $\mathbb{E}(\nu)$ and, given $\mathbb{E}(\nu)$ and our data structure, we can find these in $O(k)$ time.*

Proof. Suppose two candidate chains C and C' share (s,t). By the definition of candidate chains, (s,t) must be the final edge of C and the first edge of C'. First, identify the up to two length-3 chains in $\mathbb{E}(\nu)$ containing (s,t). Check each such chain in $O(1)$ time for the dividing property by consulting the Boolean flags. If all edges are dividing, we apply Observation 21 to test whether the chain satisfies the conditions of a candidate chain.

Next, consider candidate chains of length ≥ 4 in which (s,t) is an interior edge. Check, in $O(1)$ time via Observation 21, whether both s and t lie in a unique region R_b. If so, perform an in-order traversal of $\mathbb{E}(\nu)$ – moving up to $O(k)$ steps left from s and up to $O(k)$ steps right from t – to find the maximal contiguous chain with all edges dividing and interior vertices contained in $V(R_b)$. The chain ends when we encounter an edge whose endpoints do not lie entirely in $V(R_b)$. This identifies the unique candidate chain C of length ≥ 4 containing (s,t) as an interior edge. To find chains where (s,t) is the first or last edge, apply the above procedure to the edges immediately before and after (s,t). ◀

Update time. After each retrieval, we update bridges for all nodes along $O(k)$ root-to-leaf paths in T. For each bridge (s,t), we update its leaf pointers with constant overhead. Corollaries 27, 28, 30, and 32 show how to determine whether a bridge is canonical, dividing, part of a spanning chain, or part of a hit chain in F, respectively, in $O(k \log^2 m)$ time. Since the recourse per retrieval is $O(k \log m)$, this yields an overall update time of $O(k^2 \log^3 m)$.

▶ **Observation 26** (by Definition 9). *For any node $\nu \in T$, its bridge $e(\nu) = (s,t)$ is* canonical *in F if and only if both leaves containing s and t meet one of the following conditions:*
- *The non-point region list is empty, or,*
- *The point region list is empty and the region list contains exactly one region.*

▶ **Corollary 27.** *We can dynamically maintain, in $O(k \log^2 m)$ time, for each node $\nu \in T$ a balanced binary tree $\Lambda^*(\nu)$ of all edges $(s,t) \in \mathbb{E}^*(\nu)$ that are non-canonical in F.*

Proof. Test, using Observation 26, whether any bridge is canonical in constant time. Since the recourse is $O(k \log m)$, the set of all bridges can be updated without incurring asymptotic overhead.

To maintain $\Lambda^*(\nu)$ for each node $\nu \in T$, we follow the technique from [20] for concatenable queues. For any node ν with child x, compute $\Lambda(x)$ from $(\Lambda(\nu), e(\nu), \Lambda^*(x))$ in $O(\log m)$ time by splitting $\Lambda(\nu)$ at the bridge $e(\nu)$, and joining the result with $\Lambda^*(x)$. Traverse all $O(k)$ updated root-to-leaf paths, using the split operation, in $O(k \log^2 m)$ total time. Then, traverse the paths bottom-up. At each node ν with children x and y, we have access to the newly updated trees $\Lambda(x)$ and $\Lambda(y)$. Compute $(\Lambda(\nu), \Lambda^*(x), \Lambda^*(y))$ by splitting $\Lambda(x)$ and $\Lambda(y)$ at the endpoints of the new bridge $e(\nu)$ and joining the result. ◀

▶ **Corollary 28.** *We can dynamically maintain in $O(k \log^2 m)$ time for each node $\nu \in T$ a balanced binary tree on all edges $(s,t) \in \mathbb{E}^*(\nu)$ that are canonical but non-dividing in F.*

Proof. The set of bridges has $O(k \log m)$ recourse. Once a bridge is known to be canonical, we apply Observation 21 to determine the unique areas $R(s)$ and $R(t)$ containing s and t. We then test in constant time whether $R(s)$ and $R(t)$ are vertically separated, using stored x-coordinates. The tree is maintained using the same procedure as in Corollary 27. ◀

▶ **Lemma 29.** *For any $\nu \in T$, given $e(\nu) = (s,t)$ and $\mathbb{E}(\nu)$, we may find the at most two contiguous subchains C of $\mathbb{E}(\nu)$ with $s,t \in C$ that are spanning in F in $O(k \log m)$ time.*

Proof. Apply Lemma 25 to obtain all $O(1)$ candidate chains in $\mathbb{E}(\nu)$ containing (s,t). Let $C = (q, \ldots, r')$ be such a chain. To test whether C is spanning in F, use Observation 21 to find the unique regions $R(q)$, R_b, and $R(r')$. Construct $\mathrm{OCH}(R(q) \cup R(r'))$ in $O(k \log k)$ time and perform a convex hull intersection test with R_b in $O(\log m)$ time using the algorithm of Chazelle [6]. The chain is spanning if and only if this test returns true. ◀

▶ **Corollary 30.** *We can dynamically maintain in $O(k^2 \log^2 m)$ time for each node $\nu \in T$ a balanced binary tree of all subchains of $\mathbb{E}^*(\nu)$ that are spanning in F.*

Proof. Whenever the set of leaves of a node $\nu \in T$ changes (which occurs for $O(k \log m)$ nodes), invoke Lemma 29 on $e(\nu)$ to maintain all chains that are spanning in F (and contiguous subchains of $\mathrm{CH}(\nu)$ but not of $\mathrm{CH}(x)$ or $\mathrm{CH}(y)$). The balanced binary tree associated to $\mathbb{E}^*(\nu)$ can be maintained in an identical manner as previous corollaries. ◀

▶ **Lemma 31.** *For any node $\nu \in T$ and any edge $(x,y) \in \mathbb{E}(\nu)$, we can find all contiguous subchains of $\mathbb{E}(\nu)$ that contain (x,y) and are hit in F in $O(k \log^2 m)$ time.*

Proof. Apply Lemma 25 to find all candidate chains containing (x,y). Then, for each candidate chain, consider the adjacent edge and apply the lemma again to construct all possible hit chains. For each resulting subchain, test whether the middle edge $\mathrm{i}(s,t)$ is occupied as follows: Construct $\mathrm{band}(R(s), R(t))$ in $O(k \log k)$ time [7]. Temporarily remove $R(s)$ and $R(t)$ from F, and delete s and t from $V(F)$, in $O(k \log^2 m)$ time. Update the corresponding PHT T' without updating auxiliary data. The hull $\mathrm{CH}(V(F) \setminus \{s,t\})$ is stored at the root of T'. By intersection testing between $\mathrm{band}(R(s), R(t))$ and $\mathrm{CH}(T')$ in $O(\log m)$ time [6], we can test if any hit chain is occupied. ◀

▶ **Corollary 32.** *We can dynamically maintain in $O(k^2 \log^3 m)$ time for each node $\nu \in T$ a balanced binary tree of all subchains of $\mathbb{E}^*(\nu)$ that are hit in F.*

Proof. As with Corollary 30, we invoke Lemma 31 on $O(k \log m)$ nodes where the leaf set changes. For each, we update the associated trees using split and join operations. ◀

▶ **Theorem 33.** *Let F be a family of n simple polygons, where each region in F has at most k vertices. We can preprocess F using $O(kn)$ space and $O(k^2 n \log^3(kn))$ time, such that given $P \sim F$ we reconstruct* $\mathrm{CH}(P)$ *using $O(kn)$ space and $O(r(F,P)k^2 \log^3(kn))$ time.*

Proof. By Corollaries 27, 28, 30, and 32, we may maintain our augmented Partial Hull Tree in $O(k^2 \log^3(kn))$ time per retrieval. This data structure maintains at its root four balanced trees storing all: non-canonical edges, canonical but non-dividing edges; subchains of $\mathrm{OCH}(F)$ that are spanning in F, or hit in F. We observe that Algorithm 1 only considers occupied edges if all edges on $\mathrm{OCH}(F)$ are dividing. Then, any occupied edge corresponds to a hit subchain. Thus, we may immediately use these trees to execute Algorithm 1. This procedure performs $O(r(F,P))$ retrievals and so the theorem follows. ◀

In the full version, we note that our approach has two bottlenecks. First, the algorithm from Lemma 25 may "skip" over $O(k)$ edges to find the largest candidate chain. By applying a technique similar to skip-lists, we improve its running time by a factor k. Secondly, our approach frequently uses a subroutine where for any two regions $R(s)$ and $R(t)$ we construct $\mathrm{band}(R(s), R(t))$ in $O(k \log k)$ time. We show that by storing for each region R_i its convex hull, this construction time becomes polylogarithmic and we obtain the following:

▶ **Theorem 34.** *Let F be a family of n simple polygons where each region in F has at most k vertices. We can preprocess F using $O(kn \log n)$ space and $O(kn \log^3(kn))$ time, such that given $P \sim F$ we reconstruct* $\mathrm{CH}(P)$ *using $O(r(F,P) \cdot k \log^3(kn))$ time.*

Faster Dynamic 2-Edge Connectivity in Directed Graphs

Abstract

Let G be a directed graph with n vertices and m edges. We present a deterministic algorithm that maintains the 2-edge-connected components of G under a sequence of m edge insertions, with a total running time of $O(n^2 \log n)$. This significantly improves upon the previous best bound of $O(mn)$ for graphs that are not very sparse. After each insertion, our algorithm supports the following queries with asymptotically optimal efficiency:

- Test in constant time whether two query vertices v and w are 2-edge-connected in G.
- Report in $O(n)$ time all the 2-edge-connected components of G.

Our approach builds on the recent framework of Georgiadis, Italiano, and Kosinas [FOCS 2024] for computing the 3-edge-connected components of a directed graph in linear time, which leverages the minset-poset technique of Gabow [TALG 2016].

Additionally, we provide a deterministic decremental algorithm for maintaining 2-edge-connectivity in strongly connected directed graphs. Given a sequence of m edge deletions, our algorithm maintains the 2-edge-connected components in total time $n^{2+o(1)}$, while supporting the same queries as the incremental algorithm. This result assumes that the edges of a fixed spanning tree of G and of its reverse graph G^R are not deleted. Previously, the best known bound for the decremental problem was $O(mn \log n)$, obtained by a randomized algorithm without restrictions on the deletions.

In contrast to prior dynamic algorithms for 2-edge-connectivity in directed graphs, our method avoids the incremental computation of dominator trees, thereby circumventing the known conditional lower bound of $\Omega(mn)$.

1 Introduction

The design of dynamic graph algorithms is a classical area of research in theoretical computer science, where the input graph evolves through a sequence of updates, typically edge insertions and deletions. The goal of a dynamic algorithm is to update the solution to a problem more efficiently than recomputing it from scratch after each change. A problem is said to be *fully dynamic* if both insertions and deletions are allowed, and *partially dynamic* if only one type of update is permitted. The latter includes the *incremental* setting (only insertions) and the *decremental* setting (only deletions).

A fundamental problem in this domain is the computation and maintenance of edge-connected components in both undirected and directed graphs, driven by various practical and theoretical applications (see, e.g., [30]). Let $G = (V, E)$ be a strongly connected directed

graph (digraph) with n vertices and m edges. An edge $e \in E$ is called a *strong bridge* if its removal disconnects the graph, i.e., $G \setminus e$ is no longer strongly connected. More generally, a subset $C \subseteq E$ is a *cut* if its removal disconnects the graph. If $|C| = k$, we refer to C as a k-sized cut of G. A directed graph is said to be k-edge-connected if it contains no $(k-1)$-cuts. Two vertices v and w are k-edge-connected, denoted $v \leftrightarrow_k w$, if there exist k edge-disjoint directed paths from v to w and k edge-disjoint directed paths from w to v. (Note that paths from v to w and from w to v need not be edge-disjoint with each other.) By Menger's Theorem [27], this is equivalent to requiring that every set of fewer than k edge deletions preserves strong connectivity between v and w. A *k-edge-connected component* of G is a maximal subset of vertices $U \subseteq V$ such that $u \leftrightarrow_k v$ for all $u, v \in U$. These components form a partition of V, since $\leftrightarrow_k$ is an equivalence relation [14].

Connectivity problems are significantly more challenging in directed graphs than in undirected ones (see, e.g., [8, 18, 23]). Until recently, it was known how to compute the k-edge-connected components of undirected graphs in linear time only for $k \leq 5$ [7, 10, 12, 20, 25, 28, 29, 33, 38]. In a very recent breakthrough, Korhonen [24] presented an $k^{O(k^2)}m$ time algorithm for computing the k-edge connected components of an undirected graph, which yields linear-time algorithms for any fixed k. In contrast, for directed graphs, linear-time algorithms are only known for $k \leq 3$ [13, 16, 33].

Despite significant progress in fully dynamic algorithms for several fundamental connectivity problems in undirected graphs (see, e.g., [19, 21, 22, 31, 37]), their directed counterparts remain substantially harder [4]. This difficulty is further underscored by conditional lower bounds [1, 17]. In particular, Abboud and Vassilevska [1] showed that any fully dynamic algorithm for maintaining whether a directed graph has more than two strongly connected components (SCCs) must incur $\Omega(m^{1-\epsilon})$ update or query time (for any constant $\epsilon > 0$) unless the Strong Exponential Time Hypothesis (SETH) fails. Due to such hardness results, much of the research has focused on partially dynamic scenarios. For the problem of dynamically maintaining the SCCs of a digraph, years of effort culminated in the following breakthrough results. For the decremental setting, Bernstein, Probst, and Wulff-Nilsen [4] developed a randomized algorithm (against an oblivious adaptive adversary) with $O(m \log^4 n)$ total expected time, while very recently van den Brand et al. [39] gave a deterministic algorithm with $m^{1+o(1)}$ total update time. For the incremental problem, also very recently, Chen et al. [6] gave a deterministic algorithm with $m^{1+o(1)}$ total update time. We note that the algorithms of [6, 39] explicitly maintain the SCCs, while [4] only supports queries of whether two vertices are strongly connected.

In this paper, we revisit the dynamic maintenance of 2-edge-connected components in directed graphs, a problem first explored by Georgiadis, Italiano, and Parotsidis [15], who presented an incremental algorithm with total time $O(mn)$ and space $O(m+n)$. After each insertion, their algorithm supports the following queries in asymptotically optimal time:

- *query*(v, w): Test in $O(1)$ time whether two vertices v and w are 2-edge-connected.
- *report*$()$: Report all 2-edge-connected components in $O(n)$ time.

Moreover, when the answer to a *query*(v, w) is negative, their algorithm returns in constant time a "witness", i.e., a strong bridge that appears in all paths from v to w or in all paths from w to v.

The decremental version was studied in [11], where a randomized algorithm with total running time $O(mn \log n)$ and space $O(n^2 \log n)$ was presented.

Our results

We present new deterministic, incremental and decremental algorithms for maintaining the 2-edge-connected components of a directed graph that significantly improve upon the prior time bounds for graphs that are not very sparse.

▶ **Theorem 1.** *We can maintain the 2-edge-connected components of a digraph with n vertices through a sequence of edge insertions in $O(n^2 \log n)$ total time. After each insertion, we can test in $O(1)$ time whether two vertices are 2-edge-connected and report the components in $O(n)$ time.*

We also achieve nearly the same asymptotic bound in the decremental setting, under certain assumptions on the edges that may be deleted.

▶ **Theorem 2.** *We can maintain the 2-edge-connected components of a strongly connected digraph with n vertices through a sequence of edge deletions in $n^{2+o(1)}$ total time, provided that the edges of a fixed spanning tree of G and a fixed spanning tree of the reverse graph G^R are not deleted. After each deletion, we can test in $O(1)$ time whether two vertices are 2-edge-connected and report the components in $O(n)$ time.*

The bound stated in Theorem 2 assumes that we maintain SCCs decrementally using the algorithm of van den Brand et al. [39]. If instead we use the algorithm of Bernstein, Probst, and Wulff-Nilsen [4], we obtain a randomized $O(n^2 \log^4 n)$-time algorithm that supports constant-time *query*(v, w) queries, but does not support *report*().

Both our incremental and our decremental algorithms require $O(n^2)$ space. Our results build on the recent framework of Georgiadis, Italiano, and Kosinas [13], which computes the 3-edge-connected components of a digraph in linear time using Gabow's *minset-poset* technique [8] to represent all minimum edge-cuts of a digraph. From these results, it follows that the 2-edge-connected components of a digraph G can be identified as the strongly connected components of two specially constructed *labeling graphs*. Although these labeling graphs can have size $O(mn)$, we show how to maintain a compact representation of size $O(n^2)$ that can be efficiently updated in the dynamic setting.

Our techniques are fundamentally different from those of [11, 15]. The algorithm of [15] relies on maintaining dominator trees incrementally, while [11] maintains the SCCs of $G \setminus v$ for every vertex v, using n instances of a decremental SCCs algorithm [26]. This also supports decremental dominator tree maintenance in $O(mn \log n)$ time and $O(n^2 \log n)$ space. Importantly, [11] showed that maintaining dominator trees incrementally or decrementally in total time $O((mn)^{1-\epsilon})$ (for some constant $\epsilon > 0$) is not possible unless the OMv Conjecture [17] fails. This bound applies even to algorithms that do not explicitly maintain the dominator tree but can answer parent queries. Consequently, both [11] and [15] are subject to this hardness barrier, whereas our new algorithms are not. However, unlike [15], our algorithms do not provide a witness edge when the answer to a *query*(v, w) is negative.

2 Preliminaries and notation

We assume that the reader is familiar with standard graph terminology. All graphs in this paper are directed, i.e., an edge $e = (u, v)$ in digraph G is directed from u, the *tail* of e, to v, the *head* of e. Also, we allow G to have multiple edges between the same pair of vertices. To simplify our bounds, we will assume that G may have no more than two copies of each edge, so that the number of edges is $m = O(n^2)$. (Notice that adding more than two copies of the same edge (u, v) does not affect 2-edge-connectivity.) If C is a set of edges, then C^R denotes

the set of the reversed edges from C. We also let $G^R = (V, E^R)$ denote the reverse graph of $G = (V, E)$, i.e., the digraph that results from G after reversing the orientation of all edges. For a graph or a set of edges F, we use $V(F)$ to denote the set of the endpoints of the edges in F. If F consists of a single edge e, we may simply write $V(e)$ (which denotes the set of the endpoints of e). Also, for a graph F, we use $E(F)$ to denote the set of edges in F.

Let $G = (V, E)$ be a digraph. For any $S, T \subseteq V$, we denote the set of edges whose tail is in S and their head in T by $E(S, T) = \{(u, v) \mid (u, v) \in E, u \in S, v \in T\}$. We denote the set of outgoing edges from a set $S \subseteq V$ to the rest of the graph by $\delta(S) = E(S, V \setminus S)$, and the number of such edges by $out(S) = |\delta(S)|$. Similarly, we denote the set of incoming edges from the rest of the graph to S by $\rho(S) = E(V \setminus S, S)$ and the number of such edges by $in(S) = |\rho(S)|$. When S contains only a single vertex u, we slightly abuse notation and write $out(u), in(u)$ instead of $out(\{u\}), in(\{u\})$.

For a set of edges $E' \subseteq E$ and a set of vertices $S \subseteq V$, $\rho_{E'}(S)$ denotes the set of edges in E' that enter S from $V \setminus S$.

2.1 Flow graphs, dominators, and bridges

A *flow graph* is a directed graph with a distinguished *start vertex* s such that every vertex is reachable from s. Let $G = (V, E)$ be a strongly connected graph. Since G is strongly connected, all vertices are reachable from s and reach s, so we can view both G and G^R as flow graphs with start vertex s. To avoid ambiguities, throughout the paper, we will denote those flow graphs respectively by G_s and G_s^R. Let G_s be a flow graph with start vertex s. An edge (u, v) is a *bridge* of G_s if all paths from s to v include (u, v).[1] A vertex u is a *dominator* of a vertex v (u *dominates* v) if every path from s to v in G_s contains u. The dominator relation is reflexive and transitive. Its transitive reduction is a rooted tree, the *dominator tree* D: u dominates v if and only if u is an ancestor of v in D. The dominator tree and the bridges of a flow graph can be computed in linear time [2, 5].

2.2 Cuts

A cut is a partition of the vertices of a graph into two disjoint subsets S, T. A cut determines a cut-set $E(S, T)$, since the removal of these edges makes all vertices in T unreachable from vertices in S. We may use the term "cut" interchangeably to denote either the partition (S, T) or the set of edges $E(S, T)$. (The meaning will always be clear from the context.) We say that a cut (S, T) is a k-sized cut if $out(S) = in(T) = k$; then we say S is a k-out set and T is a k-in set. A cut (S, T) is trivial if $|S| = 1$ or $|T| = 1$. A cut C *separates vertex* s *from vertex* t if all paths from s to t contain an edge in C. We refer to such a cut C as an *s-t cut*. Any partition of the vertices into two sets S and $T = V \setminus S$, such that $s \in S$ and $t \in T$ naturally defines an s-t cut. We also refer to the partition (S, T) as an s-t cut of G. The size of this cut is equal to $|E(S, T)|$, i.e., the number of edges directed from S to T. An *s-t mincut* is a cut (S, T) of minimum size such that $s \in S$ and $t \in T$. Consider a flow graph G_s and a k-in set T such that $s \notin T$. We call T a k-sized s-cut of G. Then, all paths from s to T contain an edge in $\rho(T)$. Clearly, any cut of G is an s-cut of G_s or an s-cut of G_s^R, which allows us to focus only on the s-cuts of G.

[1] Throughout the paper, to avoid confusion, we use consistently the term *bridge* to refer to a bridge of a flow graph and the term *strong bridge* to refer to a strong bridge in the original graph.

2.3 Trees and fundamental cycles

Let T be a rooted tree. Throughout, we assume that the edges of T are directed away from the root. For each directed edge (u, v) in T, we say that u is a parent of v (and we denote it by $t(v)$) and that v is a child of u. Every vertex except the root has a unique parent. If there is a (directed) path from vertex v to vertex w in T, we say that v is an ancestor of w and that w is a descendant of v, and we denote this path by $T[v, w]$. If $v \neq w$, we say that v is a proper ancestor of w and that w is a proper descendant of v, and denote by $T(v, w]$ the path in T to w from the child of v that is an ancestor of w.

A spanning tree T of a flow graph G_s with start vertex s is rooted at s and contains a unique path from s to any other vertex. For an edge $e \notin T$, we let $T(e)$ denote the fundamental cycle of e in T, i.e., the cycle that is formed in T when we add edge e, ignoring edge directions. Let $e = (u, v) \notin T$, and let z be the nearest common ancestor of u and v in T. Then $T(e) \setminus e$ consists of two directed paths, one from z to u, and another from z to v. (One of these paths may consist of a single vertex.) For a set $S \subseteq V(S)$, we let $LCA(S)$ denote the lowest common ancestor in T of all vertices in S.

Let G_s be a flow graph and let T be a spanning tree of G_s rooted at s. We let $\mathcal{N}$ denote the set of *non-tree edges* of G_s, i.e., $\mathcal{N} = E(G_s) \setminus T$. For any vertex $v \in G_s$, we let $\rho_{\mathcal{N}}(v)$ denote the set of non-tree edges that are incoming to v.

2.4 Minimum 1-in sets

Let G_s be a strongly connected digraph with a fixed start vertex s. A set of vertices S is called a 1-in set if $s \notin S$ and $in(S) = |E(V \setminus S, S)| = 1$. For every vertex $v \neq s$ that is contained in a 1-in set, we let $M(v)$ denote the (inclusion-wise) minimum 1-in set that contains v. We call this the M-set of v. Note that $M(v)$ is well-defined due to the submodularity of cuts. Specifically, we have the following.

▶ **Lemma 3.** *Let S and S' be two 1-in sets that contain a vertex $v \neq s$. Then, $S \cap S'$ is also a 1-in set.*

Proof. We have that $S \cap S'$ and $S \cup S'$ contain v but not s. By the submodularity of cuts, we have:

$$in(S \cap S') + in(S \cup S') \leq in(S) + in(S') \tag{1}$$

Since S and S' are 1-in sets, the right hand side of (1) equals 2. Since $S \cap S'$ and $S \cup S'$ are cuts that separate v from s, we have $in(S \cap S') \geq 1$ and $in(S \cup S') \geq 1$. Now (1) implies that $in(S \cap S') = 1$. This shows that $S \cap S'$ is a 1-in set. ◀

If v is not contained in a 1-in set, then we let $M(v) = V(G)$. We use $M_R(v)$ to denote the M-set of v in G_s^R. The importance of considering the M-sets (in both G_s and G_s^R) is demonstrated in the following proposition.

▶ **Proposition 4** ([13]). *Let G be a strongly connected digraph with a fixed start vertex s. Then, for any two vertices u and v, we have $u \leftrightarrow_2 v$ if and only if $M(u) = M(v)$ and $M_R(u) = M_R(v)$.*

According to Proposition 4, in order to compute the 2-edge-connected components of G, it is sufficient to compute the M-sets in G_s and G_s^R. As in [13], our approach is to compute the partition of $V(G)$ into the sets of vertices that have same M-set in G_s, and the sets of vertices that have the same M-set in G_s^R. It follows by Gabow [8], that this partition (w.r.t.

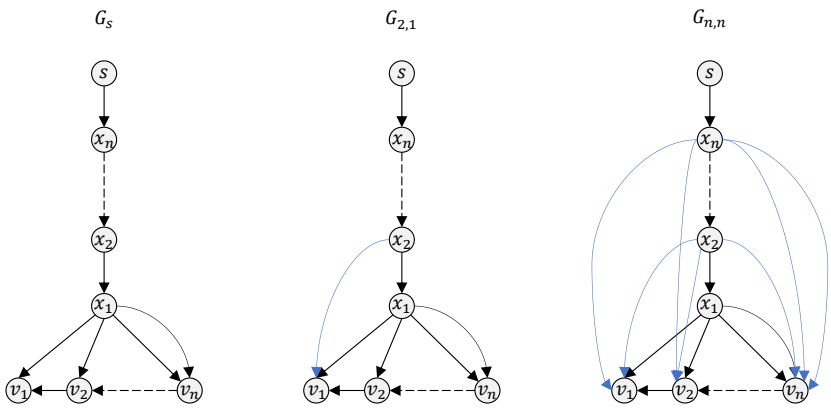

Figure 1 Example of flow graph and an insertion sequence that elicits $\Theta(n^2)$ changes of the $M(v_i)$ sets. Each graph $G_{k,l}$ is formed by adding the edges (x_i, v_j) for $1 \leq l \leq j$ and $2 \leq i \leq k$. Hence, $G_{k,l+1}$ results from $G_{k,l}$ after inserting the edge (x_k, v_{l+1}), and $G_{k+1,1}$ results from $G_{k,n}$ after inserting the edge (x_{k+1}, v_1). In G_s, we have $M(v_i) = \{x_1, v_i, v_{i+1}, \ldots, v_n\}$, for $1 \leq i \leq n$. In $G_{k,l}$, $M(v_i) = \{x_k, x_{k-1}, \ldots, x_1, v_i, v_{i+1}, \ldots, v_n\}$, for $1 \leq i \leq l$.

either G_s or G_s^R) corresponds to the strongly connected components of a *labeling graph* LG. So, our goal here is to show how to maintain this information efficiently in the incremental or decremental setting. Note that there are insertion sequences (or deletion sequences) that can cause $O(n^2)$ changes of the M-sets. See Figure 1.

First, we need to extend the definition of M-sets to edges of G_s as follows. Let e be an edge such that there is a 1-in set that contains both endpoints of e. Then $M(e)$ denotes the edge-set of the induced subgraph of the minimum 1-in set that contains both endpoints of e. To obtain the minimum 1-in set of each vertex v, [8] uses an augmented version of G_s, defined as follows. For every vertex $v \neq s$ of G_s, we introduce a new vertex v', two parallel edges of the form (v, v'), and two parallel edges of the form (v', v). Let us call $G_s^+ = (V, E)$ the resulting graph. Then, it follows that for every vertex $v \neq s$ of G_s, we have that $M(v)$ corresponds in a natural way to $M((v, v'))$ (in G_s^+).

Since, by Lemma 3, the $M(e)$ sets are closed under intersection, they admit a poset representation. For any edge $e \in E$, let $[e] = \{f : M(f) = M(e)\}$. We define the following relation on the edges of G_s: for $e, f \in E$, let $[e] \succ [f]$ if and only if $M(f) \subset M(e)$. Hence, $(\{[e]\}, \succ)$ forms a poset that represents all the minimum M-sets.

3 Computing minimum 1-in sets via Gabow's minset poset

Let $G = (V, E)$ be a strongly connected digraph, and let s be an arbitrary vertex of G. We view G as a flow graph with start vertex s. Recall that a 1-in set X is a set of vertices such that $X \subseteq V \setminus s$ and $in(X) = |E(V \setminus X, X)| = 1$. Consider the flow graph G_s, and let T be a spanning tree rooted at s. For simplicity, sometimes we slightly abuse notation and refer to T as the set of tree edges. For any set of vertices X, we denote by $T[X]$ the subgraph of T induced by X. We say that X is *cut* by T if $\rho(X) \subseteq T$ (that is, the only edges that enter X are tree edges of T), and X is *cospanned* by T if $T[X]$ is a tree. The next characterization follows from [8].

▶ **Lemma 5** ([8]). *Let G_s be a flow graph with start vertex s, and let T be a spanning tree of G_s. Any set of vertices $X \subseteq V \setminus s$ is a 1-in set of G_s if and only if it is cut and cospanned by T.*

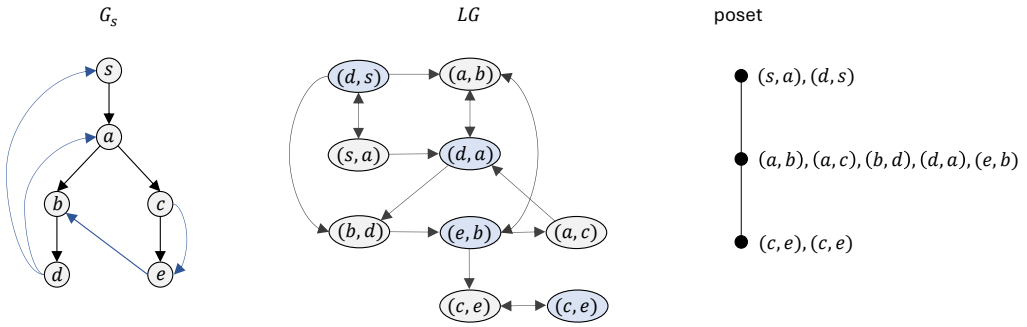

Figure 2 A strongly connected flow graph G_s, its corresponding labeling graph LG, and the minimum 1-in set poset. In G_s the tree edges are black and the non-tree edges are blue. In LG, the vertices that correspond to tree edges are gray and the vertices that correspond to non-tree edges are blue. We have $M((a,b)) = \{(a,b),(a,c),(b,d),(d,a),(e,b),(c,e),(c,e)\}$.

According to Lemma 5, if X is a 1-in set of G_s, then $T[X]$ is a tree with root r and the only edge entering X is the edge $(t(r), r) \in T$.

3.1 Labeling function and labeling graph LG

Gabow [8] defines a *labeling graph* LG with the property that the strongly connected components of LG correspond to the edges of G_s that have the same M-set. For any vertex $v \neq s$, there is at most one incoming edge to v that can be the incoming edge to $M(v)$, and the rest have the property that both of their endpoints also belong to $M(v)$. Thus, the idea is to assign a label to every edge e, which is essentially a set of pointers to edges that participate in the same M-set as e. Thus, the M-sets are given as the reachability sets of various edges with respect to this labeling. However, we cannot afford to explicitly compute the M-sets of all vertices, as their total size can be quadratic to $|V(G_s)|$.

In [8], the vertex set $V(LG)$ of LG consists of the edges of G, and the edges $(f,g) \in E(LG)$ are defined by a labeling function $\mathcal{L}_c : E \mapsto 2^E$. In our case, this labeling function becomes

$$\mathcal{L}_c(e) = \begin{cases} \rho_{\mathcal{N}}(u) \cup \rho_{\mathcal{N}}(v) & e = (u,v) \in T \\ T(e) & e \in \mathcal{N} \end{cases} \tag{2}$$

This function implies a labeling graph LG that has vertex set E (i.e., one vertex for each edge of G), and edges (e,f) where $e \in E$ and $f \in L(e)$. For $e, f \in E$, we say that f is a successor of e if there is a path from e to f in LG. The important property of the labeling graph LG is that the minimum set $M(e)$ of each edge e is equal to the set of all successors of e in LG [8]. This implies the following key proposition. (See Figure 2.)

▶ **Proposition 6** ([8, 13]). *Let G_s be a strongly connected flow graph with start vertex s, and let e and f be any two edges.*

(a) *If e is contained in a 1-in set, then $M(e) = M(f)$ if and only if e and f are strongly connected in LG.*

(b) *If e is not contained in a 1-in set, then e and f are strongly connected in LG if and only if f is also not contained in a 1-in set.*

By Proposition 6, we have that any two vertices v and w are 2-edge-connected if and only if (v,v') and (w,w') are strongly connected both in the labeling graph LG^+ of G_s^+ and in the labeling graph LG_R^+ of $(G_s^+)^R$.

Note that each tree edge $e = (v, w)$ has out-degree equal to $|\rho_{\mathcal{N}}(v)| + |\rho_{\mathcal{N}}(w)|$ in LG, while each non-tree edge f has out-degree equal to the number of tree edges in $T(f)$. Hence, LG has m vertices and $O(mn)$ edges. Nevertheless, Gabow [8] showed that the nodes $[e]$ of the corresponding poset $(\{[e]\}, \succ)$, which form a compact representation of these M-sets sufficient for our purposes, can be computed in $O(m)$ time by a clever implementation of an algorithm for computing the SCCs [7] of LG. (We remark that the node-finding algorithm of [8] does not compute the complete poset, which has $O(n)$ vertices and $O(n^2)$ edges.) The key idea is to use appropriate data structures, based on set merging [9], to avoid generating all edges of LG. This algorithm critically depends on a specific ordering of operations within the SCC algorithm, which makes it unsuitable for use in incremental or decremental settings.

4 Incremental algorithm

In this section, we present our incremental algorithm for maintaining the 2-edge-connected components of a digraph G. We consider, first, the case where G is strongly connected, and let T be a spanning tree of the corresponding flowgraph G_s, for an arbitrarily chosen start vertex s. Our algorithm operates on a modified labeling graph, denoted by $\widehat{LG}$, with the following properties: (i) $\widehat{LG}$ contains $O(n)$ vertices and $O(n^2)$ edges, (ii) the SCCs of $\widehat{LG}$ correspond to the poset nodes $[x]$ of the minimum 1-in sets of G_s, where $x \in V(G) \cup T$, and (iii) we can efficiently maintain $\widehat{LG}$ through a sequence of edge insertions.

4.1 Modified labeling graph

The modified labeling graph $\widehat{LG}$ is defined as follows. The vertex set of $\widehat{LG}$ consists of the tree edges of T and the vertices of G, i.e., $V(\widehat{LG}) = T \cup V(G)$. The edge set is defined by the following modified labeling function $\widehat{\mathcal{L}}_c : T \cup V(G) \mapsto 2^{T \cup V(G)}$:

$$\widehat{\mathcal{L}}_c(x) = \begin{cases} \{u, v\} & x = (u, v) \in T \\ \{e \in T : \exists f \in \rho_{\mathcal{N}}(v) \text{ such that } e \in T(f)\} & x = v \in V(G) \end{cases} \tag{3}$$

Hence, $(x, y) \in E(\widehat{LG})$ if and only if $y \in \widehat{\mathcal{L}}_c(x)$. Note that both LG and $\widehat{LG}$ are bipartite graphs, since any edge connects a tree edge $e \in T$ with a non-tree edge $f \in \mathcal{N}$ in the former, and a tree edge $e \in T$ with a vertex $v \in V(G)$ in the latter. While LG has m vertices and $O(mn)$ edges, $\widehat{LG}$ has $2n - 1$ vertices and $O(n^2)$ edges.

▶ **Lemma 7.** *For any two edges $f, g \in T$, g is reachable from f in LG if and only if g is reachable from f in $\widehat{LG}$.*

Proof. Suppose g is reachable from f in LG. Let P be a path from f to g in LG. Since LG is bipartite, the length of P is even. Consider two consecutive edges (x, y) and (y, z) on P, such that $x, z \in T$ and $y \in \mathcal{N}$. Also, let $x = (u, v)$. Then, by the definition of $\mathcal{L}_c$, $y \in \rho_{\mathcal{N}}(u) \cup \rho_{\mathcal{N}}(v)$, and $z \in T(y)$. Then, by the definition of $\widehat{\mathcal{L}}_c$, $\widehat{LG}$ contains (x, u) and (x, v), and either (u, z) or (v, z). In both cases, x reaches z in $\widehat{LG}$. Hence, it follows by induction on the length of P that if g is reachable from f in LG then g is also reachable from f in $\widehat{LG}$.

We show the contrapositive by similar arguments. Suppose g is reachable from f in $\widehat{LG}$. Let P be a path from f to g in $\widehat{LG}$. Since $\widehat{LG}$ is bipartite, the length of P is even. Consider two consecutive edges (x, y) and (y, z) on P, such that $x, z \in T$ and $y \in V(G)$. Also, let $x = (u, v)$. Then, by the definition of $\widehat{\mathcal{L}}_c$, $y \in \{u, v\}$, $z \in T(e)$ where $e \in \rho_{\mathcal{N}}(y)$. Then, by the definition of $\mathcal{L}_c$, LG contains the edges (x, e) and (e, z), and so x reaches z in LG. Hence, it follows by induction on the length of P that if g is reachable from f in $\widehat{LG}$ then g is also reachable from f in LG. ◀

An alternative but equivalent definition of $\widehat{LG}$ can be obtained by applying a sequence of vertex contractions to LG. Specifically, for each vertex $v \in V(G)$, we contract all non-tree edges in $\rho_{\mathcal{N}}(v)$ and subsequently eliminate any duplicate edges. While this may appear more intuitive, we adopt the original formulation as it enables the construction of $\widehat{LG}$ in $O(n^2)$ total time.

▶ **Corollary 8.** *For any two edges $f, g \in T$, $[f] = [g]$ if and only if f and g are strongly connected in $\widehat{LG}$.*

By Proposition 4 and Corollary 8, to determine whether two vertices u and v are 2-edge-connected in G, it suffices to check whether the edges (u, u') and (v, v') in the augmented graph G_s^+ are strongly connected in both the modified labeling graph of G_s^+ and that of its reverse $(G_s^+)^R$. The following lemma shows that, in fact, it is not necessary to work with the augmented graph explicitly.

▶ **Lemma 9.** *For any two vertices $u, v \in V(G)$, (v, v') is reachable from (u, u') in the modified labeling graph $\widehat{LG}^+$ of G_s^+ if and only if v is reachable from u in $\widehat{LG}$.*

Proof. Suppose $\widehat{LG}^+$ contains a path P from (u, u') to (v, v'). Since $\widehat{LG}^+$ is bipartite, and because the only non-tree edges entering (u, u') in G_s^+, except its copy (u, u'), are in $\rho_{\mathcal{N}}(u)$, the next vertex on P after (u, u') must be u. Consider now the penultimate vertex w on P. Then $w \in V(G)$, and from the definition of $\widehat{\mathcal{L}}_c$ (equation (3)), there is a non-tree edge $e \in \rho_{\mathcal{N}}(w)$ such that $(v, v') \in T(e)$. But this is possible only for $w = v$ and $e = (v', v)$. Hence, P contains a path from u to v, and so, $\widehat{LG}$ also contains a path from u to v.

Now suppose that $\widehat{LG}$ contains a path P from u to v. From the definition of $\widehat{\mathcal{L}}_c$ (equation (3)), $\widehat{LG}^+$ contains an edge from (u, u') to u. Also, since $(v', v) \in \rho_{\mathcal{N}}(v)$ and $(v, v') \in T((v', v))$, $\widehat{LG}^+$ also contains an edge from v to (v, v'). Hence, $\widehat{LG}^+$ contains a path from (u, u') to (v, v'). ◀

▶ **Corollary 10.** *Let G be a strongly connected digraph with a fixed start vertex s. Then, for any two vertices u and v, we have $u \leftrightarrow_2 v$ if and only if u and v are strongly connected in the modified labeling graph $\widehat{LG}$ of G_s and in the modified labeling graph $\widehat{LG}_R$ of G_s^R.*

4.2 Incremental construction of $\widehat{LG}$

Here we describe how to construct $\widehat{LG}$ incrementally as edges are added to a strongly connected graph G with a designated start vertex s. The labeling graph is defined with respect to a fixed spanning tree T of the flow graph G_s, rooted at s. (Similarly, we have a fixed spanning tree T_R of G_s^R, rooted at s, that defines the labeling graph of G_s^R.)

We initialize $\widehat{LG}$ by inserting a vertex for each $v \in V(G)$ and for each tree edge $e \in T$. Also, for each tree edge $e = (u, v)$, we add to $\widehat{LG}$ the edges (e, u) and (e, v).

Let v be a vertex of G, and let e be a tree edge of T. We say that e is *covered* by v if there is an edge $f \in \rho_{\mathcal{N}}(v)$ such that $e \in T(f)$, i.e., if $e \in \widehat{\mathcal{L}}_c(v)$. For each vertex $v \in V(G)$, we maintain the set of tree edges that are covered by v, using the following simple fact.

▶ **Lemma 11.** *Let v be a vertex such that $|\rho_{\mathcal{N}}(v)| \geq 1$, and let T_v be the set of tree edges that are covered by v. Then, T_v is a tree, rooted at the lowest common ancestor in T of all the vertices in $V(\rho_{\mathcal{N}}(v))$.*

Proof. Consider an edge $f \in \rho_{\mathcal{N}}(v)$. Then, v is contained in the fundamental cycle $T(f)$, so T_v is connected. Since $T_v \subseteq T$, T_v is a tree. Let $root_v$ be the root of T_v. If $\rho_{\mathcal{N}}(v)$ contains a single edge $e = (u, v)$, then T_v is rooted at $LCA(V(e))$. Now suppose $|\rho_{\mathcal{N}}(v)| > 1$. Let

$e = (u, v)$ and $e' = (w, v)$ be two edges in $\rho_{\mathcal{N}}(v)$. Let $z = LCA(u, v)$ and $z' = LCA(w, v)$. Since both z and z' are ancestors of v in T, we have $LCA(z, z') \in \{z, z'\}$. We conclude that $root_v = LCA(V(\rho_{\mathcal{N}}(v)))$. ◀

Lemma 11 allows us to use simple data structures to maintain T_v for each vertex v. Specifically, we do not maintain T_v explicitly, but keep a bit vector b_v, indexed by the vertices of $V(G)$ that indicates the vertices participating in T_v. Also, we store the current root of T_v. During the construction we maintain the following invariant (I): For any vertex u, we have $b_v[u] = 1$ if and only if $(t(u), u)$ is covered by v. Thus, $b_v[u] = 1$ if and only if $(t(u), u) \in \widehat{\mathcal{L}}_c(v)$, which means that $\widehat{LG}$ contains the edge $(v, (t(u), u))$. So, intuitively, we can view the bit vectors b_v as forming an adjacency matrix of the vertices $v \in V(G)$ in $\widehat{LG}$.

Initially, we set $b_v[u] = 0$, for all vertices $u \in V(G)$, and set $root_v = v$. (The root of T_v is the only vertex in T_v that is not marked in b_v.) Furthermore, we need to be able to test the ancestor-descendant relation in T. There are several simple $O(1)$-time tests of this relation [34]. The most convenient one for us is to number the vertices of T from 1 to n in preorder and compute the number of descendants of each vertex v. We denote these numbers by $pre(v)$ and $size(v)$, respectively. Then v is a descendant of u if and only if $pre(u) \leq pre(v) < pre(u) + size(u)$.

Suppose now that an edge $e = (u, v)$ is added into G. Then, since T is a spanning tree of G_s, e is a new non-tree edge in $\rho_{\mathcal{N}}(v)$. So, we need to find the tree edges $f \in T(e)$ such that $\widehat{LG}$ does not contain the edge (v, f). Equivalently, we need to find the vertices in $T(e)$ that are not already marked in b_v. Let x be the lowest common ancestor of u and v in T. (Note that we only use x for reference and do not need to find it explicitly.) To find the relevant unmarked vertices, we traverse the part of the cycle $T(e)$ from u to x as follows. Let $y = u$ be the current vertex. While y is not an ancestor of v, we check if $b_v[y] = 1$. If not, then we set $b_v[y] = 1$, add the edge from v to $(t(y), y)$ in $\widehat{LG}$, and set $y = t(y)$. Otherwise, we let $y = root_v$. This procedure stops as soon as y is an ancestor of v. At this point, if $b_v[y] = 0$, then we set $root_v = y$. We repeat the same procedure for $y = v$, where we stop when y becomes an ancestor of u.

▶ **Lemma 12.** *The above procedure correctly updates $\widehat{LG}$ in $O(n^2)$ total time for all edge insertions.*

Proof. It is easy to verify that the procedure maintains invariant (I) correctly, because of Lemma 11. Also, the algorithm inserts an edge (v, e) into $\widehat{LG}$ if and only if e is covered by v, which is in accordance to the labeling function $\widehat{\mathcal{L}}_c$. Now we bound the total running time for the construction of $\widehat{LG}$ after all insertions. The total running time is dominated by the time we need to locate tree edges that are just covered by each insertion. Let $e = (u, v)$ be a newly added edge to G. The above procedure visits at most two vertices that are already marked in b_v. For all other visited vertices u, we have $b_v[u] = 0$ before the visit and $b_v[u] = 1$ after the visit, excluding $root_v$, which also is visited at most twice per added edge. Hence, the total time throughout the whole sequence of insertions is bounded by $O(n^2)$. ◀

4.3 Incremental computation of the 2-edge-connected components

Let G be a strongly connected graph that undergoes edge insertions. We chose an arbitrary start vertex s, and compute a spanning trees T of G and a spanning T_R of G^R, rooted at s. We maintain two instances of the modified labeling graph of Section 4.1, $\widehat{LG}$ that represents the minimum 1-in sets of G, and $\widehat{LG}_R$ that represents the minimum 1-in sets of G^R, using

the two fixed spanning trees T and T_R. When an edge (u, v) is inserted into G, we execute the update operation of Section 4.2 for $\widehat{LG}$ and for $\widehat{LG}_R$. Note that for $\widehat{LG}_R$, we search for tree edges of T_R that are covered by u.

We maintain the SCCs of $\widehat{LG}$ and $\widehat{LG}_R$ incrementally, by running on each labeling graph the incremental SCCs algorithm of Bender et al. [3] for dense graphs. For a digraph with n vertices, the algorithm of [3] runs in $O(n^2 \log n)$ total time. The modified labeling graphs $\widehat{LG}$ and $\widehat{LG}_R$ have $O(n)$ vertices and $O(n^2)$ edges, since during their construction we never add duplicate edges. By Lemma 12, we can construct them incrementally in $O(n^2)$ time, and the total time for maintaining their SCCs is also $O(n^2 \log n)$.

We turn now to the query operations *query*(v, w) and *report*(). Each SCC of $\widehat{LG}$ (and similarly of $\widehat{LG}_R$) is represented by a canonical vertex, and the partition of the vertices into SCCs is maintained through a disjoint set union data (DSU) structure [36, 35]. The DSU data structure supports the operation *unite*(p, q), which, given canonical vertices p and q, merges the SCCs containing p and q into one new SCC and makes p the canonical vertex of the new SCC. It also supports the query *find*(v), which returns the canonical vertex of the SCC containing v. Since we aim at constant time queries, we use such a data structure that can support each *find* operation in worst-case $O(1)$ time and any sequence of *unite* operations in total time $O(n \log n)$ [36]. This way, we can identify the canonical vertex of the auxiliary component containing a query vertex in constant time. Hence, by Corollary 10, we can answer *query*(v, w) in G also in constant time, by testing if u and v are strongly connected in both $\widehat{LG}$ and $\widehat{LG}_R$.

To answer a *report*() query, we create, for each vertex $v \in V(G)$, a label *label*$(v) = \langle c_v, c_v^R, v \rangle$, where c_v and c_v^R are the canonical vertices in the SCCs of $\widehat{LG}$ and $\widehat{LG}_R$, respectively, that contain v. As above, each of these canonical vertices is available in $O(1)$ time. We form a list L consisting of *label*(v) for all $v \in V(G)$, and sort them lexicographically in $O(n)$ time using bucket sorting. Then, in the sorted list L, the vertices of the same 2-edge-connected component appear consecutively, since they have the same canonical vertices in their labels. Therefore, we can report the 2-edge-connected components of G in $O(n)$ time.

4.4 Extension to general digraphs

Now we extend our incremental algorithm to general (not strongly connected) digraphs. We note that Proposition 6 requires us to use labeling graphs that correspond to strongly connected flow graphs. To that end, we construct a two-level data structure, that uses various instances of the incremental SCCs algorithm of Bender et al. [3], as mentioned in Section 4.3.

Let G be the input digraph subject to edge insertions. The top level of our data structure, that we refer to as ISC(G), maintains the strongly connected components of G with the use of the incremental SCCs algorithm of [3]. More precisely, ISC(G) maintains the SCCs of G, represented with a DSU data structure, and the condensation of G, denoted by $\bar{G}$, which is the directed acyclic graph that results from G after we contract each SCC into its canonical vertex. We note that [3] also maintains a topological ordering of $\bar{G}$, and when a new SCC is formed, it removes loops and duplicate edges. The bottom level of our data structure maintains the information about the 1-in sets and 1-out sets within each SCC C of G, in a structure I2EC(C). Specifically, for each strongly connected component C of G, with a designated start vertex s, we store a spanning tree T of $G[C]$ and a spanning tree T_R of $G^R[C]$, rooted at s. Also, we maintain the data structures of Sections 4.2 and 4.3.

Now we describe how to handle an edge insertion. Suppose a new edge (x, y) is inserted into G. If x and y are located the same SCC C of G, then we execute the insertion procedure for I2EC(C), described in Sections 4.2 and 4.3. Otherwise, we execute the insertion in

the ISC(G) data structure. Note that this operation inserts the edge $(\mathit{find}(x), \mathit{find}(y))$ into the condensation $\bar{G}$ of G. If this insertion does not create a cycle in $\bar{G}$ then we are done. Otherwise, ISC(G) finds a new SCC of $\bar{G}$, corresponding to a new SCC of G, that is contracted into some canonical vertex. As a result, we need to update the bottom-level structure for the involved components of G.

Let C be the new SCC of G. The data structure ISC(G) identifies all components $C_1, C_2, \ldots, C_k$ of G that are merged into C after the insertion of (x, y), along with the edges $E(C_i, C_j)$ that connect distinct components. (Each such edge (u, v) satisfies $u \in C_i$, $v \in C_j$, where C_i precedes C_j in a topological ordering of the components.) Without loss of generality, assume that C_1 is the largest of these components. We choose the canonical (start) vertex s of C to be the start vertex of C_1. We refer to this component C_1 as the *principal component of* C. Also, we refer to the vertices of C_1 as the *principal vertices of* C. The remaining vertices in $C_2, \ldots, C_k$ are the *secondary vertices of* C.

Now we describe how to construct the data structure I2EC(C) for the new component C. We describe only the construction of the structures for $G[C]$. The structures for the reverse graph $G^R[C]$ are updated similarly. First, we extend the spanning tree T_1 of $G[C_1]$, which is rooted at s, to a spanning tree T of $G[C]$ rooted at s, so that $T_1 \subseteq T$. To achieve this, it suffices to traverse the edges $E(C_i, C_j)$ and the edges of the two spanning trees that we maintain for each component $C_2, \ldots, C_k$. This is enough to construct T, since the two spanning trees of each C_i form a sparse strongly connected subgraph of $G[C_i]$. (Note that we cannot afford to traverse all edges of $G[C_i]$.) Once T is constructed, we traverse it to recompute $\mathit{pre}(v)$ and $\mathit{size}(v)$ for all $v \in T$. This enables testing the ancestor-descendant relation in T in $O(1)$ time.

Next, we need to update the structures that keep track of the covered edges of T for each vertex $v \in C$. To initialize these structures for the new component C, we maintain the structures b_v and root_v, for all principal vertices v as they are. Then, we insert the nontree edges $e = (u, v)$ such that u is a secondary vertex in C. For each secondary vertex u, we compute b_u and root_u from scratch. Hence, in effect we construct I2EC(C) by inserting the secondary vertices and their adjacent edges in the data structure I2EC(C_1) of the principal component.

▶ **Lemma 13.** *The above procedure correctly updates* I2EC(C)*, for all SCCs C of G in $O(n^2 \log n)$ total time over all edge insertions.*

Proof. The correctness of the algorithm follows from Lemma 12, and the fact that the top structure ISC(G) maintains the SCCs of G. Next, we bound the total running time for any sequence of edge insertions.

First, we bound the total running time required to update the spanning tree T of $G[C]$, for each SCC formed in G. Let C be a new SCC of G that is formed by merging the components $C_1, \ldots, C_k$, where C_1 is the principal component. Let n_i be the number of vertices in each component C_i, and let $m_{ij} = |E(C_i, C_j)|$ be the number of edges connecting C_i and C_j. Then, the construction of T takes time proportional to $\sum_{i=1}^{k} n_i + \sum_{1 \le i,j \le k} m_{ij} = n_C + \sum_{1 \le i,j \le k} m_{ij}$, where $n_C = \sum_{i=1}^{k} n_i$ is the number of vertices in the new component C. Note that the second term, i.e., the sum $\sum_{1 \le i,j \le k} m_{ij}$ is charged only once during the construction of all spanning trees. Hence, the overall construction time for all spanning trees is $O(n^2 + m) = O(n^2)$.

Next, we consider the time required to maintain the data structures for the tree edges covered by each vertex $v \in V(G)$. Note that for as long as v is a principal vertex in a component C, the total time spent to process the edges in $\rho_{\mathcal{N}}(v)$ and update b_v and root_v is $O(n_C)$. Next, we consider the contribution of each vertex as a secondary vertex. Every time

we merge a sequence of secondary components $C_2, \ldots, C_k$ with a principal component C_1, we charge $O(n_C)$ time to each secondary vertex v, since we recompute b_v and $root_v$ from scratch. Let $C_v^1, \ldots, C_v^\xi$ be the sequence of SCCs that contain v as a secondary vertex. Let n_v^i be the number of vertices in C_v^i just before it gets merged into a larger component. Then, $n_v^i \leq n_v^{i+1}/2$, for $1 \leq i < \xi$, and $n_v^\xi \leq n$. The time required to maintain the data structures for the tree edges covered by v in C_v^i is proportional to n_v^i. Hence, the total time for the whole sequence of components $C_v^1, \ldots, C_v^\xi$ is bounded by $\sum_{i=1}^{\xi} n_v^i \leq \sum_{i=0}^{\log n} n/2^i < 2n$. This gives an $O(n^2)$ total bound for all vertices.

Finally, we consider the total time required to maintain the incremental SCCs data structures. Such a structure for the subgraph induced by a component C with n_C vertices requires $O(n_C^2 \log n_C)$ total time. We distribute this cost to the n_C vertices of the component, so each vertex is charged a cost of $O(n_C \log n_C)$. Hence, for as long as a vertex v is a principal vertex in its component C, it is charged a cost of $O(n_C \log n_C)$, where n_C is the number of vertices in C just before it is merged as a secondary component. If this never happens, then n_C is the final number of vertices in C. It remains to bound the contribution of v as a secondary vertex, which we can do as above. Let $C_v^1, \ldots, C_v^\xi$ be the sequence of SCCs that contain v as a secondary vertex, where each C_v^i has n_v^i vertices just before it gets merged into a larger component. As before, $n_v^i \leq n_v^{i+1}/2$, for $1 \leq i < \xi$, and $n_v^\xi \leq n$. Then, the cost charged to v for the whole sequence of components $C_v^1, \ldots, C_v^\xi$ is bounded by $\sum_{i=1}^{\xi} n_v^i \log n_v^i \leq \log n \sum_{i=0}^{\log n} n/2^i < 2n \log n$. This gives an $O(n^2 \log n)$ total bound for all vertices. ◀

5 Decremental algorithm

In this section, we present our decremental algorithm for maintaining the 2-edge-connected components of a digraph G. We can assume that G is strongly connected, as otherwise we can process each SCC separately. Let s be an arbitrarily chosen start vertex of G. Let T be a fixed spanning tree of flow graph G_s, and let T_R be a fixed spanning tree of flow graph G_s^R. (Both T and T_R are rooted at s.) The algorithm operates on the assumption that the edges of T and T_R are never deleted throughout the deletion sequence.

We describe how to efficiently update the edges of the modified labeling graph $\widehat{LG}$ of Section 4.1, as we delete edges in G. To achieve this, we need to maintain some additional information about the tree edges that are covered by each vertex $v \in V(G)$.

For a tree edge $e \in T$, we define $cover_v(e)$ to be the number of edges $f \in \rho_{\mathcal{N}}(v)$ that cover e, i.e., such that $e \in T(f)$. Then $(v, e) \in E(\widehat{LG})$ if and only if $cover_v(e) > 0$. Our approach is to maintain the $cover_v(e)$ values using a dynamic tree data structure [32]. This way, we can update $\widehat{LG}$ efficiently, and maintain its SCCs decrementally using the algorithm of [39].

A *dynamic tree* $\mathcal{T}$ is a data structure that efficiently maintains a collection of rooted trees, whose edges have real-valued costs, under dynamic operations such as linking and cutting edges, while supporting cost updates and queries on paths and subtrees. For our purposes, we will assume that each such data structure maintains a single tree that corresponds to the spanning tree T of G_s with root s. Recall that for any vertex $v \neq s$, $t(v)$ denotes the parent of v in T. Here, we also let $T[v, w]$ denote the tree path between two vertices v and w, ignoring edge directions.

We will use the following dynamic tree operations, which are supported in $O(\log n)$ time.

- *cost*(v): If $v \neq s$, then return the cost of the edge $(t(v), v)$.
- *update*(v, w, x): Add x to the cost of all edges on the tree path $T[v, w]$.
- *mincost*(v, w): Return a vertex $u \in T[v, w]$ such that the edge $(t(u), u)$ has minimum cost among the edges on the tree path $T[v, w]$.

We note that the original description of Sleator and Tarjan [32] has the operation $update(v, x)$, which adds the value x to the cost of the edges on the path from v to the root of $\mathcal{T}$, and the operation $mincost(v)$, which returns an edge of minimum cost on the path from v to the root of $\mathcal{T}$. We can implement our versions of *update* and *mincost*, by using the operation $evert(v)$ of [32], which makes v the root of $\mathcal{T}$, as follows. To implement $update(v, w, x)$, we do $evert(w)$, $update(v, x)$, and $evert(s)$. Similarly, to implement $mincost(v, w)$ we do $evert(w)$, $mincost(v)$, and $evert(s)$.

To initialize $\widehat{LG}$, we compute a spanning tree T of G rooted at s, and insert the edges of $\widehat{LG}$ as in Section 4.2. We also compute the $pre(v)$ and $size(v)$ values for all $v \in T$, so that we can test the ancestor-descendant relation in T in $O(1)$ time. Then, for each vertex $v \in V(G)$, we maintain a dynamic tree data structure $\mathcal{T}_v$, which implements the operations *update* and *mincost* on T, where each tree edge $e \in T$ has cost $cover_v(e)$. Initially, all edge costs in $\mathcal{T}_v$ are zero. Then, we process each edge $(u, v) \in \rho_{\mathcal{N}}(v)$, and execute $update(v, u, +1)$.

During the execution of the deletion sequence, we do the following. Let $e = (u, v)$ be the next edge of G to be deleted. By our assumption, $e \in \rho_{\mathcal{N}}(v)$, and we need to find the tree edges $f \in T(e)$ that are covered only by e. For each such tree edge f, we delete the corresponding edge (v, f) from $\widehat{LG}$.

To find these edges $f \in T(e)$, first we execute $update(v, u, -1)$. Then, we recursively search a tree path $T[x, y]$ for uncovered edges (that is, tree edges $f \in T[x, y]$ with $cover_v(f) = 0$), where initially $x = u$ and $y = v$, as follows. We compute $w = mincost(x, y)$, and check if $cost(w) \neq 0$. If this is the case, then all the edges on $T[x, y]$ are still covered by v, and we are done. Otherwise, we delete the edge $(v, (t(w), w))$ from $\widehat{LG}$, and repeat recursively this step for the two paths of $T[x, y] \setminus (t(w), w)$.

In more detail, if w is an ancestor of x, then we recursively search for uncovered edges on $T[x, w]$ and on $T[y, t(w)]$. Otherwise, if w is an ancestor of y, then we recursively search for uncovered edges on $T[y, w]$ and on $T[x, t(w)]$. Hence, we obtain the following bound.

▶ **Lemma 14.** *We can maintain the modified label graph $\widehat{LG}$ under a sequence of edge deletions of G in $O(n^2 \log n)$ total time.*

Proof. Consider the deletion of an edge $e \in \rho_{\mathcal{N}}(v)$. The above procedure finds a tree edge $f \in T(e)$ that becomes uncovered by v using a constant number of dynamic tree operations. For each edge f with $cover_v(f) = 0$, we delete the corresponding edge (v, f) in $\widehat{LG}$. Since $\widehat{LG}$ has $O(n^2)$ edges, and each dynamic tree operation takes $O(\log n)$ time, the bound follows. ◀

From Lemma 14 and the fact that we use the decremental algorithm of [39] to maintain the SCCs of $\widehat{LG}$, we obtain Theorem 2.

Online Makespan Scheduling Under Scenarios

Ekin Ergen
Technical University of Berlin, Germany

Abstract

We consider a natural extension of online makespan scheduling on identical parallel machines by introducing scenarios. A scenario is a subset of jobs, and the task of our problem is to find a global assignment of the jobs to machines so that the maximum makespan under a scenario, i.e., the maximum makespan of any schedule restricted to a scenario, is minimized.

For varying values of the number of scenarios and machines, we explore the competitiveness of online algorithms. We prove tight and near-tight bounds, several of which are achieved through novel constructions. In particular, we leverage the interplay between the unit processing time case of our problem and the hypergraph coloring problem both ways: We use hypergraph coloring techniques to steer an adversarial family of instances proving lower bounds for our problem, which in turn leads to lower bounds for several variants of online hypergraph coloring.

1 Introduction

We study a natural extension of *online makespan scheduling*, also known as *online load balancing*, one of the most well-known problems in the scope of online optimization. In online makespan scheduling, we know a number m of identical parallel machines in advance, in addition to which jobs j are revealed one at a time along with their processing times $p_j \geq 0$. Our task is to assign the jobs to a machine as soon as they are revealed, solely under the knowledge of the preceding jobs, so as to minimize the *makespan*, i.e., the maximum sum of processing times any machine is assigned to. This problem was initially studied by Graham almost 60 years ago, who proved that assigning every job to a currently least loaded machine is a $(2-\frac{1}{m})$-competitive algorithm [13]. It was observed that no better deterministic algorithm can exist for $m \in \{2,3\}$ [13, 9], while for larger values of m, such a tight ratio is still not known.

We extend online makespan scheduling by a *scenario-based model*: We are given a number m of machines. There is a known number K of job sets (called *scenarios*) $S_k \subseteq \{1,\dots,n\}$, $k \in [K]$, over a common ground set $\{1,\dots,n\}$. Although the number of scenarios is known, neither the number of jobs nor their processing times p_j ($j \in [n]$) are known in advance. The ground set $[n]$ is revealed in increasing order of jobs; more precisely, we are incrementally informed of $p_1,\dots,p_j$ as well as $S_k \cap \{1,\dots,j\}$ for increasing j. The task is to find a global assignment $\tau\colon \{1,\dots,n\} \to \{1,\dots,m\}$ of the jobs to machines that delivers a reasonable solution restricted to every scenario. To be more precise, the objective is to minimize the

© Ekin Ergen;
licensed under Creative Commons License CC-BY 4.0

makespan of the *worst-case scenario*, i.e., the scenario that yields the highest makespan. As in the classical online scheduling problem, a job j must be assigned irrevocably to a machine $\tau(j)$ as soon as it is revealed. In essence, we are solving a finite number of instances of Online Makespan Scheduling over the same ground set of jobs simultaneously.

The simplicity of the scenario model offers a variety of interpretations and applications. For instance, we can view the scenarios as distinct services that are provided in m (number of machines) sites to n (number of jobs) customers, where the customers are revealed one by one with their desired services and need to be assigned to one of the sites immediately. Another interpretation of our problem may concern a fair balancing of goods according to multiple agents in the following setting: Each of the K agents are interested in partitioning a subset S_k, $k \in \{1, \dots, K\}$ of n goods with weights p_j among m buckets, where the partition should be as balanced for all agents as possible (i.e., we would like to minimize the maximum bucket load for any agent). Here, the goods are revealed one by one together with the agents that are interested in them.

Moreover, even special cases of online makespan scheduling under scenarios correspond to interesting questions in their own regard. The special case $p_j \equiv 1$ of unit processing times is related to some cases of discrepancy minimization as well as hypergraph coloring.

In the large array of previous research on combinatorial optimization under scenarios, it was shown for several offline problems that optimizing under a number of scenarios is computationally harder than their underlying single-scenario counterparts. Accordingly, our goal in this work is to gain a better understanding of the intersection of scenario-based models and competitiveness, in particular how competitiveness diminishes under a growing number of scenarios.

1.1 Our Contribution

Implementing a miscellany of ideas to analyze competitiveness bounds for the varying numbers m of machines and K of scenarios, we achieve several tight bounds and further nontrivial bounds. An overview of our results, depending on the numbers m and K, can be seen in Table 1. Several of the entries are obtained via a generalization of Graham's List Scheduling Algorithm which we extend using the pigeonhole principle.

By a simple example, one can show that for any number $m \geq 2$ of machines and (at least) 3 scenarios, no algorithm with a competitive ratio better than 2 can exist, even for jobs with unit processing times. To underline the competitiveness gap between two and three scenarios, we contrast the aforementioned result with an algorithm for two machines and two scenarios, which is one of our main results.

▶ **Theorem 1.** *There exists a* $5/3$*-competitive algorithm for* Online Makespan Scheduling under Scenarios *for* $m = K = 2$.

This algorithm as well as its analysis combine techniques well-known from algorithms for online makespan scheduling with novel ideas that concern the scenario-based properties of a schedule. We first alter the definition of competitive ratio by allowing only specific lower bounds for an offlie optimum, which allows us to make structural modifications and restrictions on *worst-case* instances. What sets our analysis apart from previous work is that we alternate between forward and reverse engineering: Assuming that our algorithm obeys some fixed rules, we explore what we may assume about a well-structured worst-case instance. In spite of seemingly strong restrictions that we impose, the ratio of our algorithm is not far from the best achievable bound by any deterministic algorithm, which we show is at least $\frac{9+\sqrt{17}}{8} \approx 1.640$. Altogether, we obtain a near-complete picture of competitiveness for $m = 2$.

The remainder of the paper demonstrates a disparity between increasing the number m of machines and increasing the number K of scenarios. For a fixed but arbitrary m, we show that there exists a sufficiently large number $K(m)$ of scenarios and a family of instances with $K(m)$ scenarios, on which no deterministic online algorithm can achieve a ratio better than m. Furthermore, we can even choose all instances to have unit processing times $p_j \equiv 1$. This result is particularly noteworthy, considering that any online algorithm on m machines is trivially m-competitive: Indeed, the online output is at most the total load and an offline optimum is at least the average load, and these are by at most a factor of m apart.

To find the suitable number $K(m)$, we interpret the instances as hypergraphs, passing to a problem we call Online Makespan Hypergraph Coloring(m) instead (cf. Section 1.2). Strikingly, such a family can be created using hypertrees on which no deterministic algorithm can achieve a coloring without a monochromatic edge simultaneously.

▶ **Theorem 2.** *Let $m \in \mathbb{N}$. There exists a number $K(m)$ such that for any $r < m$, no deterministic algorithm for Online Makespan Hypergraph Coloring(m) is r-competitive, even when restricted to hypertrees with $K(m)$ hyperedges.*

The statement of Theorem 2 is best possible in the sense that the numbers $K(m)$ cannot be replaced by a global K for which the incompetitiveness holds for all m (cf. Theorem 5).

The proof of Theorem 2 can be found in the full version of the paper. To showcase some of our techniques, we sketch a proof for a similar statement for $K = 3$ in Section 4. We utilize a subhypergraph on 7 nodes as a gadget and obtain a relatively compact construction, both in terms of the hypergraph and the case distinction that we apply to analyze it.

An advantage of our approach while proving Theorem 2 is that it only features hyperforests. More precisely, we implicitly show that for every $m \in \mathbb{N}$, there is a number $n \leq (2m+1) \uparrow\uparrow 5$ of nodes[1] such that no deterministic online algorithm on n nodes that uses m colors can avoid a monochromatic hyperedge. In other words, in order to color a hyperforest with an arbitrary number n of nodes online without monochromatic edges, we need $\Omega(\text{slog}_5 n)$ colors, even if the restrictions $e \cap \{1, \dots, j\}$ of hyperedges e to revealed nodes are known upon the revelation of nodes $\{1, \dots, j\}$. Here, the emphasis is on the additional knowledge of partial hyperedges: This makes an adversarial revelation of hyperedges more challenging and to the best of our knowledge, none of the previous lower bound constructions [15, 14] are applicable under such additional information. This result addresses a completely open problem from [15] and sets a non-constant lower bound for Online Hypergraph Coloring for hypertrees under the knowledge of partial hyperedges.

▶ **Corollary 3.** *Let $n \in \mathbb{N}$. There exists no $o(\text{slog}_5 n)$-competitive deterministic algorithm for Online Hypergraph Coloring with nodes $v_1, \dots, v_n$ (revealed in this order) even if we restrict to hypertrees and additionally, the subsets $e \cap \{v_1, \dots, v_j\}$ of hyperedges $e \in E$ are known upon the assignment of node v_j.*

For unit processing times, $K = 3$ and varying m, we further propose a 2-competitive algorithm, which is best possible due to the lower bounds mentioned earlier. Although the special case of unit processing times is admittedly a restriction, the result still illustrates a contrast with the tight lower bound of m for a varying number of scenarios, which also holds already for instances with unit processing times.

[1] $F(x) \coloneqq x \uparrow\uparrow 5 \coloneqq x^{x^{x^{x^x}}}$ and $\text{slog}_5(x) \coloneqq F^{-1}(x)$.

Table 1 Overview of the competitive ratios obtained by our results. Recall that on m machines, any algorithm is trivially m-competitive.

m ↓ K →	2	3	4+
2	> 1.640, $\leq 5/3$	$= 2$	$= 2$
3	≤ 2	≥ 2, $= 2$ for $p_j \equiv 1$	≥ 2 $= 3$ for $K \geq 233$ and $p_j \equiv 1$
4+	≥ 3	≥ 2, < 4 $= 2$ for $p_j \equiv 1$	≥ 2, $< K+1$ $= m$ for K sufficiently large and $p_j \equiv 1$

1.2 Preliminaries

Throughout this paper, for $n \in \mathbb{N}$, we denote by $[n] \coloneqq \{1, \ldots, n\}$ the set of numbers 1 through n. An instance $I = (n, (p_j)_{j\in[n]}, \{S_k\}_{k\in[K]})$ of Online Makespan Scheduling under Scenarios(m, K) (OMSS(m, K)) is parametrized by a number $m \in \mathbb{N}$ of machines and a number $K \in \mathbb{N}$ of scenarios, and defined as a tuple consisting of a number $n \in \mathbb{N}$ of jobs, a processing time $p_j \geq 0$ for each job j and job subsets $S_1, \ldots, S_K \subseteq [n]$, called *scenarios*. As we usually work with a single instance at a time, we often suppress this notation in the sequel as well as the parameters m and K, which are often specified per section.

For a set $S \subseteq [n]$, we denote $p(S) \coloneqq \sum_{j\in S} p_j$. Our objective is to find a partitioning $J_1 \dot\cup \ldots \dot\cup J_m$ of the set of jobs that minimizes $\max_{k\in[K]} \max_{i\in[m]} p(J_i \cap S_k)$. In other words, we consider schedules that arise from restricting a partition to each of the scenarios, and our goal is then to minimize the makespan of the worst-case scenario, which we also call the *makespan of the schedule*. Furthermore, our instance is *online* in the sense that parameters m (number of machines) and K (the number of scenarios) are known in advance, but jobs $j \in [n]$ as well as their processing times p_j and the indices $k \in [K]$ such that $j \in S_k$ are revealed one job j at a time. Once the information of a job j is revealed in addition to already known information about the jobs in $[j-1]$, the job j must be assigned to a machine $i \in [m]$, which is an irrevocable decision.

In our analyses and arguments, we use the notion of a *completion time* of a job j. In classical scheduling, this is defined as the sum of processing times preceding (including) j that are on the same machine as j. In our setting, the restricted schedules are evaluated without idle times, meaning that such completion times might be different for different scenarios. Accordingly, we define the *completion time of job $j \in J_i \cap S_k$ in scenario S_k* as $C_j^k \coloneqq \sum_{j'\in J_i\cap S_k\cap[j]} p_{j'}$ and the *completion time* as $C_j \coloneqq \max_{k\in[K], j\in S_k} C_j^k$.

Online algorithms are often analyzed by their performance compared to the best possible outcome under full information. In existing literature, this comparison is quantified by the *competitive ratio*. An algorithm is said to have competitive ratio ρ if for every instance, it is guaranteed to output a solution that has an objective value which deviates from the value of an optimal solution under full information by at most a factor of ρ.

We also consider the special case of unit processing times $p_j \equiv 1$. In this special case, we may view our jobs as nodes, our scenarios as hyperedges containing a subset of the nodes and the partition $J_1 \dot\cup \ldots \dot\cup J_m$ as a coloring $c\colon [n] \to [m]$ of the nodes. Then, our problem can be formulated as an online hypergraph coloring problem, in which we color a hypergraph $H = (V, E)$ with a fixed number of colors $1, \ldots, m$ and seek to minimize $\max_{i\in[m], e\in E} |\{c^{-1}(i)\} \cap e|$. The nodes $j \in [n]$ are revealed one at a time in increasing order along with partial hyperedges $e \cap [j]$ $(e \in E, j \in [n])$.[2] We shall name this problem Online Makespan Hypergraph Coloring(m) (OMHC(m)) and address it in Section 4.

[2] According to this definition, hyperedges can have size 1, although such hyperedges can and will be omitted as they pose no difference with respect to the objective function.

1.3 Related Work

The problem that we introduce in this paper lies in the intersection of several well-known problems, which we would like to mention briefly.

Optimization under Scenarios. In recent years, scenario-based models have received significant attention. An instance of a scenario model over a discrete optimization problem is often given as an instance of the underlying problem; and in addition, subsets of the underlying instance (called *scenarios*) are specified. The objective function involves the objective values that are attained restricted to each scenario; e.g., the maximum of these values over scenarios or their average.

Although a significant portion of the literature is rather recent, some well-known problems have been scenario-based problems in disguise. For instance, the famous exact matching problem ([16]), which asks whether a given graph whose edges are colored blue or red has a perfect matching with exactly k blue edges for a given k, is equivalent to the matching problem under two scenarios, whereas a stochastic scenario-based model for matchings has recently been studied in [4]. Other examples include bin packing ([7, 5]), metric spanning tree ([3]) and the traveling salesperson problem ([24]).

Among the scenario-based problems with the widest array of studies is machine scheduling with its many variations, see [21] for an extensive overview. The closest to our problem is [10], in which the worst-case makespan is being minimized for parallel machine scheduling on two machines and a variable number of scenarios. Although an instance under a variable number of scenarios is not approximable with a ratio better than the trivial bound of 2, a constant number of scenarios allows a PTAS.

In some variants of scenario scheduling, e.g., in [6], a complexity gap is observed between two and three scenarios. Interestingly, we obtain a distinction between two and three scenarios as well, at least when we restrict to the special case of two machines.

Online Scheduling. As it is impossible to capture the vast amount of literature on all online scheduling problems, let us restrict to online parallel machine scheduling with the objective of minimizing the makespan. This is precisely the special case $K = 1$ of our problem.

The problem was first addressed in Graham's seminal work [13] from which we also draw inspiration in multiple ways. The competitive ratio of $2 - 1/m$ for m machines was not beaten for three decades, until it was improved slightly in [12]. Graham's List Scheduling Algorithm is evidently best possible for $m = 2$, and it was observed to be best possible for $m = 3$ as well [9]. In the following years, a stream of research narrowed the gap between upper and lower bounds for competitive ratios depending on m ([2, 17, 1]), although for $m \geq 4$, still no tight bound is known. The state-of-the-art results are Fleischer and Wahl's 1.9201-competitive algorithm ([11]) and an asymptotic lower bound of 1.88 due to Rudin III ([18]). For $m = 4$, the best known lower bound is $\sqrt{3} \approx 1.732$, due to Rudin III and Chandrasekaran ([19]).

Discrepancy Minimization, Hypergraph Coloring. A problem similar to Online Makespan Hypergraph Coloring, often called Online Hypergraph Coloring, has been studied extensively over the years. In this problem, the objective is to use the smallest number of colors while avoiding a *monochromatic hyperedge*, i.e., a hyperedge whose nodes all attain the same color. For hypertrees with n nodes, an $O(\log(n))$-competitive algorithm is known to be best possible ([14]), while for general graphs with n nodes, no $o(n)$-competitive algorithm can exist ([15]). However, this standard model differs from ours, as a hyperedge is revealed only once all of its nodes have been revealed. This nuance deems it much easier

to construct families of instances to achieve lower bounds. Moreover, due to differences in their respective objective functions, this problem does not seem to have a direct relation to Online Makespan Hypergraph Coloring. However, our approach has implications for a variant of Online Hypergraph Coloring in which partial hyperedges are known (see Section 1.1).

The reader may also notice similarities to the well-known discrepancy minimization problem (see e.g. [23, 8]): Indeed, in the usual setting of discrepancy minimization, we have $m = 2$ and the objective is to minimize the difference $\max_{e \in E} ||\{c^{-1}(1)\} \cap e| - |\{c^{-1}(2)\} \cap e||$. If all hyperedges $e \in E$ have the same size, this objective function is even equivalent to ours. In this regard, the problem that we study generalizes the ℓ_∞ norm online discrepancy minimization [22] in uniform set systems as well.

2 Extending Graham's List Scheduling

Our first observation is a simple algorithm that generalizes Graham's List Scheduling Algorithm for OMSS(m, K) and performs well when there are too many machines to force the schedule to create significant discrepancy. Our algorithm beats the trivial bound of m if $m > K + 1$.

We first observe that if the number m of machines is large enough, we can apply the pigeonhole principle to find a machine that is not among the most loaded machines of any scenario. For $s \in [m-1]$ and $k \in [K]$, we call a machine i *s-favorable with respect to the k-th scenario* if there are at least s distinct machines $i' \neq i$ that each have at least the load of machine i in the k-th scenario, i.e., $p(J_{i'} \cap S_k) \geq p(J_i \cap S_k)$.

▶ **Observation 4.** *There exists a machine i that is $\left(\lceil \frac{m}{K} \rceil - 1\right)$-favorable with respect to every scenario $k \in [K]$.*

Proof. There are at most s machines per scenario that are not s-favorable. Let $s = \lceil \frac{m}{K} \rceil - 1$. Since $m > s \cdot K$, there must be a machine i which is not non-s-favorable with respect to any scenario. ◀

In light of this observation, we propose the following algorithm: Upon the assignment of each job j, we find a machine i that is $(\lceil m/K \rceil - 1)$-favorable with respect to all scenarios k with $j \in S_k$ and assign the job j to the machine i.

▶ **Theorem 5.** *The above algorithm is $\left(\frac{m-1}{\lceil \frac{m}{K} \rceil} + 1\right)$-competitive for $m > K$.*

Notice that the aforementioned competitive ratio is strictly smaller than $K + 1$.

This algorithm is also applicable in the special case where every job appears in at most k scenarios for a fixed $k \in \mathbb{N}$, yielding a ratio of $(m-1)/\lceil \frac{m}{k} \rceil + 1$. Furthermore, plugging in $K = 1$ yields the well-known competitive ratio of $2 - 1/m$ of Graham's List Scheduling Algorithm.

3 Near-Tight Bounds for $m = 2$ Machines

When the partitioning is among two machines, a clear line can be drawn: Any algorithm is trivially 2-competitive, and if we have at least 3 scenarios, this is best possible.

▶ **Observation 6.** *For $m = 2$ and $K \geq 3$, there exists no r-competitive algorithm for any $r < 2$, even for the special case of unit processing times.*

Proof. For all jobs j below, we assume $p_j = 1$. The first instance $\mathcal{I}_1$ is given as follows: $n = m + 1$, $S_1 = \{1, 3, \ldots, m + 1\}$, $S_2 = \{2, 3, \ldots, m + 1\}$.

We consider an arbitrary algorithm that places the first jobs 1 and 2 to two distinct machines, without loss of generality, to the first and second, respectively. In this case, the makespan at the end must be 2, as two jobs $(j, j') \neq (1, 2)$ must be assigned to the same machine. However, the following assignment, which places the first two jobs together would have yielded a completion time of 1: $J_1 = \{1, 2\}, J_i = \{i + 1\}$ for $2 \leq i \leq m$. Hence, no algorithm that places two unit weight jobs in $S_1 \setminus S_2$ resp. $S_2 \setminus S_1$ to two separate machines can attain a competitive ratio better than 2.

In light of this, we consider another instance $\mathcal{I}_2$, on which assigning the first two jobs to the same machine leads to a failure. It is given by $n = m + 2$, $S_1 = \{1, 3\}$, $S_2 = \{2, 4, 5, 6, \ldots, m + 2\}$, $S_3 = \{3, 4, 5, \ldots, m + 2\}$. The first two jobs are indeed identical to those of $\mathcal{I}_1$.

By our considerations about the instance $\mathcal{I}_1$, we may assume that the first two jobs are assigned to the same machine, the first one without loss of generality. However, any assignment that places the first two jobs to the same machine admits makespan 2: Otherwise, due to the third scenario, the jobs $\{3, \ldots, m + 2\}$ must occupy one machine each. The job j that is placed to the first machine has a common scenario with either job 1 (if $j = 3$), or with job 2 (otherwise). ◀

On the other hand, this statement cannot be extended to $K = 2$. To show this, we present a minimalistic yet insightful algorithm (Algorithm 1) for makespan scheduling under $K = 2$ scenarios and $m = 2$ machines. Our general idea is to fix a simple rule for assigning *double-scenario jobs*, i.e., jobs in $S_1 \cap S_2$, and partition the *single-scenario jobs* $j \in S_1 \triangle S_2$ so that the machines are reasonably balanced even after upcoming hypothetical double-scenario jobs.

▶ **Rule 7.** *If $j \in S_1 \cap S_2$, then assign the job j to a machine i such that the makespan of the schedule was previously attained by the other machine $3 - i$. In case of a tie, select the machine that received the job $j - 1$ ($j = 1$ is assigned to the first machine if applicable).*

Throughout our analysis, we only use two types of lower bounds for the offline optimum: Processing times p_j of selected jobs j whose completion times equal the makespan, and the average load of a selected scenario S_k. Hence, while searching for the worst-case sequence of the upcoming double-scenario jobs, we may replace the actual definition of competitiveness with that of a proxy one:

▶ **Definition 8.** *We define the* proxy competitive ratio *of a schedule as*

$$\rho = \frac{\max_{i,k\in\{1,2\}} p(S_k \cap J_i)}{\max\left\{\max_{k\in\{1,2\}}\left\{\frac{p(S_k)}{2}\right\}, \max_{j\in[n]\cap \mathrm{argmax}_{\mathrm{j}\in[\mathrm{n}]}\{\mathrm{C_j}\}}\{p_j\}\right\}},$$

where C_j denotes the completion time of the job j.

The proxy competitive ratio is an upper bound on the competitive ratio. The lower bounds that we use are already well-known; e.g., Graham's List Scheduling Algorithm is analyzed by bounding the proxy competitive ratio from above. We take this approach, however, one step further and restrict ourselves to analyzing only some instances that attain the largest possible proxy competitive ratio (see next Observation). This is significantly more difficult for the competitive ratio in the usual sense, as a witness to having good or bad offline optima highly depends on how the processing times of jobs fit together numerically.

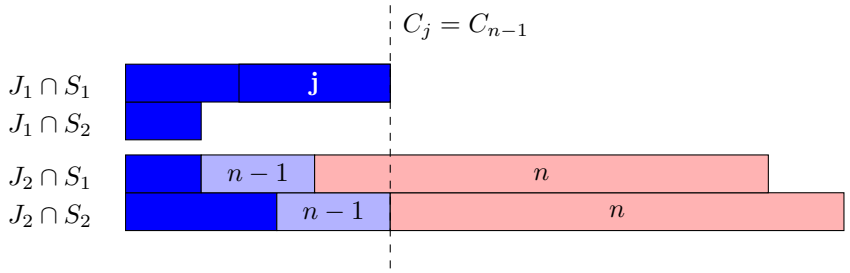

Figure 1 Illustrative description of Observation 9. Processing times p_j are given by the widths. Given the dark blue schedule, a worst outcome turns out to be the light blue job $n-1$ with a processing time p_{n-1} such that $C_{n-1} = C_j$, followed by the light red job n with $p_n = p(S_1 \cap [n-1])$.

▶ **Observation 9** (cf. Figure 1). *Let $\mathcal{A}$ be an online algorithm for OMSS$(2,2)$ obeying Rule 7. Assume that $\mathcal{A}$ has a proxy competitive ratio of at most $\frac{5}{3}$ on instances where*

(i) *$n \in S_1 \cap S_2$, and*

(ii) *$\mathcal{A}$ outputs a schedule with the following property: If $j \in [n]$ is the largest index with $j \in S_1 \triangle S_2$, then $C_j = C_{n-1}$.*

Then, $\mathcal{A}$ is $\frac{5}{3}$-competitive.

The above observation motivates the following parameter of significant value.

▶ **Definition 10.** *Consider a schedule where, without loss of generality, the makespan is attained at $S_1 \cap J_1$. The* anticipation α *of this schedule is given by the ratio*

$$\alpha := \begin{cases} \frac{p(J_1 \cap S_1)}{\max\{p(J_1 \cap S_2),\, p(J_2 \cap S_1) + p(J_1 \cap S_1) - p(J_2 \cap S_2)\}} & \text{if } p(J_2 \cap S_2) > p(J_2 \cap S_1), \\ 0 & \text{else.} \end{cases}$$

By convention, we assume $\frac{0}{0} = 1$.

In Figure 1, we have $p(J_2 \cap S_2 \cap [n-2]) > p(J_2 \cap S_1 \cap [n-2])$ and the second term of the denominator corresponds to the load $p(J_2 \cap S_1 \cap [n-1])$, i.e., the load of $J_2 \cap S_1$ after the $(n-1)$-st job is assigned. In general, anticipation measures the minimum discrepancy of a machine with respect to different scenarios after machine 2 is loaded with double-scenario jobs just enough to attain the makespan of the schedule together with machine 1. In our algorithm, one of the goals is to keep $\alpha \leq 2$ in order to brace ourselves for upcoming double-scenario jobs. The invariant which we maintain to this end is the following.

▶ **Invariant 11.** *The schedule satisfies the following assertions:*

(i) *Its proxy competitive ratio is bounded by $\rho \leq 5/3$.*

(ii) *The schedule has anticipation bounded by $\alpha \leq 2$.*

(iii) *Let k, i be given so that $J_i \cap S_k$ admits the makespan in the schedule. If the schedule is* dominated by the i-th machine, *i.e., $p(J_i \cap S_{k'}) > p(J_{3-i} \cap S_{k''})$ for all $k', k'' \in \{1,2\}$, then we have $p(J_i \cap S_k) \leq 2p(J_i \cap S_{3-k})$.*

The last property might appear somewhat unnatural at the first glance, though it is crucial for bounding the anticipation $\alpha \leq 2$ in the subsequent iterations.

Algorithm 1 shows how a single job j is assigned given a schedule of the first $j-1$ jobs where Invariant 11 is maintained. To analyze the algorithm, we prove that instances satisfying the properties in Observation 9 are always assigned so that the first $n-1$ jobs maintain Invariant 11 and the last job results in a proxy competitive ratio of at most $5/3$.

Algorithm 1 The assignment of a single job j given a $\frac{5}{3}$-competitive schedule that satisfies Invariant 11.

```
1: Rename machines and scenarios so that (J_1 ∩ S_1) is maximal
2: if j ∈ S_1 \ S_2 then
3:     return 2
4: end if
5: if j ∈ S_2 \ S_1 then
6:     if assigning j to the first machine satisfies Invariant 11 then
7:         return 1
8:     else
9:         return 2
10:    end if
11: end if
12: if j ∈ S_1 ∩ S_2 then
13:    return argmin_{i=1,2} max_{k=1,2} {p(J_i ∩ S_k)}
14: end if
```

A significant portion of the analysis is focused on proving that if line 9 is executed, Invariant 11 is indeed maintained. We refer the reader to the full version of the paper for further details.

In spite of the restrictions that arise from both the fixed double-scenario rule and how we evaluate lower bounds, we find out that our algorithm in the previous subsection is not far from being best possible.

▶ **Theorem 12.** *For $m = 2$ and $K = 2$, there exists no deterministic algorithm with competitive ratio strictly smaller than $\frac{9+\sqrt{17}}{8} \approx 1.640$.*

Proof. To ease the notation once again, let $X := 3 + \sqrt{17}$.

The first four jobs are given by $1, 2 \in S_1 \setminus S_2$, $3, 4 \in S_2 \setminus S_1$, $p_1 = p_2 = p_3 = p_4$. Any algorithm with competitive ratio better than 2 must assign these jobs so that the makespan equals 1 at the end; otherwise, we may stop revealing further jobs so that the offline optimum equals 1, while the makespan equals 2.

The fifth job fulfills $5 \in S_1 \setminus S_2$ and $p_5 = X$. Without loss of generality, it is assigned to the first machine.

The sixth job is given by $6 \in S_2 \setminus S_1$, $p_6 = \frac{X}{2}$. Now there are two options:

(i) If the sixth job is also assigned to the first machine, we reveal the seventh job with $7 \in S_2 \setminus S_1$ and $p_7 = X$. This job cannot be assigned to the first machine, as the makespan would then be $1 + \frac{3X}{2}$, while the offline optimum is X. Indeed, this would imply a ratio of at least

$$\frac{1 + \frac{9+3\sqrt{17}}{2}}{3 + \sqrt{17}} = \frac{9 + \sqrt{17}}{8}.$$

In particular, we obtain $p(S_1 \cap J_1 \cap [7]) = p(S_2 \cap J_2 \cap [7]) = 1 + X$.

(ii) If the sixth job is assigned to the second machine, we reveal the seventh job as $7 \in S_1 \cap S_2$ and $p_7 = \frac{X}{2}$. Due to similar reasoning to the other case, the seventh job must be assigned to the second machine and we again have $p(S_1 \cap J_1 \cap [7]) = p(S_2 \cap J_2 \cap [7]) = 1 + X$.

See Figure 2 for the first seven jobs in each of the cases.

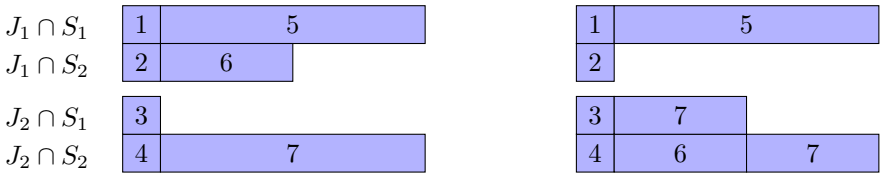

Figure 2 The first seven jobs in cases (i) and (ii) of the proof of Theorem 12, respectively. In both cases, an eighth job $8 \in S_1 \cap S_2$ forces the schedules to the desired lower bound of competitiveness.

In both of these cases, we reveal the eighth job with $8 \in S_1 \cap S_2$ and $p_8 = 2 + \frac{3X}{2}$. No matter where this job is assigned, the makespan is $3 + \frac{5X}{2}$, whereas the optimal solution $\{1, \dots, 7\} \dot{\cup} \{8\}$ achieves a makespan of $2 + \frac{3X}{2}$. Therefore, the competitive ratio is bound to be at least

$$\frac{3 + \frac{5X}{2}}{2 + \frac{3X}{2}} = \frac{6 + 5(3 + \sqrt{17})}{4 + 3(3 + \sqrt{17})} = \frac{9 + \sqrt{17}}{8},$$

as desired. ◀

Notice that the aforementioned family of instances fails to achieve small competitive ratios for reasons similar to those that require Property (iii) in Invariant 11.

It can also be shown through a simple array of instances that, no algorithm that satisfies Rule 7 can beat the bound of $5/3$, for which we refer the reader to the full version of the paper.

4 Tight Bounds for Sufficiently Many Scenarios

One of our main results (Theorem 2) states that for any number $m \in \mathbb{N}$ of machines, there exists a number K of scenarios such that no deterministic algorithm for OMSS(m, K) can have a competitive ratio less than the trivial upper bound m, even for unit processing times.

Due to space constraints, we merely sketch a proof for the special case of $m = 3$. While doing so, we showcase key ideas of the general argument, although we forfeit the restriction onto hypertrees for the sake of a more clearly structured description. In the context of scheduling, this is indeed not a significant change.

▶ **Theorem 13.** *For OMHC(3), there exists no r-competitive online algorithm for any $r < 3$, even when restricted to instances with at most 233 hyperedges of size at most 3 each.*

The problem OMHC(m), which we formulated in Section 1.2, is equivalent to the unit processing time case of OMSS(m, K) with K part of the input, so that the lower bounds are immediately implied for the latter as well.

To prove Theorem 13, we provide a family of instances on which any online algorithm is forced to output a monochromatic hyperedge of size 3. For each of the instances, we also maintain (offline) colorings $c\colon [j] \to \{\text{blue}, \text{red}, \text{yellow}\}$, with the property that if two nodes v, v' are contained in a common hyperedge, we have $c(v) \neq c(v')$. The latter coloring suggests an offline optimal value of 1 for each of the instances, implying the competitive ratio of 3 immediately. The main difference between the online and offline colorings is, as expected, that we may change the offline coloring completely at all times as long as its makespan equals 1. Among other modifications, we often employ a permutation $\pi\colon \{\text{red}, \text{blue}, \text{yellow}\} \to \{\text{red}, \text{blue}, \text{yellow}\}$ on connected components to realize this possibility. We must trace the offline coloring simultaneously because the hyperedges are often defined adversarially according to both colorings of the current hypergraph.

To differentiate between the online and offline colorings, we denote by $J_i \subseteq V$ the subset of nodes assigned to the online color i for $i \in \{1, 2, 3\}$. Right before the revelation of a node j, we implicitly mean $J_i \cap [j-1]$ whenever we mention J_i for some $i \in \{1, 2, 3\}$. Inspired by our original scheduling problem, we call the objective value $\max_{e \in E} \max_{i \in \{1,2,3\}} |e \cap J_i|$ of an instance its *makespan*. Without loss of generality, we truncate an instance as soon as the online solution is forced to obtain a makespan of 3.

Our gadget: Seven-node subhypergraph $\mathcal{S}$. Initially, we study a subhypergraph $\mathcal{S}$ that we use as a building block throughout our construction. The hypergraph $\mathcal{S}$ is given by the nodes $V(\mathcal{S}) = \{1, \dots, 7\}$ and hyperedges

$$E(\mathcal{S}) = \big\{\{1,2\}, \{1,3\}, \{2,3\}, \{1,2,3\}, \{2,4\}, \{4,5\}, \{2,5\}, \{2,4,5\}, \\ \{4,6\}, \{6,7\}, \{4,7\}, \{4,6,7\}, \{3,6\}, \{3,7\}\big\}.$$

The hyperedges have size at most 3 and the set $E(\mathcal{S})$ is closed under taking subsets of size at least 2, i.e., if $e \in E(\mathcal{S})$, $|e| = 3$ and $e' \subseteq e$ with $|e'| = 2$, then $e' \in E(\mathcal{S})$. The hypergraph $\mathcal{S}$ together with the maximal hyperedges $e_1, \dots, e_5$ is given in Figure 3.

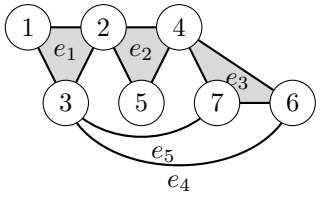

Figure 3 The hypergraph $\mathcal{S}$ with the maximal hyperedges $e_1, \dots, e_5$.

We first assume that the seven nodes in $V(\mathcal{S})$ are assigned to exactly two out of the three online colors. Since the online colors are initially symmetric, let us assume that we use the online colors 1 and 2. By a careful case distinction, we may observe:

▶ **Proposition 14.** *For any partitioning $V(\mathcal{S}) = J_1 \dot\cup J_2$ of the nodes that admits a makespan of at most 2, there exists a node coloring $c\colon V(\mathcal{S}) \to \{\text{blue}, \text{red}, \text{yellow}\}$ such that there are two hyperedges $e \in E(\mathcal{S}[J_1]), e' \in E(\mathcal{S}[J_2])$ with $c(v) \in \{\text{red}, \text{blue}\}$ (or another subset of $\{\text{blue}, \text{red}, \text{yellow}\}$ of size 2) for all $v \in e \cup e'$.*

In other words, we have induced monochromatic hyperedges of size 2 with two different colors, both with respect to the online coloring. Applying this repeatedly, we can further force the algorithm to a monochromatic hyperedge of size 3, which we show next.

Pigeonholing the two-color case. In our construction, we would like to create *copies* of the graph $\mathcal{S}$ successively, which we denote by $\mathcal{S}(t)$ for incrementing $t \in \mathbb{N}$.

A straightforward application of the pigeonhole principle yields that, if we have seven subhypergraphs $\mathcal{S}(1), \dots, \mathcal{S}(7)$ that are each partitioned onto two online colors, at least three of them (without loss of generality $\mathcal{S}(1)$, $\mathcal{S}(2)$, $\mathcal{S}(3)$) must be partitioned onto the same two online colors. Again without loss of generality, these two online colors are 1 and 2. Considering Proposition 14, we can permute the colorings of the three copies $\mathcal{S}(1)$, $\mathcal{S}(2)$ and $\mathcal{S}(3)$ each offline so that for any offline color $u \in \{\text{blue}, \text{red}, \text{yellow}\}$, there exists a copy $\mathcal{S}(t)$ with two (online) monochromatic hyperedges $e_i^t \in E(\mathcal{S}(t))$ $(i \in \{1, 2\})$ of size 2 avoiding the color u. The hypergraph in Figure 4 restricted to nodes of the form j_s^i illustrate these edges.

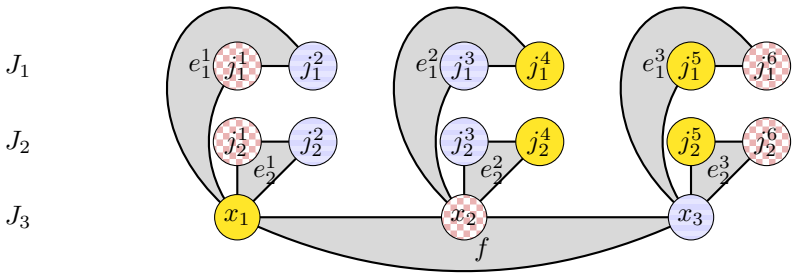

Figure 4 All fifteen relevant nodes together with the hyperedges within them. The heights of the vertices encode their online color (J_1, J_2, J_3), while their printed colors denote their offline color. Any assignment of the node x_3, given the other nodes and induced hyperedges, leads to a makespan of 3.

Once the six edges in question are found, one can insert nodes x_1, x_2, x_3 in this order, revealing hyperedges as depicted in Figure 4. To avoid a monochromatic edge, both x_1 and x_2 must be assigned the third online color. Keeping this in mind, it follows that x_3 cannot be assigned an online color without creating a monochromatic edge with respect to the online coloring. Together with the fact that the offline coloring indeed has makespan 1, we obtain:

▶ **Lemma 15.** *Any algorithm that assigns at least 7 copies of $\mathcal{S}$ to at most two online colors each is no better than 3-competitive.*

Subhypergraph $\mathcal{S}$ on Three Online Colors: The Palettes. It remains to consider the case where copies of the subhypergraph $\mathcal{S}$ are partitioned among the three colors, i.e., its nodes $\{1, \dots, 7\}$ are partitioned in nonempty sets $J_1 \dot\cup J_2 \dot\cup J_3$.

▶ **Lemma 16.** *For every online coloring $J_1 \dot\cup J_2 \dot\cup J_3$ of the nodes $V(\mathcal{S}) = \{v_1, \dots, v_7\}$ for nonempty sets $J_1 \dot\cup J_2 \dot\cup J_3$, there is an offline coloring $c\colon V(\mathcal{S}) \to \{\text{red}, \text{blue}, \text{yellow}\}$ such that two vertices exist with different online colors but the same offline color.*

In our construction, we exploit this property as follows: Let us consider a copy $\mathcal{S}(t)$ and fix two of its nodes $v_i(t) \in J_i$, $v_{i'}(t) \in J_{i'}$ provided by Lemma 16 as well as a third node $v_{i''}(t) \in J_{i''}$, where $i'' \notin \{i, i'\}$. By their choice, the nodes $v_i(t)$ ($i \in \{1, 2, 3\}$) admit at most two offline colors and avoid a third offline color $C \in \{\text{blue}, \text{red}, \text{yellow}\}$.

In this case, the subhypergraph $\mathcal{S}(t)$ is called a C *palette* (i.e., *yellow palette*, *blue palette* or *red palette*) and the corresponding nodes $v_i(t)$ are called *palette nodes*. In particular, $c(v_i(t)) \neq C$ holds for the palette nodes of a C palette. The choice of the name is motivated by the fact that, if we connect a new node w to e.g. yellow palette nodes, we are still allowed to extend the offline coloring by $c(w) = \text{yellow}$, while maintaining that the makespan of the offline coloring is 1.

The Construction. Below is a summary of our construction for the case where Lemma 15 is not applicable. Essentially, we create copies of the subhypergraph $\mathcal{S}$ which we connect with the existing hypergraph. The online color of the node v is denoted by $\varphi(v)$ and its (current) offline color by $c(v)$.

(i) We create up to 13 copies of the subhypergraph $\mathcal{S}$. By Lemma 15, we may assume that at least 7 of the copies are assigned to all three online colors (we truncate this step as soon as 7 such copies can be found). We handpick 7 such copies of $\mathcal{S}$, calling them $\mathcal{S}(1), \dots, \mathcal{S}(7)$.

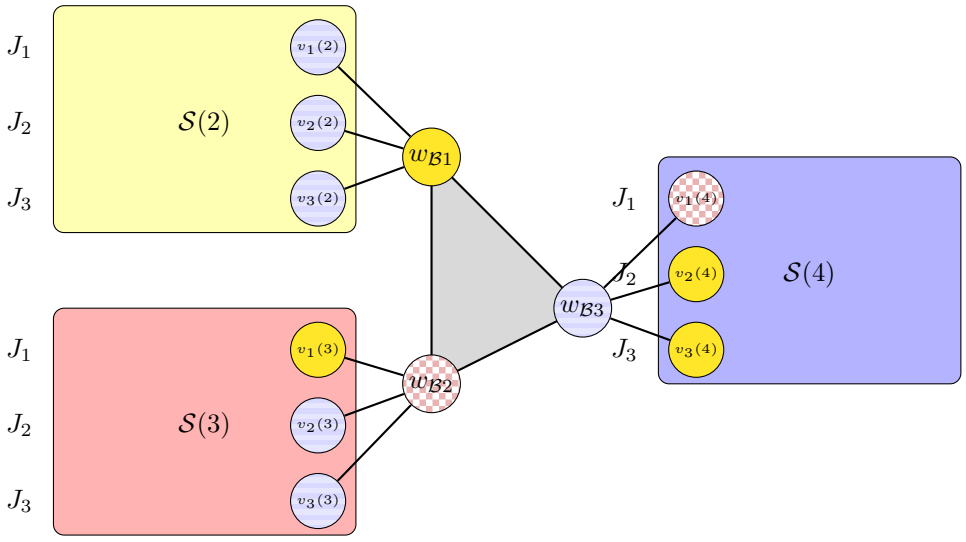

Figure 5 An example constellation of the three palettes together with the nodes $w_{\mathcal{B}t}$. The y-axis in the palettes denote the online colorings of the palette nodes respectively. The offline colors of the palette nodes might look differently, but they are never the same color as the palette, which is depicted as the color of the rectangles. The online coloring of the nodes $w_{\mathcal{B}i}$ are not yet known.

(ii) We permute the offline coloring on each copy of $\mathcal{S}$ so that $\mathcal{S}(1)$, $\mathcal{S}(4)$ and $\mathcal{S}(7)$ are yellow palettes, $\mathcal{S}(2)$ and $\mathcal{S}(5)$ are blue palettes, and $\mathcal{S}(3)$ and $\mathcal{S}(6)$ are red palettes.

(iii) We reveal a node $w_{\mathcal{A}}$ which is connected to palette nodes $v_i(1) \in V(\mathcal{S}(1)) \cap J_i$ for $i \in \{1,2,3\}$. The assignment to the online color $\varphi(w_{\mathcal{A}})$ leads to a monochromatic hyperedge $\{v_{\varphi(w_{\mathcal{A}})}(1), w_{\mathcal{A}}\}$ of online color $\varphi(w_{\mathcal{A}})$. We define $v_{\mathcal{A}} \coloneqq v_{\varphi(w_{\mathcal{A}})}(1)$.

(iv) We reveal three nodes $w_{\mathcal{B}1}$, $w_{\mathcal{B}2}$ and $w_{\mathcal{B}3}$ that are connected by the hyperedge $\{w_{\mathcal{B}1}, w_{\mathcal{B}2}, w_{\mathcal{B}3}\}$ to each other. Moreover, for each $s \in \{1,2,3\}$, the node $w_{\mathcal{B}s}$ is connected to the palette nodes $v_i(s+1)$ for $i \in \{1,2,3\}$. There is an $i \neq \varphi(w_{\mathcal{A}})$ such that $\{v_i(s+1), w_{\mathcal{B}s}\}$ is a monochromatic edge of online color i for a suitable copy $\mathcal{S}(s)$, $s \in \{1,2,3\}$. For this s, we define $v_{\mathcal{B}} \coloneqq v_i(s+1)$ and $w_{\mathcal{B}} \coloneqq w_{\mathcal{B}s}$.

(v) We reveal further copies of $\mathcal{S}$ together with edges described below, until a copy $\mathcal{C}$ is assigned to all three online colors. In the copy $\mathcal{C}$, we denote the nodes $v_i(t)$ by $w_{\mathcal{C}t}$ for clarity. The nodes $w_{\mathcal{C}t}$ of the copy $\mathcal{C}$ are connected to the palettes $\mathcal{S}(5)$, $\mathcal{S}(6)$, $\mathcal{S}(7)$ by edges depending on their offline colors, in that nodes $w_{\mathcal{C}t}$ with $c(w_{\mathcal{C}t}) = C$ are connected to the palette nodes $v_i(s)$ for all $i \in \{1,2,3\}$ and $s \in \{5,6,7\}$ such that $\mathcal{S}(s)$ is a C palette, see Figure 6. As the nodes $w_{\mathcal{C}t}$ are assigned to all three online colors, a makespan of 2 is also achieved in the online color $i \notin \{\varphi(w_{\mathcal{A}}), \varphi(w_{\mathcal{B}})\}$. More precisely, there exists a monochromatic edge $\{v_i(s), w_{\mathcal{C}t}\}$ of the online color i. We rename $v_{\mathcal{C}} \coloneqq v_i(s)$ and $w_{\mathcal{C}} \coloneqq w_{\mathcal{C}t}$.

(vi) We permute the offline coloring in each of the connected components created in (iii), (iv) and (v) again, so that $c(v_j) =$ blue and $c(w_j) =$ yellow for $j \in \{\mathcal{A}, \mathcal{B}, \mathcal{C}\}$.

(vii) We add a final node v_n together with hyperedges $\{v_n, v_j, w_j\}$ for each $j \in \{\mathcal{A}, \mathcal{B}, \mathcal{C}\}$. Now, the online color $\varphi(v_n)$ that this node is assigned to admits a makespan of 3, while extending the offline coloring by $c(v_n) =$ red maintains an offline coloring with makespan 1.

Notice that we have maintained an offline coloring of the nodes with makespan 1 so far up to the very last node, and the last node n neighbors only blue and yellow nodes by construction and therefore the offline assignment $c(n) =$ red does not increase the makespan.

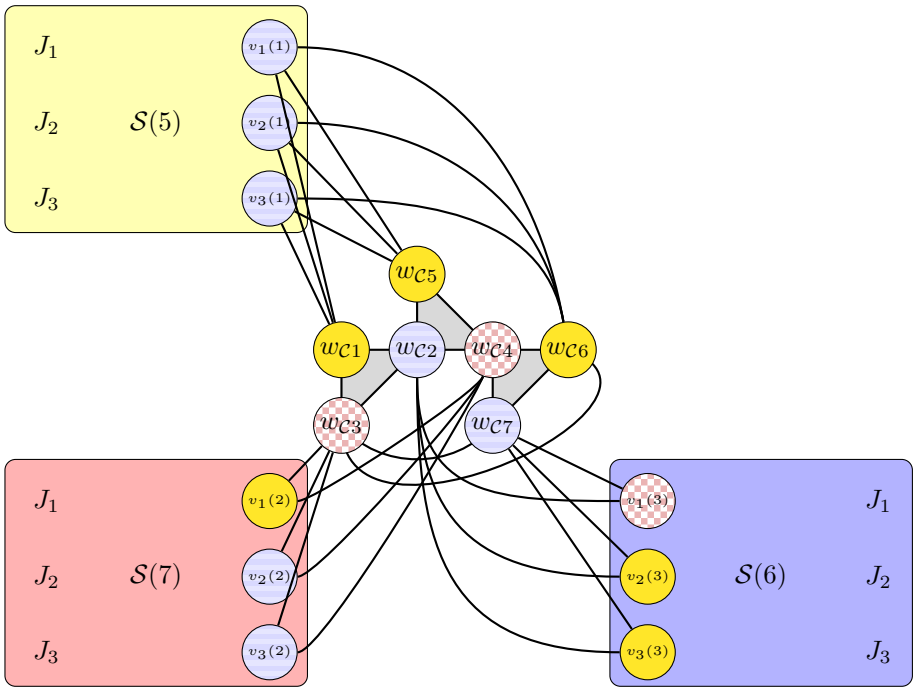

Figure 6 Partial sketch of subinstance $\mathcal{C}$.

In total, this yields that the offline optimal value is 1. A careful enumeration of introduced hyperedges reveals that 233 hyperedges suffice to create a monochromatic hyperedge for any of the cases demonstrated, which proves Theorem 13.

A Note on Theorem 2. Here, we abstain from presenting a proof of Theorem 2. Our construction in this general case is also based on incrementally creating monochromatic edges of each online color. However, we are faced with two fundamental challenges:

- **(i)** The monochromatic hyperedges increase in size rather slowly, yet unless they have size of $m-1$, they are not strong enough to act as a palette for other hyperedges in the same sense as here.
- **(ii)** To use our construction for Corollary 3, we restrict to hypertrees. This is a significant constraint, as it roughly implies that every palette may be used at most once.

Therefore, we include a more intricate recursive construction with much larger hypergraphs in the full version of the paper.

5 Tight Bounds For $K = 3$ and Unit Processing Times

In the previous section, we have established that for large enough K, there is no better-than-3-competitive algorithm for OMSS$(3, K)$, even for unit processing times. Let us reverse the parameters and ask: How competitively can we solve OMSS$(m, 3)$? This is not an easy question, indeed, even for OMSS$(m, 1)$, $m \geq 4$, a tight bound is not known. Restricting to the unit processing time case ($p_j \equiv 1$), we again obtain a tight bound, which is the smallest possible ratio (due to Theorem 5):

▶ **Theorem 17.** *For all $m \in \mathbb{N}$, there is a 2-competitive algorithm for the special case of OMSS$(m, 3)$ where the jobs have unit processing times.*

The algorithm in question employs an adapted round-robin method which assigns jobs to machines according to the scenarios they appear in. Essentially, we try to assign jobs $j \in S_1 \setminus (S_2 \cup S_3)$ and $j' \in (S_2 \cup S_3) \setminus S_1$ in a similar manner, and analogously for cyclic permutations of the indices $i \in \{1, 2, 3\}$. This gives a partition of jobs $j \in [n] \setminus (S_1 \cap S_2 \cap S_3)$ in three categories. The round robin assignments for each category are translated by roughly $m/3$, and jobs $j \in S_1 \cap S_2 \cap S_3$ are handled separately.

The algorithm is best visualized by drawing an analogue to a bingo card, for which we refer the reader to the full version.

6 Conclusion and Outlook

Throughout, we have established several competitiveness results for Online Makespan Scheduling under Scenarios. The first main takeaway from our work is a competitiveness gap between two and at least three scenarios when we consider $m = 2$ machines. This result draws a parallel to the known tractability results of several other problems, in which the line between easy and hard was drawn between two and three scenarios. Surely, the fact that the subsets of $\{1, 2, 3\}$ are not laminar, has been a deciding factor in our simple non-competitiveness result, as has been in several of the well-known results. Interestingly, restricting to the proxy competitive ratio as well as fixing the method of assigning double-scenario jobs essentially reduced the existence problem to the description of a polyhedron. We believe that similar techniques might prove useful for other cases and related problems as well.

We have further compared the behavior of competitiveness for increasing number K of scenarios and increasing number m of machines. In the special setting of unit processing times and $m = 3$ machines, the contrast is evident: On one hand, there is a 2-competitive algorithm for three scenarios and m machines for all $m \in \mathbb{N}$, which matches the lower bound obtained readily for $m = 2$. On the other hand, for K sufficiently large, the trivial upper bound of 3 cannot be beaten. That being said, $K + 1$ is a strict upper bound as well for a problem on K scenarios. To summarize, for large values of m and small values of K, we would expect the possibilities for competitive ratios to be dominated by K.

In light of our results, we may raise several open questions: In addition to the obvious task of finding tight bounds for all possibilities (m, K) of the numbers of machines and scenarios, exploring the competitiveness as m approaches to infinity in the weighted processing time case remains interesting. However, these problems have not been resolved even for $K = 1$, whence it is fair to assume challenges in further progress. Another interesting research direction is to introduce *migration*, as seen in e.g. [20]. In this model, we are allowed to revoke a bounded size of decisions in hindsight. Similarly, instead of minimizing the worst-case scenario, one could look into minimizing the average scenario or maximum regret.

Abstract

We consider algorithmic problems motivated by modular robotic reconfiguration in the *sliding square model*, in which we are given n square-shaped modules in a (labeled or unlabeled) start configuration and need to find a schedule of sliding moves to transform it into a desired goal configuration, maintaining connectivity of the configuration at all times. Recent work has aimed at minimizing the total number of moves, resulting in fully sequential schedules that can perform reconfiguration in $\mathcal{O}(n^2)$ moves, or $\mathcal{O}(nP)$ for arrangements of bounding box perimeter size P.

We provide first results in the sliding square model that exploit parallel motion, performing reconfiguration in worst-case optimal makespan of $\mathcal{O}(P)$. We also provide tight bounds on the complexity of the problem by showing that even deciding the possibility of reconfiguration within makespan 1 is NP-complete in the unlabeled case. In the labeled variant, we note that deciding the same for makespan 2 is NP-complete, while makespan 1 is straightforward.

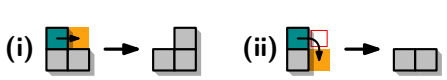
1 Introduction



Reconfiguring an arrangement of geometric objects is a fundamental task in a wide range of areas, both in theory and practice. A typical task arises from relocating a (potentially large) collection of agents from a given start into a desired goal configuration in an efficient manner, while avoiding collisions between objects or violating other constraints, such as maintaining connectivity of the overall arrangement. In recent years, the problem of modular robot reconfiguration [9, 28, 30] has enjoyed particular attention [1, 2, 3, 4, 6] in the context

of Computational Geometry: In the *sliding square model* introduced by Fitch, Butler, and Rus [19], a given start configuration of n identical modules, each occupying a square grid cell, must be transformed by a sequence of atomic, sequential moves (shown in Figure 1(a)) into a target arrangement, without losing connectivity of the underlying grid graph.

(a) Two types of move can be performed by individual modules: **(i)** Slides and **(ii)** convex transitions.

(b) Some moves can be performed in parallel transformations, as shown here.

Figure 1 Our model allows for two types of moves to occur in parallel, collision-free transformations. In this paper, we show the symmetric difference of a transformation using turquoise and yellow.

Aiming at minimizing the total number of moves, previous research has resulted in considerable progress, recently establishing [2] universal configuration in $\mathcal{O}(nP)$ moves for a 2-dimensional arrangement of n modules with bounding box perimeter size P, and $\mathcal{O}(n^2)$ in three dimensions [1, 22]. However, the resulting schedules are purely sequential, not optimally minimizing the overall time until completion, called *makespan*. With parallel motion, much lower makespan can be achieved – which is also a more challenging objective, as it requires coordinating the overall motion plan, not just at the atomic level (see Figure 1(b)), but also at the global level to maintain connectivity and avoid collisions.

1.1 Our contributions

We provide first results for *parallel* reconfiguration in the sliding squares model with no restriction on the input. We achieve tight outcomes, both on the negative and the positive side.

1. We prove that even deciding the existence of a schedule with the smallest possible makespan of 1 is NP-complete in the parallel reconfiguration model, as well as APX-hard.
2. We give an in-place algorithm that achieves makespan $\mathcal{O}(P)$, where P is the perimeter of the union of the bounding boxes of start and target configurations. We show that this is asymptotically worst-case optimal.

Due to limited space, we only provide high-level descriptions here and refer to the full version [5] for the majority of our proofs and full technical details. Additionally, we extend our results to the *labeled* variant: When individual robots are distinguishable, deciding makespan 2 is NP-complete, while makespan 1 is easy. Moreover, asymptotically worst-case optimal schedules can still be computed in polynomial time with a relaxation of the in-place requirement. For precise definitions and the problem statement, see Section 2.

1.2 Related work

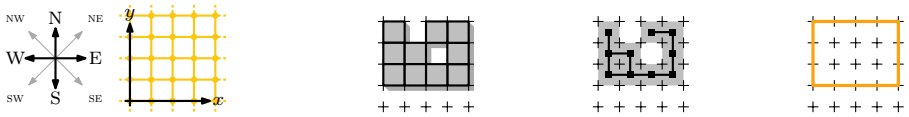
On the theoretical side, algorithmic methods for coordination the motion of many robots can be traced back to the classical work of Schwartz and Sharir [29] from the 1980s. On the practical side, [20] presented an architecture for modular robots, followed by a wide spectrum of work that often used cuboids as elementary building blocks; see [32] for a survey.

Of particular interest for the algorithmic side is the *sliding cube model* (or *square*) by Fitch, Butler, and Rus [19], introduced in the context of a modular robotic hardware [9, 28, 30]. Recent work [1, 4, 13, 22] has studied algorithmic methods for *sequentially* sliding squares and cubes, with typical schedules requiring a quadratic number of moves. Also related are models with slightly different types of moves, such as “pivoting”, see [2, 3, 10, 24].

In [24] the authors claim an algorithm for connectivity-preserving reconfiguration of sliding squares in $\mathcal{O}(n)$ parallel steps. Unfortunately, this is incorrect for general input. Nevertheless, if the input configurations are guaranteed to not contain a specific "forbidden" local pattern (a 2×2 arrangement with only two diagonally adjacent squares), then their algorithm is correct. Similar models of parallel sliding squares have been investigated experimentally [31]. However, this still leaves the existence of linear-time parallel protocols unresolved.

While the previous work on sliding squares focuses on minimizing the number of moves, a different line of research aims at minimizing the total time until completion. In [21], the authors study parallel distributed algorithms for a less restrictive model of sliding squares, obtaining $\mathcal{O}(n)$ makespan. They show how to obtain the same result in the standard sliding square model using *meta-modules*, small groups of cooperating modules that behave like a single entity. This, however, imposes extra constraints in the input. Algorithmic research on meta-modules was considered in [6, 27]. In [7, 12], the authors considered coordinated motion planning in a less constrained model (see discussion in Section 2) for labeled robots to minimize the makespan, aiming for *constant stretch*, i.e., a makespan within a constant factor of the maximum distance for a single robot. This was extended to preserve connectivity for unlabeled [8, 16] and labeled robots [18], and between obstacles [17].

Scaffolding and Meta-modules. Computing reconfiguration paths is not a simple task and, for many models, it is computationally intractable (even PSPACE-complete [3]). *Scaffolding* (proposed independently by [23] and [26]) aims at making reconfiguration simpler by restricting the scope to configurations containing a regular substructure (the *scaffold*) that remains connected between moves (thus removing complexity from the connectivity constraint) while having enough empty positions to allow modules to move through the scaffold (thus removing complexity from the free space constraints). They obtain a scaffold by using *meta-modules*, groups of modules that cooperate to move as a higher-level functional unit. Previous work has used these to translate algorithms for a particular model to another (see, e.g., [21, 27, 28]).



The drawback of these techniques is that their input must belong to the subset of configurations where modules are already organized into meta-modules (the scaffold exists in both the initial and target configuration). The authors of [8, 16] proposed an algorithm that first builds the scaffold from an arbitrary scaled configuration. They achieve *constant stretch*, i.e., a makespan within a constant factor of the maximum minimum distance for a single robot (based on previous work [7, 12]). This was extended for labeled modules [18], and between obstacles [17]. Although their techniques apply to a wider range of configurations, there are still restrictions on the input. The algorithm presented in this paper also makes use of scaffolding and meta-module techniques. To the best of our knowledge, our algorithm is the first universal one to build the scaffold and meta-modules (i.e., from arbitrary input).

Model comparison. Our model is more constrained than existing models for parallel reconfiguration under connectivity constraints [15, 16, 18, 21, 24]. Michail, Skretas, and Spirakis [24] do not explicitly require the connected backbone constraint, and do not explicitly define the collision model. The models in [16, 18] do not require the connected backbone constraint, and allow modules to enter and leave cells simultaneously, even in orthogonal directions. Similarly, [21] relaxes the free-space constraint of the convex transition move, allowing a module to move through two diagonally adjacent static modules. However, the authors disallow chain moves as shown in Figure 1(b), so that the cells involved in individual slide moves in the same transformation are disjoint. The same is true for [14, 15] where the paths of transformations at any given time stamp must be disjoint.

2 Preliminaries

We study the connected reconfiguration of squares in the infinite, two-dimensional integer grid by sliding moves in a parallel variant of the sequential *sliding squares* model, as follows.

Configurations. Each simple 4-cycle of edges in the infinite integer grid $\mathbb{Z}^2$ bounds a unit *cell* c, which is uniquely identified by its minimal integer coordinates $x(c)$ and $y(c)$. Two such cells are *edge-adjacent* (resp., *vertex-adjacent*) if their boundary cycles share an edge (resp., vertex). A *configuration* C of n square *modules* is defined by the set of occupied cells, each containing a single module. We say that C is valid if and only if its dual graph, defined by edge-adjacency, is connected, and denote by B the unique axis-aligned bounding box of minimal perimeter P that contains C; see Figure 2 for illustrations.

(a) The integer grid $\mathbb{Z}^2$. **(b)** A configuration C of 10 modules, its dual graph, and bounding box B.

Figure 2 We illustrate the relation of the integer grid and configurations.

Moves. Individual modules can perform two types of *move* into an unoccupied edge-adjacent or vertex-adjacent cell, *slides* and *convex transitions*, as illustrated in Figure 1(a). We denote a move by its start and target cells, e.g., $u \rightsquigarrow v$. In our model, both moves take an identical (unit) duration to complete, which allows us to easily extend the existing notion of move counting in sequential models [4, 13, 15, 25] to the parallel setting. Note that in our figures, the path denoting a convex transition is shown containing a circular arc for clarity. Such a path would be accurate if the corners of modules were rounded.

Transformations. The parallel execution of moves constitutes a *transformation*, which we denote by the initial and resulting configurations, e.g., $C_1 \to C_2$. A transformation is valid only if it (i) preserves connectivity and (ii) does not cause collisions.

As in a number of existing models for both sequential and parallel reconfiguration of squares in the grid [1, 4, 22, 31], connectivity is determined by the existence of a *connected backbone*: Given a configuration C, we call a subset M of modules *free* if $C \setminus M'$ is a valid configuration for any $M' \subseteq M$. Let $M \subset C_1$ refer to all moving modules during $C_1 \to C_2$. Then there exists a connectivity-preserving backbone if and only if M is free both in C_1 and in C_2. A module m is *free* if $\{m\}$ is free. In Figure 3, both transformations are illegal as they attempt to move modules that are not free (conflicts are marked in red).

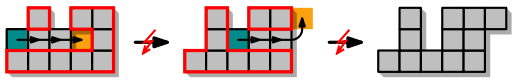


Figure 3 Moving non-free modules causes disconnections and makes transformations illegal.

Secondly, a transformation is collision-free exactly if all modules can move along their designated path at a constant rate, completing it in unit time without overlapping with any other module in the process. We illustrate a partial selection of collisions in Figure 4. Similar to the sequential variant, the defined moves and transformations are reversible, i.e., if for any transformation $C_1 \to C_2$, there exists an inverse transformation $C_2 \to C_1$.

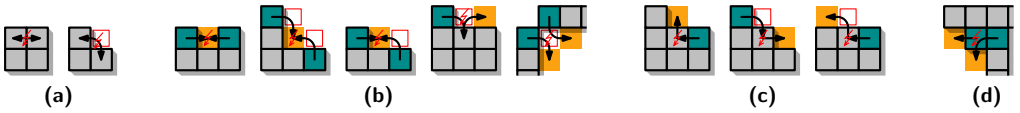

Figure 4 Collisions: (a) Modules cannot swap places or (b) enter the same cell simultaneously, (c) moves cannot meet at endpoints orthogonally, and (d) speed mismatches must be avoided.

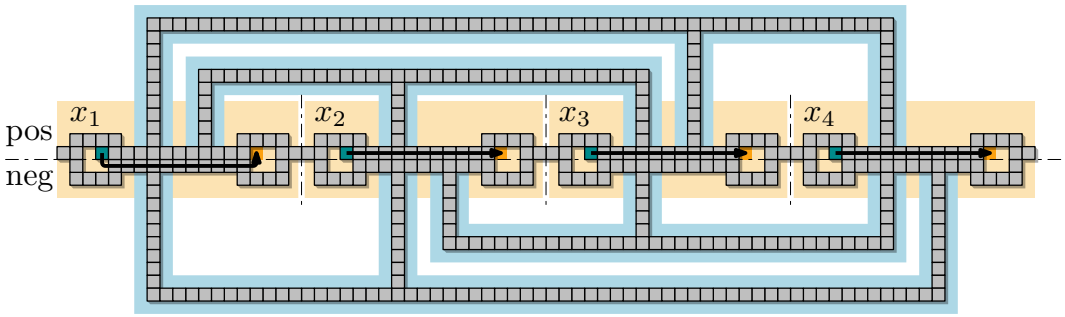
Problem statement. The Parallel Sliding Squares problem, asks for the connected reconfiguration of modules in the infinite integer grid by legal transformations, with an *instance* $\mathcal{I}$ being composed of two configurations (C_1, C_2) of n modules. A schedule is *feasible* for $\mathcal{I}$ if and only if it transforms C_1 into C_2. The *makespan* of a schedule is the number of transformations in it. The decision problem for Parallel Sliding Squares asks, given an instance $\mathcal{I}$ and $k \in \mathbb{N}^+$, whether there is a feasible schedule for $\mathcal{I}$ with makespan at most k.

Labeled problem variant. In the case of distinguishable (or *labeled*) modules, we speak of the Labeled Parallel Sliding Squares problem. This variant uses the exact same move set and collision constraints as the unlabeled variant, but configurations are now mappings between $[n]$ and $\mathbb{Z}^2$ rather than subsets thereof. This allows us to specify individual target positions and track the movement of individual modules across transformations.

Useful notation. Throughout this paper, we make use of cardinal and ordinal directions. In particular, the unit vector $(1, 0)$ points *east*, $(0, 1)$ points *north*, and their opposite vectors point *west* and *south*, respectively. For an illustration, see Figure 2(a). Throughout this paper, we use B_1 and B_2 to denote the bounding boxes of C_1 and C_2, respectively. We assume, as in the literature [25], that B_1 and B_2 share a south-west corner at $(0, 0)$.

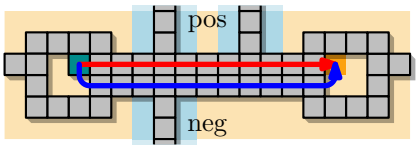
We define the (open) neighborhood $N(c)$ of a cell c as the set of cells that are edge-adjacent to c, and the closed neighborhood $N[c]$ as $N(c) \cup \{c\}$. We abuse notation to express neighborhoods of sets of cells as $N[S] = \bigcup_{c \in S} N[c]$ and $N(S) = N[S] \setminus S$. Analogously, define $N^*(S)$ (resp., $N^*[S]$) as the open (resp., closed) neighborhood using vertex-adjacency.

A feasible schedule for $\mathcal{I}$ is (*strictly*) *in-place* (as defined in [4, 25]) if and only if no intermediate configuration exceeds the union $B_1 \cup B_2$ by more than one module. We relax this constraint slightly and say that a schedule is *weakly in-place* if no intermediate configuration exceeds the union $B_1 \cup B_2$ by more than a constant number of units. Note that we do not restrict the number of modules located outside the union, only their distance to it. This corresponds to a slightly more restricted variant of the definition used in [1].



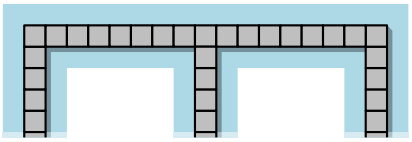
3 Computational complexity

We provide a number of complexity results for Parallel Sliding Squares, which are complementary to the NP-completeness result obtained by the authors of [4] for the sequential variant of this problem. This highlights a previously unrecognized gap in complexity, compared to closely related models for parallel, connected reconfiguration without the connected backbone constraint. In particular, in the related model studied in [16, 18], deciding the existence of schedules of makespan 2 is NP-complete, while makespan 1 is in P. We give a high-level description of our construction for the unlabeled case and refer to the full version [5] for technical details, as well as the labeled problem variant.



▶ **Theorem 1.** *Let $\mathcal{I}$ be an instance of Parallel Sliding Squares. It is NP-complete to decide whether there exists a feasible schedule of makespan 1 for $\mathcal{I}$.*

We reduce from the NP-complete problem Planar Monotone 3Sat [11], which asks whether a Boolean formula in conjunctive normal form is satisfiable. Each clause consists of at most 3 literals, all either positive or negative, and the clause-variable incidence graph must admit a plane drawing where variables are mapped to the x-axis, positive (resp., negative) clauses are mapped to the upper (resp., lower) half-plane, and edges do not cross the x-axis.



Our reduction starts with a rectilinear embedding of the clause-variable incidence graph of an instance φ of Planar Monotone 3Sat and constructs an instance $\mathcal{I}_\varphi$ of Parallel Sliding Squares using *variable* and *clause gadgets*. We then argue that φ can be satisfied if and only if there is a single parallel transformation that solves $\mathcal{I}_\varphi$. For a formula φ over m variables with k clauses, we create m copies of the variable gadget in a horizontal line, directly adjacent to one another. The literals in each monotone positive (negative) clause are then connected to by a clause gadget placed above (below) the horizontal line of variables. A simple example of our construction is depicted in Figure 5(a).

(a) Our construction for $\varphi = (x_1 \vee x_3 \vee x_4) \wedge (x_1 \vee x_2 \vee x_3) \wedge (\overline{x_1} \vee \overline{x_2} \vee \overline{x_4}) \wedge (\overline{x_2} \vee \overline{x_3} \vee \overline{x_4})$. The depicted transformation represents the satisfying assignment $\alpha(\varphi) =$ (`true`, `false`, `false`, `false`).

(b) Variable gadget (blue/red ≡ `true`/`false`).

(c) Clause gadget.

Figure 5 An overview of our hardness reduction and the two types of gadget used.

Variable gadget. The variable gadget consists of two cycles of 12 modules each, the left containing an additional module in its interior, see Figure 5(b). These circles are connected by a solid, horizontal *assignment strip* of height 2, to which individual clause gadgets (blue) are connected. In the target configuration, the extra module is located in the other circle. There are two feasible transformations, each representing either a `true` or `false` value assignment.

Clause gadget. The clause gadget consists of a thin horizontal strip that spans the gadgets of variables contained in the clause, and (up to) three vertical prongs that connect to the assignment strips of the incident variable gadgets. No squares move here, see Figure 5(c).

Due to the way in which both configurations are connected, the schedules depicted in Figure 5(b) locally sever the direct connection between the variable gadget and either all its positive or negative clauses. Thus, a satisfying assignment maps to a feasible transformation.

▶ **Corollary 2.** *Parallel Sliding Squares is* APX*-hard and cannot be approximated within a factor better than* 2 *in polynomial time unless* P = NP.

4 A worst-case optimal algorithm

In this section, we introduce a three-phase algorithm for efficiently reconfiguring two given configurations into one another. Our approach computes reconfiguration schedules linear in the perimeter P_1 and P_2 of the bounding boxes B_1 and B_2 of C_1 and C_2, respectively.

▶ **Theorem 3.** *For any instance $\mathcal{I}$ of Parallel Sliding Squares, we can compute a feasible, weakly in-place schedule of $\mathcal{O}(P_1 + P_2)$ transformations in polynomial time.*

Our algorithm consists of three phases as depicted in Figure 6: In **Phase (I)**, we identify a subconfiguration used as a "backbone" (similar to [21]), and gather $\Theta(P_1)$ many modules around a piece of this backbone, thereby enhancing its connectivity (as in [4]). We use the flexibility of this piece to construct a sweep-line structure out of meta-modules in **Phase (II)**, that is then used in **Phase (III)** to efficiently compact and transform the remaining modules into grid-aligned 3×3 squares, creating a 3-scaled configuration. In general, a configuration is *c-scaled* exactly if it is composed of $c \times c$ squares that are aligned with a corresponding $c \times c$ integer grid. By generalizing techniques from [16], we can reconfigure these efficiently:

▶ **Theorem 4.** *For any 3-scaled instance $\mathcal{I}$ of Parallel Sliding Squares, we can compute a feasible, in-place schedule of $\mathcal{O}(P_1 + P_2)$ transformations in polynomial time.*

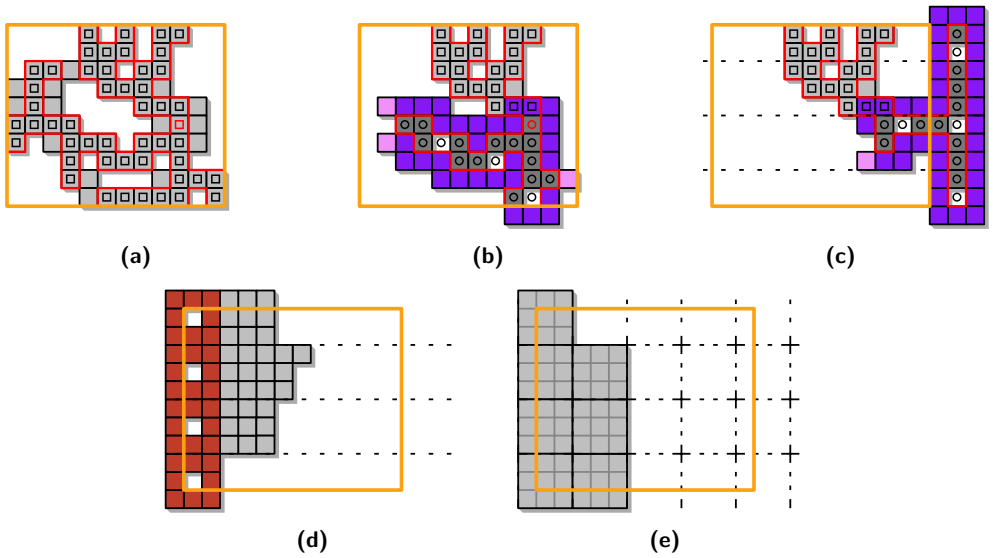


Figure 6 The high-level overview of our approach. (a) Initial configuration and (b), (c) and (e) are the result of Phases **(I–III)**, respectively. (d) shows an intermediate configuration in Phase **(III)**.

To reach our target configuration, we then simply apply **Phases (I-III)** in reverse. Although several of our techniques are inspired by previous work, they differ substantially in our context of parallel reconfiguration and considerable changes were needed.

▶ **Lemma 5.** *The bounds achieved in Theorem 3 are asymptotically worst-case optimal.*

Proof. Assume that n is even and consider two configurations C_1, C_2 contained in an $n/2 \times n/2$ bounding box B. Define C_1 to contain the $n-1$ modules adjacent to the left and bottom edges of B and a module at $(1,1)$. Define C_2 to contain the $n-1$ modules adjacent to the top and right edges of B and a module at $(n/2-1, n/2-1)$. Then, the minimum bottleneck matching between full cells in C_1 and C_2 has bottleneck $\Omega(n)$, implying that a module must make $\Omega(n)$ moves. The makespan is then $\Omega(n) = \Omega(P)$, where P is the perimeter of B. ◀

4.1 Phase (I): Gathering squares

In **Phases (I)** and **(II)**, we use an underlying connected substructure (called *skeleton*) of the initial configuration to guide the reconfiguration. Intuitively (formal definitions below), this tree-like skeleton functions as a backbone around which we move modules toward a "root" module, making a subtree "thick" (where the cells in the neighborhood of part of the skeleton are all full). This "thick" subskeleton is more "manipulable", making it easier to mold it into a sweep line in **Phase (II)**. Moving modules around a tree is an idea also used by the authors of [21]. This type of strategy becomes complicated when the tree creates bottlenecks where potential collisions happen, which they solve by strengthening the model and allowing modules to "squeeze through" bottlenecks. We achieve a stronger result in the classic sliding model via careful definition of the tree-like structure and movement schedules.

Skeleton. We define the *skeleton* of a configuration C as a valid subconfiguration S such that: $C \subset N[S]$ (every module of C is either contained in S or edge-adjacent to a module of S); and cycles in the dual graph of S are pairwise disjoint with length at most 4. We call a module in S (resp., not in S) a skeleton (resp., nonskeleton) module. In Figure 6(a), skeleton modules are highlighted with an internal square and the perimeter of the skeleton is shown in red. Note that any set of nonskeleton modules is free.

On a high level, we can compute a skeleton S of a given configuration C as follows. Think of S as a subset of C, initialized as the empty set. Modules of C are then algorithmically added to S until it satisfies the definition of a skeleton. First, all modules with even x-coordinate are added to S, then all modules with odd x-coordinate with no east and west neighbors. Next modules are added to S until it is a connected subconfiguration of C (see magenta squares in Figure 6(a)). This might introduce large cycles (greater than length 4) to S. These cycles are broken via removal of modules from S or exchanging adjacent modules. We show that careful execution of these steps will build S into a skeleton of C.

Equipped with a skeleton S, we now consider its dual graph. Contracting every cycle in the dual of S to a single vertex renders a max-degree-4 tree where each node is either a cell or a 4-cycle. We refer to the nodes of this tree as *nodes of* S and abuse notation by referring to S as a tree. Let r be the *root* node of S, arbitrarily chosen. For every nonskeleton module, we assign an adjacent module of S as its *support*. We define the *subskeleton rooted at* c (denoted S_c) as the subconfiguration containing c and its descendant nodes. The set S_c^* contains the modules in S_c and the nonskeleton modules supported by modules in S_c. The *weight* of a subskeleton S_c is defined as $|S_c^*|$. By definition, $S_r^* = C$ and $|S_r^*| = n$.

▶ **Lemma 6.** *Given a rooted skeleton S and an integer $1 < w \leq n$, there exists a node c of S such that $w \leq |S_c^*| \leq 3w$.*

Using this, we locate a module $h \in S$ (highlighted with a red marker in Figures 6(a) and 6(b)) such that $|S_h^*| \in \Theta(P)$. Afterwards, we "thicken" S_h^* into a structure called the *exoskeleton*.

Exoskeleton. An exoskeleton is made from three types of modules: *core*, *shell*, and *tail* modules; depicted respectively in dark gray, purple and pink in the figures. Recall that we wish to make the neighborhood of S_h is full. The core modules occupy the positions originally occupied by the skeleton S_h, the shell modules are the ones "coating" the skeleton, and the tail modules are "leftover" modules in the neighborhood of a leaf. We recursively thicken S_h by applying this process to its smaller subtrees, effectively converting tail or core modules at the leaves into a shell module near the root. If the core modules cover the entire subtree of S_h, it may take a linear number of transformations to move a module from a leaf

to the root. Instead, we allow empty positions inside the exoskeleton which permits us to "teleport" a module from a leaf to the root in $\mathcal{O}(1)$ transformations. Although some of the positions are empty, the structure remains connected due to its shell and the fact that these empty positions are well separated (in tree metric along S_h, see Property 4 below).

Formally, we define an *exoskeleton* X_c as follows. The *core* $\overline{X_c}$ of X_c are positions in the lattice (not necessarily full) that form a subtree of S_c containing c (since we recursively "shave off" leaves to make material for the shell). Note that $\overline{X_c}$, unlike S_c, is not a subgraph of the configuration's dual graph because of the empty positions. In our figures, we highlight core cells with an internal circle. Let $\mathcal{L}$ be the set of positions corresponding to the leaves of $\overline{X_c}$. We call $N^*(\overline{X_c} \setminus \mathcal{L}) \setminus \mathcal{L}$ the *shell* of X_c (recall $N^*(S)$ is the open neighborhood under vertex-adjacency). The following must hold:

1. All modules in X_c are in the neighborhood of its core. ($|\overline{X_c}| \geq 2$, and $X_c \subset N^*\left[\overline{X_c}\right]$.)
2. The leaves are occupied. ($\mathcal{L} \subset X_c$.)
3. All cells in the shell are occupied. ($N^*(\overline{X_c} \setminus \mathcal{L}) \setminus \mathcal{L} \subset X_c$.)
4. The depth (in $\overline{X_c}$) of every empty cell is congruent to k (mod 4) for a fixed $k \in \{0, 1, 2, 3\}$.

Figure 7 Visualizing an exoskeleton. (a) Skeleton and core cells are highlighted with an inner square and circle, respectively. (b) Highlights the core; the root is highlighted with a red circle.

The modules that are in $N^*(\ell)$, for a leaf $\ell \in \mathcal{L}$, and not in the shell or core of X_c are called the *tail* modules of ℓ. By definition, a module in X_c is either in the shell, in the core, or is a tail module. Shell modules protect the connectivity of X_c, allowing us to place empty positions in the core wherever necessary to expand the exoskeleton constant time.

We show that S_h can be reconfigured into an exoskeleton X_h in $\mathcal{O}(P)$ transformations, thereby inductively establishing Lemma 9. To this end, we first prove Lemma 7, demonstrating how small skeletons (lighter than 9) are turned into exoskeletons. In doing so, we obtain Corollary 8, which settles the base case of our induction. Lemma 7 will also be pivotal in the inductive step. All that this lemma does is take a subskeleton of weight ≤ 9 and transform it into a 3×3 square, a minimal instance of an exoskeleton ($|X_c| = 2$).

▶ **Lemma 7.** *Let C be a configuration with skeleton S in which potentially some of its subskeletons were reconfigured into exoskeletons. Let c be a skeleton node, with parent node d, such that S_c is not yet part of an exoskeleton and $|S_c^*| \leq 9$. Let M be the set of modules in S_c^* that are not contained in exoskeletons. Then, in $\mathcal{O}(1)$ transformations, M can be reconfigured so that:*

- *if $\deg(d) = 2$, either $N^*[d]$ is full or $M \cap (N^*[c] \setminus N^*[d])$ is empty (i.e., the modules in M are all contained in the neighborhood of d if this region is not full);*
- *if $\deg(d) > 2$, either $N^*[d] \cap N^*[c]$ is full or $M \cap (N^*[c] \setminus N^*[d])$ is empty (i.e., the modules in M are all contained in the intersections of the neighborhood of d and c if this region is not full).*

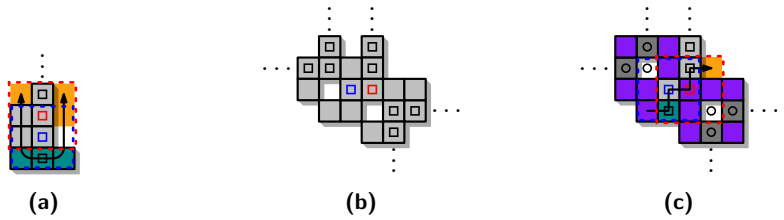

Figure 8 Illustration of Lemma 7. Modules d and c are highlighted with inner red and blue squares. The boundaries of $N^*[d]$ and $N^*[c]$ are shown with dashed red and blue lines.

At first glance, the lemma might seem overly complicated, since without any obstacle, modules can freely move along the perimeter of S (see Figure 8(a)). However, nonlocal pieces of the skeleton (connected subsets S_1 and S_2 of S are *local* if $S \cap N^*(S_1 \cup S_2)$ is connected) previously converted to exoskeletons can interfere when processing later subskeletons. Figures 8(b) and 8(c) show a configuration before and after two nonlocal pieces of the skeleton were converted into exoskeletons. Modules in the working subskeleton S_c might be part of the shell of another exoskeleton, making their movement dangerous (potentially disconnecting the nonlocal exoskeletons). We try to leave such modules in their place, changing their membership from S_c^* to the shell of the exoskeleton.

By applying Lemma 7 a constant number of times in appropriate subskeletons, we eventually obtain a solid 3×3 square from which we can construct an exoskeleton.

▶ **Corollary 8.** *Given a subskeleton S_c with $9 \leq |S_c^*|$, we can reconfigure S_c^* transforming one of its subskeletons into an exoskeleton in $\mathcal{O}(1)$ many transformations, without changing other exoskeletons or modules not in S_c^*.*

Corollary 8 provides the base case of our induction for Lemma 9. We now establish some routines for the inductive step. We assume there is a module $d \in S_h$ so that for every child c of d, S_c^* was reconfigured to an exoskeleton X_c satisfying Property 4 with $k = 0$. If $N^*[d]$ is full, we can finish by making d the root of the exoskeleton, effectively merging the children exoskeletons. Note that this will necessarily happen if d had degree 4 and is not part of a 4-cycle. Thus, assume that there is an empty position $e \in N^*[d]$. We apply a routine Inchworm-Push that fills e with local moves, using a module initially in the core of the exoskeleton X_c (making that cell empty). The routine Inchworm-Pull then moves core modules higher (in tree metric) pushing empty positions deeper until they "exit" the exoskeleton at leaves. Again, ignoring nonlocal interactions, these operations are straightforward. However, in the general case, these interactions mandate extra care.

- Inchworm-Push: Let c be a child of d, and p be the parent of d. Require that $N^*[c]$ is full. We branch into cases. (i) If c, d, and p are collinear, there is a path π in $N^*(d)$ from c to e going through only occupied cells, see Figure 9(a); (ii) If c, d and p form a bend, there is a path π in $N^*[d]$ from c to e going through d and at most one nonskeleton module, see Figures 9(b) and 9(c); (iii) In analogous cases to (i–ii), if a node in $\{c, d, p\}$ is a 4-cycle, there is a path π in $N^*(d)$ from a module in c to e going through one module in the shell of X_d, depicted in Figure 9(d). For all cases, move the modules along π making e occupied and c empty. This requires at most two transformations since there is at most one collision along π and we can decompose π into two paths with no collisions.
- Inchworm-Pull: The operation consists of four stages, each involving at most two transformations. For every empty cell p in the core, select one of its children q arbitrarily, and let $x(q)$ be its x-coordinate. Move the module from q to p in stage $j \in \{1, 2, 3, 4\}$ if

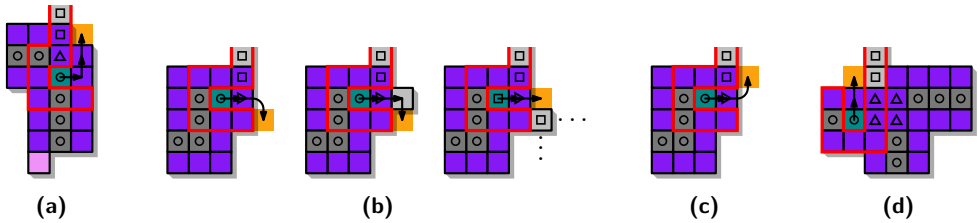

Figure 9 Inchworm-Push. Module c is colored turquoise, cell e is yellow, and d is highlighted with an inner triangle. The red curve encloses a subconfiguration around the moves that remains connected guaranteeing that the transformations do not disconnect the configuration.

$x(q) \equiv j \pmod 4$. Figure 10(a) gives two examples, in one of which p is a 4-cycle (that takes two transformations). If q is a leaf, if there is a tail module of q that is originally in S_c^* and not in another exoskeleton, move such a module to q, visualized in Figures 10(b) and 10(c). If there are no more tail modules we can update $\overline{X_c}$ by deleting q which causes the tail module that just moved to become a shell module, see Figure 10(b), or causes two shell modules to become tail modules as in Figure 10(c).

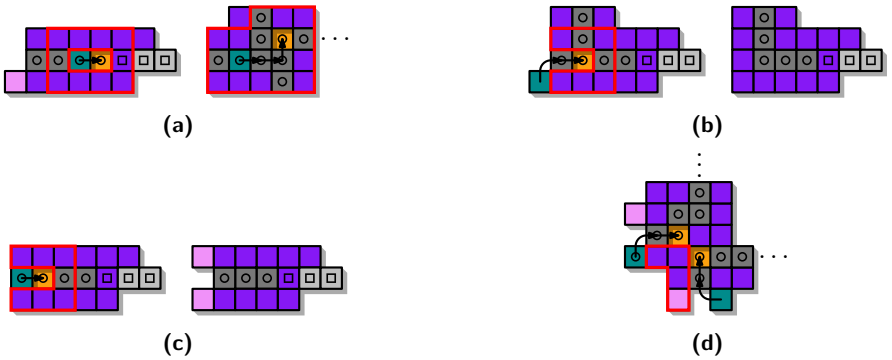

Figure 10 Inchworm-Pull. Module q is colored turquoise and empty cell p is yellow.

The reason we stagger the moves into four stages in Inchworm-Pull is to guarantee that the configuration contains enough static modules around a move. Otherwise, performing all moves in a single transformation might disconnect the configuration, as shown in Figure 10(d). In the full version [5], we argue that Inchworm-Push and Inchworm-Pull preserve connectivity and require only $\mathcal{O}(1)$ transformations. To establish local connectivity of the static modules in the neighborhood of each move, we rely on Properties 3–4.

▶ **Lemma 9.** *Given a configuration C with skeleton S, and a skeleton node d with $|S_d^*| \geq 9$, $\mathcal{O}(|S_d^*|)$ transformations are sufficient to reconfigure S_d into an exoskeleton X_d.*

Proof. If a subskeleton of S_d does not contain an exoskeleton, we can apply Corollary 8. If, after that, S_d is not the core of an exoskeleton X_d, we apply induction. Let Q be the set containing the children of d. For every child $c \in Q$ with $|S_c^*| \geq 9$ we can get an exoskeleton X_c in $\mathcal{O}(|S_c^*|)$ transformations by inductive hypothesis. For every child $c \in Q$ with $|S_c^*| < 9$, we apply Lemma 7 that either results in an exoskeleton X_c, or results in deleting c from S "compacting" all its modules in $N^*[c] \cap N^*[d]$. If after that $N^*[d]$ is not full, $N^*[d]$ contains at most three empty cells if d is a degree-2 bend in S, at most two empty cells if d is a "straight" degree-2 in S, or at most 1 empty cell if d has degree 3. (Note that if d has degree 4

and is not a 4-cycle, then $N^*[d]$ is full.) For each of these empty cells, we can fill them by applying Inchworm-Push followed by at most four applications of Inchworm-Pull to ensure that $N^*[c]$ is full for all children c of d while maintaining Property 4. This takes at most $\mathcal{O}(1)$ transformations. When $N^*[d]$ is full, the configuration contains an exoskeleton X_d except for the "4-arity" of the empty positions (Property 4). That can be resolved by applying Inchworm-Pull to X_c at most three times for each child c of d. ◀

By Lemma 6, we can choose an appropriately heavy node d of S to obtain:

▶ **Corollary 10.** *Let C be a configuration with bounding box perimeter P. We can reconfigure C so that it contains an exoskeleton X_h with $\geq 36P$ modules in $\mathcal{O}(P)$ transformations. All modules stay within $\mathcal{O}(1)$ distance from the bounding box of C.*

4.2 Phase (II): Scaffolding

Phase (I) of our algorithm recursively constructed a sufficiently large exoskeleton X_h that is now reconfigured in **Phase (II)**. The goal of this reconfiguration is to create a $\dashv$ -shaped exoskeleton, with its vertical segment precisely aligned along the right boundary of the bounding box. This vertical edge will serve as the sweep line in **Phase (III)**.

Phase (II) of our approach consists of the following three steps:

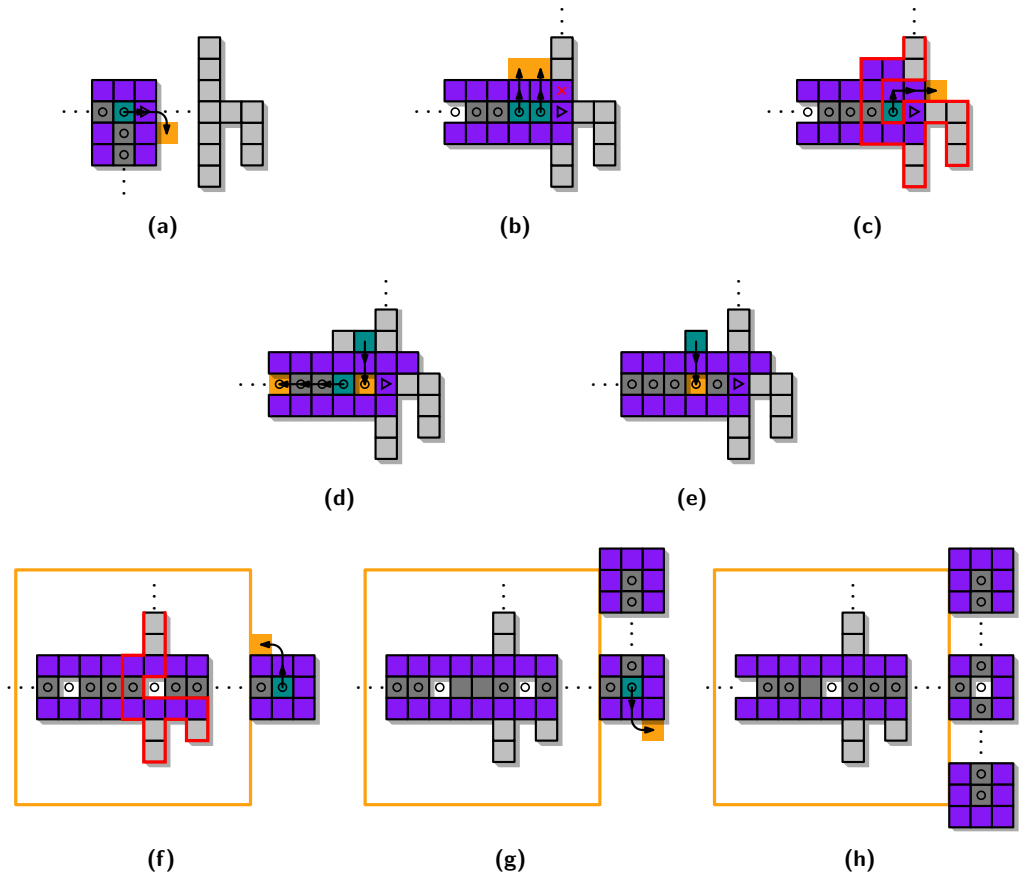
1. First "compact" X_h so that its core contains no empty cells.
2. We then choose a rightmost node c in the core of X_h and use Inchworm-Push and -Pull to grow a horizontal path from c rightward, until a 3×3 square is formed outside the bounding box, see Figures 11(a)–11(f).
3. Use Inchworm-Push and -Pull to grow the path upwards until it hits the top of the bounding box, then grow a path downwards until it hits the bottom of the bounding box, see Figures 11(f)–11(h).

We make sure that X_c always contains h so that it maintains connectivity with the subset of S that was not transformed into an exoskeleton. We can show that the connectivity properties of exoskeletons allow us to "go through" obstacles (sections of S that remained untouched in **Phase (I)**), see Figures 11(a)–11(f). That may require some extra moves as shown in Figure 11(b), where an Inchworm-Push would move the cut vertex marked with a red $\times$. In such cases, we sequentially fill in up to two cells in the neighborhood of X_c (yellow in Figure 11(b)), making all modules in π (from the definition of Inchworm-Push) noncut.

4.3 Phase (III): Creating scale

Once **Phase (II)** concludes, we are left with an intermediate configuration that contains a scaffold structure along its east boundary, recall Figure 11(h). In the remaining phase, we use this scaffold to obtain a 3-scaled configuration that can be arbitrarily reconfigured due to Theorem 4. To build squares in an efficient manner, we modify part of the exoskeleton structure created during **Phase (II)**, creating a vertical line of 3×3 meta-modules.

Sweep line. We define a scaffold structure composed of *meta-modules*, each consisting of eight modules occupying the open vertex-neighborhood of a common center cell v, i.e., one in every cell of $N^*(v)$ as shown in Figure 12(a). A *sweep line* $\ell \subset C$ is then a valid subconfiguration formed by the union of h disjoint meta-modules $M_1, \ldots, M_h$ with identical x-coordinates such that ℓ spans the full height of the bounding box of $C \setminus \ell$. Let v_i now refer to the center cell of M_i, such that $y(v_i) < y(v_j)$ exactly if $i < j$, see Figures 12(b) and 12(c).



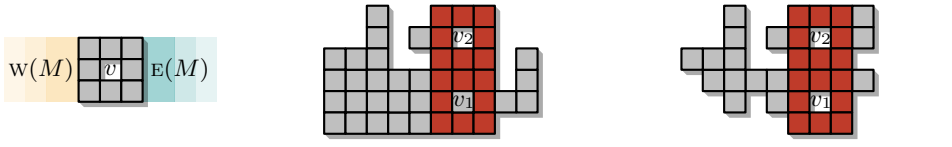


Figure 11 Building the scaffolding; bounding box of the initial configuration is shown in yellow.

For each meta-module M in a sweep line $\ell \subseteq C$, we define as its east and west strips as the cells which share a y-coordinate with one of its modules and are located within the bounding box of the full configuration C. We denote these by $\textsc{e}(M)$ and $\textsc{w}(M)$, respectively, and refer to their union for ℓ, e.g., $\textsc{w}(\ell)$. We use these to define the following characteristics.

A sweep line ℓ is *clean* exactly if every meta-module M_i either has an empty center cell v_i, or its respective west strip is fully occupied, i.e, $\textsc{w}(M_i) \subseteq C$. See Figure 12(b) for an illustration. Analogously, we call ℓ *solid* if all center cells of its meta-modules are occupied.

Furthermore, we say that is ℓ a *separator* if for every meta-module M_i in ℓ:

1. The east strip $\textsc{e}(M_i)$ does not contain modules unless all cells in $\textsc{w}(M_i)$ are full.
2. The modules in $\textsc{e}(M_i)$ are located in its x-minimal cells, thus forming a 3 cell tall rectangle with at most two additional "loose" modules.

(a) A meta-module M. **(b)** A clean sweep line (red). **(c)** A separator sweep line (red).

Figure 12 Sweep lines are formed by vertical stacks of meta-modules.

We start by transforming part of the exoskeleton from **Phase (II)** into meta-modules that form a sweep line at the eastern boundary of B.

▶ **Lemma 11.** *The vertical portion of the "⊣-shaped" exoskeleton in C can be made into a separator sweep line in $\mathcal{O}(1)$ transformations.*

This gives us a separator sweep line ℓ that is not necessarily clean or solid, located at the east edge of the configuration's bounding box B. Our goal is to move ℓ towards the west edge of B while maintaining its separator property, compacting all encountered modules into 3-tall strips in the process. We define two procedures that suffice to reach this goal.

Intuitively, the Advance operation provides a schedule that translates a sweep line by one unit to the west, and the Clean operation replaces a given sweep line with a clean one. To efficiently parallelize these operations, we split the sweep line into *leading* and *trailing* meta-modules such that M_i is trailing exactly if i is odd, and leading otherwise. At any given time, either the leading or the trailing meta-modules are active, but never both.

By repeatedly alternating between the Advance and Clean operations, we create a configuration with a clean separator sweep line that has an empty west half-space, see Figure 13.

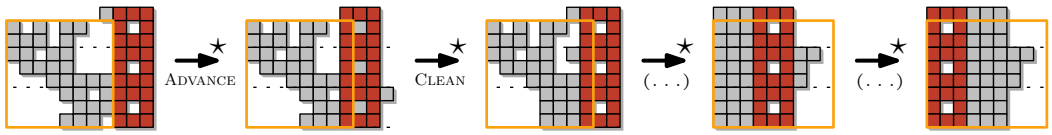

Figure 13 We alternate between the Advance and Clean operations until $\mathrm{w}(\ell) \cap C = \varnothing$.

We first argue the Clean operation can be performed in constantly many transformations. Let M_i be an active meta-module with an occupied center cell. On a high-level, we consider a rectangle induced by occupied cells in west direction within its strip. It is easy to see that we can fill an empty position immediately adjacent to this rectangle, while also cleaning the center cell of M_i by at most two subsequent transformations. By doing this for leading and trailing meta-modules separately, we conclude the following lemma.

▶ **Lemma 12.** *A configuration C with a sweep line ℓ can be cleaned by 4 strictly in-place transformations, without moving any modules east, or exceeding the bounding box B of C.*

It remains to argue that the same is true of the Advance operation. For this, we consider the three positions immediately west of an active meta-module, and distinguish eight cases based on occupied and empty cells. For all of them, we define local transformation schedules that enable us to move a meta-module one step to the east. Thus, we obtain:

▶ **Lemma 13.** *A configuration C with a clean separator sweep line ℓ can be advanced into a clean separator sweep line by $\mathcal{O}(1)$ strictly in-place transformations if $C \cap \mathrm{w}(\ell) \neq \{\varnothing\}$.*

After no more than $\mathcal{O}(P)$ many iterations consisting of Clean+Advance, we obtain a state in which $\mathrm{w}(\ell) \cap C = \varnothing$. The separator property implies that the modules in $\mathrm{e}(\ell)$ form 3-wide, horizontal stacks. It remains to show that we can make this configuration 3-scaled.

To simplify our arguments, assume that n is a multiple of nine. In the general case, n can exceed a multiple of nine by at most 8 modules. We can place these at the south-west corner of the extended bounding box B' and locally ensure the existence of a connected backbone during each transformation.

▶ **Lemma 14.** *Let C contain a clean separator sweep line ℓ with an empty west half-space. Then C can be transformed into a 3-scaled configuration in $\mathcal{O}(P)$ transformations.*

On a high level, we achieve this by filling the center cells of all meta-modules and balancing the remaining modules between their east strips such that each contains a multiple of nine. Having constructed a 3-scaled configuration, we can arbitrarily reconfigure due to Theorem 4 before applying **Phases (I-III)** in reverse to obtain our target configuration.

5 Conclusions and future work

We have presented several new results for reconfiguration in the sliding squares model, making full use of parallel motion. In particular, we showed that deciding whether there exists a single transformation that reconfigures one configuration into another is already NP-complete. Additionally, we provided algorithmic results for the unlabeled variant, including a polynomial-time algorithm that performs in-place reconfiguration in $\mathcal{O}(P)$ transformations, where P denotes the perimeter of the union of the configurations' bounding boxes.

We note that this algorithm can easily be adapted to the labeled setting by "sorting" the modules in the xy-monotone configuration using $\mathcal{O}(P)$ transformations. However, this requires a relaxation of the in-place requirement. Furthermore, deciding whether a schedule of makespan 1 exists in the labeled setting is straightforward, while the problem becomes NP-complete for a makespan of 2. Details on these results are provided in the full version [5].

Our algorithmic results are only worst-case optimal, and there are a number of possible generalizations and extensions of the setting. Previous work in the sequential setting has progressed from two dimensions to three. Can our approach be extended to higher dimensions? We are optimistic that significant speedup can be achieved, but the intricacies of three-dimensional topology may require additional tools.

Another aspect is a refinement of the involved parameters, along with fixed parameter tractability. Our hardness proofs show that the investigated problems are not FPT when parameterized by the number of transformations in the output. The number of modules in the input configuration is not a suitable parameter since it is the input size. Are there other parameters for which these problems are FPT? An interesting candidate would be the size of the symmetric difference between the two input configurations. In our hardness proofs, the size of the symmetric difference is linear on the size of the SAT instance.

Abstract

A dominating set of a graph $G = (V, E)$ is a set of vertices $D \subseteq V$ whose closed neighborhood is V, i.e., $N[D] = V$. We view a dominating set as a collection of tokens placed on the vertices of D. In the token sliding variant of the Dominating Set Reconfiguration problem (TS-DSR), we seek to transform a source dominating set into a target dominating set in G by sliding tokens along edges, and while maintaining a dominating set all along the transformation.

TS-DSR is known to be PSPACE-complete even restricted to graphs of pathwidth w, for some non-explicit constant w and to be XL-complete parameterized by the size k of the solution. The first contribution of this article consists in using a novel approach to provide the first explicit constant for which the TS-DSR problem is PSPACE-complete, a question that was left open in the literature.

From a parameterized complexity perspective, the token jumping variant of DSR, i.e., where tokens can jump to arbitrary vertices, is known to be FPT when parameterized by the size of the dominating sets on nowhere dense classes of graphs. But, in contrast, no non-trivial result was known about TS-DSR. We prove that DSR is actually much harder in the sliding model since it is XL-complete when restricted to bounded pathwidth graphs and even when parameterized by k plus the feedback vertex set number of the graph. This gives, for the first time, a difference of behavior between the complexity under token sliding and token jumping for some problem on graphs of bounded treewidth. All our results are obtained using a brand new method, based on the hardness of the so-called Tape Reconfiguration problem, a problem we believe to be of independent interest.

We complement these hardness results with a positive result showing that DSR (parameterized by k) in the sliding model is FPT on planar graphs, also answering an open problem from the literature.

1 Introduction

The *combinatorial reconfiguration* framework aims to investigate algorithmic and structural aspects of the solution space of an underlying *base problem*. For instance, given an instance of some base problem along with two feasible solutions, i.e., the source and target feasible solutions, the goal is to determine if (and in how many steps) one can transform the source to the target via a sequence of adjacent feasible solutions. Such a sequence is called a *reconfiguration sequence* and every step in the sequence (going from one solution to an adjacent one) is called a *reconfiguration step*. Reconfiguration problems arise in various fields such as combinatorial games, motion of robots, random sampling, and enumeration. It has been extensively studied for various rules and types of (base) problems such as satisfiability [25, 37], graph colorings [11, 19], vertex covers and independent sets [29, 30, 34] and matchings [12]. The reader is referred to the surveys [39, 40, 18] for a more complete overview of the field.

An alternative view of reconfiguration problems is via the notion of so-called (re)configuration graphs. Let Π be a base problem and let $\mathcal{I}$ be an instance of Π. The *configuration graph* $\mathcal{R}_\mathcal{I}$ is a graph whose nodes correspond to feasible solutions of $\mathcal{I}$ and in which two solutions are adjacent if and only if we can transform the first into the second in a single reconfiguration step. In this paper, we focus on the reachability question that asks, given two solutions S, S' of $\mathcal{I}$, whether there exists a reconfiguration sequence from S to S'. In other words, does there exist a path between S and S' in the configuration graph. Other works have focused on different problems such as the connectivity of the configuration graph or the diameter of its connected components; see, e.g. [15, 25].

A *dominating set* of a graph $G = (V, E)$ is a set of vertices $D \subseteq V$ such that $N[D] = V$. That is, the union of the closed neighborhoods of vertices of D *spans* V. The Dominating Set (DS) problem, i.e., deciding whether a graph contains a dominating set of size at most k, is one of the fundamental NP-complete problems [33]. By now, both the classical and parameterized complexity of the problem are very well understood especially when restricted to sparse graph classes and even when considering various possible parameterizations [22, 20, 2, 3]. In particular, and relevant to this work, Dominating Set is fixed-parameter tractable (FPT) parameterized by the size of the solution in nowhere-dense classes of graphs [20].

In the rest of this section, we informally state our results and put them into context. In Section 2.1, we introduce the main problem from which we will derive our results and state the hardness result we obtain for it. In Section 2.2, we explain the consequences of this result for Dominating Set Reconfiguration (DSR) and in Section 2.3, we state our main positive results.

Token jumping vs. token sliding. The main focus of this paper is to study the parameterized complexity of reconfiguration problems restricted to sparse classes of graphs and in particular the case of Dominating Set Reconfiguration, or DSR for short. There are three different natural adjacency relations one can consider between dominating sets, which gave rise to

three different models in the literature; namely the token jumping (TJ) model, the token sliding (TS) model, and the token addition/removal (TAR) model. Since the TAR model is known to be polynomially equivalent to the TJ model [13], we only discuss the other two.

In the *token jumping* model, we say that two solutions S, S' are *adjacent* if both $S \setminus S'$ and $S' \setminus S$ have size at most one. In other words, we can remove a vertex of S and add a vertex of S' to transform S into S'. In the token view of the problem, we say a token *jumps* from some vertex u to another (possibly already occupied) vertex v. In the *token sliding* model, we additionally require that $uv \in E$, i.e., the vertices u and v must be adjacent, and the token is said to *slide* on the edge uv from u to v. We shall use TS-Π and TJ-Π to denote the reconfiguration variant of problem Π under the token sliding and token jumping model, respectively. For instance, TS-DSR corresponds to DSR in the token sliding model and TJ-DSR corresponds to DSR in the jumping model.

TJ-DSR is known to be PSPACE-complete on split graphs, bipartite graphs [13, 27, 32], and planar graphs of maximum degree 3 [29] and bounded-bandwidth graphs [42][1]. On the positive side, linear-time algorithms are known for trees, interval graphs, and cographs. As for TS-DSR, the problem is known to be PSPACE-complete on circle graphs [16], split graphs [13], bipartite graphs [13], and planar bounded-bandwidth graphs of maximum degree three [42]. Polynomial-time algorithms for TS-DSR are known for circular-arc graphs, dually chordal graphs, and cographs [28, 13, 16, 4].

Even though both TS-DSR and TJ-DSR are known to be PSPACE-complete restricted to instances of constant bandwidth/pathwidth/treewidth, an exact constant above which the problems become hard is not explicit in the hardness proofs of Wrochna [42]. Determining an explicit upper bound for which the problems are hard has been left open for almost a decade now, see e.g. [8, 16, 5].[2] Our first main result consists in giving an explicit upper bound on the treewidth and even the pathwidth above which the TS-DSR problem becomes PSPACE-complete. Our proof uses a completely different approach from the one of Wrochna [42] and is based on a new problem, namely Tape Reconfiguration (Tape-Rec), we introduce and prove to also be hard (formal definitions in Section 2.1).

▶ **Theorem 1.** *TS-DSR is PSPACE-complete even when restricted to graphs of treewidth (resp. pathwidth) at most* 12 *(resp.* 18*).*

The existence of explicit constants b and w for which (i) TS-DSR is PSPACE-complete in graphs of bandwidth b, and (ii) TJ-DSR is PSPACE-complete in graphs of pathwidth or treewidth at most w is also open. Unfortunately, our proof technique does not yield such explicit constants. Moreover, it is very unlikely that a small variation of our proof technique can provide such constants since this would almost automatically imply that the problems (parameterized by dominating set size k) are also XL-complete when restricted to the aforementioned graph classes, which is in contradiction with known results [18]. This follows, in part, from the fact that our reductions construct instances in which the dominating set size is negligible with respect to n.

We note that the constants 12 and 18 are probably not optimal. In particular, the complexity status of both TJ-DSR and TS-DSR in outerplanar graphs (which are graphs of treewidth at most 2) is still open. We will discuss in more detail the proof technique in

[1] Bandwidth is a very restricted subclass of pathwidth which, in turn, is a restriction of treewidth. That is $\text{bandwidth}(G) \geq \text{pathwidth}(G) \geq \text{treewidth}(G)$.

[2] The question is open for a wealth of reconfiguration problems including Independent Set Reconfiguration, Vertex Cover Reconfiguration, Shortest Path Reconfiguration, and Dominating Set Reconfiguration.

Section 3, but note that the proof technique of Theorem 1 is *drastically* different from the one of Wrochna [42] since the size of the dominating set is linear in the size of the graph in [42] while it is independent from $n = |V(G)|$ in our proof. This, in turn, allows us to derive the non-existence of parameterized algorithms which was completely out of reach with the techniques of [42].

Parameterized complexity and the mysterious case of token sliding. A systematic study of the parameterized complexity of reconfiguration problems was initiated by Mouawad et al. [38]. This was followed by a long sequence of results trying to push the tractability boundary of many reconfiguration problems (see [18] for a survey which mainly focuses on dominating set and independent set reconfiguration results).

On general graphs, TJ-DSR and TS-DSR are W[2]-complete parameterized by the dominating sets size k plus the length of a reconfiguration sequence ℓ [38, 10]. For the parameter k alone, it was shown by Bodlaender et al. [10] that both problems are XL-complete[3] if ℓ is not given, XNL-complete if ℓ is given in binary, and XNLP-complete if ℓ is given in unary as part of the input. The constructions of Bodlaender et al. [10] result in heavily dense graphs that contain all possible subgraphs H as subgraphs. In particular, it was left as an open problem whether the token sliding and token jumping variants of the problems behave the same on H-free graphs[4].

When parameterized by ℓ alone, both TJ-DSR and TS-DSR are FPT on any class of graphs where first-order model-checking is FPT, e.g., nowhere dense classes [26] and classes of bounded twinwidth [14] (assuming a contraction sequence is given as part of the input). Indeed, for the parameter ℓ, we can find a fixed sentence expressing the existence of a reconfiguration sequence of length ℓ.

Unfortunately, the approach via first-order model-checking does not help us deal with the parameterization by k since reconfiguration sequences might be arbitrarily long compared to k. It is not possible to state the existence of such a sequence in first-order logic with a bounded length sentence. Instead, the key tool to tackle TJ-DSR parameterized by k alone is based on the notion of domination cores [20]. In fact, the complexity of TJ-DSR parameterized by k is quite well understood for sparse classes of graphs. The problem is known to be FPT parameterized by k for biclique-free graphs and semi-ladder-free graphs [35, 24] (classes encompassing nowhere dense and degenerate graphs). In particular, it restricts quite a lot the type of graph on which TJ-DSR might be XL-complete.

On the other hand, the parameterized complexity of TS-DSR remains open even when restricted to very simple graph classes such as bounded pathwidth or treewidth graphs[5] or planar graphs. This difference of knowledge between the sliding and jumping variants is also observed for other problems such as Independent Set Reconfiguration (ISR) where the token jumping version is known to be FPT (parameterized by k) on $K_{\ell,\ell}$-free graphs while its sliding counterpart is only known to be FPT on planar graphs and is open beyond [18]. Bodlaender et al. [10] mentioned that "*it would be interesting to investigate*

[3] XL is a complexity class that contains the W-hierarchy and which naturally contains most of the reconfiguration problems. In particular, when a problem is XL-complete it is very unlikely that it is FPT.

[4] A graph G is *H-free* if it does not contain H as an *induced subgraph*. That is, there is no subset of vertices in G whose induced subgraph is isomorphic to H. A graph G is *H-minor-free* if it does not contain H as a *minor*. That is, H cannot be formed from G by deleting vertices and edges and by contracting edges.

[5] Note that the parameterized complexity status of TS-DSR on bounded bandwidth graphs is trivially FPT since the number of vertices is upper bounded by a function of the bandwidth and the domination number.

for which graph classes switching between token jumping and token sliding does affect the parameterized complexities". The second goal of this paper is to study this question via the lens of Dominating Set Reconfiguration.

In the token sliding case, apart from the few polynomial results on very restricted classes, no FPT algorithm parameterized by k is known. The existence of such an algorithm is conjectured in several papers including [18, 36, 8] or the recent survey [18]. The second main contribution of this article makes a step towards closing this gap by proving the following theorem:

▶ **Theorem 2.** *TS-DSR parameterized by k is XL-complete when restricted to graphs of treewidth at most* 12 *and pathwidth at most* 18*. Moreover, it remains XL-hard when parameterized by k plus the feedback vertex set number.*

A *feedback vertex* is a subset of vertices whose deletion leaves an acyclic graph. The *feedback vertex set number* is the minimum size of a feedback vertex set. The first hardness result of Theorem 2 (for pathwidth and treewidth) is again a consequence of the hardness of the Tape-Rec problem. The second hardness result is also based on the hardness of Tape-Rec but the proof is more technical since we need to maintain a small feedback vertex set number. One can wonder if we can strengthen the result of Theorem 2 by replacing feedback vertex set number by vertex cover number. The answer is negative. A *vertex cover* is a subset of vertices whose deletion leaves an independent set. Recall that given a simple undirected graph G, a set of vertices $I \subseteq V$ is an *independent set* if the vertices of I are pairwise non-adjacent. The *vertex cover number* is the minimum size of a vertex cover. We note that TS-DSR parameterized by k plus the vertex cover number is trivially FPT. This follows from the fact that given a vertex cover C, we can partition $R = V \setminus C$ into classes such that two vertices belong to the same class if and only if they have the same neighbors in C. All classes consist of independent sets (since C is a vertex cover) and any class containing more than k vertices can be reduced since no more than k vertices can be used from a class (and all vertices of a class are "equivalent"). Hence, we obtain an instance with at most $|C| + 2^{|C|}k$ vertices (assuming no isolated vertices).

Theorem 2 answers, as mentioned before, a problem that has been left open in several previous articles [18, 36, 8, 18]. The result ensures that, even in very restricted sparse graph classes, TS-DSR and TJ-DSR behave completely differently. To our knowledge, it is the first time the token sliding and token jumping models behave differently for a reconfiguration problem on a class of bounded treewidth (and even nowhere dense)[6]. Actually, it is, as far as we know, the first reconfiguration problem that is not FPT on bounded treewidth graphs. It also ensures that TS-DSR and TS-ISR behave very differently on nowhere dense classes of graphs (since an easy applications of the lemmas of [8] ensures that TS-DSR is FPT parameterized by k plus the feedback vertex set number). Moreover, our results provide the first (and infinite) collection of graphs (any supergraph of a large enough biclique) for which TS-DSR is XL-complete parameterized by k while TJ-DSR is FPT, which partially answers the question of [10].

To sum up, our results make progress in three directions by showing that:

1. TS and TJ do not necessarily behave the same on graphs of bounded treewidth (and below);
2. ISR and DSR do not behave the same on nowhere dense graph classes; and
3. TJ-DSR and TS-DSR behave differently on infinitely many H-free graphs.

[6] For sparse graphs, such a difference has already been observed for bounded degeneracy graphs for instance [18]

We complement our negative results by positive results proving that TS-DSR is FPT on planar graphs (and actually beyond), answering a problem left open in [18].

▶ **Theorem 3.** *TS-DSR parameterized by k is FPT on planar graphs.*

To obtain the positive result, we adapt the strategy used in the token jumping model via domination cores to handle the case where the size of a forbidden minor is not too large (namely $K_{4,\ell}$-minor-free graphs). However, while the proof is almost direct in the token jumping variant whenever domination cores exist, the proof gets more technical here as connectivity matters. Note that this method cannot be generalized much further since we prove that TS-DSR is XL-complete for graphs of treewidth at most 12, and when parameterized by k plus feedback vertex set number. However, it would be interesting to understand the limit between tractability and intractability on H-minor free graphs.

Reconfiguration of connected dominating sets. Our proof techniques are actually strong enough to be generalized further to the Connected Dominating Set Reconfiguration problem (CDSR). Recall that a dominating set D is a *connected dominating set* if the graph induced by D is connected. Deciding whether a given graph contains a connected dominating set of size at most k is known to be NP-complete [33] and W[2]-complete parameterized by k [21].

TS-CDSR and TJ-CDSR, the corresponding reconfiguration variants, are known to be PSPACE-complete (even on graphs of bounded pathwidth) and W[1]-hard parameterized by $k + \ell$ [36, 10]. Moreover, TJ-CDSR parameterized by $k + \ell$ remains W[1]-hard even when restricted to 5-degenerate graphs. On the positive side, TJ-CDSR parameterized by k is known to be FPT on planar graphs [36].

TJ-CDSR parameterized by k has been conjectured to be FPT on every nowhere dense class of graphs in several papers, see e.g. [18, 36]. In [36], the authors ask whether TJ-CDSR and TS-CDSR parameterized by k are FPT on graphs of bounded pathwidth. We provide a negative answer to all of the aforementioned questions. Our proof techniques can also be adapted for other dominating set variants such as distance d dominating sets and total dominating sets which have been studied in the literature.

Related work. Deciding whether a given graph contains an independent set of size at least k is known to be NP-complete [33] and W[1]-complete parameterized by (solution size) k [21].

The Independent Set Reconfiguration (ISR) problem is another central problem that has been very widely studied under the combinatorial reconfiguration framework. Both TJ-ISR and TS-ISR are known to be PSPACE-complete restricted to planar graphs of bounded bandwidth [42, 41] and XL-complete when parameterized by the size of independent sets k [10].

Similarly to TJ-DSR, the complexity of the token jumping variant, i.e., TJ-ISR, is rather well understood. Indeed, Ito et al. [31] proved that TJ-ISR parameterized by k is FPT on planar graphs. This result has been generalized to nowhere dense and degenerate classes in [35, 1] and even to $K_{d,d}$-free graphs in [17]. The idea of these proofs is to follow a two-step strategy. First, an "important" subset X of vertices of bounded size is identified. Second, the remaining vertices are classified according to their neighborhood in X, and it is shown that if some class is too large then it can be reduced.

Again, the situation becomes a lot less clear when we consider the token sliding model, i.e., TS-ISR. For instance, while TJ-ISR is trivial on chordal graphs [32], TS-ISR is PSPACE-complete on split graphs [9]. Lokshtanov and Mouawad [34] showed that, in bipartite graphs, TJ-ISR is NP-complete while TS-ISR remains PSPACE-complete.

Just like DSR, even after a decade of research, very little is known about the parameterized complexity of ISR under the token sliding model. It was proved in [6] that TS-ISR is FPT on bipartite C_4-free graphs. The result was later generalized by Bartier et al. [8] on planar graphs and graphs of bounded maximum degree and graphs of girth at least 5 [7]. One can easily use the reduction rules introduced in [8] in order to prove that TS-ISR is FPT parameterized by k plus the feedback vertex set number of the graph, which shows that the behavior of TS-DSR and TS-ISR is very different on sparse graph classes.

2 Technical overview of our results

2.1 Tape Reconfiguration

Let Σ be an alphabet. The elements of Σ are called *letters*. A Σ-*tape* (or tape for short when Σ is clear from context) is a graph where each vertex, called a *cell*, is labeled with a subset of Σ, called its *content*. Moreover, each tape comes with two distinguished vertices, called the *start* and *end* cell, respectively. We will move a token, called *(read) head*, on each tape.

Let $\mathcal{T} = \{T_1, \ldots, T_p\}$ be a set of Σ-tapes. For $i \in [1, p]$,[7] let c_i be a cell of T_i, and $start_i$ (resp. end_i) be the start (resp. end) cell of T_i. We say that $(c_1, \ldots, c_p)$ forms a *valid configuration* if the union of their contents is Σ. Let $C = (c_1, \ldots, c_p)$ and $C' = (c'_1, \ldots, c'_p)$ be two valid configurations. We say that there is an *elementary transformation* (or a *(reconfiguration) step*) between C and C' if they differ on exactly one element, say the j-th, and $c_j c'_j$ is an edge in T_j.

Tape Reconfiguration (Tape-Rec)
Input: An alphabet Σ and a set $\mathcal{T}$ of Σ-tapes, an initial and a final configuration C_s, C_t.
Parameter: Size of the alphabet Σ plus the number of Σ-tapes.
Output: Yes, if it is possible to transform the start configuration (i.e., $(start_1, \ldots, start_p)$) into the end configuration (i.e., $(end_1, \ldots, end_p)$) via a sequence of elementary transformations while keeping a valid configuration all along.

We argue in the full version of the paper that one can always assume the number of Σ-tapes is bounded by the size of the alphabet $|\Sigma|$. Consequently, one can assume $|\Sigma|$ to be the parameter. The problem can be equivalently defined as follows. We are given a set of p graphs, each with a read head positioned on one vertex. In one step, we are permitted to slide a read head along an edge within any one of these graphs. Note that since we only allow the movement of tokens along edges we can assume that these graphs are connected. We will mostly show hardness results for this problem, and a natural question is about how the structure of the input graphs affects its complexity. As it turns out, even the simplest case – captured by the variant Path-Tape-Rec, which requires all tapes to be paths whose endpoints are the start and end cells – is already hard. In particular, we show the following:

▶ **Theorem 4.** *Tape-Rec is XL-complete.*

2.2 Consequences for TS-DSR (and TS-CDSR)

We prove that, for DSR, the results for TJ have not been generalized to TS for a good reason; TS-DSR is hard even on very restricted graph classes. Namely, we show the following:

[7] $[1, p]$ denotes the set of integers between 1 and p.

▶ **Theorem 5.** *TS-DSR and TS-CDSR are PSPACE-complete and XL-complete parameterized by k plus the feedback vertex set number, even restricted to 7-degenerate graphs of treewidth at most 12 and pathwidth at most 18.*

Note that, as far as we know, this is the first "natural" reconfiguration problem which becomes hard parameterized by k plus the feedback vertex set number of the graph. Very few problems are hard for that parameter since allowing the feedback vertex set number to be part of the parameter enables the use of very powerful algorithmic techniques (given the simple structure of graphs having a feedback vertex set of bounded size).

With minor modifications to the reduction, we obtain the following slightly weaker result for TJ-CDSR:

▶ **Theorem 6.** *TJ-CDSR is PSPACE-complete and XL-complete when parameterized by k plus the feedback vertex set number, even restricted to 5-degenerate graphs of treewidth at most 13 and pathwidth at most 19.*

Theorems 5 and 6 imply that both TS-DSR and TJ-CDSR are very hard problems, even though the connectivity constraints are quite different in both; the latter is a global condition on the dominating set while the former only wants to ensure local connectivity when moving along edges. In addition, both problems are much harder than TJ-DSR which is known to be FPT parameterized by k on nowhere dense, degenerate, biclique-free, and semi-ladder-free graphs.

2.3 Positive results for TS-DSR

We complement our hardness results with positive ones. In particular, we show that TS-DSR is FPT on planar graphs. We first prove that the following holds:

▶ **Theorem 7.** *TS-DSR parameterized by k is FPT on $K_{3,d}$-free graphs.*

As a by-product of Theorem 7, TS-DSR (parameterized by k) is FPT on planar graphs. The proof technique is inspired from [31, 35] and consists in looking at neighborhood classes in a domination core and proving that all these classes can be reduced to have bounded size. It was proven in [23] that a domination core of size $\mathcal{O}(k^{d+1})$ exists (and can be efficiently computed) even in $K_{d,d}$-free graphs (having a dominating set of size k).

▶ **Theorem 8.** *TS-DSR parameterized by k is FPT on $K_{4,d}$-minor-free graphs.*

To prove Theorem 8, we start as in the proof of Theorem 7. Although it can be seen as rather incremental compared to the previous result, reducing neighborhood classes is actually much trickier and requires more general arguments. In some steps of the proof we have to use the fact that dominating the domination core ensures that the whole graph is dominated to show that some subsets of vertices have to intersect with the dominating set (which in turn permits reducing some large enough parts of the graph).

3 Hardness results roadmap

3.1 Synchronized version and width of tape reconfiguration problems

The goal of this section is to state our main hardness results and give outlines of their proofs. In order to do so, we will need to define some auxiliary problems along the way, which we also believe to be of independent interest.

The first auxiliary problems we will need are synchronized versions of Tape-Rec and Path-Tape-Rec where we assume that all the read heads move at the same speed. We say that a tape is r-*numbered* if each cell is labeled with some integer of $[1, r]$ (the same integer possibly occurring on several cells), where the number of adjacent cells differs by at most 1 modulo r. A configuration is numbered with j if all the read heads are on a cell numbered with j. The read heads are *synchronized* if, for every pair of tapes, the numbers of the cells under their read heads differ by at most 1 modulo r. In other words, if the read head in the tape T is at a cell numbered q, then the read head in T' is on a cell numbered with q or $q \pm 1$ mod r. A transformation is synchronized if the read heads are synchronized at each step. A configuration of a synchronized instance is *valid* if read heads on the synchronized tapes are synchronized and the union of the contents of the reading heads is the whole alphabet.

The synchronized version of Tape-Rec is defined as follows:

Sync-Tape-Rec
Input: An alphabet Σ, a set $\mathcal{T}$ of r-numbered tapes and two numbered configurations C_s, C_t.
Parameter: $|\Sigma| + |\mathcal{T}|$.
Output: Yes if and only if there exists a synchronized transformation from C_s to C_t.

We similarly define the restriction Path-Tape-Rec when tapes are paths whose endpoints are the start and end cells, and its synchronized version Sync-Path-Tape-Rec where, for technical reasons, we assume that the start cells are all numbered with 1 and the numbering is non-decreasing along each tape.

Observe that the synchronization makes the problem much simpler to solve in some configurations. For instance, consider instances of Path-Tape-Rec where cells of paths are labeled with their position in the path. Then, one can easily upper bound the number of valid configurations by $2^{|\mathcal{T}|} \cdot n$ valid configurations (where n is the size of the longest tape). In particular, the following holds:

▶ Remark 9. In the particular setting where cells of paths are labeled with their position in the path, Sync-Path-Tape-Rec is FPT.

Note that we do not know if Sync-Path-Tape-Rec lies in P in that setting.

A more general problem. We will consider a harder problem whose flavor is close to Path-Tape-Rec, denoted by Multi-Tape-Rec, and prove that this problem is W[∗]-hard. The idea consists in allowing to make choices to construct a valid instance of Path-Tape-Rec by selecting tapes among some tuples. More formally, we define the problem Multi-Tape-Rec as follows:

Multi-Tape-Rec
Input: An alphabet Σ, k tuples $\mathcal{T}^1, \dots, \mathcal{T}^k$ of path Σ-tapes.
Parameter: $k + |\Sigma|$
Output: Yes if and only if there exists $i_1, \dots, i_k$ such that $\{\mathcal{T}^j_{i_j} \mid j \in [1, k]\}$ is a positive instance of Path-Tape-Rec.

There is a trivial reduction from Path-Tape-Rec to Multi-Tape-Rec; by considering an instance of Multi-Tape-Rec where each tuple has size 1. More formally, $\{T_1, \dots, T_k\}$ is a positive instance of Path-Tape-Rec if and only if the k tuples $(T_1), \dots, (T_k)$ of size 1 form a positive instance of Multi-Tape-Rec. In other words, we have no choice on the tape to choose in each tuple so we simply have an instance of Path-Tape-Rec. We will later provide

a reduction in the converse direction, proving that Path-Tape-Rec and Multi-Tape-Rec have the same complexity. We define Sync-Multi-Tape-Rec as the synchronized version of Multi-Tape-Rec as we defined Sync-Tape-Rec from Tape-Rec earlier.

Before stating our main results, let us first prove that Sync-Multi-Tape-Rec is hard. We obtain much stronger hardness results later but this proof is interesting since it illustrates the utility of having synchronized tapes to design hardness reductions with the following very simple statement.

▶ **Theorem 10.** *Sync-Multi-Tape-Rec is W[2]-hard even when* $|\Sigma| = 1$.

3.2 Hardness results for tape reconfiguration

Width of tape reconfiguration instances. In the rest of this section we will need some notions of width of a tape reconfiguration instance. Let $I = (\Sigma, (T_i)_i, C_s, C_t)$ be an instance of Tape-Rec (or any other tape problem defined above such as Multi-Tape-Rec or Sync-Tape-Rec), where Σ is the alphabet and $(T_i)_i$ is a collection of tapes. The *extended graph* of I is the graph with vertex set $\bigcup_i V(T_i) \cup \Sigma$, and where xy is an edge if either it is an edge of some T_i, or x is a cell of some T_i which contains the letter y.

We say that I is *d-degenerate* whenever its extended graph is d-degenerate. We similarly define the notion of pathwidth, treewidth, and minors of an instance I; the *pathwidth (resp. treewidth)* of I is the pathwidth (resp. treewidth) of its extended graph.

We say that a path (resp. tree) decomposition of the extended graph of I is *s-structured* if each of its bags contains vertices of at most s tapes. The utility of structured decompositions will appear naturally in future reductions. The minimum width of a s-structured path (resp. tree) decomposition is called the *s-structured pathwidth (resp. treewidth)* of I.

Hardness results. The goal of this section is to give the main hardness results for Tape-Rec and its variants. The first and one of our main results is the following:

▶ **Theorem 11.** *Tape-Rec is PSPACE-complete and XL-complete even restricted to* 5*-degenerate instances of* 2*-structured treewidth at most* 9 *and* 3*-structured pathwidth at most* 14*.*

The proof of Theorem 11 is divided into two steps. The first one consists in proving that the synchronized version of Tape-Rec, Sync-Tape-Rec, is PSPACE-complete and XL-complete. The reduction is from TJ-DSR. The proof generalizes the proof of Theorem 10. Indeed, Theorem 10 shows first how to encode a choice of vertices by a choice of tapes, and then translates checking that these vertices dominate the graph into moving read heads on these tapes. We reuse these "checking paths" to prove Theorem 11, but now we have to encode a way to reconfigure dominating sets. This can be done by arranging the checking paths between some cells that correspond to vertices of G. By doing so, our tapes are not paths anymore; they become subdivided stars. Moreover, in order to guarantee that we reconfigure dominating sets one vertex at a time, we also need to add another tape. This construction leads to the following statement which we prove in the full version of the paper:

▶ **Theorem 12.** *Sync-Tape-Rec is PSPACE-complete and XL-complete parameterized by* k *plus the feedback vertex set number, even restricted to* 3*-degenerate instances of* 1*-structured treewidth at most* 3*,* 2*-structured pathwidth at most* 5*, and whose tapes are subdivided stars.*

The second step in the proof of Theorem 11 consists in providing a very generic reduction from synchronized problems to their unsynchronized versions. This reduction allows us to prove that synchronized and unsynchronized versions of each problem are actually equivalent (up to small changes in the parameters and the structured width).

To prove this, we add a new tape and new characters to Σ that force the read heads to move at the same "speed" in all the tapes. The reduction also ensures that all the cells are useful to cover the whole alphabet Σ. Namely, we say that an instance $(\Sigma, \mathcal{T}, C_s, C_t)$ of Tape-Rec is *irreducible* if Σ cannot be written as the union of the contents of less than $|\mathcal{T}|$ cells.

Formally, we show that the following holds, which directly implies Theorem 11, when combined with Theorem 12.

▶ **Theorem 13.** *There is an FPT-reduction (and PL-reduction) Φ from instances of Sync-Tape-Rec to irreducible instances of Tape-Rec. Moreover, if I is an instance of Sync-Tape-Rec of s-structured treewidth (resp. pathwidth) w, then $\Phi(I)$ has $(s+1)$-structured treewidth (resp. pathwidth) at most $w + 3s + 3$. Furthermore, Φ increases the degeneracy by at most 2 and the feedback vertex set number by at most $3|\Sigma| + 3$.*

Theorem 11 is a direct corollary of Theorems 12 and 13. Theorem 13 is proved in the full version of the paper. We give two proofs of Theorem 13; one where one additional tape is a long path and one where it is a triangle. The spirit of the two proofs is similar but each construction allows us to reach a specific conclusion. For long paths, we guarantee that all tapes are paths and thus obtain hardness results for Path-Tape-Rec. However this path reduction comes at a cost; the size of clique-minors and treewidth increase by a function of the size of the alphabet, hence they become unbounded. We thus provide another reduction where the additional tape is a triangle that permits to control widths and degeneracy. In the end, the first reduction yields hardness results for TS-DSR parameterized by feedback vertex set number, while the second handles the bounded widths and degeneracy cases.

3.3 Consequences for (C)DSR

Let us finally explain the consequences of the results from the previous subsections on TS-DSR, TJ-CDSR, and TS-CDSR.

▶ **Theorem 5.** *TS-DSR and TS-CDSR are PSPACE-complete and XL-complete parameterized by k plus the feedback vertex set number, even restricted to 7-degenerate graphs of treewidth at most 12 and pathwidth at most 18.*

The proof of Theorem 5 follows from the next lemma:

▶ **Lemma 14.** *There is an FPT-reduction (and PL-reduction) from Tape-Rec on irreducible d-degenerate instances of s-structured treewidth (resp. pathwidth) at most w with k tapes and of feedback vertex set number f to TS-DSR and TS-CDSR with $k+1$ tokens on graphs:*

- *of treewidth (resp. pathwidth) at most $s + w + 1$ and degeneracy at most $d + 2$, or*
- *of feedback vertex set number $f + k + 1$.*

By Theorem 11, Tape-Rec is PSPACE-complete and XL-complete on 5-degenerate instances of 2-structures treewidth at most 9 and 3-structured pathwidth at most 14. Moreover, by Theorem 13, this remains true when the instances are additionally irreducible. Therefore, applying Lemma 14, we can conclude the proof of Theorem 5.

Note that considering irreducible instances in the above proof allowed us to increase the widths by at most $w + 1$. Without this assumption, a similar reduction works, but we need to introduce a twin of each x_i. This yields a reduction to possibly non-irreducible instances of Tape-Rec with slightly worse bounds (adding $2w + 1$ to the widths instead).

The reduction can also be modified to get hardness results for the parameterized (and classical) complexity of TJ-CDSR, which solves open problems from the literature. Namely, we adapt our reduction to show that TJ-CDSR is PSPACE-complete and XL-complete.

▶ **Theorem 6.** *TJ-CDSR is PSPACE-complete and XL-complete when parameterized by k plus the feedback vertex set number, even restricted to* 5*-degenerate graphs of treewidth at most* 13 *and pathwidth at most* 19*.*

3.4 Hardness of tape reconfiguration on paths

Tape-Rec is XL-complete even restricted to instances where tapes are trees (and even subdivided stars). One can then naturally wonder if the same holds when tapes are simpler graphs, for example paths. We did not succeed to obtain exactly the same hardness result but nevertheless we prove that Path-Tape-Rec is W[$*$]-hard. The W[2]-hardness is a consequence of the synchronization result used to prove Theorem 13. This result is actually quite generic and can be applied to all the problems defined before. In particular, we will get the following for free from Theorem 10:

▶ Remark 15. Multi-Tape-Rec is W[2]-hard.

Recall that there is a trivial reduction from Path-Tape-Rec to Multi-Tape-Rec. Using another idea, called the *selector gadgets*, we can provide a reduction in the converse direction, proving that Path-Tape-Rec and Multi-Tape-Rec have the same complexity. More formally, we will prove that the following holds:

▶ **Theorem 16.** *Multi-Tape-Rec and Path-Tape-Rec are equivalent under FPT-reductions.*

As a byproduct, Theorems 10 and 16 ensure that Path-Tape-Rec is W[2]-hard. We will actually prove the following more general result (as sketched above):

▶ **Theorem 17.** *Multi-Tape-Rec (and consequently Path-Tape-Rec) is W[$*$]-hard.*

To prove Theorem 17, we will generalize the ideas of Theorem 10. In the proof of Theorem 10, we gave a reduction from Dominating Set, which is a problem in W[2]. In other words, it can be expressed with a logical sentence, whose variables correspond to the vertices chosen in the dominating set, with the following shape:

$$\bigwedge_{u \in V} \bigvee_{v \in N[u]} x_v,$$

that is a conjunction of disjunctions of literals. The reduction of Theorem 10 allowed us to make a selection (by the definition of Multi-Tape-Rec) and then check the conjunction of conditions (one condition per cell), each of them corresponding to a disjunction (at least one cell has to contain ✓).

The W-hierarchy can be generalized to higher levels; W[h] problems can be expressed in the same way except that up to h nested boolean operators are allowed. Therefore, in order to prove that Multi-Tape-Rec is W[h]-hard, we build on this W[2]-hardness result and design OR gadgets and AND gadgets allowing us to lift W[$h+1$]-hardness from W[h]-hardness. Note that this has to be done without adding too many characters nor additional tapes. The details of the proof can be found in the full version of the paper.

We were not able to determine if the problem is XL-complete or not and leave as an open problem the exact complexity of Path-Tape-Rec.

Reconstructing Random Graphs from Distance Queries

Michael Krivelevich

Maksim Zhukovskii
School of Computer Science, The University of Sheffield, UK

Abstract

We estimate the minimum number of distance queries that is sufficient to reconstruct the binomial random graph $G(n,p)$ with constant diameter with high probability. We get a tight (up to a constant factor) answer for all $p > n^{-1+o(1)}$ outside "threshold windows" around $n^{-k/(k+1)+o(1)}$, $k \in \mathbb{Z}_{>0}$: with high probability the query complexity equals $\Theta(n^{4-d}p^{2-d})$, where d is the diameter of the random graph. This demonstrates the following non-monotone behaviour: the query complexity jumps down at moments when the diameter gets larger; yet, between these moments the query complexity grows. We also show that there exists a non-adaptive algorithm that reconstructs the random graph with $O(n^{4-d}p^{2-d}\ln n)$ distance queries with high probability, and this is best possible.

1 Introduction

Reconstruction of graphs was thoroughly studied in many different contexts and has various applications, e.g., in DNA sequencing [2, 13, 34], phylogenetics [1, 23, 29], and recovering neural networks [39]. A vast amount of literature is devoted to the average-case problem, i.e. to the reconstruction of random graphs [8, 12, 19, 21, 28, 31, 33, 35, 41]. In particular, the conjecture of Kelly and Ulam [24, 42] which is considered as one of the main reconstruction challenges is known to be true in binomial random graphs whp[1] [8, 28, 35].

Let G be a connected graph on $[n] := \{1,\dots,n\}$, and let $\mathcal{Q} \subset \binom{[n]}{2}$ be a set of pairs of vertices. In the usual way, we denote by $d_G(x,y)$ the graph distance between x and y in G. Let us say that $\mathcal{Q}$ *reconstructs* G, if G is the only graph on $[n]$ with distances $d_G(x,y)$ between $\{x,y\} \in \mathcal{Q}$, i.e. for every graph G' on $[n]$ such that $d_{G'}(x,y) = d_G(x,y)$ for all $\{x,y\} \in \mathcal{Q}$, we have $G' = G$. We will also call the graph $\mathcal{Q}$-*reconstructible* in this case.

In this paper, we study the model of reconstruction with an access to distance query oracle introduced in [5], although its variants were considered long before that for modelling reconstruction of a phylogenetic tree [18, 25, 43]. For every queried pair of vertices, the oracle answers the distance between these vertices in the hidden unknown graph G. For a queried pair of vertices $\{x,y\}$, we denote the oracle's answer to this query by $d(x,y)$, omitting the unknown graph in the subscript. An adaptive algorithm, at every step, selects the next query (a pair of vertices) based on the responses from the oracle to earlier queries.

[1] With high probability, that is, with probability tending to 1 as $n \to \infty$.

Let $q \in \mathbb{N}$. If there exists an adaptive algorithm $\mathtt{A}$ such that, for the hidden input graph G on $[n]$, it queries at most q pairs of vertices comprising a set $\mathcal{Q} \subset \binom{[n]}{2}$ that reconstructs G, then we call G *q-reconstructible by* $\mathtt{A}$. Let us call the minimum q such that G is q-reconstructible by some algorithm *the (distance) query complexity of* G. It is easy to see that, in the worst case, the query complexity equals $\binom{n}{2}$: all pairs should be queried in order to reconstruct the graph. For example, this is the case when G is a clique. Reyzin and Srivastava [37] showed that, even for some trees, $\Omega(n^2)$ pairs are required to query. On the other hand, Mathieu and Zhou [31] presented an algorithm such that whp a uniformly random d-regular graph on $[n]$ is $(\lfloor n \ln^2 n \rfloor + dn/2)$-reconstructible by this algorithm, and wondered whether methods similar to those developed in their paper are applicable to sparse binomial random graphs $G(n,p)$. In this paper, in contrast, we study the distance query complexity of relatively dense random graphs $G(n,p)$ assuming $p > n^{-1+\varepsilon}$ for some $\varepsilon > 0$, i.e., when the random graph has bounded diameter whp. Although our main motivation lies in attempting to achieve tight bounds for the average-case complexity in a situation where the general setup is hard to analyse, additional interest in this problem is sparked by a surprising phenomenon, which will be discussed in the next two paragraphs.

One can expect that dense graphs are typically harder to recover through distance queries, as the influence of a single edge to be recovered on distances between vertices might be less pronounced and thus harder to detect. In order to get some intuition of how the query complexity of the random graph evolves, let us first assume that p is significantly above the threshold for the property of having diameter at most 2, namely, $p^2 n - 2\ln n - \ln\ln n \to \infty$ as $n \to \infty$. In this case, whp every pair of non-adjacent vertices has at least two common neighbours. Indeed, probability that a fixed pair of vertices has at most one common neighbour equals

$$\mathbb{P}(\mathrm{Bin}(n-2, p^2) \le 1) = (1-p^2)^{n-2} + (n-2)p^2(1-p^2)^{n-3} = O\left(np^2 e^{-np^2}\right) = o(n^{-2}).$$

Therefore, by the union bound, every non-adjacent pair of vertices of $G(n,p)$ has at least two common neighbours whp. Then whp the query complexity equals $\binom{n}{2}$. Indeed, for any set $\mathcal{Q}$ of pairs of vertices of size less than $\binom{n}{2}$, changing any single adjacency relation of a pair from $\binom{[n]}{2} \setminus \mathcal{Q}$ does not influence the distance between x and y for any $\{x,y\} \in \mathcal{Q}$. Therefore, any set $\mathcal{Q}$ that does not contain all pairs does not reconstruct $G(n,p)$ whp.

On the other hand, it seems likely that for p close to the connectivity threshold $\ln n/n$, the query complexity might be much less – quasilinear, as in the case of random regular graphs. Note that, in general the query complexity does not decrease as the graph becomes sparser since, in particular, as we mention above, for certain trees, the query complexity equals $\Omega(n^2)$. Nevertheless, we show that, on average, as density decreases, the query complexity jumps down at specific moments around hitting times of diameter's increments. However, between these moments the query complexity grows quite rapidly. In particular, there exist $n^{-1+\varepsilon} \ll p_1 \ll p_2 \ll n^{-1/2}$ such that whp the diameter of $G(n,p_1)$ is larger than the diameter of $G(n,p_2)$ while the query complexity of the former is also larger.

Related work

Kannan, Mathieu, and Zhou [22, 30] presented a reconstruction algorithm that uses $\tilde{O}(n^{3/2})$ distance queries for bounded degree graphs. They also proved an information–theoretic lower bound $\Omega(n \log n/\log\log n)$ for trees with maximum degree 3 and asked whether $\tilde{O}(n)$ is achievable for all bounded degree graphs. Tight results for certain families of bounded degree graphs – trees, chordal graphs, and graphs with bounded treelength – were recently obtained

by Bastide and Groenland in [4]. In particular, they proved that for every $\Delta \geq 3$, any randomised algorithm requires $\Omega(n \log n)$ queries to reconstruct n-vertex trees of maximum degree Δ for a certain sequence of sizes of trees, which is tight since there exists a deterministic algorithm to reconstruct such trees using $O(n \log n)$ queries. In [31], Mathieu and Zhou answered the question from [22] for random d-regular graphs with constant d: whp $n \ln^2 n$ distance queries is enough to reconstruct a uniformly random d-regular graph.

A modified version of the problem where the hidden graph is a tree and it is only allowed to query pairs of leaves (that are known) comes from biology: it serves as a model of reconstructing evolutionary (phylogenetic) trees and was introduced by Waterman, Smith, Singh, and Beyer [43]. This problem is well studied: lower bounds on query complexity for deterministic and randomised algorithms were obtained in [25] and [4] respectively, and upper bounds were investigated in [11, 23, 25, 27].

Other types of query oracles explored in the literature include *all-shortest-path*, *all-distances*, and *shortest-path* queries. The first two oracles answer all shortest paths [5, 38] and all distances [5, 14] from a queried vertex respectively. The shortest-path oracle answers a shortest path between a queried pair of vertices [22, 37]. Erlebach, Hall, and Mihal'ák [15] studied reconstruction of $G(n,p)$ from all-shortest-path queries for $p = \text{const}$ and $p = n^{-1+\varepsilon}$ for specific $\varepsilon > 0$.

Mathieu and Zhou [31] also showed that their construction of the set of distance queries can be used to get an upper bound for the metric dimension of random d-regular graphs. Let us recall that the *metric dimension* $\beta(G)$ of a graph G is the minimum cardinality of $S \subset V(G)$ such that all vertices of G have different vectors of distances to the vertices from S. Such *resolving sets* S or their variants were used, in particular, to label canonically vertices of random graphs [3, 26]. The metric dimension of $G(n,p)$ was studied by Bollobás, Mitsche, and Prałat in [10]. In particular, they proved that the metric dimension of $G(n,p)$ undergoes the following "zigzag" behaviour: if $p = n^{-\alpha}$, then $\log_n \beta(G(n,p)) = 1 - (1-\alpha)\lfloor 1/(1-\alpha) \rfloor$ whp; see also [36] for related results. Although in our proof of the upper bound for the distance query complexity of $G(n,p)$ we use a resolving set whose size is far from being optimal, as we show below the "jumps" of the metric dimension and of the query complexity are synchronous – both happen around $n^{-k/(k+1)}$, $k \in \mathbb{Z}_{>0}$.

Our contribution

As follows from the next result, the query complexity drops for the first time when p passes a threshold $n^{-1/2+o(1)}$ on its way down. More generally, we prove that, for every integer constant $k \geq 1$, as soon as p passes a threshold $n^{-(k+1)/(k+2)+o(1)}$, the query complexity drops by a factor of $\Theta(np)$.

▶ **Theorem 1.** *Let $k \geq 1$ be a fixed integer, $\varepsilon > 0$, $n^{-1+\varepsilon} < p < n^{-k/(k+1)-\varepsilon}$, and let $G_n \sim G(n,p)$. Then there exist $C = C(k,\varepsilon) > 0$ and an adaptive algorithm $\mathtt{A}$ such that, for $q = \lfloor C/(n^{k-2}p^k) \rfloor$, whp G_n is q-reconstructible by $\mathtt{A}$.*

We prove Theorem 1 in Section 3.

▶ **Theorem 2.** *Let $k \geq 1$ be a fixed integer, $\varepsilon > 0$, and let $n^{k+1}p^{k+2} - 2\ln n \to \infty$ as $n \to \infty$. Then whp $G_n \sim G(n,p)$ has query complexity at least $\frac{1}{2(k+1+\varepsilon)n^{k-2}p^k}$.*

Theorem 2 is proven in Section 5. Let us emphasise that its proof is based on an explicit argument which is more efficient than the usual information-theoretic approach: we show a lower bound on the query complexity of a deterministic graph in terms of its diameter and maximum degree, see Claim 14. Unlike the information-theoretic approach, our approach

allows to bound the query complexity of any given graph. So, it actually demonstrates that, when the number of queries is less than the bound, even knowing the input graph G does not help choosing the optimal quering strategy – no matter which pairs of vertices are queried, there is always a graph $G' \neq G$ with exactly the same answers.

Note that, for any $w_n \to \infty$ as $n \to \infty$ and any

$$\left(\frac{2\ln n + w_n}{n^{k+1}}\right)^{1/(k+2)} < p < n^{-k/(k+1)-\varepsilon}, \tag{1}$$

the bounds in Theorem 1 and Theorem 2 differ by a constant factor, see Figure 1. So, roughly speaking (ignoring the constant factor) the query complexity in the interval (1) increases with p.

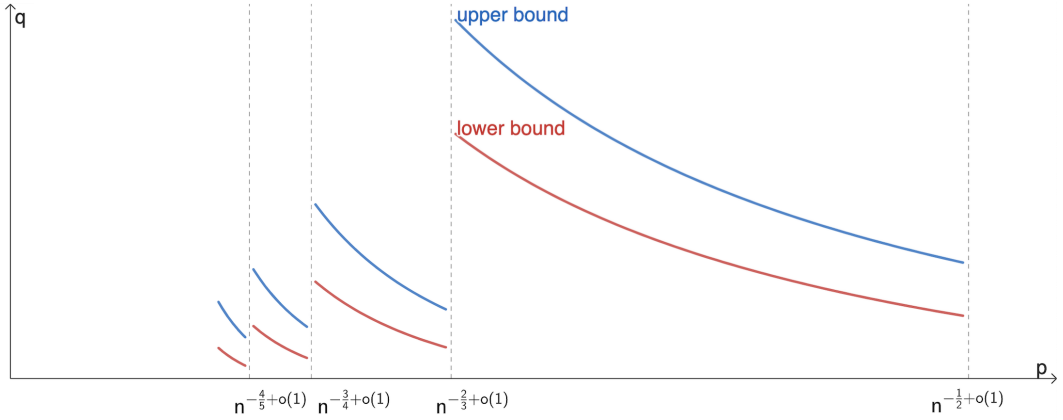

Figure 1 Upper and lower bounds for query complexity of $G(n,p)$ for p satisfying (1).

We also prove tight (up to a constant factor) bounds for "non-adaptive reconstructibility". It turns out that if the set of queried pairs $\mathcal{Q}$ is fixed, then both upper and lower bounds on the minimum $|\mathcal{Q}|$ such that $G(n,p)$ is $\mathcal{Q}$-reconstructable increase by a factor of $\log n$ when p satisfies (1).

▶ **Theorem 3.** *Let $k \geq 1$ be a fixed integer, $\varepsilon > 0$, and let $p > n^{-1+\varepsilon}$. Then there exists a set $\mathcal{Q} = \mathcal{Q}(n) \subset \binom{[n]}{2}$ of size at most $\frac{3}{n^{k-2}p^k} e^{n^k p^{k+1}} \ln n$ such that whp $G_n \sim G(n,p)$ is $\mathcal{Q}$-reconstructible.*

Theorem 3 is proven in Section 4.

▶ **Theorem 4.** *Let $k \geq 1$ be a fixed integer, $\varepsilon > 0$, and let $w_n \to \infty$ as $n \to \infty$. If*

$$\left(\frac{2\ln n + w_n}{n^{k+1}}\right)^{1/(k+2)} < p < \left(\left(\frac{1}{k+1} - \varepsilon\right)\frac{\ln n}{n^k}\right)^{1/(k+1)},$$

then there is no set $\mathcal{Q} = \mathcal{Q}(n)$ of size at most $\frac{1}{8(k+1)^2 n^{k-2}p^k} e^{n^k p^{k+1}} \ln n$ such that whp $G_n \sim G(n,p)$ is $\mathcal{Q}$-reconstructible.

Theorem 4 is proven in Section 6.

Proofs outline

For simplicity of presentation, let us assume that $p = n^{-\alpha}$, where $\frac{k}{k+1} < \alpha < \frac{k+1}{k+2}$ for some $k \in \mathbb{Z}_{>0}$. The crucial observation that allows to prove tight (up to a constant) upper bounds both for adaptive and non-adaptive query complexities is the following: if $\{v_1, x\}$ and $\{v_2, x\}$ are queried and $d(v_2, x) \geq d(v_1, x) + 2$, then v_1 and v_2 are not adjacent.

Although whp the diameter of $G_n \sim G(n,p)$ equals $k+2$, for a sufficiently large fixed set $X \subset [n]$, every vertex $v \in [n]$ has a vertex from X in its k-neighbourhood. Indeed, if X has size $\Theta\left(\frac{\ln n}{n^{k-1}p^k}\right)$, then the expected number of k-paths from a fixed vertex $v \in [n]$ to X is $\Theta(\ln n)$. Thus, using standard concentration inequalities, it is possible to overcome the union bound over the choice of $v \in [n]$ for $|X| = C\frac{\ln n}{n^{k-1}p^k}$ and C sufficiently large. Actually, the following stronger property can be proved: whp for every $v_1, v_2 \notin X$, there exists $x \in X$ such that $d_{G_n}(v_1, x) \le k$ while $d_{G_n \setminus \{v_1,v_2\}}(v_2, x) \ge k+2$, where $G_n \setminus \{v_1, v_2\}$ is a spanning subgraph of G_n that is obtained by excluding the edge $\{v_1, v_2\}$. Thus, as soon as all pairs of vertices with at least one vertex in X are queried, all the remaining adjacencies are reconstructible whp. Indeed, for non-adjacent v_1, v_2, there exists x such that $d(v_1, x) \le k$ and $d(v_2, x) \ge k+2$, thus we may reconstruct all non-adjacencies. All the other pairs of vertices must be adjacent since otherwise if we could exclude, say, the edge $\{v_1, v_2\}$, then there is an $x \in X$ such that $d(v_2, x) \le k+1$ while, in the corrupted graph, the distance between v_2 and x would be at least $k+2$. This proves Theorem 3, see details in Section 4. A counterpart of this very simple algorithm was employed by Mathieu and Zhou in [31], who showed that it allows typically to reconstruct random regular graphs with $(1+o(1))n\ln^2 n$ queries, which is tight, up to a $(\log n)^{1+o(1)}$-factor.

The proof of Theorem 1 in Section 3 is based on similar ideas but also utilises the possibility of updating queries adaptively: indeed, instead of querying all pairs $\{x \in X, v \in [n]\}$ simultaneously, we may split the set X into $\nu = \Theta(\log n)$ equal parts $X_1, \dots, X_\nu$ and then, for every $i = 1, \dots, \nu$, query a pair $\{x \in X_i, v \in [n]\}$ only if v has not yet been excluded from the consideration. A vertex v is excluded from the consideration at time i, if it has sufficiently many (at least M for some large enough constant M) vertices in the intersection of its k-neighbourhood with $X_1 \cup \ldots \cup X_i$. This allows to query the desired number of pairs whp. In order to complete the proof, it remains to observe that whp there are no v_1, v_2 that have M different vertices $x \in X$ so that $d_{G_n \setminus \{v_1,v_2\}}(v_1, x) \le k$ and $d_{G_n \setminus \{v_1,v_2\}}(v_2, x) \le k+1$. This would imply the existence of a good $x \in X$ as in the proof of Theorem 3 for any pair $\{v_1, v_2\}$.

Proofs of both lower bounds in Theorem 2 and Theorem 4 use the notion of an *undetectable pair* in a graph G having diameter $d \ge 3$ with a set of queried pairs $\mathcal{Q} \subset \binom{V(G)}{2}$: a pair of vertices $\{u_1, u_2\}$ is undetectable if $\{u_1, u_2\} \notin \mathcal{Q} \cup E(G)$ and there is no "path" $u_1 w_1 \dots w_\ell u_2$ in G, where $\ell \le d-2$, such that ℓ of its "edges" are actual edges of G, and the one remaining pair of consecutive vertices belongs to $\mathcal{Q}$. It is easy to see that if G has at least one undetectable pair, then it is not reconstructible from $\mathcal{Q}$ since the addition of the edge $\{u_1, u_2\}$ does not change answers to queries. When $\mathcal{Q}$ is small, then a simple counting proof shows that there are undetectable pairs in G_n whp. This proves Theorem 2, see details in Section 5.

In order to improve the lower bound by a factor of $\log n$ for the "non-adaptive reconstructibility" (Theorem 4), we first refine the notion of undetectability, and then introduce a randomised algorithm that finds an undetectable pair (in the refined sense) in G_n whp. Let us call a pair of vertices $\{u_1, u_2\}$ ℓ-undetectable in G, if $\{u_1, u_2\} \notin \mathcal{Q} \cup E(G)$ and there is no "path" $u_1 w_1 \dots w_\ell u_2$ in G such that ℓ of its "edges" are actual edges of G, the one remaining pair of consecutive vertices belongs to $\mathcal{Q}$, and the distance between the two vertices in this pair is at least $\ell+2$. Though the refined notion is weaker, it still allows to prove non-reconstructibility: if G has diameter d and has a pair which is ℓ-undetectable for all $\ell \le d-2$, then G is not $\mathcal{Q}$-reconstructible. Notice that, to decide whether a given pair $\{u_1, u_2\}$ is undetectable, it is sufficient to know only the edges induced by the union of k-neighbourhoods of u_1 and u_2. In Section 6, we show that the following algorithm finds an undetectable pair whp: at every step, choose a pair of vertices $\{u_1, u_2\}$ uniformly at random from the set of *unconsidered* vertices, consider all vertices in k-neighbourhoods of u_1, u_2, and check whether $\{u_1, u_2\}$ is ℓ-undetectable for all $\ell \le k$.

Structure of the paper

The rest of the paper is organised as follows. In Section 2 we recall properties of random graphs that we will use in our proofs: namely, asymptotic behaviour of sizes of balls of small radii and the diameter. Proofs of upper bounds – Theorem 1 and Theorem 3 – appear in Sections 3 and 4 respectively. In Sections 5 and 6 we prove the lower bounds, Theorems 2 and 4 respectively. Finally, in Section 7 we raise several natural questions that we leave unanswered.

2 Properties of random graphs

In this section, we describe certain properties of $G_n \sim G(n,p)$ that we will use in the proofs. We also refer the reader to monographs [9, 16, 20] for a comprehensive exposition of properties of random graphs and of probabilistic tools – especially, to [20, Chapter 2] containing well-known standard concentration inequalities (in particular, Chernoff bounds for binomial distribution [20, Theorem 2.1], Hoeffding's exponential tail bound for the hypergeometric distribution [20, Theorem 2.10], and Harris' lemma [20, Theorem 2.12]) that we will use in the proofs and will not state them explicitly.

Let us state a technical claim about the sizes of k-neighbourhoods in G_n that we will use frequently both for lower and upper bounds. For $v \in [n]$ and $r \in \mathbb{Z}_{\geq 0}$, everywhere in the paper we denote by $N_r(v)$ the (random) r-ball around v in G_n. We will also denote $N_r(U) := \cup_{v\in U} N_r(v)$ for $U \subset [n]$.

▷ Claim 5. Let k be a positive integer and let $\frac{\log^2 n}{n} \ll p \ll (n^{k-1}\log n)^{-1/k}$. Fix $v \in [n]$. With probability $1-o(n^{-2})$, in $G(n,p)$ we have $|N_r(v)| = (np)^r(1+o(\log^{-1} n))$, for all $r \in [k]$.

Proof. From the Chernoff bound, it follows that $|N_1(v)| = np(1+o(1/\log n))$ with probability $1-o(n^{-2})$. Let us prove by induction over r that, for every, $r \leq k$, $|N_r(v)| = (np)^i(1+o(1/\log n))$ with probability $1-o(n^{-2})$. Assume that for an $r \in [k-1]$, this probability bound is already obtained. Let us expose the r-ball around v and denote the set of vertices at distance exactly r by N'_r. Due to the induction assumption, we may suppose that $|N'_r| = (np)^r(1+o(1/\log n)) = o(n/\log n)$. Thus, the number of vertices in $[n]\setminus N_r(v)$ having neighbours in N'_r (denoted by $|N'_{r+1}|$) is distributed as $\mathrm{Bin}(n(1-o(1/\log n)), 1-(1-p)^{|N'_r|})$. Clearly, $N_{r+1}(v) = N_r(v) \sqcup N'_{r+1}$. Since $\mathbb{E}|N'_{r+1}| = n^{r+1}p^{r+1}(1+o(1/\log n)) \gg \log^4 n$, we get that

$$\mathbb{P}\left(\left||N'_{r+1}| - \mathbb{E}|N'_{r+1}|\right| > \mathbb{E}|N'_{r+1}|/(\ln n)^{3/2}\right) = \exp\left[-\Omega(\mathbb{E}|N'_{r+1}|/\ln^3 n)\right] = o(n^{-2})$$

by the Chernoff bound, as needed. ◁

Let us recall the result of Bollobás [7] about the asymptotic distribution of the diameter of G_n, see also [9, Chapter 10.2].

▶ **Theorem 6.** *Let $c \in \mathbb{R}$ be a constant and $p = \left(\frac{2\ln n + c}{n^k}\right)^{1/(k+1)}$. Then the diameter of G_n converges in distribution to a random variable taking values $k+1$ and $k+2$ with probabilities $e^{-e^{-c}/2}$ and $1-e^{-e^{-c}/2}$ respectively.*

Since the property of having diameter at most d is monotone, we immediately get the following corollary.

▶ **Corollary 7.** *If $n^k p^{k+1} - 2\ln n \to \infty$ as $n \to \infty$, then whp the diameter of G_n is at most $k+1$. If $n^k p^{k+1} - 2\ln n \to -\infty$ as $n \to \infty$, then whp the diameter of G_n is at least $k+2$.*

3 Proof of Theorem 1

Let us recall that $k \geq 1$ is a fixed integer, $\varepsilon > 0$, and $n^{-1+\varepsilon} < p < n^{-k/(k+1)-\varepsilon}$. We let $G_n \sim G(n,p)$. Let $M \in \mathbb{Z}$ be large enough and let us choose a large enough real $C \gg M$. Let us also set $\nu := \lceil \log_2 n \rceil$ and fix a set $X \subset [n]$ of size $\nu \left\lfloor C/(2n^{k-1}p^k) \right\rfloor$. We will need the following auxiliary statements.

▶ **Lemma 8.** *Let $i = i(n) \in [\nu]$ and let $X' \subset X$ be a fixed set of size $i \left\lfloor C/(n^{k-1}p^k) \right\rfloor$. Then with probability $1 - o(1/\log n)$, at least $(n - |X|)(1 - 2^{-i})$ vertices of $[n] \setminus X$ have at least M vertices at distance at most k in X'.*

For an edge e of a graph G, we denote by $G \setminus e$ the spanning subgraph of G obtained by deleting e. If $e \notin E(G)$, then we let $G \setminus e = G$.

▶ **Lemma 9.** *Whp there are no $v_1, v_2 \in [n]$ and $u_1, \ldots, u_M \in X$ such that, for all $j \in [M]$,*

$$d_{G_n \setminus \{v_1,v_2\}}(v_1, u_j) \leq k \quad \text{and} \quad d_{G_n \setminus \{v_1,v_2\}}(v_2, u_j) \leq k+1. \tag{2}$$

We prove Lemma 8 and Lemma 9 in Sections 3.1 and 3.2, respectively.

Let us consider a balanced partition of X into ν disjoint sets $X_1, \ldots, X_\nu$ and assume that G_n is a graph satisfying conclusions of Lemma 8 and Lemma 9 deterministically, i.e.:

1 for every $i \in [\nu]$, the number of vertices $v \in [n] \setminus X$ that have at least M vertices $u \in X_1 \cup \ldots \cup X_i$ such that $d(v,u) \leq k$ is at least $(n - |X|)(1 - 2^{-i})$;

2 there are no $v_1, v_2 \in [n]$ and $u_1, \ldots, u_M \in X$ such that (2) holds for all $j \in [M]$.

Let us prove that these conclusions imply the statement of Theorem 1.

Let us first query all pairs from $\binom{X}{2}$ in G_n. Then, we query all pairs from $X_1 \times ([n] \setminus X)$ and find all vertices $v \notin X$ such that there are at least M vertices $u \in X_1$ satisfying $d(v,u) \leq k$. Let $V_1 \subset [n] \setminus X$ be the set of all such vertices v. If $V_1 = [n] \setminus X$, then we set $\hat{i} := 1$. We then proceed by induction: assume that at step $i \in \{1, \ldots, \nu - 1\}$ disjoint sets $V_1, \ldots, V_i \subset [n] \setminus X$ are chosen and $V_1 \cup \ldots \cup V_i \neq [n] \setminus X$. We then query all pairs from $X_{i+1} \times ([n] \setminus (X \cup V_1 \cup \ldots \cup V_i))$ and find all vertices $v \notin X \cup V_1 \cup \ldots \cup V_i$ such that there are at least M vertices $u \in X_1 \cup \ldots \cup X_i \cup X_{i+1}$ satisfying $d(v,u) \leq k$. We let $V_{i+1} \subset [n] \setminus (X \cup V_1 \cup \ldots \cup V_i)$ be the set of all such v. If $V_1 \cup \ldots \cup V_{i+1} = [n] \setminus X$, then we set $\hat{i} := i+1$. From **1**, we get that, for every i, $|V_1 \cup \ldots \cup V_i| \geq (1 - 2^{-i})(n - |X|)$. Thus, the inductive procedure stops at some moment $\hat{i} \leq \nu$, i.e. $V_1 \cup \ldots \cup V_{\hat{i}} = n \setminus X$, and we query

$$\binom{|X|}{2} + \sum_{i=1}^{\hat{i}} |X_i| \cdot |[n] \setminus (X \cup V_1 \cup \ldots \cup V_{i-1})| \leq \left\lfloor \frac{C}{2n^{k-1}p^k} \right\rfloor \sum_{i=1}^{\hat{i}} n \cdot 2^{1-i} < 2n \left\lfloor \frac{C}{2n^{k-1}p^k} \right\rfloor \leq q$$

pairs.

Let us now show that G_n is reconstructible from the set of queried pairs. For every $i \leq \hat{i}$, we have to recover all adjacencies between $v_1 \in V_i$ and $v_2 \in [n]$. Without loss of generality we may assume that v_2 is either from X or from V_j for some $j > i$. Since all pairs from $V_i \times (X_1 \cup \ldots \cup X_i)$ are queried, we may consider only $v_2 \in (X_{i+1} \cup \ldots \cup X_\nu) \cup (V_{i+1} \cup \ldots \cup V_{\hat{i}})$. It is crucial that for all such v_2, the pairs $\{v_2, u\}$ for $u \in X_1 \cup \ldots \cup X_i$ are queried, so that we got both $d(v_1,u)$ and $d(v_2,u)$ from the oracle.

Let us first assume that v_1 and v_2 are non-adjacent in G_n. Let $u_1, \ldots, u_M \in X_1 \cup \ldots \cup X_i$ be at distance at most k from v_1. From **2**, it follows that there exists $u \in \{u_1, \ldots, u_M\}$ such that $d(v_1,u) \leq k$ while $d(v_2,u) \geq k+2$. It may only happen when v_1, v_2 are not adjacent. Thus, we may "reconstruct non-adjacencies" for all pairs of non-adjacent vertices in G_n.

Now, assume that G' is obtained from G_n by removing some edges that belong to $\cup_{i\le\hat{i}} V_i \times ([n]\setminus(X_1\cup\ldots\cup X_i))$ and that for G' we get exactly the same answers as for G_n for all queried pairs. Let $\{v_1,v_2\}\in G_n\setminus G'$, where $v_1\in V_i$ and $v_2\in(X_{i+1}\cup\ldots\cup X_\nu)\cup(V_{i+1}\cup\ldots\cup V_{\hat{i}})$. As above, we let $u_1,\ldots,u_M\in X_1\cup\ldots\cup X_i$ be at distance at most k from v_1 in G_n. From **2**, we get that there exists $u\in\{u_1,\ldots,u_M\}$ such that $d_{G'}(v_2,u)\ge k+2$. This inequality holds true since distances in G' cannot be less than in G_n. But then $d_{G_n}(v_2,u)\ge k+2$ as $d_{G_n}(v_2,u)=d_{G'}(v_2,u)=d(v_2,u)$ by the assumption since the pair $\{v_2,u\}$ was queried. On the other hand, $v_1\sim v_2$ in G_n and $d(v_1,u)=d_{G_n}(v_1,u)\le k$. So $d(v_2,u)\le d(v_1,u)+1\le k+1$ – a contradiction. Thus, edges are also reconstructible, Theorem 1 follows.

3.1 Proof of Lemma 8

Fix $i\in[\nu]$ and $X'\subset X$ of size $i\left\lfloor C/(2n^{k-1}p^k)\right\rfloor$. For $v\in[n]\setminus X$, we let $\mathcal{B}_v$ be the event saying that at least M vertices in X' are at distance at most k from v. We denote $\xi:=\sum_{v\in[n]\setminus X}\mathbb{1}_{\mathcal{B}_v}$ the number of such vertices. We have to prove that $\mathbb{P}(\xi<(n-|X|)(1-2^{-i}))=o(1/\log n)$.

Fix a vertex $v\in[n]\setminus X$. For any $N\in[n]$, subject to the event $\{|N_k(v)|=N\}$, the set $N_k(v)$ is a uniformly random N-subset of $[n]$ that contains v. We derive the following inequality from Hoeffding's exponential tail bound for the hypergeometric distribution (see [20, Theorem 2.10]): for every $N=(np)^k(1+o(1))$,

$$\mathbb{P}\left(|N_k(v)\cap X'|<\frac{1}{4}iC\,\middle|\,|N_k(v)|=N\right)\le\exp\left[-\frac{iC}{16-o(1)}\right]. \tag{3}$$

First of all, (3) implies that $\mathbb{P}\left(|N_k(v)\cap X'|<M\mid|N_k|=N\right)=o(1/(n\log n))$ uniformly over $N=(np)^k(1+o(1))$ if $i\ge 17\ln n/C$. By the union bound and Claim 5, we get that $\xi=n-|X|$ for such i with probability $1-o(1/\log n)$. We then further assume that $i<17\ln n/C$ and that C is so large that $e^{-2i}>n^{-2/(k+1)}$.

For $v\in[n]\setminus X'$, denote by $N_r^{\neg X'}(v)$ the r-ball around v in $G_n[[n]\setminus X']$. Due to Claim 5, with probability $1-o(1/n)$, $|N_{k-1}^{\neg X'}(v)|=(np)^{k-1}(1+o(1))$ for all $v\in[n]\setminus X'$. We then expose only edges induced by $[n]\setminus X'$ and assume that the latter event holds deterministically.

For $v\in[n]\setminus X$, we let $\mathcal{C}_v$ be the event saying that less than M vertices in X' have neighbours in $N_{k-1}^{\neg X'}(v)$. Let $\eta=\sum_{v\in[n]\setminus X}\mathbb{1}_{\mathcal{C}_v}$. Note that $\eta\ge n-|X|-\xi$. Therefore, it suffices to prove that $\mathbb{P}(\eta\ge 2^{-i}(n-|X|))=o(1/\log n)$. A vertex from X' has a neighbour in $N_{k-1}^{\neg X'}(v)$ for a fixed $v\in[n]\setminus X$ with probability

$$1-(1-p)^{(np)^{k-1}(1+o(1))}=1-e^{-n^{k-1}p^k(1+o(1))}\sim n^{k-1}p^k(1+o(1))$$

since $p<n^{-k/(k+1)-\varepsilon}$. Therefore, by the Chernoff bound,

$$\mathbb{P}(\mathcal{C}_v)\le\mathbb{P}\left(\mathrm{Bin}(|X'|,n^{k-1}p^k(1+o(1))<\frac{1}{4}iC\right)\le\exp\left[-\frac{iC}{16-o(1)}\right].$$

We get that $\mathbb{E}\eta\le e^{-i}(n-|X|)$ for $C>16$ and for large n. Since the relation $u\in N_{k-1}^{\neg X'}(v)$ on pairs (u,v) of vertices from $[n]\setminus X'$ is symmetric, every vertex from $[n]\setminus X'$ belongs to at most $(np)^{k-1}(1+o(1))$ balls $N_{k-1}^{\neg X'}(v)$, $v\in[n]\setminus X$. We shall use the following bounded difference inequality applied to η considered as a function of edges between X' and $[n]\setminus X'$:

▶ **Theorem 10** ([32]). *Let $\xi_1,\ldots,\xi_N\sim\mathrm{Bern}(p)$ be independent, and let $f:\mathbb{R}^N\to\mathbb{R}$ satisfy*

$$|f(x_1,\ldots,x_{i-1},x_i,x_{i+1},\ldots,x_N)-f(x_1,\ldots,x_{i-1},x_i',x_{i+1},\ldots,x_N)|\le c_i$$

for some $c_1,\ldots,c_N>0$ and every $i\in[N]$, $x_1,\ldots,x_N,x_i'\in\mathbb{R}$. Then, for every $t>0$,

$$\mathbb{P}(|f(\xi_1,\ldots,\xi_N)-\mathbb{E}f(\xi_1,\ldots,\xi_N)|\ge t)\le\exp\left[-\frac{t^2}{2p(1-p)\sum_{i=1}^N c_i^2+\frac{2}{3}t\max_i c_i}\right].$$

Assuming that $\hat{G}_n$ is a graph on $[n]$ such that $\hat{G}_n[[n] \setminus X'] = G_n[[n] \setminus X']$ contains exactly the exposed edges, we get that, for any pair $e \in X' \times ([n] \setminus X')$, values $\eta(\hat{G}_n)$ and $\eta(\hat{G}_n \triangle e)$ differ by at most $(np)^{k-1}(1+o(1))$ since e may change only the values of $\mathbb{1}_{\mathcal{C}_v}$ such that the vertex of e from $[n] \setminus X'$ belongs to $N_{k-1}^{\neg X'}(v)$. Therefore, we may set all c_i equal to $(np)^{k-1}(1+o(1))$. Then Theorem 10 implies that, for some constant $c > 0$,

$$\begin{aligned}\mathbb{P}(\eta \geq 2^{-i}(n-|X|)) &\leq \mathbb{P}\left(\eta \geq \frac{e}{2} \cdot e^{-i}(n-|X|)\right) \\ &\leq \exp\left[-c\frac{e^{-2i}(n-|X|)^2}{p(n-|X'|)|X'|(np)^{2k-2} + e^{-i}(n-|X|)(np)^{k-1}}\right] \\ &\leq \exp\left[-\frac{2c}{C+1} \cdot \frac{e^{-2i}n}{i(np)^{k-1}}\right] \leq \exp\left[-n^{\varepsilon(k-1)+o(1)}\right] = o\left(\frac{1}{\log n}\right),\end{aligned}$$

where the penultimate inequality is due to $e^{-2i} > n^{-2/(k+1)}$, completing the proof.

3.2 Proof of Lemma 9

Assume that $M \gg M' \gg 1/\varepsilon$.

▷ Claim 11. Fix a vertex $v \in [n]$. With probability $1 - o(n^{-2})$, $|N_{k-1}(v) \cap X| \leq M'$.

Proof. Due to Claim 5, we have that $|N_{k-1}(v)| = (np)^{k-1}(1+o(1))$ with probability $1-o(n^{-2})$. For simplicity of presentation, let us assume that $v \notin X$ (the case $v \in X$ does not differ much). Subject to $|N_{k-1}(v)| = N+1$, the random variable $|N_{k-1}(v) \cap X|$ has a hypergeometric distribution, implying that

$$\begin{aligned}\mathbb{P}(|N_{k-1}(v) \cap X| > M') &\leq (1+o(1)) \max_{N=(np)^{k-1}(1+o(1))} \frac{\binom{|X|}{M'}\binom{n-|X|-1}{N-M'}}{\binom{n-1}{N}} \\ &\leq (1+o(1))\left(\frac{|X|-M'}{n}\right)^{M'} = o(n^{-2}).\end{aligned}$$

◁

Let us define the following family of graphs $\mathcal{H}$ on $[n]$: fix a vertex v_1 and draw from this vertex $\lfloor M/M' \rfloor$ disjoint paths of length at most k to distinct vertices from X and avoiding the edge $\{v_1, v_2\}$; fix another vertex v_2 and draw from this vertex a path of length at most $k+1$ to each of the paths starting at v_1 and avoiding the edge $\{v_1, v_2\}$: these $\lfloor M/M' \rfloor$ paths from v_2 are not necessarily disjoint.

▷ Claim 12. Whp G_n does not contain any subgraph from $\mathcal{H}$.

Proof. First of all note that any $H \in \mathcal{H}$ has at least $\lfloor M/M' \rfloor$ and at most $2k\lfloor M/M' \rfloor + 2$ vertices. Moreover, for any x in this range, the number of graphs in $\mathcal{H}$ with exactly x vertices is at most $c_x n^{x-\lfloor M/M' \rfloor}|X|^{\lfloor M/M' \rfloor}$ for a certain constant c_x – there are at most $|X|^{\lfloor M/M' \rfloor}$ choices for the $\lfloor M/M' \rfloor$ ends in X of disjoint paths emanating from v_1 and at most $n^{x-\lfloor M/M' \rfloor}$ ways to choose the remaining $x - \lfloor M/M' \rfloor$ vertices. Let us bound from below the number of edges in such a graph and apply the union bound. Let us fix vertices v_1, v_2 and $u_1, \ldots, u_{\lfloor M/M' \rfloor}$ that play the role of ends of paths from v_1 in X. Note that a graph from $\mathcal{H}$ can be obtained from this set of vertices by a sequential addition of $2\lfloor M/M' \rfloor$ paths joining two vertices that are presented in the graph at the previous step. First $\lfloor M/M' \rfloor$ paths are of length at most k, and the last $\lfloor M/M' \rfloor$ paths are of length at most $k+1$. Assuming that at the j-th step the number of added vertices equals x_j, we get that the constructed graph H has density

$$\rho(H) = \frac{|E(H)|}{|V(H)|} = \frac{\sum_{j=1}^{2\lfloor M/M' \rfloor}(x_i+1)}{2+\lfloor M/M' \rfloor + \sum_{j=1}^{2\lfloor M/M' \rfloor} x_i} = \frac{x-2+\lfloor M/M' \rfloor}{x} \geq \frac{(2k+1)\lfloor M/M' \rfloor}{2k\lfloor M/M' \rfloor + 2}.$$

Finally, assuming $\lfloor M/M' \rfloor > \frac{3}{\varepsilon(k+1)}$, the expected number of subgraphs $H \in \mathcal{H}$ in G_n is at most

$$\sum_x c_x n^{x-\lfloor M/M' \rfloor} |X|^{\lfloor M/M' \rfloor} p^{x\frac{(2k+1)\lfloor M/M' \rfloor}{2k\lfloor M/M' \rfloor + 2}} = O\left(\left(\nu n^{k+2/\lfloor M/M' \rfloor} p^{k+1}\right)^{\lfloor M/M' \rfloor}\right) = O(n^{-1}).\lhd$$

Let us now fix v_1, v_2 and assume that the graph $G' := G_n \setminus \{v_1, v_2\}$ satisfies the following properties deterministically:

- for all $v \in [n]$, $|N_{k-1}(v) \cap X| \le M'$;
- $u_1, \ldots, u_M \in N_k(v_1)$;
- G' does not contain a graph from family $\mathcal{H}$.

It is then sufficient to prove that there exists $j \in [M]$ such that $u_j \notin N_{k+1}(v_2)$.

Take a shortest path P_1 (of length at most k) between v_1 and u_1. We then proceed by induction. Assume that at step $j < \lfloor M/M' \rfloor$, we found j disjoint shortest paths $P_1, \ldots, P_j$ from v_1 to $u_1, \ldots, u_j$ respectively. Let $w_1, \ldots, w_j$ be the first vertices (after v_1) on $P_1, \ldots, P_j$ respectively. We have that there exists $j' \in [M] \setminus [j]$ such that $u_{j'} \notin N_{k-1}(w_1) \cup \ldots \cup N_{k-1}(w_j)$. Without loss of generality let $j' = j+1$. Observe that the shortest path P_{j+1} between v_1 and u_{j+1} cannot intersect any of $P_1, \ldots, P_j$ outside of v_1. Eventually we get $\lfloor M/M' \rfloor$ disjoint paths from v_1 to $u_1, \ldots, u_{\lfloor M/M' \rfloor}$. If, for some $j \in [\lfloor M/M' \rfloor]$, $u_j \notin N_{k+1}(v_2)$, we are done. Otherwise, G_n contains a graph from $\mathcal{H}$ – a contradiction.

4 Proof of Theorem 3

Let $\lambda = n^k p^{k+1}$. Without loss of generality we may assume that

$$p \le \left(\frac{(k+o(1))\ln n}{(k+1)n^k}\right)^{1/(k+1)} \tag{4}$$

so that $\frac{3e^\lambda \ln n}{n^{k-2}p^k} \le \binom{n}{2}$. Let X be a fixed set of vertices of size $\left\lfloor 3e^\lambda \ln n/(n^{k-1}p^k)\right\rfloor \le \frac{n}{2}$. Let us query all the pairs from $[X \times ([n] \setminus X)] \cup \binom{X}{2}$. Thus, we query at most $\frac{3}{n^{k-2}p^k} e^\lambda \ln n$ pairs. As in the previous section, we let $G_n \sim G(n,p)$, and, for $v \in [n]$, we let $N_k(v)$ denote the set of vertices in G_n at distance at most k from v.

We further show that whp in G_n for every $v_1, v_2 \in [n] \setminus X$, there is an $x \in X$ such that x is at distance at most k from v_1 and at least $k+2$ from v_2 in the graph obtained from G_n by removing the edge $\{v_1, v_2\}$. It would immediately imply that whp G_n is q-reconstructible. Indeed, we need only to reconstruct adjacency relations between pairs of vertices $v_1, v_2 \notin X$. If v_1, v_2 are non-adjacent, then we queried $\{v_1, x\}$, $\{v_2, x\}$ such that $d(v_1, x) \le k$, $d(v_2, x) \ge k+2$. This may only happen when v_1, v_2 are non-adjacent. Then we can reconstruct all non-adjacencies. It remains to prove that we cannot delete any subset of edges from $G_n[[n] \setminus X]$ without changing the answers to the queries. If $v_1 \sim v_2$, then we queried $\{v_1, x\}$, $\{v_2, x\}$ such that $d(v_1, x) \le k$, $d(v_2, x) \le d(v_1, x) + 1$, and any shortest path from x to v_2 follows the edge $\{v_1, v_2\}$. Thus, the edge $\{v_1, v_2\}$ must be in the graph.

Therefore, the following lemma immediately imples Theorem 3.

▶ **Lemma 13.** *Whp for every $v_1, v_2 \in [n] \setminus X$, there is an $x \in X$ such that*

$$d_{G_n \setminus \{v_1, v_2\}}(v_1, x) \le k \quad \text{and} \quad d_{G_n \setminus \{v_1, v_2\}}(v_2, x) \ge k+2.$$

Proof. Fix vertices $v_1, v_2 \notin X$ and remove the edge $\{v_1, v_2\}$ if it is in G_n. Let N' be the (closed) $(k-1)$-neghbourhood of v_1 in $G_n \setminus [X \cup \{v_2\}]$, and let N_i'' be the (closed) i-neghbourhood of v_2 in $G_n \setminus [N' \cup X]$ for $i \in \{k-1, k\}$. Note that, as soon as N' is

exposed, N''_{k-1} and N''_k are defined solely by adjacencies that are entirely outside N' and their cardinalities do not depend on edges induced by N' – only on the size of N'. Therefore, due to Claim 5, we may assume that $|N'| = (np)^{k-1}(1+o(1/\log n))$, $|N''_i| = (np)^i(1+o(1/\log n))$, $i \in \{k-1, k\}$. By the Chernoff bound and due to (4), the number of neighbours of vertices from N''_{k-1} in N' is $o((np)^{k-1}/\log n)$ with probability $1-o(n^{-2})$. Note that the above makes sense only when $k \geq 2$. In the case $k = 1$, we do not need to apply the Chernoff bound since $N' = \{v_1\}$, $N''_{k-1} = \{v_2\}$, and there is no edge $\{v_1, v_2\}$ in the considered graph.

We then exclude from N' the neighbours of N''_{k-1} and get that the refined set N'_0 still has the size $(np)^{k-1}(1+o(1/\log n))$. If we can prove that with probability $1-o(n^{-2})$, there exists a vertex $x \in X$ that has a neighbour in N'_0 and does not have neighbours in $N''_k \sqcup (N' \setminus N'_0)$, we immediately get the statement of Lemma 13: if P is a path of length at most $k+1$ from v_2 to x in $G_n \setminus \{v_1, v_2\}$, then by construction the neighbour of x on P is in N'_0. Then the farthest from x vertex in $P \cap N'_0$ has a neighbour in $P \cap N''_{k-1}$ – a contradiction. The probability bound on the latter event is also immediate since

$$\begin{aligned}
&\mathbb{P}\left(\mathrm{Bin}\left(|X|, \left(1-(1-p)^{|N'_0|}\right)(1-p)^{|N''_k|+|N'\setminus N'_0|}\right) = 0\right) \\
&= \left(1-\left(1-(1-p)^{(np)^{k-1}(1+o(1/\log n))}\right)(1-p)^{(np)^k(1+o(1/\log n))}\right)^{|X|} \\
&\overset{(4)}{=} \exp\left[-(1+o(1))|X|n^{k-1}p^k e^{-\lambda}\right] = o(n^{-2}). \qquad \blacktriangleleft
\end{aligned}$$

5 Proof of Theorem 2

Without loss of generality, we assume $p = o(1)$. Let us show that Theorem 2 follows from

▷ Claim 14. Let $d \geq 3$, $\varepsilon > 0$. There exists $C = C(d, \varepsilon) > 0$ such that, for every graph G on $[n]$ with diameter at most d and maximum degree $\Delta > C$, its query complexity q satisfies:

$$q(d-1+\varepsilon)\Delta^{d-2} \geq \binom{n}{2} - |E(G)|. \tag{5}$$

Indeed, whp G_n has $(1+o(1))\binom{n}{2}p$ edges, diameter at most $k+2$ (by Corollary 7), and maximum degree $np(1+o(1))$ (by Claim 5, see also [6]), implying that the query complexity of $G(n,p)$ is at least $\frac{1}{2(k+1+\varepsilon)n^{k-2}p^k}$ whp, as needed.

Proof of Claim 14. Let q be an integer that does not satisfy (5). Let $\mathcal{Q} \subset \binom{[n]}{2}$ have size q. Let us call a pair of vertices $\{u_1, u_2\}$ *undetectable in* G if:

- u_1, u_2 are not adjacent in G,
- the pair $\{u_1, u_2\}$ was not queried,
- there is no "path" $u_1 w_1 \dots w_\ell u_2$, $\ell \leq d-2$, such that ℓ of its "edges" are actual edges of G, and the one remaining pair of consecutive vertices belongs to $\mathcal{Q}$.

Assuming that the pair $\{u_1, u_2\}$ is undetectable in G, observe that the addition of the edge $\{u_1, u_2\}$ agrees with the answers to all the queries. Indeed, if it affects some queried pair $\{w, w'\}$, then there should be a path $w \dots u_1 u_2 \dots w'$ of length at most $d-1$ in $G \cup \{u_1, u_2\}$ – a contradiction.

It remains to prove that G has an undetectable pair. For an appropriate choice of C, the number of pairs that do not satisfy the third property of an undetectable pair is at most

$$\sum_{\ell=1}^{d-2}(\ell+1)q\Delta^\ell < q((d-1)\Delta^{d-2} + (d-2)^2\Delta^{d-3}) < q(d-1+\varepsilon)\Delta^{d-2} - q$$

On the other hand, the number of pairs that satisfy the first two properties is at least $\binom{n}{2} - |E(G)| - q > q(d-1+\varepsilon)\Delta^{d-2} - q$, implying the existence of an undetectable pair. ◁

6 Proof of Theorem 4

Let $G_n \sim G(n,p)$, $N := \left\lfloor \frac{e^\lambda \ln n}{8(k+1)^2 n^{k-2} p^k} \right\rfloor$, where $\lambda = n^k p^{k+1}$. We assume that a set $\mathcal{Q} \subset \binom{[n]}{2}$ of N pairs of vertices from $[n]$ is fixed in advance to be queried. We call a pair $\{u_1, u_2\}$ *small* if

- the number of $\{v_1, v_2\} \in \mathcal{Q}$ such that $v_1 \in N_{k'}(u_1)$ and $v_2 \in N_{k-k'}(u_2)$ for some $k' \in \{0, 1, \dots, k\}$ is at most $M := 7(k+1)(np)^k N/n^2$;
- there are no $\{v_1, v_2\} \in \mathcal{Q}$ such that $v_1 \in N_{k'}(u_1)$ and $v_2 \in N_{k-1-k'}(u_2)$ for some $k' \in \{0, 1, \dots, k-1\}$;
- there are no $\{v_1, v_2\} \in \mathcal{Q}$ such that, for some $k' \in \{0, 1, \dots, k\}$, $v_1 \in N_{k'}(u_1)$, $v_2 \in N_{k-k'}(u_2)$, and either $v_2 \in N_k(u_1)$ or $v_1 \in N_k(u_2)$.

▷ Claim 15. Whp at least $\frac{1}{2}\binom{n}{2}$ pairs of vertices are small.

Proof. Due to Claim 5, whp, for every $k' \in \{0, 1, \dots, k\}$, for every $\{v_1, v_2\} \in \mathcal{Q}$, there are at most $(1+o(1))(np)^k$ *ordered* pairs (u_1, u_2) such that $v_1 \in N_{k'}(u_1)$ and $v_2 \in N_{k-k'}(u_2)$. Then whp the following holds: if the number of pairs $\{u_1, u_2\}$ satisfying the first condition in the definition of a small pair is less than $\frac{5}{6}\binom{n}{2}$, then $\frac{1}{6}n(n-1)M < (1+o(1))(k+1)(np)^k N$. The later inequality is false for large enough n. Similarly, whp, for every $\{v_1, v_2\} \in \mathcal{Q}$, there are at most $(1+o(1))k(np)^{k-1}$ *ordered* pairs (u_1, u_2) such that $v_1 \in N_{k'}(u_1)$ and $v_2 \in N_{k-1-k'}(u_2)$ for some $k' \in \{0, 1, \dots, k-1\}$. Then whp the following holds: if the number of pairs $\{u_1, u_2\}$ satisfying the second condition in the definition of a small pair is less than $\frac{5}{6}\binom{n}{2}$, then $\frac{1}{6}n(n-1) < (1+o(1))k(np)^{k-1}N$. The later inequality is false for large enough n as well.

Let us finally show that whp the number of pairs $\{u_1, u_2\}$ satisfying the third condition in the definition of a small pair is at least $\frac{5}{6}\binom{n}{2}$. We will do it in two steps: first, we will show that whp there are only $o(n^2)$ pairs $\{u_1, u_2\}$ that have in their "neighbourhood" $N_{k'}(u_1) \times N_{k-k'}(u_2)$ queried pairs $\{v_1, v_2\}$ with $d(v_1, v_2) \le k$; second, we will observe that whp as soon as a queried pair $\{v_1, v_2\}$ has $d(v_1, v_2) > k$, then the intersection of the k'-ball around v_1 and the k-ball around v_2 has size around $(np)^{k+k'}/n$ – that will be sufficient to finish the proof.

Fix a queried pair $\{v_1, v_2\}$. Since the expected number of paths of length at most k between v_1, v_2 is at most $n^{k-1}p^k(1+o(1))$, we get that the distance between v_1, v_2 is at most k with probability at most $n^{k-1}p^k(1+o(1))$ by Markov's inequality. Therefore, the expected number of pairs in $\mathcal{Q}$ that are at distance at most k is at most $n^{k-1}p^k(1+o(1)) \cdot N$. By Markov's inequality, we get that the number of such pairs in $\mathcal{Q}$ is $O_p(n^{k-1}p^k N)$. As we noted above, whp, for every pair $\{v_1, v_2\} \in \mathcal{Q}$, there are at most $(1+o(1))(k+1)(np)^k$ pairs (u_1, u_2) such that $v_1 \in N_{k'}(u_1)$, $v_2 \in N_{k-k'}(u_2)$ for some $k' \in \{0, 1, \dots, k\}$. Let us fix a sequence w_n growing to infinity with n sufficiently slowly. We get that whp, if the number of pairs $\{u_1, u_2\}$ that have $v_1 \in N_{k'}(u_1)$ and $v_2 \in N_{k-k'}(u_2)$ for some $k' \in \{0, 1, \dots, k\}$ such that $\{v_1, v_2\} \in \mathcal{Q}$ and $d(v_1, v_2) \le k$ is at least $\frac{1}{12}\binom{n}{2}$, then $\frac{1}{12}n(n-1) < w_n(np)^k n^{k-1} p^k N$. This is false for all large enough n. This proves that whp the number of pairs satisfying the last property in the definition of small pairs with the restriction that $d(v_1, v_2) \le k$ (note that it always holds for $k' \in \{0, k\}$) is at least $\frac{11}{12}\binom{n}{2}$. It then remains to prove that whp the number of pairs $\{u_1, u_2\}$ with no $\{v_1, v_2\} \in \mathcal{Q}$ such that $d(v_1, v_2) > k$ and, for some $k' \in [k-1]$, $v_1 \in N_{k'}(u_1)$, $v_2 \in N_{k-k'}(u_2)$, and either $v_2 \in N_k(u_1)$ or $v_1 \in N_k(u_2)$, is at least $\frac{11}{12}\binom{n}{2}$ as well.

As promised, we first show that whp, for any $\{v_1, v_2\}$ such that $d(v_1, v_2) > k$ and any $k' \in [k]$, the intersection of the k'-ball around v_1 and the k-ball around v_2 has size at most $(1+o(1))(np)^{k+k'}/n + \ln^2 n$. Fix v_2 and expose the k-ball around it. Due to Claim 5, with probability $1 - o(n^{-2})$, this ball $N_k(v_2)$ has size $(1+o(1))(np)^k$. Let us now observe that we may assume that all vertices from $S := N_k(v_2) \setminus N_{k-1}(v_2)$ have degrees at most $\ln^2 n$

in $N_k(v_2)$. Indeed, the complementary event implies that there exists a vertex $w \in S$ such that the total number of $(k+1)$-paths and k-paths between u in v_2 is at least $\ln^2 n$, which is false with probability $1-o(n^{-2})$: due to [40, Theorem 5], there exists $C>0$ such that, with probability $1-o(n^{-2})$, the number of paths of length at most $k+1$ between any two vertices in $G(n,p)$ is at most $C\ln n$.

Then, fix $v_1 \notin N_k(v_2)$. For $i \in \{0,1,\dots,k'-1\}$, let N'_i be the i-neighbourhood of v_1 in $[n]\setminus N_k(v_2)$, and let $N_i^{\cap}$ be the set of neighbours of N'_i in $N_k(v_2)$. Note that, for every vertex $w \in N_{k'}(v_1)\cap N_k(v_2)$, a shortest path from w to v_1 leaves $N_k(v_2)$ at some vertex $w' \in S$. Thus, the set $N_{k'}(v_1)\cap N_k(v_2)$ coincides with $\cup_{i=0}^{k'-1}[N_{k'-1-i}(N_i^{\cap})\cap N_k(v_2)]$. Then

$$|N_k(v_2)\cap N_{k'}(v_1)| \le \sum_{i=0}^{k'-2} |N_i^{\cap}|\ln^2 n (np)^{k'-2-i} + |N_{k'-1}^{\cap}| \tag{6}$$

with probability $1-o(n^{-2})$. Moreover, due to Claim 5, with probability $1-o(n^{-2})$, for every $i\in\{0,1,\dots,k'-1\}$, $|N'_i| \le (np)^i(1+o(1))$.

Expose all N'_i, $i\in\{0,1,\dots,k'-1\}$, and assume that $|N'_i| \le (np)^i(1+o(1))$ and $|N_k(v_2)| \le (1+o(1))(np)^k$ hold deterministically. Since $|N_i^{\cap}|$ is the number of vertices in $N_k(v_2)$ that have at least one neighbour in N'_i, we get, by the Chernoff bound,

$$\mathbb{P}(|N_i^{\cap}| > (np)^{k+i}p(1+(\ln\ln n)^{-1}) + \ln^2 n) \le$$
$$\mathbb{P}\left(\mathrm{Bin}\left((np)^k(1+o(1)), 1-(1-p)^{(np)^i(1+o(1))}\right) > (np)^{k+i}p\left(1+\frac{1}{\ln\ln n}\right)+\ln^2 n\right) = o\left(n^{-2}\right).$$

We finally get from (6) that with probability $1-o(n^{-2})$,

$$|N_{k'}(v_1)\cap N_k(v_2)| \le \sum_{i=0}^{k'-2} \ln^2 n (np)^{k'-2-i}((np)^{k+i}p(1+o(1))+\ln^2 n) +$$
$$(np)^{k+k'-1}p(1+o(1))+\ln^2 n = (1+o(1))(np)^{k+k'-1}p+\ln^2 n,$$

as needed. From this and since whp, for every vertex v_2 and every $k'\in[k-1]$, $|N_{k-k'}(v_2)| = (1+o(1))(np)^{k-k'}$ due to Claim 5, we get that whp, for every $\{v_1,v_2\}\in\mathcal{Q}$ satisfying $d(v_1,v_2)>k$, there at most $k\left(\frac{(np)^{2k}}{n}+(np)^{k-1}\ln^2 n\right)$ pairs (u_1,u_2) such that,

$$\text{for some } k'\in[k-1],\quad v_1\in N_{k'}(u_1),\quad v_2\in N_{k-k'}(u_2),\quad \text{and}\quad v_2\in N_k(u_1). \tag{7}$$

So, the event that the number of pairs $\{u_1,u_2\}$ that have a pair $\{v_1,v_2\}$ satisfying $d(v_1,v_2)>k$ and (7) is at least $\frac{1}{24}\binom{n}{2}$ implies

$$\frac{1}{24}n(n-1) < k\left(\frac{(np)^{2k}}{n}+(np)^{k-1}\ln^2 n\right)N,$$

which is false for all large n. Due to symmetry, we get that whp the number of pairs $\{u_1,u_2\}$ that have a pair $\{v_1,v_2\}$ satisfying $d(v_1,v_2)>k$, $v_1\in N_{k'}(u_1)$, $v_2\in N_{k-k'}(u_2)$, and $v_1\in N_k(u_2)$ is less than $\frac{1}{24}\binom{n}{2}$ as well, completing the proof. ◁

Let $\ell\in[k]$. We call a pair of vertices (u_1,u_2) *ℓ-undetectable*, if

- u_1,u_2 are not adjacent in G_n and $\{u_1,u_2\}\notin\mathcal{Q}$,
- there is no "path" $u_1w_1\dots w_\ell u_2$, such that ℓ of the pairs of consecutive vertices $\{u_1,w_1\}$, $\{w_1,w_2\}$, …, $\{w_\ell,u_2\}$ are actual edges of G_n, the one remaining pair of consecutive vertices is from $\mathcal{Q}$, and the distance between the vertices in this pair is at least $\ell+2$ in G_n.

Let us recall that whp G_n has diameter $k+2$ due to Corollary 7. Assuming that the pair $\{u_1, u_2\}$ is ℓ-undetectable for all $\ell \in [k]$, observe that whp the addition of the edge $\{u_1, u_2\}$ agrees with the answers to all the queries. Indeed, if it affects some queried pair $\{w, w'\}$, then there should be a path $w \dots u_1 u_2 \dots w'$ of length $\ell + 1 \le k + 1$ in $G_n \cup \{u_1, u_2\}$ while in G_n the distance between w, w' should be at least $\ell + 2$. This contradicts the fact that $\{u_1, u_2\}$ is ℓ-undetectable since if we consider the sequence $u_2 \dots w' w \dots u_1$ obtained form the path $w \dots u_1 u_2 \dots w'$ by replacing the prefix $w \dots u_1$ and the suffix $u_2 \dots w'$, we get that the pair $\{w, w'\}$ is queried, $d(w, w') \ge \ell + 2$, and all the other consecutive pairs of vertices are edges of G_n. Thus, whp the event that there exists a pair $\{u_1, u_2\}$ which is ℓ-undetectable for all $\ell \in [k]$ implies that G_n is not $\mathcal{Q}$-reconstructible. It then remains to prove that whp G_n has a pair $\{u_1, u_2\}$ which is ℓ-undetectable for all $\ell \in [k]$.

Let us now consider the following iterative procedure. At every step $i \ge 1$, we are given with a set of "considered" vertices $X_i \subset [n]$ (initially $X_1 = \varnothing$), then we sample a pair $\{u_1, u_2\}$ uniformly at random from $\binom{[n] \setminus X_i}{2}$ and expose $G_n[N_k(u_1)]$ and $G_n[N_k(u_2)]$. If the pair $\{u_1, u_2\}$ is not small or u_1, u_2 are adjacent (note that the exposed edges are enough to get these decisions), then we just skip this step and switch to the step $i + 1$ with $X_{i+1} := X_i \cup N_k(u_1) \cup N_k(u_2)$.

Now, assume that at the current step i, we observe that the pair $\{u_1, u_2\}$ is small and u_1, u_2 are not adjacent. Note that the pair $\{u_1, u_2\}$ is ℓ-undetectable for every $\ell \in [k-1]$ since it is small (so, due to the first bullet point in the definition of a small pair, it cannot have any "path" of length at most k from the definition of an undetectable pair). The crucial observation is that the edges between $N_k(u_1) \setminus N_k(u_2)$ and $N_k(u_2) \setminus N_k(u_1)$ have not been exposed yet unless they are entirely inside X_i. We then expose these missing edges and show that they define an event that has sufficiently large probability and implies that the pair $\{u_1, u_2\}$ is k-undetectable (see Claim 16 below). After this step, we switch to the step $i + 1$ with $X_{i+1} := X_i \cup N_k(u_1) \cup N_k(u_2)$ as before.

We perform $\tau = \lfloor n^{1/(k+1)-o(1)} \rfloor$ steps, where τ is chosen so that $\tau(np)^k = o(n/\log n)$. Due to Claim 5, whp (in the measure of the union of the balls exposed before this step) $|X_\tau| = o(n/\log n)$, implying that whp (in the same measure), for every $i \le \tau$, the probability that the pair $\{u_1, u_2\}$ we sample at step i is small (in the measure of the random pair $\{u_1, u_2\}$) is at least $1/2 - o(1)$ by Claim 15.

▷ Claim 16. There exists an event $\mathcal{B}_{u_1,u_2}$ that depends only on edges between $N_k(u_1) \setminus N_k(u_2)$ and $N_k(u_2) \setminus N_k(u_1)$, implies that the pair $\{u_1, u_2\}$ is k-undetectable, and satisfies

$$\mathbb{P}(\mathcal{B}_{u_1,u_2} \mid G_n[X_i],\, \{u_1, u_2\} \notin E(G_n),\, \{u_1, u_2\} \text{ is small}) \ge n^{-7/(8(k+1))+o(1)}.$$

Proof. Fix $k' \le k$, $v_1 \in N_{k'}(u_1)$, $v_2 \in N_{k-k'}(u_2)$ such that the pair $\{v_1, v_2\}$ was queried. Note that since $\{u_1, u_2\}$ is small, it may only happen when $v_1 \notin N_k(u_2)$, $v_2 \notin N_k(u_1)$.

Without loss of generality, assume that $k' \le k - k'$. Note that, if there exists an edge in G_n between $A(v_1) := N_{k-k'}(v_1) \setminus (X_i \cup N_k(u_2))$ and $A(v_2) := N_{k'}(v_2) \setminus N_k(u_1)$, then the distance between v_1, v_2 is at most $k + 1$. Due to Claim 5, whp

$$|N_{k-k'}(v_1)| = (1 + o(1/\log n))(np)^{k-k'}, \quad |N_k(u_1)| = (1 + o(1/\log n))(np)^k,$$
$$|N_{k'}(v_2)| = (1 + o(1/\log n))(np)^{k'}, \quad |N_k(u_2)| = (1 + o(1/\log n))(np)^k.$$

Since $|X_i| = o(n/\log n)$, due to Hoeffding's exponential tail bound for the hypergeometric distribution, whp $|A(v_1)| = (1 + o(\log^{-1} n))(np)^{k-k'}$ and $|A(v_2)| = (1 + o(\log^{-1} n))(np)^{k'}$. Then

$$\mathbb{P}(\text{there is an edge between } A(v_1) \text{ and } A(v_2)) = 1 - (1-p)^{(1+o(1/\log n))(np)^k} = 1 - e^{-\lambda + o(1)}.$$

Since $\{u_1, u_2\}$ is small, the number of queried $\{v_1, v_2\}$ in $\bigcup_{k'=0}^{k} N_{k'}(u_1) \times N_{k-k'}(u_2)$ is at most M. Now, we define the desired event $\mathcal{B}_{u_1,u_2}$: for every k' and every queried pair $\{v_1 \in N_{k'}(u_1), v_2 \in N_{k-k'}(u_2)\}$, there exists an edge between the respective $A(v_1)$ and $A(v_2)$. Then, due to the Harris inequality [17],

$$\mathbb{P}(\mathcal{B}_{u_1,u_2}) \geq (1 - e^{-\lambda+o(1)})^M \sim \exp\left[-(7/8 + o(1)) \ln n/(k+1)\right]. \qquad \lhd$$

Whp in at least $(1/2 - o(1))\tau$ steps we get a small non-adjacent pair. Due to Claim 16, we then get that the probability that, for at least one of these small pairs $\{u_1, u_2\}$, the respective event $\mathcal{B}_{u_1,u_2}$ happens is at least

$$1 - \left(1 - n^{-7/(8(k+1))+o(1)}\right)^{(1/2-o(1))\tau} = 1 - \exp\left[-\frac{1}{2} n^{\frac{1+o(1)}{8(k+1)}}\right] = 1 - o(1),$$

completing the proof.

7 Open questions

Although we get tight bounds on distance query complexity for the binomial random graph $G(n,p)$ when the edge probability p satisfies (1), as p gets closer to a hitting time of a diameter increment, the difference between the bounds increases. In particular, there is a polynomial gap between the bounds even for the "non-adaptive reconstructibility" when $p = \Theta((n^{-k} \ln n)^{1/(k+1)})$ satisfies

$$(1 - o(1)) \left(\frac{\ln n}{(k+1)n^k}\right)^{1/(k+1)} < p < \left(\frac{2\ln n + O(1)}{n^k}\right)^{1/(k+1)}.$$

It would be interesting to get at least the right power of n in the query complexity in this case.

The further natural step is to generalise our results to growing diameter, i.e. to $p = n^{-1+o(1)}$. Although Theorems 2, 3, and 4 are generalised directly to $p \gg \ln^2 n/n$, it is unclear whether it is possible to extend Theorem 1 without any significant modification of the proof method. The main complication is in the application of the bounded difference inequality (Theorem 10) since we use the fact that $e^{-2i} > n^{-2/(k+1)}$ for all $i < \ln n/C$ and some sufficiently large constant C. If k is growing, then there is no such C.

As we mention in Introduction, Mathieu and Zhou [31] proved that, for constant d, the query complexity of the random d-regular graph on $[n]$ is at most $n \ln^2 n$ whp. On the other hand, it is easy to prove the information–theoretic lower bound $\Omega(n \log n/\log\log n)$. It seems likely that the query complexity of the random d-regular graph actually equals $n(\log n)^{1-o(1)}$ whp, and we are asking whether the lower bound is tight.

An Optimal Algorithm for Shortest Paths in Unweighted Disk Graphs

Bruce W. Brewer

Haitao Wang
Kahlert School of Computing, University of Utah, Salt Lake City, UT, USA

Abstract

Given in the plane a set S of n points and a set of disks centered at these points, the disk graph $G(S)$ induced by these disks has vertex set S and an edge between two vertices if their disks intersect. Note that the disks may have different radii. We consider the problem of computing shortest paths from a source point $s \in S$ to all vertices in $G(S)$ where the length of a path in $G(S)$ is defined as the number of edges in the path. The previously best algorithm solves the problem in $O(n \log^2 n)$ time. A lower bound of $\Omega(n \log n)$ is also known for this problem under the algebraic decision tree model. In this paper, we present an $O(n \log n)$ time algorithm, which matches the lower bound and thus is optimal. Another virtue of our algorithm is that it is quite simple.

1 Introduction

Let S be a set of n points in the plane. Each point of S is associated with a disk centered at the point. Note that the disks may have different radii. The *disk graph* $G(S)$ induced by these disks has vertex set S and an edge between two vertices if their disks intersect. We consider the single-source-shortest-path (SSSP) problem of computing shortest paths from a source point $s \in S$ to all vertices in $G(S)$ where the length of a path in $G(S)$ is defined as the number of edges in the path.

The problem was studied previously. A straightforward solution is to first construct $G(S)$ explicitly and then run a breadth-first-search algorithm, which takes $\Omega(n^2)$ time since $G(S)$ may have $\Omega(n^2)$ edges in the worst case. Kaplan, Katz, Saban, and Sharir [15] proposed the first subquadratic time algorithm, and their algorithm runs in $O(n \log^4 n)$ time. Later Klost [18] gave an $O(n \log^2 n)$ time improved solution. On the other hand, it is known that the problem has an $\Omega(n \log n)$ time lower bound under the algebraic decision tree model even if all disks have the same radius [6].

In this paper, we present a new algorithm whose runtime is $O(n \log n)$, which matches the $\Omega(n \log n)$ lower bound and thus is optimal. Another virtue of the algorithm is that it is quite simple. Indeed, the most complex step of our algorithm is constructing a static additively-weighted Voronoi diagram, which can be easily done using Fortune's sweeping algorithm [14]. Aside from that, the algorithm's description in the paper is self-contained.

Concurrently with our work, de Berg and Cabello have also achieved an $O(n \log n)$ time algorithm using a different approach [4].

Related work. Disk graphs are among the most well-studied topics in computational geometry due to their applications and geometric properties, e.g., [1, 3, 7, 8, 10, 13, 20, 24]. The SSSP problem we consider is actually an *unweighted case* because the length of each edge of

© Bruce W. Brewer and Haitao Wang;

$G(S)$ is defined to be one. In the *weighted* case, the length of each edge is defined to be the Euclidean distance between the two disk centers corresponding to the two vertices of the edge. Kaplan, Katz, Saban, and Sharir [15] also gave an algorithm for the weighted case, and the algorithm runs in $O(n \log^6 n)$ time. An, Oh, and Xue [2] very recently derived an improved algorithm of $O(n \log^4 n)$ time.

The SSSP problem on *unit-disk graphs* (in which all disks have the same radius) has also been extensively studied. Cabello and Jejčič [6] first solved the unweighted case in $O(n \log n)$ time, matching the $\Omega(n \log n)$ lower bound [6]. If the points are presorted by x- and y-coordinates, Chan and Skrepetos [9] showed that it can be solved in $O(n)$ additional time. The weighted case was first solved by Roditty and Segal [22] in $O(n^{4/3+\epsilon})$ time for any $\epsilon > 0$. Later, Cabello and Jejčič [6] solved it in $O(n^{1+\epsilon})$ time. The algorithm by Cabello and Jejčič [6] is bottlenecked by a dynamic bicromatic closest pair data structure, which has since seen improvements by Kaplan, Mulzer, Roditty, Seiferth, and Sharir [16] and also by Liu [19]. Recently, Wang and Xue [25] gave a new algorithm of $O(n \log^2 n)$ time. This has been slightly reduced to $O(n \log^2 n / \log \log n)$ by Brewer and Wang [5]. Furthermore, Brewer and Wang [5] proved that the problem can be solved using $O(n \log n)$ comparisons under the algebraic decision tree model, matching an $\Omega(n \log n)$ lower bound in the same model [6].

Kaplan, Katz, Saban, and Sharir [15] also studied a "reversed version" of the shortest path problem in disk graphs. Chan and Huang [8] very recently improved the algorithm of [15]. Both algorithms used the previous SSSP algorithm for disk graphs as a decision procedure. With our new SSSP algorithm, these algorithms can be slightly improved and also simplified.

In the following, after introducing some notation and concepts in Section 2, we present our algorithm in Section 3.

2 Preliminaries

We follow the notation already defined in Section 1, e.g., n, S, s, $G(S)$.

We define S_i for $i = 0, 1, 2, \ldots$ to be the set of vertices of $G(S)$ whose distance from s in $G(S)$ is equal to i. Note that $S_0 = \{s\}$. For convenience, we define $S_{\leq i} = \cup_{j \leq i} S_j$.

For any two points p, q in the plane, let $|pq|$ denote the (Euclidean) distance between p and q.

To differentiate from other points in the plane, we refer to points of S as *sites*. For any site $v \in S$, let D_v denote the input disk centered at v and r_v the radius of D_v. Notice that two sites $u, v \in S$ have an edge (u, v) in $G(S)$ if and only if $|uv| - r_u - r_v \leq 0$. We consider r_v as the *weight* of v, and for any point $p \in \mathbb{R}^2$, we define the *(additively) weighted distance* from p to v as $d_v(p) = |vp| - r_v$. Note that if p is outside the disk D_v, then $d_v(p)$ is the smallest distance from p to any point of D_v.

For any subset $S' \subseteq S$ and a point $p \in \mathbb{R}^2$, we define a *nearest neighbor* of p to be a site in S' whose weighted distance to p is minimal. Formally, we define $\beta_p(S') = \arg\min_{v \in S'} d_v(p)$ to be a nearest neighbor of p in S'. In cases where p has more than one nearest neighbor in S', we let $\beta_p(S')$ refer to an arbitrary one. We also define $d_{S'}(p) = \min_{v \in S'} d_v(p)$.

With respect to the weights r_v of the sites v of S, we will make heavy use of the *(additively) weighted Voronoi diagram* of S, which is a partition of the plane into Voronoi regions, edges, and vertices [14, 23]. The Voronoi region $\mathrm{Vor}(u)$ of a site $u \in S$ is usually defined as the set of points nearer to u than to any other site in S. For convenience, we will let $\mathrm{Vor}(u)$ also include its boundary, defining $\mathrm{Vor}(u)$ as the set of points at least as near to u than to any other site in S. Formally, $\mathrm{Vor}(u) = \{p \in \mathbb{R}^2 : \forall\, v \in S \setminus \{u\},\ d_u(p) \leq d_v(p)\}$. This way, the

plane is covered by the Voronoi regions. The Voronoi edge between two sites $u, v \in S$ is defined by $\mathcal{E}(u,v) = \{p \in \mathbb{R} : \forall\, w \in S \setminus \{u,v\}, d_u(p) = d_v(p) < d_w(p)\}$. Note that $\mathcal{E}(u,v)$ may have multiple connected components, each of which is a straight line segment or a hyperbolic arc [14, 23]. Voronoi vertices are the points that are equidistant to at least three sites in S such that all other sites in S are farther than these. We use $\mathcal{VD}(S)$ to denote the weighted Voronoi diagram of S.

Let $\mathcal{DT}(S)$ denote the dual graph of $\mathcal{VD}(S)$. Specifically, S is the vertex set of $\mathcal{DT}(S)$, and the edge set of $\mathcal{DT}(S)$ consists of all pairs of sites $u, v \in S$ whose Voronoi regions share a Voronoi edge, i.e., $\mathcal{E}(u,v) \neq \emptyset$. Note that if the sites of S all have the same weight (i.e., all disks have the same radius), then $\mathcal{DT}(S)$ is the Delaunay triangulation of S. We define the neighborhood $N_{\mathcal{DT}}(u)$ of a site $u \in S$ to be the set of sites that share an edge with u in $\mathcal{DT}(S)$. By extension, we define the neighborhood $N_{\mathcal{DT}}(S')$ of a set $S' \subseteq S$ by $N_{\mathcal{DT}}(S') = \bigcup_{u \in S'} N_{\mathcal{DT}}(u)$.

For ease of exposition, we make the general position assumption that no three sites of S lie on the same line. The assumption can be lifted without affecting the results, e.g., by standard perturbation techniques [12, 26].

3 The algorithm

In this section, we present our algorithm to compute the sets S_i for $i = 0, 1, 2, \ldots$. It is easy to extend our algorithm to also compute predecessor information for the shortest paths.

We follow the same algorithmic scheme of Cabello and Jejčič [6] for unit-disk graphs and manage to extend their algorithm to our general disk graph case. In what follows, we first describe the algorithm, then discuss the implementation and time analysis, and finally prove its correctness.

3.1 Algorithm description

We begin with constructing the weighted Voronoi diagram $\mathcal{VD}(S)$. Then the algorithm runs in iterations, and each i-th iteration will compute the set S_i. Initially, we have $S_0 = \{s\}$. In the i-th iteration for $i \geq 1$, we compute S_i as follows, assuming that $S_{\leq i-1}$ has already been computed. Let $Q = N_{\mathcal{DT}}(S_{i-1}) \setminus S_{\leq i-1}$, i.e., the neighbors of S_{i-1} in $\mathcal{DT}(S)$ that are not in S_{i-1}. We remove a site $v \in Q$ from Q and determine whether $d_{S_{i-1}}(v) \leq r_v$. If it is, then we add v to S_i and update $Q = Q \cup (N_{\mathcal{DT}}(v) \setminus S_{\leq i})$, i.e., we add the neighbors of v in $\mathcal{DT}(S)$ that are not in $Q \cup S_{\leq i}$ to Q. We repeat this until $Q = \emptyset$, at which point the i-th iteration is complete. After the i-th iteration, we check if $S_i = \emptyset$. If so, then we are done, and the algorithm stops. Otherwise, we continue to the $i+1$-th iteration. Algorithm 1 gives the pseudocode.

3.2 Algorithm implementation and time analysis

We now discuss how to implement the algorithm efficiently.

First of all, computing $\mathcal{VD}(S)$ and thus $\mathcal{DT}(S)$ can be done in $O(n \log n)$ time [14]. Note that the combinatorial sizes of both $\mathcal{VD}(S)$ and $\mathcal{DT}(S)$ are $O(n)$ [14, 23].

Next, notice that the number of vertices added to Q on Line 7 in iteration i is at most the sum of the degrees of the vertices of S_{i-1} in the graph $\mathcal{DT}(S)$. Because the sets S_i are disjoint and $\mathcal{DT}(S)$ has $O(n)$ edges, this means that the number of vertices added to Q by Line 7 throughout the whole algorithm is $O(n)$. By the same reasoning, we conclude that

Algorithm 1 SSSP algorithm.

Input: A set of point sites S, radius r_v for each site $v \in S$, source site $s \in S$.
Output: The sets S_i for $i = 0, 1, \ldots$

```
1  i ← 0;
2  S_0 ← {s};
3  Build VD(S) and DT(S);
4  while S_i ≠ ∅ do
5  |  i ← i + 1;
6  |  S_i ← ∅;
7  |  Q ← N_DT(S_{i−1}) \ S_{≤i−1} ;
8  |  while Q ≠ ∅ do
9  |  |  v ← pop(Q);
10 |  |  if d_{S_{i−1}}(v) ≤ r_v then
11 |  |  |  S_i ← S_i ∪ {v};
12 |  |  |  Q ← Q ∪ (N_DT(v) \ S_{≤i}) ;
13 return S_i for i = 0, 1, ...;
```

the number of vertices added to Q by Line 12 throughout the whole algorithm is also $O(n)$. We can also know that the while loop on Line 8 has at most $O(n)$ iterations throughout the whole algorithm because a vertex is removed from Q in each iteration.

It remains to determine the time complexity for the operation of checking whether $d_{S_{i-1}}(v) \leq r_v$ on Line 10. To this end, it suffices to find $\beta_v(S_{i-1})$, i.e., the nearest neighbor of v in S_{i-1}. To find $\beta_v(S_{i-1})$, in the beginning of the i-th iteration, we compute the weighted Voronoi diagram for S_{i-1}, denoted by $\mathcal{VD}(S_{i-1})$, which takes $O(|S_{i-1}| \log |S_{i-1}|)$ time [14], and then construct a point location data structure for $\mathcal{VD}(S_{i-1})$ in $O(|S_{i-1}|)$ time [11,17]. After that, $\beta_v(S_{i-1})$ can be found in $O(\log n)$ time by a point location query with v on $\mathcal{VD}(S_{i-1})$. As such, the total time of Line 10 in the whole algorithm is $O(n \log n)$. As $\sum_i |S_{i-1}| = n$, the overall time for constructing $\mathcal{VD}(S_{i-1})$ in the whole algorithm is $O(n \log n)$.

We thus conclude that the time complexity of the whole algorithm is $O(n \log n)$.

3.3 Algorithm correctness

We start with proving the following two observations that our algorithm's correctness relies on.

▶ **Observation 1.** *For any two sites $u, v \in S$, they are connected by an edge in $G(S)$ if and only if $d_v(u) \leq r_u$ or $d_u(v) \leq r_v$.*

Proof. Recall that u and v have an edge if and only if $|uv| - r_u - r_v \leq 0$. Notice that $|uv| - r_u - r_v \leq 0$ holds if and only if $d_v(u) \leq r_u$ or $d_u(v) \leq r_v$. ◀

▶ **Observation 2.** *For any site $v \in S \setminus S_{\leq i-1}$, v is in S_i if and only if $d_{S_{i-1}}(v) \leq r_v$.*

Proof. By definition, S_{i-1} has a site u with $d_u(v) = d_{S_{i-1}}(v)$. If $d_{S_{i-1}}(v) \leq r_v$, then $d_u(v) \leq r_v$. By Observation 1, $G(S)$ has an edge connecting u and v. As $u \in S_{i-1}$ and $v \in S \setminus S_{\leq i-1}$, we obtain that $v \in S_i$.

If $v \in S_i$, then there is an edge in $G(S)$ connecting v to a site $u \in S_{i-1}$. By Observation 1, $d_u(v) \leq r_v$. It then follows that $d_{S_{i-1}}(v) \leq d_u(v) \leq r_v$. ◀

We now prove that the algorithm is correct. Let S'_i be the set S_i computed by our algorithm and let S_i be the "correct" set of vertices at distance i from s in $G(S)$. Then, our goal is to prove that $S'_i = S_i$ for all i. We do so by induction on i. Our base case is that $S'_0 = S_0$, which is obviously true because they are both $\{s\}$. Our inductive hypothesis is that $S'_j = S_j$ for all $j < i$. To prove that $S'_i = S_i$, we will argue both $S'_i \subseteq S_i$ and $S'_i \supseteq S_i$.

First of all, since $S'_j = S_j$ for all $j < i$, our algorithm guarantees that every site of S'_i is at distance i from s in $G(S)$ and thus $S'_i \subseteq S_i$. To see this, a site v is added to S'_i in Line 11 because $d_{S_{i-1}}(v) \leq r_v$. By Observation 2, $v \in S_i$.

We next prove that $S'_i \supseteq S_i$. Consider a site $v \in S_i$. Our goal is to show that v is also in S'_i. We will prove in Lemma 3 that there exists a vertex $u \in S_{i-1}$ and a u-v path π in $\mathcal{DT}(S)$ such that all internal vertices of π are in S_i (note that *internal vertices* refer to vertices of π excluding u and v). Let the vertices of π be $u = w_0, w_1, \ldots, w_k = v$. We argue that all w_j with $1 \leq j \leq k$ are added to S'_i. To this end, because $w_j \in S_i$ for all $1 \leq j \leq k$, it is sufficient to argue that w_j is added to Q because when w_j is popped from Q, it will pass the check on Line 10 by Observation 2 and then be added to S'_i. Indeed, w_1 is added to Q on Line 7 because $w_1 \in N_{\mathcal{DT}}(u)$. Since $w_2 \in N_{\mathcal{DT}}(w_1)$, w_2 will be added to Q on Line 12 no later than right after w_1 is added to S'_i on Line 11. Following the same argument, $w_3, w_4, \ldots, w_k = v$ will all be added to Q and thus added to S'_i as well. This proves that $v \in S'_i$. Therefore, $S'_i \supseteq S_i$.

In summary, we have proved $S'_i = S_i$ and thus the correctness of the algorithm.

▶ **Lemma 3.** *For any $i > 0$ and any site $v \in S_i$, there exist a site $u \in S_{i-1}$ and a u-v path in $\mathcal{DT}(S)$ such that all internal vertices of the path are in S_i.*

Proof. We extend the proof of [6, Lemma 1] for the unit-disk graph case to our general disk graph problem.

Let $u = \beta_v(S_{i-1})$, i.e., u is a nearest neighbor of v in S_{i-1}. Consider the line segment $\overline{uv}$ and the sites whose Voronoi regions in $\mathcal{VD}(S)$ intersect $\overline{uv}$. Let $w_0, w_1, \ldots, w_k$ be these sites in the order that their Voronoi regions intersect $\overline{uv}$ with $w_0 = u$ and $w_k = v$. Note that repetitions are possible, so it could be that $w_j = w_{j'}$ for $j \neq j'$. See Figure 1 for an example. For ease of discussion, we assume that $\overline{uv}$ does not contain any Voronoi vertices of $\mathcal{VD}(S)$ (otherwise, we could replace v by a point arbitrarily close to v and then follow the same argument). This implies that, for every $0 \leq j \leq k-1$, $\overline{uv}$ crosses the Voronoi edge between w_j and w_{j+1}. This further implies that w_j and w_{j+1} are adjacent in $\mathcal{DT}(S)$, so $\pi = w_0, w_1, \ldots, w_k$ is a u-v path in $\mathcal{DT}(S)$.

Next, we need to show that all internal vertices w_j $(1 \leq j \leq k-1)$ of π are in S_i. We will first prove that there is an edge (u, w_j) in $G(S)$ connecting u and w_j, meaning that $w_j \in S_{i-2} \cup S_{i-1} \cup S_i$ since $u \in S_{i-1}$. Then, we will show that $w_j \notin S_{i-2} \cup S_{i-1}$, so $w_j \in S_i$ must hold. This will complete the proof of the lemma.

Proving $G(S)$ has an edge (u, w_j). We first argue that $G(S)$ has an edge (u, v). Indeed, since $v \in S_i$, there is a vertex $u' \in S_{i-1}$ connecting to v by an edge in $G(S)$. By Observation 1, $d_{u'}(v) \leq r_v$. Since $u = \beta_v(S_{i-1})$, we have $d_u(v) \leq d_{u'}(v) \leq r_v$. By Observation 1, $G(S)$ has an edge (u, v).

Consider any w_j with $1 \leq j \leq k-1$. We now argue that $G(S)$ has an edge (u, w_j). Recall that $\overline{uv}$ intersects $\mathrm{Vor}(w_j)$. Let p be a point of $\overline{uv} \cap \mathrm{Vor}(w_j)$; see Figure 2. We can derive the following:

$$d_{w_j}(u) = |w_j u| - r_{w_j} \overset{(1)}{\leq} |w_j p| + |pu| - r_{w_j} \overset{(2)}{\leq} |vp| + |pu| - r_v \overset{(3)}{=} |vu| - r_v = d_v(u) \overset{(4)}{\leq} r_u,$$

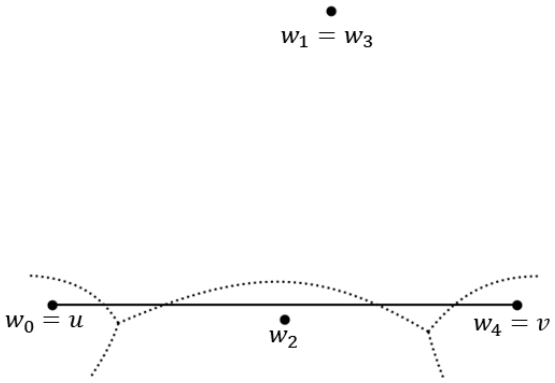

Figure 1 The segment $\overline{uv}$ passes through $\mathrm{Vor}(u)$, $\mathrm{Vor}(w_1)$, $\mathrm{Vor}(w_2)$, $\mathrm{Vor}(w_3)$, and $\mathrm{Vor}(v)$, where $w_1 = w_3$.

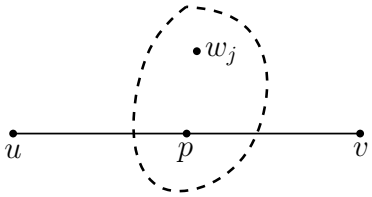

Figure 2 The region bounded by the dashed curve is $\mathrm{Vor}(w_j)$.

where (1) is due to the triangle inequality, (2) is due to $p \in \mathrm{Vor}(w_j)$ (therefore, $|w_jp| - r_{w_j} = d_{w_j}(p) \leq d_v(p) = |vp| - r_v$), (3) is due to $p \in \overline{uv}$, and (4) is due to Observation 1 and the fact that $G(S)$ has an edge (u, v). Consequently, by Observation 1, $G(S)$ has an edge (u, w_j).

Proving $w_j \notin S_{i-2} \cup S_{i-1}$. To prove that $w_j \notin S_{i-2} \cup S_{i-1}$, $1 \leq j \leq k-1$, as before, we pick a point $p \in \overline{uv} \cap \mathrm{Vor}(w_j)$ and derive the following:

$$d_{w_j}(v) \overset{(1)}{<} |w_jp| + |pv| - r_{w_j} \overset{(2)}{\leq} |up| + |pv| - r_u \overset{(3)}{=} |uv| - r_u = d_u(v) \overset{(4)}{\leq} r_v,$$

where (1) is due to the triangle inequality and our general position assumption (because $p \in \overline{uv}$, equality occurs only if u, v, and w_j are collinear, violating our general position assumption), (2) is due to $p \in \mathrm{Vor}(w_j)$ (therefore, $|w_jp| - r_{w_j} = d_{w_j}(p) \leq d_u(p) = |up| - r_u$), (3) is due to $p \in \overline{uv}$, and (4) is due to Observation 1 and the fact that $G(S)$ has an edge (u, v), as proven above.

Notice that $w_j \notin S_{i-1}$ since otherwise $d_{w_j}(v) < d_u(v)$ proved above would contradict with $u = \beta_v(S_{i-1})$. Also, since $G(S)$ has an edge (w_j, v) and $v \in S_i$, w_j cannot be in S_{i-2} (since otherwise v would be in $S_{\leq i-1}$, contradicting with that $v \in S_i$). This proves that $w_j \notin S_{i-2} \cup S_{i-1}$. ◀

The following theorem summarizes our result.

▶ **Theorem 4.** *Given a set of n disks in the plane and a source disk, shortest paths from the source to all other vertices in the disk graph induced by all disks can be computed in $O(n \log n)$ time.*

Extension to the L_∞ (resp., L_1) metric. In the L_∞ metric, each disk becomes a square centered at a site of S. For this case, an $O(n \log n)$-time algorithm was given by Klost [18] to solve the SSSP problem, which uses the involved techniques in [3]. We can solve this problem

in $O(n \log n)$ time in a much simpler way by making the following changes to Algorithm 1. First, use the L_∞ metric to measure the distance $|pq|$ of any two points p, q in the plane. Second, use additively-weighted Voronoi diagrams in the L_∞ metric instead. Note that constructing an additively-weighted Voronoi diagram for a set of n points in the L_∞ metric is equivalent to constructing a Voronoi diagram for a set of n squares in the L_∞ metric. This latter problem can be solved in $O(n \log n)$ time, e.g., by the algorithm of Papadopoulou and Lee [21]. As such, Algorithm 1 can be modified to solve the L_∞ metric case in $O(n \log n)$ time. The algorithm is much simpler than the one in [18]. The L_1 case can be treated analogously.

Abstract

The current landscape of balanced graph partitioning is divided into high-quality but expensive multilevel algorithms and cheaper approaches with linear running time, such as single-level algorithms and streaming algorithms. We demonstrate how to achieve the best of both worlds with a *linear time multilevel algorithm*. Multilevel algorithms construct a hierarchy of increasingly smaller graphs by repeatedly contracting clusters of nodes. Our approach preserves their distinct advantage, allowing refinement of the partition over multiple levels with increasing detail. At the same time, we use *edge sparsification* to guarantee geometric size reduction between the levels and thus linear running time.

We provide a proof of the linear running time as well as additional insights into the behavior of multilevel algorithms, showing that graphs with low modularity are most likely to trigger worst-case running time. We evaluate multiple approaches for edge sparsification and integrate our algorithm into the state-of-the-art multilevel partitioner KaMinPar, maintaining its excellent parallel scalability. As demonstrated in detailed experiments, this results in a 1.49× average speedup (up to 4× for some instances) with only 1% loss in solution quality. Moreover, our algorithm clearly outperforms state-of-the-art single-level and streaming approaches.

1 Introduction

Balanced graph partitioning aims to divide a graph into blocks of roughly equal size while minimizing the number of edges cut by the partition. As this is a crucial subtask in many applications [8, 14], it is of considerable interest to compute high-quality partitions within a minimal amount of time. Unfortunately, this goal seems unattainable from the viewpoint of

complexity theory – even approximating balanced graph partitioning to a constant factor is NP-hard [4]. Consequently, heuristic approaches are used in practice, covering a wide spectrum of options along the running time versus quality trade-off.

In the high-quality category, the most successful approaches use the multilevel framework. By repeatedly contracting clusters of nodes, multilevel algorithms first construct a hierarchy of increasingly smaller graphs in the *coarsening phase*. On the smallest graph, more expensive heuristics can be used to find a good *initial partition*. Finally, the *uncoarsening phase* undoes the contractions in reverse order while further improving the partition quality via local search algorithms (this is called *refinement*). Overall, multilevel partitioning combines a good initial solution with iterative refinement on a series of summarized graph representations with increasingly finer granularity. This has proven highly successful in practice, consistently achieving better solution quality than alternative approaches on real-world inputs [13, 26, 36]. However, due to lacking constraints on the size of the contracted representations, current multilevel implementations have superlinear running time.

On the other hand, *single-level* algorithms that use only a fixed number of passes on the input graph can run in linear time [50]. This is motivated by applications where the partitioning time is a potential bottleneck. For example, graph partitioning is used in various domains to efficiently distribute workloads across parallel machines [7, 11, 48]. This requires the graph partitioning step to be less expensive than the downstream computation. Taking this to the extreme, *streaming* approaches only consider a small part of the graph at once, assigning nodes greedily while using only a minimal representation of the partition state [17, 21, 31]. However, the running time guarantees of single-level and streaming algorithms come at the cost of inferior solution quality when compared to multilevel algorithms [6, 26, 53].

Contributions. In this work, we show that the described trade-off can be avoided by constructing a *linear time multilevel algorithm*. Our coarsening algorithm enforces that the graph shrinks by a constant factor with every successive contraction step, using edge sparsification to reduce the number of edges if necessary. We prove that this guarantees $\mathcal{O}(n + m)$ expected total work for n nodes and m edges, without any assumptions on the input graph. Our analysis provides a framework to understand the running time behavior of a broad class of existing multilevel algorithms. In addition, we demonstrate that graphs with low modularity are most likely to trigger worst-case running time behavior, while graphs with high modularity might already allow linear running time without using edge sparsification.

We integrate our approach into the KaMinPar shared-memory graph partitioner [29], preserving its excellent scaling behavior while guaranteeing linear work. For instance classes that approximate the worst case, our algorithm achieves practical speedups of up to 4× (1.49× in the geometric mean) over a baseline KaMinPar configuration – which is the fastest available shared-memory multilevel partitioner according to Ref. [26]. Despite this, the loss in partition quality is only 1% on average. Our algorithm outperforms both the single-level partitioner PuLP [50] and the state-of-the-art streaming partitioner CUTTANA [31], achieving 24% and 66% smaller average cuts, respectively, as well as a faster running time.

2 Preliminaries

Notation and Definitions. Let $G = (V, E, c, \omega)$ be an undirected graph with node weights $c : V \to \mathbb{N}_{>0}$, edge weights $\omega : E \to \mathbb{N}_{>0}$, $n := |V|$, and $m := |E|$. We extend c and ω to sets, i.e., $c(V' \subseteq V) := \sum_{v \in V'} c(v)$ and $\omega(E' \subseteq E) := \sum_{e \in E'} \omega(e)$. $N(v) := \{u \mid \{u, v\} \in E\}$ denotes the neighbors of $v \in V$ and $E(v) := \{e \mid v \in e\}$ denotes the edges incident to v. We

are looking for k *blocks* of nodes $\Pi \coloneqq \{V_1, \dots, V_k\}$ that partition V, i.e., $V_1 \cup \dots \cup V_k = V$ and $V_i \cap V_j = \emptyset$ for $i \neq j$. The *balance constraint* demands that $\forall i \in \{1, \dots, k\}$: $c(V_i) \leq L_{\max} \coloneqq (1+\varepsilon)\lceil \frac{c(V)}{k} \rceil$ for some imbalance parameter $\varepsilon > 0$. The objective is to minimize $\text{cut}(\Pi) \coloneqq \sum_{i<j} \omega(E_{ij})$ (weight of all cut edges), where $E_{ij} \coloneqq \{\{u,v\} \in E \mid u \in V_i, v \in V_j\}$. A *clustering* $\mathcal{C} \coloneqq \{C_1, \dots, C_b\}$ is also a partition of V, where the number of blocks b is not given in advance (there is also no balance constraint).

Multilevel Graph Partitioning. Virtually all high-quality, general-purpose graph partitioners are based on the multilevel paradigm, which consists of three phases. During coarsening, the algorithms construct a hierarchy $\mathcal{H} = \langle G =: G_1, G_2, \dots, G_\ell \rangle$ of successively coarser representations of the input graph G. Coarse graphs are built by either computing node clusterings or matchings and afterwards *contracting* them. A clustering $\mathcal{C} = \{C_1, \dots, C_b\}$ is contracted by replacing each cluster C_i with a coarse node c_i with weight $c(c_i) = c(C_i)$. For each pair of clusters C_i and C_j, there is a coarse edge $e = \{c_i, c_j\}$ with weight $\omega(e) = \omega(E_{ij})$ if $E_{ij} \neq \emptyset$, where E_{ij} is the set of all edges between clusters C_i and C_j. Once the number of coarse nodes falls below a threshold (typically, kC for some tuning constant C), *initial partitioning* computes an initial solution of the coarsest graph G_ℓ. Subsequently, contractions are undone, projecting the current solution to finer graphs and refining it. The total running time of a multilevel partitioner is the cumulative time for coarsening, initial partitioning, and refinement across all levels of the hierarchy $\mathcal{H}$.

3 Related Work

There has been a lot of research on graph partitioning, thus we refer the reader to surveys [8, 13] for a general overview and only focus on work closely related to our contributions here. As described above, modern general-purpose, high-quality graph partitioners such as Mt-Metis [38], Mt-KaHIP [3], Mt-KaHyPar [26], KaMinPar [29], and Jet [25] are mostly based on the multilevel paradigm, which constructs a hierarchy of coarser graphs during the coarsening phase.

Graph Coarsening. Early multilevel partitioners, like Chaco [32] and Metis [36], primarily employed coarsening strategies based on contracting graph matchings. While effective for mesh-like graphs due to high matching coverage (often 85-95% [35]), these strategies struggle with graphs exhibiting irregular structures, such as scale-free networks. On these graphs, small maximal matchings can result in much slower coarsening and potentially a linear number of levels. Subsequent developments addressed this limitation. Mt-Metis [39] introduced 2-hop matchings, extending small maximal matchings by further pairing nodes that have some degree of overlap in their neighborhoods until $\geq 75\%$ of nodes are contracted. This technique was subsequently also implemented by other partitioners [18, 25]. Alternative strategies focus on accelerating coarsening by grouping multiple nodes. These include methods based on cluster contraction [44, 3, 26, 29] and pseudo-matchings where nodes can match with multiple neighbors [1]. While enabling faster node reductions, they often constrain the weight of the clusters to ensure that finding a balanced initial partition is feasible. This can be problematic on graphs with highly connected hubs (e.g., the center of a star graph), potentially limiting the achievable coarsening ratio.

Graph Sparsification. Graph sparsification techniques aim to approximate a given graph with a sparser one (called *sparsifier*), typically containing substantially fewer edges while

preserving specific structural properties important for downstream tasks. This allows handling massive data sets where considering the full graph is computationally infeasible, as well as speeding up a variety of algorithms on graphs or matrices [2, 9, 22]. For graph partitioning, preserving cut properties (and thus approximately preserving the partition objective) is particularly relevant. An *ε-cut sparsifier* guarantees that every cut in the sparsifier has a weight within a $1\pm\varepsilon$ factor of the original cut. Benczúr and Karger showed that such sparsifiers with $O(n \log n/\varepsilon^2)$ edges exist for any graph and gave near-linear time constructions [9].

There are several approaches to construct sparsifiers. Spielman and Srivastava [51] introduced sparsification based on *effective resistance*, which often yields high-quality sparsifiers and preserves spectral properties closely related to cuts. However, this method can be computationally demanding. Alternatively, various heuristic sampling techniques exist, such as uniform edge sampling, k-neighbor sampling, and Forest Fire sampling [40, 42], which uses an analogy to a spreading wildfire. Chen et al. [16] provide a comparative study, suggesting that Forest Fire sampling outperforms uniform sampling for preserving cut-related properties.

KaMinPar. We integrate the techniques described in this paper into the KaMinPar [29] framework. KaMinPar is a shared-memory parallel multilevel graph partitioner. Its coarsening and uncoarsening phases are based on the *size-constrained label propagation* [44] algorithm, which is parameterized by a maximum cluster size (resp. block weight) U. In the coarsening resp. uncoarsening phase, each node is initially assigned to its own cluster resp. to its corresponding block of the partition. The algorithm then proceeds in rounds. In each round, the nodes are visited in some order. A node u is moved to the cluster resp. block K that contains the most neighbors of u without violating the size constraint U, i.e., $c(K) + c(u) \leq U$. The algorithm terminates once no nodes have been moved during a round or a maximum number of rounds has been exceeded. The coarsening further implements a 2-hop clustering strategy [29], which reduces the number of coarse nodes further whenever label propagation alone yields a node reduction factor less than 2. Since each round of size-constrained label propagation runs in linear time, and there is only a constant number of rounds, KaMinPar achieves linear time per hierarchy level for coarsening and uncoarsening.

The original paper [29] shows that KaMinPar achieves overall linear-time complexity under two key assumptions: (i) a constant node reduction factor between hierarchy levels, and (ii) bounded average degree for coarse graphs. While we will demonstrate in Theorem 1 that KaMinPar's coarsening strategy satisfies assumption (i), the inability to guarantee assumption (ii) results in a worst-case running time with an extra $log(n)$ factor.

4 Linear Time Multilevel Graph Partitioning

Multilevel algorithms construct a hierarchy $\mathcal{H} = \langle G =: G_1, G_2, \ldots, G_\ell \rangle$ of successively coarser representations of the input graph G. Each level of $\mathcal{H}$ is considered twice, during coarsening (to construct the next level) and during refinement (to improve the current partition). Assuming linear time for the coarsening and refinement on each level (see Section 3), the total sequential running time is $\Theta(\sum_{i=1}^{\ell} |V_i| + |E_i|)$. Without additional constraints on the number and size of the levels, the worst-case running time might be $\Theta(nm)$ or worse.

To obtain better guarantees, we need a geometric size reduction per level.[1] As a first step, we require that $|V_{i+1}| \leq \gamma |V_i|$ for some constant $\gamma < 1$ that is independent of G. If this is the case, the coarsened graph has constant size after a logarithmic number of steps, which

[1] In general, any series with a sum of $\mathcal{O}(1)$ works – a geometric series is, however, the most straightforward.

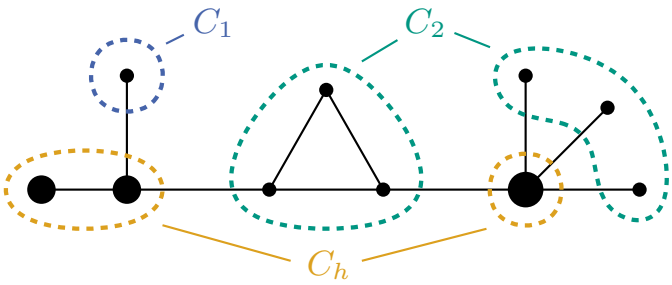

Figure 1 Illustration of Theorem 1, with examples of the different cluster types. Note that the green cluster to the right is created by 2-hop clustering.

already achieves a running time of $\mathcal{O}(n + m \log n)$. Combined with a similar guarantee for the number of edges, we get a linear total running time.

4.1 Reducing the Number of Nodes

As discussed in Section 3, the coarsening algorithms used in practice start by computing either a matching or a clustering of adjacent nodes. Typically, a maximum allowed node weight U is enforced for clusters. We use the term *size-constrained label propagation* to refer to a broad class of coarsening algorithms that form clusters of adjacent nodes and use a weight constraint. We require one essential property. In the resulting clustering, a node v never forms a singleton cluster as long as there is any adjacent cluster K with $c(K) + c(v) \leq U$.

Due to the weight constraint, size-constrained label propagation by itself is not sufficient for reducing the number of nodes (consider, e.g., a star graph). To solve this, partitioners use *2-hop clustering* as a second step, forming clusters of nodes that are not adjacent but instead have a common neighbor cluster. In the following, we provide the first formal proof that this guarantees a constant factor node reduction.

Consider a (non-isolated) node v in a singleton cluster $S = \{v\}$. Formally, we will assume that the algorithm assigns a *favorite cluster* K_S to S, out of the clusters adjacent to S. The 2-hop clustering then merges any nodes with the same favorite cluster, as long as this does not violate the weight constraint. Note that only considering favorite clusters is more restrictive than general 2-hop clustering, but is already sufficient for our purpose.

▶ **Theorem 1.** *The number of clusters obtained by size-constrained label propagation and 2-hop clustering with a maximal cluster weight $U \geq 2\frac{c(V)}{|V|}$ is at most*

$$|\mathcal{C}| \leq \frac{1}{2}|V| + \frac{c(V)}{U}$$

on any graph without isolated nodes.

Proof. We divide the set of clusters $\mathcal{C}$ into multiple subsets (see Figure 1 for an illustration). C_h is the set of *heavy* clusters with weight larger than $\frac{1}{2}U$. C_1 is the set of singleton clusters with weight at most $\frac{1}{2}U$ and C_2 is the set of clusters with multiple nodes and weight at most $\frac{1}{2}U$. Note that $\mathcal{C} = C_h \cup C_1 \cup C_2$. Let $r := \frac{1}{|C_2|}\sum_{K \in C_2} |K|$ be the average number of nodes for clusters in C_2. In combination, this results in the inequality $|V| \geq |C_h| + |C_1| + r|C_2|$.

Each singleton cluster $S \in C_1$ is only adjacent to clusters with weight larger than $U - c(S)$, and thus only clusters in C_h – otherwise, the node would have joined the lighter adjacent cluster. Consider the favorite cluster $K_S \in C_h$ of S. Due to 2-hop coarsening, there is no other cluster in C_1 with the same favorite (otherwise, 2-hop clustering would have joined them).

Algorithm 1 Graph Coarsening with Sparsification.

```
1 i ← 1, G_i ← G                                              // Input: graph G
2 while G_i not small enough do
3 |   G'_{i+1} ← Coarsen(G_i)
4 |   m̂ ← min{τ_e · |E(G_i)|, τ_d · (|E(G_i)|/|V(G_i)|) · |V(G'_{i+1})|}
5 |   if |E(G'_{i+1})| > ρ · m̂ then G_{i+1} ← Sparsify(G'_{i+1}, m̂)
6 |   else G_{i+1} ← G'_{i+1}
7 |   i += 1
8 return ⟨G_1, ..., G_i⟩                                      // Output: hierarchy H = ⟨G_1, ..., G_i⟩
```

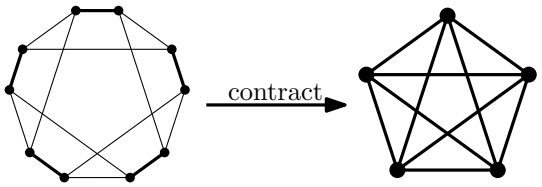

Figure 2 Contracting the bolded edges leads to increased density on the coarse graph.

Consequently, $|C_1| \leq |C_h|$. Moreover, $c(S)+c(K_S) > U$ gives, when summed over all clusters and combined with the definition of C_h, the inequality $c(V) \geq \sum_{K\in C_h} c(K)+\sum_{K\in C_1} c(K) = \sum_{K\in C_1}(c(K)+c(K_S)) + \sum_{K\in C_h\setminus\{K'_S|K'\in C_1\}} c(K) > U|C_1| + \frac{1}{2}U(|C_h|-|C_1|)$. Rearranged, this is $|C_h|+|C_1| \leq 2\frac{c(V)}{U}$.

Combining all inequalities, we get

$$\begin{aligned}
|\mathcal{C}| &= |C_h| + |C_1| + |C_2| \\
&\leq \frac{1}{r}|V| + (1-\frac{1}{r})|C_h| + (1-\frac{1}{r})|C_1| \\
&\leq \frac{1}{r}|V| + 2(1-\frac{1}{r})\frac{c(V)}{U} \\
&\leq \frac{1}{2}|V| + \frac{c(V)}{U}
\end{aligned}$$

For the final step, we use the observation that $xa+(1-x)b \leq \frac{1}{2}a+\frac{1}{2}b$ for $b \leq a$ and $x \leq \frac{1}{2}$. Since $r \geq 2$ and $U \geq 2\frac{c(V)}{|V|}$, we can apply this with $x = \frac{1}{r}$, $a = |V|$ and $b = 2\frac{c(V)}{U}$. ◀

Isolated nodes (i.e., nodes without a neighbor) are a special case as standard clustering algorithms do not handle them. Therefore, they are omitted from Theorem 1. However, it is trivial to either remove isolated nodes and reinsert them in the uncoarsening, or alternatively cluster them with each other (we do the latter).

Note that the precondition $U \geq 2\frac{c(V)}{|V|}$ is no limitation for the applicability of Theorem 1. In practice, much larger values are used for U (in our case $U = \frac{c(V)}{160k}$, see Section 4.3). However, the theorem does not include clustering approaches which limit the *number* of nodes in a cluster (e.g., allowing only matchings). We note that in this case similar, but weaker, bounds can be obtained with an analogous line of reasoning.

4.2 Reducing the Number of Edges via Sparsification

As discussed above, geometric node reduction in coarsening strategies can still lead to superlinear total running time due to increasing graph density at coarser levels (e.g., Figure 2). Achieving linear time necessitates preventing this phenomenon. Since common clustering algorithms can not guarantee a geometric reduction in the number of edges, we propose an alternative strategy: sparsifying the contracted graph when the edge count does not shrink at a sufficient rate. To validate this concern, we first show that the issue can arise on important classes of graphs using the example of Erdős-Rényi graphs. Subsequently, we will detail our sparsification approach.

Consider the coarsening hierarchy of a sparse Erdős-Rényi graph $G_0 = G(n_0, c/n_0)$ with n_0 nodes and edge probability $p_0 := c/n_0$ for some constant c. Assume that coarsening halves the number of nodes at each level by contracting pairs of nodes, and that coarse graphs also behave like Erdős-Rényi graphs. In other words, $G_i = G(n_i, p_i)$ with $n_i = n_{i-1}/2$ and $p_i \approx 1 - (1 - p_{i-1})^4$ for $i > 0$ (there is an edge between two coarse nodes if any of the four potential edges between the corresponding nodes in G_{i-1} existed). Note that $n_i = n_0/2^i$ and $p_i = 1 - (1 - p_0)^{4^i} = 1 - (1 - c/n_0)^{4^i} \approx 1 - e^{-4^i \cdot c/n_0}$. Let $i = \alpha \log(n_0)$, then $p_i \approx 1 - e^{-cn_0^{2\alpha - 1}} \xrightarrow{n_0 \to \infty} 0$ for $\alpha < \frac{1}{2}$, i.e., there are $\Theta(\log n_0)$ sparse levels. On these,

$$\frac{\mathbb{E}[m_{i+1}]}{\mathbb{E}[m_i]} = \frac{1 - (1 - p_i)^4}{p_i} \frac{n_i(n_i - 2)/8}{n_i(n_i - 1)/2} \xrightarrow{n_0 \to \infty} \frac{1 - (1 - p_i)^4}{4p_i} \approx \frac{1 - (1 - 4p_i)}{4p_i} = 1,$$

since $n_i = n_0/2^i \geq n_0/2^{\alpha \log n_0} > \sqrt{n_0} \to \infty$ and $(1 - p_i)^4 \approx 1 - 4p_i$ for small p_i. Thus, the number of coarse edges remains relatively constant, leading to overall $\mathcal{O}(m_0 \log(n_0))$ time.

To achieve linear time, we therefore limit the number of edges through sparsification as outlined in Algorithm 1. Let $G'_{i+1} = (V_{i+1}, E'_{i+1})$ denote the current graph before sparsification, obtained by contracting the previous graph G_i (line 1). We obtain $G_{i+1} = (V_{i+1}, E_{i+1})$ by sparsifying the edges of G'_{i+1} so that the size of E_{i+1} is bounded by a threshold $\hat{m}$, defined as

$$\hat{m} := \min\{\tau_e \cdot |E_i|, \tau_d \cdot \frac{|E_i|}{|V_i|} \cdot |V_{i+1}|\}.$$

Here, τ_e is the *edge threshold* parameter, limiting the coarse edge count relative to the current graph's edge count, and τ_d is the *density threshold* parameter, likewise limiting the average degree of the coarse graph. Since sparsification itself introduces computational overhead, we only apply it if the potential edge reduction is significant. Specifically, we trigger sparsification only if $|E'_{i+1}| > \hat{m}$ *and* the target edge count $\hat{m}$ represents a substantial reduction from the current edge count $|E'_{i+1}|$, quantified by the condition $|E'_{i+1}|/\hat{m} \geq \rho$, where $\rho \geq 1$ is a tunable constant (line 1). Once triggered, we use one of the following sampling algorithms to reduce the edge count to $\hat{m}$ (in expectation), before adding the sparsified graph to the hierarchy (line 1). Since our goal is to achieve overall linear time, we only consider linear time sparsification algorithms. Further, sparsification must be fast in practice for speedups to be attainable.

Uniform Sampling: UR. As a simple baseline, we consider uniform random sampling. Each edge $e \in E'_{i+1}$ is selected independently with probability $p := \hat{m}/|E'_{i+1}|$, resulting in expected $\hat{m}$ edges. Note that this approach is oblivious to edge weights – although heavier edges have larger influence on the partitioning objective and are thus likely more important.

Algorithm 2 Weighted Forest Fire: graph $G = (V, E)$, burn ratio ν, probability p. The only difference to the original Forest Fire [41] algorithm is highlighted blue.

```
1  S ← new Array() of size |E|                                   // Scores
2  b ← 0                                                         // Number of burnt edges
3  while b ≤ ν|E| do in parallel
4      Q ← new FIFO(); Q.push(random node from V)                 // BFS queue
5      T ← new Set()                                             // Visited nodes
6      while Q ≠ ∅ do
7          u ← Q.pop()
8          while N(u) \ T ≠ ∅ do
9              Sample v from N(u) \ T with prob. ω({u,v}) / Σ_{v∈N(u)\T} ω({u,v})
10             T.insert(v); Q.push(v)
11             S[{u,v}] atomic+= 1; b atomic+= 1
12             Break with prob. p
13 return S
```

Weighted Threshold Sampling: T-Weight. To incorporate edge weights, we consider a weighted threshold sampling strategy. First, we identify the weight threshold $\omega_t := \omega(e_t)$ corresponding to the $\hat{m}$-th heaviest edge e_t in G'_{i+1}. This can be done in expected time $\mathcal{O}(|E'_{i+1}|)$ using the quickselect algorithm. Based on ω_t, we partition E'_{i+1} into three disjoint sets $E'^{<}_{i+1}$, $E'^{=}_{i+1}$, and $E'^{>}_{i+1}$, for coarse edges with weight smaller than, equal to, or larger than ω_t. Edges in $E'^{<}_{i+1}$ are discarded, while edges in $E'^{>}_{i+1}$ are kept. To reach the target size $\hat{m}$, we further sample edges from $E'^{=}_{i+1}$ uniformly with probability $p := \frac{\hat{m}-|E'^{>}_{i+1}|}{|E'^{=}_{i+1}|}$.

(Weighted) Forest Fire Sampling: T-(W)FF. We further include a variation of threshold sampling that uses *Forest Fire* [42] scores rather than edge weights, as this performed well as a cut-preserving sparsifier in Ref. [16]. We include a brief description for self-containment and extend the algorithm to take edge weights into consideration (Algorithm 2). The algorithm computes edge scores by simulating fires spreading through the graph via multiple traversals starting from random nodes. When visiting a node u, the number of neighbors X to be visited is drawn from a geometric distribution paramterized by a tunable parameter p. The standard forest fire algorithm subsequently samples X distinct nodes (without replacement) from u's unvisited neighbors. We incorporate edge weights by making this sampling weight-dependent: the probability of selecting neighbor v of u is proportional to the edge weight $\omega(\{u, v\})$ relative to the total edge weight between u and its unvisited neighbors (line 9). Note that this modification (marked blue in Algorithm 2) is the only difference to Ref. [41]. Each edge traversal during this process increments the *burn* score of the edge (line 11). The algorithm stops scheduling fires once the cumulative burn score `b` exceeds $\nu|E|$ (line 3) for some *burn ratio* $\nu > 0$. After computing the edge importance scores, we use the weighted threshold sampling strategy to sparsify the graph (using the importance scores instead of edge weights).

4.3 Putting it Together

Based on the discussed insights, we propose a linear time multilevel algorithm that builds upon KaMinPar [29]. We leverage the existing clustering and refinement algorithms

available in KaMinPar, whose running time is linear in the size of the current hierarchy level (see Section 3). We introduce two necessary changes to achieve linear time for the overall algorithm. Most importantly, we introduce edge sparsification as discussed in Section 4.2, ensuring the number of edges shrinks geometrically. In addition, we replace the coarsening and initial partitioning used by the default configuration of KaMinPar with a more traditional approach. This is because the default configuration is amenable to scenarios where expensive bipartitioning happens on a relatively large graph, adding a $\Omega(n \log n)$ term to the running time in the worst-case. We refer to our technical report [30] for details.

Instead, we use size-constrained label propagation with subsequent recursive bipartitioning, following other state-of-the-art multilevel algorithms [3, 28, 44]. Similar to Mt-KaHyPar [26], the cluster weight limit is $U = \frac{c(V)}{160k}$ and we limit the node reduction per coarsening step to at most 2.5×. As this is combined with 2-hop clustering, Theorem 1 guarantees a geometric shrink factor until a size of $|V_i| = 320k$ is reached. The coarsening terminates at $160k$ nodes or if the current shrink factor is too small, thereby resulting in a graph with size $\mathcal{O}(k)$.[2] The recursive bipartitioning then requires total time $\mathcal{O}(k \log k)$, which is linear under the extremely weak assumption that $k \log k \in \mathcal{O}(n + m)$.

So far, we have argued from a sequential point of view. In the parallel setting, the consequence is that our algorithm needs only linear work. With regards to scalability, the sparsification algorithms described in Section 4.2 lend themselves to a rather straightforward parallelization. Combined with the excellent scalability of the coarsening and refinement algorithms of KaMinPar [29] and the fact that initial partitioning is insignificant for the total running time, we maintain the scalability of default KaMinPar while reducing the required work.

5 Quantifying Worst-Case Instances

As discussed, we need edge sparsification to achieve linear time if coarsening does not shrink the number of edges geometrically. However, it would be useful to understand for which graphs sparsification is required and for which it is not – both for theoretical insights into the structure of worst-case instances and to allow empirical estimates. Given a clustering C of a graph G, we are thus interested in the number of edges of G', where G' is the graph created by contracting C. If $|E(G')| \approx |E(G)|$ for clusterings computed by the coarsening algorithm, sparsification is required to further reduce the number of edges.

Intuitively, this is the case for graphs with low locality – edges might lead anywhere and are thus hard to contain in small clusters. For many random graph models, this is rather easy to decide. For example, sparse Erdős-Rényi graphs are highly non-local, thus necessitating sparsification (see Section 4.2). On the other hand, for random geometric graphs (i.e., unit disk graphs) coarsening algorithms reduce the number of edges very efficiently. However, to classify real-world instances or more complex graph models, a general criterion is needed.

Classification via Modularity. We propose that the *modularity* of a graph allows to estimate whether sparsification is necessary.[3] Modularity was introduced by Newman and Girvan to evaluate the quality of a clustering with regards to community structure [46], and modularity based community detection algorithms are used in many applications [33, 54, 55]. Given

[2] Note that sparsification ensures $\mathcal{O}(k)$ edges – although this is not necessary for linear time.
[3] There are also multiple other locality metrics, but these are less useful. For example, the clustering coefficient is based on the number of triangles. However, this does not result in any useful bounds.

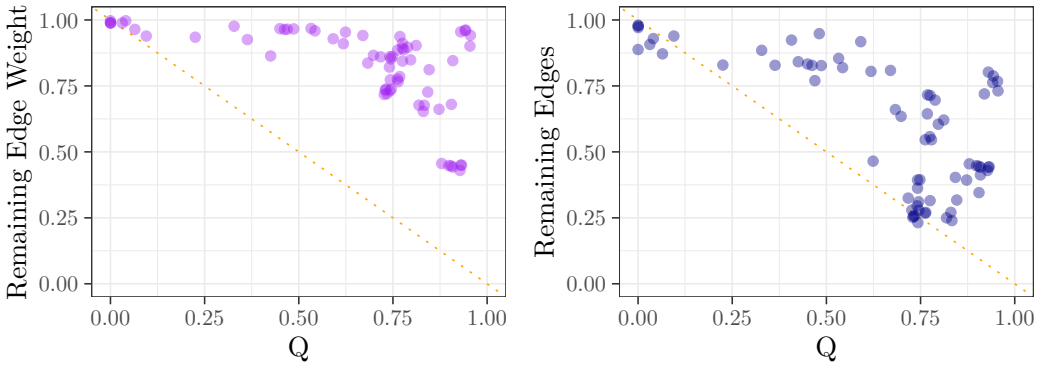

Figure 3 Remaining total edge weight (**left**) and number of edges (**right**) after one coarsening step, compared to the modularity of the graph. The y-values are denoted as a fraction of the initial value. Based on Lemma 2, we expect most points (i.e., graphs) to be in the upper right half.

a clustering $C = \{V_1, \ldots, V_{|C|}\}$, let $e_{ij} := \frac{1}{2|E|}|E(V_i, V_j)|$ denote the fraction of edges that connect cluster i and cluster j (only counted in one direction). Further, let $a_i := \sum_j e_{ij}$ be the fraction of edges with one endpoint in cluster i. The modularity of the clustering is then defined as $Q_C := \sum_i \left(e_{ii} - a_i^2\right)$, where $Q_C \in [-\frac{1}{2}, 1]$. The modularity $Q \in [0, 1]$ of the graph itself is the maximum modularity of all possible clusterings. As demonstrated in the following, modularity is a good fit for our purpose.

▶ **Lemma 2.** *For a given clustering, the total fraction of edges that connect nodes within the same cluster is bounded by*

$$Q_C \leq \sum_i e_{ii} \leq Q_C + \alpha_C$$

where $\alpha := \max_i a_i$ is the maximum fraction of edges with endpoints in the same cluster.

Proof. Since $Q_C = \sum_i \left(e_{ii} - a_i^2\right)$, the left side of the inequality follows immediately. Further, $\sum_i e_{ii} = Q_C + \sum_i a_i^2 \leq Q_C + \sum_i (\max_j a_j) a_i = Q_C + \max_i a_i$. Note that $\sum_i a_i = 1$ since each edge is connected to exactly two clusters. ◀

Lemma 2 provides a lower bound of $1 - Q_C - \alpha_C$ for the fraction of edges connecting different clusters. Unfortunately, this does not correspond directly to the edges of G' – if multiple edges connect the same pair of clusters (we say that the edges are *parallel*), they are combined into a single edge, thereby further reducing the number of remaining edges. The actual bound is thus $1 - Q_C - \alpha_C - p_C \leq \frac{|E(G')|}{|E(G)|}$, where p_C is the number of parallel edges.

Let us consider the case where the clusters are small, such as during the first steps of multilevel coarsening. Then, $1 - Q$ is an approximate lower bound for the number of edges. If clusters are small, any cluster is only incident to a small fraction of all edges and edges are unlikely to be parallel, i.e., both α_C and p_C are small. Moreover, Q_C is almost certainly smaller than Q as achieving maximum modularity often necessitates large clusters [23]. Consequently, we expect that $1 - Q \lesssim 1 - Q_C - \alpha_C - p_C \leq \frac{|E(G')|}{|E(G)|}$ if clusters are small, making $1 - Q$ an accurate bound.

Empirical Effect of Modularity. To verify whether $1 - Q$ is a useful bound in practice, we provide an empirical evaluation on a set of 71 large graphs which is used in multiple recent

works on graph partitioning [37, 43, 49]. Figure 3 shows computed modularity scores of the graphs in relation to the fraction of edges that remains after one step of our multilevel coarsening algorithm (see Section 4.1). Since computing the modularity of a graph is itself NP-hard [12], we calculate approximate scores with the well-known Louvain algorithm [10], using the implementation from NetworKit [5, 52].

With regards to the total edge weight of G' (left, corresponds to inter-cluster edges in G), $1 - Q$ is almost a strict lower bound. For most graphs, the fraction of remaining weight is much larger than $1 - Q$. The actual number of edges after combining parallel edges (right) is often significantly smaller than the weight. However, $1 - Q$ is still a mostly accurate bound. Therefore, modularity is indeed useful to predict the coarsening behavior of multilevel algorithms – graphs with low modularity are likely to be worst-case instances.

6 Experiments

Setup. We implemented the described sparsification algorithms within the KaMinPar [29] framework and compiled it using `gcc` 14.2.0 with flags `-O3 -mtune=native -march=native`. The code is parallelized using TBB [47]. All experiments are performed on a machine equipped with two 32-core Intel Xeon Gold 6530 processors (2.1 GHz) and 3 TB RAM running Rocky Linux 9.5. We only use one of the two processors (i.e., 32 cores) to avoid NUMA effects.

Competitors. In Section 6.3, we compare our algorithm against PuLP [50] (v1.1) and Cuttana [31] (commit `ed0c182` in the official GitHub repository[4]). PuLP is a linear time single-level partitioner which focuses on shared-memory scalability and low memory usage. PuLP starts by growing (unbalanced) initial clusters from a random assignment and then performs multiple iterations of alternating balancing and cut minimization. Each phase is implemented with a fixed number of label propagation rounds. The authors showed that PuLP achieves considerable speedups in comparison to multiple well-known multilevel algorithms. Cuttana is a streaming partitioner which improves upon the solution quality of previous streaming approaches with a node buffering technique. Instead of assigning each node greedily, it uses a buffer of fixed size to delay assignment until more information on the neighborhood is available or the buffer overflows. In addition, Cuttana uses a more fine-grained subpartition which allows to further refine the solution quality after the initial assignment. We use the default settings for PuLP and configure Cuttana following the parameters described by the authors, i.e., $\frac{\mathcal{K}'}{\mathcal{K}} = 4\,096$, $D_{\max} = 1\,000$ and max_qsize $= 10^6$.

Instances. We focus on graphs for which coarsening increases edge density substantially. This happens on 17 out of 71 graphs of a benchmark set used in previous works on graph partitioning [43, 37, 49] (mostly real-world k-mer and social graphs, and graphs deduced from text recompression [34]). We only use these graphs since sparsification is not triggered on the remaining instances, thus leaving the algorithm unchanged. Note that there is no running time overhead in this case. We further include 6 social graphs from the Sparse Matrix Collection [19] and generate random graphs: Erdős-Rényi graphs (using KaGen [24]), as well as Chung-Lu [45], Planted Partition, and R-MAT [15] graphs (using NetworKit [5]). These graphs are inherently non-local, thus especially challenging for linear-time partitioning. Overall, the benchmark set comprises 39 graphs (see Ref. [30]) with 511 K to 1.8 G undirected edges. The graphs deduced from text recompression feature node weights. All other graphs are

[4] `https://github.com/cuttana/cuttana-partitioner`

unweighted. Tuning experiments are performed on a subset containing 8 randomly drawn graphs spanning different types.

Methodology. We consider an *instance* as the combination of a graph and a number of blocks k. We set the imbalance tolerance to $\varepsilon = 3\%$, use $k \in \{3, 7, 8, 16, 37, 64\}$ and perform 5 repetitions for each instance using different seeds. Results (running time, edge cut) are averaged arithmetically per instance over these repetitions. When aggregating across multiple instances, we use the geometric mean to ensure that each instance has equal influence.

Performance Profiles. To compare the edge cuts of different algorithms, we use *performance profiles* [20]. Let $\mathcal{A}$ be the set of all algorithms we want to compare, $\mathcal{I}$ the set of instances, and $\text{cut}_A(I)$ the edge cut of algorithm $A \in \mathcal{A}$ on instance $I \in \mathcal{I}$. For each algorithm A, we plot the fraction of instances

$$\mathcal{P}_A(\tau) \coloneqq \frac{|\{I \in \mathcal{I} \ : \ \text{cut}_A(I) \leq \tau \cdot \min_{A' \in \mathcal{A}} \text{cut}_{A'}(I)\}|}{|\mathcal{I}|}$$

on the y-axis and τ on the x-axis. Achieving higher fractions at lower τ-values is considered better. In particular, $\mathcal{P}_A(1)$ denotes the fraction of instances for which algorithm A performs best, while $\mathcal{P}_A(\tau)$ for $\tau > 1$ illustrates the robustness of the algorithm. For example, an algorithm A with $\mathcal{P}_A(1) = 0.49$ but $\mathcal{P}_A(1.01) = 1.0$ (i.e., never more than 1% worse than the best) might be preferable to an algorithm B with $\mathcal{P}_B(1) = 0.51$ that only achieves $\mathcal{P}_B(\tau) = 1.0$ at much larger τ (indicating much worse partitions on some inputs).

6.1 Parameter Study

We begin our evaluation by tuning the parameters introduced in Section 4.2. Recall that these are the edge and density thresholds τ_e and τ_d, which control the number of coarse edges, and the minimum reduction factor ρ, which controls whether sparsification is triggered on a given hierarchy level. We use the tuning benchmark subset and $k = 16$ for this experiment to limit computational costs.

The results are shown in Figure 4, where we plot geometric mean edge cuts and running times relative to the KaMinPar baseline without sparsification for $\tau_e \in \{1/4, 1/2, 1\}$, $\tau_d \in \{1/2, 1, 2\}$ and $\rho \in \{1, 2, 3, 4, 8\}$. We observe similar speedups of up to 1.63× for weighted threshold sampling (T-Weight) and uniform sampling (UR). T-Weight achieves the highest speedup (1.63×) at $\tau_e = 1/2$, $\tau_d = 1/2$ and $\rho = 3$, while UR achieves the same speedup at slightly different parameters ($\tau_e = 1/4$, $\tau_d = 1$ and $\rho = 2$). With these parameters, edge cuts increase by 12.6% and 27.6% for T-Weight and UR, respectively. Surprisingly, more aggressive sparsification (i.e., smaller τ_e, τ_d and ρ) does not achieve larger speedups. This is likely due to several factors. First, the sparsification process itself introduces computational overhead which can counteract potential speedups, particularly when the size reduction is modest. Second, excessive sparsification degrades partition quality considerably, thereby increasing the workload required for the refinement algorithm to converge to a local optimum. Hence, moderate sparsification seems favorable.

Larger ρ seems beneficial for maintaining partition quality. At $\rho = 4$ (i.e., only sparsify if reducing the number of edges by a factor of ≥ 4), both T-Weight and UR show similar speedups as with smaller ρ and partition quality close to the baseline. We therefore pick $\tau_e = \tau_d = 1/2$ and $\rho = 4$ for subsequent experiments, where T-Weight and UR achieve speedups of 1.56× and 1.59×, while increasing edge cuts by 0.9% and 5.3%, respectively.

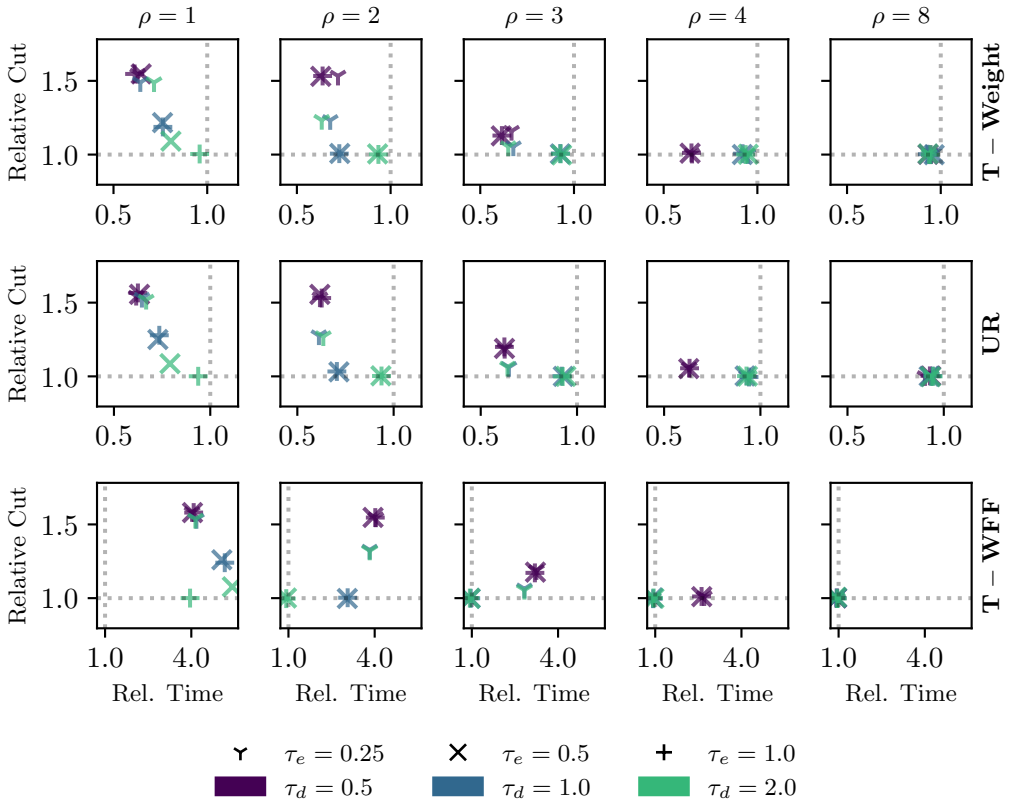

Figure 4 Relative cut and running time of KaMinPar with weighted threshold sampling (T-Weight), uniform sampling (UR), or threshold sampling via Weighted Forest Fire scores (T-WFF) versus baseline (KaMinPar without sparsification) on the tuning benchmark set with $k = 16$.

Lastly, we look at threshold sampling using Weighted Forest Fire (T-WFF) scores. For T-WFF itself, we use $p = 0.6$ and $\nu = 0.5$, since these parameters performed best during preliminary experimentation. We observe the fastest running times using parameters that do not trigger sparsification, suggesting that T-WFF does not provide practical speedups. At $\tau_e = \tau_d = 1/2$ and $\rho = 4$, T-WFF is 2.62× slower while incurring a 1.0% increase in cut size.

6.2 Effects of Sparsification

Next, we evaluate the proposed sparsification techniques on the full benchmark set. As can be seen in Figure 5, T-Weight (geometric mean running time 1.43 s) and UR (1.40 s) achieve similar speedups of 1.49× resp. 1.52× over the baseline (no sparsification, 2.13 s). T-Weight achieves considerably better partition quality (increase in average edge cut by 1.5%) than UR (increase by 5.5%). T-WFF outperforms T-FF, but is not competitive: its partition quality is slightly worse (increase by 3.9%) while much slower (7.04 s). We thus focus on T-Weight.

Looking at Figure 6, we can see that sparsification reduces the number of edges on coarse graphs considerably. Without sparsification, the graphs on the first hierarchy levels (i.e., after the first coarsening step) contain, on average, 75% of the edges of the input graphs, but only 39% of the nodes. With sparsification, the average edge count reduces to 28%.

As shown in Figure 7 (left), the speedup from T-Weight sparsification varies considerably

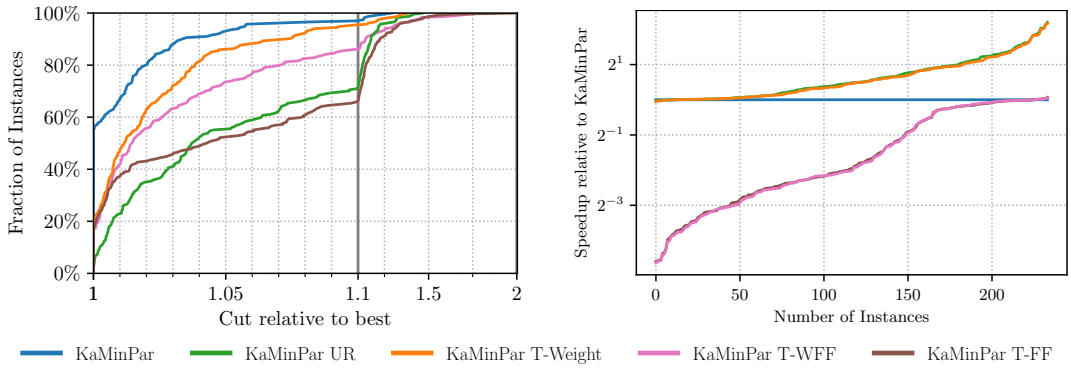

Figure 5 Partition quality as *performance profile* (**left**) and speedup over baseline (no sparsification, **right**) of sparsification algorithms: weighted threshold sampling (T-Weight), uniform sampling (UR), and threshold sampling via (Weighted) Forest Fire scores (T-(W)FF).

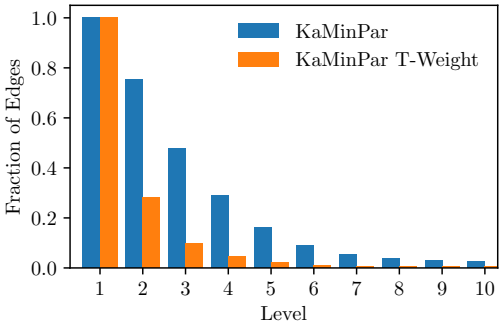

Figure 6 Relative geometric mean number of edges per hierarchy level (levels 1-10), comparing no sparsification against T-Weight (weighted threshold sampling) sparsification. Edge counts are relative to the input graphs. The final value is propagated for hierarchies shorter than 10 levels.

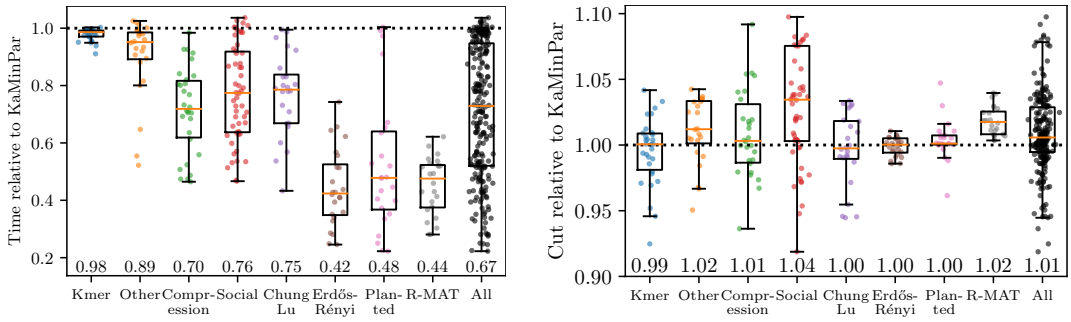

Figure 7 Comparison of KaMinPar with T-Weight sparsification relative to the baseline without sparsification grouped by graph class (lower is faster resp. higher-quality). **Left:** Relative running times with the geometric mean relative time annotated per class. **Right:** Relative cuts with the geometric mean relative cut annotated per class.

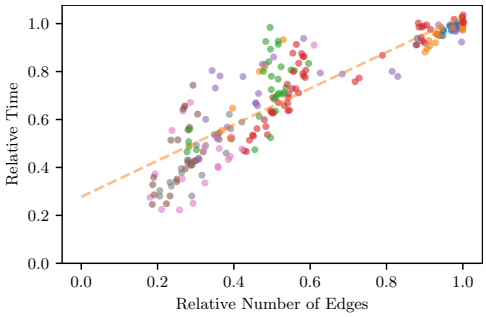

Figure 8 Relationship between running time of KaMinPar T-Weight relative to KaMinPar without sparsification and the hierarchy size ratio (number of total edges across all hierarchy levels after sparsification relative to no sparsification). Note the strong correlation (coefficient ≈ 0.893).

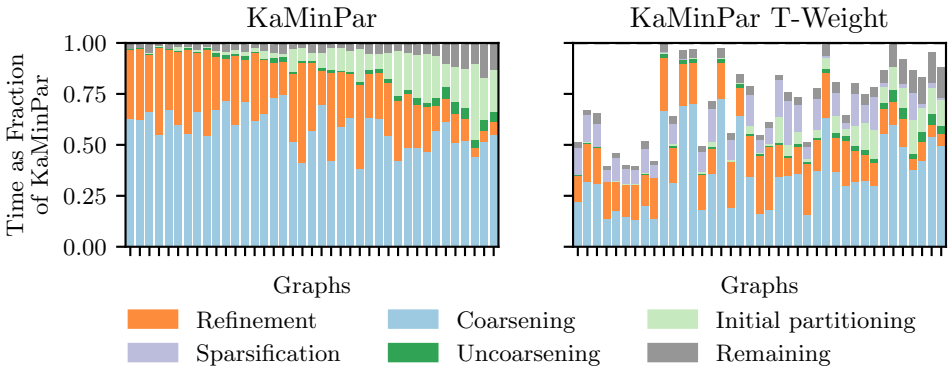

Figure 9 Relative running time attribution for KaMinPar without sparsification (**left**) and with T-Weight sparsification (**right**) using $k = 16$. Graphs are sorted by the total running time of KaMinPar without sparsification in descending order.

with graph class, with moderate cut size increases on real-world grahs (Figure 7, right). Non-local graphs with extremely low modularity (Erdős-Rényi, Planted Partition, R-MAT) show substantial gains (average speedup $> 2\times$, up to $4\times$), while real-world text recompression ($\approx 1.43\times$) and social graphs ($\approx 1.32\times$) exhibit moderate speedups. K-mer graphs see negligible benefit. This variation correlates strongly with the reduction in graph hierarchy size (number of edges across all hierarchy levels): instances with greater reduction achieve faster relative running times (Figure 8). The observed speedups stem primarily from reduced time in the coarsening and refinement phases, see Figure 9. Without sparsification, these phases consume on average 55% (1.17 s) and 23% (0.48 s) of the total partitioning time (2.13 s), respectively. Sparsification reduces these to 0.65 s and 0.32 s, respectively. This improvement comes at low cost, as the sparsification step itself averages only 0.10 s out of 1.62 s when triggered (94% of the instances).

6.3 Comparison against Competing Partitioners

Finally, we compare KaMinPar with T-Weight sparsification against alternative linear-time partitioners: single-level PuLP [50] and streaming Cuttana [31]. We found that Cuttana is rather slow and does not support node weights. Thus, we limit our benchmark set to unweighted graphs with $m \leq 2^{26}$ edges (18 out of 39 graphs).

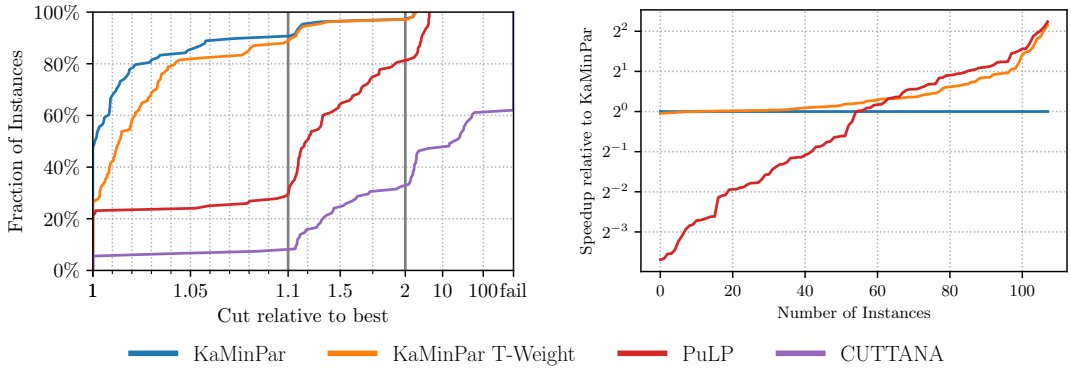

Figure 10 Partition quality (**left**) and relative running time (**right**) on the reduced benchmark set and all k values for KaMinPar without and with T-Weight sparsification, PuLP and Cuttana. Speedups are plotted relative to KaMinPar without sparsification. Cuttana is omitted from the speedup plot since it is $\geq 72\times$ slower than all other algorithms.

As shown in Figure 10 (left), KaMinPar with T-Weight sparsification computes considerably better partitions with average cuts 30% and 66% smaller than those of PuLP and Cuttana, respectively. Compared to KaMinPar *without* sparsification, edge cuts are slightly larger (cutting 1% more edges on average), but are still within a factor of 1.10 to the best cut found on 88% of all instances (vs. 90% for non-sparsifying KaMinPar). In contrast, PuLP and Cuttana compute edge cuts within factors 1.26 and 1.93 to the best cuts found on only *half of the instances*, respectively. PuLP computes the best partitions for 21% of the instances, predominantly Erdős-Rényi and Planted Partition graphs. Cuttana crashes on 39% of the instances (we exclude these instances in pairwise aggregates).

Through sparsification, the geometric mean running time of KaMinPar reduces from 0.48 s to 0.37 s. PuLP (0.63 s) is slower than non-sparsifying KaMinPar on average, but proves faster on 53 (resp. 48 vs. sparsifying KaMinPar) and twice as fast on 23 (resp. 2) out of 108 instances. Cuttana is $72\times$ slower than PuLP (and thus the other algorithms), although we note that comparing running times fairly is difficult since Cuttana interleaves computation with graph I/O from SSD (I/O times are excluded for the other algorithms).

7 Conclusion

Current graph partitioning algorithms can be classified into high-quality but superlinear multilevel algorithms, and cheaper linear time approaches such as single-level partitioning and streaming partitioning. We demonstrate both in theory and in practice that it is possible to achieve the best of both worlds at once. Our linear time multilevel algorithm uses edge sparsification to constrain the size of subsequent coarser levels, which provably guarantees linear work while maintaining scalability to many cores. We minimize quality loss by choosing appropriate thresholds for triggering the sparsification step and, if triggered, removing the edges with lowest weight. As a result, our multilevel algorithm is faster than state-of-the-art single-level and streaming approaches while consistently computing better solutions – making multilevel the preferable choice even if extremely short running time is required.

Better Indexing for Rectangular Pattern Matching

Paweł Gawrychowski
Institute of Computer Science, University of Wrocław, Poland

Adam Górkiewicz
Institute of Computer Science, University of Wrocław, Poland

Abstract

We revisit the complexity of building, given a two-dimensional string of size n, an indexing structure that allows locating all k occurrences of a two-dimensional pattern of size m. While a structure of size $\mathcal{O}(n)$ with query time $\mathcal{O}(m+k)$ is known for this problem under the additional assumption that the pattern is a square [Giancarlo, SICOMP 1995], a popular belief was that for rectangular patterns one cannot achieve such (or even similar) bounds, due to a lower bound for a certain natural class of approaches [Giancarlo, WADS 1993]. We show that, in fact, it is possible to construct a very simple structure of size $\mathcal{O}(n \log n)$ that supports such queries for any rectangular pattern in $\mathcal{O}(m + k \log^{\varepsilon} n)$ time, for any $\varepsilon > 0$.

1 Introduction

In the area of algorithms on strings, two basic algorithmic questions are pattern matching and string indexing. In the former, we aim to locate an occurrence of the pattern in the text, while in the latter the goal is to preprocess the text for multiple such queries. The complexity of both problems is well understood, at least for the case of regular strings and exact occurrences. In particular, a text of length n can be indexed in $\mathcal{O}(n)$ space, so that all k occurrences of a pattern of length m can be retrieved in $\mathcal{O}(m+k)$ time: this is a textbook application of suffix trees, already explained in the original article by Weiner [22].

In this paper, we consider two-dimensional strings, which are simply (two-dimensional) arrays of characters. Such a generalisation is naturally motivated by possible applications in image processing, and the complexity of pattern matching for two-dimensional strings has been already considered in the 70s [4, 5], and further investigated in the early 90s [1, 10]. A common assumption in all of these papers is that both the text and the pattern are square arrays, but this assumption is just to avoid clutter and can be removed without encountering any technical difficulties.

To state the results concerning indexing two-dimensional strings, let the dimensions of the text be $H \times W$, with the total size $n = HW$, and the dimensions of the pattern be $h \times w$, with the total size $m = hw$. Giancarlo [12] introduced the LSuffix tree of a matrix, based on a linearisation of a two-dimensional string (similar concept has been also used by Amir and Farach [2]). This allowed him to design an index of (asymptotically optimal) size $\mathcal{O}(n)$ that supports queries in $\mathcal{O}(m)$ time (for simplicity, we restate the bounds for constant alphabets), but only if the pattern is a square matrix. This assumption was

© Paweł Gawrychowski and Adam Górkiewicz;
licensed under Creative Commons License CC-BY 4.0

in fact inherent to his approach, as otherwise it is not clear how to linearise the strings. For the general case, he designed another structure, called the submatrix tree [11], of size $\mathcal{O}(\min(H, W)n)$ that supports queries in $\mathcal{O}(m)$ time. In the same paper, he defined an abstract notion of an index for a two-dimensional text, and proved that the size of any such index must be $\Omega(\min(H, W)n)$, making his construction essentially optimal (perhaps up to a logarithmic factor). Consequently, subsequent work focused on the case of square patterns [7, 9, 13–16, 18, 21].

Our contribution. We revisit the complexity of indexing a two-dimensional text for the general case of rectangular patterns. We observe that, in fact, the abstract notion of an index, as defined by Giancarlo [11], is somewhat restricted: he defines what it means for one pattern to be a prefix of another, and then requires that the index has a form of a compacted tree, with every node corresponding to some pattern occurring in the text, and the parent of each node corresponding to its prefix. This is consistent with the notion of one-dimensional suffix trees, but suffix trees are not the only known indexing structures. For example, suffix arrays [20] use $\mathcal{O}(n)$ space and allow retrieving the occurrences in $\mathcal{O}(m + \log n + k)$ time, even though they are not based on storing a compacted trie (although they are of course related to suffix arrays). We show that a very simple idea allows us to obtain the following result.

▶ **Theorem 1.** *For a two-dimensional text of size n, there is an $\mathcal{O}(n \log n)$-space data structure that, given a two-dimensional pattern of size m, reports all k occurrences of the pattern in the text in time $\mathcal{O}(m + k \log^{\varepsilon} n)$, for any constant $\varepsilon > 0$.*

Computational model. In the above theorem we assume the standard word RAM model with words of logarithmic (in the size of the input) length. Basic arithmetic operations on such words (and indirect addressing) are assumed to take constant time. Each character is assumed to fit in a single machine word. We measure the size of our data structures in the number of words.

2 Preliminaries

One-dimensional strings. A (one-dimensional) string is a sequence of characters. We index positions in a string starting from 1. For a string S of length n, we write $S[i]$ to denote its i-th character and $S[i\,..\,j]$ to denote the substring spanning positions i through j, inclusive. If only one endpoint is provided, we interpret the interval as a prefix or suffix: $S[..\,i] := S[1\,..\,i]$ is the prefix of length i; $S[i\,..] := S[i\,..\,n]$ is the suffix starting at position i.

Two-dimensional strings. We define two-dimensional strings as rectangular arrays of characters. We refer to the total number of characters in a two-dimensional string as its *size*. Rows and columns are indexed starting from 1. For a two-dimensional string S we write $S[i]$ to denote its i-th row, interpreted as a one-dimensional string. Consequently, $S[i][j]$ denotes the character in the i-th row and j-th column.

Meta-characters. In our algorithm, we reduce two-dimensional indexing to a collection of problems concerning one-dimensional strings. This is done by treating fixed-length fragments of rows of the two-dimensional text as atomic symbols, which we refer to as *meta-characters*. Formally, for a two-dimensional string S and a fixed width w, a meta-character is a substring of the form $S[i][j\,..\,j + w - 1]$. To effectively operate on such meta-characters, we will

represent each of them by an integer from $[\text{poly}(n)]$ that fits inside a single machine word[1], called the identifier. The identifiers of two meta-characters will be different if and only if the meta-characters themselves are different.

Compacted trie. We use the standard compacted trie, also known as a compressed trie or Patricia trie, for storing a set of strings. The strings consist of either characters or meta-characters. In either case, we assume that the symbols fit in a single machine word. A compacted trie built for a set of k strings is of size $\mathcal{O}(k)$, as we collapse maximal paths consisting of nodes with exactly one child into a single edge, thus the number of inner nodes is strictly smaller than the number of leaves. The remaining nodes are called explicit, while the dissolved nodes are called implicit.

Tools. We will need a few data structures. The first is called a deterministic dictionary.

▶ **Theorem 2** ([8]). *Given a set S of n keys, we can build a dictionary structure of size $\mathcal{O}(n)$ that allows constant-time access to any element of S (and its associated information).*

The second is a range reporting structure (we note that other trade-offs between the space and reporting time are possible, but we state only one of them to avoid clutter).

▶ **Theorem 3** ([6, Theorem 2.1]). *Given a collection of n points in $\{1,\ldots,n\}^2$, we can build a structure of size $\mathcal{O}(n)$ that, given an axis-aligned rectangle, reports all k points inside it in time $\mathcal{O}((1+k)\log^{\varepsilon} n)$, for any constant $\varepsilon > 0$.*

Finally, we need to implement *prefix search* on a compacted trie. That is, given a query string, we traverse the trie to determine whether it occurs as a prefix of any stored string. If so, we return the corresponding node (which may be implicit); otherwise, we report that no such prefix match exists.

▶ **Lemma 4.** *A compacted trie storing k strings uses $\mathcal{O}(k)$ additional space (on top of the strings themselves). Assuming constant-time read-only random access to any character, prefix search for a query string of length m takes $\mathcal{O}(m)$ time.*

Proof. To implement prefix search, we start at the root and descend following the appropriate edge. This requires storing all the edges outgoing from an explicit node in a dictionary structure, which we implement with Theorem 2. Since the total degree over all explicit nodes is $\mathcal{O}(k)$, the combined space used by all dictionaries is $\mathcal{O}(k)$. For implicit nodes, we only verify whether the subsequent characters of the query string are the same as on the edge, using constant-time read-only random access to one of the stored strings. Then, the time per each character of the query string is constant, so $\mathcal{O}(m)$ overall. ◀

3 Two-Dimensional Index Construction

In this section, we present our data structure for indexing a two-dimensional text and prove Theorem 1. The idea behind our approach is to reduce the two-dimensional pattern matching problem to a collection of one-dimensional problems. Each of these problems can then be solved efficiently by plugging in range reporting structures, as usual in the one-dimensional setting. Throughout this section, we write T to denote the $H \times W$ input text and P to denote the $h \times w$ query pattern, with $n = HW$ and $m = hw$ denoting their respective sizes.

[1] It is in fact enough that it fits in a constant number of machine words.

The data structure consists of two symmetric components, designed to handle the query depending on whether the pattern is taller or wider. Given an $h \times w$ pattern, we use one component if $h \geq w$ and the symmetric one (with rows and columns interchanged) otherwise. We describe how to handle tall patterns, i.e., those with $h \geq w$, as the other case is fully symmetric. To handle patterns of different widths, we store a separate index for each possible pattern width. More precisely, for each width $w \in \{1, \ldots, W\}$, we construct a dedicated data structure that supports searching for patterns of fixed width w and any height $h \geq w$.

For a fixed width w, we reduce the two-dimensional matching problem to a one-dimensional problem. Specifically, we interpret the pattern as a one-dimensional string of length h, where the i-th symbol is a *meta-character* corresponding to the i-th row $P[i]$ of the pattern, that is, a contiguous block of w characters from that row. As explained earlier, we will assign identifiers to these meta-characters, so that we can treat them as integers from $[\text{poly}(n)]$. We first explain how to ensure that we can access the identifier of any meta-character in the pattern and the text in constant time, after $\mathcal{O}(n \log n)$ space preprocessing of the text, and then define the one-dimensional problem.

Encoding the text. The construction follows the classical Karp-Miller-Rosenberg (KMR) approach [17], and is based on assigning integer identifiers to all fragments of the form $T[i][j\,..\,j+2^k-1]$, for all k such that $2^k \leq W$. For each such fragment, we define its identifier as the lexicographic rank of its substring among all distinct substrings of the same length, and store this value. Then, the identifier of $T[i][j\,..\,j+w-1]$ consists of the identifiers of two overlapping fragments of length $2^{\lfloor \log w \rfloor}$ that together cover the whole $T[i][j\,..\,j+w-1]$. Since there are $\mathcal{O}(n)$ fragments per length and $\mathcal{O}(\log W)$ relevant lengths, the total space required is $\mathcal{O}(n \log n)$.

Encoding the pattern. To encode a pattern row $P[i]$ of width w, we represent the corresponding meta-character by the pair of identifiers of its prefix and suffix of length 2^k, where $k = \lfloor \log w \rfloor$. To support this, during text preprocessing, we collect all distinct substrings $T[i][j\,..\,j+2^k-1]$ and store them in a compacted trie, where each leaf is labeled with the lexicographic rank among all substrings of T of length 2^k. We build a separate compacted trie for each relevant value of k; since each trie requires $\mathcal{O}(n)$ space and there are $\mathcal{O}(\log W)$ values of k, the total space used by all the compacted tries is $\mathcal{O}(n \log n)$. At query time, we extract the 2^k-length prefix and suffix of $P[i]$ and search for them in the corresponding compacted trie to obtain their identifiers. If either substring is not found, we report that the pattern does not occur in the text. Otherwise, in $\mathcal{O}(m)$ time we obtain the sought identifier for each row of the pattern.

One-dimensional problems. To complete the reduction, we must identify all occurrences of the one-dimensional meta-character pattern within the two-dimensional text. To that end, we consider all windows of w consecutive columns. Each such w-column strip defines a one-dimensional text of length H, where the j-th character is a meta-character corresponding to the block of w consecutive characters in the j-th row of the strip. Formally, to define the one-dimensional texts corresponding to each w-column strip, we fix a horizontal offset $i \in \{1, \ldots, W-w+1\}$ and define a one-dimensional text of length H consisting of the meta-characters $T[j][i\,..\,i+w-1]$ for all positions $j \in \{1, \ldots, H\}$. This gives a collection of $W-w+1$ one-dimensional texts over the same meta-character alphabet. Each occurrence of the meta-character pattern in one of these one-dimensional texts corresponds one-to-one to a two-dimensional occurrence of the original pattern in the text.

In each of these one-dimensional instances, the derived meta-character pattern has length $h \geq w$. We exploit this assumption when designing a (simple) indexing structure in Section 4.

▶ **Lemma 5.** *For a parameter w and a collection of one-dimensional texts of total length n, there is a data structure requiring $\mathcal{O}(n/w)$ additional space (on top of the strings) that, given a one-dimensional pattern of length $h \geq w$, reports all k occurrences of the pattern in the texts in time $\mathcal{O}(hw + (w+k)\log^{\varepsilon} n)$, for any constant $\varepsilon > 0$.*

We could apply Lemma 5 for each width $w \in \{1, \ldots, W\}$ to handle patterns of width w and height $h \geq w$. The total additional space is bounded by $\sum_{w=1}^{W} \mathcal{O}(n/w) = \mathcal{O}(n \log n)$, matching the requirements of Theorem 1. However, when h is smaller than $\log^{\varepsilon} n$, it holds that $w \log^{\varepsilon} n$ in the query time is larger than m. We thus handle the case of small w separately as follows.

▶ **Lemma 6.** *For a collection of one-dimensional texts of total length n, there is an $\mathcal{O}(n)$-space data structure that, given a one-dimensional pattern of any length h, reports all k occurrences of the pattern in the texts in time $\mathcal{O}(h + k)$.*

Proof. We store all suffixes of all input texts, each terminated with a distinct delimiter, in a compacted trie implemented with Lemma 4. The total number of suffixes is $\mathcal{O}(n)$, so the total required space is $\mathcal{O}(n)$. Querying for a pattern of length h is implemented by performing a prefix search for the pattern in the trie and reporting all leaves in the corresponding subtree. ◀

We apply Lemma 6 for every width $w \leq \log n$, and otherwise use Lemma 5. The total space is still $\mathcal{O}(n \log n)$. To bound the query time, we observe that whenever we use Lemma 6 the query time is $\mathcal{O}(h + k) = \mathcal{O}(m + k)$, and whenever we use Lemma 5 we can assume $w > \log n$ so the query time is $\mathcal{O}(hw + (w+k)\log^{\epsilon} n) = \mathcal{O}(m + k \log^{\epsilon} n)$.

4 One-Dimensional Index for Long Patterns

In this section, we prove Lemma 5 by designing an indexing structure for the one-dimensional setting that takes advantage of the assumption that the pattern is sufficiently long. We briefly comment that such a setup can be seen as related to locally consistent anchors, and such an assumption has been used in the literature [3]. In our case, a simple and self-contained approach based on defining some compacted tries and storing a range reporting structure is enough, though. The idea of using range searching to solve indexing is, of course, quite common in the literature [19].

Setup. We assume that the input texts allow constant-time read-only random access to the individual characters, and each of them fits in a single machine word. Throughout this section, we fix a parameter w, corresponding to the lower bound on the length of the pattern. Texts shorter than w can be discarded, as they cannot contain an occurrence of a pattern of length $h \geq w$.

Preprocessing. For each text T, we define a collection of *cuts*: positions between characters spaced at regular intervals of length w. Formally, we insert a cut at every position i such that $i \equiv 0 \pmod{w}$, including $i = 0$. Each cut partitions T into a prefix $T_1 = T[..i]$ and a suffix $T_2 = T[i+1..]$, where either may be empty. We associate the cut with the pair (T_1, T_2),

which serves as its representation. We organize the collection of cuts using a two-dimensional range reporting structure. Let $\mathcal{T}_1$ denote the set of all prefixes T_1 reversed, and let $\mathcal{T}_2$ denote the set of all suffixes T_2 extracted from the cuts. We build two compacted tries:

- $\mathcal{S}_1$, storing the strings in $\mathcal{T}_1$,
- $\mathcal{S}_2$, storing the strings in $\mathcal{T}_2$.

To ensure that each string from $\mathcal{T}_1$ and from $\mathcal{T}_2$ corresponds to a unique leaf in the respective trie, we conceptually prepend and append a distinct delimiter character to each prefix and suffix, respectively.

Next, we assign a pre-order number to each leaf of $\mathcal{S}_1$ and $\mathcal{S}_2$ via a depth-first traversal. Each cut then defines a point $(x, y) \in \mathbb{Z}^2$, where:

- x is the pre-order number of the leaf in $\mathcal{S}_1$ corresponding to the reversal of T_1,
- y is the pre-order number of the leaf in $\mathcal{S}_2$ corresponding to T_2.

This yields a collection of $\mathcal{O}(n/w)$ such points, one per cut. We store these points in an instance of Theorem 3.

Answering a query. Given a pattern P of length $h \geq w$, our goal is to report all of its occurrences in the input texts. Since the pattern has length at least w, any occurrence must span at least one cut position from the collection defined for the texts. We iterate over all positions at which such a cut could intersect an occurrence of the pattern. We refer to each such position within the pattern as an *anchor*, and consider only the first w possible anchors, to ensure that every occurrence of P is reported exactly once.

Specifically, we consider all positions $j \in \{0, 1, \ldots, w-1\}$ where the pattern may be anchored. Each such position induces a partition of P into a prefix $P_1 = P[..j]$ and a suffix $P_2 = P[j+1..]$. The task is to find and report all cuts in the texts that partition some text into (T_1, T_2) such that P_1 is a suffix of T_1 and P_2 is a prefix of T_2. This is implemented as follows. First, we extract the corresponding prefix-suffix pair (P_1, P_2) from the pattern. We then locate the (possibly implicit) node v_1 in $\mathcal{S}_1$ corresponding to the reversal of P_1, and the node v_2 in $\mathcal{S}_2$ corresponding to P_2. If either node does not exist, the current position cannot yield any occurrences and is skipped. Otherwise, let $[\ell_1, r_1]$ and $[\ell_2, r_2]$ be the ranges of pre-order numbers of leaves in the subtrees of v_1 and v_2, respectively.

The problem now reduces to a two-dimensional orthogonal range reporting query: report all stored points (x, y) that lie within the rectangle $[\ell_1, r_1] \times [\ell_2, r_2]$. Each reported point corresponds to a valid cut that certifies an occurrence of the pattern. Querying the instance of Theorem 3 yields the query bound claimed in Lemma 5.

Abstract

In train routing, the headway is the minimum distance that must be maintained between successive trains for safety and robustness. We introduce a model for train routing that requires a fixed headway to be maintained between trains, and study the problem of minimizing the makespan, i.e., the arrival time of the last train, in a single-source single-sink network. For this problem, we first show that there exists an optimal solution where trains move in convoys – that is, the optimal paths for any two trains are either the same or are arc-disjoint. Via this insight, we are able to reduce the approximability of our train routing problem to that of the min-max disjoint paths problem, which asks for a collection of disjoint paths where the maximum length of any path in the collection is as small as possible.

While min-max disjoint paths inherits a strong inapproximability result on directed acyclic graphs from the multi-level bottleneck assignment problem, we show that a natural greedy composition approach yields a logarithmic approximation in the number of disjoint paths for series-parallel graphs. We also present an alternative analysis of this approach that yields a guarantee depending on how often the decomposition tree of the series-parallel graph alternates between series and parallel compositions on any root-leaf path.

Finally, we thank the three anonymous reviewers for their careful reading of our paper and many useful suggestions.

1 Introduction

Given a rail network and a set of trains, the problem of train routing and scheduling refers to the problem of determining a route as well as a schedule for the trains to optimise some objective, such as the total travel time or the maximum travel time (also denoted as makespan). Train routing usually involves a number of real-world constraints, including train acceleration and deceleration, stopping times at stations, bidirectional arcs, presence of other trains, etc. Practical approaches to solving these complex problems often include mixed integer programming, heuristics, and simulations [3, 4, 15, 16, 22, 24], see [21, 22, 5] for surveys and an overview. However, theoretical guarantees on solutions are hard to come by, apart from some results that show NP-hardness already for some very restricted cases [15, 19].

One of the most important constraints in train routing and scheduling is that of *headway* [6, 18], which determines the minimum gap between successive trains on a link. The headway thus corresponds to a safety distance between two successive trains and is important for at least two different reasons. The first is safety: Maintaining sufficient headway between trains reduces the chances of a collision between trains. The second reason is robustness: If a train is delayed somewhat, then the headway can help ensure that this delay is not propagated to all the following trains, and the schedule can recover quickly. In fact, the importance of maintaining a headway is not restricted to train routing. In vehicular traffic, such as cars on roads, traffic often naturally forms a *platoon* – a group of vehicles following each other closely. Here, headway is again essential in maintaining safety of vehicles in the platoon, see [26] for a survey.

In this paper, our objective is understanding the impact of headway on the complexity of train routing and scheduling.[1] While numerous papers study efficient algorithms for both dynamic and static routing problems, research on efficient algorithms that account for headway is scarce. Towards this, we introduce a basic model of train routing with an exogenously defined headway requirement Δ. In our model, we are given a directed network $D = (V, A)$, where each arc a has a travel time $\tau_a \in \mathbb{Z}_{\geq 0}$, and d trains that must travel from a source s to a sink t. Headway constraints require a minimum time separation of Δ between any two trains using the same arc. Our objective is minimising the makespan – the time the last train reaches the sink t. We call this problem Train Makespan Optimization (TMO) and refer to Section 1.1 for a formal description.

Two interesting special cases of TMO arise when the headway is either very large ($\Delta = \infty$) or very small ($\Delta = 1$). In the former case, no arc can be used by two trains, and hence the paths used by the trains must be pairwise arc-disjoint. The problem for $\Delta = \infty$ thus becomes the static problem of finding d arc-disjoint s-t-paths while minimizing the length of the longest path. This is known in the literature as the Min-Max Disjoint Paths (MinMaxDP) problem [20]. In particular, the temporal dynamics, i.e., the scheduling aspect of the problem,

[1] Although, as noted, headway plays an important role in routing other vehicles as well, we use the nomenclature for trains as this is what initially motivated our work.

become irrelevant. Conversely, if $\Delta = 1$, the problem is equivalent to finding an integral *quickest flow over time*, a problem widely studied in traffic networks and transportation [28]. Hence, as Δ reduces, temporal dynamics play a larger role.

The quickest flow over time problem with aggregated arc capacities [11] generalizes the quickest flow over time problem. Here, only a limited amount of flow is allowed to traverse an arc in each time interval of length Δ. By setting these capacities to one, TMO can be seen as an integral special case of the quickest flow over time problem with aggregated arc capacities.

When studying the computational complexity of the problem from a theoretical perspective, one should note that, for large d, the size of the input is $\log(d)$ rather than d. Hence, a polynomial time algorithm must run in time polynomial in $\log(d)$ (and the other parameters). Note that this is not even sufficient time to describe a path for each train. However, we show that optimal solutions can be represented efficiently, by establishing the existence of an optimal *convoy* solution to TMO that can be described by a polynomial number of different paths and does not require waiting on any intermediate nodes. Furthermore, we show that approximating TMO, for any value of Δ, is equivalent to approximating MinMaxDP. We further develop new approximation algorithms for MinMaxDP, which translate to bounds for TMO as well. This work thus provides new results on a classical routing problem and introduces a new model to capture an important parameter in traffic routing and scheduling.

1.1 Model

We are given a directed graph $D = (V, A)$ with travel times $\tau_a \in \mathbb{Z}_{\geq 0}$ for every $a \in A$, a source $s \in V$ as well as a sink $t \in V$. We say $|A| = m$. Furthermore, we are given a minimum headway time $\Delta \in \mathbb{Z}_{\geq 1}$ (between the heads of the trains) and a number d of identical trains which we want to send from s to t. An instance of train routing is thus denoted (D, τ, d, Δ). In the following, we use $[k] \coloneqq \{1, \dots, k\}$ for $k \in \mathbb{Z}_{\geq 1}$ and $\delta^-(v)$ to denote the set of all arcs entering a node $v \in V$.

A *train routing* $(\boldsymbol{P}, \boldsymbol{\lambda})$ is a tuple consisting of a collection $\boldsymbol{P} = (P_i)_{i \in [d]}$ of s-t-paths P_i, where P_i consists of the sequence of arcs train i traverses on its way from s to t, together with a collection $\boldsymbol{\lambda} = (\lambda_i)_{i \in [d]}$ of *entry functions* $\lambda_i : P_i \to \mathbb{Z}_{\geq 0}$, where $\lambda_i(a)$ denotes the time when the nose of train i enters arc $a \in P_i$.

A train routing $(\boldsymbol{P}, \boldsymbol{\lambda})$ is *feasible* if it complies with the following two constraints:

- $\lambda_i(a) + \tau_a \leq \lambda_i(a')$ for all $i \in [d]$ and any pair of consecutive arcs a, a' on P_i,
- $|\lambda_i(a) - \lambda_{i'}(a)| \geq \Delta$ for all $i, i' \in [d]$ with $i \neq i'$ and $a \in P_i \cap P_{i'}$.

The first constraint implies that the entry function is consistent with the travel times along the path of each train. Note that this allows trains to wait at any node. The second constraint ensures that a feasible routing respects the minimum headway requirement, i.e., if two trains use the same arc, they can only do so with a temporal distance of at least Δ.

Given a feasible train routing $(\boldsymbol{P}, \boldsymbol{\lambda})$, we denote by $C_i(P_i, \lambda_i) \coloneqq \max_{a \in P_i}(\lambda_i(a) + \tau_a)$ the time when the nose of train i arrives at t. The *makespan* $C_{\max}(\boldsymbol{P}, \boldsymbol{\lambda}) \coloneqq \max_{i \in [d]} C_i(P_i, \lambda_i)$ is the time when the nose of the latest train reaches the sink t. We consider the Train Makespan Optimization (TMO) problem, where the objective is to find a feasible train routing that minimises the arrival of the last train at t. That is, we want to solve

$$\min C_{\max}(\boldsymbol{P}, \boldsymbol{\lambda}) \quad \text{s.t. } (\boldsymbol{P}, \boldsymbol{\lambda}) \text{ is a feasible train routing.}$$

1.2 The min-max disjoint paths problem

An interesting special case of TMO arises when Δ is sufficiently large compared to the travel times. In that case any (even approximately) optimal train routing sends all trains along disjoint paths – assuming that the network supports d disjoint s-t-paths. This leads us to the Min-Max Disjoint Paths (MinMaxDP) problem, which can be formalized as follows: Given a directed graph $D = (V, A)$ with two designated vertices $s, t \in V$ and travel times $\tau : A \to \mathbb{Z}_{\geq 0}$, find k pairwise arc-disjoint s-t-paths $P_1, \ldots, P_k$ minimizing the maximum travel time (i.e., makespan) $\max_{i \in [k]} \tau(P_i)$, where we use $\tau(P) \coloneqq \sum_{a \in P} \tau_a$ to shorten notation for each path P. We call $\boldsymbol{P} = (P_1, \ldots, P_k)$ a *path profile*.

Early work on MinMaxDP has focused on the case where k is constant. Indeed, Li et al. [20] – in the first paper that studied MinMaxDP – showed that, even when $k = 2$, the problem is strongly NP-hard for general digraphs and weakly NP-hard for directed acyclic graphs (DAGs). On the positive side, they also showed that MinMaxDP can be solved in pseudo-polynomial on DAGs when k is constant. By standard rounding techniques, this result can be turned into an FPTAS [13] for the same setting.

Special cases of MinMaxDP when k is part of the input have been studied under various names. Most notably, the Multi-level Bottleneck Assignment (MLBA) problem is equivalent to a special case of MinMaxDP in a DAG consisting of b layers. Dokka and Goerigk [10] recently established a strong inapproximability bound of $\Omega(b)$ for MLBA. In the full version of this article [1, Appendix A], we observe that their construction also implies that MinMaxDP (and, by extension, TMO) in DAGs does not admit approximation factors significantly better than logarithmic in k, unless every problem in NP can be solved in quasi-polynomial time (violating the exponential time hypothesis). This leads to the following theorem.

▶ **Theorem 1.** *There is no $\log^{1-\varepsilon}(k)$-approximation for MinMaxDP in DAGs for any $\varepsilon > 0$, unless NP $\subseteq$ QP.*

Moreover, MinMaxDP in bundle graphs, i.e., digraphs consisting of a sequence of parallel arcs, is equivalent to the so-called *complete* case of MLBA, from which it also inherits strong NP-hardness. For this problem, a long line of approximation algorithms starting in the 1980s [7, 17] has recently culminated in a PTAS by Das and Wiese [9] (formulated for an equivalent scheduling problem).

1.3 Contributions and overview

In the following, we provide an overview of our main contributions and the techniques used to derive these results.

Existence of optimal convoy routings. We show that any instance of TMO has an optimal solution in which any two trains either travel along the same path (with sufficient temporal distance), or follow disjoint paths (Theorem 2 in Section 2). We call such solutions *convoy routings*. In particular, convoy routings have a compact representation that is polynomial in the size of the input, even when the number of trains is exponential in the size of the network. A further consequence is that allowing trains to wait at intermediate nodes does not help to improve the optimal solution value. The proof of this result relies on an uncrossing algorithm that takes an arbitrary train routing and modifies it to ensure that any train that is the first to traverse the final arc of its path is also the first to traverse any other arc it uses. Conflicts, i.e., situations where this property is violated, are resolved iteratively, starting with those closest to the sink, with a potential function argument ensuring eventual termination of the procedure.

A flow-based additive approximation for TMO. We further provide a simple flow-based approximation algorithm for TMO that returns a convoy routing whose makespan is bounded by OPT $+\Delta$ (Theorem 4 in Section 3). This result is achieved by solving an appropriately defined quickest flow over time problem in the underlying network. Note that in practice, the headway Δ is typically much smaller than the total transit time of a train from source to sink, and hence the additive error Δ is small compared to OPT.

Reduction to MinMaxDP. Building on the previous two results, we establish a strong connection between MinMaxDP and TMO by showing that any α-approximation algorithm for MinMaxDP yields a $\max\{1+\varepsilon, \alpha\}$-approximation algorithm for TMO with polynomial runtime in the size of the input and $\frac{1}{\varepsilon}$ (Theorem 5 in Section 4). To achieve this result, we devise a gadget that encodes the choices on the number of trains on each path of a convoy routing into the routing decisions in the network. The size of this gadget is polynomial in the size of the original network and d. It thus provides an exact reduction of TMO to MinMaxDP when the number of trains d is polynomial in the size of the network. When d is large, on the other hand, there must be an arc traversed by a large number of trains and hence OPT is much larger than Δ. In this case, the additive guarantee of OPT $+\Delta$ of our flow-based algorithm for TMO mentioned above translates to a $(1+\varepsilon)$-approximation. As we mentioned previously, for sufficiently large values of Δ, TMO coincides with MinMaxDP. Thus, finding good approximation algorithms for MinMaxDP is not only sufficient but also necessary to obtain good approximations for TMO.

Approximation algorithms for MinMaxDP in series-parallel networks. In the remainder of this paper, we therefore focus on approximation algorithms for MinMaxDP. We show that a natural greedy approach achieves an approximation which is logarithmic in k on series-parallel (SePa) networks (Theorem 8 in Section 5), where k is the number of paths to be constructed. This constitutes the first non-trivial approximation result for MinMaxDP going beyond the aforementioned PTAS for bundle graphs [9], without assuming that either k or the number of layers of the graph is constant.

We prove the approximation guarantee via induction on a series-parallel decomposition of the graph. The key ingredient is showing that the greedy algorithm maintains a solution fulfilling a strong balance condition on the path lengths. Additionally, we provide an alternative analysis of the same approach that yields an upper bound of $\varphi(D)+1$ on the approximation factor, where $\varphi(D)$ denotes the number of changes from series to parallel composition on a root-leaf path in the binary tree describing the SePa-graph. To the best of our knowledge, the parameter $\varphi(D)$, which we demonstrate to be independent of the choice of the decomposition tree, has not been used in the literature before. We believe that this natural parameter can be of independent interest for designing and analysing algorithms for other problems in SePa-graphs. Our alternative analysis implies the classic greedy 2-approximation for bundle graphs by Hsu [17] as a special case. By the aforementioned reduction of TMO to MinMaxDP, the approximation results for MinMaxDP on SePa-graphs, translate to our train routing problem.

2 Existence of optimal convoy routings

Let (D, τ, d, Δ) be an instance of TMO. A *convoy routing* consists of a collection of $k \leq d$ pairwise arc-disjoint s-t-paths $\boldsymbol{P} = (P_1, \dots, P_k)$ in D, together with a vector $\boldsymbol{\sigma} \in \mathbb{Z}^k_{\geq 1}$ with $\sum_{i=1}^k \sigma_i = d$, whose i-th component σ_i denotes the number of trains using path P_i. Note that any such convoy routing $(\boldsymbol{P}, \boldsymbol{\sigma})$ can be turned into a (feasible) train routing $(\boldsymbol{P}, \boldsymbol{\lambda})$ by sending

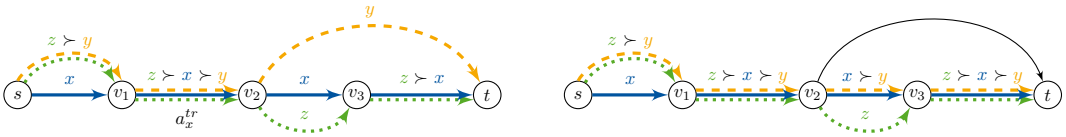

Figure 1 An example iteration of the uncrossing phase. Here $x \succ y$ means that x follows y. Train $x \in L$ is chosen by the uncrossing algorithm. As train y precedes x on a_x^{tr}, it is rerouted to use the same subpath as x from a_x^{tr} to t. The routing after this iteration is shown on the right.

σ_i trains along path P_i in single file with temporal spacing Δ between any two consecutive trains. Thus, the makespan of this train routing is $\max_{i\in[k]} \{\tau(P_i) + (\sigma_i - 1) \cdot \Delta\}$, where $\tau(P_i) := \sum_{a\in P_i} \tau_a$.

▶ **Theorem 2** (Convoy theorem). *Every instance of TMO admits an optimal solution that is a convoy routing.*

Our proof of Theorem 2 is constructive. Note that, since we allow waiting at nodes, there is always an optimal train routing $(\boldsymbol{P}, \boldsymbol{\lambda})$ which is acyclic in the sense that none of the paths contains a cycle. In order to show that any instance of TMO admits an optimal routing which is a convoy solution (i.e., to prove Theorem 2), we take an optimal acyclic train routing $(\boldsymbol{P}, \boldsymbol{\lambda})$, and modify this train routing step by step without increasing the makespan until the routing corresponds to a convoy routing.

The algorithm, which we from now on call **uncrossing algorithm**, proceeds in two phases. First, in the *uncrossing phase*, we reroute trains such that at the end of the phase, the trains that are the first ones to use their respective ingoing arc to the sink t, travel along disjoint paths. We call these trains *leaders*, and the remaining trains *non-leaders*. Afterwards, in the *assignment phase*, we assign every non-leader train a route based on the arc it uses to enter t. In particular, each such train follows its leader from s to t.

We now outline the algorithm in more detail and briefly sketch its correctness. A detailed description can be found in the full version of this article [1, Appendix B].

2.1 The uncrossing phase

We first introduce some notation. For an arc a entering t, i.e., $a \in \delta^-(t)$, we define the *leader* L_a on a as the first train using arc a. We denote by $L = \{L_a\}_{a\in\delta^-(t)}$ the set of leaders. We say that a leader x *has a conflict on arc* $a \in A$ with another train y if y uses some arc a before x. Note that this relation is not symmetric. For a leader $x \in L$, we define the *transition arc* a_x^{tr} as the first arc on which a conflict of x with another train exists when traversing P_x from t to s, i.e., in the reverse direction. Note that a_x^{tr} might not exist, in which case x is the first train on every arc on its path.

In the uncrossing phase, we pick a leader x for which a_x^{tr} exists. We reroute all trains preceding x on a_x^{tr} such that, after rerouting, they all use the same subpath as x from a_x^{tr} to t. The rerouted trains traverse every arc of this a_x^{tr}-t-path with the same temporal distance to train x as they had on arc a_x^{tr}. Hence, the rerouted trains keep their respective pairwise temporal distances on the entire path from a_x^{tr} to t and no new conflicts among the rerouted trains arise. Figure 1 shows an example of such a rerouting step. Note that this rerouting procedure also cannot create new conflicts with other trains as x was the first train on every arc of P_x from a_x^{tr} to t. Hence, the new routing is feasible and does not increase the makespan as x arrives after any rerouted train and the routing of x remains unchanged.

We iterate this procedure with the updated train routing (and the corresponding leaders and transition arcs) until every leader is the first train on all arcs of its path, which implies that all leaders use disjoint paths. In the proof of Lemma 3 below, we establish that this termination criterion is reached after a finite number of uncrossing steps.

2.2 The assignment phase

After successfully uncrossing the paths of all leaders, we receive an updated routing $(\boldsymbol{P}, \boldsymbol{\lambda})$. To achieve a convoy routing $(\boldsymbol{R}, \boldsymbol{\sigma})$, define $\boldsymbol{R} = (P_x)_{x \in L}$ where P_x is the s-t-path used by leader x in $\boldsymbol{P}$. We assign all trains that use the same arc as x to enter t in $(\boldsymbol{P}, \boldsymbol{\lambda})$ to P_x and define σ_x as the resulting number of trains that use P_x. As each train uses exactly one arc in $\delta^-(t)$, this induces a partition of $[d]$ and thus a feasible convoy routing.

To see why the makespan remains unchanged, note the following: Fix an arc $a \in \delta^-(t) \cap P_x$ for some $x \in L$. The first train from our convoy routing $(\boldsymbol{R}, \boldsymbol{\sigma})$ arrives at a no later than the corresponding leader x in $(\boldsymbol{P}, \boldsymbol{\lambda})$. This is because they use the same path, and the train from $(\boldsymbol{R}, \boldsymbol{\sigma})$ departs s immediately. Further, in both routings, the last train entering a must have a minimum temporal distance of $(\sigma_x - 1) \cdot \Delta$ to the first train entering a. In the convoy routing, this bound is tight and thus the assignment phase does not increase the makespan.

2.3 Analysis

By its construction, if the uncrossing algorithm terminates, it returns a convoy routing with a makespan no worse the one of the input routing. Theorem 2 thus follows as a consequence of the following lemma.

▶ **Lemma 3.** *The uncrossing algorithm terminates.*

Proof (sketch). We prove this using a potential function. To define this function, we extend the definition of a_y^{tr} to arbitrary, i.e., also non-leader trains, y. Informally, a_y^{tr} is the last arc on train y's path after which the set (or order) of trains driving before y changes.

The potential of a train y is the number of arcs of P_y from s to a_y^{tr}. We prove the following two statements: (i) When resolving a conflict for some leader x, we decrease its potential, (ii) The potential of all other trains does not increase when resolving a conflict of x. Together, (i) and (ii) imply that the sum of all potentials decreases in every iteration of the uncrossing phase, implying finite termination of this phase and thus of the entire algorithm. The proof of (i) and (ii) involves a careful analysis, which reveals that the transition node of a train is always on its path in the original routing, and a case distinction of possible configurations arising in the uncrossing steps. The details of this analysis can be found in the full version of this article [1, Appendix B]. ◀

3 A flow-based additive approximation for TMO

As mentioned in Section 1, TMO with $\Delta = 1$ reduces to Quickest Flow Over Time in a network with unit capacities. This problem asks for a flow over time of a given value (d units in our case) to be sent from a source to a sink in the shortest time T possible. For an in-depth discussion of flows over time, we refer to [28]. By guessing the optimal makespan T (e.g., by using parametric search [27]), Quickest Flow Over Time can, in turn, be reduced to Maximum Flow Over Time – i.e., sending a maximum amount of flow within a given time horizon. The latter problem can be solved efficiently using a classic result of Ford and Fulkerson [14]: Compute an appropriate static flow, decompose this flow into (disjoint, in the case of unit capacities) paths, and send one unit of flow along each path as long as it still reaches the sink within the time horizon.

A natural extension of this approach to the case $\Delta > 1$ is computing a quickest flow over time sending $\Delta \cdot d$ units in total, and transform it into a train routing by only sending one unit of flow (i.e., one train) every Δ time units along each path. Because, conversely, any routing of d trains also can be extended to a flow over time of value $\Delta \cdot d$ when allowing an extra period of Δ time units beyond its makespan, we obtain the following approximation guarantee for TMO. Again, a detailed proof can be found in the full version of this article [1, Appendix C].

▶ **Theorem 4.** *There is an algorithm that, given a TMO instance, computes in strongly polynomial time a convoy routing with makespan at most* $\mathrm{OPT} + \Delta$*, where* OPT *is the optimal makespan.*

4 Reduction to MinMaxDP

In this section, we examine the relationship between TMO and MinMaxDP. It is easy to see that any α-approximation for TMO implies an α-approximation for MinMaxDP, by choosing $\Delta = \alpha \cdot \sum_{a \in A} \tau_a$. Proving the converse is more involved. We use a bundle graph (see Figure 2) consisting of a sequence of parallel arcs as a gadget, attached to the source node for the MinMaxDP instance, for our reduction.

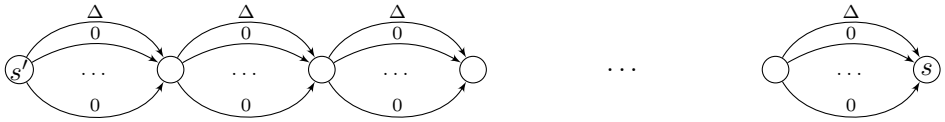

Figure 2 The gadget G_k for solving TMO via MinMaxDP. The gadget consists of a sequence of $(d - k)$ bundles. Each bundle contains an arc with travel time Δ and $k - 1$ arcs with travel time 0.

▶ **Theorem 5.** *Let $\mathcal{A}$ be an α-approximation algorithm for MinMaxDP, and let $\mathcal{R}(m)$ denote its runtime dependent on $m := |A|$. There exists a $\max\{\alpha, (1+\varepsilon)\}$-approximation for TMO with runtime in $\mathcal{O}\left(m \cdot \mathcal{R}\left(m^2(2 + \frac{1}{\varepsilon})\right)\right)$.*

Proof (sketch). We defer a formal proof to the full version of this article [1, Appendix D] and restrict ourselves to providing its intuition for now. First, consider the case $d > m(1 + \frac{1}{\varepsilon})$, i.e., when d is large. Then, OPT is much greater than Δ because some arcs are used by more than $\lceil \frac{1}{\varepsilon} \rceil$ trains, and hence the flow-based approximation from Section 3 yields a $(1 + \varepsilon)$-approximate solution.

Otherwise, when $d \leq m(1 + \frac{1}{\varepsilon})$, we utilise the given α-approximation $\mathcal{A}$ for MinMaxDP. We guess the number $k \in [m]$ of disjoint paths in an optimal convoy routing. For that k, we construct an auxiliary digraph D'_k by adding the gadget G_k described in Figure 2 prior to the source node s of the given digraph D. It is easy to see that the minimum makespan for MinMaxDP on D'_k (when k was guessed correctly) and the minimum makespan for the original TMO-instance coincide. Hence, $\mathcal{A}$'s approximation guarantee carries over to TMO. Note that the above case distinction is necessary to bound the size of D'_k polynomially. ◀

▶ Remark 6. Let $\mathcal{C}$ be a class of digraphs that is closed under adding a bundle graph prior to their source s. If $\mathcal{A}$ is an α-approximation algorithm for MinMaxDP on graph class $\mathcal{C}$, then Theorem 5 yields an approximation algorithm for TMO on graph class $\mathcal{C}$.

Bundle graphs and SePa-graphs are examples of such closed classes. Theorem 5 in conjunction with Theorem 1 from [9] yields the following stronger result for bundle graphs.

▶ **Corollary 7.** *There is a PTAS for TMO on bundle graphs.*

5 Approximation algorithm for MinMaxDP in series-parallel graphs

In this section, we describe and analyse an algorithm for approximating MinMaxDP in series-parallel graphs. Before we state our main result, we first provide a formal definition of series-parallel graphs and the parameter $\varphi(D)$ that is part of the approximation guarantee.

Series-parallel graphs. A *series-parallel digraph* $D = (V, A)$ (*SePa-graph*, for short) has a source s and a sink t and consists of either a single arc or can be obtained by a series or parallel composition of two series-parallel subgraphs D' and D''. The series composition $D = D' \odot_s D''$ merges the sink of D' with the source of D'', such that the source of D is the source of D' and the sink of D is the sink of D''. The parallel composition $D = D' \odot_p D''$ merges the two sources of D' and D'' to a single source of D and merges the sinks of D' and D'' to a single sink of D. Note that it is possible to have parallel arcs between two nodes.

The parameter $\varphi(D)$. Any SePa-graph can be described by a *binary decomposition tree*, where the leaves of the tree correspond to the arcs and the internal vertices correspond to either the series (labeled Ⓢ) or the parallel (labeled Ⓟ) composition of their children; see Figure 3 for an example. We can split the tree into arc-, S- or P-components. Such a component is a maximal connected subset of vertices in the binary decomposition tree with the same label. The *root* of a component C is the (unique) vertex $v \in C$ that is closest to the root of the binary decomposition tree. Moreover, we call the vertices that are not in the component C but whose parents are, the children of the component C. We let $\varphi(D)$ denote the maximum number of traversed S-components on a path from the root to a leaf. Note that, even if the binary decomposition tree of a SePa-graph is not unique, the number $\varphi(D)$ is (see full version [1, Appendix E]). Throughout this section, we assume that we are given a fixed binary decomposition tree of the input graph D (such a tree can be constructed in linear time [2]).

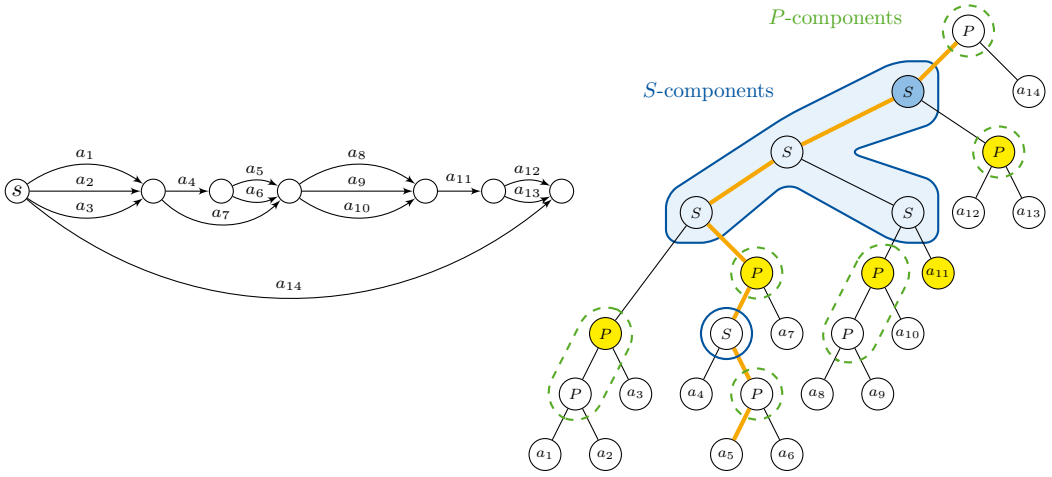

Figure 3 An example of a SePa-graph on the left. A corresponding series-parallel decomposition tree is shown on the right. Consider the large S-component (shaded in light blue), its root is highlighted blue and its children are highlighted yellow. Along the orange (bold) path (from the root to a leaf), we traverse two S-components. Also every other path traverses at most two, so $\varphi(D) = 2$.

Main result and overview. We can now formally state our main result for this section. Note that H_k denotes the k-th harmonic number, i.e., $H_k = \sum_{j=1}^{k} \frac{1}{j} \leq \log_2(k) + 1$.

▶ **Theorem 8.** *For every $\varepsilon > 0$ there is an algorithm that computes a $(\min\{H_k, \varphi(D) + 1\}) \cdot (1+\varepsilon)$-approximate path profile for MinMaxDP and runs in time polynomial in m, k, and $\frac{1}{\varepsilon}$.*

A central component of our algorithm is a *greedy composition* procedure that inductively combines path profiles in subgraphs based on the binary decomposition tree. In Section 5.1, we present this greedy composition procedure and several invariants maintained by the procedure that are crucial to our analysis. In particular, we show that if the invariants are fulfilled by the final solution, they imply the desired approximation ratio.

A remaining challenge is that it is not obvious how to initialise the procedure with solutions that satisfy the invariants at the beginning. In particular, some of the invariants are defined with respect to certain properties of the optimal solution and are thus not easy to verify. In Section 5.2, we show how to solve this issue by devising two dynamic programs, each optimising for one of the two terms whose minimum defines the approximation guarantee. Running these two DPs concurrently then yields the guarantee of the theorem (where ε is an error incurred by rounding so that the DPs run in polynomial time).

5.1 Greedy composition procedure

We use the following notation. We write $D' \sqsubseteq D$ for a series-parallel subgraph D' which corresponds to one of the vertices of the decomposition tree of D, i.e., the decomposition tree of D' is the subtree rooted at that vertex. Now consider any such subgraph $D' \sqsubseteq D$ with arc set A', source s', and sink t'. If an s-t-path P in a path profile $\boldsymbol{P}$ of D uses an arc in A', the series-parallel structure of D implies that $P \cap A'$ is an (s', t')-path in D'. We denote the length of a path P in D' by $\tau(P, D') \coloneqq \sum_{a \in P \cap A'} \tau_a$, and the length of the longest subpath of $\boldsymbol{P}$ in D' by $C_{\max}(\boldsymbol{P}, D') \coloneqq \max_{P \in \boldsymbol{P}} \tau(P, D')$. Moreover, we call $\theta(\boldsymbol{P}, D')$ the total length of arcs of path profile $\boldsymbol{P}$ in component D', that is $\theta(\boldsymbol{P}, D') \coloneqq \sum_{P \in \boldsymbol{P}} \tau(P, D')$.

Greedy composition. Let D' and D'' be two SePa-graphs, and let $\boldsymbol{P'}$ and $\boldsymbol{P''}$ be path profiles of D' and D'' consisting of k' and k'' arc-disjoint paths, respectively. For a series composition $D = D' \odot_s D''$, if $k' = k''$, the *greedy composition* of $\boldsymbol{P}$ and $\boldsymbol{P'}$ is the path profile $\boldsymbol{P} = \boldsymbol{P'} \odot_s \boldsymbol{P''}$ of D that is derived by combining the longest path in $\boldsymbol{P'}$ with the shortest path in $\boldsymbol{P''}$, the second-longest path in $\boldsymbol{P'}$ with the second-shortest path in $\boldsymbol{P''}$, and so on. Note that this construction is only defined for $k' = k''$. For a parallel composition $D = D' \odot_p D''$, the greedy composition is given by $\boldsymbol{P} = \boldsymbol{P'} \odot_p \boldsymbol{P''}$ of D, where $\boldsymbol{P}$ simply consists of the union of the $k' + k''$ paths in $\boldsymbol{P'}$ and $\boldsymbol{P''}$.

We now discuss three properties that are maintained by the greedy composition procedure described above if they are fulfilled by the path profiles that are being combined. To define these properties, we fix an arbitrary optimal path profile $\boldsymbol{P}^*$ in the graph D that defines our MinMaxDP instance. The first property we consider is consistency.

Consistency. We call a path-profile $\boldsymbol{P}$ *consistent* with $\boldsymbol{P}^*$ in $D' \sqsubseteq D$ if $\boldsymbol{P}$ and $\boldsymbol{P}^*$ use the same number of paths in D' and if

$$\theta(\boldsymbol{P}, D') \leq \theta(\boldsymbol{P}^*, D'). \tag{1}$$

Note that consistency is maintained by greedy composition, as the arcs used by the disjoint paths in the composed profile are exactly the union of the paths in the two profiles that are being combined. We now define the second property, balancedness, and show that together with consistency it implies the first of our two approximation bounds.

Balancedness. Let $\boldsymbol{P}$ be a path profile, and let $D' \sqsubseteq D$ be traversed by $k' \leq k$ paths from $\boldsymbol{P}$. Let $p_1 \geq \ldots \geq p_{k'}$ be the lengths of those paths in D'. Then $\boldsymbol{P}$ is *balanced* in D' if

$$\frac{1}{i}\left(\sum_{j=1}^{i} p_j\right) - p_{i+1} \leq C_{\max}(\boldsymbol{P}^*, D') \qquad \text{for all } i \in [k'-1]. \tag{2}$$

We first establish that balancedness – when combined with consistency – is indeed maintained by greedy composition. While this is straightforward for parallel composition, the proof for series composition requires a more involved analysis that carefully combines (1) and (2). The details of this analysis are given in the full version of this article [1, Appendix F.1].

▶ **Lemma 9.** *Let $\odot \in \{\odot_s, \odot_p\}$ and let $D^{(1)} \odot D^{(2)} = D'$. If $\boldsymbol{Q}$ and $\boldsymbol{R}$ are consistent and balanced path profiles in $D^{(1)}$ and $D^{(2)}$, respectively, then the greedy profile $\boldsymbol{P} = \boldsymbol{Q} \odot \boldsymbol{R}$ is a consistent and balanced path profile in D'.*

Crucially, the following lemma reveals that if the final solution is balanced and consistent with $\boldsymbol{P}^*$, it is a logarithmic approximation for the latter. The lemma follows from an averaging argument over (2) for $i \in [k-1]$, which can be found in the full version of this article [1, Appendix F.2].

▶ **Lemma 10.** *Let $\boldsymbol{P}$ be a consistent and balanced path profile in D. Then $C_{\max}(\boldsymbol{P}, D) \leq H_k \cdot C_{\max}(\boldsymbol{P}^*, D)$.*

We now introduce the third property, φ-boundedness, which is likewise maintained by greedy composition and implies the second bound on the approximation guarantee when fulfilled by the final solution.

φ-boundedness. We call a path profile $\boldsymbol{P}$ *φ-bounded* in $D' \sqsubseteq D$ if

$$C_{\max}(\boldsymbol{P}, D') \leq (\varphi(D') + 1) \cdot C_{\max}(\boldsymbol{P}^*, D). \tag{3}$$

Note that in this definition, the left-hand side refers to the length of the longest path of $\boldsymbol{P}$ in the subgraph $D' \sqsubseteq D$, whereas the right-hand side refers to the optimal objective value for MinMaxDP on the entire graph D. The following lemma establishes that consistency and φ-boundedness are maintained by the greedy composition when executing all compositions that correspond to one component of the decomposition tree.

▶ **Lemma 11.** *Let $D' \sqsubseteq D$ be a subgraph corresponding to a root vertex of an S-component or P-component, respectively. Let $D^{(1)}, \ldots, D^{(i)}$ be the graphs corresponding to the children of the component. Further, let $\boldsymbol{P}^{(j)}$ be a consistent and φ-bounded path profile in $D^{(j)}$ for $j \in [i]$. Then, the greedy series, respectively parallel, composition $\boldsymbol{P}$ of $\boldsymbol{P}^{(1)}, \ldots, \boldsymbol{P}^{(i)}$ is a consistent and φ-bounded path profile in D'.*

The proof of this lemma involves an induction over the components of the decomposition tree of D and can be found in the full version of this article [1, Appendix F.3].

5.2 Dynamic programs

The results in the preceding section imply that if we start from path profiles for the leaves of the decomposition tree of D that are consistent with an optimal solution and balanced or φ-bounded, respectively, then iteratively applying greedy composition will yield a path profile for D that is consistent and balanced or φ-bounded, respectively. In particular, such a profile then yields an H_k-approximation or $(\varphi(D)+1)$-approximation.

However, since we do not know the optimal solution, we do not know which path profiles fulfil these requirements. A natural approach seems to be to restrict ourselves to a solution with minimum total length (i.e., an integral minimum-cost s-t-flow of value k). However, there is a difficult trade-off between minimising the length of a longest path or minimising the total length of the solution in a subgraph, as the following example shows.

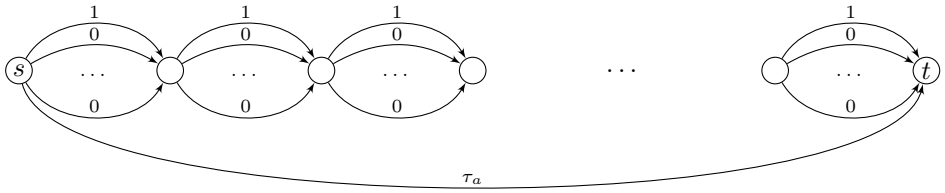

Figure 4 The depicted graph D is built as follows. Let D' be a graph with k parallel arcs (one arc with length 1 and $k-1$ arcs with length 0). We obtain D by connecting k copies of D' in series plus adding an additional arc from s to t with length τ_a.

▶ **Example 12.** Consider the graph D' depicted in Figure 4. If we set $\tau_a := k-1$, the path profile with minimal total length consists of $k-1$ paths of length 0 and one path with length $k-1$, leading to the objective value $k-1$. However, the optimal path profile consists of k paths all having length 1. On the other hand, assume that $\tau_a := 1+\varepsilon$ and create a graph D that consists of k copies of D' composed in series. In this case, solving the MinMaxDP in each subgraph D' results in all paths having length 1 inside each copy of the example, yielding to the objective value k when combining them in series. However, the optimal path profile uses exactly one arc of length $1+\varepsilon$ in each path and otherwise only length-0 arcs, yielding an objective value of $1+\varepsilon$. Thus, an algorithm which locally only considers the length of the longest path in the profile, would be a factor of k apart form the optimal value.

DP framework. In the following, we show how to resolve this issue by means of two dynamic programs. In both cases, our dynamic programming table will have the following attributes per cell:

- a subgraph $D' \sqsubseteq D$,
- the number of paths $k' \in [k]$ used in D',
- the total length $\theta' \in \Theta$ of the path profile in D'.

Recall that the total length of a path profile $\boldsymbol{P}$ in subgraph D' was defined as the sum of the lengths of the paths in D', i.e., $\theta(\boldsymbol{P}, D') := \sum_{P \in \boldsymbol{P}} \sum_{a \in A[D'] \cap P} \tau_a$. We let Θ denote the set containing all possible values that might appear as total costs.

To fill the cells of the dynamic programming table, we start with the subgraphs consisting of single arcs, i.e., $D' = (\{v, w\}, \{a = (v, w)\})$. Here, the non-empty entries of the table corresponding to D' are $(D', 1, \tau_a) = \{(a)\}$ and $(D', 0, 0) = \{\emptyset\}$, while all remaining entries corresponding to D' are empty (which is different from containing an empty path profile).

Given a cell $(D' \odot D'', \tilde{k}, \tilde{\theta})$, we combine all path profiles $\boldsymbol{P'}$ and $\boldsymbol{P''}$ of D' and D'' consisting of k' and k'' paths of total length θ' and θ'', respectively, if and only if $\tilde{\theta} = \theta' + \theta''$ and $\tilde{k} = k' + k''$ (in case of a parallel composition), or $\tilde{k} = k' = k''$ (in case of a series composition). We build path profiles for $D' \odot D''$ according to the greedy composition of the path profiles for D' and D'' as described above.

With this procedure, we obtain multiple candidates for a path profile in table entry $(D' \odot D'', \tilde{k}, \tilde{\theta})$. Below, we analyse two different strategies to pick a *good* candidate that lead to different approximation guarantees. After filling the complete table of the dynamic

program, there is a path profile $\boldsymbol{P}_\theta$ with k paths in D for each possible total-cost value $\theta \in \Theta$. In the last step, the algorithm will choose the path profile for which the longest path is as short as possible, i.e. the algorithm chooses $\arg\min_{\theta\in\Theta} C_{\max}(\boldsymbol{P}_\theta, D)$.

DP strategy for balancedness. Our first strategy for selecting the candidates for the intermediate steps aims for balancedness of the solutions and is formalised in the following lemma, that reveals that the strategy yields an H_k-approximation.

▶ **Lemma 13.** *The dynamic program which always selects the candidate $\boldsymbol{P}$ with k' paths of lengths $p_1 \geq \cdots \geq p_{k'}$ that minimises*

$$\max_{i\in\{1,\dots,k'-1\}} \left\{ \frac{1}{i}\sum_{j=1}^{i} p_j - p_{i+1} \right\}, \tag{4}$$

computes a solution with $DP \leq H_k \cdot \mathrm{OPT}$, where DP is the objective value of the computed solution and OPT *is the objective value of an optimal solution.*

The proof of this lemma is by induction on the table entries of the optimal solution and by using Lemma 9 to show that we always have a balanced candidate. Together with the choice (4), the lemma follows. A formal proof can be found in the full version of this article [1, Appendix F.4].

DP strategy for boundedness. Our second candidate selection strategy aims at φ-boundedness of the intermediate solutions. This is formalised in the following lemma, which shows that this strategy yields a $(\varphi(D)+1)$-approximation.

▶ **Lemma 14.** *The dynamic program that always selects the candidate $\boldsymbol{P}$ with k' paths of lengths $p_1 \geq \cdots \geq p_{k'}$ that minimises*

$$p_1 - p_{k'} \quad \text{in case of a series combination, and} \tag{5}$$
$$p_1 \quad \text{in case of a parallel composition} \tag{6}$$

computes a solution with $DP \leq (\varphi(D)+1)\cdot \mathrm{OPT}$, where DP is the objective value of the computed solution and OPT *is the objective value of an optimal solution.*

Similarly to the proof of Lemma 13 we follow the table entries of an optimal solution. However, here we need to consider a component of the decomposition tree of D at once and show that the entries for the subgraphs corresponding to segment roots are φ-bounded. The formal proof of this lemma can be found in the full version of this article [1, Appendix F.5].

Running time. From the size of the dynamic programming table, we can obtain the bound on its running time formalised in the lemma below. By a standard rounding approach, we can further ensure that the number of possible total-cost values $|\Theta|$ is polynomial in the size of the graph at a loss of a $(1+\varepsilon)$-factor in the approximation ratio, obtaining the desired polynomial running time; see the full version of this article [1, Appendix F.6] for details.

▶ **Lemma 15.** *The dynamic program runs in time $\mathcal{O}(m \cdot k^4 \cdot |\Theta|^2)$.*

6 Conclusion

In this paper, we introduced TMO as a natural optimisation problem that captures some of the fundamental challenges of routing trains with a headway constraint. By showing the existence of optimal train routings with a convoy structure, we linked the approximability of the problem to that of MinMaxDP, for which we then provided new approximation results in SePa-graphs. Several interesting questions arise from our work:

- Is it possible to extend the logarithmic approximation guarantee for MinMaxDP in SePa-graphs to arbitrary DAGs (where it would be best possible due to Theorem 1)?
- Conversely, can the inapproximability result from [10] for DAGs be extended to SePa-graphs (again implying that the greedy approach is best possible in those graphs)?
- Which of the results presented in this paper can be extended to the setting in which trains might have distinct sources and sinks? Note that for general DAGs even finding disjoint paths for multiple source-sink pairs is NP-hard [12] and that this still holds true in undirected SePa-graphs [23]; however, this hardness result does not carry over to directed SePa-graphs, so there is hope that our approximation results for those graphs extend to the multi commodity case.

Abstract

The Fréchet distance is a popular similarity measure that is well-understood for polygonal curves in $\mathbb{R}^d$: near-quadratic time algorithms exist, and conditional lower bounds suggest that these results cannot be improved significantly, even in one dimension and when approximating with a factor less than three. We consider the special case where the curves bound a simple polygon and distances are measured via geodesics inside this simple polygon. Here the conditional lower bounds do not apply; Efrat et al. (2002) were able to give a near-linear time 2-approximation algorithm.

In this paper, we significantly improve upon their result: we present a $(1+\varepsilon)$-approximation algorithm, for any $\varepsilon > 0$, that runs in $\mathcal{O}(\frac{1}{\varepsilon}(n + m \log n) \log nm \log \frac{1}{\varepsilon})$ time for a simple polygon bounded by two curves with n and m vertices, respectively. To do so, we show how to compute the reachability of specific groups of points in the free space at once, by interpreting the free space as one between separated one-dimensional curves. We solve this one-dimensional problem in near-linear time, generalizing a result by Bringmann and Künnemann (2015). Finally, we give a linear time exact algorithm if the two curves bound a convex polygon.

1 Introduction

The Fréchet distance is a well-studied similarity measure for curves in a metric space. Most results so far concern the Fréchet distance between two polygonal curves R and B in $\mathbb{R}^d$ with n and m vertices, respectively. Then the Fréchet distance between two such curves can be computed in $\tilde{\mathcal{O}}(nm)$ time (see e.g. [1, 5]). There is a closely matching conditional lower bound: If the Fréchet distance between polygonal curves can be computed in $\mathcal{O}((nm)^{1-\varepsilon})$ time (for any constant $\varepsilon > 0$), then the Strong Exponential Time Hypothesis fails [3]. This lower bound extends to curves in one dimension, and holds even when approximating to a factor less than three [6].

Because it is unlikely that exact strongly subquadratic algorithms exist, approximation algorithms have been developed [9, 15, 8]. The authors [15] were the first to present an algorithms which results in an arbitrarily small polynomial approximation factor (n^{ε} for any

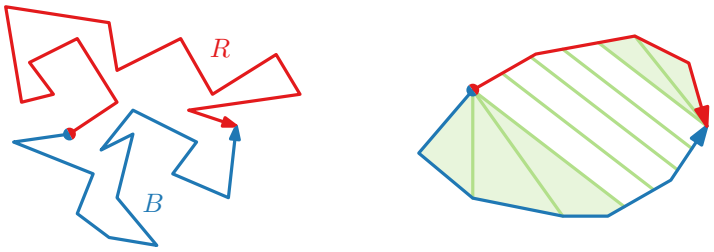

Figure 1 (left) Curves R and B bound a simple polygon. (right) A maximally-parallel matching.

$\varepsilon \in (0, 1]$) in strongly subquadratic time ($\tilde{\mathcal{O}}(n^{2-\varepsilon})$). Very recently, Cheng et al. [8] gave the first (randomized) constant-factor approximation algorithm with a strongly subquadratic running time. Specifically, it computes a $(7+\varepsilon)$-approximation in $\mathcal{O}(nm^{0.99}\log(n/\varepsilon))$ time.

For certain families of "realistic" curves, the SETH lower bound does not apply. For example, when the curves are *c-packed*, Driemel et al. [11] gave an $(1+\varepsilon)$-approximation algorithm, for any $\varepsilon \in (0, 1)$, that runs in $\tilde{\mathcal{O}}(cn/\varepsilon)$ time. Bringmann and Künnemann [4] improved the running time to $\tilde{\mathcal{O}}(cn/\sqrt{\varepsilon})$ time.

For curves in one dimension with an imbalanced number of vertices, the Fréchet distance can be computed in strongly subquadratic time without making extra assumptions about the shape of the curves. This was recently established by Blank and Driemel [2], who give an $\tilde{\mathcal{O}}(n^{2\alpha}+n)$-time algorithm when $m = n^\alpha$ for some $\alpha \in (0, 1)$.

If the two polygonal curves R and B lie inside a simple polygon P with k vertices and we measure distances by the geodesic distance inside P, then neither the upper nor the conditional lower bound change in a fundamental way. Specifically, Cook and Wenk [10] show how to compute the Fréchet distance in this setting in $\mathcal{O}(k + N^2 \log kN \log N)$ time, with $N = \max\{n, m\}$. For more general polygonal obstacles, Chambers et al. [7] give an algorithm that computes the *homotopic* Fréchet distance in $\mathcal{O}(N^9 \log N)$ time, where $N = m + n + k$ is the total number of vertices on the curves and obstacles.

Har-Peled et al. [13] investigate the setting where R and B are simple, interior-disjoint curves on the boundary of a triangulated topological disk. If the disk has k faces, their algorithm computes a $\mathcal{O}(\log k)$-approximation to the homotopic Fréchet distance in $\mathcal{O}(k^6 \log k)$ time. Efrat et al. [12] consider a more geometric setting, where R and B bound a simple polygon (see Figure 1 (left)). Here, the SETH lower bound does not apply; a 2-approximation to the geodesic Fréchet distance can be computed in $\mathcal{O}((n+m)\log nm)$ time [12]. Moreover, the authors [14] recently gave an $\mathcal{O}((n+m)\log^4 nm)$-time exact algorithm for a similar setting, where distances are measured under the L_1-geodesic distance. Their result implies a $\sqrt{2}$-approximation algorithm for the geodesic Fréchet distance.

Organization and results. In this paper, we significantly improve upon the results of Efrat et al. [12] and the authors [14]: we present a $(1+\varepsilon)$-approximation algorithm for the geodesic Fréchet distance, for any $\varepsilon \in (0, 1]$, that runs in $\mathcal{O}(\frac{1}{\varepsilon}(n + m\log n)\log nm \log \frac{1}{\varepsilon})$ time when R and B together bound a simple polygon. We give an overview of our algorithm in Section 2. Our algorithm relies on an interesting connection between matchings and nearest neighbors and is described in Section 3. There we also explain how to transform the decision problem for *far* points on B (those who are not a nearest neighbor of any point on R) into a problem between separated one-dimensional curves. This problem is about computing, given a set of "entrances" and "potential exits" (points anywhere in the parameter space), which potential exits are δ-reachable from entrances. Bringmann and Künnemann [4] study a

restricted variant of this problem in the context of Fréchet distance between c-packed curves. In addition to giving a near-linear time algorithm for the general problem, we also compute the Fréchet distance between two separated one-dimensional curves in linear time.

In the full version of this paper, we additionally describe a simple linear-time algorithm for when P is a convex polygon. We show that in this setting there is a Fréchet matching with a specific structure: a *maximally-parallel matching* (see Figure 1 (right)). We compute the orientation of the parallel part from up to $O(n+m)$ different tangents, which we find using "rotating calipers."

Preliminaries. A (polygonal) *curve* R with n *vertices* is a continuous map $R\colon [1,n] \to \mathbb{R}^d$ that is linear on each interval $[i, i+1]$ where i is an integer. Its vertices are the points $R(i)$. If the vertices lie in the plane, then we say R is two-dimensional.[1] A one-dimensional curve is defined analogously.

We denote by $R[x,x']$ the subcurve of R over the domain $[x,x']$, and abuse notation slightly to let $R[r,r']$ to also denote this subcurve when $r = R(x)$ and $r' = R(x')$. The *edges* of R are the directed line segments $R[i,i+1]$ for integers $i \in [1,n-1]$. We write $|R|$ to denote the number of vertices of R. In this work, we consider two simple, interior-disjoint curves $R\colon [1,n] \to \mathbb{R}^2$ and $B\colon [1,m] \to \mathbb{R}^2$ with $R(1) = B(1)$ and $R(n) = B(m)$, and say that they bound a simple polygon P.

A *reparameterization* of $[1,n]$ is a non-decreasing surjection $f\colon [0,1] \to [1,n]$. Two reparameterizations f and g of $[1,n]$ and $[1,m]$, describe a *matching* (f,g) between two curves R and B with n and m vertices, respectively, where any point $R(f(t))$ is matched to $B(g(t))$. The matching (f,g) is said to have *cost*

$$\max_t \; d(R(f(t)), B(g(t))),$$

where $d(\cdot,\cdot)$ is the geodesic distance between points in P. A matching with cost at most δ is called a *δ-matching*. The (continuous) *geodesic Fréchet distance* $d_{\mathrm{F}}(R,B)$ between R and B is the minimum cost over all matchings. The corresponding matching is a *Fréchet matching*.

The *parameter space* of R and B is the axis-aligned rectangle $[1,n] \times [1,m]$. Any point (x,y) in the parameter space corresponds to the pair of points $R(x)$ and $B(y)$ on the two curves. A point (x,y) in the parameter space is *δ-close* for some $\delta \geq 0$ if $d(R(x), B(y)) \leq \delta$. The *$\delta$-free space* $\mathcal{F}_\delta(R,B)$ of R and B is the set of δ-close points. Alt and Godau [1] observed that there is a one-to-one correspondence between δ-matchings between subcurves $R[x,x']$ and $B[y,y']$, and bimonotone paths from (x,y) to (x',y') through $\mathcal{F}_\delta(R,B)$. We abuse terminology slightly and refer to such paths as δ-matchings as well.

A point $q = (x',y') \in \mathcal{F}_\delta(R,B)$ is *δ-reachable* from a point $p = (x,y)$ if $x \leq x'$ and $y \leq y'$, and there exists a bimonotone (i.e., monotone in both coordinates) path in $\mathcal{F}_\delta(R,B)$ from p to q. That is, if the subcurves $R[x,x']$ and $B[y,y']$ have Fréchet distance at most δ between them. Points that are δ-reachable from $(1,1)$ are simply called δ-reachable points.

Let $\varepsilon \in (0,1]$ be a parameter. A $(1+\varepsilon)$-*approximate decision algorithm* for our problem takes a decision parameter $\delta \geq 0$, and outputs either that $d_{\mathrm{F}}(R,B) \leq (1+\varepsilon)\delta$ or that $d_{\mathrm{F}}(R,B) > \delta$. It may report either answer if $\delta < d_{\mathrm{F}}(R,B) \leq (1+\varepsilon)\delta$.

[1] Curves are inherently one-dimensional objects. We abuse terminology slightly to refer to the ambient dimension as the dimension of a curve.

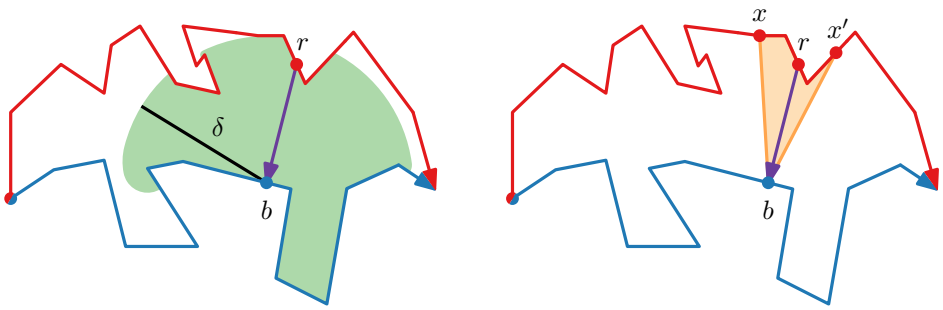

Figure 2 (left) Points r and b with $b \in NN(r)$. The region shaded in green consists of all points within geodesic distance δ of b. (right) The (r, b, δ)-nearest neighbor fan (orange).

2 Algorithmic outline

In this section we sketch the major parts of our algorithm that approximates the geodesic Fréchet distance $\delta_F := d_F(R, B)$ between curves R and B. We approximate δ_F using a $(1+\varepsilon)$-approximate decision algorithm, and use binary search to find the correct decision parameter. In Section 3.4 we relate the Fréchet distance to the geodesic Hausdorff distance δ_H, which allows us to bound the number of iterations of the binary search. In particular, we show that δ_F lies in the range $[\delta_H, 3\delta_H]$. The Hausdorff distance δ_H can be computed in $\mathcal{O}((n+m)\log nm)$ time [10, Theorem 7.1]. A binary search over $[\delta_H, 3\delta_H]$ results in a $(1+\varepsilon)$-approximation of the Fréchet distance after $\mathcal{O}(\log \frac{1}{\varepsilon})$ calls to the decision algorithm. Theorem 1 follows.

▶ **Theorem 1.** *For any $\varepsilon \in (0, 1]$, we can compute a $(1+\varepsilon)$-approximation to $d_F(R, B)$ in $\mathcal{O}(\frac{1}{\varepsilon}(n + m\log n)\log nm \log \frac{1}{\varepsilon})$ time.*

The approximate decision algorithm. In the remainder of this section we outline the approximate decision algorithm, which is presented in detail in Section 3. At its heart lies a useful connection between matchings and nearest neighbors. A *nearest neighbor* of a point r on R is any point b on B that among all points on B is closest to r. We denote the nearest neighbor(s) of r by $NN(r)$. We prove in Section 3.1 that any δ-matching matches each nearest neighbor b of r relatively close to r. Specifically, b must be matched to only points r' for which the entire subcurve of R between r and r' is within distance δ of b. We introduce the concept of a (r, b, δ)-nearest neighbor fan to capture the candidate locations for r'.

The *(r, b, δ)-nearest neighbor fan* $F_{r,b}(\delta)$ contains the point b and the maximal subcurve $R[x, x']$ that contains r and is within geodesic distance δ of b; it is the union of geodesics between b and points on $R[x, x']$, see Figure 2. We call b the *apex* of $F_{r,b}(\delta)$ and $R[x, x']$ the *leaf* of the fan. We prove in Section 3.1 that any δ-matching must match the apex b to a point in the leaf $R[x, x']$.

As r moves forward along R, so do its nearest neighbors b along B. Their nearest neighbor fans $F_{r,b}(\delta)$ move monotonically through the polygon P bounded by R and B. However, while r moves continuously along R, the points b and their nearest neighbor fans might jump discontinuously. Such discontinuities occur due to points b that are not a nearest neighbor of any point on R, and thus at points that are not the apex of a nearest neighbor fan. We classify the points on B accordingly: we call a point b on B a *near* point if it is a nearest neighbor of at least one point on R, and call b a *far* point otherwise.

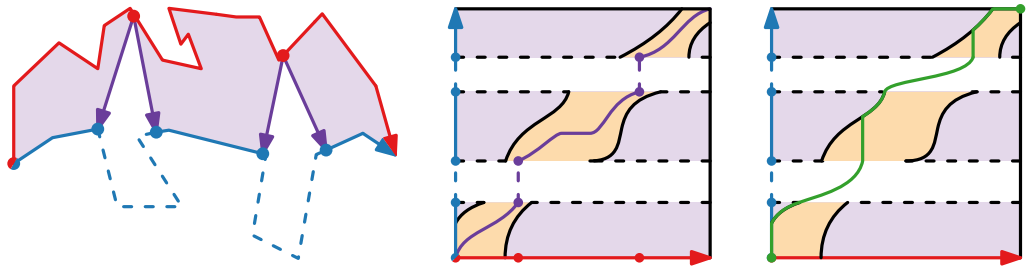

Figure 3 (left) The mappings (purple) from points on R to their nearest neighbor(s) on B. (middle) The partition of the parameter space based on near and far points on B. The partly-dashed purple curve indicates the nearest neighbor(s) on B of points on R. The beige regions correspond to the (r, b, δ)-nearest neighbor fans. (right) A δ-matching that is greedy on B inside the regions.

The distinction between near and far points induces a partition $\mathcal{H}$ of the parameter space into horizontal slabs. We consider these slabs from bottom to top, and iteratively construct a δ-matching (provided that one exists). Recall that a δ-matching is a bimonotone path in $\mathcal{F}_\delta(R, B)$ from the bottom-left corner of the parameter space to the top-right corner.

Inside a slab $H_{\text{near}} \in \mathcal{H}$ corresponding to a subcurve of B with only near points, the nearest neighbor fans correspond to a connected, x-monotone and y-monotone region $\mathcal{R}$ spanning the entire height of H_{near}. These regions are illustrated in Figure 3. The intersection between any δ-matching and H_{near} is contained in $\mathcal{R}$. The structure of $\mathcal{R}$ implies that if a δ-matching between R and B exists, there exists one which moves vertically up inside $\mathcal{R}$ whenever this is possible. Geometrically, this corresponds to greedily traversing the near points on B, and traversing parts of R only when necessary. We formalize this in Section 3.2.

Slabs whose corresponding subcurves of B have only far points pose the greatest technical challenge for our algorithm; we show how to match far points in an approximate manner in Section 3.3. Specifically, let $H_{\text{far}} \in \mathcal{H}$ correspond to a subcurve $B[b, b']$ with only far points on its interior. We compute a suitable subcurve of R that can be $(1+\varepsilon)\delta$-matched to $B[b, b']$ in the following manner. First we argue that $d(b, b') \leq 2\delta_F$. In other words, the geodesic from b to b' is short and separates R from the subcurve $B[b, b']$. We use this separating geodesic to transform the problem of creating a matching for far points into $K = \mathcal{O}(1/\varepsilon)$ one-dimensional problems.

Specifically, we discretize the separator with K points, which we call *anchors*, and ensure that consecutive anchors are at most $\varepsilon\delta$ apart. We snap our geodesics to these anchors (see Figure 4), which incurs a small approximation error. Based on which anchor a geodesic

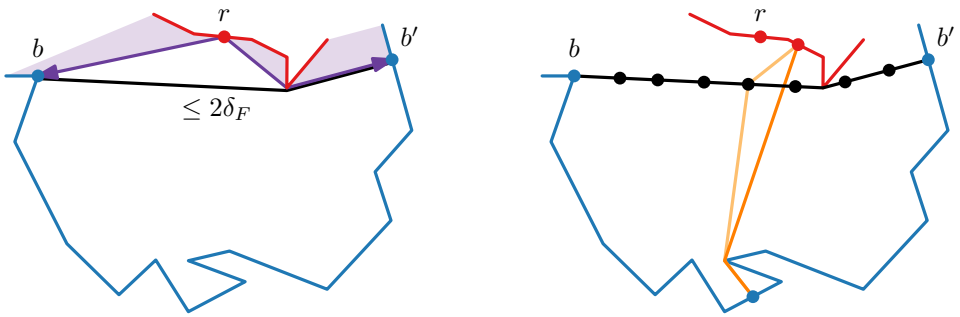

Figure 4 (left) The points b and b' are both nearest neighbor of some point r, implying a short separator. (right) Adding anchor points to the separator and snapping the orange geodesic (between arbitrary points on R and $B[b, b']$) to one.

snaps to, we partition the parameter space of R and $B[b, b']$ into regions, one for each anchor. For each anchor point, the lengths of the geodesics snapped to it can be expressed as distances between points on two separated one-dimensional curves; this results in a one-dimensional problem which we can solve exactly. In Section 3.3 we present the transformation into one-dimensional curves, and in Section 4 we present an efficient exact algorithm for the resulting one-dimensional problem.

3 Approximate geodesic Fréchet distance

3.1 Nearest neighbor fans and partitioning the parameter space

We first present useful properties of nearest neighbor fans and their relation to matchings. In Lemma 3 we give a crucial property of nearest neighbor fans, namely that *any* δ-matching between R and B matches b to only points in the leaf of the fan. For the proof, we make use of the following auxiliary lemma:

▶ **Lemma 2.** *Let $r \in R$ and $b \in NN(r)$. For any points $r' \in R$ and $b' \in B$ on opposite sides of the geodesic $\pi(r, b)$ between r and b, we have $d(r', b) \leq d(r', b')$.*

▶ **Lemma 3.** *Let $r \in R$ and $b \in NN(r)$. For any $\delta \geq 0$, every δ-matching between R and B matches b to only points in the leaf of $F_{r,b}(\delta)$.*

Proof. Fix a δ-matching (f, g) and let r' be a point matched to b by this matching. Assume without loss of generality that r' comes before r along R. Let $\hat{r}$ be a point between r' and r. The δ-matching (f, g) matches $\hat{r}$ to at least one point $\hat{b}$ after b. Thus we obtain from Lemma 2 that $d(\hat{r}, b) \leq d(\hat{r}, \hat{b}) \leq \delta$. This proves that all points between r' and r are included in the leaf of $F_{r,b}(\delta)$. ◀

We partition the parameter space into (closed) maximal horizontal slabs, such that for each slab $[1, n] \times [y, y']$, either the subcurve $B[y, y']$ contains only near points, or its interior contains only far points. Let $\mathcal{H}$ be the resulting partition. Each slab $H \in \mathcal{H}$ has two horizontal line segments, one on its bottom and one on its top side, that correspond to nearest neighbor fans. We refer to these line segments as the *entrance* and *exit intervals* of H, and refer to points on them as the *entrances* and *exits* of H. A consequence of Lemma 3 is that any δ-matching enters and leaves H through an entrance and an exit, respectively. We compute *δ-safe* entrances and exits: δ-reachable points from which (n, m) is δ-reachable. Each such point is used by a δ-matching, and is used to iteratively determine if such a matching exists.

It proves sufficient to consider only a discrete set of entrances and exits for each slab. For each slab, we identify (implicitly) a set of $\mathcal{O}(n)$ entrances and exits that contain δ-safe entrances and exits (if any exist at all). We define these entrances and exits using locally closest points and will call them transit points.

A point r on R is *locally closest* to a point b on B if perturbing r infinitesimally while staying on R increases its distance to b. The *transit* entrances and exits are those entrances and exits (x, y) where $R(x)$ is either a vertex or locally closest to $B(y)$. We show that it is sufficient to consider only transit entrances and exits:

▶ **Lemma 4.** *If there exists a δ-matching, then there exists one that enters and leaves each slab through a transit entrance and exit.*

Our algorithm computes a δ-safe transit exit for each slab. To do so, it requires the explicit entrance and exit intervals. We compute these using a geodesic Voronoi diagram.

▶ **Lemma 5.** *The partition $\mathcal{H}$ consists of $\mathcal{O}(m)$ slabs. We can compute $\mathcal{H}$, together with the entrance and exit interval of each slab, in $\mathcal{O}((n+m)\log nm)$ time in total.*

3.2 Slabs of near points

Let $H_{\text{near}} \in \mathcal{H}$ be a slab corresponding to a subcurve $\hat{B}$ of B with only near points. We use properties of nearest neighbor fans to determine a δ-safe transit exit of H_{near}. A crucial property is that the nearest neighbor fans behave monotonically with respect to their apexes, if δ is large enough. Specifically, this is the case if $\delta \geq \delta_H$, the geodesic Hausdorff distance between R and B. This is the maximum distance between a point on $R \cup B$ and its closest point on the other curve.

▶ **Lemma 6.** *Suppose $\delta \geq \delta_H$. Let b and b' be near points on B and let $R[x_1, x_1']$ and $R[x_2, x_2']$ be the leaves of their respective nearest neighbor fans. If b comes before b', then $x_1 \leq x_2$ and $x_1' \leq x_2'$.*

The monotonicity of the nearest neighbor fans, together with the fact that each point on $\hat{B}$ corresponds to such a fan, ensures that we can determine such an exit in logarithmic time (see Lemma 8). We make use of the following data structure that reports transit exits:

▶ **Lemma 7.** *Given the exit interval $[x, x'] \times \{y\}$ of H_{near}, we can report the at most three transit exits on a horizontal line segment $[i, i+1] \times \{y\}$, for any integer $1 \leq i < n$, in $\mathcal{O}(\log nm)$ time, after $\mathcal{O}(n+m)$ preprocessing time.*

▶ **Lemma 8.** *Suppose $\delta \geq \delta_H$. Let $H_{\text{near}} \in \mathcal{H}$ be a slab corresponding to a subcurve of B with only near points. Given the exit interval of H_{near}, together with a δ-safe transit entrance, we can compute a δ-safe transit exit in $\mathcal{O}(\log nm)$ time, after $\mathcal{O}(n+m)$ preprocessing time.*

Proof (sketch). Given a δ-safe transit entrance p_{enter}, the leftmost transit exit to the right of p_{enter} is δ-safe. We report it with the data structure of Lemma 7. ◀

3.3 Slabs of far points

Next we give an algorithm for computing a δ-safe transit exit of a given slab $H_{\text{far}} \in \mathcal{H}$ that corresponds to a subcurve of B with only far points on its interior. Our algorithm is approximate: given $\varepsilon \in (0, 1]$, it computes an (ε, δ)-*safe* transit exit (if one exists). This is a $(1+\varepsilon)\delta$-reachable point from which (n, m) is δ-reachable. Such a transit exit behaves like a δ-safe transit exit for the purpose of iteratively constructing a matching.

To compute an (ε, δ)-safe transit exit, we make use of an approximate decision algorithm that uses the fact that $\hat{B}$ has only far points on its interior. We present this algorithm in Section 3.3.1. In Section 3.3.2 we then apply this approximate decision algorithm in a search procedure, where we search over the $\mathcal{O}(n)$ transit exits to compute an (ε, δ)-safe one.

3.3.1 Approximate decision algorithm for far points

Let $\hat{B}$ be the subcurve of B that corresponds to H_{far}, so its interior has only far points. Let $\hat{R}$ be an arbitrary subcurve of R, for which we seek to approximately determine whether $d_{\text{F}}(\hat{R}, \hat{B}) \leq \delta$. We report either that $d_{\text{F}}(\hat{R}, \hat{B}) \leq (1+\varepsilon)\delta$, or that $d_{\text{F}}(\hat{R}, \hat{B}) > \delta$.

For our algorithm, we first discretize the space of geodesics between points on $\hat{R}$ and points on $\hat{B}$, by grouping the geodesics into few ($\mathcal{O}(1/\varepsilon)$) groups and rerouting the geodesics in a group through some representative point. Let $\hat{b}$ and $\hat{b}'$ be the first, respectively last,

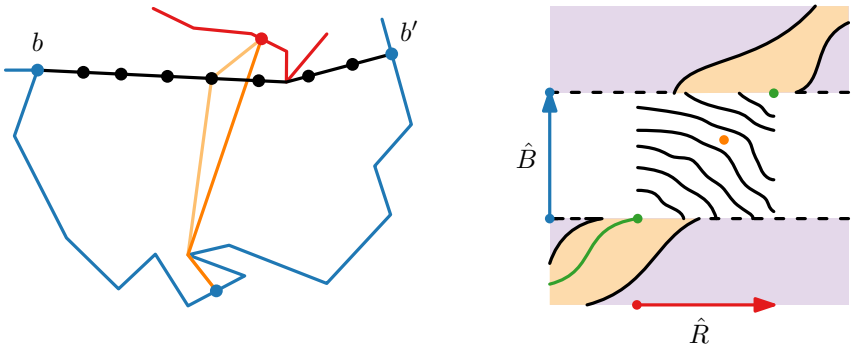

Figure 5 (left) Snapping a geodesic (orange) to an anchor. (right) The eight regions in the parameter space of $\hat{R}$ and $\hat{B}$ corresponding to the first eight (out of nine) anchors. The orange geodesic lies in region $\mathcal{R}_5$.

endpoints of $\hat{B}$. There is a point r on R with $NN(r) = \{\hat{b}, \hat{b}'\}$. We observe that this implies the geodesic $\pi(\hat{b}, \hat{b}')$ that connects $\hat{b}$ to $\hat{b}'$ is short with respect to the Fréchet distance, and thus with respect to any relevant value for δ:

▶ **Lemma 9.** $d(\hat{b}, \hat{b}') \leq 2d_{\mathrm{F}}(\hat{R}, \hat{B})$.

We assume for the remainder that $d(\hat{b}, \hat{b}') \leq 2\delta$; if this is not the case, we immediately report that $d_{\mathrm{F}}(\hat{R}, \hat{B}) > \delta$. This assumption means that the geodesic $\pi(\hat{b}, \hat{b}')$ is a short separator between $\hat{R}$ and $\hat{B}$. That is, any geodesic between a point on $\hat{R}$ and a point on $\hat{B}$ intersects $\pi(\hat{b}, \hat{b}')$. For clarity, we denote by π_{sep} the separator $\pi(\hat{b}, \hat{b}')$. We use the short separator to formulate the (exact) reachability problem as $\mathcal{O}(1/\varepsilon)$ subproblems involving one-dimensional curves. This is where we incur a small approximation error.

We discretize π_{sep} with $K + 1 = \mathcal{O}(1/\varepsilon)$ points $\hat{b} = a_1, \ldots, a_{K+1} = \hat{b}'$, which we call *anchors*, and ensure that consecutive anchors at most a distance $\varepsilon\delta$ apart, see Figure 5 (left). We assume that no anchor coincides with a vertex of $\hat{R} \cup \hat{B}$ (except for a_1 and a_{K+1}).

We route geodesics between points on $\hat{R}$ and points on $\hat{B}$ through these anchors. Specifically, for points $\hat{r} \in \hat{R}$ and $\hat{b} \in \hat{B}$, if $\pi(\hat{r}, \hat{b})$ intersects π_{sep} between consecutive anchors a_k and a_{k+1}, then we "snap" $\pi(\hat{r}, \hat{b})$ to a_k; that is, we replace it by the union of $\pi(\hat{r}, a_k)$ and $\pi(a_k, \hat{b})$ (see Figure 5 (right)). This creates a new path between $\hat{r}$ and $\hat{b}$ that goes through a_k and has length at most $d(\hat{r}, \hat{b}) + \varepsilon\delta$.

We associate an anchor a_k with the points (x, y) in the parameter space for which the geodesic $\pi(\hat{R}(x), \hat{B}(y))$ is snapped to a_k. These points form a region $\mathcal{R}_k$ that is connected and monotone in both coordinates (see Figure 5 (right)). We iteratively compute, for each region $\mathcal{R}_k$, a set of $(1 + \varepsilon)\delta$-reachable points on its boundary, such that the decision question can be answered by checking if the last set contains $(|\hat{R}|, |\hat{B}|)$. We later formulate these subproblems in terms of pairs of one-dimensional curves that are separated by a point.

We first discretize the problem. For this, we identify sets of points on the shared boundaries between the pairs of adjacent regions, such that there exists a δ-matching that enters and exits each region through such a set. Specifically, for $k = 2, \ldots, K$, we let the set S_k contain those points $(x, y) \in \mathcal{R}_{k-1} \cap \mathcal{R}_k$ for which one of $R(x)$ and $B(y)$ is a vertex or locally closest to a_k (so perturbing the point infinitesimally along its curve increases its distance to a_k). We set $S_1 = \{(1, 1)\}$. In the following lemmas, we show that these sets suit our needs and are efficiently constructable.

▶ **Lemma 10.** *If there exists a δ-matching between $\hat{R}$ and $\hat{B}$, then there exists one that goes through a point in S_k for every anchor a_k.*

▶ **Lemma 11.** *Each set S_k contains $\mathcal{O}(|\hat{R}| + |\hat{B}|)$ points and can be constructed in $\mathcal{O}((|\hat{R}| + |\hat{B}|) \log nm)$ time, after $\mathcal{O}(n + m)$ preprocessing time.*

Having constructed the sets S_k for all anchors in $\mathcal{O}(\frac{1}{\varepsilon}(|\hat{R}| + |\hat{B}|) \log nm)$ time altogether, we move to computing subsets $S_k^* \subseteq S_k$ containing all δ-reachable points, and only points that are $(1+\varepsilon)\delta$-reachable. We proceed iteratively, constructing S_{k+1}^* from S_k^*. For this, observe that for any point (x, y) in the interior of $\mathcal{R}_k$, the geodesic $\pi(\hat{R}(x), \hat{B}(y))$ was snapped to a_k. We use this fact to construct a pair of one-dimensional curves that approximately describe the lengths of these geodesics.

Let $\bar{R}_k \colon [1, |\hat{R}|] \to \mathbb{R}$ and $\bar{B}_k \colon [1, |\hat{B}|] \to \mathbb{R}$ be one-dimensional curves, where we set $\bar{R}_k(x) = -d(\hat{R}(x), a_k)$ and $\bar{B}_k(y) = d(\hat{B}(y), a_k)$ (note the difference in sign). These curves encode the distances between points on $\hat{R}$ and $\hat{B}$ when snapping geodesics to a_k. That is, $|\bar{R}_k(x) - \bar{B}_k(y)|$ is the length of $\pi(\hat{R}(x), \hat{B}(y))$ after snapping to a_k. Hence, for any pair of points $p \in S_k^*$ and $q \in S_{k+1}$, we have the following relations:

- If q is δ-reachable from p in the parameter space of $\hat{R}$ and $\hat{B}$, then it is $(1+\varepsilon)\delta$-reachable in the parameter space of $\bar{R}_k$ and $\bar{B}_k$.
- Conversely, if q is $(1+\varepsilon)\delta$-reachable from p in the parameter space of $\bar{R}_k$ and $\bar{B}_k$, then it is $(1+\varepsilon)\delta$-reachable in the parameter space of $\hat{R}$ and $\hat{B}$.

We define S_{k+1}^* as the points in S_{k+1} that are $(1+\varepsilon)\delta$-reachable from points in S_k^*, in the parameter space of $\bar{R}_k$ and $\bar{B}_k$. Computing these points is the problem involving one-dimensional curves that we alluded to earlier.

▶ **Lemma 12.** *Given S_k^*, we can compute S_{k+1}^* in $\mathcal{O}((|\hat{R}|+|\hat{B}|) \log nm)$ time, after $\mathcal{O}(n+m)$ preprocessing time.*

We apply the above procedure iteratively, computing S_k^* for each anchor a_k. These sets take a total of $\mathcal{O}(\frac{1}{\varepsilon}(|\hat{B}| + |\hat{R}|) \log nm)$ time to construct. Afterwards, if $(|\hat{R}|, |\hat{B}|) \in S_K^*$, we report that $d_{\mathrm{F}}(\hat{R}, \hat{B}) \leq (1+\varepsilon)\delta$. Otherwise, we report that $d_{\mathrm{F}}(\hat{R}, \hat{B}) > \delta$. We obtain:

▶ **Lemma 13.** *Let $\hat{R}$ be an arbitrary subcurve of R, and let $\hat{B}$ be a maximal subcurve of B with only far points on its interior. We can decide whether $d_{\mathrm{F}}(\hat{R}, \hat{B}) \leq (1+\varepsilon)\delta$ or $d_{\mathrm{F}}(\hat{R}, \hat{B}) > \delta$ in $\mathcal{O}(\frac{1}{\varepsilon}(|\hat{R}| + |\hat{B}|) \log nm)$ time, after $\mathcal{O}(n+m)$ preprocessing time.*

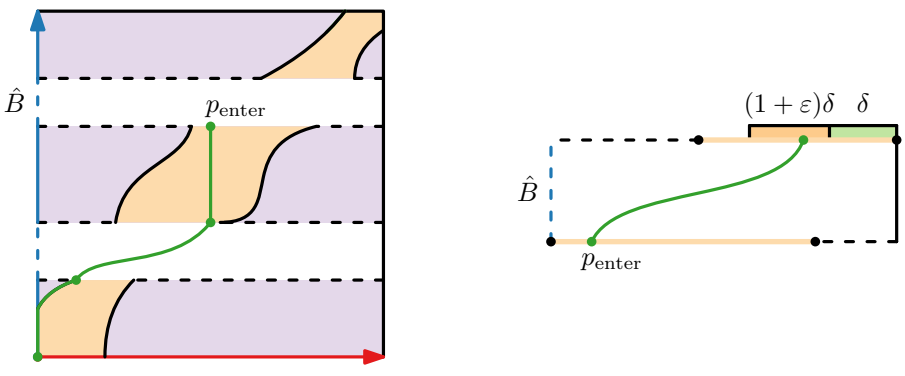

Figure 6 The subproblem of matching far points. The exit interval on the right is divided into three regions, based on reachability of points. The aim is to compute a $(1+\varepsilon)\delta$-reachable transit exit to the left of all δ-reachable transit exits.

3.3.2 Computing a good exit

Recall that we set out to compute an (ε, δ)-safe transit exit of H_{far}. We assume we are given an (ε, δ)-safe entrance $p_{\text{enter}} = (x, y)$. Since the entire exit interval of H_{far} lies in $\mathcal{F}_\delta(R, B)$, it suffices to compute a transit exit q_{exit} that is $(1+\varepsilon)\delta$-reachable from p_{enter} and that lies to the left of all transit exits that are δ-reachable from p_{enter}, see Figure 6. We compute such a transit exit q_{exit} through a search procedure, combined with the decision algorithm.

There are $\mathcal{O}(n)$ transit exits of H_{far}. To avoid running the decision algorithm for each of these, we use exponential search. The choice for exponential search over, e.g., binary search comes from the fact that the running time of the decision algorithm depends on the location of the transit exit, with transit exits lying further to the right in the exit interval of H_{far} needing more time for the decision algorithm. Exponential search ensures that we do not consider transit exits that are much more to the right than needed.

▶ **Lemma 14.** *Let $H_{\text{far}} \in \mathcal{H}$ be a slab corresponding to a subcurve $\hat{B}$ of B with only far points on its interior. Given an (ε, δ)-safe transit entrance $p = (x, y)$ of H_{far}, we can compute an (ε, δ)-safe transit exit $q = (x', y')$ in $\mathcal{O}(\frac{1}{\varepsilon}(|R[x, x']| + |\hat{B}|) \log n \log nm)$ time.*

3.4 The approximate optimization algorithm

We combine the algorithms of Sections 3.2 and 3.3 to obtain a $(1+\varepsilon)$-approximate decision algorithm, which we then turn into an algorithm that computes a $(1+\varepsilon)$-approximation of the geodesic Fréchet distance between R and B. Given $\delta \geq 0$ and $\varepsilon \in (0, 1]$, the approximate decision algorithm reports that $d_{\text{F}}(R, B) \leq (1+\varepsilon)\delta$ or $d_{\text{F}}(R, B) > \delta$.

Let δ_H be the geodesic Hausdorff distance between R and B. This distance, which is the maximum distance between a point on $R \cup B$ to its closest point on the other curve, is a natural lower bound on the geodesic Fréchet distance. If $\delta < \delta_H$, we therefore immediately return that $d_{\text{F}}(R, B) > \delta$. We can compute δ_H in $\mathcal{O}((n+m) \log nm)$ time [10].

Next suppose $\delta \geq \delta_H$. For our approximate decision algorithm, we first compute the partition $\mathcal{H}$ and the entrance and exit intervals of each of its slabs. By Lemma 5, this takes $\mathcal{O}((n+m) \log nm)$ time. We iterate over the $\mathcal{O}(m)$ slabs of $\mathcal{H}$ from bottom to top. Once we consider a slab $H \in \mathcal{H}$, we have computed an (ε, δ)-safe transit entrance $p_{\text{enter}} = (x, y)$ (except if H is the bottom slab, in which case we set $p_{\text{enter}} = (1, 1)$).

Let $\hat{B}$ be the subcurve corresponding to H. If $\hat{B}$ contains only near points, we compute a (ε, δ)-safe transit exit $q_{\text{exit}} = (x', y')$ of H in $\mathcal{O}(\log nm)$ time with the algorithm of Section 3.2. Otherwise, we use the algorithm of Section 3.3, which takes $\mathcal{O}(\frac{1}{\varepsilon}(|R[x, x']| + |\hat{B}|) \log n \log nm)$ time. Both algorithms require $\mathcal{O}(n+m)$ preprocessing time. Taken over all slabs in $\mathcal{H}$, the total complexity of the subcurves $\hat{B}$ is $\mathcal{O}(m)$. This gives the following result:

▶ **Theorem 15.** *For any $\varepsilon \in (0, 1]$, there is a $(1+\varepsilon)$-approximate decision algorithm running in $\mathcal{O}(\frac{1}{\varepsilon}(n+m) \log n \log nm)$ time.*

We turn the decision algorithm into an approximate optimization algorithm with a simple binary search. For this, we show that the geodesic Fréchet distance is not much greater than δ_H. This gives an accurate "guess" of the actual geodesic Fréchet distance.

▶ **Lemma 16.** $\delta_H \leq d_{\text{F}}(R, B) \leq 3\delta_H$.

For our approximate optimization algorithm, we perform binary search over the values $\delta_H, (1+\varepsilon)\delta_H, \ldots, 3\delta_H$ and run our approximate decision algorithm with each encountered parameter. This procedure yields a $(1+\varepsilon)^2$-approximation to the geodesic Fréchet distance. Since $(1+\varepsilon)^2 \leq 1 + 3\varepsilon$ for $\varepsilon \in (0, 1]$, scaling ε by a factor of $1/3$ gives our main result:

▶ **Theorem 1.** *For any $\varepsilon \in (0, 1]$, we can compute a $(1+\varepsilon)$-approximation to $d_{\text{F}}(R, B)$ in $\mathcal{O}(\frac{1}{\varepsilon}(n + m \log n) \log nm \log \frac{1}{\varepsilon})$ time.*

4 Separated one-dimensional curves and propagating reachability

In this section we consider the following problem: Let $\bar{R}$ and $\bar{B}$ be two one-dimensional curves with n and m vertices, respectively, where $\bar{R}$ lies left of the point 0 and $\bar{B}$ right of it. We are given a set $S \subseteq \mathcal{F}_\delta(\bar{R}, \bar{B})$ of $\mathcal{O}(n+m)$ "entrances," for some $\delta \geq 0$. Also, we are given a set $E \subseteq \mathcal{F}_\delta(\bar{R}, \bar{B})$ of $\mathcal{O}(n+m)$ "potential exits." We wish to compute the subset of potential exits that are δ-reachable from an entrance. We call this procedure *propagating reachability information* from S to E. We assume that the points in S and E correspond to pairs of vertices of $\bar{R}$ and $\bar{B}$. This assumption can be met by introducing $\mathcal{O}(n+m)$ vertices, which does not increase our asymptotic running times. Additionally, we may assume that all vertices of $\bar{R}$ and $\bar{B}$ have unique values, for example by a symbolic perturbation.

The problem of propagating reachability information has already been studied by Bringmann and Künnemann [4]. In case S lies on the left and bottom sides of the parameter space and E lies on the top and right sides, they give an $\mathcal{O}((n+m)\log nm)$ time algorithm. We are interested in a more general case however, where S and E may lie anywhere in the parameter space. We make heavy use of the concept of *prefix-minima* to develop an algorithm for our more general setting that has the same running time as the one described by Bringmann and Künnemann [4]. Furthermore, our algorithm is able to actually compute a Fréchet matching between $\bar{R}$ and $\bar{B}$ in linear time (see the full version of this paper), whereas Bringmann and Künnemann require near-linear time for only the decision version.

As mentioned above, we use prefix-minima extensively for our results in this section. Prefix-minima are those vertices that are closest to the separator 0 among those points before them on the curves. In the full version of this paper, we prove that a Fréchet matching exists that matches subcurves between consecutive prefix-minima to prefix-minima of the other curve, see Figure 7 for an illustration. We call these matchings *prefix-minima matchings*. This matching will end in a bichromatic closest pair of points, and so we can compose the matching with a symmetric matching for the reversed curves.

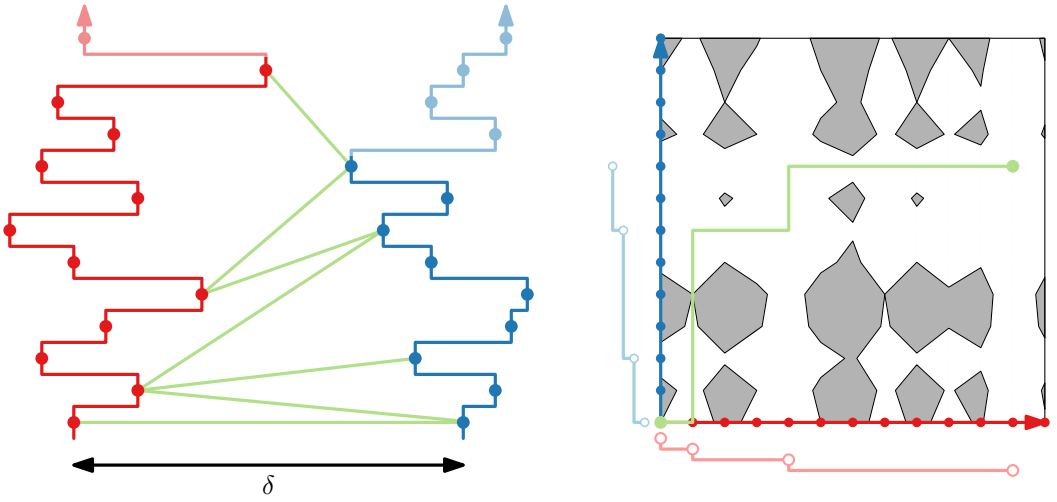

Figure 7 (left) A pair of separated, one-dimensional curves $\bar{R}$ and $\bar{B}$, drawn stretched vertically for clarity, together with a prefix-minima matching. (right) The path in $\mathcal{F}_\delta(\bar{R}, \bar{B})$ corresponding to the matching.

In Section 4.1 we introduce two geometric forests in $\mathcal{F}_\delta(\bar{R}, \bar{B})$, with leaves at S, that capture multiple prefix-minima matchings at once. It is based on *horizontal-greedy* and *vertical-greedy* matchings. We show that these forests have linear complexity and can be computed efficiently.

In Section 4.2 we do not only go forward from points in S, but also backwards from points in E using *suffix-minima*. Again we have horizontal-greedy and vertical-greedy versions. Intersections between the two prefix-minima forests and the two suffix minima forests show the existence of a δ-free path of the corresponding points in S and E, so the problem reduces to a bichromatic intersection algorithm.

4.1 Greedy paths in the free space

We wish to construct a set of canonical prefix-minima δ-matchings in the free space from which we can deduce which points in E are reachable. Naturally, we want to avoid constructing a path between every point in S and every point in E. Therefore, we investigate certain classes of prefix-minima δ-matchings that allows us to infer reachability information with just two paths per point in S and two paths per point in E. Furthermore, these paths have a combined $\mathcal{O}(n+m)$ description complexity.

We first introduce one of the greedy matchings and prove a useful property. A *horizontal-greedy δ-matching* π_{hor} is a prefix-minima δ-matching starting at a point $s = (i, j)$ that satisfies the following property: Let (i', j') be a point on π_{hor} where $\bar{R}(i')$ and $\bar{B}(j')$ are prefix-minima of $\bar{R}[i, n]$ and $\bar{B}[j, m]$. If there exists a prefix-minimum $\bar{R}(\hat{i})$ of $\bar{R}[i, n]$ after $\bar{R}(i')$, and the horizontal line segment $[i', \hat{i}] \times \{j'\}$ lies in $\mathcal{F}_\delta(\bar{R}, \bar{B})$, then either π_{hor} traverses this line segment, or π_{hor} terminates in (i', j').

For an entrance $s \in S$, let $\pi_{\text{hor}}(s)$ be the maximal horizontal-greedy δ-matching. See Figure 8 for an illustration. The path $\pi_{\text{hor}}(s)$ serves as a canonical prefix-minima δ-matching, in the sense that any point t that is reachable from s by a prefix-minima δ-matching is reachable from a point on $\pi_{\text{hor}}(s)$ through a single vertical segment:

▶ **Lemma 17.** *Let $s \in S$ and let t be a point that is reachable by a prefix-minima δ-matching from s. A point $\hat{t} \in \pi_{\text{hor}}(s)$ vertically below t exists for which the segment $\overline{\hat{t}t}$ lies in $\mathcal{F}_\delta(\bar{R}, \bar{B})$.*

A single path $\pi_{\text{hor}}(s)$ may have $\mathcal{O}(n+m)$ complexity. We would like to construct the paths for all entrances, but this would result in a combined complexity of $\mathcal{O}((n+m)^2)$. However, due to the definition of the paths, if two paths $\pi_{\text{hor}}(s)$ and $\pi_{\text{hor}}(s')$ have a point (i, j) in common, then the paths are identical from (i, j) onwards. Thus, rather than explicitly describing the paths, we instead describe their union. Specifically, the set $\bigcup_{s \in S} \pi_{\text{hor}}(s)$ forms a geometric forest $\mathcal{T}_{\text{hor}}(S)$ whose leaves are the points in S, see Figure 8. This forest has low complexity and can be constructed efficiently:

▶ **Lemma 18.** *The forest $\mathcal{T}_{\text{hor}}(S)$ has $\mathcal{O}(n+m)$ vertices.*

▶ **Lemma 19.** *We can construct a geometric graph for $\mathcal{T}_{\text{hor}}(S)$ in $\mathcal{O}((n+m)\log nm)$ time.*

4.2 Propagating reachability

Next we give an algorithm for propagating reachability information. For the algorithm, we consider three more δ-matchings that are symmetric in definition to the horizontal-greedy δ-matchings. The first is the maximal *vertical-greedy* δ-matching $\pi_{\text{ver}}(s)$, which, as the name suggests, is the maximal prefix-minima δ-matching starting at an entrance

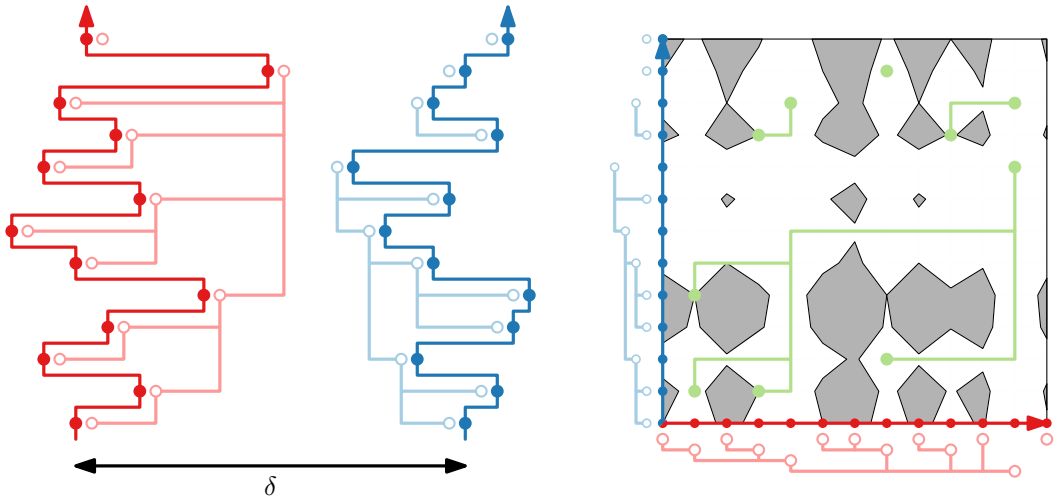

Figure 8 (left) For every vertex, its next prefix-minimum is depicted as its parent in the respective tree. (right) The horizontal-greedy δ-matchings. Paths move monotonically to the right and up.

$s \in S$ that prioritizes vertical movement over horizontal movement. The other two require a symmetric definition to prefix-minima, namely *suffix-minima*. These are the vertices closest to 0 compared to the suffix of the curve after the vertex. The maximal *reverse* horizontal- and vertical-greedy δ-matchings $\bar{\pi}_{\text{hor}}(t)$ and $\bar{\pi}_{\text{ver}}(t)$, starting at a potential exit $t \in E$, are symmetric in definition to the maximal horizontal- and vertical-greedy δ-matching, except that they move backwards, to the left and down, and their vertices correspond to suffix-minima of the curves (see Figure 9).

Consider a point $s = (i, j) \in S$ and let $t = (i', j') \in E$ be δ-reachable from s. Let $\bar{R}(i^*)$ and $\bar{B}(j^*)$ form a bichromatic closest pair of $\bar{R}[i, i']$ and $\bar{B}[j, j']$. Note that these points are unique, by our general position assumption. We prove in the full version of this paper that (i^*, j^*) is δ-reachable from s, and that t is δ-reachable from (i^*, j^*).

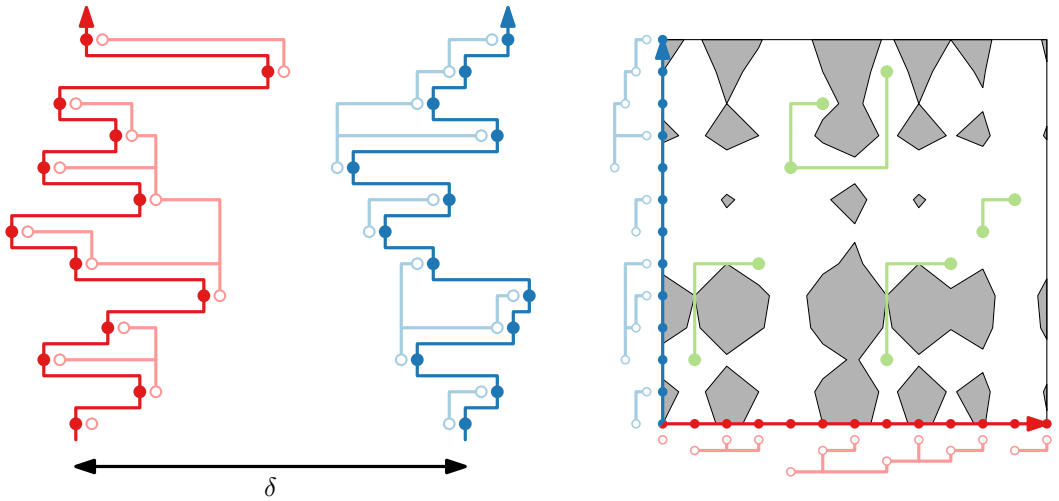

Figure 9 (left) For every vertex, its previous suffix-minimum is shown as its parent in the tree. (right) The reverse horizontal-greedy δ-matchings. Paths move monotonically to the left and down.

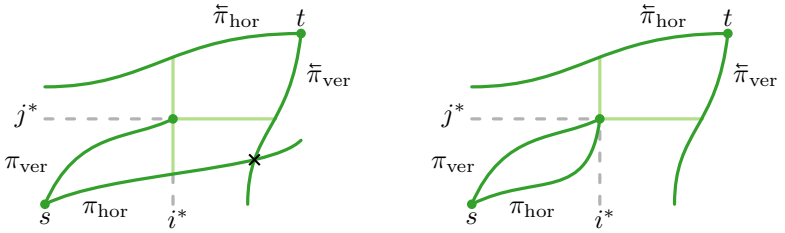

Figure 10 Two possible situations following from Lemmas 17 and 20. The paths starting at s or t are the four greedy matchings. The horizontal and vertical light green segments lie in $\mathcal{F}_\delta(R, B)$. On the right, the extensions of $\pi_{\text{hor}}(s)$ and $\pi_{\text{ver}}(s)$ respectively intersect $\overleftarrow{\pi}_{\text{ver}}(t)$ and $\overleftarrow{\pi}_{\text{hor}}(t)$.

From Lemma 17 we have that $\pi_{\text{hor}}(s)$ has points vertically below (i^*, j^*), and the vertical segment between $\pi_{\text{hor}}(s)$ and (i^*, j^*) lies in $\mathcal{F}_\delta(\bar{R}, \bar{B})$. We extend the property to somewhat predict the movement of $\pi_{\text{hor}}(s)$ near t:

▶ **Lemma 20.** *Either $\pi_{\text{hor}}(s)$ terminates in (i^*, j^*), or it contains a point vertically below t or horizontally left of t.*

Based on Lemmas 17 and 20 and their symmetric counterparts, $\pi_{\text{hor}}(s)$ and $\pi_{\text{ver}}(s)$ satisfy the properties below, and $\overleftarrow{\pi}_{\text{hor}}(t)$ and $\overleftarrow{\pi}_{\text{ver}}(t)$ satisfy symmetric properties, see Figure 10.

- $\pi_{\text{hor}}(s)$ has a point vertically below (i^*, j^*), and the vertical segment between $\pi_{\text{hor}}(s)$ and (i^*, j^*) lies in $\mathcal{F}_\delta(\bar{R}, \bar{B})$.
- $\pi_{\text{ver}}(s)$ has a point horizontally left of (i^*, j^*), and the horizontal segment between $\pi_{\text{ver}}(s)$ and (i^*, j^*) lies in $\mathcal{F}_\delta(\bar{R}, \bar{B})$.
- $\pi_{\text{hor}}(s)$ and $\pi_{\text{ver}}(s)$ both either terminate in (i^*, j^*), or contain a point vertically below t or horizontally left of t.

These properties mean that either $\pi_{\text{hor}}(s) \cup \pi_{\text{ver}}(s)$ intersects $\overleftarrow{\pi}_{\text{hor}}(t) \cup \overleftarrow{\pi}_{\text{ver}}(t)$, or the following extensions do: Let $\pi^+_{\text{hor}}(s)$ be the path obtained by extending $\pi_{\text{hor}}(s)$ with the maximum horizontal line segment in $\mathcal{F}_\delta(\bar{R}, \bar{B})$ whose left endpoint is the end of $\pi_{\text{hor}}(s)$. Define $\pi^+_{\text{ver}}(s)$ symmetrically, by extending $\pi_{\text{ver}}(s)$ with a vertical segment. Also define $\overleftarrow{\pi}^+_{\text{hor}}(s)$ and $\overleftarrow{\pi}^+_{\text{ver}}(s)$ analogously. By Lemma 17, $\pi^+_{\text{hor}}(s)$ or $\pi^+_{\text{ver}}(s)$ *must* intersect $\overleftarrow{\pi}^+_{\text{hor}}(t)$ or $\overleftarrow{\pi}^+_{\text{ver}}(t)$. Furthermore, if $\pi^+_{\text{hor}}(s)$ or $\pi^+_{\text{ver}}(s)$ intersects $\overleftarrow{\pi}^+_{\text{hor}}(t')$ or $\overleftarrow{\pi}^+_{\text{ver}}(t')$ for some potential exit $t' \in E$, then the bimonotonicity of the paths implies that t' is δ-reachable from s. Thus:

▶ **Lemma 21.** *A point $t \in E$ is δ-reachable from a point $s \in S$ if and only if $\pi^+_{\text{hor}}(s) \cup \pi^+_{\text{ver}}(s)$ intersects $\overleftarrow{\pi}^+_{\text{hor}}(t') \cup \overleftarrow{\pi}^+_{\text{ver}}(t')$.*

Recall that $\mathcal{T}_{\text{hor}}(S)$ represents all paths $\pi_{\text{hor}}(s)$. We augment $\mathcal{T}_{\text{hor}}(S)$ to represent all paths $\pi^+_{\text{hor}}(s)$. For this, we take each root vertex p and compute the maximal horizontal segment $\overline{pq} \subseteq \mathcal{F}_\delta(\bar{R}, \bar{B})$ that has p as its left endpoint. We compute this segment in $\mathcal{O}(\log n)$ time after $\mathcal{O}(n \log n)$ time preprocessing (for details, refer to the full version of this paper). We then add q as a vertex to $\mathcal{T}_{\text{hor}}(S)$, and add an edge from p to q.

Let $\mathcal{T}^+_{\text{hor}}(S)$ be the augmented graph. We define the graphs $\mathcal{T}^+_{\text{ver}}(S)$, $\overleftarrow{\mathcal{T}}^+_{\text{hor}}(E)$ and $\overleftarrow{\mathcal{T}}^+_{\text{ver}}(E)$ analogously. The four graphs have a combined complexity of $\mathcal{O}(n+m)$ and can be constructed in $\mathcal{O}((n+m)\log nm)$ time. Our algorithm computes the edges of $\overleftarrow{\mathcal{T}}^+_{\text{hor}}(E)$ and $\overleftarrow{\mathcal{T}}^+_{\text{ver}}(E)$ that intersect an edge of $\mathcal{T}^+_{\text{hor}}(S)$ or $\mathcal{T}^+_{\text{ver}}(S)$. We do so with a standard sweepline algorithm:

▶ **Lemma 22.** *Given sets of n "red" and m "blue," axis-aligned line segments in $\mathbb{R}^2$, we can report all segments that intersect a segment of the other color in $\mathcal{O}((n+m)\log nm)$ time.*

Suppose we have computed the set of edges $\mathcal{E}$ of $\overleftarrow{\mathcal{T}}^{+}_{\text{hor}}(E)$ and $\overleftarrow{\mathcal{T}}^{+}_{\text{ver}}(E)$ that intersect an edge of $\mathcal{T}^{+}_{\text{hor}}(S)$ or $\mathcal{T}^{+}_{\text{ver}}(S)$. We store $\mathcal{E}$ in a red-black tree, so that we can efficiently retrieve and remove edges from this set. Let $e \in \mathcal{E}$ and suppose e is an edge of $\overleftarrow{\mathcal{T}}^{+}_{\text{hor}}(E)$. Let μ be the top-right vertex of e. All potential exits of E that are stored in the subtree of μ are reachable from a point in S. We traverse the entire subtree of μ, deleting every edge we find from $\mathcal{E}$. Every point in E we find is marked as reachable. In this manner, we obtain:

▶ **Theorem 23.** *Let $\bar{R}$ and $\bar{B}$ be two separated one-dimensional curves with n and m vertices. Let $\delta \geq 0$, and let $S, E \subseteq \mathcal{F}_\delta(\bar{R}, \bar{B})$ be sets of $\mathcal{O}(n+m)$ points. We can compute the set of all points in E that are δ-reachable from points in S in $\mathcal{O}((n+m)\log nm)$ time.*

5 Conclusion

We studied computing the approximate geodesic Fréchet distance of two curves R and B that bound a simple polygon P, one clockwise and one counterclockwise, whose endpoints meet. Our algorithm is approximate, though the only approximate parts are for matching the far points and turning the decision algorithm into an optimization algorithm. Doing so exactly and in strongly subquadratic time remains an interesting open problem.

Our algorithm extends to the case where R and B do not cover the complete boundary of the polygon. In other words, the start and endpoints of R and B need not coincide. Geodesics between points on R and B must stay inside P. In this case, $k = |P|$ can be much greater than $n + m - 2$, which influences the preprocessing and query times of various data structures we use. The running time then becomes: $\mathcal{O}(k + \frac{1}{\varepsilon}(n + m\log n)\log k \log \frac{1}{\varepsilon})$.

Abstract

A non-trivial minimum cut (NMC) sparsifier is a multigraph $\hat{G}$ that preserves all non-trivial minimum cuts of a given undirected graph G. We introduce a flexible data structure for fully dynamic graphs that can efficiently provide an NMC sparsifier upon request at any point during the sequence of updates. We employ simple dynamic forest data structures to achieve a fast from-scratch construction of the sparsifier at query time. Based on the strength of the adversary and desired type of time bounds, the data structure comes with different guarantees. Specifically, let G be a fully dynamic simple graph with n vertices and minimum degree δ. Then our data structure supports an insertion/deletion of an edge to/from G in $n^{o(1)}$ worst-case time. Furthermore, upon request, it can return w.h.p. an NMC sparsifier of G that has $O(n/\delta)$ vertices and $O(n)$ edges, in $\hat{O}(n)$ time. The probabilistic guarantees hold against an adaptive adversary. Alternatively, the update and query times can be improved to $\tilde{O}(1)$ and $\tilde{O}(n)$ respectively, if amortized-time guarantees are sufficient, or if the adversary is oblivious. Throughout the paper, we use $\tilde{O}$ to hide polylogarithmic factors and $\hat{O}$ to hide subpolynomial (i.e., $n^{o(1)}$) factors.

We discuss two applications of our new data structure. First, it can be used to efficiently report a cactus representation of all minimum cuts of a fully dynamic simple graph. Building this cactus for the NMC sparsifier instead of the original graph allows for a construction time that is sublinear in the number of edges. Against an adaptive adversary, we can with high probability output the cactus representation in worst-case $\hat{O}(n)$ time. Second, our data structure allows us to efficiently compute the maximal k-edge-connected subgraphs of undirected simple graphs, by repeatedly applying a minimum cut algorithm on the NMC sparsifier. Specifically, we can compute with high probability the maximal k-edge-connected subgraphs of a simple graph with n vertices and m edges in $\tilde{O}(m + n^2/k)$ time. This improves the best known time bounds for $k = \Omega(n^{1/8})$ and naturally extends to the case of fully dynamic graphs.

1 Introduction

Graph sparsification is an algorithmic technique that replaces an input graph G by another graph $\hat{G}$, which has fewer edges and/or vertices than G, but preserves (or approximately preserves) a desired graph property. Specifically, for connectivity-based and flow-based problems, a variety of static sparsifiers exist, that approximately maintain cut- or flow-values in G [2, 3, 4, 8, 20, 26, 27].

Let n denote the number of vertices, m the number of edges, and δ the minimum degree of the input graph. In an undirected simple graph it is possible to reduce the number of vertices to $O(n/\delta)$ and the number of edges to $O(n)$ both in randomized and deterministic time $\tilde{O}(m)$ while preserving the value of all non-trivial minimum cuts *exactly* [10, 19, 21]. A minimum cut is considered *trivial* if one of its sides consists of a single vertex and we call the resulting multigraph a *non-trivial minimum cut sparsifier (NMC sparsifier)*.

Most sparsification algorithms assume a static graph. Maintaining an NMC sparsifier in a fully dynamic setting, where a sequence of edge insertions and deletions can be arbitrarily interleaved with requests to output the NMC sparsifier, was only recently studied: Goranci, Henzinger, Nanongkai, Saranurak, Thorup, and Wulff-Nilsen [11] show how to maintain an NMC sparsifier in a fully dynamic graph w.h.p. in $\tilde{O}(n)$ worst-case update and query time (as a consequence of Theorem 3.7 in [11]), under the assumption of an oblivious adversary. Additionally, Theorem 4.5 in [11] gives a deterministic algorithm that outputs an NMC sparsifier of size $\tilde{O}(m/\delta)$ in $\tilde{O}(m/\delta)$ worst-case query time with $\tilde{O}(\delta^3)$ amortized update time.

1.1 Our Results

In this paper, we present the first data structure for providing an NMC sparsifier of a fully dynamic graph that supports sublinear *worst-case* update and query time and works against an *adaptive* adversary. As a first application, we give an improved fully dynamic algorithm that outputs a cactus representation of *all* minimum cuts of the current graph upon request. Additionally, we use our data structure to compute the maximal k-edge connected subgraphs of an undirected simple graph with an improvement in running time for large values of k.

In more detail, we provide a data structure for a fully dynamic graph that can be updated in *worst-case* time $\hat{O}(1)$ and that allows (at any point during the sequence of edge updates) to construct an NMC sparsifier in worst-case time $\hat{O}(n)$. The probabilistic guarantees work against an *adaptive* adversary. If the update time is relaxed to be *amortized* or if the adversary is *oblivious*, the update time can be improved to $\tilde{O}(1)$ and the query time to $\tilde{O}(n)$.

Our basic approach is to maintain suitable data structures in a dynamically changing graph that allow the execution of the *static* NMC sparsifier algorithm based on random 2-out contractions proposed by Ghaffari, Nowicki, and Thorup [10] in time $\hat{O}(n)$ instead of $\tilde{O}(m)$. Our main insight is that this speedup can be achieved by maintaining

1. a dynamic spanning forest data structure (DSF) of the input graph G and
2. a dynamic cut set data structure (DCS), where the user determines which edges belong to a (not necessarily spanning) forest F of G, and, given a vertex v, the data structure returns an edge that leaves the tree of F that contains v (if it exists).

We show that these two data structures suffice to construct an NMC sparsifier of the current graph in the desired time bound. Put differently, we can avoid processing all edges of G in order to build the NMC sparsifier, and only spend time that is roughly proportional to the size of the sparsifier.

Note that the NMC sparsifier is computed from scratch every time it is requested and no information of a previously computed sparsifier is maintained throughout the dynamic updates of the underlying graph. This ensures the probabilistic guarantees hold against an adaptive adversary if the guarantees of the chosen DSF and DCS data structures do.

Our main result is the following theorem.

▶ **Theorem 1.** *Let G be a fully dynamic simple graph that currently has n nodes and minimum degree $\delta > 0$. There is a data structure that outputs an NMC sparsifier of G that has $O(n/\delta)$ vertices and $O(n)$ edges w.h.p. upon request. Each update and query takes either*

1. *worst-case $\hat{O}(1)$ and $\hat{O}(n)$ time respectively w.h.p., assuming an* adaptive *adversary, or*
2. *amortized $\tilde{O}(1)$ and $\tilde{O}(n)$ time respectively w.h.p., assuming an* adaptive *adversary, or*
3. *worst-case $\tilde{O}(1)$ and $\tilde{O}(n)$ time respectively w.h.p., assuming an* oblivious *adversary.*

Recall that $\tilde{O}$ hides polylogarithmic factors and $\hat{O}$ hides subpolynomial (i.e., $n^{o(1)}$) factors. The three cases of Theorem 1 result from using different data structures to realize our required DSF and DCS data structures. We show that with minimal overhead both data structures can be reduced to a dynamic minimum spanning forest data structure, for which many constructions have been proposed in the literature. For Case 1, we make use of the fully dynamic minimum spanning forest algorithm of Chuzhoy, Gao, Li, Nanongkai, Peng, and Saranurak [6] – the only spanning forest data structure known so far that can provide worst-case time guarantees against an adaptive adversary. Case 2 is the result of substituting the deterministic data structure of Holm, de Lichtenberg, and Thorup [15] and case 3 results from using the randomized data structure of Kapron, King, and Mountjoy [16] instead.

As a first application we can efficiently provide a cactus representation of the minimum cuts of a simple graph upon request in the fully dynamic setting. The cactus representation of all minimum cuts of a static graph is known to be computable in near linear time $\tilde{O}(m)$ using randomized algorithms [12, 18, 21]. With deterministic algorithms, the best known time bound is $m^{1+o(1)}$ [12]. We are not aware of any previous work on providing the cactus for fully dynamic graphs in sublinear time per query. Specifically, we show the following:

▶ **Theorem 2.** *Let G be a fully dynamic simple graph with n vertices. There is a data structure that w.h.p. reports a cactus representation of all minimum cuts of G. Each update and query takes either*

1. *worst-case $\hat{O}(1)$ and $\hat{O}(n)$ time respectively w.h.p., assuming an* adaptive *adversary, or*
2. *amortized $\tilde{O}(1)$ and $\tilde{O}(n)$ time respectively w.h.p., assuming an* adaptive *adversary, or*
3. *worst-case $\tilde{O}(1)$ and $\tilde{O}(n)$ time respectively w.h.p., assuming an* oblivious *adversary.*

Theorem 2 provides an improvement over one of the main technical components in [11]. Specifically, Goranci et al. [11], provide a method to efficiently maintain an NMC sparsifier of a dynamic simple graph, based on the 2-out contractions of Ghaffari et al. [10]. However, their main technical result (Theorem 3.7 in [11]) has several drawbacks. First, it needs to know an estimated upper bound $\hat{\delta}$ on the minimum degree of any graph that occurs during the sequence of updates of G. Second, they try to *maintain* the sparsifier during the updates. This results in an update time $\tilde{O}(\hat{\delta})$, and forces them to "hide" their sparsifier from an adversary, i.e., they can expose their sparsifier only if they work against an oblivious adversary. Thus, to make their minimum cut algorithm work against an adaptive adversary, they return only the *value* of the minimum cut. In contrast, our algorithm computes a sparsifier from scratch upon request, and can therefore provide a cactus representation of *all* minimum cuts, even against an adaptive adversary.

Notice that we provide a different trade-off in reporting the minimum cut: We have an update time of $\hat{O}(1)$ and a query time of $\hat{O}(n)$, whereas Theorem 1.1 of Goranci et al. [11] has an update time of $\tilde{O}(n)$ and query time $O(1)$. This trade-off is never worse (modulo

Table 1 Best known time bounds for computing the maximal k-edge-connected subgraphs in undirected graphs in the static setting. The $\tilde{O}$ expression hides polylogarithmic factors.

Algorithm	Time	Type	Range of k

Saranurak and Yuan [25]	$O(m + kn^{1+o(1)})$	Det.	$k = \log^{o(1)} n$
Nalam and Saranurak [24]	$\tilde{O}(m \cdot \min\{m^{3/4}, n^{4/5}\})$	Monte Carlo Rnd.	$k \in \mathbb{N}$
This paper	$\tilde{O}(m + n^2/k)$	Monte Carlo Rnd.	$k \in \mathbb{N}$

the subpolynomial factors) if one caches the result of a query and answers queries from the cache if the graph did not change. Furthermore, upon request, we can provide a minimum cut explicitly, and not just its value.

As a second application of our main result, we improve the time bounds for computing the (vertex sets of the) maximal k-edge-connected subgraphs in a simple undirected graph. Specifically, we have the following:

▶ **Theorem 3.** *Let G be a simple graph with n vertices and m edges, and let k be a positive integer. We can compute the maximal k-edge-connected subgraphs of G w.h.p. in $\tilde{O}(m+n^2/k)$ time w.h.p.*

For comparison, Table 1 gives an overview of the best known algorithms for computing the maximal k-edge-connected subgraphs in undirected graphs. Thorup [28] does not deal with the computation of the maximal k-edge-connected subgraphs, but the result is a consequence of his fully dynamic minimum cut algorithm as observed in [9]. The algorithm in [24] is the only one that holds for weighted graphs (with integer weights), and it has no dependency on k in the time bound. Notice that our algorithm improves over all prior results for $k = \Omega(n^{1/8})$ and $m = \Omega(n^{8/7})$.

With a reduction to simple graphs, this implies the following bounds for computing the maximal k-edge-connected subgraphs of multigraphs.

▶ **Corollary 4.** *Let G be a multigraph with n vertices and m edges, and let k be a positive integer. We can compute the maximal k-edge-connected subgraphs of G w.h.p. in $\tilde{O}(m + k^2n + kn^2)$ time w.h.p.*

Notice that Corollary 4 provides an improvement compared to the other algorithms in Table 1, depending on k and the density of the graph. For example, if δ and ϵ are two parameters satisfying $1/4 \leq \delta \leq 1$, $16/15 \leq \epsilon \leq 2$ and $\delta \leq \epsilon - 6/5$, then we have an improvement in the regime where $m = \Theta(n^\epsilon)$ and $k = \Theta(n^\delta)$ against all previous algorithms in Table 1 that work for multigraphs (i.e., except for Henzinger et al. [13], which works only for simple graphs).

Finally, the method that we use in Theorem 3 for computing the maximal k-edge-connected subgraphs in static graphs extends to the case of dynamic graphs.

▶ **Theorem 5.** *Let G be a fully dynamic simple graph with n vertices. There is a data structure that can provide the maximal k-edge-connected subgraphs of G at any point in time, with high probability, for any integer $k < n$. Each update and query takes either*

1. *worst-case* $\hat{O}(1)$ *and* $\hat{O}(n^2/k)$ *time respectively w.h.p, assuming an* adaptive *adversary,*
2. *amortized* $\tilde{O}(1)$ *and* $\tilde{O}(n^2/k)$ *time respectively w.h.p, assuming an* adaptive *adversary, or*
3. *worst-case* $\tilde{O}(1)$ *and* $\tilde{O}(n^2/k)$ *time respectively w.h.p, assuming an* oblivious *adversary.*

The results by Aamand et al. [1] and Saranurak and Yuan [25] provide algorithms for maintaining the maximal k-edge-connected subgraphs in *decremental* graphs. Georgiadis et al. [9] provide a fully dynamic algorithm that given two vertices determines whether they belong to the same k-edge connected subgraph in time $O(1)$. Their worst-case update time is $\tilde{O}(T(n,k))$, where $T(n,k)$ is the running time of any algorithm for static graphs that is used internally by the algorithm (see values in the time column of Table 1 with the additive term m removed). Thus, as in the case for dynamic minimum cut, our algorithm provides a different trade-off, with fast updates and slower query time. Notice that Theorem 5 provides an improvement over [9] (for any function $T(n,k)$ corresponding to an algorithm from Table 1) when k is sufficiently large (i.e., when $k = \Omega(n^{1/8})$).

Due to the space constraints, more details on related work, all omitted proofs, and some further details can be found in the full version of this paper.

2 Preliminaries

In this paper, we consider only undirected, unweighted graphs. A graph is called *simple* if it contains no parallel edges, conversely it is a multigraph if it does. We use common graph terminology and notation that can be found e.g. in [23]. Let $G = (V, E)$ be a graph. Throughout, we use n and m to denote the number of vertices and edges of G, respectively. We use $V(G)$ and $E(G)$ to denote the set of vertices and edges, respectively, of G; that is, $V = V(G)$ and $E = E(G)$. A *subgraph* of G is a graph of the form (V', E'), where $V' \subseteq V$ and $E' \subseteq E$. A *spanning* subgraph of G is a subgraph of the form (V, E') that contains at least one incident edge to every vertex of G that has degree > 0. If X is a subset of vertices of G, we let $G[X]$ denote the induced subgraph of G on the vertex set X. Thus, $V(G[X]) := X$, and the edge set of $G[X]$ is $\{e \in E \mid \text{ both endpoints of } e \text{ are in } X\}$. If E' is a set of edges of G, we let $G[E'] := (V, E')$.

A connected component of G is a maximal connected subgraph of G. A set of edges of G whose removal increases the number of connected components of G is called a *cut* of G. The size $|C|$ is called the *value* of the cut. A cut C with minimum value in a connected graph G is called a *minimum cut* of G. In this case, $G \setminus C = (V, E \setminus C)$ consists of two connected components. If one of them is a single vertex, then C is called a *trivial minimum cut*.

An *NMC sparsifier* of G is a multigraph H on the same vertex set as G that preserves all non-trivial minimum cuts of G, in the sense that the number of edges leaving any non-trivial minimum cut is the same in H as it is in G.

Contractions of graphs. Let $E' \subseteq E$ be a set of edges of a graph $G = (V, E)$, and let $C_1, \ldots, C_t$ be the connected components of the graph $G' = (V, E')$. The *contraction* $\hat{G}$ induced by E' is the graph derived from G by contracting each C_i, for $i \in \{1, \ldots, t\}$, into a single node. We ignore possible self-loops, but we maintain distinct edges of G that have their endpoints in different connected components of G'. Hence, $\hat{G}$ may be a multigraph even though G is a simple graph. Furthermore, there is a natural injective correspondence from the edges of $\hat{G}$ to the edges of G. We say that an edge of G is *preserved* in $\hat{G}$ if its endpoints are in different connected components of G' (it corresponds to an edge of $\hat{G}$).

A *random 2-out contraction* of G is a contraction of G that is induced by sampling from every vertex v of G two edges incident to it (independently, with repetition allowed) and setting E' to be the edges sampled in this way. Thus, E' satisfies $|E'| \leq 2|V(G)|$. The importance of considering 2-out contractions is demonstrated in the following theorem of Ghaffari et al. [10].

▶ **Theorem 6** (rephrased weaker version of Theorem 2.3 in [10]). *A random 2-out contraction of a simple graph G with n vertices and minimum degree δ has $O(n/\delta)$ vertices, with high probability, and preserves any fixed non-trivial minimum cut of G with constant probability.*

Preserving small cuts via forest decompositions. Nagamochi and Ibaraki [22] have shown the existence of a sparse subgraph that maintains all cuts of the original graph with value up to k, where k is an integer ≥ 1. Specifically, given a graph $G = (V, E)$ with n vertices and m edges, there is a spanning subgraph $H = (V, E')$ of G with $|E'| \leq k(n-1)$ such that every set of edges $C \subseteq E$ with $|C| < k$ is a cut of G if and only if C is a cut of H. A graph H with this property is given by a *k-forest decomposition* of G, which is defined as follows. First, we let F_1 be a spanning forest of G. Then, for every $i \in \{2, \ldots, k\}$, we recursively let F_i be a spanning forest of $G \setminus (F_1 \cup \cdots \cup F_{i-1})$. Then we simply take the union of the forests $H = F_1 \cup \cdots \cup F_k$. A naive implementation of this idea takes time $O(k(n+m))$. However, this construction can be completed in linear time by computing a maximum adjacency ordering of G [23].

Maximal k-edge-connected subgraphs. Given a graph G and a positive integer k, a *maximal k-edge-connected subgraph* of G is a subgraph of the form $G[S]$, where: (1) $G[S]$ is connected, (2) the minimum cuts of $G[S]$ have value at least k, and (3) S is maximal with this property. The first two properties can be summarized by saying that $G[S]$ is k-edge-connected, which equivalently means that we have to remove at least k edges in order to disconnect $G[S]$. It is easy to see that the vertex sets $S_1, \ldots, S_t$ that induce the maximal k-edge-connected subgraphs of G form a partition of V.

A note on probabilistic guarantees. Throughout the paper we use the abbreviation w.h.p. (with high probability) to mean a probability of success at least $1 - O(\frac{1}{n^c})$, where c is a fixed constant chosen by the user and n denotes the number of vertices of the graph. The choice of c only affects the values of two parameters q and r that are used internally by the algorithm of Ghaffari et al. [10], which our result is based on. Note that the specification "w.h.p" may be applied either to the running time or to the correctness (or to both).

3 Outline of Our Approach

Our main contribution is a new data structure that outputs an NMC sparsifier of a fully dynamic graph upon request. The idea is to compute the NMC sparsifier from scratch every time it is requested. For this we adapt the construction by Ghaffari et al. [10] to compute a random 2-out contraction of the graph at the current time. We can achieve a speedup of the construction time by maintaining just two data structures for dynamic forests throughout the updates of the graph.

3.1 Updates: Data Structures for Dynamic Forests

As our fully dynamic graph G changes, we rely on efficient data structures for the following two problems, which we call the "dynamic spanning forest" problem (DSF) and the "dynamic cutset" problem (DCS). In DSF, the goal is to maintain a spanning forest F of a dynamic graph G. Specifically, the DSF data structure supports the following operations.

- `insert`(e). Inserts a new edge e to G. If e has endpoints in different trees of F, then it is automatically included in F, and this event is reported to the user.
- `delete`(e). Deletes the edge e from G. If e was a tree edge in F, then it is also removed from F, and a new replacement edge is selected among the remaining edges of G in order to reconnect the trees of F that got disconnected. If a replacement edge is found, it automatically becomes a tree edge in F, and it is output to the user.

The DCS problem is a more demanding variant of DSF. Here the goal is to maintain a (not necessarily spanning) forest F of the graph, but we must also be able to provide an edge that connects two different trees if needed. Specifically, the DCS data structure supports the following operations.

- $\texttt{insert}_G(e)$. Inserts a new edge e to G.
- $\texttt{insert}_F(e)$. Inserts an edge e to F, if e is an edge of G that has endpoints in different trees of F. Otherwise, F stays the same.
- $\texttt{delete}_G(e)$. Deletes the edge e from G. If e is a tree edge in F, it is also deleted from F.
- $\texttt{delete}_F(e)$. Deletes the edge e from F (or reports that e is not an edge of F).
- `find_cutedge`(v). Returns an edge of G (if it exists) that has one endpoint in the tree of F that contains v, and the other endpoint outside of that tree.

The main difference between DSF and DCS is that in DCS the user has absolute control over the edges of the forest F. In both problems, the most challenging part is finding an edge that connects two distinct trees of F. In DCS this becomes more difficult because the data structure must work with the forest that the user has created, whereas in DSF the spanning forest is managed internally by the data structure. Both of these problems can be solved by reducing them to the dynamic minimum spanning forest (MSF) problem, as shown in the following Lemma 7.

▶ **Lemma 7.** *The DSF problem can be reduced to the DCS problem within the same time bounds. The DCS problem can be reduced to dynamic MSF with an additive $O(\log n)$ overhead for every operation.*

To realize these two data structures deterministically with worst-case time guarantees, the only available solution at the moment is to make use of the reduction to the dynamic MSF problem given in Lemma 7 and then employ the dynamic MSF data structure of Chuzhoy et. al. [6], which supports every update operation in worst-case $\hat{O}(1)$ time. Alternatively, one can solve both DSF and DCS deterministically with *amortized* time guarantees using the data structures of Holm et. al. [15]. In that case, every update for DSF can be performed in amortized $O(\log^2 n)$ time, and every operation for DCS can be performed in amortized $O(\log^4 n)$ time, by reduction to dynamic MSF. If one is willing to allow randomness, one can solve both DSF and DCS in worst-case polylogarithmic time per operation, under the assumption of an oblivious adversary with the data structure by Kapron et al. [16].

These different choices for realizing the dynamic MSF data structure give the following lemma.

▶ **Lemma 8.** *The DSF and DCS data structures can be realized in either*
1. *deterministic worst-case* $\hat{O}(1)$ *update time, or*
2. *deterministic amortized* $\tilde{O}(1)$ *update time, or*
3. *worst-case* $\tilde{O}(1)$ *update time, assuming an* oblivious *adversary.*

To handle the updates on G, any insertion or deletion of an edge is also applied in both the DSF and the DCS data structure. In particular, for DCS we only use the $\texttt{insert}_G$ and $\texttt{delete}_G$ operations and keep its forest empty. At query time, we will build the DCS forest from scratch and then fully delete it again. In order for this to be efficient, DCS needs to have already processed all edges of G.

3.2 Queries: Efficiently Contracting a Dynamic Graph

The NMC sparsifier that we output for each query is a random 2-out contraction of the graph at the current time. For this construction, we use our maintained forest data structures and build upon the algorithm of Ghaffari et al. [10], who prove the following.

▶ **Theorem 9** (Weaker version of Theorem 2.1 of Ghaffari et al. [10])**.** *Let G be a simple graph with n vertices, m edges, and minimum degree δ. In $O(m \log n)$ time we can create a contraction $\hat{G}$ of G that has $O(n/\delta)$ vertices and $O(n)$ edges w.h.p., and preserves all non-trivial minimum cuts of G w.h.p.*

Note that in particular, the contracted graph $\hat{G}$ created by the above theorem is an NMC sparsifier, as desired. We first sketch the algorithm that yields Theorem 9 as described by Ghaffari et al. [10]. Then we outline how we can adapt and improve this construction for dynamic graphs, making use of the DSF and DCS data structures. Specifically, to answer a query we show that we can build $\hat{G}$ in time proportional to the size of $\hat{G}$, which may be much lower than $O(m \log n)$. The details and a formal analysis can be found in Section 4.

Random 2-out Contractions of Static Graphs

Ghaffari et al.'s algorithm [10] works as follows (see also Algorithm 1). First, it creates a collection of $q = O(\log n)$ random 2-out contractions $G_1, \ldots, G_q$ of G, where every G_i is created with independent random variables. Now, according to Theorem 2.4 in [10], each G_i for $i \in \{1, \ldots, q\}$, has $O(n/\delta)$ vertices w.h.p., and preserves any fixed non-trivial minimum cut of G with constant probability.

In a second step, they compute a $(\delta + 1)$-forest decomposition $\hat{G}_i$ of G_i, for every $i \in \{1, \ldots, q\}$, in order to ensure that $\hat{G}_i$ has $O(\delta \cdot (n/\delta)) = O(n)$ edges w.h.p. Because G has minimum degree δ, every non-trivial minimum cut has value at most δ. Hence, each $\hat{G}_i$ still maintains every fixed non-trivial minimum cut with constant probability.

Finally, they select a subset of edges $E_{\text{con}} \subseteq E(G)$ to contract by a careful *"voting"* process. Specifically, for every edge e of G, they check if it is an edge of at least r graphs from $\hat{G}_1, \ldots, \hat{G}_q$, where r is a carefully chosen parameter. If e does not satisfy this property, then it is included in E_{con}, the set of edges to be contracted. In the end, $\hat{G}$ is given by contracting all edges from E_{con}.

An Improved Construction using Dynamic Forests

We now give an overview of our algorithm for efficiently constructing the NMC sparsifier $\hat{G}$. It crucially relies on having the DSF and DCS data structures initialized to contain the edges of the current graph G. For a fully dynamic graph, this is naturally ensured at query

Algorithm 1 Construction of the contracted graph $\hat{G}$ in Theorem 9.

```
input: a simple graph G in adjacency list representation
choose parameters q, r = Θ(log n) according to [10]
compute the minimum degree δ of G
for i ← 1 to q do
    construct a 2-out contraction G_i of G
foreach i ∈ {1, ..., q} do
    construct a (δ + 1)-forest decomposition Ĝ_i of G_i
let E_con ← ∅ // a set of edges of G to contract
foreach edge e of G do
    if e is preserved in less than r graphs from Ĝ_1, ..., Ĝ_q then
        E_con ← E_con ∪ {e}
return the graph obtained from G by contracting the edges in E_con
```

time by maintaining the two forest data structures throughout the updates, as described in Section 3.1. Since the goal is to output a graph $\hat{G}$ with $O(n/\delta)$ vertices and $O(n)$ edges w.h.p., we aim for an algorithm that takes roughly $O(n)$ time. The process is broken up into three parts.

Part 1. First, we compute the 2-out contractions $G_1, \ldots, G_q$ for $q = O(\log n)$. Each G_i can be computed by sampling, for every vertex v of G, two random edges incident to v (independently, with repetition allowed). Since the graph G is dynamic, the adjacency lists of the vertices also change dynamically, and therefore this is not an entirely trivial problem. However, in the full version of this paper we provide an efficient solution that relies on elementary data structures. Specifically, we can support every graph update in worst-case constant time, and every query for a random incident edge to a vertex in worst-case $\tilde{O}(1)$ time. Notice that each G_i, for $i \in \{1, \ldots, q\}$, is given by contracting a set E_i of $O(n)$ edges of G.

Part 2. Next, we separately compute a $(\delta + 1)$-forest decomposition $\hat{G}_i$ of G_i, for every $i \in \{1, \ldots, q\}$. Each $\hat{G}_i$ is computed by only accessing the edges of E_i plus the edges of the output (which are $O(n)$ w.h.p.). For this, we rely on the DCS data structure. Since in DCS we have complete control over the maintained forest F, we can construct it in such a way, that every connected component of $G[E_i]$ induces a subtree of F. Notice that the connected components of $G[E_i]$ correspond to the vertices of G_i. This process of modifying F takes $O(|E_i|) = O(n)$ update operations on the DCS data structure. Then, we have established the property that the tree edges that connect vertices of different connected components of $G[E_i]$ correspond to a spanning tree of G_i. Afterwards, we just repeatedly remove the spanning tree edges, and find replacements using the DCS data structure. These replacements constitute a new spanning forest of G_i. Thus, we just have to repeat this process $\delta + 1$ times to construct the desired $(\delta + 1)$-forest decomposition. Note that every graph $\hat{G}_i$ is constructed in time roughly proportional to its size (which is $O(n)$ w.h.p.). Any overhead comes from the use of the DCS data structure.

Part 3. Finally, we construct the graph $\hat{G}$ by contracting the edges $E_{<r}$ of G that appear in less than r graphs from $\hat{G}_1, \ldots, \hat{G}_q$. From Ghaffari et al. ([10], Theorem 2.4) it follows that $|E \setminus E_{<r}| = |E_{\geq r}| = O(qn) = O(n \log n)$. In the following we provide an algorithm for constructing $\hat{G}$ with only $O(n + |E_{\geq r}|)$ operations of the DSF data structure.

We now rely on the spanning forest F of G that is maintained by the DSF data structure. We pick the edges of F one by one, and check for every edge whether it is contained in $E_{<r}$ (it is easy to check for membership in $E_{<r}$ in $O(\log n)$ time). If it is not contained in $E_{<r}$, then we store it as a *candidate edge*, i.e., an edge that possibly is in $\hat{G}$. In this case, we also remove it from F, and the DSF data structure will attempt to fix the spanning forest by finding a replacement edge. Otherwise, if $e \in E_{<r}$, then we "fix" it in F, and do not process it again.

In the end all "fixed" edges of F form a spanning forest of the connected components of $G[E_{<r}]$. Note that the algorithm makes continuous progress: in each step it either identifies an edge of $E_{\geq r}$, or it "fixes" an edge of F (which can happen at most $n-1$ times). Thus, it performs $O(n + |E_{\geq r}|) = \tilde{O}(n)$ DSF operations. Since we have arrived at a spanning forest of $G[E_{<r}]$, we can build $\hat{G}$ by contracting the candidate edges stored during this process.

4 Analysis

Our main technical tools are Propositions 10 and 11. Proposition 10 allows us to create a forest decomposition of a contracted graph without accessing all the edges of the original graph, but roughly only those that are included in the output, and those that we had to contract in order to get the contracted graph. Proposition 11 has a somewhat reverse guarantee: it allows us to create a contracted graph by accessing only the edges that are preserved during the contraction (plus only a small number of additional edges).

In this section we assume that G is a fully dynamic graph that currently has n vertices. We also assume that we have maintained a DCS and a DSF data structure on G, which support every operation in U_{CS} and U_{SF} time, respectively (cf. Section 3.1). The proofs of all theorems and propositions in this section can be found in the full version of this paper.

4.1 A k-Forest-Decomposition of the Contraction

Given a set of edges to contract, the following proposition shows how to compute a k forest decomposition of the induced contracted graph. Crucially, the contracted graph H does not have to be given explicitly, but it is sufficient to know only a set of edges whose contraction yields H. Thus, the running time of the construction is independent of the number of edges of H. The whole procedure is shown in Algorithm 2.

▶ **Proposition 10.** *Let H be a contraction of G that results from contracting a given set E_{con} of edges in G. Let further k be a positive integer and n_H be the number of vertices in H. Then we can construct a k-forest decomposition of H in time $O\big((n + kn_H) \cdot U_{\text{CS}} + |E_{con}| \log n\big)$.*

Note that the number of DCS operations depends only on (1) the number n of vertices of G, (2) the number n_H of vertices of H, and (3) the number k of forests that we want to build.

4.2 Building the Contracted Graph

A contracted graph can naturally be computed from its defining set of contraction edges E_{con} in time proportional to the size of this set $|E_{\text{con}}|$. Recall that in our case E_{con} is the result of the "voting" procedure across all generated δ-forest decompositions (cf. Section 3.2), which is rather expensive to compute. We hence use a different construction that does not need to know E_{con} explicitly. Instead, it relies on an efficient oracle to certify that a given edge is not contained in E_{con}.

Algorithm 2 Compute a k-forest decomposition of the graph that is formed by contracting a set of edges E' of G.

```
let F be the empty DCS forest
foreach edge e ∈ E' do
    if the endpoints of e belong to different trees of F then
        DCS.insert_F(e)
let V be a set that consists of one vertex from every tree of F
set S ← ∅
for i ← 1 to k do
    set L ← ∅ // L will contain the edges of the current spanning forest
    foreach v ∈ V do
        let e ← DCS.find_cutedge(v)
        while e ≠ ⊥ do
            DCS.insert_F(e), and append e to L
            e ← DCS.find_cutedge(v)
    foreach e ∈ L do
        DCS.delete_G(e), and append e to S
use DCS.delete_F to remove all the edges from F
foreach e ∈ S do
    DCS.insert_G(e) // restore DCS to its original state
return S
```

▶ **Proposition 11.** *Let H be a contraction of G that results from contracting a set E_{con} of edges in G and let E_{pre} be the set of edges of G that are preserved in H. Suppose that there is a set of edges E_{check} with $E_{pre} \subseteq E_{check}$ and $E_{check} \cap E_{con} = \emptyset$, for which we can check membership in time μ. Then we can construct H in time $O(n\mu + |E_{check}| \cdot (U_{\mathrm{SF}} + \mu))$.*

Note that the number of DSF operations is proportional to the number of edges in E_{check} (the set E_{con} is not required as input to the algorithm). Thus, this algorithm becomes more efficient if only few edges are contained in $E(G) \setminus E_{\mathrm{con}}$ (since $E_{\mathrm{check}} \subseteq E(G) \setminus E_{\mathrm{con}}$). In our application, we will have $\mu = O(\log n)$.

4.3 Constructing an NMC sparsifier

We can now state our result for computing an NMC sparsifier of a simple graph using Propositions 10 and 11. Compare this to Theorem 9 and note how Theorem 12 requires initialized DSF and DCS data structures but has a running time that is independent of the number of edges in G. An outline of this procedure is given in Section 3.2.

▶ **Theorem 12.** *Let G be a simple graph with n vertices that has minimum degree $\delta > 0$ and is maintained in a DSF and a DCS data structure. Then, with high probability we can construct an NMC sparsifier of G that has $O(n/\delta)$ vertices and $O(n)$ edges. W.h.p this takes $\tilde{O}(n \cdot (U_{\mathrm{SF}} + U_{\mathrm{CS}}))$ time.*

4.4 Fully Dynamic Graphs

The result of Theorem 12 can easily be extended to fully dynamic simple graphs by maintaining the DSF and DCS data structures throughout the updates of the graph. These forest data structures can be realized in different ways, as described in Section 3.1. Depending on this choice we get a different result, and this is how we derive Theorem 1.

If G is disconnected, all minimum cuts have value 0 and an NMC sparsifier H is by definition only required to have no edges between different connected components of G. Crucially, this implies that there is no guarantee that any information of the minimum cuts within each connected component of G is preserved in H. In this case, however, we can easily strengthen the result by applying Theorem 12 to each connected component of G individually.

5 Applications

5.1 A Cactus Representation of All Minimum cuts in Dynamic Graphs

It is well-known that a graph with n vertices has $O(n^2)$ minimum cuts, all of which can be represented compactly with a data structure of $O(n)$ size that has the form of a cactus graph (for more details, see [23]). As a first immediate application of our main Theorem 1, we show how the NMC sparsifier $\hat{G}$ of any fully dynamic simple graph G can be used to quickly compute this cactus representation. This result is summarized in Theorem 2; see the full version of this paper for a detailed construction.

To obtain just a single minimum cut of G, one can apply the deterministic minimum cut algorithms of [14, 19] on $\hat{G}$, which yields a minimum cut C of $\hat{G}$ in time $\tilde{O}(|\hat{G}|) = \tilde{O}(n)$. To transform C into a minimum cut of G, we compare its size with the minimum degree δ of any node in G: If $|C| \leq \delta$, then we get a minimum cut of G by simply mapping the edges from C back to the corresponding edges of G. Otherwise, a minimum cut of G is given by any vertex of G that has degree δ (which is easy to maintain throughout the updates).

5.2 Computing the Maximal k-Edge-Connected Subgraphs

The data structure of Theorem 1 can also be used to improve the time bounds for computing the maximal k-edge-connected subgraphs of a simple graph, in for cases where k is a sufficiently large polynomial of n. Specifically, we get an improvement for $k = \Omega(n^{1/8})$, c.f. Section 1.

A general strategy for computing these subgraphs is the following. Let G be a simple graph with n vertices and m edges, and let k be a positive integer. The basic idea is to repeatedly find and remove cuts with value less than k from G. First, as long as there are vertices with degree less than k, we repeatedly remove them from the graph. Now we are left with a (possibly disconnected) graph where every non-trivial connected component has minimum degree at least k. If we perform a minimum cut computation on a non-trivial connected component S of G, there are two possibilities: either the minimum cut is at least k, or we will have a minimum cut C with value less than k. In the first case, S is confirmed to be a maximal k-edge-connected subgraph of G. In the second case, we remove C from S, and thereby split it into two connected components S_1 and S_2. Then we recurse on both S_1 and S_2. Since the graph is simple and S has minimum degree at least k, it is a crucial observation that both S_1 and S_2 contain at least k vertices (see e.g. [19]). Therefore the number of nodes decreases by at least k with every iteration and hence the total recursion depth is $O(n/k)$.

The minimum cut computation takes time $T_{\text{mc}} = \tilde{O}(m)$ [17], hence the worst-case running time of this approach is $\Theta(n/k \cdot T_{\text{mc}}) = \tilde{O}(mn/k)$. We can use Theorem 1 to bring the time down to $\tilde{O}(m + n^2/k)$ w.h.p.

▶ **Theorem 3.** *Let G be a simple graph with n vertices and m edges, and let k be a positive integer. We can compute the maximal k-edge-connected subgraphs of G w.h.p. in $\tilde{O}(m+n^2/k)$ time w.h.p.*

Through a reduction to simple graphs, Theorem 3 implies Corollary 4, which is a similar result with slightly worse time bounds for undirected *multigraphs*. Finally, the method that establishes Theorem 3 naturally extends to the case of fully dynamic simple graphs, which yields Theorem 5.
