LIPIcs – Leibniz International Proceedings in Informatics

LIPIcs is a series of high-quality conference proceedings across all fields in informatics. LIPIcs volumes are published according to the principle of Open Access, i.e., they are available online and free of charge.

Additional Reviewers
..... 0:xix

Regular Papers

Covering and Partitioning Complex Objects with Small Pieces
Anders Aamand, Mikkel Abrahamsen, Reilly Browne, Mayank Goswami, Prahlad Narasimhan Kasthurirangan, Linda Kleist, Joseph S. B. Mitchell, Valentin Polishchuk, and Jack Stade 1:1–1:16

On the Maximum Number of Tangencies Among 1-Intersecting Curves
Eyal Ackerman and Balázs Keszegh 2:1–2:15

Lower Bounding the Gromov–Hausdorff Distance in Metric Graphs
Henry Adams, Sushovan Majhi, Fedor Manin, Žiga Virk, and Nicolò Zava 3:1–3:16

Dynamic Nearest-Neighbor Searching Under General Metrics in $\mathbb{R}^3$ and Its Applications
Pankaj K. Agarwal, Matthew J. Katz, and Micha Sharir 4:1–4:15

Bifunction and Interlevel Delaunay Trifiltrations
Ángel Javier Alonso, Michael Kerber, Tung Lam, Michael Lesnick, and Abhishek Rathod 5:1–5:20

Estimating the Persistent Homology of $\mathbb{R}^n$-Valued Functions Using Function-Geometric Multifiltrations
Ethan André, Jingyi Li, David Loiseaux, and Steve Oudot 6:1–6:18

Computing L_∞ Hausdorff Distances Under Translations: The Interplay of Dimensionality, Symmetry and Discreteness
Sebastian Angrick, Kevin Buchin, Geri Gokaj, and Marvin Künnemann 7:1–7:15

Cauchy's Surface Area Formula in the Funk Geometry
Sunil Arya and David M. Mount 8:1–8:18

Intersection Patterns of Set Systems on Manifolds with Slowly Growing Homological Shatter Functions
Sergey Avvakumov, Marguerite Bin, and Xavier Goaoc 9:1–9:16

Fast Free Resolutions of Bifiltered Chain Complexes
Ulrich Bauer, Tamal K. Dey, Michael Kerber, Florian Russold, and Matthias Söls 10:1–10:21

Locally Correct Interleavings Between Merge Trees
Thijs Beurskens, Tim Ophelders, Bettina Speckmann, and Kevin Verbeek 11:1–11:15

42nd International Symposium on Computational Geometry (SoCG 2026).
Editors: Hee-Kap Ahn, Michael Hoffmann, and Amir Nayyeri
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Dynamic and Streaming Algorithms for Union Volume Estimation
Sujoy Bhore, Karl Bringmann, Timothy M. Chan, and Yanheng Wang 12:1–12:15

Dynamic Light Spanners in Doubling Metrics
Sujoy Bhore, Jonathan Conroy, and Arnold Filtser 13:1–13:16

Improved Online Hitting Set Algorithms for Structured and Geometric Set Systems
Sujoy Bhore, Anupam Gupta, and Amit Kumar 14:1–14:14

Euclidean Noncrossing Steiner Spanners of Nearly Optimal Sparsity
Sujoy Bhore, Sándor Kisfaludi-Bak, Lazar Milenković, Csaba D. Tóth, Karol Węgrzycki, and Sampson Wong 15:1–15:18

Flip Distance of Non-Crossing Spanning Trees: NP-Hardness and Improved Bounds
Håvard Bakke Bjerkevik, Joseph Dorfer, Linda Kleist, Torsten Ueckerdt, and Birgit Vogtenhuber 16:1–16:18

Fréchet Distance in the Imbalanced Case
Lotte Blank 17:1–17:17

Product Structure and Treewidth of Hyperbolic Uniform Disk Graphs
Thomas Bläsius, Emil Dohse, Deborah Haun, and Laura Merker 18:1–18:17

Splitting Sandwiches Unevenly via Unique Sink Orientations and Rainbow Arrangements
Michaela Borzechowski, Sebastian Haslebacher, Hung P. Hoang, Patrick Schnider, and Simon Weber 19:1–19:16

The Spanning Ratio of the Directed Θ_6-Graph Is 5
Prosenjit Bose, Jean-Lou De Carufel, John Stuart, and Darryl Hill 20:1–20:18

On Minimum Venn Diagrams
Sofia Brenner, Petr Gregor, Torsten Mütze, and Francesco Verciani 21:1–21:18

Disproving Two Conjectures on the Hamiltonicity of Venn Diagrams
Sofia Brenner, Linda Kleist, Torsten Mütze, Christian Rieck, and Francesco Verciani 22:1–22:16

Shortest Paths in Geodesic Unit-Disk Graphs
Bruce W. Brewer and Haitao Wang 23:1–23:15

Single-Criteria Metric $\boldsymbol{r}$-Dominating Set Problem via Minor-Preserving Support
Reilly Browne and Hsien-Chih Chang 24:1–24:17

The Typical Algebraic Shifting of Graphs and Surfaces
Denys Bulavka, Eran Nevo, and Yuval Peled 25:1–25:15

Finding a Fair Scoring Function for Top-k Selection: From Hardness to Practice
Guangya Cai 26:1–26:17

The Squishy Grid Problem
Zixi Cai, Kuowen Chen, Shengquan Du, Arnold Filtser, Seth Pettie, and Daniel Skora 27:1–27:16

Triangulating a Polygon with Holes in Optimal (Deterministic) Time
Timothy M. Chan 28:1–28:13

Charting the Diameter Computation Landscape of Intersection Graphs in 3D and Above
Timothy M. Chan, Hsien-Chih Chang, Jie Gao, Sándor Kisfaludi-Bak, Hung Le, and Da Wei Zheng 29:1–29:15

Computing the Girth of a Segment Intersection Graph
Timothy M. Chan and Yuancheng Yu 30:1–30:16

Linear-Time $(1+\varepsilon)$-Approximation Algorithms for Two-Line-Center Problems
Chaeyoon Chung, Anil Maheshwari, and Michiel Smid 31:1–31:17

Tensor Computation of Euler Characteristic Functions and Transforms
Jessi Cisewski-Kehe, Brittany Terese Fasy, Alexander McCleary, and Eli Quist ... 32:1–32:17

Near-Optimal Bounds for Parameterized Euclidean k-Means
Vincent Cohen-Addad, Karthik C. S., David Saulpic, and Chris Schwiegelshohn ... 33:1–33:17

Almost-Optimal Upper and Lower Bounds for Clustering in Low Dimensional Euclidean Spaces
Vincent Cohen-Addad, Karthik C. S., David Saulpic, and Chris Schwiegelshohn ... 34:1–34:16

On Computing the (Exact) Fréchet Distance with a Frog
Jacobus Conradi, Ivor van der Hoog, and Eva Rotenberg 35:1–35:20

Upward Book Embeddings of Partitioned Digraphs
Giordano Da Lozzo, Fabrizio Frati, and Ignaz Rutter 36:1–36:18

A Free Lunch: Manifolds of Positive Reach Can Be Smoothed Without Decreasing the Reach
Hana Dal Poz Kouřimská, André Lieutier, and Mathijs Wintraecken 37:1–37:19

On the Size of k-Irreducible Triangulations
Vincent Delecroix, Oscar Fontaine, and Arnaud de Mesmay 38:1–38:16

Locality Sensitive Hashing in Hyperbolic Space
Chengyuan Deng, Jie Gao, Kevin Lu, Feng Luo, and Cheng Xin 39:1–39:19

Computing the Intrinsic Delaunay Triangulation of a Closed Polyhedral Surface
Loïc Dubois 40:1–40:15

The Depth Poset Under Transpositions in the Filter
Herbert Edelsbrunner, Michał Lipiński, Marian Mrozek, Manuel Soriano-Trigueros, and Fedor Zimin 41:1–41:18

Compressed Data Structures for Heegaard Splitting
Henrique Ennes and Clément Maria 42:1–42:15

Unlabeled Multi-Robot Motion Planning with Improved Separation Trade-Offs
Tsuri Farhana, Omrit Filtser, and Shalev Goldshtein 43:1–43:16

Tilt Automata: Gathering Particles with Uniform External Control
Sándor P. Fekete, Jonas Friemel, Peter Kramer, Jan-Marc Reinhardt, Christian Rieck, and Christian Scheffer 44:1–44:19

Line Segment Visibility in Simple Polygons: Exact, Robust, Scalable Computation and Applications
Sándor P. Fekete, Prahlad Narasimhan Kasthurirangan, Phillip Keldenich, Fabian Kollhoff, Chek-Manh Loi, and Michael Perk 45:1–45:19

A Branch-And-Bound Algorithm for the Traveling Salesman Problem with Difficult Neighborhoods
Sándor P. Fekete, Rouven Kniep, Dominik Krupke, and Michael Perk 46:1–46:20

Computing the Skyscraper Invariant
Marc Fersztand and Jan Jendrysiak 47:1–47:23

FPT Approximations for Capacitated Sum of Radii and Diameters
Arnold Filtser and Ameet Gadekar 48:1–48:18

Algorithms for Euclidean Distance Matrix Completion: Exploiting Proximity to Triviality
Fedor V. Fomin, Petr A. Golovach, M. S. Ramanujan, and Saket Saurabh 49:1–49:15

Separators for Intersection Graphs of Spheres
Jacob Fox and Jonathan Tidor 50:1–50:16

First-Order Logic and Twin-Width for Some Geometric Graphs
Colin Geniet, Gunwoo Kim, and Lucas Meijer 51:1–51:16

Online Packing of Orthogonal Polygons
Tim Gerlach, Benjamin Hennies, and Linda Kleist 52:1–52:17

Constructing Doppelgängers of Greedy Geometric Spanners in Practice
Anirban Ghosh 53:1–53:21

Approximating Pareto Sum via Bounded Monotone Min-Plus Convolution
Geri Gokaj, Marvin Künnemann, Sabine Storandt, and Carina Truschel 54:1–54:21

Linear Time Single-Source Shortest Path Algorithms in Euclidean Graph Classes
Joachim Gudmundsson, Yuan Sha, and Sampson Wong 55:1–55:14

Optimal Randomized Clustering of Matrices
Mustafa Alper Gunes and Assaf Naor 56:1–56:18

Singular Arrange and Traverse Algorithm for Computing Reeb Spaces of Bivariate PL Maps
Petar Hristov, Ingrid Hotz, and Talha Bin Masood 57:1–57:17

On Sparse Representations of 3-Manifolds
Kristóf Huszár and Clément Maria 58:1–58:18

Improved Bound for the k-Variate Elekes–Rónyai Theorem
Yaara Jahn and Orit E. Raz 59:1–59:15

Space-Efficient Approximate Spherical Range Counting in High Dimensions
Andreas Kalavas and Ioannis Psarros 60:1–60:15

Complements of Finite Unions of Convex Sets
Chaya Keller and Micha A. Perles 61:1–61:18

Computing the Bottleneck Distance Between Persistent Homology Transforms
Michael Kerber and Elena Xinyi Wang 62:1–62:15

Unavoidable Patterns and Plane Paths in Dense Topological Graphs
Balázs Keszegh, Andrew Suk, Gábor Tardos, and Ji Zeng 63:1–63:15

Gap-ETH-Tight Algorithms for Hyperbolic TSP and Steiner Tree
Sándor Kisfaludi-Bak, Saeed Odak, Satyam Singh, and Geert van Wordragen 64:1–64:17

Near-Optimal Dynamic Steiner Spanners for Constant-Curvature Spaces
Sándor Kisfaludi-Bak and Geert van Wordragen 65:1–65:17

Fast Nearest Neighbor Search for ℓ_p Metrics
Robert Krauthgamer and Nir Petruschka 66:1–66:9

Non-Dissective Coverings by Planks
Andrey Kupavskii and János Pach 67:1–67:11

Optimal Bounds for Spanners and Tree Covers in Doubling Metrics
An La, Hung Le, Shay Solomon, Cuong Than, Vinayak, Shuang Yang, and Tianyi Zhang 68:1–68:16

Approximate Dynamic Nearest Neighbor Searching in a Polygonal Domain
Joost van der Laan, Frank Staals, and Lorenzo Theunissen 69:1–69:16

Tree-Like Shortcuttings of Trees
Hung Le, Lazar Milenković, Shay Solomon, and Cuong Than 70:1–70:15

Approximating Euclidean Shallow-Light Trees
Hung Le, Shay Solomon, Cuong Than, Csaba D. Tóth, and Tianyi Zhang 71:1–71:16

Topological Simplification Guided by Forbidden Regions
Jakub Leśkiewicz, Bartosz Furmanek, Michał Lipiński, and Dmitriy Morozov 72:1–72:17

The Complete 10-Tetrahedra Census of Orientable Cusped Hyperbolic 3-Manifolds
Shana Yunsheng Li 73:1–73:15

Manifolds of Positive Reach, Differentiability, Tangent Variation, and Attaining the Reach
André Lieutier and Mathijs Wintraecken 74:1–74:16

Geodesics of Length Less Than πR in a Set of Reach R Are Unique and Continuous with Respect to the Endpoints
André Lieutier and Mathijs Wintraecken 75:1–75:12

A Fast Algorithm for the Hecke Representation of the Braid Group, and Applications to the Computation of the HOMFLY-PT Polynomial and the Search for Interesting Braids
Clément Maria and Hoel Queffelec 76:1–76:18

Robust Algorithms for Path and Cycle Problems in Geometric Intersection Graphs
Malory Marin, Jean-Florent Raymond, and Rémi Watrigant 77:1–77:14

Mapping Chemical Space: Topological Data Analysis of Chemical Latent Space with Mapper
Dhruv Meduri, Chuan-Shen Hu, Cong Shen, Kelin Xia, and Bei Wang 78:1–78:20

D-GRIL: End-To-End Topological Learning with 2-Parameter Persistence
Soham Mukherjee, Shreyas N. Samaga, Cheng Xin, Steve Oudot, and Tamal K. Dey 79:1–79:17

Hardness of High-Dimensional Linear Classification
Alexander Munteanu, Simon Omlor, and Jeff M. Phillips 80:1–80:16

Optimal-Cost Construction of Shallow Cuttings for 3-D Dominance Ranges in the I/O-Model
Yakov Nekrich and Saladi Rahul 81:1–81:15

A Persistent Version of Latschev's Theorem
Steve Oudot and Lukas Waas 82:1–82:17

Erdős's Unit Distance Problem and Rigidity
János Pach, Orit E. Raz, and József Solymosi 83:1–83:9

The Voronoi Diagram of Four Lines in $\mathbb{R}^3$
Evanthia Papadopoulou and Zeyu Wang 84:1–84:17

ETH-Tight Complexity of Optimal Morse Matching on Bounded-Treewidth Complexes
Geevarghese Philip and Erlend Raa Vågset 85:1–85:19

Expansion of Trivariate Polynomials Using Proximity
Orit E. Raz 86:1–86:10

Robustness of Persistent Topological Features and Minimum Homological Cuts
Pepijn Roos Hoefgeest and Lucas Slot 87:1–87:15

Integer Points in Dilates of Polytopes
Shubhangi Saraf and Narmada Varadarajan 88:1–88:9

Approximating Convex Hulls via Range Queries
Thomas Schibler, Jie Xue, and Jiumu Zhu 89:1–89:15

Better Sampling Bounds for Restricted Delaunay Triangulations and a Star-Shaped Property for Restricted Voronoi Cells
Jonathan Richard Shewchuk 90:1–90:16

The Hierarchy of Manifolds in a Stratification of the Set of Equivalent Linear Neural Networks
Jonathan Richard Shewchuk and Sagnik Bhattacharya 91:1–91:19

Estimation of Conformal Metrics
Jérôme Taupin 92:1–92:15

Simplicial Approximation to CW Complexes with Spherical Delaunay Triangulations
Raphaël Tinarrage 93:1–93:22

Mixup Barcodes: Quantifying Geometric-Topological Interactions Between Point Clouds
Hubert Wagner, Nickolas Arustamyan, Matthew Wheeler, and Peter Bubenik 94:1–94:19

An Optimal Algorithm for Computing Many Faces in Line Arrangements
Haitao Wang 95:1–95:14

Media Expositions

Sliding Cubes in Parallel
Hugo A. Akitaya, Joseph Dorfer, Peter Kramer, Christian Rieck, Soham Samanta, Gabriel Shahrouzi, and Frederick Stock 96:1–96:5

"Visualizing" the CG Community
Oswin Aichholzer, Hugo A. Akitaya, Anna Brötzner, Peter Kramer, Christian Rieck, and Frederick Stock 97:1–97:4

Interactive Uniform Floodlight Illumination and Rotating Rays Voronoi Diagrams
Carlos Alegría, Ioannis Mantas, Marko Savić, and Martin Suderland 98:1–98:7

Proximity Alert: Ipelets for Neighborhood Graphs and Clustering
Gitan Balogh, June Cagan, Bea Fatima, Auguste H. Gezalyan, Danesh Sivakumar, Arushi Srinivasan, Yixuan Sun, Vahe Zaprosyan, and David M. Mount 99:1–99:8

Visualizing Higher Order Structures, Overlap Regions, and Clustering in the Hilbert Geometry
Hridhaan Banerjee, Soren Brown, June Cagan, Auguste H. Gezalyan, Megan Hunleth, Veena Kailad, Chaewoon Kyoung, Rowan Shigeno, Yasmine Tajeddin, Andrew Wagger, Kelin Zhu, and David M. Mount 100:1–100:6

From Chaos to Continents: Voronoi-Based Procedural Terrain Generation with Hydrology and 3D Visualization
Batsambuu Batbold and Lori Ziegelmeier 101:1–101:7

Tracking a Set of Moving Objects with Minimal Peak Power
Sándor P. Fekete, Malte Hoffmann, Chek-Manh Loi, and Michael Perk 102:1–102:7

Scalable Algorithmic Methods for Simulating Heavy-Rain Events
Sándor P. Fekete, Phillip Keldenich, Michael Perk, and Tobias Wallner 103:1–103:6

Interactive Visualization and Verification Tools for Tesseract Path Unfoldings
Soham Samanta, Hugo A. Akitaya, Erik Demaine, and Martin Demaine 104:1–104:5

CG Challenges

ETH Flippers Approach to Parallel Reconfiguration of Triangulations: SAT Formulation and Heuristics
Lorenzo Battini and Marko Milenković 105:1–105:6

Engineering Greedy Heuristics and Simulated Annealing Methods for the Median Triangulation Under the Parallel Flip Distance
Jacobus Conradi, Benedikt Kolbe, Philip Mayer, Jonas Sauer, and Jack Spalding-Jamieson 106:1–106:7

Shadoks Approach to Parallel Reconfiguration of Triangulations
Guilherme D. da Fonseca, Fabien Feschet, and Yan Gerard 107:1–107:7

CG#Hunters Approach to Central Triangulation Under Parallel Flip Operations
Jaegun Lee, Seokyun Kang, Hyeonseok Lee, Hyeyun Yang, and Taehoon Ahn 108:1–108:8

Preface

The 42nd International Symposium on Computational Geometry (SoCG 2026) was held in New Brunswick, NJ, USA, June 2–5, 2026, as part of the Computational Geometry Week (CG Week 2026).

To strengthen and promote research on practical aspects of computational geometry and topology, as well as connections to other fields, SoCG 2026 introduced a new track that specifically focuses on these aspects, such as implementation and software, engineering, experimentation, and applications. Thus, for the first time in 25 years, the submission and review process was organized in two tracks: Track P (Practice) and Track T (Theory). Authors could also specify that their submission falls in between the tracks if it makes relevant contributions of both theoretical and practical nature.

The symposium received a record number of 272 submissions, of which 217 were for Track T, 40 in between, 14 for Track P, and one was withdrawn later. After a thorough review process, in which each paper was evaluated by several (typically three or four) independent reviewers, the program committee accepted 95 papers for presentation, of which 76 were from Track T, 13 in between, and 6 from Track P. These proceedings contain extended abstracts of the accepted papers, limited to 500 lines (excluding references). If any supporting material does not fit in the line limit, it is persistently available at a public repository and referenced in the corresponding extended abstract.

The Best Theory Paper Award of SoCG 2026 went to the paper "On the size of k-irreducible triangulations" by Vincent Delecroix, Oscar Fontaine and Arnaud de Mesmay. The Best Practice Paper Award of SoCG 2026 went to the paper "Constructing Doppelgängers of Greedy Geometric Spanners in Practice" by Anirban Ghosh. The Best Student Paper Award of SoCG 2026 went to the paper "Fréchet Distance in the Imbalanced Case" by Lotte Blank. The Best Student Presentation Award was determined and announced at the symposium, based on ballots cast by the attendees. A selection of papers was invited to submit extended versions to forthcoming special issues of Discrete & Computational Geometry (DCG) and the Journal of Computational Geometry (JoCG) dedicated to the symposium.

The SoCG Test of Time Award 2026 went to "An efficient algorithm for planning collision-free translational motion of a convex polygonal object in 2-dimensional space amidst polygonal obstacles" by Klara Kedem and Micha Sharir, published in SoCG 1985, and to "Locality-sensitive hashing scheme based on p-stable distributions" by Mayur Datar, Nicole Immorlica, Piotr Indyk and Vahab S. Mirrokni, published in SoCG 2004.

The scientific program of CG Week 2026 was enriched by two distinguished invited speakers. An invited talk "From shape comes meaning: Bringing geometric intuition to the ethics of AI" was given by Suresh Venkatasubramanian from Brown University. A second invited talk "New directions in sublinear time algorithms" was delivered by Ronitt Rubinfeld from the Massachusetts Institute of Technology. We thank the plenary speakers for kindly accepting our invitation.

In addition to the technical papers, there were nine submissions to the multimedia exposition. Submissions were reviewed and all of them were accepted for presentation. The extended abstracts that describe these submissions are included in this proceedings volume. The multimedia content can be found at `https://computational-geometry.org/cg-week/media-exposition/2026/`.

42nd International Symposium on Computational Geometry (SoCG 2026).
Editors: Hee-Kap Ahn, Michael Hoffmann, and Amir Nayyeri
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

The 8th Computational Geometry Challenge was part of CG Week 2026. The challenge problem was about finding a central triangulation under parallel flip operations. This year, eighteen teams participated in the challenge. These proceedings contain contributions by the four top-placed teams describing their winning approaches.

We thank the authors of all submitted contributions. We are most grateful to the members of the SoCG Program Committee, the Media Exposition (CG:ME) Committee, and the CG Challenge Committee for their dedication, expertise, and hard work that ensured the high quality of the works in these proceedings. We are grateful for the assistance provided by the hundreds of external reviewers; without their help, it would have been impossible to run the selection process. Last but not least, we thank Philipp Kindermann for his meticulous work as the Proceedings Chair.

Many other people contributed to the success of SoCG 2026 and the entire CG Week. We are very grateful to the local organizers for their work in organizing the event. Finally, we thank all the members of the Test of Time Award Committee, the Young Researchers Forum (CG:YRF) Committee, the CG Challenge Advisory Board, the CG Society Board, the CG Society IT Committee, and the CG Steering Committee.

Conference Organization

SoCG Program Committee

Track P

- Chao Chen (Stony Brook University)
- Otfried Cheong (Scalgo)
- Andreas Fabri (GeometryFactory)
- Marc Glisse (Inria Saclay)
- John Hershberger (Siemens EDA)
- Michael Hoffmann (co-chair; ETH Zürich)
- Phillip Keldenich (TU Braunschweig)
- Dmitriy Morozov (Lawrence Berkeley National Laboratory)
- Sabine Storandt (University of Konstanz)
- Hubert Wagner (University of Florida)
- Jules Wulms (TU Eindhoven)

Track T

- Eyal Ackerman (University of Haifa at Oranim)
- Hee-Kap Ahn (co-chair; POSTECH)
- Pankaj Agarwal (Duke University)
- Martin Balko (Charles University)
- Huck Bennett (University of Colorado Boulder)
- Sarita de Berg (IT University of Copenhagen)
- Therese Biedl (University of Waterloo)
- Kevin Buchin (TU Dortmund)
- Sergio Cabello (University of Ljubljana)
- Jean Cardinal (Université Libre de Bruxelles)
- Mathieu Carrière (Inria Côte d'Azur)
- Éric Colin de Verdière (CNRS, LIGM, Marne-la-Vallée)
- Anne Driemel (Bonn University)
- Herbert Edelsbrunner (IST Austria)
- Arnold Filtser (Bar Ilan University)
- Xavier Goaoc (Université de Lorraine)
- Kristóf Huszár (TU Graz)
- Woojin Kim (KAIST)
- Sándor Kisfaludi-Bak (Aalto University)
- Hung Le (UMass Amherst)
- Amir Nayyeri (co-chair; Oregon State University)
- Yakov Nekrich (Michigan Technological University)
- Sharath Raghvendra (NC State)
- Paweł Rzążewski (Warsaw University of Technology)
- Frank Staals (Utrecht University)
- Primož Škraba (Queen Mary University of London)
- Shin-ichi Tanigawa (University of Tokyo)
- Katharine Turner (Australian National University)

- Carola Wenk (Tulane University)
- Sampson Wong (University of Copenhagen)
- Meirav Zehavi (Ben Gurion Univeristy)

SoCG Proceedings Chair

- Philipp Kindermann (Universität Trier)

CG Media Exposition (CG:ME) Committee

- Hugo Akitaya (University of Massachusetts Lowell)
- Maarten Löffler (Utrecht University)
- Greg Malen (Skidmore College)
- Joseph O'Rourke (co-chair; Smith College)
- Ryuhei Uehara (JAIST)
- Elena Wang (University of Fribourg)
- Alexandra Wesolek (University Potsdam)
- Lori Ziegelmeier (co-chair; Macalester College)

CG Challenge (CG:SHOP) Committee

- Oswin Aichholzer (TU Graz)
- Joseph Dorfer (TU Graz)
- Sándor Fekete (TU Braunschweig)
- Phillip Keldenich (TU Braunschweig)
- Peter Kramer (TU Braunschweig)
- Dominik Krupke (TU Braunschweig)
- Stefan Schirra (University of Magdeburg)

CG Challenge Advisory Board

- Bill Cook (University of Waterloo)
- Andreas Fabri (Geometry Factory)
- Dan Halperin (Tel Aviv University)
- Michael Kerber (TU Graz)
- Philipp Kindermann (Universität Trier)
- Joe Mitchell (Stony Brook University)
- Kevin Verbeek (TU Eindhoven)

SoCG Test of Time Award Committee

- Pankaj K. Agarwal (Duke University)
- Mark de Berg (TU Eindhoven)
- Siu-Wing Cheng (Hong Kong University of Science and Technology)
- Yusu Wang (University of California, San Diego)

Young Researchers Forum (CG:YRF) Program Committee

- André van Renssen (The University of Sydney)
- Carolin Rehs (Dortmund University)
- Evanthia Papadopoulou (Università della Svizzera italiana)
- Florian Russold (TU Graz)
- Håvard Bakke Bjerkevik (University at Albany)
- Jack Stade (University of Copenhagen)
- Meirav Zehavi (Ben-Gurion University)
- Peyman Afshani (chair) (Aarhus University)
- Rahul Saladi (Indian Institute of Science Bangalore)

Local Organizing Committee

- Jie Gao (Computer Science, Rutgers)
- David Pennock (DIMACS, Rutgers)
- Tamra Carpenter (DIMACS, Rutgers)

CG Society Board

- Benjamin Burton (University of Queensland)
- David Eppstein (University of California, Irvine)
- Bettina Speckmann (TU Eindhoven)
- Frank Staals (Utrecht University)

CG Society IT Committee

- Yossi Bokor Bleile (Aalborg University)
- Fabian Klute (Universitat Politècnica de Catalunya)
- Willem Sonke (TU Eindhoven)

CG Steering Committee

- Maike Buchin (Ruhr-Universität Bochum)
- Erin Chambers (University of Notre Dame)
- Anne Driemel (Universität Bonn)
- Marc van Kreveld (Utrecht University)
- Joe Mitchell (Stony Brook University)
- Wolfgang Mulzer (Freie Universität Berlin)

Additional Reviewers

- Eddie Aamari
- Fateme Abbasi

Abstract

We study the problems of covering or partitioning a polygon P (possibly with holes) using a minimum number of *small pieces*, where a small piece is a connected sub-polygon contained in an axis-aligned unit square. For covering, we seek to write P as a union of small pieces, and in partitioning, we furthermore require the pieces to be pairwise interior-disjoint. We show that these problems are in fact equivalent: Optimum covers and partitions have the same number of pieces.

For covering, a natural local search algorithm repeatedly attempts to replace k pieces from a candidate cover with $k-1$ pieces. In two dimensions and for sufficiently large k, we show that when no such swap is possible, the cover is a $1+\mathcal{O}(1/\sqrt{k})$ approximation, hence obtaining the first PTAS for the problem. Prior to our work, the only known algorithm was a 13-approximation that only works for polygons without holes [Abrahamsen and Rasmussen, SODA 2025]. In contrast, in the three dimensional version of the problem, for a polyhedron P of complexity n, we show that it is NP-hard to approximate an optimal cover or partition to within a factor that is logarithmic in n, even if P is simple, i.e., has genus 0 and no holes.

1 Introduction

Partitioning large objects into pieces of bounded size is a fundamental problem. One practical motivation comes from 3D printing and related manufacturing technologies: we can only produce objects that fit within the printing volume, which can be assumed to be a unit cube. If the goal is to produce a large part P, we must partition P into smaller pieces, $Q_1, \ldots, Q_k$, each of which fits within the unit cube. The small pieces can then be assembled to form the desired part P. A natural objective is to minimize the number, k, of pieces. Heuristics have been proposed to solve this problem [31, 18, 26, 30, 38, 36].

Similar partitioning problems arise in everyday settings. For instance, one might disassemble an entire broccoli head, the peeled stem included, into pieces suitable for consumption with minimal indignity. Yet even in this humble task, one strives to avoid the disarray of producing an excessive multitude of fragments. Recently, Abrahamsen and Rasmussen [5] initiated a theoretical study of partitioning polygons into few small pieces. They provided constant-factor approximation algorithms when the domain P is a simple polygon (no holes), for various definitions of what it means for a piece Q_i to be "small," each with its own algorithm and approximation factor. A particularly simple version demands that each piece Q_i be connected and contained in an axis-aligned unit square. Abrahamsen and Stade [6] showed that this version is NP-hard even when P is a simple polygon.

In this paper, we consider the problems of partitioning and covering objects with small pieces in two and three dimensions. We consider the setting where a small piece is defined as a connected subset of P contained in an axis-aligned unit square (in two dimensions) or unit cube (in three dimensions). We obtain the following results.

- We present a PTAS for covering a polygon (possibly with holes) into a minimum number of small pieces (Section 2).
- For polygons (possibly with holes), we show that the small-cover and small-partition problem have the same optimal value (Section 2.4).
- We prove that in 3D, covering or partitioning a polyhedron P of description complexity n with small pieces is NP-hard to approximate within a logarithmic factor of n, even when P is simply-connected and contained in a box of size $1 \times 2 \times 3$ (Section 3).

Our PTAS works by local search: we start with a candidate small cover and then repeatedly try to find a set of k pieces that can be swapped for a set of $k-1$ pieces. We show that this gives a $1 + \mathcal{O}(1/\sqrt{k})$ approximation algorithm, when k is sufficiently large. A result by Roy, Govindarajan, Raman, and Ray [34] shows that local search is a PTAS for discrete Set-Cover when the candidate pieces satisfy a certain *non-piercing* property. Two simply-connected pieces P, Q are *non-piercing* if $P \setminus Q$ and $Q \setminus P$ are connected. We show that a set of maximal small pieces satisfies a slightly weaker non-piercing property, but we are able to modify the pieces slightly so that the result from [34] can be used. We are then able to analyze our "continuous" local search algorithm using this result–unlike the discrete case studied in [34], note that our search space is infinite.

For many optimization algorithms, local search can be used to obtain a PTAS when a certain related graph has sublinear separators (see [8] for details). We highlight the fact that this is non-obvious for the small-cover problem. Local search gives a PTAS for *packing*

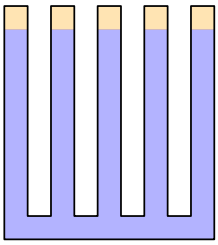

Figure 1 A comb-shaped polygon might require an arbitrarily large number of pieces for a small cover, even if it fits in a box of size $1 \times (1 + \varepsilon)$.

axis-aligned unit squares into a polyhedron in any constant dimension, since a density argument can be used to obtain the required separation bounds (see for example [24]). In contrast, for small covers, we insist that the pieces be connected, which means that there are "comb-shaped" polygons requiring many pieces, even though the polygon itself almost fits in a unit square; see Figure 1. In 3D, we show that it is NP-hard to approximate optimal small cover or partition to within a factor of $(1 - \alpha)\ln(n)$, for any $\alpha > 0$, where n is the number of bits needed to describe the input polyhedron. We also observe (Theorem 10) that for small pieces, covering and partitioning are equivalent, in the sense that the smallest number of pieces in a cover and in a partition is the same. This is in stark contrast with other geometric settings where not only the optima differ, but also covering seems considerably harder than partitioning. For instance, it is $\exists\mathbb{R}$-complete to cover a simple polygon with the minimum number of star polygons [3] (that is, the art-gallery problem) or convex polygons [2], while the corresponding partitioning problems are solvable in polynomial time [4, 16]. Details of all proofs can be found in the full version [1].

1.1 Related Work

The small cover and partitioning problems belong to the class of *decomposition problems*, which form a large, established subfield in computational geometry. In all of these problems, we want to *decompose* a polygon P into connected polygonal *pieces* that must respect certain restrictions. Here, the union of the pieces must be P, and we usually seek a decomposition into as few pieces as possible, in which case the decomposition is called *optimal*. A decomposition that allows the pieces to overlap is called a *cover*; if thee pieces are pairwise interior-disjoint, it is called a *partition*. Depending on the assumptions about the input polygon P and the requirements on the pieces, this leads to a wealth of interesting problems. There is a vast literature about such decomposition problems, as documented in several books and survey papers that give an overview of the state-of-the-art at their respective times of publication [35, 17, 15, 28, 29, 32, 33].

Earlier works studied variants of the small partitioning problem without Steiner points [20, 13], i.e., each vertex of a piece Q_i is a vertex of P. As an undesirable consequence such a partition often does not exist, e.g., if an edge of the polygon P is too long to fit in a piece.

Motivated by indoor localization using lasers, Arkin, Das, Gao, Goswami, Mitchell, Polishchuk, and Tóth [7] studied partitioning a polygon with chords (maximal segments within P), which may model laser beams that serve as "tripwires"; the goal is to cut the polygon into bounded pieces using the fewest lasers. Motivated by communication graphs for mobile robots, Fekete, Kamphans, Kröller, Mitchell, and Schmidt [23] (see also the video [9]) showed how to compute a Steiner triangulation of a simple polygon, whose edge lengths are bounded; they presented a 3-approximation for minimizing the number of Steiner points.

Worman [37] showed NP-hardness of partitioning a polygon with holes into a minimum number of pieces contained in axis-aligned unit squares, without Steiner points. More recently, Buchin and Selbach [13] proved NP-hardness of partitioning and covering with fat pieces. Combinatorial aspects of partitioning into small[er] pieces are classical problems in mathematics. For instance, *Borsuk's problem* is to partition a unit-diameter convex body (in any dimension) into fewest pieces of diameter strictly less than 1; see [12, 25, 27] for the rich history of the problem. *Conway's fried potato problem* [10, 11, 14, 19] deals with minimizing the in-radius of the pieces obtained by a specified number of hyperplane cuts of a given convex polyhedron (in d dimensions); in our terminology, Conway's problem is a *dual* small partitioning problem.

1.2 Problem Formulation

We say that a polygon Q (possibly with holes) is *small* if Q is contained in an axis-aligned unit square. We often call small polygons small *pieces*. A set $\mathcal{Q}$ of small pieces is a *small cover* of a polygon P if $\bigcup \mathcal{Q} = P$; note in particular that $Q \subseteq P$ for each small piece $Q \in \mathcal{Q}$. We say that a piece $Q \in \mathcal{Q}$ is *complete* if Q is the closure of a connected component of the intersection $P^\circ \cap S$, where P° is the interior of P and S is an axis-aligned unit square. A simpler definition would be that Q is complete if it is a connected component of $P \cap S$, but that could be a degenerate polygon, which we by definition don't allow. A small cover $\mathcal{Q}$ of P is a *small partition* of P if furthermore the pieces in $\mathcal{Q}$ are pairwise interior-disjoint. In this paper, we study the problems of finding small covers and small partitions consisting of a minimum number of pieces for a given polygon P, which may have holes. We denote these problems Small-Cover and Small-Partition, respectively.

2 A PTAS for Small-Cover in 2 dimensions

In this section, we present an $(1+\varepsilon)$-approximation algorithm for Small-Cover when the input is a polygon P, possibly with holes. In Section 2.1, we establish tools that allow us to use local search. We then show in Section 2.2 how to use these techniques to handle polygons which intersect at most D squares in the integer grid. The running time of our algorithm are polynomial in D. Finally, in Section 2.3, we extend our ideas to handle polygons that might have exponentially large diameter. We note that, for the purposes of constructing approximate solutions for Small-Cover, we will only consider *complete* small pieces, since any small piece that fits in a square S must cover a subset of the complete piece covering the same component of $P^\circ \cap S$.

2.1 Fundamentals for Local Search

Roy, Govindarajan, Raman, and Ray [34] studied the geometric set cover problem with so-called non-piercing regions. Two compact simply-connected regions A and B are *non-piercing* if $A \setminus B$ and $B \setminus A$ are both connected. We say that A and B intersect *properly* if the intersection of the boundaries $\partial A \cap \partial B$ consists of a finite set of points and in each of these points, the boundaries cross, i.e., tangential intersections are not allowed. We say that a set of compact, simply-connected regions is *properly non-piercing* if the regions are pairwise non-piercing and intersect properly.

▶ **Lemma 1** ([34]). *For a universal constant C the following holds: Let X be a (finite) set of points in $\mathbb{R}^2$ and suppose that $\mathcal{Q} = \{Q_1, \ldots, Q_q\}$ and $\mathcal{R} = \{R_1, \ldots, R_r\}$ are sets of connected regions such that $\mathcal{Q}$ and $\mathcal{R}$ each cover X. If the regions in $\mathcal{Q} \cup \mathcal{R}$ are properly non-piercing and $r \geq (1+\varepsilon)q$ for some $1 \geq \varepsilon > 0$, then there is some set of at most C/ε^2 of the pieces in $\mathcal{R}$ that can be replaced by a strictly smaller set of pieces in $\mathcal{Q}$ to obtain a cover of X.*

We start by adapting this result to the setting of covering a polygon rather than a discrete set of points. We show the following:

▶ **Lemma 2.** *There is a constant C such that the following holds: Let P be a polygon (possibly with holes) and let $\mathcal{Q}$ be an optimal small cover of P consisting of q complete pieces, and let $\mathcal{R}$ be another small cover of P consisting of r complete pieces. Then for any $1 \geq \varepsilon > 0$, if $r \geq (1+\varepsilon)q$, then there is a set of at most C/ε^2 of the pieces in $\mathcal{R}$ that can be replaced by a strictly smaller set of pieces in $\mathcal{Q}$ to obtain a small cover of P.*

It is relatively straightforward to prove Lemma 2 given Lemma 1. The strategy is to put a point in the interior of each cell of the overlay of $\mathcal{Q}$ and $\mathcal{R}$. A subset of $\mathcal{Q} \cup \mathcal{R}$ covers P if and only if it covers each of these points. The pieces in $\mathcal{Q} \cup \mathcal{R}$ are almost non-piercing, but need to be modified slightly in order to remove degeneracies and holes. The process is demonstrated informally in Figure 2 and uses an idea from [21]. The following lemma says that these modifications exist:

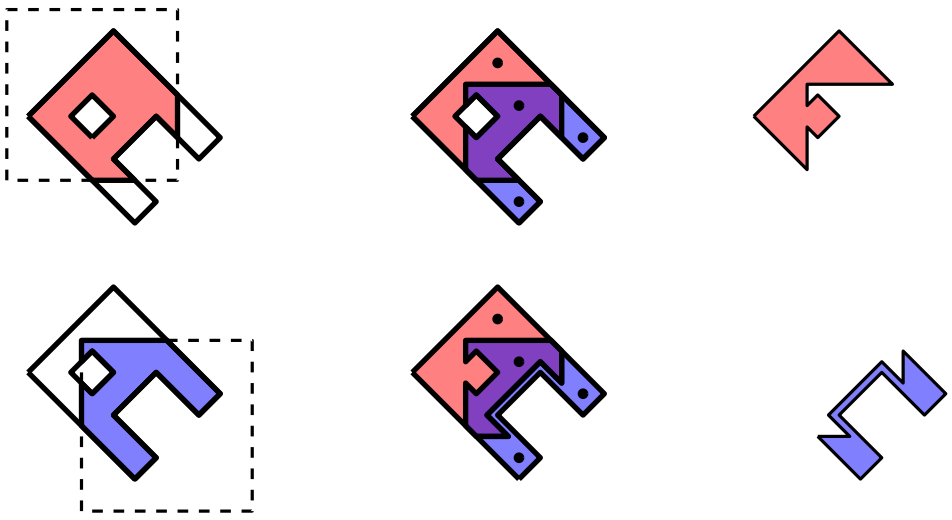

Figure 2 Given a finite set of complete small pieces that cover P, we obtain an equivalent instance of non-piercing geometric set cover. Left: a polygon and two complete small pieces. Top middle: the polygon and pieces cut the polygon into 4 cells, and we place a point in each cell. These pieces are piercing, since removing the red piece from the blue piece would disconnect it. Additionally, the red piece has a hole. Bottom middle: modifying the pieces to remove the hole and make them non-piercing. The hole in the red piece is filled, and an interval of the boundary is offset inwards so as to not pierce the blue piece. Right: removing the modified blue piece from the red piece (top) or the modified red piece from the blue piece (bottom). The remaining parts are connected, so the modified pieces are non-piercing.

▶ **Lemma 3.** *Consider a polygon P and a small cover $\mathcal{Q} = \{Q_1, \ldots, Q_q\}$ of P consisting of complete small pieces. Consider the overlay of the pieces in $\mathcal{Q}$, choose a point in the interior of each region contained in P, and let X be the set of these points. There exists a set $\mathcal{Q}' = \{Q'_1, \ldots, Q'_q\}$ of simply-connected pieces that are properly non-piercing such that $Q_i \cap X = Q'_i \cap X$ for all $i \in \{1, \ldots, q\}$. It holds in particular that for any $I \subset \{1, \ldots, q\}$, we have $X \subset \bigcup_{i \in I} Q'_i$ if and only if $P = \bigcup_{i \in I} Q_i$.*

Note that these modifications are only used in the analysis; we don't need to produce them algorithmically. We now prove Lemma 2.

Proof of Lemma 2. Let $\mathcal{S} = \mathcal{Q} \cup \mathcal{R}$ be the union of the global optimum and the local optimum. Using Lemma 3, we obtain a new set $\mathcal{S}' = \mathcal{Q}' \cup \mathcal{R}'$ of properly non-piercing pieces and a finite set of points X such that a subset of $\mathcal{S}'$ covers X if and only if the corresponding subset of $\mathcal{S}$ covers P. Since $\mathcal{Q}$ and $\mathcal{R}$ both cover P, $\mathcal{Q}'$ and $\mathcal{R}'$ must both cover X.

Recall that $q = |\mathcal{Q}| = |\mathcal{Q}'|$ and $r = |\mathcal{R}| = |\mathcal{R}'|$. If $r \geq (1+\varepsilon)q$ for some $1 \geq \varepsilon > 0$, then by Lemma 1, we can replace a set of at most $C\frac{1}{\varepsilon^2}$ of the pieces in $\mathcal{R}'$ with a strictly smaller set of pieces from $\mathcal{Q}'$ to obtain another cover of X. If we swap the corresponding pieces in $\mathcal{R}$ with the corresponding pieces in $\mathcal{Q}$, then we get a small cover of P, proving the claim. ◀

Lemma 2 gives sufficient conditions for a small cover to be a $(1+\varepsilon)$-approximation of the optimum. We say that a small cover R is a *k-local optimum* if no set of at most k pieces from $\mathcal{R}$ can be replaced by a strictly smaller set of small pieces.

▶ **Corollary 4.** *There is some constant C' such that if P is a polygon and $\mathcal{R}$ is a small cover that is a k-local optimum for $k \geq C'$ and has r complete pieces, then r is at most $1 + \frac{C'}{\sqrt{k}}$ times the size of an optimal cover of P.*

Proof. Taking C to be the constant from Lemma 2, let $C' = \sqrt{C}$ and $k_0 = \lceil C' \rceil$. Because $\mathcal{R}$ is k-local optimum, no set of at most k pieces can be replaced by a smaller set of small pieces. If $r \leq k$, then $\mathcal{R}$ is necessarily an optimal solution and the claim holds. So suppose that $r > k$. Let $\mathcal{Q}$ be an optimal small cover of P with q complete pieces. Suppose for contradiction that $r \geq \left(1 + \frac{C'}{\sqrt{k}}\right) q$. Note that for $\varepsilon := \frac{C'}{\sqrt{k}} \leq \frac{C'}{\sqrt{k_0}} \leq 1$, Lemma 2 guarantees a set of $k' \leq C/\varepsilon^2 = C\frac{k}{C'^2} = k$ pieces can be replaced by fewer pieces from $\mathcal{Q}$. A contradiction to the fact that $\mathcal{R}$ is a k-local optimum. Hence, $r < \left(1 + \frac{C'}{\sqrt{k}}\right) q$. ◀

2.2 Polygons with Small Diameter

In this section, we describe a PTAS for small covers of polygons that intersect at most D squares of the integer grid. In order to obtain a PTAS, it is sufficient by Corollary 4 to show that, for any fixed k, a k-local optimum can be found in polynomial time. The strategy is as follows: we start with some small cover of P, and then test every set of k pieces in that cover to see if it can be replaced by a smaller set. If such a swap is possible, then we perform the swap and start over with the smaller cover. This repeats until no swap can be found.

The polygon P with n vertices intersects at most D integer grid squares, so we can find an initial cover with at most Dn squares–note that the intersection of a unit square with P has at most n connected components as each side of P is incident to at most one connected component. So finding a k-local optimum requires at most a polynomial (in n and D) number of swaps, because the number of pieces decreases in each step. It remains to show how to find a swap, or determine that none exists.

Given a set of complete small pieces (*not* necessarily a cover) in P, we define a corresponding "combinatorial structure". The combinatorial structure is determined by:

- The line arrangement containing edges of P and edges of the squares bounding the pieces.
- For each bounding square S, the connected component of $P^\circ \cap S$ defining the piece (indicated with a number).

Let $\mathcal{L}$ be the set of lines containing edges of P or edges of a bounding square. For each $(\ell_1, \ell_2, \ell_3) \in \mathcal{L}^3$, the first piece of information says on which side of ℓ_3 the intersection of ℓ_1 and ℓ_2 occurs, or if the intersection is contained in ℓ_3. (This is the orientation of the triangle formed by (ℓ_1, ℓ_2, ℓ_3) or the order type of the dual of the lines.) The slope of each line in $\mathcal{L}$ is

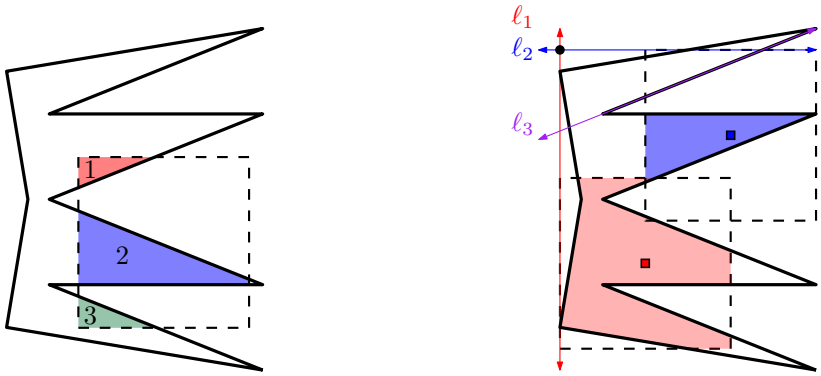

Figure 3 The combinatorial structure of a set of complete small pieces. Left: The connected components of $P^\circ \cap S$ are numbered. Right: The centers of the bounding squares of the two pieces are marked with squares. The intersection of lines ℓ_1 and ℓ_2 lies above ℓ_3..

fixed, so all the information about the arrangement of $\mathcal{L}$ can be described by equalities and (strict) inequalities that are linear in the coordinates of the bounding squares. For example, if ℓ_1 is a vertical line containing the left edge of a square with center (x_i, y_i), ℓ_2 is a horizontal line containing the top edge of a square with center (x_j, y_j), and $\ell_3 = \{(x, y) : \alpha x + \beta y = \gamma\}$ is a line containing an edge of P, then the combinatorial data contains one of:

- $\alpha(x_i - \frac{1}{2}) + \beta(y_j + \frac{1}{2}) = \gamma$,
- $\alpha(x_i - \frac{1}{2}) + \beta(y_j + \frac{1}{2}) < \gamma$, or
- $\alpha(x_i - \frac{1}{2}) + \beta(y_j + \frac{1}{2}) > \gamma$,

specifying on which side of ℓ_3 the intersection $(x_i - \frac{1}{2}, y_j + \frac{1}{2})$ of ℓ_1 and ℓ_2 occurs; see Figure 3.

A realization of a combinatorial structure is a set of pieces satisfying the constraints. Since the constraints are linear, the set of realizations of any fixed combinatorial structure is a convex set. Note that the combinatorial data does not ensure that a realization corresponds to a cover of the polygon P. For instance, it is easy to make an example where all the squares are placed almost on top of each other, while big regions of P remain uncovered. Given just the combinatorial data of a (hypothetical) arrangement, we can use linear programming (LP) to check if it can actually be realized by some set of small pieces. What we really want to be able to check is if *any* such realization corresponds to a cover of P. The following lemma says that we only need to check a single realization.

▶ **Lemma 5.** *For a given combinatorial structure, either every or no realization is a cover.*

Proof. Let A and B be realizations of a combinatorial structure with m squares. We show that A is a cover if and only if B is a cover. Suppose that A is a cover. We continuously move the bounding squares from their positions in A to their positions in B, along straight lines in the $2m$-dimensional coordinate space. If, during this process, the arrangement stops being a cover, then one of the following cases occurs: (a) part of a polygon edge is uncovered, (b) part of the interior is uncovered, or (c) a piece becomes disconnected. The cases are illustrated in Figure 4. We consider a snapshot right after the first point becomes uncovered. In case (a), the uncovered region is a triangle (or a rectangle). Note that the intersection of a right angle of this region has changed sides with respect to the polygon side independent of whether both or just one involved square is moving. In case (b), the uncovered region is a rectangle and its appearance is due to two squares that become disjoint due to the movement of at least one square. In case (c), a side of a moving square now intersects a side of the polygon which was previously disjoint. Consequently, in each case some of the combinatorial

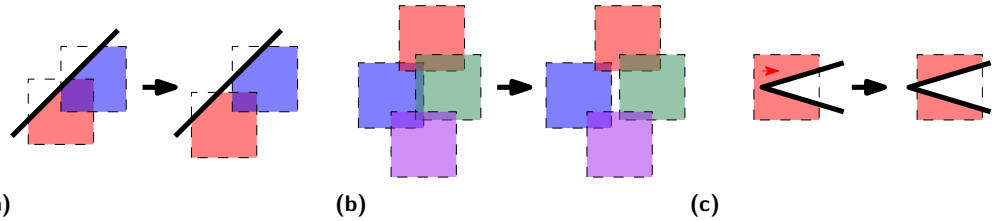

Figure 4 If the bounding squares are moving continuously, then there are three ways that a covering might stop being valid. Any of these change the arrangement of lines in $\mathcal{L}$. (a) part of an edge stops being covered. (b) part of the interior stops being covered. (c) a piece ceases to be connected.

data is changing. Since the set of realizations of a combinatorial structure is convex, we conclude that this doesn't happen. Since the arrangement forms a cover at every point in the motion, we conclude that B must be a cover.

By a symmetric argument, it is clear that if B is a cover, then A is a cover. ◀

Given a cover with complete pieces, we want to check if some set of k of its pieces can be swapped for a set of $k-1$ pieces. This is accomplished by the next lemma.

▶ **Lemma 6.** *Let P be a polygon with n vertices and consider a small cover $\mathcal{R}$ of P with m pieces. For each fixed k, we can determine in $\mathcal{O}_k((n+m)^{O(k)})$ time whether any set of k of the pieces from the cover can be replaced by $k-1$ small pieces (not necessarily from the cover) to form a cover with fewer pieces.*

Proof. For each of the $\binom{m}{k}$ k-subsets of $\mathcal{R}$, we remove it and test each of the ways of adding $k-1$ squares to the combinatorial arrangement. We need to argue that for any fixed k, there are only polynomially many ways of adding $k-1$ squares to a combinatorial structure with m squares. This corresponds to adding $2k$ vertical lines and $2k$ horizontal lines to the arrangement. A line arrangement with ℓ lines contains at most $O(\ell^2)$ intersection points. Thus there are $O(\ell^2)$ combinatorially different ways to add a new line with a fixed slope. A combinatorial structure with m squares has $n+2m$ lines. So the number of ways of adding the new $4k$ lines is $\mathcal{O}_k((n+m)^{4k})$. The intersection of a square with P can have at most n connected components, so in total there are $\mathcal{O}_k((n+m)^{4k+1})$ ways of adding k squares to the arrangement. For fixed k, this is polynomial in n and m.

For each of these candidate combinatorial structures, we need to check whether it represents a valid covering. By Lemma 5, it suffices to find a single representative set of pieces (if one exists). Each element of the combinatorial data is a linear constraint involving the coordinates of the squares and either an equality or a strict inequality. We construct an LP instance from these linear constraints, adding a new variable t and replacing each strict inequality $\mathcal{C} > 0$ with $\mathcal{C} \geq t$. To test if a solution exists, we solve the LP instance in which the objective function is to maximize t. If there is no feasible solution with $t > 0$, then we conclude that there is no valid swap with this combinatorial structure. If we find a feasible solution with $t > 0$, then we check if this solution covers all of P. We do this by constructing the pieces explicitly and computing their union. If the union does not cover P, then we know that no arrangement with this combinatorial structure does. The only free variables in the LP instance are t and the $2(k-1)$ coordinates of the newly-added bounding squares. So in order to solve the LP instance, we can just check all of the $(n+m)^{\mathcal{O}(k)}$ basic solutions. This takes (strongly-)polynomial time for a fixed k.

We should check that this procedure finds a swap if one exists. Suppose that there is a set of k pieces in the initial cover that can be swapped with $k-1$ pieces in order to obtain a new cover $\mathcal{R}'$. The cover $\mathcal{R}'$ has a combinatorial structure, which is one of the candidate structures tested by our procedure. Furthermore, $\mathcal{R}'$ is a realization of this structure with the positions of the $m-k$ old pieces being the same as in $\mathcal{R}$, so such a realization exists, and the linear programming step will find one (but the realization found is not necessarily the same one as $\mathcal{R}'$). Since $\mathcal{R}'$ is a cover, by Lemma 5, the realization found will be a cover. ◀

▶ **Theorem 7.** *There is an algorithm that, given a polygon P and a parameter ε, computes a $(1+\varepsilon)$-approximation of the optimal small cover of P. The algorithm runs in time $(Dn)^{poly(\frac{1}{\varepsilon})}$, where D is the number of integer grid squares intersecting P.*

Proof. Fix k such that $\frac{C'}{\sqrt{k}} \leq \varepsilon$, and $k \geq C'$, where C' is the constant from Corollary 4.

We can construct a cover of P with small pieces by overlaying P with the integer grid and taking the connected components of each intersection. Recall that the intersection of a unit square with P has at most n connected components. Hence, we obtain an initial solution with at most Dn pieces, where D is the number of integer grid squares intersecting P. We then check if this cover is a k-local optimum using the procedure from Lemma 6.

If this cover is not a k-local optimum, then we perform the swap and repeat the process until no more valid swaps remain. Every swap decreases the total number of pieces by 1, so the algorithm terminates after at most Dn steps, and when it does we have obtained a cover such that no set of k pieces can be swapped for a strictly smaller set of pieces. By Corollary 4, this solution has at most $(1+\varepsilon)$-times as many pieces as an optimal solution. It is clear by Lemma 6 that the entire process takes time at most $(Dn)^{\mathrm{poly}(\frac{1}{\varepsilon})}$. ◀

The algorithm in Theorem 7 runs in polynomial time on real RAM, but the bit-complexity of the coefficients can grow by a constant factor after each swap, potentially leading to exponential coefficient growth. In order to obtain an algorithm that runs in strongly-polynomial time, we can adjust the coordinates after each swap. Let m be the number of squares of the cover. We consider the LP instance L corresponding to the combinatorial structure of the cover. Here, L has two variables for all m squares, not just the new squares introduced in the latest swap. The cover that we found is a feasible solution $x \in \mathbb{R}^{2m+1}$ to L. There are two coordinates in x for each square and one for the value t in the strict inequalities. We want to find a *basic* feasible solution to L, i.e., a vertex of the polyhedron defined by the constraints, because the bit-complexity of the variables in such a solution is polynomial in n, D and the bit-complexity of the coordinates of vertices of P. The value of t (the variable for strict inequalities) should still be positive in the new solution.

This can be done in strongly-polynomial time. We can write L such that all constraints have form $\mathcal{C} \geq 0$. We start by evaluating each constraint at the feasible solution x. A constraint $\mathcal{C} \geq 0$ is *tight* if $\mathcal{C}(x) = 0$. Let $\mathcal{D}$ be the set of tight constraints and let $\mathcal{H} = \{y \in \mathbb{R}^{2m+1} \mid \forall \mathcal{C} \in \mathcal{D} : \mathcal{C}(y) = 0\}$. In other words, $\mathcal{H}$ is the affine subspace that causes the tight constraints to be tight. The solution x is a basic feasible solution if $\mathcal{H}$ has dimension 0. Otherwise, we can find a direction $v \in \mathrm{Vec}(\mathcal{H})$ such that t does not decrease when moving in direction v. We move from x in direction v until an additional constraint becomes tight.

We obtain a new feasible solution x' to L, where t at x' is at least as large as t at x. Furthermore, the dimension of $\mathcal{H}'$, the subspace of tight constraints corresponding to x', has decreased by at least 1 compared to $\mathcal{H}$. So we can repeat this process to find a basic feasible solution with the required properties. The number of arithmetic operations depends only on the number of variables and the number of constraints, so this process runs in strongly polynomial time. The bit-complexity of a basic feasible solution is polynomial in n, D and the bit-complexity of the coordinates of vertices of P. In particular, it does not increase with the number of swaps performed by the algorithm in Theorem 7.

2.3 Polygons with Large Diameter

In this section, we assume the existence of an algorithm $\mathcal{A}$ providing a $(1+\varepsilon)$-approximation for a small cover of a polygon P with diameter at most $O(n/\varepsilon)$. We show that from such an algorithm, one can design an algorithm $\mathcal{A}'$ that for an arbitrary polygon P, for which the size of a minimum cover of P is OPT, can find a value λ such that $\text{OPT} \leq \lambda \leq (1+\varepsilon_0)\text{OPT}$, where $\varepsilon_0 \leq \alpha\varepsilon$ for some universal constant α. The algorithm also provides an implicit description of a cover with this approximation guarantee. Recall that we work in the real RAM model. In particular, we can perform basic arithmetic operations like addition, multiplication, and division on the coordinates of the corners of the polygon in constant time.

▶ **Theorem 8.** *Assume there exists an algorithm $\mathcal{A}$ which for any polygon P with n vertices and diameter $O(n/\varepsilon)$ finds a $(1+\varepsilon)$-approximate minimum cover of P in time $f(n,\varepsilon)$. Then there exists an algorithm $\mathcal{A}'$ that for any n-vertex polygon P returns a value λ_P with $OPT \leq \lambda_P \leq (1+\alpha\varepsilon)OPT$, where OPT is the size of a minimal cover of P with small pieces and α is a sufficiently large universal constant. The runtime of $\mathcal{A}'$ is $f(\alpha n,\varepsilon)\cdot poly(n/\varepsilon)$. The algorithm also produces an implicit description of a $(1+\alpha\varepsilon)$-approximate cover. For any query point $q \in P$, the algorithm can in time $O(poly(n/\varepsilon)+f(4,\varepsilon))$ return all pieces in the cover containing q.*

▶ **Corollary 9.** *There is an algorithm that, given a polygon P and a parameter $0<\varepsilon<1$, computes a $(1+\varepsilon)$-approximation to the number of pieces in an optimal small cover of P. The algorithm runs in time $(n/\varepsilon)^{poly(1/\varepsilon)}$.*

The algorithm also produces an implicit description of a $(1+\varepsilon)$-approximate cover. For any query point $q \in P$, the algorithm can in time $O(poly(n/\varepsilon)+(1/\varepsilon)^{poly(1/\varepsilon)}))$ return all pieces in the cover containing q.

Proof. Use Theorem 8 with $\mathcal{A}$ being the algorithm of Theorem 7 with $D = O((n/\varepsilon)^2)$. ◀

We now sketch the idea of the reduction. We first argue that there is a set of $k = O(n)$ disjoint "large" *corridors* $\mathcal{C} = \{C_1,\ldots,C_k\}$ with each $C_i \subset P$ such that we can solve the covering problem on $C_1,\ldots,C_k$, and $P \setminus \bigcup \mathcal{C}$ separately. Each corridor C_i is constructed to have a pair of sides that are either both vertical or both horizontal and are of distance $\geq 1/\varepsilon$ apart. The remaining two sides are both contained in an edge of P. Finally, each C_i is essentially picked to be of maximum volume satisfying these properties.

We will show that the union of $(1+O(\varepsilon))$-approximate covers of $C_1,\ldots,C_k$ and $P \setminus \bigcup \mathcal{C}$ yields a $(1+O(\varepsilon))$-approximate cover of P. For $P \setminus \bigcup \mathcal{C}$, the diameter of each connected component is at most n/ε, so we can use the algorithm $\mathcal{A}$ for bounded diameter polygons. The corridors are more tricky as the size of their optimal solutions cannot be bounded in terms of n, so for those, we maintain an implicit solution. Denote by a_i and p_i the area and perimeter of C_i. If $a_i \geq p_i/\varepsilon$, one can show that the intersection C_i with the integer grid gives an $1+O(\varepsilon)$ approximate cover, and this solution is easy to describe implicitly. The tricky part is handling a corridor C_i with $a_i \leq p_i/\varepsilon$ where C_i is "long" and "skinny". Suppose that C_i has a pair of vertical edges (the horizontal case is similar). In this case, we partition C_i further into corridor sections $(S_i^j)_{j=1}^t$, all having a pair of vertical edges and width $1/\varepsilon$. We then again argue that it suffices to solve the problem on each S_i^j with an approximation ratio of $1+O(\varepsilon)$. Unfortunately, we cannot afford to find a solution for each S_i^j separately, but we can argue about a certain monotonicity of sizes of optimal covers of the S_i^j. Namely, after appropriate translations, it is either the case that $S_i^j \subset S_i^{j+1}$ for all j or it is the case that $S_i^j \supset S_i^{j+1}$ for all j. In the former case, we show that the size of the optimal cover of S_i^j is at most the size of the optimal cover of S_i^{j+1} and a similar claim holds in the latter

case. Based on these properties, and defining $\ell = \varepsilon^4 t$, we show that it suffices to approximate the minimum covers of $S_i^{\ell}, S_i^{2\ell}, \dots S_i^{\lfloor t/\ell \rfloor \ell}$. For any S_i^j with $k\ell \le j < (k+1)\ell$, for some k, we can then use the size of the approximate cover of $S_i^{(k+1)\ell}$ as an upper bound on the size of the optimal cover of S_i^j. This only requires us to run $\mathcal{A}$ on the $t/\ell = O(1/\varepsilon^4)$ instances of the form $S_i^{(k+1)\ell}$. While for some values of k, this approach might not give $1 + O(\varepsilon)$ approximation to S_i^j, the monotonicity ensures that for most values of k, the approximation is good, and suffices to give a final approximation guarantee of $1 + O(\varepsilon)$.

2.4 Equivalence of Small Covers and Partitions

The proof of Lemma 3 lets us show the equivalence of small covering and partitioning – a result which may be interesting in its own right.

▶ **Theorem 10.** *For any polygon P, possibly with holes, optimal small covers and small partitions have the same number of pieces.*

Proof. Consider an optimal small cover $\mathcal{Q}$ consisting of complete small pieces; see Figure 5.

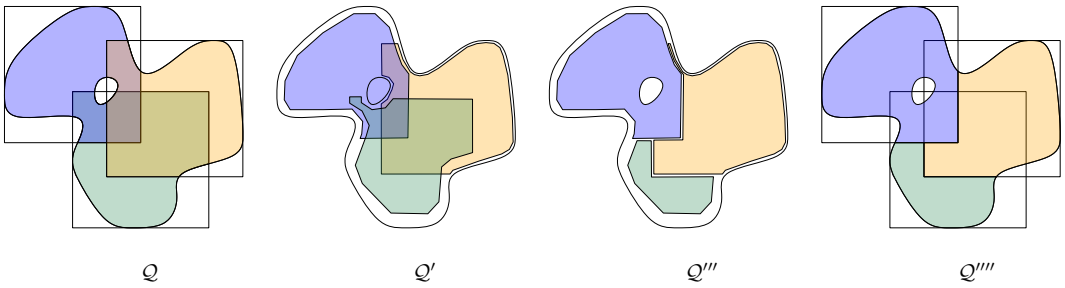

Figure 5 Steps in the proof of Theorem 10.

Consider the overlay of $\mathcal{Q}$ and choose a point in the interior of each cell which is also in P. Construct a set of proper non-piercing regions $\mathcal{Q}'$ as in Lemma 3. As described in the proof, the pieces in $\mathcal{Q}'$ are subsets of those in $\mathcal{Q}$, except that some holes of P have been filled. Importantly, the boundaries of the pieces in $\mathcal{Q}'$ are just slight perturbations of those in $\mathcal{Q}$.

The following process of *lens bypassing* is described in [34, Section 4]. Since $\mathcal{Q}'$ are non-piercing, any intersection $Q_i' \cap Q_j'$ consists of a set of *lenses*, which are regions bounded by one interval of the boundaries of each set Q_i' and Q_j'. In the process of lens bypassing, we consider an inclusion-wise minimal lens ℓ, say in the intersection $Q_i' \cap Q_j'$. Let the boundary of ℓ be $\gamma_i \cup \gamma_j$, where γ_i and γ_j are on the boundaries of Q_i' and Q_j', respectively. We change the boundary of Q_i' by replacing γ_i by a curve following γ_j (but slightly outside ℓ to avoid non-proper intersections). This effectively removes ℓ from Q_i'. It is shown [34, Lemma 4.6] that the operation results in a set of regions that are also non-piercing. Repeating the process results in a set $\mathcal{Q}''$ of pairwise disjoint regions that are subsets of the original regions $\mathcal{Q}'$ and still contain the points X.

Consider any hole H of P, i.e., H is a bounded connected component in the complement of P. Recall that in the pieces $\mathcal{Q}'$, the hole H might have been filled in some of them, so H might also be filled in some of the pieces $\mathcal{Q}''$. In our modifications from Q to Q'', we have only ever made modifications along curves that are disjoint from H. Hence, for each piece $Q_i'' \in \mathcal{Q}''$, we either have $H \subset Q_i''$ (H is filled) or $H \cap Q_i'' = \emptyset$ (H is still a hole of Q_i'' or outside the outer boundary). We can remove H from all pieces where it is filled, thus reintroducing H as a hole, and this will not break connectivity. We do so for all holes of P.

We end up with regions $\mathcal{Q}'''$ that are pairwise disjoint and all contained in P. Furthermore, the regions $\mathcal{Q}'''$ still cover P in the sense that each region in the overlay of the original cover $\mathcal{Q}$ is contained in a region in the overlay of $\mathcal{Q}'''$, except that the boundary might be slightly perturbed. We can thus create pieces $\mathcal{Q}''''$ analogous to $\mathcal{Q}'''$ using the original boundaries, and these pieces will cover all of P and still be pairwise interior-disjoint. We therefore obtain a small partition of P. ◀

3 Hardness for Small-Cover in 3 dimensions

In this section, we give a gap-preserving reduction from Set-Cover to 3-dimensional small cover. The best-known inapproximability result for Set-Cover is the following:

▶ **Theorem 11.** *(Dinur and Steurer [22]) For any $\alpha > 0$, it is NP-hard to approximate an instance of Set-Cover of size n to within a factor of $(1-\alpha)\ln(n)$.*

Our results show that Small-Cover in 3 dimensions is no easier to approximate than Set-Cover.

▶ **Theorem 12.** *Let I be an instance of Set-Cover where the universe is $U = \{1, \ldots, n\}$ and the sets are $\mathcal{S} = \{S_1, \ldots, S_m\}$. Then we can construct in polynomial time a simple polyhedron $P \subseteq \mathbb{R}^3$ with $\mathcal{O}\left(n + \sum_i |S_i|\right)$ vertices such that P has a unit cube cover of size $k+5$ if and only if U can be covered by k of the sets in $\mathcal{S}$. The vertices of P have bit-complexity at most $\mathcal{O}(\log(nm))$ and P is contained in a box of size $1 \times 2 \times 3$.*

Proof. For simplicity, we will scale the coordinates by a factor of 8. So the polyhedron P will have a cover with pieces that fit inside $8 \times 8 \times 8$-cubes. We will construct P from a union of flat plane pieces, but it can easily be thickened to obtain a non-degenerate polyhedron.

To construct P, we start by making layers of *hook* pieces. There is one type of hook piece for each of the m sets in $\mathcal{S}$. The hook piece for S_j is shown in Figure 6a. For each $i \in S_j$, we place a copy of the corresponding hook piece at z-coordinate $\frac{mi+j}{mn}$.

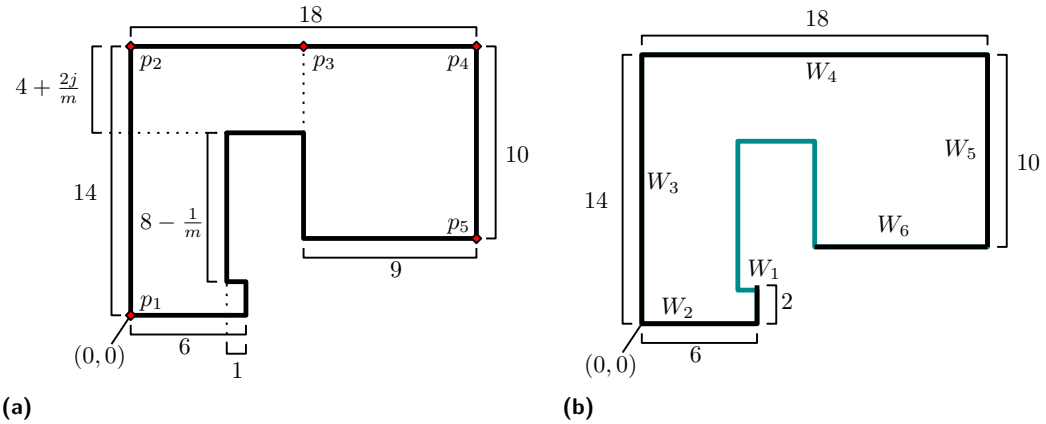

Figure 6 (a) Specification of a hook piece. The (x, y)-positions of the points p_1 through p_5 are also shown. (b) The segments marked show the wall pieces that connect the hook pieces together. Segments W_1 through W_5 extend to cover the height of the entire figure, while segment W_6 is extended over n disjoint intervals. The outline of a hook piece is shown in green.

The hook pieces are connected by a wall, which is formed by the segments marked W_1 through W_5 in Figure 6b extruded to cover the z-coordinates $[\frac{m+1}{mn}, \frac{(m+1)n}{mn}]$. Additionally, the segment marked W_6 is extruded to cover the z coordinates $[\frac{mi+1}{mn}, \frac{(m+1)i}{mn}]$ for each $i \in U$. The entire construction is illustrated in Figure 7.

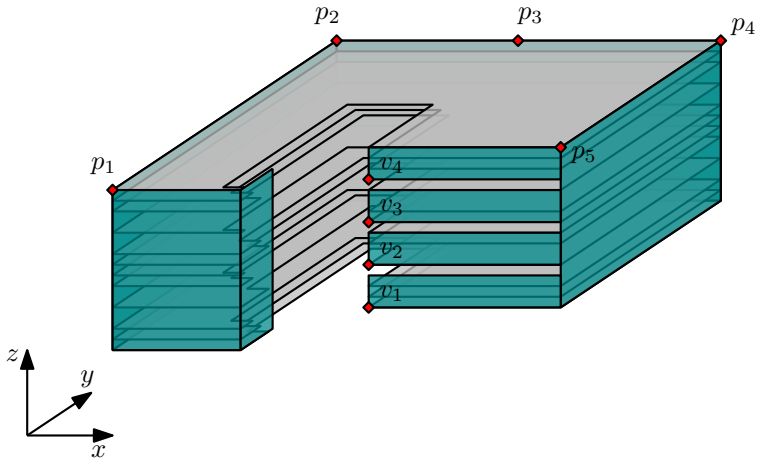

Figure 7 A rendering of the polyhedron P. The specific instance shown corresponds to $n = 4$, $m = 4$, $S_1 = \{1, 2, 3\}$, $S_2 = \{1, 3, 4\}$, $S_3 = \{1, 2, 4\}$, and $S_4 = \{2, 3, 4\}$. The hook pieces are shown in gray and the wall pieces are shown in green. The vertical scale is exaggerated for clarity.

Suppose that U can be covered by k of the sets in $\mathcal{S}$. We want to show that P can be covered with $k + 5$ pieces that fit inside an $8 \times 8 \times 8$-unit cube. First note that the 5 cubes shown in Figure 8 are sufficient to cover most of P.

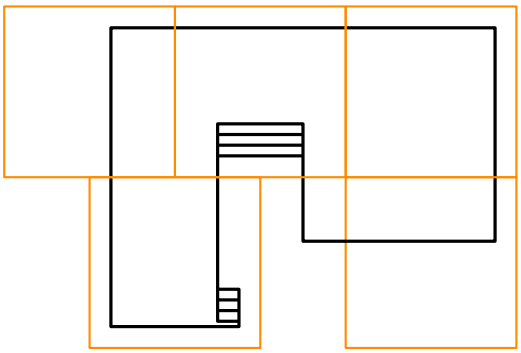

Figure 8 These 5 cubes cover most of P.

The intersection of P with each of these cubes is connected. There are n connected chunks remaining uncovered, corresponding to the n elements of U. Let Q_i be the connected part of the uncovered region containing v_i. For each S_j, there is a connected piece containing $\bigcup_{i \in S_j} Q_i$ that fits inside the cube $[4, 12] \times [2 - \frac{4j-1}{2m}, 10 - \frac{4j-1}{2m}] \times [0, 8]$, as illustrated in Figure 9a and 9b. So if U can be covered by k of the S_j, then P can be covered by $k + 5$ pieces.

Now suppose that P can be covered by $k + 5$ pieces. We first designate five points $p_1, \ldots, p_5$ (as shown in Figure 6a and 7). No $8 \times 8 \times 8$ cube can contain more than 1 of these points, so there are at least five pieces in the covering, one for each of these points. These pieces also cannot contain any of the points $v_1, \ldots, v_n$, so the remaining pieces must cover these points.

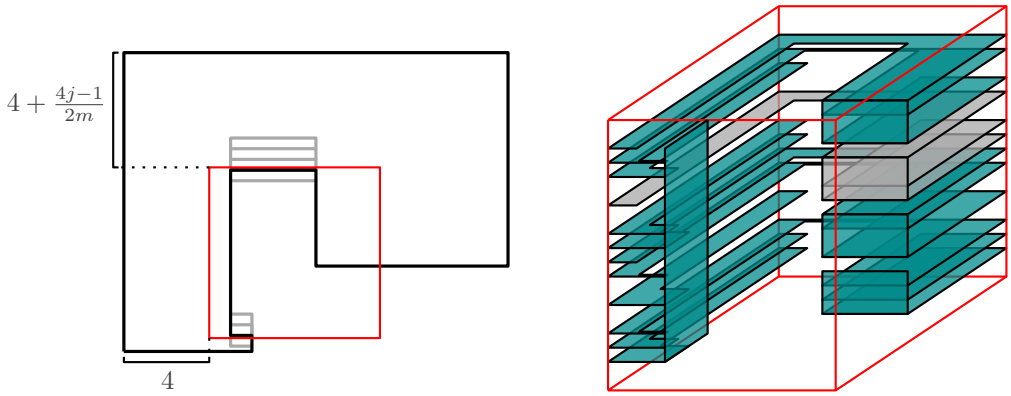

Figure 9 (a) The intersection of the cube $[4, 12] \times [2 - \frac{4j-1}{2m}, 10 - \frac{4j-1}{2m}] \times [0, 8]$ with a hook piece corresponding to S_j connects some of the Q_i. (b) A 3-dimensional view of the intersection of P with the cube $[4, 12] \times [2 - \frac{4j-1}{2m}, 10 - \frac{4j-1}{2m}] \times [0, 8]$. Shown is the example from Figure 7 with $j = 3$. The green part is connected and contains Q_1, Q_2 and Q_4. The gray part contains Q_3, but cannot be connected to the green part without leaving the cube.

Suppose that some piece Q in the cover contains $\{v_i : i \in S\}$ for some set $S \subseteq U$. We want to show that $S \subseteq S_j$ for some j. By assumption, each $i \in U$ is in some S_j, so WLOG suppose $|S| \geq 2$. Let $i, \ell \in S$ with $i \neq \ell$. So Q contains a path γ from v_i to v_ℓ. No part of the walls W_3 through W_5 is close enough to v_i to be contained in Q, so γ must connect through W_1 or W_2.

In order to get from v_i to W_1 or W_2, γ must go through some hook piece, say this hook piece corresponds to S_j. Such a connection contains y coordinates covering the interval $[2 - \frac{2j}{m}, 10 - \frac{2j-1}{m}]$ (see Figure 9a and 9b). Since Q is contained in an $8 \times 8 \times 8$-unit cube, it cannot contain points with y-coordinates covering $[2 - \frac{2j'}{m}, 10 - \frac{2j'-1}{m}]$ for any $j' \neq j$. So any v_ℓ contained in Q is connected to v_i through a hook piece corresponding to S_j. This is only possible if $\ell \in S_j$. So $S \subseteq S_j$.

Thus, U can be covered by k of the S_j if and only if P can be covered by $k + 5$ connected pieces each fitting inside an $8 \times 8 \times 8$-unit cube.

If we thicken P slightly, we obtain a simple (topologically ball-shaped) polyhedron. To see this, we observe that P is contractable. Indeed, each hook piece (strongly) deformation retracts onto walls W_1 through W_6. So all of the hook pieces deformation retract onto the wall pieces. Since the union of the wall pieces is contractable, P is contractable. ◀

We note that it is possible to trim the cover of size $k + 5$ described in the proof in order to obtain a partition, so we get hardness for both Small-Cover and Small-Partition. In fact, it is easy to see that the problems are equivalent in 3 and higher dimensions: If $Q_1, \ldots, Q_q$ form a cover for a polyhedron P, we can define $Q'_i = Q_i \setminus \bigcup_{j=1}^{i-1} Q_j$ for $i = 1, \ldots, q$. Then the pieces Q'_i are pairwise disjoint and also cover P, but they may be disconnected. However, if Q'_i is disconnected, we can connect the parts by thin tunnels, staying in the original piece Q_i so we don't violate the size constraint. These tunnels are removed from the other pieces Q'_j, and choosing them sufficiently thin, they will not disconnect any piece.

▶ **Corollary 13.** *In 3 dimensions, for any $\alpha > 0$, it is NP-hard to approximate Small-Cover and Small-Partition better than $(1 - \alpha) \ln(n)$, where n is the number of bits needed to describe the input polyhedron. This holds even when the polyhedron is simple and contained in a box of size $1 \times 2 \times 3$.*

Abstract

According to a conjecture of Pach, there are $O(n)$ tangent pairs among any family of n Jordan arcs in which every pair of arcs has precisely one common point and no three arcs share a common point. This conjecture was proved for two special cases, however, for the general case the currently best upper bound is only $O(n^{7/4})$. This is also the best known bound on the number of tangencies in the relaxed case where every pair of arcs has *at most* one common point. We improve the bounds for the latter and former cases to $O(n^{5/3})$ and $O(n^{3/2})$, respectively. We also consider a few other variants of these questions, for example, we show that if the arcs are *x-monotone*, each pair intersects at most once and their left endpoints lie on a common vertical line, then the maximum number of tangencies is $\Theta(n^{4/3})$. Without this last condition the number of tangencies is $O(n^{4/3}(\log n)^{1/3})$, improving a previous bound of Pach and Sharir. Along the way we prove a graph-theoretic theorem which extends a result of Erdős and Simonovits and may be of independent interest.

Acknowledgements We are grateful to Rom Pinchasi for many helpful discussions on the problems studied in this paper. In particular he has suggested most of the ingredients of the proofs of Theorems 7 and 5 and later found out that similar results were already proved by Pach and Sharir [23]. We thank Balázs Patkós for his comments about Theorem 9. For the proof of Theorem 10 we used some back and forth interaction with Google's Large Language Model "Gemini" (`https://gemini.google.com/`).

1 Introduction

Arrangements of curves play an important role in Computational and Combinatorial Geometry with applications in domains such as robotics, computer graphics, computer vision, and combinatorial optimization [24]. Many interesting problems in these areas can be phrased as determining the maximum number of *tangencies* among curves under various restrictions. For example, occasionally, analyzing the complexity of an arrangement of curves boils down to estimating the number of faces of size two [5]. Such faces can often be perturbed into tangency points. Another example is Erdős's famous *Unit Distance Problem* which asks for the maximum number of pairs of points that are at unit distance from each other among n distinct points in the plane. This is equivalent to asking for the maximum number of tangencies among n unit circles in the plane.

Throughout this paper we consider planar curves, that is, Jordan arcs, and assume that every two curves intersect in a finite number of points. A family of curves is *k-intersecting* if every two curves in it intersect in at most k points. Two curves are said to be *tangent* or *touching* if they have precisely one common point and this point is not a crossing point.[1] We will mainly consider the maximum number of tangencies among families of 1-intersecting curves. Such families are sometimes called *pseudo-segments*.[2] A family of curves is *precisely* 1-intersecting if every pair of curves has precisely one common point (either a crossing or a tangency point). We will always assume that no three curves share a common point, for otherwise, it is possible to have one point at which every pair of curves is tangent. Therefore, the number of tangent pairs is equal to the number of tangency points.

János Pach proposed the following nice conjecture.

▶ **Conjecture 1** (Pach [20]). *Every family of n precisely 1-intersecting planar curves in which no three curves share a common point admits $O(n)$ tangencies.*

Györgyi et al. [14] proved this conjecture for the very special case where the endpoints of the curves lie within a constant number of cells of their arrangement. Conjecture 1 was also settled by the authors for *x-monotone* curves [4]. Recall that a curve is *x-monotone* (resp., *bi-infinite* x-monotone) if it is the graph of some continuous function over some closed interval (resp., over $\mathbb{R}$). For arbitrary families of (precisely) 1-intersecting curves a non-trivial $O(n^{7/4})$ bound on the number of tangencies follows from a result of Keszegh and Pálvölgyi [17]:

▶ **Theorem 2** ([17]). *Every family of n k-intersecting planar curves admits $O_k\left(n^{2-\frac{1}{k+3}}\right)$ tangencies.*

We improve this bound for (precisely) 1-intersecting families as follows.

▶ **Theorem 3.** *Every family of n 1-intersecting planar curves admits $O(n^{5/3})$ tangencies.*

▶ **Theorem 4.** *Every family of n precisely 1-intersecting planar curves admits $O(n^{3/2})$ tangencies.*

Note that the maximum number of tangencies among n (x-monotone) 1-intersecting curves is $\Omega(n^{4/3})$. Indeed, it is not hard to construct a family admitting that many tangencies based on the famous construction of Erdős (see [21]) of n lines, n points and $\Theta(n^{4/3})$ point-line incidences (see the proof of Theorem 6).

For x-monotone 1-intersecting curves we have the following bound.

▶ **Theorem 5.** *Every family of n 1-intersecting x-monotone planar curves admits $O\left(n^{4/3}(\log n)^{1/3}\right)$ tangencies.*

This bound almost matches the above-mentioned $\Omega(n^{4/3})$ lower bound and improves by an $O\left((\log n)^{1/3}\right)$ factor a previous bound that follows from a result of Pach and Sharir [23]. For so-called *grounded* x-monotone 1-intersecting curves we have an asymptotically tight bound.

▶ **Theorem 6.** *The maximum number of tangencies among n x-monotone 1-intersecting planar curves whose left endpoints lie on a common vertical line is $\Theta(n^{4/3})$.*

---

[1] Here we follow the definition in, e.g., [22]. In other papers, e.g., [9], two curves may cross and also touch each other (at different points). However, for 1-intersecting curves the two definitions coincide.

[2] However, the term "pseudo-segments" is somewhat ill-suited in the context of tangencies, since straight-line segments can only be tangent at an endpoint.

The proofs of Theorems 5 and 6 rely on the following bounds for bi-infinite curves.

▶ **Theorem 7.** *The maximum number of tangencies among n bi-infinite x-monotone 1-intersecting curves is $\Theta(n \log n)$. In case of precisely 1-intersecting curves the maximum number of tangencies is $n-1$.*

The bound for bi-infinite x-monotone 1-intersecting curves was already proved by Pach and Sharir [23] using different and less elementary arguments. The following table summarizes all the above-mentioned results.

Table 1 Bounds on the maximum number of tangencies among n 1-intersecting curves.

	x-monotone	arbitrary
bi-infinite 1-intersecting	$\Theta(n \log n)$ [23] (Thm 7)	–
bi-inf. precisely 1-inters.	$n-1$ (Thm 7)	–
grounded 1-intersecting	$\Theta(n^{4/3})$ (Thm 6)	$\Omega(n^{4/3})$, $O(n^{3/2})$ (Cor 18)
1-intersecting	$\Omega(n^{4/3})$ [23], $O(n^{4/3}(\log n)^{1/3})$ (Thm 5)	$\Omega(n^{4/3})$, $O(n^{5/3})$ (Thm 3)
precisely 1-intersecting	$\Theta(n)$ [4]	$\Omega(n)$, $O(n^{3/2})$ (Thm 4)

1.1 A graph-theoretic theorem

For a graph H let $\mathrm{ex}(n, H)$ denote the maximum number of edges in an n-vertex *H-free* graph, that is, a graph which does not contain H as a subgraph. For a bipartite graph $H = (A \cup B, E)$ we denote by H^+ the graph we get by adding to H two new adjacent vertices a' and b' and connecting a' to every vertex in B and b' to every vertex in A. That is, $H^+ = ((A \cup \{a'\}) \cup (B \cup \{b'\}), E \cup \{(a', b')\} \cup \{(a', b) \mid b \in B\} \cup \{(a, b') \mid a \in A\})$. Erdős and Simonovits [10] proved the following result[3] when studying $\mathrm{ex}(n, Q_3)$, where Q_3 is the graph with 8 vertices and 12 edges that corresponds to a three-dimensional cube.

▶ **Theorem 8** ([10, Theorem 2])**.** *Let H be a bipartite graph with at least one edge such that $ex(n, H) = O(n^{2-\alpha})$ for some constant $0 \leq \alpha \leq 1$. Then $ex(n, H^+) = O\left(n^{2-\frac{\alpha}{\alpha+1}}\right)$.*

Observe that if $G = (A \cup B, E)$ is a bipartite H^+-free graph, then for every adjacent vertices $a \in A$ and $b \in B$ it holds that $G[(N_G(a) \setminus \{b\}) \cup (N_G(b) \setminus \{a\})]$ – the subgraph of G induced by their *open bineighborhood* – is H-free. Roughly speaking, if for every adjacent vertices in G the subgraph induced by their open bineighborhoods is not too dense because it is H-free, then it follows that G is also not too dense. We extend and refine Theorem 8 by showing that it holds whenever we have sparse subgraphs induced by open sub-bineighborhoods of pairs of (adjacent) vertices, be it for H-freeness or some other reason. To state the result we need the following definition: for a graph G and a nonnegative and nondecreasing function $f : \mathbb{R} \to \mathbb{R}$ we say that two vertices u and v have *f-sparse sub-bineighborhoods* if for every two disjoint subsets $U \subseteq N_G(u) \setminus \{v\}$ and $V \subseteq N_G(v) \setminus \{u\}$ it holds that $|E(G(U, V))| \leq f(|U \cup V|)$, where $G(U, V)$ is the bipartite subgraph $(U \cup V, \{(u, v) \in E(G) \mid u \in U \text{ and } v \in V\})$. For the proof of Theorem 3 we use the following theorem which extends Theorem 8 and may be of independent interest.

▶ **Theorem 9.** *Let G be a graph and let $f(n) = O(n^{2-\alpha})$ for some constant $0 \leq \alpha < 2$. If every pair of vertices in G has f-sparse sub-bineighborhoods, then $|E(G)| = O\left(|V(G)|^{2-\frac{\alpha}{\alpha+1}}\right)$. Moreover, if $\alpha \leq 1$, then it is enough that every pair of adjacent vertices has f-sparse sub-bineighborhoods for this bound to hold.*

[3] We present a simplified version of their result from which the original version can be easily deduced.

Clearly, Theorem 9 implies Theorem 8. Note that from Theorem 8 one can conclude by induction on t the classical Kővári-Sós-Turán Theorem [18] stating that an n-vertex $K_{t,t}$-free graph has $O_t\left(n^{2-\frac{1}{t}}\right)$ edges. It is a major open question in extremal combinatorics whether this bound is tight with positive answers only known for $t = 2$ and $t = 3$. Thus, the upper bound in Theorem 8 is tight for $\alpha = 1$ and $\alpha = \frac{1}{2}$, and, assuming that the bound of the Kővári-Sós-Turán Theorem is tight, for every $\alpha = \frac{1}{t}$ where t is a positive integer. Remarkably, for Theorem 9 we do have a matching lower bound for every $0 \leq \alpha \leq 1$.

▶ **Theorem 10.** *For every $0 \leq \alpha \leq 1$ there is a bipartite graph $G = (V, E)$ with $|E| = \Omega\left(|V|^{2-\frac{\alpha}{\alpha+1}}\right)$ edges such that every pair of vertices in G has f-sparse sub-bineighborhoods where $f(n) = O(n^{2-\alpha})$.*

1.2 Related work

Agarwal, Nevo, Pach, Pinchasi, Sharir and Smorodinsky [5] proved that any family of n pairwise intersecting x-monotone bi-infinite 2-intersecting curves admits at most $2n - 4$ tangencies. Families of 2-intersecting closed curves are called *pseudo-circles*. Erdős and Grünbaum [11] (see also [8, §7.1, Problem 14]) asked for the maximum number of tangencies among n pseudo-circles. An $\Omega(n^{4/3})$ lower bound for this problem follows from the many point-line incidences construction. The best upper bound is $O(n^{3/2})$ by a recent result of Janzer, Janzer, Methuku and Tardos [16]. As for pairwise intersecting pseudo-circles, a recent work with Damásdi, Pinchasi and Raffay [1] settled an old conjecture of Grünbaum [13] by showing that the maximum number of tangencies is $2n - 2$ in this case. A worse linear upper bound was proved in [5].

Ellenberg, Solymosi and Zahl [9] proved that any family of n plane algebraic curves of degree at most d admits $O_d(n^{3/2})$ tangencies.[4] If two curves may intersect an arbitrary number of times, then it is possible to have $\Omega(n^2)$ tangencies among n curves. Solving a conjecture of Richter and Thomassen it was shown by Pach, Rubin and Tardos [22] that if every pair of n closed curves intersects, then there are many more crossing points than tangency points. Specifically, they showed that if X denotes the crossing points and T denotes the tangency points, then $|X| = \Omega(|T|(\log\log n)^{1/8})$ and conjectured that $|X| = \Omega(|T|\log n)$.

Another line of research studies the number of tangencies between two families each consisting of disjoint curves. This problem was introduced by Pach, Suk and Treml [25] who attributed it to Ben-Dan and Pinchasi [6]. An upper bound of $O(n^{3/2})$ follows from an observation of Ben-Dan and Pinchasi and from the result of Janzer et al. [16], whereas a lower bound of $\Omega(n^{4/3})$ was shown by Keszegh and Pálvölgyi [17] using 2-intersecting curves. For two families of 1-intersecting curves a linear upper bound was proved by Pálvölgyi et nos [3]. For further related results on tangencies among curves and their applications see [5] and [22] and the references therein.

Organization

After introducing some notations and collecting a few useful lemmas in Section 2, we prove the results for arbitrary 1-intersecting curves in Section 3. Our results for x-monotone curves are presented and partially proved in Section 4. Finally, in Section 5 we prove Theorem 9 and discuss its further applications and connections to related graph theoretic results. Proofs that were omitted due to space limitation can be found in the full version of this paper [2].

[4] As mentioned before, their notion of tangency is a bit different and they actually bound the number of tangency points.

2 Notations and Tools

Recall that we assume that every two curves intersect at finitely many points and that no three curves intersect at a single point. It follows from the former assumption that we may also assume that the curves are drawn as polygonal chains. Indeed, given a set of curves $\mathcal{C}$, consider the plane graph G whose vertex set consists of the endpoints and intersection points of the curves in $\mathcal{C}$ and whose edge set consists of subcurves between consecutive vertices along the curves. By Fáry's Theorem [12] this planar graph can be embedded using straight-line edges and the same rotation system. Replacing every curve $c \in \mathcal{C}$ with the polygonal chain that consists of the edges in this embedding that correspond to edges of G that belong to c, we obtain a family of curves $\mathcal{C}'$ such that for every intersection (resp., tangency) point of two curves in $\mathcal{C}$ there is a unique intersection (resp., tangency) point between their corresponding curves in $\mathcal{C}'$, and vice versa.

For a set of curves $\mathcal{C}$ we denote by $G_{\mathcal{C}}$ the *tangency graph* of $\mathcal{C}$, that is, the graph whose vertex set is $\mathcal{C}$ and whose edge set consists of the tangent pairs of curves. By abuse of notation we sometimes interchange curves in $\mathcal{C}$ and their corresponding vertices in $G_{\mathcal{C}}$.

Let c be a curve and let p and q be two points on c. We denote by $c[p,q]$ the subcurve of c between these two points. For another curve c' that intersects c at a single point, we may also write, e.g., $c[c',q]$ instead of $c[c \cap c',q]$. If c is oriented, then we denote by c^- (resp., c^+) its starting (resp., terminating) point following its orientation. We also write $c[-,p]$ and $c[p,+]$ instead of $c[c^-,p]$ and $c[p,c^+]$, respectively. If c is an x-monotone curve and p is a point (not necessarily on c), then with some abuse of notation by writing, e.g., $c[p,+]$, we mean $c[\ell_p \cap c, +\infty)$, where ℓ_p is the vertical line through p. As usual, a round bracket indicates that an endpoint does not belong to the subcurve.

A family of x-monotone curves induces a *generalized trapezoidal partition* of the plane in the following way. From every point p which is an endpoint of a curve or an intersection point of two curves we draw a maximal vertical segment (possibly a ray or a line) that contains p and does not cross any other curve but the ones containing p. This yields a partition of the plane into *generalized trapezoids*.

▶ **Theorem 11** (Cutting Lemma for x-monotone curves [15, Proposition 2.11]). *For every family $\mathcal{C}$ of n x-monotone 1-intersecting curves and any $r > 1$ there is a subset of curves in $\mathcal{C}$ which induces a generalized trapezoidal partition of the plane into $O(r^2)$ generalized trapezoids each intersected by at most n/r curves from $\mathcal{C}$.*

We will also make use of the (asymmetric) Kővári-Sós-Turán Theorem and the recent tight bound of Janzer et al. [16] on the size of intersection-reverse sequences. The latter improves previous bounds by Marcus and Tardos [19] and by Pinchasi and Radoičić [26].

▶ **Theorem 12** (Kővári-Sós-Turán Theorem [18]). *For every $m,n,s,t \geq 1$ if $G = (A \cup B, E)$ is a bipartite graph such that $|A| = m$, $|B| = n$, and there are no s vertices in A and t vertices in B that form a complete bipartite subgraph $K_{s,t}$, then $|E| \leq (s-1)^{1/t} n m^{1-1/t} + (t-1)m$. In particular, $|E| = O_s(n^{2-1/t})$ when $m = n$ and $s \geq t$.*

▶ **Theorem 13** ([16]). *Let $A^1, \ldots, A^n$ be linear orders on some subsets of a set of n symbols such that no three symbols appear in the same order in any two distinct linear orders. Then $\sum_{i=1}^{n} |A^i| = O(n^{3/2})$.*

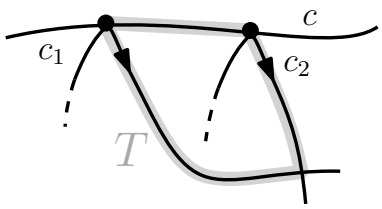

Figure 1 If c_1 and c_2 are grounded at ℓ and have the same tangency type with c, then $c_1[c,+]$ and $c_2[c,+]$ cannot cross.

3 Arbitrary 1-intersecting curves

In this section we consider 1-intersecting curves that are not necessarily x-monotone and prove Theorems 3 and 4. We begin with grounded curves. A family of curves $\mathcal{C}$ is *grounded* at a curve $c \notin \mathcal{C}$ if every curve in $\mathcal{C}$ has an endpoint on c.

▶ **Theorem 14.** *Let A be a family of curves grounded at a curve ℓ_A and let B be a family of curves grounded at a curve ℓ_B, such that all of these curves form a family of 1-intersecting curves, no curve in $A \cup \{\ell_A\}$ intersects ℓ_B and no curve in $B \cup \{\ell_B\}$ intersects ℓ_A. Then the number of tangent pairs $\{c_A \in A, c_B \in B\}$ is $O(|A \cup B|^{3/2})$.*

Proof. We refer to the curves in A as *red* curves and to the curves in B as *blue* curves. If a pair of curves of the same color touch, then we may redraw them locally such that they are disjoint, since we only care about red-blue tangencies. Thus, every pair of curves of the same color are either crossing or disjoint. Orient each curve in A away from ℓ_A and each curve in B away from ℓ_B. Then, there are four types of red-blue tangencies since every curve has a "left" side and a "right" side with respect to its orientation.

▶ **Proposition 15.** *Let c, c_1, c_2 and ℓ be four distinct curves such that: (1) $\{c, c_1, c_2, \ell\}$ is 1-intersecting; (2) c_1 and c_2 are grounded at ℓ and are oriented away from ℓ; (3) c is oriented and touches c_1 and c_2 at tangency points of the same type; and (4) c and ℓ are disjoint. Then $c_1[c,+]$ and $c_2[c,+]$ do not cross.*

Proof. Suppose that $c_1[c,+]$ and $c_2[c,+]$ cross and let T denote the simple closed curve $c[c_1,c_2] \cup c_1[c,c_2] \cup c_2[c,c_1]$, see Figure 1. Then c_1^- and c_2^- lie on different sides T.[5] However, this is impossible since both of these points are on ℓ which cannot cross T. ◀

Returning to the proof of the theorem, we consider each of the four tangency types separately. For a certain type t, we write for each curve $b \in B$ the ordered list of curves from A that touch b at a touching point of the given type. The list, denote it by $l_t(b)$, is ordered according to the order of the corresponding touching points along b.

▶ **Proposition 16.** *There are no three curves $a_1, a_2, a_3 \in A$ and two curves $b_1, b_2 \in B$ such that a_1, a_2, a_3 appear in this order both in $l_t(b_1)$ and in $l_t(b_2)$.*

Proof. Suppose for contradiction that there are such curves. Observe first that it follows from Proposition 15 that $b_1[a_1,+]$ and $b_2[a_1,+]$ do not cross. In particular $b_1[a_1,a_3]$ and $b_2[a_1,a_3]$ do not cross. Next, we claim that at least one pair of the three subcurves $a_i[b_1,b_2]$, $i = 1,2,3$, is crossing. Suppose for contradiction that these curves are pairwise disjoint. Slightly "inflate"

[5] Assuming some arbitrary orientation of T, disregarding the orientations of the other curves.

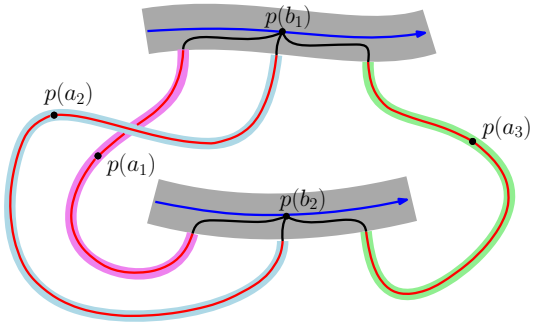

Figure 2 If the subcurves $a_i(b_1, b_2)$ were disjoint, then we could draw a crossing-free copy of $K_{2,3}$.

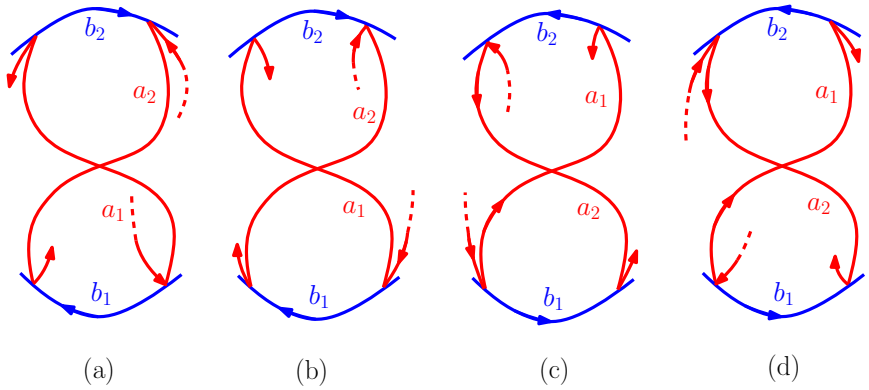

Figure 3 Illustrations for the proof of Proposition 16: $a_1[b_1, +]$ and $a_2[-, b_1]$ are crossing and together with $b_1[a_1, a_2]$ and $b_2[a_1, a_2]$ induce a partition of the plane. a_1^- and a_2^- lie on different regions of this partition for any red-blue tangency type.

b_1 and b_2 and fix a point $p(c)$ on each subcurve $c \in \{a_1(b_1, b_2), a_2(b_1, b_2), a_3(b_1, b_2), b_1(a_1, a_3), b_2(a_1, a_3)\}$. Note that these subcurves are disjoint. Next, draw a crossing-free copy of $K_{2,3}$ whose vertices are these five points and whose edges follow the corresponding subcurves, as suggested by Figure 2. Note that since a_1, a_2, a_3 touch in this order both of b_1 and b_2, the counterclockwise cyclic order of $p(a_1), p(a_2), p(a_3)$ is the same for $p(b_1)$ and $p(b_2)$. However, this contradicts the following lemma of Pinchasi and Radoičić [26].

▶ **Lemma 17** ([26, Lemma 1]). *Let G be a topological graph with no two edges belonging to a 4-cycle that crosses itself an odd number of times. For each vertex v of G let C_v denote the counterclockwise cyclic order of the neighbors of v. Then for each pair of vertices u and v, if there are more than two common neighbors of u and v, then the order of these neighbors in C_v is reversed with respect to their order in C_u.*

For the rest of the proof we will only consider the guaranteed pair of crossing subcurves among $a_i[b_1, b_2]$, $i = 1, 2, 3$, therefore we may suppose without loss of generality that $a_1(b_1, b_2)$ and $a_2(b_1, b_2)$ are crossing. We may also assume that a_1 meets b_1 before meeting b_2. Since $a_1[b_1, +]$ cannot cross $a_2[b_1, +]$ by Proposition 15, it follows that $a_1[b_1, +]$ and $a_2[-, b_1]$ are crossing. Together with $b_1[a_1, a_2]$ and $b_2[a_1, a_2]$ they induce a partition of the plane into three connected regions. For each type of red-blue tangency, the points a_1^- and a_2^- lie on two different regions, see Figure 3 for an illustration. However, this is impossible since both of these points lie on ℓ_A which does not cross any of the curves a_1, a_2, b_1, b_2. ◀

It follows from Proposition 16 and Theorem 13 that $\sum_i |l_t(b_i)| = O(|A \cup B|)^{3/2}$. Therefore, the number of red-blue tangencies is also $O(|A \cup B|)^{3/2}$. ◀

▶ **Corollary 18.** *Let $\mathcal{C}$ be a family of n 1-intersecting curves grounded at a curve ℓ. Then the number of tangencies among $\mathcal{C}$ is $O(n^{3/2})$.*

Proof. Denote by $t(n)$ the maximum number of tangencies among such a family of n curves. We prove that $t(n) = O(n^{3/2})$ by induction on n. Split ℓ into two disjoint subcurves such that $n/2$ curves from $\mathcal{C}$ are grounded at each subcurve. Using Theorem 14 and induction we get the recursive relation $t(n) \leq 2t(n/2) + O(n^{3/2})$ which implies that $t(n) = O(n^{3/2})$. ◀

▶ **Corollary 19.** *Let A be a family of curves grounded at a curve ℓ_A and let B be a family of curves grounded at a curve ℓ_B, such that $A \cup B \cup \{\ell_A, \ell_B\}$ form a family of 1-intersecting curves. Then the number of tangent pairs $\{c_A \in A, c_B \in B\}$ is $O(|A \cup B|^{3/2})$.*

Proof. If ℓ_A and ℓ_B cross at a point p, then we split each of them into two curves at p (such that p belongs to neither of them). Denote these subcurves by $\ell_A^1, \ell_A^2, \ell_B^1$ and ℓ_B^2 and note that each pair of them are disjoint. Every curve in A (resp., B) that crosses ℓ_B (resp., ℓ_A) we cut into two subcurves, such that one of them is grounded at ℓ_A^1 or ℓ_A^2 (or at ℓ_A if it was not cut) and the other is grounded at ℓ_B^1 or ℓ_B^2 (or at ℓ_B if it was not cut). It remains to bound the number of tangencies among curves grounded at ℓ_x^i, for each $x \in \{A, B\}$ and $i \in \{1, 2\}$, and the number of tangencies of pairs of curves c and c' such that c is grounded at ℓ_x^i and c' is grounded at ℓ_y^j for each $x, y \in \{A, B\}$ and $i, j \in \{1, 2\}$ such that $x \neq y$ or $i \neq j$. It follows from Corollary 18 and Theorem 14 that the total number of all of these tangencies is $O(|A \cup B|^{3/2})$. ◀

We can now deduce the main results of this section.

▶ **Theorem 4.** *Every family of n precisely 1-intersecting planar curves admits $O(n^{3/2})$ tangencies.*

Proof. Follows immediately from Corollary 18. ◀

▶ **Theorem 3.** *Every family of n 1-intersecting planar curves admits $O(n^{5/3})$ tangencies.*

Proof. Let $\mathcal{C}$ be a family of n 1-intersecting curves and let $G_{\mathcal{C}}$ be the tangency graph of $\mathcal{C}$. It follows from Corollary 19 that $G_{\mathcal{C}}$ satisfies the f-sparse sub-bineighborhoods property for $f(x) = O(x^{3/2})$. Indeed, let v_0 and v_1 be two adjacent vertices in $G_{\mathcal{C}}$ and let $V_i \subseteq N_{G_{\mathcal{C}}}(v_i) \setminus \{v_{1-i}\}$, for $i = 0, 1$, be two disjoint subsets of their neighborhoods in $G_{\mathcal{C}}$. We wish to bound $t(V_0, V_1)$ – the number of tangent pairs $\{u_0 \in V_0, u_1 \in V_1\}$. For every $i = 0, 1$ and every curve $u \in V_i$, we split u into two subcurves u_i' and u_i'' such that each of them is grounded at v_i. Denote the resulting set of curves by V_1', V_1'', V_2' and V_2'', respectively. Thus, $t(V_0, V_1) = t(V_0', V_1') + t(V_0', V_1'') + t(V_0'', V_1') + t(V_0'', V_1'')$. It follows from Corollary 19 that this sum is upper-bounded by $O(|V_0 \cup V_1)|^{3/2})$. Therefore, by Theorem 9 we have that $|E(G_{\mathcal{C}})| \leq O(n^{5/3})$. ◀

4 Tangencies among x-monotone curves

Theorem 7 is proved in the full version of this paper [2]. Here we give a short summary of the ideas of the proof. First, in the case of exactly 1-intersecting bi-infinite x-monotone curves we prove that the tangency graph cannot contain a cycle, thus has at most $n - 1$ edges. Then we prove a linear bound for a bipartite variant of counting tangencies between two families of bi-infinite x-monotone curves that are separated in the infinity and apply this to get the $O(n \log n)$ bound for the general 1-interesting case.

Next we show the main ideas needed to prove Theorem 5 and 6, the details are again in the full version of this paper [2].

Pach and Sharir [23] studied the following problem: What is the maximum number of pairs of disjoint line-segments that are *vertically visible* among a set of n segments in the plane? We say that two segments are *vertically visible* if there exists a vertical segment that intersects both of them and does not intersect any other segment in the set. The motivation for this problem came from analyzing the maximum size of the events queue in the original implementation of the Bentley-Ottmann line sweeping algorithm for enumerating all the intersections among a set of segments [7].

Pach and Sharir [23] proved that the maximum number of pairs of disjoint vertically visible line-segments within a set of n segments is $O\left(n^{4/3}\left(\log n\right)^{2/3}\right)$ and $\Omega\left(n^{4/3}\right)$. They also mentioned these bounds hold also for x-monotone 1-intersecting curves.

It is easy to see that counting disjoint vertically visible pairs can be reduced to counting touching pairs of x-monotone 1-intersecting curves and vice versa. Indeed, vertically visible curves can become tangent by replacing a very narrow part of one curve by a "spike" that touches the other curve. On the other hand, a pair of touching curves can be easily "detached" and become vertically visible. Therefore, the result of Pach and Sharir [23] implies that the maximum number of tangencies among n x-monotone 1-intersecting curves is $O\left(n^{4/3}\left(\log n\right)^{2/3}\right)$ and $\Omega\left(n^{4/3}\right)$.

We outline the proof of the upper bound of Pach and Sharir [23] and point out the modifications which lead to the better bounds of Theorem 5 and 6. First, the cutting lemma (Theorem 11) is used to partition the plane into generalized trapezoids such that every trapezoid is cut by not too many curves. Then, the number of tangencies within every trapezoid T_i is estimated and finally the sum over all the trapezoids is bounded. Regarding tangencies within T_i, one considers two subsets of curves that cut T_i: "short" curves that have at least one endpoint inside T_i and "long" curves that have no endpoint inside T_i. Therefore, the long curves behave like bi-infinite curves with respect to T_i. Thus, the number of long-long tangencies can be bounded using the $O(n \log n)$ bound of Theorem 7. In order to obtain the tight upper bound of Theorem 6 we use for this case the linear bound for the case of counting tangencies between two families of bi-infinite x-monotone curves that are separated in the infinity, see Lemma 2 in the full version of this paper [2]. The number of short-long tangencies is bounded using Kővári-Sós-Turán Theorem and a technical lemma (see the full version of this paper [2]). Finally, the number of short-short tangencies is bounded in [23] by further subdividing T_i into vertical slabs. However, we observe that one can instead use induction and this simplifies the proof and leads to a better upper bound.

4.1 Bi-infinite k-intersecting x-monotone curves

In light of the second part of Theorem 7 and [5, Theorem 2.4] it is tempting to suggest that a similar statement holds for every fixed k.

▶ **Conjecture 20.** *Every set of n pairwise intersecting bi-infinite x-monotone k-intersecting curves admits $O_k(n)$ tangencies.*

We were unable to settle this conjecture. Still, we mention a simple and weak polynomial upper bound and two observations regarding the conjecture. For the upper bound we use the following observation.

▶ **Observation 21.** *Let r and r' be two bi-infinite x-monotone curves touching from below an x-monotone curve b. Then r and r' cross at a point whose x-coordinate is between $b \cap r$ and $b \cap r'$.*

By Theorem 2 we have $O_k\left(n^{2-\frac{1}{k+3}}\right)$ tangencies among any n k-intersecting curves. One can slightly improve upon this bound in case of bi-infinite x-monotone curves.

▶ **Proposition 22.** *Let $\mathcal{L}$ be a family of k-intersecting bi-infinite x-monotone curves. Then $\mathcal{L}$ admits $O_k\left(n^{2-\frac{1}{k+1}}\right)$ tangencies.*

Proof. Note that the curves in $\mathcal{L}$ are not necessarily pairwise intersecting. Consider the tangency graph $G_{\mathcal{L}}$ and flip a fair coin for every curve $c \in \mathcal{L}$. If the outcome is "heads", delete all the edges that correspond to tangencies in which c touches another curve from below. Otherwise, if the outcome is "tails" do the same for tangencies in which c touches a curve from above. Clearly, every edge in $G_{\mathcal{L}}$ survives with probability $1/4$. Therefore, there is a bipartite subgraph $(B \cup R, E)$ with at least $|E(G_{\mathcal{L}})|/4$ edges in which every curve that corresponds to a vertex $r \in R$ touches from below the curves corresponding to its neighbors in B. It suffices to bound the size of this subgraph.

We claim that this subgraph does not contain K_{k+1,c_k} as a subgraph, for some large enough c_k to be determined later. Indeed, suppose without loss of generality that there is a subset of c_k curves $R' = \{r_1, r_2, \ldots, r_{c_k}\} \subseteq R$ each of which touches from below each of the $k+1$ curves in a subset $B' = \{b_1, b_2, \ldots, b_{k+1}\} \subseteq B$. Let ℓ be the lower envelope of the curves in B'. Then ℓ consists of at most $\lambda_{k+2}(k+1)$ curve-segments, where $\lambda_s(n)$ denotes that maximum length of an (n, s)-Davenport-Schinzel sequence [27].[6] Note that each curve $r' \in R'$ touches $k+1$ of these curve-segments (which belong to $k+1$ different curves in B'). Therefore, there are at most $\binom{\lambda_{k+2}(k+1)}{k+1}$ possibilities for the $(k+1)$-subset of curve-segments of ℓ that a curve in R' touches. Setting $c_k = 1 + \binom{\lambda_{k+2}(k+1)}{k+1}$ implies that there are two curves $r', r'' \in R'$ that touch the same $k+1$ curve-segments of ℓ. Consider one of these curve-segments s. Then it follows from Observation 21 that r' and r'' cross at a point whose x-coordinate is between $s \cap r'$ and $s \cap r''$. Since the $k+1$ curve-segments that r' and r'' touch have distinct x-projections, it follows that r' and r'' cross at least $k+1$ times, which is impossible. Thus, $(B \cup R, E)$ is a K_{k+1,c_k}-free graph and it follows from Kővári-Sós-Turán Theorem that it has at most $O_k\left(n^{2-\frac{1}{k+1}}\right)$ edges. ◀

The next observation says that if Conjecture 20 is true, then the same statement holds without requiring the curves to be bi-infinite.

▶ **Proposition 23.** *Suppose that Conjecture 20 holds for some $k > 2$. Then every set of n pairwise intersecting x-monotone $(k-2)$-intersecting curves admits $O_k(n)$ tangencies.*

Proof. Let $\mathcal{L}$ be a set of curves as in the proposition. We assume without loss of generality that no two endpoints of two curves share the same x-coordinate. There are four types of tangencies: the curve touching from above starts before/after the curve touching from below and ends before/after it. We consider each type separately and observe that the set of curves touching from above and the set of curves touching from below are disjoint sets. Call the curves in the first set *red* and the curves in the other set *blue*. Next, we extend each red curve

[6] A sequence of letters over an n-element alphabet is an (n, s)-*Davenport-Schinzel sequence* if it does not contain two consecutive identical letters and no alternating sub-sequence of two letters whose length is $s+2$. In fact a trivial bound of $O(k^3)$ on the size of the lower envelope also suffices for our purpose.

into a bi-infinite curve by shooting a very steep ray leftwards (resp., rightwards) and upwards at its left (resp., right) endpoint. Similarly, we extend each blue curve into a bi-infinite curve by shooting a very steep ray leftwards (resp., rightwards) and downwards at its left (resp., right) endpoint. The rays going leftward and upwards and the rays going rightwards and downwards have opposite slopes. Similarly, the rays going leftward and downwards and the rays going rightwards and upwards have opposite slopes. Note that this introduces at most two new intersection points between two curves while for touching curves (of the considered type) no new intersection point is introduced. ◀

According to the following observation for an even k we may assume that every non-tangent pair of curve intersects at exactly k points.

▶ **Proposition 24.** *Let $\mathcal{L}$ be a set of n bi-infinite x-monotone curves such that every pair of curves in $\mathcal{L}$ intersect at at least one and at most k points for some even k. Then there is a set $\mathcal{L}'$ of n bi-infinite x-monotone curves such that every pair of curves in $\mathcal{L}'$ is either touching at a single point or crossing at exactly k points and the number of touching pairs in $\mathcal{L}$ and $\mathcal{L}'$ is the same.*

Proof. We may assume without loss of generality that all the curves are parallel to the x-axis at $-\infty$ and $+\infty$ and denote them by $1, 2, \ldots, n$ according to their order from top to bottom at $-\infty$. Let $f : \{1, 2, \ldots, n\} \to \{1, 2, \ldots, n\}$ denote their order at $+\infty$, that is, $f(i)$ is the location of i in the order of the curves from top to bottom at $+\infty$.

If f is the identity function, then every pair of curves either touch or cross at an even number of points. In such a case, every two curves that cross at $k' < k$ points, can be redrawn very close to one of their crossing points such that they cross at $k - k'$ new crossing points. This way we get exactly k crossing points between every pair of non-touching curves. Otherwise, if f is not the identity function, then we can redraw two curves that cross an odd number of times such that they cross an even number of times and repeat this process until f becomes the identity function. Indeed, let i and j be two curves such that $i < j$ and $f(i) > f(j)$. If there are several such pairs we choose a "closest" one, that is, one which minimizes the difference $f(i) - f(j)$. Note that there is no curve l such that $f(i) > f(l) > f(j)$, for otherwise we must have both $l < i$ and $j < l$ (or else (i, l) or (l, j) would be a "reversed" pair closer than (i, j)) which is impossible since $i < j$. Therefore, $f(i) = f(j) + 1$ and it follows that we can redraw i and j such that they cross at an additional point. ◀

5 An Erdős-Simonovits-type theorem

In this section we prove Theorems 9 and 10 and discuss some of their applications and connections to other graph theoretic results. For a graph $G = (V, E)$ we denote by $\overline{d}(G) = 2|E|/|V|$ the average degree in G. The subgraph induced by a subset of vertices $U \subseteq V$ is denoted by $G[U]$. For a vertex $v \in V$ we denote by $N_G(v)$ (or simply $N(v)$ when the context is clear) the neighbors of v in G. The (*open*) *bineighborhood* of two vertices v and u is equal to $(N_G(v) \cup N_G(u)) \setminus \{u, v\}$. Assume henceforth that G is bipartite and recall that for a nonnegative and nondecreasing function $f : \mathbb{R} \to \mathbb{R}$ we say that two vertices u and v have *f-sparse sub-bineighborhoods* if for every two disjoint subsets $U \subseteq N_G(u) \setminus \{v\}$ and $V \subseteq N_G(v) \setminus \{u\}$ it holds that $|E(G(U, V))| \leq f(|U \cup V|)$, where $G(U, V)$ is the bipartite subgraph $(U \cup V, \{(u, v) \in E(G) \mid u \in U \text{ and } v \in V\})$. Theorem 9 will follow from the next result.

▶ **Theorem 25.** *Let $f : \mathbb{R} \to \mathbb{R}$ be a nonnegative and nondecreasing function and let $G = (A \cup B, E)$ be an n-vertex bipartite graph with $\overline{d}(G) \geq 16$.*

(i) *If every pair of vertices in G has f-sparse sub-bineighborhoods, then $(\overline{d}(G))^3 \leq 2^{11} n f(2\overline{d}(G))$.*

(ii) *If every pair of adjacent vertices has f-sparse sub-bineighborhoods and $|E| \geq 25n^{3/2}$, then $(\overline{d}(G))^3 \leq 2^{20} n f(2\overline{d}(G))$.*

Proof. Set $m = |E|$ and let $d = \overline{d}(G) = 2m/n$ be the average degree of G. We first replace G with a graph G' in which the degree of every vertex is roughly the average degree (while maintaining the f-sparseness property): Go over the vertices of G in an arbitrary order and replace each vertex v such that $\deg(v) > d$ by $\lfloor \deg(v)/d \rfloor$ vertices of degree d and possibly one vertex of a smaller degree. The neighbors of v are connected to the vertices that replace v in an arbitrary manner which satisfies this property. Observe that the resulting graph still has f-sparse sub-bineighborhoods for every pair of (adjacent) vertices, since each sub-neighborhood of a vertex in the new graph cannot contain two vertices that correspond to the same original vertex. Thus, every sub-neighborhood in the new graph corresponds to a sub-neighborhood in G. Furthermore, since $d = 2m/n$, the number of vertices in the new graph is at most $\sum_{v \in A \cup B} (\lfloor \deg_G(v)/d \rfloor + 1) \leq 2n$. Because the number of edges remains the same, the average degree of this graph is at least $d/2$.

Next, we repeatedly remove vertices of degree smaller than $d/8$ until no such vertices remain. We claim that at least $m/2$ edges remain after this step. Indeed, suppose for contradiction that less than $m/2$ edges remain and denote by x the number of vertices that were removed. Then at most $xd/8$ edges were removed, therefore $xd/8 > m/2 = 2nd/8$ which is impossible since $x \leq 2n$. Denote by $G' = (A' \cup B', E')$ the resulting graph and note that $|A' \cup B'| \leq 2n$, $|E'| \geq m/2$ and the degree of every vertex in G' is at least $d/8$ and at most d. Observe also that $|A' \cup B'| \geq 2|E'|/d \geq m/d = n/2$. Furthermore, G' still has the f-sparse sub-bineighborhoods property, since this property is maintained when deleting a vertex.

Considering (i), for each pair of vertices $a \in A'$ and $b \in B'$ the number of edges in the subgraph of G' induced by the union of their open bineighborhoods is at most $f(2d)$. Therefore we have $\sum_{a \in A', b \in B'} |E(G'[(N_{G'}(a) \setminus \{b\}) \cup (N_{G'}(b) \setminus \{a\}])| \leq \binom{2n}{2} f(2d) \leq 2n^2 f(2d)$. Note that every edge $(a, b) \in E'$ is counted in this sum for every pair $a' \in A'$ and $b' \in B'$ such that $a \in N_{G'}(b') \setminus \{a'\}$ and $b \in N_{G'}(a') \setminus \{b'\}$. Since a (resp., b) has at least $\frac{d}{8} - 1 \geq \frac{d}{16}$ neighbors different from b (resp., a), it follows that (a, b) is counted at least $d^2/256$ times in the above sum (here we used the assumption $d \geq 16$). Therefore, $nd/2 = m = |E| \leq 2|E'| \leq 2^{10} n^2 f(2d)/d^2$ and thus $d^3 \leq 2^{11} n f(2d)$.

Considering (ii), we have $d \geq 50n^{1/2}$ since $m \geq 25n^{3/2}$. Assume w.l.o.g. that $|B'| \geq |A'|$ and therefore $|B'| \geq n/4$ and $|A'| \leq n$. Let $\#K_{2,1}$ be the number of $K_{2,1}$'s in G' with two vertices in A' and let $\#K_{2,2}$ be the number of $K_{2,2}$'s in G'. Then,

$$\#K_{2,2} = \frac{1}{4} \sum_{a \in A', b \in B', (a,b) \in E'} |E(G'[(N_{G'}(a) \setminus \{b\}) \cup (N_{G'}(b) \setminus \{a\}])| \leq \frac{m}{4} f(2d) = \frac{dn}{8} f(2d).$$

On the other hand, denoting $s_{a,a'} = |N_{G'}(a) \cap N_{G'}(a')|$ for two distinct vertices $a, a' \in A'$ we have $\#K_{2,1} = \sum_{a \neq a' \in A'} s_{a,a'}$ and:

$$\begin{aligned} \#K_{2,2} &= \sum_{a \neq a' \in A'} \binom{s_{a,a'}}{2} = \frac{1}{2} \sum_{a \neq a' \in A'} (s_{a,a'}^2 - s_{a,a'}) \\ &\geq \frac{(\#K_{2,1})^2}{2\binom{|A'|}{2}} - \frac{\#K_{2,1}}{2} \geq \frac{(\#K_{2,1})^2}{2\binom{n}{2}} - \frac{\#K_{2,1}}{2}, \end{aligned}$$

where the second to last inequality follows from Cauchy's inequality. For $\#K_{2,1}$ we have the following lower bound:

$$\#K_{2,1} = \sum_{a \neq a' \in A'} s_{a,a'} = \sum_{b \in B'} \binom{\deg(b)}{2} \geq \frac{n}{4}\binom{d/8}{2} \geq nd^2/2^{11} \geq n^2,$$

where we used double-counting by the vertex from B' for the $K_{2,1}$'s and the inequalities $|B'| \geq n/4$ and $d \geq 50n^{1/2}$. Combining the inequalities above we get:

$$\begin{aligned}\frac{dnf(2d)}{8} &\geq \#K_{2,2} \geq \frac{(\#K_{2,1})^2}{n^2} - \frac{\#K_{2,1}}{2} \geq \frac{(\#K_{2,1})^2}{n^2} - \frac{(\#K_{2,1})^2}{2n^2} = \frac{(\#K_{2,1})^2}{2n^2} \\ &\geq \frac{n^2 d^4}{2^{22} \cdot 2n^2} = \frac{d^4}{2^{23}}.\end{aligned}$$

This implies that $d^3 \leq 2^{20} nf(2d)$, as claimed. ◀

Using Theorem 25 we can now prove Theorem 9 which we restate for convenience.

▶ **Theorem 9.** *Let G be a graph and let $f(n) = O(n^{2-\alpha})$ for some constant $0 \leq \alpha < 2$. If every pair of vertices in G has f-sparse sub-bineighborhoods, then $|E(G)| = O\left(|V(G)|^{2-\frac{\alpha}{\alpha+1}}\right)$. Moreover, if $\alpha \leq 1$, then it is enough that every pair of adjacent vertices has f-sparse sub-bineighborhoods for this bound to hold.*

Proof. Recall that every graph contains a bipartite subgraph whose size is at least half of the size of the graph. Let $G' = (A' \cup B', E')$ be such a bipartite subgraph of G, where $|E'| \geq |E(G)|/2$, and let $n = |V(G)|$ and $d' = \overline{d}(G')$. If every pair of vertices in G has f-sparse sub-bineighborhoods, then the same holds for G' and it follows from Theorem 25 that $d'^3 \leq 2^{11} nf(2d') = O(nd'^{2-\alpha})$. Thus, $d' \leq O(n^{1/(\alpha+1)})$ and the upper bound follows.

If $0 < \alpha \leq 1$ and every pair of adjacent vertices has f-sparse sub-bineighborhoods, then we may assume that $|E'| \geq 25n^{3/2}$ for otherwise the theorem trivially holds. Therefore, by Theorem 25 we have $d'^3 \leq 2^{20} nf(2d') = O(nd'^{2-\alpha})$ and $d' \leq O(n^{1/(\alpha+1)})$ as before. ◀

For the lower bound we show that an appropriate random bipartite graph meets the criteria with positive probability, the proof can be found in the full version of this paper [2].

Remarks

- The proof of Theorem 9 is quite similar to the proof of Theorem 8 in [10]. In both cases, one first makes the graph close to being regular and then uses double-counting, however, in the case of Theorem 8 the first part requires more effort. Chronologically, we first proved the first part of Theorem 9 which was needed for the proof of Theorem 3, only later did we learn about Theorem 8 and used it to prove the second part of Theorem 9.
- It would be interesting to determine whether Theorem 9 holds when one assumes sparsity of the subgraph induced by the bineighborhood of every pair of (adjacent) vertices instead of assuming sparsity of subgraphs induced by each of their sub-bineighborhoods. We note that the first part of the proof of Theorem 9 does not go through in such a case. Also, f-sparse bineighborhoods do not imply f-sparse sub-bineighborhoods.
- Theorem 9 might find other applications, e.g., in other scenarios where it can be combined with Theorem 13. Here is one example. For a graph H let $\mathrm{ex}_{\mathrm{cr}}(n, H)$ be the maximum number of edges in a topological graph on n vertices with no self-intersecting copy H. Note that $\mathrm{ex}(n, H) \leq \mathrm{ex}_{\mathrm{cr}}(n, H)$ and if H is non-planar then $\mathrm{ex}(n, H) = \mathrm{ex}_{\mathrm{cr}}(n, H)$. In [16] Theorem 13 is used to show that $\mathrm{ex}_{\mathrm{cr}}(n, C_4) = O(n^{3/2})$ (and this is tight). Using Theorem 9 this immediately implies:

▶ **Corollary 26.** *$ex_{cr}(K_{2,3}) = O(n^{5/3})$ and $ex_{cr}(n, K_{3,3}^{-}) = O(n^{5/3})$ where $K_{3,3}^{-}$ is the complete bipartite graph on $3+3$ vertices minus one edge.*

Abstract

Let G be a finite, connected metric graph and let X be a subset of G. If X is sufficiently dense in G, we show that the Gromov–Hausdorff distance matches the Hausdorff distance, namely $d_{\mathrm{GH}}(G, X) = d_{\mathrm{H}}(G, X)$. When the metric graph is the circle $G = S^1$ with circumference 2π, a recent study established the equality $d_{\mathrm{GH}}(S^1, X) = d_{\mathrm{H}}(S^1, X)$ whenever $d_{\mathrm{GH}}(S^1, X) < \frac{\pi}{6}$. Our results relax this hypothesis to $d_{\mathrm{GH}}(S^1, X) < \frac{\pi}{3}$, and furthermore, we show that the constant $\frac{\pi}{3}$ is the best possible. We lower bound the Gromov–Hausdorff distance $d_{\mathrm{GH}}(G, X)$ by the Hausdorff distance $d_{\mathrm{H}}(G, X)$ via a simple topological obstruction: the existence of a possibly discontinuous function $f\colon G \to X$ with too small distortion contradicts the connectedness of G.

1 Introduction

The Gromov–Hausdorff distance between two abstract metric spaces (X, d_X) and (Y, d_Y), denoted $d_{\mathrm{GH}}(X, Y)$, provides a dissimilarity measure quantifying how far the two metric spaces are from being isometric [13, 14, 24]. In the past two decades, this distance has found applications in topological data analysis (TDA) as a theoretical framework for shape and dataset comparison [21], which motivated the study of its quantitative aspects. However, precise computations of the Gromov–Hausdorff distance between even simple spaces are mostly unknown, with certain exceptions such as the Gromov–Hausdorff distance between a line segment and a circle [16] and between spheres of certain dimensions [19, 1, 15]. Even approximating the Gromov–Hausdorff distance by a factor of 3 in the case of trees with unit-edge length is known to be NP-hard [4, 23]. A better approximation factor can only be achieved in very special cases; for example, [20] provides a $\frac{5}{4}$-approximation scheme if

X and Y are finite subsets of the real line. Developing tools and pipelines to estimate the Gromov–Hausdorff distance is a central research direction in the applied topology community. To estimate the Gromov–Hausdorff distance between two metric spaces X, Y, one may:
(A) Find nice samples $X' \subseteq X$ and $Y' \subseteq Y$ approximating the geometry of X and Y, and
(B) Efficiently bound the Gromov–Hausdorff distance between the subsets X' and Y'.
Indeed, when X and Y are infinite continuous objects – e.g., Riemannian manifolds, metric graphs – and one wants to use computational machinery, it is often essential to resort to finite subsets approximating the geometry of the original spaces.

We reformulate the first task **(A)** as follows: how dense does the sample X' have to be in X to capture the geometry of the ambient space X? To systematize this question, we use the Hausdorff distance as a measure of density and ask if we can provide a threshold ε and constant $0 < C \leq 1$ such that $d_{\mathrm{GH}}(X, X') \geq C \cdot d_{\mathrm{H}}(X, X')$ whenever $d_{\mathrm{H}}(X, X') < \varepsilon$. In particular, $d_{\mathrm{GH}}(X, X') = d_{\mathrm{H}}(X, X')$ if $C = 1$. In [2], the authors show that when X is a manifold and $d_{\mathrm{GH}}(X, X') < \varepsilon$ (which is implied by $d_{\mathrm{H}}(X, X') < \varepsilon$) for some constant ε, then $d_{\mathrm{GH}}(X', X) \geq C \cdot d_{\mathrm{H}}(X, X')$ for some $\frac{1}{2} \leq C \leq 1$. Our study continues that investigation and proves improved results when X is a metric graph, hence relaxing the manifold assumption.

A fruitful approach to provide bounds on the Gromov–Hausdorff distance in task **(B)** is to use stable metric invariants. One associates each metric space X with a value $\psi(X)$ in a simpler metric space so that $\psi(X)$ and $\psi(Y)$ are close whenever X and Y are. An immediate example is the diameter; we have $d_{\mathrm{GH}}(X, Y) \geq \frac{1}{2}|\mathrm{diam}(X) - \mathrm{diam}(Y)|$. For further stable metric invariants, we refer the reader to curvature sets [22], to Vietoris–Rips persistence diagrams [11], and to hierarchical clustering [10]. In [25], dimension theory is used to limit the precision of metric invariants with values in Hilbert spaces.

One of the precursors of algebraic topology was Brouwer's proof of *invariance of dimension*, namely that $\mathbb{R}^m$ is not homeomorphic to $\mathbb{R}^n$ for $n > m$. Proving $\mathbb{R}^1$ is not homeomorphic to $\mathbb{R}^n$ for $n > 1$ relies only on connectedness: removing a single point from $\mathbb{R}^1$ leaves a disconnected space. To prove invariance of dimension for $n > m \geq 2$, Brouwer relied on concepts related to the *degree* of a map between spheres [8, 7], which is often now formalized using higher-dimensional homology groups. The topological obstructions to small Gromov–Hausdorff distances in [2] relied on homological tools, namely the fundamental class of a manifold. One of the key contributions of our paper is to go "back in time" and produce strong lower bounds on Gromov–Hausdorff distances using simpler topological tools: we show that small Gromov–Hausdorff distances would contradict the connectedness of a space.

Overview of our results

Let G be a connected, finite metric graph, and let $X \subseteq G$ be a subset. We show how to lower bound the Gromov–Hausdorff distance $d_{\mathrm{GH}}(G, X)$ in terms of the Hausdorff distance $d_{\mathrm{H}}(G, X)$, achieving $d_{\mathrm{GH}}(G, X) = d_{\mathrm{H}}(G, X)$. A unifying theme in our proofs is that we show that a possibly discontinuous function $f\colon G \to X$ induces a continuous and non-surjective map $\overline{f}\colon G \to G$. We then use non-surjectivity (and related properties) to lower bound the distortion of $\overline{f}$ and f, hence lower bounding $d_{\mathrm{GH}}(G, X)$. The simplest metric graph is a tree T. Let ∂T denote the leaves of T, and let $\vec{d}_{\mathrm{H}}(\partial T, X)$ denote the directed Hausdorff distance from ∂T to the sample X (see Section 2). We show:

Theorem 8. Let T be a finite metric tree and let $X \subseteq T$. If $d_{\mathrm{H}}(T, X) > \vec{d}_{\mathrm{H}}(\partial T, X)$, then $d_{\mathrm{GH}}(T, X) = d_{\mathrm{H}}(T, X)$. The interpretation is as follows: if the biggest gaps in the sampling $X \subseteq T$ are not near the leaves of T (which by Proposition 6 is typical behavior), then $d_{\mathrm{GH}}(T, X) = d_{\mathrm{H}}(T, X)$. Some control on the leaf vertices is needed:

Theorem 5. For any $\varepsilon > 0$ there exists a finite metric tree T and a closed subset $X \subseteq T$ such that $d_{\mathrm{GH}}(T, X) \leq \varepsilon \cdot d_{\mathrm{H}}(T, X)$.

When $G = S^1$ is the circle of circumference 2π, [2] shows that if $d_{\mathrm{GH}}(S^1, X) < \frac{\pi}{6}$, then $d_{\mathrm{GH}}(S^1, X) = d_{\mathrm{H}}(S^1, X)$. The following theorem improves the constant $\frac{\pi}{6}$ to $\frac{\pi}{3}$.

Theorem 11. For any subset $X \subseteq S^1$, we have $d_{\mathrm{GH}}(S^1, X) \geq \min\left\{d_{\mathrm{H}}(S^1, X),\ \frac{\pi}{3}\right\}$.

In **Theorem 12** we show that this constant $\frac{\pi}{3}$ is the best possible, namely that for any $\varepsilon \in \left(0, \frac{\pi}{6}\right)$, there exists a nonempty compact subset $X \subseteq S^1$ with $d_{\mathrm{H}}(S^1, X) = \frac{\pi}{3} + \varepsilon$ and $d_{\mathrm{GH}}(S^1, X) = \frac{\pi}{3} < d_{\mathrm{H}}(S^1, X)$. We generalize the above results for the circle and trees to general metric graphs. Let G be a finite metric graph with set of leaf vertices ∂G. We prove that if X is dense enough relative to $e(G_0)$, which is the smallest edge length between vertices in the core G_0 of G (see Section 2), then the Gromov–Hausdorff distance matches the Hausdorff distance.

Theorem 23. Let G be a finite connected metric graph and let $X \subseteq G$. If $\partial G \neq \emptyset$, suppose $d_{\mathrm{H}}(G, X) > \vec{d}_{\mathrm{H}}(\partial G, X)$. If $d_{\mathrm{GH}}(G, X) < \frac{e(G_0)}{16}$, then $d_{\mathrm{GH}}(G, X) = d_{\mathrm{H}}(G, X)$. Theorems 11 and 23 are obtained using low-dimensional versions of the Borsuk–Ulam theorem for maps from the circle into $\mathbb{R}$ or into a tree, which are proven using connectedness. Our results have corollaries allowing us to lower bound the Gromov–Hausdorff distance between two subsets $X, Y \subseteq G$, using the triangle inequality. That is, for two sufficiently dense subsets $X, Y \subseteq G$, we provide new lower bounds on $d_{\mathrm{GH}}(X, Y)$ in terms of the Hausdorff distance $d_{\mathrm{H}}(X, Y)$, which is $\mathcal{O}(n^2)$-time computable if the subsets have at most n points. We demonstrate such a corollary explicitly in the case of metric trees in Section 4.

Organization of the paper

We begin in Section 2 with background. In Section 3, we show that some control over the boundary of the metric graph is necessary. We begin with metric trees in Section 4, proceed to the circle in Section 5, and consider general metric graphs in Section 6.

2 Background and notation

We refer the reader to [9, 6] for more information on metric spaces, metric graphs, the Hausdorff distance, and the Gromov–Hausdorff distance.

2.1 Metric spaces

Let (Z, d) be a metric space. For $z \in Z$, we let $B(z; r) = \{z' \in Z \mid d(z, z') < r\}$ denote the open metric ball of radius r about z. For any $r \geq 0$ and $A \subseteq Z$, we denote the *r-thickening* of A in Z, namely, the union of metric balls of radius r centered at the points of A, by

$$A^r = \cup_{a \in A} B(a; r) = \left\{z \in Z \mid \inf_{a \in A} d(a, z) < r\right\}.$$

The *diameter* of a subset $A \subseteq Z$ is the supremum of all distances between pairs of points of A. More formally, the diameter is defined as $\mathrm{diam}(A) = \sup\{d(a, a') \mid a, a' \in A\}$.

2.2 Metric graphs

To define metric graphs, we follow Definitions 3.1.12 (quotient metric) and 3.2.9 (metric graph) of [9]. A *metric segment* is a metric space isometric to a real line segment $[0, l]$ for $l \geq 0$. Our metric graphs will be connected and have a finite number of vertices and edges.

▶ **Definition 1** (Metric Graph). *A* finite metric graph (G, d) *is the metric space obtained by gluing a finite collection E of metric segments along their boundaries to a finite collection V of vertices, and equipping the result $\left(\bigsqcup_{e \in E} e\right) / \sim$ with the quotient metric. We assume this equivalence relation results in a connected space.*

The metric segments $e \in E$ are the *edges* and the equivalence classes of their endpoints in V are the *vertices* of G. Since G is connected, we have $d(y, y') < \infty$ for all $y, y' \in G$. Since E is finite, the quotient semi-metric [9, Definition 3.1.12] is in fact a metric.[1] For an edge $e \in E$, its length $|e|$ is the length of the corresponding metric segment. Note that the length can be different from the distance between the endpoints of e according to the metric d. Extending the definition of length for a continuous path $\gamma\colon [a, b] \to G$, we define the length $|\gamma|$ as the sum of the (full or partial) lengths of the edges that γ traverses. For a vertex v of a graph, its *degree*, denoted $deg(v)$, is the number of edges incident to v. A self-loop at v contributes 2 to the degree of v. As an example, the circle S^1 can be given a metric graph structure with a single vertex v of degree 2 at the north pole, along with a self-loop. We denote the set of leaf vertices, i.e. the vertices of degree one, by ∂G. A metric graph G is therefore endowed with two layers of information: a metric structure turning it into a length space [9, Definition 2.1.6] and a combinatorial structure (V, E) as an abstract graph. Using the above definition, we are also allowing G to have single-edge cycles and multiple edges between a pair of vertices. In this paper, we only consider path connected metric graphs (G, d) with finitely many edges. Therefore, the metric graphs we consider are compact, and since a compact length space is geodesic, they are also geodesic (meaning for every $x, y \in G$ there is an isometric embedding $\gamma\colon [0, d(x, y)] \to G$ such that $\gamma(0) = x$ and $\gamma(d(x, y)) = y$). This justifies why for any $y, y' \in G$, there is always at least one *shortest path* or *geodesic path* γ in G joining y, y' whose length satisfies $|\gamma| = d(y, y')$. We define an undirected *simple loop* γ of G to be a simple path that intersects itself only at the endpoints. We denote by $\mathcal{L}(G)$ the finite set of all simple loops of the finite graph G. Since a *metric tree* is a metric graph with no loops, $\mathcal{L}(G) = \emptyset$ for a metric tree G. For a metric graph G, let $e(G)$ denote the length of the shortest edge in G. If for $A \subseteq G$ there exists a unique shortest geodesic in G between any points $a, a' \in A$, then we define the *(geodesic) convex hull* of A in G to be the union of geodesics between all a and a'. If $\operatorname{diam}(A) < \frac{e(G)}{2}$, then the convex hull of A is well-defined. Given a (connected and finite) metric graph G, let G_0 be the smallest connected subgraph of G containing the union of all simple loops of G. We call G_0 the *core of* G. If G has no leaf edges, then $G = G_0$. Note that G_0 is just G with its "hanging trees" removed, or in other words, the minimal subspace onto which G deformation retracts. We will use the following two properties about G_0. First, if G (and hence G_0) contains at least two simple loops, then at least one vertex of G_0 has degree at least 3. We can then consider the canonical graph representation of G_0 consisting of only vertices of degree at least 3. Second, we note that if a path connected subset $Z \subseteq G$ has first Betti number equal to the first Betti number of G, then $G_0 \subseteq Z$.

[1] One needs to be careful if E is infinite. Suppose one has two vertices v and v', and one edge e_n of length $\frac{1}{n}$ with endpoints v and v' for each $n \in \mathbb{N}$. The quotient semi-metric gives $d(v, v') = \inf_{n \in \mathbb{N}} \frac{1}{n} = 0$ though $v \neq v'$; this semi-metric is not a metric. These subtleties disappear since we assume E is finite.

2.3 Hausdorff distances

Let (Z, d) be a metric space. If X and Y are two subsets of Z, then the *directed Hausdorff distance* from X to Y, denoted $\vec{d}_{\mathrm{H}}(X, Y)$, is defined by

$$\vec{d}_{\mathrm{H}}(X, Y) = \sup_{x \in X} \inf_{y \in Y} d(x, y) = \inf \left\{ r \geq 0 \mid X \subseteq Y^r \right\}.$$

Note that $\vec{d}_{\mathrm{H}}(X, Y)$ is not symmetric in general. To retain symmetry, the *Hausdorff distance*, denoted $d_{\mathrm{H}}(X, Y)$, is defined as $d_{\mathrm{H}}(X, Y) = \max \left\{ \vec{d}_{\mathrm{H}}(X, Y), \vec{d}_{\mathrm{H}}(Y, X) \right\}$. In other words, the Hausdorff distance finds the infimum over all real numbers r such that if we thicken Y by r it contains X, and if we thicken X by r it contains Y. If no such r exists then the Hausdorff distance is infinity.

2.4 Gromov–Hausdorff distances

Let (X, d_X) and (Y, d_Y) be metric spaces. In equations (1)–(3) we give three equivalent definitions of the Gromov–Hausdorff distance between X and Y. The first definition follows [14]. The *Gromov–Hausdorff distance* $d_{\mathrm{GH}}(X, Y)$ is the infimum of the Hausdorff distances between $F(X)$ and $G(Y)$ in Z, with the infimum being over all metric spaces Z and all isometric embeddings $F\colon X \hookrightarrow Z$ and $G\colon Y \hookrightarrow Z$:

$$d_{\mathrm{GH}}(X, Y) = \inf_{F, G, Z} d_{\mathrm{H}}(F(X), G(Y)). \tag{1}$$

The second definition uses correspondences. A relation $\mathcal{R} \subseteq X \times Y$ is a *correspondence* if for every $x \in X$ there is some $y \in Y$ with $(x, y) \in \mathcal{R}$, and for every $y \in Y$ there is some $x \in X$ exists with $(x, y) \in \mathcal{R}$. The *distortion* of a correspondence $\mathcal{R}$ is

$$\operatorname{dis}(\mathcal{R}) = \sup_{(x,y),(x',y') \in \mathcal{R}} \left| d_X(x, x') - d_Y(y, y') \right|.$$

The *Gromov–Hausdorff* distance between two (arbitrary) metric spaces X and Y is

$$d_{\mathrm{GH}}(X, Y) = \tfrac{1}{2} \inf_{\mathcal{R} \subseteq X \times Y} \operatorname{dis}(\mathcal{R}), \tag{2}$$

where the infimum is taken over all correspondences $\mathcal{R}$ between X and Y [9, 17]. For metric spaces (X, d_X) and (Y, d_Y), let $f\colon X \to Y$ and $g\colon Y \to X$ be two (possibly discontinuous) functions between them. We define the *distortion of* f as

$$\operatorname{dis}(f) = \sup_{x, x' \in X} \left| d_X(x, x') - d_Y(f(x), f(x')) \right|.$$

The distortion of g is defined similarly. The *codistortion of* f *and* g is defined as

$$\operatorname{codis}(f, g) = \sup_{x \in X, y \in Y} \left| d_X(x, g(y)) - d_Y(f(x), y) \right|.$$

Kalton and Ostrovskii [17] show that

$$d_{\mathrm{GH}}(X, Y) = \tfrac{1}{2} \inf_{f, g} \max\{\operatorname{dis}(f), \operatorname{dis}(g), \operatorname{codis}(f, g)\}, \tag{3}$$

where $f\colon X \to Y$ and $g\colon Y \to X$ are any functions. It follows that if $d_{\mathrm{GH}}(X, Y) < C$, then there is some function $f\colon X \to Y$ with $\frac{1}{2}\operatorname{dis}(f) < C$.

2.5 Gromov–Hausdorff distances and compactness

The following result is folklore; see [3] for the proof.

▶ **Lemma 2.** *Let X be a metric space and Y be a subset thereof. Let us denote by $\overline{Y}$ the closure of Y in X. Then*

$$d_{\mathrm{H}}(X,Y) = d_{\mathrm{H}}(X,\overline{Y}) \quad \text{and} \quad d_{\mathrm{GH}}(X,Y) = d_{\mathrm{GH}}(X,\overline{Y}).$$

Furthermore, for every two subsets Y and Z of X, we have $\vec{d}_{\mathrm{H}}(Z,Y) = \vec{d}_{\mathrm{H}}(Z,\overline{Y})$.

We will consistently apply Lemma 2 when the ambient metric space is compact. Thus, when we are studying the Hausdorff and the Gromov–Hausdorff distances between a compact metric space and a subspace thereof, we can assume that the subspace is compact as well.

2.6 Gromov–Hausdorff distances and connectedness

▶ **Lemma 3.** *Let $f\colon X \to Y$ be a function between metric spaces, with X path-connected and Y geodesic. Then for every $r > \frac{\operatorname{dis}(f)}{2}$, the thickening $f(X)^r$ is path connected.*

Proof. Let $y_1, y_2 \in f(X)^r$ and $x_1, x_2 \in X$ be points such that $d_Y(y_i, f(x_i)) < r$ for $i = 1, 2$. Since Y is geodesic, the entire geodesic connecting y_i to $f(x_i)$ is contained in $B(f(x_i), r) \subseteq f(X)^r$. Pick $\varepsilon > 0$ sufficiently small to satisfy $r > \frac{\operatorname{dis}(f)}{2} + \varepsilon$. Since X is path connected, there are $z_1 = x_1, z_2, \ldots, z_{n+1} = x_2$ such that $d(z_j, z_{j+1}) < \varepsilon$ for every $j = 0, \ldots, n$. Thus, $d(f(z_j), f(z_{j+1})) < \operatorname{dis}(f) + \varepsilon$. Since Y is geodesic, there are $m_j \in Y$ such that $d(f(z_j), m_j) = d(f(z_{j+1}), m_j) = \frac{1}{2} d(f(z_j), f(z_{j+1})) < r$ and the geodesics connecting m_j to $f(z_j)$ and $f(z_{j+1})$ are contained in $f(X)^r$. ◀

2.7 Gromov–Hausdorff distances and graphs

Let G be a finite metric graph and let $X \subseteq G$ be a compact subset. To use functions $f\colon G \to X$ to prove bounds on the Gromov–Hausdorff distance, we need to be a bit careful. Indeed, even if the sample X is close to the leaves of G, it may be that $f(G)$ is not close to the leaves. Luckily, we have a lot of freedom to construct our function f:

▶ **Lemma 4.** *Let G be a finite metric graph and let $X \subseteq G$ be compact. If $d_{\mathrm{GH}}(G, X) < r$, then there is a function $f\colon G \to X$ with $\frac{1}{2}\operatorname{dis}(f) < r$ and $\vec{d}_{\mathrm{H}}(\partial G, f(G)) = \vec{d}_{\mathrm{H}}(\partial G, X)$.*

Proof. Let $\mathcal{R} \subseteq G \times X$ be a correspondence satisfying $\operatorname{dis}(\mathcal{R}) < 2r$. Fix $\varepsilon > 0$ such that $\operatorname{dis}(\mathcal{R}) + \varepsilon < 2r$. For every $v \in \partial G$, pick $x_v \in X$ as a point satisfying $d(v, x_v) = \min_{x \in X} d(v, x)$. We first recursively construct a surjective map $\widetilde{f}$ from a subset of G to $\{x_v \mid v \in \partial G\}$. Let us arbitrarily order the leaves $v_1, \ldots, v_n$ and denote the point x_{v_i} by x_i for the sake of simplicity. **Base step.** Pick any $y_1 \in G$ such that $(y_1, x_1) \in \mathcal{R}$ and set $\widetilde{f}(y_1) = x_1$. **Recursive step.** Assume we have defined $y_1, \ldots, y_m \in G$ distinct and set $\widetilde{f}(y_i) = x_i$. Pick $y \in G$ satisfying $(y, x_{m+1}) \in \mathcal{R}$. Let us distinguish two cases. If $y \notin \{y_1, \ldots, y_m\}$, then set $y_{m+1} = y$ and $\widetilde{f}(y_{m+1}) = x_{m+1}$. Otherwise, fix an arbitrary point $y_{m+1} \in G \setminus \{y_1, \ldots, y_m\}$ satisfying $d(y_{m+1}, y) < \frac{\varepsilon}{2}$ and define $\widetilde{f}(y_{m+1}) = x_{m+1}$. Consider an arbitrary extension $f\colon G \to X$ of $\widetilde{f}\colon \{y_1, \ldots, y_n\} \to \{x_1, \ldots, x_n\}$ with the property that the graph of $f|_{G \setminus \{y_1, \ldots, y_n\}}$ is contained in $\mathcal{R}$. Then $\operatorname{dis}(f) \le \operatorname{dis}(\mathcal{R}) + 2 \cdot \frac{\varepsilon}{2} < 2r$ and $\vec{d}_{\mathrm{H}}(\partial G, f(G)) = \vec{d}_{\mathrm{H}}(\partial G, X)$ by construction. ◀

It is worth noticing that in the proof above we did not use any property of ∂G, and the result can be shown with ∂G replaced by any finite subset Y of G.

3 Ratio of d_{GH} vs d_{H} can be arbitrarily small for metric trees

In this section we prove Theorem 5, a variant of Theorem 5 of [2], now adapted to metric trees. As we show in Theorems 8 and 23, the Gromov–Hausdorff distance $d_{\mathrm{GH}}(T, X)$ between a metric graph T and a subset $X \subseteq T$ can be bounded below by their Hausdorff distance $d_{\mathrm{H}}(T, X)$ when X is close enough to the leaves of T, i.e., when $d_{\mathrm{H}}(T, X) > \vec{d}_{\mathrm{H}}(\partial T, X)$. When $d_{\mathrm{H}}(T, X) < \vec{d}_{\mathrm{H}}(\partial T, X)$, however, the ratio of $d_{\mathrm{GH}}(T, X)$ over $d_{\mathrm{H}}(T, X)$ can become arbitrarily small as we show below. Furthermore, Theorem 5 suggests that ∂T may not map close to itself via correspondences with small distortion; see Figure 1.

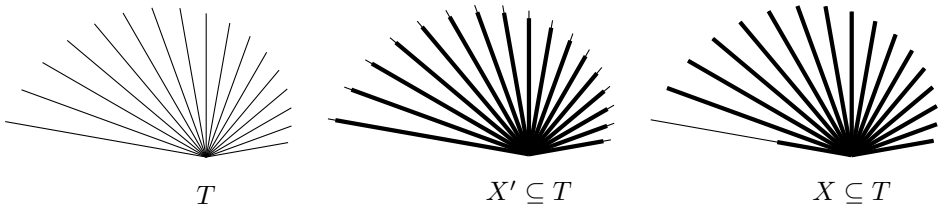

Figure 1 A sketch of the construction of Theorem 5: (left) The metric tree T, (middle) the bold superimposed $X' \subseteq T$ with small $d_{\mathrm{H}}(T, X')$, and (right) a different isometric embedding of X' into T indicated by $X \subseteq T$ with large $d_{\mathrm{H}}(T, X)$.

▶ **Theorem 5.** *For any $\varepsilon > 0$ there exists a finite metric tree T and a closed subset $X \subseteq T$ such that $d_{\mathrm{GH}}(T, X) \leq \varepsilon \cdot d_{\mathrm{H}}(T, X)$.*

Proof. Choose $n \in \mathbb{N}$ and let $\varepsilon = \frac{1}{n}$. For $t \geq 0$, let $I(t)$ be a copy of the interval $[0, t]$ with a designated basepoint 0. Define a metric tree T as the wedge of n intervals of lengths $1 + \varepsilon, 1 + 2\varepsilon, \ldots, 1 + n\varepsilon = 2$, and define a metric tree X_0 as the wedge of intervals of lengths $1, 1 + \varepsilon, 1 + 2\varepsilon, \ldots, 1 + (n-1)\varepsilon = 2 - \varepsilon$:

$$T = \bigvee_{t=1}^{n} I(1 + t \cdot \varepsilon) \quad \text{and} \quad X_0 = \bigvee_{t=0}^{n-1} I(1 + t \cdot \varepsilon).$$

Recall from (1) that $d_{\mathrm{GH}}(T, X)$ is the infimum of the Hausdorff distances between $F(T)$ and $G(X)$ in Z, with the infimum being over all metric spaces Z and all isometric embeddings $F \colon T \hookrightarrow Z$ and $G \colon X \hookrightarrow Z$. In Figure 1 we have two different isometric embeddings X', X of the same tree X_0 into $Z = T$: one with a small Hausdorff distance $d_{\mathrm{H}}(T, X') = \varepsilon$ as X' is T with each ray being shortened by ε, and one with a large Hausdorff distance $d_{\mathrm{H}}(T, X) = 1$ as X is T with the longest ray $I(2)$ of length 2 being replaced with a subray $I(1)$ of length 1. By (1), we have $d_{\mathrm{GH}}(T, X) \leq d_{\mathrm{H}}(T, X') = \varepsilon d_{\mathrm{H}}(T, X)$. ◀

4 Metric trees with coefficient 1

Section 3 demonstrates that results claiming $d_{\mathrm{GH}}(G, X) = d_{\mathrm{H}}(G, X)$ for X a subset of a metric graph G do not hold in general, even if $d_{\mathrm{H}}(G, X)$ is arbitrarily small. In this section, as well as in Section 6, we prove related results relying on bounds on $\vec{d}_{\mathrm{H}}(\partial G, X)$. In particular, we will assume the condition $d_{\mathrm{H}}(G, X) > \vec{d}_{\mathrm{H}}(\partial G, X)$ which rules out the example constructed in Theorem 5. The following proposition shows that condition has a high probability of being satisfied if X is a large uniform sample of G; see [3] for the proof.

▶ **Proposition 6.** *If G is a metric graph and X is a sample of n uniformly random points, then with high probability as $n \to \infty$, we have $d_{\mathrm{H}}(G, X) > \vec{d}_{\mathrm{H}}(\partial G, X)$.*

We prove the following results for metric trees.

▶ **Proposition 7.** *Let T be a finite tree, and let $f\colon T \to T$ be a function. If $d_{\mathrm{H}}(T, f(T)) > \vec{d}_{\mathrm{H}}(\partial T, f(T))$, then $\frac{1}{2}\mathrm{dis}(f) \geq d_{\mathrm{H}}(T, f(T))$.*

Proof. Let $\frac{1}{2}\mathrm{dis}(f) < r$ and let $\overline{x} \in T$ be a point such that $B(\overline{x}, d_{\mathrm{H}}(T, f(T))) \cap f(T) = \emptyset$. The assumption $d_{\mathrm{H}}(T, f(T)) > \vec{d}_{\mathrm{H}}(\partial T, f(T))$ implies that $T \setminus \{\overline{x}\}$ is disconnected and at least two distinct components thereof have non-empty intersection with $f(T)$ (since a tree has at least two leaves). Since $f(T)^r$ is connected by Lemma 3, we have $\overline{x} \in f(T)^r$, which implies $d_{\mathrm{H}}(T, f(T)) < r$. Since r can be taken arbitrarily, $d_{\mathrm{H}}(T, f(T)) \leq \frac{1}{2}\mathrm{dis}(f)$. ◀

▶ **Theorem 8.** *Let T be a finite metric tree and let $X \subseteq T$. If $d_{\mathrm{H}}(T, X) > \vec{d}_{\mathrm{H}}(\partial T, X)$, then $d_{\mathrm{GH}}(T, X) = d_{\mathrm{H}}(T, X)$.*

Proof. By Lemma 2, we may assume that X is compact. Suppose for a contradiction that $d_{\mathrm{GH}}(T, X) < d_{\mathrm{H}}(T, X)$. Then by Lemma 4, there is a function $f\colon T \to X \subseteq T$ with $\frac{1}{2}\mathrm{dis}(f) < d_{\mathrm{H}}(T, X) \leq d_{\mathrm{H}}(T, f(T))$ and $\vec{d}_{\mathrm{H}}(\partial T, f(T)) = \vec{d}_{\mathrm{H}}(\partial T, X) < d_{\mathrm{H}}(T, X) \leq d_{\mathrm{H}}(T, f(T))$, contradicting Proposition 7. ◀

In other words, $d_{\mathrm{H}}(T, X) = \max\{d_{\mathrm{GH}}(T, X), \vec{d}_{\mathrm{H}}(\partial T, X)\}$. All of the results in our paper have simple corollaries for two subsets of the tree or graph; we give one such example.

▶ **Corollary 9.** *Let T be a finite metric tree and let $X, Y \subseteq T$. For any $\varepsilon \geq d_{\mathrm{H}}(T, Y)$, if $d_{\mathrm{H}}(X, Y) > \vec{d}_{\mathrm{H}}(\partial T, X) + \varepsilon$, then $d_{\mathrm{GH}}(X, Y) \geq d_{\mathrm{H}}(X, Y) - 2\varepsilon$.*

Proof. We need only apply the triangle inequality:

$$
\begin{aligned}
& d_{\mathrm{H}}(X, Y) \leq d_{\mathrm{H}}(T, X) + d_{\mathrm{H}}(T, Y) \\
&= \max\left\{d_{\mathrm{GH}}(T, X), \vec{d}_{\mathrm{H}}(\partial T, X)\right\} + d_{\mathrm{H}}(T, Y) && \text{by Theorem 8} \\
&\leq \max\left\{d_{\mathrm{GH}}(X, Y) + d_{\mathrm{GH}}(T, Y), \vec{d}_{\mathrm{H}}(\partial T, X)\right\} + d_{\mathrm{H}}(T, Y) \\
&\leq \max\left\{d_{\mathrm{GH}}(X, Y) + d_{\mathrm{H}}(T, Y), \vec{d}_{\mathrm{H}}(\partial T, X)\right\} + d_{\mathrm{H}}(T, Y) && \text{since } d_{\mathrm{GH}}(T, Y) \leq d_{\mathrm{H}}(T, Y) \\
&= \max\left\{d_{\mathrm{GH}}(X, Y) + 2d_{\mathrm{H}}(T, Y), \vec{d}_{\mathrm{H}}(\partial T, X) + d_{\mathrm{H}}(T, Y)\right\} \\
&\leq \max\left\{d_{\mathrm{GH}}(X, Y) + 2\varepsilon, \vec{d}_{\mathrm{H}}(\partial T, X) + \varepsilon\right\} && \text{since } d_{\mathrm{H}}(T, Y) \leq \varepsilon.
\end{aligned}
$$
◀

As a particular case of Theorem 8, we can provide a closed formula for the Gromov–Hausdorff distance between a segment and a sample of it; see [3] for the proof.

▶ **Corollary 10.** *Let X be a compact non-empty subset of an interval $I = [a, b]$. Denote by $c = \min X$ and $d = \max X$. Then $d_{\mathrm{GH}}(I, X) = \max\left\{\frac{c-a+b-d}{2}, d_{\mathrm{H}}([c, d], X)\right\}$.*

5 The case of the circle

Before considering general metric graphs in the following section, in this section we first understand the simplest connected metric graph which is not a tree: the circle $G = S^1$. The authors of [2] showed that $d_{\mathrm{GH}}(S^1, X) = d_{\mathrm{H}}(S^1, X)$ for a compact subset $X \subseteq S^1$ with $d_{\mathrm{GH}}(S^1, X) < \frac{\pi}{6}$. A curious question regarding the optimality of the density constant $\frac{\pi}{6}$ was also posed therein [2, Question 2]. While the constant $\frac{\pi}{6}$ provides a sufficient Gromov–Hausdorff density of a subset X to guarantee the equality of its Hausdorff and Gromov–Hausdorff distances to S^1, it turns out this constant is suboptimal. In this section,

we show that $\frac{\pi}{3}$ is the optimal constant in the case of the circle. That is, for a subset $X \subseteq S^1$, the density condition $d_{\mathrm{GH}}(S^1, X) < \frac{\pi}{3}$ implies $d_{\mathrm{GH}}(S^1, X) = d_{\mathrm{H}}(S^1, X)$ (Theorem 11), and there is a compact $X \subseteq S^1$ with $\frac{\pi}{3} = d_{\mathrm{GH}}(S^1, X) < d_{\mathrm{H}}(S^1, X)$ (Theorem 12).

▶ **Theorem 11.** *For any subset $X \subseteq S^1$, we have $d_{\mathrm{GH}}(S^1, X) \geq \min\left\{d_{\mathrm{H}}(S^1, X),\ \frac{\pi}{3}\right\}$.*

Proof. This proof is closely related to [18, 12]. It suffices to show that if $d_{\mathrm{GH}}(S^1, X) < \frac{\pi}{3}$, then $d_{\mathrm{GH}}(S^1, X) \geq d_{\mathrm{H}}(S^1, X)$. Let $f\colon S^1 \to X$ be a (possibly discontinuous) function. By (3), it suffices to show that if $\frac{1}{2}\mathrm{dis}(f) < \frac{\pi}{3}$, then $\frac{1}{2}\mathrm{dis}(f) \geq d_{\mathrm{H}}(S^1, X)$, or equivalently that $\frac{\varepsilon + \mathrm{dis}(f)}{2} \geq d_{\mathrm{H}}(S^1, X)$ for all $\varepsilon > 0$ sufficiently small. Suppose $\frac{1}{2}\mathrm{dis}(f) < \frac{\pi}{3}$. Fix $\varepsilon > 0$ with $5\varepsilon < 2\pi - 3\mathrm{dis}(f)$. Form a finite triangulation K of S^1 with edges of length less than ε. Let $K^{(0)} \subseteq S^1$ be the vertex set of K. Since adjacent vertices $v_i, v_{i+1} \in K^{(0)}$ satisfy $d(v_i, v_{i+1}) < \varepsilon$, we have $d(f(v_i), f(v_{i+1})) < \varepsilon + \mathrm{dis}(f) < \pi$. Hence we can map the edge between v_i and v_{i+1} to the unique shortest path in S^1 between $f(v_i)$ and $f(v_{i+1})$, obtaining a continuous map $\overline{f}\colon K \to S^1$. Let $r = \frac{\varepsilon + \mathrm{dis}(f)}{2}$. Suppose for a contradiction that X^r is

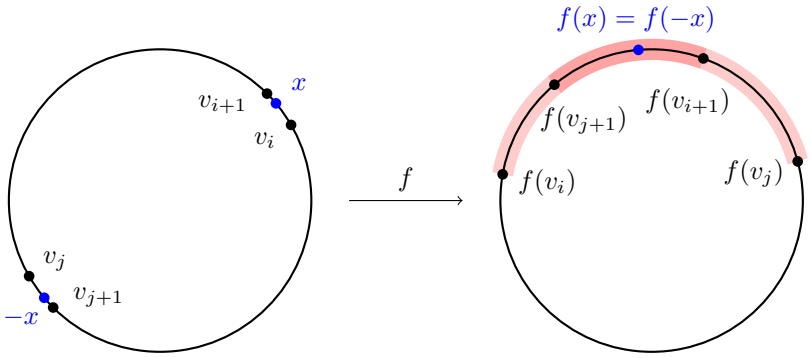

Figure 2 Proof of Theorem 11: Since $\overline{f}(x) = \overline{f}(-x)$, the shortest paths in S^1 between $f(v_i), f(v_{i+1})$ and $f(v_j), f(v_{j+1})$ intersect.

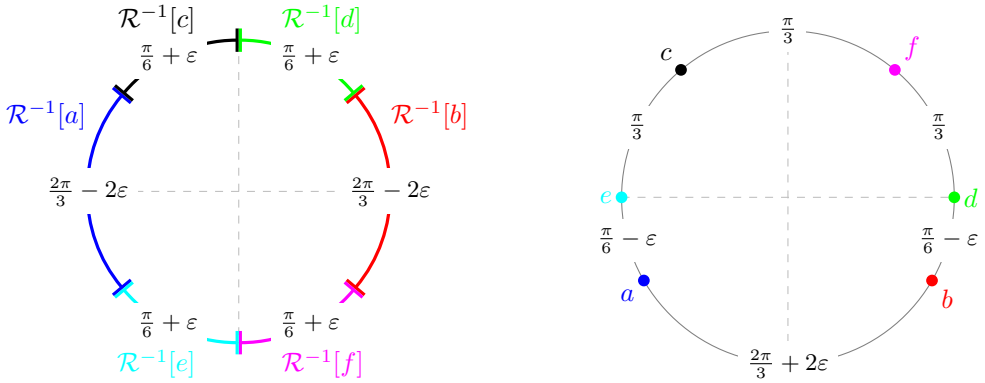
not equal to all of S^1. Then there is an arc of length at least $2r$ in S^1 that contains no points from X. So $\overline{f}$ is non-surjective, since the image of each edge in K is an edge of length less than $2r$. Hence $\overline{f}\colon K \to S^1$ is a map of degree zero. The Borsuk–Ulam theorem [5, Page 206, Exercise 21] then implies there are antipodal points $x, -x \in K$ with $\overline{f}(x) = \overline{f}(-x)$. Let x be on the closed edge between $v_i, v_{i+1} \in K^{(0)}$, and let $-x$ be on the closed edge between $v_j, v_{j+1} \in K^{(0)}$. Since $\overline{f}(x) = \overline{f}(-x)$, the shortest path in S^1 between $f(v_i), f(v_{i+1})$ intersects the shortest path between $f(v_j), f(v_{j+1})$. Since these paths in S^1 are of length less than $2r$, one of $f(v_i), f(v_{i+1})$ is at a distance less than r from one of $f(v_j), f(v_{j+1})$, i.e. $d(f(v), f(v')) < r$ for some $v \in \{v_i, v_{i+1}\}$ and $v' \in \{v_j, v_{j+1}\}$; see Figure 2. We obtain



$$\mathrm{dis}(f) > d(v, v') - d(f(v), f(v')) > (\pi - 2\varepsilon) - \tfrac{\varepsilon + \mathrm{dis}(f)}{2} = \pi - \tfrac{\mathrm{dis}(f)}{2} - \tfrac{5\varepsilon}{2}.$$

So $\frac{5\varepsilon}{2} > \pi - \frac{3\mathrm{dis}(f)}{2}$, contradicting the choice of ε. Hence it must be that $X^r = S^1$. Since $\frac{\varepsilon + \mathrm{dis}(f)}{2} = r \geq d_{\mathrm{H}}(S^1, X)$ for all $\varepsilon > 0$ sufficiently small, we are done. ◀

We now prove the optimality of $\frac{\pi}{3}$ for the circle, i.e. that $\frac{\pi}{3}$ is also a necessary condition.

▶ **Theorem 12.** *For any $\varepsilon \in \left(0, \frac{\pi}{6}\right)$, there exists a nonempty compact subset $X \subseteq S^1$ with $d_{\mathrm{H}}(S^1, X) = \frac{\pi}{3} + \varepsilon$ and $d_{\mathrm{GH}}(S^1, X) = \frac{\pi}{3} < d_{\mathrm{H}}(S^1, X)$.*

Proof. We construct X to be a six-element subset of S^1. Both X and a particular correspondence $\mathcal{R} \subseteq S^1 \times X$ are shown in Figure 3. One can check that $d_{\mathrm{H}}(S^1, X) = \frac{\pi}{3} + \varepsilon$. Also, one can check that $\mathrm{dis}(\mathcal{R}) = \frac{2\pi}{3}$, giving $d_{\mathrm{GH}}(S^1, X) \leq \frac{\pi}{3}$. So $d_{\mathrm{GH}}(S^1, X) < d_{\mathrm{H}}(S^1, X)$. Moreover, Theorem 11 implies that $d_{\mathrm{GH}}(S^1, X) = \frac{\pi}{3}$. ◀

(a) Correspondence $\mathcal{R} \subseteq S^1 \times X$ has a distortion of $\frac{2\pi}{3}$. So, $d_{\mathrm{GH}}(S^1, X) \leq \frac{\pi}{3}$.

(b) $X = \{a, b, c, d, e, f\} \subseteq S^1$ with $d_{\mathrm{H}}(S^1, X) = \frac{\pi}{3} + \varepsilon$.

Figure 3 The configuration of points $X \subseteq S^1$ is depicted to show the optimal constant for the circle.

6 Metric graphs with loops with coefficient 1

In this section, we extend our results for the circle to general metric graphs; see Theorem 23.

6.1 Distortion of continuous maps between graphs

We first need a Borsuk–Ulam theorem for maps into trees; see [3] for the proof.

▶ **Lemma 13.** *If T is a tree and $f\colon S^1 \to T$ is continuous, then there exist $x, x' \in S^1$ with $d(x, x') \geq \frac{2\pi}{3}$ and $f(x) = f(x')$.*

Note that the lower bound $\frac{2\pi}{3}$ in Lemma 13 cannot be improved, as shown in Figure 4. Recall

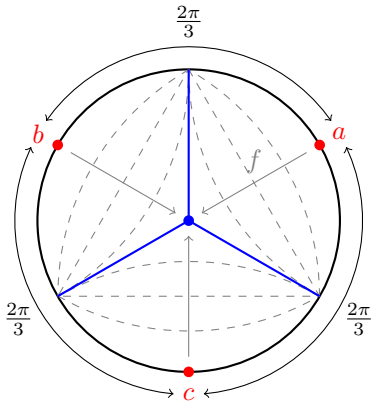


Figure 4 The lower bound in Lemma 13 is tight. The function f sends the black circle to the blue tripod. The points a, b and c are at distance $\frac{2\pi}{3}$ apart and in the same fiber of f.

that G_0 is the core of a metric graph G (see Section 2), and that $e(G_0)$ is the length of the shortest edge in G_0.

▶ **Lemma 14.** *Let (G, d) be a metric graph and γ be a simple loop. If $y, y' \in \gamma$ satisfy $d(y, y') < \frac{e(G_0)}{2}$, then there is a unique geodesic joining y and y' and it lies on γ.*

Proof. Let η be a simple path connecting y and y'. If η is not entirely in γ, its length is at least $e(G_0)$. So since $d(y, y') < \frac{e(G_0)}{2}$, a geodesic connecting the two points must lie on γ; see Figure 5. This geodesic is unique since the length of a loop is at least $e(G_0)$. ◀

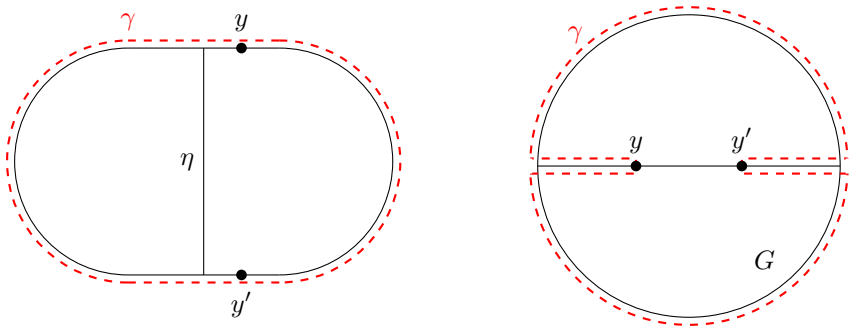

Figure 5 The assumptions in Lemma 14 are necessary. Loop γ is represented with a dashed red line. (a) If there is no bound on $e(G_0)$, then there may exist a shorter path connecting y and y' using a shortcut η. (b) If γ is not simple, then y and y' may be arbitrarily close and joined by geodesics that are not in γ.

The following lemma is the crucial step showing that a continuous map between finite graphs must send simple loops to simple loops, provided that the distortion is sufficiently small compared to the length of the shortest internal edge.

▶ **Lemma 15.** *Let $\overline{f}\colon (G, d_G) \to (G', d_{G'})$ be a continuous map between finite metric graphs. Assume that $\frac{\mathrm{dis}(\overline{f})}{2} < \frac{\min\{e(G_0), e(G_0')\}}{8}$. Then $\overline{f}$ induces an injection $\Phi\colon \mathcal{L}(G) \to \mathcal{L}(G')$ between the simple loops of G and the simple loops of G' as follows: given a simple loop $\gamma \in \mathcal{L}(G)$, $\Phi(\gamma)$ is the only simple loop of G' contained in $\overline{f}(\gamma)$.*

Proof of Lemma 15 □. For readability purposes, let us divide the proof into several claims. First, let us show that the map Φ is well-defined, i.e., for every simple loop $\gamma \in \mathcal{L}(G)$ there is a simple loop of G' contained in $\overline{f}(\gamma)$ and that simple loop is unique.

▷ Claim 16 (Existence). If γ is a simple loop of G, then $\overline{f}(\gamma)$ contains a simple loop of G'.

Proof of Claim 16. Suppose for a contradiction that $\overline{f}(\gamma)$ does not contain a loop. Since $\overline{f}(\gamma)$ is connected, it is a tree. So Lemma 13 applies to give points $x, x' \in \gamma$ with $\overline{f}(x) = \overline{f}(x')$ and $d_\gamma(x, x') \geq \frac{\mathrm{length}(\gamma)}{3}$ where d_γ is the geodesic distance on γ. We must have $d_G(x, x') \geq \frac{e(G_0)}{3}$, since if $d_G(x, x') < \frac{e(G_0)}{3} < \frac{e(G_0)}{2}$, then Lemma 14 would give that a geodesic connecting x and x' lies on γ, and so $d_G(x, x') = d_\gamma(x, x') \geq \frac{\mathrm{length}(\gamma)}{3} \geq \frac{e(G_0)}{3}$. We obtain the contradiction

$$\mathrm{dis}(\overline{f}) \geq |d_G(x, x') - d_{G'}(\overline{f}(x), \overline{f}(x'))| = d_G(x, x') \geq \frac{e(G_0)}{3} > \frac{e(G_0)}{4} > \mathrm{dis}(\overline{f}).$$

Hence $\overline{f}(\gamma)$ must contain a loop. ◁

▷ Claim 17 (Uniqueness). If γ is a simple loop, then $\overline{f}(\gamma)$ contains at most one simple loop.

Proof of Claim 17. Note that $\overline{f}(\gamma)$ is a closed subset of G' since it is the continuous image of a compact subset. Let $H = \overline{f}(\gamma)$, which is a connected subgraph of G'. Furthermore, let H_0 be the smallest connected subgraph of G' containing the union of all simple loops of H. Suppose for a contradiction that $\overline{f}(\gamma) = H$ contains at least two simple loops. Therefore,

at least one vertex of H_0 has degree at least 3. We can then consider the canonical graph representation of H_0 consisting of only vertices of degree at least 3. For every $v \in V(H_0)$, the closed subset $(\overline{f})^{-1}(v)$ has diameter at most $\mathrm{dis}(\overline{f}) < \frac{e(G_0)}{2}$. Hence, the convex hull C_v of $(\overline{f})^{-1}(v) \cap \gamma$ is well-defined. Furthermore, for every $v, v' \in V(H_0)$ with $v \neq v'$, we have $C_v \cap C_{v'} = \emptyset$. Indeed, for $x \in (\overline{f})^{-1}(v)$ and $x' \in (\overline{f})^{-1}(v')$ with $v \neq v'$, we have

$$d_G(x, x') \geq d_{G'}(v, v') - \mathrm{dis}(\overline{f}) \geq e(G'_0) - \mathrm{dis}(\overline{f}) > \mathrm{dis}(\overline{f}) \geq \max\{\mathrm{diam} C_v, \mathrm{diam} C_{v'}\}.$$

Let $|V(H_0)| = n$ and let $\gamma_1, \ldots, \gamma_n$ be the non-empty connected components of $\gamma \setminus \bigcup_{v \in V(H_0)} C_v$. For every $i \in \{1, \ldots, n\}$, note that $\overline{f}(\gamma_i)$ is contained in a connected component of $H \setminus V(H_0)$. Let $\eta_1, \ldots, \eta_m$ be the connected components of $H_0 \setminus V(H_0)$. Note that each η_j is an open-

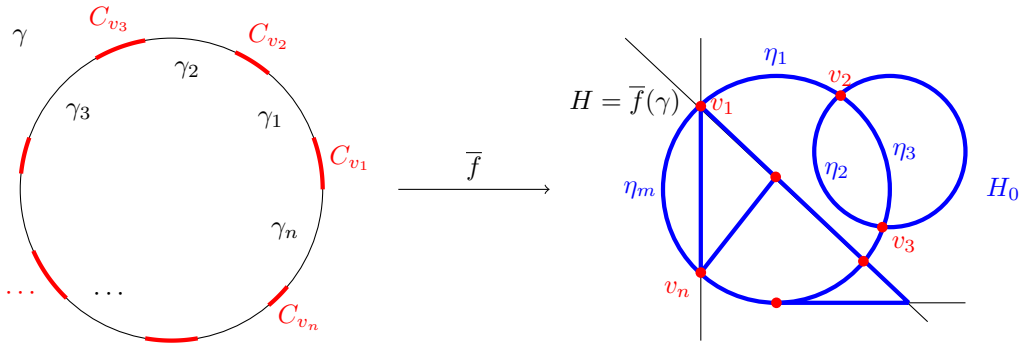

Figure 6 A representation of the objects constructed in the proof of Claim 17.

ended path in H_0. We claim that $\eta_j \cap \overline{f}(\gamma_1 \cup \cdots \cup \gamma_n) \neq \emptyset$ for every $j \in \{1, \ldots, m\}$. Let y be the midpoint of η_j. Since $H = \overline{f}(\gamma)$, there is $z \in \gamma$ such that $\overline{f}(z) = y$. For every $v \in V(H_0)$ and every $x \in (\overline{f})^{-1}(v)$,

$$d_G(z, x) \geq d_{G'}(y, v) - \mathrm{dis}(\overline{f}) \geq \tfrac{e(G'_0)}{2} - \mathrm{dis}(\overline{f}) > 2\mathrm{dis}(\overline{f}) - \mathrm{dis}(\overline{f}) = \mathrm{dis}(\overline{f}) \geq \mathrm{diam} C_v.$$

Hence, $z \notin C_v$ and so $z \in \gamma_1 \cup \cdots \cup \gamma_n$. So far, we have shown that each $\overline{f}(\gamma_i)$, for $i \in \{1, \ldots, n\}$, is contained in some connected component of $H \setminus V(H_0)$. Furthermore, among these connected components, each η_j with $j \in \{1, \ldots, m\}$ contains the $\overline{f}$-image of at least one γ_i. It will be a contradiction if we prove that $n < m$. Note that the set $\{\eta_j\}_{j=1}^m$ is in bijection with the edge set $E(H_0)$ of H_0. Hence

$$2m = 2|E(G'_0)| = \sum_{v \in V(G'_0)} \deg_{G'_0}(v) \geq 3|V(G'_0)| = 3n,$$

giving the contradiction $n < m$. It must be that $\overline{f}(\gamma)$ contains at most one simple loop. ◁

According to Claims 16 and 17, map Φ is well-defined. Lastly, we show that it is injective.

▷ Claim 18. The map $\Phi\colon \mathcal{L}(G) \to \mathcal{L}(G')$ is injective.

Proof of Claim 18. Let γ_1, γ_2, and η be three simple loops such that $\eta \subseteq \overline{f}(\gamma_1) \cap \overline{f}(\gamma_2)$. Suppose, by contradiction, that the simple loops γ_1 and γ_2 are distinct, meaning they differ by at least one edge. Without loss of generality, let us fix an edge $e \in E(G)$ that is contained in γ_1 but whose interior is disjoint from γ_2. Fix the midpoint m of e. In particular,

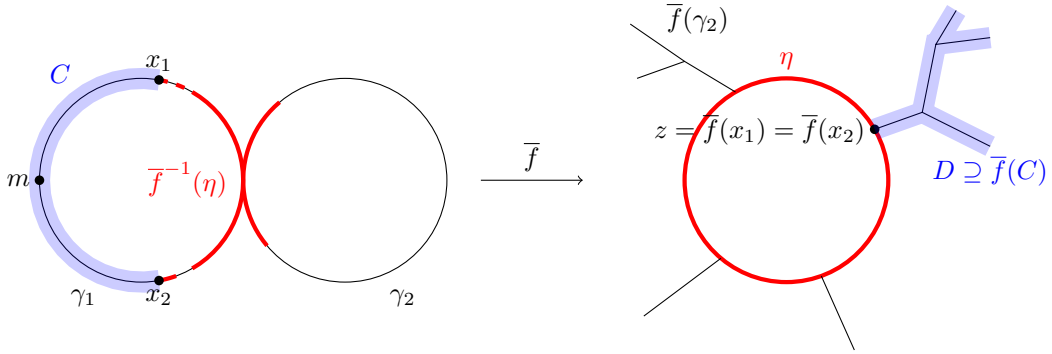

Figure 7 A representation of the objects constructed in the proof of Claim 18.

$d_G(m, \gamma_2) \geq \frac{e(G_0)}{2}$. Let us estimate $d_G(m, (\overline{f})^{-1}(\eta))$. Suppose that $x \in (\overline{f})^{-1}(\eta)$, and fix $y \in \gamma_2$ such that $\overline{f}(x) = \overline{f}(y)$. Note that $d_G(x, y) \leq \mathrm{dis}(\overline{f})$. Using the triangle inequality, we obtain

$$\begin{aligned} d_G(m, x) &\geq d_G(m, y) - d_G(x, y) \geq d_G(m, \gamma_2) - \mathrm{dis}(\overline{f}) \\ &\geq \tfrac{e(G_0)}{2} - \mathrm{dis}(\overline{f}) > 2\mathrm{dis}(\overline{f}) - \mathrm{dis}(\overline{f}) = \mathrm{dis}(\overline{f}). \end{aligned} \tag{4}$$

Hence $d(m, (\overline{f})^{-1}(\eta)) \geq \mathrm{dis}(\overline{f})$, and in particular, $\overline{f}(m) \notin \eta$. Consider the connected component C of $\gamma_1 \setminus (\overline{f})^{-1}(\eta)$ containing m. Since $(\overline{f})^{-1}(\eta)$ is closed by continuity, C is an open arc in γ_1. Let x_1 and x_2 be the two points of γ_1 on the boundary of C. Note that they both belong to $(\overline{f})^{-1}(\eta)$, and so $d_G(m, x_i) > \mathrm{dis}(\overline{f})$ by (4). Let us estimate $d_G(x_1, x_2)$. A geodesic connecting x_1 and x_2 satisfies one of the following:

(i) either it passes through m,
(ii) or it crosses $(\overline{f})^{-1}(\eta) \cap \gamma_1$,
(iii) or it uses an edge that is not in γ_1.

In all three cases, we have $d_G(x_1, x_2) > \mathrm{dis}(\overline{f})$. For (i), this follows since $d_G(m, x_i) > \mathrm{dis}(\overline{f})$. For (ii), let $A \coloneqq (\overline{f})^{-1}(\eta) \cap \gamma_1$. Since $\overline{f}(\gamma_1)$ contains η, we have $\overline{f}(A) = \eta$. The diameter of η is at least $\frac{e(G_0')}{2}$, and hence $\mathrm{diam}(A) \geq \frac{e(G_0')}{2} - \mathrm{dis}(\overline{f}) > 2\mathrm{dis}(\overline{f}) - \mathrm{dis}(\overline{f}) = \mathrm{dis}(\overline{f})$.

Finally, we also have $d_G(x_1, x_2) > \mathrm{dis}(\overline{f})$ in case (iii) since $e(G_0) > \mathrm{dis}(\overline{f})$. Since $\overline{f}$ is continuous, $\overline{f}(C)$ is contained in a connected component D of $\overline{f}(\gamma_1) \setminus \eta$. Since $\overline{f}(\gamma_1)$ contains only one loop, D is a tree. Furthermore, $\overline{f}(\gamma_1)$ is a closed subset of G' since it is the continuous image of a compact subset, and it contains only one simple loop. Thus, the closure of D in G' intersects η in only one point z. We have already observed that $\overline{f}(x_i) \in \eta$ for $i \in \{1, 2\}$. Furthermore, $\overline{f}(x_i)$ belongs to the closure of $\overline{f}(C)$ in G', which is contained in the closure of D. Therefore, $\overline{f}(x_i) = z$ since the latter is the only point in the closure of D that lies on η. This gives $\overline{f}(x_1) = z = \overline{f}(x_2)$, which contradicts the above established inequality $d_G(x_1, x_2) > \mathrm{dis}(\overline{f})$. ◁

This completes the proof of Lemma 15. ◀

6.2 Distortion of arbitrary functions between graphs

To apply Lemma 15 in the context of Gromov–Hausdorff distances, we will need a way to turn arbitrary functions into nearby continuous ones with controlled distortion, as described in the following result.

▶ **Lemma 19.** *Let $f\colon (G, d_G) \to (G', d_{G'})$ be a function between finite metric graphs with distortion $\frac{\mathrm{dis}(f)}{2} < r < \frac{\min\{e(G_0), e(G_0')\}}{4}$. Then there is a continuous map $\overline{f}\colon G \to G'$ such that $\frac{\mathrm{dis}(\overline{f})}{2} < 2r$ and $\overline{f}(G) \subseteq (f(G))^r$.*

Proof. We organize the proof into three steps, to help its readability. Let $\varepsilon > 0$ satisfy $\varepsilon + \operatorname{dis}(f) < 2r$.

Step 1: Construct a continuous map $\overline{f}$. Fix a finite triangulation K of G with edges of length at most ε such that $V(G) \subseteq K^{(0)}$. Let us construct a continuous map $\overline{f}\colon K \to G'$ as follows. For every vertex $x \in K^{(0)}$, set $\overline{f}(x) = f(x)$. Consider now two adjacent vertices x and y in $K^{(0)}$. Send the segment from x to y to the geodesic segment connecting $f(x)$ and $f(y)$ at uniform speed. The geodesic between the two points $f(x)$ and $f(y)$ is unique since $d_{G'}(f(x), f(y)) \leq \varepsilon + \operatorname{dis}(f) < \frac{e(G'_0)}{2}$.

Step 2: Estimate the distortion of $\overline{f}$. We claim that $\operatorname{dis}(\overline{f}) \leq 2(\operatorname{dis}(f) + \varepsilon) < 4r$. The second inequality is trivial. Let $x, y \in K$. Choose a closest point $x_i \in K^{(0)}$ to x. Let $x_{i+1} \in K^{(0)}$ be such that x is contained in the edge $\{x_i, x_{i+1}\}$. Note that $d_G(x, x_i) \leq \frac{\varepsilon}{2}$. Thus, by construction of $\overline{f}$,

$$d_{G'}(\overline{f}(x), f(x_i)) \leq \frac{d_{G'}(f(x_i), f(x_{i+1}))}{2} \leq \frac{\varepsilon + \operatorname{dis}(f)}{2} \tag{5}$$

Similarly, if $y_j \in K^{(0)}$ is a closest point to y, $d_G(y, y_j) \leq \frac{\varepsilon}{2}$ and $d_{G'}(\overline{f}(y), f(y_j)) \leq \frac{\varepsilon + \operatorname{dis}(f)}{2}$. By applying the triangle inequality, we obtain the following chain of inequalities:

$$\begin{aligned}
&d_{G'}(\overline{f}(x), \overline{f}(y)) \leq d_{G'}(\overline{f}(x), \overline{f}(x_i)) + d_{G'}(f(x_i), f(y_j)) + d_{G'}(\overline{f}(y_j), \overline{f}(y)) \\
&\leq \tfrac{\operatorname{dis}(f)+\varepsilon}{2} + d_G(x_i, y_j) + \operatorname{dis}(f) + \tfrac{\operatorname{dis}(f)+\varepsilon}{2} \leq 2\operatorname{dis}(f) + \varepsilon + d_G(x_i, x) + d_G(x, y) + d_G(y, y_j) \\
&\leq 2(\operatorname{dis}(f) + \varepsilon) + d_G(x, y) < 4r + d_G(x, y).
\end{aligned}$$

With similar computations, we can show that $d_G(x, y) - d_{G'}(\overline{f}(x), \overline{f}(y)) \leq 2(\operatorname{dis}(f) + \varepsilon) < 4r$. This proves $\frac{\operatorname{dis}(\overline{f})}{2} < 2r$.

Step 3: Show $\overline{f}(K) \subseteq (f(G))^r$. For every point $\overline{f}(x) \in \overline{f}(K)$, choose a closest point $x_i \in K^{(0)}$ to x as in **Step 2**. According to (5), $d_{G'}(\overline{f}(x), f(x_i)) < r$ since $\varepsilon + \operatorname{dis}(f) < 2r$. ◀

We finally obtain that the core G_0 of a graph G is preserved by a function with distortion bounded by a fraction of the shortest edge length.

▶ **Proposition 20.** *Let G be a finite metric graph and let $f\colon G \to G$ be a function with $\frac{\operatorname{dis}(f)}{2} < r < \frac{e(G_0)}{16}$. Then $G_0 \subseteq f(G_0)^r$.*

Proof. Let $\overline{f}\colon G \to G$ be the continuous map described in Lemma 19. Then $\frac{\operatorname{dis}(\overline{f})}{2} < 2r < \frac{e(G_0)}{8}$. The restriction $\overline{f}|_{G_0}\colon G_0 \to G$ is also continuous and has the same bound on its distortion. We can then apply Lemma 15 to $\overline{f}|_{G_0}$ and obtain an injection $\Phi\colon \mathcal{L}(G_0) \to \mathcal{L}(G)$. Since $\mathcal{L}(G_0) = \mathcal{L}(G)$ by construction and these sets are finite, Φ is a bijection. Hence, every simple loop of G is contained in $\overline{f}(G_0) \subseteq f(G_0)^r$ according to Lemma 19. Given that $f(G_0)^r$ is connected, it contains G_0. ◀

As an immediate consequence of Proposition 20 we obtain that the Hausdorff and the Gromov–Hausdorff distances between a graph with no leaves and a subset thereof coincide, provided that the latter is sufficiently small.

▶ **Corollary 21.** *Let G be a finite metric graph with no leaves, and let $X \subseteq G$. If $d_{\mathrm{GH}}(G, X) < \frac{e(G_0)}{16}$, then $d_{\mathrm{GH}}(G, X) = d_{\mathrm{H}}(G, X)$.*

Proof. Let $r > 0$ satisfy $d_{\mathrm{GH}}(G, X) < r < \frac{e(G_0)}{16}$. Then there is a map $f\colon G \to X$ whose distortion satisfies $\frac{\mathrm{dis}(f)}{2} < r < \frac{e(G_0)}{16}$. We can apply Proposition 20 to obtain that $G = G_0 \subseteq f(G_0)^r \subseteq X^r$. Hence $d_{\mathrm{H}}(G, X) \leq r$. Since r can be taken arbitrarily, we have $d_{\mathrm{H}}(G, X) \leq d_{\mathrm{GH}}(G, X)$. ◀

We now discuss how to lower bound the Gromov–Hausdorff distance with respect to the Hausdorff distance for graphs with leaves. The first result relies on hypotheses around the subset X of the graph G. More precisely, similarly to the tree case, we request that the subset X is sufficiently close to the leaves of G.

▶ **Proposition 22.** *Let (G, d) be a finite metric graph and let $f\colon G \to G$ be a (possibly discontinuous) function with $\frac{\mathrm{dis}(f)}{2} < \frac{e(G_0)}{16}$. If $\partial G \neq \emptyset$, suppose that $d_{\mathrm{H}}(G, f(G)) > \vec{d}_{\mathrm{H}}(\partial G, f(G))$. Then $d_{\mathrm{H}}(G, f(G)) \leq \frac{\mathrm{dis}(f)}{2}$.*

Proof. Let $r > 0$ satisfy $\frac{\mathrm{dis}(f)}{2} < r < \frac{e(G_0)}{16}$. Let $\overline{x} \in G$ be a point such that the intersection $B(\overline{x}, d_{\mathrm{H}}(G, f(G))) \cap f(G)$ is empty. If $\overline{x} \in G_0$, then $\overline{x} \in f(G)^r$ according to Proposition 20, and so $d_{\mathrm{H}}(G, f(G)) < r$. Suppose otherwise that $\overline{x} \notin G_0$. Thus, $G \setminus \{\overline{x}\}$ is disconnected, and at least two connected components thereof have non-empty intersection with X by the assumption. We can conclude as in Proposition 7. ◀

▶ **Theorem 23.** *Let G be a finite connected metric graph and let $X \subseteq G$. If $\partial G \neq \emptyset$, suppose $d_{\mathrm{H}}(G, X) > \vec{d}_{\mathrm{H}}(\partial G, X)$. If $d_{\mathrm{GH}}(G, X) < \frac{e(G_0)}{16}$, then $d_{\mathrm{GH}}(G, X) = d_{\mathrm{H}}(G, X)$.*

Proof. As in the proof of Theorem 8, by Lemma 2 we can assume that X is compact by replacing it with its closure $\overline{X}$ if necessary. Suppose, by contradiction, that $d_{\mathrm{GH}}(G, X) < d_{\mathrm{H}}(G, X)$. By Lemma 4 there is a function $f\colon G \to X$ such that $\frac{1}{2}\mathrm{dis}(f) < \min\{d_{\mathrm{H}}(G, X), \frac{e(G_0)}{16}\}$ and $\vec{d}_{\mathrm{H}}(\partial G, X) = \vec{d}_{\mathrm{H}}(\partial G, f(G))$. Note that $d_{\mathrm{H}}(G, f(G)) \geq d_{\mathrm{H}}(G, X) > \vec{d}_{\mathrm{H}}(\partial G, X) = \vec{d}_{\mathrm{H}}(\partial G, f(G))$. We can apply Proposition 22 to obtain a contradiction with the following chain of inequalities: $d_{\mathrm{H}}(G, X) \leq d_{\mathrm{H}}(G, f(G)) \leq \frac{\mathrm{dis}(f)}{2} \leq d_{\mathrm{GH}}(G, X)$. ◀

7 Conclusion and open questions

We have furthered the study of lower bounding the Gromov–Hausdorff distance between a space and a subset by their Hausdorff distance, particularly for metric graphs. This investigation sparks several open questions and new research directions, especially for spaces beyond graphs: (1) Is the density constant $\frac{e(G_0)}{16}$ in Theorem 23 optimal? (2) Do our results generalize to general length spaces? If so, under what density assumptions? (3) Are there versions of our results that hold for manifolds with boundary? (4) Are there classes of metric spaces (other than graphs) where the Gromov–Hausdorff distance between the space and a dense enough subset equals their Hausdorff distance?

Abstract

Let K be a compact, centrally-symmetric, strictly-convex region in $\mathbb{R}^3$, which is a semi-algebraic set of constant complexity, i.e. the unit ball of a corresponding metric, denoted as $\|\cdot\|_K$. Let $\mathcal{K}$ be a set of n homothetic copies of K. This paper contains two main sets of results:

(i) For a storage parameter $s \in [n, n^3]$, $\mathcal{K}$ can be preprocessed in $O^*(s)$ expected time into a data structure of size $O^*(s)$, so that for a query homothet K_0 of K, an intersection-detection query (determine whether K_0 intersects any member of $\mathcal{K}$, and if so, report such a member) or a nearest-neighbor query (return the member of $\mathcal{K}$ whose $\|\cdot\|_K$-distance from K_0 is smallest) can be answered in $O^*(n/s^{1/3})$ time; all k homothets of $\mathcal{K}$ intersecting K_0 can be reported in additional $O(k)$ time. In addition, the data structure supports insertions/deletions in $O^*(s/n)$ amortized expected time per operation. Here the $O^*(\cdot)$ notation hides factors of the form n^ε, where $\varepsilon > 0$ is an arbitrarily small constant, and the constant of proportionality depends on ε.

(ii) Let $\mathcal{G}(\mathcal{K})$ denote the intersection graph of $\mathcal{K}$. Using the above data structure, breadth-first or depth-first search on $\mathcal{G}(\mathcal{K})$ can be performed in $O^*(n^{3/2})$ expected time. Combining this result with the so-called shrink-and-bifurcate technique, the reverse-shortest-path problem in a suitably defined proximity graph of $\mathcal{K}$ can be solved in $O^*(n^{62/39})$ expected time. Dijkstra's shortest-path algorithm, as well as Prim's MST algorithm, on a $\|\cdot\|_K$-proximity graph on n points in $\mathbb{R}^3$, with edges weighted by $\|\cdot\|_K$, can also be performed in $O^*(n^{3/2})$ time.

1 Introduction

Problem statement. Let K be a compact, centrally-symmetric, strictly-convex region in $\mathbb{R}^3$, which is a semi-algebraic set of constant complexity.[1] K is the unit ball of a norm $\|\cdot\|_K$, and we denote its metric as dist_K.

[1] Roughly speaking, a semi-algebraic set in $\mathbb{R}^d$ is the set of points in $\mathbb{R}^d$ that satisfy a Boolean formula over a set of polynomial inequalities; the complexity of a semi-algebraic set is the number of polynomials defining the set and their maximum degree. See [12] for formal definitions of a semi-algebraic set and its complexity.

A *homothet* (or *homothetic copy*) of K is a scaled and translated copy of K, expressed as $K(c,\rho) := \rho K + c$, for $c \in \mathbb{R}^3$ and $\rho \geq 0$; c is the *center* of $K(c,\rho)$ and ρ is its *size*. We represent $K(c,\rho)$ as the point $(c,\rho) \in \mathbb{R}^3 \times \mathbb{R}_{\geq 0}$. Let $\mathbb{K}$ be the set of all homothets of K, represented as the halfspace $x_4 \geq 0$ of $\mathbb{R}^4$. The *K-distance* $\mathrm{dist}_K(u,v) = \|u-v\|_K$ between points $u, v \in \mathbb{R}^3$ is the minimum value of ρ for which $v \in K(u,\rho)$ (or, equivalently, $u \in K(v,\rho)$). Since K is strictly convex, the triangle inequality $\mathrm{dist}_K(u,v) \leq \mathrm{dist}_K(u,w) + \mathrm{dist}_K(w,v)$ is sharp unless w lies on the segment uv. The K-distance of a point $x \in \mathbb{R}^3$ from a homothet $K(c,\rho)$ is defined as $f_{c,\rho}(x) = \mathrm{dist}_K(c,x) - \rho$, and the K distance of another homothet $K(c',\rho')$ from $K(c,\rho)$ is $f_{c,\rho}(c') - \rho' = \mathrm{dist}_K(c,c') - \rho - \rho'$. Since K is a constant-complexity semi-algebraic set, $f_{c,\rho}$ is a semi-algebraic function of constant complexity. The homothets $K(c,\rho)$ and $K(c',\rho')$ intersect if the distance between them is non-positive, i.e., $\mathrm{dist}_K(c,c') \leq \rho + \rho'$, or equivalently, the point (c',ρ') lies above the graph of $f_{c,\rho}$ in $\mathbb{R}^4$, or vice-versa.

Let $\mathcal{K} = \{K_1, \ldots, K_n\} \subset \mathbb{K}$ be a set of n homothets of K, where $K_i = K(c_i, \rho_i)$. In this paper we study two classes of proximity problems related to $\mathcal{K}$.

Proximity queries. We wish to preprocess $\mathcal{K}$ into a data structure so that various proximity queries for a query homothet K_0, such as intersection-detection (determine whether K_0 intersects any homothet of $\mathcal{K}$; if the answer is yes, return one such intersecting homothet of $\mathcal{K}$), intersection reporting (report all homothets of $\mathcal{K}$ that intersect K_0), and nearest-neighbor queries (report the homothet of $\mathcal{K}$ at the minimum K-distance from K_0), can be performed efficiently. In addition, the data structure should support insertions and deletions of homothets of K.

Searching in the intersection graph and related problems. Let $\mathcal{G}(\mathcal{K})$ denote the intersection graph of $\mathcal{K}$, whose vertices are the homothets of $\mathcal{K}$ and (K_i, K_j) is an edge if $K_i \cap K_j \neq \emptyset$. Similarly, for a threshold parameter r_0, the *r_0-proximity graph* $\mathcal{G}_{r_0}(\mathcal{K})$ of $\mathcal{K}$ consists of those edges (K_i, K_j) for which $\mathrm{dist}_K(K_i, K_j) \leq r_0$. We study efficient implementation of graph-search problems on $\mathcal{G}(\mathcal{K})$, like BFS or DFS. We also study the *reverse shortest path* (RSP) problem on $\mathcal{K}$: given two elements $K_i, K_j \in \mathcal{K}$ and a parameter $1 \leq k < n$, compute the smallest value r^* for which $\mathcal{G}_{r^*}(\mathcal{K})$ contains a path from K_i to K_j with at most k edges.

Related work. There is extensive work on nearest-neighbor (NN) searching in many different fields including computational geometry, database systems, and machine learning. We refer the readers to various survey papers [4, 10, 20] for a general overview of known results on this topic. Here we briefly mention a few results that are most closely related to the problems studied in this paper. Agarwal and Matoušek [9] presented a dynamic NN data structure for a point set in $\mathbb{R}^d$, under the Euclidean metric, that answers a query in $O^*(n/s^\phi)$ time, where $\phi = 1 - \frac{1}{\lceil d/2 \rceil}$ and $s \in [n, n^{\lceil d/2 \rceil}]$ is a storage parameter, using $O^*(s)$ space and preprocessing; the (amortized) update time for insertions/deletions of points is $O^*(s/n)$. The bounds were slightly improved – n^ε factors were replaced by $\log^{O(1)} n$ factors – in [15,26]. Kaplan *et al.* [26] presented a dynamic NN data structure for a set S of points in $\mathbb{R}^2$ under fairly general distance functions. Its performance depends on the complexity of the Voronoi diagram of S under that distance function. For the Minkowski metric induced by a centrally-symmetric convex region, which is a semi-algebraic set of constant complexity, their data structure can answer an NN query in $O(\log^2 n)$ time, and handle insertion and deletion of a point in $O(\beta(n)\log^5 n)$ and $O(\beta(n)\log^9 n)$ amortized expected time, respectively, where $\beta(n)$, a variant of inverse Ackermann's function, is an extremely slowly growing function; see also [31] for slightly improved bounds. These data structures, however, do not extend to $\mathbb{R}^3$.

The problem of NN searching under general distance functions in $\mathbb{R}^3$ is much less understood. By reducing NN queries to ball-intersection queries [8] and using semi-algebraic range-searching data structures [1, 2, 33], an NN query amid the set $\mathcal{K}$ of n homothets in $\mathbb{R}^3$, as above, can be answered in $O^*(1)$ time using $O^*(n^4)$ space and preprocessing, or in $O^*(n^{3/4})$ time using $O(n)$ space and preprocessing. Using recent standard techniques (see, e.g., the Appendix in [1]), one can obtain a space/query-time trade-off, as well as handle insertions/deletions of objects. Using a recent result by Agarwal *et al.* [5] on the vertical decomposition of the lower envelope of trivariate functions, an NN query amid $\mathcal{K}$ can be answered in $O(\log^2 n)$ time using only $O^*(n^3)$ space, but this data structure does not support efficient deletions (insertions can be handled in a standard manner, using the dynamization technique of Bentley and Saxe [13]). Furthermore, it was not known whether an NN query amid $\mathcal{K}$ can be answered in $O^*(n^{2/3})$ time using $O^*(n)$ space.

Motivated by numerous applications, there has been work on developing fast algorithms for intersection and proximity graphs of n geometric objects. Although the intersection graph may have $\Theta(n^2)$ edges, the goal in this line of work is to develop algorithms, by exploiting the underlying geometry, that run in $O^*(n)$ time (or at least in subquadratic time). Cabello and Jejčič [14], and subsequently Chan and Skrepetos [21], presented $O(n \log n)$ implementations of BFS in unit-disk intersection graphs, which was recently extended to general disk-intersection graphs by de Berg and Cabello [22]; see also [25, 26, 29]. The algorithm in [22] can also perform DFS and Dijkstra's algorithm in $O(n \log n)$ time. Katz *et al.* [28] showed that BFS in ball-intersection graphs (for congruent or arbitrary Euclidean balls) can be implemented in $O^*(n^{2\phi/(\phi+1)})$ time, where $\phi = \lfloor d/2 \rfloor + 1$, so in $O^*(n^{4/3})$ time for $d = 3$. The problem of devising efficient implementations for BFS/DFS in more general graphs in the plane also has received some attention, see, e.g., [6, 7, 27].

The reverse shortest path (RSP) problem for unit disks was studied by Wang and Zhao [36], who gave an $O^*(n^{5/4})$-time solution. Kaplan *et al.* [25] improved the runtime to $O^*(n^{6/5})$ using the *shrink-and-bifurcate* technique (see [11]), and it was recently improved to $O^*(n^{9/8})$ by Chan and Huang [17]. The best-known RSP algorithm for arbitrary disks runs in $O^*(n^{6/5})$ expected time. Katz *et al.* [28] presented RSP algorithms for balls in $\mathbb{R}^3$ – with $O^*(n^{29/21})$ time for congruent balls and $O^*(n^{56/39})$ for arbitrary balls. The RSP problem also has been studied for other geometric objects in $\mathbb{R}^2$ [7, 17, 28].

Our results. Our main result is a dynamic data structure for answering intersection and NN queries with a homothet of $\mathbb{K}$ amid the set $\mathcal{K}$ of homothets:

▶ **Theorem 1.** *Let K be a compact, centrally-symmetric strictly convex semi-algebraic set in $\mathbb{R}^3$ of constant complexity. Let $\mathcal{K}$ be a set of n homothetic copies of K. For a storage parameter $s \in [n, n^3]$, $\mathcal{K}$ can be maintained in a dynamic data structure with $O^*(s)$ storage, that can answer an intersection-detection or NN-query (under the K-distance) with a homothet K_0 of K in $O^*(n/s^{1/3})$ time and that supports insertions/deletions in $O^*(s/n)$ amortized expected time. It can report all k objects of $\mathcal{K}$ intersecting K_0 in additional $O(k)$ time.*

Plugging Theorem 1 into Eppstein's technique [23], or its enhancement by Chan [16], for maintaining bichromatic closest pairs, using $s = n^{3/2}$, we obtain:

▶ **Corollary 2.** *Let K be a compact, centrally-symmetric strictly-convex semi-algebraic set in $\mathbb{R}^3$ of constant complexity. Let $\mathcal{K}, \mathcal{K}'$ be two sets of homothets of K of combined size n. The K-closest pair between $\mathcal{K}$ and $\mathcal{K}'$, under insertions/deletions of homothets (in $\mathcal{K}$ and $\mathcal{K}'$), can be maintained in $O^*(n^{1/2})$ amortized expected time per update.*

Theorem 1 is obtained by presenting two data structures. The first one (see Section 4.1) uses $O^*(n^3)$ space, answers a query in $O^*(1)$ time, and handles an insertion/deletion in $O^*(n^2)$ amortized expected time. (The data structure in [5] also obtains a similar space/query-time bound but it cannot handle deletions efficiently.) This data structure is based on constructing *vertical shallow cuttings*, a notion originally introduced in [15,18], of the graphs of the distance functions of $\mathcal{K}$. Roughly speaking, for a parameter $t \geq 1$, a *vertical* (n/t)*-shallow cutting* of $\mathcal{K}$ is a collection of pairwise openly disjoint semi-unbounded *pseudo-prisms* that covers the region lying below the k-level of the arrangement of $\mathcal{K}$, where each prism, consisting of all points that lie vertically below a constant-complexity semi-algebraic 3-dimensional region, intersects the graphs of only $O(n/t)$ functions of $\mathcal{K}$. The random-sampling based technique used in [15, 26] to construct a vertical shallow cutting does not immediately extend to our setting because one needs to decompose the q-level, for some parameter $q > 0$, in the 4D arrangement of the distance functions of $\mathcal{K}$ into $O^*(n^3(q+1))$ constant-complexity cells. Although a recent result [5] constructs such a decomposition of the 0-level (with $O^*(n^3)$ cells), it does not extend to larger values of q. This problem remains elusive for arrangements of arbitrary trivariate semi-algebraic functions of constant complexity, but we develop a desired decomposition technique for our setting (in Section 2) by exploiting the structural geometric properties of the distance functions of $\mathcal{K}$. This result is one of the main technical contributions of the paper. Using our result on the decomposition of the q-level, we construct a vertical (n/t)-shallow cutting of $\mathcal{K}$ of size $O^*(t^3)$, for any t (Section 3).

The second data structure is a linear-size partition tree, with $O^*(n^{2/3})$ query time, constructed on the point set $\mathcal{K}^* = \{(c_i, \rho_i) \mid 1 \leq i \leq n\} \subset \mathbb{R}^4$, that answers intersection-detection queries on $\mathcal{K}$ with a homothet of $\mathbb{K}$ as a query. The main technical challenge we face here is the construction of a so-called *test set* of $\mathcal{K}$ (see [35] and below) of size $r^{O(1)}$, which represents well the distance functions of all (n/r)*-shallow* homothets in $\mathbb{K}$, i.e., the homothets that intersect at most n/r elements of $\mathcal{K}$. By adapting the technique in [35] and again exploiting the structural geometric properties of the distance functions, we show that a test set, of size $O^*(r^4)$, with the desired properties can be constructed efficiently.

Using Theorem 1 and Corollary 2, we obtain our second set of results:

▶ **Theorem 3.**

(a) *Given a set $\mathcal{K}$ of n homothets of a constant-complexity, strictly convex, centrally-symmetric semi-algebraic set K, BFS or DFS in the intersection graph of $\mathcal{K}$ can be performed in $O^*(n^{3/2})$ expected time.*

(b) *The single-source shortest-path tree as well as the minimum spanning forest of the r_0-proximity graph of a set of n points, for any threshold parameter r_0, weighted by the pairwise K-distances, can be computed in $O^*(n^{3/2})$ time.*

Combining Theorem 3(a) with the shrink-and-bifurcate technique [11, 25] yields:

▶ **Theorem 4.** *Given a set $\mathcal{K}$ of n homothets of a constant-complexity, strictly convex, centrally-symmetric semi-algebraic set K, two designated elements $K, K' \in \mathcal{K}$, and an integer $k < n$, the RSP problem on $\mathcal{K}$, of finding the smallest r^* for which $G_{r^*}(\mathcal{K})$ contains a path between K and K' of length at most k, can be solved in $O^*(n^{62/39})$ expected time.*

Because of lack of space, the proofs of Theorems 3 and 4 and of some of the lemmas are omitted from this version.

2 Decomposing the k-Level of an Arrangement of Distance Functions

Preliminaries. Let $\mathcal{K} = \{K_1, \ldots, K_n\}$, where each K_i is a homothetic copy of K represented by a point $K_i^* = (c_i, \rho_i)$ in $\mathbb{R}^4$. For $1 \le i \le n$, set $f_i = f_{c_i,\rho_i}$, and let $\mathcal{F} := \mathcal{F}(\mathcal{K}) = \{f_i \mid 1 \le i \le n\}$. (As noted, distances from points x that lie inside some copy K_i, still measured by $f_i(x)$, are nonpositive.) We will not distinguish between a function of $\mathcal{F}$ and its graph. For a point $x \in \mathbb{R}^3$, K_i is the *nearest neighbor* of x in $\mathcal{K}$ (under the K-distance dist_K), i.e., $i = \arg\min_{1\le j\le n} f_j(x)$, if f_i appears on the lower envelope of $\mathcal{F}$ at x.

The *level* of a point $p \in \mathbb{R}^4$ in $\mathcal{A}(\mathcal{F})$ is the number of functions in $\mathcal{F}$ whose graphs lie below p. For a parameter $k < n$, the *k-level* of $\mathcal{A}(\mathcal{F})$, denoted $\mathcal{A}_k(\mathcal{F})$, is the (closure of the) locus of all points on $\bigcup\mathcal{F}$ whose level is k. We define the *$(\le k)$-level* of $\mathcal{A}(\mathcal{F})$, denoted $\mathcal{A}_{\le k}(\mathcal{F})$, to be the (closure of the) set of all points in $\mathbb{R}^4$ of level at most k, i.e., the set of points that lie on or below $\mathcal{A}_k(\mathcal{F})$ (not necessarily on $\cup\mathcal{F}$). The projection of $\mathcal{A}_k(\mathcal{F})$ onto $\mathbb{R}^3$, denoted by $\mathcal{M}_k = \mathcal{M}_k(\mathcal{K})$, is a subdivision of $\mathbb{R}^3$. If a cell $\tau^\downarrow$ of $\mathcal{M}_k$ is the projection of a cell τ of $\mathcal{A}_k(\mathcal{F})$ that lies on the graph of f_i, then K_i is the k-th nearest neighbor in $\mathcal{K}$ (under the K-distance function) of all points in $\tau^\downarrow$. Note that $A_0(\mathcal{F})$ is the lower envelope of $\mathcal{F}$, and $\mathcal{M}_0(\mathcal{K})$ is the Voronoi diagram of $\mathcal{K}$ (under the K-distance).

The decomposition. The main technical result of this section is that $\mathcal{A}_k(\mathcal{F})$ can be decomposed into $O^*(n^3(k+1))$ *elementary cells*, namely, constant-complexity semi-algebraic regions, each homeomorphic to a ball; see below for a more precise definition.

For $1 \le i \ne j \le n$, let $B_{ij} = \{x \in \mathbb{R}^3 \mid f_i(x) = f_j(x)\}$ be the *bisector* of K_i and K_j under the K-distance. Note that if $K_i \subset K_j$ then, as is easily verified, $f_j(x) < f_i(x)$ for all $x \in \mathbb{R}^3$ and B_{ij} is undefined. The following lemma gives a useful property of bisectors.

▶ **Lemma 5.** *Fix a homothet $K_i \in \mathcal{K}$. Let λ be a ray in $\mathbb{R}^3$ emanating from c_i. For any $1 \le j \ne i \le n$ such that $K_i \not\subset K_j$, λ intersects B_{ij} in at most one point, say, ξ. Furthermore, $f_i(x) \le f_j(x)$ for all $x \in c_i\xi$ (where $c_i\xi$ denotes the segment with endpoints c_i and ξ) and $f_j(x) > f_i(x)$ for all $x \in \lambda \setminus c_i\xi$.*

We are now ready to describe the decomposition of the cells of $\mathcal{A}_k(\mathcal{F})$ into elementary cells. (Our ultimate goal is to decompose the region below $\mathcal{A}_k(\mathcal{F})$ into elementary cells, but we start with this subtask.) For $1 \le i \le n$, let $\mathcal{A}_k^i = \mathcal{A}_k^i(\mathcal{F})$ denote the subset of cells of $\mathcal{A}_k(\mathcal{F})$ that lie on the graph of f_i, and let $\mathcal{M}_k^i$ denote their projections (which are the cells of $\mathcal{M}_k$ for which K_i is the k-th nearest neighbor). We describe the algorithm for decomposing the cells of $\mathcal{M}_k^i$ (or of $\mathcal{A}_k^i$). Lemma 5 implies that, for any $j \ne i$, B_{ij} can be viewed as the graph of a function $g_{ij} : \mathbb{S}^2 \to \mathbb{R}_{\ge 0}$ in spherical coordinates with c_i as the origin. That is, for a given $u \in \mathbb{S}^2$, let $\lambda(u)$ be the ray emanating from c_i in direction u, and let $x_{ij}(u)$ be the intersection point of $\lambda(u)$ with the bisector B_{ij} if such an intersection point exists; otherwise $x_{ij}(u)$ is undefined. We set $g_{ij}(u) = f_j(x_{ij}(u))$ if $x_{ij}(u)$ is defined and $+\infty$ otherwise. Let $G^{(i)} = \{g_{ij} \mid 1 \le j \ne i \le n\}$. We define the *level* of a point $x \in \mathbb{R}^3$ in (the 3D arrangement, within $\mathbb{S}^2 \times \mathbb{R}$) $\mathcal{A}(G^{(i)})$ to be the number of functions in $G^{(i)}$ whose graphs intersect the (relatively open) segment c_ix. The following lemma will be useful in analyzing the complexity of the decomposition of $\mathcal{A}_k^i$.

▶ **Lemma 6.** *For a parameter $k < n$, let τ be a 3D cell of $\mathcal{A}_k^i$. Then $\tau^\downarrow$ is a cell of level at most k in $\mathcal{A}(G^{(i)})$.*

Proof. It is obvious from the definition of $G^{(i)}$ that $\tau^\downarrow$ is a cell in $\mathcal{A}(G^{(i)})$. We now argue that its level in $\mathcal{A}(G^{(i)})$ is at most k. Choose a point $x \in \tau^\downarrow$. Let λ be the ray emanating from c_i and passing through x. Let g_{ij} be a function whose graph intersects the segment

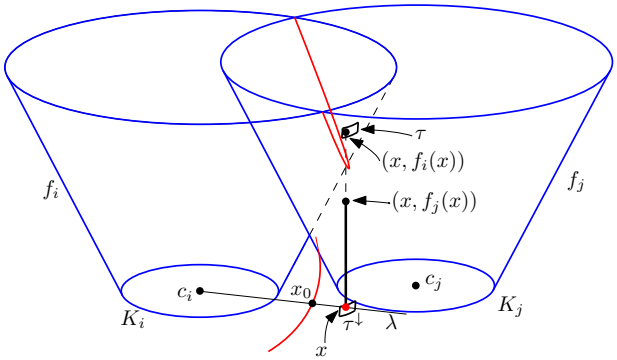

Figure 1 A bisector crossing λ. (The figure is drawn in the 3D c-space.)

$c_i x$, say, at a point $x_0 \in B_{ij}$. (See Fig. 1.) By Lemma 5, $f_i(y) < f_j(y)$ for all points y on λ preceding x_0, and $f_j(y) < f_i(y)$ for all points on λ beyond x_0. In particular, $f_i(x) > f_j(x)$. Since τ is a cell of $\mathcal{A}(\mathcal{F})$, f_j does not intersect τ, so f_j lies below τ in $\mathbb{R}^4$ (in the x_4-, or rather ρ-direction). Furthermore, $\tau \in \mathcal{A}_k(\mathcal{F})$, so there are exactly k functions of $\mathcal{F}$ whose graphs lie below τ, implying that the level of $\tau^\downarrow$ in $\mathcal{A}(G^{(i)})$ is at most k, as claimed. ◀

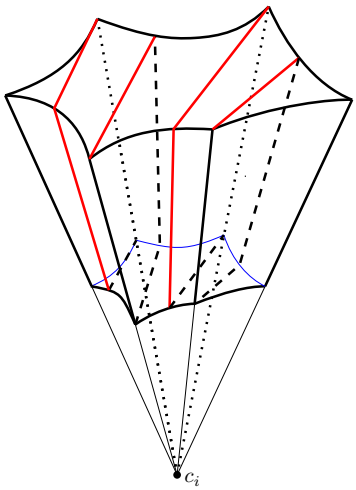

Figure 2 Vertical decomposition of a cell in the spherical coordinate system.

We decompose the cells τ of $\mathcal{A}_k^{(i)}(\mathcal{F})$ by constructing "vertical decompositions" of the corresponding 3D projections $\tau^\downarrow$ in the spherical coordinate system around c_i. As for standard vertical decompositions in 3D, we proceed in two stages. The first stage erects a wall from each edge of τ as follows. Fix an edge e of $\tau^\downarrow$. For a point $x \in e$, let $\lambda(x)$ be the ray emanating from c_i and passing through x, and let $h(x) = \lambda(x) \cap \tau^\downarrow$. By Lemma 5, $h(x)$ is a (connected) segment that touches e at one of its endpoints – it is either the top endpoint, for all points on e, or the bottom endpoint (with respect to distances from c_i). We erect the wall $\hat{e} = \bigcup_{x \in e} h(x)$ in $\tau^\downarrow$; parts of the wall may extend to infinity when $\tau^\downarrow$ is unbounded and e is a bottom edge. We repeat this step for all edges of $\tau^\downarrow$. These walls decompose $\tau^\downarrow$ into *frustums* (truncated cones), each of which, denoted by Δ, has a unique pair of *front* and *back* faces; the other faces of Δ lie on the created walls. (See Fig. 2.) The projections of the front and back faces of Δ on $\mathbb{S}^2$ (with c_i as the origin) are identical, and we denote this identical

projection by $\Delta^{\downarrow}$. The complexity of $\Delta^{\downarrow}$ may be arbitrarily large (a typical situation in the first stage of vertical decompositions in general; see, e.g., [19]). The subcell Δ itself is of the form $\Delta = \{(u, r) \mid u \in \Delta^{\downarrow}, r \in [g^-(u), g^+(u)]\}$, where g^-, g^+ are the functions of $G^{(i)}$ whose graphs contain the front and back faces of Δ, respectively.

The second stage decomposes Δ into constant-complexity frustums, which we refer to as *pseudo-cones*. We decompose $\Delta^{\downarrow}$ into spherical pseudo-trapezoids, by drawing portions of meridians within $\Delta^{\downarrow}$ from each vertex and meridian-tangency point. We then lift each pseudo-trapezoid $\sigma^{\downarrow}$ to form the pseudo-cone $\sigma = \{(u, r) \mid u \in \sigma^{\downarrow}, r \in [g^-(u), g^+(u)]\}$ in $\mathbb{R}^3$.

Repeating this step for all frustums created in the first stage, we obtain a decomposition of $\tau^{\downarrow}$ into pseudo-cones, each being a semi-algebraic set of constant complexity and bounded by up to six facets (compare with standard vertical decompositions in 3D [19]). We refer to these pseudo-cones as *elementary cells*. We note that each pseudo-cone ϕ is *defined* by a subset D_ϕ of at most seven functions of $\mathcal{F}$ (the function f_i and up to six additional functions that define the functions g_{ij} that form the frustum), in the sense that ϕ appears in the vertical decomposition of a 3D cell of $\mathcal{A}(D_\phi)$. By repeating this step for all cells of $\mathcal{M}_k^i$ and for all homothets K_i of $\mathcal{K}$, we obtain a decomposition of $\mathcal{M}_k = \mathcal{M}_k(\mathcal{K})$ into elementary cells. Finally, we lift each elementary cell of this decomposition vertically to $\mathcal{A}_k(\mathcal{F})$ in a straightforward manner, to obtain a corresponding decomposition of $\mathcal{A}_k(\mathcal{F})$.

Kaplan *et al.* [26, Lemma 6.2] have shown that the complexity of the vertical decomposition of the $(\leq k)$-level $\mathcal{A}_{\leq k}(\mathcal{G})$ of a set of $\mathcal{G}$ of m bivariate semi-algebraic functions of constant complexity is $O(k^2\psi(n/k)\lambda_s(k))$, where $\psi(r)$ is the maximum complexity of the lower envelope of a subset of $\mathcal{G}$ of size at most r, $\lambda_s(t)$ is the maximum length of Davenport-Schnizel sequences of order s composed of t symbols [34], and s is a constant depending on the complexity of the functions in $\mathcal{G}$. By applying the argument in [26] to our spherical coordinate system and using the worst-case bound $\psi(m) = O^*(m^2)$ on the complexity of the lower envelope of m constant-complexity bivariate functions [34], we conclude that the cells of $\mathcal{M}_k^i$ can be decomposed into $O^*(n^2k)$ elementary cells. Hence, $\mathcal{A}_k(\mathcal{F})$, or $\mathcal{M}_k(\mathcal{K})$, can be decomposed into $O^*(n^3k)$ elementary cells. By adapting the randomized incremental algorithm described in [26], $\mathcal{M}_k^i$, for each i, can be computed in $O^*(n^2k)$ expected time. We thus obtain:

▶ **Theorem 7.** *Let K be a compact, centrally-symmetric strictly convex semi-algebraic set in $\mathbb{R}^3$ of constant complexity. Let $\mathcal{K}$ be a set of n homothetic copies of K. The cells of $\mathcal{M}_k(\mathcal{K})$, and the cells of the k-level in the arrangement of their K-distance functions, can be decomposed into $O^*(n^3k)$ elementary cells, in $O^*(n^3k)$ expected time.*

3 Vertical Shallow Cuttings

A key notion that we need for constructing the dynamic NN data structures of Section 4 is that of a vertical shallow cutting of $\mathcal{A}(\mathcal{F})$, as studied in [15, 18, 26] (for simpler scenarios). For a parameter k, a *vertical k-shallow cutting* of $\mathcal{F}$ is a collection of pairwise openly disjoint semi-unbounded *pseudo-prisms* (prisms for short), where each prism consists of all points that lie vertically below some pseudo-cone, of the decomposition (of Section 2) that covers $\mathcal{A}_{\leq k}(\mathcal{F})$, and is thus a semi-algebraic set of constant complexity. Furthermore, the ceilings of these prisms collectively form an x_4-monotone surface that lies between $\mathcal{A}_k(\mathcal{F})$ and $\mathcal{A}_{2k}(\mathcal{F})$, and each prism is crossed by the graphs of at most $O(k)$ functions of $\mathcal{F}$. The *conflict list* of a prism σ is the set of functions whose graphs cross σ.

Following the ideas in [26], for a parameter $t \in [1, n]$, we construct a vertical (n/t)-shallow cutting as follows. We set two parameters: $r = \beta t \log t$, where β is a sufficiently large constant, independent of t, and $q = \beta \log t = r/t$. We choose a random subset $\mathsf{N} \subseteq \mathcal{F}$ consisting of

r functions, construct $\mathcal{A}_q(\mathsf{N})$, and compute the decomposition of $\mathcal{A}_q(\mathsf{N})$ into a family Ξ of pseudo-cones as described in Section 2. For each pseudo-cone $\tau \in \Xi$, we associate a label $\varphi(\tau)$ which is the function of N whose graph contains τ. Finally, we erect a semi-unbounded prism $\tau^{\uparrow}$ from each pseudo-cone τ of Ξ, given by $\tau^{\uparrow} = \bigcup\{\{c\} \times (-\infty, \rho] \mid (c, \rho) \in \tau\}$. Let $\Xi^{\uparrow}$ be the resulting set of pseudo-prisms. By Theorem 7, with large probability, $|\Xi| = O^*(r^3 q) = O^*(t^3)$. We next show that Ξ is a vertical k-shallow cutting of $\mathcal{F}$, where $k = n/t$, with high probability.

Range spaces and shallow ε-nets. Let $\Sigma = (\mathsf{X}, \mathcal{R})$ be a (finite) range space, where X is a set of objects and $\mathcal{R} \subseteq 2^{\mathsf{X}}$ a set of ranges. Let $0 < \varepsilon < 1$ be a given parameter. A subset $\mathsf{N} \subseteq \mathsf{X}$ is called a *shallow ε-net* of Σ if it satisfies the following two properties for every range $R \in \mathcal{R}$ and for any parameter $\zeta \geq 0$:

(i) If $|R \cap \mathsf{N}| \leq \zeta \log \frac{1}{\varepsilon}$ then $|R \cap \mathsf{X}| \leq \alpha(\zeta + 1)\varepsilon|\mathsf{X}|$, and

(ii) If $|R \cap \mathsf{X}| \leq \zeta\varepsilon|\mathsf{X}|$ then $|R \cap \mathsf{N}| \leq \alpha(\zeta + 1) \log \frac{1}{\varepsilon}$.

Here α is a suitable constant. Note the difference between shallow and standard ε-nets: Property (i) (with $\zeta = 0$) implies that a shallow ε-net is also a standard ε-net (possibly with a recalibration of ε). Property (ii) has no parallel in the case of standard ε-nets – there is no guarantee how a standard net interacts with small ranges (of the entire set X). The following result by Sharir and Shaul [35] is a generalization of the result on standard ε-nets [24].

▶ **Lemma 8** (Theorem 2.2 of Sharir and Shaul [35]). *Let $\Sigma = (\mathsf{X}, \mathcal{R})$ be a range space with VC-dimension d. With a suitable choice of the constant of proportionality, a random sample $\mathsf{N} \subseteq \mathsf{X}$ of $O\left(\frac{d}{\varepsilon}\log\frac{1}{\varepsilon} + \log\frac{1}{\delta}\right)$ is a shallow ε-net with probability at least $1 - \delta$.*

Ξ is a vertical shallow cutting. We apply the above result to the range space $\Sigma = (\mathcal{F}, \mathcal{R})$, so that each range in $\mathcal{R}$ is the subset of the surfaces of $\mathcal{F}$ that cross some region in $\mathbb{R}^4$, taken from some family Γ of regions. Concretely, this includes the following families Γ: (i) the set of pseudo-cones generated by the decomposition of a set of at most seven functions of $\mathcal{F}$ (recall that a pseudo-cone is defined by at most seven functions), (ii) the set of pseudo-prisms erected on these pseudo-cones, (iii) the set of edges in an arrangement of five functions of $\mathcal{F}$ (an edge in the arrangement of a subset of $\mathcal{F}$ is defined by at most five functions), and (iv) the set of rays in the positive x_4-direction. Using standard arguments, it can be shown that the VC-dimension of Σ is finite. Therefore, by applying Lemma 8 with $\varepsilon = 1/t$ and $\delta = 1/3$ and choosing the constant of proportionality appropriately, the random subset $\mathcal{R}$ is a $(1/t)$-shallow net of Σ with probability at least $2/3$, so we assume that N is indeed a $(1/t)$-shallow net of Σ. Recall that $q = \beta \log t$. Assuming $\beta \geq 2\alpha$, where α is the constant in the definition of shallow nets, the converse of property (ii) of shallow nets, with $\zeta = 1$, implies that the level of any point p on $\mathcal{A}_q(\mathsf{N})$ with respect to $\mathcal{F}$ is at least n/t. Also, by property (i), the level of p is at most $O(n/t)$. Finally, the shallow net property also implies that the size of the conflict-list of any prism in $\Xi^{\uparrow}$ is $O(n/t)$. The conflict list of all prisms can be computed in $O^*(nt^3)$ time. Hence, we obtain:

▶ **Theorem 9.** *Let K be a compact, centrally-symmetric strictly convex semi-algebraic set in $\mathbb{R}^3$ of constant complexity. Let $\mathcal{K}$ be a set of n homothetic copies of K. For any parameter $t \in [1, n-1]$, there exists a vertical (n/t)-shallow cutting Ξ of the arrangement of the distance functions of $\mathcal{K}$ of size $O^*(t^3)$. The cutting Ξ, along with the conflict list of each of its prisms, can be computed in $O^*(nt^3)$ expected time.*

4 Dynamic Data Structures for Proximity Queries

In this section we describe a dynamic data structure for answering *intersection-detection* queries amid $\mathcal{K}$. Namely, for a query homothet $K_0 \in \mathbb{K}$, determine whether K_0 intersects some homothet of $\mathcal{K}$, and, if the answer is yes, return such a homothet. In addition to answering queries, the data structure can be updated efficiently as a homothet $K_0 \in \mathbb{K}$ is inserted into $\mathcal{K}$ or deleted from $\mathcal{K}$. The data structure can be extended to answering *intersection-reporting* queries, namely, reporting all homothets of $\mathcal{K}$ that intersect K_0, at an additional cost of $O(k)$.

As already noted, the insertion of a new homothet into $\mathcal{K}$ can be handled using the standard dynamization technique by Bentley and Saxe [13] (see also [9]). That is, assume that we have an intersection-detection data structure that can handle deletions, which can be constructed in $P(n)$ time, so that a query can be answered in $Q(n)$ time and an object can be deleted in $D(n)$ time. Then the amortized insertion time is $O((P(n)/n)\log n)$, the deletion time remains $D(n)$, and the overall query time is $O(Q(n))$, assuming that $Q(n) = \Omega(n^{\varepsilon})$.

We first describe a data structure that answers a query in $O^*(1)$ time using $O^*(n^3)$ space and handles a deletion in $O^*(n^2)$ amortized expected time, and then describe a linear-size data structure that answers a query in $O^*(n^{2/3})$ time and handles a deletion in $O(\log^2 n)$ amortized expected time.

4.1 Fast query-time data structure

We follow the same approach of Agarwal and Matoušek for performing dynamic halfspace range reporting [9] (slightly improved but more involved approaches were proposed in [15, 26], but the one in [9] will do for our setting).

Data structure. Let $\mathcal{F}$ be the collection of distance functions corresponding to the elements of $\mathcal{K}$. Roughly speaking, we build a tree data structure on $\mathcal{F}$ using vertical shallow cuttings. That is, we start with $\mathcal{F}$, choose a parameter $t > 1$, compute an (n/t)-vertical shallow cutting Ξ of $\mathcal{F}$ of size $O^*(t^3)$, in $O^*(nt^3)$ time, create a child for each prism τ of Ξ, recursively construct the data structure for the conflict list $\mathcal{F}_\tau$ of every $\tau \in \Xi$, and attach it as the subtree of the child corresponding to τ. The recursion proceeds until we reach cells τ with $|\mathcal{F}_\tau| = O(1)$, in which case we just store $\mathcal{F}_\tau$ at τ, as a list, say.

A query, with a copy $K_0 = (c_0, \rho_0)$ of K, is answered in a standard way, by traversing the tree in a top-down manner. At each node (prism) τ that we visit, we know that $(c_0, \rho_0) \in \tau$. We check whether (c_0, ρ_0) lies in any child prism of τ, and, if so, recurse at that child. Otherwise, we locate the child prism τ' for which (c_0, ρ_0) lies above τ', and report any element whose function belongs to the conflict list $\mathcal{F}_{\tau'}$.

However, this simple recursive approach runs into a technical difficulty when we delete a function from $\mathcal{F}$. When deleting a function from the root, the deletion has to be propagated to some of its children, to their children, and so on. On average, each function appears in the conflict lists of $O^*(t^2)$ prisms of Ξ. When such a "good" function is deleted, the deletion is propagated to only $O^*(t^2)$ descendants, leading to $O^*(n^2)$ overall deletion time, as can easily be verified. However, some of the functions (in fact, up to n/t of them) may appear in the conflict lists of $\Omega(t^3)$ prisms of Ξ. If these "bad" functions are the first n/t functions to be deleted and then the data structure is reconstructed, the overall cost of the deletion operations will be too high. As in [9, 26], we circumvent this difficulty by maintaining a partition of $\mathcal{F}$ into a few subsets and constructing a cutting for each subset that is good for all functions in that subset (i.e., each function in the subset appears in only $O^*(t^2)$ conflict lists).

We now describe the data structure in detail. We fix a sufficiently large constant $t > 0$. The data structure is periodically reconstructed after performing some deletions. We use m to denote the size of $\mathcal{F}$ when the data structure was previously reconstructed and n to denote its current size. We reconstruct the data structure after deleting $m/2t$ functions from $\mathcal{F}$. Thus $n \geq m(1 - 1/2t)$. Let $P(r)$ denote the maximum time spent in constructing the data structure for a set of r functions. We pay for the reconstruction cost by charging $2tP(m - m/2t)/m \leq 2tP(n)/n$ time to each of the $m/2t$ delete operations that occurred before the reconstruction (the inequality holds because P is assumed to be superlinear). The data structure for $\mathcal{F}$ is a (recursively defined) tree $\Psi(\mathcal{F})$. We describe how a subtree $\Psi(\mathcal{G})$, for a subset $\mathcal{G}$ of ν functions, is constructed.

If $\nu \leq n_0$, for some sufficiently large constant n_0, then $\Psi(\mathcal{G})$ is a single leaf, and we simply store $\mathcal{G}$ at that leaf. So assume that $\nu > n_0$. The root of $\Psi(\mathcal{G})$ stores the following data:

- A partition of $\mathcal{G}$ into subsets $\mathcal{G}_1, \ldots, \mathcal{G}_u$, $u \leq \lceil \log_2 t \rceil$, as described below.
- For each $1 \leq i \leq u$, a vertical (ν/t)-shallow cutting Ξ_i for $\mathcal{G}_i$. For each $\Delta \in \Xi_i$, we store its conflict list $\mathcal{G}_{i,\Delta}$.
- For each $1 \leq i \leq u$ and $\Delta \in \Xi_i$, a pointer to the tree $\Psi(\mathcal{G}_{i,\Delta})$.
- For each function $f \in \mathcal{G}_i$, the set $L_f \subseteq \Xi_i$ of prisms Δ crossed by the graph of f.
- A counter χ that keeps track of how many functions of $\mathcal{G}$ can be deleted before we reconstruct $\Psi(\mathcal{G})$.

After the construction of $\Psi(\mathcal{G})$, before any deletions occur, the following properties hold:

(P1) The counter χ is set to $\nu/2t$.
(P2) For each i, the x_4-monotone surface formed by the pseudo-cones of Ξ_i (i.e., the ceilings of prisms of Ξ_i) lie above $\mathcal{A}_{\nu/t}(\mathcal{G}_i)$.
(P3) For every i and $\Delta \in \Xi_i$, $|\mathcal{G}_{i,\Delta}| \leq cn/t$, for some suitable absolute constant c.
(P4) Each function $f \in \mathcal{G}_i$ appears in the conflict lists of at most $\kappa := 2C_1 t^{2+\delta}$ prisms of Ξ_i, where C_1 and $\delta > 0$ are the constants appearing in (1) below.

We now describe the construction of the partition $\mathcal{G}_1, \ldots, \mathcal{G}_u$, which proceeds iteratively. Suppose we have constructed $\mathcal{G}_1, \ldots, \mathcal{G}_{i-1}$. Set $\mathcal{G}_i^* = \mathcal{G} \setminus \bigcup_{j<i} \mathcal{G}_i$ and put $\nu_i = |\mathcal{G}_i^*|$. If $\nu_i \leq \nu/t$, we stop. Otherwise, set $t_i = t\nu_i/\nu$ and $k = \nu_i/t_i = \nu/t$.

We construct a vertical k-shallow cutting Ξ_i of $\mathcal{G}_i^*$ of size $O(t_i^{3+\delta})$, for an arbitrarily small constant $\delta > 0$. For each $\Delta \in \Xi_i$, $|\mathcal{G}_{i,\Delta}^*| \leq c\nu_i/t_i = c\nu/t$. We note that

$$\sum_{\Delta \in \Xi_i} |\mathcal{G}_{i,\Delta}^*| \leq O(t_i^{3+\delta}) \frac{c\nu}{t} \leq C_1 \left(\frac{t\nu_i}{\nu}\right)^{3+\delta} \frac{\nu}{t} \leq C_1 \nu_i t^{2+\delta}. \tag{1}$$

A function $f \in \mathcal{G}_i^*$ is called *good* if it appears in the conflict list of at most κ prisms of Ξ_i and *bad* otherwise. Let $\mathcal{G}_i$ be the set of good functions of $\mathcal{G}_i^*$; set $\mathcal{G}_{i+1}^* = \mathcal{G}_i^* \setminus \mathcal{G}_i$. By (1), $|\mathcal{G}_{i+1}^*| \leq \nu_i/2$. Hence, $u \leq \lceil \log_2 t \rceil$. It is easily seen that properties (P1)–(P4) hold after the construction. This completes the description of the data structure. The total size and preprocessing time are $O^*(n^3)$.

Query procedure. Let $K(c_0, \rho_0) \in \mathbb{K}$ be a query homothet. Recall that $K(c_0, \rho_0)$ intersects a homothet of $\mathcal{K}$ if the point (c_0, ρ_0) lies above the lower envelope of the corresponding set $\mathcal{F}$ of functions. The query is performed as follows. We search $\Psi(\mathcal{F})$ in a top-down manner with (c_0, ρ_0). Suppose we are at the root of a subtree $\Psi(\mathcal{G})$. If $\Psi(\mathcal{G})$ is a leaf, we check all functions of $\mathcal{G}$ in a brute-force manner and return an answer in $O(n_0) = O(1)$ time. Otherwise, for

each $i \leq u$, we check whether (c_0, ρ_0) lies above the lower envelope of $\mathcal{G}_i$. If the answer is yes for any i, we return yes and also return an intersecting homothet (see below). Otherwise, we return no.

For a fixed $i \leq u$, we proceed as follows. We search with c_0, in a brute force manner, in $O^*(t^3) = O(1)$ time, to determine the pseudo-cone $\tau^{\downarrow}$ in the projection of Ξ_i that contains c_0. Let f_i be the function associated with τ, i.e., the ceiling of Δ lies in the graph of f_i. We test whether $\rho_0 \geq f_i(c_0)$. If so, K_i and $K(c_0, \rho_0)$ intersect, so we return yes and report K_i as an intersection witness and terminate the query. If not, (c_0, ρ_0) lies in the semi-unbounded prism Δ, and we continue the search recursively in the data structure $\Psi(\mathcal{G}_{i,\Delta})$.

Let $Q(\nu)$ be the maximum time spent by the query procedure in the subtree $\Psi(\mathcal{G})$ storing at most ν functions. Then we obtain the following recurrence:

$$Q(\nu) \leq \lceil \log_2 t \rceil Q(c\nu/t) + O(t^{3+\delta}).$$

Its solution is easily seen to be $Q(\nu) = O(n^{\varepsilon})$, for any constant $\varepsilon > 0$, provided that n_0 and t are chosen sufficiently large.

Deletion procedure. Let $f \in \mathcal{F}$ be a function that we wish to delete from $\mathcal{F}$. Again, we visit $\Psi(\mathcal{F})$ in a top-down manner. Suppose we are at the root v of a subtree $\Psi(\mathcal{G})$. If v is a leaf, then we simply delete f from $\mathcal{G}$ and stop. If v is an internal node, we first decrement the counter χ stored at v. If χ becomes 0, we reconstruct $\Psi(\mathcal{G})$ from scratch (for the current $\mathcal{G}$). Otherwise, we find the index i such that $f \in \mathcal{G}_i$. For each $\Delta \in L_f$, we delete f from $\mathcal{G}_{i,\Delta}$ and then recursively delete f from $\Psi(\mathcal{G}_{i,\Delta})$. By construction, $|L_f| \leq \kappa$. The deletion procedure maintains the properties (P3) and (P4), and (P2) is replaced with a slightly weaker property:

(P2') For every i, the x_4-monotone surface formed by the pseudo-cones of Ξ_i (i.e., the ceilings of prisms of Ξ_i) lie above or on $\mathcal{A}_{\nu/2t}(\mathcal{G}_i)$.

The correctness of the query procedure follows from property (P2'). Following the analysis in [9], the amortized deletion time, including the time spent in reconstructing the data structure, is $O^*(n^2)$. Putting everything together, and combining this with the technique of Bentley and Saxe [13] for insertions, we obtain:

▶ **Lemma 10.** *$\mathcal{K}$ can be preprocessed, in $O^*(n^3)$ expected time, into a data structure of size $O^*(n^3)$, so that an intersection-detection query, including the cost of reporting an intersecting member of $\mathcal{K}$ if one exists, can be performed in $O^*(1)$ time. A homothet can be inserted into $\mathcal{K}$ or deleted from $\mathcal{K}$ in $O^*(n^2)$ amortized expected time.*

4.2 Linear-size data structure

Next, we present a linear-size dynamic data structure that supports intersection-detection queries in $O^*(n^{2/3})$ time each, and can handle updates (insertions and deletions) in $O(\log^2 n)$ amortized expected time per update.

For a homothet $K(c_0, \rho_0)$, let $f^+_{c_0,\rho_0} = \{(c, \rho) \in \mathbb{R} \mid \rho \geq f_{c_0,\rho_0}(c)\}$ be the region lying above the graph of the distance function f_{c_0,ρ_0}, which corresponds to the set of homothets that intersect $K(c_0, \rho_0)$. Put $\mathcal{K}^* = \{(c, \rho) \mid K(c, \rho) \in \mathcal{K}\} \subset \mathbb{R}^4$. For a query homothet $K(c_0, \rho_0)$, we wish to determine whether any point of $\mathcal{K}^*$ lies in $f^+_{c_0,\rho_0}$. We construct a linear-size partition tree for answering these queries, following the same approach as in [9, 32, 35]. We need a few definitions. Let $\mathbb{F}$ be the set of distance functions corresponding to the homothets in $\mathbb{K}$. Let $P \subset \mathbb{K}$ be a set of n points (representing homothets of K). For a parameter

$k \geq 1$, we call a semi-algebraic set $\gamma \subset \mathbb{K}$, which is semi-unbounded in the $(-x_4)$-direction, *k-shallow* if $|P \cap \gamma| \leq k$. A major ingredient of the approach in [32, 35] is to construct a so-called *test set* composed of a small number of semi-algebraic sets, which represent well (in the sense made precise below) all distance functions of $\mathbb{F}$ that are (n/r)-shallow, for a given parameter $r > 1$, with respect to P. Formally, a finite collection Φ of semi-algebraic sets of constant complexity (not necessarily a subset of $\mathbb{F}$) is called a *test set* for (n/r)-shallow ranges in $\mathbb{F}$ with respect to P if it satisfies the following properties:

- **(i)** Every set in Φ is (n/r)-shallow with respect to P.
- **(ii)** The complement of the union of any m sets of Φ can be decomposed into at most $\zeta(m)$ "elementary cells" (semi-algebraic sets of constant complexity) for any $m \geq 1$, where $\zeta(m)$ is a suitable monotone increasing superlinear function of m.
- **(iii)** Any (n/r)-shallow set $\sigma \in \mathbb{F}$ can be covered by the union of at most δ ranges of Φ, where δ is a constant (independent of r).

Sharir and Shaul [35] showed that if there exists a test set of size $r^{O(1)}$ for (n/r)-shallow ranges of $\mathbb{F}$, then one can construct a linear-size partition tree on P so that an $\mathbb{F}$-emptiness query can be answered in $O^*(n/\zeta^{-1}(n))$ time, for the corresponding function ζ.

Test-set construction. We describe an algorithm for constructing a test set of size $O(r^4)$ with $\zeta(m) = O^*(m^3)$ and $\delta = 1$. Let $\mathcal{F}$ be the set of distance functions of $\mathcal{K}$ as above. We take a random subset $R \subseteq \mathcal{F}$ of $s = cr \log r$ functions, for some sufficiently large constant r, where $c > 0$ is another sufficiently large absolute constant, independent of, and much smaller than r, and construct the (standard) 4D vertical decomposition $\mathcal{A}^{\shortparallel}(R)$ of the arrangement $\mathcal{A}(R)$, of size $O^*(r^4)$, as described in [3,30,34]. By a standard random-sampling argument [24], with probability at least $1/2$, each cell of $\mathcal{A}^{\shortparallel}(R)$ is crossed by at most n/r functions of $\mathcal{F}$, provided that c is chosen sufficiently large. If this is not the case, we discard R and choose another random subset, until we find, in expected $O(1)$ trials, one with the desired property. We clip $\mathcal{A}^{\shortparallel}(R)$ within the halfspace $x_4 \geq 0$ (to restrict it to within $\mathbb{K}$). We choose a subset Ξ of the cells of $\mathcal{A}^{\shortparallel}(R)$, consisting of those cells that have at most n/r functions of $\mathcal{F}$ passing *fully below* them. By construction, these cells cover $\mathcal{A}_{\leq n/r}(\mathcal{F})$, and are contained in $\mathcal{A}_{\leq 2n/r}(\mathcal{F})$.

Let τ be a cell of Ξ. Set $\Phi_\tau = \bigcup_{(c_0,\rho_0)\in\tau} f^+_{c_0,\rho_0}$. Since τ and f_{c_0,ρ_0} are semi-algebraic sets of constant complexity, Φ_τ is also a semi-algebraic set of constant complexity. For a homothet $K_i \in \mathcal{K}$, the point $K_i^* \in \mathbb{K}$ lies in Φ_τ if and only if there is a point $(c_0, \rho_0) \in \tau$ such that $K_i^* \in f^+_{c_0,\rho_0}$. This happens when $(c_0, \rho_0) \in f_i^+$, i.e., the graph of the function f_i crosses τ or lies below τ. By construction, there are at most $n/r + n/r = 2n/r$ such functions. Consequently, Φ_τ is $(2n/r)$-shallow with respect to the points of $\mathcal{K}^*$ with $\delta = 1$.

Set $\Phi = \{\Phi_\tau \mid \tau \in \Xi\}$. Φ is a family of $O^*(r^4)$ constant-complexity semi-algebraic sets in $\mathbb{K}$, each of which is $(2n/r)$-shallow with respect to $\mathcal{K}^*$. This is the desired test set. Each set Φ_τ is unbounded in the positive x_4-direction, therefore the complement of the union of a subset of m sets is the region lying below their lower envelope. By a result in [5], the complement of their union (i.e., the region below their lower envelope) can be decomposed into $O^*(m^3)$ pseudo-prisms. Hence, we obtain:

▶ **Lemma 11.** *Let $P \subset \mathbb{K}$ be a set of n points and $r \geq 1$ a parameter. A test set Φ of size $O(r^4)$ for the functions in $\mathbb{F}$ that are (n/r)-shallow with respect to P can be computed in $O^*(r^4)$ expected time, so that $\zeta(m) = O^*(m^3)$ and $\delta = 1$.*

Using Lemma 11 and adapting the approach in [35], we can preprocess $\mathcal{K}$ into a linear-size data structure that supports intersection-detection queries in $O^*(n^{2/3})$ time. By (re)constructing portions of the partition tree periodically (as in the previous data structure), deletions can be handled efficiently. Omitting the straightforward details, we obtain:

▶ **Lemma 12.** *Let $\mathcal{K}$ be a set of n homothets of K. $\mathcal{K}$ can be preprocessed, in $O(n \log n)$ expected time, into a data structure of size $O(n)$, so that an intersection-detection query can be answered in $O^*(n^{2/3})$ time. A homothet of K can be inserted into or deleted from the data structure in $O(\log^2 n)$ amortized time.*

By combining this data structure with Lemma 10 in a standard manner [1], we can obtain the following space/query-time trade-off:

▶ **Theorem 13.** *Let $\mathcal{K}$ be a set of n homothets of K, and let $s \in [n, n^3]$ be a storage parameter. $\mathcal{K}$ can be preprocessed, in $O^*(s)$ expected time, into a data structure of size $O^*(s)$, so that an intersection-detection query can be answered in $O^*(n/s^{1/3})$ time. A homothet can be inserted into or deleted from the data structure in $O^*(s/n)$ amortized time.*

Finally, by combining this data structure with the parametric-search technique [8], we establish Theorem 1 (for answering nearest-neighbor queries in $\mathcal{K}$ under the K-distance).

Abstract

A key property of the Delaunay filtration is that it is topologically (i.e., weakly) equivalent to the offset (union-of-balls) filtration. Recently, this filtration has been extended to point clouds equipped with an $\mathbb{R}$-valued function, yielding a computable 2-parameter filtration that satisfies an analogous weak equivalence. Motivated in part by the study of time-varying data, we introduce a 3-parameter extension of the Delaunay filtration for point clouds equipped with an $\mathbb{R}^2$-valued function, also satisfying an analogous weak equivalence. For a point cloud $X \subset \mathbb{R}^d$, our trifiltration has size $O\big(|X|^{\lceil (d+1)/2 \rceil + 1}\big)$. We present an algorithm that computes this trifiltration in time $O\big(|X|^{\lceil d/2 \rceil + 2}\big)$, together with an implementation. Our experiments demonstrate that the implementation can handle thousands of points in $\mathbb{R}^3$, with memory growth that is nearly linear.

1 Introduction

Background. Given a finite point cloud $X \subset \mathbb{R}^d$, the *offset filtration* of X is the nested sequence of spaces $\mathcal{O}(X) = (\mathcal{O}(X)_r)_{r \in \mathbb{R}^+}$, where $\mathbb{R}^+ = [0, \infty)$ and $\mathcal{O}(X)_r$ is the union of closed balls of radius r centered the points of X (Figure 1). In topological data analysis (TDA), one often computes the persistent homology of $\mathcal{O}(X)$. However, directly computing $\mathcal{O}(X)$

is difficult, due to its non-combinatorial nature. Therefore, one usually instead computes the *Delaunay filtration* $\mathcal{D}(X)$ (also called the α-filtration) [30, 28] (Figure 1), a filtration of the Delaunay triangulation $\mathrm{Del}(X)$ of X that is topologically equivalent (i.e., weakly equivalent, see Definition 19) to $\mathcal{O}(X)$, and therefore has the same persistent homology. For low-dimensional Euclidean data, $\mathcal{D}(X)$ is the standard choice of filtration in TDA, because it is far more computationally efficient than alternatives like the Rips and Čech filtration. Bauer and Edelsbrunner [5] showed that $\mathcal{O}(X)$ is also weakly equivalent to a variant of $\mathcal{D}(X)$ called the *Delaunay-Čech* filtration and denoted $\mathcal{DC}(X)$, where the birth index of each simplex in the filtration is the radius of its minimum enclosing ball.

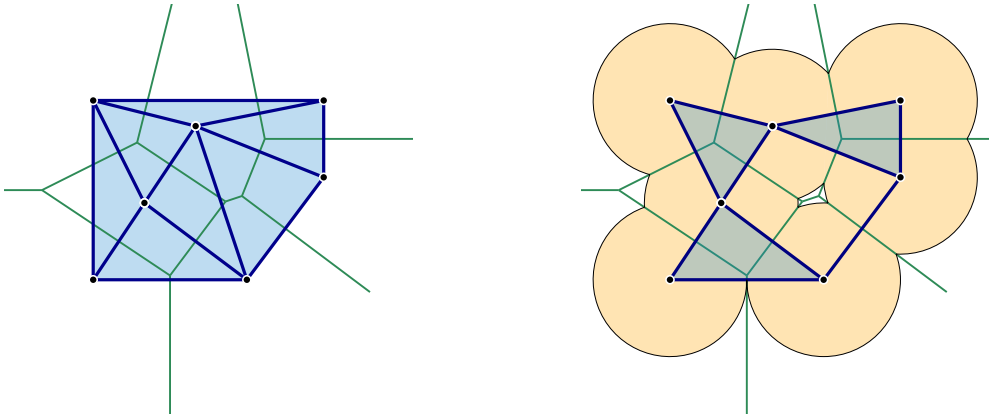

Figure 1 Left: For a point set $X \subset \mathbb{R}^2$, the Voronoi decomposition $\mathrm{Vor}(X)$ (green) and the corresponding Delaunay triangulation $\mathrm{Del}(X)$ (dark blue). Right: The offset $\mathcal{O}_r(X)$ (orange) and Delaunay complex $\mathcal{D}(X)_r \subset \mathrm{Del}(X)$ for a fixed radius r.

In many TDA applications, the point cloud X comes equipped with a function $\delta\colon X \to \mathbb{R}$ [20, 18]. It is then natural to seek a refinement of the persistent homology of X which is sensitive to the structure of this function. Functions considered in the TDA literature include (co)density, eccentricity (centrality), discrete curvature [18], partial charge [17, 16], and time [46]. To extend the persistence pipeline to point clouds equipped with multiple functions, Carlsson and Zomorodian [18] proposed *multiparameter persistence*, and specifically, the *sublevel offset bifiltration* $\mathcal{O}(\delta) = (\mathcal{O}(\delta)_{s,r})_{(s,r)\in\mathbb{R}\times\mathbb{R}^+}$, where

$$\mathcal{O}(\delta)_{s,r} = \mathcal{O}(\{x \in X \mid \delta(x) \leq s\})_r.$$

Sublevel Čech and sublevel offset bifiltrations are defined analogously, and can be computed in essentially the same way as the usual Rips and Čech filtrations. Defining an analogous sublevel Delaunay bifiltration is more subtle because of the non-monotonicity of Delaunay complexes with respect to insertion of points. However, recent work [3] introduced sublevel Delaunay and sublevel Delaunay-Čech bifiltrations that are both weakly equivalent to the sublevel offset bifiltration and amenable to efficient computation. Experiments with a publicly available implementation showed that, in practice, computing the sublevel Delaunay-Čech bifiltration is only modestly more expensive than computing the ordinary Delaunay filtration. The work [3] is part of a large body of recent work aiming to realize multiparameter persistence as a computationally viable data analysis tool; for an introduction, see [14].

Contributions. In this paper, we extend the recent results from [3] on sublevel-Delaunay bifiltrations to functions $\gamma\colon X \to \mathbb{R}^2$, where $X \subset \mathbb{R}^d$ is in general position. Specifically, we introduce the *sublevel Delaunay* and *sublevel Delaunay-Čech trifiltrations* of γ, denoted $\mathcal{D}(\gamma)$

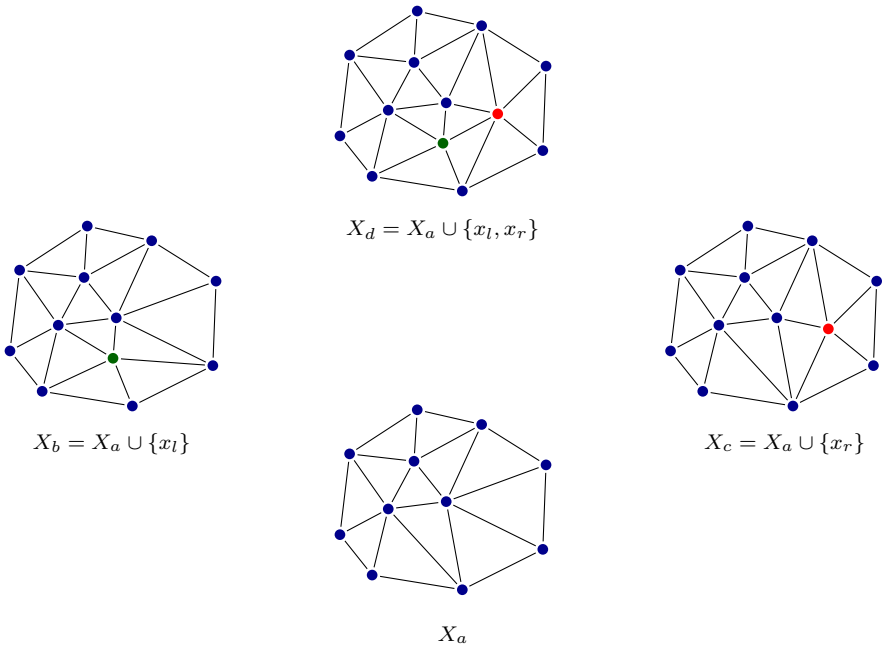

Figure 2 Non-monotonicity of Delaunay triangulations of planar point clouds X_a, $X_b = X_a \cup \{x_l\}$, $X_c = X_a \cup \{x_r\}$, and $X_d = X_a \cup \{x_l, x_r\}$. The points x_l and x_r are shown in green and red.

and $\mathcal{DC}(\gamma)$, respectively. We show that both trifiltrations have size $O(|X|^{\lceil (d+1)/2 \rceil + 1})$, can be computed in time $O(|X|^{\lceil d/2 \rceil + 2})$, and are weakly equivalent to the *sublevel offset trifiltration*, defined as follows:

▶ **Definition 1.** *The* sublevel offset trifiltration *of* γ*, denoted* $\mathcal{O}(\gamma)$*, is the collection of Euclidean subspaces* $\left(\mathcal{O}_{a,r}\right)_{(a,r)\in\mathbb{R}^2\times\mathbb{R}^+}$*, where* $\mathcal{O}_{a,r} \coloneqq \mathcal{O}(X_a)_r$ *and* $X_a \coloneqq \{x \in X \mid \gamma(x) \leq a\}$*. Here* $\leq$ *denotes the product partial order on* $\mathbb{R}^2$*.*

Our approach to defining and computing the trifiltrations $\mathcal{D}(\gamma)$, $\mathcal{DC}(\gamma)$ parallels the approach of [3] for $\mathbb{R}$-valued functions, but is necessarily more involved. To illustrate the problem, consider the four point clouds $X_a \subset X_b, X_c \subset X_d$ of Figure 2. While for any $r \in \mathbb{R}^+$, the offsets satisfy $\mathcal{O}(X_a)_r \subset \mathcal{O}(X_b)_r, \mathcal{O}(X_c)_r \subset \mathcal{O}(X_d)_r$, these containment relations do not hold for the corresponding Delaunay triangulations, nor for the Delaunay complexes of radius r. The construction of [3] applies when the point clouds are totally ordered by containment, but does not apply here because neither X_b nor X_c contains the other. In this paper, we adapt the approach of [3] to address this case.

As in the previous work on $\mathbb{R}$-valued functions, the most important part of our approach is the definition and computation of the maximum complex (i.e., colimit) of the trifiltrations $\mathcal{D}(\gamma)$ and $\mathcal{DC}(\gamma)$. This complex is the same for both trifiltrations; we call it the *incremental complex* and denote it as $\mathcal{I}$ (Definition 3). The complex $\mathcal{I}$ has vertex set X, and contains the union of the Delaunay triangulations of all sublevel sets of γ as a subcomplex. We give a characterization of $\mathcal{I}$ in terms of *conflict pairs* (see Definition 6), and use this to obtain a simple algorithm for computing $\mathcal{I}$, based on the standard Bowyer-Watson algorithm for incremental computation of Delaunay triangulations. We then introduce optimizations to this algorithm, exploiting the fact that Delaunay triangulations are *local*, in a sense made precise by Lemma 16.

For $\sigma \subset X$ non-empty, let $\gamma(\sigma) = \bigvee_{x\in\sigma} \gamma(x)$, where $\bigvee$ denotes the *join*, i.e., coordinate-wise maximum. Given $\mathcal{I}$, the trifiltration $\mathcal{D}(\gamma)$ is defined by assigning each simplex $\sigma \in \mathcal{I}$ the birth index $(\gamma(\sigma), \omega_\sigma)$, where ω_σ is the *incremental Delaunay radius*, which we will define in Definition 3. $\mathcal{DC}(\gamma)$ is defined by assigning each $\sigma \in \mathcal{I}$ the birth index $(\gamma(\sigma), m_\sigma)$, where m_σ is the radius of the minimal enclosing ball of σ. To show that $\mathcal{D}(\gamma)$, $\mathcal{DC}(\gamma)$, and $\mathcal{O}(\gamma)$ are topologically equivalent, we use an argument based on two-parameter mapping telescopes and functorial version of the nerve theorem [6]. We introduce a practical algorithm for computing $\mathcal{D}(\gamma)$ and $\mathcal{DC}(\gamma)$, and implement the algorithm to compute $\mathcal{DC}(\gamma)$. We perform experiments on point clouds in $\mathbb{R}^2$ and $\mathbb{R}^3$ with up to 16000 points. In these experiments, the memory usage scales nearly linearly, while run time scales nearly quadratically, suggesting that substantially larger computations are feasible. Our implementation is publicly available [37].

Motivation. While there is a substantial recent literature on computing bifiltrations of point cloud and metric data in TDA [23, 3, 9, 44, 2, 4], to the best of our knowledge, our work is the first to seriously engage with the algorithmic aspects of trifiltrations. We hope that our work will lower the barrier to practical data analysis with 3-parameter persistence, which has seen very limited use so far.

Our specific motivation for introducing computable Delaunay-type models of sublevel-offset trifiltrations is threefold: First, we wish to enable persistence analysis which simultaneously considers a pair of functions on a point cloud, e.g., density and eccentricity. Indeed, if one is interested in doing a topological analysis of a function on a point cloud with noise or non-uniformities in density, it becomes important to take density into account, and one simple way to do this is to treat density as an additional filtration parameter.

Second, the definition of the sublevel-offset bifiltration involves a choice of filtering direction (i.e., whether we filter by sublevel or superlevel sets). While for some functions $\delta\colon X \to \mathbb{R}$, like codensity, it is natural to fix a direction, for other functions like time or partial charge, it can be unnatural to fix a filtering direction, and one would like a more symmetric construction. To this end, one can consider the *interlevel-offset trifiltration* of δ, defined as follows:

▶ **Definition 2.** *For a function $\delta : X \to \mathbb{R}$, the* interlevel-offset trifiltration *of δ, denoted $\mathcal{O}^{\updownarrow}(\delta)$, is the collection of Euclidean subspaces $(\mathcal{O}^{\updownarrow}(\delta)_{a,b,r})_{(a,b,r)\in\mathbb{R}^2\times\mathbb{R}^+}$, where $\mathcal{O}^{\updownarrow}(\delta)_{a,b,r} \coloneqq \mathcal{O}\big(\{x \in X \mid a \le \delta(x) \le b\}\big)_r$.*

Note that $\mathcal{O}^{\updownarrow}(\delta)$ is a special case of the sublevel-offset trifiltration, namely $\mathcal{O}^{\updownarrow}(\delta) = \mathcal{O}(\gamma)$, where $\gamma = (\delta, -\delta)$. We are especially interested in computing the homology of the interlevel-offset filtration in the case that δ is a time function, as this could potentially be useful in the analysis of dynamic data such as that arising in the study of collective motion of animals [1], in the study of dynamical systems, or in the sliding-window analysis of time series [50]. While $\mathcal{O}^{\updownarrow}(\delta)$ is only one of several possible choices of a multifiltration that can be built from time-varying data (e.g., see [41, 55]), it is notable for its flexibility – unlike some alternatives, the definition does not require a consistent labeling of the points at each time step, and it accommodates different numbers of points at different time steps.

Our third motivation is the following: The *degree-Rips bifiltration* has emerged in recent years as a popular choice of density-sensitive bifiltration on metric data [52, 10, 45]. The construction is appealing in part because it requires no parameter choice, whereas the sublevel-Rips filtration of a (co)density function requires a choice of bandwidth parameter. In the same way, one can define parameter-free *degree-offset* and *degree-Čech filtrations*. We are interested in the problem of computing an analogous *degree-Delaunay filtration*

which is topologically equivalent to the degree-offset bifiltration and more computable than degree-Rips or degree-Čech for low-dimensional data. In ongoing work on this problem, we noticed that the problems of computing the sublevel Delaunay(-Čech) trifiltration and the degree-Delaunay bifiltrations are very closely related. As computing the former is somewhat simpler but already rather involved, we view the results of this paper as a key step towards the development of computationally efficient degree-Delaunay bifiltrations. However, degree-Delaunay bifiltrations will not be studied in this paper.

Other Related Work. Our work and the prior work [3] solve particular instances of a general computational problem: Given a filtered point cloud $Z = (Z_p)_{p\in P}$ indexed by a poset P, one has an associated offset filtration indexed by the product poset $P \times [0, \infty)$; the problem is to define and compute a generalized Delaunay filtration of reasonable size which is weakly equivalent to this offset filtration. The case that Z is of the form $X \to X \cup Y \leftarrow Y$ was studied by Reani and Bobrowski [51], who call the resulting generalized Delaunay filtration the *coupled α-filtration*. A more general case, where instead of considering two point clouds and their union, one considers $n \geq 2$ point clouds and their union, was treated in [27, 7]. The authors call the resulting Delaunay objects *chromatic α-complexes*.

Many works have studied time-varying point cloud or metric data through the lens of persistence. To avoid the difficulties of multiparameter persistence, such work most often either considers persistence with respect to a scale parameter and ignores persistence across the time parameter [49, 1, 59, 35, 48, 22], or fixes a scale parameter and considers extended or zig-zag persistence across time [56, 43, 42]. In particular, the problem of extending Delaunay complexes to time-varying data has been studied in [38, 29] using 1-parameter (extended) persistent homology with a fixed radius parameter. It is natural to simultaneously consider persistence with respect to both scale and time, working in the multiparameter setting. This was previously explored by Kim and Mémoli [41], who introduce and study a Rips trifiltration for time-varying metric data with consistent labels across time, and by Saunders [53] and Dey and Samaga [26], who study a version of multiparameter persistence indexed over a product of a zigzag poset and a totally ordered set.

Finally, we note that a construction similar to the one used in [3] was previously used by Sheehy to construct sparse Delaunay filtrations [54].

Outline. Section 2 covers preliminaries that are needed throughout the paper. In Section 3, we define the incremental Delaunay complex $\mathcal{I}$ of a function $\gamma\colon X \to \mathbb{R}^2$, thereby completing the definition of the trifiltrations $\mathcal{D}(\gamma)$ and $\mathcal{DC}(\gamma)$. Section 4 introduces conflict pairs and presents our characterization of $\mathcal{I}$ in terms of these. In Section 5, we apply this characterization to obtain an algorithm for computing $\mathcal{I}$. We also discuss optimizations to this algorithm. In Section 6, we establish that $\mathcal{D}(\gamma)$ and $\mathcal{DC}(\gamma)$ are weakly equivalent to the sublevel offset trifiltration $\mathcal{O}(\gamma)$. Finally, in Section 7, we describe our implementation and report the results of our experiments.

2 Preliminaries

We fix a finite set $X \subset \mathbb{R}^d$. For a set $Q \subset X$, a $(d-1)$-sphere S is a *circumsphere* of Q if all points of Q lie on S, and the circumsphere S is *empty* in X if no point of $X \setminus Q$ lies inside S. We assume X is in general position, i.e., every non-empty subset Q of X of at most $d+1$ points is affinely independent, and no point of $X \setminus Q$ lies on the smallest circumsphere of Q.

The *Delaunay triangulation* of X is the simplicial complex

$$\mathrm{Del}(X) = \{\sigma \subset X \mid \sigma \text{ is non-empty and has an empty circumsphere}\}.$$

The *Voronoi cell* of a point $x \in X$ is the region

$$\mathrm{Vor}(x, X) = \{y \in \mathbb{R}^d \mid \|y - x\| \leq \|y - x'\|, \forall x' \in X\}.$$

$\mathrm{Del}(X)$ is equal to the *nerve* of the collection of Voronoi cells $\{\mathrm{Vor}(x, X) \mid x \in X\}$; see Section 6 for the definition of the nerve. For $x \in X$ and $r \geq 0$, the *Voronoi ball* $\mathcal{V}(x, X)_r$ is the region

$$\mathcal{V}(x, X)_r = \mathrm{Vor}(x, X) \cap \mathrm{Ball}_r(x),$$

where $\mathrm{Ball}_r(x) := \{y \in \mathbb{R}^| \|x - y\| \leq r\}$ is the closed ball of radius r centered at X. Letting $\mathcal{D}(X)_r$ denote the nerve of the collection of Voronoi balls $\{\mathcal{V}(x, X)_r\}_{x \in X}$, we call $\mathcal{D}(X) := (\mathcal{D}(X)_r)_{r \in \mathbb{R}^+}$ the *Delaunay filtration* of X.

We also fix a function $\gamma = (\gamma_1, \gamma_2) \colon X \to \mathbb{R}^2$. For simplicity, throughout the paper, we assume that both γ_1 and γ_2 are injective. This assumption entails no loss of generality: one can perturb γ to enforce such injectivity, carry out our trifiltration constructions for the perturbed function, and then readily recover a correct result for the unperturbed function from this. For $i = 1, 2$, let $<_i$ denote the total order on X induced by γ_i, and let $\max_i(\sigma)$ be the maximum element of σ with respect to $<_i$.

Throughout the paper, we consider the product partial order on $\mathbb{R}^2$, given by $p \leq q$ if and only if $p_1 \leq q_1$ and $p_2 \leq q_2$. We say p, q are *comparable* if $p \leq q$ or $q \leq p$; otherwise, they are *incomparable*. For $p \in \mathbb{R}^2$, let $X_p := \{x \in X \mid \gamma(x) \leq p\}$ denote the p-sublevel set of γ.

3 Delaunay trifiltrations

▶ **Definition 3.** *The* incremental Delaunay complex*, denoted $\mathcal{I}$ is the simplicial complex whose simplices are the non-empty subsets $\sigma \subset X$ with a circumsphere S of $\sigma \setminus \{\max_1(\sigma), \max_2(\sigma)\}$ satisfying:*

- *$\max_1(\sigma)$ and $\max_2(\sigma)$ are either inside or on S,*
- *every $x \in X \setminus \sigma$ such that $\gamma(x) < \gamma(\sigma)$ is either outside S or on S.*

For a simplex $\sigma \in \mathcal{I}$, we call the infimal radius of such a sphere S the incremental Delaunay radius*, and denote this as $\omega(\sigma)$.*

Note that in Section 3, we can have $\max_1(\sigma) = \max_2(\sigma)$, in which case $\gamma(\sigma) = \gamma(\max_1(\sigma))$.

▶ **Definition 4.** *For $\gamma : X \to \mathbb{R}^2$, the* sublevel Delaunay trifiltration $\mathcal{D}(\gamma)$ *and* sublevel Delaunay-Čech trifiltration $\mathcal{DC}(\gamma)$ *are defined over $\mathbb{R}^2 \times \mathbb{R}^+$ as follows:*

$$\mathcal{D}(\gamma)_{p,r} := \{\sigma \in \mathcal{I} \mid \gamma(\sigma) \leq p \text{ and } \omega(\sigma) \leq r\},$$
$$\mathcal{DC}(\gamma)_{p,r} := \{\sigma \in \mathcal{I} \mid \gamma(\sigma) \leq p \text{ and } m(\sigma) \leq r\},$$

where $\omega(\sigma)$ denotes the incremental Delaunay radius of σ (see Definition 3) and $m(\sigma)$ is the radius of the smallest enclosing ball of σ.

▶ **Proposition 5.** *For $r \geq 0$ and $p \in \mathbb{R}^2$, we have $\mathcal{D}(X_p)_r \subset \mathcal{D}(\gamma)_{p,r}$.*

Taking r sufficiently large, Proposition 5 implies that $\mathcal{I}$ contains the Delaunay triangulation $\mathrm{Del}(X_p)$ for all $p \in \mathbb{R}^2$.

4 Conflict pairs and triples

We now characterize the simplices of $\mathcal{I}$ in a way that is conducive to computation.

Let $\mathrm{Grid}(\gamma) = \mathrm{im}\,\gamma_1 \times \mathrm{im}\,\gamma_2$, and consider $p = (p_1, p_2) \in \mathrm{Grid}(\gamma)$. If $p_1 < \max(\mathrm{im}\,\gamma_1)$, then let $p{\rightarrow} = (p_1^+, p_2)$, where p_1^+ is the element of $\mathrm{im}\,\gamma_1$ immediately after p_1. We define variants of this notation, e.g., $p{\uparrow}$ and $p_{\downarrow}$, in the analogous way. For $p \in \mathrm{Grid}(\gamma)$ with $p_1 < \max(\mathrm{im}\,\gamma_1)$ and $p_2 < \max(\mathrm{im}\,\gamma_2)$, we let $p^{\nearrow} = (p{\uparrow}){\rightarrow}$.

▶ **Definition 6** (Conflict pairs and triples)**.**

(i) *For $p \in \mathrm{Grid}(\gamma)$, a* conflict pair at p *is a pair (τ, x) such that*

- **a.** *τ is a d-simplex in $\mathrm{Del}(X_p)$,*
- **b.** *either*
  - *$(p_1 < \max(\mathrm{im}\,\gamma_1)$ and $x \in X_{p{\rightarrow}})$ or*
  - *$(p_2 < \max(\mathrm{im}\,\gamma_2)$ and $x \in X_{p{\uparrow}})$,*
- **c.** *x lies inside the circumsphere of τ.*

(ii) *For distinct conflict pairs (τ, x) and (τ, y) at p, we call (τ, x, y) a* conflict triple at p.

(iii) *We call (τ, x) a* conflict pair *if it is a conflict pair at some p, and similarly for conflict triples.*

Definition 6 is illustrated in Figure 3. Note that if (τ, x, y) is a conflict triple at p, then by the injectivity of γ_1 and γ_2, either $x \in X_{p{\rightarrow}}$ and $y \in X_{p{\uparrow}}$, or else $y \in X_{p{\rightarrow}}$ and $x \in X_{p{\uparrow}}$.

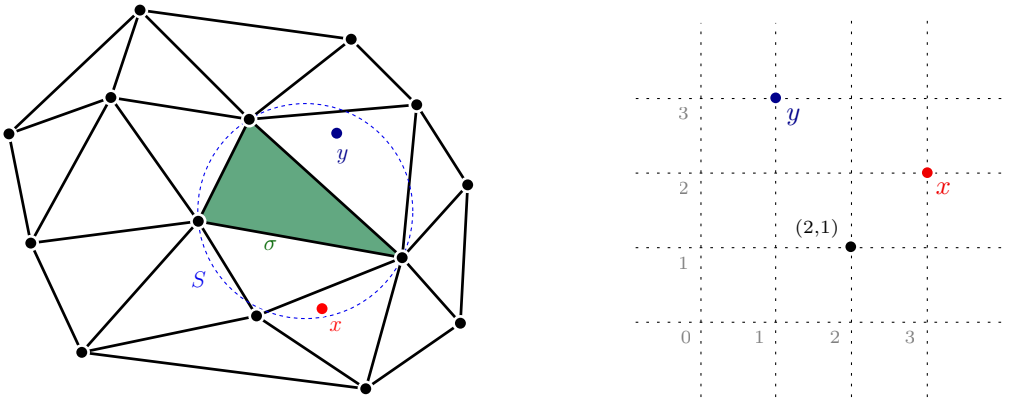

Figure 3 Let $\mathrm{Del}(X_{(2,1)})$ be as shown in black on the left, and let $\sigma \in \mathrm{Del}(X_{(2,1)})$ be the green 2-simplex with circumsphere S. Since $X_{(2,1)} = X_{(2,2)}$, we have $\mathrm{Del}(X_{(2,1)}) = \mathrm{Del}(X_{(2,2)})$, so $\sigma \in \mathrm{Del}(X_{(2,2)})$. At index $p = (2, 2)$, the point x (red) lies inside S, and belongs to $X_{p{\rightarrow}} = X_{(3,2)}$, so (σ, x) is a conflict pair at $(2, 2)$. Similarly, the point y (blue) lies inside S, and belongs to $X_{p{\uparrow}} = X_{(2,3)}$, so (σ, y) is a conflict pair at $(2, 2)$. Since (σ, x) and (σ, y) are distinct conflict pairs at $(2, 2)$, (σ, x, y) is a conflict triple at $(2, 2)$.

▶ **Lemma 7.** *If (σ, x) and (σ, y) are distinct conflict pairs, then $\gamma(x)$ and $\gamma(y)$ are incomparable.*

Proof. To arrive at a contradiction, suppose $\gamma(x) < \gamma(y)$, and (σ, y) is a conflict pair at p. Then $\gamma(x) < \gamma(y) \leq (p^{\nearrow})$. Thus, by injectivity of γ_1 and γ_2, $\gamma(x) \leq p$. Since (σ, x) is a conflict pair, we have $\sigma \notin \mathrm{Del}(X_p)$, which contradicts that (σ, y) is a conflict pair at p. ◀

Lemma 7 implies that for any d-simplex σ in $\bigcup_p \mathrm{Del}(X_p)$, the set

$$T_\sigma \coloneqq \{x \mid (\sigma, x) \text{ is a conflict pair}\}$$

is totally ordered by γ_1-coordinate. Henceforth, we assume that T_σ is given this order.

▶ **Lemma 8.** *For $x, y \in T_\sigma$, (σ, x, y) is a conflict triple if and only if x, y are ordered consecutively in T_σ.*

Proof. If x, y are ordered consecutively, then it is easily checked that (σ, x, y) is a conflict triple at p, where $p^{\nearrow} = \gamma(x) \vee \gamma(y)$. Conversely, if there exists $z \in T_\sigma$ with $x < z < y$ in the order on T_σ, then for any p with $x \in X_{p\uparrow}$ and $y \in X_{p\rightarrow}$, we have $z \in X_p$, so $\sigma \notin \mathrm{Del}(X_p)$. Hence (σ, x, y) is not a conflict triple. ◀

The next lemma follows immediately from the definition of $\mathcal{I}$.

▶ **Lemma 9.**
(i) *If (τ, x) is a conflict pair, then $\tau \cup \{x\}$ is a $(d+1)$-simplex in $\mathcal{I}$.*
(ii) *If (τ, x, y) is a conflict triple, then $\tau \cup \{x, y\}$ is a $(d+2)$-simplex in $\mathcal{I}$.*

In a way that the following proposition makes precise, every simplex is a face of a $(d+2)$-simplex or $(d+1)$-simplex coming from conflicts as above. For this, we must assume that X satisfies the Δ-*property*, i.e., the total orders $<_1$ and $<_2$ coincide in the first $d+1$ points and X is contained in the convex hull of these first $d+1$ points. This technical condition can be easily enforced in practice by simply adding $d+1$ artificial points "at infinity." The analogous condition for a single total order (or a slight variant thereof) is commonly exploited in the incremental computation of Delaunay triangulations [31, 11, 12], and is also used in the previous work on sublevel-Delaunay bifiltrations [3].

▶ **Proposition 10.** *If X has the Δ-property and $|X| \geq d+2$, then every $\tau \in \mathcal{I}(\gamma)$ is either*
- *a face of the $(d+2)$-simplex $\sigma \cup \{x, y\}$ for some conflict triple (σ, x, y), or*
- *a face of the $(d+1)$-simplex $\sigma \cup \{x\}$ for some conflict pair (σ, x) where $|T_\sigma| = 1$.*

Size. We apply the above results, together with a result about the incremental construction of Delaunay triangulations [31], to bound the size of $\mathcal{I}$:

▶ **Theorem 11.** *For constant dimension d, $\mathcal{I}$ has $O(|X|^{\lceil (d+1)/2 \rceil + 1})$ simplices.*

5 Computation

By Proposition 10, to compute $\mathcal{I}$ it suffices to compute all conflict pairs and conflict triples. In the following, we explain how to compute all conflict pairs. Once we have done so, we can easily compute all conflict triples via Lemma 8, by iterating through the set of conflict pairs T_σ for each d-simplex $\sigma \in \bigcup_{p \in \mathrm{Grid}(\gamma)} \mathrm{Del}(X_p)$.

The Bowyer-Watson algorithm. We make essential use of the *Bowyer-Watson algorithm* [15, 57], a standard incremental algorithm for computing Delaunay triangulations. Given the Delaunay triangulation $\mathrm{Del}(Y)$ of a point cloud $Y \subset \mathbb{R}^d$ and a point $y \in \mathbb{R}^d$, the Bowyer-Watson algorithm computes $\mathrm{Del}(Y \cup \{y\})$. To do so, it first identifies each d-simplex σ such that y lies inside the circumsphere of σ. Each such simplex σ is then removed from $\mathrm{Del}(Y)$, resulting in a star-convex region R centered at y. Finally, to obtain $\mathrm{Del}(Y \cup \{y\})$, the region R is retriangulated by forming the simplicial cone with base the boundary of R and apex y (See Figure 4). For σ a d-simplex as above, we call the pair (σ, y) a *BW-conflict (for Y)*.

▶ Remark 12. Note that the definition of BW-conflict is distinct from, but closely related to, that of a conflict pair given in Definition 6 (i). Namely, every conflict pair (σ, y) at p is a BW-conflict for X_p, and conversely, if $y \in X_{p\rightarrow} \cup X_{p\uparrow}$ and (σ, y) is a BW-conflict for X_p, then (σ, y) is a conflict pair.

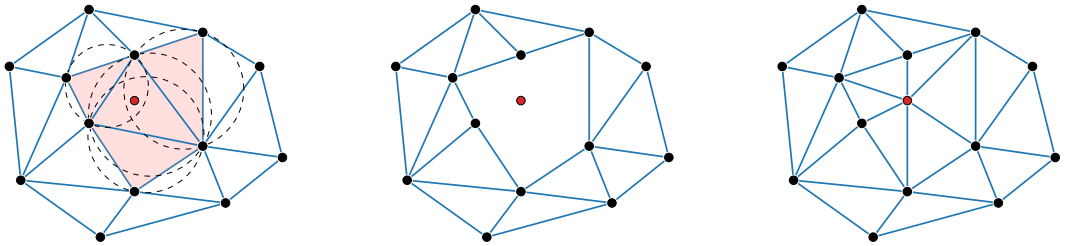

Figure 4 The Delaunay triangulation $\mathrm{Del}(Y)$ (blue), and the new point y (red). Triangles whose circumcircles contain y are shaded. We remove all these triangles, leaving an untriangulated star-convex region R centered at y. R is then retriangulated by the simplicial cone with base the boundary of R and apex y, yielding $\mathrm{Del}(Y \cup \{y\})$.

Naive Computation of Conflict Pairs. To compute all conflict pairs, a natural strategy is to traverse each horizontal and each vertical line in $\mathrm{Grid}(\gamma)$ in increasing order, iteratively applying the Bowyer-Watson algorithm. To explain this, we focus on the traversal of vertical lines, as the case of horizontal lines is symmetric. A naive version of the strategy, which already satisfies our main complexity bound (Theorem 13), is as follows: For each $a \in \operatorname{im}\gamma_1$, iterate through $\operatorname{im}\gamma_2 = \{b_1, \ldots, b_n\}$ in increasing order. For each $i < n$, let $p = (a, b_i)$. Given $\mathrm{Del}(X_p)$, if $X_{p\uparrow} \setminus X_p$ is non-empty, hence equal to $\{x\}$ for some $x \in X$, then we apply Bowyer-Watson to compute both $\mathrm{Del}(X_{p\uparrow})$ and all conflict pairs of the form (σ, x) at p.

▶ **Theorem 13.** *The above approach computes $\mathcal{I}$ in time $O(|X|^{\lceil d/2 \rceil + 2})$.*

Computing trifiltrations. Once $\mathcal{I}$ is computed, completing the computation of either $\mathcal{D}(\gamma)$ or $\mathcal{DC}(\gamma)$ amounts to computing the birth index of each simplex $\sigma \in \mathcal{I}$ in the trifiltration. Recall that the birth index of σ in $\mathcal{DC}(\gamma)$ is $(\gamma(\sigma), m_\sigma)$, where m_σ is the radius of the smallest enclosing ball of σ. Computation of the first two components of this triple is trivial. In general, smallest enclosing balls can be computed via standard algorithms with efficient implementations [58, 34, 33, 36, 32]. Assuming d is constant, computing m_σ also requires constant time. Further, recall that the birth index of σ in $\mathcal{D}(\gamma)$ is $(\gamma(\sigma), \omega_\sigma)$, where ω_σ is the incremental Delaunay radius of Definition 3. We discuss the computation of ω_σ in the full version, where we observe that ω_σ can be computed for all $\sigma \in \mathcal{I}$ in amortized constant time per simplex. From this and Theorem 13, we obtain the following:

▶ **Corollary 14.** *Both $\mathcal{D}(\gamma)$ and $\mathcal{DC}(\gamma)$ can be computed in time $O(|X|^{\lceil d/2 \rceil + 2})$.*

5.1 Optimized computation of conflict pairs

The above approach to computing conflict pairs involves considerable redundant computation across different vertical lines. We next discuss strategies for reducing this redundancy.

Whereas the unoptimized algorithm described above uses only point insertions in Delaunay triangulations, our optimizations use both insertions and deletions. Our aim in selecting these optimizations is to reduce the total number $\zeta(X)$ of insertions and deletions, which can be seen heuristically as a proxy for the total cost of the algorithm in practice. Our optimizations do not reduce $\zeta(X)$ in the worst case, and do not improve the asymptotic worst-case complexity. But in some classes of examples they yield an asymptotic reduction of $\zeta(X)$.

First, we note that for any $x \in X$, it suffices to begin the traversal of the vertical line containing $\gamma(x)$ at index $p = \gamma(x)_\downarrow$, rather than at index $(\gamma_1(x), \min_{y \in X} \gamma_2(y))$. However, to exploit this idea, one must select an algorithm to compute $\mathrm{Del}(X_{\gamma(x)_\downarrow})$. A simple approach

is to use the Bowyer-Watson algorithm with randomized insertion of points, which is known to be highly efficient in expectation [21]. However, this requires the same number of point insertions as the unoptimized algorithm, which constructs $\mathrm{Del}(X_{\gamma(x)_\downarrow})$ via point insertions in order of γ_2-value. We next introduce an alternative algorithm to compute $\mathrm{Del}(X_{\gamma(x)_\downarrow})$ which exploits the work done along the previous vertical line to reduce $\zeta(X)$ in favorable cases.

Computing $\mathbf{Del}(\boldsymbol{X_{\gamma(x)_\downarrow}})$ via deletions. Assume that we handle vertical lines in rightward order. Consider $w, x \in X$, with w immediately before x in the order $<_1$. We thus handle the vertical line containing $\gamma(w)$ immediately before the one containing $\gamma(x)$. Let W denote the final sublevel set of γ encountered as we traverse the line containing $\gamma(w)$, i.e., $W = \{y \in X \mid \gamma_1(y) \leq \gamma_1(w)\}$. Noting that $X_{\gamma(x)_\downarrow} \subset W$, let $R = W \setminus X_{\gamma(x)_\downarrow}$. We compute $\mathrm{Del}(X_{\gamma(x)_\downarrow})$ from $\mathrm{Del}(W)$ by removing the points of R one by one, using the standard algorithm of [25] to repair the Delaunay triangulation after each removal.

The number of vertex removals required to obtain $X_{\gamma(x)_\downarrow}$ from $\mathrm{Del}(W)$ is at most the number of insertions required for the subsequent traversal of the vertical line containing $\gamma(x)$, because each vertex removed must be reinserted. Thus, in all instances, this strategy increases $\zeta(X)$ by at most a factor of two, compared to the unoptimized algorithm. Further, the next example shows that this strategy can lead to an asymptotic reduction in $\zeta(X)$ on a certain family of inputs.

▶ **Example 15.** If the product partial order on $\mathbb{R}^2$ restricts to a total order on X, then $\zeta = O(|X|)$ for the optimized strategy described above, but $\zeta = O(|X|^2)$ for the unoptimized strategy. On the other hand, if the elements of X are pairwise incomparable, then $\zeta = O(|X|^2)$ for both strategies.

Reducing the number of insertions and deletions. In fact, to compute the conflict pairs first appearing on the vertical line containing $\gamma(x)$, it is not necessary to explicitly remove all points of R, but only a subset $Q \subset R$. This idea leads to a further optimization, which we call the *local algorithm*, that further reduces $\zeta(X)$. To distinguish the approaches, we call the optimized algorithm described above the *non-local algorithm*.

The local algorithm is illustrated in Figure 5. The algorithm proceeds as follows: We maintain a Delaunay triangulation T, to be modified by point removals and insertions. First, we compute $T = \mathrm{Del}(W \cup \{x\})$ from $\mathrm{Del}(W)$ via the Bowyer-Watson algorithm. We next iteratively remove from T the neighbors of x that belong to R, in arbitrary order, until x has no neighbor in R. Letting Q denote the set of removed points, after these removals, we have $T = \mathrm{Del}((W \cup \{x\}) \setminus Q)$. We then remove x from T. Finally, we insert the points of $Q \cup \{x\}$ into T in increasing order of γ_2-value, noting the BW-conflicts that arise. Each BW-conflict (σ, y) such that $x \in \sigma \cup \{y\}$ is recorded as a conflict pair.

The correctness of this approach hinges on the fact that Delaunay triangulations are local, in the sense of the following lemma. For a simplicial complex K and vertex v, the *star* of v in K, denoted $\mathrm{Star}(v, K)$, is the set of simplices of K that contain v.

▶ **Lemma 16.** *Let $Z \subset \mathbb{R}^d$ be a finite point set in general position and $z \in Z$ be a point. Let $V_z = \mathcal{N}(z, \mathrm{Del}(Z))$. Then, for any Y such that $V_z \subset Y \subset Z$, we have*

$$\mathrm{Star}(z, \mathrm{Del}(V_z)) = \mathrm{Star}(z, \mathrm{Del}(Y)).$$

▶ **Proposition 17.** *The local algorithm correctly computes all conflict pairs.*

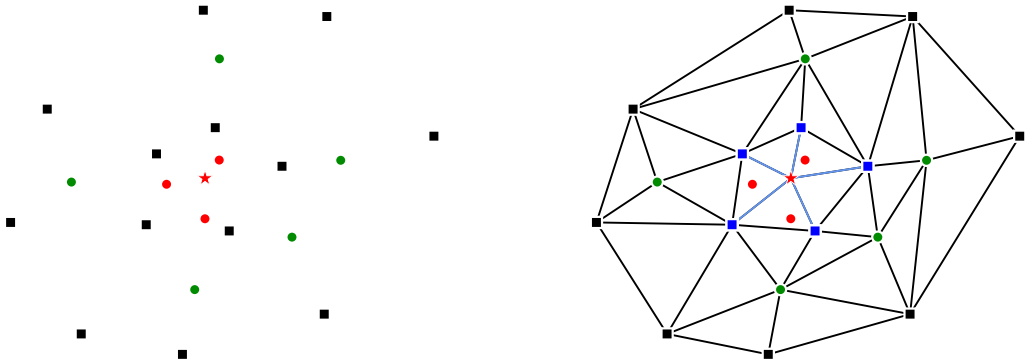

Figure 5 The left figure shows the point set W prior to inserting x (red star). Points of R are shown as green and red circles; these are the points of W with larger γ_2-value than x. Points of $X_{\gamma(x)\downarrow}$ are shown as squares; these are the points of W with smaller γ_2-value. In the non-local algorithm, all points of R are removed from the Delaunay triangulation and then re-inserted in increasing γ_2-order. In the local algorithm, points of R that are Delaunay neighbors of x (red circles) are iteratively removed until we arrive at a configuration where every Delaunay neighbor of x lies in $W \setminus R$ (blue squares, right figure). We next remove x, and then re-insert the set S of removed points (red) in increasing γ_2-order.

6 Topological equivalence of trifiltrations

Our main theoretical justification for computing Delaunay-(Čech) trifiltrations is the following:

▶ **Theorem 18.** *The trifiltrations $\mathcal{D}(\gamma)$, $\mathcal{DC}(\gamma)$, and $\mathcal{O}(\gamma)$ are all weakly equivalent.*

We begin by recalling the definition of weak equivalence; in homotopy theory, this is a standard notion of "homotopical equivalence" of diagrams of topological spaces. For a poset $\mathcal{P}$, a *$\mathcal{P}$-indexed filtration* is a collection of topological spaces $F = (F_p)_{p\in\mathcal{P}}$ such that $F_p \subset F_q$, whenever $p \leq q$. Equivalently, F is a functor from the poset category of $\mathcal{P}$ to the category of topological spaces **Top**.

▶ **Definition 19.**

(i) *Given $\mathcal{P}$-indexed filtrations F, F', a* natural transformation $\psi\colon F \to F'$ *is a collection of continuous maps $(\psi_p : F_p \to F'_p)_{p\in\mathcal{P}}$ such that the following diagram commutes for all $p \leq q$.*

$$\begin{array}{ccc} F_p & \hookrightarrow & F_q \\ \downarrow & & \downarrow \\ F'_p & \hookrightarrow & F'_q. \end{array}$$

(ii) *We call ψ a* pointwise homotopy equivalence *if each ψ_p is a homotopy equivalence.*

(iii) *We say that F and F' are* weakly equivalent*, and write $F \simeq F'$, if there exists a zigzag of pointwise homotopy equivalences connecting F and F':*

$$F \leftarrow G^1 \rightarrow G^2 \leftarrow G^3 \rightarrow \cdots \leftarrow G^k \rightarrow F'.$$

To show that $\mathcal{D}(\gamma) \simeq \mathcal{O}(\gamma)$, we characterize $\mathcal{D}(\gamma)$ as the nerve of a cover of a certain trifiltration $\mathcal{TO}$ in $\mathbb{R}^d \times \mathbb{R}^2$, which we call the *telescopic offset trifiltration*. A functorial version of the nerve theorem [6] then implies that $\mathcal{D}(\gamma) \simeq \mathcal{TO}$. In addition, a simple deformation retraction argument gives that $\mathcal{TO} \simeq \mathcal{O}(\gamma)$. Hence, $\mathcal{D}(\gamma) \simeq \mathcal{O}(\gamma)$. Similar constructions have previously been used to establish weak equivalence of 1-parameter and 2-parameter filtrations in [19, 23]. Our proof that $\mathcal{DC}(\gamma) \simeq \mathcal{O}(\gamma)$ is very similar; it uses a description of Delaunay-Čech complexes as nerves, which extends a construction of Blaser and Brun [8].

In [3], the analogous results for sublevel Delaunay(-Čech) bifiltrations were instead proven via discrete Morse theory, by extending an argument of Bauer and Edelsbrunner [5] to the 2-parameter setting. While we expect that approach to extend to our 3-parameter setting, we find our nerve-based approach to be more intuitive. In what follows, we outline the proof that $\mathcal{D}(\gamma) \simeq \mathcal{O}(\gamma)$. The proof that $\mathcal{DC}(\gamma) \simeq \mathcal{O}(\gamma)$ appears entirely in the full version.

Functorial nerve theorem for closed, semi-algebraic sets. A *cover* of a set $X \subset \mathbb{R}^d$ is a set $C = \{C(i)\}_{i \in I}$ of subsets of X whose union is X. The *nerve* of C is the simplicial complex

$$\mathrm{Nrv}(C) = \left\{ \sigma \subset I \mid \sigma \neq \emptyset,\ \bigcap_{i \in \sigma} C(i) \neq \emptyset \right\}.$$

We say C is a *good* cover if every intersection of cover elements is either empty or contractible.

These definitions extend naturally to $\mathcal{P}$-indexed filtrations, as follows: For F a $\mathcal{P}$-indexed filtration, a *cover* of F is a collection of $\mathcal{P}$-indexed filtrations $\mathcal{C} = \{\mathcal{C}(i)\}_{i \in I}$, such that for each $p \in \mathcal{P}$, $\{\mathcal{C}(i)_p\}_{i \in I}$ is a cover of F_p. We say that $\mathcal{C}$ is *good* if for each p, $\{\mathcal{C}(i)_p\}_{i \in I}$ is a good cover of F_p. We define $\mathrm{Nrv}(\mathcal{C})$, the *nerve of* $\mathcal{C}$, to be the $\mathcal{P}$-indexed filtration given by $\mathrm{Nrv}(\mathcal{C})_p = \mathrm{Nrv}(\{\mathcal{C}(i)_p\}_{i \in I})$, with structure maps the inclusions.

We will use the following functorial version of the nerve theorem for semi-algebraic sets; see also [6] for a thorough treatment of other variants of the nerve theorem.

▶ **Theorem 20.** *Let $\mathcal{C} = \{\mathcal{C}(i)\}_{i \in I}$ be a finite, good cover of a $\mathcal{P}$-indexed filtration F such that for each $p \in \mathcal{P}$ and $i \in I$, $\mathcal{C}(i)_p$ is closed and semi-algebraic. Then $F \simeq \mathrm{Nrv}(\mathcal{C})$.*

Proof. This follows immediately from [6, Theorem 5.9], using the fact that an inclusion of closed semi-algebraic sets satisfies the homotopy extension property [24, Theorem 4]. ◀

▶ Remark 21. Theorem 20 is proven in [6, Theorem 4.10] under the additional assumption that each $\mathcal{C}(i)_p$ is compact, via a somewhat different argument.

Telescopic offset trifiltration. For $(p, r) \in \mathbb{R}^2 \times \mathbb{R}^+$, the *telescopic offset* $\mathcal{TO}_{p,r} \subset \mathbb{R}^d \times \mathbb{R}^2$ is given by

$$\mathcal{TO}_{p,r} \coloneqq \bigcup_{q \leq p} \mathcal{O}(\gamma)_{q,r} \times \{q\}. \tag{1}$$

Equivalently,

$$\mathcal{TO}_{p,r} = \bigcup_{x \in X} \mathrm{Ball}_r(x) \times [\gamma(x), p],$$

where $[\gamma(x), p] = \{q \in \mathbb{R}^2 \mid \gamma(x) \leq q \leq p\}$. Varying p and r, we obtain the *telescopic offset trifiltration* $\mathcal{TO} \colon \mathbb{R}^2 \times \mathbb{R}^+ \to \mathbf{Top}$. Let $\psi \colon \mathcal{TO} \to \mathcal{O}(\gamma)$ be the natural transformation induced by the projection of $\mathbb{R}^d \times \mathbb{R}^2$ onto the first d coordinates.

▶ **Lemma 22.** *The natural transformation ψ is a pointwise homotopy equivalence.*

A cover by telescopic Voronoi balls. We next define our cover of $\mathcal{TO}$. For $x \in X$, we define the *telescopic Voronoi cell*

$$\mathrm{Tel}(x) \coloneqq \mathrm{cl}\Big(\bigcup_{\gamma(x) \le q} \mathrm{Vor}(x, X_q) \times \{q\} \Big),$$

where cl denotes the closure. For $(p, r) \in \mathbb{R}^2 \times \mathbb{R}^+$, we define the *telescopic Voronoi ball*

$$\begin{aligned} \mathcal{T}(x)_{p,r} &\coloneqq \mathrm{cl}\Big(\bigcup_{\gamma(x) \le q \le p} \mathcal{V}(x, X_q)_r \times \{q\} \Big) \\ &= \mathrm{Tel}(x) \cap (\mathrm{Ball}_r(x) \times \{y \in \mathbb{R}^2 \mid y \le p\}). \end{aligned}$$

See Figure 6 for an illustration in the case $d = 1$. Allowing p and r to vary, the spaces $\mathcal{T}(x)_{p,r}$ assemble into a trifiltration $\mathcal{T}(x) \colon \mathbb{R}^2 \times \mathbb{R}^+ \to \mathbf{Top}$. We let $\mathcal{T} = \{\mathcal{T}(x)\}_{x \in X}$.

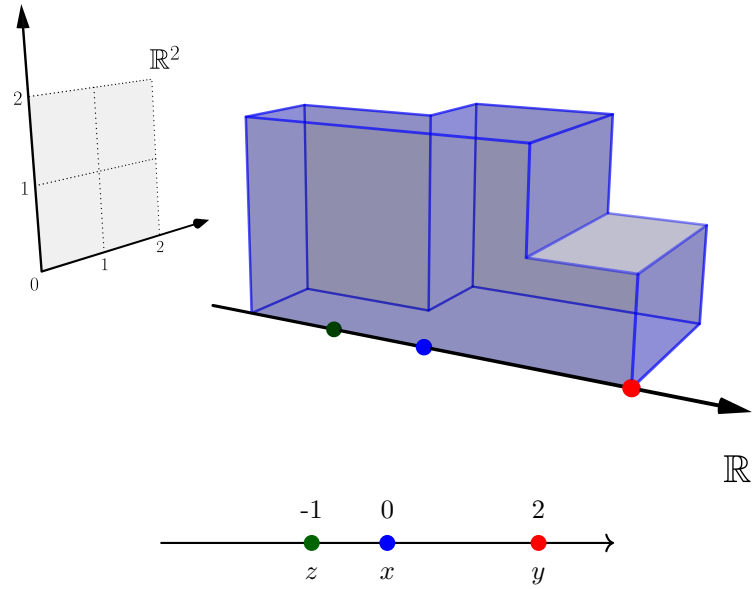

Figure 6 The point set X consists of three points x (blue), y (red), and z (green) in $\mathbb{R}$, whose function values are $\gamma(x) = (0, 0)$, $\gamma(y) = (0, 1)$, and $\gamma(z) = (1, 0)$. The telescopic Voronoi ball $\mathcal{T}(x)_{p,r}$ of radius $r = 2$ at $p = (2, 2)$ for the point x (blue) is shown as the blue shaded polyhedron.

▶ **Lemma 23.** *The set $\mathcal{T}$ is a good cover of $\mathcal{TO}$.*

In what follows, we identify simplices of $\mathrm{Nrv}(\mathcal{T})$ with their corresponding subsets of X.

▶ **Lemma 24.** *The trifiltrations $\mathrm{Nrv}(\mathcal{T})$ and $\mathcal{D}(\gamma)$ are equal.*

▶ **Proposition 25.** *We have $\mathcal{D}(\gamma) \simeq \mathcal{O}(\gamma)$.*

7 Implementation

We have written a C++ program to compute the *Delaunay-Čech trifiltration* $\mathcal{DC}(\gamma)$ for a function $\gamma : X \to \mathbb{R}^2$, where $X \subset \mathbb{R}^d$. The code is available on Bitbucket[1]. Our code builds upon a prior implementation of the algorithm from [3] for computing the Delaunay-Čech filtration of an $\mathbb{R}$-valued function. Our program accepts a text file as input, where each line represents the coordinate of a point $x \in \mathbb{R}^d$ along with its function value $\gamma(x)$, and outputs a chain complex representation of $\mathcal{DC}(\gamma)$ in the `scc2020` format, as described in [40]. Both the local and non-local algorithms are implemented. Our implementation computes the incremental Delaunay complex essentially as described in Section 5. However, there are minor differences, which arise because some simplifications that have been incorporated into this paper have not yet been implemented in the code. As in [3], simplices are stored in a simplex tree [13, 47], and minimum enclosing balls are computed in CGAL [32].

Experiments. The test suite we use, obtained from [39], consists of point clouds obtained by sampling 1-spheres (S^1) and unit squares ($[0,1]^2$) in $\mathbb{R}^2$, and 2-spheres (S^2), tori ($S^1 \times S^1$) and unit cubes ($[0,1]^3$) in $\mathbb{R}^3$, with 5% noise drawn from a uniform distribution and perturbation to ensure general position. We consider point clouds of 500, 1000, 2000, 4000, 8000, 16000 points, with four point clouds per type and size.

For each point cloud X we computed the interlevel Delaunay-Čech trifiltration of four different functions $\delta : X \to \mathbb{R}$, using the local algorithm. The four functions are:

- *codensity*, $\delta(x) = -\sum_{y \neq x} \exp\left(-\frac{\|x-y\|^2}{\sigma^2}\right)$, with σ chosen as the 0.1^{th} percentile of the non-zero distances between points in X,
- L_1-*coeccentricity*, $\delta(x) = -\sum_{y \in X} \frac{\|x-y\|}{|X|}$,
- *height*, $\delta(x) = x_d$, where x_d is the last coordinate of x,
- *random*, where for each $x \in X$, $\delta(x)$ is chosen uniformly at random from $[0,1]$.

All experiments were performed on a computer with an Intel Core i7-5960X CPU @3.00GHz and 64GB of memory, running Ubuntu 20.04.6 LTS. The code was compiled with `g++ 9.4.0`.

The full results of the experiments are available on Zenodo[2]. A representative subset of the results is given in Table 1; this data is plotted in Figure 7. We observe that across all examples, the size of the incremental Delaunay complex and the memory usage grow nearly linearly as a function of the input size. In contrast, the runtime grows nearly quadratically. Thus, our experiments indicate that our approach is memory efficient, and therefore that substantially larger computations should be feasible.

Table 2 compares the performance of the local and non-local algorithms on three types of examples, with $|X|$ up to 4000. While the local algorithm offers no improvement over the non-local algorithm in the first example type (interlevel trifiltrations), for the two other example types, the local algorithm is always faster by a factor of between 3 and 14, and the factor increases with the size of the data set.

[2] `https://doi.org/10.5281/zenodo.19227801`

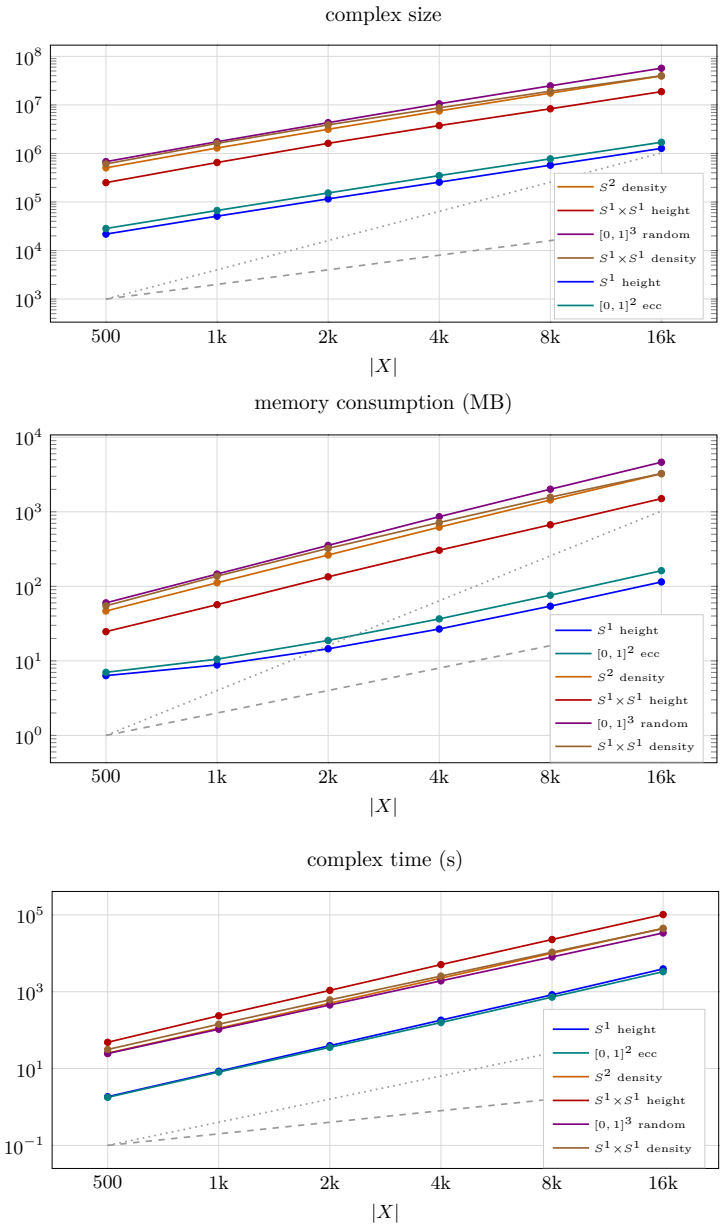

Figure 7 Log-log plots of complex size (top), memory consumption in MB (middle), and time in seconds (bottom) as a function of input size $|X|$, for the computations reported in Table 1. For reference, in each plot, the graphs of a line $y = c_1 x$ and quadratic $y = c_2 x^2$ are shown as dashed and dotted lines, respectively, for some choices of c_1 and c_2 that vary among the three plots. The slope of these lines is determined by the corresponding exponent. In the top plot, for each type of example, the sizes (y-values) are well fit by a translate of the line representing $y = c_1 x$, reflecting that the sizes grow nearly linearly. In the middle plot, the same is very nearly true, indicating that memory consumption also grows nearly linearly. In the bottom plot, for each type of example, the runtimes (y-values) are well fit by a translate of the line representing $y = c_2 x^2$, reflecting that the runtimes grow nearly quadratically.

Table 1 Complex size, running time (in seconds), and the memory consumption (in MB) for computing the interlevel Delaunay-Čech trifiltration via the local algorithm. We also report the size of the Delaunay complex and the time required to compute it.

Table 2 Comparison of the non-local and local algorithms across several datasets. In the interlevel case (S^1, $\gamma_1 = \text{height}$, $\gamma_2 = -\text{height}$), the local algorithm removes all points of R, but incurs a slight overhead from searching for vertices to remove, resulting in marginally worse running times than the non-local algorithm. In the other cases, the local algorithm performs substantially better.

Abstract

Given an unknown $\mathbb{R}^n$-valued function f on a metric space X, can we approximate the persistent homology of f from a finite sampling of X with known pairwise distances and function values? This question has been answered in the case $n = 1$, assuming f is Lipschitz continuous and X is a sufficiently regular geodesic metric space, and using filtered geometric complexes with fixed scale parameter for the approximation. In this paper we answer the question for arbitrary n, under similar assumptions and using function-geometric multifiltrations. Our analysis offers a different view on these multifiltrations by focusing on their approximation properties rather than on their stability properties. We also leverage the multiparameter setting to provide insight into the influence of the scale parameter, whose choice is central to this type of approach. From a practical standpoint, we show that our approximation results are robust to input noise, and that function-geometric multifiltrations have good statistical convergence properties. We also provide an algorithm to compute our estimators, and we use its implementation to conduct extensive experiments, on both synthetic and real biological data, in order to validate our theoretical results.

1 Introduction

Let X be a metric space and $f\colon X \to \mathbb{R}^n$ a function, both unknown. Suppose we are given a finite point cloud P sampled from X, such that the pairwise distances between the points of P are known, as well as the function values at the points of P. Given this input, can we approximate the persistent homology $H_*(f)$ of f (i.e., the persistence module induced in homology from the multifiltration of X by the sublevel sets of f) with provable guarantees? This question was addressed in [10] in the case $n = 1$. The authors proposed an estimator based on a nested pair of Rips complexes $\mathcal{R}^\delta(P) \subseteq \mathcal{R}^{2\delta}(P)$, where δ is a user-defined parameter, which they filtered by the values of f at the vertices using lower-star filtrations. The estimator was then the image of the morphism of 1-parameter persistence modules

induced in homology by the inclusion $\mathcal{R}^\delta(P) \hookrightarrow \mathcal{R}^{2\delta}(P)$. We denote by $H_*(\mathcal{R}^{\delta\to 2\delta}(\hat{f}|_P))$ this estimator. Assuming both the domain X and the function f are sufficiently regular (typically, X is a compact geodesic metric space with positive convexity radius ϱ_X, and f is c-Lipschitz continuous), and P is an ε-sample of X in the geodesic distance for some small enough value of ε (specifically, $\varepsilon < \varrho_X/4$), they proved that the estimator is $2c\delta$-interleaved with $H_*(f)$ for any choice of parameter δ within the range $[2\varepsilon, \varrho_X/2)$. Thus, in cases where ε is known or can be estimated reliably, one can get an $O(2c\varepsilon)$-interleaving with the target $H_*(f)$, hence an $O(2c\varepsilon)$-matching with its barcode, by the algebraic stability theorem [2, 8, 9]. Under a reasonable sampling model, ε goes to zero as the number of sample points goes to infinity, hence so does the approximation error, which means that the proposed estimator is consistent. This approach has since been applied in various contexts, notably in clustering where the algorithm ToMATo [11] is an instance of the method in homology degree 0. However, two fundamental questions were left open in [10, 11]:

Q1 how to estimate ε, or to choose parameter δ directly, when ε is unknown;

Q2 how to generalize the approach to arbitrary n, i.e., to vector-valued functions f.

Q2 is precisely the question we asked at the beginning. Q1 is related to the general problem of scale parameter estimation, which has received a lot of attention in statistics, including in the context of topological data analysis (TDA) – see e.g. [4, 6, 23].

Contributions

In this paper we address both Q1 and Q2 using a unified persistence-based approach.

For Q2 we study the extension of the estimator $H_*(\mathcal{R}^{\delta\to 2\delta}(\hat{f}|_P))$ from [10] to vector-valued functions $f\colon X \to \mathbb{R}^n$, where the codomain $\mathbb{R}^n$ is equipped with the product order, and we generalize its approximation guarantee to this setting. For the sake of generality we assume f to be ω-continuous for some modulus of continuity ω, that is: $\|f(x) - f(y)\|_\infty \leq \omega(d_X(x,y))$ for any $x, y \in X$, where $\omega\colon \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ is a non-decreasing subadditive function such that $\omega(\delta)$ goes to 0 as δ does. This includes Lipschitz or Hölder continuous functions as special cases. Under this assumption, our first main result (Theorem 3) states that the estimator $H_*(\mathcal{R}^{\delta\to 2\delta}(\hat{f}|_P))$ is $\omega(2\delta)$-interleaved with its target $H_*(f)$ for any choice of δ within the range $[2\varepsilon, \varrho_X/2)$, under the same regularity condition on X and ε-sampling condition on P as before. Our proof takes inspiration from the one in [10] but uses a new, purely diagrammatic formulation that clarifies it and makes it hold for any $n \geq 1$.

For Q1 we propose two complementary approaches. The first one infers a relevant choice of δ under an appropriate statistical model. This model assumes the points P are sampled i.i.d. according to some unkown probability distribution μ that is supposed to be (a, b)-standard. When parameters a, b are known, we show that there is an explicit optimal choice δ_k for parameter δ, as a function of the sample size k, that makes the sequence of approximations $\left(H_*(\mathcal{R}^{\delta_k\to 2\delta_k}(\hat{f}|_P))\right)_{k\in\mathbb{N}}$ a quasi-minimax estimator of $H_*(f)$. When a, b are unknown, as would generally be the case in practice, we show that δ_k can be effectively estimated by some $\hat{\delta}_k$ under our statistical model, so that the sequence $\left(H_*(\mathcal{R}^{\hat{\delta}_k\to 2\hat{\delta}_k}(\hat{f}|_P))\right)_{k\in\mathbb{N}}$ is again a quasi-minimax estimator of $H_*(f)$. These statements are summarized in Theorem 5.

Our second approach to addressing Q1 is meant for cases where our statistical model does not hold and ε cannot be estimated reliably. We follow the general philosophy underpinning persistent homology by letting δ vary over $\mathbb{R}_{\geq 0}$ and treating it as an extra parameter for persistence. This means that our estimator now becomes the $(n+1)$-parameter persistence module $H_*(\mathcal{R}^{\bullet\to 2\bullet}(\hat{f}|_P))$ indexed over $\mathbb{R}_{\geq 0} \times \mathbb{R}^n$, where the notation $\bullet$ indicates that the Rips parameter is also a filtration parameter. In order to enable comparisons, the target $H_*(f)$

must also be extended to $\mathbb{R}_{\geq 0} \times \mathbb{R}^n$, which we do by taking its left Kan extension $\mathrm{Lan}_\iota H_*(\mathscr{f})$ along the poset embedding $\iota : \mathbb{R}^n \xrightarrow{\cong} \{0\} \times \mathbb{R}^n \hookrightarrow \mathbb{R}_{\geq 0} \times \mathbb{R}^n$. The extension $\mathrm{Lan}_\iota H_*(\mathscr{f})$ merely contains copies of $H_*(\mathscr{f})$ in each vertical hyperplane $\{\delta\} \times \mathbb{R}^n$, connected by horizontal identities, as illustrated in Figure 1. Our third main result (Theorem 6) states that the n-dimensional interleavings happening between $H_*(\mathscr{f})$ and $H_*(\mathcal{R}^{\delta \to 2\delta}(\mathscr{f}|_P))$ inside each vertical hyperplane $\{\delta\} \times \mathbb{R}^n$ for $\delta \in [2\varepsilon, \varrho_X/2)$ commute with the horizontal morphisms in $H_*(\mathcal{R}^{\bullet \to 2\bullet}(\mathscr{f}|_P))$ and in $\mathrm{Lan}_\iota H_*(\mathscr{f})$, so that, within any vertical slab $[2\varepsilon, \delta_0] \times \mathbb{R}^n$ with $\delta_0 < \varrho_X/2$, they all together form a *vertical* $\omega(2\delta_0)$*-interleaving* (i.e., an $\omega(2\delta_0)$-interleaving along the direction $(0, 1, \cdots, 1)^\top$ in $\mathbb{R}_{\geq 0} \times \mathbb{R}^n$) between $H_*(\mathcal{R}^{\bullet \to 2\bullet}(\mathscr{f}|_P))$ and $\mathrm{Lan}_\iota H_*(\mathscr{f})$.

Since vertical interleavings are stronger than ordinary interleavings (Remark 1), Theorem 6 not only provides approximation guarantees for any interleaving-stable invariant of $\mathrm{Lan}_\iota H_*(\mathscr{f})$ by the corresponding invariant of $H_*(\mathcal{R}^{\bullet \to 2\bullet}(\mathscr{f}|_P))$, but it also offers refined statements for invariants that behave in a particular way under vertical interleavings, such as for instance multigraded Betti numbers as proven in the full version [1] and illustrated in Figure 2.

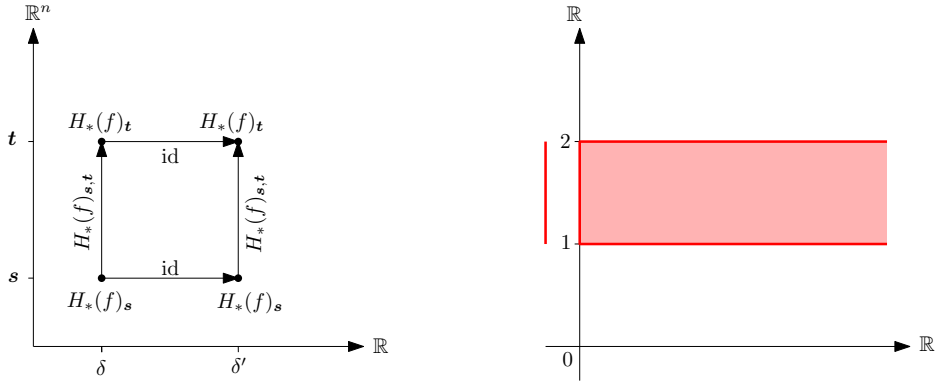

Figure 1 Left: an illustration of the left Kan extension $\mathrm{Lan}_\iota H_*(\mathscr{f}) : \mathbb{R}_{\geq 0} \times \mathbb{R}^n \to \mathbf{vec}$, with identity maps horizontally and the structural morphisms of $H_*(\mathscr{f})$ vertically. **Right**: (case $n = 1$) the left Kan extension of the interval module $\Bbbk^{[1,2]}$ is the interval module $\Bbbk^{\mathbb{R}_{\geq 0} \times [1,2]}$ (in red).

In practice, function values may be corrupted with measurement noise, meanwhile geodesic distances may have to be approximated from the input data. Our framework can account for these imprecisions by suitably adapting the parameters of the estimators and their approximation bounds (see the full version [1, Section 3.3]).

Still for practical purposes, we discuss the computation of our estimators, in particular we provide an algorithm for computing a free presentation of $H_*(\mathcal{R}^{\bullet \to 2\bullet}(\mathscr{f}|_P))$, and thus also of $H_*(\mathcal{R}^{\delta \to 2\delta}(\mathscr{f}|_P))$ for any fixed $\delta \geq 0$, in time that is comparable to that of computing a free presentation of the persistent homology of a single multifiltration. From a free presentation, a variety of invariants, including multigraded Betti numbers, can be derived using existing software. We have implemented our algorithm and used it in our experiments.

Structure of the paper

We provide background material in Section 2. Our problem statement, estimators, and main results are detailed in Section 3. In Section 4 we discuss algorithmic aspects. Finally, in Section 5 we present experimental results that illustrate our theoretical guarantees and we investigate additional properties of our estimators. Further algorithmic details, as well as the proofs of our main results, can be found in the full version [1].

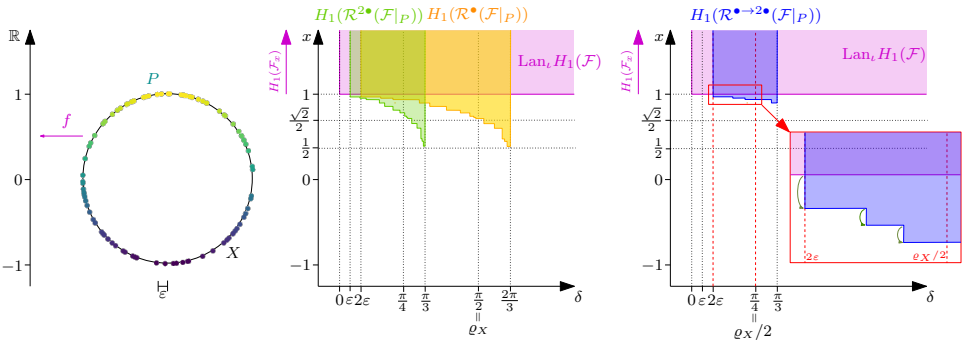

Figure 2 Left: the vertical height function on a sampled unit circle X in the plane. Distances on the circle are given by arclength. **Center**: $H_1(\mathscr{f})$ has a single interval summand (in magenta), starting at height 1, which extends to the free module $\mathrm{Lan}_\iota H_1(\mathscr{f})$ generated at $(0,1)$ in $\mathbb{R}_{\geq 0} \times \mathbb{R}$. The modules $H_1(\mathcal{R}^{\bullet}(\mathscr{f}|_P))$ (in yellow) and $H_1(\mathcal{R}^{2\bullet}(\mathscr{f}|_P))$ (in green) are interval modules in this simple scenario. **Right**: the estimator $H_1(\mathcal{R}^{\bullet\to 2\bullet}(\mathscr{f}|_P))$ (in blue), which is also an interval module, approximates the target $\mathrm{Lan}_\iota H_1(\mathscr{f})$ in the vertical interleaving distance within any slab $[2\varepsilon, \delta_0] \times \mathbb{R}$ with $\delta_0 < \varrho_X/2$, as per Theorem 6. In turn, the vertical interleaving between the two modules implies a vertical matching between their multigraded Betti numbers within the slab (illustrated by green arrows in the close-up view), as per Corollary 3.8 in the full version [1].

2 Background

We assume some familiarity with basic category theory, algebraic topology, measure theory, and topological data analysis. Let **Top** denote the category of topological spaces, and **vec** (resp. **Vec**) the category of finite-dimensional (resp. all) vector spaces over a fixed field $\Bbbk$. We also fix an arbitrary degree in homology, denoted by $*$, and we write $H_*(-)$ for singular homology groups in degree $*$ with coefficients in $\Bbbk$.

Filtrations and persistence modules

We see $\mathbb{R}^n$ as the product of n copies of the real line, equipped with the product order noted $\leq$. Thus, two points $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^n$ satisfy $\boldsymbol{x} \leq \boldsymbol{y}$ whenever $\boldsymbol{x}_i \leq \boldsymbol{y}_i$ for all $1 \leq i \leq n$. We denote by $(-\infty, \boldsymbol{x}]$ the downset $\{\boldsymbol{y} \in \mathbb{R}^n \mid \boldsymbol{y} \leq \boldsymbol{x}\}$, and by $[\boldsymbol{x}, +\infty)$ the upset $\{\boldsymbol{y} \in \mathbb{R}^n \mid \boldsymbol{y} \geq \boldsymbol{x}\}$. An *$n$-parameter filtration* is a functor $\mathcal{F} : \mathbb{R}^n \to \mathbf{Top}$ whose constituent maps are inclusions, which means that we have a topological space $\mathcal{F}_{\boldsymbol{x}}$ for all $\boldsymbol{x} \in \mathbb{R}^n$ and an inclusion $\mathcal{F}_{\boldsymbol{x},\boldsymbol{y}} \colon \mathcal{F}_{\boldsymbol{x}} \hookrightarrow \mathcal{F}_{\boldsymbol{y}}$ for all $\boldsymbol{x} \leq \boldsymbol{y} \in \mathbb{R}^n$. An *$n$-parameter persistence module* is a functor $M : \mathbb{R}^n \to \mathbf{Vec}$, which means that we have a $\Bbbk$-vector space $M_{\boldsymbol{x}}$ for all $\boldsymbol{x} \in \mathbb{R}^n$ and a $\Bbbk$-linear map $M_{\boldsymbol{x},\boldsymbol{y}} \colon M_{\boldsymbol{x}} \to M_{\boldsymbol{y}}$ for all $\boldsymbol{x} \leq \boldsymbol{y} \in \mathbb{R}^n$, such that $M_{\boldsymbol{x},\boldsymbol{x}} = \mathrm{Id}_{M_{\boldsymbol{x}}}$ and $M_{\boldsymbol{x},\boldsymbol{z}} = M_{\boldsymbol{y},\boldsymbol{z}} \circ M_{\boldsymbol{x},\boldsymbol{y}}$ for all $\boldsymbol{x} \leq \boldsymbol{y} \leq \boldsymbol{z} \in \mathbb{R}^n$. A *morphism* of persistence modules $M \to N$ is a natural transformation between functors, i.e., a family of linear maps $\varphi_{\boldsymbol{x}} \colon M_{\boldsymbol{x}} \to N_{\boldsymbol{x}}$ such that $N_{\boldsymbol{x},\boldsymbol{y}} \circ \varphi_{\boldsymbol{x}} = \varphi_{\boldsymbol{y}} \circ M_{\boldsymbol{x},\boldsymbol{y}}$ for all $\boldsymbol{x} \leq \boldsymbol{y} \in \mathbb{R}^n$.

Geodesic metric spaces

Throughout the paper, unless otherwise specified, (X, d_X) is a compact geodesic metric space. This means that, for all $x, y \in X$, there is a shortest continuous path from x to y in X, of length equal to $d_X(x, y) < \infty$. In particular, the space is path-connected. Let P be a finite set of points of X. Given $\varepsilon > 0$, we say P is a *geodesic ε-sample* of X if $d_{\mathrm{H}}(P, X) < \varepsilon$, where d_{H}

denotes the Hausdorff distance in (X, d_X). Define $B_X(x, r)$ as the open geodesic ball centered at $x \in X$ with radius r, given by $B_X(x, r) = \{x' \in X \mid d_X(x, x') < r\}$. A ball $B_X(x, r)$ is said to be *convex* if, for any pair of points y and y' in $B_X(x, r)$, the shortest path in X that connects y to y' is unique and included in $B_X(x, r)$. Let $\varrho(x) := \inf\{r > 0 \mid B(x, r) \text{ is not convex}\}$, and let $\varrho_X := \inf\{\varrho(x) \mid x \in X\} \geq 0$. This quantity, called the *convexity radius* of X, plays an important role because intersections of convex sets are convex and therefore contractible, so the Nerve Lemma [13, Corollary 4G.3] applies to unions of balls of radii less than ϱ_X.

Functional and geometric filtrations

Given a geodesic metric space (X, d_X) and a function $\ell\colon X \to \mathbb{R}^n$, the *sublevel filtration* $\mathcal{F} : \mathbb{R}^n \to \mathbf{Top}$ of ℓ is defined by $\mathcal{F}_{\boldsymbol{x}} := \ell^{-1}((-\infty, \boldsymbol{x}])$ for all $\boldsymbol{x} \in \mathbb{R}^n$. The *persistent homology* of $\mathcal{F}$ (and, by extension, of ℓ) is the persistence module $H_*(\mathcal{F})$ (also written $H_*(\ell)$) defined by $H_*(\mathcal{F})_{\boldsymbol{x}} := H_*(\mathcal{F}_{\boldsymbol{x}})$ and $H_*(\mathcal{F})_{\boldsymbol{x},\boldsymbol{y}} := H_*(\mathcal{F}_{\boldsymbol{x},\boldsymbol{y}})$ for all $\boldsymbol{x} \leq \boldsymbol{y} \in \mathbb{R}^n$.

Given a finite set P of points in X, and a real parameter $\delta \geq 0$, we call *δ-offset* of P the union of open geodesic balls $\mathcal{O}^\delta(P) := \bigcup_{p\in P} B_X(p, \delta)$. We call *$\delta$-Čech Complex* of P the nerve of the collection of balls $\{B_X(p, \delta) \mid p \in P\}$, defined as the abstract simplicial complex $\mathcal{C}^\delta(P) := \{\emptyset \neq \sigma \subseteq P \mid \bigcap_{p\in\sigma} B_X(p, \delta) \neq \emptyset\}$. For $\delta < \varrho_X$, the balls $B_X(p, \delta)$ and their intersections are either empty or convex, so the Nerve Lemma [13, Corollary 4G.3] ensures that the homology groups $H_*(\mathcal{O}^\delta(P))$ and $H_*(\mathcal{C}^\delta(P))$ are isomorphic. We call *δ-Rips complex* of P the abstract simplicial complex $\mathcal{R}^\delta(P) := \{\emptyset \neq \sigma \subseteq P \mid \max_{p,q\in\sigma} d_X(p, q) < \delta\}$. Čech and Rips complexes of P are related as follows: $\mathcal{C}^\delta(P) \subseteq \mathcal{R}^{2\delta}(P) \subseteq \mathcal{C}^{2\delta}(P)$ for all $\delta \geq 0$.

Interleavings

Let $\boldsymbol{v} \in \mathbb{R}^n_{\geq 0}$ be a fixed vector, and let $\varepsilon \geq 0$. Given any functors $F, G : \mathbb{R}^n \to \mathcal{C}$ to some category $\mathcal{C}$, we say F and G are *$\varepsilon\boldsymbol{v}$-interleaved* if there are two natural transformations $f : F \to G[\varepsilon\boldsymbol{v}]$ and $g : G \to F[\varepsilon\boldsymbol{v}]$ such that $g[\varepsilon\boldsymbol{v}] \circ f = \varphi_F^{2\varepsilon\boldsymbol{v}}$ and $f[\varepsilon\boldsymbol{v}] \circ g = \varphi_G^{2\varepsilon\boldsymbol{v}}$. Here, $-[\varepsilon\boldsymbol{v}]$ denotes the $\varepsilon\boldsymbol{v}$-shift functor, defined on objects by $F[\varepsilon\boldsymbol{v}]_{\boldsymbol{x}} := F_{\boldsymbol{x}+\varepsilon\boldsymbol{v}}$ and on morphisms by $F[\varepsilon\boldsymbol{v}]_{\boldsymbol{x},\boldsymbol{y}} := F_{\boldsymbol{x}+\varepsilon\boldsymbol{v},\boldsymbol{y}+\varepsilon\boldsymbol{v}}$ for all $\boldsymbol{x} \leq \boldsymbol{y} \in \mathbb{R}^n$. Meanwhile, $\varphi_F^{2\varepsilon\boldsymbol{v}}\colon F \to F[2\varepsilon\boldsymbol{v}]$ and $\varphi_G^{2\varepsilon\boldsymbol{v}}\colon G \to G[2\varepsilon\boldsymbol{v}]$ denote the natural morphisms from F and G to their respective $2\varepsilon\boldsymbol{v}$-shifts, defined by $(\varphi_F^{2\varepsilon\boldsymbol{v}})_{\boldsymbol{x}} := F_{\boldsymbol{x},\boldsymbol{x}+2\varepsilon\boldsymbol{v}}$ and $(\varphi_G^{2\varepsilon\boldsymbol{v}})_{\boldsymbol{x}} := G_{\boldsymbol{x},\boldsymbol{x}+2\varepsilon\boldsymbol{v}}$ for all $\boldsymbol{x} \in \mathbb{R}^n$. The *$\boldsymbol{v}$-interleaving distance* is defined as follows:

$$d_{\mathrm{i}}^{\boldsymbol{v}}(F, G) = \inf\{\varepsilon \geq 0 \mid \text{ there exists an } \varepsilon\boldsymbol{v}\text{-interleaving between } F \text{ and } G\} \in [0, +\infty].$$

In the following, we consider two specific types of interleavings:

1. **Ordinary interleavings**: Let $\boldsymbol{v} = \mathbf{1} := (1, \cdots, 1)^T$. Then, $\varepsilon\mathbf{1}$-interleavings are ordinary ε-interleavings from the TDA literature, and $d_{\mathrm{i}}^{\mathbf{1}}$ is called the *ordinary interleaving distance*.
2. **Vertical interleavings**: Let $\boldsymbol{v} = \mathbf{1}_0 := (0, 1, \cdots, 1)^T$. Then, $\varepsilon\mathbf{1}_0$-interleavings are called *vertical ε-interleavings*, and $d_{\mathrm{i}}^{\mathbf{1}_0}$ is called the *vertical interleaving distance*.

▶ Remark 1. Vertical interleaving implies ordinary interleaving. Indeed, the vertical interleaving maps can be composed with the horizontal structure morphisms of the modules to form an ordinary interleaving. The amplitude ε of the interleaving does not change in the process. Therefore, vertical interleaving is a stronger condition than ordinary interleaving.

3 Problem statement and main results

Let (X, d_X) be a compact geodesic metric space with positive convexity radius ϱ_X, and let $\ell : X \to \mathbb{R}^n$ be a continuous function. Here, $\mathbb{R}^n$ is equipped with the ∞-norm. Both X and ℓ are unknown. By the Heine–Cantor Theorem, ℓ admits a modulus of continuity

$\omega\colon \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$. Neither ω nor ϱ_X need to be known, as they only play a role in our bounds and not in our constructions. The function $\boldsymbol{f}$ is not assumed to be pointwise finite-dimensional (i.e., $\dim H_*(\boldsymbol{f})_{\boldsymbol{x}}$ finite for every $\boldsymbol{x} \in \mathbb{R}^n$), however our assumptions imply a form of tameness for the persistence module $H_*(\boldsymbol{f})$ (see Corollary 4).

Our input is a finite point cloud $P \subseteq X$ such that $\boldsymbol{f}|_P$, the restriction of $\boldsymbol{f}$ to P, is known, as well as the pairwise geodesic distances $d_X(p,q)$ between the points $p, q \in P$. The problem we address is that of estimating $H_*(\boldsymbol{f})$, the persistent homology of the sublevel filtration of $\boldsymbol{f}$, from our input. For this we assume that P is a geodesic ε-sample of X, for some possibly unknown ε that we assume to be small enough compared to the convexity radius ϱ_X.

To build our estimator, we first construct the *function-Rips multifiltration* $\mathcal{R}^\bullet(\boldsymbol{f}|_P) := \left\{\mathcal{R}^\delta\left(\mathcal{F}_{\boldsymbol{x}} \cap P\right)\right\}_{\delta\in\mathbb{R}_{\geq 0},\, \boldsymbol{x}\in\mathbb{R}^n}$ from the restriction of $\boldsymbol{f}$ to P. Then, following [10], our estimator is a smoothed version of $H_*(\mathcal{R}^\bullet(\boldsymbol{f}|_P))$, denoted by $H_*(\mathcal{R}^{\bullet\to 2\bullet}(\boldsymbol{f}|_P))$ and defined formally as the image of the morphism of persistence modules induced in homology by the inclusion of the filtration $\mathcal{R}^\bullet(\boldsymbol{f}|_P)$ into its horizontal rescaling by a factor of 2, that is:

$$H_*(\mathcal{R}^{\bullet\to 2\bullet}(\boldsymbol{f}|_P)) := \operatorname{Im}\ H_*\left(\mathcal{R}^\bullet(\boldsymbol{f}|_P) \hookrightarrow \mathcal{R}^{2\bullet}(\boldsymbol{f}|_P)\right),$$

where $\mathcal{R}^{2\bullet}(\boldsymbol{f}|_P) := \left\{\mathcal{R}^{2\delta}(\mathcal{F}_{\boldsymbol{x}} \cap P)\right\}_{\delta\in\mathbb{R}_{\geq 0},\, \boldsymbol{x}\in\mathbb{R}^n}$.

▶ Remark 2. It is known that a single Rips complex of a finite sampling can recover the homological type of a sufficiently regular underlying continuous space [14, 16]. Yet, in full generality it takes a pair of Rips complexes with parameters within a factor of at least 2 of each other to do so [7]. Similarly, it was recently shown that $H_*(\mathcal{R}^\bullet(\boldsymbol{f}|_P))$ itself can approximate $H_*(\boldsymbol{f})$ provided X has curvature bounded above locally [22]. Yet, it is unknown whether the same holds in our more general setting, which is why we use $H_*(\mathcal{R}^{\bullet\to 2\bullet}(\boldsymbol{f}|_P))$.

In the course of our analysis of the behavior of $H_*(\mathcal{R}^{\bullet\to 2\bullet}(\boldsymbol{f}|_P))$, we will consider intermediate constructions, namely the persistent homologies of:

- the *function-offset filtration* $\mathcal{O}^\bullet(\boldsymbol{f}|_P) := \left\{\mathcal{O}^\delta(\mathcal{F}_{\boldsymbol{x}} \cap P)\right\}_{\delta\in\mathbb{R}_{\geq 0},\, \boldsymbol{x}\in\mathbb{R}^n}$;
- the *function-Čech filtration* $\mathcal{C}^\bullet(\boldsymbol{f}|_P) := \left\{\mathcal{C}^\delta(\mathcal{F}_{\boldsymbol{x}} \cap P)\right\}_{\delta\in\mathbb{R}_{\geq 0},\, \boldsymbol{x}\in\mathbb{R}^n}$.

These can also serve as alternative estimators when they can be built, for instance – in the case of $\mathcal{C}^\bullet(\boldsymbol{f}|_P)$ – when we can test whether finitely many open geodesic balls intersect.

We use our estimators in two types of scenarios: (1) when we have an estimate of the value ε for which P is an ε-sample of X, and (2) when we do not have such an estimate.

3.1 Estimating $H_*(\boldsymbol{f})$ with known ε

Suppose we know ε or some reasonable estimate. Then we can approximate our target $H_*(\boldsymbol{f})$ by restricting our estimators to a vertical hyperplane $\{\delta\} \times \mathbb{R}^n \subseteq \mathbb{R}_{\geq 0} \times \mathbb{R}^n$ for a suitable choice of parameter δ. We denote these restrictions respectively by $H_*(\mathcal{O}^\delta(\boldsymbol{f}|_P))$, $H_*(\mathcal{C}^\delta(\boldsymbol{f}|_P))$ and $H_*(\mathcal{R}^{\delta\to 2\delta}(\boldsymbol{f}|_P))$.

▶ **Theorem 3.** *Let X be a compact geodesic space, let $\boldsymbol{f} : X \to \mathbb{R}^n$ be an ω-continuous function for some modulus of continuity $\omega : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$, and let P be a finite geodesic ε-sample of X. Then:*

(i) *for $\forall \delta \geq \varepsilon$, the modules $H_*(\boldsymbol{f})$ and $H_*(\mathcal{O}^\delta(\boldsymbol{f}|_P))$ are ordinarily $\omega(\delta)$-interleaved;*

(ii) *for $\forall \delta \in [\varepsilon, \varrho_X)$, the modules $H_*(\boldsymbol{f})$ and $H_*(\mathcal{C}^\delta(\boldsymbol{f}|_P))$ are ordinarily $\omega(\delta)$-interleaved;*

(iii) *for $\forall \delta \in [2\varepsilon, \frac{\varrho_X}{2})$, modules $H_*(\boldsymbol{f})$ and $H_*(\mathcal{R}^{\delta\to 2\delta}(\boldsymbol{f}|_P))$ are ordinarily $\omega(2\delta)$-interleaved.*

The proof of this result is given in the full version [1, Section 4]. The conclusion still holds under noisy input function values or geodesic distances, as detailed in [1, Section 3.3].

Theorem 3 can be read in two different ways. First, when the modulus of continuity ω is known, we obtain explicit bounds on the interleaving distance between our estimators and the target $H_*(f)$. Second, when we only know that f is continuous, the Heine–Cantor Theorem implies that f admits some modulus of continuity ω, and even without knowning that ω, we are guaranteed by Theorem 3 that our estimators converge to $H_*(f)$ as ε goes to zero under suitable choices of parameter δ.

When ε is known exactly, the best choice for δ is the lower bound of its admissible interval, i.e., $\delta = \varepsilon$ in Items i and ii and $\delta = 2\varepsilon$ in Item iii. When ε is only known approximately, the admissible interval provides some leeway for the choice of δ.

An immediate consequence of Theorem 3 is that $d_{\mathrm{i}}^{\mathbf{1}}$-stable invariants computed on our estimators approximate the corresponding invariants defined on the target $H_*(f)$. For instance, the approximation guarantee obtained for the multigraded Betti numbers of $H_*(\mathcal{R}^{\delta\to 2\delta}(f|_P))$ is given in the full version [1, Corollary 3.3].

Another consequence of Theorem 3 (i) is that, under our assumptions, the persistence module $H_*(f)$ satisfies the following form of tameness, as proven in the full version [1].

▶ **Corollary 4.** *Let X, ω, f be as in Theorem 3. Then the module $H_*(f)$ is tame in the sense that the rank $\mathrm{rk}(H_*(f)_{\boldsymbol{x},\boldsymbol{y}})$ is finite for all $\boldsymbol{x} < \boldsymbol{y} \in \mathbb{R}^n$ with $\boldsymbol{x}_i < \boldsymbol{y}_i$ for each $i \in \{1, \cdots, n\}$.*

Suppose now the points of P are i.i.d. samples drawn from some unknown probability measure μ supported on X. In this setting, standard statistical techniques can be used to estimate ε with high probability, then Theorem 3 can be applied to get statistical estimates of $H_*(f)$ or of any $d_{\mathrm{i}}^{\mathbf{1}}$-stable invariant thereof. We summarize our results in Theorem 5. The relevant statistical background and definitions are provided in the full version [1, Section 2], together with the analysis of the statistical estimators [1, Section 6].

▶ **Theorem 5.** *Let X, ω and f be as in Theorem 3. Assume that the convexity radius satisfies $\varrho_X > 0$, that the modulus of continuity ω has a controlled vanishing rate $\delta = O(\omega(\delta))$ as $\delta \to 0$, and that the points $p_1, \ldots, p_k$ of P are i.i.d. samples drawn from some unknown (a,b)-standard probability measure μ whose support is the entire space X.*

- **(i)** *Suppose a, b are known. Let $\delta_k := 4\left(\frac{2\log k}{ak}\right)^{1/b}$. Then, the sequences of approximations $\left(H_*(\mathcal{O}^{\delta_k}(f|_P))\right)_{k\in\mathbb{N}}$, $\left(H_*(\mathcal{C}^{\delta_k}(f|_P))\right)_{k\in\mathbb{N}}$ and $\left(H_*(\mathcal{R}^{\delta_k\to 2\delta_k}(f|_P))\right)_{k\in\mathbb{N}}$ of $H_*(f)$ are ω-quasi-minimax consistent estimators of $H_*(f)$ in the following sense: their expected interleaving distances to $H_*(f)$ are at most a constant times $\omega\left(8\left(\frac{2\log k}{ak}\right)^{1/b}\right)$; meanwhile, in the worst case over n, X, f as above, for any other estimator of $H_*(f)$, the supremum over all (a,b)-standard measures μ of the expected interleaving distance between the estimator and its target $H_*(f)$ is at least a constant times $\omega\left(\frac{1}{2}\left(\frac{1}{ak}\right)^{1/b}\right)$.*
- **(ii)** *Suppose a, b are unknown, and assume further that X is a compact smooth manifold and that the measure μ decomposes as $\mu = \mu_1 + \mu_2$, where $\mu_2(X) > 0$ and μ_2 is absolutely continuous with respect to the uniform measure on X, with a positive density on X. Then, there is an explicit sequence of random positive numbers $(\hat{\delta}_k)_{k\in\mathbb{N}}$ such that the induced plug-in estimators $\left(H_*(\mathcal{O}^{\hat{\delta}_k}(f|_P))\right)_{k\in\mathbb{N}}$, $\left(H_*(\mathcal{C}^{\hat{\delta}_k}(f|_P))\right)_{k\in\mathbb{N}}$, and $\left(H_*(\mathcal{R}^{\hat{\delta}_k\to 2\hat{\delta}_k}(f|_P))\right)_{k\in\mathbb{N}}$ are ω-quasi-minimax consistent estimators of $H_*(f)$.*

3.2 Estimating $H_*(f)$ with unknown ε

When ε is unknown and cannot be effectively estimated – for instance when the assumptions in Theorem 5 are not satisfied, we adopt the traditional approach in persistence theory which is to not fix the scale parameter δ but rather to consider it as an extra filtration

parameter. This means using the full $(n+1)$-parameter modules $H_*(\mathcal{O}^\bullet(f|_P))$, $H_*(\mathcal{C}^\bullet(f|_P))$ and $H_*(\mathcal{R}^{\bullet\to 2\bullet}(f|_P))$ as estimators. In order to state approximation results, we extend our target $H_*(f)$ to a persistence module over $\mathbb{R}_{\geq 0}\times\mathbb{R}^n$ by taking its left Kan extension $\mathrm{Lan}_\iota H_*(f)$ along the poset embedding $\iota:\mathbb{R}^n\hookrightarrow\mathbb{R}_{\geq 0}\times\mathbb{R}^n$ given by $\boldsymbol{x}\mapsto(0,\boldsymbol{x})$ for all $\boldsymbol{x}\in\mathbb{R}^n$. Since the category $\mathbb{R}^n$ is small and the category **Vec** is cocomplete, $\mathrm{Lan}_\iota H_*(f)$ is well-defined as a functor $\mathbb{R}_{\geq 0}\times\mathbb{R}^n\to\mathbf{Vec}$, and given pointwise by the colimit formula [19]:

$$\forall(\delta,\boldsymbol{x})\in\mathbb{R}_{\geq 0}\times\mathbb{R}^n,\quad \mathrm{Lan}_\iota H_*(f)_{(\delta,\boldsymbol{x})}=\varinjlim_{\substack{\boldsymbol{y}\in\mathbb{R}^n\\ \iota(\boldsymbol{y})\leq(\delta,\boldsymbol{x})}} H_*(f)_{\boldsymbol{y}}\cong H_*(f)_{\boldsymbol{x}}. \tag{1}$$

Moreover, $\mathrm{Lan}_\iota H_*(f)$ has structural morphisms that are identity maps horizontally (i.e., along the first coordinate axis) and the structural morphisms of $H_*(f)$ vertically (i.e., along any direction orthogonal to the first coordinate axis), as illustrated in Figure 1.

▶ **Theorem 6.** *Let X, ω, f, P and ε as in Theorem 3. Then:*

- **(i)** *for $\forall\delta_0\geq\varepsilon$, within the slab $[\varepsilon,\delta_0]\times\mathbb{R}^n$, the restricted modules $\mathrm{Lan}_\iota H_*(f)|_{[\varepsilon,\delta_0]\times\mathbb{R}^n}$ and $H_*(\mathcal{O}^\bullet(f|_P))|_{[\varepsilon,\delta_0]\times\mathbb{R}^n}$ are vertically $\omega(\delta_0)$-interleaved;*
- **(ii)** *for $\forall\delta_0\in[\varepsilon,\varrho_X)$, within the slab $[\varepsilon,\delta_0]\times\mathbb{R}^n$, the restricted modules $\mathrm{Lan}_\iota H_*(f)|_{[\varepsilon,\delta_0]\times\mathbb{R}^n}$ and $H_*(\mathcal{C}^\bullet(f|_P))|_{[\varepsilon,\delta_0]\times\mathbb{R}^n}$ are vertically $\omega(\delta_0)$-interleaved;*
- **(iii)** *for $\forall\delta_0\in[2\varepsilon,\varrho_X/2)$, within the slab $[2\varepsilon,\delta_0]\times\mathbb{R}^n$, the restricted modules $\mathrm{Lan}_\iota H_*(f)|_{[2\varepsilon,\delta_0]\times\mathbb{R}^n}$ and $H_*(\mathcal{R}^{\bullet\to 2\bullet}(f|_P))|_{[2\varepsilon,\delta_0]\times\mathbb{R}^n}$ are vertically $\omega(2\delta_0)$-interleaved.*

The proof is given in the full version [1, Section 5]. Similar to Theorem 3, the conclusion still holds under noisy input function values or geodesic distances – see [1, Section 3.3].

This approximation result encapsulates the previous one in the sense that restricting the estimators to the vertical hyperplane $\{\delta\}\times\mathbb{R}^n$ for $\delta=\delta_0$ recovers Theorem 3. However, the result says something deeper, namely: that the interleavings in the vertical hyperplanes $\{\delta\}\times\mathbb{R}^n$, for δ ranging over $[\varepsilon,\delta_0]$ (resp. $[2\varepsilon,\delta_0]$), commute with the horizontal structural morphisms of the modules, so that they all together form a vertical interleaving in the slab $[\varepsilon,\delta_0]\times\mathbb{R}^n$ (resp. $[2\varepsilon,\delta_0]\times\mathbb{R}^n$). Intuitively, this means that prominent features in $H_*(f)$ are not just present in $H_*(\mathcal{R}^{\delta\to 2\delta}(f|_P))$ at individual scales δ in the range $[2\varepsilon,\delta_0]$, but that they persist across large ranges of scales in $H_*(\mathcal{R}^{\bullet\to 2\bullet}(f|_P))$. In particular, they are not ephemeral in $\mathbb{R}_{\geq 0}\times\mathbb{R}^n$ and can be captured by stable invariants.

In terms of approximation accuracy, the result says that, the more one looks to the left (i.e., toward small positive values of δ_0) in the parameter space $\mathbb{R}_{\geq 0}\times\mathbb{R}^n$, the more precisely the estimators approximate the target, until some point where δ_0 becomes too small and the approximation breaks down. On the opposite side, the more one looks to the right (i.e., toward large values of δ_0), the more the estimators drift away from the target, until again the approximation eventually breaks down if the estimator is $H_*(\mathcal{C}^\bullet(f|_P))$ or $H_*(\mathcal{R}^{\bullet\to 2\bullet}(f|_P))$. See Figure 2 for an illustration, and Figure 3 for a comparison of Theorem 6 with Theorem 3.

Theorem 6, like its counterpart Theorem 3, implies that provably $d_{\mathrm{i}}^{\mathbf{1}}$-stable invariants computed from our estimators approximate the corresponding invariants defined on their target, which this time is $\mathrm{Lan}_\iota H_*(f)$. And since the interleaving is now vertical – hence stronger than an ordinary interleaving according to Remark 1, we can get more precise statements for some invariants. For instance, the induced bottleneck matching on multigraded Betti numbers is vertical, as proven in the full version [1] and illustrated in Figure 2.

4 Estimators Computation

Our main estimators, $H_*(\mathcal{R}^{\delta\to 2\delta}(f|_P))$ and $H_*(\mathcal{R}^{\bullet\to 2\bullet}(f|_P))$, derive from the function Rips filtration $\mathcal{R}^\bullet(f|_P)$, whose computation is standard – see [1, Section 7] for details. Here we focus on the computation of invariants once $\mathcal{R}^\bullet(f|_P)$ has been built. The difficulty

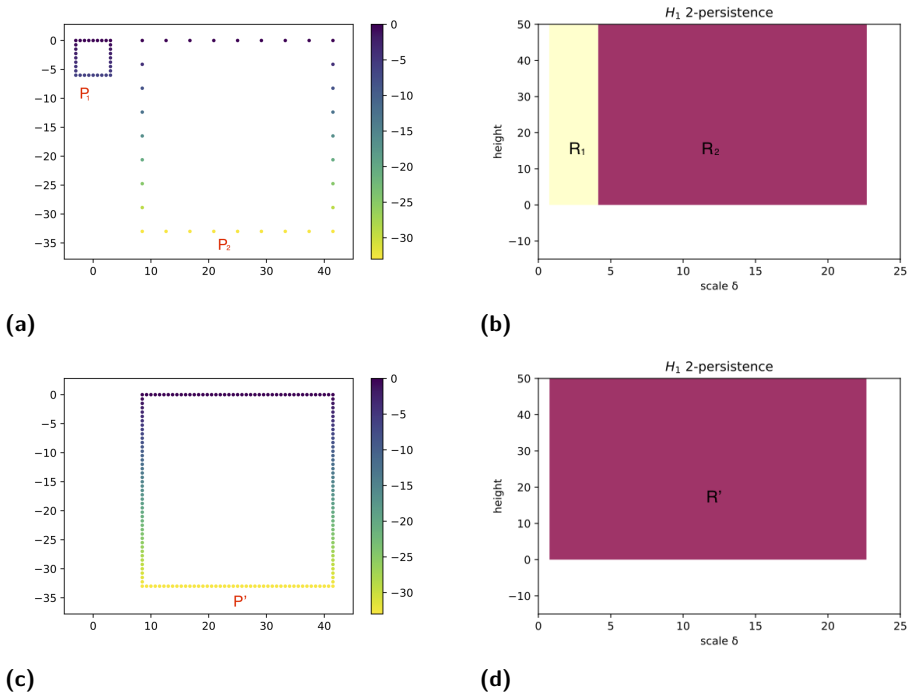

Figure 3 Contrasting Theorem 6 with Theorem 3. **(a)**: The input is $P = P_1 \sqcup P_2$, where P_1 and P_2 are two point clouds regularly sampled from two disjoint squares X_1, X_2 in the plane. Distances within each square are shortest-path distances along the boundary, while distances between squares are infinite. Here $\mathscr{f}$ is the vertical height function, and its persistent homology in degree 1 is considered. **(b)**: The estimator $H_1(\mathcal{R}^{\bullet\to 2\bullet}(\mathscr{f}|_P))$ is an interval-decomposable module whose summands have half-open rectangle supports, respectively R_1 (in yellow) and R_2 (in red). The scalings of X_1, X_2, and their respective sampling densities, have been adjusted so that $R_1 \cap R_2 = \emptyset$ while $R_1 \cup R_2$ is a single rectangle R' shown in subfigure **(d)**. In turn, the interval module with support R' can be realized as the degree 1 persistent homology of another sample P' from a square in the plane, shown in subfigure **(c)**. Theorem 6 guarantees that $H_1(\mathcal{R}^{\bullet\to 2\bullet}(\mathscr{f}|_P))$ is interleaved with $\mathrm{Lan}_\iota H_1(\mathscr{f}|_{X_1})$ over R_1 and with $\mathrm{Lan}_\iota H_1(\mathscr{f}|_{X_2})$ over R_2, leading to the two summands in **(b)**. By contrast, Theorem 3 only guarantees interleavings within the vertical slices, which is not sufficient to discriminate the module with two summands in **(b)** from the module with a single summand in **(d)**.

is that our estimators do not come from a single filtration, but from the inclusion of two nested filtrations sitting inside $\mathcal{R}^\bullet(\mathscr{f}|_P)$. For some invariants, such as the Hilbert function or rank invariant, existing algorithms adapt straightforwardly [5]. However, for minimal free presentations – from which many invariants, including multigraded Betti numbers, derive – there is no efficient existing algorithm, except in special situations such as when homology in degree 0 is considered, see the full version [1, Section 7.2.3] for details.

To address this, we provide an algorithm for the general problem of computing a free presentation of the image of any morphism of finitely presented persistence modules $\tau : M \to N$, and then we apply it to the special case of $H_*(\mathcal{R}^{\bullet\to 2\bullet}(\mathscr{f}|_P))$. Here we merely outline the mathematical construction of a free presentation of $\mathrm{Im}(\tau)$, which explains our approach. The algorithmic details and pseudocode are provided in [1, Section 7]. Note that a simpler variant to obtain a free presentation of the cokernel of τ appeared in [12, Proposition 4.14].

Let $\tau : M \to N$ be a morphism between finitely presented persistence modules, with respective free presentations $p_1 : P_1 \to P_0$ and $q_1 : Q_1 \to Q_0$. Since P_0 is projective, we can lift τ to a map $\gamma : P_0 \to Q_0$ so that the following diagram commutes:

$$\begin{array}{ccccccccc} P_1 & \xrightarrow{p_1} & P_0 & \xrightarrow{p_0} & M & \longrightarrow & 0 \\ & & \downarrow{\scriptstyle \gamma} & & \downarrow{\scriptstyle \tau} & & \\ Q_1 & \xrightarrow{q_1} & Q_0 & \xrightarrow{q_0} & N & \longrightarrow & 0. \end{array} \tag{2}$$

From this diagram, we can derive a free presentation of $\mathrm{Im}(\tau)$ as follows. Consider the pullback P_1' of the subdiagram $P_0 \xrightarrow{\gamma} Q_0 \xleftarrow{q_1} Q_1$, i.e., the kernel of the morphism $P_0 \oplus Q_1 \xrightarrow{\gamma - q_1} Q_0$, where $(\gamma - q_1)(u, v) := \gamma(u) - q_1(v)$ for any $(u, v) \in P_0 \oplus Q_1$. Let $\pi_0 : P_1' \to P_0$ and $\pi_1 : P_1' \to Q_1$ denote the canonical projections from $P_1' \subseteq P_0 \oplus Q_1$ to P_0 and Q_1, respectively. Next, let P_2' be the free cover of P_1', yielding the surjection $\beta : P_2' \twoheadrightarrow P_1'$. We illustrate these morphisms in the following commutative diagram, where P_1', P_0, Q_0, Q_1 form a pullback square:

$$\begin{array}{ccccccccc} P_2' & \xrightarrow{\beta} & P_1' & \overset{\pi_0}{\longrightarrow} & & & & & \\ & \searrow^{\pi_1} & & & & & & & \\ & & & & P_1 & \xrightarrow{p_1} & P_0 & \xrightarrow{p_0} & M & \longrightarrow & 0 \\ & & & & & & \downarrow{\scriptstyle \gamma} & & \downarrow{\scriptstyle \tau} & & \\ & & & & Q_1 & \xrightarrow{q_1} & Q_0 & \xrightarrow{q_0} & N & \longrightarrow & 0 \end{array} \tag{3}$$

This diagram yields a free presentation of $\mathrm{Im}(\tau)$ as follows (proof is in the full version [1]):

▶ **Proposition 7.** *The sequence $P_2' \xrightarrow{\pi_0 \circ \beta} P_0 \xrightarrow{\eta} \mathrm{Im}(\tau) \to 0$ is exact, where η comes from the factorization of $\tau \circ p_0$ through its image $\mathrm{Im}(\tau)$. Consequently, the morphism $\pi_0 \circ \beta : P_2' \to P_0$ is a free presentation of $\mathrm{Im}(\tau)$, and in fact a finite free presentation.*

5 Experiments

In this section, we illustrate our approximation and convergence results through practical experiments on both synthetic and real-world datasets.

5.1 Toy examples

We validate the claims in Theorems 3 and 6 through a simple example consisting of two circles with distinct radii and concentration levels, as shown in Figure 4 (a). In Figure 4 (b) we analyze the error between the estimator $H_1(\mathcal{R}^{\delta \to 2\delta}(f|_P))$ and the target $H_1(f)$ as a function of the scale parameter δ. As guaranteed by Theorem 3, for δ within the range $[2\varepsilon, \varrho_X/2)$ the error between the estimator and the target is small, controlled by δ. The approximation remains good even for δ going beyond that range, which is not explained by the theory but occurs here because the space and function are very regular in this example.

In Figure 4 (c) we show a visualization of our estimator $H_1(\mathcal{R}^{\bullet \to 2\bullet}(f|_P))$ using `MMA` [17]. As expected from Theorem 6, we observe two topological features in our estimator, corresponding to the two circles in the dataset. The values of δ at which these features appear then disappear are aligned with the endpoints of the interval of values of δ for which $H_1(\mathcal{R}^{\delta \to 2\delta}(f|_P))$ is a good approximation of $H_1(f)$ in Figure 4 (b).

For comparison, in Figure 4 (d) we show a visualization of the estimator $H_1(\mathcal{C}^{\bullet}(f|_P))$ using `MMA`, for which we use the Euclidean distance instead of the geodesic distance in order to enable the construction of the function–Čech filtration. Again, we see two topological features corresponding to the two circles, and $H_1(\mathcal{C}^{\delta}(f|_P))$ is a good approximation of $H_1(f)$ for δ within a fairly large range.

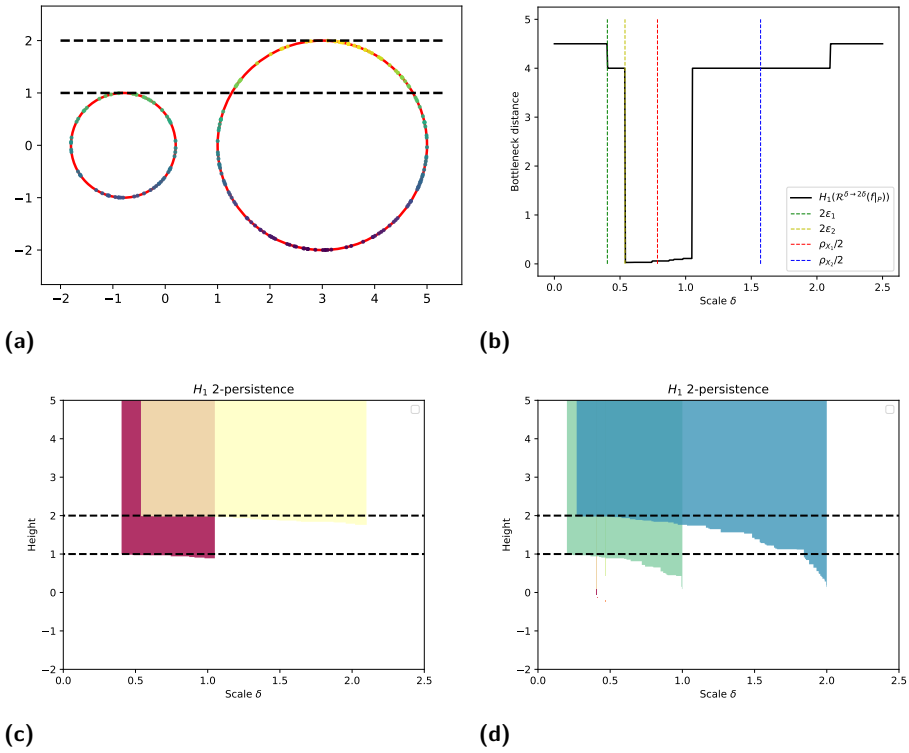

Figure 4 (a): A sample P from a space $X = X_1 \sqcup X_2$ composed of two circles equipped with geodesic distances, each uniformly sampled with distinct radii and concentration levels. The target function $f\colon X \to \mathbb{R}$ is the height function on the two circles. The barcode of the target $H_1(f)$ consists of two infinite bars, each originating from a level marked as a dashed line. **(b)**: Bottleneck distance between the barcode of the estimator $H_1\left(\mathcal{R}^{\delta\to 2\delta}(f|_P)\right)$ and that of the target $H_1\left(f\right)$ as a function of δ. Here, ε_1 (resp. ε_2) is the sampling error of X_1 (resp. X_2), and ϱ_{X_1} (resp. ϱ_{X_2}) the convexity radius of X_1 (resp. X_2). All infinite bars are truncated at 10 to ensure the bottleneck distances are finite. **(c)**: Visualization of the estimator $H_1\left(\mathcal{R}^{\bullet\to 2\bullet}(f|_P)\right)$ computed using `MMA`. **(d)**: Visualization of the estimator $H_1\left(\mathcal{C}^{\bullet}(f|_P)\right)$ computed using `MMA`. Each colored region represents a persistent topological feature. Dashed lines indicate birth times of bars in the barcode of $H_1(f)$.

We now add noise to the dataset sampled from the two circles, as shown in Figure 5 (a). As proven in the full version [1, Section 3.3], the trend is the same. While the theory requires a factor $\alpha > 2$ in $H_1(\mathcal{R}^{\bullet\to\alpha\bullet}(f|_P))$ to handle metric noise, Figure 5 shows that, in this example, the estimator $H_1(\mathcal{R}^{\bullet\to 2\bullet}(f|_P))$ performs well even with $\alpha = 2$.

5.2 Real dataset of immune cells (involving Lipschitz functions)

In this section, we consider the digitized immunohistochemistry dataset from [24]. This dataset is comprised of manually annotated cell locations from three cell types, namely cytotoxic T lymphocytes, regulatory T lymphocytes, and macrophages, each characterized by the expression of one of the proteins CD8, FoxP3, and CD68, respectively – see Figure 6.

The index $i \in \{1, 2, 3\}$ refers to the protein in the ordered set $\{\text{CD8}, \text{FoxP3}, \text{CD68}\}$, and $f_i\colon [0,1]^2 \to \mathbb{R}$ denotes the negative density estimate associated with that protein. Since the functions f_i are unknown, we estimate the density of each point cloud using kernel density

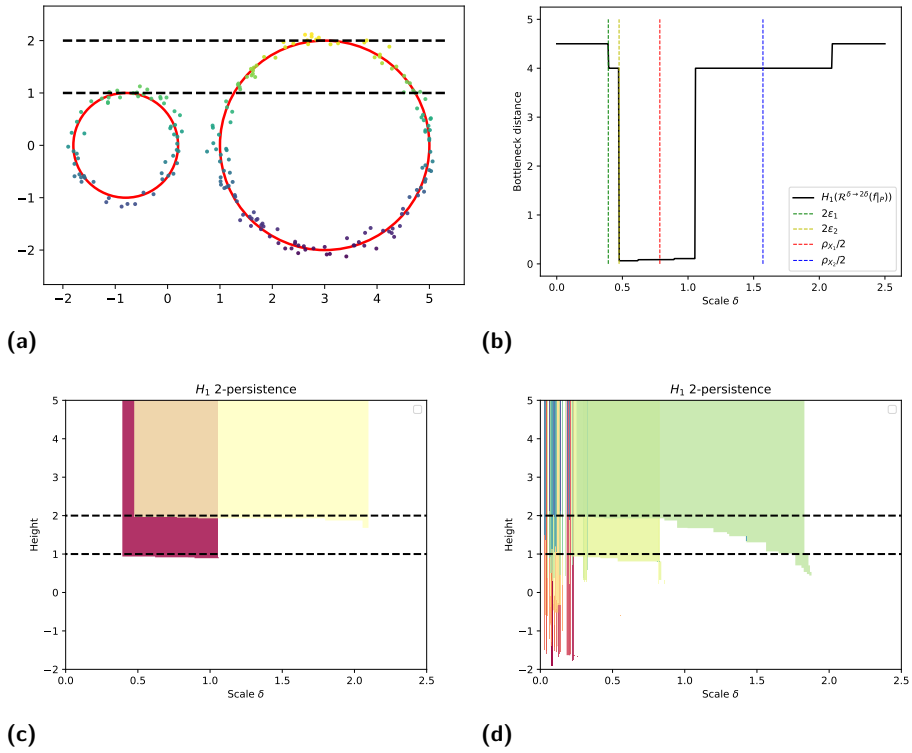

Figure 5 A noisy analog of Figure 4.

Figure 7 Interleaving distance between our estimators and the target $H_1(\mathscr{f})$ w.r.t. the scale δ.

estimation, which yields approximations – also called $\mathscr{f}_1, \mathscr{f}_2, \mathscr{f}_3$ for simplicity – that are Lipschitz continuous by construction. We then discretize the domain $[0,1]^2$ on a grid (using a resolution of $1\,000 \times 1\,000$ for Section 5.2.1 and of 500×500 for Section 5.2.2) and compute the persistence module of the cubical complex induced by the estimated function on this grid, which serves as a proxy for the ground-truth target.

In the following experiments, in order to reach smaller Hausdorff distances between the sample X_k and the domain $X = [0,1]^2$, we first draw 10,000 points uniformly from X, and then select X_k using k-means farthest point sampling applied to this set. In practice, the choice of the rate δ_k prescribed in Theorem 5 can be improved significantly when the sample X_k is well-behaved. We propose heuristics to estimate good rates in non-asymptotic regimes.

(a) Hilbert signed bars of $H_1(\mathcal{C}^\bullet(\mathscr{f}_1|_{X_k}))$.

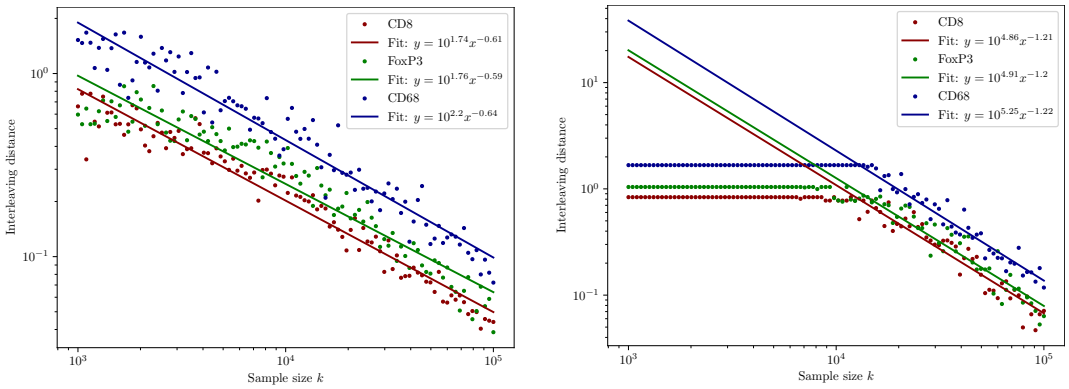
(b) Pointwise dimension of $H_1(\mathcal{C}^\delta(X_k))$ w.r.t δ.

Figure 8 Heuristic to determine a good multiplicative constant for the rate δ_k, where $k = 50\,000$.

5.2.1 Estimating a single function $\mathscr{f}_i$

We empirically validate our theoretical results by examining the estimators $H_1(\mathcal{C}^\delta(\mathscr{f}_i|_{X_k}))$ with $i \in \{1,2,3\}$ built from the three associated point clouds. We first focus on the convergence rate of the estimators as the sample size k increases, with respect to the choice of scale parameter δ_k. From Theorem 5, since the sampling measure is known – namely the uniform measure on $[0,1]^2$, which is (a,b)-standard with parameters $a = \frac{\pi}{4}$ and $b = 2$ – we

can derive an asymptotic theoretical rate $\delta_k = 4\left(\frac{8\log(k)}{\pi k}\right)^{\frac{1}{2}}$. However, as shown in Figure 7, this choice of δ_k is very conservative, and consequently the estimators $H_1(\mathcal{C}^{\delta_k}(\ell_i|_{X_k}))$ do not perform better than the zero module. This is explained by the fact that δ_k is designed for worst-case sampling measures and asymptotic regimes. As shown in Figure 7, the estimators $H_1(\mathcal{C}^{\delta_k}(\ell_i|_{X_k}))$ achieve good performance only when δ_k is smaller than 0.02, which would require sample sizes k larger than 10^6.



Another option is to consider the estimated rate $\hat{\delta}_k$ mentioned in Theorem 5, defined as $\hat{\delta}_k := d_{\mathrm{H}}(X_{s_k}, X_k)$ where $X_{s_k} \subseteq X_k$ consists of the first s_k sample points of X_k. In Figure 7, we observe that this rate is far less conservative than δ_k and already exhibits its asymptotic behavior when k is larger than 50 000, achieving good performance. In this example though, the rate $\hat{\delta}_k$ has some limitations:

- the bad behavior of the corresponding estimators on small sample sizes ($k \leq 10^4$);
- the dependence of $\hat{\delta}_k$ on a parameter β, which needs to be tuned;
- the fact that the knowledge of the ambient dimension and the probability measure from which the points are sampled are not leveraged.

Here is a heuristic we apply to select a relevant rate δ'_k. Since the dimension of the domain is known, we set δ'_k to be a fixed fraction of the theoretical rate δ_k. This choice is motivated in the full version [1] and ensures that, up to a multiplicative constant, the rate $(1/k)^{1/d}$ cannot be improved for any (possibly deterministic) k-sample of a d-dimensional space. To determine a good multiplicative constant, we notice from Figure 7 that, when $\delta \in [0, d_{\mathrm{H}}(X_k, X))$, the error of the estimators $H_1(\mathcal{C}^{\delta}(\ell_i|_{X_k}))$ soars, due to the fact that $\mathcal{C}^{\delta}(X_k)$ and X do not have the same topology. According to Theorem 3, the optimal scale δ is then given as the smallest value lying above that interval, that is: $d_{\mathrm{H}}(X_k, X)$. Our rate δ'_k is an estimate of this value. In order to compute it, we look at the topological changes of $\mathcal{C}^{\delta}(X_k)$ as δ increases. Since the measure is uniform and thus does not exhibit pathological local behaviors, the artifacts in the topological type of $\mathcal{C}^{\delta}(X_k)$ should all vanish roughly at the same scale, and slightly before $d_{\mathrm{H}}(X_k, X)$. This phenomenon, suggested by the shape of the curves in Figure 7, is further illustrated in Figure 8(a), where we consider the *Hilbert function signed barcode* [18, 21] of $H_1(\mathcal{C}^{\bullet}(\ell_1|_{X_k}))$: after an initial transition phase ($\delta < 0.005$) during which a concentration of positive generators appears, followed then by a concentration of negative generators, the structure of the module stabilizes as these positive and negative generators cancel each other out. This is highlighted when summing the signed generators within the half-plane $(-\infty, \delta] \times \mathbb{R}$, or equivalently, when computing the pointwise dimension of $H_1(\mathcal{C}^{\delta}(X_{50\ 000}))$, for δ ranging from 0 to $+\infty$, as shown in Figure 8(b). Since the convexity radius ϱ_X is infinite in this case, we have $H_1(\mathcal{C}^{\delta}(X_k)) \cong H_1(\mathcal{O}^{\delta}(X_k)) \cong H_1(X)$ for all $\delta > d_{\mathrm{H}}(X_k, X)$, and so our heuristic to determine a suitable rate $(\delta'_k)_{k\in\mathbb{N}}$ from a sample X_{k_0} for some sufficiently large $k_0 \in \mathbb{N}$ is:

1. Compute the pointwise dimension of $H_1(\mathcal{C}^{\delta}(X_{k_0}))$ as in Figure 8(b) for a range of δ;
2. Identify the transition phase of $\dim H_1(\mathcal{C}^{\delta}(X_{k_0}))$;
3. Choose a scale δ^* past this phase, so that $\delta \in [\delta^*, \infty) \mapsto \dim H_1(\mathcal{C}^{\delta}(X_{k_0}))$ is constant;
4. Define the rate $(\delta'_k)_k$ for $k \in \mathbb{N}$ as $\delta'_k := \frac{\delta^*}{\delta_{k_0}}\delta_k$.

In Figure 9, we observe that both rates δ'_k and $\hat{\delta}_k$ achieve good performance asymptotically, with a convergence rate that is at least of the order of $\left(\frac{\log(k)}{k}\right)^{1/2}$. However, the asymptotic regime is reached earlier with δ'_k than with $\hat{\delta}_k$ – while, as we said, it is not reached with δ_k.

(a) Convergence rate with $\delta'_k = \frac{1}{15}\delta_k$. **(b)** Convergence rate with $\hat{\delta}_k$.

Figure 9 Interleaving distance between the estimators and the target w.r.t. the sample size k.

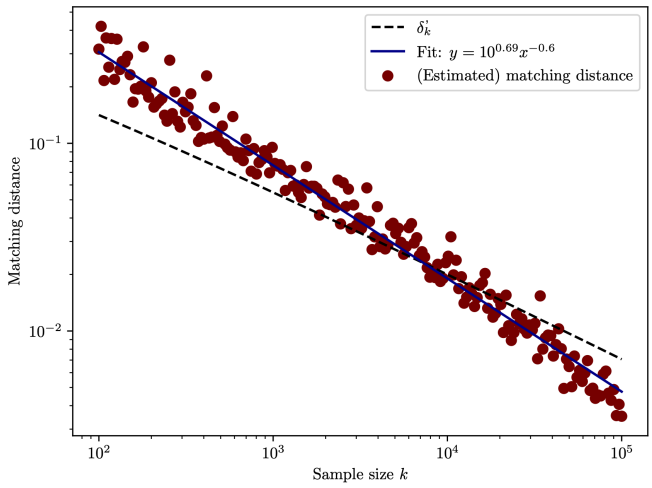


Figure 10 Estimated matching distance between the estimator $H_0(\mathcal{R}^{\delta'_k \to 2\delta'_k}(\mathcal{f}|_{X_k}))$ and the ground truth $H_0(\mathcal{f})$ as a function of the sample size k under random sampling.

5.2.2 Estimating the combined functions $(\mathcal{f}_1, \mathcal{f}_2, \mathcal{f}_3)$

We now study the function $\mathcal{f} = (\mathcal{f}_1, \mathcal{f}_2, \mathcal{f}_3)\colon [0,1]^2 \to \mathbb{R}^3$ and approximate the corresponding 3-parameter persistence module $H_0(\mathcal{f})$. For this we employ the estimator $H_0(\mathcal{R}^{\delta'_k \to 2\delta'_k}(\mathcal{f}|_{X_k})) \cong H_0(\mathcal{R}^{2\delta'_k}(\mathcal{f}|_{X_k}))$, where, for each sample size k, the scale parameter is given by the same δ'_k as in Section 5.2.1. Since computing the interleaving distance in this context is NP-hard [3], we use the matching distance [15] as a proxy, estimated via Monte Carlo with $1,000$ random lines in $\mathbb{R}^3$. The results are shown in Figure 10. Notably, the observed convergence rate matches that of the previous experiment in Figure 9(a), which suggests that the empirical convergence rate is independent of the number of parameters.

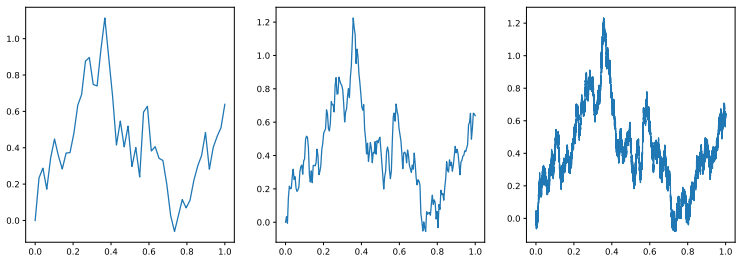

Figure 11 Samplings of a Brownian motion on $[0,1]$ with, respectively, 50, 200, and 10^6 points.

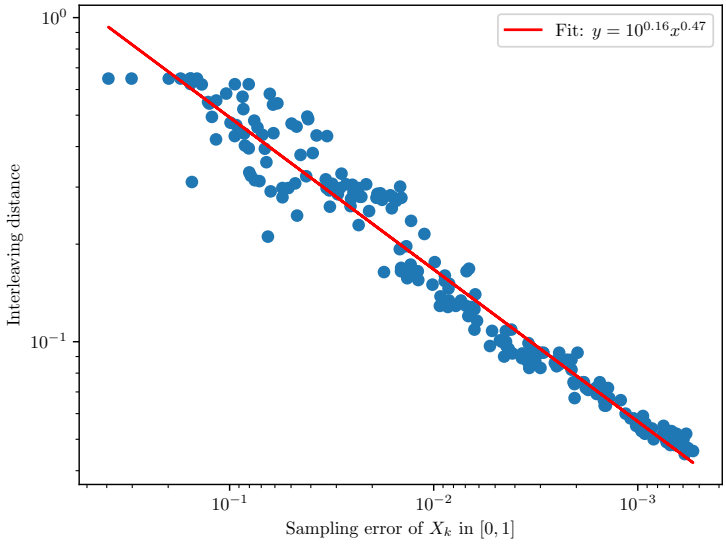

Figure 12 Log–log plot of the convergence of $H_0(\mathcal{C}^{\varepsilon_k}(f|_{X_k}))$ toward $H_0(f)$ for a Brownian motion f. The x-axis represents the sampling error $\varepsilon_k = d_{\mathrm{H}}(X_k, [0,1])$, and the y-axis represents the interleaving distance between $H_0(\mathcal{C}^{\varepsilon_k}(f|_{X_k}))$ and $H_0(f)$.

5.3 Brownian motion in 1-d (involving a Hölder function)

The Brownian motion is not Lipschitz continuous but almost surely almost everywhere ω-continuous for any modulus of continuity ω of the form $\omega\colon x \mapsto c\,x^{\frac{1}{2}-\varepsilon}$, with $\varepsilon > 0$ and $c > 0$ large enough [20, Corollaries 1.20 and 5.3]. Let $f : [0,1] \to \mathbb{R}$ be a realization of a standard Brownian motion, which can be approximated by a Rademacher random walk.

For each $k \in \mathbb{N}$, we build a k-sample X_k in $[0,1]$ according to the uniform distribution, as shown in Figure 11 for several values of k. Then, since our goal here is to illustrate Theorem 3, we assume we have access to the sampling error $\varepsilon_k := d_{\mathrm{H}}(X_k, [0,1])$ and so we use the estimator $H_0(\mathcal{C}^{\varepsilon_k}(f|_{X_k}))$ to approximate the target $H_0(f)$ for various sample sizes k. The corresponding results are shown in Figure 12. A regression analysis of the experimental data indicates that $d_{\mathrm{i}}^{\mathbf{1}}\left(H_0(\mathcal{C}^{\varepsilon_k}(f|_{X_k})), H_0(f)\right) \approx 10^{0.16}\,{\varepsilon_k}^{0.47}$, which aligns closely with the theoretical prediction from Theorem 3, stating that the interleaving distance between $H_0(\mathcal{C}^{\varepsilon_k}(f|_{X_k}))$ and $H_0(f)$ should be at most $\omega(\varepsilon_k) \lesssim {\varepsilon_k}^{1/2}$.

5.4 Timings

In the following table we report the running times for some of our experiments. Only the first one involves our algorithm for computing a presentation of $H_*(\mathcal{R}^{\bullet\to 2\bullet}(\mathscr{f}|_P))$. For all computations we used an Intel® Core™ i9-12900K CPU (5.2 GHz max) equipped with 125 GB of RAM.

Experiment	Estimator	#Params	#Points	Filt. size	Filt. time	Invariant time
2 circles	$H_1(\mathcal{R}^{\bullet\to 2\bullet}(\mathscr{f}\|_P))$	2	220	13,110	11.8 ms	6.5 ms (presentation)
Immune cells (single $\mathscr{f}_i$)	$H_1(\mathcal{C}^\bullet(\mathscr{f}_i\|_{X_k}))$	2	6172	24,370	864 ms	50.3 ms (Hilbert measure)
Brownian motion	$H_0(\mathcal{C}^{\varepsilon_k}(\mathscr{f}\|_{X_k}))$	1	10,000	37,359	1.21 s	5.4 ms (barcode)

Computing L_∞ Hausdorff Distances Under Translations: The Interplay of Dimensionality, Symmetry and Discreteness

Abstract

To measure the similarity of the *shape* of point sets, rather than their mere closeness in space, various notions of a *Hausdorff distance under translation* have been investigated. Specifically, let P and Q denote point sets of n and m points, respectively, in $\mathbb{R}^d$. We consider the task of computing the minimum distance $d(P, Q + \tau)$ over an admissible set of translations $\tau \in T$, where $d(\cdot, \cdot)$ denotes the Hausdorff distance under the L_∞-norm. As variants, we distinguish between *continuous* ($T = \mathbb{R}^d$) or *discrete* (T is a given finite set of t translations) as well as *directed* or *undirected* (choosing the directed or undirected Hausdorff distance for $d(\cdot, \cdot)$).

We seek to apply the paradigm of fine-grained complexity to understand the complexity of these variants, and in particular: How is the running time influenced by the dimension d, the relationship between n and m, and the specific choice of variant? As our main results, we obtain:

- The asymmetric definition of the most studied variant, the continuous directed Hausdorff distance, results in an *intrinsically asymmetric* time complexity: While (Chan, SoCG'23) established a symmetric $\tilde{O}((nm)^{d/2})$ upper bound for all $d \geq 3$ and proved it to be conditionally optimal for *combinatorial* algorithms whenever $m \leq n$, we show that this lower bound does not hold for the case $n \ll m$, by providing a combinatorial, almost-linear-time algorithm for $d = 3$ and $n = m^{o(1)}$. We further prove *general*, i.e., non-combinatorial, conditional lower bounds for $d \geq 3$, in particular: (1) $m^{\lfloor d/2 \rfloor - o(1)}$ for small n and (2) $n^{d/2-o(1)}$ for $d = 3$ and small m.
- We observe that the directed and undirected case is closely related, in particular, all our lower bounds for $d \geq 3$ hold for both the directed and undirected variant. A remarkable exception is the case of $d = 1$ for which we provide a conditional separation. Specifically, in contrast to the undirected variants being solvable in near-linear time (Rote, IPL'91), we show that the directed variants are at least as hard as the additive problem MaxConv LowerBound introduced in (Cygan, Mucha, Wegrzycki and Wlodarczyk, TALG'19).
- We show that the discrete variants reduce to a variant of 3SUM for $d \leq 3$. This gives a barrier in proving a tight lower bound of these variants under the Orthogonal Vectors Hypothesis (OVH); in contrast, the continuous variants admit a tight conditional lower bound under OVH in $d = 2$ (Bringmann, Nusser, JoCG'21).

These results reveal an intricate interplay of dimensionality, symmetry and discreteness in determining the fine-grained complexity of computing Hausdorff distances under translation.

1 Introduction

Consider the classic Hausdorff distance of given point sets P and Q, which comes in two flavors: the *directed* Hausdorff distance $\delta_{\overrightarrow{H}}(P,Q) \coloneqq \max_{p\in P} \min_{q\in Q} \|p-q\|$, as well as the *undirected* Hausdorff distance $\delta_H(P,Q) \coloneqq \max\{\delta_{\overrightarrow{H}}(P,Q), \delta_{\overrightarrow{H}}(Q,P)\}$. Here and throughout the paper, we fix our metric space to be $(\mathbb{R}^d, L_\infty)$. The two variants are sometimes also referred to as one-sided/bidirectional or one-way/two-way. Furthermore, δ_H yields a metric, in contrast to $\delta_{\overrightarrow{H}}$. For any constant $d \in \mathbb{N}$ and point sets P and Q of n and m points in $\mathbb{R}^d$, we can compute these distance in near-linear time[1] $\tilde{O}(n+m)$ using L_∞-nearest neighbor search, e.g., in a range tree [18].

A computationally more challenging task is to compute the Hausdorff distance under some transformation, i.e., to minimize the Hausdorff distance of P' and Q among all sets P' obtained from P using a set of admissible transformations. Such notions are well-studied from the perspective of *shape matching* or *geometric pattern matching*, see, e.g. [3, 4], where P and Q model geometric objects and we are interested in comparing their general shapes rather than their mere closeness in space. In this paper, we focus on arguably one of the most basic settings, i.e., computing L_∞ Hausdorff distances under translation. Specifically, when T denotes a set of admissible translations, the Hausdorff distance under translation is defined as $\min_{\tau\in T} \delta(P+\tau, Q)$ where δ denotes either the directed or undirected Hausdorff distance, i.e., $\delta \in \{\delta_{\overrightarrow{H}}, \delta_H\}$.

The most popular setting is $T = \mathbb{R}^d$, which yields the natural translation-invariant version of the Hausdorff distance; we refer to this as the **(continuous) Hausdorff distance under translation (HuT)**. This measure has received significant interest from the computational geometry community both for L_∞ and other norms [20, 16, 17, 21, 11, 10, 5, 7, 9], yet only for $d = 2$ tight upper and conditional lower bounds are known (see below for details).

Another natural version is to let T be a finite set given as part of the input. We refer to this as the **discrete Hausdorff distance under translation (DiscHuT)**. This version occurs naturally in the context of approximating the (continuous) Hausdorff distance under translation. More precisely, computing an α-approximation for the continuous version can be achieved by choosing $f(\alpha, d)$ many translations T such that $\min_{\tau\in T} \delta_{\overrightarrow{H}}(P+\tau, Q) \leq \alpha \min_{\tau\in\mathbb{R}^d} \delta_{\overrightarrow{H}}(P+\tau, Q)$. Since we can compute the discrete Hausdorff distance under translation in time $\tilde{O}(|T|(|P|+|Q|))$, this yields baseline α-approximation algorithms for the continuous Hausdorff distance under translation with running time $\tilde{O}(f(\alpha,d)(n+m))$; see also [15, 22]. Consequently, obtaining faster algorithms for the discrete Hausdorff distance

[1] Throughout the paper, we use $\tilde{O}(\cdot)$, to hide polylogarithmic terms in n and m. Since we assume d to be constant, this includes factors of the form $\log^{O(d)} nm$.

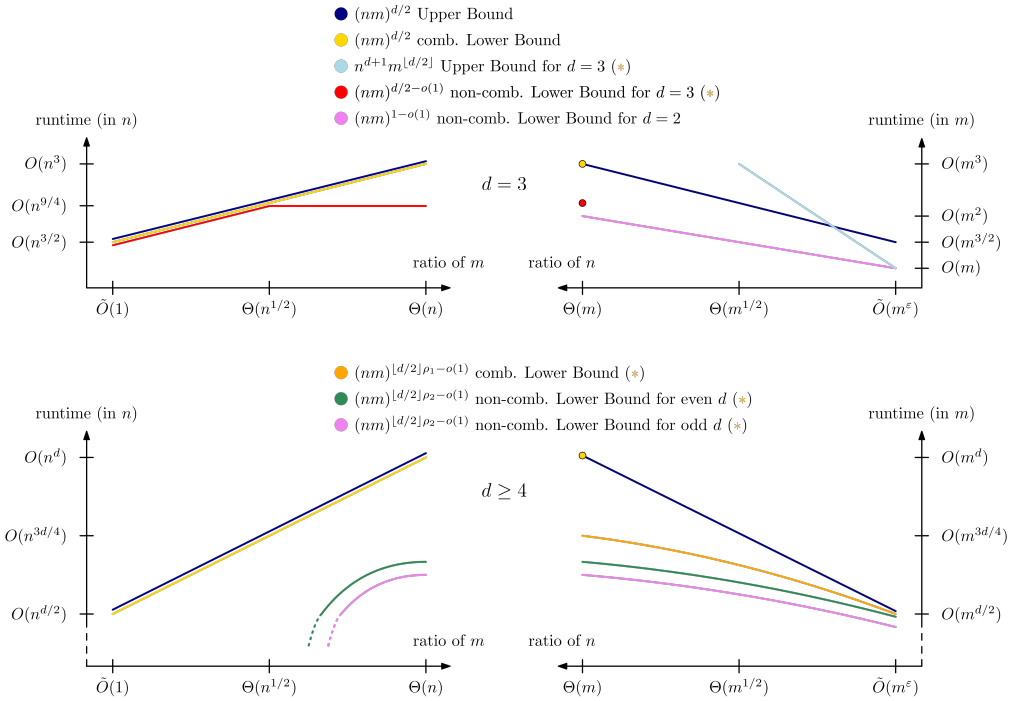

Figure 1 Schematic figure of upper and lower bounds for directed Hausdorff under Translation in 3-D (upper figure) and d-D for $d \geq 4$ (lower figure), novel results are marked with $(*)$. ρ_1, ρ_2 are functions on the ratio of n, m which correspond to values described in Theorem 3.7.

under translation transfers to faster approximation algorithms for the continuous version. Furthermore, the discrete version recently received interest from the perspective of a structural fine-grained complexity theory: the directed discrete Hausdorff distance under translation is part of a problem pair that is fine-grained complete for the class $\mathsf{FOP}_{\mathbb{Z}}$, a class of polynomial-time problems formed from first-order properties on finite additive structures [14] (further discussion can be found in the full version).

Previous works on Hausdorff distances under translation mostly focus –with notable exceptions such as [7, 9]– on a single particular variant, often considering particular dimensions d and the *balanced* case, in which all inputs sets (i.e., P, Q, and in the discrete case also T) have roughly equal size n. In this work, we aim to give a more comprehensive analysis, which reveals an intricate interplay between the dimensionality, symmetry (directed/undirected and the relationship between n and m), and discreteness.

1.1 Our Results

Our first question concerns the fine-grained complexity of the algorithmically most studied variant, the (continuous) directed Hausdorff distance under translation. The currently best upper bounds are $O(nm \log nm)$ for $d \leq 2$ [11], $O((nm)^{d/2} \log nm)$ for $d = 3$ [10][2], and $O((nm)^{d/2}(\log\log nm)^{O(1)})$ for general $d \geq 4$ [9]. This suggests the following question:

Question 1: *Is $(nm)^{d/2 \pm o(1)}$ the time complexity of directed Hausdorff L_∞-distance under Translation?*

[2] While [10] only considers the case $m = n$, their analysis also holds for distinct n, m. A short explanation of their approach can also be found in the full version.

Table 1 An overview of known results of the L_∞-Hausdorff distance under Translation in 1-D and 2-D for the balanced case, i.e., $n = m$ ($= t$ in the discrete setting). Upper Bounds are marked in blue, lower bounds in green, while results under non-standard hypothesis are additionally marked with (†). Novel results are denoted with (∗) . Results referring to the full version are marked with §.

$d = 1$	**Directed**	**Undirected**

Discrete	$\tilde{O}(n^2)$ (§) (∗) $n^{2-o(1)}$ (3.14)†	$\tilde{O}(n^2)$ (§) (∗) $n^{2-o(1)}$ (3.14)†

A conditional lower bound of Bringmann and Nusser [7] (based on the Orthogonal Vectors Hypothesis) answers this question positively for $d = 2$. Subsequently, Chan [9] gave evidence of optimality even for $d \geq 3$, by proving a conditional lower bound of $(nm)^{d/2-o(1)}$ for *combinatorial* algorithms[3] in the case that $m \leq n$. However, proving such a conditional lower bound against *general* algorithms for $d \geq 3$ (or better conditional lower bounds than $(nm)^{1-o(1)}$ for the case $n \ll m$) remained open until this work. Furthermore, for $d = 1$, no $\tilde{O}(n + m + (nm)^{d/2}) = \tilde{O}(n + m)$ algorithms are known, raising the question whether any superlinear lower bound can be proven for $d = 1$.

As our first main contribution, we give a perhaps surprising *negative* answer to Question 1: For $d = 3$ and $n = m^{o(1)}$, there exists an almost-linear time $m^{1+o(1)}$ algorithm, showing that in an unbalanced setting, the upper bound of $\tilde{O}((nm)^{d/2})$ can indeed be beaten (Section 3.4). Interestingly, this stands in contrast to the case of moderately small m: For $d = 3$ and any $m \leq \sqrt{n}$ we prove a tight conditional lower bound of $(nm)^{d/2-o(1)}$, by combining the proof techniques of Chan's combinatorial k-clique lower bound [9] and the tight 3-uniform hyperclique lower bound for Klee's measure problem in 3D [19] (Section 3.2). This reveals that the time complexity of the directed Hausdorff distance under translation is *inherently asymmetric* in n and m and breaks with tradition for algorithmic results on the Hausdorff distance under translation.

We investigate the case of small n further and observe that our algorithmic approach could plausibly generalize to an $\tilde{O}(n^{d+1}m^{\lfloor d/2 \rfloor})$ algorithm (we elaborate on the missing ingredient in Section 3.4) – such an algorithm would beat the baseline algorithm for all odd d and small values of n. We also show that such an algorithm would indeed be conditionally tight: we also prove a corresponding lower bound of $m^{\lfloor d/2 \rfloor - o(1)}$ for all $d \geq 4$, assuming the 3-uniform hyperclique hypothesis (Section 3.1).

Our conditional lower bounds can be adapted to the case of $n = \Theta(m)$, but no longer match the upper bound. In fact, we obtain a conditional lower bound of $n^{2.25-o(1)}$ for $d = 3$ which still leaves a gap of $n^{0.75 \pm o(1)}$ to the upper bound of $\tilde{O}(n^3)$. It remains an open problem to settle the full time complexity for *any* relationship between n and m. An intriguing possibility consistent with our results is the existence of an $\tilde{O}(n^{\lceil d/2 \rceil}m^{\lfloor d/2 \rfloor})$-time algorithm.

[3] Here, combinatorial algorithms refers to algorithms that avoid the use of algebraic techniques underlying fast matrix multiplication algorithms beating $n^{3-o(1)}$ running time.

We turn to our second main question.

Question 2: *How does the choice of dimension, directed vs. undirected and discrete vs. continuous affect the time complexity?*

We observe that the time complexity of computing Hausdorff distances under translation exhibits an intricate interplay between the different aspects of the problem, illustrated in Table 1 and Figure 1.

On directed vs. undirected

A folklore reduction from computing the undirected Hausdorff distance to computing the directed Hausdorff distance under translation (Observation 2.3) shows that the undirected case is never harder than the (balanced) directed case. Could there exist a reduction in the other direction?

We show that in full generality, such a reduction appears unlikely: While for all $d \geq 3$, we can transfer our conditional lower bounds for the directed case to analogous bounds in the undirected case (analogous to the OVH-based lower bound for $d = 2$ [7], which also transfers to the undirected case) (Section 3.5), we obtain a conditional separation for $d = 1$. Notably, Rote [20] obtains a $\tilde{O}(n+m)$-time algorithm for computing the undirected Hausdorff distance under translation in $d = 1$. For the directed setting, we give a fine-grained reduction from the quadratic-time L_∞-Necklace Alignment problem [6], which in turn is at least as hard as the MaxConv LowerBound problem studied in [12]. We remark that we are not aware of any conditional lower bound for MaxConv LowerBound under an established hypothesis from fine-grained complexity theory; however, the question of subquadratic equivalence between this problem and the well-studied $(\min, +)$-convolution problem was raised as an open problem in 2017 [12]. We believe that our reduction to the (discrete or continuous) directed Hausdorff distance adds further reason to study the apparent quadratic-time complexity of MaxConv LowerBound, in hopes to either refute or justify this hardness barrier.

Circumventing the separation in $d = 1$, we give a general reduction from the undirected setting to the directed setting that blows up the dimension (Section 3.5). This allows us to transfer the lower bounds from the directed case for $d = 1$ to the undirected case in $d = 2$. In particular, we conclude that if MaxConv LowerBound truly requires quadratic-time, the undirected setting is near-linear time solvable if and only if $d = 1$.

On discrete vs. continuous

The tight lower bound based on OVH [7] convincingly settles the fine-grained complexity of the continuous setting in $d = 2$. In contrast, the only justification of hardness of the discrete setting is given by our reductions from MaxConv LowerBound and L_∞-Necklace Alignment (see above and the full version). Is there any reason why a tight lower bound based on OVH does not exist for the discrete setting?

We find evidence for the non-existence of such a reduction by showing a fine-grained reduction from (directed or undirected) discrete Hausdorff distance under translation in $d \leq 3$ to the All-Ints 3SUM problem (in the full version). In particular, this implies a tight fine-grained reduction from the balanced setting to 3SUM. Thus, establishing quadratic-time OVH-hardness of the balanced, discrete setting implies a tight reduction from OV to 3SUM, which is a central open problem in fine-grained complexity theory, and suffers from barriers based on the Nondeterministic Strong Exponential Time Hypothesis, see [8].

We remark that we obtain further connections from the class of additive problem $\mathsf{FOP}_{\mathbb{Z}}$ to the discrete variants. For space reasons, these results are deferred to the full version.

2 Preliminaries

A brief definition of relevant problems as well as the used hardness hypotheses can be found in the full version. We there also give a brief overview of known algorithms for the continuous and discrete variant.

We recall the Hausdorff distance as a distance measure between two point sets P, Q of sizes n, m. The metric space used for this paper will be $(\mathbb{R}^d, L_\infty)$. The undirected (symmetric) and directed (asymmetric) variant are defined as:

$$\delta_{\overrightarrow{H}}(P,Q) \coloneqq \max_{p\in P}\min_{q\in Q}\|p-q\|_\infty \qquad \delta_H(P,Q) \coloneqq \max\{\delta_{\overrightarrow{H}}(P,Q), \delta_{\overrightarrow{H}}(Q,P)\}$$

We show almost all of our conditional lower bounds already for the *decision variant* of Hausdorff under Translation, which receives a test distance $\delta > 0$ as additional input[4]. Clearly, the corresponding optimization problems, finding a translation minimizing δ, are at least as hard. Specifically, we study:

▶ **Definition 2.1** (Hausdorff under Translation (*HuT*)). *Given sets $P, Q \subset \mathbb{R}^d$ of n and m points, respectively, and a real value $\delta > 0$. Decide whether:*

$$\exists \tau \in \mathbb{R}^d : \delta_{\overrightarrow{H}}(P+\tau, Q) \le \delta \quad \equiv \quad \exists \tau \in \mathbb{R}^d\ \forall p \in P\ \exists q \in Q : \|(p+\tau)-q\|_\infty \le \delta$$

▶ **Definition 2.2** (Discrete Hausdorff under Translation (*DiscHuT*)). *Given sets $P, Q \subset \mathbb{Z}^d$ of n and m points, respectively, a real value $\delta > 0$ as well as a set of at most t translations $T \subset \mathbb{Z}^d$. Decide whether:*

$$\exists \tau \in T : \delta_{\overrightarrow{H}}(P+\tau, Q) \le \delta \quad \equiv \quad \exists \tau \in T\ \forall p \in P\ \exists q \in Q : \|(p+\tau)-q\|_\infty \le \delta$$

Note that our definition of the discrete variant assumes all input entries to be polynomially bounded integers[5].

To obtain the *undirected* versions of the above problems, we replace $\delta_{\overrightarrow{H}}(P+\tau, Q)$ by $\delta_H(P+\tau, Q)$, and denote the problem by *(Disc)uHuT*. If not specified otherwise, we consider the directed versions. We call the case in which all input sets have roughly equal size, i.e., $Q = \Theta(|P|)$ and additionally for the discrete case $|T| = \Theta(|P|)$, the *balanced* parameter setting, otherwise we say the parameters are *lopsided*.

Lastly, we give a folklore reduction from undirected to directed Hausdorff under Translation that works for both the continuous and discrete variant. By setting $\sigma = (M, 0, \ldots, 0)$ for a sufficiently large M, we see that $\delta_H(P+\tau, Q) = \delta_{\overrightarrow{H}}((P \cup (\sigma - Q)) + \tau, Q \cup (\sigma - P))$.

▶ **Observation 2.3.** *The undirected (Discrete) Hausdorff under Translation problem with input sizes n, m reduces to the directed version with input sizes $n' = m' = n + m$.*

While this reduction introduces additional points to the input, we discuss in the full version that an input size maintaining reduction to a single instance of directed HuT is unlikely.

As our model of computation, we use the Real RAM for continuous HuT, while for the discrete HuT variant with point sets in $\mathbb{Z}^d$ we assume a Word RAM machine model with word size $\Theta(\log n)$.

[4] Note that the case $\delta = 0$, i.e., finding an exact match, allows an almost-linear-time algorithm [13] and is thus uninteresting for our purposes.

[5] One may also assume rational coordinates, which is equivalent by a scaling argument.

2.1 Translation Problems

For clarity of presentation, it is often useful to view the Hausdorff under Translation decision problem as a translation problem involving certain *shapes*.

▶ **Definition 2.4** (Translation Problem). *Given a set of n points P and m shapes $\mathcal{Q}$ in $\mathbb{R}^d$. Compute a translation $\tau \in T \subseteq \mathbb{R}^d$ such that*

$$\forall p \in P \ \exists Q \in \mathcal{Q} : p + \tau \in Q.$$

For an instance of HuT with point sets P, Q and $\delta > 0$, if we construct hypercubes $\mathcal{Q}$ with side length 2δ and centers $q \in Q$, the region $T^* = \bigcap_{p \in P} \bigcup_{\hat{Q} \in \mathcal{Q}} \hat{Q} - p$ is exactly the region of feasible translations, i.e., we have $\tau \in T^* \iff \forall p \in P \ \exists q \in Q : \delta_{\overrightarrow{H}}(P + \tau, Q) \leq \delta$ [1]. We call this case, where all shapes $\mathcal{Q}$ are hypercubes of the same size, the *Translation Problem with Hypercubes (TPwC)*. In case all shapes of Q are axis-aligned boxes (of arbitrary size), we call it the *Translation Problem with Boxes (TPwB)*. While the TPwC problem is equivalent to HuT, there is no reduction to HuT known within the same ambient space from the Translation Problem with Boxes or even from the translation problem with hypercubes of different sizes. We further use a third variant.

▶ **Definition 2.5** (Translation Problem with Orthants (TPwO)). *Given a target box B with a maximum side length δ_0. Given a set of k Translation Problem with Hypercube instances, each on a point set P_i and hypercubes $\mathcal{Q}_i$ with side length $\delta > \delta_0$, such that $\sum_{i \in [k]} |P_i| = n$, $\sum_{i \in [k]} |\mathcal{Q}_i| = m$. Compute a translation $\tau \in \mathbb{R}^d$ such that $\forall i \in [k] : P_i + \tau \subset B$ and*

$$\forall i \in [k] \ \forall p_i \in P_i \ \exists Q_i \in \mathcal{Q}_i : p_i + \tau \in Q_i.$$

We call the shapes of the TPwO instance, i.e., the shapes of its sub-instances, orthants as within the target box all hypercubes are indistinguishable from orthants. An important property of this problem, which we will use later, is that we may fix the side-length of all orthants to a value $\delta > \delta_0$. Similar to [9, Lemma 3], the TPwO problem reduces to the TPwC and thus has a reduction to HuT, its proof is deferred to the full version. A converse reduction, from HuT to TPwO, is generally not known.

▶ **Lemma 2.6.** *The Translation Problem with Orthants on n points and m orthants reduces in linear time to the Translation Problem with Hypercubes on $\Theta(n)$ points and $\Theta(m)$ hypercubes.*

3 Technical Overview for Selected Results

In this section, we discuss the main ideas of our lower bounds and algorithm. We present the general structure of the proofs and give sketches on the most important technical details. For space reasons, we defer further details as well as a complete discussion of our results and further extensions to the full version.

3.1 (Non-)Combinatorial Lower Bounds for Arbitrary n, m

For our lower bounds in higher dimensions ($d \geq 4$), we give a reduction in three steps from the k-hyperclique problem to HuT, see the full version for a formal definition and its hardness hypothesis.

In the first step, we encode any k-tuple of vertices of a hypergraph $H = (V, E)$ as cells inside a $\lfloor d/2 \rfloor$-dimensional hypercube, see Figure 2. The used encoding was introduced by Chan [9]. For any non-edge $\bar{e} \in \binom{V}{3} \setminus E$, the *feasible region* of $\bar{e}$ are the cells inside the

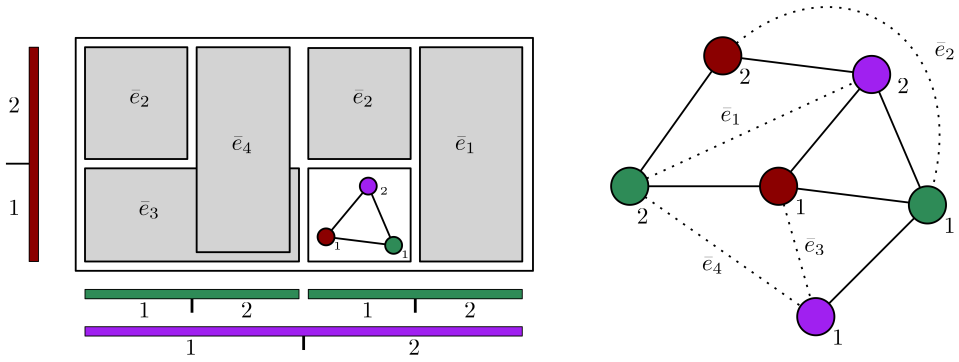

Figure 2 An example of an encoding of a 3-partite graph to a 2-D box (skewed cube). Normal lines represent edges, dotted lines represent a subset of non-edges. The gray boxes correspond to the forbidden regions of the respective non-edge. Note that in our reductions, we aim to cover the complement of these regions, the feasible regions.

hypercube for which the corresponding k-tuple does not include $\bar{e}$. In contrast, the cells for which the corresponding k-tuple includes all vertices of $\bar{e}$ are called the *forbidden region*. For each non-edge, we construct a covering of its feasible region with axis-aligned boxes[6], see Lemma 3.5 for the exact covering. As a k-clique is a k-tuple which does not contain any non-edge, a cell that lies within the feasible regions of all non-edges encodes a k-clique. In Lemma 3.6 we reduce finding a cell inside all feasible regions to the intermediate Translated Box-Shape Problem (Definition 3.2) with our desired values of n, m.

In the second step, the resulting Translated Shape Problem is reduced to the Translation Problem with Boxes, see Lemma 3.3.

Lastly, in our third step we reduce the Translation Problem with Boxes in $\lfloor d/2 \rfloor$-D to the Translation Problem with Orthants in d dimensions with n points and m orthants, see Lemma 3.1. As given in Lemma 2.6, the Translation Problem with Orthants has a linear time reduction to directed Hausdorff under Translation, which yields our lower bound.

We go through the steps in backwards order, starting with the last, third step.

Step 3: From Boxes to Orthants

We reduce the Translation Problem with Boxes to the Translation Problem with Orthants. We implement the natural idea to cover boxes of arbitrary aspect ratios by orthants (large hypercubes), at the cost of doubling the underlying dimension. As this basic idea allows additional, unintended solutions, we need a technical translation gadget that ensures soundness. Figure 3 gives a visual intuition of the proof in 1-D.

▶ **Lemma 3.1.** *The Translation Problem with Boxes in d-D with input parameters n, m reduces in linear time to the Translation Problem with Orthants in $2d$-D with input parameters $n' = \Theta(n), m' = \Theta(m)$.*

Proof Sketch. We define the coordinate-wise transformations

$$c : p \mapsto (p, p), \qquad c^+ : [a, b] \mapsto [a, \infty) \times (-\infty, b], \qquad c^- : [a, b] \mapsto (-\infty, b] \times [a, \infty).$$

[6] As we only consider axis-aligned boxes in this paper, we may only call these boxes.

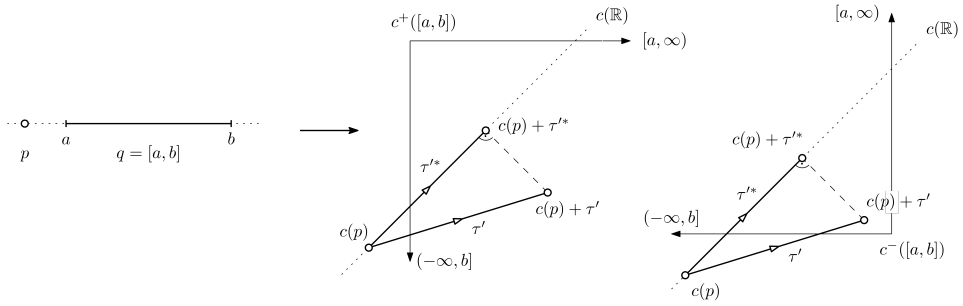

Figure 3 The reduction of a box in 1-D, i.e., an interval $[a, b]$, to orthants in 2-D. We prove that for each feasible translation τ' there exists a feasible translation τ'^* which lies on the diagonal $c(\mathbb{R})$. For that, we always assume that the translation τ' lies between the diagonal $c(\mathbb{R})$ and the vertex of the orthant, i.e., for this example the orthant of c^- is relevant.

For points in $\mathbb{R}^d$, we define the transformation f as the coordinate-wise application of c. For our analysis, we further apply f to sets or intervals in which case we apply f element-wise. For boxes in $\mathbb{R}^d$, we define the transformations $f_1, ..., f_{2^d}$ as all possible combinations of the coordinate-wise application of c^+, c^-. Note that the images of f_i are orthants.

Given an instance of the Translation Problem with Boxes with P being the point set and $\mathcal{B}$ being the set of boxes. We construct the sub-instances $(f(P), f_1(\mathcal{B})), ..., (f(P), f_{2^d}(\mathcal{B}))$ of the resulting Translation Problem with Orthants instance, the target box is simply the bounding box of $\mathcal{B}$. We claim that

$$\begin{aligned} &\exists \tau \in \mathbb{R}^d \ \forall p \in P \ \exists B \in \mathcal{B} : p + \tau \in B \\ \iff &\exists \tau' \in \mathbb{R}^{2d} \ \forall i \in [2^d] \ \forall p' \in f(P) \ \exists C \in f_i(\mathcal{B}) : p' + \tau' \in C. \end{aligned}$$

For the proof, we see that a feasible translation $f(\tau) \in f(\mathbb{R}^d)$ for the right side for *any* $i \in [2^d]$ is a feasible translation for the left side, so we prove that a feasible translation $\tau' \notin f(\mathbb{R}^d)$ can be transformed to a feasible translation $\tau'^* \in f(\mathbb{R})$. Choosing the $i \in [2^d]$ such that τ' always lies on the correct side of $f(\mathbb{R}^d)$, where all vertices of our constructed orthants $f_i(\mathcal{B})$ lie, enables us to move τ' to its closest point τ'^* on $f(\mathbb{R}^d)$, giving $p' + \tau' \in C \implies p' + \tau'^* \in C$ for all $p' \in f(P), C \in f_I(\mathcal{B})$. The full proof details can be found in the full version. ◀

Step 2: The intermediate Translated Box-Shape Problem

We introduce an intermediate problem, the Translated Box-Shape Problem, similar to the one of [9, Problem 4] using hypercubes. In contrast to the Translation Problem with Boxes, it allows composing boxes into shapes for which translated copies can be instantiated with a single translation object. Thus, a set of n^2 boxes, structured appropriately, can be described by a shape of n boxes and n translation objects.

▶ **Definition 3.2.** (Translated (Box-)Shape Problem). *Let $\mathcal{Z}$ be a set of shapes in $\mathbb{R}^d$, composed of a union of boxes. Let m be the total number of boxes over all shapes of $\mathcal{Z}$. Given a set $\mathcal{S}$ of n objects where each object is the translate of some shape in $\mathcal{Z}$, decide whether $\bigcap_{S \in \mathcal{S}} S \neq \emptyset$.*

We further give a reduction from the Translated Shape Problem to the Translation Problem with Boxes, analog to [9, Lemma 3]. Its proof again is deferred to the full version.

▶ **Lemma 3.3.** *The Translated (Box-)Shape Problem with n translation objects and a total of m boxes reduces to the Translation Problem with Boxes with $|P| = \Theta(n)$ and $|\mathcal{Q}| = \Theta(m)$.*

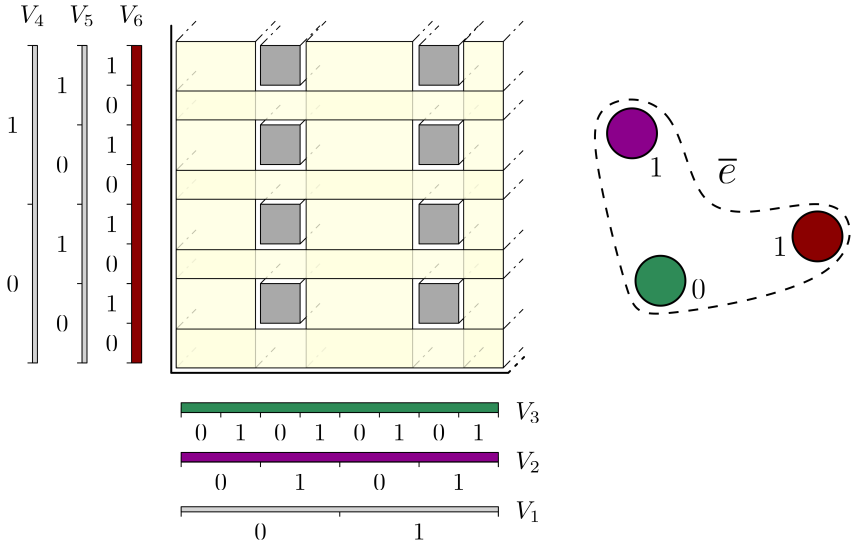

Figure 4 An example of the feasible region of a non-edge $\bar{e} \in V_2 \times V_3 \times V_6 \setminus E$ covered by boxes, depicted in yellow, within a d-dimensional hypercube projected to 2 dimensions.

Lastly, we give a simple observation allowing, by repeated application, to compose arbitrary many individual Translated (Box-)Shape Problems without additional overhead.

▶ **Observation 3.4.** *Given two instances of the Translated Shape Problem with inputs $\mathcal{S}_1, \mathcal{Z}_1$ and $\mathcal{S}_2, \mathcal{Z}_2$ of size n_1, m_1 and n_2, m_2 in a shared universe. Deciding whether $\bigcap_{S \in \mathcal{S}_1 \cup \mathcal{S}_2} S \neq \emptyset$ reduces to a single instance of the Translated Shape Problem with $\mathcal{S} = \mathcal{S}_1 \cup \mathcal{S}_2$, $\mathcal{Z} = \mathcal{Z}_1 \cup \mathcal{Z}_2$ of size $n \leq n_1 + n_2$ and $m \leq m_1 + m_2$.*

Step 1: From k-Hyperclique to the Translated Box-Shape Problem

In the remaining step, along the basic idea presented in the beginning of Section 3.1, we encode the k-hyperclique problem to a d-dimensional hypercube and reduce finding a cell that lies in the feasible regions of all non-edges to the Translated (Box-)Shape Problem with the desired distribution of parameters n, m. As our approach will also provide novel combinatorial lower bounds, we more generally consider a u-uniform hypergraph with $u \in \{2, 3\}$.

We first give the encoding of the hypergraph to a d-dimensional hypercube and show that the feasible regions of the non-edges can be covered efficiently. The same encoding for a graph can exemplarily be seen in Figure 2, note that for illustrative reasons we there have not covered the feasible but the forbidden regions.

▶ **Lemma 3.5.** *Let $d \in \mathbb{N}$ and $u \in \{2, 3\}$ be constant and let $k \in \mathbb{N}$ be constant with $d|k$. Given a u-uniform hypergraph $H = (V, E)$ with $|V| = n$, where V is partitioned into k color classes $V = V_1 \cup V_2 \cup ... \cup V_k$. There is an encoding of $V_1 \times ... \times V_k$ to a d-dimensional hypercube so that for each $\bar{e} \in \binom{V}{u} \setminus E$ the feasible region of $\bar{e}$ can be covered by $O(n^{k/d-1})$ boxes, which can be computed in $O(n^{k/d-1})$ time.*

Proof Sketch. By scaling, we assume that the d-dimensional hypercube has a side-length of $n^{k/d}$. Given the numbers $x_1, ..., x_{k/d} \in [n]$, we use the canonical function

$$\text{ind} : (x_1, ..., x_{k/d}) \mapsto x_1 \cdot n^{k/d-1} + x_2 \cdot n^{k/d-2} + ... + x_{k/d}$$

to address an integer point in the range $[0, n^{k/d} - 1]$ We denote each unit hypercube as a cell, its relative origin can be addressed by $(\text{ind}(X_1), ..., \text{ind}(X_d))$ where $X_1, ..., X_d \in [n]^{k/d}$.

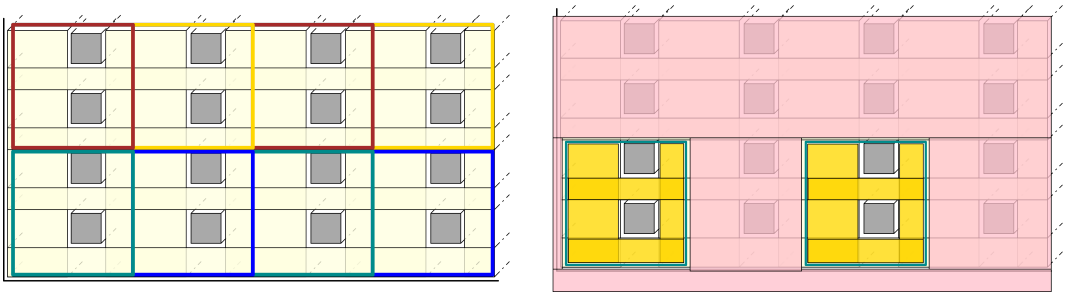

Figure 5 Left: The decomposition of a (skewed) hypercube in 2-D into four identical sub-regions, marked in red, yellow, green, and blue. Boxes in equal color denote a common sub-region, here in each row there are two sub-regions that are split into two parts each.
Right: The boxes used to cover the feasible region of the green sub-regions, in yellow, as well as the boxes covering the complement of the green sub-region, marked in pink.

The encoding of H to the hypercube is the same as used in [9]. We evenly assign the k color-classes to the d dimensions, i.e., the color classes $V_1, ..., V_{k/d}$ are assigned to the first dimension, the classes $V_{k/d+1}, ..., V_{2k/d}$ to the second dimension, etc. A k-tuple $(v_1, ..., v_k) \in V_1 \times ... \times V_k$ is bijectively assigned to the cell

$$\text{cell}((v_1, ..., v_k)) = (\text{ind}(v_1, ..., v_{k/d}), \text{ind}(v_{k/d+1}, ..., v_{2k/d}), ..., \text{ind}(v_{(d-1)k/d}, ..., v_k)).$$

For any non-edge $\bar{e} \in V^u \setminus E$, we cover the feasible region of $\bar{e}$ using at most $O(dn^{k/d-1})$ boxes $\mathcal{B}$, as can be seen in Figure 4. A full proof can be found at in the full version. ◀

Using Lemma 3.5, we can already turn a k-(hyper-)clique instance into a Translated (Box-)Shape instance with $n = O(|V|^u), m = O(|V|^{k/d-1+u})$ as we can treat each feasible region of the $O(|V^u|)$ non-edges as an independent shape with $O(|V|^{k/d-1})$ boxes each. Observation 3.4 allows to compose the resulting independent instances.

To extend the reduction to arbitrary parameter choices of n, m, independently for each non-edge we decompose the hypercube into n smaller identical parts such that in each part the feasible region of a non-edge can be covered by m boxes as shown in Lemma 3.5. This allows a reduction to the Translated Shape Problem with m boxes and n translation objects.

▶ **Lemma 3.6.** *Let $\lambda \in [0, 1]$, $u \in \{2, 3\}$ be constant, and $d, k \in \mathbb{N}$ be constants with $d|k$. Given a u-regular hypergraph $H = (V, E)$ and its encoding to a d-dimensional hypercube as constructed in Lemma 3.5. We reduce the problem of finding a k-(hyper-)clique in H in $O(|V|^{k/d})$ time to an instance of the Translated (Box-)Shape Problem with $n = O(|V|^{u\lambda k/d+u})$ translates of common shapes consisting of $m = O(|V|^{(1-\lambda)k/d+u})$ boxes.*

Proof Sketch. By Observation 3.4, it suffices to consider the feasible regions of a single non-edge $\bar{e}$ and reduce finding a cell that lies in its feasible regions to a Translated (Box-)Shape instance with $n' = O(|V|^{u\lambda k/d})$ translates of a single shape with $m' = O(|V|^{(1-\lambda)k/d})$ boxes.

We consider the encoding of the hypergraph to the d-dimensional hypercube as given in Lemma 3.5. As $\bar{e}$ is a u-tuple, its included vertices are only encoded in up to u dimensions, it thus suffices to consider the hypercube projected to these u dimensions.

We construct $((|V|^{k/d})^\lambda)^u = n'$ many sub-regions that decompose the u-dimensional hypercube: We decompose each single dimension into $(|V|^{k/d})^\lambda$ many (not necessarily continuous) slices that are identical under translation, i.e., when translated so that two slices have the same relative origin, the feasible and forbidden regions of $\bar{e}$ within these slices match. These one-dimensional slices can be combined independently in all dimensions, yielding the desired decomposition of the full u-dimensional hypercube into identical sub-regions.

The feasible region of $\bar{e}$ in each sub-region can be covered by m boxes. As the sub-regions are identical, we can construct a Translated (Box-)Shape instance with n' translation objects and a single shape with m boxes. A full proof can be found in the full version. ◀

Resulting Lower Bounds

Combining our results from Lemmas 3.1, 3.3, and 3.6, we get lower bounds for arbitrary distributions of n, m. However, as the bounds deteriorate with growing values of n, we only get tight lower bounds for $n = m^{o(1)}$. We consider other cases in the full theorem statement which can be found with its proof in the full version.

▶ **Theorem 3.7.** *Let $\varepsilon > 0, \lambda \in (0, 1], d \in \mathbb{N}_{\geq 4}$ be constant. Under the k-hyperclique hypothesis, there is no $O((nm)^{\lfloor \frac{d}{2} \rfloor \frac{\lambda+3}{3\lambda+3} - \varepsilon})$ algorithm for directed HuT in d-D with $n = \Theta(m^\lambda)$.*

3.2 Tight Non-Combinatorial Lower Bound in 3-D

Chan [9] has proven a tight lower bound that applies for distributions $m \in O(n)$ in 3-D. We give a non-combinatorial version of this $(nm)^{d/2-o(1)}$ lower bound for $m \in O(n^{1/2})$.

We reduce from the k-Hyperclique problem, combining Chan's ideas with the work of Künnemann [19] using *prefix covering designs*. As done in Section 3.1, we encode a k-tuple of vertices inside a d-dimensional hypercube. However, we use a redundant encoding based on the prefix covering designs, that is, each color class is encoded more than once to our hypercube. The full proof is presented in the full version.

▶ **Corollary 3.8.** *Let $\varepsilon > 0$. For any $\lambda \in (0, 1/2]$, there is no $O((nm)^{3/2-\varepsilon})$ (non-combinatorial) algorithm for directed Hausdorff under Translation in 3-D with $m = \Theta(n^\lambda)$ under the k-hyperclique hypothesis.*

3.3 Connections to Additive Problems

We draw several connections between the Hausdorff distance under Translation and several additive problems. Below we highlight a conditional lower bound in 1D and conditional upper bound in 3D. Omitted proofs and additional results are given in the full version.

We first show that even for one-dimensional instances, directed HuT inherits hardness from quadratic-time barriers from problems such as *MaxConv LowerBound*.

▶ **Definition 3.9** (MaxConv LowerBound, MaxConvLB)**.** *Given integer arrays A, B, C of length[7] n. Determine whether $C[k] \leq \max_{i+j=k}(A[i] + B[j])$ holds for all $k \in \{2, ..., n\}$.*

In an investigation of hardness results from $(\min, +)$-convolution, Cygan, Mucha, Wegrzycki and Wlodarczyk [12] studied the closely related MaxConv LowerBound problem and gave a subquadratic reduction to L_∞-Necklace Alignment (in turn, L_∞-Necklace Alignment admits a subquadratic reduction to $(\min, +)$-Convolution [6]). Cygan et al. raised the natural question whether MaxConv LowerBound is subquadratic equivalent to $(\min, +)$-convolution; to the best of our knowledge, neither a positive or negative resolution is known.

For the (continuous) directed HuT we get hardness by a reduction from the Linear Alignment problem, shown in the full version. Further, using a reduction from L_∞-Necklace Alignment to Linear Alignment, we get a reduction from MaxConv LowerBound to directed

[7] Other common definitions use for C an array of size $2n$. For convenience, we stick to this definition.

HuT. Interestingly, we obtain such a lower bound even for discrete directed HuT by directly reducing from MaxConv LowerBound. These reductions illuminate why no subquadratic algorithms are known for directed variants, despite near-linear algorithms for their undirected counterparts [20].

▶ **Theorem 3.10.** *If 1-dimensional discrete HuT can be solved in time $T(n)$, then the MaxConv LowerBound problem can be solved in time $O(T(n))$.*

Proof sketch. Given arrays A, B, C of positive values as inputs from MaxConv LowerBound. We construct T, P, Q as arrays for DiscHuT. By abuse of notation, we allow Q to be indexed negatively. We define $T = [-(kM + C[k])]_{k\in[n]}$, $P = [iM + A[i] + M/4]_{i\in[n]}$, $Q = [-zM + M/4]_{z\in\{-n,\dots,0\}} \cup [-(jM + B[j])]_{j\in[n]}$, $\delta = \frac{M}{4} - 1$, where M is a large number with $M > 4 \cdot \max_{i,j,k} (A[i] + B[j] + C[k])$.

Now, if A, B, C is a NO-instance to MaxConv LowerBound, then there is a k^* such that for all $i < k^*$ we have $A[i] + B[k^* - i] < C[k^*]$. From this we can derive that $|p_i + \tau_{k^*} - q_{k^*-i}| \leq \delta$, where p_i, q_{k^*-i}, and τ_{k^*} denote the points in P, Q, and T, respectively, corresponding to $A[i]$, $B[k^* - i]$ and $C[k^*]$. Thus, we have a YES-instance to DiscHuT. Analogously, a YES-instance to MaxConv results in a NO-instance to DiscHuT. See the full version for the full proof. ◀

We give an upper bound to discrete HuT, which stems from a reduction from 3-dimensional Discrete HuT to 3-SUM. On a very high level, the basic idea consists of a complement trick, which enables a quantifier switch in the discrete HuT problem.

▶ **Corollary 3.11.** *Let $d \leq 3$. If 3-SUM can be solved in time $T(n)$, then we can solve d-dimensional balanced Discrete HuT in time $\tilde{O}(T(n \log(n)) + n \log(n))$.*

3.4 A Faster Algorithm for $m \gg n$

For $n = m^{o(1)}$, Theorem 3.7 gives a $(nm)^{\lfloor d/2 \rfloor - o(1)}$ lower bound, which for even d matches the best known algorithm running in time $O((nm)^{d/2})$ [9], while for odd d it seems to have some slack. Intuitively, one might expect that the known $(nm)^{d/2-o(1)}$ combinatorial lower bound for $m = O(n)$ [9] also transfers to the case of $m \gg n$. Surprisingly, in 3-D the $(nm)^{1-o(1)}$ lower bound of [7] is tight for $n = m^{o(1)}$ as we give an $O(m^{1+o(1)})$ algorithm.

The algorithm uses a structural insight from [10, Theorem 7], which we turn algorithmic. The full description and proof can be found in the full version. Our algorithm relies on an algorithm recently introduced by Agarwal and Steiger [2], which in 3-D computes the vertices of the union of m unit cubes in an output-sensitive runtime of $\tilde{O}(m)$. Assuming an algorithm that computes the vertices of the union of m unit hypercubes in d-D in time $\tilde{O}(m^{\lfloor d/2 \rfloor})$, our algorithm directly generalizes to higher dimensions with a runtime of $\tilde{O}(m^{\lfloor d/2 \rfloor} n^{d+1})$.

▶ **Theorem 3.12.** *Directed Hausdorff under Translation in 3-D can be solved in time $\tilde{O}(n^4 m)$.*

Its existence forbids $(nm)^{d/2-o(1)}$ lower bounds for arbitrary distributions of n, m for $d = 3$, and we give compelling intuition for a similar result in odd $d > 3$.

▶ **Corollary 3.13.** *Let $d = 3$, $\kappa > 0$ and set $\lambda = \frac{\kappa}{d+2}$. For $n = O(m^\lambda)$, directed Hausdorff under Translation in d-D can be solved in time $O(m^{\lfloor d/2 \rfloor} n^{d+1}) < O(m^{\lfloor d/2 \rfloor + \kappa})$.*

This result points to a discrepancy in complexity, at least for $d = 3$ but potentially also for all odd d. While we have a $\tilde{O}(m)$ algorithm for $n = m^{o(1)}$, there is a $(nm)^{d/2-o(1)}$ tight (combinatorial) lower bound for $m \in O(n)$ [9]. It remains unknown where the cutoff point is located, i.e., for which values of n, m do we start to get faster than $(nm)^{d/2 \pm o(1)}$ algorithms?

3.5 Transferring Lower Bounds to the Undirected Setting

As of now, all here presented lower bounds only apply to the directed Hausdorff under Translation setting. Chan [9] already raised the question if these bounds transfer to the undirected setting, however there are no such lower bounds known so far for $d \geq 3$. Only for $d = 2$, lower bounds for the undirected setting are known [7], which match the bounds for the directed variant. For $d = 1$, we have an optimal $\tilde{O}(n + m)$ algorithm [20].

We partially resolve this question by providing a reduction from the Translation Problem with Orthants to undirected Hausdorff under Translation, maintaining all instance parameters.

▶ **Theorem 3.14.** *If we can decide the undirected Hausdorff under Translation problem in d-D with point sets of size n, m in time $T(n, m)$, we can decide the Translation Problem with Orthants in d-D with n points and m orthants in time $T(n, m) + O(n + m)$.*

Proof Sketch. We only give intuition on the reduction to a uHuT instance from a single TPwC sub-instance of our TPwO input. The full proof is given in the full version.

For an individual TPwC instance, given the point set P and the set of hypercubes $\mathcal{C}$ of side length δ. Note that the target box B of our TPwO instance implies that the translated point set $P + T$ and the set of feasible translations T is restricted, we may assume that $T \subseteq [-\delta/3, \delta/3]^d$ and $P + T \subseteq B \subseteq b + [-2\delta/3, 2\delta/3]^d$, where $b \in \mathbb{R}^d$ is some relative origin.

We strategically place additional points in the TPwC sub-instance to allow a reduction to uHuT. These points are located on the vertices and middle points of all faces of a $b + [-\delta, \delta]^d$ extended target box. As the translation and translated point set are restricted, any hypercube that intersects the target box $b + [-2\delta/3, 2\delta/3]^d$ also intersects the extended target box $b + [-\delta, \delta]^d$ when translated. Thus, we can place auxiliary points such that under all translations each hypercube C of our TPwC instance has an auxiliary point which lies inside C. Having this property, the reduction to uHuT is imminent. ◀

All lower bounds for HuT in $d \geq 3$ dimensions presented so far, as well as the combinatorial $(nm)^{d/2-o(1)}$ lower bound for $m \in O(n)$ of Chan [9], can be directly applied to undirected Hausdorff under Translation as they use the Translation Problem with Orthants as an intermediate problem. At the cost of doubling the dimension using Lemma 3.1, we generally reduce any instance of directed Hausdorff under Translation to the undirected setting.

▶ **Corollary 3.15** (Excerpt from full version)**.** *We get the following results:*

- *For arbitrary n, m, there is no $O((nm)^{d/2-\varepsilon})$ combinatorial algorithm for undirected Hausdorff under Translation in d-D under the k-clique hypothesis.*
- *For $\min(n, m) \in O(\max(n, m)^{1/2})$, there is no $O((nm)^{3/2-\varepsilon})$ algorithm for undirected Hausdorff under Translation in 3-D under the k-hyperclique hypothesis.*
- *If balanced (discrete) undirected Hausdorff under Translation in 2-D can be solved in time $T_2(n)$, then MaxConv LowerBound can be solved in time $O(T_2(n) + n)$.*

Cauchy's Surface Area Formula in the Funk Geometry

Sunil Arya
Department of Computer Science and Engineering, Hong Kong University of Science and Technology, Hong Kong

David M. Mount
Department of Computer Science, University of Maryland, College Park, MD, USA

Abstract

Cauchy's surface area formula expresses the surface area of a convex body as the average area of its orthogonal projections over all directions. While this tool is fundamental in Euclidean geometry, with applications ranging from geometric tomography to approximation theory, extensions to non-Euclidean settings remain less explored. In this paper, we establish an analog of Cauchy's formula for the Funk geometry induced by a convex body K in $\mathbb{R}^d$, for the Holmes–Thompson surface area. The formula is based on central projections to boundary points of K. We show that when K is a convex polytope, the formula reduces to a weighted sum of contributions associated with the vertices of K. Finally, as a consequence of our analysis, we derive a generalization of Crofton's formula for surface areas in the Funk geometry. By viewing Euclidean, Minkowski, Hilbert, and hyperbolic geometries as limiting or special cases of the Funk setting, our results provide a unified framework for these classical surface area formulas.

1 Introduction

Cauchy's surface area formula is a surprising and elegant result in Euclidean geometry. It states that the surface area of any convex body is a constant multiple of the average $(d-1)$-dimensional measure of its orthogonal projections, or "shadows", taken over all possible directions. To state the result formally in any dimension $d \geq 1$, let S^d denote the d-dimensional unit sphere, λ_d denote the standard d-dimensional Lebesgue measure, ω_d denote the volume of a d-dimensional Euclidean unit ball, and $(\cdot \mid \cdot)$ denote orthogonal projection. Cauchy's formula states that for any convex body K in $\mathbb{R}^d$, its surface area is

$$\frac{1}{\omega_{d-1}} \int_{S^{d-1}} \lambda_{d-1}\big(K \mid u^\perp\big)\, du, \tag{1}$$

where $u^\perp$ is the linear subspace orthogonal to u. The related *Crofton formula* allows us to express the surface area of a convex body K as the average number of lines that intersect K, assuming that the lines are sampled from an appropriate measure.

Cauchy's formula is computationally fundamental, as it underpins algorithms in applications where estimating global geometric properties from lower-dimensional measurements is a recurring task, including geometric tomography [18], stereology [10], and surface area

estimation for digitized 3D objects [24, 22]. Integral formulas of this form are the essential first steps in efficient sampling processes, such as computing ε-nets [3, 14], since they implicitly define the probability distribution upon which to base the sampling.

Modern applications have increasingly explored non-Euclidean spaces, such as the *Hilbert geometry* and its close relative, the *Funk geometry*. (See Section 2 for definitions.) These geometries arise naturally whenever the domain of interest is a convex set. Examples include the analysis of discrete probability distributions in machine learning, where the domain is the probability simplex [12, 25], analysis of networks through hyperbolic geometry [21], analysis of positive definite matrices in deep learning [20, 23], and lattice-based cryptosystems [8]. Hilbert is more widely studied than Funk, but Faifman argues that for many applications, including computing volumes and areas, the Funk geometry is more natural and yields cleaner results [16].

While the metric properties of these spaces are well-understood in differential geometry [16, 26, 27], computational aspects of these geometries are only beginning to emerge. Recent work has employed the Hilbert geometry for polytope approximation [7, 8], clustering [25], and approximate membership queries [2]. Despite this growing algorithmic interest, the integral geometry of these spaces lacks the computational primitives required for efficient implementations. A major barrier is that the standard definition of surface area (the Holmes–Thompson area [19]) relies on symplectic forms or global integrals involving the polar body, making direct numerical evaluation prohibitively complex for high-dimensional or large-scale settings.

In this paper, we bridge this gap by establishing explicit Cauchy and Crofton formulas for the Funk geometry. Our formulas transform the abstract definitions of Finsler area into simple, concrete geometric quantities, which are readily accessible to discrete computation. Beyond the specific interest in Funk geometry, our results reveal it as a unifying bridge connecting diverse geometric settings.

Our main result is a Funk analog of Cauchy's formula. Let K be a convex body in $\mathbb{R}^d$, and let G be a convex set contained in the interior of K. Our objective is to compute the Holmes–Thompson surface area of G in the Funk geometry induced by K, which we denote by $\text{area}_K^F(G)$. For simplicity, let us assume for now that K's boundary is strictly convex, implying that for each direction $u \in S^{d-1}$, there is a unique boundary point $v_K(u)$ whose supporting hyperplane is orthogonal to u (see Figure 1(a)). Define the *central shadow* $S_K(G, u)$ as the slice of the cone subtended by G at $v_K(u)$, orthogonal to the direction u:

$$S_K(G, u) \;=\; -u^* \cap \text{cone}(G - v_K(u)),$$

where $-u^*$ is the hyperplane tangent to S^{d-1} at $-u$ and $\text{cone}(G - v_K(u))$ is the translation of the subtended cone to the origin (see Figure 1(b)). The measure of this section captures the "visual size" of G as seen from the boundary point $v_K(u)$. Just as the Euclidean formula averages orthogonal shadows, our Funk formula averages these central shadows. We show that G's surface area is proportional to the average area of these shadows, taken over all directions u.

▶ **Theorem 1.1.** *Let G and K be two convex bodies in $\mathbb{R}^d$ such that $G \subset \text{int}(K)$. Then*

$$\text{area}_K^F(G) \;=\; \frac{1}{\omega_{d-1}} \int_{S^{d-1}} \lambda_{d-1}(S_K(G, u))\, d\sigma(u),$$

where σ denotes the rotation-invariant surface measure on S^{d-1}.

This offers a "tomographic interpretation" in the sense that the intrinsic Funk surface area can be recovered solely from these central slices, which capture the visibility of G from the boundary of K. It is interesting to note that, while the Holmes–Thompson surface area

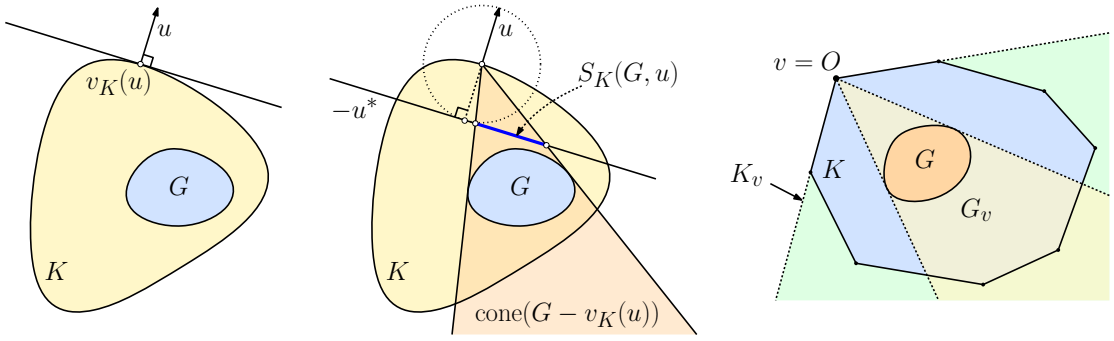

Figure 1 (a) The boundary point $v_K(u)$, (b) the central shadow $S_K(G,u)$ (translated so that $v_K(u)$ coincides with the origin), and (c) vertex decomposition.

of G (presented in Section 2.2) is defined in terms of the areas of the polars of Finsler balls in the Funk geometry induced by K, the formula of Theorem 1.1 involves only simple Euclidean quantities and the standard Lebesgue measure.

Our formulation connects the Funk geometry to several classical settings. When K is expanded to infinity, the central shadows become parallel projections, and our result converges to a Cauchy-type formula for the surface area in Minkowski spaces. In the special case where K is a Euclidean ball, this limit yields the classical Euclidean Cauchy formula. Furthermore, for a finite Euclidean ball K, our formula yields the exact surface area in the Beltrami-Klein model of hyperbolic geometry [13], generalizing planar observations by Alexander *et al.* [5]. Finally, for arbitrary convex bodies, our Funk surface area serves as a constant-factor approximation for the Hilbert surface area, with factors depending only on the dimension d. These results have been omitted due to space restrictions, but they appear in the full version of the paper [9].

Crucially for algorithmic applications, we derive a *discrete surface area formula* when K is a polytope. We show that the Funk surface area of a body G nested within K can be decomposed into a sum of local terms associated with the *vertices of* K. Each vertex v of K is naturally associated with a pointed cone $K_v = \text{cone}(K - v)$, which is the cone subtended by K after translating v to the origin (see Figure 1(c)). The body G is similarly associated with a cone $G_v = \text{cone}(G - v)$. In Section 2.3, we define a simple shadow-based notion of the Funk volume of G_v with respect to K_v, which we denote by $\text{vol}^F_{K_v}(G_v)$. We show that the total surface area of G can be expressed as the sum of these cone-based Funk volumes over the vertices of K.

▶ **Theorem 1.2** (Vertex Decomposition for Polytopes). *Let K be a convex polytope in $\mathbb{R}^d$, and let $G \subset \text{int}(K)$ be a convex body. For each vertex $v \in V(K)$, let $K_v = \text{cone}(K - v)$ and $G_v = \text{cone}(G - v)$. Then*

$$\text{area}^F_K(G) \;=\; \sum_{v \in V(K)} \text{vol}^F_{K_v}(G_v).$$

While the cone-based Funk volume defined in Section 2.3 involves integration, it can be readily estimated through random sampling. Furthermore, this decomposition scales linearly with the vertex count of K (see the discussion following the proof of Theorem 1.1 in Section 4). This is in contrast to prior Crofton measures for Hilbert geometries, which involve quadratic enumerations over face pairs [30].

Finally, we establish a *Funk–Crofton formula* (Theorem 4.4), expressing the Funk surface area as the K-dependent measure of the set of line parameters whose associated lines intersect the body. This result provides the basis for Monte-Carlo estimation of surface area, similar to methods used in Euclidean geometry [1, 22]. That is, one can approximate the Funk surface area simply by sampling from the associated parameter distribution and counting intersections of the corresponding lines with the body, bypassing the need for complex analytical evaluation.

1.1 Related Work

The study of integral geometry in projective Finsler spaces has a rich history in differential geometry [6, 29, 31]. Schneider [29] established the existence of Crofton measures for general projective Finsler spaces using the dual Holmes–Thompson volume. For the specific case of *polytopal Hilbert geometries*, he derived an explicit Crofton measure involving a combinatorial decomposition over pairs of complementary faces of the polytope [30]. Our work differs by focusing on Funk geometry and providing a decomposition based on the *vertices* of the ambient polytope, which as noted above offers significant computational advantages.

In the planar setting, Alexander [4] and later Alexander, Berg, and Foote [5] derived elegant Cauchy-type perimeter formulas for the Hilbert geometry using trigonometric integrals. Note that in this case, Hilbert and Funk surface areas coincide. Like ours, their formulas are explicit and admit a shadow interpretation in the Beltrami-Klein disk model of hyperbolic geometry. However, their techniques are specialized to the plane and do not seem to extend to arbitrary convex domains in higher dimensions. In contrast, our approach unifies these perspectives by showing that the "average of shadows" principle holds for general convex bodies in any dimension, with integrands that are directly interpretable as measures of central projections.

2 Preliminaries

Let us begin by presenting notation and terminology that will be used throughout the paper. We use $\langle \cdot, \cdot \rangle$ for the standard inner (dot) product on $\mathbb{R}^d$, and $\| \cdot \| = \sqrt{\langle \cdot, \cdot \rangle}$ for the Euclidean norm. Let O denote the origin, let B^d be the Euclidean unit ball centered at O, and let $S^{d-1} = \partial B^d$ be the unit sphere. Given a linear subspace $E \subset \mathbb{R}^d$ and a set $K \subset \mathbb{R}^d$, let $K \,|\, E$ denote the orthogonal projection of K onto E.

A *convex body* in $\mathbb{R}^d$ is a compact convex set with nonempty interior. Given a convex set K, we denote its boundary and interior by ∂K and $\mathrm{int}(K)$, respectively. For $\alpha \geq 0$, αK denotes the dilation of K by factor α about the origin, and for $x \in \mathbb{R}^d$, $K + x$ denotes the translate of K by x. Given a convex body K and a direction $u \in S^{d-1}$, the *support function* of K is $h_K(u) = \sup\{\langle u, x \rangle : x \in K\}$, and the corresponding supporting hyperplane is

$$H_K(u) \;=\; \{x \in \mathbb{R}^d : \langle u, x \rangle = h_K(u)\}.$$

For $1 \leq k \leq d$, let λ_k denote the k-dimensional Hausdorff measure on $\mathbb{R}^d$. In particular, λ_d is the Lebesgue measure, and on any C^1 k-dimensional submanifold of $\mathbb{R}^d$, λ_k agrees with the usual k-dimensional surface area. Let σ denote the standard rotation-invariant surface measure on S^{d-1}. Finally, let $\omega_d = \lambda_d(B^d)$.

Given two C^1 hypersurfaces $\Phi, \Psi \subset \mathbb{R}^d$ and a differentiable map $f : \Phi \to \Psi$, the Jacobian of f at $x \in \Phi$ is the local area-stretch factor induced by the differential $Df(x)$ on the tangent space of Φ at x. Equivalently, it is the factor appearing in the change-of-variables formula for surface integrals (see, for example, [15]).

Given two convex sets $A, B \subset \mathbb{R}^d$, their *Minkowski sum* is

$$A + B \;=\; \{a + b \,:\, a \in A,\; b \in B\}.$$

Given a convex body $K \subset \mathbb{R}^d$, its *difference body* is

$$\Delta(K) \;=\; K + (-K),$$

which is centrally symmetric (see Figure 2(a)).

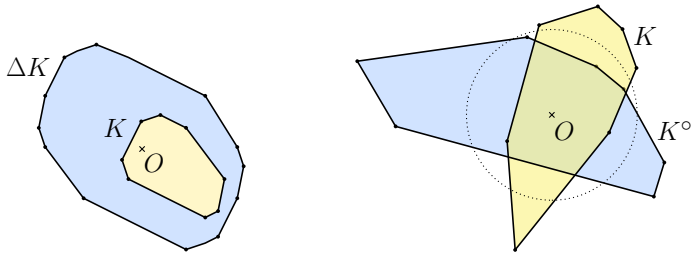

Figure 2 (a) The difference body of a convex body and (b) the polar of a convex body.

For any nonempty set $K \subset \mathbb{R}^d$, its *polar*, denoted K°, is defined by

$$K^\circ \;=\; \{y \in \mathbb{R}^d \,:\, \langle x, y\rangle \le 1 \text{ for all } x \in K\}$$

(see Figure 2(b)). The polar has several standard properties (see, for example, Barvinok [11]). It is always closed, convex, and contains the origin. If $O \in \mathrm{int}(K)$, then K° is bounded. Moreover, if K is a convex body with $O \in \mathrm{int}(K)$, then K° is also a convex body, and $(K^\circ)^\circ = K$. Finally, polarity reverses inclusion: if $K_1 \subseteq K_2$, then $K_2^\circ \subseteq K_1^\circ$.

For a linear subspace $E \subseteq \mathbb{R}^d$ and a nonempty set $G \subseteq E$, define the polar of G in E by

$$G^{\circ_E} \;=\; \{y \in E : \langle x, y\rangle \le 1,\; \text{for all } x \in G\}.$$

The next lemma is the standard duality between sections and projections, stated in the form needed later. A proof may be found in [33, Theorem 2.2.9 and Corollary 2.2.10].

▶ **Lemma 2.1** (Projection-Section Duality). *Let $K \subseteq \mathbb{R}^d$ be a convex body such that $O \in \mathrm{int}(K)$, and let E be a linear subspace of $\mathbb{R}^d$. Then the polar in E of the section $K \cap E$ equals the orthogonal projection of K° onto E. That is,*

$$(K \cap E)^{\circ_E} \;=\; K^\circ \,\big|\, E.$$

2.1 The Funk and Hilbert Geometries

In this section, we introduce the Funk and Hilbert geometries and the related Finsler structures used to define volume and surface area. Let K be a convex body in $\mathbb{R}^d$. For any two distinct points $x, y \in \mathrm{int}(K)$, let y' denote the point where the ray directed from x through y intersects ∂K (see Figure 3(a)). The *Funk distance* with respect to K, denoted $\mathrm{dist}_K^F(\cdot,\cdot)$, is defined to be

$$\mathrm{dist}_K^F(x, y) \;=\; \ln \frac{\|x - y'\|}{\|y - y'\|},$$

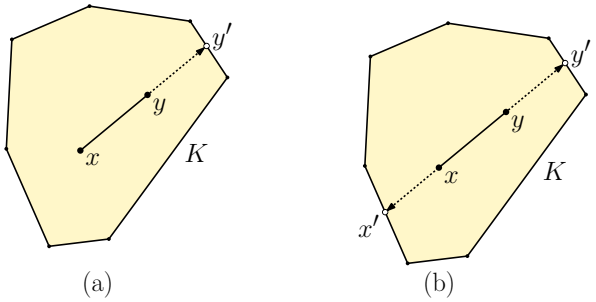

Figure 3 (a) The Funk distance and (b) the Hilbert distance.

where $\mathrm{dist}^F_K(x,y) = 0$ if $x = y$. The Funk distance is nonnegative, asymmetric, satisfies the triangle inequality, and is invariant under invertible affine transformations [27]. Because of its asymmetry, this is often referred to as a weak metric or quasi-metric.

The *Hilbert distance* with respect to K, denoted $\mathrm{dist}^H_K(\cdot,\cdot)$, is the symmetrization of the Funk distance. Letting x' denote the point where the directed ray from y through x intersects ∂K, it is defined to be

$$\mathrm{dist}^H_K(x,y) \;=\; \frac{1}{2}\Big(\mathrm{dist}^F_K(x,y) + \mathrm{dist}^F_K(y,x)\Big) \;=\; \frac{1}{2}\ln\frac{\|y-x'\|}{\|x-x'\|}\frac{\|x-y'\|}{\|y-y'\|}$$

(see Figure 3(b)). It is well known that this is a metric (symmetric, positive except when $x = y$, and satisfying the triangle inequality). Observe that the quantity in the logarithm is the cross ratio $(x, y; y', x')$, and hence the Hilbert distance is invariant under invertible projective transformations.

Before defining volume and surface areas, let us first introduce some related concepts. Given a convex body D in $\mathbb{R}^d$ with $O \in \mathrm{int}(D)$ and $u \in \mathbb{R}^d$, the *Minkowski functional* (or *gauge*) induced by D is defined by

$$\|u\|_D \;=\; \inf\{\lambda > 0 \,:\, u \in \lambda D\}.$$

This functional is positively homogeneous and subadditive. If D is centrally symmetric, then $\|\cdot\|_D$ is a norm in the usual sense; in general, it is the Minkowski functional (or gauge) of D. A *Finsler metric* on a manifold is a continuous function on its tangent bundle, whose restriction to each tangent space is such a gauge. It is well known that both the Funk and Hilbert geometries induce a Finsler structure [34].

To define the Finsler structure for Funk, consider any $x \in \mathrm{int}(K)$. Identify the tangent space at x, denoted T_x, with $\mathbb{R}^d$. For each nonzero $v \in T_x$, let x^+ denote the point where the ray emanating from x in direction v intersects ∂K (see Figure 4(a)), and let t be a positive scalar such that $x + tv = x^+$. The resulting Finsler gauge at x is defined as

$$\mathrm{Finsler}^F_K(x,v) \;=\; \frac{1}{t} \quad\text{and}\quad \mathrm{Finsler}^F_K(x,0) \;=\; 0.$$

This defines a gauge whose unit ball, denoted $B^F_K(x)$, is $K - x$. Thus, the ball is just a translate of K such that x coincides with the origin.

The Finsler structure for Hilbert is a symmetric variant of the Funk Finsler structure. For each $x \in \mathrm{int}(K)$ and each nonzero vector $v \in T_x$, let x^+ be as before, and let x^- be the point where the ray emanating from x in direction $-v$ intersects ∂K (see Figure 4(a)). Let t^+ and t^- be positive scalars such that $x + t^+v = x^+$ and $x - t^-v = x^-$. Then

$$\mathrm{Finsler}^H_K(x,v) \;=\; \frac{1}{2}\left(\frac{1}{t^+} + \frac{1}{t^-}\right) \quad\text{and}\quad \mathrm{Finsler}^H_K(x,0) \;=\; 0.$$

Since this gauge is symmetric, it is a norm. Its unit ball, denoted $B^H_K(x)$, is centrally symmetric (see Figure 4(b)). If K is a polytope, then so is $B^H_K(x)$.

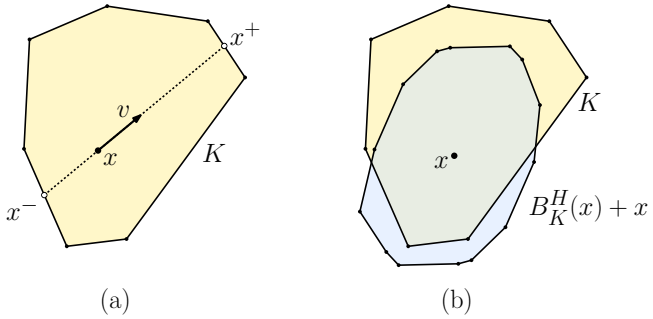

Figure 4 (a) The Finsler structure and (b) the Finsler ball for Hilbert (recentered about x).

The following lemma relates the polar of the Finsler ball in the Hilbert metric to the difference body of $(K - x)^\circ$. The lemma is a straightforward consequence of the Finsler interpretation of the Hilbert metric (see, e.g., [26, 31]).

▶ **Lemma 2.2.** *Given a convex body $K \subset \mathbb{R}^d$ and $x \in \text{int}(K)$, $B_K^H(x)^\circ = \frac{1}{2}\Delta((K - x)^\circ)$.*

2.2 Holmes–Thompson Volume and Surface Area

There are several ways to define volume and surface area in Finsler spaces. The volume of a subset $G \subset \text{int}(K)$ arises by integrating the weighted contributions of volume elements over G, where the weight of each element depends on the local geometry, as expressed through the Finsler ball. Intuitively, as the size of the Finsler ball decreases, the relative importance of the associated Lebesgue volume element increases. Due to the reciprocal nature of polarity, as the volume of the Finsler ball decreases, the volume of its polar increases. This gives rise to the following definitions, due to Holmes and Thompson [19].

Let us first consider the Funk geometry. Given a convex body K and $x \in \text{int}(K)$, the Holmes–Thompson volume element is obtained by scaling the Lebesgue volume element $d\lambda_d(x)$ by the ratio of the Lebesgue volume of the polar of the Funk Finsler ball, $\lambda_d\left(B_K^F(x)^\circ\right)$, and the Lebesgue volume of the unit Euclidean ball, ω_d [17, 19]. Define the *Funk volume element* to be

$$d\,\text{vol}_K^F(x) \;=\; \frac{1}{\omega_d}\lambda_d\left(B_K^F(x)^\circ\right)\, d\lambda_d(x).$$

Recall that $B_K^F(x) = K - x$. The *Funk volume* of any convex body $G \subset \text{int}(K)$ is

$$\text{vol}_K^F(G) \;=\; \int_{x\in G} d\,\text{vol}_K^F(x).$$

The Holmes–Thompson surface area in the Funk geometry is defined analogously. At each smooth boundary point $x \in \partial G$, let T_x denote the tangent space to ∂G at x, viewed as a linear subspace of $\mathbb{R}^d$ and equipped with the induced Hausdorff measure. The *Funk surface-area element* is given by

$$d\,\text{area}_K^F(x) \;=\; \frac{1}{\omega_{d-1}}\lambda_{d-1}\left(\left(B_K^F(x) \cap T_x\right)^{\circ_{T_x}}\right)\, d\lambda_{d-1}(x).$$

By Lemma 2.1, we can express this alternatively in terms of the projected polar as

$$d\,\text{area}_K^F(x) \;=\; \frac{1}{\omega_{d-1}}\lambda_{d-1}\left(B_K^F(x)^\circ \,\middle|\, T_x\right)\, d\lambda_{d-1}(x).$$

Since $B_K^F(x) = K - x$, this is exactly

$$d\,\mathrm{area}_K^F(x) \;=\; \frac{1}{\omega_{d-1}}\lambda_{d-1}\left((K-x)^\circ \;\middle|\; T_x\right)\, d\lambda_{d-1}(x). \tag{2}$$

The *Funk surface area* of $G \subset \mathrm{int}(K)$ is

$$\mathrm{area}_K^F(G) \;=\; \int_{x\in\partial G} d\,\mathrm{area}_K^F(x).$$

The Holmes–Thompson volume and surface area in the Hilbert geometry are defined analogously, replacing the Funk Finsler ball $B_K^F(x)$ by the Hilbert Finsler ball $B_K^H(x)$. We denote the resulting quantities by $\mathrm{vol}_K^H(G)$ and $\mathrm{area}_K^H(G)$.

Faifman showed that the Hilbert- and Funk-based volumes and surface areas are related up to factors that depend on dimension.

▶ **Lemma 2.3** (Faifman [16]). *Let $K \subset \mathbb{R}^d$ be a convex body, let $G \subset \mathrm{int}(K)$ be a convex body, and let $\beta(d) = \binom{2d}{d}/2^d$. Then*

$$\begin{aligned}\mathrm{vol}_K^F(G) \;&\le\; \mathrm{vol}_K^H(G) \;\le\; \beta(d)\cdot \mathrm{vol}_K^F(G) \qquad \textit{and}\\ \mathrm{area}_K^F(G) \;&\le\; \mathrm{area}_K^H(G) \;\le\; \beta(d-1)\cdot \mathrm{area}_K^F(G).\end{aligned}$$

2.3 Cones

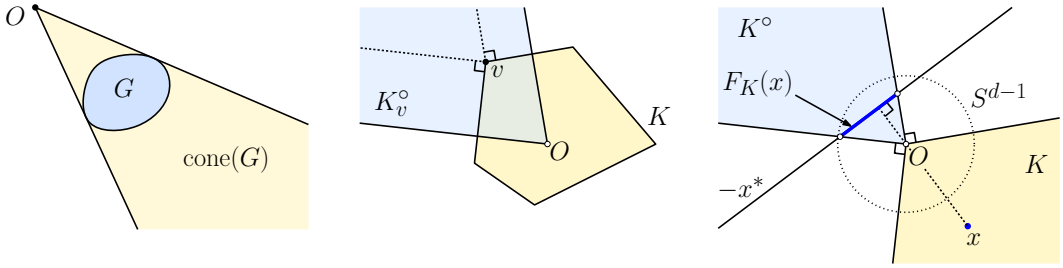
The standard Cauchy formula relies on orthogonal projections. We shall see that in the context of the Funk geometry induced by a convex body, the appropriate generalization utilizes central projections towards the boundary of the body. Such projections naturally involve cones. Throughout this paper, a *cone* in $\mathbb{R}^d$ denotes a full-dimensional convex set closed under positive scaling (i.e., if x is in the set, then λx is in the set for all $\lambda \ge 0$). We assume our cones are *pointed*, meaning that they contain no lines. This implies that each cone has a unique *apex* at the origin.

The *conical hull* of a convex set $G \subset \mathbb{R}^d$, denoted $\mathrm{cone}(G)$, is the smallest cone containing G, that is,

$$\mathrm{cone}(G) \;=\; \{\gamma x \,:\, x \in G \text{ and } \gamma \ge 0\}$$

(see Figure 5(a)). Let $K \subset \mathbb{R}^d$ be a closed, full-dimensional convex set. For any boundary point $v \in \partial K$, the *normal cone* at v consists of all outer normal vectors to K at v:

$$\{u \in \mathbb{R}^d : \langle u, x - v\rangle \le 0, \text{ for all } x \in K\}.$$



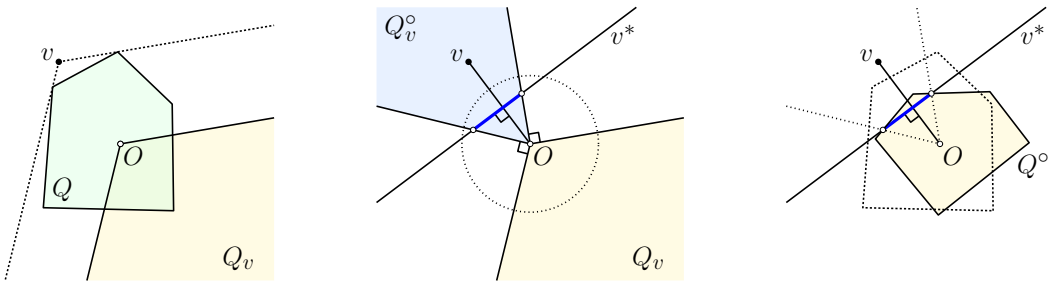
(see Figure 5(b)). In the cases of primary interest to us, such as when v is a vertex of a polytope or the apex of a pointed cone, the tangent cone $K_v = \mathrm{cone}(K - v)$ is pointed. In these settings, the normal cone is full-dimensional and coincides with the polar cone K_v°.

For any nonzero vector $z \in \mathbb{R}^d$, we denote the associated *dual hyperplane* by

$$z^* = \{u \in \mathbb{R}^d \,:\, \langle u, z\rangle = 1\}.$$

For a pointed cone $K \subset \mathbb{R}^d$ and a vector $x \in \mathrm{int}(K)$, we define the *dual cross-section* $F_K(x)$ to be the intersection of the polar cone K° with the dual hyperplane associated with $-x$ (see Figure 5(c)). That is,

$$F_K(x) \;:=\; K^\circ \cap -x^* \;=\; K^\circ \cap (-x)^* \;=\; \{y \in K^\circ : \langle x, y\rangle = -1\}. \tag{3}$$



(a) (b) (c)

Figure 5 (a) The cone cone(G), (b) the normal cone K_v°, and (c) $F_K(x)$.

Geometrically, this is the slice of the polar cone by a hyperplane orthogonal to the direction x. Since x lies in the interior of K, and every vector in K° has nonpositive inner product with every vector in K, this hyperplane intersects K° in a bounded set.

Next, we establish a simple technical lemma relating the polar of a body to the polar of its subtended cones. This result allows us to characterize the facets of the polar polytope using local cone geometry.

▶ **Lemma 2.4.** *Let $Q \subset \mathbb{R}^d$ be a convex body containing the origin in its interior. Let $v \in \mathbb{R}^d \setminus \text{int}(Q)$. Let $Q_v = \text{cone}(Q - v)$ be the cone subtended by Q at v (see Figure 6(a)). Then the intersection of the polar cone Q_v° with the dual hyperplane $v^* = \{y \in \mathbb{R}^d : \langle v, y\rangle = 1\}$ coincides with the slice of the polar body Q° by v^*, that is, $Q_v^\circ \cap v^* = Q^\circ \cap v^*$ (see Figure 6(b) and (c)).*

(a) (b) (c)

Figure 6 (a) The cone Q_v, (b) $Q_v^\circ \cap v^*$, and (c) $Q^\circ \cap v^*$.

Proof. By definition, a vector $y \in Q_v^\circ$ if and only if $\langle z, y\rangle \leq 0$ for all $z \in Q_v$. Since Q_v is the conical hull of $Q - v$, this condition is equivalent to:

$$\langle x - v, y\rangle \;\leq\; 0, \quad \forall x \in Q.$$

Restricting our attention to the hyperplane v^*, where $\langle v, y\rangle = 1$, this inequality becomes:

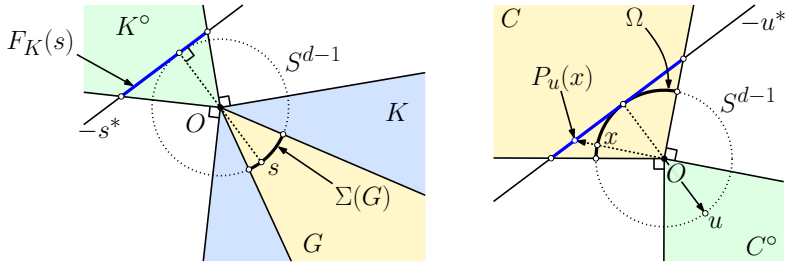
$$\langle x, y\rangle - \langle v, y\rangle \leq 0 \iff \langle x, y\rangle - 1 \leq 0 \iff \langle x, y\rangle \leq 1, \quad \forall x \in Q.$$

The condition $\langle x, y\rangle \leq 1$ for all $x \in Q$ is exactly the definition of the polar body Q°. Thus, restricted to the hyperplane v^*, the condition for membership in the polar cone is identical to the condition for membership in the polar body. ◀

When applied to the vertices of a polytope, this lemma provides a functional characterization of the boundary of the polar body. Recall that for a polytope K with $O \in \operatorname{int}(K)$, the facets of the polar body K° are in one-to-one correspondence with the vertex set $V(K)$ [35]. Specifically, for each vertex $v \in V(K)$, the dual facet is the intersection of K° with the supporting hyperplane v^*. Lemma 2.4 implies that this facet is exactly $K_v^\circ \cap v^*$, which matches the definition of the dual cross-section $F_{K_v}(-v)$.

▶ **Corollary 2.5.** *Let $K \subset \mathbb{R}^d$ be a convex polytope with $O \in \operatorname{int}(K)$. For each vertex $v \in V(K)$, the facet of K° dual to v, denoted F_v, is given by*

$$F_v \;=\; K_v^\circ \cap v^* \;=\; F_{K_v}(-v).$$



Furthermore, $\partial K^\circ = \bigcup_{v \in V(K)} F_v$.

Extending the definition of Funk volume from bounded convex bodies to unbounded cones requires care. If G and K are pointed cones in $\mathbb{R}^d$ with $(G \setminus \{O\}) \subset \operatorname{int}(K)$, the standard Funk distance is degenerate, and the classical volume is infinite. However, the projective nature of Funk geometry allows us to define a meaningful volume for G relative to K by considering cross-sections. Faifman [16] demonstrated that the Funk geometry is essentially projective. A key consequence is that the Holmes–Thompson volume of the section $G \cap H$, measured with respect to the ambient section $K \cap H$, is invariant to the choice of the hyperplane H, provided $K \cap H$ is bounded. We call such a hyperplane *admissible*.

This invariance implies that the volume is intrinsic to the nested cone structure itself. We define the *cone Funk volume* of G relative to K by the integral

$$\operatorname{vol}_K^F(G) \;:=\; \frac{1}{\omega_{d-1}} \int_{\Sigma(G)} \lambda_{d-1}(F_K(s))\, d\sigma(s), \qquad \text{where } \Sigma(G) := S^{d-1} \cap G \tag{4}$$

(see Figure 7(a)). In the full version of the paper [9], we show that this integral coincides with $\operatorname{vol}_{K\cap H}^F(G \cap H)$ for any admissible hyperplane H, thus justifying this terminology.

(a) (b)

Figure 7 (a) Defining $\operatorname{vol}_K^F(G)$ and (b) the gnomonic projection.

When dealing with spherical cross-sections of cones, it is useful to relate their spherical measures to the Euclidean measures of corresponding hyperplane sections. Let $C \subset \mathbb{R}^d$ be a pointed cone, let $\Omega = C \cap S^{d-1}$, and let $u \in S^{d-1}$ satisfy $\langle x, u \rangle < 0$ for all $x \in \Omega$. The associated gnomonic projection maps Ω onto the hyperplane section $-u^* \cap C$ (see Figure 7(b)). A straightforward Jacobian computation yields the following lemma (see, e.g., [16, Lemma 3.10]).

▶ **Lemma 2.6** (Cone gnomonic projection). *Let $C \subset \mathbb{R}^d$ be a pointed cone, let $\Omega = C \cap S^{d-1}$, and let $u \in S^{d-1}$ satisfy $\langle x, u\rangle < 0$, for all $x \in \Omega$ (equivalently, $u \in \mathrm{int}(C^\circ)$). Define*

$$P_u(x) \;:=\; -\frac{x}{\langle x, u\rangle} \qquad (x \in \Omega).$$

Then $P_u(\Omega) = -u^* \cap C$, and

$$\lambda_{d-1}(P_u(\Omega)) \;=\; \int_\Omega |\,\langle x, u\rangle\,|^{-d}\, d\sigma(x).$$

3 Vertex Decomposition for Convex Polytopes

In this section, we establish a discrete surface area formula for the case where K is a convex polytope. Our result provides a vertex-based decomposition of the Funk surface area similar in spirit to that of Alexander *et al.* [5] in the planar Hilbert geometry, but derived by a distinct approach that applies in arbitrary dimensions.

Our proof proceeds by decomposing the Funk surface area of G into local contributions associated with the vertices of the ambient polytope K. For each vertex $v \in V(K)$, let $K_v = \mathrm{cone}(K - v)$ and $G_v = \mathrm{cone}(G - v)$ denote the local cones subtended at v. We will show that the total Funk surface area of G is the sum of the Funk volumes of the cones G_v relative to K_v. We begin with a lemma that expresses the Funk volume of $\mathrm{cone}(G)$ relative to a pointed cone K as a boundary integral involving the projected areas of the dual cross-sections $F_K(x)$. In the statement below, T_x denotes the tangent space of G at x.

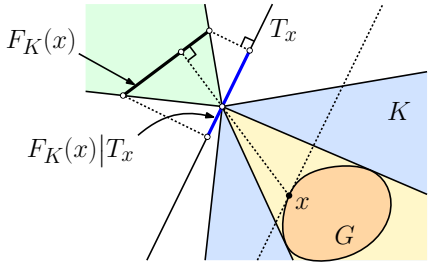


Figure 8 Lemma 3.1.

▶ **Lemma 3.1.** *Let $K \subset \mathbb{R}^d$ be a pointed cone and let $G \subset \mathrm{int}(K)$ be a convex body. Then*

$$2 \cdot \mathrm{vol}_K^F(\mathrm{cone}(G)) \;=\; \frac{1}{\omega_{d-1}} \int_{\partial G} \lambda_{d-1}\big(F_K(x) \,\big|\, T_x\big)\, d\lambda_{d-1}(x)$$

(see Figure 8).

The next step in our derivation utilizes the dual facet characterization (Corollary 2.5) to decompose the projection of the polar body into a sum over its facets.

▶ **Lemma 3.2.** *Let $K \subset \mathbb{R}^d$ be a convex polytope. For any $x \in \mathrm{int}(K)$ and any $(d-1)$-dimensional linear subspace T,*

$$2\lambda_{d-1}\big((K - x)^\circ \,\big|\, T\big) \;=\; \sum_{v \in V(K)} \lambda_{d-1}\big(F_{K_v}(x - v) \,\big|\, T\big)$$

(see Figures 9(a) and (b)).

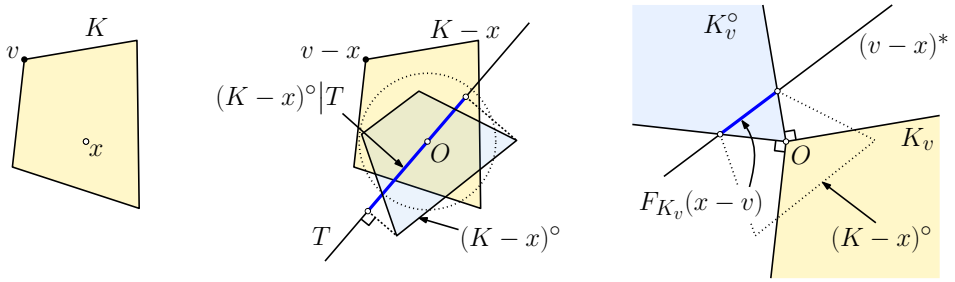

Figure 9 Lemma 3.2 and its proof.

The proofs of Lemmas 3.1 and 3.2 appear in the full version of the paper [9].
We are now ready to prove the vertex decomposition theorem from Section 1.

Proof. (Of Theorem 1.2) For each $v \in V(K)$, applying Lemma 3.1 to the pair $(K_v, G - v)$ yields

$$2 \cdot \mathrm{vol}^F_{K_v}(G_v) \;=\; \frac{1}{\omega_{d-1}} \int_{\partial(G-v)} \lambda_{d-1}\left(F_{K_v}(x') \,\middle|\, T_{x'}\right)\, d\lambda_{d-1}(x').$$

Perform the change of variables $x = x' + v$. Then $\partial(G - v)$ maps to ∂G, and the tangent spaces are identified as $T_{x'} = T_x$, yielding

$$2 \cdot \mathrm{vol}^F_{K_v}(G_v) \;=\; \frac{1}{\omega_{d-1}} \int_{\partial G} \lambda_{d-1}\left(F_{K_v}(x - v) \,\middle|\, T_x\right)\, d\lambda_{d-1}(x).$$

Summing over $v \in V(K)$ and using linearity of integration, we have

$$2 \sum_{v \in V(K)} \mathrm{vol}^F_{K_v}(G_v) \;=\; \frac{1}{\omega_{d-1}} \int_{\partial G} \left[\sum_{v \in V(K)} \lambda_{d-1}\left(F_{K_v}(x - v) \,\middle|\, T_x\right) \right] d\lambda_{d-1}(x).$$

By Lemma 3.2, the term in brackets is equal to $2\,\lambda_{d-1}((K - x)^\circ \,|\, T_x)$. Substituting this and dividing by 2 yields

$$\sum_{v \in V(K)} \mathrm{vol}^F_{K_v}(G_v) \;=\; \frac{1}{\omega_{d-1}} \int_{\partial G} \lambda_{d-1}\left((K - x)^\circ \,\middle|\, T_x\right)\, d\lambda_{d-1}(x).$$

By Eq. (2), the right-hand side is exactly $\mathrm{area}^F_K(G)$. ◀

4 Cauchy-Type Formulas for General Convex Bodies

We now derive the general Cauchy formula from the polytope case. The key additional ingredient is a representation of the Funk volume of a cone as an average of the areas of its central shadows. Combined with Theorem 1.2, this yields the formula for polytopal K, and the general case then follows by approximation.

▶ **Lemma 4.1** (Funk Volume of a Cone). *Let K and G be pointed cones in $\mathbb{R}^d$ with $(G \setminus \{O\}) \subset \mathrm{int}(K)$. Let $U = K^\circ \cap S^{d-1}$ (the spherical image of the polar cone), and for $u \in U$, let $S(u) = -u^* \cap G$ (see Figure 10(a)). Then*

$$\mathrm{vol}^F_K(G) \;=\; \frac{1}{\omega_{d-1}} \int_U \lambda_{d-1}(S(u))\, d\sigma(u). \tag{5}$$

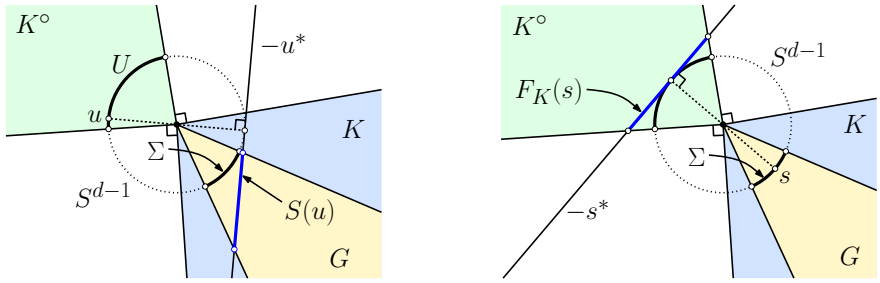

Figure 10 Lemma 4.1 and its proof.

Proof. Let $\Sigma = S^{d-1} \cap G$ and define the double integral

$$I \;=\; \frac{1}{\omega_{d-1}} \int_U \int_\Sigma |\langle s, u\rangle|^{-d}\, d\sigma(s)\, d\sigma(u).$$

Since the integrand is nonnegative, by Tonelli's theorem [28, Theorem 8.8(a)], we may integrate in either order. We will show that one order leads to the right-hand side of Eq. (5), and the other leads to the left-hand side.

First fix $u \in U$ and consider the inner integral in s. Since $u \in K^\circ$ and $(G \setminus \{O\}) \subset \mathrm{int}(K)$, we have $\langle s, u\rangle < 0$ for all $s \in \Sigma$. Applying Lemma 2.6 to the cone G with center u, we obtain

$$\int_\Sigma |\langle s, u\rangle|^{-d}\, d\sigma(s) \;=\; \lambda_{d-1}(-u^* \cap G) \;=\; \lambda_{d-1}(S(u))$$

(see Figure 10(a)). Substituting into I yields the right-hand side of Eq. (5).

Next fix $s \in \Sigma$ and consider the inner integral in u. Since $s \in \Sigma \subset \mathrm{int}(K)$ and $U = K^\circ \cap S^{d-1}$, we have $\langle u, s\rangle < 0$ for all $u \in U$. Applying Lemma 2.6 to the cone K° with center s, we obtain

$$\int_U |\langle u, s\rangle|^{-d}\, d\sigma(u) \;=\; \lambda_{d-1}(-s^* \cap K^\circ) \;=\; \lambda_{d-1}(F_K(s))$$

(see Figure 10(b)). Substituting into I, we obtain

$$I \;=\; \frac{1}{\omega_{d-1}} \int_\Sigma \lambda_{d-1}(F_K(s))\, d\sigma(s).$$

By the definition of Funk volume (Eq. (4)), this expression is exactly $\mathrm{vol}_K^F(G)$, which matches the left-hand side of Eq. (5). ◀

With the cone formula established, we now derive the Cauchy formula for arbitrary convex bodies. Let $K \subset \mathbb{R}^d$ be a convex body and let $G \subset \mathrm{int}(K)$ be a convex body. For almost every direction $u \in S^{d-1}$, the support set $K \cap H_K(u)$ is a singleton; denote its unique point by $v_K(u)$ [32, Theorem 2.2.11]. On the exceptional null set, choose $v_K(u)$ arbitrarily in $K \cap H_K(u)$. For each $u \in S^{d-1}$, define the central shadow by

$$S_K(G, u) \;:=\; -u^* \cap \mathrm{cone}(G - v_K(u))$$

(recall Figure 1). We are now ready to prove Theorem 1.1.

Proof of Theorem 1.1. Assume first that K is a convex polytope. For each vertex $v \in V(K)$, let

$$U_v \;:=\; K_v^\circ \cap S^{d-1}$$

denote the spherical image of the normal cone at v. The collection $\{U_v\}_{v\in V(K)}$ forms a partition of S^{d-1} up to a set of σ-measure zero. For almost every $u \in U_v$, the support point of K in direction u is unique and equals v. Recalling that $G_v = \mathrm{cone}(G - v)$, it follows that for almost every $u \in U_v$,

$$S_{K_v}(G_v, u) \;=\; S_K(G, u).$$

Therefore, by Theorem 1.2 and Lemma 4.1, we obtain

$$\begin{aligned}
\mathrm{area}_K^F(G) \;&=\; \sum_{v\in V(K)} \mathrm{vol}_{K_v}^F(G_v) \\
&=\; \sum_{v\in V(K)} \frac{1}{\omega_{d-1}} \int_{U_v} \lambda_{d-1}(S_{K_v}(G_v, u))\, d\sigma(u) \\
&=\; \frac{1}{\omega_{d-1}} \sum_{v\in V(K)} \int_{U_v} \lambda_{d-1}(S_K(G, u))\, d\sigma(u) \\
&=\; \frac{1}{\omega_{d-1}} \int_{S^{d-1}} \lambda_{d-1}(S_K(G, u))\, d\sigma(u).
\end{aligned}$$

This establishes the result when K is a polytope. The general case follows by approximating K in the Hausdorff metric by convex polytopes K_m, applying the polytopal identity to K_m, and passing to the limit using the continuity of polarity and the Dominated Convergence Theorem; details appear in the full version [9]. ◀

From a computational perspective, when K is a polytope, the preceding proof yields a natural Monte-Carlo estimator. The identity

$$\mathrm{area}_K^F(G) \;=\; \sum_{v\in V(K)} \frac{1}{\omega_{d-1}} \int_{U_v} \lambda_{d-1}(S_{K_v}(G_v, u))\, d\sigma(u)$$

decomposes the surface area into local contributions indexed by the vertices of K. The sampling distribution depends only on the spherical normal-cone decomposition $\{U_v\}_{v\in V(K)}$, while the sampled quantity is the $(d-1)$-dimensional volume of the corresponding central shadow. Thus one may sample a vertex v with probability proportional to $\sigma(U_v)$ and then sample a direction u uniformly from U_v, for example by triangulating the normal cone into simplicial cones. This gives an unbiased estimator whose evaluation uses only geometry local to the chosen vertex. In particular, it avoids direct use of the Holmes–Thompson definition through Eq. (2), which would require integrating

$$\lambda_{d-1}\big((K - x)^\circ \,\big|\, T_x\big)$$

over all $x \in \partial G$.

Using Lemma 2.6, we can rewrite the shadow integral in Theorem 1.1 in terms of the spherical cross-sections of the subtended cones. For any $v \in \partial K$, let

$$\Sigma(G, v) \;:=\; S^{d-1} \cap \mathrm{cone}(G - v)$$

denote the spherical cross-section of the cone subtended by G at v. The following corollary gives a double-integral representation of the Funk surface area.

▶ **Corollary 4.2** (Double-Integral Formula for Funk Area). *Let G and K be convex bodies in $\mathbb{R}^d$ with $G \subset \mathrm{int}(K)$. Then*

$$\mathrm{area}_K^F(G) \;=\; \frac{1}{\omega_{d-1}} \int_{S^{d-1}} \int_{\Sigma(G, v_K(u))} |\langle s, u\rangle|^{-d}\, d\sigma(s)\, d\sigma(u).$$

Proof. By Theorem 1.1,

$$\mathrm{area}_K^F(G) \;=\; \frac{1}{\omega_{d-1}} \int_{S^{d-1}} \lambda_{d-1}(S_K(G,u))\, d\sigma(u).$$

For each $u \in S^{d-1}$,

$$S_K(G,u) \;=\; -u^* \cap \mathrm{cone}(G - v_K(u)).$$

Since $v_K(u)$ is a support point of K in direction u and $G \subset \mathrm{int}(K)$, we have $\langle s, u\rangle < 0$ for all $s \in \Sigma(G, v_K(u))$. Applying Lemma 2.6 with $C = \mathrm{cone}(G - v_K(u))$ and center u, we obtain

$$\lambda_{d-1}(S_K(G,u)) \;=\; \int_{\Sigma(G, v_K(u))} |\langle s, u\rangle|^{-d}\, d\sigma(s).$$

Substituting this into the preceding formula completes the proof. ◀

We now recast Corollary 4.2 as a Crofton formula on oriented lines. For each $u \in S^{d-1}$, choose $v_K(u) \in K \cap H_K(u)$ as above, and let

$$\mathcal{P} \;:=\; \{(u,s) \in S^{d-1} \times S^{d-1} ST\, \langle s, u\rangle < 0\}.$$

For $(u,s) \in \mathcal{P}$, let $\ell_K^+(u,s)$ denote the oriented line through $v_K(u)$ in direction s. For fixed $u \in S^{d-1}$, a direction $s \in S^{d-1}$ with $\langle s, u\rangle < 0$ belongs to $\Sigma(G, v_K(u))$ if and only if the ray from $v_K(u)$ in direction s meets G. Thus Corollary 4.2 can be rewritten as follows.

▶ **Lemma 4.3** (Funk–Crofton formula for oriented lines). *Let G and K be convex bodies in $\mathbb{R}^d$ with $G \subset \mathrm{int}(K)$. Then*

$$\mathrm{area}_K^F(G) \;=\; \frac{1}{\omega_{d-1}} \int_{\mathcal{P}} \mathbf{1}_{\{\ell_K^+(u,s) \cap G \neq \emptyset\}}\, |\, \langle s, u\rangle\, |^{-d}\, d\sigma(s)\, d\sigma(u).$$

Replacing each oriented line by its underlying unoriented line, we obtain the following K-dependent parameter-space Crofton formula.

▶ **Theorem 4.4** (Funk–Crofton formula for unoriented lines). *Let G and K be convex bodies in $\mathbb{R}^d$ with $G \subset \mathrm{int}(K)$. Then*

$$\mathrm{area}_K^F(G) \;=\; \frac{1}{\omega_{d-1}} \int_{\mathcal{P}} \mathbf{1}_{\{L_K(u,s) \cap G \neq \emptyset\}}\, |\, \langle s, u\rangle\, |^{-d}\, d\sigma(s)\, d\sigma(u),$$

where $L_K(u,s)$ denotes the unoriented line underlying $\ell_K^+(u,s)$.

Proof. Since intersection with G is independent of orientation, the indicator in Lemma 4.3 is unchanged when $\ell_K^+(u,s)$ is replaced by its underlying unoriented line $L_K(u,s)$. ◀

Concluding Remarks and Open Problems

We established an explicit Cauchy-type formula for the Holmes–Thompson surface area in the Funk geometry induced by a convex body $K \subset \mathbb{R}^d$. This formula expresses the surface area of a convex body G as the average, over directions $u \in S^{d-1}$, of the $(d-1)$-dimensional measures of the corresponding central shadows of G (Theorem 1.1). For polytopal K, this identity admits a discrete vertex-based decomposition (Theorem 1.2), and the same framework yields a Crofton-type representation in terms of an explicit measure on the space of unoriented lines intersecting G (Theorem 4.4).

Taken together, these results provide a concrete shadow-averaging principle for surface area in a projective Finsler setting. From a computational perspective, our formulas involve Euclidean $(d-1)$-dimensional volumes of explicitly defined slices or projections, thereby avoiding direct evaluation of the Holmes–Thompson definitions through polars of pointwise Finsler balls. In the polytopal case, the resulting decomposition is especially simple, replacing more combinatorial Crofton descriptions based on pairs of faces by a sum over vertices and normal cones.

Our work raises several natural open problems. A first direction is to develop provably efficient randomized algorithms for estimating Funk surface area from the Cauchy and Crofton formulas, ideally with explicit variance bounds and high-probability guarantees. For polytopal K, this includes efficient sampling from the spherical normal-cone decomposition and efficient evaluation or approximation of the associated central shadows. It would also be interesting to determine to what extent these formulas can serve as practical primitives for geometric computation in Funk- and Hilbert-type domains, in a manner analogous to the role of Cauchy and Crofton formulas in Euclidean stereology, tomography, and randomized surface area estimation.

A second direction is to investigate whether this shadow-based approach extends beyond surface area to higher-order intrinsic quantities, such as the Holmes–Thompson analogs of quermassintegrals or curvature measures. A third is to better understand the relationship with Hilbert geometry, especially by identifying conditions on K under which the Funk formula yields the exact Hilbert surface area beyond the known cases of $d = 2$ and ellipsoids. More generally, it would be interesting to determine how geometric properties of K govern the approximation gap between Hilbert and Funk surface areas.

Abstract

A theorem of Matoušek asserts that for any $k \geq 2$, any set system whose shatter function is $o(n^k)$ enjoys a fractional Helly theorem of order k: in the k-wise intersection hypergraph, positive density implies a linear-size clique. Kalai and Meshulam conjectured a generalization of that phenomenon to *homological shatter functions*. It was verified for set systems with bounded homological shatter functions and whose ground set has a *forbidden homological minor* (which includes $\mathbb{R}^d$ by a homological analogue of the van Kampen-Flores theorem). We present two contributions to this line of research:

- We study homological minors in certain manifolds (possibly with boundary), for which we prove analogues of the van Kampen-Flores theorem and of the Hanani-Tutte theorem.
- We introduce graded analogues of the Radon and Helly numbers of set systems and relate their growth rate to the original parameters. This allows to extend the verification of the Kalai-Meshulam conjecture to sufficiently slowly growing homological shatter functions.

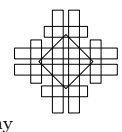
1 Introduction



A classical line of research in discrete geometry investigates generalizations of properties of convex sets beyond convexity, with a particular attention to topological conditions. At least three distinct lines of inquiry emerged:

(A) Generalizing families of convex sets into *acyclic/good covers*, meaning set systems in topological spaces such that every subfamily has empty or homologically/homotopically trivial intersection; an early example is Helly's topological theorem [15], see also the survey of Tancer [34] for an overview.

(B) Reformulating properties of convex sets of $\mathbb{R}^d$ as properties of linear maps into $\mathbb{R}^d$ and investigating their generalizations to *continuous* maps into $\mathbb{R}^d$, typically via theorems of Borsuk-Ulam type; an early example is the topological Radon theorem of Bajmóczy and Bárány [3] and more examples can be found *e.g.* in the survey of Bárány and Soberón [5].

(C) Analyzing set systems whose nerve enjoy properties of nerves of convex sets, like *d-collapsibility* or *d-Lerayness*; an early example is the sharpening of the Fractional Helly theorem by Kalai [18] and the work of Alon et al. [1] establishes several landmark results.

Two decades ago, Kalai and Meshulam [19] proposed conjectures relating approaches (A) and (C), towards what they called a theory of *homological VC dimension*. First, in order to generalize the notion of *good cover*, let us measure the complexity of the intersection patterns of a set system $\mathcal{F}$ in a topological space by its *hth homological shatter function*

$$\phi_{\mathcal{F}}^{(h)}: \left\{ \begin{array}{ccc} \mathbb{N} & \to & \mathbb{N} \cup \{\infty\} \\ k & \mapsto & \sup \left\{ \tilde{\beta}_i \left(\bigcap_{F \in \mathcal{G}} F; \mathbb{Z}_2 \right) \;\middle|\; \mathcal{G} \subset \mathcal{F}, |\mathcal{G}| \leq k, 0 \leq i \leq h \right\}. \end{array} \right. \tag{1}$$

Here h is some fixed parameter, and $\tilde{\beta}_i(\cdot; \mathbb{Z}_2)$ is the ith reduced Betti number with coefficients in $\mathbb{Z}_2$. (The set systems $\mathcal{F}$ with $\phi_{\mathcal{F}}^{(\infty)} \equiv 0$ are the acyclic covers and include good covers and convex sets.) The conjectures are about nerves of set systems whose intersection patterns have polynomially-growing topological complexity. In particular, their combination [19, Conjectures 6 and 7] (see also [13, Conjecture 1.9]) implies that polynomially-growing homological shatter functions give rise to a "*positive density implies big clique*" phenomenon:

▶ **Conjecture 1** (Kalai and Meshulam)**.** *For any $d \in \mathbb{N}$ and any function $\Psi : \mathbb{N} \to \mathbb{N}$ such that $\Psi(n) = O(n^d)$, there exists $\beta : (0,1) \to (0,1)$ such that the following holds. For any $\alpha > 0$ and any set system $\mathcal{F}$ in $\mathbb{R}^d$ with $\phi_{\mathcal{F}}^{(d)} \leq \Psi$, if a proportion α of the $(d+1)$-element subsets of $\mathcal{F}$ have nonempty intersection, then some $\beta(\alpha)|\mathcal{F}|$ members of $\mathcal{F}$ have a point in common.*

Such conditions that a positive density of d-faces in the nerve implies the existence of a linear-size face is called a *fractional Helly theorem* (see Section 1.1.1).

Conjecture 1 is a topological analogue of a theorem of Matoušek [25] which asserts that every set system with polynomial (combinatorial) shatter function enjoys a fractional Helly theorem.

Conjecture 1 was confirmed for functions Ψ that are bounded ([13, Corollary 1.3], building on [16, 17, 28]). The main contribution of the present paper is to extend that confirmation to some diverging homological shatter functions and to set systems on certain manifolds.

1.1 Context and motivation

Before we state our results precisely (in Section 1.2) let us provide some context and motivation, as well as introduce some necessary terminology.

1.1.1 Combinatorial background: convexity parameters of set systems

The classical theorems of Helly, Radon and Carathéodory have initiated a rich theory of the combinatorial properties of convexity, whose landmarks include the centerpoint theorem, Tverberg's theorem, the colorful Helly and Carathéodory theorems, the fractional Helly theorem, the selection lemma, the weak ε-net theorem, the (p,q)-theorem, etc. We refer the interested reader to the monograph of Bárány [4] and the textbook of Matoušek [22]. These classical convexity theorems have algorithmic consequences for instance in optimization and geometric data analysis [8, § 6 – 7] or in property testing [7], and one motivation for their extension beyond the convex setting is that several of these benefits generalize as well [24, 11].

We can associate to any set system $\mathcal{F}$ with ground set X some parameters inspired by convexity properties, for instance:

- The *Helly number* $\mathrm{h}_{\mathcal{F}}$ of $\mathcal{F}$ is the smallest integer h with the following property: If in a finite subfamily $\mathcal{G} \subset \mathcal{F}$, every h members of $\mathcal{G}$ intersect, then $\mathcal{G}$ has nonempty intersection. If no such h exists, we set $\mathrm{h}_{\mathcal{F}} = \infty$.

- The *Radon number* $\mathrm{r}_{\mathcal{F}}$ of $\mathcal{F}$ is the smallest integer r such that every r-element subset $S \subset X$ can be partitioned into two nonempty parts $S = P_1 \sqcup P_2$ such that $\mathrm{conv}_{\mathcal{F}}(P_1) \cap \mathrm{conv}_{\mathcal{F}}(P_2) \neq \emptyset$. (The set $\mathrm{conv}_{\mathcal{F}}(P)$, the *$\mathcal{F}$-convex hull* of a subset $P \subset X$, is the intersection of all the members of $\mathcal{F}$ that contain P.) If no such r exists, we set $\mathrm{r}_{\mathcal{F}} = \infty$.

Hence, letting $\mathcal{C}_d$ denote the set of all halfspaces in $\mathbb{R}^d$, Radon's lemma asserts that $\mathrm{r}_{\mathcal{C}_d} = d+2$ and Helly theorem that $\mathrm{h}_{\mathcal{C}_d} = d+1$. A classical result by Levi [21] asserts that for every set system $\mathcal{F}$ we have $\mathrm{h}_{\mathcal{F}} \leq \mathrm{r}_{\mathcal{F}} - 1$. (This is often stated for convexity spaces but it holds for set systems, see [2, App. C].) Similar relations between such parameters have been investigated over the years, like for instance the partition conjecture of Eckhoff [10] refuted by Bukh [6].

Conjecture 1 pertains to a parameter inspired by the *fractional Helly theorem* [20, 18], which asserts that in $(d+1)$-wise intersection hypergraphs of convex sets of $\mathbb{R}^d$, positive density implies a linear-size clique. Here is the associated parameter:

- The *fractional Helly number* $\mathrm{fh}_{\mathcal{F}}$ of $\mathcal{F}$ is the smallest integer s such that there exists a function $\beta_{\mathcal{F}} : (0,1) \to (0,1)$ with the following property: For every finite subfamily $\mathcal{F}' \subset \mathcal{F}$, whenever a fraction α of the s-tuples of $\mathcal{F}'$ have nonempty intersection, a subset $\mathcal{G}$ of $\mathcal{F}'$ of size $\beta_{\mathcal{F}}(\alpha)|\mathcal{F}'|$ has nonempty intersection.

Again, the fractional Helly theorem states that $\mathrm{fh}_{\mathcal{C}_d} = d+1$. The significance of the fractional Helly number was highlighted by Alon et al. [1], who proved that intersection-closed set systems with bounded fractional Helly number enjoy a *weak ε-net theorem*, a *Tverberg-type theorem*, a *selection lemma*, etc. It is tempting to reformulate Conjecture 1 as

> *For any function $\Psi : \mathbb{N} \to \mathbb{N}$ such that $\Psi(n) = O(n^d)$, every set set system $\mathcal{F}$ in $\mathbb{R}^d$ such that $\phi^{(d)}_{\mathcal{F}} \leq \Psi$ has fractional Helly number at most $d+1$.*

We note, however, that this statement is weaker than Conjecture 1 in that it does not assert that the function $\beta()$ underpinning the fractional Helly number depends only on Ψ and d.

1.1.2 Homological background: homological minors

A classical way to extend the theory of planar graphs is to consider embeddings of graphs into surfaces and of simplicial complexes into $\mathbb{R}^d$ or other topological spaces.

There is a rich theory of embedding of graphs on surfaces, both structural (a classic being the Heawood inequality [31]) and computational (*e.g.* the use of graph genus for parameterized complexity). Let us mention, in particular, the strong Hanani-Tutte theorem which asserts that a graph is planar if it can be drawn so that every pair of independent edges cross an even number of times. This statement generalizes to the projective plane [29, 9] but was found to fail in genus 4 [12].

Going to dimension higher than 2 changes the nature of the problems drastically, already because Fáry's theorem no longer holds. (For every $d \geq 3$ there are simplicial complexes that embed in $\mathbb{R}^d$ piecewise linearly but not linearly.) It is thus sometimes convenient to relax the notion of embedding and work with chain maps, and this was done in particular to analyze intersection patterns [14, 28, 13] using a notion of *homological minors* [35].

Formally, the *support of a singular chain* is the union of (the images of) the singular simplices with nonzero coefficient in that chain, and the *support of a simplicial chain* is the subcomplex induced by the simplices with nonzero coefficient in that chain. We write $\mathrm{supp}(\sigma)$ for the support of a (singular or simplicial) chain σ. A chain map $a : C_*(K) \to \mathrm{C}^{\mathrm{sing}}_*(X)$ (resp. $a : C_*(K) \to \mathcal{C}_*(T)$) is *nontrivial* if, for every vertex v of K, the support of $a(v)$ has odd size. Two faces in a simplicial complex K are *adjacent* if they have at least one vertex in common. A *homological almost-embedding* of a simplicial complex K into a topological space X (resp. into another simplicial complex L) is a nontrivial chain map $a : C_*(K) \to \mathrm{C}^{\mathrm{sing}}_*(X)$ (resp.

$a : C_*(K) \to C_*(L)$) such that any two non-adjacent faces $\sigma, \tau \in K$ have images with disjoint support, that is $\mathrm{supp}(a(\sigma)) \cap \mathrm{supp}(a(\tau)) = \emptyset$. In particular, for every embedding f the associated chain map $f_\#$ is a homological (almost) embedding.

Let Δ_N denote the N-dimensional simplex and for K a simplicial complex let $K^{(t)}$ denote its t-dimensional skeleton. It turns out that there is a homological version of the van Kampen-Flores theorem (see for instance [14, Corollary 14]):

▶ **Theorem 2.** *For any $d \geq 1$, $\Delta_{d+2}^{(\lceil d/2 \rceil)}$ does not homologically almost embed into $\mathbb{R}^d$.*

A simplicial complex K is a *homological minor* of a topological space or simplicial complex X if there is a homological almost-embedding of K into X. Theorem 2 thus asserts that $\Delta_{d+2}^{(\lceil d/2 \rceil)}$ is not a homological minor of $\mathbb{R}^d$, *i.e.*, that $\mathbb{R}^d$ has $\Delta_{d+2}^{(\lceil d/2 \rceil)}$ as *forbidden homological minor*.

1.1.3 Parameters of set systems with a forbidden homological minor

Matoušek [23] bounded the Helly number of topological set systems in $\mathbb{R}^d$ in which every subfamily intersects in a bounded number of connected components, all contractible. His approach starts from a set systems in $\mathbb{R}^d$, uses Ramsey theory to build a map from $\Delta_{d+2}^{(\lceil d/2 \rceil)}$ into $\mathbb{R}^d$ that is "constrained" by the known intersection patterns of $\mathcal{F}$ so that the intersection forced by the van Kampen-Flores theorem reveals a new intersection in $\mathcal{F}$.

This approach was generalized by Goaoc et al. [14] to set systems in $\mathbb{R}^d$ of bounded $\lceil d/2 \rceil$-level topological complexity, where the *h-level topological complexity* of $\mathcal{F}$ is the maximum over $\mathbb{N}$ of the homological shatter function $\phi_{\mathcal{F}}^{(h)}$, that is

$$\mathrm{hc}_{\mathcal{F}}^{(h)} := \max \left\{ \max_{0 \leq i < h} \tilde{\beta}_i \left(\bigcap_{A \in \mathcal{G}} A; \mathbb{Z}_2 \right) \;\middle|\; \mathcal{G} \subset \mathcal{F} \right\}. \tag{2}$$

That generalization relied on homological minors and replaced the construction of the "constrained map" by the (simpler) construction of a "constrained chain map". The only aspect of the method that is specific to $\mathbb{R}^d$ is the use of the forbidden homological minor given by Theorem 2, so the approach readily generalizes to set systems whose ground set is a topological space with a forbidden homological minor, see the discussions in [28, §5.2] and [13, §2.2]. This method was refined and extended to analyze other parameters of set systems whose ground set has a forbidden homological minor [28, 26, 13].

1.1.4 Proof of Conjecture 1 for bounded homological shatter functions

Conjecture 1 was proven for bounded homological shatter functions in three steps:

- First, Holmsen and Lee [17, Theorem 1.1] proved that the fractional Helly number of *any* set system can be bounded by a function of its Radon number. Specifically, letting $\Psi_{\mathrm{r}\to\mathrm{fh}}(x)$ denote the supremum of the fractional Helly number of a set system with Radon number x, they proved that for every $r \geq 3$ we have $\Psi_{\mathrm{r}\to\mathrm{fh}}(r) \leq r^{r^{\lceil \log_2 r \rceil} + r \lceil \log_2 r \rceil}$.
- Second, Patáková [28, Theorem 2.1] proved that the Radon number of *any* set system whose ground set has K as forbidden homological minor can be bounded by a function of its $(\dim K)$-level topological complexity.
- Third, Goaoc, Holmsen and Patáková [13, Theorem 1.2] proved that for every set systems $\mathcal{F}$ whose ground set has K as forbidden homological minor, if the fractional Helly number $\mathrm{fh}_{\mathcal{F}}$ is bounded then it is at most $\mu(K) + 1$, where $\mu(K)$ denotes the maximum sum of dimensions of two disjoint simplices in K.

1.2 Statement of the results

Our main contribution is to confirm Conjecture 1 for some diverging homological shatter functions and on some manifolds. This decomposes into five independent results.

Throughout the paper, we work with compact piecewise-linear (PL) manifolds (possibly with boundary); see [32, §1] for an introduction. We first generalize Theorem 2:

▶ **Theorem 3.** *For every integers $d \geq 3$ and b there exists $N = N(d, b)$ such that $\Delta_N^{(\lceil d/2 \rceil)}$ does not homologically almost embed in any compact, $(\lceil d/2 \rceil - 1)$-connected, d-dimensional PL manifold (possibly with boundary) $\mathcal{M}$ with $\beta_{\lceil d/2 \rceil}(\mathcal{M}; \mathbb{Z}_2) \leq b$.*

This partially answers [28, Problem 3], [13, Conjecture 1.7] and [26, Conjecture 2] and extends the previous confirmation of Conjecture 1 from set systems in $\mathbb{R}^d$ to set systems on manifolds. This also extends several results on set systems with bounded topological complexity (Helly's theorem, Radon's theorem, (p, q)-theorem, ...) from $\mathbb{R}^d$ to sufficiently connected manifolds (see [28, 13]). We can relax the connectivity assumption (see [2, App. B]) but not remove it.

One ingredient in the proof of Theorem 3 is the following analogue of the Hanani-Tutte theorem for homological almost-embeddings, which is of independent interest.

▶ **Theorem 4.** *Let K be a simplicial complex of dimension $k > 1$ and let $\mathcal{M}$ be a compact $2k$-dimensional PL manifold (possibly with boundary). If there exists a triangulation T of $\mathcal{M}$ and a non-trivial chain map $f : C_*(K; \mathbb{Z}_2) \to C_*(T; \mathbb{Z}_2)$ in general position such that the images of any two non-adjacent k-faces $\sigma, \tau \in K$ intersect in an even number of points, then K is a homological minor of $\mathcal{M}$.*

We formalize what we mean by general position in Section 2.

The homological shatter function $\Phi_{\mathcal{F}}^{(h)}$ defined in Equation (1) can be reformulated as a *graded* version of the topological complexity $\mathrm{hc}_{\mathcal{F}}^{(h)}$ defined in Equation (2), where the value for parameter t considers only intersections of subfamilies of size at most t: $\phi_{\mathcal{F}}^{(h)}(t) = \sup_{\substack{\mathcal{F}' \subset \mathcal{F} \\ |\mathcal{F}'| \leq t}} \mathrm{hc}_{\mathcal{F}'}^{(h)}$. We systematize this viewpoint and define graded analogues of other parameters of set systems. For instance here are the *graded Radon* and *graded Helly* numbers:

$$\mathrm{r}_{\mathcal{F}}(t) \coloneqq \sup_{\substack{\mathcal{F}' \subset \mathcal{F} \\ |\mathcal{F}'| \leq t}} \mathrm{r}_{\mathcal{F}'} \quad \text{and} \quad \mathrm{h}_{\mathcal{F}}(t) \coloneqq \sup_{\substack{\mathcal{F}' \subset \mathcal{F} \\ |\mathcal{F}'| \leq t}} \mathrm{h}_{\mathcal{F}'}. \tag{3}$$

It is straightforward to see that if the graded Helly numbers of a set system do not grow fast enough, then they are ultimately stationary and the set system has bounded Helly number (Lemma 10). We prove a similar condition for (graded) Radon numbers:

▶ **Theorem 5.** *Let $\mathcal{F}$ be a set system. If $\lim_{t \to \infty} \mathrm{r}_{\mathcal{F}}(t) - \log_2 t = -\infty$, then $\mathrm{r}_{\mathcal{F}} < \infty$.*

As a application, we extend Patáková's theorem from bounded to sufficiently slowly diverging homological shatter function (Corollary 12). This, in turns yields fractional Helly theorems for sufficiently slowly diverging homological shatter functions.

▶ **Corollary 6.** *For every simplicial complex K there exists a function $\Psi_K : \mathbb{N} \to \mathbb{N}$ with $\lim_{t \to \infty} \Psi_K(t) = +\infty$ such that the following holds. If $\mathcal{F}$ is a set system whose ground set has K as forbidden homological minor and such that $\phi_{\mathcal{F}}^{(\dim K)}(t) \leq \Psi_K(t)$ for t large enough, then $\mathcal{F}$ has fractional Helly number at most $(\mu(K) + 1)$.*

We then investigate more graded numbers and establish more relations between graded and ungraded numbers. As an application, we extend the Holmsen-Lee bound on $\Psi_{\mathrm{r} \to \mathrm{fh}}(\cdot)$. Let $\Xi : \mathbb{N} \to \mathbb{N}$ be the function defined by $\Xi(r) := r^{r^{\lceil \log_2 r \rceil} + r \lceil \log_2 r \rceil}$.

▶ **Theorem 7.** *Let $\Psi : \mathbb{N} \to \mathbb{N}$ and $t_0 \in \mathbb{N}$ such that $\Psi(t) < t + 1$ for every $t \geq t_0$. If there exists an integer $t_1 \geq {t_0}^2$ such that $\Xi(\Psi(t_1)) < \frac{t_1}{t_0}$, then every set system whose graded Radon number function is bounded from above by Ψ has bounded fractional Helly number.*

With Theorem 7 we can strengthen Corollary 6, as a close inspection of the proof reveals that the function β associated to the fractional Helly number depends only on Ψ and t_0. (It also allows a slightly faster growth than Corollary 12.) We postpone this to the full version of the paper.

2 On homological minors

In this section we prove Theorems 3 and 4. For completeness, we start with a consequence of the simplicial approximation theorem that allows us to work purely in simplicial homology:

▶ **Lemma 8** ([2, App. A])**.** *A simplicial complex K is a homological minor of a compact PL manifold (possibly with boundary) $\mathcal{M}$ if and only if K is a homological minor of some triangulation of $\mathcal{M}$.*

When counting intersection points between chains, we focus on intersections that are stable under small perturbation. We therefore consider generic intersections, meaning intuitively that the chains intersect transversally. We formalize this in terms of linking numbers.[1]

Let X be a triangulation of $\mathbb{S}^{2k-1}$. Let S_1 and S_2 be two subcomplexes of X with $|S_1|$ and $|S_2|$ homeomorphic to $\mathbb{S}^{k-1}$. Suppose that the simplicial complex $X \setminus S_2$ induced by X on the vertices not in S_2 has a geometric realization homotopy equivalent to $\mathbb{S}^{2k-1} \setminus \mathbb{S}^{k-1}$ (this can always be ensured up to taking a subdivision of X). The *linking number* of S_1 and S_2 in X is 1 if the homology class $[S_1]$ generates $H_{k-1}(X \setminus S_2; \mathbb{Z}_2) \cong \mathbb{Z}_2$, and 0 if $[S_1]$ is trivial in $H_{k-1}(X \setminus S_2; \mathbb{Z}_2)$. (Exchanging S_1 and S_2 in this definition yields the same result.)

Let T be a triangulation of a compact PL manifold (possibly with boundary) $\mathcal{M}$. Two k-chains $z_1, z_2 \in C_k(T; \mathbb{Z}_2)$ *intersect generically* in vertex v if the closed star B of v in T satisfies: $B \cap z_1 \cap z_2 = \{v\}$, $D_1 := z_1 \cap B$ and $D_2 := z_2 \cap B$ are k-dimensional balls, and the spheres ∂D_1 and ∂D_2 have linking number 1 in ∂B. Two k-chains $z_1, z_2 \in C_k(T; \mathbb{Z}_2)$ are *in general position* if $z_1 \cap z_2$ consists of finitely many vertices, and z_1 and z_2 intersect generically in each of these vertices. Two k-chains $z_1, z_2 \in C_k(T; \mathbb{Z}_2)$ *intersect evenly* if they are in general position and $\mathrm{im}(z_1) \cap \mathrm{im}(z_2)$ has even size.

For K a k-dimensional complex, a simplicial chain map $f : C_\bullet(K; \mathbb{Z}_2) \to C_\bullet(T; \mathbb{Z}_2)$ is in *general position* if for every non-adjacent k-faces $\sigma, \tau \in K$, the chains $f(\sigma)$ and $f(\tau)$ are in general position and for each vertex $v \in f(\sigma) \cap f(\tau)$, σ and τ are the only faces of K whose images under f intersect the closed star of v in T. We say that a simplicial map $f : K \to T$ is in *general position* if the associated chain map $f_\#$ is.

For any compact PL manifold (possibly with boundary) $\mathcal{M}$ of dimension $2k$, there exists a map $\cap_\mathcal{M} : H_k(\mathcal{M}; \mathbb{Z}_2) \times H_k(\mathcal{M}; \mathbb{Z}_2) \to \mathbb{Z}_2$, called the *intersection form* of $\mathcal{M}$, such that $\cap_\mathcal{M}([z_1], [z_2]) \in \mathbb{Z}_2$ counts the intersection points of z_1 and z_2 modulo 2. We use no property of intersection forms besides their existence, and refer the interested reader to Prasolov [30, Chapter 2, §2.7] for a precise definition and to Paták and Tancer [27] for an brief account.

The next result is due to Paták and Tancer [27, Proposition 21] and formulated following the presentation of Skopenkov [33], which is better suited for our purpose. (More precisely, we reformulated [33, Theorem 1.1.5] using [33, Lemma 2.1.1].) Note that the proofs by Paták-Tancer [27] and by Skopenkov [33] use only PL maps.

[1] Intuitively, this generalizes the idea that in the plane, two curves cross at a point x if the branches of the curves alternate around x.

▶ **Theorem 9.** *Let L be a simplicial complex of dimension $k > 1$ and let $\mathcal{M}$ be a compact, $(k-1)$-connected, $2k$-dimensional PL manifold (possibly with boundary). The following statements are equivalent:*

- **(i)** *There exists a triangulation T of $\mathcal{M}$ and a simplicial map $f : L \to T$ in general position such that the images of any two non-adjacent faces intersect evenly.*
- **(ii)** *There exists a triangulation R of $\mathbb{R}^{2k}$ and a simplicial map $g : L \to R$ in general position and a map α that sends each k-face of L to an element of $H_k(\mathcal{M}; \mathbb{Z}_2)$ such that any two non-adjacent k-faces $\sigma, \tau \in L$ have images that intersect in an even number of points if and only if $\cap_{\mathcal{M}}(\alpha(\sigma), \alpha(\tau)) = 0$.*

2.1 A homological Hanani-Tutte theorem

Let us now prove Theorem 4. Let K be a simplicial complex of dimension $k > 1$ and let T be a triangulation of a compact PL manifold (possibly with boundary) $\mathcal{M}$ of dimension $2k$. Let $f : C_*(K; \mathbb{Z}_2) \to C_*(T; \mathbb{Z}_2)$ be a non-trivial chain map in general position such that the images of any two non-adjacent k-faces $\sigma, \tau \in K$ intersect evenly.

Our goal is to prove that K is a homological minor of $\mathcal{M}$. This requires repeatedly subdividing the triangulation T. In what follows, every time we subdivide a triangulation T_i into T_{i+1}, all chain maps to T_i and subcomplexes of T_i are also subdivided to T_{i+1}. Also, throughout the proof we identify every pure ℓ-dimensional simplicial complex with the unique ℓ-chain with coefficients in $\mathbb{Z}_2$ it supports; we abuse the terminology and say that we add (pure) simplicial complexes over $\mathbb{Z}_2$ to mean that we add the corresponding chains.

If f is a homological almost-embedding we are done. Otherwise, there exist some non-adjacent k-faces $\sigma, \tau \in K$ such that $f(\sigma) \cap f(\tau)$ is non-empty. By assumption, this intersection is a set of vertices of even size, so let $x, y \in f(\sigma) \cap f(\tau)$ be two distinct such vertices. Recall that f is in general position, $f(\sigma)$ and $f(\tau)$ intersect generically in x and in y. We set out to construct a refinement T' of T and a new map $f' : C_*(K; \mathbb{Z}_2) \to C_*(T'; \mathbb{Z}_2)$ that is also in general position, differs from f only on σ and τ, and satisfies $f'(\sigma) \cap f'(\tau) = (f(\sigma) \cap f(\tau)) \setminus \{x, y\}$ as well as $f'(\alpha) \cap f'(\beta) = f(\alpha) \cap f(\beta)$ for any $\alpha \in \{\sigma, \tau\}$ and any k-face $\beta \in K \setminus \{\sigma, \tau\}$. Iterating this procedure produces the announced homological almost-embedding of K into a triangulation of $\mathcal{M}$.

Figure 1 The setup for the construction of T' and f'.

Let B_x and B_y denote the closed stars of x and y in T. For $z \in \{x, y\}$ and $\alpha \in \{\sigma, \tau\}$ let $D_{\alpha,z} := \operatorname{supp}(f(\alpha)) \cap B_z$. Since $f(\sigma)$ and $f(\tau)$ intersect generically in x and y, the complexes $D_{\sigma,x}, D_{\sigma,y}, D_{\tau,x}$ and $D_{\tau,y}$ are k-dimensional balls, the $(k-1)$-spheres $\partial D_{\sigma,x}$ and $\partial D_{\tau,x}$ have linking number 1 in ∂B_x, and similarly $\partial D_{\sigma,y}$ and $\partial D_{\tau,y}$ have linking number 1 in ∂B_y.

We subdivide T into T_1 so that the closed star B'_x of x and B'_y of y in T_1 are disjoint from ∂B_x and ∂B_y, respectively. In particular, for $z \in \{x, y\}$ and $\alpha \in \{\sigma, \tau\}$, letting $D'_{\alpha,z} := \operatorname{supp}(f(\alpha)) \cap B'_z$, the pair $(\partial D'_{\alpha,z}, \partial B'_z)$ is homeomorphic to $(\mathbb{S}^{k-1}, \mathbb{S}^{2k-1})$. The

genericity of x and y in $f(\sigma) \cap f(\tau)$ is preserved through the subdivision $T \to T_1$ so the four complexes $D'_{\bullet,\bullet}$ are k-dimensional balls and their bounding spheres have the same linking numbers in $\partial B'_x$ and $\partial B'_y$ as their counterparts on ∂B_x and ∂B_y.

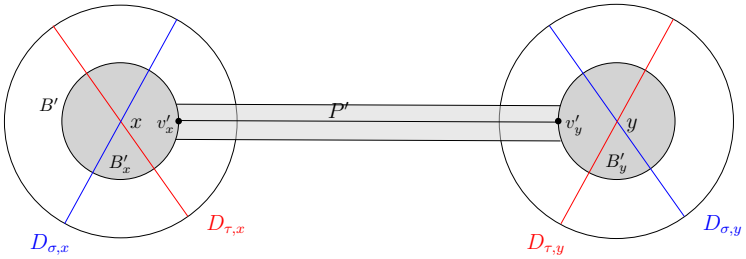

Figure 2 The construction of B'.

Up to subdividing T_1 into T_2, there exist vertices v'_x and v'_y in $\partial B'_x$ and $\partial B'_y$, respectively, and a path P' in the 1-skeleton of T_2 from v'_x to v'_y such that, letting $N(P')$ denote the closed star of P' in T_2, the closed star of $N(P')$ is disjoint from the image of f. The union $B' := B'_x \cup N(P') \cup B'_y$ is a ball. Observe that in $\partial B'$, the $(k-1)$-spheres $\partial D'_{\sigma,x}$ and $\partial D'_{\tau,x}$ retain the linking number 1 that they have on $\partial B'_x$. Similarly, in $\partial B'$, the $(k-1)$-spheres $\partial D'_{\sigma,y}$ and $\partial D'_{\tau,y}$ retain the linking number 1 that they have on $\partial B'_y$.

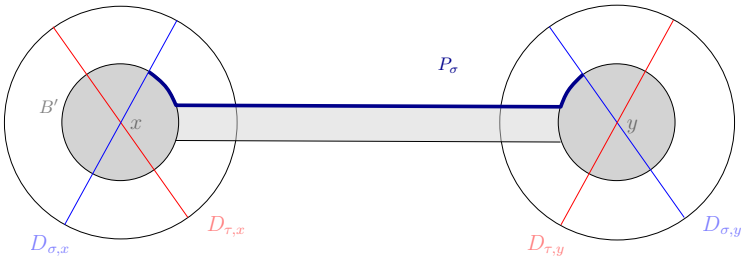

Figure 3 The path P_σ.

Thus, up to further subdividing T_2 into T_3, there exist a path P_σ in the 1-skeleton of $\partial B'$ that connects $\partial D'_{\sigma,x}$ to $\partial D'_{\sigma,y}$ and with relative interiors disjoint from the image of f. (Here we use that $\partial D'_{\alpha,z}$ is of codimension $k \geq 2$ in $\partial B'$.) Up to subdividing the triangulation further, we can pipe $D_{\sigma,x}$ and $D_{\sigma,y}$ together by a tube F_σ found in a neighborhood of the path P_σ [32, §5.10]. The tube $(F_\sigma, F_\sigma \cap D_{\sigma,x}, F_\sigma \cap D_{\sigma,y})$ is homeomorphic to $\big(\mathbb{D}^k \times [0,1], \mathbb{D}^k \times \{0\}, \mathbb{D}^k \times \{1\}\big)$. Moreover, by the (PL) general position theorem for embeddings [32, §5.3], we can take F_σ such that $\partial B'$ and ∂F_σ intersect in a generic way. By taking F_σ in a sufficiently small neighborhood U of P_σ so that $(U, \partial B' \cap U)$ is homeomorphic to $(\mathbb{R}^{2k}, \mathbb{R}^{2k-1} \times \{0\})$, and the triple $(F_\sigma \cap \partial B', F_\sigma \cap D_{\sigma,x} \cap \partial B', F_\sigma \cap D_{\sigma,y} \cap \partial B')$ is homeomorphic to $\big(\mathbb{D}^{k-1} \times [0,1], \mathbb{D}^{k-1} \times \{0\}, \mathbb{D}^{k-1} \times \{1\}\big)$.

Now, let C_σ be the sum $D_{\sigma,x} + \partial F_\sigma + D_{\sigma,y}$ (over $\mathbb{Z}_2$). Note that C_σ is contained in the union of $B_x \cup B_y$ and the closed star of $N(P')$, and therefore intersects the image of f only inside $B_x \cup B_y$. We note that $F_\sigma \cap \partial B'$ also pipes the $(k-1)$-spheres $D_{\sigma,x} \cap \partial B'$ and $D_{\sigma,y} \cap \partial B'$. Indeed, $(F_\sigma \cap \partial B', F_\sigma \cap D_{\sigma,x} \cap \partial B', F_\sigma \cap D_{\sigma,y} \cap \partial B') = (F_\sigma \cap \partial B', F_\sigma \cap \partial(D_{\sigma,x} \cap B'), F_\sigma \cap \partial(D_{\sigma,y} \cap B'))$ is homeomorphic to $\big(\mathbb{D}^{k-1} \times [0,1], \mathbb{D}^{k-1} \times \{0\}, \mathbb{D}^{k-1} \times \{1\}\big)$. It follows that $C_\sigma \cap \partial B'$ is homeomorphic to the connected sum of two $(k-1)$-spheres, and is therefore homeomorphic to a $(k-1)$-sphere.

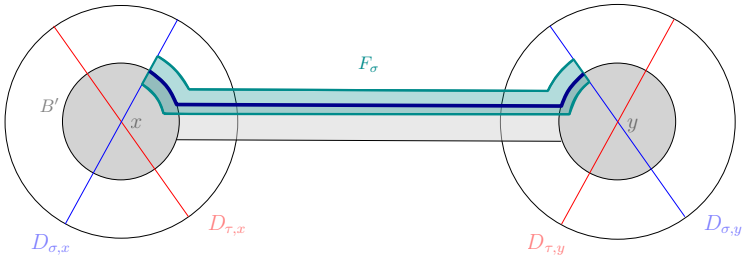

Figure 4 The piping F_σ between $D_{\sigma,x}$ and $D_{\sigma,y}$ in a neighborhood of P_σ.

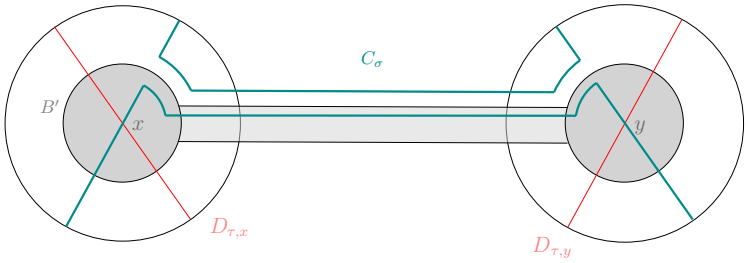

Figure 5 The chain $C_\sigma = D_{\sigma,x} + \partial F_\sigma + D_{\sigma,y}$ over $\mathbb{Z}_2$.

We claim that, in $\partial B'$, the linking number between $C_\sigma \cap \partial B'$ and $D_{\tau,x} \cap \partial B'$ equals the linking number between $D_{\sigma,x} \cap \partial B'$ and $D_{\tau,x} \cap \partial B'$, that is 1. This follows from the fact that the chain C_σ differs from $D_{\sigma,x}$ by $\partial F_\sigma + D_{\sigma,y}$, and that each of $\partial F_\sigma \cap \partial B'$ and $D_{\sigma,y} \cap \partial B'$ is a boundary in $\partial B' \setminus D_{\tau,x}$. The same claim holds if we exchange x for y.

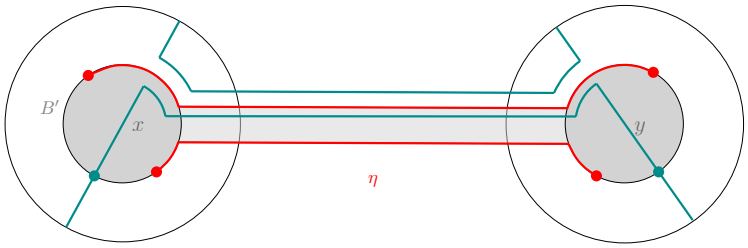

Figure 6 The chain $\eta \in C_k(\partial B' \setminus C_\sigma; \mathbb{Z}_2)$ such that $\partial\eta = D_{\tau,x} \cap \partial B' + D_{\tau,y} \cap \partial B'$ over $\mathbb{Z}_2$.

Altogether, we get that $D_{\tau,x} \cap \partial B'$ and $D_{\tau,y} \cap \partial B'$ are in the same homology class in $\partial B' \setminus C_\sigma$. Hence, their sum is a boundary, and there exists a chain $\eta \in C_k(\partial B' \setminus C_\sigma; \mathbb{Z}_2)$ such that the support of $\partial\eta$ is the sum over $\mathbb{Z}_2$ of $D_{\tau,x} \cap \partial B'$ and $D_{\tau,y} \cap \partial B'$. We finally set

$$f'(\sigma) = \underbrace{f(\sigma) + D_{\sigma,x} + D_{\sigma,y}}_{\substack{f(\sigma) \text{ with its restriction to } B_x \cup B_y \text{ removed}}} + C_\sigma \qquad \text{and} \qquad f'(\tau) = \underbrace{f(\tau) + D'_{\tau,x} + D'_{\tau,y}}_{\substack{f(\tau) \text{ with its restriction to } B' \text{ removed}}} + \eta$$

We set $f'(\omega) = f(\omega)$ for every other face $\omega \in K$. Extending f' linearly yields a chain map, since both $f'(\sigma) - f(\sigma)$ and $f'(\tau) - f(\tau)$ are cycles [2]. The chain map f' is as announced: $f'(\sigma) \cap f'(\tau) = f(\sigma) \cap f(\tau) \setminus \{x, y\}$ and every other intersection remains unchanged. This concludes the proof of Theorem 4.

[2] They are even boundaries, ensuring that f' is chain homotopic to f

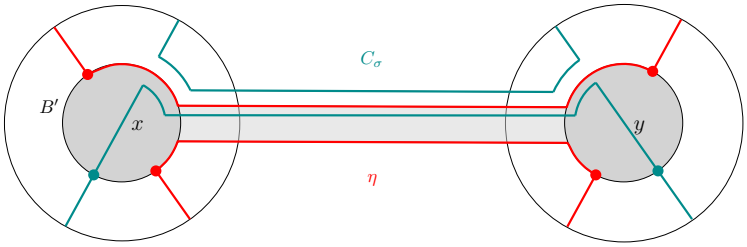

Figure 7 The chains C_σ and η reroute $f(\sigma)$ and $f(\tau)$ so as to remove intersections in B_x and B_y.

2.2 Forbidden homological minors for manifolds

We now prove Theorem 3. First, note that the odd-dimensional case reduces to the even-dimensional one. Indeed, for every $k \geq 2$, if $\mathcal{M}$ is a compact, $(k-1)$-connected, $(2k-1)$-dimensional PL manifold (possibly with boundary), then $\mathcal{M} \times [0,1]$ is a compact, $(k-1)$-connected, $2k$-dimensional PL manifold (possibly with boundary). Moreover, $\beta_k(\mathcal{M} \times [0,1]; \mathbb{Z}_2) = \beta_k(\mathcal{M}; \mathbb{Z}_2)$ and any homological minor of $\mathcal{M}$ is a homological minor of $\mathcal{M} \times [0,1]$. If the statement holds for d even and $b \in \mathbb{N}$ with some $N(b,d)$, then it holds with $d-1$ and b by putting $N(d-1,b) := N(d,b)$. So let us now consider the even-dimensional case.

Let $k \geq 2$ and $b \in \mathbb{N}$, and let $\mathcal{M}$ be a compact, $(k-1)$-connected, $2k$-dimensional PL manifold (possibly with boundary). Let us fix N and suppose that $K = \Delta_N^{(k)}$ is a homological minor of $\mathcal{M}$. By Lemma 8, there exist a triangulation T of $\mathcal{M}$ and a (simplicial) homological almost-embedding $C_*(K) \to C_*(T)$. Actually, letting $S := T^{(k)}$, we have that there exists a homological almost-embedding $a : C_*(K; \mathbb{Z}_2) \to C_*(S; \mathbb{Z}_2)$.

We apply Theorem 9 with $L = S$. Condition (i) holds with $T = S$ and f the identity, so Condition (ii) also holds. Hence, there exists a triangulation R of $\mathbb{R}^{2k}$, a simplicial map $g : S \to R$ in general position, and a map α that sends each k-face of S to an element of $H_k(\mathcal{M}; \mathbb{Z}_2)$ such that any two non-adjacent k-faces $\sigma, \tau \in S$ intersect evenly if and only if $\cap_{\mathcal{M}}(\alpha(\sigma), \alpha(\tau)) = 0$. We let $\tilde{\alpha} : C_k(S) \to H_k(\mathcal{M}; \mathbb{Z}_2)$ denote the linear extension of α.

Consider the chain map $b : C_*(K; \mathbb{Z}_2) \to C_*(R; \mathbb{Z}_2)$ defined by $b = g_\# \circ a$. Note that b is nontrivial since a is nontrivial and g is a simplicial map. Moreover, the fact that b is a chain map in general position follows from three observations:

- since g is a simplicial map in general position, $g_\#$ is a chain map in general position,
- since a is a homological almost-embedding, it is also a chain map in general position, and
- the composition of a homological almost-embedding and a chain map in general position is a chain map in general position.

Notice that for $N \geq 2k+3$, not every independent k-faces of K can have images under b that intersect evenly. Indeed Theorem 4 would then imply that K is a homological minor of $\mathbb{R}^{2k}$, which would contradict the homological van Kampen-Flores theorem (Theorem 2). We use Ramsey's theorem to show that this contradiction can be reached for some subcomplex of K.

So consider two non-adjacent k-faces $\sigma, \tau \in K$ and put $a(\sigma) = \sigma_1 + \sigma_2 + \ldots + \sigma_s$ and $a(\tau) = \tau_1 + \tau_2 + \ldots + \tau_t$. Since a is a homological almost-embedding, $\mathrm{supp}(a(\sigma))$ and $\mathrm{supp}(a(\tau))$ are disjoint, and σ_i and τ_j are thus non-adjacent for every $(i,j) \in [s] \times [t]$. Hence, given $(i,j) \in [s] \times [t]$, $g(\sigma_i)$ and $g(\tau_j)$ intersect evenly if and only if $\cap_{\mathcal{M}}(\alpha(\sigma_i), \alpha(\tau_j)) = 0$. We can thus count the intersections of $b(\sigma)$ and $b(\tau)$ (the following equalities are modulo 2 and Card () denotes the cardinal):

$$\begin{aligned}\operatorname{Card}(b(\sigma)\cap b(\tau)) &= \sum_{i\in[s],j\in[t]} \operatorname{Card}(g(\sigma_i)\cap g(\tau_j))\\ &= \sum_{i\in[s],j\in[t]} \cap_{\mathcal{M}}(\alpha(\sigma_i),\alpha(\tau_j))\\ &= \sum_{i\in[s]} \cap_{\mathcal{M}}(\alpha(\sigma_i),\tilde{\alpha}(a(\tau))) = \cap_{\mathcal{M}}(\tilde{\alpha}(a(\sigma)),\tilde{\alpha}(a(\tau))).\end{aligned}$$

Let $r = \beta_k(\mathcal{M};\mathbb{Z}_2)$. The map $\beta : C_k(K) \to H_k(\mathcal{M};\mathbb{Z}_2)$ defined by $\beta = \tilde{\alpha}\circ a$ induces a coloring of the k-simplices of K by the (at most 2^r) elements of $H_k(M;\mathbb{Z}_2)$. Let N' denote the number of vertices of $\operatorname{sd}\Delta^{(k)}_{2k+2}$. By the hypergraph Ramsey theorem, for N large enough (as a function of r and k) there exists a subset W of N' vertices in K such that β is constant over all k-simplices of $K[W]$; let us denote by $\square$ this constant value. In particular, for every k-faces σ,τ of $K[W]$ such that σ and τ are not adjacent, we have, modulo 2, $\operatorname{Card}(b(\sigma)\cap b(\tau)) = \cap_{\mathcal{M}}(\beta(\sigma_1),\beta(\tau_1)) = \cap_{\mathcal{M}}(\square,\square)$. Let us fix a bijection from the vertices of $\operatorname{sd}\Delta^{(k)}_{2k+2}$ to W and extend it to a chain map $j : C_*\left(\operatorname{sd}\Delta^{(k)}_{2k+2}\right) \to C_*(K[W])$. Also, let $h : C_*\left(\Delta^{(k)}_{2k+2}\right) \to C_*\left(\operatorname{sd}\Delta^{(k)}_{2k+2}\right)$ denote the subdivision chain map, where each i-face of $\Delta^{(k)}_{2k+2}$ is mapped to the sum of the i-faces of $\operatorname{sd}\Delta^{(k)}_{2k+2}$ that it contains. In particular, for every k-face σ of $\Delta^{(k)}_{2k+2}$, the chain $h(\sigma)$ is supported on $k!$ k-faces of $\operatorname{sd}\Delta^{(k)}_{2k+2}$.

Let us examine the properties of $b\circ j\circ h$. First, it is a nontrivial chain map (because b, j and h are). Moreover, $j\circ h$ is a homological almost-embedding (since j and h are), and its composition with the chain map in general position b yields a chain map in general position. Furthermore, any two non-adjacent k-faces $\sigma,\tau \in \Delta^{(k)}_{2k+2}$ have images under $b\circ j\circ h$ that intersect evenly. To see this, let us put $j\circ h(\sigma) = \sigma_1+\sigma_2+\ldots+\sigma_s$ and $j\circ h(\tau) = \tau_1+\tau_2+\ldots+\tau_s$. Since $j\circ h$ is a homological almost-embedding, $\operatorname{supp}(j\circ h(\sigma))$ and $\operatorname{supp}(j\circ h(\tau))$ are disjoint. It follows that for every $i,j\in[s]$ the k-simplices σ_i and τ_j are non-adjacent. We therefore have, modulo 2,

$$\begin{aligned}\operatorname{Card}(b\circ j\circ h(\sigma)\cap b\circ j\circ h(\tau)) &= \sum_{i,j\in[s]} \operatorname{Card}(b(\sigma_i)\cap b(\tau_j))\\ &= \sum_{i,j\in[s]} \cap_{\mathcal{M}}(\beta(\sigma_i),\beta(\tau_j)) = \sum_{i,j\in[s]} \cap_{\mathcal{M}}(\square,\square).\end{aligned}$$

To sum up, the cardinal of $b\circ j\circ h(\sigma)\cap b\circ j\circ h(\tau)$ has the same parity as $\cap_{\mathcal{M}}(\square,\square)s^2$. Since $s = k!$ is even, σ and τ have images under $b\circ j\circ h$ that intersect evenly.

To conclude, $b\circ j\circ h$ is a nontrivial chain map in general position from $\Delta^{(k)}_{2k+2}$ to R such that independent faces have images that intersect evenly. By Theorem 4 this means that $\Delta^{(k)}_{2k+2}$ is a homological minor of $\mathbb{R}^{2k}$, a contradiction with Theorem 2. Thus, for N large enough, the initial hypothesis that $\Delta^{(k)}_N$ is a homological minor of $\mathcal{M}$ cannot be true.

3 Graded parameters of set systems

In this section we present our contributions on set systems of parameters.

3.1 Graded Radon and Helly numbers

Each relation between parameters of a set system yields a relation between their graded analogues. From Levi's inequality we get the following inequality between the graded Helly and Radon numbers (defined in Section 1.1.1):

$$\forall t \in \mathbb{N}, \qquad \mathrm{h}_{\mathcal{F}}(t) = \sup_{\substack{\mathcal{F}' \subset \mathcal{F} \\ |\mathcal{F}'| \leq t}} \mathrm{h}_{\mathcal{F}'} \leq \sup_{\substack{\mathcal{F}' \subset \mathcal{F} \\ |\mathcal{F}'| \leq t}} (\mathrm{r}_{\mathcal{F}'} - 1) = \mathrm{r}_{\mathcal{F}}(t) - 1. \tag{4}$$

It follows from the definitions of graded parameters that each one is a non-decreasing function that converges to the ungraded parameter (possibly ∞). We notice that if a graded Helly number is asymptotically sublinear then it is bounded:

▶ **Lemma 10.** *Let $\mathcal{F}$ be a set system and $t_0 \in \mathbb{N}$. If $\mathrm{h}_{\mathcal{F}}(t) < t$ for all $t > t_0$, then $\mathrm{h}_{\mathcal{F}} \leq t_0$.*

Proof. By definition, we have $\mathrm{h}_{\mathcal{F}}(t) \leq t$ for every $t \in \mathbb{N}$. Moreover, $\mathrm{h}_{\mathcal{F}}(t) \neq \mathrm{h}_{\mathcal{F}}(t-1)$ if and only if $\mathrm{h}_{\mathcal{F}}(t) = t$. The assumption and a straightforward induction therefore implies that for every $t > t_0$ we have $\mathrm{h}_{\mathcal{F}}(t) = \mathrm{h}_{\mathcal{F}}(t_0) \leq t_0$. ◀

The growth of graded Radon numbers is at most linear [2, App. D] and rather constrained:

▶ **Lemma 11.** *Let $\mathcal{F}$ be a set system and $t \geq 2$ an integer. If $\mathrm{r}_{\mathcal{F}}(t) > \mathrm{r}_{\mathcal{F}}(t-1)$, then $\mathrm{r}_{\mathcal{F}}(t-1) \geq 1 + \log_2\left(1 + \frac{t}{\mathrm{h}_{\mathcal{F}}(t)}\right)$.*

Proof. Let X denote the ground set of $\mathcal{F}$ and let $n = \mathrm{r}_{\mathcal{F}}(t-1)$. Suppose that $\mathrm{r}_{\mathcal{F}}(t) > n$, so that there exist a subset $\mathcal{G} = \{G_1, G_2, \ldots, G_t\} \subset \mathcal{F}$ and a subset $S \subseteq X$ of size n such that

- **(i)** there is no partition of S into two parts whose $\mathcal{G}$-convex hulls intersect,
- **(ii)** for every $i \in [t]$, there exists a partition $\mathcal{P}_i$ of S into two parts whose $(\mathcal{G} \setminus \{G_i\})$-convex hulls intersect.

Recall that given $\mathcal{F}' \subseteq \mathcal{F}$, the $\mathcal{F}'$-convex hull $\mathrm{conv}_{\mathcal{F}'}(P)$ of a subset $P \subset X$ is the intersection of all the members of $\mathcal{F}'$ that contain P. In particular, for any $P \subseteq X$ such that $P \not\subseteq G_i$ we have $\mathrm{conv}_{\mathcal{G}}(P) = \mathrm{conv}_{\mathcal{G}\setminus\{G_i\}}(P)$. Conditions (i) and (ii) therefore imply that every $G_i \in \mathcal{G}$ contains one or the other part of $\mathcal{P}_i$.

There are at most $2^{n-1} - 1$ partitions of S in two nonempty parts. Let us assume that $t > (2^{n-1}-1)h$ for some integer h, so that by the pigeonhole principle there exist $h+1$ indices $i_1, i_2, \ldots, i_{h+1}$ such that the partitions $\mathcal{P}_{i_1}, \mathcal{P}_{i_2}, \ldots, \mathcal{P}_{i_{h+1}}$ coincide. Let $\{P_1, P_2\}$ be that partition of S. Let us put $\mathcal{G}' = \{A \in \mathcal{G} \colon P_1 \subseteq A \text{ or } P_2 \subseteq A\}$. We make two observations:

- $\cap_{A \in \mathcal{G}'} A$ coincides with $\mathrm{conv}_{\mathcal{G}}(P_1) \cap \mathrm{conv}_{\mathcal{G}}(P_2)$ and is therefore empty.
- every choice of h elements in $\mathcal{G}'$ has nonempty intersection. Indeed, $\mathcal{G}'$ contains G_{i_1}, G_{i_2}, $\ldots$, $G_{i_{h+1}}$, so that any choice of h elements from $\mathcal{G}'$ is bound to miss G_{i_j} for at least one $j \in [h+1]$ and their intersection must then contain $\mathrm{conv}_{\mathcal{G}\setminus\{G_{i_j}\}}(P_1) \cap \mathrm{conv}_{\mathcal{G}\setminus\{G_{i_j}\}}(P_2) \neq \emptyset$.

For $h \geq \mathrm{h}_{\mathcal{F}}(t)$ these conditions are incompatible. We therefore have $t \leq (2^{n-1} - 1)\,\mathrm{h}_{\mathcal{F}}(t)$, and the statement follows. ◀

We can now prove that any set system with sufficiently slowly growing graded Radon numbers has finite Radon number.

Proof of Theorem 5. Let $\mathcal{F}$ be a set system with infinite Radon number. If the Helly number $\mathrm{h}_{\mathcal{F}}$ is also infinite, then by Lemma 10 there exists an increasing sequence $\{t_i\}_{i\in\mathbb{N}}$ such that $\mathrm{h}_{\mathcal{F}}(t_i) = t_i$, and therefore $\mathrm{r}_{\mathcal{F}}(t_i) \geq t_i + 1$ by Inequality (4); this prevents $\mathrm{r}_{\mathcal{F}}(t) - \log_2 t$ from going to $-\infty$ as $t \to \infty$. So suppose that the Helly number $\mathrm{h}_{\mathcal{F}}$ is finite. The assumption that $\mathrm{r}_{\mathcal{F}} = \infty$ ensures that there exists an increasing sequence $\{t_i\}_{i\in\mathbb{N}}$ such that $\mathrm{r}_{\mathcal{F}}(t_i) > \mathrm{r}_{\mathcal{F}}(t_i - 1)$. Lemma 11 implies that $\mathrm{r}_{\mathcal{F}}(t_i) > \mathrm{r}_{\mathcal{F}}(t_i - 1) \geq \log_2 t_i - \log_2 \mathrm{h}_{\mathcal{F}}$. Again, this prevents $\mathrm{r}_{\mathcal{F}}(t) - \log_2 t$ from going to $-\infty$ as $t \to \infty$. The statement follows by contraposition. ◀

3.2 Consequences for topological set systems

Let us finally consider topological set systems with slowly growing homological shatter function and ground set with a forbidden homological minor.

▶ **Corollary 12.** *For every simplicial complex K there exists a function $S_K : \mathbb{N} \to \mathbb{N}$ with $\lim_{t\to\infty} S_K(t) = +\infty$ such that the following holds. Any set system $\mathcal{F}$ whose ground set has K as forbidden homological minor and satisfies $\phi_{\mathcal{F}}^{(\dim K)}(t) \leq S_K(t)$ for t large enough has finite Radon number.*

Proof. Recall that $\Psi^{(K)}_{\mathrm{hc}\to\mathrm{r}}(x)$ denotes the supremum of the Radon number of a set system with $(\dim K)$-level topological complexity at most x and whose ground set has K as forbidden homological minor. Patáková [28] proved that $\Psi^{(K)}_{\mathrm{hc}\to\mathrm{r}}(x)$ is finite for every K and x.

For $t \in \mathbb{N}$, we define $S_K(t) = \max\{x \in \mathbb{N} \mid \Psi^{(K)}_{\mathrm{hc}\to\mathrm{r}}(x) \leq \frac{1}{2}\log_2 t\}$. This ensures that $\Psi^{(K)}_{\mathrm{hc}\to\mathrm{r}}(S_K(t)) \leq \frac{1}{2}\log_2 t$ for every $t \in \mathbb{N}$. Observe that $\lim_{t\to\infty} S_K(t) = \infty$ since $\Psi^{(K)}_{\mathrm{hc}\to\mathrm{r}}(x)$ is finite for every $x \in \mathbb{N}$.

Now consider a set system $\mathcal{F}$ with function $\phi_{\mathcal{F}}^{(\dim K)} \leq S_K$ and whose ground set has K as forbidden homological minor. Let $t \in \mathbb{N}$ and consider a subset $\mathcal{F}' \subseteq \mathcal{F}$ of size t. The ground set of $\mathcal{F}'$ also has K as forbidden homological minor. Moreover, $\mathcal{F}'$ has $(\dim K)$-level topological complexity at most $\phi_{\mathcal{F}}^{(\dim K)}(t) \leq S_K(t)$. It follows that $\mathrm{r}_{\mathcal{F}'} \leq \Psi^{(K)}_{\mathrm{hc}\to\mathrm{r}}(S_K(t)) \leq \frac{1}{2}\log_2 t$. This holds for every $\mathcal{F}' \subseteq \mathcal{F}$ of size t, so $\mathrm{r}_{\mathcal{F}}(t) \leq \frac{1}{2}\log_2 t$. This inequality holds for every $t \in \mathbb{N}$ so Theorem 5 implies that $\mathcal{F}$ has bounded Radon number. ◀

We can finally prove a fractional Helly theorem for diverging homological shatter functions.

Proof of Corollary 6. Recall that $\Psi_{\mathrm{r}\to\mathrm{fh}}(y)$ denotes the supremum of the fractional Helly number of a set system with Radon number y. Holmsen and Lee [17, Theorem 1.1] proved that $\Psi_{\mathrm{r}\to\mathrm{fh}}(y)$ is finite for every y. Let S_K denote the function from Corollary 12. Now consider a set system $\mathcal{F}$ whose ground set has K as forbidden homological minor and satisfies $\phi_{\mathcal{F}}^{(\dim K)} \leq S_K$. Corollary 12 ensures that $\mathrm{r}_{\mathcal{F}}$, the Radon number of $\mathcal{F}$, is finite. It follows that the fractional Helly number of $\mathcal{F}$ is at most $\Psi_{\mathrm{r}\to\mathrm{fh}}(\mathrm{r}_{\mathcal{F}})$, and is therefore finite. From there, [13, Theorem 1.2] ensures that this fractional Helly number is at most $\mu(K) + 1$. ◀

3.3 Other graded parameters and relations

With the intersection hypergraph of $\mathcal{F}$ in mind, we say that a set $\mathcal{G}$ in a set system $\mathcal{F}$ is a *clique* if the intersection of all members of $\mathcal{G}$ is non-empty. The colorful Helly theorem suggests the following parameter:

- The *colorful Helly number* $\mathrm{ch}_{\mathcal{F}}$ of $\mathcal{F}$ is the smallest number of colors m such that for every coloring of a subfamily $\mathcal{F}' \subset \mathcal{F}$ with m colors, if every subfamily that contains exactly one element of each color is a clique, then at least one color class is a clique.

We say that a set $\mathcal{G}$ in a set system $\mathcal{F}$ is a *c-wise clique* if every c-element subset of $\mathcal{G}$ is a clique. Clearly a clique is a c-wise clique, and when $c \geq \mathrm{h}_{\mathcal{F}}$ the converse is true. To analyze set systems with large, infinite or unknown Helly numbers, it is useful to consider variants of the colorful and fractional Helly numbers where cliques are replaced by c-wise cliques:

- The *cth colorful Helly number* $\mathrm{ch}_{\mathcal{F}}^{(c)}$ of $\mathcal{F}$ is the smallest number of colors $m \geq c$ such that for every coloring of a subfamily $\mathcal{F}' \subset \mathcal{F}$ with m colors, if every subfamily of $\mathcal{F}'$ that contains exactly one element of each color forms a c-wise clique, then at least one color class is a c-wise clique.
- The *cth fractional Helly number* $\mathrm{fh}_{\mathcal{F}}^{(c)}$ of $\mathcal{F}$ is the smallest integer s such that there exists a function $\beta_{\mathcal{F}} : (0,1) \to (0,1)$ with the following property: For every finite subfamily $\mathcal{F}' \subset \mathcal{F}$, whenever a fraction α of the s-tuples of $\mathcal{F}'$ forms a c-wise clique, a subset $\mathcal{G}$ of $\mathcal{F}'$ of size $\beta_{\mathcal{F}}(\alpha)|\mathcal{F}'|$ forms a c-wise clique.

Obviously for every set system $\mathcal{F}$, if $c \geq \mathrm{h}_{\mathcal{F}}$, then $\mathrm{fh}_{\mathcal{F}}^{(c)} = \mathrm{fh}_{\mathcal{F}}$ and $\mathrm{ch}_{\mathcal{F}}^{(c)} = \mathrm{ch}_{\mathcal{F}}$. Holmsen [16, Theorem 1.2] proved that $\mathrm{fh}_{\mathcal{F}}^{(c)} \leq \mathrm{ch}_{\mathcal{F}}^{(c)}$ for every set system $\mathcal{F}$ and every $c \in \mathbb{N}$. A close inspection of that proof provides another bridge between the graded and ungraded parameters:

▶ **Lemma 13.** *Let $\ell > c$ be integers. Every set system $\mathcal{F}$ such that $\mathrm{ch}_{\mathcal{F}}^{(c)}(c\ell) \leq \ell$ satisfies $\mathrm{fh}_{\mathcal{F}}^{(c)} \leq \mathrm{ch}_{\mathcal{F}}^{(c)}(c\ell)$.*

Proof. Let $c < \ell$, let $\mathcal{F}$ be a set system and let $\ell' := \mathrm{ch}_{\mathcal{F}}^{(c)}(c\ell)$. By definition of $\mathrm{ch}_{\mathcal{F}}^{(c)}(\cdot)$, the c-uniform hypergraph recording which c-element subsets of $\mathcal{F}$ form cliques cannot contain a certain pattern on $c\ell'$ vertices, namely the *complete ℓ'-tuples of missing edges* [17, §3]. This is the only property needed to ensure that $\mathrm{fh}_{\mathcal{F}}^{(c)} \leq \ell'$ [16, Theorem 1.2]. ◀

Let $\Psi_{\mathrm{r}\to\mathrm{ch}}^{(c)}(x)$ denote the supremum of the cth colorful Helly number of a set system with Radon number x. Holmsen and Lee [17, Theorem 2.2] proved that $\Psi_{\mathrm{r}\to\mathrm{ch}}^{(c)}(x) \leq \max\left(\Xi(x), c\right)$ for every $c \geq x - 1$, where $\Xi : \mathbb{N} \to \mathbb{N}$ is the function defined by $\Xi(r) := r^{r^{\lceil \log_2 r \rceil} + r\lceil \log_2 r \rceil}$. Applying this inequality to subsets of size t we get:

$$\mathrm{ch}_{\mathcal{F}}^{(c)}(t) \leq \max\left(\Xi\left(\mathrm{r}_{\mathcal{F}}(t)\right), c\right) \qquad \text{for every } \mathcal{F}, c, t \text{ such that } c \geq \mathrm{h}_{\mathcal{F}}(t). \tag{5}$$

Proof of Theorem 7. Let $\Psi : \mathbb{N} \to \mathbb{N}$ and $t_0 \in \mathbb{N}$ such that $\Psi(t) < t + 1$ for every $t \geq t_0$. Also suppose that there exists an integer $t_1 \geq {t_0}^2$ such that $\Xi\left(\Psi(t_1)\right) < \frac{t_1}{t_0}$. We now consider a set system $\mathcal{F}$ such that $\mathrm{r}_{\mathcal{F}}(t) \leq \Psi(t)$ for every $t \in \mathbb{N}$ and argue that $\mathrm{fh}_{\mathcal{F}}$, the fractional Helly number of $\mathcal{F}$, is bounded.

By Levi's inequality (4) we have $\mathrm{h}_{\mathcal{F}}(t) \leq \mathrm{r}_{\mathcal{F}}(t) - 1 \leq \Psi(t) - 1$. It follows that $\mathrm{h}_{\mathcal{F}}(t) < t$ for every $t \geq t_0$, so by Lemma 10 we have $\mathrm{h}_{\mathcal{F}} \leq t_0$. Hence, the graded version (5) of the Holmsen-Lee inequality applies with $c = t_0$ and every t, that is $\mathrm{ch}_{\mathcal{F}}^{(t_0)}(t) \leq \max\left(\Xi\left(\Psi(t)\right), t_0\right)$.

Let us apply Lemma 13 with $c = t_0$ and $\ell = \frac{t_1}{t_0}$. Observe that $\ell > c$ holds because ${t_1} > {t_0}^2$, and that $\mathrm{ch}_{\mathcal{F}}^{(c)}(c\ell) \leq \ell$ follows from the assumption that $\Xi\left(\Psi(t_1)\right) \leq \frac{t_1}{t_0}$, as

$$\mathrm{ch}_{\mathcal{F}}^{(c)}(c\ell) = \mathrm{ch}_{\mathcal{F}}^{(t_0)}(t_1) \leq \max\left(\Xi\left(\Psi(t_1)\right), t_0\right) \leq \frac{t_1}{t_0} = \ell.$$

Hence, $\mathrm{fh}_{\mathcal{F}}^{(t_0)} \leq \mathrm{ch}_{\mathcal{F}}^{(t_0)}(t_1)$. Since $\mathrm{h}_{\mathcal{F}} \leq t_0$ we have $\mathrm{fh}_{\mathcal{F}}^{(t_0)} = \mathrm{fh}_{\mathcal{F}}$ and the statement follows. ◀

Abstract

In a k-critical bifiltration, every simplex enters along a staircase with at most k steps. Examples with $k > 1$ include degree-Rips bifiltrations and models of the multicover bifiltration. We consider the problem of converting a k-critical bifiltration into a 1-critical (i.e. free) chain complex with equivalent homology. This is known as computing a free resolution of the underlying chain complex and is a first step toward post-processing such bifiltrations.

We present two algorithms. The first one computes free resolutions corresponding to path graphs and assembles them to a chain complex by computing additional maps. The simple combinatorial structure of path graphs leads to good performance in practice, as demonstrated by extensive experiments. However, its worst-case bound is quadratic in the input size because long paths might yield dense boundary matrices in the output. Our second algorithm replaces the simplex-wise path graphs with ones that maintain short paths which leads to almost linear runtime and output size.

We demonstrate that pre-computing a free resolution speeds up the task of computing a minimal presentation of the homology of a k-critical bifiltration in a fixed dimension. Furthermore, our findings show that a chain complex that is minimal in terms of generators can be asymptotically larger than the non-minimal output complex of our second algorithm in terms of description size.

analyzed. In this context, the first step of a computational pipeline for two parameters typically consists of the computation of a *bifiltration* of simplicial complexes, that is, a family of simplicial complexes indexed by $\mathbb{N}^2$ that grows when increasing the parameters. We refer to the parameter set $\mathbb{N}^2$ as the *grades* of the bifiltration. A bifiltration can be equivalently described by determining the *support* of each simplex, that is, the set of grades at which the simplex is part of the complex. A bifiltration is called *free* or 1-*critical* if the support of every simplex is a *principal upset*, that is, the upward closure of a single element in the parameter space. More generally, a bifiltration is k-*critical* if the support of a simplex is the upward closure of at most k elements; see Figure 1 for a visualization.

A bifiltration gives rise to a bifiltered chain complex $C_\bullet$

$$0 \longleftarrow C_0 \xleftarrow{\partial_1} C_1 \longleftarrow \cdots \longleftarrow C_{d-1} \xleftarrow{\partial_d} C_d$$

with the k-simplices at a given grade forming the basis of the k-chains at that grade. Free and k-critical filtered chain complexes are defined analogously.

Bifiltered chain complexes arise naturally in various constructions for topological data analysis, and several constructions produce bifiltrations that are not free. The most prominent example is given by the degree-Rips bifiltration [19, 23, 24, 7]. Other examples are the approximate multi-cover bifiltration [1] and Delaunay core bifiltration [6]. On the other hand, free bifiltrations are most suitable for algorithmic and computational purposes. There are fast algorithms for minimizing a bifiltered chain complex without changing its homology [14, 15, 22] as well as for computing the homology of a chain complex in terms of a minimal presentation [20, 18, 15, 4], but both approaches require free chain complexes as input.

In homological algebra, a standard technique is to replace a general chain complex by a free one, connected to the original chain complex by a chain map that induces an isomorphism in homology (a *quasi-isomorphism*). The free chain complex together with the chain map is called a *free resolution* of the original complex. The problem studied in this paper is how to efficiently compute a free resolution of a non-free bifiltered chain complex.

At the homology level, one way to address the case of a non-free bifiltration was proposed by Chacholski, Scolamiero and Vaccarino [8]: given a segment $C : C_{m+1} \to C_m \to C_{m-1}$ of a chain complex, the authors describe an algorithm to compute a free chain complex $F : F_{m+1} \to F_m \to F_{m-1}$ such that $H_m(C)$ and $H_m(F)$ are isomorphic, that is, a *free*

implicit representation. This algorithm suffices if one is interested in a presentation of $H_m(C)$ for further processing. Methods to compute a projective implicit representation from families of simplicial complexes and general simplicial maps have been developed in [11, 12], where, as in our approach, graph theoretic methods are used to speed up computations.

There are good reasons to work on the level of entire chain complexes instead. First of all, there are potential computational advantages, especially if one is interested in multiple homology dimensions (see Section 6). Moreover, the chain complex structure can encode subtle information on the data that is lost at the homology level: for example, two chain complexes may have isomorphic homology in every dimension without being quasi-isomorphic.

Computing free resolutions of general chain complexes is a standard task in computational algebra, available in the computer algebra software Macaulay2 for a much wider range of chain complexes. In the context of applied topology, we are mostly interested in very large bifiltered chain complexes with millions of generators but a simple combinatorial structure (i.e., simplicial boundary maps). The goal of this paper is to develop specialized and highly optimized algorithms for this type of input data, which the general purpose algorithms implemented in existing computer algebra systems are not tailored for.

Contributions. Our main contribution is to propose two algorithms to compute a free resolution of a bifiltered chain complex. Both algorithms rely on the same simple idea of expanding any k-critical simplex in dimension p into a sequence of k free copies, with consecutive copies related by $(p+1)$-dimensional elements at the join of their grades. In algebraic terms, this corresponds to a free resolution of the upset module associated to the simplex. In order to construct a valid total complex, the algorithms introduce further maps to establish the chain complex property while maintaining quasi-isomorphism to the original filtered complex. Finding these maps is computationally inexpensive and takes place at a purely combinatorial level.

The algorithms differ mainly in the choice of free resolution of the upset modules. In the first algorithm, the *path algorithm*, the free resolution corresponds to the chain complex of a filtered path graph (as a simple special case of a cellular resolution [5, 21]). We give an example of a family of simplicial bifiltrations so that the resulting free chain complex has a dense boundary matrix (for any choice of basis). This example shows tightness of the worst-case runtime $O(n^2)$, where n is the number of input generators (description size).

The second algorithm, the *log-path algorithm*, extends the path algorithm by adding additional relations to the free resolution of a simplex, such that any pair of copies of a simplex is connected via a sequence of relations of logarithmic length. This ensures sparsity of the boundary matrices in the output chain complex, but also requires adding further higher relations (*syzygies*). Again, further maps are required to establish the chain complex property of the resulting total complex, allowing the algorithm to maintain sparsity and obtain a resolution with worst-case run time in $O(n \log^2 n)$.

Our findings lead to an interesting observation: as shown by our worst case example, a minimal resolution may require dense boundary matrices, while a non-minimal resolution may actually admit a sparse matrix representation, with asymptotically fewer non-zero entries ($O(n \log^2 n)$ instead of $O(n^2)$, where n is the description size of the complex). This observation suggests that minimizing chain complexes does not necessarily speed-up subsequent algorithmic tasks, at least in certain worst-case examples.

We provide implementations of the path and log-path algorithms, in addition to the Chacholski–Scolamiero–Vaccarino algorithm for computing free implicit representations of homology. Systematic tests on various k-critical bifiltrations show that the overhead of

the log-path algorithm over the path algorithm does not exceed a factor of 3 in run time and a factor of 2 in the number of non-zero entries for our examples, while showing the expected improvement on the mentioned worst-case examples. Subsequently minimizing the free chain complex yields a further significant reduction of the size. Furthermore, we consider the task of computing minimal presentations of homology in all degrees, comparing the approach of first computing a "global" free resolution with the approach of computing free implicit representations. Our results show a clear computational advantage for the global approach. Remarkably, for some instances, computing *all* minimal presentations using a free resolution is faster than computing a *single* minimal presentation using the Chacholski–Scolamiero–Vaccarino algorithm.

2 Bifiltered chain complexes

Bifiltrations. A *simplicial bifiltration* $\mathcal{K}$ is an abstract simplicial complex together with a collection of subcomplexes $(\mathcal{K}_s)_{s\in\mathbb{N}^2}$ such that $\mathcal{K}_s \subseteq \mathcal{K}_t$ whenever $s \leq t$ (which means that $s_1 \leq t_1$ and $s_2 \leq t_2$). As shown in Figure 1, each simplex σ enters $\mathcal{K}$ along a staircase bounding the *support* of σ, denoted $\operatorname{supp}(\sigma)$, which is an *upset* (an upward closed subset of $\mathbb{N}^2$). There is a unique minimal set of grades $\mathcal{G}(\sigma) := \{x_1, \ldots, x_m\} \subseteq \mathbb{N}^2$ such that $\operatorname{supp}(\sigma) = \{s \in \mathbb{N}^2 \mid \exists x_i \leq s\}$. If $m \leq k$ for each $\sigma \in \mathcal{K}$, then the bifiltration is *k-critical*.

Bipersistence modules. Simplicial bifiltrations give rise to bifiltered chain complexes. We first describe the elementary building blocks. Each p-simplex σ has a support $\operatorname{supp}(\sigma)$ with minimal generating set $\mathcal{G}(\sigma) = \{x_1, \ldots, x_m\}$, determining an *upset module* $U_{\{x_1,\ldots,x_m\}}$ (which we also denote by U_σ for brevity) given by

$$(U_\sigma)_s := \begin{cases} \Bbbk, & \text{if } \exists\, x_i \leq s, \\ 0 & \text{otherwise} \end{cases} \qquad \text{and} \qquad (U_\sigma)_{s,t} = \begin{cases} \mathrm{id}_\Bbbk, & \text{if } \exists\, x_i \leq s, \\ 0 & \text{otherwise} \end{cases}$$

as illustrated in Figure 2. This is a special case of a *bipersistence module* M, which is a family $(M_s)_{s\in\mathbb{N}^2}$ of vector spaces over a field $\Bbbk$ together with a family of homomorphisms $(M_{s,t} \colon M_s \to M_t)_{s\leq t\in\mathbb{N}^2}$. Although our results extend to arbitrary fields straightforwardly, we will stick to the case $\Bbbk = \mathbb{Z}_2$ in order to simplify the exposition. A *morphism of bipersistence modules* $\varphi : M \to N$ is a natural transformation, that is, a family of linear maps $(f_s)_{s\in\mathbb{N}^2}$ that commute with the structure maps of M and N: $f_t \circ M_{s,t} = N_{s,t} \circ f_s$ for $s \leq t$.

A direct sum of upset modules, each generated by a single grade, is called *free*. A *basis* of a free bipersistence module F is a set of elements $\{b^{x_1}, \ldots, b^{x_n}\}$ where each $b^{x_i} \in F_{x_i}$, such that every $v \in F_y$, for any grade y, can be written in unique way as a linear combination of images of the basis elements under the structure maps (which are inclusions into the vector space $\bigcup_z F_z$). Note that the grades appearing in this linear combination with a non-zero coefficient must be less or equal to y. A morphism f between free modules is then determined by the images of the basis elements for the domain, and can be encoded by a matrix $[f]$.

Chain complexes. The upset modules associated to the simplices assemble to

$$0 \longleftarrow C_0 \xleftarrow{\partial_1} C_1 \xleftarrow{\partial_2} \cdots \xleftarrow{\partial_{i-1}} C_{i-1} \xleftarrow{\partial_i} C_i \xleftarrow{\partial_{i+1}} C_{i+1} \longleftarrow \cdots,$$

which is a *bifiltered chain complex* with $C_i := \bigoplus_{\sigma\in\mathcal{K}^{(i)}} U_\sigma$ and *boundary maps* $\partial_i : C_i \to C_{i-1}$ inherited from the simplicial complex $\mathcal{K}$, satisfying $\partial_i \circ \partial_{i+1} = 0$. The notion of a k-critical bifiltered chain complex is defined analogously to the setting of a simplicial bifiltration.

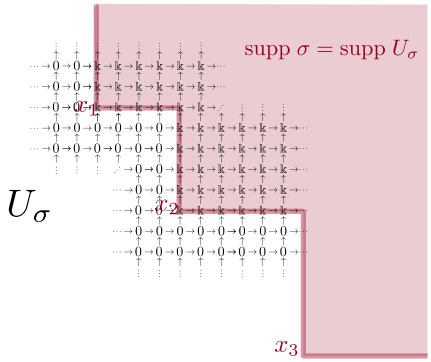

Figure 2 The upset module U_σ induced by the simplex σ.

Even though a bifiltered chain complex has a simple combinatorial structure, a *free chain complex* (a chain complex $F_\bullet$ with each F_i free) is preferred in computational (and algebraic) settings. This motivates the goal of finding a *free resolution*, that is, a free chain complex together with a chain map $F_\bullet \to C_\bullet$ that induces an isomorphism $H_i(F_\bullet) \cong H_i(C_\bullet)$ on homology for each $i \geq 0$. Such a chain map is called a *quasi-isomorphism*.

Data representation. The list of all simplices of a bifiltration $\mathcal{K}$, each with a lexicographically ordered list of the minimal generating set of its support, and a list of its facets gives a full combinatorial description of $\mathcal{K}$ and will serve as the *input* to our algorithms. This data representation generalizes to regular cell complexes, and in our case to bifiltered chain complexes where $\Bbbk = \mathbb{Z}_2$. For the simplicial case, the number of facets is constant for each simplex dimension, ensuring sparsity. Therefore the description size of the input is given, up to a constant factor, by the total number of generators in this list. Our *output* is a free resolution $F_\bullet$ of our input chain complex $C_\bullet$, again represented in the same data format.

3 Free implicit representations of homology

FI-reps. To compute the homology $H_m(C_\bullet)$ of a k-critical chain complex in a chosen dimension m, Chacholski, Scolamiero, and Vaccarino [8] provide a procedure to construct a free chain complex segment $X \xleftarrow{f} Y \xleftarrow{g} Z$ from the input segment

$$C_{m-1} \xleftarrow{\partial_m} C_m \xleftarrow{\partial_{m+1}} C_{m+1}. \tag{1}$$

such that $H_m(C_\bullet) \cong \ker f / \operatorname{im} g$. The pair of graded matrices $([f], [g])$ is called a *free implicit representation (FI-rep)* of $H_m(C_\bullet)$ [20], and it serves as input for the computation of minimal presentations of $H_m(C_\bullet)$ [20, 18].

The Chacholski–Scolamiero–Vaccarino algorithm. We consider an input complex $C_\bullet$ induced by a simplicial bifiltration $\mathcal{K}$. The first step is to extend each U_σ in C_{m-1}, induced by an $(m-1)$-simplex σ, to a free upset module $U_{\{0\}}$. The resulting free module $D_{m-1} := \bigoplus_{\sigma \in \mathcal{K}^{(m-1)}} U_{\{0\}}$, whose basis we denote by $\{b^0_\sigma\}_{\sigma \in \mathcal{K}^{(m-1)}}$, contains C_{m-1} as a submodule, since the support of U_σ is contained in the support of $U_{\{0\}}$. Thus, postcomposing ∂_m with this submodule inclusion does not affect the kernel: we have $\ker \partial_m = \ker \iota \circ \partial_m$.

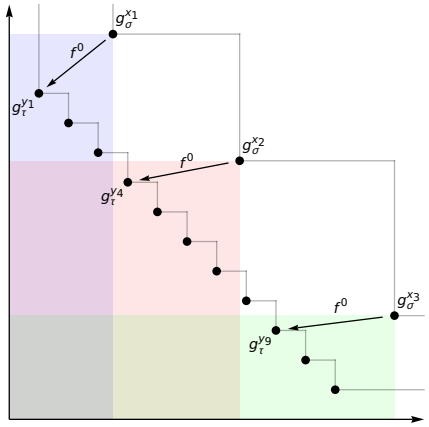

Figure 3 f^0_{m+1} sends each generator g^x_σ to a generator g^y_τ of the facet τ of σ whose grade y is in the downset of x (say, with the smallest first coordinate).

As a second step, we *cover* each U_σ in C_{m+1}, induced by an $(m+1)$-simplex σ by a free bipersistence module. This means that we replace each upset module U_σ by the free module $G_\sigma \coloneqq \bigoplus_{x_i \in \mathcal{G}(\sigma)} U_{\{x_i\}}$, connected to the upset module by a surjection $G_\sigma \twoheadrightarrow U_\sigma$ since the support of G_σ equals the support of U_σ. We call the basis elements $g_\sigma^{x_i}$ the *generators* of U_σ. The module G_{m+1} arises from C_{m+1} by covering U_σ by G_σ for each $(m+1)$-simplex via a canonical surjection $G_{m+1} \xrightarrow{\alpha_{m+1}} C_{m+1}$. Hence, precomposing ∂_{m+1} with α_{m+1} does not affect the image. The input (1) can now be replaced by (2) which has isomorphic homology.

$$D_{m-1} \xleftarrow{\iota \circ \partial_m} C_m \xleftarrow{\partial_{m+1} \circ \alpha_{m+1}} G_{m+1}, \tag{2}$$

As the third and final step it remains to replace C_m. We first construct G_m analogously to G_{m+1}, by substituting each U_σ in C_m by G_σ. Precomposing $\iota \circ \partial_m$ with the surjection $G_m \xrightarrow{\alpha_m} C_m$ yields a map $\gamma \coloneqq \iota \circ \partial_m \circ \alpha_m \colon G_m \to D_{m-1}$, as depicted in (3). For $\sigma \in \mathcal{K}^{(m)}$ with $\partial\sigma = \tau_0 + \cdots + \tau_m$, the resulting map γ sends a generator g^x_σ in G_m to $b^0_{\tau_0} + \cdots + b^0_{\tau_m}$ in D_{m-1}.

$$\begin{array}{ccccccc} & & & & R_m & & \\ & & & & \downarrow{\scriptstyle p^1_m} & & \\ & & & & G_m & \xleftarrow{f^0_{m+1}} & G_{m+1} \\ & & & \overset{\gamma}{\swarrow} & \downarrow{\scriptstyle \alpha_m} & & \downarrow{\scriptstyle \alpha_{m+1}} \\ D_{m-1} & \xleftarrow{\iota} & C_{m-1} & \xleftarrow{\partial_m} & C_m & \xleftarrow{\partial_{m+1}} & C_{m+1} \end{array} \tag{3}$$

Replacing C_m by G_m makes it necessary to also replace the map $\partial_{m+1} \circ \alpha_{m+1} \colon G_{m+1} \to C_m$ by a map $f^0_{m+1} \colon G_{m+1} \to G_m$, representing ∂_{m+1} on the generators and also making the diagram commute. This map f^0_{m+1} sends each generator g^x_σ of an $(m+1)$-simplex σ with $\partial\sigma = \tau_0 + \cdots + \tau_m$ to $f^0_{m+1}(g^x_\sigma) = g^{y_0}_{\tau_0} + \cdots + g^{y_m}_{\tau_m}$, where each $g^{y_i}_{\tau_i}$ is a generator of τ_i chosen such that its grade satisfies $y_i \leq x$; such a y_i always exists because the faces τ_i of a simplex σ are present in the bifiltration whenever σ itself is present. The map f^0_{m+1} thus makes the square in (3) commute and is therefore called a *lift* of ∂_{m+1}. See Figure 3 for an illustration.

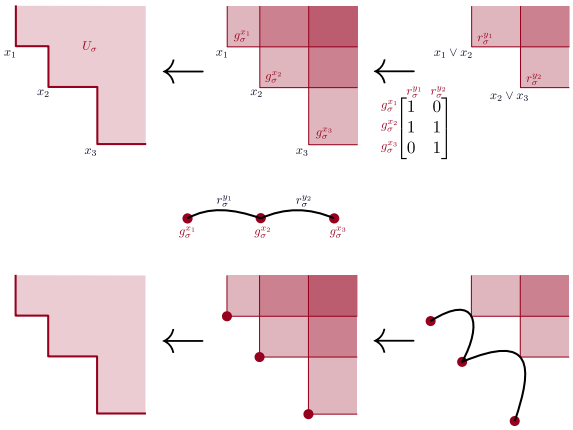

Figure 4 The top row illustrates the free resolution of U_σ as in Diagram 4 and the middle row shows its path resolution. We often visualize both at once as in the bottom row.

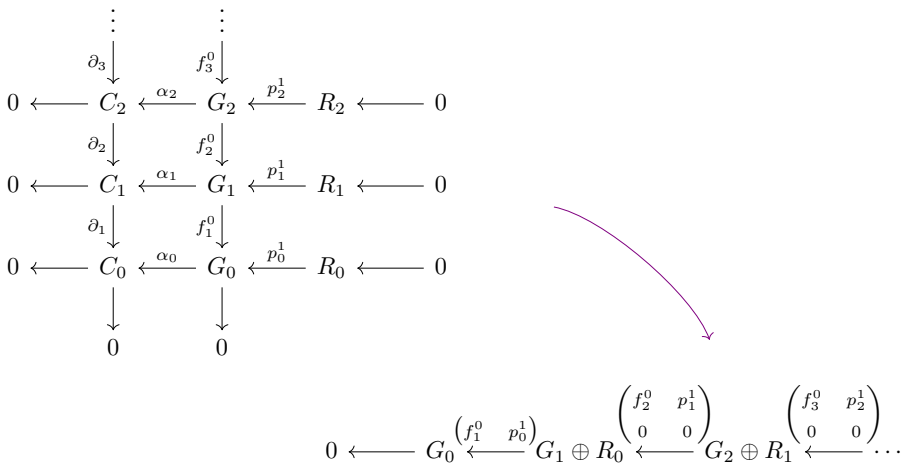
Note that the kernel of γ may not be isomorphic to the kernel of ∂_m; the surjection α_m maps each generator g_σ^x of an m-simplex in G_m to the same potential cycle in C_m, thus increasing the dimension of the kernel. This can be resolved by relating these generators appropriately. Assume that the generators $g_\sigma^{x_1}, \dots, g_\sigma^{x_k}$ of U_σ are ordered w.r.t. the first coordinate of their grades. To represent U_σ correctly, two consecutive generators $g_\sigma^{x_i}$ and $g_\sigma^{x_{i+1}}$ have to be identified at the join $y_i = x_i \vee x_{i+1}$ of their grades by a *relation* $r_\sigma^{y_i}$. With the free bipersistence module $R_\sigma \coloneqq \bigoplus_{y_i} U_{\{y_i\}}$ with basis $\{r_\sigma^{y_i}\}_i$, we can present U_σ by generators and relations via

$$0 \longleftarrow U_\sigma \xleftarrow{\alpha_\sigma} G_\sigma \xleftarrow{p_\sigma^1} R_\sigma, \tag{4}$$

where $p_\sigma^1(r_\sigma^{y_i}) = g_\sigma^{x_i} + g_\sigma^{x_{i+1}}$. Since p_σ^1 is injective, α_σ is surjective, and $\ker \alpha_\sigma = \operatorname{im} p_\sigma^1$, the sequence in (4) is a short exact sequence. This means that $(G_\sigma \xleftarrow{p_\sigma^1} R_\sigma, \alpha_\sigma)$ already determines a *free resolution* of U_σ, as defined in Section 2, where U_σ is considered as a chain complex concentrated in degree 0.

The free resolution in Diagram 4 has a simple combinatorial structure, given by a path graph $\mathcal{P}_\sigma$ with k vertices corresponding to the generators $g_\sigma^{x_i}$ and $k-1$ edges $\{g_\sigma^{x_i}, g_\sigma^{x_{i+1}}\}$ corresponding to the relations $r_\sigma^{y_i}$. Note that vertices and edges implicitly carry the grades of the generators and relations. The morphism p_σ^1 is represented by the (graded) incidence matrix of the graph. We call this free resolution the *path resolution* of U_σ, see Figure 4. Note that a path resolution is a special case of a *cellular resolution* [5, 21].



We now use the free resolution to replace the map $\partial_{m+1} \circ \alpha_{m+1}$ in (2), assembling the following output complex from (3)

$$D_{m-1} \xleftarrow{\gamma_m} G_m \xleftarrow{\begin{pmatrix} f_{m+1}^0 & p_m^1 \end{pmatrix}} G_{m+1} \oplus R_m. \tag{5}$$

By construction, the homology of this complex segment in degree m is isomorphic to that of (2), and hence to that of the input complex.

4 Path algorithm

Description. We now turn to the problem of finding a *free resolution*, that is, a chain complex of free modules that is quasi-isomorphic to the input $C_\bullet$, thus preserving homology in *all* dimensions. For this problem, extending the codomain of $\partial_i : C_i \to C_{i-1}$ to a free module generated in degree 0, as done in the Chacholski–Scolamiero–Vaccarino algorithm, is not feasible anymore, since this changes $H_{i-1}(C_\bullet)$. Instead, we now carry out the step of substituting C_i by its free resolution $G_i \xleftarrow{p_i^1} R_i \leftarrow 0 \leftarrow \cdots$ in every dimension i and replacing ∂_{i+1} by the (zeroth) lifts $f_{i+1}^0 \colon G_{i+1} \to G_i$, yielding maps $\begin{pmatrix} f_{i+1}^0 & p_i^1 \end{pmatrix}$ as illustrated in (6).

(6)

However, the sequence of maps, arising from this construction, does not yield a chain complex. Given a relation $r_\sigma^{y_j}$ in R_i, we obtain

$$f_i^0 \circ p_i^1(r_\sigma^{y_j}) = f_i^0(g_\sigma^{x_j}) + f_i^0(g_\sigma^{x_{j+1}}) = g_{\tau_0}^{z_1} + \cdots + g_{\tau_i}^{z_i} + g_{\tau_0}^{z_1'} + \cdots + g_{\tau_i}^{z_i'}.$$

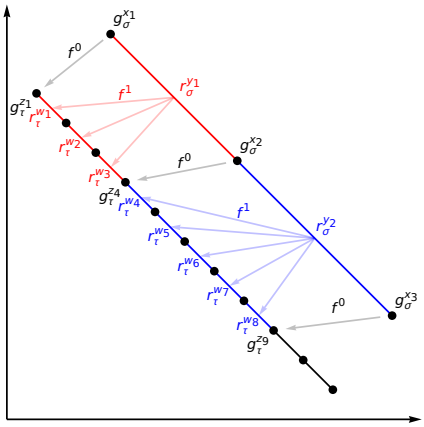
This term (also the term $f_{i-1}^0 \circ f_i^0$) may not vanish, since the generators of σ may be sent to different generators of its boundary simplices τ_j by f_i^0, i.e., $g_{\tau_j}^{z_j} \neq g_{\tau_j}^{z_j'}$. However, it vanishes modulo relations, in the sense that its representative vanishes in $G_{i-1}/\operatorname{im} p_{i-1}^1$, see Lemma 1.

▶ **Lemma 1** (Path Lemma). *For any $g_\tau^{x_j}$, $g_\tau^{x_\ell}$ in G_{i-1}, there is a unique set of distinct relations $r_\tau^{w_j}, \ldots, r_\tau^{w_{\ell-1}}$ in R_{i-1} such that $p_{i-1}^1(r_\tau^{w_j} + \cdots + r_\tau^{w_{\ell-1}}) = g_\tau^{x_j} + g_\tau^{x_\ell}$.*

Proof. This can be seen combinatorially. The free resolution of U_τ corresponds to the path graph $\mathcal{P}_\tau$, in the sense that the restriction of p_{i-1}^1 to a map $R_\tau \to G_\tau$ corresponds to the boundary map of the path graph. The relations $r_\tau^{w_j}, \ldots, r_\tau^{w_{\ell-1}}$ then define the unique path connecting the vertices $g_\tau^{x_j}$ and $g_\tau^{x_\ell}$ in $\mathcal{P}_\tau$. ◀

The map p_i^1 sends the edge $r_\sigma^{y_j}$ of $\mathcal{P}_\sigma$ to the vertices $g_\sigma^{x_j}$ and $g_\sigma^{x_{j+1}}$ which in turn are mapped to $g_{\tau_j}^{z_j}$ and $g_{\tau_j}^{z_j'}$ on $\mathcal{P}_{\tau_j}$ by f_i^0. We can therefore modify the boundary map in (6) by additionally sending $r_\sigma^{y_j}$ to the path $r_{\tau_j}^{w_1} + \cdots + r_{\tau_j}^{w_\ell}$ guaranteed by Lemma 1, see Figure 5. This defines a correction term $f_i^1 : R_i \to R_{i-1}$ such that $p_{i-1}^1 \circ f_i^1 = f_i^0 \circ p_i^1$. The maps f_i^1 are called the *first lifts* of ∂_i.

Even after adding the correction term f_i^1 to (6), the resulting maps may still fail to be boundary maps, since the composition $f_{i-1}^0 \circ f_i^0(g_\sigma^x)$ need not vanish for each generator g_σ^x in G_i, as seen in Figure 6. Again, $f_{i-1}^0 \circ f_i^0(g_\sigma^x)$ is a sum consisting of pairs $g_\tau^y, g_\tau^{y'}$ of possibly



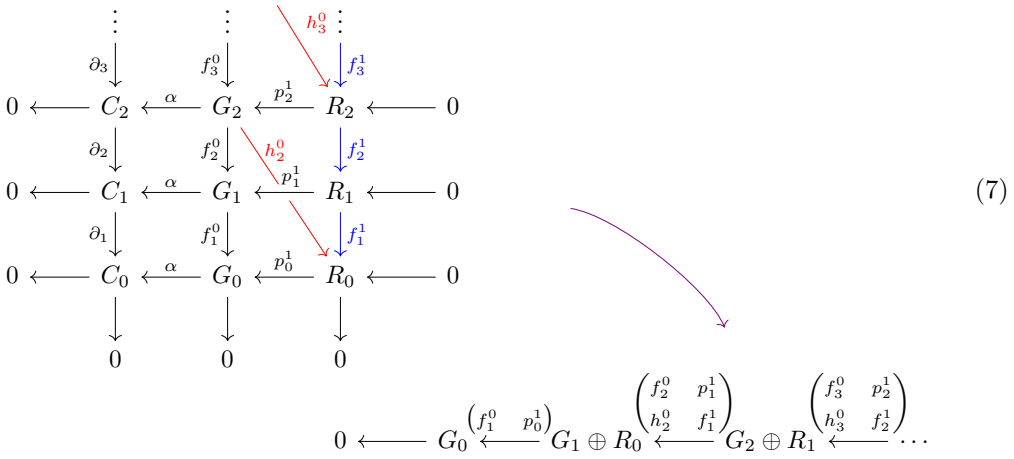


Figure 5 f_i^1 sends each edge r_σ^y to the path connecting the images of its endpoints under f_i^0.

different generators of the same simplex τ, which can be connected by a path of relations as above. A second correction term $h_i^0 \colon G_i \to R_{i-2}$ is defined analogously to the lifts f_i^1. By construction, h_i^0 satisfies $p_{i-2}^1 \circ h_i^0 = f_{i-1}^0 \circ f_i^0$, making the following diagram commute:

(7)

Adding h_i^0 and f_i^1 to the boundary maps in (6) yields the desired free resolution of $C_\bullet$. The next theorem, proved in A.1 of the full version [3], shows correctness of the path algorithm.

▶ **Theorem 2.** *The chain complex on the right side of* (7) *is a free resolution of* $C_\bullet$.

Path algorithm. For the description of the algorithm and its asymptotic time complexity, we assume that the input $C_\bullet$ is induced by a k-critical bifiltration of a simplicial complex with fixed dimension d, given as a list of simplices σ, each with its dimension, grades $\mathcal{G}(\sigma)$ and boundary $\partial\sigma$. The output is described by a list of generators and relations (each carrying a grade) as well as their images under the maps p_i^1, f_i^0, f_i^1 and h_i^0 (which together form the boundary maps of the free resolution). The output is initialized as an empty list.

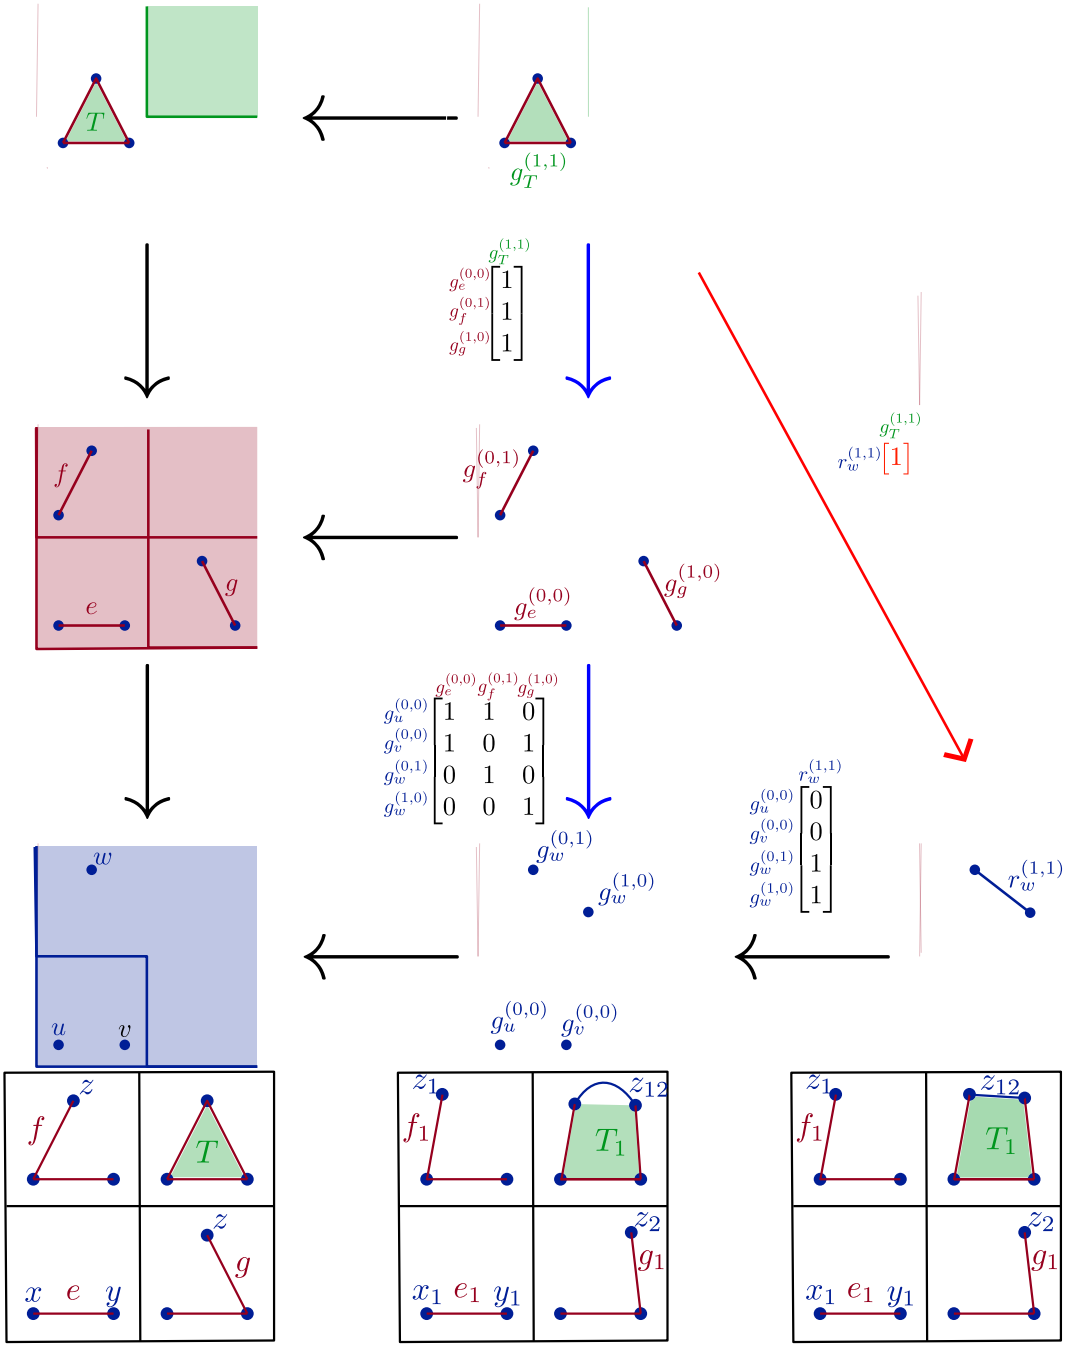

Figure 6 Construction of Diagram 7 for the bifiltration on the bottom left. The boundary defect $f_0^1 \circ f_1^1 \neq 0$, can be repaired by adding the red correction morphism which corresponds to a change of the boundary of T_1 in the bottom-middle cell complex. This yields the bottom-right output.

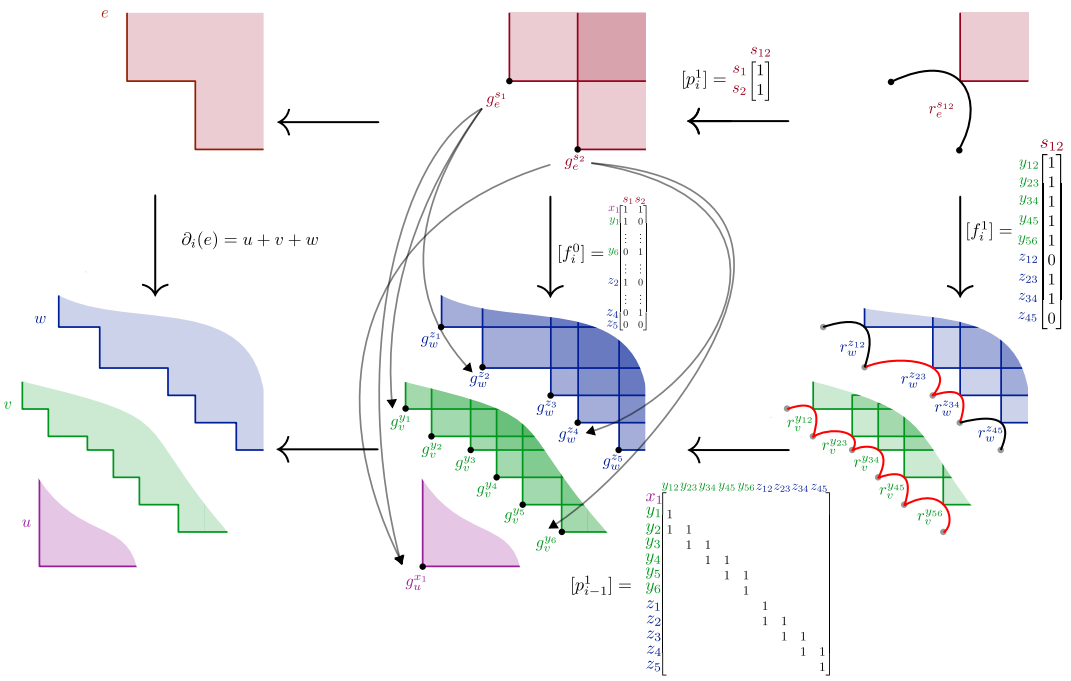

Figure 7 Construction of f_i^1. The relation $r_e^{s_{12}}$ is mapped to the paths $r_w^{z_{23}} + r_w^{z_{34}}$ and $r_v^{y_{12}} + \cdots + r_v^{y_{56}}$ in the path resolutions of w and v, highlighted in red.

1. Compute the bases of $G_i \oplus R_{i-1}$ and the matrices $[p_i^1]$. For each i-simplex σ and $x_j \in \mathcal{G}(\sigma)$, add a generator $g_\sigma^{x_j}$ to G_i. For any two consecutive $x_j, x_{j+1} \in \mathcal{G}(\sigma)$, add a relation $r_\sigma^{y_j}$ with $y_j = x_j \vee x_{j+1}$ to R_i. Moreover, define $p_i^1(r_\sigma^{y_j}) := g_\sigma^{x_j} + g_\sigma^{x_{j+1}}$.
2. Compute the matrices $[f_i^0]$. For each generator g_σ^x in G_i, find generators $g_{\tau_0}^{x_0}, \ldots, g_{\tau_i}^{x_i}$ for $\tau_0 + \cdots + \tau_i = \partial\sigma$ such that $x_j \leq x$ and define $f_i^0(g_\sigma^x) := g_{\tau_0}^{x_0} + \cdots + g_{\tau_i}^{x_i}$.
3. Compute $[f_i^1]$ and $[h_i^0]$. For $[f_i^1]$, perform a matrix multiplication $[f_i^0][p_i^1]$. The resulting columns are indexed by the relations r_σ^y in R_i and consist of one pair of generators $g_\tau^{z_j}, g_\tau^{z_\ell}$ for each facet τ of σ. Such a pair is connected by a path $c_\tau := r_\tau^{w_j} + \cdots + r_\tau^{w_\ell}$ in $\mathcal{P}_\tau$, and we set $f_i^1(r_\sigma^y) := \sum_\tau c_\tau$; see Figure 7. For $[h_i^0]$, proceed analogously to multiply $[f_{i-1}^0][f_i^0]$. The resulting columns are indexed by the generators g_σ^x in G_i and consist of one pair of generators $g_\tau^{z_j}, g_\tau^{z_\ell}$ in G_{i-2} for each codimension 2 face τ of σ. Such a pair is connected by a path $c_\tau := r_\tau^{w_j} + \cdots + r_\tau^{w_\ell}$ in $\mathcal{P}_\tau$, and we set $h_i^0(g_\sigma^x) := \sum_\tau c_\tau$.

Complexity. The running time of the path algorithm is $O(nk)$ for a k-critical bifiltration of description size n; see A.2. in the full version [3]. This runtime is worst-case optimal, since the description size of a computed free resolution can be $\Omega(nk)$ in the worst-case. The reason is that the paths in the computation of f_i^1 and h_i^0 can be of size up to k, and many simplices may require such long paths in the worst case. Figure 8 gives a construction for which the matrix $[h_2^0]$ is of size $\Omega(nk)$; see Figure 15 in [3] for a similar construction for $[f_1^1]$.

A free chain complex is *minimal* if there is no quasi-isomorphic free chain complex with a smaller number of generators. In general, free resolutions computed by the path algorithm are not minimal. However, a slight modification of the construction in Figure 8 yields the following result (see A.3. in the full version [3] for details).

▶ **Proposition 3.** *There is a k-critical simplicial bifiltration of description size n for which the path algorithm computes a free resolution represented by matrices of description size $\Omega(nk)$. This free resolution is minimal, and no other choice of basis yields a smaller description size.*

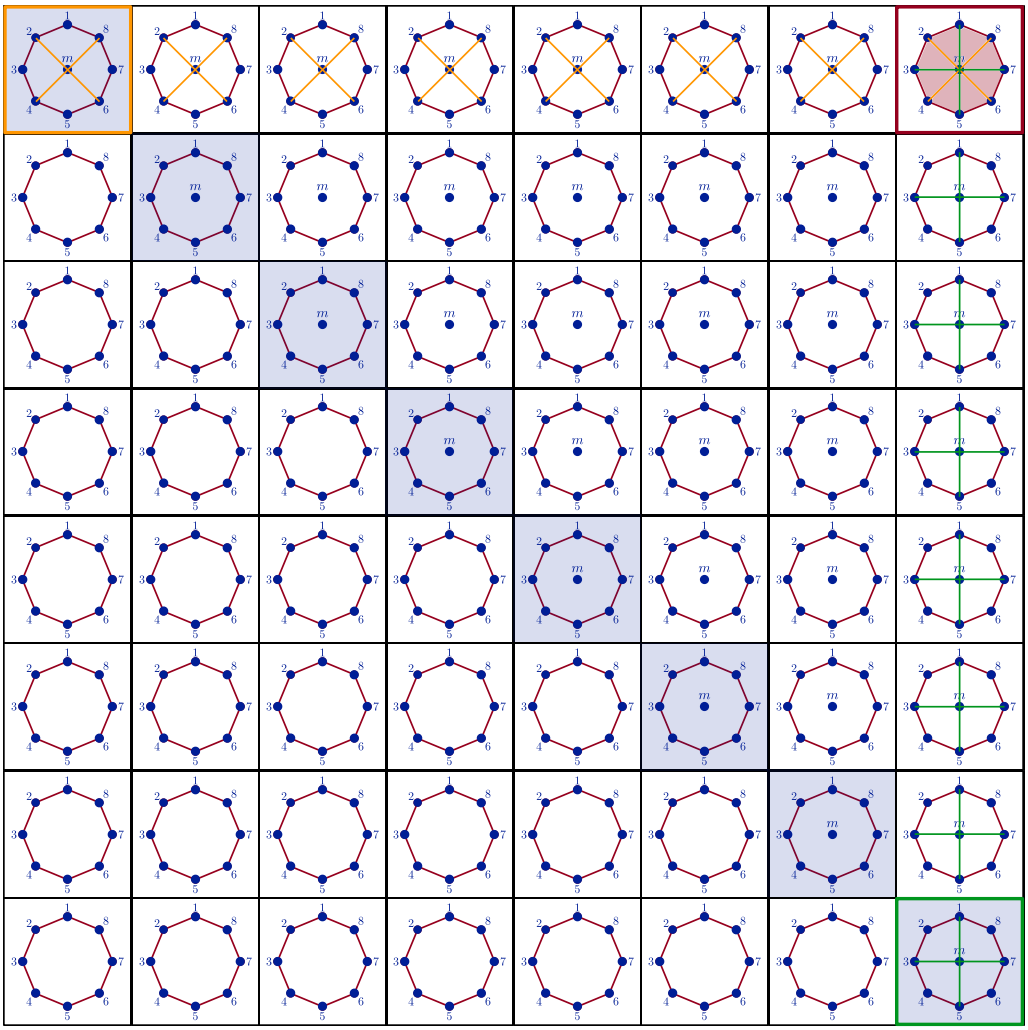

Figure 8 The *wheel* bifiltration consists of $\ell + 1$ 0-simplices, ℓ 1-simplices and ℓ 2-simplices, with $\ell = 8$ in this case. The only ℓ-critical 0-simplex is m entering the bifiltration along the blue staircase. This forces f_1^0 to map all generators of the orange (resp. green) 1-simplices to a generator of m with orange (resp. green) grade. The composition $f_1^0 \circ f_2^0$ then maps each generator of a purple 2-cell to the sum of a generator of m with orange grade and one with a green grade. The orange and green generators of m are connected by $\ell - 1$ relations. This yields $\ell - 1$ non-zero entries in each of the ℓ columns of $[h_i^0]$, making it dense.

5 Log-path algorithm

Shortcuts. In the preceding section, we leveraged the fact that the upset modules induced by simplices of a bifiltration admit path-shaped resolutions, allowing us to compute the correction terms f_i^1 and h_i^0 in a simple way. In the worst case, many generators and relations are mapped to long paths, making the matrices $[f_i^1]$ and $[h_i^0]$ dense ($\Omega(nk)$ size) and leading to a quadratic running time of $\Theta(nk)$ for the path algorithm.

Such long paths can be avoided by introducing shortcuts in the path resolution $\mathcal{P}_\sigma$ (4), as illustrated in Figure 9. Recall that the grades $\mathcal{G}(\sigma) = \{x_1, \cdots, x_{n_\sigma}\}$ generating $\mathrm{supp}(\sigma)$ are totally ordered (by their first coordinate). Now any two vertices $g_\sigma^{x_j}$ and $g_\sigma^{x_\ell}$ with $j < \ell$

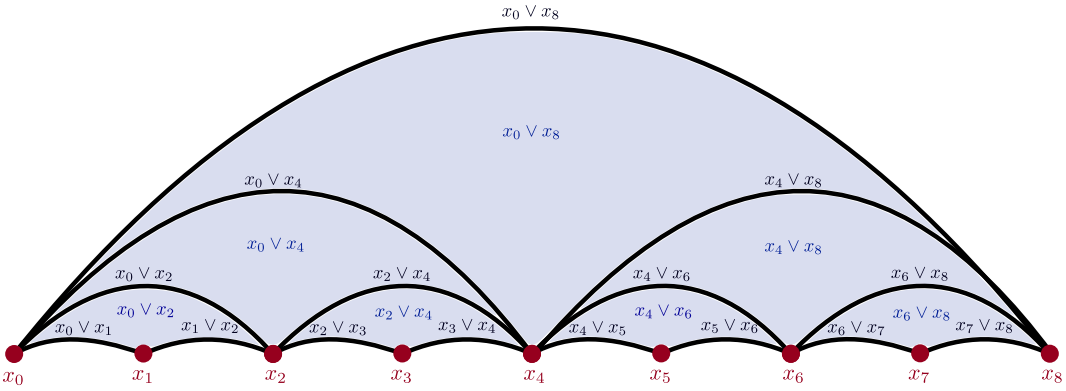

Figure 9 Log-path resolution labeled by the grades of its generators, relations and syzygies.

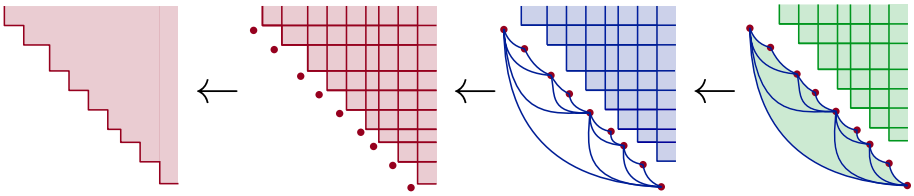

Figure 10 The new resolution of length 2 of an upset module U_σ.

are connected by an additional shortcut edge if there are numbers $s \geq 0, t > 0$ with $j = s2^t$ and $\ell = (s+1)2^t$. Extending $\mathcal{P}_\sigma$ by this edge corresponds to adding a relation r_σ^z to R_σ, where $p_\sigma(r_\sigma^z) = g_\sigma^{x_j} + g_\sigma^{x_\ell}$ and $z = x_j \vee x_\ell$. In total, only $O(n_\sigma)$ many edges are added.

This construction ensures that any two vertices $g_\sigma^{x_j}$ and $g_\sigma^{x_\ell}$ with $j < \ell$ are connected by a monotone path of length logarithmic in n_σ. A shortest monotone path can be constructed in a greedy way. We start in $g_\sigma^{x_j}$ and take the longest possible edge in each step that does not overshoot $g_\sigma^{x_\ell}$. We conclude the following extension of Lemma 1 (proved in [3, B.1]).

▶ **Lemma 4** (Log-path Lemma). *For any $g_\sigma^{x_j}$, $g_\sigma^{x_\ell}$ in G_σ, there exist $r_\sigma^{y_1}, \dots, r_\sigma^{y_m}$ in R_σ with $m = O(\log n_\sigma)$ such that $p_\sigma^1(r_\sigma^{y_1} + \cdots + r_\sigma^{y_m}) = g_\sigma^{x_j} + g_\sigma^{x_\ell}$. Moreover, the elements $r_\sigma^{y_1}, \dots, r_\sigma^{y_m}$ can be computed in $O(\log n_\sigma)$ time.*

Log-path resolutions. Lemma 4 appears to resolve the size issue: the same algorithm as in the previous section can be used, except that in the construction of h_i^0 and f_i^1 use Lemma 4 instead of Lemma 1. Then, the number of nonzero boundary coefficients for every generator and relation has only size $O(\log n_\sigma)$ instead of $O(n_\sigma)$, which would lead to an output boundary matrix with $O(n \log k)$ nonzero entries.

Now recall that a key reason for why the path construction in (7) yields a chain complex is the uniqueness of paths between vertices. This leads to the vanishing of the terms $h_i^0 \circ f_{i+1}^0 + f_{i-1}^1 \circ h_{i+1}^0$ and $h_i^0 \circ p_i^1 + f_{i-1}^1 \circ f_i^1$ when composing boundary maps in (7). However, after adding shortcut edges the paths between vertices are no longer unique. As illustrated in Figure 11, for a relation r_σ^y, the terms $h_i^0 \circ p_i^1(r_\sigma^y)$ and $f_{i-1}^1 \circ f_i^1(r_\sigma^y)$, when restricted to a component, may correspond to different paths connecting the same endpoints and may therefore enclose a cycle.

Any such cycle constitutes an obstruction to the vanishing of $h_i^0 \circ p_i^1 + f_{i-1}^1 \circ f_i^1$. To eliminate these obstructions, we fill the cycles with faces, or, in algebraic terms, introduce syzygies, thus extending the modified relations to a free resolution, as depicted in Figure 10:

$$0 \longleftarrow U_\sigma \xleftarrow{p_\sigma^0} G_\sigma \xleftarrow{p_\sigma^1} R_\sigma \xleftarrow{p_\sigma^2} S_\sigma \longleftarrow 0. \tag{8}$$

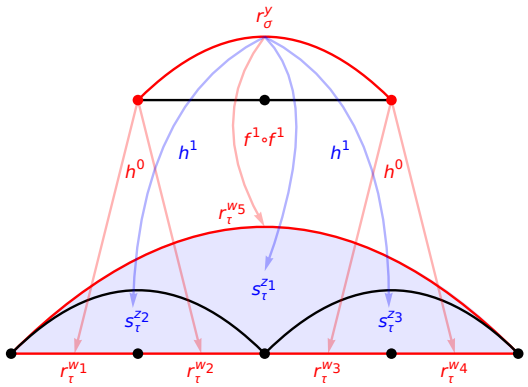

Figure 11 Cycle formed by paths $h^0 \circ p^1(r_\sigma^y)$ and $f^1 \circ f^1(r_\sigma^y)$ and its filling triangles $h^1(r_\sigma^y)$.

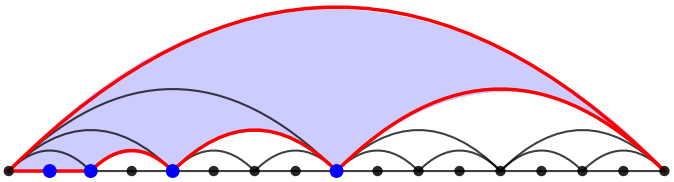

Figure 12 A simple red cycle in $\mathcal{L}$ for $k = 4$, together with the filling triangles in blue corresponding to the non-extremal vertices (with respect to the total order). Here each triangle $(x_{(s-1)2^t}, x_{s2^t}, x_{(s+1)2^t})$, with $s > 1$ odd, corresponds bijectively to its middle vertex x_{s2^t}.

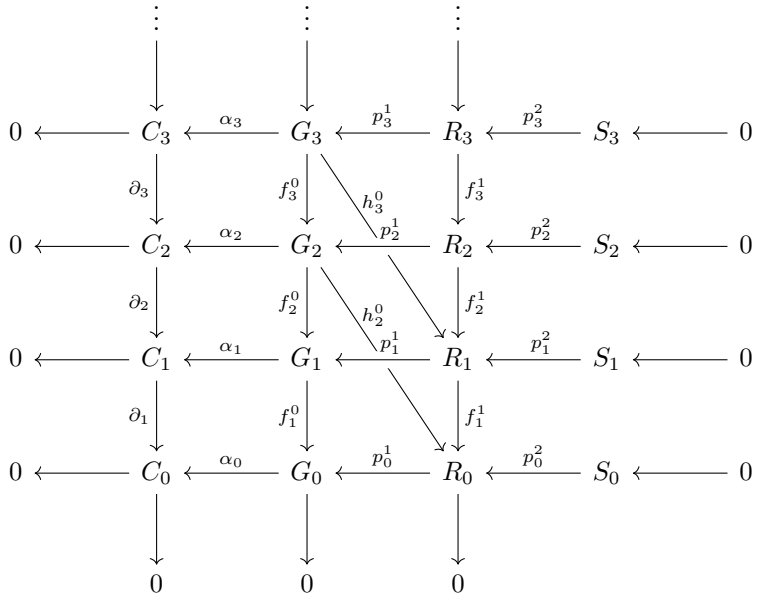
The syzygies s_σ^z for S_σ correspond to the triangles with vertex grades $(x_{(s-1)2^t}, x_{s2^t}, x_{(s+1)2^t})$ for any odd $s > 0$; see Figure 9. The grade z is given by the grade of the longest edge, that is, $x_{(s-1)2^t} \vee x_{(s+1)2^t}$. The map p_σ^2 is defined by sending s_σ^z to the sum of the three edges of the triangle. We call (8) the *log-path resolution* of U_σ, noting that it is a bifiltered two-dimensional simplicial chain complex $\mathcal{L}_\sigma$. Its construction yields the following property:

▶ **Lemma 5.** *Let $r_\sigma^{y_1}, \ldots, r_\sigma^{y_l}$ be a cycle in R_σ. Then there exists a unique chain $s_\sigma^{z_1} + \cdots + s_\sigma^{z_q}$ of $q \leq l-2$ elements in S_σ such that $p_\sigma^2(s_\sigma^{z_1} + \cdots + s_\sigma^{z_q}) = r_\sigma^{y_1} + \cdots + r_\sigma^{y_l}$. Moreover, this chain can be computed in $O(l) = O(\log k)$ time.*

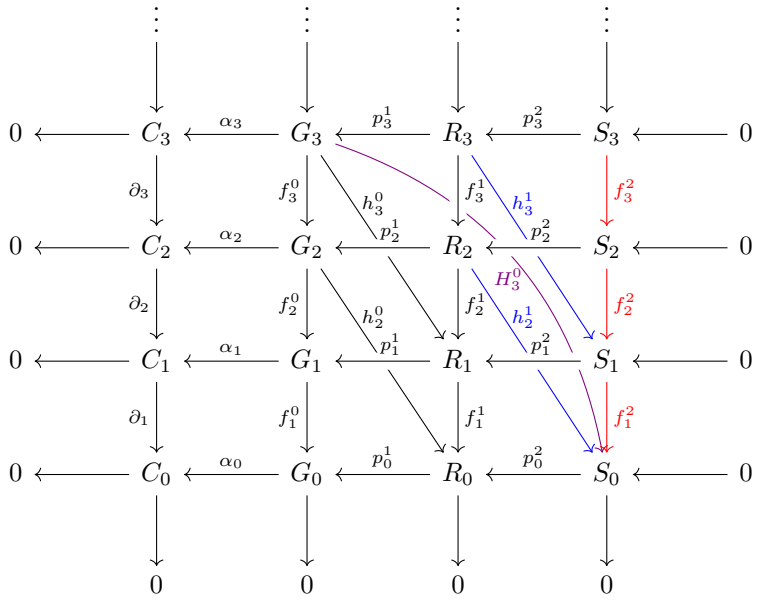
To fill a cycle in $\mathcal{L}_\sigma$, we decompose it into simple cycles and use the observation that a simple cycle is filled with the triangles corresponding to the non-extremal vertices x_{s2^t} of the cycle, see Figure 12. See B.2 of the full version [3] for details.



Log-path algorithm. We now describe the algorithm, again assuming that the input is a k-critical simplicial bifiltration of size n and constant dimension d with chain complex $C_\bullet$.

Step 1: Compute the log-path resolution $\mathcal{L}_i : G_i \xleftarrow{p_i^1} R_i \xleftarrow{p_i^2} S_i$ of each module C_i. This requires iterating through the generators of each input simplex and adding a total of $O(n)$ relations and syzygies, which takes $O(n)$ time in total.

Step 2: Compute $f_i^0 : G_i \to G_{i-1}$ in $O(n \log k)$ time as in Section 4.



Step 3: Compute the maps $f_i^1 : R_i \to R_{i-1}$ and $h_i^0 : G_i \to R_{i-2}$ as in the path algorithm, except that paths between $g_\sigma^{x_j}, g_\sigma^{x_\ell}$ coming from the same simplex σ are computed via Lemma 4. We can find every path in $O(\log k)$ time and compute matrices $[f_i^1]$ and $[h_i^0]$ with at most $O(\log k)$ entries per column in a total running time of $O(n \log k)$ for this step.

Step 4. All maps computed in the previous steps yield the following extension of (7).

(9)

A construction as in Section 4 leads to boundary morphisms whose composition is non-zero. Again, the boundary defect is repaired by introducing correction maps f_i^2, h_i^1, and H_i^0:

(10)

Commutativity of Diagram (9) yields the following observation

▶ **Lemma 6.** *The following morphisms map to the kernel of* p_i^1*:*

$$f_{i+1}^1 \circ p_{i+1}^2, \quad f_{i+1}^1 \circ f_{i+2}^1 + h_{i+2}^0 \circ p_{i+2}^1, \quad \text{and} \quad h_{i+2}^0 \circ f_{i+3}^0 + f_{i+1}^1 \circ h_{i+3}^0. \tag{11}$$

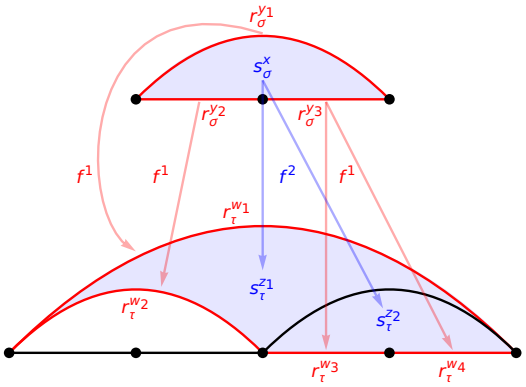


Figure 13 Cycle $f^1 \circ p^2(s_\sigma^x)$ and its filling triangles $f^2(s_\sigma^x)$.

The log-path resolution $\mathcal{L}_i$ of C_i is the direct sum of the simplicial chain complexes $\mathcal{L}_\sigma$, taken over each simplex σ in C_i. The map p_i^1 is given by the 1-dimensional boundary map of this complex, and hence its kernel is the collection of cycles in the 1-skeletons of $\mathcal{L}_\sigma$. More specifically, each triangle s_σ^z in S_{i+1} is sent by p_{i+1}^2 to its boundary, a sum of three edges.

By Lemma 6, applying f_{i+1}^1 to this boundary yields another cycle in R_i, which by construction of $\mathcal{L}_i$ decomposes as $\sum_\tau c_\tau$ for τ running over the facets of σ. For each such cycle c_τ, by Lemma 5 there is a unique chain b_τ in S_i such that $p_i^2(b_\tau) = c_\tau$, as illustrated in Figure 13. The map f_{i+1}^2 is then defined via $f_{i+1}^2(s_\sigma^z) := \sum_\tau b_\tau$, with τ running over the facets of σ. Thus f_{i+1}^2 repairs the boundary defect $f_{i+1}^1 \circ p_{i+1}^2$ as $f_{i+1}^1 \circ p_{i+1}^2 = p_i^2 \circ f_{i+1}^2$. Similar arguments lead to correction terms h_i^1, and H_i^0 satisfying

$$h_i^0 \circ p_i^1 + f_{i-1}^1 \circ f_i^1 = p_{i-2}^2 \circ h_i^1 \quad \text{and} \quad h_{i-1}^0 \circ f_i^0 + f_{i-2}^1 \circ h_i^0 = p_{i-3}^2 \circ H_i^0. \tag{12}$$

Their construction is analogous to the above, and we omit the details.

Note that in each of the three cases f_{i+1}^2, h_i^1, and H_i^0, the construction involves matrix multiplication (evaluation of the left hand sides in (12)), but also cycle filling (invoking Lemma 5). The former is efficient, as paths of logarithmic length lead to sparse matrices $[h_i^0]$ and $[f_i^1]$. More precisely, the column sparsity of $[f_i^1]$ and $[h_i^0]$ is $O(\log k)$, while in $[p_i^2]$ every column has exactly three non-zero entries. All sparse matrix products in Step 4 can thus be computed in $O(n \log^2 k)$ and the worst case column sparsity of the results is $O(\log^2 k)$. The resulting matrices contain cycles of length $O(\log^2 k)$, which can be filled by triangles in $O(\log^2 k)$ time. Overall, Step 4 takes $O(n \log^2 k)$ time.

We can now assemble the output chain complex as

$$0 \longleftarrow G_0 \xleftarrow{\begin{pmatrix} f_1^0 & p_0^1 \end{pmatrix}} G_1 \oplus R_0 \xleftarrow{\begin{pmatrix} f_2^0 & p_1^1 & 0 \\ h_2^0 & f_1^1 & p_0^2 \end{pmatrix}} G_2 \oplus R_1 \oplus S_0 \xleftarrow{\begin{pmatrix} f_3^0 & p_2^1 & 0 \\ h_3^0 & f_2^1 & p_1^2 \\ H_3^0 & h_2^1 & f_1^2 \end{pmatrix}} G_3 \oplus R_2 \oplus S_1 \longleftarrow \cdots \tag{13}$$

▶ **Theorem 7.** *The chain complex* (13) *is a free resolution of* $C_\bullet$.

For a proof, see chapters B.3 and B.4 of the full version [3]. We summarize our observations on the running time in the following theorem.

▶ **Theorem 8.** *A free resolution of the chain complex* $C_\bullet$ *induced by a* k*-critical bifiltration of description size* n *can be computed in* $O(n \log^2 k)$ *time and has* $O(n \log^2 k)$ *size.*

Applying this result to the modified wheel example ([3, A.3]) yields a non-minimal free resolution with smaller description size than any minimal one. Thus, perhaps surprisingly, minimal free resolutions are not asymptotically optimal in terms of description size.

6 Experimental evaluation

We implemented the path and log-path algorithm for computing a free resolution of a bifiltered chain complex in a C++ library called MULTI-CRITICAL [1]. The benchmark files are available upon request. The code expects a bifiltration given in scc2020 format [17], with the difference that for every simplex an arbitrarily long sequence of bigrades can be specified. The output is a chain complex in "proper" scc2020 format, representing a free filtered chain complex. Instead of outputting the result of our algorithms directly, the software can also post-process the filtered chain complex with the *multi-chunk* [16] library for minimizing the chain complex [14, 15].

All experiments were performed on a workstation with an Intel(R) Xeon(R) CPU E5-1650 v3 CPU (6 cores, 12 threads, 3.5GHz) and 64 GB RAM, running Ubuntu 16.04.5.

Test instances. We ran our experiments on a total of 342 test instances from different sources. First, we generated degree-Rips bifiltrations for (noisy) point samples drawn from a torus embedded in $\mathbb{R}^5$, from the "swiss roll" embedded in $\mathbb{R}^3$, and from the 7-dimensional unit cube, using the python package TADASETS. In all cases, we generated the complex up to 3-simplices.

Furthermore, we used a simple method for generating bifiltrations of a simplicial complex equipped with two non-negative real-valued functions f_0 and f_1 on its simplices, described in Figure 14. We employed this construction on meshes from the Aim@Shape repository[2], using the squared mean curvature and the distance to the barycenter as the two functions. Furthermore, we bifiltered the Delaunay triangulations from the same point samples as above (torus, cube, swiss roll) using the minimum enclosing radius of a simplex and the average distance to the $\lfloor \log n \rfloor$-nearest neighbors as filter functions. In all cases, we generated k-critical instances with $k = 2, 4, 8$. We computed the filtration values with CGAL [10, 26, 13].

Finally, we generated wheel bifiltrations as in Figure 8 for different sample sizes.

Comparison of path and log-path algorithms. Table 1 shows some of the results obtained from both algorithms on these datasets; the results for the other instances are similar.

In almost all cases, the log-path algorithm is slower than the path algorithm by a factor of up to 3 and produces an output complex of around twice the size. Also, it uses around twice as much memory (not shown in the table). Moreover, minimizing the chain complex (rightmost column of Table 1) further reduces the complex size significantly, generally at a small cost – sometimes it even saves time because the time used for minimization is less than the cost of producing the larger output file.

The only exception is the wheel bifiltration, where our experiments show the expected asymptotic worst-case behavior, with the log-path algorithm outperforming the path algorithm. In this case, minimizing the chain complex produced by the log-path algorithm will necessarily introduce a dense matrix and destroy the advantage of the log-path algorithm – for instance, its running time in the instance in the last row of Table 1 is 33 seconds, with 14.4 seconds for minimization itself and 18 seconds to write the 2.3 GB output file.

[1] Most recent version at `https://bitbucket.org/mkerber/multi_critical/src/main/`
[2] `http://visionair.ge.imati.cnr.it/`

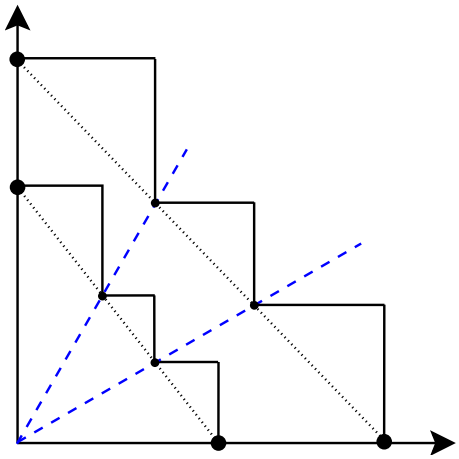

Figure 14 The figure shows the construction for two simplices σ and τ. The bigrades $(0, f_0(\sigma))$ and $(f_1(\sigma), 0)$ are connected by a line segment (dotted line), and the positive quadrant is equally dissected using $(k-2)$ lines through the origin (blue dashed lines, here $k = 4$). The intersection of dotted and dashed lines yield $(k-2)$ further bigrades for σ. The staircase for σ is drawn in solid. The same construction is done for τ; note that if $f_0(\sigma) \leq f_0(\tau)$ and $f_1(\sigma) \leq f_1(\tau)$, the staircase for σ is below the staircase for τ. In particular, the construction bifilters a simplicial complex if the functions f_0 and f_1 respect its face relations.

Computing minimal presentations. For a multi-critical filtered chain complex, we investigate the task of computing minimal presentation matrices for homology. We provide two variants: In the first variant, we compute a free resolution of the input chain complex with the path algorithm (which is usually faster than the log-path algorithm, as seen in the previous experiment) and subsequently minimize using MULTI-CHUNK. We then compute minimal presentations for each homology degree separately using the MPFREE library [18, 15].

The second variant operates by directly structuring the input complex into chain complex segments per degree. It then uses the Chacholski–Scolamiero–Vaccarino algorithm to compute a free implicit representation for each segment, before finally employing MPFREE once more to generate a minimal presentation.

The results of this experiment are presented in Table 2. For the degree-Rips instances, the first variant provides a modest improvement over the second. The reason is that the vast majority of simplices are in the top dimension 3, so that computing the presentation for H_2 is the bottleneck in the computation. This step, however, does not differ significantly in both approaches: most of the time is spent to determine which 3-simplices are killing 2-cycles, by reducing the boundary matrix for 2- and 3-simplices.

For the bifunction instances, the speed-up of the first variant using free resolutions is much more pronounced. The reason is that these instances have a more balanced distribution of simplices over different dimensions: while for the second variant, the algorithm for H_k still has to find the bounding $(k+1)$-simplices for every k, the multi-chunk algorithm makes use of the clearing optimization [9] and hence avoids the reduction of large parts of the boundary matrices. Remarkably, this technique is so effective that computing *all* minimal presentations via free resolutions is faster than computing a *single* minimal presentation via the approach using the Chacholski–Scolamiero-Vaccarino algorithm, even though restricting to a single dimension k allows this approach to disregard all chains in dimensions other than $k+1$, k, or $k-1$.

Table 1 Comparison of the path and the log-path algorithm. All times are in seconds. The "size" columns give the size of the input and output files. For deg-Rips and Delaunay, the numbers are averaged over 5 independently generated instances.

Comparison with Macaulay2. While the Macaulay2 software includes a general `freeResolution` routine [25], it is unsuitable for our purposes. Its use requires converting our bigraded input into a graded chain complex over $\mathbb{Z}_2[x, y]$, a conversion that we found to be slow itself. More importantly, the core computation in Macaulay2 was orders of magnitude slower than our method, even on much smaller instances. We infer that the software was not designed for the large inputs typical of TDA. The conversion script is available on request.

7 Discussion

Our experimental evaluation suggests that the path algorithm often exhibits slightly better performance, which the log-path algorithm is more robust towards "bad" instances, with a relatively low overhead. Together, both variants contribute towards an efficient computational pipeline for multi-critical bifiltrations. Our results also complement recent development for computing degree-Rips bifiltrations more efficiently [2]. The finding that minimal chain complexes may necessitate a quadratic size in sparse matrix representations suggests that these representations may not be universally ideal for boundary matrices. Specifically, the matrix in Figure 8 admits a linear-size description, illustrating a gap in current approaches. It would be interesting to balance effective worst-case compression with efficient matrix processing, possibly by using an alternative data structure or by selective shortcutting.

Finally, our approach partially extends to simplicial complexes filtered with three parameters: a simplexwise minimal free resolution now has length 2, and suitable connecting maps compose into the same diagram as (10). Moreover, as described by Miller and Sturmfels [21], the simplexwise free resolution carries the structure of a planar graph, leading to a cubic-time algorithm. To break the cubic barrier, we will need to generalize the shortcut idea of Section 5 from paths to planar graphs, extending the free resolution of a simplex to length 3 (and introducing even more maps). We leave the details to future work.

Locally Correct Interleavings Between Merge Trees

Abstract

Merge trees are typically used as a topological summary of scalar fields. To analyze e.g. a time-varying scalar field via its merge tree representation, one needs a suitable method to match and compare two merge trees. We consider the interleaving distance as a method to match and compare merge trees. An *interleaving* between two merge trees consists of two maps, one in each direction. These maps must satisfy ancestor relations and hence introduce a "shift" between points and their image. An optimal interleaving minimizes the maximum shift; the interleaving distance is the value of this shift. However, to study the evolution of merge trees, we need not only a number but also a meaningful matching between the two trees. The two maps of an optimal interleaving induce a matching, but due to the bottleneck nature of the interleaving distance, this matching fails to capture local similarities between the trees. In this paper we hence propose a notion of local optimality for interleavings. To do so, we define the *residual interleaving distance*, a generalization of the interleaving distance that allows additional constraints on the maps. This allows us to define *locally correct interleavings*, which use a range of shifts across the two merge trees that reflect the local similarity well. We give a constructive proof that a locally correct interleaving always exists.

1 Introduction

Terrains that vary over time are a common data type in various application areas, such as scientific computing or geographic information science. Typically such data sets are very large; to analyze them efficiently one often needs a compact abstraction that captures salient features. Topological data analysis (TDA) provides several *topological descriptors*, such as persistence diagrams, Reeb graphs, and Morse-Smale complexes, that can serve as abstractions for 2D, 3D, or higher-dimensional terrains. In this paper we focus in particular on *merge trees*, which are graph-based descriptors that encode the evolution of connected components of sublevel or superlevel sets of a terrain (see Figure 1). In the context of time-varying terrains, they have been used for feature tracking [7], cluster detection [16], and various other tasks in scientific visualization [17].

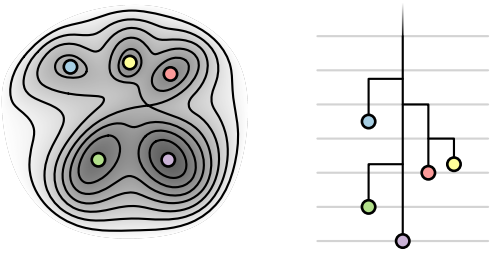

Figure 1 A terrain and its merge tree; leaves and internal vertices represent minima and saddles.

To analyze temporal sequences of terrains one does not only need a compact representation, but also efficient ways to compare these representations over time. For merge trees in particular, several distance measures have been proposed, including the (local) edit distance [13, 14], the Wasserstein distance [11], and the interleaving distance [8]. However, a distance measure returns only a numeric value that quantifies the similarity of two merge trees T_1 and T_2. In many application scenarios, we would also like to track the merge trees over time and hence need to understand which parts of T_1 most closely correspond to parts of T_2. That is, we are interested in a matching between T_1 and T_2.

The interleaving distance in fact relies on a type of matching between the two trees: the so-called *interleaving*. An interleaving is a pair of ancestor-preserving maps, one from T_1 to T_2 and one from T_2 to T_1, whose compositions send points to ancestors: if a point x of T_1 is mapped to a point y of T_2, then y must be mapped to an ancestor of x, and vice versa. The *interleaving distance* is the maximum *shift* – the distance between a point and its image – minimized over all interleavings between the trees. We give exact definitions of the interleaving distance and interleavings in Sections 2 and 3.

Two merge trees typically admit many optimal interleavings. The interleaving distance is a bottleneck measure and hence a given optimal interleaving might be locally quite "loose": the shift might exceed what is needed and thereby fail to capture local similarities between the trees; see Figure 2. In the following we are hence developing a notion of locally optimal interleavings which allows us to distinguish between "tight" and "loose" optimal interleavings.

Contributions. Our work is inspired by the concept of locally correct Fréchet matchings [3]; the *Fréchet distance* is a bottleneck measure for curves based on a matching between points on the curves. A locally correct Fréchet matching is then an optimal matching that remains optimal even when considering any two matched subcurves. This is a desirable feature, however, it cannot be directly reproduced for the interleaving distance. First of all, there might not even be a one-to-one correspondence between the points of T_1 and T_2. Furthermore,

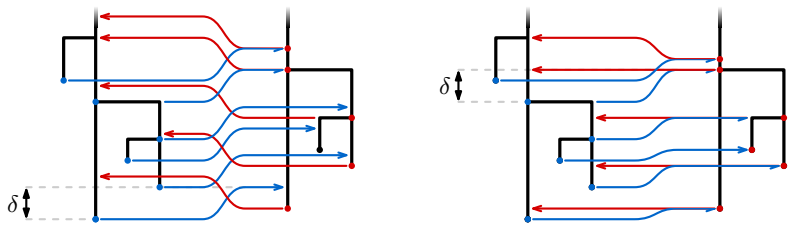

Figure 2 Two optimal interleavings between two merge trees (both with shift δ). Intuitively, the right interleaving induces a tighter and more meaningful matching than the left interleaving.

two optimal interleavings between different pairs of subtrees do not necessarily combine into an optimal interleaving between the two complete trees. As a first step we hence introduce a novel generalization of the interleaving distance that can handle additional constraints on the maps. Specifically, we aim to use constraints that force a point x to be mapped to an ancestor of a particular point y within the other tree. Over interleavings that satisfy such constraints, we aim to minimize the maximum shift over points x that are either unconstrained or map to a strict ancestor of their corresponding point y. We refer to the resulting distance as the *residual interleaving distance*. In Section 3, we provide formal definitions and show that an optimal interleaving exists for any constraints.

In Section 4 we then propose a definition for *locally correct interleavings* that builds upon the residual interleaving distance. Specifically, we define a restriction of an interleaving $\mathcal{I} = (\alpha, \beta)$ to two subsets S_1 of T_1 and S_2 of T_2 as the restriction of α to S_1 together with the restriction of β to S_2. We call $\mathcal{I}$ locally correct if it minimizes the residual interleaving distance with respect to any restriction of $\mathcal{I}$. We constructively prove that a locally correct interleaving always exists. All omitted proofs can be found in the full version.

Related work. The interleaving distance between merge trees was defined by Morozov, Beketayev, and Weber [8] as a tool to study the stability of merge trees. The authors of [1] establish a connection between the interleaving distance and the Gromov-Hausdorff distance, and they argue that approximating the interleaving distance within a factor of 3 is NP-hard. They also describe an $\mathcal{O}(\min(n, \sqrt{rn}))$-approximation algorithm, where n is the total size of the trees and r is the ratio of the longest to the shortest edge. Touli and Wang [15] provide an equivalent definition of the interleaving distance in terms of a single map and use this characterization to design an FPT-algorithm for computing the interleaving distance exactly. More recently, the authors of [6] show that the interleaving distance can be formulated in terms of a related metric [9] for labeled merge trees, also known as phylogenetic trees.

Several attempts have been made to develop versions of the interleaving distance that can be used in practical applications. In particular, the results in [6] gave rise to heuristic algorithms for computing the interleaving distance [4] and for comparing terrains [16, 18]. Pegoraro [10] uses yet another reformulation of the interleaving distance, in terms of couplings, as the basis of a heuristic for computing the distance via linear integer programming. Lastly, the authors of [2] introduce a variant of the interleaving distance that imposes total orders on the merge trees, which can be computed efficiently via a connection to the Fréchet distance between one-dimensional curves.

2 Preliminaries

Let T be a rooted tree, that is, a tree with one vertex identified as the *root*. In the remainder of this paper, we identify T with a *topological realization*: we represent each edge of T by a unit segment $[0, 1]$ and connect these segments according to the adjacencies of their corresponding edges in T. We distinguish elements of the topological realization T, which we refer to as *points* of T, from vertices of the combinatorial tree, which we denote by $V(T)$. A *merge tree* is a pair (T, f), where T is a finite rooted tree, and $f\colon T \to \mathbb{R} \cup \{\infty\}$ is a continuous *height function* on T that is strictly increasing towards the root and such that the root has height ∞. When clear from context, we use T to refer to the pair (T, f).

For two points x_1 and x_2 of T, we say x_1 is a *descendant* of x_2, written $x_1 \preceq x_2$, if there exists an f-monotonically increasing path in T from x_1 to x_2. If furthermore $x_1 \neq x_2$ then x_1 is a *strict descendant* of x_2. We say x_2 is a *(strict) ancestor* of x_1 if x_1 is a (strict) descendant of x_2. Lastly, for a point x and a height value $h \geq f(x)$, we use $x|^h$ to denote the unique ancestor of x at height $f(x|^h) = h$ (see Figure 3a).

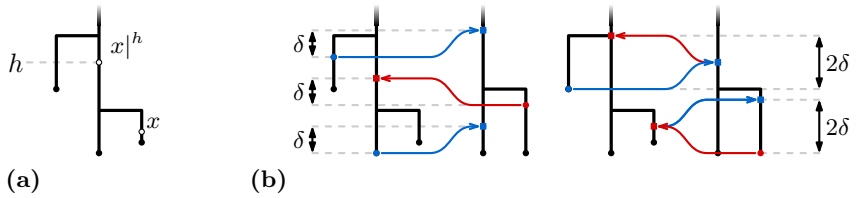

Figure 3 **(a)** The point $x|^h$ is the ancestor of x at height h. **(b)** A pair of δ-compatible maps. Left: **C1** and **C2** ensure that each point is mapped to a point of the other tree δ higher. Right: **C3** and **C4** ensure that both compositions map points to their ancestor 2δ higher.

Compatible maps. The original definition of the interleaving distance between two merge trees (T_1, f_1) and (T_2, f_2) was given by Morozov, Beketayev, and Weber [8].

▶ **Definition 1** ([8]). *Fix a value $\delta \geq 0$. Two continuous maps $\alpha\colon T_1 \to T_2$ and $\beta\colon T_2 \to T_1$ are* δ-compatible *between T_1 and T_2 if for all $x \in T_1$ and all $y \in T_2$:*

(C1) $f_2(\alpha(x)) = f_1(x) + \delta$,
(C2) $f_1(\beta(y)) = f_2(y) + \delta$,
(C3) $\beta(\alpha(x)) = x|^{f_1(x)+2\delta}$, *and*
(C4) $\alpha(\beta(y)) = y|^{f_2(y)+2\delta}$.

The interleaving distance $d(T_1, T_2)$ *between T_1 and T_2 is the infimum δ for which there exist δ-compatible maps (see Figure 3b).*

Critical values. It has been shown [1, 15] that the interleaving distance between any two merge trees attains a value in a set of *critical values*. Specifically, let $\Delta := \Delta(T_1, T_2)$ be the union of three sets Δ_1, Δ_2, and Δ_3, with

$$\begin{aligned} \Delta_1 &:= \{|f_1(v) - f_2(w)| : v \in V(T_1), w \in V(T_2)\}, \\ \Delta_2 &:= \{\tfrac{1}{2}|f_1(v_1) - f_1(v_2)| : v_1, v_2 \in V(T_1)\}, \\ \Delta_3 &:= \{\tfrac{1}{2}|f_2(w_1) - f_2(w_2)| : w_1, w_2 \in V(T_2)\}. \end{aligned} \tag{1}$$

▶ **Lemma 2** ([1, 15]). *For any two merge trees T_1 and T_2, it holds that $d(T_1, T_2) \in \Delta(T_1, T_2)$.*

3 Generalizing the interleaving distance

The interleaving distance is based on a pair of maps. As noted in [1], we can relax the requirements on these maps to allow varying height differences between points and their images. Building on this relaxed definition, we introduce a generalized version of the interleaving distance that accommodates constraints on the maps we consider. Specifically, each constraint specifies that a point x must be mapped to an ancestor of a particular point y within the other tree. Our goal is then to find the optimal pair of maps that "extends" a given set of constraints. We call the corresponding distance the *residual interleaving distance*. To define it formally, we first introduce *partial up-maps*, which represent the allowed maps between the two merge trees. In Section 3.1 we relax Definition 1 using partial up-maps. In Section 3.2 we then give the formal definition of the residual interleaving distance.

Partial up-maps. Let (T_1, f_1) and (T_2, f_2) be two merge trees. An *arrow* from T_1 to T_2 is any pair of points $(x, y) \in T_1 \times T_2$ such that $f_1(x) \leq f_2(y)$. The *shift* of an arrow (x, y) is the height difference between x and y, denoted $\sigma(x, y) := f_2(y) - f_1(x)$. Consider a subset of points $S \subseteq T_1$. A map $\varphi\colon S \to T_2$ is a *partial up-map* from S to T_2 if (i) $f_2(\varphi(x)) \geq f_1(x)$

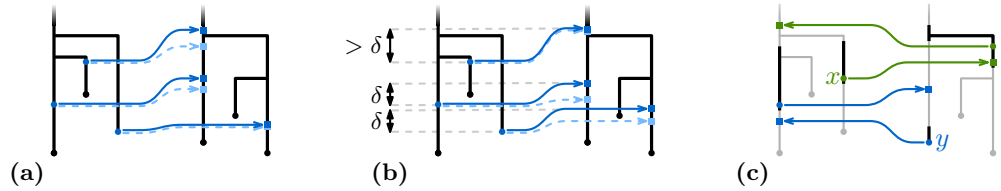

Figure 4 **(a)** A partial up-map (non-dashed) that extends another partial up-map (dashed). **(b)** A partial up-map φ (dashed) and the map $\varphi^{\uparrow}[\delta]$ (non-dashed). **(c)** A partial interleaving.

for all points x of S and (ii) it *preserves ancestors*, that is, $x_1 \preceq x_2$ implies $\varphi(x_1) \preceq \varphi(x_2)$ for all points x_1, x_2 of S. We use $\mathrm{dom}(\varphi) \coloneqq S$ to denote the *domain* of φ. For each point x of S, the pair $(x, \varphi(x))$ is an arrow. The *graph* of φ is the set of arrows of φ, denoted $A_\varphi \coloneqq \{(x, \varphi(x)) : x \in S\}$. We define the *shift* of the partial up-map φ as the supremum shift over all arrows of φ:

$$\sigma(\varphi) \coloneqq \sup\{\sigma(a) : a \in A_\varphi\}. \tag{2}$$

Given an arrow (x, y) from S to T_2, we say φ *extends* (x, y) if $\varphi(x) \succeq y$, and we say φ *uses* (x, y) if $\varphi(x) = y$. Similarly, for a subset $S' \subseteq S$ and a partial up-map φ' from S' to T_2, we say φ *extends* or *uses* φ' if, respectively, φ extends or uses all arrows of φ' (Figure 4a).

For any $\delta \geq 0$, we can define a partial up-map $\varphi^{\uparrow}[\delta]$ from S to T_2 that extends φ and such that the shift of each arrow is at least δ. Specifically, for each point x of S, let $h_x \coloneqq \max(f_1(x) + \delta, f_2(\varphi(x)))$ and define $\varphi^{\uparrow}[\delta](x) \coloneqq \varphi(x)|^{h_x}$ (see Figure 4b).

▶ **Lemma 3.** *For any $\delta \geq 0$, the map $\varphi^{\uparrow}[\delta]$ is a partial up-map that extends φ.*

Proof. Let $\varphi' \coloneqq \varphi^{\uparrow}[\delta]$. By construction, we have $f_2(\varphi'(x)) \geq f_1(x)$. To see that φ' preserves ancestors, take two points x_1, x_2 of S such that x_2 is an ancestor of x_1. Since φ preserves ancestors, $\varphi(x_2)$ is an ancestor of $\varphi(x_1)$. If $\varphi'(x_1) = \varphi(x_1)$, we get $\varphi'(x_1) \preceq \varphi(x_2) \preceq \varphi'(x_2)$. Otherwise $\varphi'(x_1)$ is a strict ancestor of $\varphi(x_1)$. By construction, $f_2(\varphi'(x_1)) = f_1(x_1) + \delta \leq f_1(x_2) + \delta \leq f_2(\varphi'(x_2))$. Both $\varphi'(x_1)$ and $\varphi'(x_2)$ are ancestors of $\varphi(x_1)$, so $\varphi'(x_2)$ is an ancestor of $\varphi'(x_1)$. So φ' is a partial up-map, and by construction also extends φ. ◀

We define arrows and up-maps from a subset S of T_2 to T_1 symmetrically.

Partial interleavings. Fix two subsets $S_1 \subseteq T_1$ and $S_2 \subseteq T_2$. A *partial interleaving* $\mathcal{P}$ between S_1 and S_2 is a pair of partial up-maps $\varphi\colon S_1 \to T_2$ and $\psi\colon S_2 \to T_1$ such that for all points x of S_1 and all points y of S_2 it holds that if $\varphi(x) \preceq y$ then $\psi(y) \succeq x$, and if $\psi(y) \preceq x$ then $\varphi(x) \succeq y$ (Figure 4c). The *shift* of $\mathcal{P}$, denoted $\sigma(\mathcal{P})$, is the maximum of the shift of φ and the shift of ψ. The *graph* of $\mathcal{P}$ is the union of the graph of φ and the graph of ψ, denoted $A_{\mathcal{P}} \coloneqq A_\varphi \cup A_\psi$. Given another partial interleaving $\mathcal{P}' = (\varphi', \psi')$, we say $\mathcal{P}$ *extends* $\mathcal{P}'$ if φ extends φ' and ψ extends ψ'. Similarly, $\mathcal{P}$ *uses* $\mathcal{P}'$ if φ uses φ' and ψ uses ψ'.

▶ **Lemma 4.** *For any $\delta \geq 0$, the pair $(\varphi^{\uparrow}[\delta], \psi^{\uparrow}[\delta])$ is a partial interleaving that extends (φ, ψ).*

Proof. Denote $\varphi' \coloneqq \varphi^{\uparrow}[\delta]$ and $\psi' \coloneqq \psi^{\uparrow}[\delta]$. By Lemma 3, the maps φ' and ψ' are partial up-maps that extend φ and ψ, respectively. Therefore, it suffices to show that the pair (φ', ψ') is a partial interleaving. Let x be a point of S_1 and y be a point of S_2 such that $\varphi'(x) \preceq y$. By construction, the point $\varphi'(x)$ is an ancestor of $\varphi(x)$, so y is also an ancestor of $\varphi(x)$. Since (φ, ψ) is a partial interleaving, the point $\psi(y)$ must be an ancestor of x. As $\psi'(y)$ is an ancestor of $\psi(y)$, we get $\psi'(y) \succeq x$. Symmetrically, if $\psi'(y) \preceq x$ then $\varphi'(x) \succeq y$. ◀

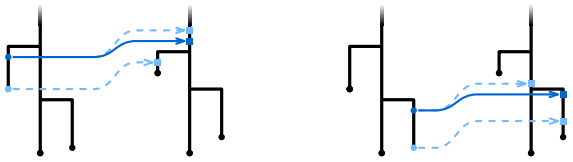

Figure 5 The shift of the dashed interleaving is not equal to a critical value, so we can obtain another interleaving (non-dashed) with strictly smaller shift by "pushing down" the image of each point. If we push below a vertex (right) we carefully need to choose the correct subtree.

3.1 Complete Interleavings

If $S_1 = T_1$, we call a partial up-map $\alpha\colon S_1 \to T_2$ a *complete up-map*, or simply an *up-map*, from T_1 to T_2. Symmetrically, if $S_2 = T_2$, we call a partial up-map $\beta\colon S_2 \to T_1$ a (complete) up-map from T_2 to T_1. Correspondingly, if $S_1 = T_1$ and $S_2 = T_2$, we call the partial interleaving (α, β) a *(complete) interleaving*. The defining property for a complete interleaving then becomes that for all $x \in T_1$ it holds that $\beta(\alpha(x)) \succeq x$ and for all $y \in T_2$ it holds that $\alpha(\beta(y)) \succeq y$.

▶ **Lemma 5.** *$d(T_1, T_2) = \inf\{\delta : T_1$ and T_2 admit a complete interleaving with shift $\delta\}$.*

Optimal interleavings. The interleaving distance is defined as an infimum, but in both [5, 10] the authors prove that the infimum can be replaced by a minimum: there always exists an interleaving with shift $d(T_1, T_2)$ (Theorem 6). We call an interleaving that realizes the interleaving distance an *optimal interleaving*. Both proofs rely on alternative definitions of the interleaving distance, namely in terms of labellings [5] and in terms of couplings [10]. We can show the same statement more directly: if the shift δ of an interleaving $\mathcal{I}$ is not equal to a critical value, we can obtain an interleaving whose shift $\delta' < \delta$ is equal to a critical value. Intuitively, we "push down" each arrow of $\mathcal{I}$ so that its shift becomes δ' (see Figure 5). Later, in Section 3.2, we describe a formal construction to prove a generalization of Theorem 6.

▶ **Theorem 6.** *Any two merge trees T_1 and T_2 admit an optimal interleaving.*

3.2 Residual Interleaving Distance

Fix a partial interleaving $\mathcal{P} = (\varphi, \psi)$. We refer to a (partial) interleaving that extends $\mathcal{P}$ as a (*partial*) *$\mathcal{P}$-extension*. We first observe that there always exists a complete $\mathcal{P}$-extension. Indeed, the maps that take every point of T_1 to the root at ∞ of T_2, and every point of T_2 to the root at ∞ of T_1 form a complete interleaving that extends $\mathcal{P}$.

Our goal is to find a "tightest possible" complete $\mathcal{P}$-extension, that is, an interleaving that extends $\mathcal{P}$ and minimizes the shift of the remaining arrows. For some intuition, consider the example in Figure 6. The map φ consists of a single (dashed) arrow (x, y). Intuitively, the map α_2 describes a "tighter" extension of φ than the map α_1. However, if we only disregard the shift of (x, y), the shift of the remaining arrows of α_1 is equal to the (supremum) shift of the remaining arrows of α_2. The arrow (x, y) implicitly induces a "fan" of arrows that all valid up-maps need to extend. Specifically, any ancestor of x needs to be mapped to an ancestor of y. To distinguish between the maps α_1 and α_2, we therefore not only disregard the shift of (x, y), but of any arrow that is "contained" within such a fan.

Formally, we define the *fan* of an arrow (x, y) as the set of arrows (x', y) for all ancestors x' of x with height at most that of y, written,

$$F[(x, y)] \coloneqq \{(x', y) : x' \in T_1 \text{ such that } x' \succeq x \text{ and } f_1(x') \leq f_2(y)\}.$$

The *fan* of a collection of arrows A, denoted $F[A]$, is the union of all fans $F[a]$ for $a \in A$. We refer to the fan $F[A_\varphi]$ as the *fan* of φ.

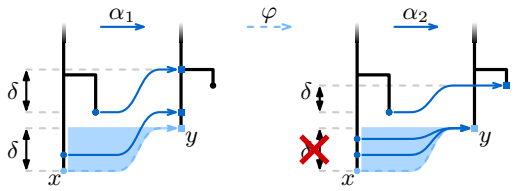

Figure 6 The φ-residual shift of arrows within the fan $F[(x, y)]$ (illustrated with the shaded area) is equal to 0, so the φ-residual shift of α_2 is smaller than the φ-residual shift of α_1.

We use fans to define the *φ-residual shift*, or *φ-shift* for short. Recall that we use A_φ to denote the set of all arrows $(x, \varphi(x))$. For an arrow a from T_1 to T_2, the φ-residual shift of a, denoted $\sigma_\varphi(a)$, is zero if a lies within $F[A_\varphi]$, and is $\sigma(a)$ otherwise. Similar to the definition of shift in Eq. 2, we define the φ-residual shift of an up-map φ', denoted $\sigma_\varphi(\varphi')$, as the supremum φ-residual shift over all arrows of φ'. That is,

$$\sigma_\varphi(x, y) \coloneqq \begin{cases} 0 & \text{if } (x, y) \in F[A_\varphi], \\ \sigma(x, y) & \text{else,} \end{cases} \qquad \sigma_\varphi(\varphi') \coloneqq \sup\{\sigma_\varphi(a) : a \in A_{\varphi'}\}.$$

Consider again the example in Figure 6. We disregard the shifts of all arrows within the fan $F[(x, y)]$. As a result, the φ-shift of α_2 is δ', whereas the φ-shift of α_1 is δ.

We define the *ψ-(residual) shift* of a partial up-map ψ' symmetrically. Finally, for a partial interleaving $\mathcal{P}' = (\varphi', \psi')$, we define the *$\mathcal{P}$-residual* shift, or *$\mathcal{P}$-shift*, of $\mathcal{P}'$ as the maximum of the φ-shift of φ' and the ψ-shift of ψ', denoted $\sigma_\mathcal{P}(\mathcal{P}')$.

▶ **Definition 7.** *The $\mathcal{P}$-residual interleaving distance $d_\mathcal{P}(T_1, T_2)$ between T_1 and T_2 is the infimum δ for which there exists a complete $\mathcal{P}$-extension whose $\mathcal{P}$-residual shift is δ.*

When they are clear from context, we omit the arguments T_1 and T_2 and simply write $d_\mathcal{P}$ to denote the $\mathcal{P}$-residual interleaving distance between T_1 and T_2. We say an extension is *optimal* if its residual shift is equal to the residual interleaving distance.

Critical values and pairs. For the remainder of this section, we consider *finite* partial interleavings $\mathcal{P}$: both $\mathrm{dom}(\varphi)$ and $\mathrm{dom}(\psi)$ consist of finitely many points. Recall from Section 2 that the non-residual interleaving distance always attains a value in the set of critical values $\Delta \coloneqq \Delta(T_1, T_2)$. For the residual interleaving distance, this set Δ is not always sufficient (see Figure 7). Therefore, we extend Δ to a set of $\mathcal{P}$-critical values. Specifically, we "mark" all vertices in T_1 and T_2, and all points x of T_1 and y of T_2 that appear in an arrow (x, y) or (y, x) of $\mathcal{P}$. We call these the *$\mathcal{P}$-critical points* of T_1 and T_2, denoted $C_1[\mathcal{P}]$ and $C_2[\mathcal{P}]$ respectively. Since $\mathcal{P}$ is finite, there are only finitely many critical points. We

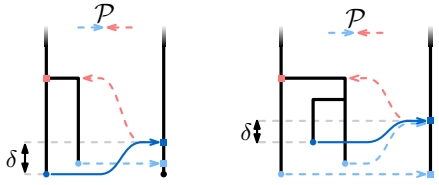

Figure 7 In both examples, the non-dashed arrow is (part of) an optimal interleaving; the value δ is not equal to a critical value. It is equal to a $\mathcal{P}$-critical value.

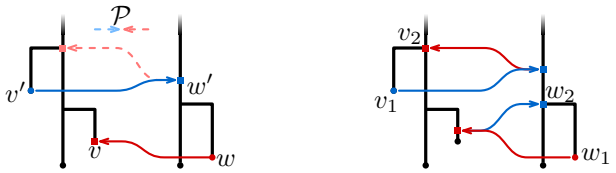

Figure 8 There are two types of critical pairs: arrow critical pairs (w, v) and (v', w') (left) and zigzag critical pairs (v_1, v_2) and (w_1, w_2) (right). The pair (v', w') correspond to a $\mathcal{P}$-critical value.

define a set $\Delta_1[\mathcal{P}]$ that contains all height differences between critical points:

$$\Delta_1[\mathcal{P}] \coloneqq \{|f_1(v) - f_2(w)| : v \in C_1[\mathcal{P}], w \in C_2[\mathcal{P}]\}.$$

We define the set of $\mathcal{P}$-*critical values* as the set $\Delta[\mathcal{P}](T_1, T_2) \coloneqq \Delta_1[\mathcal{P}] \cup \Delta_2 \cup \Delta_3$, where Δ_2 and Δ_3 are as defined in Eq. (1). Each critical value corresponds to a pair of critical points; we refer to such a pair b as a $\mathcal{P}$-*critical pair*. We distinguish two types; see Figure 8.

- If $b = (v, w)$ for a point $v \in C_1[\mathcal{P}]$ and a point $w \in C_2[\mathcal{P}]$, then b is an *arrow critical pair* that corresponds to the critical value $\sigma(v, w)$. We say a partial interleaving (φ, ψ) *uses* b if $\varphi(v) = w$. The case that $b = (w, v)$ is symmetric.
- If $b = (v_1, v_2)$ for two vertices v_1, v_2 in $V(T_1)$, then b is a *zigzag critical pair* that corresponds to the critical value $\frac{1}{2}(f_1(v_2) - f_1(v_1))$. We say a partial interleaving (φ, ψ) *uses* b if there is a point $y \in T_2$ with $f_2(y) = f_1(v_1) + \frac{1}{2}(f_1(v_2) - f_1(v_1))$ such that $\varphi(v_1) = y$ and $\psi(y) = v_2$. The case that $b = (w_1, w_2)$ for two vertices w_1, w_2 in $V(T_2)$ is symmetric.

Similar to Lemma 2, we show that the $\mathcal{P}$-residual interleaving distance always attains a value in the set of $\mathcal{P}$-critical values. A $\mathcal{P}$-critical pair is a *realizing* critical pair if it corresponds to the $\mathcal{P}$-residual interleaving distance. We can additionally show that there always exists an optimal $\mathcal{P}$-extension and that any such extension uses a realizing critical pair.

▶ **Lemma 8.** *Let $\mathcal{P}$ be a finite interleaving. For any complete $\mathcal{P}$-extension with $\mathcal{P}$-shift δ that does not use a critical pair that corresponds to δ, there exists another $\mathcal{P}$-extension whose $\mathcal{P}$-shift is equal to a $\mathcal{P}$-critical value that is strictly less than δ.*

Proof sketch. Consider a $\mathcal{P}$-extension $\mathcal{I} = (\alpha, \beta)$ with $\mathcal{P}$-shift δ, and assume $\mathcal{P}$ does not use a critical pair that corresponds to δ. We modify $\mathcal{I}$ into an extension $\mathcal{I}' = (\alpha', \beta')$ whose $\mathcal{P}$-shift is equal to a $\mathcal{P}$-critical value that is strictly less than δ. Let $\delta' \in \Delta[\mathcal{P}]$ be the greatest value that satisfies $\delta' < \delta$. Intuitively, we modify $\mathcal{I}$ by "pushing down" each arrow (recall Figure 5). We describe the construction of α'; the construction of β' is symmetric.

We assume, without loss of generality, that each arrow of α has shift at least δ'. Otherwise, we replace α by $\alpha^{\uparrow}[\delta']$. Since the residual shift of an arrow is bounded by its shift, and since $\delta' < \delta$, the φ-residual shift of $\alpha^{\uparrow}[\delta']$ is bounded by δ. For $x \in T_1$, let $v_x \in C_1[\mathcal{P}]$ be the highest descendant critical point of x; if $x \in C_1[\mathcal{P}]$, then $v_x = x$. Moreover, let $w_x \in C_2[\mathcal{P}]$ be the highest descendant critical point of $\alpha(v_x)$. Let $h_x \coloneqq \max(f_1(x) + \delta', f_2(w_x))$. We define $\alpha'(x)$ as the ancestor of w_x at height h_x, that is, $\alpha'(x) \coloneqq w_x|^{h_x}$.

It is not hard to prove that α' is an up-map that extends φ. To show that the φ-shift of α' is bounded by δ', we argue that any arrow (x, y) of α' with shift strictly greater than δ' must be inside the fan of φ. Specifically, we show that then also the shift δ^* of the arrow (v_x, w_x) is strictly greater than δ'. The pair (v_x, w_x) is a critical pair; since $\mathcal{I}$ does not use a critical pair that corresponds to δ, it moreover follows that δ^* cannot be equal to δ. So, by choice of δ', we get $\delta^* > \delta$. As a result, (v_x, w_x), and therefore also (x, w_x) must lie within the fan of φ: their residual shift is 0. Symmetrically, the map β' is an up-map that extends ψ and has ψ-shift at most δ'. We can then argue that the resulting pair $\mathcal{I}'$ is an interleaving. ◀

Lemma 8 directly implies Corollaries 9 and 10.

▶ **Corollary 9.** *If $\mathcal{P}$ is finite, then any optimal $\mathcal{P}$-extension uses a realizing critical pair.*

▶ **Corollary 10.** *If $\mathcal{P}$ is finite, then $d_{\mathcal{P}}(T_1, T_2) \in \Delta[\mathcal{P}](T_1, T_2)$.*

Let $\delta_1 \in \Delta[\mathcal{P}]$ be the greatest value that satisfies $\delta_1 \leq d_{\mathcal{P}}$ and let $\delta_2 \in \Delta[\mathcal{P}]$ be the smallest value that satisfies $\delta_2 > d_{\mathcal{P}}$. By definition of $d_{\mathcal{P}}$, for all $\varepsilon > 0$ there is a $\mathcal{P}$-extension with $\mathcal{P}$-shift $d_{\mathcal{P}} + \varepsilon$. In particular, for ε small enough, there is a $\mathcal{P}$-extension $\mathcal{I}$ with $\mathcal{P}$-shift $\delta_1 < \sigma_{\mathcal{P}}(\mathcal{I}) < \delta_2$. In other words, there are no critical pairs that correspond to $\sigma_{\mathcal{P}}(\mathcal{I})$. This means that $\mathcal{I}$ cannot use a critical pair that corresponds to the $\mathcal{P}$-shift of $\mathcal{I}$. By Lemma 8, it then follows that there exists a $\mathcal{P}$-extension with $\mathcal{P}$-shift $\delta_1 = d_{\mathcal{P}}$.

▶ **Theorem 11.** *Any finite partial interleaving $\mathcal{P}$ between any two merge trees T_1 and T_2 admits an optimal $\mathcal{P}$-extension.*

Isolated extensions. To reason about "greatest" shifts and "highest" ancestors, it is useful to have optimal extensions that satisfy two additional finiteness properties. Specifically, assume the $\mathcal{P}$-residual interleaving distance is strictly positive, that is, $d_{\mathcal{P}} > 0$. We say an optimal $\mathcal{P}$-extension $\mathcal{I}$ is *isolated* if (1) the $\mathcal{P}$-shift of only finitely many arrows of $\mathcal{I}$ is equal to $d_{\mathcal{P}}$, and (2) there exists some $\varepsilon > 0$ such that for each arrow (x, y) of $\mathcal{I}$ with $\mathcal{P}$-shift at least $d_{\mathcal{P}} - \varepsilon$, there exists a descendant x' of x, such that (x', y) is an arrow in $\mathcal{I}$ with the same target and $\mathcal{P}$-shift $d_{\mathcal{P}}$.

▶ **Lemma 12.** *If $\mathcal{P}$ is finite and $d_{\mathcal{P}} > 0$, there exists an isolated $\mathcal{P}$-extension.*

4 Locally correct interleavings

The interleaving distance is a bottleneck distance: it yields a single value that quantifies the worst discrepancy between the two merge trees. While this global value is useful for comparison, we are interested in the actual interleavings that realize the distance. Importantly, we seek interleavings that are not only globally optimal, but also locally meaningful. Specifically, if a part of the interleaving is fixed, we want the remainder to be optimal relative to this fixed part. To formalize this notion of local optimality, we build upon the residual interleaving distance introduced in the previous section.

Let (T_1, f_1) and (T_2, f_2) be two merge trees, and fix a partial interleaving $\mathcal{P} = (\varphi, \psi)$. For a subset $S_1 \subseteq \mathrm{dom}(\varphi)$, we define the *restriction* of φ to S_1 as the map $\varphi|_{S_1} \colon S_1 \to T_2$ given by $\varphi|_{S_1}(x) \coloneqq \varphi(x)$ for all points x of S_1. Any restriction of φ is a partial up-map, and φ extends all of its restrictions. The *restriction* of ψ to a subset $S_2 \subseteq T_2$ is defined symmetrically. Lastly, the pair $\mathcal{R} = (\varphi|_{S_1}, \psi|_{S_2})$ is a partial interleaving such that $\mathcal{P}$ extends $\mathcal{R}$. We call $\mathcal{R}$ a *restriction* of $\mathcal{P}$. Let $\mathcal{I}$ be a complete interleaving. We make the following observation:

▶ **Observation 13.** *For any restriction $\mathcal{R}$ of $\mathcal{I}$, it holds that $d_{\mathcal{R}}(T_1, T_2) \leq \sigma_{\mathcal{R}}(\mathcal{I})$.*

A complete interleaving $\mathcal{I}$ is *locally correct* if for all restrictions $\mathcal{R}$ of $\mathcal{I}$, the $\mathcal{R}$-residual shift of $\mathcal{I}$ is equal to the $\mathcal{R}$-residual interleaving distance.

▶ **Definition 14.** *A complete interleaving $\mathcal{I} = (\alpha, \beta)$ is* locally correct *if and only if for all $S_1 \subseteq T_1$ and $S_2 \subseteq T_2$, the restriction $\mathcal{R} = (\alpha|_{S_1}, \beta|_{S_2})$ satisfies*

$$d_{\mathcal{R}}(T_1, T_2) = \sigma_{\mathcal{R}}(\mathcal{I}). \tag{3}$$

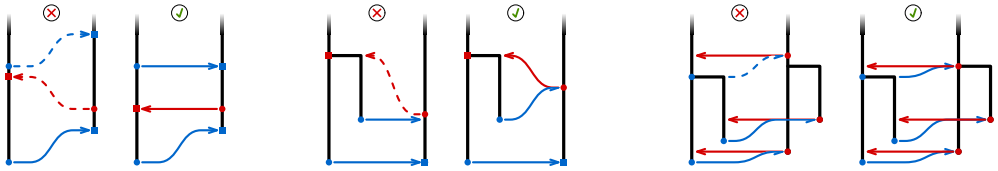

Figure 9 Three pairs of merge trees; for each pair we show an interleaving that is locally correct (✓), and one that is not (⊗). If we fix the non-dashed arrows in the ⊗ cases, the dashed arrows violate Eq. (3); e.g. for the middle example, if we fix the blue arrows, then the image of the red point needs to be an ancestor of both blue points, requiring a shift greater than the interleaving distance.

See Figure 9 for some examples of interleavings that are (not) locally correct.

Suppose $\mathcal{I}$ is locally correct. Taking $\mathcal{R}$ as the empty restriction, we see that $\mathcal{I}$ satisfies $d(T_1, T_2) = \sigma(\mathcal{I})$. In other words, any locally correct interleaving is an optimal interleaving. The reverse is not necessarily true; not every optimal interleaving is locally correct (see Figure 2). That raises the question: does a locally correct interleaving always exist? In the remainder of this section, we answer this question affirmatively.

▶ **Theorem 15.** *Any two merge trees T_1 and T_2 admit a locally correct interleaving.*

Overview of the proof. To prove Theorem 15, we give an explicit construction of a locally correct interleaving. Specifically, we incrementally build a partial interleaving $\mathcal{P}$ by augmenting it with "bottleneck" arrows. We show that with every augmentation, the $\mathcal{P}$-residual interleaving distance strictly decreases, until, after a finite number of iterations, it becomes zero. To conclude the proof, we then show that any complete interleaving that extends the resulting partial interleaving $\mathcal{P}$ is locally correct.

4.1 Bottlenecks

The interleaving distance is determined by the greatest shift among all arrows of an optimal interleaving. Locally, we might improve such an interleaving by "pushing down" some of the arrows, thereby decreasing their shifts. However, we cannot do this for all arrows; otherwise, we would obtain an interleaving whose shift is strictly smaller than the interleaving distance. We are interested in a *bottleneck*: a set of arrows that we cannot "push down".

We first define the *relative difference* of two, not necessarily related, partial up-maps φ and φ'. Specifically, consider the set of points for which either φ is defined and φ' is not, or for which both are defined but where they do not agree:

$$S \coloneqq \operatorname{dom}(\varphi) \setminus \{x \in \operatorname{dom}(\varphi) \cap \operatorname{dom}(\varphi') : \varphi(x) = \varphi'(x)\}.$$

We define the relative difference of φ and φ' as the restriction of φ to S, denoted $\varphi \setminus \varphi' \coloneqq \varphi|_S$. Similarly, for two partial interleavings $\mathcal{P} = (\varphi, \psi)$ and $\mathcal{P}' = (\varphi', \psi')$, we define the *relative difference* $\mathcal{P} \setminus \mathcal{P}'$ as the pair of relative differences $(\varphi \setminus \varphi', \psi \setminus \psi')$. The resulting pair is a restriction of $\mathcal{P}$, so it directly follows that any relative difference is a partial interleaving.

Augmentations. Fix a partial interleaving $\mathcal{P} = (\varphi, \psi)$. In the remainder of this section, we assume that $\mathcal{P}$ is finite, and that the $\mathcal{P}$-residual interleaving distance is strictly positive, that is, $d_{\mathcal{P}} > 0$. A $\mathcal{P}$-extension $\mathcal{Q}$ is a $\mathcal{P}$-*augmentation* if (i) the $\mathcal{P}$-residual shift of $\mathcal{Q}$ is at most $d_{\mathcal{P}}$, that is, $\sigma_{\mathcal{P}}(\mathcal{Q}) \leq d_{\mathcal{P}}$, and (ii) the $\mathcal{Q}$-residual interleaving distance is strictly less than $d_{\mathcal{P}}$, that is, $d_{\mathcal{Q}} < d_{\mathcal{P}}$. We say that $\mathcal{Q}$ is *minimal* if it does not extend any other $\mathcal{P}$-augmentation.

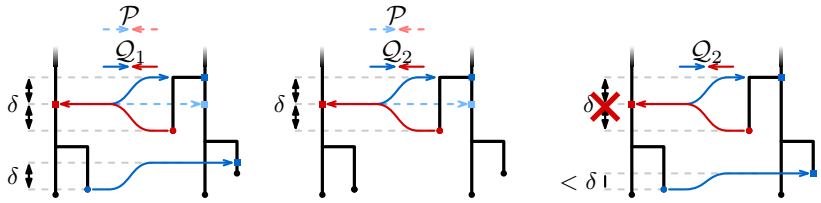

Figure 10 A partial interleaving $\mathcal{P}$ and two augmentations $\mathcal{Q}_1$ and $\mathcal{Q}_2$. $\mathcal{Q}_1$ is not a minimal augmentation, as $\mathcal{Q}_2$ is strictly smaller. The $\mathcal{Q}_2$-residual shift is strictly smaller than δ (right).

▶ **Lemma 16.** *Any finite interleaving $\mathcal{P}$ with $d_{\mathcal{P}} > 0$ admits a finite minimal $\mathcal{P}$-augmentation.*

Let $\mathcal{Q}$ be a minimal $\mathcal{P}$-augmentation. We refer to the relative difference $\mathcal{Q} \setminus \mathcal{P}$ as a $\mathcal{P}$-*bottleneck*. Intuitively, a bottleneck captures a minimal set of arrows that we need to "add" to decrease the residual interleaving distance. See Figure 10 for an illustration.

Recall (the proof of) Lemma 8. If we apply the lemma to a given $\mathcal{P}$-extension $\mathcal{I}$ that does not use a realizing critical pair, we can construct another $\mathcal{P}$-extension $\mathcal{I}'$ that has strictly smaller shift. The exact same proof still works for a slightly stronger statement: it suffices to assume that the relative difference $\mathcal{I} \setminus \mathcal{P}$ does not use a realizing critical pair.

▶ **Observation 17.** *Let $\mathcal{P}$ be a finite interleaving and let $\mathcal{I}$ be a $\mathcal{P}$-extension. If $\mathcal{I} \setminus \mathcal{P}$ does not use a realizing critical pair, there exists a $\mathcal{P}$-extension $\mathcal{I}'$ with $\sigma_{\mathcal{P}}(\mathcal{I}') < \sigma_{\mathcal{P}}(\mathcal{I})$.*

We use this observation to prove the following lemma.

▶ **Lemma 18.** *If $\mathcal{P}$ is finite and $d_{\mathcal{P}} > 0$, any $\mathcal{P}$-bottleneck $\mathcal{Q} \setminus \mathcal{P}$ uses a realizing critical pair.*

Proof. Let $\mathcal{I}$ be an optimal $\mathcal{Q}$-extension. Since $\mathcal{Q}$ extends $\mathcal{P}$, so does $\mathcal{I}$. Moreover, as $\mathcal{I}$ is optimal, the $\mathcal{Q}$-shift of $\mathcal{I}$ is equal to the $\mathcal{Q}$-residual interleaving distance, that is, $\sigma_{\mathcal{Q}}(\mathcal{I}) = d_{\mathcal{Q}}$. Since $\mathcal{Q}$ is an augmentation, the shift of all arrows of $\mathcal{Q} \setminus \mathcal{P}$ is at most $d_{\mathcal{P}}$, and $d_{\mathcal{Q}} < d_{\mathcal{P}}$. Combining, we obtain $\sigma_{\mathcal{P}}(\mathcal{I}) \leq d_{\mathcal{P}}$. In other words, $\mathcal{I}$ is an optimal $\mathcal{P}$-extension. By Observation 17, it follows that $\mathcal{I} \setminus \mathcal{P}$ uses a realizing critical pair b. As $d_{\mathcal{Q}} < d_{\mathcal{P}}$, we get that the $\mathcal{Q}$-shift of the arrows that correspond to b must be 0. In other words, $\mathcal{Q} \setminus \mathcal{P}$ uses b. ◀

A direct consequence of Lemma 18 is that if, for a given $\mathcal{P}$-extension $\mathcal{Q}$, the relative difference $\mathcal{Q} \setminus \mathcal{P}$ does not use a realizing critical pair, then $\mathcal{Q}$ cannot be a $\mathcal{P}$-augmentation. In other words, we have the following corollary:

▶ **Corollary 19.** *Let $\mathcal{P}$ be a finite interleaving with $d_{\mathcal{P}} > 0$, and let $\mathcal{Q}$ be a $\mathcal{P}$-extension. If $\sigma_{\mathcal{P}}(a) < d_{\mathcal{P}}(T_1, T_2)$ for all arrows $a \in A_{\mathcal{Q}}$, then $d_{\mathcal{Q}}(T_1, T_2) \geq d_{\mathcal{P}}(T_1, T_2)$.*

For a partial interleaving $\mathcal{P} = (\varphi, \psi)$, we use $\mathcal{P}.\varphi$ and $\mathcal{P}.\psi$ to denote φ and ψ, respectively.

4.2 Constructing a Locally Correct Interleaving

We show that a locally correct interleaving always exists by incrementally constructing one. Specifically, let $\mathcal{P}$ be an empty interleaving. We iteratively replace $\mathcal{P}$ with a finite minimal $\mathcal{P}$-augmentation, and we show that after a finite number of iterations the $\mathcal{P}$-residual interleaving distance becomes zero, at which point we stop iterating. We conclude by showing that for the resulting partial interleaving $\mathcal{P}$, any optimal $\mathcal{P}$-extension is locally correct. For this, we maintain three invariants throughout the entire construction. First, we argue that $\mathcal{P}$ remains *dominant*: the shift of each arrow of $\mathcal{P}$ is strictly greater than $d_{\mathcal{P}}$. Secondly, we

show that for all restrictions of $\mathcal{P}$ it holds that $d_{\mathcal{R}} \geq \sigma_{\mathcal{R}}(\mathcal{P})$; we say $\mathcal{P}$ is partially locally correct. Lastly, we show that after each step of the construction, $\mathcal{P}$ "specifies" at least one additional vertex of the input merge trees. Since each vertex can be specified at most once, it follows that the construction terminates.

Invariants. Formally, let $\mathcal{P}$ be a partial interleaving and assume $d_{\mathcal{P}} > 0$. Recall that another partial interleaving $\mathcal{Q}$ uses $\mathcal{P}$ if they completely agree on the domains of $\mathcal{P}.\varphi$ and $\mathcal{P}.\psi$.

▶ **Lemma 20.** *Let $\mathcal{P}$ be a dominant, finite interleaving with $d_{\mathcal{P}} > 0$. For any finite minimal $\mathcal{P}$-augmentation $\mathcal{Q}$, (i) $\mathcal{Q}$ uses $\mathcal{P}$, and (ii) $\mathcal{Q} \setminus \mathcal{P}$ uses only realizing critical pairs.*

We use this lemma to argue that $\mathcal{P}$ remains locally correct throughout the construction.

▶ **Lemma 21.** *Let $\mathcal{P}$ be a finite interleaving and suppose $d_{\mathcal{P}} > 0$. Let $\mathcal{Q}$ be a finite minimal $\mathcal{P}$-augmentation. If $\mathcal{P}$ is dominant and locally correct, then so is $\mathcal{Q}$.*

Proof. We first argue that $\mathcal{Q}$ is dominant. Let a be an arrow of $\mathcal{Q}$. If a is also an arrow of $\mathcal{P}$, then from the fact that $\mathcal{P}$ is dominant we know that $\sigma(a) > d_{\mathcal{P}} > d_{\mathcal{Q}}$. Otherwise, a must be an arrow of the bottleneck $\mathcal{Q} \setminus \mathcal{P}$. By Lemma 20, it then directly follows that $\sigma(a) = d_{\mathcal{P}} > d_{\mathcal{Q}}$.

Next, we argue that $\mathcal{Q}$ is locally correct. Consider a restriction $\mathcal{R}$ of $\mathcal{Q}$; we need to show that $d_{\mathcal{R}} \geq \sigma_{\mathcal{R}}(\mathcal{Q})$. If $\mathcal{R} = \mathcal{Q}$, we immediately obtain $\sigma_{\mathcal{R}}(\mathcal{Q}) = 0 \leq d_{\mathcal{R}}$. Otherwise, let $\mathcal{R}'$ be the restriction of $\mathcal{R}$ to the domains of $\mathcal{P}.\varphi$ and $\mathcal{P}.\psi$. Since $\mathcal{Q}$ uses $\mathcal{P}$, it follows that $\mathcal{R}'$ uses $\mathcal{P}$ and is hence a restriction of $\mathcal{P}$. If $\mathcal{R}' = \mathcal{P}$, then by definition of an augmentation we know that the $\mathcal{R}'$-shift of any arrow of $\mathcal{Q}$ is $d_{\mathcal{P}}$. We obtain $\sigma_{\mathcal{R}'}(\mathcal{Q}) = d_{\mathcal{P}}$. Moreover, since $\mathcal{R} \neq \mathcal{Q}$, the $\mathcal{R}$-shift of at least one arrow of $\mathcal{Q} \setminus \mathcal{P}$ is non-zero. We obtain $\sigma_{\mathcal{R}}(\mathcal{Q}) = \sigma_{\mathcal{R}'}(\mathcal{Q}) = d_{\mathcal{P}}$. Since $\mathcal{Q}$ is a minimal augmentation and extends $\mathcal{R}$, we know that $\mathcal{R}$ cannot be an augmentation of $\mathcal{P}$. It follows that $d_{\mathcal{R}} \geq d_{\mathcal{P}}$. Putting it together, we obtain $d_{\mathcal{R}} = \sigma_{\mathcal{R}}(\mathcal{Q})$.

Lastly, if $\mathcal{R}' \neq \mathcal{P}$, then since $\mathcal{P}$ is locally correct and $\mathcal{R}'$ is a restriction of $\mathcal{P}$, we have

$$d_{\mathcal{R}'} \geq \sigma_{\mathcal{R}'}(\mathcal{P}). \tag{4}$$

We first show that $\sigma_{\mathcal{R}'}(\mathcal{P}) \geq \sigma_{\mathcal{R}}(\mathcal{Q})$. First, none of the arrows of $\mathcal{R} \setminus \mathcal{R}'$ are arrows of $\mathcal{P}$, so $\sigma_{\mathcal{R}'}(\mathcal{P}) = \sigma_{\mathcal{R}}(\mathcal{P})$. Next, the $\mathcal{R}$-residual shift of $\mathcal{Q}$ is the maximum of the $\mathcal{R}$-residual shifts of $\mathcal{P}$ and $\mathcal{Q} \setminus \mathcal{P}$. Since $\mathcal{P}$ is dominant, we know that the shift of any arrow of $\mathcal{P}$ is strictly greater than $d_{\mathcal{P}}$. As $\mathcal{P} \setminus \mathcal{R}$ is not empty, it follows that $\sigma_{\mathcal{R}}(\mathcal{P}) > d_{\mathcal{P}}$. On the other hand, by definition of an augmentation, we know that the shift of any arrow of $\mathcal{Q} \setminus \mathcal{P}$ is at most $d_{\mathcal{P}}$. So, we get $\sigma_{\mathcal{R}}(\mathcal{Q}) = \max(\sigma_{\mathcal{R}}(\mathcal{P}), \sigma_{\mathcal{R}}(\mathcal{Q} \setminus \mathcal{P})) = \sigma_{\mathcal{R}}(\mathcal{P})$. Combining, we obtain $\sigma_{\mathcal{R}'}(\mathcal{P}) \geq \sigma_{\mathcal{R}}(\mathcal{Q})$.

Next, we argue that $d_{\mathcal{R}} \geq d_{\mathcal{R}'}$. By construction, $\mathcal{R}$ extends $\mathcal{R}'$. As observed before, we have $\sigma_{\mathcal{R}'}(\mathcal{P}) = \sigma_{\mathcal{R}}(\mathcal{P}) > d_{\mathcal{P}}$. Combining with Equation (4), we obtain $d_{\mathcal{R}'} \geq \sigma_{\mathcal{R}'}(\mathcal{P}) > d_{\mathcal{P}}$. Let a be an arrow of $\mathcal{R} \setminus \mathcal{R}'$. Then a is an arrow of the bottleneck $\mathcal{Q} \setminus \mathcal{P}$, so the shift of a is exactly $d_{\mathcal{P}}$. In other words, $\sigma_{\mathcal{R}'}(a) = d_{\mathcal{P}} < d_{\mathcal{R}'}$. This means that we can apply Corollary 19, for the finite interleaving $\mathcal{R}'$ and the $\mathcal{R}'$-extension $\mathcal{R}$, to obtain $d_{\mathcal{R}} \geq d_{\mathcal{R}'}$.

Thus, $d_{\mathcal{R}} \geq d_{\mathcal{R}'} \geq \sigma_{\mathcal{R}'}(\mathcal{P}) = \sigma_{\mathcal{R}}(\mathcal{Q})$, which concludes the proof. ◀

Recall that for each arrow (x, y), with $x \in T_1$ and $y \in T_2$, of $\mathcal{P}$, both x and y are critical points. However, only the point x has a "specified" target in the other tree. We say a point $x \in T_1$ or $y \in T_2$ is *specified* by $\mathcal{P}$, if $x \in \mathrm{dom}(\mathcal{P}.\varphi)$ or $y \in \mathrm{dom}(\mathcal{P}.\psi)$ respectively (see Figure 11). For our last invariant, we argue that $\mathcal{P}$ specifies all critical points that are not vertices, i.e., $C_1[\mathcal{P}] \setminus V(T_1) \subseteq \mathrm{dom}(\mathcal{P}.\varphi)$ and $C_2[\mathcal{P}] \setminus V(T_2) \subseteq \mathrm{dom}(\mathcal{P}.\psi)$.

▶ **Lemma 22.** *Let $\mathcal{P}$ be a finite interleaving and suppose $d_{\mathcal{P}} > 0$. Let $\mathcal{Q}$ be a finite minimal $\mathcal{P}$-augmentation. If $\mathcal{P}$ is dominant and specifies all critical points that are not vertices, then so does $\mathcal{Q}$. Moreover, $\mathcal{Q}$ specifies at least one vertex that $\mathcal{P}$ does not specify.*

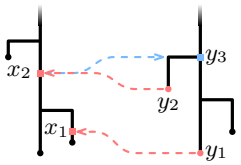

Figure 11 The points x_1, x_2, y_1, y_2 and y_3 are all critical, but only x_2, y_1 and y_2 are specified.

Proof. By Lemma 20, we know that the bottleneck $\mathcal{Q} \setminus \mathcal{P}$ uses only $\mathcal{P}$-critical pairs. Consider such a pair b. If b is an arrow critical pair, then without loss of generality assume $b = (x, y)$ for a point $x \in T_1$ and a point $y \in T_2$; the case $b = (y, x)$ is symmetric. By definition of an arrow critical pair, both x and y are $\mathcal{P}$-critical points. So the pair b does not create any additional $\mathcal{Q}$-critical points. As $\mathcal{P}$ already specifies all critical points that are not vertices and $\mathcal{Q}$ uses $\mathcal{P}$, we know that x must be a vertex. Since $\mathcal{P}$ is dominant, the shift of any arrow of $\mathcal{P}$ is strictly greater than $d_{\mathcal{P}}$. Moreover, the shift of any arrow of $\mathcal{Q} \setminus \mathcal{P}$ is exactly $d_{\mathcal{P}}$. Hence, the vertex x cannot be specified by $\mathcal{P}$: at least one new vertex is specified.

If b is a zigzag critical pair, then without loss of generality assume $b = (x_1, x_2)$ for two points x_1 and x_2 of T_1; if it is a pair of points of T_2 the argument is analogous. By definition of a zigzag critical pair, we know that both $x_1 \in V(T_1)$ and $x_2 \in V(T_1)$. Moreover, there is a point $y \in T_2$ such that $Q.\varphi(x_1) = y$ and $Q.\psi(y) = x_2$. So, x_1 is a vertex that is specified by $\mathcal{Q}$ but not by $\mathcal{P}$. Lastly, b creates a single $\mathcal{Q}$-critical point y, which is immediately specified. ◀

Finishing the proof of Theorem 15. Let $\mathcal{P}$ be the empty interleaving. Trivially, $\mathcal{P}$ is dominant and locally correct. Moreover, there are no (unspecified) critical points that are not vertices. Now, we iteratively replace $\mathcal{P}$ with a finite minimal $\mathcal{P}$-augmentation until the $\mathcal{P}$-residual interleaving distance becomes zero. By applying Lemmas 21 and 22 inductively, we maintain that $\mathcal{P}$ is dominant and locally correct, and specifies all critical points that are not vertices. Additionally, by Lemma 22, each iteration specifies at least one additional vertex. So after i iterations, at least i vertices are specified, and the total number of iterations is at most $|V(T_1)| + |V(T_2)|$. Afterwards, the residual interleaving distance is zero. Lemma 23 guarantees that a locally correct interleaving exists; its proof is similar to that of Lemma 21.

▶ **Lemma 23.** *Let $\mathcal{P}$ be a locally correct partial interleaving with $d_{\mathcal{P}} = 0$. Any optimal $\mathcal{P}$-extension is locally correct.*

Computing a locally correct interleaving. We sketch how the above construction can be translated into an incremental algorithm. To compute the residual interleaving distance, we modify the dynamic program by Touli and Wang [15] to also incorporate constraints induced by partial interleavings. We use the output to extract some augmentation. We then iteratively reduce the set of critical pairs by repeatedly calling the modified dynamic program until we obtain a (finite) minimal augmentation. This minimal augmentation, in turn, reduces the residual interleaving distance; we iterate until it has dropped to zero. To obtain a locally correct interleaving, we select suitable entries from the table filled by the modified dynamic program. A naive implementation of this algorithm takes n iterations, each of which needs to compute the residual interleaving distance $O(n^2)$ times to obtain a minimal augmentation (since an augmentation contains $O(n^2)$ critical pairs). So, the total running time of our algorithm is $O(n^3 T(n))$, where $T(n)$ is the running time of computing the residual interleaving distance. The algorithm by Touli and Wang [15] takes $O(n^4 2^\tau \tau^{\tau+2} \log n)$ time, where τ is a parameter related to the maximum degrees in the input trees.

5 Conclusion

We introduced locally correct interleavings between merge trees, which are optimal interleavings that are "tight". For this, we introduced the residual interleaving distance: a generalized version of the interleaving distance that can accommodate constraints on the interleavings. We presented a constructive proof that there always exists a locally correct interleaving.

We plan to further investigate the complexity of computing a locally correct interleaving, and we will study the effect of partial interleavings on the running time of the modified dynamic program. Furthermore, we will explore the effects of replacing the dynamic program with the approximation algorithm [1] or one of the variants or heuristics. Moreover, it would be interesting to study other (local) criteria of interleavings. Since locally correct interleavings are not necessarily unique, we could minimize their *total* shift, for a suitable definition of total. We could also consider a *lexicographic* optimization, inspired by lexicographic Fréchet matchings [12]. Lastly, we want to explore in which way locally correct interleavings can be translated to meaningful matchings between terrains.

Abstract

The *union volume estimation* problem asks to $(1 \pm \varepsilon)$-approximate the volume of the union of n given objects $X_1, \ldots, X_n \subset \mathbb{R}^d$. In their seminal work in 1989, Karp, Luby, and Madras solved this problem in time $O(n/\varepsilon^2)$ in an oracle model where each object X_i can be accessed via three types of queries: obtain the volume of X_i, sample a random point from X_i, and test whether X_i contains a given point x. This running time was recently shown to be optimal [Bringmann, Larsen, Nusser, Rotenberg, and Wang, SoCG'25]. In another line of work, Meel, Vinodchandran, and Chakraborty [PODS'21] designed algorithms that read the objects in one pass using polylogarithmic time per object and polylogarithmic space; this can be phrased as a dynamic algorithm supporting insertions of objects for union volume estimation in the oracle model.

In this paper, we study algorithms for union volume estimation in the oracle model that support both *insertions* and *deletions* of objects. We obtain the following results:

1. an algorithm supporting insertions and deletions in polylogarithmic update and query time and linear space (this is the first such dynamic algorithm, even for 2D triangles);
2. an algorithm supporting insertions and suffix queries (which generalizes the sliding window setting) in polylogarithmic update and query time and space;
3. an algorithm supporting insertions and deletions of convex bodies of constant dimension in polylogarithmic update and query time and space.

1 Introduction

In the *union volume estimation* problem, we are given *objects* $X_1, \ldots, X_n$, which are assumed to be measurable sets in $\mathbb{R}^d$, and the task is to $(1 \pm \varepsilon)$-approximate the volume of $\bigcup_{i=1}^n X_i$.[1] This is a fundamental problem in computer science, with connections to several areas such as

[1] A discrete variant of the problem, estimating the *cardinality* of the union of sets $X_1, \ldots, X_n \subset \mathbb{Z}^d$, can be easily reduced to the continuous version, by replacing each grid point with a unit grid cell.

network reliability [32, 34], DNF counting [34], general model counting [45, 14], probabilistic databases [35, 21, 46], and probabilistic query evaluation on databases [13, 12]. Perhaps the most popular special case in computational geometry is *Klee's measure problem* [36], where each object is a d-dimensional axis-aligned box. There has been extensive work on Klee's measure problem (either exact or approximate) in constant dimensions [44, 15, 16, 37, 27, 10].

To capture a wide variety of input objects with a unified framework, Karp and Luby [33] introduced an *oracle model*. An algorithm in this model can access each object X_i exclusively via three types of queries: (i) X_i.SIZE() gives the volume of X_i, (ii) X_i.SAMPLE() samples a point uniformly at random from the set X_i, and (iii) X_i.CONTAINS(x) tests whether a given point x is contained in X_i. The time complexity of the algorithm is measured by the number of queries plus the number of additional steps; that is, each query is assumed to take unit time. In a seminal result, Karp, Luby, and Madras [34] gave an algorithm in the oracle model that solves union volume estimation in time $O(n/\varepsilon^2)$ with constant success probability, where ε is the approximation precision. Black-box usage of this result also yields the best known algorithms for several applications, including DNF counting. (For Klee's measure problem, it implies an $O(nd/\varepsilon^2)$-time approximation algorithm [9]; in small dimensions, this was improved to $O((n + 1/\varepsilon^2)\log^{O(d)} n)$ time at last year's SoCG [10].) Only recently has a matching lower bound been established: $\Omega(n/\varepsilon^2)$ queries are necessary to solve union volume estimation in the oracle model [10].

With the static setting now fully understood, attention naturally shifts to the dynamic setting, where the input evolves over time through insertions and deletions of objects. The study of *dynamic union volume estimation* has a twofold motivation. On one hand, it captures modern data-driven applications where datasets are inherently mutable, and volume estimates must be maintained continuously rather than recomputed from scratch after each update. On the other hand, the dynamic setting presents a compelling theoretical challenge, as it is far from obvious whether the tools developed for the static setting can be dynamized efficiently. Indeed, dynamic geometric problems have repeatedly proven to be substantially more difficult than their static counterparts. An extensive body of work in recent years deals with dynamic geometric problems such as set cover [2, 17], independent set [28, 7, 6], planar point location [43], connectivity [19, 18], and nearest neighbor search [1], yet in this broader context dynamic union volume estimation remains largely unexplored. The following question has not been resolved even for very simple classes of objects such as triangles in $\mathbb{R}^2$:

Q1: Can we solve dynamic union volume estimation in the oracle model under insertions and deletions of objects in $\text{poly}\left(\log n, \frac{1}{\varepsilon}\right)$ *update and query time?*

An even more demanding paradigm is the (one-pass) streaming setting, where the algorithm has to not only handle updates, but use space that is typically required to be polylogarithmic in the input size. Earlier work has explored streaming algorithms under strong restrictions on the input objects. For example, Tirthapura and Woodruff [47] designed a dynamic streaming algorithm for Klee's measure problem on axis-aligned boxes. However, the problem remains unaddressed for more general classes of objects:

Q2: Can we solve dynamic union volume estimation in the oracle model under insertions and deletions of objects in $\text{poly}\left(\log n, \frac{1}{\varepsilon}\right)$ *space as well as update and query time?*

In the restricted *insertion-only* setting, Meel, Vinodchandran, and Chakraborty [40] gave a positive answer to this question, using $O\left(\frac{1}{\varepsilon^2}\log^2(n)(\log\log(n) + \log(\frac{1}{\varepsilon}))\right)$ time per update and query, and $O\left(\frac{1}{\varepsilon^2}\log(n)\right)$ space in the oracle model.[2] However, their algorithm cannot handle deletions.

[2] In this paper, we assume that points from the input objects and $O(\log n)$-bit integers fit into a machine

2 Our contributions

2.1 Dynamic algorithm with insertions and deletions

We answer our driving question (Q1) positively, not only for 2D triangles, 3D simplices, and other common types of objects encountered in computational geometry, but in the full generality of the oracle model. Our new dynamic algorithm can handle arbitrary sequences of both insertions and deletions.

More precisely, we consider an initially empty multiset of objects $\mathcal{X}$ under the updates INSERT(X), which adds object X to $\mathcal{X}$, and DELETE(X), which removes object X from $\mathcal{X}$. Upon query ESTIMATE(), the algorithm outputs a $(1 \pm \varepsilon)$-approximation to the volume $\mathrm{vol}\left(\bigcup_{X \in \mathcal{X}} X\right)$.

During insertion/deletion the algorithm is given oracle access to the inserted/deleted object. We also need the ability to *store* objects (or their oracles), in case of future lookup of the previously inserted objects. We make the natural assumption that (i) the argument of INSERT(X) and DELETE(X) is a *pointer* to the oracle of X, (ii) we can store a pointer in a machine word, and (iii) knowing the pointer allows us to access the oracle to which the pointer is pointing. In this interpretation, $\mathcal{X}$ is treated as a multiset of pointers: the same pointer can be inserted multiple times, and upon deletion, the multiplicity of the pointer is decreased by one. Naturally, the multiplicity of any pointer must be non-negative throughout the process (in particular, objects being deleted must have previously been inserted).

▶ **Theorem 1.** *There is a dynamic algorithm in the oracle model that maintains a multiset $\mathcal{X}$ of objects under updates* INSERT(X) *and* DELETE(X)*. Upon query* ESTIMATE()*, it outputs a $(1 \pm \varepsilon)$-approximation to* $\mathrm{vol}\left(\bigcup_{X \in \mathcal{X}} X\right)$ *with high probability. The amortized expected update time is $O(\log^5(n/\varepsilon)/\varepsilon^2)$, the query time is $O(\log^4(n)/\varepsilon^2)$, and the space complexity is $O(n + \log^4(n)/\varepsilon^2)$.*

Note that since the algorithm operates in the general oracle model, it works well even for *high-dimensional* objects (e.g., for simplices in $\mathbb{R}^d$, with polynomial dependence on d).

2.2 Streaming algorithm with insertions and suffix queries

In our remaining results, we turn to streaming algorithms and our driving question (Q2) and show that polylogarithmic time *and* space can be achieved in certain settings. We first consider the *sliding window* setting [22], which supports insertions of objects and querying over the last w objects for a fixed window size w; thus, objects are deleted in the same order as they are inserted. Numerous results and techniques have been developed in the sliding window setting (see [41, 3, 8] for an overview and [48, 30, 25] for recent work), but no such result was known for union volume estimation.

We obtain the first efficient sliding-window algorithm for union volume estimation. Again, it works in the general oracle model! Moreover, the result holds in an extension of the sliding-window setting, where at each time $t = 1, \ldots, n$ an object X_t is inserted (but cannot be deleted), and a query ESTIMATE(s) may return a $(1 \pm \varepsilon)$-approximation to the volume of the *suffix* $\mathrm{vol}(X_s \cup \cdots \cup X_t)$ with high probability for *any* number s the user specifies.

word, and space complexity counts the number of machine words. An arithmetic operation on machine words is assumed to take unit time. Both are natural assumptions for a continuous universe. Some previous work such as [40] focuses on sets from a finite universe and studies bit complexity; when stating previous work in the introduction, we have translated their results into our setting. In the finite universe Ω, different trade-offs between $\log(n)$ and $\log|\Omega|$ were obtained in [39, 42].

▶ **Theorem 2.** *There is an algorithm that implicitly maintains a sequence of objects $X_1, \ldots, X_t$ of aspect ratio M. The algorithm supports update* INSERT(X)*, which appends an object X (as X_{t+1}) to the sequence, and query* ESTIMATE(s)*, which outputs a $(1 \pm \varepsilon)$-approximation to $\mathrm{vol}(X_s \cup \cdots \cup X_t)$ with high probability. The update time is $O(\log^2(n/\varepsilon)/\varepsilon^2)$, the query time is $O(\log(n)/\varepsilon^2)$, and the space complexity is $O(\log(M)\log(n)/\varepsilon^2)$.*

Our algorithm not only generalizes previous insertion-only results [40], but is also remarkably simple. Note that the space bound depends on the aspect ratio M, defined as the ratio of the largest volume of any object ever inserted and the smallest volume of any object ever inserted. In many applications, M is a polynomial in n and thus $\log(M) = O(\log n)$. Furthermore, geometric algorithms in the sliding window setting [24, 20] usually have logarithmic dependencies on parameters such as the aspect ratio or spread.

2.3 Streaming algorithm for convex bodies with insertions and deletions

Lastly, we consider streaming algorithms that support *both* insertions and deletions. We manage to develop an efficient algorithm for a reasonably wide class of geometric objects – namely, convex bodies in any constant dimension:

▶ **Theorem 3.** *Given $R \geq r > 0$, there is an algorithm that implicitly maintains a multiset $\mathcal{X}$ of convex bodies in $[0, R]^d$, where each convex body contains a ball of radius r, under updates* INSERT(X) *and* DELETE(X)*. Upon query* ESTIMATE$()$*, it outputs a $(1 \pm \varepsilon)$-approximation to $\mathrm{vol}\left(\bigcup_{X \in \mathcal{X}} X\right)$ with high probability. The expected update and query time and space are $O(\mathrm{polylog}(\frac{nR}{\varepsilon r})/\varepsilon^2)$ for constant d.*

The bounds depend polylogarithmically on R/r, which is common in volume estimation algorithms for a single convex object [23] as well as geometric streaming algorithms [29, 26].

Previously, Tirthapura and Woodruff obtained an efficient dynamic streaming algorithm only for axis-aligned boxes [47] (with $\mathrm{poly}(\log n, \log \Delta, \frac{1}{\varepsilon}, d)$ update time and space in a discrete universe $\{1, \ldots, \Delta\}^d$). To emphasize the generality of our algorithm, note that many non-convex objects can be decomposed into a small number of convex objects, e.g., non-convex polyhedra of constant combinatorial complexity in constant dimensions can be decomposed into a constant number of simplices, to which our algorithm can be applied.

3 Technical overview

3.1 Dynamic algorithm with insertions and deletions

Karp, Luby and Madras' algorithm [34] and subsequent work are based on the observation that we can estimate the volume of a union U by maintaining a finite random subset $S^{(\ell)} \subset U$ that selects every point independently with probability density $1/2^\ell$. It turns out that the "right" choice of ℓ is one such that $|S^{(\ell)}| \approx \log(n)/\varepsilon^2$; in this case $2^\ell |S^{(\ell)}|$ provides a good estimate of the volume of U.

Meel, Vinodchandran, and Chakraborty [40] described a particularly simple way to maintain such a random set $S^{(\ell)}$ for insertion-only updates: when a new object X is inserted, we remove from $S^{(\ell)}$ all points that are contained in X, then add to $S^{(\ell)}$ freshly sampled points in X with density $1/2^\ell$. This step is inexpensive for the right choice of ℓ since $|S^{(\ell)}|$ is logarithmic. If $|S^{(\ell)}|$ becomes too big, we increment ℓ (thereby halving the sampling rate and also $|S^{(\ell)}|$ in expectation) and move on.

Difficulty arises in the presence of deletions: the volume is no longer monotonically increasing, and the right choice of ℓ may increase or decrease over time. Our first observation is that the *deletion-only* case can be handled by a variant of Meel, Vinodchandran, and

Chakraborty's insertion-only algorithm. Roughly, we can maintain $S^{(\ell)}$ for the right ℓ by keeping a counter on the number of objects containing each sample point (recall that $|S^{(\ell)}|$ is logarithmic for the right ℓ). When an object X is deleted, we decrement the counters of all points in $S^{(\ell)} \cap X$, and when a counter drops to 0, the point is removed from $S^{(\ell)}$. When the number of surviving sample points drops below logarithmic, we decrease ℓ, rebuild $S^{(\ell)}$ by iterating over all objects that has not been deleted (recall that we can store pointers to all objects), and reinitialize the counters.

A popular technique in dynamic computational geometry by Bentley and Saxe [4], called the *logarithmic method*, transforms deletion-only data structures into fully dynamic ones. It works by decomposing a fully dynamic set into logarithmically many deletion-only subsets, increasing the update and query time by typically just a logarithmic factor. The logarithmic method applies to so-called *decomposable* problems that satisfy the following property: if the input is decomposed into subsets, then the answer to the original problem can be quickly obtained from the answers to the individual subsets. Unfortunately, union volume estimation is *not* a decomposable problem: We cannot determine the volume of the union of $\mathcal{X}_0 \cup \cdots \cup \mathcal{X}_{\log n}$ just from the volume of the union of each $\mathcal{X}_i$.

Nevertheless, we show that a novel variant of the logarithmic method can still work. Recall that the deletion-only data structure already maintains a sample for each $\mathcal{X}_i$. For each sample point we keep track of more counters – specifically, how many sets from the other $\mathcal{X}_i$'s contain the point. These counters provide enough information to avoid double counting and help us estimate the union volume accurately. One issue though is that many counters need to be adjusted when one of the deletion-only data structures changes ℓ and recomputes $S^{(\ell)}$. Fortunately, we manage to bound the total number of such changes, so the amortized cost for maintaining all counters remains polylogarithmic. See Section 5 for details.

3.2 Streaming algorithm with insertions and suffix queries

The dynamic algorithm with arbitrary insertions and deletions needs linear space because the data structure rebuilds on the remaining objects when the "right" ℓ decreases. However, in the sliding window setting and more generally the setting of suffix queries, the remaining objects are contiguous in time and need not be stored explicitly. We obtain a streaming algorithm in this case by a simple yet non-trivial generalization of Meel, Vinodchandran, and Chakraborty's algorithm. Specifically, we keep the timestamp when each point in $S^{(\ell)}$ is sampled. For each ℓ we keep track of the largest timestamp $s^{(\ell)}$ such that discarding points older than $s^{(\ell)}$ from $S^{(\ell)}$ makes $|S^{(\ell)}|$ logarithmically bounded. This timestamp $s^{(\ell)}$ is monotonically increasing over time for each fixed ℓ. To estimate the volume of the union of $X_s \cup \cdots \cup X_t$ for a given s at time t, we identify the smallest ℓ for which $s^{(\ell)} \le s$, and output $2^\ell |S^{(\ell)} \cap (X_s \cup \ldots \cup X_t)|$. See Section 6 in the full version [5] for details.

3.3 Streaming algorithm for convex bodies with insertions and deletions

Our streaming algorithm for low-dimensional convex objects for arbitrary insertions and deletions is based on another simple sampling strategy. First, it is not difficult to discretize the space $\mathbb{R}^d$ to a grid $[\Delta]^d$ for some large Δ, so that the volume of the union U is close to the number of grid points in $U \cap [\Delta]^d$. The idea now is to select a random subset $R^{(\ell)}$ of the grid $[\Delta]^d$ in the beginning, and maintain the intersection $S^{(\ell)} := U \cap R^{(\ell)}$ during the updates. Using a pairwise independent family of hash functions, $R^{(\ell)}$ can be represented implicitly with logarithmically many bits.

When we insert or delete an object X, we just need to insert or delete $X \cap R^{(\ell)}$ to or from $S^{(\ell)}$ (viewed as a multiset of points). An issue is that the space usage may be large for a $S^{(\ell)}$ with a "wrong" sampling rate, and we do not know which ℓ is the right choice beforehand. Furthermore, a wrong choice may become right at a later time. This issue can be resolved by representing $S^{(\ell)}$ by data structures for sparse vectors [26, 31], which support adding numbers to a given coordinate, as well as recovering the vector when its norm is below a threshold. In this way, we essentially just pay for the space at the right sampling rate.

A question remains: how to enumerate the points of $X \cap R^{(\ell)}$ for a given object X and for our implicitly represented set $R^{(\ell)}$? For the case where the objects are rotated (non-axis-aligned) boxes in constant dimension, and for a particular pairwise independent family of hash functions, we observe that this subproblem directly reduces to integer linear programming (ILP) with a constant number of constraints and variables, and therefore can be solved efficiently by well-known algorithms [38]. For more general convex objects in constant dimension, we bound each object X by a small rotated box $B \supseteq X$, use an ILP to enumerate the points of $B \cap R^{(\ell)}$ and discard those not in X. By "small" we mean that the volume of B is comparable to that of X, so in particular the number of discarded points is small. See Section 7 in the full version [5] for details.

Our approach is related to Tirthapura and Woodruff's algorithm [47] for axis-aligned boxes. Their idea was to directly adapt a streaming algorithm for approximately counting distinct elements to estimate $|U \cap [\Delta]^d|$: to insert or delete an object X, we cannot afford to literally insert or delete all points in $|X \cap [\Delta]^d|$, but they showed how to efficiently simulate the effect for a specific distinct elements algorithm in the case of axis-aligned boxes. Our approach is more modular in that we apply sparse recovery only as a black box. Our main contribution however is the realization, via solving an ILP, that this type of approach works far more generally than for axis-aligned boxes, namely, for general convex objects.

4 Preliminaries

We assume that all relevant parameters (the precision ε, an upper bound n on the number of operations, etc.) are given at initialization. Knowing n is in line with the usual assumptions in streaming algorithms; it can easily be avoided but this complicates notation. The phrase "with high probability" means that the probability is at least $1 - n^{-\Omega(1)}$. We denote $[n] := \{1, 2 \ldots, n\}$. The notation $a \in b \pm c$ means that $b - c \le a \le b + c$. Similarly, $a \in (1 \pm \varepsilon)b$ means that $(1 - \varepsilon)b \le a \le (1 + \varepsilon)b$, and we say that a is a $(1 \pm \varepsilon)$-approximation to b.

As in all previous work, our algorithms exploit the close relation between volume estimation and sampling. The notion of ℓ-samples is central:

▶ **Definition 4** (ℓ-sample). *Let U be a measurable set and $\ell \in \mathbb{Z}$. A random finite subset $S \subset U$ is an* ℓ-sample *of U, denoted $S \sim \mathrm{Pois}(U, \ell)$, if $|S \cap V| \sim \mathrm{Pois}(\mathrm{vol}(V)/2^\ell)$ for every measurable subset $V \subseteq U$.*

It follows from this definition that: (i) if $S \sim \mathrm{Pois}(U, \ell)$, then $S \cap V \sim \mathrm{Pois}(V, \ell)$ for any measurable subset $V \subseteq U$; (ii) if $S \sim \mathrm{Pois}(U, \ell)$ and $T \sim \mathrm{Pois}(V, \ell)$ are independent and U, V are disjoint, then $S \cup T \sim \mathrm{Pois}(U \cup V, \ell)$.

▶ **Definition 5** (level). *For a measurable set U, we define* $\mathrm{level}(U)$ *as the unique integer such that* $\frac{32 \log n}{\varepsilon^2} \le \frac{\mathrm{vol}(U)}{2^{\mathrm{level}(U)}} < \frac{64 \log n}{\varepsilon^2}$.

We will see later that if $S \sim \mathrm{Pois}(U, \ell)$ where $\ell \approx \mathrm{level}(U)$, then $|S|$ concentrates around its expectation $\mathrm{vol}(U)/2^\ell$.

Let U denote the union we are interested in. Each of our algorithms morally maintains an ℓ-sample $S^{(\ell)}$ of U for every $\ell \in \mathbb{Z}$ throughout the updates; upon query, it identifies some $L \approx \text{level}(U)$ and outputs $2^L|S^{(L)}|$. However, there are two pitfalls. First, the identification of L actually requires inspecting the outcomes of the random sets $S^{(\ell)}$, so L is a random variable and this complicates the concentration analysis. Second, we cannot afford to maintain all sets $S^{(\ell)}$ at once. Our algorithms only explicitly store those $S^{(\ell)}$ with $\ell \approx \text{level}(U)$; for such ℓ we have $\mathbb{E}|S^{(\ell)}| \approx \text{vol}(U)/2^{\text{level}(U)} = \Theta(\log(n)/\varepsilon^2)$. For $\ell \ll \text{level}(U)$ the set $S^{(\ell)}$ is too large and must be compressed or discarded. Naturally, this further complicates the algorithms.

5 Dynamic algorithm with insertions and deletions

In this section, we prove Theorem 1 by presenting a fully dynamic (non-streaming) algorithm for union volume estimation in linear space and polylogarithmic update time. Throughout we assume that the volume of each object is in the range $[(3n/\varepsilon)^2, (3n/\varepsilon)^4]$. The general case can be easily reduced to this case; see Lemma 4.1 in the full version [5].

5.1 Preparations

We will use the Karp–Luby–Madras algorithm as a subroutine:

▶ **Theorem 6** (Karp, Luby, Madras [34]). *Let $n \in \mathbb{N}$ be a parameter. There is an algorithm $\text{KLM}(\mathcal{X})$ that computes a (1 ± 0.5)-approximation to $\text{vol}(\bigcup_{X\in\mathcal{X}} X)$ with probability at least $1 - n^{-3}$ and runs in time $O(|\mathcal{X}| \log n)$.*

We need a somewhat technical notion that is "close" to an ℓ-sample at the right level ℓ.

▶ **Definition 7.** *Let U be a measurable set. A family of pairs $\{(\ell_1, R_1), \dots, (\ell_N, R_N)\}$ is called an* ensemble *of U if $\ell_k \in \text{level}(U) \pm 1$ and $R_k \sim \text{Pois}(U, \ell_k)$ for all $k \in [N]$. A random pair (L, S) is called a* (δ, N)-digest *of U if there exists an ensemble $\mathcal{E}$ of U such that $|\mathcal{E}| \le N$ and $\mathbb{P}[(L, S) \notin \mathcal{E}] \le \delta$. The ensemble $\mathcal{E}$ is called a* support ensemble *of the digest (L, S).*

▶ **Lemma 8.** *Fix measurable sets $V \subseteq U$. If $\mathcal{E}$ is an ensemble of U, then with probability at least $1 - \frac{2|\mathcal{E}|}{n^4}$, we have $\left|2^\ell\,|R \cap V| - \text{vol}(V)\right| \le \varepsilon\,\text{vol}(U)$ for all $(\ell, R) \in \mathcal{E}$.*

Proof. Consider an arbitrary $(\ell, R) \in \mathcal{E}$. By definition, $\ell \le \text{level}(U) + 1$ and $R \sim \text{Pois}(U, \ell)$. In particular, $|R \cap V| \sim \text{Pois}(\lambda)$ where $\lambda := \text{vol}(V)/2^\ell$. Let us write $d := \varepsilon\,\text{vol}(U)/2^\ell \ge \varepsilon\lambda$. By concentration of Poisson variables [11],

$$\begin{aligned}
&\mathbb{P}\left(\left|2^\ell\,|R \cap V| - \text{vol}(V)\right| > \varepsilon\,\text{vol}(U)\right) \;=\; \mathbb{P}(||R \cap V| - \lambda| > d) \\
&\le 2\exp\left(-\frac{d^2}{2(\lambda + d)}\right) \le 2\exp\left(-\frac{\varepsilon d}{2(1+\varepsilon)}\right) = 2\exp\left(-\frac{\varepsilon^2\,\text{vol}(U)}{2(1+\varepsilon)\cdot 2^\ell}\right) \le 2\mathrm{e}^{-4\log n} \le \frac{2}{n^4}
\end{aligned}$$

where the second last step uses $\frac{\text{vol}(U)}{2^\ell} \ge \frac{\text{vol}(U)}{2^{\text{level}(U)+1}} \ge \frac{16\log n}{\varepsilon^2}$. Taking a union bound over all $(\ell, R) \in \mathcal{E}$ proves the lemma. ◀

▶ **Corollary 9.** *Fix measurable sets $V \subseteq U$. If S is a (δ, N)-digest of U, then*

$$\mathbb{P}\left(\left|2^L\,|S \cap V| - \text{vol}(V)\right| \le \varepsilon\,\text{vol}(U)\right) \ge 1 - \delta - \frac{2N}{n^4}.$$

Proof. Let $\mathcal{E}$ be a support ensemble of (L, S), so $|\mathcal{E}| \le N$ and $\mathbb{P}[(L, S) \notin \mathcal{E}] \le \delta$. The event in the statement is implied by $(L, S) \in \mathcal{E}$ and the event in Lemma 8. ◀

▶ **Lemma 10.** *Let $n \in \mathbb{N}$ and $\varepsilon \in (0, \frac{1}{4}]$ be parameters. There is an algorithm* ERASE-RESAMPLE$(\mathcal{X}, L)$ *that, given a multiset $\mathcal{X}$ of $m \le n$ objects and a random variable L, returns a set S of size $|S| = O(\log(n)/\varepsilon^2)$ such that (L, S) is a $(\delta, 3)$-digest of $U := \bigcup_{X \in \mathcal{X}} X$ for $\delta := \frac{2}{n^3} + \mathbb{P}[L \notin \text{level}(U) \pm 1]$. The algorithm runs in time $O(m \log(n)/\varepsilon^2)$.*

Algorithm 1 Digesting a decremental union.

```
function ERASE-RESAMPLE(𝒳, L)
    S := ∅
    foreach X ∈ 𝒳 do
        foreach x ∈ S do
            if X.CONTAINS(x) then
                remove x from S
        sample a random number N ~ Pois(X.SIZE/2^L)
        if |S| + N > 160 log(n)/ε^2 then
            return ∅
        for k = 1, ..., N do
            x := X.SAMPLE()
            add x to S
    return S
```

Proof. The algorithm is described as Algorithm 1. The bound on the size $|S|$ is clear. The running time analysis is also easy: there are m iterations, each running in time $O(\log(n)/\varepsilon^2)$ due to the bound on $|S|$ (and on $|S| + N$).

Next, we show the correctness. Assume first that the algorithm does not return from the if-clause. Let $X_1, \dots, X_m$ be the objects in $\mathcal{X}$ in the order enumerated by the foreach-loop, and write $U := \bigcup_{i=1}^m X_i$. We define the random set $X_i^{(L)}$ as the set of points sampled from X_i in the for-k-loop; observe that $X_i^{(L)} \sim \text{Pois}(X_i, L)$ for every $i \in [n]$. Let S_i be the set S at the end of the iteration for $X = X_i$. Note that with $S_0 := \emptyset$ the algorithm computes $S_i = (S_{i-1} \setminus X_i) \cup X_i^{(L)}$ in each iteration. It follows that $S_i = \bigcup_{j=1}^i X_j^{(L)} \setminus (X_{j+1} \cup \dots \cup X_i)$. Since the random sets $X_j^{(L)} \setminus (X_{j+1} \cup \dots \cup X_i) \sim \text{Pois}(X_j \setminus (X_{j+1} \cup \dots \cup X_i), L)$ are L-samples with disjoint supports and the union of supports is $\bigcup_{j=1}^i X_j$, we have $S_i \sim \text{Pois}(\bigcup_{j=1}^i X_j, L)$.

Now let us analyze the probability of the algorithm aborting. Observe that the algorithm aborts if and only if $|S_i| > 160 \log(n)/\varepsilon^2$ for some $i \in [n]$. By the monotonicity of the size of the support $\bigcup_{j=1}^i X_j$, we have $\mathbb{P}[|S_1| > 160 \log(n)/\varepsilon^2] \le \dots \le \mathbb{P}[|S_n| > 160 \log(n)/\varepsilon^2]$. Fix $L \in \text{level}(U) \pm 1$. Since $(1+\varepsilon)\frac{\text{vol}(U)}{2^L} \le (1+\varepsilon)\frac{\text{vol}(U)}{2^{\text{level}(U)-1}} \le (1+\varepsilon)\frac{128 \log n}{\varepsilon^2} \le \frac{160 \log n}{\varepsilon^2}$, we have

$$\mathbb{P}\left(|S_n| > \frac{160 \log n}{\varepsilon^2}\right) \le \mathbb{P}\left(|S_n| > (1+\varepsilon)\frac{\text{vol}(U)}{2^L}\right) \le \frac{2}{n^4},$$

where the second inequality follows from Lemma 8 by interpreting (L, S_n) as a size-1 ensemble of U and plugging in $V := U$. By a union bound over all events $|S_i| > 160 \log(n)/\varepsilon^2$, it follows that the algorithm aborts with probability at most $\frac{2}{n^3}$, if $L \in \text{level}(U) \pm 1$.

If the algorithm does not abort, then we have shown above that it returns a set $S = S_n \sim \text{Pois}(\bigcup_{j=1}^n X_j, L) = \text{Pois}(U, L)$. It follows that we can compare the distribution of (L, S) with the size-3 ensemble $\mathcal{E} := \{(\ell, \text{Pois}(U, \ell)) \colon \ell \in \text{level}(U) \pm 1\}$. We can bound the error probability $\mathbb{P}[(L, S) \notin \mathcal{E}]$ by the probability that $L \notin \text{level}(U) \pm 1$ plus the probability that the algorithm aborts assuming $L \in \text{level}(U) \pm 1$, and we have bounded the latter probability by $\frac{2}{n^3}$. This proves the claim. ◀

5.2 Digesting decremental union

Next we study the decremental setting. That is, we receive a set of objects $\mathcal{X}$ and want to build a data structure that allows efficient deletions. At any time, it needs to quickly report a digest of the union of the surviving objects (i.e., objects that have not been deleted).

Algorithm 2 Digest data structure for decremental union.

parameters: n, ε
public variables: $\mathcal{X}, S, L$
function INITIALIZE($\mathcal{Y}$)
  let $\mathcal{X} := \mathcal{Y}$ and $L := \infty$
  REFRESH()
function REFRESH
  $v := \mathrm{KLM}(\mathcal{X})$
  let L' be the unique integer such that $\frac{32 \log n}{\varepsilon^2} \le v/2^{L'} < \frac{64 \log n}{\varepsilon^2}$
  $L := \min\{L - 1, L'\}$
  $S :=$ ERASE-RESAMPLE($\mathcal{X}, L$)
  foreach $x \in S$ **do**
    compute and store $m_x := \#\{X \in \mathcal{X} : X.\text{CONTAINS}(x)\}$
function DELETE(X)
  $\mathcal{X} := \mathcal{X} \setminus X$
  foreach $x \in S$ **do**
    if $X.\text{CONTAINS}(x)$ **then**
      $m_x := m_x - 1$
    if $m_x = 0$ **then**
      $S := S \setminus \{x\}$ and forget m_x
  if $|S| < \frac{24 \log n}{\varepsilon^2}$ **then**
    REFRESH()
    return true
  else
    return false

▶ **Lemma 11.** *Let $n \in \mathbb{N}$ and $\varepsilon \in (0, \frac{1}{16}]$ be parameters. Algorithm 2 supports* INITIALIZE($\mathcal{X}$)*, which initializes with a multiset $\mathcal{X}$ of $m \le n$ objects whose volumes are in $[(3n/\varepsilon)^2, (3n/\varepsilon)^4]$, and* DELETE($X$)*, which removes object X from $\mathcal{X}$. The algorithm maintains a pair (L, S) which is a $(\frac{18}{n^2}, 6n)$-digest of $\bigcup_{X \in \mathcal{X}} X$ at any point in time, and $|S| = O(\log(n)/\varepsilon^2)$. In total,* INITIALIZE *and any sequence of* DELETE *operations run in expected time $O(m \log^2(n/\varepsilon)/\varepsilon^2)$. The space complexity is $O(m + \log(n)/\varepsilon^2)$.*

Moreover, the set S only rarely gains new points: DELETE(X) *returns true if the set S after the deletion is not a subset of the set S before the deletion (and false otherwise); and over any sequence of deletions only $O(\log(n/\varepsilon))$ deletions return true, with probability $1 - O(n^{-2})$.*

Proof. Fix the initial objects and an arbitrary sequence of m deletions. After $t = 0, 1, \ldots, m$ deletions, let U_t be the union of the surviving objects, and let L_t, S_t be the variables L, S in the algorithm. We claim that (L_t, S_t) is a $(\frac{9(t+1)}{n^3}, 3(t+1))$-digest of U_t.

Let us prove the claim by induction. First consider initialization ($t = 0$). By Theorem 6, with probability at least $1 - n^{-3}$ KLM computes $v \in (1 \pm 0.5)\,\mathrm{vol}(U_0)$, and in this case the algorithm computes $L \in \mathrm{level}(U_0) \pm 1$. Thus, ERASE-RESAMPLE returns a $(\frac{3}{n^3}, 3)$-digest (L_0, S_0) of U_0 by Lemma 10.

Now we proceed to $t \geq 1$. By the induction hypothesis, (L_{t-1}, S_{t-1}) is a $(\frac{9t}{n^3}, 3t)$-digest of U_{t-1}. Let $\mathcal{E}$ be a support ensemble of (L_{t-1}, S_{t-1}). Define

$$\mathcal{E}' := \{(\ell, R \cap U_t) : (\ell, R) \in \mathcal{E},\ \ell \leq \text{level}(U_t) + 1\}.$$

Observe that $|\mathcal{E}'| \leq |\mathcal{E}| \leq 3t$ and $\mathcal{E}'$ is an ensemble of U_t since $\text{level}(U_t) \leq \text{level}(U_{t+1})$.

Let E be the event that $(L_{t-1}, S_{t-1}) \in \mathcal{E}$. Let F be the event that $\left|2^\ell |R \cap U_t| - \text{vol}(U_t)\right| \leq \varepsilon\,\text{vol}(U_{t-1})$ for all $(\ell, R) \in \mathcal{E}$. Note that $\mathbb{P}(\overline{E}) \leq \frac{9t}{n^3}$ by the induction hypothesis, and $\mathbb{P}(\overline{F}) \leq \frac{2 \cdot 3t}{n^4} < \frac{6}{n^3}$ by Lemma 8.

Assuming $E \cap F$, we have $L_{t-1} \in \text{level}(U_{t-1}) \pm 1$ and $2^{L_{t-1}} |S_{t-1} \cap U_t| \in \text{vol}(U_t) \pm \varepsilon\,\text{vol}(U_{t-1})$. Let us distinguish three cases and derive further consequences:

(1) If $L_{t-1} \leq \text{level}(U_t)$, then

$$|S_{t-1} \cap U_t| \geq \frac{\text{vol}(U_t)}{2^{\text{level}(U_t)}} - \varepsilon \frac{\text{vol}(U_{t-1})}{2^{\text{level}(U_{t-1})-1}} \geq \frac{32 \log n}{\varepsilon^2} - \varepsilon \frac{128 \log n}{\varepsilon^2} \geq \frac{24 \log n}{\varepsilon^2}.$$

So the algorithm does not refresh. As a result, $L_t = L_{t-1} \leq \text{level}(U_t)$ and $S_t = S_{t-1} \cap U_t$, thus $(L_t, S_t) \in \mathcal{E}'$.

(2) If $L_{t-1} \geq \text{level}(U_t) + 2$, then

$$|S_{t-1} \cap U_t| \leq \frac{\text{vol}(U_t)}{2^{\text{level}(U_t)+2}} + \varepsilon \frac{\text{vol}(U_{t-1})}{2^{\text{level}(U_{t-1})-1}} < \frac{16 \log n}{\varepsilon^2} + \varepsilon \frac{128 \log n}{\varepsilon^2} \leq \frac{24 \log n}{\varepsilon^2}.$$

So the algorithm refreshes. During refresh, the algorithm computes $L' \in \text{level}(U_t) \pm 1$ with probability at least $1 - \frac{1}{n^3}$ by Theorem 6, and then we have $L_t = \min\{L_{t-1} - 1, L'\} = L' \in \text{level}(U_t) \pm 1$. Hence, it returns a $(\frac{3}{n^3}, 3)$-digest (L_t, S_t) of U_t by Lemma 10.

(3) Otherwise $L_{t-1} = \text{level}(U_t)+1$, and the algorithm may or may not refresh. If it does, then (L_t, S_t) is a $(\frac{3}{n^3}, 3)$-digest of U_t as in case (2). If it does not, then $L_t = L_{t-1} = \text{level}(U_t)+1$ and $S_t = S_{t-1} \cap U_t$, thus $(L_t, S_t) \in \mathcal{E}'$.

Taking all cases into account, recalling $\mathbb{P}(\overline{E \cap F}) \leq \mathbb{P}(\overline{E}) + \mathbb{P}(\overline{F}) \leq \frac{9t+6}{n^3}$, and adding the error probability $\frac{3}{n^3}$ of the new digest after refreshing, we conclude that (L_t, S_t) is a $(\frac{9(t+1)}{n^3}, 3(t+1))$-digest of U_t. (In particular, it is a $(\frac{18}{n^2}, 6n)$-digest of the union of the remaining objects.)

As a consequence, with probability at least $1 - O(n^{-2})$ we have $L_0 \in \text{level}(U_0) \pm 1$ and $L_{m-1} \in \text{level}(U_{m-1}) \pm 1$. On the other hand, $\text{level}(U_0) \leq O(\log(n/\varepsilon))$ and $\text{level}(U_{m-1}) \geq 0$ (because each object has volume in $[(3n/\varepsilon)^2, (3n/\varepsilon)^4]$), and every refresh causes L to decrease by at least one. So the number of calls to REFRESH is bounded by $O(\log(n/\varepsilon))$. Since we have $S_t \subseteq S_{t-1}$ except when we do a refresh, it follows that the set S can only gain points during $O(\log(n/\varepsilon))$ many deletions, with probability $1 - O(n^{-2})$.

The size bound $|S| = O(\log(n)/\varepsilon^2)$ follows from Lemma 10.

It remains to bound the running time and space usage. For INITIALIZE and REFRESH, the subroutine KLM runs in $O(m \log n)$ time by Theorem 6; the subroutine ERASE-RESAMPLE runs in $O(m \log(n)/\varepsilon^2)$ time by Lemma 10; and the loop runs in $O(m \log(n)/\varepsilon^2)$ time since $|S| = O(\log(n)/\varepsilon^2)$ and each point in S is tested against at most m objects.

For DELETE, we spend $O(\log(n)/\varepsilon^2)$ time in the loop. An extra $O(m \log(n)/\varepsilon^2)$ time may be incurred by a refresh. As we argued before, there are at most $O(\log(n/\varepsilon))$ refreshes throughout the deletion sequence with probability $1 - O(n^{-2})$. There can be at most m refreshes with the remaining probability $O(n^{-2})$. So the expected time for the whole deletion sequence is $O(m \log(n)/\varepsilon^2 \cdot (\log(n/\varepsilon) + m/n^2)) \leq O(m \log^2(n/\varepsilon)/\varepsilon^2)$.

Finally, let us analyze the space complexity. Storing $\mathcal{X}$ in a binary search tree needs $O(m)$ space. Storing S and the counters m_x in a table needs $O(\log(n)/\varepsilon^2)$ space. Storing L needs constant space. So the algorithm uses $O(m + \log(n)/\varepsilon^2)$ space in total. ◀

5.3 Handling insertions

In this section, we apply the decremental data structure from the previous section to derive a dynamic algorithm for union volume estimation, using a novel variant of the logarithmic method [4]. Throughout the algorithm, the remaining objects are partitioned into bins $\mathcal{X}_0, \dots, \mathcal{X}_{\log n}$. Each bin $\mathcal{X}_j$ holds at most 2^j objects and is implemented by the decremental data structure. Every now and then, we merge some (small) bins into a larger bin by re-initializing the target bin with the objects in the source bins. Between any two merges that involve a bin $\mathcal{X}_j$, it undergoes deletions only. At any time, we can access a digest $(\mathcal{X}_j.L, \mathcal{X}_j.S)$ of the union $\bigcup_{X \in \mathcal{X}_j} X$. Additionally, for every point $x \in \mathcal{X}_j.S$, we keep track of the number $n_x := \#\{X \in \mathcal{X}_0 \cup \dots \cup \mathcal{X}_{j-1} : x \in X\}$.

▶ **Theorem 12.** *Let $n \in \mathbb{N}$ and $\hat{\varepsilon} \in (0, \frac{1}{16}]$ be parameters. Algorithm 3 maintains an initially empty multiset $\mathcal{X}$ of objects, where each object has volume in $[(3n/\hat{\varepsilon})^2, (3n/\hat{\varepsilon})^4]$, under updates* INSERT$(X)$ *and* DELETE(X) *and query* ESTIMATE$()$*, which $(1 \pm \hat{\varepsilon})$-approximates the volume of the union of $\mathcal{X}$ and is correct with high probability. The amortized expected update time is $O(\log^5(n/\hat{\varepsilon})/\hat{\varepsilon}^2)$, the query time is $O(\log^4(n)/\hat{\varepsilon}^2)$, and the space complexity is $O(n + \log^4(n)/\hat{\varepsilon}^2)$.*

Algorithm 3 Dynamic union volume estimation with arbitrary insertions and deletions.

parameters: $n, \hat{\varepsilon}$
function INITIALIZE
  for $j = 0, \dots, \log n$ **do**
    $\mathcal{X}_j$.INITIALIZE$(\emptyset)$ with parameters n and $\varepsilon := \hat{\varepsilon}/(1 + \log n)$
function INSERT(X)
  let h be the minimal integer such that $1 + \sum_{j=0}^{h} |\mathcal{X}_j| \le 2^h$
  $\mathcal{X}_h$.INITIALIZE$(\{X\} \cup \mathcal{X}_0 \cup \dots \cup \mathcal{X}_h)$ `/* merge */`
  $\mathcal{X}_j$.INITIALIZE$(\emptyset)$ for $j = 0, \dots h-1$
  foreach $x \in \mathcal{X}_h.S$ **do**
    $n_x := 0$
  foreach $x \in \bigcup_{j=h+1}^{\log n} \mathcal{X}_j.S$ **do**
    if X.CONTAINS(x) **then**
      $n_x := n_x + 1$
function DELETE(X)
  find the bin $\mathcal{X}_j$ containing X
  refreshed := $\mathcal{X}_j$.DELETE(X)
  if refreshed **then**
    foreach $x \in \mathcal{X}_j.S$ **do**
      $n_x := \#\{X \in \mathcal{X}_0 \cup \dots \cup \mathcal{X}_{j-1} : X$.CONTAINS$(x)\}$
  foreach $x \in \bigcup_{k=j}^{\log n} \mathcal{X}_k.S$ **do**
    if X.CONTAINS(x) **then**
      $n_x := n_x - 1$
function ESTIMATE$()$
  denote $S_j := \mathcal{X}_j.S$ and $L_j := \mathcal{X}_j.L$ for $j = 0, 1, \dots, \log n$
  compute $R_j := \{x \in S_j : n_x = 0\}$ for $j = 0, 1, \dots, \log n$
  return $\sum_{j=0}^{\log n} 2^{L_j} |R_j|$

Proof. Fix a sequence of at most n insertions and deletions. Then the partition of surviving objects into bins $\mathcal{X}_1, \dots, \mathcal{X}_{\log n}$ is determined; in particular $U_j := \bigcup_{X \in \mathcal{X}_j} X$ is determined, and we write $V_j := U_j \setminus (U_0 \cup \cdots \cup U_{j-1})$. Note that the union of the surviving objects $U := \bigcup_{j=0}^{\log n} U_j = \bigcup_{j=0}^{\log n} V_j$ is a disjoint union of V_j's, thus $\operatorname{vol}(U) = \sum_{j=0}^{\log n} \operatorname{vol}(V_j)$.

Now let us consider a call to ESTIMATE. By Lemma 11, each S_j is a $(\frac{18}{n^2}, 6n)$-digest of U_j. Note that the algorithm computes $R_j := V_j \cap S_j$, so by Corollary 9, we have $2^{L_j}|R_j| \in \operatorname{vol}(V_j) \pm \varepsilon \operatorname{vol}(U_j)$ with probability at least $1 - \frac{18}{n^2} - \frac{12n}{n^4} = 1 - O(n^{-2})$. By a union bound, this holds for all j simultaneously with probability $1 - O(n^{-1})$. Under this event,

$$\sum_{j=0}^{\log n} 2^{L_j}|R_j| \in \operatorname{vol}(U) \pm \varepsilon \sum_{j=0}^{\log n} \operatorname{vol}(U_j).$$

We can crudely bound the additive error by $\varepsilon(1 + \log n)\operatorname{vol}(U) = \hat{\varepsilon}\operatorname{vol}(U)$, just as desired.

Next we analyze the running time. We will charge the cost of DELETE to insertions. Note that in DELETE, it takes time $O(\log^2(n))$ to compute the bin j containing X, if for each j we store (pointers to) all objects in $\mathcal{X}_j$ in a binary search tree. The last for-loop takes time $O(\log^2(n)/\varepsilon^2)$. To bound the running time of the "if refreshed" block, we change our viewpoint and focus on the sequence of deletions occurring between two merges of a particular bin $\mathcal{X}_j$.

- The total cost of $\mathcal{X}_j$.DELETE is $O(2^j \log^2(n/\varepsilon)/\varepsilon^2)$ in expectation by Lemma 11.
- With probability $1 - O(n^{-2})$, there are $O(\log(n/\varepsilon))$ refreshes between two merges of bin $\mathcal{X}_j$ by Lemma 11, so the if-block is executed $O(\log(n/\varepsilon))$ times. Each time, the algorithm recomputes n_x for every $x \in S_j$ by testing against at most $\sum_{k=0}^{j-1} 2^k \le 2^j$ objects, which takes time $O(2^j \log(n)/\varepsilon^2)$. Therefore, the total contribution of the if-block is $O(2^j \log^2(n/\varepsilon)/\varepsilon^2)$ in expectation.

Therefore, over the sequence of deletions between two merges of $\mathcal{X}_j$, deletions from $\mathcal{X}_j$ take expected total time $O(2^j \log^2(n/\varepsilon)/\varepsilon^2)$. Note that at least 2^j insertions occur between two merges of bin $\mathcal{X}_j$. We can thus charge the cost of deletions to insertions. Each insertion is charged $O(\log n)$ times (once for every bin), so we charge each insertion with a cost of $O(\log^3(n/\varepsilon)/\varepsilon^2)$ in expectation.

Now we analyze the running time of INSERT. It depends on the value h. By Lemma 11, the merge step costs $O\left(\sum_{j=0}^{h} 2^j \log^2(n/\varepsilon)/\varepsilon^2\right) = O\left(2^h \log^2(n/\varepsilon)/\varepsilon^2\right)$, which can be expensive in the worst case. However, bin $\mathcal{X}_h$ is merged at most once every 2^h updates, so it contributes amortized cost $O(\log^2(n/\varepsilon)/\varepsilon^2)$ to each insertion. Summing over all h, the amortized cost of merges is $O(\log^3(n/\varepsilon)/\varepsilon^2)$ per insertion. Next we consider the foreach-loops. Since each digest contains $O(\log(n)/\varepsilon^2)$ points by Lemma 11, and the algorithm spends constant time on each point, these loops take time $O(\log^2(n)/\varepsilon^2)$. To summarize, INSERT runs in amortized expected time $O(\log^3(n/\varepsilon)/\varepsilon^2) = O(\log^5(n/\varepsilon)/\hat{\varepsilon}^2)$ (and DELETE runs in amortized time 0).

The running time of ESTIMATE is clearly $O(\log^2(n)/\varepsilon^2) = O(\log^4(n)/\hat{\varepsilon}^2)$.

The space of bin $\mathcal{X}_j$ is $O(2^j + \log(n)/\varepsilon^2)$ by Lemma 11, and we can charge the space of counters n_x to it. In total the space complexity is $O\left(\sum_{j=0}^{\log n}(2^j + \log(n)/\varepsilon^2)\right) = O(n + \log^4(n)/\hat{\varepsilon}^2)$. ◀

Theorem 1 now follows from Theorem 12 together with Lemma 4.1 in [5].

Abstract

A t-spanner of a point set X in a metric space $(\mathcal{X}, \delta)$ is a graph G with vertex set P such that, for any pair of points $u, v \in X$, the distance between u and v in G is at most t times $\delta(u, v)$. We study the problem of maintaining a spanner for a dynamic point set X – that is, when X undergoes a sequence of insertions and deletions – in a metric space of constant doubling dimension. For any constant $\varepsilon > 0$, we maintain a $(1+\varepsilon)$-spanner of P whose total weight remains within a constant factor of the weight of the minimum spanning tree of X. Each update (insertion or deletion) can be performed in $\text{poly}(\log \Phi)$ time, where Φ denotes the aspect ratio of X. Prior to our work, no efficient dynamic algorithm for maintaining a light-weight spanner was known even for point sets in low-dimensional Euclidean space.

1 Introduction

Let $X \subset \mathcal{X}$ be a set of points in the metric $(\mathcal{X}, \delta_X)$. A graph $G = (X, E, \delta)$ with vertex set X is a *geometric graph* if the weight function on the edges is the distance function δ. In other words, the weight of each edge is the distance between its endpoints in $\mathcal{X}$. Observe that if G is a geometric graph, then by the triangle inequality, for every $x, y \in X$, $\delta_G(x, y) \geq \delta(x, y)$. Given a parameter t, called the *stretch*, we say that G is a (geometric) *t-spanner* for X if $\delta_G(x, y) \leq t \cdot \delta(x, y)$ for every $x, y \in X$. The natural goal is to construct, for a given stretch t, a t-spanner with small number of edges and a small total weight.

Lightness and *sparsity* are two central measures for evaluating spanners. For a spanner $G = (X, E)$, the lightness is the ratio $w(G)/w(\text{MST})$ between the total weight of G and the weight of a minimum spanning tree on X. The sparsity of G is the ratio $|E(G)|/|E(\text{MST})| \approx |E(G)|/|X|$, comparing the number of edges of G to that of an MST. Since every spanner (with finite stretch) is connected and therefore contains a spanning tree, the lightness and sparsity of G constitute a measure of how close a spanner (specifically $w(G)$ and $|E(G)|$) to the optimal weight and the optimal number of edges of a spanner with finite stretch. A long line of research has studied spanners in Euclidean spaces [5, 49, 41, 29, 32, 14, 45],

doubling [35, 21, 51, 36, 33, 19, 13], planar and minor-free metric [18, 39, 25, 12], and general graphs [48, 4, 30, 28, 24, 33, 44, 16]. Of particular interest, we focus on *low-dimensional Euclidean space*, and more generally on *doubling metrics*.

Doubling metrics. Let $B(x,r) = \{y|\delta(x,y) \leq r\}$ be a ball of radius $r \geq 0$ centered at a point $x \in \mathcal{X}$. A metric $(\mathcal{X}, \delta)$ has *doubling dimension* d if for every $r > 0$, every ball of radius r can be covered by at most 2^d balls of radius $r/2$: $\forall x \in X, r > 0,\ \exists Y \subseteq X : |Y| \leq 2^d$ and $B_X(x,r) \subseteq \cup_{y \in Y} B_X(y, r/2)$. The study of spanners in doubling metrics was initiated by Gao, Guibas, and Nguyen [35], who proved that any n-point set in a metric space of doubling dimension d admits a $(1+\varepsilon)$-spanner with $\varepsilon^{-O(d)}n$ edges. Smid [51], via an analysis of the *greedy algorithm*, showed that greedy $(1+\varepsilon)$-spanners have $\varepsilon^{-O(d)}n$ edges and achieve lightness $\varepsilon^{-O(d)} \log n$. While it has long been known that d-dimensional Euclidean point sets admit $(1+\varepsilon)$-spanners with lightness $\varepsilon^{-O(d)}$, it remained a major open problem whether an analogous result holds for metric spaces of low doubling dimension. In a major breakthrough, Gottlieb [36] proved that any metric space of doubling dimension d admits a $(1+\varepsilon)$-spanner with lightness $(d/\varepsilon)^{O(d)}$. Gottlieb devised a complicated spanner construction instead of the classic greedy spanner. Later, Filtser and Solomon [33] showed that the greedy spanner is existentially optimal, concluding that it has lightness $(d/\varepsilon)^{O(d)}$ as well. Finally, Borradaile, Le, and Wulff-Nilsen [19] showed the greedy spanner has weight $\varepsilon^{-O(d)}$, which is optimal.

Dynamic Spanners. The problem of maintaining a sparse $(1+\varepsilon)$-spanner for a point set X under insertions and deletions has also been studied over the years. Already back in 1999, Arya et al. [6] obtained polylogarithmic update time in a restricted model with random updates (a deletion removes a uniformly random point from S, and an insertion results in a uniformly random point in the updated set). Later, Bose et al. [20] studied the problem in the context of θ-graphs, and presented an algorithm that supports insertions only and achieves polylogarithmic update time. Gao et al. [35] studied kinetic and dynamic geometric spanners for points in bounded doubling dimensions, and obtained a fully dynamic spanner with worst-case update time $O(\log \Phi)$, where Φ is the *aspect ratio* of the point set X, defined as the ratio between the maximum and minimum pairwise distances in X. Krauthgamer and Lee [43] obtained similar results for proximity search, where the time bounds of their dynamic updates depend also in the aspect ratio. For proximity search, later, Cole and Gottlieb [26] removed the dependency on the aspect ratio. For the Euclidean plane, Abam et al. [1] presented an algorithm with $O(\log n)$ update time. For doubling metrics, Roditty [50] presented the first fully dynamic algorithm for maintaining a geometric $(1+\varepsilon)$-spanner, with update time depending only on the number of points in X. The algorithm obtained in [50] supports insertions in amortized $O(\log n)$ time and deletions in amortized $\tilde{O}(n^{1/3})$ time where $\tilde{O}$ hides polylogarithmic factors, and maintains spanner with $O(n/\varepsilon^d)$ edges. Gotllieb and Roditty [37] gave a dynamic spanner that supports insertions in $O\big(\varepsilon^{-O(d)} \log^2 n\big)$ amortized time and deletions in $O\big(\varepsilon^{-O(d)} \log^3 n\big)$ amortized time. Later, in [38],[1] they gave a $(1+\varepsilon)$-spanner of constant degree that supports updates in $\varepsilon^{-O(d)} \log n$ worst-case time.

Roughly speaking, these "classic" constructions of dynamic spanners for doubling metric are based on a *net tree* (see Section 2). While it is straightforward to construct a sparse spanner from a net tree, this tool is too rough to obtain lightness. Indeed, in Figure 1 we illustrate the net tree of the path graph, and show that it has lightness $\Omega(\log n)$. A more

[1] Gotllieb and Roditty [38] additionally assume that they can query the distance between a deleted point and a non-deleted point, which (for example) is possible for Euclidean metrics.

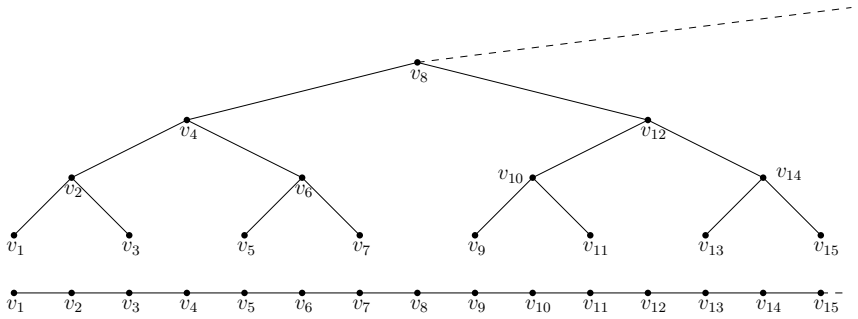

Figure 1 On bottom: The path graph P_n. All edges are unit weight. On top: a depiction of the net tree T of P_n. There is a laminar hierarchy of nets; the 2^i-net is $N_i = \{v_j \in P_n \mid j \mod 2^i = 0\}$ (all vertices at hight i in the tree and above). The net-tree spanner contains all the tree edges, and many additional edges. The weight of the edge $\{v_i, v_j\}$ is $|i-j|$. The tree T has depth $\log n$, and the total weight of the edges going from depth i vertices to depth $i+1$ is $\Theta(n)$. Thus $w(T) = \Theta(n \cdot \log n)$. As the weight of the MST of P_n is $n-1$, the net-tree spanner has lightness $\Omega(\log n)$.

recent approach to constructing dynamic sparse spanners is using *locality-sensitive orderings (LSO)* (introduced by Chan, Har-Peled, and Jones [22]). In the full version of the paper, we summarize the history of LSO, and prove that LSO-based spanners have logarithmic lightness (even for $\mathbb{R}^1$).

While there is a substantial body of work on dynamic spanners in Euclidean metrics and, more generally, in doubling metrics, as summarized above, there is comparatively little work on dynamic *light* spanners. Controlling lightness is arguably a significantly harder objective, as evidenced by the extensive literature in the offline setting (see, e.g., [45, 5, 49, 18, 44, 47, 13, 33, 36, 29, 14, 23] and the references therein).

▶ **Question 1.** *Can we design a dynamic algorithm that maintains a* light-weight *spanner for a point set under dynamic updates in doubling metrics with polylogarithmic update time?*

Partial progress toward Question 1 was made by Eppstein and Khodabandeh [31], who showed that one can maintain a *low-recourse* light spanner for dynamic point sets in low-dimensional Euclidean space. The *recourse* of a dynamic spanner is the number of edges that change after each insertion or deletion. They obtained a construction with amortized $O(1)$ recourse per insertion and amortized $O(\log \Phi)$ recourse per deletion. However, their result addresses recourse rather than efficiency: the actual time to update the spanner can be very large (no faster than just recomputing a spanner from scratch), and therefore their work does not resolve the question of achieving polylogarithmic (or even sublinear) update time.

1.1 Our Contribution

We resolve Question 1 in the affirmative. We say a set of points X is (a, b)-bounded if $\min_{u,v \in X} \delta(u, v) \geq a$ and $\max_{u,v \in X} \delta(u, v) \leq b$.

▶ **Theorem 2.** *Let $(\mathcal{X}, \delta)$ be a metric space with doubling dimension d, and let $\varepsilon > 0$ and $\Phi > 0$ be parameters. Let $X \subseteq \mathcal{X}$ be a set of points undergoing insertions and deletions, such that at all times X is $(1, \Phi)$-bounded. We maintain a $(1+\varepsilon)$-spanner L of X with lightness at most $\varepsilon^{-O(d)}$, where each insertion/deletion to X can be processed in time $(\varepsilon^{-1} \cdot \log \Phi)^{O(d)}$.*

For the sake of simplicity, we state our theorem as though the maximum distance Φ must be given in advance, and the minimum distance between points in X must be at least 1. Using standard techniques [43, 31] we could remove these restrictions at no loss in the running

time: we obtain a data structure whose update time depends adaptively on the aspect ratio Φ of the current point set X (see the full version of the paper). Additionally, we remark that we do not need to know the doubling dimension d in advance; the value d only appears in the runtime analysis.

Techniques. Our proof begin somewhat similarly to Eppstein and Khodabandeh [31]: roughly speaking, we seek to maintain a *greedy spanner* on top of a *dynamic sparse spanner* of points X (crucially, this spanner is much more structured than just the greedy spanner on the complete geometric graph on X). In Section 3, we first give a new (and arguably much simpler[2]) algorithm and analysis that such a spanner can be maintained with bounded recourse. After each insertion/deletion, we identify $O(\log \Phi)$ edges (u, v) of our greedy spanner L which might have to change, to satisfy the greedy spanner invariants: roughly speaking, we examine the distance $\delta_{L<}(u, v)$ between u and v in the graph consisting of all of edges of L that are shorter than (u, v)[3], and we insert or delete (u, v) to L based on whether $\delta_{L<}(u, v) \leq (1 + \varepsilon)\delta(u, v)$. Our key technical contribution (in Section 4) is to show that we can efficiently maintain estimates of $\delta_{L<}(u, v)$ even as we insert or delete edges into L.

1.2 Related Work

Dynamic Graph Spanners. In general graphs, the goal is to maintain, under edge updates, for any integer $k \geq 2$, a spanner with stretch $2k - 1$ and $\widetilde{O}(n^{1+1/k})$ edges. Assuming the Erdős–Girth conjecture, this trade-off is essentially optimal. The dynamic spanner problem was initiated by Ausiello et al. [7], and has since been studied extensively; see, for example, [8, 17, 27, 10, 34]. However, these works focus primarily on *sparsity*, and the resulting techniques do not naturally extend to maintaining *light* spanners. Moreover, due to inherent degree barriers in general graphs, this line of work exclusively considers *edge updates*. In contrast, in geometric and other structured metric spaces, vertex updates are often the more natural model, since the underlying graph need not be maintained explicitly. This distinction is crucial for light spanners, whose construction and analysis rely fundamentally on geometric structure rather than purely combinatorial sparsification.

Online Spanners. Spanners have also been studied extensively in the closely related *online* model. In this setting, points from a metric space arrive one by one, and at each step, the algorithm is given the subset of points that arrived so far. The goal is to maintain a t-spanner at all times. Unlike in the fully dynamic setting, the algorithm is allowed to *add* edges when a new point arrives, but may never remove previously added edges. In addition, the total number of points n is not known in advance. A number of algorithms and lower bounds have been obtained for this model, which addressed both sparsity and lightness guarantees along with stretch, under online constraints; see, e.g., [11, 15, 2, 3, 9, 40, 46]. These results achieve near-optimal trade-offs in the online regime and highlight the fundamental differences between incremental constructions and fully dynamic settings.

---

[2] We avoid the *bucketing* technique in the algorithm of [31] and instead work with all spanner edges at once; we maintain spanner invariants that work in doubling metrics and not just Euclidean metrics (unlike the *leapfrog property* used in [31]); and finally, we give a simple worst-case bound on the recourse of $O(\log \Phi)$, rather than using a potential function to bound the amortized recourse.

[3] Our description here assumes we want to maintain a greedy spanner, but actually we maintain a slightly more robust type of spanner which we call the *delayed greedy spanner*: we work with distances $\delta^*(u, v)$ rather than $\delta_{L<}(u, v)$, as defined in Section 2.2. We do this to control cascading changes to L.

2 Net trees and greedy spanners

Preliminaries. Throughout this paper, let $M = (\mathcal{X}, \delta)$ be a metric space with constant doubling dimension $d = O(1)$. For any vertex $x \in \mathcal{X}$ and radius $r > 0$, we let $B(x, r)$ denote the set of points within distance r of x; that is, $B(x, r) \coloneqq \{y \in \mathcal{X} : \delta(x, y) \leq r\}$. If G is a (geometric) graph, we use the notation $\delta_G(\cdot, \cdot)$ to denote shortest-path distances on G. For any positive integer n, we write $[n]$ to mean $\{i \in \mathbb{Z} : 0 \leq i \leq n\}$. Throughout this paper, we fix some sufficiently small positive integer $\varepsilon > 0$ and aim to construct a light $(1 + O(\varepsilon))$-spanner; our Theorem 2 will follow after rescaling $\varepsilon \leftarrow \varepsilon/O(1)$.

2.1 Net-Tree Spanners

In this subsection, we review the classic net-tree spanner [35].

Net tree. Let $X \subseteq \mathcal{X}$ be a set of points. Assume that the smallest distance between points in X is 1, and the largest distance is Φ; for simplicity we assume $\Phi = 2^i$ for some integer i. A *Δ-net* of X is a set of points N such that every point $x \in X$ is within distance Δ of some point in N, and any two net points in N are at distance greater than Δ. A Δ-net can be constructed greedily. A *net hierarchy* of X is a hierarchical sequence of nets $(N_0, N_1, \ldots, N_{\log \Phi})$ such that every N_i is a subset of N_{i-1}, and N_i is a 2^i-net of N_{i-1}; we take $N_0 = X$. Observe that (by a geometric series) every point in X is within distance 2^{i+1} of some net point in N_i. Moreover, the *packing bound* of doubling metrics implies that there are not too many points close together in each Δ-net.

▶ **Observation 3** (Packing bound). *Let N be a set of points that are pairwise at distance at least Δ. For any $\alpha \geq 1$ and $x \in \mathcal{X}$, there are at most $\alpha^{O(d)}$ points in $B(x, \alpha \cdot \Delta) \cap N$.*

An implicit representation of the net hierarchy $\mathcal{N}$ can be maintained using a data structure called the *net tree* [35, 43, 42]. We will sometimes abuse terminology and call $\mathcal{N}$ a net tree.

Net-tree spanner. The net-tree spanner was introduced (under the name "deformable spanner") by Gao, Guibas, and Nguyen [35]; similar ideas were independently designed by Krauthgamer and Lee [43]. The *ε-net-tree spanner* of X with respect to the net tree $\mathcal{N} = (N_0, \ldots, N_{\log \Phi})$ is the graph with vertex set X and with the following edge set: for every scale $i \in [\log \Phi]$, add an edge between any two vertices $u, v \in N_i$ if $\delta(u, v) \leq c \cdot 2^i$, where $c \coloneqq 4 + 16\varepsilon^{-1}$.

▶ **Lemma 4** ([35, Theorem 3.2]). *An ε-net-tree spanner of X is a $(1 + \varepsilon)$-spanner of X.*

For any pair of vertices (u, v), we say the *scale* of (u, v) is the value i such that $\delta(u, v) \in [2^{i-1}, 2^i)$. Observe that an edge (u, v) at scale i in an ε-net-tree spanner has both endpoints in the $O(\varepsilon) \cdot 2^i$-net of the net tree (not the 2^i-net). The packing bound implies that every vertex in the ε-net-tree spanner has degree at most $\varepsilon^{-O(d)} \cdot \log \Phi$. In fact, using a charging argument, one can show that the ε-net-tree spanner contains at most $\varepsilon^{-O(d)} \cdot n$ edges: that is, it is *sparse*. We frequently denote the ε-net-tree spanner as S.

Dynamic maintenance. Gao, Guibas, and Nguyen [35] showed that the net tree spanner can be maintained dynamically. We summarize their guarantee below.

▶ **Lemma 5** (Rephrasing of [35, Theorem 4.2]). *There is a data structure that implicitly maintains a hierarchy of nets $\mathcal{N} = (N_0, N_1, \ldots, N_{\log \Phi})$ of a point set X undergoing insertions and deletions. Each insertion or deletion can be processed in $O(\log \Phi)$ time. Moreover*[4]*, for any constant $\varepsilon > 0$, one can maintain an ε-net-tree spanner of X with respect to $\mathcal{N}$, in $O(\log \Phi)$ time per insertion or deletion.*

We will make use of Lemma 5, but we will have to slightly unwrap the black box – we will need some control on how the net tree $\mathcal{N}$ changes after each insertion or deletion. Fortunately, [35] update the net tree $\mathcal{N}$ in a simple and structured way. Inserting a point x into X has the following result, described in Figure 2.

$i_0 \leftarrow$ smallest scale such that the scale-i_0 net $N_{i_0} \in \mathcal{N}$ satisfies $\delta(x, N_{i_0}) < 2^{i_0}$
update $\mathcal{N}$ by inserting x into net $N_i \in \mathcal{N}$ for all $i < i_0$

Figure 2 Pseudocode for [35] algorithm to update net $\mathcal{N}$ after inserting point x into X.

Deleting a point x from X is described in Figure 3.

update $\mathcal{N}$ by deleting x from every net $N_i \in \mathcal{N}$
for every scale $i \leftarrow 1, 2, \ldots, \log \Phi$:
  while there exists some point $y \in N_{i-1}$ with $\delta(u, N_i) > 2^i$, add y to N_i

Figure 3 Pseudocode for [35] algorithm to update net $\mathcal{N}$ after deleting point x from X.

We will not discuss the details of the data structures or algorithms that [35] use to implement these two operations efficiently. We have unwrapped the [35] black box so that we can prove that every insertion/deletion of a point x only changes $\mathcal{N}$ "locally" nearby x.

▶ **Lemma 6.** *Let $\mathcal{N}^{\text{old}} = (N_0^{\text{old}}, \ldots, \mathcal{N}_{\log \Phi}^{\text{old}})$ be a net tree for point set X. Let $\mathcal{N} = (N_0, \ldots, N_{\log \Phi})$ be the net tree produced from $\mathcal{N}^{\text{old}}$ by the [35] algorithm after a point x is inserted into (resp. deleted from) X. For any scale $i \in [\log \Phi]$, every point y in the symmetric difference of N_i and N_i^{old} satisfies $\delta(y, x) \le 2^i$.*

Proof. When x is inserted into X (according to the pseudocode in Figure 2), the lemma follows trivially from the [35] algorithm description: the only point that could differ between N_i and N_i^{old} is x. We now argue that the lemma holds when x is deleted from X (according to the pseudocode in Figure 3). By construction, the only point that could be removed from N_i^{old} is x; that is, the set $N_i^{\text{old}} \setminus N_i$ is either $\varnothing$ or $\{x\}$. So it remains to show that every point y in $N_i \setminus N_i^{\text{old}}$ satisfies $\delta(y, x) \le 2^i$. The proof is by induction on i. When $i = 0$, every point in $\texttt{DS}.X$ is contained in N_0^{old}, so $N_0 \setminus N_0^{\text{old}} = \varnothing$ and the claim holds trivially. Now consider $i > 0$. Consider some point $y \in N_i \setminus N_i^{\text{old}}$. By the algorithm description, the point y satisfies

$$\delta(y, N_i^{\text{old}} \setminus \{x\}) > 2^i.$$

There are two cases. In the first case, suppose $y \in N_{i-1}^{\text{old}}$. Because N_i^{old} is a 2^i-net for N_{i-1}^{old}, we have $\delta(y, N_i^{\text{old}}) \le 2^i$. We conclude that $\delta(y, x) \le 2^i$ as desired. In the second case, suppose $y \notin N_{i-1}^{\text{old}}$; thus $y \in N_{i-1} \setminus N_{i-1}^{\text{old}}$, and by induction we have that $\delta(y, x) \le 2^{i-1} < 2^i$. ◀

[4] Note that the phrasing of [35, Theorem 4.2] does not explicitly separate the maintenance of the net hierarchy $\mathcal{N}$ from the maintenance of the spanner (they just state the existence of a dynamic spanner); however, our phrasing of Lemma 5 is immediate from their proof. In our application, we will need to dynamically maintain an ε_1-net-tree spanner of X and an ε_2-net-tree spanner of X (for two different values $\varepsilon_1 \neq \varepsilon_2$) *with respect to the same net tree* $\mathcal{N}$. This is possible using the data structure of [35].

We need one more guarantee from [35] (see full paper for details).

▷ Claim 7. Consider the data structure of [35] that maintains a hierarchy of nets $(N_0, N_1, \ldots, N_{\log \Phi})$ of X and an ε-net-tree spanner. Let $c_\varepsilon = 4 + 16\varepsilon^{-1}$. Given a scale $i \in [\log \Phi]$ and a query point $x \in \mathcal{X}$, one can find all vertices in $N_i \cap B(x, 100 \cdot c_\varepsilon \cdot 2^i)$ in time $\varepsilon^{-O(d)} = O(1)$.

2.2 Invariants for Our Light Spanner: Delayed Greedy Spanner

While the net-tree spanner S is sparse and can be maintained dynamically, it could have lightness $\Omega(\log n)$ (see Figure 1). We aim to find a subgraph of S with $O(1)$ lightness. Intuitively, we want to maintain a greedy $(1+\varepsilon)$-spanner H of the graph S: the greedy spanner (and even the *approximate* greedy spanner) are light [19, 33]. Recall that the greedy spanner initializes $H \leftarrow \varnothing$ and processes edges in S from smallest to largest; when we process (u, v), we add (u, v) to H iff $\delta_H(u, v) > (1+\varepsilon)\delta_S(u, v)$. In other words, the greedy spanner satisfies: for every edge (u, v) in S, letting $H_{<(u,v)}$ denote the set of edges in H with smaller[5] lengths than (u, v), we have $\delta_{H_{<(u,v)}}(u, v) > (1+\varepsilon)\delta_S(u, v)$ iff $(u, v) \in L$.

Delayed greedy spanner. We maintain a light spanner, denoted $S \subseteq S$ that doesn't obey the greedy spanner invariants exactly; rather, we define a more robust set of invariants. For any scale $i \in [\log \Phi]$, we define the set of edges $L[i] \subseteq L$ to be the set of all edges in L with *scale strictly less than* i; that is, every edge in $L[i]$ has length at most 2^{i-1}. For any edge (u, v) of the ε-net-tree spanner at scale i, we define $\delta^*(u, v) := \delta_{L[i]}(u, v)$; recall that $\delta_{L[i]}(\cdot, \cdot)$ denotes the shortest-path metric in the geometric graph induced by $L[i]$. To construct our light spanner, we maintain a subset of edges $L \subseteq S$ with the following properties:

▶ **Invariant 8.** *Every edge $(u, v) \in S \setminus L$ satisfies $\delta^*(u, v) \leq (1+\varepsilon) \cdot \delta(u, v)$.*

▶ **Invariant 9.** *Every edge $(u, v) \in L$ satisfies $\delta^*(u, v) > (1 + \frac{\varepsilon}{3}) \cdot \delta(u, v)$.*

If L satisfies Invariants 8 and 9, we call L a *delayed greedy spanner* of S (because there is a delay between the time an edge is added to the spanner and the time it is taken into account when making the next decision). We emphasize that the delayed greedy spanner invariants are different than the greedy spanner invariants for H: in our invariants, the choice of adding (u, v) to the spanner depends on $L[i]$ (the set of edges in L with *scale* strictly smaller than the scale of (u, v)), rather than $H_{<(u,v)}$ (the set of edges in the greedy spanner H that are strictly shorter than $\delta(u, v)$). Nevertheless, we show that any set of edges L that satisfies Invariants 8 and 9 is a $(1 + O(\varepsilon))$-spanner (Lemma 10) and has constant lightness (Lemma 11).

▶ **Lemma 10.** *Let S be an ε-net-tree spanner for X, and let $L \subseteq S$. If Invariant 8 holds, then L is a $(1+3\varepsilon)$-approximate spanner for (X, δ).*

Proof. By Lemma 4, the ε-net-tree spanner S is a $(1+\varepsilon)$-spanner for (X, δ). Moreover, Invariant 8 implies that L is a $(1+\varepsilon)$-spanner for S: by triangle inequality it suffices to check that every edge of S is preserved up to $1+\varepsilon$ approximation in L, and indeed, for every edge $(u, v) \in S$, we have $\delta_L(u, v) \leq \delta^*(u, v) \leq (1+\varepsilon)\delta(u, v) \leq (1+\varepsilon)\delta_S(u, v)$. We conclude that L is a spanner for (X, δ) with stretch $(1+\varepsilon)^2 \leq (1+3\varepsilon)$. ◀

[5] assume all edge lengths in S are distinct, by breaking ties arbitrarily

▶ **Lemma 11.** *Let S be an ε-net-tree spanner for X, and let $L \subseteq S$. If Invariants 8 and 9 hold, then L has lightness $\varepsilon^{-O(d)}$.*

Proof. We use, as a black box, the fact that the greedy $(1+\frac{\varepsilon}{3})$-spanner in a metric space of doubling dimension d has lightness $\varepsilon^{-O(d)}$ [19]. We consider the shortest-path metric δ_L induced by the edges of L; because (X, δ) has doubling dimension d, the stretch bound of Lemma 10 together with the definition of doubling dimension implies that the doubling dimension of (X, δ_L) is $O(d)$ (see [33, Observation 7]). Consider building the greedy $(1+\frac{\varepsilon}{3})$-spanner $\hat{L}$ of L: that is, we initialize $\hat{L} \leftarrow \varnothing$, then iterate over the edges of L from smallest to largest[6], and add an edge $(u,v) \in L$ into the spanner $\hat{L}$ iff $\delta_{\hat{L}}(u,v) > (1+\frac{\varepsilon}{3})\delta_L(u,v)$. The greedy spanner $\hat{L}$ has lightness $\varepsilon^{-O(d)}$. We now *charge* every edge of L to an edge of $\hat{L}$. If an edge $(u,v) \in L$ is added to $\hat{L}$, then charge (u,v) to itself. Otherwise, suppose $(u,v) \in L$ is not added to $\hat{L}$. This means that there is a path P between u and v in $\hat{L}$ (at the instant that (u,v) is considered) with length at most $(1+\frac{\varepsilon}{3})\delta_L(u,v)$. Because S is a geometric graph, $\delta_S(u,v) = \delta(u,v)$; i.e., P has length at most $(1+\frac{\varepsilon}{3})\delta(u,v)$. Let i be the scale of (u,v), meaning that $\delta(u,v) \in [2^{i-1}, 2^i)$. The path P contains some scale-i edge (u',v') in the greedy spanner $\hat{L}$: otherwise, if P contained only scale-j edges with $j < i$, we would have $\delta^*(u,v) \le (1+\frac{\varepsilon}{3}) \cdot \delta(u,v)$, contradicting Invariant 9. Charge (u,v) to the scale-i edge (u',v').

We now claim that every edge (u',v') in $\hat{L}$ is charged at most $\varepsilon^{-O(d)}$ times. Indeed, whenever a scale-i edge (u',v') is charged by a scale-i edge (u,v), we have $\delta(u,u') \le (1+\frac{\varepsilon}{3})2^i$; this is because, by definition of charging, u' lies on a path u and v with length at most $(1+\frac{\varepsilon}{3})\delta(u,v) \le (1+\frac{\varepsilon}{3})2^i$. The packing bound (Observation 3) implies that there are only $\varepsilon^{-O(d)}$ scale-i edges that could charge (u',v'). Because we only charge scale-i edges in L to scale-i edges in $\hat{L}$, we conclude that L is at most $\varepsilon^{-O(d)}$ times heavier than L, which is $\varepsilon^{-O(d)}$ times heavier than the minimum spanning tree on X. ◀

3 Light Spanner with Worst-Case Recourse Bounds

We now describe how to maintain our light spanner L, satisfying Invariants 8 and 9. The current section focuses on describing a spanner with a small *recourse* bound, and proving that our updates maintain Invariants 8 and 9. In Section 4, we explain how to perform these updates quickly. We maintain a data structure *DS*. It stores:

- a set of points *DS*.X
- a net-tree *DS*.$\mathcal{N}$ on the points DS.X
- an ε-net-tree spanner *DS*.S of DS.X with respect to DS.$\mathcal{N}$
- a subgraph *DS*.$L \subseteq$ DS.S called the *light spanner*, such that Invariants 8 and 9 hold.

All these variables are initialized as $\varnothing$. The data structure supports two operations – insertion and deletion of a point x. We say that a procedure Insert(x) *correctly implements insertion* of point x if the procedure assigns DS.$X \leftarrow$ DS.$X \cup \{x\}$ and updates DS.$\mathcal{N}$, DS.S, and DS.L to satisfy the descriptions above. Similarly, a procedure Delete(x) *correctly implement deletion* of a point x if it assigns DS.$X \leftarrow$ DS.$X \setminus \{x\}$ and updates DS.$\mathcal{N}$, DS.S, and DS.L.

3.1 Insertion

To insert a point x, we first update the net-tree according to [35] (as summarized in our Lemma 5) and then recompute the spanner edges DS.L nearby x to satisfy the invariants. The pseudocode is given below. Our key insight is that when we recompute spanner edges at level i, we only need to recompute edges with endpoints in $B(x, O(2^i))$.

[6] by triangle inequality, it suffices to examine only the edges of L when building the greedy spanner, rather than all pairs of vertices in L

```
DS.INSERT(x):
  DS.X ← DS.X ∪ {x}
  update DS.𝒩 and DS.S according to Lemma 5
  DS.RECOMPUTE(x)

DS.RECOMPUTE(x):
  for every scale i ← 0, 1, ..., log Φ:
      for every scale-i edge (u, v) of DS.S with u, v ∈ B(x, 4 · 2^i):
          if δ*(u, v) > (1 + ε) · δ(u, v):
              DS.L ← DS.L ∪ {(u, v)}
          else:
              DS.L ← DS.L \ {(u, v)}
```

▶ **Lemma 12.** *The procedure DS.INSERT(x) correctly implements the insertion of a point x.*

Proof. Let $\mathcal{N}^{\text{old}}$, S^{old}, L^{old}, and X^{old} denote $\texttt{DS}.\mathcal{N}$, $\texttt{DS}.S$, $\texttt{DS}.L$, and $\texttt{DS}.X$ (respectively) before the insertion process. For brevity, we write $\mathcal{N}$, S, L, and X instead of $\texttt{DS}.\mathcal{N}$, $\texttt{DS}.S$, $\texttt{DS}.L$, and $\texttt{DS}.X$. By Lemma 5, the variables $\texttt{DS}.X$, $\texttt{DS}.\mathcal{N}$ and $\texttt{DS}.S$ are correctly maintained. Moreover, we have that $L \subseteq S$, because (by description of the algorithm) $S^{\text{old}} \subseteq S$ and (by assumption) $L^{\text{old}} \subseteq S^{\text{old}}$.

It remains to show that that every edge (u, v) in S satisfies Invariants 8 and 9. Suppose that edge (u, v) is at scale i (that is, $\delta(u, v) \in (2^{i-1}, 2^i]$). Note that the distance $\delta^*(u, v) = \delta_{L[i]}(u, v)$ depends only on the edges in L with scale strictly less than i; thus, it suffices to show that (u, v) satisfies the two invariants at the moment after the for-loop processes scale i. If $u, v \in B(x, 4 \cdot 2^i)$, then (u, v) satisfies the two invariants by description of the algorithm. Now suppose that some endpoint, without loss of generality u, is not in $B(x, 4 \cdot 2^i)$. In this case, (u, v) is in L if and only if (u, v) is in L^{old}. There are two cases:

- **Suppose that (u, v) is not in L.** Thus (u, v) is not in L^{old}. To satisfy Invariant 8, we must show $\delta_{L[i]}(u, v) \leq (1+\varepsilon)\cdot\delta(u, v)$. In fact, we show that either $\delta_{L[i]}(u, v) \leq \delta_{L^{\text{old}}[i]}(u, v)$ or $\delta_{L^{\text{old}}[i]}(u, v) > 2\delta(u, v)$; see Figure 4. This suffices, as L^{old} satisfies Invariant 8: we conclude that $\delta_{L[i]}(u, v) \leq \delta_{L^{\text{old}}[i]}(u, v) \leq (1 + \varepsilon)\delta(u, v)$ as desired. Consider a shortest path P in $L^{\text{old}}[i]$ between u and v. The description of the algorithm implies that the only edges that that change between $L[i]$ and $L^{\text{old}}[i]$ are in the ball $B(x, 4 \cdot 2^{i-1})$. Because we assumed $\delta(u, x) > 4 \cdot 2^i$, triangle inequality implies that endpoints of any edge (u', v') in $L^{\text{old}}[i] \setminus L[i]$ are far from u: specifically, $\delta(u, u') \geq 4 \cdot 2^i - 4 \cdot 2^{i-1} = 2 \cdot 2^i$, and so $\delta_{L^{\text{old}}}(u, u') \geq 2 \cdot 2^i$. If P has length $\geq 2 \cdot 2^i$ then we are done; otherwise, P does not include any edges in $L^{\text{old}}[i] \setminus L[i]$, and so P is also a path in $L[i]$ as desired.
- **Suppose (u, v) is in L.** Thus (u, v) is in L^{old}. To satisfy Invariant 9, we must show that $\delta_{L[i]}(u, v) > (1 + \frac{\varepsilon}{3}) \cdot \delta(u, v)$. We claim that either $\delta_{L[i]}(u, v) \geq \delta_{L^{\text{old}}[i]}(u, v)$, or $\delta_{L[i]}(u, v) \geq 2\delta(u, v)$. This suffices to prove the claim, because L^{old} satisfies Invariant 9 and so $\delta_{L^{\text{old}}[i]}(u, v) > (1 + \frac{\varepsilon}{3})\delta(u, v)$; thus, in either case, $\delta_{L[i]}(u, v) > (1 + \frac{\varepsilon}{3})\delta(u, v)$. Let P be a shortest path between u and v in $L[i]$. If $\delta_{L[i]}(u, v) \geq \delta_{L^{\text{old}}[i]}(u, v)$ then we are done. Otherwise, if $\delta_{L[i]}(u, v) < \delta_{L^{\text{old}}[i]}(u, v)$, then P must contain some edge of $L[i]$ that is not in $L^{\text{old}}[i]$. But the description of the algorithm implies that any such edge has endpoints in $B(x, 4 \cdot 2^{i-1})$. By triangle inequality and our assumption that $\delta(u, x) \geq 4 \cdot 2^i$, we have $\delta(u, u') \geq 2 \cdot 2^i$, and so P has length at least $2 \cdot 2^i$ as desired. ◀

We remark that the INSERT procedure has bounded recourse: at most $\varepsilon^{-O(d)} \log \Phi$ edges change in the spanner L. This is because, for every scale $i \in \lceil \log \Phi \rceil$, there are at most $\varepsilon^{-O(d)}$ scale-i edges in the ε-net-tree spanner in $B(x, 4 \cdot 2^i)$, by definition of net-tree spanner and packing bound (Observation 3).

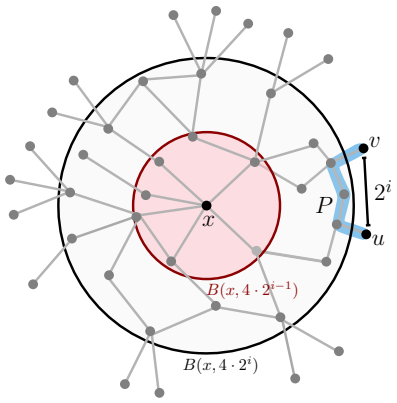

Figure 4 A light spanner L^{old}. For a given scale i, the spanners $L[i]$ and $L^{\text{old}}[i]$ differ only within the ball $B(x, 4 \cdot 2^{i-1})$. A scale-i pair (u, v) outside of $B(x, 4 \cdot 2^i)$. A short path P between u and v in L^{old} does not wander inside $B(x, 4 \cdot 2^{i-1})$, so P is also in L.

3.2 Deletion

The procedure for deleting a point x is similar to insertion. The procedure *DS*.DELETE(x) first updates the net tree according to [35], then deletes all edges in L that were incident to x, and finally recompute the spanner edges nearby x using the DS.RECOMPUTE procedure. The pseudocode and analysis are fairly similar to insertion procedure (albeit slightly more complicated). We defer all details to the full version of the paper.

▶ **Lemma 13.** *The procedure DS.DELETE(x) correctly implements the deletion of a point x.*

We pause to remark that in our proof of Lemma 12 (and also Lemma 13), we have actually proved the following claim, which will be helpful later.

▶ **Lemma 14.** *Consider the data structure DS before and after running DS.INSERT(x) or DS.DELETE(x). Let S^{old} (resp. L^{old}) denote DS.S (resp. DS.L) before the insertion/deletion is performed. Let (u, v) be a scale-i edge in DS.S, with some endpoint outside of $B(x, 4 \cdot 2^i)$. Then (u, v) is an edge in S^{old}, and either (1) $\delta_{DS.L[i]}(u, v) = \delta_{L^{\text{old}}[i]}(u, v)$, or (2) both $\delta_{DS.L[i]}(u, v)$ and $\delta_{L^{\text{old}}[i]}(u, v)$ are larger than $2\delta(u, v)$.*

4 Implementing Updates Quickly

In this section, we show how to modify the data structure so that the DS.INSERT and DS.DELETE procedures can be executed quickly. By prior work on the net-tree spanner (Lemma 5), the net-tree DS.$\mathcal{N}$ and the ε-net-tree spanner DS.S can be maintained in $O(\log \Phi)$ time. The DS.RECOMPUTE procedure iterates over each of the $\log \Phi$ scales. For each scale i, it examines the $\varepsilon^{-O(d)} \log \Phi$ many scale-i edges in $B(x, 4 \cdot 2^i)$; by Claim 7 these edges can be found in $\varepsilon^{-O(d)} = O(1)$ time. Each examined edge (u, v) is added or removed from DS.L depending on $\delta^*(u, v)$. This means that the bottleneck for a fast update time is the computation of $\delta^*(u, v)$:

▶ **Lemma 15.** *The procedure DS.INSERT and DS.DELETE run in $\varepsilon^{-O(d)} \cdot \tilde{O}(\log \Phi)$ time, plus the time needed for $\varepsilon^{-O(d)} \cdot \log \Phi$ many computations of $\delta^*(u, v)$.*

Unfortunately, we don't know how to design a data structure that maintains these distances. To get around this, we first observe that it suffices to maintain an *approximation* for $\delta^*(u,v)$.

▶ **Definition 16.** *We say a value $\tilde{d}$ is an α-approximation for a value d if $d \le \tilde{d} \le \alpha \cdot d$. For any function $d(u,v)$ on pairs of points (we will take $d(u,v) = \delta^*(u,v)$ and $d(u,v) = \delta_{\mathtt{DS}.L}(u,v)$), we say that $\tilde{d}(u,v)$ is a coarse α-approximation for $d(u,v)$ if:*

$$\tilde{d}(u,v) = \begin{cases} \text{if } d(u,v) \le 2\delta(u,v) \text{ then} & d(u,v) \le \tilde{d}(u,v) \le \alpha \cdot d(u,v) \\ \text{if } d(u,v) > 2\delta(u,v) \text{ then} & \tilde{d}(u,v) \ge 2 \cdot \delta(u,v) \end{cases}$$

In other words, a coarse α-approximation $\tilde{d}(u,v)$ for $\delta^*(u,v)$ lets us either detect when $\delta^*(u,v)$ is very large or provides an α-approximation for $\delta^*(u,v)$. Throughout this section, we set $\alpha := 1 + \frac{\varepsilon}{3}$. As we show in Lemma 19, even if we used coarse α-approximations $\tilde{\delta}^*(u,v)$ instead of the real distances $\delta^*(u,v)$ in the $\mathtt{DS}$.RECOMPUTE procedure, our spanner L still satisfies Invariants 8 and 9 after the $\mathtt{DS}$.INSERT and $\mathtt{DS}$.DELETE procedures.

Augmenting the data structure with distance estimates. We now show that we can modify our data structure to efficiently maintain coarse α-approximations of $\delta^*(u,v)$ for every edge (u,v) in the ε-net-tree $\mathtt{DS}.S$. In fact, we maintain something stronger: we need to store several auxiliary values in order to maintain the coarse approximations. Let $\kappa \ge \frac{1024}{3}$ be a sufficiently large constant, and let $\varepsilon_{\text{small}} \leftarrow \frac{\varepsilon}{3 \cdot \kappa \cdot \log \Phi}$. Our data structure $\mathtt{DS}$ maintains (in addition to the points $\mathtt{DS}.X$, the net-tree $\mathtt{DS}.\mathcal{N}$, the ε-net-tree spanner $\mathtt{DS}.S$, and the light spanner $\mathtt{DS}.L$) the following objects:

- An $\varepsilon_{\text{small}}$-net tree spanner $\mathtt{DS}.S_{\text{small}}$ for $\mathtt{DS}.\mathcal{N}$
- For every scale $i \in [\log \Phi]$ and every edge (u,v) in $\mathtt{DS}.S_{\text{small}}$ at scale i, a value $\mathtt{DS}.\tilde{\delta}^*(u,v)$ which is a *coarse* $(1 + \kappa \cdot i \cdot \varepsilon_{\text{small}})$-approximation for $\delta^*(u,v)$.
- For every scale $i \in [(\log \Phi) - 2]$ and every edge (u,v) in $\mathtt{DS}.S_{\text{small}}$ at scale i, a value $\mathtt{DS}.\tilde{\delta}_L(u,v)$ which is a $(1 + \kappa \cdot i \cdot \varepsilon_{\text{small}})$-approximation for $\delta_{\mathtt{DS}.L}(u,v)$.

Observe that this data structure does indeed maintain a coarse $\frac{\varepsilon}{3}$-approximation for every edge in $\mathtt{DS}.S$: this is because $\mathtt{DS}.S \subset \mathtt{DS}.S_{\text{small}}$, and $\kappa \cdot i \cdot \varepsilon_{\text{small}} < \frac{\varepsilon}{3}$ so the estimates $\mathtt{DS}.\tilde{\delta}^*(u,v)$ are coarse $\frac{\varepsilon}{3}$-approximations for $\delta^*(u,v)$. The reason we maintain estimates for every edge in $\mathtt{DS}.S_{\text{small}}$ and not just every edge in $\mathtt{DS}.S$ is to control the distortion, which will accumulate by a $(1 + O(\varepsilon_{\text{small}}))$ factor at each scale.

We highlight two differences between the estimates $\mathtt{DS}.\tilde{\delta}^*(u,v)$ and $\mathtt{DS}.\tilde{\delta}_L(u,v)$, for a scale-$i$ edge (u,v). First, the value $\mathtt{DS}.\tilde{\delta}^*(u,v)$ seeks to estimate $\delta^*(u,v)$, which is the distance between u and v in the subgraph $\mathtt{DS}.L[i]$ which consists of all edges in $\mathtt{DS}.L$ with scale strictly smaller than i. On the other hand, $\mathtt{DS}.\tilde{\delta}_L(u,v)$ estimates distances in the graph $\mathtt{DS}.L$; note that the shortest path between u and v in $\mathtt{DS}.L$ may include edges in $\mathtt{DS}.L$ at scale i and $i+1$, in addition to edges in $\mathtt{DS}.L[i]$. The second key difference is that $\mathtt{DS}.\tilde{\delta}^*(u,v)$ is only required to be a $(1 + \kappa \cdot i \cdot \varepsilon_{\text{small}})$-approximation of $\delta^*(u,v)$ when $\delta^*(u,v) \le 2\delta(u,v)$, whereas $\mathtt{DS}.\tilde{\delta}_L(u,v)$ is always a $(1 + \kappa \cdot i \cdot \varepsilon_{\text{small}})$-approximation of $\delta_{\mathtt{DS}.L}(u,v)$. Why do we need these two types of estimates? Ultimately, our algorithm for INSERT and DELETE will only use the estimates $\mathtt{DS}.\tilde{\delta}^*(u,v)$, to determine whether or not the edge (u,v) should be added. But in order to compute $\mathtt{DS}.\tilde{\delta}^*(u,v)$ for some pair (u,v) at scale i, we will need to estimate $\delta_{\mathtt{DS}.L}(u',v')$ for pairs (u',v') at scale $\le i - 3$.

The fast insert/delete procedures. Below, we give pseudocode for a modified DS.RECOMPUTE procedure called *DS.RECOMPUTEFAST*, which uses the estimates $\mathtt{DS}.\tilde{\delta}^*(u,v)$ instead of the true distances $\delta^*(u,v)$. We define the procedures *DS.INSERTFAST* and *DS.DELETEFAST* to be identical to DS.INSERT and DS.DELETE, except that they use DS.RECOMPUTEFAST instead of DS.RECOMPUTE, and they also maintain a $\varepsilon_{\text{small}}$-net-tree spanner $\mathtt{DS}.S_{\text{small}}$ in addition to the ε-net-tree spanner $\mathtt{DS}.S$.

```
DS.RecomputeFast(x):
  for every scale i ← 0, 1, ..., log φ:
      DS.UpdateDistEstimates(x, i) ⟨⟨recomputes estimates DS.δ̃*(·,·) and DS.δ̃_L(·,·).⟩⟩
      for every scale-i edge (u, v) of DS.S with u, v ∈ B(x, 8 · 2^i):
          d̃ ← DS.δ̃*(u, v) ⟨⟨a ε/3-good estimate for δ*(u, v)⟩⟩
          if d̃ > (1 + ε) · δ(u, v):
              DS.L ← DS.L ∪ {(u, v)}
          else:
              DS.L ← DS.L \ {(u, v)}
```

In Section 4.1, we describe the procedure DS.UPDATEDISTESTIMATES and prove that it correctly maintains estimates for $\delta^*(u,v)$ and $\delta_L(u,v)$. For now, we just state lemmas which summarize the guarantees of DS.UPDATEDISTESTIMATES (Lemmas 17 and 18). Assuming the lemmas hold, we prove the correctness of the fast insert/delete procedures (Lemma 19).

▶ **Lemma 17.** *DS.UPDATEDISTESTIMATES runs in time* $(\varepsilon^{-1} \cdot \log \Phi)^{O(d)}$.

▶ **Lemma 18.** *Consider the execution of DS.INSERTFAST*(x) *or DS.DELETEFAST*(x). *Let* $i \in [\log \Phi]$ *be a scale, and consider the data structure DS at the instant after the execution of the call DS.UPDATEDISTESTIMATES*(x,i) *during the insertion/deletion process. Assume that every edge* (u,v) *of DS.S with scale strictly smaller than* i *satisfies Invariants 8 and 9. Then:*

- *for every scale-*i *edge* (u,v) *in the* $\varepsilon_{\text{small}}$*-net-tree spanner* $\mathtt{DS}.S_{\text{small}}$, *the value* $\mathtt{DS}.\tilde{\delta}^*(u,v)$ *is a coarse* $(1+\kappa \cdot i \cdot \varepsilon_{\text{small}})$*-approximation for* $\delta^*(u,v)$.
- *for every scale-*$(i-2)$ *edge* (u,v) *in the* $\varepsilon_{\text{small}}$*-net-tree spanner* $\mathtt{DS}.S_{\text{small}}$, *the value* $\mathtt{DS}.\tilde{\delta}_L(u,v)$ *is a* $(1+\kappa \cdot i \cdot \varepsilon_{\text{small}})$*-approximation* $\delta_{\mathtt{DS}.L}(u,v)$.

▶ **Lemma 19.** *The procedure DS.INSERTFAST*(x) *(resp. DS.DELETEFAST*(x)*) correctly implements insertion (resp. deletion) of* x. *It runs in time* $(\varepsilon^{-1} \cdot \log \Phi)^{O(d)}$.

Proof. The runtime bound follows from Lemmas 15 and 17. The proof of correctness is almost identical to that of Lemmas 12 and 13 except in one place: we need to argue that every scale-i edge (u,v) in $\mathtt{DS}.S$ with both endpoints in $B(x, 4 \cdot 2^i)$ satisfies Invariants 8 and 9.

For every such edge (u,v), the algorithm checks if $\mathtt{DS}.\tilde{\delta}^*(u,v) > (1+\varepsilon)\delta(u,v)$ and includes (u,v) in L iff the inequality holds. At the instant the algorithm makes the check, we may assume (by induction) that every edge (u',v') in $\mathtt{DS}.S$ with scale strictly smaller than i satisfies Invariants 8 and 9. Thus, by Lemma 18, the value of $\mathtt{DS}.\tilde{\delta}(u,v)$ is a coarse $(1+\kappa \cdot i \cdot \varepsilon_{\text{small}})$-approximation for $\delta^*(u,v)$. As $i \in [\log \Phi]$, in particular we conclude that $\mathtt{DS}.\tilde{\delta}(u,v)$ is a coarse $(1+\frac{\varepsilon}{3})$-approximation for $\delta^*(u,v)$. There are two cases.

Case 1: $\mathtt{DS}.\tilde{\delta}(u,v) \le (1+\varepsilon)\delta(u,v)$. In this case, (u,v) is not in $\mathtt{DS}.L$. We claim that $\delta^*(u,v) \le (1+\varepsilon)\delta(u,v)$, so that (u,v) satisfies Invariant 8. Indeed, we have $\delta^*(u,v) < 2\delta(u,v)$; otherwise, the definition of coarse α-approximation means that $\mathtt{DS}.\tilde{\delta}(u,v) > 2\delta(u,v)$, which contradicts our assumption that $\mathtt{DS}.\tilde{\delta}(u,v) \le (1+\varepsilon)\delta(u,v)$. Thus, the definition of coarse α-approximation implies $\delta^*(u,v) \le \mathtt{DS}.\tilde{\delta}(u,v)$ and so $\delta^*(u,v) \le (1+\varepsilon)\delta(u,v)$ as desired.

Case 2: $\texttt{DS}.\tilde{\delta}(u,v) > (1+\varepsilon)\delta(u,v)$. In this case, (u,v) is added to $\texttt{DS}.L$. We claim that $\delta^*(u,v) > (1+\frac{\varepsilon}{3})\delta(u,v)$, so that (u,v) satisfies Invariant 9. For contradiction, suppose that $\delta^*(u,v) \leq (1+\frac{\varepsilon}{3})\delta(u,v)$. The definition of coarse $(1+\frac{\varepsilon}{3})$-approximation implies $\texttt{DS}.\tilde{\delta}(u,v) \leq (1+\frac{\varepsilon}{3})\cdot\delta^*(u,v)$. Combining these two inequalities, we conclude that $\texttt{DS}.\tilde{\delta}(u,v) \leq \left(1+\frac{\varepsilon}{3}\right)\left(1+\frac{\varepsilon}{3}\right)\delta(u,v) \leq (1+\varepsilon)\delta(u,v)$, contradicting the Case 2 assumption. ◀

Theorem 2 follows from Lemmas 19, 10, and 11 (after rescaling $\varepsilon \leftarrow \varepsilon/3$).

4.1 The procedure UpdateDistEstimates

We defer the details of UpdateDistEstimates to the full version of our paper.

5 Conclusion and Open Questions

We have designed the first dynamic light spanner for point sets in Euclidean and doubling metrics, with update time $(\log \Phi)^{O(d)}$. Our work leaves open two interesting open questions. First, is it possible to maintain a dynamic light spanner with recourse or time bounds *independent* of the aspect ratio Φ and instead depends only on the number of points $n = |X|$? Second, can we obtain a runtime bound where the exponent of $\log \Phi$ (or $\log n$) is independent of d? Ideally, we would like to handle updates in time $\varepsilon^{-O(d)} \cdot \log n$, which would match the best runtime for dynamic sparse spanners.

Abstract

In the online hitting set problem, sets arrive over time, and the algorithm has to maintain a subset of elements that hit all the sets seen so far. Alon, Awerbuch, Azar, Buchbinder, and Naor (SICOMP 2009) gave an algorithm with competitive ratio $O(\log n \log m)$ for the (general) online hitting set and set cover problems for m sets and n elements; this is known to be tight for efficient online algorithms. Given this barrier for general set systems, we ask: *can we break this double-logarithmic phenomenon for online hitting set/set cover on structured and geometric set systems?*

We provide an $O(\log n \log\log n)$-competitive algorithm for the weighted online hitting set problem on set systems with linear *shallow-cell complexity*, replacing the double-logarithmic factor in the general result by effectively a single logarithmic term. As a consequence of our results we obtain the first bounds for weighted online hitting set for natural geometric set families, thereby answering open questions regarding the gap between general and geometric weighted online hitting set problems.

1 Introduction

In the *hitting set problem*, we are given a set system $\mathcal{I} = (U, \mathcal{F})$, with ground set U and a collection of subsets $\mathcal{F}$ of U; every element e has a cost c_e. The goal is to select a minimum-cost subset $S \subseteq U$ that hits every set in $\mathcal{F}$. This problem has been a central one in algorithm design because of its many applications, and also because it serves as a test-bed for new techniques. The hitting set problem is equivalent to the *set cover* problem on a "dual" set system $\mathcal{I}^*$, which contains an element e_S for each original set $S \in \mathcal{F}$, and a set S_e for each element $e \in U$, such that $e \in S \iff e_S \in S_e$; i.e., we flip the roles of U and $\mathcal{F}$. Henceforth, we focus on hitting set.

In the offline setting, the hitting set (or the set cover) problem has been widely studied, with $(1 \pm o(1))\ln|U|$-approximation algorithms in the worst-case, which are best-possible if $P \neq NP$ [20]. In addition, hitting set has also been extensively studied for special set systems – most notably, those with low *VC-dimension* or bounded *shallow cell complexity (SCC)* [12, 7, 18, 11, 10, 26, 8], which result in constant-factor approximations for set systems like pseudo-disks and half-spaces in $\mathbb{R}^2$. These measures of set complexity arise not only in geometric and combinatorial settings, but in non-geometric problems like job scheduling [4].

The progress for structured set systems in the *online* setting – where sets arrive over time, and must be hit as they arrive – has been more limited. While results are known for online hitting set (and set cover) for specific problems like intervals in $\mathbb{R}$ or 2-dimensional squares (see [18, 21]), general techniques are not known. The *offline* algorithms use quasi-uniform sampling procedures [26, 8] or black-box algorithms to find ε-nets [18], which have seemed difficult to extend to the online setting. As far as we know, the results for geometric instances have been restricted to the *unweighted* versions of the problems, and the $O(\log n \log m)$-competitiveness of [2] (where $n = |U|$ and $m = |\mathcal{F}|$) remains the only general result for weighted online hitting set, even for set systems with bounded VC dimension/SCC. We ask:

Can we achieve better competitive ratios for broad classes of set systems? Specifically, can we match the performance gains seen in structured offline settings?

1.1 Our Results

Our main results answer this question positively. Recall that the VC dimension of a set system is the largest set of elements that can be shattered. The *shallow cell complexity* $\varphi_{\mathcal{F}}(\cdot,\cdot)$ is a finer-grained notion, bounding the number of sets of size k in any restriction of the set system to ℓ elements.

The Unweighted Case. For unit-cost instances, we adapt the offline Net-Finder algorithm [22] to the online setting to give improved algorithm for set systems with small shallow cell complexity (SCC) and VC dimension:

▶ **Theorem 1** (Unweighted Hitting Set). *There is a randomized online algorithm for (unweighted) hitting set that has competitive ratio* $O(\log n \cdot (d + \log(d \cdot \varphi(d\,\mathsf{OPT}\,\log n, d))))$*, where* $\varphi(\cdot,\cdot)$ *is the shallow cell complexity (SCC) and* d *the VC dimension of the set system.*

We mention two corollaries of this work:

(i) For set systems with **"linear" SCC** (i.e., where $\varphi(\ell, k) = \text{poly}(k)$) and constant VC-dimension, the competitive ratio becomes $O(\log n)$. This gives hitting set and set cover algorithms for intervals in $\mathbb{R}$, lines and pseudo-disks – which includes disks and axis-aligned squares – in $\mathbb{R}^2$, and half-spaces in $\mathbb{R}^3$. (Table 1 gives the relevant bounds.) This result unifies and extends prior results for intervals, unit disks, and half-spaces [19], as well as for axis-aligned squares in $\mathbb{Z}^2$ [21]. This resolves the open problem [19, §8, Prob. #1] regarding hitting sets for arbitrary (not necessarily unit) disks in $\mathbb{R}^2$ (see also [21, §6, Prob. #1]), and another open problem in [21, §6, Prob. #5] which asks for results for hitting squares using non-integral point sets.

(ii) For set systems with **VC-dimension d**, we have $\varphi(\ell, k) \leq \ell^d$, and hence the competitive ratio becomes $O(d \log n \cdot \log(d\mathsf{OPT} \log n))$. Comparing this to the offline bound of $O(d \log(d \cdot \mathsf{OPT}))$, our online algorithm incurs only a near-logarithmic overhead.

The Weighted Case. If elements have arbitrary non-negative costs, we do not know of any prior online algorithms, so our result extending [8] to the online setting gives the first algorithm for structured set systems in this weighted case. Here, we state a special case of our result – for the "linear" case where $\varphi(\ell, k) = \text{poly}(k)$ – and defer the more detailed result to Theorem 16.

▶ **Theorem 2** (Weighted Hitting Set). *There is a randomized online algorithm for weighted hitting set that has competitive ratio* $O(\log n \log\log n)$ *for any set system with linear SCC.*

Table 1 Bounds on the SCC and VC dimensions of some primal/dual set systems from [23, 24]. Primal bounds give results for corresponding the hitting set problem, and dual bounds give results for the corresponding set cover problem. A triangle is α-fat if the ratio of the radius of the smallest enclosing ball to that of the largest inscribed ball is at most α.

Objects	Primal		Dual	
	$\varphi(\ell, k)$	VC-dim	$\varphi(\ell, k)$	VC-dim
Intervals in $\mathbb{R}$	$O(k)$	2	$O(1)$	2
Lines in $\mathbb{R}^2$	$O(k)$	2	$O(k)$	2
Pseudo-disks in $\mathbb{R}^2$	$O(k)$	3	$O(k)$	$O(1)$
α-Fat triangles in $\mathbb{R}^2$			$O(k \log^* {}^m/_k + {}^k/_\alpha \log^2 {}^1/_\alpha)$	7
Half-spaces in $\mathbb{R}^3$	$O(k^2)$	4	$O(k^2)$	4

This immediately extends the geometric results listed above in i to the weighted setting; to the best of our knowledge, these are the first results for weighted hitting set for these geometric instances. Our results for axis-aligned squares answers an open problem about weighted hitting sets from [21, §6, Prob. #4].

In both the unweighted and weighted cases, we lose nearly-logarithmic factors over the offline results: such a "price of uncertainty" is in line with typical losses for online vs. offline set cover. Moreover, such a logarithmic loss is unavoidable for the online setting, even for very structured set systems: [19] show a lower bound of $\Omega(\log n)$ for online hitting intervals on a line; observe that we can get exact offline algorithms for this problem.

1.2 Our Techniques

We demonstrate that online relax-and-round approaches can be successfully combined with net-finding and quasi-uniform sampling offline algorithms to resolve open problems in the area. The first step in both the unweighted and weighted cases is to use an online algorithm for fractional hitting set, losing an $O(\log n)$-factor in the competitive ratio. Starting from [18], we know that rounding a fractional solution reduces to finding an ε-net in a set-system, where each element e with fractional value x_e is replaced by $\lceil nx_e \rceil$ *clones*. Since the fractional solution is feasible, each set in the original instance now contains at least n clones, so finding a hitting set in the original instance reduces to finding an ε-net (for $\varepsilon = 1/n$) that hits all sets of size at least n in this new set system $\mathcal{J}$. We start with the elegant algorithm of [22], which first samples each element with a certain base probability; now, for any large set T not hit by this sample, it selects elements of T independently with probability proportional to $1/|T|$ into the sample.

Carrying out this procedure in the online setting has two main issues: firstly, the fractional solution evolves over time, and the x_e values may increase as sets arrive. As a result, if an element e is contained in sets S_1 and S_2, the number of clones of e in the corresponding sets in the new set system $\mathcal{J}$ may be different, which affects the VC dimension and the SCC of $\mathcal{J}$. Secondly, the initial sampling step in [22] requires knowledge of all the elements in the set system; but in the online setting, new clones of an element appear when its fractional value increases. We handle the first issue by showing that the VC dimension and the SCC of the new set system $\mathcal{J}$ can be related to those of the original instance, and for the second issue, we replace the sampling step by a *deferred* sampling step.

The online algorithm for weighted hitting set adapts the quasi-uniform sampling algorithm of [8] to the online setting. This algorithm builds a chain of nested sets of clones, starting with the entire set V_0 of clones, with each subsequent set V_ℓ having size $({}^1/_2 + \delta_\ell)$ times the

size of $V_{\ell-1}$. Here δ_ℓ is a small bias term, which ensures that most sets S of the hitting set instance have at least half their elements survive to the next level. Sets whose size falls below $n/2^\ell$ are said to be "dangerous" and must select a "backup" element to hit them. The choice of this backup element is done to ensure that no element is picked too often. Apart from the challenge of the new clones arriving online, finding the backups seems like an inherently offline problem, since it seems to require knowing the entire set system. However, we view the problem of finding backup elements as a load-balancing problem, and show how to choose backups that increases the probability by a logarithmic factor. Existing presentations of the algorithm also build the layers iteratively, discarding sets that are covered by each layer to get the set system for the next layer – we observe that these optimizations are inessential, and removing them allows a clean online implementation. (See Algorithm 4 in Section 5.)

1.3 Related Work

Offline. Hitting set for geometric instances has been widely studied, see, e.g., [12, 7, 18, 11, 10, 26, 8]. The work of [7] gave an $O(d \log(d\,\mathsf{OPT}))$-approximation for the NP-hard hitting set problem in the offline case for set systems of VC dimension d. [18] reinterpreted their algorithm as first solving an LP relaxation for hitting set using multiplicative weights, and then rounding it using an ε-net algorithm. The use of shallow cell complexity in covering/hitting problems first appears in [11, 26], and was formally defined in [8]. These elegant papers gave the first results for *weighted* hitting set, where elements have costs, and the goal is to minimize the total cost of picked elements (as opposed to their cardinality); their approach is called *quasi-uniform* sampling. [1] extend the ε-net algorithm from [22] to the setting where the ε-net is in terms of element "sizes" and not their cardinality.

Online. [19] studied (unweighted) online hitting set in geometric settings, and gave optimal $\Theta(\log n)$-competitive ratio for hitting intervals on a line, and half-planes and unit disks in the plane $\mathbb{R}^2$. Their techniques did not extend to arbitrary disks; [15] gave an $O(\log n \log M)$-competitive algorithm for the setting where the disks have radii in $[1, M]$. Theorem 1 settles the question by giving an $O(\log n)$-competitive algorithm for arbitrary disks.

[21] give an $O(\log n)$-competitive algorithm for hitting set where the points are on the $n \times n$-grid, and the arriving sets are axis-aligned squares $S \subseteq [0, n)^2$. A partial answer to avoiding integrality of the points was given in [14] who give an $O(k^2 \log n \log M)$-competitive algorithm for homothetic copies of a regular k-gon for $k \geq 4$, with scaling factors in $[1, M]$. The above result of [15] extends this to positive homothets of any convex body in $\mathbb{R}^2$ with scaling factors in $[1, M]$. Theorem 1 settles the question for squares without any reliance on M; it remains unclear if our results can extend to positive homothets of convex bodies.

Our techniques do not seem to directly extend to the continuous setting (the "piercing set" problem), on which there is substantial work – see [9, 16, 17, 13]. Our techniques do not seem to give improved results for higher-dimensional covering/hitting problems (with the exception of hitting sets for half-spaces in $\mathbb{R}^3$), since the shallow-cell complexity $\varphi(\ell, k)$ of the associated set systems now depends polynomially on ℓ as well.

[5] give an $O(\log 1/\varepsilon)$-competitive algorithm to maintain *online ε-nets* for intervals and axis-aligned rectangles in the unweighted setting; since $\varepsilon = 1/\mathsf{OPT}$, and we lose an $O(\log n)$ factor in solving the fractional relaxation, their work can be combined with our framework to infer an $O(\log n (\log \mathsf{OPT})^2)$-competitive algorithm for hitting axis-aligned rectangles. In contrast, our general result for bounded VC dimension set systems gives an $O(\log n \log(\log n \cdot \mathsf{OPT}))$-competitive algorithm.

2 Notation and Definitions

Hitting Set: Offline and Online. $e \in U$ has a cost $c_e \geq 0$; the unweighted case is when $c_e = 1$ for all e. Let $n = |U|$ and $m = |\mathcal{F}|$. The LP relaxation for the *hitting set problem* is

$$\min_{x \in [0,1]^n} \Big\{ \sum_e c_e x_e \mid \sum_{e \in S} x_e \geq 1 \; \forall S \in \mathcal{F} \Big\}; \tag{1}$$

let $\mathsf{LP}(\mathcal{I})$ denote the optimal value of this LP on instance $\mathcal{I}$. Restricting the variables to be Boolean gives us the optimal set cover value, denoted $\mathsf{OPT}(\mathcal{I})$. Observe that $\mathsf{LP}(\mathcal{I}) \leq \mathsf{OPT}(\mathcal{I})$.

In an online fractional hitting set instance, an adversary fixes the instance $\mathcal{I}$, as well as an ordering $S_1, S_2, \ldots, S_m$ on the sets in $\mathcal{F}$; let $\mathcal{F}^t := \{S_1, \ldots, S_t\}$. The algorithm knows the element set U in advance. At each time $t \in [m]$, a set $S_t \in \mathcal{F}$ arrives and reveals identities of the elements in it. The algorithm must now produce a solution $\{x_e^t\}_{e \in U}$, such that x^t is a solution to the LP relaxation with instance $\mathcal{F}_t = (U, \mathcal{F}^t)$. The solution must be *monotone* – $x^t \leq x^{t+1}$ – in other words, elements cannot be dropped once they are picked. A (randomized) algorithm for this problem is α-*competitive* if $\mathbb{E}[\sum_{e \in U} c_e x_e^m] \leq \alpha \cdot \mathsf{OPT}(\mathcal{I})$, for every instance $\mathcal{I}$. If the solutions $x^t \in \{0,1\}^n$, then we have an algorithm for the online (integral) hitting set problem; we will denote the set of elements corresponding to x^t by C^t.

Dual Set Systems. The *dual set system* of the set system $\mathcal{I} = (U, \mathcal{F})$ is the set system $\mathcal{I}^* = (F, \mathcal{E})$, where we have a set E for every element e in U, an element s for every set $S \in \mathcal{F}$, and $s \in E \iff e \in S$. The *hitting set* problem for the system $\mathcal{I}$ is equivalent to the set cover problem on the dual system $\mathcal{I}^*$.

2.1 Shallow Cell Complexity

For a set system $(U, \mathcal{F})$ and a subset $U' \subset U$, denote the induced collection of sets as $\mathcal{F}_{U'} := \{S \cap U' \mid S \in \mathcal{F}\}$.

▶ **Definition 3** (Shallow Cell Complexity). *A set system $\mathcal{I} = (U, \mathcal{F})$ is said to have* shallow cell complexity *(SCC) $\varphi : \mathbb{Z}_+ \times \mathbb{Z}_+ \to \mathbb{Z}_+$ if for any $\ell, k \in \mathbb{Z}_+$, and for any subset $U' \subset U$ with $|U'| = \ell$, the number of distinct subsets of size at most k in $\mathcal{F}_{U'}$ is at most $\ell \cdot \varphi(\ell, k)$.*

Crucially, the number of distinct sets in $\mathcal{F}_{U'}$ is bounded by $\ell \cdot \varphi(\ell, k)$ rather than the worst-case $\binom{\ell}{k}$. If the VC dimension of the set system $\mathcal{I}$ is d, the shattering lemma [25, Ch. 15] implies that $\ell \cdot \varphi(\ell, k) \leq \binom{\ell}{d} \approx (\mathrm{e}\ell/d)^d$.

We focus on functions φ which are well-behaved, in the sense of [23].

▶ **Definition 4** (Well-Behaved SCC). *A function $\varphi(\cdot, \cdot)$ is (a, b)-*well-behaved *for constants $a \in (1, 2)$ and $b \geq 2$ if it is non-decreasing in both arguments, and for all positive integers $\ell \geq k \geq b$, we have $\varphi(\ell, k) \leq (\varphi(\ell/2, k/2))^a$.*

Well-behavedness is easy to verify for the common case of $\varphi(\ell, k) = k^c$ for some constant $c \geq 0$. Henceforth, our focus will be on such functions.

3 Uniform Set Systems

The first step of our approach is the following "uniformization" procedure, that takes any online algorithm $\mathcal{A}$ for (fractional) hitting set, and some instance $\mathcal{I} = (U, \mathcal{F})$ with n elements and m sets, and produces a new instance $\mathcal{J} = (V, \mathcal{G})$ with $N := n(n+1)$ elements and

$M := m$ sets in an online manner. For each set $S_j \in \mathcal{F}$, we have a corresponding set $T_j \in \mathcal{G}$. For each element $e \in U$, there are at most $n+1$ "clone" elements $\{(e,i) \mid i \in \{0,\dots,n\}\}$ in V, each of the same cost as that of e.

Recall that the sets in $\mathcal{F}$ appear in the order $S_1,\dots,S_m$. The algorithm $\mathcal{A}$ maintains a fractional solution x^t at time t (i.e., after the arrival of the set S_t). Without loss of generality, we assume that the fractional values x^t_e never exceed 1 – indeed, if these values ever exceed 1, we can reduce them to 1 without violating feasibility. The element-set containment is defined in Algorithm 1. When the set S_t arrives, the algorithm $\mathcal{A}$ updates the fractional solution to x^t. The solution x^t is now used to define the elements in the corresponding set T_t in the instance $\mathcal{J}$: $T_t := \{(e,i) : e \in S_t, i \le \lceil n \cdot x^t_e \rceil\}$.

Before analyzing this algorithm, we give a useful definition:

▶ **Definition 5** (Projection). *For a subset $T \subseteq V$, define its projection, $\mathsf{proj}(T) := \{e : (e,i) \in T \text{ for some } i\}$, as the set of elements in U whose clones are present in T.*

Algorithm 1 Uniformize($\mathcal{I}, \mathcal{A}$).

```
for sets S_1 to S_m do
    pass set S_t to algorithm A, and let x^t be the resulting solution
    define a new set T_t ∈ G as {(e,i) | e ∈ S_t, i ≤ ⌈n · x^t_e⌉}.
```

▶ **Theorem 6.** *Suppose $\mathcal{A}$ is a (deterministic) ρ-competitive online algorithm for fractional set cover. Given an instance $\mathcal{I} = (U,\mathcal{F})$, let Uniformize($\mathcal{I},\mathcal{A}$) generate the instance $\mathcal{J} = (V,\mathcal{G})$. Then the instance $\mathcal{J}$ satisfies the following properties:*

- **(i)** *Any solution for $\mathcal{I}$ can be converted into a solution for $\mathcal{J}$ of the same cost, and vice versa.*
- **(ii)** *Each set $T_t \in \mathcal{G}$ contains at least $B := n$ elements in $\mathcal{G}$.*
- **(iii)** *$N' \le B(1 + \sum_e x_e)$, where N' denotes the number of elements in V contained in at least one set in $\mathcal{G}$. Hence, in the unweighted setting, $N' \le B(1 + \rho\,\mathsf{OPT}(\mathcal{I}))$.*
- **(iv)** *We have $\mathsf{VCdim}(\mathcal{G}) \le \mathsf{VCdim}(\mathcal{F})$, also $\varphi_{\mathcal{G}}(\ell,k) \le k \cdot \varphi_{\mathcal{F}}(\ell,k)$.*

Proof. For the first claim, let $U' \subseteq U$ be a solution to $\mathcal{I}$. Then, $V' := \{(e,0) : e \in U'\}$ is a solution to $\mathcal{J}$. Conversely, if V' is a solution to $\mathcal{J}$, then $\mathsf{proj}(V')$ is a solution to $\mathcal{I}$. The second claim follows from the feasibility of x^t. Indeed, for each set S_t, $\sum_{e \in S_t} \min(x^t_e, 1) \ge 1$. Therefore, $\sum_{e \in S_t} \lceil n \min(x^t_e, 1) \rceil \ge n$. But the left-hand side above is exactly equal to $|T_t|$.

To prove property iii, observe that the number of clones of an element e is at most $nx^m_e + 1$. Summing over all elements, we see that $N' \le n(\sum_e x_e + 1)$. In the unweighted setting, $\sum_e x_e \le \rho \cdot \mathsf{OPT}(\mathcal{I})$.

For property iv, we first consider the VC dimension of $\mathcal{G}$. Let $V' \subseteq V$ be shattered by the sets in $\mathcal{G}$. We first observe that V' contains at most one clone corresponding to an element $e \in U$. Indeed, suppose V' contains (e,i) and (e,i') for two distinct indices $i < i'$. Now every set $T \in \mathcal{G}$ containing (e,i') also contains (e,i). Thus, there is no set in $\mathcal{G}$ that contains (e,i'), but does not contain (e,i), a contradiction. This implies that the corresponding set $U' = \{e : (e,i) \in V' \text{ for some } i\}$ is also shattered by $\mathcal{F}$. Thus, $\mathsf{VCdim}(\mathcal{G}) \le \mathsf{VCdim}(\mathcal{F})$.

Finally, we bound the SCC of the set system $\mathcal{J}$. Fix two positive integers ℓ and k. Let V' be a subset of V with $|V'| \le \ell$. Let $\mathcal{G}'$ be the distinct sets in $\mathcal{G}_{V'}$ of size at most k. Let U' denote $\mathsf{proj}(V')$ and $\mathcal{F}'$ denote $\{\mathsf{proj}(T) : T \in \mathcal{G}'\}$. Since $|U'| \le \ell$ and each set in $\mathcal{F}'$ has size at most k, $|\mathcal{F}'| \le \ell \cdot \varphi_{\mathcal{F}}(\ell,k)$.

Consider a set $S \in \mathcal{F}'$ and let $\mathcal{G}'(S)$ be the collection of sets $T \in \mathcal{G}'$ for which $\mathsf{proj}(T) = S$. We claim that if $T, T' \in \mathcal{G}'(S)$ then either $T \subseteq T'$ or $T' \subseteq T$. Indeed, suppose $T = T_t \cap V'$ and $T' = T_{t'} \cap V'$ for some times t and t' respectively. Assume w.l.o.g. that $t < t'$. Then $x_e^t \leq x_e^{t'}$ for each element e. Therefore, if $(e, i) \in T$, then $e \in S$. Therefore $(e, i) \in T'$ as well. This shows that $T \subseteq T'$. Since each of the sets in $\mathcal{G}'(S)$ has at most k elements, we see that $|\mathcal{G}'(S)| \leq k$. Summing over all the sets $S \in \mathcal{F}'$, we see that $|\mathcal{G}'| \leq \ell \cdot \varphi_{\mathcal{F}}(\ell, k) \cdot k$. This shows that $\varphi_{\mathcal{G}}(\ell, k) \leq k \cdot \varphi_{\mathcal{F}}(\ell, k)$. ◀

Since we can perform this "uniformization" process to go from $\mathcal{I}$ to $\mathcal{J}$ in an online fashion – and we can also convert solutions to $\mathcal{J}$ back to solutions to $\mathcal{I}$ online – we henceforth imagine working with the instance $\mathcal{J}$, and want to hit every set of $\mathcal{J}$ by picking one of the B elements in it.

4 Unweighted Online Hitting Set

In this section, we study the unweighted version of the online hitting set problem. Consider the instance $\mathcal{J} = (V, \mathcal{G})$ generated by the Uniformize routine in Algorithm 1. We rely on the structural properties established in Theorem 6: there exists a subset $V' \subseteq V$ of size $|V'| = N'$ with the guarantee that each element in V' is contained in at least one set in $\mathcal{G}$. Moreover, each set in $\mathcal{G}$ contains at least B elements, and our solution must hit this set. We first describe the offline algorithm of [23], and then extend it to an online algorithm.

4.1 The NetFinder Algorithm

We consider the following offline algorithm for finding ε-nets (see Algorithm 2) [23]. The algorithm maintains a subset H of V', which is initialized to the empty set. In the base sampling step (line 2), each element in V' is added to H with probability α/B. In the alteration step (line 5), we consider each set T_t. While a set T_t is not yet hit by some element in H, we add each element in T_t to the set H independently with probability $\beta/|T_t|$.

Algorithm 2 Net-Finder-V1.

```
1 for each element e ∈ V' do
2 |  select e into H independently w.p. α/B ;          // Base Sampling
3 for sets T_1 to T_m do
4 |  while T_t is not hit by H do
5 |  |  add each element in T_t into H independently w.p. β/|T_t| ;   // Alteration
```

Let ε denote B/N'. Since each set in $\mathcal{G}$ has size at least B, any ε-net in the set system $(V', \mathcal{G})$ must hit all the sets in $\mathcal{G}$. The following guarantee now follows from [23, Theorem 7.6]:

▶ **Theorem 7.** *Assume that the set system $\mathcal{G}$ has SCC $\varphi_{\mathcal{G}}$ and VC dimension d. Define $\varepsilon = B/N'$. For $\alpha = O(d + \ln(d \cdot \varphi_{\mathcal{G}}(O(d/\varepsilon), O(d)))) \cdot O(1/\varepsilon)$ and $\beta = O(d)$, the Net-Finder-V1 Algorithm picks $O(1/\varepsilon) \cdot \log \varphi_{\mathcal{G}}\big(O(d/\varepsilon), O(d)\big) + O(d/\varepsilon)$ elements in expectation.*

4.2 Implementing NetFinder Online

We show how to implement Algorithm 2 online. There are two technical difficulties:

(i) The parameter α used in Algorithm 2 depends on N' (see Theorem 7). But in the online setting, elements contained in a set are revealed over time, and hence N' changes over time. We address this using a standard doubling trick: we divide the execution into *phases*. In a single phase, the value of N' lies in the range $[2^a, 2^{a+1})$ for some non-negative integer a.

(ii) The base sampling step in Algorithm 2 should not be performed for elements $e \in V \setminus V'$. As observed above, the set V' only gets revealed over time. Crucially, base sampling can be deferred: we sample an element $e \in V'$ only upon the arrival of the first set T_t containing it.

The algorithm, Net-Finder-V2, is given in Algorithm 3. First, we find the nearest power of 2 which is larger than N' and define ε accordingly (line 3). Observe that the quantity α is a function of ε (as given in Theorem 7). The rest of the algorithm is essentially the same as Net-Finder-V1, but we perform base sampling on an element only when the first set containing it arrives. Thus, we classify the elements in V as being either *fresh* or *stale*; initially, each element is fresh. An element becomes stale when we encounter the first set containing it. The alteration steps are then done exactly as in Net-Finder-V1. It follows that the statement of Theorem 7 holds for this algorithm as well.

Algorithm 3 Net-Finder-V2.

```
1 for sets T_1 to T_m do
2     Update V' := ∪_{t'≤t} T_{t'} and N' = |V'|
3     Let a be such that N' ∈ [2^a, 2^{a+1}).  Set ε = B/2^{a+1}.
4     for each fresh element e ∈ T_t do
5         select e into H independently with probability α(ε)/B ;   // Base Sampling
6         mark e as stale
7     while T_t is not hit by H do
8         select each element in T_t independently w.p. β/|T_t| ;   // Alteration
```

4.3 The Final Algorithm

We now describe the online hitting set algorithm combining Algorithm 1 and Algorithm 3. If $\mathcal{A}$ is an online algorithm for fractional hitting set and $\mathcal{I} = (U, \mathcal{F})$ an instance of the online hitting set, we use Algorithm 1 to obtain the instance $\mathcal{J} = (V, \mathcal{G})$, such that each set $S_t \in \mathcal{F}$ gives rise to set $T_t \in \mathcal{G}$. In each iteration t, Net-Finder-V2 maintains H as a valid hitting set for $\mathcal{J}$ by potentially adding elements from T_t. Then, we recover the corresponding hitting set for $\mathcal{I}$ by projecting the solution back, i.e., using the set $\mathsf{proj}(H)$. We get the following result:

▶ **Theorem 8.** *Given an online ρ-competitive algorithm for fractional online hitting set, there is an online randomized algorithm for unweighted hitting set that has expected competitive ratio*

$$O(\rho\, d) + O\left(\rho \log\left(d\, \varphi_{\mathcal{F}}(\rho\, d\, \mathsf{OPT}(\mathcal{I}), d)\right)\right)$$

for any instance $\mathcal{I} = (V, \mathcal{F})$, where the set system $\mathcal{F}$ has SCC $\varphi_{\mathcal{F}}$ and VC dimension d.

Proof. We need to bound the expected size of $\mathsf{proj}(H)$. Since $|\mathsf{proj}(H)| \le |H|$, it suffices to bound $\mathbb{E}[|H|]$. Consider a phase during the algorithm when N' stays in the range $[2^a, 2^{a+1})$ for some a. Observe that $\varepsilon = B/2^{a+1}$.

Using the notation in Section 4.1, Theorem 7 implies that $\mathbb{E}[|H|]$ is at most

$$O(1/\varepsilon)\cdot\log\varphi_{\mathcal{G}}\big(O(d/\varepsilon), O(d)\big)+O(d/\varepsilon) = O(2^{a+1}/B)\cdot\log\varphi_{\mathcal{G}}\big(O(d2^{a+1}/B), O(d)\big)+O(d2^{a+1}/B).$$

Summing over all a (which forms a series dominated by the last term) and using N' to denote the final value of $|V'|$, we see that the $\mathbb{E}[|H|]$ is at most

$$O(N'/B)\cdot\log\varphi_{\mathcal{G}}\big(O(N'/B), O(d)\big) + O(dN'/B).$$

Theorem 6 gives $N'/B \le 1 + \rho\,\mathsf{OPT}(\mathcal{I})$ and $\varphi_{\mathcal{G}}(\ell, k) \le k\varphi_{\mathcal{F}}(\ell, k)$, and hence the proof. ◀

▶ **Corollary 9.** *Given an online ρ-competitive algorithm for fractional online hitting set, there is an online randomized algorithm for (unweighted) online hitting set that has expected competitive ratio $O(d\rho \cdot \log(d\rho \cdot \mathsf{OPT}(\mathcal{I})))$, if the input set system $\mathcal{F}$ has VC dimension d.*

Furthermore, if the SCC $\varphi_{\mathcal{F}}$ of the set system satisfies $\varphi_{\mathcal{F}}(\ell, k) = \mathrm{poly}(k)$, then the expected competitive ratio is $O(d\rho \log d)$.

Proof. If the set system has VC dimension d, then $\varphi_{\mathcal{F}}(\ell, k) = O(\ell^d)$. Theorem 8 now implies the desired bound on the competitive ratio. The result for the case $\varphi_{\mathcal{F}}(\ell, k) = \mathrm{poly}(k)$ also follows from Theorem 8. ◀

Setting $\rho = \log n$ in Corollary 9 implies Theorem 1.

5 Online Algorithm for Weighted Hitting Sets

We now consider the weighted case of the hitting set problem on an online instance $\mathcal{J} = (V, \mathcal{G})$. We use $N = |V|$ to denote the size of the universe, and $B = n$ to denote a lower bound on the size of each set in this instance. In lieu of the size guarantee, we give a per-element guarantee and show that each element $e \in V$ which lies in at least one set is chosen with probability at most α/B, for some parameter $\alpha = \alpha(N, B) \geq 1$. We adapt the quasi-uniform sampling framework of [8] to the online setting. For convenience, we follow the exposition of that algorithm as presented in [23, Chapter 8].

5.1 Element Levels

The idea of the algorithm is natural: we construct a nested family of sets starting with $V_0 = V$, where each subsequent set $V_{\ell+1}$ is a uniformly random subset of size roughly $(1/2 + \delta)$ times that of the previous set V_ℓ, for a small "bias" term δ. The process ends at a level L^* with the corresponding set V_{L^*} having size $\approx N/B$. If we chose V_{L^*} as our hitting set H, the probability of each element $e \in H$ would be $\approx 1/B$, as desired. As sets in $\mathcal{G}$ are hit only with constant probability by V_{L^*}, we require "alterations" (backups) to ensure validity.

We assume that $\varphi_{\mathcal{G}}$ that is (a, b)-well-behaved for some positive constants a, b. (Recall Definition 4.) Let c_1 be a large enough constant and assume $B \geq c_1$. For brevity, define

$$N_\ell = \frac{c_1 N}{2^\ell} \qquad B_\ell = \frac{B}{2^\ell}. \tag{2}$$

Now we can define the element levels as follows:

1. Define L^* to be the largest value $\ell \in [0, \log B/c_1]$ such that

$$h_{\mathcal{G}}(N_\ell, B_\ell) \overset{\text{(def.)}}{=} \sqrt{\frac{8 \ln(B_\ell \cdot \lceil \log N_\ell \rceil \cdot \varphi_{\mathcal{G}}(N_\ell, B_\ell))}{B_\ell}} \leq 1/2. \tag{3}$$

   If $L^* = 0$ (or if $h_{\mathcal{G}}(N_0, B_0) > 1/2$), we return V as the hitting set. Since we have $L^* = \log \frac{B}{c_1}$ or $h_{\mathcal{G}}(N_{L^*}, B_{L^*}) > 1/2$, it follows that

$$\frac{1}{2^{L^*}} = O\left(\frac{1}{B} + \frac{\log(\log N \cdot B_{L^*} \cdot \varphi_{\mathcal{G}}(N_{L^*}, B_{L^*}))}{B}\right) = O\left(\frac{\log(\log N \cdot B_{L^*} \cdot \varphi_{\mathcal{G}}(N_{L^*}, B_{L^*}))}{B}\right). \tag{4}$$

2. Define $V_0 = V$. For each $\ell \in \{0, 1, \ldots, L^* - 1\}$, let $V_{\ell+1}$ be a random subset of V_ℓ of size

$$|V_\ell| \cdot (1/2 + h_{\mathcal{G}}(|V_\ell|, B_\ell)).$$

3. The *level* of element e is defined as the largest $\ell \in \{0, 1, \ldots, L^*\}$ such that $e \in V_\ell$.

Since the elements of V are given up-front, we define subsets V_ℓ before sets in $\mathcal{G}$ arrive.

5.2 The Weighted Hitting Set Algorithm

Given the notion of element levels, the main idea of the algorithm of [8], is the following: for each set $T \in \mathcal{G}$, consider the first level where $|T \cap V_\ell|$ is smaller than $B/2^\ell$. If this (low-probability) bad event happens, we pick some element in T at level $\ell - 1$ to hit it (since $|T \cap V_0| = |T| \geq B$, $\ell > 0$). The choice of this "backup" element is done consistently so that no element is chosen with too high a probability – showing such backup elements can be chosen is precisely where the small SCC of set system plays a role.

Algorithm 4 Offline Small SCC Hitting Set.

1 Define element levels and sets $V_\ell \leftarrow \{e \in V \mid \mathsf{level}(e) \geq \ell\}$ as in Section 5.1
2 **foreach** *arriving set* $T \in \mathcal{G}$ **do**
3 **foreach** *level* $\ell \in \{0, 1, 2, \ldots, L^* - 1\}$ **do**
4 define backup element $\gamma_\ell(T) \in V_\ell \cap T$ as in Section 5.3.1
5 **if** $|T \cap V_{\ell+1}| < B/2^{\ell+1}$ **then**
6 add element $\gamma_\ell(T)$ to the hitting set Q_ℓ
7 Let V' be the elements in V contained in at least one set in $\mathcal{G}$
8 **return** $H = Q_0 \cup \ldots \cup Q_{L^*-1} \cup (V_{L^*} \cap V')$

The algorithm (presented in 4) follows this outline: For each arriving set T of size at least B, and each level ℓ, we define a backup element, namely $\gamma_\ell(T)$, that will hit it in case of the bad event happening at the next level. This bad event at level ℓ is that the size of $T \cap V_\ell$ is smaller than $B/2^\ell$. Since each arriving set T is of size at least B, it either experiences a bad event at some level $\{0, 1, \ldots, L^* - 1\}$, or intersects the final set V_{L^*}. It is now easy to check that the solution returned by the algorithm is feasible; the remaining part is to show that each element belongs to this hitting set with probability α/B for some suitable parameter α.

In order to implement this algorithm in an online fashion, we need to define the backup element in line 4 in an online fashion; we do this in the next section with only a small loss in performance over the offline setting.

5.3 Backup Elements and Consistent Rounding

The next lemma defines a good backup map that can be maintained online:

▶ **Lemma 10.** *Consider a set system $(X, \mathcal{H})$. For any positive integers k and i, let $\mathcal{H}_i$ be the subsets in $\mathcal{H}$ of sizes in $[2^i k, 2^{i+1}k)$. Then there exists a map $\gamma^* : \mathcal{H} \to X$ such that $\gamma^*(S) \in S$ for each $S \in \mathcal{H}$ and for each integer $i \geq 0$, the number of sets from the subcollection $\mathcal{H}_i$ (i.e., the "scale-i" sets) mapped by γ^* to any element $e \in X$ is at most*

$$\mathrm{load}^*_{\mathcal{H}}(k, i) := \varphi_{\mathcal{H}}(|X|, 2^{i+1}k) \cdot 2^{i+1}k.$$

Moreover, if the sets in $\mathcal{H}$ arrive online, we can maintain such a map γ such that the number of sets assigned to each element is at most $\mathrm{load}_{\mathcal{H}}(k, i) := \lceil \log |X| \rceil \cdot \mathrm{load}^*_{\mathcal{H}}(k, i)$.

Proof. The first part of the lemma is proved in [23, Lemma 8.18]. For the second claim, we do the following. Fix an integer $i \geq 0$. We build a map $\gamma_i : \mathcal{H}_i \to X$ online using a basic result about algorithms for online load-balancing: it says that if jobs arrive online and each job must be assigned to one of some subset of "valid" machines, then the greedy algorithm ensures that the number of jobs assigned to any machine is at most $\lceil \log \#\text{machines} \rceil$ factor higher than the optimal maximum load [3]. In our setting, the jobs are sets from $\mathcal{H}_i$ and the

machines are elements of X, which shows that the load of each element with respect to the sets in $\mathcal{H}_i$ is only $\lceil \log N \rceil$ worse than in γ^*. Finally, the map $\gamma : \mathcal{H} \to X$ merely combines all these maps $\{\gamma_i\}$ into one, completing the claim. ◀

The following "bias" term will be crucial for the rest of the analysis:

$$h_{\mathcal{H}}(\ell, k) := \sqrt{\frac{8 \ln(k \cdot \lceil \log \ell \rceil \cdot \varphi_{\mathcal{H}}(\ell, k))}{k}}. \tag{5}$$

▶ **Lemma 11.** *Consider set system $(X, \mathcal{H})$ and a positive integer k such that $|S| \geq k$ for all $S \in \mathcal{H}$, and where $h_{\mathcal{H}}(|X|, k) \leq 1/2$. Let $Y \subseteq X$ be a uniformly random subset of size $|X| \cdot \big(1/2 + h_{\mathcal{H}}(|X|, k)\big)$. Suppose the sets in $\mathcal{H}$ are revealed online one by one. Let γ be the online mapping defined in Lemma 10. Then, defining*

$$Q := \{\gamma(S) \mid S \in \mathcal{H}, |S \cap Y| < k/2\}$$

gives us a set $Q \subseteq X$ (which is maintained in an online fashion) such that

- **(i)** *for each $S \in \mathcal{H}$, either $|S \cap Y| \geq k/2$ or $S \cap Q \neq \varnothing$, and*
- **(ii)** *each $e \in X$ belongs to Q w.p. $O(1/k^2)$, where the probability is over the choice of Y.*

Proof. This proof follows that of [23, Lemma 8.13], the only differences are that (a) the procedure is performed online, and (b) the load of any element is higher by $\lceil \log |X| \rceil$ due to the online load balancing in Lemma 10. Accordingly, the second term $h_{\mathcal{H}}(|X|, k)$ in the sampling probability contains a term corresponding to $\lceil \log |X| \rceil$, which helps to control the probability of any element being chosen into Q.

We now give a sketch of the proof. A Chernoff bound implies that if we pick a random subset $Y \subseteq X$ of size $|X| \cdot (1/2 + \delta)$ with $\delta \leq 1/2$, any set S of size at least k has

$$\Pr[|S \cap Y| < k/2] \leq \exp(-|S|/2 \cdot \delta^2). \tag{6}$$

(See [6] for a proof.) As in the statement of Lemma 10, we partition $\mathcal{H}$ into sets $\mathcal{H}_i$ based on the set sizes. Now we add an element e to Q if $e = \gamma(S)$ for some set $S \in \mathcal{H}$ and $|S \cap Y| \leq k/2$. By a union bound, the probability of e being added to Q is at most

$$\Pr[e \in Q] \leq \sum_{i \geq 0} \sum_{S \in \mathcal{H}_i : \gamma(S) = e} \Pr[|S \cap Y| < k/2] \leq \sum_{i \geq 0} \mathrm{load}_{\mathcal{H}}(k, i) \cdot \exp(-2^{i-1} k \cdot h_{\mathcal{H}}(|X|, k)^2).$$

For brevity, define $\Lambda := \lceil \log |X| \rceil$. Using the definition of $h_{\mathcal{H}}(\ell, k)$ in (5) and Lemma 10, we see that the above expression is at most

$$\leq \sum_{i \geq 0} \frac{2^{i+1} k}{k^{2^{i+2}}} \frac{\Lambda \cdot \varphi_{\mathcal{H}}(|X|, 2^{i+1} k)}{(\Lambda \cdot \varphi_{\mathcal{H}}(|X|, k))^{2^{i+2}}} \overset{(\star)}{\leq} \sum_{i \geq 0} \frac{2^{i+1} k}{k^{2^{i+2}}} \underbrace{\frac{(\Lambda \cdot \varphi_{\mathcal{H}}(|X|, k))^{2(i+1)}}{(\Lambda \cdot \varphi_{\mathcal{H}}(|X|, k))^{2^{i+2}}}}_{\leq 1} \leq O(1/k^2),$$

where inequality $(\star)$ used the fact that $\Lambda = \lceil \log |X| \rceil \geq 1$, $\varphi_{\mathcal{H}}$ is (a, b)-well-behaved and that $k \geq b$ (we assume the constant in $O(1/k^2)$ is at least b^2 and hence the upper bound on the probability of this event is trivial if $k < b$). This completes the proof of the lemma. ◀

In summary, we know that for any set system $(X, \mathcal{H})$, if we pick a random subset Y of about half (plus some "bias" term $h_{\mathcal{H}}(|X|, k)$ that depends on the SCC and the extra load $\lceil \log |X| \rceil$) of the elements, then most sets of size at least B have at least $B/2$ elements in common with Y, and moreover, each element $e \in X$ is picked as a backup element (due to sets that have fewer than $B/2$ elements) with probability at most $O(1/k^2)$.

5.3.1 Defining backup maps in Algorithm 4

We can now use Lemma 10 to define the maps γ_ℓ used in line 4 of Algorithm 4. Fix an index $\ell \in \{0, \ldots, L^* - 1\}$. Consider the set system $(V_\ell, \mathcal{G}_\ell)$ where $\mathcal{G}_\ell$ is the collection of subsets $T \in \mathcal{G}$ for which $|T \cap V_\ell| \geq B/2^\ell$. We now use Lemma 10 with $X = V_\ell, \mathcal{H} = \mathcal{G}_\ell$ and $k = B_\ell = B/2^\ell$. We set γ_ℓ to be the resulting online map $\gamma : \mathcal{G}_\ell \to V_\ell$. Observe that the set Q defined in Lemma 10 is same as the set Q_ℓ defined in Algorithm 4. We show next that maps γ_ℓ (and the resulting backup sets Q_ℓ) ensure a low probability of picking elements.

5.4 Probability of Picking Elements

To bound the probability of selecting an element e in the hitting set constructed by Algorithm 4, we first relate $h_{\mathcal{G}}\big(N_\ell, B_\ell\big)$ for varying values of ℓ (See [6] for the proofs).

▷ Claim 12. For any $\ell < L^*$ we have $h_{\mathcal{G}}\big(N_{\ell+1}, B_{\ell+1}\big) \geq \sqrt{\frac{2}{a}} \cdot h_{\mathcal{G}}\big(N_\ell, B_\ell\big)$.

▷ Claim 13. For any $\ell \leq L^*$ we have $|V_\ell| \leq c_1\, N/2^\ell$, and for each $e \in V$, $Pr[e \in V_\ell] \leq \frac{c_1}{2^\ell}$.

▶ **Theorem 14.** *In Algorithm 4, each element $e \in V$ is selected in the set H with probability at most $O\big(\frac{1}{B} \cdot \log(B_{L^*} \cdot \log N \cdot \varphi_{\mathcal{G}}(N_{L^*}, B_{L^*}))\big)$.*

Proof. Recall that if $L^* = 0$, we return the entire set V as the solution (which clearly hits all sets of size at least B); using (4), we get

$$\Pr[e \in H] = 1 \leq O\bigg(\frac{\log(B_L \cdot \log N \cdot \varphi_{\mathcal{G}}(c_1 N, N))}{B}\bigg). \tag{7}$$

Else, by a union bound, the probability that $e \in H$ is

$$\sum_{\ell=0}^{L^*-1} \Big(\Pr[e \in V_\ell] \Pr[e \in Q_\ell \mid e \in V_\ell]\Big) + \Pr[e \in V_L^*] = \sum_{\ell=0}^{L^*-1} \frac{c_1}{2^\ell} \cdot (B_\ell)^{-2} + \frac{c_1}{2^{L^*}},$$

where we used Claim 13 and Lemma 11ii for the first expressions, and Claim 13 again for the second. Now simplifying using the definition (2) for the first term, and the inequality (4) for the second, we get

$$\Pr[e \in H] \leq \frac{c_1}{B^2} \cdot \sum_{\ell=0}^{L^*-1} 2^\ell + O\bigg(\frac{\log(\log N \cdot B_{L^*} \cdot \varphi_{\mathcal{G}}(N_{L^*}, B_{L^*}))}{B}\bigg).$$

Finally, the geometric sum gives $2^{L^*} \leq \frac{B}{c_1}$, and results in the claimed bounds. ◀

5.5 The Algorithm for Weighted Hitting Sets

We now combine Algorithm 1 and Algorithm 4 to get an online weighted hitting set algorithm. We first give a simple observation about Algorithm 1 (See [6] for the proof).

▷ Claim 15. Let $\mathcal{I} = (U, \mathcal{F})$ be an instance of the weighted online hitting set problem. Then, Algorithm 1 can be implemented such that (let x_e be the solution at the end of the instance) (i) $\sum_e c_e x_e \leq 4\rho\, \mathsf{OPT}(\mathcal{I})$, (ii) if $x_e^t \neq 0$ for any time t and element e, then $x_e^t \geq 1/n$.

The online weighted hitting set algorithm is as follows: Algorithm 1 (with the changes in Claim 15) takes an instance $\mathcal{I} = (U, \mathcal{F})$ of the weighted hitting set problem and outputs an online instance $\mathcal{J} = (V, \mathcal{G})$ (which has the properties stated in Theorem 6). Since the backup maps γ_ℓ can be defined in an online manner, Algorithm 4 can be implemented on the instance $\mathcal{J}$ in an online manner. This gives us an online hitting set H. The hitting set for $\mathcal{I}$ is just $\mathsf{proj}(H)$. We now state the main result about the competitive ratio of this algorithm.

▶ **Theorem 16.** *Given an online ρ-competitive algorithm for fractional online hitting set, there is a randomized (weighted) online hitting set algorithm with expected competitive ratio*

$$O\big(\rho \cdot \log(B_{L^*} \log n \cdot \varphi_{\mathcal{F}}(N_{L^*}, B_{L^*}))\big).$$

Here L^* is the level associated with the instance $(V, \mathcal{G})$ as given by (3)*.*

Proof. Let e be an element in V. If e does not appear in any of the sets $\cup_t T_t$, then it is not selected by Algorithm 4. Otherwise its selection probability is upper bounded by Theorem 14.

Consider an element $e \in U$ (note that U is the ground set of the original instance $\mathcal{I}$). We now bound the probability that it gets selected. Let x_e be the final fractional value of e in Algorithm 1. If $x_e = 0$, then no clones of e appear in any of the sets in the instance $\mathcal{G}$, and hence, none of these clones gets added to H in Algorithm 4. Therefore probability of e getting selected is 0. Now suppose $x_e > 0$. Claim 15 shows that $x_e \geq 1/n$. Let Y_e be the set of clones corresponding to e in the set V. In other words, $Y_e = \{(e, i) : i \leq \lceil \min(1, nx_e) \rceil\}$. Since $x_e \geq 1/n$, $|Y_e| \leq 2nx_e$. Now, any clone (e, i) gets added to H with probability at most

$$O\Big(\frac{1}{B} \cdot \log(B_{L^*} \log N \cdot \varphi_{\mathcal{G}}(N_{L^*}, B_{L^*}))\Big).$$

Therefore, the probability that any of the clones of e gets added to H is at most $|Y_e|$ times the above expression. Thus, the probability of selection of e is at most (recall that $B = n$)

$$O\big(\log(B_{L^*} \log N \cdot \varphi_{\mathcal{G}}(N_{L^*}, B_{L^*}))\big) x_e.$$

The desired result now follows from the fact that $\sum_e c_e x_e = 4\rho \cdot \mathsf{OPT}$ (using Claim 15), that $N = O(n^2)$ and that $\varphi_{\mathcal{G}}(N_{L^*}, B_{L^*}) \leq B_{L^*} \cdot \varphi_{\mathcal{F}}(N_{L^*}, B_{L^*})$ due to Theorem 6. ◀

The guarantee of Theorem 16 depends on the value of L^*, which depends on the form of φ. We now apply the above result for the most interesting case: that of set systems with linear SCC, i.e., where $\varphi_{\mathcal{F}}(\ell, k) = \text{poly}(k)$.

▶ **Corollary 17** (Linear SCC)**.** *Suppose we are given an online ρ-competitive algorithm for fractional online weighted hitting set and the arriving instance $\mathcal{I} = (U, \mathcal{F})$, $n := |U|$, satisfies $\varphi_{\mathcal{F}}(\ell, k) = \text{poly}(k)$. Then there is an online randomized algorithm for (weighted) online hitting set that has expected competitive ratio $O\big(\rho \log \log n\big)$.*

Corollary 17, whose proof is deferred to the full version of the paper, implies Theorem 2.

Abstract

A Euclidean noncrossing Steiner $(1+\varepsilon)$-spanner for a point set $P \subset \mathbb{R}^2$ is a planar straight-line graph that, for any two points $a, b \in P$, contains a path whose length is at most $1+\varepsilon$ times the Euclidean distance between a and b. We construct a Euclidean noncrossing Steiner $(1+\varepsilon)$-spanner with $O(n/\varepsilon^{3/2})$ edges for any set of n points in the plane. This result improves upon the previous best upper bound of $O(n/\varepsilon^4)$ obtained nearly three decades ago. We also establish an almost matching lower bound: There exist n points in the plane for which any Euclidean noncrossing Steiner $(1+\varepsilon)$-spanner has $\Omega_\mu(n/\varepsilon^{3/2-\mu})$ edges for any $\mu > 0$. Our lower bound uses recent generalizations of the Szemerédi-Trotter theorem to disk-tube incidences in geometric measure theory.

1 Introduction

Spanners are a classical tool for data compression in graphs and network optimization. Formally, a t-spanner for an edge-weighted graph $G = (V, E, w)$ and a (stretch) parameter $t \geq 1$, is a subgraph H of G in which the shortest-path distance between any two vertices in V is at most t times larger than in G [3]. *Metric spanners* can approximate distances in a finite metric space (X, d) by setting $V = X$ and the edge weights to be the metric distances between the vertices. Geometric networks [69] are an important class of metric spanners, with applications in the design of physical networks in low-dimensional Euclidean spaces. Results in Euclidean spaces are also applicable for other settings via metric embeddings into Euclidean spaces [5, 28, 66, 67].

For Euclidean spanners in the plane, research efforts have diverged into two distinct regimes: (1) $(1+\varepsilon)$-*spanners*, where the stretch $t = 1+\varepsilon$ is arbitrarily close to 1, and the minimum size and weight of a $(1+\varepsilon)$-spanner is bounded by a function of $1/\varepsilon$ [63, 10, 61, 64], and (2) *plane* spanners, where the edges of the spanner are noncrossing line segments in $\mathbb{R}^2$ [27, 24, 56, 26, 46]. Researchers have made strides in both regimes over the last decade, and have uncovered optimal or near-optimal trade-offs between key parameters (see details below). However, very little attention was given to spanners that meet a dual objective: $1+\varepsilon$ stretch for arbitrarily small $\varepsilon > 0$ *and* noncrossing edges in $\mathbb{R}^2$.

This paper focuses on this dual objective. The problem may have avoided scrutiny because it has seemingly trivial answers: On the one hand, a simple instance of four points at the vertices of a square shows that a noncrossing straight-line Euclidean spanner cannot achieve stretch less than $\sqrt{2}$. If we insist on noncrossing edges and stretch close to 1, then we must allow *Steiner points*. On the other hand, if Steiner points are allowed, then the planarization of an optimal $(1+\varepsilon)$-spanner (by introducing Steiner vertices at edge crossings) provides a *noncrossing* Steiner $(1+\varepsilon)$-spanner with the same weight. However, planarization substantially increases the number of edges (hence the size of the spanner). Our goal is to find the best trade-offs between $\varepsilon > 0$ and the number of Steiner points for a Euclidean noncrossing Steiner $(1+\varepsilon)$-spanner in $\mathbb{R}^2$.

▶ **Problem 1.** *Determine $s(n, \varepsilon)$, defined as the minimum integer such that every set of n points in Euclidean plane admits a Euclidean noncrossing Steiner $(1+\varepsilon)$-spanner with at most $s(n, \varepsilon)$ Steiner points.*

This problem was also posed as Open Problem 17 in a survey by Bose and Smid [27, Section 4] in 2013. The best bound available at that time was given by Arikati et al. [9]: They constructed a Euclidean noncrossing Steiner $(1+\varepsilon)$-spanner with $O(n/\varepsilon^4)$ Steiner points by taking rectangular decompositions for n points in $O(1/\varepsilon)$ equally spaced directions.

Previous work. There are several possible approaches to address Problem 1. For n points in the plane, there are $(1+\varepsilon)$-spanners with $O(n/\varepsilon)$ edges (e.g., θ-graphs [37]); and this bound is the best possible. Since the edges of a spanner may pairwise cross, a naïve analysis of straightforward planarization would lead to a Euclidean Steiner $(1+\varepsilon)$-spanner with $O(n^2/\varepsilon^2)$ Steiner points.

Alternatively, one could try to bound the number of edge crossings in a $(1+\varepsilon)$-spanner (without Steiner points). Given a set $P \subset \mathbb{R}^2$ of n points, the greedy $(1+\varepsilon)$-spanner of Althöfer et al. [7] is constructed as follows: sort the $\binom{n}{2}$ possible edges by nondecreasing length, initialize an empty graph $H = (P, \emptyset)$, and add an edge ab to H if $d_H(a, b) > (1+\varepsilon) \cdot d(a, b)$. The greedy $(1+\varepsilon)$-spanner has $O(n/\varepsilon)$ edges [7, 30, 31]; and Eppstein and Khodabandeh [49]

proved that every edge ab crosses $O(1/\varepsilon^8)$ edges that are longer than ab. Consequently, it has $O(n/\varepsilon^9)$ crossings: planarization would create this many Steiner points. This bound is weaker than the previous bound of $O(n/\varepsilon^4)$ by Arikati et al. [9].

For n points in the plane and $k \in \mathbb{N}$, the *emanation graph of grade* k, introduced by Hamedmohseni et al. [54], is constructed by shooting 2^{k+1} rays from each given point, where the shorter rays stop the longer ones upon collision. The emanation graph of grade k is a noncrossing Steiner spanner with $O(2^k n)$ Steiner points. Hamedmohseni et al. [54] show that the stretch factor is at most $\sqrt{10}$, but for every $k \in \mathbb{N}$, there are point sets for which the stretch factor is arbitrarily close to $\sqrt{2}$; hence this approach does not lead to $(1+\varepsilon)$-spanners.

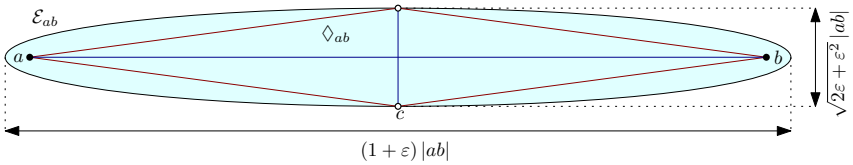

Figure 1 An ellipse $\mathcal{E}_{ab}$ with foci a and b, and major axis of length $(1+\varepsilon)\,|ab|$, and rhombus $\Diamond_{ab}$.

Cone-restricted spanners. Let P be a set of n points in the plane. For any $a, b \in P$, any ab-path of length at most $(1+\varepsilon)\,|ab|$ lies in an ellipse $\mathcal{E}_{a,b}$ with foci a and b and major axis $(1+\varepsilon)\cdot|ab|$; see Figure 1. Note that for small $\varepsilon > 0$, the ellipse $\mathcal{E}_{ab}$ is long and narrow. It is known that in every ab-path of length at most $(1+\varepsilon)\,|ab|$, the total length of the edges that make an angle $\alpha \le O(\sqrt{\varepsilon})$ with the line segment ab is $\Omega(|ab|)$ [18]. The angle threshold $\alpha \le O(\sqrt{\varepsilon})$ is the best possible: For example, if c is an intersection point of $\mathcal{E}_{ab}$ and its minor axis, the ab-path (a, c, b) has length $|ac| + |cb| = (1+\varepsilon)\,|ab|$, but both ac and cb make an angle of $\Theta(\sqrt{\varepsilon})$ with ab. We define a variant of Euclidean $(1+\varepsilon)$-spanners (with or without Steiner points), where we require an ab-path, for all $a, b \in P$, in which *all* edges make an angle $O(\sqrt{\varepsilon})$ with the line segment ab.

▶ **Definition 2.** *Let P be a set of n points in $\mathbb{R}^d$, for constant dimension $d \in \mathbb{N}$, and let $\alpha \in (0, \pi/2]$. A (Steiner) graph $G = (V, E)$, with $P \subseteq V$, is a* cone-restricted *(Steiner) $(1+\varepsilon)$-spanner for P if for every $a, b \in P$, there is an ab-path $(a = p_0, p_1, \ldots, p_m = b)$ in G such that $\sphericalangle(\overrightarrow{ab}, \overrightarrow{p_{i-1}p_i}) \le \sqrt{\varepsilon}$ for all $i = 1, \ldots, m$.*

Note that if G is a cone-restricted (Steiner) $(1+\varepsilon)$-spanner for P, then for every $a, b \in P$, there is an ab-path of length at most $(1+\varepsilon)\,|ab|$ that lies in the rhombus $\Diamond_{ab}$ spanned by a, b, and the two intersection points of $\mathcal{E}_{ab}$ with its minor axis; see Lemma 9.

1.1 Contributions and technical highlights

Upper bound. Our first contribution is a noncrossing Steiner $(1+\varepsilon)$-spanner with $O(n/\varepsilon^{3/2})$ Steiner vertices. This improves upon the previous best result by Arikati et al. [9], which has $O(n/\varepsilon^4)$ Steiner vertices.

▶ **Theorem 3.** *For every $\varepsilon > 0$ and every set of n points in Euclidean plane, there is a noncrossing Steiner $(1+\varepsilon)$-spanner with $O(n/\varepsilon^{3/2})$ Steiner vertices. Furthermore, there is such a spanner that is cone-restricted, and can be computed in $O((n \log n)/\varepsilon^{3/2})$ time.*

Arikati et al. [9] construct a set of noncrossing graphs G_i for $1 \le i \le k$. The final spanner is $\bigcup_{i=1}^{k} G_i$, where a Steiner vertex is added at every edge crossing between G_i and G_j, $i \ne j$. Our construction improves on the construction of Arikati et al. [9] in several ways. First, we

use fewer graphs G_i when constructing our spanner. Specifically, we use $k = O(1/\sqrt{\varepsilon})$ instead of $k = O(1/\varepsilon)$ graphs. Whereas the previous construction [9] uses $O(1/\varepsilon)$ rotated copies of the point set to approximate the L_2 distance with the L_1 distance in one of the copies, we instead use $O(1/\sqrt{\varepsilon})$ carefully chosen linear transformations to achieve cone-restricted paths between all pairs of points. Second, our graphs G_i are of smaller size than those in Arikati et al. [9]. Both constructions obtain G_i by refining the Balanced Box Decomposition into an axis-parallel spanner under the L_1 metric. We are able to use the properties of our linear transformations to obtain the same stretch guarantee using a coarser refinement of the Balanced Box Decomposition. In particular, we obtain $|G_i| = O(n)$, improving on $|G_i| = O(n/\varepsilon^2)$ in [9]. Third, our construction fills some details that are missing from both [9] and [27, Chapter 4].

Lower bounds. Our second contribution is an almost matching lower bound on the number of Steiner vertices in any Euclidean noncrossing Steiner $(1+\varepsilon)$-spanner.

▶ **Theorem 4.** *For every sufficiently small $\varepsilon, \mu > 0$ and every $n \in \mathbb{N}$, there exists a set of n points in the Euclidean plane for which every noncrossing Steiner $(1+\varepsilon)$-spanner has $\Omega_\mu(n/\varepsilon^{3/2-\mu})$ Steiner vertices, where the constant hidden in the $\Omega_\mu(.)$ notation depends only on μ.*

To the best of our knowledge, the best previous unconditional lower bound follows from the known size lower bound of $\Omega(n/\sqrt{\varepsilon})$ for Euclidean Steiner $(1+\varepsilon)$-spanners [63], which also applies to noncrossing spanners. In this paper, the canonical example to prove lower bounds is the following construction: consider the unit square $[0,1]^2$ and let A (resp., B) be the set of equally spaced points on the left (resp., right) side of $[0,1]^2$ so that the distance between any two consecutive points in A (resp., B) is $4\sqrt{\varepsilon}$. The point set P is the union of points in A and B; see Figure 2 for an illustration. Observe that: (i) the minimum pairwise distance in P is $4\sqrt{\varepsilon}$, (ii) the maximum pairwise distance (a.k.a., diameter) in P is $\sqrt{2}$, and (iii) for any $a \in A$ and $b \in B$, the slope of the segment ab is between -1 and 1. Let G be a noncrossing Steiner $(1+\varepsilon)$-spanner with the minimal number of Steiner points for P.

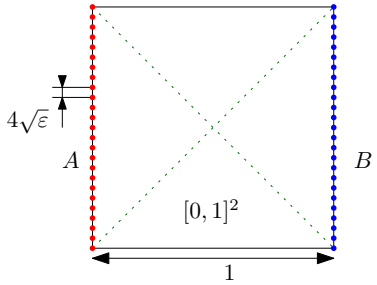

Figure 2 Point set $A \cup B$, where A and B lie on two opposite sides of a unit square.

First, we sketch key ideas behind a weaker $\Omega(n/\varepsilon)$ lower bound (the proof can be found in the full version of the paper).

▶ **Theorem 5.** *For every sufficiently small $\varepsilon > 0$ and every $n \in \mathbb{N}$, there exists a set of n points in the Euclidean plane for which every noncrossing Steiner $(1+\varepsilon)$-spanner has $\Omega(n/\varepsilon)$ Steiner vertices.*

Let $A_0 \subseteq A$ consist of every third point from the bottom third of the left side, and $B_0 \subseteq B$ consist of every third point from the top third of the right side. This ensures $|A_0|, |B_0| = \Omega(1/\sqrt{\varepsilon})$ and for each pair $(a,b) \in A_0 \times B_0$ the segment ab has slope in $[\frac{1}{3}, 1]$.

For each pair $(a, b) \in A_0 \times B_0$, let γ_{ab} denote a shortest path in G from a to b. We apply the result of Bhore and Tóth [18, Lemma 4] to conclude that the set E_{ab} of edges in γ_{ab} having angle at most $3\sqrt{\varepsilon}$ with ab satisfies $\|E_{ab}\| \geq \frac{7}{9}|ab|$, i.e., the total length of the edges in E_{ab} is at least $\frac{7}{9}|ab|$. Moreover, using a geometric argument, we can show that for distinct pairs $(a, b), (a', b') \in A_0 \times B_0$, the sets E_{ab} and $E_{a'b'}$ are pairwise disjoint.

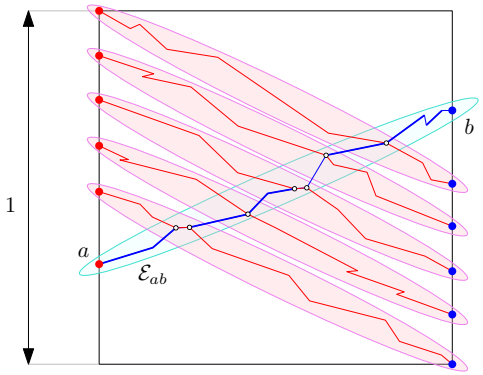

Figure 3 An ab-path and its intersections with other paths between point pairs of slope $-1/2$.

Now, consider the collection of all ellipses $\mathcal{E}_{cd}$ with $c, d \in A \cup B$ and slope $-\frac{1}{2}$ (see Figure 3). As these ellipses are pairwise disjoint (Lemma 10), each such ellipse creates a Steiner vertex wherever γ_{ab} (for $(a, b) \in A_0 \times B_0$) intersects it. Since there are $\Theta(1/\sqrt{\varepsilon})$ such disjoint ellipses, and each path γ_{ab} must cross $\Theta(1/\sqrt{\varepsilon})$ of them, each path γ_{ab} contains $\Theta(1/\sqrt{\varepsilon})$ Steiner points in these intersections. The bound on the total length $|\gamma_{ab}| \leq (1+\varepsilon)|ab| < 2$ combined with the pigeonhole principle implies that the average length of an edge in E_{ab} is $O(\sqrt{\varepsilon})$. Consequently, E_{ab} contains at least $\Omega(1/\sqrt{\varepsilon})$ edges. Since there are $\Omega(1/\varepsilon)$ pairs in $A_0 \times B_0$ and the sets E_{ab} are edge-disjoint, the total number of edges is $\Omega(1/\varepsilon) \cdot \Omega(1/\sqrt{\varepsilon}) = \Omega(1/\varepsilon^{3/2}) = \Omega(n/\varepsilon)$ for the basic construction. See the full version for a detailed proof.

This lower bound is already stronger than the lower bound of $\Omega(n/\sqrt{\varepsilon})$ that can be derived from the crossing case [63]. However, the limitation of this approach is the fact that the pigeonhole argument can give only $\Omega(1/\sqrt{\varepsilon})$ edges per path γ_{ab}. To improve this to $\Omega_\mu(n/\varepsilon^{3/2-\mu})$ for any $\mu > 0$, we will use techniques from geometric measure theory (see the full version for the full proof of Theorem 4). To use these tools, we first need to show that most of the spanner paths have certain properties. Let M be the square of side-length $1/8$ in the middle of $[0, 1]^2$. We decompose M into an $O(1/\sqrt{\varepsilon}) \times O(1/\sqrt{\varepsilon})$ grid consisting of square *windows* and analyze the structure of spanner paths within each window. We will also restrict our attention to ellipses $\mathcal{E}_{ab}$ where the corresponding segment ab has slope $\lambda \in [1/4, 3/4]$, and we say that such ellipses and spanner paths are in the *positive bundle*, or ab has slope $\lambda \in [-3/4, -1/4]$, where the corresponding ellipses and spanner paths belong to the *negative bundle*. The key properties we establish are:

- Each window W contains crossing ellipses for each slope in the positive and negative bundles.
- Each spanner path γ_{ab} is *adventurous* in at most $c/\sqrt{\varepsilon}$ windows, meaning it goes outside a narrow strip $R_W(\gamma_{ab})$ of width $O(\varepsilon)$ in only a small number of windows. Here c is a small constant.
- Each spanner path γ_{ab} is *skewed* in at most $c/\sqrt{\varepsilon}$ windows, meaning its direction deviates significantly from the direction of the segment ab in only a small number of windows. Again, c is a small constant.

- More than half of the windows in M are *well-behaved*, meaning they are crossed by sufficiently many non-adventurous, non-skewed spanner paths from both the positive and negative bundles.

In a well-behaved window W, we can also identify collections Ψ_W^+ and Ψ_W^- of spanner paths such that each path $\gamma \in \Psi_W^+ \cup \Psi_W^-$ is non-adventurous, non-skewed, and the paths and their corresponding strips $R_W(\gamma)$ of width $O(\varepsilon)$ have the following properties (see Figure 4):

(i) Paths in Ψ_W^+ and Ψ_W^- pairwise cross within the window.

(ii) The directions of the strips $R_W(\gamma)$ corresponding to these paths differ by at least $\Omega(\sqrt{\varepsilon})$.

(iii) The strips corresponding to distinct paths have small intersection areas, at most half the area of any individual strip.

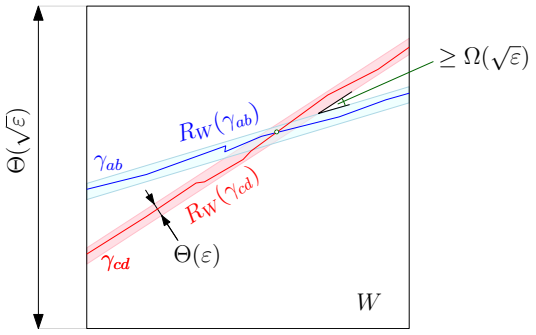

Figure 4 A well-behaved window W with two non-adventurous non-skewed paths $\gamma_{ab}, \gamma_{cd} \in \Psi_W^+$.

After this preparation, we want to analyze the number of Steiner vertices. A natural tool would be the classical Szemerédi–Trotter theorem which states that for any set of ℓ lines in the plane, the number of points incident to at least r of these lines is at most $O(\ell^2/r^3 + \ell/r)$. Ideally, we would like to apply this theorem to count the number of Steiner vertices incident to many spanner paths. However, the Szemerédi–Trotter theorem does not directly apply, since our spanner paths are not straight lines.

Motivated by problems in geometric measure theory, the Szemerédi–Trotter theorem was generalized to *disk-tube incidences* [53]. Instead of points and lines, we count intersections between δ-disks (small disks of radius δ) and δ-tubes (long rectangles of width δ). Fu, Gan and Ren [52] recently proved that only $O_\mu(|\mathcal{T}|^2/r^3)$ disjoint r-rich disks (each intersecting at least r tubes) exist when tubes in $\mathcal{T}$ are sufficiently well-spaced and separated in direction.[1]

We apply their theorem to the tubes formed by the strips $R_W(\gamma_{ab})$ corresponding to the spanner paths with $\delta = \Theta(\sqrt{\varepsilon})$ for every well-behaved window W (see Figure 4). Properties (i), (ii) and (iii) guarantee that the collection of tubes in each well-behaved window W satisfies the spacing and direction separation conditions required by the result of Fu, Gan and Ren [52].

The theorem of Fu, Gan and Ren [52] implies that only $O_\mu(1/(\varepsilon r^3))$ disjoint r-rich δ-disks can intersect tubes in our collection. In their result, there is a technical requirement that $r > \delta^{1-2\mu}|\mathcal{T}_{\max}|$, and so the smallest value of r we can choose is $r = \Omega_\mu(1/\varepsilon^\mu)$. This means that most of the $\Theta(1/\varepsilon)$ crossing points are not covered by the r-rich disks. Therefore, there must exist $\Omega_\mu(1/\varepsilon)$ crossing points where the Steiner vertex is incident to fewer than

[1] The exact definition of *sufficiently well-spaced* is quite technical and is guided by the $\mu > 0$ parameter (see the full version for details).

$r_0 = \Theta_\mu(1/\varepsilon^\mu)$ spanner paths from our tube collection. Counting the tube crossings at these low-degree Steiner vertices yields at least $\Omega_\mu(1/\varepsilon)/r_0^2 = \Omega_\mu(1/\varepsilon^{1-2\mu})$ such vertices per window, and summing over all $\Omega(1/\varepsilon)$ well-behaved windows gives the $\Omega_\mu(1/\varepsilon^{2-2\mu})$ lower bound on the number of Steiner vertices in G. Since $n = \Theta(1/\sqrt{\varepsilon})$, this implies the desired lower bound of $\Omega_\mu(n/\varepsilon^{3/2-2\mu})$. Finally, we scale μ by a factor of 2. This concludes the sketch of the proof of Theorem 4, see the full version for details.

Theorem 4 leaves a small gap of roughly $\varepsilon^{o(1)}$ between our upper and lower bounds. We are able to show that this gap can be closed if we restrict our attention to cone-restricted spanners which were used in the construction of Theorem 3. The proof of Theorem 6 uses a generalization of the celebrated Crossing Lemma to so-called degenerate crossings [2, 70].

▶ **Theorem 6.** *For every sufficiently small $\varepsilon > 0$ and every $n \in \mathbb{N}$, there exists a set of n points in the plane for which every cone-restricted plane Steiner $(1+\varepsilon)$-spanner has $\Omega(n/\varepsilon^{3/2})$ Steiner vertices. Up to constant factors, this lower bound is the best possible (cf. Theorem 3).*

Organization. After covering further related works (Section 1.2) and the preliminaries (Section 2), we provide the construction for our sparse noncrossing Steiner spanner (Section 3). Due to space limitations, complete proofs are deferred to the full version. The proofs of the lower bounds (Theorems 4–6) are also deferred to the full version.

1.2 Further related previous work

As noted above, Euclidean spanners have been studied under two independent regimes:

$(1+\varepsilon)$-Spanners. The first Euclidean $(1+\varepsilon)$-spanners for arbitrary $\varepsilon > 0$ were obtained independently by Clarkson [37] and Keil [57], and these works also introduced the fixed-angle Θ-graph (a close variant of the Yao graph [81]) as a basic construction tool. Ruppert and Seidel [76] extended this to $\mathbb{R}^d$, by giving $(1+\varepsilon)$-spanners with $O(n/\varepsilon^{d-1})$ edges for constant d. Le and Solomon [63] proved that this dependence on ε is tight: for every $\varepsilon > 0$ and constant d, there exist point sets in $\mathbb{R}^d$ for which any $(1+\varepsilon)$-spanner must have $\Omega(\varepsilon^{-(d-1)})$ edges whenever $\varepsilon = \Omega(n^{-1/(d-1)})$.

Another key parameter of a spanner is its *lightness*. For a set of points, it is the ratio between its total edge weight and the weight of the MST of the point set. Building on the greedy spanner of Althöfer et al. [7], Das et al. [41] proved that this construction achieves constant lightness and stretch $1+\varepsilon$ in $\mathbb{R}^3$, which was later extended to all $\mathbb{R}^d$ by Das et al. [42]. Rao and Smith [72] established that the greedy $(1+\varepsilon)$-spanner in $\mathbb{R}^d$ has lightness $1/\varepsilon^{O(d)}$, and a long line of refinements culminated in the bound $O(\varepsilon^{-d}\log(1/\varepsilon))$ by Le and Solomon [63]. Besides achieving small *stretch* and *sparsity*[2], spanners are often required to satisfy additional desirable properties such as bounded degree or diameter. There has been extensive work on understanding the optimal trade-offs among these parameters for Euclidean spanners (see, e.g., [10, 17, 47, 45, 61]).

Euclidean Steiner spanners. Steiner points can significantly reduce the weight of distance approximation structures (see, e.g., [48, 77]). Note that a Steiner t-spanner for a point set P must guarantee stretch t only for point pairs in P. Le and Solomon [62] constructed Steiner $(1+\varepsilon)$-spanners of sparsity $O(\varepsilon^{(1-d)/2})$ in $\mathbb{R}^d$ for all $d \geq 2$, and this bound is the

[2] The sparsity of a spanner is the ratio of the number of edges in the spanner to the size of MST.

best possible [18]. In the plane, Bhore and Tóth [18] constructed Steiner $(1+\varepsilon)$-spanners of lightness $O(1/\varepsilon)$, this bound is also tight [63]. In dimensions $d \geq 3$, the current best upper and lower bounds for lightness are $\widetilde{O}(1/\varepsilon^{(d+1)/2})$ and $\Omega(1/\varepsilon^{d/2})$ [18, 63]. Recent work has also analyzed online algorithms for Euclidean Steiner spanners and obtained several asymptotically tight bounds [15, 19].

Noncrossing spanners. Chew [33] first proved the existence of a Euclidean spanner with stretch $\sqrt{10}$ and $O(n)$ noncrossing edges, the stretch was later improved to 2 [34]. Keil and Gutwin [58] showed that the Delaunay triangulation is a 2.42-spanner. Later, Bonichon et al. [23] gave tight bounds of $\sqrt{4+2\sqrt{2}}$ for the L_1- and L_∞-Delaunay graphs. Subsequently, Bose et al. [25] showed that the Yao graph is a $8\sqrt{2}$-spanner. See the comprehensive survey by Bose and Smid [27] for results on plane spanners up to 2013. Since then, several core questions raised in that survey on plane spanners have seen notable progress. The long-open existence of bounded-degree plane spanners has been resolved for degree 4 through constructions of Bonichon et al. [24]. Later, Kanj et al. [56] obtained improved stretch bounds. Bose et al. [26] further tightened the trade-off by giving an algorithm to construct degree-8 plane spanners with stretch ≈ 4.414. Dumitrescu and Ghosh [46] strengthened lower bounds on plane-spanner dilation. For degree 3, progress has been obtained for restricted families of point sets, such as points in convex position [20]. The framework has also been extended to constrained visibility, where van Renssen and Wong [79] showed that visibility graphs among polygonal obstacles admit noncrossing spanners with bounded degree and constant stretch (see also [16, 1] for some recent work on plane spanners in polygonal domains). Further developments include refined stretch analysis for planar variants of θ-like geometric graphs [26], as well as general geometric conditions under which sweepline-based constructions produce planar spanners [65].

Previous work related to cone-restricted spanners. We have defined *cone-restricted* $(1+\varepsilon)$-spanners for finite point sets in the plane (Definition 2). Similar concepts have previously been used for other purposes. In a *geometric graph* $G = (V, E)$, the vertices are distinct points in the plane and the edges are straight-line segments. A geometric graph is *strongly monotone* [8, 59, 51] if for every $a, b \in V$, there is a ab-path $(a = v_0, v_1, \ldots, v_m = b)$ in which $\sphericalangle(\overrightarrow{ab}, \overrightarrow{v_{i-1}v_i}) \leq \pi/2$ for all $i = 1, \ldots, m$. However, this property does not guarantee any stretch factor.

A geometric graph is *angle-monotone with width* γ [21, 43, 68] if for every $a, b \in V$, there is an ab-path in which the angle between any two edges is at most γ. For example, the axis-aligned grid graph induced by n points in the plane is angle monotone with width $(\pi/2)$, and is a $\sqrt{2}$-spanner, however, it uses $O(n^2)$ Steiner vertices. Dehkordi et al. [43] constructed, for n points in $\mathbb{R}^2$, a plane angle-monotone graph of width $\pi/2$ using $O(n)$ Steiner points. Bonichon et al. [21] showed that the half-θ_6 graph [22] is angle-monotone with width $2\pi/3$, and $O(n)$ edges, however, it is not necessarily planar. Lubiw and Mondal [68] constructed an angle monotone graph with width $\pi/2$ with $O(n^2 \log\log n/\log n)$ edges without Steiner vertices (but with crossings). They also consider a version of the problem with Steiner vertices, however, they require the angle-monotone property for all pairs of vertices (including Steiner vertices), and allow additional crossings. For every $\gamma > 0$ and every set P of n points in the plane, they construct a Steiner angle-monotone graph of width γ with $O(\frac{n}{\gamma} \log \Phi(P))$ edges, where $\Phi(P)$ is an unbounded parameter that depends on the point configurations.

Other constraints imposed on ab-path include *greedy* [66, 71], *self-approaching* [6] and *increasing-chord* [40] properties: A geometric graph $G = (V, E)$ is *greedy* if for every $a, b \in V$, there is an ab-path $(a = v_0, v_1, \ldots, v_m = b)$ that monotonically gets closest to b, that is,

$d(v_i, b) < d(v_{i-1}, b)$ for all $i = 1, \ldots, m$. It is *self-approaching* if $d(v_j, v_k) \leq d(v_i, v_k)$ for all $0 \leq i < j < k \leq m$; and *increasing-chord* if there is an ab-path that is self-approaching in both directions. The self-approaching and increasing-chord properties imply a stretch factor of 5.34 [55], at most $2\pi/3$ [74] (see also [4]), resp., while the greedy property alone does not imply any stretch guarantee.

We also mention a couple of concepts that sound similar to cone-restricted spanners, but are different. The classical θ- and Yao-graphs are constructed by connecting every vertex v to a "closest" point in cones of apex v and aperture θ. They are known to be $O(\theta)$-spanners for $\theta \leq \pi/2$, but the ab-paths of length $O(\theta) \cdot d(a, b)$ are not necessarily cone-restricted: They may contain (short) edges that make an arbitrary angle with the line segment ab.

Another concept, under a similar name, was introduced by Carmi and Smid [29]: A geometric graph is *θ-angle-constrained* if for every vertex $v \in V$ the angle between any two edges incident to v is *at least* θ. They note that the classical greedy $(1+\varepsilon)$-spanner by Althöfer et al. [7] is $\Omega(\varepsilon)$-angle constrained. For every $\theta \in (0, \pi/3)$, and n points in the plane, one can construct a θ-angle-constrained $(1 + O(\theta))$-spanner in $O(n \log n)$ time [29]; and this is not always possible for $\theta > \pi/3$ [12].

Connections to incidences and geometric measure theory. Szemerédi and Trotter [78] proved that n points and ℓ lines in $\mathbb{R}^2$ determine $O(n^{2/3}\ell^{2/3} + n + \ell)$ point-line incidences, and this bound is the best possible [50]. Motivated by connections to geometric measure theory [80] significant progress was made on a generalization to disk-tube incidences, which is the number of intersections between well-spaced disks of radius δ and *δ-tubes*, where a δ-tube is the δ-neighborhood of a line, in a unit square $[0, 1]^2$; see [39, 44, 52, 53].

The number of disk-tube incidences (used in multiple scales) was instrumental in several recent breakthroughs in combinatorial geometry and geometric measure theory. For example, Heilbronn's classical problem [75] asks for the minimum $h(n) > 0$ such that any set P of n points in the unit square $[0, 1]^2$ determines a nondegenerate triangle $\Delta(abc)$ of area at most $h(n)$. A line segment ab is the base of a triangle $\Delta(abc)$ of area A if and only if there exists a point $c \in P$ in the $\frac{2A}{d(a,b)}$-neighborhood of the line spanned by ab. Cohen et al. [38, 39, 82] recently proved $h(n) \geq \Omega(n^{-8/7-1/2000})$, improving on the previous bound $h(n) \geqq \Omega(n^{8/7})$ by Komlós et al. [60]. In another recent breakthrough using this machinery, Ren and Wang [73] completely solved the Furstenberg set problem.

2 Preliminaries

Balanced Box Decomposition. In our upper bound construction, we will use the Balanced Box Decomposition (BBD) of Arya et al. [11]. Given a set of points P, the BBD partitions the bounding box of P into a set of tiles, such that each tile is either a rectangle or defined by an outer rectangle and a sticky inner rectangle.

▶ **Definition 7** (Sticky). *In $\mathbb{R}^1$, an inner interval of width w is sticky with respect to an outer interval if its distances to the endpoints of the outer interval are either $= 0$ or $\geq w$. In $\mathbb{R}^d$, an inner box is sticky with respect to an outer box if their projections onto each of the d coordinate axes are sticky.*

▶ **Theorem 8** (BBD [11]). *Given a set of points P, one can partition the bounding box of P into $O(n)$ tiles such that*

(a) *each tile is either a rectangle, or an outer rectangle with a sticky inner rectangular hole,*
(b) *the rectangle, outer rectangle, and inner rectangle must have an aspect ratio of ≤ 3,*
(c) *each tile contains at most one point of P, moreover, this point lies on the tile's boundary.*

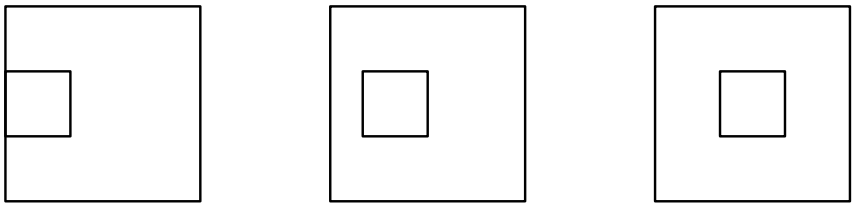

Figure 5 The middle figure shows an inner box that is not sticky, due to its x-projection.

Properties of cone-restricted spanners. We prove here that every cone-restricted (Steiner) $(1+\varepsilon)$-spanner is, in fact, a (Steiner) $(1+\varepsilon)$-spanner; which justifies calling them $(1+\varepsilon)$-spanners in Definition 2. (See also [21].)

▶ **Lemma 9.** *Let $a, b \in \mathbb{R}$, and let $\gamma = (a = p_0, p_1, \ldots, p_m = b)$ be a polygonal path such that $\sphericalangle(\overrightarrow{ab}, \overrightarrow{p_{i-1}p_i}) \leq \sqrt{\varepsilon}$ for all $i = 1, \ldots, m$. Then for $0 < \varepsilon \leq 1$,*

1. *the length of γ is bounded by $|\gamma| \leq (1+\varepsilon)\,|ab|$, and*
2. *$\gamma \subset \Diamond_{ab}$, where $\Diamond_{ab}$ is the rhombus $\Diamond_{ab}$ spanned by a, b, and the two intersection points of $\mathcal{E}_{ab}$ with its minor axis (cf. Figure 1).*

Basic point set for lower bounds. Our lower bounds are based on the same basic point set, which is known to give asymptotically tight bounds for lightness and sparsity for both Steiner and non-Steiner $(1+\varepsilon)$-spanners in the plane [18, 62, 63].

Let $\varepsilon \in (0, \frac{1}{16})$, and assume w.l.o.g. that $\varepsilon = 4^{-k}$ for some $k \in \mathbb{N}$. We first construct a point set P of size $|P| = 2(2^{k-2}+1) = \Theta(\varepsilon^{-1/2})$. Consider the unit square $[0,1]^2$. Let A be a set of $2^{k-2}+1$ equally spaced points on the left side of $[0,1]^2$; and B a set of $2^{k-2}+1$ equally spaced points on the right side of U. Our point set is $P = A \cup B$; see Figure 2.

Note that the minimum distance between any two points in A (resp., B) is $2^{2-k} = 4\sqrt{\varepsilon}$; the diameter of P is $\sqrt{2}$. Note also that for any $a \in A$ and $b \in B$, the segment ab makes an angle at most $\pi/4$ with a vertical line, in particular the absolute value of the slope of ab is at most 1.

We observe two easy properties of the point set $P = A \cup B$.

▶ **Lemma 10.** *If ab and $a'b'$ are parallel, then the ellipses $\mathcal{E}_{ab}$ and $\mathcal{E}_{a'b'}$ are disjoint.*

Next, we have a lower bound on the angle between two nonparallel segments ab and $a'b'$.

▶ **Lemma 11.** *For any $a, a' \in A$ and $b, b' \in B$, the following hold:*

(1) *if ab and $a'b'$ are parallel, then $\mathcal{E}_{ab}$ and $\mathcal{E}_{a'b'}$ are disjoint;*

(2) *if ab and $a'b'$ are nonparallel, then $\sphericalangle(ab, a'b') > 2\sqrt{\varepsilon}$.*

3 A sparse noncrossing Steiner spanner

Construction. Our construction is based on the noncrossing Steiner $(1+\varepsilon)$-spanner of Arikati et al. [9]. See also Section 4 in the survey by Bose and Smid [27].

We are given a set P of n points in the plane, and a parameter $\varepsilon > 0$. Let $k \in \mathbb{N}$. Note that $k = k(\varepsilon)$ and will be chosen later based on ε. We will construct a set of planar straight-line graphs G_i for $i \in \{1, \ldots, k\}$. Then we will construct the final spanner $G = \bigcup_{i=1}^{k} G_i$ as the union of the graphs G_i, where a Steiner point is inserted at each edge crossing between edges in G_i and G_j for $i \neq j$. For $i \in \{1, \ldots, k\}$, the graph G_i will be such that the edges have two

possible directions: they either make an angle of $i \cdot \frac{\pi}{k}$ or $(i+\delta) \cdot \frac{\pi}{k}$ with the positive x-axis, where δ is a positive integer[3]. Consider the affine transformation $T_i : \mathbb{R}^2 \to \mathbb{R}^2$ that maps unit vectors of direction $i \cdot \frac{\pi}{k}$ and $(i+\delta) \cdot \frac{\pi}{k}$ to unit vectors along the positive x- and y-axes, respectively. By applying the transformation on G_i, we obtain an axis-parallel graph $T_i(G_i)$ on the point set $T_i(P)$.

It remains to construct the axis-parallel graph $T_i(G_i)$. We use the Balanced Box Decomposition (BBD), which we introduced in Section 2. Recall that the BBD divides the bounding box of $T_i(P)$ into $O(n)$ tiles. For each of these $O(n)$ axis-aligned tiles, we will further subdivide the tile into at most $9K^2$ axis-aligned rectangles. If a tile contains no hole, we subdivide it into rectangles using K equally spaced horizontal lines and K equally spaced vertical lines. If a tile contains a hole, we first subdivide it into at most 9 rectangles using the four lines spanned by the four sides of the inner rectangle, and then subdivide each of these rectangles using K equally spaced horizontal lines and K equally spaced vertical lines. See Figure 6.

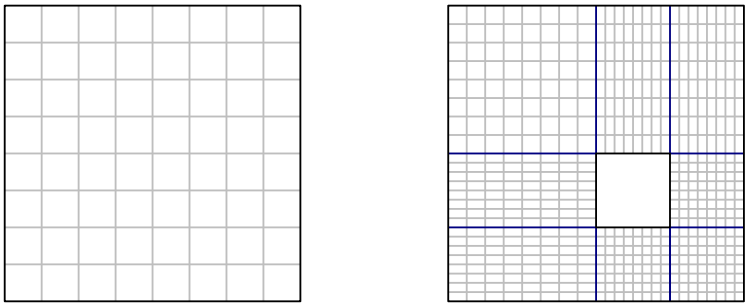

Figure 6 Further subdividing a tile into $\leq 9K^2$ rectangles, first by the four lines spanned by the sides of the inner rectangle (dark blue), and second by equally spaced axis-parallel lines (grey).

This yields a partition of the bounding box of $T_i(P)$ into $O(nK^2)$ axis-aligned rectangles such that each point in $T_i(P)$ lies on the boundary of one of the rectangles. This partition defines the axis-parallel graph $T_i(G_i)$. In particular, the vertices of the graph are the points $T_i(P)$ and the vertices of the rectangles in the partition, and the edges of the graph are the edges of the rectangles in the partition, or a pair of edges connected to a vertex of $T_i(G_i)$ if the vertex lies on an edge of a rectangle. This completes the construction of $T_i(G_i)$. We can apply the inverse transformation T_i^{-1} to obtain the graph G_i. Finally, by constructing the union $G = \bigcup_{i=1}^{k} G_i$ and adding Steiner points at edge crossings, we obtain the final graph.

A key difference between our construction and that of Arikati et al. [9] is that we use linear transformations, instead of rotated copies, of the BBD construction. This difference ultimately leads to our improved bound on the number of Steiner points. In particular, the properties of our linear transformations (Lemmas 12 and 13) allow us to use significantly fewer graphs and a significantly coarser refinement of the BBD, which correspond to smaller values for the parameters k and K, respectively.

Next, we define the parameters δ, k and K and compare them to [9]. Our linear transformations use $\delta = 3$, whereas the rigid motions of Arikati et al. [9] correspond to $\delta = \frac{k}{2}$. We use $k = O(\sqrt{1/\varepsilon})$ and $K = 100$, instead of the $k = O(1/\varepsilon)$, and $K = O(1/\varepsilon)$ used in [9]. Notably, we have $|G_i| = O(n)$ instead of $|G_i| = O(n/\varepsilon^2)$ in [9]. We will show that, even with fewer and smaller graphs G_i, we still obtain a $(1+\varepsilon)$-spanner.

[3] We choose $\delta = 3$, whereas Arikati et al. [9] choose $\delta = \frac{k}{2}$.

Stretch analysis. We will prove that G is a $(1+\varepsilon)$-spanner for the new construction, i.e., for the new values of k, δ and K. Let $a, b \in P$. Define $\sphericalangle ab$ to be the angle between the vector $\overrightarrow{ab}$ and the positive x-axis. For the remainder of this section, we will assume without loss of generality that $\sphericalangle ab \in [(i+1)\cdot\frac{\pi}{k}, (i+2)\cdot\frac{\pi}{k})$ where $i \in \{1, \ldots, k\}$. The next lemma is to prove that the transformation T_i sends vector $\overrightarrow{ab}$ into the angle class $[\frac{\pi}{12}, \frac{5\pi}{12})$. See Figure 7. The lemma assumes that ε is sufficiently small, and thus k is sufficiently large.

▶ **Lemma 12.** *If* $\sphericalangle ab \in [(i+1)\cdot\frac{\pi}{k}, (i+2)\cdot\frac{\pi}{k})$, *then* $\sphericalangle(T_i(a)T_i(b)) \in [\frac{\pi}{12}, \frac{5\pi}{12})$.

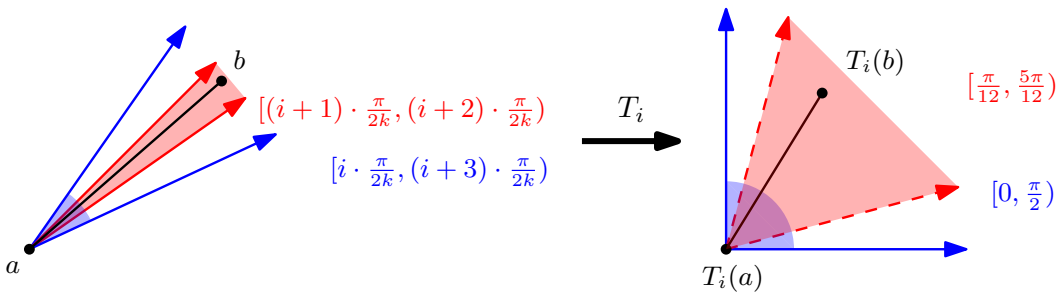

Figure 7 A visualization of the transformation T_i, which sends the unit vectors in the directions $i\cdot\frac{\pi}{k}$, $(i+\delta)\cdot\frac{\pi}{k}$ (left, blue) to the unit x- and y-vectors (right, blue). Lemma 12 states that the angle class $[(i+1)\cdot\frac{\pi}{k}, (i+2)\cdot\frac{\pi}{2k})$ (left, red) will be sent into the angle class $[\frac{\pi}{12}, \frac{5\pi}{12})$ (right, red).

Next, we use Lemma 12 to show that there is a staircase path in the graph $T_i(G_i)$.

▶ **Lemma 13.** *If* $\sphericalangle(T_i(a)T_i(b)) \in [\frac{\pi}{12}, \frac{5\pi}{12})$, *then there is an* xy*-monotone axis-parallel path from* $T_i(a)$ *to* $T_i(b)$ *in the graph* $T_i(G_i)$.

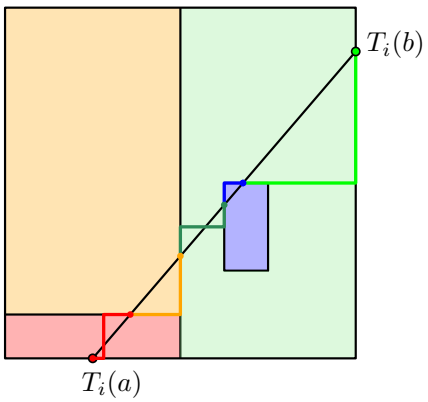

Figure 8 Replacing $T_i(a)T_i(b) \cap \tau$ with an xy-monotone axis-parallel path, for each tile τ.

Proof sketch. We trace the segment $T_i(a)T_i(b)$ across the tiles in the Balanced Box Decomposition of $T_i(P)$, and within each tile, we replace the segments in $T_i(a)T_i(b) \cap \tau$ with xy-monotone axis-parallel paths in $T_i(G_i)$. Let $cd \in T_i(a)T_i(b) \cap \tau$ be a segment connecting boundary points of τ. We have four cases, where the colors refer to Figure 8:

1. (Orange, Blue) c and d are on the outer boundary and cd connects adjacent sides of τ.
2. (Red) c and d are on the outer boundary and cd connects opposite sides of τ.
3. (Light green) c lies on the inner boundary and cd connects perpendicular sides of τ.
4. (Dark green) c lies on the inner boundary and cd connects parallel sides of τ.

In Cases 1 and 3, constructing the axis-parallel path is relatively straightforward, we can follow the outer boundary, or the extension of the inner boundary and the outer boundary. In Cases 2 and 4, we prove that Lemma 12, in combination with the $K = 100$ constructed horizontal and vertical lines, is sufficient to obtain the "Z-shaped" paths in Figure 8. ◀

The final step is to observe that, since there is an xy-monotone axis-parallel path from $T_i(a)$ to $T_i(b)$ in $T_i(G_i)$, by reversing the transformation T_i, we obtain a cone restricted path from a to b in G. By Lemma 9, the length of this path is at most $(1+\varepsilon)|ab|$. Therefore, G is a $(1+\varepsilon)$-spanner.

Number of Steiner points. A Steiner vertex is inserted at each edge crossing between edges in G_i and G_j, where $1 \le i < j \le k = O(\sqrt{1/\varepsilon})$. The next lemma will help bound the number of crossings between edges in G_i and G_j. In this lemma, we will assume that ε is sufficiently small and thus k is sufficiently large, so that $\sin \frac{3\pi}{k} = \Omega(\frac{1}{k})$.

▶ **Lemma 14.** *Let $1 \le i < j \le k = O(\sqrt{1/\varepsilon})$, and e be an edge of G_i. Then G_j contains at most $O(\sqrt{1/\varepsilon})$ edges that both (i) intersect e and (ii) are at least as long as e.*

Proof. Let τ be a tile in the Balanced Box Decomposition of $T_j(P)$. Let the outer rectangle of τ have height h and width w. Recall that T_j sends the unit vectors in the directions $i \cdot \frac{\pi}{k}$ and $(i+3) \cdot \frac{\pi}{k}$ to the unit x- and y-vectors. Therefore, the inverse transformation $T_j^{-1}(\tau)$ sends the axis-parallel rectangle τ to a parallelogram. The side lengths are preserved, but the angle between the sides is not. Specifically, $T_j^{-1}(\tau)$ is a parallelogram with side lengths h and w, and two of the four angles of the parallelogram are $\frac{3\pi}{k}$. The area of the parallelogram is $hw \cdot \sin \frac{3\pi}{k}$.

Next, we will bound the number of tiles τ where $T_j^{-1}(\tau)$ intersects e, and where one of the sides of τ is at least as long as e. Let this set of tiles be J. Each tile $\tau \in J$ has aspect ratio at most three, so both sides of τ must be at least a third of the length of e. Consider the disk centered at the midpoint of e, with radius twice the length of e. The area of this disk is $4\pi|e|^2$. Each parallelogram $T_j^{-1}(\tau)$, where $\tau \in J$ intersects e, has side lengths $\ge \frac{|e|}{3}$, and has a smallest angle equal to $\sin \frac{3\pi}{k}$. So each parallelogram $T_j^{-1}(\tau)$ covers a region of area $\Omega(|e|^2/k)$ in the interior of the ball, since $\sin \frac{3\pi}{k} = \Omega(\frac{1}{k})$ for $k \ge 1$. Moreover, the parallelograms $T_j^{-1}(\tau)$ cover disjoint regions since the tiles $\tau \in J$ are disjoint. Therefore, there are $O(k)$ tiles in J.

Finally, each edge of G_j that intersects e and are at least as long as e must lie inside some tile in J. Moreover, every tile in J contains only $O(K^2) = O(1)$ edges. Therefore, since there are $O(k)$ tiles satisfying the desired property, there are also $O(k) = O(\sqrt{1/\varepsilon})$ edges satisfying the desired property. ◀

For every edge e in G_i, there are $O(\sqrt{1/\varepsilon})$ edges in G_j that are longer than e and cross e. So there are $O(1/\varepsilon)$ edges in $\bigcup_j G_j$ longer than e and crossing e. Next, we count the total number of edge crossings between G_i and G_j for $1 \le i, j \le k$. We charge each edge crossing to the shorter edge. There are $O(n/\sqrt{\varepsilon})$ possible choices for the shorter edge, and $O(1/\varepsilon)$ possible choices for the longer edge. Therefore, $\bigcup_i G_i$ has $O(n/\varepsilon^{3/2})$ edge crossings and our noncrossing Steiner $(1+\varepsilon)$-spanner has the same number of Steiner points.

Running time analysis. Computing the Balanced Box Decomposition for n points in the plane takes $O(n \log n)$ time [11]. Each tile can be subdivided into $O(1)$ rectangles in $O(1)$ time. So each G_i can be computed in $O(n \log n)$ time. All G_i's can be computed in $O((n \log n)/\sqrt{\varepsilon})$ time. Finally, we compute the edge crossings and thus the Steiner points. All crossings

among m segments can be computed in $O(m \log m + s)$ time, where s is the number of crossings [13, 32]; also see [14, Chapter 2]. With $m = O(n/\sqrt{\varepsilon})$ and $s = O(n/\varepsilon^{3/2})$, the overall running time is bounded by $O((n \log n)/\varepsilon^{3/2})$.

Putting this all together, we obtain the following theorem.

▶ **Theorem 3.** *For every $\varepsilon > 0$ and every set of n points in Euclidean plane, there is a noncrossing Steiner $(1+\varepsilon)$-spanner with $O(n/\varepsilon^{3/2})$ Steiner vertices. Furthermore, there is such a spanner that is cone-restricted, and can be computed in $O((n \log n)/\varepsilon^{3/2})$ time.*

4 Conclusion and Future Directions

We studied Problem 1 on the minimum number of Steiner points required to construct a noncrossing Euclidean $(1+\varepsilon)$-spanner, thereby almost resolving Open Problem 17 from the survey of Bose and Smid [27]. Our lower and upper bounds, $\Omega_\mu(n/\varepsilon^{3/2-\mu}) \le s(n,\varepsilon) \le O(n/\varepsilon^{3/2})$, match up to a subpolynomial factor in ε.

An important direction for future work is to understand the trade-off between planarity, *total weight*, and the number of Steiner points. In particular, known constructions have not been analyzed in terms of lightness, and it remains open whether one can achieve near-optimal weight while retaining asymptotically optimal sparsity in noncrossing Steiner $(1+\varepsilon)$-spanners.

As discussed in Section 1, the number of *edge crossings* is another structural measure of complexity for geometric (*non-Steiner*) spanners. It remains an open problem whether a tighter analysis of the number of crossings in a (greedy) $(1+\varepsilon)$-spanner could potentially match our upper bound $O(n/\varepsilon^{3/2})$: Determine the minimum $c(n,\varepsilon)$ such that every set of n points in the plane admits a (non-Steiner) $(1+\varepsilon)$-spanner with at most $c(n,\varepsilon)$ edge crossings.

We observe that the $(1+\varepsilon)$-stretch constraint is essential for obtaining meaningful bounds. If the stretch requirement is relaxed and one merely requires that each ab-path lies inside the ellipse $\mathcal{E}_{ab}$, then for the basic example (Section 2) with $n = \Theta(\sqrt{1/\varepsilon})$ points, a grid of side length $\sqrt{\varepsilon}$ already yields a solution with $n/\sqrt{\varepsilon}$ Steiner points, but the stretch increases to $\sqrt{2}$. The approximation of straight-line segments using grid paths that satisfy additional nondegeneracy conditions is related to the literature on *digital segments* [35, 36].

Finally, the connection to disk-tube incidences raises another intriguing open problem: How many Steiner points are required to construct a noncrossing geometric graph for a set P of n points in the plane if, instead of the spanner condition, for every $a, b \in P$, one requires an ab-path whose Fréchet distance from the straight-line segment ab is at most ε?

Abstract

We consider the problem of reconfiguring non-crossing spanning trees on point sets. For a set P of n points in general position in the plane, the flip graph $\mathcal{F}(P)$ has a vertex for each non-crossing spanning tree on P and an edge between any two spanning trees that can be transformed into each other by the exchange of a single edge (coined a flip). This flip graph has been intensively studied, lately with an emphasis on determining its diameter $\operatorname{diam}(\mathcal{F}(P))$ for sets P of n points in convex position. For this case, the current best bounds are $14/9 \cdot n - O(1) \leq \operatorname{diam}(\mathcal{F}(P)) < 15/9 \cdot n - 3$, obtained in a recent breakthrough work [Bjerkevik, Kleist, Ueckerdt, and Vogtenhuber; SODA 2025]. The crucial tool for both the upper and lower bound are so-called *conflict graphs*, which the authors stated might be the key ingredient for determining the diameter (up to lower-order terms).

In this paper, we pick up the concept of conflict graphs from the above-mentioned work and show that this tool is even more versatile than previously hoped. As our first main result, we use conflict graphs to show that computing the flip distance between two non-crossing spanning trees is NP-hard, even for point sets in convex position. Interestingly, the result still holds for more constrained flip operations, concretely, compatible flips (where the removed and the added edge do not cross) and rotations (where the removed and the added edge share an endpoint).

Additionally, we present new insights on the diameter of the flip graph, by this directly extending the line of research from [BKUV SODA25]. Their lower bound is based on a constant-size pair of trees, one of which is of a type we refer to as *stacked*. We show that if one of the trees is stacked, then the lower bound is indeed optimal up to a constant term, that is, there exists a flip sequence of length at most $14/9 \cdot (n-1)$ to any other tree.

Lastly, we improve the lower bound on the diameter of the flip graph $\mathcal{F}(P)$ for n points in convex position to $11/7 \cdot n - o(n)$.

1 Introduction

Non-crossing configurations such as triangulations, spanning trees, matchings, or polygonizations on planar point sets are fundamental structures in computational geometry, with wide applications. In dynamic environments or interactive settings, it is often necessary to transform one configuration into another through a sequence of local modifications, while ensuring that the non-crossing property is preserved at every step and that the intermediate configurations are of the same type. This process, known as (discrete) reconfiguration, raises natural algorithmic questions: Given two non-crossing configurations, is it possible to convert one into the other using only basic operations? If so, it is of interest to bound the length of a shortest reconfiguration sequence between any two configurations, to compute the length of an optimal sequence between two given configurations, and to efficiently determine a short(est) sequence.

These questions can be nicely rephrased in terms of a so-called *flip graph*. The flip graph of a discrete reconfiguration problem has a vertex for each configuration and an edge between any two configurations that can be transformed into one another by a single basic discrete operation, called a *flip*. In terms of the flip graph, the above-mentioned three questions then read as follows: Is the flip graph connected? What is the diameter of the flip graph? Can a shortest path (flip sequence) between two vertices of the flip graph be computed efficiently?

For many types of geometric graphs, the most classical flip operation is the exchange of one edge with another edge, see also Figure 1. For instance, it is known that the flip graph of triangulations on a set of n points in the plane in convex position [31] and has diameter exactly $2n - 10$ [35, 36]. For decades, it has been a tantalizing and important open problem in theoretical computer science whether a shortest flip sequence between two triangulations of a convex point set can be computed in polynomial time. This problem is equivalent to the complexity of computing the rotation distance between two rooted binary trees.

In this work, we consider flips between non-crossing geometric spanning trees. Let P denote a set of n points in the plane in general position, that is, no three points of P are collinear. A *non-crossing spanning tree on* P is a spanning tree that has P as its vertex set and whose edges are pairwise non-crossing straight-line segments. A *flip* in a non-crossing spanning tree T on P is the exchange of one edge of T by a different one such that the resulting graph is again a non-crossing spanning tree T' on P; see Figure 1 for an example. The according flip graph $\mathcal{F}(P)$ has a vertex for each non-crossing spanning tree on P and an edge between any two trees whenever they can be transformed into each other by a single edge flip. For two trees T and T' on P, we denote their flip distance, the length of a shortest path between T and T' in $\mathcal{F}(P)$, by $\mathrm{dist}(T, T')$.

In 1996, Avis and Fukuda [10] showed in their famous reverse search paper that $\mathcal{F}(P)$ is connected for any n-point set P in general position, and that its radius is bounded from above by $n-2$, implying $\mathrm{diam}(\mathcal{F}(P)) \leq 2n-4$. In 1999, Hernando, Hurtado, Márquez, Mora,

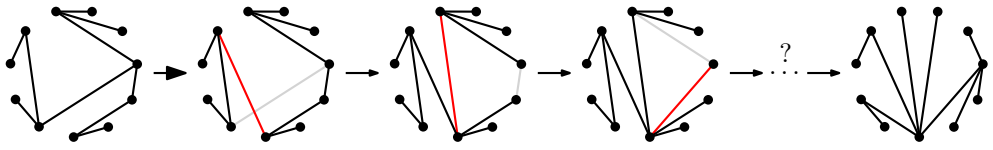

Figure 1 Reconfiguration of non-crossing spanning trees on convex point sets by edge exchange. The appearing edge is highlighted in red and the disappearing edge in gray. Can you complete the sequence to obtain the tree on the right? How many further flips are needed?

and Noy [25] showed that for convex n-point sets P, it holds that $\operatorname{diam}(\mathcal{F}(P)) \geq \lfloor 3/2 \cdot n \rfloor - 5$. Since then, the flip graph $\mathcal{F}(P)$ of non-crossing geometric spanning trees on point sets P in convex position has been subject of intensive study; see the discussion in Section 1.1 below for some details. For a long time, it was conjectured that the true value for its diameter should be $3/2 \cdot n + c$ for some constant c. Very recently, Bjerkevik, Kleist, Ueckerdt, and Vogtenhuber [13] refuted this conjecture by obtaining the currently best known bounds of $14/9 \cdot n + O(1) \leq \operatorname{diam}(\mathcal{F}(P)) \leq 15/9 \cdot n - O(1)$ for the diameter of the flip graph on non-crossing spanning trees on point sets in convex position. The crucial tool for both the upper and lower bound are so-called *conflict graphs*, which the authors introduced and stated might be the key ingredient for determining the diameter of the flip graph of spanning trees for point sets in convex position (up to lower-order terms). Their lower bound is based on a constant-size example containing a tree belonging to a family of trees that we call *stacked*.

In this work, we pick up the concept of conflict graphs from [13] and show that this tool is even more versatile than previously hoped. We prove that the flip distance between two trees can be as high as $11/7 \cdot n - o(n)$, by this directly extending the line of research from [13].

▶ **Theorem 1.** *For any set P of $n \geq 3$ points in convex position, the flip graph $\mathcal{F}(P)$ of non-crossing spanning trees on P has diameter at least $(11/7 - o(1))n$.*

We further show that if one of the trees is stacked, then the lower bound from [13] is indeed the best possible. In other words, whenever one of the trees is stacked, then there exists a flip sequence of length at most $14/9 \cdot n - O(1)$ to any other tree.

▶ **Theorem 2.** *Let T, T' be non-crossing trees on $n \geq 3$ points in convex position. If T is a stacked tree, then $\mathit{dist}(T, T') \leq \frac{14}{9}(n-1)$.*

Moreover, we use conflict graphs beyond the expectations of [13], showing that they can also be used to prove that computing the flip distance between two non-crossing spanning trees is NP-hard, even for point sets in convex position.

▶ **Theorem 3.** *Given two non-crossing spanning trees T, T' on a point set and an integer δ, the decision problem of whether there exists a flip sequence of length at most δ between T and T' is NP-complete, even for point sets in convex position.*

Interestingly, this result still holds for more constrained flip operations, concretely, *compatible* flips (where the removed and the added edge do not cross) and *rotations* (where the removed and the added edge share an endpoint). In Figure 1, while the first flip is just an edge exchange, the second flip a compatible flip, and the third flip is a rotation.

▶ **Theorem 4.** *Given two non-crossing spanning trees T, T' on a point set and an integer δ, the decision problem of whether there exists a compatible flip sequence / a rotation sequence of length at most δ between T and T' is NP-complete, even for point sets in convex position.*

We point out that the latter two statements constitute the first hardness results for flip graphs on point sets in convex position. Moreover, Theorem 4 refutes the long-held belief that the flip distance can be computed in polynomial time when the so-called happy edge property holds, because that property holds for compatible flips of non-crossing spanning trees on convex point sets. See Section 1.1 for more background and Table 1 for an overview of complexity status for various flip graphs of non-crossing structures on point sets.

Outline. We discuss further related work in Section 1.1 and introduce the central concepts from [13] that are required for our work in Section 2. In Section 3, we prove NP-completeness for deciding the length of a shortest (general, compatible, or rotational) flip sequence between

Table 1 Overview of complexity results. Results obtained in this work are marked by [*].

two spanning trees on a convex point set. In Section 4, we show that the flip distance between two trees on a convex n-point set is at most $14/9 \cdot (n-1)$ if one of them is stacked. In Section 5, we improve the lower bound on the diameter of the tree flip graph for n points in convex position to $(11/7 - o(1))n$. We conclude with a summary and open problems in Section 6. Full details and proofs of all statements marked by ($\star$) can be found in the arXiv version of our paper [12].

1.1 Related work

We review the related work in two aspects, concerning the connectedness and diameter bounds on the one hand, and the computational complexity of computing a shortest flip sequence on the other hand.

Connectedness and Diameter. For triangulations, connectedness of the flip graph for point sets was shown by Lawson [31] and for simple polygons by Hurtado, Noy, and Urrutia [28]. In both cases, the diameter of the flip graph is in $O(n^2)$. Hurtado, Noy, and Urrutia [28] provided a matching lower bound of $\Omega(n^2)$ for both settings. For triangulations of convex point sets, Sleator, Tarjan, and Thurston [36] showed that the diameter of the flip graph is at most $2n - 10$, which is tight for $n > 13$ as proven by Pournin [35]. There are many more results on flips in triangulations; see for example [21–24, 27, 37–39].

For non-crossing spanning trees of point sets in general position, Avis and Fukuda [10] showed that the flip graph is connected for flips, compatible flips, and rotations, and has a diameter at most $2n - 4$. Nichols, Pilz, Tóth, and Zehmakan [33] gave an upper bound on the diameter of $O(n \log(n))$ for empty triangle rotations. Aicholzer, Aurenhammer, and Hurtado [1] proved that the flip graph is connected for edge slides (where the source and the target edge together with some other edge of the tree form an empty triangle). They also provided an exponential upper bound on the diameter, which was later improved to $O(n^2)$ by Aichholzer and Reinhart [8]. For point sets in convex position, determining the exact diameter of the flip graph has gained considerable attention in the last couple of years. Starting from the benchmark upper bound of $2n - 4$ [10] and the conjectured to be essentially tight lower bound of $\lfloor 3n/2 \rfloor - 5$ [25], the upper bound was subsequently improved

[1] In a very recent arXiv preprint, Dorfer [20] announced that computing the flip distance between triangulations of convex point sets is NP-complete. This (potential since not yet reviewed) result was inspired by and initiated after the submission of the work at hand, and uses similar techniques: Introducing a notion of conflict graphs, showing that the flip distance is closely tied to the size of a largest acyclic subset, and proving NP-hardness of computing the largest acyclic subset.

to $2n - \log(n)$ [2] and $2n - \sqrt{n}$ [16]. The leading constant factor of 2 was broken by Bousquet, de Meyer, Pierron, and Wesolek [15], who improved the upper bound to $1.96n$. The latest advancement before the work at hand is due to the recent work [13], which improved the upper bound to $5/3 \cdot n - 3$ and the lower bound to $14/9 \cdot n - O(1)$. We note that the lower bound of $14/9 \cdot n - O(1)$ is not only the best bound for points in general position, but also holds for restricted flip types. When restricting the flips to compatible flips or rotations in the convex setting, the best standing upper bounds on the diameter of the flip graphs of spanning trees are $5/3 \cdot n - 2$ and $7/4 \cdot (n-1)$, respectively, due to Aichholzer, Dorfer, and Vogtenhuber [5].

For plane spanning paths, connectedness of the flip graph is an interesting open problem. So far, the flip graph has been shown to be connected for convex point sets [9] (with diameter $2n - 6$ for $n > 4$ [18]), wheel sets and double circles [6], as well as point sets with two convex layers [30]. For matchings, the connectedness problem becomes a parity issue: While the flip graph of odd matchings is known to be connected [3], the connectedness of the flip graph remains an open question for perfect matchings. Partial progress has been made for convex point sets by Hernando, Hurtado, Noy [26] and for the case when an unbounded number of edges can be exchanged by Houle, Hurtado, Noy, and Rivera-Campo [27].

Computational complexity of shortest flip sequences and the happy edge property. In several settings, there is a close connection between the existence of NP-hardness proofs or polynomial-time algorithms and the happy edge property. A reconfiguration problem has the *happy edge property* if edges that are in the initial as well as the target configuration (and thus are *happy*) can remain in the configuration throughout the entire flip sequence.

The happy edge property holds for triangulations of point sets in convex position [36], but not for triangulations of general point sets or polygons [14]. The latter fact was used to show that the flip distance problem for triangulations of point sets and polygons is NP-complete [7,32] and also APX-hard on point sets [34]. In contrast, on point sets without empty convex pentagons, the flip distance can be computed in polynomial time [21]. If we consider point sets in convex position, the flip graph is the 1-skeleton of a famous polytope, the *associahedron*. For the more general case of graph associahedra [19], the shortest path problem has been recently shown to be NP-hard [29]. Finding shortest paths in the associahedron or equivalently shortest flip sequences between triangulations of convex point sets might also be hard by a very recent arXiv preprint [20].

In the case of perfect matchings on general point sets, NP-hardness of computing a shortest flip sequence was shown via counterexamples to the happy edge property [11]. For convex point sets, the happy edge property holds and the flip distance between two matchings can be determined in linear time [26]. Similarly, for the reconfiguration of odd matchings on general point sets, the happy edge property also does not hold and the flip distance is NP-hard to compute [3].

All these results support the long standing belief that the happy edge property is tied to the complexity of graph reconfiguration problems: If the happy edge property holds, then the problem is supposedly easy to solve. If it doesn't hold, the problem should be hard to solve.

Most recently, this pattern has been broken, when Aichholzer and Dorfer [4] provided a linear time algorithm to determine the flip distance between non-crossing spanning paths of convex point sets, despite the existence of counterexamples to the happy edge property. What remained open (until now) is the other direction: Is there a graph reconfiguration problem for which it is NP-hard to compute the flip distance, even though the problem has the happy edge property? We give an affirmative answer to this question in this work: The happy edge property holds for compatible flips on non-crossing spanning trees on convex point sets [5], but the flip distance is NP-hard to compute as shown in Theorem 4.

2 Fundamental concepts: Edge pairs, conflict graphs, and blowups

Our results build on insights from Bjerkevik, Kleist, Ueckerdt, and Vogtenhuber [13]. In the following, we introduce some of their concepts.

Linear Representation. A convex point set is usually visualized by equally spaced points on a circle. A *linear representation* of a non-crossing tree T on a convex point set is constructed by cutting open the circle and unfolding the points into a horizontal line segment, called the spine. Edges in T can be illustrated nicely by semi-circles connecting their end points above the spine. Given two trees (for example the initial tree and the target tree of a flip sequence) in the same linear representation, it is convenient to represent the edges of one tree above the spine and the edges of the other tree below the spine. For an example, see Figure 2. If an edge between two consecutive vertices on the spine is contained in both trees we will in later parts of the paper depict this by drawing it as a straight line between the two vertices instead of two semicircles.

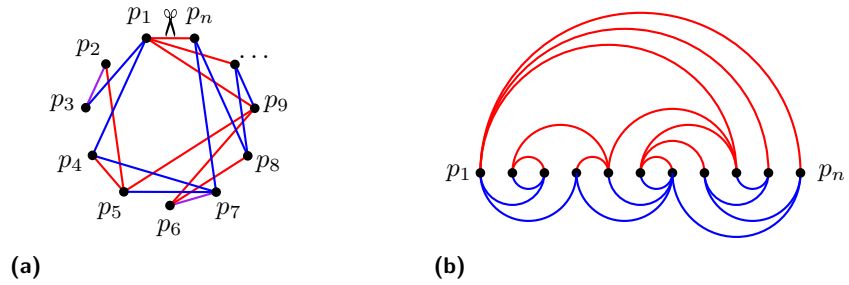

Figure 2 Figure reproduced from [13]. a Two non-crossing trees T, T' on a circularly labeled point set in convex position and b its linear representation with T above and T' below the spine.

By labeling the vertices along the linear representation by $p_1, ..., p_n$, we get a natural notion of the *length* of an edge. Concretely, the length of the edge p_ip_j is defined as $|i - j|$. We say a point p_k is *covered* by an edge p_ip_j with $i < j$ if $i \leq k \leq j$. An edge *covers* another edge if it covers both of its endpoints.

Gaps and Edge Pairing. A *gap* in the convex hull is the open line segment between two consecutive points p_i and p_{i+1} on the spine. For every tree T, there is a natural *gap-edge bijection* between gaps in the linear representation and edges of T: Each gap is assigned to the shortest edge that covers the gap. This assignment is indeed a bijection by Lemma 3.1 in [13]. For an example, consider Figure 3a. Based on the assigned gap, edges of T are partitioned into three groups. In particular, an edge is *short* if it shares both vertices with its gap, *near* if it shares one vertex with its gap, and *long* if shares no vertex with its gap.

For two trees T and T', we obtain an edge-edge bijection by pairing two edges that are assigned to the same gap of the linear representation. The authors of [13] explain how to handle nine types of edge pairs. For our results it is sufficient to concentrate on near-near pairs where the two edges are distinct. We call a gap g_i with edges e_i from T and e'_i from T'

above if e_i and e'_i are adjacent and e_i is longer than e'_i, see Figure 3b.

below if e_i and e'_i are adjacent and e_i is shorter than e'_i, see Figure 3c.

crossing if e_i and e'_i are not adjacent, equivalently, the two edges cross if drawn in the same convex point set, see Figure 3d.

The set of all above, below, and crossing gaps is denoted by A, B, and C, respectively.

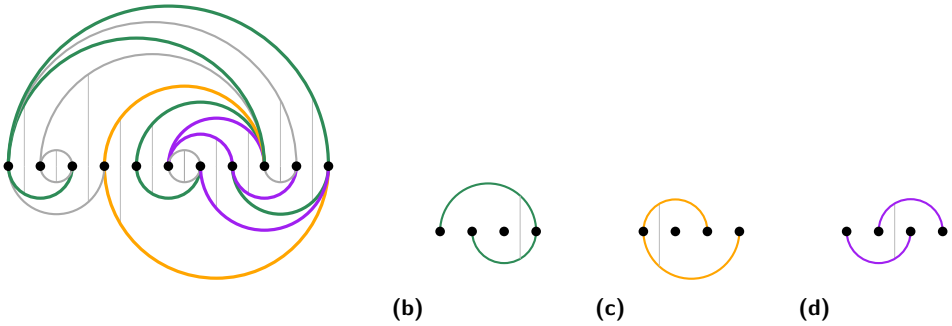

Figure 3 a Illustration of the gap-edge and edge-edge bijection. Examples of an above b, a below c, and a crossing pair d. Edges belonging to near-near pairs in A, B, and C are colored green, orange, and purple, respectively (also in several other figures).

Conflict Graphs. *Conflict graphs* were introduced as a tool to find the largest set of near-near pairs where the initial edge can be flipped directly to the target edge. The conflict graph H has a vertex for each (gap associated to a) near-near pair and a directed edge from a pair (e_i, e_i') to (e_j, e_j') if the edge e_i needs to be removed before the flip that adds e_j' and removes e_j can be performed. We denote the set of vertices in H by $V(H)$. There exist three types of conflicts. Specifically, there is a directed edge $\overrightarrow{g_i g_j}$ in H, from g_i to g_j if

type 1 e_i crosses e_j', see Figure 4a.

type 2 e_j' covers e_i and e_i covers g_j, see Figure 4b.

type 3 e_i covers e_j' and e_j' covers g_i, see Figure 4c.

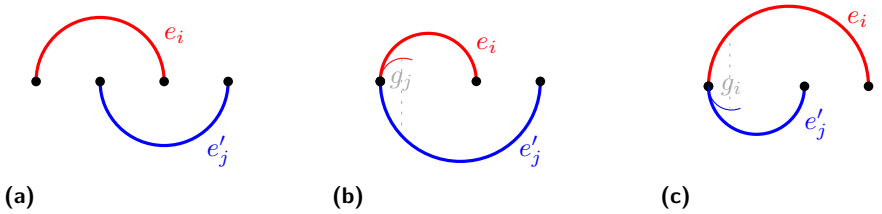

Figure 4 Figure reproduced from [13]. Examples of conflicts: a type 1, b type 2, c type 3.

We slightly abuse terminology and view the vertices of H interchangeably as gaps and as near-near pairs. Let $\mathrm{ac}(H)$ denote the largest number of vertices in H which induce an acyclic subgraph. The authors of [13] derive the following relations between acyclic sets in the conflict graph and flip distances.

▶ **Theorem 5** ([13, Theorem 2.1]). *Let T, T' be two non-crossing trees on linearly ordered points $p_1, \ldots, p_n$ with corresponding conflict graph $H = H(T, T')$.*

(i) *If $V(H)$ is non-empty, then* $\mathrm{dist}(T, T') \leq \max\{\frac{3}{2}, 2 - \frac{\mathrm{ac}(H)}{|V(H)|}\}(n-1)\}$. *If $V(H)$ is empty, then* $\mathrm{dist}(T, T') \leq \frac{3}{2}(n-1)$.

(ii) *If $V(H)$ is non-empty, then there is a constant c depending only on T and T' such that for all $\bar{n} \geq 1$, we have* $\mathrm{diam}(\mathcal{F}_{\bar{n}}) \geq \left(2 - \frac{\mathrm{ac}(H)}{|V(H)|}\right)\bar{n} - c$.

Moreover, we will use the following lemma on the sets of above, below, and crossing gaps.

▶ **Lemma 6** ([13, Lemma 3.2]). *Each of A, B, and C is an acyclic set of H.*

Blowups. By default, a flip sequence based on the described edge-edge bijection is not necessarily a shortest one and can in fact be very far from optimal. The authors of [13] overcome this by introducing *blowups* for near-near pairs. For trees T and T', the β-blowup is a pair of trees $\beta \cdot T$ and $\beta \cdot T'$ obtained by the following construction. For every gap g that corresponds to a near-near pair (e, e'), insert a set $V(e) = V(e')$ of β additional points in the gap g. In $\beta \cdot T$ add an edge from each $v \in V(e)$ to the endpoint of e that is not adjacent to g. Proceed similarly in $\beta \cdot T'$ for e'. Part (ii) of Theorem 5 is obtained by considering blowups.

▶ **Lemma 7** ([13, Lemma 23, arXiv-Version]). *The flip distance from $\beta \cdot T$ to $\beta \cdot T'$ is at least $(\beta - 2n)(2|V(H)| - \mathrm{ac}(H))$, where $H = H(T, T')$.*

3 NP-Completeness results

In this section we sketch proofs for our hardness results. Theorem 3 states that the decision problem of whether there exists a flip sequence of length at most δ between two non-crossing spanning trees T, T' is NP-complete. In fact, this holds even for point sets in convex position. Our proof of Theorem 3 goes via an intermediate problem. Specifically, we show that it is NP-complete to decide whether a directed graph H has an acyclic subset of size at least k, even if H is the conflict graph of two non-crossing trees with a given linear representation.

▶ **Proposition 8.** *Given two non-crossing trees T, T' on a convex point set, with a linear representation and corresponding non-empty conflict graph $H = H(T, T')$, as well as an integer k, it is* NP*-complete to decide whether* $\mathrm{ac}(H) \geq k$.

Our proof of Proposition 8 is a reduction from the NP-complete problem Planar Max-2SAT. We consider a restricted version [17], in which we are given a 2SAT-formula ϕ with variable-set X and clause-set $\mathcal{C}$ whose vertex-clause incidence graph G_ϕ admits an *aligned drawing*, namely, a drawing with all variables on a horizontal line L and no edge crossing L or any other edge. In particular, every clause lies either in the upper or lower halfplane defined by L. Additionally given an integer t, Planar Max-2SAT asks whether X admits a truth assignment such that at least t clauses in $\mathcal{C}$ are satisfied.

For fixed ϕ and t, we construct two non-crossing trees T, T' with a linear representation and an integer k such that the following are equivalent:

- The conflict graph $H = H(T, T')$ admits an acyclic subset of size at least k.
- The 2SAT-formula ϕ admits a truth assignment that satisfies at least t clauses.

To construct T and T', we model the variables and clauses in ϕ with small gadgets. In doing so, we also discuss the conflicts that occur. Recall that each gap has a type: above, below, or crossing. In fact, it will be enough for us to focus on the *mixed conflicts*, i.e., those between gaps of different types. We also remark that our construction only has conflicts $\overrightarrow{g_i g_j}$ of type 1, i.e., where e_i properly crosses e'_j as illustrated in Figure 4a.

Let $x \in X$ be a variable and $d = \deg(x)$ be its degree in G_ϕ, i.e., x occurs (negated or non-negated) in exactly d clauses. The variable-gadget for x consists of $8d + 1$ pairs of edges, of which $6d$ are near-near pairs and hence their corresponding $6d$ gaps are vertices in the conflict graph $H = H(T, T')$. The gadget is illustrated in Figure 5a and the corresponding mixed conflicts in Figure 5b. The $6d$ gaps form a path P of double conflicts in the conflict graph H, i.e., every acyclic subset is an independent set in P. We partition P into two independent sets $t(x)$ and $f(x)$ by alternating the gaps in $t(x)$ and $f(x)$ along P. Later we ensure that every acyclic subset S of H with $|S| \geq k$ either contains all of $t(x)$ or all of $f(x)$, which encodes the two possible truth assignments True and False for variable x.

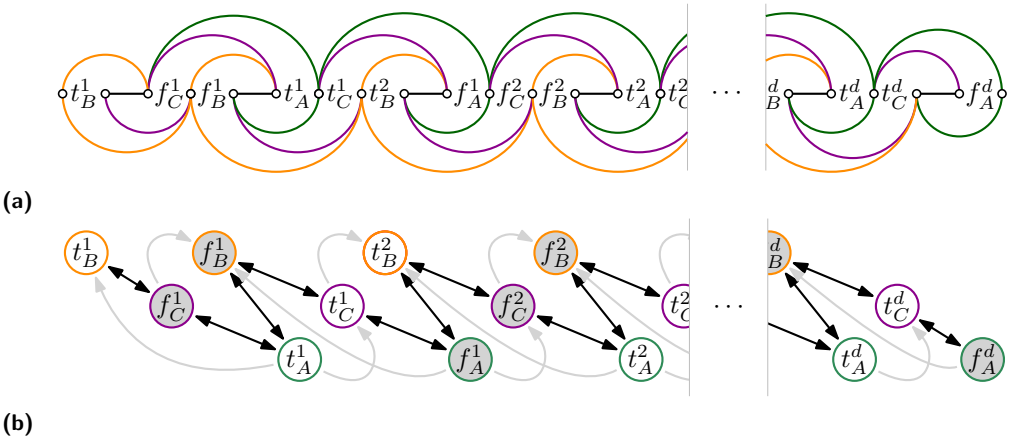

Figure 5 Illustration of a variable-gadget and the graph of its mixed conflicts.

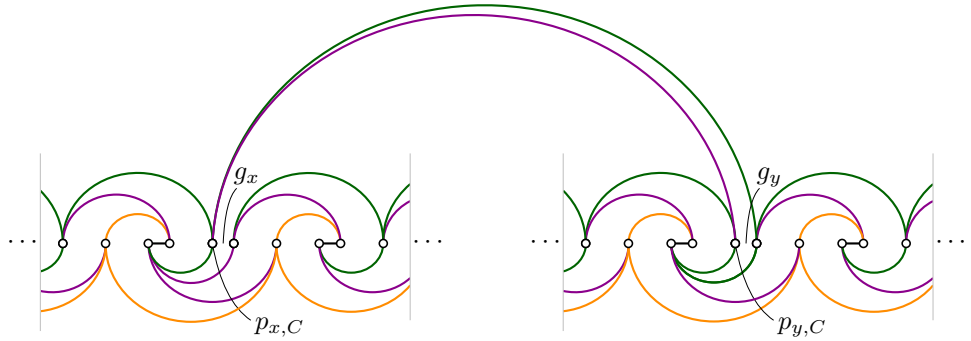
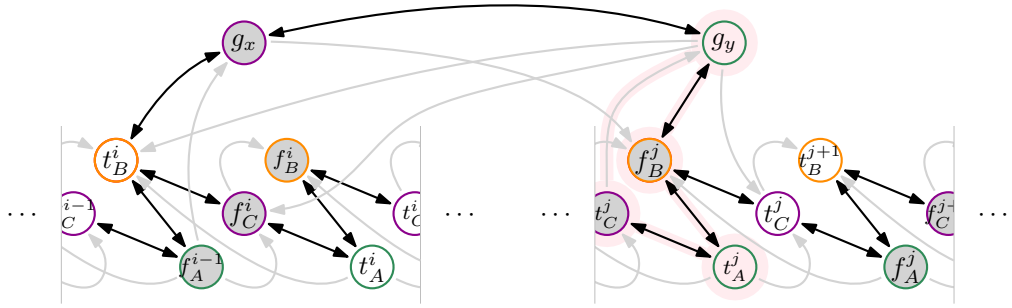
We place each variable-gadget at the position of the corresponding variable in the aligned drawing of G_ϕ in such a way that the rightmost point of any gadget coincides with the leftmost point of the next gadget (immediately to the right). Secondly, for each clause C with incident variables x and y we introduce a new gap g_x in the variable-gadget of x and a new gap g_y in the variable-gadget of y. For each $z \in \{x, y\}$, the edge pair for g_z has an edge of length 3 in the variable-gadget of z and an edge connecting the gadgets of x and y. See Figures 6a and 7a for an illustration. To ensure that different clause-gadgets do not cross, long edges are put in the halfplane that contains the clause C in the aligned drawing of G_ϕ. Further, the position of g_z on the path P of length $6\deg(z)$ in the variable-gadget of z is chosen with respect to the order of incident edges at z in the drawing of G_ϕ.



Moreover, g_z is chosen such that it has a double conflict with a gap in $t(z)$ if z appears negated in C, and a double conflict with a gap in $f(z)$ if z appears non-negated in C. This ensures that an acyclic set S contains the gap g_z only if the truth assignment of variable z satisfies the clause C. A double conflict between the two gaps g_x, g_y of the clause-gadget ensures that at most one of g_x, g_y is in any acyclic set S. There are six further mixed conflicts between g_x, g_y and the variable-gaps, as illustrated in Figures 6b and 7b. Given a truth assignment, we choose all of $t(x)$ when x is True, $f(x)$ when x is False, and one gap g_z in each satisfied clause. That this gives an acyclic subset S of $H(T, T')$, relies on the following observation.

▶ **Observation 9.** *For every mixed conflict $\overrightarrow{g_1 g_2}$ one of the following holds:*



- *g_1 is above*
- *g_2 is below*
- *g_1 and g_2 have a double conflict*
- *there is a g_1-g_2-path of three double conflicts with three gaps of some variable-gadget*

In fact, each of the sets A, B, C of all above, all below, and all crossing gaps, respectively, is acyclic by Lemma 6. Thus with Observation 9 it follows that every set $S \subseteq V(H)$ with no double conflict and none of the exceptional conflicts in Observation 9 is acyclic by taking first $A \cap S$, then $C \cap S$, and finally $B \cap S$ for a topological ordering.

This way, every truth assignment satisfying t of ϕ corresponds to an acyclic set $S \subseteq V(H)$ containing exactly half of all variable-gaps and exactly t of all clause-gaps. Finally, for the other direction (getting a truth assignment from an acyclic subset S), we need to ensure that for every variable x we have $t(x) \subseteq S$ or $f(x) \subseteq S$, as long as S is large enough. To this end, let $m = |\mathcal{C}|$ and for each variable-gadget we apply an m-blowup to the first and last

(a)

(b)

Figure 6 Illustration of a clause-gadget for a clause above the horizontal line and its conflict graph. The special conflict corresponding to the last option in Observation 9 is highlighted.

gap, a $2m$-blowup to all other variable-gaps, while applying no blowup to the clause-gaps. See Figure 8 for an illustration. Setting $k = m(12m + 6 - |X|) + t$ concludes our reduction from Planar Max-2SAT and thus the proof of Proposition 8.

In order to finally prove Theorem 3, we now reduce the problem of finding large acyclic subsets in conflict graphs to the problem of finding short flip sequences in β-blowups.

▶ **Theorem 10.** *Let T and T' be two non-crossing spanning trees on n vertices with a linear representation and non-empty conflict graph $H(T, T')$, and $k > 0$ be an integer. Let $\beta = 4n^2 + 2n$. Then the following are equivalent.*

- *The conflict graph $H = H(T, T')$ has an acyclic subset of size at least k.*
- *The flip distance between $\beta \cdot T$ and $\beta \cdot T'$ is at most $(\beta+1)(2|V(H)| - k) + 2(n - |V(H)|)$.*

Proof. For convenience, let us denote $|H| = |V(H)|$. Assume H does not contain an acyclic set of size k, i.e., $\mathrm{ac}(H) < k$. Then by Lemma 7,

$$\begin{aligned}\mathrm{dist}(\beta \cdot T, \beta \cdot T') &\geq (\beta - 2n)(2|H| - \mathrm{ac}(H)) \geq (\beta + 1 - (2n + 1))(2|H| - k + 1)\\ &= (\beta + 1)(2|H| - k) + (\beta + 1) - (2n + 1)(2|H| - k + 1)\\ &> (\beta + 1)(2|H| - k) + 2(n - |H|).\end{aligned}$$

For the last inequality observe that $|H| < n$ and hence $(2n+1)(2|H|-k+1) \leq (2n+1)(2n-1) \leq 4n^2$, which together with $\beta = 4n^2 + 2n > 4n^2 + 2(n - |H|)$ gives the desired lower bound.

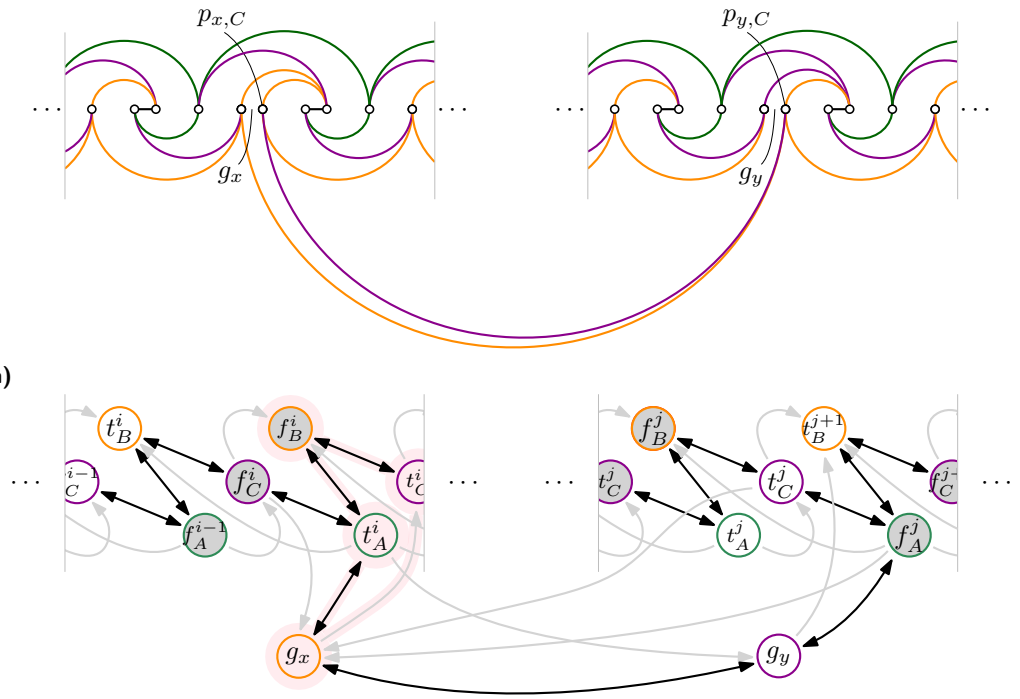


Figure 7 Illustration of a clause-gadget for a clause below the horizontal line and its conflict graph. The special conflict corresponding to the last option in Observation 9 is highlighted.

Conversely, assume $H = H(T, T')$ has an acyclic subset of size k, i.e., $\mathrm{ac}(H) \geq k$. Then, the conflict graph $H^\beta = H(\beta \cdot T, \beta \cdot T')$ of the blowup has an acyclic set of size $k \cdot (\beta + 1)$, i.e., $\mathrm{ac}(H^\beta) \geq k(\beta + 1)$. For the original trees T, T' we have n vertices and $n - 1$ gaps, of which $|H|$ are affected by the blowup. Thus, each of $\beta \cdot T$ and $\beta \cdot T'$ has $n + \beta|H|$ vertices and $n - 1 + |\beta|$ edges. Moreover, $|V(H^\beta)| = (\beta + 1)|H|$.

Using one flip for each edge pair in the largest acyclic subset and two flips for each other edge pair gives the desired bound of

$$\mathrm{dist}(\beta \cdot T, \beta \cdot T') \leq (\beta + 1)(2|H| - \mathrm{ac}(H)) + 2(n - 1 - |H|) < (\beta + 1)(2|H| - k) + 2(n - |H|).$$

and hence completes the proof. ◀

We remark that the proof of Theorem 10 produces a flip sequence that contains non-compatible flips. Next, we modify the proof to the case of flip sequences that contain only compatible flips or only rotations. In fact, a direct flip for an above pair or a below pair is already a rotation. Further, flipping any near edge to a short edge covering its associated gap is also a rotation. We do, however, need to deal with large collections of crossing edge pairs. To this end, we use the following fact.

▶ **Lemma 11** (⋆). *Let T, T' be two trees that differ in a single crossing pair. Then the rotation flip distance between $\beta \cdot T$ and $\beta \cdot T'$ is at most $\beta + 2$.*

With Lemma 11 in place, we prove that finding short compatible flip sequences and short rotation sequences is NP-hard as well. As before, we use the shorthand notation $|H| = |V(H)|$.

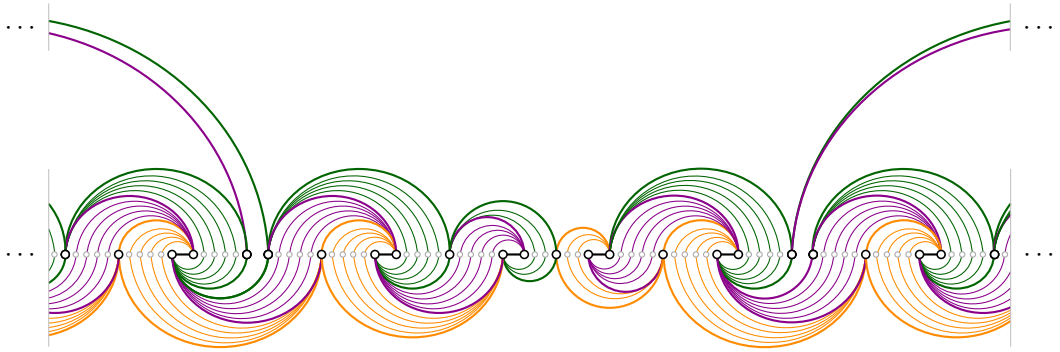

Figure 8 Applying an m-blowup (here $m = 2$) to the first and last gap of each variable-gadget and $2m$-blowups to all other gaps in variable-gadgets.

▶ **Theorem 12** ($\star$). *Let T and T' be two non-crossing spanning trees on n vertices with a linear representation, and $k > 0$ be an integer. Let $\beta = 4n^2 + 4n$. The following are equivalent.*

- *The conflict graph $H = H(T, T')$ has an acyclic subset of size at least k.*
- *The compatible flip distance* $\mathrm{dist}_{\mathrm{comp}}(\beta \cdot T, \beta \cdot T') \leq (\beta + 1)(2|H| - k) + |H| + 4(n - |H|)$.
- *The rotation flip distance* $\mathrm{dist}_{\mathrm{rot}}(\beta \cdot T, \beta \cdot T') \leq (\beta + 1)(2|H| - k) + |H| + 4(n - |H|)$.

4 Stacked Trees

In this section, we improve the upper bound for the special case where in one of the two trees, the (relevant) edges can be partitioned into independent "stacks" of nested edges. This can be seen as a first natural generalization of an upper bound where one tree is a separated caterpillar, that is, a tree with two stacks [13, Section 6, arXiv-Version]. Further, the top tree in the best previously known lower bound example in [13], depicted in Figure 9, has this property. Throughout this section, we refer to a non-crossing spanning tree on a convex point set in linear representation simply as a tree.

We call a tree T *stacked* if its edge set can be partitioned into sets $S_1, \ldots, S_k$ such that

(i) no edge in S_i covers an edge in S_j for $i \neq j$, and

(ii) each S_i is totally ordered by the covering relation.

Let T' be another tree on the same vertex set. We say that T is *stacked with respect to T'* if the subset N of edges in T that are in near-near pairs of (T, T') admits a partition into sets $S_1, \ldots, S_k$ satisfying properties (i) and (ii). Note that if T is stacked then it is stacked with respect to any T'. We refer to the edge sets S_i as *stacks (with respect to T')*.

4.1 The Special Case: Three stacks

Fix trees T and T'. We first assume that T has exactly three stacks S_1, S_2 and S_3 with respect to T'. Let $\mathcal{P}_N$ be the set of near-near pairs of (T, T'). We partition $\mathcal{P}_N$ into 9 different sets. A pair $(e, e') \in \mathcal{P}_N$ will be put into sets by the following rules.

- A_i if e belongs to stack S_i and (e, e') is an above pair.
- $B_{i,j}$, $i \neq j$ if e belongs to stack S_i, (e, e') is a below pair or a crossing pair and e' crosses an edge in a different stack S_j.
- If e belongs to stack S_i, (e, e') is a below pair or a crossing pair and e' does not cross an edge in any other stack S_j, we assign (e, e') arbitrarily to one of the two sets $B_{i,j}$.

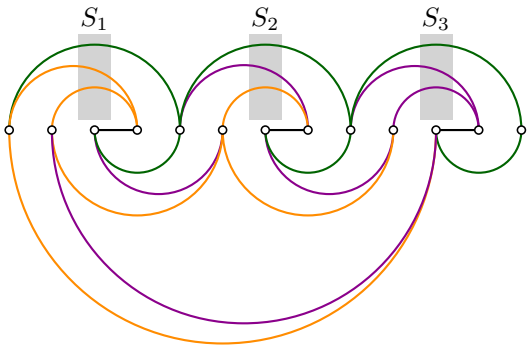

Figure 9 The best previously known lower bound example from [13]. The top tree is a stacked tree with three stacks. The bottom tree is neither stacked, nor stacked with respect to the top tree.

For this to be well-defined, we need to verify that (e, e') cannot belong to both $B_{i,j}$ and $B_{i,j'}$ for $j \neq j'$. The edge e' covers two gaps adjacent to its endpoints. One of these is covered by e. If e' intersects edges $f \in S_j$ and $g \in S_{j'}$, then the other gap is covered by both f and g, which is a contradiction, since f does not cover g or vice versa by the definition of stacks.

▶ **Lemma 13** (⋆). *For all choices of x, y, z such that $\{x, y, z\} = \{1, 2, 3\}$, both $H_x := A_y \cup A_z \cup B_{x,y} \cup B_{x,z}$ and $H_{x,y} := A_z \cup B_{y,z} \cup B_{x,y} \cup B_{x,z}$ are acyclic.*

We are now ready to obtain the following upper bound on the flip distance if one of the two trees is a stacked tree with three stacks.

▶ **Theorem 14.** *Let T, T' be non-crossing trees on $n \geq 3$ points in convex position. Let T be a stacked tree with three stacks. Then* $\mathrm{dist}(T, T') \leq {}^{14}/_{9}(n-1)$.

Proof. Each element of $V(H)$ is contained in four of the nine acyclic sets $H_1, H_2, H_3, H_{1,2}, H_{2,1}, H_{1,3}, H_{3,1}, H_{2,3}, H_{3,2}$ from Lemma 13. Thus, the average size of these sets is ${}^{1}/_{9}\Sigma_{i=1}^{9}|H_i| = {}^{4}/_{9}|V(H)|$ and, consequently, the largest acyclic set is of size at least ${}^{4}/_{9}|V(H)|$. By Theorem 5(i), there exists a flip sequence from T to T' of length at most ${}^{14}/_{9}(n-1)$. ◀

4.2 Trees with arbitrarily many stacks

We now consider a pair of trees T and T' where T is a stacked tree and let $S_1, \ldots, S_k$ denote the stacks of T with respect to T'. Let G be the graph with $S_1, \ldots, S_k$ as its vertices and an edge between S_i and S_j with $i \neq j$ if there is a near edge e in S_i paired with a near edge e' that crosses an edge in S_j. Then G is a subset of a triangulation of a convex polygon and therefore 3-colorable. We let the colors be denoted by 1, 2 and 3.

We partition the set of near-near pairs into 9 different sets, based on the 3-coloring. A pair $(e, e') \in \mathcal{P}_N$ will be put into a set by the following rules.

- A_i if e belongs to a stack with color i and (e, e') is an above pair.
- $B_{i,j}$, $i \neq j$ if e belongs to a stack with color i, (e, e') is a below pair or a crossing pair and e' crosses an edge in a stack with a color $j \neq i$.
- If e belongs to a stack with color i, (e, e') is a below or a crossing pair and e' does not cross an edge in any other stack, we assign (e, e') arbitrarily to one of the two sets $B_{i,j}$.

Lemma 15, which is a slight extension of Lemma 13, can be used to prove Theorem 16 in a similar way as Theorem 14 is derived from Lemma 13.

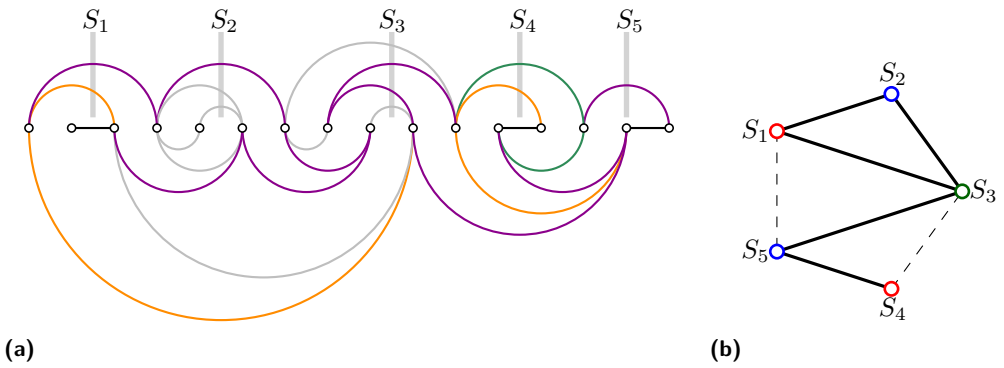

Figure 10 (a) A pair of trees where one tree is stacked and (b) the resulting graph G with a proper 3-coloring.

▶ **Lemma 15** (⋆). *Let* $\{x, y, z\} = \{1, 2, 3\}$. *Then* $H_x = A_y \cup A_z \cup B_{x,y} \cup B_{x,z}$ *and* $H_{x,y} = A_z \cup B_{y,z} \cup B_{x,y} \cup B_{x,z}$ *are acyclic.*

▶ **Theorem 16.** *Let* T, T' *be non-crossing trees on* $n \geq 3$ *points in convex position. Let* T *be stacked with respect to* T'. *Then* $\operatorname{dist}(T, T') \leq {}^{14}/_{9}(n-1)$.

We remind the reader that if T is stacked, then it is stacked with respect to any T'. Thus, the same statement without "with respect to T'" is true a fortiori.

5 A new lower bound

We construct trees T^i and $\tilde{T}^i$ iteratively, and show that their conflict graph has $7i$ vertices and a largest acyclic subset of size at most $3i + 1$. The latter divided by the former tends to ${}^{3}/_{7}$, which allows us to use Theorem 5 (ii) to prove $\operatorname{diam}(\mathcal{F}_n) \geq {}^{11}/_{7} \cdot n - o(n)$.

We start with the trees T^1 and $\tilde{T}^1$ illustrated in Figure 11. These are trees on vertices $v_1, \ldots, v_8, x, y, v_9$ labeled from left to right along the spine and have short edges v_2v_3, v_6v_7 and xy as well as edges e_i and $\tilde{e}_i$ for $i = 1, \ldots, 7$, respectively.

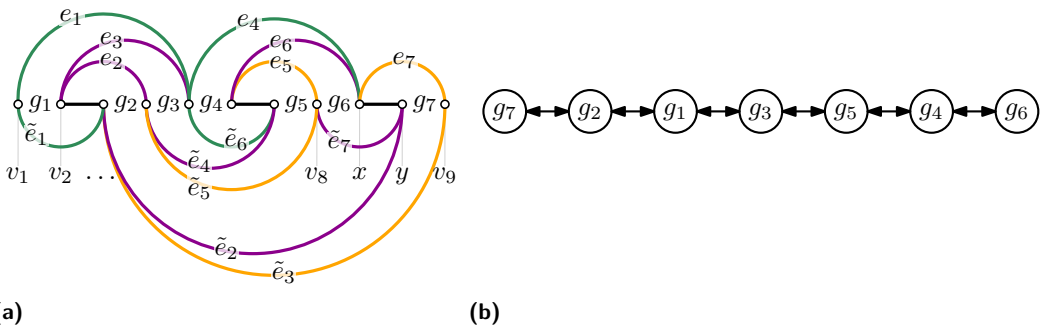

Figure 11 Illustration of T^1 and $\tilde{T}^1$ and the relevant part of the conflict graph.

Next, we construct T^ℓ and $\tilde{T}^\ell$ inductively for $\ell \geq 2$. Assume that $T^{\ell-1}$ and $\tilde{T}^{\ell-1}$ are given. Add vertices $v_1^\ell, \ldots, v_5^\ell$ from left to right to the left of $v_1^{\ell-1}$ and let $v_6^\ell = v_2^{\ell-1}$. Further, add a vertex v_7^ℓ between $v_3^{\ell-1}$ and $v_4^{\ell-1}$, a vertex v_8^ℓ between $v_8^{\ell-1}$ and x, and a vertex v_9^ℓ to the right of $v_9^{\ell-1}$. For an illustration consider Figure 12.

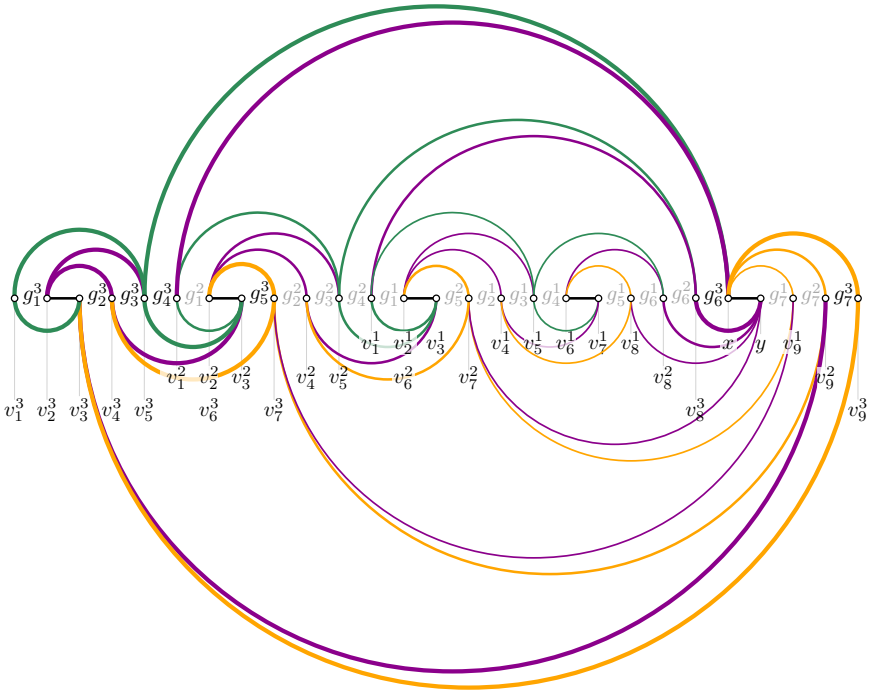

Figure 12 Illustration for the iterative construction of T^ℓ and $\tilde{T}^\ell$ from $T^{\ell-1}$ and $\tilde{T}^{\ell-1}$ for $\ell = 3$.

The edges in $T^{\ell-1}$ and $\tilde{T}^{\ell-1}$ are also present in T^ℓ and $\tilde{T}^\ell$, respectively, except that the right endpoint of $e_4^{\ell-1}$ and $e_6^{\ell-1}$ (which was x) is changed to v_8^ℓ, and the left endpoint of $\tilde{e}_2^{\ell-1}$ and $\tilde{e}_7^{\ell-1}$ (which was $v_3^{\ell-1}$) is changed to v_7^ℓ. Correspondingly, we change $g_2^{\ell-1}$ to $v_7^\ell v_4^{\ell-1}$ and $g_6^{\ell-1}$ to $v_8^{\ell-1}v_8^\ell$. We put a short edge $v_2^\ell v_3^\ell$ in both T^ℓ and $\tilde{T}^\ell$. Lastly, we add the following edges to T^ℓ and $\tilde{T}^\ell$

$$e_1^\ell = v_1^\ell v_5^\ell, \quad e_2^\ell = v_2^\ell v_4^\ell, \quad e_3^\ell = v_2^\ell v_5^\ell, \quad e_4^\ell = v_5^\ell x, \quad e_5^\ell = v_6^\ell v_7^\ell, \quad e_6^\ell = v_1^{\ell-1} x, \quad e_7^\ell = x v_9^\ell,$$
$$\tilde{e}_1^\ell = v_1^\ell v_3^\ell, \quad \tilde{e}_2^\ell = v_3^\ell v_9^{\ell-1}, \quad \tilde{e}_3^\ell = v_4^\ell v_3^{\ell-1}, \quad \tilde{e}_4^\ell = v_5^\ell v_3^{\ell-1}, \quad \tilde{e}_5^\ell = v_4^\ell v_7^\ell, \quad \tilde{e}_6^\ell = v_8^\ell y, \quad \tilde{e}_7^\ell = v_3^\ell v_9^\ell,$$

with corresponding gaps

$$g_1^\ell = v_1^\ell v_2^\ell, \quad g_2^\ell = v_3^\ell v_4^\ell, \quad g_3^\ell = v_4^\ell v_5^\ell, \quad g_4^\ell = v_5^\ell v_1^{\ell-1}, \quad g_5^\ell = v_3^{\ell-1} v_7^\ell, \quad g_6^\ell = v_8^\ell x, \quad g_7^\ell = v_9^{\ell-1} v_9^\ell.$$

We next show properties of the trees T^ℓ and $\tilde{T}^\ell$ resulting form the iterative construction.

▶ **Lemma 17** (⋆). *The following are true for T^ℓ and $\tilde{T}^\ell$:*

- **(i)** *T^ℓ and $\tilde{T}^\ell$ are both non-crossing spanning trees,*
- **(ii)** *their near-near pairs are $(e_i^j, \tilde{e}_i^j)$, with associated gaps g_i^j, for $1 \le i \le 7$ and $1 \le j \le \ell$,*
- **(iii)** *for $1 \le j \le \ell$, the conflict graph has bidirected edges $g_7^j \leftrightarrow g_2^j \leftrightarrow g_1^j \leftrightarrow g_3^j \leftrightarrow g_5^j \leftrightarrow g_4^j \leftrightarrow g_6^j$,*
- **(iv)** *for $1 \le j < j' \le \ell$, the conflict graph has a bidirected edge $g_6^j \leftrightarrow g_7^{j'}$.*

▶ **Lemma 18.** *The conflict graph $H(T^\ell, \tilde{T}^\ell)$ has 7ℓ vertices and its largest acyclic sets have size at most $3\ell + 1$.*

Proof. That the conflict graph has 7ℓ vertices follows immediately from Lemma 17 (ii). Observe that from every bidirected path of length seven given in Lemma 17 (iii), we can pick at most four gaps for the acyclic set. Furthermore, the only way to pick four is to pick

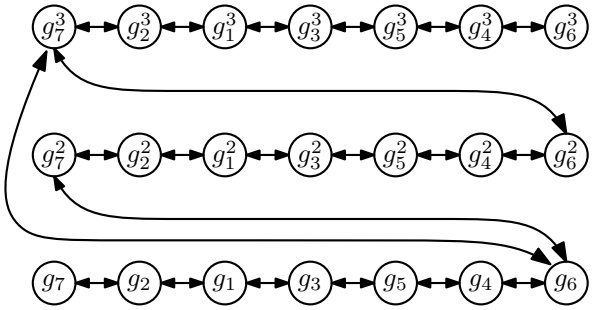

Figure 13 The relevant double conflicts in the conflict graph $H(T^\ell, \tilde{T}^\ell)$ for $\ell = 3$.

the gaps g_7^j, g_1^j, g_5^j and g_6^j, see also Figure 13. Now assume the cardinality of an acyclic set exceeds $3\ell + 1$. Then, by the pigeonhole principle, there exist at least two paths of length seven from which there are four pairs in the acyclic set. In particular, the set contains g_6^j and $g_7^{j'}$ for some $j < j'$ which are in double conflict by Lemma 17 (iv), contradicting acyclicity. ◀

Together, Lemma 18 and Theorem 5 imply the following.

▶ **Theorem 19.** *As a function of* n, $\operatorname{diam}(\mathcal{F}_n) \geq {}^{11}/_{7} \cdot n - o(n)$.

Proof. By Lemma 18 and Theorem 5 (ii), for any fixed ℓ, we have

$$\operatorname{diam}(\mathcal{F}_n) \geq \left(2 - \frac{3\ell+1}{7\ell}\right) n - c = \left(\frac{11}{7} - \frac{1}{7\ell}\right) n - c$$

for some c depending on ℓ. As a consequence, for any $\epsilon > 0$, $\operatorname{diam}(\mathcal{F}_n) \geq \left(\frac{11}{7} - \epsilon\right) n$ for sufficiently large n: Choose ℓ such that $\frac{1}{7\ell} < \epsilon$ and n large enough that $(\epsilon - \frac{1}{7\ell})n \geq c$, and calculate

$$\operatorname{diam}(\mathcal{F}_n) \geq \left(\frac{11}{7} - \frac{1}{7\ell}\right) n - c = \left(\frac{11}{7} - \epsilon\right) n + \left(\epsilon - \frac{1}{7\ell}\right) n - c \geq \left(\frac{11}{7} - \epsilon\right) n.$$

It follows that $\operatorname{diam}(\mathcal{F}_n) \geq \frac{11}{7} n - o(n)$. ◀

6 Conclusion

For spanning trees on convex point sets we proved that finding shortest flip sequences is NP-hard and we improved the current best lower bound on the diameter of the flip graph.

Interesting future directions include determining the exact diameters for flip graphs on point sets in convex as well as general position. We are also hopeful that our techniques for NP-hardness are fruitful in other settings. Very exciting is a recently announced breakthrough by Dorfer [20] concerning the complexity of computing the flip distance of triangulations on convex point sets, which is inspired by our methods.

Fréchet Distance in the Imbalanced Case

Lotte Blank
University of Bonn, Germany

Abstract

Given two polygonal curves P and Q defined by n and m vertices with $m \leq n$, we show that the discrete Fréchet distance in 1D cannot be approximated within a factor of $2-\varepsilon$ in $\mathcal{O}((nm)^{1-\delta})$ time for any $\varepsilon, \delta > 0$ unless OVH fails. Using a similar construction, we extend this bound for curves in 2D under the continuous or discrete Fréchet distance and increase the approximation factor to $1+\sqrt{2}-\varepsilon$ (resp. $3-\varepsilon$) if the curves lie in the Euclidean space (resp. in the L_∞-space). This strengthens the lower bound by Buchin, Ophelders, and Speckmann to the case where $m = n^\alpha$ for $\alpha \in (0,1)$ and increases the approximation factor of 1.001 by Bringmann. For the discrete Fréchet distance in 1D, we provide an approximation algorithm with optimal approximation factor and almost optimal running time. Further, for curves in any dimension embedded in any L_p space, we present a $(3+\varepsilon)$-approximation algorithm for the continuous and discrete Fréchet distance using $\mathcal{O}((n+m^2)\log n)$ time, which almost matches the approximation factor of the lower bound for the L_∞ metric.

1 Introduction

The Fréchet distance is a distance metric for polygonal curves, where each curve is represented as a piecewise-linear interpolation between its vertices. There are different variants of this metric and the two most common variants are the discrete and the continuous Fréchet distance. Alt and Godau [3] were the first to study the computational complexity of the Fréchet distance. Let n and m denote the number of vertices of the two curves, which we refer to as their complexities, with $n \geq m$. They showed that the continuous Fréchet distance can be computed in $\mathcal{O}(nm \log n)$ time. Eiter and Mannilla [21] defined the discrete Fréchet distance and gave an $\mathcal{O}(nm)$ time algorithm. Although both results were slightly improved later [15, 11, 1], Bringmann [6] showed that for d-dimensional curves with $d \geq 2$ it is very unlikely that significantly faster algorithms exists: unless the Strong Exponential Time Hypothesis (SETH) fails, no (1.001)-approximation algorithm for the continuous or discrete Fréchet distance can run in $\mathcal{O}((nm)^{1-\delta})$ time for any $\delta > 0$. Later, Bringmann and Mulzer [10] extended this result for the discrete Fréchet distance in 1D and increased the approximation factor up to $1.4-\varepsilon$ for any $\varepsilon > 0$[1]. For the continuous and the discrete Fréchet distance in 1D, Buchin, Ophelders, and Speckmann [12] showed a hardness result for approximation factors up to $3-\varepsilon$, but only in the case where $n = m$. A recent result by Blank and Driemel [5] shows that the continuous Fréchet distance in 1D can indeed be computed faster when $m = n^\alpha$ with $\alpha \in (0,1)$, namely in $\mathcal{O}(n \log n + m^2 \log^2 n)$ time.

[1] In [10], this result is stated only for $n = m$, but the same construction works for the case $n \neq m$ as well.

Related Work. In recent years, many works have studied approximation algorithms for the Fréchet distance [18, 26, 27]. This line of research culminated in the first constant-factor approximation algorithm for the Fréchet distance that runs in subquadratic time, due to Cheng, Huang, and Zhang [17]. Their randomized $(7+\varepsilon)$-approximation algorithm for the continuous Fréchet distance runs in $\mathcal{O}(nm^{0.99}\log(n/\varepsilon))$ time for any $\varepsilon > 0$ and succeeds with probability at least $1 - 1/n^6$.

A simple idea to 3-approximate the Fréchet distance between curves where $m = n^\alpha$ with $\alpha \in (0,1)$ in subquadratic time is the following. Compute a curve P' of complexity $n' \in o(n)$ and its distance δ to P such that every curve Q of complexity m has Fréchet distance at least δ to P. Then compute the Fréchet distance δ' between P' and Q. Using triangle inequality, one can show that the Fréchet distance between P and Q is at least $\max\{\delta'/2, \delta\}$ and at most $3 \cdot \max\{\delta'/2, \delta\}$, which yields a 3-approximation. The difficulty of this approach is to compute such a curve P'. Two related variants of this simplification problem have been studied. The first is computing an optimal *m-simplification* of P, that is, a curve P^* of complexity at most m minimizing the Fréchet distance to P among all curves of complexity at most m. The second is computing an optimal *δ-simplification*, that is, a curve P^* of minimum complexity among all curves that have Fréchet distance at most δ to P. However, no previous result achieved a subquadratic running time for curves in arbitrary dimension when the approximation factor on the complexity of the simplified curve is constant [2, 4, 7, 13, 16, 22, 28].

A different approach to reduce the running time of computing the Fréchet distance is via Fréchet distance oracles. Such an oracle is a data structure that preprocesses an input curve and subsequently answers Fréchet distance queries with respect to query curves. Driemel and Har-Peled [19] described a data structure of size $\mathcal{O}(n\log n)$ using $\mathcal{O}(m^2\log n\log(m\log n))$ query time, which approximates the continuous Fréchet distance up to a (large) constant factor. For exact queries, [14] presented a data structure of size $\mathcal{O}(nm)^{\mathrm{poly}(d,m)}$ and query time in $\mathcal{O}((md)^{\mathcal{O}(1)}\log(nm))$, where the query complexity m is given at preprocessing time. Blank and Driemel [5] showed that for curves in 1D, there is a data structure of size $\mathcal{O}(n\log n)$ that computes the continuous Fréchet distance exactly in $\mathcal{O}(m^2\log^2 n)$ time. For the discrete Fréchet distance, Filtser and Filtser [22] improved [20] and presented a data structure with size in $\mathcal{O}(1/\varepsilon)^{kd}\log(\varepsilon)^{-1}$ that approximates the discrete Fréchet distance within a factor of $(1+\varepsilon)$ using expected $\widetilde{\mathcal{O}}(kd)$ query time, where $\widetilde{\mathcal{O}}(\cdot)$ hides polylogarithmic factors in n. Gudmundsson, Seybold, and Wong [24] used the lower bound construction by Bringmann [6] to show in a similar fashion to [8, 20, 25] the following. In 2D, there exists no Fréchet distance oracle with $\mathrm{poly}(n)$ preprocessing time and $\mathcal{O}((nm)^{1-\delta})$ query time and approximation factor 1.001 unless SETH fails.

Our Results. Our first set of results shows lower bounds for algorithms that approximate the Fréchet distance conditioned on the Orthogonal Vectors Hypothesis (OVH). We show that the discrete Fréchet distance between 1-dimensional curves cannot be $(2-\varepsilon)$-approximated in $\mathcal{O}((nm)^{1-\delta})$ time for any $\varepsilon, \delta > 0$ unless OVH fails. This increases the approximation factor of $1.4-\varepsilon$ by Bringmann and Mulzer [10]. Using a similar construction in 2D, we show that the continuous and discrete Fréchet distance cannot be approximated within a factor less than $1+\sqrt{2}$ (resp. 3) when the curves lie in the Euclidean space (resp. in the L_∞-space) in $\mathcal{O}((nm)^{1-\delta})$. This leads to lower bounds for Fréchet distance oracles as well and answers an open question by [24].

To obtain this first set of results, we reduce from the *Orthogonal Vector Problem:* Given two sets of vectors $U, V \subset \{0,1\}^d$ of size m and n, do there exist two vectors $u \in U$ and $v \in V$ such that $\langle u, v\rangle = 0$? Then, the results follow by OVH, which is implied by SETH [29, 9].

Table 1 Upper and Lower Bounds for the Fréchet distance Computation.

Upper Bounds						
	Discrete			Continuous		
1D	$\mathcal{O}(mn)$	exact	[21, 1]	$\widetilde{\mathcal{O}}(mn)$	exact	[3, 11, 15]
	$\widetilde{\mathcal{O}}(n+m^2)$	2-approx.	Cor.20	$\widetilde{\mathcal{O}}(n+m^2)$	exact	[5]
dD	$\mathcal{O}(mn)$	exact	[21, 1]	$\widetilde{\mathcal{O}}(mn)$	exact	[3, 11, 15]
	$\widetilde{\mathcal{O}}(n+m^2)$	$(3+\varepsilon)$-approx.	Thm.23	$\widetilde{\mathcal{O}}(n+m^2)$	$(3+\varepsilon)$-approx.	Thm.23
	$\widetilde{\mathcal{O}}(nm^{0.99})$	$(7+\varepsilon)$-approx.	[17]	$\widetilde{\mathcal{O}}(nm^{0.99})$	$(7+\varepsilon)$-approx.	[17]

Lower Bounds						
	Discrete			Continuous		
1D	$\nexists\ \mathcal{O}(m^{2-\delta})$	$(3-\varepsilon)$-approx.	[12]	$\nexists\ \mathcal{O}(m^{2-\delta})$	$(3-\varepsilon)$-approx.	[12]
	$\nexists\ \widetilde{\mathcal{O}}((mn)^{1-\delta})$	$(1.4-\varepsilon)$-approx.	[10]			
	$\nexists\ \widetilde{\mathcal{O}}((mn)^{1-\delta})$	$(2-\varepsilon)$-approx.	Thm.9			
2D		$\nexists\ \mathcal{O}((mn)^{1-\delta})$	(1.001)-approx.		[6]	
		$\nexists\ \mathcal{O}((mn)^{1-\delta})$	$(1+\sqrt{2}-\varepsilon)$-approx. in L_2		Thm.10	
		$\nexists\ \mathcal{O}((mn)^{1-\delta})$	$(3-\varepsilon)$-approx. in L_∞		Thm.10	

▶ **Definition 1** (Orthogonal Vectors Hypothesis (OVH)). *For all $\delta > 0$ there exists a $c > 0$ such that there is no algorithm solving OV instances $U, V \subset \{0,1\}^d$ of size m and n with $m \leq n$ and $d = c \log n$ in time $\mathcal{O}((nm)^{1-\delta})$.*

We construct a curve P of complexity $\mathcal{O}(n+m)$ depending on V and the size of U and a curve Q of complexity $\mathcal{O}(m)$ depending only on U. Then, we show that the Fréchet distance between P and Q is at most 1 if and only if the OV instance has a solution. In order to get a lower bound also for the case where $n \gg m$, we construct P such that the main part of P lies in a ball of radius 1. Hence, this main part can be matched to a single point of Q. Further, to obtain an inapproximability result of $2-\varepsilon$ in 1D, the points of P and Q have integer coordinates. Hence, there are only three different values that the vertices of the main part of P can have. This significantly restricts our possibilities to define P and is the main difference to the construction by Bringmann and Mulzer [10]. They also note in their paper that obtaining a lower bound for an approximation factor of 1.4 or higher requires a significantly different construction compared to theirs.

On the positive side, we present a data structure that preprocesses a 1-dimensional curve of complexity n in $\mathcal{O}(n \log n)$ time using $\mathcal{O}(m)$ space that 2-approximates the discrete Fréchet distance to query curves of complexity m in $\mathcal{O}(m^2 \log m)$ time. Hence, there exists a 2-approximation algorithm for the discrete Fréchet distance in $\mathcal{O}(n \log n + m^2 \log m)$ time matching our approximation factor lower bound and essentially the time lower bound by [12]. Secondly, we match our approximation factor lower bound in the L_∞-space by giving a simple $(3+\varepsilon)$-approximation algorithm for the discrete and continuous Fréchet distance using $\mathcal{O}((n+m^2)\log n)$ time for curves in any dimension under any L_p-norm. Table 1 summarizes the results of this paper and related work.

2 Preliminaries

For any two points $p_1, p_2 \in \mathbb{R}^d$, $\overline{p_1 p_2}$ denotes the directed line segment connecting p_1 with p_2. A polygonal curve P of complexity n is formed by ordered line segments $\overline{P(i)P(i+1)}$ of points $P(1), P(2), \ldots, P(n)$, where $P(i) \in \mathbb{R}^d$. It can be viewed as a function $P : [1, n] \to \mathbb{R}^d$,

where $P(i+\alpha) = (1-\alpha)P(i) + \alpha P(i+1)$ for $i \in \{1, \dots, n\}$ and $\alpha \in [0,1]$. This curve is also denoted with $\langle P(1), \dots, P(n)\rangle$. We call the points $P(i)$ vertices and the line segments $\overline{P(i)P(i+1)}$ edges of P. Further, $P[s,t]$ is the subcurve of P obtained from restricting the domain to the interval $[s,t]$. Two curves $P = \langle P(1), \dots, P(n)\rangle$ and $Q = \langle Q(1), \dots, Q(m)\rangle$ can be composed into the curve $P \circ Q = \langle P(1), \dots, P(n), Q(1), \dots, Q(m)\rangle$. For a number $k \in \mathbb{N}_0$, define P^k be the composition of k copies of P.

Let $P : [1,n] \to \mathbb{R}^d$ and $Q : [1,m] \to \mathbb{R}^d$ be two polygonal curves. A *continuous matching* M between P and Q is defined by two functions $h_P \in \mathcal{F}_n$ and $h_Q \in \mathcal{F}_m$ and consists of the tuples $(h_P(a), h_Q(a))$ for $a \in [0,1]$, where $\mathcal{F}_n$ is the set of all continuous, non-decreasing functions $h : [0,1] \to [1,n]$ with $h(0) = 1$ and $h(1) = n$, respectively $\mathcal{F}_m$ for m. Then, the *(continuous) Fréchet distance* between P and Q is defined as

$$d_{\mathrm{F}}(P,Q) = \min_{\text{continuous matching } M} \max_{(x,y)\in M} \|P(x) - Q(y)\|.$$

For a fixed δ, the *free space* $F_\delta(P,Q)$ is a subset of $[1,n] \times [1,m]$ such that $(x,y) \in F_\delta(P,Q)$ if and only if $\|P(x) - Q(y)\| \le \delta$. Points in $([1,n] \times [1,m]) \setminus F_\delta(P,Q)$ are contained in the non-free space. Hence, the continuous Fréchet distance between P and Q is at most δ if a continuous matching $M \subset F_\delta(P,Q)$ between P and Q exists.

A *discrete matching* M between P and Q is an ordered sequence that starts in $(1,1)$, ends in (n,m) and for any consecutive tuples (i,j), (i',j') in M it holds that $(i',j') \in \{(i+1,j), (i,j+1), (i+1,j+1)\}$. Then, the *discrete Fréchet distance* between P and Q is

$$d_{\mathrm{dF}}(P,Q) = \min_{\text{discrete matching } M} \max_{(i,j)\in M} \|P(i) - Q(j)\|.$$

The *free space matrix* M_δ is an $n \times m$ matrix, where $M_\delta[i,j] = 1$ if $|P(i) - Q(j)| \le \delta$ and otherwise $M_\delta[i,j] = 0$. We say that (i,j) is *reachable* if $d_{\mathrm{dF}}(P[1,i], Q[1,j]) \le \delta$.

▶ **Observation 2.** *Let P_1, P_2, Q_1, Q_2 be curves. If $d_F(P_1,Q_1) \le \delta$ and $d_F(P_2,Q_2) \le \delta$, then $d_F(P_1 \circ P_2, Q_1 \circ Q_2) \le \delta$. For the discrete Fréchet distance, the analogue statement holds.*

▶ **Observation 3.** *Let P and Q be polygonal curves, then $d_F(P,Q) \le d_{dF}(P,Q)$.*

3 Approximation lower bounds for the imbalanced case

In this section, we show a lower bound for the discrete Fréchet distance in 1D and for the discrete and continuous Fréchet distance in 2D depending on OVH. The construction for both bounds is very similar and we start with giving a schematic view of the reduction.

Let $U, V \subset \{0,1\}^d$ be two sets of size m and n, where $m \le n$ and denote with v_{ik} (resp. u_{ik}) the k-th bit of the i-th vector of V (resp. U). We construct two 1-dimensional (resp. 2-dimensional) curves P and Q of complexity $\mathcal{O}(nd)$ and $\mathcal{O}(md)$, where P depends on V and Q on U. We show that their discrete (and continuous) Fréchet distance is at most 1 if and only if two vectors that are orthogonal exist in V and U. Define

$$P = P_s \circ (P^*)^{m-1} \circ P_{null} \circ \bigcirc_{i=1}^{n} \left((P_0)^{d+1} \circ P_1 \circ \bigcirc_{\ell=1}^{d} P_{v_{i\ell}} \circ P_1\right) \circ P_{null} \circ (P^*)^{m-1} \circ P_s,$$

$$Q = (Q^*)^{m-1} \circ \bigcirc_{j=1}^{m} \left(Q_{null} \circ Q_c \circ (Q_1)^{d+1} \circ Q_0 \circ \bigcirc_{\ell=1}^{d} Q_{u_{j\ell}} \circ Q_0 \circ Q_c\right) \circ Q_{null} \circ (Q^*)^{m-1},$$

where the subcurves are defined later. Since the complexity of P can be arbitrarily larger than the complexity of Q, we construct the curve P such that the main part of P, i.e., in between the two subcurves P_{null}, is contained in a ball of radius 1. Then, we can match this whole part to a single point on Q. This point is Q_c in our construction. At a high

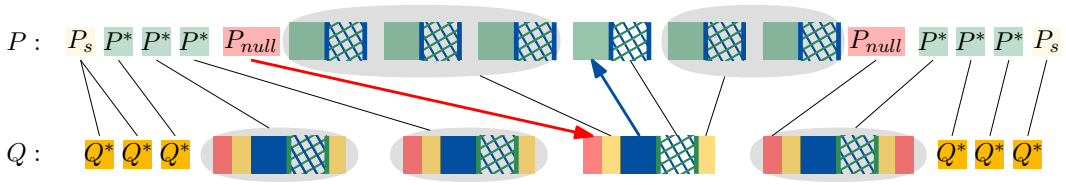

Figure 1 A schematic view of the construction of the curves P and Q. Here, Q_{null} is drawn in red, P_0 and Q_0 in green, P_1 and Q_1 in blue, and Q_c in orange.

level idea, we want to enforce that in a matching that realizes the Fréchet distance, the two subcurves P_{null} get roughly matched to different subcurves Q_{null}. Then, the subcurve in between the two points matched to P_{null} contains $(Q_1)^{d+1}$ as a subcurve. Now, we enforce that $(Q_1)^{d+1}$ gets roughly matched to $(P_0)^{d+1}$. Hence, afterwards $\bigcirc_{k=1}^{d} P_{v_{ik}}$ and $\bigcirc_{\ell=1}^{d} Q_{u_{j\ell}}$ have to be matched together for some i and j. We will show that this is only possible if $\langle v_i, u_j \rangle = 0$. This matching is schematically visualized in Figure 1. We define

$$P_s = \langle (-1,0) \rangle, \quad P_{null} = \langle (-5,0) \rangle, \quad P^* = \langle (-3,0) \rangle \circ \langle P_0 \rangle^{2d+3} \circ \langle (-3,0) \rangle,$$
$$Q_c = \langle (0,0) \rangle, \quad Q_{null} = \langle (-4,0) \rangle, \quad Q^* = \langle (-2,0), (0,0), (-2,0) \rangle,$$

for 2D and the definition carries over directly to 1D. The curves P_0, P_1, Q_0, and Q_1 are visualized in Figure 2. For the 1D setting, let

$$P_0 = \langle -1, 1 \rangle, \quad P_1 = \langle -1, 0 \rangle, \quad Q_0 = \langle -2, 1 \rangle, \quad Q_1 = \langle -2, 2 \rangle.$$

For the 2D constructions, define eight points with distance 1 to $(0,0)$ where $a_1 = (-1,0)$ and the direction of a_{i+1} is the direction of a_i rotated by $\pi/4$, i.e., in L_2

$$a_1 = (-1,0), \quad a_2 = (-1/\sqrt{2}, -1/\sqrt{2}), \quad a_3 = (0,-1), \quad a_4 = (1/\sqrt{2}, -1/\sqrt{2}),$$
$$a_5 = (1,0), \quad a_6 = (1/\sqrt{2}, 1/\sqrt{2}), \quad a_7 = (0,1), \quad a_8 = (-1/\sqrt{2}, 1/\sqrt{2}),$$

and in L_∞

$$a_1 = (-1,0), \quad a_2 = (-1,-1), \quad a_3 = (0,-1), \quad a_4 = (1,-1),$$
$$a_5 = (1,0), \quad a_6 = (1,1), \quad a_7 = (0,1), \quad a_8 = (-1,1).$$

Define $c = \sqrt{2}$ and $\tilde{a} = a_8 + a_7$ in L_2 and $c = 2$ and $\tilde{a} = 2a_8$ in L_∞. Note that c is defined such that ca_1 is the point with distance 1 to a_8 and a_2 that maximizes the distance to $(0,0)$ and $\tilde{a}$ such that $\|\tilde{a} - a_2\| = 1 + c$ and $\|\tilde{a} - a_8\| = 1$. Then we set

$$P_0 = \langle a_1, a_2, \dots a_7, a_8, a_7 \dots, a_1 \rangle, \quad P_1 = \langle a_1, a_2, \dots, a_8, a_1, a_2, a_1 a_8, \dots, a_1 \rangle,$$
$$Q_0 = \langle 2a_1, 2a_2, \dots, 2a_8, ca_1, 2a_8, \dots, 2a_1 \rangle, \quad Q_1 = \langle 2a_1, 2a_2, \dots, 2a_7, \tilde{a}, 2a_7, \dots, 2a_1 \rangle.$$

We show that this results in an inapproximability result of $(1 + c - \varepsilon)$ for time in $\mathcal{O}((nm)^{1-\delta})$.

▶ **Lemma 4.** *If there exist indices i and j such that $\langle v_i, u_j \rangle = 0$, then in every construction for P and Q above it holds that $d_{dF}(P, Q) \leq 1$.*

Proof. For every construction of P and Q, it holds that $d_{\mathrm{dF}}(P^*, Q^*) \leq 1$, $d_{\mathrm{dF}}(P_s, Q^*) \leq 1$. Further, for $x, y \in \{0, 1\}$ with $\langle x, y \rangle = 0$, it holds that $d_{\mathrm{dF}}(P_x, Q_y) \leq 1$. Then, we can match the following with Fréchet distance at most 1 and the lemma follows by Observation 2

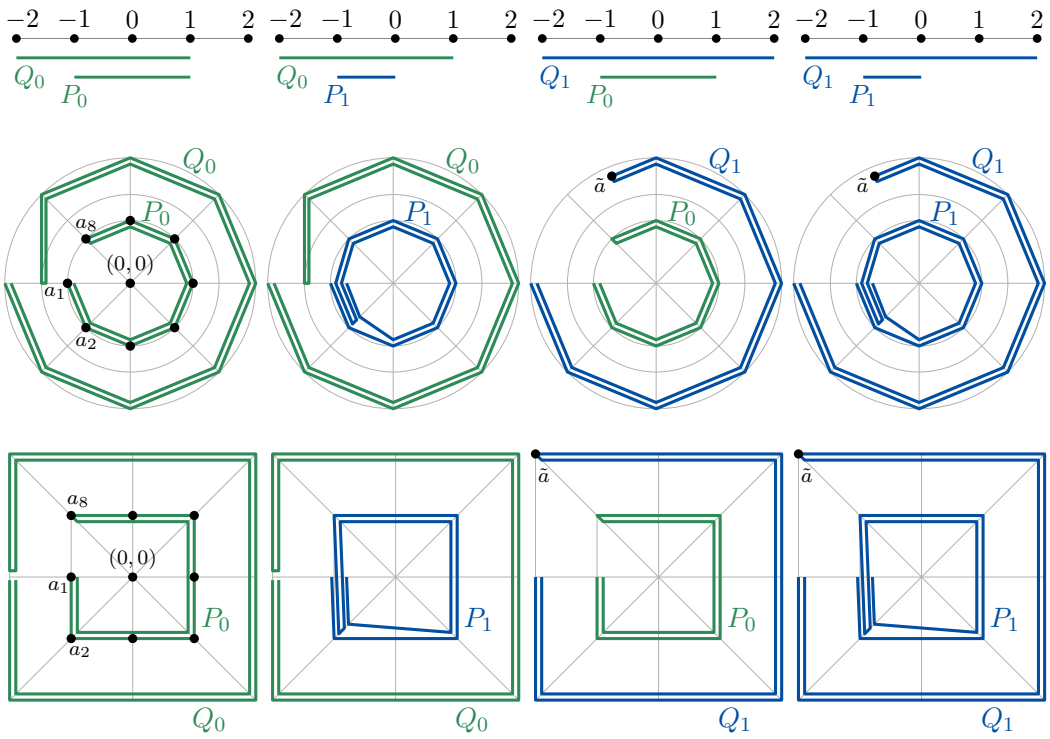

Figure 2 The curves P_0, P_1, Q_0, and Q_1. The upper curves are defined in 1D, the middle curves for the L_2-metric in 2D and the lower curves for the L_∞-metric in 2D.

$P_s \circ (P^*)^{m-j}$	and	$(Q^*)^{m-1}$,
$(P^*)^{j-1} \circ P_{null}$	and	$\bigcirc_{k=1}^{j-1} (Q_{null} \circ Q_c \circ (Q_1)^{d+1} \circ Q_0 \circ \bigcirc_{\ell=1}^{d} Q_{u_{k\ell}} \circ Q_0 \circ Q_c) \circ Q_{null}$,
$\bigcirc_{k=1}^{i-1} \left((P_0)^{d+1} \circ P_1 \circ \bigcirc_{\ell=1}^{d} P_{v_{k\ell}} \circ P_1\right)$	and	Q_c,
$(P_0)^{d+1} \circ P_1 \circ \bigcirc_{\ell=1}^{d} P_{v_{i\ell}} \circ P_1$	and	$(Q_1)^{d+1} \circ Q_0 \circ \bigcirc_{\ell=1}^{d} Q_{u_{j\ell}} \circ Q_0$,
$\bigcirc_{k=i+1}^{n} \left((P_0)^{d+1} \circ P_1 \circ \bigcirc_{\ell=1}^{d} P_{v_{k\ell}} \circ P_1\right)$	and	Q_c,
$P_{null} \circ (P^*)^{m-j}$	and	$\bigcirc_{k=j+1}^{m} (Q_{null} \circ Q_c \circ (Q_1)^{d+1} \circ Q_0 \circ \bigcirc_{\ell=1}^{d} Q_{u_{k\ell}} \circ Q_0 \circ Q_c) \circ Q_{null}$,
$(P^*)^{j-1} \circ P_s$	and	$(Q^*)^{m-1}$. ◀

To show the other direction, we first prove some lemmas.

▶ **Lemma 5.** *Consider the 1D setting and let $Q' = \bigcirc_{\ell=1}^{d'} Q_{\sigma_\ell}$, where $\sigma_\ell \in \{0,1\}$ for every ℓ. Further, let $s \leq t$ be such that $P[s,t]$ is a subcurve in between the two subcurves P_{null} and $d_{dF}(Q', P[s,t]) < 2$. Then $P[s,t] = \bigcirc_{\ell=1}^{d'} P_{\pi_\ell}$ where $\pi_\ell = 0$ if $\sigma_\ell = 1$ and $\pi_\ell \in \{0,1\}$ if $\sigma_\ell = 0$ for every ℓ.*

Proof. It holds that every second vertex of Q' is -2 and the vertices of value -1 on $P[s,t]$ are the only vertices on $P[s,t]$ within distance less than 2 to those vertices of Q'. Further, it holds that the vertices with value -1 of $P[s,t]$ have distance less than two only to the vertices of value -2 of Q'. Hence, since the vertices of value -1 on $P[s,t]$ are exactly every second vertex on $P[s,t]$, we must traverse $P[s,t]$ and Q' synchronously. Therefore, if $\sigma_\ell = 0$ then $\pi_\ell \in \{0,1\}$ and if $\sigma_\ell = 1$ then $\pi_\ell = 0$ by construction. ◀

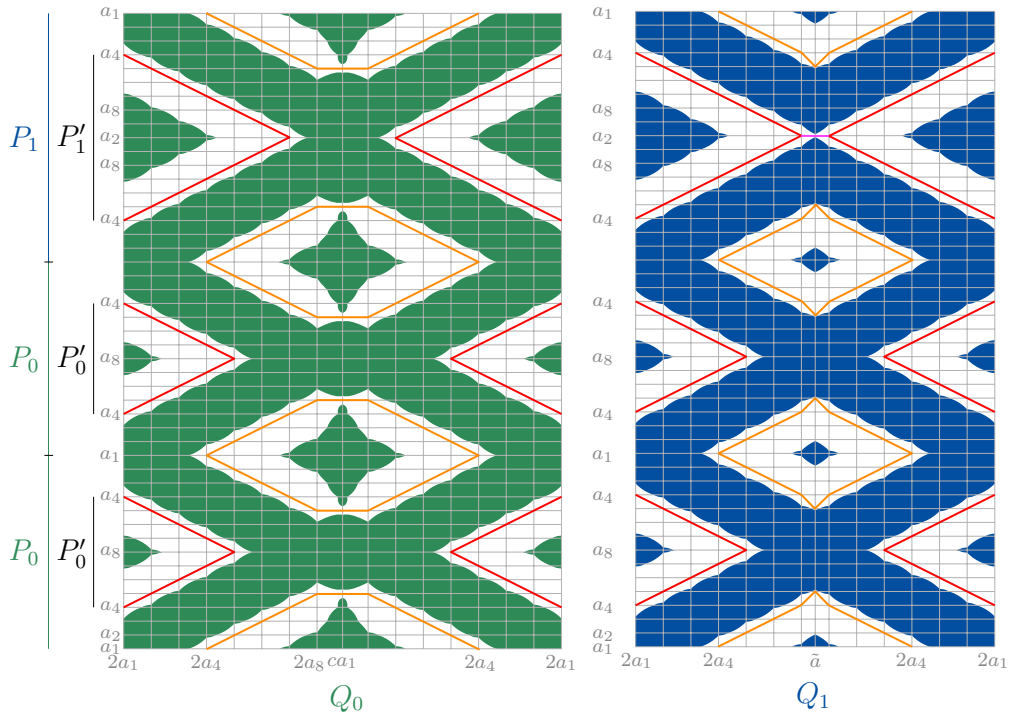

Figure 3 In white: the non-free space of the curve Q_0 and $P_0 \circ P_0 \circ P_1$ on the left and of the curve Q_1 and $P_0 \circ P_0 \circ P_1$ on the right. The red, orange and pink paths visualize the proof of Lemma 6.

In 2D, we also want to show a bound for the continuous Fréchet distance. Then the vertices of Q can also be matched to points on edges of P. We use the notation of the following subcurve of P_0 (resp. P_1): $P_0' = \langle a_4, a_5, \ldots, a_8, \ldots, a_4 \rangle$ (resp. $P_1' = \langle a_4, \ldots, a_8, a_1, a_2, a_1, a_8, \ldots, a_4 \rangle$).

▶ **Lemma 6.** *Consider the 2D setting. For any subcurve P' of P in between the two subcurves P_{null} with $d_F(P', Q_y) < 1 + c$ for $y \in \{0, 1\}$, it holds that P_x' is a subcurve of P' and P' is a subcurve of $\langle a_4, a_3, a_2 \rangle \circ P_x \circ \langle a_2, a_3, a_4 \rangle$, where $x = 0$ if $y = 1$ and $x \in \{0, 1\}$ if $y = 0$.*

Proof. We show this lemma by constructing paths in the non-free space for $\delta = 1 + c$ (see Figure 3). First observe that $\|2a_i - a_j\| \geq 1 + c$ for any $i, j \in \{1, \ldots, 8\}$ with $i - j \geq 3 \mod 8$.

Assume that the first (resp. last) vertex of Q_y is matched to a point on a subcurve P_x' with $x \in \{0, 1\}$. Then, there must exist a path completely contained in the free space ending at the last (resp. first) vertex of Q_y. This cannot be the case since there exists a continuous matching between P_x' and $\langle 2a_1, 2a_2 \ldots, 2a_5, \ldots, 2a_1 \rangle$ that is completely contained in the non-free space (see the red paths in Figure 3). Therefore, the first as well as the last vertex of Q_y has to be matched to a point on a subcurve P'' of P such that $P'' = \langle a_4, a_3, a_2, a_1, a_2, a_3, a_4 \rangle$.

Next, we show that P' contains exactly one P_x' as a subcurve. Since $\|ca_1 - a_5\| \geq 1 + c$ (resp. $\|\tilde{a} - a_5\| \geq 1 + c$), there exists a path that is completely contained in the non-free space between $\langle a_5, a_4, \ldots a_2, a_1, a_2, \ldots, a_4, a_5 \rangle$ and $\langle 2a_8, ca_1, 2a_8, 2a_7, \ldots, 2a_4, 2a_5, \ldots, 2a_8, ca_1, 2a_8 \rangle$ (resp. $\langle \tilde{a}, 2a_7, \ldots, 2a_4, 2a_5, \ldots, \tilde{a} \rangle$) (see the orange paths in Figure 3). Hence by construction of P, it follows that P_x' is a subcurve of P' and P' is a subcurve of $\langle a_4, a_3, a_2 \rangle \circ P_x \circ \langle a_2, a_3, a_4 \rangle$ with $x \in \{0, 1\}$. It remains to show that $x \neq 1$, if $y = 1$. This follows since the distance between a_2 and $2a_7$, $\tilde{a}$, $2a_7$ is at least $1 + c$ (see the pink path in Figure 3). ◀

The next lemma follows directly by the construction of the curves and Lemma 6.

▶ **Lemma 7.** *Consider the 2D setting and let* $Q' = \bigcirc_{\ell=1}^{d'} Q_{\sigma_\ell}$*, where* $\sigma_\ell \in \{0,1\}$ *for every* ℓ*. Further, let* $s \le t$ *be such that* $P[s,t]$ *is a subcurve in between the two subcurves* P_{null} *and* $d_F(Q', P[s,t]) < 1 + c$*. Then,* $P'_{\pi_1} \circ \bigcirc_{\ell=2}^{d'-1} P_{\pi_\ell} \circ P'_{\pi_{d'}}$ *is a subcurve of* $P[s,t]$ *and* $P[s,t]$ *is a subcurve of* $\langle a_4, a_3, a_2\rangle \circ \bigcirc_{\ell=1}^{d'} P_{\pi_\ell} \circ \langle a_2, a_3, a_4\rangle$ *where* $\pi_\ell = 0$ *if* $\sigma_\ell = 1$ *and* $\pi_\ell \in \{0,1\}$ *if* $\sigma_\ell = 0$ *for every* ℓ*.*

▶ **Lemma 8.** *If* $d_{dF}(P,Q) < 2$ *(resp.* $d_F(P,Q) < 1 + c$*) in the 1D (resp. 2D) construction, then there exist two indices* i *and* j *such that* $\langle v_i, u_j\rangle = 0$*.*

Proof. Let M be a discrete (resp. continuous) matching that realizes the discrete (resp. continuous) Fréchet distance between P and Q. Assume that $d_{\mathrm{F}}(P,Q) < 2$ (resp. $d_{\mathrm{dF}}(P,Q) < 1 + c$), then in the matching M, the two points of value P_{null} of P must be matched to two distinct points q_1, q_2 on Q both on an edge that contains the value Q_{null}, since they are the only points within distance at most $1 + c \le 3$ to P_{null}. Let $P'_0 = P_0$ and $P'_1 = P_1$ in the 1D setting. Define j such that q_1 is contained on an incident edge to the j-th Q_{null} on Q. Then, the first $(Q_1)^{d+1}$ after the j-th Q_{null} on Q must be matched to a subcurve P' of P such that $P'_1 \circ (P_0)^{d+1} \circ P'_1$ is a subcurve of P' by Lemma 5 and Lemma 7. The only time we have $(P_0)^{d+1}$ in P is before $P_1 \circ \bigcirc_{\ell=1}^{d} P_{v_{i\ell}}$ for an i. Hence by Lemma 5 and Lemma 7, there exists an index i such that in the matching M the subcurve $P'_{v_{i,1}} \circ \bigcirc_{\ell=2}^{d-1} P_{v_{i,\ell}} \circ P'_{v_{i,d}}$ is matched to a subcurve of $\bigcirc_{\ell=1}^{d} Q_{u_{j,\ell}}$ and $v_{i,\ell} = 0$ if $u_{j,\ell} = 1$. Hence, it holds that $\langle v_i, u_j\rangle = 0$. ◀

By Lemma 4 and Lemma 8 together with Observation 3, the next two theorems follow.

▶ **Theorem 9.** *For any* $\delta, \varepsilon > 0$*, there does not exist a* $(2-\varepsilon)$*-approximation algorithm for the discrete Fréchet distance between 1-dimensional curves of complexity* n *and* m *using* $\mathcal{O}((nm)^{1-\delta})$ *time unless OVH fails.*

▶ **Theorem 10.** *For any* $\delta, \varepsilon > 0$*, there does not exist a* $(k-\varepsilon)$*-approximation algorithm for the continuous or discrete Fréchet distance between 2-dimensional curves of complexity* n *and* m *using* $\mathcal{O}((nm)^{1-\delta})$ *time unless OVH fails, where* $k = 3$ *(resp.* $k = 1 + \sqrt{2} \approx 2.41$*) if the curves lie in the* L_∞*-space (resp. in the Euclidean space).*

Our construction gives also a bound on Fréchet distance oracles (proof in the full version).

▶ **Theorem 11.** *Assume OVH holds true. For any* $\delta > 0$*, there exists a* $c > 0$ *such that for any* n *and* $m > c \log n$ *there is no data structure storing a curve of complexity* n *with* $\mathrm{poly}(n)$ *preprocessing time, that when given a query curve of at most complexity* m *can answer continuous or discrete Fréchet distance queries in* $\mathcal{O}((nm)^{1-\delta})$ *query time within the same approximation factor as in Theorem 9 and Theorem 10.*

4 2-Approximation for the discrete Fréchet distance in 1D

Given a value m and a 1-dimensional curve P of complexity $n \ge m$. We want to preprocess P in near-linear time and store information about P using $\mathcal{O}(m)$ space such that for any 1-dimensional query curve Q of complexity at most m we can approximate the discrete Fréchet distance between P and Q in $\mathcal{O}(m^2 \log m)$ time.

Preprocessing. Define $\delta_m = \min\{d_{\mathrm{dF}}(P,Q) \mid Q \text{ has complexity } m\}$. We want to compute a curve P' such that $d_{\mathrm{dF}}(P,P') \le \delta_m/2$. The complexity of P' might be n, but it should be possible to store a compact description of P' in $\mathcal{O}(m)$ space. To compute P', we first compute the optimal m-simplification P^* of P for the discrete Fréchet distance. The curve P^* is

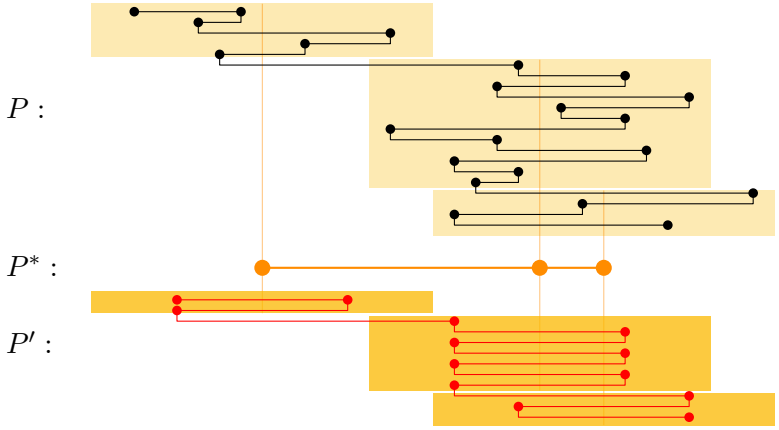

Figure 4 The black curve is P and the middle curve is an optimal 3-simplification for P. The red curve below is the compressed curve P'. Here, $k_1 = 3$, $k_2 = 7$, $k_3 = 3$ and $z_1 = -1$, $z_2 = -1$, $z_3 = 1$.

computed via searching over the possible values δ for δ_m and then computing the optimal δ-simplification. We compute the optimal δ-simplification of P using Algorithm 1. It begins by finding the longest prefix $P[1, i_1]$ that is contained in a 2δ-interval, whose center becomes the first vertex of the δ-simplification. Then, it continues by finding the largest index i_2 such that $P[i_1 + 1, i_2]$ is contained in a 2δ-interval and again the center of this interval is added to the δ-simplification. This process is repeated until the final vertex of P is reached.

Algorithm 1 Optimal δ-simplification of P.

$\ell \leftarrow 1$, $a \leftarrow P(1)$, $b \leftarrow P(1)$
for $i = 1$ *to* n **do**
  if $P(i) \leq a + 2\delta$ *and* $b - 2\delta \leq P(i)$ **then**
    $a \leftarrow \min\{a, P(i)\}$, $b \leftarrow \max\{b, P(i)\}$
  else
    $p_\ell \leftarrow \frac{a+b}{2}$, $a \leftarrow P(i)$, $b \leftarrow P(i)$, $i_\ell \leftarrow i - 1$, $\ell \leftarrow \ell + 1$
Return $P_\delta = \langle p_1, \ldots, p_\ell \rangle$, $i_0 = 0, i_1, \ldots, i_\ell = n$

The proof of the following lemma is in the full version.

▶ **Lemma 12.** *Algorithm 1 computes an optimal δ-simplification P_δ of P using $\mathcal{O}(n)$ time.*

If the complexity of the δ-simplification is greater than m, it holds that $\delta_m > \delta$. Otherwise, $\delta_m \leq \delta$. In contrast to higher dimensions, the optimal m-simplification for any m of a 1-dimensional curve P has distance $\delta_m \in \{|P(i) - P(j)|/2 \mid i, j \in \{1, \ldots, n\}\}$ to P, where the distance is only defined by two vertices of P. By Frederickson and Johnson [23], we can search over all possible values for δ_m using $\mathcal{O}(\log n)$ calls of Algorithm 1 and get the following lemma.

▶ **Lemma 13.** *We can compute an optimal m-simplification P^* of P together with a discrete matching that realizes the discrete Fréchet distance between P^* and P in $\mathcal{O}(n \log n)$ time.*

Let $P^* = \langle p_1, \ldots, p_\ell \rangle$ be an optimal m-simplification of P. Let M be the discrete matching between P and P^* computed by Algorithm 1, and $P(i_j)$ be the last vertex of P that is matched to p_j; i.e. $M = ((1,1),(2,1)\ldots,(i_1,1),(i_1+1,2),(i_1+2,2),\ldots,(i_2,2),(i_2+1,3),\ldots,(i_\ell,\ell))$.

We construct a curve P' that has discrete Fréchet distance at most $\delta_m/2$ to P and can be stored in a compressed way using $\mathcal{O}(m)$ space (see Figure 4). We call P' a *compressed simplification*. For every $(x, y) \in M$, define $r_x = p_y - \delta_m/2$ if $P(x) < p_y$ and $r_x = p_y + \delta_m/2$ otherwise. Then, it holds that $|r_x - P(x)| \leq \delta_m/2$. The compressed simplification P' is $\langle r_1, \ldots, r_n \rangle$ after deleting the vertices with identical predecessor, so that P' contains r_i only if $r_i \neq r_{i-1}$. For every j, we count the total number k_j that P' contains $p_j \pm \delta_m/2$ and define $z_j \in \{-1, 1\}$ such that the first time P' contains $p_j + z_j\delta_m/2$ is before P' contains $p_j - z_j\delta_m/2$. Therefore, the values $p_1, \ldots, p_\ell$, $k_1, \ldots, k_\ell$, $z_1, \ldots, z_\ell$, and δ_m fully describe P'. The next lemma follows directly by construction and $\ell \leq m$.

▶ **Lemma 14.** *Given P and its optimal m-simplification P^*, we can compute in $\mathcal{O}(n)$ time a curve P' such that $d_{dF}(P, P') \leq \delta_m/2$ and P' can be stored using $\mathcal{O}(m)$ space.*

The Query Algorithm. In the following, we give a 2-approximation query algorithm for the discrete Fréchet distance between P and any query curve Q of complexity m. We use the precomputed compressed simplification P' and compute $d_{\mathrm{dF}}(P', Q)$ if it is at least $\frac{3}{2}\delta_m$.

▶ **Lemma 15.** *If $d_{dF}(P', Q) \leq \frac{3}{2}\delta_m$, then $d_{dF}(P, Q) \in [\delta_m, 2\delta_m]$. Otherwise, define δ such that $\frac{3}{2}\delta = d_{dF}(P', Q)$. Then, $d_{dF}(P, Q) \in [\delta, 2\delta)$.*

Proof. By definition of δ_m, it holds that $d_{\mathrm{dF}}(P, Q) \geq \delta_m$ for every curve Q of complexity m. Further, by Lemma 14 it holds that $d_{\mathrm{dF}}(P, P') \leq \delta_m/2$. Hence, if $d_{\mathrm{dF}}(P', Q) \leq \frac{3}{2}\delta_m$, then

$$\delta_m \leq d_{\mathrm{dF}}(P, Q) \leq d_{\mathrm{dF}}(P', Q) + d_{\mathrm{dF}}(P, P') \leq \frac{3}{2}\delta_m + \frac{1}{2}\delta_m \leq 2\delta_m.$$

Otherwise, it holds that $\frac{3}{2}\delta = d_{\mathrm{dF}}(P', Q) > \frac{3}{2}\delta_m$. Hence, $\delta > \delta_m$. Therefore,

$$\delta < \frac{3}{2}\delta - \frac{1}{2}\delta_m \leq d_{\mathrm{dF}}(P', Q) - d_{\mathrm{dF}}(P', P) \leq d_{\mathrm{dF}}(P, Q) \leq d_{\mathrm{dF}}(P', Q) + d_{\mathrm{dF}}(P', P) < 2\delta.$$ ◀

Using Lemma 15, we could simply compute $d_{\mathrm{dF}}(P', Q)$ to get a 2-approximation algorithm for $d_{\mathrm{dF}}(P, Q)$. However, computing $d_{\mathrm{dF}}(P', Q)$ with known discrete Fréchet distance algorithms takes roughly $\mathcal{O}(m \cdot \sum_{i=1}^{\ell} k_i)$ time and $\sum_{i=1}^{\ell} k_i$ could be n. In the following, we make use of the special structure of P' to get a faster algorithm that decides whether $d_{\mathrm{dF}}(P', Q) \leq \frac{3}{2}\delta$ for any value $\delta \geq \delta_m$. We use the concept of the free space matrix $M_{(3/2)\delta}$, but do not compute all reachable entries explicitly. Define $s_i = \sum_{j=1}^{i-1} k_j + 1$ to be the index of the first vertex with value $p_i \pm \delta_m/2$ in P' and $s_{\ell+1} = |P'| + 1$. Algorithm 2 iterates over the sub-curves $P'[s_i, s_{i+1} - 1]$ of P' from $i = 1$ to ℓ and stores in the set F_{pre} the indices j of the vertices of Q such that $(s_i - 1, j)$ is reachable (see the hatched cells in Figure 5). Using F_{pre}, in iteration i we successively compute the set F_{new} of indices such that $(s_{i+1} - 1, j)$ is reachable and make use of the following property.

▶ **Observation 16.** *For any point $q \in \mathbb{R}$, it holds that exactly one of the following is true:*

- *$|q - p_i| \leq \delta$ and $|q - P'(s_i + x)| \leq \frac{3}{2}\delta$ for all $x \in \{0, \ldots, k_i - 1\}$, or*
- *$|q - p_i| \in (\delta, 2\delta]$ and $|q - P'(s_i + x)| \leq \frac{3}{2}\delta$ for all even (resp. odd) $x \in \{0, \ldots, k_i - 1\}$ and $|q - P'(s_i + x)| > \frac{3}{2}\delta$ for all odd (resp. even) $x \in \{0, \ldots, k_i - 1\}$, or*
- *$|q - p_i| > 2\delta$.*

By Observation 16, it holds that whenever $|Q(j) - p_i| \leq \delta$, there exists an number a such that $(s_i + x, j)$ with $x \in \{0, \ldots, k_i - 1\}$ is reachable if and only if $x \geq a$ and whenever $|Q(j) - p_i| > 2\delta$, then $(s_i + x, j)$ is not reachable for any integer $x \in \{0, \ldots, k_i - 1\}$ and we

set $a = \infty$. When $|Q(j) - p_i| \in (\delta, 2\delta]$, things get slightly more complicated. However, we can still store a number a such that $(s_i + x, j)$ is reachable for all $x \in \{a, a+2, \dots\}$ with $x \leq k_i - 1$. Since there might be more reachable pairs $(s_i + x, j)$, we store a set A of size at most m and a number u which can be used to reconstruct all other reachable pairs $(s_i + x, j)$ with $x \in \{0, \dots, a\}$. Then, let $B \subset \{0, \dots, \min\{k_i - 1, a\}\}$ be the set such that for all $x \leq \min\{k_i - 1, a\}$ it holds that $(s_i + x, j - 1)$ is reachable if and only if $x \in B$. It holds that $B \neq \emptyset$ only if $|Q(j-1) - p_i| \in (\delta, 2\delta]$. In that case, define $z = 0$ (resp. $z = 1$) if $Q(j-1)$ and $Q(j)$ lie on the same side (resp. different sides) of p_i. Then for any $x + z > 0$, it holds that that $(s_i + x + z, j - 1)$ is reachable if and only if $x \in B$. Using this property, we store a counter u that counts the sum of the values z until we reach again a vertex with $|Q(j') - p_i| \notin (\delta, 2\delta]$. If $x + z = 0$, we additionally check whether $(s_i - 1, j - 1)$ or $(s_i - 1, j)$ is reachable by looking at the set F_{pre}. If one of them is reachable, then $(s_i, j - 1) = (s_i + (u - u), j)$ is reachable and we add the current number u to the stored set A. In short, we intend to maintain the following invariant. During iteration i of the outer for-loop and at the end of iteration j of the inner for-loop, it holds that $(s_i + x, j)$ is reachable with $x \in \{0, \dots, k_i - 1\}$ if and only if

a) $x \in \{u - z \mid z \in A\} \cup \{a\}$ or **b)** $x > a$ and $|Q(j) - P'(s_i + x)| \leq (2/3)\delta$.

See Figure 5 for an example. Here, during iteration $i = 3$ of the outer for-loop and at the end of iteration $j = 7$ (resp. $j = 8$) of the inner for-loop, it holds that $A = [0, 2]$, $u = 2$, and $a = \infty$ (resp. $A = [\,]$, $u = 0$, and $a = 0$).

Algorithm 2 Decision Algorithm for $d_{\text{dF}}(P', Q) \leq \frac{3}{2}\delta$.

▶ **Lemma 17.** *Assume that at the beginning of iteration i of the outer for-loop after setting $F_{pre} \leftarrow F_{new}$, it holds $(s_i - 1, j)$ is reachable if and only if $j \in F_{pre}$. Then, at the end of iteration i it holds that $(s_{i+1} - 1, j)$ is reachable if and only if $j \in F_{new}$.*

Proof. Denote with A_j, a_j, and u_j the value of A, a, and u at the end of iteration j in the inner for-loop of Algorithm 2. Then, we show that the following invariant is true; for every $x \in \{0, \dots, k_i - 1\}$, it holds that $(s_i + x, j)$ is reachable if and only if

a) $x \in \{u_j - z \mid z \in A_j\} \cup \{a_j\}$ or **b)** $x > a_j$ and $|Q(j) - P'(s_i + x)| \leq (2/3)\delta$.

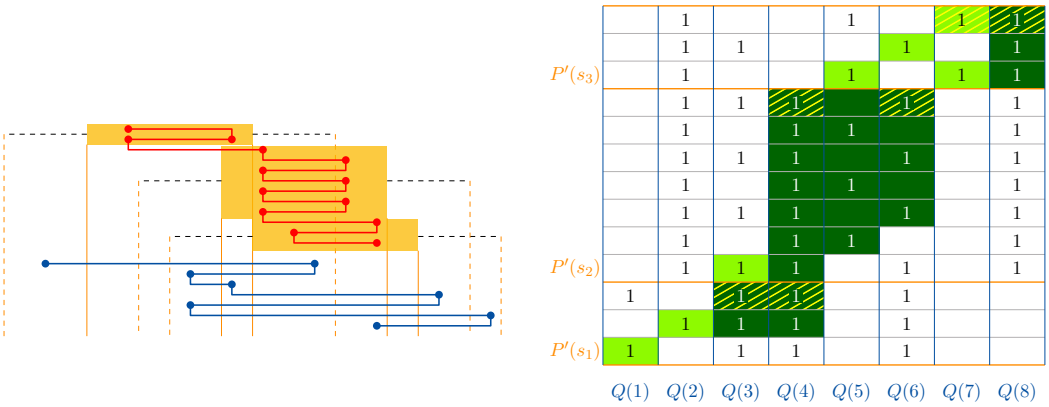

Figure 5 The compressed curve P' and the query curve Q are on the left. On the right is the free space matrix of P' and Q, where only 1-entries are added. The dark green cells visualize the parameter a and the light green cells the set $\{u - z \mid z \in A\}$. The hatched cells are the cells that have been in F_{pre} and F_{new}.

We prove this invariant via induction on j. For $j = 0$, the invariant clearly holds as $\{u_j - z \mid z \in A_j\} \cup \{a_j\} = \{\infty\}$. Now assume the invariant holds for $j-1$. Let $x \in \{0, \ldots, k_i - 1\}$. Then, by definition of the discrete Fréchet distance $(s_i + x, j)$ is reachable if and only if $|Q(j) - P(s_i + x)| \leq \frac{2}{3}\delta$ and $(s_i + x - 1, j)$, $(s_i + x, j - 1)$, or $(s_i + x - 1, j - 1)$ is reachable. We consider three different cases.

1. If $|Q(j) - p_i| > 2\delta$, then $(s_i + x, j)$ is not reachable, since $|Q(j) - P(s_i + x)| > \frac{2}{3}\delta$. By line 5 of Algorithm 2, the invariant holds.
2. If $|Q(j) - p_i| \leq \delta$, then $|Q(j) - P(s_i + x)| \leq \frac{2}{3}\delta$ for any $x \in \{0, \ldots, k_i - 1\}$. Further, observe that if $(s_i + y, j)$ is reachable for $y \in \{0, \ldots, k_i - 1\}$, then $(s_i + x, j)$ is also reachable for every $y \leq x \leq k_i - 1$. Define $y \in \{0, \ldots, k_i - 1\}$ to be the minimum such that $(s_i + y, j)$ is reachable. Hence, by line 13 it holds that the invariant holds if $a_j = y$. Unless $y = 0$ and $(s_i - 1, j)$ or $(s_i - 1, j - 1)$ is reachable, it must hold that $(s_i + y, j - 1)$ is reachable as otherwise y would not be the minimum. Further again since y is the minimum and by the invariant for $j - 1$, it holds that $y = \min\{u_{j-1} - z \mid z \in A_{j-1}\} \cup \{a_{j-1}\}$. Now, consider the special case that $y = 0$ and $(s_i - 1, j)$, or $(s_i - 1, j - 1)$ is reachable. By assumption, it holds that $(s_i - 1, j)$ (resp. $(s_i - 1, j - 1)$) is reachable if and only if $j \in F_{\text{pre}}$ (resp. $j - 1 \in F_{\text{pre}}$). Hence, a_j is set to y by line 9–12 and the invariant is true.
3. It remains the case that $\delta < |Q(j) - p_i| \leq 2\delta$.
   a. First, consider the case that $x \geq a_{j-1}$. Then since $(s_i + a_{j-1}, j - 1)$ is reachable by the induction hypothesis, it holds that $|Q(j-1) - p_i| \leq 2\delta$. Hence, $|Q(j-1) - P(s_i + x)| \leq \frac{2}{3}\delta$ or $|Q(j - 1) - P(s_i + x - 1)| \leq \frac{2}{3}\delta$. Further again by the induction hypothesis it holds that $(s_i + x, j - 1)$ or $(s_i + x - 1, j - 1)$ is reachable. Hence, by line 7–8 the invariant holds for $x \geq a_{j-1}$.
   b. Otherwise, it holds that $x < a_{j-1}$. Consider the special case that $x = 0$ and $(s_i + x, j)$ is reachable because $|Q(j) - P(s_i + x)| \leq \frac{2}{3}\delta$ and $(s_i - 1, j)$ or $(s_i - 1, j - 1)$ are reachable. Then by 9 and the assumption on F_{pre}, it holds that $u_j \in A_j$. Otherwise it holds that $(s_i + x, j)$ is reachable if and only if $(s_i + x, j - 1)$ or $(s_i + x - 1, j - 1)$ is reachable and $|Q(j) - p_i| \leq \frac{3}{2}\delta$. This is true because it holds that either $|Q(j) - P(s_i + x)| \leq \frac{2}{3}\delta$ or $|Q(j) - P(s_i + x - 1)| \leq \frac{2}{3}\delta$ since $\delta < |Q(j) - p_i| \leq 2\delta$. Hence, $x - 1 \in A_{j-1}$ or $x \in A_{j-1}$. Therefore, $A_{j-1} \neq [\,]$ and by the algorithm it holds that $\delta < |Q(j - 1) - p_i| \leq 2\delta$. If

$\min\{Q(j-1), Q(j)\} > p_i$ or $\max\{Q(j-1), Q(j)\} < p_i$, then $(s_i + x, j)$ is reachable if and only if $(s_i + x, j-1)$ is reachable by Observation 16. Otherwise $(s_i + x, j)$ is reachable if and only if $(s_i + x - 1, j - 1)$ is reachable. This is ensured by line 7–8.

This proves that the invariant is true for every j. Note that $(s_{i+1} - 1, j) = (s_i + k_i - 1, j)$. By the invariant it holds that $(s_i + k_i - 1, j)$ is reachable if and only if $|P'(s_{i+1} - 1) - Q(j)| \leq \frac{3}{2}\delta$ and $a_j < k_i$ or $u_j - k_i + 1 \in A_j$. Hence the lemma follows by line 15–16. ◀

▶ **Lemma 18.** *For any value $\delta \geq \delta_m$, we can decide whether $d_{dF}(P', Q) \leq \frac{3}{2}\delta$ in $\mathcal{O}(m\ell)$ time.*

Proof. We run Algorithm 2 and output $d_{\mathrm{dF}}(P', Q) \leq \frac{3}{2}\delta$ if and only if $m \in F_{\mathrm{new}}$ at the end of Algorithm 2. The running time of Algorithm 2 is in $\mathcal{O}(m\ell)$, since the array A is sorted and in every iteration of the inner for loop at most one point gets appended to A. By induction on the index i of s_i and Lemma 17, it holds that $(|P'|, m) = (s_{\ell+1} - 1, m)$ is reachable if and only if $d_{\mathrm{dF}}(P', Q) \leq \frac{3}{2}\delta$. ◀

It remains to optimize the δ value. First, we decide whether $d_{\mathrm{dF}}(P', Q) \leq \frac{3}{2}\delta_m$ or not using Algorithm 2. If $d_{\mathrm{dF}}(P', Q) \leq \frac{3}{2}\delta_m$, then $d_{\mathrm{dF}}(P, Q) \in [\delta_m, 2\delta_m]$ by Lemma 15 and δ_m is a 2-approximation for $d_{\mathrm{dF}}(P, Q)$. Otherwise $d_{\mathrm{dF}}(P', Q) > \frac{3}{2}\delta_m$. In this case, we use the observation that the discrete Fréchet distance between P' and Q gets realizes by a point to point distance between a vertex of P' and a vertex of Q. Hence,

$$d_{\mathrm{dF}}(P', Q) \in \{|(p_i \pm \delta/2) - Q(j)| \mid i \in \{1, \ldots, \ell\}, j \in \{1, \ldots, m\}\}.$$

We sort these values in $\mathcal{O}(m^2 \log m)$ time and search over the ones that are greater $\frac{3}{2}\delta_m$. Using Algorithm 2, we compute in $\mathcal{O}(m^2 \log m)$ time $\frac{3}{2}\delta = d_{\mathrm{dF}}(P', Q)$. Then, it holds that $d_{\mathrm{dF}}(P, Q) \in [\delta, 2\delta]$ by Lemma 15. Therefore, we get the following theorem:

▶ **Theorem 19.** *For a given value m, there exists a data structure that preprocesses a 1-dimensional curve P of complexity n in $\mathcal{O}(n \log n)$ time using $\mathcal{O}(m)$ space such that for any 1-dimensional query curve Q of complexity at most m, we can approximate the discrete Fréchet distance between P and Q within a factor of 2 in $\mathcal{O}(m^2 \log m)$ time.*

The next corollary is a direct consequence of the theorem above.

▶ **Corollary 20.** *Given two 1-dimensional curves P and Q of complexity n and m with $n \geq m$. There exists a 2-approximation algorithm to compute the discrete Fréchet distance between P and Q in $\mathcal{O}(n \log n + m^2 \log m)$ time.*

By Theorem 9, it follows that there does not exist an algorithm using $\mathcal{O}(n \log n + m^2 \log m)$ time with a better approximation factor. Further, the lower bound in [12] shows the almost optimality of the running time.

5 $(3 + \varepsilon)$-approximation Algorithm for the Fréchet distance

In this section, we give a $(3+\varepsilon)$-approximation algorithm to compute the continuous/discrete Fréchet distance between two curves P and Q of complexity n resp. m with $m \leq n$. We describe this section for the continuous Fréchet distance, but everything works analogously for the discrete Fréchet distance as well. We begin with the decision variant for δ. In the first step, using the curve Q, we compute a curve P' of complexity at most $2m$ such that $d_{\mathrm{F}}(P, P') \leq \delta$ or decide that $d_{\mathrm{F}}(P, Q) > \delta$ in linear time.

▶ **Lemma 21.** *Algorithm 3 computes a curve P' of complexity at most $2m$ with $d_F(P, P') \leq \delta$ or returns $d_F(P, Q) > \delta$ in $\mathcal{O}(n)$ time.*

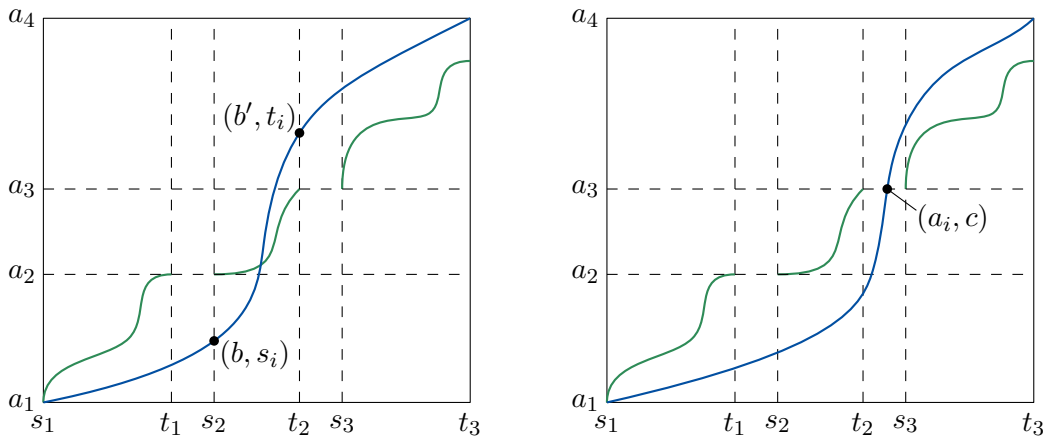

Figure 6 The green curve is a matching between the curves $P[a_i, a_{i+1}]$ and $Q[s_i, t_i]$ computed in Algorithm 3. The blue curves visualize the matching used in the proof of Lemma 21.

Proof. In the i-th iteration of the while-loop, it holds that $s_i \geq i$ by line 3 of Algorithm 3. Further, it holds that $a_i \leq a_{i+1}$ for every i and line 6 has running time $\mathcal{O}(a_{i+1} - a_i)$ as $\overline{Q(s_i)Q(t_i)} \subset \overline{Q(s_i)Q(\lfloor s_i + 1 \rfloor)}$. Hence, the running time follows. If a curve P' is returned, it holds that $d_{\mathrm{F}}(P, P') \leq \delta$ by line 6 and Observation 2. The complexity of P' is at most $2m$ since there are at most m iterations of the while loop. It remains to show correctness for the case when $d_{\mathrm{F}}(P, Q) > \delta$ is returned. Assume that $d_{\mathrm{F}}(P, Q) > \delta$ is returned and in fact it holds $d_{\mathrm{F}}(P, Q) \leq \delta$. Let M be the matching between P and Q that realizes the Fréchet distance. We consider two cases (see Figure 6). In the first case, there exist b, b' and an index i such that $(b, s_i), (b', t_i) \in M$ with $b \leq a_i$ and $b' > a_{i+1}$. This contradicts line 6 of the algorithm. Otherwise, there must exist an index i and a parameter c such that $(a_i, c) \in M$ with $t_{i-1} \leq c < s_i$. This contradicts line 3. Hence, it follows that $d_{\mathrm{F}}(P, Q) > \delta$. ◀

Algorithm 3 Simplification of P depending on Q.

```
1  s_1 ← 1, a_1 ← 1, i ← 1
2  while True do
3      s_i ← min{s ≥ ⌊s_{i−1} + 1⌋ | ‖P(a_i) − Q(s)‖ ≤ δ} ∪ {∞}
4      if s_i = ∞ then
5          Return d_F(P, Q) > δ
6      Find largest a_{i+1} such that ∃ t_i ≤ ⌊s_i + 1⌋ with d_F(P[a_i, a_{i+1}], Q(s_i)Q(t_i)) ≤ δ
7      if a_{i+1} = n then
8          Return P' = ⟨Q(s_1), Q(t_1), Q(s_2), Q(t_2), ..., Q(s_i), Q(t_i)⟩
9      i ← i + 1
```

Lemma 21 can be easily adapted such that it holds for the discrete Fréchet distance. Given P', we decide whether $d_{\mathrm{F}}(P', Q) \leq 2\delta$ in $\mathcal{O}(m^2)$ time [3] or slightly faster [15]. If $d_{\mathrm{F}}(P', Q) \leq 2\delta$, then $d_{\mathrm{F}}(P, Q) \leq d_{\mathrm{F}}(P', Q) + d_{\mathrm{F}}(P, P') \leq 3\delta$. Otherwise, it holds that $d_{\mathrm{F}}(P, Q) \geq d_{\mathrm{F}}(P', Q) - d_{\mathrm{F}}(P, P') > \delta$. Hence, we obtain the following lemma.

▶ **Lemma 22.** *Given two curves P and Q of complexity n and m in any metric space M. Assume that we can compute distances in M in constant time. We can 3-approximate the decision variant of the continuous/discrete Fréchet distance in $\mathcal{O}(n + m^2)$ time.*

For curves in the Euclidean space, Colombe and Fox (Theorem 11 of [18]) show how to transform a decision algorithm into an approximate optimization algorithm increasing the running time by a $\mathcal{O}(\log(n/\varepsilon))$ factor. Since all L_p-norms on $\mathbb{R}^d$ are equivalent and Lemma 22 holds for all L_p-norms, we can adopt their approach such that we can use it for all L_p-norms.

▶ **Theorem 23.** *There exist a $(3+\varepsilon)$-approximation algorithm for the continuous/discrete Fréchet distance using $\mathcal{O}((n+m^2)\log(n/\varepsilon))$ time.*

Abstract

Hyperbolic uniform disk graphs (HUDGs) are intersection graphs of disks with some radius r in the hyperbolic plane, where r may be constant or depend on the number of vertices in a family of HUDGs. We show that HUDGs with constant clique number do not admit *product structure*, i.e., that there is no constant c such that every such graph is a subgraph of $H \boxtimes P$ for some graph H of treewidth at most c. This justifies that HUDGs are described as not having a grid-like structure in the literature, and is in contrast to unit disk graphs in the Euclidean plane, whose grid-like structure is evident from the fact that they are subgraphs of the strong product of two paths and a clique of constant size [Dvořák et al., '21, MATRIX Annals]. By allowing H to be any graph of constant treewidth instead of a path-like graph, we reject the possibility of a grid-like structure not merely by the maximum degree (which is unbounded for HUDGs) but due to their global structure. We complement this by showing that for every (sub-)constant r, HUDGs admit product structure, whereas the typical hyperbolic behavior is observed if r grows with the number of vertices.

Our proof involves a family of n-vertex HUDGs with radius $\log n$ that has bounded clique number but unbounded treewidth, and one for which the ratio of treewidth and clique number is $\log n / \log \log n$. Up to a $\log \log n$ factor, this negatively answers a question raised by Bläsius et al. [SoCG '25] asking whether balanced separators of HUDGs with radius $\log n$ can be covered by less than $\log n$ cliques. Our results also imply that the local and layered tree-independence number of HUDGs are both unbounded, answering an open question of Dallard et al. [arXiv '25].

1 Introduction

In this paper, we investigate the structure of *hyperbolic uniform disk graphs (HUDGs)*, i.e., graphs G for which there is an r such that G is the intersection graph of disks with radius r in the hyperbolic plane. The structure of these graphs heavily depends on r, where r may be constant or a function depending on the number n of vertices for a family of HUDGs. In the literature [3, 5], HUDGs with very small r are described as almost Euclidean or grid-like, and as firmly hyperbolic or more hierarchical for larger r; see Figure 1. However, the state of the

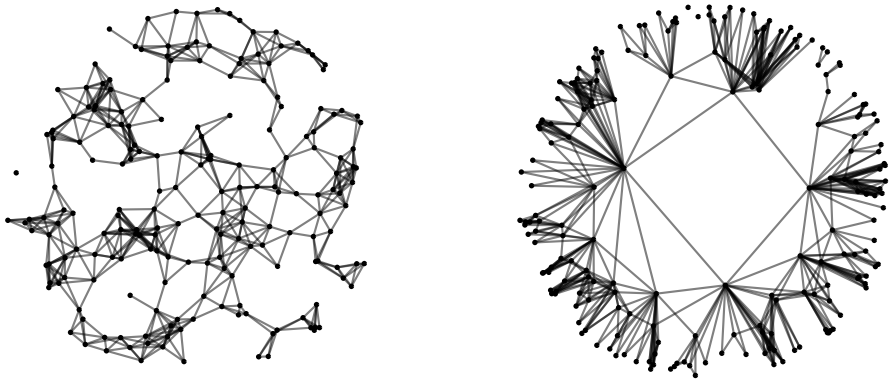

Figure 1 HUDGs with random vertex positions. Left: The radius r is so small (think of $1/\sqrt{n}$) that it is indistinguishable from the Euclidean setting. Right: The disk radius r is logarithmic in n.

art cannot fully explain in what sense the grid-like structure depends on r. We contribute to the understanding of the structure of HUDGs by formalizing when a graph has a grid-like structure and showing that this is indeed not satisfied by HUDGs, unless the radius is small. We do so by showing that HUDGs do not admit a so-called *product structure*, and thereby also deepen the understanding of this notion. Before stating our results precisely, we review what is already known on the structure of HUDGs and how it depends on the radius r.

We start with small radii and work our way up from there. Locally, the hyperbolic plane behaves like the Euclidean plane, which sets the expectation that very small r yield graphs similar to *Euclidean unit disk graphs (EUDGs)*, which are defined as intersection graphs of unit disks in the Euclidean plane. While there are always HUDGs that are not EUDGs independent of how small we choose r, every EUDG is in fact a HUDG if we choose r sufficiently small [3]. Sufficiently small here means that r shrinks with the number of vertices n. EUDGs [8] are a well studied graph class that allows for balanced separators that can be covered with $O(\sqrt{n})$ cliques [14]. We remark that balanced separators are arguably one of the main reasons why HUDGs, EUDGs, and more generally disk graphs, are interesting from an algorithmic perspective. For HUDGs, there are balanced separators that can be covered with $O((1+1/r)\log n)$ cliques [5]. Interestingly, this matches the $\sqrt{n}$ bound of the Euclidean case for $r \in \Theta(1/\sqrt{n})$ up to a $\log n$ factor and improves for larger r. In fact, if $r \in \Omega(1)$, this gives separators coverable with $\log n$ cliques. This gives a strong argument that the structure of HUDGs changes when going from sub-constant to at least constant r. This change in structure is also reflected in the fact that several problems can be solved more efficiently for constant r than in the Euclidean setting [5, 30]. Summarizing, there is strong evidence that the structure of HUDGs change significantly between sub-constant r and constant r.

This raises the question whether there is a similar structural difference between constant r and super-constant r. While the above separators do not continue to get smaller, there are indications that super-constant r makes a difference, and that in particular $r \in \Theta(\log n)$ is an interesting case. For HUDGs with $r \in \Theta(\log n)$, the independent set problem can be solved in polynomial time [5]. Moreover, HUDGs with $r \in \Theta(\log n)$ and random vertex positions are so-called hyperbolic random graphs [31]; a random graph model that is popular due to its resemblance to real-world networks in regards to properties like clustering, diameter, and degree distribution [22, 23, 26]. While this indicates a significant difference between constant and growing r, the state of the art does not make the structural differences explicit. The only structural insight we are aware of is that large stars, or more generally high-degree vertices with sparse neighborhoods, require r to grow logarithmically with the degree [3].

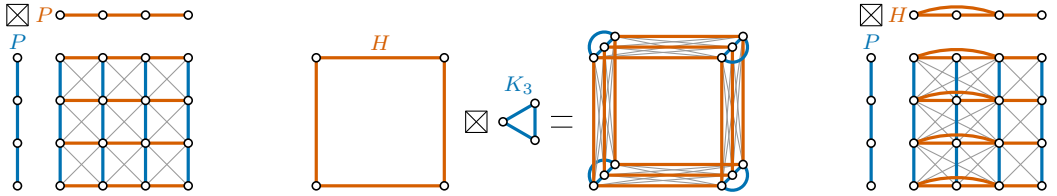

Figure 2 The strong product of two paths (left), of a graph H and a clique (middle), and a graph H with a path (right).

The main result of this paper is to show that every class of HUDGs with constant radius r has product structure, while there are HUDGs with growing radius that do not. This closes two gaps in the literature: First, it justifies why HUDGs with large radii should be considered *not* grid-like. And second, the contrast to HUDGs with constant radius shows a stark structural difference between constant radius compared to larger radii, say $\log n$.

Concerning the notion of grid-like structure, observe that $\sqrt{n} \times \sqrt{n}$-grids are EUDGs and thus also HUDGs for small radius. However, the grid-like structure of EUDGs goes far beyond merely containing grids. In fact, EUDGs are in general rather grid-like in the sense that there may be large cliques locally, but the global structure of every EUDG behaves like (the subgraph of) a grid. This notion of being "grid-like" can be formalized using the *strong product* of graphs, which we introduce formally in Section 2. For now, it suffices to know that the strong product $P_a \boxtimes P_b$ of two paths on a and b vertices, respectively, is the $a \times b$-grid with diagonals. Moreover, the strong product $H \boxtimes K_k$ of a graph H with the complete graph K_k expands each vertex of H to a k-clique as shown in Figure 2. Dvořák, Huynh, Joret, Liu, and Wood [20] show that every EUDG G is a subgraph of $P \boxtimes P \boxtimes K_k$, where P is a path and k is linear in the clique number ω of G. Equivalently, one can partition the vertices of a EUDG into sets of size $O(\omega)$ so that contracting each set into a single vertex yields a subgraph H of a grid (with diagonals), yielding a product of the form $H \boxtimes K_k$.

More generally, the concept of product structure allows us to view the graphs of a graph class as subgraphs of the product of simpler graphs; usually a graph with small treewidth and a path. We say a graph class $\mathcal{G}$ admits *product structure* if for every $G \in \mathcal{G}$, we have $G \subseteq H'' \boxtimes P$ for some graph H'' of constant treewidth and some path P. In our proofs, we show a stronger statement, namely that the graphs we consider are subgraphs of $H \boxtimes K_k$ for some hyperbolic tiling H. Since planar graphs, which include hyperbolic tilings, admit product structure, this implies $H \subseteq H' \boxtimes P \boxtimes K_3$ for some graph H of constant treewidth [16,17], so with $H'' = H' \boxtimes K_3 \boxtimes K_k$ we obtain a product of the form $H'' \boxtimes P$. Note that the above mentioned result on EUDGs can be viewed in this framework by choosing $H = P \boxtimes P$. We remark that replacing one of the paths in the product $P \boxtimes P \boxtimes K_k$ by a graph H', enables graphs that go beyond Euclidean square-grids. In particular, it allows for high-degree vertices. That is, rejecting a grid-like structure via product structure is significantly stronger than showing that a graph class does not allow for a decomposition of the form $P \boxtimes P \boxtimes K_k$. To finish the discussion on grid-like structure, let us mention that "having product structure" does not need to be seen as a binary decision. For this, the *row-treewidth* of a graph G is the smallest t such that $G \subseteq H'' \boxtimes P$ for some graph H'' of treewidth t and some path P. The row-treewidth of a graph class is the maximum

row-treewidth among all contained graphs, possibly as a function depending on the number of vertices if it is unbounded. Now, among graph classes admitting product structure, we consider a class to have a stronger grid-like structure if the row-treewidth is small.

Our results that some families of HUDGs admit product structure while others do not, make HUDGs also interesting from the product structure perspective. Product structure has proved to be a useful tool for many graph-theoretic (see [28] for a survey) and algorithmic [1,6] applications. While naturally, the literature concentrates on graph classes that admit product structure [7, 15, 16, 19, 27, 28], it is also interesting to find graph classes that do not admit product structure, for an other reason than the presence of large cliques. Interestingly, many known constructions are geometric intersection graphs, namely different kinds of string graphs with constant clique number [29, 32]. By showing that HUDGs do not admit product structure, we contribute to an improved understanding of the limitations of this notion.

1.1 Main Results and Discussion

The following theorem states our main result that HUDGs do not admit product structure, even when restricted to constant clique size, rejecting the possibility of a global grid-structure.

▶ **Theorem 1.** *Hyperbolic uniform disk graphs with constant clique number do not admit product structure.*

Our proof of Theorem 1 requires the radius to grow with the graph size. This is indeed necessary as HUDGs with constant or sub-constant disk radius do admit product structure.

▶ **Theorem 2.** *Every family of hyperbolic uniform disk graphs with clique number and disk radius in $O(1)$ admits product structure. In contrast, for every super-constant r, there are families of hyperbolic uniform disk graphs with constant clique number and disk radius in $\Theta(r)$ not admitting product structure.*

This confirms the observations of previous results [3, 5] that HUDGs become similar to the Euclidean case for small radii, whereas they differ significantly for large radii. As having product structure in some sense restricts the complexity of the neighborhood of an individual vertex, this in particular indicates that HUDGs become more complex (and for some applications more interesting) when allowing the radius to grow with the graph size. We show the first part of Theorem 2 in Section 4 and the second in Section 3.

Bounds on the Row-Treewidth. We actually prove more fine-grained results that go beyond the binary question of having product structure. Recall that a graph class admits product structure if and only if it has bounded row-treewidth, i.e., a super-constant lower bound and a constant upper bound on the row-treewidth disprove and prove product structure, respectively. Our lower and upper bounds on the row-treewidth depending on clique number ω and disk radius r are shown in Table 1. The first two rows show our lower bounds that grow with r (as long as $r \in O(\log n)$), where we have the two cases $\omega \in O(1)$ and $\omega \in O(\log \log n)$. The first case is most relevant for product structure as growing clique size immediately rejects product structure, whereas the second case gives the stronger lower bound. Then, the third row gives our upper bound, whereas the last row is from the literature and is discussed at the end of this section. Before doing so, we discuss each result in Table 1 in more detail.

The first lower bound in Table 1 assumes constant clique number $\omega \in O(1)$. Note that there are two regimes for the radius r. For radii smaller than $\log n$, the lower bound grows with increasing radius until it reaches a row-treewidth of $\Omega(\log \log n)$ for radius $r \in \Theta(\log n)$. For larger radii, the lower bound stops to grow with r. We note that any super-constant

Table 1 Overview of lower and upper bounds for the row-treewidth. The lower bounds mean that for every radius r in the given regime, there exists a family of HUDGs with radius $\Theta(r)$ and the given bounds on the clique number ω and the row-treewidth. The upper bounds hold for all HUDGs with radius r and clique number ω (both of which may depend on the graph size n).

ω	row-treewidth		comment
	$r \in O(\log n)$	$r \in \Omega(\log n)$	
$O(1)$	$\Omega(\log r)$	$\Omega(\log \log n)$	Cor. 15 and 16; implies Thm. 1 and 2
$O(\log \log n)$	$\Omega(r)$	$\Omega(\log n)$	Cor. 15 and 16
variable	$O(\omega \cdot 3^{8r})$		Thm. 17; implies Thm. 2 for $r, \omega \in O(1)$
variable	$O(\omega(1+\frac{1}{r})\log n)$		follows from treewidth bound [5]

radius already implies super-constant row-treewidth and thus refutes product structure, yielding Theorem 1 and the second part of Theorem 2. That is, the specific lower bounds are significantly stronger than Theorem 1 as they refute product structure for every growing radius and not only for the class of all HUDGs. For the lower bound given in the next row of Table 1, we allow slightly growing clique number $\omega \in O(\log \log n)$, which yields exponentially larger lower bounds for the row-treewidth compared to the first row. We remark that all our lower bounds are linear in the size of the largest clique-minor, known as the Hadwiger number.

Turning to our upper bound (bottom part of Table 1), observe that it only depends on ω and r. Assuming both to be constant directly implies the first part of Theorem 2. Moreover, for growing clique number ω (but constant r), this is the best upper bound one can hope for, as the clique number is a lower bound on the row-treewidth. Concerning growing radius, note that the radius r contributes exponentially to the row-treewidth. While it might be possible to improve this upper bound, we note that our lower bounds for growing radius imply that there has to be a dependence on r. We remark that we strengthen our upper bound in terms of product structure. For this, recall that the upper bound on the row-treewidth means that every HUDG with radius r is a subgraph of $H'' \boxtimes P$ for some graph H'' of treewidth $O(\omega \cdot 3^{8r})$. We show the stronger statement that for every HUDG G with radius r and clique number ω, we have $G \subseteq H \boxtimes K_k \subseteq H' \boxtimes P \boxtimes K_k$, for some hyperbolic tiling H, some graph H' of treewidth 3, some path P, and $k \in O(\omega \cdot 3^{8r})$. Our proof is similar to the Euclidean case [20], but instead of the Euclidean square-grid, we construct a suitable tiling of the hyperbolic plane. Interestingly, the tiling depends on r and becomes more hyperbolic for large r and more Euclidean for small r. With our tiling, we also contribute to the rich field of constructing hyperbolic tilings with various favorable properties [9, 13, 33].

▶ **Theorem 3.** *For each $r > 0$ there is an (irregular) tiling of the hyperbolic plane such that*
- *every tile can be covered by $O(3^{8r})$ disks of radius r and*
- *each two points with distance at most $2r$ lie in the same tile or in two adjacent tiles.*

The last upper bound in Table 1 directly follows from the literature, which we discuss next.

Connections to the State of the Art. Our lower bounds are based on the fact that the row-treewidth is asymptotically lower-bounded by the treewidth in the neighborhood of a vertex [18]. Notably, the neighborhoods of HUDGs are called *strongly hyperbolic uniform disk graphs (SHUDGs)* and are an interesting graph class in their own right [3]. In fact, the much studied hyperbolic random graphs are SHUDGs with random vertex positions [31]. The core of our lower bounds for the row-treewidth of HUDGs are the following bounds on the treewidth of SHUDGs.

▶ **Theorem 4.** *There are families of n-vertex strongly hyperbolic uniform disk graphs with radius $\Theta(\log n)$ and*

- *clique number $O(\log\log n)$ and treewidth $\Omega(\log n)$*
- *clique number $O(1)$ and treewidth $\Omega(\log\log n)$.*

To connect this to the results by Bläsius, von der Heydt, Kisfaludi-Bak, Wilhelm, and Van Wordragen [5], recall that they show that n-vertex HUDGs with radius r have balanced separators that can be covered with $(1+1/r)\log n$ cliques. This implies that the treewidth is $O(\omega(1+1/r)\log n)$ [21], which is an upper bound for the row-treewidth (which is why we list it in Table 1). For r at least constant, this gives separators coverable with $O(\log n)$ cliques, i.e., treewidth $O(\omega\log n)$. The authors of [5] raise the question whether this can be improved, in particular for increasing radius r. With Theorem 4, we give a negative answer to this, up to a $\log\log n$ factor: The family with clique number $\omega\in O(\log\log n)$ has treewidth $\Omega(\log n)=\Omega(\omega\log n/\log\log n)$.

In addition, Theorem 4 provides the first known example of a family of SHUDGs with constant clique number but unbounded treewidth. Graph classes with this property are also called *not* (tw,ω)*-bounded*. By Dallard, Milanič, and Štorgel [12], graph classes with bounded tree-independence number are (tw,ω)-bounded, so our constructed family of SHUDGs has unbounded tree-independence number. Since SHUDGs are neighborhoods of vertices in HUDGs, it follows that the local tree-independence number of HUDGs is unbounded, which in turn implies that their layered tree-independence number is unbounded [24]. This gives a negative answer to an open question of Dallard, Milanič, Munaro, and Yang [11].

▶ **Corollary 5.** *The local tree-independence number and the layered tree-independence number of hyperbolic uniform disk graphs are unbounded.*

Note that for these two answered open questions, the first comes from the HUDG side and the other is more related to product structure. This underscores that HUDGs and product structure form an interesting combination.

2 Preliminaries

We assume familiarity with some graph-theoretic terminology; also see the full version [2].

2.1 Product Structure

Separators and Treewidth. The *treewidth* $\mathrm{tw}(G)$ of a graph G is linearly tied to the *separation number*, i.e., the smallest integer s such that every subgraph of G has a balanced separator of size s [21], [10, Lemma 7.20]. If G has a clique-minor of size k, then $\mathrm{tw}(G)\geq k-1$.

Strong Product. For two graphs G and H, the *strong product* $G\boxtimes H$ is defined as follows; also see Figure 3. $G\boxtimes H$ has vertex set $V(G\boxtimes H)=V(G)\times V(H)$, i.e., every vertex $u=(u_G,u_H)$ of $G\boxtimes H$ corresponds to a vertex u_G in G and to a vertex u_H in H. Two vertices $u=(u_G,u_H)$ and $v=(v_G,v_H)$ are adjacent in $G\boxtimes H$ if one of the following is true.

- u and v are the same vertex in G and adjacent in H, i.e., $u_G=v_G$ and $u_Hv_H\in E(H)$.
- u and v are the same vertex in H and adjacent in G, i.e., $u_H=v_H$ and $u_Gv_G\in E(G)$.
- u and v are adjacent in G and H, i.e., $u_Gv_G\in E(G)$ and $u_Hv_H\in E(H)$.

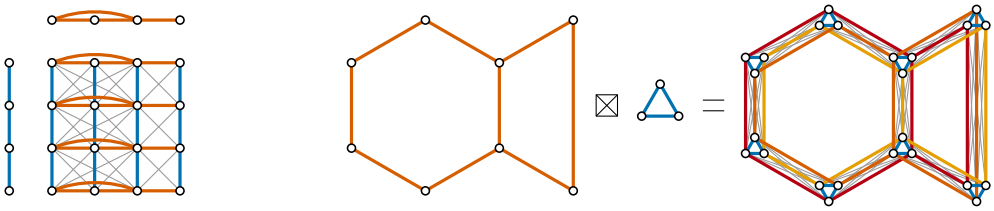

Figure 3 Left: Strong product of a graph H (red) with a path P (blue). The three different types of edges are color coded in red (edge in H, same vertex in P), blue (edge in P, same vertex in H), and gray (edge in H and P). Right: Strong product of a graph (red) with a K_3 (blue).

Row-Treewidth and Product Structure. We are usually interested in products of the form $H \boxtimes P$ where H has small treewidth and P is a path (of arbitrary length). Assume G is a subgraph of such a product $G \subseteq H \boxtimes P$ and assume that H is chosen such that $\text{tw}(H)$ is minimum with this property. Then, we call $\text{tw}(H)$ the *row-treewidth* of G. We say that a graph family $\mathcal{G}$ has *product structure* if the graphs in $\mathcal{G}$ have row-treewidth $O(1)$, i.e., there exists a constant that upper-bounds the row-treewidth of every graph $G \in \mathcal{G}$.

For products of the form $G = H \boxtimes K_k$, think of G as being obtained as follows. Start with H and replace each vertex with a k-clique and each edge with a complete bipartite graph between the corresponding k-cliques. The treewidth of $H \boxtimes K_k$ is $(\text{tw}(H) + 1) \cdot k - 1$.

2.2 Hyperbolic Geometry and Tilings

While this paper is about graphs in the hyperbolic plane, most of it can be understood with only little knowledge of hyperbolic geometry. We thus only provide a brief introduction. Formally, hyperbolic geometry is obtained from Euclidean geometry by replacing the parallel axiom: Instead of having exactly one parallel to a line through some given point not on the line, there are infinitely many, where two lines are considered parallel if they do not intersect. Thus, many concepts familiar from Euclidean geometry still apply as long as the parallel axiom is not involved, e.g., definitions of distances, angles, disks, (regular) polygons, and congruency are unchanged and the triangle inequality holds. However, some geometric laws like trigonometric formulas work differently, which we only introduce when needed; see [25].

Basic Properties. Our illustrations sometimes use the Poincaré disk model, which maps the hyperbolic plane into a unit disk of the Euclidean plane. However, we do not need any knowledge about this model and the illustrations should be helpful regardless. The core property of the hyperbolic plane relevant for this paper is the following. The hyperbolic plane expands exponentially, while at the same time behaving like the Euclidean plane locally. To concretize, consider a disk D of radius r. If r is small, then the area and circumference of D are quadratic and linear in r, respectively, like in the Euclidean plane. If the radius r increases, the area and circumference both grow exponentially like $\Theta(e^r)$. This has two interesting effects. First, the hyperbolic plane has more space. This becomes more pronounced at bigger scales, i.e., when we look at a large region. Secondly, in Euclidean geometry one can scale objects to change their size while keeping them structurally the same, e.g., think of similar triangles. In the hyperbolic plane, however, the scale makes a big structural difference, and there is no scaling operation that changes all distances by the same factor.

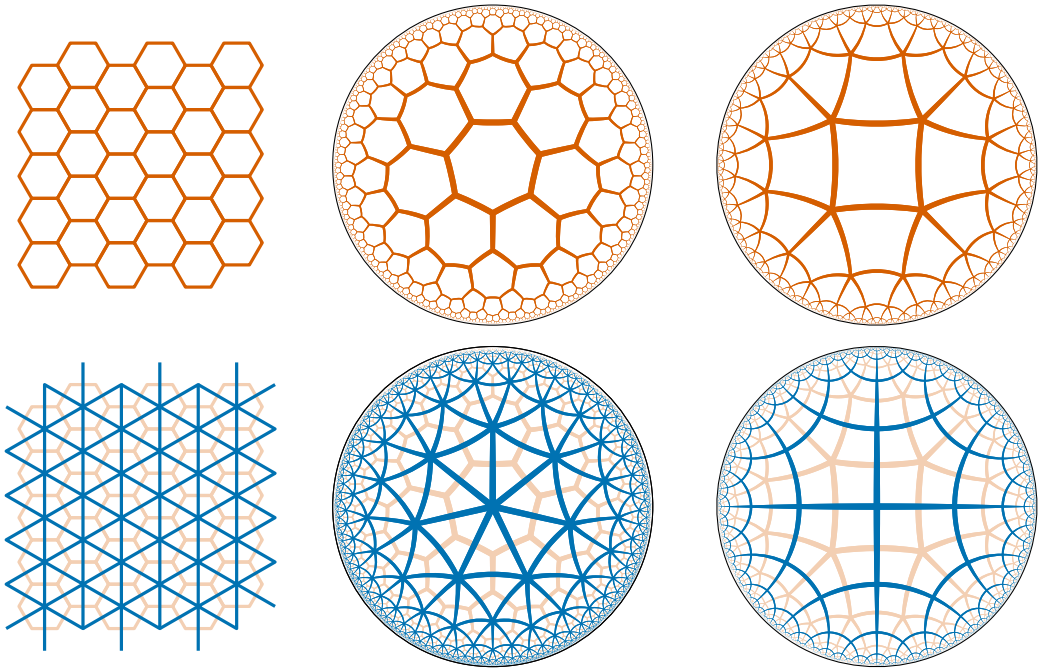

Figure 4 Regular tilings (top) together with their duals (bottom). From left to right: A Euclidean $\{6,3\}$ tiling, a hyperbolic $\{7,3\}$ tiling, and a hyperbolic $\{4,5\}$-tiling. While the tiles seem to get smaller towards the boundary of the Poincaré disk, they are all congruent.

Hyperbolic Tilings. A *regular tiling* is a partition of the plane into congruent regular polygons; see Figure 4. The Euclidean plane can be tiled with triangles, squares, and hexagons. These tilings have the Schläfli symbols $\{3,6\}$, $\{4,4\}$, and $\{6,3\}$, respectively, where $\{p,q\}$ indicates that each tile is a p-gon and q such p-gons meet at each corner. For any p and q with $\frac{1}{p}+\frac{1}{q}<\frac{1}{2}$, we obtain a regular tiling of the hyperbolic plane. While Euclidean tilings can be scaled arbitrarily, the size of the tiles in a hyperbolic $\{p,q\}$-tiling is determined by p and q and can be derived from basic trigonometry. Observe in Figure 4 that the exponential expansion of the hyperbolic plane is reflected in the tilings, which can be seen as a discretization of the plane. We also consider (irregular) tilings, where the tiles do not need to be congruent. We usually interpret tilings as infinite[1] plane graphs. Then the corners are the vertices, the sides are the edges, and the p-gons are the *faces*. The *dual* of such a plane graph has one vertex per face and two faces are adjacent if they share an edge.

2.3 Geometric Graphs

A graph G is a *(Euclidean) unit disk graph (EUDG)* if it is the intersection graph of disks of radius 1 in the Euclidean plane. We also interpret the disk centers as the *positions* of the corresponding vertices and use terms like *distance*, i.e., two vertices are connected if and only if their distance is at most 2. We say that G is a *hyperbolic uniform disk graph (HUDG)* if there exists a *disk radius* r such that G is the intersection graph of hyperbolic disks of radius r. The radius r can depend on the graph and makes an important difference.

[1] Throughout the paper, we implicitly assume that all considered graphs are finite. Tilings are the only exception. But also for tilings, we are usually only interested in a finite subgraph.

We are usually interested in the asymptotics of r with respect to the graph size n. We say that a HUDG G *has disk radius* r if it is the intersection graph of hyperbolic disks of radius r. Moreover, we say that a family $\mathcal{G}$ of HUDGs *has disk radius* $r(n)$ if every $G \in \mathcal{G}$ with n vertices has disk radius $r(n)$. This lets us use asymptotics, i.e., $\mathcal{G}$ *has disk radius* $\Theta(r(n))$ if there exist constants c_1, c_2 such that every sufficiently large n-vertex graph $G \in \mathcal{G}$ has disk radius r_G for $c_1 r(n) \leq r_G \leq c_2 r(n)$.[2]

A graph is a *strongly hyperbolic uniform disk graph (SHUDG)* [3] if it is a HUDG with disk radius r such that all vertices have distance at most $2r$ from the origin. This means that a vertex placed at the origin would be universal, i.e., adjacent to all other vertices of the graph. Note that the neighborhood of every vertex in a HUDG induces an SHUDG. Studying SHUDGs is in some sense similar to studying families of HUDGs with large disk radius: SHUDGs with bounded average degree have disk radius $\Omega(\log n)$ [3].

3 HUDGs Do Not Admit Product Structure

In this section, we show that HUDGs with constant clique number do not admit product structure (Theorem 1). While our construction initially has disk radius $\Theta(\log n)$, we extend it to arbitrary super-constant disk radii to prove the second part of Theorem 2. This is tight as we show in Section 4 that every family of HUDGs with disk radius in $O(1)$ and constant clique number has indeed product structure. Similarly, we provide families of HUDGs for the lower bounds in the second row of Table 1 for every super-constant disk radius. These results are summarized in Corollaries 15 and 16 at the end of the section.

To reject product structure, we use that, asymptotically, the treewidth in the neighborhood of some vertex is a lower bound on the row-treewidth [16, 18]. Since SHUDGs describe the neighborhoods of vertices in a HUDG, we aim for a family of SHUDGs with constant clique number but unbounded treewidth to prove Theorem 1 (see the full version [2] for details).

▶ **Theorem 6.** *There is a family of n-vertex SHUDGs with disk radius in $\Theta(\log n)$, clique number in $O(\log \log n)$, and treewidth in $\Omega(\log n)$.*

We then identify an induced subgraph within each of the constructed SHUDGs to prove Theorem 1. In addition, Theorems 6 and 7 together prove Theorem 4.

▶ **Theorem 7.** *There is a family of n-vertex SHUDGs with disk radius in $\Theta(\log n)$, clique number in $\Theta(1)$, and treewidth in $\Omega(\log \log n)$.*

3.1 Proof of Theorem 6

For each integer $r \geq 2$, we construct an n-vertex SHUDG G_r by placing $n \in \Theta(2^r)$ vertices into the hyperbolic plane, which yields $r \in \Theta(\log n)$ for the disk radius as required by Theorems 6 and 7. First, we place a vertex at the origin which we call the *root*. Second, for $2 \leq k \leq r$, let A_k be a regular 2^k-gon with side lengths $2r$ whose center is at the origin. We align these polygons such that for each $k > 2$, every other edge of A_k has the same perpendicular bisector as some edge of A_{k-1}; see Figure 5. Now, let V_k denote the vertex set of A_k and let V_1 contain exactly the root. We say a vertex is in the *k-th level* if it is contained in V_k. The vertex set of G_r is defined as the union of all V_k, $k \in [r]$, and two vertices are adjacent if and only if their distance is at most $2r$. In particular, the sides of

[2] We note that this is the natural way to use asymptotics. We only make this explicit as asymptotics can be unintuitive in this context, e.g., "the class of all HUDGs with radius $\Theta(\log n)$" is not well-defined.

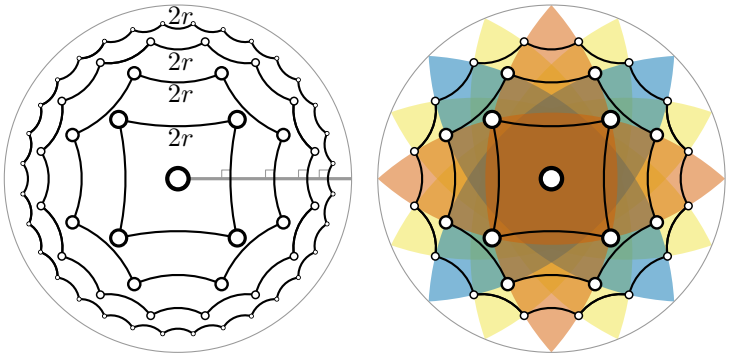

Figure 5 Left: Vertex positions of G_r constructed for Theorem 6. The k-th level, $k \geq 2$, induces a 2^k-cycle with consecutive vertices having angular distance $2\pi/2^k$. Right: Equivalent construction inspired by separators in [4], where vertices are placed at intersection points of hypercycles.

the polygons are also edges in G_r, and there are no further edges within a level as chords in a regular polygon are strictly longer than their sides. That is, each level induces a cycle, where the angular distance between any two adjacent vertices in level k is $2\pi/2^k$. Note that the number of vertices is indeed in $\Theta(2^r)$. In the full version [2, Lemma 11] we show that all vertices are adjacent to the root, i.e., G_r is a SHUDG, as required. Without going into detail, we note that the above construction is inspired by an analysis in [4]; see Figure 5.

To bound the clique number and treewidth of G_r, we count the neighbors in each level.

▶ **Lemma 8.** *For every $2 \leq i \leq j \leq r$, every vertex of G_r in level i has at least two and at most $4\sqrt{2^{j-i}}$ neighbors in level j, where the upper bound is tight up to a constant factor.*

Before giving a proof sketch, let us discuss the implications to the structure of G_r. For this, consider a vertex v in some level i and the two closest vertices in level $i+1$, one to the left and one to the right. Now let T denote the tree induced by the four edges from the root to the first level and the edges to the two closest neighbors for each vertex in levels $2, \ldots, r-1$, see Figure 6. Observe that, apart from the root having degree 4, T is a spanning binary tree. That is, the number of descendants of some vertex grows with base 2 in T, whereas the number of neighbors in G_r grows with base $\sqrt{2}$. Hence, for a vertex in level i, there are far fewer neighbors than descendants in level j, provided $j - i$ is sufficiently large. This observation is key to bounding the clique number of G_r.

Proof sketch. Observe that for a vertex v_i in level i, the two closest vertices v_j^ℓ, v_j^r in level j are adjacent and have a very small angular distance to v_i (see Figure 6). Since v_j^ℓ, v_j^r are connected to the root, one can conclude that they also have edges to v_i.

For the upper bound, we use some trigonometric formulas to bound the maximum angular distance of two adjacent vertices with fixed distances from the root. Since we know from the construction how many vertices we have in each level, this gives us the number of neighbors, see again Figure 6. We refer to [2, Lemma 13] for a full proof. ◀

By the lower bound of Lemma 8, since each two levels are connected by edges, contracting each of the r levels yields an r-clique.

▶ **Corollary 9.** *The treewidth of G_r is at least $r \in \Omega(\log n)$, where n is the number of vertices.*

Next, the upper bound enables us to conclude the following lemma for triangles in G_r.

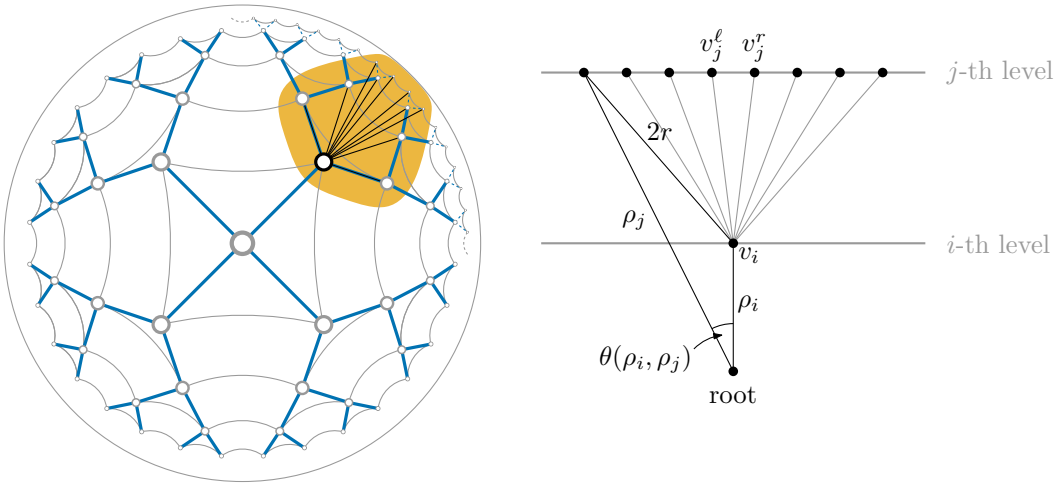

Figure 6 Left: A spanning tree (blue) guiding the structure of G_r, and the neighborhood of some vertex (black and orange). Note that the number of neighbors increases with the level, but slower than the number of descendants in the tree, whereas the angle in which a vertex has neighbors shrinks. Right: The number of neighbors a vertex v_i has in level j is determined by the angle $\theta(\rho_i, \rho_j)$ to the leftmost neighbor, where ρ_i and ρ_j are the radii of the two levels.

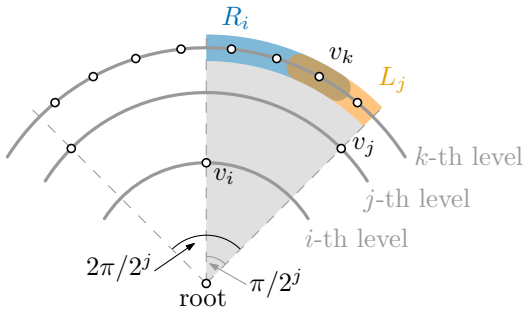

Figure 7 A triangle of G_r, where v_k lies both in the neighborhood of v_i (blue) and of v_j (orange). We conclude that the right half of the neighborhood of v_i plus the left half of the neighborhood of v_j is larger than the number of vertices in level k that lie between v_i and v_j (gray wedge).

▶ **Lemma 10.** *For every triangle in G_r with vertices v_i, v_j, and v_k on levels $2 \leq i \leq j \leq k$, respectively, we have $k - j \leq j - i + 6$.*

Proof sketch. We consider the number of neighbors v_i and v_j have in level k and compare the sum with the number of vertices in level k that lie between v_i and v_j (Figure 7). The first is $O(\sqrt{2^{k-i}})$ by Lemma 8, whereas the second is $\Omega(2^{k-j})$ by construction, yielding the desired bound, which we show in the full version [2, Lemma 15]. ◀

It follows from Lemma 10 that if a clique in G_r has vertices in levels i and $j \geq i$ with $\Delta = j - i$, then all further vertices of the clique in larger levels are in levels $j, \dots, j + \Delta + 6$. Applying this to all pairs of vertices in a clique, we obtain that the distances $|i - j|$ between the levels i, j shrink exponentially. We formalize this in the following lemma.

▶ **Lemma 11.** *Let $r \geq 1$, $c \geq 0$ be integers, and let $S \subseteq [r]$ be a set such that for every three elements $i < j < k$ of S, we have $k - j \leq j - i + c$. Then $|S| < \log_2(r) + c + 2$.*

Proof sketch. We claim that for an optimal set S^*, we may choose the elements greedily, adding always the largest element so that $k - j \leq j - i + c$ is maintained for every $i < j < k$ in S^*. In [2, Lemma 16] we show that S^* contains roughly the c largest elements and starting from there, leaves exponentially growing gaps when smaller elements are added. ◀

Putting everything together, we conclude that the clique number of G_r is indeed $O(\log \log n)$.

▶ **Lemma 12.** *The clique number of G_r is at most $O(\log r) = O(\log \log n)$, where n is the number of vertices of G_r.*

Proof. Consider a clique C in G_r whose size we aim to bound. First recall that each level induces a cycle and thus has clique number 2. Hence, up to a factor of 2, we may assume that the vertices of C are in pairwise distinct levels. Now each three vertices of C in levels $i < j < k$ form a triangle and thus satisfy $k - j \leq j - i + 6$ by Lemma 10. Then, Lemma 11 shows that C contains only $2(\log_2(r) + 8) \in O(\log r) = O(\log \log n)$ vertices. ◀

Finally, Corollary 9 and Lemma 12 together prove Theorem 6.

3.2 Proof of Theorem 7

Our goal is to construct SHUDGs with radius $r \in \Theta(\log n)$, clique number $O(1)$, and treewidth $\Omega(\log \log n)$, which implies Theorem 1. We do so by taking a subgraph of the graph G_r for $r \geq 8$ constructed in Section 3.1 that has constant clique number but unbounded treewidth. For this, let G'_r be the subgraph of G_r that is induced by the root and the vertices in levels 2^k for $k = 3, \ldots, \log_2(r)$. Recall that G_r has r levels, where the k-th level contains 2^k vertices for $k \geq 2$, and thus the r-th level contains more than half of the vertices of G_r. Thus, G'_r has $\Theta(\log r) = \Theta(\log \log n)$ levels and $\Theta(n)$ vertices, where n is the number of vertices of G_r. Further recall that in G_r, and thus also in G'_r, Lemma 8 shows that each two levels are connected by edges. Hence, we again obtain a clique-minor by contracting each level.

▶ **Lemma 13.** *The treewidth of G'_r is at least $\Omega(\log r) = \Omega(\log \log n)$, where n is the number of vertices of G'_r.*

To bound the clique number, recall that the distance between two levels i and j refers to $|i - j|$, and not, e.g., to the hyperbolic distance.

▶ **Lemma 14.** *The clique number of G'_r is at most 5.*

Proof sketch. For the main idea, recall from Lemmas 10 and 11 that in G_r, the distances between the levels used by a clique shrink exponentially from the root to the outermost level, i.e., most vertices of any clique are in the outer levels. In contrast, we choose the levels for G'_r with exponentially growing distances, i.e., mostly inner levels are chosen. Thus, for every clique in G_r, the levels chosen for G'_r hit only very few vertices of the clique. We formalize this in the full version [2, Lemma 19]. ◀

This concludes the proof that hyperbolic uniform disk graphs do not admit product structure as Lemmas 13 and 14 together show Theorem 7, which in turn proves Theorem 1.

3.3 Dependence on the Disk Radius

The graph families we construct for Theorems 6 and 7 have disk radius $\Theta(\log n)$, which we extend to arbitrary radii by adding more vertices or stopping the construction earlier, see the full version [2]. Note that for super-constant r, we obtain unbounded row-treewidth thus no product structure. This proves the second part of Theorem 2 and strengthens Theorem 4.

▶ **Corollary 15.** *For every $r \in O(\log n)$, there are families of n-vertex HUDGs with disk radius in $\Theta(r)$,*
- *clique number in $O(\log r)$, and (row-)treewidth in $\Omega(r)$, respectively*
- *clique number in $O(1)$, and (row-)treewidth in $\Omega(\log r)$.*

▶ **Corollary 16.** *For every $r \in \Omega(\log n)$, there are families of n-vertex SHUDGs with disk radius in $\Theta(r)$,*
- *clique number in $O(\log \log n)$, and (row-)treewidth in $\Omega(\log n)$, respectively*
- *clique number in $O(1)$, and (row-)treewidth in $\Omega(\log \log n)$.*

4 Product Structure for Small Disk Radius

In this section, we show that HUDGs whose disk radius and clique number are (sub-)constant admit product structure, which finishes the proof of Theorem 2. In fact, we show that every HUDG G with disk radius r and clique number ω is a subgraph of $H \boxtimes K_k$, where H is a hyperbolic tiling and $k \in O(\omega \cdot 3^{8r})$, which emphasizes their grid-structure. Since H is planar, and planar graphs are subgraphs of $H' \boxtimes P \boxtimes K_3$ with $\text{tw}(H') = 3$ [16], it follows that $G \subseteq H' \boxtimes P \boxtimes K_{3k}$. This implies that $G \subseteq H'' \boxtimes P$ for the graph $H'' = H' \boxtimes K_{3k}$ of treewidth $O(\omega \cdot 3^{8r})$, i.e., G has row-treewidth $O(\omega \cdot 3^{8r})$. Thus, in the following theorem, the product $H \boxtimes K_{O(\omega \cdot 3^{8r})}$ is the strongest statement and the others follow.

▶ **Theorem 17.** *For every HUDG G with disk radius r and clique size ω it holds that $G \subseteq H \boxtimes K_{O(\omega \cdot 3^{8r})} \subseteq H' \boxtimes P \boxtimes K_{O(\omega \cdot 3^{8r})}$, where H is a (possibly irregular) hyperbolic tiling and H' is a graph of treewidth at most 3. Moreover, the row-treewidth of G is in $O(\omega \cdot 3^{8r})$.*

Note that Theorem 17 indeed implies the first part of Theorem 2 since the row-treewidth only depends on ω and r, and thus we obtain product structure for every graph class with (sub-)constant clique number and disk radius. Further note that we also obtain an upper bound on the row-treewidth if clique number or disk radius are super-constant for some family of HUDGs. However, in these cases the upper bound on the row-treewidth also grows and thus we do not obtain product structure, which is no surprise given Section 3.

Recall that [20] shows that EUDGs with clique number ω are subgraphs of $H \boxtimes K_{O(\omega)}$, where H is a square-grid with diagonals. To find the product $H \boxtimes K_k$ for HUDGs, we lift their approach to the hyperbolic setting with two major changes. Not surprisingly, we replace the Euclidean tiling by a hyperbolic tiling to adjust to the geometry. However, we also need to face different disk radii since, in contrast to [20], we cannot freely choose the size of our tiles. For large disk radii, we solve this by merging tiles, whereas we subdivide tiles for small disk radii as needed. To do so, we provide a geometric interpretation of what we aim for. Two tiles are called *adjacent* if they are adjacent in the dual, i.e., if they share an edge.

▶ **Theorem 3.** *For each $r > 0$ there is an (irregular) tiling of the hyperbolic plane such that*
- *every tile can be covered by $O(3^{8r})$ disks of radius r and*
- *each two points with distance at most $2r$ lie in the same tile or in two adjacent tiles.*

Observe that this indeed implies that every HUDG with radius r and clique number ω is a subgraph of $H \boxtimes K_k$, where H is the dual of the tiling from Theorem 3, and $k \in O(\omega \cdot 3^{8r})$. To see this, consider the partition $\mathcal{P}$ with one part for the vertices of each tile. By the first property, each part contains at most $O(\omega \cdot 3^{8r})$ vertices since each disk of radius r covers a clique and thus at most ω vertices. Thus, we have $G \subseteq Q \boxtimes K_k$ for the quotient $Q = G/\mathcal{P}$ that is obtained by contracting the vertices in each tile, and some $k \in O(\omega \cdot 3^{8r})$. Then, by

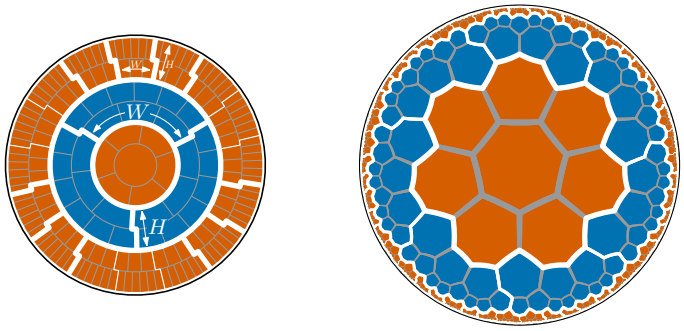

Figure 8 To ensure that non-adjacent tiles are sufficiently far from each other, we merge 7-gons as indicated by the white lines. High-level, we define rings of height $H \approx 2r$, which we cut into parts of width $W \in O(3^{4r})$ (left). Locally, however, we stick to the 7-gons from a $\{7, 3\}$-tiling (right).

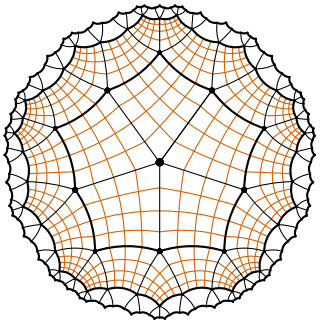

Figure 9 A $\{4, 5\}$-tiling (black) that is subdivided (red) so that each small tile can be covered by $O(1)$ disks of radius r.

the second property, the endpoints of every edge lie in the same or in adjacent tiles, so the quotient Q is a subgraph of the dual H of the tiling from Theorem 3. Together, we obtain $G \subseteq Q \boxtimes K_k \subseteq H \boxtimes K_k$, as required by Theorem 17.

The main challenge of this section is to prove Theorem 3, for which we refer to the full version [2]. For an overview, if r is at least some carefully chosen constant, we start with a regular $\{7, 3\}$-tiling whose tiles are merged until the second property of Theorem 3 is satisfied (Figure 8). Here, the tiles have a rapidly growing maximum degree to meet the requirements of the hyperbolic plane. The case for small radii then starts with a regular $\{4, 5\}$-tiling, where we subdivide the tiles until they are small enough for the first property (see Figure 9). This results in a tiling that gets more Euclidean the smaller r is, in the sense that locally, it looks like a Euclidean square grid.

5 Open Questions

In this paper, we characterize for which functions r families of HUDGs with constant clique number and disk radius r admit product structure: If $r \in O(1)$, then every family has bounded row-treewidth and thus admits product structure, otherwise there are families with unbounded row-treewidth. However, our upper bound is exponential in the disk radius, whereas our lower bound is logarithmic. It is an interesting open question whether the exponential dependency is necessary, both for Theorems 3 and 17. We conjecture that it is indeed necessary for the tiling, but believe that the base can be improved, which would also improve the bound on the row-treewidth. Note that even if there is an exponential lower bound for the tiling, it does not necessarily transfer to the row-treewidth of HUDGs.

▶ **Question 18.** *What is the row-treewidth of HUDGs with clique number ω and disk radius r?*

With our lower-bound construction, we show that there are SHUDGs with radius $\Theta(\log n)$ having treewidth $\Omega(\omega \frac{\log n}{\log \log n})$. This almost matches the upper bound of $O(\omega \cdot \log n)$ [5, 21]. We ask whether the remaining gap can be closed. Moreover, we ask whether similar lower bounds are possible for other clique numbers than $\omega \in O(\log \log n)$; specifically for constant ω.

▶ **Question 19.** *Is there a family of n-vertex HUDGs with clique number ω and treewidth $\Theta(\omega \cdot \log n)$? Is there a family with constant clique number and treewidth $\Theta(\log n)$?*

Finally, we conjecture that our lower bound for the row-treewidth stops growing at logarithmic grid radius because there are no HUDGs that require larger radius.

▶ **Question 20.** *Are there families of HUDGs that do not admit a disk representation in the hyperbolic plane such that the disk radius is $O(\log n)$?*

Abstract

The famous Ham-Sandwich theorem states that any d point sets in $\mathbb{R}^d$ can be simultaneously bisected by a single hyperplane. The α-Ham-Sandwich theorem gives a sufficient condition for the existence of biased cuts, i.e., hyperplanes that do not cut off half but some prescribed fraction of each point set. We give two new proofs for this theorem. The first proof is completely combinatorial and highlights a strong connection between the α-Ham-Sandwich theorem and Unique Sink Orientations of grids. The second proof uses point-hyperplane duality and the Poincaré-Miranda theorem and allows us to generalize the result to and beyond oriented matroids. For this we introduce a new concept of rainbow arrangements, generalizing colored pseudo-hyperplane arrangements. Along the way, we also show that the realizability problem for rainbow arrangements is $\exists\mathbb{R}$-complete, which also implies that the realizability problem for grid Unique Sink Orientations is $\exists\mathbb{R}$-complete.

1 Introduction

The famous *Ham-Sandwich theorem*, originally proven by Stone and Tukey in 1942 [30], states that given any d mass partitions or point sets in $\mathbb{R}^d$, there is a hyperplane that simultaneously bisects all of them. As the name suggests, this can be illustrated using the following food-based analogy: assume you have a 3-dimensional sandwich consisting of bread, ham, and cheese, that you want to share with your friend. You want to do this fairly, meaning that both of you get exactly half of the bread, half of the ham, and half of the cheese. The Ham-Sandwich theorem now says that you can always get a fair division with a single straight cut, no matter how you assembled the sandwich[1].

[1] In his book "Algorithms in Combinatorial Geometry", Edelsbrunner illustrates this by saying that such a cut can be found even if the cheese is still in the fridge [12].

The Ham-Sandwich theorem has initiated the study of *mass partitions*, where the general question is how many mass distributions or point sets can be simultaneously bisected with some specific type of cut. Studied variants include partitions with several hyperplanes [7, 9, 18, 19, 25], partitions using general convex sets [1, 3, 8], partitions using fans and cones [6, 24, 27], or partitions using fixed shapes [26]. For more information on mass partitions, we refer to the recent survey by Roldán-Pensado and Soberón [23].

If you like cheese significantly more than your friend does, you might not want to share your sandwich fairly, but you perhaps want to have more of the cheese. A natural question is which such biased partitions are still possible with just a single cut. The *α-Ham-Sandwich theorem* gives a sufficient condition for when such cuts are possible. In particular, it states that if your ingredients are *well-separated*, then any biased cut is possible. Formally, well-separation is defined as follows (see also Figure 1 for an illustration).

▶ **Definition 1.** *A family $\mathcal{F} = (A_1, \dots, A_d)$ of d point sets (or mass distributions) is said to be* well-separated *if for any index set $I \subset [d]$,[2] there exists a hyperplane that separates the convex hull of (the support of) $\bigcup_{i\in I} A_i$ from the convex hull of (the support of) $\bigcup_{i\in[d]\setminus I} A_i$.*

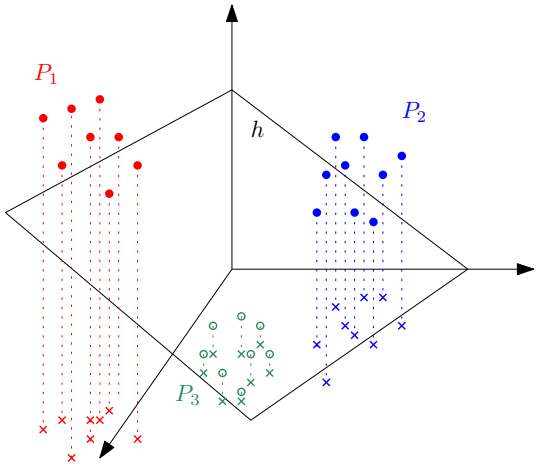

Figure 1 A family of well-separated point sets $\mathcal{F} = (P_1, P_2, P_3)$ in $\mathbb{R}^3$. The hyperplane h separates $P_1 \cup P_2$ from P_3.

The α-Ham-Sandwich theorem has been shown both for mass distributions, by Bárány, Hubard, and Jerónimo [5], as well as for finite point sets, by Steiger and Zhao [28]. In this manuscript, we focus on the discrete variant for point sets, so we only formally state this version here. However, before getting there, let us remark that we orient a hyperplane $h \in \mathbb{R}^d$ defined by points $p_1 \in P_1, \dots, p_d \in P_d$ according to the orientation of the simplex $(p_1, \dots, p_d) \in h$, that is, a point q is below h iff the following $(d+1) \times (d+1)$ matrix A has a negative determinant: $A_{j,d+1} = 1$ for all $j \in [d+1]$, $A_{i,\cdot} = p_i$ for all $i \in [d]$ and $A_{d+1,\cdot} = q$. If the matrix A has a positive determinant we say that q is above h. If q is on h, then A has determinant 0.

With this, we can now formally define α-cuts (see also Figure 2) and state the discrete α-Ham-Sandwich theorem.

[2] Herein and henceforth, $[d]$ refers to the set $\{1, \dots, d\}$.

▶ **Definition 2.** *Let $\mathcal{P} = (P_1 \dots, P_d)$ be well-separated and in weak general position*[3]*. Given $(\alpha_1, \dots, \alpha_d) \in [|P_1|] \times \cdots \times [|P_d|]$, an* $(\alpha_1, \dots, \alpha_d)$-cut *is a hyperplane h_α such that for each $i \in [d]$, one point of P_i is on h_α and exactly $\alpha_i - 1$ points of P_i are below it.*

▶ **Theorem 3.** *Let $\mathcal{P} = (P_1 \dots, P_d) \subset \mathbb{R}^d$ be well-separated and in weak general position. Then for every $(\alpha_1, \dots, \alpha_d) \in [|P_1|] \times \cdots \times [|P_d|]$, there exists a unique $(\alpha_1, \dots, \alpha_d)$-cut.*

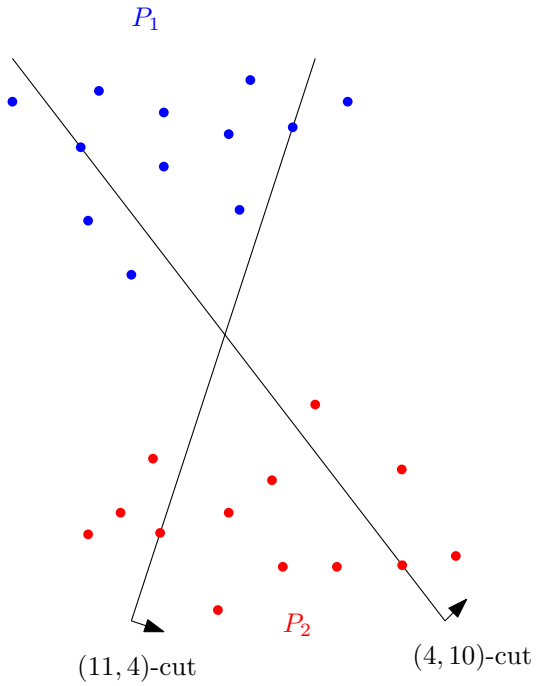

Figure 2 Well-separated point sets in $\mathbb{R}^2$ with two α-cuts.

The proof of the continuous version for mass distributions by Bárány, Hubard, and Jerónimo [5] uses Brouwer's fixpoint theorem. On the other hand, the proof of the discrete version for point sets by Steiger and Zhao [28] uses an elegant inductive argument to show that every α-cut is unique and then deduces the existence from the pigeonhole principle. However, we think that there is a gap in their inductive argument, which we elaborate on in the appendix of the full version of this paper. While it is possible that their proof can be fixed using some additional arguments, we are taking a different route and instead provide two new proofs of the α-Ham-Sandwich theorem for point sets.

The first proof, presented in Section 2, uses the combinatorial framework of *Unique Sink Orientations*. A Unique Sink Orientation (USO) is an orientation of the edge set of a hypercube such that every subcube has a unique sink. USOs were formally defined by Szabó and Welzl [31], based on earlier work by Stickney and Watson [29] who investigated USOs as a combinatorial abstraction of the candidate solutions of a special class of linear complementarity problems. The concept of USOs has been generalized to *grids*, which are products of complete graphs [15]. A *grid USO* is an orientation of a grid where every subgrid has a unique sink.

[3] Weak general position means that any hyperplane containing one point of each of the sets $P_1, \dots, P_d$ cannot contain any other points of $\mathcal{P}$.

Our second new proof of the α-Ham-Sandwich theorem, presented in Section 3, considers the setting under the well-known point-hyperplane duality: given d sets of hyperplanes with a dual notion of "well-separated", we prove the existence of a point that lies above or below the correct number of hyperplanes in each set. In fact, we present a more general result, replacing the arrangement of hyperplanes by a *rainbow arrangement*, a concept that we formally introduce in Section 3.1. Informally, a colored generalized arrangement is a family $\mathcal{F} = (H_1, \dots, H_d)$, where each H_i is a set of pseudo-hyperplanes in $\mathbb{R}^d$. In a rainbow arrangement, we further require that any colorful choice of pseudo-hyperplanes $h_1 \in H_1, \dots, h_d \in H_d$ intersect in a single point. The main result of Section 3.3 is the following theorem.

▶ **Theorem 4.** *Let $\mathcal{F} = (H_1, \dots, H_d) \subset \mathbb{R}^d$ be a well-separated colored generalized arrangement where each color class H_i has size n_i. Then for every $(\alpha_1, \dots, \alpha_d) \in [n_1] \times \cdots \times [n_d]$, there is a point $x_\alpha \in \mathbb{R}^d$ lying on one and above exactly $\alpha_i - 1$ pseudo-hyperplanes of color i for all $i \in [d]$. If $\mathcal{F}$ is additionally a rainbow arrangement, then the point x_α is unique.*

Using the topological representation theorem, Theorem 4 allows us to deduce a version of the α-Ham-Sandwich theorem for oriented matroids (Corollary 11).

In Section 4, we generalize Theorem 4 even further by relaxing the well-separation condition to the notion of (β, γ)-*separation*, which we introduce in the same section.

Finally, our notion of rainbow arrangements can be viewed as a higher-dimensional generalization of *bicolored order types*, introduced by Aichholzer and Brötzner [2]. In Section 5, we show that deciding whether a rainbow arrangement can be realized by a hyperplane arrangement is $\exists\mathbb{R}$-complete already in two dimensions (i.e., for bicolored order types, see Theorem 21). Given the connection between the α-Ham-Sandwich theorem and grid USOs, and based on recent results by Borzechowski, Fearnley, Gordon, Savani, Schnider, and Weber [10], this allows us to conclude that deciding whether a grid USO is realizable is also $\exists\mathbb{R}$-complete (see Corollary 22).

2 First Proof: Unique Sink Orientations

A grid graph is a generalization of the d-dimensional hypercube: While the latter is the Cartesian product of d copies of K_2 (the complete graph on two vertices), the former is the Cartesian product of complete graphs of arbitrary size. Formally, a d-dimensional *grid graph* Γ parameterized by $n_1, \dots, n_d \in \mathbb{N}_{\geq 2}$ is the graph on $[n_1] \times \cdots \times [n_d]$, where two vertices are adjacent if and only if they differ in exactly one coordinate. We say the grid has d *dimensions* and each dimension i has n_i *directions*.

The subgraph Γ' of Γ induced by the vertices $V(\Gamma') = N_1 \times \cdots \times N_d$ for non-empty $N_i \subseteq [n_i]$ is called an *induced subgrid* of Γ. Note that if we have $|N_i| = 1$ for some i, then the induced subgrid loses a dimension. If $|N_i| \leq 2$ for all $i \in [d]$, we say that Γ' is a *subcube* of Γ. An orientation of the edges of a grid graph is called a *Unique Sink Orientation (USO)* if every induced subgrid has a unique sink (i.e., a unique vertex that has no outgoing edges) [15].

▶ **Lemma 5.** *Let σ be a grid orientation. Assume that every induced subgrid has a (not necessarily unique) sink, and that σ is a USO when restricted to any subcube. Then σ is a USO.*

Proof. As every subgrid has a sink by assumption, it remains to show that this sink is unique. Assume for the sake of contradiction that there is a subgrid that has two sinks $a = (a_1, \dots, a_d)$ and $b = (b_1, \dots, b_d)$. Consider now the subcube spanned by a and b (i.e.,

the subcube induced by $\{a_1, b_1\} \times \cdots \times \{a_d, b_d\}$). As a and b were sinks in the subgrid, they are also sinks in this subcube. We have thus found a subcube with two sinks, so σ restricted to this subcube is not a USO. This is a contradiction to the second assumption. ◀

Let $\mathcal{P} = (P_1, \dots, P_d) \subset \mathbb{R}^d$ be a well-separated point set in weak general position. For $i \in [d]$, let $P_i = \{p_1^i, \dots, p_{|P_i|}^i\}$. Let $\Gamma_\mathcal{P}$ be the grid graph parameterized by $|P_1|, \dots, |P_d|$. We recall the following orientation $\sigma_\mathcal{P}$ on $\Gamma_\mathcal{P}$, which was presented in [10] and is illustrated in Figure 3. For any edge between two vertices $v = (a_1, \dots, a_{i-1}, a_i, a_{i+1}, \dots, a_d)$ and $v' = (a_1, \dots, a_{i-1}, a'_i, a_{i+1}, \dots, a_d)$ of $\Gamma_\mathcal{P}$, let h be the colorful hyperplane spanned by the points $p^1_{a_1}, \dots, p^{i-1}_{a_{i-1}}, p^i_{a_i}, p^{i+1}_{a_{i+1}}, \dots, p^d_d$, and let h' be the colorful hyperplane spanned by $p^1_{a_1}, \dots, p^{i-1}_{a_{i-1}}, p^i_{a'_i}, p^{i+1}_{a_{i+1}}, \dots, p^d_d$. If $p^i_{a'_i}$ lies above h, we orient v' towards v; otherwise orient v towards v'. It turns out that $p^i_{a'_i}$ lies above h if and only if $p^i_{a_i}$ lies below the hyperplane h',[4] so this orientation is well-defined.

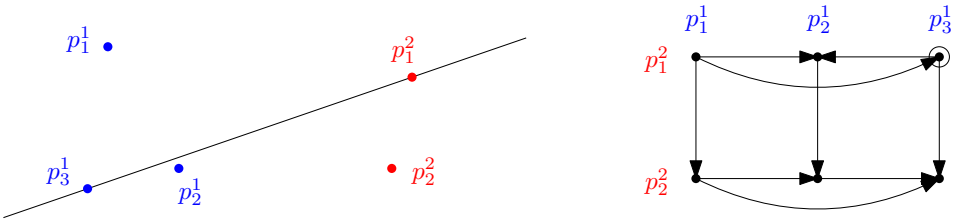

Figure 3 Well-separated point sets in $\mathbb{R}^2$ with the corresponding grid orientation. The line drawn on the left is represented by the highlighted vertex on the right.

The following lemma is key to our first proof of Theorem 3.

▶ **Lemma 6.** *Let $\mathcal{P} = (P_1, \dots, P_d) \subset \mathbb{R}^d$ be well-separated and in weak general position. Then the orientation $\sigma_\mathcal{P}$ is a grid USO.*

Note that this lemma was already proved in [10]. However, their proof uses Theorem 3. To avoid the cyclic dependency, we provide here an alternative proof that uses the following version of the α-Ham-Sandwich theorem for mass distributions.

▶ **Theorem 7** (Bárány, Hubard, and Jerónimo [5])**.** *Let $K_1, \dots, K_d$ be well-separated convex bodies in $\mathbb{R}^d$, and $\alpha_1, \dots, \alpha_d$ given constants with $0 \le \alpha_i \le 1$ for $i \in [d]$. Then there is a unique hyperplane h such that for all $i \in [d]$, h intersects K_i, and the proportion of the volume of K_i below h is α_i.*

Proof of Lemma 6. We first show that every subgrid has a sink. By the definition of $\sigma_\mathcal{P}$, a subgrid is spanned by subsets $P'_i \subseteq P_i$ and a sink corresponds to a $(1, \dots, 1)$-cut. As any subset of a well-separated point set in weak general position is again well-separated and in weak general position, the existence of such a $(1, \dots, 1)$-cut is guaranteed by applying Theorem 7 with the convex sets being the convex hulls of $P'_1, \dots, P'_d$, and $\alpha_i = 0$ for $i \in [d]$.

We now argue that every subcube is a USO. A subcube is spanned by at most two points per P_i. Let Q_i be the set of these at most two points. As argued before, $(Q_1, \dots, Q_d)$ is well-separated and in weak general position. Further, the convex hull of the at most two points per P_i is a line segment. Hence, by applying Theorem 7 on these convex hulls, we obtain the existence of all possible $(\alpha_1, \dots, \alpha_d)$-cuts of $(Q_1, \dots, Q_d)$ for all $(\alpha_1, \dots, \alpha_d) \in$

[4] This can be seen by projecting to $\mathbb{R}^2$ such that $h \cap h'$ is mapped to the origin.

$[|Q_1|] \times \cdots \times [|Q_d|]$. Hence, in the subcube, each possible *outmap* (i.e., a binary vector at each vertex that encodes whether the incident edge along each dimension is incoming or outgoing) is present. This implies that the subcube is indeed a USO [31].

The claim now follows from Lemma 5. ◀

The α-Ham-Sandwich theorem for point sets (Theorem 3) now follows easily.

▶ **Theorem 3.** *Let $\mathcal{P} = (P_1 \dots, P_d) \subset \mathbb{R}^d$ be well-separated and in weak general position. Then for every $(\alpha_1, \dots, \alpha_d) \in [|P_1|] \times \cdots \times [|P_d|]$, there exists a unique $(\alpha_1, \dots, \alpha_d)$-cut.*

Proof. By Lemma 6, the orientation $\sigma_{\mathcal{P}}$ is a grid USO. We define a function $r : [|P_1|] \times \cdots \times [|P_d|] \to \{0, \dots, |P_1| - 1\} \times \cdots \times \{0, \dots, |P_d| - 1\}$ that assigns to each vertex of the grid graph $\Gamma_{\mathcal{P}}$ a tuple $(a_1, \dots, a_d)$ such that a_i is the number of the vertex's outgoing edges in the dimension i. Then [15, Theorem 2.14] states that r is a bijection. This implies that for every $(\alpha_1, \dots, \alpha_d) \in [|P_1|] \times \cdots \times [|P_d|]$, there is a unique $(\alpha_1, \dots, \alpha_d)$-cut, as required. ◀

3 Second Proof: Rainbow Arrangements and the Poincaré-Miranda Theorem

We provide definitions and preliminaries on the Poincaré-Miranda Theorem in Sections 3.1 and 3.2 and present the proof of Theorem 4 in Section 3.3.

3.1 Point-Hyperplane Duality and Rainbow Arrangements

In this subsection, we argue why our α-Ham-Sandwich theorem for rainbow arrangements (Theorem 4) is a generalization of the one for point sets (Theorem 3). We first consider the point-hyperplane dual of Theorem 3. The dual of every input point is a hyperplane, and the well-separation of the point set translates to the property that for every subset S of $[d]$, there exists a point above all the dual hyperplanes of the points in $\cup_{i \in S} P_i$ and below those of the points in $\cup_{i \notin S} P_i$. The dual of an $(\alpha_1, \dots, \alpha_d)$-cut is then a point lying on one dual hyperplane and above exactly $\alpha_i - 1$ hyperplanes of each color i. Theorem 3 is equivalent to the statement that such a point is unique for every $(\alpha_1, \dots, \alpha_d)$.

With this interpretation in mind, we now define our generalized arrangements, where we define an *oriented pseudo-hyperplane* as a subset of $\mathbb{R}^d$ that is homeomorphic to $\mathbb{R}^{d-1}$ and divides $\mathbb{R}^d$ into two parts: a positive and a negative side. We say a point p lies *above* (*below*) an oriented pseudo-hyperplane H if and only if p is contained in the positive (negative) side.

▶ **Definition 8** (Generalized Arrangement, Rainbow Arrangement). *A family $\mathcal{F}$ of oriented pseudo-hyperplanes in $\mathbb{R}^d$ is called a* generalized arrangement *if for all $k \in [d+1]$, the intersection of any k of them is a (not necessarily connected) $(d-k)$-dimensional manifold*[5] *and $\mathbb{R}^d \setminus \bigcup \mathcal{F}$ has finitely many connected components (which we call* cells*).*

A generalized arrangement is colored *if $\mathcal{F}$ is partitioned into d pairwise disjoint subfamilies $H_1, \dots, H_d$. We think of this as coloring each oriented pseudo-hyperplane with one of d colors and call the H_i's* color classes*.*

A colored generalized arrangement is a rainbow arrangement *if for each choice of one oriented pseudo-hyperplane per color class, $h_1 \in H_1, \dots, h_d \in H_d$, we have that the intersection $h_1 \cap \dots \cap h_d$ is a single point.*

[5] For the sake of convenience, we consider the empty set to be a manifold of any dimension. In particular, it is the only manifold of dimension -1.

Note that our arrangements differ significantly from the well-known concept of *pseudo-hyperplane arrangements*, where the intersection of any k pseudo-hyperplanes is required to be homeomorphic to $\mathbb{R}^{d-k}$. In particular, while every pseudo-hyperplane arrangement is also a generalized arrangement, the converse is not true.

The following definition of well-separation is a dual version of the notion of well-separation for point sets.

▶ **Definition 9** (Well-Separated). *A colored generalized arrangement $\mathcal{F} = (H_1, \dots, H_d)$ in $\mathbb{R}^d$ is* well-separated *if for every sign vector $s \in \{+,-\}^d$, there exists a point $x_s \in \mathbb{R}^d$ such that*

- *x_s lies in an unbounded cell,*
- *x_s lies above all oriented pseudo-hyperplanes in H_i iff $s_i = +$,*
- *and x_s lies below all oriented pseudo-hyperplanes in H_i iff $s_i = -$,*

for all $i \in [d]$.

3.2 The Poincaré-Miranda Theorem

In our proof, we will use the Poincaré-Miranda theorem, which we briefly recall.

▶ **Theorem 10** (Poincaré-Miranda theorem). *Consider d continuous functions*

$$f_1, \dots, f_d : [-1,1]^d \to \mathbb{R}.$$

Assume that for each variable x_i, the function f_i is non-positive whenever $x_i = -1$ and non-negative whenever $x_i = 1$. Then there exists a point x^* in $[-1,1]^d$ with $f_i(x^*) = 0$ for all $i \in \{1, \dots, d\}$.

The theorem was first stated by Poincaré [21] without proof. It was later shown by Miranda [20] that it is equivalent to Brouwer's fixed point theorem. Since then, the theorem has found numerous applications and generalizations; see, e.g., [4] and the references therein.

3.3 The Second Proof

We define the *k-level* of a family H of oriented pseudo-hyperplanes to be the set of points that lie (i) on at least one oriented pseudo-hyperplane of H and (ii) on or above exactly k oriented pseudo-hyperplanes of H. We are now ready to prove our generalization of the α-Ham-Sandwich theorem.

▶ **Theorem 4.** *Let $\mathcal{F} = (H_1, \dots, H_d) \subset \mathbb{R}^d$ be a well-separated colored generalized arrangement where each color class H_i has size n_i. Then for every $(\alpha_1, \dots, \alpha_d) \in [n_1] \times \cdots \times [n_d]$, there is a point $x_\alpha \in \mathbb{R}^d$ lying on one and above exactly $\alpha_i - 1$ pseudo-hyperplanes of color i for all $i \in [d]$. If $\mathcal{F}$ is additionally a rainbow arrangement, then the point x_α is unique.*

We prove the existence of a point x_α by showing that the corresponding α_i-levels intersect, see Figure 4 for an illustration. The uniqueness for rainbow arrangement additionally uses a counting argument.

Proof. By assumption $\mathcal{F}$ is well-separated, so for each vector $s \in \{+,-\}^d$ there is a point x_s in an unbounded cell that lies above or below all oriented pseudo-hyperplanes of a color class. Consider a subset $I \subset [d]$ and a family of vectors $s^1, \dots, s^k$ in $\{+,-\}^d$ for which $s^1_i = \dots = s^k_i$ for all $i \in I$. Let $\mathcal{F}_\mathcal{I} = \cup_{i \in I} H_i$ be the generalized arrangement consisting only of oriented pseudo-hyperplanes of color classes in I. We claim that the points $x_{s^1}, \cdots, x_{s^k}$ lie in a common unbounded cell of $\mathcal{F}_\mathcal{I}$. Indeed, assume for the sake of contradiction that

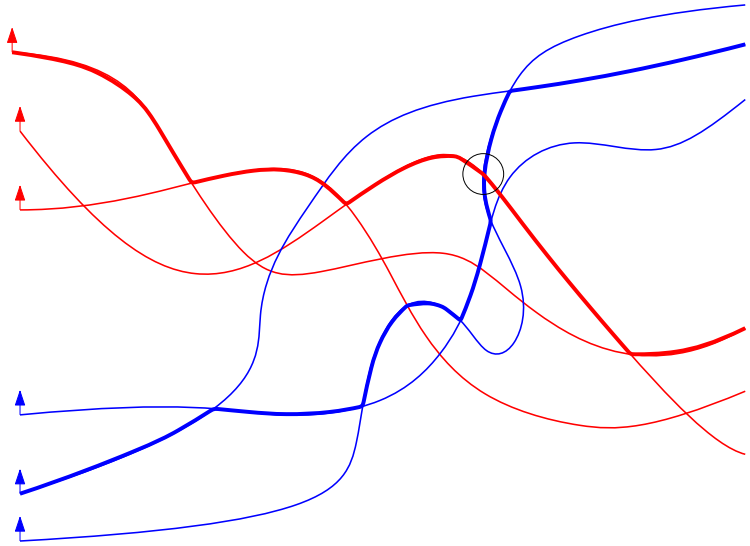

Figure 4 A rainbow arrangement with colors red and blue. The red 3-level and the blue 2-level are highlighted and intersect in a unique point.

two of the points x_{s^i} and x_{s^j} lie in different unbounded cells. Then there is an oriented pseudo-hyperplane of $\mathcal{F}_\mathcal{I}$ separating them. However, by definition, x_{s^i} and x_{s^j} must lie on the same side of any oriented pseudo-hyperplane in $\mathcal{F}_\mathcal{I}$, a contradiction.

Now consider the cube $[-1,1]^d$. Note that each face of the cube can be encoded by a vector z in $\{*,-1,1\}^d$, such that the face contains all vertices v of the cube such that $v_i = z_i$ for all i with $z_i \neq *$. We call such a face *characterized* by the set $\{i \mid z_i \neq *\}$.

Next, consider the following embedding of the cube into $\mathbb{R}^d$: Each vertex v in $\{-1,1\}^d$ is mapped to the point x_s with $s \in \{+,-\}^d$ such that $v_i = -1$ if and only if $s_i = -$ for $i \in [d]$. Then as we already argued above, for every face of the cube characterized by a set $I \subseteq [d]$, all its vertices are in a common unbounded cell of $\mathcal{F}_I$, so we can extend the embedding defined on the facets of a face to the entire face. After applying a homeomorphism on $\mathbb{R}^d$ that maps this embedding to the cube $[-1,1]^d \subset \mathbb{R}^d$ we can thus assume that all oriented pseudo-hyperplanes of the color class H_i have the facet $x_i = -1$ on their negative side, and the facet $x_i = 1$ on their positive side.

Consider now the α_i-level L of some color class H_i. We define a function f_i for which $f_i(x) = 0$ if x is on L, $f_i(x) > 0$ if x is above L and $f_i(x) < 0$ if x is below L. To achieve this, set $f_i(x) = 0$ for all points x that lie on L. For all other points x, let $d(x, L)$ denote the distance of x to L. If x is below L, we set $f_i(x) = -d(x, L)$, and if x is above L, we set $f_i(x) = d(x, L)$. Since the distance is a continuous function, f_i is continuous.

By construction, the functions f_i satisfy the conditions of the Poincaré-Miranda theorem. We thus get that there is a point x^* in $[-1,1]^d$ for which $f_i(x^*) = 0$ for all $i \in \{1,\ldots,d\}$. Recall that by the definition of a generalized arrangement, no point can lie on $d+1$ of our pseudo-hyperplanes. Thus, x^* is a point lying on exactly one and above exactly $\alpha_i - 1$ oriented pseudo-hyperplanes of color i for all $i \in [d]$, as required.

Note that x^* lies on one oriented pseudo-hyperplane of each color class. If the arrangement is a rainbow arrangement, then there are only $n_1 \cdot \ldots \cdot n_d$ many possible locations for x^*. As each of these points can only be the solution for one α-vector and there are $n_1 \cdot \ldots \cdot n_d$ different α-vectors, it follows that for each α-vector the solution must be unique. ◀

By the famous topological representation theorem of Folkman and Lawrence [14], Theorem 4 also has implications for oriented matroids. To explain this, we will assume familiarity with oriented matroids as presented for example in the Handbook of Discrete and Computational Geometry [22]. In particular, we consider uniform oriented matroids of rank $d+1$. We denote such an oriented matroid by $M = (E, \mathcal{L})$, where E is the ground set and $\mathcal{L} \subseteq \{-, 0, +\}^E$. Coloring E corresponds to a partition into classes (colors) as $E = E_1 \sqcup \cdots \sqcup E_d$. If we use $c(e)$ to denote the color of element $e \in E$, then we take well-separation to mean that for all $s \in \{-, +\}^d$, there exists a covector $v \in \mathcal{L}$ with $v_e = s_{c(e)}$ for all $e \in E$. By applying the Folkman-Lawrence representation theorem and then Theorem 4, we thus get the following corollary in this setting.

▶ **Corollary 11** (α-Ham-Sandwich for Oriented Matroids). *Let $M = (E, \mathcal{L})$ be a uniform oriented matroid of rank $d+1$ in covector representation with $\mathcal{L} \subseteq \{-, 0, +\}^E$. Assume that M is well-separated, and in particular, E is partitioned into d classes $E = E_1 \sqcup \cdots \sqcup E_d$ (colors). Then for every $\alpha \in [|E_1|] \times \cdots \times [|E_d|]$, there is a covector $v^\alpha \in \mathcal{L}$ with exactly one zero and exactly $(\alpha_i - 1)$ minuses on the subset E_i, for all $i \in [d]$.*

4 Generalizing Well-Separation

Using the Poincaré-Miranda theorem, we can prove an even more general statement by relaxing the definition of well-separation. (Recall the definition of a k-level of a set of oriented pseudo-hyperplanes, as defined in Section 3.3.)

▶ **Definition 12** ((β, γ)-separated). *Let $\mathcal{F} = (H_1, \ldots, H_d)$ be a colored generalized arrangement in $\mathbb{R}^d$, where each color class H_i has size n_i. Let $\beta = (\beta_1, \ldots, \beta_d)$ and $\gamma = (\gamma_1, \ldots, \gamma_d)$ be vectors such that $\beta_i, \gamma_i \in [n_i]$ and $\beta_i \leq \gamma_i$ for all $i \in [d]$. The colored generalized arrangement $\mathcal{F}$ is called* (β, γ)-separated *iff for every sign vector $s \in \{+, -\}^d$, there exists a point $x_s \in \mathbb{R}^d$ such that*

- *x_s lies in an unbounded cell,*
- *x_s lies above the γ_i-level of H_i iff $s_i = +$,*
- *and x_s lies below the β_i-level of H_i iff $s_i = -$,*

for all $i \in [d]$.

Note that by setting $\beta = (1, \ldots, 1)$ and $\gamma = (n_1, \ldots, n_d)$ we recover the definition of well-separated.

▶ **Theorem 13.** *Let $\mathcal{F} = (H_1, \ldots, H_d)$ be a (β, γ)-separated colored generalized arrangement where each color class H_i has size n_i. Then for every $(\alpha_1, \ldots, \alpha_d) \in \{\beta_1, \ldots, \gamma_1\} \times \cdots \times \{\beta_d, \ldots, \gamma_d\}$, there is a point $x_\alpha \in \mathbb{R}^d$ lying on one and above exactly $\alpha_i - 1$ oriented pseudo-hyperplanes of color i for all $i \in [d]$.*

Proof. By assumption $\mathcal{F}$ is (β, γ)-separated, so for each vector $s \in \{+, -\}^d$ there is a point x_s in an unbounded cell that lies above or below all relevant levels of a color class as stated in Definition 12. As the arrangement has finitely many cells, we can place a large enough ball B that contains all the bounded cells. Observe that we can assume x_s to lie outside of B. Consider a subset $I \subseteq [d]$ and a family of vectors $s^1, \ldots, s^k$ for which $s^1_i = \ldots = s^k_i$ for all $i \in I$. Let $\mathcal{F}_\mathcal{I}$ be the union of all relevant levels, that is, the α_i-levels for $\alpha_i \in \{\beta_i, \ldots, \gamma_i\}$, of the color classes $i \in I$. We claim that the points $x_{s^1}, \ldots, x_{s^k}$ lie in a common unbounded cell of $\mathcal{F}_\mathcal{I}$. Indeed, assume for the sake of contradiction that two of the points x_{s^i} and x_{s^j} lie in different unbounded cells. Then there is a level of $\mathcal{F}_\mathcal{I}$ separating them outside of B. However, by definition, x_{s^i} and x_{s^j} must lie on the same side of any relevant level in $\mathcal{F}_\mathcal{I}$.

We thus indeed have that all the points $x_{s^1}, \dots, x_{s^k}$ lie in a common unbounded cell of $\mathcal{F}_{\mathcal{I}}$ outside of B. Now we use the same argument as in the proof of Theorem 4. In particular, we can again find an embedding of the cube $[-1,1]^d$ where each face F_I characterized by a subset $I \subseteq [d]$ lies in this common unbounded cell of $\mathcal{F}_{\mathcal{I}}$. After applying a homeomorphism on $\mathbb{R}^d$ that maps this embedding to the cube $[-1,1]^d \subset \mathbb{R}^d$ we can thus assume that all relevant levels of the color class H_i have the facet $x_i = -1$ on their negative side, and the facet $x_i = 1$ on their positive side.

We now take the same functions f_i as in the proof of Theorem 4, which satisfy the conditions of the Poincaré-Miranda theorem. We thus get that there is a point x^* in $[-1,1]^d$ for which $f_i(x^*) = 0$ for all $i \in \{1, \dots, d\}$. ◀

We think that it is instructive to translate Theorem 13 back to the original setting of colored point sets in $\mathbb{R}^d$ (i.e., the primal setting). Note that in Definition 12, the condition that x_s must lie in an unbounded face has technical reasons: In the proof of Theorem 13, it allows us to easily embed the cube that we need for the Poincaré-Miranda theorem. However, we can get away without this assumption in the case of (straight) hyperplanes: In that case, the k-levels are guaranteed to be connected and piecewise linear, and thus we can embed the cube without assuming that the points x_s lie in unbounded faces. Therefore, when going to the primal setting, we can omit this technical assumption and define (β, γ)-separation for point sets as follows.

▶ **Definition 14.** *Let $\mathcal{P} = (P_1, \dots, P_d) \subset \mathbb{R}^d$ be in weak general position and let $\beta, \gamma \in [|P_1|] \times \cdots \times [|P_d|]$ with $\beta_i \leq \gamma_i$ for all $i \in [d]$ be arbitrary. We say that $\mathcal{P}$ is (β, γ)-separated if for every sign vector $s \in \{+,-\}^d$, there exists a hyperplane h_s such that*

- *h_s lies strictly above at least γ_i points of P_i iff $s_i = +$,*
- *and h_s lies above at most $\beta_i - 1$ points of P_i iff $s_i = -$,*

for all $i \in [d]$.

By dualizing the point set and applying Theorem 13 for the dual hyperplanes, we thus get the following corollary for (β, γ)-separated point sets.

▶ **Corollary 15.** *Let $\mathcal{P} = (P_1, \dots, P_d) \subset \mathbb{R}^d$ be (β, γ)-separated for some $\beta, \gamma \in [|P_1|] \times \cdots \times [|P_d|]$ and in general position[6]. Then for every $(\alpha_1, \dots, \alpha_d) \in \{\beta_1, \dots, \gamma_1\} \times \cdots \times \{\beta_d, \dots, \gamma_d\}$, there exists a unique $(\alpha_1, \dots, \alpha_d)$-cut.*

5 Rainbow Arrangements and Bicolored Stretchability

In this section, we take a closer look at well-separated rainbow arrangements in $\mathbb{R}^2$, where pseudo-hyperplanes are also called pseudo-lines. Concretely, such an arrangement consists of well-separated blue and red oriented pseudo-lines such that every blue and red pseudo-line intersect (and thus cross) exactly once.

An interesting question is whether a given rainbow arrangement can be realized using (straight) lines. In the following, we will prove that deciding this is $\exists\mathbb{R}$-complete. Concretely, we prove that the following formalization of what we call *bicolored stretchability* is $\exists\mathbb{R}$-complete.

[6] We require general position (no $d+1$ points on a common hyperplane) to ensure that the dual arrangement is indeed a generalized arrangement. However, one could easily adapt our proofs to also make this work for weak general position.

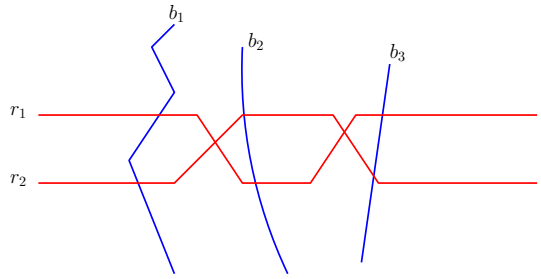

Figure 5 A well-separated rainbow arrangement in $\mathbb{R}^2$. Red pseudo-lines are oriented from left to right, blue pseudo-lines from top to bottom. Note that in order to intersect the blue pseudo-lines in this order, the two red pseudo-lines need to cross twice. In particular, this means that there is no combinatorially equivalent arrangement using straight lines, i.e., this is a NO-instance of bicolored stretchability.

▶ **Definition 16** (Bicolored Stretchability). *Given a combinatorial description of a well-separated rainbow arrangement in $\mathbb{R}^2$ (by specifying for each blue pseudo-line, the order in which it crosses the red pseudo-lines, and vice versa),* bicolored stretchability *is the problem of deciding whether there exists a two-colored well-separated line arrangement with the same combinatorial description.*

In particular, in a YES-instance of bicolored stretchability, all colorful crossings along every line have to happen in the prescribed order.

Observe that, given an instance of bicolored stretchability and a guess for the line arrangement (specifying each line and its color), we can efficiently verify (in a real-RAM machine) whether this guess indeed describes a well-separated line arrangement that is combinatorially equivalent to the bicolored stretchability instance (well-separation can be checked e.g. by comparing the slopes of the lines). Erickson, van der Hoog, and Miltzow [13] conveniently proved that such a verification algorithm on a real-RAM machine is enough to prove membership in $\exists\mathbb{R}$.

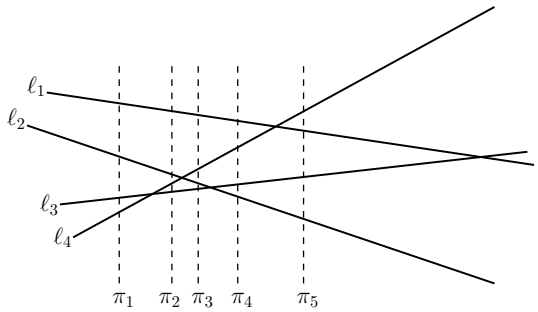

Figure 6 A YES-instance of allowable sequences. The sequence of permutations $\pi_1, \ldots, \pi_5$ can be found in the arrangement by sweeping from left to right.

In order to prove $\exists\mathbb{R}$-hardness, we will provide a reduction from the $\exists\mathbb{R}$-complete problem *allowable sequences* [17]. This problem can be formulated both in its primal form (using point sets) as well as its dual form (using line arrangements). For more details regarding this duality, see e.g., [16]. The following dual formulation will be convenient for our purpose.

▶ **Definition 17** (Allowable Sequences). *Given a sequence of permutations $\pi_1, \ldots, \pi_k$ of $[n]$, where π_{i+1} differs from π_i by a swap of two adjacent items for all $i \in [k-1]$,* allowable sequences *is the problem of deciding whether there exists a line arrangement of n lines such that sweeping the arrangement from left to right and recording how the relative order of the lines changes yields a sequence of permutations that contains the sequence $\pi_1, \ldots, \pi_k$.*

Consider now such a sequence $\pi_1, \ldots, \pi_k$ of permutations of $[n]$, i.e., an instance of allowable sequences. We build an instance of bicolored stretchability as follows: We introduce $n+4$ red pseudo-lines $r_{-1}, r_0, r_1, \ldots, r_n, r_{n+1}, r_{n+2}$ and $2k$ blue pseudo-lines $b_1, \ldots, b_k$ and $b'_1, \ldots, b'_k$. We call the four red lines $r_{-1}, r_0, r_{n+1}, r_{n+2}$ control lines. For each $i \in [k]$, we require both b_i and b'_i to first intersect r_{-1}, r_0 in order, then $r_1, \ldots, r_n$ in the order of the permutation π_i, and finally r_{n+1} and r_{n+2} in order. Conversely, for each $i \in [n]$, we require r_i to intersect the $2k$ blue pseudo-lines in the order $b_1, b'_1, b_2, b'_2, \ldots, b_k, b'_k$. Finally, the control lines are specified such that

- r_{-1} intersects the blue pseudo-lines in the order $b'_1, b_1, \ldots, b'_k, b_k$,
- r_0 intersects the blue pseudo-lines in the order $b_1, b'_1, \ldots, b_k, b'_k$,
- r_{n+1} has to first intersect $b_1, \ldots, b_k$ and then $b'_1, \ldots, b'_k$ in that order,
- and r_{n+2} has to first intersect $b_k, \ldots, b_1$ and then $b'_k, \ldots b'_1$.

Clearly, this construction can be implemented in polynomial time and it remains to prove correctness. However, before getting to the correctness proof, we first observe that this indeed yields a combinatorial description of a rainbow arrangement.

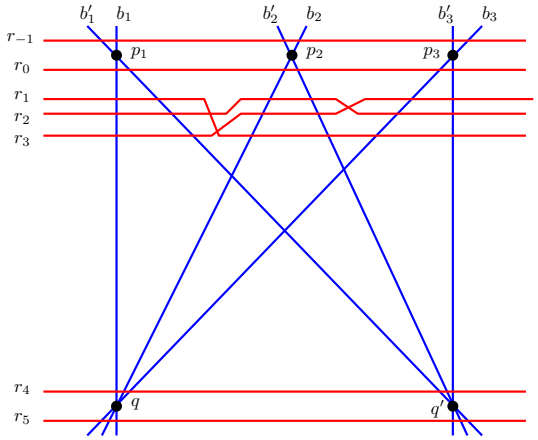

Figure 7 An illustration of the proof of Lemma 18 with $k = n = 3$. Concretely, r_{-1}, r_0, r_4, r_5 are the four control lines.

▶ **Lemma 18.** *There exists a well-separated rainbow arrangement with the combinatorial description described in the construction above.*

Proof. This proof is illustrated in Figure 7. We start by drawing the four control lines as straight horizontal lines in the order (top to bottom) $r_{-1}, r_0, r_{n+1}, r_{n+2}$, making sure that the pairs r_{-1}, r_0 and r_{n+1}, r_{n+2} are relatively close to each other while there is a big gap between r_0 and r_{n+1}. Next, we place k points $p_1, \ldots, p_k$ with increasing x-coordinates between r_{-1} and r_0, and we place two points q and q' with increasing x-coordinates between r_{n+1} and r_{n+2}. The blue lines b_i and b'_i are then drawn as straight lines where b_i goes through p_i and q, and b'_i goes through p_i and q' for all $i \in [k]$. It remains to draw $r_1, \ldots, r_n$ as pseudo-lines

just below r_0. Note that just below r_0, the blue lines read as $b'_1, b_1, \ldots, b'_k, b_k$ from left to right, which is what we need for our red pseudo-lines. Clearly, the red pseudo-lines can be drawn such as to ensure the proper intersections along each of the blue lines. It is not hard to see that this thus yields a well-separated rainbow arrangement. ◀

Next, we prove that applying the construction to a YES-instance of allowable sequences yields a YES-instance of bicolored stretchability. The construction is similar to the proof of Lemma 18. The difference is that, by our assumption that we are given a YES-instance of allowable sequences, we can now ensure that all red lines are straight as well.

▶ **Lemma 19.** *If the permutation $\pi_1, \ldots, \pi_k$ can be realized by a line arrangement (with straight lines), then the corresponding instance of bicolored stretchability can also be realized with straight lines.*

Proof. We take the line arrangement that realizes $\pi_1, \ldots, \pi_k$ and color all n lines red. Next, choose k points $p_1, \ldots, p_k$ above the arrangement with increasing x-coordinates, corresponding to the permutations $\pi_1, \ldots, \pi_k$. In other words, by walking from p_i vertically downward, we are guaranteed to observe the permutation π_i, for all $i \in [k]$. Moreover, we ensure that we will not observe any crossing of two red lines while walking vertically downward. This means that we could even walk at a very small angle (i.e., almost vertically) and still observe the correct permutation.

Next, we choose two points q, q' below the arrangement such that q is to the left of q'. By moving both q and q' vertically down towards negative infinity, we can guarantee that for all $i \in [k]$, the straight blue line b_i (or b'_i, respectively) drawn through p_i and q (or q', respectively) observes the permutation π_i. It remains to draw the control lines:

- r_{-1} is drawn as a horizontal line just above the points $p_1, \ldots, p_k$,
- r_0 is drawn as a horizontal line just below $p_1, \ldots, p_k$,
- r_{n+1} is drawn as a horizontal line just above q, q',
- and r_{n+2} is drawn horizontally just below q, q'. ◀

It remains to prove the other direction, i.e., that a realization of the constructed instance of bicolored stretchability also implies a realization of the allowable sequences instance.

▶ **Lemma 20.** *Assume that given $\pi_1, \ldots, \pi_k$, the constructed instance of bicolored stretchability can be realized using straight lines. Then there also exists a straight-line realization of the allowable sequences instance $\pi_1, \ldots, \pi_k$.*

Proof. Consider the straight-line realization of the bicolored stretchability instance. By construction of the control lines r_{-1} and r_0, b_i and b'_i have to cross at a point p_i that lies above the lines $r_1, \ldots, r_n$ for all $i \in [k]$. Moreover, we know that the control line r_{n+2} lies below the other lines and intersects the blue lines in the order $b_k, \ldots, b_1, b'_k, \ldots, b'_1$. In particular, let q be an arbitrary point on r_{n+2} that lies in-between b_1 and b'_k.

Next, for each $i \in [k]$, draw a new line b''_i through p_i and q. Observe that b''_i intersects r_{n+2} in q, and in particular q lies between the intersections of r_{n+2} with b'_i and b_i, respectively. Since b_i and b'_i intersect $r_1, \ldots, r_n$ in the same order (given by π_i), so does b''_i. This means that each of the lines b''_i observes the correct permutation, and they all pass through the same point q that lies on r_{n+2}. Thus, we can apply a projective transformation that turns r_{n+2} into the line at infinity, which in turn ensures that the lines $b''_1, \ldots, b''_k$ are parallel. We conclude that the red lines $r_1, \ldots, r_n$ after the transformation are a realization of the original allowable sequences instance. ◀

Putting all of this together, we conclude that bicolored stretchability is indeed $\exists\mathbb{R}$-complete.

▶ **Theorem 21.** *Bicolored stretchability is $\exists\mathbb{R}$-complete.*

Proof. We argued that it is contained in $\exists\mathbb{R}$ by using the verification-approach in [13]. $\exists\mathbb{R}$-hardness follows from our reduction from allowable sequences above, where correctness follows from combining Lemma 19 and Lemma 20. ◀

Certainly, Theorem 21 also implies $\exists\mathbb{R}$-hardness for the realizability problem of more general two-colored rainbow arrangements (that are not necessarily well-separated). Concretely, this also implies that realizability of bicolored order types (that were studied in, e.g., [2]) is $\exists\mathbb{R}$-hard. However, the well-separation condition is useful for us, as it allows us to also conclude that realizability of grid USO[7] is $\exists\mathbb{R}$-complete.

▶ **Corollary 22.** *Deciding whether a given grid USO is realizable is $\exists\mathbb{R}$-complete, even in two dimensions.*

Proof. Note that containment in $\exists\mathbb{R}$ follows again by giving a real-RAM verifier, and we will not go into the details of this. Instead, we explain why USO realizability is $\exists\mathbb{R}$-hard based on prior work: It was proven in [10] that realizable grid USOs correspond to well-separated hyperplane arrangements. This allows us to reduce bicolored stretchability to realizability of two-dimensional grid USO: Given the well-separated rainbow arrangement, construct the orientation as described in Section 2. This must yield a two-dimensional grid USO. If this grid USO is realizable, then by [10] there exists a well-separated line arrangement corresponding to this grid USO, which hence must have the same combinatorial description as the initial well-separated rainbow arrangement. Conversely, any well-separated line arrangement with the same combinatorial information implies that the constructed orientation is realizable. ◀

Abstract

Given a finite set $P \subset \mathbb{R}^2$, the directed Theta-6 graph, denoted $\vec{\Theta}_6(P)$, is a well-studied geometric graph due to its close relationship with the Delaunay triangulation. The $\vec{\Theta}_6(P)$-graph is defined as follows: the plane around each point $u \in P$ is partitioned into 6 equiangular cones with apex u, and in each cone, u is joined to the point whose projection on the bisector of the cone is closest. Equivalently, the $\vec{\Theta}_6(P)$-graph contains an edge from u to v exactly when the interior of ∇_u^v is disjoint from P, where ∇_u^v is the unique equilateral triangle containing u on a corner, v on the opposite side, and whose sides are parallel to the cone boundaries. It was previously shown that the spanning ratio of the $\vec{\Theta}_6(P)$-graph is between 4 and 7 in the worst case (Akitaya, Biniaz, and Bose *Comput. Geom.*, 105-106:101881, 2022). We close this gap by showing a tight spanning ratio of 5. This is the first tight bound proven for the spanning ratio of any $\vec{\Theta}_k(P)$-graph. Our lower bound models a long path by mapping it to a converging series. Our upper bound proof uses techniques novel to the area of spanners. We use linear programming to prove that among several candidate paths, there exists a path satisfying our bound.

1 Introduction

Studying the distance-preserving properties of particular families of graphs in the plane has been an active area of research for decades. This area has numerous applications, such as motion planning, or wireless routing. We will focus on geometric graphs where each vertex is a point in the plane, and each edge is weighted by the Euclidean distance between its endpoints. Given a geometric graph G, the spanning ratio of a subgraph H is a measure of how well distances of G are preserved. In particular, a subgraph H is called a *c-spanner* of G if for every edge uv in G, the shortest path in H from u to v is at most c times the length of the edge uv in G [15]. The smallest such c is referred to as the *spanning ratio* of H. Finding a tight bound on the spanning ratio of different geometric graphs is a fundamental problem in computational geometry. A particular graph of interest is the *Delaunay triangulation*. It has an edge uv when there exists a disk with u and v on its boundary and no vertices in its interior. The spanning ratio of the Delaunay triangulation has been studied for nearly 40 years, and the first constant upper bound proven was $\frac{1+\sqrt{5}}{2}\pi \approx 5.083$ [12]. Currently, the spanning ratio of the Delaunay triangulation is only known to be between 1.593 [21]

and 1.998 [20], and finding the exact value remains a major open problem [15]. The first plane geometric graph proven to have a constant spanning ratio is the $\square$-Delaunay graph, whose empty region is a square [9]. The proof was then generalized to the $\triangle$-Delaunay graph, whose empty region is an equilateral triangle [10].

Delaunay triangulations have many desirable properties. A Delaunay triangulation is a plane graph, meaning that it contains roughly $3|V|$ undirected edges, therefore the average vertex degree is approximately 6. However, it is possible for a vertex to have arbitrarily large degree. In many applications, such as signal transmission, such a large degree may be problematic. Instead, we focus on a closely-related geometric graph with bounded outdegree of 6.

Given a finite set $P \subset \mathbb{R}^2$ and integer $k > 1$, we can construct a geometric graph on P with at most k outgoing edges per vertex as follows. For each vertex $u \in P$, partition the plane into k equiangular cones about u. Then, add an edge from u to the *nearest* vertex in each cone about u. Repeat this process for each vertex of P. If *nearest* is measured by the Euclidean distance, then the resulting graph is known as a Yao-k graph, first studied by Yao [22]. The directed Theta-k graph, denoted $\vec{\Theta}_k$, is defined similarly, except that *nearest* is measured using a distance function whose unit disk is a regular k-gon. In particular, the $\vec{\Theta}_k$-graph contains an edge from u to v in cone C when the orthogonal projection of uv onto the cone bisector is minimal among all vertices v in cone C. We refer to the undirected version as the Θ_k-graph. Since being introduced by Clarkson [11] and Keil and Gutwin [13], Θ_k-graphs have been studied extensively. For $k \geq 4$, the Θ_k-graph is known to be a spanner of the complete graph [2, 4, 6, 11, 13, 17]. On the other hand, the $\vec{\Theta}_k$-graph is known to be a constant spanner for $k \geq 6$ [1, 6, 17] and also for $k = 4$ [4]. Despite extensive research, tight bounds on the spanning ratio are only known for the Θ_{4k+2}-graph when $k \geq 1$. In general, results claiming tight bounds on the spanning ratio of any geometric graph are rare. To the best of our knowledge, the only other geometric graphs with known tight spanning ratios are the three generalized Delaunay graphs whose empty regions are either a triangle, square, or hexagon. See Table 1.

Table 1 Other geometric graphs with known tight spanning ratios.

Reference	Graph	Spanning Ratio	Notes
[6]	Θ_{4k+2} $(k \geq 1)$	$1 + 2\sin(\theta/2)$	Also for constrained version [8]

[16]	$\hexagon$-Delaunay	2	

The $\vec{\Theta}_6$-graph has a special symmetry. For two points $u, v \in P$, we can define ∇_u^v to be the unique equilateral triangle whose sides have slopes $-\sqrt{3}$, 0, and $\sqrt{3}$ and u is on a corner and v is on the opposite side. Then the $\vec{\Theta}_6$-graph contains an edge from u to v exactly when the interior of ∇_u^v contains no vertices of P. Readers familiar with Delaunay triangulations may notice that the $\vec{\Theta}_6$-graph is essentially two rotated copies of a $\triangle$-Delaunay graph. The $\triangle$-Delaunay graph, often referred to as the TD-Delaunay graph, has a spanning ratio of 2 in the worst case, hence the Theta-6 graph inherits this upper bound. On the other hand, the $\vec{\Theta}_6$-graph does not preserve distances nearly as well as its undirected counterpart. The first bounds on the spanning ratio of the $\vec{\Theta}_6$-graph were given by Akitaya, Biniaz, and Bose [1]. For any $\epsilon > 0$, they construct a $\vec{\Theta}_6$-graph whose spanning ratio is at least $4 - \epsilon$. Then, they show that constructing a path in an arbitrary $\vec{\Theta}_6$-graph is not as straightforward as selecting

the outgoing edge in the cone containing the destination. This technique is known as *greedy routing*, and it produces efficient paths in $\vec{\Theta}_k$-graphs only when $k \geq 7$ [17]. Greedy routing in $\vec{\Theta}_6$-graphs can lead to a spiraling path of unbounded length. Instead, the authors of [1] give an upper bound of 7 for the spanning ratio of $\vec{\Theta}_6$-graphs using the following technique. Given an edge from a to b, they show that the *greedy* path from b to a has length at most 6 times the length of the edge from a to b. Then, for any two vertices s, t, it suffices to find an intermediate vertex x such that there are short paths from s to x and t to x. Indeed, a path from s to t can be formed by concatenating the path from s to x with the greedy paths corresponding to each edge on the path from t to x. The authors leave it as an open problem to close the gap between 4 and 7. As the title of our paper suggests, we close this gap by showing that the $\vec{\Theta}_6$-graph has a tight spanning ratio of 5.

Our proof uses elements from [1] along with several novel techniques in the area of spanners. Most notably, we use linear programming to prove the existence of a short path. At a high level, our proof is an induction on the distance between points, and it proceeds as follows. We define a special region R between s and t, and show that if there exists a vertex $x \in R$, then induction provides two paths, from s to x and from x to t, which can be concatenated to form a sufficiently short path from s to t. Then, for the rest of the proof, we assume that no vertices are in the interior of R. Importantly, we are able to show that any edge uv on the greedy path that crosses R must pay a "toll". More precisely, v is guaranteed to be at least twice as close to t as u. We leverage this property by applying induction after a candidate path crosses R. The difficulty is that there are multiple candidate paths, and determining which path is sufficiently short is non-trivial. Our solution is to assume that there is no sufficiently short candidate path. This allows us to prove inequalities corresponding to each candidate path, then we can use linear programming to show that the system is infeasible. In essence, assuming that there is no short path leads to a contradiction.

2 Preliminaries

The geometric graphs we study are weighted, directed graphs whose vertex sets contain points in the plane. We denote the directed edge from vertex u to vertex v by uv, and with a slight abuse of notation, when $p, q \in \mathbb{R}^2$, we denote the segment from p to q as pq. In general, for an edge uv and a norm $\|\cdot\|$, the value $\|uv\|$ is exactly the factor by which the unit disk of $\|\cdot\|$ must be scaled such that the unique translate with u in the center has v on the boundary. For example, $\|\cdot\|_2$ refers to the Euclidean norm whose unit disk is a circle with radius 1. We also let $\|uv\|_x$ (resp. $\|uv\|_y$) denote the absolute difference in x-coordinate (resp. y-coordinate) from u and v. The *Manhattan norm*, $\|uv\|_1 := \|uv\|_x + \|uv\|_y$, has a tipped square with side length $\sqrt{2}$ as its unit disk. For an edge uv in a geometric graph, we define its weight to be $\|uv\|_2$, the usual distance from u to v. Let $\|\cdot\|_{\hexagon}$ denote the *hexagonal norm* whose unit disk is a regular hexagon with east and west vertices equal to $(1, 0)$ and $(-1, 0)$, respectively. On the other hand, let $\|\cdot\|_{\bigcirc}$ denote the *tipped hexagonal norm* whose unit disk is a tipped regular hexagon with north and south vertices equal to $(0, \frac{2}{\sqrt{3}})$ and $(0, \frac{-2}{\sqrt{3}})$, respectively. See Figure 1. Notice that we always have $\|uv\|_{\bigcirc} \leq \|uv\|_2 \leq \|uv\|_{\hexagon}$, and equality holds exactly when uv has slope $-\sqrt{3}$, 0, or $\sqrt{3}$.

In a geometric graph G, we define the length of a path to be the sum of the weights of its edges. For any norm $\|\cdot\|$ and path $\mathcal{P}$, we define $\|\mathcal{P}\| := \sum_{uv \text{ on } \mathcal{P}} \|uv\|$. If v is a vertex on a path $\mathcal{P}$, then we define the *truncated path* $\mathcal{P}_v$ as the subpath of $\mathcal{P}$ which ends at v. For two vertices u, v in a geometric graph G, we let $d_G(u, v)$ denote the length of the shortest path in G from u to v. Recall that all edges are weighted by the Euclidean norm.

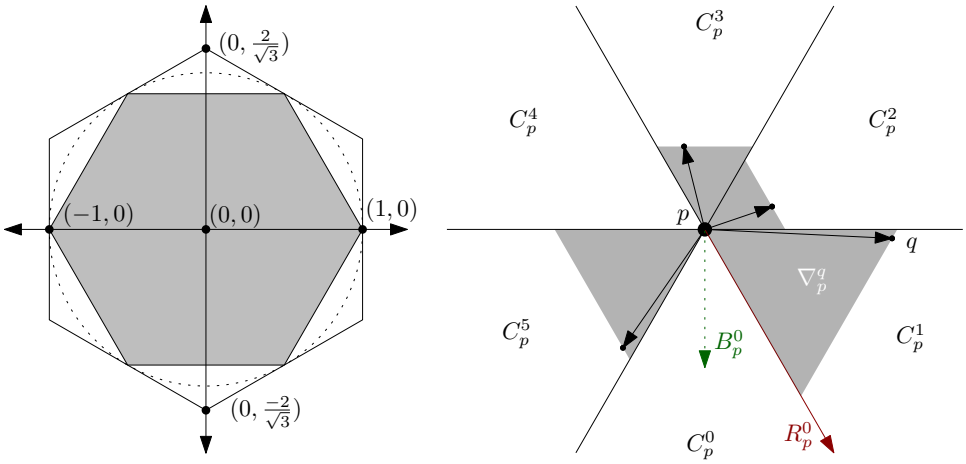

Figure 1 Left: The dotted circle represents the unit disk in the standard Euclidean norm ($\|\cdot\|_2$). The shaded inner hexagon is the unit disk in the $\|\cdot\|_{\hexagon}$-norm. The outer tipped hexagon is the unit disk in the $\|\cdot\|_{\pentagon}$-norm. Right: The six cones about p are labeled in counterclockwise order from C_p^0 below p. The dotted green bisector is B_p^0 and the red ray is R_p^0. The empty shaded triangle in C_p^1 is ∇_p^q. Each shaded region is empty.

Then for a constant $c \geq 1$, G is said to be a c-spanner if for all points u, v in G, we have $d_G(u, v) \leq c\|uv\|_2$. The *spanning ratio* of G is the least c for which G is a c-spanner. The spanning ratio of a class of graphs $\mathcal{G}$ is the least c for which all graphs in $\mathcal{G}$ are c-spanners.

For any point p, consider the three lines passing through p with slopes $-\sqrt{3}$, 0, and $\sqrt{3}$. These lines partition the plane into six cones about p, which we label counter-clockwise by C_p^i for $i \in \mathbb{Z}_6$ starting with C_p^0 directly below p. Here, $\mathbb{Z}_6$ refers to the integers modulo 6. See Figure 1. For each cone C_p^i, we denote its bisector by B_p^i. Throughout this paper, we adopt the convention that cones are closed sets, otherwise we write $\text{int}(R)$ to denote the interior of region R. For $i \in \mathbb{Z}_6$, we define the ray $R_p^i := C_p^i \cap C_p^{i+1}$. For points $p, q \in \mathbb{R}^2$ with $q \in C_p^i$, we let ∇_p^q denote the triangular region $\{r \in C_p^i \mid \|pr\|_{\hexagon} \leq \|pq\|_{\hexagon}\}$. For any equilateral triangle T, we let $\|T\|$ denote the side length of T. Notice that $\|\nabla_p^q\| = \|pq\|_{\hexagon}$. For any finite point set $P \subset \mathbb{R}^2$, we make the *general position assumption* that no two vertices lie on a line with slope $-\sqrt{3}$, 0, or $\sqrt{3}$. The directed Theta-6 graph of P, denoted $\vec{\Theta}_6(P)$, contains an edge from vertex u to vertex v exactly when $\text{int}(\nabla_u^v) \cap P = \emptyset$. Intuitively, a vertex has an outgoing edge to the nearest vertex in each of its six cones, measured using the $\|\cdot\|_{\hexagon}$-norm. For any vertices $u, v \in P$, we let $\pi(u, v)$ denote the *greedy path* from u to v. In particular, every edge ab of $\pi(u, v)$ satisfies $b \in C_a^i \iff v \in C_a^i$. If w is a vertex along the path $\pi(u, v)$, then the subpath terminating at w is denoted by $\pi(u, v)_w$. Note that if $w \neq v$, then $\pi(u, v)_w$ is not necessarily the same as $\pi(u, w)$.

3 Lower Bound

▶ **Lemma 1.** *For any $\epsilon > 0$, there exists a $\vec{\Theta}_6$-graph with spanning ratio at least $5 - \epsilon$.*

Proof. Let $\epsilon > 0$ be arbitrarily small. We will construct a $\vec{\Theta}_6$-graph with spanning ratio at least $5-\epsilon$, shown in Figure 2. For the following construction, set $0 < \delta < \frac{\epsilon}{72}$. Define the points $t := (0, 0)$, $s := (-1, 0) + \delta(1, -1), a := (-\frac{1}{2}, \frac{\sqrt{3}}{2}) + \delta(1, -2), b := (\frac{1}{2}, \frac{\sqrt{3}}{2}) + \delta(-2, -3), c := (1, 0) + \delta(-6, 1)$. Next, let p^0 be the unique point such that tp^0 has slope $-\delta$ and p^0c has slope $\sqrt{3} - \delta$. Next, let q^0 be on segment ct such that p^0q^0 has slope $\delta - \sqrt{3}$. For $i > 0$, let

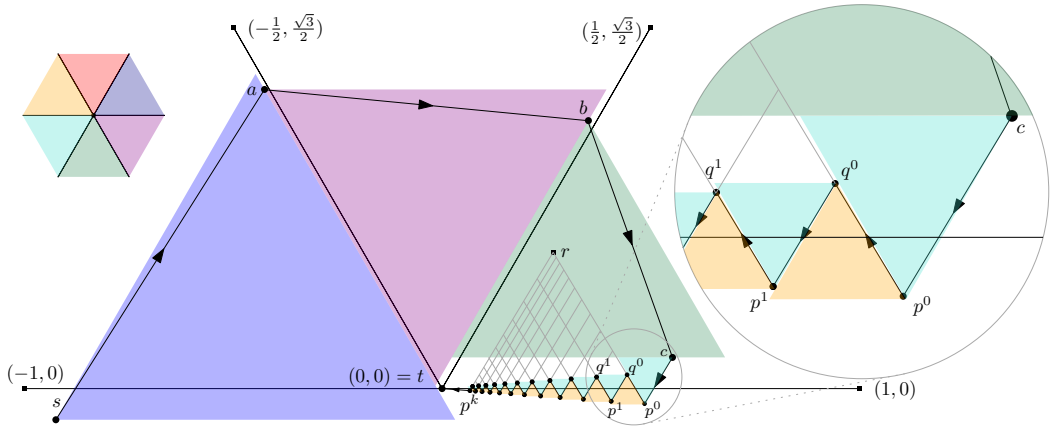

Figure 2 Graph construction achieving a spanning ratio lower bound of $5 - \epsilon$. The shortest path from s to t is the greedy path $s, a, b, c, p^0, q^0, p^1, q^1, ..., , q^{k-1}, p^k, t$. Top Left: The colour coding for edges based on direction.

q^i be on ct such that $\frac{\|q^{i-1}q^i\|_2}{\|tq^i\|_2} = \frac{\|q^0c\|_2}{\|tc\|_2}$. For $i > 0$, also define p^i to be on tp^0 such that p^iq^i has slope $\delta - \sqrt{3}$. We let k be the least integer such that p_k has x-coordinate less than δ. We have constructed the point set $P := \{t, s, a, b, c\} \cup \{p^0, p^1, ..., p^k\} \cup \{q^0, q^1, ..., q^{k-1}\}$. In $\vec{\Theta}_6(P)$, the shortest path from s to t is $s, a, b, c, p^0, q^0, p^1, q^1, ...q^{k-1}, p^k, t$ since from the perspective of any vertex on the path, all subsequent vertices lie in the same cone. Now we will lower bound the length of this path. First, we have

$$
\begin{aligned}
1 &= \|(-1,0)(-\frac{1}{2}, \frac{\sqrt{3}}{2})\|_2 && \text{since } \sqrt{\left(\frac{1}{2}\right)^2 + \left(\frac{\sqrt{3}}{2}\right)^2} = 1, \\
&\leq \|(-1,0)s\|_2 + \|sa\|_2 + \|a(-\frac{1}{2}, \frac{\sqrt{3}}{2})\|_2 && \text{by triangle inequality,} \\
&\leq \|(-1,0)s\|_1 + \|sa\|_2 + \|a(-\frac{1}{2}, \frac{\sqrt{3}}{2})\|_1 && \text{since } \|\cdot\|_2 \leq \|\cdot\|_1, \\
&= 2\delta + \|sa\|_2 + 3\delta && \text{by definition.} \qquad (1)
\end{aligned}
$$

which implies $\|sa\|_2 \geq 1 - 5\delta$. Using the same technique, we can obtain the following bounds: $\|ab\|_2 \geq 1 - 8\delta$ and $\|bc\|_2 \geq 1 - 12\delta$. Next, let r be the unique point such that p^kr has slope $\sqrt{3} - \delta$ and rp^0 has slope $\delta - \sqrt{3}$. Then by unfolding, notice that the path $p^0, q^0, p^1, q^1, ..., p^{k-1}, q^{k-1}, p^k$ has length $\|p^0r\|_2 + \|rp^k\|_2$. See Figure 2. By the triangle inequality, we have $\|p^0(1,0)\|_1 \leq \|p^0c\|_x + \|p^0c\|_y + \|c(1,0)\|_1 \leq 2\delta + 2\delta + 7\delta = 11\delta$ and $\|tp^k\|_1 = \|tp^k\|_x + \|tp^k\|_y \leq \delta + \delta = 2\delta$. Next, we claim that r approaches $(\frac{1}{2}, \frac{\sqrt{3}}{2})$ as $\delta \to 0$.

▷ Claim 2. We have $\|r(\frac{1}{2}, \frac{\sqrt{3}}{2})\|_2 \leq 17\delta$. See full version for details [5].

Now we can apply the same technique used to prove inequality (1) to obtain $\|p^0r\|_2 \geq 1 - 28\delta$ and $\|rp^k\|_2 \geq 1 - 19\delta$. Therefore the total length of the path is at least

$$
\begin{aligned}
d_{\vec{\Theta}_6(P)}(s,t) &= \|sa\|_2 + \|ab\|_2 + \|bc\|_2 + \|cp^0\|_2 + \left(\sum_{i=0}^{k-1} \|p^iq^i\|_2\right) + \|q^{k-1}p^k\|_2 + \|p_kt\|_2 \\
&\geq (1 - 5\delta) + (1 - 8\delta) + (1 - 12\delta) + (1 - 28\delta) + (1 - 19\delta) \\
&= 5 - 72\delta > 5 - \epsilon.
\end{aligned}
$$

Then since $\|st\|_2 \leq 1$, the spanning ratio of $\vec{\Theta}_6(P)$ is at least $5 - \epsilon$. ◀

4 Upper Bound

The goal of this section is to prove Theorem 3.

▶ **Theorem 3.** *For any point set $P \subset \mathbb{R}^2$ in general position, we have $d_{\vec{\Theta}_6(P)}(s,t) \leq 5\|st\|_{\bigcirc} \leq 5\|st\|_2$ $\forall s,t \in P$.*

Let $P \subset \mathbb{R}^2$ be a point set in general position, and let $G := \vec{\Theta}_6(P)$. Recall that the $\|\cdot\|_{\hexagon}$-norm is used to define G, however Theorem 3 is expressed in terms of the $\|\cdot\|_{\bigcirc}$-norm. The following lemma describes the exact relationship between $\|\cdot\|_{\hexagon}$ and $\|\cdot\|_{\bigcirc}$.

▶ **Lemma 4.** *Let $u \in \mathbb{R}^2$, $i \in \mathbb{Z}_6$, and $v \in C_u^i$. Then*

$$\|uv\|_{\hexagon} = \|uv\|_{\bigcirc} + \frac{1}{2}\min(\|C_u^i \cap C_v^{i-2}\|, \|C_u^i \cap C_v^{i+2}\|).$$

Proof. Suppose without loss of generality that $i = 0$ and v is to the right of the bisector B_u^0. See Figure 3. Then $\|C_u^0 \cap C_v^2\| \leq \|C_u^0 \cap C_v^4\|$. Let a be the orthogonal projection of v on R_u^0. Also let b be the intersection of R_u^0 with a horizontal line through v. Then

$$\|uv\|_{\bigcirc} + \frac{1}{2}\|C_u^0 \cap C_v^2\| = \|ua\|_2 + \|ab\|_2 = \|ub\|_2 = \|uv\|_{\hexagon}.$$

The other cases follow by symmetry. ◀

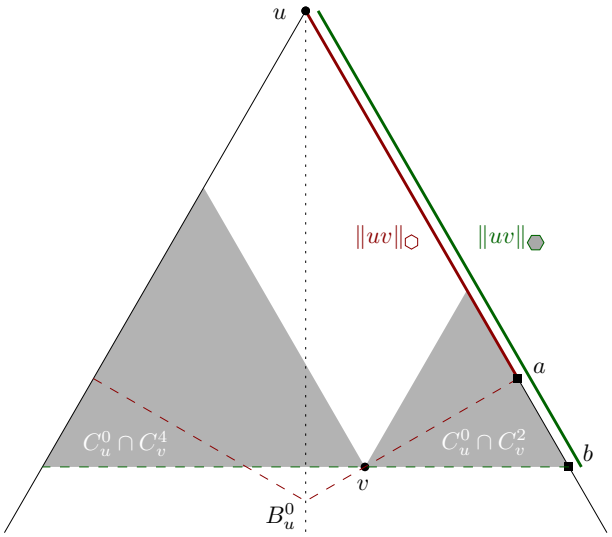

Figure 3 Lemma 4 with $v \in C_u^0$. The dotted vertical ray is the bisector B_u^0. The horizontal green dashed segment represents all points $p \in C_u^0$ such that $\|up\|_{\hexagon} = \|uv\|_{\hexagon}$. The red dashed segments represent all points $p \in C_u^0$ such that $\|up\|_{\bigcirc} = \|uv\|_{\bigcirc}$.

The next lemma finds use in proving Theorem 3

▶ **Lemma 5.** *Let $u, v, t \in P$ and $i \in \mathbb{Z}_6$. Suppose $u, v \in C_t^i \cup C_t^{i+1}$ between B_t^i and B_t^{i+1}. Then if $v \in C_u^{i+3} \cup C_u^{i+4}$, we have $\|uv\|_{\hexagon} \leq 2(\|ut\|_{\bigcirc} - \|vt\|_{\bigcirc})$.*

Proof. Without loss of generality, suppose $i = 0$. If $v \in C_u^3$, then define $p := R_u^2 \cap R_v^1$, otherwise, if $v \in C_u^4$, then define $p := R_u^4 \cap R_v^5$. Let v' and p' be the orthogonal projections of v and p on R_u^3. See Figure 4. Then

$$\|uv\|_{\hexagon} = \|up\|_2 = 2\|up'\|_2 \leq 2\|uv'\|_2 = 2(\|ut\|_{\bigcirc} - \|vt\|_{\bigcirc}).$$ ◀

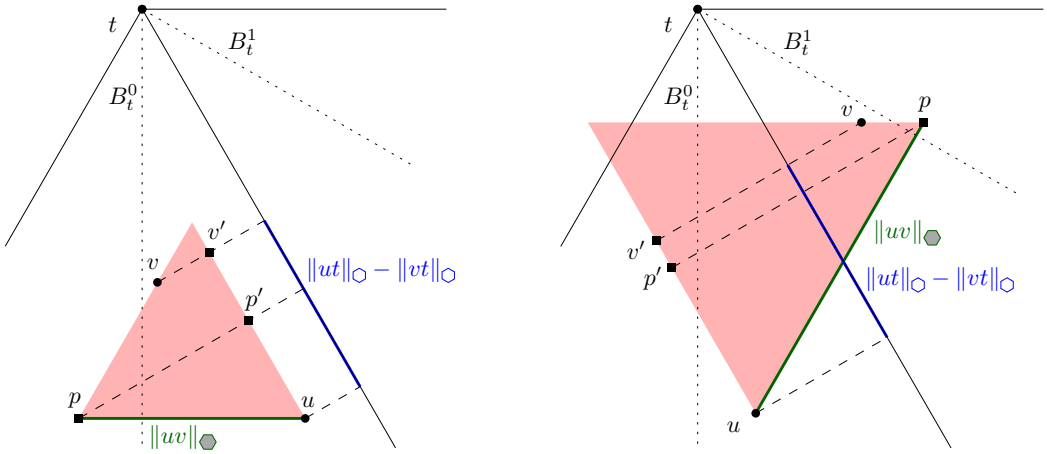

Figure 4 For the proof of Lemma 5, we assume $i = 0$ and show the case when $v \in C_u^4$ on the left and $v \in C_u^3$ on the right.

We prove Theorem 3 by induction on the hexagonal distance $\|\cdot\|_{\hexagon}$ between vertices. For the base case, consider the closest pair of vertices $s, t \in P$ (i.e. $\|st\|_{\hexagon}$ is minimal). Minimality implies $\text{int}(\nabla_s^t)$ must not contain any vertices of P. Therefore there must be an edge from s to t, yielding $d_G(s,t) = \|st\|_2 \leq 5\|st\|_{\bigcirc}$.

For the remainder of the proof, fix $s, t \in P$ and suppose that for any vertices $u, v \in P$, if $\|uv\|_{\hexagon} < \|st\|_{\hexagon}$, then $d_G(u,v) \leq 5\|uv\|_{\bigcirc}$. We will assume $\|st\|_{\hexagon} = 1$ since our argument holds when scaling the point set. Without loss of generality, suppose $s \in C_t^0$, with s being to the right of B_t^0. Define the triangle $T = C_t^0 \cap C_s^2$, and denote its side length by $y_0 := \|T\|$. Notice that y_0 describes the *hex* distance from s to the nearest boundary, and by Lemma 4, we obtain $5\|st\|_{\bigcirc} = 5 - 2.5y_0$. Suppose towards a contradiction that $5\|st\|_{\bigcirc} < d_G(s,t)$. Our approach is to analyse paths from s to t, which will allow us to prove inequalities based on our faulty assumption. These inequalities will form a linear system, then linear programming will help us show that the system is infeasible. The first step in our proof is to establish an empty region which we refer to as R.

▶ **Definition 6** (Empty Region R). *Consider the points $p := B_s^3 \cap B_t^1$ and $q = B_s^4 \cap B_t^0$. See Figure 5. Let Q denote the parallelogram with vertices s, q, t, p, and define the region $R := Q \cup \nabla_s^p \cup \nabla_s^q$.*

Let y be the vertex such that sy is the edge in C_s^3 and consider the quantity $y_1 := 1 - \|\nabla_s^y\|$ describing the hexagonal distance $\|\cdot\|_{\hexagon}$ from y to the horizontal line through t. In addition to proving that R is empty, the following lemma proves that y_0 and y_1 cannot both be large. Geometrically, s must be near R_t^0 and y must be near R_t^1. See Figure 5.

▶ **Lemma 7.** *If $d_G(s,t) > 5\|st\|_{\bigcirc}$, then int$(R)$ does not contain any vertices of P. Furthermore, $y \in C_t^1$ and*

$$2.5y_0 + 3.5y_1 < 1 \tag{2}$$

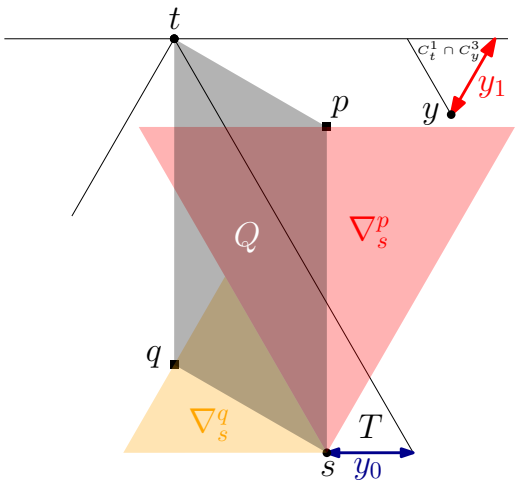

Figure 5 The red triangle is ∇_s^p, the orange triangle is ∇_s^q, and the shaded parallelogram is Q. Their union is R, whose interior can be assumed to not contain any vertices by Lemma 7. Furthermore, there exists a vertex $y \in C_t^1$ close to the horizontal line through t. The triangle T has side-length y_0 and the triangle $C_t^1 \cap C_y^3$ has side-length y_1.

Proof. See Figure 6. If there exists a vertex $w \in Q$ with $w \notin \{s, t\}$, then $\|wt\|_{\hexagon} < 1$. We obtain

$$\begin{aligned} d_G(s,t) &\leq d_G(s,w) + d_G(w,t) && \text{by triangle inequality,} \\ &\leq 5\|sw\|_{\hexagon} + 5\|wt\|_{\hexagon} && \text{by induction,} \\ &= 5\|st\|_{\hexagon} && \text{by } \|\cdot\|_{\hexagon} \text{ collinearity.} \end{aligned}$$

Therefore we may assume parallelogram Q contains no vertices. Next we will rule out the

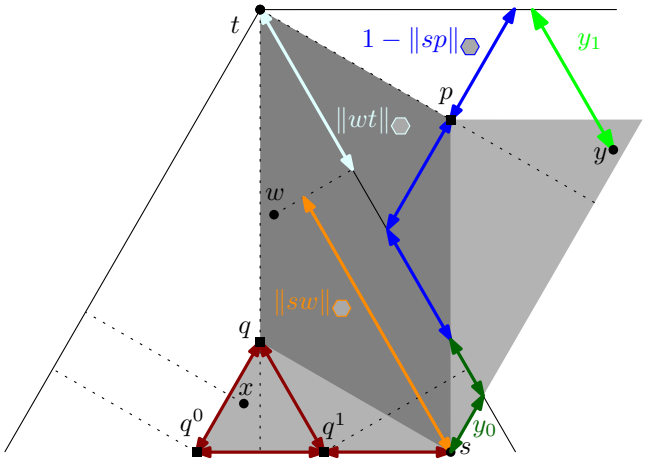

Figure 6 If there is a vertex w in the dark shaded parallelogram, denoted Q, then induction yields paths from s to w and from w to t. If there is an edge sy in the light shaded triangle $\nabla_s^p \setminus Q$, then induction yields a path from y to t. Similarly, if there is an edge sx in the light shaded triangle $\nabla_s^q \setminus Q$, then induction yields a path from x to t.

possibility of $y \in C_t^5 \cup C_t^0$. If $y \in C_t^5$, then we have

$$\begin{aligned} d_G(s,t) &\leq \|sy\|_{\hexagon} + d_G(y,t) && \text{by triangle inequality,} \\ &\leq 1 + 5y_0 && \text{by induction as } \|yt\|_{\bigcirc} \leq \|yt\|_{\hexagon} = \|\nabla_t^y\| \leq \|T\| \\ &< 5\|st\|_{\hexagon} && \text{since } y_0 \leq 0.5 \text{ and } 5 - 2.5y_0 = 5\|st\|_{\hexagon}. \end{aligned}$$

On the other hand if $y \in C_t^0$ or $y \in C_t^1$ below B_t^1, then we use Lemma 5 to obtain $\|sy\|_{\hexagon} \leq 2(\|st\|_{\bigcirc} - \|yt\|_{\bigcirc})$. Indeed, if sy crosses B_t^0, then let $z := sy \cap B_t^0$ and apply Lemma 5 to both sz and zy. We obtain

$$\begin{aligned} d_G(s,t) &\leq \|sy\|_{\hexagon} + d_G(y,t) && \text{by triangle inequality,} \\ &\leq 2(\|st\|_{\bigcirc} - \|yt\|_{\bigcirc}) + 5\|yt\|_{\bigcirc} && \text{by Lemma 5 and induction,} \\ &= 2\|st\|_{\bigcirc} + 3\|yt\|_{\bigcirc} \\ &< 5\|st\|_{\bigcirc} && \text{since } \|yt\|_{\bigcirc} < \|st\|_{\bigcirc}. \end{aligned}$$

Therefore we may assume $y \in C_t^1$ above the bisector B_t^1. We have $\|yt\|_{\hexagon} \leq \|C_t^1 \cap C_s^3\| = 1 - y_0$. Recall that $y_1 := 1 - \|\nabla_s^y\|$, and notice that we also have $y_1 = \|C_t^1 \cap C_y^3\|$. By Lemma 4, $\|yt\|_{\bigcirc} = \|yt\|_{\hexagon} - \frac{1}{2}y_1$. This gives us

$$\begin{aligned} 5 - 2.5y_0 &< d_G(s,t) && \text{by assumption,} \\ &\leq \|sy\|_{\hexagon} + d_G(y,t) && \text{by triangle inequality,} \\ &\leq (1 - y_1) + (5(1 - y_0) - 2.5y_1) && \text{by } \|\nabla_s^y\| = \|sy\|_{\hexagon} \text{ and induction.} \end{aligned} \tag{3}$$

By re-arranging inequality (3), we obtain $2.5y_0 + 3.5y_1 < 1$, proving (2). Notice that $2y_0 + 3(1 - \|sp\|_{\hexagon}) = 1$ by symmetry of isosceles triangles. We have

$$y_1 < \frac{1 - 2.5y_0}{3.5} < \frac{1 - 2y_0}{3} = 1 - \|sp\|_{\hexagon},$$

which implies that the region $\text{int}(\nabla_s^p)$ contains no vertices. Indeed, if there were a point $u \in \text{int}(\nabla_s^p)$, then $1 - y_1 = \|sy\|_{\hexagon} \leq \|su\|_{\hexagon} \leq \|sp\|_{\hexagon}$. Thus far we have shown that Q and ∇_s^p do not contain vertices in their interior, hence it remains to argue that $\text{int}(\nabla_s^q)$ is also empty. Towards a contradiction, assume there is a vertex $x \in \text{int}(\nabla_s^q)$. If x is to the right of the bisector B_t^0, then we have

$$\begin{aligned} d_G(s,t) &\leq \|sx\|_{\hexagon} + d_G(x,t) && \text{by triangle inequality,} \\ &\leq 2(\|st\|_{\bigcirc} - \|xt\|_{\bigcirc}) + 5\|xt\|_{\bigcirc} && \text{by Lemma 5 and induction,} \\ &= 2\|st\|_{\bigcirc} + 3\|xt\|_{\bigcirc} \\ &< 5\|st\|_{\bigcirc} && \text{since } \|xt\|_{\bigcirc} < \|st\|_{\bigcirc}. \end{aligned}$$

On the other hand if x is to the left of the bisector B_t^0, then let $q^0 := R_q^5 \cap R_s^4$ and $q^1 := R_q^0 \cap R_s^4$. Notice that $\|sq^0\|_{\hexagon} = 2\|sq^1\|_{\hexagon}$. We have

$$\begin{aligned} d_G(s,t) &\leq \|sx\|_{\hexagon} + d_G(x,t) && \text{by triangle inequality,} \\ &\leq \|sq^0\|_{\hexagon} + 5\|xt\|_{\bigcirc} && \text{by induction,} \\ &\leq 2\|sq^1\|_{\hexagon} + 5\|q^0t\|_{\bigcirc} && \text{since } \|xt\|_{\bigcirc} \leq \|q^0t\|_{\bigcirc}, \\ &= 2(2(\|st\|_{\bigcirc} - \|q^1t\|_{\bigcirc})) + 5\|q^1t\|_{\bigcirc} && \text{by Lemma 5 and } \|q^0t\|_{\bigcirc} = \|q^1t\|_{\bigcirc}, \\ &= 4\|st\|_{\bigcirc} + \|q^1t\|_{\bigcirc} \\ &\leq 5\|st\|_{\bigcirc} && \text{since } \|q^1t\|_{\bigcirc} \leq \|st\|_{\bigcirc}. \end{aligned}$$

Therefore the region $\text{int}(\nabla_s^q)$ contains no vertices. This completes the proof. ◀

Now that we have established an empty region R and the position of y, we would like to analyse the greedy path from y to t. Recall that for any vertices $u, v \in P$, the greedy path from u to v is denoted $\pi(u, v)$. Every edge ab of $\pi(u, v)$ satisfies $b \in C_a^i \iff v \in C_a^i$. Intuitively, the greedy path simply follows the edge in the direction of the destination. In [1] the authors show that for every edge uv of $\pi(s, t)$, we have $\|ut\|_{\hexagon} > \|vt\|_{\hexagon}$. However, this does not guarantee that the greedy path is an efficient path to t. The main reason is that $\pi(s, t)$ may spiral around t arbitrarily many times while making negligible progress. The authors of [1] show how to avoid a spiraling greedy path by assuming there is an edge from t to s and using the empty triangle ∇_t^s as an obstruction. This is done in Lemmas 2, 3 and 4 from [1], which we restate here using our notation.

▶ **Lemma 8** (Lemma 2 in [1]). *If edge uv is on $\pi(u, t)$ and $u \in C_t^i$, then $v \in C_t^{i-1} \cup C_t^i \cup C_t^{i+1}$.*

▶ **Lemma 9** (Lemma 3 in [1]). *Let $s, t \in P$ and assume ts is an edge of $\vec{\Theta}_6(P)$. Assume the vertices a, b, c appear in this order in $\pi(s, t)$, not necessarily distinct or consecutive. Then if a and c are both in the same cone C_t^i for $i \in \mathbb{Z}_6$, then $int(\nabla_a^b) \cap int(\nabla_t^c) = \emptyset$.*

▶ **Lemma 10** (Lemma 4 in [1]). *Let $s, t \in P$ and assume ts is an edge of $\vec{\Theta}_6(P)$. Then for $i \in \mathbb{Z}_6$, we have*

$$\sum_{\substack{ab \in \pi(s,t) \\ a \in C_t^i}} \|ab\| \leq \|\nabla_t^s\|$$

Instead of working with an empty triangle that forces the greedy path not to spiral as in [1], we will ignore any spiraling by only using the greedy path up to and including the first edge that crosses the boundary R_t^0. Despite this change, the arguments in [1] can be applied in our setting to prove Lemma 11 which is a slightly modified version of Lemma 4 from [1].

▶ **Lemma 11.** *Fix $j \in \mathbb{Z}_6$ and let $s, t, u, v \in P$ such that uv is an edge of $\pi(s, t)$ and no edge of the truncated greedy path $\pi(s, t)_u$ crosses R_t^j. For $i \in \mathbb{Z}_6$, let f_i denote the first vertex of $\pi(s, t)_u$ in C_t^i. If no such vertex f_i exists, let $f_i := t$. Then $\|\pi(s, t)_v\|_{\hexagon} \leq \sum_{i=0}^{5} \|f_i t\|_{\hexagon}$.*

Proof. Suppose without loss of generality that $i = 0$. For any point p below t, let p' denote the intersection of the horizontal line through p with the ray R_t^0. We claim that if ab and cd are edges of $\pi(s, t)_v$ such that $a, c \in C_t^0$, then the segments $a'b'$ and $c'd'$ are disjoint. Furthermore, both $a'b'$ and $c'd'$ are subsegments of $f_0't$. This claim follows from Lemma 9 of [1] since the path $\pi(s, t)_u$ is assumed to not cross R_t^j. We sum all edges with source in C_t^0 to obtain

$$\sum_{\substack{ab \text{ on } \pi(s,t)_v \\ a \in C_t^0}} \|ab\|_{\hexagon} = \sum_{\substack{ab \text{ on } \pi(s,t)_v \\ a \in C_t^0}} \|a'b'\|_{\hexagon} \leq \|f_0't\|_{\hexagon} = \|f_0 t\|_{\hexagon}.$$

The lemma follows by summing over the edges in all cones C_t^i for $i \in \mathbb{Z}_6$. ◀

For the rest of the section, we make Assumptions 12 and 13 to help us prove Theorem 3. For the cases when these assumptions do not hold, see the full version [5]. The first assumption roughly states that the greedy path from y spirals counterclockwise around t without making significant progress to t. We define $u^y v^y$ to be the first edge of $\pi(y, t)$ which crosses R_t^0. If such an edge does not exist, let $u^y := t$ and $v^y := t$. Then the first assumption can be stated as follows:

▶ **Assumption 12.** *There exists a vertex $q \in C_t^5$ on $\pi(y, t)_{v^y}$ with $\|qt\|_{\hexagon} > y_0$.*

Our second assumption is that there is no edge uv crossing R_t^5 such that $u \in T$ and $v \in C_u^4$.

▶ **Assumption 13.** *For every vertex $u \in T$, we have $P \cap int(C_t^0 \cap C_u^4) \neq \emptyset$.*

Let sx be the edge in C_s^4. By Assumption 13, x exists and $x \in C_t^0$. Combining our two assumptions allows us to naturally consider two candidate paths, loosely referred to as the *x-path* and the *y-path*, and show that one of them is sufficiently short to force a contradiction with $d_G(s,t) > 5\|st\|_{\bigcirc}$. Informally, the x-path travels clockwise around t, whereas the y-path travels in the opposite direction. Where these two paths meet, they must compete for space. The lengths of the paths are primarily dictated by their *long* edges which cross cone boundaries around t. These *long* edges come with large empty regions which squeeze the other path closer to t. We formalize this intuition below.

Recall that $u^y v^y$ is the first edge of $\pi(y,t)$ that crosses the boundary R_t^0. Consider the candidate path sy concatenated with $\pi(y,t)_{v^y}$, which we loosely refer to as the y-path, ending at v^y. Overall, the y-path progresses counterclockwise about t until C_t^5, however it is still possible that the y-path reverses direction and ends up crossing R_t^0 from C_t^1 to C_t^0. Maintaining full generality, we may only assume that for some $i \in \{0,1\}$, we have $u^y \in C_t^i$ and $v^y \in C_t^{1-i}$, which follows from Lemma 8. In light of Lemma 11, we need not concern ourselves with every edge of this path. An upper bound can be established from only the first vertex of each cone. In fact, we only need to upper bound the value $\|f_i t\|_{\hexagon}$ where f_i is the first vertex of C_t^i, hence we look to the previous cone for structure. For $i \in \{1,2,3,4,5\}$, let $y^i \in C_t^i$ be the vertex of $\pi(y,t)_{u^y}$ which maximizes $\|C_t^i \cap C_{y^i}^{i-2}\|$. See Figure 7 for example.

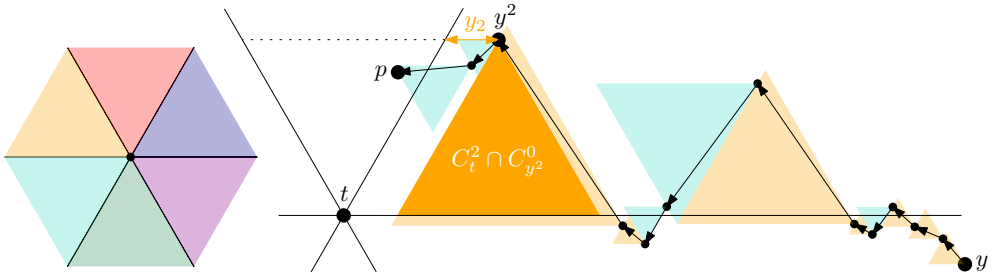

Figure 7 In this example, p is the first vertex of $\pi(y,t)_{v^y}$ in cone C_t^3. The highest vertex of $\pi(y,t)_{v^y}$ in C_t^2 is y^2 by definition. The maximal triangle $C_t^2 \cap C_{y^2}^0$ is coloured orange, and $y_2 = \|y^2 t\|_{\hexagon} - \|C_t^2 \cap C_{y^2}^0\|$. Observation 14 implies that y^2 has a greater y-coordinate than p, thus $\|C_t^2 \cap C_{y^2}^0\|$ provides an upper bound on $\|pt\|_{\hexagon}$.

▶ **Observation 14.** *For $i \in \{1,2,3,4,5\}$, no vertex of $\pi(y,t)_{y^i}$ is in $int(C_t^{i+1})$.*

Proof. The observation holds for $i = 1$ since $y^1 = y$. Then for $i \in \{2,3,4,5\}$, consider the first vertex v of C_t^{i+1} on $\pi(y,t)_{u^y}$. Then y^i and t must be on opposite sides of the line $R_v^{i-1} \cup R_v^{i+2}$, which implies $\|y^i t\|_{\hexagon} > \|vt\|_{\hexagon}$, meaning that y^i appears before v on $\pi(y,t)_{u^y}$. ◀

Observation 14 implies y^1, y^2, y^3, y^4, y^5 appear in order on $\pi(y,t)_{u^y}$. Intuitively, y^i is the head of a *long* edge whose tail is in the previous cone C_t^{i-1}. Indeed, if the tail was in the same cone as y^i, then $\|C_t^i \cap C_{y^i}^{i-2}\|$ would not be maximal. We define the distance y_i from y^i to C_t^{i+1} as $y_i := \|C_t^i \cap C_{y^i}^{i+2}\|$. Equivalently, $y_i = \|y^i t\|_{\hexagon} - \|C_t^i \cap C_{y^i}^{i-2}\|$. By Assumption 12, the y-path must pass through cones $C_t^1, \ldots, C_t^5$, hence y_i is well-defined for $i \in \{1,2,3,4,5\}$. Also notice that the region $\text{int}(C_t^i \cap C_{y^i}^{i-2})$ is empty since y^i is necessarily the head of an

edge from C_t^{i-1}. Next, for each $i \in \mathbb{Z}_6$, we let Y_i be the value of $\|ut\|_{\hexagon}$ where u is the first vertex of $\pi(y,t)_{u^y}$ with $u \in C_t^i$. If no such vertex $u \in C_t^i$ exists, then $Y_i := 0$. First, we have $Y_1 = \|yt\|_{\hexagon} \le 1 - y_0$. Next, for $i \in \{1,2,3,4,5\}$, cone C_t^{i+1} can only be visited from cone C_t^i on $\pi(y,t)_{u^y}$, therefore we see that for $i \in \{1,2,3,4,5\}$,

$$y_0 + Y_1 \le 1 \qquad \text{and} \qquad y_i + Y_{i+1} \le y_i + \|C_t^i \cap C_{y^i}^{i-2}\| = \|y^i t\|_{\hexagon} \le Y_i \tag{4}$$

We include these inequalities in our system which will eventually be proven infeasible. Next we will discuss the second candidate path: the x-path. Recall sx is the edge in $C_s^4 \cap C_t^0$. We will define the analogous variables for x as we did for y. Let $u^x v^x$ be the first edge of $\pi(x,t)$ that crosses R_t^0. As before, Lemma 8 implies that for some $i \in \{0,1\}$, we have $u^x \in C_t^i$ and $v^x \in C_t^{1-i}$. If no such crossing exists, then set $u^x := t$ and $v^x := t$. For $i \in \{0,5,4,3,2\}$, let $x^i \in C_t^i$ be the vertex of $\pi(x,t)_{u^x}$ which maximizes $\|C_t^i \cap C_{x^i}^{i+2}\|$. We define the distance x_i from x^i to C_t^{i-1} as $x_i := \|C_t^i \cap C_{x^i}^{i-2}\|$. If no such x^i exists, then define $x_i := 0$. However, we will later argue in Claim 19 that the vertices x^0, x^5, x^4, x^3 must exist, otherwise the x-path is sufficiently short to force a contradiction. Observe that for $i \in \{5,4,3,2\}$ the region $C_t^i \cap C_{x^i}^{i+2}$ is empty since x^i is the head of an edge from C_t^{i+1}. Next, for each $i \in \mathbb{Z}_6$, we let X_i be the value of $\|ut\|_{\hexagon}$ where u is the first vertex of $\pi(x,t)_{u^x}$ with $u \in C_t^i$. If no such vertex u exists, then $X_i := 0$. Since greedy paths decrease in $\|\cdot\|_{\hexagon}$-norm, then we have $X_0 = \|xt\|_{\hexagon} \le 1$. Next, for $i \in \{5,4,3,2,1\}$, if v is the first vertex of $\pi(x,t)_{u^x}$ in C_t^i, then its predecessor u must be in cone C_t^{i+1}, therefore we see that for $i \in \{5,4,3,2,1\}$,

$$X_0 \le 1 \quad \text{and} \quad x_{i+1} + X_i \le x_{i+1} + \|C_t^{i+1} \cap C_{x^{i+1}}^{i+3}\| = \|x^{i+1}t\|_{\hexagon} \le X_{i+1}. \tag{5}$$

Intuitively, the only vertices in cone C_t^i that are important to us are x^i and y^i. Now we consider possible paths from s to t. We could take the y-path from s to v^y, then apply induction at v^y. By Lemma 11, this yields

$$\begin{aligned} 5 - 2.5y_0 &\le d_G(s,t) \\ &\le \|sy\|_{\hexagon} + \|\pi(y,t)_{v^y}\|_{\hexagon} + d_G(v^y,t) \\ &\le (1-y_1) + (Y_1+Y_2+Y_3+Y_4+Y_5+Y_0) + 5||v^y t||_{\bigcirc}. \end{aligned} \tag{6}$$

On the other hand, we could instead follow the x-path from s to v^x, then apply induction at v^x. Similarly, we obtain

$$\begin{aligned} 5 - 2.5y_0 &\le d_G(s,t) \\ &\le \|sx\|_{\hexagon} + \|\pi(x,t)_{v^x}\|_{\hexagon} + d_G(v^x,t) \\ &\le (1-y_0-x_0) + (X_0+X_5+X_4+X_3+X_2+X_1) + 5||v^x t||_{\bigcirc}. \end{aligned} \tag{7}$$

While we have proven several inequalities (2),(4),(5),(6),(7), they are not yet strong enough to form an infeasible system. First, notice that since R may not contain vertices, then $u^y v^y$ must cross both B_t^0 and B_t^1. By the following lemma, this implies that the edge $u^y v^y$ makes significant progress towards t.

▶ **Lemma 15.** *Let $u, v, t \in P$ with edge uv contained in ∇_u^t. Assume uv crosses both B_t^0 and B_t^1, then $2\|vt\|_{\bigcirc} \le \|uv\|_{\hexagon}$.*

Proof. Suppose without loss of generality that $u \in C_t^0$ with u to the left of B_t^0, and $v \in C_t^1$ with v above B_t^1. See Figure 8. Consider the point $t' := B_t^0 \cap R_v^5$. Since u is to the left of B_t^0, then the segment vt' is contained in ∇_u^v, hence $\|vt'\|_2 \le \|\nabla_u^v\| = \|uv\|_{\hexagon}$. On the other hand, consider the point $v' := R_t^1 \cap B_v^3$. Then considering that vt' and $v't$ have respective slopes $\sqrt{3}$ and 0, then we have $2\|vt\|_{\bigcirc} = 2\|v't\|_2 = \|vt'\|_2 \le \|uv\|_{\hexagon}$. ◀

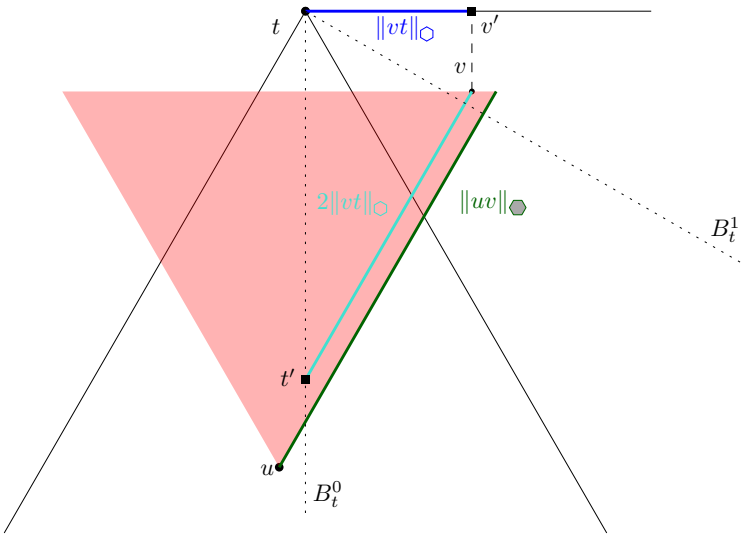

Figure 8 Lemma 15 where $u \in C_t^0$ with u to the left of B_t^0, and $v \in C_t^1$ with v above B_t^1.

Lemma 15 quantifies the toll required for an edge to cross the empty region. Intuitively, the distance to t is halved each time the empty region R is crossed. In order to also apply Lemma 15 to $u^x v^x$, we require two observations, which follow from Assumptions 12 and 13.

▶ **Observation 16.** *If x^1 exists, then $\|x^1 t\|_{\hexagon} \leq 1 - y_0$.*

Proof. Suppose on the contrary that $\|x^1 t\|_{\hexagon} > 1 - y_0$. See Figure 9. Since greedy paths decrease in $\|\cdot\|_{\hexagon}$-norm to their destination, then $\|y^i t\|_{\hexagon}$ is monotonically decreasing, whereas $\|x^i t\|_{\hexagon}$ is monotonically increasing for $i \in \{1, 2, 3, 4, 5\}$. This means that $\|y^i t\|_{\hexagon} \leq \|y^1 t\|_{\hexagon} \leq 1 - y_0 < \|x^1 t\|_{\hexagon} \leq \|x^i t\|_{\hexagon}$. In particular, the empty regions $C_t^i \cap C_{x^i}^{i+2}$ for $i \in \{2, 3, 4\}$ imply that $Y_3 \leq x_2$, $Y_4 \leq x_3$, and $Y_5 \leq x_4$. Assumption 12 implies $Y_5 \geq y_0$, therefore (4) implies $\min(x_2, x_3, x_4) \geq y_0$. However this yields $1 - y_0 < \|x^1 t\|_{\hexagon} < 1 - x_0 - x_5 - x_4 - x_3 - x_2 \leq 1 - 3y_0$, which implies $y_0 < 0$. This is a contradiction, hence we may assume $\|x^1 t\|_{\hexagon} \leq 1 - y_0$ for the rest of the proof. ◀

▶ **Observation 17.** *There is no edge uv on $\pi(x, t)_{v^x}$ with $u \in C_t^5$ and $v \in T$.*

Proof. If there were such an edge uv on $\pi(x, t)_{v^x}$ with $u \in C_t^5$ and $v \in T$, the empty region $\text{int}(\nabla_u^v)$ contradicts Assumption 13. See Figure 10. ◀

Observations 16 and 17 together imply that the edge $u^x v^x$ crosses both B_t^0 and B_t^1 since the interior of region R is empty by Lemma 7. Therefore Lemma 15 applies to $u^x v^x$ as well. Furthermore, we can ensure that $\|v^x t\|_{\hexagon} \leq x_0$ by the following claim.

▷ Claim 18. There is no vertex to the left of B_t^0 in the interior of C_x^2.

Proof. Assume there is such a vertex $p \in C_x^2$ to the left of B_t^0. Note that we must have $p \in C_s^3$ since $C_x^2 \cap C_s^4 \subseteq \nabla_s^x$ and ∇_s^x contains no vertices. This means that p is above ∇_s^y, yielding $\|pt\|_{\hexagon} \leq y_1$. See Figure 11. Let u^1 be the vertex of $T := C_t^0 \cap C_s^2$ minimizing $\|u^1 t\|_{\hexagon}$. Then we take the edge $u^1 u^2$ in $C_{u^1}^4$. By Assumption 13, we have $u^2 \in C_t^0$. If $u^2 \in C_x^2$, then set $u^3 := u^2$. Otherwise take the edge $u^2 u^3$ in $C_{u^2}^2$. We must have $u^3 \in C_s^3$, hence we apply induction from u^3 to t. This yields

$$\begin{aligned} 5 - 2.5y_0 &< d_G(s, t) \\ &\leq d_G(s, u^1) + \|u^1 u^2\|_{\hexagon} + \|u^2 u^3\|_{\hexagon} + d_G(u^3, t) \\ &\leq 5y_0 + 1 + 1 + 5y_1. \end{aligned} \tag{8}$$

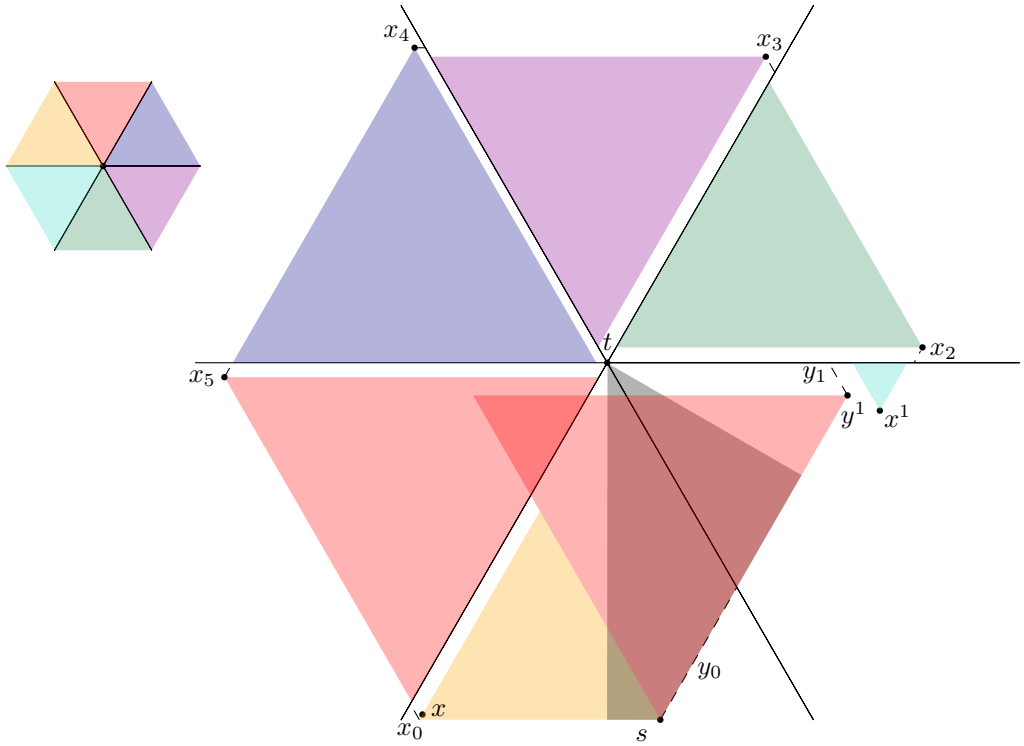

Figure 9 Observation 16: From Assumption 12, there cannot exist x^1 such that $\|x^1 t\| > 1 - y_0$.

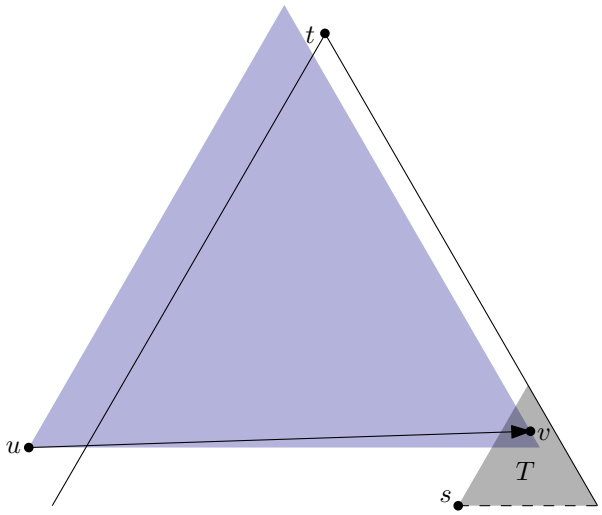

Figure 10 Observation 17: If uv is an edge from C_t^5 to T, then the region $C_v^4 \cap C_t^0$ contains no vertices in its interior, contradicting Assumption 13.

However, the system of inequalities (2,8) is infeasible. Therefore we may assume that the region $C_x^2 \cap C_t^0$ to the left of B_t^0 is empty for the remainder of the proof. ◁

In order to further restrict the set of solutions to our linear system of inequalities towards infeasibility, we will consider several cases with more granularity. We will first consider the direction in which the edge $u^y v^y$ crosses the boundary R_t^0 in order to strengthen our upper

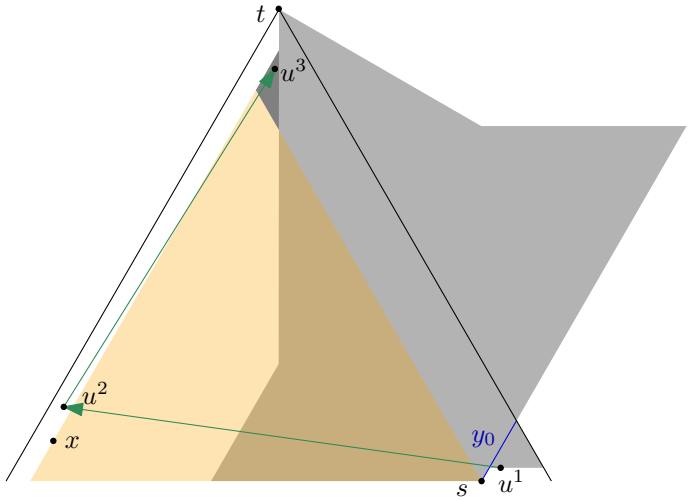

Figure 11 If there is a vertex to the left of B_t^0 in C_x^2 (the dark grey region), then we can form a path that passes through s, u^1, u^2, u^3, t. Induction is used to bound $d_G(s, u^1)$ and $d_G(u^3, t)$, whereas u^1u^2 and u^2u^3 are edges in G (in green).

bound on $\|v^y t\|_{\bigcirc}$. Recall that $5\|v^y t\|_{\bigcirc}$ accounts for the path from v^y to t by induction, hence it is an important quantity to reduce. We will apply the same analysis to $u^x v^x$ to also upper bound $\|v^x t\|_{\bigcirc}$, then lastly we will consider the trade-off between the x-path and y-path. In Figure 12, we show an example of the x-path and y-path that compete for space.

Next, we show in Claim 19 that the x-path must visit the cone C_t^3.

▷ Claim 19. The path $\pi(x,t)_{v^x}$ must contain a vertex in C_t^3.

Proof. If the claim did not hold, then $u^x v^x$ would necessarily cross R in the counterclockwise direction. See Figure 13. If $\pi(x,t)_{v^x} \cap C_t^5 \neq \emptyset$, then we use Lemma 11 and apply induction at v^x to obtain

$$\begin{aligned} 5 - 2.5y_0 &< d_G(s,t) \\ &\leq \|sx\|_{\hexagon} + \|\pi(x,t)_{v^x}\|_{\hexagon} + d_G(v^x,t) \\ &\leq (1 - x_0 - y_0) + (X_0 + X_5 + X_4) + 5||v^x t||_{\hexagon} \\ &\leq (1 - x_0 - y_0) + 1 + (1 - x_0) + (1 - x_0 - x_5) + 5\min(x_0, \frac{x_5}{2}). \end{aligned} \tag{9}$$

However, the linear system (2,9) is infeasible. On the other hand if $\pi(x,t)_{v^x} \cap C_t^5 = \emptyset$, then

$$\begin{aligned} d_G(s,t) &\leq \|sx\|_{\hexagon} + \|\pi(x,t)_{v^x}\|_{\hexagon} + d_G(v^x,t) \\ &\leq (1 - x_0 - y_0) + X_0 + 5||v^x t||_{\hexagon} \\ &\leq (1 - x_0 - y_0) + 1 + 5x_0 \\ &\leq 4 - y_0 && \text{since } x_0 \leq 1/2, \\ &\leq 5 - 2.5y_0 && \text{since } y_0 \leq 1/2. \end{aligned}$$

which is a contradiction. To summarize, $\pi(x,t)_{v^x}$ must enter C_t^3. ◁

First, notice that $u^y v^y$ can cross R_t^0 either in the clockwise or counterclockwise direction:

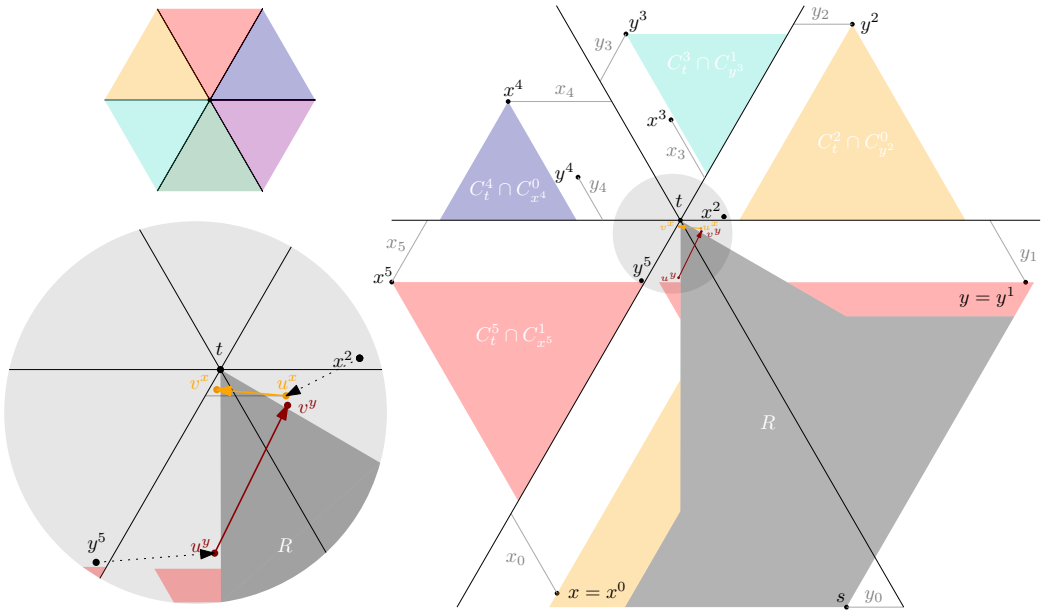

Figure 12 Top Left: The colour coding for edges based on direction. Right: The grey region R contains no vertices in its interior by Lemma 7. The triangular regions are coloured according to their edge direction. This example shows the case when $v^y \in C_t^1$ (case $Y1$), $v^x \in C_t^0$ (case $X0$), and $j = 3$ (case J3). Notice that the empty turquoise region $C_t^3 \cap C_{y^3}^1$ constrains the position of x^3, forcing x^2 to be considerably closer to t. Lower Left: This enlarged view shows the edges that cross the empty grey region R. Notice that the edges $u^x v^x$ and $u^y v^y$ both make considerable progress towards t (quantified in Lemma 15).

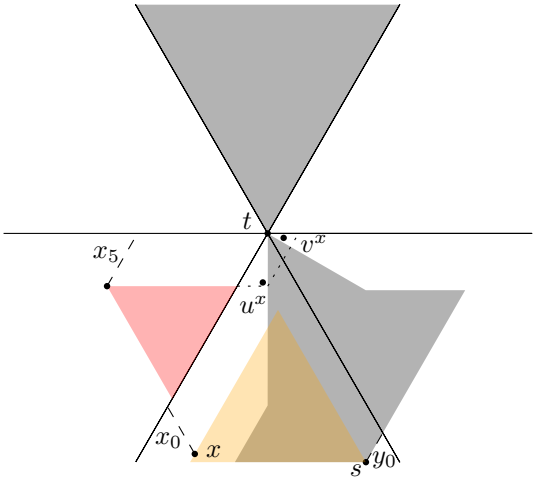

Figure 13 Claim 19: If $\pi(x,t)_{v^x}$ does not enter C_t^3, then we can form an infeasible system of linear inequalities.

Case Y0: $v^y \in C_t^0$. Then we must have $u^y \in C_t^1$. We obtain the following two inequalities:

$$||v^y t||_{\bigcirc} \leq y_1, \qquad \text{by empty region int}(\nabla_s^y). \tag{10}$$

$$||v^y t||_{\bigcirc} \leq \frac{1}{2}\min(y_2, y_3, y_4), \qquad \text{by Assumption 12 and Lemma 15.} \tag{11}$$

Case Y1: $v^y \in C_t^1$. Then we must have $u^y \in C_t^0$. We obtain

$$||v^y t||_{\bigcirc} \leq x_0, \qquad \text{by Claim 18.} \tag{12}$$

$$||v^y t||_{\bigcirc} \leq \frac{Y_0}{2}, \qquad \text{by Lemma 15.} \tag{13}$$

Similarly, $u^x v^x$ can also cross R_t^0 in one of two possible ways.

Case X0: $v^x \in C_t^0$. Then we have

$$||v^x t||_{\bigcirc} \leq y_1, \qquad \text{by Observation 16 and empty region int}(\nabla_s^y). \tag{14}$$

$$||v^x t||_{\bigcirc} \leq \frac{X_1}{2}, \qquad \text{by Lemma 15.} \tag{15}$$

Case X1: $v^x \in C_t^1$. Then $u^y \in C_t^0$. We have

$$||v^x t||_{\bigcirc} \leq x_0, \qquad \text{by Claim 18 and 17.} \tag{16}$$

$$||v^x t||_{\bigcirc} \leq \frac{1}{2}\min(x_5, x_4, x_3), \qquad \text{by Claim 19 and Lemma 15.} \tag{17}$$

Next, we will derive several useful inequalities that reflect the balance between the two candidate paths. Intuitively, if $\pi(y,t)_{v^y}$ is long, then the empty regions $C_t^i \cap C_{y^i}^{i-2}$ must be large, leaving no room for the other path $\pi(x,t)_{v^x}$. We formalize this trade-off as follows. Let j be the greatest index in $\{2,3,4,5\}$ such that $\|C_t^j \cap C_{y^j}^{j-2}\| > x_j$. For example when $j=3$, see Figure 12.

Case: No such j exists. Then by definition we must have

$$Y_{i+1} \leq \|C_t^i \cap C_{y^i}^{i-2}\| \leq x_i \quad \text{for } 2 \leq i \leq 5. \tag{18}$$

Case: $j \in \{2,3,4,5\}$. As j is maximal, then $\|C_t^i \cap C_{y^i}^{i-2}\| \leq x_i$ for $j < i \leq 5$. Next, since $\|C_t^j \cap C_{y^j}^{j-2}\| > x_j$, then we must have $\|y^k t\|_{\hexagon} > \|x^k t\|_{\hexagon}$ for $2 \leq k \leq j$. By the empty regions $C_t^i \cap C_{y^i}^{i-2}$, we must have

$$Y_{i+1} \leq \|C_t^i \cap C_{y^i}^{i-2}\| \leq x_i \quad \text{for } j < i \leq 5, \quad \text{and} \quad X_{k-1} \leq y_k \quad \text{for } 2 \leq k \leq j. \tag{19}$$

We denote the cases where $j \in \{2,3,4,5\}$ as J2, J3, J4, J5, and observe that for each case, we yield four inequalities from (19).

Under Assumptions 12 and 13 we have the following possibility space: {Y0, Y1} × {X0, X1} × {(18), J2, J3, J4, J5}. In total there are $2 \times 2 \times 5 = 20$ possibilities, and in every case, the inequalities (2), (4), (5), (6), (7) also hold. It can be shown that the linear system of inequalities is infeasible for 16 of the 20 possibilities. In the full version [5], we show that for the remaining four cases, we can define a third candidate path which is sufficiently short for a contradiction. These remaining four cases are (X1, Y1, J2), (X1, Y1, J3), (X1, Y1, J4), (X0, Y0, J3).

Abstract

An *n-Venn diagram* is a diagram in the plane consisting of n simple closed curves that intersect only finitely many times such that each of the 2^n possible intersections of their interiors is represented by a single connected region. An n-Venn diagram has at most $2^n - 2$ crossings, and if this maximum number of crossings is attained, then only two curves intersect in every crossing. To complement this, Bultena and Ruskey considered n-Venn diagrams that minimize the number of crossings, which implies that many curves intersect in every crossing. Specifically, they proved that the total number of crossings in any n-Venn diagram is at least $L_n := \lceil \frac{2^n-2}{n-1} \rceil$, and if this lower bound is attained, then essentially all n curves intersect in every crossing. Diagrams achieving this bound are called *minimum* Venn diagrams, and are known only for $n \leq 7$. Bultena and Ruskey conjectured that they exist for all $n \geq 8$. In this work, we establish an asymptotic version of their conjecture. For $n = 8$ we construct a diagram with 40 crossings, only 3 more than the lower bound $L_8 = 37$. Furthermore, for every n of the form $n = 2^k$ for some integer $k \geq 4$, we construct an n-Venn diagram with at most $(1 + \frac{33}{8n})L_n = (1 + o(1))L_n$ many crossings. Via a doubling trick this also gives $(n+m)$-Venn diagrams for all $0 \leq m < n$ with at most $40 \cdot 2^m$ crossings for $n = 8$ and at most $(1 + \frac{33}{8n})\frac{n+m}{n}L_{n+m} = (2 + o(1))L_{n+m}$ many crossings for $k \geq 4$. In particular, we obtain n-Venn diagrams with the smallest known number of crossings for all $n \geq 8$. Our constructions are based on partitions of the hypercube into isometric paths and cycles, using a result of Ramras.

1 Introduction

An *n-Venn diagram* is a collection of $n \geq 1$ simple closed curves in the plane that intersect in only finitely many points and that create exactly 2^n connected regions, one for every possible combination of being inside or outside with respect to each curve. It is easy to see that in any intersection point of at least two curves, at least two of them must cross, and thus we refer to any such intersection point as a *crossing*. A Venn diagram is *simple* if every crossing involves only two curves; see Figure 1.

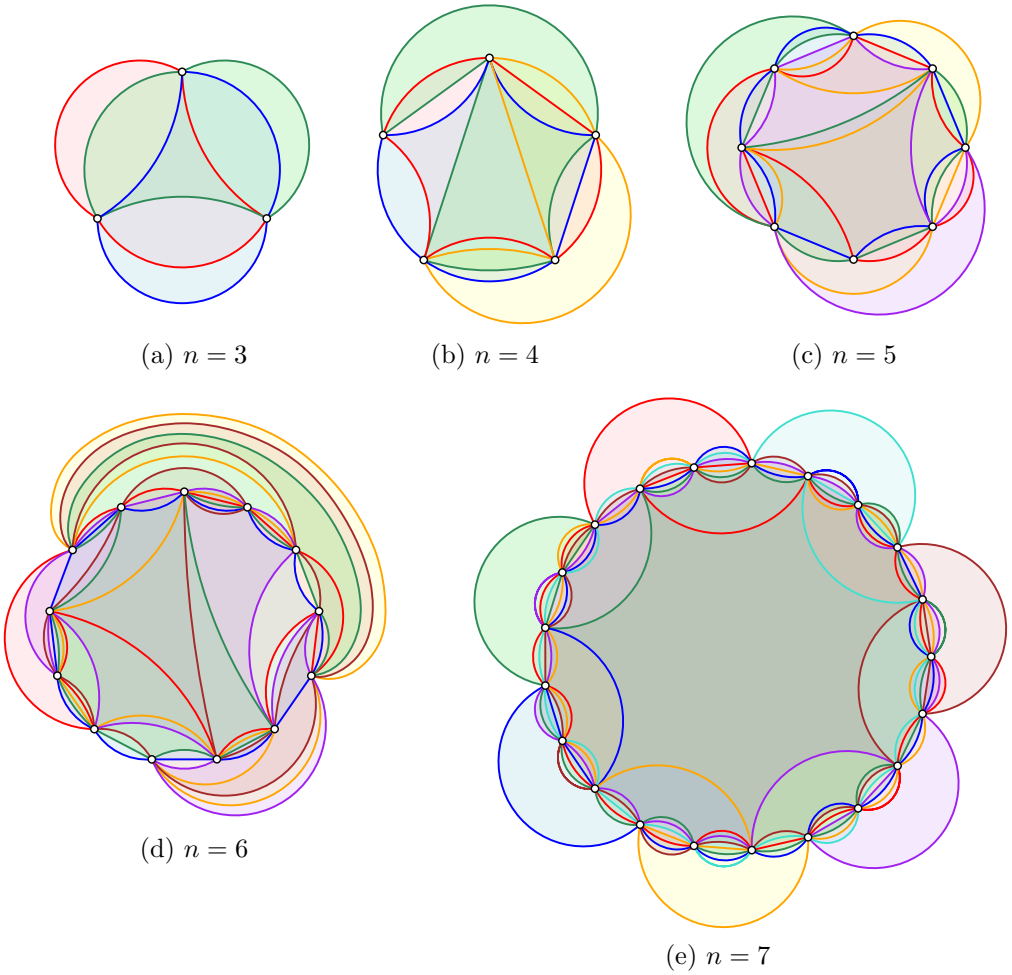
(a) $n = 3$ (b) $n = 4$ (c) $n = 5$

Figure 1 Simple Venn diagrams for $n = 3, 4, 5$, maximizing the number of crossings. For $n = 3, 4, 5$ the number of crossings $2^n - 2$ equals $6, 14, 30$. The diagrams (a)+(c) are rotationally symmetric. All diagrams are monotone and convex.

Venn diagrams are an appealing tool to visualize sets and their containment relations, and they are named after the English mathematician John Venn (1834–1923), who used them in the context of propositional logic [24]. Despite the simple definition, many questions about Venn diagrams lead to interesting and challenging mathematical and computational problems, which triggered a long and fruitful line of research devoted to them; see Ruskey and Weston's survey [19] and the many beautiful illustrations therein. These problems touch and connect various areas such as discrete geometry, graph drawing, graph theory, poset theory, coding theory, and enumerative combinatorics.



General constructions of n-Venn diagrams, valid for every $n \geq 1$, were provided already by Venn [24] and much later by Edwards [7, 8]. In fact, these two constructions are connected via the well-known binary reflected Gray code, a listing of all 2^n binary strings of length n such that any two consecutive strings differ in a single bit.

Particularly pleasing for the human eye are rotationally *symmetric* Venn diagrams, such as the ones in Figure 1 (a)+(c) and Figure 2 (a)+(e). They exist if and only if $n \geq 2$ is a prime number. The necessity of this condition was established by Henderson [13], and the sufficiency, i.e., a construction valid for all prime n was shown by Griggs, Killian and Savage [10]. Their approach builds a symmetric chain partition in the so-called necklace poset. The problem to find *simple* symmetric n-Venn diagrams is open in general. Solutions for small cases are only known for $n = 1, 3, 5, 7, 11, 13$ [16], and for general prime n a construction is known that guarantees at least half of all crossings to be simple [15].

A *k-region* in an n-Venn diagram is a region that lies inside of exactly k of the curves, and outside the remaining $n - k$ curves. A *monotone* diagram is one in which for every $0 < k < n$, every k-region is adjacent to both a $(k-1)$-region and a $(k+1)$-region. A *convex* diagram is one in which every curve is convex. It is not hard to show that convex diagrams are monotone. Bultena, Grünbaum and Ruskey [3] also proved the converse, namely that every monotone diagram is isomorphic to a convex one. Thus, the combinatorial notion of monotonicity completely captures the geometric notion of convexity.

The number of non-isomorphic simple n-Venn diagrams for $n = 1, \ldots, 6$ is $1, 1, 1, 1, 20$, $3\,430\,404$, and the number of monotone simple diagrams is $1, 1, 1, 1, 11, 32\,255$ [2, 6, 12] (OEIS A386795 and A390247, respectively).

A well-known conjecture in the area, raised by Peter Winkler [26] in 1984 and reiterated in [27, 28], was that every simple n-Venn diagram can be extended to a simple $(n+1)$-Venn diagram by adding a suitable curve. Very recently, Winkler's conjecture was disproved by Brenner, Kleist, Mütze, Rieck, and Verciani [2], who constructed counterexamples to the conjecture for all $n \geq 6$. In particular, out of the $3\,430\,404$ many 6-Venn diagrams, 72 are

(a) $n = 3$ (b) $n = 4$ (c) $n = 5$

(d) $n = 6$ (e) $n = 7$

Figure 2 Non-simple Venn diagrams for $n = 3, 4, 5, 6, 7$ that minimize the number of crossings. For those values of n, the number of crossings $L_n = \lceil \frac{2^n-2}{n-1} \rceil$ equals $3, 5, 8, 13, 21$. Only in the diagrams (a) and (e) every crossing involves all n curves. The diagrams (a) and (e) are symmetric. The diagram (a) is monotone, while (b)–(e) are not monotone. None of the diagrams is convex, though (a) can be made convex by fixing the crossings and moving the centers of the circular arcs.

not extendable to a 7-Venn diagram. Already earlier, Grünbaum [11] proposed a variant of Winkler's conjecture, by dropping the requirement for the diagrams to be simple. Grünbaum's conjecture was settled affirmatively by Chilakamarri, Hamburger and Pippert [5], using a classical theorem in graph theory of Whitney [25], later generalized by Tutte [23].

1.1 Maximizing and minimizing the number of crossings

In this work, we are particularly interested in the number of crossings in an n-Venn diagram. It is easy to see that simple n-Venn diagrams have exactly $2^n - 2$ many crossings, and this is the largest possible number of crossings among all n-Venn diagrams. To complement this, Bultena and Ruskey [4] considered Venn diagrams with the smallest possible number of crossings. They proved that any n-Venn diagram with $n \geq 2$ has at least

$$L_n := \left\lceil \frac{2^n - 2}{n - 1} \right\rceil$$

many crossings, and they called diagrams achieving this lower bound *minimum* Venn diagrams. If $(2^n - 2)/(n-1)$ is integral, which happens for $n = 2, 3, 7, 19, 43, 55, 127, 163, \ldots$ (this is OEIS sequence A014741 incremented by 1), then this means that every crossing of the diagram involves all n curves. So far, minimum Venn diagrams are only known for $n \leq 7$; see Figure 2. Bultena and Ruskey [4] conjectured that minimum n-Venn diagrams exist for all $n \geq 8$, and this is also mentioned as an open problem in Ruskey and Weston's survey [19].

As a partial result, Bultena and Ruskey [4] proved that among *monotone* n-Venn diagrams with $n \geq 2$, the smallest possible number of crossings is $\binom{n}{\lfloor n/2 \rfloor}$, and this lower bound is achievable. Note that $\binom{n}{\lfloor n/2 \rfloor} = \frac{2^n}{\sqrt{\pi n/2}}(1 + o(1))$, so this is still a $\Theta(\sqrt{n})$-factor away from the general lower bound L_n.

The problem of minimizing crossings in Venn diagrams can be seen as a variant of the well-known and heavily studied *crossing number problem* [9, 20], where one attempts to draw a graph in the plane with the goal of minimizing the number of edge crossings. Even for the complete graph K_n or the hypercube Q_n, this quantity is not known exactly.

1.2 Our results

Our first construction yields n-Venn diagrams for the case when n is a power of 2 in which the number of crossings is minimized up to a $(1 + o(1))$-factor (as $n \to \infty$).

▶ **Theorem 1.** *There is an* 8*-Venn diagram with* 40 *crossings, and for every* $k \geq 4$ *and* $n := 2^k$*, there is an* n*-Venn diagram with exactly*

$$\left(1 + \frac{33}{8n} - \frac{2}{2^{n/2}} - \frac{2n}{2^n}\right)\frac{2^n}{n} \leq \left(1 + \frac{33}{8n}\right) L_n = (1 + o(1))L_n$$

many crossings.

The 8-Venn diagram with 40 crossings is shown in Figure 3.

For a general number of curves, i.e., when n is not necessarily a power of 2, we apply a doubling construction to obtain an n-Venn diagram in which the number of crossings is minimized up to a $(2 + o(1))$-factor.

▶ **Theorem 2.** *For every* $0 \leq m \leq 7$ *there is an* $(8+m)$*-Venn diagram with* $40 \cdot 2^m$ *crossings, and for every* $k \geq 4$*,* $n := 2^k$ *and* $0 \leq m < n$*, there is an* $(n+m)$*-Venn diagram with exactly*

$$\left(1 + \frac{33}{8n} - \frac{2}{2^{n/2}} - \frac{2n}{2^n}\right)\frac{2^{n+m}}{n} \leq \left(1 + \frac{33}{8n}\right)\frac{n+m}{n} L_{n+m} \leq (2 + o(1))L_{n+m}$$

many crossings.

Figure 4 shows the approximation ratio guaranteed by Theorem 2 for all $8 \leq n + m \leq 255$.

In particular, Theorem 2 gives n-Venn diagrams with the smallest known number of crossings for all $n \geq 8$; see Table 1.

1.3 Duals of Venn diagrams

Venn diagrams are conveniently studied by considering their dual graph; see Figure 5. Specifically, we consider the *n-dimensional hypercube Q_n*, or *n-cube* for short, the graph formed by all subsets of $[n] := \{1, 2, \ldots, n\}$, with an edge between any two sets that differ in a single element. For an edge $e = \{x, x \cup \{i\}\}$ of Q_n, we refer to i as its *direction*.

n	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
lower bound $L_n = \lceil \frac{2^n-2}{n-1} \rceil$ [4]	0	2	3	5	8	13	21	37	64	114	205	373	683	1261	2341	4369
Figure 2	0	2	3	5	8	13	21									
Theorem 2								40	80	160	320	640	1280	2560	5120	5118
monotone $\binom{n}{\lfloor n/2 \rfloor}$ [4]	0	2	3	6	10	20	35	70	126	252	462	924	1716	3432	6435	12870

The dual graph $Q(D)$ of an n-Venn diagram D satisfies the following properties:

(1) It is a spanning subgraph of Q_n, i.e., all 2^n vertices are present. Specifically, the vertex in $Q(D)$ corresponding to a region of the diagram D is the set of all indices of curves that contain this region in their interior.

(2) It is a plane graph, i.e., it is drawn in the plane without edge crossings, such that each face has even length 2ℓ for some integer $2 \leq \ell \leq n$ and contains exactly two edges of ℓ distinct directions. These ℓ directions correspond to the ℓ curves intersecting in the crossing corresponding to the face.

(3) For every $j \in [n]$, the two subgraphs of $Q(D)$ induced by all vertices x with $j \in x$, and with $j \notin x$, respectively, are connected. This corresponds to the jth curve being simple.

Conversely, the dual of any subgraph of Q_n satisfying these properties is an n-Venn diagram.

Clearly, the number of crossings of the diagram D equals the number of faces of the dual graph $Q(D)$. If D is a minimum n-Venn diagram, then almost all crossings involve all n curves, i.e., in the dual graph $Q(D)$, almost all faces have length $2n$.

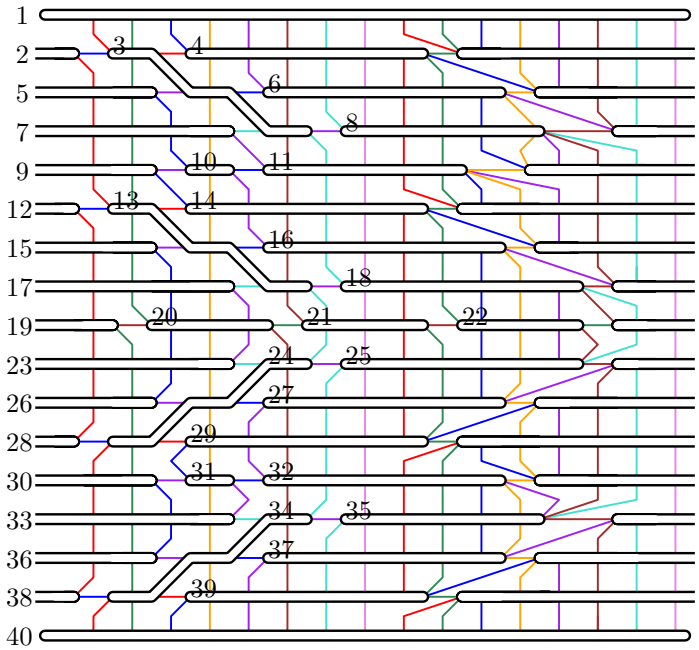

Figure 3 An 8-Venn diagram with 40 crossings obtained from Theorem 1. The 8 curves are drawn with colors. Each black/white bubble represents one crossing that has to be contracted to a single point, where the open bubbles at the left and right boundary wrap around at the bottom.

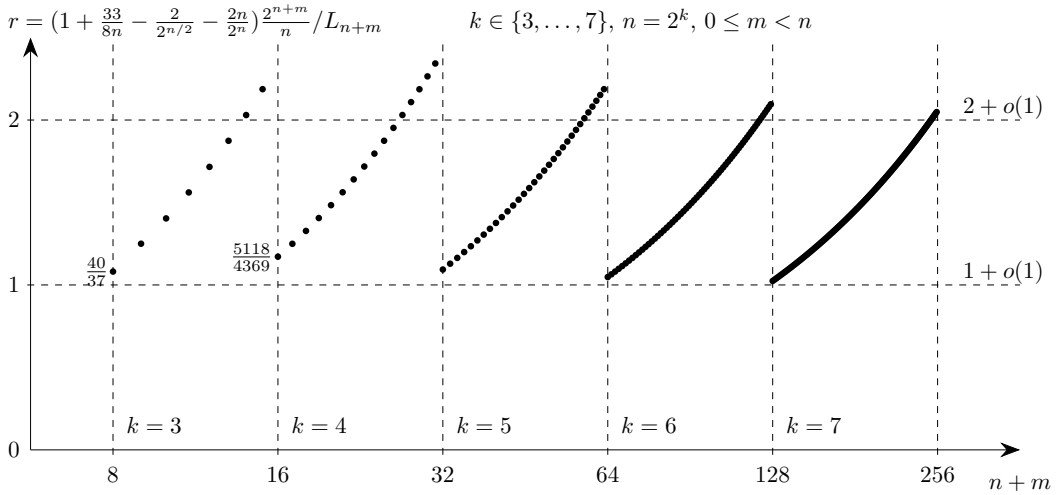

Figure 4 Log-linear plot of the ratio r of the number of crossings of the Venn diagrams obtained from Theorem 2 and the lower bound.

1.4 Proof ideas

Our proofs of Theorems 1 and 2 are constructive, and we proceed to give an informal sketch of the main steps of these constructions.

Using the characterization presented in the previous section, we build n-Venn diagrams by constructing planar spanning subgraphs of the hypercube Q_n satisfying conditions ①–③, with the goal of minimizing the number of faces.

For $n = 2^k$ we start with a partition of Q_n into isometric cycles of length $2n$ that is derived from a partition of Q_{n-1} into isometric paths found by Ramras [18]. These cycles are translates of a single isometric cycle of length $2n$ by a certain linear subspace of $\mathbb{Z}_2^n$ of dimension $d := 2^k - k - 1$. For our construction we choose a slightly different basis of this space, denoted by C_k, than originally used by Ramras.

In the first step of the construction, we embed the isometric cycles of the partition into the plane concentrically in an order that is specified by a certain Hamiltonian path R of Q_d (see Figure 9). Each vertex of Q_d represents coefficients of a linear combination of the basis C_k, so consecutive concentric cycles in this order differ only by one element of the basis C_k. This guarantees that there are edges between consecutive cycles that create mainly large faces, but also some 6-faces. These edges between pairs of consecutive cycles are added in the second step.

In the last step, some cycle edges shared by 6-faces are removed to further reduce the total number of faces. For this purpose we specify a Hamiltonian path R that contains long runs in its flip sequence. A *run* is a contiguous increasing or decreasing subsequence with increment or decrement 1, respectively. Interestingly, our construction of such long-run Hamiltonian cycles uses the same partition into isometric cycles as the aforementioned Venn diagram construction.

For values of n that are not powers of 2, we use a straightforward doubling construction (see Lemma 10) to derive n-Venn diagrams with relatively few crossings from the ones of the next smaller power of 2 constructed as described before. This is why the number of crossings increasingly deviates from the lower bound L_n the farther the distance from the next smaller power of 2 gets, until the next larger power of 2 resets the process, which explains the behavior seen in Figure 4.

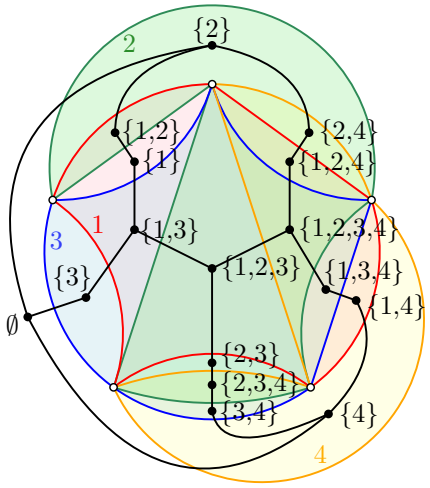

Figure 5 The dual of the 4-Venn diagram from Figure 2 (b) is a spanning subgraph of the 4-cube.

2 Isometric partitions of hypercubes

2.1 Preliminaries

Recall that $[n] = \{1, 2, \ldots, n\}$. We also define $2^{[n]} := \{x \mid x \subseteq [n]\}$. For $x \subseteq [n]$ we write $\overline{x} := [n] \setminus x$ for the complement of x w.r.t. the ground set $[n]$. Given a vertex x of Q_n, we refer to $\overline{x}$ as the *antipodal* vertex of x. For $x \subseteq [n]$ and an integer $k \geq 1$ we define $k \cdot x := \{ki \mid i \in x\}$. All these operations thread in the natural way over sets and sequences. For example, for a set $X \subseteq 2^{[n]}$ and an integer $k \geq 1$ we have $k \cdot X = \{k \cdot x \mid x \in X\}$.

For $x, y \subseteq [n]$ we define the symmetric difference as $x \oplus y := (x \setminus y) \cup (y \setminus x)$. For any set $X \subseteq 2^{[n]}$ we define the *span* of X by $\langle X \rangle := \{x_1 \oplus x_2 \oplus \cdots \oplus x_t \mid t \in \{0, \ldots, n\}$ and $x_i \in X$ for all $i \in [t]\}$.

We refer to an edge $e = \{x, x \oplus \{i\}\}$ of direction i in Q_n as an *i-edge*. The *flip sequence* of a path or cycle P in Q_n, denoted by $\sigma(P)$, is the sequence of directions of edges along P. We write $|\sigma(P)|$ for the length of this sequence. For example, the flip sequence of the path $P = (\{1,2\}, \{1,2,3\}, \{1,3\}, \{3\}, \{2,3\})$ in Q_3 is $\sigma(P) = (3, 2, 1, 2)$ and we have $|\sigma(P)| = 4$.

A subgraph H of a graph G is *isometric* if it preserves distances, i.e., $d_H(u, v) = d_G(u, v)$ for any two vertices $u, v \in V(H)$. In particular, a path in the hypercube Q_n is isometric if and only if it contains no two edges of the same direction. A cycle in Q_n is isometric if and only if the edges of the same direction come in pairs that lie oppositely on the cycle.

2.2 Partition into isometric paths

Ramras [18] described a partition of the hypercube Q_{n-1}, for $n = 2^k$ and $k \geq 1$, into isometric paths. For this we consider the sequence of sets $(B_k)_{k \geq 1}$ defined recursively by $B_1 := \emptyset$ and

$$B_k := B_{k-1} \cup \{\{1, 2^{k-1} + 1\}, \{2, 2^{k-1} + 2\}, \ldots, \{2^{k-1} - 1, 2^k - 1\}\} \text{ for } k \geq 2. \tag{1}$$

According to this definition, the first few sets are

$$B_1 = \emptyset, \qquad B_2 = \{\{1,3\}\}, \qquad B_3 = \{\{1,3\}, \{1,5\}, \{2,6\}, \{3,7\}\},$$
$$B_4 = \{\{1,3\}, \{1,5\}, \{2,6\}, \{3,7\}, \{1,9\}, \{2,10\}, \{3,11\}, \{4,12\}, \{5,13\}, \{6,14\}, \{7,15\}\}.$$

The sets in B_k, viewed as binary (characteristic) vectors, are linearly independent and hence they form the basis of a linear subspace $\langle B_k \rangle$ of dimension $|B_k| = 2^k - k - 1$ of the space $\mathbb{Z}_2^n$. For any $x \in \langle B_k \rangle$, Ramras [18] defines a path $P(x)$ of length $n-1$ in Q_{n-1} by

$$P(x) := (x, x \oplus \{1\}, x \oplus \{1,2\}, \ldots, x \oplus \{1,2,\ldots,n-1\}). \tag{2}$$

The flip sequence along this path is $\sigma(P) = (1, 2, \ldots, n-1)$, and the end vertices of $P(x)$ are antipodal in Q_{n-1}, i.e., the last vertex $x \oplus \{1,2,\ldots,n-1\}$ is the complement of the first vertex x w.r.t. the ground set $[n-1]$. The following theorem is illustrated on the left hand side of Figure 6.

▶ **Theorem 3** ([18, Thm. 2.5]). *For any $k \geq 1$ and $n := 2^k$, the isometric paths $P(x)$ of length $n-1$ defined in (2) for all $x \in \langle B_k \rangle$ form a partition of the vertex set of Q_{n-1}.*

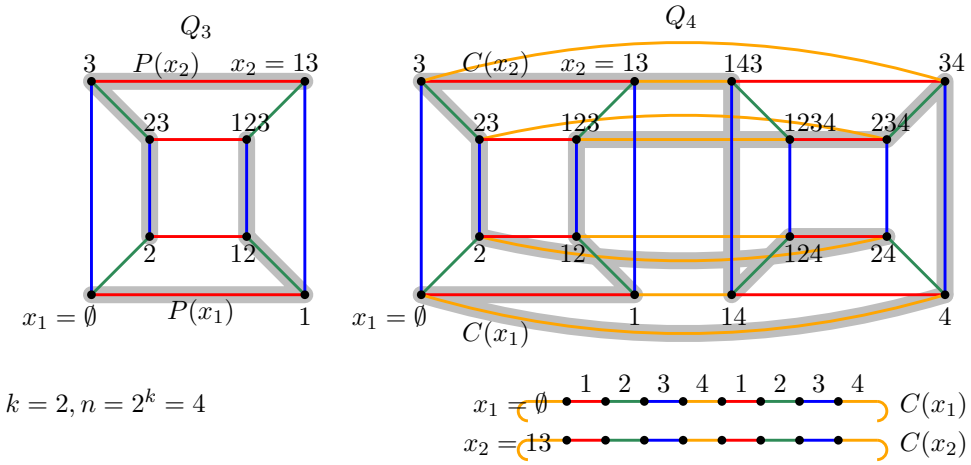

Figure 6 Illustration of Theorem 3 (left) and Corollary 5 (right) for the case $k = 2$. The bottom right shows a schematic illustration of the cycles showing only the starting vertices on the left and the flip sequences along each cycle.

2.3 Finding another basis for $\langle B_k \rangle$

For our purposes, we choose a different basis of the subspace $\langle B_k \rangle$, namely one that contains a larger number of 2-sets $\{a, b\}$ with $|b - a| = 2$. We define

$$\begin{aligned} &C_1 := O_1 := \emptyset, \\ &O_k := \{\{1,3\}, \{3,5\}, \ldots, \{2^k-3, 2^k-1\}\} \text{ for } k \geq 2, \text{ and} \\ &C_k := O_k \cup 2C_{k-1} \text{ for } k \geq 2. \end{aligned} \tag{3}$$

According to this definition, the first few sets are

$$\begin{aligned} &O_1 = \emptyset, \quad O_2 = \{\{1,3\}\}, \quad O_3 = \{\{1,3\}, \{3,5\}, \{5,7\}\}, \\ &O_4 = \{\{1,3\}, \{3,5\}, \{5,7\}, \{7,9\}, \{9,11\}, \{11,13\}, \{13,15\}\}, \end{aligned}$$

and

$$\begin{aligned} &C_1 = \emptyset, \quad C_2 = \{\{1,3\}\}, \quad C_3 = \{\{1,3\}, \{3,5\}, \{5,7\}, \{2,6\}\}, \\ &C_4 = \{\{1,3\}, \{3,5\}, \{5,7\}, \{7,9\}, \{9,11\}, \{11,13\}, \{13,15\}, \{2,6\}, \{6,10\}, \{10,14\}, \{4,12\}\}. \end{aligned}$$

Note that $|b-a| = 2$ for every $\{a,b\} \in O_k$ and furthermore, $|O_k| = 2^{k-1}-1$ and $|C_k| = 2^k - k - 1$.

▶ **Lemma 4.** *The sets B_k and C_k defined in (1) and (3), respectively, satisfy $\langle B_k \rangle = \langle C_k \rangle$ for any $k \geq 1$.*

The proof of Lemma 4 can be found in the preprint [1].

2.4 Partition into isometric cycles

From Theorem 3 it follows that for $n = 2^k$

$$C(x) := (P(x), \overline{P(x)} \cup \{n\}) \tag{4}$$

is an isometric cycle of length $2n$ in Q_n, with flip sequence $\sigma(C(x)) = (1,2,\ldots,n,1,2,\ldots,n)$, and furthermore, the cycles $C(x)$ for all $x \in \langle B_k \rangle$ form a partition of the vertex set of Q_n. Combining this with Lemma 4 we obtain the following isometric partition into cycles, which is the starting point of our constructions later on; see the right hand side of Figure 6.

▶ **Corollary 5.** *For any $k \geq 1$ and $n := 2^k$, the isometric cycles $C(x)$ of length $2n$ defined in (4) for all $x \in \langle C_k \rangle$ form a partition of the vertex set of Q_n.*

The following lemma describes the edges between the cycles $C(x)$, and it is illustrated in Figure 7. The proof is elementary, and we omit it.

▶ **Lemma 6.** *Let $k \geq 2$ and $n := 2^k$, and let $x, y \in \langle C_k \rangle$ be such that $y = x \oplus \{a,b\}$ with $a < b$. Then the cycles $C(x)$ and $C(y)$ have the following edges between them in Q_n:*

- **(i)** *From the start/end vertex of each of the two a-edges of $C(x)$, there is a b-edge to the end/start vertex of the corresponding a-edge of $C(y)$.*
- **(ii)** *From the start/end vertex of each of the two b-edges of $C(x)$, there is an a-edge to the end/start vertex of the corresponding b-edge of $C(y)$.*

If $b = a+2$, then in addition the following edges are present:

- **(iii)** *From the start/end vertex of each of the two a-/$(a+2)$-edges of $C(x)$, there is an $(a+1)$-edge to the end/start vertex of the corresponding $(a+2)$-/a-edge of $C(y)$.*

For $b > a+2$ we write $E(x,\{a,b\})$ for the set of four edges shown in Figure 7 (a1). Furthermore, for $b = a+2$ we write $E_{\diagdown}(x,a)$ and $E_{\diagup}(x,a)$ for the two sets of three edges shown in parts (b1) and (b2) of the figure, respectively. Lastly, we write $F(x,\{a,b\})$ for the 4-cycle shown in part (a2) of the figure.

3 Long-run Gray code construction

Given a path or cycle P in Q_n and integer $\rho \in [n]$, an *increasing* or *decreasing ρ-run* in its flip sequence $\sigma(P)$ is a contiguous subsequence $(a, a+1, a+2, \ldots, a+\ell)$ or $(a+\ell, a+\ell-1, \ldots, a+1, a)$ such that $a+\ell \leq \rho$. In words, it is a sequence of values that are increasing or decreasing (with increment 1 or decrement 1, respectively) such that all flipped directions are at most ρ. The parameter $\ell \geq 0$, which is one less than the length of the subsequence, is called the *length* of the run.

A ρ-run is *maximal* if it cannot be extended, i.e., if it is not contained in another ρ-run. Note that two maximal ρ-runs may overlap in at most one element, namely the last element of an increasing run and the first element of a decreasing run, or vice versa. Furthermore, note that a maximal ρ-run of length 0 does not overlap with any other ρ-runs, and a maximal ρ-run

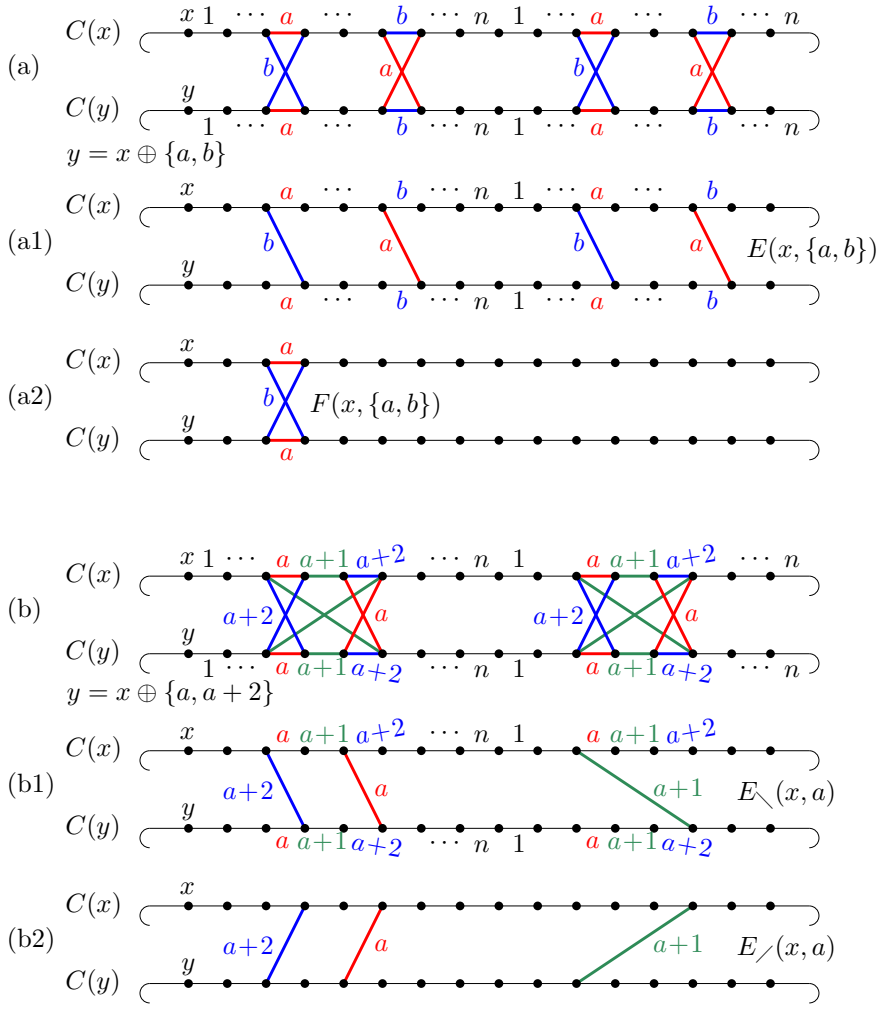

Figure 7 Illustration of Lemma 6 and definitions of the edge sets $E(x, \{a, b\})$, $F(x, \{a, b\})$, $E_{\diagdown}(x, a)$, and $E_{\diagup}(x, a)$.

of length 1 does not overlap with two other ρ-runs in the first and last element, as this would create a flip sequence $a+1, a, a+1, a$ or $a, a+1, a, a+1$, i.e., a 4-cycle, which is impossible. A *ρ-run partition* of $\sigma(P)$ is obtained by considering all maximal ρ-runs in $\sigma(P)$, and removing, from every pair of consecutive overlapping runs, the element in which they overlap from one of the two runs. For example, the flip sequence $\sigma(P) = (3, 1, 2, 3, 2, 1, 2, 4, 3, 2, 4)$ has the maximal 3-runs $(\overline{3}, 1, 2, \overline{3}, 2, \overline{1, 2}, \not{4}, \underline{3, 2}, \not{4})$, where increasing and decreasing runs are marked by overbrackets and underbrackets, respectively, and the cancelled elements are not contained in any 3-run. Thus we obtain $(\boxed{3}, \boxed{1, 2}, \boxed{3, 2, 1}, \boxed{2}, \not{4}, \boxed{3, 2}, \not{4})$ as a 3-run partition of $\sigma(P)$, where the boxes indicate the runs. Similarly, $(\boxed{3}, \boxed{1, 2, 3}, \boxed{2, 1}, \boxed{2}, \not{4}, \boxed{3, 2}, \not{4})$, $(\boxed{3}, \boxed{1, 2}, \boxed{3, 2}, \boxed{1, 2}, \not{4}, \boxed{3, 2}, \not{4})$ and $(\boxed{3}, \boxed{1, 2, 3}, \boxed{2}, \boxed{1, 2}, \not{4}, \boxed{3, 2}, \not{4})$ are also valid 3-run partitions.

Although there may be different ρ-run partitions, their number and total length, i.e., sum of lengths of all runs, is the same, and we denote these quantities by $\nu_\rho(P)$ and $\lambda_\rho(P)$. Note that the number of entries of $\sigma(P)$ exceeding ρ equals $|\sigma(P)| - \nu_\rho(P) - \lambda_\rho(P)$. In the example from before we have $\nu_3(P) = 5$ and $\lambda_3(P) = 4$.

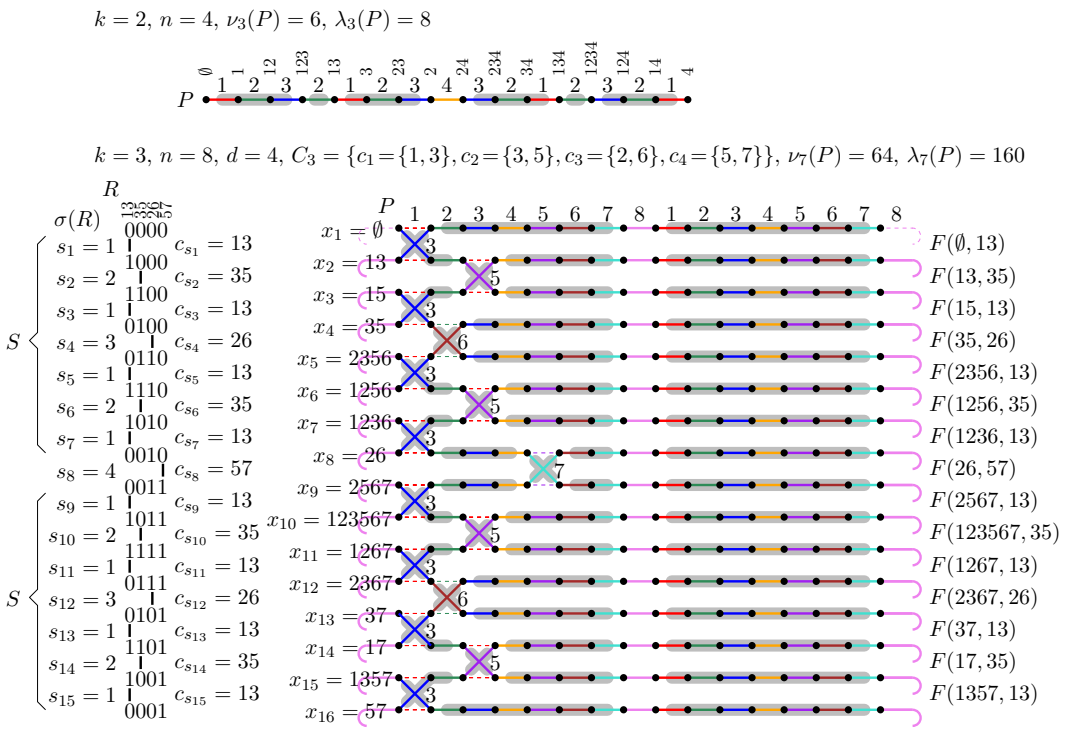

Figure 8 Illustration of the proof of Lemma 7. The edges that are removed while taking the symmetric difference are dashed, including the wrap-around edge of the first cycle. The subsequences highlighted in gray are $(n-1)$-runs.

Our first aim is to find a Hamiltonian path P in the hypercube Q_n for $n = 2^k$ for which the quantity $\nu_{n-1}(P) + 2\lambda_{n-1}(P)$ is as large as possible, i.e., we want to maximize the number of flipped directions contained in long $(n-1)$-runs. We shall see that maximizing this quantity corresponds to minimizing the number of crossings in the Venn diagrams constructed in the next section (see Lemma 9).

▶ **Lemma 7.** *Let $k \geq 2$ and $n := 2^k$. There is a Hamiltonian path P in Q_n that satisfies*

$$\nu_{n-1}(P) = \begin{cases} 6 & \text{if } k = 2, \\ \frac{17}{8} \cdot \frac{2^n}{n} - 4 & \text{if } k \geq 3, \end{cases} \quad \text{and } \lambda_{n-1}(P) = \begin{cases} 8 & \text{if } k = 2, \\ 2^n - \frac{25}{8} \cdot \frac{2^n}{n} + 4 & \text{if } k \geq 3. \end{cases}$$

Proof. For $k = 2$ we take the Hamiltonian path P with $\sigma(P) = (\boxed{1,2,3}, \boxed{2}, \boxed{1,2,3}, \boxed{4}, \boxed{3,2,1}, \boxed{2}, \boxed{3,2,1})$, proving that $\nu_3(P) = 6$ and $\lambda_3(P) = 8$; see the top part of Figure 8.

For $k \geq 3$ we construct a Hamiltonian path P in Q_n as follows; see the bottom part of Figure 8. We start with the partition of Q_n into cycles given by Corollary 5. Formally, we define the cycle factor $\mathcal{C} := \bigcup_{x \in \langle C_k \rangle} C(x)$. Each of the cycles of $\mathcal{C}$ has length $2n$ and the total number of cycles is $2^n/(2n) = 2^{2^k}/2^{k+1} = 2^{2^k-k-1} = 2^d$ for $d := 2^k - k - 1$. Recall that $|C_k| = 2^k - k - 1 = d$.

Let $(c_1, \ldots, c_d)$ be a sequence obtained by sorting all elements of the set C_k such that $c_1 = \{1,3\}, c_2 = \{3,5\}, c_3 = \{2,6\}$, and the remaining elements appear in arbitrary order. We take a Hamiltonian path R in Q_d whose flip sequence $\sigma(R) =: (s_1, \ldots, s_{2^d-1})$ alternates copies of the subsequence $S := (1,2,1,3,1,2,1)$ with single flips $s_{8i} \geq 4$ for $i \geq 1$, starting with S, i.e., $\sigma(R) = (S, s_8, S, s_{16}, S, s_{24}, \ldots, S, s_{2^d-8}, S)$. For example, we may take for R the

well-known binary reflected Gray code in Q_d. Note that $\sigma(R)$ contains exactly 2^{d-3} copies of S. We define an ordering $x_1, \dots, x_{2^d}$ of all elements of $\langle C_k \rangle$ recursively by $x_1 \coloneqq \emptyset$ and $x_{i+1} \coloneqq x_i \oplus c_{s_i}$ for $i = 1, \dots, 2^d - 1$. Note that this definition is valid since each element of $\langle C_k \rangle$ is a linear combination of the basis C_k, and R visits all d-tuples of $\{0,1\}$-coefficients.

Consider the symmetric difference of the edge sets of the cycle factor $\mathcal{C}$ with all 4-cycles $F(x_i, c_{s_i})$ for $i = 1, \dots, 2^d - 1$. Each of the 4-cycles has a pair of opposite edges in common with two consecutive cycles from the factor, and thus glues them together to a single cycle. Therefore, the resulting set of edges is a Hamiltonian cycle in Q_n. Removing one of its n-edges gives a Hamiltonian path P in Q_n. Note that the 4-cycles $F(x_i, c_{s_i})$ and $F(x_{i+1}, c_{s_{i+1}})$ are edge-disjoint for $i = 1, \dots, 2^d - 2$.

In the remainder of the proof we compute the quantities $\nu_{n-1}(P)$ and $\lambda_{n-1}(P)$. Recall from (2) and (4) that for each cycle $C(x_i)$, $i = 1, \dots, 2^d$, the flip sequence is $\sigma(C(x_i)) = (1, 2, \dots, n, 1, 2, \dots, n)$, i.e., it has two maximal $(n-1)$-runs of length $n-2$ each. Observe from Figure 8 that when gluing together the eight cycles $C(x_i)$ for which $s_i \in \{1,2,3\}$ belongs to a copy of S in $\sigma(R)$, the flip sequence of the resulting cycle has the $(n-1)$-run partition

$$\big(\boxed{3,2},\boxed{5},\boxed{4,\dots,n-1},\not{n},\boxed{1,\dots,n-1},\not{n},$$
$$\boxed{3},\boxed{6},\boxed{3,\dots,n-1},\not{n},\boxed{1,\dots,n-1},\not{n},$$
$$\boxed{3,2},\boxed{5},\boxed{4,\dots,n-1},\not{n},\boxed{1,\dots,n-1},\not{n},$$
$$\boxed{3},\boxed{2,\dots,n-1},\not{n},\boxed{1,\dots,n-1},\not{n},$$
$$\boxed{3,2},\boxed{5},\boxed{4,\dots,n-1},\not{n},\boxed{1,\dots,n-1},\not{n},$$
$$\boxed{3},\boxed{6},\boxed{3,\dots,n-1},\not{n},\boxed{1,\dots,n-1},\not{n},$$
$$\boxed{3,2},\boxed{5},\boxed{4,\dots,n-1},\not{n},\boxed{1,\dots,n-1},\not{n},$$
$$\boxed{3},\boxed{2,\dots,n-1},\not{n},\boxed{1,\dots,n-1},\not{n}\big),$$

consisting of 30 runs of total length $16n - 46$.

When taking the symmetric difference with the $2^{d-3} - 1$ remaining 4-cycles $F(x_i, c_{s_i})$ with $s_i \geq 4$, then inserting each such 4-cycle splits two runs $\boxed{2,\dots,n-1}$ into two times two runs $\boxed{2,\dots,a-1}$, $\boxed{a+1,\dots,n-1}$ and two trivial runs $\boxed{b}$, where $\{a,b\} \coloneqq c_{s_i}$ such that $a < b$, i.e., the number of runs increases by 4 and the total length decreases by 4.

Lastly, note that removing one n-edge from the resulting Hamiltonian cycle to break it into the Hamiltonian path P does not change any $(n-1)$-runs.

Combining these observations, we obtain

$$\nu_{n-1}(P) = 30 \cdot 2^{d-3} + 4 \cdot (2^{d-3} - 1) = \frac{17}{8} \cdot \frac{2^n}{n} - 4 \quad \text{and}$$
$$\lambda_{n-1}(P) = (16n - 46) \cdot 2^{d-3} - 4 \cdot (2^{d-3} - 1) = 2^n - \frac{25}{8} \cdot \frac{2^n}{n} + 4,$$

where we used the relation $2^d = \frac{2^n}{2n}$. ◀

For a general dimension that is not necessarily a power of 2 we generalize the result from before by applying a straightforward product construction.

▶ **Corollary 8.** *Let $k \geq 2$, $n \coloneqq 2^k$, and $0 \leq m < n$. There is a Hamiltonian path P in Q_{n+m} that satisfies*

$$\nu_{n-1}(P) = \begin{cases} 6 \cdot 2^m & \text{if } k = 2, \\ 2^m\big(\frac{17}{8} \cdot \frac{2^n}{n} - 4\big) & \text{if } k \geq 3, \end{cases} \text{ and } \lambda_{n-1}(P) = \begin{cases} 8 \cdot 2^m & \text{if } k = 2, \\ 2^m\big(2^n - \frac{25}{8} \cdot \frac{2^n}{n} + 4\big) & \text{if } k \geq 3. \end{cases}$$

Proof. We use the fact that Q_{n+m} is isomorphic to the Cartesian product $Q_n \,\square\, Q_m$. Consequently, if P is a Hamiltonian path in Q_n and R is a Hamiltonian path in Q_m with flip sequence $\sigma(R) =: (s_1, \dots, s_{2^m-1})$, then Q_{n+m} has a Hamiltonian path P' with flip sequence

$$\sigma(P') = \big(\sigma(P), s_1+n, \mathrm{rev}(\sigma(P)), s_2+n, \sigma(P), \dots, s_{2^m-2}+n, \sigma(P), s_{2^m-1}+n, \mathrm{rev}(\sigma(P))\big),$$

where $\mathrm{rev}(\sigma(P))$ denotes the reverse of the sequence $\sigma(P)$. By taking the Hamiltonian path P in Q_n given by Lemma 7 and any Hamiltonian path R in Q_m, the lemma follows. ◀

Note that as $n \to \infty$, we have $\lambda_{n-1}(P) = (1-o(1))2^{n+m}$, i.e., almost all flips along the Hamiltonian path P belong to an $(n-1)$-run.

4 Proof of Theorem 1

In this section, we describe our constructions of almost-minimum n-Venn diagrams for the case where n is a power of 2, thus proving Theorem 1.

▶ **Lemma 9.** *Let $k \geq 3$, $n := 2^k$, $d := 2^k - k - 1$, and $\rho := 2^{k-1} - 1 = n/2 - 1$, and let P be a Hamiltonian path in Q_d. Then there is an n-Venn diagram with exactly $2 \cdot \frac{2^n}{n} - \nu_\rho(P) - 2\lambda_\rho(P) - 2$ many crossings.*

Proof. To prove the lemma, we construct a plane subgraph $H \subseteq Q_n$ satisfying properties ①–③ stated in Section 1.3 that has exactly $2 \cdot \frac{2^n}{n} - \nu_\rho(P) - 2\lambda_\rho(P) - 2$ many faces, as follows. We start with the partition of Q_n into cycles given by Corollary 5. Formally, we define the cycle factor $\mathcal{C} := \bigcup_{x \in \langle C_k \rangle} C(x)$. Each of the cycles of $\mathcal{C}$ has length $2n$ and the total number of cycles is $2^n/(2n) = 2^{2^k}/2^{k+1} = 2^{2^k-k-1} = 2^d$. Recall that $|C_k| = 2^k - k - 1 = d$.

Let $c = (c_1, \dots, c_d)$ be a sequence obtained by sorting all elements of the set C_k such that all 2-sets from $O_k \subseteq C_k$ appear first and with increasing minimum values, and the remaining 2-sets appear afterwards in arbitrary order. That is, we choose the first ρ elements as $(c_1, \dots, c_\rho) = (\{1,3\}, \{3,5\}, \dots, \{2^k-3, 2^k-1\})$, which is the order from (3), or equivalently, $c_i = \{2i-1, 2i+1\}$ for $1 \leq i \leq \rho$. Recall that $|O_k| = 2^{k-1} - 1 = \rho \leq d$.

We consider the flip sequence $\sigma(P) =: (s_1, \dots, s_{2^d-1})$ of the given Hamiltonian path P in Q_d. The ρ-runs in this sequence will be particularly relevant for our construction. We define an ordering $x_1, \dots, x_{2^d}$ of all elements of $\langle C_k \rangle$ recursively by $x_1 := \emptyset$ and $x_{i+1} := x_i \oplus c_{s_i}$ for $i = 1, \dots, 2^d - 1$. Note that this definition is valid since each element of $\langle C_k \rangle$ is a linear combination of the basis C_k, and P visits all d-tuples of $\{0,1\}$-coefficients.

To construct H, we first embed the cycles of the factor $\mathcal{C}$ in the plane by nesting them concentrically according to this ordering, i.e., $C(x_1)$ is the outermost cycle, and for $i = 1, \dots, 2^d - 1$, the cycle $C(x_{i+1})$ is nested concentrically inside $C(x_i)$.

Next, we add edges between every pair of consecutive cycles $C(x_i)$ and $C(x_{i+1})$ for $i = 1, \dots, 2^d - 1$ according to the following rules; see Figure 9. We first fix a ρ-run partition of P throughout, so whenever we refer to a ρ-run in the following, we mean a run in this fixed partition. If $s_i \leq \rho$, then we have $c_{s_i} = \{a, a+2\}$ for $a := 2s_i - 1$. If the entry s_i of $\sigma(P)$ is contained in an increasing ρ-run, then we add the three edges of $E_\diagdown(x_i, a)$, and if it is contained in a decreasing ρ-run, then we add the three edges of $E_\diagup(x_i, a)$ instead. If the run has length 0, i.e., it consists only of a single entry, we treat it as one of the two cases, say, increasing. On the other hand, if $s_i > \rho$, then we add the four edges of $E(x_i, c_{s_i})$.

In this way, we obtain an intermediate connected plane graph with $C(x_1)$ as the outer face and $C(x_{2^d})$ as the innermost face that has either 3 or 4 faces between cycles $C(x_i)$ and $C(x_{i+1})$ for $i = 1, \dots, 2^d - 1$, namely if $s_i \leq \rho$ or $s_i > \rho$ holds, respectively. Since the

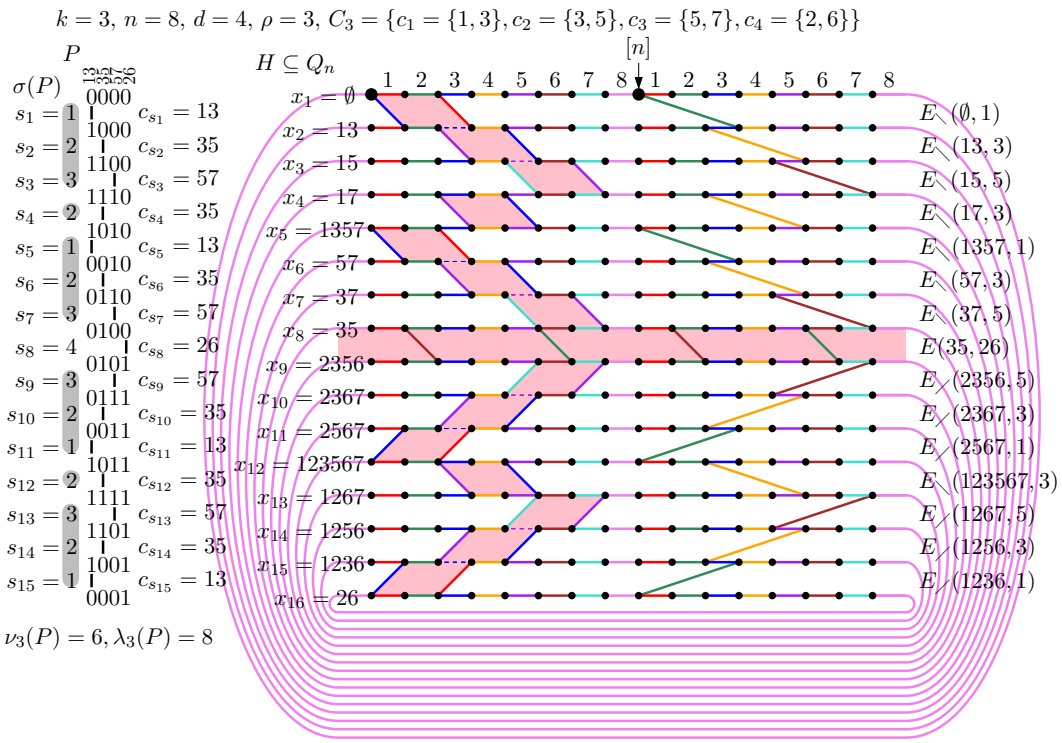

Figure 9 Illustration of the proof of Lemma 9 for the case $k = 3$, i.e., $n = 8$. The dashed edges are deleted, so they are not part of H. The constructed dual graph H of an 8-Venn diagram has 40 faces, i.e., the corresponding Venn diagram has 40 crossings; see Figure 3, only 3 more than the lower bound $L_8 = 37$. All faces except the red ones have maximum possible length $2n$.

number of entries s_i in $\sigma(P)$ with $s_i \le \rho$ is exactly $\nu_\rho(P) + \lambda_\rho(P)$, the number of faces of the intermediate graph is exactly

$$2 + 4(2^d - 1) - (\nu_\rho(P) + \lambda_\rho(P)) = 2 \cdot \frac{2^n}{n} - \nu_\rho(P) - \lambda_\rho(P) - 2.$$

In the last step of constructing H, we remove edges from some of the cycles $C(x_i)$, $i = 2, \dots, 2^d - 1$, according to the following rules: If s_{i-1} and s_i belong to the same increasing ρ-run in $\sigma(P)$, then we have $c_{s_{i-1}} = \{a-2, a\}$ and $c_{s_i} = \{a, a+2\}$ for $a := 2s_i - 1$, and then we remove the first a-edge of $C(x_i)$. If s_{i-1} and s_i belong to the same decreasing ρ-run in $\sigma(P)$, then we have $c_{s_{i-1}} = \{a, a+2\}$ and $c_{s_i} = \{a-2, a\}$ for $a := 2s_i + 1$, and then we remove the first a-edge of $C(x_i)$. This completes the description of how to construct the subgraph H of Q_n.

Note that each removed edge decreases the number of faces by 1. Since the number of removed edges is exactly $\lambda_\rho(P)$, the number of faces of H is exactly

$$2 \cdot \frac{2^n}{n} - \nu_\rho(P) - 2\lambda_\rho(P) - 2,$$

as claimed. It remains to check that the graph $H \subseteq Q_n$ just defined satisfies conditions ①–③.

Condition ① holds since the cycles $C(x_i)$ for $i = 1, \dots, 2^d$ form a partition of Q_n by Corollary 5. To verify condition ②, first observe in Figure 7 (a1), (b1) and (b2) that no two edges from any of the sets $E(x, \{a, b\})$, $E_\diagdown(x, a)$, or $E_\diagup(x, a)$ are crossing and thus

H is a plane graph. Furthermore, observe from Figure 7 (a1) that the four facial cycles between two cycles obtained by adding the edge set $E(x, \{a, b\})$ have lengths $2(b-a)+2$ and $2(n-(b-a))+2$ and flip sequences

$$(a, a+1, \ldots, b-1, a, b, b-1, \ldots, a+1, b), \text{ and}$$
$$(b, b+1, \ldots, n, 1, 2, \ldots, a-1, b, a, a-1, \ldots, 1, n, n-1, \ldots, b+1, a),$$

respectively. Similarly, observe from Figures 7 (b1) and (b2) that the three facial cycles between two cycles obtained by adding the edge set $E_{\diagdown}(x, a)$ or $E_{\diagup}(x, a)$ have lengths 6, $2n$, and $2n$ and flip sequences

$$(a, a+1, a, a+2, a+1, a+2),$$
$$(a+2, a+3, \ldots, n, 1, 2, \ldots, a-1, a+1, a+2, a+1, \ldots, 1, n, n-1, \ldots, a+3, a), \text{ and}$$
$$(a, a+1, \ldots, n, 1, 2, \ldots, a-1, a+2, a, a-1, \ldots, 1, n, n-1, \ldots, a+3, a+1),$$

respectively. It can be checked directly that the aforementioned faces, as well as the outer face $C(x_1)$ and the innermost face $C(x_{2^d})$ satisfy condition ②.

In the last step of the construction we removed some edges from the cycles $C(x_i)$. Specifically, for each increasing or decreasing run of length $\ell \geq 2$, we glue together ℓ adjacent 6-cycles, creating a new facial cycle of length $4\ell+2$. Observe that the adjacent 6-faces have edge directions shifted by 2 and therefore their directions overlap only in the largest resp. smallest direction, and the shared direction is the direction of the edge that was removed. It follows that the resulting cycles of length $4\ell+2$ also satisfy condition ②.

To prove condition ③ we establish by induction on $i = 1, \ldots, 2^d$ that for every direction $j \in [n]$ every vertex x of $C(x_i)$ is connected in H to either the vertex $\emptyset$ or $[n]$ along a path that avoids any j-edges. Specifically, x is connected to $\emptyset$ if $j \notin x$ and to $[n]$ if $j \in x$.

To settle the induction basis $i = 1$, recall that the flip sequence of $C(x_1)$ is $\sigma(C(x_1)) = (1, 2, \ldots, n, 1, 2, \ldots, n)$, so removing any two j-edges for some $j \in [n]$ from $C(x_1)$ results in two antipodal paths of length $n-1$, respectively containing vertex $\emptyset$ and vertex $[n]$.

For the induction step $i \to i+1$, it suffices to show that every vertex of $C(x_{i+1})$ is connected in H to some vertex of $C(x_i)$ along a path that has no j-edges. We distinguish two cases according to which edges were added between $C(x_i)$ and $C(x_{i+1})$.

In the case when the four edges of $E(x_i, c_{s_i})$, $c_{s_i} =: \{a, b\}$, were added between $C(x_i)$ and $C(x_{i+1})$, observe that the two added a-edges are incident to antipodal vertices of $C(x_{i+1})$, and the same is true for the two added b-edges. Hence removing any two j-edges, where $j \in [n]$, from $C(x_{i+1})$ results in two subpaths that are both connected to $C(x_i)$ along an edge of $E(x_i, c_{s_i})$ that is not a j-edge, even if $j \in \{a, b\}$.

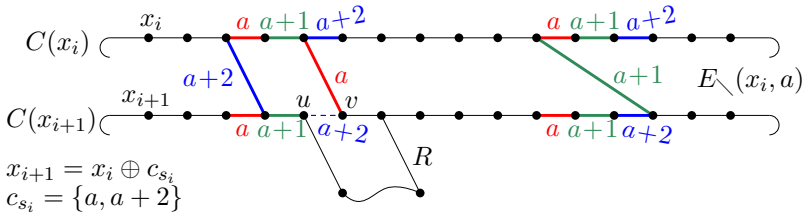

Figure 10 Verification of condition ③ in the proof of Lemma 9.

Now we consider the case when the three edges of $E_{\diagdown}(x_i, a)$ were added between $C(x_i)$ and $C(x_{i+1})$ (i.e., we have $b = a+2$). The third case when the edges of $E_{\diagup}(x_i, a)$ were added is analogous. We will also assume w.l.o.g. that the first $(a+2)$-edge on $C(x_{i+1})$ was

removed; otherwise the situation is even simpler; see Figure 10. We denote the removed $(a+2)$-edge by $\{u, v\}$. If $j \notin \{a, a+1, a+2\}$, then removing the j-edges from $C(x_{i+1})$ results in three subpaths that are all connected to $C(x_i)$, each path along an edge of $E_\diagdown(x_i, a)$. If $j = a+2$, then removing also the second $(a+2)$-edge from $C(x_{i+1})$ results in two subpaths of $C(x_{i+1})$ that are both connected to $C(x_i)$, since the added edges of directions a and $a+1$ are incident to antipodal vertices of $C(x_{i+1})$. For the last case $j \in \{a, a+1\}$ recall that there is a path R between u and v along the face of H containing these two vertices and vertices of $C(x_{i+j})$ for $j \geq 2$, and the path R does not contain edges of directions a or $a+1$. The path R and the two edges of $E_\diagdown(x_i, a)$ that are not of direction j connect all vertices of $C(x_{i+1})$ to $C(x_i)$ along a path not containing any j-edges. This shows that the graph H indeed satisfies condition ③. ◀

With Lemma 9 in hand, we are now in position to prove Theorem 1.

Proof of Theorem 1. For $k \geq 3$ we define $n := 2^k$, $d := 2^k - k - 1$ and $\rho := 2^{k-1} - 1 = n/2 - 1$.

If $k = 3$, we have $n = 8$, $d = 4$ and $\rho = 3$. We apply Lemma 7 for $\widehat{k} := k - 1 = 2$, $\widehat{n} := 2^{\widehat{k}} = 4$ to obtain a Hamiltonian path P in Q_4 with $\nu_3(P) = 6$ and $\lambda_3(P) = 8$. Therefore, Lemma 9 yields an 8-Venn diagram with exactly $2 \cdot \frac{2^8}{8} - 6 - 2 \cdot 8 - 2 = 40$ crossings; see Figures 3 and 9.

If $k \geq 4$, we apply Corollary 8 for $\widehat{k} := k - 1$, $\widehat{n} := 2^{\widehat{k}} = 2^{k-1} = n/2$ and $\widehat{m} := d - \widehat{n} = 2^{k-1} - k - 1$ to obtain a Hamiltonian path P in $Q_{\widehat{n}+\widehat{m}} = Q_d$ with

$$\nu_\rho(P) = \nu_{\widehat{n}-1}(P) = \left(\frac{17}{8} \cdot \frac{2^{\widehat{n}}}{\widehat{n}} - 4\right) 2^{\widehat{m}} = \frac{17}{8} \cdot \frac{2^n}{n^2} - \frac{2^{n/2}}{n/2} \quad \text{and}$$

$$\lambda_\rho(P) = \lambda_{\widehat{n}-1}(P) = \left(2^{\widehat{n}} - \frac{25}{8} \cdot \frac{2^{\widehat{n}}}{\widehat{n}} + 4\right) 2^{\widehat{m}} = \frac{2^n}{2n} - \frac{25}{8} \cdot \frac{2^n}{n^2} + \frac{2^{n/2}}{n/2}.$$

Therefore, Lemma 9 yields an n-Venn diagram with exactly

$$2 \cdot \frac{2^n}{n} - \nu_\rho(P) - 2\lambda_\rho(P) - 2 = \left(1 + \frac{33}{8n} - \frac{2}{2^{n/2}} - \frac{2n}{2^n}\right) \frac{2^n}{n}$$

many crossings.

Finally, note that the inequality $\frac{2^n}{n} \leq L_n = \lceil \frac{2^n - 2}{n-1} \rceil$ holds for all $n \geq 2$. ◀

5 Proof of Theorem 2

We now show how to lift the construction of n-Venn diagrams for the case when n is a power of 2 to the general case, thus proving Theorem 2. The lifting is achieved via the following straightforward doubling construction.

We say that a face of the dual graph of an n-Venn diagram is *colorful* if it has length $2n$ and contains two antipodal vertices of Q_n. In the primal Venn diagram, such a face corresponds to a crossing involving all n curves for which the cyclic ordering of curves around the crossing can be split into two halves such that every curve appears exactly once in each half. Consequently, there is a way to draw an additional curve through this crossing that crosses (not only intersects) each of the n existing curves.

▶ **Lemma 10.** *If there is an n-Venn diagram D whose dual graph has a colorful face, then there is an $(n+1)$-Venn diagram whose dual graph has a colorful face and with twice as many crossings as D.*

The proof of Lemma 10 can be found in the preprint [1]. With Lemma 10 in hand, we are now in position to prove Theorem 2.

Proof of Theorem 2. The duals of the Venn diagrams from Theorem 1 all have a colorful face, namely the outer face $C(x_1)$, so applying Lemma 10 (m times) proves the theorem. ◀

6 Remarks and open problems

We conclude with some remarks and challenging open problems.

- Is there a minimum 8-Venn diagram, i.e., one with only 37 crossings? The best one we found has 40 crossings; see Figure 3.
- Lemma 7 gives a Hamiltonian path P in Q_n, $n = 2^k$, with

$$\nu_{n-1}(P) + 2\lambda_{n-1}(P) = 2 \cdot 2^n - \frac{33}{8} \cdot \frac{2^n}{n} + 4.$$

  Is there another construction that would decrease the constant $\frac{33}{8}$? If so, then this would directly improve the same constant in Theorems 1 and 2. One can easily prove an upper bound of $\nu_{n-1}(P) + 2\lambda_{n-1}(P) \le 2 \cdot 2^n - \frac{2^n}{n}$.
- A long-standing problem due to Slater [21] is whether there exists a Hamiltonian path P in Q_n such that any two consecutive entries of the flip sequence differ by ± 1. Put differently, if we write $\mu(P)$ for the number of such consecutive entries of $\sigma(P)$, then the goal is to find a Hamiltonian path P with $\mu(P) = 2^n - 2$. While such a path exists for $n \le 6$, it does not exist for $n = 7$ [22] and $n = 8$ (computer experiments by Dimitrov, Gregor and Lužar; see [17, Problem 10]). We clearly have $\mu(P) \ge \lambda_n(P) \ge \lambda_{n-1}(P)$, so Lemma 7 and Corollary 8 yield a Hamiltonian path P for which $\mu(P) = (1-o(1)) \cdot (2^n - 2)$, which can be seen as an approximate solution to Slater's problem (cf. [14]).

Abstract

In 1984, Winkler conjectured that every simple Venn diagram with n curves can be extended to a simple Venn diagram with $n+1$ curves. This conjecture is equivalent to the statement that the dual graph of any simple Venn diagram has a Hamilton cycle. In this work, we construct counterexamples to Winkler's conjecture for all $n \geq 6$. As part of this proof, we computed all 3.430.404 simple Venn diagrams with $n = 6$ curves (even their number was not previously known), among which we found 72 counterexamples.

We also disprove another conjecture about the Hamiltonicity of the arrangement graph of a Venn diagram. Specifically, while working on Winkler's conjecture, Pruesse and Ruskey proved that this graph has a Hamilton cycle for every simple Venn diagram with n curves, and conjectured that this also holds for non-simple diagrams. We construct counterexamples to this conjecture for all $n \geq 4$.

1 Introduction

Venn diagrams are a popular tool to illustrate the relations between sets and operations on them, such as union and intersection, or the well-known inclusion-exclusion principle. Historically, these diagrams were introduced by John Venn [18] (1834–1923) in the context of formal logic. Most illustrations that one finds depict the Venn diagram with three sets represented by unit circles; see Figure 1 (a). It may even come as a surprise that Venn diagrams exist for any number of sets, not just three. Formally, an *n-Venn diagram* is a collection of n simple closed curves in the plane that intersect in only finitely many points

(a) $n = 3$ (b) $n = 4$ (c) $n = 5$

(d) $n = 3$ (e) $n = 4$ (f) $n = 5$

Figure 1 Venn diagrams with $n = 3, 4, 5$ curves: (a), (b), (c) are simple, whereas (d), (e), (f) are non-simple; (a), (b), (d) are reducible, whereas (c), (e), (f) are irreducible; (a), (b), (c), (d) are monotone, whereas (e), (f) are not monotone; (a), (b), (c), (d), (f) are exposed, whereas (e) is not exposed.

and create exactly 2^n regions, one for every possible combination of being inside or outside of each of the n curves. Figures 1 (b)+(c) display diagrams with $n = 4$ and $n = 5$ curves, respectively.

A Venn diagram is *simple* if at most two of the n curves intersect in any point: The three diagrams in the top row of Figure 1 are simple, whereas the three diagrams in the bottom row are non-simple. An easy application of Euler's formula shows that a simple Venn diagram has exactly $2^n - 2$ crossings, whereas non-simple diagrams may have much fewer. For humans, simple Venn diagrams tend to be easier to read than non-simple diagrams.

1.1 Winkler's conjecture

In 1984, Peter Winkler [20] raised the following intriguing conjecture about extending a simple Venn diagram by adding one curve to it.

▶ **Conjecture 1.** *Every simple n-Venn diagram can be extended to a simple $(n+1)$-Venn diagram by the addition of a suitable curve.*

He also mentioned the conjecture as an unsolved open problem in his popular book [21] on mathematical puzzles, and reiterated it in his "Puzzled" column [22] in the Communications of the ACM. The conjecture is also listed as the first open problem in Ruskey and Weston's inspiring survey [15] on Venn diagrams.

For small cases, the conjecture is easily verifiable by hand for all simple Venn diagrams on $n \in \{3, 4, 5\}$ curves, simply because there are so few of them; the 20 diagrams for $n = 5$ can be found in [6, 10]. Another class of Venn diagrams for which the conjecture is easily

seen to be true are reducible diagrams. An n-Venn diagram is *reducible* if one of its curves can be removed so that the remaining $n-1$ curves form an $(n-1)$-Venn diagram. Otherwise the diagram is called *irreducible*. The diagram in Figure 1 (c) is irreducible. If a diagram is reducible, then the curve C that can be removed splits every region of the resulting $(n-1)$-Venn diagram into two, and therefore this curve touches every region in the n-Venn diagram. We can thus add an $(n+1)$st curve by following the curve C and subdividing every region into two, changing sides along C exactly once along every segment between two consecutive crossings. Thus, the interesting instances of Conjecture 1 are irreducible diagrams.

Grünbaum [9] modified Winkler's conjecture, dropping the requirement for the diagrams to be simple. This makes the problem harder in the sense that more diagrams are allowed, but easier in the sense that there is substantially more freedom when adding the new curve. This variant of the conjecture was proved subsequently by Chilakamarri, Hamburger and Pippert [4], by using a straightforward reduction to a classical result of Whitney [19].

1.1.1 Translation to a Hamilton cycle problem

Problems on Venn diagrams such as Winkler's conjecture are best discussed by considering the *dual graph* of the Venn diagram, i.e., the plane graph that has a vertex inside every region, and edges connecting vertices corresponding to neighboring regions; see Figure 2. For this, we consider the *n-dimensional hypercube Q_n*, or *n-cube* for short, the graph formed by all bitstrings of length n, with an edge between any two bitstrings that differ in a single bit. The dual graph $Q(D)$ of a simple n-Venn diagram D satisfies the following properties:

(1) It is a connected subgraph of Q_n that is also spanning, i.e., all 2^n vertices are present. Specifically, the vertex in $Q(D)$ corresponding to a region of the diagram D is the characteristic vector of the inside/outside relation with respect to each curve, where 0 and 1 represent outside and inside, respectively.[1]

(2) It is a plane quadrangulation, i.e., it is drawn in the plane without edge crossings, and every face (including the outer face) is a 4-cycle.

(3) For every position $i \in \{1,\dots,n\}$ and every bit $b \in \{0,1\}$, the subgraph of $Q(D)$ induced by all vertices x with $x_i = b$ is connected.

Conversely, the dual of any subgraph of Q_n satisfying these properties is an n-Venn diagram.

We refer to subgraphs of Q_n satisfying (1)–(3), which are the duals of n-Venn diagrams, as *n-Venn quadrangulations*.

Extending the diagram D by a single curve means that the new curve has to enter and leave every region of D exactly once, splitting it into two, one of them inside and the other one outside the newly added curve. This corresponds to traversing a Hamilton cycle in the dual graph $Q(D)$, i.e., a cycle in the graph that visits every vertex exactly once; see Figure 2 (b)+(c).

Conjecture 1 can thus be restated equivalently as follows: For $n \geq 2$, every n-Venn quadrangulation admits a Hamilton cycle.

[1] When considering the diagram in the plane, then the inside and outside of a curve C are the bounded and unbounded region of $\mathbb{R}^2 \setminus C$, respectively.

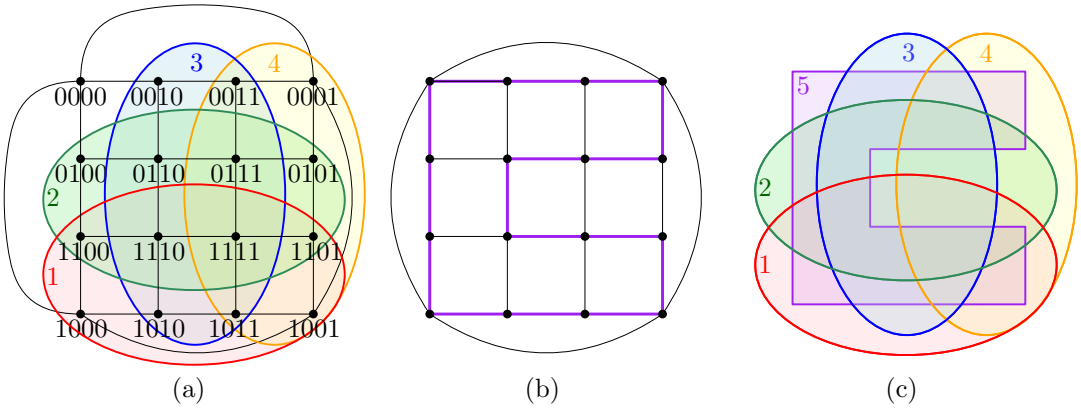

Figure 2 (a) A 4-Venn diagram and its dual graph, a 4-Venn quadrangulation; (b) a Hamilton cycle in the quadrangulation; (c) the 5-Venn diagram obtained from (a) by adding the curve corresponding to the Hamilton cycle in (b).

1.1.2 The counterexamples

As Q_n is a bipartite graph, Venn quadrangulations are bipartite, too. A necessary condition for the existence of a Hamilton cycle in a bipartite graph is the existence of a perfect matching. We provide counterexamples to Conjecture 1 by constructing, for every $n \geq 6$, an n-Venn quadrangulation that has no perfect matching and thus no Hamilton cycle. One of our counterexamples for $n = 6$ is shown in Figure 3.

▶ **Theorem 2.** *For every $n \geq 6$ there is an n-Venn quadrangulation that has no perfect matching and hence no Hamilton cycle. Its dual is a simple n-Venn diagram that cannot be extended to a simple $(n+1)$-Venn diagram by adding a suitable curve.*

As mentioned before, for $n \leq 5$ all simple n-Venn diagrams are extendable, so Theorem 2 is best possible in the sense that the counterexamples for $n = 6$ are minimal. In fact, as part of our proof of Theorem 2 we computed all distinct 6-Venn diagrams and analyzed their properties, summarized in the next theorem, Figure 4 and Table 1. Specifically, we consider two diagrams the same if they differ only by mirroring and/or stereographic projection. Equivalently, we count their dual n-Venn quadrangulations up to graph isomorphism. Prior to this work, the number of simple n-Venn diagrams was only known up to $n \leq 5$. Specifically, for each $n \leq 4$ there is only one, and for $n = 5$ there are 20 [6, 10].

To state the next theorem, we define a few relevant properties. A *k-region* in an n-Venn diagram is a region that lies inside of exactly k of the n curves (and outside of the remaining $n-k$ curves). A *monotone* Venn diagram is one in which for every $0 < k < n$, every k-region is adjacent to both a $(k-1)$-region and a $(k+1)$-region. Bultena, Grünbaum and Ruskey [3] proved that monotone diagrams are precisely the ones that can be drawn such that every curve has a convex shape. An *exposed* diagram is one in which the outer region is bounded by all n curves. It is not hard to see that any monotone diagram is also exposed. Chilakamarri, Hamburger and Pippert [5] constructed n-Venn diagrams for every n in which all regions are (combinatorial) triangles, quadrangles or pentagons, in particular, they are not exposed for $n \geq 6$.

[2] This drawing was produced using a `SageMath` program [16] developed by Manfred Scheucher for his and Felsner's work [7] on pseudocircle arrangements. We used this program with Scheucher's permission, using as input the 6-Venn quadrangulation on the right.

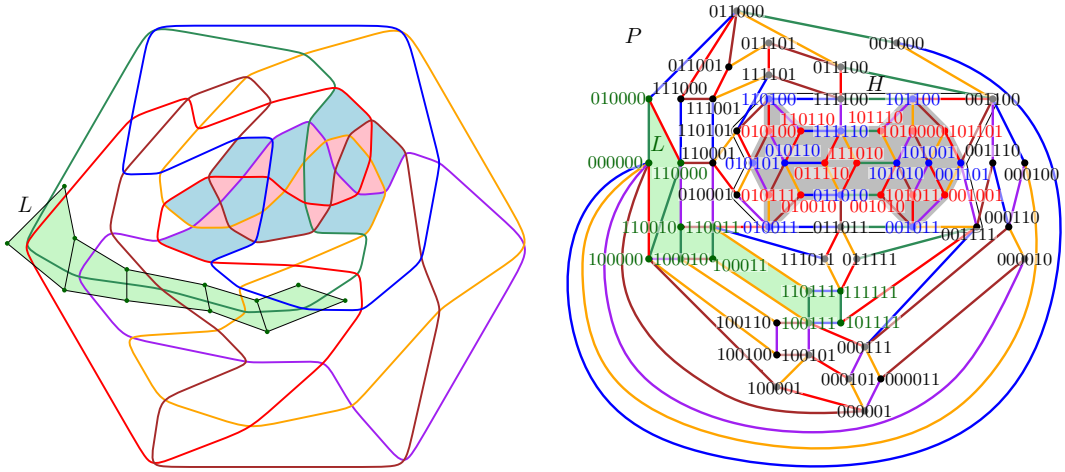

Figure 3 (Left) A counterexample to Winkler's conjecture for $n = 6$, namely a simple 6-Venn diagram that cannot be extended to a simple 7-Venn diagram by adding a suitable curve. Highlighted are 12 red regions that are surrounded by only 11 blue regions, which is a local obstruction for extendability.[2] (Right) The dual graph of the diagram on the left, namely a 6-Venn quadrangulation P that has no perfect matching and hence no Hamilton cycle. Edges are colored according to the colors of the curves. The highlighted subgraph H contains a subset of 12 red vertices in one partition class and their 11 blue neighbors, witnessing the non-existence of a perfect matching. The green subgraph L is the ladder used for extending the counterexample to all values of $n > 6$, and all those extensions contain a copy of H.

▶ **Theorem 3.** *There are* 3.430.404 *non-isomorphic 6-Venn quadrangulations (i.e., simple 6-Venn diagrams up to mirroring and/or stereographic projection). Of these,* 72 *do not have a Hamilton cycle (i.e., the diagram cannot be extended to a simple 7-Venn diagram),* 60 *do not have a Hamilton path, and* 17 *do not have a perfect matching. Furthermore, of the corresponding Venn diagrams,* 157.619 *are reducible,* 32.255 *are monotone and* 267.510 *are not exposed, and all those are extendable to a 7-Venn diagram.*

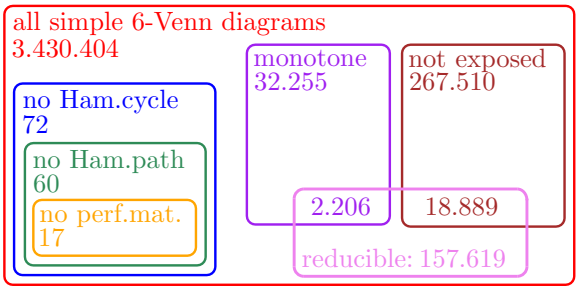

Figure 4 Census of 6-Venn diagrams and their properties stated in Theorem 3, visualized as an Euler diagram. The sizes of the boxes are not to scale.

As a consequence of Theorem 3, there are 6-Venn quadrangulations (in total $72 - 17 = 55$ many) that have a perfect matching but no Hamilton cycle, and 6-Venn quadrangulations (in total $60 - 17 = 43$ many) that have a perfect matching but no Hamilton path.

The programs we used for computing all simple 6-Venn diagrams and the result files with all 6-Venn quadrangulations are available for download [2].

1.2 Pruesse and Ruskey's conjecture

While working on Winkler's conjecture, Pruesse and Ruskey [14] considered the question of finding a Hamilton cycle not in the dual graph of a Venn diagram, but in the arrangement graph whose vertices are the crossings of the curves, and curve segments between consecutive crossings form the edges; see Figure 5. Note that these graphs may have multiple edges.

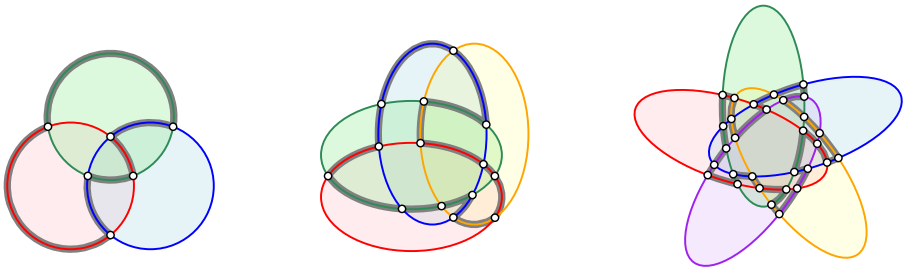

Figure 5 Hamilton cycles in the arrangement graphs of the Venn diagrams from Figure 1 (a)–(c).

▶ **Theorem 4** ([14, Cor. 1]). *For $n \geq 2$, the arrangement graph of any simple n-Venn diagram has a Hamilton cycle.*

Their proof demonstrates that the arrangement graph of a simple Venn diagram is 4-connected for $n \geq 3$, and thus a well-known theorem of Tutte [17] implies Hamiltonicity. Pruesse and Ruskey also conjectured that their result generalizes to non-simple diagrams.

▶ **Conjecture 5** ([14, Conj. 1]). *For $n \geq 2$, the arrangement graph of any (not necessarily simple) n-Venn diagram has a Hamilton cycle.*

1.2.1 The counterexamples

We disprove Conjecture 5 by providing counterexamples for all $n \geq 4$. Similarly to Theorem 2, our counterexamples have an even number of vertices and do not admit a perfect matching, which would be necessary for having a Hamilton cycle. One of the counterexamples for $n = 4$ is shown in Figure 6.

▶ **Theorem 6.** *For every $n \geq 4$, there is a non-simple n-Venn diagram whose arrangement graph has an even number of vertices and no perfect matching, and hence no Hamilton cycle.*

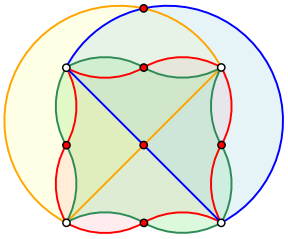

Figure 6 A counterexample to Pruesse and Ruskey's conjecture for $n = 4$, namely a non-simple 4-Venn diagram whose arrangement graph has an even number of vertices and no perfect matching, and hence no Hamilton cycle. The 6 red vertices form an independent set, and the complement has only 4 vertices, witnessing the non-existence of a perfect matching.

We remark that the counterexamples constructed in the proof of Theorem 6, including the one shown in Figure 6, are actually monotone. With straightforward modifications the diagrams can also be made *crossing*, i.e., such that whenever two curves meet, they cross.

2 Proof of Theorem 2

Our first lemma describes a technique to construct a simple $(n+1)$-Venn diagram from a simple n-Venn diagram, by carefully gluing together two slitted copies of the smaller diagram, surrounding one of the copies with an additional curve. In this process, a certain local substructure H is preserved, and we will later apply the lemma by taking for H a substructure that witnesses non-extendability. The lemma is conveniently stated in the language of the dual Venn quadrangulations.

If e is an edge of Q_n whose end vertices differ in the kth bit, then we refer to k as the *type* of the edge e. A *ladder* in an n-Venn quadrangulation is a subgraph L on pairwise distinct vertices $x_1, \dots, x_n$ and $y_1, \dots, y_n$ such that $x_1 = 0^n$, $y_n = 1^n$, for some $k \in [n] := \{1, \dots, n\}$ all pairs (x_i, y_i) for $i = 1, \dots, n$ are edges of type k in L, and for $i = 1, \dots, n-1$ all pairs (x_i, x_{i+1}) and (y_i, y_{i+1}) are edges of arbitrary type in L; see Figure 7. A ladder for $n = 6$ is highlighted in green in Figure 3. We note that in a Venn quadrangulation, every 4-cycle also bounds a face, i.e., either the inside or outside of the 4-cycle is empty, because otherwise condition ③ would be violated. Consequently, in a ladder, each of the 4-cycles $(x_i, x_{i+1}, y_{i+1}, y_i)$ for $i = 1, \dots, n-1$ bounds a 4-face.

▶ **Lemma 7.** *Consider an n-Venn quadrangulation P that contains a ladder L and a subgraph H with $L \cap H = \emptyset$. Then there is an $(n+1)$-Venn quadrangulation P' that contains a ladder L' and a copy H' of H such that $L' \cap H' = \emptyset$.*

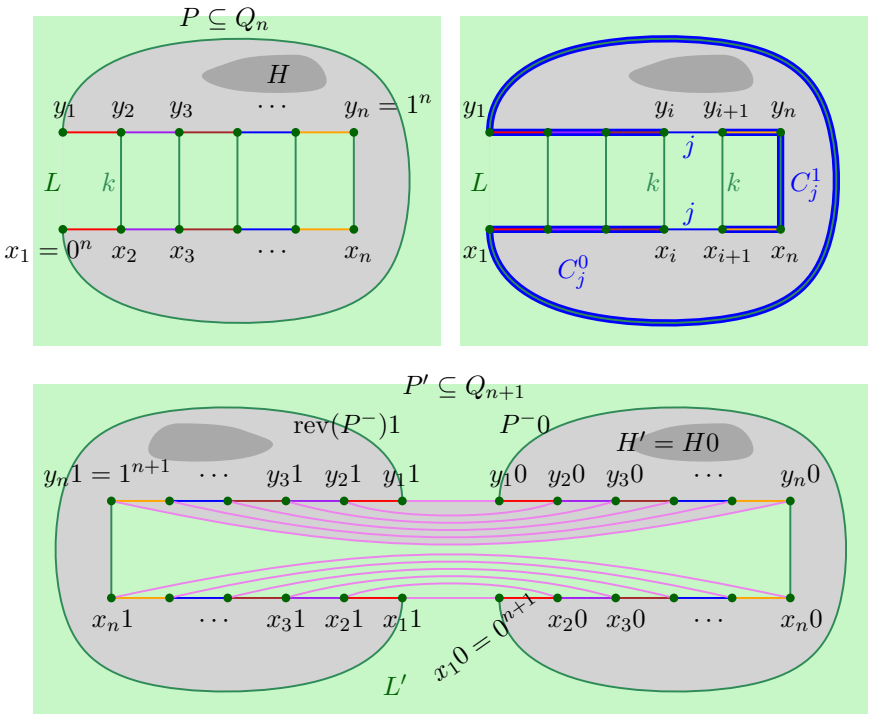

Figure 7 Illustration of Lemma 7.

The proof of Lemma 7 is illustrated in Figure 7.

Proof. Let $x_1, \dots, x_n$ and $y_1, \dots, y_n$ be the vertices of the ladder L in P as defined before, and let $k \in [n]$ be the type of the edges (x_i, y_i) for $i = 1, \dots, n$. We write C for the outer cycle of L, i.e., for the graph $C := L \setminus \{(x_i, y_i) \mid i = 2, \dots, n-1\}$. Note that in every 4-cycle of a Venn quadrangulation, there are edges of exactly two different types, and opposite edges have the same type. Consequently, both edges (x_i, x_{i+1}) and (y_i, y_{i+1}) of L (and C) have the same type for $i = 1, \dots, n-1$, and because of the condition $x_1 = 0^n$ and $y_n = 1^n$, every type $j \in [n] \setminus \{k\}$ appears for exactly one pair of opposite edges (x_i, x_{i+1}) and (y_i, y_{i+1}) for some $i = 1, \dots, n-1$. We write C_j^0 and C_j^1 for the two connected subgraphs of C obtained from C by removing both edges (x_i, x_{i+1}) and (y_i, y_{i+1}), such that the first one contains the vertex $x_1 = 0^n$ and the second one contains the vertex $y_n = 1^n$.

We assume w.l.o.g. that the 4-cycle (x_1, x_2, y_2, y_1) bounds the outer face of P. Let P^- be the graph obtained from P by removing the edges (x_i, y_i) of the ladder L for all $i = 2, \dots, n-1$. Let $\mathrm{rev}(P^-)$ denote the plane graph obtained from P^- by mirroring. Appending a 0-bit to all vertices of P^- and a 1-bit to all vertices of $\mathrm{rev}(P^-)$ gives the graphs P^-0 and $\mathrm{rev}(P^-)1$. We let P' be the plane graph obtained by connecting P^-0 and $\mathrm{rev}(P^-)1$ via $2n$ additional type-$(n+1)$ edges (x_j0, x_j1) and (y_j0, y_j1) for all $j = 1, \dots, n$. It is straightforward to check that P' satisfies conditions ①–③. In particular, the connectivity condition ③ is ensured via the subgraphs C_j^0 and C_j^1 for all bit positions $j \in [n] \setminus \{k\}$, and for the bit position k it is ensured via the subgraphs $C0$ and $C1$.

Note that P' contains a ladder L' on the vertices $x_10, \dots, x_n0, y_n0$ and $x_11, \dots, x_n1, y_n1$. Clearly, $H0$ is a copy of H in P' that is disjoint from L'. ◀

We are now ready to prove Theorem 2.

Proof of Theorem 2. The 6-Venn quadrangulation P from Figure 3 has no perfect matching, as witnessed by the marked subgraph H. Specifically, H contains a subset of 12 vertices from one partition class (marked red) whose neighborhood (marked blue) has only size 11. This is the easy direction of Hall's marriage theorem.

Repeatedly applying Lemma 7 to P with the subgraph H and the ladder L marked in Figure 3 yields an n-Venn quadrangulation without perfect matching for all $n > 6$. This completes the proof. ◀

3 Proof of Theorem 3

In this section we describe our `C++` and `SageMath` programs that compute all 6-Venn quadrangulations. For the reader's convenience, the code and data produced by them are available for download [2]. Specifically, the 6-Venn quadrangulations are provided in `graph6` format, and in a compact binary adjacency list representation. The following explanations are valid for general n, but have a reasonable computation time only for $n \leq 6$. Table 1 provides the counts of Venn diagrams with various properties for all $n = 1, \dots, 6$.

Maybe surprisingly, the computational proof of Theorem 3 was the technically most demanding part of this work, even though in the end there are relatively few 6-Venn quadrangulations in total ($< 10^7$ many). In fact, we had first found a counterexample to Winkler's conjecture for $n = 7$ (using different methods that involved SAT solvers) and a proof of Theorem 2 for $n \geq 7$, before finding the few counterexamples for $n = 6$.

Table 1 Counts of n-Venn diagrams with different properties for $n = 1, \ldots, 6$ curves. Every second row (unmarked) counts the diagrams up to mirroring and/or stereographic projection, or equivalently, the number of non-isomorphic n-Venn quadrangulations. Every other row (marked with *) counts the diagrams up to mirroring, or equivalently, the number of non-isomorphic n-Venn quadrangulations with a marked vertex which represents the outer region. We note that Mamakani, Myrvold and Ruskey [12] have counted 39.020 monotone 6-Venn diagrams before, which is in disagreement with our count of 77.395.

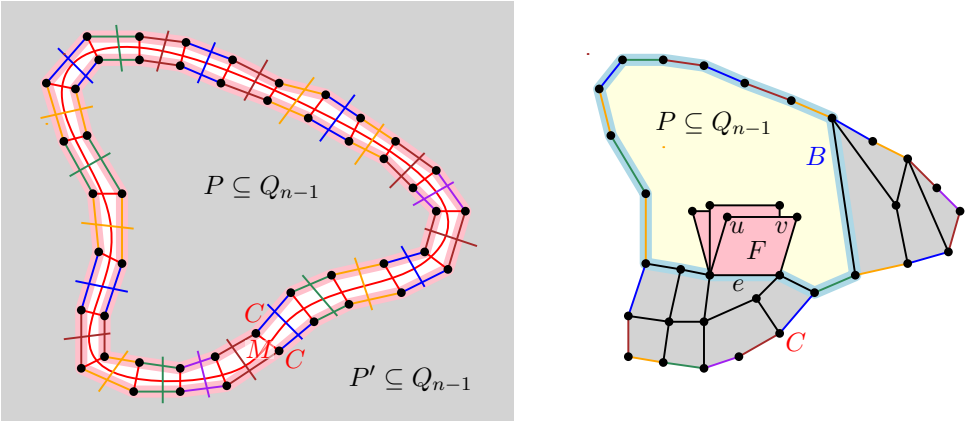
3.1 Dynamic programming on two halves of a Venn diagram

We consider a simple n-Venn diagram D and one of its curves, say the nth one. In the dual graph $Q(D)$, the edges dual to the ones on the curve are all edges of $Q(D)$ of type n, and they form a matching M in $Q(D)$; see Figure 8 (a). Removing the matching edges M and removing the nth bit from all vertex labels splits $Q(D)$ into two subgraphs $P, P' \subseteq Q_{n-1}$, each of which satisfies the following conditions (cf. (1)–(3) from before):

(1') It is a connected subgraph of Q_{n-1} that is also spanning, i.e., all 2^{n-1} vertices are present.

(2') It is a plane graph in which every inner face is a 4-cycle, whereas the length of the outer face is at least $2n - 2$.

The outer face is bounded by a cycle C, which is the same for P and P', and we refer to it as the *boundary cycle*. Furthermore, we refer to any subgraph of Q_{n-1} satisfying (1')–(2') with boundary cycle C as a *C-quadrangulation*. Conversely, given two C-quadrangulations $P, P' \subseteq Q_{n-1}$ with $C =: (x_1, \ldots, x_\ell)$, we may consider the union



$$H := P1 \cup P'0 \cup \big\{(x_i 0, x_i 1) \mid i = 1, \ldots, \ell\big\} \subseteq Q_n, \tag{1}$$

where $P1$ and $P'0$ are obtained from P and P' by appending a 1-bit or 0-bit to all vertices, respectively. If this graph H satisfies the connectivity condition (3), then H is an n-Venn quadrangulation. In this case we say that P and P' are *compatible*.

We can therefore compute all simple n-Venn quadrangulations as follows:

(i) Compute all cycles C of Q_{n-1} up to automorphisms of the hypercube.

(ii) For every cycle C computed in step (i), compute all C-quadrangulations, i.e., subgraphs of Q_{n-1} satisfying (1')–(2') with C as the boundary cycle.

(a) (b)

Figure 8 (a) Splitting an n-Venn quadrangulation into two C-quadrangulations $P, P' \subseteq Q_{n-1}$. (b) Recursively computing C-quadrangulations by including/excluding 4-faces F to fill the inner face B.

(iii) For any two C-quadrangulations $P, P' \subseteq Q_{n-1}$ computed in step (ii), check if they are compatible, i.e., compute the graph H as in (1) and check whether H satisfies condition ③. If so, store it.

(iv) From the list of n-Venn quadrangulations stored in step (iii), filter out isomorphic duplicates.

(v) Analyze properties of all non-isomorphic n-Venn quadrangulations resulting from step (iv) according to the different properties, namely existence of a perfect matching and a Hamilton cycle or path, being monotone, exposed, reducible etc.

In the following, we describe each of these five steps in more detail. The first three steps are implemented as a single `C++` program, for efficiency reasons, and take approximately 30 hours to compute on a single desktop computer. The last two steps are implemented in `SageMath`, where several convenient high-level functions are available for working with graphs, and take approximately 60 hours to compute.

For validation purposes, we also computed the reducible 6-Venn diagrams in a different way, namely by inserting all possible Hamilton cycles into the 20 known 5-Venn quadrangulations, confirming the count of 157.619. Similarly, we also computed the monotone 6-Venn diagrams in a different way, using the method described in [12], confirming the count of 32.255.

3.1.1 Step (i): Computing all cycles C of Q_{n-1}

Any cycle $C = (x_1, \ldots, x_\ell)$ in Q_{n-1} can be described by the first vertex x_1 and the sequence of edge types $(\tau_1, \ldots, \tau_\ell)$, i.e., $\tau_i \in [n-1]$ is the type of the edge of C between vertices x_i and x_{i+1} for $i = 1, \ldots, \ell$ (where $x_{\ell+1} := x_1$). The automorphisms of the hypercube are given by all permutations of positions and taking the exclusive-or with an arbitrary fixed bitstring of length n. Consequently, we can assume w.l.o.g. that $x_1 = 0^{n-1}$. Note that for any sequence $\tau = (\tau_1, \ldots, \tau_\ell)$ of edge types from $[n-1]$, there is a unique permutation σ on $[n-1]$ such that $\sigma(\tau) = (\sigma(\tau_1), \ldots, \sigma(\tau_\ell))$ is lexicographically minimal, i.e., for every prefix $(\sigma(\tau_1), \ldots, \sigma(\tau_p))$, $p = 1, \ldots, \ell$, of the permuted sequence, if it contains r different types, then these are the types $1, \ldots, r$. Therefore, we can assume w.l.o.g. that $\tau = \sigma(\tau)$ is lexicographically minimal and furthermore, for every cyclic shift and/or reversal τ' of the sequence τ, we have $\tau \leq_{\text{lex}} \sigma(\tau')$. Factoring out the automorphisms of Q_{n-1} in this way drastically reduces the number of distinct cycles C that need to be considered.

In the following, we describe another observation that allows us to restrict the lengths of the boundary cycles to consider. As mentioned before, the total number of crossings in a simple n-Venn diagram D is $2^n - 2$. Clearly, this number equals the number of faces of $Q(D)$. The number of vertices of $Q(D)$ is 2^n, and therefore Euler's formula yields $2^{n+1} - 4$ for the number of edges of $Q(D)$. These edges split into n different matchings $M_1, M_2, \ldots, M_n$ according to their types, and we can therefore always guarantee that one matching M_i has size $|M_i| \geq \frac{2^{n+1}-4}{n}$, and the fraction on the right should be rounded up to the next even integer, because the corresponding boundary cycle in the hypercube must have even integral length. For $n = 6$ this yields the lower bound $|M_i| \geq 22$ for one of the matchings. By symmetry, we can thus restrict our search to cycles C in Q_5 of lengths $22, 24, 26, 28, 30, 32$. Note that if C has the maximum length 2^{n-1}, then it is a Hamilton cycle in Q_{n-1}, and the resulting n-Venn diagram H obtained by pairing two compatible C-quadrangulations is reducible and thus extendable.

The number of cycles of lengths $22, 24, 26, 28, 30, 32$ in Q_5 up to automorphisms is 819.049, $2.168.994, 3.859.153, 4.028.138, 1.934.320, 237.675$, respectively. The last number agrees with the fifth entry of OEIS sequence A159344, as it should.

3.1.2 Step (ii): Computing all C-quadrangulations

For a fixed cycle C in Q_{n-1} as computed in the previous step, we aim to compute all C-quadrangulations. This is done recursively, by filling the inside of C with 4-faces, one at a time. In each step, the current partial C-quadrangulation P has an inner face B that still needs to be quadrangulated; see Figure 8 (b). For this we consider every edge e along B, and every 4-cycle F in Q_{n-1} that contains e (there are $n - 3$ such 4-cycles). Every such

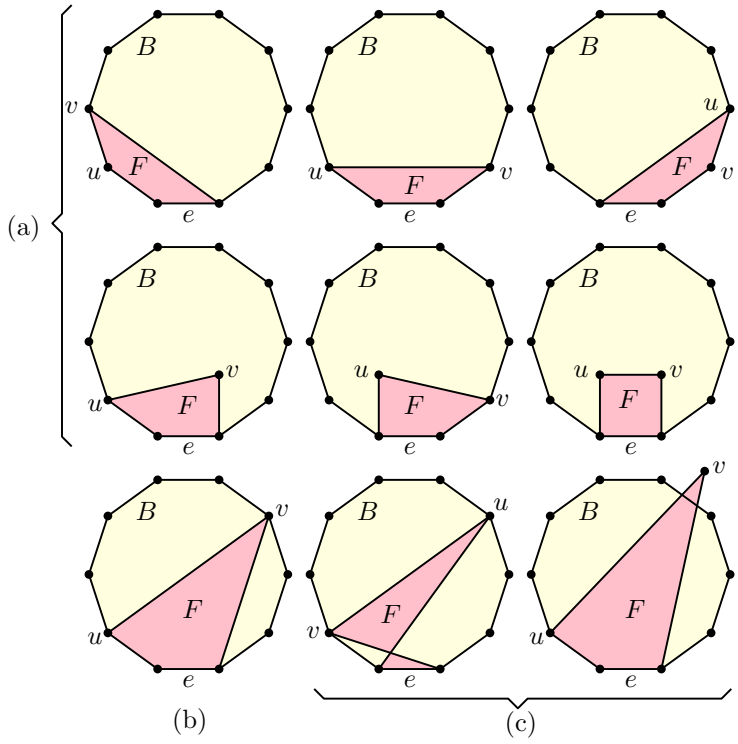


Figure 9 Different cases in the recursion to compute all C-quadrangulations.

4-cycle F containing e has two additional vertices u and v. We locate u and v in P and distinguish the following cases: If u and v are on B but in the wrong cyclic order, then F is excluded, i.e., it will not be added to P as a 4-face. Similarly, if u or v are present in P but not on B, then F is excluded. These two cases are shown in Figure 9 (c), respectively. If u and v are on B but not next to e (Figure 9 (b)), then F is ignored for this recursion step (because including F would split the inner face bounded by B into two separate faces). If u and v are next to e on B or not in P (Figure 9 (a) shows the six possible such cases), then F is eligible for a branching step. Specifically, we branch and recurse on the two possibilities of either including F, updating B accordingly, or excluding F, which does not change B. Some care has to be taken to choose a clever branching order to avoid recomputing the same C-quadrangulation along different insertion orderings of its 4-faces, and also to keep the recursion tree small, i.e., to enforce and detect dead ends quickly (for details, see our `C++` implementation [2]). Such a dead end would be an edge e on B for which all 4-cycles F containing e are excluded (apart possibly from one that can be included "behind" e).

3.1.3 Step (iii): Pairing up C-quadrangulations

For a fixed cycle C of Q_{n-1}, after computing all C-quadrangulations, we consider all pairs P, P' of them, and check if P and P' are compatible, i.e., whether the graph H defined in (1) satisfies condition ③. This is achieved by a simple graph search, run separately for every bit position $i \in [n]$ and bit value $b \in \{0, 1\}$, i.e., $2n$ searches in total. This can be slightly optimized by first doing the graph searches separately within each graph P and P', checking whether and how the subgraphs given by a fixed $i \in [n]$ and $b \in \{0, 1\}$ intersect with C (already this may lead to discarding P or P', independently of the other), and then computing the overall connectivity resulting from that.

3.1.4 Step (iv): Filtering out isomorphic graphs

After computing all n-Venn quadrangulations as described in the previous step, we need to filter out duplicates, i.e., graphs that are isomorphic copies. These isomorphic copies can arise from two different boundary cycles C and C', obtained by splitting the same diagram along two different curves. The filtering is achieved by first computing a canonical graph labeling, available in `SageMath` via the function `canonical_label()` (which internally uses the tool `bliss`), and conversion into `graph6` format, so that the isomorphism test becomes a string comparison.

3.1.5 Step (v): Analyzing properties of n-Venn quadrangulations

The different properties of a given n-Venn quadrangulation can be checked straightforwardly, either by efficient algorithms (perfect matchings, monotone, exposed, reducible) or by brute-force (Hamilton cycle/path), using standard `SageMath` functions. For $n = 6$ there are relatively few graphs and they are relatively small and sparse (64 vertices and 124 edges), so this is fast enough.

4 Proof of Theorem 6

In this section, we prove Theorem 6.

Proof of Theorem 6. We inductively construct a family of non-simple monotone n-Venn diagrams D_n for $n \geq 2$; see Figures 10 and 11. These are not the counterexamples yet, but those will be built from D_n later by small modifications. Specifically, we describe D_n as a

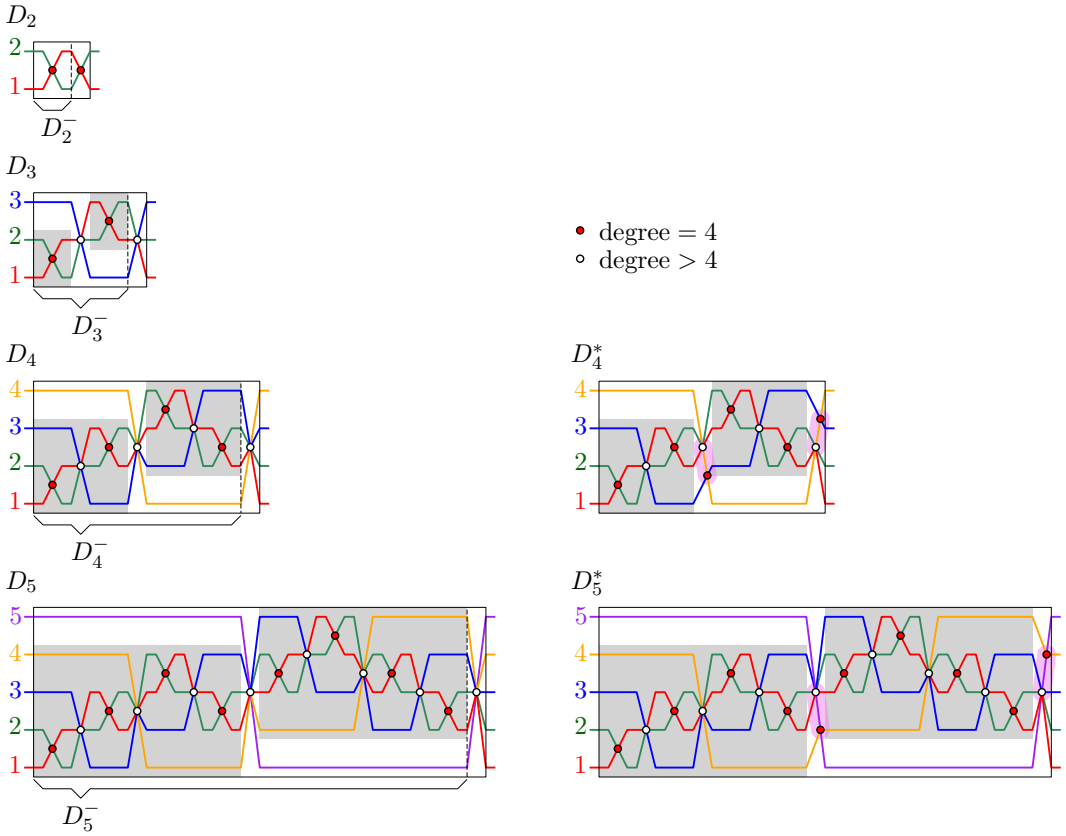

Figure 10 Non-simple Venn diagrams D_n, $n \geq 2$, and D_n^*, $n \geq 4$, constructed in the proof of Theorem 6. Another drawing of D_4^* is shown in Figure 6.

wire diagram, i.e., each crossing occurs within a horizontally separated narrow vertical strip, and outside of these strips the n curves are aligned to horizontal lines at heights $1, 2, \ldots, n$. Furthermore, the diagram wraps around cylindrically at the left and right boundary. The curves are labeled $1, 2, \ldots, n$ from bottom to top at the boundaries, according to their height.

For the induction basis $n = 2$, we take D_2 as the wire diagram obtained from the unique Venn diagram with 2 curves, which has 2 crossings; see Figure 10. For the induction step $n \to n+1$, let D_n^- be the diagram obtained from D_n by removing the rightmost crossing. To construct D_{n+1}, we take a copy of D_n^- vertically aligned at heights $1, \ldots, n$, a second copy of D_n^- but reversed (mirrored along a vertical line, i.e., left and right are interchanged) to the right of the first copy and vertically aligned at heights $2, \ldots, n+1$; see Figure 11. We then add the curve $n+1$ starting on the left at height $n+1$ above the first copy of D_n^-, staying there until its right side, then crossing below the reversed second copy of D_n^- to height 1, staying there until its right side, and finally crossing back up to height $n+1$ at the right boundary. The curves $1, \ldots, n$ are connected between the two copies of D_n^- through one additional crossing with the curve $n+1$, and to the right of the second copy through a second additional crossing with the curve $n+1$, creating two additional crossings in total, so that the ordering of curves on the right boundary becomes $1, \ldots, n+1$, as desired. One can easily verify the following properties inductively:

(i) The total number of crossings in D_n is 2^{n-1}. In particular, the arrangement graph of D_n has an even number of vertices.

(ii) The subgraph of D_n given by curve 1 and curve 2 contains all crossings, and exactly one pair of parallel edges between any two consecutive crossings. Every second crossing involves only the curves 1 and 2, i.e., the degree of the corresponding vertices is 4, and these vertices form an independent set.

(iii) Exactly two of the crossings in D_n involve all n curves, i.e., the degree of the corresponding vertices is $2n$, and the clockwise cyclic orderings of the curves around the two crossings are $n{-}1, 1, 2, \ldots, n{-}2, n, n{-}2, \ldots, 2, 1, n{-}1, n$ and $n, 1, 2, \ldots, n{-}1, n, n{-}1, \ldots, 2, 1$, respectively.

From (ii) we see in particular that the arrangement graph of D_n has a perfect matching and a Hamilton cycle, i.e., it is *not* a counterexample to Conjecture 5. However, for $n \geq 4$ we can modify D_n to obtain a diagram D_n^* as follows; see Figure 12: From the first crossing involving all n curves, we slightly shift down the curve $n-1$, and from the second crossing

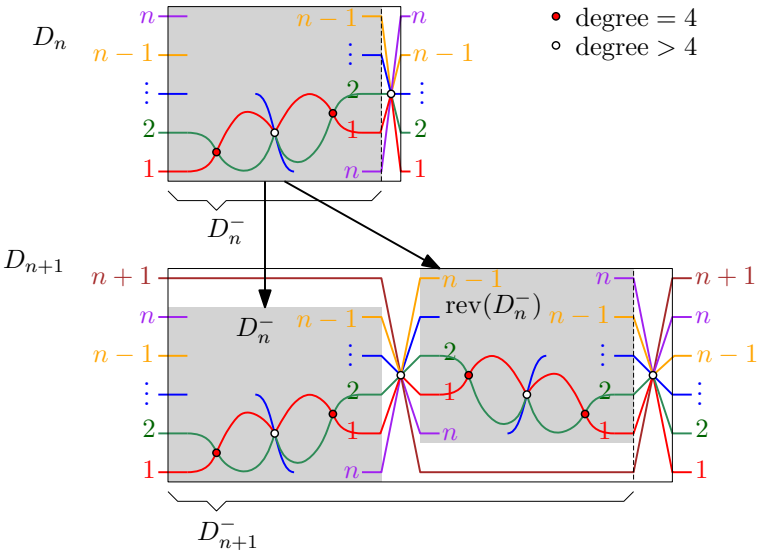

Figure 11 Illustration of the general inductive construction of D_{n+1} from D_n. The reversed copy of D_n^- is denoted rev(D_n^-).

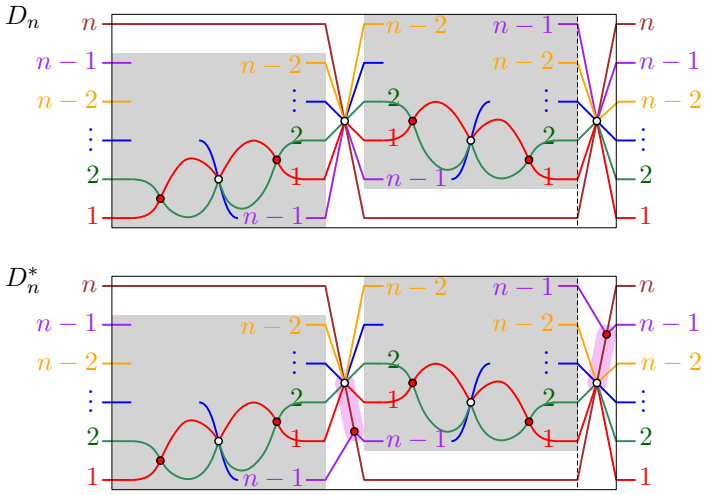

Figure 12 Modification of the diagram D_n to obtain D_n^* by slightly shifting the curve $n-1$.

involving all n curves, we slightly shift up the curve $n-1$, so that each of these two crossings is split into two, one of degree 4 and the other of degree $2n-2$ (this is possible because of (iii)). By (i), the number of vertices of D_n^* is $2^{n-1}+2$, an even number. Furthermore, in the arrangement graph of D_n^*, let U be the independent set of all degree 4 vertices and let $\overline{U}$ be its complement. From (ii) we obtain that $|U| = 2^{n-1}/2+2 = 2^{n-2}+2$ and $|\overline{U}| = 2^{n-1}/2 = 2^{n-2}$, and consequently $|U| > |\overline{U}|$. This inequality and the fact that U is an independent set shows that D_n^* does not have a perfect matching. This is the easy direction of Tutte's theorem on perfect matchings. ◀

5 Open questions

A natural question that remains open is whether Winkler's conjecture holds for monotone Venn diagrams. We believe that the answer is "no", but there are no counterexamples for $n \leq 6$ (recall Figure 4). One idea to find a monotone n-Venn quadrangulation without a perfect matching for $n \geq 7$ would be to extend the local obstruction H highlighted in Figure 3, but so far we have not succeeded in this endeavor.

Computationally, it could be interesting to find all non-simple Venn diagrams for $n = 4$ or $n = 5$ curves and analyze their properties. What can be said about the asymptotic number of n-Venn diagrams as n grows, or about the proportion of diagrams with certain properties?

In addition to these questions, there is a large number of other intriguing problems on Venn diagrams, concerning symmetry, convexity, number of crossings, restrictions on the allowed shapes of the curves (triangles, rectangles etc.), to be found in the survey [15]. For example, is there a simple n-Venn diagram with rotational symmetry made of n congruent curves for every prime number n (see [8, 11, 13])?

Abstract

Let S be a set of n points in a polygon P with m vertices. The geodesic unit-disk graph $G(S)$ induced by S has vertex set S and contains an edge between two vertices whenever their geodesic distance in P is at most one. In the weighted version, each edge is assigned weight equal to the geodesic distance between its endpoints; in the unweighted version, every edge has weight 1. Given a source point $s \in S$, we study the problem of computing shortest paths from s to all vertices of $G(S)$. To the best of our knowledge, this problem has not been investigated previously. A naive approach constructs $G(S)$ explicitly and then applies a standard shortest path algorithm for general graphs, but this requires quadratic time in the worst case, since $G(S)$ may contain $\Omega(n^2)$ edges. In this paper, we give the first subquadratic-time algorithms for this problem. For the weighted case, when P is a simple polygon, we obtain an $O(m + n\log^3 n \log^2 m)$-time algorithm. For the unweighted case, we provide an $O(m + n\log n \log^2 m)$-time algorithm for simple polygons, and an $O(\sqrt{n}\,(n+m)\log(n+m))$-time algorithm for polygons with holes.

1 Introduction

Let S be a set of n points in the plane. The *unit-disk graph* induced by S has vertex set S and contains an edge between two vertices if their Euclidean distance is at most one. Equivalently, the unit-disk graph is the intersection graph of the set of congruent disks of radius 1/2 centered at the points of S: each disk corresponds to a vertex, and two disks are adjacent precisely when they intersect. Unit-disk graphs are extensively studied in computational geometry due to their rich geometric structure and numerous applications [12]. One motivation arises from wireless ad-hoc networks. Here, each point of S models a device capable of transmitting and receiving wireless signals within a fixed range, which we normalize to one. Thus, two devices can communicate directly exactly when they are connected by an edge in the corresponding unit-disk graph. Many fundamental algorithmic tasks for wireless networks reduce to classical graph problems on unit-disk graphs, such as coloring, independent set, and dominating set [12]. A central question is how to route a message between two devices s and t. If s and t are not within communication range, then the message must be relayed via intermediate devices. In graph terms, the message must follow an s-t path in the unit-disk graph, and ideally one of minimum length. For this reason, the shortest path problem in unit-disk graphs plays a key role in both theory and applications.

Another natural application of unit-disk graphs arises in motion planning with recharging/refueling. Suppose a vehicle (for example, a delivery drone) must travel from a start point s to a target point t, but lacks sufficient battery capacity to traverse this distance directly. Instead, it may need to stop at intermediate charging stations. Consider the graph

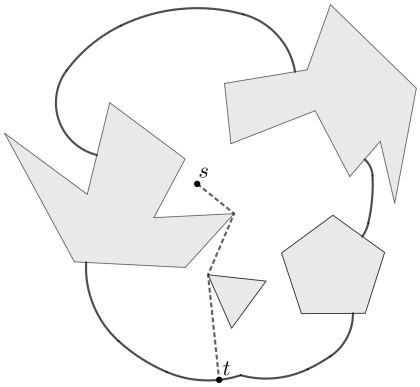

Figure 1 Illustrating a geodesic unit disk centered at s (the black solid curve is the boundary of the disk). A unit-length s-t path under geodesic distance (the dashed path) is also shown.

whose vertices represent charging stations and where two stations are connected by an edge if the vehicle can travel between them on a full charge. After scaling the maximum travel distance on a full charge to one, this graph is precisely a unit-disk graph. Thus, the motion planning problem reduces to finding a shortest s-t path in the unit-disk graph.

Now consider the above applications in the presence of obstacles that must be avoided. In wireless ad-hoc networks, an obstacle may prevent a signal from traveling directly between two devices, forcing it to bend around buildings or terrain features. In the motion planning scenario, obstacles may correspond to physical barriers or restricted regions. In such environments, Euclidean distance no longer reflects the true travel cost between two points. Instead, the relevant distance is the *geodesic distance*, i.e., the length of a shortest obstacle-avoiding path between two points. Figure 1 illustrates a "geodesic unit disk".

Problem definition. Motivated by these applications, we study *geodesic unit-disk graphs*, defined as follows. Let P be a polygonal domain with h holes and a total of m vertices in the plane. Thus, P is a closed, multiply connected region whose boundary consists of $h+1$ disjoint polygonal cycles. The holes of P, together with the region outside P, are referred to as *obstacles*. For any two points in P, their *geodesic distance* is the length of a shortest path between them in P. Let S be a set of points (also called *sites*) contained in P. The *geodesic unit-disk graph* $G(S)$ induced by S has vertex set S and contains an edge between two sites whenever their geodesic distance is at most one. In the *unweighted case*, every edge of $G(S)$ has weight 1; in the *weighted case*, the weight of an edge is the geodesic distance between its endpoints. The appropriate choice of model depends on the application. Given a source site $s \in S$, we consider the single-source shortest-path (SSSP) problem in $G(S)$: for a given polygonal domain P, site set S, and source s, compute shortest paths in $G(S)$ from s to all other vertices. To the best of our knowledge, this problem has not been studied previously.

Related work. As discussed above, problems on Euclidean unit-disk graphs (i.e., when S is given in the plane without obstacles) are well studied [12]. For the unweighted case, Cabello and Jejčič [8] gave an $O(n \log n)$-time algorithm for the SSSP problem, matching an $\Omega(n \log n)$ lower bound [8]. Chan and Skrepetos [9] later obtained an $O(n)$-time algorithm under the assumption that the points are presorted by x- and y-coordinates.

For the weighted case, Roditty and Segal [28] obtained an $O(n^{4/3+\epsilon})$-time algorithm for any $\epsilon > 0$. Cabello and Jejčič [8] improved this to $O(n^{1+\epsilon})$ time. Their runtime has since been reduced due to improvements in dynamic bichromatic closest-pair structures, first by Kaplan,

Mulzer, Roditty, Seiferth, and Sharir [20] and then by Liu [23]. Most recently, Wang and Xue [29] proposed a new algorithm that avoids dynamic bichromatic closest-pair structures, and their algorithm runs in $O(n \log^2 n)$ time; Brewer and Wang [7] further improved the time to $O(n \log^2 n / \log\log n)$ by refining a key bottleneck subproblem.

We note that various other problems involving geodesic disks in polygons have also been studied, including separators [4], clustering [5], and piercing [6], among others.

1.1 Our results

A straightforward approach is to construct $G(S)$ explicitly and then run a standard SSSP algorithm. However, $G(S)$ may contain $\Omega(n^2)$ edges, leading to quadratic time in the worst case. In this paper, we present three subquadratic-time algorithms for three problem variants.

1. For the *weighted* case, when P is a simple polygon, we obtain an $O(m + n \log^3 n \log^2 m)$-time algorithm. When applied to the Euclidean setting by taking $m = O(1)$ (i.e., P is the entire plane), our runtime is only roughly a logarithmic factor slower than the current best bound of $O(n \log^2 n / \log\log n)$ [7,29]. The Euclidean algorithms in [7,29] rely crucially on a grid decomposition of the plane, a technique that does not extend naturally to the polygon setting since a grid cell may be fragmented into multiple disconnected components by the boundary of P. We therefore use a different algorithmic strategy.
2. For the *unweighted* case in a simple polygon, we give an $O(m + n \log n \log^2 m)$-time algorithm. Applied to the Euclidean setting, this matches the $\Omega(n \log n)$ lower bound [8].
3. When P has holes, the problem becomes substantially more challenging. For the unweighted case in this setting, we develop an $O(\sqrt{n}\,(n+m)\log(n+m))$-time algorithm.

Our techniques involve solving two subproblems that may be interesting in their own rights. Indeed, solving these problems is one of the major contributions of this paper.

Subproblem 1: Deletion-only geodesic unit-disk range emptiness queries. In this problem, we preprocess a set S of n points inside a simple polygon P of m vertices to support two operations: (1) given a query point q, determine whether there exists a point $p \in S$ whose geodesic distance to q is at most 1, and if so return such a point; and (2) delete a point from S. We refer to the first operation as a *geodesic unit-disk range emptiness (GUDRE)* query.

Using the dynamic randomized nearest neighbor data structure of Agarwal, Arge, and Staals [1], each deletion can be supported in $O(\log^7 n \log m + \log^6 n \log^3 m)$ expected amortized time, and each GUDRE query can be answered in $O(\log^2 n \log^2 m)$ time. In the Euclidean case (i.e., when P is the entire plane), one can preprocess S in $O(n \log n)$ time and support both queries and deletions in $O(\log n)$ time [14,30].

We obtain the following result. After an $O(m)$-time *global* preprocessing step for P, we can, for any given set S of n points in P, build a data structure in $O(n \log^3 m + n \log^2 m \log n)$ time such that deletions take $O(\log n \log^3 m)$ amortized time and GUDRE queries take $O(\log n \log^2 m)$ time. Our result is remarkable in three aspects. First, compared to applying [1], our result improves deletion time by a factor of $O(\log^5 n)$ and improves query time by a factor of $O(\log n)$, while being deterministic rather than randomized (note that [1] also supports insertions and more general queries). Second, when applied to the Euclidean case (with $m = O(1)$), our bounds match the optimal Euclidean results of [14,30]. Third, our result has an interesting *implicit* nature: after the global preprocessing of P, the construction time for any given S depends only logarithmically on m.

Subproblem 2: Implicit additively weighted geodesic Voronoi diagram. In this problem, we wish to construct a nearest neighbor data structure for a set S of n additively weighted points in a simple polygon P with m vertices, under the requirement that the data structure be *implicitly* constructed. That is, after a global preprocessing of P, the time to build the data structure for S should depend only logarithmically on m. Such a data structure is referred to as an *implicit Voronoi diagram*.

An *explicit* diagram for S can be built in $O((n+m)\log(n+m))$ time [19], after which weighted nearest neighbor queries can be answered in $O(\log(n+m))$ time via standard point location queries [13, 21]. However, this explicit approach cannot be used in the implicit setting, as even constructing a point location data structure requires $\Omega(m)$ time.

For the unweighted version of this implicit problem, the method in [1] obtains the following: after $O(m)$-time global preprocessing, one can build a structure for S in $O(n \log n \log m + n \log^3 m)$ time that answers nearest neighbor queries in $O(\log n \log^2 m)$ time.

The weighted case is more challenging, as several geometric properties used in [1] no longer hold in the presence of weights. We develop a new method and show that, after $O(m)$-time global preprocessing of P, a data structure for S can be built in $O(n \log n \log^2 m \ + \ n \log^3 m)$ time, and each weighted nearest neighbor query can be answered in $O(\log n \log^2 m)$ time.

Outline. In the rest of the paper, after introducing preliminary concepts in Section 2, we present our algorithm for the weighted case in simple polygons in Section 3. This algorithm relies on the solutions to the two subproblems. Section 4 discusses the first subproblem. For the unweighted case, we describe our algorithm for simple polygons in Section 5, and extend it to polygons with holes in Section 6. Thus, Section 6 is the only section dealing with polygons with holes. Due to space constraints, many details and proofs are omitted but can be found in the full paper.

2 Preliminaries

We follow the notation in Sect. 1, e.g., m, n, S, P, s, and $G(S)$. Throughout the paper, P is a simple polygon unless stated otherwise (an exception is Sect. 6, where P may have holes).

We use $\overline{pq}$ to denote the line segment connecting points p and q, and $|\overline{pq}|$ to denote its (Euclidean) length. For any geometric object R in the plane, let ∂R denote its boundary.

For any two points $s, t \in P$, let $\pi(s,t)$ denote a shortest s-t path in P. If multiple shortest paths exist (which can happen only when P has holes), $\pi(s,t)$ may refer to an arbitrary one. Let $d(s,t)$ denote the geodesic distance between s and t, i.e., the length of $\pi(s,t)$. We assume that $\pi(s,t)$ is oriented from s to t. It is known that every interior vertex of $\pi(s,t)$ (i.e., except s and t) is a vertex of P. The vertex of $\pi(s,t)$ adjacent to t is called the *anchor* of t in $\pi(s,t)$, and the vertex of $\pi(s,t)$ adjacent to s is called the *anchor* of s.

Notation for the simple polygon case. When P is a simple polygon, for any three points $s, t, r \in P$, the vertex of $\pi(s,t) \cap \pi(s,r)$ farthest from s is called the *junction vertex* of $\pi(s,t)$ and $\pi(s,r)$. For a point $s \in P$ and a segment $\overline{tr} \subseteq P$, let c be the junction vertex of $\pi(s,t)$ and $\pi(s,r)$. Following standard terminology [16, 22], the paths $\pi(c,t)$ and $\pi(c,r)$ together with $\overline{tr}$ form a *funnel*, denoted $F_s(\overline{tr})$; see Figure 2. The point c is the *cusp* of the funnel, and $\pi(c,t)$ and $\pi(c,r)$ are the two *sides*, each of which is a concave chain.

When P is a simple polygon, we will frequently use the data structure of Guibas and Hershberger [15, 17], referred to as the *GH data structure*. It can be built in $O(m)$ time and supports computing $d(s,t)$ in $O(\log m)$ time for any $s, t \in P$. It can also return the anchors

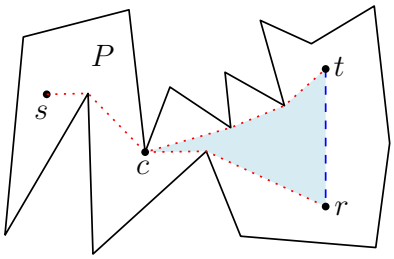

Figure 2 Illustrating a funnel $F_s(\overline{tr})$ (the light blue region).

of s and t on $\pi(s,t)$, and even a compact representation of $\pi(s,t)$ that supports binary search along the path. Furthermore, it can compute the junction vertex of $\pi(s,t)$ and $\pi(s,r)$ for any $s,t,r \in P$.

Balanced polygon decomposition (BPD). For a simple polygon P, we will use a *balanced polygon decomposition* (BPD) [11, 15, 16]. A line segment inside P connecting two vertices of P that is not an edge of P is called a *diagonal*. Chazelle [10] proved that P must contain a diagonal d that partitions P into two subpolygons, each with at most $2n/3$ vertices. Recursively decomposing the subpolygons until each becomes a triangle yields the BPD.

The BPD can be represented by a tree T_P, called the *BPD-tree*. Each node v of T_P corresponds to a subpolygon P_v of P: the root corresponds to P itself, and each leaf corresponds to a triangle. Let d_v denote the diagonal used to split P_v into its two child subpolygons. The triangles at the leaves of T_P form a triangulation of P. The entire decomposition and T_P can be constructed in $O(m)$ time [15].

Geodesic Voronoi diagram. We will also make extensive use of the *geodesic Voronoi diagram* of S in P [2, 19, 24, 27]. For a site $u \in S$, its *Voronoi region* is defined as

$$\mathrm{Vor}(u) = \{p \in P : d(u,p) \le d(v,p) \text{ for all } v \in S \setminus \{u\}\}.$$

We treat $\mathrm{Vor}(u)$ as including its boundary. For two sites $u, v \in S$, the *Voronoi edge* $\mathcal{E}(u,v)$ is the locus of points $p \in P$ satisfying $d(u,p) = d(v,p) \le d(z,p)$ for all $z \in S \setminus \{u,v\}$.

If P is a simple polygon, then $\mathcal{E}(u,v)$ has a single connected component [2], while in general polygonal domains it may have multiple components [19]. Each component consists of a sequence of hyperbolic arcs (including line segments as a degenerate case). We do not use special notation for *Voronoi vertices*, i.e., points equidistant to at least three sites and strictly farther from all others. Let $\mathcal{VD}(S)$ denote the geodesic Voronoi diagram of S in P.

The definitions extend naturally to the additively weighted case. Each site u has a weight $w(u)$, and the *weighted distance* from u to any $p \in P$ is $w(u) + d(u,p)$. Replacing geodesic distances by weighted distances yields the weighted geodesic Voronoi diagram. Note that all weights considered in this paper are additive.

3 The weighted case in a simple polygon

We now consider the SSSP problem in weighted geodesic unit-disk graphs within a simple polygon. Here, S lies inside a simple polygon P, and for every edge $e(u,v)$ of $G(S)$ connecting two sites $u, v \in S$, the weight of $e(u,v)$ is defined to be the geodesic distance $d(u,v)$.

To solve the problem, as discussed in Section 1.1, it seems difficult to extend the Euclidean case algorithm in [7, 29]. Another direction is to extend the $O(n^{1+\epsilon})$-time algorithm of Cabello and Jejčič [8], which relies on a dynamic weighted *bichromatic closest pair (BCP)*

data structure. Combining with the randomized dynamic BCP structures [20,23], the runtime improves to $O(n \log^4 n)$ expected time. But this approach does not seem to generalize to the polygon case due to the lack of an efficient dynamic weighted BCP structure under geodesic distance.

We instead take a different approach that avoids BCP altogether. Our algorithm runs in $O(m + n \log^3 n \log^2 m)$ deterministic time. Notably, when applied to the Euclidean case by treating P as the whole plane (i.e., $m = O(1)$), the running time becomes $O(n \log^3 n)$, which is even faster than the algorithm of [8] combined with dynamic BCP structures [20, 23].

In what follows, we first describe the algorithm and then discuss its implementation.

3.1 Algorithm description

Given a source point $s \in S$, our goal is to compute shortest paths from s to all other vertices v in $G(S)$. Let $d_G(v)$ denote the shortest-path distance from s to v in $G(S)$. Our algorithm maintains an array $\mathrm{dist}[\cdot]$ such that, at termination, $\mathrm{dist}[v] = d_G(v)$ for all $v \in S$. With standard modifications, the predecessor information can also be maintained so that the shortest path tree from s can be obtained.

We maintain two subsets A and B of S. The set A consists of all sites v whose values $\mathrm{dist}[v]$ have been finalized, and $B = S \setminus A$. We further partition A into two subsets, A_1 and A_2, such that no site of A_1 is adjacent to any site of B in $G(S)$. Initially, we set $\mathrm{dist}[s] = 0$, $A_2 = A = \{s\}$, $A_1 = \emptyset$, and $B = S \setminus \{s\}$. We also initialize $\mathrm{dist}[v] = \infty$ for every $v \in S \setminus \{s\}$.

In each iteration, we select $a = \arg\min_{v \in A_2} \mathrm{dist}[v]$, and perform two subroutines:

Subroutine I. Compute the set $B_a = \{\, b \in B : d(a, b) \le 1 \,\}$, i.e., all sites in B that are adjacent to a in $G(S)$.

Subroutine II. For each site $b \in B_a$, compute $\sigma_b = \arg\min_{p \in A_2} \big(\mathrm{dist}[p] + d(p, b)\big)$, and set $\mathrm{dist}[b] = \mathrm{dist}[\sigma_b] + d(\sigma_b, b)$.

Afterward, we move all sites of B_a from B into A_2, and we move a from A_2 into A_1. This completes one iteration. The algorithm terminates once A_2 becomes empty.

Algorithm correctness. Although the algorithm looks simple, its correctness is not immediate. See the full paper for the proof. In particular, we show that the algorithm maintains the following two invariants. (I) For every site $v \in A$, we have $\mathrm{dist}[v] = d_G(v)$. (II) For every site $v \in A_1$, every site u adjacent to v in $G(S)$ is already in A. Using these, we can show that after the algorithm terminates, $\mathrm{dist}[v] = d_G(v)$ holds for every site $v \in S$.

3.2 Algorithm implementation and time analysis

The main difficulty lies in implementing the two subroutines efficiently. Indeed, each subroutine corresponds precisely to one of the two subproblems introduced in Section 1.1.

We maintain the set A_2 in a min-heap with $\mathrm{dist}[v]$ as the key for all $v \in A_2$. Thus, extracting $a = \arg\min_{v \in A_2} \mathrm{dist}[v]$ takes $O(\log n)$ time, and each insertion into A_2 also takes $O(\log n)$ time. We now discuss the implementation of the two subroutines.

Subroutine I. To compute B_a, we repeatedly locate a point $b \in B$ with $d(a, b) \le 1$ and delete it from B, stopping once no such point remains. Thus, the task reduces exactly to supporting *deletion-only geodesic unit-disk range emptiness* (GUDRE) queries, as introduced in Section 1.1. Given a set B of points in P, we require a data structure that supports:

Delete: Remove a point from B.
GUDRE query: Given a point $a \in P$, determine whether there exists $b \in B$ with $d(a, b) \leq 1$, and if so, return such a point.

One of our main results in this paper is the following theorem, proved in Section 4.

▶ **Theorem 1.** *Let P be a simple polygon with m vertices, and assume that a GH data structure for P has been built in $O(m)$ time. For any set S of n points in P, we can construct a data structure for S in $O(n \log^3 m + n \log n \log^2 m)$ time such that each deletion takes $O(\log n \log^3 m)$ amortized time and each GUDRE query takes $O(\log n \log^2 m)$ time.*

Using Theorem 1, we implement Subroutine I as follows. Initially, $B = S \setminus \{s\}$. We build the GUDRE data structure for B in $O(m + n \log^3 m + n \log n \log^2 m)$ time, where the $O(m)$ term is for constructing the GH data structure. Since the algorithm performs $O(n)$ deletions and GUDRE queries overall, the total time spent in Subroutine I is $O(m + n \log n \log^3 m)$.

Subroutine II. For the second subroutine, observe that each σ_b is essentially the (additively) *weighted nearest neighbor* of b in A_2, where each site $p \in A_2$ has weight $\mathrm{dist}[p]$, and the weighted distance from p to a query point q is defined as $\mathrm{dist}[p] + d(p, q)$. Thus, we require a weighted nearest neighbor data structure for A_2.

Furthermore, since at the end of each iteration, we will move all points of B_a from B to A_2 and move a from A_2 to A_1, we need a dynamic data structure for A_2 that supports both insertions and deletions. A direct dynamic data structure supporting both insertions and deletions appears difficult to obtain. However, we show that the problem can be reduced so that only insertions are needed. The key is the following Lemma 2.

▶ **Lemma 2.** *For any site $p_1 \in A_1$ and any site $p_2 \in A_2$, we have $\mathrm{dist}[p_1] \leq \mathrm{dist}[p_2]$. Moreover, whenever a site b is added to A_2, we have $\mathrm{dist}[a] < \mathrm{dist}[b]$, and $\mathrm{dist}[p_1] < \mathrm{dist}[b]$ holds for all $p_1 \in A_1$.*

We maintain a balanced binary search tree T_A whose leaves store the sites of A in increasing order of $\mathrm{dist}[\cdot]$. By Lemma 2, the points of A can always be arranged so that all sites of A_1 appear to the left of all sites of A_2; we refer to this as the *ordering property* of T_A. For each node v of T_A, let A_v denote the set of sites whose leaves lie in the subtree rooted at v. For each v, we construct a weighted nearest neighbor data structure $\mathcal{D}_v$ for A_v, where each $p \in A_v$ has weight $\mathrm{dist}[p]$.

Given a point $b \in B$, we compute σ_b as follows. Because of the ordering property and the definition of a, all sites of $A_2 \setminus \{a\}$ lie in leaves strictly to the right of the leaf of a. In T_A, we find a set V_b of $O(\log n)$ nodes whose leaf ranges form a partition of the leaves to the right of a (including the leaf of a). For each $v \in V_b$, using $\mathcal{D}_v$, we compute a weighted nearest neighbor p_v of b in A_v and treat each p_v as a candidate for σ_b. We then return the candidate minimizing $\mathrm{dist}[p_v] + d(p_v, b)$. Thus, computing σ_b requires $O(\log n)$ weighted nearest neighbor queries plus $O(\log n)$ geodesic distance queries. Recall that a GH data structure for P can be built in $O(m)$ time, after which each distance query $d(p_v, b)$ is computable in $O(\log m)$ time.

Next we address updates. At the end of each iteration, for every $b \in B_a$, after computing $\mathrm{dist}[b]$, we insert b into T_A. This places b at a leaf, and for each node v on the path to the root, we insert b into $\mathcal{D}_v$. By Lemma 2, the ordering property of T_A is preserved automatically. Therefore, there is no need to delete a from T_A, and each $\mathcal{D}_v$ need only support insertions.

To build an insertion-only data structure $\mathcal{D}_v$, one might attempt Bentley's logarithmic method [3] together with a static geodesic Voronoi diagram for A_v. Since computing the geodesic Voronoi diagram of A_v in P requires $\Omega(m)$ time (note that the best algorithm

can compute the diagram in $O(m + |A_v| \log |A_v|)$ time [24]), rebuilding these diagrams n times would lead to $\Omega(mn)$ total time, which is too slow. Instead, we require an *implicit* construction whose dependence on m is only polylogarithmic. This is exactly the subproblem introduced in Section 1.1. In the full paper, we establish the following result.

▶ **Theorem 3.** *Let P be a simple polygon with m vertices, and assume that a GH data structure for P has been built in $O(m)$ time. Given a set S of n weighted sites in P, we can construct a weighted nearest neighbor data structure for S in $O(n \log^3 m + n \log n \log^2 m)$ time such that each query can be answered in $O(\log n \log^2 m)$ time.*

With Theorem 3, we construct $\mathcal{D}_v$ for every node v of T_A. Using Bentley's method, each insertion into $\mathcal{D}_v$ takes amortized $O(\log n \log^3 m + \log^2 n \log^2 m)$ time. Each weighted nearest neighbor query takes $O(\log^2 n \log^2 m)$ time. Since T_A has height $O(\log n)$, computing σ_b takes $O(\log^3 n \log^2 m)$ time, and inserting a site b into T_A takes amortized $O(\log^2 n \log^3 m + \log^3 n \log^2 m)$ time. Thus, the total running time of Subroutine II over the entire algorithm is $O(m + n \log^2 n \log^3 m + n \log^3 n \log^2 m)$, including the $O(m)$ time required to build the GH data structure for P in Theorem 3. It is actually bounded by $O(m + n \log^3 n \log^2 m)$.

▶ **Theorem 4.** *The SSSP problem in the weighted geodesic unit-disk graph in a simple polygon of m vertices for a set of n points can be solved in $O(m + n \log^3 n \log^2 m)$ time.*

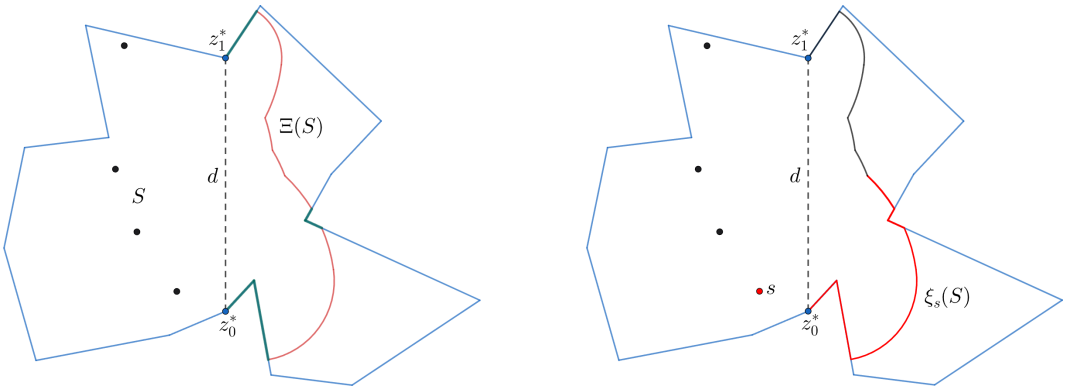
4 Deletion-only geodesic unit-disk range emptiness (GUDRE) queries

In this section, we prove Theorem 1 for the deletion-only GUDRE query problem. The problem can be reduced to a *diagonal-separated* problem by using the balanced polygon decompositions (BPD) of simple polygons as described in Section 2.

Diagonal-separated deletion-only GUDRE queries. Consider a diagonal d that partitions P into two subpolygons P_L and P_R. In the diagonal-separated setting, we assume that all points of S lie in P_L, and every query point q lies in P_R. We have the following result.

▶ **Lemma 5.** *Let P be a simple polygon with m vertices, and assume that a GH data structure has been built for P. Given a diagonal d that partitions P into two subpolygons P_L and P_R, and a set S of n points contained in P_L, we can construct a data structure for S in $O(n \log^2 m + n \log n \log m)$ time that supports the following operations:*

1. Delete: *delete a point from S in $O(\log n \log^2 m)$ amortized time.*
2. GUDRE query: *for any query point $q \in P_R$, determine whether there exists a point $p \in S$ with $d(p, q) \leq 1$, and if so, return such a point as a witness, in $O(\log n \log m)$ time.*



Theorem 1 can be proved using Lemma 5 and the BPD of P.

4.1 Proof of Lemma 5 – a very brief sketch

We give a very brief sketch of the proof of Lemma 5. See the full paper for all details. We follow the notation in the lemma statement, e.g., P, S, d, P_L, P_R, n, m. Without loss of generality, we assume that d is vertical and P_R is locally to the right of d. Let z_0^* and z_1^* denote the lower and upper endpoints of d, respectively.

For each point $p \in P$, we define D_p as the *geodesic unit-disk* centered at p, which consists of all points $q \in P$ with $d(p, q) \leq 1$. We define ∂P_R to be $\partial P \cap P_R$.

For any query point $q \in P_R$, we need to know whether $D_q \cap S = \emptyset$. Observe that $D_q \cap S \neq \emptyset$ if and only if $q \in \cup_{p \in S} D_p$. Based on this observation, our strategy is to maintain an implicit representation of $\mathcal{D}_R(S)$, where $\mathcal{D}_R(S)$ is the portion of $\cup_{s \in S} D_s$ in P_R. To this end, we propose a concept *right envelope* as follows.

(a) $\Xi^\circ(S)$ is red and $\Xi^\diamond(S)$ is green.

(b) $\xi_s(S)$ is colored with red.

Figure 3 Illustrations of $\Xi(S)$. The region bounded by $\Xi(S)$ and d is $\mathcal{D}_R(S)$.

Right envelope. Roughly speaking, the *right envelope* $\Xi(S)$ of $\mathcal{D}_R(S)$ is the boundary of $\mathcal{D}_R(S)$ excluding d. Specifically, $\Xi(S)$ is union of $\Xi^\circ(S)$ and $\Xi^\diamond(S)$, with $\Xi^\circ(S) = \{p \in P_R : d(S,p) = 1\}$ and $\Xi^\diamond(S) = \{p \in \partial P_R : d(S,p) < 1\}$. In general, $\Xi^\circ(S)$ is a collection of circular arcs each belonging to ∂D_s for some point $s \in S$, while $\Xi^\diamond(S)$ is a collection of segments on ∂P_R; see Figure 3a.

Note that $\mathcal{D}_R(S)$ may have multiple connected components. We can show that for each connected component $\mathcal{D}$ of $\mathcal{D}_R(S)$, $\mathcal{D} \cap d$ consists of a single segment of d and $\mathcal{D}$ is simply connected (i.e., there are no holes), meaning that $\partial\mathcal{D}$ is composed of a segment of d and a simple curve connecting the two endpoints of $\mathcal{D} \cap d$.

For any point $s \in S$, define $\xi_s(S)$ as the set of points $p \in \Xi(S)$ such that $d(s,p) \le d(s',p)$ for any other point $s' \in S$. In other words, if we consider the geodesic Voronoi diagram $\mathcal{VD}(S)$ of S, then $\xi_s(S)$ consists of all points $p \in \Xi(S)$ in the Voronoi region of s; see Figure 3b. A useful property is that if $\xi_s(S) \neq \emptyset$, then $\xi_s(S)$ is a single connected portion of $\Xi(S)$.

Answering queries using the right envelope. Intuitively, for any point $q \in P_R$, $q \in \mathcal{D}_R(S)$ if and only if q is "to the left of" $\Xi(S)$. However, the question is how to interpret "left."

In the Euclidean case where P is the entire plane and d becomes a vertical line, $\Xi(S)$ is a y-monotone curve. Due to this property, there is a trivial way to determine whether q is to the left of $\Xi(S)$: First find by binary search the arc of $\Xi(S)$ intersecting the horizontal line through q, and then determine whether q is to the left of the arc [14, 30].

In our problem, however, $\Xi(S)$ is no longer y-monotone. Intuitively, this is because P is not "large enough" and ∂P changes the "shape" of $\Xi(S)$. Thus, we need a new approach. At a very high level, our strategy is to develop some concepts analogous to those in the Euclidean case. Specifically, we introduce an order $\prec_R$ for any two points of P_R; this order corresponds to the y-coordinate order in the Euclidean case. We also define a *traversal order* $\prec_\Xi$ for any two points of $\Xi(S)$; in the Euclidean case, this would be the order of traversing on $\Xi(S)$ from bottom to top as $\Xi(S)$ is y-monotone. In addition, we define an order $\prec_L$ for all points of S based on their geodesic distances to the lower endpoint z_0^* of d (i.e., for any two points $s, t \in S$, define $s \prec_L t$ if $d(s, z_0^*) < d(t, z_0^*)$). A useful property is that these three orders are consistent with each other, which is crucial to the success of our approach.

A brief data structure description. Our data structure $\Psi(S)$ is a complete binary tree whose leaves from left to right store the points of S under the order $\prec_L$. For each node v, let S_v be the subset of points S stored in the leaves of the subtree rooted at v. We wish to store an implicit representation of $\Xi(S_v)$ at v. Let $I(S_v)$ be the set of points $s \in S_v$ such that $\xi_s(S_v) \neq \emptyset$. We consider $I(S_v)$ a list of its points sorted under $\prec_L$.

If v is the root, then we store $I(S_v)$ at v explicitly. If we store $I(S_v)$ at v explicitly for all nodes $v \in \Psi(S)$, then $\Psi(S)$ would take super-linear space. We instead employ a standard space saving technique [18, 26], where we store a point $s \in S$ in the highest node v such that $s \in I(S_v)$. Using this strategy, the total space of $\Psi(S)$ is $O(n)$.

For a node v with left child u and right child w, define $r_u = \max_{\prec_L} I(S_v) \cap I(S_u)$, i.e., among all points in $I(S_v) \cap I(S_u)$, r_u is the largest one following the order $\prec_L$. Symmetrically, define $r_w = \min_{\prec_L} I(S_v) \cap I(S_w)$. We can show that $I(S_u) \cap I(S_v)$ is a prefix of $I(S_u)$ and $I(S_w) \cap I(S_v)$ is a suffix of $I(S_w)$. Hence, $I(S_v)$ is the concatenation of $I(S_u)_{\leq r_u}$ and $I(S_w)_{\geq r_w}$, where the notation $I(S_u)_{\leq r_u}$ represents the prefix of $I(S_u)$ up to and including r_u and $I(S_w)_{\geq r_w}$ represents the suffix of $I(S_w)$ from and including r_w. We store both r_u and r_w at v. As $I(S_v)$ is the concatenation of $I(S_u)_{\leq r_u}$ and $I(S_w)_{\geq r_w}$, we only store $I(S_u)_{>r_u}$ in a list $arcs(u)$ at u and similarly store $I(S_w)_{<r_w}$ in $arcs(w)$ at w. This means that in a descent from the root of $\Psi(S)$, we can do the following. Let v be the current node in our descent and assume $arcs(v) = I(S_v)$, which is true initially when v is the root. Suppose v has left child u and right child w. We can cut $arcs(v)$ at r_u to obtain $I(S_u)_{\leq r_u}$ and $I(S_w)_{\geq r_w}$. As $I(S_u)_{>r_u}$ is stored in $arcs(u)$, we can concatenate $I(S_u)_{\leq r_u}$ and $I(S_u)_{>r_u}$ to obtain $I(S_u)$. We can do likewise to obtain $I(S_w)$. In an ascent, we can simply reverse this process to obtain $I(S_v)$ from $I(S_u)$ and $I(S_w)$ using r_u and r_w. To facilitate the queries, additional information will also be maintained such as the endpoints of $\xi_s(S_v)$ for each point $s \in arcs(v)$.

5 The unweighted simple polygon case

In this section, we present our SSSP algorithm for unweighted $G(S)$ when P is a simple polygon. To solve the problem, a natural idea is to see whether the algorithms for the Euclidean case can be adapted. Two algorithms are known that can solve the Euclidean case in $O(n \log n)$ time [8, 9]. The algorithm in [9] relies on constructing a grid in the plane, which seems inherently not applicable to the polygon setting as explained in Section 1.1.

We therefore adapt the approach of [8]. After introducing notation, we first describe the algorithm at a high level and then discuss its implementation and time analysis.

5.1 Notation

We follow the notation already defined in Sections 1 and 2, including m, n, S, P, s, $G(S)$, $\mathcal{VD}(S)$, $\mathcal{E}(u, v)$, $\mathrm{Vor}(u)$. For any subset $S' \subseteq S$ and a point $p \in P$, let $\beta_p(S')$ denote the nearest neighbor of p in S' and $d(S', p) = \min_{q \in S'} d(q, p)$. Note that $d(\beta_p(S'), p) = d(S', p)$.

We define S_i for $i = 0, 1, 2, \ldots$ to be the set of vertices of $G(S)$ whose shortest path lengths from s in $G(S)$ are equal to i. Clearly, $S_0 = \{s\}$. Define $S_{\leq i} = \cup_{j \leq i} S_j$.

Our goal is to compute the sets S_i, for $i = 0, 1, 2, \ldots$. In our discussion, we will focus on describing the algorithm to compute these sets. By slightly modifying the algorithm, we can also compute the predecessor information of the shortest paths.

Let $V(P)$ denote the set of vertices of P, which are also referred to as *obstacle vertices*. For ease of exposition, we make the following general position assumptions: (1) the shortest paths in P between any two points in $V(P) \cup S$ are unique, and (2) no point in $V(P) \cup S$ is equidistant (in geodesic distance) to two other points in $V(P) \cup S$. Note that the second

assumption implies that no obstacle vertex lies on a Voronoi edge of $\mathcal{VD}(S)$, which further means that each Voronoi edge of $\mathcal{VD}(S)$ is one-dimensional. The second assumption also implies that the nearest neighbor of a site $p \in S$ in any subset $S' \subseteq S$, i.e., $\beta_p(S')$, is unique.

We use $\mathcal{DT}(S)$ to denote the dual graph of $\mathcal{VD}(S)$. Specifically, the vertex set of $\mathcal{DT}(S)$ is S, and two sites $u, v \in S$ have an edge in $\mathcal{DT}(S)$ if their Voronoi regions in $\mathcal{VD}(S)$ share a Voronoi edge, i.e., $\mathcal{E}(u, v) \neq \emptyset$. For any site $u \in S$, we define $N_{\mathcal{DT}}(u)$ as the set of vertices of $\mathcal{DT}(S)$ adjacent to u; we also refer to sites of $N_{\mathcal{DT}}(u)$ as *neighbors* of u in $\mathcal{DT}(S)$. For a subset $S' \subseteq S$, by slightly abusing the notation, we let $N_{\mathcal{DT}}(S') = \bigcup_{u \in S'} N_{\mathcal{DT}}(u)$.

5.2 Algorithm description

We first construct the geodesic Voronoi diagram $\mathcal{VD}(S)$. The algorithm then proceeds in iterations. Initially, we have $S_0 = \{s\}$. In the i-th iteration for $i \geq 1$, we compute the set S_i as follows. We assume that S_{i-1} is available. Let $Q = N_{\mathcal{DT}}(S_{i-1}) \setminus S_{\leq i-1}$, i.e., the sites in S adjacent to those of S_{i-1} in $\mathcal{DT}(S)$ but not in $S_{\leq i-1}$. For each site $p \in Q$, we remove p from Q and determine whether $d(S_{i-1}, p) \leq 1$. If so, we add p to S_i. In addition, we update $Q = Q \cup (N_{\mathcal{DT}}(p) \setminus S_{\leq i})$, i.e., add the sites of $N_{\mathcal{DT}}(p)$ that are not in $Q \cup S_{\leq i}$ to Q for the current S_i. We repeat this until Q becomes empty. The i-th iteration finishes once Q become empty. If $S_i = \emptyset$, then the algorithm stops; otherwise, we proceed with the next iteration. See Algorithm 1 for the pseudocode.

Correctness. It is not obvious why the algorithm is correct. See the full paper for the proof.

Algorithm 1 SSSP algorithm for the simple polygon case.

```
1  i ← 0, S_0 ← {s}, build VD(S) and DT(S);
2  while S_i ≠ ∅ do
3  |  i ← i + 1, S_i ← ∅;
4  |  Q ← N_DT(S_{i-1}) \ S_{≤i-1} ;
5  |  while Q ≠ ∅ do
6  |  |  p ← pop(Q);
7  |  |  if d(S_{i-1}, p) ≤ 1 then
8  |  |  |  S_i ← S_i ∪ {p};
9  |  |  |  Q ← Q ∪ (N_DT(p) \ S_{≤i}) ;
10 return S_i for i = 0, 1, ...;
```

5.3 Algorithm implementation and time analysis

First of all, computing $\mathcal{VD}(S)$ can be done in $O(m + n \log n)$ time [24] (see also [2, 25, 27] for other algorithms). Note that the combinatorial size of $\mathcal{VD}(S)$ is $O(n + m)$ [2]. Therefore, $\mathcal{DT}(S)$ can be obtained from $\mathcal{VD}(S)$ in additional linear time. In addition, since $\mathcal{DT}(S)$ has n vertices and is a planar graph, $\mathcal{DT}(S)$ has $O(n)$ edges.

Throughout the whole algorithm, each edge of $\mathcal{DT}(S)$ is considered at most four times (twice for each vertex) in the construction of the neighborhood sets. Specifically, the edge (u, v) for $u \in S_i$ will be considered by Line 9 in the i-th iteration and by Line 4 in the $i+1$-th iteration. There are $O(n)$ edges in $\mathcal{DT}(S)$, so there are at most $O(n)$ insertions (and thus pop operations) to Q. Hence, the while loop on Line 5 has at most $O(n)$ iterations throughout the whole algorithm. It remains to determine the time complexity for the operation of checking whether $d(S_{i-1}, p) \leq 1$ on Line 7.

Notice that $d(S_{i-1}, p) \leq 1$ if and only if S_{i-1} has a point q with $d(q, p) \leq 1$. Hence, the problem can be solved by a geodesic unit-disk range emptiness (GUDRE) query. Using Theorem 1, we construct a GUDRE data structure for S_{i-1} in $O(|S_{i-1}| \cdot (\log^3 m + \log n \log^2 m))$ time at the beginning of each i-th iteration of Algorithm 1. Using a GUDRE query, whether $d(S_{i-1}, p) \leq 1$ can be determined in $O(\log n \log^2 m)$ time by Theorem 1. Note that no deletions on S_{i-1} are needed. Since $\sum_i |S_{i-1}| = n$, the overall time for constructing the GUDRE data structure for S_{i-1} in all iterations of the algorithm is $O(n(\log^3 m + \log n \log^2 m))$.

We conclude that the total time of the algorithm is $O(m + n \log n + n(\log^3 m + \log n \log^2 m))$, which is $O(m + n \log n \log^2 m)$.

▶ **Theorem 6.** *Given a simple polygon P of m vertices, a set S of n points in P, and a source point $s \in S$, we can compute shortest paths from s to all points of S in the geodesic unit-disk graph of S in $O(m + n \log n \log^2 m)$ time.*

6 The unweighted polygonal domain case

When P is a polygonal domain with holes, the framework of Algorithm 1 continues to apply. The main difficulty is algorithmic. Unlike the simple polygon setting, we do not have an efficient analogue of Theorem 1 for polygonal domains (even without deletions) that would allow us to evaluate the condition $d(S_{i-1}, p) \leq 1$ on Line 7.

As before, the algorithm proceeds in iterations, with the ith iteration responsible for computing S_i. Our key idea is to distinguish between iterations based on the size of S_i. If $|S_i| \geq \sqrt{n}$, we classify the iteration as *heavy*; otherwise, it is *light*. We design separate procedures for these two types, referred to as the *heavy-iteration procedure* and the *light-iteration procedure*, respectively. At the start of iteration i, the value of $|S_i|$ is not known in advance. Our strategy is therefore to always begin with the light-iteration procedure. If, during its execution, more than $\sqrt{n}$ sites are discovered for S_i, we immediately abort the light-iteration procedure and switch to the heavy-iteration procedure.

A useful observation is that there can be at most $\sqrt{n}$ heavy iterations, since the sets $S_1, S_2, \ldots$ are disjoint, their union is S, and each heavy iteration has at least $\sqrt{n}$ sites.

We only give a very brief sketch below. See the full paper for the details. We follow the notation and the discussion in Section 5.1. While the heavy-iteration procedure is relatively easy, the light procedure is quite interesting.

Heavy-iteration procedure. We compute the geodesic Voronoi diagram $\mathcal{VD}(S_{i-1})$ of S_{i-1} in P in $O((|S_{i-1}| + m) \log(|S_{i-1}| + m))$ time. With the diagram and a point location data structure, for each site $p \in S \setminus S_{\leq i-1}$, we can compute $\beta_p(S_{i-1})$ and its geodesic distance from p in $O(\log(m + |S_{i-1}|))$ time [19]; note that their geodesic distance is $d(S_{i-1}, p)$. If $d(S_{i-1}, p) \leq 1$, we add p to S_i. This computes S_i in $O((|S_i| + m) \log(|S_{i-1}| + m) + n \log(|S_{i-1}| + m))$ time, which is $O((n + m) \log(n + m))$. Since the number of heavy iterations in the entire algorithm is $O(\sqrt{n})$, the total time of all heavy procedures in the algorithm is $O(\sqrt{n}(n + m) \log(n + m))$.

Light-iteration procedure. The procedure runs in rounds, and each round computes at least one new point for S_i. If a round does not compute any new point for S_i, then we can assert that all sites of S_i have been computed. If after a round $|S_i|$ becomes larger than or equal to $\sqrt{n}$, then we terminate the procedure and switch to the heavy-iteration procedure.

In each round, we search in the neighborhoods of the sites of S_{i-1} and the current S_i. We find that we do not need $\mathcal{VD}(S_{i-1})$ in the entire P to conduct this search, and only a "small portion" of it suffices. More specifically, suppose there is a shortest path $\pi(S_{i-1}, v)$ from a

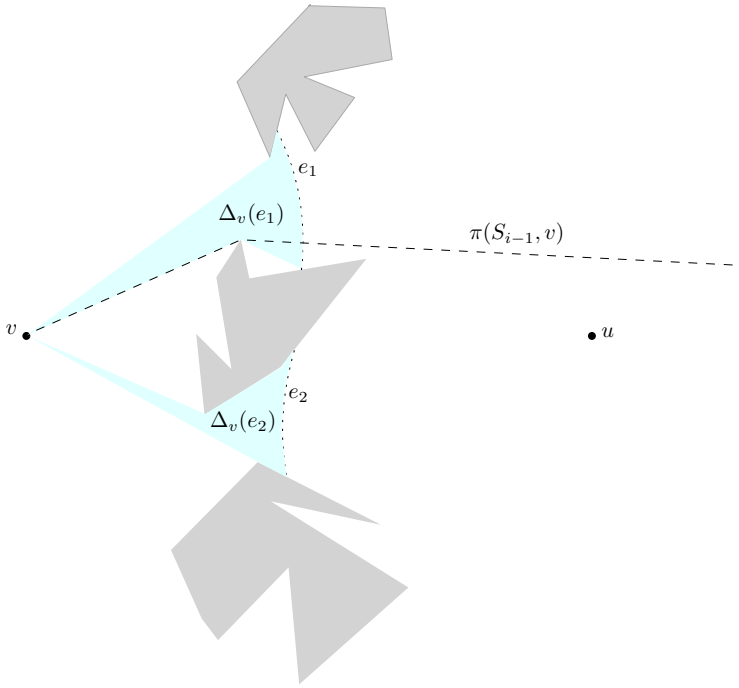


Figure 4 The gray polygons are obstacles. The path $\pi(S_{i-1}, v)$ (dashed polyline) passes through the connected component e_1 (dotted curve) of $\mathcal{E}(u, v)$, so $\pi(S_{i-1}, v) \cap \mathrm{Vor}(v)$ is contained in $\Delta_v(e_1)$ (the upper light blue region).

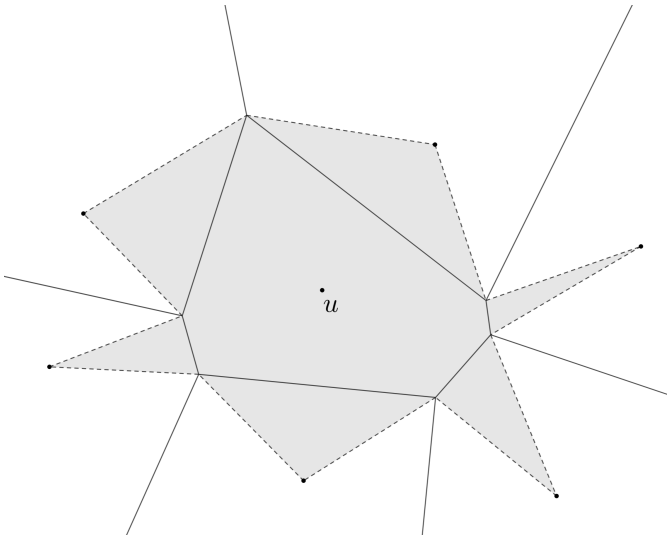

Figure 5 The Voronoi diagram is drawn with solid segments. The shaded region is $\bigstar(u)$.

site of S_{i-1} to v and $\pi(S_{i-1}, v)$ enters $\mathrm{Vor}(v)$ through $\mathrm{Vor}(u)$ for a neighbor $u \in N_{\mathcal{DT}}(v)$. Consider the Voronoi edge $\mathcal{E}(u, v)$ of $\mathcal{VD}(S)$ between u and v. This edge may be comprised of multiple connected components $e_1, \ldots, e_k$ where each component is a sequence of hyperbolic arcs. For each component e, let $\Delta_v(e)$ be the subregion of $\mathrm{Vor}(v)$ bounded by $\pi(v, a)$, $\pi(v, b)$, and e, where a and b are the two endpoints of e (note that $\pi(v, a)$ and $\pi(v, b)$ must be in $\mathrm{Vor}(v)$). We observe that for any point p in e, there exists a shortest path $\pi(p, v)$ that is inside $\Delta_v(e)$. Therefore, if we want to include the shortest path $\pi(S_{i-1}, v)$ through $\mathcal{E}(u, v)$, the only portion of $\mathrm{Vor}(v)$ that we need to include when constructing the Voronoi diagram for S_{i-1} is union of $\Delta_v(e)$ for all components $e \subseteq \mathcal{E}(u, v)$. See Figure 4. Motivated by this, for each site u, we define $\bigstar(u)$ to be the union of $\mathrm{Vor}(u)$ and all $\Delta_v(e)$ for all $v \in N_{\mathcal{DT}}(u)$ and all connected components $e \subseteq \mathcal{E}(u, v)$; see Figure 5. By including $\bigstar(u)$ in our "work region" for computing the Voronoi diagram for S_{i-1}, we ensure that for all $v \in N_{\mathcal{DT}}(u)$, if $\pi(S_{i-1}, v)$ crosses $\mathcal{E}(u, v)$, then this path will be included in our work region. This leads to a total of $O(\sqrt{n}(n + m) \log(n + m))$ time for all light procedures.

Abstract

Given an unweighted graph G, the *minimum r-dominating set problem* asks for a subset of vertices S of the smallest cardinality, such that every vertex in G is within radius r to some vertex in S. While the r-dominating set problem on planar graph admits PTAS from Baker's shifting/layering technique when r is a constant, the problem becomes significantly harder when r can depend on n. In fact, under Exponential-Time Hypothesis, Fox-Epstein *et al.* [SODA 2019] observed that no efficient PTAS can exist for the unbounded r-dominating set problem on planar graphs. One may consider even harder weighted-variant known as the *vertex-weighted metric r-dominating set*, where edges are associated with lengths, and every vertex is associated with a positive-valued weight, and the goal is to compute an r-dominating set with minimum total weight. As a result, people resorted to *bicriteria* algorithms by allowing the returned solution to use radius-$(1+\varepsilon)r$ balls instead, in addition to the total weight being a $1+\varepsilon$ approximation to the optimal value.

We establish the first *single-criteria* polynomial-time $O(1)$-approximation algorithm for the vertex-weighted metric r-dominating set problem on planar graphs when r is part of the input, and can be arbitrarily large compared to n. Our new (single-criteria) $O(1)$-approximation algorithm uses the quasi-uniformity sampling technique of Chan *et al.* [SODA 2012] by bounding the *shallow cell complexity* of the (unbounded) radius-r ball system to be linear in n. To this end we have two technical innovations:

1. The discrete ball system on planar graphs are neither pseudodisks nor have well-defined boundaries for standard union-complexity arguments. We construct a *support graph* for arbitrary distance ball systems as contractions of Voronoi cells; the sparseness comes as a byproduct.

2. We present an assignment of each depth-(≥ 3) cell to a unique 3-tuple of ball centers. This allows us to use standard Clarkson-Shor techniques to reduce the counting to cells of depth *exactly* 3, which we prove to be size $O(n)$ by a novel geometric argument based on our support being a Voronoi contraction.

1 Introduction

The concept of *distance balls* is of fundamental importance to any given metric space (X, d) as the concept of *open sets* to any topological space. A *distance ball* $B(v, r)$ in a metric space (X, d) with radius r centered at point v is the subset of points $\{u \in X : d(u, v) \leq r\}$ in X. Many of the algorithmic success on graphs can be attributed to new understandings of the structure of distance balls in the corresponding graph metric.

The role of distance balls. Take the *minimum dominating set* – one of the 21 famous NP-complete problems of Karp – as an example. Given an unweighted graph G, the *minimum dominating set problem* (Dominating Set for short) asks for a subset of vertices S of smallest cardinality, such that every vertex in G is either in S, or is adjacent to some vertex in S. Dominating Set can also be interpreted as an instance of the *set cover problem*: Consider the set $\mathcal{R} \coloneqq \{B(v, 1) : v \in V_G\}$ of 1-neighborhood balls. Observe that a set S is dominating in G if and only if every vertex is covered by the subset of 1-neighborhood balls in $\mathcal{R}$ centered in S. In other words, a minimum solution of the set-cover instance $(V_G, \mathcal{R})$ is a minimum dominating set in G. This simple observation immediately implies an $O(\log n)$-approximation to Dominating Set, where n is the number of nodes in G, by the standard greedy set cover algorithm. $O(\log n)$-approximation is the best possible (under popular beliefs in complexity) if we make no further assumptions on the graph [25, 15]; this is essentially because the interaction between 1-neighborhood balls in general graphs can be complex and unruly.

What if we consider special classes of graphs with additional geometry constraints? One of the most well-studied examples is *planar graphs*, graphs with a drawing in the plane where no two edges cross each other. Planar graphs exhibit many helpful traits for algorithm design; particularly, several partitioning tools exist, including *separators* [43, 47, 59], *low-diameter decompositions* [41, 4, 9], and an algorithmic paradigm now famously known as *Baker's shifting/layering technique* [1] which utilizes diameter-treewidth property [23] and the decomposability of planar graphs into k-outerplanar graphs. The idea is to compute a BFS-tree from an arbitrary node, then focus only on a few consecutive layers at a time. If the optimization problem at hand is *local* (for Dominating Set, node coverage can be checked by examining immediate neighbors), then a major portion of the optimal solution would be preserved within the consecutive layers. By iterating over the initial shift value and removing one out of every $O(1/\varepsilon)$ layers in the BFS-tree, one may guarantee a $(1 + \varepsilon)$-approximation to the optimal solution. This is the main idea behind the polynomial-time approximation scheme (PTAS) of Dominating Set on unweighted planar graphs [1].

Not surprisingly, the same layering technique can be applied to the *r-dominating set problem* (r-Dominating Set for short) in planar graphs for any absolute constant r, where the goal is similar to Dominating Set but every node in S can "cover" a vertex subset of radius r [18]. r-Dominating Set was introduced by Barilan, Kortsarz, and Peleg [3] and later rediscovered in several other context [30, 18]. However, one encounters some trouble when generalizing Baker's technique to minor-free graphs. This is because arbitrary minor-free graph no longer satisfies the diameter-treewidth property (imagine adding one extra vertex connecting to every node in a planar graph; the diameter becomes 2 but the graph is K_6-minor-free). One possible way to overcome the issue is to apply the Robertson-Seymour structural theorem for minor-free graphs [33, 58], which seems to be overkill. Another, possibly more satisfying solution, is to understand what the $O(1)$-radius neighborhood balls can look like in a minor-free graph. This is the route taken by the *local search* approach. On planar graphs, typical local search analysis [10] is usually done by applying an *exchange*

argument on the base graph G, utilizing the fact that planar graphs have small separators [43] (in the form of an r-division [29]). Har-Peled and Quanrud [35] observed that, for problems like r-dominating set, the exchange argument in a typical local search analysis can be performed on the *intersection graph* of $O(1)$-neighborhood balls [48, 12] (more accurately, the subgraph $G_{\mathcal{R}}$ induced by the union of the local search solution and the optimal solution). They further observed that the intersection graph $G_{\mathcal{R}}$ over $O(1)$-radius balls in minor-free graph G, while not necessarily itself minor-free, must have *polynomial expansion* [50]. Without going into definitions, the class of graphs with polynomial expansion coincide with those that have sublinear-size separators for all subgraphs [21]. Thus one can apply the same kind of exchange argument using separator decomposition on the ball intersection graph $G_{\mathcal{R}}$.

Arbitrary radii and arbitrary weights. The r-dominating set problem becomes significantly harder when r can depend on n [22]. In the literature this is usually refer to as the the *metric/unbounded r-dominating set problem* [26, 27], where we further allow arbitrary nonnegative *edge-length ℓ* on the input graph, in addition to the covering radius r (now measuring with respect to ℓ) becoming part of the input. We can even consider a weighted variant of the problem, where every vertex is associated with a positive-valued *weight w*, and the goal is to compute an r-dominating set with minimum total weight (instead of minimum cardinality). Baker's layering technique no longer applies, nor does the local search strategy for the most part. (There is an exception [42, 26] which we will talk about in the technical section.) This is somewhat expected because the unbounded r-dominating set problem is no longer "local", and the intersection graph of radius-r balls may be dense and have complex interactions. In fact, under Exponential-Time Hypothesis, Fox-Epstein *et al.* [44, 28] proved that no efficient PTAS can exist for the unbounded r-dominating set problem on planar graphs. Thus, recent work has resorted to *bicriteria* algorithms, allowing the returned solution to use a dominating set of radius $(1+\varepsilon)r$ instead, in addition to the total weight being a $1+\varepsilon$ approximation to the optimal value [22, 28]. The idea is to embed the original planar/minor-free graph metric into some other *tree-like metrics*, where the r-dominating set problem can easily be solved using dynamic programming. Unfortunately one has to suffer some form of distortion (which translates to the slack in covering radius); the best result so far gives $+\varepsilon\Delta$-additive embedding of diameter-Δ minor-free graphs into graphs of $O_\varepsilon(1)$ treewidth [13, 14]. This line of research has been fruitful and ultimately leads to bicriteria EPTAS for planar graphs [28] and bicriteria Q(Q)PTAS for minor-free graphs [26, 27].

But what if we really want to solve the unbounded r-dominating set problem without compromise on the radius r? The lower bound result [44, 28] leaves us no choice but to look at $O(1)$-approximation (or at least, $(1+\varepsilon)$-approximation with running time $n^{f(\varepsilon)}$). The existence of such algorithm was explicitly asked by Filtser and Le [27].

Our contribution. We establish the first polynomial-time $O(1)$-approximation algorithm for the (vertex)-weighted metric r-dominating set problem for unbounded r. We emphasize that r is part of the input, and can be arbitrarily large compared to n.

▶ **Theorem 1.** *Let G be an arbitrary n-node planar graph, where each vertex v is associated with a weight $w(v)$. Let r be an arbitrary radius parameter. There is a polynomial-time algorithm that computes an r-dominating set in G whose weight is $O(1)$ times the optimum.*

1.1 Techniques

Our new (single-criteria) $O(1)$-approximation algorithm for weighted r-dominating set on planar graphs uses the quasi-uniformity sampling technique, originally designed for weighted set cover problem on geometric shapes [63, 11]. But first, we have to describe a bit of (technical) history and two immediate challenges when adapting to our setting.

Challenge 1: Planar support. Geometric set cover problems have their own history and success [7, 16, 17, 62]. Notably, for an unweighted set cover instance $(X, \mathcal{R})$, the result of Brönnimann and Goodrich [7] provided a recipe to achieve $O(1)$-approximation. Their pioneering use of multiplicative weight update algorithm requires the existence of small ε-*net*: First, find an ε-net N for the dual set system $(\mathcal{R}, X)$ (notice that here the ε-net is in the dual and thus a subset of ranges in $\mathcal{R}$). If there are element x in X not covered by N, *double* the weight of every range in $\mathcal{R}$ that covers x, to increase the chance of choosing one such range in the next round. As a result, by setting $\varepsilon = \Theta(1/\mathrm{opt})$, this implies an $O(g(\mathrm{opt}))$-approximation for any set cover instance, given the dual system has an ε-net of size $O(\frac{1}{\varepsilon} \cdot g(\frac{1}{\varepsilon}))$. (See [24] for an LP interpretation and a simpler proof.)

For set system of bounded VC-dimension [61], there is always an ε-net of size $O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ [36]. Also, if the VC-dimension of a primal system is d, then the dual system has VC-dimension at most 2^d [34]. To get $O(1)$-approximation, however, we need a much stronger assumption of $O(\frac{1}{\varepsilon})$-size ε-net *in the dual system*. This is not always achievable even for simple geometric shapes like lines and rectangles [49]; in fact, among the basic geometric shapes, only a handful are known to have linear-size ε-net, including halfspaces in 2D and 3D [46, 51, 45], unit-cubes in 3D [17], and family of pseudodisks in the plane (both primal and dual) [53].

For our application of unbounded r-dominating set problem, the "geometric shapes" are the radius-r balls in planar graphs, which is discrete in nature, lacking well-defined boundary curves to even make the definition of pseudodisks meaningful. One might sneer at the issue and say, "there must be a way; how can distance balls in the plane be much different from pseudodisks?" But even if we redefine the notion of pseudodisks combinatorially (for every pair of regions A and B, all three sets $A \cap B$, $A \setminus B$, and $B \setminus A$ are connected), the distance balls are still not pseudodisk. In fact, they can be *piercing* in the sense of Raman-Ray [54], as illustrated by Figure 1.

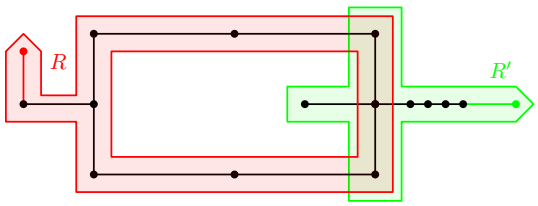

Figure 1 Two distance balls R and R' that are piercing. Here both R and R' have radius 6.

Fortunately, Pyrga and Ray [53] provided an alternative method to obtain linear-size ε-net (in the dual) – to construct a *sparse support* for the primal system $(X, \mathcal{R})$. We say a set system $(X, \mathcal{R})$ has a *support*, if for any subsystem $(X', \mathcal{R}_{|X'})$ of $(X, \mathcal{R})$, there is an undirected graph H on the elements of X' such that for every set R in $\mathcal{R}_{|X'}$, the subgraph H_R of H induced by the elements of R is connected. The support is *sparse* if every such graph H is sparse. The work of Pyrga and Ray [53] implies that if $(X, \mathcal{R})$ has bounded VC-dimension and a sparse support, then the dual system $(X, \mathcal{R})$ has ε-net of size $O(\frac{1}{\varepsilon})$.

Our first technical contribution is to compute a support for any collection of distance balls in any *arbitrary* graph (not just planar graphs). Crucially, if the given graph is planar, then so is the support. We remind the reader that our original goal is to solve the r-dominating set problem with unbounded r; thus the construction of the support has to hold for balls of unbounded radii as well. This is the first construction of its kind; most previous work on sparse support focus on geometric shapes, and almost entirely restricted to *planar support* for set systems that are pseudodisks [53] and their generalizations [54]. For piercing systems like axis-parallel rectangles, there are configurations where no planar support can exist [52].

Instead of focusing on planarity, we shift the narrative by arguing that a support graph for $(X, \mathcal{R})$ is really a *connectivity sketch* that exists for every graph G on X, as long as the sets in $\mathcal{R}$ are *distance balls* on G. Our construction for support on arbitrary balls in G can be described simply as follows: Build a *Voronoi diagram* of $V(G)$ with respect to balls centers, then contract every Voronoi cell into a single node. We argue that the contracted graph is a support of G. (The benefit of this additional property becomes evident when we tackle the next challenge.) Both planarity and sparseness come as a byproduct of the fact that contraction of the Voronoi diagram is a *minor* of G. (See Theorem 2 for a precise statement.) (A similar Voronoi diagram idea can be found in the work of Le [42, 26]; but their version only enables single-criteria algorithm for *unweighted* metric r-dominating set problem.)

Challenge 2: Linear shallow cell complexity. There is another, perhaps more severe, obstacle to overcome. We want to solve the *weighted* version of the r-dominating set problem. The Brönnimann-Goodrich MWU approach relies on computing regular ε-net (as subset of balls covering the vertices); the *size* bound on ε-net translates to approximation guarantee on *size* of the cover, and thus can only work in the unweighted setting. Varadarajan [63] extended the ε-net idea to the weighted setting. This *quasi-uniformity sampling technique* computes ε-nets that samples each set in $\mathcal{R}$ with (roughly) equal probability, which then can be made aware of the weights on $\mathcal{R}$. Chan, Grant, Könemann, and Sharpe [11] later polished this technique and made connection to a more refined measure on set systems called *shallow cell complexity*. In our context, cell complexity refers to the number of different equivalent classes (called *cells*) of points that are covered by the same subset of r-balls. We say a cell has *depth* k if the points within are covered by up to k balls. A set system has shallow cell complexity $f(|\mathcal{R}|, k)$ if the number of cells of depth at most k is bounded by $f(|\mathcal{R}|, k)$; for the purpose of obtaining $O(1)$-approximation for set cover, one requires the shallow cell complexity to be $O(|\mathcal{R}| \cdot \operatorname{poly} k)$.

The quasi-uniformity sampling technique can be used to solve the *constant* r case for weighted r-dominating set problem on minor-free graphs (and graphs with bounded expansion as well [20]). This is because in the case of constant radius r, the *whole* cell complexity is linearly bounded [57, 38], which directly bounds the shallow counterpart. Unfortunately, it is known that the cell complexity of r-balls on a planar graph can be cubic in r [38], and thus cannot help in the unbounded r setting.

One way to see why halfspaces and pseudodisks are special is that they both have linear *union complexity* [40, 17]. Application of the classical Clarkson-Shor technique then implies that the shallow cell complexity is bounded by $O(|\mathcal{R}| \cdot k)$. When working with arbitrary-radius balls on graphs however, we run into trouble applying Clarkson-Shor. First, there is no well-defined notion of union complexity for a collection of subgraphs. One would imagine the support can take the role as the linear-size object at the base case for Clarkson-Shor; but this intuition is insufficient. The main issue is that for pseudodisks, the number of cells can be charged to the complexity of the whole pseudodisk arrangement by Euler's formula, and every crossing in the arrangement is uniquely defined by two pseudodisks. There is no immediate equivalent object for distance balls that allows for such counting.

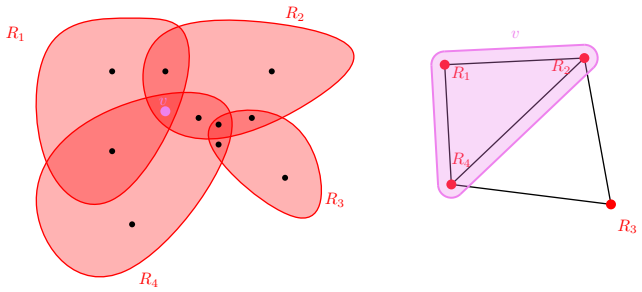

Figure 2 A set system with a dual support. The red regions containing the violet vertex v form a connected subgraph in the support.

Our solution is to reimagine the unique representative argument by Raman and Ray for the non-piercing family [55]; the new proof is substantially different and relies on geometric properties of distance balls, instead of topological properties of curve sweeping [55, §6]. First we argue that every cell can be charged to a unique 3-tuple of ball centers (Lemma 7). This allows us to apply Clarkson-Shor and reduce the problem to counting cells of depth 1, 2, and 3. Depth 1 and 2 are straightforward; for depth-3 cells, we exploit the additional property that our support for distance balls came from contracting *Voronoi cells* with respect to the ball centers, and thus the number of depth-3 cells can be counted towards the complexity of the Voronoi diagram, which is asymptotically the same as the planar support (Lemma 13).

2 Terminology and Support Graphs

Let's first introduce the terminology needed for concrete discussion. Our support construction actually works for balls in an arbitrary *directed* graph. We refer to the digraph that our ball system lives on as the *underlying graph* G. Note that all results apply to balls in undirected graphs. A *ball* D can be defined using a pair (c_D, r_D) where c_D is a vertex of G called the *center*, and a *radius* r_D which is a real number. Ball D is then defined to be the set of all vertices v whose shortest path from c_D has length at most r_D.

Given a system $(U, \mathcal{R})$, the *dual system* $(\mathcal{R}, U)$ has the elements of U treated as subsets of $\mathcal{R}$: if element e in U is a member of set R in $\mathcal{R}$ in the primal system, then R is a member of *set* e in the dual system. We use the term *dual support* of $(U, \mathcal{R})$ to refer to a support graph of the dual system $(\mathcal{R}, U)$. (We give an example of a dual support in Figure 2.) Although our r-dominating set application demands primal support, the set system of balls *of equal radius* is self-dual, Thus, we do not differentiate the support for the primal from the dual, but instead describe the support for the dual system since it is conceptually easier.

In Section 3 we construct a dual support for any system of balls, by contracting cells of the Voronoi diagram of the underlying graph (with respect to ball centers) into a minor.

▶ **Theorem 2** (Support). *Any system of balls $\mathcal{R}$ on an underlying digraph G has a dual support $H(\mathcal{R})$ such that if G does not contain a minor K with minimum vertex degree two, then neither does $H(\mathcal{R})$.*

▶ Remark. Unfortunately the min-degree requirement cannot be dropped in general. For example, if G is P_2-minor-free, we have a set of disjoint vertices. But two balls can centered on the same vertex, and thus connected in the dual support, which implies the existence of an edge and so the support is not P_2-minor-free. Still the restriction is not severe as most of the interesting minor-free graph classes satisfy the min-degree condition, including K_h-minors for $h \geq 3$, grid minors, and all forbidden minors for bounded-genus graphs.

Since planar graphs can be classified by their excluded minors, these results imply a planar dual support for the ball system $\mathcal{R}$ on G. We then proceed to show that $\mathcal{R}$ has linear shallow cell complexity in Section 4.

▶ **Theorem 3** (Shallow Cell Complexity). *Let G be a planar graph. Any system of balls $(V_G, \mathcal{R})$ has shallow cell complexity $O(|\mathcal{R}| \cdot k^2)$.*

2.1 Applications

In addition to the result on computing unbounded r-dominating set in planar graphs, the supports also have their own implications. An important property of our support construction is that we only ever contract edges that are within radius r of a ball center. This means that if G is an unweighted graph with *polynomial expansion* and we are considering constant-radius balls, the support graph will also have polynomial expansion, allowing us to use the sublinear separators from Har-Peled and Quanrud [35] to get the same PTAS results for unweighted problems as Raman and Ray [54] achieved for non-piercing regions. If r is not bounded by a constant, we can achieve the same when G is minor-free [65].

Another natural use of supports is for problems relating to geodesic disks in a polygonal domain (possibly with holes). It is known that planar metrics and polygonal domains are *equivalent*: any system of geodesic disks in a polygonal domain in $\mathbb{R}^2$ can be represented as a system of balls in a planar graph, and vice versa [6]. By the equivalence, our techniques naturally give planar supports for geodesic disks in polygonal domains.

2.2 Related Work on Support Graphs

Van Cleemput [60] and Voloshina and Feinberg [64] used the existence of a planar support graph to give meaningful notion of planarity in the hypergraph setting. As such, support graphs have seen interest in (hyper)graph drawing community [37, 39, 8]. In the realm of optimization, Pyrga and Ray [53] used support graphs to construct linear-sized ε-nets for several set systems with bounded VC dimension, including halfspaces in $\mathbb{R}^3$ and pseudodisks (more generally, r-admissable regions) in $\mathbb{R}^2$. Here the support graphs were required to be *sparse* (i.e. with linearly many edges) in order to bootstrap existing ε-net sizes down to $O(\frac{1}{\varepsilon})$. Later on support graphs that are *planar* were used by Mustafa and Ray [48] to show a PTAS for various optimization problem in the geometric setting. Instead of ε-net, they exploited the existence of *sublinear-size* separators in planar graphs to show that an $O_\varepsilon(1)$-swap local search algorithm gives a $(1+\varepsilon)$-approximation for minimum geometric hitting set. The same paradigm of analyzing local search with separators on planar support was extended to other problems, such as maximum independent set and generalized set cover (including dominating set and hitting set) in pseudodisks and non-piercing regions [12, 19, 32, 54], terrain guarding [31, 2], and covering the boundary of a simple orthogonal polygon with rectangles [5]. (A survey on the many use of support can be found in Raman and Singh [56].)

3 Existence of Support Graph

To begin constructing the dual support for a system of balls $\mathcal{R}$ in a graph G, we will first modify G slightly and reduce to the case where *every ball in $\mathcal{R}$ has the same radius*. We will refer to the new graph as G'. (Recall we work with the general case of digraphs.) We augment digraph G by adding a new node corresponding to each ball in $\mathcal{R}$. (For clarity, we refer to original vertices of G as *vertices* and new vertices corresponding to $\mathcal{R}$ as *nodes*.) For each ball R in $\mathcal{R}$, we create a single node, x_R, which has only one edge: an outgoing edge

into c_R, the center of the ball R. We give the edge a weight of $r_{\max} - r_R$, where $r_{\max}$ is defined to be $\max_{R' \in \mathcal{R}} r_{R'}$. This allows us to instead consider each R in $\mathcal{R}$ to be centered at x_R, all with the same radius $r_{\max}$, and the balls will still define the same set system $\mathcal{R}$ over the vertices in G. Finally, remove all vertices which are not contained in any ball of $\mathcal{R}$ and slightly perturb the edge weights (without changing any ball containment relations) so that every vertex v has a unique closest ball center in $\{x_R : R \in \mathcal{R}\}$.

To build the dual support, we construct a *Voronoi partition* of G' with respect to the set of nodes. A *Voronoi partition* $\mathcal{F}$ of a graph G' with respect to a set of nodes S is a partition of $V_{G'}$ into subsets such that for every node $R \in S$, there is a corresponding subset $F_R \in \mathcal{F}$ which contains all vertices u in G' for which $d(x_R, u) \leq \min_{x_R \in S \setminus \{x_R\}} d(x_{R'}, u)$. For clarity, we will refer to each set F_R in $\mathcal{F}$ as the *Voronoi cell* of R. In our case, we construct the Voronoi partition $\mathcal{F}_{\mathcal{R}}$ of G' with respect to $\{x_R : R \in \mathcal{R}\}$, which we identify as $\mathcal{R}$. Each cell F_R in the Voronoi partition is a connected subset of G' because for every vertex v in F_R reachable from x_R, the vertices on the shortest path between x_R and v must belong to F_R as well. Thus we can simply contract every F in $\mathcal{F}_{\mathcal{R}}$ to a (contraction)-minor on only the nodes in $\mathcal{R}$. This final graph H, we claim, is a dual support for $(G, \mathcal{R})$.

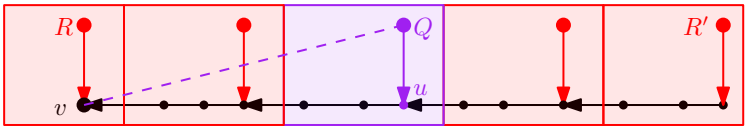

Figure 3 An illustration of the proof to Lemma 4 that π can only pass through Voronoi cells of $\mathcal{R}_v$. The purple region is the Voronoi cell F_Q.

▶ **Lemma 4.** *For any vertex v in G', the set of balls $\mathcal{R}_v \subseteq \mathcal{R}$ that contain v must induce a connected subgraph in H.*

Proof. Consider any vertex v which is contained in at least two balls in $\mathcal{R}$. Vertex v must be in the Voronoi cell F_R of some ball R by construction of G'. We claim that for any other ball R' of $\mathcal{R}$ that also contains v, there is a path from $x_{R'}$ to v in G', denoted as π, that only passes through Voronoi cells corresponding to balls that contain v.

Since we have removed all vertices which have no incoming path from any ball, every vertex along π in G' must be in some cell. Assume that some vertex u along π is contained in some Voronoi cell F_Q corresponding to a ball Q that does not contain v. By definition of Voronoi cell, we have that $d(x_Q, u) \leq d(x_{R'}, u)$. By the definition of shortest paths, we know that $d(x_{R'}, v) = d(x_{R'}, u) + d(u, v)$. By triangle inequality, we then have the following:

$$d(x_Q, v) \leq d(x_Q, u) + d(u, v) \leq d(x_{R'}, u) + d(u, v) = d(x_{R'}, v).$$

But, $d(x_{R'}, v) \leq r_{\max}$ and $d(x_Q, v) > r_{\max}$ since v is in R' but not in Q, contradiction. ◀

Proof of Theorem 2. Construct H as described above. By Lemma 4, we know that H satisfies the definition of a dual support for system $(V_G, \mathcal{R})$. It remains to show that if G has no minor K with minimum degree two, then neither can H. This is done by arguing that G' has no such minors, and then the fact that H is a minor of G' concludes the proof.

When constructing G', we only perform two types of operations that would affect the existence of minors: deleting vertices and adding in nodes $\{x_R\}$ of degree one. Let K be a minor model (as a collection of disjoint vertex subsets called *supernodes*) of G' that has minimum degree two. If K only contains vertices but not nodes in G', then K must appear in G as well (even though G' was obtained by removing some vertices from G). So at least one supernode η of K must contain some degree-1 x_R that was added in G'.

For an edge (η, η') to exist in K, there must be a vertex/node $u \in \eta$ and a vertex/node $u' \in \eta'$ such that (u, u') is an edge of G'. For η containing x_R, x_R must not be the only vertex/node in η, since η have degree at least 2. Because η is connected, the neighbor of x_R is also in η and the (sole) edge incident on x_R must be contracted. This, however, means that there can be no edge (x_R, u') in G' that corresponds to an edge (η, η') in K, so there is a minor K' isomorphic to K where x_R was simply deleted and thus x_R is not in η. Since this holds for all x_R, there must be some minor of G isomorphic to K, a contradiction. ◀

4 Shallow Cell Complexity of Balls in Planar Graphs

Shallow cell complexity was introduced by Chan *et al.* [11] as a combinatorial analog of union complexity. We introduce the terminology within our context of distance balls on graphs.

Define the *hit set* of a vertex v with respect to $\mathcal{R}$ to be the subset of balls in $\mathcal{R}$ which contain v. A *cell* of the system $(V_G, \mathcal{R})$ is a set of vertices in V_G that have the same hit set of incident balls. *Cell complexity* is simply the number of cells in $(V_G, \mathcal{R})$, where as *shallow* cell complexity counts the number of cells of a particular *depth* k in $\mathcal{R}$, denoted $Cell_k$, the equivalence classes of vertices whose hit set has size k. We say the set system has *shallow cell complexity* $f(n, k)$ if for depth k, there are at most $f(n, k)$ cells. Our goal for the section is to show that for a planar graph G, the shallow cell complexity for any system of balls $(V_G, \mathcal{R})$ is $O(|\mathcal{R}| \cdot k^2)$ (Theorem 3). Just as in the support constructions in § 3, we again reduce to the case where *every ball in our system* $\mathcal{R}$ *has the same radius.*

Proof of Theorem 3. We use two key lemmas proven later in the subsections. The first claims that for every cell c of depth k, there is a unique encoding of c, $\langle \alpha(c), \beta(c), \gamma(c) \rangle$, where each member of the tuple is a ball of $\mathcal{R}$ (Lemma 7 in Section 4.1). Importantly, the encoding is unique among cells of depth k, not universally. This naively implies that there is at most $O(|\mathcal{R}|^3)$ cells of depth k. Using the standard Clarkson–Shor arguments argument, we can improve this to $O(|\mathcal{R}| \cdot k^2)$ if the number of cells of depth (at most) 3 is $O(|\mathcal{R}|)$ (Lemma 13 in Section 4.2). More precisely: Sample the regions of $\mathcal{R}$ with probability $1/k$. A cell c with unique encoding appears in the sample as depth-3 cell with probability at least $(ek)^{-3}$. The expected number of depth-3 cells in the sample is at most $O(|\mathcal{R}|/k)$, so the number of depth-k cells in $\mathcal{R}$ is at most $O(|\mathcal{R}| \cdot k^2)$. ◀

4.1 Unique 3-Site Encoding of Cells

We begin by assigning each cell of $Cell_k$ an *unique* encoding for each fixed depth $k \geq 3$. This encoding will depend on the set of incident balls corresponding to c. Specifically, the encoding will be formed by a 3-tuple of regions in $\mathcal{R}$, which we will refer to as $\langle \alpha, \beta, \gamma \rangle$. In assigning the encoding, we do not modify to the set system at all. Instead, we fix an arbitrary vertex v_c for cell c as its *representative*. We denote the cell containing v as $Cell(v)$.

For a cell c, we begin by designating its $\langle \alpha, \beta \rangle$*-type*. We define $\alpha(v)$ as the furthest ball from v that contains v. Similarly, we define $\beta(v)$ as the second furthest ball from v that contains v. For cell c, its $\langle \alpha, \beta \rangle$*-type* is simply $\langle \alpha(v_c), \beta(v_c) \rangle$. (Notice that $\alpha(v_c)$ and $\beta(v_c)$ might be different if one chooses a different v_c from cell c, and thus the $\langle \alpha, \beta \rangle$-type of c depends on its representative.) Let $\pi_{\alpha,\beta}(v)$ be the union of $\pi(\alpha(v), v)$ and $\pi(\beta(v), v)$, where $\pi(x, y)$ is the shortest path from x to y in G.

▶ **Lemma 5.** *For a vertex v with $\alpha(v) = D_1$ and $\beta(v) = D_2$, every vertex v' in $\pi_{\alpha,\beta}(v)$ with $\alpha(v') = D_1$ and $\beta(v') = D_2$ satisfies $hit(v') \subseteq hit(v)$.*

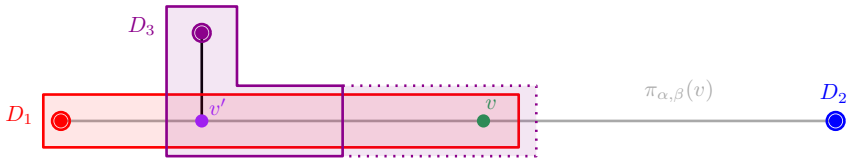

Figure 4 Given two vertices v, v' satisfying $\alpha(v) = \alpha(v') = D_1$, $\beta(v) = \beta(v') = D_2$ and $v' \in \pi(D_1, v)$, any ball D_3 containing v' must also contain v.

Proof. Assume the contrary. Then, there is some vertex v' which is contained within some ball D_3 such that $v \notin D_3$. By definition of α and β, it must be that the center of D_3 is closer to v' than D_1 and D_2. However, since v' is either in $\pi(c_{D_1}, v)$ or $\pi(c_{D_2}, v)$, this means that D_3 is closer to v than one of D_1 or D_2, and thus D_3 must contain v, a contradiction by the assumption that all balls have equal radius. (See Figure 4.) ◀

The third component of our encoding, γ, can now be defined. For $k = 3$, γ is simply the remaining ball after removing α and β. For $k \geq 4$, we define γ procedurally after fixing α, β. Denote the set of all cells of depth k with $\alpha(v_c) = D_1$ and $\beta(v_c) = D_2$ as $C_k(D_1, D_2)$. We additionally collect the representatives v_c of each $c \in C_k(D_1, D_2)$ into a corresponding set $V_k(D_1, D_2)$. Let $T_D(S)$ be the shortest path tree from the center x_D of a ball D to a set of vertices S. Consider the shortest path tree $T_{D_1}(V_k(D_1, D_2))$. We will process all $v_c \in V_k(D_1, D_2)$ using the plane drawing of $T_{D_1}(V_k(D_1, D_2))$.

Perform a depth-first traversal starting at x_D, processing children in clockwise order. The depth-first traversal $T_{D_1}(V_k(D_1, D_2))$ of gives a total ordering of the vertices in $V_k(D_1, D_2)$, which also induces a total ordering σ on the corresponding cells $C_k(D_1, D_2)$. For brevity, we will index the cells based on their order in σ (the ith cell as c_i) in a cyclic manner. For the ith cell c_i in the total ordering, we assign $\gamma(c_i)$ to be an arbitrary ball D with $D \in hit(v_{c_i})$ and $D \notin hit(v_{c_{i-1}})$. Since $|hit(v_{c_i})| = |hit(v_{c_i-1})| = k$ and $hit(v_{c_i}) \neq hit(v_{c_i-1})$ (by the definition of cell), such a D must always exist, and thus we can assign $\gamma(c_i)$ to all cells.

We now show that this definition of γ is sufficient to ensure that each distinct cell c of size k has a unique encoding. First, we use Lemma 5 to show that the representative vertices of cells with the same α and β cannot form ancestor relationships in $T_{D_1}(V_k(D_1, D_2))$.

▶ **Observation 6.** *For any two distinct cells $c, c' \in C_k(D_1, D_2)$, v_c cannot be an ancestor of $v_{c'}$ in $T_{D_1}(V_k(D_1, D_2)$ or $T_{D_2}(V_k(D_1, D_2)$.*

Proof. First consider $T_{D_1}(V_k(D_1, D_2))$. If v_c were an ancestor of $v_{c'}$, then v_c would be in $\pi(D_1, v_{c'})$. This would imply that $hit(v_{c'}) \subseteq hit(v_c)$ by Lemma 5. However, since c and c' have depth k, $|hit(v_c)| = |hit(v_{c'})| = k$. The subset relationship would hence require that $hit(v_c) = hit(v_{c'})$, and thus c and c' are the same class, which is a contradiction. A symmetric argument applies for $T_{D_2}(V_k(D_1, D_2))$. ◀

This means that for any c, c' with the same α and β, $\pi(\alpha(v_c), v_c) \not\subseteq \pi(\alpha(v_c), v_{c'})$.

▶ **Lemma 7.** *For $k \geq 3$, every cell c of depth k has a unique encoding $\langle \alpha(c), \beta(c), \gamma(c) \rangle \in \mathcal{R}^3$.*

Proof. If two cells have the same depth and α and β, they are both indexed by the same traversal order σ. Consider two cells c_i, c_j such that $\langle \alpha(c_i), \beta(c_i), \gamma(c_i) \rangle = \langle \alpha(c_j), \beta(c_j), \gamma(c_j) \rangle = (D_1, D_2, D_3)$ and $|hit(v_{c_i})| = |hit(v_{c_j})| = k$.

We need to consider how c_i and c_j were assigned the same γ. Recall that we force adjacent cells c_{i-1}, c_i to not just have different γ assignments, but that the $\gamma(c_i)$ not contain $\gamma(c_{i-1})$. This forces $v_{c_{i-1}}$ and $v_{c_{j-1}}$ to not be contained by D_3. Let a be the lowest common ancestor

of $v_{c_{i-1}}$ and $v_{c_{j-1}}$ in $T_{D_1}(V_k(D_1, D_2))$. Similarly, let b be the lowest common ancestor of $v_{c_{i-1}}$ and $v_{c_{j-1}}$ in $T_{D_2}(V_k(D_1, D_2))$. We consider the cycle F formed by the union of the following shortest paths: $\pi(a, v_{c_{i-1}})$ to $\pi(v_{c_{i-1}}, b)$ to $\pi(b, v_{c_{j-1}})$ to $\pi(v_{c_{j-1}}, a)$. Since G is planar, F describes the boundary of some region $R(F)$. Since $i-1 < i < j-1 < j$, by the definition of our traversal one of v_{c_i} or v_{c_j} lies in $R(F)$ and the other lies outside. (We give an example $R(F)$ as a gray region in Figure 5.) This means that, for D_3 to contain both v_{c_i} and v_{c_j}, D_3 must also contain some vertex u' of F. Assume WLOG that u' lies on $\pi(D_3, v_{c_j})$. Since u' lies on F, it must be on one of $\pi(D_1, v_{c_{i-1}}), \pi(D_1, v_{c_{j-1}}), \pi(D_2, v_{c_{i-1}})$, or $\pi(D_2, v_{c_{i-1}})$.

- If u' is in $\pi(D_1, v_{c_{i-1}})$ or $\pi(D_1, v_{c_{j-1}})$, then we know that D_3 must be further from u' than D_1 since D_3 cannot contain $v_{c_{i-1}}$ or $v_{c_{j-1}}$. However, since $\alpha(v_{c_j}) = D_1$, D_3 must be closer to u' than D_1 since u' is on $\pi(D_3, v_{c_j})$ and $\alpha(v_{c_j})$ is the furthest ball from v_{c_j} which still contains it. (See left subfigure of Figure 5.)
- Similarly, if u' is in $\pi(D_2, v_{c_{i-1}})$ or $\pi(D_2, v_{c_{j-1}})$, then D_3 must be further from u' than D_2 since D_3 cannot contain $v_{c_{i-1}}$ or $v_{c_{j-1}}$. However, since $\beta(v_{c_j}) = D_2$, D_3 must be closer to u' than D_2 since u' is on $\pi(D_3, v_{c_j})$ and $\beta(v_{c_j})$ is the second furthest ball from v_{c_j}, while D_3 is at best third furthest. (See right subfigure of Figure 5.)

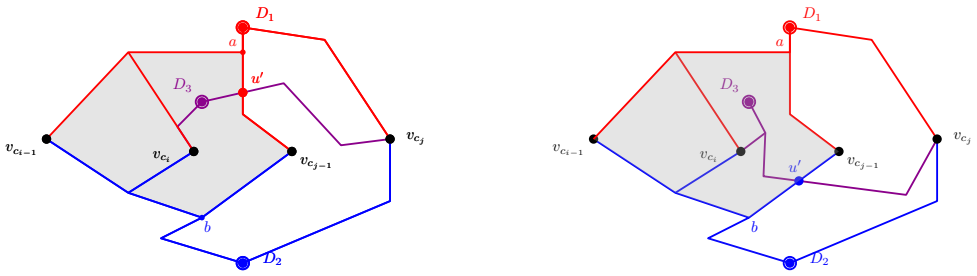

Figure 5 If two cells c_i, c_j have the same $\gamma(c_i) = \gamma(c_j) = D_3$, then there must D_3 must contain a vertex u' of $\gamma_{\alpha,\beta}(v_{c_{j-1}})$ or $\gamma_{\alpha,\beta}(v_{c_{j-1}})$. The region $R(F)$ corresponding to the simple cycle F is given in gray.
Left: u' is in $\pi(D_1, v_{c_{j-1}})$. Right: u' is in $\pi(D_2, v_{c_{j-1}})$.

We get a contradiction in both cases, which means that $\gamma(c_i)$ cannot equal $\gamma(c_j)$, and thus every cell c of the same depth $k \geq 3$ must have a unique encoding $\langle \alpha(c), \beta(c), \gamma(c) \rangle$. ◀

4.2 Depth-3 Cells

Now that we have a unique encoding $\langle \alpha(v_c), \beta(v_c), \gamma(v_c) \rangle$ for every cell c of depth k, we can proceed to give a bound on $|Cell_3|$.

For each c in $Cell_3$, we consider its encoding $\langle \alpha(v_c), \beta(v_c), \gamma(v_c) \rangle$. Since c only has depth 3, we know that these are simply the balls of $hit(v_c)$, placed in order of distance from v_c. Our first step is to select one of the three balls of $hit(v_c)$ as $base(v_c)$. Next, we iterate through every ball D in $\mathcal{R}$ and count the number of cells that have been assigned D. We accomplish this by constructing a planar graph G_D on the neighbors of D in the Voronoi partition graph H. Summing over all D, this yields a total count of $O(|\mathcal{R}|)$ cells. We start with an important lemma regarding the order of distances to balls from vertices that lie on a shortest path.

▶ **Lemma 8.** *Given any ball D of $\mathcal{R}$, a vertex v, some vertex v' on $\pi(x_D, v)$, and a distinct ball $D' \in \mathcal{R}$, if $d(x_{D'}, v') \leq d(x_D, v')$, then for all $v'' \in \pi(v', v)$, $d(x_{D'}, v'') \leq d(x_D, v'')$.*

Proof. For any $v'' \in \pi(v', v)$, because v' is between x_D and v'' on $\pi(x_D, v)$, $d(x_D, v'') = d(x_D, v') + d(v', v'')$. We also know that $d(x_{D'}, v'') \leq d(x_{D'}, v') + d(v', v'')$. Since $d(x_{D'}, v') \leq d(x_D, v')$, we can simply plug in to get $d(x_{D'}, v'') \leq d(x_D, v') + d(v', v'') = d(x_D, v'')$. ◀

▶ **Observation 9.** *For a cell c and ball $D' \in hit(v_c)$, all vertices v in $\pi(x_D, v_c)$ must lie in the Voronoi cell of a ball in $hit(v_c)$.*

Proof. Consider a ball $D' \notin hit(v_c)$ for which a vertex v of $\pi(x_D, v_c)$ lies in the Voronoi cell F_D. If this is the case, then all the vertices after v in $\pi(x_D, v_c)$ will be closer to D' than they are to D, and since D contains v_c, D' must also then contain v_c, which is a contradiction. ◀

This means that the shortest paths from the centers of the balls hit by v_c to the vertex v_c must stay within the Voronoi cells of $hit(v_c)$. This observation, paired with Lemma 8, allows us to define $base(v_c)$ based on $\pi(x_{\alpha(v_c)}, v_c)$. We consider two cases:

- *Case 1: Some vertex v in $\pi(x_{\alpha(v_c)}, v_c)$ lies in $F_{\beta(v_c)}$.* Assign $base(v_c) \leftarrow \beta(v_c)$.
- *Case 2: No vertex v in $\pi(x_{\alpha(v_c)}, v_c)$ lies in $F_{\beta(v_c)}$.* Assign $base(v_c) \leftarrow \gamma(v_c)$.

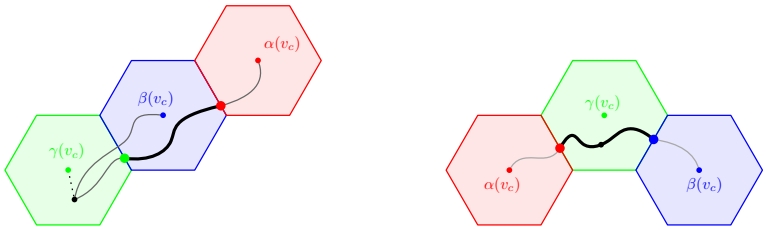

Figure 6 Showing the subwalk of Lemma 10 and how to select *base*. Left: Case 1. Right: Case 2.

Now that we have assigned every cell to a ball, we consider a ball D and the set $resident(D)$, which is the set of cells c with $base(c) = D$. We will consider the cells of $resident(D)$ in relation to the neighbors of D within the Voronoi partition graph H.

▶ **Lemma 10.** *For a ball D and every cell c of $resident(D)$, there is a subwalk π_c of $\pi_{\alpha,\beta}(v_c)$ with the (nonempty set of) interior vertices lying in D and the end vertices lying in distinct neighbors D', D'' of D in H.*

Proof. If cell c is a *case-1* cell, we have that a vertex v in $\pi(x_{\alpha(v_c)}, v_c)$ which lies in $F_{\beta(v_c)}$. By Lemma 8, no vertex of $\pi(v, v_c)$ can lie in $F_{\alpha(v_c)}$. Additionally, v_c must lie in $F_{\gamma(v_c)}$ by definition of α and β. Let u be the first vertex of $\pi(v, v_c)$ which lies in $F_{\gamma(v_c)}$. Let v' be last vertex of $\pi_{\alpha,\beta}(v_c)$ which lies in $F_{\alpha(v_c)}$. The subwalk $\pi_{\alpha,\beta}(v_c)[v', u]$ satisfies this condition.

If cell c is a *case-2* cell, we have no such vertex and $\pi(x_{\alpha(v_c)}, v_c)$ lies entirely in $\alpha(v_c)$ or $\gamma(v_c)$. Let u be the last vertex of $\pi(x_{\alpha(v_c)}, v_c)$ which lies in $F_{\alpha(v_c)}$ and let u' be the last vertex of $\pi(x_{\beta(v_c)}, v_c)$ that lies in $F_{\beta(v_c)}$. We then can take our subpath to be $\pi_{\alpha,\beta}(v_c)[u, u']$, and this will satisfy the condition. ◀

We now consider the neighbors of D in the Voronoi support H, $N_H(D)$. In Lemma 10, the subwalk π_c of cell c in $resident(D)$ runs between the two balls of $hit(v_c) \setminus D$, both of which must be in $N_H(D)$ since H is simply the contraction of the Voronoi partition of G. We can now define a graph G_D on $N_H(D)$ to count the number of cells in $resident(D)$. For every cell c of $resident(D)$, add an edge e_c between the balls of $hit(v_c) \setminus D$. Since the underlying graph G is planar, we can sketch a drawing of G_D as follows:

To draw the curve ζ_c corresponding to cell c of $resident(D)$, we first consider the subpath π_c that we get from Lemma 10, using a plane drawing of G_D. Let v be the first endpoint of π_c lying in a ball D_1 and v' be the second endpoint of π_c lying in a ball D_2. We first draw

the center x_{D_1} in its location on any plane drawing of the underlying graph G. We then sketch ζ_c on $\pi(x_{D_1,v})$. This is followed by sketching π_c, and then finally sketching the walk $\pi(v', x_{D_2})$. Since this sketch is over a path, we will refer to this walk in G as $\pi(\zeta_c)$.

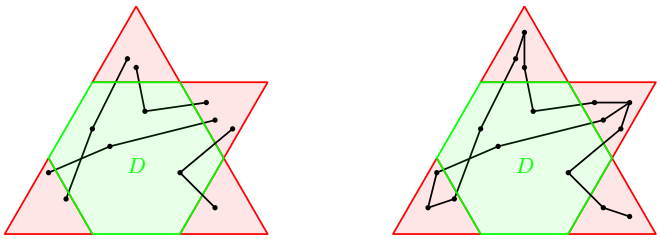

Figure 7 Left: a set of subwalks of cells in $resident(D)$. Right: the walks $\pi(\zeta_c)$ for each $c \in resident(D)$.

▶ **Lemma 11.** *For a given ball D in $\mathcal{R}$ and two distinct cells c and c' in $resident(D)$, if $\pi(\zeta_c)$ and $\pi(\zeta_{c'})$ share a common vertex v, then e_c and $e_{c'}$ share a common endpoint D'.*

Proof. Let $e_c = (D_1, D_2)$ and $e_{c'} = (D_3, D_4)$. For c (c'), the common vertex v must lie on a shortest path from either x_{D_1} or x_{D_2} (x_{D_3} or x_{D_4}) to v_c ($v_{c'}$) by construction. Without loss of generality, assume x_{D_1} and x_{D_3}. One of x_{D_1} or x_{D_3} must be at least as close as the other to v_c. Without loss of generality, assume x_{D_1}. By Lemma 8, this implies that D_1 contains $v_{c'}$, and is thus in $hit(v_{c'})$. We know that D is contained within $hit(v_{c'})$, as we only ever assign $base(v_{c'})$ to a member of $hit(v_{c'})$. Thus, in order for c' to be depth 3, D_1 must be either the same as D_3 or D_4. Thus, e_c and $e_{c'}$ have a common endpoint. ◀

Lemma 11 implies that ζ_c and $\zeta_{c'}$ only cross if e_c and $e_{c'}$ share an endpoint. Since the only crossings occur between edges incident on the same vertex, G_D can be redrawn with these crossings removed. This immediately implies the following:

▶ **Lemma 12.** *G_D is a simple planar graph.*

▶ **Lemma 13.** *There are $O(|\mathcal{R}|)$ cells of depth at most 3.*

Proof. We first quickly argue that there is $O(n)$ cells of depth at most 2. By the definition of cell, there is at most n cells of depth 1, one for each ball in $\mathcal{R}$. By the existence of a planar dual support (Theorem 2) on $\mathcal{R}$ with respect to all vertices of G, we know that for every cell of depth 2 corresponding to vertices v incident on balls R and R', the connectivity of $\mathcal{R}_v$ requires that R and R' share an edge. Since the dual support is planar, there is at most $3|\mathcal{R}| - 6$ such pairs, and thus at most $O(n)$ cells of depth 2.

For depth-3 cells, every edge of G_D corresponds to a resident depth-3 cell c of D, so $|resident(D)| \leq |E(G_D)|$. By Lemma 12, $|resident(D)| \leq 3|V(G_D)|$. By charging the depth-3 cells to the total number of edges across all G_D for all $D \in \mathcal{R}$ using the planarity of G_D, $|resident(D)| \leq 3|N_H(D)|$. Summing over all neighborhoods in the contracted Voronoi diagram of $\mathcal{R}$ in G, we know the sum of degrees is at most $6|\mathcal{R}|$. Thus, $|Cell_3| \leq 18|\mathcal{R}|$. ◀

Abstract

We initiate a statistical study of Kalai's exterior algebraic shifting, focusing on concentration phenomena for random triangulations of a fixed space. First, for a uniform n-vertex refinement of any given graph G, we show that asymptotically almost-surely (a.a.s.) its exterior algebraic shifting is an explicit shifted graph depending only on n and the Betti numbers of G. Next, for any given compact connected Riemannian surface S, sample n points independently at random according to the volume measure, and consider the resulted a.a.s. unique Delaunay triangulation. We prove that a.a.s. its exterior algebraic shifting is an explicit shifted complex depending only on n and the Euler genus of S, and in particular is area-rigid. In both results the expected shifted complex is a *homology lex-segment* complex, a notion we define combinatorially and characterize numerically à la Björner–Kalai.

As a tool to prove the result on surfaces, we prove a universality result on edge contractions: for every fixed surface triangulation K, every dense enough point set in the surface yields a Delaunay triangulation that edge contracts to K.

1 Introduction

A simplicial complex K on the vertex set $[n]$ is *shifted* if for all $1 \leq i < j$, $j \in A \in K$ implies that $(A \setminus \{j\}) \cup \{i\} \in K$. Erdős, Ko and Rado [11] introduced combinatorial shifting operators, which reduce problems on simplicial complexes to the shifted case. These operators have been used in many problems in extremal combinatorics, see Frankl's survey [13]. Kalai [16] introduced the exterior algebraic shifting operator on simplicial complexes, which is a canonical way to associate a shifted complex with a given simplicial complex, based on the exterior face ring over a fixed infinite field. Algebraic shifting has found many applications in combinatorics, especially in f-vector theory, and is interesting on its own, see, e.g., Kalai's survey [18].

While algebraic shifting preserves the face numbers and Betti numbers of simplicial complexes, it is not determined by them in general, not even in dimension 1, see Example 1.5 below. However, it is determined for all n vertex triangulations of a fixed 1-dimensional compact manifold, by the properties mentioned above together with [24, Theorem 4.6] in order to combine the exterior algebraic shifting of each connected component. In dimension 2, for any fixed compact connected surface without boundary, all its n vertex triangulations have the same face numbers (and of course also the same Betti numbers). While the exterior algebraic shifting is constant on n vertex triangulations of the 2-sphere, see [18, Sec.2.4] or [19, Footnote 2], it is not constant for higher Euler genus surfaces; see [19] for a characterization of the possible shifted complexes for small Euler genus surfaces. Although the exterior algebraic shifting is not constant in these cases, it was observed in [19, Remarks 5.3] that many of the triangulations of the torus have the same exterior algebraic shifting. Naturally the following question arises: is there a *typical* exterior algebraic shifting of a surface triangulation?

We study the expected asymptotic behavior of the exterior algebraic shifting over triangulations of a fixed compact space X. Two natural random models come to mind: (1) fix the topology of the space and sample a random n-vertex triangulation $U_n(X)$ of it uniformly, or, (2) fix a metric and a volume form on the space and consider the random Delaunay model, where an n points set P_n is sampled at random according to the volume measure, and the unique Delaunay complex $\mathrm{Del}(P_n)$ they define is considered – this complex turns out to be an embedded triangulation of X, for X a Riemannian surface and n large enough [22, 10].

We analyze the first model for 1-dimensional spaces and the second model for closed connected Riemannian surfaces. (We will consider only surfaces without boundary.) In both cases we show *concentration*, namely, that a.a.s. (i.e., with probability tending to 1 as $n \to \infty$) the resulted shifted complex is the unique *homology lex-segment* on n vertices with the same homology as X, denoted by $\Delta(X, n)$. We describe $\Delta(X, n)$ for graphs and surfaces.

Let $G = (V, E)$ be a fixed graph, and $|G|$ denote its geometric realization, namely its corresponding topological space. Denote: c is the number of connected components of G, $|V| = m + c - 1$ its number of vertices, $|E| = m + b - 1$ its number of edges; thus $b = \beta_1(|G|)$, the first Betti number of G. Let K be a subdivision of G on $n + c - 1$ vertices. Then we have: the exterior algebraic shifting $\Delta^{ex}(K)$ is the same over any field and is a homology lex-segment if and only if it equals

$$\Delta(|G|, n + c - 1) := [n + c - 1] \cup \left\{ A \in \tbinom{[n]}{2} \colon A < \{2, 3 + b\} \right\}. \tag{1}$$

Here and throughout the rest of the article the order $\leq$ stands for the lexicographic order.

Let us denote by (N_g) S_g the (non) orientable closed connected surface with Euler genus g, i.e., g is double the standard genus for orientable surfaces. If K is a triangulation of S_g (N_g) on $n \geq 4 + 3g$ vertices, then its exterior algebraic shifting $\Delta^{ex}(K)$ $(\Delta_2^{ex}(K))$ over a field of characteristic zero (two) is a homology lex-segment if it equals

$$\begin{aligned} \Delta_2(N_g, n) = \Delta(S_g, n) := [n] \cup \left\{ A \in \tbinom{[n]}{2} \colon A < \{4, 5 + 3g\} \right\} \\ \cup \left\{ A \in \tbinom{[n]}{3} \colon A < \{1, 4, 5 + 2g\} \right\} \cup \{\{2, 3, 4\}\}. \end{aligned} \tag{2}$$

On the other hand, if K is a triangulation of N_g, the exterior algebraic shifting $\Delta_0^{ex}(K)$ over a field of characteristic zero is a homology lex-segment if it equals

$$\Delta_0(N_g, n) := [n] \cup \left\{ A \in \tbinom{[n]}{2} \colon A < \{4, 5 + 3g\} \right\} \cup \left\{ A \in \tbinom{[n]}{3} \colon A < \{1, 4, 6 + 2g\} \right\}. \tag{3}$$

We will avoid explicitly mentioning the characteristic of the field except where it is necessary.

The following universality result is our main technical result, of independent interest. It says that for *every* fixed surface triangulation K, all fine enough Delaunay triangulations of same surface do edge contract to K. Formally:

▶ **Theorem 1.1** (Universality for edge contractions). *Let S be a closed connected Riemannian surface and K a triangulation of S. Then, there exists $\rho > 0$ small enough such that if $P \subseteq S$ is a ρ-dense point set, locally in general position, then there exists a sequence of edge contractions from $\mathrm{Del}(P)$ to K such that each intermediate complex triangulates S.*

Being *locally in general position* here means that within every small neighborhood, whose size depends on S, no point of P is on a geodesic between other two points of P and no four of its points lie on a circle. Theorem 1.1 is used to prove the following asymptotic behavior of a random Delaunay triangulation, namely concentration for the exterior algebraic shifting.

▶ **Theorem 1.2** (Concentration of exterior algebraic shifting for Random Delaunay on surfaces). *Let S be a closed connected Riemannian surface. Then, for the random Delaunay model on S there holds:*

- *If S is orientable then, a.a.s., the exterior algebraic shifting satisfies $\Delta^{ex}(\mathrm{Del}(P_n)) = \Delta(S, n)$.*
- *If S is nonorientable and $p \in \{0, 2\}$ then, a.a.s., the exterior algebraic shifting over any fixed field of characteristic p satisfies $\Delta_p^{ex}(\mathrm{Del}(P_n)) = \Delta_p(S, n)$, where Δ_p stands for the exterior algebraic shifting operation over a field of characteristic p.*

Area-rigidity, a generalization of graph-rigidity [1, 2], is concerned with the infinitesimal version of the following question: given a simplicial complex with its vertices embedded in $\mathbb{R}^2$, is there a non-trivial continuous motion of its vertex set that preserves the area of each 2-face. Both area and graph-rigidity admit a characterization in terms of algebraic shifting [21, 6]. While the graph of every surface triangulation is 3-rigid [12], the area-rigidity of its 2-skeleton is a conjecture [6, Conj. 5.1] known to hold for surfaces of small genus [6, Cor. 1.3]. If true, the barycentric subdivision of a surface triangulation would be a homology lex-segment, see Conj. 6.2. Combining the algebraic shifting characterization of area-rigidity [6, Thm.1.2 and Claim 2.2] and Theorem 1.2 we obtain an affirmative answer to the area-rigidity conjecture for surfaces [6, Conj. 5.1] for Delaunay triangulations in the asymptotic regime.

▶ **Corollary 1.3.** *Let S be a closed connected Riemannian surface. Then, a.a.s. $\mathrm{Del}(P_n)$ is area-rigid.*

For uniform random triangulations of a one dimensional compact topological space we show the following concentration for the exterior algebraic shifting.

▶ **Theorem 1.4** (Concentration of exterior algebraic shifting for uniform triangulations in dimension 1). *Let G be a finite graph. Then, a.a.s., the exterior algebraic shifting over any fixed field satisfies $\Delta^{ex}(U_n(|G|)) = \Delta(|G|, n)$.*

The probabilistic conclusion in this theorem can not be upgraded to a deterministic one:

▶ **Example 1.5.** Let G be the graph on 5 vertices containing K_4 and 7 edges, denote by v its vertex of degree one, and by u the neighbor of v. Let R be the n vertex refinement of G obtained by subdividing the edge vu by $n-5$ new vertices. Then K_4 is a subgraph of R hence the edge $\{3, 4\} \in \Delta^{ex}(R)$. But by Theorem 1.4 a.a.s. $\{3, 4\} \notin \Delta^{ex}(H)$ for a uniform n vertex refinement H of G.

Theorems 1.4 and 1.2 lead to the following natural conjecture.

▶ **Conjecture 1.6.** *For every fixed Euler genus g, a.a.s., the exterior algebraic shifting over any fixed field satisfies $\Delta^{ex}(U_n(S_g)) = \Delta(S_g, n)$.*

Outline. In Section 2 we provide preliminaries on exterior algebraic shifting, homology lex-segments, and Delaunay triangulations; in Section 3 we prove Theorem 1.1; in Section 4 we prove Theorem 1.2; in Section 5 we prove Theorem 1.4; in Section 6 we discuss concentration for triangulations of other spaces.

2 Preliminaries

2.1 Algebraic shifting

We recall Kalai's definition [16]. Let K be a simplicial complex with vertex set N, $\mathbb{F}$ be an field extension of a base field $\mathbb{F}'$ of transcendence degree at least n^2, and consider the exterior algebra mod the ideal generated by non-faces $\bigwedge K = \bigwedge \mathbb{F}^N / \operatorname{span}\{e_A \colon A \notin K\}$, called the *exterior face ring of* K. Here the e_i's form the standard basis of $\mathbb{F}^N$, and e_A stands for the exterior product $e_{a_1} \wedge \ldots \wedge e_{a_k}$ where $A = \{a_1 < \ldots < a_k\}$. Take $(f_i)_{i \in N}$ a generic change of basis of $\mathbb{F}^N$, namely all n^2 entries of the transition matrix are algebraically independent over the base field $\mathbb{F}'$. Then, the *exterior algebraic shifting of* K is the simplicial complex given by

$$\Delta^{ex}(K) = \{B \subseteq N \colon \overline{f_B} \notin \operatorname{span}_{\mathbb{F}}\{\overline{f_A} \colon A < B\}\},$$

where $f_A = f_{a_1} \wedge \ldots \wedge f_{a_k}$ and its bar $\overline{f_A}$ denotes its image in $\bigwedge K$. The simplest such complex is obtained when all initial sets are in the exterior algebraic shifting. When taking into account Betti numbers this leads to the construction of homology lex-segment complexes as follows. Let $\mathbf{f} = (f_0, f_1, \dots)$ and $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots)$ be two non-negative integer vectors and set $n = f_0$. Let $I([n], r, m)$ denote the first m elements in $\binom{[n]}{r+1}$ in lex order. Similarly to [3] for $r \geq 0$ we set $\chi_{r-1} = \sum_{j \geq r} (-1)^{j-r}(f_j - \beta_j)$ and consider the families of sets $E = \bigcup_{r \geq 0} I([2, n], r, \chi_r + \beta_r)$ and $C = \bigcup_{r \geq 0} I([2, n], r, \chi_r)$ and finally set $K_{\mathbf{f},\boldsymbol{\beta}} = (1 * C) \cup E$ to be the cone over C with apex 1, union E. A simplicial complex K is a *homology lex-segment complex* if $K = K_{f(K),\beta(K)}$. Next, we describe pairs $(\mathbf{f}, \boldsymbol{\beta})$ giving rise to homology lex-segment complexes. For it, let $\partial_r(n, m)$ denote the minimum m' such that $I([n], r-1, m')$ contains $\partial I([n], r, m) = \{A \in \binom{[n]}{r} \colon A \subseteq B, B \in I([n], r, m)\}$.

▶ **Lemma 2.1** ([5, Lemma A.3])**.** *Let* $\mathbf{f}$, $\boldsymbol{\beta}$ *be two non-negative integer vectors. Then,* $K_{\mathbf{f},\boldsymbol{\beta}}$ *is a simplicial complex with* $f(K_{\mathbf{f},\boldsymbol{\beta}}) = \mathbf{f}$ *and* $\beta(K_{\mathbf{f},\boldsymbol{\beta}}) = \boldsymbol{\beta}$ *if and only if* $\chi_{-1} = 1$ *and* $\partial_r(n-1, \chi_r + \beta_r) \leq \chi_{r-1}$ *for* $r \geq 1$*, where* $n = f_0$*.*

Now, the descriptions of homology lex-segment complexes given in (1)–(3) follows, see also [5, Appendix]. The following corollary is a consequence of [24, Theorem 4.6].

▶ **Corollary 2.2.** *Let* K *and* K' *be triangulations of surfaces* S *and* S' *resp., intersecting in a single 2-face* B*, i.e.,* $K \cap K' = \langle B \rangle$*. Then,* $(K \cup K') \setminus \{B\}$ *is a triangulation of the connected-sum surface* $(S \cup S) \setminus B$*. Moreover, if* $\Delta^{ex}(K)$ *and* $\Delta^{ex}(K')$ *are homology lex-segment complexes then* $\Delta^{ex}((K \cup K') \setminus \{B\})$ *is a homology lex-segment complex as well.*

▶ **Corollary 2.3.** *Let* S *be a closed connected surface with Euler genus* g*, then it admits a triangulation whose exterior algebraic shifting is a homology lex-segment complex.*

Proof. By [19, Theorem 1.2] there is a triangulation of the torus on 10 vertices and a triangulation of the projective plane on 7 vertices whose exterior algebraic shifting are homology lex-segments, see Figure 1(2-3). By Corollary 2.2 attaching iteratively g copies of this triangulation along 2-faces we obtain a triangulation of S_g, or N_g, that is a homology lex-segment complex. ◀

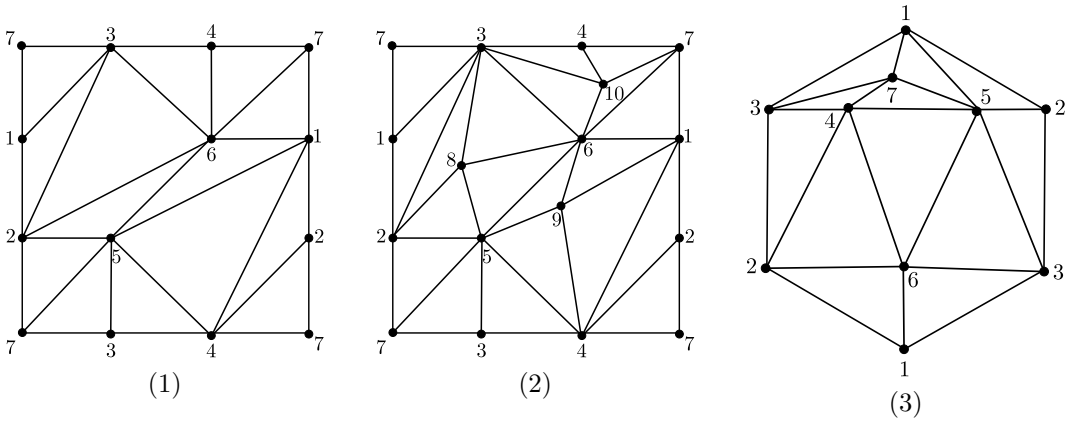

Figure 1 (1) An irreducible triangulation of the torus on 7 vertices. (2) Triangulation of the torus on 10 vertices whose exterior algebraic shifting is a homology lex-segment. (3) Triangulation of the projective plane on 7 whose exterior algebraic shifting is a homology lex-segment over fields with characteristic 0 and 2.

Edge contraction and vertex-split. Let K be a simplicial complex and $e = \{u, v\} \in K$. We say that K' is *obtained from K by contracting the edge e* if K' is obtained from K by replacing every occurrence of the vertex u with the vertex v (and removing duplicated faces). The inverse operation of an edge contraction is called a *vertex-split*. In the case that K is a surface triangulation, an edge contractions results in a triangulation of the same surface if and only if the contracted edge is not part of a missing triangle, namely a triangle not in K whose boundary is contained in K; such edge is called *contractible*. The triangulation of the torus in Figure 1(1) is obtained from Figure 1(2) by means of three edge contractions. Namely, $\{2, 8\}, \{4, 10\}$ and $\{1, 9\}$. Performing a vertex-split on a simplicial complex can only make its exterior algebraic shifting simpler. To state this precisely we set $\operatorname{Tail}(K, A) = \{B \in K \colon A \leq B\}$.

▶ **Proposition 2.4** ([6, 19]). *Let K be a surface triangulation on n vertices and K' obtained from K by a vertex-split. If $\{1, 3, n\} \in \Delta^{ex}(K)$, then $\{1, 3, n+1\} \in \Delta^{ex}(K')$. Moreover, for $m \geq 3$ we have that*

$$|\operatorname{Tail}(\Delta^{ex}(K), \{m+1, m+2\})| \geq |\operatorname{Tail}(\Delta^{ex}(K'), \{m+1, m+2\})|, \text{ and}$$
$$|\operatorname{Tail}(\Delta^{ex}(K), \{1, m+1, m+2\})| \geq |\operatorname{Tail}(\Delta^{ex}(K'), \{1, m+1, m+2\})|.$$

▶ **Corollary 2.5.** *Let K be a surface triangulation and K' obtained from K by a vertex-split. If $\Delta^{ex}(K)$ is a homology lex-segment complex, then $\Delta^{ex}(K')$ is as well.*

Proof. On the one hand, Proposition 2.4 implies that

$$|\operatorname{Tail}(\Delta^{ex}(K'), \{5, 6\})| \leq |\operatorname{Tail}(\Delta^{ex}(K), \{5, 6\})| = 0.$$

On the other hand, Proposition 2.4 also says that $\{1, 3, n'\} \in \Delta^{ex}(K')$, where n' is the number of vertices in K'. Then, the tails $\operatorname{Tail}(\Delta^{ex}(K'), \{4, 5\})$ and $\operatorname{Tail}(\Delta^{ex}(K'), \{1, 4, 5\})$ are totally ordered sets of same sizes as the corresponding tails w.r.t. K, and hence equal to the corresponding tails w.r.t. K (these sizes are determined solely by the Euler genus of the surface). To conclude, $\Delta^{ex}(K')$ is a homology lex-segment complex. ◀

The following lemma and its proof are similar to [19, Lemma 4.10] and [28].

▶ **Lemma 2.6.** *Let K be a triangulation of a disc with at least one edge e adjacent to at least one interior vertex. Then, there exists a contractible edge incident to at least one interior vertex. Moreover, if both endpoints of e are interior then there exists a contractible edge incident to two interior vertices.*

2.2 The Delaunay complex

Riemannian surfaces. An *embedding* of a simplicial complex K into a surface S is a continuous injective map from its geometric realization into S. We will denote by $|K|$ the image of the embedding of K in S. If this map is a homeomorphism then K is said to be a *triangulation* of S. If in addition S has a smooth structure then an embedding is called (piecewise) smooth if restricting it to each edge of K gives rise to a (piecewise) smooth map.

▶ **Theorem 2.7** ([15])**.** *Let K be a simplicial complex and S be a surface with a smooth structure. If K is a triangulation of S then it can be smoothly embedded into S.*

Now, let S be a connected closed Riemannian surface, i.e., compact and without boundary. By the Hopf–Rinow theorem [9] every two points on S are connected by a minimal length geodesic. For $p, q \in S$ let us denote by $d(p, q)$ the distance between p and q given by a minimal length geodesic joining them. For $X \subseteq S$ and $\epsilon > 0$ we will denote $B(X, \epsilon) = \{q \in S \colon d(X, q) < \epsilon\}$ the open neighborhood of a set X of radius ϵ. The *injectivity radius at* $p \in S$, denoted by $\mathrm{r}_{\mathrm{inj}}(p)$, is the largest real number r such that whenever $d(p, q) < r$, then there exists a unique minimal geodesic from p to q. The *injectivity radius of* S is defined as $\mathrm{r}_{\mathrm{inj}}(S) = \inf_{p \in S} \mathrm{r}_{\mathrm{inj}}(p)$. A subset $A \subseteq S$ is said to be *strongly convex* if for every two elements $p, q \in A$ there exists a unique minimal geodesic joining them, this geodesic is contained in A and there is no other geodesic in A joining p and q. The *strong convexity radius at* p is

$$\mathrm{r}_{\mathrm{scv}}(p) = \sup\{r \colon B(p, r') \text{ is strongly convex for every } r' < r\}.$$

The strong convexity radius of S is $\mathrm{r}_{\mathrm{scv}}(S) = \inf_{p \in S} \mathrm{r}_{\mathrm{scv}}(p) > 0$, see [20, 1.9.9].

Tubular neighborhood. For each point $p \in S$ the exponential map at p is the smooth map $\exp_p \colon T_pS \to S$ that assigns for every vector $X \in T_pS$ the point $\gamma(\|X\|)$ where γ is the geodesic starting at p with tangent vector $\gamma'(0) = X/\|X\|$. Here the norm is given by the Riemannian metric on T_pS. Now, let γ be a smooth curve in S and $\epsilon > 0$. At each point $p = \gamma(t)$ let $X \in T_pS$ be an orthonormal vector with respect to $\gamma'(t)$ (there are two choices, one the negative of the other, but both result in the same tubular neighborhood) and set

$$I(p, \epsilon) = \{\exp_p(tX) \colon t \in (-\epsilon, \epsilon)\} \text{ and } I(\gamma, \epsilon) = \bigcup_{p \in \gamma} I(p, \epsilon).$$

There exists $\epsilon > 0$ such that the sets $I(p, \epsilon)$ are all disjoint for $p \in \gamma$ [26, Proposition 7.26]. In this case $I(\gamma, \epsilon)$ is called the *tubular neighborhood of* γ *with radius* ϵ. For a simple curve γ with distinct endpoints a and b we extend its tubular neighborhood by adding a cap on each end point. Concretely, we set $\tilde{I}(\gamma, \epsilon') = B(a, \epsilon') \cup B(b, \epsilon') \cup I(\gamma, \epsilon')$ where $0 < \epsilon' \leq \epsilon$ is chosen to be small enough in order for the caps to be disjoint embedded discs.

Delaunay complex. Let $P \subseteq S$ be a finite subset, *the Delaunay complex of* P *in* S, denoted by $\mathrm{Del}(P)$, is the simplicial complex whose faces are given by subsets $A \subseteq P$ for which there exists an open ball $B(x, \epsilon) \subseteq S$ disjoint from P such that $A \subseteq cl(B(x, \epsilon))$ [8]. Although $\mathrm{Del}(P)$ always defines a simplicial complex, its geometric realization is in general not homeomorphic

to S. In the case of surfaces a density condition suffices to ensure that for a subset $P \subseteq S$ locally in general position, $\mathrm{Del}(P)$ is a smoothly embedded triangulation of S. We make this requirement precise now. Set $\mathrm{r}_{\mathrm{Del}}(S) = \min\{\mathrm{r}_{\mathrm{inj}}(S)/6, \mathrm{r}_{\mathrm{scv}}(S)\}$. A subset $P \subseteq S$ is *locally in general position* if no point is on the minimal geodesic between other two points at distance less than $\mathrm{r}_{\mathrm{Del}}(S)$, and no four points are simultaneously on the boundary of a ball of radius less than $\mathrm{r}_{\mathrm{Del}}(S)$. A set of points $P \subseteq S$ is *ρ-dense* if there is at least one point of P in any ball in S of radius greater or equal to ρ. The existence of a Delaunay triangulation is given by the following theorem, see also [10, Theorem 2].

▶ **Theorem 2.8** ([22]). *Let S be a closed connected Riemannian surface and $\rho \leq \mathrm{r}_{\mathrm{Del}}(S)$. If $P \subseteq S$ is a ρ-dense finite subset locally in general position, then $\mathrm{Del}(P)$ is a geodesically embedded triangulation of S.*

To control the behaviour of Delaunay edges we will repeatedly use the following bound on their length.

▶ **Lemma 2.9.** *Let $P \subseteq S$ be a ρ-dense finite subset such that $\mathrm{Del}(P)$ is a geodesically embedded triangulation of S. Then, for each edge $e \in \mathrm{Del}(P)$ its embedding γ_e has length strictly less than 2ρ.*

Proof. Let $B(x, r)$ be a ball witnessing that $e = \{u, v\}$ is a edge. Then, $r < \rho$ since otherwise it contains $B(x, \rho)$ whose intersection with P is empty contradicting the ρ-dense assumption. Then, $\mathrm{length}(\gamma_e) = d(u, v) \leq d(u, x) + d(x, v) = 2r < 2\rho$ as desired. ◀

3 The refinement of a triangulation

In this section we prove our universality Theorem 1.1. The proof of this theorem proceeds in two steps. The first step, Proposition 3.10, shows that for $\rho > 0$ small enough, a ρ-dense Delaunay triangulation $\mathrm{Del}(P)$ of a surface S edge contracts to a subdivision the original triangulation K of S. The second step, Proposition 3.11, verifies that the edges of a subdivision of K can be contracted in order to reach K. The following is the definition of a subdivision we require, see [23, Sect. 15].

▶ **Definition 3.1.** *Let S be a surface and K, K' be two simplicial complexes embedded in S. The embedding $|K'|$* is a subdivision of *$|K|$ if the embedding of every face of K' is contained in the embedding of some face of K, and the embedding of every face of K is given by a union of the embeddings of finitely many faces from K'. For a face $A \in K$ we denote by K'_A the subcomplex of K' whose realization $|K'_A|$ is a subdivision of $|A| \subseteq S$.*

The following definitions and lemmas pave the way to Proposition 3.10, where we contract edges of $\mathrm{Del}(P)$, locally in small balls around the vertices of K, to reach a subdivision of K; see Figures 2 and 3.

Recall that for an embedded simplicial complex K, the *open star of a face $A \in K$* is the open subset $st^\circ(A, K) \subseteq |K|$ given by the union of the relative interiors of the faces containing A, including A itself. The *closed star* $st(A, K)$ is the closed set $\mathrm{cl}\, st^\circ(A, K)$ or equivalently it is the union of the closures of all the faces containing A [23].

▶ **Definition 3.2.** *Let K be a simplicial complex embedded in S. A family of closed discs with smooth boundaries $\mathcal{B}_0 = \{B_v \subseteq B'_v \subseteq B''_v : v \in K_0\}$ is a* layered vertex cover *if* (1) *$B_v \subseteq \mathrm{int}\, B'_v$ and $B'_v \subseteq \mathrm{int}\, B''_v$,* (2) *$B''_v \cap B''_u = \emptyset$ for every pair of distinct vertices $v, u \in K_0$,* (3) *$v \in B_v \subseteq B'_v \subseteq B''_v \subseteq st^\circ(v, K)$.*

The following intuitive and simple lemma guarantees that a layered vertex cover exists.

▶ **Lemma 3.3.** *Let S be a Riemannian surface, K an embedded triangulation of S. Then, there exists $\epsilon > 0$ such that $\{B(v,\epsilon) \subseteq B(v,2\epsilon) \subseteq B(v,3\epsilon) \colon v \in K_0\}$ is a layered vertex cover.*

▶ **Definition 3.4.** *Let K be a simplicial complex piecewise smoothly embedded in S and $\mathcal{B}_0$ a layered vertex cover. The embedding is* transversal with respect to $\mathcal{B}_0$ *if*

1. *for each edge $e = \{u,v\}$ its embedding γ_e intersects ∂B_v exactly once, at a point $a_{e,v}$,*
2. *for each edge $e = \{u,v\}$ its embedding γ_e is given by a concatenation $\gamma_{e,u} \circ \widetilde{\gamma_e} \circ \gamma_{e,v}$ where $\gamma_{e,u}$ is a smooth curve in B_u connecting $a_{e,u}$ and u, $\gamma_{e,v}$ is smooth curve in B_v connecting v to $a_{e,v}$ and $\widetilde{\gamma_e}$ is a smooth curve connecting $a_{e,v}$ and $a_{e,u}$.*

The following lemma guarantees the existence of a transversal embedding.

▶ **Lemma 3.5.** *Let K be a triangulation of S, then K admits a piecewise smooth embedding in S that is transversal with respect to some layered vertex cover.*

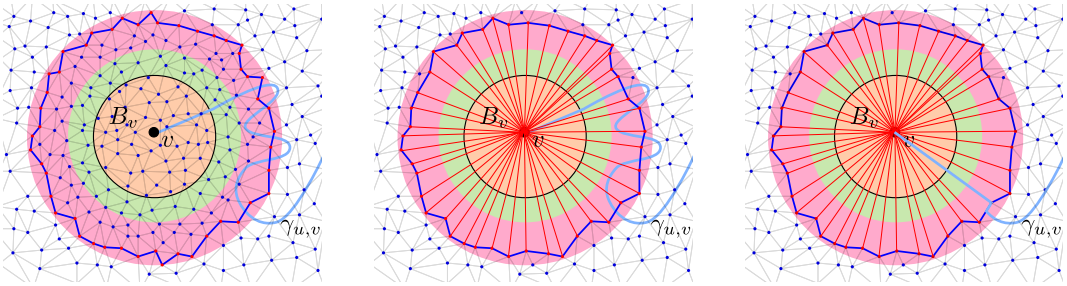
▶ **Definition 3.6.** *Let K be a piecewise smooth embedding into S that is transversal with respect to the layered vertex cover $\mathcal{B}_0$. A family of closed discs $\mathcal{B}_1 = \{B_e \subseteq S \colon e \in K_1\}$ is an* edge cover *if it satisfies the following four conditions:* (1) $\widetilde{\gamma_e} \subseteq \operatorname{int} B_e$, (2) $B_e \subseteq st^\circ(e,K)$, (3) $B_e \cap B_{e'} = \emptyset$ *for every pair of distinct edges $e, e' \in K_1$,* (4) $B_e \cap B''_v = \emptyset$ *if $v \notin e$.*

▶ **Lemma 3.7.** *Let K be a simplicial complex piecewise smoothly embedded in S that is transversal with respect to the layered vertex cover $\mathcal{B}_0$. Then, there exists $\delta > 0$ such that $\{B(\widetilde{\gamma_e},\delta) \colon e \in K_1\}$ is an edge cover.*

Proof. The curve $\widetilde{\gamma_e}$ is contained in the interior of the tubular neighborhood with caps $\operatorname{int} \widetilde{I}(\widetilde{\gamma_e})$ and consequently by setting $0 < \delta \leq d(\widetilde{\gamma_e}, \partial \widetilde{I}(\gamma_e))$ we guarantee that the resulting set is an embedded disc. Property (1) holds by construction, and small enough δ clearly guarantees (2) as well. Since $\widetilde{\gamma_e}$ and $\widetilde{\gamma_{e'}}$ are disjoint for every pair of distinct edges $e, e' \in K$, then by setting $\delta \leq d(\widetilde{\gamma_e}, \widetilde{\gamma_{e'}})/2$ property (3) holds. Finally, as $\gamma_e \cap B''_v = \emptyset$ for $v \notin e$ since $B''_v \subseteq st^\circ(v,K)$ then by setting $0 < \delta \leq d(\widetilde{\gamma_e}, B''_v)$ also property (4) is satisfied. ◀

▶ **Lemma 3.8.** *Let S be a closed connected Riemannian surface, let $X \subseteq D \subseteq S$ be a pair of discs in S and $P \subseteq S$ a ρ-dense finite set such that $\operatorname{Del}(P)$ is a triangulation of S. If $2\rho < \min\{d(X, \partial D), \mathrm{r}_{\mathrm{scv}}(S)\}$, then the restriction of $\operatorname{Del}(P)$ to the triangles all whose vertices are in D, denoted by Del_D, contains a unique maximal disc subcomplex $\operatorname{Del}_{D,X}$ containing X. Further, all the boundary vertices of $\operatorname{Del}_{D,X}$ lie outside of X.*

Proof. As $2\rho < \mathrm{r}_{\mathrm{scv}}(S)$, every cycle on the edges of Del_D is fully contained in the disc D, hence so is its inner connected component disc C. Since $\operatorname{Del}(P)$ is a triangulation of S, it has a subcomplex that triangulates C, and its triangles are present in Del_D because they are contained in D. Thus, Del_D is a simply connected planar pure 2-dimensional complex, hence a *cacti*, see e.g. [7], namely the union of maximal simplicial discs, every two of them are either disjoint or intersect in a single vertex, and the bipartite graph whose vertices correspond to the set A of discs and the set B of their intersection points and whose edges ab correspond to incidences $b \in a$ for $(a,b) \in A \times B$, is a forest.



Denote by $\operatorname{Del}_{D,X}$ the maximal disc in the decomposition that contains X. It is left to show that $\operatorname{Del}_{D,X}$ is well defined. Indeed, for every point $x \in X$, each vertex in a triangle A in $\operatorname{Del}(P)$ containing x is of distance at most 2ρ from x. Since $2\rho < \mathrm{r}_{\mathrm{scv}}$ the embedding of A is contained in $B(x,2\rho)$ since this last one is strongly convex. Moreover, given that $2\rho < d(x,\partial D)$ the ball $B(x,2\rho)$, and consequently A as well, is contained in D. Thus, the

triangle A is in Del_D, and consequently there exists a unique disc component $\mathrm{Del}_{D,X}$ in the cacti that contains X. Further, as $2\rho < d(X, \partial D)$, for a vertex $v \in \mathrm{Del}(P)$ lying in X, all its neighbors are in D, hence such v can not be on the boundary of $\mathrm{Del}_{D,X}$. ◀

▶ **Lemma 3.9.** *Let $B \subseteq B' \subseteq B'' \subseteq S$ closed discs with smooth boundary such that $B \subseteq \operatorname{int} B'$, $B' \subseteq \operatorname{int} B''$, $\rho > 0$ and $P \subseteq S$ a ρ-dense finite point set such that $\mathrm{Del}(P)$ is a triangulation of S. If $2\rho < \min\{d(B, \partial B'), d(B', \partial B''), \mathrm{r_{scv}}\}$, then the vertex set of $\partial\,\mathrm{Del}_{B'',B}$ is contained in $B'' \setminus B'$ and every edge between boundary vertices of $\mathrm{Del}_{B'',B}$ is disjoint from B.*

Proof. As $B \subseteq B'$, the maximal discs $\mathrm{Del}_{B'',B}$ and $\mathrm{Del}_{B'',B'}$ from Lemma 3.8 satisfy, by definition, that they are equal, and their boundary vertices lie in $B'' \setminus B'$.

Now, let $e = \{u, v\}$ be a Delaunay edge with endpoints in $B'' \setminus B'$. Then, $\gamma_e \cap B = \emptyset$ since $d(B, \partial B') > 2\rho$ and all edges have length at most 2ρ. ◀

(1) (2) (3)

Figure 2 (1) The Delaunay triangulation in a neighborhood of the vertex v, where layered vertex cover of v is depicted. The vertices of $\partial\,\mathrm{Del}_{B''_v,B_v}$ (marked in red) and its edges (marked in blue) are disjoint from B_v. The embedding $\gamma_{u,v}$ is shown in light blue. (2) The triangulation obtained after contracting edges inside D_v. The resulting simplicial complex is a cone. Note that the vertices on the boundary of D_v form a strict subset of those on the boundary of $\mathrm{Del}_{B''_v,B_v}$. (3) The embedding of the edge $\gamma_{u,v}$ is modified: after intersecting ∂D_v, it continues along the shortest path to v.

▶ **Proposition 3.10.** *Let S be a closed Riemannian manifold and K a triangulation of S. There exist a piecewise smooth embedding of K in S and a density $\rho > 0$ such that the following holds. If $P \subseteq S$ is a ρ-dense finite set locally in general position, then $\mathrm{Del}(P)$ admits a sequence of edge contractions reaching a subdivision of K.*

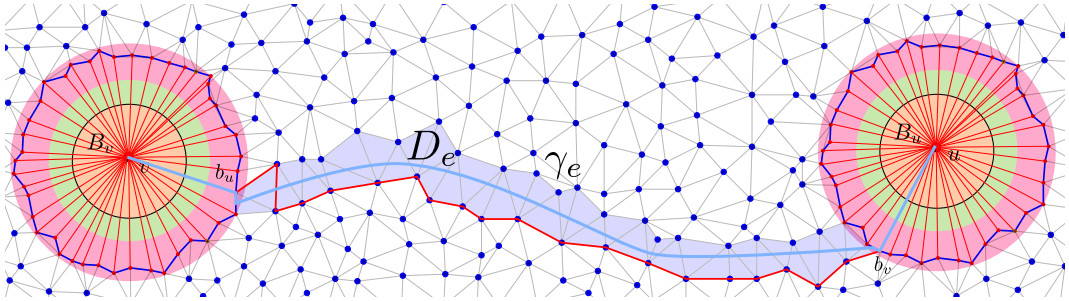


Figure 3 Edge approximation in a Delaunay triangulation inside the edge neighborhood Del_e.

Proof. First, by Lemma 3.5 the triangulation K admits a piecewise smooth embedding in S that is transversal with respect to some layered vertex cover $\mathcal{B}_0$. In addition, let $\mathcal{B}_1$ be the edge cover guaranteed by Lemma 3.7. Finally, set $\rho > 0$ small enough, to be specified below, that depends only on S, on the embedding of K, on the layered vertex cover $\mathcal{B}_0$ and on the edge cover $\mathcal{B}_1$.

Let $\rho < \mathrm{r}_{\mathrm{Del}}(S)$ and $P \subseteq S$ a ρ-dense finite subset locally in general position. Then, Theorem 2.8 implies that the simplicial complex $\mathrm{Del}(P)$ is a triangulation of S.

Call an edge in a triangulated disc *diagonal* if both its vertices belong to the boundary of the disc. Now, let $\mathrm{Del}_{B''_v,B_v}$ be the disc guaranteed by Lemma 3.8, see Figure 2(1). We proceed to select a subcomplex of $\mathrm{Del}_{B''_v,B_v}$ without diagonal edges while still containing B_v in its interior. For it, let e be a diagonal edge in $\mathrm{Del}_{B''_v,B_v}$. Then e splits this complex into two connected components both of which are discs. By taking $2\rho < \min\{d(B_v, \partial B'_v), d(B'_v, \partial B''_v), \mathrm{r}_{\mathrm{scv}}(S)\}$, Lemma 3.9 guarantees that the embedding γ_e does not intersect B_v. We iterate this procedure with the component having B_v in its interior. The resulting triangulated disc D has no diagonal edges and contains B_v in its interior. In D we proceed to iteratively contract edges whose both endpoints are in the interior of D, see Lemma 2.6. The resulting complex D_v is a star with boundary ∂D and we identify the apex vertex with v, see Figure 2(2). Let K' denote the result of applying this sequence of edge contractions to $\mathrm{Del}(P)$ for every vertex $v \in K_0$.

Next we modify the embedding of K so that its edges are realized on the 1-skeleton of K'. For it, let $e = \{u, v\} \in K_1$ and $\mathrm{Del}_{B_e,\widetilde{\gamma_e}} \subseteq \mathrm{Del}(P)$ given by Lemma 3.8[1], where we have applied the lemma to a small enough neighborhood of $\widetilde{\gamma_e}$. Since $\widetilde{\gamma_e}$ intersects ∂D_u and ∂D_v so does $\mathrm{Del}_{B_e,\widetilde{\gamma_e}}$. Let γ'_e be a shortest path in the graph metric contained in the 1-skeleton of $\mathrm{Del}_{B_e,\widetilde{\gamma_e}}$ between ∂D_u and ∂D_v with endpoints $b_{e,u}$ and $b_{e,v}$ respectively, see Figure 3. We need to make sure that for $e = vu$ and $e'' = vu''$ the vertices $b_{e,v}$ and $b_{e'',v}$ in D_v are distinct. Indeed, by taking $4\rho < d(\gamma_e \cap (B''_v \setminus B_v), \gamma_{e''} \cap (B''_v \setminus B_v))$ for every two edges e, e'' both containing v as a vertex, we guarantee that $b_{e,v}$ and $b_{e'',v}$ are distinct. Finally, replace the embedding γ_e by the concatenation $\gamma'_{e,u} \circ \gamma'_e \circ \gamma'_{e,v}$ where $\gamma'_{e,u}$ is the unique edge in D_u from $b_{e,u}$ to u and similarly $\gamma'_{e,v}$ is the unique edge in D_v from $b_{e,v}$ to v, see Figures 2(3) and 3. Since the cyclic order at every vertex of K is preserved, the embedded simplicial complex coincides with K (combinatorially) and it is subdivided by $|K'|$. ◀

▶ **Proposition 3.11.** *Let K, K' be two embedded triangulations of a surface S such that $|K'|$ is a subdivision of $|K|$. Then, there exists a sequence of edge contractions from K' to K.*

Proof. We proceed by induction on the number of edges of K'. We split the analysis into two cases, in each case we perform an edge contraction to reduce the number of edges and proceed by induction. If the vertex sets $K_0 = K'_0$ then the simplicial complexes coincide. Let us assume then that K' has more vertices and consequently there exists a face $A \in K$ such that its subdivision K'_A has at least one interior vertex. We split the analysis into two cases, either there exists such a triangle A, or else A must be an edge.

Case 1: If A is a triangle, we let K'_A be the subdivision of a 2-face with an interior vertex. Then, by Lemma 2.6 there exists a contractible edge incident to an interior vertex.

[1] The definition of $\mathrm{Del}_{B,X}$ applies to every connected subspace X contained in the interior of a disc B. Indeed, as X is far enough from the boundary of B then an open neighborhood of X is contained in $\mathrm{Del}(P) \cap B$, hence X is contained in a maximal disc component – this is $\mathrm{Del}_{B,X}$.

Case 2: Suppose that there are no more 2-faces of K whose subdivision has an interior vertex. Let K'_e be the subdivision of an edge $e \in K$ with a vertex in its relative interior and let $f = \{a, b\} \in K'_e$ an edge. If f is contractible, then we contract it and proceed by induction. Otherwise, f is part of a missing triangle $T = \{a, b, c\}$ in K', hence c must be in K'_e as we excluded Case 1.

The boundary of T is contained in the disc D formed by the embedded two triangles in K that contain e. Thus, the boundary of T bounds a disc D_T realized inside $|D|$ which is a subcomplex of K' with an interior vertex; all vertices of D_T belong to K'_e. As K'_e has finitely many vertices, proceeding in this manner for an edge f' in $K'_e \cap D_T$ and so on, we finally find a contractible edge in K'_e, similar to the proof of Lemma 2.6. ◀

4 Concentration of exterior algebraic shifting for Random Delaunay

Let ν be a volume measure on S and U_S be the random variable on S uniformly distributed with respect to ν, i.e., for a ν-measurable subset $V \subseteq S$ we have that $\mathbb{P}(U_S \in V) = \nu(V)/\nu(S)$. For $n \in \mathbb{N}$ let P_n denote the random variable of picking n (unlabelled) points from S independently uniformly at random according to ν. Equivalently, we can consider the stochastic process $(P_n)_{n\in\mathbb{N}}$ where at each step we pick a new point in S uniformly at random and independent from the previous choices. We are interested in sampling points that are locally in general position (g.p. for short), i.e., (1) no point is on the minimal geodesic between other two points at distance less than $\mathrm{r}_{\mathrm{Del}}(S)$, and (2) no four points are simultaneously on the boundary of a ball of radius less than $\mathrm{r}_{\mathrm{Del}}(S)$.

▶ **Lemma 4.1.** *Let S be a closed connected Riemannian surface, $\rho > 0$ fixed, and P_n as above. Then, P_n is almost-surely locally in g.p for every $n \in \mathbb{N}$, and a.a.s. ρ–dense.*

Proof. For the first part we proceed by induction on n. Denote by E_n the event that P_n is locally in g.p. Observe that $\mathbb{P}(E_n) = \mathbb{P}(E_n|E_{n-1})\mathbb{P}(E_{n-1})$ and that $\mathbb{P}(E_{n-1}) = 1$ by induction. Conditioned on E_{n-1}, the probability of E_n is given by the probability of picking a point that is not in the union of the sets determined by the complements of the conditions (1) and (2) in the definition of g.p. above. Since these complements have ν-measure 0 in S and there are finitely many of them, the conclusion follows.

For the second part let $\{B(x, \rho/2) \colon x \in I\}$ be a finite open cover of S, which exists since S is compact. Then, it is enough to guarantee that $P_n \cap B(x, \rho/2) \neq \emptyset$ for every $x \in I$. Indeed, if this is true, then for every $y \in S$ there exists $x \in I$ such that $y \in B(x, \rho/2)$ and $p \in P \cap B(x, \rho/2)$. Then, $d(y, p) \leq d(y, x) + d(x, p) < \rho$ as claimed. It follows that

$$\begin{aligned}\mathbb{P}(P_n \text{ is } \rho\text{–dense}) &\geq \mathbb{P}(\forall x \in I, P_n \cap B(x, \rho/2) \neq \emptyset) \geq 1 - \sum_{x\in I} \mathbb{P}(P_n \cap B(x, \rho/2) = \emptyset) \\ &\geq 1 - |I|(1 - \mu)^n,\end{aligned}$$

where $\mu = \min_{x\in I} \nu(B(x, \rho/2))/\nu(S) > 0$. The conclusion now follows by taking $n \to \infty$. ◀

Proof of Theorem 1.2. Let K be a triangulation of S given by Corollary 2.3 and set $\rho > 0$ as required by Theorem 1.1 when applied to K and S. By Lemma 4.1 P_n is a.a.s. ρ–dense and is locally in general position. Then, Theorem 1.1 guarantees that $\mathrm{Del}(P_n)$ admits a sequence of edge contractions reaching K. Since $\Delta^{ex}(K)$ is a homology lex-segment then Corollary 2.5 implies that $\Delta^{ex}(\mathrm{Del}(P_n))$ is a homology lex-segment as well. ◀

5 Concentration of exterior algebraic shifting for the uniform model

One dimensional complexes. Let X be a compact one dimensional topological space. It admits natural triangulations each given by some graph G. Let $\mathrm{sd}(G)$ denote the barycentric subdivision of G, namely the one obtained by introducing a new vertex at the interior of each edge of G, subdividing that edge into two edges. The following proposition holds for exterior algebraic shifting over any field:

▶ **Proposition 5.1.** *Let G be a graph, then $\Delta^{ex}(\mathrm{sd}\, G)$ is a homology lex-segment.*

Proof. First, we claim that $\mathrm{Tail}(\Delta^{ex}(\mathrm{sd}\, G), \{3,4\}) = \emptyset$. Otherwise there exists a connected subgraph H of $\mathrm{sd}\, G$ that is a 2-hypercycle and consequently is 3-edge connected, see [17, Theorem 5.4]. However, this is not possible for if $e = \{u, v\} \in H$ and we assume without loss of generality that $u \in V(\mathrm{sd}\, G) \setminus V(G)$ then the degree of u in H is at most 2. Since algebraic shifting outputs a shifted simplicial complex with identical Betti numbers we conclude that $\Delta^{ex}(\mathrm{sd}\, G) = [n] \bigcup \{A \in \binom{[n-\beta_0]}{2} : A \leq \{2, \beta_1 + 2\}\}$ as wanted. ◀

Proof of Theorem 1.4. First, by Propositions 5.1 and 2.4 with $m = 2$, the event that $\Delta^{ex}(U_n(|G|)) = \Delta(|G|, n)$ contains the event E that every edge of G is subdivided. In addition, since the order in which we subdivide an edge is not important the model $U_n(|G|)$ can be viewed as a balls and bins model where the bins represent the edges of G and the balls represent the new vertices. Therefore, the probability that E does not occur is at most $|E|(1 - 1/|E|)^n$ which tends to 0 as $n \to \infty$. ◀

Two dimensional complexes. We show here that unlike the one-dimensional case, the uniform triangulation of the 2-disc and of the disjoint union of two 2-discs do not have a concentrated exterior algebraic shifting.

▶ **Proposition 5.2.** *Let K be a triangulation of a disc with n interior vertices and m boundary vertices, then*

$$\Delta^{ex}(K) = [n+m] \bigcup \left\{ A \in \binom{[n+m]}{3} : A \leq \{1, 3, 3+n\} \right\}.$$

Proof. Since K is part of a triangulation of a sphere, then $\{1,4,5\} \notin \Delta^{ex}(K)$. Moreover, since the homology of K is trivial, then there is no 2-face whose smallest vertex is strictly larger than 1. Since the 1-skeleton of K is 2-hyperconnected, see [17], then $\{2, n+m\} \in \Delta^{ex}(K)$. Combining this with the fact that K is Cohen–Macaulay, even shellable, its algebraic shifting is pure implying that $\{1, 2, m+n\} \in \Delta^{ex}(K)$ and $\{4,5\} \notin \Delta^{ex}(K)$. Thus, the remaining edges must be of the form $\{3, k\}$, and the remaining triangles of the form $\{1, 3, k\}$, forming initial lex-segments of edges and of triangles by the shiftedness of $\Delta^{ex}(K)$. The claim now follows from the fact that algebraic shifting preserves the f-vector. ◀

▶ **Corollary 5.3.** *Let X be a 2-dimensional disc, then $\Delta^{ex}(U_n(X))$ is not concentrated.*

Proof. By well-known estimates [27, 14] for the number of n-vertex triangulations of the disc with m boundary vertices, it can be derived that for every fixed $m \geq 3$ there exists $\varepsilon_m > 0$ such that $\mathbb{P}(U_n(X) \text{ has } m \text{ boundary vertices}) = \varepsilon_m + o(1)$ as $n \to \infty$. In consequence, the probability that the 2-faces satisfy $\Delta^{ex}(U_n(X)) = \left\{ A \in \binom{[n+m]}{3} : A \leq \{1, 3, 3+n\} \right\}$, for every fixed m, is bounded away from 0 as n grows. ◀

▶ **Lemma 5.4.** *Let K_1, K_2 be the triangulations of two disjoint discs with n_1, n_2 interior vertices and m_1, m_2 boundary vertices respectively. Set $n = n_1 + n_2$ and $m = m_1 + m_2$, then*

$$\Delta^{ex}(K_1 \sqcup K_2) = [n+m] \bigcup \{\{i,j\} : 1 \le i \le 3,\ i \le t \le n+m-i\} \bigcup \left\{ A \in \binom{[n+m-2]}{3} : A \le \{1,3,n-3\} \right\}.$$

Proof. The proof follows by applying Proposition 5.2 and [24, Theorem 4.6] for exterior shifting of a disjoint union of simplicial complexes. ◀

▶ **Corollary 5.5.** *Let $X = X_1 \sqcup X_2$ be two disjoint 2-dimensional discs, then $\Delta^{ex}(U_n(X))$ is neither concentrated nor a homology lex-segment.*

Proof. Let K_1, K_2 and n and m as in Lemma 5.4, then we have that $\{2, n+m-1\} \notin \Delta^{ex}(K_1 \sqcup K_2)$ while $\{1, n+m-1\}, \{3, n-3\} \in \Delta^{ex}(K_1 \sqcup K_2)$, showcasing that the complex is not an homology lex-segment. The lack of concentration follows from Corollary 5.3. ◀

6 Concluding remarks

Conjecture 1.6 states that the exterior shifting of the uniform triangulation $U_n(S_g)$ of a fixed orientable surface is a homology lex-segment. In particular, this implies that $U_n(S_g)$ is a.a.s. K_6-free (as otherwise the shifting contains the edge $\{5,6\}$). To the best of our knowledge, this statement is not known, although [4] shows that a fixed neighborhood around *almost* every vertex is a.a.s. planar. We now suggest an even more far-reaching problem, which arises naturally as a possible approach to extending our proof of Theorem 1.2 to Conjecture 1.6:

▶ **Problem 6.1.** *Fix an Euler genus g. Show that there exists a Riemannian metric for S_g such that for every fixed $\rho > 0$, $U_n(S_g)$ can a.a.s. be embedded in S_g such that every edge has length less than ρ.*

In addition, note that in order to prove the analogous Theorem 1.4 for graphs, we first showed the deterministic statement Proposition 5.1 on their barycentric subdivision. We conjecture that its analog holds for barycentric subdivision of surfaces as well:

▶ **Conjecture 6.2.** *If K is a surface triangulation, then $\Delta^{ex}(\mathrm{sd}(K))$ is a homology lex-segment.*

Conjecture 6.2 follows from the following one, for exterior algebraic shifting over any field:

▶ **Conjecture 6.3** ([6, Conj.5.1] for the case of characteristic zero)**.** *For every triangulation K on n vertices of a connected compact surface without boundary, $\{1,3,n\} \in \Delta^{ex}(K)$.*

Proof of Conjecture 6.2 modulo Conjecture 6.3. Let K triangulate S_g and denote $m = f_0(\mathrm{sd}(K))$. The 1-skeleton of $\mathrm{sd}(K)$ is 3-hyperconnected, see e.g. [25, Thm.3.4.2], and similarly over every field, hence $\{3,m\} \in \Delta^{ex}(\mathrm{sd}(K))_1$. To see that $\{5,6\} \notin \Delta^{ex}(\mathrm{sd}(K))_1$, it is enough to remove from $\mathrm{sd}(K)$ vertices of degree at most 4 one by one until we reach a collection of isolated vertices; see Kalai [17, Lem.4.3(i)] for shifting over a field of characteristic zero, and the same proof holds over every field. First we remove vertices at the barycenter of edges of K (their degree is 4), then we remove vertices at the barycenter of triangles of K (their degree at this stage is 3), to reach the original vertices of K, and no higher dimensional faces. As $\Delta^{ex}(\mathrm{sd}(K))$ is shifted and has the same number of edges as $\mathrm{sd}(K)$, we conclude

that $\Delta^{ex}(\mathrm{sd}(K))_1 = \{A \in \binom{[m]}{2} : A < \{4, 5+3g\}\}$. Assuming Conjecture 6.3, $\{1,3,m\} \in \Delta^{ex}(\mathrm{sd}(K))_2$, and as $\Delta^{ex}(\mathrm{sd}(K))$ is a shifted simplicial complex, not containing the edge $\{5,6\}$ with the same face and Betti numbers as $\mathrm{sd}(K)$ we conclude that $\Delta^{ex}(\mathrm{sd}(K))_2 = \{A \in \binom{[m]}{3} : A < \{1,4,5+2g\}\} \cup \{\{2,3,4\}\}$. ◀

In order to extend Theorem 1.2 to fields of characteristics different from 0 and 2 we only need to show that Corollary 2.3 holds over such fields. We leave this as an open problem.

▶ **Problem 6.4.** *Let K be the triangulation of either the torus or the projective plane appearing in Figure 1(2-3). Then for every prime p, the exterior algebraic shifting of K over a field of characteristic p, $\Delta_p^{ex}(K)$, is a homology lex-segment.*

Finding a Fair Scoring Function for Top-k Selection: From Hardness to Practice

Guangya Cai
University of Minnesota, Twin Cities, MN, USA

Abstract

We study the problem of finding a fair linear scoring function over (numerical) attributes for top-k selection, ensuring fairness through a proportional representation constraint on the protected group. Existing algorithms do not scale efficiently, particularly in higher dimensions. Our hardness analysis shows that in more than two dimensions, no algorithm is likely to scale efficiently with respect to dataset size, and the computational complexity is likely to grow rapidly with dimensionality. However, the hardness results also provide key insights guiding algorithm design, leading to our two-pronged solution: (1) For small k, our analysis reveals a gap in the hardness barrier. By addressing various engineering challenges, including achieving efficient parallelism, we turn this potential of efficiency into an optimized geometry-based algorithm delivering substantial performance gains. (2) For large k, where the hardness is robust, we employ a practically efficient optimization-based algorithm which, despite being theoretically worse, achieves superior real-world performance. Experimental evaluations on real-world datasets then explore scenarios where worst-case behavior does not manifest, identifying areas critical to practical performance. Our solution achieves speedups of up to several orders of magnitude compared to the state of the art, an efficiency made possible through a tight integration of hardness analysis, algorithm design, practical engineering, and empirical evaluation.

1 Introduction

Selecting a subset of items from a large dataset based on specific criteria is critical for decision-making. Each item is typically assigned a score derived from its attributes, and the top-scoring items are selected. A scoring function determines these scores, typically a linear one that weights and sums the attribute values by importance. The problem of selecting the k highest scoring items from a dataset of n items ($k \leq n$) is called *Top-k Selection*.

Given the rise of automated decision-making software, ensuring fairness in tasks like top-k selection has become crucial. Among different ways of quantifying fairness (e.g., [21, 50, 52]), a common one is based on proportional representation: Each item has categorical attributes (e.g., gender, race, ethnicity), and one or a combination of them is considered *sensitive*. A specific value of this sensitive attribute denotes membership in a minority or historically disadvantaged group, often referred to as a *protected* group. The aim is to select a top-k subset where the protected group's proportion mirrors its proportion in the entire dataset.

Many applications seek top-k selections that are both fair and high-quality, often achieved by applying proportional fairness constraints. Prior work (e.g., [51, 13, 49]) typically applies these constraints after scores are determined, which might result in group-dependent selection

criteria and thus, potential legal risks (e.g., Ricci vs. DeStefano [42]). A fair scoring function from the outset is thus preferable. Moreover, one may also wish to find such a function within a subset of scoring functions. For instance, one may start with an existing, unfair scoring function and seek a "nearby" fair one, where attribute weights do not vary by a lot. Even knowing that no such nearby function exists can be informative, revealing some negligence in the original design. Consider the following variation of the example from [6]:

▶ **Example 1.** *A college admissions officer designs a scoring function based on applicants' normalized GPA (g) and SAT score (s), initially setting $f(c) = 0.5 \times g + 0.5 \times s$ and admitting the top-500 applicants. However, this may yield only 150 women whereas the fairness constraint is that at least 40% women should be admitted, possibly due to a gender disparity in the SAT score [44]. To meet the fairness constraint while preserving the explainability, the officer searches for a nearby fair scoring function with weights in the range of $[0.45, 0.55]$. An algorithm may find a fair function $f(c) = 0.55 \times g + 0.45 \times s$; if no such function exists, it reports failure, indicating the equal-weight design may be unsuitable. The officer may then adjust the design and, with the algorithm's help, obtain a fair function $f(c) = 0.6 \times g + 0.4 \times s$.*

Prior work has explored finding such fair scoring functions [6], but existing algorithms scale poorly with dataset size and worse with dimensionality. Since the general fairness constraints considered in [6] may introduce additional overhead, we focus on the simplest possible one on top-k selection, which ignores the relative rankings within the top-k (as in Example 1). For such a simple fairness constraint, do we have better algorithms that are efficient for large, high-dimensional datasets in practice, preferably running in $O(n \cdot \text{polylog}(n))$ time?

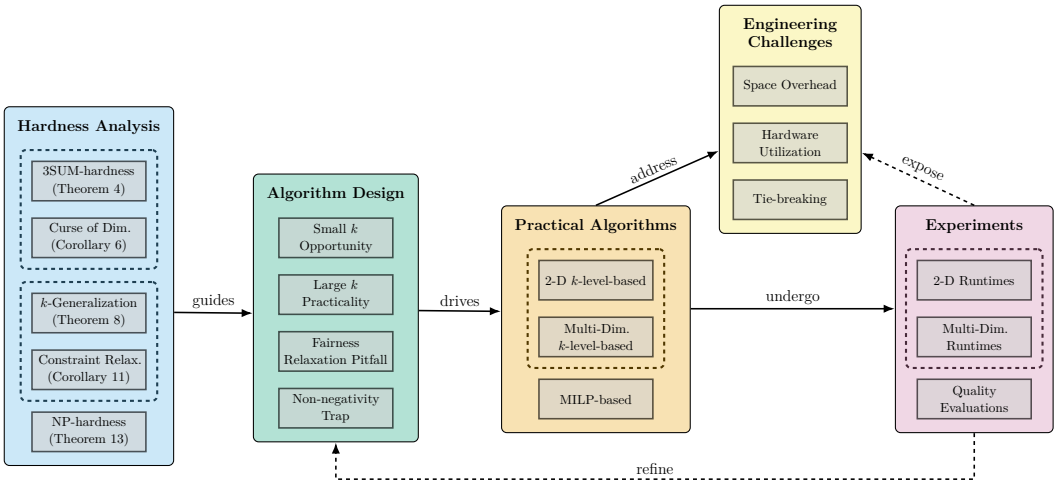

Figure 1 The structure and interplay of key results and components in this work. Solid arrows denote the primary workflow and direct influences, while dashed arrows indicate feedback.

Our contributions. To answer this question, we conduct an end-to-end, integrated study combining hardness analysis, algorithm design, practical engineering and empirical evaluation into a unified framework that yields an efficient solution. While some of the components may be of independent interest, their primary significance in this work lies in their interconnection. Our two-pronged solution, as well as many insights, emerge from the integration (see Figure 1).

Related work. Fair top-k selection under proportional fairness constraints has been widely studied [51, 31, 13, 6, 49] (see [52] for a review). Most existing work uses a single attribute or a fixed scoring function. Ref. [6] instead searched for a linear scoring function (i.e., a weight

vector) satisfying the fairness constraints while minimizing angular distance from a given one. Their method supports various fairness constraints but scales poorly with dataset size and dimensionality (see Section 4.2). Besides applying fairness constraints, ref. [35] introduced alpha-fairness – a metric capturing disparities between protected group proportions in the top-k subset and the entire dataset – and methods to find a weight vector optimizing this metric. However, their approach lacks a formal runtime analysis, still scales poorly, and breaks ties arbitrarily which may be unsuitable for fairness considerations (see Section 5.1).

2 Preliminaries

In the Fair Top-k Selection problem, we are given a set, $\mathcal{C}$, of candidates (or items), where each candidate $c \in \mathcal{C}$ has d scoring attributes and one sensitive attribute. The scoring attributes are represented by a point $p(c) = (p_1, p_2, \ldots, p_d) \in \mathbb{R}^d$, and the sensitive attribute by a label $A(c) \in \{\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_m\}$. The label $\mathcal{G}_1$ denotes the protected group. Following [52], we also use $\mathcal{G}_i$ to denote the subset of candidates with $A(c) = \mathcal{G}_i$, particularly for $i = 1$.

We consider the class of linear scoring functions defined by a weight vector $w = (w_1, w_2, \ldots, w_d)$, where each $w_i \geq 0$ (a common assumption [46, 12, 6]). The score of a candidate c is computed as $f(p(c)) = w \cdot p(c) = \sum_{i=1}^{d} w_i p_i$. Since ties may occur, the top-k subset for a given w may not be unique. We consider all top-k subsets and regard w as fair if any of its top-k subsets satisfies the fairness constraint. This is embodied as follows:

▶ **Definition 2.** *For a given w and an integer $k \leq n$, a subset $\tau_k^w \subseteq C$ is a top-k subset if $|\tau_k^w| = k$ and for any pair of candidates that $c \in \tau_k^w$ and $c' \in C \setminus \tau_k^w$, $w \cdot p(c) \geq w \cdot p(c')$.*

We now formalize our notion of fairness. Let τ_k^w denotes a top-k subset for w. Let $L_k^{\mathcal{G}_1}$ (resp., $U_k^{\mathcal{G}_1}$) denote the desired lower (resp. upper) bound on the number of protected group candidates in τ_k^w, ideally near $k \cdot (|\mathcal{G}_1|/n)$. Then, w is a fair scoring weight vector if

$$L_k^{\mathcal{G}_1} \leq |\tau_k^w \cap \mathcal{G}_1| \leq U_k^{\mathcal{G}_1}. \tag{1}$$

Finally, one may wish to limit the search for a fair weight vector to a subset of the weight vector space. We denote this subset by V and describe it via a set of l linear inequalities. Without loss of generality, we further assume $||w||_1 = \sum_{i=1}^{d} w_i = 1$ (recall $w_i \geq 0$). Then, V can be effectively regarded as a subset of $\mathbb{R}^{d-1}$. Formally, we define our problem as follows:

▶ **Problem 3.** *We are given a set of n candidates with d scoring attributes and one sensitive attribute. Each candidate, c, has a point $p(c)$ in $\mathbb{R}^d$ and a label $A(c) \in \{\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_m\}$. We are also given a non-negative integer $k \leq n$, non-negative integers $L_k^{\mathcal{G}_1}$ and $U_k^{\mathcal{G}_1}$, and a subset V of the weight vector space described by l linear inequalities. The goal is to find a real-valued weight vector $w = (w_1, w_2, \ldots, w_d) \in V$, where $w_i \geq 0$ for all i and $||w||_1 = 1$, such that*

$$L_k^{\mathcal{G}_1} \leq |\tau_k^w \cap \mathcal{G}_1| \leq U_k^{\mathcal{G}_1}.$$

Although our formulation allows $p(c)$ to be in $\mathbb{R}^d$, in practice, scoring attribute values are typically normalized to $[0, 1]^d$, as they are equivalent via uniform translation and scaling.

3 Hardness

Known algorithms for the Fair Top-k Selection problem [6] do not scale well with the dataset size, especially in higher dimensions. We establish (conditional) lower bounds that shed light on this limitation. In particular, we focus here more on the **practical implications** of these hardness results (Remarks within the section), rather than on their proofs ([11, Section 3]).

3.1 Hardness results in fixed dimensions

We show that for any fixed dimension, $d \geq 3$, the Fair Top-k Selection problem is 3SUM-Hard [47, 22], hence is unlikely to be solvable in $O(n^{2-\delta})$ time for any constant $\delta > 0$. Furthermore, based on a result in [20], we show that the problem is unlikely to be solvable in $O(n^{d-1})$ time for any $d \geq 3$. All our conditional lower bounds are established for a special case of the problem, where k is approximately $n/2$, $\mathcal{G}_1$ contains only one candidate, and $L_k^{\mathcal{G}_1} = U_k^{\mathcal{G}_1}$.

For the 3SUM-hardness, it is known that deciding whether three points in a given set in $\mathbb{R}^2$ lie on a line (a.k.a point collinearity problem) is 3SUM-Hard [22]. By a reduction from the collinearity problem to the Fair Top-k Selection problem, we show the following:

▶ **Theorem 4** (3SUM-hardness). *For any $d \geq 3$, Fair Top-k Selection cannot be solved in $O(n^{2-\delta})$ time for any constant $\delta > 0$, assuming the 3-SUM hypothesis.*

▶ **Remark 5.** *For large datasets, practical efficiency typically requires algorithms with run times $O(n \cdot \text{polylog}(n))$. However, our reduction suggests that such an efficient algorithm is unlikely to exist for general problem instances in dimensions $d \geq 3$.*

The point collinearity problem is a special case of the Affine Degeneracy problem in $\mathbb{R}^d$: deciding whether $d+1$ points lie on a hyperplane. Using a similar approach we have:

▶ **Corollary 6** (Curse of Dimensionality). *For any constant $d \geq 3$, Fair Top-k Selection in $\mathbb{R}^d$ is at least as hard as the Affine Degeneracy problem in $\mathbb{R}^{d-1}$.*

▶ **Remark 7.** *In a certain decision tree model, all algorithms for the Affine Degeneracy problem require $\Omega(n^d)$ time [20]. This suggests a lower bound of $\Omega(n^{d-1})$ for Fair Top-k Selection in $\mathbb{R}^d$ for $d \geq 3$. However, the reduction only applies if d is a constant, since the number of constructed instances also grows exponentially with d (see Section 3.3).*

3.2 Hardness results for more general cases

The conditional lower bounds in fixed dimensions are established using a special case of the problem. Here, we show that our conditional lower bounds also hold when the value of k, the number of candidates of $\mathcal{G}_1$, and the fairness constraint are more general and realistic.

We begin with definitions of key concepts. For a point set $S \subseteq \mathbb{R}^d$, a point $q \in \mathbb{R}^d$ is a *dominated* (resp. *dominating*) point of S if for any point $p \in S$, $q_i < p_i$ (resp. $q_i > p_i$) for all $1 \leq i \leq d$. For any non-negative weight vector, a dominated (resp. dominating) point has a lower (resp. higher) score than any point in S. We say a candidate c is a *dominated* (resp. *dominating*) candidate of a candidate set C if $p(c)$ is a dominated (resp. dominating) point.

With these concepts, we first consider a general k value. Suppose that we have an efficient algorithm that can only handle $k = \beta n$, where $0 < \beta < 1$ is a fixed constant. We show that it can also be applied to solve the instance in Corollary 6 efficiently.

▶ **Theorem 8** (k-Generalization). *Given a polynomial-time algorithm for Fair Top-k Selection with $k = \beta n$, where $0 < \beta < 1$ is a fixed constant, one can solve the Fair Top-k Selection with $k = (n-1)/2 - d + 1$ in the same asymptotic run time.*

Proof. Since k is expected to be small in practice, we consider the case $\beta n < (n-1)/2 - d + 1$ first. We construct C' from C by adding dominated candidates, making the size of C' to be $(n-1)/2\beta - (d-1)/\beta$. Then, we run the algorithm for Fair Top-k Selection with $k = \beta n$ on C'. Given the size of C', we have $k = (n-1)/2 - d + 1$. Since all candidates in $C' \setminus C$

are dominated ones, none of them will be in the top-k subset for any $k \leq n$. So, the top-k selection result will only contain candidates in C. The reduction takes $O(n)$ time with β being a constant. The case $\beta n > (n-1)/2 - d + 1$ can also be similarly handled. ◀

▶ **Remark 9.** *This reduction extends the lower bounds in Section 3.1 to a broad range of k where $k = \beta n$. However, for a sufficiently small k (e.g., $k = O(\text{polylog}(n))$), the reduction breaks down as C' requires adding too many candidates, causing it to take more than $O(n)$ time. This reveals that the previous lower bounds may not be applicable for a small k.*

Next, we consider a larger number of candidates of $\mathcal{G}_1$ and more general fairness constraints. Consider a dataset with two groups, where n_1 and n_2 denote the number of candidates of $\mathcal{G}_1$ and the other group. By adding both dominated and dominating candidates, we have:

▶ **Theorem 10** (Group-balancing). *Given a polynomial-time algorithm for Fair Top-k Selection with $n_1 = n_2 = n/2$ and $L_k^{\mathcal{G}_1} = U_k^{\mathcal{G}_1} = k \cdot (n_1/n) = k/2$, one can solve the Fair Top-k Selection with $n_1 = 1$ and $L_k^{\mathcal{G}_1} = U_k^{\mathcal{G}_1} = 1$ in the same asymptotic run time.*

Theorem 10 still has a restriction on the fairness constraint that $L_k^{\mathcal{G}_1} = U_k^{\mathcal{G}_1}$. By carefully manipulating the number of dominated and dominating candidates, we are able to show:

▶ **Corollary 11** (Constraint Relaxation). *Given a polynomial-time algorithm for Fair Top-k Selection with $L_k^{\mathcal{G}_1} = k \cdot (n_1/n) - \sigma_L$ and $U_k^{\mathcal{G}_1} = k \cdot (n_1/n) + \sigma_U$, where σ_L and σ_U are non-negative integers, one can solve the Fair Top-k Selection with $n_1 = 1$ and $L_k^{\mathcal{G}_1} = U_k^{\mathcal{G}_1} = 1$ in the same asymptotic run time.*

▶ **Remark 12.** *Intuitively, relaxing the fairness constraint should make the problem computationally easier. However, our reduction suggests that this is unlikely to be the case, as better algorithms imply a violation of the lower bounds established in Section 3.1.*

3.3 Hardness result in arbitrary dimensions

Corollary 6 suggests a possible extension to arbitrary dimensions, since Affine Degeneracy is NP-hard in arbitrary dimensions [20]. However, a direct extension fails because the reduction requires generating 2^{d-1} Fair Top-k Selection instances to circumvent the non-negativity of the weight vector. To resolve this issue, we use an alternative problem, Maximum Independent Set, for the reduction, starting from its binary integer programming formulation [36].

▶ **Theorem 13** (NP-hardness). *Fair Top-k Selection is NP-hard in arbitrary dimensions.*

▶ **Remark 14.** *The failure to extend Corollary 6 under non-negativity may appear to reveal a gap in the hardness barrier. Moreover, this non-negativity appears to permit efficient mathematical optimization techniques (Section 5.2), which typically operate outside the decision-tree model (Corollary 6). However, our NP-hardness result shows that such methods may not work efficiently for the worst case. Notably, the relaxation technique, essential to many efficient solvers for our formulation (Section 5.2), also plays a key role in the reduction.*

4 From hardness results to algorithm design

As stated, our two-pronged solution is guided by the hardness results. Here, we examine these insights in details. Also, we examine the case of small k that is critical to our solution.

4.1 Implications for algorithm design

Our hardness results, starting from restricted cases, show that the problem becomes hard to solve for $d \geq 3$ (Remark 5) and demonstrate the curse of dimensionality (Remark 7). Extending these results to more general cases yields key insights for algorithm design:

- **Small k Opportunity.** The reduction technique used in Theorem 8 breaks down for a sufficiently small k (Remark 9). This suggests the potential of a more efficient algorithm by explicitly leveraging k in the design.
- **Large k Practicality.** The hardness of the problem is robust for a large k, making the existence of worst-case efficient algorithms unlikely. Therefore, designing efficient algorithms for large k should focus on real-world performance.
- **Fairness Relaxation Pitfall.** Relaxing the fairness constraint may appear to make the problem easier, making an algorithm that starts with a loose constraint and gradually tightens it seems attractive. However, such relaxation does not reduce worst-case computational hardness (Remark 12), limiting its value.
- **Non-negativity Trap.** With the failure to extend Corollary 6, non-negativity of variables (weights) and most coefficients (scoring attribute values) appears to open the door to efficient mathematical programming techniques (Remark 14). However, our NP-hardness result shows that this non-negativity may not yield runtime improvements.

Drawing on these insights, we arrive at a two-pronged solution: a theoretically grounded algorithm for a small k, and a practically efficient algorithm for a large k. Next, we demonstrate that the lower bounds are indeed breakable for a small k.

4.2 The case of small k

The Fair Top-k Selection problem can be solved by the algorithms in [6], which run in $O(n^2(k + \log n))$ (improvable to $O(n^2 \log n)$) for $d = 2$ and $O(n^{2d+2})$ for a constant $d \geq 3$. In contrast, our algorithm explicitly incorporates k, allowing it to run fast when k is small.

Like [6], our algorithm employs a dual transformation, but we adopt a different one given in [12, 48] that is better suited to our setting. Let $p = (p_1, p_2, \ldots, p_d)$ be $p(c)$ of a candidate $c \in C$. We transform p into a hyperplane $H(p)$ defined by ($x_1, x_2, \cdots x_d$ are variables)

$$(p_1 - p_d)x_1 + (p_2 - p_d)x_2 + \cdots + (p_{d-1} - p_d)x_{d-1} - x_d + p_d = 0. \tag{2}$$

Given the dual transformation, *k-level* and *cell* can be defined accordingly ([11, Section 4.2]). One important property of the k-level is that if a hyperplane has a cell that is part of the $(k-1)$-level, then the primal point corresponding to the hyperplane is the kth point for some weight vectors, since there are exactly $k-1$ hyperplanes lying "above" in the x_d dimension.

We now proceed to the algorithm. Assume the $(k-1)$-level is constructed and cells adjacencies are identified, with hyperplanes in general position (i.e, no more than d hyperplanes intersect at a point), and ties in top-k selection broken arbitrarily. Our algorithm first finds an arbitrary weight vector $t \in V$ and locates a $(k-1)$-level cell intersected by the downward ray induced by t. Next, we obtain the corresponding top-k subset and count the number of candidates of $\mathcal{G}_1$ in the top-k subset, $n_k^{\mathcal{G}_1}$, and test it against $L_k^{\mathcal{G}_1}$ and $U_k^{\mathcal{G}_1}$. If the fairness constraint is satisfied, we output t. If not, we traverse the $(k-1)$-level by visiting adjacent cells. For each newly visited cell, we test if its projection onto the first $d-1$ coordinates intersects V. If it is, we update the $n_k^{\mathcal{G}_1}$ as the top-k subsets of adjacent cells differ in at most one candidate. We maintain the $n_k^{\mathcal{G}_1}$ during the traversal and whenever the top-k subset changes, test $n_k^{\mathcal{G}_1}$ against $L_k^{\mathcal{G}_1}$ and $U_k^{\mathcal{G}_1}$. The algorithm stops when either a fair weight vector is obtained from a $(k-1)$-level cell or all relevant $(k-1)$-level cells have been visited.

For the runtime analysis, leveraging known results of the k-level [37, 1, 24, 15], along with an application of an efficient convex polyhedra intersection algorithm [7], we have:

▶ **Theorem 15.** *In fixed dimensions, Fair Top-k Selection can be solved in $O(nk^{1/3}\log n)$ time for $d = 2$ and in $O(nk^{3/2}\log^4 n)$ time for $d = 3$, both with $l = O(n)$. In $d \geq 4$ dimensions, it can be solved in $O(n^{\lfloor d/2\rfloor}k^{\lceil d/2\rceil})$ (expected) time with a sufficiently small l.*

▶ **Remark 16.** *Notice that the algorithm relies on assumptions that do not fully align with the problem setting (Section 5.1). With careful refinements and thorough analysis, one can show that the bounds still hold. However, as the algorithm chiefly illustrates the key component for breaking the lower bounds, its full resolution is deferred to the practical context (Section 5.1).*

5 Practical algorithms

The k-level-based algorithm above builds on theoretically efficient algorithms for constructing the k-level, yet few have been empirically evaluated. Moreover, existing studies of a related algorithm show worse empirical performance than simpler heuristics [2, 25]. To make it practical, we identify key engineering challenges and present corresponding solutions. For large k, our algorithm design principle shifts from theoretical guarantees to practical efficiency. As a result, we present an algorithm based on mixed-integer linear programming (MILP).

5.1 Practical k-level-based algorithms

We identify three key engineering challenges for k-level-based algorithms to become practical:

- **Space Overhead.** The k-level-based algorithm constructs the entire k-level, whose structural complexity may grow quickly with n and d. For large datasets, it may exhaust internal memory, requiring much slower external-memory solutions. Yet users may seek a fair weight vector within a small, explainable region, making a full k-level unnecessary.
- **Hardware Utilization.** A prior theoretically efficient algorithm [25] exhibits bad memory performance, which contributes to its slow run time in practice. Moreover, many algorithms are not naturally parallelizable and cannot exploit modern multi-core systems. Bridging the theory-practice gap for parallel algorithms is even more challenging [9].
- **Tie-breaking.** Most theoretical algorithms for constructing the k-level assume general position (limiting ties among candidates) and break ties arbitrarily for simplicity. However, for the fair top-k selection, tie-breaking can affect the number of protected group candidates selected, impacting fairness. In our problem setting, an algorithm must be designed to account for all possible tie-breaking outcomes when evaluating fairness.

Next, we present practical k-level-based algorithms, focusing on our methods addressing these challenges. (Tie-breaking will be revisited in Section 5.2 for the MILP-based algorithm.)

5.1.1 2-D k-level-based algorithm

Our algorithm in 2-D is an adaptation of an algorithm in [14] (briefly outlined in [8]). The algorithm is a sweep-line algorithm using two kinetic priority queues, S_1 and S_2, to keep track of the k-level cell. Viewing the x-coordinate of the sweep-line as "time", S_1 (resp. S_2) contains the k (resp. $n-k$) lines lying above (resp. below) at the time instant. The algorithm proceeds by processing internal queue events or updating queues during the sweep.

Space overhead. We note that in this algorithm, S_1 actually maintains the top-k subset during the sweep. Instead of explicitly constructing the $(k-1)$-level, one can simply check whether the top-k subset induced by S_1 satisfies the fairness constraint. Even better, following the theoretical algorithm (Section 4.2), one can use a variable to keep track of the number of lines of $\mathcal{G}_1$ in S_1. The space usage reduces to $O(n)$ by avoiding the explicit construction.

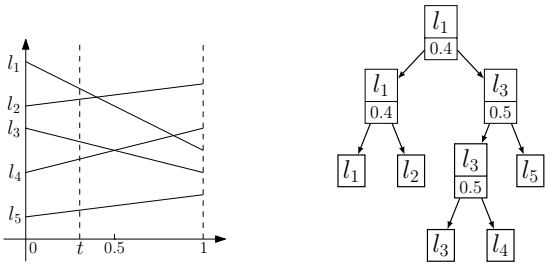

Figure 2 Maximum kinetic tournament tree (right) for lines (left) at $x = t$. We augment the tree with the replacement operation, which can be implemented by substituting the target line (i.e., l_1 in this example) at the leaf level and propagating updates along the path to the root.

Hardware utilization. Our low-level optimizations focus on the kinetic priority queue, a critical component for the real-world performance (see discussions in Section 6.2.1). In [14], fully dynamic kinetic priority queues are used, which may exhibit bad memory performance. However, observe that the sizes of S_1 and S_2 are fixed throughout the sweep; to correctly update them, one only has to replace the minimum (resp. maximum) element of S_1 (resp. S_2) with the maximum (resp. minimum) element of S_2 (resp. S_1) at the "time" instant of crossing. We use the kinetic tournament tree [8] for implementing the kinetic priority queue, in which this replacement can be done in $O(\log n)$ time (see Figure 2). Since the tree configuration is fixed, we further flatten trees into linear arrays for better cache performance, using a pre-order traversal layout. (Other layouts [29] might work better but are not explored.)

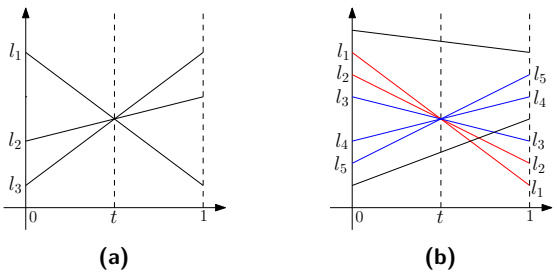

Figure 3 **(a)** Three lines intersect at $x = t$. The tie is broken by perturbing x to $x = t + \epsilon$. This, in fact, sorts the lines by their slopes, and orders l_3 ahead of l_1 and l_2 for a max-queue. **(b)** For $k = 3$, we have $l_1, l_2 \in S_1$ (red) and $l_3, l_4, l_5 \in S_2$ (blue) before the intersection. For correct configurations of S_1 and S_2 at $x = t + \epsilon$, one can exchange l_1 for l_5 and l_2 for l_4 between S_1 and S_2.

Tie-breaking. The algorithm in [14] assumes no more than two lines intersect at a point. To resolve this issue, we apply the symbolic perturbation [19], which provides a tie-breaking rule that compares the slopes of lines (see Figure 3a). Also, pairs of lines to exchange are carefully identified for correctly updating S_1 and S_2 (see Figure 3b). However, the top-k subset induced by the resulting S_1 is only one of the tie-breaking outcomes. To correctly

account for all tie-breaking outcomes, we collect all intersecting lines at this "time" instant (including duplicates) by a guided tree traversal. Each intersecting line can be found with an additional $O(\log n)$ cost. To avoid enumerating all possible top-k subsets, we compute tight lower and upper bounds on the number of $\mathcal{G}_1$ members and use these bounds to test fairness.

5.1.2 Multi-dimensional k-level-based algorithm

Our multi-dimensional algorithm adapts the method in [4], later implemented in [5] for rank-regret minimization. Although not as fast as the best theoretical algorithm, it may be better at exploiting modern multi-core systems as suggested in [4]. However, no parallel implementation currently exists. Starting from a cell and its top-k subset, the algorithm explores adjacent cells by testing potential top-k subsets, formed by swapping one top-k element with an outsider. The test can be done by finding a separating hyperplane via a linear program. This enables enumeration of all valid top-k subsets in a breadth-first manner.

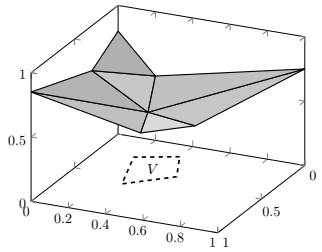

Figure 4 $(k-1)$-level (triangular mesh) and V (dashed region on the x-y plane) in 3-D. Testing cell intersection is equivalent to finding a point w in V whose downward-directed ray from $(w_1, w_2, +\infty)$ hits the cell (triangle). The constraints (points in V) can be incorporated into the linear program.

Space overhead. We incorporate weight vector space constraints (i.e., V) into each linear program, restricting it to find only weight vectors within V when testing a potential top-k subset (see Figure 4). This approach reduces the number of cells (i.e., top-k subsets) visited during the traversal, and thus space usage, especially when V only defines a small region.

Hardware utilization. Notice that the algorithm can be regarded as a breadth-first search algorithm on a graph, where each cell is a node and each edge connects a pair of adjacent cells. Therefore, a method for parallel BFS can be applied. However, since the graph is not known explicitly and finding an adjacent node can be expensive, efficient but sophisticated level-synchronous parallel algorithms (e.g. [34, 41]) may be difficult and less beneficial to adapt. Here we take a simpler approach by distributing jobs for finding adjacent nodes. Each thread independently takes a job for testing whether the given potential top-k subset is valid. If it is, it generates subsequent jobs. We use a global job queue for parallel job distribution. To reduce synchronization costs, a lock-free queue with relaxed FIFO ordering [30] (and a memory reclamation scheme [10]) is used, since a strict FIFO order is not needed. To keep track of the processed top-k subsets, we use a lock-free hash table [40]. Since the table size increases monotonically, we use an insertion-only table with memory reclamation disabled for further reducing runtime overhead. Notably, our lockless approach improves efficiency but introduces subtle implementation issues. For example, preventing premature thread termination requires carefully accounting for dequeue and emptiness-check linearization points [27] (specifically, under the restricted out-of-order specification [26]) of the job queue.

Tie-breaking. We modify linear programs to allow points lying on the hyperplane rather than enforcing strict separation. This approach enables the algorithm to enumerate all possible top-k subsets, as a top-k subset with ties (typically) corresponds to a lower-dimensional cell (see [11, Section 5.1.2]). In the extreme case, the run time will increase by a lot, but this rarely occurs in practice. Nevertheless, we still trade some efficiency for ease of implementation.

5.2 Mixed-integer linear programming-based algorithm

For a large k value, our focus becomes designing a practically efficient algorithm, which results in an algorithm based on MILP. We note that MILP is NP-hard and all known algorithms run in exponential times in the worst case. However, in practice, an MILP solver can be quite fast, and it was shown that an MILP-based algorithm is efficient for finding a linear scoring function for the reverse top-k query [16], making it an approach worth considering.

For simplicity, assume without loss of generality that each scoring attribute value is in the range of $[0, 1]$. We define a indicator variable $\delta_c \in \{0, 1\}$ for each candidate c satisfying

$$-1 \leq w \cdot p(c) - \lambda - \delta_c \leq 0 \tag{3}$$

for any given weight vector w and a cut-off value $\lambda \in [0, 1]$. δ_c encodes the top-k subset membership of c for a (w, λ) pair defining a separating hyperplane (see [11, Section 5.2]).

To ensure a value of λ will be infeasible unless it yields k candidates with $\delta_c = 1$, the constraint $\sum_c \delta_c = k$ is applied. Moreover, the fairness constraint can be encoded as follows:

$$L_k^{\mathcal{G}_1} \leq \sum_{A(c)=\mathcal{G}_1} \delta_c \leq U_k^{\mathcal{G}_1}. \tag{4}$$

Finally, constraints on the weight vector (i.e., V) can also be easily incorporated. We arrive at a MILP with a weight vector, a cut-off value, and n indicator variables as its unknown variables. Finding a fair weight vector becomes finding a feasible solution to the MILP.

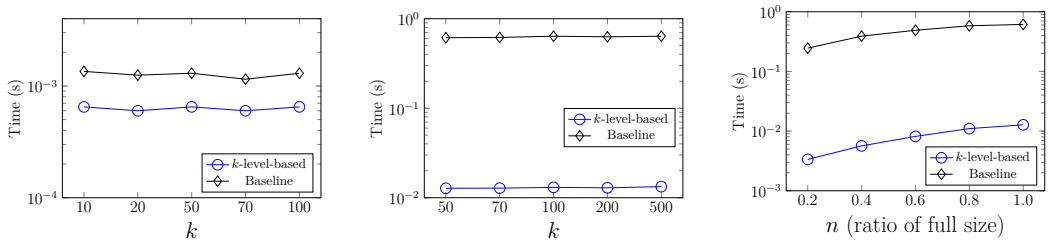
Now, let us revisit the "Non-negativity Trap" (see Section 4.1). In our MILP formulation, all variables (w, λ and δ_c) and most of the coefficients ($p(c)$) are non-negative. The main issue is the negative coefficient of λ, which prevent direct adaptations of the techniques such as those in [3, 43]. While one might hope to circumvent this inconvenience, our NP-hardness result show that the problem may be fundamentally intractable in the worst case. This also suggests that the practical success of the MILP-based algorithm is largely heuristic.

For our implementation, we use Gurobi [23] – a state-of-the-art, mathematical programming tool – to solve the MILP. This solver also exploits parallelism to enhance performance.

Tie-breaking. The tie-breaking consideration has already been embodied in our MILP formulation which naturally addresses it. Notice that if $w \cdot p(c) = \lambda$, δ_c is free to choose its value. If the top-k subset is not unique for a weight vector, all possible top-k subsets will be considered in the MILP. The fairness constraint is applied to further restrict values of δ_c.

6 Experiments

We present experimental results on real-world datasets, including both run times and quality evaluations. We conclude with key observations and discussions of algorithm selection.



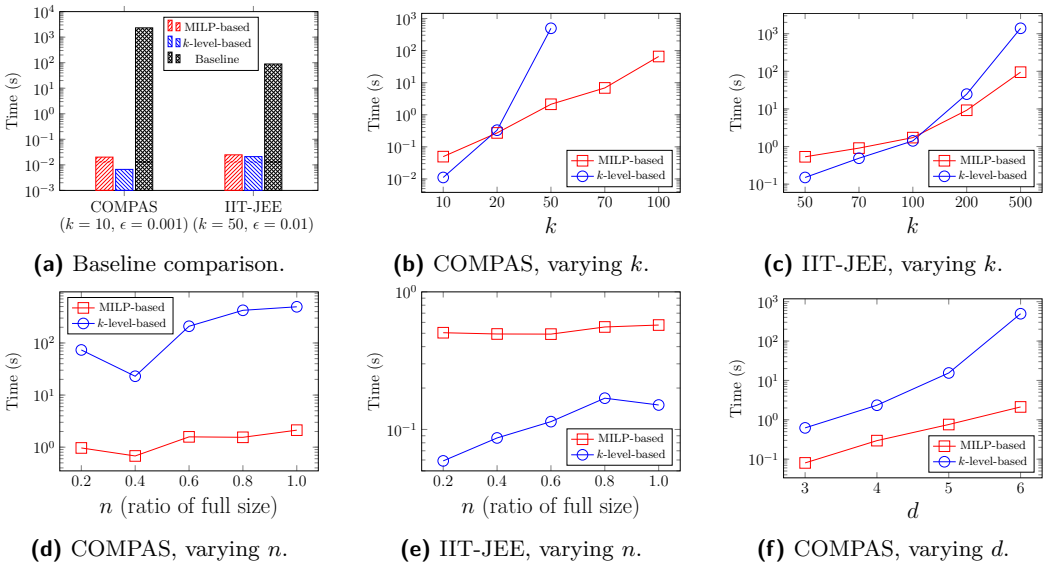
6.1 Experimental setup

In our experiments, a weight vector w^o is provided as an input. If w^o is unfair, the algorithm is run to find a "nearby" fair weight vector w^f. More formally, for a given unfair w^o, one aims to find a fair w^f such that $|w_i^f - w_i^o| \leq \epsilon$ for all $1 \leq i \leq d$, where ϵ is user-specified parameter that limits the allowable deviation. A failure is reported if no such fair w^f exists. We used two real-world datasets, *COMPAS* ($n = 7214$, $2 \leq d \leq 6$) [38] and *IIT-JEE* ($n = 384\,977$, $2 \leq d \leq 3$) [28], with preprocessing as needed. 2DRAYSWEEP and ATC$_+$ from [6] were implemented as baselines, with several enhancements incorporated. By default, $k = 50$, with $\epsilon = 0.1$ for $d = 2$ and $\epsilon = 0.05$ for $d \geq 3$. See [11, Section 6.1] for the full experimental setup and `https://github.com/caiguangya/fair-topk` for the code, data, and container [33].

6.2 Runtime experiments

Since our main focus is execution speed, we start with runtime experiments and highlight speedups from better hardware utilization that also enable more informed comparisons [32].

6.2.1 Runtime experiments for 2-D datasets



(a) COMPAS, varying k. **(b)** IIT-JEE, varying k. **(c)** IIT-JEE, varying n.

Figure 5 Runtime experimental results for 2-D datasets.

Varying k. As shown in Figures 5a and 5b, our k-level-based algorithm consistently outperformed the baseline, achieving over 40x speedups on the larger dataset (IIT-JEE). Notably, its performance remained stable as k increased. In fact, the line-sweeping step only contributed a small fraction of the total run time in our experiments. The algorithm [14] we adapted is output-sensitive, running efficiently when the actual k-level complexity is low. Moreover, it is known that the best known complexity of the k-level in 2-D, i.e., $O(nk^{1/3})$ [18], might not be a tight one [45], and the "average" complexity can be significantly lower [17].

Varying n. Figure 5c shows run times with n controlled by sampling 20%–100% of the IIT-JEE dataset. For the baseline, the run time increased mildly as n increased, performing better than its worst-case time complexity would suggest. However, our algorithm was still substantially faster. Comparing two algorithms side-by-side, both exchange orders of lines during the sweep, but the baseline considers all pairs, while our k-level-based approach uses kinetic tournament trees to skip many exchanges, directly reducing their number. Since many tree operations incur an $O(\log n)$ overhead, efficient implementation becomes critical. The experiments reveal an area where an efficient implementation should focus, and our optimizations (Section 5.1.1) addresses this need effectively (Section 6.2.3), enhancing the algorithm's performance in scenarios where the worst-case behavior does not manifest.

6.2.2 Runtime experiments for multi-dimensional datasets

(a) Baseline comparison. **(b)** COMPAS, varying k. **(c)** IIT-JEE, varying k.

(d) COMPAS, varying n. **(e)** IIT-JEE, varying n. **(f)** COMPAS, varying d.

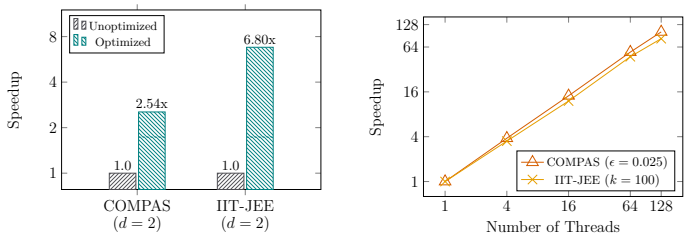


Figure 6 Runtime experimental results for multi-dimensional datasets ($3 \leq d \leq 6$).

Baseline comparison. In higher-dimensional experiments, the baseline regularly failed to finish within the time limit, so a smaller value of ϵ was used. As shown in Figure 6a, for the IIT-JEE dataset ($d = 3$), our MILP-based and k-level-based algorithms achieved 3598x and 4222x speedups, respectively. For the COMPAS dataset ($d = 6$), we had to further lower the value of ϵ, and our algorithms were five orders of magnitude faster. Due to the inefficiency of the baseline, subsequent experiments report only the run times of our two algorithms.

Varying k. As shown in Figures 6b and 6c, the MILP-based algorithm outperformed the k-level-based one for larger k, especially on the higher-dimensional dataset (COMPAS), while the k-level-based algorithm was faster for smaller k and lower dimensions (IIT-JEE). These results align with known bounds on the k-level complexity for $d \geq 3$. Unlike in 2-D, the multi-dimensional k-level algorithm's run time is more dependent on k, as each top-k subset will generate $O(nk)$ linear programs. Notably, the MILP-based algorithm also performed well on the lower-dimensional dataset (IIT-JEE) despite a larger number of (indicator) variables.

Varying n. As shown in Figures 6d and 6e, the run time of the k-level-based algorithm generally increased as n increased. However, some anomalies appeared since a larger n does not always yield more k-level cells, especially when only part of the k-level is explored. The MILP-based algorithm showed more stable run times despite increasing variable count.

Varying d. Figure 6f shows run times with d controlled by selecting subsets of COMPAS scoring attributes after preprocessing. The run times of both algorithms increased significantly as d increased. For the k-level-based algorithm, this aligns with the known results of k-level structural complexity. Besides, the $O(d!n)$ cost of the linear programming algorithm [39] we used also contributed to the run time increase. The MILP-based algorithm also showed significant slowdown, despite the number of variables only increasing by 1 as d increased by 1.

(a) Memory access. **(b)** Parallelism.

Figure 7 Performance gains from better hardware utilization, measured by total run time.

Notably, for $d = 3$, the k-level-based algorithm was slower than the MILP-based algorithm – unlike what we observed on the IIT-JEE dataset with the default $k = 50$ (Figure 6c). We note that this 3-D dataset created by selecting three attributes contains many candidates with identical scoring attribute values, which exposed the tie-breaking inefficiency in our implementation. However, since this lower-dimensional dataset is derived from a higher-dimensional one, it may contain fewer scoring attributes than intended to distinguish each candidate. Therefore, the slowdown is more likely an artifact rather than a real-world issue.

6.2.3 Hardware utilization

Memory access. Figure 7a shows the performance gains from optimizing the tournament tree of the 2-D k-level-based algorithm. We compared optimized and unoptimized versions, with the latter approximating a fully dynamic tournament tree while avoiding self-balancing by inserting new nodes into vacancies left by deletions. Our experimental results show notable speedups of 2.54x and 6.80x respectively, highlighting the benefits of our optimizations.

Parallelism. Figure 7b shows the efficiency of our parallel implementation of the multi-dimensional k-level-based algorithm. k and ϵ were default unless specified. Our implementation showed strong parallel scalability up to 128 threads, achieving speedups of 102x and 83x over the (stand-alone) sequential implementation on COMPAS and IIT-JEE, respectively.

6.3 Quality evaluation experiments

The quality was evaluated using the following metrics: (1) **Found/Unfair ratio**: the ratio between the number of input unfair weight vectors and found fair ones. (2) $\boldsymbol{w}$ **difference**: the average L_1 distance between w^o and w^f. (3) $\boldsymbol{\mathcal{G}_1}$ **proportion**: the average $\mathcal{G}_1$ candidate proportion in the top-k subset derived from w^f. (4) **Utility loss**: the average relative utility difference between the top-k subset derived from w^o and w^f. (See [11, Section 6.3].)

Table 1 shows the experimental results. We note that the k-level-based algorithm achieved better results for the w difference and utility loss. In fact, these two metrics are related, as a closer w^f to w^o typically yields a top-k subset with high-utility candidates. Our k-level-based algorithm naturally favors "nearby" weight vectors due to its breadth-first search approach with w^o as the starting point, while the MILP-based algorithm does not directly leverage w^o.

6.4 Observation summary and algorithm selection

We summarize key experimental observations and discuss algorithm selection based on them.

Table 1 Outcome quality evaluation for COMPAS dataset ($k = 50$).

ϵ	Fairness constraint	Found/Unfair ratio	w difference		$\mathcal{G}_1$ proportion		Utility loss	
			k-level	MILP	k-level	MILP	k-level	MILP
0.05	[34%, 66%]	19/39	**0.149**	0.211	66.0%	**65.7%**	**0.476%**	1.210%
	[40%, 60%]	8/44	**0.144**	0.213	59.8%	**59.5%**	**0.449%**	1.328%
	[44%, 56%]	6/47	**0.155**	0.202	**55.3%**	55.6%	**0.718%**	1.319%
0.025	[40%, 60%]	3/44	**0.088**	0.090	60.0%	**59.3%**	**0.121%**	0.142%
0.05		8/44	**0.144**	0.213	59.8%	**59.5%**	**0.449%**	1.328%
0.075		18/44	**0.247**	0.308	59.9%	**59.7%**	**2.416%**	3.187%

2-D. The k-level-based algorithm is the preferred method, with following key observations:

- Run times remained stable across k for both datasets, suggesting that k-level structural complexity may have limited impact on run time in real-world 2-D scenarios.
- Varying n experiments indicate that the k-level-based algorithm's advantage over the baseline may stem from the use of the kinetic priority queue that directly reduces the number of pairwise line exchanges, rather than the worst-case run time improvement.

In particular, building on the second observation, our implementation of the k-level-based algorithm was purposely engineered to further improve the performance (Figure 7a).

Multi-dimensions. By our algorithm design principle (Section 4), determining a threshold value of k is crucial. However, some previous discussions may not apply here, as our concern shifts to real-world performance. For real-world datasets, we have following key observations:

- The k-level-based algorithm outperformed the MILP-based algorithm for a small k, but its run time grew more rapidly with k, unlike its stable performance in 2-D.
- Run times of both algorithms increased dramatically with dimensionality d, with the k-level-algorithm increasing more rapidly, partly due to the LP algorithm used.
- The k-level-based algorithm performed better on the IIT-JEE dataset but worse on the 3-D COMPAS dataset with $k = 50$ (Figures 6c and 6f), likely due to an artifact exposing an inefficiency in our implementation for tie-breaking.

For algorithm selection, the first two observations suggest that as d increases, the threshold value of k at which the MILP-based algorithm becomes superior is likely to decrease. However, the last one suggests that performance comparisons between the two can be influenced by the underlying data distribution. Precisely defining a threshold value of k remains non-trivial, as the performance of the MILP-based algorithm is inherently heuristic. Nonetheless, our experimental results still indicate that this threshold is inversely correlated with d.

7 Conclusion

We presented an integrated study on finding a fair linear scoring function for top-k selection. Our hardness analysis established the theoretical foundation and guided the algorithm design, leading to our two-pronged solution: A k-level-based algorithm for small k and a MILP-based algorithm for large k. Practical engineering then addressed implementation challenges to ensure the solution works in practice. Finally, empirical evaluation explored real-world scenarios, identifying areas critical to practical performance. (See Figure 1 for the roadmap.) Our result is a practically efficient solution that is significantly faster than the state of the art, accompanied by many insights which we believe can inform future studies.

Abstract

In this paper we consider the problem of approximating Euclidean distances by the infinite integer grid graph. Although the topology of the graph is fixed, we have control over the edge-weight assignment $w : E \to \mathbb{R}_{\geq 0}$, and hope to have grid distances be asymptotically isometric to Euclidean distances, that is:

For all grid points u, v, $\text{dist}_w(u, v) = (1 \pm o(1))\|u - v\|_2$.

We give three methods for solving this problem, each attractive in its own way.

- Our first construction is based on an embedding of the recursive, non-periodic *pinwheel tiling* of Radin and Conway [15, 16, 9] into the integer grid. Distances in the pinwheel graph are asymptotically isometric to Euclidean distances, but no explicit bound on the rate of convergence was known. We prove that the multiplicative distortion of the pinwheel graph is $(1+1/\Theta(\log^{\xi} \log D))$, where D is the Euclidean distance and $\xi = \Theta(1)$. The pinwheel tiling approach is conceptually simple, but can be improved quantitatively.
- Our second construction is based on a hierarchical arrangement of *highways*. It is simple, achieving stretch $(1+1/\Theta(D^{1/9}))$, which converges doubly exponentially faster than the pinwheel tiling approach.
- The first two methods are deterministic, with rigorous guarantees. An even simpler approach is to sample the edge weights independently and randomly from a common distribution $\mathscr{D}$. Whether there exists a distribution $\mathscr{D}^*$ that makes grid distances Euclidean, asymptotically and in expectation, is major open problem in the theory of *first passage percolation*. Previous experiments show that when $\mathscr{D}$ is a Fisher distribution (which is continuous), grid distances are within 1% of Euclidean distances. We demonstrate experimentally that this level of accuracy can be achieved by a simple 2-point distribution that assigns weights 0.41 or 4.75 with probability 44% and 56%, respectively.

1 Introduction

In this paper we consider a natural geometric problem tangentially related to metric embeddings, spanners, and, in its randomized form, percolation theory. Suppose we wish to approximate Euclidean distances between points on the plane, but with a simple *discrete* structure: the integer grid graph $\mathsf{Grid} = (\mathbb{Z} \times \mathbb{Z}, \{\{u, v\} \mid \|u - v\|_1 = 1\})$. If we consider all edges of $E(\mathsf{Grid})$ to have unit length, then Grid can be regarded as a $\sqrt{2}$-spanner since for any $(u, v) \in (\mathbb{Z}^2)^2$,

$$\|u - v\|_2 \leq \mathrm{dist}_{\mathsf{Grid}}(u, v) \leq \sqrt{2} \cdot \|u - v\|_2.$$

Now define $\mathsf{Grid}[w]$ to be Grid endowed with a non-negative edge-weight assignment $w : E(\mathsf{Grid}) \to \mathbb{R}_{\geq 0}$, and let dist_w be the distance function with respect to w. We consider the natural question: does there exist a $\mathsf{Grid}[w^*]$ that is an asymptotic 1-spanner of the Euclidean plane?

▶ **Question 1** (The Squishy Grid Problem)**.** Does there exist a weight function w^* such that for all $u, v \in V(\mathsf{Grid})$ dist_{w^*} is asymptotically Euclidean? That is,

$$\mathrm{dist}_{w^*}(u, v) = (1 \pm o(1))\|u - v\|_2.$$

If so, we may distinguish various types of convergence:
Polynomial. $\mathrm{dist}_{w^*}(u, v) = \|u - v\|_2 \pm O(\|u - v\|_2)^{1-\Omega(1)}$.
Subpolynomial. $\mathrm{dist}_{w^*}(u, v) = \|u - v\|_2 \pm (\|u - v\|_2)^{o(1)}$.
Constant. $\mathrm{dist}_{w^*}(u, v) = \|u - v\|_2 \pm O(1)$.

Before discussing our approach to answering Question 1 we review the history of Question 1 and its connections to percolation theory.

1.1 History of the Problem and Related Results

G. Tardos (personal communication) made us aware of a 1990 book chapter of Pach, Pollack, and Spencer [14] who attributed some version of Question 1 to Paul Erdős. Pach et al. [14] proved that for any fixed $\epsilon > 0$ there exists a graph $G[\epsilon]$ on the vertex set $\mathbb{Z} \times \mathbb{Z}$ such that for all u, v,

$$\|u - v\|_2 \leq \mathrm{dist}_{G[\epsilon]}(u, v) \leq (1 + \epsilon)\|u - v\|_2 + O(5^{1/\epsilon}).$$

Unfortunately, $G[\epsilon]$ is not planar and obviously depends on ϵ, so it does not lead to a resolution of Question 1. Burago and Ivanov [6] exhibited a regular, weighted graph G on the vertex set $\mathbb{Z} \times \mathbb{Z}$ for which

$$\|u - v\|_2 \leq \mathrm{dist}_G(u, v) \leq \|u - v\|_2 + C,$$

for some absolute constant C. However, G is also not planar.

Borradaile and Eppstein [4] considered a more general problem: given a point set $P \in \mathbb{R}^2$, compute a weighted planar graph $G = (P \cup S, E)$ with *Steiner points* S such that $\mathrm{dist}_G(u, v)$ $(1 + \epsilon)$-approximates the Euclidean distance $\|u - v\|_2$. They proved that $|S| = O_{\epsilon,\alpha}(|P|)$ suffices, where α is the sharpest angle in the Delaunay triangulation of P. A result of Chang, Krauthgamer, and Tan [8] implies an upper bound of $O_\epsilon(|P| \operatorname{polylog} |P|)$, which is slightly superlinear but independent of α.

The problem was first posed to us by G. Bodwin, not as a deterministic design problem (Question 1) but as a *randomized* one. Whenever $\mathscr{D}$ is a distribution over $\mathbb{R}_{\geq 0}$, let $\mathsf{Grid}[\mathscr{D}]$ be the distribution of weighted graphs such that for each $e \in E(\mathsf{Grid})$, $w(e) \sim \mathscr{D}$ is sampled independently from the distribution. Is it possible to find a distribution $\mathscr{D}^*$ such that distances in $\mathsf{Grid}[\mathscr{D}^*]$ are Euclidean in expectation? In more detail:

▶ **Question 2** (Randomized Squishy Grid Problem)**.** Does there exist a distribution $\mathscr{D}^*$ over $\mathbb{R}_{\geq 0}$ such that if $\mathsf{Grid}[w] \sim \mathsf{Grid}[\mathscr{D}^*]$ is a randomly weighted graph, for all $u, v \in V(\mathsf{Grid})$,

$$\mathbb{E}(\mathrm{dist}_w(u,v)) = (1 \pm o(1))\|u - v\|_2.$$

The randomized process implicit in Question 2 is actually not new, but dates back to at least a 1965 paper of Hammersley and Welsh [11], who called it *first passage percolation*. They imagined an *orchard* in which trees were planted on the integer lattice. One tree is initially infected, and the time taken for an infected tree to infect a cardinal neighbor is governed by a distribution $\mathscr{D}$ on $\mathbb{R}_{\geq 0}$. One can then ask: how far does the infection spread by time t? and what does the set of infected trees look like?

Many basic questions in first passage percolation theory remain open, and we can quickly summarize the known facts related to Question 2. Let $\mathbf{0} = (0,0)$ be the origin and e_θ be the unit vector with angle θ degrees. We interpret ne_θ to mean the integer point in $V(\mathsf{Grid})$ nearest to ne_θ. The *time constant* $\mu_0(\mathscr{D})$ is such that $\lim_{n\to\infty} \mathrm{dist}_w(\mathbf{0}, ne_0)/n = \mu_0$ almost surely, which exists if, whenever $w_1, \ldots, w_4 \sim \mathscr{D}$ are independently sampled, $\mathbb{E}(\min\{w_1, w_2, w_3, w_4\}) < \infty$ [12]. It follows that $0 \leq \mu_0 \leq \mathbb{E}(w_1 \sim \mathscr{D})$, with the latter inequality holding with equality only if $w_1 \sim \mathscr{D}$ is constant almost surely [11]. Similarly, the time constants for other angles $\mu_\theta(\mathscr{D}) = \lim_{n\to\infty} \mathrm{dist}_w(\mathbf{0}, ne_\theta)/n$ exist, and collectively define the limiting *shape* of the balls under distribution $\mathscr{D}$. Let $B(t) = \{u \in \mathbb{Z}^2 \mid \mathrm{dist}_w(\mathbf{0}, u) \leq t\}$ be the ball of radius t around the origin. The Cox-Durrett shape theorem [10] shows that with probability 1, as $t \to \infty$, $B(t)/t$ tends to a fixed *limit shape* $\mathcal{B}(\mathscr{D}) \subset \mathbb{R}^2$. When $\mu_0(\mathscr{D}) > 0$, $\mathcal{B}(\mathscr{D})$ is bounded, convex, and has the same symmetries as $\mathbb{Z}^2$, and when $\mu_0(\mathscr{D}) = 0$, $\mathcal{B}(\mathscr{D})$ is $\mathbb{R}^2$ itself. See [2] for an extensive survey of first passage percolation theory.

In the context of answering Question 2 we can rescale any non-trivial distribution $\mathscr{D}$ so that its time constant $\mu_0(\mathscr{D}) = 1$, i.e., distances from the origin to points on the x- and y-axes are asymptotically isometric. In light of the Cox-Durrett theorem, Question 2 asks whether there exists a $\mathscr{D}$ for which $\mathcal{B}(\mathscr{D})$ is the unit L_2 ball $\{x \mid \|x\|_2 \leq 1\}$.

Unfortunately, there are no results characterizing $\mathcal{B}(\mathscr{D})$ for *any* non-trivial distribution $\mathscr{D}$. It is not even known whether there exists $\mathscr{D}$ such that

$$\lim_{n\to\infty} \frac{\mathbb{E}(\mathrm{dist}_w(\mathbf{0}, ne_0))}{n} = \lim_{n\to\infty} \frac{\mathbb{E}(\mathrm{dist}_w(\mathbf{0}, ne_{45}))}{n} = 1, \tag{1}$$

i.e., $\mathcal{B}(\mathscr{D})$ coincides with the unit L_2-ball on the eight (inter)cardinal directions. On the other hand, we have solid experimental evidence that $\mathcal{B}(\mathscr{D})$ can get within 1% of the unit L_2-ball, for certain distributions $\mathscr{D}$. An experimental study of Alm and Deijfen [1] looked at various continuous distributions $\mathscr{D}$. When $\mathscr{D}$ is the uniform distribution, the limit shape $\mathcal{B}(\mathscr{D})$ approximates the L_2-ball to with 4%, whereas when $\mathscr{D}$ is exponential the limit shape is about 1.5% away from the L_2-ball. The best empirical approximation to the L_2-ball came from a Fisher distribution, with error less than 1%.

1.2 Results and Findings

We provide two approaches to answering Question 1 and present experimental evidence that Question 2 can be answered in the affirmative, using simple discrete distributions.

Our first construction is based on Radin and Conway's *pinwheel tiling* [15, 16, 9], a conceptually simple tiling that emerges from the observation that a right triangle with proportions $1 : 2 : \sqrt{5}$ can be partitioned into five right triangles with the same proportions. It is known [16] that when regarded as a plane graph G_{PW} with edges weighted according to Euclidean distance, distances in the pinwheel tiling are Euclidean *in the limit*, that is,

$$\lim_{d\to\infty} \max_{u,v:\|u-v\|>d} \frac{\mathrm{dist}_{G_{\mathrm{PW}}}(u,v)}{\|u-v\|_2} = 1.$$

However the rate of convergence is unknown. We embed the pinwheel tiling into the grid graph, and prove a bound on its convergence, namely that for a constant $\xi = \Theta(1)$,

$$\mathrm{dist}_{G_{\mathrm{PW}}}(u,v) = \left(1 + O\left(\frac{1}{\log^{\xi}\log\|u-v\|_2}\right)\right)\|u-v\|_2.$$

A natural problem is to optimize the *convergence* rate of the construction. We give a new, simple construction of a weight function w of the grid that is asymptotically Euclidean, with a ***polynomial*** convergence rate, namely: $\mathrm{dist}_w(u,v) = \|u-v\|_2 + O(\|u-v\|_2^{8/9})$.

The construction is based on laying out "highways" in the plane, which are paths cleaving closely to a line with a certain slope a, whose edge weights are equal and chosen to approximate Euclidean distances along the highway. For example, when $a \in [0,1]$, the weights are $\frac{\sqrt{a^2+1}}{a+1}$. In order to get a $(1+o(1))$-distance approximation, it is necessary that the set of slopes of all highways be dense in $[0,\pi)$. Thus, there are infinitely many slopes, and infinitely many parallel highways of each slope, whose intersection pattern is quite complicated. The tricky part in the design stage is to decide what to do with intersecting highways. We give a simple method that eliminates intersections while guaranteeing polynomial convergence.

Alm and Deijfen's [1] experimental study of first passage percolation selected $\mathscr{D}$ from various continuous distributions such as uniform, exponential, Gamma, and Fisher distributions. For several of these distributions the limit shape $\mathcal{B}(\mathscr{D})$ approximated the L_2-ball within a few percent, with a Fisher distribution being the best. Our experiments show that very simple distributions with support size 2 or 3 can replicate the accuracy of the continuous distributions [1]. For example, the improbable distribution $\mathscr{D}_2$:

$$\Pr_{w_0\sim\mathscr{D}_2}\left(w_0 = \begin{Bmatrix} 0.41401 \\ 4.75309 \end{Bmatrix}\right) = \begin{Bmatrix} 0.44273 \\ 0.55727 \end{Bmatrix}$$

empirically approximates the Euclidean metric to within about 0.75%, and a certain 3-point distribution $\mathscr{D}_3$ approximates it to within 0.622%. A very natural question is whether other L_p metrics can be approximated, in expectation, by various distributions. We illustrate that the uniform distribution and some Gamma distributions approximate L_p metrics with $p < 2$. None of our experiments support the possibility that L_p metrics with $p > 2$ can be approximated.

1.3 Organization

We present the construction based on pinwheel tilings in Section 2, as well as new bounds on the convergence of the stretch of the pinwheel graph. The highway construction is presented in Section 3, having polynomial convergence. We present the experimental findings in Section 4 and conclude with a discussion of several open problems related to Questions 1 and 2 in Section 5. Sections 2, 3, and 4 are written to be independent.

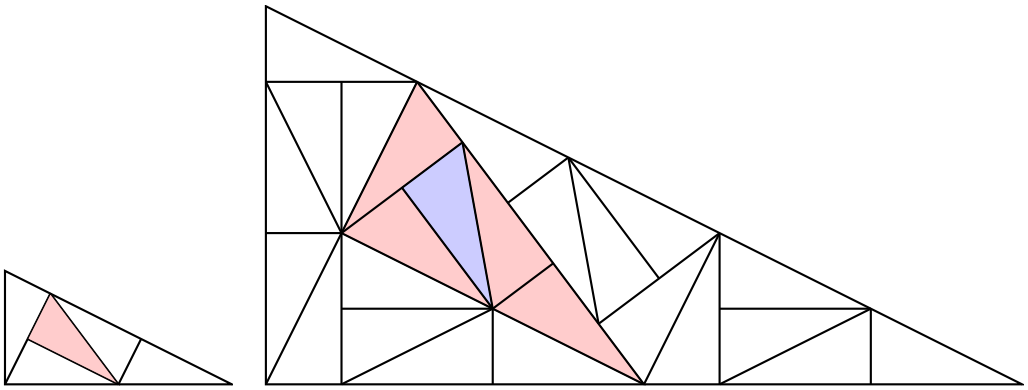

Figure 1 **(A)** $\mathscr{T}_1$, containing $\mathscr{T}_0$ in red. **(B)** $\mathscr{T}_2$, containing $\mathscr{T}_1$ in red, and $\mathscr{T}_0$ in blue.

2 A Deterministic Construction Based on Pinwheel Tilings

The "pinwheel" tiling of Radin [15] is an example of a non-periodic tiling using a single tile type (and its reflection). Let $\mathscr{T}_0, \mathscr{T}_1, \mathscr{T}_2, \ldots$ be a series of tilings of ever larger triangular swatches of the plane, and let $\mathscr{T}_\omega$ be the tesselation of the plane achieved in the limit. $\mathscr{T}_0$ consists of a single right triangle with side lengths $1, 2, \sqrt{5}$. In general $\mathscr{T}_{i+1}$ is formed from $\mathscr{T}_i$ by taking four additional copies of $\mathscr{T}_i$, suitably reflected, rotated, and translated, so that they form a larger triangle with the same $1 : 2 : \sqrt{5}$ proportions. Figure 1 illustrates the construction of $\mathscr{T}_2$ from $\mathscr{T}_1$ and $\mathscr{T}_0$.

2.1 Pinwheel Tilings

By construction $\mathscr{T}_\omega$ is a tiling of the plane using *atomic* triangles with side lengths $1, 2, \sqrt{5}$. Due to the recursive nature of the construction, we can also regard $\mathscr{T}_\omega$ as a tiling using $\sqrt{5}^i, 2\sqrt{5}^i, \sqrt{5}^{i+1}$ triangles, for any integer $i \geq 0$. Observe from Figure 1 that the boundary of $\mathscr{T}_{i+1}$ is obtained from the boundary $\mathscr{T}_i$ by scaling by $\sqrt{5}$, translation, and rotation by $\arctan(1/2)$. We will henceforth define $\gamma = \arctan(1/2)$. As $\gamma/(2\pi)$ is irrational, the orientation of tiles in $\mathscr{T}_\omega$ is uniformly distributed in $[0, 2\pi)$. Radin and Sadun [16] used this fact to prove an isoperimetric property of pinwheel tilings, namely that there are finite subsets of tiles from $\mathscr{T}_\omega$ whose area/perimeter^2 is arbitrarily close to that of the circle. Suppose we regard $\mathscr{T}_\omega$ as a plane graph G_ω, whose vertices and edges are the union of the vertices and edges of all atomic triangles. Radin and Sadun [16] proved that for $u, v \in V(G_\omega)$, $\mathrm{dist}_{G_\omega}(u, v) = (1 + o(1))\|u - v\|_2$. Although the multiplicative stretch is 1 *in the limit*, their proof implies no particular rate of convergence. We prove the following.

▶ **Theorem 1.** *Let G_ω be the plane graph of the pinwheel tiling $\mathscr{T}_\omega$, whose edges are weighted according to the Euclidean distance between their endpoints. Then for any $u, v \in V(G_\omega)$,*

$$\|u - v\|_2 \leq \mathrm{dist}_{G_\omega}(u, v) \leq (1 + O(1/(\log\log\|u - v\|_2)^\xi)) \cdot \|u - v\|_2, \qquad \text{for some } \xi > 0.$$

2.2 Distribution of Tile Orientations

If T is a triangle in the recursive tiling with dimensions $\sqrt{5}^i, 2\sqrt{5}^i, \sqrt{5}^{i+1}$, we call T a *level-i* triangle. As a first step toward proving Theorem 1, we analyze the orientations of the triangles contained within a single large triangle. Given a triangle T of level x, let $\mathrm{Ang}(T, k)$ denote the set of angles attained by the hypotenuses of all level-$(x - k)$ triangles contained within T. We observe that the elements of this set are characterized by an arithmetic recurrence.

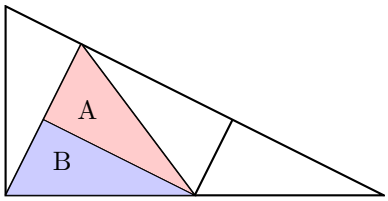

Figure 2 Two triangles within T. The hypotenuses of T, A, B have angles $-\gamma, -2\gamma, 0$, respectively.

▶ **Observation 2.** *Suppose a triangle T of level x has its hypotenuse at angle θ. For $0 \le k \le x$, $\mathrm{Ang}(T,k) \supseteq \{\theta + (2t-k)\gamma \,|\, t \in \{0,\dots,k\}\}$.*

Proof. We proceed by induction on k, with the base case $k = 0$ being trivial. Consult Figure 2, where two triangles A and B of level-$(x-1)$ are depicted. Observe that the hypotenuse of A (resp. B) is rotated by an angle of $-\gamma$ (resp. $+\gamma$) relative to that of the exterior triangle. By the inductive hypothesis,

$$\mathrm{Ang}(A,k-1) \supseteq \{\theta - \gamma + (2t-k+1)\gamma \mid t \in [0,k-1]\} = \{\theta + (2t-k)\gamma \mid t \in [0,k-1]\}$$
$$\mathrm{Ang}(B,k-1) \supseteq \{\theta + \gamma + (2t-k+1)\gamma \mid t \in [0,k-1]\} = \{\theta + (2t-k)\gamma \mid t \in [1,k]\},$$

and the union of these sets is exactly $\{\theta + (2t-k)\gamma \,|\, t \in \{0,\dots,k\}\}$. ◀

Consider some $\lambda \in \mathbb{R}$, and denote by $\{\lambda\} = \lambda - \lfloor\lambda\rfloor$ the fractional part of λ. It is well known due to Weyl's criterion that if λ is irrational, the set $S(\lambda, N) = \{\{kx\} : 1 \le k \le N\}$ becomes uniformly distributed in $[0,1)$ as $N \to \infty$ [5]. Moreover, the rate of convergence is controlled by the *irrationality exponent* $\mu(\lambda)$ which measures the asymptotic quality of rational approximations to λ. For a real number λ, $\mu(\lambda)$ is defined to be the supremum of the set of real numbers μ such that $0 < \left|\lambda - \frac{p}{q}\right| < \frac{1}{q^\mu}$ has infinitely many solutions for integers p, q with $q > 0$. A finite irrationality exponent implies that a number does not have a sequence of rational approximations that are "too good." For sets $S \subseteq U \subseteq \mathbb{R}$, we say S is an *ε-cover* of U if for every $x_1 \in U$ there exists $x_2 \in S$ satisfying $|x_1 - x_2| < \varepsilon$. When $\mu(\lambda)$ is finite, $S(\lambda, N)$ is an ε-cover of $[0,1)$ for $N = \varepsilon^{1-\mu(\lambda)-o(1)}$ [13]. The following corollary follows by applying this fact to Observation 2.

▶ **Corollary 3.** *Given a triangle T of level-x, $\mathrm{Ang}(T,k)$ is a θ-cover of $[0,2\pi)$ for $k = \theta^{1-\mu(\gamma/\pi)-o(1)}$.*

Before bounding the irrationality exponent $\mu(\gamma/\pi)$, we quickly review some terminology related to the algebraic numbers $\overline{\mathbb{Q}}$. For $\alpha \in \overline{\mathbb{Q}}$, its *minimal polynomial* is the unique polynomial $P \in \mathbb{Z}[x]$ of lowest degree with relatively prime coefficients such that $P(\alpha) = 0$. We say the *degree* of α is the degree of P, while the *height* of α is the absolute value over coefficients of P.

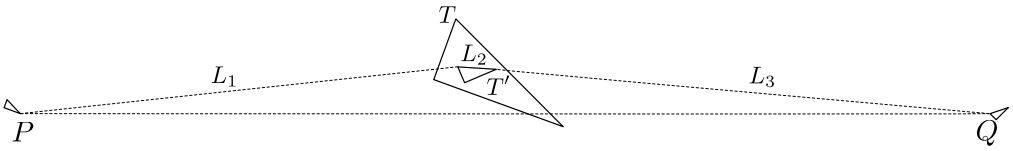
Both γ and π can be expressed in the form $\beta \ln \alpha$ where $\alpha \in \overline{\mathbb{Q}}$ and $\beta \in \mathbb{Q}(i)$. Since $e^{i\gamma} = \frac{2+i}{\sqrt{5}}$, $\gamma = -i \ln(\frac{2+i}{\sqrt{5}})$. Similarly, π can be written as $-i \ln(-1)$. A great deal of work in the mid-20th century yielded various lower bounds on linear forms in logarithms of algebraic numbers. A history of the problem up to 1976 can be found in [3]. For our purposes, we choose a simple bound due to Baker.

▶ **Theorem 4** (Baker [3])**.** *Suppose for $n \ge 1$ we have algebraic numbers $\alpha_1, \dots, \alpha_n, \beta_1, \dots, \beta_n \in \overline{\mathbb{Q}} \setminus 0$. If the logarithms $\ln \alpha_i$ are linearly independent over the rational numbers, then*

$$|\beta_1 \ln \alpha_1 + \cdots + \beta_n \ln \alpha_n| > H^{-C},$$

where H is the maximum of the heights of the β_i and C is a function of n, the numbers α_i, and the degrees of the numbers β_i.

Consider arithmetic expressions of the form $\beta_1 \ln \alpha_1 + \beta_2 \ln \alpha_2$ where $\alpha_1, \alpha_2 \in \overline{\mathbb{Q}} \setminus 0$ are fixed and $\beta_1, \beta_2 \in \mathbb{Z} \setminus 0$. Now β_1 and β_2 have degree 1, so the exponent C becomes a constant, and $H = \max\{|\beta_1|, |\beta_2|\}$. Applying Baker's theorem (Theorem 4) and dividing both sides by $|\beta_1 \ln \alpha_2|$ yields $\left|\frac{\ln \alpha_1}{\ln \alpha_2} + \frac{\beta_2}{\beta_1}\right| > \frac{1}{|\beta_1 \ln \alpha_2| H^C} \geq \frac{1}{|\ln \alpha_2| H^{C+1}}$. By choosing $\alpha_1 = \frac{2+i}{\sqrt{5}}$ and $\alpha_2 = -1$, the ratio $\frac{\ln \alpha_1}{\ln \alpha_2}$ is exactly γ/π. Recall that this number is irrational, satisfying the criteria that $\ln \alpha_1$ and $\ln \alpha_2$ are linearly independent over the rationals. Since $\gamma/\pi < 1$, clearly we can replace H by β_1 to obtain $\left|\frac{\ln \alpha_1}{\ln \alpha_2} + \frac{\beta_2}{\beta_1}\right| > \frac{1}{|\ln \alpha_2| \beta_1^{C+1}}$. Comparing this with the definition of the irrationality exponent, this is sufficient to see that $\mu(\gamma/\pi)$ is at most $C+1$ and therefore finite. Henceforth let $\mu = \mu(\gamma/\pi)$. It is worth noting that the constant C given by Theorem 4 is effectively computable, though the order of magnitude is impractical.[1]



2.3 Convergence of Stretch

We define $f(d)$ to be the maximum stretch guaranteed by G_ω, over all pairs of vertices at Euclidean distance at least d.

$$f(d) = \sup \left\{ \frac{\text{dist}_{G_\omega}(u, v)}{\|u - v\|_2} \;\middle|\; u, v \in V(G_\omega) \text{ and } \|u - v\|_2 \geq d \right\}.$$

▶ **Lemma 5.** *Fix any distance d and let $f(d) = 1+\varepsilon$. There exists a function $n = \varepsilon^{(1-\mu)/2-o(1)}$ such that if $d = \Omega(5^n/\varepsilon)$, then $f(3d) < 1 + \varepsilon - \Omega(5^{-n})$.*

Proof. Consider any two vertices $P, Q \in G_\omega$ with $|\overline{PQ}| = D \geq 3d$ when we regard them as points in the plane. Begin by choosing a parameter $\delta = \delta(\varepsilon)$ and identifying a triangle T satisfying the following properties: T intersects $\overline{PQ}$, the projection of T onto $\overline{PQ}$ lies entirely within the middle third of $\overline{PQ}$, and the hypotenuse of T has length exactly δD. Now choose a parameter $\theta = \theta(\varepsilon)$ and let $n = n(\theta)$ be large enough such that $\text{Ang}(T, n)$ is a θ-cover of $[0, \pi)$. Finally, select a triangle T' within T, and exactly n levels below T, whose hypotenuse creates an angle less than θ with $\overline{PQ}$.

We now construct a path as follows. Let p and q be the endpoints of the hypotenuse of T' closer to P and Q respectively. Let $L_1 = \overline{Pp}$, $L_2 = \overline{pq}$, and $L_3 = \overline{Qq}$. $|L_1|$ and $|L_3|$ must each be at least d, so by the definition of the stretch function f, G_ω approximates L_1 and L_3 to within $1 + \varepsilon$ stretch.

Let ℓ_1, ℓ_2, and ℓ_3 be the projections of L_1, L_2, and L_3 onto $\overline{PQ}$. We claim that $\text{dist}_{G_\omega}(P, p)/|\ell_1| < (1 + \varepsilon)(1 + 5\delta^2)$. Since p lies within T, its projection onto $\overline{PQ}$ is a distance at most δD from p and at least $D/3$ from P. Therefore, $|L_1|/|\ell_1|$ is bounded by $\sqrt{(D/3)^2 + (\delta D)^2}/(D/3) = \sqrt{1 + 9\delta^2} < 1 + 5\delta^2$. By definition of f, $\text{dist}_{G_\omega}(P, p)/|L_1| \leq 1 + \varepsilon$.

[1] One estimate, also due to Baker [3], states that $C = \ln A_1 \ln^2 A_2 (16nd)^{200n}$ suffices when the β_i are rational, where A_i is the height of α_i and d is the degree of the field extension $\mathbb{Q}[\alpha_1, \alpha_2]/\mathbb{Q}$. For our purposes, $A_1 = 4$, $A_2 = 2$, $n = 2$, and $d = 4$, giving $C \approx 2^{2800}$. Baker remarks it is possible to argue C is much lower in reality, but the required analysis is quite technical and beyond the scope of this paper.

The same is true for $\text{dist}_{G_\omega}(q,Q)/|\ell_3|$. On the other hand, $\text{dist}_{G_\omega}(p,q)/|\ell_2|$ is trivially bounded by $|L_2|/|\ell_2| \le 1/\cos\theta$ since p and q are joined directly by an edge in G_ω. Combining the bounds on each component, we write

$$\text{dist}_{G_\omega}(P,Q) < (1+\varepsilon)(1+5\delta^2)(|\ell_1|+|\ell_3|) + \frac{|\ell_2|}{\cos\theta}.$$

We normalize by $1/D$ to obtain the stretch, and because this inequality holds for arbitrary P, Q satisfying $|\overline{PQ}| \ge 3d$, it holds for the supremum as well.

$$\begin{aligned} f(3d) &= \sup_{P,Q\in V(G_\omega)} \left\{ \frac{\text{dist}_{G_\omega}(P,Q)}{|\overline{PQ}|} \;\middle|\; |\overline{PQ}| \ge 3d \right\} \\ &< (1+\varepsilon)(1+5\delta^2)\left(1 - \frac{|\ell_2|}{D}\right) + \frac{|\ell_2|}{D\cos\theta} \\ &\le (1+\varepsilon)(1+5\delta^2)(1-5^{-n/2}\delta\cos\theta) + 5^{-n/2}\delta \end{aligned}$$

Letting $\kappa = 5^{-n/2}$, this is upper bounded by

$$< 1 + \varepsilon + 6\delta^2 + \kappa\delta(1-(1+\varepsilon)\cos\theta)$$

At this point we fix $\theta = \sqrt{\varepsilon}$, so $\cos\theta > 1 - \varepsilon/2$.

$$< 1 + \varepsilon + 6\delta^2 - \kappa\delta\varepsilon(1-\varepsilon)/2 = 1 + \varepsilon + \delta(6\delta - \kappa\varepsilon(1-\varepsilon)/2)$$

Finally, we pick $\delta < \kappa\varepsilon/24$.

$$\le 1 + \varepsilon - \Omega(\delta^2) = 1 + \varepsilon - \Omega(5^{-n}).$$

By Corollary 3, we choose $n(\theta) = n(\sqrt{\varepsilon}) = (\sqrt{\varepsilon})^{1-\mu-o(1)}$. The only remaining detail is to address that the triangles T and T' used in this argument do indeed exist. The length of the hypotenuse of T was taken to be δD, and then we chose T' to be n levels beneath that of T. Therefore, we have implicitly assumed $D \ge 5^{n/2}/\delta > \Omega(5^n/\varepsilon)$, consistent with the assumption in the statement of the lemma. ◀

Theorem 1 now follows easily from this lemma; see the full version [7].

2.4 Pinwheel Tilings on the Grid

▶ **Theorem 6.** *There exists a weight function w such that* Grid$[w]$ *has stretch 1, asymptotically. In particular, for any $u, v \in V(\text{Grid})$,*

$$\|u-v\|_2 - O(1) \le \text{dist}_w(u,v) \le (1+O(1/(\log\log\|u-v\|_2)^\xi))\cdot\|u-v\|_2, \quad \textit{for some } \xi > 0.$$

The proof of this theorem can be found in the full version [7].

3 A Deterministic Construction with Faster Convergence

In this section, we give a deterministic construction based on *highways* with faster convergence. Specifically, we establish the following result as Theorem 7:

▶ **Theorem 7.** *There exists an assignment $W : E(\text{Grid}) \to \mathbb{R}_{\ge 0}$ such that for any $u, v \in V(\text{Grid})$,*

$$\|u-v\|_2 - 1 \le \text{dist}_W(u,v) \le \|u-v\|_2 + O\left(\|u-v\|_2^{\frac{8}{9}}\right).$$

We prove Theorem 7 in two steps. First, we show that the same statement holds for the finite square grid $[n] \times [n]$ (Theorem 8), then we give a black-box reduction from the infinite case to the finite case.

▶ **Theorem 8.** *There exists a weight assignment $W(n)$ to edges of the finite grid on $[n] \times [n]$ such that for any $u, v \in [n]^2$,*

$$\|u - v\|_2 - 1 \leq \text{dist}_{W(n)}(u, v) \leq \|u - v\|_2 + O\left(\|u - v\|_2^{\frac{8}{9}}\right).$$

The proof of Theorem 8 follows from the constructions presented in Section 3.1 and Section 3.2.

3.1 Highways

Given a line $\ell = ax + b$ in $\mathbb{R}^2$ we define the Highway(ℓ) to be a grid-path that tracks ℓ; see Figure 3.

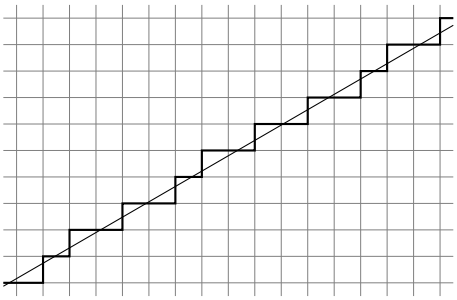


Figure 3 A grid-path that tracks ℓ.

Specifically, let $v \in V(\mathsf{Grid})$ be a grid-point, and consider the 1×1 square $[v-0.5, v+0.5) \times [v-0.5, v+0.5)$. If ℓ intersects this square, then we include v in $V(\ell)$. Whenever $u, v \in V(\ell)$ are adjacent grid points, Highway(ℓ) contains the edge $\{u, v\} \in E(\mathsf{Grid})$. If $a \in [-1, 1]$ we let w_ℓ assign every edge in Highway(ℓ) the weight $\frac{\sqrt{a^2+1}}{|a|+1}$, which is the asymptotic ratio between the Euclidean distance of points on ℓ and the number of edges taken along the grid path Highway(ℓ). Otherwise we write ℓ as $x = a^{-1}(y - b)$ with $a^{-1} \in [-1, 1]$ and use weight $\frac{\sqrt{a^{-2}+1}}{|a^{-1}|+1}$. All off-highway edges have weight ∞.

This weight assignment guarantees a discrepancy of at most 1 between Euclidean distances and grid distances along Highway(ℓ). The proof of Lemma 9 appears in [7].

▶ **Lemma 9.** *Let* Highway(ℓ) *denote the highway that approximates a line ℓ of the form $y = ax + b$. Then for any two points $u, v \in V(\text{Highway}(\ell))$, $|\text{dist}_{w_\ell}(u, v) - \|u - v\|_2| \leq 1$.*

The highway transformation can also be applied to a line *segment* s. We use the same notation Highway(s).

3.2 The Hierarchical Highway Construction

We are trying to find a weight assignment for the finite grid $[n] \times [n]$ in order to prove Theorem 8. The construction is parameterized by $(k_i)_{1 \leq i \leq m}$, where $k_1 = \lfloor n^{1/5} \rfloor$, $\quad k_{i+1} = \lfloor k_i^{1/2} \rfloor$, and m is minimum such that $k_m < 100$.

The construction is based on a hierarchical system of lines in $\mathbb{R}^2$ which will eventually be embedded as highways in the grid. The lines at level i have angles selected from $(\theta_{i,j})_{0\le j<k_i}$, where $\theta_{i,j} = \frac{\pi \cdot j}{k_i}$. Fixing i and one such angle $\theta_{i,j}$, there are many lines with angle $\theta_{i,j}$, spaced at distance k_i^4. For $i \in [1,m], j \in [0, k_i - 1], t \in \mathbb{Z}$, define

$$\ell_{i,j,t} = \left\{(x,y) \in \mathbb{R}^2 \;\middle|\; y \cdot \cos\theta = x \cdot \sin\theta + t \cdot k_i^4\right\}.$$

Define $\mathsf{Lines}[i] = \{\ell_{i,j,t}\}$ to be the set of all lines at level i.

We cannot choose a weight function $W(n)$ that agrees with $w_{\ell_{i,j,t}}$ for *every* line $\ell_{i,j,t}$ due to intersections. Our solution is to avoid this issue by removing all line intersections, which introduces distortions in distances that must be bounded.

Below we define a procedure to remove parts of $\ell_{i,j,t}$, leaving a set of line *segments* $\mathcal{L}_{i,j,t}$. Define $\mathsf{Segments}[i] = \bigcup \mathcal{L}_{i,j,t}$ to be the set of all line segments at level i. If O is an object or collection of objects, define

$$\mathrm{Fat}(O,\delta) = \{p \mid \exists q \in O \text{ such that } \|p-q\|_2 \le \delta\}$$

to be all points within distance δ of O. Specifically, $\mathrm{Fat}(\ell,\delta)$ is a strip if ℓ is a line, and a hippodrome if ℓ is a segment.

Once $\mathsf{Segments}[1], \ldots, \mathsf{Segments}[i-1]$ are constructed, we construct $\mathsf{Segments}[i]$ as follows. For each $\ell_{i,j,t} \in \mathsf{Lines}[i]$ initialize $\ell \leftarrow \ell_{i,j,t}$ and proceed to remove parts of ℓ in Steps 1 and 2.

Step 1. Set $\ell \leftarrow \ell - \mathrm{Fat}(\mathsf{Lines}[i] - \{\ell\}, k_i)$, i.e., we remove every part of ℓ within distance k_i of any other line at level i.

Step 2. For each segment $s \in \bigcup_{i'<i} \mathsf{Segments}[i']$ such that $\mathrm{Fat}(s,k_i) \cap \ell \neq \emptyset$, let $\overline{AB} = \mathrm{Fat}(s,k_i) \cap \ell$. If $\|A-B\|_2 \ge k_i$, set $\ell \leftarrow \ell - \overline{AB}$. Otherwise, let $B' \in \ell_{i,j,t}$ be such that $\|A-B'\| = k_i$ and $B \in \overline{AB'}$, and set $\ell \leftarrow \ell - \overline{AB'}$. See Figure 4. Define $\mathcal{L}_{i,j,t} = \ell$, and include all line segments of $\mathcal{L}_{i,j,t}$ in $\mathsf{Segments}[i]$.

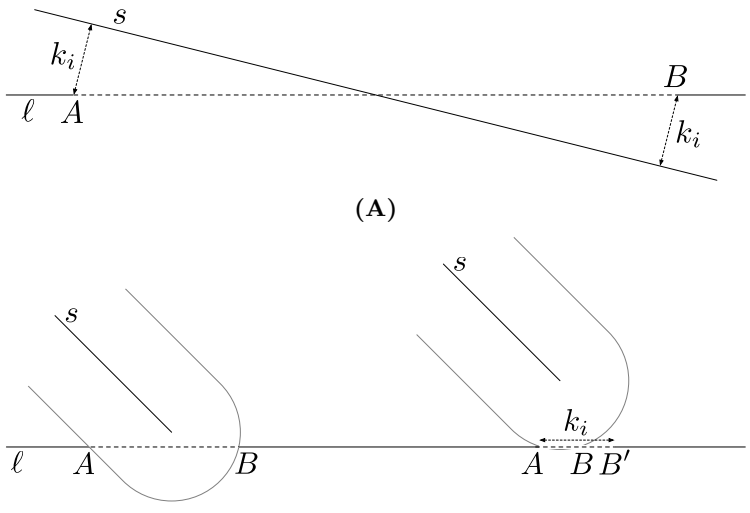

Figure 4 Illustrations of various cases in Step 2. **(A)** ℓ and s intersect. The segment $\ell \cap \mathrm{Fat}(s,k_i)$ is removed from ℓ. **(B)** ℓ and s do not intersect. Left: $\overline{AB} \ge k_i$ and $\overline{AB}$ is removed from ℓ. Right: $\overline{AB} < k_i$ and B' is such that $\overline{AB'} = k_i$ is removed from ℓ.

The weight assignment $W(n)$ is now constructed as follows. For each line segment $s \in \bigcup_i \mathsf{Segments}[i]$, let $W(n)$ agree with w_s at all edges in the corresponding highway segment $\mathrm{Highway}(s)$. All edges not appearing in any line segment have weight 2.

▶ **Lemma 10.** *Fix any $s \in \mathsf{Segments}[i]$, $s' \in \mathsf{Segments}[i']$, where $s \neq s'$ and $i \geq i'$. For any points $u \in s, u' \in s'$, $\|u - v\|_2 \geq k_i$.*

Proof. Steps 1 and 2 ensure that all remaining points on $\mathcal{L}_{i,j,t}$ lie outside

$$\mathrm{Fat}\left(\bigcup_{i'<i} \mathsf{Segments}[i'] \cup (\mathsf{Lines}[i] - \{\ell_{i,j,t}\}), k_i\right),$$

and that any two consecutive segments on $\mathcal{L}_{i,j,t}$ are separated by distance at least k_i. This implies that the Euclidean distance between any $u \in s$ and $u' \in s'$ is at least k_i. ◀

Lemma 11 shows that distances under $W(n)$ are approximately Euclidean, up to a multiplicative stretch of $1 + O(k_i^{-1})$ and additive stretch $O(k_i^4)$, for every index i.

▶ **Lemma 11.** *For any $u, v \in [n]^2$ and $i \in [m]$.*

$$\|u - v\|_2 - 1 \leq \mathrm{dist}_{W(n)}(u, v) \leq \|u - v\|_2 + O\left(k_i^{-1}\|u - v\|_2 + k_i^4\right).$$

Proof. Observe that the highways corresponding to all segments in $\bigcup_i \mathsf{Segments}[i]$ are vertex-disjoint. Thus, every grid path P from u to v can be written as $B_0A_1B_1A_2B_2\cdots A_kB_k$, where each $A_j \subset \mathrm{Highway}(s)$ for some $s \in \bigcup_i \mathsf{Segments}[i]$ and each B_j is disjoint from all highway segments, and therefore consists of only weight-2 edges. (One or both of B_0, B_k may be empty.) By Lemma 9, $W(A_j)$ is at least the Euclidean distance between its endpoints minus one, and $W(B_j)$ is at least the Euclidean distance multiplied by 2, which implies that $W(B_j)$ is at least the Euclidean distance plus 1 for $1 \leq j \leq k-1$, so $W(P)$ is at least $\|u - v\|_2 - 1$.

Turning to the upper bound, We bound the distance $\mathrm{dist}_{W(n)}(u, v)$ by explicitly constructing a path that stays within the vicinity of a single line $\ell_{i,j,t}$. Since level-i lines occur at angular intervals of $\frac{\pi}{k_i}$ and parallel lines are spaced k_i^4 apart, we can always find an $\ell^* = \ell_{i,j,t}$ satisfying the following properties. First, the difference in angle between ℓ^* and $\overline{uv}$ is at most $\frac{\pi}{2k_i}$. Second, the distance from u to ℓ^* is at most $k_i^4/2$. Let A and B be the closest grid points on $\mathrm{Highway}(\ell^*)$ from u and v respectively. It follows that

$$\mathrm{dist}_{W(n)}(u, A) + \mathrm{dist}_{W(n)}(v, B) = O\left(k_i^4 + \|u, v\|_2 \sin\left(\frac{\pi}{2k_i}\right)\right) = O(k_i^4 + k_i^{-1}\|u - v\|_2). \quad (2)$$

It remains to bound $\mathrm{dist}_{W(n)}(A, B)$. A trivial upper bound is $\mathrm{dist}_{W(n)}(A, B) \leq 2\cdot\sqrt{2}\|A - B\|_2$, so if $\|A - B\|_2 < 100k_i^4$ we are done. Henceforth we shall assume that $\|A - B\|_2 \geq 100k_i^4$. We would prefer to follow the A-B path along $\mathrm{Highway}(\ell^*)$, but sections of this highway have effectively been removed by Steps 1 and 2 of the construction. We bound the stretch induced by the gaps in the highway introduced in Steps 1 and 2 separately.

Step 1 Stretch. Fix a direction $\theta_{i,j'}$ different from ℓ^*'s direction $\theta_{i,j}$. Whenever ℓ^* intersects a line with angle $\theta_{i,j'}$, Step 1 causes $\mathrm{Highway}(\ell^*)$ to lose $\frac{k_i}{\sin|\theta_{i,j} - \theta_{i,j'}|} = O(k_i^2)$ edges. There are k_i angles, and parallel lines with angle $\theta_{i,j'}$ are spaced k_i^4 apart, so the total number of edges removed from the A-B path in $\mathrm{Highway}(\ell^*)$ in Step 1 is

$$O\left(k_i^2 \cdot k_i \cdot \frac{\|A - B\|_2}{k_i^4}\right) = O(k_i^{-1}\|A - B\|_2). \quad (3)$$

The additive stretch induced by walking across the gaps induced by Step 1 is also $O(k_i^{-1}\|A - B\|_2)$ as all these edges have weight 2.

Step 2 Stretch. Whenever part of Highway(ℓ^*) is removed by Step 2 we do *not* walk precisely in the direction of ℓ^* but take a *detour* to a lower level highway. Suppose that in Step 2, a segment $s \in \bigcup_{i'<i} \mathsf{Segments}[i']$ causes an interval $\overline{CD}$ of ℓ^* to be removed. Define E, F to be the points on s closest to C, D, respectively. When our path reaches C, we walk from C to E, then to F along Highway(s), then to D. See Figure 5. By construction $\|C-E\|_2, \|D-F\|_2 = O(k_i)$. Since $\|E-F\|_2 \le \|C-D\|_2$ and by Lemma 9 $\mathrm{dist}_{W(n)}(E,F) = \|E-F\|_2 \pm 1$, the additive stretch due to the conflict with s is at most

$$\mathrm{dist}_{W(n)}(C,E) + \mathrm{dist}_{W(n)}(E,F) + \mathrm{dist}_{W(n)}(F,D) - \mathrm{dist}_{w_{\ell^*}}(C,D) = O(k_i).$$

The last task is to bound the number of such segments interfering with the A-B path. Observe that s is a segment of a line at level $i-1$ or lower. Thus, by Lemma 10 any two such segments s, s' are at distance at least $k_{i-1} \ge k_i^2$, and the total additive stretch caused by Step 2 detours is

$$O\left(k_i \cdot \frac{\|A-B\|_2}{k_i^2}\right) = O(k_i^{-1}\|A-B\|_2). \tag{4}$$

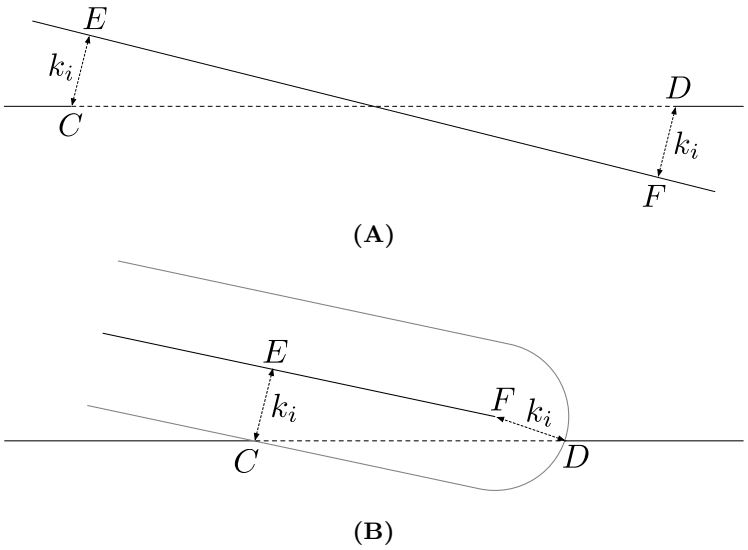

Figure 5 Step 2 detours from the proof of Lemma 11. **(A)** The case when segment s intersects ℓ^*. **(B)** When segment s does not intersect ℓ^*, but $\mathrm{Fat}(s, k_i)$ does.

Combining Equations (2)–(4), we conclude that

$$\begin{aligned}\mathrm{dist}_{W(n)}(u,v) &\le \mathrm{dist}_{W(n)}(u,A) + \mathrm{dist}_{W(n)}(A,B) + \mathrm{dist}_{W(n)}(B,v)\\ &\le \|u-v\| + O\left(k^{-1}\|A-B\|_2 + k_i^{-1}\|u-v\|_2 + k_i^4\right)\\ &= \|u-v\|_2 + O\left(k^{-1}\|u-v\|_2 + k_k^4\right).\end{aligned}$$

◀

Proof of Theorem 8. Recall that by the definition of the sequence (k_i), for any pair of points u, v with Euclidean distance $d = \|u-v\|_2 > 100^9$, there exists some index $1 \le i \le m$ such that $k_i \in \left[d^{1/9}-1, d^{2/9}\right]$. Applying Lemma 11, we have

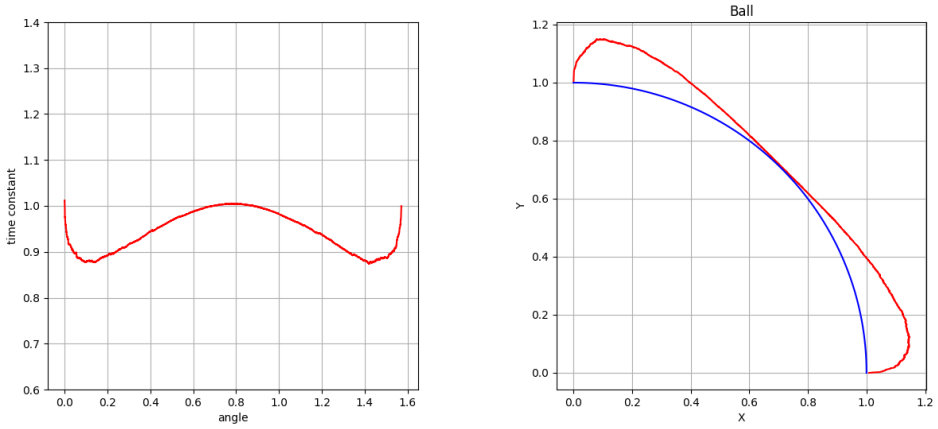
$$\mathrm{dist}_W(u,v) \le \|u-v\|_2 + O\left(\frac{1}{k_i}\cdot\|u-v\|_2 + k_i^4\right) \;\le\; \|u-v\|_2 + O\left(\|u-v\|_2^{8/9}\right).$$

The theorem holds trivially when $d \le 100^9$, which completes the proof of Theorem 8. ◀

In the full version [7] we give a black-box reduction from any finite construction on $[n]\times[n]$, like that of Theorem 8, to a construction on $\mathbb{Z}\times Z$, yielding Theorem 7.

4 Experimental Findings in the Squishy Grid

If Question 2 seems too daunting, a natural idea is to simplify the problem by considering only *monotone* paths, that is, paths that use the fewest number of edges.



▶ **Question 3.** Define $\text{monodist}_w(u,v)$ to be the length of the shortest u-v path that uses $\|u-v\|_1$ edges. Is there a distribution $\mathscr{D}^*$ over $\mathbb{R}_{\geq 0}$ such that if $\mathsf{Grid}[w] \sim \mathsf{Grid}[\mathscr{D}^*]$ is a randomly weighted graph, for all $u,v \in V(\mathsf{Grid})$, $\mathbb{E}(\text{monodist}_w(u,v)) = (1 \pm o(1))\|u-v\|_2$?

At first glance this problem may seem easier, or more plausible, than Question 2. Whereas it is an open problem finding a distribution $\mathscr{D}$ satisfying Equation (1) (the time constant in the 0° and 45° directions are 1), this is nearly trivial when we consider monodist. Refer to [7] for proof.

▶ **Lemma 12.** *There exists a distribution $\mathscr{D}$ on $\mathbb{R}_{\geq 0}$ such that*

$$\lim_{n\to\infty} \frac{\mathbb{E}(\text{monodist}_w(\mathbf{0}, ne_0))}{n} = \lim_{n\to\infty} \frac{\mathbb{E}(\text{monodist}_w(\mathbf{0}, ne_{45}))}{n} = 1.$$

Let $B_{\text{mono}}(t) = \{u \in \mathbb{Z}^2 \mid \text{monodist}_w(\mathbf{0},u) \leq t\}$ and $\mathcal{B}_{\text{mono}}(\mathscr{D})$ be the limiting shape of $B_{\text{mono}}(t)/t$ in $\mathsf{Grid}[w] \sim \mathsf{Grid}[\mathscr{D}]$ as $t \to \infty$. Thus, $\mathcal{B}_{\text{mono}}(\mathscr{D})$ coincides with the L_2-ball in the eight intercardinal directions N, E, S, W, NE, SE, SW, NW. If $\mathcal{B}_{\text{mono}}(\mathscr{D})$ were convex, then it would have to be quite close to the L_2-ball. Unfortunately, our experiments show that $\mathcal{B}_{\text{mono}}(\mathscr{D})$ is *not* convex, which casts serious doubt on Question 3 having an affirmative answer. See Figure 6.

(A) **(B)**

Figure 6 **(A)** The stretch of $\text{monodist}_w(\mathbf{0}, ne_\theta)/\|ne_\theta\|_2$, as a function of the angle $\theta \in [0, \frac{\pi}{2}]$, expressed in radians. **(B)** The shape of $\mathcal{B}_{\text{mono}}(\mathscr{D}_{\epsilon^*})$.

In retrospect, Question 3 is less likely than Question 2 to be answered in the affirmative since $\text{monodist}_w(\mathbf{0},(n,m))$, $m \leq n$, is much more sensitive to small deviations in m than $\text{dist}_w(\mathbf{0},(n,m))$ Considering the cases when $m = 0, m = 0.1n$, and $m = n$, $\text{monodist}_w(\mathbf{0},(n,m))$ is the minimum of $\binom{n+0}{0} = 1$, $\binom{n+0.1n}{0.1n} \approx 1.39^n$, and $\binom{2n}{n} \approx 4^n$ different paths, respectively. This sharp jump from constant to exponential in the vicinity $m = 0$ does not exist in Question 2. Assuming the variance of $\mathscr{D}$ is sufficiently large, $\text{dist}_w(\mathbf{0}, ne_0)$ is the minimum of an exponential number of plausible shortest paths.

4.1 Discrete Distributions for First Passage Percolation

When dealing with discrete distributions the most natural measure of complexity is *support size*. Therefore, we study Question 2 experimentally by considering the space of 2- and 3-point distributions. For a fixed integer k, the k-point distribution $\mathscr{D}(\{(p_i, x_i)\}_{i=1}^k)$, is such that $\Pr_{w_0 \sim \mathscr{D}}(w_0 = x_i) = p_i$. It is determined by $2k-1$ parameters, as $p_k = 1-(p_1+\cdots+p_{k-1})$.

4.1.1 Experimental Methodology

To identify locally optimal distributions among k-point discrete distributions of the form $\mathscr{D}\big(\{(p_i, x_i)\}_{i=1}^k\big)$, we employ a two-layer iterative strategy:

- We first perturb the probability vector $(p_1, \ldots, p_k)$.
- For fixed probabilities $(p_1, \ldots, p_k)$, we generate k random initial values $x_1, x_2, \ldots, x_k$ and then alternate between the following two update steps:

  Perturbation Step. We perturb each value x_i and compute the estimated directional stretch for both $\theta = 0$ and $\theta = \frac{\pi}{4}$. Let μ_θ be the empirical ratio $\frac{\mathrm{dist}_w(\mathbf{0}, ne_\theta)}{n}$, obtained from this round of simulation. Here $n \approx 30{,}000$.

  Normalization Step. We normalize the values $\{x_i\}_{i=1}^k$ by setting $x_i \leftarrow \frac{x_i}{\sqrt{\mu_0 \cdot \mu_{\frac{\pi}{4}}}}$. This scaling ensures that the average stretch along the cardinal and intercardinal directions remains close to 1, thereby facilitating comparisons between distributions.

4.1.2 2-Point Distributions

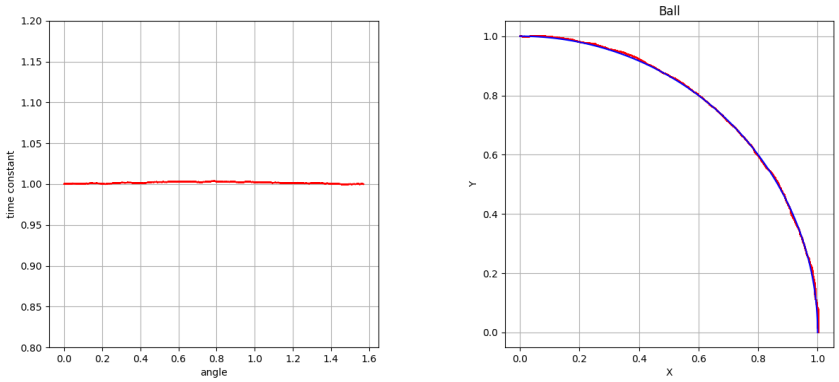
The best 2-point distribution identified with this method is $\mathscr{D}_2$, given below. Roughly speaking, every edge weight is either 0.41 or 4.75, 44% and 56% of the time, respectively.

$$\mathscr{D}_2 = \{(0.44273, 0.41401), (0.55727, 4.75309)\}.$$

We find that $\mathsf{Grid}[w] \sim \mathsf{Grid}[\mathscr{D}_2]$ empirically approximates Euclidean distances up to stretch 1.00750, i.e., up to (3/4)% error. Figure 7(A) plots the observed stretch $\mathrm{dist}_w(\mathbf{0}, ne_\theta)/\|ne_\theta\|_2$ as a function of the angle $\theta \in [0, \pi/2)$. Figure 7(B) shows the set of all grid points whose empirical graph distance from the origin first exceeds n. The resulting boundary is visually close to a Euclidean circle, suggesting that $\mathscr{D}_2$ induces an approximately isotropic metric in expectation.

(A) **(B)**

Figure 7 Results on the 2-point distribution $\mathscr{D}_2$.**(A)** Stretch $\mathrm{dist}_w(\mathbf{0}, ne_\theta)/\|ne_\theta\|_2$, as a function of the angle $\theta \in [0, \frac{\pi}{2}]$. **(B)** The empirical distance-n ball in $\mathsf{Grid}[w] \sim \mathsf{Grid}[\mathscr{D}_2]$.



Note that $\mathbb{E}(w_0 \sim \mathscr{D}_2) \approx 2.83$, meaning that $\text{dist}_w(\mathbf{0}, ne_0) \approx n$ is likely to be realized by a highly non-monotone path, consistent with the observations in Figure 6.

4.1.3 3-Point Distributions

$\mathscr{D}_2$ does not leave much room for improvement, but we are able to eke out a slightly better empirical stretch of 1.00622 with a 3-point distribution $\mathscr{D}_3$.

$$\mathscr{D}_3 = \mathscr{D}(\{(0.34809, 0.20647), (0.25735, 2.51586), (0.39456, 9.32215)\}).$$

See Figure 8 for visual representations of the empirical stretch of $\mathscr{D}_3$.

(A) **(B)**

Figure 8 Results on the 3-point distribution $\mathscr{D}_3$. **(A)** Stretch $\frac{\text{dist}_w(\mathbf{0}, ne_\theta)}{\|ne_\theta\|_2}$, as a function of $\theta \in [0, \frac{\pi}{2}]$. **(B)** The empirical distance-n ball in $\mathsf{Grid}[w] \sim \mathsf{Grid}[\mathscr{D}_3]$.

5 Conclusion

In this paper we asked how well the integer grid graph Grid can approximate Euclidean distances, if weighted appropriately. We gave two deterministic weighting schemes that answer Question 1, the best one achieving a ***polynomial*** additive stretch, that is, $\mathbb{E}[\text{dist}_w(u, v)] = \|u - v\|_2 + O(\|u - v\|_2^{1-\delta})$ for $\delta = 1/9$. Improving the additive stretch to something ***subpolynomial*** $\|u - v\|_2^{o(1)}$ seems to require a new approach to the problem. Our "highway" method seems incapable of achieving subpolynomial additive error, and even if Question 2 is answered affirmatively (choosing weights i.i.d. from some distribution $\mathscr{D}^*$), the tail bounds here only give polynomial additive error [2].

We conjecture that no weighting achieves subpolynomial additive error.

▶ **Conjecture 13.** *The additive error* $\text{dist}_w(u, v) - \|u - v\|_2$ *of* $w : E(\mathsf{Grid}) \to \mathbb{R}_{\geq 0}$ *is a function of* $d = \|u - v\|_2$.
Weak Conjecture. *There is no* w *with constant additive error* $O(1)$*, independent of* d.
Strong Conjecture. *There is no* w *with subpolynomial additive error* $d^{o(1)}$.

In the randomized setting, Question 2 is equivalent to an old problem in *first passage percolation* [2, 11] that is unsolved, but has some empirical evidence in its favor. Alm and Deijfen [1] showed that when $\mathscr{D}$ is a certain Fisher distribution, that $\mathsf{Grid}[w] \sim \mathsf{Grid}[\mathscr{D}]$

approximates Euclidean distances to less than 1% error. In this paper, we demonstrated that a simple 2-point distribution $\mathscr{D}_2$ achieves 0.75% error, and that a 3-point distribution $\mathscr{D}_3$ achieves 0.622% error. It is an interesting open problem to prove that in $\mathsf{Grid}[w] \sim \mathsf{Grid}[\mathscr{D}_2]$, the expected error of dist_w is less than 1%.

Triangulating a Polygon with Holes in Optimal (Deterministic) Time

Timothy M. Chan
Siebel School of Computing and Data Science, University of Illinois at Urbana-Champaign, IL, USA

Abstract

We consider the problem of triangulating a polygon with n vertices and h holes, or relatedly the problem of computing the trapezoidal decomposition of a collection of h disjoint simple polygonal chains with n vertices total. Clarkson, Cole, and Tarjan (1992) and Seidel (1991) gave randomized algorithms running in $O(n \log^* n + h \log h)$ time, while Bar-Yehuda and Chazelle (1994) described deterministic algorithms running in $O(n + h \log^{1+\varepsilon} h)$ or $O((n + h \log h) \log\log h)$ time, for an arbitrarily small positive constant ε. No improvements have been reported since. We describe a new $O(n + h \log h)$-time algorithm, which is optimal and deterministic.

More generally, when the given polygonal chains are not necessarily simple and may intersect each other, we show how to compute their trapezoidal decomposition (and in particular, compute all intersections) in optimal $O(n + h \log h)$ deterministic time when the number of intersections is at most $n^{1-\varepsilon}$.

To obtain these results, Chazelle's linear-time algorithm for triangulating a simple polygon is used as a black box.

1 Introduction

Triangulating a simple polygon is one of the most basic problems in computational geometry, with numerous applications. Chazelle's deterministic linear-time algorithm [5] represents one of the landmark results in the area, improving previous deterministic $O(n \log\log n)$-time algorithms by Tarjan and Van Wyck [28] and Kirkpatrick, Klawe, and Tarjan [20] and previous randomized $O(n \log^* n)$-time algorithms by Clarkson, Tarjan, and Van Wyck [10] and Seidel [27]. Here, n denotes the number of vertices in the input polygon and $\log^*$ is the (very slow-growing) iterated logarithm function.

In this paper, we study an extension of the problem: triangulating a polygon with h holes (where the holes themselves are disjoint simple polygons enclosed in an outer simple polygon). See Figure 1 (left). The problem can be equivalently stated in a number of different ways:

1. Computing the *trapezoidal decomposition* of a polygon with h holes. The decomposition (also called the "trapezoidization", or "vertical decomposition", or "vertical visibility map") is obtained by adding vertical line segments from each vertex to the edge immediately above/below the vertex. Linear-time reductions from trapezoidal decompositions to triangulations and vice versa are known [14].
2. Computing the trapezoidal decomposition of a collection of h disjoint simple polygonal chains. See Figure 1 (right). (We can enclose the chains with a bounding box and turn each chain into an infinitesimally thin hole, while increasing n and h by only a constant factor.)

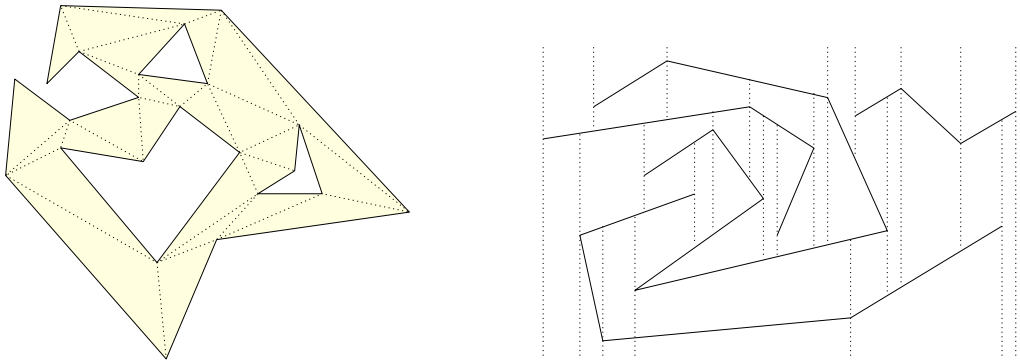

Figure 1 (Left) A triangulation of a polygon with 3 holes. (Right) The trapezoidal decomposition of 5 disjoint simple polygonal chains.

3. Computing the trapezoidal decomposition of a plane straight-line graph (a graph drawn on the plane with straight-line edges without crossings, where edges are ordered around each vertex) with h connected components. (We can make tiny cuts to eliminate cycles and then take an Euler tour to turn each component into a chain, while increasing n and h by only a constant factor.)

Previous randomized $O(n \log^* n)$-time algorithms for simple polygons can be adapted to solve the problem in $O(n \log^* n + h \log h)$ expected time [8, 27]. In 1994, Bar-Yehuda and Chazelle [3] gave deterministic algorithms running in $O(\min\{n + h \log^{1+\varepsilon} h, (n + h \log h) \log\log h\})$ time for an arbitrarily small constant $\varepsilon > 0$. These results came close to the known lower bound of $\Omega(n + h \log h)$,[1] but there is still an extra factor of $\log^* n$ for randomized algorithms, and $\log^{\varepsilon} h$ or $\log\log h$ for deterministic. No improvement has been reported since, deterministic or randomized.

Meanwhile, a number of papers (e.g., [7, 19, 24, 29]) have given algorithms for various problems related to shortest paths and visibility in polygonal domains (polygonal environments with multiple disjoint polygonal obstacles) whose time complexities are dominated by that of the triangulation problem and would be optimal if the triangulation complexity is $O(n + h \log h)$. However, with the current gap of knowledge, these papers needed to state their results more awkwardly, either by assuming that a triangulation of the free space of the polygonal domain (a polygon with holes) is given, or by adding an extra term T to the time bound where T represents the unknown complexity of the triangulation problem. (A similar story occurred for various computational problems about simple polygons in the days before Chazelle's linear-time algorithm.)

Main result. We give the first optimal algorithm for triangulating a polygon with holes in $O(n + h \log h)$ time. The algorithm is deterministic.

Many applications follow [7, 19, 24, 29]. (For example, combining with Wang's result [29] yields an optimal $O(n + h \log h)$-time algorithm for finding the Euclidean shortest path between two given points amidst h disjoint polygonal obstacles with n vertices total.)

[1] An $\Omega(h \log h)$ lower bound in the algebraic decision tree model can be shown by a simple reduction from sorting: to sort h numbers $x_1, \ldots, x_h \in (-1, 1)$, create a polygon that has a triangular outer boundary with vertices $(-1, 1), (1, 1), (0, -1)$, and a sufficiently small hole near (x_i, x_i^2) for each $i \in \{1, \ldots, h\}$.

Previous approaches. Known approaches, as well as our new algorithm, work with the reformulation of the problem in terms of the trapezoidal decomposition of h disjoint polygonal chains.

One could try to directly modify Chazelle's linear-time algorithm for $h = 1$ [5], but this appears difficult (considering how notoriously complicated his algorithm was). Bar-Yehuda and Chazelle's approach was to directly reduce the general h case to the $h = 1$ case: join the multiple polygonal chains into one connected component by adding vertical line segments, and then apply Chazelle's algorithm as a black box. To do so, the first observation is that polygonal chains intersecting a common vertical line can be joined together this way by *Jordan sorting* (the problem of sorting intersections of polygonal chains along a line), which is solvable by known techniques [18]. Roughly, their idea was then to build an *interval tree* [11, 26] for the x-spans of the chains, and solve the problem for each level of the interval tree (since each level consists of vertically separated instances in which chains intersect a common vertical line). The remaining task is merging the results of these $O(\log h)$ levels. Bar-Yehuda and Chazelle proposed a binary divide-and-conquer over the $O(\log h)$ levels, yielding $O((n + h \log h) \log \log h)$ time overall, and alternatively a divide-and-conquer with a larger fan-out, yielding $O(n + h \log^{1+\varepsilon} h)$. This approach seems hard to improve further.

A different approach is randomized divide-and-conquer, as done by Clarkson et al. and Seidel [10, 27]. The trapezoidal decomposition of a random sample of $n/\log n$ edges allows us to divide the problem into subproblems of roughly logarithmic size. Assigning input elements to subproblems requires some form of "point location" and would normally cost $O(\log n)$ per element, but can be done faster knowing that the input elements comes from h chains. Since the recursion has $O(\log^* n)$ levels, the running time inherently increases by a $\log^* n$ factor, unfortunately. Even for $h = 1$ (the case of a simple polygon), Clarkson et al. and Seidel's methods do not achieve linear time (Amato, Goodrich, and Ramos [1] described a randomized linear-time algorithm which is simpler than Chazelle's, but still relies on some of Chazelle's ingredients and is still complicated). Furthermore, randomization seems essential: such random sampling methods where the sample size is large is generally harder to derandomize.

Our approach. The difficulty of improving the random sampling approach turns out to be overstated. We observe that in combination with another known divide-and-conquer strategy via *planar graph separators* [22] or *r-divisions* [15, 16], the random sampling approach can indeed achieve optimal $O(n + h \log h)$ expected running time. The reason the $\log^* n$ factor is avoidable is that we can recurse for a constant number of levels (in fact, just once) and then switch to Chazelle's algorithm (or more precisely Bar-Yehuda and Chazelle's algorithm, which calls Chazelle's) in the base case when the input size is sufficiently small – the $h \log h$ term is big enough to absorb the cost of the switch. The idea of combining sampling with r-divisions and invoking Chazelle's in the base case is not original and can be viewed as a variant of an existing randomized algorithm by Eppstein, Goodrich, and Strash [13] for a related problem (see below). Still, it is interesting that this implication has not been noted earlier, and we include this optimal randomized solution in Appendix A.

Our main contribution is in obtaining an optimal deterministic algorithm. To do so, we combine ideas from both the random sampling approach and Bar-Yehuda and Chazelle's deterministic approach, even though the two approaches appear different and incompatible. To derandomize the sampling approach, we need to compute a subset of the input edges that "behave" like a random sample, known as an *ε-net* in the literature [17, 23] (with ε being $\frac{\text{polylog}\, n}{n}$ in our case). Constructing a net deterministically appears challenging, especially

since we can only afford linear time. We observe a simple way to construct a net in linear time when the trapezoidal decomposition is given, by using planar graph separators or r-divisions (the net size is suboptimal, but is good enough for our purposes).

However, there is an obvious circularity issue: we are not given the trapezoidal decomposition, since that is what we want to compute! Our key idea is to go back to Bar-Yehuda and Chazelle's interval-tree approach, which gives a partition of the input into $O(\log n)$ subsets where we already know how to compute the trapezoidal decomposition of each subset. Although merging their trapezoidal decompositions is not easy, merging their nets is: the union of the nets of the subsets is a net for the whole input (the net size is worsen by an $O(\log n)$ factor, but is still good enough for our purposes). By building the trapezoidal decomposition of the net in combination with an r-division, we can then divide the problem into subproblems of polylogarithmic size. The detailed description of the whole algorithm is given in Section 3, and is just about 2 pages long.

When there are intersections. In the last part of the paper, we address an extension of the problem: computing the trapezoidal decomposition of polygonal chains that may not be simple, i.e., may self-intersect, and may intersect each other. The decomposition is defined in the same way, except that we also add vertical segments from each intersection point to the edge immediately above/below. The crux of the problem lies in the computation of the intersections. (Once all the intersection points are known, we could actually reduce to the non-intersecting case to obtain the final trapezoidal decomposition.)

The problem of computing all self-intersections of one chain (the $h = 1$ case) is already challenging. Chazelle [5] posed the (still open) question of whether there is an $O(n+X)$-time algorithm, where X denotes the number of intersections. Known line-segment intersection algorithms [9, 25, 6, 2] can solve the problem in $O(n \log n + X)$ time, which is optimal when $X \gg n \log n$ but not when X is sublinear; they do not exploit the fact that the input line segments form a connected chain. Clarkson, Cole, Tarjan [8] showed that the random sampling approach yields an $O(n \log^* n + X)$ expected time bound for this problem. On the other hand, Eppstein, Goodrich, and Strash [13] used random sampling in combination with r-divisions to obtain an alternative $O(n + X \log^{(c)} n)$ expected time bound for an arbitrarily large constant c, where $\log^{(c)}$ denotes the logarithm function iterated c times. Thus, their algorithm runs in optimal linear expected time when $X \ll n/\log^{(c)} n$. We are not aware of any *deterministic* result better than $O(n \log n + X)$, however.

We present a deterministic algorithm for computing the trapezoidal decomposition of a non-simple polygonal chain with X intersections in $O(n + Xn^{\varepsilon})$ time. Thus, our algorithm runs in optimal linear time when $X \ll n^{1-\varepsilon}$. (This case is already sufficient for various applications; for example, Eppstein and Goodrich [12] provided empirical evidence that road networks tend to have $X \approx \sqrt{n}$ intersections.)

More generally, when there are multiple chains ($h > 1$), Clarkson, Cole, and Tarjan [8] obtained an $O(n \log^* n + h \log h + X)$ expected time bound. Our deterministic algorithm, presented in Section 4, takes $O(n + h \log h + Xn^{\varepsilon})$ time. (In Appendix A, we also note an extension of Eppstein, Goodrich, and Strash's randomized algorithm with $O(n + h \log h + X \log^{(c)} n)$ expected time bound.)

2 Preliminaries

We begin with some standard definitions.

Trapezoidal decomposition. For a set S of n line segments in the plane, the *trapezoidal decomposition*, denoted $TD(S)$, is the subdivision of the plane formed by S together with vertical line segments drawn from each vertex v of the arrangement (i.e., each endpoint and

each intersection point) to the segment immediately above and below v. The faces in this subdivision are indeed trapezoids (or triangles) where the left and right sides (if exist) are vertical and the top and bottom sides (if exist) are parts of the input segments of S. If S is disjoint, $TD(S)$ has $O(n)$ trapezoids and can be constructed in $O(n \log n)$ time [11, 26]. If S has X intersections, $TD(S)$ has $O(n+X)$ trapezoids and can be constructed in $O((n+X) \log n)$ time by the classic Bentley–Ottmann sweep [4, 26] or in $O(n \log n + X)$ time by the fastest known algorithms [9, 25, 6].

The trapezoidal decomposition of a collection P of (not necessarily simple) polygonal chains, denoted $TD(P)$, is defined as the trapezoidal decomposition of its edge set.

r-division. We use the following weak definition of r-divisions [15]: For a planar graph G with n vertices, an *r-division* is a subset B of $O(n/\sqrt{r})$ vertices such that every connected component in $G - B$ has size at most r. An r-division can be viewed as an extension of planar graph separators, and can be constructed in $O(n)$ time by known algorithms [16, 21] for any given r.

In our application, we consider an r-division of the dual[2] of a trapezoidal decomposition. Here, B is a subset of trapezoids. Construct the subdivision of the plane formed by the sides of the trapezoids in B. The cells of this subdivision will be referred to as the *regions* of the r-division in this paper. Each region is a polygon possibly with holes, which is the union of at most r trapezoids (a region could also just be a single trapezoid, for example, when it is from B). The total number of sides in all the regions[3] is $O(n/\sqrt{r})$. (With a stronger version of r-divisions [15, 21], it is possible to ensure that there are $O(n/r)$ regions, each having at most $O(\sqrt{r})$ sides and at most $O(1)$ holes, though this will not be necessary for our application.)

Interval tree. For a set $\mathcal{I}$ of h intervals, the *interval tree* [11, 26] is a binary tree defined recursively as follows. If $\mathcal{I} = \emptyset$, the tree is just a single node. Otherwise, let a, b, m be the minimum, maximum, and median endpoint. At the root, store $[a, b]$, which we call the *range*, and m, which we call the *pivot value*. At the root, also store all intervals of $\mathcal{I}$ containing m. Recursively build the interval tree for the subset of all intervals of $\mathcal{I}$ completely left of m (this is the left subtree) and the interval tree for the subset of all intervals of $\mathcal{I}$ completely right of m (this is the right subtree). The resulting tree has $O(\log h)$ height, and can be constructed in $O(h \log h)$ time. Note that each interval of $\mathcal{I}$ is stored in exactly one node.

3 Computing the trapezoidal decomposition of h disjoint simple polygonal chains

We now present our main deterministic algorithm for computing the trapezoidal decomposition of h disjoint simple polygon chains (from which an algorithm for triangulating a polygon with h holes would follow).

▶ **Theorem 1.** *Given a collection P of h disjoint simple polygonal chains with a total of n vertices, we can compute $TD(P)$ in $O(n + h \log h)$ deterministic time.*

[2] In the dual graph, the vertices are the trapezoids, and two trapezoids are adjacent if their boundaries (vertical sides or parts of input line segments) overlap.

[3] We use sides instead of edges to avoid confusion between geometric and graph terminologies.

Proof. Let s and t be parameters to be set later. Our algorithm is described in a series of steps below. The purpose of Steps 0–2 is to compute a subset R satisfying a certain property. Afterwards, Steps 3–5 use its trapezoidal decomposition $TD(R)$ to divide the problem into smaller subproblems and then solve these subproblems.

0. For each chain $p \in P$, let I_p be the interval determined by the smallest and largest x-coordinate in p; these can be generated in $O(n)$ time. Build the interval tree for these $O(h)$ intervals in $O(h \log h)$ time. For each node v of the tree, let P_v be the list of all chains $p \in P$ whose intervals I_p are stored at v. Note that each chain appears in exactly one list.

1. For each node v of the interval tree with pivot value m_v:

a. Sort the intersections of P_v with the vertical line $x = m_v$ (note that all chains in P_v intersect this line). This is an instance of the *Jordan sorting* problem for multiple disjoint polygonal chains. Bar-Yehuda and Chazelle [3] showed that this can be done in $O(n_v + h_v \log h_v)$ time (by adapting a known Jordan sorting algorithm for a single polygonal chain [18]), where n_v and h_v are the number of vertices and chains in P_v respectively. Note that $\sum_v n_v = n$ and $\sum_v h_v = h$.

b. Join all chains in P_v into a single simple, connected component P'_v by adding vertical line segments between all pairs of consecutive intersection points along $x = m_v$, by using the output of step 1(a). (Not all such vertical segments are needed to connect the chains, as shown in Figure 2 (left), but this would not matter.) Apply Chazelle's algorithm [5] to compute $TD(P'_v)$, and thus $TD(P_v)$, in $O(n_v)$ time.

c. Compute an s-division of the dual of $TD(P_v)$ in $O(n_v)$ time. Preprocess the regions of the s-division for point location [26] in linear time. Let R_v be the subset of all $O(n_v/\sqrt{s})$ edges of P_v that participate in the region boundaries in this s-division (this excludes vertical sides). Then R_v obeys the following property:[4]

> $(*)$ Given any vertical line segment e not intersecting R_v, the segment e can intersect at most $O(s)$ edges of P_v; furthermore, these edges can be found in $O(\log n + s)$ time.

This property is easy to see: any such segment e must lie completely inside a region in the s-division, which can be found by point location [26] in $O(\log n)$ time, and there are at most $O(s)$ edges of P_v participating in the region.

2. Let R be the union of all the R_v's, together with $O(h)$ extra line segments of zero length at the start vertices of the chains of P. Note that $|R| = O(n/\sqrt{s} + h)$, and R satisfies the following property:[5]

> $(\dagger)$ Given any vertical line segment e not intersecting R, the segment e can intersect at most $O(s \log h)$ edges of P; furthermore, these edges can be found in $O((\log n + s) \log h)$ time.

This follows immediately from property $(*)$, since the x-coordinate of a vertical segment e can lie in the ranges of only $O(\log h)$ nodes v of the interval tree.

---

[4] This property basically says that R_v is an $O(s/n_v)$-*net* [17, 23] of the edge set of P_v, in the set system corresponding to edges intersecting vertical line segments. The size of our net ($O(n_v/\sqrt{s})$) isn't the smallest possible (which would be $O(n_v/s)$) but is good enough for our purposes.

[5] This property basically says that R is an $O((s \log h)/n)$-net of the edge set of P (ignoring the zero-length segments).

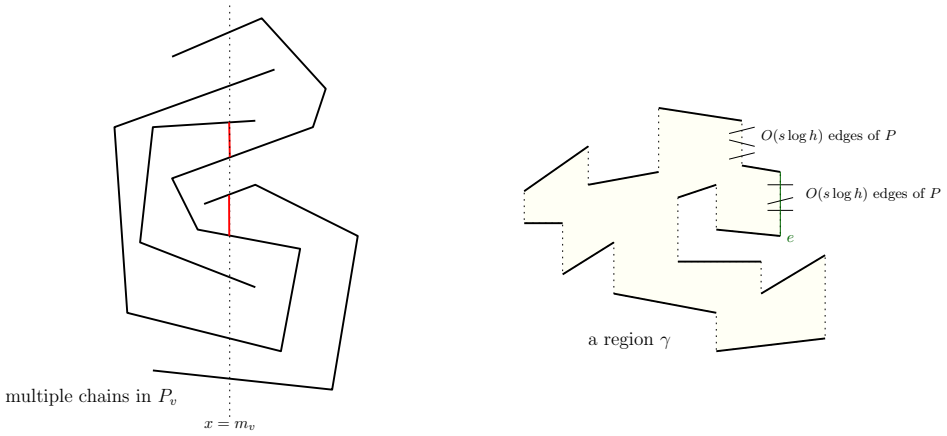

Figure 2 (Left) In Step 1b, we can join multiple chains in P_v intersecting a vertical line $x = m_v$ into a single component, for example, by adding the red vertical segments shown. (Right) In Step 4, we find the $O(s \log h)$ edges of P intersecting each vertical side e of a region γ; the non-vertical sides are parts of edges of R. Each region γ is the union of $O(t)$ trapezoids of $TD(R)$, and the total number of sides over all regions γ is $O(|R|/\sqrt{t})$.

3. Compute $TD(R)$ in $O(|R| \log |R|)$ time, and compute a t-division of the dual of $TD(R)$ in $O(|R|)$ time.

4. For each region γ in the t-division and each vertical side e of the boundary $\partial\gamma$, compute all intersections of e with P. Since the interior of e does not intersect R, we know that e has at most $O(s \log h)$ intersections with P by property (†), and they can be found in $O((\log n + s) \log h)$ time. (See Figure 2 (right).) By summing over all $O(|R|/\sqrt{t})$ choices of e, there are at most $O((|R|/\sqrt{t}) \cdot s \log h)$ such intersections in total and they can be found in $O((|R|/\sqrt{t}) \cdot (\log n + s) \log h)$ time.

   Cut the chains of P at all these intersection points to obtain a new collection P' of polygonal chains. In order to cut, we may need to sort the intersections along each edge of P, but this costs at most a logarithmic factor per intersection, i.e., $O((|R|/\sqrt{t}) \cdot s \log h \cdot \log n)$ in total. The number of vertices in P' is $n' \le n + O((|R|/\sqrt{t}) \cdot s \log h)$, and the number of chains in P' is $h' \le h + O((|R|/\sqrt{t}) \cdot s \log h)$.

5. For each region γ in the t-division, let P'_γ be the chains of P' inside γ, and compute $TD(P'_\gamma)$ by applying Bar-Yehuda and Chazelle's previous algorithms [3] in $O(n'_\gamma + h'_\gamma \log^{O(1)} h'_\gamma)$ time, where n'_γ and h'_γ are the number of vertices and chains in P'_γ respectively.[6] Note that $\sum_\gamma n'_\gamma = n'$ and $\sum_\gamma h'_\gamma = h'$. Furthermore, $\max_\gamma h'_\gamma \le O(t \cdot s \log h)$ (since there are at most $O(t)$ sides in γ, and at most $O(t)$ start vertices of chains inside γ due to those extra segments of zero length added to R).

   Afterwards, we can piece together $TD(P'_\gamma)$ (after clipping to γ) over all regions γ, to obtain $TD(P)$ in $O(n')$ additional time.

The total running time for Steps 0–1 is $O(n + h \log h)$. The running time for Step 3 is $O(|R| \log |R|) = O((n/\sqrt{s} + h) \log n)$ time, as $|R| = O(n/\sqrt{s} + h)$. The total running time for Steps 4–5 is at most $O(n + ((|R|/\sqrt{t}) \cdot s \log h \cdot \log n) + (h + (|R|/\sqrt{t}) \cdot s \log h) \log^{O(1)}(t \cdot s \log h))$.

[6] We could avoid Bar-Yehuda and Chazelle's algorithm and use some slower algorithm running in $O(n'_\gamma + (h'_\gamma)^{O(1)})$ time, if we bootstrap one more time.

Setting $s = \log^2 n$ and $t = \log^8 n$ gives an overall time bound of $O(n + h \log n + h(\log\log n)^{O(1)}) = O(n + h \log n)$, which is the same as $O(n + h \log h)$ (since the second term dominates only if $h \geq n/\log n$, but then $\log n = O(\log h)$). ◀

As a corollary, we can test whether a collection P of h polygonal chains has any intersection in $O(n + h \log h)$ deterministic time: simply run the above algorithm to attempt to compute $TD(P)$, and run Chazelle's linear-time algorithm [5] to check simplicity of the resulting (connected) diagram.

4 When there are a sublinear number of intersections

In this section, we consider the more general case when the polygonal chains may self-intersect or intersect each other, with sublinear number of intersections. Extra ideas are needed. In particular, the interval-tree idea is no longer applicable, and edges may now cross non-vertical sides of the boundary of a region.

In the following lemma, we begin with a special case where we have b subcollections of chains with no intersections within each subcollection.

▶ **Lemma 2.** *Let P be a collection of h simple polygonal chains with a total of n vertices. Suppose P is partitioned into b subcollections $P_1, \ldots, P_b$ such that there are no intersections within each subcollection P_i. Then we can compute $TD(P)$ in $O(n + h \log h + b^{O(1)} X \log^{O(1)} n)$ deterministic time, where X is the number of intersections.*

Proof. Let ℓ be the maximum number of vertices per chain in P. Let s and t be parameters to be set later. We describe an algorithm below to compute all intersections of P. Steps 1–2 compute a subset R satisfying a certain property. Afterwards, Steps 3–5 use its trapezoidal decomposition $TD(R)$ to divide the problem into smaller subproblems and then solve these subproblems.

1. For each $i \in \{1, \ldots, b\}$:
   a. Apply Theorem 1 to compute $TD(P_i)$ in $O(n_i + h_i \log h_i)$ time, where n_i and h_i are the number of vertices and chains in P_i respectively.
   b. Compute an s-division of $TD(P_i)$ in $O(n_i)$ time. Preprocess the regions of the s-division for point location [26] in linear time. Let R_i be the subset of all $O(n_i/\sqrt{s})$ edges of P_i that participate in the boundaries of regions in this s-division.
2. Let R be the union of all the R_i's, together with $O(h)$ extra line segments of zero length at the start vertices of the chains of P. Note that $|R| = O(n/\sqrt{s} + h)$, and R satisfies the following property, similar to before:

   (†) Given any vertical line segment e not intersecting R, the segment e can intersect at most $O(bs)$ edges of P; furthermore, these edges can be found in $O(b(\log n + s))$ time.
3. Compute $TD(R)$ in $O(|R| \log |R| + X)$ time, and compute a t-division of $TD(R)$ in $O(|R| + X)$ time.
4. For each region γ in the t-division and each vertical side e of the boundary $\partial\gamma$, compute all intersections of e with P. Since the interior of e does not intersect R, there are at most $O(bs)$ such intersections and they can be found in $O(b(\log n + s))$ time by property (†). By summing over all $O((|R| + X)/\sqrt{t})$ choices of e, there are at most $O(((|R| + X)/\sqrt{t}) \cdot bs)$ such intersections in total and they can be found in $O(((|R| + X)/\sqrt{t}) \cdot b(\log n + s))$ time.

Cut the chains of P at all these intersection points to obtain a new collection P' of polygonal chains. In order to cut, we may need to sort the intersections along each edge of P, but this costs at most a logarithmic factor per intersection, i.e., $O(((|R|+X)/\sqrt{t}) \cdot bs \cdot \log n)$ in total. The number of vertices in P' is $n' \le n + O(((|R|+X)/\sqrt{t}) \cdot bs)$, and the number of chains in P' is $h' \le h + O(((|R|+X)/\sqrt{t}) \cdot bs)$.

5. For each region γ in the t-division, let P'_γ be the set of all chains of P' with start vertices in γ, let Q_γ be the set of all non-vertical sides of $\partial\gamma$, and apply Theorem 1 to test whether $P'_\gamma \cup Q_\gamma$ has any intersection in $O(n'_\gamma + (h'_\gamma + |Q_\gamma|)\log n)$ time, where n'_γ and h'_γ are the number of vertices and chains in P'_γ respectively. Note that $\sum_\gamma n'_\gamma = n'$ and $\sum_\gamma h'_\gamma = h'$ and $\sum_\gamma |Q_\gamma| = O((|R|+X)/\sqrt{t})$. If the answer is no, mark the region γ *good* and mark all the chains in P'_γ *good*; otherwise, mark the region γ *bad* and mark all the chains in P'_γ *bad*. If γ is good, all chains in P'_γ do not intersect each other and stay inside γ (since chains in P' do not intersect the vertical sides of $\partial\gamma$). Thus, good chains do not intersect each other. On the other hand, the number of bad regions is at most $O(X)$, since we can charge each bad region to a unique intersection (note that each chain is in just one P'_γ); so, the number of bad chains is at most $O(bstX)$, since each P'_γ has at most $O(bs \cdot t)$ chains.

6. For each bad chain p' in P', find all regions γ in the t-division that are intersected by p'. To do so, begin with the region γ containing the start vertex of p'. Find the next line segment $e \in Q_\gamma$ intersected by p', if exists, by brute force in $O(\ell t)$ time, since p' has size at most $O(\ell)$ and Q_γ has size at most $O(t)$. Then reset γ to the neighboring region defined by e, and repeat. The total time is at most $O(\ell t \cdot bstX)$, since every region γ visited by p' after the first can be charged to a unique intersection, and there are at most $O(bstX)$ bad chains p'.

7. For each bad chain p' in P' and each good region γ intersected by p' (all such regions have been identified from step 6), compute all intersections of p' with the good chains of P'_γ by brute force in $(\ell \cdot \ell bst)$ time (since P'_γ has at most $O(\ell \cdot bst)$ edges). The total time is at most $O(\ell \cdot \ell bst \cdot bstX)$.

8. Lastly, compute all intersections among the bad chains, which have $n'' = O(\ell \cdot bstX)$ edges, e.g., by the Bentley–Ottmann sweep [4] in $O((n''+X)\log n'')$ time.

The total running time for Step 1 is $O(n + h\log h)$. The running time for Step 3 is $O(|R|\log|R| + X) = O((n/\sqrt{s}+h)\log n + X)$ time. The total running time for Steps 4–5 is at most $O(n + ((|R|+X)/\sqrt{t}) \cdot bs \cdot \log n + h\log n)$. The total running time for Steps 6–8 is $O((b\ell st)^{O(1)}X)$.

Setting $s = \log^2 n$ and $t = b^2\log^6 n$ gives an overall time bound of $O(n + h\log h + (b\ell)^{O(1)}X\log^{O(1)} n)$.

By initially subdividing the input chains into subchains of length $\log n$, we can lower ℓ to $\log n$ while increasing h to $h + O(n/\log n)$; the $O(h\log h)$ term would then be increased to $O(n + h\log h)$.

After computing all intersections, we can turn P into a collection of at most h disjoint simple chains with $O(n+X)$ vertices, by making tiny cuts to eliminate cycles and taking an Euler tour of each connected component (to traverse the components, we may need to sort intersection points along each edge, but this costs at most $O(X\log n)$ time). Afterwards, we can apply Theorem 1 to compute $TD(P)$ in $O(n + X + h\log h)$ additional time. ◀

Finally, we combine the above lemma with an $n^{\Theta(\varepsilon)}$-way divide-and-conquer to solve the general problem:

▶ **Theorem 3.** *Given a collection P of h (not necessarily simple) polygonal chains with a total of n vertices, we can compute $TD(P)$ in $O(n + h \log h + Xn^{\varepsilon})$ deterministic time for an arbitrarily small constant $\varepsilon > 0$, where X is the number of intersections.*

Proof. Divide P into b subcollections $P_1, \ldots, P_b$, each with n/b vertices, possibly by splitting at most b of the input chains. Suppose P_i has h_i chains and X_i intersections. Note that $\sum_i h_i \leq h + b$ and $\sum_i X_i \leq X$. Recursively compute $TD(P_i)$, whose output gives us the X_i intersections of each P_i. Subsequently, P_i can be turned into a non-intersecting collection of at most h_i simple chains with $O(n/b + X_i)$ vertices. Now, apply Lemma 2 to compute $TD(P)$ in $O(n + X + h \log h + b^{O(1)} X \log^{O(1)} n)$ time.

The total running time satisfies the recurrence

$$T(n, h, X) \leq \max_{\substack{h_1, \ldots, h_b, \\ X_1, \ldots, X_b : \\ \sum_i h_i \leq h + b, \\ \sum_i X_i \leq X}} \left(\sum_{i=1}^{b} T(n/b, h_i, X_i) + O(n + h \log h + b^{O(1)} X \log^{O(1)} n) \right),$$

which solves to $T(n, h, X) = O((n + h \log h + b^{O(1)} X \log^{O(1)} n) \cdot \log_b n)$. Setting $b = n^{\varepsilon/c}$ for a sufficiently large constant c yields the result. ◀

The main open question is whether the running time of the above theorem could be improved to $O(n + h \log h + X)$. A more modest goal is to find a deterministic algorithm with running time $O(n + h \log h + X \log^{O(1)} n)$.

A When randomization is allowed

In this appendix, we describe a simpler randomized algorithm, which can be viewed as a variant of an algorithm for $h = 1$ by Eppstein, Goodrich, and Strash [13]:

▶ **Theorem 4.** *Given a collection P of h (not necessarily simple) polygonal chains with a total of n vertices, we can compute $TD(P)$ in $O(n + h \log h + X \log^{(c)} n)$ expected time for an arbitrarily large constant c, where X is the number of intersections.*

Proof. Let E be the edge set of P. Let s and t be parameters to be set later. The algorithm works as follows:

1. Let R be a random subset of E of size n/s.

2. Compute $TD(R)$ in $O(|R| \log |R| + X)$ time [6, 9, 25], and compute a t-division of $TD(R)$. Preprocess $TD(R)$ for point location [26] in $O(|R|)$ time.

3. For each trapezoid $\tau \in TD(R)$, we generate the list E_τ of all edges of E intersecting τ (called a "conflict list"). To do this, we begin with the trapezoid τ containing the start vertex of a chain, which can be found in $O(\log n)$ time by point location. Let e be the first edge of the chain. We then walk along e in $TD(R)$ to identify the next trapezoid intersected by e; this requires $O(\deg(\tau))$ time, where $\deg(\tau)$ denotes the number of neighboring trapezoids of τ. We continue until we encounter the endpoint of e, then reset e to the next edge, and repeat. The total time is $O(h \log n)$ for the h point location queries, plus $O(\sum_{\tau \in TD(R)} |E_\tau| \cdot \deg(\tau))$ for the walks.

   Clarkson and Shor [9, Lemma 4.3 and Corollary 4.4] showed that

   (i) $\sum_{\tau \in TD(R)} |E_\tau| \cdot \deg(\tau)$ has expected value $O((n/s + X/s^2) \cdot s) = O(n + X/s)$;
   (ii) $\max_{\tau \in TD(R)} |E_\tau| = O(s \log n)$ with probability at least (say) $1 - O(1/n^2)$.

   If (ii) fails, we can afford to switch to a naive $O(n^2)$-time algorithm. So, from now on, assume that (ii) holds.

4. For each region γ in the t-division and each (vertical or non-vertical) side e of the boundary $\partial\gamma$, find the intersections of e with P. There are $O(s \log n)$ such intersections by (ii) and they can be generated in $O(s \log n)$ time (from the output of Step 3). By summing over all $O(|R|/\sqrt{t})$ choices of e, there are $O((|R|/\sqrt{t}) \cdot s \log n)$ such intersections in total and they can be generated in $O((|R|/\sqrt{t}) \cdot s \log n)$ time.

   Cut the chains of P at all these intersection points to obtain a new collection P' of polygonal chains. Note that the intersections are generated in sorted order along the chains from Step 3. The number of vertices in P' is $n' \le n + O((|R|/\sqrt{t}) \cdot s \log n)$, and the number of chains in P' is $h' \le h + O((|R|/\sqrt{t}) \cdot s \log n)$.

5. For each region γ in the t-division, let P'_γ be the chains of P' inside γ, and compute $TD(P'_\gamma)$ recursively. Let n'_γ and h'_γ be the number of vertices and chains in P'_γ respectively. Note that $\sum_\gamma n'_\gamma = n'$ and $\sum_\gamma h'_\gamma = h'$. Furthermore, $\max_\gamma n'_\gamma \le O(t \cdot s \log n)$ by (ii).

   Afterwards, we can piece together $TD(P'_\gamma)$ (after clipping to γ) over all regions γ, to obtain $TD(P)$ in $O(n')$ additional time.

Set $s = \log n$ and $t = \log^6 n$. The total expected running time satisfies the recurrence

$$T(n,h,X) \;\leq \max_{\substack{\sum_\gamma n'_\gamma \leq n + O(n/\log n) \\ \sum_\gamma h'_\gamma \leq h + O(n/\log n) \\ \sum_\gamma X_\gamma \leq X \\ \max_\gamma n'_\gamma \leq O(\log^8 n)}} \left(\sum_\gamma T(n'_\gamma, h'_\gamma, X_\gamma) + O(n + h\log n + X) \right).$$

For the base case, we have $T(n,h,0) = O(n + h\log^{O(1)} n)$ by Bar-Yehuda and Chazelle's algorithm [3], and $T(n,h,X) = O(n^2)$ by a naive algorithm for $X > 0$. Applying the recursion for $c+1$ levels before switching to the base case yields a total time bound of $O(n + h\log n + \sum_{j=1}^{c+1}(h + n/\log^{(j)} n)\log^{O(1)}(\log^{(j)} n) + X((\log^{(c+1)} n)^8)^2) \leq O(n + h\log h + X\log^{(c)} n)$. ◀

Charting the Diameter Computation Landscape of Intersection Graphs in 3D and Above

Abstract

Recent research on computing the diameter of geometric intersection graphs has made significant strides, primarily focusing on the 2D case [14, 11, 8] where truly subquadratic-time algorithms were given for simple objects such as unit-disks and (axis-aligned) squares. However, in three or higher dimensions, there is no known truly subquadratic-time algorithm for any *intersection graph of* non-trivial objects, even basic ones such as unit balls or (axis-aligned) unit cubes. This was partially explained by the pioneering work of Bringmann et al. [5] which gave several truly subquadratic lower bounds, notably for unit balls or unit cubes in 3D when the graph diameter Δ is at least $\Omega(\log n)$, hinting at a pessimistic outlook for the complexity of the diameter problem in higher dimensions. In this paper, we substantially extend the landscape of diameter computation for objects in three and higher dimensions, giving a few positive results. Our highlighted findings include:

1. A truly subquadratic-time algorithm for deciding if the diameter of unit cubes in 3D is at most 3 (Diameter-3 hereafter), the first algorithm of its kind for objects in 3D or higher dimensions. Our algorithm is based on a novel connection to pseudolines, which is of independent interest.
2. A truly subquadratic time lower bound for Diameter-3 of unit balls in 3D under the Orthogonal Vector (OV) hypothesis, giving the first separation between unit balls and unit cubes in the small diameter regime. Previously, computing the diameter for both objects was known to be quadratic hard when the diameter is $\Omega(\log n)$ [5].
3. A near-linear-time algorithm for Diameter-2 of unit cubes in 3D, generalizing the previous result for unit squares in 2D [5].
4. A truly subquadratic-time algorithm and lower bound for Diameter-2 and Diameter-3 of rectangular boxes (of arbitrary dimension and sizes), respectively.

1 Introduction

Computing the diameter of sparse graphs is *quadratic hard*: under the Strong Exponential Time Hypothesis (SETH), there is no $O(n^{2-\varepsilon})$ algorithm for distinguishing diameter 2 vs. 3 of graphs with n vertices and $\tilde{O}(n)$[1] edges [19]. That is, the trivial algorithm for computing the diameter by doing BFS from every vertex is essentially optimal. Since then, the major research focus has been on substantially beating the BFS-based algorithm for structural families of graphs, especially planar/minor-free graphs and geometric intersection graphs. For planar/minor-free graphs, truly-subquadratic algorithms were known [6, 15, 13, 16, 8]. For geometric intersection graphs, the complexity of computing the diameter remains poorly understood, due to the sheer diversity of geometric objects underlying the graphs and the fact that geometric intersection graphs can have $\Omega(n^2)$ edges.

The pioneering work of Bringmann *et al.* [5] studied the diameter of intersection graphs of several types of objects. In dimension three and above, they considered (axis-parallel) hypercubes[2] and balls. Let Diameter-Δ be the problem to decide if a given input graph has diameter at most Δ or at least $\Delta+1$. They showed that it is quadratic hard to solve: (1) Diameter-2 for hypercubes in $\mathbb{R}^{12}$ under the (3-uniform 6-)Hyperclique Hypothesis; (2) Diameter-3 for (not necessarily axis-aligned) unit segments and equilateral triangles in $\mathbb{R}^2$ under the Orthogonal Vector (OV) Hypothesis; and (3) Diameter-$\Omega(\log n)$ for unit balls and unit cubes in $\mathbb{R}^3$, and axis-parallel line segments in $\mathbb{R}^2$, all under the OV Hypothesis.

The hardness results can be interpreted as indicating that the radius-Δ neighborhood balls of each geometric shape class are sufficiently complex and expressive, capable of encoding the hard instances used in various fine-grained reductions. One possible way to quantify the complexity of the set system of neighborhood balls is the notion of *VC-dimension*. Given a set system $(U, \mathcal{F})$ with a ground set U and a family $\mathcal{F}$ of subsets of U, its *VC-dimension* is the cardinality of the largest $S \subseteq U$ such that S is *shattered* by $\mathcal{F}$ – for every $S' \subseteq S$, there is some $X \in \mathcal{F}$ such that $X \cap S = S'$. We say that a graph G has *distance VC-dimension* at most d if the set system of radius-r neighborhood balls $(V_G, \{N^r[v]\}_{r\geq 0})$ has VC dimension at most d. Planar graphs (more generally, minor-free graphs) [12, 4, 17, 13, 16] and intersection graphs of pseudo-disks [1, 14, 11] both have bounded distance VC-dimension, whereas intersection graphs of unit segments and equilateral triangles do not. Recently Chan *et al.* [8] gave truly-subquadratic-time diameter algorithms for squares and unit-disks in the plane – both shapes being pseudo-disks, thus with finite distance VC-dimension. Together, these results hinted at *finite VC-dimension* as an overarching property for fast diameter computation.

We undertake a comprehensive study of computing diameter on geometric intersection graphs. Our results are presented in a pair of papers. While the companion paper [9] focuses solely on the 2D case, this paper is devoted to three or higher dimensions. In the higher-dimensional case, there is no known truly-subquadratic-time algorithm for any non-trivial type of objects, even for basic ones such as unit balls or unit cubes. Upper bound techniques for the 2D cases [5, 14, 11, 8] heavily rely on planarity in various places, most notably in bounding the VC dimension using the non-planarity of K_5 [14, 11, 8]. These planarity-specific techniques, in addition to the negative results by Bringmann *et al.* [5], hint at a pessimistic outlook for the complexity of diameter problems in higher dimensions.

[1] $\tilde{O}(\cdot)$ hides polylogarithmic factors in n.
[2] In this paper, hypercubes and boxes are axis-parallel by default, unless noted otherwise.

Table 1 Previous and new time bounds for deciding whether an intersection graph of geometric objects has diameter at most Δ. All hypercubes/boxes are axis-aligned. New results are shown in bold. Conditional lower bounds marked "(OV)", "(3H6)", and "(combK4)" assume the Orthogonal Vectors hypothesis, the 3-uniform 6-hyperclique hypothesis, and the combinatorial 4-clique hypothesis, respectively, where the latter is for combinatorial algorithms (all upper bounds are obtained from combinatorial algorithms). See the full version for definitions. "2D Paper" refers to the companion paper in the pair [9].

Graph class		Lower bound	Upper bound
Unit balls	2D		$O^*(n^{2-1/18})$ for general Δ [8] $O^*(n^{2-1/9})$ for $\Delta = O(1)$ [8] $\tilde{O}(n^{4/3})$ for $\Delta = 2$ (2D Paper [9])
	3D	$\Omega^*(n^2)$ for general Δ (OV) [5] $\Omega^*(n^2)$ for $\Delta = 3$ (OV) (Thm. 9)	
	dD	$\Omega^*(n^2)$ for $\Delta = 2$ & $d = 7$ (combK4) (Thm. 5)	
Unit hypercubes	2D		$O(n \log n)$ for $\Delta = 2$ [5] $O^*(n^{7/4})$ for $\Delta = O^*(1)$ [14] $\tilde{O}(n^{2-1/8})$ for general Δ [8] $O^*(n)$ for const. Δ (2D Paper [9])
	3D	$\Omega^*(n^2)$ for general Δ (OV) [5]	$\tilde{O}(n)$ for $\Delta = 2$ (Thm. 3) $\tilde{O}(n^{2-1/13})$ for $\Delta = 3$ (Thm. 3)
	4D	$\Omega^*(n^2)$ for $\Delta = 3$ (OV) (Thm. 5)	
	dD	$\Omega^*(n^2)$ for $\Delta = 2$ & $d = 12$ (3H6) [5] $\Omega^*(n^2)$ for $\Delta = 2$ & $d = 10$ (3H6) (Thm. 5) $\Omega^*(n^2)$ for $\Delta = 2$ & $d = 6$ (combK4) (Thm. 5)	
Cubes	2D		$O^*(n^{2-1/12})$ for general Δ [8]
	3D	$\Omega^*(n^2)$ for general Δ (OV) [5] $\Omega^*(n^2)$ for $\Delta = 3$ (OV) (Thm. 3)	$\tilde{O}(n^{2-1/5})$ for $\Delta = 2$ (Thm. 7)
Boxes	2D	$\Omega^*(n^2)$ for $\Delta = 3$ (OV) (Thm. 3)	$\tilde{O}(n^{7/4})$ for $\Delta = 2$ (Full ver.)
	3D		$\tilde{O}(n^{2-1/6})$ for $\Delta = 2$ (Thm. 7)

▶ **Question 1.** *Does a truly-subquadratic-time algorithm for computing the diameter exist for any natural class of geometric intersection graphs in 3D or higher dimensions?*

As a starting point, the hardness landscape for unit cubes seems peculiar. Recall that Bringmann *et al.* [5] showed that in 12D, distinguishing diameter 2 versus 3 is already quadratic hard (under the Hyperclique Hypothesis). However in 3D, the quadratic hardness does not kick in until $\Delta \geq \Omega(\log n)$. Duraj, Konieczny, and Potępa [14] solves the 2D case in time $\tilde{O}(\Delta n^{7/4})$ for Diameter-Δ, which was later extended by [8] to solve Diameter in $\tilde{O}(n^{2-1/8})$ time for general Δ. What about unit cubes in 3D? The same question can be asked about unit balls, which typically behave similarly to unit cubes.

▶ **Question 2.** *What is the complexity landscape of Diameter-Δ for unit cubes and unit balls in constant dimensions? Do radius-Δ neighborhood balls of their intersection graphs have bounded VC-dimension, in particular in 3D?*

1.1 Our Contributions

We provide a comprehensive study on basic objects in higher dimensions; our results are summarized in Table 1. As corollaries, we make significant progress towards Question 1 and Question 2. Below, we discuss each of the contributions in more detail.

Unit cubes versus unit balls. Our first result is a separation between unit (hyper)cubes and unit balls: Diameter-3 for unit balls is hard, whereas Diameter-3 for unit cubes admits a truly subquadratic-time algorithm.

▶ **Theorem 3.** *There is no $O(n^{2-\varepsilon})$ algorithm for Diameter-3 for unit balls in $\mathbb{R}^3$ under the OV hypothesis for any $\varepsilon > 0$, while for unit cubes in $\mathbb{R}^d$ for $d \geq 3$, Diameter-3 and Diameter-2 can be solved in $\tilde{O}(n^{2-1/13})$ and $\tilde{O}(n)$ time, respectively.*

Our lower bound for Diameter-3 of unit balls is by reducing from Diameter-2 of sparse tripartite graphs $G = (A \cup B \cup C, E)$, which is quadratic hard under the OV hypothesis. Our first idea for the reduction would be to create a unit ball for each vertex in $A \cup B \cup C$, as well as a unit ball for each edge in E. We encode edges in the original graph G by intersection: a vertex $u \in A \cup B \cup C$ is incident to an edge $uv \in E$ if and only if the unit balls corresponding to u and uv intersect. Then a length-2 path $a \to b \to c$ in G will correspond to a length-4 path $(\!|a|\!) \to (\!|ab|\!) \to (\!|b|\!) \to (\!|bc|\!) \to (\!|c|\!)$ in the intersection graph, where $(\!|x|\!)$ is the unit ball corresponding to (a vertex or an edge) x. With this idea, we could obtain hardness of Diameter-4. To obtain a lower bound for Diameter-3, we do not create unit balls for the middle set of vertices B; the path would then be $(\!|a|\!) \to (\!|ab|\!) \to (\!|bc|\!) \to (\!|c|\!)$. The difficulty is to guarantee that $(\!|ab|\!)$ only intersects $(\!|bc|\!)$, not $(\!|\tilde{b}c|\!)$ for some other vertex $\tilde{b} \in B$; in the Diameter-4 case, this is enforced by the ball $(\!|b|\!)$. Here, we achieve the guarantee by introducing an angle parameter δ to control the intersections of the balls and prevent unwanted edges from being added. See Section 2.

The algorithms for Diameter-2 and 3 for unit cubes in Theorem 3 are perhaps most interesting. First, we show that *the VC-dimension of the 2- and 3-neighborhoods of 3D unit cubes is bounded by a constant.* Here we depart from existing techniques for the 2D case [14, 11, 8], which rely on the non-planarity of K_5. In a small region, unit cubes behave like orthants, and so the intersection between unit cubes corresponds to a *dominance* relation. We divide the sequence of dominance relations on the length-2 and length-3 path into a number of special cases, bound the VC-dimension of each by 1 or 2 via direct arguments, and then bound the overall VC-dimension by combining subsystems together. See Section 3.1 and Section 4.1 for details.

Our VC-dimension bound, in combination with existing techniques [8], is enough to imply truly-subquadratic-time algorithms for Diameter-2 and Diameter-3, but because of large constants, the running time would be awfully close to quadratic (about $O(n^{1.99999992})$ for Diameter-3). We further build on the proof ideas to give ultra efficient algorithms: In the case of Diameter-2, because the subsystems from various cases actually all have VC-dimension 1, we are able to use orthogonal range searching, in combination with divide-and-conquer, to achieve *near-linear time.* (Large constants appear in the logarithmic factors, instead of in the main polynomial factor.) For Diameter-3, because the subsystems from various cases actually turn out to be special kinds of 2-dimensional systems corresponding to *pseudoline arrangements*, we are able to use known range searching techniques, in combination with a grid approach, to achieve a more reasonable running time $\tilde{O}(n^{2-1/13})$. (We find it surprising that pseudolines turn out to be relevant for a problem about 3D unit cubes!) The technical details are intricate, as we need to work with abstract pseudolines that are only implicitly represented via certain oracles. See Section 3 and §4 of full paper for details.

Our constant bound on the VC-dimension of the 2- and 3-neighborhoods of 3D unit cube graphs suggests an intriguing open question of independent interest to combinatorial geometers: do r-neighborhoods similarly have bounded VC-dimension for all constant $r > 3$?

▶ **Conjecture 4** (VC-Dimension of Unit-Cube Graphs). *There exists a function f such that the VC dimension of $(V, \{N^r[v]\}_{v\in V, r\geq 0})$ is at most $f(r)$, where $N^r[v]$ is the r-neighborhood of v in the unit cube graph $G = (V, E)$.*

Combining with [8], Conjecture 4 would imply that unit-cube graphs of constant diameter admit a truly-subquadratic-time algorithm for computing diameter, which is a natural class of intersection graphs motivated by Question 1.

Unit-hypercubes in 4^+D. Next, we show that Diameter-3 is quadratic hard for unit hypercubes in 4D. Therefore, there is no longer a meaningful separation between unit hypercubes and unit balls in dimension 4. When the dimension is even higher, say at least 6D, we can get hardness results for Diameter-2, under the *3-uniform 6-hyperclique (3H6)* hypothesis or *combinatorial 4-clique (combK4)* hypothesis, by refining Bringmann *et al.*'s previous proof [5] which required 12 dimensions. We also rule out near-linear time combinatorial algorithms in 4D under the *combinatorial boolean matrix multiplication (BMM)* hypothesis. See Section 2 of full paper for details.

▶ **Theorem 5.** *Let $\varepsilon \in (0, 1)$ be any given parameter. There is no $O(n^{2-\varepsilon})$ algorithm for:*
1. *Diameter-3 for unit hypercubes in $\mathbb{R}^4$ under the OV hypothesis.*
2. *Diameter-2 of unit balls in $\mathbb{R}^7$ under the CombK4 hypothesis.*
3. *Diameter-2 for unit hypercubes in $\mathbb{R}^6$ and $\mathbb{R}^{10}$ under CombK4 / 3H6 hypotheses, resp.*

▶ **Theorem 6.** *Let $\varepsilon \in (0, 1)$ be any given parameter. There is no combinatorial $O(n^{3/2-\varepsilon})$ algorithm for Diameter-2 of unit hypercubes in $\mathbb{R}^4$ under the combinatorial BMM hypothesis.*

Cubes and boxes. In 2D, the intersection graphs of (non-unit) squares admit a truly subquadratic-time algorithm for computing the diameter (of any value) [8]. In 3D, we show that for (non-unit) cubes, Diameter-3 is quadratic-hard; this, along with the algorithms in Theorem 3, gives a separation between cubes and their unit counterparts. In contrast, we show that Diameter-2 of (non-unit) cubes is solvable in truly-subquadratic time. Even for the more general case of 3D boxes, we also obtain a truly-subquadratic-time algorithm. (Note that this result is new even for 2D rectangles!) Instead of relying on VC-dimension, this subquadratic algorithm uses a different, grid-based approach. Grid-based approaches have been used before for solving other problems about boxes [7, 10], but one challenge arises from the fact that 3D boxes (or cubes) have quadratic *union complexity*, unlike 3D unit cubes or orthants. We show that in the case of diameter 2, some of the sides are irrelevant and some boxes can actually be replaced by orthants. See Section 5 of full paper for details.

▶ **Theorem 7.** *There is no $O(n^{2-\varepsilon})$ algorithm for Diameter-3 for (non-unit) cubes in $\mathbb{R}^3$ under the OV hypothesis for any $\varepsilon > 0$. On the other hand, Diameter-2 can be solved in time $\tilde{O}(n^{2-1/5})$ for cubes and $\tilde{O}(n^{2-1/6})$ for boxes in $\mathbb{R}^3$.*

Finite VC-dimension as a sufficient condition? Our collection of results for many types of objects in 2D (in the companion paper [9]) and higher-dimensional cases reinforces the same pattern: truly subquadratic-time algorithms are mostly for graphs with bounded VC dimension. We conjecture that these are special cases of a broader phenomenon.

▶ **Conjecture 8** (VC-Dimension vs Diameter Conjecture). *Diameter-Δ of the intersection graph of low-complexity geometric objects (regardless of the dimension) can be solved in truly-subquadratic time if the VC dimension of Δ-neighborhoods is bounded by a constant.*

Here, by low-complexity, we mean that the geometric object has constant description complexity. A positive resolution of Conjecture 8 would provide a powerful algorithmic tool for solving the diameter problem on geometric intersection graphs. A non-trivial test case for Conjecture 8 is (non-unit) disks in 2D: the distance VC dimension is at most 4 [11] whereas currently there is no known truly-subquadratic algorithm even for DIAMETER-2.

It is tempting to strengthen Conjecture 8 to an "if and only if" statement; however, our truly-subquadratic algorithm for DIAMETER-2 of boxes in Theorem 7 provides a counter-example: the intersection graphs of diameter 2 for boxes and rectangles have unbounded VC-dimension. (For proof of unbounded VC-dimension, see the full paper for details)

Graph preliminaries. Throughout this paper, let $G = (V, E)$ be a geometric intersection graph on n geometric objects $\mathcal{O}$. The input will be $\mathcal{O}$ and the graph will be implicit. We use $d(u, v)$ to denote the distance between two vertices $u, v \in V$ in G. We denote the 1-hop *neighborhood* of a vertex $v \in V$ by $N[v]$, and the *r-neighborhood ball* of v by $N^r[v] := \{u \in V : d(u, v) \leq r\}$.

Shatter dimension. For a set system $(U, \mathcal{F})$, define $Sh(n) := \max_{|S|=n} |\{S \cap F : F \in \mathcal{F}\}|$. The *shatter dimension* of the set system is the minimum d such that $Sh(n) = O(n^d)$. By the Sauer-Shelah Lemma [20, 21], if the VC-dimension is d, then the shatter dimension is d. The converse partially holds: if the shatter dimension is d, then the VC-dimension is $O(d \log d)$.

2 Diameter-3 for Unit Balls in 3D

▶ **Theorem 9.** *Assuming the OV hypothesis, there is no $O(n^{2-\varepsilon})$ time algorithm for deciding if the intersection graph of a given set of n unit balls in $\mathbb{R}^3$ has diameter at most 3.*

The reduction is from DIAMETER-2 for n-vertex *sparse tripartite graphs* $G = (A \cup B \cup C, E)$, where the number of edges m is $\tilde{O}(n)$. It is well-known that solving DIAMETER-2 for sparse tripartite graphs in truly-subquadratic time would break the OV hypothesis [19].

▶ **Lemma 10** (DIAMETER-2 sparse tripartite graphs)**.** *There is no $O(n^{2-\varepsilon})$ time algorithm for deciding if a sparse tripartite graph has diameter at most 2, assuming the OV hypothesis.*

In this section, we work with balls of radius 1/2 instead of 1. Let $\varepsilon = \Theta(1/n^4)$ and $\delta = \Theta(1/n^3)$. First, we map every vertex v in $A \cup C$ to a distinct number, also denoted by v, in $[\varepsilon, 2\varepsilon]$, such that $\min_{a_1, a_2 \in A:\, a_1 \neq a_2} |a_1 - a_2| \geq \Omega(\varepsilon/n)$ and $\min_{c_1, c_2 \in C:\, c_1 \neq c_2} |c_1 - c_2| \geq \Omega(\varepsilon/n)$. Vertices of B are mapped to distinct numbers in $[0.9, 1]$ such that $\min_{b_1, b_2 \in B:\, b_1 \neq b_2} |b_1 - b_2| \geq \Omega(1/n)$. Then we create four sets of balls as follows.

1. For every vertex $a \in A$, we add a ball centered at $s_a = (1 + a\cos\delta, a\sin\delta, 0)$.
2. For every edge $(a, b) \in (A \times B) \cap E$, we add a ball centered at $p_{ab} = (1 + a\cos\delta - b\sin\delta, a\sin\delta + b\cos\delta, \sqrt{1 - b^2})$.
3. For every edge $(b, c) \in (B \times C) \cap E$, we add a ball centered at $q_{bc} = (-c, b, \sqrt{1 - b^2})$.
4. For every vertex $c \in C$, we add a ball centered at $t_c = (-c, 0, 0)$.

Let $\mathcal{B}_i$ be the set of balls created in step i for $i \in [4]$ and $\mathcal{B} := \cup_i \mathcal{B}_i$. Observe that:

▶ **Observation 11.** *Let $(\!|p|\!)$ be the ball of radius 1/2 centered at a point p. We have:*

1. *$(\!|s_a|\!) \cap (\!|p_{\tilde{a}b}|\!) \neq \emptyset$ if and only if $a = \tilde{a}$.*
2. *$(\!|p_{ab}|\!) \cap (\!|q_{\tilde{b}c}|\!) \neq \emptyset$ if and only if $b = \tilde{b}$.*
3. *$(\!|p_{bc}|\!) \cap (\!|t_{\tilde{c}}|\!) \neq \emptyset$ if and only if $c = \tilde{c}$.*
4. *Every two balls in $\mathcal{B}_i$ intersect for every $i \in [4]$.*
5. *For any two balls $b_1 \in \mathcal{B}_i$ and $b_2 \in \mathcal{B}_j$ such that $|i - j| \geq 2$, $b_1 \cap b_2 = \emptyset$.*

Proof. For item 1, observe that

$$\begin{aligned}\|s_a - p_{\tilde{a}b}\|_2^2 &= ((a-\tilde{a})\cos\delta + b\sin\delta)^2 + ((a-\tilde{a})\sin\delta - b\cos\delta)^2 + 1 - b^2 \\ &= (a-\tilde{a})^2(\cos^2\delta + \sin^2\delta) + b^2(\sin^2\delta + \cos^2\delta) + 1 - b^2 \;=\; (a-\tilde{a})^2 + 1,\end{aligned}$$

which is exactly 1 if $a = \tilde{a}$, and at least $1 + \Omega(1/n^{10})$ if $|a - \tilde{a}| \geq \Omega(\varepsilon/n)$.

For item 2, observe that

$$\begin{aligned}&\|p_{ab} - q_{\tilde{b}c}\|_2^2 \\ =&(1 + a\cos\delta - b\sin\delta + c)^2 + (a\sin\delta + b\cos\delta - \tilde{b})^2 + (\sqrt{1-b^2} - \sqrt{1-\tilde{b}^2})^2 \\ =&(1 + \Theta(\varepsilon) - \Theta(\delta) + \Theta(\varepsilon))^2 + (\Theta(\varepsilon\delta) + b - \Theta(\delta^2) - \tilde{b})^2 + (\sqrt{1-b^2} - \sqrt{1-\tilde{b}^2})^2 \\ =&(1 - \Theta(1/n^3))^2 + (|b - \tilde{b}| \pm \Theta(1/n^6))^2 + (\sqrt{1-b^2} - \sqrt{1-\tilde{b}^2})^2,\end{aligned}$$

which is $1 - \Theta(1/n^3)$ if $b = \tilde{b}$, and at least $1 + \Omega(1/n^2)$ if $|b - \tilde{b}| \geq \Omega(1/n)$.

For item 3, observe that $\|q_{bc} - t_{\tilde{c}}\|_2^2 = (\tilde{c} - c)^2 + 1$, which is exactly 1 if $c = \tilde{c}$, and at least $1 + \Omega(1/n^{10})$ if $|c - \tilde{c}| \geq \Omega(\varepsilon/n)$. Item 4 is easy to check. For item 5, observe that $\|s_a - t_c\|_2 \geq 1 + a\cos\delta + c \geq 1 + \Omega(1/n^4)$, whereas $\|s_a - q_{bc}\|_2$ and $\|p_{ab} - t_c\|_2$ are both $\sqrt{2} \pm o(1)$. ◀

In the real RAM model, balls $\mathcal{B}$ can clearly be constructed in $O(n+m) = \tilde{O}(n)$ time. In the RAM model, it suffices to approximate all coordinates up to $O(1/n^{10})$ additive error, which can be done in $\tilde{O}(1)$ time (we could actually pick "nice" choices of $b \in B$ so that b and $\sqrt{1-b^2}$ are both rational, and also a nice δ so that $\cos\delta$ and $\sin\delta$ are both rational). Thus, the reduction can be done in $\tilde{O}(n)$ time. Theorem 9 follows from the following lemma.

▶ **Lemma 12.** *Let K be the intersection graph of the set of balls $\mathcal{B}$. Then G has diameter at most 2 if and only if K has diameter at most 3.*

Proof. Observe by item 4 of Observation 11 that the balls in the same set $\mathcal{B}_i$ induce a clique in K. By item 5 of Observation 11, there is no edge between two balls in $\mathcal{B}_i$ and $\mathcal{B}_j$ when $|j - i| \geq 2$. Thus, *K has diameter at most 3 if and only if for every ball $[\![s_a]\!] \in \mathcal{B}_1$ and every ball $[\![t_c]\!] \in \mathcal{B}_4$, $d_K(s_a, t_c) \leq 3$.* Here we slightly abuse the notation by using the center of the ball to denote the corresponding vertex in K.

Suppose that G has diameter at most 2. Let $P = (a, b, c)$ be any path of length 2 in G. Then by Observation 11, $(s_a, p_{ab}, q_{bc}, t_c)$ is a path of length 3 in K. Thus, K has diameter at most 3 by the above observation. For the other direction, if K has diameter at most 3, then for any two vertices s_a and t_c (such that $[\![s_a]\!] \in \mathcal{B}_1$ and $[\![t_c]\!] \in \mathcal{B}_4$), a path of length 3 between s_a and t_c in K must be of the form $(s_a, p_{\tilde{a}b}, q_{\tilde{b}c}, t_c)$. Then again by Observation 11, $a = \tilde{a}$ and $b = \tilde{b}$, and therefore, (a, b, c) is a path of length 2 in G. ◀

3 A Near-Linear Diameter-2 Algorithm for 3D Unit Cubes

In this section, we present an $\tilde{O}(n)$-time algorithm for testing whether the diameter of a 3D unit-cube graph is ≤ 2. This shows that the near-linear Diameter-2 result of Bringmann *et al.* [5] for 2D unit squares surprisingly extends to 3D (ignoring logarithmic factors). It also complements our lower bound result in Theorem 6, which shows conditionally that there are no similar, near-linear combinatorial Diameter-2 algorithms for 4D unit hypercubes.

In Section 3.1, we study the combinatorial problem of bounding the VC-dimension of the distance-2 neighborhoods of 3D unit-cube graphs as a warm-up. In the full version, we use ideas from the combinatorial proof to design a near-linear-time divide-and-conquer algorithm.

For a point $p \in \mathbb{R}^3$, denote $[\![p]\!]$ the unit cube centered at p. For simplicity, assume that the input is in general position, e.g., all coordinates are distinct. We will solve the problem in a slightly more general setting for 3 point sets P, Q, R, testing whether all distances between $[\![p]\!]$ and $[\![r]\!]$ for $(p, r) \in P \times R$ are exactly 2 in the tripartite intersection graph of the unit cubes centered at P, Q, R. The original problem reduces to the case when P, Q, R are all equal to the input point set (or almost equal, if we want to ensure general position); the diameter of the original point set is at most 2 iff every pair in $P \times R$ has distance exactly 2.

3.1 VC-dimension bound

For two points $p, q \in \mathbb{R}^3$, write $p \prec_x q$ if p has smaller x-coordinate than q, and $p \succ_x q$ if p has larger x-coordinate than q. Define $\prec_y$, $\succ_y$, $\prec_z$, $\succ_z$ similarly. Define the trivial relation $\top$ which is always true. A *generalized dominance relation* is a relation $\lhd$ where $p \lhd q$ iff $p \lhd_x q$ and $p \lhd_y q$ and $p \lhd_z q$, for some choices of $\lhd_x \in \{\prec_x, \succ_x, \top\}$, $\lhd_y \in \{\prec_y, \succ_y, \top\}$, and $\lhd_z \in \{\prec_z, \succ_z, \top\}$.

The motivation for considering generalized dominance relations is this: Consider a uniform grid with unit side-length. Inside a grid cell, any unit cube is equivalent to an orthant. If p lies in a grid cell and q lies in a neighboring grid cell, then the condition that $[\![p]\!]$ and $[\![q]\!]$ intersect corresponds precisely to $p \lhd q$ for some generalized dominance relation.

Let P, Q, R be 3 point sets in $\mathbb{R}^3$. Let $\lll = (\lhd_1, \lhd_2)$ be 2 generalized dominance relations in $\mathbb{R}^3$. For each $r \in R$, we can write $N^2_{\lll}[r]$ as $\{p \in P : \exists q \in Q \text{ with } p \lhd_1 q \text{ and } q \lhd_2 r\}$. Define the set system $\mathcal{S}_{\lll}(P, Q, R) := (P, \{N^2_{\lll}[r] : r \in R\})$. We first prove that this set system has bounded VC-dimension by bounding its shatter dimension.

Previous proofs of bounded distance VC-dimension usually involve planarity arguments (avoidance of K_5), but for the 3D problem here, we use a different strategy. We divide into easier cases based on the separability of the given point sets – in the following, we say that two sets are *x-separated* if they are separated by a plane orthogonal to the x-axis; we define *y-* and *z-separation* similarly. We first show how to handle the case when P and Q are both x- and y-separated by a simple direct argument:

▶ **Lemma 13.** *If P and Q are both x- and y-separated, then $\mathcal{S}_{\lll}(P, Q, R)$ has VC-dimension 1.*

Proof. Consider points $p, p' \in P$. Suppose $\{p\}$ and $\{p'\}$ are both shattered (by $\mathcal{S}_{\lll}(P, Q, R)$). Then there exist $r, r' \in R$ with $p \in N^2_{\lll}[r]$, $p' \notin N^2_{\lll}[r]$, $p' \in N^2_{\lll}[r']$, $p \notin N^2_{\lll}[r']$. Let $q, q' \in Q$ with $p \lhd_1 q \lhd_2 r$ and $p' \lhd_1 q' \lhd_2 r'$.

For any $\lhd_i$, we define $\lhd_{ix}$, $\lhd_{iy}$, and $\lhd_{iz}$ to be the x-, y-, and z-coordinate dominance relation, respectively. Because P and Q are x- and y-separated, we already know that $p \lhd_{1x} q'$, $p \lhd_{1y} q'$, and $p' \lhd_{1x} q$, $p' \lhd_{1y} q$. Note that $p \lhd_{1z} q'$ or $p' \lhd_{1z} q$, because otherwise, we must have $\lhd_{1z} \neq \top$ and $q' \lhd_{1z} p \lhd_{1z} q \lhd_{1z} p' \lhd_{1z} q'$: a contradiction. Thus, $p \lhd_1 q'$ or $p' \lhd_1 q$, implying $p \in N^2_{\lll}[r']$ or $p' \in N^2_{\lll}[r]$. ◀

We then handle the case when P and R are separated along all 3 axes.

▶ **Lemma 14.** *If P and R are x-, y-, and z-separated, then $\mathcal{S}_{\lll}(P, Q, R)$ has shatter dimension at most 6.*

Proof. Without loss of generality, say $P \subset (-\infty, 0)^3$ and $R \subset (0, \infty)^3$. Consider the following 6 set systems of the form $\mathcal{S}_{\lll}(P, Q \cap \Lambda, R)$, where Λ can be one of

$$((0,\infty) \times (0,\infty) \times \mathbb{R}), \quad (\mathbb{R} \times (0,\infty) \times (0,\infty)), \quad ((0,\infty) \times \mathbb{R} \times (0,\infty)),$$
$$((-\infty,0) \times (-\infty,0) \times \mathbb{R}), \quad (\mathbb{R} \times (-\infty,0)) \times (-\infty,0)), \quad ((-\infty,0) \times \mathbb{R} \times (-\infty,0)).$$

Each set system has VC-dimension at most 1 by Lemma 13 (or symmetric variants).

Each set in $\mathcal{S}_{\lll}(P, Q, R)$ can be expressed as the union of 6 sets (one of each) from these 6 set systems (since a point $q \in Q$ must has two positive coordinates or two negative coordinates). So, the number of distinct sets in $\mathcal{S}_{\lll}(P, Q, R)$ is at most $O(|P|^6)$. ◀

It remains to reduce the general case to the case when P and R are separated along all 3 axes. We accomplish this by a simple grid idea:

▶ **Lemma 15.** *For any $P, Q, R \subset \mathbb{R}^3$, $\mathcal{S}_{\lll}(P, Q, R)$ has shatter dimension at most* 51*.*

Proof. Build a (non-uniform) grid formed by the x-, y-, and z-coordinates of all the points of P. The grid has $O(|P|^3)$ cells. For each grid cell interior γ, consider the 8 octants at an arbitrary point inside γ; for each such octant τ, the set system $\mathcal{S}_{\lll}(P \cap \tau, Q, R \cap \gamma)$ has shatter dimension at most 6 by Lemma 14. For each $r \in R \cap \gamma$, the set $N^2_{\lll}[r]$ is the union of 8 sets (one of each) from the set systems for the 8 octants. So for each γ, the number of distinct sets in $\{N^2_{\lll}[r] : r \in R \cap \gamma\}$ is $O((|P|^6)^8)$, summing across all cells gives $|\{N^2_{\lll}[r] : r \in R\}| = O(|P|^3 \cdot (|P|^6)^8)$. ◀

We can now bound the shatter dimension for unit cubes.

▶ **Lemma 16.** *For any $P, Q, R \subset \mathbb{R}^3$ with $R \subset (0,1)^3$, write $N^2[r]$ as*

$$\Big\{p \in P : \exists q \in Q \text{ with } [\![q]\!] \text{ intersecting both } [\![p]\!] \text{ and } [\![r]\!]\Big\}.$$

Then the set system $(P, \{N^2[r] : r \in R\})$ has shatter dimension at most 37179*.*

Proof. Fix $\alpha = (\alpha_P, \alpha_Q) \in (\mathbb{Z}^3)^2$ with $\|\alpha_P - \alpha_Q\|_\infty \le 1$. For $p \in \alpha_P + (0,1)^3$ and $q \in \alpha_Q + (0,1)^3$, $[\![p]\!]$ intersects $[\![q]\!]$ iff $p - \alpha_P \lhd_1 q - \alpha_Q$, where we define $\lhd_{1x}$ to be $\succ_x$ if $x(\alpha_Q) = x(\alpha_P) + 1$, and $\prec_x$ if $x(\alpha_Q) = x(\alpha_P) - 1$, and $\top$ if $x(\alpha_Q) = x(\alpha_P)$; we define $\lhd_{1y}$ and $\lhd_{1z}$ in the same way. Similarly, for $q \in \alpha_Q + (0,1)^3$ and $r \in (0,1)^3$, $[\![q]\!]$ intersects $[\![r]\!]$ iff $q - \alpha_Q \lhd_2 r$ for some generalized dominance relation $\lhd_2$. Define the set system $\mathcal{S}_\alpha := \mathcal{S}_{\lll}\big(P \cap (\alpha_P + (0,1)^3) - \alpha_P, (Q \cap (\alpha_Q + (0,1)^3)) - \alpha_Q, R\big)$.

Each set $N^2[r]$ is the union of at most 27^2 sets (one of each) from the set systems $\mathcal{S}_\alpha$ for the at most 27^2 choices of α. By Lemma 15, we have $|\{N^2[r] : r \in R\}| = O((|P|^{51})^{27^2})$. ◀

▶ **Theorem 17.** *For any $P, Q, R \subset \mathbb{R}^3$, the set system $(P, \{N^2[r] : r \in R\})$ has shatter dimension at most* 37179*.*

Proof. Build a uniform grid of side length 1. For each grid cell $\alpha_R + (0,1)^3$ (with $\alpha_R \in \mathbb{Z}^3$), the number of different $N^2[r]$ sets over all $r \in R \cap (\alpha_R + (0,1)^3)$ is $O(|P \cap (\alpha_R + (-2,3)^3)|^{37179})$ by Lemma 16. Since each point $p \in P$ belongs to $O(1)$ number of expanded cells $\alpha_R + (-2,3)^3$, the sum over all α_R is $O(|P|^{37179})$. ◀

In the interest of simplicity, we have not optimized the above constant (which admittedly is quite large, but fortunately will not matter in our final algorithm).

3.2 Algorithm

Knowing that the VC-dimension is bounded, we could apply the framework of Chan et al. [8] to obtain a subquadratic algorithm for Diameter-2 of 3D unit cubes. However, the exponent would be very close to 2 (much worse than our more general result for arbitrary 3D boxes in Theorem 7, see the full version). We present a faster, direct algorithm that runs in *near-linear* time. The key observation is that although the final shatter dimension bound is large, the proof in Section 3.1 tells us that the set system is in some sense "made up of" a constant number of simpler subsystems with much smaller VC-dimension, namely, VC-dimension 1 (Lemma 13)! We can't just solve the problem for each subsystem separately – the diameter problem isn't decomposable that way. Instead, we "encode" each subsystem by adding a single coordinate value to each element, and in the end reduce the whole problem to an orthogonal range searching problem for vectors in a sufficiently large constant dimension. Due to lack of space, see the full version of the paper for the algorithm.

4 Subquadratic Diameter-3 Algorithm for 3D Unit Cubes

In this section, we present a subquadratic algorithm for testing whether the diameter of a 3D unit-cube graph is at most 3. This complements our lower bound results, which show conditionally that there are no similar Diameter-3 algorithms for 3D unit-ball graphs (Theorem 9) nor for 4D unit-hypercube graphs (Theorem 6). This result is more challenging than our result for diameter 2 in Section 3. As before, we warm up by studying the corresponding combinatorial problem of bounding the VC-dimension of the 3-neighborhoods of 3D unit-cube graphs (Section 4.1). The combinatorial proof will reveal a surprising connection to 2D pseudolines that we defer to the full paper.

Again, for a point $p \in \mathbb{R}^3$, recall that $[\![p]\!]$ denotes the unit cube centered at p. For simplicity, assume all coordinates are distinct. Like before, we will solve the problem in a slightly more general setting for 4 point sets P, Q, R, S, testing whether all distances between $[\![p]\!]$ and $[\![s]\!]$ for $(p, s) \in P \times S$ are at most 3 in the 4-partite intersection graphs of the unit cubes centered at P, Q, R, S.

4.1 VC-dimension bound

Following Section 3.1, we begin with the corresponding problem for generalized dominance relations. Let P, Q, R, S be four point sets in $\mathbb{R}^3$. Let $\lll = (\lhd_1, \lhd_2, \lhd_3)$ be three generalized dominance relations in $\mathbb{R}^3$. For each $s \in S$, we can write $N^3_{\lll}[s]$ as $\{p \in P : \exists (q, r) \in Q \times R$ with $p \lhd_1 q$ and $q \lhd_2 r$ and $r \lhd_3 s\}$. Define the set system $\mathcal{S}_{\lll}(P, Q, R, S) := (P, \{N^3_{\lll}[s] : s \in S\})$. We first prove that this set system has bounded shatter dimension.

As in Section 3.1, we do not use planarity arguments like previous proofs. Instead, we divide into cases based on separability of the given point sets. But as we go from 2- to 3-neighborhoods, we face more challenges. The first case turns out to be the most crucial (and interesting), where as the one that follows it is similar to Lemma 14.

▶ **Lemma 18.** *If P and Q are x-separated, Q and R are y-separated, and R and S are z-separated, then the set system $\mathcal{S}_{\lll}(P, Q, R, S)$ has VC-dimension at most 2.*

Proof. Suppose $p \lhd_j q$ iff $p \lhd_{jx} q$ and $p \lhd_{jy} q$ and $p \lhd_{jz} q$ with $\lhd_{jx} \in \{\prec_x, \succ_x, \top\}$, $\lhd_{jy} \in \{\prec_y, \succ_y, \top\}$, and $\lhd_{jz} \in \{\prec_z, \succ_z, \top\}$. We may assume that $\lhd_{1x} \neq \top$ (because if not, we can shift all the x-coordinates of P sufficiently far downward and replace $\lhd_{1x}$ with $\prec_x$), and similarly, all other $\lhd_{jx}, \lhd_{jy}, \lhd_{jz}$ are not $\top$. We first prove the following property:

Figure 1 In the yz plane, if p is dominated by q and p' is dominated by q', but p is not dominated by q' and p' is not dominated by q, then (i) and (ii) depict the only two possibilities.

Property: Let $p, p' \in P$ and $s, s' \in S$. If $p \in N^3_{\lll}[s]$, $p' \in N^3_{\lll}[s']$, $p \notin N^3_{\lll}[s']$, $p' \notin N^3_{\lll}[s]$, then $p \prec_y p'$ implies $s' \blacktriangleleft_y s$, where $\blacktriangleleft_y \in \{\prec_y, \succ_y\}$ is a relation determined solely from the choices of $\lhd_1, \lhd_2, \lhd_3$.

Proof: Let $q, q' \in Q$ and $r, r' \in R$ with $p \lhd_1 q \lhd_2 r \lhd_3 s$ and $p' \lhd_1 q' \lhd_2 r' \lhd_3 s'$. We may assume neither $p \lhd_1 q'$ nor $p' \lhd_1 q$, because otherwise, $p \in N^3_{\lll}[s']$ or $p' \in N^3_{\lll}[s]$. Because P and Q are x-separated, we already know $p \lhd_{1x} q'$ and $p' \lhd_{1x} q$. So, there are two remaining possibilities: (i) $p \lhd_{1y} q \lhd_{1y} p' \lhd_{1y} q'$ and $p' \lhd_{1z} q' \lhd_{1z} p \lhd_{1z} q$, or (ii) $p' \lhd_{1y} q' \lhd_{1y} p \lhd_{1y} q$ and $p \lhd_{1z} q \lhd_{1z} p' \lhd_{1z} q'$. (See Figure 1.)

Define $\blacktriangleleft_{1z} \in \{\prec_z, \succ_z\}$ to be $\lhd_{1z}$ iff $\lhd_{1y}$ is $\prec_y$. Then $p \prec_y p'$ implies $q' \blacktriangleleft_{1z} q$.

Similarly, we may assume neither $q \lhd_2 r'$ nor $q' \lhd_2 r$, because otherwise, $p \in N^3_{\lll}[s']$ or $p' \in N^3_{\lll}[s]$. Because Q and R are y-separated, $q \lhd_{2y} r'$ and $q' \lhd_{2y} r$. There are two remaining possibilities: (i) $q \lhd_{2z} r \lhd_{2z} q' \lhd_{2z} r'$ and $q' \lhd_{2x} r' \lhd_{2x} q \lhd_{2x} r$, or (ii) $q' \lhd_{2z} r' \lhd_{2z} q \lhd_{2z} r$ and $q \lhd_{2x} r \lhd_{2x} q' \lhd_{2x} r'$.

Define $\blacktriangleleft_{2x} \in \{\prec_x, \succ_x\}$ to be $\lhd_{2x}$ iff $\lhd_{2z}$ is $\blacktriangleleft_{1z}$. Then $q' \blacktriangleleft_{1z} q$ implies $r \blacktriangleleft_{2x} r'$.

Similarly (and lastly), we may assume neither $r \lhd_3 s'$ nor $r' \lhd_3 s$, because otherwise, $p \in N^3_{\lll}[s']$ or $p' \in N^3_{\lll}[s]$. Because R and S are z-separated, $r \lhd_{3z} s'$ and $r' \lhd_{3z} s$. There are two remaining possibilities: (i) $r \lhd_{3x} s \lhd_{3x} r' \lhd_{3x} s'$ and $r' \lhd_{3y} s' \lhd_{3y} r \lhd_{3y} s$, or (ii) $r' \lhd_{3x} s' \lhd_{3x} r \lhd_{3x} s$ and $r \lhd_{3y} s \lhd_{3y} r' \lhd_{3y} s'$.

Define $\blacktriangleleft_y \in \{\prec_y, \succ_y\}$ to be $\lhd_{3y}$ iff $\lhd_{3x}$ is $\blacktriangleleft_{2x}$. Then $r \blacktriangleleft_{2x} r'$ implies $s' \blacktriangleleft_y s$. □

Now, consider 3 points $p, p', p'' \in P$, with $p \prec_y p' \prec_y p''$. Suppose $\{p, p''\}$ and $\{p'\}$ are both shattered. Then there exist $s, s' \in S$ with $p, p'' \in N^3_{\lll}[s]$, $p' \notin N^3_{\lll}[s]$, $p' \in N^3_{\lll}[s']$, $p, p'' \notin N^3_{\lll}[s']$. Applying the property twice yields $s' \blacktriangleleft_y s$ and $s \blacktriangleleft_y s'$: a contradiction. ◀

▶ **Lemma 19.** *If (a) P, Q are both x- and y-separated, or (b) Q, R are both x- and y-separated, or (c) R, S are both x- and y-separated, then $\mathcal{S}_{\lll}(P, Q, R, S)$ has VC-dimension 1.*

Proof. Consider 2 points $p, p' \in P$. Suppose $\{p\}$ and $\{p'\}$ are both shattered. Then there exist $s, s' \in S$ with $p \in N^3_{\lll}[s]$, $p' \notin N^3_{\lll}[s]$, $p' \in N^3_{\lll}[s']$, $p \notin N^3_{\lll}[s']$. Let $q, q' \in Q$ and $r, r' \in R$ with $p \lhd_1 q \lhd_2 r \lhd_3 s$ and $p' \lhd_1 q' \lhd_2 r' \lhd_3 s'$.

For (a), $p \lhd_{1x} q'$, $p \lhd_{1y} q'$, and $p' \lhd_{1x} q$, $p' \lhd_{1y} q'$ by the separation assumptions. Note that $p \lhd_{1z} q'$ or $p' \lhd_{1z} q$, because otherwise, $q' \lhd_{1z} p \lhd_{1z} q \lhd_{1z} p' \lhd_{1z} q'$: a contradiction. Thus, $p \lhd_1 q'$ or $p' \lhd_1 q$, implying $p \in N^3_{\lll}[s']$ or $p' \in N^3_{\lll}[s]$.

Claims (b) and (c) follow from a similar argument. ◀

We now handle the case when P and S are separated along all 3 axes, by invoking the previous cases some constant number of times:

▶ **Lemma 20.** *If P and S are x-, y-, and z-separated, then $\mathcal{S}_{\lll}(P, Q, R, S)$ has shatter dimension at most* 21*.*

Proof. Denote $\mathbb{R}_+$ and $\mathbb{R}_-$ to be $(0, \infty)$ and $(-\infty, 0)$, respectively. Without loss of generality, say $P \subset \mathbb{R}^3_-$ and $S \subset \mathbb{R}^3_+$. Consider the following 15 set systems.

$$\begin{aligned}
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R}_+ \times \mathbb{R}_- \times \mathbb{R}), \quad R \cap (\mathbb{R} \times \mathbb{R}_+ \times \mathbb{R}_-), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R} \times \mathbb{R}_+ \times \mathbb{R}_-), \quad R \cap (\mathbb{R}_- \times \mathbb{R} \times \mathbb{R}_+), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R}_- \times \mathbb{R} \times \mathbb{R}_+), \quad R \cap (\mathbb{R}_+ \times \mathbb{R}_- \times \mathbb{R}), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R}_- \times \mathbb{R}_+ \times \mathbb{R}), \quad R \cap (\mathbb{R}_+ \times \mathbb{R} \times \mathbb{R}_-), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R} \times \mathbb{R}_- \times \mathbb{R}_+), \quad R \cap (\mathbb{R}_- \times \mathbb{R}_+ \times \mathbb{R}), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R}_+ \times \mathbb{R} \times \mathbb{R}_-), \quad R \cap (\mathbb{R} \times \mathbb{R}_- \times \mathbb{R}_+), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R}_+ \times \mathbb{R}_+ \times \mathbb{R}), \quad R, \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R}_+ \times \mathbb{R} \times \mathbb{R}_+), \quad R, \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R} \times \mathbb{R}_+ \times \mathbb{R}_+), \quad R, \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R}_- \times \mathbb{R}_- \times \mathbb{R}), \quad R \cap (\mathbb{R}_+ \times \mathbb{R}_+ \times \mathbb{R}), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R}_- \times \mathbb{R} \times \mathbb{R}_-), \quad R \cap (\mathbb{R}_+ \times \mathbb{R} \times \mathbb{R}_+), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q \cap (\mathbb{R} \times \mathbb{R}_- \times \mathbb{R}_-), \quad R \cap (\mathbb{R} \times \mathbb{R}_+ \times \mathbb{R}_+), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q, \quad R \cap (\mathbb{R}_- \times \mathbb{R}_- \times \mathbb{R}), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q, \quad R \cap (\mathbb{R}_- \times \mathbb{R} \times \mathbb{R}_-), \quad S)\\
&\mathcal{S}_{\lll}(P, \quad Q, \quad R \cap (\mathbb{R} \times \mathbb{R}_- \times \mathbb{R}_-), \quad S).
\end{aligned}$$

The first 6 set systems have VC-dimension at most 2 by Lemma 18 (or symmetric variants); the next 9 have VC-dimension 1 by Lemma 19 (or symmetric variants).

Each set in $\mathcal{S}_{\lll}(P, Q, R, S)$ can be expressed as the union of 15 sets one from each of these 15 set systems: this is because, in any point sequence $\langle p, q, r, s\rangle$ with $p \in (-\infty, 0)^3$ and $s \in (0, \infty)^3$, there must be a consecutive pair going from negative to positive x-coordinate, and a consecutive pair going from negative to positive y-coordinate, and a consecutive pair going from negative to positive z-coordinate; all 3 such pairs could be distinct, or 2 of them could be the same. So, $|\mathcal{S}_{\lll}(P, Q, R, S)| = O((|P|^2)^6 \cdot |P|^9)$. ◀

We can now reduce the general case to the case when P and S are separated along all 3 axes.

▶ **Lemma 21.** *For any $P, Q, R, S \subset \mathbb{R}^3$, $\mathcal{S}_{\lll}(P, Q, R, S)$ has shatter dimension ≤ 171.*

Proof. Build a (non-uniform) grid formed by the x-, y-, and z-coordinates of all the points of P. The grid has $O(|P|^3)$ cells. For each grid cell γ, consider the 8 octants at an arbitrary point inside γ; for each such octant τ, the set system $\mathcal{S}_{\lll}(P \cap \tau, Q, R, S \cap \gamma)$ has shatter dimension at most 18 by Lemma 20. For each $s \in S \cap \gamma$, the set $N^3_{\lll}[s]$ is the union of 8 sets (one of each) from the set systems for the 8 octants. So for each γ, the number of distinct sets in $\{N^3_{\lll}[s] : s \in S \cap \gamma\}$ is $O((|P|^{21})^8)$. Thus, we have $|\{N^3_{\lll}[s] : s \in S\}| = O(|P|^3 \cdot (|P|^{21})^8)$. ◀

As before, unit cubes reduce to generalized dominance relations:

▶ **Lemma 22.** *For any $P, Q, R, S \subset \mathbb{R}^3$ with $S \subset (0, 1)^3$, write $N^3[s]$ as*

$$\Big\{p \in P : \exists (q, r) \in Q \times R \text{ s.t. } [\![p]\!] \text{ intersects } [\![q]\!], [\![q]\!] \text{ intersects } [\![r]\!], \text{ and } [\![r]\!] \text{ intersects } [\![s]\!]\Big\}.$$

Then the set system $(P, \{N^3[s] : s \in S\})$ has shatter dimension at most 3365793*.*

Proof. Fix $\alpha = (\alpha_P, \alpha_Q, \alpha_R) \in (\mathbb{Z}^3)^3$ with $\|\alpha_R\|_\infty, \|\alpha_Q - \alpha_R\|_\infty, \|\alpha_P - \alpha_Q\|_\infty \le 1$. For $p \in \alpha_P + (0,1)^3$ and $q \in \alpha_Q + (0,1)^3$, $[\![p]\!]$ intersects $[\![q]\!]$ iff $p - \alpha_P \lhd_1 q - \alpha_Q$, for some generalized dominance relation $\lhd_1$ as in the proof of Lemma 16. Similarly, for $q \in \alpha_Q + (0,1)^3$ and $r \in \alpha_R + (0,1)^3$, $[\![q]\!]$ intersects $[\![r]\!]$ iff $q - \alpha_Q \lhd_2 r - \alpha_R$ for some generalized dominance relation $\lhd_2$. Similarly, for $r \in \alpha_R + (0,1)^3$ and $s \in (0,1)^3$, $[\![r]\!]$ intersects $[\![s]\!]$ iff $r - \alpha_R \lhd_3 s$ for some generalized dominance relation $\lhd_3$. Define the set system $\mathcal{S}_\alpha = \mathcal{S}_{\lll}(P \cap (\alpha_P + (0,1)^3) - \alpha_P, (Q \cap (\alpha_Q + (0,1)^3)) - \alpha_Q, (R \cap (\alpha_R + (0,1)^3)) - \alpha_R, S)$.

Each set $N^3[s]$ is the union of at most 27^3 sets (one of each) from the set systems $\mathcal{S}_\alpha$ for the at most 27^3 choices of α. By Lemma 21, we have $|\{N^3[s] : s \in S\}| = O((|P|^{171})^{27^3})$. ◀

▶ **Theorem 23.** *For any $P, Q, R, S \subset \mathbb{R}^3$, the set system $(P, \{N^3[s] : s \in S\})$ has shatter dimension at most* 3365793*.*

Proof. Build a uniform grid of side length 1. For each grid cell $\alpha_S + (0,1)^3$ (with $\alpha_S \in \mathbb{Z}^3$), the number of different $N^3[s]$ sets over all $s \in S \cap (\alpha_S + (0,1)^3)$ is $O(|P \cap (\alpha_S + (-3,4)^3)|^{3365793})$ by Lemma 22. Since each point $p \in P$ belongs to $O(1)$ number of expanded cells $\alpha_S + (-3,4)^3$, the sum over all α_S is $O(|P|^{3365793})$. ◀

4.2 Algorithm

Knowing that the VC-dimension is bounded, we could at this point apply the framework of [8] to obtain a subquadratic algorithm for Diameter-3 in 3D unit cubes. However, the exponent would be *extremely* close to 2 (around $2 - 1/(4 \cdot 3365794) \approx 1.99999993$). We present a faster, direct algorithm with a more reasonable exponent smaller than 2. The key observation is that although the final shatter dimension bound is large, the proof in Section 4.1 tells us that the set system is in some sense "made up of" a (very large but) constant number of simpler subsystems with much smaller VC-dimension, of 1 and 2 (Lemma 18 and Lemma 19). As in our Diameter-2 algorithm, we can't just solve the problem for each subsystem separately, because the diameter problem isn't decomposable. Instead, we "encode" each subsystem as an extra "2-dimensional constraint", and in the end reduce the whole problem to a "multi-level" range searching problem in a sufficiently large constant dimension.

Multi-level range searching [2, 18] is usually solved by sampling-based geometric divide-and-conquer techniques, e.g., via so-called "cuttings", but analogs of cuttings provably do not exist for abstract set systems, even with VC-dimension 2 (e.g., see [3, Remark 4.7]). Fortunately, our proof of VC-dimension 2 in the full paper reveals a stronger property, namely, that the 3-neighborhoods there actually form a *point-pseudoline system*. (It is quite unexpected that 3D unit cubes could naturally produce pseudoline arrangements.) Cuttings and multi-level range searching exists for pseudolines. Due to lack of space, details of the algorithm are given in the full paper.

Computing the Girth of a Segment Intersection Graph

Timothy M. Chan
Siebel School of Computing and Data Science, University of Illinois Urbana-Champaign, IL, USA

Yuancheng Yu
Siebel School of Computing and Data Science, University of Illinois Urbana-Champaign, IL, USA

Abstract

We present an algorithm that computes the girth of the intersection graph of n given line segments in the plane in $O(n^{1.483})$ expected time. This is the first such algorithm with $O(n^{3/2-\varepsilon})$ running time for a positive constant ε, and makes progress towards an open question posed by Chan (SODA 2023). The main techniques include (i) the usage of recent subcubic algorithms for bounded-difference min-plus matrix multiplication, and (ii) an interesting variant of the planar graph separator theorem. The result extends to intersection graphs of connected algebraic curves or semialgebraic sets of constant description complexity.

1 Introduction

Intersection graphs of geometric objects have received considerable attention in computational geometry. They generalize planar graphs (every planar graph is an intersection graph of disks in 2D by the Koebe–Andreev–Thurston theorem), and they arise in numerous applications (for example, unit disk graphs can be used to model communication networks, and intersection graphs of line segments in 2D can be used to model road networks). Over the years, researchers have studied many standard computational problems on geometric intersection graphs, aiming for algorithms that run faster than those for general graphs. The problems considered include the computation of connected components [1], all-pairs shortest paths [17], diameter [10, 15], minimum cut [12], maximum matching [6], and finding small-sized subgraphs (such as triangles, cycles of a fixed length, cliques of a fixed size, etc.) [14].

In this paper, we focus on another of the most basic graph algorithm problems, which has not been as well explored in the context of geometric intersection graphs: the computation of the *girth*, i.e., the length of the shortest cycle (see Figure 1). Girth is related to various topics in graph theory, including the chromatic number, treewidth, diameter, Ramsey theory, etc. [5, 22, 39, 27, 18, 23]. It can be computed in $O(mn)$ or $O(n^\omega)$ time for general unweighted undirected graphs with n vertices and m edges [32], where $\omega < 2.371339$ is the matrix multiplication exponent [2]. For the case of planar graphs, a series of papers [24, 25, 13, 46] culminated in a linear-time algorithm by Chang and Lu [19]. However, for intersection graphs, we are aware of only two main algorithmic results:

1. Kaplan et al. at ESA'19 [33] gave an $O(n \log n)$-time algorithm for computing the girth of the intersection graph of n disks in 2D (in the case of unit disks, this was subsequently improved by Klost and Mulzer [35] to an $O(n)$-time algorithm which does not require the disks be given, just the graph).

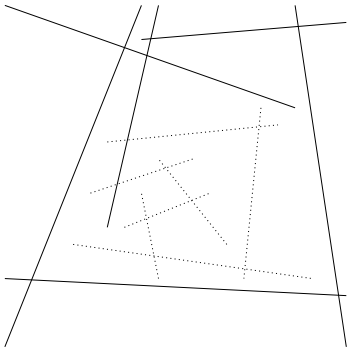

Figure 1 An example of the shortest cycle of a segment intersection graph (segments not in the shortest cycle are dotted). The girth is 6.

2. Chan at SODA'23 [14] gave an $\widetilde{O}(n^{3/2})$-time[1] algorithm for computing the girth of the intersection graph of n line segments in 2D.

Chan's work naturally raises the following question:

Is there an $O(n^{3/2-\varepsilon})$-time algorithm for computing the girth of the intersection graph of n line segments for some constant $\varepsilon > 0$?

The case of line segments is particularly important, not only because of direct relevance to road networks, for example, but also because it serves as a stepping stone towards the general case of algebraic curves or semialgebraic sets in the plane.

1.1 New result

We answer the above open question in the affirmative by presenting the first algorithm that breaks the $n^{3/2}$ barrier. Specifically, our algorithm computes the girth for the intersection graph of n line segments in 2D in $O(n^{1.483})$ expected time. The algorithm also extends to intersection graphs of algebraic curves or semialgebraic sets where each object is connected and has constant description complexity – essentially, most families of constant-size objects in 2D that are commonly encountered.

1.2 Why is the problem challenging?

First note that Kaplan et al.'s approach [33] is not applicable for our problem, as it exploited special properties of disks that do not hold for line segments (namely, that any intersection graph of disks with girth more than 3 must be planar). For the related problem of finding short cycles, Chan [14] extended Kaplan et al.'s result to arbitrary fat objects in any constant dimension, by using a shifted quadtree approach, but line segments are not fat.

For intersection graphs of line segments, Chan [14] has already given an $O(n^{1.408})$-time algorithm for detecting a triangle (i.e., 3-cycle), and an $\widetilde{O}(n)$-time algorithm for detecting a 4-cycle. Thus, it suffices to handle the remaining case when the girth is greater than 4. It is known that any intersection graph of n line segments without 4-cycles must be sparse, i.e., has $O(n)$ edges. We can explicitly construct the arrangement of the line segments and form a planar graph of $O(n)$ size whose vertices are the endpoints and intersection points. This

[1] The $\widetilde{O}$ notation hides polylogarithmic factors.

way, our problem is reduced to a variant of the girth problem on a planar graph, where the cost of a cycle is the number of turns – turning at an intersection point has unit cost, but going straight through an intersection has zero cost.

However, this variant does not seem directly reducible to the standard girth problem on planar graphs. One could create a gadget at each intersection point and obtain a graph with 0/1 edge weights, such that the weight of a path in the new graph corresponds to the number of turns along the path. But the resulting graph would no longer be planar (it would be 1-*planar* instead); besides, unintended small cycles would be introduced in such a gadget. In addition, many properties about shortest paths in planar graphs no longer hold. For example, two shortest paths in a planar graph cannot cross more than once (if ties are broken carefully), but two minimum-turn paths may cross numerous times. Consequently, many techniques devised for shortest-path-related problems in planar graphs (e.g., based on some kind of Monge property [29], or abstract Voronoi diagrams [11, 30], or VC-dimension arguments [37, 26, 36, 15]) seem to fall apart for our problem.

One technique that still works is *separators*. In fact, Chan's previous $\widetilde{O}(n^{3/2})$-time algorithm is obtained by a simple application of separators. We can divide the graph into two parts by a separator of size $O(\sqrt{n})$, and recurse on both parts. This handles the case when the shortest cycle lies completely in one part. To deal with the remaining case when the shortest cycle passes through a separator vertex, we can run BFS from each of the $O(\sqrt{n})$ separator vertices, in $\widetilde{O}(n^{3/2})$ total time.

For the case when the girth is a constant (or for detecting a cycle of a fixed constant length), Chan [14] has shown how to adapt the separator approach to obtain a faster algorithm running in $\widetilde{O}(n^{\omega/2}) \leq O(n^{1.186})$ time. The main observation is that the $O(\sqrt{n})$ calls to BFS is overkill – we only need to compute shortest path distances with *both* sources and destinations from the $O(\sqrt{n})$ separator vertices. We can compute such distances recursively as we compute the girth. Combining the output of the two recursive calls involves computing min-plus products of $O(\sqrt{n}) \times O(\sqrt{n})$ distance matrices. When the matrix entries are integers bounded by a constant, min-plus product reduces to $O(1)$ number of standard (Boolean) matrix product. This is roughly how the $\widetilde{O}(n^{\omega/2})$ time bound was obtained.

For larger girth, however, this approach does not work well, because the complexity of min-plus product grows for larger integer values. (Another issue is the use of *color-coding* [3] in Chan's cycle detection algorithm [14], which led to exponential dependence on the cycle length.)

On the other hand, when the girth g is very large, one could obtain an $\widetilde{O}(n^2/g)$-time algorithm by a well-known hitting set technique [44, 47] (there exists a subset of $\widetilde{O}(n/g)$ vertices which hit all shortest paths of length $\Omega(g)$). The main difficulty lies in the intermediate case, when the girth is not too small and not too large.

1.3 Our approach

Ingredient 1: Bounded-difference min-plus matrix multiplication. The previous separator-based approach faces an $n^{3/2}$ barrier because min-plus matrix multiplication is widely conjectured to require near-cubic time (according to the "All-Pairs Shortest Paths (APSP) hypothesis" from fine-grained complexity [45]). Our first idea is to employ recent results which solve certain powerful special cases of min-plus product in truly subcubic time – namely, the case when the input matrices are integer-valued and satisfy a *bounded-difference* property, i.e., the difference between any two adjacent entries (in each row or in each column) is at most a constant. Chan and Lewenstein [16] gave the first truly subquadratic algorithm for the related min-plus convolution problem for bounded-difference sequences,

while Bringmann et al. [9] gave the first truly subcubic algorithm for bounded-difference min-plus product. Bringmann et al.'s original algorithm ran in $O(n^{2.8244})$ time, and after a series of improvements [31, 20], Chi et al. [21] obtained the current best running time of $\widetilde{O}(n^{(3+\omega)/2}) \leq O(n^{2.686})$ (see Section 2.1).

Bounded-difference min-plus convolution and matrix multiplication have recently been applied to solve a variety of problems from different domains, including language edit distance and RNA folding [9], single-source replacement paths and Range Mode [31], tree edit distance [40], approximate APSP [43], knapsack [7, 8], etc. Our algorithm, being one of the first applications to a computational geometry problem, is thus noteworthy.

Ingredient 2: A variant of the planar-graph separator theorem. Why is the bounded-difference property relevant in our application? Suppose the separator S is connected, e.g., is a cycle (as in Miller's version of the separator theorem [41]). Then for any vertex q and two adjacent separator vertices $s, s' \in S$, $d(s, q)$ and $d(s', q)$ differ by at most 1 due to the triangle inequality. Thus, the distance matrices we encounter during recursion would indeed satisfy the bounded-difference property.

Unfortunately, cycle separators do not always exist when the given planar graph is not 2-connected. Our key idea is to use an interesting variant of the planar-graph separator theorem, which holds for any planar graphs: given any $\alpha > 0$, there always exists a separator S consisting of two subsets P and Q, where

- the first subset P has size $O(n^{1/2+\alpha})$ but has at most 2 connected components (in fact, at most 2 paths);
- the second subset Q may not be connected but has size $O(n^{1/2-\alpha})$.

We are not aware of this variant of the separator theorem explicitly stated before (though we will not be surprised if it appeared before), but it follows by straightforward modification of standard proofs. See Section 2.2 for the precise statement and proof.

This variant of separators is exactly the tool we need to break the $n^{3/2}$ barrier: since P has only $O(1)$ connected pieces, we can use bounded-difference min-plus products to compute distances involving P faster; on the other hand, since Q has size $\ll \sqrt{n}$, we can afford to compute distances involving Q more naively. We choose the trade-off parameter α carefully to balance cost. This is the main high-level idea of our algorithm. Quite a bit of technical effort, however, is needed to make the idea work (for example, the number of connected components may grow as we recurse, but not by much, as we will show, and we eventually need two separate recursive algorithms, one for computing distances and one for computing the girth). See Sections 3–4 for the detailed algorithm and analysis.

Ingredient 3: Ensuring simplicity of walks. When computing a shortest path between two vertices, we do not need to worry about ensuring simplicity of the path, since a shortest walk must automatically be a shortest path (if a vertex is repeated, we can take a short-cut to obtain a shorter walk). However, more care is needed for the shortest cycle problem in undirected graphs. When concatenating several shortest paths to form a candidate cycle (via min-plus products of several distance matrices), one potential issue is that the resulting closed walk might become trivial (we might be completely retracing our steps, so that short-cutting yields an empty walk!). The earlier algorithm by Chan [14] for detecting constant-length cycles used the color-coding technique [3] to ensure simplicity, but unfortunately color-coding yields exponential dependence on the cycle length. For general graphs, there are other strategies to ensure simplicity, (e.g., by computing shortest paths in different subgraphs with some vertices and edges removed, or with directions added, so as to avoid concatenating two

identical shortest paths). But ensuring simplicity is trickier in our setting, since we need to retain the bounded-difference property if we work with new subgraphs. Still, we have found one way to deal with this technical issue, using ideas given in Section 2.3.

2 Preliminaries

Before presenting our algorithm, we begin by providing more details on the three ingredients mentioned in the introduction.

Let $\delta_G(u, v)$ denote the shortest-path length between u and v in an unweighted undirected graph G. Let $\delta_G[A, B]$ denote the distance matrix $\{\delta_G(u, v)\}_{u\in A, v\in B}$ for two vertex subsets A and B in a graph G. Let $G[S]$ denote the subgraph of G induced by a vertex subset S.

2.1 Bounded-difference min-plus product

Given two matrices A, B, their *min-plus product* $A \star B$ is defined as

$$(A \star B)(i, j) = \min_k (A(i, k) + B(k, j)).$$

As mentioned, we will use a known subcubic algorithm for computing the min-plus product of two $n \times n$ integer matrices that satisfy a bounded-difference property. The following is due to Chi et al. [21]:

▶ **Lemma 1.** *Given two integer $n \times n$ matrices A and B where each column of A satisfies the bounded-difference property (i.e., $|A(i, j) - A(i + 1, j)| \leq O(1)$ for every i, j), we can compute their min-plus product $A \star B$ in $\widetilde{O}(n^{(3+\omega)/2}) \leq O(n^{2.686})$ expected time.*

The same holds if instead each row of A satisfies the bounded-difference property (i.e., $|A(i, j) - A(i, j + 1)| \leq O(1)$), or if the property holds for B rather than A.

2.2 A variant of the planar separator theorem

The second ingredient is an interesting variant of the planar-graph separator theorem, in which the separator is divided into two subsets P and Q: P may be larger but has only 2 connected pieces, while Q may not be connected but is smaller. The precise statement is given below (the original theorem corresponds to the case when $p = \sqrt{n}$ with unit loads, while our application requires the case when $p \gg \sqrt{n}$). The proof follows by modifying standard proofs [38, 34, 28].

▶ **Lemma 2.** *Let $G = (V, E)$ be a planar graph with n vertices, where each vertex has a nonnegative* weight *and a nonnegative* load*, with total weight W, total load Λ, and the maximum individual vertex weight is at most εW for a sufficiently small constant $\varepsilon > 0$. For a given parameter p, we can partition V into subsets V_1, V_2, S, in $O(n)$ time, such that*

- *the total weight of V_i is at most $3W/4$ for each $i \in \{1, 2\}$;*
- *there are no edges in $V_1 \times V_2$;*
- *S can be further partitioned into P and Q such that P is the union of at most two paths of length $O(p)$, and Q has total load at most $O(\Lambda/p)$.*

Proof. We first assume that G is connected. Let $\mathcal{T}$ be a BFS tree of G from a fixed source vertex. For any $uv \notin \mathcal{T}$, let $\text{cycle}(\mathcal{T}, uv)$ denote the unique cycle in $\mathcal{T} \cup \{uv\}$ (called the *fundamental cycle*), which consists of uv and the unique path in $\mathcal{T}$ connecting u and v.

Let Σ be a (combinatorial) triangulation of $\mathcal{T}$. Define face weights of Σ by examining each vertex v, picking an arbitrary incident face f, and adding v's weight to f. Then the total face weight is W. Consider the dual tree with respect to $\mathcal{T}$ in Σ (which has maximum degree 3).

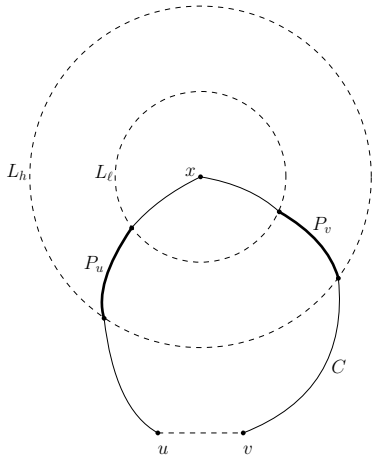

Figure 2 Proof of Lemma 2. Solid curves consist of edges in G, whereas dashed curves may contain edges in the triangulation but not in G.

By standard results on tree separators [34, 28]. we can find an edge which separates this dual tree into two parts each with total face weight at most $3W/4$. In Σ, this corresponds to an edge uv such that either side of $C = \text{cycle}(\mathcal{T}, uv)$ has total face weight at most $3W/4$; this also bounds the total weight of the vertices strictly inside/outside C. If $|C| \leq p$ then the desired separator can obtained by setting $P = C$ and $Q = \emptyset$. Below we may assume $|C| > p$.

Let x be the lowest common ancestor of u, v in $\mathcal{T}$, and $\mathcal{T}'$ be the subtree of $\mathcal{T}$. Let $L_i \subset V$ be the set of vertices in level i of $\mathcal{T}'$ (with $L_0 = \emptyset$). Let m be the smallest integer such that the total weight of vertices in the first m levels of $\mathcal{T}'$ is at least $W/2$. By the pigeonhole principle, there exists $\ell \in [m - p, m)$ such that L_ℓ has total load at most Λ/p. Similarly there exists $h \in (m, m + p]$ such that L_h has total load at most Λ/p.

If $V_{\leq \ell} = \bigcup_{i=1}^{\ell} L_i$ has weight at least $W/4$, then since $V_{\leq \ell}$ has weight at most $W/2$ by definition of m, the desired separator can be obtained by setting $Q = L_\ell$ and $P = \emptyset$.

Similarly, if $V_{\geq h} = \bigcup_{i=h}^{\infty} L_i$ has weight at least $W/4$, then the desired separator can be obtained by setting $Q = L_h$ and $P = \emptyset$.

In the remaining case, $V_m = \bigcup_{i=\ell+1}^{h-1} L_i$ has weight at least $W/2$. Let $V_{\text{in}}, V_{\text{out}}$ be the set of vertices in V_m that are strictly inside or outside C, respectively. Without loss of generality, say V_{in} has weight at least $W/4$. Recall that V_{in} has weight at most $3W/4$ by definition of C. Let P_u (resp. P_v) be the portion of the shortest path from x to u (resp. v) with levels between ℓ and h. Then P_u and P_v are paths of length $O(p)$. The desired separator can be obtained by setting $P = P_u \cup P_v$ and $Q = L_\ell \cup L_h$. See Figure 2.

Finally, we consider the general case when G may have multiple connected components. If all components have weight at most $W/2$, a trivial separator exists with $S = \emptyset$. On the other hand, if G has one component of weight at least $W/2$, we can apply the lemma to the largest-weight component and add the remaining components to the smaller of the two subsets V_1, V_2 in terms of weight (which would still have total weight at most $3W/4$). ◀

2.3 Ensuring simplicity of walks

In this subsection, we formulate a type of *legal alternating* closed walks so that a shortest closed walk of this type is automatically a simple cycle. This will be useful later in Section 4. (Warning: both the formulation and the proof of correctness below are somewhat subtle.)

In the following, we imagine that a separator has been computed, and the two parts are colored red and blue, while the separator vertices are colored white.

▶ **Lemma 3.** *Let G be an undirected graph, where each vertex is colored red, blue, or white, and there are no edges between red and blue vertices. Consider a closed walk C which is the concatenation of simple paths $\pi_0^R, \tau_0, \pi_0^B, \tau_0', \ldots, \pi_{k-1}^R, \tau_{k-1}, \pi_{k-1}^B, \tau_{k-1}'$ with $k \geq 1$, where each π_i^R consists of red and white vertices only and has at least one red vertex, each π_i^B consists of blue and white vertices only and has at least one blue vertex, and each τ_i and τ_i' consist of white vertices only (but may be empty). Then C must contain a nontrivial simple cycle.*

Proof. Suppose that two consecutive edges of C are identical, i.e., we see 3 consecutive vertices u, v, u in C. If uv is the last edge of π_i^R and vu is the first edge of τ_i, then u and v are white vertices and we can remove v from C and still have a closed walk satisfying the stated condition. If uv is the last edge of π_i^R, and τ_i is empty, and vu is the first edge of π_i^B, then u and v must again be white vertices and we can remove v from C and still have a closed walk satisfying the stated condition. After handling all other similar cases, we may assume that no two consecutive edges of C are identical. Now, C forms a subgraph where every vertex has degree at least 2, and so must contain a nontrivial simple cycle. ◀

▶ **Lemma 4.** *Let G be an undirected graph, where each vertex is colored red, blue, or white, and there are no edges between red and blue vertices. Let R, B, and W be the subset of red, blue, and white vertices respectively. Define the following:*

- *A simple path π from u to v in G is a* legal red path *if π lies in $G[R \cup W]$, $u, v \in W$, and $\delta_{G[R\cup W]}(u, v) \neq \delta_{G[W]}(u, v)$.*
- *A simple path π from u to v in G is a* legal blue path *if π lies in $G[B \cup W]$, $u, v \in W$, and $\delta_{G[B\cup W]}(u, v) \neq \delta_{G[W]}(u, v)$.*
- *A closed walk C is a* legal alternating walk *if it is the concatenation of simple paths $\pi_0^R, \tau_0, \pi_0^B, \tau_0', \ldots, \pi_{k-1}^R, \tau_{k-1}, \pi_{k-1}^B, \tau_{k-1}'$ with $k \geq 1$, where each π_i^R is a legal red path, each π_i^B is a legal blue path, and each τ_i and τ_i' lie in $G[W]$.*

Then

(i) *the girth of G is at most the length of a shortest legal alternating closed walk;*

(ii) *furthermore, equality holds if the girth of G is not equal of girth of $G[R \cup W]$ or the girth of $G[B \cup W]$.*

Proof. For (i), consider a shortest legal alternating closed walk C. Then C is the concatenation of simple paths $\pi_0^R, \tau_0, \pi_0^B, \tau_0', \ldots, \pi_{k-1}^R, \tau_{k-1}, \pi_{k-1}^B, \tau_{k-1}'$ with $k \geq 1$, where each π_i^R is a legal red path, each π_i^B is a legal blue path, and each τ_i and τ_i' lie in $G[W]$. Each π_i^R must pass through at least one red vertex, because $\delta_{G[R\cup W]}(u(\pi_i^R), v(\pi_i^R)) \neq \delta_{G[W]}(u(\pi_i^R), v(\pi_i^R))$, where $u(\pi)$ and $v(\pi)$ denote the starting and ending vertices of a path π. Similarly, each π_i^B must pass through at least one blue vertex. So, the condition in Lemma 3 is satisfied, and C must contain a nontrivial simple cycle. Hence, the girth of G is at most the length of C.

For (ii), consider a shortest simple cycle C in G, of length g. If there are multiple shortest simple cycles, pick one with the minimum number of non-white vertices. We can express C as a concatenation of simple paths $\pi_0^R, \pi_0^B, \ldots, \pi_{k-1}^R, \pi_{k-1}^B$ with $k \geq 1$, where each π_i^R lies in $G[R \cup W]$, uses at least one red vertex, and starts and ends with white vertices, and each π_i^B lies in $G[B \cup W]$, uses at least one blue vertex, and starts and ends with white vertices. (Note that C contains at least one red and at least one blue vertex, by the assumption in stated in (ii).) If $\delta_{G[R\cup W]}(u(\pi_i^R), v(\pi_i^R)) = \delta_{G[W]}(u(\pi_i^R), v(\pi_i^R))$ for some i, then we can replace π_i^R with a shortest path γ from $u(\pi_i^R)$ to $v(\pi_i^R)$ in $G[W]$, and obtain a closed walk which is

the concatenation of two non-identical simple paths γ and $C \setminus \pi_i^R$, and so must contain a nontrivial simple cycle; the cycle has length at most g and uses fewer non-white vertices: a contradiction. Thus, each π_i^R is a legal red path. Similarly, each π_i^B is a legal blue path. Hence, C is a legal alternating closed walk. ◀

(An astute reader might wonder why we have overcomplicated the definition of legal alternating walk by including the white subpaths τ_i, since part (ii) of the proof of Lemma 4 does not require them. The purpose for including them is computational, as we will see later: without them, intermediate distance matrices may no longer satisfy the bounded-difference property.)

3 Multiple Distances in Clustered Planar Graphs

As a warm-up, we first present an algorithm for a subproblem (of independent interest), on computing all distances with sources and destinations from a given subset X, in an intersection graph of line segments. It is actually more convenient to solve the problem for a more general family of graphs, which we call *clustered planar graphs*, where each vertex in a planar graph is replaced by a "cluster" of c vertices:

▶ **Definition 5.** *A c-*clustered planar graph *refers to the product graph $\widehat{G} = G \times K_c$ where $G = (V, E)$ is a planar graph and K_c is the c-clique. In other words, the vertices of $\widehat{G}$ are pairs $(v, j) \in V \times \{1, \ldots, c\}$, and there is an edge between two vertices (u, i) and (v, j) whenever $uv \in E$ or $u = v$.*

Known shortest-path-related algorithms for planar graphs do not necessarily generalize to clustered planar graphs (because of the lack of Monge property, VC-dimension arguments, etc.). We prove the following result, which beats the obvious $\widetilde{O}(xn)$ time bound, for example, when x is around $\sqrt{n}$:

▶ **Theorem 6.** *Let $\widehat{G} = G \times K_c$ be a c-clustered planar graph, where $G = (V, E)$ has n vertices and $c = O(1)$. Suppose each edge of $\widehat{G}$ has a nonnegative integer weight bounded by $O(1)$. Given a subset X of x vertices in G, we can compute $\delta_{\widehat{G}}[X \times K_c, X \times K_c]$ in $\widetilde{O}(n^{3/2-\alpha} + n^{(1/2+\alpha)(3+\omega)/2} + x^{(3+\omega)/2} + x^2 n^{1/2-\alpha})$ expected time for any given α.*

Proof. We will solve an extended problem: given G, $\widehat{G}$, X, and an additional subset B of β vertices in G such that B has γ components in G, we want to compute $\delta_{\widehat{G}}[(B \cup X) \times K_c, (B \cup X) \times K_c]$. (Initially, $B = \emptyset$ and $\beta = \gamma = 0$.)

Step 1: Build a separator. Give each vertex in $V \setminus B$ weight 1 and each vertex in B weight $1 + w$ for a parameter w (assuming $n + w\beta \gg (1 + w)/\varepsilon$); the total weight is $n + w\beta$. Give each vertex in $V \setminus B$ load 1 and each vertex in B load n/β; the total load is $O(n)$. We apply Lemma 2 for a value p to be set later, to partition V into V_1, V_2, S such that

- $|V_i| + w|V_i \cap B| \le 3(n + w\beta)/4$ for each $i \in \{1, 2\}$;
- there are no edges of G in $V_1 \times V_2$;
- S can be further partitioned into P and Q such that P is the union of at most two paths in G of length $O(p)$, and Q has total load at most $O(n/p)$ – this implies that $|Q| \le O(n/p)$ and $|Q \cap B| \le O(\frac{n/p}{n/\beta}) = O(\beta/p)$ simultaneously.

Let $\widehat{V} = V \times K_c$, $\widehat{S} = S \times K_c$, $\widehat{P} = P \times K_c$, $\widehat{Q} = Q \times K_c$, $\widehat{B} = B \times K_c$ and $\widehat{X} = X \times K_c$.

Step 2: Recurse. For each $i \in \{1,2\}$, we recursively solve the problem for $G_i = G[V_i \cup S]$, $\widehat{G}_i = G_i \times K_c$ (with edge weights inherited from $\widehat{G}$), $B_i = (V_i \cap B) \cup P \cup (Q \cap B)$, and $X_i = V_i \cap X$.

Let $n_i = |V_i \cup S|$, $\beta_i = |B_i|$, γ_i be the number of components of B_i in G_i, and $x_i = |X_i|$. Then $n_1+n_2 \le n+O(p+n/p)$, $\beta_1+\beta_2 \le \beta+O(p+\beta/p)$, $n_i+w\beta_i \le 3(n+w\beta)/4+O(w(p+n/p))$, and $x_1 + x_2 \le x$.

To bound γ_i, consider a component C of B_i in G_i. If C does not visit S, then C is an original component of B (since $S \cap B \subseteq B_i$). If C visits a vertex of P, then C contains one of the two paths in P (since $P \subseteq B_i$). If C visits a vertex of $Q \cap B$, then C can be charged to that vertex. It follows that $\gamma_1 + \gamma_2 \le \gamma + O(1 + \beta/p)$.

Step 3: Compute $\delta_{\widehat{G}}[\widehat{B} \cup \widehat{X}, \widehat{B} \cup \widehat{X}]$. We now compute $\delta_{\widehat{G}}[\widehat{B} \cup \widehat{X}, \widehat{B} \cup \widehat{X}]$ by the following expression:

$$\delta_{\widehat{G}_1}[\widehat{B} \cup \widehat{X}, \widehat{B} \cup \widehat{X}] \vee \delta_{\widehat{G}_2}[\widehat{B} \cup \widehat{X}, \widehat{B} \cup \widehat{X}] \vee \tag{1}$$

$$(\delta_{\widehat{G}}[\widehat{B} \cup \widehat{X}, \widehat{Q}] \star \delta_{\widehat{G}}[\widehat{Q}, \widehat{B} \cup \widehat{X}]) \vee \tag{2}$$

$$\Big((\delta_{\widehat{G}_1}[\widehat{B} \cup \widehat{X}, \widehat{P}] \vee \delta_{\widehat{G}_2}[\widehat{B} \cup \widehat{X}, \widehat{P}]) \star (\delta_{\widehat{G}_1}[\widehat{P}, \widehat{P}] \star \delta_{\widehat{G}_2}[\widehat{P}, \widehat{P}])^n \star (\delta_{\widehat{G}_1}[\widehat{P}, \widehat{B} \cup \widehat{X}] \vee \delta_{\widehat{G}_2}[\widehat{P}, \widehat{B} \cup \widehat{X}])\Big), \tag{3}$$

where $M \vee M'$ denotes the entry-wise minimum of two matrices M and M', and M^k denotes the k-th power under min-plus product.

The expression is correct because for $\widehat{u}, \widehat{v} \in \widehat{B} \cup \widehat{X}$, if a shortest path π from $\widehat{u}$ to $\widehat{v}$ in $\widehat{G}$ avoids $\widehat{S}$, then its length is $\delta_{\widehat{G}_1}(\widehat{u}, \widehat{v})$ or $\delta_{\widehat{G}_2}(\widehat{u}, \widehat{v})$; otherwise, if π passes through $\widehat{Q}$, then its length is $(\delta_{\widehat{G}}[\widehat{B} \cup \widehat{X}, \widehat{Q}] \star \delta_{\widehat{G}}[\widehat{Q}, \widehat{B} \cup \widehat{X}])(\widehat{u}, \widehat{v})$; otherwise, if π passes through $\widehat{P}$, starting from $\widehat{G}_i$ and ending in $\widehat{G}_j$, then its length is $(\delta_{\widehat{G}_1}[\widehat{B} \cup \widehat{X}, \widehat{P}] \star (\delta_{\widehat{G}_1}[\widehat{P}, \widehat{P}] \star \delta_{\widehat{G}_2}[\widehat{P}, \widehat{P}])^n \star \delta_{\widehat{G}_j}[\widehat{P}, \widehat{B} \cup \widehat{X}])(\widehat{u}, \widehat{v})$.

To evaluate the expression, we first compute $\delta_{\widehat{G}}[\widehat{V}, \widehat{Q}]$ and $\delta_{\widehat{G}_i}[\widehat{V}, \widehat{Q}]$ for each $i \in \{1,2\}$ by running BFS from each vertex of $\widehat{Q}$. Since $|Q| = O(n/p)$, this part takes $\widetilde{O}(n^2/p)$ time.

The matrix $\delta_{\widehat{G}_i}[\widehat{B} \cup \widehat{X}, \widehat{B} \cup \widehat{X}]$ is available, since $(B \cup X) \cap (V_i \cup S) \subseteq B_i \cup X_i \cup Q$, and we know $\delta_{\widehat{G}_i}[\widehat{B}_i \cup \widehat{X}_i, \widehat{B}_i \cup \widehat{X}_i]$ from the two recursive calls, and we already know $\delta_{\widehat{G}_i}[\widehat{V}, \widehat{Q}]$.

The matrices $\delta_{\widehat{G}_i}[\widehat{B} \cup \widehat{X}, \widehat{P}]$ and $\delta_{\widehat{G}_i}[\widehat{P}, \widehat{P}]$ are also available, since $P \subseteq B_i$.

We now describe how to compute $\delta_{\widehat{G}}[\widehat{B} \cup \widehat{X}, \widehat{Q}] \star \delta_{\widehat{G}}[\widehat{Q}, \widehat{B} \cup \widehat{X}]$ in (2). For any component $\widehat{C} \subseteq \widehat{B}$, the columns of $\delta_{\widehat{G}}[\widehat{C}, \widehat{Q}]$ satisfy the bounded-difference property, after reordering the rows according to an Euler tour of a spanning tree of C – some rows may need to be duplicated, but the number of rows increases by only a constant factor. (Note that all vertices in a common cluster $\{v\} \times K_c$ are within a constant distance from each other.) Since B has γ components, we can compute $\delta_{\widehat{G}}[\widehat{B}, \widehat{Q}] \star \delta_{\widehat{G}}[\widehat{Q}, \widehat{B} \cup \widehat{X}]$ by Lemma 1 in $\widetilde{O}(\gamma(\beta + n/p + x)^{(3+\omega)/2})$ time. The product $\delta_{\widehat{G}}[\widehat{B} \cup \widehat{X}, \widehat{Q}] \star \delta_{\widehat{G}}[\widehat{Q}, \widehat{B}]$ is symmetric. It remains to compute $\delta_{\widehat{G}}[\widehat{X}, \widehat{Q}] \star \delta_{\widehat{G}}[\widehat{Q}, \widehat{X}]$: here, since we don't have the bounded-difference property, we naively compute the product in $O(|X|^2|Q|) = O(x^2 n/p)$ time.

Finally, we describe how to compute (3). The columns of $\delta_{\widehat{G}_i}[\widehat{P}, \widehat{P}]$ satisfy the bounded-difference property, after dividing the matrix into two parts and reordering the rows, since P is the union of at most two walks; so, we can compute $\delta_{\widehat{G}_1}[\widehat{P}, \widehat{P}] \star \delta_{\widehat{G}_2}[\widehat{P}, \widehat{P}]$ in $\widetilde{O}(p^{(3+\omega)/2})$ time. We can compute the n-th power by repeated squaring using $O(\log n)$ bounded-difference matrix products. (Note that if the columns of a matrix M satisfy the bounded-difference property, then the columns of a product $M \star M'$ also satisfy the bounded-difference property.)

The rows of $\delta_{\widehat{G}_i}[\widehat{B} \cup \widehat{X}, \widehat{P}]$ satisfy the bounded-difference property (after dividing the matrix into two parts), and so the other products can be computed in a similar way.

Running time. The time complexity $T(n, \beta, \gamma, x)$ of the algorithm satisfies the following recurrence:

$$T(n,\beta,\gamma,x) \le \max_{\substack{n_1,n_2,\beta_1,\beta_2,x_1,x_2:\\ n_i+w\beta_i\le 3(n+w\beta)/4+O(w(p+n/p)),\\ n_1+n_2\le n+O(p+n/p),\\ \beta_1+\beta_2\le\beta+O(p+\beta/p),\\ \gamma_1+\gamma_2\le\gamma+O(1+\beta/p),\\ x_1+x_2\le x}} \Big(T(n_1,\beta_1,\gamma_1,x_1)+T(n_2,\beta_2,\gamma_2,x_2)+ \widetilde{O}(n+n^2/p+ \gamma(\beta+p+n/p+x)^{(3+\omega)/2}+x^2n/p)\Big).$$

Solving the recurrence. Intuitively, one could choose $p \approx n^{1/2+\alpha}$, and think of β as $\widetilde{O}(p)$ and γ as $\widetilde{O}(1)$, and see that the cost is upper bounded by $n^{3/2-\alpha} + x^{(3+\omega)/2} + x^2 n^{1/2-\alpha}$ for any sufficiently small positive α (as long as $\omega < 3$), at least at the top few levels of the recursion.

Formally, let r be a fixed parameter, to be set later, with $r \gg w(p + n/p)\log n$. For a node u in the recursion tree, let $n_u, \beta_u, \gamma_u, X_u$ denote its input parameters. Suppose we stop the recursion at a node u whenever $n_u + w\beta_u \le r$; in particular, this condition implies $n_u \le r$ and $\beta_u \le r/w$ simultaneously. Then the parent v of each leaf satisfies $\mu_v + w\beta_v > r$. This recursion subtree has depth at most $O(\log \frac{n+w\beta}{r})$. Let ξ be the size of this recursion subtree. Then $\sum_v (n_v + w\beta_v) \le O((n+w\beta+\xi\cdot w(p+n/p))\log\frac{n+w\beta}{r})$, where the summation is over each v that is the parent of some leaf. Thus, $\xi \le O(\frac{1}{r}\sum_v(n_v+w\beta_v)) \le O(\frac{n+w\beta}{r}\log\frac{n+w\beta}{r}) + o(\xi)$, implying that $\xi \le O(\frac{n+w\beta}{r}\log\frac{n+w\beta}{r})$.

This leads to a new recurrence:

$$T(n,\beta,\gamma,x) \le \max_{\substack{x_1,x_2,\ldots:\\ \sum_k x_k\le x}} \sum_{k=1}^{O(\frac{n+w\beta}{r}\log\frac{n+w\beta}{r})} \big(T(r, r/w, \gamma+\widetilde{O}(1+\beta/p), x_k)+ \widetilde{O}\big(n+n^2/p+ \gamma(\beta+p+n/p+x)^{(3+\omega)/2}+x^2n/p\big)\big).$$

We now set $\beta = n^{1/2+\alpha}$, $w = n^{1/2-\alpha}$, $r = n/t$, and $p = n^{1/2+\alpha}/\log^{1+\varepsilon} n$ for a sufficiently large constant t. Note that indeed $r \gg w(p + n/p)\log n$. By loosely bounding r/w by $(n/t)^{1/2+\alpha}$, the recurrence becomes:

$$T(n,n^{1/2+\alpha},\gamma,x) \le \max_{\substack{x_1,x_2,\ldots:\\ \sum_k x_k\le x}} \sum_{k=1}^{O(t\log t)} \big(T(n/t,(n/t)^{1/2+\alpha},\gamma+\widetilde{O}(1),x_k)+ \widetilde{O}(n^{3/2-\alpha}+\gamma(n^{(1/2+\alpha)(3+\omega)/2}+x^{(3+\omega)/2}) x^2n^{1/2-\alpha})\big).$$

This solves to $T(n, n^{1/2+\alpha}, \gamma, x) = \widetilde{O}(n^{3/2-\alpha}+(1+\gamma)(n^{(1/2+\alpha)(3+\omega)/2}+x^{(3+\omega)/2})+x^2n^{1/2-\alpha})$. ◀

▶ **Corollary 7.** *Given a set A of line segments in $\mathbb{R}^2$ and a subset $X \subset A$ of x segments, we can compute $\delta_G[X, X]$, where G is the intersection graph of A, in $\widetilde{O}(\mu^{3/2-\alpha}+\mu^{(1/2+\alpha)(3+\omega)/2}+ x^{(3+\omega)/2} + x^2\mu^{1/2-\alpha})$ expected time for any given α, where μ is the number of endpoints and intersection points of A.*

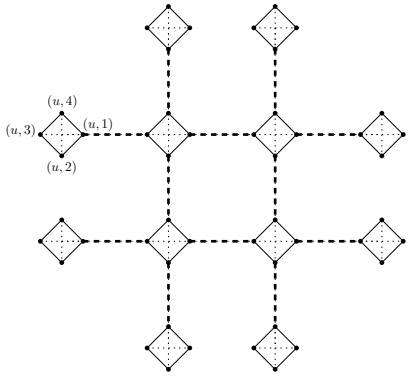

Figure 3 The clustered planar graph $\widehat{H}$. The dotted edges and the dashed edges have weight 0, while the solid edges have weight 1. Edges with weight 2 are omitted.

Proof. For simplicity, we assume that the given segments are in general position (e.g., no 3 segments intersect at a common point).

First we compute the intersections of the line segments in A, for example, by applying Bentley and Ottmann's plane-sweep algorithm [4], which runs in $O(\mu \log \mu)$ time.

Let H be the *planarized intersection graph* of A, i.e., the planar graph formed by the arrangement of A, where the vertices consist of the segment endpoints and intersection points of A, and the edges of H correspond to pairs of adjacent vertices in the arrangement.

Let $\widehat{H}$ be the clustered planar graph $H \times K_4$ (see Figure 3). Number the edges incident to each vertex of H from $\{1, 2, 3, 4\}$ in clockwise order. Give the edge $(u, i)(v, j)$ weight 0 in $\widehat{H}$ if uv is in H and the i-th edge incident to u coincides with the j-th edge incident to v. In addition, for each vertex u of degree 4 in H, give the edges $(u, 1)(u, 2)$, $(u, 2)(u, 3)$, $(u, 3)(u, 4)$, $(u, 4)(u, 1)$ weight 1, and give the edges $(u, 1)(u, 3)$ and $(u, 2)(u, 4)$ weight 0. Give all other edges weight 2 in $\widehat{H}$. Let $u(s)$ denote the left endpoint of a segment s. Then for any two segments s and t, the distance between s and t in G is equal to the distance between $(u(s), 1)$ and $(u(t), 1)$ in $\widehat{H}$. So, the result immediately follows by applying Theorem 6 to $\widehat{H}$ and $\{u(s) : s \in X\}$. ◀

4 Girth for Line Segments

We now present our girth algorithm for intersection graphs of line segments. It is tempting to continue to work within the clustered planar graph framework, but unfortunately a clustered planar graph by definition contains short cycles in every cluster (furthermore, when generalizing from segments to curves later, an additional difficulty is that simple cycles in the planarized intersection graph may not correspond to simple cycles in the intersection graph – see Figure 4).

We propose another recursive algorithm, which is also based on our separator lemma but proceeds differently: on one hand, we have to work with intersection graphs instead of clustered planar graphs, and also have to deal with the issue of ensuring simplicity of walks; on the other hand, Corollary 7 is available as a subroutine to compute distances, so fewer input arguments are needed in the new recursive algorithm (notably, we don't need an additional input set B).

Figure 4 These are not simple cycles in the intersection graph!

▶ **Theorem 8.** *Given a set A of n line segments in $\mathbb{R}^2$, we can compute the girth g_G of its intersection graph G of A in $O(n^{1.483})$ expected time, under the promise that the girth is more than 4.*

Proof. It is known that any intersection graph of n line segments with girth more than 4 must have $O(n)$ edges [42].

Step 1: Build a separator. We first construct the planarized intersection graph $H = (V_H, E_H)$, as in the proof of Corollary 7, in $\widetilde{O}(n)$ time. Note that $\mu = |V_H| = O(n)$. Define the weight of a point $p \in V_H$ to be 1 if it is the left endpoint of a segment, and 0 otherwise; the total weight is n. We can apply Lemma 2 (with unit loads), for a value p to be set later, to partition V_H into V_1, V_2, S_H such that

- V_i has weight at most $3n/4$ for each $i \in \{1, 2\}$;
- there are no edges of H in $V_1 \times V_2$;
- S_H can be further partitioned into P_H and Q_H such that P_H is the union of at most two paths in H of length $O(p)$, and $|Q_H| = O(n/p)$.

For each $i \in \{1, 2\}$, let A_i consist of the segments $s \in A$ for which all points of V_H on s are in V_i. Note that $|A_i| \le 3n/4$. Let P consist of the segments with at least one point in P_H. Let Q consist of the segments with at least one point in Q_H and no points in P_H. Let $S = P \cup Q$. Note that P is the union of at most two walks of length $O(p)$ in G (since any path in H corresponds to a walk in G).

Step 2: Recurse. For each $i \in \{1, 2\}$, we recursively solve the problem for $A_i \cup P$ to obtain the girth g_{G_i} of the intersection graph G_i of $A_i \cup P$. (Note that the assumption that G has girth more than 4 implies that G_i also has girth more than 4.)

Let $n_i = |A_i \cup P|$. Then $n_1, n_2 \le 3n/4 + O(p)$ and $n_1 + n_2 \le n + O(p)$.

Step 3: Compute $\delta_{G_i}[P, P]$. For each $i \in \{1, 2\}$, we compute $\delta_{G_i}[P, P]$ by Corollary 7 in $\widetilde{O}(n^{3/2-\alpha} + n^{(1/2+\alpha)(3+\omega)/2} + p^{(3+\omega)/2} + p^2 n^{1/2-\alpha})$ expected time.

Step 4: Compute the girth g_G. We first run BFS from each segment of Q to find the length g_Q of the shortest cycle visiting Q in G. This part takes $\widetilde{O}(n^2/p)$ time.

Next, we compute the length g_{legal} of the shortest legal alternating closed walk where the segments in A_1 are red, the segments in A_2 are blue, and the segments in P are white (discarding the segments in Q). By Lemma 4, the girth $g_{G[A_1 \cup A_2 \cup P]}$ of $G[A_1 \cup A_2 \cup P]$ is equal to $\min\{g_{\text{legal}}, g_{G_1}, g_{G_2}\}$. The final answer is $g_G = \min\{g_{G[A_1 \cup A_2 \cup P]}, g_Q\}$.

To compute g_{legal}, for each $i \in \{1, 2\}$, we first compute the "legal" distance matrices $\delta'_{G_i}[P, P]$: for $u, v \in P$, let

$$\delta'_{G_i}(u, v) = \begin{cases} \delta_{G_i}(u, v) & \text{if } \delta_{G_i}(u, v) \neq \delta_{G[P]}(u, v), \\ +\infty & \text{otherwise.} \end{cases}$$

We already know the matrix $\delta_{G_i}[P, P]$. We can compute $\delta_{G[P]}$ naively in $\widetilde{O}(p^\omega)$ time. Consequently, we know the matrix $\delta'_{G_i}[P, P]$.

Next, we compute

$$\delta''_{G_i}[P,P] = \delta'_{G_i}[P,P] \star \delta_{G[P]}.$$

Although $\delta'_{G_i}[P,P]$ may not satisfy a bounded-difference property, the rows of $\delta_{G[P]}$ satisfy the bounded-difference property, after dividing the matrix into two parts and reordering the columns, since P is the union of at most two walks. So, we can compute $\delta''_{G_i}[P,P]$ in $\widetilde{O}(p^{(3+\omega)/2})$ time by Lemma 1. It also follows that the rows of $\delta''_{G_i}[P,P]$ satisfy the bounded-difference property. Finally, let

$$Z_k = \bigvee_{i=1}^{k} (\delta''_{G_1}[P,P] \star \delta''_{G_2}[P,P])^i.$$

From the definition of legal alternating walks, we see that $Z_n(u,u)$ is precisely the length of the shortest legal alternating closed walk starting at $u \in P$. Thus, g_{legal} is the smallest diagonal entry in Z_n. We can compute Z_n recursively by the following formula:

$$Z_k = (Z_{k/2} \star Z_{k/2}) \vee (\delta''_{G_1}[P,P] \star \delta''_{G_2}[P,P]).$$

(This assumes that k is even, and the odd case is similar.) This requires $O(\log n)$ min-plus matrix products, and all intermediate matrices satisfy the bounded-difference property. So, Z_n can be computed in $\widetilde{O}(p^{(3+\omega)/2})$ time.

Running time. The time complexity $T(n)$ of the algorithm satisfies the following recurrence:

$$T(n) \le \max_{\substack{n_1,n_2:\\ n_1,n_2\le 3n/4+O(p),\\ n_1+n_2\le n+O(p)}} \Big(T(n_1)+T(n_2)+\widetilde{O}(n^2/p + n^{3/2-\alpha} + n^{(1/2+\alpha)(3+\omega)/2} + p^{(3+\omega)/2} + p^2 n^{1/2-\alpha})\Big).$$

To balance the three terms n^2/p, $n^{(1/2+\alpha)(3+\omega)/2}$, and $p^2 n^{1/2-\alpha}$, we set $p = n^{1/2+\rho}$ and $\alpha = 3\rho$, with $\rho = \frac{3-\omega}{22+6\omega} > 0.0173$, using the latest bound $\omega < 2.371339$ [2]. Then the recurrence becomes:

$$T(n) \le \max_{\substack{n_1,n_2:\ n_1,n_2\le 3n/4+o(n),\\ n_1+n_2\le n+o(n)}} \big(T(n_1)+T(n_2)+\widetilde{O}(n^{3/2-\rho})\big),$$

which solves to $T(n) = \widetilde{O}(n^{3/2-\rho}) \le O(n^{1.483})$. ◀

Finally, we remove the assumption that girth is more than 4:

▶ **Corollary 9.** *Given n line segments in $\mathbb{R}^2$, we can compute the girth of the intersection graph in $O(n^{1.483})$ expected time.*

Proof. We can check whether the intersection graph G contains a 3-cycle in $O(n^{1.408})$ time by an algorithm of Chan [14, Theorem 5.1], or a 4-cycle in $\widetilde{O}(n)$ time by another algorithm of Chan [14, Theorem 6.2]. So, we may assume that the girth is greater than 4, and the result follows from Theorem 8. ◀

In the full version, we describe how to modify our algorithms more generally for arbitrary algebraic curves or semialgebraic sets that are connected and have constant description complexity.

Our results are unlikely to be optimal. Although we do not know how to improve Corollary 7, we are currently working on ideas that might further improve the time bound of Corollary 9 for the case of line segments, by exploiting special properties about intersection graphs with large girth.

Abstract

Given a set S of n points in the plane, we study the two-line-center problem: finding two lines that minimize the maximum distance from each point in S to its closest line. We present a $(1+\varepsilon)$-approximation algorithm for the two-line-center problem that runs in $O((n/\varepsilon)\log(1/\varepsilon))$ time, which improves the previously best $O(n\log n + (n/\varepsilon^2)\log(1/\varepsilon) + (1/\varepsilon^3)\log(1/\varepsilon))$-time algorithm. We also consider three variants of this problem, in which the orientations of the two lines are restricted: (1) the orientation of one of the two lines is fixed, (2) the orientations of both lines are fixed, and (3) the two lines are required to be parallel. For each of these three variants, we give the first $(1+\varepsilon)$-approximation algorithm that runs in linear time. In particular, for the variant where the orientation of one of the two lines is fixed, we also give an improved exact algorithm that runs in $O(n\log n)$ time and show that it is optimal.

1 Introduction

Given a set S of n points in the plane, we study the two-line-center problem: finding two lines that minimize the maximum distance from each point in S to its closest line. This is a special case of the k-line-center problem, which asks, for a given set S of n points in the plane, to find k lines minimizing the maximum distance from each point in S to its closest line. A more general framework is projective clustering: Given $P \subset \mathbb{R}^d$, the goal is to find k flats of dimension j that best fit P under a given distance measure. It has wide applications in data mining [4, 5], unsupervised learning [23], database management [10], and computer vision [24].

The k-line-center problem is known to be NP-hard [21] when k is part of the input (even in the plane), and various approaches including approximation algorithms and randomized methods [1, 3, 7, 9, 11, 13, 16, 17, 18] have been studied.

Figure 1 In each case, both yellow and gray pairs satisfy the restriction, but the yellow pair has the smaller maximum width.

When $k = 1$, the problem becomes computing the width of a point set. This can be done exactly in $O(n \log n)$ time [22], and an $\Omega(n \log n)$ lower bound is known [20]. A $(1+\varepsilon)$-approximation algorithm running in $O(n + 1/\varepsilon)$ time was given in [11].

When $k = 2$, i.e., the two-line-center problem, an exact algorithm with running time $O(n^2 \log^2 n)$ is known [19]. The authors in [2] presented a $(1+\varepsilon)$-approximation algorithm that runs in $O(n \log n + (n/\varepsilon^2) \log(1/\varepsilon) + \varepsilon^{-7/2} \log(1/\varepsilon))$ time. Later, as the $(1+\varepsilon)$-approximation algorithm for the width problem was improved from $O(n + \varepsilon^{-3/2})$ to $O(n + 1/\varepsilon)$ [11], their algorithm is consequently improved to $O(n \log n + (n/\varepsilon^2) \log(1/\varepsilon) + (1/\varepsilon^3) \log(1/\varepsilon))$, even though it is not explicitly mentioned.

Observe that the two-line-center problem is equivalent to finding a pair of slabs whose union covers the input point set while minimizing their maximum width.

We study the two-line-center problem and three natural variants. Let $\mu = \min\{n, 1/\varepsilon^2\}$, and let w^* denote the maximum width of an optimal pair of slabs in each problem. Each variant is illustrated in Figure 1. Table 1 summarizes the previous and new results.

1. **General:** Given a set S of n points in the plane, we study the problem of finding a pair of slabs whose union covers S while minimizing the maximum of their widths. We present an $O(n + (\mu/\varepsilon) \log \mu)$-time algorithm that finds a pair of slabs whose union covers S and whose maximum width is at most $(1+\varepsilon)w^*$. The running time can be expressed as both $O((n/\varepsilon) \log(1/\varepsilon))$ and $O(n + (1/\varepsilon^3) \log(1/\varepsilon))$.
2. **One Fixed Orientation:** Given a set S of n points in the plane and an orientation θ, we study the problem of finding a pair of slabs such that one of them has orientation θ and their union covers S while minimizing the maximum of their widths. We present an exact algorithm that runs in $O(n \log n)$ time, improving the previously best $O(n \log^3 n)$-time algorithm [6], and show that this is optimal.

   We also present an $O(n + \mu \log \mu)$-time algorithm that finds a pair of slabs such that one of them has orientation θ, their union covers S, and their maximum width is at most $(1+\varepsilon)w^*$. The running time can be expressed as $O(n \log(1/\varepsilon))$ and $O(n + 1/\varepsilon^2 \log(1/\varepsilon))$.
3. **Two Fixed Orientations:** Given a set S of n points in the plane and two orientations, θ_1 and θ_2, we study the problem of finding two slabs, one has orientation θ_1 and the other has orientation θ_2, whose union covers S while minimizing the maximum of their widths. We present an $O(n + 1/\varepsilon)$-time algorithm that finds a pair of slabs such that one has orientation θ_1 and the other has orientation θ_2, their union covers S, and their maximum width is at most $(1+\varepsilon)w^*$.
4. **Parallel:** Given a set S of n points in the plane, we study the problem of finding a pair of parallel slabs whose union covers S while minimizing the maximum of their widths. We present an $O(n + \mu/\varepsilon)$-time algorithm that finds a pair of parallel slabs such that their union covers S and their maximum width is at most $(1+\varepsilon)w^*$.

		$\boldsymbol{O(\frac{n}{\varepsilon})}$, $\boldsymbol{O(n + \frac{1}{\varepsilon^3})}$ (full version)

1.1 Outline

In Section 2, we introduce the notation that will be used throughout the paper.

In Section 3, we introduce three key ingredients used throughout the paper. In Section 3.1, we modify the concept of an *anchor pair* (as introduced in [2]) and show how to compute it. In Section 3.2, we use an anchor pair to compute a 10-approximation for the general two-line-center problem in $O(n)$ time. In Section 3.3, we recall the concept of an *ε-certificate* (as defined in [3]), a subset of the input point set that suffices to obtain a $(1+\varepsilon)$-approximate solution, and show how to compute it in $O(n)$ time using an anchor pair from Section 3.1 and a 10-approximate solution from Section 3.2.

In Section 4, we address the one-fixed-orientation two-line-center problem. In Section 4.2, we give an $O(n)$-time decision algorithm, assuming the points are sorted. In Section 4.3, we present an $O(n \log n)$-time exact algorithm and prove its optimality. In Section 4.4, we give a $(1+\varepsilon)$-approximation algorithm.

In Section 5, we address the general two-line-center problem. Using an anchor pair (Section 3.1) and a 10-approximate solution (Section 3.2), we compute a candidate set of orientations for one of the slabs of a $(1+\varepsilon)$-approximate solution. Combining this with the algorithm from Section 4 and an ε-certificate (Section 3.3), we obtain a $(1+\varepsilon)$-approximation algorithm.

Due to space constraints, we address the remaining two problems in the full version.

For the two-fixed-orientations two-line-center problem, we first present a 2-approximation algorithm, and then refine it to obtain a $(1+\varepsilon)$-approximation.

For the parallel two-line-center problem, we use the *gap-ratio* of a pair of slabs (as defined in [12]) and consider two cases separately, depending on whether the gap-ratio of an optimal pair is small or large. Combining these with an ε-certificate, we obtain a $(1+\varepsilon)$-approximation algorithm.

2 Preliminaries

For a set P of points in the plane, we denote its diameter by $\mathrm{diam}(P)$, its width by $\mathrm{width}(P)$, and its convex hull by $\mathrm{conv}(P)$. If $P = \emptyset$, then $\mathrm{width}(P) = 0$. For a slab σ, we denote its width by $w(\sigma)$, which is the distance between the two bounding lines of σ (see Figure 2(a)).

For a line ℓ, we say that ℓ has orientation $\theta \in [0, \pi)$ if θ is the counterclockwise angle from the x-axis to ℓ. A slab σ is said to have orientation $\theta \in [0, \pi)$ if its two bounding lines have orientation θ (see Figure 2(a)). For a finite set P of points in the plane, let $\sigma_\theta(P)$ denote the minimum-width slab of orientation θ that encloses P, and define $\mathrm{width}_\theta(P) = w(\sigma_\theta(P))$ (see Figure 2(b)).

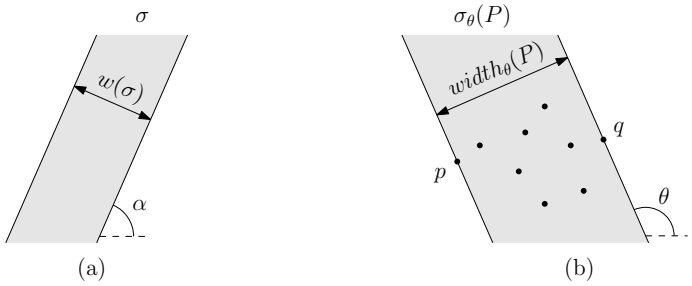

Figure 2 (a) The orientation of σ is α. (b) For a set P of points and an orientation θ, $\sigma_\theta(P)$ and $\mathrm{width}_\theta(P)$ are shown. Observe that (p, q) is an antipodal pair of P with respect to θ.

For a set P of points in the plane and an orientation $\theta \in [0, \pi)$, we say that a pair (p, q) with $p, q \in P$ is an *antipodal pair* of P with respect to θ if p lies on one bounding line of $\sigma_\theta(P)$ and q lies on the other (see Figure 2(b)).

For two finite sets A and B in the plane, let $d(A, B)$ denote the minimum distance between a point of A and a point of B. For two points p and q in the plane, let ℓ_{pq} be the line passing through p and q.

For each of the four problems, we assume that $w^* > 0$, where w^* denotes the maximum width of an optimal pair of slabs for that problem. The case where $w^* = 0$ can be detected and handled in linear time. See the appendix in the full version.

Throughout the paper, let $\varepsilon > 0$ be a sufficiently small real number and let S denote an input set of n points in the plane. Due to space constraints, the proofs of the theorems and lemmas marked with a star(*) are provided in the full version.

3 Ingredients

In this section, we describe three key ingredients used throughout the paper: (1) an anchor pair, (2) a linear-time 10-approximation algorithm, and (3) an ε-certificate.

Throughout this section, we denote by $\Sigma^* = (\sigma_1^*, \sigma_2^*)$ an optimal pair of slabs for the general two-line-center problem, and let $w^* = \max\{w(\sigma_1^*), w(\sigma_2^*)\}$.

3.1 An Anchor Pair and Its Candidate Set

We first define an anchor pair and show that a candidate set for an anchor pair of Σ^* of constant size can be computed in $O(n)$ time. Recall that S denotes the input set of n points in the plane.

▶ **Definition 1** (Anchor pair). *For a pair of slabs $\Sigma = (\sigma_1, \sigma_2)$, we call a pair of points $p, q \in \mathbb{R}^2$ an **anchor pair of Σ** if*
(1) *$p, q \in \sigma_1$ and $d(p, q) \geq \mathrm{diam}((\sigma_1 \setminus \sigma_2) \cap S)/4$, or*
(2) *$p, q \in \sigma_2$ and $d(p, q) \geq \mathrm{diam}((\sigma_2 \setminus \sigma_1) \cap S)/4$.*
Note that p or q may lie in $\sigma_1 \cap \sigma_2$. (See Figure 3.)

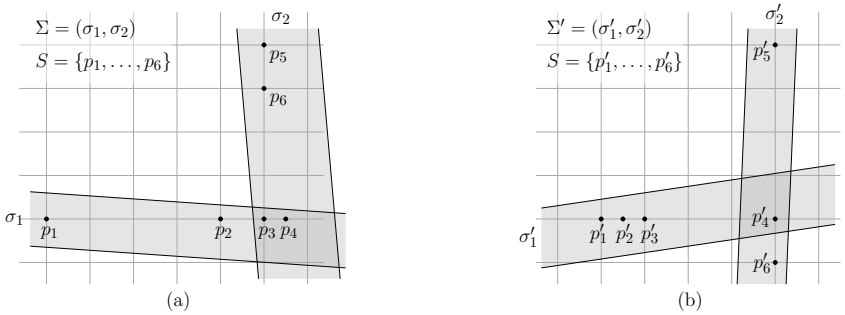

Figure 3 (a) Both (p_2, p_3) and (p_3, p_4) are anchor pairs of Σ, satisfying **(1)** and **(2)**, respectively. (b) (p'_1, p'_2) is an anchor pair of Σ', satisfying **(1)**, but (p'_4, p'_6) is not.

We remark that the authors in [2] used the concept of an anchor pair, defined slightly differently. They showed that a candidate set of constant size can be computed in $O(n \log n)$ time. In the proof of the following lemma, we point out a gap in their proof. By adopting our definition of an anchor pair, we both resolve this gap and obtain its candidate set in $O(n)$ time.

▶ **Lemma 2*.** *We can compute, in $O(n)$ time, a set of at most 11 pairs of points such that for any pair Σ of slabs whose union covers S, at least one of them is an anchor pair of Σ.*

3.2 A Linear-Time 10-Approximation Algorithm

In this section, we give a 10-approximation algorithm for the general two-line-center problem that runs in $O(n)$ time. We remark that the authors in [2] gave a 6-approximation algorithm that runs in $O(n \log n)$ time.

By Lemma 2, we can find a set of at most 11 pairs of points, at least one of which is an anchor pair of Σ^* in $O(n)$ time. For the moment, assume that we have an anchor pair (p, q) of Σ^*. Without loss of generality, assume that $p, q \in \sigma_1^*$ and $d(p, q) \geq \text{diam}((\sigma_1^* \setminus \sigma_2^*) \cap S)/4$.

Let $p_1, p_2, \ldots, p_n$ be the points of S, indexed in increasing order of their distance from ℓ_{pq}. (We do not actually sort them. The indices are used only for reference.) For three points $\alpha, \beta, \gamma \in \mathbb{R}^2$, let $\sigma(\alpha, \beta; \gamma)$ denote the slab whose center line is $\ell_{\alpha\beta}$ and one bounding line passes through γ (see Figure 4).

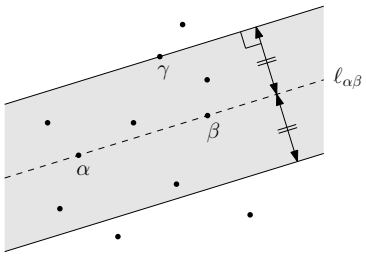

Figure 4 For three points $\alpha, \beta, \gamma \in \mathbb{R}^2$, the gray region represents $\sigma(\alpha, \beta; \gamma)$.

The following lemma implies the existence of a pair of slabs whose maximum width is at most $10w^*$, and one of which is parallel to ℓ_{pq}.

▶ **Lemma 3*.** *There exists a point $r \in S$ such that $\sigma(p, q; r)$ covers all points of $(\sigma_1^* \setminus \sigma_2^*) \cap S$ and $w(\sigma(p, q; r)) \leq 10w^*$. For such r, $\text{width}(S \setminus \sigma(p, q; r)) \leq w^*$.*

Naive Approach and Idea

By Lemma 3, there exists a point $r \in S$ such that both $w(\sigma(p,q;r))$ and $\text{width}(S \setminus \sigma(p,q;r))$ are at most $10w^*$. We now give a brief idea of using a binary search to find such a point r.

Consider the slab $\sigma(p,q;p_i)$ and the set $S \setminus \sigma(p,q;p_i)$ for $1 \le i \le n$. Observe that as i increases, the width $w(\sigma(p,q;p_i))$ increases, while $\text{width}(S \setminus \sigma(p,q;p_i))$ decreases[1]. Using this monotonicity, we can find an index i that minimizes the unimodal function $\max\{w(\sigma(p,q;p_i)), \text{width}(S \setminus \sigma(p,q;p_i))\}$.

More specifically, at each step of the binary search over a range of indices $[s,e] \subseteq [1,n]$, we compute the median index m and evaluate $w(\sigma(p,q;p_m))$ and $\text{width}(S \setminus \sigma(p,q;p_m))$. If $w(\sigma(p,q;p_m)) \ge \text{width}(S \setminus \sigma(p,q;p_m))$, we set the range to $[s,m]$. Otherwise, we set it to $[m,e]$. Let j be the index obtained by the binary search. Observe that j minimizes $\max\{w(\sigma(p,q;p_i)), \text{width}(S \setminus \sigma(p,q;p_i))\}$ over all $1 \le i \le n$. By Lemma 3, we have $\max\{w(\sigma(p,q;p_j)), \text{width}(S \setminus \sigma(p,q;p_j))\} \le 10w^*$.

Note that the time required in each step is dominated by computing $\text{width}(S \setminus \sigma(p,q;p_m))$, which takes $O(n \log n)$ time [22]. Therefore, the overall running time is $O(n \log^2 n)$.

To reduce the time complexity, we avoid computing $width(S \setminus \sigma(p,q;p_m))$ from scratch at every step by sacrificing exactness. We remark that the authors in [2] presented an $O(n \log n)$-time binary search algorithm by reducing the time for each step to $O(n)$. We present an $O(n)$-time binary search algorithm in which each step takes time linear in the size of the current range of indices, even when the points are not sorted. Our algorithm uses the following incremental algorithm that computes a 6-approximation of the width of a point set.

▶ **Theorem 4** (Theorem A.3 of [11]). *Given an online sequence of points in the plane, we can maintain a* 6*-approximation of the width with* $O(1)$ *space and update time.*

We show the following theorem. See the full version for the proof.

▶ **Theorem 5*.** *In* $O(n)$ *time, we can compute a pair of slabs that forms a* 10*-approximation for the general two-line-center problem.*

3.3 An ε-certificate

Before defining an ε-certificate, we first define the notion of an *ε-expansion*. We remark that the definitions in this section are from [3].

▶ **Definition 6** (ε-expansion).

(i) *For an interval* $[a,b]$*, we define its* ε-expansion *to be the interval* $[a - \varepsilon(b-a)/2, b + \varepsilon(b-a)/2]$*. See Figure 5(a).*

(ii) *For a slab centered on a line* ℓ *with width* w*, we define its* ε-expansion *to be the slab centered on the line* ℓ *having width* $(1+\varepsilon)w$*. See Figure 5(b).*

Now we define an ε-certificate in both $\mathbb{R}^1$ and $\mathbb{R}^2$.

▶ **Definition 7** (ε-certificate).

(i) *Let* P *be a set of* n *points on the real line and* $\varepsilon > 0$*. We say that a subset* $Q \subseteq P$ *is an* ε-certificate *of* P *if for any pair of intervals whose union covers* Q*, the union of their* ε*-expansions covers* P*.*

[1] Throughout this section, we refer to a non-decreasing (resp., non-increasing) function simply as an increasing (resp., decreasing) function.

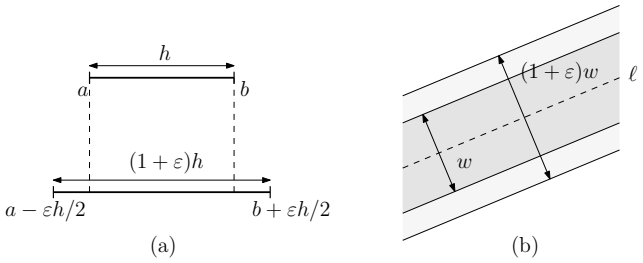

Figure 5 (a) The ε-expansion of an interval. (b) The ε-expansion of a slab.

(ii) *Let P be a set of n points in the plane and $\varepsilon > 0$. We say that a subset $Q \subseteq P$ is an* ε-certificate *of P if for any pair of slabs with the same width whose union covers Q, the union of their ε-expansions covers P. We emphasize that the two slabs must have the same width.*

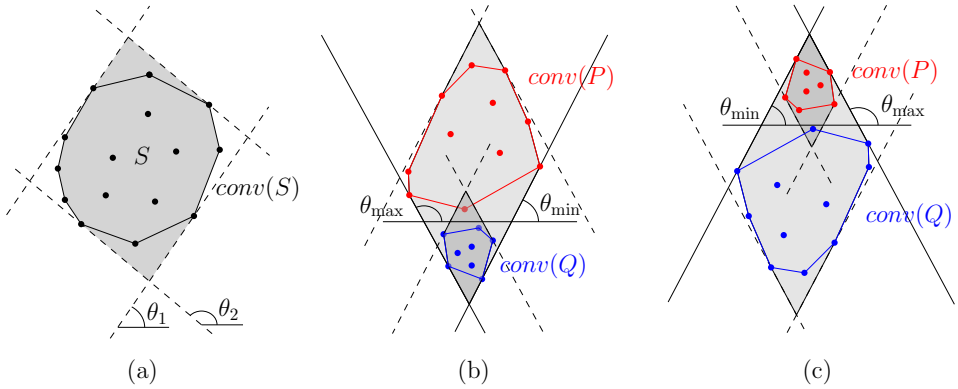
We note that the existence of an ε-certificate of size $1/\varepsilon^{O(1)}$ was shown in [3]. By proving the following theorem, we refine the hidden constant and show how to construct such an ε-certificate in linear time.

▶ **Theorem 8*.** *For a set S of n points in the plane and $\varepsilon > 0$, an ε-certificate of S of size $O(1/\varepsilon^2)$ can be computed in $O(n)$ time.*

We show that Theorem 8 directly gives a $(1+\varepsilon)$-approximation algorithm that runs in $O(n + \text{poly}(1/\varepsilon))$ time for each of the four problems.

▶ **Theorem 9*.** *For each of the four problems whose optimal solution can be found in $T(n)$ time, we can compute a $(1+\varepsilon)$-approximate solution in $O(n + T(1/\varepsilon^2))$ time.*

For the general two-line-center problem, $T(n) = O(n^2 \log^2 n)$ [19]. By Theorem 9, we obtain a $(1+\varepsilon)$-approximation algorithm running in $O(n+(1/\varepsilon^4)\log^2(1/\varepsilon))$ time. In Section 5, however, we present another algorithm with an improved running time. For the other variants as well, we present $(1+\varepsilon)$-approximation algorithms with better running times than those obtained by applying Theorem 9 with a known exact algorithm as $T(n)$ (see Table 1).



4 One Fixed Orientation

By rotating the coordinate system, we assume without loss of generality that the given orientation θ is 0. Throughout this section, we denote by (σ_1^*, σ_2^*) an optimal pair of slabs for the one-fixed-orientation problem, where σ_1^* is horizontal. Let $w^* = \max\{w(\sigma_1^*), w(\sigma_2^*)\}$.

4.1 Orientation-constrained Width and Dominance

In this section, we recall the concept of an orientation-constrained width and present geometric properties as introduced in [6]. Let $\theta_1 \leq \theta_2$ be two orientations. For a set P of points in the plane, we define the $[\theta_1, \theta_2]$-constrained width of P as $\text{width}_{[\theta_1,\theta_2]}(P) := \min_{\theta\in[\theta_1,\theta_2]} \text{width}_\theta(P)$. We also define $\sigma_{[\theta_1,\theta_2]}(P) := \bigcap_{\theta\in[\theta_1,\theta_2]} \sigma_\theta(P)$ (see Figure 6(a)).

Consider two non-empty sets P and Q of points in the plane that can be separated by a horizontal line, thus $\text{conv}(P) \cap \text{conv}(Q) = \emptyset$. Then, there are exactly two outer common tangents. Let $\theta_{\min} \leq \theta_{\max}$ be the orientations of these lines. We say that P *dominates* Q if $\sigma_{[\theta_{\min},\theta_{\max}]}(Q) \subseteq \sigma_{[\theta_{\min},\theta_{\max}]}(P)$. See Figure 6. By construction, note that either P or Q dominates the other.

(a) (b) (c)

Figure 6 (a) For a point set S and orientations θ_1 and θ_2, the gray region represents $\sigma_{[\theta_1,\theta_2]}(S)$. (b, c) For two point sets P (red) and Q (blue), the two lines represent their outer common tangents. (b) P dominates Q. (c) Q dominates P.

▶ **Lemma 10** ([6]). *With the above notation, suppose that P dominates Q. Then*
(i) $\text{width}_{[\theta_{\min},\theta_{\max}]}(P \cup Q) = \text{width}_{[\theta_{\min},\theta_{\max}]}(P)$, *and*
(ii) *If* $\text{width}(P \cup Q) < d(\text{conv}(P), \text{conv}(Q))$, *then* $\text{width}(P \cup Q) = \text{width}_{[\theta_{\min},\theta_{\max}]}(P)$.

4.2 Decision algorithm

In this section, we present a decision algorithm for a given parameter $\omega > 0$. The algorithm determines whether there exists a pair of slabs of width ω such that one of them is horizontal and their union covers S. If such a pair exists, we report YES. Otherwise, we report NO.

The points $s_1, s_2, \ldots, s_n$ of S are assumed to be sorted in decreasing order of their y-coordinates. For simplicity, we assume that no two input points have the same y-coordinate. Our approach follows that of the previously known algorithm from [6] but removes the dependency on the data structures they used. As a result, we obtain an $O(n)$-time decision algorithm (after sorting), improving upon the previous $O(n \log^2 n)$ bound.

Consider a horizontal slab σ_ω of width ω, and imagine sweeping σ_ω downward over the plane. For a fixed position of σ_ω, let $S_a \subseteq S$ be the set of points strictly above σ_ω, and let $S_b \subseteq S$ be the set of points strictly below σ_ω. Referring to Figure 7, observe that S_b dominates S_a from the beginning until a certain moment, after which S_a dominates S_b until the end, assuming that both S_a and S_b are non-empty. Observe that the answer to the decision problem is YES if and only if there exists a placement of σ_ω such that $\text{width}(S \setminus \sigma_\omega) \leq \omega$ (equivalently, $\text{width}(S_a \cup S_b) \leq \omega$).

Assumption. For the case where the answer is YES, we assume that there exists a placement of σ_ω such that S_a dominates S_b. The other case can be handled symmetrically by sweeping σ_ω upward from the bottom.

Notation. If both S_a and S_b are non-empty, there exist two outer common tangents of them. Observe that these tangent lines do not intersect each other inside σ_ω. Let ℓ_1 denote the right tangent and ℓ_2 denote the left tangent. We denote their orientations by θ_1 and θ_2, respectively. See Figure 7(a). Let $a_1 \in S_a$ and $b_1 \in S_b$ be the points of tangency defining ℓ_1, and similarly, let $a_2 \in S_a$ and $b_2 \in S_b$ be the points of tangency defining ℓ_2. If either S_a or S_b is empty, then ℓ_1 and ℓ_2 (and consequently $\{a_i, b_i, \theta_i \mid i = 1, 2\}$) are undefined.

▶ **Observation 11*.** *With the above notation, S_a dominates S_b if and only if $\theta_1 \leq \theta_2$.*

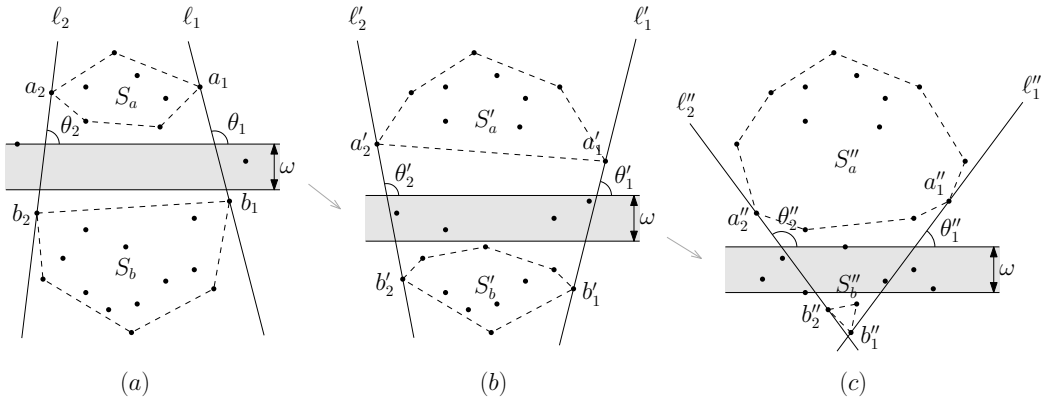


Figure 7 Three snapshots of the sweeping process for a point set. (a) S_a, S_b, and $\{\ell_i, a_i, b_i, \theta_i \mid i = 1, 2\}$ are shown according to the notation defined above. Observe that S_b dominates S_a. (b, c) We use the notations S'_a, S'_b and S''_a, S''_b (and the associated primed and double-primed variables) analogously for the two horizontal slabs positioned below. Observe that S'_a (resp., S''_a) dominates S'_b (resp., S''_b). (a–c) Observe that $\theta_1 \geq \theta'_1 \geq \theta''_1$ and $\theta_2 \leq \theta'_2 \leq \theta''_2$.

4.2.1 Overview of the Algorithm

In this section, we give an overview of the data structures maintained throughout the algorithm and explain how the main loop proceeds. We begin by recalling a data structure for maintaining the convex hull of a point set under a special sequence of insertions and deletions.

▶ **Lemma 12** ([25]). *We can dynamically maintain the convex hull of a set P of points in the plane to support each* window-sliding update *(i.e., either insert a point below all points of P or delete the topmost point of P) in $O(1)$ amortized time. The convex hull can be explicitly reported in $O(h)$ time, where h is the number of vertices of the convex hull.*

We note that in the above data structure, the neighbors of any given vertex on the convex hull can be found in $O(1)$ time. Although it is not explicitly mentioned in [25], it can be achieved since each point p (implicitly) maintains two pointers to its left and right neighbors, respectively, if p is a vertex of the current convex hull (see Sections 3.1 and 4 of [25]).

Observe that as σ_ω moves downward, a point is inserted into S_a below all existing points of S_a, or the topmost point of S_b is deleted from S_b. We refer to each such moment as *an event*. Each event corresponds to a window-sliding update of either S_a or S_b, and we have at most $2n$ events.

Data structures and Main loop

As σ_ω moves downward, we maintain the following using the notation defined above:
- the dynamic data structures for $\text{conv}(S_a)$ and $\text{conv}(S_b)$ (from Lemma 12),
- the tangent lines ℓ_1 and ℓ_2, with their corresponding points a_1, b_1, a_2, and b_2,
- the two antipodal pairs of S_a with respect to the orientations θ_1 and θ_2, respectively.

Initially, we start with a position of σ_ω such that S_a contains only s_1, the topmost point of S. If the corresponding set S_b is empty, we stop the algorithm and report YES. Otherwise, we initialize the data structures for $\text{conv}(S_a)$ and $\text{conv}(S_b)$, respectively. Then we find ℓ_1 and ℓ_2, together with $\{a_i, b_i, \theta_i \mid i = 1, 2\}$. Note that the two antipodal pairs of S_a with respect to θ_1 and θ_2 are both (s_1, s_1).

In the main loop of our decision algorithm, we do the following as σ_ω moves downward. If S_b dominates S_a, we just update the above data structures. Once S_a begins to dominate S_b, we include, for every next event, an additional step that tests whether $\mathrm{width}_{[\theta_1,\theta_2]}(S_a) \leq \omega$, using the maintained data structures. If this condition holds, we stop the algorithm and report YES; otherwise, we proceed the algorithm.

If S_b becomes empty, we set $\theta_1 = 0$ and $\theta_2 = \pi$. We then test whether $\mathrm{width}_{[\theta_1,\theta_2]}(S_a) = \mathrm{width}(S_a) \leq \omega$. If this condition holds, we report YES; otherwise, we report NO.

The correctness of this algorithm, assuming that all data structures are maintained properly and the test $\mathrm{width}_{[\theta_1,\theta_2]}(S_a) \leq \omega$ is evaluated correctly, is guaranteed by the following lemma.

▶ **Lemma 13*.** *For any placement of σ_ω where S_a dominates S_b, we have* $\mathrm{width}(S_a \cup S_b) \leq \omega$ *if and only if* $\mathrm{width}_{[\theta_1,\theta_2]}(S_a) \leq \omega$.

4.2.2 Maintaining Data Structures and Testing the Width Condition

In this section, we describe how to maintain the data structures and test the condition $\mathrm{width}_{[\theta_1,\theta_2]}(S_a) \leq \omega$ for each event that occurs as σ_ω moves downward.

We begin by proving Lemma 14, which motivates the part of the algorithm that tests whether $\mathrm{width}_{[\theta_1,\theta_2]}(S_a) \leq \omega$. Let σ_ω be a horizontal slab of width ω where S_a dominates S_b. Recall that θ_1 and θ_2 are the orientations of the right and left outer tangent lines, respectively. By Observation 11, we have $\theta_1 \leq \theta_2$. Now, let σ'_ω be another horizontal slab of width ω, positioned below σ_ω (the two slabs may partially overlap). We use the notations S'_a, θ'_1, and θ'_2 analogously for σ'_ω. Then, it always holds that $[\theta_1, \theta_2] \subseteq [\theta'_1, \theta'_2]$.

▶ **Lemma 14*.** *With the above notation, assume that* $\mathrm{width}_{[\theta_1,\theta_2]}(S_a) > \omega$. *Then,* $\mathrm{width}_{[\theta'_1,\theta'_2]}(S'_a) \leq \omega$ *if and only if* $\mathrm{width}_{[\theta'_1,\theta_1]}(S'_a) \leq \omega$ *or* $\mathrm{width}_{[\theta_2,\theta'_2]}(S'_a) \leq \omega$.

We first note that the data structures (from Lemma 12) for $\mathrm{conv}(S_a)$ and $\mathrm{conv}(S_b)$ can be maintained in $O(n)$ total time, since each event corresponds to a window-sliding update.

We now describe how to handle each event depending on its type: either an insertion into S_a or a deletion from S_b.

We first observe that if the point being inserted or deleted lies strictly between ℓ_1 and ℓ_2, then nothing changes except the convex hulls (see Figure 8). Therefore, we assume that the point corresponding to an event does not lie strictly between ℓ_1 and ℓ_2.

Insertion into S_a

Let p be the point inserted into S_a, and assume that p lies to the right of ℓ_1 (see Figure 9). The case where p lies to the left of ℓ_2 can be handled symmetrically.

Tangent searching. By our assumption, ℓ_2 remains unchanged, while ℓ_1 changes. Let ℓ'_1 denote the new tangent line, and let θ'_1 denote its orientation. Let $S'_a = S_a \cup \{p\}$. Analogously, let $a'_1 \in S'_a$ and $b'_1 \in S_b$ be the points lying on ℓ'_1. Note that $a'_1 = p$. We find b'_1 by traversing $\mathrm{conv}(S_b)$ clockwise from b_1; we refer to this as the *insertion-type tangent searching procedure*. This procedure takes $O(1+k)$ time, where k is the number of vertices on $\mathrm{conv}(S_b)$ strictly between b_1 and b'_1. We say that these vertices are *involved* in the procedure.

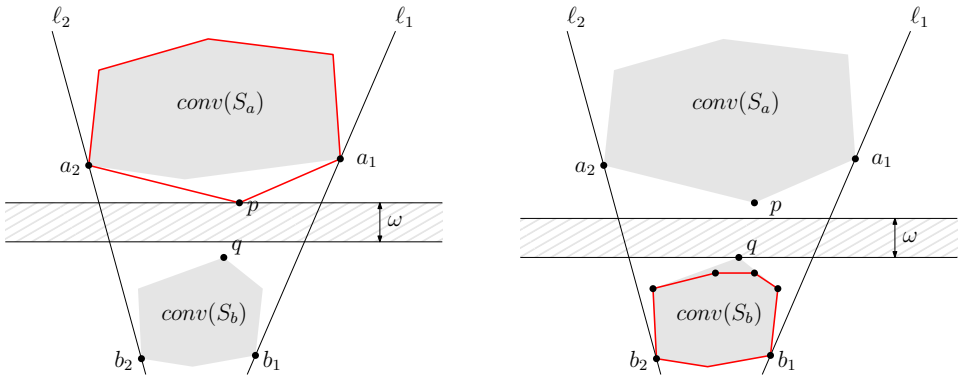

Figure 8 (a) p is inserted into S_a. (b) q is deleted from S_b. The red polygons show the convex hulls immediately after the events. Observe that the tangent lines ℓ_1 and ℓ_2 remain unchanged.

Antipodal pair searching. Now we find the antipodal pairs of S'_a with respect to θ'_1 and θ_2 (since ℓ_2 does not change). Let q be the point such that (a_1, q) is the antipodal pair of S_a with respect to θ_1.

For the orientation θ'_1, observe that $a'_1 (= p)$ is one point of the antipodal pair of S'_a. We can find the other point by traversing $\text{conv}(S'_a)$ clockwise from q. Let q' denote the point such that (a'_1, q') is the antipodal pair of S'_a with respect to θ'_1. We refer to this as the *insertion-type antipodal-pair searching procedure*, which takes $O(1 + k')$ time, where k' is the number of vertices on $\text{conv}(S'_a)$ (equivalently, on $\text{conv}(S_a)$) strictly between q and q'. We say that these vertices are *involved* in the procedure.

For the orientation θ_2, observe that a_2 is always one point of the antipodal pairs for both S_a and S'_a. Let r be the point such that (a_2, r) forms an antipodal pair of S_a with respect to θ_2 (see Figure 9(b)). Let r' be the point such that (a_2, r') forms an antipodal pair of S'_a with respect to θ_2. Then $r' = r$ if p lies to the left of the line of orientation θ_2 passing through r, and $r' = p$ otherwise.

Testing the width condition. If S'_a does not dominate S_b, there is nothing left to do. This can be easily detected by Observation 11. Otherwise, we need to test whether $\text{width}_{[\theta'_1, \theta_2]}(S'_a) \leq \omega$. By Lemma 14, it suffices to determine whether $\text{width}_{[\theta'_1, \theta_1]}(S'_a) \leq \omega$. We do this by following the antipodal pairs of S'_a from the one corresponding to θ'_1 to that of θ_1. Note that p is always one point of the antipodal pairs of S'_a for all orientations between θ'_1 and θ_1, since p lies to the right of ℓ_1. Hence, (p, q) is the antipodal pair of S'_a with respect to θ_1, and (p, q') is the one with respect to θ'_1 as explained above. By traversing $\text{conv}(S'_a)$ counterclockwise starting from q', we can visit all antipodal pairs corresponding to the range of orientations $[\theta'_1, \theta_1]$ in order. Following them sequentially allows us to find an orientation $\theta \in [\theta'_1, \theta_1]$ that minimizes $\text{width}_\theta(S'_a)$. This procedure takes $O(1 + k')$ time, where, as before, k' is the number of vertices on $\text{conv}(S'_a)$ (equivalently, on $\text{conv}(S_a)$) that lie strictly between q and q'. Note that this is bounded by the time required for the insertion-type antipodal-pair searching procedure.

The total time for handling point insertions as σ_ω moves downward depends on the two procedures: the insertion-type tangent searching procedure and the insertion-type antipodal-pair searching procedure. We conclude that it takes $O(n)$ time in total by showing that each input point can be involved at most once in each of the procedures.

▶ **Lemma 15*.** *Each point of S can be involved in the insertion-type tangent searching procedure and the insertion-type antipodal-pair searching procedure at most once, respectively, in the entire algorithm.*

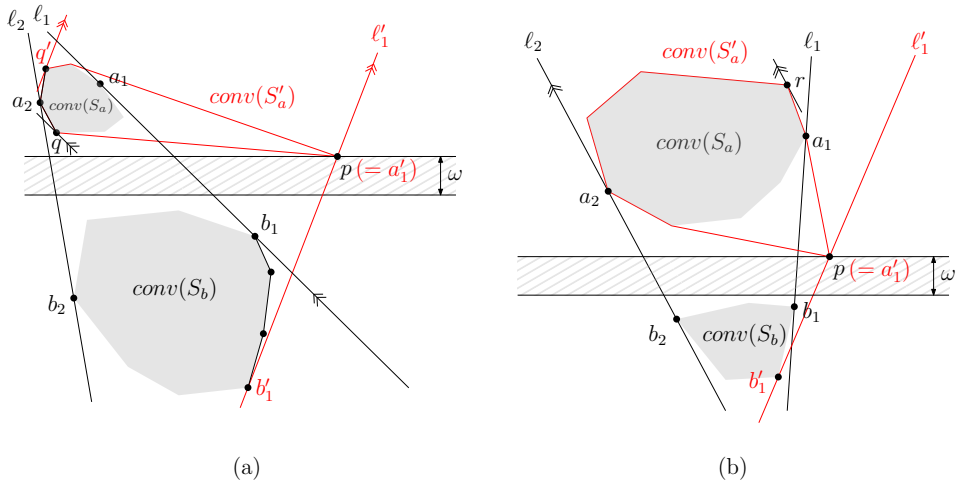

Figure 9 Two cases of insertions. In each figure, the changes after the insertion are shown in red: $\mathrm{conv}(S'_a)$, a'_1, b'_1, and ℓ'_1. In (a), observe that p becomes a point of the antipodal pair of S'_a with respect to θ_2. In contrast, in (b), the antipodal pair of S'_a with respect to θ_2 remains (a_2, r) even after inserting p. In (a), two points are involved in the tangent searching procedure, and one point is involved in the antipodal-pair searching procedure.

In a symmetric way, we handle the deletion of a point from S_b. We provide a brief summary below, and the full details are given in the full version.

Deletion from S_b (Summary)

Let p be the point deleted from S_b. We assume that p lies on ℓ_1, that is $p = b_1$ (see Figure 10).

Tangent searching. By our assumption, ℓ_2 remains unchanged, while ℓ_1 changes. Let ℓ'_1 denote the new tangent line, and let θ'_1 denote its orientation. Define $S'_b = S_b \setminus \{p\}$. Analogously, let $a'_1 \in S_a$ and $b'_1 \in S'_b$ be the points lying on ℓ'_1.

Let t be the counterclockwise neighbor of p on $\mathrm{conv}(S_b)$. We find a'_1 and b'_1 by traversing $\mathrm{conv}(S_a)$ clockwise from a_1 and $\mathrm{conv}(S'_b)$ clockwise from t, simultaneously. We refer to this as the *deletion-type tangent searching procedure*, which takes $O(1 + k_1 + k_2)$ time, where k_1 is the number of points on $\mathrm{conv}(S_a)$ strictly between a_1 and a'_1, and k_2 is the number of points on $\mathrm{conv}(S'_b)$ strictly between t and b'_1. We say that these $k_1 + k_2$ points are *involved* in the procedure.

Antipodal pair searching. We find the antipodal pairs of S_a with respect to θ'_1. (Observe that a'_1 is one point of the antipodal pair.) Let q be the point such that (a_1, q) is the antipodal pair of S_a with respect to θ_1 and let q' be the point such that (a'_1, q') is the antipodal pair of S_a with respect to θ'_1. (see Figure 10). We find q' by traversing $\mathrm{conv}(S_a)$ clockwise from q. We refer to this as the *deletion-type antipodal-pair searching procedure*, which takes $O(1 + k')$ time, where k' is the number of vertices on $\mathrm{conv}(S_a)$ strictly between q and q'. We say that these vertices are *involved* in the procedure.

Testing the width condition. By Lemma 14, it suffices to determine whether $\text{width}_{[\theta_1', \theta_1]}(S_a) \leq \omega$. Recall that (a_1, q) and (a_1', q') are the antipodal pairs of S_a with respect to θ_1 and θ_1', respectively. We do this by traversing $\text{conv}(S_a)$ clockwise, from a_1 to a_1' and from q to q' simultaneously. This takes $O(1 + k_1 + k')$ time, where, as before, k_1 is the number of points on $\text{conv}(S_a)$ strictly between a_1 and a_1', and k' is the number of vertices on $\text{conv}(S_a)$ strictly between q and q'. This is bounded by the total time required by the deletion-type tangent searching procedure and the deletion-type antipodal-pair searching procedure.

The total time for handling point deletions as σ_ω moves downward depends on the two procedures: the deletion-type tangent searching procedure and the deletion-type antipodal-pair searching procedure. We conclude that it takes $O(n)$ time in total by showing that each input point can be involved at most twice in each of the procedures.

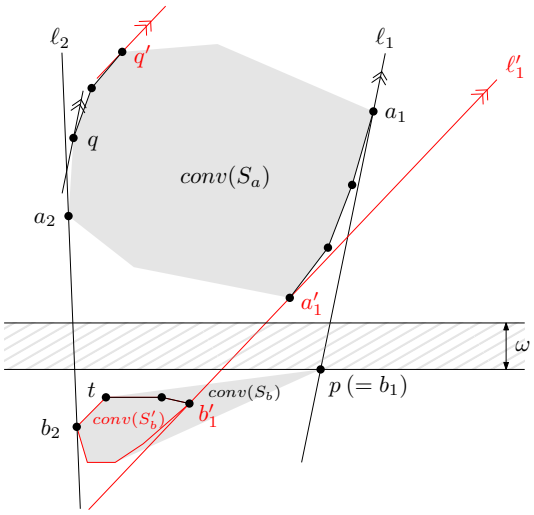

Figure 10 Changes after the deletion of p are shown in red: $\text{conv}(S_b')$, a_1', b_1', and ℓ_1'. Observe that (a_1', q') becomes the antipodal pair of S_a with respect to θ_1' after the deletion. Observe that three points ($k_1 = 2, k_2 = 1$) are involved in the deletion-type tangent searching procedure and one point is involved in the deletion-type antipodal-pair searching procedure.

▶ **Lemma 16*.** *Each point of S can be involved in the deletion-type tangent searching procedure and the deletion-type antipodal-pair searching procedure at most twice, respectively, in the entire algorithm.*

Observe that the initialization of all data structures can be done in $O(n)$ time by Lemma 12. By Lemma 15 and 16, the total time to process all events and to evaluate the condition $\text{width}_{[\theta_1', \theta_1]}(S_a) \leq \omega$ as σ_ω moves downward is $O(n)$. Now we conclude the following theorem.

▶ **Theorem 17.** *Given a set S of n points in the plane, sorted by their y-coordinates, and a real value $\omega > 0$, we can decide in $O(n)$ time whether there exists a pair of slabs of width ω whose union covers S and one of which is horizontal.*

4.3 Optimization Algorithm

We give a brief summary of our approach to obtain Theorem 18. Full details of the algorithm and the proof of its optimality are provided in the full version. We first sort the points of S so that $s_1, \ldots, s_n$ are ordered in decreasing order of their y-coordinates. Let W denote

the set of all pairwise differences between the y-coordinates of points in S. Since W can be represented as a sorted matrix [14], we can identify two consecutive values $w_0, w_1 \in W$ such that $w_0 < w^* \leq w_1$ in $O(n \log n)$ time, by combining our decision algorithm described in Section 4.2 with an efficient selection algorithm for sorted matrices [15].

Observe that the sequence of changes in the sets S_a and S_b that occur as σ_w moves downward is the same for any $w_0 < w < w_1$. Using this observation, we show that w^* can be computed by tracking $width(S_a \cup S_b)$ as σ_w moves downward, for any $w_0 < w < w_1$. We track $width(S_a \cup S_b)$ by following essentially the same procedure as in the decision algorithm. The authors of [6] also use this idea, but their algorithm requires an additional data structure, which results in an extra logarithmic factor.

▶ **Theorem 18*.** *Given a set S of n points in the plane and an orientation θ, we can find a pair of slabs such that one of them has orientation θ and their union covers S while minimizing the maximum of their widths in $O(n \log n)$ time.*

4.4 Approximation Algorithm

Recall that in Section 3.3, we showed that an ε-certificate $Q \subseteq S$ of size $O(1/\varepsilon^2)$ can be computed in $O(n)$ time. After obtaining Q, we find a pair of slabs (σ_1, σ_2) such that their union covers Q, σ_1 has orientation θ, and the maximum of their widths is minimized. Without loss of generality, we assume that σ_1 and σ_2 have the same width (otherwise, we expand the smaller one). Since $Q \subseteq S$, it follows that $w(\sigma_1) = w(\sigma_2) \leq w^*$. Such a pair can be found in $O(|Q| \log |Q|)$ time by Theorem 18.

Let (σ_1', σ_2') be the pair of slabs obtained by taking the ε-expansions of σ_1 and σ_2, respectively. By the definition of an ε-expansion, σ_1' has orientation θ and $w(\sigma_1') = w(\sigma_2') \leq (1+\varepsilon)w^*$. Furthermore, by the definition of an ε-certificate, $\sigma_1' \cup \sigma_2'$ covers S. Therefore, (σ_1', σ_2') forms a $(1+\varepsilon)$-approximate solution.

It takes $O(n + |Q| \log |Q|)$ time to obtain (σ_1', σ_2'). Let $\mu = \min\{n, 1/\varepsilon^2\}$, then we have $|Q| = O(\mu)$. Therefore, the total running time is $O(n + \mu \log \mu)$, which can be expressed as both $O(n \log(1/\varepsilon))$ and $O(n + (1/\varepsilon^2)\log(1/\varepsilon))$. We now conclude the following theorem.

▶ **Theorem 19.** *Given a set S of n points in the plane and an orientation θ, we can find a pair of slabs such that their union covers S, one of them has orientation θ, and the maximum of their widths is at most $(1+\varepsilon)w^*$ in $O(n + \mu \log \mu)$ time, where $\mu = \min\{n, 1/\varepsilon^2\}$.*

5 General Two-Line-Center

Throughout this section, we denote by $\Sigma^* = (\sigma_1^*, \sigma_2^*)$ an optimal pair of slabs for the general two-line-center problem. Let $w^* = \max\{w(\sigma_1^*), w(\sigma_2^*)\}$.

We begin by proving Lemma 20, which will be used to compute a candidate set of orientations for one of the slabs in a $(1+\varepsilon)$-approximate solution.

▶ **Lemma 20*.** *Let p and q be two points in $\mathbb{R}^2$, let $\widetilde{w} > 0$ be a real number, let $c \geq 1$ be a constant, and let $\varepsilon > 0$ be a real number. In $O(1/\varepsilon)$ time, we can compute a set Γ of $O(1/\varepsilon)$ orientations, such that the following holds:*
For every finite set P of points in $\mathbb{R}^2$ and for every slab σ, if

(1) *$P \subset \sigma$,* **(2)** *$p, q \in \sigma$,* **(3)** *$d(p,q) \geq \mathrm{diam}(P)/4$, and* **(4)** *$w(\sigma) \leq \widetilde{w} \leq c \cdot w(\sigma)$,*
then there exists an orientation $\gamma \in \Gamma$ and a slab σ', such that

(1) *$P \subset \sigma'$,* **(2)** *$w(\sigma') \leq (1+\varepsilon) \cdot w(\sigma)$, and* **(3)** *$\sigma'$ has the orientation γ.*

By Lemma 2, we can compute a set F of at most 11 pairs such that one of them is an anchor pair of Σ^* in $O(n)$ time. For the moment, assume that we have an anchor pair (p, q) of Σ^*. (We will repeat the following process for every pair in F.) Without loss of generality, assume that $p, q \in \sigma_1^*$ and $d(p, q) \geq diam((\sigma_1^* \setminus \sigma_2^*) \cap S)/4$.

By Theorem 5, we can compute $\widetilde{w}$ such that $w^* \leq \widetilde{w} \leq 10w^*$ in $O(n)$ time.

Consider a slab σ_0^* that has the same orientation as σ_1^*, has width w^*, and contains σ_1^*. In particular, if $w(\sigma_1^*) = w^*$, then σ_0^* is σ_1^*.

Observe that $P = S \cap (\sigma_1^* \setminus \sigma_2^*)$ and σ_0^* satisfy the four conditions in the statement of Lemma 20 for (p, q) and the value $\widetilde{w}$ computed above, with $c = 10$. Therefore, in $O(1/\varepsilon)$ time, we can compute a set Γ of $O(1/\varepsilon)$ orientations such that there exists a slab σ' with orientation $\gamma \in \Gamma$ that covers $S \cap (\sigma_1^* \setminus \sigma_2^*)$ and satisfies $w(\sigma') \leq (1 + \varepsilon)w^*$. This implies that there exists a pair of slabs whose union covers S, one of which has an orientation from Γ, and whose maximum width is at most $(1 + \varepsilon)w^*$.

For every $\gamma \in \Gamma$, we find a pair of slabs whose union covers S, one of which has orientation γ, and whose maximum width is minimized. By Theorem 18, this can be done in $O((n/\varepsilon) \log n)$ time in total. We repeat this procedure for every pair in F, which adds only a constant factor to the running time. Observe that each of the pairs of slabs we obtain has the property that its union covers S. Among these pairs, we output the one with the smallest maximum width. Thus, we conclude the following lemma.

▶ **Lemma 21.** *We can find a pair of slabs such that their union covers S and the maximum of their widths is at most $(1 + \varepsilon)w^*$ in $O((n/\varepsilon) \log n)$ time.*

To further refine the logarithmic term, we compute an ε-certificate Q of S (see Section 3.3). By Theorem 8, this can be done in $O(n)$ time and $|Q| = O(1/\varepsilon^2)$. We then compute a $(1 + \varepsilon)$-approximate pair (σ_1, σ_2) for the general two-line-center problem on Q, which can be done in $O((|Q|/\varepsilon) \log |Q|)$ time by Lemma 21. Without loss of generality, we assume that σ_1 and σ_2 have the same width (otherwise, we expand the smaller one). Let $w = w(\sigma_1) = w(\sigma_2)$. Since $Q \subseteq S$, it is clear that $w \leq (1 + \varepsilon)w^*$.

Let (σ_1', σ_2') be the pair of slabs obtained by taking the ε-expansions of σ_1 and σ_2, respectively. By definition, $\sigma_1' \cup \sigma_2'$ covers S, and $w(\sigma_1') = w(\sigma_2') \leq (1 + \varepsilon)^2 w^* \leq (1 + 3\varepsilon)w^*$.

The total running time is $O(n + (\mu/\varepsilon) \log \mu)$, where $\mu = \min\{n, 1/\varepsilon^2\}$, which can also be expressed as both $O((n/\varepsilon) \log(1/\varepsilon))$ and $O(n + (1/\varepsilon^3) \log(1/\varepsilon))$. By replacing ε with $\varepsilon/3$, we obtain the following theorem.

▶ **Theorem 22.** *Given a set S of n points in the plane, we can find a pair of slabs such that their union covers S and the maximum of their widths is at most $(1+\varepsilon)w^*$ in $O(n+(\mu/\varepsilon) \log \mu)$ time, where $\mu = \min\{n, 1/\varepsilon^2\}$.*

Abstract

The weighted Euler characteristic transform (WECT) and Euler characteristic function (ECF) have proven to be useful tools in a variety of applications. However, current methods for computing these functions are either not optimized for GPU computation or do not scale to higher-dimensional settings. In this work, we present a tensor-based framework for computing such topological descriptors which is highly optimized for GPU architectures and works in full generality across simplicial and cubical complexes of arbitrary dimension. Experimentally, the framework demonstrates significant speedups over existing methods when computing the WECT and ECF across a variety of two- and three-dimensional datasets. Computation of these transforms is implemented in a publicly available Python package called `pyECT`.

1 Introduction

The field of topological data analysis (TDA) utilizes invariants from topology to study the shape of data. Among the invariants employed are homology and the original topological invariant, the Euler characteristic [10]. In practice, a single invariant is not typically robust enough to capture the shape of data. For this reason, filtrations (i.e., nested sequences of

© Jessi Cisewski-Kehe, Brittany Terese Fasy, Alexander McCleary, and Eli Quist;
licensed under Creative Commons License CC-BY 4.0

shapes) are often constructed from data and topological invariants are then applied. This allows for significantly more information to be retained, leading to constructions such as persistence diagrams [9] and Euler characteristic functions [21].

Topological transforms [24] further extend the idea of applying topological invariants to filtrations by constructing a parameterized family of filtrations and then applying topological invariants. The starting point for topological transforms is typically a geometric simplicial or cubical complex K in $\mathbb{R}^n$. For each direction vector $\mathbf{s} \in \mathbb{S}^{n-1}$, a directional filtration of K is constructed and then a topological invariant is applied to that filtration. Applying the Euler characteristic (EC) to a single directional filtration results in an Euler characteristic function (ECF), while applying it to each directional filtration in $\mathbb{S}^{n-1}$ results in the Euler characteristic transform (ECT) [15, 24]. The ECT is a *complete invariant*: a geometric simplicial complex K in $\mathbb{R}^n$ can be reconstructed solely from its ECT [11, 19]. In other words, no information is lost when passing from the simplicial complex K to its ECT.

Useful variants of the ECF and ECT are the weighted Euler characteristic function (WECF) and the weighted Euler characteristic transform (WECT) for weighted complexes [12]. Much like the ECT, the WECT is a complete invariant for weighted geometric complexes [12]. Moreover, the WECT has been employed in a broad range of applications, including: in oncology for predicting survival rates of patients with glioblastoma multiforme brain tumors [6], in plant biology for classifying seed phenotypes [1], and in image classification tasks [3, 4, 12]. Numerous software packages already exist for computing the WECT and its variants, including those presented in [1, 6, 13, 14, 17, 18]. While many of these packages provide useful tools, they are either not optimized for GPU architectures or are limited in the types (or dimension) of complexes they can process.

In this work, we provide a fully tensor-based framework for computing WECFs and WECTs. Our implementation applies to arbitrary geometric simplicial and cubical complexes in Euclidean spaces. The tensor operations we use are highly optimized for fast computation on modern GPU hardware, providing significant speedups over existing implementations.

2 Background

In this section, we provide necessary foundations in computational topology and tensor computation to develop the main results. For simplicity, we restrict our attention to (abstract) simplicial complexes; however, our results and code also work for cubical complexes.

For a simplicial complex K and for any $i \in \{0, 1, \ldots, \dim(K)\}$, we denote the set of i-simplices of K by K_i. We use the notation $\mathrm{sub}(K)$ for the set of subcomplexes of K. Furthermore, we define $k = |K|$ and $k_i = |K_i|$.

▶ **Definition 1** (Lower-Star Filtrations). *Let K be a simplicial complex with vertex set K_0. A* vertex filter *on K is a function $f\colon K_0 \to \mathbb{R}$. For a vertex filter $f\colon K_0 \to \mathbb{R}$, the* lower-star filtration *induced by f is the function $F\colon \mathbb{R} \to \mathrm{sub}(K)$, defined as*

$$F(t) := \{\sigma \in K \mid \max_{v \in \sigma} f(v) \leq t\}. \tag{1}$$

The main examples of lower-star filtrations used in this paper are directional filtrations. These are defined for any (abstract) simplicial complex K with a function $\ell\colon K_0 \to \mathbb{R}^n$. In practice, simplicial complexes are often naturally embedded in $\mathbb{R}^n$ and, in this setting, the function ℓ simply maps each vertex to its coordinates.

▶ **Definition 2** (Vertex Height Functions and Directional Filtrations). *Let K be a simplicial complex with a map $\ell\colon K_0 \to \mathbb{R}^n$ and let $\mathbf{s} \in \mathbb{S}^{n-1}$ be a direction vector. The* vertex height function *in direction $\mathbf{s}$ is the map $h_{\mathbf{s}}\colon K_0 \to \mathbb{R}$ defined as $h_{\mathbf{s}}(v) := \ell(v) \cdot \mathbf{s}$. The* directional filtration *of K in direction $\mathbf{s}$, denoted as $H_{\mathbf{s}}$, is the lower-star filtration of K induced by $h_{\mathbf{s}}$.*

2.1 Weighted Euler Characteristic Functions and Transforms

Here, we introduce weighted Euler characteristic functions and transforms. For a more thorough review, see the survey paper [15].

▶ **Definition 3** (Weighted Simplicial Complexes). *A* weighted simplicial complex *is a pair* (K, ω)*, where* K *is a simplicial complex and* $\omega \colon K \to \mathbb{R}$ *is a function called a* weight function*.*

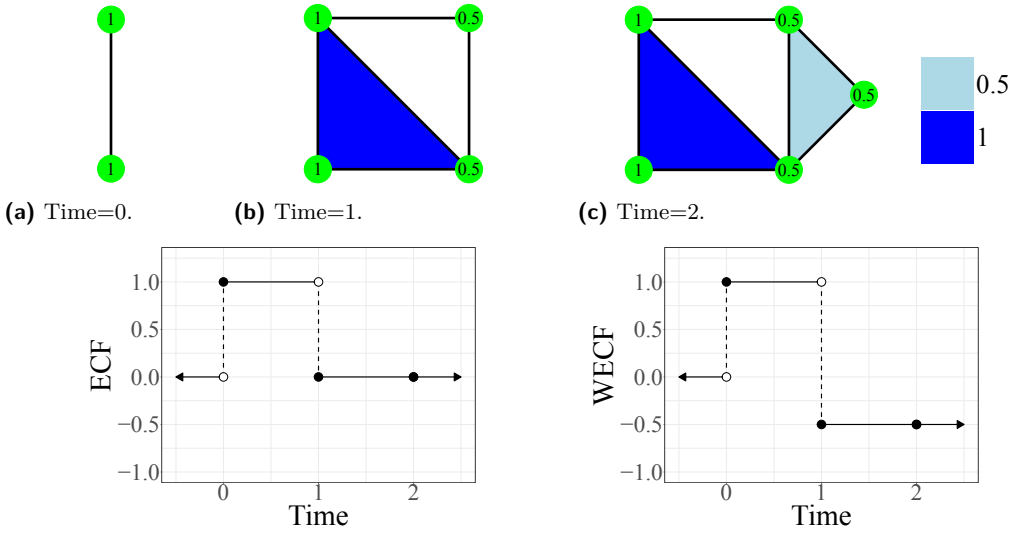
Weighted simplicial complexes are often used to model various types of data. For example, triangular meshes are widely used to model three-dimensional surfaces, with weight functions capturing scalar fields on the surface. Another example comes from image data, where grayscale images are converted into weighted simplicial complexes via the *Freudenthal triangulation* [4, 12] with weights derived from the pixel intensities.

▶ **Definition 4** (Weighted Euler Characteristic). *The* weighted Euler characteristic (WEC) *of a weighted simplicial complex* (K, ω) *is*

$$\chi(K, \omega) := \sum_{\sigma \in K} (-1)^{\dim \sigma} \omega(\sigma).$$

Note that the Euler characteristic is a special case of the WEC, where the weight function is equal to the constant function $\mathbf{1} \colon K \to \mathbb{R}$. While the WEC is a remarkably useful invariant given its simplicity, there is limited information that a single number can capture about a simplicial complex. To incorporate more information, we apply the WEC to a filtration:

▶ **Definition 5** (Weighted Euler Characteristic Function). *Let* $\mathbb{K} = (K, \omega)$ *be a weighted simplicial complex and let* $f \colon K_0 \to \mathbb{R}$ *be a vertex filter of* K *with lower-star filtration* F*. The* weighted Euler characteristic function[1] *of* $\mathbb{K}$ *induced by* f *is the function* $\mathrm{WECF}_f \colon \mathbb{R} \to \mathbb{R}$ *defined as*



$$\mathrm{WECF}_f(t) := \chi\big(F(t), \omega|_{F(t)}\big). \tag{2}$$

▶ **Definition 6** (Directional WECF). *Let* $\mathbb{K} = (K, \omega)$ *be a weighted simplicial complex with a function* $\ell \colon K_0 \to \mathbb{R}^n$ *and let* $\mathbf{s} \in \mathbb{S}^{n-1}$ *be a direction vector. The* directional WECF *of* $\mathbb{K}$ *in direction* $\mathbf{s}$ *is the WECF of* $\mathbb{K}$ *induced by the height function* $h_{\mathbf{s}}$*.*

▶ Remark 7. In image analysis tasks (and their three-dimensional analogs), there are two common (W)ECFs considered. The first (implemented in [13, 25, 26]) uses the pixel intensities as the vertex filter. We refer to the resulting ECF simply as the ECF of an image. The second, which we refer to as the directional WECF of an image, uses the pixel intensities as weights and the height function $h_{\mathbf{s}}$ for a given direction vector $\mathbf{s} \in \mathbb{S}^1$ as the vertex filter. This method is implemented in [1, 14, 23].

▶ **Example 8.** An illustration of the directional ECF and directional WECF is presented in Figure 1. The full simplicial complex, including weighted vertices, is displayed in Figure 1(c). The filtration is along direction $(1, 0)$, and the corresponding ECF and WECF are included in Figure 1(d) and Figure 1(e), respectively. The ECF and WECF are the same until time 1 when two new vertices are introduced with weights of 0.5.

[1] Weighted Euler characteristic functions are also known as weighted Euler characteristic curves. Due to their general lack of continuity, we use the term function rather than curve.

(a) Time=0. **(b)** Time=1. **(c)** Time=2.

(d) ECF in direction (1,0). **(e)** WECF in direction (1,0).

Figure 1 Filtration of a simplicial complex (a)–(c) along direction (1,0), with vertex weights shown in green discs. The weight assigned to a simplex is the maximum weight of its vertices. The corresponding ECF and WECF are displayed in (d) and (e) respectively.

Typically, there is no canonical direction vector to choose when computing directional WECFs. Hence, it is common to choose *all* directions, resulting in the weighted Euler characteristic transform (WECT).

▶ **Definition 9** (Weighted Euler Characteristic Transform). *Let* $\mathbb{K} = (K, \omega)$ *be a weighted simplicial complex with a map* $\ell\colon K_0 \to \mathbb{R}^n$. *The weighted Euler characteristic transform of* $\mathbb{K}$ *is the function* $\mathrm{WECT}_{\mathbb{K}}\colon \mathbb{S}^{n-1} \times \mathbb{R} \to \mathbb{R}$ *defined as*

$$\mathrm{WECT}_{\mathbb{K}}(\mathbf{s}, t) := \mathrm{WECF}_{h_{\mathbf{s}}}(t) = \chi\big(H_{\mathbf{s}}(t), \omega\big). \tag{3}$$

2.2 Existing Frameworks for Computation of the ECF and (W)ECT

Due to its simplicity and ease of computation, the WECT and its variants are widely used in applied settings (resulting in many available software packages). `Demeter` [1] is a Python package that computes the directional ECF and ECT of axis-aligned cubical complexes. Note that it incorporates an optimization of bucket sorting the filtration values of each vertex. However, this package does not work for generic simplicial complexes, and only computes the special case of the unweighted ECT. Next, the `SINATRA` package [23] is an R package that computes the directional ECF and ECT through an algorithm similar to `Demeter`. However, unlike `Demeter`, `SINATRA` works for arbitrary, unweighted simplicial complexes. Note that as `Demeter` and `SINATRA` are not optimized for speed, they are not included in the experimental comparison. Third, `EuCalc`[2] [14] is a highly optimized package that uses a preprocessing step to compute critical points of the directional ECF. This allows for efficient computation of the exact directional ECF (as opposed to a vectorization of it). The package only accepts axis-aligned cubical complexes as input, but does generalize

[2] `https://github.com/HugoPasse/Eucalc`

to weighted complexes. Finally, the `DECT` package[3] [17] is a Python package designed to compute the differentiable ECT (DECT) of simplicial complexes. While the DECT is a slightly different variant, the package also includes an implementation for computing the ECT of simplicial or cubical complexes. Although it does not allow for weighted complexes, this package is designed for GPU architectures, making it an interesting point of comparison. Furthermore, [18] provides further optimizations for computing the DECT on CUDA GPUs, but is consequently a far less general framework.

The `FastTopology` framework[4] [13] is a highly optimized implementation for computing the ECF of lower-star filtrations of two- and three-dimensional axis-aligned cubical complexes. While it is designed to be highly parallelizable on CPU architectures, it does not directly support vectorized computation (e.g., on a GPU) or the WECF. `GPU ECC` [25, 26] is a GPU-based implementation of the ECF. Unlike the other existing packages, it is designed for GPU architectures. However, it is highly optimized for image data, so it only works for axis-aligned cubical complexes and does not generalize to weighted complexes. Additionally, it does not compute the directional ECF or ECT, and currently is only available as an implementation on Windows systems (which is unavailable in our computation environment).

The framework presented in this paper, `pyECT`, admits several advantages over these existing packages for computing the WECT and ECF. First, unlike all existing frameworks (except `SINATRA`), `pyECT` works in full generality across arbitrary weighted simplicial and cubical complexes; see Table 1. Second, `pyECT` provides methods for computing both the WECFs of lower-star filtrations and WECTs of weighted geometric complexes. This generality is not available in any of these existing packages. Third, the tensor operations used in `pyECT` are highly optimized for modern GPU hardware, resulting in significant speedups over these existing packages. The `GPU ECC` package admits this advantage as well, but is far less general as it only accepts axis-aligned cubical complexes and does not compute the directional WECF or WECT. Finally, the tensor-based approach used in `pyECT` yields simple code (our core WECT algorithm is around 25 lines of code) that is easily readable, maintable, and customizable.

One minor disadvantage of `pyECT` is that it does not compute exact EC values at all heights of the directional ECF (which is available in `EuCalc`). While computing exact values retains more information and can be an advantage for reconstruction tasks, it leads to difficulties in vectorizing the (W)ECT. However, vectorizations of the WECT are in fact more desirable for many real-world applications, especially when used as input to distance-based methods or machine learning pipelines (such as those in [1, 12, 15, 24]).

Table 1 Comparison of supported input types for ECT packages.

Package	Simplicial Complexes	Cubical Complexes	Axis-Aligned Cubical Complexes
`pyECT`	✓ yes	✓ yes	✓ yes
`EuCalc`	✗ no	✗ no	✓ yes
`FastTopology`	✗ no	✗ no	✓ yes
`Demeter`	✗ no	✗ no	✓ yes
`SINATRA`	✓ yes	✓ yes	✓ yes

2.3 Tensor Operations

Our algorithm almost exclusively uses tensor operations. These operations have highly optimized implementations in PyTorch [2, 16] that run in parallel on both CPUs and GPUs. Here, we review tensors and the tensor operations used in our algorithm.

For any positive integer m, let $[[m]] := \{0, 1, \dots, m-1\}$. For $\{m_i\}_{i=0}^{d-1} \subset \mathbb{Z}_+$, a d-dimensional tensor of shape $(m_0, m_1, \dots, m_{d-1})$ is a function

$$T\colon [[m_0]] \times [[m_1]] \times \cdots \times [[m_{d-1}]] \to \mathbb{R}.$$

We exclusively use one-dimensional tensors (vectors), two-dimensional tensors (matrices), and three-dimensional tensors. A specific dimension of a tensor is called an *axis*. We now introduce the tensor operations utilized in our algorithm.

1. Zeros: Given a shape L, $\texttt{zeros}(L)$ is the tensor with shape L, where every value is 0.
2. Element-wise operations: Any function $f\colon \mathbb{R} \to \mathbb{R}$ can be applied to tensors element-wise by post-composition. That is, if T is a tensor, then $f(T)$ is the tensor with the same shape as T and values $f(T)[i_0, i_1, \dots, i_{d-1}] = f\big(T[i_0, i_1, \dots, i_{d-1}]\big)$.
3. Matrix multiplication: If T and S are tensors with shape (m_0, m_1) and (m_1, m_2) respectively, we use the notation $T * S$ to denote their matrix multiplication.
4. Cumulative sum: Let T be a tensor of shape (m_0, m_1). Then, $\texttt{CumulativeSum}(T)$ is the tensor with shape (m_0, m_1) and values

$$\texttt{CumulativeSum}(T)[i, j] = \sum_{\substack{k \in [[m_1]] \\ k \le j}} T[i, k].$$

   In this work, we use the cumulative sum on two-dimensional tensors along the second axis. However, the cumulative sum can be defined over any axis of a tensor.
5. Reduce maximum: Let T be a tensor of shape $(m_0, m_1, \dots, m_{d-1})$ and let $p \in [[d]]$. Then, $\texttt{ReduceMax}(T, p)$ is the tensor with shape $(m_0, \dots, m_{p-1}, m_{p+1}, \dots, m_{d-1})$ and values

$$\texttt{ReduceMax}(T, p)[i_0, \dots, i_{p-1}, i_{p+1}, \dots i_{d-1}] = \max_{j \in [[m_p]]} T[i_0, \dots, i_{p-1}, j, i_{p+1}, \dots i_{d-1}].$$

6. Advanced indexing: Let T be a tensor with shape (m_2, m_3), and let I be a tensor with shape (m_0, m_1) and values in $[[m_2]]$. The tensor $T[I]$ has shape (m_0, m_1, m_3) and values

$$T[I][i, j, k] = T\big[I[i, j], k\big].$$

7. Scatter add: Let S be a tensor with shape (m_0, m_1), let I be a tensor with shape (m_0, m_2) and values in $[[m_1]]$, and let T be a tensor with shape (m_2). The function $\texttt{ScatterAdd}(I, T)$ updates S in-place by adding to it the difference tensor D with shape (m_0, m_1) and values

$$D[i, j] = \sum_{\substack{k \in [[m_2]] \\ I[i,k] = j}} T[k]. \tag{4}$$

   That is, for a tensor S, we have $\texttt{ScatterAdd}(I, T)(S) = S + D$, where $+$ is taken element-wise and S is updated in place. In practice, the tensor D is not explicitly built.

3 Computation of WECFs

In this section, we present a new algorithm for computing the WECFs of a weighted simplicial complex with respect to a finite set of vertex filters. Computation of the WECT of a weighted geometric simplicial complex is a special case of Algorithm 1, and corresponds to the case where the vertex filters are height functions; see Example 10.

We fix a weighted simplicial complex $\mathbb{K} = (K, \omega)$ and a set of vertex filters $\{f_0, f_1, \ldots, f_{m-1}\}$ for the entirety of this section. To simplify notation, we extend each $f_p \colon K_0 \to \mathbb{R}$ to K by defining $f_p^{\max} \colon K \to \mathbb{R}$ as

$$f_p^{\max}(\sigma) = \max_{v \in \sigma} f_p(v).$$

We fix enumerations $K_0 = \{v_0, v_1, \ldots, v_{k_0-1}\}$ and $K_i = \{\sigma_0^i, \sigma_1^i, \ldots, \sigma_{k_i-1}^i\}$ for each $i \geq 1$.

Our algorithm uses the following inputs

- `Complex`: A list of tuples:
  - `Complex`$[0] =$ (`Filters`, `VertexWeights`)
    - `Filters` is a tensor with shape (k_0, m) and values `Filters`$[a, p] = f_p(v_a)$.
    - `VertexWeights` is a tensor with shape (k_0) and values `VertexWeights`$[a] = \omega(v_a)$.
  - for $i \geq 1$: `Complex`$[i] =$ (i-`SimplexVertices`, i-`SimplexWeights`)
    - i-`SimplexVertices` is a tensor with shape $(k_i, i+1)$ and values in $[[k_0]]$. The rows of this tensor correspond to the vertex sets of each i-simplex.
    - i-`SimplexWeights` is a tensor with shape (k_i) and values i-`SimplexWeights`$[b] = \omega(\sigma_b^i)$.
- `NumVals`: The number of values to sample the filter functions over.

In order to discretize the filtration height parameter, define `MaxVal` as

$$\texttt{MaxVal} = \max_{\substack{p \in [[m]] \\ v \in K_0}} |f_p(v)|.$$

We discretize $[-\texttt{MaxVal}, \texttt{MaxVal}]$ by evenly sampling `NumVals` points. That is, we define the map $\beta \colon [[\texttt{NumVals}]] \to [-\texttt{MaxVal}, \texttt{MaxVal}]$ by

$$\beta(q) = q \frac{2 * \texttt{MaxVal}}{\texttt{NumVals} - 1} - \texttt{MaxVal}.$$

The function β has a left inverse $\alpha \colon [-\texttt{MaxVal}, \texttt{MaxVal}] \to [[\texttt{NumVals}]]$ defined as

$$\alpha(t) = \left\lceil \frac{(\texttt{NumVals} - 1)(\texttt{MaxVal} + t)}{2 * \texttt{MaxVal}} \right\rceil. \tag{5}$$

The maps α and β are order-preserving and satisfy

$$\alpha(t) \leq q \iff t \leq \beta(q) \tag{6}$$

for all $t \in [-\texttt{MaxVal}, \texttt{MaxVal}]$ and $q \in [[\texttt{NumVals}]]$.[5]

Here, we prove that Algorithm 1 produces the tensor `WECFs` with shape $(m, \texttt{NumVals})$ and values

$$\texttt{WECFs}[p, q] = \mathrm{WECF}_{f_p}\big(\beta(q)\big). \tag{7}$$

[5] In other words, α and β form a Galois connection.

Algorithm 1 `ComputeWECFs(Complex, NumVals)`.

Input: `Complex`, `NumVals`
Output: `WECFs`: a tensor of shape $(m, \texttt{NumVals})$ and values $\texttt{WECFs}[p,q] = \mathrm{WECF}_{f_p}(\beta(q))$.

```
Filters, VertexWeights ← Complex[0]
diffWECFs ← zeros(m, NumVals)

VIndices ← α(Filters)
ScatterAdd(VIndices^T, VertexWeights)(diffWECFs)

for i = 1 to dim(K) do
    SimplexVertices, SimplexWeights ← Complex[i]
    SimpIndices ← VIndices[SimplexVertices]
    MaxSimpIndices ← ReduceMax(SimpIndices, 1)

    ScatterAdd(MaxSimpIndices^T, (−1)^i * SimplexWeights)(diffWECFs)
end for

WECFs ← CumulativeSum(diffWECFs)
return WECFs
```

The algorithm begins by initializing a zero-tensor `diffWECFs` with shape $(m, \texttt{NumVals})$. Next, the vertex filter values are mapped to indices in $[[\texttt{NumVals}]]$ by applying the map α elementwise to the tensor `Filters`. This gives the tensor `VIndices` with values

$$\texttt{VIndices}[a,p] = \alpha\big(f_p(v_a)\big). \tag{8}$$

The operation $\texttt{ScatterAdd}(\texttt{VIndices}^T, \texttt{VertexWeights})$ is then applied to `diffWECFs`, resulting in adding to `diffWECFs` the tensor D_0 with shape $(m, \texttt{NumVals})$ and values

$$D_0[p,q] = \sum_{\substack{a \in [[k_0]] \\ \texttt{VIndices}[a,p]=q}} \texttt{VertexWeights}[a].$$

Next, inside the for-loop, fix an $i \in \{1, 2, \ldots, \dim(K)\}$. The tensor `SimplexVertices` has rows indexed by K_i with the entries in each row corresponding to the vertex sets of simplices in K_i. Therefore, the tensor `MaxSimpIndices` has shape (k_i, m) and values

$$\begin{aligned}
\texttt{MaxSimpIndices}[b,p] &= \max_{j \in [[i+1]]} \texttt{VIndices}\big[\texttt{SimplexVertices}[b,j], p\big] \\
&= \max_{v \in \sigma_b^i} \alpha\big(f_p(v)\big) \\
&= \alpha\big(\max_{v \in \sigma_b^i} f_p(v)\big) \qquad \text{as } \alpha \text{ is order-preserving} \\
&= \alpha\big(f_p^{\max}(\sigma_b^i)\big).
\end{aligned} \tag{9}$$

The operation $\texttt{ScatterAdd}(\texttt{MaxSimpIndices}^T, (-1)^i * \texttt{SimplexWeights})$ updates `diffWECFs` by adding to it the tensor D_i with shape $(m, \texttt{NumVals})$ and values

$$D_i[p,q] = \sum_{\substack{b \in [[k_i]] \\ \texttt{MaxSimpIndices}[b,p]=q}} (-1)^i \texttt{SimplexWeights}[b].$$

After the conclusion of the for loop, we have $\texttt{diffWECFs} = \sum_{i=0}^{\dim(K)} D_i$. Finally, a cumulative sum is applied to `diffWECFs` to obtain the tensor `WECFs`. From the fact that the cumulative sum is a linear operator, we have

$$\texttt{WECFs} = \sum_{i=0}^{\dim(K)} \texttt{CumulativeSum}(D_i).$$

The cumulative sum of D_0 has values

$$\begin{aligned}
\texttt{CumulativeSum}(D_0)[p,q] &= \sum_{q' \le q} \sum_{\substack{a \in [[k_0]] \\ \texttt{VIndices}[a,p] = q'}} \texttt{VertexWeights}[a] \\
&= \sum_{\substack{a \in [[k_0]] \\ \texttt{VIndices}[a,p] \le q}} \texttt{VertexWeights}[a] \\
&= \sum_{\substack{a \in [[k_0]] \\ \alpha(f_p(v_a)) \le q}} \texttt{VertexWeights}[a] && \text{by Equation (8)} \\
&= \sum_{\substack{a \in [[k_0]] \\ f_p(v_a) \le \beta(q)}} \texttt{VertexWeights}[a] && \text{by Equation (6)} \\
&= \sum_{\substack{v \in K_0 \\ f_p(v) \le \beta(q)}} \omega(v). && (10)
\end{aligned}$$

Likewise, for any $i \in \{1, \dots, \dim(K)\}$, Equation (9) together with the same argument used to show Equation (10) gives

$$\texttt{CumulativeSum}(D_i)[p,q] = \sum_{\substack{\sigma \in K_i \\ f_p^{\max}(\sigma) \le \beta(q)}} (-1)^i \omega(\sigma).$$

Therefore, the tensor `WECFs` has values

$$\begin{aligned}
\texttt{WECFs}[p,q] &= \sum_{\substack{v \in K_0 \\ f_p(v) \le \beta(q)}} \omega(v) + \sum_{i=1}^{\dim(K)} \sum_{\substack{\sigma \in K_i \\ f_p^{\max}(\sigma) \le \beta(q)}} (-1)^i \omega(\sigma) \\
&= \sum_{\substack{\sigma \in K \\ f_p^{\max}(\sigma) \le \beta(q)}} (-1)^{\dim(\sigma)} \omega(\sigma) \\
&= \mathrm{WECF}_{f_p}\left(\beta(q)\right).
\end{aligned}$$

▶ **Example 10.** Computing a discretization of the WECT of a weighted simplicial complex $\mathbb{K} = (K, \omega)$ with a map $\ell \colon K_0 \to \mathbb{R}^n$ is a special case of Algorithm 1 as follows. Consider a tensor D, with shape (d, n), of direction vectors over which to sample the WECT. For any $p \in [[d]]$, let $\mathbf{s}_p \in \mathbb{R}^n$ be the p-th row of D. Let V be the tensor, with shape (k_0, n), of the vertex coordinates of K. Then, the tensor $V * D^T$ has values

$$(V * D^T)[a,p] = h_{\mathbf{s}_p}(v_a).$$

Therefore, using the tensor $V * D^T$ as the `Filters` tensor in Algorithm 1 produces a discretization of the WECT over the finite sample of directions in D.

3.1 Complexity Analysis

Here, we analyze the asymptotic complexity of Algorithm 1. Assume that the ambient dimension n is fixed. Let k be the total number of simplices of K, let m be the number of vertex filters, and let `NumVals` be the number of values to sample the vertex filters over.

The input `Complex` requires $\Theta(km)$ memory usage. The algorithm first initializes a zero tensor `diffWECFs` of shape $(m, \texttt{NumVals})$, requiring $\Theta(m\texttt{NumVals})$ memory. The function α (see Equation (5)) is then applied elementwise to `Filters`, taking $\Theta(km)$ time.

Next, the operation $\texttt{ScatterAdd}(\texttt{VIndices}^T, \texttt{VertexWeights})$ is applied to `diffWECFs`. ScatterAdd adds a value from `VertexWeights` to `diffWECFs` for each entry of $\texttt{VIndices}^T$, resulting in a time complexity of $\Theta(km)$ and no additional memory usage as the operation is performed in place.

Now, for a fixed dimension $i \in \{1, 2, \dots n\}$, the tensor

$$\texttt{SimpIndices} = \texttt{VIndices}[\texttt{SimplexVertices}]$$

with shape $(k_i, i+1, m)$ is constructed, taking $\Theta(km)$ time and memory. This tensor is then reduced along the second axis by taking the maximum values, creating the tensor `MaxSimpIndices` with shape (k_i, m) in $\Theta(km)$ time and memory. The tensor `diffWECFs` is then updated by applying the map

$$\texttt{ScatterAdd}(\texttt{MaxSimpIndices}^T, (-1)^i * \texttt{SimplexWeights})$$

which takes $\Theta(km)$ time and memory.

Thus, we have a total time and memory complexity of $\Theta(nkm) = \Theta(km)$ after conclusion of the for-loop. Finally, a cumulative sum is applied to `diffWECFs`, taking $\Theta(m\texttt{NumVals})$ time and using no additional memory. This results in $\Theta(m(k + \texttt{NumVals}))$ for Algorithm 1 as the final time and memory complexity. In practice, m and `NumVals` are typically held constant. Indeed, this is necessary to achieve consistent vectorizations of data. Holding m and `NumVals` constant results in a final time and memory complexity of $\Theta(k)$ for Algorithm 1.

4 Experiments

In order to demonstrate the efficacy of our implementation, we evaluate and compare the runtime of Algorithm 1 with existing methods (see Section 2.2) on a variety of datasets.[6]

4.1 Experimental Design

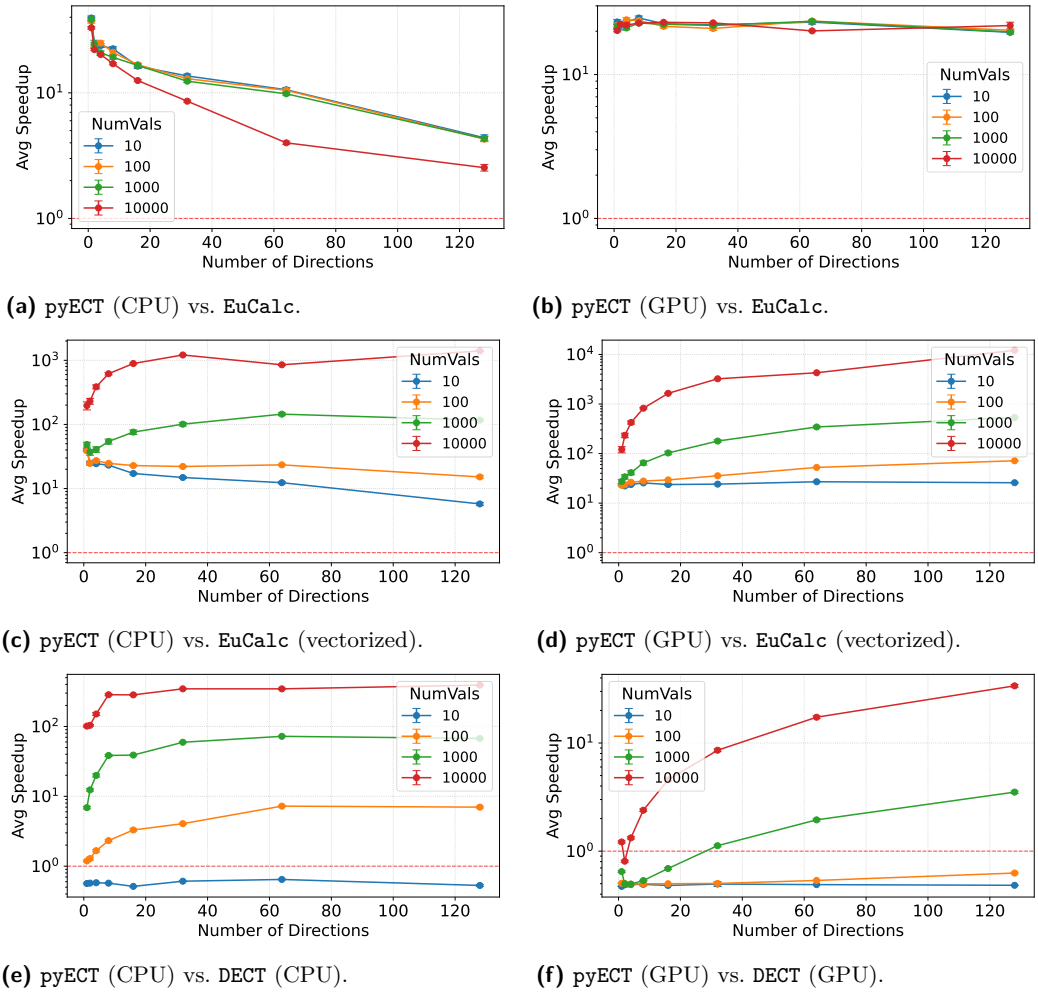
Experiments were performed on a single node with a single CPU or a single GPU (unless otherwise specified). EPYC Rome CPUs and NVIDIA A100 GPUs were used. Runtimes for CPU experiments were recorded using the `time` Python library using the performance counter for benchmarking. For the GPU experiments, runtimes were recorded using `PyTorch`'s `torch.cuda.Event` API to prevent inaccurate timing from asynchronous GPU operations. The methods were evaluated on the following two- and three-dimensional datasets:

- **Fashion-MNIST** [27]. Fashion-MNIST is a dataset consisting of 28×28 grayscale images of clothing items. Its training partition consists of 60000 images with equal representation

[6] The implementation of `pyECT` can be accessed here: `https://anonymous.4open.science/r/pyECT-anonymous-902F/`. The source code for reproducing experiments (with instructions) is available here: `https://anonymous.4open.science/r/pyECT-experiments-anonymous-0E4F/`.

across ten classes (6000 images per class). In our experiments, we use a random subset of 1000 images sampled uniformly without replacement from the training partition, which are then converted to cubical complexes.

- **ImageNet** [7, 20]. The ImageNet Sample Image dataset [20], which consists of 1000 samples from the Large Scale Visual Recognition Challenge (ILSVRC) 2012-2017 subset of the ImageNet dataset [7] was used. All images in the sample were converted to grayscale using the ITU-R 601-2 luma transform within the Pillow Python library [5]. Then, the images were padded to the maximum dimensions of all images in the dataset, resulting in each image having uniform size of 1632×2400 pixels. The padded pixels were assigned a pixel intensity value of 1.0 (on a zero to one scale), and the images were converted to cubical complexes.
- **3DCCs**. A synthetic dataset of 1000 three-dimensional cubical complexes was generated. Each complex has dimension $100 \times 100 \times 100$, with pixel intensities drawn i.i.d. from the uniform distribution on $[0, 1]$.
- **Stanford Bunny and Armadillo** [22]. The Stanford 3D Scanning Repository provides triangulated mesh models of three-dimensional objects. We use the Bunny and Armadillo models. The meshes were converted to (unweighted) simplicial complexes after preprocessing to de-duplicate vertices, edges, and faces. In the resulting simplicial complexes, the Bunny dataset consists of 2503 vertices, 7473 edges, and 4968 faces. The Armadillo is significantly larger, consisting of 172974 vertices, 518916 edges, and 345944 faces.



4.2 Results

We now present the experimental results, measured by the average speedup factor of our method over existing methods. The average speedup factor is defined as the runtime of the baseline method (e.g., `EuCalc`, `DECT`, or `FastTopology`) divided by the runtime of the proposed method, `pyECT`, averaged across all images in the dataset. Across all figures, error bars represent 95% confidence intervals.

WECT Results

In this section, we present results on the average speedup of `pyECT` over `EuCalc` and `DECT` when computing the WECT of the Fashion-MNIST and ImageNet datasets. As `EuCalc` does not provide a GPU implementation, all results for `EuCalc` are measured on the CPU. Also, as `EuCalc` does not natively provide a vectorized result, we provide results both including and excluding the vectorization time.

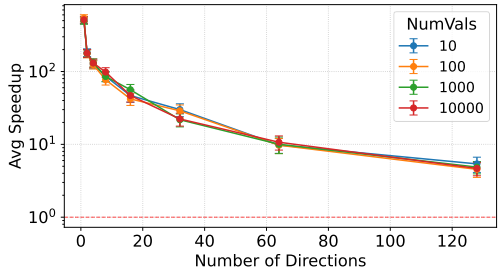
The results for Fashion-MNIST are shown in Figure 2. Across all settings, `pyECT` demonstrates speedups over both `EuCalc` and `DECT`. When comparing against `EuCalc` (Figure 2(a)–(d)), `pyECT` demonstrates a speedup in both CPU and GPU implementations – even without the vectorization step. However, the GPU implementation of `pyECT` significantly outperforms the CPU implementation as the number of directions increases, which is especially pronounced when including the vectorization time for `EuCalc`. As expected, when increasing the number of values used in the filtration, the speedup factor of `pyECT` over `EuCalc` increases drastically. When comparing against `DECT` (subfigures (e) and (f)), `pyECT` also demonstrates significant speedups. While the computation speed is comparable for low numbers of directions and filtration heights, `pyECT` significantly outperforms `DECT` for larger choices of parameters. Also, as `DECT` is optimized for GPU architectures, the average speedup on GPU architectures is less pronounced than that of other comparisons. However, when constrained to CPU architectures, `pyECT` is much faster, indicating another advantage of `pyECT`'s general applicability for all scenarios.

(a) `pyECT` (CPU) vs. `EuCalc`.

(b) `pyECT` (GPU) vs. `EuCalc`.

(c) `pyECT` (CPU) vs. `EuCalc` (vectorized).

(d) `pyECT` (GPU) vs. `EuCalc` (vectorized).



(e) `pyECT` (CPU) vs. `DECT` (CPU).

(f) `pyECT` (GPU) vs. `DECT` (GPU).

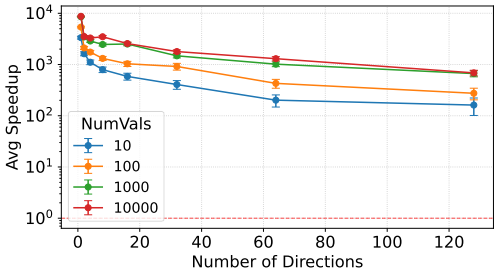


Figure 2 A comparison for computing on the Fashion-MNIST dataset for WECT computation. Figures (a) and (b) compare `pyECT` with `EuCalc` excluding the vectorization time, (c) and (d) compare `pyECT` with `EuCalc` including the vectorization time, and (e) and (f) compare `pyECT` with `DECT`. CPU implementations of `pyECT` are shown on the left and GPU implementations are shown on the right. Vertical axes are not consistent across subfigures. In nearly all cases, `pyECT` outperforms the baseline methods. This behavior is especially pronounced when using the GPU architecture with large numbers of directions and filtration heights.

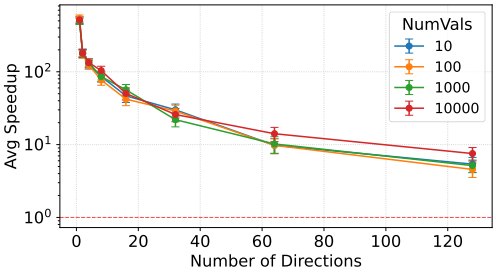
The average speedup results on the ImageNet are shown in Figure 3. When comparing against `EuCalc` (both with and without the vectorization step, in Figures 3a–3d), `pyECT` demonstrates a significant speedup in both CPU and GPU implementations. This speedup is especially pronounced for the GPU implementation of `pyECT`, as it is much more stable to large numbers of directions and filtration height values. Due to the large size of the complexes in this dataset, the CPU speedup of `pyECT` is less pronounced than on the Fashion-MNIST dataset (especially for large numbers of directions and heights). Furthermore, the vectorization time of `EuCalc` is less impactful on this dataset, as the vectorization step is less significant compared to the overall runtime for the large complexes. In the GPU implementation of `pyECT`, we observe a trend where the average speedup increases as the number of height filtration values increases. While this behavior appears counterintuitive, in reality the vectorized code encounters less efficient memory access patterns at lower numbers



of heights, which leads to a smaller advantage over `EuCalc` with the smaller tensor values. For a technical description of memory access patterns specific to the GPU hardware used in these experiments, we refer the reader to [8]. In the comparison against `DECT` (Figures 3e and 3f), `pyECT` again demonstrates significant speedups. In fact, due to the large size of the complexes in this dataset, `DECT` was unable to compute the WECT for large numbers of directions and height values (due to memory constraints on the GPU). This results in the appearance of missing values in Figures 3e and 3f. Note, however, that `pyECT` is still able to compute the WECT in these scenarios, demonstrating its memory efficiency. Furthermore, in the cases where the WECT could be computed by `DECT`, the `pyECT` implementation outperforms `DECT` for larger numbers of directions and height filtration values.

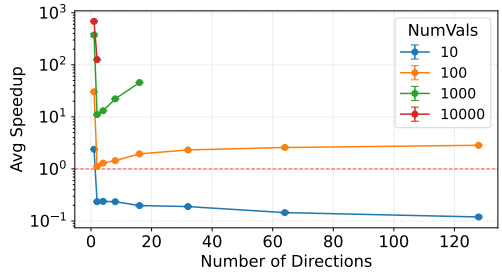
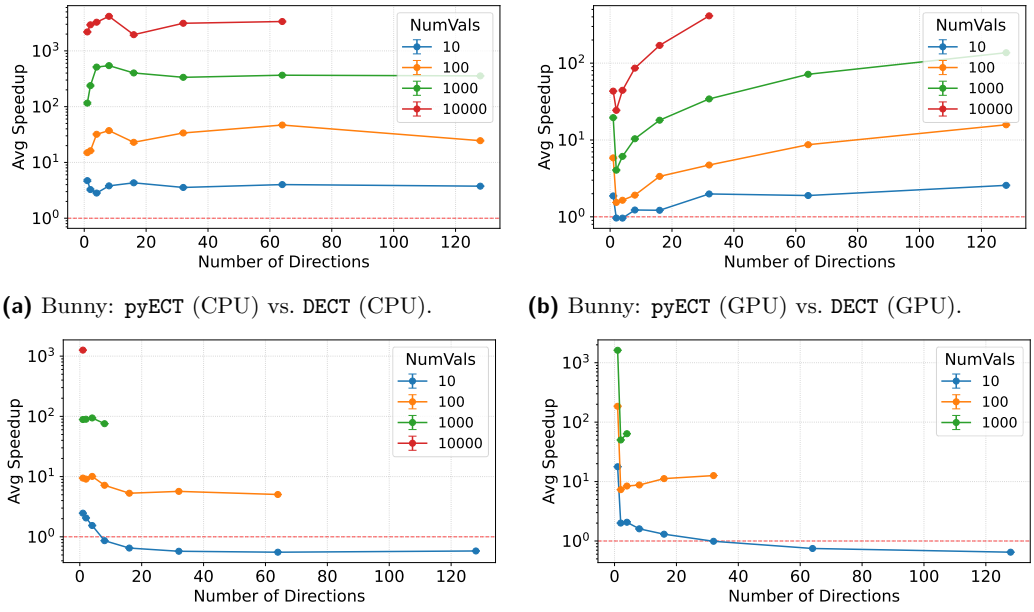
(b) `pyECT` (GPU) vs. `EuCalc`.



(c) `pyECT` (CPU) vs. `EuCalc` (vectorized).

(d) `pyECT` (GPU) vs. `EuCalc` (vectorized).

(e) `pyECT` (CPU) vs. `DECT` (CPU).



(f) `pyECT` (GPU) vs. `DECT` (GPU)

Figure 3 A comparison for computing on the ImageNet dataset for WECT computation. Figures (a) and (b) compare `pyECT` with `EuCalc` excluding the vectorization time, (c) and (d) compare `pyECT` with `EuCalc` including the vectorization time, and (e) and (f) compare `pyECT` with `DECT`. Note that vertical axes are not consistent across subfigures. `DECT` was unable to compute the WECT for large numbers of directions and heights due to memory constraints, resulting in missing values in (e) and (f). However, `pyECT` was able to compute the WECT in these scenarios.

Speedup results for the comparison of `pyECT` against `DECT` on the three-dimensional mesh datasets are presented in Figure 4. Note that experiments were run 10 times on each mesh dataset to generate the average and confidence interval values shown in the plots.

For large choices of directions and filtration heights in both datasets, `DECT` was unable to compute the ECT due to memory constraints. While this results in missing values in all subplots, from the cases where `DECT` was able to compute the ECT, `pyECT` outperforms `DECT` (especially for larger choices of parameters). The memory issues are more pronounced in the Armadillo dataset (due to its larger size). Note that while `pyECT` demonstrates significant speedups in the GPU implementations, its advantage is even more pronounced in the CPU implementations, highlighting the versatility of `pyECT` across different hardware architectures.

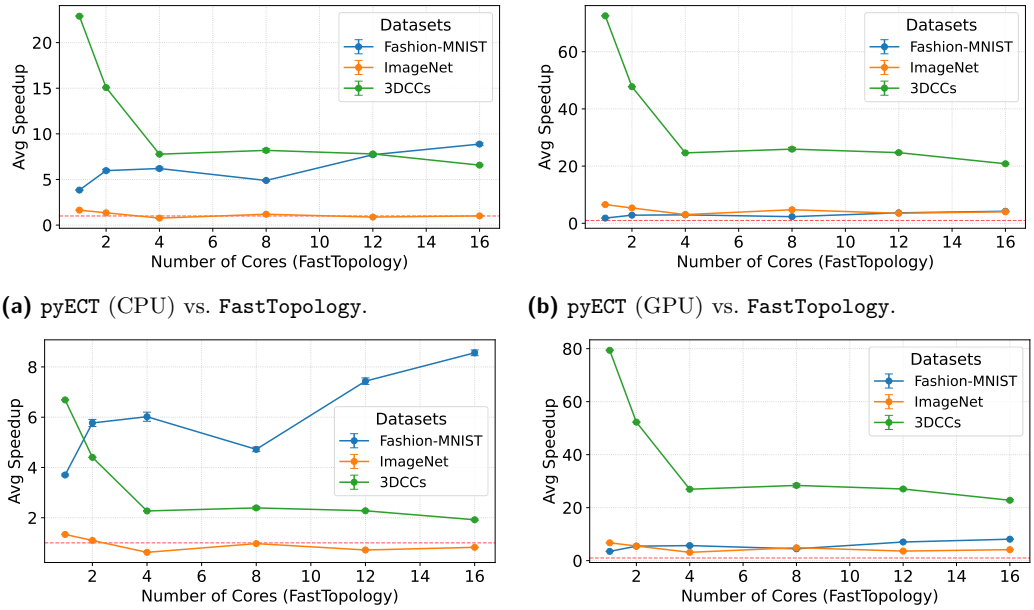
(b) Bunny: `pyECT` (GPU) vs. `DECT` (GPU).

(c) Armadillo: `pyECT` (CPU) vs. `DECT` (CPU).



(d) Armadillo: `pyECT` (GPU) vs. `DECT` (GPU).

Figure 4 A comparison of `pyECT` against `DECT` for computing the ECT on the Stanford Bunny and Armadillo meshes. Note that vertical axes are not consistent across subfigures. In many cases, `DECT` was unable to compute the ECT due to memory constraints (leading to missing values in the plots). However, `pyECT` was able to compute the ECT in all scenarios, and especially outperforms `DECT` for large numbers of directions and filtration heights.

ECF Results

In this section, we present the speedup of `pyECT` over `FastTopology` when computing the ECF of the Fashion-MNIST, ImageNet, and 3DCCs datasets. Due to the consistent computation graph structure of the ECF algorithm, `pyECT` is able leverage the PyTorch TorchDynamo compilation framework. These compiled runtimes are also measured and compared with `FastTopology`. As `FastTopology` is parallelizable across multiple CPU cores, we include results for `FastTopology` using 1, 2, 4, 8, 12, and 16 CPU cores. Note that `FastTopology` does not provide a GPU implementation. The results are presented in Figure 5. We observe that `pyECT` provides a significant speedup over `FastTopology` in nearly all cases. When constrained to CPU architectures, `pyECT` has a less pronounced speedup, but is still comparable in speed on a single CPU core when compared with the fully parallelized `FastTopology` implementation. When utilizing GPU architectures, `pyECT` demonstrates a significant speedup over the fully parallelized `FastTopology`, especially on the three-dimensional 3DCCs dataset. The compilation strategy further increases the speed of `pyECT` on GPU architectures, but adds unrewarded overhead on CPU architectures.

Next, to verify the efficiency of the computation on the GPU, we compute the ECF of 2D and 3D images with intensity drawn uniformly and measure throughput as in [25, 26]. For 2D images (sizes 2048^2, 4096^2, and 8192^2) with data pre-loaded into GPU memory, uncompiled `pyECT` achieves 1.11–1.13 GPix/s at 1,000 thresholds and 2.40–2.52 GPix/s at 10,000 thresholds, while the compiled version achieves 1.28–1.32 GPix/s and 2.52–4.11 GPix/s, respectively. For 3D images (sizes 128^3, 256^3, and 512^3), uncompiled `pyECT` achieves 0.48–0.49 GVox/s at 1,000 thresholds and 1.05–1.09 GVox/s at 10,000 thresholds, while the compiled version achieves 0.43–0.56 GVox/s and 1.09–1.76 GVox/s, respectively.

(a) `pyECT` (CPU) vs. `FastTopology`.

(b) `pyECT` (GPU) vs. `FastTopology`.

(c) `pyECT` (compiled, CPU) vs. `FastTopology`.

(d) `pyECT` (compiled, GPU) vs. `FastTopology`.

Figure 5 A comparison of average speedup of `pyECT` over `FastTopology` when computing the ECF of multiple datasets. The comparison evaluates both uncompiled and compiled versions of `pyECT`. Note that vertical axes are not consistent across subfigures.

5 Discussion

In this work, we present a tensor-based framework for computing WECFs (including ECFs and the WECT). This framework allows for efficient computation of these functions using tensor operations, which are well-suited for modern GPU hardware. Furthermore, our method works in full generality for weighted simplicial complexes (or cubical complexes) of arbitrary dimension. Our framework is implemented in a publicly available Python package called `pyECT`. Experimentally, `pyECT` demonstrates a significant speedup over existing methods across a variety of datasets.

The `pyECT` package also contains a variety of tools for constructing and working with simplicial/cubical complexes. Our package includes fully vectorized methods for building weighted Freudenthal complexes and weighted cubical complexes from images. Additionally, `pyECT` has dedicated methods for computing ECFs of images and WECTs of weighted geometric simplicial complexes in $\mathbb{R}^n$. These two special cases are implemented as `PyTorch` neural network modules. Future work includes using this framework in differentiable forms

of topological transforms (as in [17]) and incorporating these transforms into neural network architectures. Additionally, we believe that this work will encourage further investigation into vectorized methods for computing other topological functions and transforms.

Abstract

The k-means problem is a classic objective for modeling clustering in a metric space. Given a set of points in a metric space, the goal is to find k representative points so as to minimize the sum of the squared distances from each point to its closest representative. In this work, we study the approximability of k-means in Euclidean spaces parameterized by the number of clusters, k.

In seminal works, de la Vega, Karpinski, Kenyon, and Rabani [STOC'03] and Kumar, Sabharwal, and Sen [JACM'10] showed how to obtain a $(1+\varepsilon)$-approximation for high-dimensional Euclidean k-means in time $2^{(k/\varepsilon)^{O(1)}} \cdot dn^{O(1)}$.

In this work, we introduce a new fine-grained hypothesis called *Exponential Time for Expanders Hypothesis* (XXH) which roughly asserts that there are no non-trivial exponential time approximation algorithms for the vertex cover problem on near perfect vertex expanders. Assuming XXH, we close the above long line of work on approximating Euclidean k-means by showing that there is no $2^{(k/\varepsilon)^{1-o(1)}} \cdot n^{O(1)}$ time algorithm achieving a $(1+\varepsilon)$-approximation for k-means in Euclidean space. This lower bound is tight as it matches the algorithm given by Feldman, Monemizadeh, and Sohler [SoCG'07] whose runtime is $2^{\widetilde{O}(k/\varepsilon)} + O(ndk)$.

Furthermore, assuming XXH, we show that the seminal $O(n^{kd+1})$ runtime exact algorithm of Inaba, Katoh, and Imai [SoCG'94] for k-means is optimal for small values of k.

1 Introduction

The k-clustering problem represents a fundamental task in data mining and machine learning, providing a model for grouping data points based on similarity. Given a set of points P in a metric space (X, Δ), the objective is to select a set $C \subseteq X$ of k points, referred to as *centers*, and the goal is to minimize an objective function typically defined as the sum of the z-th powers of the distances from each point $p \in P$ to its nearest center in C. This general formulation encompasses several widely studied problems: k-median corresponds to $z = 1$, k-means uses $z = 2$ (minimizing the sum of squared distances), and k-center is when $z \to \infty$ (minimizing the maximum distance).

The algorithmic exploration of k-means, arguably the most popular variant, gained significant traction with the seminal work of Lloyd [49]. Since then, the problem has attracted substantial attention across diverse research communities, including operations research, machine learning, and theoretical computer science.

The computational complexity of k-means problem inherently depends on the structure of the underlying metric space (X, d) and this paper focuses on the setting where points reside in Euclidean space $\mathbb{R}^d$. From a complexity theoretic perspective, Euclidean k-means is known to be NP-Hard even under seemingly restricted conditions, such as when the points lie in the Euclidean plane ($\mathbb{R}^2$) but k is part of the input [58, 51], or when $k = 2$ but the dimension d is large [24, 5]. On the algorithmic side, the best-known exact algorithm for Euclidean k-means was proposed by Inaba, Katoh, and Imai [40], running in time $O(n^{kd+1})$. Remarkably, this has remained the state-of-the-art exact algorithm for over three decades.

Given the hardness of finding exact solutions, particularly in high dimensions, a significant line of research has focused on developing efficient $(1+\varepsilon)$-approximation algorithms. Early breakthroughs by Fernandez de la Vega, Karpinski, Kenyon, and Rabani [30] and Kumar, Sabharwal, and Sen [46] demonstrated that a $(1+\varepsilon)$-approximation for high-dimensional Euclidean k-means could be achieved in time $2^{(k/\varepsilon)^{O(1)}} \cdot dn^{O(1)}$. Subsequent improvements, leveraging techniques such as *coresets* by Feldman, Monemizadeh, and Sohler [29], refined the runtime to $O(ndk) + 2^{\widetilde{O}(k/\varepsilon)}$. Further work by Jaiswal, Kumar, and Sen [42], followed by Jaiswal, Kumar, and Yadav [43], utilized a simpler approach based on D^2*-sampling* to achieve $O(nd \cdot 2^{\widetilde{O}(k/\varepsilon)})$ runtime (see also [1, 10] for a generalized approach).

All these different approaches seem to have hit a running-time barrier at $2^{k/\varepsilon}$ (up to logarithmic factors in the exponent). This contrasts sharply with the related k-center problem, where Agarwal and Procopiuc [4] showed that a $(1+\varepsilon)$-approximation can be obtained much faster, in time $n \log k + (k/\varepsilon)^{O(k^{1-1/d})}$. This runtime for k-center is known to be essentially optimal under the Exponential Time Hypothesis (ETH) [13]. Furthermore, there exists a close relationship between k-means and the Partial Vertex Cover (PVC) problem; indeed, many known hard instances for k-means are derived from hard PVC instances [7, 48, 18]. Interestingly, Manurangsi [53] demonstrated that PVC admits a $(1+\varepsilon)$-approximation in time $\varepsilon^{-O(k)} n^{O(1)}$ (where k is the solution size). This implies that the specific k-means instances derived from PVC can be approximated more efficiently than the runtime of the current best $(1+\varepsilon)$-approximation algorithms for Euclidean k-means.

This discrepancy motivates the central question of our work: When parameterized by the number of clusters k, is the current exponential dependency in k/ε for approximating Euclidean k-means inherent, signifying a fundamental computational gap compared to k-center and PVC-related instances? Or, is it possible to devise a significantly faster approximation algorithm, potentially achieving a runtime closer to those known for related problems and offering a more unified algorithmic picture for k-clustering? More concretely:

▶ **Question 1.** *Is it possible to design a* $(1+\varepsilon)$*-approximation to* k*-means running in time* $O(nd) + \varepsilon^{-O(k)}$ *?*

A negative answer to the above question would also imply progress toward understanding the hardness of exact algorithms. Currently, we are not aware of any fine-grained lower bound that matches the algorithm of Inaba et al. [40]. The closest result we know of is by Cohen-Addad, de Mesmay, Rotenberg, and Roytman [14], who showed that if the centers must be selected from a prescribed set of "candidate centers", then no exact algorithm with a runtime of $n^{o(k)}$ exists for k-median or k-means, even when the dimension is four. It remains an open problem whether a similar result holds for the classic version where centers can be placed anywhere in $\mathbb{R}^d$, and whether an $n^{o(d)}$ lower bound also applies when k is constant.

A negative answer to Question 1 would answer those two questions: modern dimension-reduction [52] and coreset computation [23] reduce the dimension and the number of distinct input points while preserving the clustering cost within a $(1 \pm \varepsilon)$ factor. Thus, as we show in the full version, any lower bound for approximation algorithms translates into a lower bound for exact algorithms, making progress toward demonstrating the optimality of [40].

Negative answers to such questions typically arise from *fine-grained complexity* assumptions, such as the Exponential Time Hypothesis (ETH) [38, 39], or the more modern Gap Exponential Time Hypothesis (Gap-ETH) [55, 26]. Indeed these two assumptions have been very fruitful in explaining the intractability of various important geometric optimization problems [56, 50, 25, 45]. However, Question 1 involves two parameters, k and ε. Suppose we aim to rule out $2^{(k/\varepsilon)^{1-o(1)}} \cdot \mathrm{poly}(n,d)$-time algorithms, then our parameter of interest is the quantity k/ε, where k and ε are free variables constrained only by the fixed ratio k/ε. To the best of our knowledge, such results are not known under ETH or Gap-ETH. In fact, proving such results entail several technical challenges which we discuss in Section 2.1.

1.1 Our Results

In this paper we make substantial progress towards answering these questions. We introduce a hypothesis morally capturing a Gap Exponential Time Hypothesis for Vertex Cover on Near Perfect Vertex Expanders, and we call it *E**x**ponential Time for E**x**panders **H**ypothesis* (denoted **XXH**). This hypothesis is formally stated in Section 3, but an informal discussion about the statement of this hypothesis is given in Section 2.2. Assuming XXH, we are able to answer Question 1 in the following way:

▶ **Theorem 2** (Answer to Question 1; informal statement)**.** *Assuming XXH, for every* $\beta > 0$*, there is no randomized algorithm running in time* $2^{(k/\varepsilon)^{1-\beta}} \cdot \mathrm{poly}(n,d)$ *that can* $(1+\varepsilon)$*-approximate the Euclidean* k*-means problem whenever* $k \gg 1/\varepsilon$*.*

The formal statement of the lower bound is Theorem 12. This result might appear surprising due to the known close connection between vertex cover and k-means. Specifically, a partial vertex cover can be approximated within a $(1+\varepsilon)$ factor in $\varepsilon^{-O(k)} n^{O(1)}$ time [53] (where k is the solution size). This might lead one to expect an approximation scheme for k-means with similar complexity.

For example, reductions such as those in Cohen-Addad et al. [14] and Awasthi et al. [7] (see also [48]) transform the vertex cover instance into a k-means instance by creating a point for each edge of the input graph and positioning the points in space such that pairs of edges sharing a common vertex are close to each other. The hardness proof then relies on distinguishing between two kinds of instances:

(1) Instances derived from graphs admitting a vertex cover of size k, i.e., the edge set can be partitioned to k stars. In this case, the corresponding point set can be partitioned into k clusters such that all points within the same cluster are close (say distance 1, representing edges covered by the same vertex from the cover).

(2) Instances derived from graphs where any set of k vertices leaves at least a constant fraction (say δ fraction) of the edges uncovered. Consequently, in any partitioning of the corresponding point set into k clusters, either a constant fraction of these clusters contain points that are far apart (say distance 3, i.e., representing pairs of edges that do not share one of the selected k vertices) or a few clusters contain a lot of points (and most pairs are far apart).

The hardness for k-means then follows from the difficulty of distinguishing between these two cases based on the clustering cost. Specifically, it involves separating instances admitting a lower cost (e.g., n, associated with Case 1) from those necessitating a higher cost (e.g., $(1-\delta)n + 2\delta n = n + \delta n$, associated with Case 2), where δ is related to the minimum fraction of uncovered edges in the latter case.

However, since partial vertex cover can be approximated within a $(1+\varepsilon)$ factor, for any $\varepsilon > 0$, in time $\varepsilon^{-O(k)}n^{O(1)}$, and since the objective scales linearly with the number of edges not covered (i.e., clients that are at squared distance 3, instead of 1, from their center), this type of instance can be solved in time $\varepsilon^{-O(k)}n^{O(1)}$. Therefore, one cannot expect to boost the lower bound running time from the partial vertex cover result to $2^{(k/\varepsilon)^{1-o(1)}}$.

Thus, to show that the k-means problem requires an exponential dependency in ε, we need to develop a novel reduction framework.

To establish the above conditional lower bound for the Euclidean k-means problem, we first reduce the vertex cover problem in the non-parameterized setting to an intermediate graph problem, essentially in the parameterized setting, but with reduced structure so as to fail standard algorithmic techniques for partial k-vertex cover, while retaining enough structure to embed the graph problem into the Euclidean k-means problem. We direct the reader to Section 2 for further details where we also try to clarify how vertex expansion in the vertex cover problem helps us overcome several technical difficulties.

Theorem 2 implies lower-bounds for exact algorithms as well:

▶ **Corollary 3.** *Assuming XXH, for every $\beta > 0$, there is no algorithm that for any k, d solves the Euclidean k-means problem in time $n^{(k\sqrt{d})^{1-\beta}}$, nor in time $n^{d^{1-\beta}}$.*

Note that this result contrasts the running time of k-means clustering with that of k-center, which admits an exact algorithm running in time $O\left(n^{k^{1-1/d}}\right)$ [4]. The current state of the art algorithm enumerating over all Voronoi partitions in time $O(n^{kd+1})$ by Inaba, Katoh and Imai [40] is thus a likely candidate for being optimal – in particular, it is almost optimal for constant k.

1.2 Further Related Work

Hardness of Clustering. As we mentioned previously, the k-means and k-median problems are NP-hard, even when $k = 2$ (and d is large) [24, 5], or when $d = 2$ (and k is large) [58, 51]. When both parameters are part of the input, the problems become APX-hard [32, 41, 33, 7, 19, 20]. Most techniques to show hardness of approximation are based on reducing from covering problems to clustering problems, for instance through structured instances of max k-coverage or set cover. Recent works have used different approaches: [19] showed how to use hardness of some coloring problems to prove hardness of approximation for k-median and k-means in general metric spaces, and [20] focused on Euclidean spaces and tried to pinpoint what combinatorial structures allow for gap-preserving embeddings to Euclidean space.

For general metrics, the connection between k-clustering and the set cover problem (or rather max-coverage) has been known since the fundamental work of Guha and Khuller [32], who established the best known hardness of approximation bounds. This connection was observed again when analyzing the parameterized complexity of the problem: Cohen-Addad, Gupta, Kumar, Lee and Li [17] showed how to approximate k-median and k-means up to factors $1 + 2/e$ and $1 + 8/e$ respectively and showed that this is tight assuming Gap-ETH (see also [22, 54, 3, 12, 35]).

FPT algorithms via Sketching. The past decades have seen the development of very powerful sketching and compression methods that allow reducing the dimension to $O(\log k/\varepsilon^2)$ [52] and the number of distinct input points to $\widetilde{O}(k\varepsilon^{-z-2})$ ($z = 1$ for k-median, $z = 2$ for k-means) via the construction of coresets [28, 11, 37, 23, 21]. Perhaps surprisingly, these bounds are independent of the original input size and dimension and can be computed in near-linear time, which allows for the construction of simple FPT algorithms. Applying the $O(n^{kd+1})$ algorithm of [40] indeed gives a complexity of $2^{\widetilde{O}(k/\varepsilon^2)}$ plus the near-linear time to sketch the input; naively enumerating all partitions yields a running time of $k^{\widetilde{O}(k/\varepsilon^{z+2})}$, plus the time to sketch the input.

We crucially remark that the dependency on ε cannot be substantially improved: [21] showed a lower bound of $\Omega(k\varepsilon^{-2})$ for coresets, and [47] showed the optimality of the dimension reduction. Therefore, one cannot hope to go below $2^{\Omega(k/\varepsilon^2)}$ and answer Question 1 using only these techniques.

Other parameters were studied for k-means clustering: most notably, the cost has been investigated by Fomin, Golovach and Simonov [31]. They presented a $D^D\text{poly}(nd)$ exact algorithm for k-median, where D is an upper bound on the cost.

From Continuous to Discrete Clustering. The other standard technique to design FPT algorithms is to find a small set of candidate centers that contains a near-optimal solution. This approach was used, for instance, by [8] to obtain the first algorithm running in time $2^{(k/\varepsilon)^{O(1)}}d^{O(1)}n\log^{O(k)}(n)$, by [46] to improve the running time, and by [9] for the capacitated clustering problem.

Approximation Algorithms in Euclidean Spaces. To compute a $(1+\varepsilon)$-approximation in time polynomial in n and k, any algorithm must have a running time at least doubly exponential in d, as the problem is APX-hard in dimension $\Omega(\log n)$. The best of these algorithms is from [16], with a near-linear running time of $f(\varepsilon, d)n\,\text{polylog}\,n$. If one sticks to algorithms polynomial in n, k and d, the lower bounds on the approximation ratio are 1.06 for k-median and 1.015 for k-means, conditioned on P $\neq$ NP [20]. The upper bounds are still quite far: 2.41 for k-median, and 5.96 for k-means [15].

2 Our Techniques

We would like to now convey the conceptual and technical ideas that went into proving the lower bound in Theorem 2. As alluded to earlier in this section, hard instances of Euclidean k-means are typically constructed from the Vertex Cover problem, where every edge is mapped to a client and the partition of the edge set (which is the client set) by an optimal vertex cover also yields the optimal clustering for the k-means objective.

2.1 Motivation and Technical Background

Current Understanding of the Landscape. Starting from Gap-ETH (for 3-SAT) [26, 55], it is easy to show that there is no $2^{o(n)}$ time algorithm to $1+\delta$ approximate the Vertex Cover problem (on sparse graphs) for some small constant $\delta > 0$. By a standard reduction, this implies that Euclidean k-means cannot be approximated within $1+\delta$ in time $2^{o(n)}$, albeit when k is linear in n (the number of clients). On the other hand, starting from ETH [38, 39], it is easy to show (for example following the reduction in [24] or [5]) that Euclidean 2-means cannot be exactly solved in $2^{o(n)}$ time. Thus, we can show that there is no $2^{o(k/\varepsilon)} \cdot \text{poly}(n)$ time algorithm for $1+\varepsilon$ approximating Euclidean k-means problem, when either (i) $k = \Omega(n)$ and $\varepsilon = \Omega(1)$, or (ii) $k = 2$ and $\varepsilon = 1/\Omega(n)$.

Exploring Uncharted Territories. From the above discussion, we know that if k was $\Omega(n)$ then we cannot obtain a $2^{o(n)}$ time approximation algorithm, but what if k was approximately $\sqrt{n}$? Then algorithmic techniques based on coresets yield a $(1+\varepsilon)$ approximation in time $2^{\widetilde{O}(\sqrt{n}/\varepsilon)}$. But is it possible to do better?

We can try to answer this from the lower bound viewpoint. We can look at the above mentioned Gap-ETH hard instance, i.e., the setting $k = \Omega(n)$ and $\varepsilon = \Omega(1)$ and duplicate each point n times to obtain a point-set with $N = n^2$ points, and we have that there is no $2^{\sqrt{N}}$ time algorithm that can constant approximate the objective. But we cannot even rule out the possibility that there is an *exact* algorithm running in time $2^{N^{0.51}}$ for this value of k. Ideally, we would like to be able to rule out algorithms running in time $2^{N^{0.5+\rho}}$ that provide a $(1+\Omega(1/N^{\rho}))$ approximate solution, for every $\rho \in [0, 0.5]$. Thus, the result that we are shooting for is:

$$\textit{Rule out } 2^{o(k/\varepsilon)} \cdot \text{poly}(n) \textit{ time algorithms, when } k/\varepsilon \textit{ is fixed,}$$

i.e., we want the lower bound to hold on the entire tradeoff curve between the number of clusters k and the accuracy of clustering ε. To the best of our knowledge, there are no such results known in fine-grained complexity. Thus, we are motivated to develop a new framework to prove such results.

Technical Challenges. One approach is to start from the lower bound given in (ii), i.e., when $k = 2$ and $\varepsilon = 1/\Omega(n)$, and reduce it to a different instance of k-means, where k has increased (say to $\sqrt{n}$), but also ε has increased to $1/\sqrt{n}$ (all this with a linear blowup in size). But this requires "gap creation", a notorious challenging task, potentially much harder than even proving Gap-ETH from ETH!

Therefore, we pursue the approach of starting from the lower bound given in (i), i.e., when $k = \Omega(n)$ and $\varepsilon = \Omega(1)$, and reduce it to a different instance of k-means, where k has decreased (say to $\sqrt{n}$), and ε has also decreased to $1/\sqrt{n}$. This is the approach of trading off the gap to reduce the number of clusters.

A (Failed) Simple Approach. Let $G = ([n], E)$ be a vertex cover instance (where $|E| := m = O(n)$) which is hard to approximate to $1+\delta$ factor (for some positive constant δ) under Gap-ETH. Thus, size of an optimal vertex cover of G, denoted α_G is $\Omega(n)$. Suppose, our target k-means instance is when $k = o(m)$ and $\varepsilon = \Omega(\delta k/\alpha_G)$: then we may simply look at the embedding where each edge $\{u, v\} \in E$ is mapped to the point (i.e., client), $\mathbf{e}_u + \mathbf{e}_v \in \mathbb{R}^n$, where $\mathbf{e}_i$ is the standard basis vector which is 1 on i^{th} coordinate, and 0 everywhere else. If we were asked to cluster this client set to α_G clusters minimizing the k-means objective in Euclidean metric, then the optimal solution would simply be the partition based on some

optimal vertex cover of G. Thus, we could hope that even when asked to cluster the clients to k parts, the optimal solution would be to first cluster the clients into α_G clusters (based on the vertex cover) and then merge clusters, so as to end up with only k clusters in the end. However, since $k \ll \alpha_G$, we can have near-optimal cost from clustering which do not correspond to any vertex cover of G. For example, a typical obstacle is when we have the following clustering: $k-1$ clusters each contain a single client, and one cluster contains all the remaining points. It is entirely possible that such clusterings also have low cost.

Embedding via Color Coding. To overcome the above issue (of imbalancedness) of clustering, we introduce a color coding based embedding technique. Given G and a target number of clusters k, we first uniformly and independently randomly color each vertex v in G, with a color in $[k]$ (and let color of v be denoted by c_v). Thus each edge (consisting of two vertices), also gets (at most) two colors. Now, consider the embedding where each edge $\{u, v\} \in E$ is mapped to the point (i.e., client), $\mathbf{e}_u + \mathbf{e}_v + \mathbf{e}_{c_u} + \mathbf{e}_{c_v} \in \mathbb{R}^{n+k}$. Consider the clustering of this client set to k parts in the following way. Let $S \subset [n]$ be any optimal vertex cover of G and $S := S_1 \dot\cup \cdots \dot\cup S_k$ be a partition of the vertices in the vertex cover based on the coloring. Then the alleged optimal clusters would be given by the edges covered by $S_1, \ldots, S_k$, i.e., cluster i would be all edges (i.e., the corresponding points of these edges) in G covered by the vertices in S_i (break ties arbitrarily).

The embedding of the colors of the edges, forces the optimal clusters to have a dominating color, and since the colors are uniformly spread, the obstacle mentioned in the above approach (without coloring), would yield high clustering cost and thus can now be ruled out.

That said, there is a more serious obstacle that is not addressed: when we merge clusters in the completeness and soundness case, the graph topology affects the k-means cost; we elaborate on this next.

Need for Vertex Expansion. Consider two graphs G_1 and G_2, both on n vertices and are d-regular. Suppose G_1 looks like a random d regular graph, and thus is a very good vertex expander, and for every subset S of vertices of size $O(n/d)$ we have that the number of unique neighbors is about $|S| \cdot (d - O(1))$ [59]. On the other hand suppose that G_2 is obtained by first taking $n/(2d-6)$ disjoint copies of $K_{d-3,d-3}$ and then adding a random 3-regular graph to connect these copies.

We encounter the following problem when we merge clusters as described above: G_1 behaves in the way we expect it to, whereas the G_2 has a very low cost even if it doesn't have a good vertex cover. This is because if we take the $d-3$ sized independent set in a $K_{d-3,d-3}$ then we do get a very good vertex cover of $K_{d-3,d-3}$ but in addition if all (or even a large fraction of) the edges of $K_{d-3,d-3}$ were in the same cluster then each edge has $2d-8$ other edges that is adjacent to it in the cluster. On the other hand, if we take the edges incident to an independent set in G_1, then a typical edge has $d-1$ other edges incident to it. This makes the analysis of completeness and soundness impossible without knowing more about the graph topology.

2.2 New Hypothesis: Exponential Time for Expanders Hypothesis

Exponential Time for Expanders Hypothesis (XXH). To remedy the situation we introduce a working hypothesis that the gap vertex cover problem cannot be solved in time $2^{n^{1-o(1)}}$ on random graphs. For the sake of keeping the proofs clean (to the extent possible), we state the hypothesis in Section 3 in terms of vertex expanders which makes it directly usable. Under this hypothesis, we use the color coding embedding that was described earlier and with a lot of technical effort are able to derive the conclusion given in Theorem 2.

Informally, XXH asserts that for some constants ζ, δ, such that $\zeta \ll \delta$, no randomized algorithm running in $2^{n^{1-o(1)}}$ time can take as input a d-regular vertex expander $G := ([n], E)$ and distinguish between the following:
Completeness: There exist $n/2$ vertices that cover at least $(1-\zeta)$ fraction of E.
Soundness: Every subset of V of size $n/2$ does not cover δ fraction of the edges.

Plausibility of XXH. A key observation connecting random graphs and expander graphs is that random d-regular graphs are known to be very strong vertex expanders with constant probability (see Theorem 4.2 in [59]). Consequently, making progress on understanding the inapproximability of the Vertex Cover problem on vertex expanders is closely related to the hardness of the vertex cover problem on random graphs.

XXH formalizes this hardness on vertex expanders and, via our main reduction (Theorem 12), links it directly to the Euclidean k-means problem. This connection implies we live in one of three possible worlds. The first is where XXH is false and the Euclidean k-means admits a much faster algorithm (such as $2^{(k/\varepsilon)^{0.99}} \cdot \mathrm{poly}(n)$ time), and this would yield new algorithms for computing Vertex Cover on random-like graphs. The second is where XXH is false but there are no new faster algorithms for Euclidean k-means, and this would force a deeper, computational understanding of vertex expanders themselves. The third world is where XXH is true, and thus the current Euclidean k-means algorithm is nearly optimal. The reader is directed to Section 3.2 for more discussion on these three possibilities.

Investigating the truth of XXH (the third world) leads to natural questions of independent interest. For instance, Ramanujan graphs are known to be near-perfect vertex expanders for small sets [57], so we ask: does the Vertex Cover problem admit a PTAS when the input graph is a Ramanujan graph? Progress on this question would directly help us better understand XXH.

As partial evidence for XXH, in Corollary 11 we show that if we forego the expansion property, then under the Unique Games Conjecture it is possible to show from [6] that no polynomial-time algorithm can take as input a d-regular graph $G := ([n], E)$ and distinguish between the following:
Completeness: There exist $n/2$ vertices that cover at least a $(1-\zeta)$ fraction of E.
Soundness: Every subset of V of size $n/2$ fails to cover an $\Omega(\sqrt{\zeta})$ fraction of the edges.

Our Message. We wish to highlight two key aspects of the XXH hypothesis. First, it fundamentally acts as a fine-grained complexity assumption regarding the hardness of the Vertex Cover problem on random instances. Second, it establishes an important connection: developing better approximation algorithms for Euclidean k-means would provide non-trivial approaches to solving Vertex Cover on expander graphs, a problem of significant independent interest. In addition, even if weaker versions of XXH are true (and proved in the future), this would imply weaker lower bounds for $(1+\varepsilon)$-approximating the Euclidean k-means problem (see Remark 14 for details).

2.3 Proof Overview of Theorem 2

We now give an overview of the completeness and soundness cases. Recall that we are given a d-regular graph $G = ([n], E)$, and we have constructed a point $\mathbf{e}_u + \mathbf{e}_v + \mathbf{e}_{c_u} + \mathbf{e}_{c_v} \in \{0,1\}^{n+k}$, for each edge (u, v) whose end points have colors c_u and c_v.

In the completeness case, we have that there are $n/2$ vertices cover $1-\zeta$ fraction of edges, so our strategy to cluster is straightforward: first form $n/2$ clusters, each one corresponding to a vertex in the vertex cover solution, and then identify each cluster with a color by looking

at the color of the common vertex in each cluster (which is a star graph). Then, each color class would be a cluster, and we have k clusters, and we can show that the cost is $3|E| - (1 - 7\zeta)kd$.

However, our soundness analysis is highly non-trivial, and involves several tools and arguments of different flavors. Suppose we have a clustering of P whose k-means cost is about $3|E| - (1 - \delta^5)kd$ (where $\zeta \leq \delta^5/10$), then we first connect the cost of cluster C_i (for $i \in [k]$) with certain properties of the graph G_i in the following way:

▶ **Lemma 4** (Informal statement). *For every cluster C_i we have its cost is equal to:*

$$3|C_i| - 1 + (\gamma_i - \kappa_i)(|C_i| - 1) - \frac{1}{|C_i|} \cdot \sum_{v \in V_i} d_{i,v}^2,$$

where $d_{i,v}$ is the degree of v in the graph G_i (induced by edges in C_i), γ_i is the fraction of pairs of edges in G_i that have no color in common, and κ_i is the fraction of pairs of edges that have two colors in common.

Next, we show that if γ_i (fraction of pairs of edges with no color in common) and κ_i (fraction of pairs of edges with two colors in common) are not too large, then there is a dominant single color in the cluster C_i.

▶ **Lemma 5** (Informal statement). *If κ_i and γ_i are bounded by some small constants, then there is a large fraction of edges in G_i that have the same color.*

Then, we show that we can identify a large subcollection of clusters for which both κ_i and γ_i are small. In addition, we assume that the cost of the clustering $C_1, \dots, C_k$ is at most $3|E| - (1 - \delta^5)dk$. Then, for each cluster in this subcollection, we can relate a bound on the sum of the squared degrees of the vertices in the subcollection to the clustering cost appearing in Lemma 4.

▶ **Lemma 6** (Informal statement). *There is some $I \subseteq [k]$ such that for all $i \in I$, it holds that κ_i and γ_i are small and $\sum_{i \in I} |E_i| \geq (1 - 38\delta^2) \cdot |E|$. In addition, we also have for all $i \in I$:*

$$\frac{\sum_{v \in G_i} d_{i,v}^2}{\sum_{v \in G_i} d_{i,v}} \geq (1 - \delta^3) \cdot \frac{d}{2}.$$

Finally, we show that a cost of clustering $3|E| - (1 - \delta^5)dk$ implies that we can construct a set of vertices $S \subseteq [n]$ of size slightly more than $n/2$ such that we cover $(1 - 10\delta^{1.5})$ fraction of the edges, contradicting the soundness assumption of XXH for small enough δ. This step is quite involved, and we skip providing more details about it here.

3 Exponential Time for Expanders Hypothesis

In this section, we formally introduce the Exponential Time for Expanders Hypothesis which is then used in the next section to prove conditional lower bounds for the Euclidean k-means problems for small k.

3.1 New Hypothesis: Exponential Time for Expanders Hypothesis

We first define the notion of vertex expansion relevant to this submission.

▶ **Definition 7** (Small Set Vertex Expanders). *Given constants $\alpha > 0$, a d-regular graph $G = (V, E)$ on n vertices, and an integer $k := k(n)$, we say that G is a (k, α)-small set vertex expander if for every subset $S \subseteq V$ of size at most n/k we have that $|\{u \in V : \exists\{u, v\} \in E \text{ and } v \in S\}| \geq (1 - \alpha) \cdot d \cdot |S|$.*

Now, we can define our new hypothesis.

▶ **Hypothesis 8** (Exponential Time for Expanders Hypothesis – XXH(δ, ζ, α)). *Given constants $\delta, \zeta, \alpha \in (0, 1)$, the XXH$(\delta, \zeta, \alpha)$ assumption states that the following holds for all $\beta > 0$: No randomized algorithm running in $2^{n^{1-\beta}}$ time can, given as input a d-regular $(\text{polylog}n, \alpha)$-small set vertex expander $G = (V = [n], E)$ with $d = (\log n)^L$ (for some $L > 1$), distinguish between the following with probability 0.9:*

Completeness: *There exist $n/2$ vertices that cover at least $(1 - \zeta)$ fraction of E.*

Soundness: *For every $S \subseteq V$ of size $n/2$, there are at least $\delta \cdot |E|$ many edges which are not covered by any vertex in S.*

3.2 Plausibility of XXH: Three Possible Worlds

For the sake of the discussion in this subsection, we refer to the event "Clustering Barrier is Breached" to simply denote the existence of an algorithm much faster than $2^{k/\varepsilon} \cdot \text{poly}(n)$ for $1 + \varepsilon$ approximating the Euclidean k-means problem. In Section 4, we proved that assuming XXH, the clustering barrier cannot be breached. Therefore, we are living in one of three possible worlds. The first world is where XXH is false and the clustering barrier is breached. The second world is where XXH is false, but the clustering barrier cannot be breached. Finally, the third world is where XXH is true (and thus the clustering barrier cannot be breached from Theorem 12).

The message we want to convey here is that only one of the above three worlds is possible, and regardless of which world is proven to be the one we live in, it will shed new light on problems of interest to the algorithmic community.

3.2.1 World I: XXH is False and Clustering Barrier is Breached

XXH may be viewed as a fine-grained assumption for the vertex cover problem on random instances, which we elaborate on below. Thus, our reduction from XXH instances to Euclidean k-means instances, as given in Theorem 12, can be used to make oracle calls to the efficient algorithm for the Euclidean k-means problem (since the clustering barrier is breached in this world) to solve XXH instances efficiently (i.e., in mildly sub-exponential time). This would imply a separation in this world between worst-case and average-case instances of the gap vertex cover problem (brushing aside many details to make a succinct claim).

XXH as a Fine-Grained Assumption for Random Instances. Theorem 4.2 in [59] shows that for some large universal constant C, a random d-regular graph is a $(C, \frac{2}{d})$-small set vertex expander with a probability of 0.5. Thus, making progress on the inapproximability of the vertex cover problem for vertex expanders is morally similar to proving the hardness of approximation for vertex cover on random d-regular graphs. Or in this world, we would make algorithmic progress on understanding vertex cover on random graphs through (hypothetical) clustering algorithms.

3.2.2 World II: XXH is False but Clustering Barrier is not Breached

In this world, XXH is false, possibly because[1] the vertex cover problem is computationally easy on small set vertex expanders. For *spectral* expanders, it is sometimes possible to apply Hoffman's ratio bound [34] to obtain non-trivial speedups when the spectral gap is large. However, vertex expanders, while intuitively similar to edge expanders (and spectral ones), are poorly understood. In fact, explicit constructions with parameters close to those obtained for random graphs were developed only recently [36]. Thus, falsifying XXH motivates a better understanding of vertex expanders from the computational viewpoint of optimization problems.

Nevertheless, Theorem 11 in [2] shows that the *exact* vertex cover problem remains as hard on spectral expanders as it is on general graphs.

3.2.3 World III: XXH is True

The first evidence that XXH might be true is that the hard instances of vertex cover constructed by [27] are essentially built from random label cover instances which have strong expansion properties after PCP composition. Moreover, XXH only promises expansion for small sets (sub-polynomial size sets), and thus it is unlikely that such a local structure can be algorithmically used.

Also, it can be formally argued that on small sets, Ramanujan graphs are near-perfect vertex expanders [57]. Therefore, as a way to prove XXH, one can first ask whether the vertex cover problem admits a PTAS on Ramanujan graphs. It is possible that the answer to this question is negative, although there are no techniques to handle such questions, and thus XXH opens this new line of exploration.

3.3 Small Progress on XXH under Unique Games Conjecture

In this subsection, we show that without the vertex expansion property, it is possible to obtain a weak version of XXH under the unique games conjecture [44].

Let Φ denote the cumulative density function of the standard normal distribution and, for any $\rho \in [-1,1], \mu \in [0,1]$, let $\Gamma_\rho(\mu)$ denote $\Pr[X \leq \Phi^{-1}(\mu) \wedge Y \leq \Phi^{-1}(\mu)]$ where X, Y are normal random variables with means 0, variances 1 and covariance ρ. The main intermediate result of [6] is the following:

▶ **Theorem 9** (Theorem 1 from [6]). *For any $q \in (0, 1/2)$ and any $\varepsilon > 0$, it is UG-hard to, given a regular graph $G = (V, E)$, distinguish between the following two cases.*

- *(Completeness) G contains an independent set of size at least $q \cdot |V|$.*
- *(Soundness) For any subset $T \subseteq V$, the number of edges with both endpoint in T is at least $|E| \cdot \left(\Gamma_{-q/(1-q)}(\mu) - \varepsilon\right)$ where $\mu = |T|/|V|$.*

This means that, in the completeness case, there is a vertex cover of size at most $(1-q)\cdot|V|$. On the other hand, in the soundness case, if we consider any subset $S \subseteq V$ of size at most $(1-q)\cdot|V|$, then the number of edges *not* covered is exactly the same as the number of edges with both endpoints in $(V \setminus S)$, which is at least $(\Gamma_{-q/(1-q)}(q) - \varepsilon)\cdot|E|$. We will evaluate this approximation factor for $q = \frac{1}{2} - \zeta$.

[1] We are not addressing here the concern that XXH might be false in this world because of the setting of the parameters.

▷ Claim 10. Let $q := \frac{1}{2} - \zeta$ where $\zeta > 0$ is small enough. We have: $\Gamma_{-q/(1-q)}(q) \geq \frac{\sqrt{\zeta}}{3}$.

Assuming the above claim (which will be proved later), we have the following corollary from Theorem 9 by setting $\varepsilon \ll \sqrt{\zeta}$:

▶ **Corollary 11.** *There exists $\delta, \zeta > 0$ with $\delta^2 > \zeta/33$ such that it is UG-hard to, given a regular graph $G = (V, E)$, distinguish between the following two cases.*
Completeness: *There exist $|V|/2$ vertices that cover at least $(1 - \zeta)$ fraction of E.*
Soundness: *For every $S \subseteq V$ of size $|V|/2$, there are at least $\delta \cdot |E|$ many edges which are not covered by any vertex in S.*

This corollary is weaker than the promise given in XXH in the following ways. First, and most importantly, the hard instances of Corollary 11 need not be vertex expanders. Second, the conditional lower bound under the Unique Games Conjecture is only against polynomial-time algorithms, whereas XXH rules out sub-exponential time algorithms.

Between the two remarks made above, the first one is the major obstacle, and this is mainly to do with our state of poor understanding of vertex expanders. Once the toolkit develops on this topic, it is conceivable that some additional progress can be made on XXH.

4 Conditional Lower Bound for Euclidean k-means with Few Clusters

We prove in this section our main result, the hardness of approximating k-means when parameterized by k. The formal theorem is:

▶ **Theorem 12** (Fine-Grained Hardness for Approximation of Euclidean k-means from XXH)**.** *Suppose XXH(δ, ζ, α) is true for some constants $\delta, \zeta, \alpha \in (0, 1)$ satisfying $\delta \leq 10^{-3}$, $\zeta \leq \delta^5/10$, and $\alpha \leq \delta^{10}$. Let $L > 1$ be the constant defining the degree $d = (\log |V|)^L$ in the XXH hypothesis.*

Let $\widetilde{k} : \mathbb{N} \to \mathbb{N}$ be a non-decreasing function and $\widetilde{\varepsilon} : \mathbb{N} \to (0, 1)$ be a non-increasing function. Define $f(n) := \frac{\widetilde{k}(n)}{\widetilde{\varepsilon}(n)}$. Assume that for all sufficiently large n, $f(n)$ satisfies the smoothness condition $f(n) \leq C \cdot f(n-1)$ for some constant $C \geq 1$. Furthermore, assume the following asymptotic limits hold:

- $\widetilde{k}(1) \geq \frac{1}{\widetilde{\varepsilon}(1)} \geq 2/\delta^5$.
- $f(n) = \omega(\log n)$ *and* $f(n) = o\left(\frac{n}{\log^L n}\right)$.
- $\widetilde{\varepsilon}(n) = o\left(\frac{1}{(\log n)^{\omega(1)}}\right)$.
- $\widetilde{k}(n) \cdot \widetilde{\varepsilon}(n) = \omega\left((\log n)^{2L}\right)$.

Then the following holds for all $\beta > 0$: No randomized algorithm can, given as input exactly n points in $\mathbb{R}^{\text{poly}(n)}$ and an integer $\widetilde{k}(n)$, run in $2^{f(n)^{1-\beta}} \cdot \text{poly}(n)$ time and output a $(1 + \widetilde{\varepsilon}(n))$-approximate estimate of the $\widetilde{k}(n)$-means cost with probability at least 0.9.

In this section, we actually prove the following theorem, which applies for $\widetilde{k}$ and $\widetilde{\varepsilon}$ bounded in a specific way and then show that it immediately implies Theorem 12 above.

▶ **Theorem 13.** *Let $\delta, \zeta, \alpha \in (0, 1)$ be some constants satisfying $\delta \leq 10^{-3}$, $\zeta \leq \delta^5/10$, and $\alpha \leq \delta^{10}$. There is a randomized algorithm running in linear time in the input size, which takes as input an integer k (where $k > \sqrt{|V|} \cdot d$, $k = o(|V|/d^{\omega(1)})$) and a d-regular $(\text{polylog}|V|, \alpha)$-small set vertex expander $G = (V, E)$ (where $d = (\log |V|)^L$, for some $L > 1$), and outputs a point-set $P \subseteq \mathbb{R}^{O(|V|)}$ of at most $|E|$ points such that with probability at least 0.95, the following holds:*

Completeness: *If there are $|V|/2$ vertices covering at least $1-\zeta$ fraction of E, then there is a clustering of P such that the k-means cost is at most $3|E| - (1-7\zeta)kd$.*

Soundness: *If every $|V|/2$ vertices miss at least δ fraction of E, then every clustering of P has k-means cost at least $3|E| - (1-\delta^5)kd$.*

▶ Remark 14. It is worth noting that the reduction in Theorem 13 applies even for weaker versions of XXH. For example, if one day in the future, XXH was proved against algorithms running in time $2^{\sqrt{n}}$ instead of the currently stated $2^{n^{1-o(1)}}$ runtime algorithms, then we can recover that there is no randomized algorithm running in time much faster than $2^{\sqrt{k/\varepsilon}} \cdot \mathrm{poly}(n,d)$ that can $(1+\varepsilon)$-approximate the Euclidean k-means problem.

Abstract

The k-median and k-means clustering objectives are classic objectives for modeling clustering in a metric space. Given a set of points in a metric space, the goal of the k-median (resp. k-means) problem is to find k representative points so as to minimize the sum of the distances (resp. sum of squared distances) from each point to its closest representative. Cohen-Addad, Feldmann, and Saulpic [JACM'21] showed how to obtain a $(1+\varepsilon)$-factor approximation in low-dimensional Euclidean metric for both the k-median and k-means problems in near-linear time $2^{(1/\varepsilon)^{O(d^2)}} n \cdot \text{polylog}(n)$ (where d is the dimension and n is the number of input points).

We improve this running time to $2^{\widetilde{O}(1/\varepsilon)^{d-1}} \cdot n \cdot \text{polylog}(n)$, and show an almost matching lower bound: under the Gap Exponential Time Hypothesis for 3-SAT, there is no $2^{o(1/\varepsilon^{d-1})} n^{O(1)}$ algorithm achieving a $(1+\varepsilon)$-approximation for k-means.

1 Introduction

The k-median and k-means problems are minimization tasks of classic objectives for modeling clustering in a wide variety of applications arising in data mining and machine learning. Given a set of points $P \subset X$ and a set of *candidate centers* $\mathcal{S} \subset X$ in a metric space (X, Δ),

the goal of the k-median problem[1] is to find a set of k points $S \subset \mathcal{S}$, called *centers*, so as to minimize the sum of the distances (given by Δ) from each point of P to its closest center in S (in the k-means problem, the goal is to instead minimize the sum of the squared distances from each point of P to its closest center in S).

The algorithmic study of k-median started in the early '60s in the operations research community [36, 46, 29], while the study of k-means was arguably initiated by the seminal work of Lloyd [39], which applied clustering to quantization of analog signals. Since then, both problems have received a tremendous amount of attention. Naturally, the complexity of the problems varies with the underlying metric space hosting the input points. On the negative side, both problems are known to be NP-hard in Euclidean space, even when the points lie in the Euclidean plane (and k is large) [44, 40], or when $k = 2$ [23, 2] (and the dimension is large). When both k and d are arbitrary, several groups of researchers have shown hardness of approximation results for both problems [6, 37, 17, 19]. Even stronger hardness results hold if the input lives in an arbitrary metric space (see Guha and Kuller [28] and [18]).

Fine-Grained Complexity. Despite those hardness results, the importance of Euclidean inputs in statistics and machine learning applications has led researchers to develop methods and algorithms, in particular through the study of the parameterized complexity of the problem, when the input lies in an Euclidean space. Both the dimensionality of the input, d, and the target number of clusters, k, have been studied as parameters. For exact algorithms, the seminal work of Inaba, Katoh and Imai [31] has shown that one can compute an exact solution to the k-median and k-means problems in time $O(n^{kd+1})$ – as opposed to the naive brute-force enumeration which runs in $\widetilde{O}(k^n)$ time. On the negative side, Cohen-Addad, de Mesmay, Rotenberg and Roytman [11] much later showed that there is no $n^{o(k)}$ exact algorithm for (discrete) k-median or k-means problem, even when the dimension is four, and thus partially showing the optimality of the $O(n^{kd+1})$ algorithm.

To circumvent this hardness, researchers have turned to approximation algorithms. When the dimension d and the precision ε are taken as parameters, a line of work [5, 35, 27, 20, 10, 13] improved the running time of approximation schemes from quasi-polynomial time, $2^{(\log(n)/\varepsilon)^{d-1}}$, to $2^{(1/\varepsilon)^{O(d^2)}}n$. The doubly exponential dependency in d^2 stands in stark contrast with other similar results, e.g., for the Traveling Salesperson Problem (TSP). For this problem, Kisfaludi-Bak, Nederlof and Wegrzycki [34] recently settled the exact dependency on d, by showing an algorithm running essentially in time $2^{O\left(1/\varepsilon^{d-1}\right)}n$, and a lower bound of $2^{\Omega\left((1/\varepsilon)^{d-1}\right)}$ under the Gap-ETH hypothesis [25, 42]. In light of this result, we consider the following question:

▶ **Question 1.** *Is it possible to obtain a $2^{O\left(1/\varepsilon^{d-1}\right)}n^{O(1)}$ approximation scheme for k-median and k-means problems in low-dimensional inputs? Would it be possible to get an even faster $2^{o\left(1/\varepsilon^{d-1}\right)}n^{O(1)}$ approximation scheme for both problems?*

1.1 Our Results

In this paper, we make substantial progress towards answering Question 1. Our first contribution is the design of an improved algorithm:

▶ **Theorem 2.** *For every $\varepsilon > 0$ and dimension d, the k-median and k-means problems in $\mathbb{R}^d$ can both be approximated to a $(1+\varepsilon)$-factor in time $2^{\widetilde{O}\left(1/\varepsilon^{d-1}\right)}n \cdot \mathrm{polylog}(n)$.*[2]

[1] This variant is sometimes referred to as the *discrete* k-median problem. In the continuous k-median problem we are allowed to pick the k centers S from anywhere in X.

[2] The $\widetilde{O}$ notation hides an exponential dependency in d, and polynomial dependency in $\log(1/\varepsilon)$.

The above algorithm is our main contribution, and improves on the techniques of [13]. It also readily extends to the continuous k-median and k-means problems (see Remark 4).

On the technical side, this algorithm deepens our understanding of the *quadtree* decomposition for clustering. A long line of work based on this decomposition [5, 35, 27, 20, 10, 13] improved the running time of approximation schemes (i.e., $(1+\varepsilon)$-factor approximation algorithms for any small enough constant ε) for clustering from quasi-polynomial time, $2^{(\log(n)/\varepsilon)^{d-1}}$, to $2^{(1/\varepsilon)^{O(d^2)}}n$ [13]. The main conceptual insight of these works is to bound the number of *portals* necessary along the decomposition so that forcing a path to go through portals incurs at most a $(1+\varepsilon)$-factor distortion. The main contribution of [13] is that after processing a tiny fraction of the input, only a constant number of portals are sufficient at each level of the quadtree decomposition. However, this constant remains much larger than that required for other natural problems.

Indeed, carefully analyzing the performances of the quadtree dissection and the number of required portals to achieve a $(1+\varepsilon)$-factor approximation has been a fruitful direction of research to design approximation schemes in Euclidean space. The initial work of Arora [3, 4] showed approximation schemes for the Traveling Salesperson Problem (TSP) and other routing problems, first in quasi-polynomial time (for $d > 2$) and then with running time $n\log(n)^{O(1/\varepsilon)^{d-1}}$. For TSP, the running time was subsequently significantly improved: first by Rao and Smith [45] who achieved $(1/\varepsilon)^{1/\varepsilon^{d-1}}n\log n$, then by Bartal and Gottlieb [7] who brought it down to $2^{1/\varepsilon^{O(d)}}n$, linear in n, but suboptimal in d. Finally, [34] settled the exact dependency on d, by showing an algorithm running essentially in time $2^{O\left(1/\varepsilon^{d-1}\right)}n$, and a lower bound of $2^{\Omega\left((1/\varepsilon)^{d-1}\right)}\mathrm{poly}(n)$ under the Gap-ETH hypothesis [25, 42].

In light of this literature, our contribution is therefore an improved analysis of the quadtree dissection for clustering problems, that allows us to (almost) match the number of portals required for the well-studied TSP. This requires an analysis and techniques distinct from those for TSP, in particular because they fail if distances are squared – as what happens in the k-means problem. We note that, due to its simplicity, applications of the quadtree extend far beyond approximation algorithms in low-dimensional space. For clustering, quadtrees are used for instance in the streaming scenario, when memory has to be kept low [8], but also to design linear time algorithms in high-dimensional spaces [21] or to construct differentially-private algorithms [12]. Therefore, better understanding the quadtree's performance, even in the simplest scenario, is likely to have a far-reaching impact.

We complement Theorem 2 with a conditional lower bound, which shows the near-optimality of our algorithm under the Gap-ETH hypothesis:

▶ **Theorem 3.** *Assuming the Gap-ETH hypothesis, for every integer $d \geq 2$, there exists a constant $c > 0$ such that no approximation scheme can, given an instance of discrete k-means (or discrete k-median) with N points in Euclidean space $\mathbb{R}^d$ and a parameter $\varepsilon > 0$, compute a $(1+\varepsilon)$-factor approximation in time $2^{c(1/\varepsilon)^{d-1}}\mathrm{poly}(N)$.*

This lower bound is obtained by amalgamating the technical ideas of [37, 11, 17] and the framework of de Berg, Bodlaender, Kisfaludi-Bak, Marx and van der Zanden [24]. Ideas to reduce the Vertex Cover problem to clustering problems were elaborated in [37, 11, 17], and [24] built a framework to prove fine-grained lower bounds for a host of geometric problems in low dimensions. We put them together to obtain Theorem 3. The proof is deferred to the full version.

Extensions. The framework developed in [13] applies to many variants of k-means (and k-median), namely prize-collecting k-means, k-means with outliers and Facility location. As our structure theorem is a direct improvement of theirs, we also improve the running time

for those problems. We give a sketch of the arguments in the full version. Our analysis also improves the result for doubling metric (a generalization of Euclidean space), however attaining a non-tight complexity $2^{\widetilde{O}(1/\varepsilon^d)}$. We therefore focused this paper on the Euclidean setting, for which our analysis is almost tight.

1.2 Our Techniques

For the ease of presentation, we detail below our upper bound for the k-means problem in the Euclidean plane (i.e., with $d = 2$). Our input is a set of points $P \subset \mathbb{R}^2$, a set of candidate centers $\mathcal{C} \subset \mathbb{R}^2$, and the goal is to compute a set of centers $S \in \mathcal{C}^k$ ($\mathcal{C}^k$ is the k-wise partition product of $\mathcal{C}$) that minimizes the sum of squared distances from points of P to their closest center in S.

Our starting point is the quadtree dissection equipped with portals. We briefly recall in the next few paragraphs its construction and main property.

First, find an axis-aligned rectangle that contains all input points. Then, randomly split the rectangle into 4 axis-aligned rectangles of side length reduced by a factor of approximately 2. Continue this splitting recursively until each rectangle contains a single point: this defines a recursive decomposition of the input. We say that two points are *cut at level i* when the smallest rectangle containing both points is at the i^{th} level of the decomposition. Assuming that the leaves of the decomposition have diameter 1, the rectangles at the i^{th} level have diameter roughly 2^i.

Now, a set of *portals* is placed regularly along the boundary of each rectangle. Instead of connecting points to centers via straight lines, we consider only *portal-respecting* paths, defined as follows. To connect two points p and q cut at level i, a portal-respecting path consists of a sequence of segments connecting $p, p_1, ..., p_i, q_i, ..., q_1, q$, where p_j (resp. q_j) is a portal of the rectangle at level j containing p (resp. q). Considering only those paths enforces some detours, but a simple dynamic program can compute the best portal-respecting solution, whose complexity naturally depends (exponentially) on the number of portals. Furthermore, if $1/\rho$ many portals are placed along each boundary, it can be computed that a portal-respecting path between two points p, q cut at level i has length (essentially) $\|p - q\| + \rho 2^i$. Indeed, since the boundaries of the rectangles are geometrically decreasing, the detour to go through a portal at level i dominates all others; and since the rectangles at this level have diameter 2^i, by regularly placing $1/\rho$ many portals, we can ensure that there is a portal at distance at most $\rho 2^i$ from the point where the straight line path crosses the boundary. Therefore, the goal of the analysis is to show that, for a small number of portals, a portal-respecting solution with almost optimal cost exists.

The standard argument goes as follows. The main property of the quadtree decomposition is that, for any pair of points $p, q \in \mathbb{R}^2$, the probability that they are cut at level i is $\|p-q\|/2^i$. By using $1/\rho$ portals, the detour to connect p and q via portals in case they are cut at level i is $\rho 2^i$. Therefore, the expected detour at level i is $\|p - q\|/2^i \cdot \rho 2^i = \rho\|p - q\|$. Since there are $\log n$ levels in the decomposition, the expected detour is $\rho\|p - q\| \cdot \log n$, and one has to take $\rho = \varepsilon/\log n$ to get a tiny expected detour.

However, having $\log n/\varepsilon$ many portals does not yield an efficient algorithm. More importantly, this analysis does not extend to k-means problem: although the expected distance between p and q is small, the expected *squared* distance is not! Indeed, the expected squared detour at level i is $\|p - q\|/2^i \cdot (\rho 2^i)^2 = \rho^2\|p - q\|2^i$, and the term 2^i cannot be easily controlled. To cope with this, [13] introduced a careful preprocessing of the input, to ensure that no point is cut at a level higher than $\|p - q\|/\varepsilon$. In that case, taking $1/\varepsilon^2$ portals is enough to ensure a small detour – and also small squared detour, as this is not an average-case argument (unlike the previously seen argument). This preprocessing is

essentially the following: start from a constant-factor approximate solution $\mathcal{A}$ (which is a set of k centers), and for each point p, let $\mathcal{A}_p$ be its distance to the closest center of $\mathcal{A}$. If the ball $B(p, \mathcal{A}_p/\varepsilon)$ is cut by the decomposition at a level higher than $\log(\mathcal{A}_p/\varepsilon^2)$, then replace p by a copy of its closest center in $\mathcal{A}$. They showed that each point is replaced with probability at most ε, therefore yielding an expected cost increase of $\varepsilon\text{cost}(P, \mathcal{A}) = O(\varepsilon)\text{OPT}$. Furthermore, [13] showed that placing $1/\varepsilon^3$ many portals ensured that, for any center of $\mathcal{A}$, either it can be connected to the optimal solution through portals with a small detour, or one can assume that the center is part of the optimal solution. Therefore, after preprocessing, each client can be connected through portals to the optimal solution, and dynamic programming allows to compute a near-optimal solution.

However, this analysis may be seen as "worst-case", in the sense that it treats all the clients for which the ball is cut at a level below $\log(\mathcal{A}_p/\varepsilon^2)$ in the same way. Our contribution is to mix the average-case analysis with the techniques of [13] in order to reduce the number of necessary portals. We carefully define a budget for each point, according to the level where the point is cut from the approximate solution $\mathcal{A}$, as in [13], but now also according to the level where it is cut from the optimal solution. We first show that, with constant probability, this budget is very cheap, namely an ε-fraction of the optimal cost. We then show that this budget is enough to pay for the preprocessing of the input, and for the detour incurred by making a solution portal-respecting. The algorithm is the same as the one of [13]: our contribution lies in a much tighter analysis.

This analysis differs from [13] as the detour they tolerated was independent of the optimal solution: using this additional information allows us to be more precise, and reduce the number of required portals to $(\log(1/\varepsilon)/\varepsilon)^{d-1}$, instead of $1/\varepsilon^{O(d)}$. Although the global picture remains similar, finding the right balance between a budget (1) small enough to not blow up the cost, and (2) that is still enough to pay for making the optimal solution portal-respecting is a non-trivial extension of their proof. Indeed, it requires new insights on the way to connect a point p that is *badly cut*, namely cut from its optimal center s at a level higher than $\log(\|p-s\|/\varepsilon)$. For this, we show that our budget allows to connect the point in a portal-respecting way to the center $\widetilde{s}$ closest to $\mathcal{A}(p)$, where $\mathcal{A}(p)$ is the closest center to p in the constant-factor approximate solution $\mathcal{A}$.

1.3 Further Related Work

We covered previously the hardness results for k-means and k-medians; in terms of upper-bound, for general metrics a recent breakthrough from [15] achieves a $(2+\varepsilon)$-approximation for k-median, and a 5.6-approximation for k-means [9]. Those two works improve a long line of works, based on primal-dual techniques and the so-called Lagrangian-multiplier preserving algorithms for Facility Location, see e.g. [33, 32, 38].

To improve those approximation ratio, one can resort to algorithms parameterized by the number of clusters, k: one can get FPT algorithm with approximation matching the lower bound of [32], namely $1+2/e$ for k-median and $1+8/e$ for k-means [16].

Other techniques, specific to Euclidean Space, have been developed in the past decades. Dimension reduction [41] and coreset [22] allow to reduce the dimension of the input to $O(\log k/\varepsilon^{-2})$ and the number of distinct points to $\widetilde{O}(k\varepsilon^{-O(1)})$, hence leading to simple FPT algorithms based on naive enumeration. Recent papers improved this simple approach, reducing the dependency in k (in the exponent) [1].

We covered in the introduction most of the literature related on low-dimensional clustering – which is the study of the problems parameterized by d. To compute a $(1+\varepsilon)$-approximation in time polynomial in n and k, any algorithm must have a running time at least doubly exponential in d, as the problem is APX-hard in dimension $\Omega(\log n)$. The best of these algorithms is from [13], with a near-linear running time of $f(\varepsilon, d) \cdot n \operatorname{polylog} n$.

Finally, tractability of clustering has also been studied with different parameters, e.g., the cost by Fomin, Golovach and Simonov [26], who showed a $D^D\text{poly}(nd)$ exact algorithm for k-median, where D is the optimal cost.

We present in the full version how to adapt the argument for k-median. The main body contains the proof of the structure theorem that allows to reduce the number of portals required by the quadtree. We extend the algorithmic results to other objectives in the full version.

2 Preliminaries

2.1 Definitions

We consider the Euclidean space $\mathbb{R}^d$, with the ℓ_2 metric: $\text{dist}(p,q) := \sqrt{\sum_{i=1}^d (p_i - q_i)^2}$. For any point p and $r \geq 0$, the ball centered at p of radius r is $B(p,r) := \{x \in \mathbb{R}^d : \text{dist}(p,x) \leq r\}$. The (discrete) k-median and k-means problems are defined as follows: we are given a set of *clients* P and of *candidate centers* $\mathcal{C}$. A *solution* is any subset of $\mathcal{C}$ with size k. The goal is to compute the solution $\mathcal{S}$ that minimizes $\text{cost}(P,\mathcal{S}) := \sum_{p\in P} \text{dist}(p,\mathcal{S})^z$, with $z = 1$ for k-median and $z = 2$ for k-means. We say a solution is an α-approximation if its cost is at most α times the minimal cost.

▶ Remark 4. We consider in this paper the *discrete* Euclidean clustering. In the continuous version, centers can be placed arbitrarily in the space. A classical result shows how to reduce continuous to discrete, by computing a set of $1/\varepsilon^d \cdot |P|$ candidate centers that contain a $(1+\varepsilon)$-approximation [43].

For some set of points $\mathcal{S}$, and any point $p \in \mathbb{R}^d$, we define $\mathcal{S}(p) = \arg\min_{s\in\mathcal{S}} \text{dist}(p,s)$ be the closest point in $\mathcal{S}$ to p ; and we let $\mathcal{S}_p := \text{dist}(p,\mathcal{S}(p))$ be the distance from p to its closest point in $\mathcal{S}$.

We assume that the minimal distance between two points is 1, and denote $\text{diam}(P)$ the maximum distance between two points of P. We also assume that $P \subset B(0,\text{diam}(P))$. Using standard arguments for clustering problems, we can assume $\text{diam}(P) = \text{poly}(n)$ [14].

A hierarchical decomposition $\mathcal{D}$ is a sequence $\mathcal{B}_1, \mathcal{B}_2 \ldots$ such that for any i, $\mathcal{B}_i$ is a partition of P, and $\mathcal{B}_i$ is a refinement of $\mathcal{B}_{i+1}$: namely, every part of $\mathcal{B}_i$ is fully contained in a part of $\mathcal{B}_{i+1}$ (note that in this definition, parts are increasing with i).

2.2 The Hierarchical Decomposition and Its Properties

▶ **Lemma 5.** *For any set of points $P \subset \mathbb{R}^d$ and any $\rho > 0$, there is a randomized hierarchical decomposition $\mathcal{D}$ such that the diameter of a part $B \in \mathcal{B}_i$ is at most 2^{i+1}, $|\mathcal{D}| \leq \lceil \log(\text{diam}(P)) \rceil$, each part $B \in \mathcal{B}_i$ is refined in at most $2^{O(d)}$ parts at level $i-1$, and:*

1. *for any $p \in \mathbb{R}^d$, radius r, and level i, we have*

$$\Pr[\mathcal{D} \text{ cuts } B(p,r) \text{ at a level } i] \leq dr/2^i.$$

2. *for every part $B \in \mathcal{B}_i$ of the decomposition, there is a set of at most $1/\rho^{d-1}$ many* portals *such that for every points $p \in B, q \notin B$ there is a portal $x \in \mathcal{P}_B$ close to the line connecting p to q, i.e., $\|p-x\| + \|x-q\| \leq \|p-q\| + \rho 2^{i+1}$. Furthermore, any portal of level $i+1$ that lies in B is also a portal of B.*

This decomposition can be found in time $(1/\rho)^{O(d)} n \log(\text{diam}(P))$.

In Euclidean space, this decomposition is precisely the quadtree dissection. The previous statement is an adaptation of Lemma 2.3 in [13] to Euclidean space. The improved Property 1 is shown, e.g., in Lemma 11.3 of [30]. Since $\text{diam}(P) = \text{poly}(n)$, the decomposition can be computed in near-linear time.

We denote $\tau(\varepsilon, d) = \log(d) + \log(1/\varepsilon)$, a parameter often used throughout this paper.

A *portal-respecting* path between two points p and q cut at level i consists of a sequence of segments connecting $p, p_1, ..., p_i, q_i, ..., q_1, q$, where p_j (resp. q_j) is a portal of the rectangle at level j containing p (resp. q). By extension, a solution to k-means is portal-respecting if all paths connecting clients to center are portal-respecting. Recall that $\mathcal{A}_p$ is the distance from p to the closest point in a solution $\mathcal{A}$. An important definition we will use is that of badly cut, slightly modified from [13]:

▶ **Definition 6.** *Let $P \subset \mathbb{R}^d$, $\mathcal{D}$ be a hierarchical decomposition of P, and $\varepsilon > 0$.*

For any ball $B(x, r)$, we define $\mathrm{lvl}(x, r)$ *the level at which the ball $B(x, r)$ is cut by $\mathcal{D}$.*

We say a ball $B(x, r)$ is badly cut w.r.t. $\mathcal{D}$ *if* $\mathrm{lvl}(x, r) \geq \log(3r) + \tau(\varepsilon, d)$. *We say a point p is* badly cut w.r.t. $\mathcal{D}$ and $\mathcal{A}$ *if $B(p, 3\mathcal{A}_p)$ is badly cut w.r.t. $\mathcal{D}$ (namely,* $\mathrm{lvl}(p, 3\mathcal{A}_p) \geq \log(3\mathcal{A}_p) + \tau(\varepsilon, d)$*).*

In the following, we will consider badly cut points w.r.t. two different sets: $\mathcal{A}$ will be a constant factor approximation, known to the algorithm, and $\mathcal{S}$ a slight modification of the optimal solution, unknown to the algorithm, that we will specify later; those two solutions being independent of the decomposition $\mathcal{D}$. For input points in P, we will examine whether they are badly cut w.r.t. $\mathcal{D}$ and $\mathcal{A}$. For centers of $\mathcal{A}$, it will be w.r.t. $\mathcal{D}$ and $\mathcal{S}$. Furthermore, $\mathcal{D}$ will always be the same, hence we say for simplicity badly cut w.r.t. $\mathcal{A}$ (or w.r.t. $\mathcal{S}$).

The following lemma bounds the probability of being badly cut, and is a direct consequence of Property 1.

▶ **Lemma 7.** *Let $P, S \subset \mathbb{R}^d$ and $\mathcal{D}$ a random hierarchical decomposition given by Lemma 5, with $\rho = O(\varepsilon/\log(1/\varepsilon))$. For any point $p \in \mathbb{R}^d$, the probability that p is badly cut w.r.t. S is at most ε.*

Given a random decomposition, each point is assigned a *budget*. In the following definition, one can think of $\mathcal{A}$ as an $O(1)$-approximation known by the algorithm, and $\mathcal{S}$ as the optimal solution. We show in Lemma 12 that this budget is small, and that one can compute a solution with cost at most the optimal cost plus the budget.

▶ **Definition 8.** *Let $P \subset \mathbb{R}^d$, $\mathcal{D}$ be a hierarchical decomposition of P, $\varepsilon > 0$, $\mathcal{A}$ and $\mathcal{S}$ be two solutions to k-means on P.*

For a ball $B(x, r)$, its detour *with respect to B and $\mathcal{D}$ is* $\det_{\mathcal{D}}(x, r) = \varepsilon 2^{\mathrm{lvl}(x,r)} r + \varepsilon^2 2^{2\,\mathrm{lvl}(x,r)}$.

A point $p \in P$ has budget *with respect to $\mathcal{A}$ and $\mathcal{S}$ $b(p, \varepsilon) = b_1(p, \varepsilon) + b_2(p, \varepsilon) + b_3(p, \varepsilon)$, with*

$$b_1(p,\varepsilon) = \begin{cases} \det_{\mathcal{D}}(p, 3\mathcal{A}_p) \text{ if } \mathrm{lvl}(p, 3\mathcal{A}_p) \leq \log(3\mathcal{A}_p) + \tau(\varepsilon, d) \\ 0 \text{ otherwise} \end{cases}$$

$$b_2(p,\varepsilon) = \begin{cases} \det_{\mathcal{D}}(p, 3(\mathcal{A}_p + \mathcal{S}_p)) \text{ if } \mathrm{lvl}(p, 3(\mathcal{A}_p + \mathcal{S}_p)) \leq \log(3(\mathcal{A}_p + \mathcal{S}_p)) + \tau(\varepsilon, d) \\ 36d\mathcal{A}_p^2 + 16d\mathcal{S}_p^2 \text{ otherwise} \end{cases}$$

$$b_3(p,\varepsilon) = \begin{cases} \det_{\mathcal{D}}(\mathcal{A}(p), 3\mathcal{S}_{\mathcal{A}(p)}) \text{ if } \mathrm{lvl}(\mathcal{A}(p), 3\mathcal{S}_{\mathcal{A}(p)}) \leq \log(3\mathcal{S}_{\mathcal{A}(p)}) + \tau(\varepsilon, d) \\ 0 \text{ otherwise} \end{cases}$$

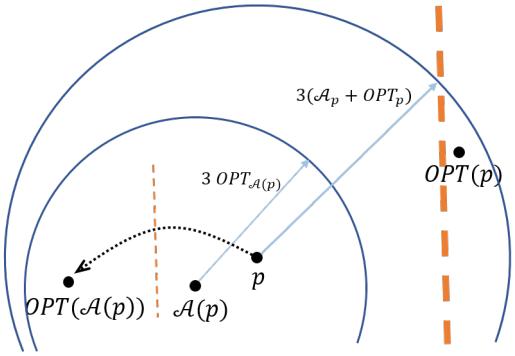

Figure 1 Illustration of one case of the distinction. $B(p, 3(\mathcal{A}_p + \mathrm{OPT}_p))$ is badly cut by the thick orange-dashed line, so p cannot be connected via portals to $\mathrm{OPT}(p)$. However, p and $\mathcal{A}(p)$ are not badly cut, so p can be connected to $\mathrm{OPT}(\mathcal{A}(p))$ instead, making a detour through the thin orange-dashed line. The cost of this reassignment is charged to $b_2(p)$.

3 Structure Theorem and the Approximation Algorithm

3.1 Roadmap

Now that all definitions are in place, we give a more precise high-level overview of the proof of Theorem 2. Our goal is to show that the decomposition of Lemma 5 with $\rho = \varepsilon/\log(1/\varepsilon)$ is precise enough for a dynamic program to compute a portal-respecting solution that is a $(1+\varepsilon)$-approximation.

To do this, we show that one can find a solution $\mathcal{S}^*$ such that: (1) it is a $(1+\varepsilon)$-approximation, and (2) the detour from each point to $\mathcal{S}^*$ is at most the budget of the point. To conclude, it is enough to bound the budget, which is a mere application of Lemma 5 and first-moment analysis. To find such a solution $\mathcal{S}^*$, we start from the optimal solution (which respects (1) but not (2)), and transform it such that each client can be connected through the portals.

First, consider the easy case where a client p is not badly cut, and $B(p, 3(\mathcal{A}_p + \mathrm{OPT}_p))$ is not badly cut. Then, the detour from p to OPT_p can be charged to $b_2(p, \varepsilon)$, as the closest optimal center to p lies in the latter ball. When this ball is badly cut, instead of serving p by its closest center $\mathrm{OPT}(p)$, we serve it by $\mathrm{OPT}(\mathcal{A}(p))$. We show that this can always be charged to the budget of p. Indeed, in the sub-case where $\mathcal{A}(p)$ itself is not badly cut, we can show that the detour between p and $\mathrm{OPT}(\mathcal{A}(p))$ is affordable compared to the distance between them; and this distance can be charged to the budget $b_2(p, \varepsilon)$. This sub-case is illustrated in Figure 1. However, in the sub-case where $\mathcal{A}(p)$ is badly cut as well, we have no choice but to add the center to OPT. This results in a solution with slightly too many centers – in expectation $(1+\varepsilon)k$, since each center is badly cut with probability ε – and we will need to remove some centers of the optimal solution without increasing the cost too much. This step is already presented in [13], and we recall it in Section 3.2.

This essentially concludes the case where p is not badly cut. When it is badly cut, the decomposition $\mathcal{D}$ approximates its distances poorly; however, this happens with tiny probability, and we can afford to move p to $\mathcal{A}(p)$ (charging this movement to $b_1(p, \varepsilon)$). A case analysis, similar to the previous one, then shows that the detour between $\mathcal{A}(p)$ to OPT can be charged to $b_2(p, \varepsilon)$ and $b_3(p, \varepsilon)$.

In the remainder of this section, we show how to remove some centers from the optimal solution (to then add the badly cut centers of $\mathcal{A}$), then prove the structure theorem that shows the existence of a solution satisfying (1) and (2). We explain in Section 3.4 the dynamic program that relies on this structure theorem and enables the computation of a good approximation, to conclude the proof of Theorem 2.

3.2 Preparing the Instance

We consider the mapping of the centers of OPT to $\mathcal{A}$ defined as follows: for any $f \in \text{OPT}$, let $\mathcal{A}(f)$ denote the center of $\mathcal{A}$ that is the closest to f. Recall that for a client c, $\mathcal{A}(c)$ is the center serving c in $\mathcal{A}$.

For any center ℓ of $\mathcal{A}$, define $\psi(\ell)$ to be the set of centers of OPT that are mapped to ℓ, namely, $\psi(\ell) = \{f \in \text{OPT} \mid \mathcal{A}(f) = \ell\}$. Define $\mathcal{A}^1$ to be the set of centers ℓ of $\mathcal{A}$ for which there exists a unique $f \in \text{OPT}$ such that $\mathcal{A}(f) = \ell$, namely $\mathcal{A}^1 = \{\ell \in \mathcal{A} \mid |\psi(\ell)| = 1\}$. Let $\mathcal{A}^0 = \{\ell \in \mathcal{A} \mid |\psi(\ell)| = 0\}$, and $\mathcal{A}^{\geq 2} = \mathcal{A} \setminus (\mathcal{A}^1 \cup \mathcal{A}^0)$. Similarly, define $\text{OPT}^1 = \{f \in \text{OPT} \mid \mathcal{A}(f) \in \mathcal{A}^1\}$ and $\text{OPT}^{\geq 2} = \{f \in \text{OPT} \mid \mathcal{A}(f) \in \mathcal{A}^{\geq 2}\}$. Note that $|\text{OPT}^{\geq 2}| = |\mathcal{A}^0| + |\mathcal{A}^{\geq 2}|$, since $|\text{OPT}^1| = |\mathcal{A}^1|$ and, w.l.o.g., $|\text{OPT}| = |\mathcal{A}| = k$.

As shown in [13], one can remove some of the centers from $\text{OPT}^{\geq 2}$ to obtain the following result:

▶ **Lemma 9** (See Step 1. and Lemma 4.1 in [13]). *There exists a set $\mathcal{H} \subseteq OPT^{\geq 2}$ such that:*

- $|\mathcal{H}| = \lfloor \varepsilon \cdot |OPT^{\geq 2}|/2 \rfloor$,
- *for any $\ell \in \mathcal{A}$, the center in $\psi(\ell)$ closest to ℓ is not in $\mathcal{H}$,*
- *let $OPT' = OPT \setminus \mathcal{H}$: OPT' has cost at most $(1 + O(\varepsilon))\text{cost}(OPT) + O(\varepsilon)\text{cost}(\mathcal{A})$.*

Furthermore, we transform the input set P to give it more structure, as follows. Given a randomized hierarchical decomposition $\mathcal{D}$ and a solution $\mathcal{A}$, we define the set $\widetilde{P}$ as follows. For every point p,

$$\widetilde{p} = \begin{cases} \mathcal{A}(p) \text{ if } p \text{ is badly cut w.r.t. } \mathcal{D} \text{ and } \mathcal{A} \\ p \text{ otherwise.} \end{cases}$$

We note that $\widetilde{P} := \{\widetilde{p} : p \in P\}$ is a random variable that depends on the randomness of $\mathcal{D}$.

3.3 Construction of a Structured Solution

Using Lemma 9, we can now show the existence of a near-optimal portal-respecting solution. Let $\mathcal{A}$ be a fixed solution, and OPT' the solution from Lemma 9 for P. Let $\mathcal{D}$ be a randomized hierarchical decomposition, and $B_{\mathcal{D}}$ be the set of centers of $\mathcal{A}$ that are badly cut w.r.t. OPT', i.e., $c \in B_{\mathcal{D}}$ when the ball $B(c, 3\text{OPT}'_c)$ is cut at some level greater than $\log(3\text{OPT}'_c) + \tau(\varepsilon, d)$.

▶ **Definition 10.** *For $\varepsilon > 0$, we say that $\mathcal{D}$ has* ε-small distortion *if*

1. *the total budget w.r.t. $\mathcal{A}$ and OPT' is bounded: $\sum_{p \in P} b(p, \varepsilon) \leq \varepsilon(\text{cost}(P, OPT) + \text{cost}(P, \mathcal{A}))$.*
2. *there exists a solution $\mathcal{S}^*$ that contains $B_{\mathcal{D}}$ with $\sum_{p \in P} (\text{dist}(p, \widetilde{p}) + \text{dist}(\widetilde{p}, \mathcal{S}^*))^2 \leq (1 + \varepsilon)\text{cost}(P, OPT) + \varepsilon\text{cost}(P, \mathcal{A})$,*
3. *for each point $p \in P$, its detour to $\mathcal{S}^*$ is at most $b(p, \varepsilon)$, namely there is a center $s \in \mathcal{S}^*$ cut from $\widetilde{p}$ at level i such that $(\text{dist}(p, \widetilde{p}) + \text{dist}(\widetilde{p}, s) + \varepsilon 2^i)^2 \leq (\text{dist}(p, \widetilde{p}) + \text{dist}(\widetilde{p}, \mathcal{S}^*))^2 + b(p, \varepsilon)$.*

As explained in the introduction, we will use those properties as follows: a standard dynamic program will compute the best *portal-respecting* solution that minimizes $\widetilde{\text{cost}}(P,\mathcal{S}) := \sum_p (\text{dist}(p,\widetilde{p}) + \text{dist}(\widetilde{p},\mathcal{S}))^2$. Making the solution portal-respecting incurs an error $\varepsilon 2^i$ for two points cut at level i: Property 3 therefore bounds this error by $b(p,\varepsilon)$. Property 1 of Definition 10 ensures that the total budget is bounded, and Property 2 relates $\widetilde{\text{cost}}$ to cost.

Our main structural theorem for k-means in low dimension is the following:

▶ **Theorem 11** (Structure Theorem). *For any $\varepsilon > 0$, $\mathcal{D}$ has ε-small-distortion with probability at least $2/3$.*

The rest of the paper is dedicated to the proof of this theorem.

3.3.1 Bounding the Budget

▶ **Lemma 12.** *Fix two solutions $\mathcal{A}$ and $\mathcal{S}$, and let $b(p,\varepsilon)$ be the budget of p w.r.t. solutions $\mathcal{A}$ and $\mathcal{S}$. With probability $2/3$ (over the randomness of $\mathcal{D}$), $\sum_p b(p,\varepsilon) = O(d^2\log(1/\varepsilon)\cdot\varepsilon)(\text{cost}(P,\mathcal{A}) + \text{cost}(P,\mathcal{S}))$*

Proof. We bound the expectation of the budget and then use Markov's inequality. Recall that any ball $B(x,r)$ is cut at level i with probability $dr/2^i$, and is badly cut with probability ε. Furthermore, when $B(x,r)$ is cut at level i, then $\det_{\mathcal{D}}(x,r) = \varepsilon r 2^i + \varepsilon^2 2^{2i}$.

To simplify the analysis slightly, we first analyze the expectation of the variable

$$\beta(x,r) := \begin{cases} \det_{\mathcal{D}}(x,r) \text{ when } \text{lvl}(x,r) \le \log(r) + \tau(\varepsilon,d) \\ 0 \text{ otherwise.} \end{cases}$$

To do so, we distinguish between the cases where $\text{lvl}(x,r)$ is at most $\log(r)$, between $\log(r)$ and $\log(r)+\tau(\varepsilon,d)$, and at least $\log(r)+\tau(\varepsilon,d)$. This gives the following upper bound:

$$\begin{aligned}
\mathbb{E}[\beta(x,r))] &\le \sum_{i\le\log(r)} \det_{\mathcal{D}}(x,r) + \sum_{i=\log(r)}^{\log(r)+\tau(\varepsilon,d)} \det_{\mathcal{D}}(x,r)\cdot\Pr[\mathcal{D}\text{ cuts } B(p,r) \text{ at a level } i] \\
&\le \sum_{i\le\log(r)} \left(\varepsilon 2^i r + \varepsilon^2 2^{2i}\right) + \sum_{i=\log(r)}^{\log(r)+\tau(\varepsilon,d)} \left(\varepsilon 2^i r + \varepsilon^2 2^{2i}\right)\cdot\frac{dr}{2^i} \\
&\le 3\varepsilon r^2 + \sum_{i=\log(r)}^{\log(r)+\tau(\varepsilon,d)} \left(\varepsilon d r^2 + \varepsilon^2 2^i\cdot dr\right) \\
&\le 3\varepsilon r^2 + \tau(\varepsilon,d)\cdot\varepsilon d r^2 + \varepsilon^2\cdot dr\cdot 2^{\log(r)+\tau(\varepsilon,d)} \\
&= O(d^2\log(1/\varepsilon))\varepsilon r^2,
\end{aligned}$$

where the last line uses $2^{\tau(\varepsilon,d)} = 2^{\log(d)+\log(1/\varepsilon)} = O(d/\varepsilon)$.

Since $b_1(p,\varepsilon) = \beta(p,3\mathcal{A}_p)$ and $b_3(p,\varepsilon) = \beta(\mathcal{A}(p),3\mathcal{S}_{\mathcal{A}(p)})$, we directly get $\mathbb{E}[b_1(p,\varepsilon) + b_3(p,\varepsilon)] \le O(d^2\log(1/\varepsilon)\varepsilon)(\mathcal{A}_p^2 + \mathcal{S}_p^2)$. Bounding $b_2(p,\varepsilon)$ is only slightly more complicated: $b_2(p,\varepsilon) = \beta(p,\mathcal{A}_p+\mathcal{S}_p) + X(p,\varepsilon)$, where $X(p,\varepsilon) := 36d\mathcal{A}_p^2 + 16d\mathcal{S}_p^2$ when $\text{lvl}(p,3(\mathcal{A}_p+\mathcal{S}_p)) > \log(3(\mathcal{A}_p+\mathcal{S}_p)) + \tau(\varepsilon,d)$. Therefore, it is enough to compute $\mathbb{E}[X(p,\varepsilon)]$.

Properties of the decomposition in Lemma 5 ensure that $\text{lvl}(p,3(\mathcal{A}_p+\mathcal{S}_p)) > \log(3(\mathcal{A}_p+\mathcal{S}_p)) + \tau(\varepsilon,d)$ with probability at most ε, and therefore $\mathbb{E}[X(p,\varepsilon)] \le \varepsilon\cdot(36d\mathcal{A}_p^2 + 16d\mathcal{S}_p^2)) = O(\varepsilon d(\mathcal{A}_p^2+\mathcal{S}_p^2))$.

Therefore, $\mathbb{E}[b_2(p,\varepsilon)] = \mathbb{E}[\beta(p,3(\mathcal{A}_p+\mathcal{S}_p)] + \mathbb{E}[X(p,\varepsilon)] \le O(d^2\log(1/\varepsilon)\cdot\varepsilon)(\mathcal{A}_p^2+\mathcal{S}_p^2)$.

Summing these inequalities for b_1, b_2, b_3, and for all $p\in P$ we get $\mathbb{E}[\sum_{p\in P} b(p,\varepsilon)] \le O(d^2\log(1/\varepsilon)\cdot\varepsilon)(\text{cost}(P,\mathcal{A}) + \text{cost}(P,\mathcal{S}))$. Markov's inequality concludes the lemma. ◀

3.3.2 Construction of $\mathcal{S}^*$

To construct $\mathcal{S}^*$, we start from the solution OPT' obtained from Lemma 9 and apply the two following steps.

For any $\ell \in \mathcal{A}$, define f_ℓ to be its closest center in $\psi(\ell)$, breaking ties arbitrarily. We start with $\mathcal{S}^* = \mathrm{OPT}'$ obtained from Lemma 9. Note that for every $\ell \in \mathcal{A}^1 \cup \mathcal{A}^{\geq 2}$, the second property of Lemma 9 ensures that f_ℓ is a center of OPT'. $\mathcal{S}^*$ is then transformed as follows:

- **Step 1.** For each center $\ell \in B_{\mathcal{D}} \setminus \mathcal{A}^0$ (i.e., ℓ is badly cut w.r.t. $\mathcal{D}$ and OPT', and $\psi(\ell) \neq \emptyset$), replace f_ℓ by ℓ in $\mathcal{S}^*$.
- **Step 2.** Add all centers of $\mathcal{A}^0$ badly cut w.r.t. $\mathcal{D}$ and OPT' to $\mathcal{S}^*$.

The two key properties of that procedure are the following:

▶ **Fact 13** (Claim 4.3 and 4.4 in [13]). *With probability* $4/5$, $|\mathcal{S}^*| \leq k$, *so* $\mathcal{S}^*$ *is a valid solution, and* $\mathrm{cost}(P, \mathcal{S}^*) \leq (1+\varepsilon)\mathrm{cost}(P, OPT) + \varepsilon\mathrm{cost}(P, \mathcal{A})$. *Furthermore, for any point* p, *it holds that* $\mathrm{dist}(p, \mathcal{S}^*) \leq 2\,\mathrm{dist}(p, OPT') + \mathrm{dist}(p, \mathcal{A})$.

In addition, the construction of $\mathcal{S}^*$ ensures the below whose proof is in the full version:

▶ **Fact 14.** *For any point* p,

$$\mathrm{dist}(p, \widetilde{p}) + \mathrm{dist}(\widetilde{p}, \mathcal{S}^*) \leq 3\mathcal{A}_p + 2OPT'_p$$
$$\mathrm{dist}(p, \mathcal{S}^*(\mathcal{A}(p))) \leq 3\mathcal{A}_p + 2OPT'_p.$$

Furthermore, for any center $\ell \in \mathcal{A}$, *it holds that* $\mathrm{dist}(\ell, \mathcal{S}^*) \leq 2\,\mathrm{dist}(\ell, OPT')$.

We can now use this solution $\mathcal{S}^*$ to show $\mathcal{D}$ has ε-small distortion.

3.3.3 Bounding the cost of $\mathcal{S}^*$

▶ **Lemma 15.** $\mathcal{S}^*$ *contains* $B_{\mathcal{D}}$, *and with probability at least* $4/5$ *it holds that*

$$\sum_{p\in P} \left(\mathrm{dist}(p, \widetilde{p}) + \mathrm{dist}(\widetilde{p}, \mathcal{S}^*)\right)^2 \leq (1+\varepsilon)\mathrm{cost}(P, OPT) + \varepsilon\mathrm{cost}(P, \mathcal{A})$$

Proof. By construction, $\mathcal{S}^*$ does contain $B_{\mathcal{D}}$. To simplify the equations, we write p b.c. when p is badly cut w.r.t. $\mathcal{A}$ (in which case $\widetilde{p} = \mathcal{A}(p)$). It holds that

$$\sum_{p\in P} \left(\mathrm{dist}(p, \widetilde{p}) + \mathrm{dist}(\widetilde{p}, \mathcal{S}^*)\right)^2 \leq \sum_{p\in P} \mathrm{dist}(p, \mathcal{S}^*)^2 + \sum_{p \text{ b.c.}} \left(\mathrm{dist}(p, \widetilde{p}) + \mathrm{dist}(\widetilde{p}, \mathcal{S}^*)\right)^2. \tag{1}$$

By Fact 13, the first term is at most $(1+\varepsilon)\mathrm{cost}(P, \mathrm{OPT}) + \varepsilon\mathrm{cost}(P, \mathcal{A})$: thus, we focus only on the second term. For this, we use Fact 14:

$$\begin{aligned}\sum_{p \text{ b.c.}} \left(\mathrm{dist}(p, \widetilde{p}) + \mathrm{dist}(\widetilde{p}, \mathcal{S}^*)\right)^2 &\leq \sum_{p \text{ b.c.}} \left(3\mathcal{A}_p + 2\mathrm{OPT}'_p\right)^2 \\ &\leq 18 \sum_{p \text{ b.c.}} \mathcal{A}_p^2 + \mathrm{OPT}'^2_p\end{aligned}$$

Each point p is badly cut with probability ε: therefore, in expectation, it holds that

$$\begin{aligned}\mathbb{E}[18 \sum_{p \text{ b.c.}} \mathcal{A}_p^2 + \mathrm{OPT}'^2_p] &\leq 18\varepsilon \sum_{p\in P} \mathcal{A}_p^2 + \mathrm{OPT}'^2_p \\ &\leq 18\varepsilon(\mathrm{cost}(P, \mathcal{A}) + \mathrm{cost}(P, \mathrm{OPT}'))\end{aligned}$$

Using Markov's inequality, it holds with probability 4/5 that

$$\sum_{p \text{ b.c.}} \left(\text{dist}(p,\widetilde{p}) + \text{dist}(\widetilde{p},\text{OPT}')\right)^2 \leq 18 \cdot 5 \cdot \varepsilon(\text{cost}(P,\mathcal{A}) + \text{cost}(P,\text{OPT}')).$$

Plugging this bound into Equation (1) and using Lemma 9 to bound the cost of OPT', we conclude:

$$\begin{aligned}&\sum_{p\in P} (\text{dist}(p,\widetilde{p}) + \text{dist}(\widetilde{p},\mathcal{S}^*))^2 \\ &\quad\leq (1+\varepsilon)\text{cost}(P,\text{OPT}) + \varepsilon\text{cost}(P,\mathcal{A}) + 18\cdot 5\cdot\varepsilon(\text{cost}(P,\mathcal{A}) + \text{cost}(P,\text{OPT}')) \\ &\quad= (1+O(\varepsilon))\text{cost}(P,\text{OPT}) + O(\varepsilon)\text{cost}(P,\mathcal{A}).\end{aligned}$$

◀

3.3.4 Bounding the detour

We now show that the detour incurred by connecting $\widetilde{P}$ to $\mathcal{S}^*$ through portals of the decomposition $\mathcal{D}$ is within the budget defined in Definition 8.

▶ **Lemma 16.** *Let $P \subset \mathbb{R}^d$, $\mathcal{A}$ be a solution for k-means on P and $\mathcal{D}$ be a randomized decomposition. Let $\mathcal{S}^*$ be the solution from Lemma 15.*

Then, for any $p \in P$, there is a center $s \in \mathcal{S}^*$ cut from $\widetilde{p}$ at some level i such that $(\text{dist}(p,\widetilde{p}) + \text{dist}(\widetilde{p},s) + \varepsilon 2^i)^2 \leq (\text{dist}(p,\widetilde{p}) + \text{dist}(\widetilde{p},\mathcal{S}^*))^2 + b(p,\varepsilon)$.

Proof. We recall that any point $x \in \mathbb{R}^d$ is badly cut w.r.t. $\mathcal{D}$ and a set S when the ball $B(x, 3\,\text{dist}(x,S))$ is cut at level higher than $\log(9\,\text{dist}(x,S)) + \tau(\varepsilon,d)$. We recall our construction of $\widetilde{P}$ and $\mathcal{S}^*$: When a point p is badly cut w.r.t $\mathcal{D}$ and $\mathcal{A}$, $\widetilde{p} = \mathcal{A}(p)$; when a center $\ell \in \mathcal{A}$ is badly cut w.r.t $\mathcal{D}$ and OPT', $\ell \in \mathcal{S}^*$.

To show the lemma, we make a case distinction, first according to whether p is badly cut or not w.r.t. $\mathcal{D}$ and $\mathcal{A}$. In the case where it is badly cut, it holds that $\widetilde{p} = \mathcal{A}(p)$. Then, we have the following cases.

1. If $\mathcal{A}(p)$ is badly cut w.r.t. $\mathcal{D}$ and OPT', then $\mathcal{A}(p) \in \mathcal{S}^*$: therefore, $\widetilde{p} = \mathcal{A}(p) = \mathcal{S}^*(p)$, and $\widetilde{p}$ and $\mathcal{S}^*(p)$ are not cut, e.g. $i = -\infty$. Therefore, $s = \mathcal{A}(p)$ satisfies the lemma, with $(\text{dist}(p,\widetilde{p}) + \text{dist}(\widetilde{p},s) + \varepsilon 2^i)^2 = \text{dist}(p,\widetilde{p})^2$.
2. $\mathcal{A}(p)$ is not badly cut w.r.t. $\mathcal{D}$ and OPT'. Let $s = \mathcal{S}^*(\mathcal{A}(p))$, and i be the level at which $\mathcal{A}(p)$ and s are cut. We write $(\text{dist}(p,\widetilde{p}) + \text{dist}(\widetilde{p},s) + \varepsilon 2^i)^2 = (\mathcal{A}_p + \text{dist}(\widetilde{p},\mathcal{S}^*))^2 + 2\varepsilon 2^i \cdot \mathcal{A}_p + 2\varepsilon 2^i \cdot \mathcal{S}^*_{\mathcal{A}(p)} + \varepsilon^2 2^{2i}$.

   By Fact 14, $s \in B(\mathcal{A}(p), 2\text{OPT}'_{\mathcal{A}(p)})$, and so $i \leq i' := \text{lvl}\left(\mathcal{A}(p), 3\text{OPT}'_{\mathcal{A}(p)}\right)$. Combined with the fact that $\mathcal{A}(p)$ is not badly cut, it therefore holds that $2\varepsilon 2^i \cdot \mathcal{S}^*_{\mathcal{A}(p)} + \varepsilon^2 2^{2i} \leq 2\varepsilon 2^{i'} \cdot 2\text{OPT}'_{\mathcal{A}(p)} + \varepsilon^2 2^{2i'} \leq b_3(p)$. Thus, it is enough to bound $2\varepsilon 2^i \cdot \mathcal{A}_p$. For this, we refine our case distinction, according to whether the ball $B(p, 3(\mathcal{A}_p + \text{OPT}'_p))$ is badly cut or not, and use the budget from $b_2(p)$.
   a. If the ball is not badly cut, then we remark that Fact 14 ensures that both s and $\mathcal{A}(p)$ are in $B(p, 3(\mathcal{A}_p + \text{OPT}'_p))$, and therefore $i \leq i'' := \text{lvl}(p, 3(\mathcal{A}_p + \text{OPT}'_p))$. Therefore, $2\varepsilon 2^i \cdot \mathcal{A}_p \leq \varepsilon 2^{i''} 3(\mathcal{A}_p + \text{OPT}'_p) \leq b_2(p)$.
   b. If this ball is badly cut, then we use $i \leq i' \leq \log(3\text{OPT}'_{\mathcal{A}(p)}) + \tau(\varepsilon,d)$ in addition to $\text{OPT}'_{\mathcal{A}(p)} \leq \mathcal{A}_p + \text{OPT}'_p$ as follows: $2\varepsilon 2^i \cdot \mathcal{A}_p \leq 6\varepsilon \cdot \text{OPT}'_{\mathcal{A}(p)} \cdot 2^{\tau(\varepsilon,d)}\mathcal{A}_p \leq 6d(\mathcal{A}_p + \text{OPT}'_p)\mathcal{A}_p \leq b_2(p)$.

   Combining these cases, we get that when $\mathcal{A}(p)$ is not badly cut, $(\text{dist}(p,\widetilde{p}) + \text{dist}(\widetilde{p},s) + \varepsilon 2^i)^2 \leq (\mathcal{A}_p + \text{dist}(\widetilde{p},\mathcal{S}^*))^2 + b_2(p) + b_3(p)$.

We now turn to the case where p is not badly cut. In that case, $\widetilde{p} = p$: we therefore only need to bound $\left(\text{dist}(p, \mathcal{S}^*) + \varepsilon 2^i\right)^2$ and the details of this are presented in the full version. ◀

3.4 The Algorithm: how to use the Structure Theorem

Suppose that $\mathcal{D}$ has ρ-small-distortion, for $\rho = O(\varepsilon/\log(1/\varepsilon))$ (where the O hides dependencies in d), and let $\mathcal{S}^*$ be the solution provided by Definition 10. As explained previously, our algorithm will be a standard dynamic program working as follows. The decomposition $\mathcal{D}$ will be augmented with a set of portals, as defined in Lemma 5, with $\rho = \varepsilon/\log(1/\varepsilon)$. The dynamic program (described later in greater detail) computes the best portal-respecting solution, namely, the solution where each path connecting a client to a center crosses boundaries of $\mathcal{D}$ only at portals. More precisely, it computes the portal-respecting solution with (almost) smallest $\widetilde{\text{cost}}(P, \mathcal{S}) := \sum_p (\text{dist}(p, \widetilde{p}) + \text{dist}(\widetilde{p}, \mathcal{S}))^2$

▶ **Theorem 17.** *There exists an algorithm running in time* $(2/\varepsilon)^{O\left(\log(1/\varepsilon)/\varepsilon\right)^{d-1}} \cdot n \log^3 n$ *that computes a portal-respecting solution* $\mathcal{S}$ *such that* $\widetilde{\text{cost}}(P, \mathcal{S}) \leq (1+\varepsilon) \min_{\mathcal{S}'} \widetilde{\text{cost}}(P, \mathcal{S}')$.

The preciseness and nestedness of portal sets ensure that, when two points x and y are cut at level i, then the portal-respecting path between x and y has length $\|x - y\| + \rho 2^{i+1}$. Furthermore, the algorithm from Theorem 17 computes a solution at least as good as $\mathcal{S}^*$: by Property 3 of Definition 10, the portal-respecting $\widetilde{\text{cost}}$ of $\mathcal{S}^*$ is at most $\sum_p (\text{dist}(p, \widetilde{p}) + \text{dist}(\widetilde{p}, \mathcal{S}^*))^2 + b(p, \rho)$. Property 1 ensures that the total budget is at most $\rho(\text{cost}(P, \text{OPT}) + \text{cost}(P, \mathcal{A})) = O(\rho)\text{cost}(P, \text{OPT})$, since $\mathcal{A}$ is an $O(1)$-approximation. Combined with Property 2 of Definition 10, this shows that the portal-respecting $\widetilde{\text{cost}}$ of the solution computed by the algorithm is at most $(1 + O(\varepsilon))\text{cost}(P, \text{OPT})$.

To wrap up, we note that the portal respecting $\widetilde{\text{cost}}$ is an upper bound on cost: going in straight lines instead of going through portals only improves the cost, and for any point p, $\text{dist}(p, \mathcal{S}) \leq \text{dist}(p, \widetilde{p}) + \text{dist}(\widetilde{p}, \mathcal{S})$. Therefore, the solution computed by the dynamic program is a $(1 + O(\varepsilon))$-approximation for k-means.

The algorithm used to show Theorem 17 is a quite standard dynamic program (DP), described in detail in [13] and is deferred to the full version.

Abstract

The continuous Fréchet distance $\mathcal{D}_F(\pi, \sigma)$ between two polygonal curves π and σ is classically computed by exploring the *free space diagram* over the two curves. [SoCG'25] recently proposed a radically different approach: they approximate $\mathcal{D}_F(\pi, \sigma)$ by computing paths in a discrete graph that models a joint traversal of π and σ, recursively bisecting edges until the discrete distance converges to the continuous one. They implement their "frog-based" technique, and claim that it yields substantial practical speedups compared to the state-of-the-art implementations.

In this paper, we revisit this technique. We observe that, in its current form, it has three limitations: (i) it does not use exact arithmetic, (ii) its recursive bisection introduces the required monotonicity events to realise the Fréchet distance only in the limit, and (iii) it applies a heuristic simplification technique which is overly conservative. Motivated by theoretical interest, we develop new techniques that guarantee exactness, polynomial-time convergence and near-optimal lossless simplifications. We provide an open-source C++ implementation of our variant.

Our primary contribution is an extensive empirical evaluation on a broad, publically available, suite of real-world and synthetic data sets. Among the frog-based variants, exact computation indeed introduces overhead and increases median runtime. Yet, our new approach is often faster in the worst case, worst ten percent, or even the average runtime due to its worst-case convergence guarantees. More surprisingly, the implementation of [SoCG'19] dominates all frog-based implementations in performance – this finding contrasts previously published claims. These results provide a much-needed nuanced perspective on the capabilities and limitations of frog-based techniques: we showcase its theoretical appeal, but highlight its limited practical feasibility.

1 Introduction

The continuous Fréchet distance between two polygonal curves π and σ is classically described using the analogy of a person walking along π and a dog walking along σ, each moving continuously and monotonically. The continuous Fréchet distance $\mathcal{D}_F(\pi, \sigma)$ is the infimum

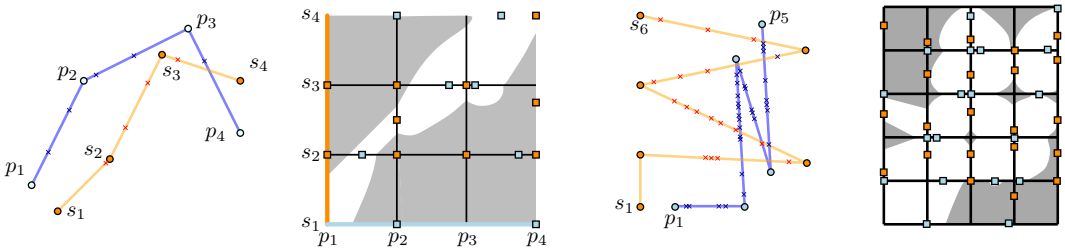

Figure 1 Two curves (π, σ) with their parameter space. White space indicates that the corresponding points are within some distance Δ. In each grid, we illustrate the edge events. For each monotonicity event defined by an edge e and vertices (x_1, x_2) we show the event on e with a cross.

over all such traversals of the maximum distance between them. A discrete analogue is defined similarly by imagining two frogs that hop monotonically along the vertices of π and σ, leading to the discrete Fréchet distance $\mathbb{D}_F(\pi, \sigma)$.

Let $\pi = (p_1, \ldots, p_n)$ and $\sigma = (s_1, \ldots, s_m)$. From an algorithmic and practical perspective, it is possible to decide whether their continuous or discrete decision problems is less than some input value Δ in an efficient manner. For a given value Δ, deciding whether $\mathbb{D}_F(\pi, \sigma) \leq \Delta$ reduces to determining whether there exists a monotone path in an $n \times m$ vertex-weighted grid where the weight of (p_i, s_j) is $d(p_i, s_j)$. Removing all vertices with weight greater than Δ and performing a graph search from (p_1, s_1) to (p_n, s_m) takes $O(nm)$ time. The continuous decision problem admits a related construction that we discuss in the preliminaries.

Computing the Fréchet distance and monotonicity events. Computing the *value* of the Fréchet distance is considerably more intricate. The continuous distance is realised by one of three types of events (see Figure 1). Vertex events correspond to distances between pairs of vertices in $\pi \times \sigma$; edge events correspond to distances between a vertex of one curve and an edge of the other; and monotonicity events correspond to triples (e, s, s'), where e is an edge of one curve, s, s' are vertices of the other curve, and the corresponding distance value is realised by the point on e minimising the maximum distance to s and s'. The discrete distance $\mathbb{D}_F(\pi, \sigma)$ is always realised by a vertex event. As there are $O(nm)$ such events one may therefore compute all distances, sort them, and apply the decision procedure, yielding an $O(nm \log nm)$ algorithm (or $O(nm)$ with a simple dynamic program). This version is also easy to make exact, as one can simply square the vertex-weights to maintain rational input. For the continuous setting, monotonicity events introduce two significant difficulties:

- There are $O(n^3 + m^3)$ such events, so no quadratic-time algorithm can enumerate them.
- Edge and monotonicity events involve equations that contain several square root monomials. They therefore offer no straightforward way to avoid numerical imprecision, even if the input is integral. This causes problems, not only for computing the distance value, but even for computing the correct combinatorial traversal that realises the Fréchet distance.

An exact decision procedure for the continuous variant was provided by [10], who use exact geometric predicates to test $\mathcal{D}_F(\pi, \sigma) \leq \Delta$ in $O(nm)$ time. Their implementation allows an approximation of $\mathcal{D}_F(\pi, \sigma)$ to b bits precision via binary search in $O(nm(\log nm + \log b))$ time, but it does not compute the exact value.

Approaching the continuous Fréchet distance with a frog. [26] recently proposed a different approach. Given (π, σ) they construct what they call the VE-graph whose vertices correspond to all vertex and edge events. In this graph, there is an edge between two vertices if they share

a cell and either the edge is monotone, or the events lie on an edge of the same curve (see Figure 2). The vertices are weighted by the event distance, and the shortest path from $(1, 1)$ to (n, m) in this graph corresponds to a (non-monotone) person-dog traversal γ. If γ happens to be xy-monotone, its continuous counterpart realises the Fréchet distance. Otherwise, non-monotonicities certify that the Fréchet distance is realised by a monotonicity event. Instead of computing monotonicity events, their algorithm bisects each edge of π and σ where γ is non-monotone in the corresponding row or column. This creates higher-complexity curves (π', σ') on which they recurse. They call this *refinement*, and its recursive application yields increasingly complex curves whose vertex and edge events approach the continuous Fréchet distance $\mathcal{D}_F(\pi, \sigma)$. In the limit, this procedure converges to introducing the necessary monotonicity events and thereby computes the continuous Fréchet distance through discrete shortest paths.

Their second contribution is a clever simplification technique that is agnostic to how the Fréchet distance between curves is computed. They show how to simplify two input curves (π, σ) into lower-complexity curves $(\overline{\pi}, \overline{\sigma})$ such that $\mathcal{D}_F(\pi, \sigma) = \mathcal{D}_F(\overline{\pi}, \overline{\sigma})$. The procedure is iterative: they first compute simplified curves $(\overline{\pi}, \overline{\sigma})$ and evaluate $\mathcal{D}_F(\overline{\pi}, \overline{\sigma})$ using any method. This yields a person-dog traversal, from which they generate a witness certifying whether $\mathcal{D}_F(\overline{\pi}, \overline{\sigma}) = \mathcal{D}_F(\pi, \sigma)$ holds. If not, the curves are partially un-simplified, reintroducing complexity until the criterion is satisfied. Based on our observations, this simplification step is likely the main source of the speedy performance of their implementation.

Applications of Fréchet distance. The Fréchet distance has many well-known applications, in particular in the analysis and visualisation of movement data [11, 15, 29, 37], and has enjoyed continued interest in many different settings [1, 2, 7, 17–19, 23]. It is a versatile measure used across a wide range of domains, including handwriting [33], coastlines [30], geographic outlines [21], trajectories of vehicles, animals, and sports players [9, 15, 32, 34], air traffic [8], and protein structures [28]. These typically provide their own Fréchet distance implementations. A recent and particularly active domain is *trajectory clustering*, where the task is to group (sub)curves into clusters such that each cluster has low pairwise Fréchet distance. Several approaches adopt this principle, including the subtrajectory clustering algorithm of [3], the map construction and clustering algorithms [11, 12], the clustering method of [13] (implemented in the `MOVETK` library [24]), the clustering algorithm of [16], and the clustering of [35]. In the *vast* majority of these examples, the implementation computes the discrete Fréchet distance, as this is considerably easier to evaluate in practice.

Two of these approaches [11, 12] compute the *semi-weak* Fréchet distance, in which the person and the dog are not required to be monotone within an edge. This variant corresponds to the edge-monotone minimum-cost traversal computed from [26] before their curve refinement procedure is applied. These examples illustrate the need for efficient and adaptable Fréchet distance implementations, and highlight why the refinement-based approach of [26] is appealing: it suggests the possibility of computing the exact continuous Fréchet distance through a discrete traversal mechanism that is compatible with existing algorithmic paradigms and interfaces.

Contribution. We re-examine the frog-based framework of [26], as we improve three aspects of their contribution.

Contribution 1: exact-value computations. We find the overarching method conceptually very interesting (and even elegant), however, their algorithm does not compute the exact Fréchet distance. They state that "as the calculation of the optimal Fréchet distance involves

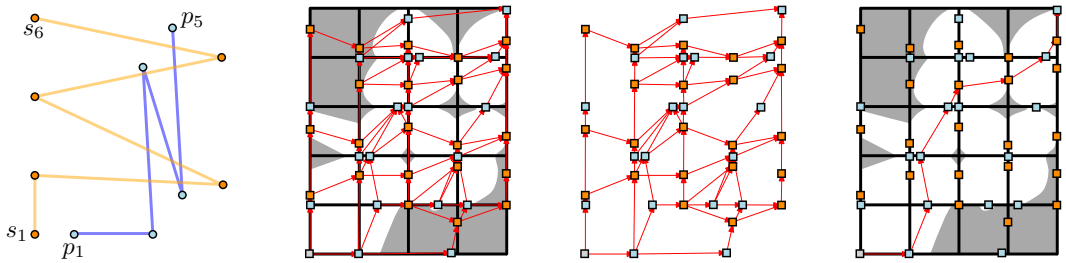

Figure 2 Two pairs of curves (π, σ) and their VE-graph which is a directed and vertex-weighted graph. The minimum-cost path from $(1, 1)$ to (n, m) in this graph is not a monotone traversal.

distances, impreciseness is unavoidable". This is not necessarily true as there exist exact-evaluation predicates. In theory, one can even assume a real RAM. Their current approach would remain imprecise under such assumptions:

1. Their implementation inherently uses floating-point arithmetic and thus imprecision.
2. However, even with exact real-valued arithmetic, their edge bisection does not introduce the monotonicity events that realise the exact Fréchet distance. This refinement converges to the correct value only in the limit, with no bound on the number of required iterations.

Their lossless simplification step is theoretically sound and would yield the exact Fréchet distance under real-valued arithmetic. However, the procedure is somewhat crude: to ensure that the Fréchet distance remains unchanged after simplification, they impose overly conservative constraints on how the curves may be simplified. The original paper briefly acknowledges the possibility of an exact algorithm, but quickly states that "from implementation point of view such a modification seems pointless, and we did not pursue it any further". Our motivation is to understand to what extent this framework *can* be made exact and efficient, and to provide the required components to do so.

1. We explain in detail how to unpack square-root expressions for exact evaluation. This is non-trivial, particularly for monotonicity events and curve simplifications where several square-root terms must be handled simultaneously.
2. We replace their heuristic refinement procedure with a new output-sensitive algorithm that generates the required monotonicity events on demand. As a consequence, we obtain provable polynomial-time convergence, even under real-valued computations.
3. We strengthen the lossless simplification technique. Whilst the method from [26] works as a black-box given any Fréchet computation algorithm that outputs a traversal, we note that this frog-based paradigm allows for a tighter algorithm and analysis. This leads to an alternative and new algorithm for lossless simplification under the frog-based method.

Contribution 2: exact implementation. We provide an open-source C++ implementation of our adapted algorithm with our exact arithmetic and monotonicity event-generation. This thereby is the first exact implementation. We experientially compare our solution to the one provided in [26]. Unsurprisingly, our median running times increase due to exact computation. Our exact-value representations simply do not allow for vectorisation, which comes at performance cost. Somewhat unexpectedly, the worst-case running time drastically improves. We can show instances where the recursive refinement encounters its worst-case behaviour and terminates with an approximation only after many refinement steps. For some data sets, the worst-case behaviour is such that even our average time is an improvement.

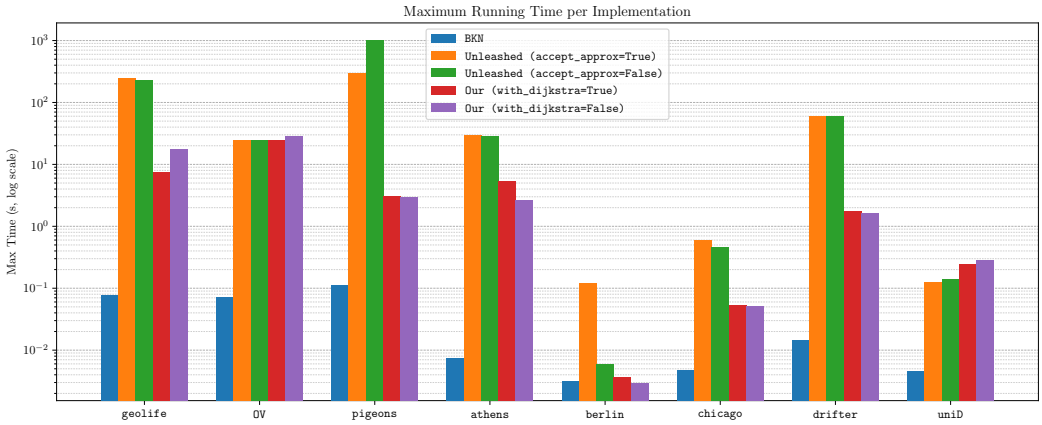

Figure 3 Maximum running times in seconds, log-scale, for curves from eight data sets.

Contribution 3: extensive empirical analysis. Our final contribution is the most significant. The original publication [26] claims that their running times are significantly faster than previous Fréchet computations. Across all our data sets, we observe a substantially different performance profile. In particular, the highly-optimised implementation of Bringmann, Künnemann, and Nusser `BKN` [10] dominates all frog-based implementations in performance (e.g., Figure 3). As a consequence of our discovery, the authors of [26] posted on their ArXiV version an errata explaining that their experimental setup was flawed.

At first sight, our empirical analysis may appear unfavourable to our contribution, as it shows that on many practical instances the performance of this new frog-based approach is surpassed by classical techniques. However, we argue for our significance: we provide the first exact Fréchet distance implementation. Moreover, the empirical analysis reported at SoCG'25 [26] claimed strong practical performance over [10]. Our broader evaluation provides a necessary complementary picture, contradicting this claim. We view this contrast as valuable to our community: it clarifies that this technique is valuable, but also clearly shows the limits of its use. Ultimately, we argue that the frog-based technique of [26] is of genuine theoretical interest, as it can be augmented to compute the exact Fréchet distance in a unique manner with provable guarantees. At the same time, its practical use is debatable.

2 Preliminaries

The input consists of polygonal curves π and σ. A *curve* $\pi = (p_1, \ldots, p_n)$ is an ordered sequence of *vertices* connected by straight-line *edges*. We implicitly endow every n-vertex curve π with a bijective, monotone parametrisation $\pi : [1, n] \to \mathbb{R}^d$ such that $\pi(i) = p_i$ for all integers i. For $t \in [i, i+1]$, the mapping is defined by linear interpolation $\pi(t) := p_i + (p_{i+1} - p_i)\,(t - i)$.

For an ordered pair of curves (π, σ) of sizes (n, m), a *traversal* is any pair of continuous, monotone mappings $\alpha : [0, 1] \to [1, n]$ and $\beta : [0, 1] \to [1, m]$. The (continuous) Fréchet distance $\mathcal{D}_F(\pi, \sigma)$ is defined as $\mathcal{D}_F(\pi, \sigma) := \inf_{\text{traversals } (\alpha,\beta)} \max_{t\in[0,1]} d\big(\pi(\alpha(t)), \sigma(\beta(t))\big)$.

Equivalently, consider the parameter space $\Gamma_{\pi,\sigma} := [1, n] \times [1, m]$, subdivided into an $n \times m$ grid. A traversal corresponds to any continuous, xy-monotone curve $\gamma(t) = (\alpha(t), \beta(t))$ from $(1, 1)$ to (n, m) in $\Gamma_{\pi,\sigma}$. We therefore freely consider traversals as monotone curves.

Deciding. We can decide whether $\mathcal{D}_F(\pi,\sigma) \leq \Delta$ as follows. The area $\{(a,b) \in [1,n]\times[1,m] \mid d(\pi(a),\sigma(b)) \leq \Delta\}$ is the *free space*. Via DFS over the free space we decide in $O(nm)$ time whether the free space contains a monotone curve from $(1,1)$ to (n,m), i.e., $\mathcal{D}_F(\pi,\sigma) \leq \Delta$ [5].

Computing. The Fréchet distance is realised by one of three types of *events*:

- *Vertex events*: distances between pairs of vertices in $\pi \times \sigma$.
- *Edge events*: distances between a vertex of one curve and an edge of the other.
- *Monotonicity events*: triples (e,s,s') where e is an edge of one curve and s,s' are vertices of the other, corresponding to minimising the maximum distance to s and s'.

A naive algorithm enumerates all events in $O(nm^2+mn^2)$ time, sorts them, and performs a binary search with the decision algorithm to obtain $\mathcal{D}_F(\pi,\sigma)$. [5] observed that many monotonicity events are irrelevant and achieved an $O(nm\log nm)$-time exact algorithm. [25] gave a considerably simpler approach: as Δ increases, connected components of the free space merge, and a *critical value* is the smallest Δ at which a new merge occurs. Each cell has one connected component, implying $O(nm)$ critical values. By comparing adjacent cells, all critical values can be generated in $O(nm\log nm)$ time. The fastest known algorithm is by [14], running in $O\big(n^2\sqrt{\log n}\,(\operatorname{loglog} n)^{3/2}\big)$ time.

Retractability. For curves (π,σ) and a minimum-cost traversal $\gamma = \{\gamma(t) \mid t \in [0,1]\}$, define $\operatorname{cost}(\gamma) := \max_{(a,b)\in\gamma} d\big(\pi(a),\sigma(b)\big)$. Let $(a,b) \in \gamma$ be a point that attains this maximum. Then γ decomposes into two open curves: γ_1 from $(1,1)$ to (a,b) and γ_2 from (a,b) to (n,m). [26] call γ *retractable* if γ_1 and γ_2 are minimum-cost monotone curves for their respective subcurves, and if γ_1 and γ_2 are themselves retractable (Figure 4). Computing the Fréchet distance using an adaption of Dijkstra yields a retractable traversal.

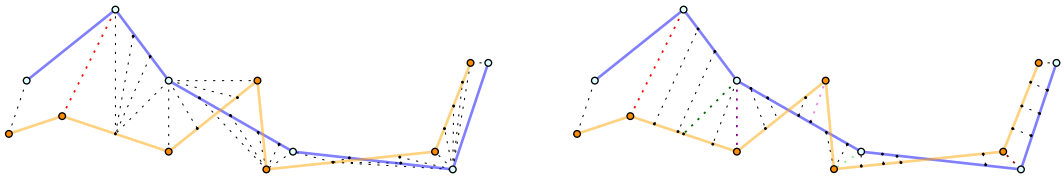

Figure 4 (Left) A traversal between two curves where the red leash realises $\mathcal{D}_F(\pi,\sigma)$. The traversal may be "lazy": a large Fréchet distance allows long pauses while the other curve progresses. (Right) A retractable traversal achieves progressively smaller bottleneck leash lengths.

3 The frog-based approach

We paraphrase and explain the frog-based approach from [26], defining their VE-graph slightly differently to reduce the number of edge-cases the definition incurs. We then detail how to make it converge in a polynomial number of rounds, even on a real-RAM, by creating an algorithm that generates the required monotonicity events on the fly.

▶ **Definition 1.** *Each edge e of the grid $\Gamma_{\pi,\sigma}$ has an edge event defining a point that we call an* edge-distance yardstick *(or* eddy*). $V(\pi,\sigma)$ denotes the set of all grid vertices and eddys.*

▶ **Definition 2.** *The VE-graph is a directed vertex-weighted graph on $V(\pi,\sigma)$ where the weight of each vertex is the distance between the pairs of points corresponding to the vertex. For each cell of $\Gamma_{\pi,\sigma}$, consider its four corners and eddys. We connect these points in an xy-monotone manner. In addition, the bottom horizontal eddy has a directed edge to the top horizontal eddy, and the left vertical eddy has a directed edge to the right vertical eddy; see Fig. 5.*

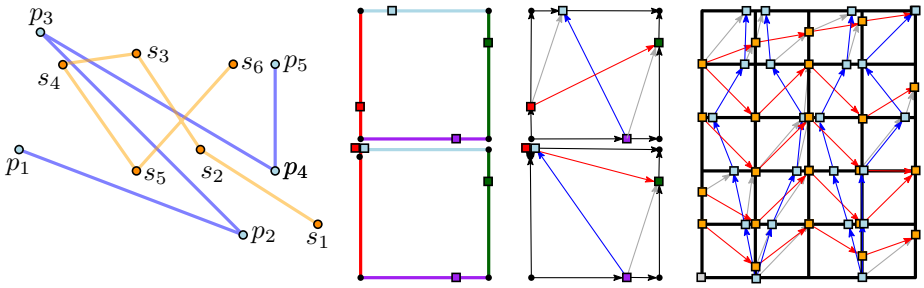

Figure 5 The VE graph considers for each cell the four corners and the four eddys. We include all monotone edges between these vertices. Edges connecting the eddys between horizontal (or vertical) edges may be non-monotone. If vertices coincide, then the picture gets a bit messy.

▶ **Definition 3.** *A path in the VE-graph is VE-respecting if it runs from* $(1,1)$ *to* (n,m) *and, within every row and every column, its restriction to the row or column is connected.*
