$$\mathcal{V}_E(\pi,\sigma) := \min_{\text{VE-respecting path } P} \max_{\text{vertex } v \in P} \text{weight}(v). \qquad \text{Observe that } \mathcal{V}_E(\pi,\sigma) \leq \mathcal{D}_F(\pi,\sigma).$$

From a path realizing the VE distance, one may also derive an upper bound on $\mathcal{D}_F(\pi,\sigma)$.

▶ **Definition 4.** *Let* P *be a path realizing* $\mathcal{V}_E(\pi,\sigma)$ *then* P *is a curve. One can greedily morph* P *into a traversal by ensuring that one never decreases in either coordinate. This defines an* xy*-monotone traversal* $\gamma(t) = (\alpha(t), \beta(t))$*. The* Interpolated VE distance *is then defined as:*

$$\mathcal{I}_{VE}(\pi,\sigma) := \max_{t\in[0,1]} d\big(\pi(\alpha(t)), \sigma(\beta(t))\big). \qquad \text{Observe that } \mathcal{D}_F(\pi,\sigma) \leq \mathcal{I}_{VE}(\pi,\sigma).$$

The *elevation function* maps $(a,b) \in \Gamma_{\pi,\sigma}$ to $d(\pi(a),\sigma(b))$. The sublevel sets of this function are clipped ellipses, whose minima on each cell edge occur precisely at the corresponding eddys. It follows that $\mathcal{V}_E(\pi,\sigma) = \mathcal{D}_F(\pi,\sigma) = \mathcal{I}_{VE}(\pi,\sigma)$ whenever the path P realizing $\mathcal{V}_E(\pi,\sigma)$ is monotone. This is the core of the frog-based refinement approach (Algorithm 1).

Algorithm 1 Refinement Procedure from [26].

1: Compute the VE-graph, the value $\mathcal{V}_E(\pi,\sigma)$, and the path P realising it
2: **if** P is monotone **then** $\mathcal{V}_E(\pi,\sigma) = \mathcal{D}_F(\pi,\sigma)$ so **return** $\mathcal{V}_E(\pi,\sigma)$
3: Otherwise, insert vertices on π for every non-x-monotone column, and vertices on σ for every non-y-monotone row. Then recurse on the refined curves (π,σ).

3.1 The approach in [26]: bisecting and convergence

Har-Peled, Raichel, and Robson [26] execute step 3 of Algorithm 1 in a heuristic manner. Let P be a path realising $\mathcal{V}_E(\pi,\sigma)$ for the current input (π,σ). If P is non-monotone in a column that corresponds to an edge e of π then they introduce a vertex half-way e (likewise, they bisect edges of σ for each row where P is non-monotone). Thus, given P they bisect some edges and create higher-complexity curves (π,σ) on which they recurse.

Recall that each monotonicity event (e,p,p') corresponds to a point on the edge e; we refer to such a point as a *monotonicity vertex*. Let (π',σ') be the curves obtained from (π,σ) by inserting, on π and σ respectively, a vertex at every monotonicity vertex. It is observed in [26] that the path P realising $\mathcal{V}_E(\pi',\sigma')$ is xy-monotone, and therefore $\mathcal{V}_E(\pi',\sigma') = \mathcal{D}_F(\pi,\sigma)$. Under exact-value arithmetic, the recursive halving procedure of [26] inserts in the limit all monotonicity vertices of π and σ, and thus converges to the exact Fréchet distance $\mathcal{D}_F(\pi,\sigma)$.

3.2 Our approach and rate of convergence

In [26] they use floating-point arithmetic. Therefore, the computation is non-exact. Moreover, bisecting edges will typically not generate the exact monotonicity vertices. They remark that under exact computations one can compute and introduce monotonicity vertices instead, but do not provide details, and naively there are cubicly many such events. Floating-point arithmetic is not unavoidable. Many libraries support exact arithmetic (e.g., CGAL). We engineer a solution that alters step 3 to provide guarantees for exactness and convergence: Let the path P realising $\mathcal{V}_E(\pi, \sigma)$ be not x-monotone in a column C corresponding to an edge e. Let the subpath of P restricted to C be from a to b. We execute step 3 by computing the minimum number of monotonicity vertices that need to be introduced on e such that, next iteration, the min-cost path from a to b is monotone. Our algorithm is inspired by the critical values from [5, 25] from the preliminaries, but ultimately has a different objective.

On efficiency. Exact-value arithmetic inevitably incurs overhead. Evaluating exact geometric predicates is substantially slower than using floating-point arithmetic. Moreover, the resulting values must be maintained as abstract algebraic objects rather than bit-level representations, preventing efficient vectorisation. This is partly why the algorithm from [10] does not use exact arithmetic even though it is integrated in CGAL. We therefore expect exact computation to increase median running times when we introduce exact arithmetic. To mitigate this effect, we restrict the input to 32-bit integers, as this allows the most frequent operation – the computation of dot products – to still be efficient. For our exact arithmetic, based on the computed dot products, we discuss in the full version our own integer-based kernel, to remain practically somewhat competitive [20]. Importantly, our algorithm does not rely on integrality assumptions: it applies unchanged under any exact-evaluation kernel.

High-level overview. In the full version [20] we develop the following algorithm: the input is a column C where P is not x-monotone, corresponding to an edge e of π. Let P, restricted to C, go from a to b. We create two new cells by extending a horizontal segment from a and b. We discard all cells of C that do not intersect P. We index the remaining cells as $C_1, \cdot, C_k$ from bottom to top, which induce horizontal segments $h_1, \ldots, h_{k+1}$. Imagine Δ increasing from 0 to ∞. For each value of Δ and each pair (i, j) with $i < j$, h_i can Δ-*reach* h_j if there exists a monotone path from a point on h_i to a point on h_j in the Δ free space (see Figure 6).

A value Δ is an *join event* if there exist (i, j) such that h_i can Δ-reach h_j from Δ onward. In this case, h_i can also Δ-reach all $h_{j'}$ with $j' \in [i, j)$. We compute the minimum number of join events to realise a monotone path from h_1 to h_k using a linked–list of buckets.

The horizontal segments are partitioned into buckets, each forming a vertical interval $[i, j]$ such that h_i can Δ-reach h_j. We initialise Δ as 0, and every horizontal segment forms its own bucket. We then merge buckets in a bottom-up fashion, maintaining the minimum Δ required such that h_1 can Δ-reach h_i for increasing i. Between $(h_1, \ldots, h_i)$ and h_{i+1}, we compute the smallest value $\Delta' \geq \Delta'$ for h_1 can Δ-reach h_{i+1} using a min-heap that contains join events and other events that indicate for which pair $(j, i + 1)$ the join event is relevant.

Whenever we pop the next event, we update Δ. If the updated Δ allows us to Δ-reach h_{i+1} from h_1 then we merge h_{i+1} into the bucket. We then keep incrementing i until h_1 cannot Δ-reach h_{i+1}, at which point we continue the event-based approach. Whenever we merge h_k into the bottom bucket, h_1 can Δ-reach h_k. When all buckets are joined, we have all join events required for a monotone path from h_1 to reach h_k. From this, we obtain the minimum number of monotonicity vertices needed so that, in the next iteration, the min-cost path from a to b is monotone. Doing this for all non-monotone rows and columns implies:

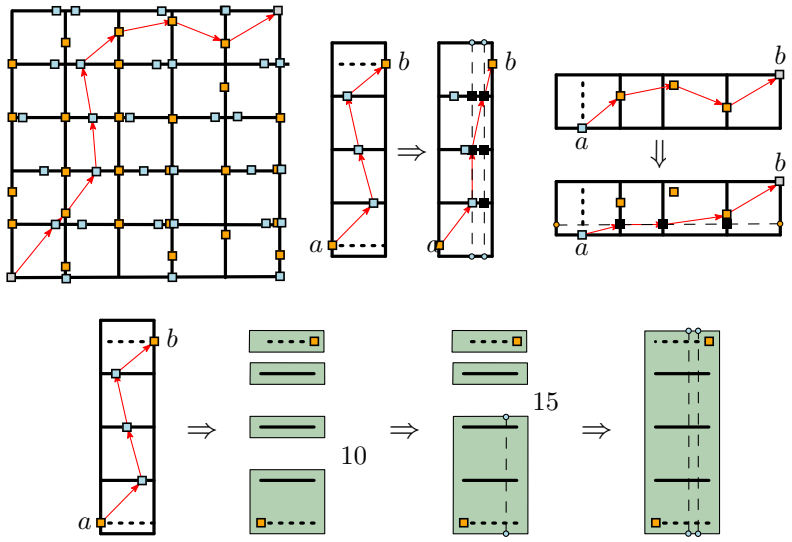

Figure 6 The input is a non-monotone path P in the VE-graph. We identify all rows and columns where P is non-monotone. For a column, we isolate the horizontal segments and bucket them. Between buckets, we store the minimum leash at which a monotone path from bottom to top exists.

▶ **Theorem 5.** *Let (π, σ) be the original input curves with n and m vertices. Algorithm 1 can be supported by a data structure using $O(n + m + M)$ space, where $M \in O(n^3 + m^3)$ is the number of introduced monotonicity vertices. Each recursive call runs in $O(nm + M)$ time for Step 1 and $O((n + m + M) \log^2(n + m + M))$ time for Step 3. Under exact-value arithmetic, the procedure returns the exact Fréchet distance after $O(n^3 + m^3)$ recursive calls.*

4 Lossless Fréchet distance simplification

The second (perhaps even main) contribution of [26] is a black-box lossless simplification algorithm. Computing $\mathcal{D}_F(\pi, \sigma)$ for large complexity curves π and σ is an expensive operation. It would be preferable if we would have access to some lower-complexity curves $(\overline{\pi}, \overline{\sigma})$ where $\mathcal{D}_F(\pi, \sigma) = \mathcal{D}_F(\overline{\pi}, \overline{\sigma})$. Then we could simply operate on these lower-complexity curves to output the distance. Har-Peled, Raichel, and Robson [26] can, for any Fréchet computation algorithm, achieve this using any *vertex-restricted* curve simplification:

▶ **Definition 6.** *We define for π a (vertex-restricted) simplification $\overline{\pi}$ as any subset of vertices in π, ordered by their index. For any $\mu \in \mathbb{R}_{\geq 0}$ we say $\overline{\pi}$ is a μ-simplification if $\mathcal{D}_F(\pi, \overline{\pi}) \leq \mu$.*

The curve simplification used in [26] is some heuristic combination of techniques from [6, 22].

Naïvely, one can $(1 + \varepsilon)$-approximate $\mathcal{D}_F(\pi, \sigma)$ with simplifications by fixing some ε and μ. Compute μ-simplifications $(\overline{\pi}, \overline{\sigma})$ and set $M = \mathcal{D}_F(\overline{\pi}, \overline{\sigma})$. By the triangle inequality, $M - 2\mu \leq \mathcal{D}_F(\pi, \sigma) \leq M + 2\mu$. If $\mu \leq \varepsilon M$, then M $(1 + \varepsilon)$-approximates $\mathcal{D}_F(\pi, \sigma)$; otherwise μ is decreased cleverly until we terminate after $O(\log_{1+\varepsilon} n)$ rounds [22].

[26] avoids this approximation step by exploiting triangle inequalities more directly. Let $(\overline{\pi}, \overline{\sigma})$ be any vertex-restricted simplification of (π, σ) and consider the traversals $\gamma_0(t)$, $\gamma_1(t)$, and $\gamma_2(t)$ realising $\mathcal{D}_F(\pi, \overline{\pi})$, $\mathcal{D}_F(\overline{\pi}, \overline{\sigma})$, and $\mathcal{D}_F(\overline{\sigma}, \sigma)$, respectively. They combine these traversals in linear time into a traversal $\gamma(t) = (\alpha(t), \beta(t))$ between (π, σ) whose maximum

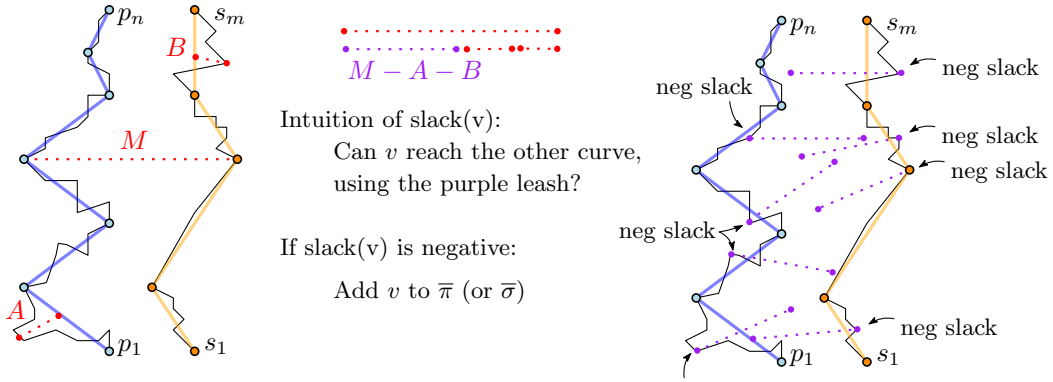

Figure 7 Curves (π, σ) and their simplifications. The value $LB(\overline{\pi}, \overline{\sigma})$ is the maximum leash length M between $(\overline{\pi}, \overline{\sigma})$, minus the maximum leash lengths A and B between $(\pi, \overline{\pi})$ and $(\sigma, \overline{\sigma})$.

leash length gives an upper bound on $\mathcal{D}_F(\pi, \sigma)$. Conversely, $\mathcal{D}_F(\pi, \sigma)$ is at least $\mathcal{D}_F(\overline{\pi}, \overline{\sigma})$ minus the Fréchet distances from each curve to its simplification, and we get the following:

$$\mathcal{D}_F(\overline{\pi}, \overline{\sigma}) - \mathcal{D}_F(\pi, \overline{\pi}) - \mathcal{D}_F(\sigma, \overline{\sigma}) \;\leq\; \mathcal{D}_F(\pi, \sigma) \;\leq\; \max_{t \in [0,1]} d(\pi(\alpha(t)), \sigma(\beta(t))).$$

Computing $\mathcal{D}_F(\pi, \overline{\pi})$ and $\mathcal{D}_F(\sigma, \overline{\sigma})$ is costly, so they compute greedy traversals $\gamma_0^*(t)$ and $\gamma_2^*(t)$ that overestimate these values instead, yielding $\mathcal{D}_F^*(\pi, \overline{\pi})$ and $\mathcal{D}_F^*(\sigma, \overline{\sigma})$. Combined, these give a greedy traversal $\gamma^*(t) = (\alpha^*(t), \beta^*(t))$ that over-estimates $\mathcal{D}_F(\pi, \sigma)$ and leads to

$$LB(\bar{\pi}, \bar{\sigma}) := \mathcal{D}_F(\bar{\pi}, \bar{\sigma}) - \mathcal{D}_F^*(\pi, \bar{\pi}) - \mathcal{D}_F^*(\sigma, \bar{\sigma}) \leq \mathcal{D}_F(\pi, \sigma) \leq \max_{t \in [0,1]} d(\pi(\alpha^*(t)), \sigma(\beta^*(t))). \quad (1)$$

Introducing slack. Given $LB(\overline{\pi}, \overline{\sigma})$ and $\gamma^*(t)$, each curve vertex v receives a *slack* $\texttt{slack}(v) := LB(\overline{\pi}, \overline{\sigma}) - g_v$, where g_v is the maximum leash length attained at v along $\gamma^*(t)$ (Figure 7). Negative slack marks v as a bottleneck. Each vertex p of $\overline{\pi}$ or $\overline{\sigma}$ inherits the minimum slack of all original vertices between p and the next vertex. Slack is then heuristically propagated: every vertex adopts the minimum slack among its eight closest neighbours along $\overline{\pi}$ or $\overline{\sigma}$. The slack of an edge is the minimum slack of its endpoints. They then perform the following:

> while there exists a negative-slack edge e on $\overline{\pi}$ (resp. $\overline{\sigma}$), and the edge e is not an edge of π (resp. σ), un-simplify the edge e (reintroducing missing vertices).

By construction of slack, its propagation, and (1), the process ends with $\mathcal{D}_F(\pi, \sigma) = \mathcal{D}_F(\overline{\pi}, \overline{\sigma})$.

Our contribution. In the full version, we observe that the above technique, while elegant, is overly conservative and somewhat coarse [20]. We refine it in two ways.

(i) Tighter bounds. Their lower bound uses the global maximum leash length M between $(\overline{\pi}, \overline{\sigma})$, minus the global maxima A and B between $(\pi, \overline{\pi})$ and $(\sigma, \overline{\sigma})$, respectively. When M, A and B are realised at unrelated parts of the traversal (see Figure 7), this yields an unnecessarily small value $LB(\overline{\pi}, \overline{\sigma}) = M - A - B$. This in turn causes more vertices than needed to trigger unsimplification. Using the frog-based framework, we obtain a sharper bound (Figure 8). For each edge of $\overline{\pi}$ we compute the maximum leash length between that edge and π, and assign this as a negative weight. In the VE-graph, the eddys on this edge add this negative weight to their own weight. The min-cost path in this reweighted graph

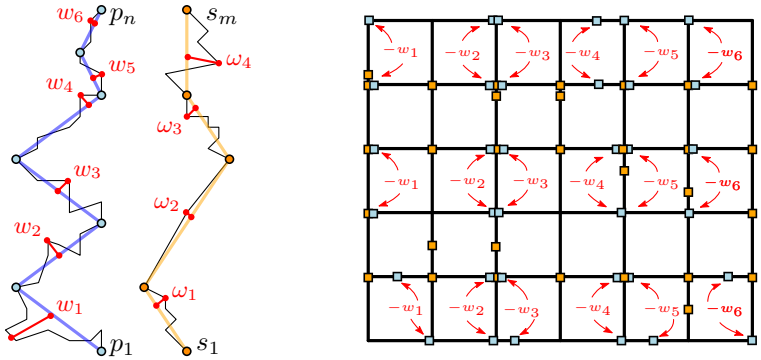

Figure 8 Given $(\pi, \overline{\pi})$ we can give a weight to each edge of $\overline{\pi}$. Each edge over $\overline{\pi}$ is a column in the parameter space, in which we apply its negative weight on the corresponding eddys.

yields a lower bound for $\mathcal{D}_F(\pi, \sigma)$ by the same triangle-inequality argument as in [26], but now based on local rather than global maxima. For many instances, this increases the lower bound and therefore the slack of vertices – causing our algorithm to unsimplify fewer edges.

(ii) A tighter slack propagation rule. Their propagation step takes the minimum slack over each block of eight consecutive vertices. This removes any edge cases for applying the slack, ensuring their correctness. However, this method is also rather crude and causes unnecessary unsimplification. We tighten this step by propagating slack along at most two edges per vertex, avoiding this coarse eight-neighbour spread.

5 Experiments and empirical analysis

Our primary contribution is a C++ implementation of our exact variant of the frog-based technique, together with an extensive empirical evaluation. We provide two implementations: `Exact_Dijkstra`, which computes the path P in the `VE`-graph using Dijkstra's algorithm in a manner similar to [26] and yields a traversal with retractability properties; and `Exact_Sweepline`, which instead employs a sweepline to compute P, guaranteeing linear space usage. We compare our implementations to `Unleashed`: the Julia code of [26], which is their fastest version. To obtain the most accurate output from `Unleashed`, we invoke `frechet_c_compute` with `accept_approximation=false` (this still approximates). We also include a version with approximation parameters enabled. Finally, we include the `BKN` algorithm of [10], the fastest known alternative implementation (which is also inexact). We do not use its CGAL variant, as it is slower, while still being inexact.

Experiments. The analysis in [26] uses three animal-tracking data sets: `Geolife`, `Birds`, and `Pigeons`. These trajectories are goal-oriented. Their implementation benefits from this in one major way compared to [10]: as a simplification is applied, this greatly reduces complexity. Consequently, they operate on significantly smaller effective input.

The lossless simplification of [26] applies to any Fréchet algorithm, including [10]. We *could* enable a direct comparison by applying it to [10]. Yet, we deliberately refrain from doing so: the simplification incurs overhead, and [10] is so fast that this may actually slow it down. Despite not using simplifications, our experiments will show that [10] dominates the frog-based approaches, removing the need to improve it further. All experiments are single-threaded and executed on an AMD Ryzen 5 7600X (4.7 GHz) with 96 GB RAM.

Table 1 Overview of all data sets used in our experiments.

Name	Real world	# curves	total # vertices	median # vertices	# of curves compared
`Geolife`	yes	18671	24895648	506	300 choose 2
`Pigeons`	yes	539	6229319	7502	300 choose 2
`Athens`	yes	120	72439	662	120 choose 2
OV	no	220	39060	130	110 (already pairs)
`Chicago`	yes	888	118360	121	100 choose 2
`Berlin`	yes	27188	192223	7	100 choose 2
`Drifter`	yes	2012	1792084	997	100 choose 2
`UniD`	yes	362	214076	495	100 choose 2

Data. Our real-world data sets are summarised in Table 1. The first two (`Geolife`, `Pigeons`) are from [26]. We additionally include `Athens`, `Chicago`, and `Berlin` GPS traffic data sets, widely used in Fréchet benchmarks [4, 11, 27, 36]. We include the `Drifter` data set of [16], containing drifting-buoy trajectories. We add the UnID data set from [31] which is a traffic dataset captured on German highways. Except for `Drifter`, these sets are goal-oriented with minimal backtracking; lossless simplification therefore removes relatively many vertices, which favours the frog-based approaches. Finally, we include a set `OV`[1] of difficult synthetic pairs of curves that are derived from Orthogonal Vectors instances [10].

The `Geolife` data set alone induces over 170,000,000 pairs of curves, so we cannot possibly compute the Fréchet distance between all pairs of curves. We follow [26] and subsample. In our case, we compare all 45,000 pairs among a subselection of 300 curves from the `Geolife` and `Pigeons` data sets. We further augment the analysis by comparing all curves from the `Athens` data set and from the adversarial `OV` data set. To broaden our evaluation, we also include the remaining real-world data sets, where, due to time constraints, we subsample curves and compare all pairs among them. The experiments are primarily bottlenecked by the `Unleashed` implementation[2], and the full evaluation requires several days to complete. Our results indicate no substantial qualitative differences between sampling 100×100 or 300×300 curves from the same data.

Criteria. Our primary evaluation metric is running time (including file-reading time). For exactness, our approach is the most accurate if the input coordinates fit within a 32-bit integer, followed closely by `BKN`; Table 2 briefly reports accuracies for the data sets satisfying this condition. We could compare across all data by truncating all input to 32-bit coordinates, but we refrain from doing so since `BKN` can handle this data natively (albeit inexact).

5.1 Comparing frog-based approaches

We first compare our frog-based implementations to `Unleashed`. This comparison is motivated mainly by scientific curiosity: exact-value computation is more difficult than computing an approximation, so one naturally expects a performance penalty. Our interest is in quantifying this penalty – in other words, in understanding the practical cost

[1] Obtained via personal communication with one author from [10], available with our source code
[2] A time limit of 5 minutes was hit multiple times

Table 2 Accuracy errors, obtained by converting exact square root distances to a `double`.

Data set	Max	Mean	Median
		`Exact`	
`OV`	0	0	0
`athens`	0	0	0
`UnID`	0	0	0
		`BKN`	
`OV`	$3.039939 \cdot 10^{-13}$	$2.756980 \cdot 10^{-13}$	$3.039939 \cdot 10^{-13}$
`athens`	$9.337306 \cdot 10^{-10}$	$5.865283 \cdot 10^{-12}$	$1.269745 \cdot 10^{-12}$
`UnID`	$9.337306 \cdot 10^{-10}$	$5.865283 \cdot 10^{-12}$	$1.269745 \cdot 10^{-12}$
		`Unleashed`	
`OV`	$4.499666 \cdot 10^{-6}$	$1.430129 \cdot 10^{-6}$	$1.181895 \cdot 10^{-16}$
`athens`	$9.267924 \cdot 10^{-6}$	$1.948025 \cdot 10^{-7}$	$9.974841 \cdot 10^{-15}$
`UnID`	$9.337306 \cdot 10^{-10}$	$5.865283 \cdot 10^{-12}$	$1.269745 \cdot 10^{-12}$

of exactness. Table 3 compares the efficacy of the `Unleashed` implementation versus `Exact_Sweepline` (the comparison remains roughly the same when we set for `Unleashed` the boolean `accept_approximation=true`, or when we compare to `Exact_Dijkstra` instead).

As expected, the median running time of our exact variants deteriorates. However, we note that our exact approach has considerably better worst-case performance, even on this advantageous real-world data. On some instances, `Unleashed` is a factor 100 slower. Whenever our worst-case is slower, it is not slower by much. For data sets where curves have sizable complexity, our method becomes the preferred method from the 90th percentile onwards. On the mapconstruction data sets, the median number of vertices is very small. The OV data set is a difficult instance where our exact computations are extremely costly. We note that except for worst-case outliers, the approaches are relatively competitive. We think that this data nicely represent the cost of exact value computation, and the benefit of worst-case guarantees for runtime.

5.2 Comparing Fréchet distance computations

We now provide a comparison between our exact frog-based method, the approach of [26], and the state-of-the-art `BKN` implementation [10]. In this wider evaluation, we consider two configurations of `Unleashed`: the version with `accept_approximation=false` (which, still returns an approximation) and the supposedly faster configuration that sets `accept_approximation=true`. Our exact implementations use either Dijkstra or a sweepline.

5.3 Results

Table 4 shows the full set of experimental results. These results highlight the volatility of the frog-based approach: the standard deviation of these approaches is considerably larger than `BKN` (although lessened for our implementation). Regardless of evaluation criterion (maximum, mean or median running time) the `BKN` algorithm dominates in performance[3].

[3] Due to technical constraints, there is system overhead negatively influencing the measured time for `BKN`. This is particularly noticeable for instances of the `berlin` data set since they have so few vertices. Their approach is the fastest overall in our measurements, but it is arguably still faster.

Table 3 Summary of running times in seconds. For both `Unleashed` (`accept_approx = false`) and `Exact_Sweeline`. The best times across the two methods are in blue.

We illustrate the performance profile of these algorithms using Dolan–Moré plots (Figures 9–12). These plots can be read as follows. The x-axis shows a factor $\tau \geq 1$, indicating how many times slower an algorithm may be compared to the best on each instance. The y-axis shows the percentage of instances on which this holds. Thus, if an algorithm's plot contains the point (p, τ) then on p percent of the instances, it is τ times slower than the best performing algorithm. Similarly, $\tau = 1$ reveals how often each algorithm is the best, while a horizontal line such as $p = 90$ indicates how much slower the worst 10% of cases become (which, for `BKN`, is minimal). As τ increases, the curves show how quickly each algorithm "catches up". An algorithm is considered better if its curve approaches the horizontal line $p = 100$ more rapidly. These profiles mirror our observations: `BKN` is consistent; our method lags on median instances, however if the data set contains high enough complexity curves, it frequently and significantly overtakes `Unleashed` as we approach the worst case.

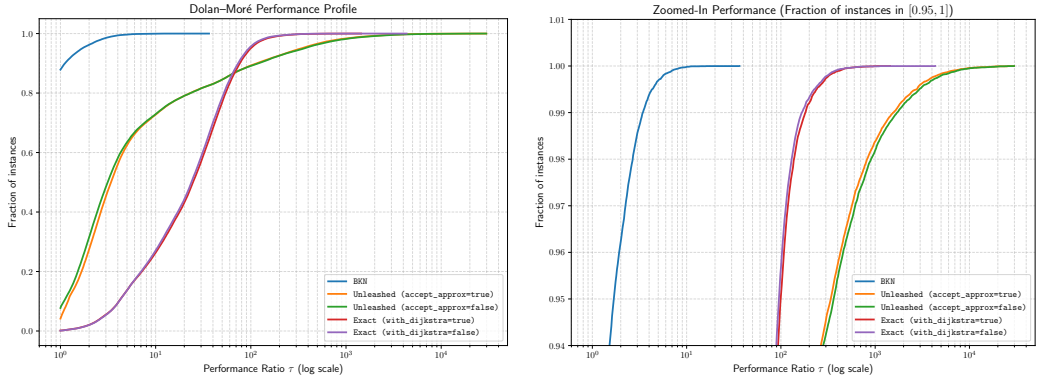

Figure 9 Dolan–Moré performance profile on all pairs of the first 300 curves from the `geolife` data set (44850 in total) from [26].

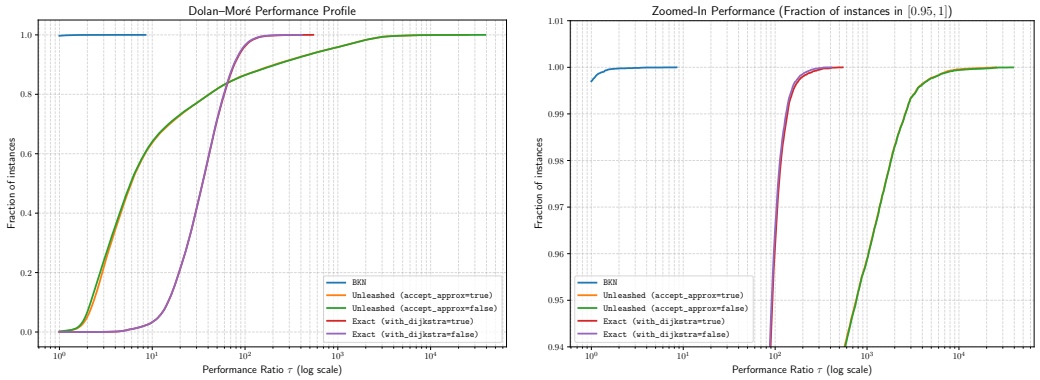

Figure 10 Dolan–Moré performance profile on all pairs of the first 300 curves from the `pigeons` data set (44850 in total) from [26].

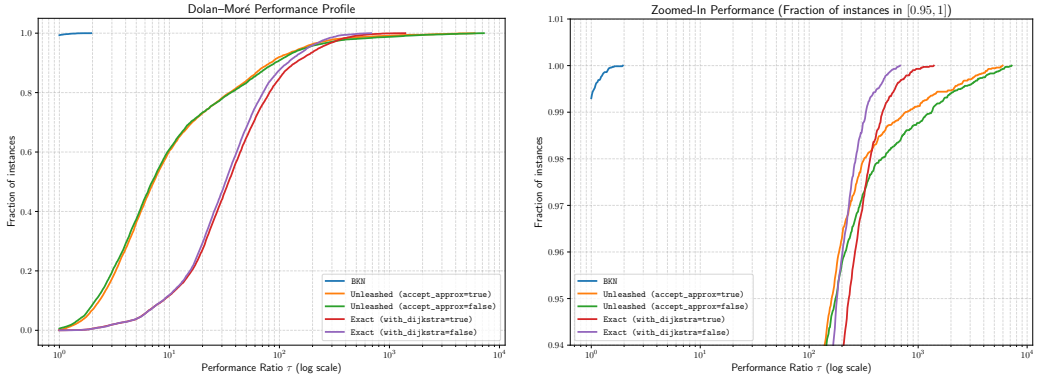

Figure 11 Dolan–Moré profile on pairs from the `athens` data set (7139 in total) from [35].

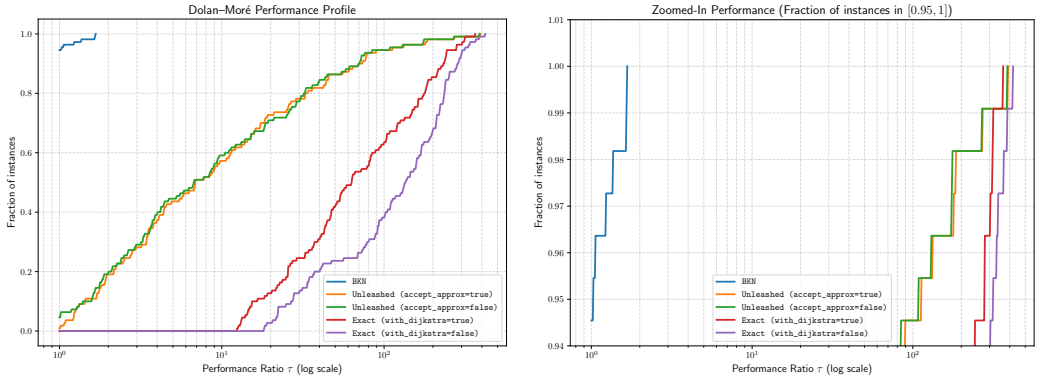

Figure 12 Dolan–Moré performance profile on all pairs from the `OV` data set (110 in total).

6 Conclusion

We studied the frog-based framework for computing the Fréchet distance introduced in [26]. On the theoretical side, we identified three aspects of the original algorithm that incur avoidable inaccuracies in the distance computation or introduce avoidable heuristic overhead.

Specifically, the method of [26] consists of two main components. The first is the computation of the Fréchet distance between (π, σ) via a discrete weighted graph whose complexity is increased iteratively each round, through a process they call *refinement*. Their process heuristically bisects edges of (π, σ), increasing the graph complexity, until the discrete min-cost path through this graph realises the Fréchet distance. We provide a new refinement scheme that offers worst-case guarantees on this process. Our more elaborate refinement is careful not to drastically increase the time per round, yet it yields an explicit upper bound on the convergence rate – which we consider theoretically meaningful.

The second component is a lossless curve simplification procedure that produces curves $(\overline{\pi}, \overline{\sigma})$ of lower complexity such that $\mathcal{D}_F(\pi, \sigma) = \mathcal{D}_F(\overline{\pi}, \overline{\sigma})$ – effectively reducing the input size. Although correct, the original simplification is overly conservative: it relies on a lower bound that is unnecessarily weak, and it avoids geometric corner cases by aggressively propagating vertex slack across a constant but wide neighbourhood. Exploiting the weighted-graph structure already inherent in the frog-based method, we present a more refined construction that attains a higher lower bound. Consequently, our simplifications have lower complexity.

Our primary contribution is an empirical evaluation. We supply an openly available test suite, which enables a reproducible comparison between frog-based implementations and the highly optimised algorithm of Bringmann, Künnemann and Nusser [10]. Our results stand in contrast to the conclusions of [26]: On our broader range of real-world data sets, `BKN` consistently outperforms both frog-based variants. Notably, after removing near-duplicate consecutive points through simplification, the data set curve have *very* few vertices remaining for modern hardware. We have reason to believe that, on larger inputs, the performance gap between our method and `Unleashed` widens. However, we are not aware of real-world benchmark sets whose median complexity exceeds 1,000 "distinct" vertices, and synthetic data behaves entirely differently under lossless simplification. We argue that existing benchmarks are becoming outdated and that the community should develop more modern ones.

We note that the `BKN` algorithm is currently very fast, but still inexact (although it obtains very good approximation ratios). We find it an interesting open problem to augment this code base to allow for exact computations. We note that this is not as straightforward as adding an exact computation kernel (which, the codebase variant in CGAL already has) but that it also requires algorithmic changes to change its decision variant algorithm into the actual computation of the Fréchet distance.

Regarding the experimental results, our findings might seem discouraging: our implementation and analysis describe an approach that does not, in practice, match the performance of the current state-of-the-art. However, we consider this outcome important for the community. Our study offers a transparent and verifiable assessment of the frog-based method and demonstrates that its practical behaviour is volatile and underwhelming.

At the same time, our analysis reaffirms that the frog-based framework is theoretically compelling. We show that this method in particular enables a significantly more fine-grained lossless simplification procedure than general-purpose methods. Nevertheless, our experiments indicate that its main value lies in its theoretical insights rather than in practical performance.

Upward Book Embeddings of Partitioned Digraphs

Abstract

In 1999, Heath, Pemmaraju, and Trenk [SIAM J. Comput. 28(4), 1999] extended the classic notion of book embeddings to digraphs, introducing the concept of *upward book embeddings*, in which the vertices must appear along the spine in a topological order and the edges are partitioned into pages, so that no two edges in the same page cross. For a partitioned digraph $G = (V, \bigcup_{i=1}^{k} E_i)$, that is, a digraph whose edge set is partitioned into k subsets, an upward book embedding is required to assign edges to pages as prescribed by the given partition. In a companion paper, Heath and Pemmaraju [SIAM J. Comput. 28(5), 1999] proved that the problem of testing the existence of an upward book embedding of a partitioned digraph is linear-time solvable for $k = 1$ and recently Akitaya, Demaine, Hesterberg, and Liu [GD, 2017] have shown the problem NP-complete for $k \geq 3$. In this paper, we study upward book embeddings of partitioned digraphs and focus on the unsolved case $k = 2$. Our first main result is a novel characterization of the *upward embeddings* that support an upward book embedding in two pages. We exploit this characterization in several ways, and obtain a rich picture of the complexity landscape of the problem. First, we show that the problem remains NP-complete when $k = 2$, thus closing the complexity gap for the problem. Second, we show that, for an n-vertex partitioned digraph with a prescribed planar embedding, the existence of an upward book embedding that respects the given planar embedding can be tested in $O(n \log^3 n)$ time. Finally, leveraging the SPQ(R)-tree decomposition of biconnected graphs into triconnected components, we present a cubic-time testing algorithm for biconnected directed partial 2-trees.

1 Introduction

Book embeddings are a classic and influential topic in combinatorial and algorithmic graph theory. The notion of a book as a topological space was introduced in the late 60s by Persinger [48] and Atneosen [5], and later developed in its current and more popular form by the seminal work of Ollmann [47]. In a ***book embedding*** of a graph $G = (V, E)$, all vertices lie along a line – referred to as the ***spine*** – while edges are placed into distinct half-planes bounded by the spine, known as the ***pages*** of the book. Therefore, constructing such an embedding for G amounts to computing a pair (π, σ), where $\pi : V \leftrightarrow \{1, \ldots, |V|\}$ is a linear ordering of the vertices and $\sigma : E \to \{1, \ldots, k\}$ is a partition of the edges into k pages so that no two edges in the same page cross according to π, i.e., their end-vertices do not alternate in π; see Fig. 1a for an example. The minimum value of k for which this is possible is the ***book thickness*** of G (also called ***stack number*** or ***page number***).

Research on book embeddings originated from problems in VLSI circuit design [20], and has since found applications in sorting permutations [49, 52], fault-tolerant processing [50], compact graph encodings [40, 46], graph drawing [14, 25, 29, 33], computational origami [1, 45], parallel process scheduling [13], parallel matrix computations [36], and other domains. For a more comprehensive overview of applications, see [28]. The notion of book embedding was extended to digraphs by Heath, Pemmaraju, and Trenk [37] by introducing the natural requirement that in a book embedding (π, σ) of a digraph G the ordering π must be a topological ordering of G; see Figs. 1b and 1c for an example. Such book embeddings are called ***upward book embeddings*** as they are naturally depicted with vertices placed on a vertical line and edges drawn as arcs monotonically increasing in the y-direction in their page.

Next, we provide an overview of the major algorithmic results on book embeddings; in the full version [21], we also discuss combinatorial results. Concerning undirected graphs, already in 1979, Bernhart and Kainen [10] showed that the graphs of book thickness 1 are the outerplanar graphs and that the graphs of book thickness 2 are the sub-Hamiltonian (planar) graphs. Whereas the former are recognizable in linear time [54], recognizing the latter is NP-complete, even for planar triangulations [55]. Recently, Ganian et al. [31] presented a sub-exponential-time algorithm for testing sub-Hamiltonicity, which is asymptotically tight under ETH. Concerning digraphs, the problem of testing the existence of an upward book embedding in k pages is called Upward Book Embedding. For more than two decades, the only known NP-completeness result for the problem was the one shown by Heath and Pemmaraju [35] when $k = 6$. Recently, in two subsequent papers, Binucci et al. [16] and Bekos et al. [8, 9] closed the computational gap by showing NP-completeness for $k \geq 3$ and $k = 2$, respectively. These results, together with the linear-time algorithm for $k = 1$ [35], completely characterize the complexity of the Upward Book Embedding problem with respect to k. For $k = 2$, efficient algorithms have been devised for special classes [15, 42, 43].

Partitioned book embeddings. Due to the NP-hardness of testing the existence of a book embedding (π, σ), it is natural to study the complexity of the problem if π or σ is given as part of the input. If the vertex ordering π is fixed, the problem becomes the k-coloring problem for circle graphs. The problem is clearly linear-time solvable for $k \leq 2$. Unger [53] showed that it is NP-complete for $k \geq 4$. The complexity of the case $k = 3$ is still open [6, 7], although a

quasi-polynomial-time algorithm for $k = 3$ has recently been proposed [51]. Conversely, if the partition σ into k pages is given, for undirected graphs, there are polynomial-time algorithms for $k = 1$ [35] and $k = 2$ [4, 38, 39], whereas the problem is NP-complete for $k \geq 3$ [3]. For directed graphs, in which the vertex ordering has to be a topological ordering, the problem is called Partitioned Upward Book Embedding. For $k = 1$ it coincides with the "unpartitioned" case, solved in [35, 37]. For $k > 1$, it was first studied by Akitaya et al. [1]. They connected the problem to applications in map folding [45] and attributed it to Edmonds, who, in 1997, posed the question specifically for $k = 4$ when the edges assigned to each page form a matching. They showed NP-completeness for $k = 3$ and for $k \geq 4$ even if the edges in each page form a matching. For $k = 2$, they gave a linear-time algorithm for the special case when the edges in each page form a matching. However, they left the complexity of the general case for $k = 2$ open. See Table 1 for an overview of the complexity landscape.

Our Contributions. We study the Partitioned Upward Book Embedding problem in the unsolved case $k = 2$. As every upward book embedding corresponds to an upward planar drawing, i.e., the edges are drawn as non-crossing y-monotone curves, we make use of combinatorial descriptions of such drawings, called ***upward embeddings*** [11]. Our first main result is a characterization of the upward embeddings that support an upward book embedding in two pages. We exploit this characterization in several ways and obtain a rich picture of the complexity landscape of the problem. First, we show that the problem remains NP-complete when $k = 2$, thus closing the complexity gap and exhibiting a sharp contrast with the undirected case, where the problem is linear-time solvable [39]. Our proof also implies that the problem is W[1]-hard with respect to the treewidth. Second, we show that, when the planar embedding is prescribed, the problem can be solved in $O(n \log^3 n)$ time. Our algorithm is inspired by the network-flow approach of Bertolazzi et al. [11] and requires the use of several non-trivial ingredients arising from our characterization. Finally, in the variable-embedding setting, we present a cubic-time algorithm for biconnected directed partial 2-trees. Our algorithm exploits a compact representation, called *descriptor pair*, of the features of upward embeddings of subgraphs that admit an extension to an upward embedding, satisfying our characterization, of the entire graph. This allows us to compute, for the subgraph associated with each node of the SPQ(R)-tree, its set of realizable descriptor pairs by dynamic programming. While we focus on the decision problem, all our algorithms are constructive and can be modified to compute an upward book embedding, if one exists. A full version of the paper with complete proofs can be found in [21].

2 Preliminaries

For basic definitions on graphs and their drawings see [22, 27] or the full version of the paper.

Two planar drawings of a connected digraph are ***topologically equivalent*** if they have the same clockwise order of the edges around each vertex and the same clockwise order of the edges along the boundary of the outer face. A ***planar embedding*** is a class of topologically equivalent planar drawings. A ***plane digraph*** is a planar digraph together with a planar embedding. A planar embedding of a digraph is ***bimodal*** if, for every vertex v, the edges that have their tail at v are consecutive in the clockwise order of the edges incident to v.

Upward planarity. A ***switch*** in a digraph G is a source or a sink. A drawing of G is ***upward*** if every edge is represented by a Jordan arc that is strictly increasing in the y-direction from its tail to its head. If G admits an upward planar drawing, it is an ***upward planar digraph***. Let $\mathcal{E}$ be a bimodal planar embedding of G. An ***angle*** at a vertex v is an ordered pair (e_1, e_2) of edges incident to v where e_2 immediately follows e_1 in clockwise order around v. An angle (e_1, e_2) is a ***switch angle*** if v is the head or the tail of both e_1 and e_2, otherwise it is a ***flat angle***. The set of angles of $\mathcal{E}$ is denoted as $\mathcal{A}_\mathcal{E}$. An ***angle assignment for $\mathcal{E}$*** is a function $\lambda\colon \mathcal{A}_\mathcal{E} \to \{-1, 0, 1\}$, and it is ***upward-consistent*** if it satisfies the following conditions: **(C1)** For each angle a in $\mathcal{A}_\mathcal{E}$, we have $\lambda(a) = 0$ if and only if a is flat. **(C2)** For each vertex v of G, we have $\sum_a \lambda(a) = 2 - \deg(v)$, where the sum is over the angles at v. **(C3)** For each face f of $\mathcal{E}$, we have $\sum_a \lambda(a) = -2$ if f is an internal face and $\sum_a \lambda(a) = 2$ if f is the outer face, where the sum is over the angles in f.

Let Γ be an upward planar drawing with planar embedding $\mathcal{E}$, see Fig. 2. Clearly, $\mathcal{E}$ is bimodal. Also, it defines an angle assignment λ_Γ as follows. Let $a = (e_1, e_2)$ be an angle of $\mathcal{E}$. If a is flat, then $\lambda_\Gamma(a) = 0$. Otherwise, consider the geometric angle α in Γ corresponding to a. We define $\lambda_\Gamma(a) = -1$ if $\alpha < \pi$ and $\lambda_\Gamma(a) = 1$ if $\alpha > \pi$. Note that λ_Γ is upward-consistent.

A pair $(\mathcal{E}, \lambda)$ of a planar embedding $\mathcal{E}$ and an angle assignment λ is an ***upward embedding*** if there exists an upward planar drawing Γ with embedding $\mathcal{E}$ such that $\lambda = \lambda_\Gamma$. Angles a with $\lambda(a) = 0$ are flat; also, we say that an angle a is ***large*** if $\lambda(a) = 1$ and ***small*** if $\lambda(a) = -1$. An angle assignment is determined by *assigning* each switch to an incident angle, which corresponds to making that angle large; a switch angle to which no switch is assigned is small. A digraph equipped with an upward embedding is an ***upward plane digraph***.

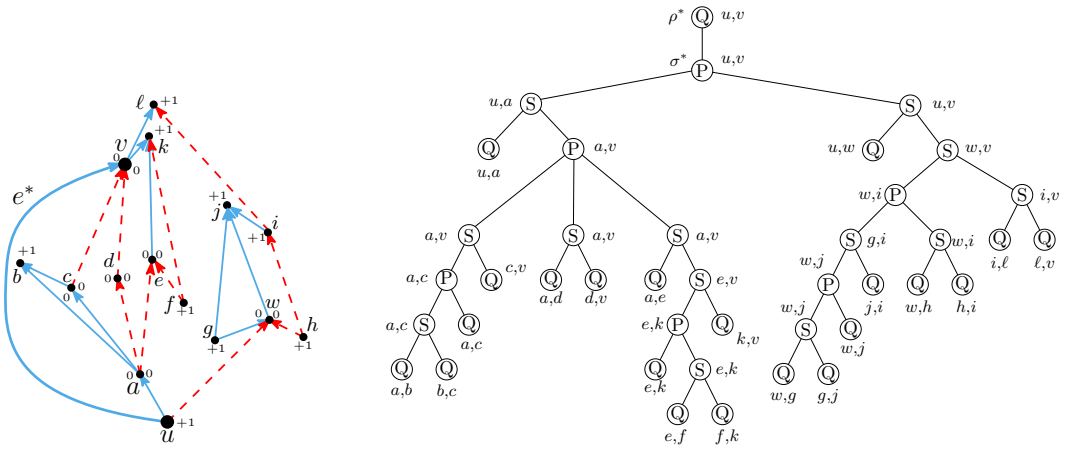

Figure 3 (a) An upward planar drawing Γ of a biconnected partitioned directed partial 2-tree G. The labeling λ_Γ of the angles determined by Γ is shown; the missing labels are equal to -1. (b) The SPQ-tree of G rooted at the Q-node corresponding to the edge e^* of G.

▶ **Theorem 1** ([11, 26]). *Let $\mathcal{E}$ be a planar embedding and λ be an angle assignment for $\mathcal{E}$. The pair $(\mathcal{E}, \lambda)$ is an upward embedding if and only if $\mathcal{E}$ is bimodal and λ is upward-consistent.*

Upward Book Embeddings. An n-vertex ***partitioned digraph*** is a digraph $G = (V, \bigcup_{i=1}^{k} E_i)$ whose edge set is partitioned into k sets. An ***upward book embedding*** (in k pages) of G is a bijection $\pi\colon V \leftrightarrow \{1, \ldots, n\}$ such that: **(i)** for each edge $e = (u, v)$, it holds that $\pi(u) < \pi(v)$, and **(ii)** for any $i \in \{1, \ldots, k\}$, no two edges $(u, v), (w, x) \in E_i$ cross, where (u, v) and (w, x) ***cross*** if $\pi(u) < \pi(w) < \pi(v) < \pi(x)$ or $\pi(w) < \pi(u) < \pi(x) < \pi(v)$. We focus on the case $k = 2$ and let $L := E_1$ and $R := E_2$. We often omit that our upward book embeddings are in two pages and call ***left*** and ***right*** the edges in L and R, respectively, since an upward book embedding (π, σ) of $G = (V, L \cup R)$ determines an upward planar drawing of G where the vertices lie along a vertical line, called ***spine***, so that the y-coordinate of each vertex v is $\pi(v)$, and each edge (u, v) in L (resp. in R) is drawn as a semi-circle to the left (resp. to the right) of the spine. In all the illustrations, the edges in L are blue and solid, while the edges in R are red and dashed.

An upward planar drawing ***respects*** a planar embedding $\mathcal{E}$ if it belongs to the equivalence class $\mathcal{E}$. An upward book embedding ***respects*** a planar embedding $\mathcal{E}$ if the associated upward planar drawing Γ does and ***respects*** an upward embedding $(\mathcal{E}, \lambda)$ if it respects $\mathcal{E}$ and $\lambda_\Gamma = \lambda$.

In an upward embedding $(\mathcal{E}, \lambda)$, a vertex v is ***4-modal*** if: **(i)** If v is not a switch, then in clockwise order around v in $\mathcal{E}$ we have all outgoing left edges, all outgoing right edges, all incoming right edges, and all incoming left edges; one of the former two sets and/or one of the latter two sets might be empty. **(ii)** If v is a source (resp. a sink), then in clockwise order around v in $(\mathcal{E}, \lambda)$ we have the large angle at v, all outgoing left edges, and all outgoing right edges (resp. the large angle at v, all incoming right edges, and all incoming left edges); one of the two sets might be empty. Also, $(\mathcal{E}, \lambda)$ is ***4-modal*** if all vertices are 4-modal.

▶ **Property 2.** *Let Γ be an upward book embedding of a partitioned digraph $G = (V, L \cup R)$ and let $(\mathcal{E}, \lambda)$ be the upward embedding of G defined by Γ. Then $(\mathcal{E}, \lambda)$ is 4-modal.*

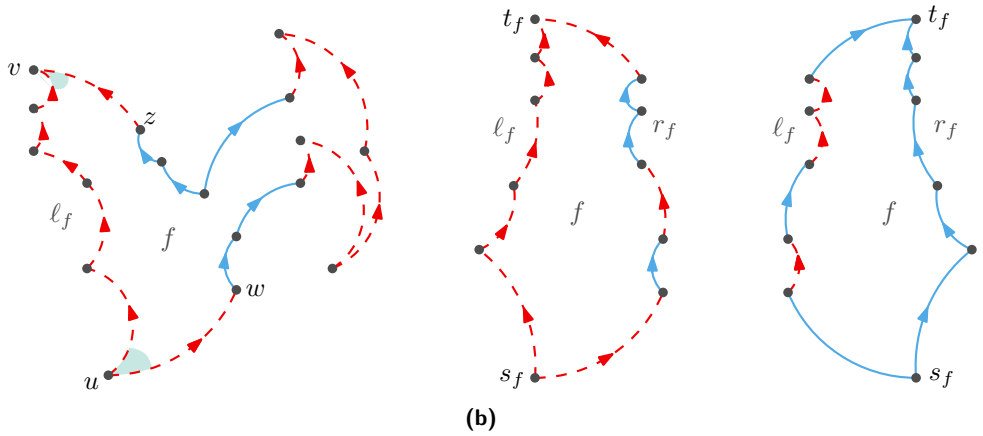

Figure 4 Impossible faces in (a) an upward plane digraph and (b) a plane st-graph.

Partial 2-trees. A graph is an (undirected) ***partial 2-tree*** if, equivalently, it has treewidth at most two, or it excludes K_4 as a minor, or it is a subgraph of a 2-tree, which is a graph that can be obtained from an edge by repeatedly inserting a degree-2 vertex adjacent to two adjacent vertices. Notably, the class of partial 2-trees includes the ***series-parallel graphs***.

Let G be a biconnected partial 2-tree and let $e^* = (u^*, v^*)$ be an edge of G, see Fig. 3. The ***SPQ-tree*** T of G with respect to e^* is a rooted tree that describes a recursive decomposition of G into smaller partial 2-trees; it is a specialization of the well-known ***SPQR-tree***, which is defined for general biconnected planar graphs [24, 34], and can be computed in linear time.

The root of T is a Q-node ρ^* associated with G and with a single child σ^*. Define $G - e^*$ as the ***pertinent graph*** of σ^*, and let u^* and v^* be the ***poles*** of σ^*. We proceed recursively. Suppose we are given a quadruple $\langle \mu, u, v, G_\mu \rangle$, where μ is a node of T with poles u and v, and G_μ is its pertinent graph (initially, this is $\langle \sigma^*, u^*, v^*, G - e^* \rangle$). Three cases can occur:

- If G_μ is a single edge (u, v), then μ is a Q-node representing that edge; μ is a leaf of T.
- If G_μ is not biconnected, then μ is an S-node. Let w be an arbitrary cut-vertex of G_μ. Then μ has two children ν_1 and ν_2 in T corresponding to the two subgraphs G_{ν_1} and G_{ν_2}, respectively, obtained by splitting G_μ at w. The poles of ν_1 are u and w, and those of ν_2 are w and v. The construction of T recurses on $\langle \nu_1, u, w, G_{\nu_1} \rangle$ and on $\langle \nu_2, w, v, G_{\nu_2} \rangle$.
- If G_μ is biconnected, then μ is a P-node. Then μ has k children $\nu_1, \ldots, \nu_k$, where k is the number of subgraphs $G_{\nu_1}, \ldots, G_{\nu_k}$ obtained by splitting G_μ at u and v. For $i = 1, \ldots, k$, the poles of ν_i are u and v, and the construction of T recurses on $\langle \nu_i, u, v, G_{\nu_i} \rangle$.

A ***directed partial 2-tree*** is a digraph whose underlying graph is a partial 2-tree, where the underlying graph is the undirected graph obtained by ignoring the edge directions. An SPQ-tree of a biconnected directed partial 2-tree G is an SPQ-tree of its underlying graph, although the edges of the pertinent graph of each node are oriented as in G.

3 Characterization for Upward Embeddings

In this section we characterize the upward embeddings $(\mathcal{E}, \lambda)$ of a partitioned upward plane digraph $G = (V, L \cup R)$ that allow for the construction of an upward book embedding. For a face f of $\mathcal{E}$, let $\mathcal{L}_f$ (resp. $\mathcal{R}_f$) be the set of maximal directed paths in the boundary of f that consist of edges with f to their right (resp. to their left). The face f is ***impossible*** if it satisfies one of the following two conditions (see Fig. 4a):

(i) $\mathcal{L}_f$ contains a path ℓ_f with the following properties: a) ℓ_f consists of edges in R; b) the rest of the boundary of f is not a single edge; and c) let e_f^u and e_f^v be the edges of ℓ_f incident to the extremes u and v of ℓ_f, respectively; then the angle in f incident to u and to the right of e_f^u and the angle in f incident to v and to the right of e_f^v are small.

(ii) $\mathcal{R}_f$ contains a path r_f with the following properties: a) r_f consists of edges in L; b) the rest of the boundary of f is not a single edge; and c) let e_f^u and e_f^v be the edges of r_f incident to the extremes u and v of r_f, respectively; then the angle in f incident to u and to the left of e_f^u and the angle in f incident to v and to the left of e_f^v are small.

A ***good embedding*** is an upward embedding $(\mathcal{E}, \lambda)$ that is 4-modal and that is such that no face of $\mathcal{E}$ is impossible. We now prove our characterization.

▶ **Theorem 3.** *Let G be a partitioned upward plane digraph with upward embedding $(\mathcal{E}, \lambda)$. Then G admits an upward book embedding respecting $(\mathcal{E}, \lambda)$ if and only if $(\mathcal{E}, \lambda)$ is good.*

Sketch. We sketch the proof for the case where G is connected; the general case is discussed in the full version. For the necessity, let Γ be an upward book embedding of G respecting $(\mathcal{E}, \lambda)$. Then $\mathcal{E}$ is 4-modal by Property 2. Suppose, for a contradiction, that a face f of $\mathcal{E}$ is impossible. W.l.o.g., assume that $\mathcal{L}_f$ contains a path ℓ_f satisfying condition (i) and let u, v, e_f^u, e_f^v be defined as above. Let further w and z be the vertices adjacent to u and v, respectively, such that the edge (u, w) follows e_f^u in clockwise order around u and the edge (z, v) follows e_f^v in counter-clockwise order around v. Since Γ is upward planar, the order of the vertices of ℓ_f along the spine is the same as their order in ℓ_f, with u below v; also, w lies above u and z below v. If w or z lies in the strip S_{uv} delimited by the horizontal lines through u and v, then (u, w) or (z, v) would cross an edge of the path ℓ_f, because the small angles in $(\mathcal{E}, \lambda)$ force the edges (u, w) and (v, z) to be to the right of e_f^u and e_f^v, respectively. However, no point of the spine lies to the right of ℓ_f and in the strip S_{uv}. It follows that w has to lie above v and z below u. This, however, implies that the edges (u, w) and (z, v) cross each other, given that they are both drawn to the right of the spine. This proves the necessity.

For the sufficiency, we build on a procedure by Bertolazzi et al. [12], who showed that any upward plane digraph can be augmented to a plane st-graph by adding edges, while maintaining the upward embedding. A ***plane st-graph*** G is an upward plane digraph with one source s and one sink t that are incident to the outer face. The boundary of each face f of G consists of two directed paths ℓ_f and r_f, called ***left*** and ***right path***, respectively. In the full version, we extend the technique of Bertolazzi et al. and show that, by suitably adding paths and carefully assigning their edges to L and R, we can augment a good embedding of the given partitioned upward plane digraph G to a good embedding of a partitioned plane st-graph. For this reason, we now assume that G is a partitioned plane st-graph. In this case, a face f is impossible if ℓ_f only consists of edges in R and r_f is not a single edge, or if r_f only consists of edges in L and ℓ_f is not a single edge; see Fig. 4b.

To show that a partitioned plane st-graph G with a good embedding $(\mathcal{E}, \lambda)$ admits an upward book embedding Γ, we use the fact that it can be constructed starting from the left path ℓ_{f_O} of the outer face f_O by repeatedly adding the right path of an internal face whose left path already belongs to the graph, see, e.g., [2, 23, 30, 44]. We start by drawing in Γ the edges of ℓ_{f_O} as semi-circles in their assigned side of the spine. When we draw the right path r_f of a face f whose left path ℓ_f already belongs to the subgraph of G drawn in Γ, we distinguish two cases. First, if r_f is a single edge e, then, since G is simple, ℓ_f contains an internal vertex. Since f is not impossible, $e \in R$. Then we just draw e as a semi-circle to

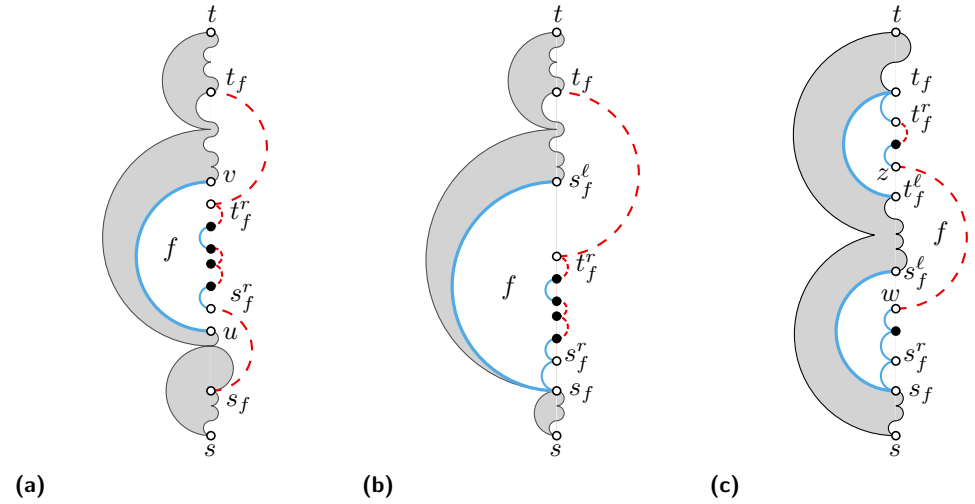

Figure 5 Illustrations for the proof sketch of Theorem 3.

the right of the spine. Second, if r_f is not a single edge, as in Fig. 5, then ℓ_f contains a left edge (u, v), since f is not impossible. If both the first and the last edge of r_f are in R, we place all the internal vertices of r_f on the spine between u and v in the order in which they appear along r_f and draw the edges of r_f as semi-circles in their assigned side of the spine; see Fig. 5a. Otherwise, if the first edge of r_f is in L and its last edge is in R, then also the first edge of ℓ_f is in L due to the 4-modality of $(\mathcal{E}, \lambda)$. We can then choose (u, v) as the first edge of ℓ_f and proceed as discussed in the previous case; see Fig. 5b. The case where the first edge of r_f is in R and its last edge is in L is analogous. Finally, if both the first and the last edge of r_f are in L, then so are the first edge (s_f, s_f^ℓ) and the last edge (t_f^ℓ, t_f) of ℓ_f, by the 4-modality of $(\mathcal{E}, \lambda)$. If ℓ_f is a single edge, then it plays the role of (u, v) and we place the internal vertices of r_f and draw its edges as above. Otherwise, since f is not impossible, r_f contains an edge $(w, z) \in R$. We embed the internal vertices of the subpath of r_f from its start to w, including w, between s_f and s_f^ℓ in the order as they appear along r_f, and we embed the internal vertices of the subpath of r_f from z to its end, including z, between t_f^ℓ and t_f in the order as they appear along r_f, and draw the edges of r_f as semi-circles in their assigned side of the spine; see Fig. 5c. ◀

4 Computational Complexity with Variable Embedding

In this section we study the complexity of testing whether a partitioned digraph $G = (V, L \cup R)$ admits an upward book embedding in two pages. We show that the problem is NP-complete by exploiting Theorem 3 and the NP-hardness of Upward Planarity Testing.

▶ **Theorem 4.** *It is* NP*-complete to decide whether a partitioned planar digraph admits an upward book embedding.*

Proof. Clearly, the problem is in NP. In order to prove NP-hardness, we give a reduction from Upward Planarity Testing, which was proved to be NP-hard by Garg and Tamassia [32]. Given a planar digraph $G = (V, E)$, we construct a partitioned digraph $G' = (V', L \cup R)$ as follows. Subdivide each edge $e \in E$ with a new vertex v_e; these subdivision vertices, together with the vertices in V, form V'. The edge set L consists of the edges outgoing from vertices

in V (and incoming into vertices in $V' \setminus V$), and the edge set R consists of the remaining edges. Clearly, G' can be constructed from G in polynomial time. It remains to show that G' admits an upward book embedding if and only if G admits an upward planar drawing.

For the necessity, observe that an upward book embedding Γ' of G' is an upward planar drawing of G'. Then an upward planar drawing Γ of G is obtained from Γ' by (i) placing each vertex of G in Γ as in Γ' and by (ii) drawing in Γ each edge $e = (u, w)$ of G as the Jordan arc formed by the union of the drawings of (u, v_e) and of (v_e, w) in Γ'.

For the sufficiency, suppose that G admits an upward planar drawing Γ. An upward planar drawing Γ' of G' can be constructed from Γ by placing each subdivision vertex v_e at any internal point of the Jordan arc representing the edge e. Let $(\mathcal{E}', \lambda')$ be the upward embedding corresponding to Γ'. We prove that $(\mathcal{E}', \lambda')$ is 4-modal. Consider any vertex v of G'. If $v \notin V$, then v has one incoming and one outgoing edge in G', hence it is trivially 4-modal. If $v \in V$ then, by construction, all the edges outgoing from v (incoming into v), if any, are in L (resp. are in R) and are consecutive in the clockwise order of the edges incident to v, due to the bimodality of Γ. It follows that v is 4-modal. Finally, $(\mathcal{E}', \lambda')$ has no impossible face, since by construction any maximal directed path in the boundary of any face contains both an edge in L and an edge in R. Hence, $(\mathcal{E}', \lambda')$ is a good embedding. By Theorem 3, we have that G' admits an upward book embedding respecting $(\mathcal{E}', \lambda')$. ◀

Upward Planarity Testing is known to be W[1]-hard with respect to the treewidth [41]. Also, the reduction shown in Theorem 4 constructs a graph which is a subdivision of the original instance of Upward Planarity Testing. Since any two graphs, one of which is a subdivision of the other one, have the same treewidth, we get the following.

▶ **Corollary 5.** *It is W[1]-hard with respect to the treewidth to decide whether a partitioned digraph admits an upward book embedding.*

Furthermore, by subdividing the edges twice, rather than once, so that the edges incident to vertices in V are in L and the other edges in R, the reduction gives an instance where one edge part induces a matching and the other one a forest of stars. This is in sharp contrast with the fact that the problem is linear-time solvable when both edge parts are matchings [1].

5 Test for Graphs with a Fixed Planar Embedding

In this section we show how to exploit the characterization of Theorem 3 in order to prove that, for an n-vertex partitioned plane digraph G with a given planar embedding $\mathcal{E}$, it can be tested in $O(n \log^3 n)$ time whether G admits an upward book embedding respecting $\mathcal{E}$. We assume that G is connected and refer to the full version for the case in which it is not.

We review a tool for testing whether G admits an upward planar drawing Γ respecting $\mathcal{E}$. By Theorem 1, the bimodality of $\mathcal{E}$ is necessary for the existence of Γ and can be tested in $O(n)$ time. Thus, the existence of Γ corresponds to the existence of an upward-consistent angle assignment λ for $\mathcal{E}$, which can be decided by the following strategy of Bertolazzi et al. [11]. Starting from the plane digraph G with planar embedding $\mathcal{E}$, one can construct a planar flow network $\mathcal{N}$, as illustrated in Fig. 6, where:

- for each switch v of G, the network $\mathcal{N}$ contains a source s_v supplying a single unit of flow;
- for each face f of $\mathcal{E}$, the network $\mathcal{N}$ contains a sink t_f that demands a number of units of flow equal to $n_f/2 - 1$ or $n_f/2 + 1$, depending on whether f is an internal face or the outer face of $\mathcal{E}$, respectively (where n_f is the number of switch angles incident to f);
- for each angle α in $\mathcal{E}$ at a switch of G, the network $\mathcal{N}$ contains a node w_α; and

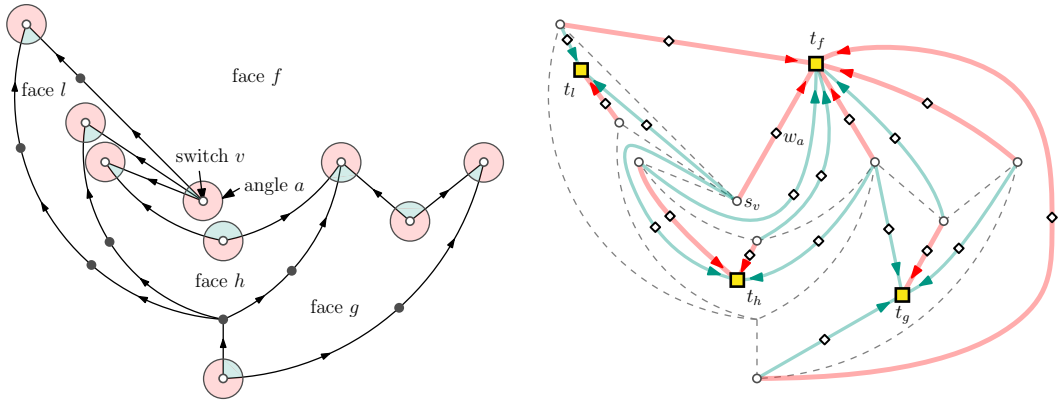

Figure 6 (a) An upward planar drawing of a digraph G; large and small angles at switches of G are depicted as red and green sectors of discs, respectively. (b) The network $\mathcal{N}$ constructed from the planar embedding of G; the edges of G, which are not part of $\mathcal{N}$, are drawn as gray dashed curves. Arcs of $\mathcal{N}$ traversed by the flow are red and thick, whereas arcs with no flow are green and thin.

- the network $\mathcal{N}$ contains an arc from each source s_v to each node w_α such that the angle α is incident to v in $\mathcal{E}$ and an arc from each node w_α to each sink t_f such that the angle α is incident to f in $\mathcal{E}$; all such arcs have a capacity of a single unit of flow.

By [11], there exists an upward-consistent angle assignment λ for $\mathcal{E}$ if and only if $\mathcal{N}$ admits a feasible flow whose value is the sum d_T of the demands of the sinks in $\mathcal{N}$. Indeed, upward-consistent angle assignments and (integral) feasible flows with value d_T are in bijection. Namely, from an upward-consistent angle assignment λ, one gets a feasible flow for $\mathcal{N}$ with value d_T by assigning flow 1 only to arcs incident to a node w_α where α is assigned a large angle by λ, and from a feasible flow for $\mathcal{N}$ with value d_T, one gets an upward-consistent angle assignment λ by assigning a large angle to each switch angle α such that the arcs incident to node w_α are assigned one unit of flow, and a small angle to all other switch angles. Testing whether G admits an upward planar drawing respecting $\mathcal{E}$ then becomes equivalent to testing whether $\mathcal{N}$ admits a flow whose value is d_T, which can be done in $O(n \log^3 n)$ time [17].

Our idea is to modify $\mathcal{N}$ so that there is an upward-consistent angle assignment λ for $\mathcal{E}$ such that $(\mathcal{E}, \lambda)$ is a good embedding if and only if $\mathcal{N}$ has a feasible flow whose value is d_T. The correspondence is actually stronger: As we show in the full version, the integral feasible flows with value d_T for the modified network are in bijection with the upward-consistent angle assignments λ for $\mathcal{E}$ such that $(\mathcal{E}, \lambda)$ is a good embedding. We show an algorithm, called $\mathcal{N}$-modifier, that performs a sequence of modifications to $\mathcal{N}$. Along the way, $\mathcal{N}$-modifier might stop and conclude that G has no upward book embedding respecting $\mathcal{E}$.

The $\mathcal{N}$-modifier algorithm. We start by describing the modifications to $\mathcal{N}$ to ensure 4-modality. Consider any vertex v of G. If v is not a switch, then its 4-modality does not depend on the angle assignment, thus we check whether in $\mathcal{E}$, in clockwise order around v, we have outgoing left edges, outgoing right edges, incoming right edges, and incoming left edges. If the test is negative, then G admits no upward book embedding respecting $\mathcal{E}$. If v is a switch, say a source, then we check whether in $\mathcal{E}$ the outgoing left edges are consecutive. If the test is negative, then G admits no upward book embedding respecting $\mathcal{E}$. If the test is positive and v has no outgoing left edges or no outgoing right edges, the processing of v is concluded. If the test is positive and v has both outgoing left and outgoing right edges, we modify $\mathcal{N}$ as follows; see Fig. 7. Let e be the left edge outgoing from v such that the edge e'

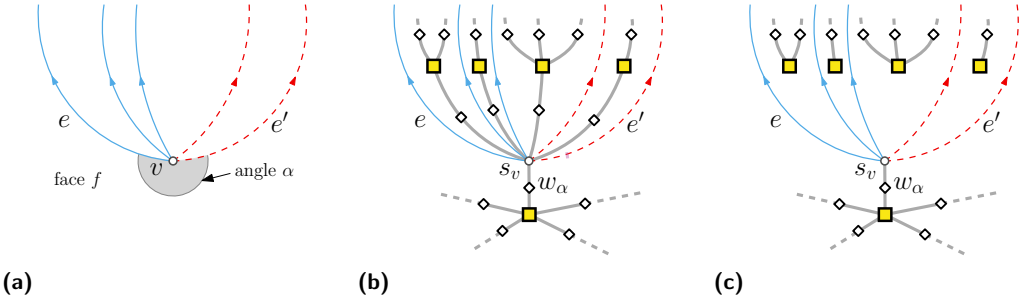

Figure 7 Modifying $\mathcal{N}$ to ensure 4-modality. (a) A vertex v with both outgoing left edges and outgoing right edges. (b) The part of $\mathcal{N}$ close to v (the edges of G are not in $\mathcal{N}$, but they are shown to maintain a visual reference with (a)). (c) Removal of the neighbors of s_v different from w_α.

preceding e in clockwise order around v is a right edge, let α be the angle (e, e'). For each angle $\beta \neq \alpha$ incident to v in $\mathcal{E}$, the algorithm $\mathcal{N}$-MODIFIER removes w_β and its incident arcs from $\mathcal{N}$. This forces the arc (s_v, w_α) to be assigned one unit of flow, hence making α large.

We next describe the modifications $\mathcal{N}$-MODIFIER applies to $\mathcal{N}$ in order to ensure the absence of impossible faces. Consider any face f of $\mathcal{E}$ and any maximal directed path ℓ_f in the boundary of f with f to its right (the treatment of the maximal directed paths with f to their left is analogous). If ℓ_f contains a left edge or if the rest of the boundary of f is a single edge, then the processing of ℓ_f is concluded. Otherwise, let u and v be the extremes of ℓ_f, let e_f^u and e_f^v be the edges of ℓ_f incident to u and v, let α_f^u be the angle in f incident to u and to the right of e_f^u, and let α_f^v be the angle in f incident to v and to the right of e_f^v. By Theorem 3, at least one of the angles α_f^u and α_f^v has to be large. By the maximality of ℓ_f, both α_f^u and α_f^v are switch angles. We say that α_f^u (resp. α_f^v) is ***enlargeable*** if the node $w_{\alpha_f^u}$ (resp. the node $w_{\alpha_f^v}$) is in $\mathcal{N}$. Note that, even if u (resp. v) is a switch of G, $w_{\alpha_f^u}$ (resp. $w_{\alpha_f^v}$) might not be in $\mathcal{N}$, because of some previous modification of $\mathcal{N}$. We distinguish three cases.

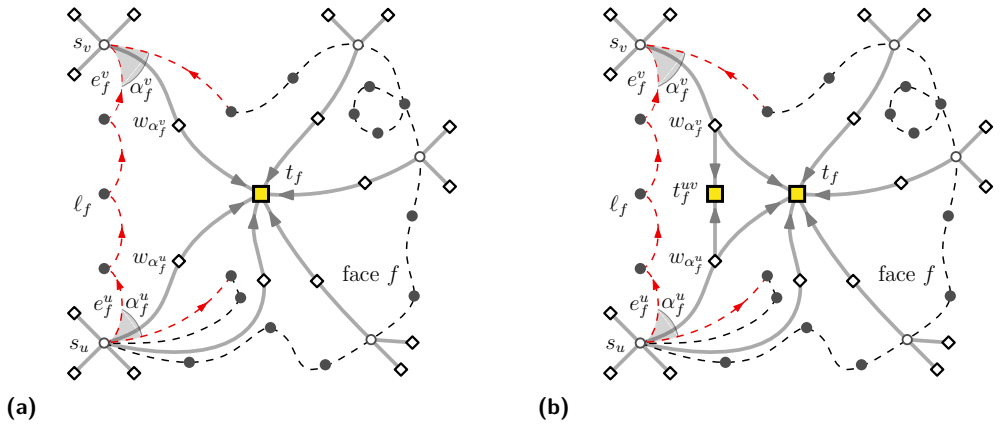

Figure 8 Modifying $\mathcal{N}$ to avoid impossible faces determined by ℓ_f, when both α_f^u and α_f^v are enlargeable. The part of $\mathcal{N}$ associated with f before (a) and after (b) the modification.

- If neither α_f^u nor α_f^v is enlargeable, then G admits no upward book embedding respecting $\mathcal{E}$.
- If just one of α_f^u and α_f^v, say α_f^u, is enlargeable, we modify $\mathcal{N}$ as follows: For each angle $\beta \neq \alpha_f^u$ incident to u in $\mathcal{E}$, we remove w_β and its incident arcs from $\mathcal{N}$, thus forcing the arc $(s_u, w_{\alpha_f^u})$ to be assigned one unit of flow and making α_f^u large.

- Finally, suppose that both α_f^u and α_f^v are enlargeable, as in Fig. 8. If there exists no angle $\beta \neq \alpha_f^u$ incident to u whose corresponding node w_β is in $\mathcal{N}$, or no angle $\beta \neq \alpha_f^v$ incident to v whose corresponding node w_β is in $\mathcal{N}$, then the processing of ℓ_f is concluded, since it is already guaranteed that one of α_f^u and α_f^v will be a large angle. Otherwise, we add to $\mathcal{N}$ a sink t_f^{uv} with demand 1, as well as arcs $(w_{\alpha_f^u}, t_f^{uv})$ and $(w_{\alpha_f^v}, t_f^{uv})$ with capacity 1, and decrease by 1 the demand of t_f. This forces one of $(w_{\alpha_f^u}, t_f^{uv})$ and $(w_{\alpha_f^v}, t_f^{uv})$ (and consequently one of $(s_u, w_{\alpha_f^u})$ and $(s_v, w_{\alpha_f^v})$) to be assigned one unit of flow, hence making large α_f^u or α_f^v, respectively. Note that $\mathcal{N}$ remains a planar flow network.

The described algorithm is the main ingredient for the proof of the following theorem.

▶ **Theorem 6.** *Let G be an n-vertex partitioned plane digraph with planar embedding $\mathcal{E}$. It is possible to test in $O(n \log^3 n)$ time whether G admits an upward book embedding respecting $\mathcal{E}$.*

Sketch. In the full version, we prove the mentioned bijection between the feasible flows with value d_T of the network $\mathcal{N}$ constructed by $\mathcal{N}$-MODIFIER and the upward-consistent angle assignments λ such that $(\mathcal{E}, \lambda)$ is a good embedding. Then Theorem 3 implies that G has an upward book embedding respecting $\mathcal{E}$ if and only if $\mathcal{N}$-MODIFIER did not conclude the opposite and $\mathcal{N}$ has a feasible flow with value d_T. Since $\mathcal{N}$-MODIFIER can be easily implemented to run in $O(n)$ time and the algorithm by Borradaile et al. [17] to test whether $\mathcal{N}$ has a feasible flow with value d_T runs in $O(n \log^3 n)$ time, the theorem follows. ◀

6 Test for Biconnected Partitioned Directed Partial 2-Trees

In this section we show how to test whether an n-vertex biconnected partitioned directed partial 2-tree $G = (V, L \cup R)$ admits an upward book embedding in two pages. We leverage tools introduced in [18, 19] to efficiently test whether a directed partial 2-tree is upward planar. Note that, lacking a characterization such as the one in Theorem 3, it would be prohibitive to lift such tools to work for our problem. Let e^* be an edge of G. We test in $O(n^2)$ time whether G admits a good embedding with e^* on the outer face. Repeating this test for all $O(n)$ choices of e^* yields an $O(n^3)$-time algorithm to decide whether G admits a good embedding. By Theorem 3, this is equivalent to testing whether G admits an upward book embedding.

Let T be an SPQ-tree of G, rooted at the Q-node ρ^* corresponding to e^*. Let μ be a node of T with poles u and v and with pertinent graph G_μ. A ***uv-external good embedding*** of G_μ is a good embedding of G_μ in which u and v are incident to the outer face. The requirement that e^* is incident to the outer face of any upward embedding $(\mathcal{E}, \lambda)$ of G implies that the restriction of $(\mathcal{E}, \lambda)$ to G_μ is indeed a uv-external good embedding of G_μ.

A uv-external good embedding $(\mathcal{E}_\mu, \lambda_\mu)$ of G_μ can be succinctly represented by a ***descriptor pair***, which consists of a ***shape descriptor*** $\langle \tau_l, \tau_r, \lambda^u, \lambda^v, \rho_l^u, \rho_r^u, \rho_l^v, \rho_r^v \rangle$ and of a ***pbe descriptor*** (short for partitioned book embedding descriptor) $\langle p_l^u, p_r^u, p_l^v, p_r^v, \chi_l, \chi_r, \alpha_l^u, \alpha_r^u, \alpha_l^v, \alpha_r^v \rangle$, with the following meaning. Let the ***left outer path*** P_l (resp. the ***right outer path*** P_r) be the path obtained by traversing the boundary of the outer face f_μ of $\mathcal{E}_\mu$ from u to v in clockwise (resp. counterclockwise) direction. The label τ_l (τ_r) is the sum of the labels assigned by λ_μ to the angles in f_μ at the vertices of P_l (resp. P_r), excluding u and v. The values λ^u and λ^v are the labels of the angles at u and v in f_μ, respectively. The label ρ_l^u is `in` or `out` depending on whether the edge of P_l incident to u is incoming or outgoing at u, respectively; the values ρ_r^u, ρ_l^v, and ρ_r^v are defined analogously. The label p_l^u is L or R depending on whether the edge of P_l incident to u belongs to L or R, respectively; the values p_r^u, p_l^v, and p_r^v are defined analogously. The label χ_l is 1 if P_l is a directed path from u to v and all its edges belong to L or if P_l is a directed path from v to u and all its

edges belong to R, it is 0 otherwise. The label χ_r is defined analogously for P_r. The label α_l^u is 1 if P_l contains a directed path from u to a vertex $w \notin \{u, v\}$ whose edges belong to L or a directed path from a vertex $w \notin \{u, v\}$ to u whose edges belong to R and if λ_μ assigns a small angle at w in f_μ; the label α_l^u is 0 otherwise. The labels α_r^u, α_l^v, and α_r^v are defined analogously, with respect to P_r rather than P_l and/or with respect to v rather than u.

The information in a descriptor pair fully describes how a uv-external good embedding of G_μ interfaces with the rest of G for the construction of a good embedding of G with e^* on the outer face. That is, for a good embedding $(\mathcal{E}, \lambda)$ of G with e^* on the outer face, let $(\mathcal{E}_\mu, \lambda_\mu)$ be the uv-external good embedding of G_μ in $(\mathcal{E}, \lambda)$, and let (σ, ω) be the descriptor pair of $(\mathcal{E}_\mu, \lambda_\mu)$. Replacing $(\mathcal{E}_\mu, \lambda_\mu)$ with *any* other uv-external good embedding of G_μ with descriptor pair (σ, ω) still results in a good embedding of G with e^* on the outer face. Even more, for a uv-external good embedding $(\mathcal{E}_\mu, \lambda_\mu)$ of G_μ with descriptor pair (σ, ω), let ν be a child of μ with poles w and z, and let (σ', ω') be the descriptor pair of the wz-external good embedding $(\mathcal{E}_\nu, \lambda_\nu)$ of G_ν in $(\mathcal{E}_\mu, \lambda_\mu)$. Replacing $(\mathcal{E}_\nu, \lambda_\nu)$ with *any* other wz-external good embedding of G_ν with descriptor pair (σ', ω') results in a uv-external good embedding of G_μ *with descriptor pair* (σ, ω). This allows us to only keep track of the descriptor pairs (σ, ω) that are "realizable" by G_μ, rather than of the actual uv-external good embeddings of G_μ. This is formalized by the notion of ***feasible set*** $\mathcal{F}_\mu$ for μ, which contains all the descriptor pairs (σ, ω) such that G_μ admits a uv-external good embedding with descriptor pair (σ, ω).

The core of our algorithm consists of a bottom-up computation of the feasible set $\mathcal{F}_\mu$ for each node μ of T. If μ is a **non-root Q-node**, then G_μ has a unique uv-external good embedding, hence $\mathcal{F}_\mu$ contains a unique descriptor pair and is computed in $O(1)$ time.

If μ is an **S-node**, let ν_1 and ν_2 be the children of μ in T and let w be the unique vertex shared by G_{ν_1} and G_{ν_2}. We combine every descriptor pair (σ_1, ω_1) in $\mathcal{F}_{\nu_1}$ with every descriptor pair (σ_2, ω_2) in $\mathcal{F}_{\nu_2}$; for every such combination, we assign the two angles at w in the outer face with every possible label in $\{-1, 0, 1\}$. We test in $O(1)$ time whenever the combination and the assignment result in a descriptor pair (σ, ω) of a good embedding of G_μ, by checking whether the properties of Theorems 1 and 3 are satisfied. In the positive case, we add (σ, ω) to $\mathcal{F}_\mu$. Thus, the computation of $\mathcal{F}_\mu$ takes time $O(|\mathcal{F}_{\nu_1}| \cdot |\mathcal{F}_{\nu_2}|)$, which is in $O(|V(G_{\nu_1})| \cdot |V(G_{\nu_2})|)$. This sums up to $O(n^2)$ time over all S-nodes of T.

If μ is a **P-node** with children $\nu_1, \ldots, \nu_k$, we cannot just combine the descriptor pairs in $\mathcal{F}(\nu_1), \ldots, \mathcal{F}(\nu_k)$, as the number of combinations might be super-polynomial. Instead, we consider every descriptor pair that *might* describe a uv-external good embedding of G_μ and test whether it is in $\mathcal{F}_\mu$. This is done as follows. A set $\mathcal{U}_n$ of descriptor pairs is ***n-universal*** if: (i) for every h-vertex biconnected partitioned directed partial 2-tree H with $h \leq n$, for every two vertices u_H and v_H of H, and for every $u_H v_H$-external good embedding $(\mathcal{E}_H, \lambda_H)$ of H, the descriptor pair of $(\mathcal{E}_H, \lambda_H)$ is in $\mathcal{U}_n$, and (ii) for every descriptor pair (σ, ω) in $\mathcal{U}_n$, there exists a biconnected partitioned directed partial 2-tree H that contains two vertices u_H and v_H and admits a $u_H v_H$-external good embedding $(\mathcal{E}_H, \lambda_H)$ with descriptor pair (σ, ω). Note that $\mathcal{F}_\mu \subseteq \mathcal{U}_n$. We can construct an n-universal set $\mathcal{U}_n$ with $|\mathcal{U}_n| \in O(n)$ in $O(n)$ time.

Consider a uv-external good embedding $(\mathcal{E}_\mu, \lambda_\mu)$ of G_μ with descriptor pair (σ, ω). Assume, w.l.o.g. up to a change of the indices, that the clockwise order around u in $\mathcal{E}_\mu$ of the pertinent graphs of the children of μ starting at the outer face is $G_{\nu_1}, \ldots, G_{\nu_k}$. The ***descriptor sequence*** of $(\mathcal{E}_\mu, \lambda_\mu)$ is the sequence $\mathcal{S}_\mu = [(\sigma_1, \omega_1), \ldots, (\sigma_k, \omega_k)]$ of the descriptor pairs of the uv-external good embeddings of $G_{\nu_1}, \ldots, G_{\nu_k}$ in $(\mathcal{E}_\mu, \lambda_\mu)$. The ***contracted descriptor sequence*** of $(\mathcal{E}_\mu, \lambda_\mu)$ is obtained from $\mathcal{S}_\mu$ by identifying equal consecutive descriptor pairs, see Fig. 9. Finally, the ***generating set*** $\mathcal{G}(\sigma, \omega)$ for (σ, ω) is the set of contracted descriptor

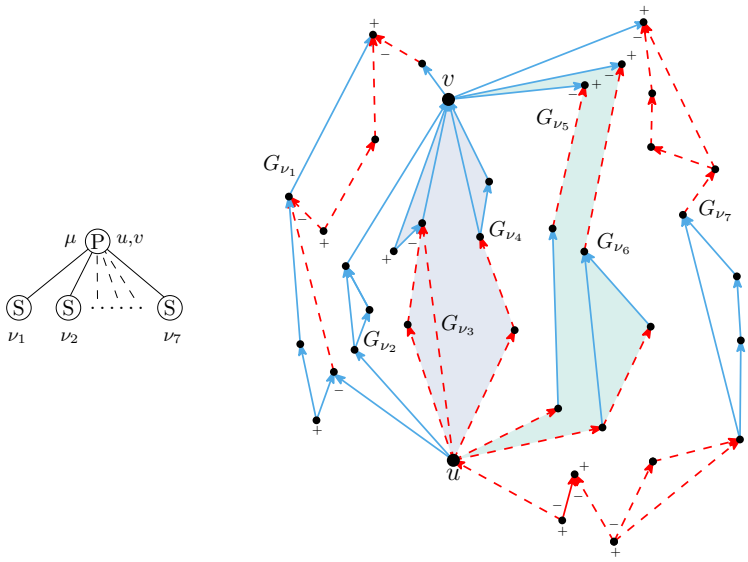

Figure 9 A uv-external good embedding $(\mathcal{E}_\mu, \lambda_\mu)$ of G_μ. Large and small angles on the outer faces of the embeddings of $G_{\nu_1}, G_{\nu_2}, \ldots, G_{\nu_7}$ are marked $+$ and $-$, respectively. The descriptor pair (σ, ω) of $(\mathcal{E}_\mu, \lambda_\mu)$ has $\sigma = \langle 1, 2, 0, -1, \texttt{out}, \texttt{in}, \texttt{out}, \texttt{out}\rangle$ and $\omega = \langle L, R, L, L, 0, 0, 1, 0, 0, 0\rangle$. The descriptor sequence of $(\mathcal{E}_\mu, \lambda_\mu)$ is $[(\sigma_1, \omega_1), (\sigma_2, \omega_2), \ldots, (\sigma_7, \omega_7)]$, where $\sigma_1 = \langle 1, -1, 1, 1, \texttt{out}, \texttt{out}, \texttt{out}, \texttt{out}\rangle$, $\sigma_2 = \langle 0, 0, 1, 1, \texttt{out}, \texttt{out}, \texttt{in}, \texttt{in}\rangle$, $\sigma_3 = \sigma_4 = \langle 0, 0, 1, 1, \texttt{out}, \texttt{out}, \texttt{in}, \texttt{in}\rangle$, $\sigma_5 = \sigma_6 = \langle -1, 1, 1, 1, \texttt{out}, \texttt{out}, \texttt{out}, \texttt{out}\rangle$, $\sigma_7 = \langle -2, 2, 1, 1, \texttt{in}, \texttt{in}, \texttt{out}, \texttt{out}\rangle$, $\omega_1 = \langle L, L, L, L, 0, 0, 1, 0, 0, 0\rangle$, $\omega_2 = \langle L, L, L, L, 1, 0, 0, 0, 0, 0\rangle$, $\omega_3 = \omega_4 = \omega_5 = \omega_6 = \langle R, R, L, L, 0, 0, 0, 0, 0, 0\rangle$, and $\omega_7 = \langle R, R, L, L, 0, 0, 1, 0, 0, 0\rangle$. The contracted descriptor sequence of $(\mathcal{E}_\mu, \lambda_\mu)$ is $[(\sigma_1, \omega_1), (\sigma_2, \omega_2), (\sigma_3, \omega_3), (\sigma_5, \omega_5), (\sigma_7, \omega_7)]$.

sequences that a P-node with poles w and z can have in a wz-external good embedding with descriptor pair (σ, ω). We can prove that $\mathcal{G}(\sigma, \omega)$ has size $O(1)$, can be constructed in $O(1)$ time, and that each contracted descriptor sequence in $\mathcal{G}(\sigma, \omega)$ has length $O(1)$.

In order to compute $\mathcal{F}_\mu$, we construct the generating set $\mathcal{G}(\sigma, \omega)$ of (σ, ω), for each descriptor pair (σ, ω) in $\mathcal{U}_n$, in overall $O(n)$ time. For each contracted descriptor sequence $\mathcal{C}$ in $\mathcal{G}(\sigma, \omega)$, we test whether $\mathcal{C}$ is ***realizable*** by G_μ, i.e., whether there exists a uv-external good embedding of G_μ whose contracted descriptor sequence $\mathcal{C}'$ is a subsequence of $\mathcal{C}$ containing the first and last elements of $\mathcal{C}$, which ensures that $\mathcal{C}'$ belongs to $\mathcal{G}(\sigma, \omega)$. We decide whether $\mathcal{C}$ is realizable by G_μ in $O(k)$ time, by constructing an auxiliary graph with vertex set $(\{\nu_1, \ldots, \nu_k\}, \{(\sigma_1, \omega_1), \ldots, (\sigma_\ell, \omega_\ell)\})$ and with an edge between ν_i and (σ_j, ω_j) if (σ_j, ω_j) belongs to $\mathcal{F}_{\nu_i}$, and by then testing whether each vertex in $\{\nu_1, \ldots, \nu_k\}$ can be assigned to a neighbor, so that both (σ_1, ω_1) and $(\sigma_\ell, \omega_\ell)$ are assigned at least one vertex. We add (σ, ω) to $\mathcal{F}_\mu$ if some $\mathcal{C}$ in $\mathcal{G}(\sigma, \omega)$ is realizable by G_μ. Since $|\mathcal{U}_n| \in O(n)$, $|\mathcal{G}(\sigma, \omega)| \in O(1)$, and the realizability of a contracted descriptor sequence can be decided in $O(k)$ time, the computation of $\mathcal{F}_\mu$ takes $O(nk)$ time, which sums up to $O(n^2)$ time over all P-nodes of T.

Finally, if μ is the **root Q-node** ρ^*, we treat it as a P-node with two children, corresponding to e^* and $G - e^*$, and compute $\mathcal{F}_{\rho^*}$ in $O(n)$ time. Then G has a good embedding with e^* on the outer face if and only if $\mathcal{F}_{\rho^*}$ is non-empty. We thus get the following.

▶ **Theorem 7.** *Let G be an n-vertex biconnected partitioned directed partial 2-tree. It is possible to test in $O(n^3)$ time whether G admits an upward book embedding.*

7 Conclusions

We studied upward book embeddings of partitioned digraphs, focusing on the unsolved case of two pages – one of the final open algorithmic book-embedding problems. We closed the complexity gap for the problem by proving its NP-hardness. We provided a characterization of the upward embeddings that admit such layouts and combined this with several algorithmic tools, including flow techniques, SPQ-decompositions, and compact embedding representations, obtaining efficient testing and embedding algorithms for digraphs with a fixed planar embedding and for biconnected partial 2-trees with variable embedding. We aim to (i) remove the linear overhead in our algorithm for biconnected partial 2-trees caused by rerouting the SPQ-tree at each Q-node, and (ii) extend the method to arbitrary simply connected partial 2-trees. The latter is challenging due to nested biconnected components in the block-cut-vertex tree, which must be arranged while keeping cut vertices 4-modal and avoiding impossible faces. Additional research directions include:

- studying the complexity of the problem for partitioned digraphs with few sources;
- determining whether the problem is NP-complete for bounded-treewidth instances; and
- developing FPT algorithms for parameters more restrictive than treewidth.

A Free Lunch: Manifolds of Positive Reach Can Be Smoothed Without Decreasing the Reach

Abstract

Assumptions on the reach are crucial for ensuring the correctness of many geometric and topological algorithms, including triangulation, manifold reconstruction and learning, homotopy reconstruction, and methods for estimating curvature or reach. However, these assumptions are often coupled with the requirement that the manifold be smooth, typically at least C^2.

In this paper, we prove that any manifold with positive reach can be approximated arbitrarily well by a C^∞ manifold without significantly reducing the reach. More precisely, given a manifold with reach R, we construct a manifold that is ε-close to it in the C^1 sense (both the manifold and its tangent spaces are close), and has reach at least $R - \varepsilon$. The proof employs techniques from differential topology – partitions of unity and smoothing using convolution kernels.

This result implies that nearly all theorems established for C^2 or manifolds with a certain reach naturally extend to manifolds with the same reach, even if they are not C^2, for free!

1 Introduction

What is the reach? The *reach* of a set is a number that captures the geometric properties of its *shape*. Roughly speaking, it provides a bound on the set's curvature and quantifies how far apart different parts of the set are from each other. As a key descriptor of a shape's complexity, the reach plays a crucial role as an assumption in many geometric and topological algorithms.

Formally, the reach of a (closed) set $\mathcal{S} \subset \mathbb{R}^d$ is the minimum of the distance between $\mathcal{S}$ and its *medial axis*, that is, the set of points in $\mathbb{R}^d$ for which the closest point in $\mathcal{S}$ is not unique. We illustrate these notions in Figure 1.

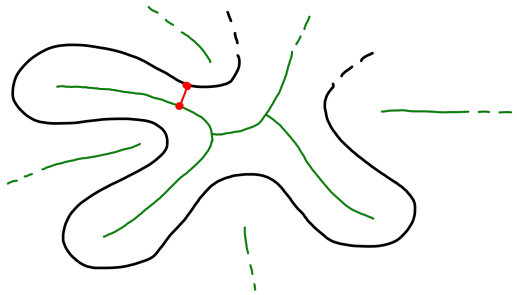

Figure 1 The medial axis (green) of a curve (black) in the plane. The reach is indicated in red.

The early history of the reach. The reach was first introduced by Federer in [20]. Notably, earlier work by Erdős explored what we now refer to as the *medial axis*, although it did not address the reach itself [18, 19]. While Erdős studied the medial axis and Federer considered its complement, the term "medial axis" itself was coined only later, by Blum [12]. A related notion, the *cut locus* in Riemannian geometry, has a significantly longer history, with its origins traced to the work of Poincaré [34], Whitehead [38], and Myers [31, 32][1].

Due to their wide applicability, these concepts have been reintroduced multiple times. For instance, the (closure of) medial axis was reintroduced as the *central set* by Milman and Waksman [30], its complement as the *unique footprint set* by Kleinjohann [25], and the reach was referred to as the *condition number* by Niyogi, Smale, and Weinberger [33].

The reach and differentiability. In [20], Federer established that the reach is stable under $C^{1,1}$-diffeomorphisms of the ambient space. Here, $C^{1,1}$ denotes a C^1 map whose derivative is Lipschitz, and by a $C^{1,1}$-diffeomorphism, we mean that both the diffeomorphism and its inverse are $C^{1,1}$. Federer also mentioned, without extensive detail [20, Remark 4.20], that the graph of a function has positive reach if and only if the function itself is $C^{1,1}$. Lytchak [27, 28] later proved that a topological submanifold of the Euclidean space without boundary has positive reach if and only if it is a $C^{1,1}$-submanifold. A quantified version of this statement can be found in [26].

The reach in computational geometry and topology, and manifold learning. The reach encapsulates the geometric complexity of a shape in a single non-negative value, making it a crucial assumption for ensuring the correctness of many geometric and topological algorithms. Several key classes of algorithms that depend on reach assumptions include:

- *Triangulation algorithms for surfaces and manifolds* (see for example [7, 6, 8, 13, 14, 15]).
- *Manifold learning or reconstruction and manipulation* (see for example [3, 4, 10, 22, 23, 36, 29, 5]).
- *Homotopy inference* (see for example [33, 37]).

All these algorithms have as input a point cloud queried from a manifold. Their output, and its correctness, varies:

- *Triangulation algorithms* produce as output a simplicial complex – often, but not always a variant of the Delaunay triangulation. Such algorithms are perceived as correct if the output complex is (piecewise linearly) homeomorphic to the underlying manifold.

[1] See [35] for a nice overview of the early history of the cut locus.

- *Manifold learning algorithms* output a description of an approximation of the given manifold – for example as the zero set of a function or a projection operator. Such algorithms are correct if the output approximation is homeomorphic to the underlying manifold and sufficiently geometrically close to it.
- *Homotopy inference algorithms* output a simplicial complex, which is correct if it is homotopy equivalent to the underlying manifold.

For the success of these algorithms, it is essential to provide criteria that guarantee their correctness and quality. Such criteria are often formulated using the reach of the manifold.

In addition, *reach estimation* in and by itself is an important topic in inference (see for example [1, 2, 11]). The typical setting for this type of problems involves a point cloud, which is drawn from a probability measure whose support is a manifold satisfying a regularity condition. Such condition can, for example, be a guarantee that the reach of the manifold in question is larger than some (very small positive) constant. The goal is to estimate the actual reach of the manifold, with a guaranteed precision margin.

Most of the aforementioned works assume that **the manifold in question is at least C^2**, in addition to having positive reach. This assumption is often made because it allows the use of the full machinery of differential and Riemannian geometry. For instance, the second fundamental form is always well-defined in the C^2 setting [16, 17]. Yet, this condition is not entirely natural. Manifolds with positive reach are indeed at least $C^{1,1}$, see [26, 27, 28], and by Rademacher's theorem [21], they are C^2 almost everywhere, but not necessarily everywhere.

On the other hand, requiring the manifold in question to be $C^{1,1}$ is quite natural, as it encompasses many configurations commonly found in modern modeling software, such as computer-aided design (CAD). This is because the majority of manufactured objects can be modeled as $C^{1,1}$ surfaces: For instance, consider a line segment and a circular arc intersecting at a point where their tangents coincide, as illustrated in Figure 2. This configuration has positive reach but is only $C^{1,1}$.

Figure 2 A $C^{1,1}$ transition (in red) between a circular arc and a straight line segment.

As a consequence of the results presented in this article (primarily Theorem 1), all aforementioned results can be extended from C^2 manifolds with positive reach to arbitrary manifolds with positive reach; hence the paper title.

Our settings. In this work, we identify an embedded manifold locally (in a neighborhood of a point p) as a graph of a map from its tangent space to its normal space at p. This approach, which we illustrate in Figure 3, allows us to compare homeomorphic manifolds ($\mathcal{M}$ and $\mathcal{M}'$ in Figure 3), embedded in Euclidean space of the same dimension, by comparing their corresponding maps and their derivatives (f and F in the figure). We say that two such manifolds are close *in the C^1 sense*, if, roughly speaking, both the manifolds and their tangent spaces are close. Formally, this is a condition on the corresponding maps f and F, and we explain it in Definition 11.

Throughout the paper, we denote the dimension of the manifolds $\mathcal{M}$ and $\mathcal{M}'$ by n, and the dimension of the ambient Euclidean space by d.

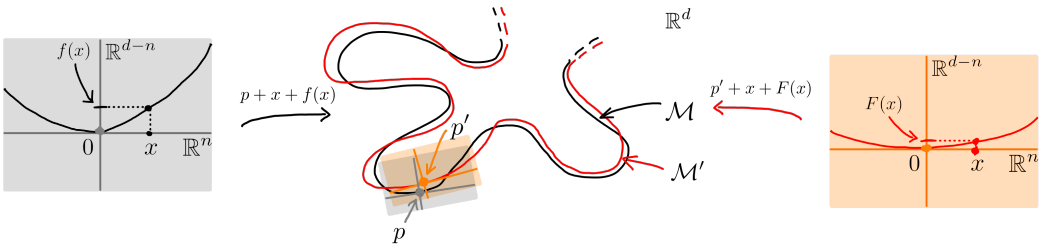

Figure 3 In our setting, we view manifolds locally as graphs of functions.

Our contribution. Our main contribution is the following statement:

▶ **Theorem 1.** *Let $\mathcal{M} \subset \mathbb{R}^d$ be a compact manifold of (positive) reach R, and $\varepsilon > 0$. Then there exists a C^∞ manifold $\mathcal{M}'$ such that:*

- *$\mathcal{M}$ and $\mathcal{M}'$ are ε-close as embedded manifolds in the C^1 sense.*
- *The reach R' of $\mathcal{M}'$ satisfies $R' \geq R - \varepsilon$.*

▶ Remark 2. We can either remove the compactness assumption (because we only need a locally finite cover in the proof of the theorem) or we can assume that the reach is not decreased by ε. More precisely, if the manifold $\mathcal{M}$ is compact, we can increase the reach R' of the manifold $\mathcal{M}'$ by scaling it by a factor $R/(R-\varepsilon)$, and achieve $R' \geq R$. However, this may increase the distance between $\mathcal{M}$ and $\mathcal{M}'$ in the C^1 sense (by $\mathcal{O}(\varepsilon)$).

In addition, our result can be restated in terms of density in the space of submanifolds:

▶ **Corollary 3.** *The space of C^∞ embedded submanifolds of $\mathbb{R}^d$ with reach R is dense (in the C^1 topology) in the space of $C^{1,1}$ embedded submanifolds of $\mathbb{R}^d$ with reach R.*

This reformulation of the main theorem stands in a long line of density results from functional analysis and differential topology[2]. Such results have been widely used to extend results from a smaller to a larger class of functions, without any extra effort. Hence, our result establishes a new link between computational geometry, topology, and manifold learning on the one hand, and functional analysis and differential topology on the other.

The main results from this paper might appear trivial to experts in differential topology at first glance: It is well known that Lipschitz functions can be smoothed while preserving the Lipschitz bounds of both the function and its derivative – a fact that is straightforward and proved succinctly in Lemmas 15 and 16. However, this observation alone is far from sufficient to achieve the main result of the paper.

Outline. The structure of the paper closely follows the different steps in the proof of Theorem 1. Let us provide you with an outlook:
Step 1: We start with a compact submanifold $\mathcal{M}$ of $\mathbb{R}^d$ of positive reach. For each point $p \in \mathcal{M}$, we can find a neighbourhood in which $\mathcal{M}$ is a *graph of a function from the (affine) tangent to the normal space at p*. Since the reach of $\mathcal{M}$ is positive, this function is $C^{1,1}$, and we use the bound on the Lipschitz constant of its derivative to control the angles between nearby tangent spaces.

We fix an ε and select a sample of points $p \in \mathcal{M}$ whose neighbourhoods cover $\mathcal{M}$ (see Figure 4). We only work with one neighbourhood at a time.

[2] We refer to Chapter 2 of [24] for an extensive overview.

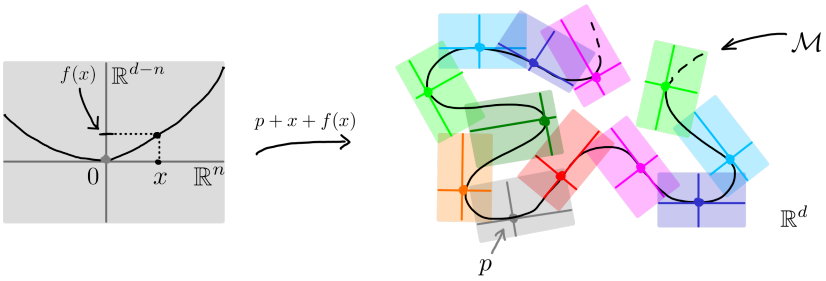

Figure 4 First we cover the manifold $\mathcal{M}$ with neighbourhoods in each of which $\mathcal{M}$ is representable as a graph of a function.

Step 2: We identify the point p with $0 \in \mathbb{R}^d$, and the tangent and normal spaces $T_p\mathcal{M}$ and $N_p\mathcal{M}$ with the first n and last $d-n$ coordinates of $\mathbb{R}^d$, respectively. Following this identification, we denote the map describing $\mathcal{M}$ by f, and its domain by U.

Our first goal is to smooth f in a neighbourhood of 0. We split U into three regions: a neighbourhood U_1 of 0, a region U_3 covering the vicinity of ∂U, and a transition region U_2 in between. We then use *kernel-based smoothing* to define a function

$$F : U \subseteq \mathbb{R}^n \to \mathbb{R}^{d-n}$$

that is smooth in U_1 and equals f in U_3 (see Figure 5). To achieve this, we employ a *partition of unity function*. We revise the background on smoothing and partitions of unity in Section 2.1. These techniques allow us to control the Lipschitz constant of F and its derivative, on which we give explicit bounds in Sections 3.1 and 3.2. We use *operator norms* to formulate these bounds. The background on operator norms is also presented in Section 2.1.

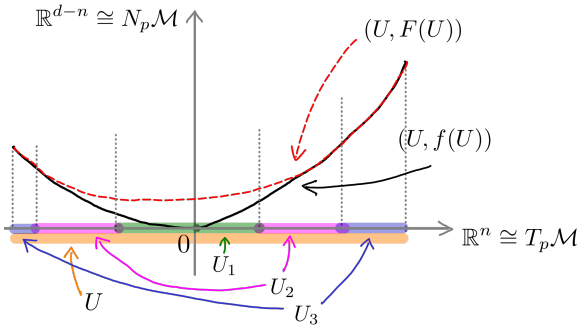

Figure 5 The function F (red) is smooth on the set U_1 (green) and equals f on the set U_3 (blue).

Step 3: We perform surgery on the manifold $\mathcal{M}$, and replace the graph of $p+f$ by the graph of $p+F$. We abuse notation and call this manifold $\mathcal{M}'$, although it is "only" smooth in a neighbourhood of the point p for now. Then we estimate the reach of $\mathcal{M}'$. To this end, we leverage a result by Federer, which characterizes the reach of a manifold through the distance from a point on it to the affine tangent space of another point on it. We pick two points in $p', q' \in \mathcal{M}'$ and investigate the distance from q' to the affine tangent space of p'. It turns out that bounding this distance is straightforward when p' does **not** lie in the graph of $p+F$. In the other case, we establish the bound using the relationship between the functions F and f, and the Lipschitz constants of f and its derivative. We cover these results in Section 3.3.

Step 4: We repeat Steps 2 and 3 iteratively for each point p of our sample, until we have smoothed the whole of $\mathcal{M}$. The process is illustrated in Figure 6. In each iteration, we have a one-parameter freedom in the choice of the smoothing kernel.

In this final step of the proof, we show that both the point sample and the smoothing kernels can be chosen in such a way that at the end, the smooth manifold $\mathcal{M}'$ satisfies the conditions of Theorem 1. This final step is described in Section 4.

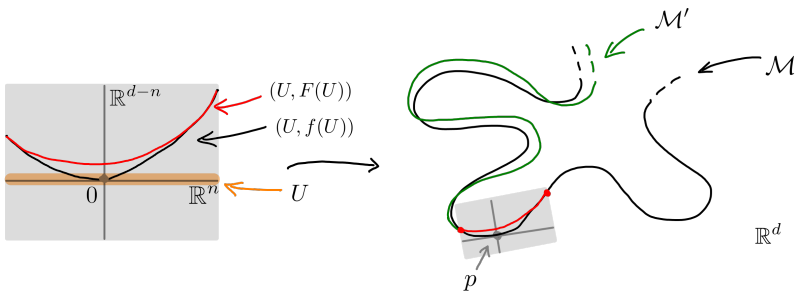

Figure 6 We construct the manifold $\mathcal{M}'$ iteratively. In each neighbourhood (gray), we replace the original manifold ($(U, f(U))$, in black) by a smooth piece ($(U, F(U))$, in red).

We indicate all the results in the paper that are (most probably) well known to experts in differential topology as "Folklore". We provide proofs of these statements,as well as the proofs of all our statements except the main theorem, in the full version of this article.

2 Preliminaries

We assume that the reader is reasonably familiar with sets of positive reach. Furthermore, we recall a characterization of the reach given by Federer [20] and results on Lipschitz-continuity of maps from a tangent space into a normal space of a manifold in the full version of this article.

2.1 Results from differential topology

In this section we recall three elementary tools from differential topology: partition of unity functions, the smoothing process, and operator norms. We adopt the formulation and notation used by Hirsch [24, Chapter 2].

Partition of unity functions

Partition of unity functions allow us to localize constructions and proofs in differential topology. They are defined as follows:

▶ **Definition 4.** *Let M be a C^k manifold, with $0 \leq k \leq \infty$, and $\mathcal{U} = \{U_i\}_{i \in I}$, with an index set I, an open cover of M. A* C^k partition of unity *subordinate to $\mathcal{U}$ is a family of C^k maps $\psi_i : M \to [0, 1]$, $i \in I$, with the following properties:*

- *For every $i \in I$, the support*[3] $\operatorname{supp}(\psi_i)$ *of ψ_i is contained in the set U_i.*
- *The collection $\{\operatorname{supp}(\psi_i)\}_{i \in I}$ of the supports of ψ_i is locally finite.*
- *The maps ψ_i sum to the function that is identically equal to 1, that is,*

$$\sum_i \psi_i(x) = 1.$$

[3] The support of a function ψ is the closure of the set $\psi^{-1}(\mathbb{R} \setminus \{0\})$.

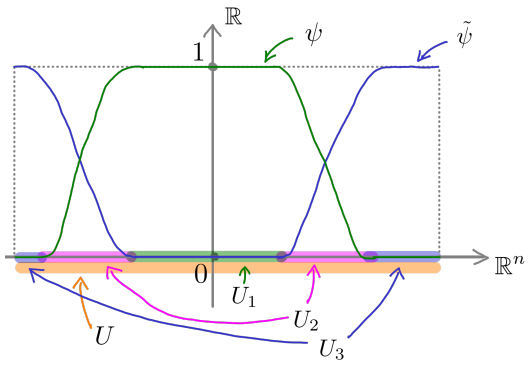

Figure 7 A cover $\{U_1 \cup U_2, U_2 \cup U_3\}$ of a set $U \subseteq \mathbb{R}^n$, and the corresponding family $\{\psi, \tilde{\psi}\}$ of partition of unity functions.

We illustrate the concept for our setting in Figure 7. We can find a partition of unity for any open cover:

▶ **Theorem 5** (Theorem 2.1 of [24]). *Let M be a C^k manifold with $1 \leq k \leq \infty$. Every open cover of M has a subordinate C^k partition of unity.*

Kernel smoothing

Kernel smoothing is, broadly speaking, a process that averages a map using a *kernel* function, making the result at least as smooth as the kernel itself. The kernel is defined as follows:

▶ **Definition 6** (Smoothing kernel). *A (smooth) map $\varphi : \mathbb{R}^n \to \mathbb{R}$ is called a* convolution *or a* smoothing kernel *if it is non-negative, has compact support, and $\int_{\mathbb{R}^n} \varphi = 1$.*

The support radius *of the smoothing kernel φ is the smallest value $\sigma \in \mathbb{R}_{\geq 0}$, for which the support* $\mathrm{supp}(\varphi)$ *of φ is contained in the closed ball of radius σ centred at the origin:*

$$\mathrm{supp}(\varphi) \subset B(0, \sigma) \subset \mathbb{R}^n.$$

We illustrate the smoothing radius in Figure 8.

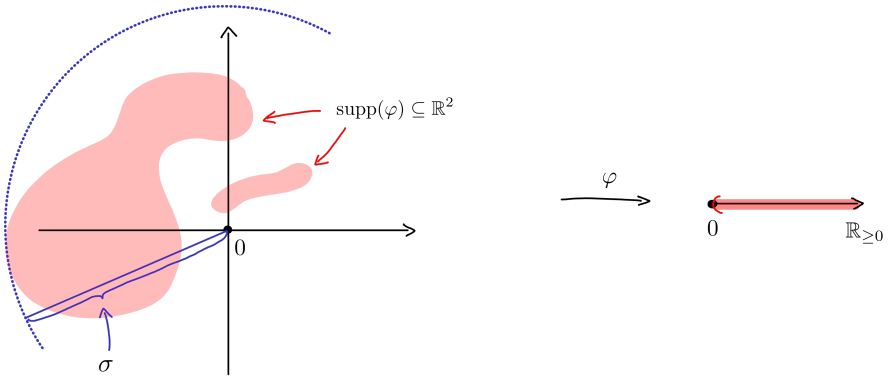

Figure 8 The support radius of the smoothing kernel φ.

Smoothing relies on neighbourhoods, determined by the support radius of the kernel. For smoothing of a map on a given set to be well-defined, the map itself must be well-defined on a sufficiently thick neighborhood surrounding the set. Consequently, it is sometimes necessary to shrink the domain of the map where the smoothing will be applied:

▶ **Definition 7.** *Consider a smoothing kernel with support radius σ. Given an open set $U \subset \mathbb{R}^n$, the* shrinking U_σ *of U is defined as*

$$U_\sigma = \{x \in U | B(x, \sigma) \subset U\}.$$

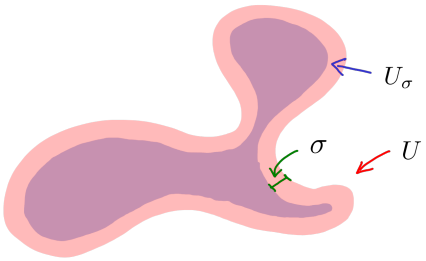

Figure 9 The shrinking of a set as defined in Definition 7.

The smoothing process, or in other words, the *convolution*, is carried out through integration:

▶ **Definition 8** (Convolution)**.** *Let $\varphi : \mathbb{R}^n \to \mathbb{R}$ be a smoothing kernel with support radius σ, $U \subset \mathbb{R}^n$ an open set, and $f : U \to \mathbb{R}^{d-n}$ a continuous map. The* convolution *of f by φ is the map*

$$\varphi * f : U_\sigma \to \mathbb{R}^{d-n}, \qquad x \mapsto \varphi * f(x) = \int_{\mathbb{R}^n} \varphi(y) f(x-y) \mathrm{d}y.$$

Smoothing improves the smoothness of the map, and commutes with differentiation:

▶ **Theorem 9** ([24, Theorem 2.3 (a) and (b)])**.** *Let $\varphi : \mathbb{R}^n \to \mathbb{R}$ be a smoothing kernel with support radius $\sigma > 0$, $U \subset \mathbb{R}^n$ an open set and $f : U \to \mathbb{R}^{d-n}$ a continuous map. The convolution $\varphi * f : U_\sigma \to \mathbb{R}^{d-n}$ has the following properties:*

- *If φ is C^k, with $1 \leq k \leq \infty$, then so is $\varphi * f$, and for each finite $\ell \leq k$,*

$$D^\ell(\varphi * f) = D^\ell(\varphi) * f$$

  on U_σ.
- *If f is C^k, with $1 \leq k \leq \infty$, then so is $\varphi * f$, and for each finite $\ell \leq k$,*

$$D^\ell(\varphi * f) = \varphi * (D^\ell f).$$

Operator norms

The last result we need is the convergence of smoothed maps to the original map. We consider convergence of the map itself as well as its first k derivatives with respect to the so-called C^k *norm*. We define this norm in two steps:

▶ **Definition 10.** *The norm $\|.\|$ of a k-linear map*

$$S : \mathbb{R}^n \times \cdots \times \mathbb{R}^n \to \mathbb{R}^m, \qquad (u_1, \ldots, u_k) \mapsto S(u_1, \ldots, u_k),$$

is defined as

$$\|S\| = \max_{|u_i|=1} |S(u_1, \ldots, u_k)|.$$

Consider a C^k map $f : U \to \mathbb{R}^{d-n}$, and its rth order derivative $D^r f$. For $r \geq 1$, the map $D^r f(x)$ is an r-linear map at each point $x \in U$, and we use the above definition to measure the norm $\|D^r f(x)\|$ of $D^r f$ at x. For $r = 0$, the notation $\|D^r f(x)\| = \|D^0 f(x)\|$ should be understood as $|f(x)|$.

▶ **Definition 11** (C^k norm). *Let $f : U \to \mathbb{R}^{d-n}$ be a C^k map, $U \subset \mathbb{R}^n$ an open set, and $C \subset U$ any subset of U. The C^k norm of f on C is defined as*

$$\|f\|_{k,C} = \sup\{\|D^r f(x)\| \mid x \in C, 0 \leq r \leq k\}.$$

We can now define the convergence we will use:

▶ **Theorem 12** ([24, Theorem 2.3 (c)]). *Let $U \subset \mathbb{R}^n$ be an open set with a compact subset $C \subset U$, and $f : U \to \mathbb{R}^{d-n}$ a C^k map, with $0 \leq k \leq \infty$. For any $\varepsilon > 0$ there exists a value $\sigma > 0$ such that $C \subset U_\sigma$, and any C^k smoothing kernel φ with support radius σ satisfies*

$$\|\varphi * f - f\|_{k,C} \leq \varepsilon.$$

▶ Remark 13. The operator 2-norm of a matrix A is defined as

$$\|A\|_2 = \sup_{v \neq 0} \frac{|Av|}{|v|} = \max_{|v|=1} |Av|,$$

where $|\cdot|$ denotes the usual Euclidean (2-)norm.

For the first derivative of a function f, evaluated at a point x, the norm from Definition 10 coincides with the operator 2-norm, that is, $\|D^1 f(x)\| = \|D^1 f(x)\|_2$. In particular,

$$\|Df\|_{0,C} = \sup\{\|Df(x)\|_2 \mid x \in C\} \qquad \text{and} \qquad \|f\|_{1,C} = \max\{\|f\|_{0,C}, \|Df\|_{0,C}\}.$$

In this paper, we primarily focus on the case where $k = 1$, as estimating the first derivative proves to be the main challenge in our proofs. Consequently, much of our work involves dealing with operator 2-norms.

In addition, we often make a choice of the map f on which we perform the smoothing. The lemma below implies that our choice does not depend on the map f itself, but only on its Lipschitz constant.

▶ **Lemma 14** (Folklore). *We adapt the settings from Theorem 12. If the map f is L-Lipschitz, then for any point $x \in U_\sigma$ and $y \in B(0, \sigma)$ it holds that $|f(x - y) - f(x)| \leq L\sigma$. As a consequence,*

$$\|\varphi * f - f\|_{0,C} \leq L\sigma.$$

3 On the control over Lipschitz constants while smoothing and using partition of unity functions

This section consists of three parts, in which we

- recall that smoothing by convolution does not affect Lipschitz constants;
- set the stage to define the function F that locally describes our smoothed manifold $\mathcal{M}'$, and determine the Lipschitz constant of F and its derivative;
- establish two bounds on the distance between the affine tangent space of a point on the graph of F, and another point in $\mathcal{M}'$.

3.1 Lipschitz constants for smoothings by convolution

In this section we focus on Lipschitz constants. To this end, we denote the Lipschitz constant of a function g by L_g. We recall that a function $g : \mathbb{R}^n \to \mathbb{R}^m$ is Lipschitz with constant L_g if for all points $y_1, y_2 \in \mathbb{R}^n$,

$$|g(y_2) - g(y_1)| \leq L_g \, |y_2 - y_1| \,. \tag{1}$$

Similarly, if g is differentiable, the derivative Dg of g is Lipschitz with constant L_{Dg} if for all points $y_1, y_2 \in \mathbb{R}^n$,

$$\left\|Dg(y_2) - Dg(y_1)\right\|_2 \leq L_{Dg}|y_2 - y_1|. \tag{2}$$

We first recall that smoothing does not influence the Lipschitz constant of a function or its derivative.

The result of the convolution of a function g by a kernel is just a barycenter of translates of g. Since the minimal Lipschitz constant satisfied by a function defines a semi-norm on functions, it is a convex functional. As a result:

▶ **Lemma 15** (Folklore). *Let $g : \mathbb{R}^n \to \mathbb{R}^{d-n}$ be an L_g-Lipschitz map and $\varphi : \mathbb{R}^n \to \mathbb{R}$ a smoothing kernel. Then the smoothing by convolution $\varphi * g$ is also L_g-Lipschitz.*

Moreover, since convolution commutes with derivation, we get:

▶ **Lemma 16** (Folklore). *Let $g : \mathbb{R}^n \to \mathbb{R}^{d-n}$ be a function whose* first derivative *is L_{Dg}-Lipschitz. Let further $\varphi : \mathbb{R}^n \to \mathbb{R}$ be a smoothing kernel. Then the first derivative of the smoothing by convolution $\varphi * g$ is also L_{Dg}-Lipschitz.*

3.2 Interpolation between a Lipschitz function and its smoothing by convolution

In this section, we consider an interpolation F between a map f locally describing our manifold, and its convolution $\varphi * f$, using a partition of unity function ψ. A formal definition of the function F will follow shortly. We illustrate this construction in Figure 10.

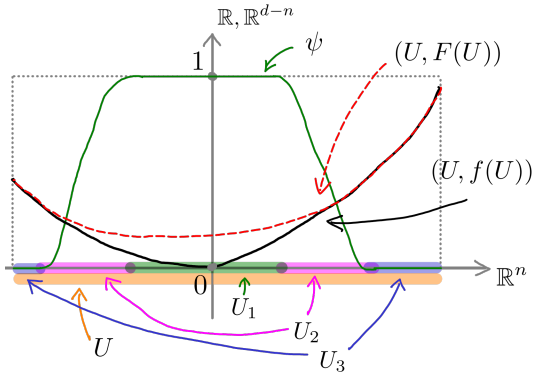

Figure 10 The superposed graphs of f, F, and ψ show that F is smooth on U_1 and $F = f$ on U_3.

To be able to use local arguments, we need to prove that the Lipschitz constants of F and its first derivative are close to the Lipschitz constants of f and its first derivative.

The Lipschitz constants of the function F were studied in [9], leading to a result similar to our Lemma 17. Our key contribution lies in determining the Lipschitz constant of the *derivative* of F, a significantly more intricate task and one that is crucial for proving the main result.

Throughout the rest of this paper, we operate under the following settings:

- We consider a function $f : U \subseteq \mathbb{R}^n \to \mathbb{R}^{d-n}$ whose graph is (locally) the manifold $\mathcal{M}$. Such a map exists due to Theorem 27 of the full version of this article. Moreover, both f and its derivative Df are Lipschitz, and we denote their Lipschitz constants by L_f and L_{Df}, respectively.
- We cover the domain U with two sets $\{U_1 \cup U_2, U_2 \cup U_3\}$ and consider a partition of unity subordinate to this cover. We denote the partition of unity function corresponding to the set $U_1 \cup U_2$ by ψ, and the closure of its support by

  $$\overline{\operatorname{supp} \psi} = C.$$

  We assume C to be compact. We denote the Lipschitz constants of ψ and its derivative $D\psi$ by L_ψ and $L_{D\psi}$, respectively, write

  $$L_{\psi,D\psi} = \max\{L_\psi, L_{D\psi}\}, \tag{3}$$

  and note that

  $$\sup_{y\in C} \|D\psi(y)\|_2 = \|D\psi\|_{0,C} \leq L_\psi \leq L_{\psi,D\psi}. \tag{4}$$

- For $\varepsilon > 0$ we choose a smoothing kernel $\varphi_\varepsilon : U \to \mathbb{R}$ such that

  $$\|\varphi_\varepsilon * f - f\|_{1,C} \leq \varepsilon. \tag{5}$$

  Such kernel exists due to Theorem 12. We recall (see Remark 13) that inequality (5) holds if and only if both of the following inequalities hold:

  $$\sup_{y\in C} \|(\varphi_\varepsilon * Df - Df)(y)\|_2 = \|\varphi_\varepsilon * Df - Df\|_{0,C} \leq \varepsilon, \tag{6}$$

  and

  $$\sup_{y\in C} |(\varphi_\varepsilon * f - f)(y)| = \|\varphi_\varepsilon * f - f\|_{0,C} \leq \varepsilon. \tag{7}$$

- The (locally) smoothed manifold $\mathcal{M}'$ is then locally described by the graph of the function

  $$F : U \to \mathbb{R}^{d-n}, \qquad x \mapsto F(x) = (1 - \psi(x))f(x) + \psi(x)(\varphi_\varepsilon * f(x)). \tag{8}$$

▶ **Lemma 17.** *The function F is Lipschitz on C with Lipschitz constant $(L_\psi\varepsilon + L_f)$.*

▶ **Lemma 18.** *The first derivative DF of the function F is Lipschitz on C with Lipschitz constant $(3L_{\psi,D\psi}\varepsilon + L_{Df})$.*

3.3 On bounding the reach of $\mathcal{M}'$ in terms of Lipschitz constants

Let $\mathcal{M}'$ denote the manifold that

- equals the graph of the function $p + F$ inside the neighbourhood of the point p;
- equals $\mathcal{M}$ outside of this neighbourhood.

Our next goal is to bound the reach of $\mathcal{M}'$. To this end, we use a result by Federer [20] that characterizes the reach of a manifold through the distance from a point on it to a tangent space of another point on it. We provide two different bounds on this distance. In order to prove the latter, we also establish bounds on the angle between tangent spaces of the graphs of f and F.

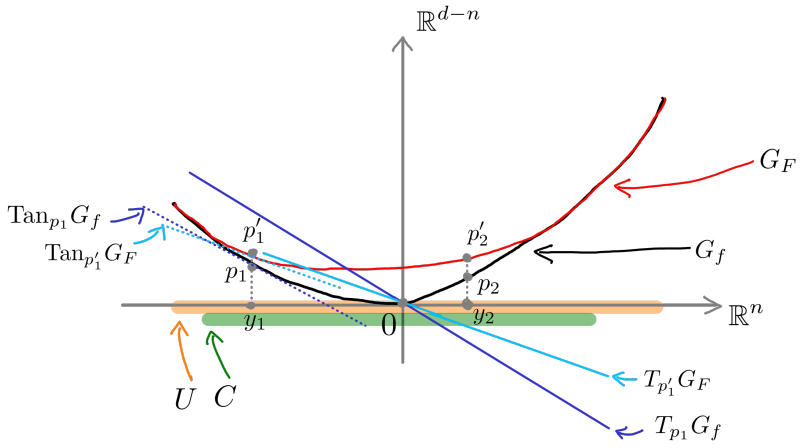

Figure 11 Illustration of the setup for this section.

We adapt the following settings, in addition to the ones established in Section 3.2: We fix two points $y_1, y_2 \in C, y_1 \neq y_2$, and label their graphs by

$$p_1 = (y_1, f(y_1)), \quad p_2 = (y_2, f(y_2)) \qquad \text{and} \qquad p_1' = (y_1, F(y_1)), \quad p_2' = (y_2, F(y_2)).$$

We write G_f and G_F for the graph of f and F, respectively, and $T_{p_1} G_f$ and $\mathrm{Tan}_{p_1} G_f$ (resp. $T_{p_1'} G_F$ and $\mathrm{Tan}_{p_1'} G_F$) for the tangent and affine tangent space of f at p_1 (resp. of F at p_1').

We illustrate this setup in Figure 11.

▶ **Lemma 19.** *The distance between the point p_2' and the affine tangent space $\mathrm{Tan}_{p_1'} G_F$ is bounded by*

$$d(p_2', \mathrm{Tan}_{p_1'} G_F) \leq \tfrac{1}{2}(3L_{\psi, D\psi}\varepsilon + L_{Df}) \left|p_2' - p_1'\right|^2. \tag{9}$$

This has the following consequence: Let $\rho > 0$ be small enough that the ρ-neighbourhood of y_1 is contained in C, $B(y_1, \rho) \subseteq C$. Then the graph G_F of the function F in this neighbourhood is contained in the union of balls

$$\bigcup_{v \in \mathbb{R}^n : |v| = r \leq \rho} B\left(p_1' + \begin{pmatrix} v \\ DF(y_1)v \end{pmatrix}, \tfrac{1}{2}(3L_{\psi, D\psi}\varepsilon + L_{Df})\, r^2\right).$$

We illustrate the settings of Lemma 19 in Figure 12.

As an auxiliary result needed to prove Proposition 22, we obtain a bound on the angle between the affine tangent spaces $\mathrm{Tan}_{p_1} G_f$ and $\mathrm{Tan}_{p_1'} G_F$, as well as a bound on the Hausdorff distance between two neighbourhoods contained in these spaces. We note that the angle between two affine spaces is equal to the angle between the corresponding vector spaces. The angle between two vector subspaces A and B is defined as

$$\angle A, B \underset{\text{def.}}{=} \max_{a \in A \setminus \{0\}} \min_{b \in B \setminus \{0\}} \angle a, b = \max_{b \in B \setminus \{0\}} \min_{a \in A \setminus \{0\}} \angle a, b.$$

▶ **Lemma 20.** *Assume that $\varepsilon \leq \frac{1}{L_{\psi, D\psi} + 1}$. Then the angle between the affine tangent spaces $\mathrm{Tan}_{p_1} G_f$ and $\mathrm{Tan}_{p_1'} G_F$ is bounded by*

$$\angle(\mathrm{Tan}_{p_1} G_f, \mathrm{Tan}_{p_1'} G_F) \leq \arcsin\left(L_{\psi, D\psi}\varepsilon + \varepsilon\right).$$

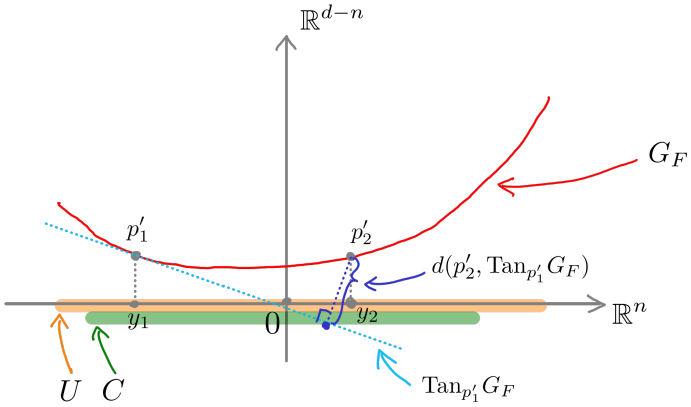

Figure 12 Illustration of the settings of Lemma 19.

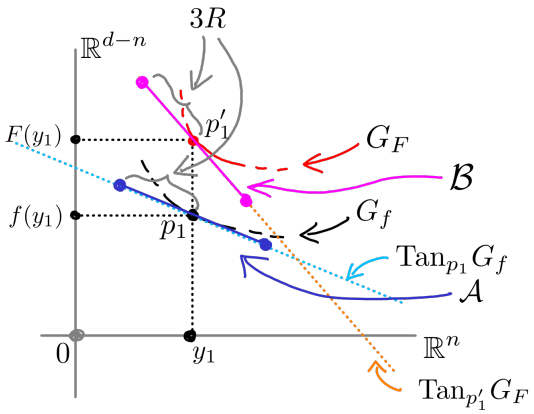

Figure 13 The $3R$-neighbourhoods of the points p_1 (in dark blue) and p'_1 (in pink) in the corresponding affine tangent spaces.

▶ **Corollary 21.** *Let $R > 0$ denote the reach of the manifold $\mathcal{M}$, and consider the n-dimensional neighbourhood of size $3R$ of the point p_1 in the affine tangent space $\mathrm{Tan}_{p_1} G_f$:*

$$\mathcal{A} = p_1 + \{T \in T_{p_1} G_f \mid |T| \leq 3R\}.$$

Similarly, consider a $3R$-neighbourhood of the point p'_1 in the affine tangent space $\mathrm{Tan}_{p'_1} G_F$:

$$\mathcal{B} = p'_1 + \{T \in T_{p'_1} G_F \mid |T| \leq 3R\}.$$

Assume that $\varepsilon \leq \frac{1}{L_{\psi, D\psi}+1}$. Then the Hausdorff distance between the two neighbourhoods is upper bounded:

$$d_H(\mathcal{A}, \mathcal{B}) \leq \varepsilon \left(6RL_{\psi, D\psi} + 6R + 1\right).$$

The settings of Corollary 21 are illustrated in Figure 13.

At last, we bound the distance between the affine tangent space $p + \mathrm{Tan}_{p'_1} G_F$ and a point $q' \in \mathcal{M}'$ that does not lie on the graph of $p + F$. We illustrate the settings in Figure 14.

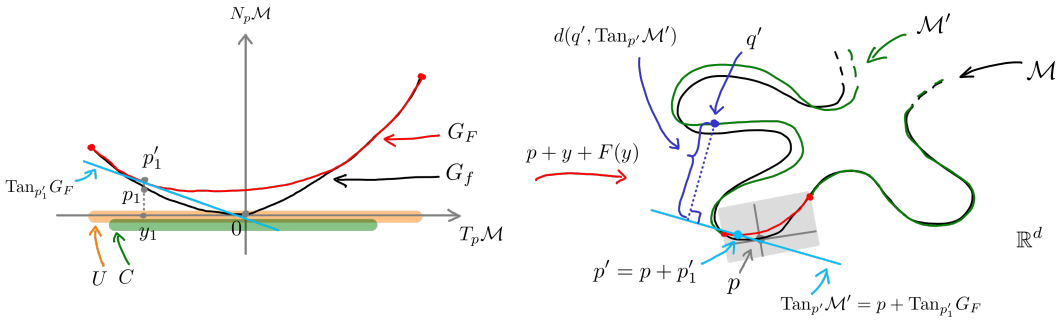

Figure 14 Illustration of the setup of Proposition 22.

▶ **Proposition 22.** *Let $q' \in \mathcal{M}' \backslash (p + G_F)$, and assume that $\varepsilon \leq \frac{1}{L_{\psi, D\psi}+1}$. Write $p + p_1' = p'$. Then the distance between the point q' and the affine tangent space $\mathrm{Tan}_{p'}\,\mathcal{M}' = p + \mathrm{Tan}_{p_1'}\,G_F$ is bounded by*

$$d(q', \mathrm{Tan}_{p'}\,\mathcal{M}') \leq \frac{|q' - p'|^2}{2R} + \frac{\varepsilon^2}{2R} + \varepsilon\,(6RL_{\psi, D\psi} + 6R + 4)\,. \tag{10}$$

Therefore, if $\varepsilon < R$ and $|q' - p'| \geq \beta$, then

$$d(q', \mathrm{Tan}_{p'}\,\mathcal{M}') \leq \frac{|q' - p'|^2}{2R'},$$

with

$$R' = \frac{R}{1 + \frac{12\varepsilon R}{\beta^2}\,(RL_{\psi, D\psi} + R + 1)}.$$

4 Proof of the main theorem

We now have all the necessary tools to prove our main result. Before proceeding, let us restate the theorem:

▶ **Theorem 1.** *Let $\mathcal{M} \subset \mathbb{R}^d$ be a compact manifold of (positive) reach R, and $\varepsilon > 0$. Then there exists a C^∞ manifold $\mathcal{M}'$ such that:*

- *$\mathcal{M}$ and $\mathcal{M}'$ are ε-close as embedded manifolds in the C^1 sense.*
- *The reach R' of $\mathcal{M}'$ satisfies $R' \geq R - \varepsilon$.*

Proof. We proceed as discussed in the introduction.

Step 1. In the first step we select a sample P of the manifold $\mathcal{M}$ (see also Figure 15, right). To this end, we choose a parameter $0 < \delta \leq R/2$, and let P be a $\sqrt{\delta R}/16$-net[4] on $\mathcal{M}$, meaning that

- for every point $x \in \mathcal{M}$ one can find a point $\mathsf{p} \in \mathsf{P}$, such that $|x - \mathsf{p}| \leq \sqrt{\delta R}/16$,
- for all $\mathsf{p}, \mathsf{q} \in \mathsf{P}$, $|\mathsf{p} - \mathsf{q}| \geq \sqrt{\delta R}/16$.

Such a net exists thanks to [13, Lemma 5.2, Section 5.1.1].

[4] The factor 16 in $\sqrt{\delta R}/16$ is almost certainly suboptimal. However, it simplifies the proof by a margin.

Due to these properties, the $\sqrt{\delta R}/16$-balls centred at the points of the sample P cover $\mathcal{M}$. In addition, we consider balls of radius $\sqrt{\delta R}/2$ centred at the points of P.

We need one more ingredient before we start iteratively visiting neighbourhoods of each point $\mathsf{p} \in \mathsf{P}$ – a fixed partition of unity function, which we rescale at every iteration. To this end, we split the ball $B(0,4) \subseteq \mathbb{R}^n$ into three sets,

$$V_1 = B(0,1), \quad V_2 = \{x \in \mathbb{R}^n \mid 1 \leq |x| < 2\}, \quad V_3 = \{x \in \mathbb{R}^n \mid 2 \leq |x| \leq 4\}.$$

The two sets $\{V_1 \cup V_2, V_2 \cup V_3\}$ then cover the ball $B(0,4)$, and we let ψ_0 be the partition of unity function corresponding to the set $V_1 \cup V_2$. Then $\psi_0 \equiv 1$ on V_1, and $\psi_0 \equiv 0$ on V_3.

Next, we select a point $\mathsf{p} \in \mathsf{P}$, and restrict our attention to the ball $B(\mathsf{p}, \sqrt{\delta R}/2)$ of radius $\sqrt{\delta R}/2$ centred at p.

Step 2. Let f be a function whose graph describes the manifold $\mathcal{M}$ in the ball $B(\mathsf{p}, \sqrt{\delta R}/2)$. To be more concrete, choose $f : T_{\mathsf{p}}\mathcal{M} \cap B(0, \sqrt{\delta R}/2) \to N_{\mathsf{p}}\mathcal{M}$ as in Theorem 27 in the full version of this article, or [26] which gives a more extensive version of Theorem 27. Due to this theorem and our choice of δ, the derivative of f is $\frac{1}{R-\delta}$-Lipschitz on the whole domain $T_{\mathsf{p}}\mathcal{M} \cap B(0, \sqrt{\delta R}/2)$.

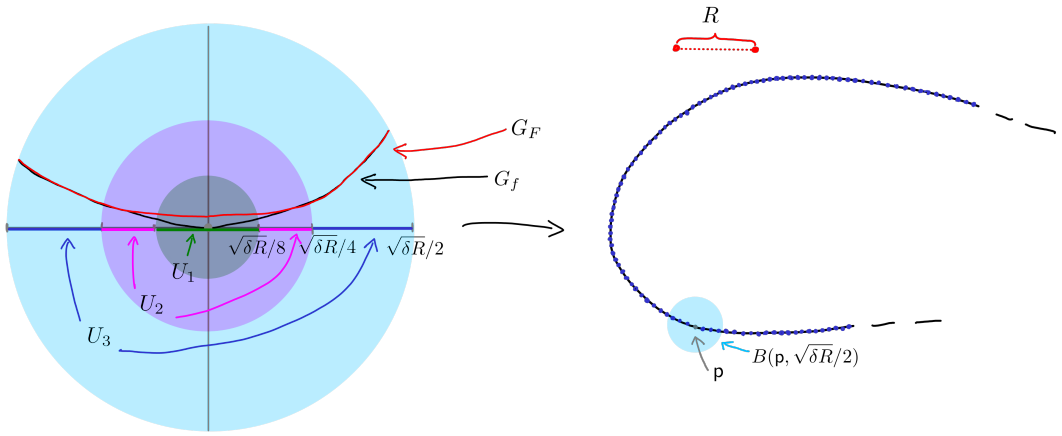

Figure 15 The point sample P at a piece of the manifold $\mathcal{M}$, and the neighbourhoods U_1, U_2, and U_3.

We apply the smoothing construction described in Section 3.2. As ingredients, we need a partition of unity function, and a smoothing kernel.

Partition of unity function: We map the neighbourhood $T_{\mathsf{p}}\mathcal{M} \cap B(0, \sqrt{\delta R}/2)$ diffeomorphically to the ball $B(0,4) \subseteq \mathbb{R}^n$ using the canonical identification of the tangent space $T_{\mathsf{p}}\mathcal{M}$ with $\mathbb{R}^n$ and the map $x \mapsto \frac{8}{\sqrt{\delta R}} \cdot x$. The preimages of the sets V_1, V_2, and V_3 under this map are, respectively,

$$U_1 = \left\{x \in T_{\mathsf{p}}\mathcal{M} \mid |x| < \sqrt{\delta R}/8\right\},$$
$$U_2 = \left\{x \in T_{\mathsf{p}}\mathcal{M} \mid \sqrt{\delta R}/8 \leq |x| < \sqrt{\delta R}/4\right\},$$
$$U_3 = \left\{x \in T_{\mathsf{p}}\mathcal{M} \mid \sqrt{\delta R}/4 \leq |x| \leq \sqrt{\delta R}/2\right\}.$$

The sets U_1, U_2, and U_3 are illustrated in Figure 15, on the left. We define ψ by scaling the partition of unity function ψ_0: $\psi(x) = \psi_0\left(\frac{8x}{\sqrt{\delta R}}\right)$. Then ψ is the partition of unity function corresponding to the set $U_1 \cup U_2$ in the cover $\{U_1 \cup U_2, U_2 \cup U_3\}$ of $T_{\mathsf{p}}\mathcal{M} \cap B(0, \sqrt{\delta R}/2)$, and thereby, $\psi \equiv 1$ on U_1, and $\psi \equiv 0$ on U_3. Furthermore:

▶ **Lemma 23.** *The Lipschitz constants of ψ and its derivative are bounded by $L_\psi \leq \frac{8}{\sqrt{\delta R}} L_{\psi_0}$ and $L_{D\psi} \leq \frac{64}{\delta R} L_{D\psi_0}$.*

By decreasing δ if necessary, we can also assume that $\frac{8}{\sqrt{\delta R}} L_{\psi_0} \leq \frac{64}{\delta R} L_{D\psi_0}$. Thus:

$$L_{\psi, D\psi} = \max\{L_\psi, L_{D\psi}\} \leq \frac{64}{\delta R} L_{D\psi_0}. \tag{11}$$

Smoothing kernel: Let $C = \overline{\operatorname{supp} \psi}$. For $0 < \rho < \frac{1}{1+\frac{64}{\delta R} L_{D\psi_0}}$ we choose a smoothing kernel $\varphi_\rho : T_{\mathsf{p}}\mathcal{M} \cap B(0, \sqrt{\delta R}/2) \to \mathbb{R}$ such that

$$\|\varphi_\rho * f - f\|_{1,C} \leq \rho. \tag{5}$$

Such kernel exists due to Theorem 12. With these choices we define

$$F : T_{\mathsf{p}}\mathcal{M} \cap B(0, \sqrt{\delta R}/2) \to N_{\mathsf{p}}\mathcal{M}, \quad x \mapsto F(x) = (1 - \psi(x))f(x) + \psi(x)(\varphi_\rho * f(x)). \tag{8}$$

Step 3. We write $\mathcal{M}'$ for the manifold that coincides with $\mathcal{M}$ outside of the ball of radius $\sqrt{\delta R}/2$ centred at the point p, and is the graph of $\mathsf{p} + F$ inside this ball.

To be more concrete, we recall that we can write each point $p \in \mathcal{M} \cap B(\mathsf{p}, \sqrt{\delta R}/2)$ as $p = \mathsf{p} + y + f(y)$, with $y \in T_{\mathsf{p}}\mathcal{M}$. With this in mind we define, for each $p \in \mathcal{M}$:

$$p' \underset{\text{def.}}{=} \begin{cases} \mathsf{p} + y + F(y), & \text{if } p \in B(\mathsf{p}, \sqrt{\delta R}/2), \\ p, & \text{otherwise,} \end{cases}$$

and let $\mathcal{M}' = \{p' \mid p \in \mathcal{M}\}$.

We stress that

- inside the ball $B(\mathsf{p}, \sqrt{\delta R}/16)$, $\mathcal{M}'$ is smooth (C^∞), and
- $\mathcal{M}' = \mathcal{M}$ not only outside of the ball $B(\mathsf{p}, \sqrt{\delta R}/2)$, but already outside of the ball $B(\mathsf{p}, \sqrt{\delta R}/4)$.

Next, we set forth to bound the reach of $\mathcal{M}'$. We choose two points $p', q' \in \mathcal{M}'$, and estimate the distance between q' and the affine tangent space $\operatorname{Tan}_{p'} \mathcal{M}'$ – our bounds from Lemma 19 and Proposition 22 yield:

▶ **Lemma 24.** *Let $p', q' \in \mathcal{M}'$ be two points in the manifold $\mathcal{M}'$. Then the distance between q' and the affine tangent space $\operatorname{Tan}_{p'} \mathcal{M}'$ is bounded by*

$$d(q', \operatorname{Tan}_{p'} \mathcal{M}') \leq \frac{|p' - q'|^2}{2R'},$$

with

$$R' = \frac{R}{\max\left\{3 \cdot 64 L_{D\psi_0} \frac{\rho}{\delta} + \frac{1}{1 - \frac{\delta}{R}}, 1 + 3 \cdot 64 \frac{\rho}{\delta}\left(\frac{64}{\delta} L_{D\psi_0} + R + 1\right)\right\}}. \tag{12}$$

Thus, due to Federer's Theorem [20, Theorem 4.18], the reach of the manifold $\mathcal{M}'$ satisfies $\operatorname{rch}(\mathcal{M}') \geq R'$, with R' as in equation (12).

Step 4. Here we apply the smoothing construction iteratively for all points of P. The correctness of the construction relies on two observations: The first observation is that (12) can be made as close to R as needed. The second observation is that the manifold is locally changed only a finite number of times that (which in the non-compact case requires specific choices of δ, ϵ, and ρ).

Because P is a $\sqrt{\delta R}/16$-net, it is locally finite. In particular, the number of points of P contained in a ball of radius $\sqrt{\delta R}/2$ centred at any point is $\mathcal{O}(8^d)$, as can be seen by a simple packing argument, see e.g. [13, Lemma 5.3, Section 5.1.1] for similar arguments. However, with every iteration of the construction, the points in a $\sqrt{\delta R}/2$ neighbourhood of the point p (which is the centre of the local smoothing operation) move[5] by at most ρ, due to (5).

This means that the points can move at most by $N_V\rho$, where N_V is the maximal number of times any point is visited. We claim that

▷ Claim 25. If we pick $N_C = 8^{d+1}$ and assume that $\rho \leq \frac{\sqrt{\delta R}/16}{2\cdot 8^{d+1}} = \frac{\sqrt{\delta R}/32}{N_C}$, then $N_V \leq N_C$.

Proof of Claim 25. Write $N_V(i)$ for the maximal number of times any point is visited after i iterations of the surgery process. The number $N_V(i)$ is upper bounded by the number of points of P that, during the iterative process (up to iteration i), end up in a ball of radius $\sqrt{\delta R}/2$ around the displaced point, which can move as well. Because the points move by at most $\rho N_V(i)$ and need to enter the ball of radius $\sqrt{\delta R}/2$, they must initially lie inside a ball of radius $\sqrt{\delta R}/2 + 2\rho N_V(i)$. In other words, in order for a surgery centered at point q to impact point p, the original positions of p and q must lie at distance at most $\sqrt{\delta R}/2 + 2\rho N_V(i)$ apart. Because the points in the sample are originally $\sqrt{\delta R}/16$ separated, a packing argument gives the following relation:

$$N_V(i) \leq \left(\frac{\sqrt{\delta R}/2 + 2\rho N_V(i)}{\sqrt{\delta R}/16} \right)^d . \tag{13}$$

If we take ρ sufficiently small, for example $\rho \leq \frac{\sqrt{\delta R}/16}{2\cdot 8^{d+1}}$, then equation (13) is not satisfied for $N_V(i) = N_C$ with $N_C = 8^{d+1}$. This means that for any i, we have that $N_V(i) \leq N_C$. In particular at the end of the process the maximal number of times any point is visited is upper bounded by N_C, i.e. $N_V \leq N_C$. ◁

For the given $\varepsilon > 0$, we now choose ρ and δ such that R' from equation (12) satisfies $|R - R'| \leq \varepsilon/(4N_C)$. This is always possible. One can set $\delta = \varepsilon/(4N_C)$; the choice for ρ is a bit more subtle but choosing $\rho = \mathcal{O}(\delta^4)$ works if δ (and equivalently ε) is sufficiently small. Additionally, as we have seen, δ has to be sufficiently small so that $\rho N_C = 8^{d+1}\mathcal{O}(\delta^4) \leq \sqrt{\delta R}/32$. This in particular means that even after the iterative process (that moves the points of P) the resulting set is still a $\sqrt{\delta R}/8$ cover, which means that every point in the manifold is smoothed. This is the reason we started with a $\sqrt{\delta R}/16$-net and U_1 is of size $\sqrt{\delta R}/8$.

Let $p, q \in \mathcal{M}$ be arbitrary. We now note that:

- Every pair of points p and q in the manifold is visited/perturbed by the smoothing process at most N_C times (each).
- We have picked ρ and δ such that $|R - R'| \leq \varepsilon/(4N_C)$, where here the difference between the reach R and R' is interpreted as between each iteration of the smoothing process.

[5] This $\sqrt{\delta R}/2$ size bound is not tight, in fact it can easily be improved to $\sqrt{\delta R}/4 + (\sqrt{\delta R}/4)^2$ by noting that the part of $\mathcal{M}$ whose projection onto $T_{\mathsf{p}}\mathcal{M} \cap B(0, \sqrt{\delta R}/2)$ falls outside U_2 is not perturbed.

This means that the characterization of the reach (for the points p and q) of Lemma 24 only changes $2N_C$ times, and thus for a total of less than ε. Because the choice of p and q is arbitrary, the reach after the smoothing has decreased by at most ε. ◀

Abstract

A triangulation of a surface is k-irreducible if every non-contractible curve has length at least k and any edge contraction breaks this property. Equivalently, every edge belongs to a non-contractible curve of length k and there are no shorter non-contractible curves. We prove that a k-irreducible triangulation of an orientable surface of genus g has $O(k^2g)$ triangles, which is optimal. This is an improvement over the previous best bound $k^{O(k)}g^2$ of Gao, Richter and Seymour [*Journal of Combinatorial Theory, Series B, 1996*].

1 Introduction

The main objects of study in this article are **(surface) triangulations**. There are many inequivalent definitions of those, and for us they will be simplicial complexes homeomorphic to surfaces. Rephrased in a graph-theoretical language, this means that a triangulation is a graph embedded in a surface where all the faces are topological disks and have degree three, and the graph is **simple**: multiple edges and loops are forbidden.

In 1922, Steinitz [41] proved that all triangulations of the 2-dimensional sphere could be obtained from the tetrahedron by *splitting vertices*. Nowadays, it is more common to consider the inverse operation of **contracting an edge**, which consists in identifying the endpoints of an edge and collapsing the two adjacent triangles. Such a contraction must preserve the properties of triangulations, and in particular must not induce multiple edges and loops. Thus, Steinitz proved that the tetrahedron is the unique **irreducible triangulation** of the sphere: every triangulation of the sphere can be reduced to the tetrahedron by iteratively contracting edges, and the tetrahedron cannot be contracted further.

Barnette initiated the study of the analogous problem on the projective plane [3], which led to the classification of irreducible triangulations of surfaces up to Euler genus 4 by Sulanke [42] by means of the computer program `surftri`. It is now known that for every

surface of Euler genus g, the number of irreducible triangulations is finite and that they have at most $13g - 4$ vertices, see Joret and Wood [29]. The latter improves previous bounds by Barnette and Edelson [2] and by Nakamoto and Ota [38]. This bound has been extended to surfaces with boundaries by Boulch, Colin de Verdière and Nakamoto [6].

A closed curve on a surface is **non-contractible** if it is not homotopic (intuitively, if it cannot be deformed continuously) to a point. Any closed walk on the edges of a triangulation determines a closed curve on the underlying surface. The **edge-width** of a triangulation is the length of the shortest (by the number of edges) non-contractible closed walk. A triangulation is **k-irreducible** if it has edge-width at least k and it is irreducible for this property: any edge contraction reduces this edge-width. Equivalently, every edge belongs to a non-contractible curve of length k and there are no shorter non-contractible curves. We refer to the PhD thesis of Melzer for a proof of this equivalence [36, Lemma 3.1] and for a thorough introduction to k-irreducible triangulations, in particular the different motivations for which they have been introduced.

Since loops and multiple edges are forbidden, triangulations of surfaces of positive Euler genus have edge-width at least 3. From the definitions, it is easy to see that irreducible triangulations and 3-irreducible triangulations match. Therefore, k-irreducible triangulations generalize irreducible triangulations, and one is naturally led to wonder about their combinatorial properties.

This problem was first studied by Malnič and Nedela [34] who proved that the number of k-irreducible triangulations of a surface is finite (they also observed that this follows from a variant of Robertson-Seymour theory), see also Juvan, Malnič and Mohar [30]. The current best known bound, due to Gao, Richter and Seymour [25] is that a k-irreducible triangulation of a surface of Euler genus g has $k^{O(k)}g^2$ edges. In that paper, the authors say that they expect the correct bound to depend linearly on g instead of quadratically. In his aforementioned PhD thesis, Melzer [36, p. 18] states "Our expectation would be something like $O(k^2g)$, but we lack any evidence at all to conjecture". Our main result confirms the expectations of Gao, Richter, Seymour and Melzer for orientable surfaces.

▶ **Theorem 1.** *Any k-irreducible triangulation of an orientable surface S of genus g has at most $966k^2g = O(k^2g)$ edges.*

The bound $O(k^2g)$ in Theorem 1 is tight up to the value of the constant which we have not tried to optimize: intuitively it can be achieved by taking g connected sums of tori resembling k by k grids. We refer to Melzer [36, Section 6.2] for precise descriptions of families of k-irreducible triangulations of size $\Theta(k^2g)$. One interesting follow-up question would be to determine the correct constant in some asymptotic regimes in g and k.

Note that an immediate application of the Euler formula yields similar bounds for the number of vertices and faces.

Irreducible systems of curves. Our proof of Theorem 1 is actually a consequence of a stronger result on system of curves that we introduce now. We investigate k-irreducible triangulations from the powerful perspective initiated by (de Graaf and) Schrijver in a series of papers (see e.g., [39, 40, 19, 20]), which consists in encoding the metric structure of an embedded graph using a system of curves. Note that this approach was already implicit in Steinitz's proof of his aforementioned theorem, as explained in Chang [10].

For the case of k-irreducible triangulations, this is done as follows. One first observes that instead of considering shortest non-contractible closed walks, one could consider instead shortest non-contractible closed curves crossing the triangulation exactly at the vertices.

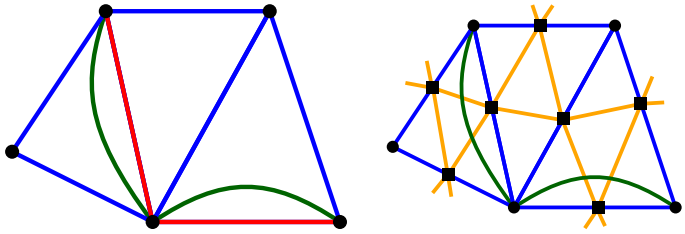

Figure 1 The triangulation in blue, a walk in red, its corresponding noose in green and the medial graph in orange.

Such curves are commonly called **nooses** in structural graph theory. If one defines the length of those curves as this number of intersections, one sees that any non-contractible closed walk in a triangulation can be deformed to a non-contractible noose of the same length and vice-versa, see Figure 1, left. The length of a shortest non-contractible noose is called the **face-width** (also called **representativity** in, e.g. [25]), and therefore we can equivalently define k-irreducibility as having face-width at least k and being irreducible for this property.

The **medial graph** M of a triangulation T of a surface S is the embedded graph in S which has a vertex in the middle of each edge of T and in each face f of T we add edges between vertices of M that belong to consecutive edges of f. See Figure 1, right for an illustration. Note that M is a simple face-bipartite 4-regular graph and that the length of a noose c for T is equal to half the number of transverse intersections it has with M. Because M is 4-regular, it can be considered as a **system of curves** $\mathcal{C} = (c_1, \dots, c_n)$. The **crossing number** of a system of curves $\mathcal{C}$, denoted by $\mathrm{cr}(\mathcal{C})$ is its number of intersections. The **length** of a curve c with respect to $\mathcal{C}$ is the number of intersections of c and $\mathcal{C}$, denoted by $\mathrm{cr}(c, \mathcal{C})$.

The strength of this perspective is that this allows to understand metric deformations of T (e.g., edge contractions) under the lens of topological deformations (homotopies) of $\mathcal{C}$. For instance, it follows from the work of Schrijver [40] that on an orientable surface, the system of curves corresponding to a minor-minimal graph of face-width k is necessarily in **minimal position**: it contains no contractible curves and its crossing number $\mathrm{cr}(\mathcal{C})$ is minimized over all families $\mathcal{C}'$ homotopic to $\mathcal{C}$ (we refer to Section 2 for the background on homotopies and a precise statement of Theorem 4 by Schrijver).

A **smoothing** of a system of curves $\mathcal{C}$ is the system of curves obtained from $\mathcal{C}$ by removing a vertex v and reconnecting the incident strands in one of two ways as in Figure 2. Note that a smoothing may change the number of components.

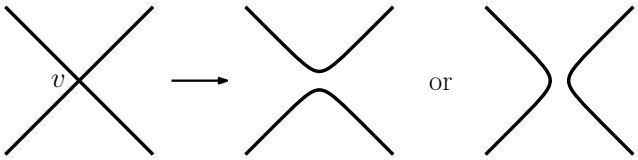

Figure 2 A smoothing at v.

A system of curves $\mathcal{C}$ on a surface S is a **k-irreducible** system of curves for some $k \geqslant 1$ if it is connected and:

- Every non-contractible closed curve c on S transverse to $\mathcal{C}$ satisfies $\mathrm{cr}(c, \mathcal{C}) \geqslant k$, and
- for every system of curves $\mathcal{C}'$ obtained by a smoothing of $\mathcal{C}$, there is a non-contractible closed curve c such that $\mathrm{cr}(c, \mathcal{C}') < k$.

Finally, a system of curves on a surface is **face-bipartite** if there is a 2-coloration of its faces (connected components of the complement) such that any two adjacent faces have different colors. We now have all the ingredients to state our second theorem.

▶ **Theorem 2.** *Let $\mathcal{C}$ be a face-bipartite k-irreducible system of curves on an orientable surface of genus g. The crossing number of $\mathcal{C}$ is at most $120k^2g = O(k^2g)$.*

Connections to systolic geometry. Theorems 1 and 2 provide discrete counterparts to results in systolic geometry. This subfield of differential geometry investigates topological spaces endowed with continuous metrics (typically Riemannian) and aims at understanding the structure and properties of their shortest non-contractible curves, called **systoles**. We refer to the book of Katz [31] for an introduction.

The famed systolic inequality of Gromov [26] states that for any surface of genus g and area A, the systole has length $O(\sqrt{A/g}\log g)$. This is known to be tight: Brooks [8] and Buser and Sarnak [9] provided families of hyperbolic surfaces achieving this bound. There are discrete analogues of these results for embedded graphs [28, 16, 33], showing that the edge-width of a triangulation with n triangles is similarly bounded by $O(\sqrt{n/g}\log g)$ and that this is asymptotically tight. Equivalently, this shows that any triangulation of edge-width k has $\Omega(k^2g/\log^2 g)$ triangles[1]. Bounding the size of k-irreducible triangulations then amounts to looking for a *reverse systolic inequality*, bounding how far from this lower bound a locally extremal object for the systolic inequality can be. From this perspective, it is noteworthy that the logarithmic factor, which is known to be required for the systolic inequality, disappears in our bounds in Theorems 1 and 2, even though our bounds are also tight.

We are not aware of any works investigating continuous versions of such a reverse systolic inequality. One difficulty is that the space of Riemannian metrics on a surface is not compact, and extremal surfaces for the systolic inequality in negative Euler characteristic are expected to exhibit singularities, see for example Gromov [26, pp.62-65]. This can be addressed by adding additional assumptions on the curvature, restricting to hyperbolic surfaces as in Fortier Bourque and Rafi [7], or nonpositively curved surfaces as in Katz and Sabourau [32]. Since the discrete setting of triangulations does not suffer from these analytic issues, it provides a convenient testbed for the study of locally extremal surfaces. The framework of geodesic currents of Bonahon [5] could provide an interesting middle-ground between these two worlds, keeping a continuous flavour but with strong compactness properties.

Related works. Many articles in computational geometry in the last twenty years have been targeted at understanding topologically meaningful curves on surfaces, from the perspectives of both algorithms and combinatorics. We refer to the dedicated chapter by Éric Colin de Verdière in the handbook of computational geometry [15] for a survey of this active field of research. Our proof techniques deal specifically with families of curves in minimal position on surfaces, a problem for which polynomial-time algorithms have been recently provided by Chang and de Mesmay [12], and Dubois [23]. The study of systolic properties of surfaces through the lens of such systems of curves has been instrumental in recent works of Cossarini [17] and Cossarini and Sabourau [18]. The medial graph construction connects homotopy of curves with electrical moves, as studied in Chang and Erickson [13], Chang, Cossarini and Erickson [11] and Aranguri, Chang and Fridman [1]. Very recently, Delecroix, Fontaine and Lazarus [22] have made algorithmic Schrijver's concept of *kernel* [40], which generalizes our k-irreducible triangulations to metric structures which are extremal with respect to the entire set of lengths of non-contractible curves (the *length spectrum*).

[1] Note that the growth is sensibly different if one considers the number of vertices instead of the number of triangles, see Melzer [36, Section 2.2]

Organization of the paper. After some preliminaries in Section 2, we first explain how Theorem 2 implies Theorem 1 in Section 3. Then the main ingredient is Proposition 7 proven in Section 4. Namely given a k-irreducible system of curves, it shows the existence of $O(g)$ curves of length at most $2k$ filling S. This immediately yields a first bound (Theorem 13), albeit one not linear in g. Section 5 introduces additional combinatorial tools to obtain the tight bound of Theorem 2. Due to line restrictions, some proofs are deferred to the full version [21], which provides slightly more general results and a treatment of one case of non-orientable surface.

2 Preliminaries

In this section we provide the main definitions used throughout the paper. The central objects of study are topological surfaces and curves on them whose definitions are recalled in Section 2.1. A (discrete) geometry on a surface allowing to measure lengths can then be defined in two related ways: either by the mean of an embedded graph also called combinatorial surface (see Section 2.2), or using a system of curves as in Section 2.3.

2.1 Surfaces and curves

In this paper, we use the term **surface** for a closed orientable topological surface. It is always denoted by S and is sometimes implicit. We refer to Massey [35] for topological background.

Curves. A **curve** on a surface S is a continuous map $c : [0, 1] \to S$ and a **closed curve** on S is a continuous map $c : \mathbb{S}^1 \to S$, where $\mathbb{S}^1$ is the one-dimensional circle $\mathbb{R}/\mathbb{Z}$. Since all the curves in this article are closed, we will often just write curve instead of closed curve. Two closed curves c and c' on S are **(freely) homotopic** if there is a continuous map $h : [0, 1] \times \mathbb{S}^1 \to S$ such that $h(0, t) = c(t)$ and $h(1, t) = c'(t)$. Being freely homotopic is an equivalence relation on closed curves on S and we refer to **(free) homotopy classes** for an equivalence class of closed curves with respect to free homotopy. We always denote curves with latin letters and homotopy classes with greek letters. A closed curve is **contractible** if it is homotopic to a constant curve. A curve is **simple** if it does not self-intersect. A closed curve is **primitive** if it is not homotopic to the k-fold concatenation of a curve c for some $k \geqslant 2$. In particular, a primitive curve is not contractible.

2.2 Combinatorial surfaces

Combinatorial surfaces. A **combinatorial surface** is an embedding $\phi : G \to S$ of a graph $G = (V, E)$, possibly with multiple edges and loops, in a surface S, such that $S \setminus \phi(G)$ is a disjoint union of open disks. These disks are called the **faces** of G. The counterclockwise sequence of arcs (i.e., oriented edges) in the boundary of a face is called a **face boundary** or **facial walk**. The **degree of a face** is the length of its facial walk.

Two combinatorial surfaces $\phi : G \to S$ and $\phi' : G' \to S'$ are **isomorphic** if there exists a graph isomorphism $\theta : G \to G'$ and a homeomorphism $\psi : S \to S'$ such that $\phi' \circ \theta = \psi \circ \phi$. The isomorphism class of a combinatorial surface can be conveniently encoded by a **rotation system** describing the circular orderings of the (oriented) edges around each vertex. See Mohar and Thomassen [37] for more details on this structure. Most of the time, the embedding ϕ is implicit and we identify G and the corresponding combinatorial surface.

Let $\phi : G \to S$ be a combinatorial surface. The **length (with respect to G)** of a curve c in S that crosses only the vertices of G and not its edges is the number of times this curve passes through a vertex of G. It is denoted $\mathrm{cr}(c, G)$. The **systole** of G is the minimum length

over all non-contractible closed curves c on S passing only through vertices of G of $\mathrm{cr}(c, G)$. We will use the common abuse of language to also call systole such a non-contractible closed curve of minimal length when it leads to no confusion.

Triangulation. A combinatorial surface (S, G) is a **triangulation** if G is simple (no loops nor multiple edges) and every face has degree 3. A triangulation T on a surface S is **k-irreducible** if

1. the systole of T is equal to k
2. for every edge $e = (uv)$ of T, there is a non-contractible curve c of length k on T crossing consecutively u and v.

▶ Remark 3. In line with the introduction, we define our triangulations to be simplicial, but note that this is implied by k-irreducibility for $k \geqslant 3$. Indeed, if there is a loop or a bigon formed of two parallel edges, it has to be contractible and thus bounds a disk, but then the edges inside that disk cannot belong to a systole as there would be a shortcut, violating k-irreducibility.

2.3 Systems of curves

Systems of curves. A **system of curves** on a surface S is a family $\mathcal{C} = (c_1, \ldots, c_p)$ of non-contractible closed curves on S in *general position*, i.e., they only cross transversely and at most two curves cross at a point.

An **intersection** of $\mathcal{C}$ is a pair $(i, s) \neq (j, t)$ such that $c_i(s) = c_j(t)$. Because a system of curves is in general position, the set of intersections is an isolated subset of points in S. The **crossing number of $\mathcal{C}$** is its number of intersections. Note that $\mathcal{C}$ defines a 4-regular embedded graph on S whose vertex set is the intersections of $\mathcal{C}$ and its edges are segments of the curves c_i. Conversely, a 4-regular embedded graph $\phi : G \to S$ determines a system of curves by "going straight" at each crossing. We will freely use this identification and use the vocabulary of embedded graphs, i.e., vertices, edges and faces for a system of curves $\mathcal{C}$. Note however that in this context the embedded graph might not be a combinatorial surface because its complement could have topology. a system of curves is **connected** if the corresponding graph is connected.

Two systems of curves $\mathcal{C} = \{c_1, \ldots, c_p\}$ and $\mathcal{C}' = \{c'_1, \ldots, c'_p\}$ are **homotopic** if for all i in $[1, p]$, c_i is freely homotopic to c'_i. We say that a system of curves $\mathcal{C}$ is in **minimal position** if it contains no contractible curves and has the minimal crossing number over all systems of curves homotopic to $\mathcal{C}$. We say that two curves **intersect essentially** if they intersect at least once in minimal position.

Length of curves. Let $\mathcal{C}$ be a system of curves on S and c be a curve transverse to $\mathcal{C}$. The **length** of c with respect to $\mathcal{C}$ is the number of crossings of c with $\mathcal{C}$. We recall that this quantity is denoted $\mathrm{cr}(c, \mathcal{C})$. The **length** of a free homotopy class γ is the minimal number of crossings of a representative c of γ with $\mathcal{C}$. We use the notation $\mathrm{cr}(\gamma, C)$ as a shortcut for $\min_{c \in \gamma} \mathrm{cr}(c, C)$. For $\mathcal{C}$ in minimal position, we define the **systole** of $\mathcal{C}$ to be $\min_{\gamma} \mathrm{cr}(\gamma, \mathcal{C})$ where γ runs over all non-trivial free homotopy classes of closed curves in S. Here again, we sometimes also call a closed curve achieving this minimum length a systole.

We say that a system of curves $\mathcal{C}$ in minimal position on a surface S is **filling** if for any non-trivial homotopy class γ we have $\mathrm{cr}(\gamma, \mathcal{C}) > 0$. Equivalently, a system of curves $\mathcal{C}$ in minimal position on a surface S is filling if and only if it corresponds to a combinatorial surface (i.e. the complement of the curves is a disjoint union of topological disks).

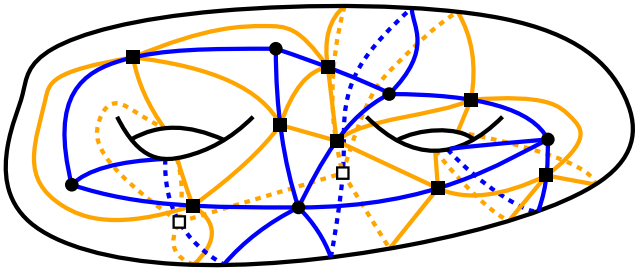

Figure 3 A graph G in blue on a genus 2 surface and its medial graph in orange.

***k*-irreducible systems of curves.** Recall from the definition that a system of curves is k-irreducible for some $k \geqslant 1$ if it is connected and:

- for every non-contractible closed curve c on S we have $\mathrm{cr}(c, \mathcal{C}) \geqslant k$, and
- for every system of curves $\mathcal{C}'$ obtained by a smoothing (pictured in Figure 2) of $\mathcal{C}$, there is a non-contractible closed curve c such that $\mathrm{cr}(c, \mathcal{C}') < k$.

A system of curves $\mathcal{C}$ is **tight** if it does not contain a contractible curve disjoint from the other curves and if for any smoothing $\mathcal{C}'$ of $\mathcal{C}$ there is a curve in minimal position with respect to $\mathcal{C}$ and $\mathcal{C}'$ which is shorter with respect to $\mathcal{C}'$ than with respect to $\mathcal{C}$. This is an equivalent reformulation of a notion introduced by Schrijver, who proved the following theorem:

▶ **Theorem 4** ([39, Theorem 5]). *A system of curves is tight if and only if it is made of primitive curves in minimal position.*

It is immediate that a k-irreducible system of curves is tight, and therefore it is in minimal position. Note also that a k-irreducible system of curves is necessarily filling.

▶ Remark 5. In this article, we often alternate between different metric models. In order to minimize confusion, we use the following guidelines:

- in a triangulation T, we consider curves which are walks on the edges of the triangulation, and their lengths are the number of edges that they use.
- in a combinatorial surface G, we consider curves which cross G only at vertices, and their lengths are the number of vertices that they cross.
- in a system of curves $\mathcal{C}$, we consider curves which are in general position with respect to $\mathcal{C}$, and their lengths are their number of intersections with $\mathcal{C}$.

3 From triangulations to system of curves

The goal of this section is to prove how Theorem 1 on k-irreducible triangulations follows from Theorem 2 on k-irreducible system of curves.

Let T be a k-irreducible triangulation on S with vertex set V. We first explain how to associate a system of curves to T, and we then study its properties. Let G be a subgraph of T with the same vertex set V and minimal (with respect to edge inclusion) for the property that every non-contractible curve c intersecting G only at V satisfies $\mathrm{cr}(c, G) \geqslant k$. Let M be the medial graph of G: recall that it is the graph with a vertex at the midpoint of every edge of G and two midpoints are connected by an edge of M whenever their supporting edges in G are consecutive in a face of G, see Figure 3. The graph M is 4-regular and is thus naturally associated to a system of curves $\mathcal{C}$ on S. We call $\mathcal{C}$ a **system of curves associated to T** (note that there can be many of them, depending on the choice of G). As proven in [40], for any homotopy class γ of curves in S we have $\mathrm{cr}(\gamma, \mathcal{C}) = 2\,\mathrm{cr}(\gamma, G)$.

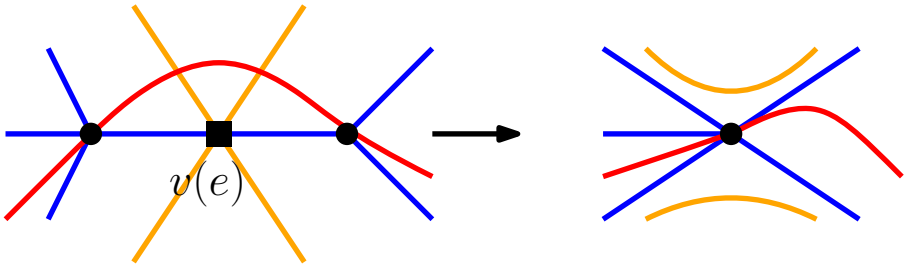

Figure 4 The contraction of an edge in G. The blue graph is G, the orange one is $\mathcal{C}$ and the red curve is c.

▶ **Proposition 6.** *Let T be a k-irreducible triangulation on S. Then any system of curves associated to T is face-bipartite, $2k$-irreducible and in minimal position.*

Proof. Let us denote as before by G an (edge inclusion-wise) minimal subgraph of T such that the length of a shortest non-contractible noose on G is still k, and by $\mathcal{C}$ the system of curves associated to G. As $\mathrm{cr}(c, G) \geqslant k$ for every non-contractible curve c, $\mathrm{cr}(\gamma, \mathcal{C}) = 2\,\mathrm{cr}(\gamma, G) \geqslant 2k$ for every non-trivial homotopy class γ.

Let $\mathcal{C}'$ be a smoothing of $\mathcal{C}$. As shown in [40], a smoothing of $\mathcal{C}$ either corresponds to an edge deletion or an edge contraction in G. We work separately on these two cases.

1. Assume that $\mathcal{C}'$ is obtained from $\mathcal{C}$ by a smoothing corresponding to deleting the edge e. Let $G' = G \setminus \{e\}$. Then by definition of G, there is a non-contractible curve c such that $\mathrm{cr}(c, G') < k$. Thus $\mathrm{cr}(\gamma, \mathcal{C}') \leqslant 2 \cdot \mathrm{cr}(c, G') < 2k$ where γ is the homotopy class of c.
2. Assume that $\mathcal{C}'$ is obtained from $\mathcal{C}$ by a smoothing corresponding to contracting the edge $e = (uv)$. As T is a k-irreducible triangulation, there is a systole c of T going through u and v consecutively. Thus this systole is also a systole of G with the same property and is also a systole of $\mathcal{C}$ crossing two consecutive edges of $\mathcal{C}$ around the vertex $v(e)$ (see Figure 4). Thus, the smoothing reduces the length of c and $\mathrm{cr}(\gamma, \mathcal{C}') < 2k$ where γ denotes the homotopy class of c.

Since G is connected, so is $\mathcal{C}$. Therefore the system of curves $\mathcal{C}$ is $2k$-irreducible. It follows from Theorem 4 that it is in minimal position. Finally, it is face-bipartite by construction: the faces of the medial graph are either faces or vertices of T. ◀

We are now ready to prove Theorem 1 assuming Theorem 2. We restate it for convenience.

▶ **Theorem 1.** *Any k-irreducible triangulation of an orientable surface S of genus g has at most $966k^2g = O(k^2g)$ edges.*

Proof. As before, let G be a minimal subgraph of T such that the length of a shortest non-contractible noose on G is k, and let $\mathcal{C}$ be its associated system of curves. By Proposition 6, any system of curves associated to T is a $2k$-irreducible system of curves. Thus by Theorem 2, the crossing number $\mathrm{cr}(\mathcal{C})$ of $\mathcal{C}$ is at most $120(2k)^2g = 480k^2g$.

Now let M be the medial graph of G from which is built the system of curves $\mathcal{C}$. It is such that $|V(M)| = \mathrm{cr}(\mathcal{C})$ and because it is quartic $|E(M)| = 2\,\mathrm{cr}((C))$. The graph M is face bipartite and the classes of the bipartition are in bijection with the vertices $V(G)$ and the faces $F(G)$ of G. These bijections preserve the degree and hence $\sum_{v \in V(G)} \deg_G(v) = |E(M)| = 2\,\mathrm{cr}(\mathcal{C})$. Now, by Proposition 6, $\mathcal{C}$ is in minimal position. In particular, $\mathcal{C}$ has

neither monogon nor bigon. In other words, each face of M has degree at least 3. Thus $\sum_{v \in V(G)} \deg_G(v) \geqslant 3|V(G)|$. We conclude that $|V(T)| = |V(G)| \leqslant \frac{2}{3}\mathrm{cr}(\mathcal{C}) \leqslant \frac{2}{3}480k^2g = 320k^2g$, and $|E(T)| \leqslant 3|V(T)| + 6g - 6 \leqslant 966k^2g$. ◀

4 Short filling systems for k-irreducible systems of curves

The main result of this section is the following proposition, which extracts from k-irreducibility a more topological property: the existence of a filling family of short curves.

▶ **Proposition 7.** *Let $\mathcal{C}$ be a face-bipartite k-irreducible system of curves. Then there is a set of curves of lengths at most $2k$ with respect to $\mathcal{C}$ which is in minimal position and filling.*

The proof of this proposition relies partially on the notion of universal cover. We refer to Massey [35, Chapter 5] for an introduction to this classical object in algebraic topology and to Farb and Margalit [24, Section 1.2] for the specifics in the case of curves on surfaces. Given a curve $c : \mathbb{S}^1 \to S$ in a surface S, a *lift* $\tilde{c} : \mathbb{R} \to \tilde{S}$ of c is a map to the universal cover $\tilde{S}$ that commutes with the projections $\mathbb{R} \to S^1$ and $\tilde{S} \to S$. When the lift $\tilde{c}$ is simple we call it a *line*.

Proof. We first observe that we can assume that k is even. Indeed, if this is not the case, since $\mathcal{C}$ is k-irreducible and face-bipartite, $\mathcal{C}$ is $(k-1)$-irreducible. We will build a set of curves of lengths at most $2k$ made of systoles and some curves that are obtained by concatenation of two systoles, and then show that these curves are filling.

The following claim is standard in geometry of curves on surfaces. As it is used many times throughout our proof, we provide a standalone proof.

▷ Claim 8. Let c and c' be non-contractible curves on S in minimal position. Then any two lifts $\tilde{c}$ and $\tilde{c'}$ in the universal cover $\tilde{S}$ are lines that intersect at most once.

Proof. Assume that the lift $\tilde{c}$ has a self-intersection. Then it forms a monogon: there is a disk in $\tilde{S}$ bounded by a subline of $\tilde{c}$. By homotopy, one can remove this monogon contradicting the fact that c was in minimal position on S. Therefore, $\tilde{c}$ and $\tilde{c'}$ are lines in $\tilde{S}$.

Let us assume for contradiction that two lifts $\tilde{c}$ and $\tilde{c'}$ intersect twice. Then, since $\tilde{S}$ is contractible, they form a bigon: there is a disk in $\tilde{S}$ bounded by one subline α of $\tilde{c'}$ and one subline β of $\tilde{c}$. Now, the homotopy moving α to β projects to a homotopy on the surface, and leads to a new pair of curves intersecting less. This contradicts the hypothesis that c and c' were in minimal position. ◁

The next claim is the first step in defining the systoles we will work with.

▷ Claim 9. Let v be a crossing of $\mathcal{C}$ and e, e' two edges adjacent to v that are consecutive for the counter-clockwise ordering of edges around v. Then there is a systole that passes consecutively through e and e'.

Proof. Let $\mathcal{C}'$ be the system of curves obtained by smoothing v and connecting e with e'. As $\mathcal{C}$ is a k-irreducible system, there is a non-contractible curve c in minimal position with respect to both $\mathcal{C}$ and $\mathcal{C}'$ and such that $\mathrm{cr}(c, \mathcal{C}') < k$. Since $\mathcal{C}$ and $\mathcal{C}'$ differ from each other only at v, the curve c goes from e to e' in a neighborhood of v. If we pick c with the property that $\mathrm{cr}(c, \mathcal{C}') < k$ and $\mathrm{cr}(c, \mathcal{C})$ minimal, then it passes only once consecutively through e and e' and $\mathrm{cr}(c, \mathcal{C}') = \mathrm{cr}(c, \mathcal{C}) - 2$.

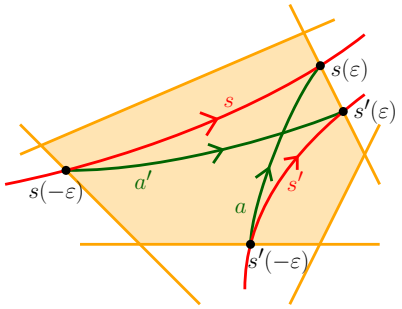

Figure 5 Wedding of two systoles s and s'.

As $\mathcal{C}$ is face-bipartite, all crossing numbers of curves with respect to $\mathcal{C}$ are even. Since k is even, we must have $\mathrm{cr}(c, \mathcal{C}') = k - 2$ and $\mathrm{cr}(c, \mathcal{C}) = k$. The curve c is therefore a systole, this concludes the proof of the claim. ◁

Let e_1, e_2, e_3 and e_4 be the four consecutive edges around a vertex v of $\mathcal{C}$. By Claim 9 there is a systole s_1 crossing consecutively e_1 and e_2. Similarly, there is a systole s_2 crossing consecutively e_2 and e_3. We denote by $\mathcal{S}$ a set of curves containing a pair of such systoles s_1 and s_2 for each vertex of $\mathcal{C}$. Note that by definition a systole is in minimal position with respect to $\mathcal{C}$.

We first handle the case where the surface is a torus.

▷ Claim 10. If the surface S is a torus and v is a vertex of $\mathcal{C}$ and s_1 and s_2 are the two corresponding systoles of $\mathcal{S}$, then s_1 and s_2 intersect essentially.

The proof is provided in the full version [21]. Since on a torus, any pair of curves intersecting essentially is filling, Claim 10 concludes the proof for the torus with the family $\mathcal{S}$. In the rest of the proof we assume that the surface has negative Euler characteristic. Therefore its universal cover is homeomorphic to an open disk and can be endowed with a boundary at infinity $\partial\tilde{S}$ which is a circle. The lifts of curves in $\tilde{S}$ are lines with endpoints on this boundary, and two curves are homotopic if and only if there exists lifts of the two curves having the same endpoints. Furthermore, no two lifts have exactly one endpoint in common. We refer to [24, Section 1].

We now define curves obtained by concatenations of two systoles. They will be used to fill the surface S. Let s and s' be two systoles in $\mathcal{S}$ that start in the same face f of $\mathcal{C}$ and such that $\mathcal{C} \cup \{s, s'\}$ is in minimal position. Up to homotopy we can further assume that the first crossings with the boundary of f occurs for both s and s' at time $\pm\varepsilon$ and that s and s' do not intersect in this initial face. Namely $s([-\varepsilon, \varepsilon]) \cap s'([-\varepsilon, \varepsilon]) = \emptyset$ and that the points $s(\varepsilon)$, $s(-\varepsilon)$, $s'(-\varepsilon)$ and $s'(\varepsilon)$ appear on the boundary of f in that counterclockwise order. Let a and a' be arcs in the face f that are in minimal position and go respectively from $s'(-\varepsilon)$ to $s(\varepsilon)$ and $s(-\varepsilon)$ to $s'(\varepsilon)$. These two arcs intersect exactly once. We define a new curve t by the concatenation $t := a \cdot s|_{[\varepsilon,-\varepsilon]} \cdot a' \cdot s'|_{[\varepsilon,-\varepsilon]}$, see Figure 5. We say that t is obtained by **wedding** s and s' if t is in minimal position with respect to itself. Equivalently, we can make a wedding if in the universal cover $\widetilde{S}$ of S the two lifts of s and s' starting from the same lift $\widetilde{f}$ of f do not intersect. By definition, a wedding has length $2k$ with respect to $\mathcal{C}$. If such a wedding is put in minimal position with respect to $\mathcal{C}$ by a homotopy, it might even get shorter.

We define the set $\mathcal{S}_2$ to be a set of representatives of the homotopy classes of all possible weddings of systoles in $\mathcal{S}$ such that $\mathcal{C} \cup \mathcal{S} \cup \mathcal{S}_2$ is in minimal position. The following claim proves that the curves in $\mathcal{S} \cup \mathcal{S}_2$ intersect every possible simple closed curve on the surface.

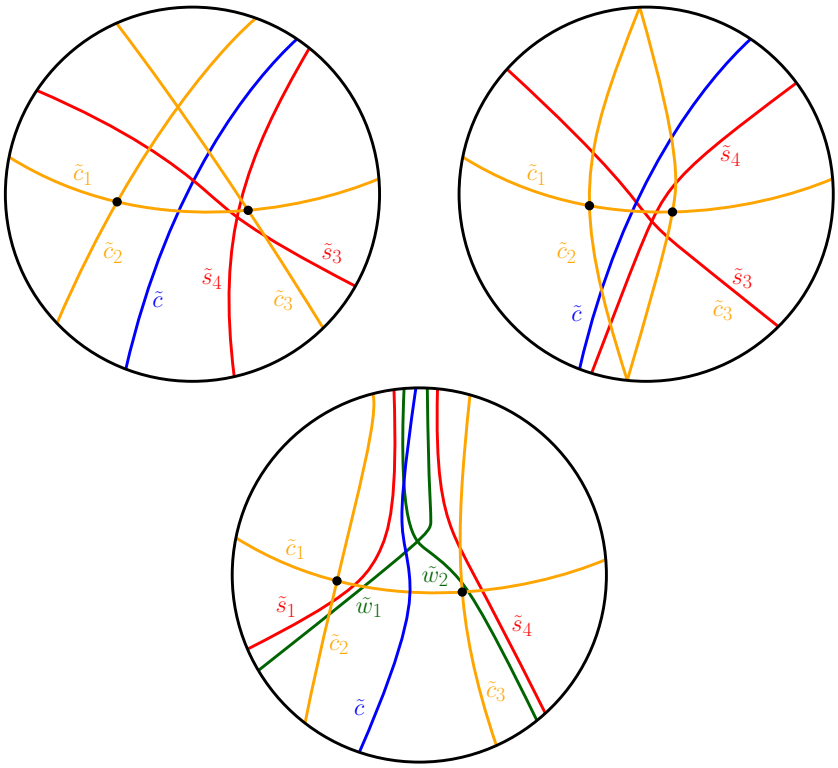

Figure 6 The three different cases leading to the proof of claim 11.

▷ Claim 11. Let c be a non-contractible simple closed curve. Then there exists $s \in (\mathcal{S} \cup \mathcal{S}_2)$ such that c and s intersect essentially.

Proof. We first put c in minimal position with respect to $\mathcal{C} \cup \mathcal{S} \cup \mathcal{S}_2$. Since $\mathcal{C}$ is filling, there is an edge $e = (uv)$ of $\mathcal{C}$ that intersects c. Let c_1 be the curve of $\mathcal{C}$ containing the edge e and c_2 and c_3 be the curve crossing c_1 at u and v respectively. We denote by s_1 and s_2 the two systoles in $\mathcal{S}$ corresponding to u and by s_3 and s_4 the ones corresponding to v. We will prove that c intersects either s_1, s_2, s_3, s_4 or one of their pairwise weddings.

In the universal cover, our local picture lifts as in Figure 6, yielding lines $\tilde{c_1}$, $\tilde{c_2}$, $\tilde{c_3}$, $\tilde{s_1}$, $\tilde{s_2}$, $\tilde{s_3}$, $\tilde{s_4}$ and $\tilde{c}$. The lines $\tilde{c_1}$,$\tilde{c_2}$, $\tilde{c_3}$ intersect pairwise at most once and are simple because $\mathcal{C}$ is in minimal position. We do a case by case analysis depending on the topology of $\tilde{c_2}$ and $\tilde{c_3}$. The only ingredient we use is the fact that each pair of these curves intersect at most once.

If $\tilde{c_2}$ and $\tilde{c_3}$ intersect, then it is immediate that $\tilde{c}$ intersects at least one of the curves $\tilde{s_1}$, $\tilde{s_2}$, $\tilde{s_3}$ or $\tilde{s_4}$, see top left Figure 6. The same happens if c_2 and c_3 are homotopic since in that case $\tilde{c_2}$ and $\tilde{c_3}$ have the same endpoints in $\partial\tilde{S}$. Since these intersections are forced by the endpoints on $\partial\tilde{S}$ and homotopies do not move these endpoints, these intersections on $\tilde{S}$ project to essential intersections on S. See top right Figure 6.

The last case is if $\tilde{c_2}$ and $\tilde{c_3}$ are disjoint (including at their endpoints) as in bottom Figure 6. Then the wedding w of s_1 and s_4 based at the added crossing lifts to two lines $\tilde{w_1}$ and $\tilde{w_2}$ which cross the lines $\tilde{c_1}$ and $\tilde{c_2}$, respectively $\tilde{c_2}$ and $\tilde{c_3}$ the same way that $\tilde{s_1}$ and $\tilde{s_4}$ do. In particular, this wedding exists since $\tilde{w_1}$ and $\tilde{w_2}$ cannot cross again due to $\tilde{c_1}, \tilde{c_2}$ and $\tilde{c_3}$ acting as barriers for $\tilde{s_1}$ and $\tilde{s_4}$. Since $\tilde{c}$ intersects $\tilde{e}$, it must intersect either $\tilde{w_1}$ or $\tilde{w_2}$ and thus c intersects w essentially. This concludes the proof. ◁

Therefore, the family $\mathcal{S} \cup \mathcal{S}_2$, intersects every possible simple non-contractible curve in the surface: it is filling. This claim concludes the proof. ◀

We encapsulate this last result in the following definition: we say that a system of curves $\mathcal{C}$ is **k-saturating** if there exists another system of curves $\mathcal{S}$ such that:

- $\mathcal{C} \cup \mathcal{S}$ is in minimal position,
- Each curve in $\mathcal{S}$ has length at most k, and
- The system of curves $\mathcal{S}$ is filling.

Therefore, Proposition 7 shows that a face-bipartite k-irreducible system of curves is $2k$-saturating. The following lemma shows that one can extract a filling family of size $O(g)$ from any filling family. This is certainly folklore, see for example Chen [14, Theorem 3.15]. We include a proof in the full version [21] for completeness.

▶ **Lemma 12.** *Let $\mathcal{C}$ be a filling system of curves in minimal position on a closed orientable surface S of genus $g \geqslant 1$. Then there is a sub-system $\mathcal{C}' \subset \mathcal{C}$ of at most $3g-1$ curves which is also filling.*

We can now combine our tools to obtain a first polynomial upper bound.

▶ **Theorem 13.** *Let $\mathcal{C}$ be a k-saturating system of curves. Then the crossing number of $\mathcal{C}$ is at most $2((3g-1)\cdot k)^2$.*

Proof. By the definition of a k-saturating system of curves and thanks to Lemma 12, there exists a filling family $\mathcal{S} = (s_i)_{i\in I}$ of closed curves of length at most k with respect to $\mathcal{C}$ and of size at most $3g-1$. In particular, for every $i \in I$, $\mathrm{cr}(s_i, \mathcal{C}) \leqslant k$.

Recall that by the definition of k-saturating, the system $\mathcal{C} \cup \mathcal{S}$ is in minimal position. We think of $\mathcal{S}$ as a 4-valent graph that is a combinatorial surface. In other words:

- Every curve of $\mathcal{C}$ intersect transversely the curves s_i, and
- Every intersection vertex of $\mathcal{C}$ is inside a face of $\mathcal{S}$.

We denote by F the faces of $\mathcal{S}$. For such a face f, let $p(f)$ denote the perimeter of f i.e. the number of crossings of $\mathcal{C}$ with the boundary of f. Then, by double counting, $\sum_{f\in F} p(f) = 2\,\mathrm{cr}(\mathcal{S}, \mathcal{C}) \leqslant 2 \cdot k \cdot \#\mathcal{S} \leqslant 2(3g-1)k$.

Similarly let $n(f)$ denote the number of vertices of $\mathcal{C}$ in the face f. Then $\mathrm{cr}(\mathcal{C}) = \sum_{f\in F} n(f)$. As $\mathcal{C}$ is in minimal position, the restriction of $\mathcal{C}$ to any face f is also in minimal position. This implies that any two curves in $\mathcal{C}$ cross at most once in f, since otherwise they would form a bigon and thus would not be in minimal position. Thus $n(f) \leqslant \dfrac{p(f)\cdot(p(f)-1)}{2}$. So

$$\mathrm{cr}(\mathcal{C}) = \sum_{f\in F} n(f) \leqslant \sum_{f\in F} \frac{p(f)^2}{2} - \frac{p(f)}{2} \leqslant \frac{1}{2}\left(\sum_{f\in F} p(f)\right)^2 \leqslant \frac{(2(3g-1)k)^2}{2}. \qquad \blacktriangleleft$$

Combining Proposition 7 and Theorem 13 provides us with a first bound of $O(k^2g^2)$ on the number of vertices in a k-irreducible system of curves, and thus on the number of edges in a k-irreducible triangulation via the reduction in Section 3. In the next section we add another ingredient to strengthen this bound to $O(k^2g)$.

▶ Remark 14. Note that the family $\mathcal{C}$ in Theorem 13 is not assumed to be k-irreducible, and thus this theorem could be of independent interest. It is easy to see that Theorem 13 is tight up to a constant factor, by considering a genus g orientable surface obtained by identifying opposite edges in a $2g$-gon, and a system of curves made of k parallel curves between each pair of opposite edges.

5 Upper bounds for k-irreducible systems of curves

In this section, we show:

▶ **Theorem 2.** *Let $\mathcal{C}$ be a face-bipartite k-irreducible system of curves on an orientable surface of genus g. The crossing number of $\mathcal{C}$ is at most $120k^2g = O(k^2g)$.*

To prove this result, we first establish a preliminary lemma on configuration of arcs in a disk. An **arc** in a disk is a curve with endpoints on the boundary of the disk. For a system of arcs $\mathcal{A}$ in minimal position in a disk, we denote by d the largest distance between a face of $\mathcal{A}$ and the boundary of the disk (where we measure lengths in terms of crossings with $\mathcal{A}$) and by n the number of intersections between pairs of arcs of $\mathcal{A}$. The following inequality allows us to bound n in terms of d and p.

▶ **Lemma 15.** *Let $\mathcal{A}$, p, d, n be as above. Then $(6d+7)p \geqslant n$.*

Our proof relies on a recent structural result of Hickingbotham, Illingworth, Mohar and Wood [27] and the fact that a graph of treewidth k with n vertices has less than kn edges (see, e.g., Baste, Noy and Sau [4]).

Proof. Let G be the intersection graph of $\mathcal{A}$: it has one vertex per arc of $\mathcal{A}$ and an edge between vertices corresponding to intersecting pair of arcs. By definition, G has p vertices and n edges.

Let M_G be the map graph of $\mathcal{A}$ which has one vertex for each face of $\mathcal{A}$, including the outer face, and edges between vertices corresponding to faces that share at least one vertex. Let $\mathrm{rad}(M_G)$ be its radius, that is, the minimum radius of a ball that covers M_G. Then, by [27, Theorem 5], we have $\mathrm{tw}(G) \leqslant 6 \cdot \mathrm{rad}(M_G) + 7$, where $\mathrm{tw}(G)$ denotes the tree-width of G.

Let v_∞ be the vertex of M_G corresponding to the external face. Then v_∞ is at distance at most d from every face of $\mathcal{A}$ in the dual graph of $\mathcal{A}$. It follows from the definitions that the distances in the map graph are smaller than the one in the dual graph, so v_∞ is at distance at most d in M_G from every point of M_G. Thus $\mathrm{rad}(M_G) \leqslant d$ and $\mathrm{tw}(G) \leqslant 6d+7$.

Since a graph of tree-width t and v vertices has strictly less than tv edges, $(6d+7)p \geqslant n$. ◀

We can now conclude the proof of Theorem 2.

Proof of Theorem 2. The proof starts like the proof of Theorem 13. By Proposition 7 and Lemma 12, a k-irreducible system of curves is $2k$-saturating and thus there is a filling family $\mathcal{S}$ of at most $3g-1$ closed curves of length at most $2k$ with respect to $\mathcal{C}$. We think of $\mathcal{S}$ as a 4-valent combinatorial surface with a family of faces F and denote by $n(f)$ the number of vertices of $\mathcal{C}$ in a face f, and by $p(f)$ the perimeter of f, i.e., the number of intersections of $\mathcal{C}$ and the boundary of f.

▷ Claim 16. For any face f of F, $n(f) \leqslant (3k+7) \cdot p(f)$

Proof. Assume that there is a face f such that $n(f) > (3k+7)p(f)$. By Lemma 15, $(6d+7)p(f) > (3k+7)p(f)$ and thus $d > k/2$. In this case, there is a point R in f so that any path from R to the boundary of f crosses more than $k/2$ curves of $\mathcal{C}$. This point R lies in a face of $\mathcal{C}$, and this implies that smoothing one of the vertices on the boundary of that face cannot change the length of any non-contractible closed curve of length k, since any such curve going through (two consecutive edges adjacent to) that vertex (as in Claim 9) must be longer than k. See Figure 7. Thus $\mathcal{C}$ is not a k-irreducible system of curves. ◁

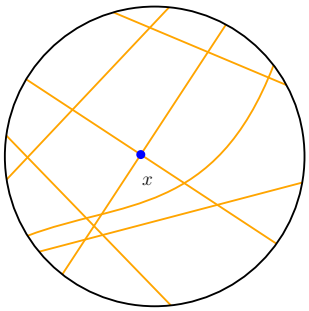

Figure 7 A system of arcs in a disk with a face x at distance 2 and a blue vertex that may be smoothed without changing the length of any curve of length smaller than 2.

We conclude using $\sum_{f\in F} n(f) = \mathrm{cr}(\mathcal{C})$ and $\sum_{f\in F} p(f) = 2\,\mathrm{cr}(\mathcal{S},\mathcal{C}) \leqslant 2(3g-1)2k$, which gives

$$\mathrm{cr}(\mathcal{C}) = \sum_{f\in F} n(f) \leqslant \sum_{f\in F} (3k+7)\cdot p(f) \leqslant (3k+7)2(3g-1)2k \leqslant 120k^2 g. \qquad \blacktriangleleft$$

Abstract

For a metric space (X, d), a family $\mathcal{H}$ of locality sensitive hash functions is called (r, cr, p_1, p_2) sensitive if a randomly chosen function $h \in \mathcal{H}$ has probability at least p_1 (at most p_2) to map any $a, b \in X$ in the same hash bucket if $d(a, b) \leq r$ (or $d(a, b) \geq cr$). Locality Sensitive Hashing (LSH) is one of the most popular techniques for approximate nearest-neighbor search in high-dimensional spaces, and has been studied extensively for Hamming, Euclidean, and spherical geometries. An (r, cr, p_1, p_2)-sensitive hash function enables approximate nearest neighbor search (i.e., returning a point within distance cr from a query q if there exists a point within distance r from q) with space $O(n^{1+\rho})$ and query time $O(n^{\rho})$ where $\rho = \frac{\log 1/p_1}{\log 1/p_2}$. But LSH for hyperbolic spaces $\mathbb{H}^d$ remains largely unexplored. In this work, we present the first LSH construction native to hyperbolic space. For the hyperbolic plane ($d = 2$), we show a construction achieving $\rho \leq 1/c$, based on the hyperplane rounding scheme. For general hyperbolic spaces ($d \geq 3$), we use dimension reduction from $\mathbb{H}^d$ to $\mathbb{H}^2$ and the 2D hyperbolic LSH to get $\rho \leq 1.59/c$. On the lower bound side, we show that the lower bound on ρ of Euclidean LSH extends to the hyperbolic setting via local isometry, therefore giving $\rho \geq 1/c^2$.

1 Introduction

Locality Sensitive Hashing (LSH) is a hashing scheme in which similar items are more likely to hash to the same bucket. Indyk and Motwani, in their seminal work [27, 25], developed LSH for general metric spaces and provided hash function constructions for the Hamming distance. The LSH framework provides an efficient data structure for the Approximate Nearest Neighbor Search (ANNS) problem, which is particularly challenging in the high-dimensional regimes. Since then, LSH has been developed for various similarity measures such as ℓ_1 [1, 35], ℓ_2 [18, 2], ℓ_p [18], cosine similarity [15], Jaccard similarity [11, 10],

angular (spherical) distances [47], etc. With support for similarity search, data independence, mild dependence on data dimension, and simplicity in implementation, LSH serves as an algorithmic tool for classical problems such as clustering, near-duplicate detection, and efficient information retrieval for very large datasets. LSH has also been used widely in database and machine learning pipelines in industry [22, 12, 16, 44, 42, 17, 32, 4, 7]. For a nice survey, please refer to [2].

Hyperbolic geometry is a non-Euclidean geometry. It drops the parallel postulate of Euclidean geometry. In hyperbolic geometry, for any line and a point not on that line, there are at least two distinct lines through the point that do not intersect the original line. Hyperbolic geometry has received increasing attention in modern data analysis because it naturally models hierarchical, tree-like, and exponentially branching structures that arise throughout science and technology. Unlike Euclidean spaces, where volume grows polynomially, hyperbolic spaces exhibit exponential volume growth, matching the combinatorial growth of hierarchies, taxonomies, knowledge graphs, and high-dimensional networks with latent tree-like structure. This geometric compatibility yields embeddings with dramatically reduced distortion: objects that are far apart in a hierarchy can be faithfully separated, and geodesics efficiently capture ancestry, flow, and community structure. As a result, hyperbolic embeddings now underpin state-of-the-art methods in network representation learning, hierarchical clustering, and discrete geometric data analysis [38, 24, 21, 48, 19, 13, 14, 49, 30, 46]. It is also the most important space representing the negative curvature phenomena arising from complex geometric situations [34, 45]. Namely, according to Gromov's hyperbolization program [23], spaces with complicated topology tend to resemble spaces with negative curvature. Hyperbolic geometry provides the fundamental model for negatively curved spaces, offering the canonical framework in which their curvature and geometric behavior are understood.

Moreover, the hyperbolic plane offers an unusually tractable analytic structure: its constant negative curvature provides explicit formulas for distance, geodesics, convexity, and isometries, enabling efficient optimization for machine-learning tasks. Its rich isometry group and uniformization properties are directly linked to complex analysis and conformal representations, providing tools that scale from theoretical guarantees to practical algorithms for dimensionality reduction, visualization, and manifold learning.

These applications provide strong motivation for developing efficient algorithms in hyperbolic space, and in this paper, we study locality-sensitive hashing in hyperbolic space, a topic that, to our best knowledge, has not been studied before.

1.1 LSH Framework

We first recall the formal definitions on LSH and the Approximate Nearest Neighbor Search (ANNS) problem.

▶ **Definition 1** (Locality Sensitive Hashing). *Consider a metric space (X, d)[1], let U be a countable set and $\mathcal{H}$ be a family of functions from X to U. $\mathcal{H}$ is an (r, cr, p_1, p_2)-sensitive LSH family, where $r > 0, c > 1$, $0 < p_2 < p_1 < 1$ are real numbers, if for any two points $x, y \in X$ and a hash function h chosen uniformly at random from $\mathcal{H}$ the following holds*

$$d(x,y) \le r \implies \Pr_{h\sim\mathcal{H}}[h(x) = h(y)] \ge p_1,$$
$$d(x,y) \ge cr \implies \Pr_{h\sim\mathcal{H}}[h(x) = h(y)] \le p_2.$$

[1] LSH is well-defined with a general dissimilarity measure, i.e., the triangle inequality does not necessarily hold. However, the approximate nearest neighbor search problem is typically studied in a metric space. Thus, we define LSH within the same context.

▶ **Definition 2** ((c,r)-approximate Nearest Neighbor Search Problem). *Let P be a point set in metric space (X,d). For any query point $x \in X$, if there exists a point $y \in P$ s.t. $d(x,y) \le r$, then the algorithm returns $y' \in P$ s.t. $d(x,y') \le c \cdot r$.*

Previous works [27, 22] have shown that the approximate nearest neighbor search problem can be solved by LSH, as formally stated below.

▶ **Proposition 3.** *Given an (r, cr, p_1, p_2)-sensitive family $\mathcal{H}$, the (c,r)-ANNS problem can be solved using $O(n^{1+\rho})$ space, and $O(n^{\rho}\log n)$ query time, where $\rho = \rho(\mathcal{H}) = \frac{\log(1/p_1)}{\log(1/p_2)}$.*

Since both the space and time complexity are determined by ρ, we regard ρ as an important performance parameter of LSH families. Namely, we ask for the tight bounds of ρ related to the approximation factor c for a specific metric space.

The tradeoff between the approximation factor c and the performance exponent ρ is intrinsically tied to the geometry of the underlying metric space. Previous studies have established a few tight bounds, with $\rho = \Theta(1/c)$ for Hamming distances and $\rho = \Theta(1/c^2)$ for Euclidean distances [27, 18, 2, 37, 40]. For the unit sphere under angular distance, Charikar [15] proposed LSH based on hyperplane rounding schemes, which are refined by subsequent work [3] showing $\rho = \Theta(1/c^2)$. However, LSH remains underexplored for spaces of negative curvature, such as hyperbolic space. From a theoretical perspective, this gap is notable because hyperbolic geometry exhibits exponential volume expansion, which fundamentally distinguishes itself from the polynomial growth of Euclidean space. Therefore, even extending standard space-partitioning techniques such as quadtree [31] to hyperbolic geometry is non-trivial.

Last, we remark that there has also been work on improved bounds (and empirical performance) for LSH in the data-dependent setting [4, 7, 8, 5, 6, 28]. The focus of this paper is on the data-independent case where the hash function is oblivious to input data P.

1.2 Our Results and Techniques

In this paper, we give the first LSH construction in the hyperbolic space. We start with an LSH design for points in the hyperbolic plane, and then consider LSH families for high-dimensional hyperbolic spaces.

For points in $\mathbb{H}^2$, we are inspired by the hyperplane rounding scheme by Charikar [15] for cosine similarity between vectors. The hyperplane rounding scheme partitions the space by selecting a random hyperplane passing through the origin. Each data point is assigned a bit (0 or 1) determined by the sign of its projection onto the hyperplane's normal vector. In our construction, we partition the space using a random geodesic, which is a circular arc orthogonal to the unit circle in the Poincaré disk model.

A technical caveat here is that we require a well-defined measure on the set of all geodesics. Such a measure is essential to ensure that random sampling of geodesics is meaningful and invariant under hyperbolic isometries. Fortunately, the classical integral geometry provides the needed theory. With some careful crafting using Crofton's formula, we are able to show that our construction yields $\rho \le 1/c$ in $\mathbb{H}^2$. This is formally stated as below.

▶ **Theorem 4.** *For points in the hyperbolic plane $\mathbb{H}^2$ and $r > 0, c > 1$, there exists an (r, cr, p_1, p_2)-sensitive family $\mathcal{H}$, for some $0 < p_2 < p_1 < 1$, such that $\rho(\mathcal{H}) = \frac{\log(1/p_1)}{\log(1/p_2)} \le 1/c$.*

To handle points in high-dimensional hyperbolic space, we use a random projection to low-dimensional hyperbolic space. First, we provide a refined analysis of the Johnson-Lindenstrauss type dimension-reduction result in [9]. Given a point set P in a metric space (X,d), we say a dimension reduction is an (α,β)-approximation to dimension k,

if there exists a mapping f that projects P into a k-dimension space $(\hat{X}, \hat{d})$, such that $\alpha \cdot d(p_i, p_j) \leq \hat{d}(f(p_i), f(p_j)) \leq \beta \cdot d(p_i, p_j)$ for any $p_i, p_j \in P$. In the literature, the embedding distortion is defined as β/α.

▶ **Theorem 5** (Informal Version of Theorem 12). *Let $k \in \mathbb{N}, k \geq 1$, if there exists an (α, β)-approximate dimension reduction for an n-dimension Euclidean point set to k-dimension Euclidean space, then there exists an (α, β)-approximate dimension reduction for a $(n+1)$-dimension hyperbolic point set to $(k+1)$-dimension hyperbolic space.*

Theorem 5 may be of independent interest. For example, an immediate corollary would be a Johnson-Lindenstrauss lemma for hyperbolic space. Namely, for n points in a high-dimensional hyperbolic space, their pairwise distances can be preserved within $(1 \pm \varepsilon)$-approximation while the dimension can be reduced to $O(\log n/\varepsilon^2)$, for $0 < \varepsilon < 1$.

In the context of LSH, our goal is to apply dimension reduction to obtain a projected point set in $\mathbb{H}^2$ and then employ our random geodesic partition technique. By Theorem 5, this task reduces to finding a Euclidean dimension reduction to a straight line ($k = 1$). Interestingly, this has been explored in the first Euclidean LSH construction [18], where they sample a projection matrix from the p-stable distribution (the Gaussian distribution for $p = 2$) and project the input point set onto a straight line. We adopt this scheme and analyze the distance distortion in the hyperbolic plane. Formally, we obtain the following result for a general hyperbolic space.

▶ **Theorem 6.** *For points in d-dimensional hyperbolic space $\mathbb{H}^d$ with $d \geq 3$ and $r > 0, c > 1$, there exists an (r, cr, p_1, p_2)-sensitive family $\mathcal{H}$, for some $0 < p_2 < p_1 < 1$, such that $\rho(\mathcal{H}) = \frac{\log(1/p_1)}{\log(1/p_2)} \leq 1.59/c$.*

The existence of this family immediately implies that a sublinear query time of $\tilde{O}(n^\rho)$ for Hyperbolic ANNS is possible, for $c > 1.59$ in dimension $d \geq 3$. To the best of our knowledge, this is the first worst-case, data-oblivious sublinear query time guarantee for the ANNS problem in high-dimensional hyperbolic space.

We remark that prior work [31] has shown *Locality Sensitive Ordering (LSO)* is not possible in hyperbolic space: no small collection of total orders can make all hyperbolic neighborhoods contiguous. This impossibility stems from the exponential volume growth of $\mathbb{H}^d$, which forces many mutually distant regions to interleave along a global ordering. Therefore, a global geometric linearization is not possible for hyperbolic space. On the other hand, our results confirm that this barrier does not apply to LSH, since hashing only requires distinguishing near and far points with good *probability*, which can be achieved by the randomized geodesic-partition scheme.

On the lower bound side, it is straightforward to argue that the Euclidean LSH lower bound on ρ extends to the hyperbolic setting. This follows from the fact that hyperbolic space is locally Euclidean; by scaling down a "hard" Euclidean dataset to a sufficiently small diameter, it can be embedded into hyperbolic space with arbitrarily low distortion. Therefore, we have the following result for the hyperbolic LSH lower bound.

▶ **Theorem 7.** *Fix $d \in \mathbb{N}$, $c > 1$, then there exists $0 < \tau < 1$, such that any $(\tau d, c\tau d, p_1, p_2)$-sensitive hashing family $\mathcal{H}$ in $\mathbb{H}^d$, for $0 < p_2 < p_1 < 1$, must satisfy $\rho(\mathcal{H}) \geq 1/c^2 - o_d(1)$.*

Our results leave a gap on ρ between $O(1/c)$ and $\Omega(1/c^2)$. Closing this gap remains a major open problem on this topic.

Experiments. We show the performance of the proposed LSH constructions in both the hyperbolic plane and high-dimensional spaces. We observe that the value of ρ for a random point set is a lot lower than $1/c$, which suggests the potential of the hyperbolic LSH in real-world applications.

1.3 Related Work on ANNS in Hyperbolic Spaces

Nearest neighbor query against a given set of n points in the hyperbolic plane can be solved by using a standard point location query in the hyperbolic Voronoi diagram (that can be efficiently constructed [39]). With linear storage, a nearest-neighbor query can be performed in $O(\log n)$ time. This method is limited to 2D hyperbolic space. For n points in $\mathbb{H}^d$ for a constant d, a $(1+\varepsilon)$-approximate nearest neighbor search can be done in time $O(d^{O(d)} \log n \log(1/\varepsilon)/\varepsilon^d)$ with space $O(nd^{O(d)} \log(1/\varepsilon)/\varepsilon^d)$ [31]. The performance deteriorates as d increases. Similar to the Euclidean setting, LSH is typically applied in high-dimensional spaces.

Krauthgamer and Lee [33] studied approximate nearest neighbor in locally doubling, δ-hyperbolic spaces [23]. Specifically, they considered a δ-hyperbolic metric space that has local geometry of type $(\lambda, \delta/3)$ in which every ball of radius $\delta/3$ in X can be covered by λ balls of half the radius. With $O(n^2)$ storage and query time $\lambda^{O(1)} \log^2 n$, an approximate nearest neighbor with an $O(\delta)$ additive error is returned. Note that this result relies on a bounded doubling parameter λ, which is not necessarily true for a general point set in hyperbolic space $\mathbb{H}^d$.

On the practical side, Wu and Charikar [50] used Euclidean nearest neighbor search oracle as a black box for ANNS in hyperbolic spaces. Prokhorenkova et. al. [41] used graph-based nearest neighbor search on a similarity graph and analyzed query time assuming that the points are uniformly distributed within a ball of radius R. Another relevant result is by [5], which shows a data-dependent LSH for general metric space. In their construction, the LSH performance depends on the *cutting modulus* of the metric space.

2 Locality Sensitive Hashing for $\mathbb{H}^2$

In this section, we show the LSH construction in $\mathbb{H}^2$ that yields Theorem 4. We adopt the Poincaré disk model for points in $\mathbb{H}^2$, defined on the unit disk $\mathbb{D} = \{z \in \mathbb{C} : |z| < 1\}$. The space is equipped with the metric $ds = \frac{2|dz|}{1-|z|^2}$, which induces the following distance function:

$$d_{\mathbb{H}}(u, v) = \operatorname{arccosh}\left(1 + 2\frac{|u-v|^2}{(1-|u|^2)(1-|v|^2)}\right).$$

Geometrically, geodesics in $\mathbb{D}$ correspond to circular arcs orthogonal to the unit circle boundary C_∞, with diameters passing through the origin as special cases.

The locality sensitive hash functions we use are *random geodesics* in the Poincaré disk model. For this purpose we require a well-defined probability measure on the set of all geodesics to ensure that random sampling of geodesics is meaningful and invariant under hyperbolic isometries. Luckily, the classical integral geometry [43] provides the needed theory. Integral geometry studies the measures on the spaces of all lines, or totally geodesic planes in Euclidean, hyperbolic, or spherical spaces, such that the measures are invariant under isometries. The fundamental theorems of Poincaré, Cauchy and Crofton show that one can recover basic geometric quantities such as lengths, areas, or volumes of an object by averaging over the set of geodesics intersecting the object.

In the hyperbolic plane, the isometrically invariant probability measure on the space of all geodesics is given by the *kinematic measure* [43]. Take a point q and a non-zero tangent vector v at q in the hyperbolic plane. The polar coordinate of a geodesic γ with respect to (q, v) is a pair (t, θ) where t is the hyperbolic distance from γ to q and θ is the angle of the perpendicular from q to γ with the tangent vector v. The kinematic measure in geodesic polar coordinates (t, θ) is

$$d\mu(t, \theta) = \cosh(t)\, dt\, d\theta.$$

The remarkable feature of the above formula is that it is independent of the choices of q and v. This measure reflects the fact that the volume element in hyperbolic geometry grows exponentially with t.

Since the space of all geodesics in $\mathbb{H}^2$ has infinite total measure, we limit our choices of geodesics in the family of all geodesics intersecting a hyperbolic disk $B(0, R)$ of radius R centered at the origin. By Crofton's formula, the measure of the set of geodesics that intersect a convex body is proportional to the perimeter of that body. Specifically, the corresponding measure is obtained by integrating the invariant element $d\mu$ over the disk:

$$\int_0^{2\pi} \int_0^R \cosh(t)\, dt\, d\theta = 2\pi \sinh(R). \tag{1}$$

Now, we choose R such that the disk $B(0, R)$ centered at the origin with radius R contains all points of P. Our final bound on the performance parameter ρ does not depend on R, and in practice, one can choose R to be a sufficiently large value. Note that in practice, hyperbolic embedding typically avoids using points that are far from the origin due to practical concerns on resolution and numerical instability [36].

A geodesic γ is chosen with probability density function $\frac{\cosh(t)}{2\pi \sinh(R)}$ to be at polar coordinate (t, θ) where t is taken from $[0, R]$ and θ is taken from $[0, 2\pi)$. In the Poincaré disk model, geodesics appear as Euclidean circular arcs, so γ is a circular arc with Euclidean center $c \in \mathbb{R}^2$ and radius $b > 0$. Specifically, define $c = \coth(t)e^{i\theta}$ (here convert $e^{i\theta}$ from the complex plane to the Euclidean plane) and $b = 1/\sinh t$. Define a hash function $\mathbb{H}^2 \to \{-1, 1\}$ by

$$h_\gamma(x) = \operatorname{sgn}\left(\|x - c\|^2 - b^2\right).$$

where x is the Euclidean coordinate of a point in $\mathbb{H}^2$. We can also rewrite the geodesic γ using the Minkowski model with inner product $\langle z, z\rangle = -z_1^2 + z_2^2 + z_3^2$. Let the geodesic γ be given by $\{x \in \mathbb{H}^2 | \langle x, u\rangle = 0\}$ for a point u in the de Sitter space $\{y \in \mathbb{R}^{2,1} | \langle y, y\rangle = 1\}$:

$$u = (\sinh t, \cosh t \cos\theta, \cosh t \sin\theta).$$

Note that (t, θ) is polar coordinate with respect to the point $q = (1, 0, 0)$ and $v = (0, 1, 0)$. Then the formula for $h_\gamma(x)$ is $\operatorname{sgn}\langle x, u\rangle$. This is exactly the same formula as in the Euclidean space. The advantage of this formula over the above one is that it is intrinsic to hyperbolic geometry, i.e., invariant under hyperbolic isometry.

With this setup, we present the hash function in $\mathbb{H}^2$ below.

Input: A point set $P \subset \mathbb{H}^2$

1. Let R be a radius such that P is contained in the ball $B(0, R)$.
2. Let μ_R denote the normalized kinematic measure restricted to the set of geodesics intersecting $B(0, R)$.
3. Sample a random geodesic $\gamma \sim \mu_R$.
4. Hash a point $x \in P$ to $h_\gamma(x) \in \{+1, -1\}$ according to which side of γ it lies on (ties have measure zero).

For brevity, we write $h(x)$ for $h_\gamma(x)$ when it is clear from context. Figure 1 demonstrates how the hash function works as a separator.

The key to proving Theorem 4 is a characterization of the collision probability under our hashing scheme, given in the following lemma.

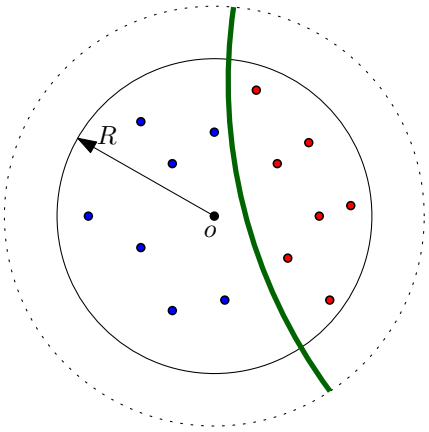

Figure 1 Illustration of the hashing scheme in $\mathbb{H}^2$. If two points are far, then they are more likely to be separated by a random geodesic (the green arc). Points in blue are assigned label $+1$ and points in red are assigned label -1.

▶ **Lemma 8.** *Given two points x, y in $\mathbb{H}^2$ of distance $d_{\mathbb{H}}(x, y) = r$, the kinematic measure μ of the set of all geodesics separating x, y is $2r$. In particular, if $x, y \in B(0, R)$, the ball of radius R is centered at 0, the collision probability with respect to the normalized kinematic measure μ_R is*

$$\Pr[h(x) = h(y) | d_{\mathbb{H}}(x, y) = r] = 1 - \frac{r}{\pi \sinh(R)}. \tag{2}$$

Proof. We use the Poincaré disk model for $\mathbb{H}^2$ in the calculation below. For two points x, y in $\mathbb{H}^2$ of distance $d_{\mathbb{H}}(x, y) = r$, let X be the set of all geodesics in $\mathbb{H}^2$ separating x, y and Y be the set of all geodesics intersecting $B(0, R)$. Note that when $x, y \in B(0, R)$, $X \subset Y$, i.e., $X \cap Y = X$. This shows,

$$\Pr[h(x) \neq h(y) | d_{\mathbb{H}}(x, y) = r] = \frac{\mu(X \cap Y)}{\mu(Y)} = \frac{\mu(X)}{\mu(Y)}. \tag{3}$$

By Equation (1), $\mu(Y) = 2\pi \sinh(R)$. Next we show $\mu(X) = 2r$, where $d_{\mathbb{H}}(x, y) = r$.

By the isometric invariance of the kinematic measure, to compute $\mu(X)$, we may assume, after applying a suitable isometry, that the midpoint of x and y is the origin, and that both points lie on the x-axis. Use the polar coordinate (t, θ) of a random geodesic γ with respect to $(0, x\text{-axis})$. If γ intersects the segment from x to y, the furthest intersection is x or y. Figure 2 illustrates this scenario. By the hyperbolic cosine law, we get

$$\tanh(t) = \tanh(\frac{r}{2}) \cos(\theta).$$

It follows that X in the polar coordinate is

$$X = \{(t, \theta) | \theta \in [-\pi, \pi], 0 \leq t \leq \operatorname{arctanh}(\tanh(\frac{r}{2}) \cos\theta)\}.$$

Therefore,

$$\mu(X) = 2 \int_{-\pi/2}^{\pi/2} \int_{0}^{\operatorname{arctanh}(\tanh(\frac{r}{2}) \cos\theta)} \cosh(t)\, dt\, d\theta.$$

The double integral enjoys a very simple and elegant result, which is r as shown in Claim 9.

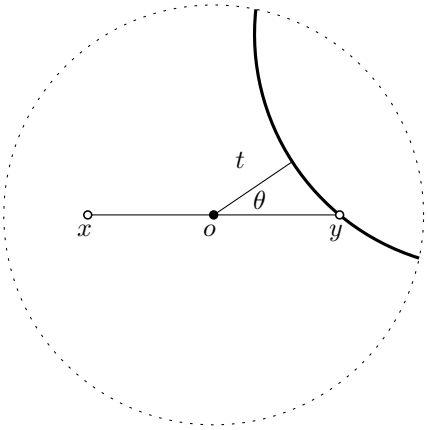

Figure 2 The geodesic intersects y, yielding the maximum value of t.

▷ Claim 9. Let r be a real number.

$$\int_{-\pi/2}^{\pi/2} \int_{0}^{\operatorname{arctanh}(\tanh(r/2)\cos\theta)} \cosh(t)\, dt\, d\theta = r$$

Therefore, $\mu(X) = 2r$. Furthermore, the probability that x, y are separated by γ when γ is chosen from Y is:

$$\Pr[h(x) \neq h(y) | d_{\mathbb{H}}(x,y) = r] = \frac{2r}{2\pi \sinh(R)}$$

and the collision probability is:

$$\Pr[h(x) = h(y) | d_{\mathbb{H}(x,y)} = r] = 1 - \frac{r}{\pi \sinh(R)}$$

This finishes the proof. ◀

The detailed calculation of Claim 9 is deferred to the full version [20]. For now we focus on the upper bound of ρ, note that the lemma immediately gives

$$p_1 = 1 - r/\pi \sinh(R),\ p_2 = 1 - cr/\pi \sinh(R)$$

In order to bound $\rho = \frac{\log 1/p_1}{\log 1/p_2}$, we apply Lemma 1 in [18], copied below.

▶ **Lemma 10** (Lemma 1 [18]). *For $x \in [0,1)$ and $\ell > 1$ such that $1 - \ell x > 0$,*

$$\frac{\log(1-x)}{\log(1-\ell x)} \leq \frac{1}{\ell}.$$

This shows that $\rho \leq 1/c$. Thus we conclude the proof of Theorem 4.

3 Dimension Reduction in Hyperbolic Space

In this section, we prove the dimension reduction result (Theorem 12). We use the Poincaré half-space model of the hyperbolic space $\mathbb{H}^d$. Each point in $\mathbb{H}^d$ is represented by a pair (z, x) with $z \in \mathbb{R}^+$ and $x \in \mathbb{R}^{d-1}$. The hyperbolic distance between two points $p_1 = (z_1, x_1)$ and $p_2 = (z_2, x_2)$ is defined by the following function

$$d_{\mathbb{H}}(p_1, p_2) = \operatorname{arccosh}\left(1 + \frac{\|x_1 - x_2\|^2 + (z_1 - z_2)^2}{2 z_1 z_2}\right),$$

where $\|x_1 - x_2\|$ is the Euclidean distance between x_1, x_2. For a set of n points $P = \{p_i = (z_i, x_i)\} \subseteq \mathbb{H}^d$, we would like to perform dimension reduction to generate $P' = \{p'_i\}$ in $\mathbb{H}^k$ and keep the pairwise distances similar. The method by Benjamini and Makarychev [9] is to perform dimension reduction for the Euclidean point set $X = \{x_i\} \subseteq \mathbb{R}^{d-1}$ by a function f to $X' = \{x'_i\} \subseteq \mathbb{R}^{k-1}$ and define $P' = \{p'_i\}$ with $p'_i = (z_i, x'_i)$ in $\mathbb{H}^k$. Below, we present a refined analysis that yields slightly tighter bounds on the distortion. Essentially, we show that the bound on the distortion of the Euclidean distances of X' (compared to X) carries over to bound the distortion of the hyperbolic distance of P' compared to P.

▶ **Definition 11.** *Let $f : (U, d_U) \to (V, d_V)$ be a map between two metric spaces. If there are positive constants γ_1, γ_2 such that for any $u_1, u_2 \in U$,*

$$\gamma_1 \cdot d_U(u_1, u_2) \leq d_V(f(u_1), f(u_2)) \leq \gamma_2 \cdot d_U(u_1, u_2),$$

we say that the distance stretch is upper bounded by γ_2 and lower bounded by γ_1 and the distortion is γ_2/γ_1.

▶ **Theorem 12.** *Given n points $P = \{p_i = (z_i, x_i)\}$ in $\mathbb{H}^d$. Suppose we have a function $f : \mathbb{R}^{d-1} \to \mathbb{R}^{k-1}$ for n input points $X = \{x_i\}$ such that $\forall x_i, x_j \in X$,*

$$\gamma_1 \cdot \|x_i - x_j\| \leq \|f(x_i) - f(x_j)\| \leq \gamma_2 \cdot \|x_i - x_j\|,$$

with $0 < \gamma_1 \leq 1$ and $\gamma_2 \geq 1$. Then the stretch bounds and distortion of the map

$$g(p) = g((z, x)) = (z, f(x))$$

are the same: $\forall p_i = (z_i, x_i), p_j = (z_j, x_j) \in P$,

$$\gamma_1 \cdot d_{\mathbb{H}}(p_i, p_j) \leq d_{\mathbb{H}}(g(p_i), g(p_j)) \leq \gamma_2 \cdot d_{\mathbb{H}}(p_i, p_j).$$

The proof follows the main idea in [9], but we have slightly improved analysis and bounds. Specifically, the main idea is to analyze the behavior of the function

$$F_{z_1,z_2}(r) = \operatorname{arccosh}\left(1 + \frac{r^2 + (z_1 - z_2)^2}{2z_1 z_2}\right), \tag{4}$$

which is an increasing function of r, when $z_1, z_2 > 0$. For completeness, we include the full proof in the full version [20].

▶ **Lemma 13.** *For $z_1, z_2 > 0$,*
1. *For $\gamma \geq 1$, $F_{z_1,z_2}(\gamma \cdot r) \leq \gamma \cdot F_{z_1,z_2}(r)$.*
2. *For $0 < \gamma' \leq 1$, $F_{z_1,z_2}(\gamma' \cdot r) \geq \gamma' \cdot F_{z_1,z_2}(r)$.*

Proof of Theorem 12. $d_{\mathbb{H}}(g(p_i), g(p_j)) = F_{z_i,z_j}(\|f(x_i) - f(x_j)\|)$. By definition, $\gamma_1\|x_i - x_j\| \leq \|f(x_i) - f(x_j)\| \leq \gamma_2\|x_i - x_j\|$, with $0 < \gamma_1 \leq 1$ and $\gamma_2 \geq 1$. The claim follows from $d_{\mathbb{H}}(g(p_i), g(p_j)) = F_{z_i,z_j}(\|f(x_i) - f(x_j)\|)$, that $F_{z_i,z_j}(x)$ is a monotonically increasing function of x and Lemma 13. ◀

Specifically, one can apply Johnson Lindenstrauss Lemma [29] on the Euclidean coordinates $\{x_i\}$ – by random linear projection to dimension $O(\log n/\varepsilon^2)$ – and arrive at a corresponding Johnson-Lindenstrauss Lemma in hyperbolic geometry.

▶ **Corollary 14** (Johnson Lindenstrauss Transform in $\mathbb{H}^d$)**.** *For n points $P = \{(z_i, x_i)\}$ in $\mathbb{H}^d$ we can project it to points $P' = \{(z_i, x'_i)\}$ in $\mathbb{H}^k$ with $k = \Theta(\log n/\varepsilon^2) + 1$ and stretch upper and lower bounded by $1 \pm \varepsilon$ respectively.*

4 Locality Sensitive Hashing for $\mathbb{H}^d$

A distribution D is called p-stable [51] with $p \geq 0$ if for any n real numbers $v_1, v_2, \cdots, v_n$ and random independent variables $X_1, X_2, \cdots X_n$ with distribution D, $\sum_i v_i X_i$ has the same distribution as the variable $(\sum_i |v_i|^p)^{1/p} X$, where X is a random variable with distribution D. A Gaussian distribution $\mathcal{N}(0,1)$ is 2-stable. This property has been used to build Euclidean LSH [18], to sketch high-dimensional vectors [26], and for many other applications.

Consider n points $P = \{p_i\}$ in $\mathbb{H}^d$. We use random projection to project these points to $P' = \{p'_i\}$ in $\mathbb{H}^2$ using the method in Section 3. In particular, we take a vector $\vec{a}$ with dimension $d-1$ where each entry is independently taken from a Gaussian distribution $\mathcal{N}(0,1)$. For $p_i = (z_i, x_i)$ in the upper half space model, we have $p_i = (z_i, x'_i)$ in $\mathbb{H}^2$, where $x'_i = \vec{a} \cdot x_i$. We then use the LSH mechanism in Section 2 to map these points into buckets. In this section, we analyze the performance of this mechanism.

In our case, the value $\vec{a} \cdot (p - q)$ for any two vectors $p, q \in \mathbb{R}^{d-1}$ is also a Gaussian distribution with zero mean and variance $\|p - q\|^2$, or, the distribution of $\|p - q\| Z$ with $Z \sim \mathcal{N}(0,1)$. Take $f(z)$ to be the probability density function of the absolute value of $\mathcal{N}(0,1)$:

$$f(z) = \frac{2}{\sqrt{2\pi}} e^{-z^2/2}.$$

To calculate the probability that p_1, p_2 are mapped to the same bucket, we take $s = \|x_1 - x_2\|$ and $r = d_{\mathbb{H}}(p_1, p_2) = F_{z_1,z_2}(s)$, where

$$F_{z_1,z_2}(s) = \operatorname{arccosh}\left(1 + \frac{s^2 + (z_1 - z_2)^2}{2 z_1 z_2}\right),$$

is an increasing function of s. Suppose p_1, p_2 are mapped to points p'_1, p'_2 with $s' = \|x'_1 - x'_2\|$ and $r' = d_{\mathbb{H}}(p'_1, p'_2) = F_{z_1,z_2}(s')$. s' follows the distribution of sZ with $Z \sim \mathcal{N}(0,1)$. Recall that using the LSH for $\mathbb{H}^2$ the probability that p'_1, p'_2 map to the same bucket is $1 - \frac{r'}{w}$ where $w = 2 \sinh R$. Now we have,

$$p(r) = \Pr(h(p_1) = h(p_2)) = \int_{z=0}^{\infty} f(z) \left(1 - \frac{F_{z_1,z_2}(s \cdot z)}{w}\right) dz.$$

We can get an upper bound of $p(r)$.

▶ **Lemma 15.**

$$p(r) \leq 1 - \alpha \frac{r}{w}, \ \alpha \approx 0.63. \tag{5}$$

Proof. We first rewrite:

$$\int_{z=0}^{\infty} f(z) \left(1 - \frac{F_{z_1,z_2}(s \cdot z)}{w}\right) dz = 1 - \int_{z=0}^{1} f(z) \frac{F_{z_1,z_2}(s \cdot z)}{w} dz - \int_{z=1}^{\infty} f(z) \frac{F_{z_1,z_2}(s \cdot z)}{w} dz$$

For the first integral, by Lemma 13, $F_{z_1,z_2}(s \cdot z) \geq z \cdot F_{z_1,z_2}(s) = zr$ in the range of $0 < z \leq 1$.

$$\int_{z=0}^{1} f(z) \frac{F_{z_1,z_2}(s \cdot z)}{w} dz \geq \int_{z=0}^{1} f(z) z \frac{r}{w} dz = \sqrt{\frac{2}{\pi}} (1 - e^{-1/2}) \frac{r}{w} \approx .31 \frac{r}{w}$$

For the second integral, $z \geq 1$, $F_{z_1,z_2}(s \cdot z) \geq F_{z_1,z_2}(s) = r$.

$$\int_{z=1}^{\infty} f(z) \frac{F_{z_1,z_2}(s \cdot z)}{w} dz \geq \int_{z=1}^{\infty} f(z) \frac{r}{w} dz \approx .32 \frac{r}{w}$$

Adding them together gives us:

$$p(z) \leq 1 - .63\frac{r}{w}$$ ◀

We also have a lower bound of $p(r)$.

▶ **Lemma 16.**

$$p(r) \geq 1 - \frac{r}{w}. \tag{6}$$

Proof. Here, z follows the distribution of the absolute value of a Gaussian distribution $\mathcal{N}(0,1)$, $z \geq 0$, $\mathbb{E}[z] = \sqrt{2/\pi}$ and $\mathbb{E}[z^2] = 1$.

The function $\operatorname{arccosh}(x)$ with $x > 1$ is concave and monotonically increasing. For a concave function $b(x)$ one can write it as

$$b(x) \leq b(x_0) + b'(x_0)(x - x_0).$$

Applying this for $b(x) = \operatorname{arccosh}(x)$ at $x = 1 + \frac{s^2 z^2 + (z_1 - z_2)^2}{2z_1 z_2}$ and $x_0 = 1 + \frac{s^2 + (z_1 - z_2)^2}{2z_1 z_2}$ we have

$$F_{z_1,z_2}(sz) \leq F_{z_1,z_2}(s) + b'(x_0) \cdot \frac{s^2(z^2 - 1)}{2z_1 z_2}$$

Taking expectation over z on both sides and recall $\mathbb{E}[z^2] = 1$ we have

$$\mathbb{E}[F_{z_1,z_2}(sz)] \leq F_{z_1,z_2}(s) + b'(x_0) \cdot \frac{s^2(\mathbb{E}[z^2] - 1)}{2z_1 z_2} = F_{z_1,z_2}(s) = r$$

Now we have

$$p(r) = 1 - \mathbb{E}[F_{z_1,z_2}(sz)]/w \geq 1 - r/w$$

This finishes the proof. ◀

Thus $p_1 = p(r) \geq 1 - r/w$. $p_2 = p(c \cdot r) \leq 1 - \frac{\alpha c r}{w}$. Since we need $p_1 > p_2$, this requires that $c \geq 1/\alpha \approx 1.59$.

Now we can estimate the function $\rho = \frac{\log 1/p(r)}{\log 1/p(c \cdot r)}$. Again we apply Lemma 10 and get

$$\rho = \frac{\log 1/p(r)}{\log 1/p(c \cdot r)} \leq \frac{\log(1 - \frac{r}{w})}{\log(1 - \frac{\alpha c r}{w})} \leq \frac{1}{\alpha c} \approx \frac{1.59}{c}.$$

This concludes Theorem 6.

5 Lower Bound

The lower bound on the performance parameter ρ for LSH of ℓ_p metrics has been studied in [37, 40]. Theorem 5.2 in [40] stated that for points of the Hamming cube $\{0,1\}^d$ and some $0 < \delta < 1$, an (r, R, p_1, p_2)-sensitive LSH of Hamming distance, with $r = \delta d/c$ and $R = \delta d$, must have

$$\rho(c) = \frac{\log 1/p_1}{\log 1/p_2} \geq \frac{1}{c} - o_d(1)$$

This lower bound can be used to generate a lower bound of $1/c^p$ for ℓ_p distance – by using ℓ_p distance on the same point set. In particular, it shows that LSH for Euclidean distances has $\rho \geq 1/c^2$. We will use the same construction to show a lower bound on ρ for hyperbolic distance.

▶ **Theorem 7.** *Fix $d \in \mathbb{N}$, $c > 1$, then there exists $0 < \tau < 1$, such that any $(\tau d, c\tau d, p_1, p_2)$-sensitive hashing family $\mathcal{H}$ in $\mathbb{H}^d$, for $0 < p_2 < p_1 < 1$, must satisfy $\rho(\mathcal{H}) \geq 1/c^2 - o_d(1)$.*

Proof. For a point x_i of the Hamming cube $\{0,1\}^d$, we define $p_i \in \mathbb{H}^{d+1}$ to be (z, x_i) in the half-space model, with a very large value of z to be decided later. Now consider the hyperbolic distance of p_i, p_j:

$$d_{\mathbb{H}}(p_i, p_j) = \operatorname{arccosh}\left(1 + \frac{\|x_i - x_j\|^2}{2z^2}\right)$$

For any $0 < \varepsilon < 1$, we take $z \geq \sqrt{d/2\varepsilon}$. Thus $\frac{\|x_i - x_j\|^2}{2z^2} \leq \varepsilon$. Use the generalized power series (Puiseux series)

$$\operatorname{arccosh}(1+x) = \sqrt{2}\sum_{t=0}^{\infty} \frac{(-1)^t \binom{2t}{t}}{(2t+1)8^t} x^{t+1/2} = \sqrt{2x}\left(1 - \frac{1}{12}x + \frac{3}{160}x^2 - \frac{5}{896}x^3 + \cdots\right)$$

This gives us, for small positive x,

$$\sqrt{2x}(1 - \frac{1}{12}x) \leq \operatorname{arccosh}(1+x) \leq \sqrt{2x}.$$

We can now bound

$$\sqrt{\|x_i - x_j\|_1}(1 - \varepsilon/12) \leq d_{\mathbb{H}}(p_i, p_j) \cdot z \leq \sqrt{\|x_i - x_j\|_1},$$

where the ℓ_1 distance (same as the Hamming distance) $\|x_i - x_j\|_1$ is the same as the squared ℓ_2 distance $\|x_i - x_j\|_2^2$. Now we build an (r_h, R_h, p_1, p_2)-sensitive LSH such that $r_h \cdot z \leq \sqrt{r}$ and $\sqrt{R}(1 - \varepsilon/12) \leq R_h \cdot z$. Take $R_h = c_h \cdot r_h$, we have

$$\frac{1}{c} = \frac{r}{R} \geq \left(\frac{r_h}{R_h}\right)^2 (1 - \varepsilon/12)^2 = \frac{1}{c_h^2}(1 - \varepsilon/12)^2$$

Combining everything, a LSH for $\mathbb{H}^{d+1}$ must have

$$\rho(c_h) \geq \frac{1}{c} - o_d(1) \geq \frac{1}{c_h^2}(1 - \varepsilon/12)^2 - o_d(1) = \Omega(1/c_h^2)$$ ◀

6 Experiments

We implement our Locality Sensitive Hashing algorithms in both $\mathbb{H}^2$ and $\mathbb{H}^d$. We aim to evaluate the LSH performance in terms of ρ in practice.

We first explain the synthetic data we use. For each $d \in \{2, 10, 100, 1000\}$, we generate a dataset of 1000 points by uniformly random sampling in a hyperbolic sphere of the same radius, $R = \log(199)$. This radius was chosen so that after the points are projected to $\mathbb{H}^2$ and mapped to the Poincare disk model, the points lie inside a Euclidean circle of radius 0.99. Further, we set $r = 0.2$ with varying $c = 1.5 + k$ for $k = 0, 1...17$ to compute the value of p_1 and p_2. We illustrate results on p_1, p_2 in Figure 3 and ρ in Figure 4 for different choices of c obtained by averaging over 1000 repetitions.

We see that, as expected, p_1 and p_2 are close to 1 in all cases. Due to the randomness of the data, the probabilities vary slightly in percentage. Since ρ is related to the complements of these probabilities, varying slightly in proportion when so close to 1 causes the significant differences in ρ values that we are observing. However, in all cases, the ρ graphs are below

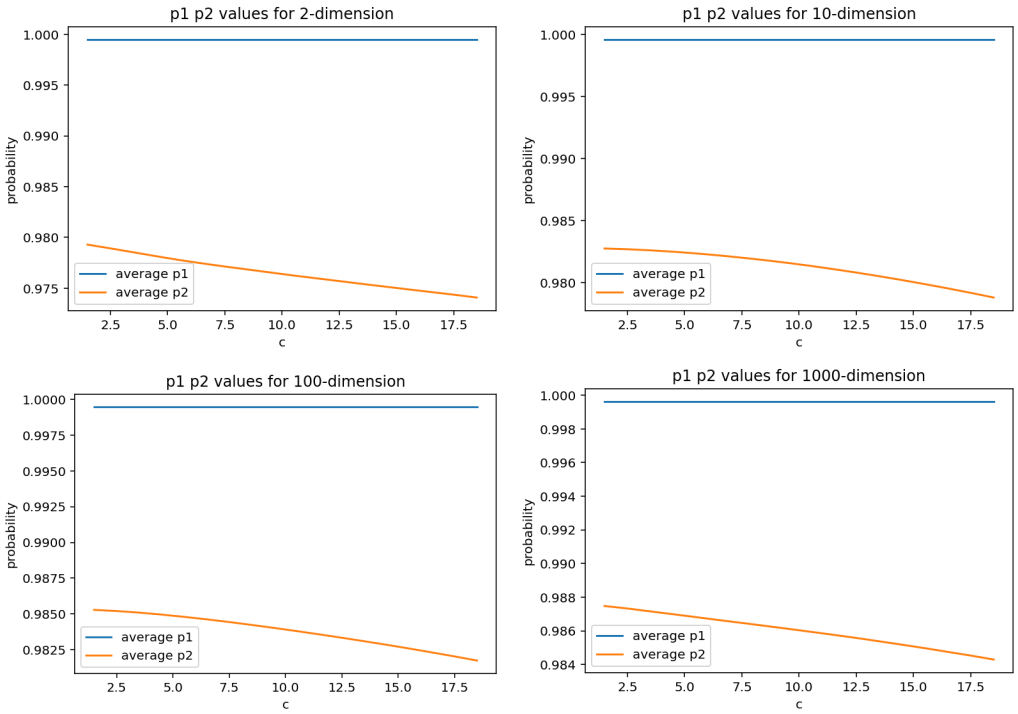

Figure 3 Average p_1, p_2 of Hyperbolic LSH with varying c for different dimensions (y-values do not start at 0).

$1/c$. We note that they are not exactly $1/c$ because we considered all pairs of points with distance below r or above cr, not exactly equal to r or cr, so $1/c$ should be an upper bound of what we obtain.

Next, we use the same data for $d = 2$, but vary $c = 1 + .1k$ for $k = 1, ...10$ to see if the LSH still works for small values of c even though our proof only has guarantees for $c \geq 1.59$. From Figure 5 we see fairly similar results, just p_2 varying less, but LSH still achieves ρ lower than $\frac{1}{c}$.

We also generated some data for $d = 1000$, varying R so that the points lie in a circle of Euclidean radii .9 and .999. We see that p_1, p_2 and ρ change a little, but not significantly and still fall well within the theoretical bounds.

Lastly, we generate similar data for $d = 2$, but containing 2000 points. Then, we analyze p_1 and p_2 for pairs of points that are at the boundary of acceptable distances. Precisely, we choose pairs of points that have distance within $[.9r, r]$ or $[cr, 1.1cr]$. This gives us an approximately linear graph for p_2 and ρ curve that approximates $\frac{1}{c}$.

The experiment setup with a fixed r and a reasonably large constant c (rather than $1 + \varepsilon$ for a very small ε) is motivated by real world applications such as similarity learning which focuses on differentiating data elements that are very similar or sufficiently far away. Many data modalities and data tasks fall into this category. For example, in image recognition the goal is to recognize two pictures with similar scenes or semantics. But for two pictures on completely different subjects, it is sufficient to know that they are far away and the exact values of dissimilarities are less important. One important take-away message from our experiments is that the empirical value of ρ with the synthetic data set is very small with a mild dependency on dimension and decreasing value of c. It is much smaller than

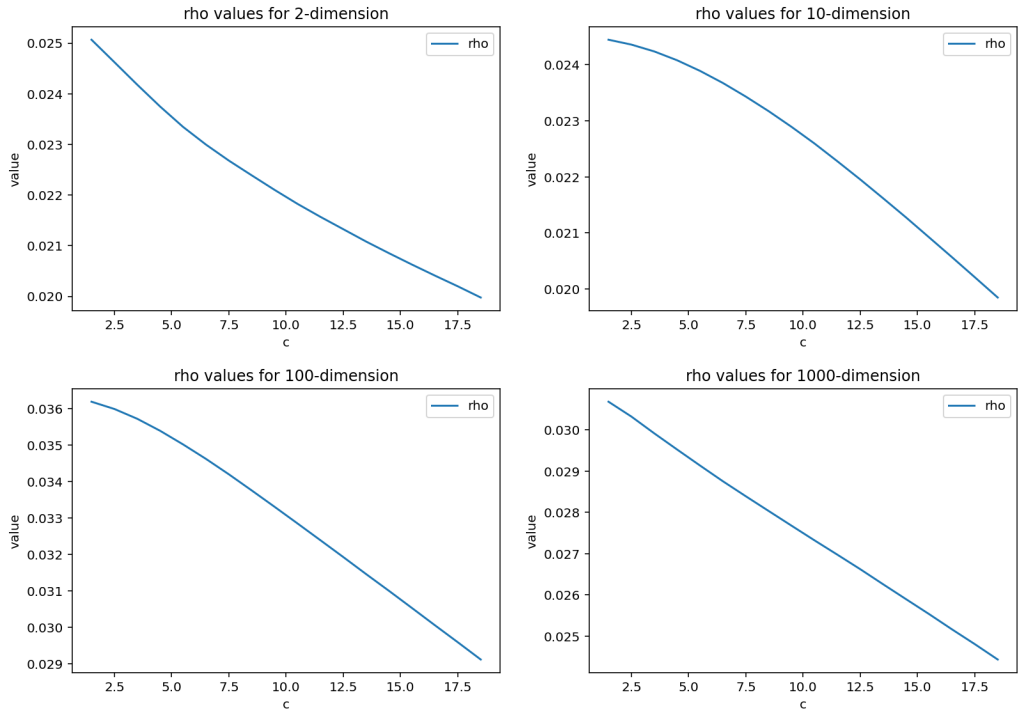

Figure 4 Average ρ of Hyperbolic LSH with varying c for different dimensions (y-values do not start at 0).

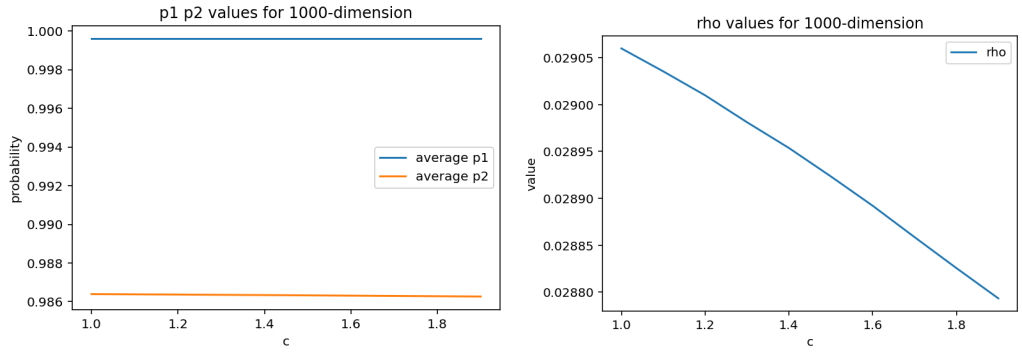

Figure 5 Average ρ and average p_1, p_2 in high-dimension when c is small (y-values do not start at 0).

our theoretical upper bound – partly because we consider all pairs whose distance are often much smaller than r or much greater than cr. Since the storage requirement for approximate nearest neighbor data structure built with LSH grows in terms of $O(n^{1+\rho})$ and the query cost grows in terms of $O(n^{\rho})$. The empirical small value of ρ suggests great potential for practical use.

7 Conclusion

To our knowledge, this is the first work for locality sensitive hashing in hyperbolic space. Our construction achieves a performance parameter $\rho = O(1/c)$ for general hyperbolic space. To complement, we show there is a lower bound of $\rho \approx \Omega(1/c^2)$. The major open question is whether there can be improvement with a better ρ or show a stronger lower bound for

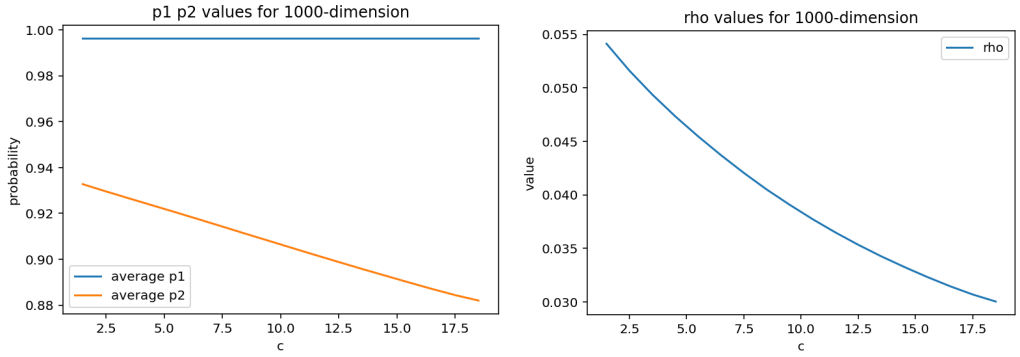

Figure 6 Average ρ and average p_1, p_2 in high dimension and $R = .9$ in Euclidean coordinates (y-values do not start at 0).

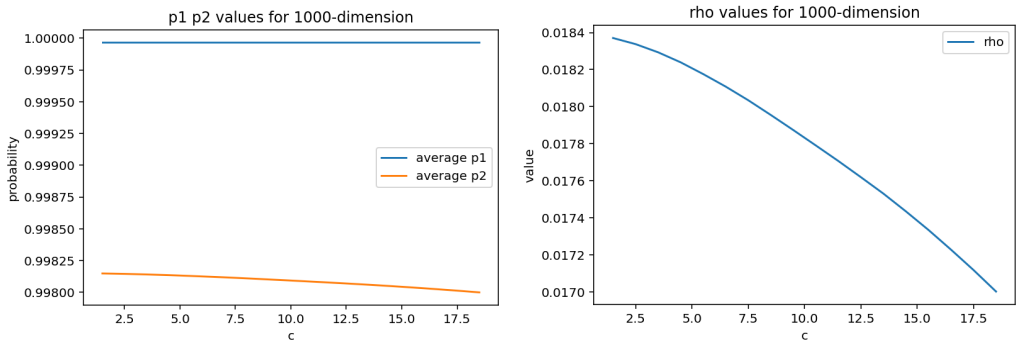

Figure 7 Average ρ and average p_1, p_2 in high dimension and $R = .999$ in Euclidean coordinates (y-values do not start at 0).

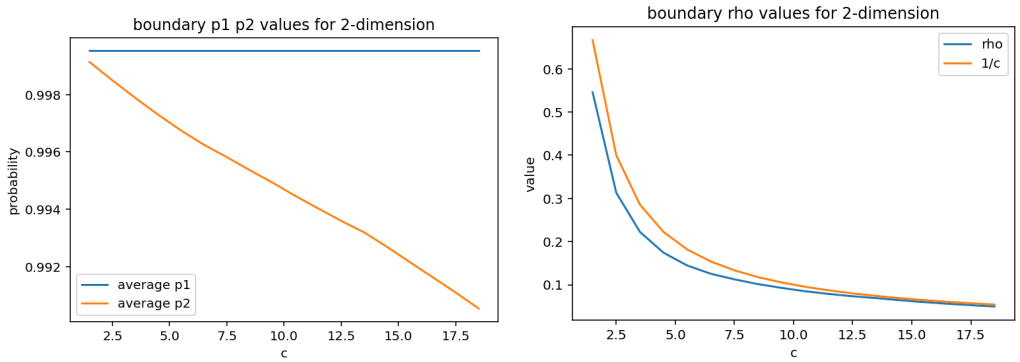

Figure 8 Average ρ and average p_1, p_2 for only pairs at distance approximately r or cr (y-values do not start at 0).

the LSH of hyperbolic distances. Note that prior results are obtained from Boolean analysis that give lower bounds on the Hamming space, which implies a lower bound for ℓ_p spaces. We believe novel techniques are required to show a non-trivial lower bound for hyperbolic space. Another open direction is data-dependent LSH, which outperforms classical LSH in Euclidean and Hamming space. It would be interesting to see if this result extends to hyperbolic space.

Computing the Intrinsic Delaunay Triangulation of a Closed Polyhedral Surface

Loïc Dubois[1]
Notre Dame, IN, USA

Abstract

Every surface that is intrinsically polyhedral can be represented by a portalgon: a collection of polygons in the Euclidean plane with some pairs of equally long edges abstractly identified. While this representation is arguably simpler than meshes (flat polygons in $\mathbb{R}^3$ forming a surface), it has unbounded *happiness*: a shortest path in the surface may visit the same polygon arbitrarily many times. This pathological behavior is an obstacle towards efficient algorithms. On the other hand, Löffler, Ophelders, Staals, and Silveira [SoCG 2023] recently proved that the (intrinsic) Delaunay triangulations have bounded happiness.

In this paper, given a closed polyhedral surface S, represented by a triangular portalgon T, we provide an algorithm to compute the Delaunay triangulation of S whose vertices are the singularities of S (the points whose surrounding angle is distinct from 2π). The time complexity of our algorithm is polynomial in the number of triangles and in the logarithm of the aspect ratio r of T. Within our model of computation, we show that the dependency in $\log r$ is unavoidable. Our algorithm can be used to pre-process a triangular portalgon before computing shortest paths on its surface, and to determine whether the surfaces of two triangular portalgons are isometric.

1 Introduction

In one of its simplest forms a *triangulation* is a finite collection of disjoint triangles in the Euclidean plane, together with a partial matching of the sides of the triangles such that any two matched sides have the same length (Figure 1). This simple representation appears under different names in the literature (intrinsic triangulation [26, 27], portalgon [20]). Cutting out the triangles from the plane and identifying the matched sides isometrically, respecting the orientations of the triangles, provides a (compact, orientable) *polyhedral* surface. This surface is *closed* if, in addition, it is connected and without boundary.

In this paper we consider the *Delaunay* triangulation of a closed polyhedral surface whose vertex set consists of the singularities (the points surrounded by an angle distinct from 2π) of the surface (except for flat tori, see below). It is generically unique. Our main contribution is an algorithm to compute it from any triangulation of the surface, whose time complexity is polynomial in the number of triangles and in the logarithm of the aspect ratio of the input triangulation. Our second contribution is a lower bound showing that the dependency in the logarithm of the aspect ratio is unavoidable in our model of computation.

Before describing our contributions in more detail, we discuss related works.

1.1 Related works

Polyhedral surfaces can also be obtained from *meshes*, flat triangles in $\mathbb{R}^3$ glued along their edges. Moreover, every mesh defines a triangulation of its surface. Yet triangulations are more general than meshes: most triangulations cannot be obtained from a mesh. Some recent algorithms advantageously operate on triangulations of polyhedral surfaces without reference to a mesh [25, 31, 17]. In this context the adjective "intrinsic" is sometimes placed before the name "triangulation" to make the distinction with the particular triangulations arising from a mesh. In the mathematical community, a prominent example is that of a translation surface [21, 32, 14, 12], which arises naturally in the study of billiards in rational polygons.

Triangulations are so general that not all of them are suitable for computation, compared to meshes. Prominently, a fundamental problem on polyhedral surfaces is to compute the distance or a report a shortest path between two points. On a mesh, shortest paths can be computed in time polynomial in the number of triangles. For example, an algorithm of Mitchell, Mount, and Papadimitriou [22] propagates waves along the surface, starting from the source, in a discrete manner. See also Chen and Han [4]. On a generic triangulation however (not arising from a mesh), the number of times a shortest path visits a triangle is not bounded by any function of the number of triangles, as noted for example almost 20 years ago by Erickson [8]. Recently, Löffler, Ophelders, Staals, and Silveira [20] coined the term *happiness* of a triangulation, for the maximum number of times a shortest path visits a triangle. They adapted the single-source shortest paths algorithm of Mitchell, Mount, and Papadimitriou [22] from meshes to triangulations, whose time complexity now depends on the happiness of the triangulation (it is more efficient on triangulations of *low* happiness).

This raises the problem of replacing any given triangulation by another triangulation of the same surface whose happiness is "low". Among the many remeshing algorithms [13, 28, 24, 29], only few have been ported to the general context of intrinsic triangulations [26], and the only solution we are aware of that compares to our main result (Theorem 1 below), by Löffler, Ophelders, Staals, and Silveira [20, Section 5], is restricted to particular inputs whose surfaces are all homeomorphic to an annulus; we will use it as a black box. Importantly, the same authors also showed that Delaunay triangulations have bounded happiness [20, Section 4.2].

Delaunay triangulations are classical objects of computational geometry [5, 11, 2], closely related to shortest paths. While mostly known in the plane, they generalize to closed polyhedral surfaces, see for example the depiction of Bobenko and Springborn [3]. To compute a Delaunay triangulation from an arbitrary intrinsic triangulation there are, to our knowledge, only two approaches, and neither compares to our main result (Theorem 1). One approach computes a Voronoi diagram with a suitably adapted multiple-source shortest path algorithm, and then derives from it a Delaunay tessellation, see for example Mount [23], Liu, Chen, and Tang [18], and Liu, Xu, Fan, and He [19]. Another approach starts from an initial triangulation and flips its edges until it reaches a Delaunay triangulation; it was proved to terminate by Indermitte, Liebling, Troyanov, and Clémençon [3, 15].

1.2 Our results

In order to state our results precisely, it now matters to make the distinction between a triangulation and the data structure representing it, and to allow for more general polygons than triangles. Following Löffler, Ophelders, Staals, and Silveira [20], we call *portalgon* the collection T of polygons in the Euclidean plane and the partial matching of their sides. We denote by $\mathcal{S}(T)$ the associated polyhedral surface. We say that the portalgon T is *triangular* if all polygons are triangles. The sides of the polygons, once identified, constitute a graph T^1 embedded on $\mathcal{S}(T)$ (the polygons themselves correspond to the faces of T^1): it is this graph T^1 that we call *triangulation* if T is triangular, and we call T^1 a *tessellation* in general.

We consider, on a closed polyhedral surface S, the unique Delaunay tessellation $\mathcal{D}$ of S whose vertices are exactly the singularities of S, with a single very special exception: if S has no singularity, then S is a flat torus and we let $\mathcal{D}$ be any of the Delaunay tessellations of S that have exactly one vertex, for one can be mapped to the other via an orientation-preserving isometry of S anyway. In any case, we say that $\mathcal{D}$ is *the* Delaunay tessellation of S, in a slight abuse.[2] It is "generically" a triangulation, but not always. If not, then triangulating the faces of $\mathcal{D}$ along any vertex-to-vertex arcs provides a Delaunay triangulation. The *aspect ratio* of a triangular portalgon T is the maximum side length of a triangle of T divided by the smallest height of a triangle of T (possibly another triangle). Our main contribution is:

▶ **Theorem 1.** *Let T be a portalgon of n triangles, of aspect ratio r, whose surface $\mathcal{S}(T)$ is closed. One can compute the portalgon of the Delaunay tessellation of $\mathcal{S}(T)$ in $O(n^3 \log^2(n) \cdot \log^4(r))$ time.*

As already mentioned, the only two methods we are aware of for computing a Delaunay tessellation from an arbitrary triangulation are the flip algorithm and the computation of the dual Voronoi diagram. The time complexities of these algorithms are not bounded by any polynomial in n and $\log(r)$.

Applications of Theorem 1 are detailed in the full version of the paper. Briefly, on the portalgon returned by Theorem 1, shortest paths can be computed in $O(n^2 \log^{O(1)} n)$ time. And Theorem 1 enables to test whether the surfaces of two given portalgons are isometric, simply by computing and comparing the portalgons of the associated Delaunay tessellations.

We analyze our algorithms within the real RAM model of computation described by Erickson, van der Hoog, and Miltzow [10]. It is an extension of the standard integer word RAM, with an additional memory array storing reals, and with additional instructions. On such a machine, we represent each polygon of a portalgon T by the list of its vertices, and each vertex is by its two coordinates, stored in the memory array dedicated to reals. So displacing (translating or rotating) the polygons in the plane provides different representations of T. When modifying a portalgon T, we actually modify our representation of T, using elementary operations that are easily seen to be achievable by a real RAM.

Within this model of computation, our second contribution is a lower bound that backs our main result, Theorem 1, by showing that the polynomial dependency in the logarithm of the aspect ratio is unavoidable:

▶ **Theorem 2.** *Let $c \in (0, 1)$. There are a flat torus S, and for every $x \in (1, \infty)$, a representation of a portalgon T_x, with two triangles, whose aspect ratio is $O(x^2)$, whose surface is S, that satisfy the following. There is no real RAM algorithm computing a representation of the portalgon of the Delaunay tessellation of S from T_x in $O((\log x)^c)$ time.*

Altogether Theorem 1 and Theorem 2 show that, within our model of computation, the complexity of computing the Delaunay tessellation from an arbitrary triangulation of a (closed, orientable) polyhedral surface is polynomial in the number of triangles and in the logarithm of the aspect ratio of the input triangulation.

1.3 Overview of the proof of Theorem 1

The proof of Theorem 2 is deferred to the full version of the paper. This extended abstract focuses on the proof of Theorem 1, of which we now provide an overview.

[2] Given a set V of points of the surface, finite, non-empty, and containing all the singularities, our results easily extend to Delaunay triangulations whose vertex set is V, but this is incidental to us.

We introduce a slight variation of happiness, more suitable to our needs, which we call *segment-happiness*. To prove Theorem 1, the crux of the matter is to replace the input triangular portalgon by another triangular portalgon of the same surface, whose segment-happiness is "low". For this purpose, our approach is to first focus on portalgons T whose surface $\mathcal{S}(T)$ is *flat*: the interior of $\mathcal{S}(T)$ has no singularity. Note that here we allow $\mathcal{S}(T)$ to have boundary, and this boundary may have singularities. The *systole* of $\mathcal{S}(T)$ is the smallest length of a non-contractible geodesic closed curve in $\mathcal{S}(T)$. Our key technical result is:

▶ **Proposition 3.** *Let T be a portalgon of n triangles, whose sides are all smaller than $L > 0$. Assume that $\mathcal{S}(T)$ is flat. Let $s > 0$ be smaller than the systole of $\mathcal{S}(T)$. One can compute in $O(n \log^2(n) \cdot \log^2(2 + L/s))$ time a portalgon of $O(n \cdot \log(2 + L/s))$ triangles, whose surface is isometric to that of T, and whose segment-happiness is $O(\log(n) \cdot \log^2(2 + L/s))$.*

Sections 3–5 are devoted to the proof of Proposition 3. In Section 3 we focus on particular portalgons, whose surfaces are all homeomorphic to an annulus; the definitions and results of this section are used by the algorithm of Proposition 3. In Section 4 we describe the algorithm for Proposition 3. It is a finely tuned combination of elementary operations such as inserting and deleting edges and vertices in graphs. While the algorithm itself is relatively simple, its analysis is more involved, and is sketched in Section 5. In this section, we first provide a combinatorial analysis, and then we prepare for the geometric analysis by introducing a new parameter on the simple geodesic paths e of a flat surface, *enclosure*, possibly of independent interest. Informally, e is enclosed when a short non-contractible loop can be attached to a point of e not too close to the endpoints of e. We then use enclosure to analyze the algorithm from a geometric point of view, proving Proposition 3.

We then extend Proposition 3 from flat surfaces to surfaces having singularities in their interior, essentially by cutting out caps around these singularities. To get a cleaner result, we also replace $2 + L/s$ by the aspect ratio of T, and we replace segment-happiness by happiness, obtaining:

▶ **Proposition 4.** *Let T be a portalgon of n triangles, of aspect ratio r. One can compute in $O(n \log^2(n) \cdot \log^2(r))$ time a portalgon of $O(n \cdot \log(r))$ triangles, whose surface is $\mathcal{S}(T)$, and whose happiness is $O(n \log(n) \cdot \log^2(r))$.*

The proof of Proposition 4 is omitted from this extended abstract. We have not discussed Delaunay tessellations yet. Still, we are almost ready to prove Theorem 1. Indeed, once we have a portalgon of low happiness, we can compute shortest paths on the surface. And, as already mentioned, shortest path algorithms classically extend to construct Voronoi diagrams and then Delaunay tessellations. Formally:

▶ **Proposition 5.** *Let T be a portalgon of n triangles, of happiness h, such that $\mathcal{S}(T)$ is closed. One can compute the portalgon of the Delaunay tessellation of $\mathcal{S}(T)$ in $O(n^2 h \log(nh))$ time.*

The proof of Proposition 5 is omitted from this extended abstract. We insist that the proof of Proposition 5 is incidental to us, and Proposition 5 is not surprising at all. Our contribution is really the proof of Proposition 4. Theorem 1 is immediate from Proposition 4 and Proposition 5:

Proof of Theorem 1. Proposition 4 computes in $O(n \log^2(n) \cdot \log^2(r))$ time a portalgon T' of $O(n \cdot \log(r))$ triangles, whose happiness is $O(n \log(n) \cdot \log^2(r))$. Proposition 5 then computes the portalgon of the Delaunay tessellation from T' in $O(n^3 \log^2(n) \cdot \log^4(r))$ time. ◀

2 Preliminaries

We use without review standard notions of graph theory and low dimensional topology and geometry, referring to textbooks for details [6, 1, 30, 7]. We only mention that on a surface S, a path $p : [0, 1] \to S$ is **simple** if its restriction to the interval $(0, 1)$ is injective, in which case the image of $(0, 1)$ by p is the **relative interior** of p. We denote by $\ell(p)$ the length of a geodesic path p. Throughout the paper, logarithms are in base two.

The definition of Delaunay tessellation given by Bobenko and Springborn [3, Section 2] is not used in this extended abstract.

2.1 Portalgons, tessellations, and polyhedral surfaces

A **portalgon** T is a disjoint collection of oriented polygons in the Euclidean plane, together with a partial matching of the sides of the polygons such that any two matched sides have the same length. It is **triangular** if all polygons are triangles. See Figure 1. Any subset of the polygons defines a **sub-portalgon** T' of T: two sides of polygons are matched in T' if and only if they are matched in T. In a portalgon T, identifying the matched sides, isometrically, and respecting the orientations of the polygons, provides **the surface of** T, denoted $\mathcal{S}(T)$; it is a 2-dimensional Riemannian manifold whose metric may have singularities. The sides of the polygons of T correspond to a graph T^1 embedded on $\mathcal{S}(T)$, the **1-skeleton** of T.

A **polyhedral surface** is any Riemannian manifold S (possibly with singularities) isometric to the surface of a portalgon. And when we say that a portalgon T is **a portalgon of** S, we implicitly fix an isometry between $\mathcal{S}(T)$ and S. A **tessellation** of S is any 1-skeleton of a portalgon of S, it is a **triangulation** if the portalgon is triangular.

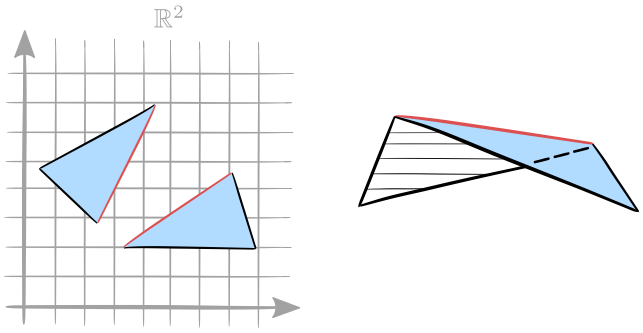

Figure 1 (Left) A triangular portalgon T: two triangles in the Euclidean plane, with two sides matched in red. (Right) The surface $\mathcal{S}(T)$, and the 1-skeleton T^1.

Consider a polyhedral surface S, a triangulation T^1 of S, a vertex x of T^1, and the sum a of the angles of faces of T^1 around x. The point x is a **singularity** if x lies in the boundary of S and $a \neq \pi$, or if x lies in the interior of S and $a \neq 2\pi$. Every other point of S is **flat**. This does not depend on any particular triangulation of S. A surface S is **flat** if its interior has no singularity (although its boundary may have singularities). The closed flat surfaces are called **flat tori**.

2.2 Aspect ratio, systole, happiness, and segment-happiness

The **aspect ratio** of a triangular portalgon T is the maximum side length of a triangle of T divided by the smallest height of a triangle of T (possibly another triangle). Note that the aspect ratio is always greater than or equal to $2/\sqrt{3} > 1$, because the maximum side length of a triangle is always greater than or equal to $2/\sqrt{3}$ times its smallest height.

The **systole** of a polyhedral surface S is the smallest length of a non-contractible geodesic closed curve in S, except in the particular case where every closed curve in S is contractible, in which case the systole is ∞. The important thing is that for every positive real s smaller than the systole of S, any non-contractible closed curve in S is longer than s.

The **happiness** of a portalgon T is the maximum number of times a shortest path in $\mathcal{S}(T)$ visits the image of a polygon of T, maximized over all the shortest paths of $\mathcal{S}(T)$ and all the polygons of T (see [20, Section 3]). We introduce a variation, more suitable to our needs. In a polyhedral surface S, a **segment** is a simple geodesic path e whose relative interior is disjoint from any singularity of S. The **segment-happiness** of e in S, denoted $h_S(e)$, is the maximum number of intersections between e and a shortest path of S, maximized over all the shortest paths of S. The **segment-happiness** of a portalgon T is then the maximum segment-happiness $h_{\mathcal{S}(T)}(e)$, maximized over the edges e of its 1-skeleton T^1. A priori, the segment-happiness of a portalgon T differs from the happiness of T. Indeed a path in $\mathcal{S}(T)$ may visit many times a face of T^1 without intersecting any edge of T^1 more than once, if the face has high degree. However, if T is triangular, then the happiness and the segment-happiness of T do not differ by more than a constant factor.

3 Tubes and bifaces

In this section we focus on particular triangular portalgons. See Figure 2. A **tube** is a triangular portalgon X whose surface $\mathcal{S}(X)$ is homeomorphic to an annulus and has no singularity in its interior, and whose 1-skeleton X^1 has exactly one vertex on each boundary component of $\mathcal{S}(X)$. Among tubes, a **biface** is a portalgon B of two triangles whose respective sides s_0, s_1, s_2 and s'_0, s'_1, s'_2, in order (clockwise say), are such that s_0 is matched with s'_0 and s_1 is matched with s'_1. Its 1-skeleton B^1 has four edges: two loop edges forming the two boundary components of $\mathcal{S}(B)$, which we call **boundary edges**, and two edges whose relative interiors are included in the interior of $\mathcal{S}(B)$, which we call **interior edges**.

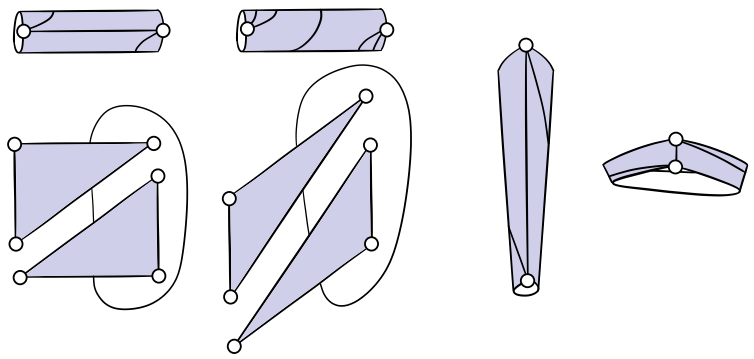

Figure 2 (From left to right) A good biface, a biface not good, a thin biface, a thick biface.

We say that a biface B is **good** if the two interior edges e and f of B^1 satisfy both of the following up to possibly exchanging e and f. First, e is a shortest path in $\mathcal{S}(B)$. Second, cut $\mathcal{S}(B)$ along e, and consider the resulting quadrilateral. If this quadrilateral has two diagonals then f is shortest among the two diagonals. We will distinguish good bifaces. A good biface B is **thin** if every interior edge of B^1 is longer than every boundary edge of B^1. Otherwise B is **thick**. While tubes and bifaces have unbounded happiness, good bifaces on the other hand satisfy the following:

▶ **Lemma 6.** *Given a good biface B, let e be an interior edge of B^1. Then $h_{\mathcal{S}(B)}(e) \leq 6$.*

We will use the elementary operation of replacing a tube by a good biface:

▶ **Proposition 7.** *Let X be a tube with n triangles, whose sides are smaller than $L > 0$. Let $s > 0$ be smaller than the systole of $\mathcal{S}(X)$. One can compute a good biface whose surface is $\mathcal{S}(X)$ in $O(n \log n \cdot \log(2 + L/s))$ time.*

Proposition 7 is similar to a result described by Löffler, Ophelders, Silveira, and Staals [20, Theorem 45], building upon a ray shooting algorithm of Erickson and Nayyeri [9].

4 Description of the algorithm

In this section we describe our algorithm for Proposition 3. We first describe the elementary operations and the data structure, before giving the algorithm itself. Along the way, we provide informal explanations of our choices. We do not prove anything, as the analysis of the algorithm is deferred to Section 5.

4.1 Inserting vertices and edges

Informally, our goal is to "improve the geometry" of a triangular portalgon T. We will make this precise in Section 5. Roughly, the issue is that, without any condition on T, the edges of T^1 that lie in the interior of $\mathcal{S}(T)$ can be arbitrarily long, so one of them may intersect some shortest path arbitrarily many times by wrapping around the surface, and so the segment-happiness of T can be arbitrarily large. A naive way of shortening an edge is to cut the edge in two at its middle point.

InsertVertices. Given a triangular portalgon T, consider every edge e of T^1 that lies in the interior of $\mathcal{S}(T)$, and insert the middle point of e as a vertex in T^1.

Applying **InsertVertices** to a *triangular* portalgon T produces a portalgon T' whose polygons are usually not triangles. We now consider transforming T' into a triangular portalgon. To do that we repeatedly cut the polygons of T'. We need a definition. In the plane consider a polygon P, two vertices $u \neq v$ of P, and the rectilinear segment a between u and v. If the relative interior of a is included in the interior of P then a is called a vertex-to-vertex arc of P. It is easily seen that if P is not a triangle then P has at least one vertex-to-vertex arc. Among the vertex-to-vertex arcs of P, the shortest ones are the **shortcuts** of P. We emphasize that we consider the shortest ones among all the vertex-to-vertex arcs, without fixing the endpoints, but the endpoints are chosen among the vertices of P. In a portalgon T every polygon P corresponds to a face F of T^1, and every shortcut of P corresponds to a path whose relative interior is included in F: we say of this path that it is a shortcut of F.

InsertEdges. Given a portalgon T, as long as there is a face of T^1 that is not a triangle, insert a shortcut of this face as an edge in T^1.

We shall apply **InsertVertices** followed by **InsertEdges** to a triangular portalgon T in order to produce another triangular portalgon T', hopefully with a "nicer geometry". The problem is now that T'^1 has more vertices than T^1. All the other operations of the algorithm are devoted to keeping the number of vertices low.

4.2 Deleting vertices

From now on it is important that every surface considered is flat, there is no singularity in its interior. Given a triangular portalgon T, assuming that the surface $\mathcal{S}(T)$ is flat, we consider decreasing the number of vertices of T^1. To do that we naturally consider deleting some vertices. Not all vertices can be deleted. For example a vertex incident to a loop edge cannot be deleted. Also we will not delete vertices that lie on the boundary of the surface $\mathcal{S}(T)$. A vertex of T^1 is **weak** if it lies in the interior of $\mathcal{S}(T)$ and is not incident to any loop edge in T^1. It is **strong** otherwise.

DeleteVertices. Given a triangular portalgon T whose surface $\mathcal{S}(T)$ is flat, construct a maximal independent set V of weak vertices of T^1 that have degree smaller than or equal to six. For every vertex $v \in V$ delete v and its incident edges from T^1.

After performing **DeleteVertices**, the polygons of T are usually not triangles anymore, but this will be solved by applying **InsertEdges** after each application of **DeleteVertices**. Observe that in **DeleteVertices** we delete only vertices of degree smaller than or equal to six. Informally, the reason is that deleting a weak vertex of degree $d \geq 3$ creates a face of degree d around it. We then insert $d-3$ edges in this face when applying **InsertEdges**. The problem is that only a constant number of edges can be inserted in each face without risking to destroy our improvements on the geometry of the tessellation. This is why we make sure that $d = O(1)$ beforehand. The exact bound on d is not really important (although changing it would change some constants of the algorithm), but it must be at least six so that we can still remove a fraction of the excess vertices this way, at least when most of them are strong. Similar ideas can be found in the literature, see for example Kirkpatrick [16, Lemma 3.2].

4.3 Simplifying tubes

The operation **DeleteVertices** cannot delete strong vertices, and among them the vertices that lie the interior of the surface and are incident to a loop edge. In this section we describe an operation for deleting such vertices.

In order to grasp the intuition, observe, informally, that it is possible that almost all the vertices of T^1 lie in the interior of $\mathcal{S}(T)$ and are incident to a loop edge. Fortunately, it turns out that in this case there must be a sub-portalgon X of T such that X is a tube and the interior of $\mathcal{S}(X)$ contains loop edges of X^1. We delete such loop edges by replacing X by a good biface with Proposition 7. There is one subtlety: we must choose X carefully so that we replace any concatenation of tubes by a single biface when possible, in order to delete the loops in-between the tubes, instead of replacing each tube individually. That leads to:

SimplifyTubes. In a triangular portalgon T whose surface $\mathcal{S}(T)$ is flat, do the following:

1. In T^1 build a set J of loop edges that lie in the interior of $\mathcal{S}(T)$ and are pairwise disjoint, as follows. There are two cases:
   - **a.** If $\mathcal{S}(T)$ is homeomorphic to a torus, do the following. Let J contain two disjoint loop edges of T^1 if there exist two such edges, otherwise let $J = \emptyset$.
   - **b.** Otherwise do the following. Construct a set J' of loop edges by considering every vertex v of T^1 that lies in the interior of $\mathcal{S}(T)$ and is incident to a loop edge, and by putting one of the loop edges incident to v in J'. Then build a subset $J \subseteq J'$ by removing from J' every $e \in J'$ satisfying both of the following. First, cutting $\mathcal{S}(T)$

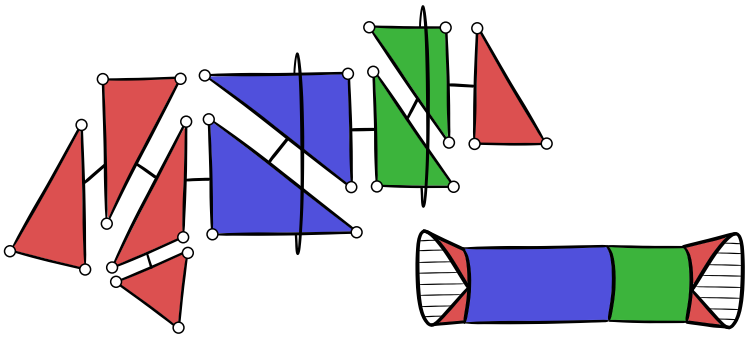

Figure 3 Data structure for **Algorithm**: a portalgon whose polygons are partitioned, here by color, inducing sub-portalgons called regions, and a region singularized as active, here in red.

along the loops in J', and considering the resulting connected components, two such components are adjacent to e (instead of one), say S_0 and S_1. Second, each one of the two sub-portalgons of T whose surfaces are S_0 and S_1 is a tube.

2. Cut the surface $\mathcal{S}(T)$ along the loops in J. Each resulting component is the surface of a sub-portalgon X of T. If X is a tube replace X by a good biface B.

The idea behind step 1b is to remove loops from J' so that step 2 replaces a concatenation of tubes by a single good biface when possible, instead of replacing the tubes individually.

4.4 Data structure for marking bifaces as inactive

We are almost ready to give the algorithm, but there is still one important thing to describe. In step 2 of **SimplifyTubes**, if the good biface B is *thin* we will not just replace X by B, but we will also make sure to not modify B ever again. In this sense B becomes inactive. Doing so requires a data structure remembering which parts of the portalgon are inactive.

See Figure 3. The data structure maintains a portalgon R together with a partition of the polygons of R. Each set X of polygons in the partition defines a sub-portalgon of R which we call **region**. One region is singularized as the **active** region R_A. The other regions are **inactive**. Note that the surface of the active region may be disconnected, and that the surfaces of distinct inactive regions may be adjacent.

The data structure will be initialized by setting $R_A = R$, without inactive region. Then the algorithm will apply the routines **InsertVertices**, **InsertEdges**, **DeleteVertices**, and **SimplifyTubes** to the active region R_A, and mark as inactive every thin biface encountered in step 2 of **SimplifyTubes**. The surface of R_A will diminish over time as more and more regions are marked inactive. This may increase the numbers of connected components and boundary components of $\mathcal{S}(R_A)$, ruining our efforts to keep the combinatorial complexity of R_A bounded. To counteract this, we introduce:

Gardening. Every connected component of $\mathcal{S}(R_A)$ is the surface of a sub-portalgon X of R_A. If X is a tube replace X by a good biface B, and mark B as inactive.

We described everything that the algorithm can do to the data structure. This immediately implies three invariants maintained by the algorithm. First, 1) Every polygon of the active region has degree at most six, and 2) Every inactive region is a good biface. For the last invariant we need a definition. Recall that in R if two sides s and s' of polygons are matched

then s and s' correspond to an edge e of R^1. If moreover s and s' belong to different polygons, and if their respective polygons belong to different regions, we say that e is **separating**. Then e is a loop, for it is a boundary edge of a biface by 2), and e belongs to the interior of $\mathcal{S}(R)$. The third invariant is that 3) The separating loops are pairwise disjoint (no two of them are based at the same vertex of R^1).

4.5 Algorithm

The algorithm repeatedly applies two parts. The first part "improves the geometry" by applying **InsertVertices** and then **InsertEdges**. However this increases the number of vertices. So the second part applies **SimplifyTubes**, **DeleteVertices**, and **InsertEdges**, together with **Gardening**. The second part can only remove a fraction of the vertices at once, so it is repeated several times. It turns out that 350 repetitions suffice.

Algorithm. Given a triangular portalgon T whose surface $\mathcal{S}(T)$ is flat, and $N \geq 1$, do the following. Initialize the data structure by letting R be the input portalgon T, and by letting the active region R_A be R itself, without inactive region. Repeat N times the following:

1. Apply **InsertVertices** to R_A. Then apply **InsertEdges** to R_A.
2. Repeat 350 times the following:
   a. Apply **Gardening**. Then apply **SimplifyTubes** to R_A but in step 2 of **SimplifyTubes**, whenever B is thin, mark B as inactive. Apply **Gardening** again.
   b. Apply **DeleteVertices** to R_A. Then apply **InsertEdges** to R_A.

In the end return R.

When proving Proposition 3, we will apply **Algorithm** with $N = \lceil \log(2 + L/s) \rceil$.

5 Analysis of the algorithm

In this section, we sketch the analysis of **Algorithm** (Section 4) to prove Proposition 3.

5.1 Combinatorial analysis

▶ **Proposition 8.** *Apply* **Algorithm** *to a portalgon T of n triangles, whose surface $\mathcal{S}(T)$ is flat. During the execution the number of polygons of the active region R_A is $O(n)$.*

In this extended abstract, we only sketch the proof of Proposition 8.

Sketch of proof. We consider R^1_A, the 1-skeleton of the active region R_A, and we show that the number m_A of vertices of R^1_A remains $O(n)$ throughout the execution. There are two loops in the algorithm: the main loop, which repeats N times, and the interior loop, which repeats 350 times within each iteration of the main loop. To prove the lemma, we consider a single iteration of the main loop, we assume that m_A exceeds n by at least a constant factor at the beginning of the iteration, and we prove that m_A has decreased after the iteration.

The iteration starts with **InsertVertices**. This is the only moment where m_A may increase, and we prove that m_A is multiplied by at most a constant factor. Then the iteration applies the interior loop, and we claim that, as long as m_A exceeds n by a constant factor, m_A is divided by at least a constant factor by each iteration of the interior loop. We show that this claim implies the lemma as the interior loop is applied sufficiently many times to counteract the initial increase of m_A. To prove the claim, we show that for **DeleteVertices** to remove a fraction of the vertices of R^1_A, it suffices that m_A vastly exceeds the genus and the number of boundary components of $\mathcal{S}(R_A)$, and that almost all of the vertices of R^1_A are weak. We show that this is ensured by first applying **Gardening** and **SimplifyTubes**. ◀

5.2 Enclosure

To analyze **Algorithm** from a geometric point of view, we introduce, on the segments of a flat surface S, a parameter that we call *enclosure*. So consider a segment e of S. See Figure 4.

Informally, e is "enclosed" in S when a short non-contractible loop can be attached to a point of e not too close to the endpoints of e. Formally, consider a point x in the relative interior of e. We denote by $\langle x \rangle_e$ the minimum length of the two sub-segments of e separated by x. Assume that there exists a loop γ based at x in S, such that γ is geodesic except possibly at its basepoint. Further assume that its length satisfies $\ell(e) < \langle x \rangle_e$. In this case γ and e are necessarily in *general position*: informally, they do not overlap, more formally, every sufficiently short sub-path of γ is either disjoint from e or its intersection with e is a single point. There are two cases: either γ crosses e at x, or γ meets x on only one side of e. If γ crosses e at x, then we say that γ **encloses** e **in** S. Also we say that γ encloses e **by a factor of** $\langle x \rangle_e / \ell(\gamma)$ in S. The **enclosure** $c_S(e) \geq 1$ is the supremum of the ratios $\langle x \rangle_e / \ell(\gamma)$ over all the basepoints x in the relative interior of e, and over all the loops γ based at x that enclose e in S. It is conventionally set to one if there is no loop enclosing e in S.

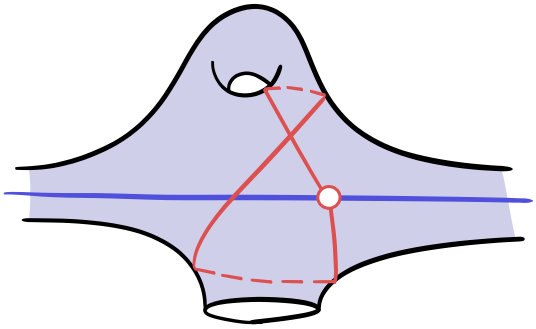

Figure 4 The red loop encloses the blue segment in the surface.

The segment-happiness $h_S(e)$ and the length $\ell(e)$ can be bounded from above using the enclosure $c_S(e)$. Our bound depends on the surface S. More precisely, on the systole of S and the diameter of S. But instead of the diameter of S, we consider a triangulation of S, and we use its number n of triangles together with the maximum length L of its edges. This will be more convenient to us when analyzing **Algorithm**. We prove:

▶ **Proposition 9.** *Let e be a segment of S. Let $s > 0$ be smaller than the systole of S. Assume that there is a triangulation of S with $n \geq 1$ triangles, whose edges are all smaller than $L > 0$. Then $h_S(e) = O(c_S(e) \cdot (1 + \log c_S(e) + \log n + \log\lceil L/s \rceil))$ and $\ell(e)/s = O(c_S(e) \cdot n \cdot \lceil L/s \rceil^2)$.*

In Proposition 9 the $O()$ notation does not depend on S, it involves a universal constant. In the second inequality of Proposition 9 the exact powers above $\lceil L/s \rceil$ and n, here 2 and 1, do not matter to us. We need only a polynomial in $\lceil L/s \rceil$ and n.

5.3 Geometric analysis

The geometric analysis of **Algorithm** consists in two properties on the enclosure and the length of the edges involved in any execution: Lemma 10 and Proposition 12 below, whose proofs we sketch in Section 5.3.1 and Section 5.3.2. Each proof relies on properties of enclosure that are independent of **Algorithm**, or of any portalgon, and can be seen as independent mathematical contributions of us. In this extended abstract we only explain how these properties of enclosure serve to analyse **Algorithm**.

In this section, we fix a portalgon T of n triangles, whose sides are smaller than some positive real L, and whose surface $\mathcal{S}(T)$ is flat. We abbreviate $S = \mathcal{S}(T)$. We apply the algorithm **Algorithm** to T, and we discuss the execution of the algorithm.

5.3.1 The separating loops are not very enclosed

▶ **Lemma 10.** *Any time during the execution every separating loop e satisfies $c_S(e) \leq 2$.*

Lemma 10 follows from the following property of enclosure:

▶ **Proposition 11.** *Assume that S contains the surface of a thin biface B, and let e be one of the two boundary edges of B^1. Then $c_S(e) \leq 2$.*

Proof of Lemma 10. Only step 2 of **SimplifyTubes** may create a separating loop, by marking a *thin* biface B as inactive. Then B is is never touched again by the algorithm. So the algorithm maintains the invariant that every separating loop e is adjacent to the surface of at least one inactive region that is a *thin* biface. So $c_S(e) \leq 2$ by Proposition 11. ◀

5.3.2 The very enclosed edges shorten exponentially fast

▶ **Proposition 12.** *After $i \geq 1$ iterations of the main loop, let e be an edge of R^1_A. If $c_S(e) > 22000 \cdot i$ then $\ell(e) < 2^{1-i}L$.*

To prove Proposition 12, we analyze each routine applied. Informally, each application of **InsertVertices** "improves the geometry" of the active region, and the rest of the algorithm does not deteriorate this improvement too much. Formally:

▶ **Lemma 13.** *Consider the active regions R_A and R'_A respectively before and after some application of* **InsertVertices**. *Assume that there is an edge e' of R'^1_A such that $c_S(e') > 2$. Then there is an edge e of R^1_A such that $c_S(e) \geq c_S(e')$ and $\ell(e) \geq 2\ell(e')$.*

Lemma 13 follows from the following (easy) property of enclosure:

▶ **Lemma 14.** *Let $f \subseteq e$ be segments in S. Then $c_S(e) \geq c_S(f)$.*

Proof of Lemma 13. First observe that e' is not included in the boundary of $\mathcal{S}(R'_A)$ because e' is enclosed and thus not included in the boundary of S, and because e' is not a separating loop by Lemma 10. So there is an edge e of R^1_A such that e' is one of the two half-segments obtained after the insertion of the middle point of e as a vertex. Then $\ell(e) = 2\ell(e')$. And $c_S(e) \geq c_S(e')$ by Lemma 14. ◀

▶ **Lemma 15.** *Consider the active regions R_A and R'_A respectively before and after some application of* **InsertEdges**. *Assume that there is an edge e' of R'^1_A such that $c_S(e') > 14$. Then there is an edge e of R^1_A such that $c_S(e) \geq c_S(e') - 12$ and $\ell(e) \geq (1 - 12/c_S(e')) \cdot \ell(e')$.*

Lemma 15 follows from the following (key) property of enclosure:

▶ **Proposition 16.** *Let F be a face of a tessellation of S. Assume that F has a shortcut e such that $c_S(e) > 6$. Then F has a side f such that $c_S(f) \geq c_S(e) - 4$ and $\ell(f) \geq (1 - 4/c_S(e)) \cdot \ell(e)$.*

Proof of Lemma 15. Here we crucially use the fact that every polygon of R_A has degree at most six. so that at most three edges are inserted within the polygon. Indeed either e' was already an edge of R^1_A and there is nothing to do, or e' has been inserted in some face F of R^1_A. At most three edges were inserted in F, and Proposition 16 applied at most three times gives a boundary edge e of F such that $c_S(e) \geq c_S(e') - 12$ and $\ell(e) \geq (1 - 12/c_S(e'))\ell(e')$. ◀

▶ **Lemma 17.** *Consider the active regions R_A and R'_A respectively before and after some application of* **SimplifyTubes**. *Assume that there is an edge e' of R'^1_A such that $c_S(e') > 6$. Then there is an edge e of R^1_A such that $c_S(e) \geq c_S(e') - 5$ and $\ell(e) \geq (1 - 4/c_S(e')) \cdot \ell(e')$.*

Lemma 17 is similar to Lemma 15, its proof is omitted in this extended abstract.

Proof of Proposition 12. Consider the active regions R_A and R'_A respectively at the beginning of the algorithm, and after i iterations of the main loop. Assume that there is an edge e' in R'^1_A such that $c_S(e') > 22000 \cdot i$. During those i iterations there has been i applications of **InsertVertices**, $351i$ applications of **InsertEdges**, and $350i$ applications of **SimplifyTubes**. Also $12 \cdot 351i + 5 \cdot 350i < 11000i$. So Lemma 13, Lemma 15, and Lemma 17 imply that there is an edge e in R^1_A such that $\ell(e) \geq 2^i(1 - 11000i/c_S(e'))\ell(e') > 2^{i-1}\ell(e')$. And $\ell(e) \leq L$ because e belongs to the input triangulation T^1. ◀

5.4 Proof of Proposition 3

We need a last (easy) lemma:

▶ **Lemma 18.** *Let S be a flat surface. Assume that S contains the surface of a tube X. Then the systole of $\mathcal{S}(X)$ is greater than or equal to the systole of S.*

Proof of Proposition 3. Apply **Algorithm** to T with $N = \lceil \log(2 + L/s) \rceil$, resulting in a triangular portalgon R. By Proposition 8 the number of polygons of the active region is $O(n)$ throughout the execution. So in the end R has $O(n \cdot \log(2 + L/s))$ triangles; Indeed each iteration of the main loop marks $O(n)$ triangles as inactive, and there are $\lceil \log(2 + L/s) \rceil$ iterations of the main loop. We have two claims that immediately imply the proposition.

Our first claim is that the algorithm takes $O(n \log^2(n) \cdot \log^2(2 + L/s))$ time. Let us prove this first claim. Each application of **InsertVertices** or **InsertEdges** takes $O(n)$ time. And each application of **SimplifyTubes** or **Gardening** takes $O(n \log(n) \cdot \log(2 + \Lambda/s))$ time by Proposition 7 and Lemma 18, where Λ is the maximum length reached by an edge of the 1-skeleton of the active region during the execution. Now let us bound Λ. If at some point an edge e of the 1-skeleton of the active region is longer than L then $c_S(e) = O(\log(2 + L/s))$ by Proposition 12. Moreover $\ell(e)/s = O(c_S(e) \cdot n\lceil L/s \rceil^2)$ by Proposition 9. This proves $\log(2 + \Lambda/s) = O(\log(n) + \log(2 + L/s))$, which proves the claim.

Our second claim is that in the end every edge e of R^1 satisfies $h_S(e) = O(\log(n) \cdot \log^2(2 + L/s))$. Let us prove this second claim. First observe that if e is in R^1_A then $c_S(e) < 22000 \log(2 + L/s)$, for otherwise Proposition 12 would imply $\ell(e) < 2s$, implying that no loop encloses e in S, a contradiction. In this case $h_S(e) = O(\log(2 + L/s) \cdot (\log(n) + \log(2 + L/s)))$ by Proposition 9, and we are done. Every other edge of R^1 belongs to the 1-skeleton of an inactive good biface B. Every boundary edge e of B^1 is either a boundary component of S or a separating loop, so $c_S(e) \leq 2$ by Lemma 10, and so $h_S(e) = O(\log(n) + \log(2 + L/s))$ by Proposition 9. Every interior edge f of B^1 then satisfies $h_S(f) = O(\log(n) + \log(2 + L/s))$ by Lemma 6. This proves the second claim, and the proposition. ◀

Abstract

The depth poset of a filtered Lefschetz complex reflects the dependencies between the cancellations of different shallow birth-death pairs. Using the fast algorithms for computing the depth poset in [9] and for updating the persistence diagram under transpositions in [7], we give a complete case analysis of how transpositions of cells in the filter affect the depth poset. In addition, we present statistics on the depth poset for random point data and its sensitivity to the transpositions that occur in random straight-line homotopies.

1 Introduction

The field of *topology optimization* aims at the design of shapes whose large- and small-scale connectivity is subject to modifications applied in order to satisfy constraints and optimize objective functions. The traditional approach is numerical and optimizes through repeated local improvement; see the text by Bendsøe [4] and the major revision by Bendsøe and Sigmund [5]. More recently, the methods of topological data analysis have matured and provide an alternative approach to this seasoned problem; see e.g. the "big steps" algorithm by Nigmetov and Morozov [19], which is closely related to the work presented in this paper. Specifically, we aim at exploring the space of shapes that relate to each other through the

cancellation and interchange of the critical points of a function. This is naturally related to the simplification of functions and shapes, as studied in [1, 3, 11], but goes beyond this work by casting light on the space of possible simplifications.

An overarching goal for the presented work is to uncover the potential new tools from combinatorial dynamics pioneered by Forman [13, 12], offering discrete counterparts for classic concepts such as the Conley index, Morse decomposition, and connection matrix [16, 17, 18].

The primary technical prerequisites for our work are the depth poset of a filter on a complex, as introduced in [9], the well established concept of persistent homology; see the text by Edelsbrunner and Harer [10], and the vineyard algorithm for computing persistence along a parametrized family of functions, as originally described in [7]. The depth poset collects all dependencies between cancellations of *shallow birth-death pairs* (formerly known as *apparent pairs* [2] and *close pairs* [8]) and thus provides a global yet discrete representation of the space of shapes reachable by sequences of such cancellations. We mention that shallow pairs appeared in other seemingly unrelated contexts, for example in fast adaptive sorting [20]. Our main contribution is the complete case analysis of how transpositions in the filter affect the depth poset. Working toward establishing the depth poset as a first class object, we also present statistics on the size and shape of this poset and its variation under transpositions.

Outline. Section 2 explains the technical background needed for our results. Section 3 gives the complete case analysis of how a transposition in the filter affects the depth poset of the same. Section 4 presents statistical results that probe the depth poset and homotopies between them for random PL height functions on Delaunay mosaics of Poisson point processes.

2 Background

This section presents the background we need to study the relations and orders in which our results are couched. Besides standard material, we need concepts from persistent homology and its matrix reduction algorithms. We refer to [10] for more comprehensive background.

Relations. We adapt the terminology from graph theory, in which a relation consists of *(directed) arcs* that connect *nodes*. Each arc goes from its *source* to its *target*, both of which are nodes. A *(directed) path* is a sequence of arcs such that the target of each arc is the source of the next arc, and it goes from the source of the first arc to the target of the last arc. It is a *directed cycle* if the target of the last arc is also the source of the first arc. The relation is *acyclic* if it has no directed cycle. Note however that an acyclic relation may have *undirected cycles*, such as two disjoint paths that connect the same two nodes.

An acyclic relation has a unique *transitive closure*, which is the possibly larger (acyclic) relation that has an arc from a source to a target whenever there is such a path. A *partial order* is an acyclic relation that is its own transitive closure, and in situations where we wish to emphasize the nodes rather than the arcs, we refer to it as a *partially ordered set*, or a *poset*, for short. Two nodes in a poset are *comparable* if there is an arc that connects them, and we write $a \leq b$ if a is the source and b is the target of the connecting arc. A *total order* is a partial order in which any two nodes are comparable. It is a *linear extension* of a partial order on the same nodes if $a \leq b$ in the partial order implies $a \leq b$ in the total order.

In this paper we work with Lefschetz complexes with coefficients in $\mathbb{Z}/2\mathbb{Z}$ for simplicity, which can be viewed as chain complexes with a fixed bases. In particular, they avoid the complications that come with concrete geometric descriptions of the cells. This type of complex was introduced first under the more modest name of a *complex* in the book by Lefschetz [15]. We borrow the below definition from [9].

▶ **Definition 2.1.** *A* Lefschetz complex *with coefficients in* $\mathbb{Z}/2\mathbb{Z}$ *is a triplet* $(K, \dim, \kappa)$*, in which* K *is a finite set of elements, called* cells*,* $\dim\colon K \to \mathbb{Z}$ *maps each cell to its* dimension*, and* $\kappa\colon K \times K \to \mathbb{Z}/2\mathbb{Z}$ *is the* incidence map *satisfying* $\sum_{y \in K} \kappa(z,y) \cdot \kappa(y,x) = 0$ *for all* $z, x \in K$ *and* $\kappa(y,x) \neq 0$ *only if* $\dim y = \dim x + 1$*. For simplicity, we write just* K *for a Lefschetz complex assuming that* dim *and* κ *are implied. If* $\kappa(y,x) \neq 0$*, then we say that cell* x *is a* facet *of* y *and cell* y *is a* cofacet *of* x*, we denote this relation by* $x \preceq y$*. The transitive closure of the facet relation forms a partial order on* K *called the* face relation*.*

An injective function on a complex, $f\colon K \to \mathbb{R}$, that satisfies $f(a) < f(b)$ whenever $a \prec b$ is called a *filter* of K. A total order in which a precedes b iff $f(a) < f(b)$ is then a linear extension of the face relation; see the left panel of Figure 1.

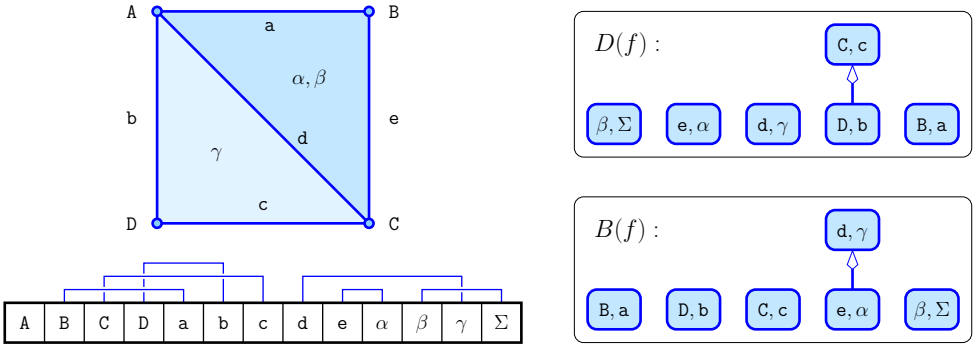

Figure 1 *Upper left:* a complex with four vertices, five edges, three triangles (α, β, γ, in which α and β have the same boundary), and one 3-cell (Σ, which is sandwiched between α and β). *Lower left:* the ordering implied by a filter, with birth-death pairs as indicated (see definition below). *Right:* the death and birth relations on the birth-death pairs as computed by Algorithms 1 and 2 below.

Persistent Homology and Transpositions. Given a filter on a complex, $f\colon K \to \mathbb{R}$, we construct the complex by adding one cell at a time following the implied order. After adding i cells, we arrive at a subcomplex $K_i \subseteq K$, and we refer to the resulting sequence of subcomplexes as a *filtration* of K. Fixing a dimension, p, and a coefficient field, e.g. $\mathbb{Z}/2\mathbb{Z}$, we apply the degree-p homology functor to each subcomplex and thus get a linear sequence of vector spaces connected by linear maps:

$$\mathsf{H}_p(\emptyset) = \mathsf{H}_p(K_0) \to \mathsf{H}_p(K_1) \to \ldots \to \mathsf{H}_p(K_n) = \mathsf{H}_p(K); \tag{1}$$

see e.g. [14] for the needed background in algebraic topology. Whenever the added cell has dimension p, it either gives *birth* to a degree-p homology class or it gives *death* to a degree-$(p-1)$ homology class. This is classic Morse theory, and the novelty in persistence is that for each death-giving $(p+1)$-cell we find a unique birth-giving p-cell whose class it ends. We call these the degree-p *birth-death pairs* of f, denoted $BD_p(f)$. It is also possible that some birth-giving p-cells do not get paired, and they reflect the degree-p homology of K. A convenient combinatorial representation of this information is the *persistence diagram*, denoted $\mathrm{Dgm}_p(f)$, which maps $(a,b) \in BD_p(f)$ to the point $(f(a), f(b)) \in \mathbb{R}^2$.

An important property is the stability of the persistence diagram, originally proved in [6]. In a nutshell, it says that for two monotonic functions, $f, g\colon K \to \mathbb{R}$, there is a bijection between $\mathrm{Dgm}_p(f)$ and $\mathrm{Dgm}_p(g)$ such that the maximum coordinate difference between corresponding points is bounded from above by the absolute maximum of $f(a) - g(a)$ over all cells $a \in K$. This will be instrumental in the following construction.

Consider two filters, $f_0, f_1 \colon K \to \mathbb{R}$, and the straight-line homotopy defined by $f_\lambda(a) = (1-\lambda)f_0(a) + \lambda f_1(a)$ for $0 \leq \lambda \leq 1$. These functions imply a 1-parameter family of persistence diagrams for each dimension p. Mapping every point $(f_\lambda(a), f_\lambda(b)) \in \mathrm{Dgm}_p(f_\lambda)$ to $(f_\lambda(a), f_\lambda(b), \lambda) \in \mathbb{R}^3$, we effectively stack up these diagrams, and because of stability, the points form continuous curves in $\mathbb{R}^3$. Following the terminology in [7], we call these curves *vines* and the collection of vines a *vineyard*. Assuming K is finite, there are only finitely many values of λ for which f_λ is not a filter (because it assigns the same value to at least two cells). These values split $[0,1]$ into finitely many open intervals with a unique ordering of the cells in each. In the generic case, the orderings in any two consecutive intervals differ by a single *transposition* of two adjacent cells. Such a transposition may or may not affect the birth-death pairs, and if it does, we call it a *switch*. As established in [7], there are only three kinds of switches: the *BB-type*, which swaps the birth-giving cells between two pairs, the *DD-type*, which swaps the death-giving cells between two pairs, and the *BD-type*, which swaps a birth-giving with a death-giving cell; see Figure 2. Observe that in the first two cases, the two affected points belong to the same-degree persistence diagram, while in the third case the affected points belong to persistence diagrams of consecutive degrees.

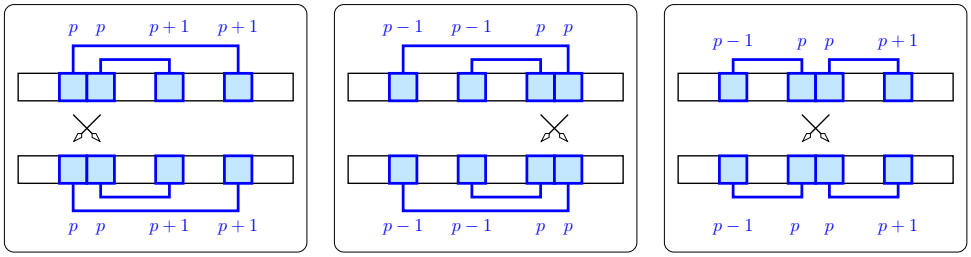

Figure 2 The three types of switches. *From left to right:* swapping two birth-giving cells (BB-type), swapping two death-giving cells (DD-type), and swapping a birth-giving with a death-giving cell (BD-type). In the first two cases, the intervals that correspond to the pairs are nested – before and after the switch – and in the third case, they are disjoint – again before and after the switch.

Cancellation of Shallow Pairs. Given a filtered Lefschetz complex, we are interested in simplifying it. The natural operation to this end is the *cancellation* of a cell b with one of its facets a. The operation produces a new Lefschetz complex $(K', \dim', \kappa')$ where $K' = K \setminus \{a, b\}$, $\dim'$ is the restriction of dim to K', and the new incidence map is defined for $x, y \in K'$ by $\kappa'(y, x) = \kappa(y, x) + \kappa(y, a) \cdot \kappa(b, x)$; see the schematic cancellation of the pair (a, b) in Figure 3.

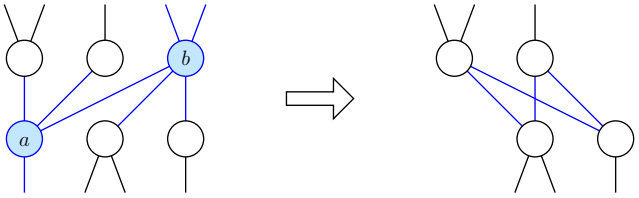

Figure 3 To cancel $a \prec b$, we connect all facets of b to all cofacets of a. The remainder of the face relation is unchanged.

A cancellation may have side-effects, such as changing the homotopy type of the complex or making a cell a facet of another cell that precedes it in the filter. In contrast, a cancellation preserves the homology of the Lefschetz complex [9]. To avoid the need to reorganize the

filter, we restrict ourselves to cancellations where this is not necessary. Even more, we restrict ourselves to canceling *shallow pairs*, $a \prec b$, for which a is the last facet of b and b is the first cofacet of a in the ordering of the filter; see [9] but also [2], where they are referred to as *apparent pairs*. If $a \prec b$ is a shallow pair, then all other facets of b precede a and all other cofacets of a succeed b, so the new filter is obtained by removing a and b, and no reordering is necessary. The following basic properties are obvious or proved in [9]:

- every shallow pair is a birth-death pair of the filter;
- after a shallow pair is canceled, the remaining birth-death pairs are unchanged;
- there is at least one shallow pair, unless the face relation is empty.

Because of the third property, we can keep canceling shallow pairs until the face relation runs empty. We call the resulting sequence of canceled pairs a *shallow cancellation order*, which by the first two properties is a total order of the birth-death pairs of the original filter. However, there may be many orderings of the birth-death pairs such that each pair is shallow at the time it gets canceled, which motivates the next concept.

▶ **Definition 2.2.** *The* depth poset *of a filter on a Lefschetz complex, $f\colon K \to \mathbb{R}$, is the intersection of all shallow cancellation orders of f, denoted* $\mathrm{Depth}(f)$.

This concept was introduced in [9], along with some of its fundamental properties, which we state without proof.

▶ **Lemma 2.3.** *Let $f\colon K \to \mathbb{R}$ be a filter on a Lefschetz complex, $\varphi = (x, y)$ and $\psi = (a, b)$ two birth-death pairs of f, (φ, ψ) an arc in* $\mathrm{Depth}(f)$, *$\sigma = (s, t)$ a shallow pair of f, and $f'\colon K \setminus \{s, t\}$ the filter after canceling σ. Then*

1. *nodes connected by an arc in* $\mathrm{Depth}(f)$ *are nested; that is: $f(a) < f(x) < f(y) < f(b)$;*
2. *arcs of* $\mathrm{Depth}(f)$ *respect dimensions; that is:* $\dim a = \dim x$ *and* $\dim b = \dim y$;
3. *canceling σ has no side-effects; that is:* $\mathrm{Depth}(f') = \mathrm{Depth}(f) \cap [BD(f') \times BD(f')]$.

By Property 2, $\mathrm{Depth}(f)$ is the disjoint union of posets $\mathrm{Depth}_p(f) \subseteq BD_p(f) \times BD_p(f)$.

Matrix Reduction Twice. While the definition of the depth poset is constructive, it is in terms of possibly exponentially many total orders on the birth-death pairs. Alternatively, it can be constructed as the transitive closure of two relations, both of which can be computed efficiently by reducing the boundary matrix of the complex. We review the algorithms and refer to [9] for a proof of correctness.

▶ **Definition 2.4.** *The* death relation *of a filter on a Lefschetz complex, $f\colon K \to \mathbb{R}$, denoted $D(f) \subseteq BD(f) \times BD(f)$, records the left-to-right column operations during the reduction of the boundary matrix in reverse order of the birth-giving cells; see Algorithm 1.*

The arcs in the death relation correspond to the off-diagonal non-zero entries in the columns of death-giving cells in U_1:

$$D(f) = \{((x, y), (a, b)) \in BD(f) \times BD(f) \mid y \neq b \text{ and } U_1[y, b] = 1\}. \tag{2}$$

To make sense of U_1, consider the matrix V_1 that stores the chains whose boundaries are the cycles in R_1. Initially, V_1 is the identity matrix and we maintain it by applying the same column operations as performed on R_1. If we ignore the deletions of rows and columns, we retain the matrices in their original sizes, and it is not difficult to see that they satisfy $R_1 = \Delta V_1$ and $\Delta = R_1 U_1$ throughout the algorithm, so $U_1 = V_1^{-1}$.

▶ **Definition 2.5.** *The* birth relation *of a filter on a Lefschetz complex, $f\colon K \to \mathbb{R}$, denoted $B(f) \subseteq BD(f) \times BD(f)$, records the bottom-to-top row operations during the reduction of the boundary matrix in the order of the death-giving cells; see Algorithm 2.*

Algorithm 1 Bottom to Top Column Reduction.

Input: Δ (the boundary matrix)
Output: R_1U_1 (a decomposition of Δ)

$R_1 = \Delta$; $U_1 = \mathrm{Id}$;
while $R_1 \neq 0$ **do**
  let $R_1[x, y]$ be the leftmost non-zero entry in the lowest non-zero row;
  while $\exists b > y$ such that $R_1[x, b] = 1$ **do**
    add column y to column b in R_1; $U_1[y, b] = U_1[y, b] + 1$
  end while;
  delete row x and column y from R_1
end while.

Algorithm 2 Left to Right Row Reduction.

Input: Δ (the boundary matrix)
Output: R_2U_2 (a decomposition of Δ)

$R_2 = \Delta$; $U_2 = \mathrm{Id}$;
while $R_2 \neq 0$ **do**
  let $R_2[x, y]$ be the lowest non-zero entry in the leftmost non-zero column;
  while $\exists a < x$ such that $R_2[a, y] = 1$ **do**
    add row x to row a in R_2; $U_2[a, x] = U_2[a, x] + 1$
  end while;
  delete row x and column y from R_2
end while.

The arcs in the birth relation correspond to the off-diagonal non-zero entries in the rows of birth-giving cells in U_2:

$$B(f) = \{((x, y), (a, b)) \in BD(f) \times BD(f) \mid x \neq a \text{ and } U_2[a, x] = 1\}. \tag{3}$$

To rationalize U_2, we introduce the matrix V_2 that stores the chains whose coboundaries are the cocycles, i.e. $R_2 = V_2\Delta$ assuming we ignore the deletions of rows and columns. Similarly $\Delta = U_2R_2$, so $U_2 = V_2^{-1}$.

The right panel of Figure 1 shows examples of the death and birth relations of a filter. A noteworthy feature of this example are the pairs $(\mathtt{d}, \gamma)$ and (β, Σ). In spite of the fact that $\mathtt{d}$ is an edge of β, which prevents $(\mathtt{d}, \gamma)$ from being shallow, there is no arc connecting the two pairs in the depth poset. Indeed, the two pairs are neither nested nor do their dimensions match, so an arc would contradict the first two properties in Lemma 2.3. Hence, it must be possible to cancel $(\mathtt{d}, \gamma)$ before canceling (β, Σ), and this can indeed be done if we first cancel $(\mathtt{e}, \alpha)$, which is the sole predecessor of $(\mathtt{d}, \gamma)$ in the poset. Geometrically, the cancellation of $(\mathtt{e}, \alpha)$ attaches β to $\mathtt{d}$ twice, which in modulo-2 arithmetic is counted as no attachment.

It is not difficult to see that the two relations are neither necessarily their own transitive closures nor necessarily their own transitive reductions, and while they express different pieces of information, they are not necessarily disjoint. Nevertheless, they determine the depth poset as the transitive closure of their union; see [9] for a proof. This is important so we state the claim more formally.

▶ **Theorem 2.6.** *Let $f\colon K \to \mathbb{R}$ be a filter on a Lefschetz complex. Then* $\mathrm{Depth}(f)$ *is the transitive closure of $D(f) \cup B(f)$.*

3 Case Analysis

A transposition preserves all birth-death pairs, unless it is a switch, in which case the two transposed cells replace each other in their respective pairs. Consider for example the filter in Figure 1 and entertain what happens when we transpose the edges c and d. Comparing Figures 1 and 4, we note that (C, c) and (d, γ) got replaced by (C, d) and (c, γ), and the death and birth relations both lost their only arc. It should however be noted that a transposition

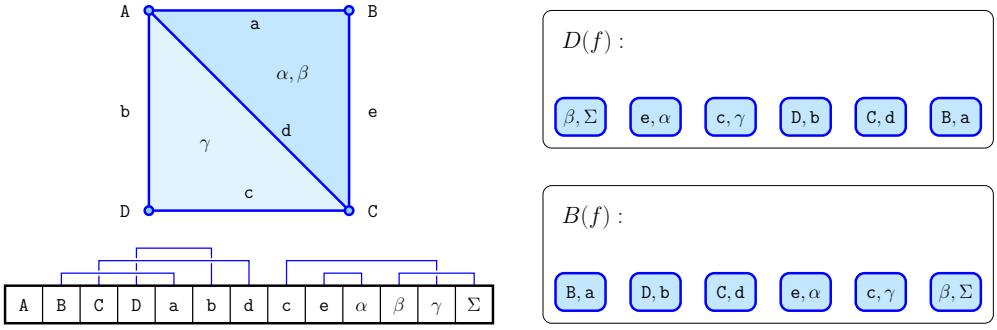

Figure 4 The only difference to the example in Figure 1 is the order of the edges c and d. To the *right*, we see the death and birth relations, which are both empty.

may change the depth poset without affecting the birth-death pairs. To see this, we organize a complete case analysis along the classification of transpositions into three types: of two birth-giving cells, of two death-giving cells, and of a birth-giving with a death-giving cell.

Prior to the case analysis, we state two lemmas that will both be repeatedly used. The first excludes certain configurations of birth-death pairs.

▶ **Lemma 3.1.** *Let $f\colon K \to \mathbb{R}$ be a filter on a Lefschetz complex, and $a \prec y$ two cells in K. If a is the last facet of y in the ordering implied by f, and a is not yet paired when we encounter y in the ordering of the filter, then (a, y) is a birth-death pair of f.*

Proof. Consider the standard matrix reduction algorithm for persistent homology, which reduces the columns of the ordered boundary matrix from left to right. Since a is the last facet of y, the lowest non-zero entry in column y is in row a. When the algorithm arrives at y, a is not yet paired, so there is no pivot in its row. It follows that this entry remains and becomes a pivot, which is equivalent to (a, y) becoming a birth-death pair. ◀

The second lemma addresses a property of ordered boundary matrices that amounts to a reformulation of Lemma 4.6 in [9]. We state it without proof.

▶ **Lemma 3.2.** *Let $f\colon K \to \mathbb{R}$ be a filter on a Lefschetz complex, Δ the corresponding ordered boundary matrix, x a row of Δ, and y a column of Δ. Then any two boundary matrices obtained by canceling all birth-death pairs with pivots below row x or to the left of column y following shallow but possibly different cancellation orders are the same.*

3.1 Case I: Birth-birth Transpositions

Let (x, y) and (a, b) be two nested or otherwise overlapping birth-death pairs with matching dimension, so $f(a) < f(x) < f(y) < f(b)$ or $f(x) < f(a) < f(y) < f(b)$ and $\dim a = \dim x = \dim y - 1 = \dim b - 1$. As illustrated in Figure 5, we assume that a and x are consecutive in the ordering, so either the two pairs are incomparable in the depth poset, or they are

connected by an arc but not by a path of two arcs. To prepare the analysis, we cancel the birth-death pairs whose pivots are below row x or to the left of column y in the ordered boundary matrix. By Lemma 3.2, the sequence in which these pairs are canceled does not affect the remaining portion of the boundary matrix. After the cancellations, (x, y) is shallow and (a, b) is either shallow or has (x, y) as its sole predecessor in the depth poset. Similarly, we cancel all birth-death pairs with pivots below row a or to the left of column y in the boundary matrix after transposing a and x. The two operations commute, so we can alternatively transpose a and x after the mentioned cancellations. Refer to Figure 5 for the three sub-cases as defined after the initial cancellations:

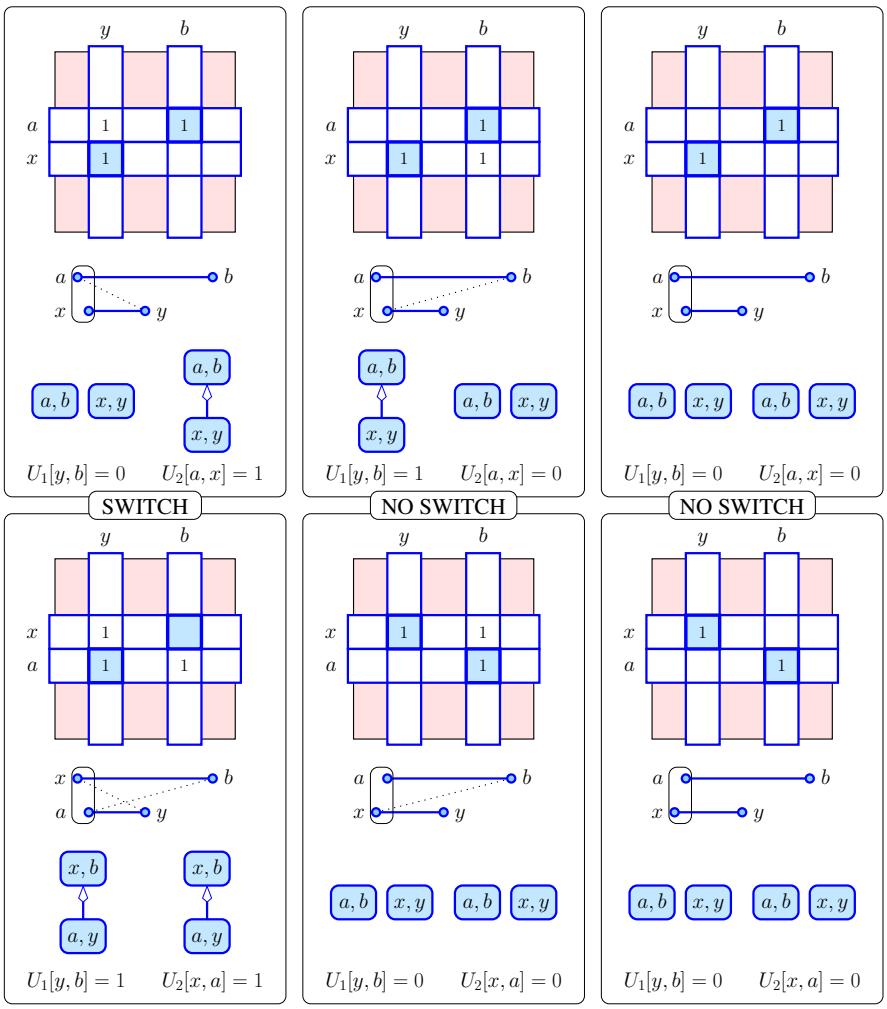

Figure 5 The configurations before and after the transposition of two birth-giving cells. *From left to right:* Cases I.1, I.2, I.3, with the configuration before and after the transposition at the *top* and the *bottom*, respectively, or vice versa for the inverse transposition. Within each panel, we show the relevant birth- and death-giving cells as rows and columns of the boundary matrix, respectively, the two birth-death pairs as bars with *dotted* face relation, and the corresponding nodes and arcs in the death and birth relations.

Case I.1: $a \prec y$ and $x \not\prec b$, as illustrated in the upper left panel of Figure 5. Since (a, b) is not shallow, it must be that (x, y) precedes (a, b) in the depth poset before the transposition of a and x. To see that the transposition is a switch note that after transposing, a is

the last facet of y and is not yet paired before we encounter y from the left, so (a, y) is a birth-death pair by Lemma 3.1. By the stability of the persistence diagram [6], (x, b) is another pair after the transposition, and the remaining pairs are unchanged; see the lower left panel of Figure 5. Finally, reading the two panels from bottom to top, we have the inverse switch defined by $x \prec y$ and $a \prec b$.

Case I.2: $a \not\prec y$ and $x \prec b$, as illustrated in the upper middle panel of Figure 5. Like in Case I.1, (x, y) is a predecessor of (a, b) before the transposition of a and x. Since a is not a facet of y, (x, y) remains shallow, so the transposition is not a switch. But since the two pairs are no longer nested, they are also no longer comparable by Lemma 2.3; see the lower middle panel of Figure 5. Reading the two panels from bottom to top, we have the inverse transposition defined by $a \not\prec y$ and $x \prec b$, but now for two overlapping pairs.

Case I.3: $a \not\prec y$ and $x \not\prec b$, as illustrated in the upper right panel of Figure 5. Like in Case I.2, the transposition of a and x maintains (x, y) as a shallow pair, so the transposition is not a switch. The two pairs are incomparable before the transposition because x is not a facet of b and y is not a cofacet of a, and after the transposition because the pairs are no longer nested; see the lower right panel of Figure 5. The inverse transposition is defined by $a \not\prec y$ and $x \not\prec b$, but now for pairs that are neither nested nor disjoint.

When the transposition of a and x is not a switch, then the changes described in Cases I.2 and I.3 are exhaustive, but if it is a switch, there may be changes beyond those described in Case I.1. We need notation to describe them. Letting $\varphi = (x, y)$ and $\psi = (a, b)$ be two birth-death pairs, the former is a predecessor of the latter in the death relation if $U_1[y, b] = 1$ and in the birth relation if $U_2[a, x] = 1$. We therefore write

$$\mathrm{Pred}_1(a,b) = \{\varphi \mid (\varphi,\psi) \in D\} = \{(x,y) \in BD(f) \mid y \neq b \text{ and } U_1[y,b] = 1\}; \tag{4}$$
$$\mathrm{Pred}_2(a,b) = \{\varphi \mid (\varphi,\psi) \in B\} = \{(x,y) \in BD(f) \mid a \neq x \text{ and } U_2[a,x] = 1\}; \tag{5}$$
$$\mathrm{Succ}_1(a,b) = \{\varphi \mid (\psi,\varphi) \in D\} = \{(x,y) \in BD(f) \mid b \neq y \text{ and } U_1[b,y] = 1\}; \tag{6}$$
$$\mathrm{Succ}_2(a,b) = \{\varphi \mid (\psi,\varphi) \in B\} = \{(x,y) \in BD(f) \mid x \neq a \text{ and } U_2[x,a] = 1\}, \tag{7}$$

and $\mathrm{Pred}_1^{\mathrm{bef}}(a,b)$, $\mathrm{Pred}_1^{\mathrm{aft}}(a,b)$ for the sets before and after a transposition, etc. We begin with the changes of the successors in the death relation and write $\oplus$ for the symmetric difference operation between sets.

▶ **Lemma 3.3.** *Let $f\colon K \to \mathbb{R}$ be a filter on a Lefschetz complex, (x, y) and (a, b) birth-death pairs of matching dimension, a precedes x, y precedes b, and a, x are consecutive in the ordering implied by the filter. Then $a \prec y$ iff $(x, y) \in \mathrm{Pred}_2(a, b)$ iff the transposition of x and a is a BB-type switch (see the left panels in Figure 5), and in this case*

$$\mathrm{Succ}_1^{\mathrm{aft}}(a,y) = \mathrm{Succ}_1^{\mathrm{bef}}(x,y) \oplus (x,b) \oplus \mathrm{Succ}_1^{\mathrm{bef}}(a,b); \quad \mathrm{Succ}_1^{\mathrm{aft}}(x,b) = \mathrm{Succ}_1^{\mathrm{bef}}(a,b); \tag{8}$$
$$\mathrm{Succ}_2^{\mathrm{aft}}(a,y) = \mathrm{Succ}_2^{\mathrm{bef}}(x,y) \oplus \{(x,b),(a,b)\}; \quad \mathrm{Succ}_2^{\mathrm{aft}}(x,b) = \mathrm{Succ}_2^{\mathrm{bef}}(a,b); \tag{9}$$
$$\mathrm{Pred}_1^{\mathrm{aft}}(a,y) = \mathrm{Pred}_1^{\mathrm{bef}}(x,y); \quad \mathrm{Pred}_1^{\mathrm{aft}}(x,b) = \mathrm{Pred}_1^{\mathrm{bef}}(a,b); \tag{10}$$
$$\mathrm{Pred}_2^{\mathrm{aft}}(a,y) = \mathrm{Pred}_2^{\mathrm{bef}}(x,y); \quad \mathrm{Pred}_2^{\mathrm{aft}}(x,b) = \mathrm{Pred}_2^{\mathrm{bef}}(a,b). \tag{11}$$

Otherwise, the depth relation remains as is, except if $x \prec b$ (see the middle panels in Figure 5), in which case $\mathrm{Succ}_1^{\mathrm{aft}}(x,y) = \mathrm{Succ}_1^{\mathrm{bef}}(x,y) \oplus (a,b) \oplus \mathrm{Succ}_1^{\mathrm{bef}}(a,b)$, while all other sets of successors and predecessors of (x, y) and (a, b) remain unchanged.

Proof. The two equivalences follow from the completeness of the case analysis displayed in Figure 5. To see (8), consider rows a and x in the boundary matrix before and after the switch. With reference to the upper left panel of Figure 5 – which shows the matrix before the switch – we give names to the portions of these rows delimited by columns y and b:

$$M_a = \{R_1[a,t] \mid f(y) \le f(t) < f(b)\}; \quad N_a = \{R_1[a,t] \mid f(b) \le f(t)\}; \tag{12}$$
$$M_x = \{R_1[x,t] \mid f(y) \le f(t) < f(b)\}; \quad N_x = \{R_1[x,t] \mid f(b) \le f(t)\}. \tag{13}$$

Canceling (x,y) changes row a to $(M_a + M_x)|(N_a + N_x)$, in which the bar means catenation. At this time, (a,b) is a shallow pair, so $M_a + M_x = 0$, which implies $M_a = M_x$. Columns y and b in U_1 are transposed copies of rows x and a at the moment before (x,y) and then (a,b) are canceled. Hence, column y in U_1 is $(M_x|N_x)^T$, and column b is $(N_a + N_x)^T$. This is before the transposition of a and x. After the transposition, column y in U_1 is $(M_a|N_a)^T$, and column b is $(N_x + N_a)^T$. Using $M_a = M_x$ and $N_a = N_x + (N_a + N_x)$, we rewrite these relations in different notation:

$$U_1^{\text{aft}}[y,t] = \begin{cases} U_1^{\text{bef}}[y,t] & \text{for } f(y) \le f(t) < f(b), \\ U_1^{\text{bef}}[y,t] + U_1^{\text{bef}}[b,t] & \text{for } f(b) \le f(t); \end{cases} \tag{14}$$
$$U_1^{\text{aft}}[b,t] = U_1^{\text{bef}}[b,t]. \tag{15}$$

Finally, we translate the relations into the notation of the lemma using (6), and get (8) from (14) and (15). We omit the arguments for the remaining relations in Lemma 3.3. ◀

The symmetric cases – when x precedes a so the birth-birth transpositions go from the lower to the upper panes in Figure 5 – are similar and the same relations between the successors and predecessors before and after the transposition apply.

3.2 Case II: Death-death Transpositions

The setting is similar to Case I: (x,y) and (a,b) are nested or otherwise overlapping birth-death pairs of matching dimension, but now we assume that y and b are consecutive in the ordering implied by the filter. As before, we prepare the analysis by canceling all birth-death pairs whose pivots are below row x or to the left of column y. After these cancellations, (x,y) is shallow, and (a,b) is shallow or it has (x,y) as its sole predecessor in the depth poset. Refer to Figure 6 for the three sub-cases as defined after the initial cancellations:

Case II.1: $a \not\prec y$ and $x \prec b$ for a nested pair, as illustrated in the upper left panel of Figure 6. The transposition is a switch, and reading the two left panels from bottom to top, we have the inverse switch defined by $x \prec y$ and $a \prec b$.

Case II.2: $a \prec y$ and $x \not\prec b$ for a nested pair, as illustrated in the upper middle panel of Figure 6. The transposition is not a switch, and reading the two middle panels from bottom to top, we have the inverse transposition defined by the same two conditions for overlapping pairs.

Case II.3: $a \not\prec y$ and $x \not\prec b$ for a nested pair, as illustrated in the upper right panel of Figure 6. Again this transposition is not a switch, and reading the two right panels from bottom to top, we have the inverse transposition defined by the same two conditions for overlapping pairs.

The sub-cases are strictly symmetric to Cases I.1, I.2, I.3, with identical arguments for the symmetric actions. While omitting other details, we state the result symmetric to Lemma 3.3, which describes the changes to the death and birth relations beyond the pairs that contain the transposed cells.

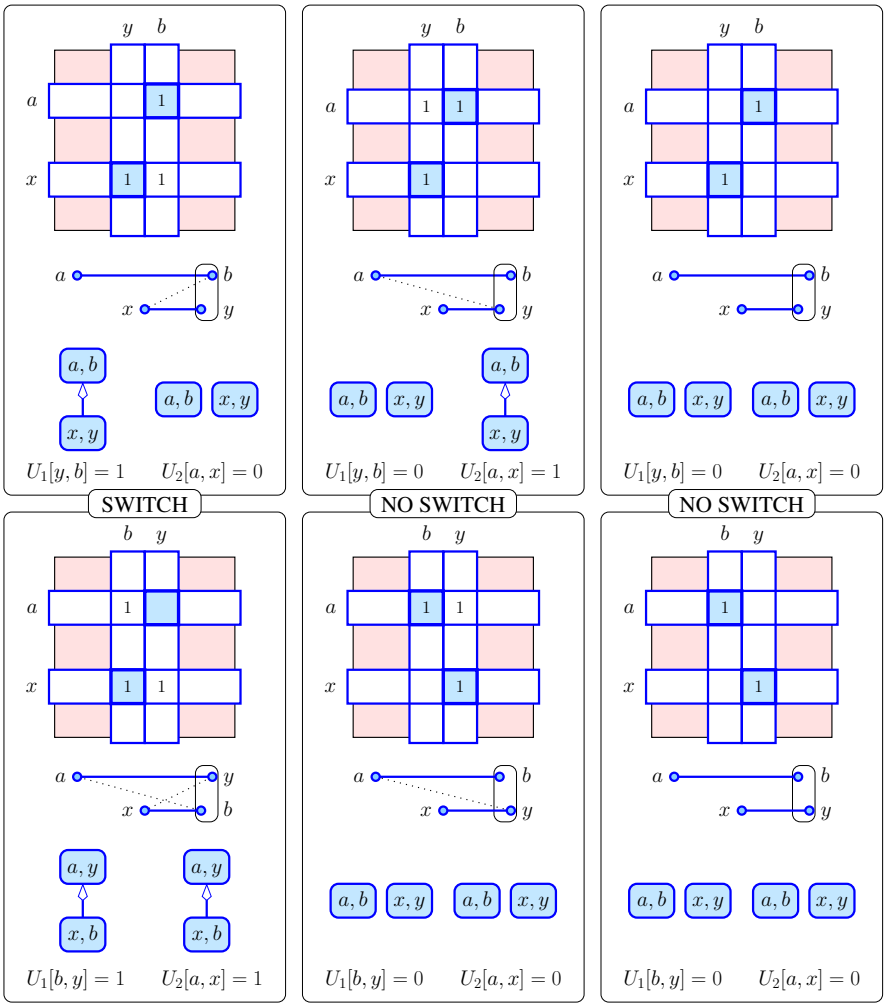

Figure 6 The configurations before and after the transposition of two death-giving cells in the filter. *From left to right:* Cases II.1, II.2, II.3, with the configuration before the transposition at the *top* and after the transposition at the *bottom*, or vice versa for the inverse transposition. Within each panel, we show the relevant birth-giving cells as rows and death-giving cells as columns of the matrix, the two birth-death pairs as bars, and the corresponding nodes and relations in the death and birth relations.

▶ **Lemma 3.4.** *Let $f\colon K \to \mathbb{R}$ be a filter on a Lefschetz complex, (x,y), (a,b) birth-death pairs of matching dimension, a precedes x, y precedes b, and y,b are consecutive in the ordering implied by the filter. Then $x \prec b$ iff $(x,y) \in \mathrm{Pred}_1(a,b)$ iff the transposition of y and b is a DD-type switch (see the left panels in Figure 6). and in this case*

$$\mathrm{Succ}_1^{\mathrm{aft}}(x,b) = \mathrm{Succ}_1^{\mathrm{bef}}(x,y) \oplus \{((a,y),(a,b)\}; \qquad \mathrm{Succ}_1^{\mathrm{aft}}(a,y) = \mathrm{Succ}_1^{\mathrm{bef}}(a,b); \quad (16)$$

$$\mathrm{Succ}_2^{\mathrm{aft}}(x,b) = \mathrm{Succ}_2^{\mathrm{bef}}(x,y) \oplus (a,y) \oplus \mathrm{Succ}_2^{\mathrm{bef}}(a,b); \quad \mathrm{Succ}_2^{\mathrm{aft}}(a,y) = \mathrm{Succ}_2^{\mathrm{bef}}(a,b); \quad (17)$$

$$\mathrm{Pred}_1^{\mathrm{aft}}(x,b) = \mathrm{Pred}_1^{\mathrm{bef}}(x,y); \qquad \mathrm{Pred}_1^{\mathrm{aft}}(a,y) = \mathrm{Pred}_1^{\mathrm{bef}}(a,b); \quad (18)$$

$$\mathrm{Pred}_2^{\mathrm{aft}}(x,b) = \mathrm{Pred}_2^{\mathrm{bef}}(x,y); \qquad \mathrm{Pred}_2^{\mathrm{aft}}(a,y) = \mathrm{Pred}_2^{\mathrm{bef}}(a,b). \quad (19)$$

Otherwise, the depth relation remains as is, except if $a \prec y$ (see the middle panels in Figure 6), in which case $\mathrm{Succ}_2^{\mathrm{aft}}(x,y) = \mathrm{Succ}_2^{\mathrm{bef}}(x,y) \oplus (a,b) \oplus \mathrm{Succ}_2^{\mathrm{bef}}(a,b)$, while all other sets of sets of successors and predecessors of (s,y) and (a,b) remain unchanged.

3.3 Case III: Birth-death Transpositions

Case III is characterized by the transposition of cells b and x, in which (a, b) and (x, y) are disjoint or overlapping birth-death pairs with consecutive dimensions, so $f(a) < f(b) < f(x) < f(y)$ or $f(a) < f(x) < f(b) < f(y)$ and $\dim a + 1 = \dim b = \dim x = \dim y - 1$. Similar to Cases I and II, we prepare the analysis by canceling all pairs whose pivots lie below the rows or to the left of columns b and x. This includes all predecessors of (a, b) and (x, y), so after these cancellations, both are shallow. Refer to Figure 7 for the two sub-cases, with the conditions referring to the complex after the initial cancellations:

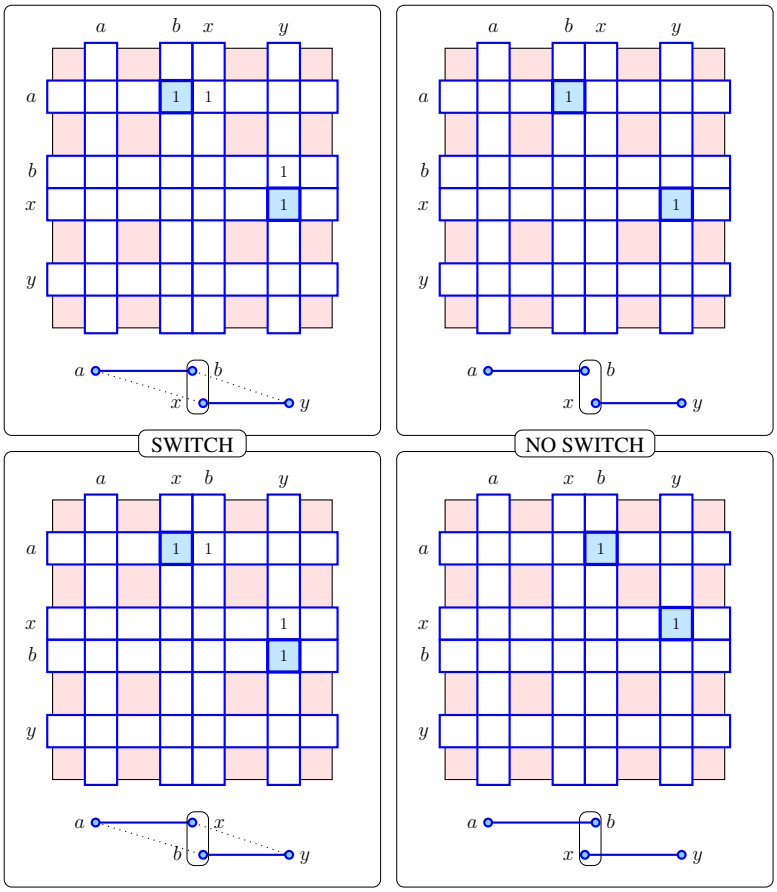

Figure 7 The configurations in Cases III.1 and III.2 on the *left* and *right*, before and after the transposition of a birth-giving cell with a death-giving cell. Within each panel, we show the relevant rows and columns of the matrix, and the corresponding birth-death pairs as bars.

Case III.1: $a \prec x$ and $b \prec y$ for nested pairs, as illustrated in the upper left panel of Figure 7. After transposing b and x, (a, x) and (b, y) are both shallow, so the transposition is a switch and the two new pairs are birth-death pairs of the new filter. By the first two properties in Lemma 2.3, there is no arc connecting the two pairs in the depth poset. The inverse transposition is symmetric and follows the same rules.

Case III.2: $a \not\prec x$ and $b \not\prec y$ for nested pairs, as illustrated in the upper right panel of Figure 7. After transposing b and x, (a, b) and (x, y) are still shallow, so the transposition is not a switch. The inverse transposition is defined by the same conditions but now for two overlapping pairs, as illustrated in the bottom right panel of Figure 7.

There are no additional cases, because the relevant birth-death pairs are shallow both before and after the transposition, which excludes configurations different from the ones illustrated in Figure 7. Observe that Case III.1 is quite different from all others, because the transposition changes the types of two cells: b from death- to birth-giving, and x from birth- to death-giving. Hence, their corresponding rows and columns in the boundary matrix assume different roles, which may have a profound impact on the depth poset. We prove that this is in fact not the case for the successors, but it can be for the predecessors.

Recall that Algorithm 1 records the column reductions for all cells alike, but only the ones for death-giving cells turn into arcs of the death relation. Symmetrically, Algorithm 2 records the row reductions for all cells, but only the ones for birth-giving cells that also belong to birth-death pairs turn into arcs of the birth relation. We will now make use of the so far neglected information. Letting a and x be the birth-giving cells of the two pairs in a BD-type switch, we collect the reductions of column x prior to reaching row a as arcs in the death relation, and letting y and b be death-giving cells of these pairs, we collect the reductions of row b prior to reaching column y as arcs in the birth relation.

▶ **Lemma 3.5.** *Let $f\colon K \to \mathbb{R}$ be a filter on a Lefschetz complex, (a,b) and (x,y) birth-death pairs of consecutive dimensions, and b,x consecutive in the ordering implied by the filter. Then $a \prec x$ and $b \prec y$ iff the transposition of b and x is a BD-type switch (see the left panels in Figure 7), and in this case*

$$\mathrm{Succ}_1^{\mathrm{aft}}(a,x) = \mathrm{Succ}_1^{\mathrm{bef}}(a,b); \qquad \mathrm{Succ}_1^{\mathrm{aft}}(b,y) = \mathrm{Succ}_1^{\mathrm{bef}}(x,y); \tag{20}$$

$$\mathrm{Succ}_2^{\mathrm{aft}}(a,x) = \mathrm{Succ}_2^{\mathrm{bef}}(a,b); \qquad \mathrm{Succ}_2^{\mathrm{aft}}(b,y) = \mathrm{Succ}_2^{\mathrm{bef}}(x,y); \tag{21}$$

$$\mathrm{Pred}_1^{\mathrm{aft}}(a,x) = \{(t,x) \mid U_1^{\mathrm{bef}}[t,x] = 1, f(t) > f(a)\}; \quad \mathrm{Pred}_1^{\mathrm{aft}}(b,y) = \mathrm{Pred}_1^{\mathrm{bef}}(x,y); \tag{22}$$

$$\mathrm{Pred}_2^{\mathrm{aft}}(a,x) = \mathrm{Pred}_2^{\mathrm{bef}}(a,b); \quad \mathrm{Pred}_2^{\mathrm{aft}}(b,y) = \{(b,s) \mid U_2^{\mathrm{bef}}[b,s] = 1, f(s) < f(y)\}. \tag{23}$$

Otherwise, the depth relation remains as is (see the right panels in Figure 7).

Proof. To prove (20) and (21), we first consider rows b and x in the boundary matrix (after canceling all birth-death pairs whose pivots are below row x or to the left of column b). Before the transposition, b gives death, so there is no pivot in its row. We claim that this implies that the two rows are equal. Indeed, if there is a column in which the entries in rows b and x are different, then the leftmost such entry would be a pivot, which is a contradiction to the assumptions. Since the two rows are the same, transposing them makes no difference, other than exchanging their names. This implies $\mathrm{Succ}_1^{\mathrm{aft}}(a,x) = \mathrm{Succ}_1^{\mathrm{bef}}(a,b)$ as well as $\mathrm{Succ}_1^{\mathrm{aft}}(b,y) = \mathrm{Succ}_1^{\mathrm{bef}}(x,y)$. The symmetric argument implies the corresponding relations for the successors in the birth relation.

To prove (22) and (23), we recall that rows b and x are equal, so in the death relation the predecessors of (x,y) before the transposition are the predecessors of (b,y) after the transposition and, symmetrically, in the birth relation the predecessors of (a,b) before the transposition are the predecessors of (a,x) after the transposition. The remaining predecessors of (a,x) and (b,y) are determined while canceling the birth-death pairs with pivots below and to the left of the rows and columns of these pairs. We can get this information from column x in U_1 and row b in U_2 as computed before the transposition. ◀

The symmetric cases – in which we read the panels in Figure 7 from bottom to top – are similar. This completes the case analysis of changes to the depth poset caused by the transposition of two cells that are consecutive in the filter.

4 Computational Experiments

In this section, we present measurements of the depth poset collected while running the algorithms on 1-, 2-, and 3-dimensional random functions and straight-line homotopies between them. For each set of parameters, the results are averaged over ten repeats.

4.1 Random Piecewise Linear Functions

To minimize complications and avoid boundary effects as well as any essential homology, we construct the random functions on a regular cubical subdivision of the d-dimensional torus. Choosing a positive integer, n, we use $(\mathbb{R}/n\mathbb{Z})^d$ as a model of the d-torus, and subdivide it with the unit d-cubes of $(\mathbb{Z}/n\mathbb{Z})^d + [0,1]^d$. We furthermore kill its essential homology classes by adding 2^d *extra cells*, namely the empty set as the sole (-1)-cell and $\binom{d}{p}$ $(p+1)$-cells, each with boundary equal to a subdivided p-torus, for $1 \leq p \leq d$. Write $K = K(n,d)$ for the resulting complex, which consists of $\binom{d}{p}n^d$ p-cubes, for $0 \leq p \leq d$, plus the 2^d extra cells.

As an example, let $d = 2$ in which case the torus is the n-by-n square grid, which is subdivided into n^2 unit square cells. The (-1)-cell facilitates reduced homology, which pairs the empty set with the component. In addition, there are two 2-cells killing the essential degree-1 homology classes, each a polygon whose boundary consists of n edges, a horizontal integer line for one and a vertical integer line in the square grid for the other polygon. Finally, there is the 3-cell whose boundary is the entire n-by-n square grid.

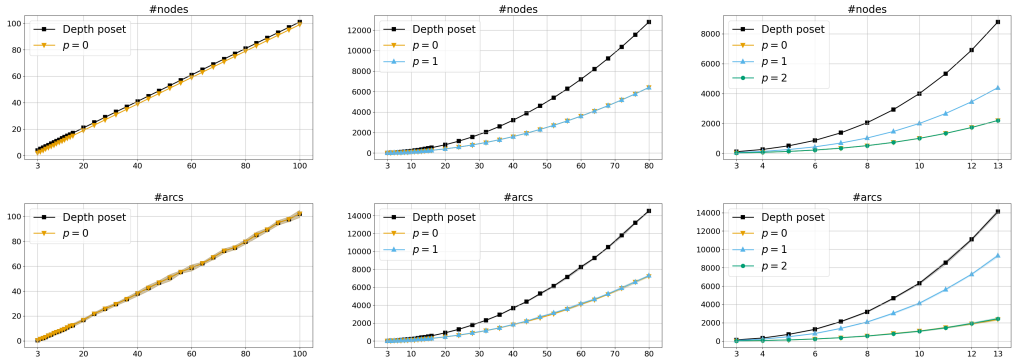

Figure 8 *From left to right:* the average number of nodes (*upper row*) and arcs (*lower row*) in the transitive reduction of the depth poset of a random function on the d-torus, for $d = 1, 2, 3$, respectively. Because of the symmetries in the construction, the curves for $p = 0$ and $p = d - 1$ are nearly identical.

To turn this complex into a random function, $f\colon K \to \mathbb{R}$, we choose $f(\gamma)$ in $[p, p+1]$, whenever $p = \dim \gamma$. In particular, we choose $f(\gamma)$ uniformly at random in $[p, p+1]$ whenever γ is a p-cube, and we set $f(\gamma) = p+1$ whenever it is an extra p-cell. In spite of the extra cells that kill the essential homology of the d-torus, we will refer to f as a *random function on the d-torus*. By construction, the filter that orders the cells by value is also ordered by dimension. We may think of f as a piecewise constant function, but there is an alternative interpretation as a piecewise linear function. Letting $\hat{K} = \hat{K}(n,d)$ be the barycentric subdivision of K, each vertex $\hat{\gamma} \in \hat{K}$ is the center of a cell $\gamma \in K$, and we map $\hat{\gamma}$ to $\hat{f}(\hat{\gamma}) = f(\gamma)$. We then get $\hat{f}$ on the underlying space of K by piecewise linear interpolation of its values at the vertices. By construction, each center of a p-cell in K is a critical point of index p of $\hat{f}$. All critical points are paired up as nodes of the depth poset, which implies that n and d determine the number of nodes for each $-1 \leq p \leq d$; see the upper row in Figure 8. In contrast, the number of arcs in the depth poset has a small but non-zero variance; see the lower row of Figure 8.

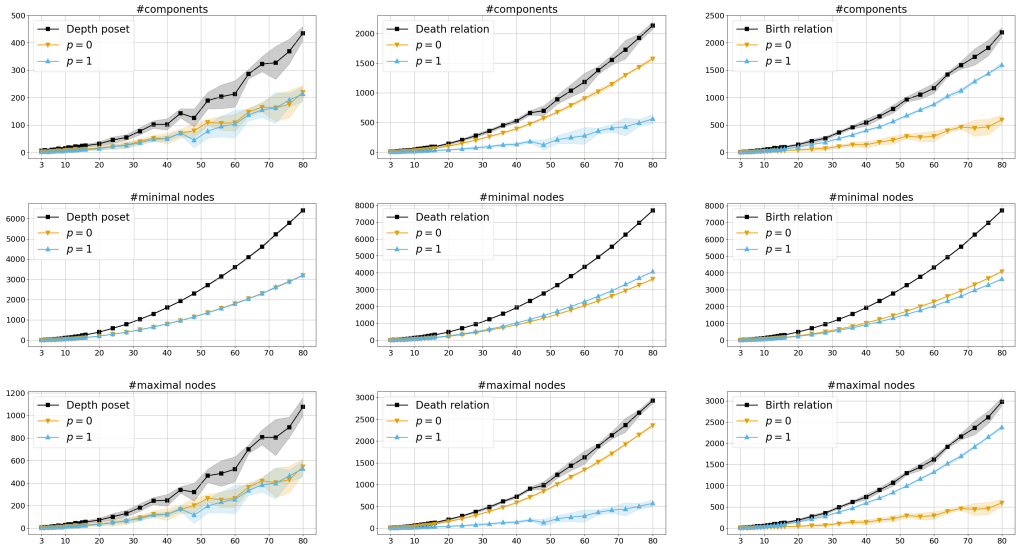

Figure 9 *From left to right:* the average numbers of components, minimal nodes, and maximal nodes of the depth poset, the death relation, and the birth relation of a random function on the 2-torus, respectively. Because of symmetry, the curves for the death and birth relations are nearly identical.

As proved in [9], the depth poset splits by the dimensions of the nodes, but depending on the data it may split further. The upper row in Figure 9 shows that it indeed does so for random functions on the 2-torus. Each component has at least one minimal and one maximal node, but there may be more, and the middle and lower rows of the same figure support this possibility. Recall that the minimal nodes of the depth poset are exactly the shallow pairs, which explains why their number has barely any variance. In $d = 2$ dimensions, there are $4n^2$ incident vertex-edge pairs, and such a pair is shallow iff the edge precedes the other three incident edges of the vertex, and the vertex succeeds the other incident vertex of the edge. Indeed, if an incident vertex-edge pair satisfies these conditions, then it is a pair in persistence as well as shallow, and if it does not satisfy these conditions, it may or may not be a pair in persistence but it is certainly not shallow. Since the vertices and edges are ordered randomly and independently, the edge is first among four with probability $\frac{1}{4}$ and the vertex is second among two with probability $\frac{1}{2}$. Ignoring the extra (-1)-cell, the chance of such a pair to be shallow is therefore $\frac{1}{8}$. Symmetrically, there are $4n^2$ incident edge-square pairs, and ignoring the extra 3-cell, the chance of an incident edge-square pair to be shallow is again $\frac{1}{8}$. This implies that the expected number of shallow pairs is $n^2 + O(1)$; see the first panel in the middle row of Figure 9. Each shallow pair is also a minimal node in the death and birth relations, but both have additional minimal nodes; see the symmetry of the curves in the second and third panels in the middle row of Figure 9, which is a consequence of the symmetry of cubically subdividing the torus. We observe that there are many more minimal nodes than there are maximal nodes. Curiously, the depth poset has many fewer maximal nodes than the death and birth relations, while the difference seems less dramatic for the minimal nodes.

By definition, a poset has no directed cycle, but it may have undirected cycles (pairs of paths that connect the same two nodes). For a 1-dimensional function, the death and birth relations have no undirected cycles either but, perhaps surprisingly, the union of these two relations can have such cycles. Figure 10 shows the average number of (undirected) cycles (which we compute as #components + #arcs − #nodes), together with the average height (defined as the number of arcs in the longest directed path in the relation).

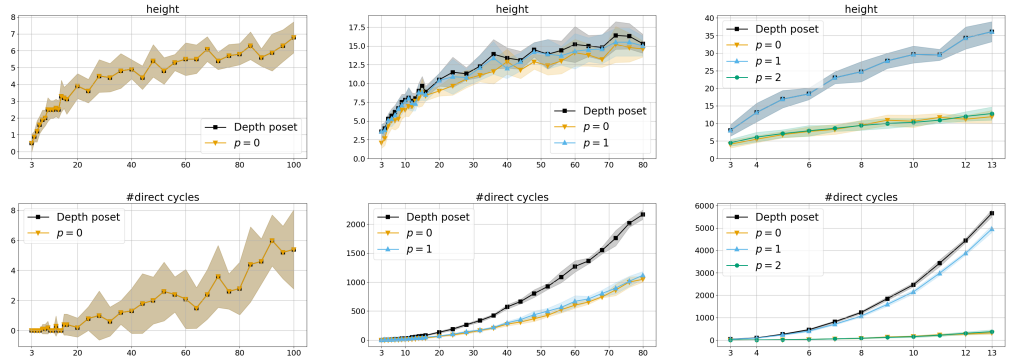

Figure 10 *From left to right:* the average height (*upper row*) and the average number of undirected cycles (*lower row*) in the depth poset of a random function on the d-torus, for $d = 1, 2, 3$, respectively.

4.2 Straight-line Homotopies

Letting $f_0, f_1 \colon K \to \mathbb{R}$ be two random functions on the d-torus, the *straight-line homotopy* between them is the 1-parameter family of functions $f_\lambda(\gamma) = (1 - \lambda)f_0(\gamma) + \lambda f_1(\gamma)$, for all $\gamma \in K$ and $0 \leq \lambda \leq 1$. To collect the statistics, we perform the transpositions of cells in sequence and one at a time. Given two cells of not necessarily the same dimension, $\gamma, \eta \in K$, the parameter at which their values match is

$$\lambda(\gamma, \eta) = \frac{f_0(\eta) - f_0(\gamma)}{[f_0(\eta) - f_0(\gamma)] - [f_1(\eta) - f_1(\gamma)]}. \tag{24}$$

The relevant such parameter values are the ones in $[0, 1]$. Instead of sorting them, it is more efficient to maintain the filter, and at each step transpose the two cells whose values match next. If this pair is not unique, we break ties and transpose the cells in sequence. As shown

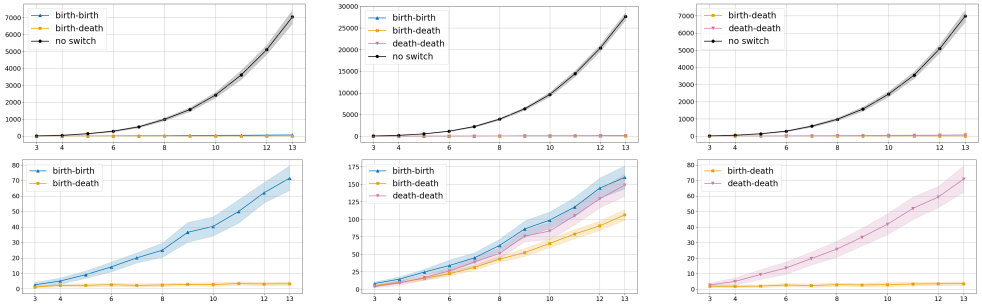

Figure 11 *From left to right:* the average number of transpositions (*upper row*) and switches (*lower row*) between pairs of vertices, edges, and 2-cells for the straight-line homotopy between two random functions on the 2-torus, respectively.

in the upper row of Figure 11, the transpositions that are not switches outnumber those that are switches, so it is useful to draw the curves of the latter on a more appropriate scale, which we do in the lower row of the same figure. As shown in the lower row of Figure 11, there are barely any BD-type switches of two vertices or two 2-cells, and even for edges, there are fewer BD-type switches than switches of BB-type and switches of DD-type.

An interesting aspect of the transpositions is how much they change the depth poset. Every switch affects exactly two nodes, while a transposition that is not a switch leaves all nodes unchanged. The effect on the arcs is less predictable, so we measure the change by counting the arcs that are different before and after the transposition. Not surprisingly, there

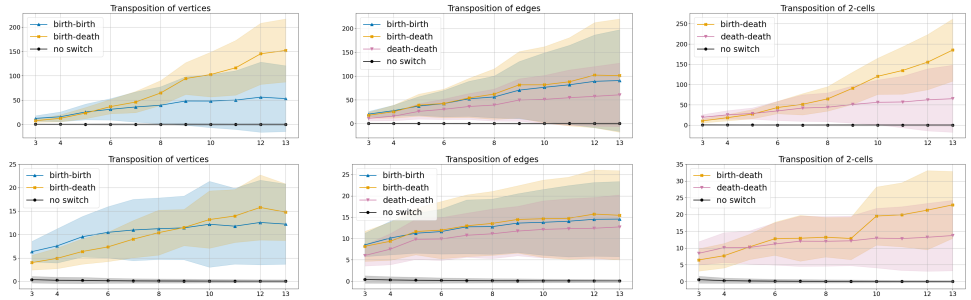

Figure 12 *From left to right*: the average number of arcs in the depth poset (*upper row*) and in the transitive reduction of the depth poset (*lower row*) that are different before and after the transposition of two vertices, two edges, and two 2-cells during a straight-line homotopy between two random functions on the 2-torus, respectively. We distinguish between different kinds of switches and non-switches.

are barely any arcs that change when the transposition is not a switch. Also not surprisingly, there are significantly more arcs that change in the depth poset as compared to the transitive reduction of the poset. Because of the limited size of the random functions in our experiment, it is difficult to gauge how the size of the symmetric difference of the arcs before and after the transposition grows with the size of the function. In any case, it seems to grow much slower than the total number of arcs, which we observe to grow quadratically in n; see the middle panel in the lower row of Figure 8.

5 Discussion

The main contribution of this paper is the complete analysis of how transpositions of cells in the filter affect the depth poset of a filtered Lefschetz complex. This analysis provides further evidence for the relative significance of birth-death switches, as they mark a more extensive re-organization of the persistent homology than all other types of transpositions. Our initial computational experiments suggest that the birth-death switches are more rare than all other types, and that the number of arcs that change grows much slower than the total number of arcs in the depth poset. This work calls for further research in at least the following three directions:

- investigate the links between the transposition induced changes in the depth poset and the bifurcations in the associated gradient dynamics;
- extend the notion of a depth poset from discrete Morse functions to discrete vector fields as introduced in Forman [12], or even to multi-vector fields as studied in [16, 17];
- study the depth poset stochastically for various models of random functions and for homotopies between them.

We finally mention that the algorithms in this paper and its precursor [9] are closely related to the algorithms for topology optimization described by Nigmetov and Morozov [19]. Can the more global topological information provided by the depth poset be harvested to get faster or better methods for topology optimization?

Compressed Data Structures for Heegaard Splitting

Abstract

Heegaard splittings provide a natural representation of closed 3-manifolds by gluing handlebodies along a common surface. These splittings can be equivalently given by two finite sets of meridians lying on the surface, which define a Heegaard diagram. We present a data structure to effectively represent Heegaard diagrams as normal curves with respect to triangulations of a surface of complexity measured by the space required to express the normal coordinates' vectors in binary. This structure can be significantly more compressed than triangulations of 3-manifolds, giving exponential gains for some families. Even with this succinct definition of complexity, we establish polynomial-time algorithms for comparing and manipulating diagrams, performing stabilizations, detecting trivial stabilizations and reductions, and computing topological invariants of the underlying manifolds, such as their fundamental and homology groups. We also contrast early implementations of our techniques with standard software programs for 3-manifolds, achieving faster algorithms for the average cases and exponential gains in speed for some particular presentations of the inputs.

1 Introduction

Since the early days of computational topology, *3-manifolds* have attracted researchers' keen interest [27, 31, 40] for lying exactly midway between the well-understood surfaces and the wildly behaved 4-manifolds. For example, several 3-manifold problems were related to important questions in complexity theory: S^3 recognition was proved by Schleimer to be in NP [50], whereas approximations of some quantum invariants are firmly tied to quantum computing and are known to be #P-hard [1, 2]. Similarly, the problems of classifying [17, 39] and manipulating the geometry and topology of these spaces [8, 42] have also received significant theoretical and practical attention, with implementations of different methods publicly available in the most important software in the field, `Regina` [12] and `SnapPy` [18].

The algorithmic point of view is particularly relevant for the construction of *censuses* of homomorphism classes of 3-manifolds [7, 9, 10, 13]. Drawing inspiration from the related problem of knot classification (this time, up to ambient isotopies), where the cumulative work

of researchers [11, 15, 21] has culminated in the widely accessible census of $\sim 350'000'000$ prime knot diagrams, computational methods are expected to foster the elaboration of tables of 3-manifolds, particularly valuable assets in the proposition and verification of conjectures, as well as in the discovery of counterexamples.

Abstracting modern approaches [6, 9, 11, 13] of the construction of censuses of topological spaces, one requires (1) compact data structures to represent massive amounts of (candidate) spaces and the iterative construction of all spaces up to a maximum complexity; (2) efficient operations to disqualify inputs (such as composite knots, links, non-prime 3-manifolds) and simplify the representation combinatorics (Reidemeister moves, Pachner moves, etc); and, (3) methods for discriminating spaces, such as invariants. For 3-manifolds, these steps are usually addressed through *triangulations* – homeomorphic copies described by a finite set of tetrahedra and gluing rules among their faces – of complexity often measured by the number of tetrahedra. On the other hand, theoretical bounds on the minimal number of tetrahedra to represent some spaces [19, 33, 34, 44] and the difficulty of generating particular structures, such as hyperbolicity [44], can limit the effectiveness of triangulation-based censuses.

Heegaard splittings emerge as an alternative to triangulations. They depict a closed 3-manifold M as the result of gluing two better-behaved pieces called *handlebodies* along a common boundary. Splittings can also be combinatorially described by *Heegaard diagrams*, two sets of curves in a surface whose intersection pattern conveys a lot of topological information about M. We suggest here a new data structure to represent Heegaard diagrams based on *normal coordinates*, of a size as large as *binary* of the number of intersections between the two sets of curves. The gain in measuring the complexity of 3-manifolds through this notion is not to be overlooked: we present in Section 5 families of manifolds whose diagrams' complexity grows linearly with the size of the input, but whose triangulations necessarily use exponentially many tetrahedra. However, what is more important is that due to the proliferation of efficient operations in normal coordinates [24, 41, 48, 49, 53], we can establish polynomial-time algorithms even in this compressed notion of complexity, leading to basic manipulations of Heegaard splittings and the computation of simple 3-manifold invariants such as the fundamental and homology groups. Moreover, as we point out in Remark 9, some important complexity results about 3-manifolds – such as sphere (co-)recognition – are still preserved if we assume compressed inputs, which tells us much about the inherent difficulty of these problems. We hope that these techniques are useful for the study and classification of topological spaces that are beyond the reach of efficiency when represented by other methods.

The paper begins with a background section on both low-dimensional and computational topology (Section 2), where we review some of the concepts and results that will be needed in the later parts. Our contribution starts in Section 3, where we formally present our data structure for Heegaard splittings. Section 4 establishes basic algorithms in this structure, which are further expanded the paper's full version. We compare early implementations of these algorithms with triangulation-dependent methods in Section 5.

Before we close this introduction, we draw the reader's attention to two subtleties of the current work. First, although most of our tools apply to *generalized* Heegaard splittings defined for *orientable compact* 3-manifolds, potentially with boundary [37, 51], we will focus solely on *closed* 3-manifolds. Therefore, all 3-manifolds here will be assumed orientable and closed, unless explicitly stated otherwise. Second, we assume throughout a *unit-cost RAM model* with some bit-size W [26]. This means that the four integer operations and integer comparison can be executed in constant time, provided that the numbers involved have binary representations of size at most W.

2 Background material

2.1 Background on low-dimensional topology

We assume the reader is acquainted with the basic notions of surface theory at the level of [25], referring to the paper's full version for details. We use Σ to denote a general surface and Σ_g the (unique) closed surface of genus g. Whenever possible, we reserve Greek letters for multicurves and Latin letters for curves and arcs. All (multi)curves are assumed simple. As usual, we do not differentiate (multi)curves from their isotopy classes if no confusion arises.

The *mapping class group* of the surface Σ_g, $\mathrm{Mod}(\Sigma_g)$, is the group of orientation-preserving $\Sigma_g \to \Sigma_g$ homeomorphisms up to isotopy. For each g, $\mathrm{Mod}(\Sigma_g)$ is finitely generated as a group by an alphabet $\mathcal{L}$, consisting of *Dehn twists* about $3g-1$ (isotopy classes of) canonically defined essential curves $s_1, \ldots, s_{3g-1}$ [43]. Formally, a Dehn twist $\tau_s : \Sigma_g \to \Sigma_g$ about s is given by cutting out a cylindrical regular neighborhood around the curve, applying a 2π left-twist to one of the cylinder's boundaries, and gluing the cylinder back into the surface. We call the curves $s_1, \ldots, s_{3g-1}$ the surface's *Lickorish generators*. Hopefully without confusion, we also call the Dehn twists in the alphabet $\mathcal{L} = \{\tau_{s_1}, \ldots, \tau_{s_{3g-1}}\}$ Lickorish generators.

An essential multicurve γ in Σ_g is a *system* if Σ_g cut along γ, $\Sigma_g \backslash \gamma$, is a $2g$ punctured sphere. A system γ in Σ_g can be used to construct the genus g *handlebody* $\mathcal{H}_\gamma$ where we attach 2-handles along the curves γ in $\Sigma \times \{0\}$ and fill any spherical boundary component with 3-handles. Note that $\partial \mathcal{H}_\gamma = \Sigma_g$ and that $\mathcal{H}_\gamma$ is homeomorphic to the direct sum of g solid tori. Components of γ are *meridians* of $\mathcal{H}_\gamma$ in the sense that they bound disks in the handlebody's interior. Two systems γ and γ' in Σ_g will be called *equivalent* if γ' is a set of meridians in $\mathcal{H}_\gamma$ (which implies that γ is a set of meridians in $\mathcal{H}_{\gamma'}$).

Let c_1, c_2 be two components of a system γ and p an arc from a puncture corresponding to c_1 to a puncture corresponding to c_2 in $\Sigma_g \backslash \gamma$. The *band sum* of c_1, c_2 and p is the curve c in $\Sigma_g \backslash \gamma$ obtained by the surgery of Figure 1. One can show that c is a meridian in $\mathcal{H}_\gamma$ [22, 37], so $\gamma' = \gamma - \{c_1\} \cup \{c\}$ is a system equivalent to γ. We call this whole operation a *disk slide*. With finitely many applications of disk slides and isotopies, a system γ can be transformed into any equivalent system γ' [37].

A genus g *Heegaard splitting* is the closed 3-manifold resulting from the gluing of two handlebodies with boundaries homeomorphic to Σ_g through a gluing map $f : \Sigma_g \to \Sigma_g$. In fact, one might assume that f is given by a $\phi \in \mathrm{Mod}(\Sigma_g)$ composed with some canonical orientation-reversing homeomorphism. This means that a Heegaard splitting can be represented by a pair (Σ_g, ϕ) where ϕ is a word on Lickorish generators. We call this pair the *Heegaard word* for the splitting. Every closed 3-manifold has a Heegaard splitting [46, 47].

Note that if we fix a system of meridians α on one of the two handlebodies, $\mathcal{H}_\alpha$, then $\beta = \phi(\alpha)$ is a system of meridians of the *other* handlebody, $\mathcal{H}_\beta$. We call the tuple $(\Sigma_g, \alpha, \beta)$ a *Heegaard diagram*. Heegaard diagrams are algorithmically independent of words: any two systems α and β will define the same splitting, provided that the curves are meridians in their respective handlebodies. Diagrams are therefore not unique for a given splitting. For example, if β and β' are *isotopic diagrams* on Σ_g – that is, β and β' are isotopic multicurves in Σ_g – then $(\Sigma_g, \alpha, \beta)$ and $(\Sigma_g, \alpha, \beta')$ define the same manifold. Similarly, if β is equivalent to β', we say that the diagrams are *equivalent* and $(\Sigma_g, \alpha, \beta)$ and $(\Sigma_g, \alpha, \beta')$ also define the same 3-manifold. In this sense, disk slides play for Heegaard diagrams a role similar to the Reidemeister moves for knots.

A splitting $(\Sigma_g, \mathcal{H}_\alpha, \mathcal{H}_\beta)$ is *reducible* if there is a curve c in Σ_g that is a meridian of both $\mathcal{H}_\alpha$ and $\mathcal{H}_\beta$. We call a diagram $(\Sigma_g, \alpha, \beta)$ *reducible* if either (1) there is a component $a \in \alpha$ and a component $b \in \beta$ that are isotopic in Σ_g; or (2) there is a separating curve s, disjoint

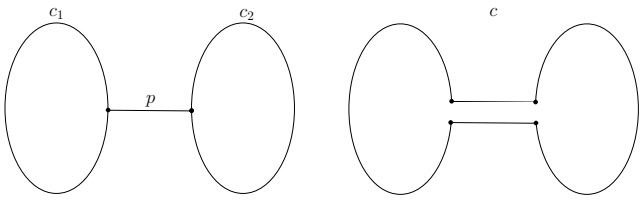

Figure 1 The result c of a band sum of c_1, c_2, and p.

from both α and β, and such that $\Sigma_g \backslash s$ defines a connected sum of two Heegaard splittings of smaller genera. The uniqueness of fundamental group decomposition [3] and [51][Theorem 6.3.5] imply that a reducible diagram represents a reducible splitting. A reducible splitting can always be written as the connected sum of sub-splittings [3, 37].

A presentation $\langle x_1, \ldots, x_g | r_1, \ldots, r_g \rangle$ of the *fundamental group* $\pi_1(M)$ can be obtained as follows [30, 37]: label the curves $a_1, \ldots, a_g \in \alpha$ and $b_1, \ldots, b_g \in \beta$ and give them an orientation; then traverse each curve b_i along the assumed orientation and, whenever it intersects some a_j, we append x_j to the relation r_i if the index of the intersection is positive, otherwise we append x_j^{-1} to it. Because the *first (integral) homology group of* M, $H_1(M)$ is the abelianization of $\pi_1(M)$ [28], we can present $H_1(M)$ as $\langle x_1, \ldots, x_g | r'_1, \ldots, r'_g, [x_i, x_j] \rangle$, where each $r'_i = x_1^{k_i^1} \ldots x_g^{k_i^g}$ can be computed by commuting the generators x_j in the relations r_i. Note that k_i^j equals the algebraic intersection number $\hat{i}(b_i, a_j)$ and we store this information in a $g \times g$ *presentation matrix* for $H_1(M)$, whose Smith normal form carries all the necessary information of the homology group.

2.2 Background on computational topology

Heegaard diagrams consist of three essential components that any candidate data structure must encode: a surface, Σ_g, and two multicurves, α and β. Starting with the surface, a graph $T = (V, E)$ embedded in Σ is a *cellular embedding* if the manifold defined by cutting Σ along T, $\Sigma \backslash T$, is homeomorphic to a collection of disks. We call each component of $\Sigma \backslash T$ a *face* of T. A cellular embedding T in the surface Σ is said to be *oriented* if we assign to each face an ordered list of its vertices, consistent with the orientation of Σ as in the right-hand rule. We assume every cellular embedding to be oriented. A cellular embedding T is a *(generalized) triangulation* of Σ if exactly three edges of T bound each face. We define the size of a triangulation, $|T|$, as the number of faces; note that $|V|, |E| = O(|T|)$ where $|V|$ is the number of vertices of the triangulation and $|E|$ is the number of edges. Surface triangulations are not to be confused with the similar concept of 3-manifold triangulations.

Every oriented surface can be described as a data structure by a triangulation. For the triangulations themselves, we assume that they are given as a set of vertices, edges, and triangles, with bidirectional pointers between vertices and edges, and between edges and the triangles, therefore requiring a total space of $O(|T|)$. In particular, determining whether two triangles are adjacent, getting the incident vertices and edges of a triangle, and finding triangles bounded by a specific edge take constant time. Other, more compact data structures for triangulation, such as CGAL's [20], can be converted into our structure in time $O(|T|)$ and at a similar cost to memory. More general cellular embeddings are treated similarly.

A curve c is *edged* with respect to T if it is disjoint from its faces. We represent an edged curve as a data structure by the list $E_T(c) = \{e \in E : |c \cap e| = e\}$, assumed to be ordered according to an implicit traversing orientation of c. Similarly, a multicurve γ can be represented by a set of $\#\gamma$ edge lists, one for each component, which we denote as $E_T(\gamma)$. We

assume that no two components can share an edge, nor can the same component be incident to a vertex more than once; nevertheless, two distinct components can share a vertex. The *complexity* of $E_T(\gamma)$ is $\|E_T(\gamma)\| = \sum_{c\in\gamma} |E_T(c)|$.

On the other hand, a multicurve γ is called *standard* in T if it intersects the graph only at the edges and transversely. If γ is standard, we represent it as a collection of words in a finite alphabet: arbitrarily orient the edges E and take $E^{\pm} = E \cup E^{-1}$ for the letters. Then for each component c of γ, the word $I_T(c)$ in $(E^{\pm})^*$ is given by traversing c along some arbitrary direction and, whenever we intersect an edge $e \in E$, we append e^i to $I_T(c)$ where i is the index of the intersection. An *intersection sequence* representation for γ, $I_T(\gamma)$, is the set $\{I_T(c)\}_{c\in\gamma}$. While $E_T(\gamma)$ is well defined at the multicurve level, intersection sequences are defined only up to isotopies inside the cellular embedding's faces. Moreover, cyclic permutations and taking inverses of the words $I_T(c)$ in $I_T(\gamma)$ define the same isotopy classes.

Instead of working with explicit intersection sequences, we will often assume *straight line programs* (*SLPs*) to express $I_T(c)$. Formally, an SLP on the alphabet $E^{\pm}$ is a finite sequence of equations $[x_1 = \mathrm{EXPR}_1, \ldots, x_\ell = \mathrm{EXPR}_\ell]$, where the left-hand side, x_i, are symbols not in $E^{\pm}$ called *variables*, and the expressions on the right-hand side, $\mathrm{EXPR}_i \in (E^{\pm} \cup \{x_1, \ldots, x_{i-1}\})^*$, are called *assignments*. Each assignment EXPR_i is assumed to be a symbol from $E^{\pm}$, in which case the assignment is called *simple*, or of the form $\mathrm{EXPR}_i = x_{j_1}^{\pm 1} \cdot x_{j_2}^{\pm 1} \cdot \cdots \cdot x_{j_k}^{\pm 1}$, where $1 \le j_1, \ldots, j_k < i$, in which case we say the assignment is *proper*. In particular, the SLP $[x_1, \ldots, x_\ell]$ represents a word w in $(E^{\pm})^*$ if recursively substituting the appropriate x_j in each proper assignment, gives x_ℓ equal to w. We call ℓ the *length* of the SLP and define its *complexity* $m = \sum_{i=1}^{\ell} |\mathrm{EXPR}_i|$, where $|\mathrm{EXPR}_i|$ is the number of variables and symbols in the assignment $|\mathrm{EXPR}_i|$. Given any word $e_1 \ldots e_n$ in $(E^{\pm})^*$, one can trivially build an SLP of complexity $2n$, but there are instances in which SLPs can be used to give exponential gains over uncompressed representation of words [49]. Nonetheless, even in extremely compressed cases, several useful operations can still be efficiently performed, as stated in the following lemma, proved in the paper's full version. Here and throughout, we assume that $\lg k$ is the number of bits necessary to represent the potentially signed integer k; in particular, $\lg k = \log k + 2$ if k is signed and $\log k + 1$ if unsigned.

▶ **Lemma 1.** *Let $\langle x_1, \ldots, x_\ell \rangle$ be an SLP of complexity m representing a word $w \in (E^{\pm})^*$. In a unit-cost RAM model of bit-size $m + \lg k$, for a fixed $k \in \mathbb{Z}^+$, one can compute*

(a) *an SLP of w^{-1} in time $O(1)$;*

(b) *an SLP of w^k in time $O(\lg k)$;*

(c) *the number of occurrences of a symbol $e \in E^{\pm}$ in w, $e(w)$, in time $O(m)$.*

We will assume that every intersection sequence $I_T(c)$ is given by an SLP of complexity $\|I_T(c)\|$ and let $\|I_T(\gamma)\| = \sum_{c\in\gamma} \|I_T(c)\|$.

Now, suppose that $T = (V, E)$ is a triangulation. A standard (multi)curve γ is *normal* if it intersects each face of T in *elementary arcs* that connect distinct sides of the triangle in which they are contained. Equivalently, γ is normal if each (uncompressed) intersection sequence in $I_T(\gamma)$ is *cyclic reduced*, that is, if there are no substrings of type ee^{-1} or $e^{-1}e$ in any of the cyclic permutations of the components' sequences. When the curve c is normal for a triangulation, its isotopy class is fixed by the number of times it intersects each labeled edge [48], implying that we can describe it through a vector in $N_T(c)$ in $\mathbb{N}^{|E|}$. We call $N_T(c)$ the curve's *normal coordinates*, whose complexity, $\|N_T(c)\|$, is the number of bits necessary to store this vector, i.e., $\sum_{e\in E} \lg e(c) = \sum_{e\in E} (\log e(c) + 1)$. Naturally, we define $N_T(\gamma)$ as the set $\{N_T(c)\}_{c\in\gamma}$.

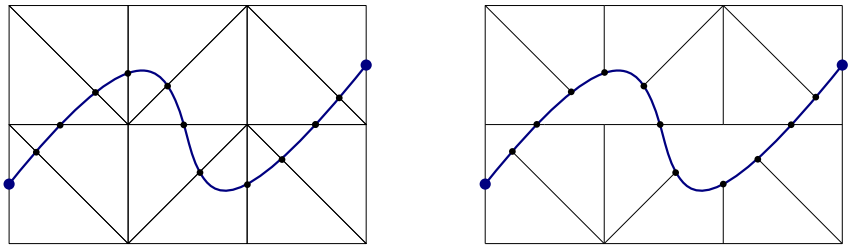

Figure 2 Left: the overlay graph of a normal arc (blue) with respect to a triangulation (black). Right: its street complex.

▶ Remark 2. We could represent a normal multicurve γ with a *single* vector $\sum_{c\in\gamma} N_T(\gamma)$. Similarly, it is possible (and common) to extend the notion of SLPs to encode more than one uncompressed word, which, in our case, implies giving all components of γ as a single SLP. Although these approaches are more parsimonious, they are less useful for our needs. Moreover, Lemma 5.1 of [24] gives an algorithm to transform, in time $O(|T|\|N_T(\gamma)\|)$, the normal coordinates of a multicurve given by a sum of its components' coordinates to our expected form.

Any normal (multi)curve γ partitions the edges of T into segments called *ports*. The *overlay graph* of γ is defined by having as vertices the union of V and the intersections $E \cap \gamma$, and as edges the union of the ports and the elementary arcs of γ (see Figure 2). The overlay graph splits each triangle t of the original triangulation into two types of regions: *junctions*, which are adjacent to three edges of T, and *blocks*, which are adjacent to only two. A port of the overlay graph is called *redundant* if it separates blocks. Following Erickson and Nayyeri [24], we define the *street complex* of γ, $S(T,\gamma)$, by deleting redundant ports and their endpoints from the overlay graph. In practice, the street complex merges blocks into longer faces called *streets*; naturally, $S(T,\gamma)$ is a cellular embedding in the surface triangulated by T, see Figure 2. We define the *crossing sequence* of a street in $S(T,\gamma)$ as the intersection sequence of a curve that crosses the street from one end to the other with respect to the original triangulation T. For simplicity, we assume that any port that separates two junctions is a degenerate street with a crossing sequence of length 1. The street complexes of all multicurves in this paper will have complexity $O(|T|)$ [24].

3 Data structure for Heegaard diagrams

Normal coordinates suggest a very natural encoding of Heegaard diagrams and, consequently, of closed 3-manifolds. Explicitly, we propose representing $(\Sigma_g, \alpha, \beta)$ by a tuple $(T, E_T(\alpha), N_T(\beta))$, where $T = (V, E)$ is a triangulation, $E_T(\alpha)$ is an edge representation of α, and $N_T(\beta)$ is a normal coordinate representation of β. We will often refer to the pair $(T, E_T(\alpha))$ as a *marked triangulation* of Σ_g, in which context $N_T(\beta)$ will be called the diagram itself. The *complexity* of the diagram is

$$\|(T, E_T(\alpha), N_T(\beta))\| = |T| + \|E_T(\alpha)\| + \|N_T(\beta)\|. \tag{1}$$

We note that $\|E_T(\alpha)\| = O(|T|) = O(\|N_T(\beta)\|/|\beta \cap E|)$, that is, for complexity purposes, only the last term of (1) matters. However, for the sake of clarity, we will still refer to the terms of equation (1) arising from the marked triangulation in our analyses. All complexities will be reported under the assumption that $|\beta \cap T| = \Omega(|T|^2)$, as otherwise there are some faster trivial algorithms.

Our choices of data structures for α and β allow us to represent curves of exponentially many intersection points with respect to the complexity of the diagram. Referring to the discussion at the end of Section 2.1, more intersections may lead to more complicated fundamental groups and, consequently [44][Proposition 2.6.6], more complicated 3-manifolds. In this sense, our structure is significantly more compressed than representations of Heegaard diagrams with *both* α and β edged, which can have, at most, $E_T(\alpha) \times E_T(\beta) = O(|T|^2)$ intersections.

Complexity gains are also noticeable if we compare our structure with triangulations of 3-manifolds. The usual algorithm to triangulate Heegaard diagrams [29] takes polynomial-time in $|\alpha \cap \beta|$. Moreover, as we empirically verify in Section 5, converting a Heegaard word to a diagram can be exponentially faster than converting the word to a triangulation for some choices of input and at least as fast for the general case. On the downside, it is unclear how to obtain and manipulate geometric information (such as *hyperbolicity*) or to compute certain quantum invariants directly from Heegaard diagrams, making triangulations still preferable for these kinds of problems.Refer to Section 6 of the paper's full version.

As stated in the introduction, our goal is to establish basic efficient algorithms even in this very compressed setting. For such a purpose, we will make extensive use of the next two results. The first of them is (almost) fully established by Erickson and Nayyeri [23].

▶ **Theorem 3.** *Suppose that $(T, E_T(\alpha), N_T(\beta))$ is a genus g Heegaard diagram of complexity m. In a unit-cost RAM model of bit-size $\log|\beta \cap E| = O(m/|T|)$, one may compute*

(a) *the street complex $S(T, \beta)$ in time $O(m|T|)$;*

(b) *SLPs of total complexity $O(m|T|)$ of the crossing sequence of* all *streets of $S(T, \gamma)$ in time $O(m|T|)$;*

(c) *SLPs $I_T(\beta)$ of complexity $O(m)$, in time $O(m)$.*

For the next theorem, we might assume that a Heegaard word ϕ is given in a *power-notation form*, that is, $\phi = \tau_{s_n}^{k_n} \circ \cdots \circ \tau_{s_1}^{k_1}$, $s_i \neq s_{i+1}$ for $1 \leq i < n$, and with each $k_i \in \mathbb{Z}$ in signed binary. A *fully uncompressed* Heegaard word $\phi' = \tau_{s'_{|\phi'|}}^{\pm 1} \circ \ldots \tau_{s'_1}^{\pm 1}$, with some s'_i potentially equal to s'_{i+1}, can be put in power-notation form in time $O(|\phi'|)$ with a unit-cost RAM model of bit-size $\lg|\phi'|$. For convenience, we shall also assume that the Lickorish generators are given as edged curves with respect to T. Nevertheless, even if we suppose that $\mathcal{L}$ is given by normal coordinates or intersection sequences, the theorem still holds with similar complexity bounds by multiple applications of Theorem 4.9 of the full version.

▶ **Theorem 4.** *Suppose $\phi = \tau_{s_n}^{k_n} \circ \cdots \circ \tau_{s_1}^{k_1}$, $s_i \neq s_{i+1}$ for $1 \leq i < n$, is a Heegaard word in $\mathrm{Mod}(\Sigma_g)$ and let T be a triangulation of Σ_g with edged α and Lickorish generators. There is an algorithm to compute intersection sequences $I_T(\phi(\alpha))$ in time $\Theta(g|T| + n|T|\lg k)$ in a unit-cost RAM model of bit-size $\lg k$ where $\lg k = \sum_{i=1}^{n} \lg k_i$. Moreover, the Heegaard diagram $(T, E_T(\alpha), N_T(\phi(\alpha)))$ of complexity $O(|T|^3 \lg^2 k)$ can be computed in time $O((|T| \lg k)^{10})$.*

Proof. For each $s \in \mathcal{L}$, denote its edge list by $E_T(s) = \{e_{s,1}, \ldots, e_{s,\|E_T(s)\|}\}$, where $e_{s,j} \in E$ for $1 \leq j \leq \|E_T(s)\|$, and define $I_T(s, j)$ as (an SLP of) the intersection sequence of a normal curve isotopic to s starting at a face adjacent to $e_{s,j}$. We can compute $I_T(s, j)$ for each $1 \leq j \leq \|E_T(s)\|$ in time $O(g|T|)$ (Lemma 3.4 in the full version). We also compute $I_T(a)$ for each $a \in \alpha$; in total, this initial step takes time $O(g|T|)$.

Let $I_T(\beta_0) = I_T(\alpha)$. Assuming $k_i > 0$, we recursively construct $I_T(\beta_i)$, for $1 \leq i \leq n$, by replacing any occurrence of an edge $e_{s_i,j} \in E_T(s_i)$ in the SLPs $I_T(\beta_{i-1}) = \{[x_1 = \mathrm{EXPR}_1, \ldots, x_p = \mathrm{EXPR}_p]\}_{b \in \beta}$ with an SLP $[y_1, \ldots, y_q]$ of $I_T(s_i)^{k_i} \cdot s_{i,j}$, that is,

$$I_T(\beta_i) = \{[y_1, \ldots, y_q, x'_{q+1} = \mathrm{EXPR}'_1, \ldots, x'_{q+p} = \mathrm{EXPR}'_q]\}_{b \in \beta}$$

where EXPR'_r is the word EXPR_r with each occurrence of x_t substituted by x'_{p+t} and each occurrence of $s_{i,j}$ substituted by y_q. The case of $k_i < 0$ is treated similarly. By Lemma 1, we note that this can be done in time $O(\|I_T(\beta_{i-1})\| + \lg k_i \|I_T(s_i)\|)$ in the assumed model of computation. In particular, $I_T(\beta_i)$ is an intersection sequence representation of $\beta_i = \tau_{s_i}^{k_i} \circ \cdots \circ \tau_{s_1}^{k_1}(\alpha)$ and has complexity

$$\begin{aligned} O(\|I_T(\beta_i)\|) &= O(\|I_T(\beta_{i-1})\| + \lg k_i \|I_T(s_i)\|) \\ &= O\left(\|I_T(\alpha)\| + \sum_{i'=1}^{i} \lg k_{i'} \|I_T(s_{i'})\|\right) \\ &\leq O\left(|T| + |T| \sum_{i'=1}^{i} \lg k_{i'}\right) = O\left(|T| \sum_{i'=1}^{i} \lg k_{i'}\right), \end{aligned}$$

where in the second line we recursively applied the equation of the first. The total time to compute $I_T(\beta) = I_T(\beta_n)$ is bounded by $n \times \|I_T(\beta)\| = O(n|T| \lg k)$, and, in the case $k_i = 1$ for all $1 \leq i \leq n$, this becomes $\Theta(n^2|T|) = \Theta(n|T| \lg k)$.

Although $I_T(\beta)$ is, by construction, standard in T, it might not be normal. We can use the main algorithm of [45] to deterministically compute, in time $O(\|I_T(\beta)\|^{10})$, cyclic reduced SLPs for β with complexity $O(\|I_T(\beta)\|^2)$. Alternatively, this can be done with a randomized algorithm in time $O(\|I_T(\beta)\|^3)$ with probability of error at most δ and in a unit-cost RAM model of bit-size $O(\|I_T(\beta)\| + \lceil 1/\delta \rceil)$ [53]. Part (c) of Lemma 1 finishes the proof. ◀

4 Algorithms on Heegaard diagrams

We now describe some polynomial-time algorithms and operations on a genus g Heegaard diagram $(T, E_T(\alpha), N_T(\beta))$ with complexity m and representing a closed 3-manifold M. We choose here to highlight algorithms that refer back to the discussion on censuses from the introduction, giving examples on how to simplify the underlying combinatorics of splittings (Theorem 5), disqualify inputs (Theorem 6), and compute invariants (Theorems 7 and 8). For the complexities reported, we assume a unit-cost RAM model of bit-size $\log |\beta \cap E| = O(\|N_T(\beta)\|/|T|)$.

▶ **Theorem 5** (`DO A DISK SLIDE`). *A diagram $(T, E_T(\alpha), N_T(\beta'))$, where β' is the result of applying a disk slide on any two components of β, can be computed in time $O(m|T|)$.*

Proof. Compute the street complex $S(T, \beta)$; recall that it has complexity of $O(|T|)$. Using breadth-first in the dual graph of $S(T, \beta)$, find, in time $O(|T|^2)$, the shortest arc p that connects faces adjacent to b_1 and b_2 and that does not cross any component of β, which can be avoided by adding infinite weights to the edges of $S(T, \beta)$ not in T. Note that such an arc must exist because no component of β can be separating in the surface. Moreover, because p is shortest and therefore intersects at most $O(|T|)$ streets in $S(T, \beta)$, we can compute using Part (b) of Theorem 3, an SLP of complexity $O(m|T| + |T|) = O(m|T|)$ of an intersection sequence of p with respect to T, call it $I_T(p)$.

Suppose that p is not trivial, that is, it is not just a single point. By Theorem 6.2 of [24], find, in time $O(m|T|)$, SLPs of the intersection sequences of b_1 and b_2 with respect to T starting at edges adjacent to the endpoint faces of p, call them $I_T(b_1)$ and $I_T(b_2)$. Finally, let $I_T(b) = I_T(b_2)^{-1} \circ I_T(p)^{-1} \circ I_T(b_1) \circ I_T(p)$. Note that $I_T(b)$ already is an intersection sequence of a normal curve in T. For, since p is a shortest path, it is normal in $S(T, \beta)$, which implies that it is also normal in T. Moreover, p has junctions as endpoints; if it had streets as endpoints, there would be a shorter arc connecting b_1 to b_2 starting at one of

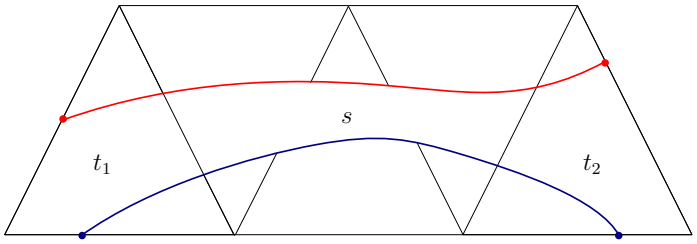

Figure 3 Diagram for the proof of Theorem 5. The red and blue curves represent b_1 and b_2, respectively. The black lines represent the other edges of $S(T, \beta)$. The edges e_1 and e_2 are adjacent to s and t_1 and t_2, respectively.

the ends of the street. Therefore, any other reduction in $I_T(b)$ would necessarily arise by p entering a junction of $S(T, \beta)$ through a non-redundant port e that is also intersected by either b_1 or b_2. But then, the other triangle in T adjacent to e is adjacent to either b_1 or b_2, implying that p is not shortest. By repeated applications of Part (c) of Lemma 1, one can compute, in time $O(|T| \times m)$, the number of (unsigned) occurrences of each edge of E in the SLP of $I_T(b)$, resulting in $N_T(b)$.

If p is trivial, then b_1 and b_2 bound the same face in $S(T, \beta)$. Nonetheless, because the curves are not isotopic, there exists at least one face bounded by b_1 and not bounded by b_2. We call such a face *good*. Choose, in time $O(|T|)$, a non-good face t_1 that is adjacent to a good face through an edge e_1, see Figure 3. Note that e_1 is the endpoint of a street s of sides in b_1 and b_2. Look for the other end of this street, e_2 – again, because b_1 and b_2 are not isotopic, the street has another end. Let t_2 be the face (in fact, a junction) not equal to s, but also adjacent to e_2. Compute, again through [24][Theorem 6.2], the sequence of faces adjacent to b_1 starting at t_1 and going all the way up to t_2 without crossing s, call this sequence $I_T(\widetilde{b_1})$. Compute the related sequence for b_2, this time starting in t_2, call it $I_T(\widetilde{b_2})$. Let $I_T(b) = I_T(\widetilde{b_2}) \circ I_T(\widetilde{b_1})$, note that it is also normal in T as b_1 and b_2 are normal and it enters t_1 and t_2 through distinct edges. Part (c) of Lemma 1 finishes this case. ◀

▶ **Theorem 6** (`DETECT REDUCTION`). *There is an algorithm that runs in time $O(\text{poly}(m, |T|))$ and detects whether a diagram is reducible. Moreover, if the diagram is reducible, it returns either an isotopic pair of $a \in \alpha$ and $b \in \beta$, or a separating curve s.*

Proof. We divide the algorithm into two parts, corresponding to the two hypotheses of reducibility of diagrams, namely the existence of an isotopic pair of meridians $a \in \alpha$ and $b \in \beta$, or of an essential separating curve that splits Σ_g into subdiagrams. For the first case, apply [41][Theorem 6.3] to find, in polynomial-time on the input, an isotopic diagram (α, β') in efficient position. This procedure increases the complexity of β to $m' = m(1 + 2|T|)$ We note that although this subroutine is polynomial-time on the input, the author of [41] does not provide an estimation of the polynomial degree, and any attempt on our part to give one would be out of the scope of this paper. Because we made the diagram efficient, there can only be a component $a \in \alpha$ isotopic to some $b' \in \beta'$ if $e(b') = 0$ for all $e \in E_T(\alpha)$. If that is the case, we trace $S(T, b')$. Since $b' \cap a = \emptyset$, the curve a is still fully in the edges of the street complex. Nonetheless, a is isotopic to b' if and only if they cobound a cylinder [25], a case that can be determined in time $O(|S(T, b')|)$. Checking this for every pair of curves a and b' that do not intersect – there can be at most g^2 of these pairs – gives a test for the first hypothesis.

If the above test returns no clear reduction pair, we look for a separating curve, s, disjoint from α and β, which exists if and only if s is non-contractable in $\Sigma'' = \Sigma_g \backslash (\alpha \cup \beta)$. Because $\Sigma' = \Sigma_g \backslash \beta$ is a $2g$ puncture sphere, Σ'' is a union of (potentially one) punctured spheres, and

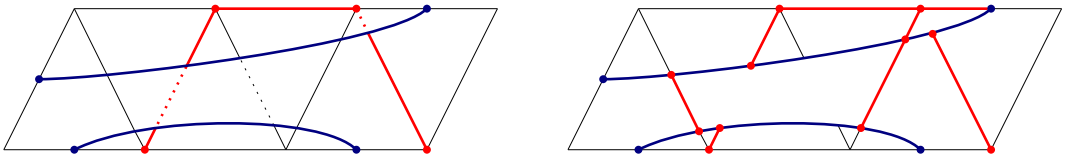

Figure 4 Diagram illustrating the proof of Theorem 6. Left: part of the overlay graph defined by the β curves (blue) with respect to a triangulation (black) and the corresponding embeddings of a segment of the α curves (red). Redundant ports are shown in dashed. A cellular embedding of the surface Σ'' can be obtained by puncturing the diagram along both blue and red curves. Right: another cellular embedding for Σ'' in which we enlarge the holes punctured when cutting α by moving redundant ports in $E_T(\alpha)$ to both ends of the streets.

it embeds a non-contractable curve if and only if one of its components is not a disk. This means that we only need to compute a cellular embedding of Σ'' and check its topological type. We start computing a triangulation for Σ' as in the proof of Theorem 5 by tracing $S(T,\beta)$ and disconnecting from the gluing rules the edges of $E_{S(T,\beta)}(\beta)$. We then want to further cut Σ' along α. But, because α is edged with respect to T, each segment of $E_T(\alpha)$ will be a port in the overlay graph of β (with respect to T). Each such a port will either be non-redundant – in which case it will still be an edge of $S(T,\beta)$) – or it will be redundant – in which case it will be in the crossing sequence of some non-degenerate street and will be deleted to form $S(T,\beta)$ (left side of Figure 4). Therefore, for each street in $E_{S(T,\beta)}(\beta)$ (degenerate or not), we can use Part (c) of Lemma 1 and Part (b) of Theorem 3 to determine, in time $O(\|E_T(\alpha)\| \times m|T|)$, if there is an occurrence of an edge in $E_T(\alpha)$ in a street's crossing sequence and delete from the complex $S(T,\beta)$ (the interior of) any such a street. Because the streets are disks in Σ', bounded by one or two segments of β, we note that, topologically, deleting the full interior of the streets that are transverse to some edge in $E_T(\alpha)$ is equivalent to puncturing a hole corresponding to a redundant port of the overlay graph by simply "enlarging" the hole (right side of Figure 4). This means that we have a cellular embedding of Σ'' which can be queried, in polynomial-time, for its topological type. Assuming that Σ'' has a component that is not a disk: we can use the techniques of [23] (refer to Section 2.3 of [14] for details) to find, in time $O(|T'|)$ a non-contractable curve s in Σ'' expressed as an SLP of complexity $O(m|T| + |T|) = O(m|T|)$. We finally compute $S(T,s)$, in time $O(m|T|^2)$, to check whether a diagram is defined on each component of $\Sigma_g \backslash s$. For such, we need only to find 1. the number of α and β components on each side of s; and, 2. whether s is not isotopic to an α or β curve by again looking for bounded cylinders. ◀

▶ **Theorem 7** (`GET` $H_1(M)$)**.** *The Smith normal form of the presentation matrix of $H_1(M)$ can be found in time $\widetilde{O}(m^2g^3 + m|T|)$, where $\widetilde{O}$ indicates some hidden polylogarithmic factors.*

Proof. We first compute the presentation matrix K of the homology group whose coefficients are algebraic intersection numbers between the diagram's curves. Because we assume that each a_j is a list of edges $E_T(a_j)$, given an SLP $I_T(b_i)$,

$$\hat{i}(b_i, a_j) = \sum_{e \in E_T(a_j)} e(I_T(b_i)) - e^{-1}(I_T(b_i)),$$

which, by Lemma 1, can be computed in time $O(\|I_T(b_i)\| \times \|E_T(a_j)\|)$. Therefore, referring to Theorem 3 to compute $I_T(\beta)$, the total computational time of this procedure is $O\Big(m|T| + \sum_{i=1}^{g}\sum_{j=1}^{g} \|I_T(b_i)\|\|E_T(a_j)\|\Big) = O(m|T| + m|T|)$. Finally, we reduce the matrix K to its Smith normal form in time $\widetilde{O}(g^3m^2)$ by the Kannan-Bachem algorithm [52]. ◀

▶ **Theorem 8** (`GET` $\pi_1(M)$)**.** *A presentation of* $\pi_1(M)$ *can be computed in time* $O(m|T|)$*.*

Proof. Given $I_T(\beta) = \{I_T(b)\}_{b\in\beta}$ delete, in linear time on the complexity of the SLPs, all references to edges $E - E_T(\alpha)$ and substitute each edge of $E_T(\alpha)$ by the symbol that represents its associated component $a \in \alpha$, here seen as a generator $\pi_1(M)$. This gives g distinct SLPs $r_i = [x_1^i = \text{EXPR}_1^i, \dots, x_{\ell_i}^i = \text{EXPR}_{\ell_i}^i]$ whose complexities add up to m and describe the relations of the presentation of $\pi_1(M)$. A presentation of $\pi_1(M)$ can then be defined with generators $a_1, \dots, a_g, x_1^1, \dots, x_{\ell_i-1}^1, \dots, x_{\ell_g-1}^g$ and relators $(x_j^i)^{-1} \cdot \text{EXPR}_j^i$ (this corresponds to repeated applications of a Tietze move [36] to the presentation of $\pi_1(M)$ computed using the method described at the end of Section 2.1). The output is a balanced presentation of $\pi_1(M)$ with $\|I_T(\beta)\|$-many generators and relators. The total time is dictated by Theorem 3. ◀

▶ Remark 9. Because the outputted presentation of $\pi_1(M)$ in Theorem 8 has linear size on the input, most complexity results about *uncompressed presentations* of 3-manifolds (such as triangulations) that appeal to the fundamental groups still hold in our *compressed* data structure. This is the case, for example, of Zentner's proof that sphere recognition lies in co-`NP` [55] (assuming the generalized Riemann hypothesis). Similarly, the usual bounds on the volume [16] and diameter [54] of hyperbolic 3-manifolds can be naturally translated to our notion of complexity.

5 Examples and experiments

Given a Heegaard word presentation (Σ_g, ϕ) of a closed 3-manifold M, there exist algorithms to compute, in linear time on the length of ϕ, a triangulation of M with as many tetrahedra [1, 2, 5, 38]. This implies, for example, that the first homology group of M, $H_1(M)$, can be computed in polynomial-time on $|\phi|$. These algorithms should be contrasted with Theorem 4, which says that SLPs of the intersection sequence $I_T(\beta = \phi(\alpha))$ can be computed in linear time on the complexity of ϕ *measured in power-notation form*. Because the fundamental group of M depends only on $I_T(\beta)$, algebraic information on splittings with significantly complicated gluing maps can be retrieved by Theorems 7 and 8.

Here, we explore the gains from the compressed data structure by comparing an early implementation of our methods with `SnapPy`'s [18] `Twister` [4] module, commonly used to compute triangulations from Heegaard words. Since experiments are limited to Heegaard words as input, there is no need to use proper normal coordinates or even triangulations of Σ_g; instead, we may compute the SLPs of the induced diagram with respect to general cellular embeddings, therefore avoiding the high cost of cyclic reductions. This guarantees that, for the problems analyzed, our theoretical complexity is at least equal to `Twister`'s. Even without these simplifying assumptions, we are still exponentially faster in the worst cases, as we show in the following section about lens spaces.

5.1 Genus 1

Heegaard splittings over the genus 1 surface – i.e., the torus – form the well-known family of *lens spaces*. Every lens space is uniquely given by a pair of integers $L(p, q)$, which, for a Heegaard splitting (Σ_g, a, b), represents the algebraic intersection numbers of b with the usual longitude and meridian of the torus (there is some ambiguity in the values of p, q, see [47]). A Dehn twist about the meridian m of the torus maps (p, q) to $(p + q, q)$, while about the longitude ℓ maps to $(p, q - p)$. This gives a representation of $\text{Mod}(\Sigma_1)$ in $\mathbb{Z}^2$ from which the homology of the Heegaard splitting (Σ_g, ϕ) can be exactly computed by $|\phi|$ matrix

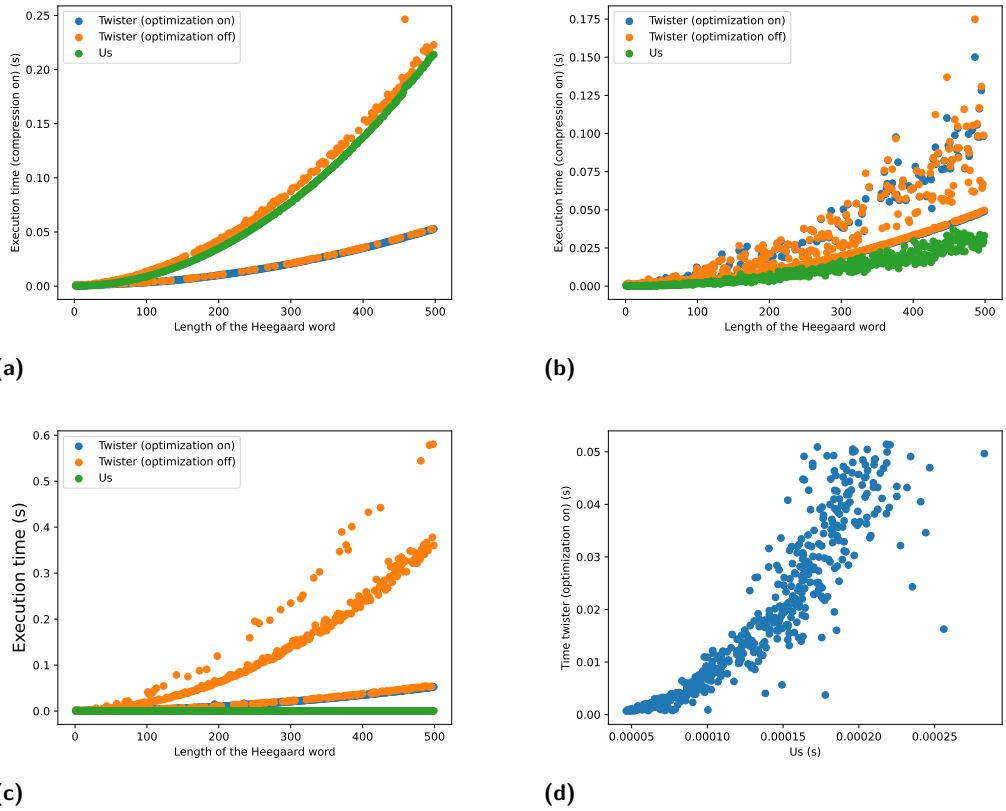

Figure 5 Experiments with computing the homology group H_1 of Heegaard splittings over the torus. Averages were computed for 30 repetitions.

multiplications and one query on the final value of q. We used this approach to benchmark the accuracy of our method, which returned the expected H_1 for input words ϕ of length up to 1000, the maximum size we tested.

Figure 5 compares the average computational time needed to find $H_1(\Sigma_1, \phi)$ taken by our method and by `Twister` for four different families of ϕ indexed by an integer n: (a) words of form $(\tau_m \tau_\ell^{-1})^n$; (b) uniformly sampled words of length n; (c) words of form τ_ℓ^n; and (d) words of form τ_ℓ^n, but this time, given in power-notation form. Averages were taken over 30 repetitions. In all cases, we compared our times with `Twister`'s with and without optimization (where, by optimization, the authors mean the greedy folding of tetrahedra; refer to their documentation for details[1]). Although optimization drastically reduces computational time, it seems to increase numerical error. In every instance, except for (d), we first transformed the words into a power-notation form before using them to compute $I_T(b)$; in total, this can be done in linear time on $|\phi|$.

▶ Remark 10. A direct application of the representation of $\mathrm{Mod}(\Sigma_1)$ implies that, for the family of case (a), $H_1^n = \mathbb{Z}/f_{2n}$ where f_n is the n-th Fibonacci number (starting at 0). We used this relation to benchmark the accuracy of the methods for different values of n. While our technique always agrees with the expected value for up to $n = 500$, `Twister` (with optimization both on and off) started deviating for values of $n \geq 25$. Interestingly, we did not observe divergences for higher genii splittings.

[1] Available at `https://snappy.computop.org`.

Case (a) is where our advantages compared to `Twister` are the worst. This is because the words $(\tau_m \tau_\ell^{-1})^n$ do not admit a non-trivial power-notation form, which is mainly responsible for our gains in the other cases. Nevertheless, it is worth highlighting that, while `Twister` is partially implemented in `C++`, our code is fully `python`. Case (b) represents the average case of computing the homology of lens spaces given a gluing map ϕ. We notice that we are now consistently faster for all values of n tested. This happens exactly as we explore redundancies by first putting the word in power-notation form, with significant gains every time the same Dehn twist occurs in sequence (since $\mathrm{Mod}(\Sigma_g)$ has two generators, this will be the case quite often). The gains due to repetitions are further highlighted in (c): while `Twister` is bound to take $O(n^c)$, for some $c > 1$, to compute the homologies, our approach takes time $O(n + \lg n)$, where the linear dependence comes solely from compressing the inputs to power-notation. In fact, if we assume the words already in power-notation, we are exponentially faster than `Twister`, as shown in case (d).

We can actually explore our structure's usage of power-notation to compute invariants of families of 3-manifolds that would necessarily require exponentially many tetrahedra to be represented. The minimum number of tetrahedra in a *layered triangulation* of a lens space $L(p, q)$ is $\sum_i (a_i) - 1$, where $(a_0, \ldots, a_k)$ is the continued fraction expansion of q/p [34]. Moreover, [32, 35] discovered families of lens spaces – including the spaces defined by $p = 2n, q = 1$ and $p = 4n, q = 2n - 1, n \geq 2$ – for which layered triangulations are minimal among *all* triangulations. So, for example, while the family $L(2^n, 1)$ necessarily requires exponentially many tetrahedra to be represented, it can be encoded in linear space in our data structure. It seems natural to expect that there are many other families of manifolds, with diagrams exponentially smaller than the minimum number of tetrahedra, for which our techniques can provide real computational gains compared to any existing method.

Abstract

We study unlabeled multi-robot motion planning for unit-disk robots in a polygonal environment. Although the problem is hard in general, polynomial-time solutions exist under appropriate separation assumptions on start and target positions. Solovey et al. (RSS'15) provide a near-optimal solution assuming that start/target positions must have pairwise distance at least 4, and at least $\sqrt{5} \approx 2.236$ from obstacles. This raises the question of whether polynomial-time algorithms can be obtained in even more densely packed environments.

In this paper we present a generalized algorithm that achieve different trade-offs on the robots-separation and obstacles-separation bounds, all significantly improving upon the state of the art. Specifically, we obtain polynomial-time constant-approximation algorithms to minimize the total path length when (i) the robots-separation is $2\frac{2}{3}$ and the obstacles-separation is $1\frac{2}{3}$, or (ii) the robots-separation is ≈ 3.291 and the obstacles-separation ≈ 1.354. Additionally, we introduce a different strategy yielding a polynomial-time solution when the robots-separation is only 2, and the obstacles-separation is 3. Finally, we show that without any robots-separation assumption, obstacles-separation of at least 1.5 may be necessary for a solution to exist.

1 Introduction

In the classic multi-robot motion-planning (MRMP) problem, a set of robots operate in a common workspace, and need to reach a set of target positions. More precisely, given a set of m starting positions and a set of m target positions, the goal is to compute a motion strategy for the robots to reach the targets while avoiding collisions with the boundary of the workspace and with other robots. In this paper we consider unit-disk robots that are moving in a polygonal workspace in the plane. If each robot is assigned to a specific target, the problem is referred to as *labeled* MRMP, and otherwise it is *unlabeled* MRMP.

The MRMP problem and its variants have been widely investigated, both from theoretical and practical perspectives (see, e.g., [3, 4, 5, 6, 9, 11] for some of the more recent works on the problem). Very recently, both the labeled and unlabeled variants of MRMP for unit disks in polygons with holes were shown to be PSPACE-hard [1]. Many other variants of the problem are known to be hard as well, see e.g. [8, 12, 14, 16].

Interestingly, the separation between the robots plays a key role in the difficulty of the problem. Adler, de Berg, Halperin, and Solovey [2] show that in a simple polygonal workspace with n vertices and m unit-disk robots, when the ***robots-separation***, denoted ρ, is 4 (i.e., all the start and target positions are at least distance 4 apart), a solution for unlabeled MRMP always exists, and can be found in $\tilde{O}(mn + m^2)$ time. In [7] this result is further improved by distinguishing between ***monochromatic*** robots-separation (i.e. the distance between two start or two target positions), and ***bichromatic*** robots-separation (i.e. the distance between a start position and a target position). The algorithmic approach in both papers [7, 2] is similar and does not provide any reasonable approximation on the length of the solution, i.e., the total length of the paths in the motion plan.

Solovey, Yu, Zamir, and Halperin [15] present a different approach for unlabeled MRMP, with optimality guarantee even in polygons with holes, but at the cost of adding an additional assumption on the distance between the obstacles to any start and target position. Specifically, they consider the case when the robots-separation is $\rho = 4$, and the ***obstacles-separation***, denoted ω, is $\sqrt{5} \approx 2.236$. Under these assumptions, they present an algorithm that runs in $\tilde{O}(m^4 + n^2m^2)$ time and returns a solution of total length at most $\mathrm{OPT} + 4m$. Here and throughout the paper, OPT denotes the minimum possible sum of lengths of the paths in a collision-free motion plan.

Notice that when assuming a large robots-separation ($\rho \geq 4$), the overall "density" of the robots inside the workspace becomes small, which may require the workspace to be much larger than the number of robots operating in it. Also, assuming a large obstacles-separation requires adding an additional buffering "layer" around the obstacles. This motivates the question of whether we can find weaker assumptions on either the robots-separation or the obstacles-separation, that are sufficient for having a polynomial time algorithm for unlabeled MRMP. Surprisingly, in this paper we show that both the robots-separation and obstacles-separation assumptions can be significantly relaxed, while still enabling a polynomial-time algorithm that achieves a constant-factor approximation of the solution length.

In previous works, namely [2, 7, 15], the algorithmic approach uses a ***monotone*** strategy, where robots move to their target position one by one according to some order, while other robots must remain at their start/target positions. The main result in our paper uses a weakly-monotone strategy. In a ***weakly-monotone*** motion plan, each start/target position p is associated with a revolving area - a disk of radius $r > 1$ that contains the unit disk centered at p and is empty of obstacles and other unit disks centered at other start/target positions. The robots move to their target position one by one according to some order, while other robots must remain inside the revolving area associated with their current position. Such a weakly-monotone strategy was used, e.g., in [4, 13] for a variant of labeled MRMP with unit-disk robots.

Our contribution. In this paper we present two different algorithms for unlabeled MRMP, that provide tighter trade-offs between robot-separation and obstacles-separation assumptions. In particular, for a parameter $0 \leq \varepsilon \leq 1$, a polygonal environment of complexity n, and m unit-disc robots, our first algorithm computes in $\tilde{O}(m^4 + n^2m^2)$ time a collision-free motion plan of total length $O(\mathrm{OPT})$, assuming that $\rho = \max\{4 - 2\varepsilon, 2 + \varepsilon\}$ and $\omega =$

$\max\{1+\varepsilon, \sqrt{(3-\sqrt{3}-\varepsilon)^2+1}\}$ (see Theorem 9). In Table 1 we highlight three interesting values of ε that minimizes either ρ, ω or the guaranteed length of the solution. This algorithm can be viewed as a generalization of the algorithm in [15], and indeed, as a consequence of our analysis we positively resolve a conjecture made in [15], by showing that $\omega = 1.614$ is sufficient when $\rho = 4$. Moreover, in the full version of our paper [10] we show that a monotone motion plan (such as the one produced by the algorithm in [15]) may not always exist when $\omega < 1.614$, and therefore to achieve smaller separation bounds one must use a different strategy. Indeed, as mentioned above, our motion plan is weakly-monotone. Interestingly, we also show that a weakly-monotone motion plan may not always exist when $\omega < 1.354$.

Note that our first algorithm does not cover the case of $\rho = 2$, which is the optimal (monochromatic) robots-separation. We therefore present a second algorithm using a completely different approach, which given a simple polygon with n vertices and m unit-disk robots, computes in $O(m^3 + mn^2)$ time a collision-free motion plan of total length $\mathrm{OPT} + O(m^2)$, assuming that $\rho = 2$ and $\omega = 3$ (see Theorem 10). Finally, we show that $\omega = 1.5$ may be necessary for a solution to exist.

Table 1 Summary of algorithms and their separation assumptions.

ω	ρ	Solution length	Running time	Notes	Reference
1	4	no guarantee	$\tilde{O}(mn + m^2)$	Simple polygons	[2, 7]
$\sqrt{5}$	4	$OPT + 4m$	$\tilde{O}(m^4 + n^2m^2)$		[15]
≈ 1.614	4	$OPT + 4m$	$\tilde{O}(m^4 + n^2m^2)$		Theorem 9
≈ 1.354	≈ 3.291	$O(OPT)$	$\tilde{O}(m^4 + n^2m^2)$		Theorem 9
$1\frac{2}{3}$	$2\frac{2}{3}$	$O(OPT)$	$\tilde{O}(m^4 + n^2m^2)$		Theorem 9
3	2	$OPT + O(m^2)$	$\tilde{O}(m^3 + mn^2)$	Simple polygons	Theorem 10

Technical ideas and overview of the paper

Our approach in the first algorithm generalizes the strategy of Solovey et al. [15] for unlabeled MRMP, which is briefly described as follows. Given a set S of start positions, a set T of target positions, and a polygonal workspace $\mathcal{W}$, first compute an optimal set Γ of paths assigning each starting point to a target point (a perfect matching). This set of paths minimizes the sum of geodesic distances, when ignoring the other robots in the workspace. Then, one can show that when assuming $\rho = 4$ and $\omega = \sqrt{5}$, there is always at least one target which is a so-called standalone goal, that is, a target t that does not block any other path in Γ. Such a target is useful because we can place a robot there and then treat it as an obstacle. However, there might be some other robot that blocks the path that leads to t, in which case we can make a switch: we push the last robot that blocks this path to t. This switching process is possible because of the assumption $\omega = \sqrt{5}$. Then, run the algorithm recursively, but after removing the start and target positions that where satisfied in the previous recursive step, and updating the workspace to treat the robot at t as an obstacle.

Our weakly-monotone motion plan is obtained by inserting a very important modification to the algorithm of [15]: instead of choosing a standalone target in each iteration, we relax the requirement and require only an "almost standalone" target – a target that may interrupt

other paths, but only by a small amount. In our strategy, we distinguish between "blocking" and "interrupting" positions. Instead of always switching paths when another robot is standing in the way, we allow robots that interrupt a path by only a small amount to move away from the path. A robot that interrupts a given path may move slightly in its close neighborhood (a disk of radius equal to the amount of interruption plus one) in order to clear the way. In contrast, a robot that blocks a path may not have enough wiggle room, and we will switch the paths.

As suggested above, this combined strategy can be viewed as a generalization of [15]: we introduce another parameter, called the "overlap parameter", which is used to determine whether a position is blocking a path or only interrupting it. This parameter allows us to define a set of constraints on ρ and ω, that allows (i) the existence of an interrupting target, (ii) the option to switch paths in the case when a robot is blocking a path, and (iii) the existence of a sufficiently large free neighborhood for an interrupting robot to clear the way. It turns out that there is an interesting trade-off between these constraints, leading to the main result of our paper (Theorem 9).

Note that the concept of interrupting positions raises some issues that were not present in the algorithm of [15]. For example, in each iteration of the recursive algorithm we need to take into account that the robot placed on a target may still interrupt other paths. In [15] this is solved simply by removing a unit disk around the interrupting target from the workspace. However, in our case, such a robot may still need to move in order to clear the way for other robots. Moreover, if we simply treat it as an obstacle, the assignment of paths in the next iteration may be too large. We solve this issue by observing that it is actually enough to remove a smaller disk around a settled target when computing the paths, while still allowing it to move within its small neighborhood when planning the motion in the following iterations. Another issue is that there may be two or more robots that interrupt a path and may need to move simultaneously. Here we describe a simple motion with respect to the ray connecting the robot moving on the path with the interrupting robots.

In Section 3, we systematically define and analyze the constraints that are required for each part of this strategy, each constraint depends on the overlap parameter. In Section 4 we present the complete generalized algorithm and prove its correctness. Then, we show how to choose an overlap parameter and adjust constraints to get the minimum possible obstacles-separation and the minimum possible robots-separation.

In our first algorithm, to clear a path, we only move robots that intersect that path. Such a strategy cannot work when the robots-separation is exactly 2, because a robot that intersect a path may be block by other robots that do not intersect that path, and thus will not be able to move and clear the path. Therefore, to achieve a separation bound of 2 between the robots, we present in Section 5 a completely different strategy, which we call the Exodus algorithm. In this strategy, we also iteratively pick a path between start and target positions that were not yet satisfied, and move a robot along that path, however, in contrast to the first algorithm, we clear the path completely by also moving robots that do not intersect the path. In simple polygons, this strategy allows us to assume robots-separation of only 2, with obstacles-separation of 3, and it applies also for labeled MRMP (see Theorem 10).

Note that the monochromatic separation must be at least 2, so the robots-separation is almost optimal (the bichromatic separation can be 0). In Section 6 we preset lower bounds on the obstacles-separation, and we leave open the question of what is the upper bound on ω when robots-separation is optimal.

2 Preliminaries

We consider a set of m unit-disk robots, moving in a polygonal ***workspace*** $\mathcal{W} \subseteq \mathbb{R}^2$ (which may be simple or cluttered with polygonal obstacles), whose overall number of edges is n. Below, we mostly follow the notations in [7] and [15].

The ***obstacle space*** $\mathcal{O}$ is the complement of the workspace $\mathcal{W}$, that is, $\mathcal{O} = \mathbb{R}^2 \setminus \mathcal{W}$. We refer to the points in $\mathcal{W}$ as positions, and say that a robot is at position $x \in \mathcal{W}$ when its center is positioned at the point x. For a point $x \in \mathbb{R}^2$ and a radius $r \in \mathbb{R}_+$, we define $D_r(x)$ to be the open disk of radius r centered at x. The unit-disk robots are defined to be open sets, and therefore two robots collide if and only if the distance between their positions is strictly less than 2. In addition, a robot collides with the obstacle space $\mathcal{O}$ if and only if its center is at distance strictly less than 1 from $\mathcal{O}$. The set of all positions in $\mathcal{W}$ where a unit-disk robot does not collide with the obstacle space is called the ***free space***, denoted $\mathcal{F} = \{x \in \mathbb{R}^2 \mid D_1(x) \cap \mathcal{O} = \emptyset\}$. Note that the free space is a closed set, and denote by $\partial\mathcal{F}$ the boundary of $\mathcal{F}$.

In the multi-robot motion-planning problem, we are given a workspace $\mathcal{W}$ with n edges and two sets $S = \{s_1, \ldots, s_m\}$ and $T = \{t_1, \ldots, t_m\}$ of points in the free space $\mathcal{F}$. The goal is to plan a collision-free motion for m robots, each positioned on a different starting point in S, such that by the end of the motion every target position in T is occupied by some robot. When the robots are distinguishable (i.e. labeled), the robot that starts at position s_i is required to end up at the target t_i. Otherwise, when the robots are indistinguishable (i.e., unlabeled), it does not matter which robot ends up at which target position, as long as all targets are occupied at the end of the motion.

Formally, we wish to find a set Γ of continuous paths $\gamma_1, \ldots, \gamma_m$, where $\gamma_i : [0,1] \to \mathcal{F}$ for every $1 \leq i \leq m$, and such that $\bigcup_{i=1}^m \gamma_i(0) = S$ and $\bigcup_{i=1}^m \gamma_i(1) = T$. In addition, the paths need to be collision-free, i.e., at any point in time $t \in [0,1]$, there are no i, j such that $\gamma_i(t)$ and $\gamma_j(t)$ are at distance strictly less than 2. Denote the size of a solution Γ by $|\Gamma| = \sum_{\gamma_i \in \Gamma} |\gamma_i|$, where $|\gamma|$ is the length of a path γ in the L_2 norm. In the optimization version of the problem, we are interested in finding a solution Γ which minimizes $|\Gamma|$, i.e., minimizing the sum of lengths of the paths.

Separation assumptions. We denote by ω the ***obstacles-separation*** assumption on an instance of MRMP, i.e., we assume that for every $p \in S \cup T$ and every point $x \in \mathcal{O}$, it holds that $\|x - p\| \geq \omega$. We denote by ρ the ***robots-separation*** assumption, i.e., we assume that for every $p_1, p_2 \in S \cup T$ it holds that $\|p_1 - p_2\| \geq \rho$.

Overlapping, blocking and interrupting positions

Let $p, q \in \mathcal{F}$ be two points in the free space. We define the ***overlap*** of p and q to be $\max\{0, 2 - \|p - q\|\}$ (see Figure 1). If $\mathcal{D}_1(p) \cap \mathcal{D}_1(q) = \emptyset$, then their overlap is 0. Otherwise, we say that p, q are ***ε-overlapping*** for $\varepsilon = 2 - \|p - q\|$, and note that $\|p - q\| = 2 - \varepsilon$.

We say that a position $p \in \mathcal{F}$ is ***ε-blocking*** a path γ if there exists $0 \leq t \leq 1$ such that the overlap of p and $\gamma(t)$ is **strictly larger than ε**. Blocking robots (i.e. robots that are placed on blocking positions) may be impossible to clear from the path, and we will have to make a "switch". We say that a point $p \in \mathcal{F}$ is ***ε-interrupting*** a path γ if for every $0 \leq t \leq 1$, the overlap of p and $\gamma(t)$ is **at most ε** (that is, it is not ε-blocking). Interrupting robots (i.e. robots that are placed on interrupting positions) will have enough wiggle room to move away from γ and "clear" the path. Notice that if for every $0 \leq t \leq 1$ the overlap of p

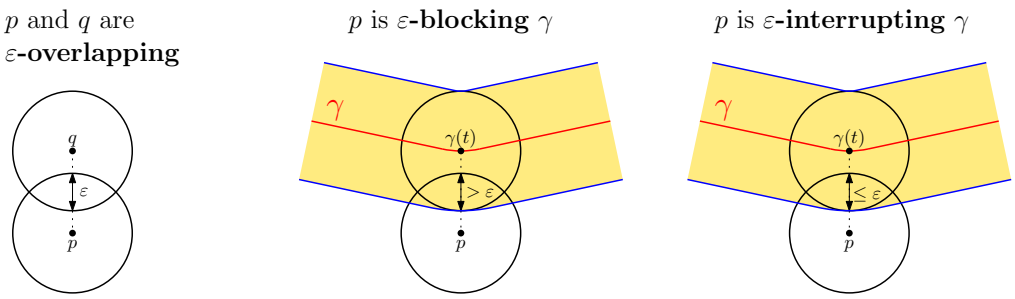

Figure 1 Overlapping, blocking, and interrupting positions.

and $\gamma(t)$ is 0, then for every $0 \leq t \leq 1$ it holds that $\|\gamma(t) - p\| > 2$, and therefore in this case we say that p is 0-interrupting γ. We say that a path γ is ***ε-blocked*** if there exists $s \in S$ that ε-blocks it, and that γ is ***ε-interrupted*** if no $s \in S$ is ε-blocking it.

The overlap parameter. For the analysis in Section 3, we fix a parameter $0 \leq \varepsilon \leq 1$ which we call the ***overlap parameter***. In these sections, for simplicity of the presentation, we sometimes omit ε from the above notions and just say "blocking" or "interrupting". In our analysis, we introduce a set of constrains described as functions of ε, which are required for the different parts of our algorithm to work. In Section 4 we show how to choose ε in order to optimize different separation bounds.

3 Constraints for tighter separation bounds

To give an intuition for the required constraints, we first provide a high-level overview of our strategy. The algorithm is recursive, and its input is the overlap parameter ε, a set S of starting positions, a set T of target positions, and a workspace $\mathcal{W}$. In each recursive iteration, one robot is moving to a target position, then S,T and $\mathcal{W}$ are updated accordingly.

The first step is to compute an ***optimal-assignment path set***, as it is defined in [15]:

▶ **Definition 1.** *Let Γ be a set of m geodesic paths $\gamma_1, \ldots, \gamma_m$, where $\gamma_i : [0,1] \to \mathcal{F}$ for every $1 \leq i \leq m$, and such that $\bigcup_{i=1}^{m} \gamma_i(0) = S$, $\bigcup_{i=1}^{m} \gamma_i(1) = T$. We say that Γ is an optimal-assignment path set for $S, T, \mathcal{W}$ if it minimizes $\sum_{i=1}^{m} |\gamma_i|$ over all such path sets.*

Note that an optimal assignment path set Γ is not necessarily a feasible solution, because it ignores possible collisions between robots. This also means that the sum of paths in Γ is at most the length of an optimal solution to our MRMP problem. Let $\Gamma = \{\gamma_1, \ldots, \gamma_m\}$ be an optimal-assignment path set for $S, T, \mathcal{W}$.

In Section 3.1 we present a useful lemma showing that a blocking robot can enter the geodesic path that it blocks. This lemma will be useful throughout the analysis, and it requires one constraint on the obstacles-separation, and another on the robots-separation.

The next step is to find a target $t \in T$ which does not block any path in Γ (other than the path γ from $s \in S$ to t). Then we can move a robot from s to t along γ, and it will not block other paths in the following iterations. Note that t may still interrupt other paths. In Section 3.2 we show that such a target always exists, when assuming an additional constraint on the robots-separation.

If there is a position $s' \in S$, which blocks the path γ, we need to make a switch, i.e., we construct a new path in $\mathcal{F}$ from s' to t, which is not blocked by any other robot. In Section 3.3 we show how to construct such a switch path γ', under all the constraints defined earlier. If there is no such blocking position s', we simply set $\gamma' \leftarrow \gamma$.

We now have a path γ' from some $s'' \in S$ (which may be either s or s') to the target t, which in not blocked by any robots, but may be interrupted. In Section 3.4 we show how to move a robot from s'' to t along γ', while all interrupting robots (either on start or target positions) move slightly in order to clear the path. For this we introduce two additional constraints, one on the obstacles-separation, and one on the robots-separation.

Finally, we prepare the input for the next recursive iteration, by removing s'' from S, t from T, and $D_{1-\varepsilon}(t)$ from $\mathcal{W}$. Removing $D_{1-\varepsilon}(t)$ from $\mathcal{W}$ ensures that the robots placed on t does not block any path that will be computed in any of the next iterations.

In Section 4 we present the complete algorithm based on the building blocks presented in this section, prove its correctness and analyze its running time and approximation factor.

3.1 Geodesics and blocking positions in the free space

We begin by introducing the constraints under which a blocking robot positioned on some $p \in S \cup T$ can enter a geodesic path $\gamma : [0,1] \to \mathcal{F}$ between some start and target positions, via a straight line segment connecting it to the path.

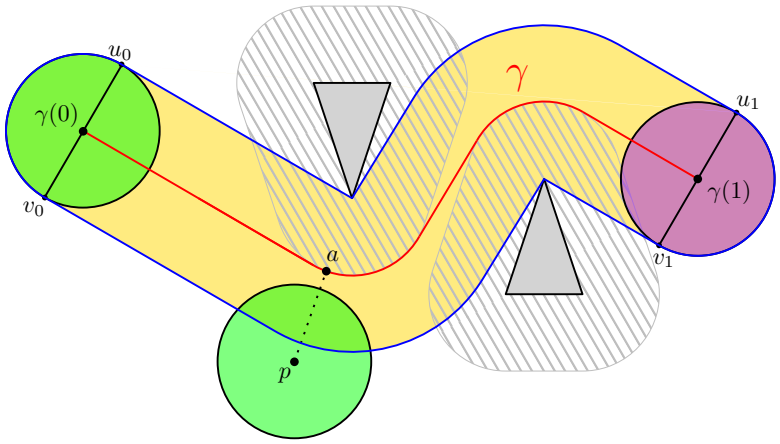

Figure 2 A geodesic path γ in $\mathcal{F}$ from a start position $\gamma(0) \in S$ to a target position $\gamma(1) \in T$ is illustrated in red. The obstacles are in gray, and the trace of γ is highlighted in yellow. A position p is blocking/interrupting γ. The point a is the closest point to p on γ.

A geodesic path between two positions $x, y \in \mathcal{F}$ is a shortest length path $\gamma : [0,1] \to \mathcal{F}$ where $\gamma(0) = x$ and $\gamma(1) = y$. Denote by $\mathcal{D}_1(\gamma) = \bigcup_{0 \le t \le 1} \mathcal{D}_1(\gamma(t))$ the ***trace*** of γ (see Figure 2). For $0 \le t_1 \le t_2 \le 1$, denote by $\gamma[t_1, t_2]$ the subpath of γ between $\gamma(t_1)$ and $\gamma(t_2)$.

In the full version of the paper [10], we provide some very useful geometric properties of geodesic paths in the free space, which result in the following constraints. Note that we have one constraint on the obstacles-separation, and another on the robots-separation.

▶ **Constraint 1.** $\omega \ge \sqrt{(3 - \sqrt{3} - \varepsilon)^2 + 1}$

▶ **Constraint 2.** [1] $\rho \ge \sqrt{\frac{1}{2}^2 + \left(3 - \frac{\sqrt{3}}{2} - \varepsilon\right)^2}$

[1] Note that later we introduce two more constraints on ρ that together make Constraint 2 redundant, however, Lemma 2 holds already for this weaker constraint and may be of independent interest.

Let $\gamma : [0,1] \to \mathcal{F}$ be a geodesic path. We say that a point a on γ is ***locally closest*** to p if there exists $\delta > 0$ such that $D_{\|p-a\|}(p) \cap \gamma[a-\delta, a+\delta] = a$.

▶ **Lemma 2.** *Let $\gamma : [0,1] \to \mathcal{F}$ be a geodesic path such that $\gamma(0), \gamma(1) \in S \cup T$, and let $p \in S \cup T$ be a position which is ε-blocking γ. Let $a = \gamma(t)$ be a point on γ which is locally closest to p and such that $\|p-a\| < 2-\varepsilon$. If Constraints 1 and 2 hold, then $\overline{pa} \subset \mathcal{F}$.*

Intuitively, Lemma 2 states that a robot blocking γ and positioned on p can move to a along the path $\overline{pa}$, as long as no other robots are standing in its way (see Figure 2).

3.2 Existence of an ε-interrupting target

We now define formally a generalization of the standalone goal defined in [15] (Definition 3). Our definition depends on the overlap parameter ε, and it is equivalent to a standalone goal for $\varepsilon = 0$. Let $\Gamma = \{\gamma_1, \ldots, \gamma_m\}$ be an optimal-assignment path set for $S, T, \mathcal{W}$.

▶ **Definition 3.** *A target position $t \in T$ is an* ***ε-interrupting target****, if for every path $\gamma \in \Gamma$ such that $\gamma(1) \neq t$, it holds that t is not ε-blocking γ.*

To show that an ε-interrupting target always exists, we need an additional constraint.

▶ **Constraint 3.** $\rho \geq 4 - 2\varepsilon$

The following theorem is a generalization of Theorem 4 in [15]. The proof follows a similar logic, however, we need to take into account some issues that arise from the generalized definition and Constraints 1–3. See the full version [10] for a complete proof.

▶ **Theorem 4.** *Let Γ be an optimal-assignment path set for $S, T, \mathcal{W}$. If Constraints 1–3 hold, then there exists an ε-interrupting target.*

3.3 Dealing with a blocked geodesic path

Let $\Gamma = \{\gamma_1, \ldots, \gamma_m\}$ be an optimal-assignment path set for $S, T, \mathcal{W}$, and assume w.l.o.g. that $\gamma_i(0) = s_i$ for every $1 \leq i \leq m$. Consider a geodesic path γ_i from s_i to t_j, and assume that is it ε-blocked. Our goal in this section is to describe the switching process: we find another start point $s_k \in S$ and a path $\gamma'_k \subset \mathcal{F}$ from s_k to t_j such that γ'_k is not ε-blocked. Moreover, we describe a path in $\mathcal{F}$ from s_i to t_ℓ, where $t_\ell = \gamma_k(1)$ (see Figure 3). The sum of lengths of these new paths will not be much longer than the original.

For a position $s_k \in S$ that ε-blocks γ_i, denote by $0 \leq w_{i,k} \leq 1$ the largest value such that $\gamma_i(w_{i,k})$ is the point on γ_i locally closest to s_k. We say that $s_k \in S$ is the ***last to ε-block*** γ_i if for any $s_x \in S \setminus \{s_k\}$ that ε-blocks γ_i, we have $w_{i,k} \geq w_{i,x}$ (i.e. the last locally closest point to s_k on γ_i is the closest to $\gamma_i(1)$ along γ_i).

Let s_k be the last to ε-block γ_i, and set $w = w_{i,k}$. Consider the paths $\gamma'_k = \overline{s_k\gamma_i(w)} \circ \gamma_i[w,1]$ and $\gamma'_i = \gamma_i[0,w] \circ \overline{\gamma_i(w)s_k} \circ \gamma_k$ (where γ_k is the geodesic path from s_k to t_ℓ, see Figure 3). We call γ'_i and γ'_k the ***switch paths*** of i and k, respectively. Notice that $\|s_k - \gamma_i(w)\| < 2-\varepsilon$, and therefore $|\gamma'_k| + |\gamma'_i| < |\gamma_k| + |\gamma_i| + 4 - 2\varepsilon$. The following theorem will help us in showing that the switch paths are not blocked (see [10] for a full proof).

▶ **Theorem 5.** *Assume that Constraints 1–3 hold. Then (i) both γ'_i and γ'_k are in $\mathcal{F}$, (ii) $\overline{s_k\gamma_i(w)}$ is not ε-blocked by any $p \in T \cup S \setminus \{s_k\}$, (iii) γ'_k is not ε-blocked by any $s_j \in S \setminus \{s_k\}$, and (iv) if t_j is not ε-blocking γ_k then it does not ε-block γ'_i.*

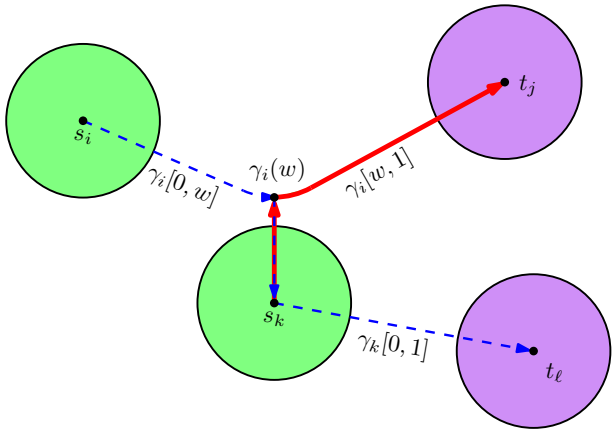

Figure 3 s_k is the last to ε-block γ_i. The switch paths are γ_i' (dashed blue) and γ_k' (red).

3.4 Dealing with robots interrupting a path

In this subsection, we discuss how to move a robot along an ε-interrupted path. We describe simple motion paths for the interrupting robots to clear the way, and we analyze the extra distance traveled by the interrupting robots. We note that shorter paths can be shown for the interrupting robots, however, as this does not effect the correctness of the algorithm, we chose to keep this part simple and describe a simple (yet rather short) motion path.

As mentioned at the beginning of this section, our motion plan consists of a weakly-monotone collision free path set, that is, robots moves to targets according some ordering one by one; when one robot travels from its starting position to some target, the other robots must stay in a small disk centered at their current position (which is either a start or a target position). To ensure that an interrupting robot is able to clear the way while remaining in a disk of radius $1+\varepsilon$ around a start/target position, we introduce two additional constraints.

▶ **Constraint 4.** $\omega \geq 1+\varepsilon$

▶ **Constraint 5.** $\rho \geq 2+\varepsilon$

Consider a robot A traveling in constant speed along a path γ_A from start position $s \in S$ to some target position $t \in T$. Let $p \in S \cup T$ be either a start or a target position, occupied by another robot B, which is ε-interrupting γ_A. We describe a motion plan for B by constructing a ***clearance path*** $\tilde{\gamma}_B : [0,1] \to \mathbb{R}^2$, along which the robot B will travel with constant speed, as follows.

Let $\gamma_A[w_1,w_2]$ be a maximal subpath where $\|\gamma_A(w) - p\| \leq 2$ for every $w \in [w_1,w_2]$, that is, when A travels along $\gamma[w_1,w_2]$, the robot B must clear the way. Note that there could be more than one such maximal subpath for B. We define the corresponding subpath $\tilde{\gamma}_B : [w_1,w_2] \to \mathbb{R}^2$ for B using a polar coordinate system, where p is the pole. Denote by r_x the radius and by θ_x the angle of a point x, and let $\tilde{\gamma}_B(w) := \big(2 - r_{\gamma_A(w)}, \theta_{\gamma_A(w)} + \pi\big)$.

The next lemma shows that the clearance path of B is feasible and relatively short. See [10] for the full proof.

▶ **Lemma 6.** *$\tilde{\gamma}_B(w)[w_1,w_2]$ is a continuous path that starts and ends at p, such that (i) $\tilde{\gamma}_B[w_1,w_2] \subset D_\varepsilon(p) \subset \mathcal{F}$, and (ii) $|\tilde{\gamma}_B[w_1,w_2]| \leq |\gamma_A[w_1,w_2]|$ for $0 \leq \varepsilon \leq 1$.*

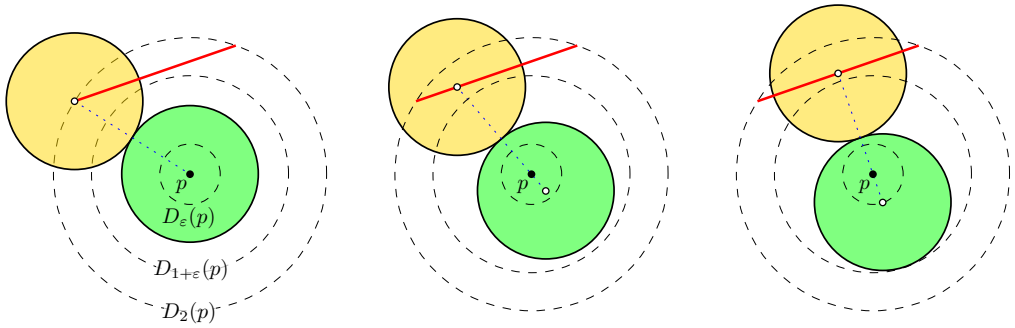

Figure 4 Left: the robot B is initially positioned at p. In red is a maximal subpath of γ_A where B needs to clear the way. Middle, right: the robot B move inside $\mathcal{D}_\varepsilon(p)$ while maintaining distance exactly 2 from the robot A.

Recall that B may interrupt γ_A in more than one maximal subpath, so overall we define the clearance path $\tilde{\gamma}_B : [0,1] \to \mathbb{R}^2$ as

$$\tilde{\gamma}_B(w) = \begin{cases} p, & \text{if } \|p - \gamma_A(w)\| \geq 2, \\ \left(2 - r_{\gamma_A(w)}, \theta_{\gamma_A(w)} + \pi\right), & \text{if } \|p - \gamma_A(w)\| < 2. \end{cases}$$

In addition, we construct such a clearance path for any other robot that interrupts γ_A. In the full version [10] we prove the following theorem, which shows that clearance paths are collision-free, assuming Constraints 1–5.

▶ **Theorem 7.** *Let A be a robot traveling in constant speed along a path γ_A from start position $s \in S$ to some target position $t \in T$, and let $\{\tilde{\gamma}_B \mid B \neq A\}$ be the set of clearance paths defined for the other robots. If Constraints 1–5 hold for $0 \leq \varepsilon \leq 1$, then the motion plan that corresponds to the paths $\gamma_A \cup \{\tilde{\gamma}_B \mid B \neq A\}$ is collision-free.*

4 Unlabeled MRMP with improved separation trade-offs

In this section we present and analyze the algorithm based on the tools developed in the previous section. The input for the algorithm is an overlap parameter ε, a workspace $\mathcal{W}$, a set S of starting positions and a set T of target positions, such that Constraints 1–5 hold. In addition, we assume that each connected component of $\mathcal{F}$ contains an equal number of start and target positions (as otherwise, there is no solution).

For the simplicity of the analysis, in this section we provide an iterative version of the algorithm. In the i'th iteration, for $1 \leq i \leq m$, the algorithm constructs a collision-free motion plan for all the robots over the time interval $[i-1, i]$, in which a single robot is moving from a start position to a target position along an ε-interrupted path (Section 3.3), and the other robots may move in their small neighborhood to clear the way (Section 3.4). The output path for a robot A will then be the concatenation $\gamma_A^* : [0, m] \to \mathcal{F}$ of the paths $\gamma_A : [i-1, i] \to \mathcal{F}$ constructed for it in all iterations. We then update S and T according to the path that was chosen, and remove from $\mathcal{W}$ a disk of radius $1 - \varepsilon$ around the target.

At the beginning of this section we gave a high level description of our algorithm, and a more detailed pseudo code is provided in Algorithm 1. Below, we prove that this algorithm returns a collision-free motion plan, with total length $O(\mathrm{OPT})$, where OPT is the optimal size of a solution to the problem.

Algorithm 1 Motion Plan for Unlabeled Disks.

Input: $\mathcal{W}$, S, T, and $0 \leq \varepsilon \leq 1$ such that Constraints 1–5 hold
Output: A collision-free motion plan

- For each robot $A \in [m]$, initialize an empty path γ_A^*.
- While $S \neq \emptyset$:
  1. Compute an optimal-assignment path set Γ for $S, T, \mathcal{W}$.
  2. Find an ε-interrupting target t_j, and let $\gamma_i \in \Gamma$ be the path from s_i to t_j.
  3. If γ_i is not ε-blocked, set $A \leftarrow i$, $s_A \leftarrow s_i$, $\gamma_A \leftarrow \gamma_i$.
  4. Else, let s_k be the last to ε-block γ_i, and set $A \leftarrow k$, $s_A \leftarrow s_k$, and $\gamma_A \leftarrow \gamma'_k$, where γ'_k is the switch path (Section 3.3).
  5. For all $B \neq A$, set $\gamma_B \leftarrow \tilde{\gamma}_B$, where $\tilde{\gamma}_B$ is the clearance path (Section 3.4).
  6. For each robot $B \in [m]$ set $\gamma_B^* \leftarrow \gamma_B^* \circ \gamma_B$.
  7. Set $\mathcal{W} \leftarrow \mathcal{W} \setminus \mathcal{D}_{1-\varepsilon}(t_j)$, $S \leftarrow S \setminus \{s_A\}$, $T \leftarrow T \setminus \{t_j\}$.
- Return the set of paths $(\gamma_1^*, \ldots, \gamma_m^*)$.

▶ **Theorem 8.** *Consider an input $\mathcal{W}$, S, T, and $0 \leq \varepsilon \leq 1$ such that Constraints 1–5 hold. If each connected component of $\mathcal{F}$ contains an equal number of start and target positions, then Algorithm 1 is guaranteed to return a collision-free motion plan Γ^*.*

Proof. First, observe that the solution returned by the algorithm is a path set that matches every start position in S to a unique target in T, because in each iteration we find a path between some $s \in S$ and $t \in T$ and then remove them from S and T for the next iteration.

Consider the first iteration of the algorithm. By Theorem 4, an ε-interrupting target t_j exists, and let γ_i be the path from s_i to t_j. If γ_i is ε-blocked, let $s_k \in S$ be the last to block γ_i, and by Theorem 5(iii), the switch path γ'_k is in $\mathcal{F}$, and it is not blocked by any other robot. Otherwise, γ_i is not blocked. In any case we choose an ε-interrupted path that leads to t_j, and by Theorem 7 the motion plan computed in this iteration is collision-free.

In the following iteration, after removing $D_{1-\varepsilon}(t_j)$ from $\mathcal{W}$, Constraints 1–5 still hold for the updated sets S and T: the robots-separation does not change, so Constraints 2, 3, and 5 still hold, and specifically by Constraint 3 for every $p_1, p_2 \in S \cup T$ we have $\|p_1 - p_2\| \geq 4 - 2\varepsilon$. Therefore, for every $p \in S \cup T \setminus \{t_j\}$ and $x \in D_{1-\varepsilon}(t_j)$ we have $\|p - x\| \geq 3 - \varepsilon$, which satisfies both Constraint 1 ($\|p - x\| \geq \rho_\varepsilon$) and Constraint 4 ($\|p - x\| \geq 1 + \varepsilon$), for any $0 \leq \varepsilon \leq 1$.

However, we also need to take into account the robot that is now positioned on t_j. The main observation that we will use is that t_j does not block any path γ in the free space of $\mathcal{W} \setminus D_{1-\varepsilon}(t_j)$; the reason is that the distance between any point on $a \in \gamma$ and a point $p \in D_{1-\varepsilon}(t_j)$ is at least 1, and therefore the $\|t_j - a\| \geq 2 - \varepsilon$ which means that the overlap between t_j and a is at most ε.

Consider an iteration $a > 1$ of the algorithm, and denote by $\mathcal{W}_a, S_a, T_a$ the sets $\mathcal{W}, S, T$ at the beginning of iteration a. The first step is to compute an optimal-assignment path set Γ_a. Let Γ_{a-1} be the optimal-assignment path set for $\mathcal{W}_{a-1}, S_{a-1}, T_{a-1}$. At the beginning of iteration a, we have $\mathcal{W}_a = \mathcal{W}_{a-1} \setminus \mathcal{D}_{1-\varepsilon}(t_j)$ and $T_a = T_{a-1} \setminus \{t_j\}$, where t_j is an ε-interrupting target in Γ_{a-1}. Since t_j does not block any path in Γ_{a-1}, the disk $\mathcal{D}_{1-\varepsilon}(t_j)$ does not overlap with the trace of any path in $\Gamma_{a-1} \setminus \{\gamma_i\}$. Therefore, any path $\gamma \in \Gamma_a \setminus \{\gamma_i\}$ is in the free space of $\mathcal{W}_a$. If γ_i was not blocked in iteration $a - 1$, then $S_a = S_{a-1} \setminus \{s_i\}$, and thus $\Gamma_a \setminus \{\gamma_i\}$ corresponds to a matching of S_a and T_a, which implies that Γ_a exists. Otherwise, $S_a = S_{a-1} \setminus \{s_k\}$, where $s_k \in S_{a-1}$ is the last to ε-block γ_i. Let t_ℓ be the target that

was matched to it in Γ_{a-1}, and let $\gamma_k \in \Gamma_{a-1}$ be the path from s_k to t_ℓ. Observe that $\Gamma_{a-1} \setminus \{\gamma_i, \gamma_k\}$ corresponds to a matching between $S_a \setminus \{s_i, s_k\}$ and $T_{a-1} \setminus \{t_k, t_\ell\}$, and thus to have a matching between S_a and T_a we need to find a path in the free space of $\mathcal{W}_a$ between s_i and t_ℓ. We show that the switch path γ_i' from s_i to t_ℓ as defined in Section 3.3, has this property. Recall that γ_i' is a concatenation of $\gamma[1, w]$, $\overline{\gamma_i(w)s_k}$, and γ_k. The paths γ_i, γ_k are in Γ_{a-1} and therefore lie in the free space of $\mathcal{W}_{a-1}$. By Theorem 5(i), the entire path γ_i' is in the free space of $\mathcal{W}_{a-1}$. We thus need to show that the disk $\mathcal{D}_{1-\varepsilon}(t_j)$ does not overlap with the trace of γ_i'. Indeed, since t_j is an ε-interrupting target, it does not block γ_k, and therefore by Theorem 5(iv) it is also not blocking γ_i'.

The next step is to find an ε-interrupting target t_j. For this, notice that Theorem 4 still holds, because it considers only start and target positions in S_a and T_a. Let $\mathcal{A}$ be the set of robots that are already lying on target positions. Notice that we can also apply Theorem 5 on $\mathcal{W}_a, S_a, T_a$ and Γ_a, and we just need to make sure that no robot in $\mathcal{A}$ can block the switch path γ_k'. As mentioned above, this is true in general, that is, for any path $\gamma \in \Gamma_a$ from $s \in S_a$ to $t \in T_a$, no robot in $\mathcal{A}$ can block γ, because the overlap between any such robot and any point on γ is at most ε. In other words, robots in $\mathcal{A}$ can only interrupt paths in Γ_a.

The final step is using Theorem 7 to construct the clearance paths. Notice that this construction applies for any $p \in S \cup T$, and therefore it can be applied for the ε-interrupted path, even if there were robots in all the start and target positions, except for the endpoints of the path.

Lastly, notice that the concatenation of the paths that correspond to a robot A from all the iterations of the algorithm results in a continuous path. This is because each clearance path starts and ends at the same start/target position. ◀

In the full version of the paper [10] we prove the following theorem.

▶ **Theorem 9.** *Given a polygonal workspace $\mathcal{W}$ with n edges, a set S of m starting positions and a set T of m target positions, there is an algorithm that computes in $\tilde{O}(m^4+n^2m^2)$ time a collision-free motion plan of length $O(OPT)$, where OPT is the length of an optimal solution, or reports that such a motion plan does not exist, assuming that $\rho = \max\{4-2\varepsilon, 2+\varepsilon\}$ and $\omega = \max\{1+\varepsilon, \sqrt{(3-\sqrt{3}-\varepsilon)^2+1}\}$.*

The length of our solution. Note that in fact we bound the size of the solution with the term $(1+c)(\mathrm{OPT}+(4-2\varepsilon)m)$ where c is the maximum number of start/target positions that may collide a unit disk under our robots-separation constraints. For example, when the robots-separation is 2 then $c = 6$. We discuss this further in the full version of the paper [10].

Optimizing the separation bounds. We now optimize the overlap parameter over Constraints 1–5, to achieve either the smallest obstacles-separation or the smallest robots-separation possible. Recall that Constraints 1 and 4 specify the required obstacles-separation bounds, while Constraints 2, 3, and 5 specify the required robots-separation bounds. We highlight three interesting values of ε:

- For $\varepsilon = 0$ the motion plan is monotone, and the length of the solution is at most $\mathrm{OPT}+4m$. In this case, we obtain $\omega = \sqrt{13-6\sqrt{3}} \approx 1.614$ and $\rho = 4$.
- For $\varepsilon > 0$, the motion plan is weakly-monotone.
- For $\varepsilon = \frac{15-6\sqrt{3}}{13} \approx 0.354$, the obstacles-separation is minimized, and we obtain $\omega = 1+\frac{15-6\sqrt{3}}{13} \approx 1.354$ and $\rho = 4-2\frac{15-6\sqrt{3}}{13} \approx 3.291$.
- For $\varepsilon = \frac{2}{3}$, the robots-separation is minimized, and we obtain $\omega = 1\frac{2}{3}$ and $\rho = 2\frac{2}{3}$.

Lower bounds. In the full version of the paper [10] we present lower bounds on the obstacles-separation when the motion plan is required to be (weakly) monotone. We provide an instances of the problem in which (i) $\omega \approx 1.614$ and no monotone motion plan exists, and (ii) $\omega \approx 1.354$ and no weakly-monotone motion plan exists. This shows that to obtain lower obstacles-separation assumptions, a completely different approach is required.

5 The Exodus algorithm: reducing the robots-separation bound

In this section we introduce a different algorithmic strategy for MRMP which we call the *Exodus Algorithm*. This strategy is more global in the sense that it also moves robots that do not directly block a path, and therefore it allows for robots-separation of 2, while requiring obstacles-separation of only 3. Whereas the previous algorithm relies on local path-clearing and larger robots-separation, Exodus replaces these local adjustments with a synchronized outward movement of all robots in order to clear the trace of a geodesic path, so that the selected robot can reach its target via this path. Note that in this section, we assume that the workspace $\mathcal{W}$ is a simple polygon. Due to space considerations, we give an overview of the algorithm and the main result here, see [10] for a formal description and proofs.

Algorithm overview. Given the sets $S, T \subset \mathcal{F}$ as before, the first step of the algorithm is to compute an optimal-assignment path set $\Gamma = \{\gamma_1, \ldots, \gamma_m\}$ for $S, T, \mathcal{W}$. Assume w.l.o.g. that $\gamma_i(0) = s_i$ and $\gamma_i(1) = t_i$ for every $1 \leq i \leq m$. The algorithm then proceeds iteratively. In each iteration, we select a target position $t_i \in T$ which is not yet occupied by a robot. We first extend the path γ_i so that its start and end points are on the boundary of $\mathcal{F}$. The extended path partitions $\mathcal{F}$ into maximally connected sub-regions of $\mathcal{F}$, which we call pockets. We then split each pocket using the angle bisectors corresponding to the reflex subchain of γ_i that defines the pocket. We call the cells in this refined partition Exodus cells. Each Exodus cell contains a single straight-line edge of γ_i. All the other robots are then moved outwards from the extended path by two units (which is possible because $\omega = 3$), and the movement direction for each robot is determined by the Exodus cell in which it lies. This process clears the trace of γ_i, allowing a robot positioned on s_i to move along γ_i until reaching t_i, while all the other robots remain fixed at their offset locations. After the robot reaches its target t_i, all the other robots return to their original positions by applying the inverse movement (which is possible because $\rho = 2$, i.e., no start position is too close to t_i). This iterative "corridor-opening" process motivates the name *Exodus Algorithm*. The procedure repeats until all robots reach their assigned targets. In each iterative step, $m - 1$ robots are moving $4m$ units each, while the selected robot moves along a shortest path to its assigned target (as before, $|\Gamma| \leq \mathrm{OPT}$). Since there are exactly m iterations, we obtain the following theorem.

▶ **Theorem 10.** *Given a simple polygonal workspace $\mathcal{W}$ with n edges, a set S of m starting positions and a set T of m target positions, such that $\rho = 2$ and $\omega = 3$, the Exodus algorithm computes in $\tilde{O}(m^3 + mn^2)$ time a collision-free motion plan of size at most $OPT + 4m^2 - 4m$, where OPT is the length of an optimal solution.*

▶ Remark 11 (Labeled MRMP). In the labeled setting, where each start position is already associated with a specific target, we do not compute an optimal-assignment path set. Instead, we simply compute the geodesic paths between each start and its corresponding target using Wang's Euclidean shortest-path algorithm [17], and then apply the same iterative procedure described above. In this case, the running time becomes $O(m^2 \log n + mn^2)$, as no matching step is required. The motion of the robots during the corridor-opening iterations remains unchanged, and the size of the solution remains at most $\mathrm{OPT} + 4m^2 - 4m$.

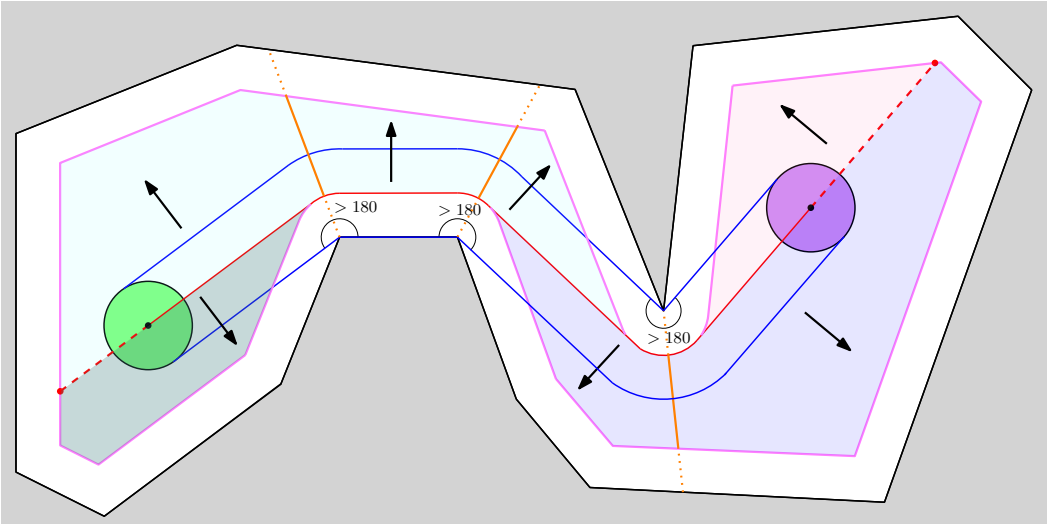

Figure 5 The extended geodesic $\hat{\gamma}$ is in red, and its trace is in blue. In pink is $\partial\mathcal{F}$. Each colored region represents a distinct pocket induced by $\hat{\gamma}$, and the orange rays are the angle bisectors generated at the corresponding reflex vertices of $\partial\mathcal{F}$. These bisectors subdivide each pocket into Exodus cells, within which a single direction vector is illustrated by the black arrows.

6 Discussion and future work

In this paper we provide multi-robot motion plans that require tighter assumptions on the density of the input setting. Note that for the Exodus algorithm we require $\rho = 2$. This separation bound is tight for monochromatic robots-separation, however, the bichromatic robots-separation can potentially be 0. This raises the question of what is the minimum obstacles-separation for which we can remove the robots-separation assumption completely.

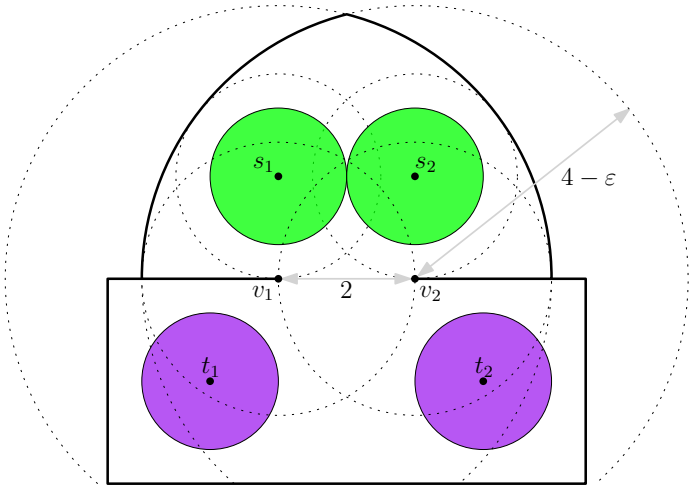

Figure 6 Unlabeled MRMP with obstacles-separation of $1.5 - \varepsilon$, for which no solution exists.

In the full version of the paper [10] we also present lower bounds for the amount of obstacles-separation needed so that a solution to the MRMP problem always exists, without any assumptions on the separation between robots. In the unlabeled case, we prove that obstacles-separation of at least 1.5 is sometimes needed (see Figure 6), and in the labeled case, we observe that obstacles-separation of at least 2 is sometimes necessary (see Figure 7).

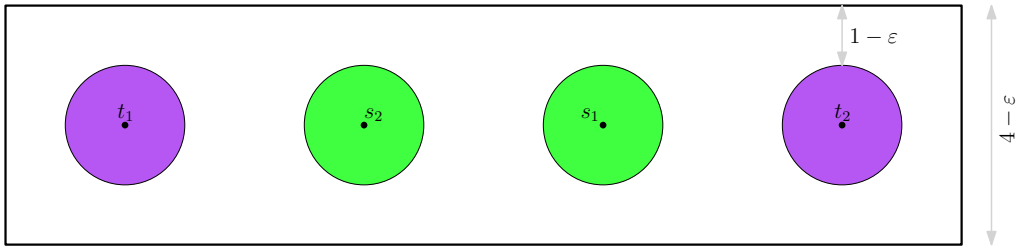

Figure 7 Labeled MRMP with obstacles-separation of $2-\varepsilon$, for which no solution exists.

Abstract

Motivated by targeted drug delivery, we investigate the gathering of particles in the full tilt model of externally controlled motion planning: A set of particles is located at the tiles of a polyomino with all particles reacting uniformly to an external force by moving as far as possible in one of the four axis-parallel directions until they hit the boundary. The goal is to choose a sequence of directions that moves all particles to a common position. Our results include a polynomial-time algorithm for gathering in a completely filled polyomino as well as hardness reductions for approximating shortest gathering sequences and for determining whether the particles in a partially filled polyomino can be gathered. We pay special attention to the impact of restricted geometry, particularly polyominoes without holes. As a corollary, we make progress on an open question from [Balanza-Martinez et al., SODA 2020] by showing that deciding whether a given position can be occupied remains NP-hard in polyominoes without holes. Our results build on a connection we establish between tilt models and the theory of synchronizing automata.

1 Introduction

We investigate a problem motivated by targeted drug delivery [48]: How can initially dispersed drug-carrying particles be gathered at a common position? Problems of this type are closely related to advances in micro-scale robotics [50]. However, environmental constraints and the

severely limited capabilities of robotic agents at micro- and nano-scale rule out autonomous movement. Instead, a global external force, e.g., an electromagnetic field, can be used to move and steer simple robotic particles. The challenge is to use geometry to control a large swarm of particles through uniform signals within a non-uniform environment [12, 16].

Abstract mathematical models [9, 23], commonly called *tilt models* in reference to gravity as a potential external force, have been developed to tackle this problem from an algorithmic perspective. They model the environment as a *polyomino*, i.e., a finite, connected region of the square tiling, with particles positioned at tiles and moving on axis-parallel paths up, down, left, or right. Two major variants exist: In the *single step model* (S1), particles can be precisely controlled via unit steps to adjacent positions, whereas the *full tilt model* (FT) takes imprecision into account by only allowing particles to move maximally until blocked.

Algorithms and complexity results for a variety of applications [15, 25, 44, 51] have been discovered using tilt models. To investigate algorithmic approaches to targeted drug delivery, we consider particles located at the tiles of a polyomino and look for a *gathering sequence*, i.e., a sequence of moves that relocates all particles to the same tile. It is already known that gathering sequences of length $\mathcal{O}(n_c D^2)$ always exist in S1, where n_c is the number of convex corners of the polyomino and D its diameter, but finding sequences of minimum length is NP-hard [13]. Very little is known about gathering in FT, apart from the brief observation in [52] that gathering sequences do not exist for all polyominoes in FT. We remedy this situation with a comprehensive study of gathering in FT.

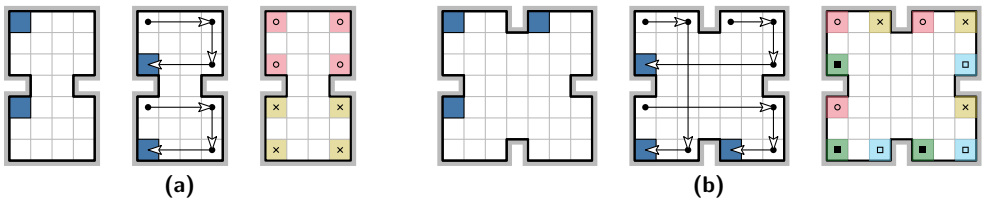

Figure 1 Two examples where gathering a set of particles is impossible in the full tilt model. Both examples depict, from left to right, a set of particles (blue squares) inside a polyomino, a sequence of moves leading to all possible configurations, and a partition of reachable positions yielding a congruence. Example **(a)** prohibits gathering by keeping the particles in different congruence classes, whereas the particles in **(b)** always occupy distinct positions of the same class.

As a first observation, we can see that the full tilt model exhibits several interesting complications that render gathering impossible. The authors of [52] already recognized that particles may become trapped in separate parts of the polyomino, see Figure 1(a). However, this is not the only difficulty. Remarkably, even if all tiles reachable from the initial particle positions are mutually reachable, gathering may still be impossible, see Figure 1(b).

Apart from practical applications, tilt models fascinate with simple, intuitive problems that nevertheless exhibit surprising complexity. A central question is how the computational complexity of a problem relates to the geometric complexity of the environment. Two fundamental problems are Occupancy, which asks if any of a given set of particles can be moved to a specified tile, and ShapeReconfiguration, which asks if a given configuration of particles can be transformed into another given configuration. Both are proven PSPACE-complete in FT for general polyominoes in [7], where the authors pose the complexity for *simple* polyominoes, i.e., polyominoes without holes, as an open problem. We also consider a supplementary class of polyominoes we call *mazes*: collections of horizontal and vertical lines that only intersect in T-shaped and +-shaped junctions, see Figure 2(b).

1.1 Our contributions

We provide a wealth of insights into the gathering of particles in the full tilt model. Let a given polyomino have n corners, $n_c \leq n$ of which are convex. We prove the following results.

- When particles are initially positioned at every tile of a polyomino, a gathering sequence of length $\mathcal{O}(n_c n^2)$ can be computed, if one exists at all (Theorem 4 and Corollary 6).
- There are polyominoes with shortest gathering sequences of length $\Omega(n^2)$ (Theorem 7).
- Finding a shortest gathering sequence is NP-hard, even in simple mazes (Theorem 14).
- There is a polynomial-time 4-approximation for minimizing the length of a gathering sequence in simple mazes (Theorem 16), but there is no polynomial-time constant-factor approximation in general simple polyominoes (unless P = NP; Theorem 17).
- Determining whether a subset of tiles has a gathering sequence is PSPACE-complete in mazes (Corollary 13) and NP-hard in simple polyominoes (Theorem 18).

The last of these results allows us to derive progress on the open question from [7] regarding the complexity of Occupancy and ShapeReconfiguration in simple polyominoes. We show that both remain NP-hard (Corollary 19). Throughout this paper, we utilize a so far overlooked connection between tilt models and automata theory, in particular synchronizing automata. Since this topic is unlikely to be widely known among the computational geometry community, we give a brief survey in Section 3.1. We expect that more insights for tilt models can be gained by exploring this approach further. Conversely, the geometric nature of tilt models could lead to new ways to tackle open questions in automata theory. As we shall see, the discrepancy between the upper and lower bounds on the worst-case lengths of gathering sequences is closely related to a longstanding open problem known as Černý's conjecture.

Full proofs and details for statements marked by ($\star$) as well as several corollaries that exceed the space limit of this extended abstract, including results on the parameterized complexity of tilt problems, can be found in the full version [32].

1.2 Related work

Apart from the aforementioned work [13, 52] on gathering in the single step model, tilt models have been investigated for a variety of purposes. These include realizing permutations of labeled rectangular configurations [9, 10, 11, 73], simulating dual-rail logic circuits [10, 11, 64], sorting and classifying polyominoes [44], mapping an unknown region [51], and filling and draining a polyomino [33]. Notably, gathering all particles in a completely filled polyomino is strictly more difficult than draining to a freely chosen sink: While gathering requires a single position p to be reachable from everywhere, which suffices to guarantee drainability to a sink placed at p [33], this does not ensure gatherability, see Figure 1(b). A major line of research is concerned with the assembly of structures from particles that can be glued together [7, 8, 15, 20, 46, 53, 63], which is strongly related to universal reconfiguration [25].

The study of the computational complexity of fundamental tilt problems was initiated in [9], where the problems now known as Occupancy and ShapeReconfiguration were originally shown NP-hard in FT. They were later settled to be PSPACE-complete [7]. In the single step model, Occupancy is solvable in polynomial time [23], whereas ShapeReconfiguration remains PSPACE-complete [24]. Restricted variants consider moves limited to two or three directions [23, 27] or deterministic move sequences [6].

Taking the maximal movement of the full tilt model and adding individual control leads to the rules of the game Ricochet Robots [30, 36]. Holzer and Schwoon [39] used related ideas in their investigation of Atomix; we cannot reuse their construction because we need a tighter analysis of the length of move sequences. Other related models examine uniform movement in a rectangle, e.g., by sweeping lines [2, 5], or the rules of the game 2048 [1, 3].

The gathering of point particles inside a polygon has been considered by Bose and Shermer [22], but their setting uses repulsion from a point within the polygon, whereas tilt models could be interpreted to use repulsion from a point at infinity. More closely related is the problem of localizing robots with severely limited capabilities [54, 57]. A sequence of movement commands that leads a robot from an initially unknown position in a polygonal environment to a definite position is equivalent to gathering all point particles in the environment at the same final position.

2 Preliminaries

In this section, we give the rigorous definitions omitted from Section 1 in favor of intuition. Every polyomino P has an associated *dual graph* $G_P = (V, E)$, see Figure 2(b), where $V \subset \mathbb{Z}^2$ and $E = \{\{u, v\} : u \in V, v \in V, \|u - v\|_1 = 1\}$, and a *boundary* ∂P, an axis-aligned polygon with integer side lengths that separates V from $\mathbb{Z}^2 \setminus V$. We identify the vertices of V with the tiles of P and call them *pixels*. As a general convention throughout this text, n will denote the number of corners of ∂P, $n_c \leq n$ the number of convex corners, and $N = |V|$ the number of pixels of a given polyomino. Pixels are uniquely determined as the intersection of two *segments*, a *row segment* and a *column segment*, which are maximally contiguous parts of rows and columns; a *corner pixel* is adjacent to two perpendicular sides of ∂P, i.e., next to a convex corner, see Figure 2(a). Formally, a maze is a *thin* polyomino (it contains no 2×2 squares) in which all corner pixels have degree 1, see Figure 2(b).

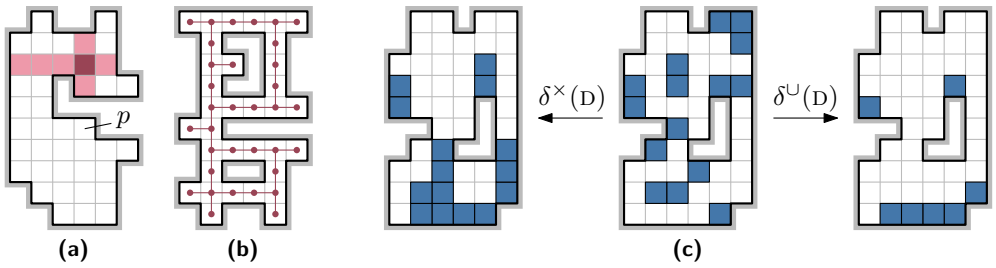

Figure 2 (a) A simple polyomino with a darkly shaded pixel at the intersection of two lightly shaded segments and a corner pixel p. **(b)** A non-simple maze and its dual graph. **(c)** Downwards moves in the blocking and merging variants of the full tilt model acting on a configuration.

A set $C \subseteq V$ of all pixels containing particles is called a *configuration*. Pixels $p \in C$ are *occupied*, those in $V \setminus C$ are *free*. We use the set $\mathbb{D} = \{\text{U}, \text{D}, \text{L}, \text{R}\}$ as shorthand for the directions up, down, left, and right. Formally, a tilt model defines a function $\delta : \mathbb{D} \to (2^V \to 2^V)$, i.e., it maps directions to transformations of configurations. A transformation $\delta(v)$, $v \in \mathbb{D}$, is called a *move*. δ is inductively extended to a function on $\mathbb{D}^*$, the set of (possibly empty) sequences of directions, by setting $\delta(wv) = \delta(v) \circ \delta(w)$, for $v \in \mathbb{D}$ and $w \in \mathbb{D}^*$, and $\delta(\varepsilon) = \mathrm{id}$, where ε is the empty sequence and id the identity function. Particles in the full tilt model are usually blocked when colliding with other particles, but for the purpose of gathering, they merge instead, see Figure 2(c). A formal definition of the *blocking* and *merging* variants for the direction L is as follows; definitions for the other directions are analogous.

Full tilt (blocking): $p \in \delta^{\times}(\text{L})(C)$ if and only if p is one of the $|R \cap C|$ leftmost pixels of the row segment R containing p.

Full tilt (merging): $p \in \delta^{\cup}(\text{L})(C)$ if and only if p is the leftmost pixel of the row segment R containing p and $R \cap C \neq \varnothing$.

Both variants agree on singleton configurations, and the set of singleton configurations is closed under all moves. This gives rise to the function $\delta^1 : \mathbb{D} \to (V \to V)$ defined as $\delta^1(v)(p) = q$ whenever $\delta^\times(v)(\{p\}) = \delta^\cup(v)(\{p\}) = \{q\}$ for $v \in \mathbb{D}$. When δ is clear from the context, we simplify the notation by writing $C \cdot w$ instead of $\delta(w)(C)$ and $C \xrightarrow{w} C'$ to mean $C' = \delta(w)(C)$, and use moves $\delta(v)$ and directions $v \in \mathbb{D}$ interchangeably.

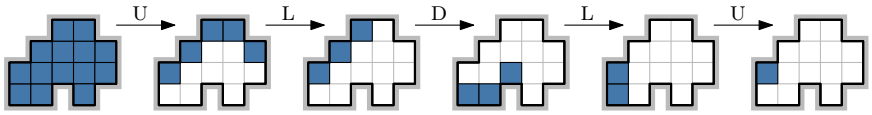

Figure 3 The sequence ULDLU is a gathering sequence for this polyomino in the full tilt model.

A *gathering sequence for a configuration* C is a sequence of directions $w \in \mathbb{D}^*$ such that $|\delta^\cup(w)(C)| = 1$, in which case C is a *gatherable configuration*; a *gathering sequence for a polyomino* P is a gathering sequence for the configuration V, see Figure 3, making P a *gatherable polyomino*. We define $\mathrm{sgs}(C)$ to be the minimum length of a gathering sequence (i.e., the length of a *shortest gathering sequence*) for a gatherable configuration C, and assign $\mathrm{sgs}(P) = \mathrm{sgs}(V)$ for a gatherable polyomino P.

The uniform movement of particles connects the merging variant to the motion of single particles: One can either consider a configuration to be gathered by merging, or move a single particle initially positioned at one of several possible positions aiming to localize it.

▶ **Observation 1.** *For* $w \in \mathbb{D}^*$ *and* $C \subseteq V$, $\delta^\cup(w)(C) = \bigcup_{p \in C} \{\delta^1(w)(p)\} = \bigcup_{p \in C} \delta^\times(w)(\{p\})$.

The single step analogue of Observation 1 is implicitly contained in [13]. Several simple consequences follow: A gathering sequence for a configuration C is also a gathering sequence for every $C' \subseteq C$. If w is a gathering sequence for C, then so is ww' for every $w' \in \mathbb{D}^*$. Prepending works for V: If w is a gathering sequence for V, then so is $w'w$ for every $w' \in \mathbb{D}^*$.

We investigate three problems in the full tilt model for a given polyomino P.

- FullGathering: Find a gathering sequence for P or decide that P is not gatherable.
- ShortestGatheringSequence: Assuming P is gatherable, compute a gathering sequence for P of minimum length $\mathrm{sgs}(P)$.
- SubsetGathering: Decide if a given configuration $C \subseteq V$ is gatherable.

We will use two algebraic properties of the full tilt model. First, every move is idempotent, i.e., $\delta(v) \circ \delta(v) = \delta(v)$ for all $v \in \mathbb{D}$. Secondly, when two moves in opposite directions are applied in sequence, the first is nullified, e.g., $\delta(\mathrm{L}) \circ \delta(\mathrm{R}) = \delta(\mathrm{L})$. Thus, we can generally assume that sequences of moves alternate between perpendicular directions.

3 Gathering particles by synchronizing automata

The notation introduced in Section 2 differs slightly from established conventions and may be considered unnecessarily heavy. It does, however, expedite a point we want to make: Tilt models are transition functions of automata. A *semi-automaton*[1] is a triple (Q, Σ, δ), where Q is a finite, non-empty set of *states*, Σ is a finite, non-empty *alphabet*, and $\delta : \Sigma \to (Q \to Q)$ is a *transition function* mapping letters of Σ to transformations of Q. As usual, δ gets extended to a function over *words* $w \in \Sigma^*$. An *acceptor* is a 5-tuple $(Q, \Sigma, \delta, q_0, F)$, where (Q, Σ, δ) is

[1] All (semi-)automata considered in this text are complete, deterministic, and finite.

a semi-automaton, $q_0 \in Q$ an *initial state*, and $F \subseteq Q$ a set of *accepting states*. The *language accepted by an acceptor* A is the set of words $L(A) = \{w \in \Sigma^* : q_0 \cdot w \in F\}$. For simplicity, we will refer to both semi-automata and acceptors as *automata*. Now it is easy to see that a tilt model defines an automaton $(2^V, \mathbb{D}, \delta)$ for a polyomino P with dual graph $G_P = (V, E)$. We can even restate some established problems in the language of automata theory.

▶ **Example 2.** We are given a polyomino P, configurations $C, C' \subseteq V$, and a pixel $p \in V$.
ShapeReconfiguration: Is $L((2^V, \mathbb{D}, \delta, C, \{C'\}))$ non-empty?
Occupancy: Is $L((2^V, \mathbb{D}, \delta, C, \{C' \subseteq V : p \in C'\}))$ non-empty?

Although interesting, this connection is of no immediate use due to the exponential size of the set of states. Indeed, we would not expect a polynomial description because Occupancy and ShapeReconfiguration are PSPACE-complete in FT [7], whereas emptiness of $L(A)$ can be checked in time polynomial in the size of A [38]. The approach via automata shows its merit when we consider the analogue to gathering sequences, synchronizing words.

3.1 A brief overview of synchronizing automata

A word $w \in \Sigma^*$ is a *synchronizing word* for a set $Q' \subseteq Q$ if there is a state $q \in Q$ such that $p \xrightarrow{w} q$ for all $p \in Q'$, in which case Q' is a *synchronizing set*. The minimum length of a synchronizing word for a synchronizing set Q' is called the *reset threshold* $\mathrm{rt}(Q')$. A *synchronizing automaton* $A = (Q, \Sigma, \delta)$ has a synchronizing set of states Q, in which case we define $\mathrm{rt}(A) = \mathrm{rt}(Q)$. We now briefly summarize some important results; more information can be found in several excellent surveys [38, 60, 69, 70].

It has been (re-)discovered multiple times how to check if an automaton is synchronizing and, if so, find a synchronizing word of length $\mathcal{O}(|Q|^3)$. Eppstein's work [31] is particularly noteworthy for its careful analysis of the time and space requirements. Černý's conjecture states that $\mathrm{rt}(A) \leq (|Q| - 1)^2$ holds for every synchronizing automaton A. It is named in honor of foundational work by Černý, see [29] for a translation into English, that established the corresponding lower bound via a series of synchronizing automata. Remarkably, this seemingly simple conjecture has resisted attempts at a general solution for decades, although it has been proven for special classes of automata, e.g., Eulerian automata [43], monotonic automata [31], and others [70]. Since an improvement of the asymptotic bound $\mathcal{O}(|Q|^3)$ has proven elusive, researchers have looked at the coefficient α of the cubic term. The current best value is $\alpha \leq 0.1654$ due to Shitov [65], who expanded on ideas by Szykuła [67]. Kiefer and Ryzhikov [47] recently improved the running time of an algorithm for the more general problem of finding a word w that minimizes $|Q \cdot w|$ (called the *rank* of w).

A lower bound on the approximation ratio for $\mathrm{rt}(A)$ was improved several times [18, 19, 35], until Gawrychowski and Straszak [34] showed that $\mathrm{rt}(A)$ is NP-hard to approximate within a factor $|Q|^{1-\varepsilon}$ for every $\varepsilon > 0$. On the practical side, engineering efforts have resulted in implementations that find shortest synchronizing words for instances with over 500 states [68].

Deciding if a subset $S \subseteq Q$ is synchronizing is PSPACE-complete, as stated by Natarajan [56] and formally proven by Rystsov [59]. This problem is strongly related to IntersectionNonEmptiness: Given a family of automata over the same alphabet, decide whether they accept a common word. Kozen [49] originally proved this problem PSPACE-complete, and it remains NP-hard for tally automata [55, 66], i.e., automata over a unary alphabet.

3.2 Efficient gathering in the full tilt model

By Observation 1, a gathering sequence for a polyomino P corresponds precisely to a synchronizing word for the automaton $(V, \mathbb{D}, \delta^1)$. Thus, we could solve FullGathering by applying Eppstein's algorithms [31] to $(V, \mathbb{D}, \delta^1)$ to decide if it is synchronizing in $\mathcal{O}(N^2)$ time

and, if so, find a gathering sequence for P in $\mathcal{O}(N^3)$ time. We now sketch algorithms with running times of $\mathcal{O}(n^2)$ and $\mathcal{O}(n_c n^2)$, respectively, that use only ∂P as input. This can make a huge difference as the number of pixels N might not be polynomial in the number of corners n.

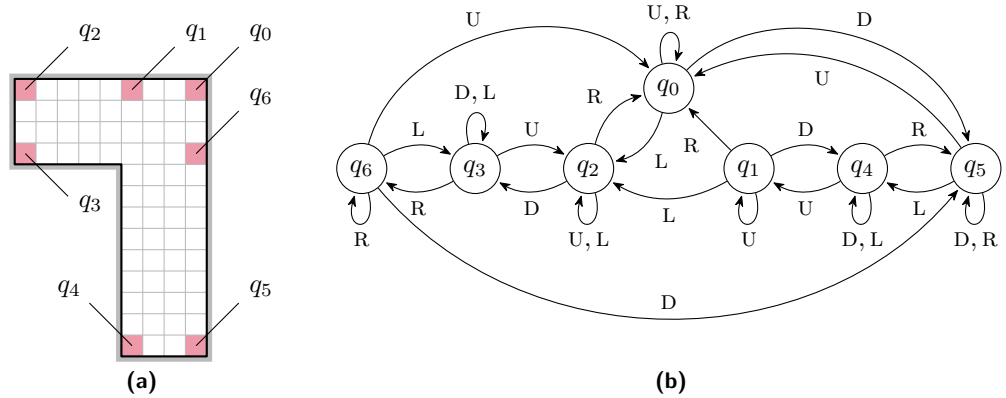

Figure 4 (a) A polyomino P and its significant pixels. **(b)** The full tilt automaton $A(P)$.

The key observation is that $\delta^{\cup}$ very quickly reduces the set of occupied pixels to one of size $\mathcal{O}(n)$. Consider the set $S \subseteq V$ of *significant pixels* that contains all corner pixels and possibly *helper pixels*, which are found by extending sides of ∂P that meet at reflex corners until they hit another side of ∂P. Figure 4(a) illustrates the significant pixels of a polyomino P with helper pixels q_1 and q_6. Observe that $|S| \leq 2n - n_c$ because at most two helper pixels are included per reflex corner. Any sequence of two moves in perpendicular directions changes the position of a particle from any pixel $p \in V$ to one in S, e.g., $\delta^1(\text{DL})(p) \in S$. S is closed under δ^1, i.e., after the move sequence DL we can focus on δ^1 restricted to S. We call the resulting automaton $A(P) = (S, \mathbb{D}, \delta^1)$ the *full tilt automaton* of P, see Figure 4(b).

▶ **Lemma 3** ($\star$). *A polyomino P is gatherable if and only if the full tilt automaton $A(P)$ is synchronizing, in which case* $\text{rt}(A(P)) \leq \text{sgs}(P) \leq \text{rt}(A(P)) + 1$ *holds.*

It is a well-known fact [56, 70] that an automaton (Q, Σ, δ), with $|Q| > 1$, is synchronizing if and only if every unordered pair of states $\{s, t\} \subseteq Q$ has a synchronizing word. This suggests a strategy of iteratively merging pairs. To efficiently determine synchronizing words for pairs in $A(P)$, we construct the *pair automaton* $A(P)^{\leq 2} = (S^{\leq 2}, \mathbb{D}, \delta^{\leq 2})$, where $S^{\leq 2} = \{\{p, q\} : p, q \in S\}$ and $\delta^{\leq 2}(v)(\{p, q\}) = \{\delta^1(v)(p)\} \cup \{\delta^1(v)(q)\}$. Note that $S^{\leq 2}$ also contains all singletons $\{p\} \subseteq S$. A word w with $p \cdot w = q \cdot w$ in $A(P)$ corresponds precisely to a path labeled w from $\{p, q\}$ to $\{p \cdot w\}$ in the digraph underlying $A(P)^{\leq 2}$. Using breadth-first search on this digraph to build a shortest-path forest allows to pre-compute the next step on a shortest path to a singleton for every pair of states, if such a path exists.

To cut down the number of pairs that need to be considered, we initially reduce S to corner pixels only by repeatedly applying two perpendicular moves, e.g., DL. Observe that if $p \in S$ is a helper pixel, then $p \cdot \text{DL} < p$ in terms of their lexicographic order, as at least one coordinate decreases. Thus, $\mathcal{O}(n)$ applications of DL suffice to eliminate all helper pixels (and all corner pixels not at lower-left corners) from S. This way we need to check at most $\mathcal{O}(n_c)$ pairs, improving the running time for non-simple polyominoes with many reflex corners.

▶ **Theorem 4** ($\star$). *Given the boundary ∂P of a polyomino P with $n_c \leq n$ convex corners, a gathering sequence for P, if one exists, can be computed in $\mathcal{O}(n_c n^2)$ time.*

If we are only interested in the (non-)existence of a gathering sequence, we can stop after computing the shortest-path forest. A gathering sequence exists if and only if every pair of states has been assigned a successor on a path to a singleton [31].

▶ **Corollary 5.** *Given the boundary ∂P of a polyomino P with n corners, one can decide in $\mathcal{O}(n^2)$ time whether P is gatherable.*

3.3 Worst-case bounds for gathering sequences in FT

Once a polyomino is known to be gatherable, how long can a shortest gathering sequence be in the worst case? An upper bound matches the running time of the algorithm.

▶ **Corollary 6.** *For every gatherable polyomino P,* $\mathrm{sgs}(P) \in \mathcal{O}(n_c n^2)$.

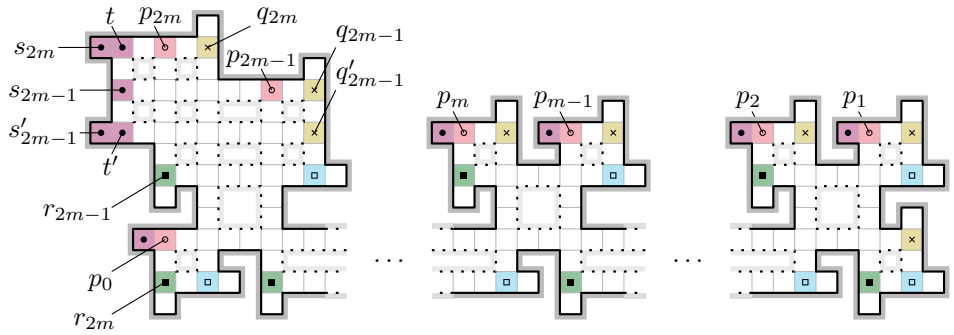

Figure 5 A family of polyominoes P_m with $\mathrm{sgs}(P_m) \in \Omega(n^2)$ in FT. Important classes of pixels are marked with distinct colors and symbols. Dotted areas indicate optional holes that can turn the simple polyomino into a maze, ensuring the construction works for both special cases.

▶ **Theorem 7** (⋆). *There is an infinite family P_m, $m \in \mathbb{N}$, of gatherable simple polyominoes such that* $\mathrm{sgs}(P_m) \in \Omega(n^2)$*, where the number of corners n grows with m.*

Proof sketch. The basic idea of the construction, depicted in Figure 5, is to place two particles on a directed cycle of length $2m + 1$, spaced apart by m positions. Moving against the direction of the cycle leads to dead ends, except at p_{2m-1}. There, LU allows to skip one step on the cycle, which can be used to reduce the distance between the particles by 1. To reduce the distance again, the whole cycle has to be traversed, resulting in $\Omega(m)$ iterations of $\Omega(m)$ moves to gather the particles, for a total of $\Omega(m^2) = \Omega(n^2)$. ◀

4 Simulating binary automata with uniformly controlled particles

If Černý's conjecture is true, then the $\Omega(n^2)$ lower bound on $\mathrm{sgs}(P)$ is actually tight.

▶ **Conjecture 8.** *For every gatherable polyomino P with n corners,* $\mathrm{sgs}(P) \in \mathcal{O}(n^2)$.

The geometric structure of polyominoes should make Conjecture 8 easier to prove than Černý's conjecture. Alas, we must dampen this hope, because particles in polyominoes can be used to simulate binary automata, i.e., automata with alphabet $\Sigma = \{0, 1\}$.

To simulate an automaton $A = (Q, \{0, 1\}, \delta)$, the main idea is to build a polyomino $P(A)$ that has every state $q \in Q$ represented by a pixel $\overline{q}$, and use fixed sequences of moves to embody transitions. A single particle is placed inside $P(A)$, its presence at $\overline{q}$ signifying that

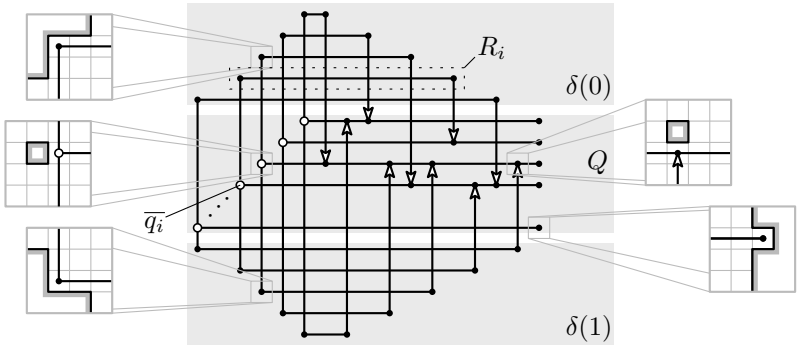

Figure 6 Schematic overview of the construction of $P(A)$ from a binary automaton A. Three blocks represent, from top to bottom, transitions for 0, states $q_i \in Q$, and transitions for 1. We zoom in to show how the schema is realized by the boundary $\partial P(A)$. See Figure 7 for a specific example.

A is in state q. We use the clockwise cycle URDL and the counter-clockwise cycle DRUL to express transitions for 0 and 1, respectively. By carefully constructing the boundary of $P(A)$, we guarantee that all minimal sequences of moves between two pixels $\overline{q_i}$ and $\overline{q_j}$ can be decomposed into combinations of URDL and DRUL, thus ensuring that minimal sequences of moves between pixels representing states are in correspondence with transitions in A.

Without loss of generality, let $Q = \{q_0, q_1, \ldots, q_{|Q|-1}\}$, and set $\overline{Q'} = \{\overline{q} : q \in Q'\}$ for sets $Q' \subseteq Q$. Our construction of $P(A)$ is schematically illustrated in Figure 6. Every state $q_i \in Q$ gets assigned a row of width $6|Q|$ including the representative pixel $\overline{q_i}$. These rows are stacked, with left-aligned rows of width $6|Q|-1$ in between, and the $\overline{q_i}$ are aligned on an upward diagonal, from $\overline{q_{|Q|-1}}$ in the bottom left up to $\overline{q_0}$. A 1×1 hole is placed to the left of every $\overline{q_i}$ except $\overline{q_{|Q|-1}}$, which is next to the outer boundary.

To implement the transitions $\delta(0)(q_i)$ in the top block, rows R_i of width $6i+3$ are stacked and aligned on the left with $\overline{q_i}$. A 1×1 hole is placed below the pixel at the intersection of the rightmost column of R_i and the row of $\overline{q_j}$ when $q_j = \delta(0)(q_i)$. This allows us to simulate a transition for 0 by the sequence of moves URDL. Similar rows and holes are constructed for $\delta(1)(q_i)$ in the bottom block, except now the rows are arranged from bottom to top and of width $6(|Q|-i)-1$, allowing us to simulate 1 by DRUL. The full construction requires $6|Q|$ convex corners and $6(3|Q|-2)$ reflex corners, for a total of $n = 12(2|Q|-1)$, and involves $N \in \mathcal{O}(|Q|^2)$ pixels. Thus, both $\partial P(A)$ and $G_{P(A)}$ can be computed in polynomial time.

For a specific example consider the binary automaton A_0 that accepts the words containing exactly one 0, see Figure 7(a). The polyomino $P(A_0)$ resulting from our construction is depicted in Figure 7(b), where marked pixels show congruence classes of pixels reachable from $\overline{Q}$, in particular those traversed on cycles URDL and DRUL.

▶ **Observation 9.** *For all $p, q \in Q$, $p \xrightarrow{0} q \Leftrightarrow \overline{p} \xrightarrow{\text{URDL}} \overline{q}$ and $p \xrightarrow{1} q \Leftrightarrow \overline{p} \xrightarrow{\text{DRUL}} \overline{q}$.*

▶ **Lemma 10** (⋆). *For all $p \in Q$, with representative pixels $\overline{p} \in P(A)$, and all $w \in \mathbb{D}^*$ with $\overline{p} \cdot w \in \overline{Q}$, there is $w' \in \{\text{URDL}, \text{DRUL}\}^*$ with $|w'| \leq |w|$ that satisfies $\overline{q} \cdot w' = \overline{q} \cdot w$ for all $q \in Q$.*

▶ **Theorem 11.** *A set $S \subseteq Q$ of states of an automaton $A = (Q, \{0,1\}, \delta)$ is synchronizing if and only if its set of representatives $\overline{S}$ is gatherable in $P(A)$, in which case $\operatorname{sgs}(\overline{S}) = 4\operatorname{rt}(S)$.*

Proof. For the forward direction, let $w \in \{0,1\}^*$ be a synchronizing word for S of minimum length. Use Observation 9 to build a gathering sequence $\overline{w} \in \{\text{URDL}, \text{DRUL}\}^*$ for $\overline{S}$ satisfying $|\overline{w}| = 4|w|$. Assume, for sake of contradiction, that there is a gathering sequence $\overline{w}' \in \mathbb{D}^*$

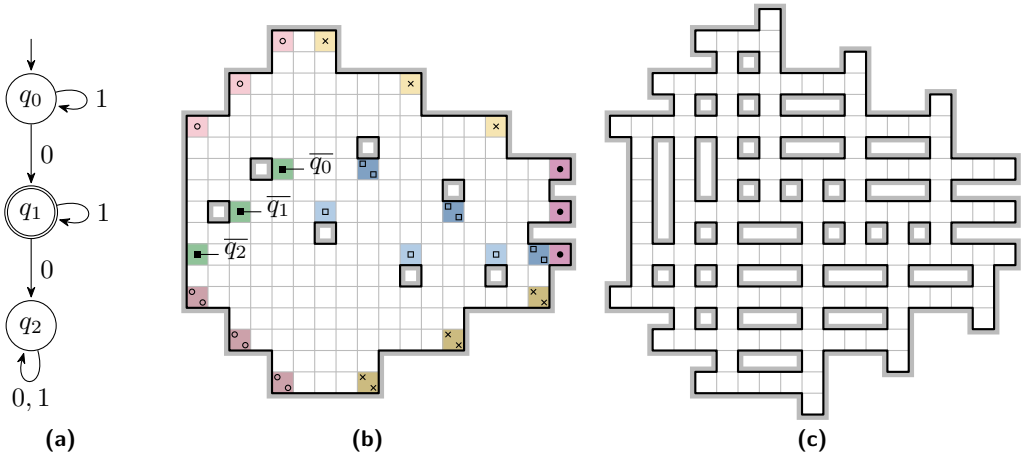

Figure 7 (a) The binary automaton A_0 that accepts all words containing exactly one 0. **(b)** The polyomino $P(A_0)$. Colors and symbols indicate congruence classes of pixels reachable from representatives $\overline{q_i}$. **(c)** $P(A_0)$ turned into a maze $M(A_0)$ by adding holes and pixels of degree 1.

with $|\overline{w}'| < |\overline{w}|$. First apply Lemma 10 to $\overline{w}'$ and then Observation 9 to get a synchronizing word $w' \in \{0,1\}^*$ for S with $|w'| < |w|$, contradicting the assumption that w has minimum length. The backward direction is very similar. ◀

▶ **Corollary 12** (⋆). *If* $\mathrm{sgs}(P) \in \mathcal{O}(n^2)$ *for every gatherable polyomino* P *with* n *corners, then every synchronizing binary automaton* $A = (Q, \{0,1\}, \delta)$ *has* $\mathrm{rt}(A) \in \mathcal{O}(|Q|^2)$.

While a quadratic upper bound on the reset threshold for synchronizing binary automata would not settle Černý's conjecture, it would be remarkable progress. After decades of research, the existence of such an upper bound is still an open problem, suggesting that a proof for Conjecture 8 may be hard to find.

It is easy to adapt the construction of $P(A)$ to produce a maze $M(A)$, at the cost of possibly requiring $\Omega(|Q|^2)$ corners, by adding more holes as well as pixels of degree 1 next to corner pixels, as illustrated for $M(A_0)$ in Figure 7(c).

▶ **Corollary 13.** SubsetGathering *is* PSPACE*-complete, even in mazes.*

Proof. It is easy to see that a non-deterministic algorithm for SubsetGathering could run in polynomial space, which implies containment in NPSPACE = PSPACE [62].

To prove PSPACE-hardness, we reduce from SubsetSynchronizability: Given an automaton $A = (Q, \Sigma, \delta)$ and a set $S \subseteq Q$, determine if S is synchronizing. This problem was originally shown PSPACE-hard by Rystsov [59], and Vorel [72] proved it remains so for $\Sigma = \{0,1\}$. We construct $P(A)$ for a given binary automaton $A = (Q, \{0,1\}, \delta)$ in polynomial time. By Theorem 11, $S \subseteq Q$ is synchronizing if and only if $\overline{S}$ is gatherable. This property remains true when $P(A)$ is turned into a maze $M(A)$. ◀

We want to note that PSPACE-hardness of SubsetGathering in general polyominoes also follows from [7], but we welcome an alternative proof in keeping with our automata theme.

5 Approximating gathering sequences in simple polyominoes

We first show that ShortestGatheringSequence is NP-hard even in simple mazes. To do this, we reduce from ShortestCommonSupersequence where, given an alphabet Σ and a set S of words over Σ, we want to find a shortest word $\overline{w}$ such that for each $w \in S$, there

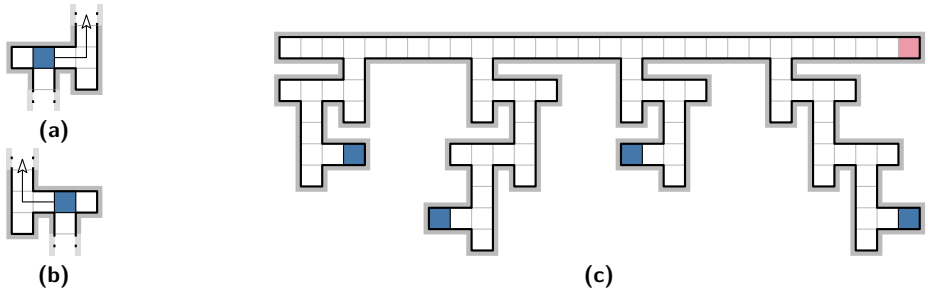

Figure 8 (a) 0-gadget, move sequence RU. **(b)** 1-gadget, move sequence LU. **(c)** The gathering instance for the words 10, 001, 01, and 111. A shortest supersequence is 10011 and the corresponding shortest gathering sequence is LU RU RU LU LU R. The particles gather in the red pixel.

exists a sequence $i_1 < \cdots < i_{|w|}$ with $w_j = \overline{w}_{i_j}$ for each j, i.e., $\overline{w}$ is a supersequence of each word $w \in S$. This problem is already NP-hard if $\Sigma = \{0, 1\}$ [58]. Gerbush and Heeringa [35] used a reduction from a generalized problem to prove inapproximability of the reset threshold of synchronizing automata, which inspired our approach.

▶ **Theorem 14.** ShortestGatheringSequence *is* NP*-hard in simple mazes.*

Proof. Given a set S of words over $\{0, 1\}$, $|S| > 1$, we construct a simple maze as follows: We start with a (sufficiently long) row segment R. For each word $w \in S$, we create a vertical path gadget consisting of the symbol gadgets shown in Figures 8(a) and 8(b) in the order imposed by w. We attach this gadget to the bottom of R, see Figure 8(c). Clearly, this construction is a maze without holes. In each path gadget, we focus on the particle furthest from R as any gathering sequence for these particles is also a gathering sequence for the full polyomino.

We show that there exists a supersequence for S of length k if and only if there exists a gathering sequence of length $2k + 1$ in the corresponding maze. Let $\overline{w} \in \{0, 1\}^*$ be a supersequence for S with $|\overline{w}| = k$. We replace each 0 in $\overline{w}$ with the moves RU and each 1 with LU. In each of the path gadgets, the particle progresses to the next symbol gadget if and only if the symbol in $\overline{w}$ aligns with the moves for its current symbol gadget. Otherwise, it remains in its row. Thus, after the $2k$ moves, all particles have progressed to the row segment R. To gather them in R's rightmost pixel, we add one final R move.

Conversely, let $\overline{w}' \in \mathbb{D}^*$ be a gathering sequence. Without loss of generality, let $|\overline{w}'|$ be minimal. Then, $\overline{w}'$ alternates between horizontal and vertical moves and the first move is horizontal because a vertical move has no effect in the first step. Additionally, $\overline{w}'$ does not contain any D-move as particles can only gather in the row segment R and all shortest sequences to any pixel in R consist of only the moves U, L, and R. Finally, since $|S| > 1$, the last move is horizontal as particles from different path gadgets have to gather in the leftmost or rightmost pixel of R. Therefore, $\overline{w}'$ is a sequence of length $2k + 1$ for some k, consisting of RU and LU subsequences and ending with a horizontal move. We ignore the final move and replace each RU with a 0 and each LU with a 1 to construct a word $\overline{w}$ of length k. As before, a particle progresses to the next symbol gadget exactly if the word in the path gadget contains the corresponding symbol at the position of the particle's gadget. Therefore, since $\overline{w}'$ is a gathering sequence and all particles end up in R, $\overline{w}$ is a supersequence for S. ◀

On the other hand, we can approximate the length of a shortest gathering sequence to within a factor of 4 in simple mazes. To achieve this, we first observe that all such instances have exactly one row or column segment where the particles can gather. Throughout the remainder of this section, we only consider segments consisting of at least two pixels.

▶ **Lemma 15** (⋆). *Let P be a gatherable simple maze with $N > 1$ pixels. Then all row or column segments of P have at least one end point that is a corner pixel and exactly one segment has two corner pixel end points.*

▶ **Theorem 16.** *Let P be a gatherable simple maze. Then we can compute a gathering sequence for P of length at most $4 \cdot \mathrm{sgs}(P)$ in polynomial time.*

Proof. Assume $N > 1$. By Lemma 15, there exists a unique segment R whose end points are both corner pixels and any other segment has exactly one corner pixel. Clearly, all particles have to gather in R as particles initially located in R's corner pixels cannot enter any other segment. It suffices to focus on particles located at corner pixels as all other particles are also gathered by gathering sequences for corner pixels in simple mazes. Now consider a particle p located in the corner pixel of a horizontal segment $S_1 \neq R$. To reach R, p has to pass a sequence of alternating horizontal and vertical segments $S_1, \ldots, S_\ell$ with $S_\ell = R$. Therefore, the shortest sequence moving p to R consists of alternating $\{\mathrm{L}, \mathrm{R}\}$ and $\{\mathrm{U}, \mathrm{D}\}$ moves. Note that p cannot return to S_i after progressing to S_{i+1} and then moving in any direction perpendicular to S_i because the intersection pixel between any consecutive segments S_i, S_{i+1} has degree 3 by the definition of mazes.

Let d be the maximum length of a shortest sequence from any corner pixel to R and consider the sequence URDL. Any particle initially located at a corner pixel progresses to the next segment with at least one of the four moves. Thus, the sequence $(\mathrm{URDL})^d$ is at most four times as long as the shortest sequence moving all particles to R. Finally, the last move in any gathering sequence is perpendicular to R to gather all particles in one of R's end points. ◀

For arbitrary simple polyominoes, there is likely no polynomial-time algorithm approximating $\mathrm{sgs}(P)$ within any constant factor. To show this, we extend our reduction from ShortestCommonSupersequence to unbounded alphabets. If the alphabet size is not fixed, the problem is hard to approximate within any constant factor $\alpha \geq 1$ unless P = NP [41].

We can use the same approach to construct a polyomino as in Theorem 14, i.e., we attach a path gadget consisting of symbol gadgets for each given word to a baseline segment where particles gather. It suffices to generalize the symbol gadget for larger alphabets.

▶ **Theorem 17** (⋆). *Unless* P = NP*, there is no polynomial-time approximation algorithm for* ShortestGatheringSequence *in simple polyominoes with approximation ratio $\alpha \in \mathcal{O}(1)$.*

6 Gathering subsets in simple polyominoes

Like previous reductions for the full tilt model [7, 9], our PSPACE-hardness proof for SubsetGathering in Corollary 13 requires polyominoes with holes. We can retain a weaker hardness result for simple polyominoes by reducing from IntersectionNonEmptiness of *tally automata*, i.e., automata over the unary alphabet $\{0\}$: Given a family $A_i = (Q_i, \{0\}, \delta_i, q_i, F_i)$ of tally automata, determine whether $\bigcap_i L(A_i) \neq \varnothing$, i.e., whether the A_i accept a common word. The NP-hardness of this variant goes back to seminal work by Stockmeyer and Meyer [66]. A newer, independent proof by Morawietz, Rehs, and Weller [55] emphasizes that this variant remains NP-hard if the graphs underlying the automata are cycles. Inspection of the proof reveals that we may also assume the lengths of all cycles to be odd and greater than 1, since they are chosen to be products of large primes. Finally, we may assume all automata to have at least one non-accepting state (or the automaton would accept all words). We implicitly include these restrictions when talking about tally automata in the following.

Given a family $A_i = (Q_i, \{0\}, \delta_i, q_i, F_i)$, $1 \leq i \leq k$, of k tally automata, we construct a simple polyomino $P(A_1, \ldots, A_k)$ and an initial configuration as follows.

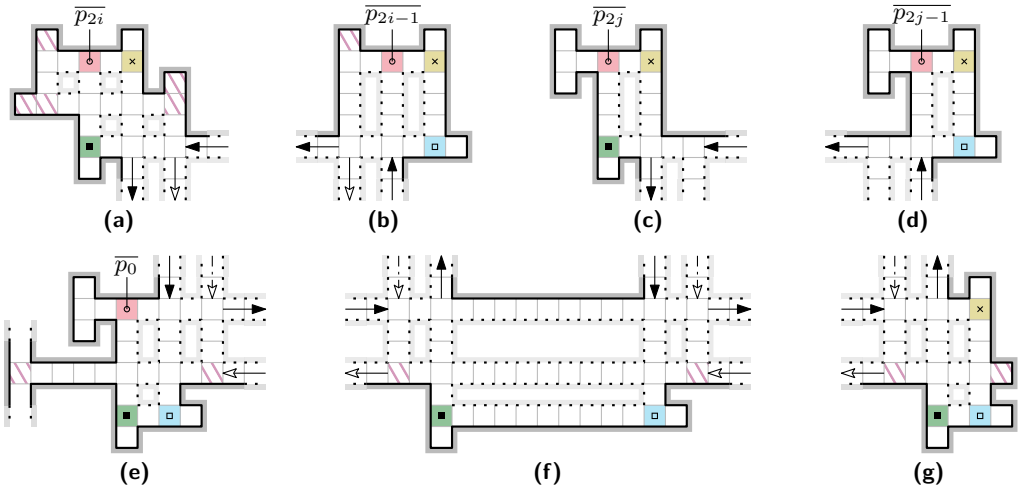

Figure 9 Gadgets used in the reduction from tally automata intersection. Pixels marked with colors and symbols indicate the cycle RDLU between pixels representing states, which is continued between gadgets via the black arrows. The stroked tiling pattern highlights pixels with a safe path to the goal area using the white arrows. Dotted areas specify optional holes that turn the simple polyomino into a maze. **(a)** Accepting state with even index. **(b)** Accepting state with odd index. **(c)** Rejecting state with even index. **(d)** Rejecting state with odd index. **(e)** Start gadget including $\overline{p_0}$ and access to the goal area to the left. **(f)** Bridge gadget. **(g)** End gadget connecting $\overline{p_0}$ to $\overline{p_1}$.

Consider an automaton A_i with $|Q_i| = 2m + 1$ for some $m \geq 1$. Number its states $p_0, \ldots, p_{2m}$ such that $p_0 \notin F_i$ and $p_j \to p_{(j+1) \bmod |Q_i|}$ for all $0 \leq j < |Q_i|$. Place a *start gadget* containing a pixel $\overline{p_0}$ representing p_0, followed horizontally by $m - 1$ *bridge gadgets* and a final *end gadget*; see Figures 9(e)–9(g). Above the partial construction, $2m$ gadgets are placed, from right to left, for the remaining states $p_j \in \{p_1, \ldots, p_{2m}\}$, depending on two factors: the parity of j and whether p_j is accepting. Gadgets for the four possible combinations are depicted in Figures 9(a)–9(d), each containing a representative pixel $\overline{p_j}$.

Partial constructions for A_i are stacked vertically and connected to a *goal area* to the left, which is simply a column segment ending in pixels of degree 1. For a set $S \subseteq \bigcup_i Q_i$, we define $\overline{S} = \{\overline{q} : q \in S\}$ to be the set of representative pixels for states in S. The initial configuration is $C_0 = \bigcup_i \{\overline{q_i}\}$, i.e., the representative pixels for the initial states. Figure 10 depicts a small but complete example of the construction for two tally automata.

▶ **Theorem 18** (⋆). SUBSETGATHERING *is* NP*-hard in simple polyominoes.*

Proof sketch. A common word $0^\ell \in \bigcap_i L(A_i)$ leads to a gathering sequence $(\text{RDLU})^\ell\,\text{LDRDLD}$ for C_0 in $P(A_1, \ldots, A_k)$. For the reverse direction, we argue that if there is any gathering sequence for C_0, then it must first move all particles to representatives of accepting states, which can be done with a (shorter) sequence of the form $(\text{RDLU})^{\ell'}$, which corresponds to a common word $0^{\ell'}$ for the automata. Since the reduction uses a polynomial number of constant-size gadgets, it can be executed in polynomial time. ◀

▶ **Corollary 19.** OCCUPANCY *and* SHAPERECONFIGURATION *are* NP*-hard in the blocking variant of* FT*, even in simple polyominoes.*

Proof. Take the construction from Theorem 18 for k automata and extend the goal area upwards so that there are k pixels above the topmost intersection. The distinction between $\delta^\times$ and $\delta^\cup$ only matters in the goal area, since that is the only segment that can possibly

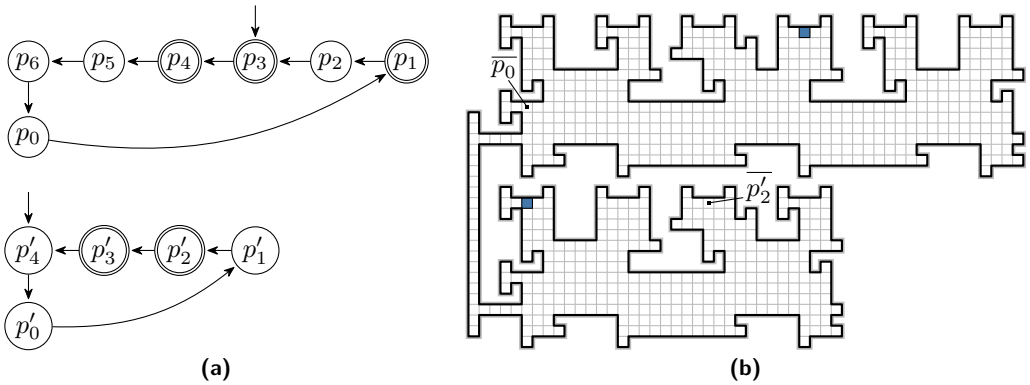

Figure 10 Instance of SubsetGathering produced by the reduction from tally automata intersection. **(a)** Two tally automata, A_1, A_2; both accept the word of length 8. **(b)** The simple polyomino $P(A_1, A_2)$; $(\text{RDLU})^8$ LDRDLD is a gathering sequence for its initial configuration C_0.

Table 1 Overview of complexity results for gathering problems in FT, unless P = NP.

Problem	Geometry	Complexity	Reference
FullGathering	General / Simple	$\mathcal{O}(n_c n^2)$ / $\Omega(n^2)$	**Thms. 4, 7**
		$\mathcal{O}(n^2)$ conj.	**Conj. 8**

	Simple	NP-hard	**Thm. 18**

contain more than one particle at a time. Now the kth pixel from the top in the goal area can be occupied – and the configuration consisting of the k topmost pixels in the goal are can be reached – if and only if the automata accept a common word. ◀

7 Conclusions

See Table 1 for an overview of our results. The reduction from Section 6 transfers to the related problem of *collecting* [52] a given set of particles into a *connected* configuration in the blocking variant of FT. Our hardness results also apply if the particles are to be gathered at a specified position, since one could simply check all possible positions if this was practical. In the case of FullGathering, it is still possible to find a gathering sequence $w \in \mathbb{D}^*$ such that $V \xrightarrow{w} \{p\}$ for a given pixel p in polynomial time, or decide that no such sequence exists: Assume there are two distinct pixels q_1, q_2 such that $V \xrightarrow{w_i} \{q_i\}$ for $w_1, w_2 \in \mathbb{D}^*$. Then $\{q_1\} \xrightarrow{w_2} \{q_2\}$ and $\{q_2\} \xrightarrow{w_1} \{q_1\}$, i.e., all pixels where particles can be gathered are mutually reachable. Thus, one can check if all particles can be gathered at a given pixel p by using the techniques from Section 3 to find a gathering sequence targeting an unspecified pixel q, and then check if p is reachable from q. If either step fails gathering at p is impossible.

It may be worth reiterating that our algorithmic results are polynomial in the number n of corners of a given polyomino, whereas our hardness reductions produce the dual graph with N pixels, i.e., the respective problems are hard even for a unary representation of space.

A number of open questions remain. While closing the gap between the worst-case bounds $\Omega(n^2)$ and $\mathcal{O}(n_c n^2)$ for $\text{sgs}(P)$ in general polyominoes looks very hard due to its connection to Černý's conjecture, it may be feasible to close the gap in special classes of polyominoes. Is it easier to prove an upper bound $\text{sgs}(P) \in \mathcal{O}(n^2)$ for simple polyominoes?

We have shown SubsetGathering, Occupancy, and ShapeReconfiguration to be NP-hard in simple polyominoes but did not definitively settle their complexity. Can these problems be shown to remain PSPACE-complete in simple polyominoes?

ShortestGatheringSequence can be approximated within a constant factor in simple mazes, which is NP-hard in general simple polyominoes. Is SubsetGathering also easier in simple mazes? We conjecture it to be polynomially solvable in this case.

Abstract

The weak visibility polygon of a line segment s inside a simple polygon P, denoted by $V_P(s)$, is the region of the polygon that is visible from at least one point on s. Given its fundamental nature in computational geometry, several algorithms have been proposed to compute weak visibility polygons efficiently, each with different trade-offs in terms of preprocessing time, query time, and space complexity. Although there are many applications that require computing these polygons such as computer graphics, robot motion planning, and network communication systems, there is a lack of *any* implementations of these algorithms in the literature – not to mention one that is exact, robust, and scalable. Furthermore, weak segment visibility polygons are used as basic building blocks in several other algorithms, such as in minimum-link path computation.

In this work, we present an implementation of an optimal linear-time algorithm for computing the weak visibility polygon of a segment inside a triangulated simple polygon. Our implementation provides exact, robust geometric primitives and optimizations to handle large inputs with more than 18 000 000 vertices. We demonstrate two concrete applications: (1) construction of window partitions, a standard data structure in visibility algorithms, and (2) support for optimal minimum-link path queries between two points in a simple polygon, the latter serving as a direct use case of the former. Experimental results on a variety of polygon families confirm that the end-to-end running time scales linearly with the size of the polygon and is dominated by the cost of computing the triangulation, validating the practicality and scalability of the approach. The implementation is released as open source in the format of a CGAL package to support reproducibility and further research.

1 Introduction

Developing efficient methods for geometric problems is at the core of computational geometry. The usual quality measure for such algorithms is their asymptotic worst-case complexity, making non-trivial, linear runtime an ultimate achievement, such as Chazelle's $\mathcal{O}(n)$ triangulation algorithm [11]. While this is undoubtedly one of the intellectual pinnacles of the field, and widely used as a subroutine for achieving fast asymptotic worst-case complexities for many other algorithms, its sophistication also highlights a serious issue: We are not aware of any practical implementation, leaving a serious question posed by none other than Chazelle himself, "Can computational geometry meet the algorithmic needs of practitioners?" [12].

Achieving this goal requires significant additional effort, often involving tough choices and scientific expertise. From the practical side, asymptotic worst-case complexity does not suffice; instead, we require actual *scalability*: what size instances can indeed be solved in reasonable time? This matters not only for hard problems, but also for algorithms for relatively "easy" tasks that are used as repetitive subroutines when dealing with more complex problems.

Another serious challenge is to achieve *robustness*, i.e., ensuring that an implementation does not fail catastrophically in the vicinity of geometric degeneracies? As demonstrated by Kettner, Mehlhorn, Pion, Schirra and Yap [33], even simple algorithms such as Graham's scan [23] can produce completely erroneous results when simply run with floating point arithmetic. An important tool to aid in achieving robustness is the use of *exact* computations, combined with correct handling of all degenerate special cases such as collinear points and overlaps, ensuring that numerical issues cannot lead to any errors. Achieving this with managable performance impact has been one of the goals in community efforts such as CGAL [55], which won the SoCG Test of Time Award in 2023; among many relevant publications, see Boissonat [5] for a practical paper on triangulations. Finally, an implementation can only be used if it is *available*, i.e., its code is published in a usable state and under a suitable license.

In this paper, we demonstrate practical progress along these lines. We describe (and provide) a practical solution for a fundamental problem of Computational Geometry: Compute the *weak visibility polygon of a segment* ℓ within a simple polygon P. This task occurs in a wide variety of problems, such as in robot navigation or optimal surveillance, e.g., in the classical Watchman Problem; see the surveys by Mitchell [45, 44]. In theory, the weak visibility polygon of a segment can be computed in linear time, combining Chazelle's $\mathcal{O}(n)$ triangulation algorithm with an $\mathcal{O}(n)$ algorithm by Guibas, Hershberger, Leven, Sharir and Tarjan [24]. However, to this date, there is no scalable, robust and exact implementation that solves this problem. Indeed, we are unaware of *any* open source implementation. Further relevance is highlighted by the relation to problems such as the Art Gallery Problem, which is not only NP-hard, but even known to be $\exists\mathbb{R}$-complete [1], illustrating the fragility of solutions and the need for robust solutions. Our implementation has all these properties.

- It is *scalable*: We can solve instances with 18 000 000 points within seconds.
- It is *robust* and *exact*: We use exact arithmetic for all computations.
- It is also *available*: it comes as a CGAL package that can be used out of the box.

In this way, we literally follow Chazelle's Recommendation #1 in his 1996 task force report for the first practice track of SoCG, which is also central for SoCG's new practice track: "production and dissemination of geometric code" [12]. In addition, we showcase

two major use cases to demonstrate the practical applicability of our code for large-scale instances: we show how to compute a *window partition* of a polygon P, as well as computing the *minimum link* path between two points in P, for polygons with up to 2 000 000 vertices.

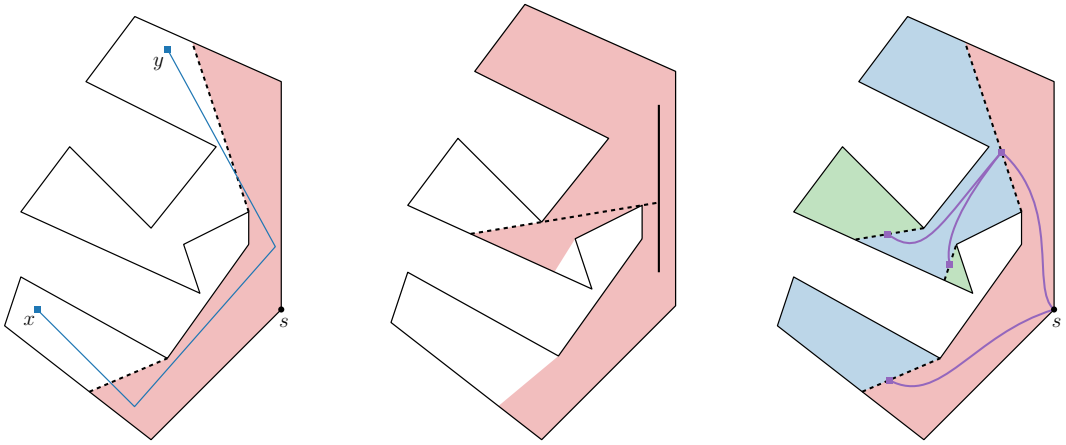

Figure 1 *Left:* $V_P(s)$ is given in red and the windows are marked using dashed lines. A minimum link path between x and y is marked in blue; $d_L(x, y) = 3$. Note that the shortest (Euclidean) path between x and y is not a minimum link path. *Middle:* A segment $\ell \in P$ is marked with a solid black line and $V_P(\ell)$ is marked in red. Note that windows of $V_P(\ell)$ can be defined by points in the interior of ℓ. *Right:* The window partition $\mathcal{W}(s)$ and the window tree T_s of s. Points with link distance one are colored red, with two are colored blue, and with green are colored green. T_s is marked in purple.

1.1 Preliminaries

In the following, P denotes a simple polygon and n its number of vertices. Two points x and y are *visible* to each other if the line segment $xy \subset P$. The *visibility polygon of a point* $s \in P$, denoted by $V_P(s)$, is the set of all points in P visible to s. Given a segment $\ell = pq$ inside of P, the *weak visibility polygon* $V_P(\ell)$ is the set of all points in P that are visible from some point on ℓ, i.e., $V_P(\ell) := \{p \in P \mid \exists\ s \in \ell : p \in V_P(s)\}$; see Figure 1.

For two points $p, q \in P$, the *link distance* $d_L(p, q)$ between them is the minimum number of edges in any polygonal path within P between x and y (see Figure 1, *Left*). Consider a point $s \in P$ and its visibility polygon $V_P(s)$. The vertices of $V_P(s)$ are either vertices of P or the shadows of reflex vertices of P seen by s. The edges of $V_P(s)$ between reflex vertices and their shadows are called *windows*. A window w is a chord of P and divides P into two parts; define $P(w, s)$ to be part of P which does not contain s. The *window partition* $\mathcal{W}_P(s)$ is the partition of P returned by Algorithm 1 described by Suri [50] given input s. We drop the subscript P from $\mathcal{W}_P(s)$ when it is clear from context which polygon we are referring to.

Algorithm 1 Window-Partition(x, P).

1: Compute $V_P(x)$;
2: Let $w_1, w_2, \ldots, w_k$ be the windows of $V_P(x)$;
3: **for** $i = 1$ to k **do**
4: Recursively call Window-Partition$(w_i, P(w_i, x))$;
5: **end for**
6: Output $R(x) := V_P(x)$;

Let $R(w)$ denote the region generated by a window w. The rooted dual tree T_s of $\mathcal{W}(s)$ has as vertices the windows defining $\mathcal{W}(s)$ and edges between two vertices if their regions share a common boundary. The root of T_s is s. We refer to T_s as the *window tree* of s. See Figure 1, *Right*. Let $g(u, v)$ denote the minimum distance of two nodes u, v in T_s and consider a point $p \in R(w)$. The link distance $d_L(s, p)$ is $g(s, w) + 1$ [50].

Constructing a triangulation $\mathcal{T}$ of a polygon P takes linear time [11]. Thus, computing $V_P(\ell)$ for a segment ℓ in P takes linear time – first triangulate P, then use the algorithm from [24]. As we are unaware of any implementation of [11], we use a constrained Delaunay triangulation of P provided by CGAL [5]. This has a worst-case complexity of $\mathcal{O}(n^2)$ [8] but works extremely well in practice, avoids degenerate triangles and thus simplifies our workflow. Our implementation runs in linear time given $\mathcal{T}$ as in [24]. To achieve this runtime, we implemented a specialized data structure called a *finger tree* [30, 29] (see Section 2.1). To the best of our knowledge, all previous implementations of finger trees are in functional programming languages like Haskell or Scala [29, 22]; we used C++ for their iterative versions. We implemented an improvement to [24] suggested in [50]; this allows us to compute $V_P(\ell)$ in time linear in the number of triangles in $\mathcal{T}$ it intersects rather than n. Apart from allowing us to reliably compute $V_P(\ell)$ even in extremely large input polygons, this is crucial to compute window trees in $\mathcal{O}(n)$. All our implementations use exact number types and handle degeneracies. In Section 2, we review the algorithms introduced in [24, 50] and discuss relevant implementation details. We recommend readers familiar with these results to skim through our implementation notes in Section 2 before skipping to Section 3.

1.2 Related work

Computing visibility polygons is central to computational geometry. We focus on weak visibility polygons of segments inside simple polygons; for a more general overview of visibility problems, see [56, 46, 48, 21, 15]. Given a triangulation of a polygon, Guibas, Hershberger, Leven, Sharir and Tarjan [24] presented an $\mathcal{O}(n)$ algorithm that computes the visibility polygon. A number of algorithms have been proposed for data structures that can efficiently compute these for a query segment ℓ, each with its own trade-offs in terms of preprocessing time, query time, and space complexity. We summarize the most relevant ones in Table 1.

Table 1 A summary of theoretical data structures to compute the visibility polygon of a line segment in a triangulated simple polygon. The value k is the size of $V_P(\ell)$ for a query segment ℓ.

Data Structure	Preprocessing Time	Size	Query Time
Bose, Lubiw and Munro [6]	$\mathcal{O}(n^3 \log n)$	$\mathcal{O}(n^3)$	$\mathcal{O}(k \log n)$
Bygi and Ghodsi [9]	$\mathcal{O}(n^3 \log n)$	$\mathcal{O}(n^3)$	$\mathcal{O}(k + \log n)$

Our results are given in bold. We remark that implementing the more recent results with improved output sensitive query time [3, 6, 9, 13] with exact predicates seems extremely challenging. It is also unclear if these will lead to improvements in runtime in practice (see Section 4 for experiments).

Computing segment visibility is a crucial subroutine in several important geometric data structures; perhaps the most well-known one being window partitions and window trees [50]. Other than computing minimum link paths, window partition is also used in convex decomposition algorithms [7, 38] as well as in pursuit evasion problems [52].

Minimum link paths have numerous applications across domains: in motion planning, where turns are expensive and their number should be minimized [47]; in communication systems design under line-of-sight constraints, where a min-link path minimizes the number of necessary repeaters; in placement of telescoping manipulators with flexible telescopic links [34]; in curve simplification by approximating curves with minimum link paths [25, 31, 43]; and in VLSI layouts, where wires typically run along orthogonal axes, motivating the study of link path problems in rectilinear settings [54, 14]. For a comprehensive overview, we refer the reader to [39, Chapter 12] and [40]. There also exist several works on implementing minimum link paths: [53] is restricted to rectilinear paths and is the only work with a publicly available implementation we could find, [20, 57] also consider rectilinear paths, and [17, 58] are restricted to rectilinear environments. Baum, Bläsius, Gemsa, Rutter, and Wegner use minimum link paths in [4] to simplify the boundary of a polygon in a corridor; this is the only other experimental paper on (non-rectilinear) minimum link paths we are aware of. While the authors provided parts of their non-public implementation to us and the paper provides valuable insights into optimizing minimum link path computations for a specific source-target pair, their implementation is tailored to their specific use case and does not offer a method to compute optimal paths between two arbitrary points in a simple polygon.

2 Weak visibility of a segment

In this section, we give an overview of the algorithm by Guibas, Hershberger, Leven, Sharir and Tarjan [24] for computing the visibility polygon of a segment inside a simple polygon P. For a more detailed explanation we refer the reader to the original paper. Consider a triangulated simple polygon P and line segment $\ell = ab$ in P. The algorithm has two steps: first, we compute the *shortest path tree* from both a and b (see Section 2.1 for a definition). Simple data structures can compute this in $\mathcal{O}(n \log n)$ time, reduced to $\mathcal{O}(n)$ using a *finger tree*. In the second step, we compute $V_P(\ell)$ in linear time by iterating over all edges of the polygon and testing if any part of them is visible from ℓ. We only require (amortized) constant time to determine this for each edge of P (and to return the part of this edge that is seen) when we have the shortest path trees of a and b. We discuss details in Section 2.2.

2.1 Shortest path tree

Let P be a simple polygon with n vertices and let s be a given *source vertex* of P. For two points $x, y \in P$, let $\pi(x, y)$ denote the Euclidean shortest path between x and y inside P. Lee and Preparata [37] showed that for all vertices v of P, $\pi(s, v)$ is a polygonal path whose corners are vertices of P and that $\bigcup_v \pi(s, v)$ over all vertices v forms a tree rooted at s. We use $Q_P(s)$ to denote this *shortest-path tree* rooted at s – the vertices of $Q_P(s)$ are vertices of P and (u, v) is an edge of the tree if it is an edge of either $\pi(s, u)$ or $\pi(s, v)$.

Let $\mathcal{T}$ be a triangulation of P and G the dual graph of $\mathcal{T}$. Let $d = uw$ be a diagonal or and edge of P and let a be the deepest common ancestor of u and w in $Q_P(s)$, see Figure 2 *Left*. Then the path $\pi(a, u)$ and $\pi(a, w)$ are two outward convex chains [37], i.e., the convex hull of each subpath lies outside of the region bounded by $\pi(a, u)$, $\pi(a, w)$, and uw. Following [37], we call $F = F_{uw} = \pi(a, u) \cup uw \cup \pi(a, w)$ the *funnel* of d with *cusp* a.

We compute $Q_P(s)$ in linear time by maintaining funnels of diagonals in $\mathcal{T}$ as we process its vertices. We maintain the current funnel F_{uw} as a sorted list $[u_l, u_{l-1}, \ldots, u_1, a, w_1, \ldots, w_k]$ where $a = u_0 = w_0$ is the cusp of F, $\pi(a, u) = [u_0, u_1, \ldots, u_l]$ and $\pi(a, w) = [w_0, w_1, \ldots, w_k]$ with $u_l = u$ and $w_k = w$. We call Algorithm 2 [24] with s and an adjacent vertex v_1 as the initial funnel F; for an interior source point s, we start by locating the triangle containing s and create three funnels, one for each edge, with cusp s.

Algorithm 2 ComputePath(F).

1: $u \leftarrow$ first element of F and $w \leftarrow$ last element of F;
2: $a \leftarrow \text{CUSP}(F)$;
3: $\triangle uwx \leftarrow$ unique unprocessed triangle incident to $d = uw$;
4: Compute $v \in F$ such that vx is a tangent of F at v;
5: Split $F \cup \{x\}$ into $F_1 = [u, \ldots, v, x]$ and $F_2 = [x, v, \ldots, w]$;
6: **if** $v \in \pi(a, u)$ **then**
7: $\quad \text{CUSP}(F_1) \leftarrow v$ and $\text{CUSP}(F_2) \leftarrow a$;
8: **else if** $v \in \pi(a, w)$ **then**
9: $\quad \text{CUSP}(F_1) \leftarrow a$ and $\text{CUSP}(F_2) \leftarrow v$;
10: **end if**
11: $\pi(s, x) \leftarrow \pi(s, x) \cup vx$;
12: Call ComputePath(F_1) and ComputePath(F_2) if ux or wx is a diagonal of P;

We explain Lines 4 and 11 of Algorithm 2 in more detail. As $\pi(a, u)$ and $\pi(a, w)$ are outward convex, the slopes of the segments defining them are monotonic. Thus, we can do a binary search on these slopes to find the point of tangency for x to F in Line 4; see Figure 2, *Left*. We do not store shortest paths explicitly as suggested by Line 11, we simply store back pointers from x to v; $\pi(s, x)$ is computed by following these pointers until we reach s.

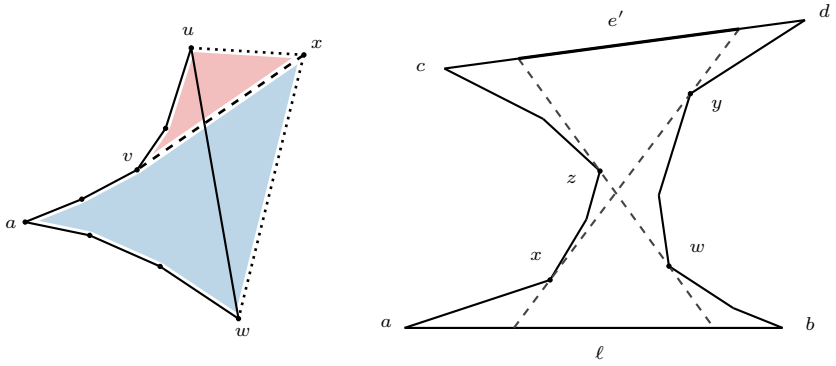

Figure 2 *Left:* Splitting the funnel $F = [u, \ldots, w]$ when a new vertex x is processed. F is split into two sub-funnels $F_1 = [u, \ldots, v, x]$ (red) and $F_2 = [x, v, \ldots, w]$ (blue). *Right:* Hourglass for visibility polygon calculation [24].

Although using binary search as above is straightforward with a binary search tree, it requires $\log n$ time, as $\pi(s, u)$ and $\pi(s, v)$ (and thus our list representing F) might contain $\mathcal{O}(n)$ elements. For an overall linear runtime, we need to find v in (amortized) constant time. This is achieved by storing the list F as a so-called *finger tree* [26]. Our finger trees are modified 2-3 search trees which include pointers (called *fingers*) to the last and first element

of F. They allow for access to v, as well as the splitting of F at v in $\mathcal{O}(\log \delta)$ time, where δ is the distance from v to the nearest finger. See Guibas, McReight, Plass and Roberts [26] for details on properties of finger trees. Gibiansky [22] also provides valuable insights.

Implementation notes. To the best of our knowledge, all implementations of finger trees are in functional programming languages; we implemented an iterative version in C++. As suggested in [24], we can use simpler data structures such as linked lists to represent funnels, resulting in a runtime of $\mathcal{O}(n \log n)$ instead. To compare with our finger tree implementation, we use CGAL's built-in `Multiset` class, as it supports search and split natively. In Section 4, we evaluate the performance of our finger tree implementation against CGAL's `Multiset` class. Collinear points pose a challenge for balanced trees, as orientation checks alone cannot establish a strict ordering. By carefully distinguishing cases, we ensure that the funnel remains free of collinearities at all times.

2.2 Segment visibility polygon

Given a polygon P and a segment $\ell = ab$ inside of P, recall that the weak visibility polygon $V_P(\ell)$ contains all points in P that are visible from a point on ℓ, i.e., $V_P(\ell) = \{s \in P \mid \exists t \in \ell : s \text{ is visible from } t\}$. The following structural lemma is crucial.

▶ **Lemma 1** ([24]). *If a point interior to an edge $e' = cd$ is visible from a segment $\ell = ab$ then (up to swapping c and d) the two paths $\pi(a, c)$ and $\pi(b, d)$ are outward convex.*

Consider such an edge $e' = cd$. The structure formed by ℓ, e', $\pi(a, c)$ and $\pi(b, d)$ is called an *hourglass*, see Figure 2, *Right*. When running the shortest path tree algorithm with a as the source, the funnel $F_{e'}$ has x as its cusp and y as an adjacent vertex. Similarly, when running the algorithm with b as the source, the funnel $F_{e'}$ has w as its cusp and z as an adjacent vertex. These two tangents define the visible section of e'.

During the computation of the $Q_P(s)$, we check, for each vertex v, in constant time if $\pi(s, v)$ is outward convex or not. To extract the visibility polygon, we iterate over the vertices of the polygon and check whether an edge is (partially) visible as explained above. Then we connect continuous visible portions of the boundary, skipping over invisible edges, by connecting visible vertices with their shadow vertices (defined by the tangents). While the algorithm defined in [24] is not output sensitive (taking $\mathcal{O}(n)$ time regardless of the size of $V_P(\ell)$), we explain in Section 2.3 modifications to this algorithm to have this characteristic.

Implementation notes. Although point visibility is available in CGAL [28], our implementation can also compute the visibility polygon of a point s by essentially treating it as degenerate segment, simplifying window extraction. Figure 3 shows the visibility polygon $V_P(s)$ of a query point s. All labeled points are collinear, so the point c is visible from s. We call these low-dimensional features caused by degeneracies *needles* and the polygons that have them *non-regularized*. Often needles are undesired; however, for the implementation of the window partition tree in Section 2.4, we require such visibility polygons. Thus, the visibility polygons we generate are non-regularized; we provide a simple linear-time post-processing function that regularizes visibility polygons for use cases where such polygons are preferred.

2.3 Output sensitivity

A naive implementation of Algorithm 1 using [24] would, for each window, compute a complete shortest path tree of P, resulting in a worst case runtime of $\Omega(n^2)$. Suri [50] suggested modifications to [24] to make the computation of segment visibility output sensitive. The

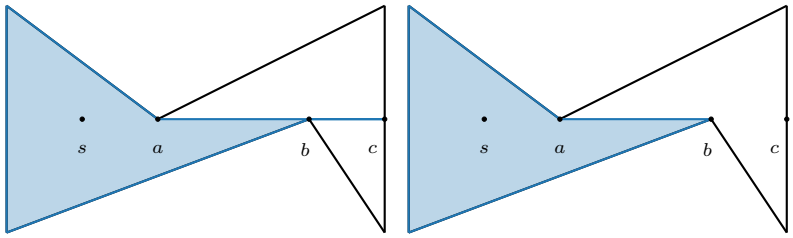

Figure 3 Non-regularized and regularized visibility polygon of s. All labeled points are collinear.

main idea is to synchronize the shortest path tree computation of both endpoints of a segment ℓ and abort the computation of the visibility polygon if an edge is no longer visible from ℓ.

Let P be a simple polygon and $\mathcal{T}$ be a triangulation of the interior of P. For a given segment $\ell = ab$, we start by computing the shortest path tree rooted in a and b along the triangles intersected by ℓ. When processing the next point x in a triangle $\triangle uwx$, we only continue with a diagonal ux if either $\pi(a, u)$ and $\pi(b, x)$, or $\pi(a, x)$ and $\pi(b, u)$ are both outward convex. Symmetrically, we only continue with diagonal wx if either $\pi(a, w)$ and $\pi(b, x)$, or $\pi(a, x)$ and $\pi(b, w)$ are both outward convex. The resulting runtime to compute a visibility polygon $V_P(\ell)$, is $\mathcal{O}(k_\ell)$, where k_ℓ is the number of triangles intersected by $V_P(\ell)$. To ensure that the implementation achieves this runtime, we carefully adjust the traversal of the polygon boundary to only consider vertices that are part of the considered triangles.

Note that k_ℓ can be arbitrarily large compared to the size of the visibility polygon $V_P(\ell)$, e.g., for a triangular visibility polygon that intersects many triangles of $\mathcal{T}$. However, exploiting the fact that each triangle is intersected by at most three partitions [50], we obtain a linear-time algorithm to compute the window partition $\mathcal{W}(s)$ of a point s in P. Note that to start the shortest-path tree computation, we have to locate a triangle intersecting ℓ. We do this using CGAL's built-in `locate` function, which in the worst case has a linear runtime.

2.4 Window partition

To compute the window partition $\mathcal{W}(s)$, we combine Algorithm 1 with our output sensitive visibility polygon computation. The algorithm initially computes a single triangulation $\mathcal{T}$ of P, which we use to compute the non-regularized visibility polygon of s, giving us the initial set of windows. Then, for each window w, we can compute the visibility polygon $R(w) := V_{P(w,s)}(w)$ on the remaining polygon $P(w, s)$. We reuse $\mathcal{T}$ by checking if the next vertex is in $P(w, s)$. This window partition forms the basis for our implementation of the minimum link path algorithms in Section 3.

3 Minimum link path

For a simple polygon P and two interior points s and t, the *link distance* $d_L(s, t)$ between s and t is the minimum number of line segments (links) required to form a polygonal path from s to t that is completely contained in P. The link metric has received considerable attention in computational geometry [49, 50, 42, 2, 41, 35, 27], typically focusing on answering distance queries and not constructing actual minimum link paths. Using window partition trees and other observations, Arkin, Mitchell and Suri [2] proposed an algorithm that can answer link distance queries in $\mathcal{O}(\log n)$ time with $\mathcal{O}(n^3)$ preprocessing time and space. Although the authors mention that the path can be constructed by backtracking through the windows, no details are provided. We implemented two linear time algorithms [50] for answering minimum link path queries based on window partitions: an exact algorithm and an (additive) approximation algorithm that is at most four links longer than the optimal solution.

3.1 Exact algorithm

To construct exact minimum link paths from a source point s to any target point t in a simple polygon P, we use the window partition $\mathcal{W}(s)$ rooted at s. First, we locate the region $R(w)$ that contains t and then traverse the unique path $(w, w_1 \dots s)$ from w to s in T_s. Our construction of $\mathcal{W}(s)$ informs us of a minimum link path from s to t in P that has a vertex on each of the windows $w, w_1, \dots, s$ in that order. Constructing T_s takes $\mathcal{O}(n)$ time and space [50] and locating the target node takes $\mathcal{O}(n)$. Point location could be reduced to $\mathcal{O}(\log n)$ time with preprocessing, but the preprocessing takes super-linear time [15, Chapter 6]. In Section 3.3, we explain how we reconstruct the minimum link path in P in linear time.

3.2 Approximation algorithm

To compute an additive $(\mathrm{OPT}+4)$ approximative minimum link path from p to q in a simple polygon P, we can use the window partition $\mathcal{W}(s)$ of an arbitrary point $s \in P$. For two vertices u and v of T_s, let $g(u, v)$ denote the distance in T_s between them.

▶ **Lemma 2** ([50]). *Let w_1, w_2 be two nodes of T_s, and let $p \in R(w_1), q \in R(w_2)$ be two points of P. Then $g(w_1, w_2) - 1 \leq d_L(p, q) \leq g(w_1, w_2) + 3$.*

The idea is to first identify the two regions $R(w_p)$ and $R(w_q)$ that contain p and q in $\mathcal{W}(x)$ respectively. Then, we identify the lowest common ancestor w_0 of w_p and w_q in T_s. This allows us to construct two paths: one from w_p to w_0 and one from w_q to w_0. Finally, we have to connect the two paths with an additional link on w_0.

Note that, even if $w_0 = w_p$ or $w_0 = w_q$, i.e., the path is directed in T_s, we may still require an additional link using the above algorithm: let $w_0 = w_p$ and $w_0, w_1, \dots, w_q$ be a directed path in T_s. As in Section 3.1, we construct a path from q to p with one vertex v_i on each window w_i for $0 \leq i \leq t$. Unlike the exact algorithm, we cannot guarantee that p is visible from v_0, we can only guarantee the existence of a point v_0' on w_0 that is visible from p. Therefore, we may need to add an additional link from v_0 to v_0' and then to p.

We precompute window partitions rooted at a set of seed vertices and answer queries by probing a small subset of them. At query time, a small set of candidate seed vertices is chosen, e.g., the k nearest to the endpoints. Additionally, we post-process the candidates by removing any introduced loops. The algorithm returns a path with a minimum number of links among all candidates and runs in time proportional to the number of candidates and the cost of locating nodes and reconstructing paths, i.e., $\mathcal{O}(k \cdot n)$ in the worst case for k candidates. Note that Lemma 2 also provides a lower bound on the link distance between p and q that can be used to evaluate the quality of the approximated path.

3.3 Path reconstruction

Now we reconstruct the path from s to t for the exact algorithm detailed in the prior sections. Specifically, we look to construct $(s, p_0, p_1, \dots, p_j, t)$, where p_i belongs to the window w_i. This is done backwards from t. For the step from w_0 to s, any point on w_0 works because s sees all points on w_0. For going from a window w_{i+1} to w_i, this can easily be done in $O(1)$ by extending w_{i+1} to a line and determining its intersection with w_i. However, especially if t is not fixed when constructing the window partition, e.g., because we are answering multiple queries with the same source s, we need to find a point on the last window w_j that sees t. There is a straightforward algorithm that can do this in linear time: compute $V_{R(w_j)}(t)$ and intersect this with w_j to obtain the maximal connected subsegment of w_j that sees t. In practice, this approach is not preferable due to the lack of efficient implementations of

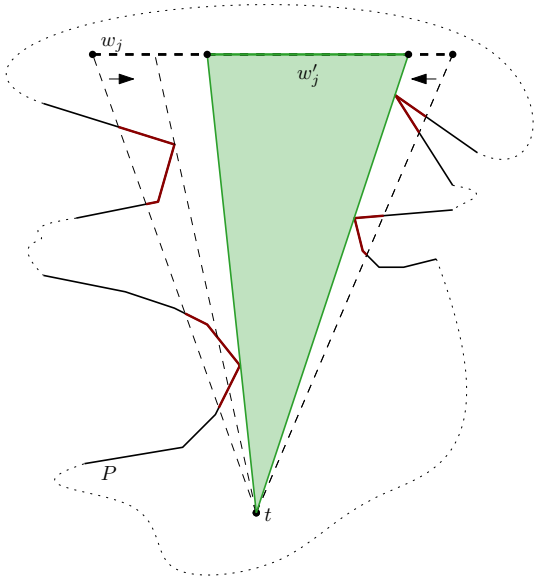

Figure 4 Illustration of the routine described in Section 3.3. The interior point t emits two initial rays defining a cone through the endpoints of window w_j. Several boundary chains (in red) intersect these rays; walking these chains tightens the cone whenever an occluding vertex yields a stricter supporting direction. The intersection of the final cone with w_j is the visible subsegment w'_j. The arrows indicate the direction in which the cone tightens.

visibility algorithms for non-regularized polygons that often appear in the generated window partitions, see Figure 3. The linear-time algorithm available in CGAL [28] is not directly applicable, as it requires the polygon to be simple. Additionally, the triangular expansion approach implemented in CGAL, which is often preferred in practical applications, requires a triangulation of each window, which cannot be directly derived from our triangulation of P, as windows are not necessarily edges of the triangulation; even if we had such a triangulation, the interface of CGAL's visibility package does not allow specifying a triangulation as input. Even without these issues, triangulating each region separately would result in a (practical) superlinear worst-case runtime.

To avoid these problems, we compute the maximal connected subsegment w'_j of w_j that is visible from t in linear (in the complexity of $R(w_j)$) time as follows. Consider the ray between t and the left endpoint of w_j; this possibly intersects $\partial R(w_j)$. Consecutive hitting points define chains of edges on one side of the ray that occlude parts of w. March through the vertices in these chains and choose the vertex defining the rightmost ray from t through it. We find the supporting ray for the right endpoint symmetrically. If these supporting rays cross, w_j is not visible from t (an impossibility). Otherwise, they define the maximal subsegment on w_j visible from t; see Figure 4 for an illustration. Because each other step of path reconstruction takes time $O(1)$, this allows path reconstruction for source s in time $O(|R(w_j)| + j)$ once $\mathcal{W}(s)$ is computed and the window containing t is identified.

For the approximation algorithm, we apply the above procedure for both the windows containing s and t; apart from this and an added segment on the window defining their deepest common ancestor, the situation is analogous.

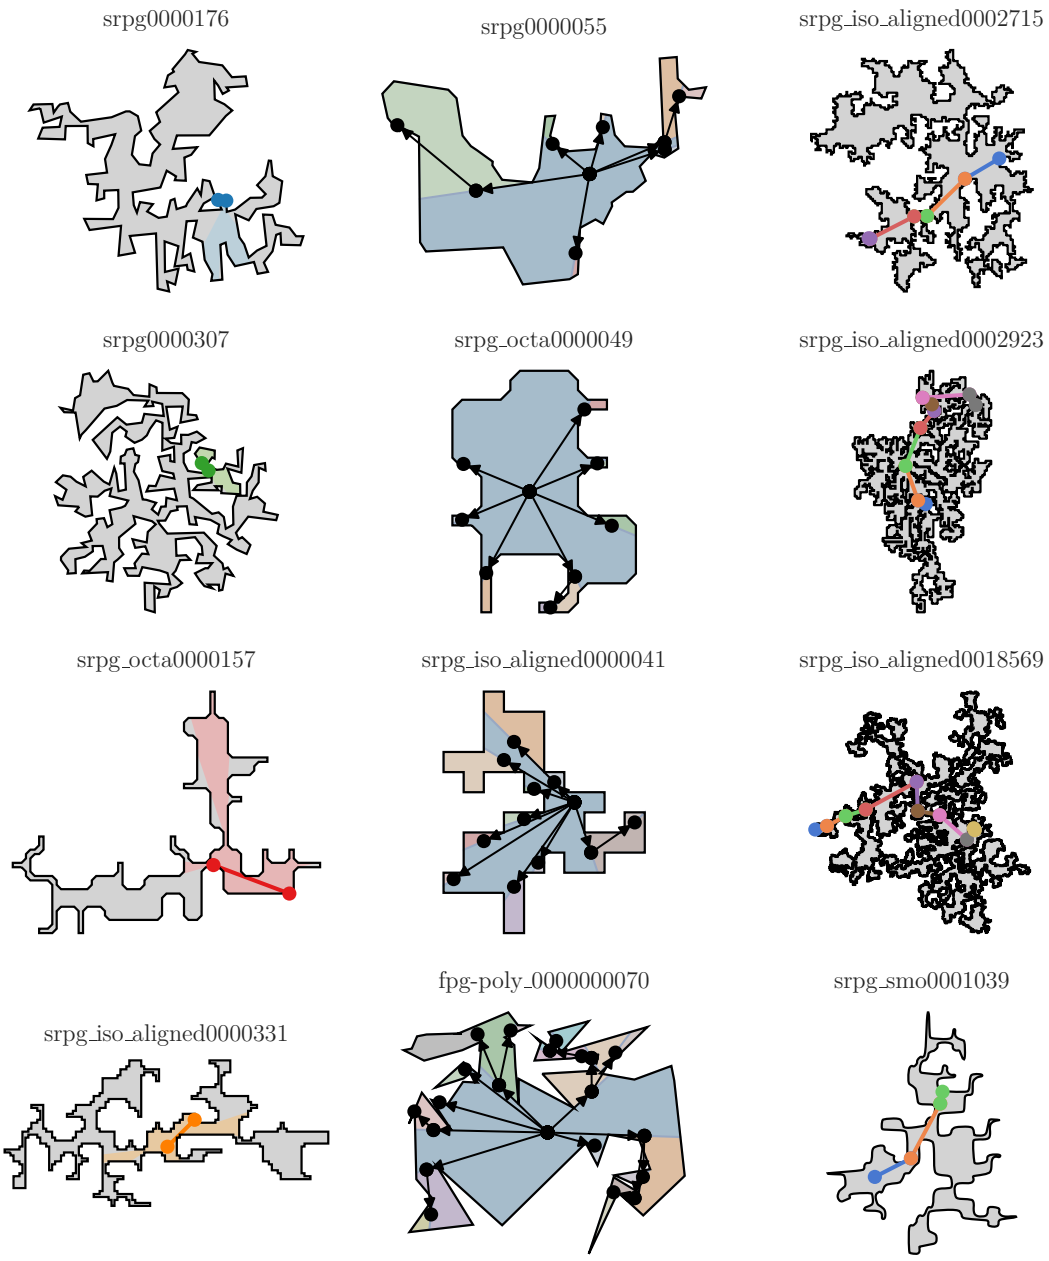

Figure 5 Outputs for the algorithms described in our paper. *Left Column:* Weak visibility polygon of a segment in a simple polygon. *Middle Column:* Window partition of a simple polygon from a source point s. *Right Column:* Minimum link path between two points s and t in a simple polygon.

4 Experimental evaluation

In this section, we present the experimental evaluation of our implementations, see Figure 5 for some example outputs. All experiments were run on otherwise idle workstations equipped with AMD Ryzen 7 5800X CPUs and 128 GiB of DDR4-3200 memory, using Ubuntu Linux 24.04.3 LTS as operating system. The core routines were implemented in C++17, compiled against CGAL 6.0.1 and Boost 1.83.0 using g++ 13.3.0. Our instances and code are publicly available[1]. To guard against programming errors, our code contains large amounts of optional checks and assertions. We also ran a suite of tests with these checks enabled, using instrumentation with tools such as the undefined behavior and address sanitizers of our compiler, which should catch essentially all memory errors. We validated that all paths and visibility polygons found in our experiment stay within the given polygon, and any approximate path has at least the same number of links as the corresponding exact link path.

4.1 Weak line segment visibility

For evaluating our implementation, we consider the following research questions.

RQ1 How does our implementation scale to large inputs, and how is the total runtime distributed onto the individual subroutines?

RQ2 Is there a measurable difference between using finger trees and CGAL's multiset? Which of the two approaches is faster?

RQ3 How does the performance of our implementation depend on the size of the output?

To address these questions, we randomly generate segments for simple polygons from the Salzburg Database of Geometric Inputs[2] [19], the largest of which has 18 556 888 vertices. These polygons are of various types and include polygons with many collinear points or other degeneracies. To generate segments, we sample a source point uniformly at random within the given polygon, compute the visibility polygon of that point, and then either sample a target point in the visibility polygon or pick a random vertex of it. The former approach corresponds to sampling segments inside polygons uniformly at random, whereas the latter focuses on placing one of the endpoints on the boundary of the polygon, exercising edge cases. Using each polygon and each approach twice results in a total of 24 096 instances. For each such instance, and each of the two shortest path tree data structures, we compute the exact visibility polygon five times, measuring the runtime (both total and of various subroutines). Figure 6 depicts the resulting runtimes. We can see that the overall runtime is dominated by computing a triangulation of the input polygon, which we do via CGAL's constrained Delaunay triangulation (CDT). Even CGAL's `mark_in_domain` routine, which simply flags the CDT's triangles that constitute the polygon, is typically more expensive than the actual visibility computation. The fact that the runtime for the visibility computation seems to be almost unaffected by the size of the input polygon can be explained by the fact that it – except for a few small operations such as finding the segment endpoints in the triangulation – mostly depends on the size of the output polygon; see Figure 7, *Left*. On our inputs, the implementation using finger trees is slightly faster than the one using CGAL's `Multiset`, see Figure 7 *Right*. In a preliminary microbenchmark based on building funnels by left insertion, our finger trees became significantly faster already at around 15 funnel vertices; this makes a difference even for the typically small funnels we encounter in our algorithm. We therefore used our finger trees in our other experiments.

[1] `https://doi.org/10.5281/zenodo.19194126`

[2] We used all valid simple polygons from `https://zenodo.org/records/3784789` not labeled as contrived.

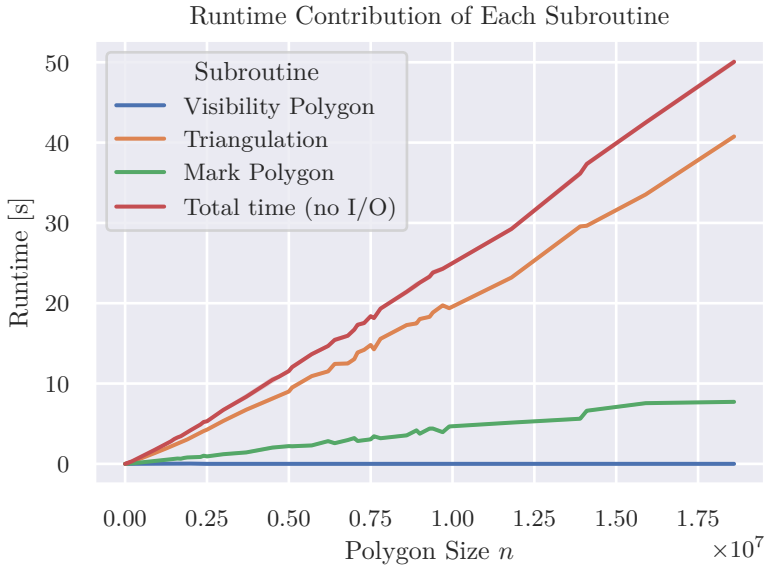

Figure 6 The runtime of different subroutines (triangulating the polygon, marking faces in the polygon, and computing the visibility polygon itself).

4.2 Minimum link paths

Recall that computing a window partition is a basic routine that is useful in different contexts. Furthermore, we only need one window partition from a source point s to compute shortest link-distance paths to any target t, and only a constant number to approximate shortest link-distance paths for any source-target pair inside our polygon. We therefore study the performance of our window partition on its own, as well as in the context of minimum link paths, addressing the following research questions.

RQ4 How does our window partition implementation scale to large polygons?

RQ5 How does it compare to the other parts of our exact minimum link path implementation?

RQ6 How does the approximate minimum link path algorithm perform w.r.t. runtime and solution quality?

To answer these questions, we randomly selected a sample of 1000 simple polygons with at most 2 000 000 vertices from [19]. For each such polygon P, we generate 10 source points $s \in P$ uniformly at random and computed a window partition for each source. Furthermore, for each source point s, we generate a random target point $t \in P$ outside of the visibility polygon of s and computed an exact minimum link s-t-path, as well as an approximate minimum link path using $k = 7$ randomly chosen source points for the window partitions in our approximation. The resulting runtimes are depicted in Figure 8. For each path computed using the approximation algorithm, Figure 9 shows the absolute, additive error depending on the number of window partitions k; the quality of the approximation notably improves with higher k. One should, however, note that increasing k makes both preprocessing and path reconstruction more expensive, both scaling linearly in k.

Overall, we find that both our window partition and minimum link path implementation scale well to large polygons; in fact, in our experiments, time spent inputting, verifying and outputting polygons was typically orders of magnitude higher than pure computation time. If we want to query minimum link paths from a single source s, each subsequent query helps

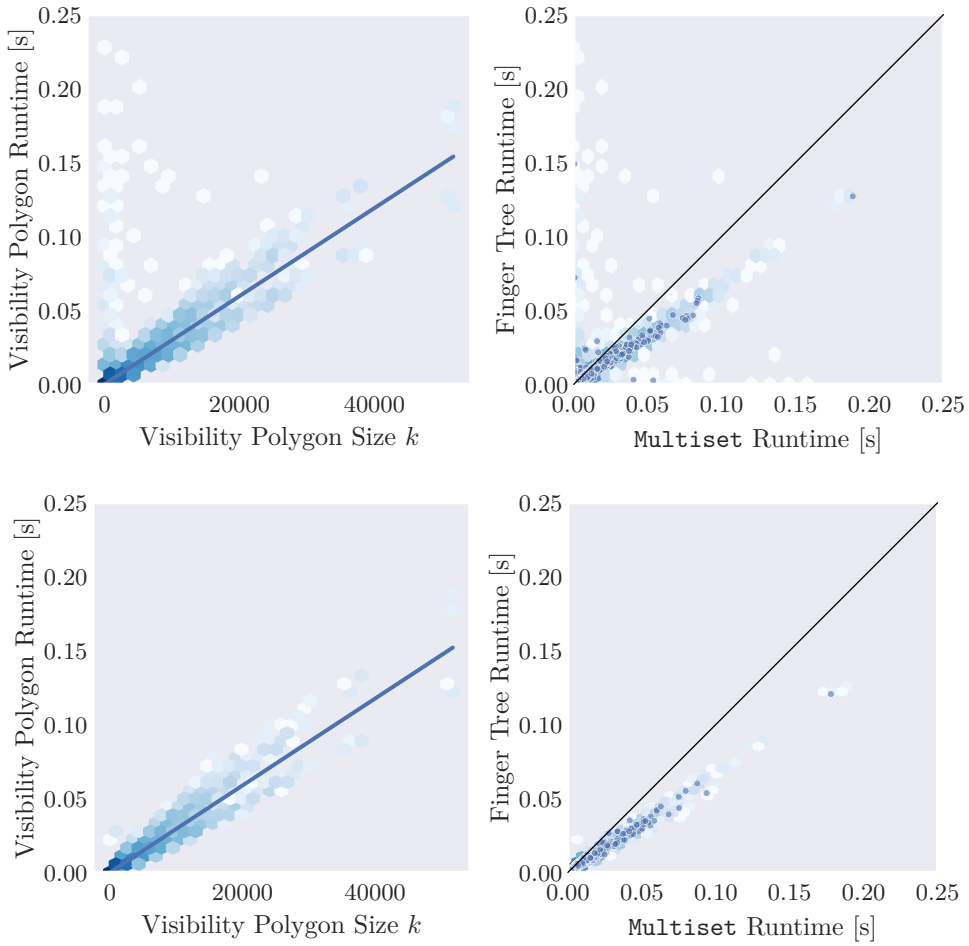

Figure 7 *Top Left:* Runtime dependence on the size of the output visibility polygon, excluding preprocessing such as triangulating the polygon. The hexagonal bin plot shows the underlying distribution similar to a scatter plot, for which we have too many data points; darker hues correspond to a higher concentration of data points, the gray area contains none. *Top Right:* Plot of the runtime using CGAL's `Multiset` and our finger tree implementation with a random sample of data points; the finger tree is better for points below the black diagonal. *Bottom:* The same data as the top row, but dropping the two worst runtime measurements (out of five) for each instance/data structure combination. As our algorithm is deterministic, it is likely that the noise in the top row is simply due to runtime artifacts such as interrupts and scheduling of background processes.

amortizing the cost of computing a window partition; similarly, for doing many queries for different sources and targets in the same polygon, the approximate algorithm can be used to amortize the cost of computing a constant number of window partitions. Depending on the relative importance of runtime versus solution quality, the approximation may be preferable.

5 Conclusions

We presented a scalable, robust and exact implementation for computing the weak visibility polygon of a line segment in a simple polygon. We also demonstrated two concrete applications: computing the window partitioning, and computing the link distance between two points inside a simple polygon. For further improvement on the algorithm engineering side, we could parallelize the shortest path tree and window partition implementations.

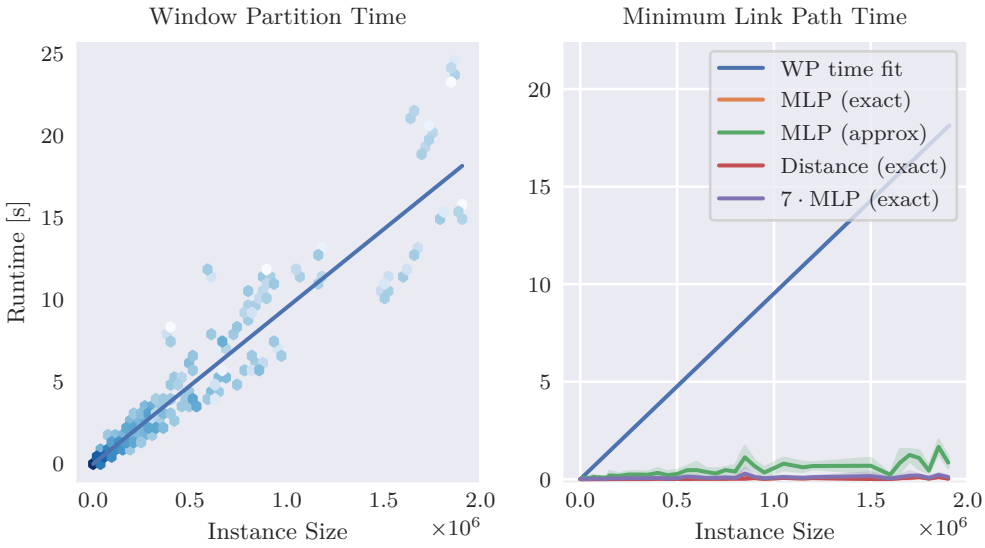

Figure 8 *Left:* The runtime distribution of our window partition implementation, which overall appears to scale linearly, with some instances slightly below and some slightly above the average. *Right:* Comparison of the individual components, showing only the regression line for the window partition time to improve readability. It can be seen that, once a window partition is computed, computing the link distance is very cheap. A single path reconstruction has almost negligible cost, whereas $k = 7$ reconstructions for the approximate approach are more noticable, but still clearly dominated by the window partition time.

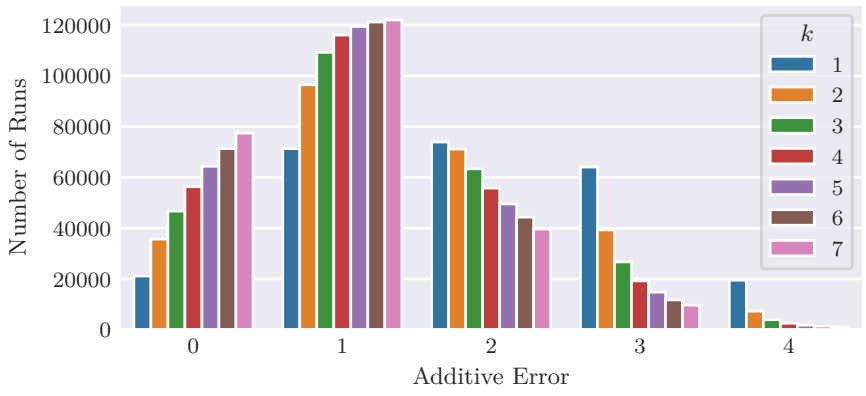

Figure 9 The additive approximation error of our approximate minimum link paths, depending on k, the number of source points used to compute window partitions. In particular, for $k \geq 4$, the majority of queries result in an error of 0 or 1.

An immediate generalization is to non-simple polygons. Suri and O'Rourke [51] studied algorithms for computing visibility polygons with holes. Following the approach described in [10], we can extend our implementation to handle polygons with holes by first splitting the polygon into simple subpolygons and then computing the union of these visibility polygons. The same can be considered for link distance in polygons with holes [42, 40].

Another set of applications arises from using our implementation as a critical tool for dealing with more complex optimization problems that require frequent visibility queries as the critical subroutine. An important example is the Watchman Route Problem (WRP), in which the goal is to find a cheapest tour in a (simple or non-simple) polygon P for a watchman along which every point in P can be seen; here "cheapest" may refer to a minimization of total length or correspond to the number of involved edges. (There are numerous other variants, such as using multiple watchmen.) While a minimum-length watchman tour inside a simple polygon can be computed in polynomial time inside a simple polygon, with the best known time bounds [18] being $\mathcal{O}(n^3 \log n)$ for the "anchored" WRP, in which the tour is required to pass through a specified anchor point, and $\mathcal{O}(n^4 \log n)$ for the "floating" WRP, in which no anchor point is specified; this is only efficient in theory, and we are not aware of any practical implementations. Moreover, the problem is NP-hard for non-simple polygons (with an immediate reduction from the TSP), so practical computation requires more involved exact algorithms that combine the computation of shortest tours with set cover, i.e., many segment visibility computations along the way. This resembles practical approaches for computing optimal solutions for instances of the excruciatingly difficult Art Gallery Problem; as previous work has shown, this may actually hinge on the theoretically "easy" visibility computations instead of the "hard" set cover. For example, of the computation time reported by Kröller, Baumgartner, Fekete and Schmidt [36], 80% was spent on (point) visibility computations: "It is obvious that data structure updates and geometric support procedures are – by far – computationally most expensive, whereas solving the LPs has virtually no runtime impact." See [16] for a deeper dive into how provably optimal solutions for polygons with up to thousands of vertices can be computed. We are optimistic that our newly developed implementation for segment visibility will be a milestone towards similar progress for Watchman Problems, as well as many of the ensuing variants.

Abstract

The Traveling Salesman Problem with Neighborhoods (TSPN) generalizes the classical Traveling Salesman Problem (TSP) by requiring a tour to visit a set of polygonal regions rather than fixed points, a natural goal that arises in various applications. While the geometric TSP allows arbitrarily close approximation and provably optimal solutions for benchmark instances of significant size, the TSPN is considerably more challenging, both in theory (due to APX-hardness) and practice, for which only benchmark instances up to 16 regions have been solved to optimality.

Here we present a branch-and-bound algorithm that combines a spectrum of geometry-based filters (for reducing the number of considered sequences) with Second-Order Cone Programs (SOCP) (for computing optimal tours for a given permutation of neighborhoods). This allows us to solve larger polygonal TSPN instances than before to within an optimality tolerance of 0.1%; moreover, while previous work (both in theory and practice) relied on relatively benign neighborhoods, we can handle non-convex, non-simple neighborhoods of different sizes. In experiments on 490 benchmark instances with up to 50 polygons each, our method achieves a 99.6 % optimality rate within 300 s, with the remaining two instances solved within 595 s. For 68 larger instances of size $n = 60$, our method still allows solving 86.8 % of instances to optimality within 900 s, leaving only 3 of the instances with optimality gaps above 3 %, with the maximum being 5.53 %.

1 Introduction

The Traveling Salesman Problem (TSP) asks for the shortest route that visits a given set of points. Central to many applications, it has also become *the* prototype of a provably difficult, NP-hard optimization problem. A natural geometric generalization of the TSP is the Traveling Salesman Problem with Neighborhoods (TSPN), which asks for a shortest roundtrip that visits each of a given family $P_1, \ldots, P_n$ of regions in the plane; see Figure 1 for an example. This reflects scenarios in which the locations to be visited are not point-sized, but subject to some flexibiliy. Moreover, the TSPN combines the search for optimal touring with aspects of set cover: among others, discrete variants of both the Lawn Mowing Problem (LMP) and the Art Gallery Problem (AGP) can be seen as special cases of the TSPN.

50 polygons, solved in 0.45s

Figure 1 Example TSPN instance with a feasible solution.

Even though both the TSP and the TSPN are NP-hard (making them comparable in theoretical complexity), it can be argued that the TSPN is considerably more challenging. This is clearly reflected in theory: While the geometric TSP allows polynomial-time approximation schemes (Arora [6], Mitchell [38]), APX-hardness of the TSPN was established by de Berg et al. [14]. Moreover, a wide range of sophisticated approximation algorithms rely on assumptions on the shape of the neighborhoods, such as special shapes (e.g., line segments or disks), congruency, convexity, or fatness; see *Related Work* for further details.

A similar gap can be observed on the practical side. The discrete nature of the TSP allows employing a large toolbox of advanced methods from combinatorial optimization and integer programming, enabling provably optimal solutions for point sets of considerable size (such as the 85 900-city instance solved by [3, 12]). On the other hand, the TSPN requires considerable additional effort: even for a given order in which the neighborhoods must be visited, computing a shortest tour is non-trivial. As a consequence, the state of the art until now are provably optimal solutions for benchmark instances up to just 16 regions [29]; see Figure 2 (Left) for an example instance. While hardware and solvers have improved significantly since its publication 13 years ago, solving the problem as a MIQCP with Gurobi on modern hardware did not significantly change the results (see Section 4.6 for details).

Another key difference between discrete TSP in a graph and continuous TSPN in geometry arises from accuracy and error bounds: For a given graph with integer edge weights, verifying that a given bound is met is straightforward; however, in a geometric setting with algebraic complications arising from Euclidean distances and floating-point arithmetic, that is far from clear. The well-known TSPLIB instances [41] use distances rounded to the nearest integers, while even LP solvers such as CPLEX [33] and Gurobi [31] operate with an *optimality tolerance*: The final result is within a given small tolerance of the provable optimum.

Contributions. We present a branch-and-bound algorithm that combines the search for an optimal order for a given set of neighborhoods with Second-Order Cone Programs (SOCP) for computing the best tour for any given sequence of neighborhoods. This significantly

expands the range of instances that can be solved to within an optimality tolerance of 0.1%; note that even the default tolerance of Gurobi is already 0.1‰. Across 490 diverse benchmark instances with up to 50 polygons each, 99.6 % are solved to optimality within a time limit of 300 s, with the remaining two instances solved within 595 s. For 68 larger instances of size $n = 60$, our method still allows solving 86.8 % of instances within 900 s, leaving only 3 of the instances with optimality gaps above 3 %, with the maximum being 5.53 %. Note that $16! \approx 2 \cdot 10^{13}$, while $50! \approx 3 \cdot 10^{64}$ and $60! \approx 8 \cdot 10^{81}$. What is more, we achieve this for non-convex neighborhoods of different sizes, including neighborhoods with holes and even disconnected regions. See Figure 2 for a comparison with the previous state of the art. We also evaluate the impact of various algorithmic design choices, along with geometry-based filters, providing perspectives for even larger instances.

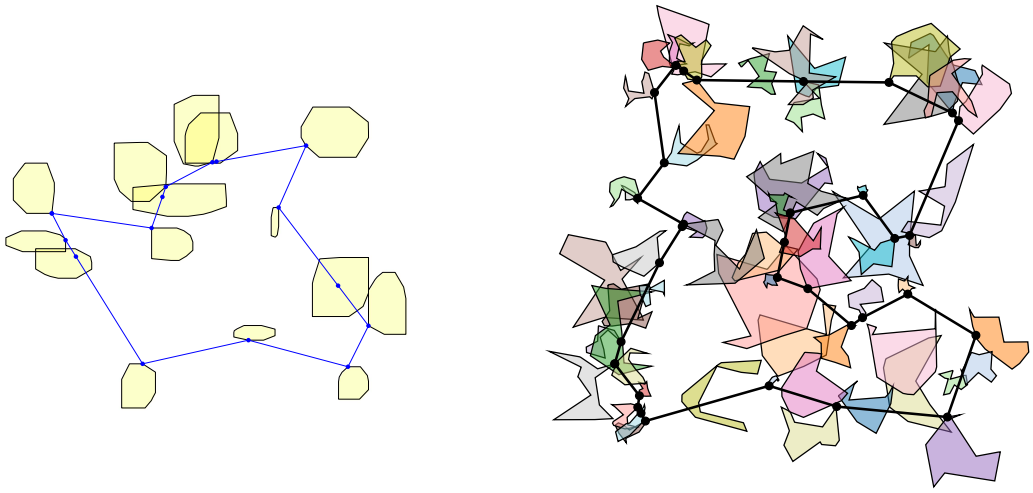

Figure 2 (Left) Previous state of the art [29]: optimal solution for $n = 15$ fat convex regions. (Right) This paper: optimal solution for $n = 60$ non-convex regions of various aspect ratios.

Related Work. A special case of TSPN is the Close-Enough TSP (CE-TSP), where each neighborhood is a circle, which is also related to the Lawn Mowing Problem [4, 5, 26, 27]. Branch-and-bound algorithms have been studied for CE-TSP [19, 13] (possibly with obstacles [15]); however, the TSPN allows arbitrary (including non-convex) neighborhoods, making it more general. A common approach to such problems is to discretize neighborhoods into representative points and solve a Generalized TSP (GTSP) [36], e.g. by a heuristic [32, 42] or an exact method [9, 16]. Advancements in machine learning have also led to unsupervised learning methods for CE-TSP [25, 24]. Many heuristics and approximation algorithms for the TSPN rely on assumptions (e.g., fatness [39, 23], disjoint neighborhoods [14], or comparable region diameters [21]) to manage its APX-hardness. Recently, Antoniadis et al. [2] developed an FPTAS for minimum-perimeter convex polygon intersecting a set of convex objects. Specialized approaches address specific settings such as aerial vehicle routing [34], and hybrid methods combine meta-heuristics with TSP solvers [45]. Non-convex Mixed Integer Nonlinear Programming (MINLP) formulations have been proposed for TSPN, including symmetric and asymmetric variants [29], with algorithmic improvements to reduce solution times. However, computational tests were limited to smaller or convex neighborhoods. Other work derives approximations and bounds for the metric TSPN using the MST with Neighborhoods [11].

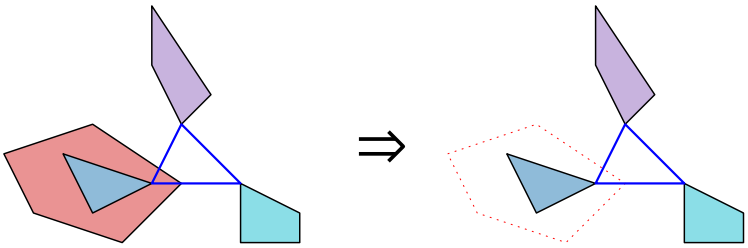

Figure 3 Example of *superset elimination*: a polygon fully contained in another.

Preliminaries. We are given a set of n polygons $\mathcal{P} = \{P_1, \ldots, P_n\}$ in the plane. Polygons may be non-convex and may contain holes. A *tour* is a closed curve in the plane that intersects each polygon $P_i \in \mathcal{P}$ at least once. Without loss of generality, we may assume that an optimal tour is a polygonal cycle visiting one *hitting point* $h(P_i) \in P_i$ for each polygon $P_i \in \mathcal{P}$, connected by straight-line segments. We represent a tour T by the ordered sequence of its hitting points, $(h(P_{\pi(1)}), \ldots, h(P_{\pi(n)}))$, where π is a permutation of $[n]$ and $h(P_{\pi(i)}) \in P_{\pi(i)}$ for all i. The length of T is the sum of the Euclidean distances between consecutive hitting points, including the distance between the last and the first hitting point. Overall, the goal is to find a feasible tour of minimum total length. By triangle inequality, optimal tours cannot self-intersect, so this is a simple polygon of minimum perimeter that intersects all $P_i \in \mathcal{P}$.

2 Preprocessing

Preprocessing is a crucial step in most practical optimization algorithms, as it can significantly reduce the search space and improve algorithmic efficiency. See the literature on MIP presolve [1] and SAT preprocessing [7] for more details on the extensive use of preprocessing in combinatorial optimization. We also investigated and implemented several preprocessing techniques for TSPN instances that either eliminate polygons entirely when any tour that visits the remaining polygons will necessarily cover them, simplify polygons by cutting off unnecessary parts or replacing them with simpler shapes, or add annotations that guide the branch-and-bound algorithm. We first describe basic geometric simplification rules in Section 2.1 and then discuss order annotations in Section 2.2.

2.1 Basic Simplification

We iteratively apply the following three simplification rules until no further reduction is possible. In practice, these rules eliminate nearly all holes and many large polygons.

▶ **Theorem 1** (Superset elimination). *Let $\mathcal{P}$ be a set of polygons in a TSPN instance. If a polygon $P \in \mathcal{P}$ is fully contained in another polygon $P' \in \mathcal{P}$ (see Figure 3), then P' can be safely removed without affecting the optimal tour.*

Proof. Any tour that visits P necessarily intersects P', since P' completely contains P. ◀

▶ **Theorem 2** (Hole removal). *Let $\mathcal{P}$ be a set of polygons for a TSPN instance. Suppose a polygon $P \in \mathcal{P}$ contains a hole h, and there exists a polygon $P' \in \mathcal{P}$ lying entirely outside h (see Figure 4). Then the hole h can be removed from P without affecting the optimal tour.*

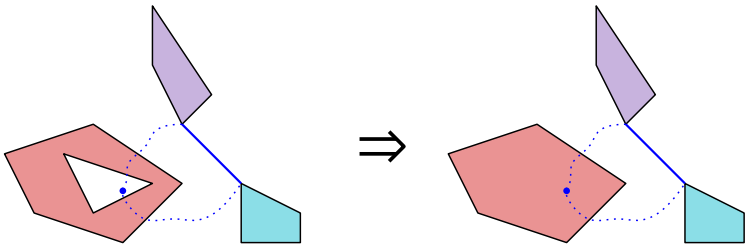

Figure 4 Example of *hole removal*: the hole can be discarded when another polygon lies outside of it. If we were to visit it, we would already intersect the polygon containing it.

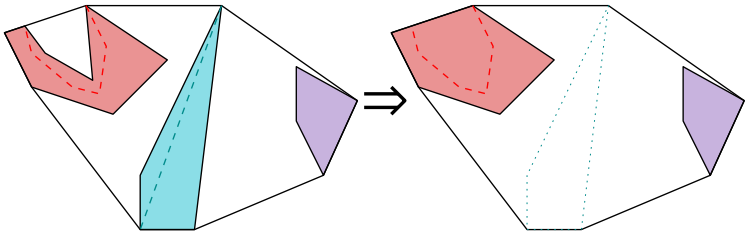

Figure 5 Example of *pocket removal*: of the red polygon, we can remove the pocket, and the blue polygon, we can remove entirely.

Proof. Any tour visiting P' must pass through P, since P' lies outside the hole. If the tour enters the hole h, it already intersects P on the way to or from P'. Thus coverage of h guarantees coverage of P, and the hole does not impose any additional constraint. ◀

▶ **Theorem 3** (Pocket removal). *Let B be a convex closed curve containing an optimal TSPN tour for an instance $\mathcal{P}$, e.g., the convex hull of $\mathcal{P}$. Suppose that a polygon $P \in \mathcal{P}$ contains a path with both endpoints on B, fully lying inside P. This path, together with the arc of B between its endpoints, forms a closed curve that encloses a region (the* pocket*). If at least one polygon of $\mathcal{P}$ lies fully outside the enclosed area, then the enclosed region may be added to P, i.e., the pocket can be removed, without affecting the optimal tour. Furthermore, if also the enclosed region fully contains a polygon from $\mathcal{P}$, then P itself can be safely removed.*

Proof. A tour entering the enclosed region must cross the enclosing path. As the tour must also visit polygons outside the enclosed region, it must cross this path again when leaving. Each crossing intersects P, so P is inevitably covered. If the enclosed region also contains polygons from $\mathcal{P}$, the tour must enter and leave the region, crossing the path at least twice. Thus, removing the pocket preserves feasibility, and P becomes redundant. ◀

Note that the second case of Theorem 3 is automatically handled by Theorem 1 once the pocket has been removed from the polygon, because the enclosed polygon will be fully contained in the modified polygon. If B is not the convex hull, we may first intersect all polygons with B. This ensures that pockets adjacent to B are also removed consistently and that the simplification rules behave exactly as in the convex-hull case.

2.2 Order Annotations

Our algorithm suffers from a large branching factor, as it considers every possible ordering of input polygons. Fortunately, geometric properties of optimal tours let us prune many insertion choices, in particular for polygons that intersect the boundary of a tour-enclosing

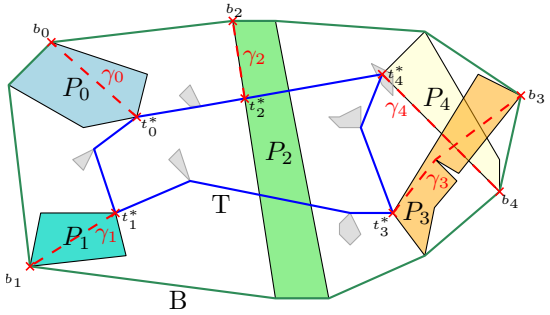

Figure 6 Illustration for b and t^* on B and T. Note that P_3 and P_4 overlap, so we can have $\mathcal{P}'_B = \{P_0, P_1, P_2, P_3\}$ or $\mathcal{P}'_B = \{P_0, P_1, P_2, P_4\}$ as maximal sets. While preprocessing would remove P_2 (via pocket removal and superset elimination, cf. Figure 5), we retain it here to emphasize that Theorem 5 holds independently of preprocessing.

hull B, such as the convex hull of all polygons $\mathcal{P}$. A key property is that an optimal tour must respect the order of the polygons along this hull. Although this is intuitive, complications arise when polygons overlap, because the order is then only partially defined. Let $\sigma_B : [|\mathcal{I}_B|] \to \mathcal{I}_B$ be a cyclic order on a subset $\mathcal{I}_B \subseteq [n]$ of indices. The relation $\circlearrowleft_{\sigma_B}(i,j,k)$ is satisfied if either index is not in $\mathcal{I}_B$ or polygons P_i, P_j, P_k are not pairwise disjoint, or if in the cyclic order of σ_B, index j lies between indices i and k following the fixed orientation of σ_B.

▶ **Definition 4.** *Let $\sigma_B : [|\mathcal{I}_B|] \to \mathcal{I}_B$ be a cyclic order on a subset $\mathcal{I}_B \subseteq [n]$ of indices, then $\circlearrowleft_{\sigma_B}(i,j,k)$ is defined as*

$$\circlearrowleft_{\sigma_B}(i,j,k) = \begin{cases} 1 & \text{if } \{i,j,k\} \nsubseteq \mathcal{I}_B \vee P_i \cap P_j \neq \emptyset \vee P_j \cap P_k \neq \emptyset \vee P_i \cap P_k \neq \emptyset \\ 1 & \text{if } (\sigma_B^{-1}(j) - \sigma_B^{-1}(i)) \bmod |\mathcal{I}_B| \leq (\sigma_B^{-1}(k) - \sigma_B^{-1}(i)) \bmod |\mathcal{I}_B| \\ 0 & \text{otherwise} \end{cases}.$$

▶ **Theorem 5.** *Let B be a simple closed convex curve that contains an optimal TSPN tour for a given instance. Let $\mathcal{I}_B \subseteq [n]$ and $\mathcal{P}_B = \{P_j : j \in \mathcal{I}_B\}$ be the set of polygons intersecting B, and for each polygon fix the reference points $\{b_j \in P_j \cap B \mid j \in \mathcal{I}_B\}$ which define a cyclic order σ_B on $\mathcal{I}_B$ that corresponds to the order of the reference points along B. Then there exists an optimal tour T with visiting order π such that, for every $a < b < c \in [n]$ the order of their hitting points coincides with the order along B, i.e. $\forall a < b < c \in [n] : \circlearrowleft_{\sigma_B}(\pi(a), \pi(b), \pi(c))$.*

Proof. Let T be an optimal tour contained in a simple closed convex curve B. Both T and B are counterclockwise oriented. For each $P_j \in \mathcal{P}_B$ we fix a reference point $b_j \in P_j \cap B$ which is used to define the order σ_B on $\mathcal{I}_B$. As T is feasible it must visit all polygons; for all $j \in \mathcal{I}_B$ we choose the hitting point $t_j^* \in P_j \cap T$ minimizing the geodesic distance in P_j to b_j. Let γ_j be a shortest path in P_j from b_j to t_j^* and denote γ_j^{-1} its reversal. By convexity of B, γ_j meets B only at b_j; by minimality, γ_j meets T only at t_j^*; and since $\gamma_j \subseteq P_j$, it can intersect $\gamma_{j'}$ only if $P_j \cap P_{j'} \neq \emptyset$, see Figure 6.

Let $\phi : [m] \to \mathcal{I}_B$ be an injection with $m \leq n$ that defines an ordered subsequence (induced by σ_B) corresponding to pairwise disjoint polygons, i.e., $\forall i \neq j \in [m] : P_{\phi(i)} \cap P_{\phi(j)} = \emptyset$ and $\forall i < j < k \in [m] : \circlearrowleft_{\sigma_B}(\phi(i), \phi(j), \phi(k))$. We write $[\cdot,\cdot]_B$ for the arc of B, and $[\cdot,\cdot]_T$ for the subpath of T between two points following B's and T's orientation respectively. For each $i \in [m]$ we define the closed curve Γ_i between $b_{\phi(i)}$ and $b_{\phi(i+1)}$ (indices should be seen modulo m) as $\Gamma_i = [b_{\phi(i)}, b_{\phi(i+1)}]_B \cup \gamma_{\phi(i+1)} \cup [t^*_{\phi(i+1)}, t^*_{\phi(i)}]_T^{-1} \cup \gamma_{\phi(i)}^{-1}$, which bounds a simply connected region R_i. Thus, each region boundary is explicitly composed of: (i) the

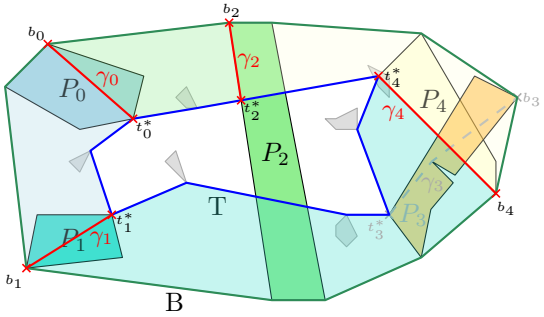

Figure 7 The paths of $\mathcal{P}'_B = \{P_0, P_1, P_2, P_4\}$ tile the area between B and T, forming a cycle of regions and boundaries. We can also see that it is important to select a pairwise disjoint set of polygons, as the crossing paths of P_3 and P_4 would break the argument otherwise. While one can find an alternative b_3 to avoid this, we need to remember that we actually do not know T in advance but provide an argument that works for any T.

arc of B, (ii) the two shortest paths $\gamma_{\phi(i)}, \gamma_{\phi(i+1)}$, and (iii) the corresponding subpath of T. These regions are interior-disjoint and tile exactly the annular portion between B and T, see Figure 7. Each shortest path $\gamma_{\phi(i)}$ with $i \in [m]$ has two incident regions, one on each side which means that the regions form a cycle around T.

Tracing T along the subpaths $[t^*_{\phi(i)}, t^*_{\phi(i+1)}]_T$ implies that T is a concatenation of hitting points that respect $\circlearrowleft_{\sigma_B}(\cdot,\cdot,\cdot)$ for any valid injection ϕ which implies that $\circlearrowleft_{\sigma_B}(\cdot,\cdot,\cdot)$ holds for all triples of pairwise disjoint polygons in $\mathcal{P}_B$. Degenerate contacts between T and B (or degenerate γ_j) can be removed by an infinitesimal perturbation preserving optimality and incidences. Hence, for any $\circlearrowleft_{\sigma_B}$, there exists an optimal tour T for which every triple $P_{\pi(a)}, P_{\pi(b)}, P_{\pi(c)} \in \mathcal{P}_B$ with $a < b < c$ must satisfy $\circlearrowleft_{\sigma_B}(\pi(a), \pi(b), \pi(c))$. ◀

During preprocessing, we annotate each polygon $P_i \in \mathcal{P}_B$ intersecting the convex hull B with its position in the cyclic order σ_B, together with the indices of all polygons $P_j \in \mathcal{P}_B$ that overlap with P_i. This information enables us to select a maximal subset of pairwise disjoint polygons $\mathcal{P}'_B \subseteq \mathcal{P}_B$, which induces a total order that any optimal tour can respect.

3 Branch-and-Bound Algorithm

Our branch-and-bound algorithm (Algorithm 1) explores the space of polygon orderings by incrementally building sequences: starting from a small initial subsequence that is guaranteed to be extendable to an optimal solution (Section 3.2), it repeatedly selects a polygon not yet in the sequence and creates a child node for each possible insertion position, forming a search tree (Section 3.3). For each candidate sequence, a Second-Order Cone Program (SOCP) computes the optimal tour for that ordering (Section 3.1). If this tour visits all polygons, it is a feasible solution (see Figure 8); otherwise, the SOCP provides a lower bound on any tour extending this partial sequence – if it exceeds the best known solution, no completion can improve upon it and the entire subtree is pruned. This builds on the framework of Coutinho et al. [13] for the CE-TSP, which we improve and extend to handle the TSPN.

Throughout the search, the algorithm keeps track of the incumbent (best known feasible) solution and the node with the lowest lower bound, which together define the current optimality gap. As the search tree can grow large, the order in which nodes are evaluated can have significant impact on performance: finding good feasible solutions early strengthens

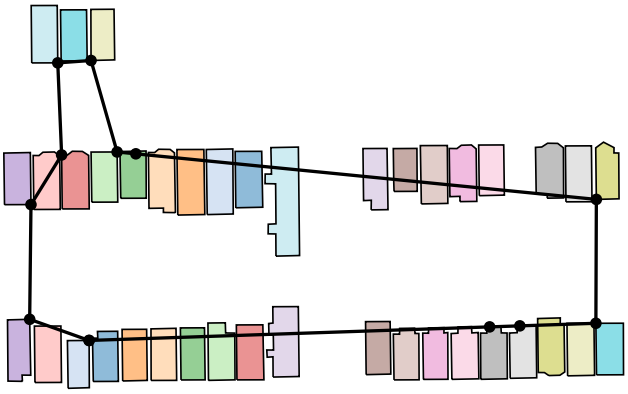

Figure 8 Illustration of implicit coverage in the TSPN. Many polygons will be covered naturally when connecting other polygons, without needing to explicitly model them in the optimization.

pruning, while evaluating nodes with low lower bounds tightens the optimality gap. A search strategy balances these objectives (Section 3.4). Search is terminated if this gap is smaller than a desired threshold, or if all nodes are explored.

3.1 Touring a Sequence of Polygons

By Dror et al. [20], the Touring Polygons Problem (TPP) that asks for the shortest tour visiting a given sequence of polygons can be solved in polynomial time for convex polygons when the visitation order and a start and end point are fixed. The runtime of the algorithm was later improved by Tan and Jiang [43] to $O(k^2m)$ for k convex regions with a total number of m vertices. If the start and end points are not fixed, we can still solve it in polynomial time using a Second-Order Cone Program (SOCP), similar to Coutinho et al. [13].

▶ **Theorem 6.** *Let $P_0, \dots, P_{n-1} \subset \mathbb{R}^2$ be convex polygons. Then the shortest tour visiting these polygons in order can be computed in polynomial time.*

Proof. A convex polygon P_i can be represented by linear constraints $S_i(x, y)$. We formulate the problem as a Second-Order Cone Program (SOCP), which can be solved in polynomial time via interior-point methods [8]. For each i, introduce a point $(x_i, y_i) \in \mathbb{R}^2$ constrained by $S_i(x_i, y_i)$, ensuring $(x_i, y_i) \in P_i$. For readability, all indices are assumed modulo n.

To encode the total tour length, let $d_i \geq 0$ be the distance between (x_i, y_i) and (x_{i+1}, y_{i+1}). We introduce auxiliary variables $\hat{x}_i, \hat{y}_i$ subject to $\hat{x}_i \geq x_i - x_{i+1}$, $\hat{x}_i \geq x_{i+1} - x_i$, $\hat{y}_i \geq y_i - y_{i+1}$, $\hat{y}_i \geq y_{i+1} - y_i$, and impose second-order cone constraints $d_i^2 \geq \hat{x}_i^2 + \hat{y}_i^2$.

All constraints are linear or second-order cone constraints, so the formulation is an SOCP of polynomial size. Therefore, the shortest tour can be computed in polynomial time. ◀

As we ultimately aim to solve TSPN instances with non-convex polygons (and potentially holes if preprocessing does not eliminate them), we must extend the SOCP approach. Dror et al. [20] showed that the problem becomes NP-hard for non-convex polygons, so no polynomial-time algorithm can be expected in general. We propose two strategies, both based on convex decompositions, which partition a non-convex polygon into convex components, see Figure 9.

The first approach is to replace the SOCP by a Mixed-Integer SOCP (MISOCP). For a non-convex polygon P_i', let $\mathcal{R}_i$ be its convex decomposition. Introduce a binary variable $r_c \in \mathbb{B}$ for each convex piece $c \in \mathcal{R}_i$ and enforce $\sum_{c \in \mathcal{R}_i} r_c = 1$. Let $S_i^c(x, y)$ be the linear constraints

defining ∂c. To ensure $(x, y) \in P'_i$, impose the implications $r_c = 1 \Rightarrow S^c_i(x, y) \quad \forall c \in \mathcal{R}_i$. These implications can be modeled using indicator constraints (when supported) or with Big-M formulations, where M can be bounded using the polygon's bounding box. Both indicator and Big-M constraints tend to produce weak relaxations for the MISOCP solver, which provides limited guidance to its internal branch-and-bound. To improve the relaxation, one may additionally include the convex-hull constraints $S_i(x, y)$ of P'_i, which are redundant but can strengthen the continuous relaxation.

The second approach retains the efficient SOCP formulation and incorporates convex decomposition only through branching. Instead of encoding the convex components by binary variables, the branch-and-bound tree explicitly chooses which convex part of a non-convex polygon the tour must hit. This extends the branching decision from the visitation order

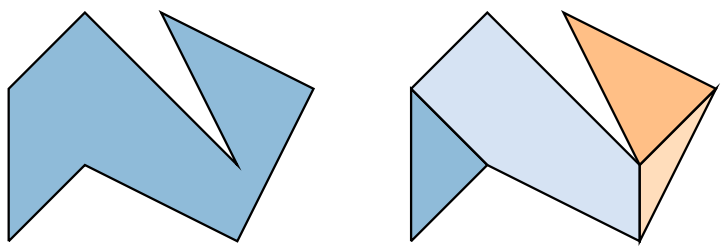

Figure 9 A non-convex polygon (left) and its decomposition in convex areas (right).

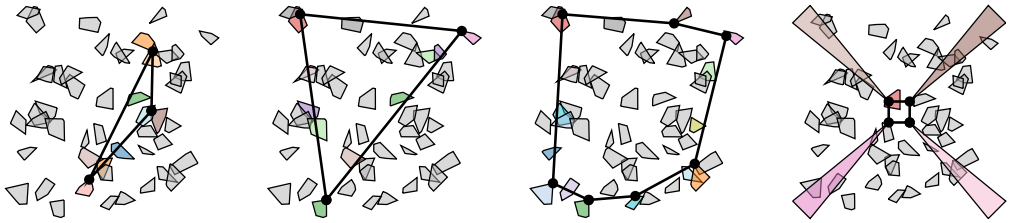

Figure 10 Root node strategies (left to right): Random, LEFP, CHR, and an example demonstrating poor CHR performance.

to the choice of the convex component, while avoiding indicator and Big-M constraints entirely. As a result, this approach avoids the weak relaxations that appear in the MISOCP formulation, although it may increase the size of the search tree.

For polygons without holes, a minimum convex decomposition can be computed in polynomial time [30, 10]. For polygons with holes, a decomposition is always possible, for example by triangulation, but finding a minimal decomposition is NP-hard [37]. In practice, our preprocessing eliminates all holes from the benchmark instances, so the NP-hard minimal decomposition is not needed. The theoretical caveat remains for degenerate instances where hole removal cannot apply, e.g., when every other polygon lies inside the hole.

Finally, any non-convex polygon can either weaken the relaxation in the MISOCP approach or introduce substantial branching overhead. However, in optimal tours we often observe that visitation points of spanning polygons, meaning those not implicitly covered by connections between other polygons, tend to lie on extreme points, that is, on the convex hull of the polygon. This motivates a lazy strategy in which every polygon is initially replaced by its convex hull, making all polygons appear convex in the relaxation. Only when a computed visitation point lies outside the true polygon do we enforce its full non-convex geometry.

3.2 Root Node

The root node's initial polygon sequence must be extendable to an optimal solution. Any sequence of up to three polygons trivially satisfies this condition. We evaluate four strategies: **Random** selects three polygons at random. **Longest Edge (LE)** selects the two polygons with largest pairwise distance. **Longest Edge+Farthest Polygon (LEFP)** extends LE by adding the polygon farthest from both. **Convex Hull (CHR)** selects polygons based on their convex hull positions.

Using the observations from Section 2.2, we can construct larger initial sequences: for any set of pairwise disjoint polygons intersecting the convex hull, σ_B defines a total order that an optimal solution can respect. Finding a cardinality-maximal set of such polygons is an instance of the NP-hard *maximum independent set* problem, but optimality is not required here; a greedy heuristic yields a sufficiently large set in practice. This preserves completeness while often producing significantly stronger initial relaxations. Although it is possible to construct artificial instances where this strategy produces arbitrarily weak relaxations, for example by placing polygons on the convex hull that protrude far inward and thereby induce an initial tour of negligible length, such instances appear to be rare in practice. Figure 10 illustrates three of the strategies, including an example where CHR performs poorly.

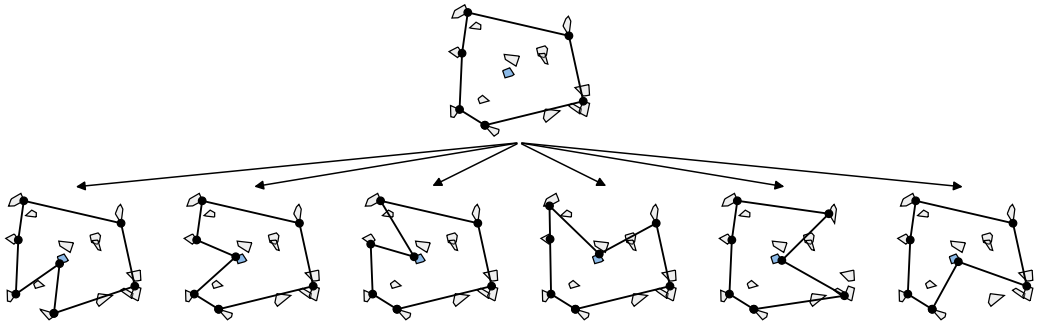

Figure 11 Branching on the insertion position of the selected farthest polygon.

3.3 Branching

When the (partial) tour in a node does not cover all polygons, we branch by selecting a missing polygon and creating a new branch for each possible insertion position. In our implementation, we select the polygon that lies farthest from the current tour, see Figure 11.

We consider three modeling strategies for handling non-convex polygons. **Eager indicator-based modeling (EIM)** models non-convex polygons explicitly using indicator variables in a MISOCP formulation. Because convex hulls often contain the extremal points that serve as optimal hitting points, we propose a lazy strategy that initially replaces each polygon by its convex hull and only models it as non-convex when necessary. Both of the following strategies employ this lazy approach. **Indicator-based modeling (IM)** uses the same indicator-variable formulation as EIM but only introduces it when the convex hull replacement is insufficient. **Decomposition branching (DB)** avoids indicator variables entirely by decomposing the polygon into convex parts and creating one branch per part, see Figure 12.

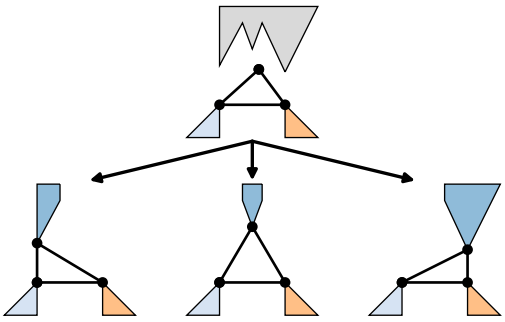

Figure 12 Branching on a non-convex polygon by decomposing it into convex pieces.

3.4 Search Strategies

We implement four strategies to select the next node for exploration during the search.

Best First Search (BFS) selects the node with the smallest lower bound, improving the global bound quickly. However, incomplete sequences tend to have shorter estimated lengths, so BFS often prioritizes them over full coverage. **Depth First Search (DFS)** continues

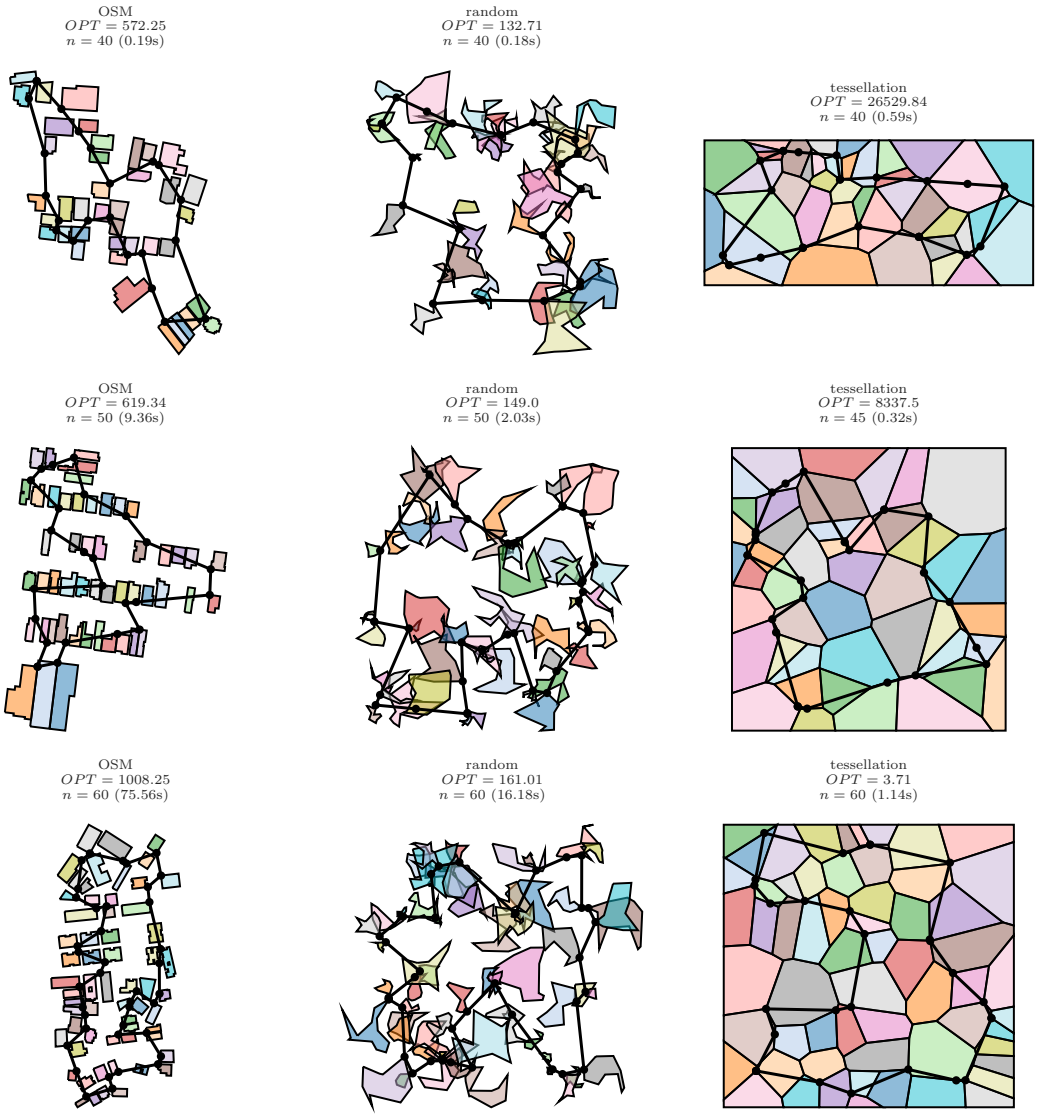

Figure 13 Example solutions within 0.1 % of optimality for instances of size $n \in \{40, 50, 60\}$.

exploring the most promising child, quickly reaching feasible solutions. Good incumbents strengthen pruning, though DFS largely ignores lower bounds. **DFS+BFS** behaves like DFS, but reorders the queue by lower bounds whenever a node is pruned or a new solution is found, combining rapid incumbent improvements with lower-bound tightening.

4 Empirical evaluation

Our algorithm is implemented in C++ and uses Gurobi 12.0 [31] to solve the SOCP and MISOCP formulations. Geometry operations rely on Boost.Geometry 1.83 [28] and CGAL 6.0.1 [44] with exact predicates and constructions. We compiled using g++ 13.3 and ran all experiments on an AMD Ryzen 7900 workstation with 96 GiB of DDR5-5200 RAM under Ubuntu 24.04. We use the term *optimality gap* to refer to the relative difference between the best known upper bound and the global lower bound, i.e., $^{ub}/_{lb} - 1$. The optimality tolerance is the maximum allowed optimality gap after which the algorithm can terminate.

4.1 Research questions

Our experimental evaluation aims to answer the following questions.

Q1 How does the choice of root node sequence affect runtime across instance types?

Q2 Which search strategy (DFS, BFS, or a combined DFS+BFS) offers the best trade-off between time-to-solution and bound improvement?

Q3 For non-convex polygons, does decomposition branching outperform indicator-based modeling in practice with respect to runtime and relaxation quality?

Q4 How does relaxing the optimality tolerance affect the performance and how does our approach scale with increasing instance sizes?

4.2 Experiment design

To answer our questions, we collected and generated a large set of 558 instances, consisting of instances from the following instance classes. In all cases, the coordinates of points in the instances are either integers or double precision floating-point numbers.

random We generated 20 random instances with $n \in \{5, 10, 15, 20, 30, 40, 50, 60\}$ random polygons with roughly 45 % concave points and between 10 and 15 edges. Polygons may overlap and may have holes. This resulted in 160 random instances.

tessellation Instances derived from well-known publicly available benchmark instance sets. To obtain polygonal regions, we applied a Voronoi tessellation to point sets from various sources. These include point sets previously used in the CG:SHOP challenges [18, 17], TSPLIB instances [41], and point sets from the Salzburg Database of Polygonal Inputs [22]. In total we generated 78 instances with $n \leq 60$ polygons.

OSM Instances derived from *Open Street Map* (OSM) data [40]. Our dataset covers building footprints from 20 major cities. We used a quadtree-like subdivision to achieve desired sizes of $n \in \{5, 10, 15, 20, 30, 40, 50, 60\}$ and then randomly sampled two instances from each city in our collection. This resulted in a total of 320 instances.

All instances were preprocessed with the techniques from Section 2, resulting in 360 (out of 558) altered instances with no holes. This took 0.01 s on average, with a maximum of 0.06 s. The resulting instances show reduced complexity. In particular, the number of convex pieces (i.e., the number of convex components in an optimal convex decomposition) decreased by an average of 2.9 per instance. Example instances and their optimal solutions can be found in Figure 13. Unless stated otherwise, all experiments use the full set of 558 instances.

4.3 RQ1: Root node selection

The choice of the root node sequence can significantly influence the search performance. A larger root sequence yields a tighter initial lower bound and fixes the relative order of more polygons. However, it may include polygons that would otherwise be implicitly covered by the tour (see Figure 8), unnecessarily enlarging the explicit sequence and increasing both the branching factor and the SOCP size at every node. We compared four strategies for selecting the root node sequence with a time limit of 60 s and 1 % optimality tolerance. CHR selects polygons based on the convex hull order, LE selects two polygons that are farthest apart, LEFP extends LE by adding a third polygon that maximizes the distance to the first two, and Random selects a random sequence, see Section 3.2 for details. Figure 14 shows the number of instances and the optimality gaps after 60 s. Overall, using a CHR and LEFP strategy appear to be best across our benchmarks with solutions within 1 % tolerance found

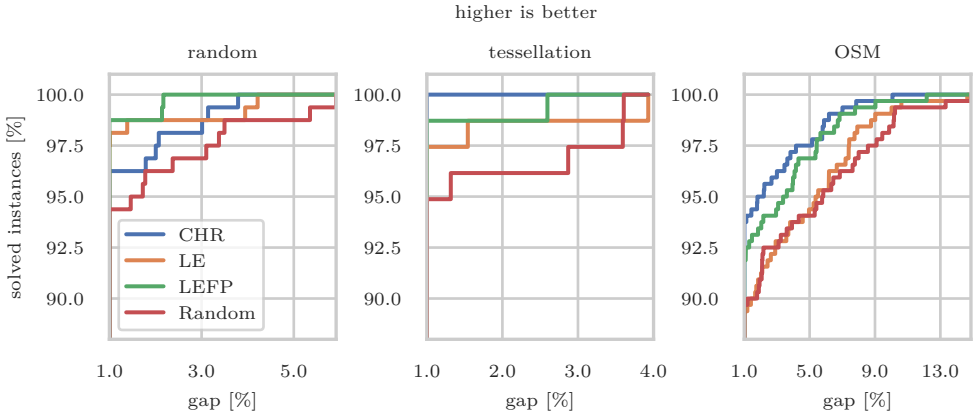

Figure 14 Gaps for different root node strategies after 60 s with 1 % optimality tolerance, separated by instance type. CHR and LEFP outperform the others, with CHR strongest on OSM and tessellation instances and LEFP more robust on random instances.

in 95.16 % and 94.80 % of the instances, respectively. LEFP was more robust for instances that contain many intersections (such as our random instances), while CHR performed best on average for the OSM and tessellation instances which have many polygons on their convex hull. LE performed reasonably well but suffers from bad initial lower bounds. Random root selection is not recommended due to high variance and inferior median performance.

4.4 RQ2: Search strategy

The choice of search strategy affects how quickly solutions are found and how fast the global lower bound improves. We compared the three strategies from Section 3.4 – DFS, BFS, and combined DFS+BFS – with a time limit of 60 s for optimality tolerances of 1 % and 5 %. The outcomes are shown in Figure 15. We observe that for 5 % optimality tolerance, DFS and DFS+BFS have similar performance with about 98 % of the instances solved to optimality, while DFS+BFS is the winner for smaller tolerances with about 95 % of the instances solved to 1 % optimality. DFS achieves the fastest time-to-first-solution in most instances, while BFS improves the global lower bound more quickly. The combined DFS+BFS provides a good trade-off, particularly when slightly relaxed optimality tolerances are acceptable (it often terminates quickly for moderate gaps). For the remainder of our experiments, we use the DFS+BFS strategy as it provides the best overall performance.

4.5 RQ3: Decomposition branching

We evaluate the performance of the three modeling strategies for non-convex polygons introduced in Section 3.3. IM represents non-convex regions using indicator variables, which can result in long solve times at individual nodes. In contrast, DB avoids indicator variables but increases the size of the search tree, potentially leading to more branching. In both DB and IM, each polygon is initially replaced by its convex hull and only treated as non-convex when necessary. EIM does not employ this lazy strategy and models all non-convex polygons explicitly from the outset. We compared all approaches with a time limit of 60 s and an optimality tolerance of 1 %, excluding the purely convex instances (480 instances remaining). The results are shown in Figure 16. DB and IM exhibit very similar performance. While DB is slightly faster on some instances, it solves fewer instances to within 1 % optimality within

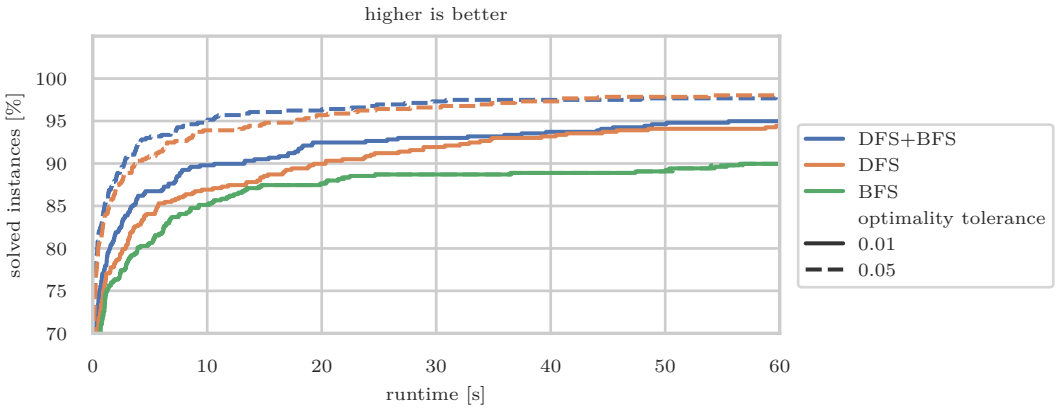

Figure 15 Instances solved within 60 s for different search strategies with 1 % and 5 % optimality tolerance. DFS+BFS offers the best trade-off between fast solutions (DFS) and rapid lower-bound improvement (BFS).

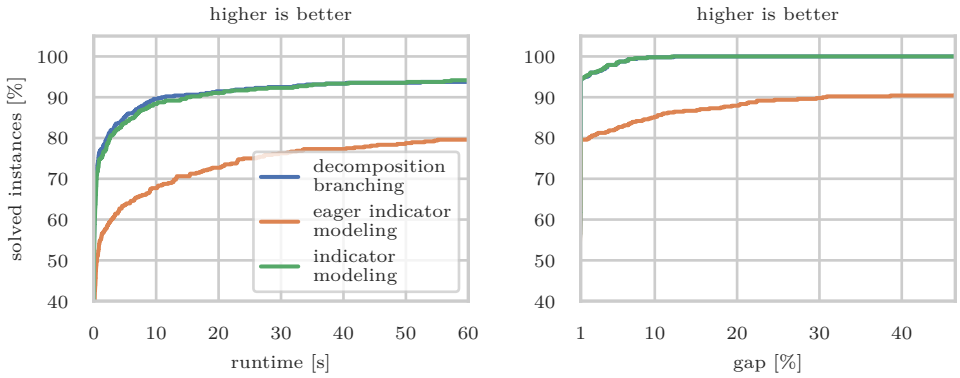

Figure 16 (Left) Runtime for solving instances with decomposition branching as well as eager and non-eager indicator-based modeling within a time limit of 60 s and 1 % optimality tolerance. (Right) Optimality gaps for the remaining instances. Decomposition branching has a slightly better performance than indicator-based modeling, and eager indicator-based modeling performs worse.

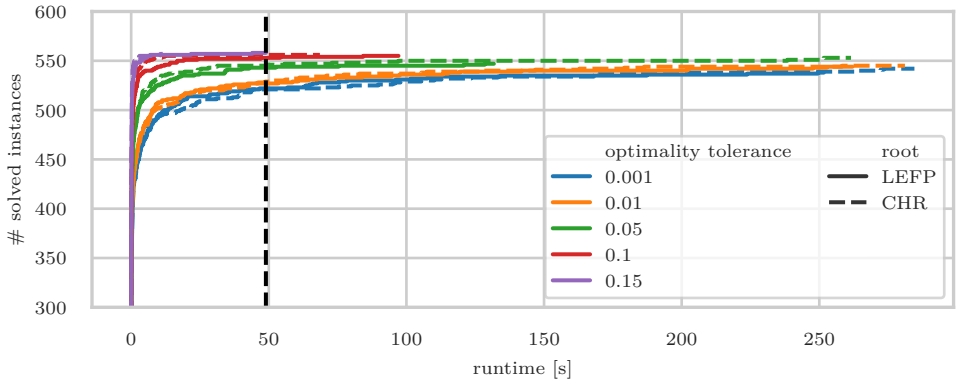

Figure 17 Number of instances solved within a given optimality tolerance within a given time. Wider gaps of 5 % to 15 % substantially reduce computation time, while for smaller gaps of 0.1 %, not all instances could be solved within the time limit.

the time limit (93.75 % for DB vs. 94.17 % for IM). In contrast, EIM performs substantially worse, solving only 79.58 % of instances within the time limit. Overall, these results support the use of the lazy initialization strategy for non-convex polygons. Because DB and IM perform similarly but DB avoids the need for indicator variables, we adopt decomposition branching as our default approach for the remainder of the experiments.

4.6 RQ4: Scalability with optimality tolerance

Relaxing the optimality tolerance is often acceptable in practical applications and can significantly reduce computation time in exact optimization. Gentilini et al. [29] reported optimal solutions for up to 16 convex regions which impose less complexity than our general polygonal regions. We evaluated the performance of both the CHR and LEFP root node strategies with DFS+BFS search for optimality tolerances of 0.1 %, 1 %, 5 %, 10 %, and 15 % with a time limit of 300 s. This instance set comprises 558 instances with sizes ranging from $n = 5$ to $n = 60$ polygons of varying complexity. The number of solved instances after a given time is shown in Figure 17. We observe negligible differences between 0.1 % and 1 %, whereas tolerating 5 %, 10 % or 15 % often yields large savings in solve time and increases the number of instances solved. For 0.1 % tolerance, runs using the CHR root node strategy yielded the best results with 97.13 % of all instances solved to optimality in less than 300 s. The instances not solved to optimality had either $n = 50$ or $n = 60$ polygons. More precisely, for $n = 50$, only 2 out of 65 instances were not solved to optimality within the time limit, with a maximum optimality gap of 0.83 %. Both instances can however be solved to the desired tolerance within 595 s and 368 s, respectively. The remaining 14 unsolved instances of size 60 all had gaps within 7 %. A subsequent run with a time limit of 900 s solved 5 additional instances to 0.1 % optimality, leaving 9 instances unsolved with a maximum gap of 5.53 %. This amounts to a total of 98.39 % of all instances solved to optimality within 900 s. Relaxing the requirements for an optimal solution to 15 % allows the LEFP strategy to solve all instances within less than 50 s.

Comparison to previous work. Prior to our geometric branch-and-bound approach, TSPN was commonly modeled as a MINLP and solved using general-purpose MINLP solvers. In these formulations, subtour elimination constraints are typically enforced through a cutting-plane framework where a relaxation of the problem is solved, subtours are detected for example via max-flow separation, and violated constraints are added as they are identified.

A representative example of this line of work is the method of Gentilini et al. [29]. Their approach integrates COUENNE, Ipopt, and CPLEX, and incorporates TSPN-specific strengthening techniques within COUENNE. Nevertheless, the method remains fundamentally based on the classical MINLP formulation and therefore inherits its high-dimensional spatial branching behavior. Empirical results reported in their study indicate practical tractability primarily for relatively small instances, typically with $n \leq 30$ within a few percent optimality gap, but on older hardware and with less efficient solvers than those available today.[1]

Our approach differs both conceptually and algorithmically. Instead of branching in the high-dimensional MINLP formulation, we perform branch-and-bound directly in the underlying planar geometry. Node relaxations are solved as SOCPs, allowing the algorithm to exploit the polynomial-time solvability of convex subproblems. This design shifts the computational effort from generic nonlinear spatial branching toward geometry-aware decisions.

4.7 Threats to Validity

All solutions were validated, and a set of unit tests ensured correctness of core components. Results were checked for consistency between objective values and lower bounds across different runs. Feasibility of the resulting tours was independently verified after the optimization. However, as with any empirical evaluation, there are threats to validity. Implementation bugs may affect results, though we took care to minimize this risk through testing and validation. The choice of Gurobi as the underlying SOCP solver may influence performance; different solvers could yield varying results. Due to the nature of these solvers, all computations were performed using floating-point arithmetic, which may introduce numerical inaccuracies. Finally, the selected instance sets, while diverse, may not cover all possible scenarios encountered in practice.

5 Conclusion and Future Work

We presented significant practical progress for the TSPN with arbitrary neighborhoods of differing sizes, not only picking the best out of $n!$ permutations, but also computing the best tour for a given order of regions; even for k convex regions with m vertices and given start and end point, the fastest known algorithm for this task requires a time of $O(k^2m)$ [43].

At this point, we are able to solve all instances in our benchmark set of size up to $n = 50$ to within 0.1 % of optimality within reasonable time, and 86.8 % of the larger instances of size $n = 60$, with small optimality gap for the remaining ones. With our current techniques, this size appears to be the threshold between manageable and intractable instances without resorting to runtimes in the order of hours.

This raises the question of how to extend this range by employing more advanced geometric ideas. We are optimistic that further progress is possible, e.g., by using enhanced pruning strategies and additional cuts during the branch-and-bound, making use of further theoretical insights into the structure of locally optimal trajectories.

[1] We note that a similar MIQCP-based approach was implemented by the authors in preliminary experiments which did not yield competitive results and can be found along with the source code.

Computing the Skyscraper Invariant

Abstract

We develop the first algorithms for computing the Skyscraper Invariant [FJNT24]. This is a filtration of the classical rank invariant for multiparameter persistence modules defined by the Harder-Narasimhan filtrations along every central charge supported at a single parameter value.

Cheng's algorithm [Cheng24] can be used to compute HN filtrations of arbitrary acyclic quiver representations in polynomial time in the total dimension, but in practice, the large dimension of persistence modules makes this direct approach infeasible. We show that by exploiting the additivity of the HN filtration and the special central charges, one can get away with a brute-force approach. For d-parameter modules, this produces an FPT ε-approximate algorithm with runtime dominated by $\mathcal{O}(1/\varepsilon^d \cdot T_{\text{DEC}})$, where T_{DEC} is the time for decomposition, which we compute with AIDA [DJK25].

We show that the wall-and-chamber structure of the module can be computed via lower envelopes of degree $d-1$ polynomials. This allows for an exact computation of the Skyscraper Invariant roughly in $\mathcal{O}(n^d \cdot T_{\text{DEC}})$ time for n the size of the presentation and enables a fast hybrid algorithm.

For 2-parameter modules, we have implemented not only our algorithms but also, for the first time, Cheng's algorithm. We compare all algorithms and, as a proof of concept for data analysis, compute a filtered version of the Multiparameter Landscape for biomedical data.

Introduction. Multiparameter Persistence Modules (MPM) provide a way to capture topological features of multifiltered data. Unlike the one parameter case, the decomposition of an MPM is, in general, neither easy to interpret nor robust to noise [4]. To use MPM in practice, one needs invariants that are informative, stable, computable, and easy either to

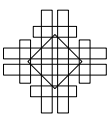

Figure 1 View from Empire State Building, Gotscho-Schleisner, 1932.

interpret or to integrate into a statistical or Machine Learning pipeline. A first example is given by the *rank invariant* [11, 12] and its vectorisations [16, 60], which have been used for applications in biology [61, 6]. In [27, 26] Fersztand, Jacquard, Tillmann, and Nanda introduced the *Skyscraper Invariant* (Figure 1), a *filtration* of the rank invariant.

Given a d-parameter module V, $\theta \in \mathbb{R}_+$ and parameters $\alpha \leq \beta \in \mathbb{R}^d$, the value $s_V^\theta(\alpha, \beta)$ of the skyscraper invariant is the rank of the structure map $V_\alpha \to V_\beta$ after – informally – restricting it to elements that persist over a parameter region whose volume is at most $1/\theta$. It is defined by the *Harder-Narasimhan* filtration for a central charge concentrated at α. It is strictly stronger than the rank invariant, carries a more discriminating erosion-distance [26], and induces filtrations of all the aforementioned vectorisations of the rank invariant. To compute an ε-approximation of the Skyscraper Invariant, we need to compute the HN filtration at each α on an ε-grid in the parameter space.

Contributions. In Section 1, we give an elementary introduction to Harder-Narasimhan (HN) filtrations and a post-hoc motivation for their utility in Persistence Theory.

For quiver representations, computing HN filtrations was recently made possible in polynomial time via Cheng's algorithm [15], described in Section 4. We present the first implementation of Cheng's algorithm using the random method introduced in [30] to compute shrunk subspaces.

The obtained algorithm computes with high probability the Skyscraper Invariant in $\mathcal{O}(\mathfrak{t}(V)^{19}\varepsilon^{-11d})$ time, up to poly-logarithmic factors, where $\mathfrak{t}(V)$, the *thickness* of V, is the maximal pointwise dimension. We optimized Cheng's algorithm to our setting, leading in Proposition 23 to an improvement of a factor $\mathfrak{t}(V)^2\varepsilon^{-2d}$ compared to the general version of the algorithm (Corollary 22). Building on ideas from [35], we propose and implement further optimisations that yield considerable empirical speed-ups.

A priori, this method is generally not directly applicable to the large data considered in TDA applications. In Section 2 we introduce a strategy which significantly cuts the computation time of the Skyscraper Invariant: Algorithm 2 reduces the computation of the HN filtration at $\alpha \in \mathbb{R}$ to *indecomposable* submodules *uniquely generated* at α. It blends the

decomposition algorithm AIDA and kernel computation with MPFREE[1].

Unfortunately, even when restricted to these small submodules, Cheng's algorithm in this form turns out to be too slow, which we prove experimentally in Table 2. Let $k \coloneqq \max_{W \subset V} \mathfrak{t}(W)$ be the maximal thickness of an indecomposable, uniquely generated submodule. We observed that for modules generated by the Persistent Homology of many typical bifiltrations, k is always 1 when the underlying point set is 2-dimensional (Conjecture 10). Otherwise, k is rarely larger than 3.

This low dimensionality enables the computation of the HN filtration with a brute-force method, which we describe and improve in Section 3. Together with Algorithm 2, this leads to an exhaustive search algorithm to compute the Skyscraper Invariant up to an ε error. Its runtime is fixed-parameter tractable (FPT) in k: $\mathcal{O}\left(1/\varepsilon^d \left(T_{\text{DEC}}(V) + \mathfrak{t}(V) 2^{k^2+\mathcal{O}(k)}\right)\right)$, where T_{DEC} is the time needed for decomposition.

The bottleneck of this computation is the iteration over all α in an ε-grid, resulting in the $1/\varepsilon^d$-factor in the computation time. To avoid this, we investigate, in Section 5, how the HN filtration at $\alpha \in \mathbb{R}^d$ changes when α varies. We define an equivalence relation $\sim_{\text{HN}(V)}$ on $\mathbb{R}^d$ by requiring the HN filtrations of V at two equivalent degrees to differ only by an update of the degrees of the generators and relations of their factors [28, Definition 6.13].

▶ **Theorem 1.** *Let V be f.p., have bounded support, and let $\bigcup_{j \in J} C_j$ be the tiling of $\mathbb{R}^d$ induced by the Betti-numbers of V. The partition induced by $\sim_{HN(V)}$ on every C_j is given by the minimisation diagram of a finite set of multilinear polynomials of degree $d-1$.*

This partition is a slice of the *wall-and-chambers* structure (e.g. [32]).

For 2-parameter modules, the equivalence classes are convex polygons and easy to compute using Algorithm 5. The full procedure, [28, Algorithm 7], creates a data structure from which the value of the Skyscraper Invariant can be queried in average time $\log(n) + \mathfrak{t}(V) \log \mathfrak{t}(V)$, where n is the number of generators and relations of a minimal presentation of V.

Our final algorithm, the *parallel grid scan*, blends this exact computation with the approximation to avoid the $(1/\varepsilon^d)$-bottleneck (Figure 13). We have implemented it and use it to demonstrate the applicability of the Skyscraper Invariant in data analysis by computing filtered Multiparameter Landscapes for biological data from [61].

Related Work. Many informative invariants of MPM have been proposed in the literature, including, among others, [9, 8, 41, 48, 53, 2], and for some, there are also implemented algorithms [21, 60, 16, 13, 47, 45, 62]. All of these are either not stronger than the rank invariant, not (yet) practically computable for large modules, or unstable in interleaving distance, demonstrating the advantage of our work. The idea of computing filtrations has also appeared in [7, 52]. An algorithm for the Skyscraper Invariant has been implemented in the special case of ladder persistence modules [37]. The computation of HN filtrations of quiver representations is an active topic in complexity theory [35, 30].

1 The Skyscraper Invariant for Multiparameter Persistence Modules

Multiparameter Persistence. Topological Data Analysis seeks to compute topological invariants from geometric data. In a typical setting, one constructs a simplicial complex X filtered by a map $f\colon X \to \mathbb{R}^d$. The sublevel sets $X_{\leq \alpha} \coloneqq \{x \in X \mid f(x) \leq \alpha\}$ assemble to a

[1] `https://github.com/JanJend/AIDA`, `https://bitbucket.org/mkerber/mpfree/`

functor $X_{\leq \bullet}\colon \mathbb{R}^d \to \mathbf{SCpx}$ via inclusion. Composition with homology $\mathbf{H}_*(-;\mathbf{k})$ over a fixed field $\mathbf{k}$ yields a functor $V\colon \mathbb{R}^d \to \mathbf{Vect}_\mathbf{k}$ - a *Multiparameter Persistence Module*.

The most important use case in practice are *density-scale* bifiltrations:

▶ **Example 2.** A standard 1-parameter pipeline [22] on a point set looks as follows: One constructs the Vietoris-Rips complex, filtered by one parameter, and computes its first persistent homology group, which decomposes into a barcode or persistence diagram (Figure 2).

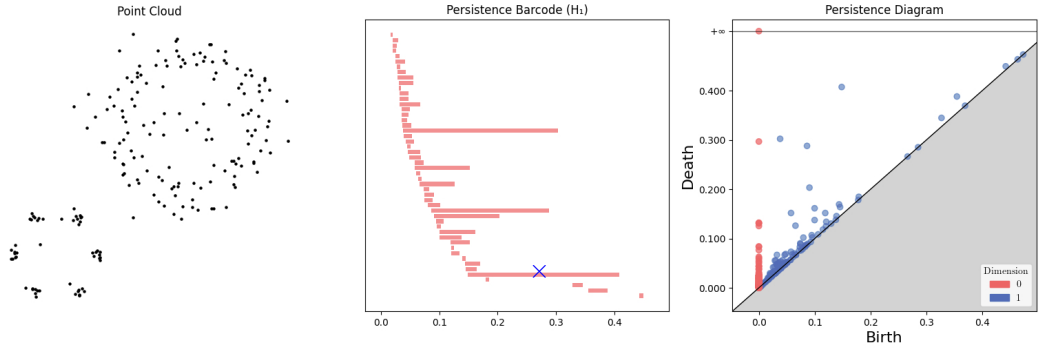

Figure 2 The lower left circle produces the bar marked with the blue cross.

The large circle on the right is impossible to detect with this technique without knowing the intensity of the noise we need to remove. Instead, we filter the simplicial complex again.

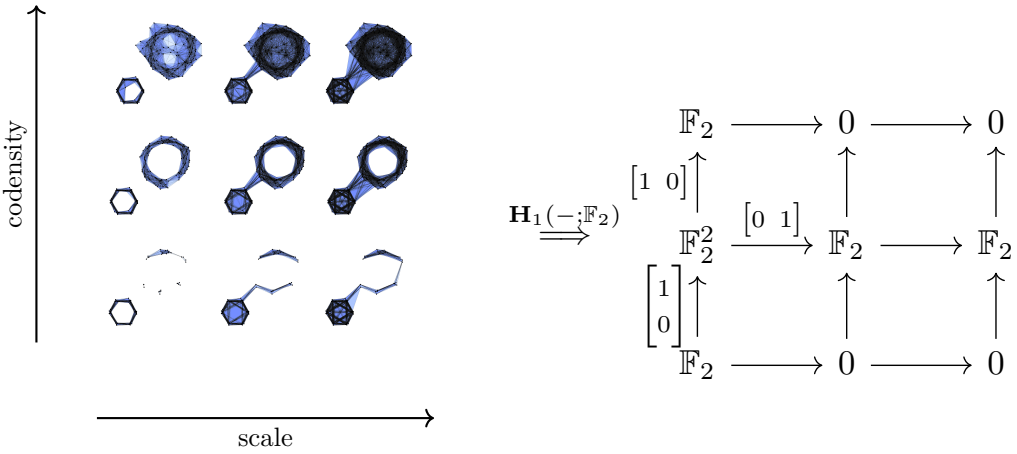

Figure 3 A 3×3 Density-Rips bifiltration of Figure 2 and its first homology group over $\mathbb{F}_2$.

Intervals. The analog of a *bar* in the multiparameter case is the *Interval Module*.

▶ **Definition 3** (Interval Module)**.** *A sub poset $I \subset \mathbb{R}^d$ is an* interval *if, with respect to the order, it is convex and connected. The module $\mathbf{k}[I]\colon \mathbb{R}^d \to \mathbf{Vect}_\mathbf{k}$ is defined as*

$$\mathbf{k}[I]_\alpha = \begin{cases} \mathbf{k} & \text{if } \alpha \in I \\ 0 & \text{otherwise} \end{cases} \qquad \mathbf{k}[I]_{\alpha\to\beta} = \begin{cases} \mathrm{Id}_\mathbf{k} & \text{if } \alpha, \beta \in I \\ 0 & \text{otherwise} \end{cases}.$$

An interval module *is a persistence module that is isomorphic to $\mathbf{k}[I]$ for some interval I.*

Motivation. The Skyscraper Invariant arises from the *Harder-Narasimhan filtration* [31] of persistence modules for a specific set of stability conditions. We will explain how one *could* arrive at considering HN filtrations even without prior knowledge of geometric invariant theory [54]. This theory was originally developed for persistence modules in [27] and [26].

Lifetime. Let V be a *multiparameter* persistence module. A sensible idea to extend the barcode is the following: search for an element with a "maximal lifetime" (an idea developed further in [52]). By "lifetime", we mean for any element $v \in V_\alpha$, with $\alpha \in \mathbb{R}^d$, the set

$$L_v := \{\beta \in \mathbb{R}^d \mid \alpha \leq \beta \text{ and } V_{\alpha\to\beta}(v) \neq 0\}$$

of parameter values under which v persists and "maximal" refers here to its volume. To assure that every lifetime has a finite volume, we will assume that every module is bounded, which can always be realised by restricting the module to a bounded subset of $\mathbb{R}^d$.

▶ **Example 4.** Consider again the bifiltered simplicial complex $\mathrm{VR}(X)\colon \mathbb{R}^2 \to \mathbf{SCpx}$ obtained from the point set X from Figure 2 filtered by a kernel density estimate. The 2-parameter module produced by $\mathbf{H}_1(\mathrm{VR}(X), \mathbb{F}_2)$ can be visualized by its *Hilbert function* - the pointwise dimension, which we denote by $\underline{\dim}_{\mathbf{k}}\, \mathbf{H}_1(\mathrm{VR}(X), \mathbb{F}_2)\colon \mathbb{R}^d \to \mathbb{N}$.

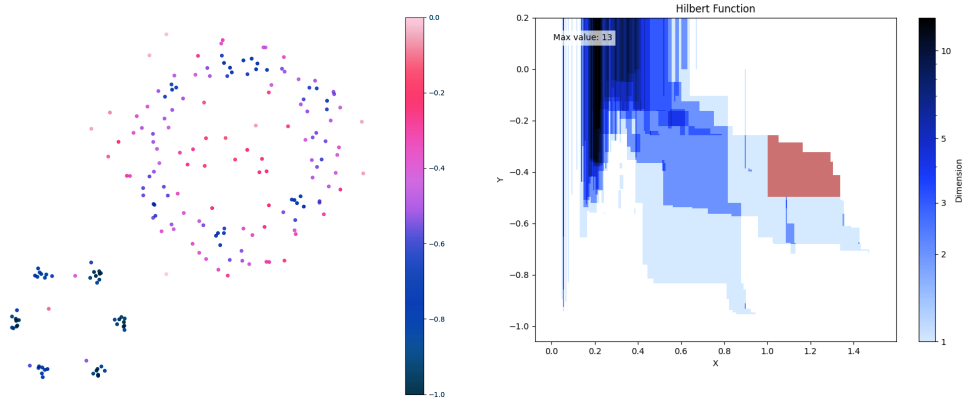

Figure 4 X coloured by density estimate and the Hilbert function of the module $\mathbf{H}_1(\mathrm{VR}(X), \mathbb{F}_2)$.

There is a non-zero vector at $\alpha = (1.0, -0.5)$ corresponding to the large circle in $\mathrm{VR}(X)_{1.0}$ after filtering out points of density lower than 0.5. We mark its lifetime red in Figure 4.

After finding the vector v of maximal lifetime, the submodule $\langle v\rangle$ of V generated by v is an interval module and L_v is the support $\mathrm{supp}\langle v\rangle$ of $\langle v\rangle$. Hence, if we compute the quotient $V/\langle v\rangle$, and repeat this process, we obtain a filtration of V in terms of interval modules.

Additivity. The element of maximal lifetime is not compatible with direct sums of modules.

▶ **Example 5.** Consider now Figure 5, where we return to the module from Figure 3. It can be split into two indecomposable summands, each roughly corresponding to one circle in the point set. The element of maximal lifetime is the vector $(1,1)^t \in \mathbb{F}_2^2$.

If we instead consider the *minimal* lifetime of an element, the construction becomes additive, meaning the desired vector lies in a direct summand:

$$\text{If } v \in V,\ w \in W, \text{ then for } v + w \in V \oplus W\colon \quad L_{v+w} = L_v \cup L_w. \tag{1}$$

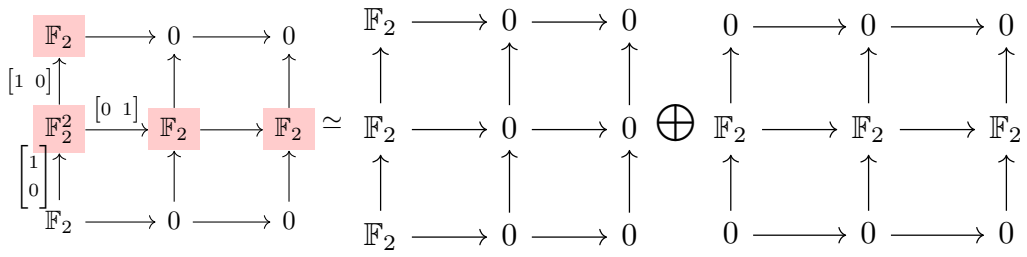

Figure 5 The maximal lifetime in the left module is indicated by red boxes.

This enables the use of decomposition algorithms (e.g. [20]) to speed up the search. Now, a priori, this element is not well defined, since in every non-zero persistence module we can find a sequence of elements whose lifetime approaches a set of empty volume. To fix this, we choose a concrete parameter value $\alpha \in \mathbb{R}^d$ and demand that the element be in V_α.

▶ **Definition 6.** *Let $S \subset V$ be a subset of V. We denote by $\langle S \rangle \subset V$ its* induced submodule.

Since we are only considering elements at α, we can now restrict our computations to $\langle V_\alpha \rangle$ – and this module is simpler than V:

▶ **Definition 7.** *V is* uniquely generated *if it has a set of generators of the same degree.*

In particular, $\langle V_\alpha \rangle$ is more decomposable than V. Still, the choice of an element is not unique: there could be multiple vectors whose lifetime has the same (minimal) volume. This is the first hint that one should not only consider single elements in V_α, but instead consider *submodules* of arbitrary dimension generated at a parameter value α.

Stability. Let $U \subset V_\alpha$ be any sub vector space. The integral of the Hilbert function $\underline{\dim}\langle U \rangle$ over $\mathbb{R}^d$ would be the natural generalisation of the volume of the lifetime. However, using this definition would never make a subvector space of dimension higher than 1 be the candidate for minimal lifetime. We need to average over the dimension of U.

▶ **Definition 8.** *Let $U \subset V_\alpha$. The* slope *of $\langle U \rangle$ (at α) is defined as*

$$\mu(\langle U \rangle) \coloneqq \frac{\dim_{\mathbf{k}} U}{\int_{\mathbb{R}^d} \underline{\dim}_{\mathbf{k}} \langle U \rangle} = \frac{\dim_{\mathbf{k}} \langle U \rangle_\alpha}{\int_{\mathbb{R}^d} \underline{\dim}_{\mathbf{k}} \langle U \rangle}.$$

By replacing, in the last term, $\langle U \rangle$ with any *persistence module we get a general definition of the slope at α. A module is called* semistable *[54, 42, 10] if no submodule has a higher slope.*

The maximal submodule of highest slope $\langle U_1 \rangle \subset \langle V_\alpha \rangle$ is semistable. We define $\langle U_2 \rangle$ as the maximal submodule of highest slope in $\langle V_\alpha \rangle / \langle U_1 \rangle$ and continue iteratively. This produces a sequence of semistable modules $(\langle U_i \rangle)_{i \in [\ell]}$. By defining inductively $F^i \coloneqq U_i + F^{i-1}$, we arrive at the *Harder-Narasimhan-filtration* [31]

$$0 = \langle F^0 \rangle \subsetneq \langle F^1 \rangle \subsetneq \cdots \subsetneq \langle F^\ell \rangle = \langle V_\alpha \rangle \tag{2}$$

of $\langle V_\alpha \rangle$ by [26, Theorem (A)]. The semistable modules $\langle U_i \rangle$ are by definition isomorphic to the factors $\langle F^i \rangle / \langle F^{i-1} \rangle$. The sequence $\mu(\langle U^i \rangle)$ of slopes is decreasing in i, but this is not obvious. For a formal treatment, see [26] and [28, §2.4].

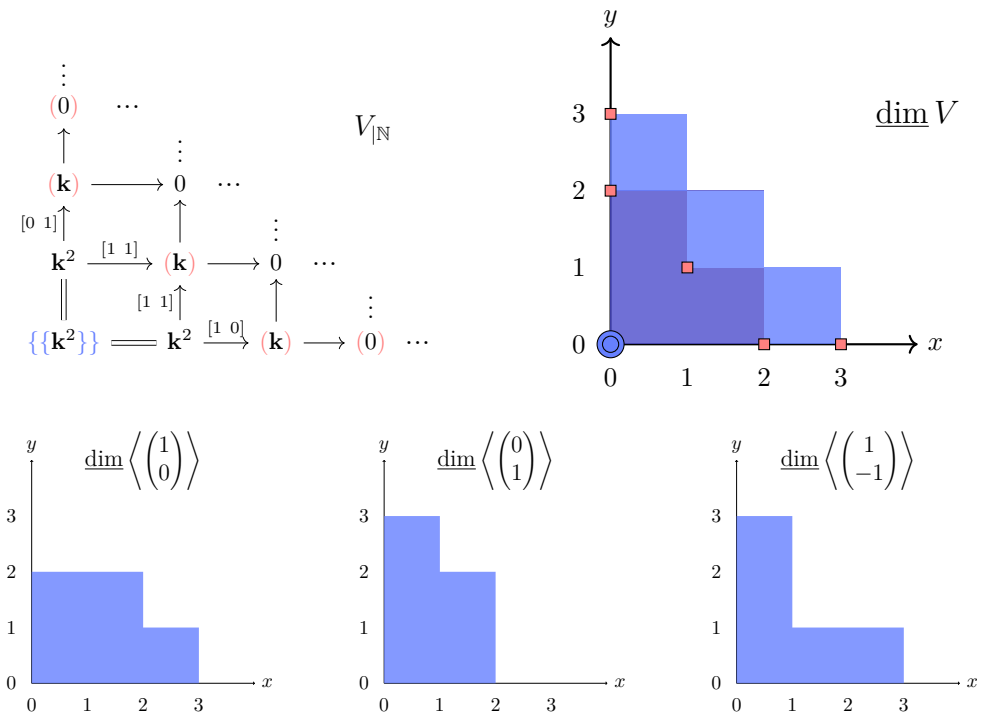

Figure 6 A module, its dimension over $\mathbb{R}^2$, and candidates for submodules of high slope.

▶ **Example 9.** In Figure 6, we construct a semistable module V that is not an interval.

At $\alpha := (0,0)$, each of the three shown submodules has slope $1/5$. Every other dimension 1 subspace has a lifetime equal to the whole support of the module and therefore slope $1/6$. The whole module on the other hand has slope $2/9$, so it is semistable.

Because of the existence of modules like Example 9, the factors of the Harder-Narasimhan filtration at α should generally not all be intervals. Surprisingly, they did turn out to be intervals for all of our examples of density-scale bifiltrations of point sets in $\mathbb{R}^2$.

▶ **Conjecture 10.** *Let $S \subset \mathbb{R}^2$ be a finite point set and $X_\bullet$ be any density-scale bifiltration of S. All indecomposable uniquely generated submodules of $\mathbf{H}_1(X_\bullet, \mathbf{k})$ are intervals.*

Then, in particular, all factors of the Harder-Narasimhan filtration are intervals by additivity.

The Skyscraper Invariant. Let $0 \hookrightarrow F^1 \hookrightarrow \ldots \hookrightarrow F^\ell = V_\alpha$ be the HN filtration at α.

▶ **Definition 11.** *[26] For $\alpha \leq \beta \in \mathbb{R}^d$ and $\theta \in \mathbb{R}$, the Skyscraper Invariant is*

$$s_V^\theta(\alpha,\beta) := \dim_{\mathbf{k}} \langle F^i \rangle_\beta = \sum_{j=1}^{i} \dim_{\mathbf{k}} \langle U_j \rangle_\beta \qquad \text{where } i \text{ is maximal with } \mu(U^i) \geq \theta.$$

This value only depends on the Hilbert function of the factors $\underline{\dim}\langle U_j \rangle$. Since $s_V^0(\alpha,\beta) = \dim_{\mathbf{k}} \langle V_\alpha \rangle_\beta = \operatorname{rank}(V_{\alpha \to \beta})$, the Skyscraper Invariant filters the rank invariant.

▶ **Example 12.** The modules V and W cannot be distinguished by the rank invariant.

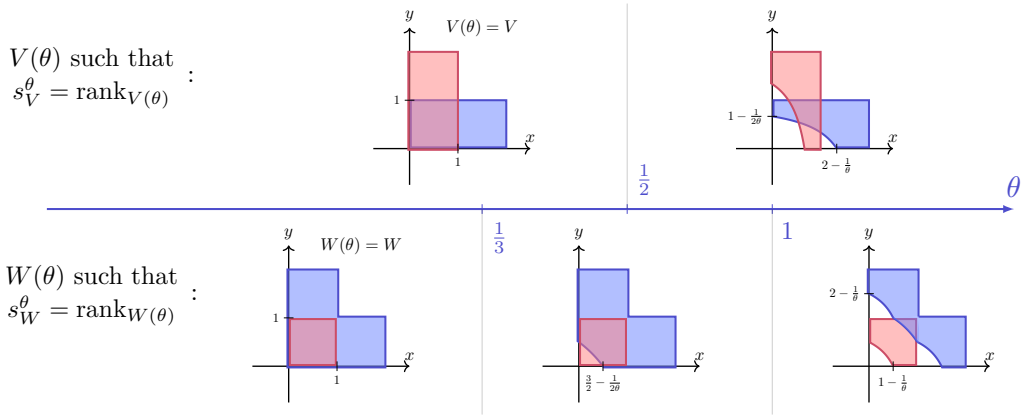

Figure 7 We visualise the Skyscraper Invariant by modules whose rank invariant is $s^\theta(\bullet, \bullet)$.

Distances. For each $\theta \in \mathbb{R}$, $s_V^\theta(\bullet, \bullet)$ is a functor from $(\mathbb{R}^d)^{\mathrm{op}} \times \mathbb{R}^d$ to $(\mathbb{Z} \cup \{+\infty\})^{\mathrm{op}}$. This allows for an *erosion distance* d_{E} [56, 55] under which the Skyscraper Invariant is stable [26, Theorem 3.7] with respect to the interleaving distance [14].

Approximation. Given $s_V^\theta(\alpha, \beta)$ for all α, β in a grid $\mathcal{G}$, we can define the functor $\widehat{s}_V^\theta(\bullet, \bullet)$ over $(\mathbb{R}^d)^{\mathrm{op}} \times \mathbb{R}^d$ via a projection to the next lower element in $\mathcal{G}$.

▶ **Lemma 13** ([28, Lemma 3.4]). *If $\mathcal{G}$ ε-approximates* $\mathrm{supp}(V)$*, then* $d_E(s, \widehat{s}) \leq \varepsilon$.

Intervals and Data Structures. After computing the HN filtrations, we need to store the Hilbert functions of the filtration factors and their associated slopes. The Hilbert functions of each factor $\langle U_i \rangle$ can be stored as a list of $\dim_{\mathbf{k}} U_i$ *intervals*, $\{W_{i,j}\}_{j \in J}$, each being assigned the slope of $\langle U_i \rangle$. For each $\alpha \in \mathcal{G}$, this results in a list of at most $\mathfrak{t}(V)$ intervals. To compute $s_V^\theta(\alpha, \beta)$ from this list, we count how many $(W_{i,j})$ with an associated slope greater than θ contain β. The latter can be done in $\mathcal{O}(\log(m))$ time where m is the number of relations of the interval. Since $m \leq n$, This puts the query time in $\mathcal{O}(\mathfrak{t}(V) \log(n))$.

Presentations. The data structure in which persistence modules come is that of a *presentation*. This is a set of generators and a set of relations among the generators. They are collected in a matrix where each row corresponds to a generator and each column to a relation. The rows and columns are endowed with the parameter value – or *degree* – of the corresponding generator or relation, making this a *graded matrix* or *monomial matrix* [49]. If we write A^G for the free module generated by a tuple of degrees G, then a graded matrix is nothing but a linear map $M \colon A^R \to A^G$ and it presents V iff $V \xrightarrow{\sim} A^G / \mathrm{Im}(M)$.

Each finitely encoded persistence modules [51] has a finite minimal presentation which can be extended to a *minimal resolution*. The degrees of the generators, relations, higher relations etc. in a minimal resolution are independent of the chosen resolution and form multi-subsets $b_0(V)$, $b_1(V), \ldots,$ $b_d(V) \subset \mathbb{R}^d$ – the *graded Betti numbers* of V. We denote the category of bounded finitely presented persistence modules by $\mathrm{Pers}_{\mathrm{fp}}^{\mathrm{b}}(\mathbb{R}^d)$.

2 Computing the Skyscraper Invariant Approximately

Our definition of the HN filtration given in the previous section is actually not consistent with the classical one [31, 42]. Instead of a filtration of $\langle V_\alpha \rangle$ one really considers a filtration of V. Only by the observation [26, Proposition 3.3] it actually restricts to one of $\langle V_\alpha \rangle$. The first simplification in our algorithms is the computation of this submodule $\langle V_\alpha \rangle$.

Induced Submodules. Computing a presentation for any induced submodule can be done by computing the kernel of a graded matrix in the category of persistence modules. For $d = 2$, this can be done with the LWKR-algorithm (Lesnick, Wright, Kerber, and Rolle [43, 40]) and for $d = 3$ there is an unpublished algorithm [5] by Bender, Gäfvert, and Lesnick. When d is larger, we rely on classical machinery, like Schreyer's algorithm [23], which is too slow in practice. We will therefore focus on the 2-parameter case for this paper.

Algorithm 1 `SubmoduleGeneration` (cf. [1, Section 7.2]).

Input: A graded matrix $M \in \mathbf{k}^{G\times R}$ presenting V and a finite subset $S \subset V$
Output: A presentation $N \in \mathbf{k}^{\deg(S)\times R_S}$ of $\langle S\rangle$

For each element in S find coordinates in G to get a graded matrix $M_S \in \mathbf{k}^{G\times \deg(S)}$
Compute $\begin{bmatrix} N \\ K \end{bmatrix} := \ker [M_S \ M] \in \mathbf{k}^{(\deg(S)\cup R)\times R_S}$
return $N \in \mathbf{k}^{\deg(S)\times R_S}$

▶ **Proposition 14.** *Algorithm 1 computes a presentation of* $\langle S\rangle$.

Proof. See [28, Proposition 3.1] for a chase in the following diagram:

$$\begin{array}{ccccccc} A[R_S] & \xrightarrow{N} & A[\deg(S)] & \xrightarrow{q} & \langle S\rangle & \longrightarrow & 0 \\ {\scriptstyle -K}\downarrow & & \downarrow{\scriptstyle M_S} & & \downarrow{\scriptstyle \iota} & & \\ A[R] & \xrightarrow{M} & A[G] & \xrightarrow{p} & V & \longrightarrow & 0. \end{array}$$

◀

Approximate Computation. We condense the ideas from Section 1 into an algorithm.

Algorithm 2 ε-approximation of the Skyscraper Invariant.

Input: $\varepsilon \in \mathbb{R}$; a graded matrix $M \in \mathbf{k}^{G\times R}$ presenting $V \in \mathrm{Pers}^{\mathrm{b}}_{\mathrm{fp}}(\mathbb{R}^d)$.
Output: For each $\alpha \in \varepsilon\mathbb{Z}^d \cap \mathrm{supp}(V)$: Lists $(W_{t,j}, \mu_t)_{t\in[\ell]}$ of elements in $\mathcal{P}(\mathbb{R}^d) \times \mathbb{R}$.

Decompose V into $\bigoplus_{i\in I} V_i$;
for $\alpha \in \varepsilon\mathbb{Z}^d \cap \mathrm{supp}(V)$ **do**
  for $i \in I$ **do**
    Compute $\langle (V_i)_\alpha\rangle$ with Algorithm 1; Decompose $N_i \xrightarrow{\sim} \bigoplus_{j\in J_i} N_{i,j}$
    for $j \in J_i$ **do**
      $(U_{i,j,t},\ \mu_{i,j,t})_{t\in[\ell_{i,j}]} \leftarrow$ HN-Filtration$_\alpha$-Factors$(N_{i,j})$
  $(U_t, \mu_t)_{t\in[\ell]} \leftarrow \mathrm{SORT}\left(\{((U_{i,j,t},\ \mu_{i,j,t})_{t\in[\ell_{i,\alpha,j}]}\}_{i,j}\right)$
  $\forall t \in [\ell]$, decompose $\underline{\dim} U_t$ into intervals $\{W_{t,j}\}_{\mathcal{J}_t}$; **return** $(W_{t,j}, \mu_t)_{t\in[\ell],j\in\mathcal{J}_t}$

Correctness. Denote by $n = |G| + |R|$ the input size, $\mathfrak{t}(V)$ the thickness of V, k the maximal thickness of a uniquely generated indecomposable submodule, and by $T_{\text{HN-F}}$, T_{KER}, and T_{DEC} the times to compute the HN filtration, kernels, and decomposition for d-parameter modules.

▶ **Proposition 15.** *Algorithm 2 returns an ε-approximation of the Skyscraper Invariant in*

$$\mathcal{O}\left(1/\varepsilon^2 \left(T_{\text{KER}}(n,d) + T_{\text{DEC}}(n,d) + (\mathfrak{t}(V)/k)(T_{\text{HN-F}}(n,k,d))\right)\right) \text{ time for } d = 2.$$

Proof. Correctness follows from additivity (Equation 1) and the fact that we only need the ordered list of Hilbert functions of factors. At each step there are at most $\mathfrak{t}(V)/k$ indecomposable submodules of thickness k generated at α. ◀

3 Finding Highest-Slope Submodule

We will explain how to compute the Harder-Narasimhan filtration of $\langle V_\alpha \rangle$ with an exhaustive search. To do so, we must compute slopes. The slope $\mu_\alpha(V)$ at α is entirely determined by the Hilbert function of $\langle V_\alpha \rangle$ and thus by its Betti numbers.

▶ **Proposition 16.** *Let $V \in \mathrm{Pers}^b_{fp}(\mathbb{R}^d)$, then*

$$\int_{\mathbb{R}^d} \underline{\dim}\, V = \sum_{i=0}^{d} (-1)^{d+i} \sum_{\gamma \in b_i(V)} \prod_{j=1}^{d} \gamma_j. \tag{3}$$

Proof. Consider a minimal free resolution $0 \to F_d \to \cdots \to F_0 \to V \to 0$ which will be of maximal length d by Hilbert's Syzygy theorem. In our bounded case, it will even be exactly of length d by duality of free and injective resolutions (first proved by Miller in [50] and rediscovered in [3] for the computation of Multiparameter Persistent Cohomology). Each F_i has a basis with degrees at $b_i(V)$. By exactness, for each $\alpha \in \mathbb{R}^d$ we have

$$\dim_{\mathbf{k}} V_\alpha = \sum_{i=0}^{d} (-1)^i \dim_{\mathbf{k}} (F_i)_\alpha = \sum_{i=0}^{d} (-1)^i \sum_{\gamma \in b_i(V)} \mathbb{1}_{\{\gamma \leq \alpha\}}. \tag{4}$$

Let $B \in \mathbb{R}^d$ be large enough that $\mathrm{supp}(V) \subset \prod_{j\in[d]} (-\infty, B_j]$, then

$$\int_{\mathbb{R}^d} \underline{\dim}\, V = \int_{\prod_{j\in[d]}(-\infty,B_j]} \underline{\dim}\, V = \sum_{i=0}^{d} (-1)^i \sum_{\gamma \in b_i(V)} \prod_{j=1}^{d} (B_j - \gamma_j)\,. \tag{5}$$

As a function of B, Equation 5 is a polynomial and constant, so we can set $B = 0$. ◀

Iteration over subspaces. Instead of considering $\langle V_\alpha \rangle$, we assume without loss of generality, that V is uniquely generated at 0. Recall that $\mathfrak{t}(V) = \max \underline{\dim}\, V$, and choose any basis $\mathbf{k}^{\mathfrak{t}(V)} \xrightarrow{\sim} V_0$. We want to find the sub vector space $U \subset \mathbf{k}^{\mathfrak{t}(V)}$ for which $\langle U \rangle \subset V$ has the highest slope. An exhaustive search would involve computing $\mu(\langle U \rangle)$ with Algorithm 1 for *all* sub vector spaces $U \subset V_0$. This is clearly possible if we work over a finite field, but also in the infinite case, the finite presentation of V allows only a finite number of non-isomorphic submodules. Since all software uses finite fields, we fix a prime power q and $\mathbf{k} = \mathbb{F}_q$.

Denote by $\mathcal{P}V_0$ the set of 1-dimensional subspaces of V_0 and define $W_{\max} \in \arg\max_{W \in \mathcal{P}V_0} \mu(\langle W \rangle)$

▶ **Proposition 17.** *Let $1 < k \leq \mathfrak{t}(V)$ and define $V_k := \{W \in \mathcal{P}V_0 \mid \mu(\langle W \rangle) \geq \mu(\langle W_{max} \rangle)/k\}$. If for every k-subspace $U \subset V_0$ it holds that $\mathcal{P}U \not\subset V_k$, then $\langle W_{max} \rangle \subset V$ has a higher slope than any other submodule of thickness k.*

Proof. Consider any $U \subset V_0$ of dimension k. By assumption, there is a 1-dimensional subspace $T \in \mathcal{P}U \subset \mathcal{P}V_0$ which is not in V_k. Therefore, $\mu(\langle T \rangle) < \mu(\langle W_{\max} \rangle)/k$.

$$\mu(\langle U \rangle) = k \Big/ \int_{\mathbb{R}^d} \underline{\dim}_{\mathbf{k}} \langle U \rangle < k \Big/ \int_{\mathbb{R}^d} \underline{\dim}_{\mathbf{k}} \langle T \rangle = k\mu(\langle T \rangle) < \mu(\langle W_{\max} \rangle). \qquad ◀$$

Every k-dimensional vector space over $\mathbb{F}_q$ contains exactly $(q^k - 1)/(q - 1)$ subspaces of dimension 1, so the premise of Proposition 17 is trivially satisfied if $|V_k| < (q^k - 1)/(q - 1)$. V_0 has $\sim q^{\mathfrak{t}(V)^2/4}$ subspaces, but only $\sim q^{\mathfrak{t}(V)}$ of these are 1-dimensional.

Algorithm 3 Exhaustive search for the highest-slope submodule.

Input: A graded matrix $M \in \mathbb{F}_q^{B_0 \times B_1}$ presenting $V \in \mathrm{Pers}_{\mathrm{fp}}^{\mathrm{b}}(\mathbb{R}^d)$ generated at 0.
Output: A subspace $S \subset V_0$ such that $\langle S \rangle$ is the submodule of maximal slope.

```
slopes: ({Subsets of V_0} → ℝ) ← {}; for W ∈ PV_0 do
    Pick any v ≠ 0 ∈ W, N_0 ← Algorithm 1(M, v)
    Compute a resolution N_i ∈ k^{B_{i-1} × B_i}; b_i(V) ← B_i
    slopes.append ( v ↦ Σ_{i=0}^{d} (-1)^{d+i} Σ_{γ ∈ b_i(V)} Π_{j=1}^{d} γ_j )
v_max ← arg max slopes; V_k ← {w ∈ PV_0 | slopes(w) ≥ slopes(v_max)/k}
for 1 ≤ k ≤ t(V) do
    if |V_k| ≥ (q^k − 1)/(q − 1) then
        for W ∈ Gr_k V_0 do
            Pick a basis B ⊂ W, N_0 ← Algorithm 1(M, B)
            Compute a resolution N_i ∈ k^{B_{i-1} × B_i}; b_i(V) ← B_i
            slopes.append ( B ↦ Σ_{i=0}^{d} (-1)^{d+i} Σ_{γ ∈ b_i(V)} Π_{j=1}^{d} γ_j )
return arg max (slopes)
```

▶ **Proposition 18.** *Algorithm 3 returns the correct result in* $\mathcal{O}(T_{\mathrm{KER}} \cdot q^{\mathfrak{t}(V)^2/4+\mathcal{O}(\mathfrak{t}(V))})$ *time.*

Proof. Correctness follows from Proposition 16 and Proposition 17. Algorithm 1 computes a kernel for each subspaces of $\mathbb{F}_q^{\mathfrak{t}(V)}$, of which there are $\sum_i \binom{\mathfrak{t}(V)}{i}_q \sim q^{(\mathfrak{t}(V)/2)^2+\mathcal{O}(\mathfrak{t}(V))}$. ◀

By calling Algorithm 3 recursively on the quotient by the submodule of highest slope we can compute the whole HN filtration at α in $\mathcal{O}(\mathfrak{t}(V) \cdot T_{\mathrm{KER}} \cdot q^{\mathfrak{t}(V)^2/4+\mathcal{O}(\mathfrak{t}(V))})$ time.

4 Cheng's Algorithm

Building on the work of [19, 33], Cheng reduced the computation of HN filtrations of representations of finite acyclic quivers to the shrunk subspace problem, which can be solved in deterministic polynomial-time for large enough fields [15]. This algorithm can be directly applied to persistence modules over a finite poset [26, Remark 1.13].

It does not follow directly from Lemma 13 that computing the HN filtration after restriction to the grid produces an error on $s_V^\bullet(\bullet,\bullet)$ less than ε in the erosion distance, because this could change which submodule has the highest slope. Instead, one needs to apply the functoriality of the HN filtration [24] on an interleaving [26, Theorems 2.9 and 3.7].

Shrunk subspace problem. Fix two integers $N, N' > 0$ and a field $\mathbf{k}$. The space of $N \times N'$ matrices with coefficients in $\mathbf{k}$ is denoted $\mathbf{k}^{N \times N'}$ and we write $\otimes$ for the Kronecker product.

▶ **Definition 19** (shrunk subspace). *Let* $\mathcal{A} \subset \mathbf{k}^{N \times N'}$ *be a subspace. A subspace* $U \subset \mathbf{k}^{N'}$

is a shrunk subspace *of* $\mathcal{A}$ *it it maximizes* $\quad \dim_{\mathbf{k}} U - \dim_{\mathbf{k}} \sum_{A \in \mathcal{A}} AU.$

Observe that the being a shrunk subspace of $\mathcal{A}$ *is closed under intersections. We can thus define the* minimal shrunk subspace *of* $\mathcal{A}$.

For the purpose of this paper, we present a simple random algorithm introduced in [29, Theorem 6.7] for $\mathbf{k} = \mathbb{Q}$. We extend this algorithm to any field using [34, Lemma 5.3]

▶ **Proposition 20.** *Fix a field* $\mathbf{k}$ *and* $\eta > 0$. *Given an integer* $N > 0$ *and a subspace* $\mathcal{A} \subset \mathbf{k}^{N\times N}$ *generated by a family of* ℓ *matrices, there exists a random algorithm to compute the minimal shrunk subspace of* $\mathcal{A}$ *using at most* $C_{\mathbf{k}}\ell N^{8+\eta}$ *arithmetic operations for some constant* $C_{\mathbf{k}} > 0$.

From persistence module to shrunk subspace. Fix $W \in \mathrm{Pers}_{\mathrm{fp}}^{\mathrm{b}}(\mathbb{R}^d)$ and a number $\varepsilon > 0$. Assume that the support of W is contained in a bounded cube $B \subset \mathbb{R}^d$ and let $\mathcal{G} \coloneqq (\varepsilon\mathbb{Z}^d) \cap B$. We denote by $V \colon \mathcal{G} \to \mathbf{Vect}$ the restriction of W to $\mathcal{G}$. Using the Persistence-Algebra library one can compute the structure maps of V in time $n^3(1/\varepsilon)^d + n^2(1/\varepsilon)^{2d}$.

Let $\alpha \in \mathcal{G}$, and let $\{\alpha, \beta_1, \dots, \beta_k\} \coloneqq \{\beta \in \mathcal{G} \mid \beta \geq \alpha\}$. Define $p_0 \coloneqq \dim V_\alpha$ and $q_0 \coloneqq \sum_{i=1}^{k} \dim V_{\beta_i}$. Consider the following subspace of $\mathbf{k}^{q_0\times p_0}$:

$$\mathcal{A}_\alpha \coloneqq \left\{ \begin{pmatrix} \lambda_1 V_{\alpha\to\beta_1} \\ \vdots \\ \lambda_k V_{\alpha\to\beta_k} \end{pmatrix} \;\middle|\; \lambda \in \mathbf{k}^k \right\} \tag{6}$$

▶ **Proposition 21** ([36, Theorem 4.3])**.** *Let* $p, q > 0$ *and let* $0 = F^0 \hookrightarrow F^1 \hookrightarrow \cdots \hookrightarrow F^\ell = V_\alpha$ *be the HN filtration of* V *at* α. *Let* $i(p,q)$ *be the maximum integer* $0 \leq i \leq \ell$

$$\text{such that either } i = 0 \quad \text{or} \quad \mu(F^i/F^{i-1}) > \frac{p}{p+q}.$$

The minimal shrunk subspace of $\mathbf{k}^{p\times q} \otimes \mathcal{A}_\alpha$ *is* $\mathbf{k}^q \otimes F^{i(p,q)}$.

Cheng also observed in the above Theorem that when $(p,q) \coloneqq (p_0, q_0)$, either $\ell = 1$ or $0 < i(p_0, q_0) < \ell$ [15, Corollary 3.4]. They thus devised Algorithm 4.

Algorithm 4 HN-Cheng.

```
1 Input: A finite poset 𝒢, α ∈ 𝒢 and V : 𝒢 → Vect_k uniquely generated at α.
2 Output: The list of modules in the HN filtration of V along α
3 Let U ⊂ V_α such that k^{q_0} ⊗ U is the minimal shrunk subspace of k^{p_0×q_0} ⊗ 𝒜_α
    computed by Proposition 20 ;
4 if U ∈ {0, V_α} then
5   return {0, V};
6 if U ≠ ∅ then
7   return HN-Cheng(𝒢, α, ⟨U⟩) ∪ (U + HN-Cheng(𝒢, α, ⟨V_α/U⟩));
```

▶ **Corollary 22.** *Given* $V \in \mathrm{Pers}_{fp}^{b}(\mathbb{R}^d)$ *and* $\varepsilon > 0$, *there is a random algorithm to compute an* ε*-approximation of* s_V *in time* $\mathcal{O}(\mathfrak{t}(V)^{19}\varepsilon^{-11d})$ *up to poly-logarithmic factors.*

Proof. By [26] (as detailed in [28, Corollary 4.5]), applying for every $\alpha \in \mathcal{G}$ Algorithm 4 to the restriction of V to $\mathcal{G}$ yields an ε-approximation of s_V. By Proposition 20 with $\ell \coloneqq kp_0q_0$ and $N \coloneqq p_0q_0$, line 3 in Algorithm 4 takes $\mathcal{O}(|\mathcal{G}|(p_0q_0)^{9+\eta/2}) = \mathcal{O}(\mathfrak{t}(V)^{18+\eta}\varepsilon^{-10d-\eta})$ for any $\eta > 0$. The recursive step adds a factor $\mathfrak{t}(V)$, whence the desired complexity. ◀

Improvements to Cheng's algorithm. By harnessing the block structure of (6), we are able to improve the complexity in Proposition 20 for the subspaces appearing in Algorithm 4.

▶ **Proposition 23.** *Given $V \in \mathrm{Pers}^b_{fp}(\mathbb{R}^d)$ and $\varepsilon > 0$, there is a random algorithm to compute an ε-approximation of s_V in time $\mathcal{O}(\mathfrak{t}(V)^{17}\varepsilon^{-9d})$ up to poly-logarithmic factors.*

Further empirical improvements can be obtained by computing $i(p,q)$ in Proposition 21 for small integers $p, q > 0$ such that $\frac{p}{q} \approx \frac{p_0}{q_0}$. Indeed, the complexity of computing $F^{i(p,q)}$ is heavily dependent on the size of pq. For simplicity, assume that $\frac{p}{q} > \frac{p_0}{q_0}$. If $F^{i(p,q)} \neq 0$, then we can replace U by $F^{i(p,q)}$ in Algorithm 4. Otherwise, we know that there are no submodule $U \subset V$ such that $\mu(U) > \frac{p}{p+q}$. We keep choosing better approximations $\frac{p}{q}$ of $\frac{p_0}{q_0}$ (so with higher values of p, q) until either we find a proper submodule in the HN filtration of V at α, or we can guarantee that V is semistable at α.

Finally, given $p, q > 0$ and a matrix $A \in \mathbf{k}^{p\times q} \otimes \mathcal{A}_\alpha$, our implementation uses the block structure of A to partially reduce it: Since $A = (\lambda_{ij} V_{\alpha \to \beta_{i \bmod k}})_{ij}$ for some $\Lambda \in \mathbf{k}^{pk\times q}$, we column-reduce the first q block rows of A by reducing Λ and each $(V_{\alpha\to\beta_i})_{1\le i\le k}$.

These two empirical improvements led to significant speed-ups (see [28, Table 3]).

5 Exact Computation of the Skyscraper Invariant

The slope in relation to α. For many computations on persistence modules, it is often enough to perform them only at those parameter values that share each of their coordinates with a generator or relation (cf. the barcode template [43, 44]). We call the set of these parameters, $\mathrm{Grid}(V) \subset \mathbb{R}^d$, the *induced grid* of V. It partitions $\mathbb{R}^d$ into rectangular cells.

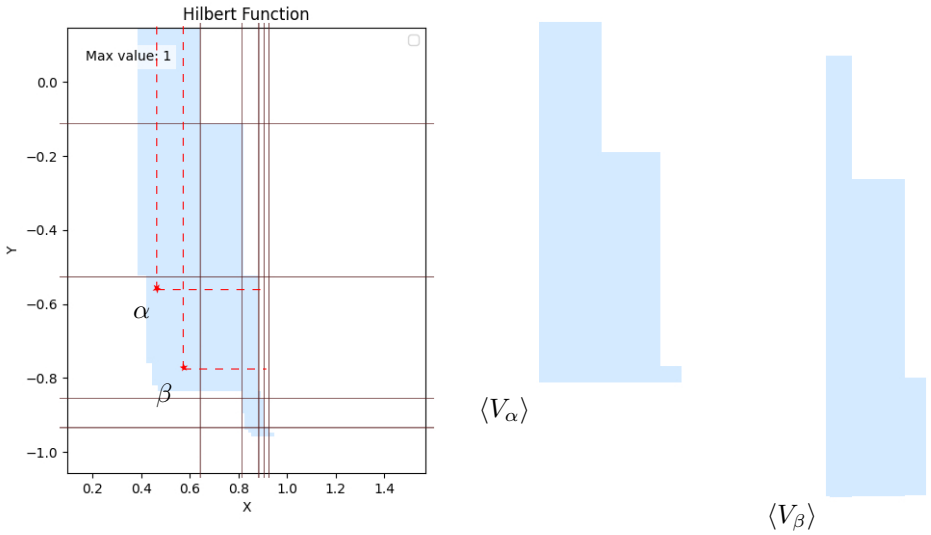

Figure 8 The direct summand corresponding to the small circle in Figure 2 with an overlaid grid.

Consider any cell C in the grid on the left in Figure 8, which is slightly coarser than the induced grid. For all $\alpha \in C$, the submodules $\langle V_\alpha \rangle$ will look qualitatively similar: Each has a presentation with the same underlying matrix. We will use this fact to avoid recomputing decompositions and HN filtrations for every $\alpha \in C$ on an ε-grid.

For $J \subset [d]$, denote by $F_J \subset \mathbb{R}^d$ the hyperplane spanned by the coordinate axes indicated by J, with the origin at α. The graded Betti numbers, which lie in some F_J for $|J| < d$, will be shifted to align with $\alpha \in C$ when α changes (Figure 9).

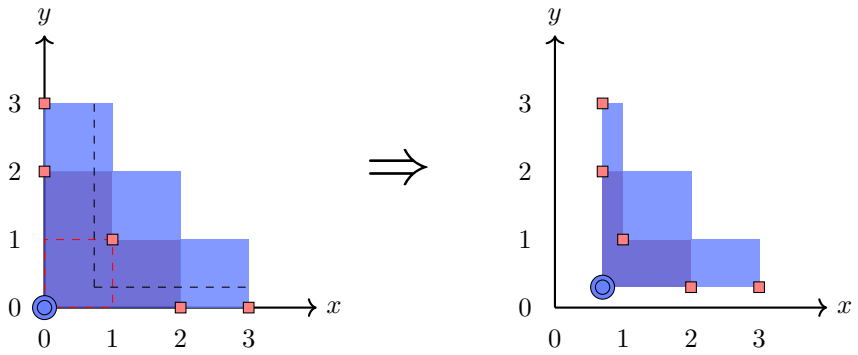

Figure 9 The uniquely generated module from Example 9 after cutting it off.

▶ **Lemma 24.** *Let V be generated at 0. For α in the first cell of Grid(V), the function $\alpha \mapsto \mu\left(\langle V_\alpha \rangle\right)^{-1}$ is a multilinear polynomial of degree d which we denote by p_V and*

$$p_V(\alpha) = \frac{1}{\mathfrak{t}(V)} \sum_{J \subset [d]} (-1)^{|J|} \int_{F_{[d]\setminus J}} \underline{\dim}\, V_{|F_{[d]\setminus J}} \alpha^J = \sum_{J \subset [d]} (-1)^{|J|} \mu\left(V_{|F_{[d]\setminus J}}\right)^{-1} \alpha^J. \tag{7}$$

In particular, the leading coefficient is $(-1)^d$ and the constant term is $\mu(V)^{-1}$.

Proof by picture: Figure 10. Full proof in [28, Lemma 6.5]

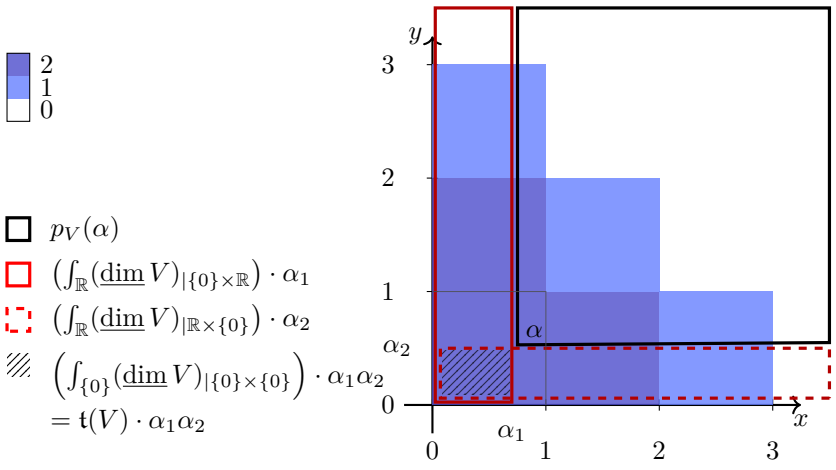

Figure 10 Equation 7 is obtained by exclusion-inclusion of the red and black rectangles. ◀.

▶ **Observation 25.** *To find the submodule of highest slope for all α in a grid cell C at the same time, compute the lower envelope of the slope polynomials of all non-isomorphic submodules. Since they have the same leading term $(-1)^d \alpha^{[d]}$ we can omit it for the computation of this diagram. For the important case of $d = 2$, this is the lower envelope of a set of planes in $\mathbb{R}^3$ and can be computed efficiently as the upper convex hull of its dual point set [18, 14.2].*

We describe this computation for $d = 2$, where after ignoring the degree-2 part, the slope-polynomials are linear and so the minimisation diagram is convex-polygonal.

Algorithm 5 Highest Slope Submodule in a Grid Cell.

Input: A graded matrix M presenting V uniquely generated at α; $C \subset \mathbb{R}^2$
Output: A convex polygonal subdivision $\{S_i\}_{i\in I}$ of C. For each $i \in I$ a sub vector space $W \subset V_\alpha$ and the truncated slope polynomial $p_{\langle W\rangle}$.

```
slope-polynomials ∈ ({Finite Subsets of V_α} × ℝ³) [ ] ← empty array
for sub vector space W ⊂ V_α do
    N ← Algorithm 1(M, B), for some basis B ⊂ W; K ∈ k^{R×S} ← ker N
    b_0(⟨W⟩) ← (deg(B)), b_1(⟨W⟩) ← R, b_2(⟨W⟩) ← S
    slope-polynomials.append(B, 1/|B| (∫(dim V)_{|F_1} x_1 + ∫(dim V)_{|F_2} x_2 + ∫ dim V))
subdivision {S_i}_{i∈I} ← LowerEnvelope( slope-polynomials)
return {(S_j ∩ C, slope-polynomials_j)}_{j∈J such that S_j∩C≠∅}
```

The thickness-6 module from Table 1 produces the following subdivision.

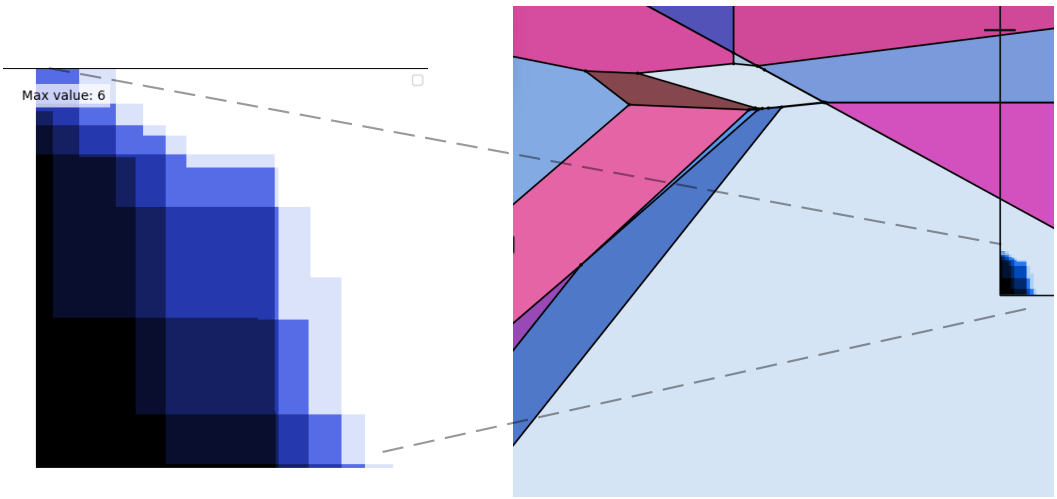

Figure 11 The minimisation diagram overlaid on the Hilbert function.

Arrangements. We ran Algorithm 5 for all modules used in Table 1. In each case, as in Figure 11, the first grid cell lies entirely in one face of the subdivision.

▶ **Proposition 26.** *Algorithm 5 is correct and runs in expected time* $\mathcal{O}(\mathfrak{t}(V)^3 2^{\mathfrak{t}(V)^2/4+\mathcal{O}(\mathfrak{t}(V))})$.

Proof. Correctness follows from Lemma 24 and Observation 25. The runtime is the same as for Algorithm 3, except that kernel computation is in $\mathfrak{t}(V)^3$ for 2-parameter modules and we compute a lower envelope. That can be done in expected time $n \log n$, putting the runtime in

$$\mathcal{O}\left(2^{\mathfrak{t}(V)^2/4+\mathfrak{t}(V)} \log(2^{\mathfrak{t}(V)^2/4+\mathcal{O}(\mathfrak{t}(V))})\right) = \mathcal{O}\left(\mathfrak{t}(V)^2 2^{\mathfrak{t}(V)^2/4+\mathcal{O}(\mathfrak{t}(V))}\right). \quad \blacktriangleleft$$

Exact Computation of the Skyscraper Invariant. For each $i \in I$, there is a highest-slope submodule $W^{\{i\}} \subset \langle V_\alpha\rangle$ associated with the face S_i. By computing the quotient $V^{\{i\}} := \langle V_\alpha\rangle / W^{\{i\}}$ and recursively calling Algorithm 5 on the pair $(V^{\{i\}}, S_i)$, we obtain a nested sequence of subdivisions of the grid cell C and an associated tree of filtration factors. Glueing these for all grid cells, we obtain a data structure from which we can compute the exact value of $s^\theta_V(\alpha, \beta)$ by locating α in the nested subdivisions [28, Section 6.4].

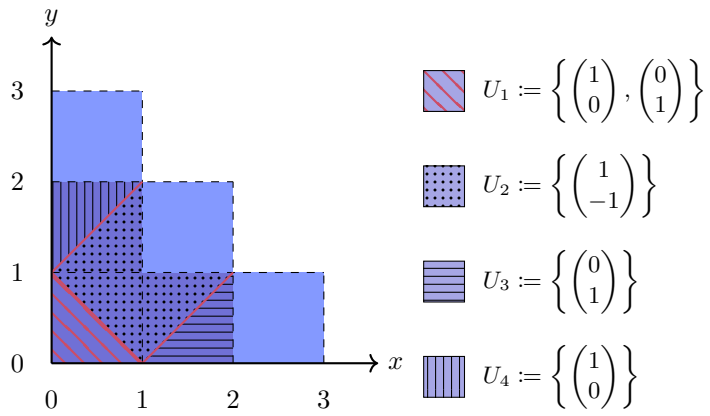

Figure 12 The wall and chamber structure of the stable module from Example 9.

Wall and Chamber Structure. For all β in a region of this nested sequence of subdivisions, the module V has equivalent HN filtrations. This is one implication of Theorem 1.

Parallel grid scanning: The final algorithm. In practice, where one wants to compute filtered vectorisations of the Skyscraper Invariant, it is not a problem to restrict the module to an ε-grid $\mathcal{G}$ and use Algorithm 2. The real power of Theorem 1 and Algorithm 5 lies in the fact that it is a recipe to avoid recomputations: For any direct summand V_i of the input module, the induced grid $\mathrm{Grid}(V_i)$ is typically coarser than $\mathcal{G}$ in some places and finer than $\mathcal{G}$ in others. We therefore overlay the two grids to form the *restriction* or *parallel* grid and use Algorithm 5 only for those cells in each $\mathrm{Grid}(V_i)$ that intersect $\mathcal{G}$. This technique enables fast computation of the Skyscraper Invariant at high resolution.

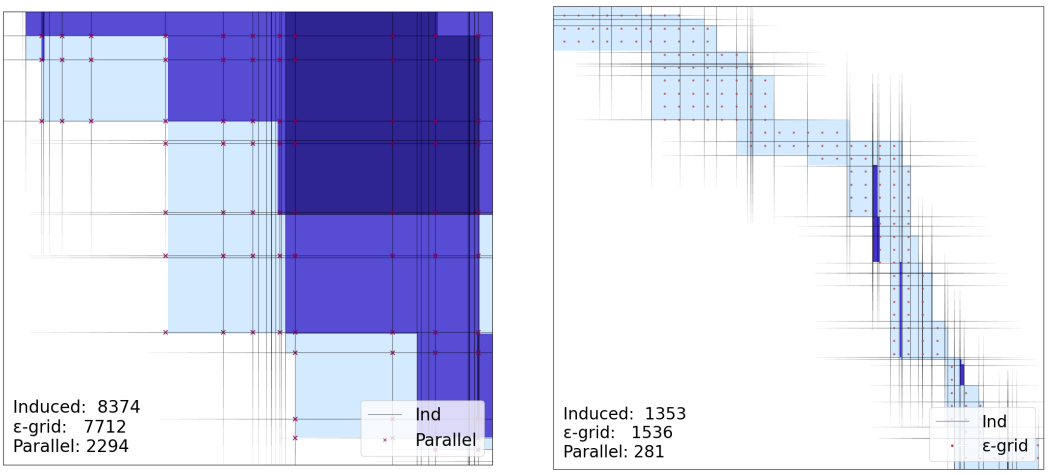

Figure 13 Enlarged detail of the Hilbert functions of $\mathbf{H}_1$ from the dataset [61] used in Section 7. Left: the induced grid in black lines overlaid on the support and the restriction grid marked with purple crosses. Right: the induced grid indicated by black lines and the ε-grid indicated by red dots. Bottom left corners: number of points in the overlaid grids - the parallel grid is much smaller.

6 Experiments

All experiments are performed on an i7-1255U Processor without any parallelisation. A timeout was set to 10 min and each run is averaged over 5 instances whenever possible. Our software and experiments are built using the PERSISTENCE-ALGEBRA C++ library[2].

Harder-Narasimhan filtrations. To generate indecomposable uniquely generated submodules of non-zero thickness we used synthetically generated noisy samples of a torus embedded in $\mathbb{R}^3$ (cf Conjecture 10) and random presentation matrices. We test the exhaustive search Algorithm 3 and its filter Proposition 17. For thickness 9, Algorithm 3 always timed out.

Table 1 Runtime (ms) of Algorithm 3. Columns indexed by dimension/thickness.

Dataset	Variant	2	3	4	5	6	7	8
Torus	with filter	2.2	2.8	5.5	19.5	202	2.7k	–
Torus	w/o filter	2.8	2.8	5.3	18.8	206	2.7k	–
Random	with filter	8.1	4.8	6.4	28.9	454	5.9k	100k
Random	w/o filter	3.6	2.3	5.1	27.1	265	3.6k	61.5k

We conclude that the filter (Proposition 17) for Algorithm 3 is barely helpful.

Runtime of Cheng's algorithm. After restricting the torus generated modules to equidistant grids, we have used Cheng's algorithm (Algorithm 4) over $\mathbb{F}_2$ and $\mathbb{Q}$. Since we can only generate modules from bifiltrations over $\mathbb{F}_2$, we interpreted them as $\mathbb{Q}$-modules when possible.

Table 2 Runtimes of Algorithm 4(ms). An asterisk means that some, and a dash that all instances timed out. Columns are indexed by dimension/thickness, and rows by grid size.

$\mathbb{Q}$ / $\mathbb{F}_2$	2	3	4	5	6	7
2x2	1.9/1.8	1.8/3.0	1.8/4.3	5.0/5.0	4.4/10.3	11.6/33.4
3x3	8.7/18.5	15.2/27.4	21.8/43.2	76.6/157k*	40.8/3.7k	53.0/301
4x4	113/2.0k	1.1k/117k*	412/223*	720/33.6k	499/66.6k	177/38.4k*
5x5	1.8k/154k*	11.8k/283*	36.8k/279k*	11.3k/–	5.2k/254k*	2.7k/–
6x6	61.5k/–	205k/–	323k/–	39.4k/–	66.6k/–	16.1k/–

We observe a great variability of runtimes for Cheng's algorithm depending on whether the heuristic introduced at the end of Section 4 successfully computes and certifies the correctness of all the HN filtrations. The random algorithm from [30] performs computations on square matrices with $\mathfrak{t}(V)^2\varepsilon^{-d}r$ rows for a large enough $r > 0$. For $\mathbf{k} = \mathbb{Q}$ (but not for $\mathbf{k} = \mathbb{F}_2$), we have observed in our experiments that $r = 1$ is large enough.

Comparison. Table 2 shows the strong dependence of Algorithm 4 on the size of the grid to which the uniquely graded module has to be restricted. Algorithm 3 does not require this restriction but, as visible in Table 1, it is highly dependent on the thickness of the input.

[2] `https://github.com/JanJend/Skyscraper-Invariant`, `https://github.com/JanJend/Persistence-Algebra`

The asymptotic runtimes of the algorithms suggest that for practical grids ($> 50 \times 50$), Cheng's algorithm would outperform the exhaustive search not before $\mathfrak{t}(V) \geq 20$. At that point, the number of arithmetic operations is too large for any computer to handle.

Runtime on practical data. We used benchmark data from [39, 61] to compare the parallel grid scan algorithm with Algorithm 2.

Table 3 Runtime (s) over a 50×50 grid on small point sets: density-alpha [63], multicover bifiltrations [59, 17] from sampled spheres and of random points. Number of points in the name.

Data	Circle	D7.5k	D15k	D30k	MC46	MC96	MC175
n	100	140	219	333	3.3k	9.1k	19.6k
Parallel	0.03	0.16	0.42	1.25	0.08	0.41	1.45
Alg 2	1.87	0.47	0.41	0.76	12.68	32.97	73.54

The parallel grid scan should not show the same quadratic dependency on the grid size of Algorithm 2. Table 4 confirms this and shows that our algorithm computes the Skyscraper Invariant in a practical timeframe for relevant data sizes.

Table 4 Runtime (s) on 40k points, uniformly sampled, and 4k locations in hypoxic2 (*grid-size*).

Data	uni 200, $\mathbf{H}_1$	uni 200, $\mathbf{H}_0$	Hyp 20	Hyp 40	Hyp 80	Hyp 160
n	113k	93.5k	9.4k	9.4k	9.4k	9.4k
Parallel	299.7	422.0	54.8	93.4	167.5	311.3

7 Application and Conclusion

Filtered Landscapes. The Multiparameter Landscape [60] is directly defined by the ranks of the diagonal maps $V_\alpha \to V_{\alpha+(t,t)}$. Therefore, we can filter the Landscape by replacing the rank with the Skyscraper Invariant. As an example, we will use the IHC stained sample LargeHypoxicRegion1 of a tumour, for which the authors of [61] analyse the location of immune cells using Multiparameter Landscapes.

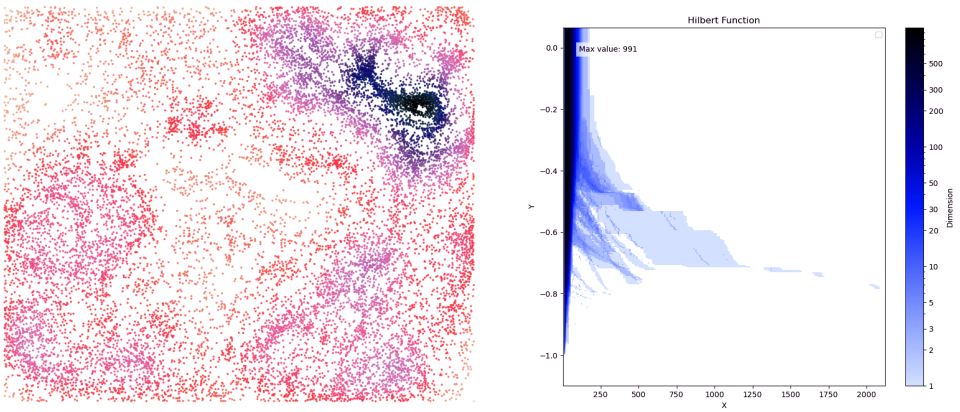

Figure 14 Immune cells in tumor tissue with density estimate and Hilbert function of $\mathbf{H}_1$.

Using MULTIPERS [46], we computed its density-alpha bifiltration with FUNCTION-DELAUNAY [63], a minimal presentation of the first persistent homology group thereof with MPFREE [40], and restricted it to a 300×300 grid. Computing the Skyscraper Invariant on this 35360×25553 matrix took around 5 minutes.

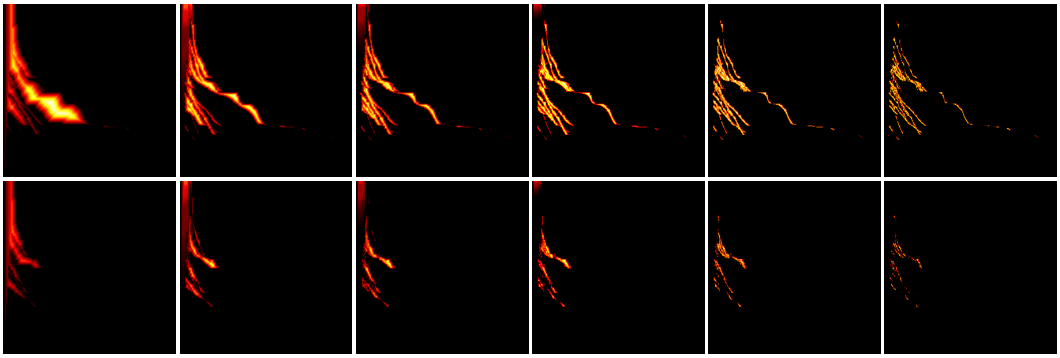

Figure 15 The filtered Landscape for $\mathbf{H}_1$ of Figure 14 with $\theta = 0, 450, 900, \ldots, 7200$ and $k = 1, 2$.

Since the filtered Landscapes are stable [26, Corollary 3.12], their differences are too, revealing elements of *long* lifetime.

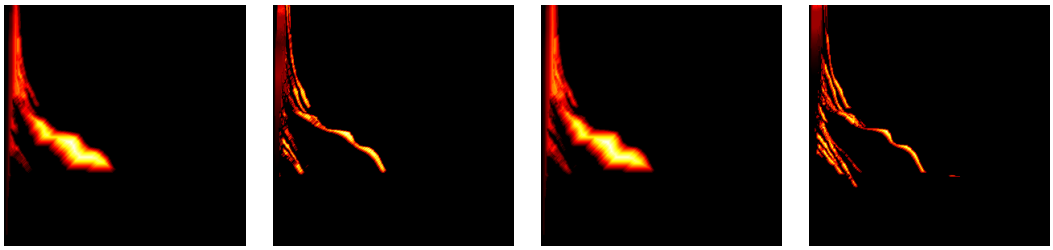

Figure 16 The differences $L_0 - L_1$, $L_1 - L_2$, $L_0 - L_2$, and $L_2 - L_4$ from the first row.

Conclusion. With our algorithms and the induced filtered Landscapes practitioners have a new invariant for topological data analysis that is robust to noise, finer than the rank invariant, efficiently computable, and is interpretable directly from its visual representation.

Open Problems. To incorporate invariants into Machine Learning pipelines, the authors of [58] define a framework which needs to be extended to include the Skyscraper Invariant. Instead of Landscapes, one can also filter other vectorizations of the rank invariant. By changing the stability condition [26], we obtain different HN filtrations and invariants. Can our methods be adapted to this general setting?

For each $\theta \in \mathbb{R}$, the Skyscraper invariant can be Möbius inverted [57], just like the rank invariant [48]. What are the properties of this path?

FPT Approximations for Capacitated Sum of Radii and Diameters

Arnold Filtser
Bar-Ilan University, Ramat Gan, Israel

Ameet Gadekar
CISPA Helmholtz Center for Information Security, Saarbrücken, Germany

Abstract

The Capacitated Sum of Radii problem involves partitioning a set of points P, where each point $p \in P$ has capacity U_p, into k clusters that minimize the sum of cluster radii, such that the number of points in the cluster centered at point p is at most U_p. We begin by showing that the problem is APX-hard, and that under gap-ETH there is no parameterized approximation scheme (FPT-AS). We then construct a ≈ 5.83-approximation algorithm in FPT time (improving a previous ≈ 7.61 approximation in FPT time). Our results also hold when the objective is a general monotone symmetric norm of radii. We also improve the approximation factors for the uniform capacity case, and for the closely related problem of Capacitated Sum of Diameters.

1 Introduction

Clustering is a fundamental problem in several domains of computer science, including, data mining, operation research, and computational geometry, among others. In particular, center based clustering problems such as k-median, k-means, and k-center have received significant attention from the research community for more than half a century [66, 55, 69, 9, 7, 61, 38, 53, 68, 59, 23, 15, 33, 32, 31, 34, 25, 1, 49]. In these problems, we are given a set P of n points together with a distance function (metric) and a positive integer k. The goal is to partition P into k parts called *clusters* and choose a *center* point for each cluster, so that to minimize a clustering objective that is a function of the point distances to their centers. A related fundamental problem that helps reduce *dissection effect* due to k-center [70, 28] (see Figure 1) is called Sum of Radii. Here the goal is to choose k-size subset X of P (called centers, as before) and assign every point to an element in X. This partitions the set P into possible k clusters, $C_1, \cdots, C_k$, where cluster C_i corresponds to the set of points assigned to $x_i \in X$. The radius of cluster C_i centered at $x_i \in X$ is the maximum distance of a point in

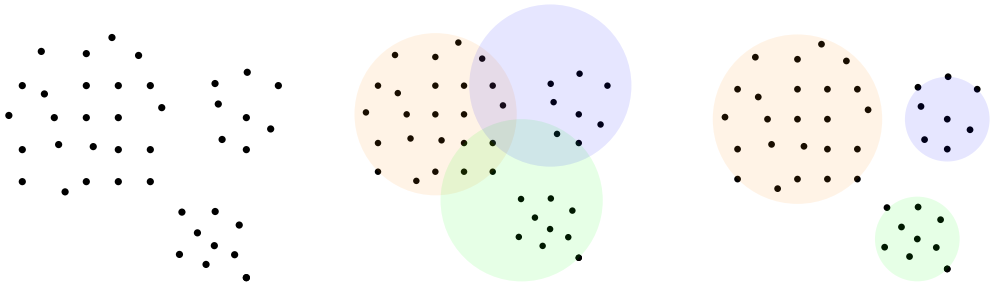

Figure 1 The optimal 3-center solution (middle) splits the ground-truth clusters, whereas the Sum of Radii objective (right) avoids this dissection.

P_i to x_i. The objective is the sum of radii of the clusters $C_1, \cdots, C_k$.[1]

In the recent years Sum of Radii received a great share of interest in all aspects [28, 45, 46, 46, 14, 43, 21, 29, 56, 11, 58, 12, 3, 17, 42, 18]. Nevertheless, its computational landscape is not yet fully understood. While, the problem is NP-hard [45] even in weighted planar graphs and in metrics of bounded doubling dimensions, it is known to admit a QPTAS (quasi polynomial time approximation scheme) [45] in general metrics, thus prompting a possibility of PTAS (polynomial time approximation scheme).[2] This is in contrast to related clustering problems like k-center, k-median, and k-means which are all known to be APX-hard [55, 57, 8]. Currently, the present best known approximation factor in polynomial time is $(3+\varepsilon)$ due to Buchem, Ettmayr, Rosado, and Wiese [21] (improving over previous results of [28, 43]). Additionally, there is a recent $(2+\varepsilon)$-approximation algorithm [29] that runs in FPT time[3] (fixed parameter tractable).

Capacitated clustering

We are interested in a much more challenging generalization where each point p has an inherent capacity $U_p \geq 0$, indicating an upper bound on the number of points it can serve as a center of a cluster in the solution.[4] This is known as the *Non-Uniform Capacitated* clustering problem. If all the points have the same capacity U, the problem is referred to as the *Uniform Capacitated* clustering problem. Capacitated clustering naturally models many applications: in *load balancing*, cluster centers correspond to servers with limited service capacity, the radius captures latency, and minimizing the sum of radii models reducing aggregate latency subject to serve load; in *wireless sensors*, each cluster head can accommodate only bounded number of devices due to bandwidth, memory, or battery limitations, the radius corresponds to communication range, and optimizing the sum of radii reflects minimizing total communication energy. Capacitated clustering is thoroughly studied: Capacitated k-center admits a constant factor approximation in polynomial time for both uniform [60] and non-uniform capacities [37, 5]. There are several bi-criteria polytime approximations for k-median [30, 22, 24, 39, 63, 64].

---

[1] Alternatively, in the Sum of Radii problem we choose centers $x_1, \ldots, x_k \in X$, and radii $r_1, \ldots, r_k \in \mathbb{R}_{\geq 0}$ so that $P \subseteq \cup_{i=1}^{k} \mathsf{ball}(x_i, r_i)$. The objective is to minimize $\sum_{i=1}^{k} r_i$.

[2] If Sum of Radii is APX-hard (equivalently, does not admit a PTAS) then NP$\subseteq$QP (in particular there is a quasi-polynomial time algorithm solving SAT). It is widely believed that NP$\not\subseteq$QP.

[3] In this paper, by FPT time, we mean FPT w.r.t. the parameter k.

[4] Formally, following Footnote 1, a valid solution to the capacitated version also contains an assignment $\sigma : P \to \{x_1, \ldots, x_k\}$ such that if $\sigma(p) = x_i$ then $\delta(p, x_i) \leq r_i$, and for every i, $|\sigma^{-1}(x_i)| \leq U_{x_i}$.

There are FPT approximation algorithms for capacitated k-median and capacitated k-means with approximation factors $(3+\varepsilon)$ and $(9+\varepsilon)$ respectively [35] (improving over [2, 73]). On the other hand, assuming gap-ETH[5], in FPT time it is impossible to approximate k-median and k-means with factors better than $(1+\frac{2}{e})$ and $(1+\frac{8}{e})$, respectively (even without capacities) [32]. There is a $4+\varepsilon$ FPT-approximation for uniform capacitated k-center [58, 50][6].

For capacitated Sum of Radii (CapSoR) (see Table 1 for a summary of previous and new results), Inamdar and Varadarajan [56] constructed an FPT time algorithm providing an 28-approximation for Sum of Radii with uniform capacities. This was later improved to $4+\varepsilon$ by Bandyapadhyay, Lochet, and Saurabh [11], and finally to $3+\varepsilon$ by Jaiswal, Kumar, and Yadav [58]. For non-uniform capacities, the latter paper obtained $(4+\sqrt{13}+\varepsilon) \approx 7.61$ approximation in FPT time, improving over the previous approximation of $15+\varepsilon$ [11].

From the lower bound side, the authors in [58] showed that assuming ETH[7], there is some constant $\beta > 0$, such that any β-approximation for CapSoR (with non-uniform capacities) requires $2^{\Omega(k/\operatorname{poly}\log k)}n^{O(1)}$ time. The first contribution of this paper is to show that CapSoR is APX hard for an explicit factor and even with uniform capacities. That is compared to [58] we removed the ETH assumption, used only uniform capacities, and showed an explicit factor of inapproximability. This is in contrast to the uncapacitated version which is believed to admit a PTAS (assuming $NP \not\subseteq QP$).

▶ **Theorem 1** (APX-hard). *For every constant $\varepsilon > 0$, it is NP-hard to approximate Uniform CapSoR to within a factor of $(1+1/e-\varepsilon)$.*

Earlier, Bandyapadhyay, Lochet, and Saurabh [11] showed that assuming ETH[7], no FPT algorithm can solve CapSoR exactly (even with uniform capacities). However, until this point, nothing ruled out the existence of an FPT-Approximation Scheme (FPT-AS) or PAS for Parameterized Approximation Scheme[8]. The second contribution of this paper is to show that assuming gap-ETH[5], no such FPT-AS exists.

▶ **Theorem 2** (No FPT-AS). *Assuming gap-ETH, for every $\varepsilon > 0$ and any function f, there is no $f(k)n^{o(k)}$ time algorithm that approximates Uniform CapSoR to within a factor of $(1+1/e-\varepsilon)$.*

Note that if we allow $n^{O(k)}$ time, then we can exactly solve Sum of Radii using brute-force, even with non-uniform capacities. Therefore, Theorem 2 not only rules out FPT-approximation algorithms for achieving approximation better than factor of $(1+1/e-\varepsilon)$ for this problem, but also implies that the best algorithm in this context essentially is the naive brute-force algorithm, which runs in $n^{O(k)}$ time.

Next, as the best we can hope for is a constant factor approximation in FPT time, we turn to improving this factor. The main result of the paper is a $(3+\sqrt{8}+\varepsilon) \approx 5.83$ FPT-approximation for non-uniform CapSoR, significantly improving the present best [58]

[5] Informally, gap-ETH says that there exists an $\varepsilon > 0$ such that no sub-exponential time algorithm for 3-SAT can distinguish whether a given 3-SAT formula has a satisfying assignment or every assignment satisfies at most $(1-\varepsilon)$ fraction of the clauses.

[6] In fact, [50] obtained a 2-approximation for capacitated k-center under *soft* assignments (where different centers can be co-located). In contrast, in this paper we consider only *hard* assignments (where we can open only a single center at each point). One can use [50] to obtain a 4-approximation for uniform capacitated k-center w.r.t. hard assignments. See Section 3 for a further discussion.

[7] Informally, ETH (Exponential Time Hypothesis), says that there is no subexponential time algorithm for 3-SAT.

[8] Such algorithms find $(1+\varepsilon)$-approximation in time $f(k,\varepsilon)n^{g(\varepsilon)}$ for some fixed functions f and g.

factor of $(4+\sqrt{13}+\varepsilon) \approx 7.61$. The theorem also mentions cluster capacities and other objectives. These will be explained in the following sub-sections.

▶ **Theorem 3** (Main Theorem). *There is a (deterministic) FPT-approximation algorithm that finds a $(3+2\sqrt{2}+\varepsilon)$-approximation for Non-uniform CapSoR for any $\varepsilon > 0$, and runs in time $2^{O(k^2 \log k + k \log(k/\varepsilon))} n^{O(1)}$. Furthermore, the algorithm yields $(3+2\sqrt{2}+\varepsilon)$-approximation for non-uniform capacities even when the objective is a monotone symmetric norm of the radii.*
Both results hold also w.r.t. cluster capacities.

Table 1 Summary of our results and previous results for CapSoR and CapSoD. The results for CapSoD are implicit in the corresponding references. Furthermore, CapSoD makes sense only for the cluster capacities. While CapSoR with the ℓ_∞ objective corresponds to the Capacitated k-Center problem, CapSoD with the ℓ_∞ objective corresponds to the Capacitated Max-k-Diameter problem. While our algorithms are deterministic for non-uniform capacities, the algorithms for the uniform capacity case are randomized. The inapproximability result, assuming gap-ETH, rules out any $f(k)n^{o(k)}$ time algorithm that can approximate uniform CapSoR (even with ℓ_1 objective) to a factor better than $(1+1/e)$.

1.1 Other norm objectives

In the Sum of Radii problem the goal is to choose k balls covering all the metric points such that the sum of radii $\sum_i r_i$ is minimized. A natural generalization is to optimize alternate objectives. Specifically, given a norm $\|\cdot\| : \mathbb{R}^k \to \mathbb{R}_{\geq 0}$, the task is to choose balls covering all metric points so as to minimize the norm of the radii vector $\|(r_1, \ldots, r_k)\|$. A canonical example is the ℓ_p norm where $\|(r_1, \ldots, r_k)\|_p = \left(\sum_{i=1}^k r_i^p\right)^{1/p}$, which has been studied over two decades [19, 13]. The ℓ_1 norm objective recovers the Sum of Radii problem, while the ℓ_∞ norm objective ($\|(r_1, \ldots, r_k)\|_\infty = \max_{i\in[1,k]} r_i$) corresponds to the classical k-center problem. The other ℓ_p-norm objectives interpolate between these two fundamental problems in clustering. In particular, they capture objectives such as sum of squared radii,[9] which has received attention in practice, especially in wireless network applications where it naturally models power consumption [4, 65]. This perspective further extends to objectives that impose non-uniform weights on the radii, such as ordered weighted norms or cascaded multi-level ℓ_p norms. These allow the norm objective to encode heterogeneous priorities or costs across clusters in practical settings [54]. The strength of such generalizations has been recently studied [27, 1], which not only unified the existing FPT-AS for several different problems such as k-median, k-means, and k-center, but also lead to FPT-AS for advanced problems such as priority k-center [48, 10, 72], ℓ-centrum [71, 62], ordered k-median [25, 20], and Socially Fair k-median [6, 16, 67, 44], many of which were previously unresolved.

The authors in [58] constructed an algorithm for the uniform capacitated Sum of Radii with ℓ_p norm of radii with approximation factor $(1+\varepsilon)(2\cdot 4^{p-1}+1)^{1/p}$ in FPT time. In particular, this implies a $(3+\varepsilon)$ FPT-approximation for uniform capacitated Sum of Radii ($p=1$) and $(4+\varepsilon)$ FPT-approximation[6] for uniform capacitated k-center ($p=\infty$). In our work, we generalize and improve these results. Specifically, we obtain a $(3+\varepsilon)$ FPT-approximation w.r.t. any monotone symmetric norm of radii, thus generalizing the ℓ_p norm objective of [58]. Further, we also improve the approximation ratio for the ℓ_p norm objective to $(1+\varepsilon)(2\cdot 3^{p-1}+1)^{1/p}$.

▶ **Theorem 4** (Uniform). *There is a randomized algorithm for Uniform CapSoR, oblivious to the objective, that runs in $2^{O(k^2+k\log(k/\varepsilon))}n^{O(1)}$ time, and with probability at least $3/5$ returns a solution* Sol*, such that* Sol *is a $(3+\varepsilon)$-approximation w.r.t. any monotone symmetric norm objective (simultaneously). Furthermore, for $1<p<\infty$,* Sol *is a $(1+\varepsilon)(2\cdot 3^{p-1}+1)^{1/p}$-approximation w.r.t. the ℓ_p norm objective.*

For the special case of $p=\infty$, the ℓ_∞ norm objective is simply the k-center problem. Here a simple corollary of Theorem 4 implies $(3+\varepsilon)$ FPT-approximation algorithm for k-center with uniform capacities, improving the state of the art factor of 4 due to [58, 50]. Note that for $p\in(1,\infty]$, the approximation factor of our Theorem 4 is better than that of [58]. In fact, the approximation factor of our algorithm for ℓ_p norm objective equals $\max_{\alpha\in[0,1]}\left(\frac{(2+\alpha)^p+1}{1+\alpha^p}\right)^{1/p}$, which is slightly better than the stated factor. For example, it equals ≈ 2.414 and ≈ 2.488 for $p=2$ and $p=3$, respectively (instead of the stated ≈ 2.65 and ≈ 2.67). Similarly, [58] explicitly claimed approximation factors of 3 and ≈ 3.2, respectively. However, if we optimize their final expression, it yields factors ≈ 2.92 and ≈ 3.191 for $p=2$ and $p=3$, respectively. See the full version for further discussion.

[9] Sum of squared radii is essentially equivalent to the ℓ_2 objective: an α-approximation algorithm for the ℓ_2 objective yields an α^2-approximation to the sum of squared radii.

For non-uniform Capacitated Sum of Radii, [58] obtained approximation factor of $(4+\sqrt{13}+\varepsilon) \approx 7.61$ w.r.t. any ℓ_p-norm objective in $2^{O(k^3+k\log(k/\varepsilon))}n^{O(1)}$ time. As stated in Theorem 3 above, for non-uniform Capacitated Sum of Radii, we obtain approximation factor of $(3+\sqrt{8}+\varepsilon) \approx 5.83$ w.r.t. any monotone symmetric norm objective, in $2^{O(k^2\log k+k\log(k/\varepsilon))}n^{O(1)}$ time. Thus we improve over [58] on three fronts (see Table 1): (1) approximation factor, (2) generalizing to any monotone symmetric norm from ℓ_p norms, and (3) running time.

1.2 Sum of Diameters and cluster capacities

A closely related problem is the Sum of Diameters problem, which has been studied extensively and predates Sum of Radii [51, 52, 70, 26, 40, 28, 14, 40, 43]. Here, the goal is to partition the point set P into k clusters $C_1, \ldots, C_k$, and the objective is to minimize the sum of cluster diameters $\sum_{i=1}^{k} \mathrm{diam}(C_i)$, where the diameter of a cluster is $\mathrm{diam}(C_i) = \max_{x,y\in C_i} \delta(x,y)$ the maximum pairwise distance between two cluster points. Note that, unlike Sum of Radii, in this problem, there are no centers representing the clusters. Furthermore, this problem is NP-hard to approximate to a factor better than 2 in polynomial time [40] (unlike Sum of Radii, which admits a QPTAS). A simple observation shows that any α-factor approximation for Sum of Radii implies 2α-factor approximation for Sum of Diameters in a black-box way (and vice-versa).[10] This trick has often been used to design approximation algorithms for Sum of Diameters. In fact, the current state-of-the-art algorithms for Sum of Diameters, including a polynomial-time $(6+\varepsilon)$-approximation [21] and a quasi-polynomial-time $(2+\varepsilon)$-approximation [45], are based on this implicit trick by applying it to the polynomial-time $(3+\varepsilon)$-approximation and QPTAS for Sum of Radii, respectively.

Capacitated Sum of Diameters

We introduce the problem of Capacitated Sum of Diameters (CapSoD). Here we are initially given k capacities $U_1, \ldots, U_k$, the goal is to partition the point set P into k clusters $C_1, \ldots, C_k$, such that for every i, $|C_i| \le U_i$, while the objective is to minimize the sum of cluster diameters. We call the capacities uniform if all the capacities are equal $U_1 = \cdots = U_k$, and non-uniform otherwise. Under uniform capacities, the reduction mentioned in Footnote 10 goes through. Thus an α approximation algorithm to uniform capacitated Sum of Radii transfers in a black-box manner into a 2α approximation algorithm for the uniform capacitated Sum of Diameters, with the same running time. In particular, by using [58], one can obtain a $6+\varepsilon$-approximation for uniform capacitated Sum of Diameters in FPT time. In fact, similarly to Sum of Radii, one can study Capacitated Sum of Diameters w.r.t. any norm objective, and the reduction will still go through. Thus it follows from [58] that for any ℓ_p norm objective, uniform capacitated Sum of Diameters admits $2(1+\varepsilon)(4^{p-1}+1)^{1/p}$ FPT approximation. Similarly, using our Theorem 4, we can obtain FPT time $6+\varepsilon$ approximation for uniform capacitated Sum of Diameters w.r.t. to any monotone symmetric norm, or $2(1+\varepsilon)(3^{p-1}+1)^{1/p}$-approximation w.r.t. ℓ_p norm objective. Sum of Diameters is a fundamental and important problem. Its capacitated version was not previously explicitly studied simply because there was nothing to say beyond this simple reduction.

[10] Given a set of points P, denote by $\mathcal{R}$ and $\mathcal{D}$ the value of the optimal solutions to Sum of Radii and Sum of Diameters respectively. It holds that $\mathcal{R} \le \mathcal{D} \le 2\cdot\mathcal{R}$. Indeed, consider an optimal solution to Sum of Diameters of cost $\mathcal{D}$, then by picking arbitrary center in each cluster we obtain a solution for Sum of Radii of cost at most $\mathcal{D}$ (thus $\mathcal{R} \le \mathcal{D}$). On the other hand, given a solution to Sum of Radii of cost $\mathcal{R}$, the clusters induced by the balls constitute a solution to Sum of Diameters of cost at most $2\cdot\mathcal{R}$ (thus $\mathcal{D} \le 2\cdot\mathcal{R}$).

In our work, we go beyond this reduction and directly design novel approximation algorithms for capacitated Sum of Diameters with significantly better approximation factors than twice that of Sum of Radii.

▶ **Theorem 5** (Uniform Diameters). *There is a randomized algorithm that given an instance of the Uniform CapSoD runs in $2^{O(k\log(k/\varepsilon))}n^{O(1)}$ time, and with probability at least 3/5 returns a solution* Sol*, such that* Sol *is a $(4+\varepsilon)$-approximation w.r.t. any monotone symmetric norm objective (simultaneously). Furthermore, for $1 < p < \infty$,* Sol *is a $(2+\varepsilon)(2^{p-1}+1)^{1/p}$-approximation w.r.t. the ℓ_p norm objective.*

Finally, we proceed to consider the more challenging problem of non-uniform Capacitated Sum of Diameters. Here we obtain a $7+\varepsilon$ approximation w.r.t. to any monotone symmetric norm objective.

▶ **Theorem 6** (Non-Uniform Diameters). *For any $\varepsilon > 0$, there is a (deterministic) algorithm running $2^{O(k^2+k\log(k/\varepsilon))}n^{O(1)}$-time and returns a $(7+\varepsilon)$-approximation for Non-uniform CapSoD w.r.t. any monotone symmetric norm objective.*

1.2.0.1 Cluster capacities

Bandyapadhyay, Lochet, and Saurabh [11] introduced the problem of Capacitated Sum of Radii where each point $p \in P$ has a capacity U_p, and a cluster centered in p can contain at most U_p points. This corresponds for example to a scenario where we want to construct water wells, and a well constructed at point p can serve up to U_p clients. However, an equally natural problem is where one is given k capacities $U_1, \ldots, U_k$, and the goal is to construct k clusters with arbitrary centers, such that the i'th cluster contains at most U_i points. This problem is similar to our capacitated Sum of Diameters, and can correspond to a scenario where one wants to distribute already existing k water tanks (for example in a tent village during a festival). We refer to the two versions of the problem as node capacities, and cluster capacities, respectively. Note that for uniform capacities the two versions coincide. Further, note that the reduction from Sum of Radii to Sum of Diameters mentioned in Footnote 10 holds in the capacitated version w.r.t. cluster capacities. Our results on node capacities in Theorem 3 hold for cluster capacities as well ($3+2\sqrt{2}+\varepsilon$ approximation for any monotone symmetric norm objective). No results on Sum of Radii with non-uniform cluster capacities were previously known.

Organization. Due to space constraints, we defer all algorithms and technical proofs to the full version. In the next section, we outline the main technical ideas behind our results.

2 Overview of techniques

In this section, we highlight our conceptual and technical contributions. Due to space constraints, we begin with our main theorem (Theorem 3) and present the key ideas behind our algorithm for non-uniform capacities in Section 2.1. Then, in Section 2.2, we delve into the algorithmic ideas for uniform capacities. Note however, that from a pedagogical viewpoint, it is easier to begin reading first Section 2.2, followed by Section 2.1. We now set up basic notations required for the exposition.

Notations. We denote by $\mathcal{I}$ an instance of capacitated Sum of Radii or capacitated Sum of Diameters, depending upon the context. For uniform capacities, $\mathcal{I}$ consists of metric space (P,δ), a positive integer k, and a uniform capacity $U > 0$. The elements in P are called points. For non-uniform node capacities, U is replaced by corresponding node capacities

$\{U_p\}_{p\in P}$, and for non-uniform cluster capacities, U is replaced by corresponding cluster capacities $\{U_1, \cdots, U_k\}$. We denote by $\mathcal{C} = \{C_1, \cdots, C_k\}$ an optimal (but fixed) clustering for $\mathcal{I}$. For ease of analysis, we assume that $|\mathcal{C}| = k$, otherwise, we can add zero radius clusters to make it k, without increasing the cost of $\mathcal{I}$. Note that the clusters in $\mathcal{C}$ are disjoint. When $\mathcal{I}$ is an instance of capacitated Sum of Radii, we denote by r_i^* and o_i as the radius and the center of cluster $C_i \in \mathcal{C}$, respectively, and let $O = \{o_1, \cdots, o_k\}$. In this case, we let $\text{OPT} = r_1^* + \cdots + r_k^*$. When $\mathcal{I}$ is an instance of capacitated Sum of Diameters, we denote by d_i^* as the diameter of cluster $C_i \in \mathcal{C}$. In this case, we let $\text{OPT} = d_1^* + \cdots + d_k^*$. It is known that we can guess in FPT time in k, a set (ε-approximation) $\{r_1, \cdots, r_k\}$ corresponding to $\{r_1^*, \cdots, r_k^*\}$ such that $\sum_{i\in[k]} r_i \leq (1+\varepsilon) \cdot \sum_{i\in[k]} r_i^*$ and $r_i \geq r_i^*$. Similarly, let $\{d_1, \cdots, d_k\}$ denote ε-approximation of $\{d_1^*, \cdots, d_k^*\}$. A feasible solution to $\mathcal{I}$ is a partition of P (along with centers for Sum of Radii) such that the capacities are respected. For a point $p \in P$ and a positive real r, denote by $\mathsf{ball}(p, r)$ as the set of points from P that are at a distance at most r from p.

▶ Remark 7 (Point assignment using matching and flows). In this section (and throughout the paper), we will focus on presenting a set of centers and their corresponding radii as our solution. This approach suffices because, given such a set of centers and radii, we can determine in polynomial time whether there exists a corresponding feasible solution (i.e., feasible assignment of points to the centers/clusters) with the same cost. Moreover, we can also find such a solution by defining an appropriate flow problem (see the full version).

▶ Remark 8 (FPT and bounded guessing). We assume that our algorithms have a power to make $\text{poly}(k)$ guesses each with success probability $p(k)$. Such algorithms can be transformed into a randomized FPT algorithms that are correct with constant probability. See the full version for more details.

2.1 Non-uniform capacitated Sum of Radii

For ease of exposition, in this technical overview we highlight our ideas for cluster capacities (see paragraph 1.2.0.1). Transitioning to node capacities introduces several more challenges which we will not discuss here. Other than the basic FPT framework mentioned in the preliminaries above, our algorithm is fundamentally different from these of [11, 58], and hence we do not attempt to compare them (in contrast, for uniform capacities the algorithms are similar).

Consider the following simple and natural strategy of processing clusters in $\mathcal{C}$ iteratively (see the full version for pseudo-code). Initially all the clusters in $\mathcal{C}$ are unprocessed (colored red). We will process the clusters in $\mathcal{C}$ in non-decreasing order of their radii, denoted as $C_1, \cdots, C_k$. Let $U_1, \cdots, U_k$ be the corresponding cluster capacities. Consider the first iteration when we process C_1. Suppose we could find a dense ball $D_1 = \mathsf{ball}(y_1, r_1)$ of radius r_1 in P such that $|D_1| \geq |C_1|$. Then, we could create a cluster $C_1' \subseteq D_1$ of size $|C_1|$[11] with radius r_1, matching the optimal cost. To make this cluster permanent, we delete the points from D_1 to prevent them from being reassigned in later iterations. However, this could create problems – (i) C_1' may contain points from other clusters, so in the future iterations when we process these clusters then the densest ball may not have enough points, and (ii) we need to make sure the points of C_1 are taken care by some cluster in our solution. Our algorithm is based on the following two key ideas that handle these two issues:

[11] Even though $|C_1|$ is unknown, in retrospect, we will be able to use Remark 7 to obtain such a clustering.

Invariant: do not touch the unprocessed. We ensure that, throughout the algorithm, every unprocessed cluster in $\mathcal{C}$ has all of its points intact. In other words, during the processing iteration of C_i, all its points are present.

Making progress: Good dense balls. An immediate implication of the above invariant is that when we process C_i, there is a ball of radius r_i containing at least $|C_i|$ points. Let $D_i = \mathsf{ball}(y_i, r_i)$ be the densest ball w.r.t. the remaining points during the iteration of C_i. Note that such a ball contains at least $|C_i|$ points due to the above invariant. Consider the smallest radius cluster $C_j \in \mathcal{C}$ that intersects D_i, and call C_j the *anchor* for D_i. See top-left figure in Figure 3, where D_i is the ball centered at y with radius r_i, $C_i = C_5$ and $C_j = C_8$. Now, consider the extended ball $D'_i := \mathsf{ball}(y_i, r_i + 2r_j)$, and note that $C_j \subseteq D'_i$. Now, if C_i intersects D'_i, then C_i is not far from y_i (see top-right figure in Figure 3). In this case, we call D_i a good dense ball, and will be able to process C_i. Thus, our first goal when processing the cluster C_i is to find a good dense ball.

Finding good dense ball in FPT time. Suppose D'_i does not intersect C_i, then we can temporarily delete $D'_i = \mathsf{ball}(y_i, r_i + 2r_j)$ since this ball does not contain any point of C_i (see top-left figure in Figure 3, where $C_i = C_5$ and $C_j = C_8$). Furthermore, we end up deleting at least one cluster (specifically, C_j), so this process of temporarily deleting balls can repeat at most k times before C_i intersects the extended ball D'_i. Once we have a good dense ball $D_i = \mathsf{ball}(y_i, r_i)$ for C_i, consider the extended ball $D'_i := \mathsf{ball}(y_i, r_i + 2r_j)$, where r_j is the radius of the anchor C_j for D_i. There are two cases:

Case 1: Hop through the anchors. Suppose we are lucky, and it turns out that $r_j \leq r_i$. Then, y_i can serve all the points of C_i within radius $3r_i + 2r_j \leq 5r_i$. See top-right figure in Figure 3, where $C_j = C_3$. We now mark C_i as processed (color black). Note that, in this case, we do not delete any points.

Case 2: Otherwise "Exchange". Suppose we are not lucky, and it turns out that $r_j > r_i$ (see bottom-left figure in Figure 3 where $r_i = r_5 > r_8 = r_j$). In this case, our basic approach is to open the cluster C_i at D_i, and thus relieving the clusters intersecting D_i from their responsibility for these points. In exchange, these clusters will become responsible for C_i points. The crux of the argument is that as the anchor C_j has the minimal radius among the clusters intersecting D_i, each such cluster C_q has radius larger than r_i. Thus from C_q's perspective, the points of C_i are "nearby". Hence C_q can accept responsibility for a number of C_i points proportional to the number of C_q points taken (and thus everybody is taken care of).

In more details: we create a new cluster $C'_i \subseteq D_i$ out of the points in D_i (recall $|D_i| \geq |C_i|$ and see Footnote 11). To make this assignment permanent, we delete D_i, and mark C_i as processed (color black). However, we end up taking points from other clusters (and also end up deleting points from these clusters). The key observation is that as we process the clusters in non-decreasing order and $r_j > r_i$, D_i does not contain points from clusters processed via Case 1. Since we maintain the invariant that the points of unprocessed clusters are not deleted, we have to mark the clusters intersecting D_i as processed (color black). However, before marking these clusters as processed, we need to ensure that they are accounted for in our solution. To this end, we use a novel idea of exchanging points. Since we have created a new cluster C'_i out of D_i, any cluster $C_{j'}$ that has lost, say, $n_{j'} > 0$ points in this process, can instead claim back $n_{j'}$ points from the original cluster C_i (depicted by islands in C_5 in bottom-left figure in Figure 3) by paying slightly more cost since, in this case, we have $r_i < r_j \leq r_{j'}$. Here, we use the fact that C_j is the anchor for D_i, and hence r_j is the smallest radius intersecting D_i. We call such clusters partitioned clusters. Specifically, the radius of

the partitioned $C_{j'}$ is at most $\delta(o_{j'}, y_i) + \delta(y_i, p) \leq (r_{j'} + r_i) + (r_i + 2r_j + 2r_i) \leq 7r_{j'}$, for $p \in C_i$, as $r_j \leq r_{j'}$. See bottom-left figure in for an illustration. Note that a cluster $C_{j'}$ can be partitioned multiple times by different C_i's (we track the clusters that partitioned $C_{j'}$ by $\mathsf{Partitions\text{-}of}(C_{j'})$), as shown in bottom-right figure in Figure 3. However, $o_{j'}$ can still serve all the points of the modified $C_{j'}$ within cost $7r_{j'}$, since, in this case, the radii of the clusters partitioning $C_{j'}$ are strictly less than $r_{j'}$. While it is hard to find $o_{j'}$, in the full version, we show how to find another point that can serve all the points of the partitioned cluster $C_{j'}$ within radius $7r_{j'}$.

Note that, we get different approximation factors in Case 1 and Case 2. In the technical section, we interpolate between these two factors to obtain an improved approximation factor for the algorithm.

2.2 Uniform capacities

Our algorithm builds upon the algorithm of [58]. The algorithm divides the clusters in $\mathcal{C}$ into two categories: heavy and light. A cluster $C \in \mathcal{C}$ is *heavy* if $|C| > U/k^3$; otherwise, it is a *light* cluster. The intuition behind this partition is the following: some heavy cluster must exist, and given such heavy cluster $C \in \mathcal{C}$, a randomly selected point from P belongs to C with probability at least $\text{poly}(1/k)$. Therefore, with probability at least $k^{-O(k)}$, we can obtain a set $X \subseteq P$ containing a single point x_i from every heavy cluster $C_i \in \mathcal{C}$. For every heavy cluster C_i, we wish to open a cluster $B_i = \mathsf{ball}(x_i, 2r_i)$ that will take care of C_i points (note $C_i \subseteq B_i$). We will assume that the union of these balls, $\cup_{x_i \in X} B_i$, covers the point set P (this assumption catches the essence of the problem, as we can greedily take care of light clusters not covered by this union). Let $\mathcal{L} \subseteq P$ be the set of points corresponding to the light clusters in $\mathcal{C}$. For each light cluster $C_t \in \mathcal{C}$, arbitrarily assign it to a heavy cluster $C_i \in \mathcal{C}$ such that C_t intersects B_i. Then, for each heavy cluster C_i, consider the set $S_i := C_i \cup (\mathsf{ball}(x_i, 2r_i + 2r_{\ell(i)}) \cap \mathcal{L})$, where $r_{\ell(i)}$ is the maximum radius of a light cluster assigned to C_i. Note that S_i contains C_i, and all the light clusters assigned to C_i. If $|S_i| \leq U$, then we can open cluster $C'_i = S_i$ without violating the uniform capacity. For the other case, note that $|S_i| \leq (1 + 1/k^2)U$ since there can be at most k light clusters assigned to C_i, each of which has at most U/k^3 points. Let $I \subseteq [k]$ be the indices of heavy clusters, and let $I' \subseteq I$ be the indices of heavy clusters for whom S_i violated the capacity constraint. [58] used a very neat matching based argument to construct $|I'|$ balls $\{\hat{C}_i\}_{i \in I'}$ each with a unique radius from $\{r_i\}_{i \in I}$ (the heavy clusters) such that $\cup_{i \in I'} \hat{C}_i$ contains at least U/k^2 points from each S_i (for $i \in I'$). These clusters $\{\hat{C}_i\}_{i \in I'}$ are then used to unload enough points from the overloaded heavy clusters. Now, $\{\mathsf{ball}(x_i, 2r_i + 2r_{\ell(i)})\}_{i \in I}$ together with $\{\hat{C}_i\}_{i \in I'}$ is a valid feasible solution. The ℓ_1 norm cost (CapSoR cost) of this solution is bounded by $\sum_{i \in I}(2r_i + 2r_{\ell(i)}) + \sum_{j \in I} r_j \leq 3 \sum_{i \in [k]} r_i \leq (3 + \varepsilon)\text{OPT}$, where we used that fact that $C_{\ell(i)}$ is distinct for each C_i, and that in $\cup_{i \in I'} \hat{C}_i$ we used the radius of every heavy cluster at most once. On the other hand, the ℓ_∞ cost (Capacitated k-Center) can only be bounded by $(4 + \varepsilon)\text{OPT}$. It is also possible to bound the approximation factor for general ℓ_p norm objective.

Improvement for ℓ_p norm objectives

Our modification to get a better factor is very small, but leads to a significant improvement. Specifically, we fine tune the definition of $C_{\ell(i)}$ for C_i. [58] assigned each light cluster C_j to an arbitrary heavy cluster C_i such that C_j intersects the extended ball B_i, and let $r_{\ell(i)}$ to be the maximum radius of a light cluster assigned to C_i. Instead, we assign each light

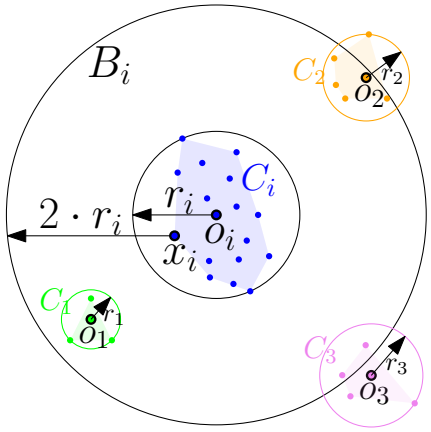

Figure 2 The sampled point x_i belongs to the heavy cluster, C_i.

cluster C_j to an arbitrary heavy cluster C_i such that B_i contains its center o_i, while $r_{\ell(i)}$ remains the maximum radius of a light cluster assigned to C_i. The crux is that now the ball $\mathsf{ball}(x_i, 2r_i + r_{\ell(i)})$ contains the heavy cluster C_i and all the light clusters assigned to it. In the example shown in Figure 2, we consider a heavy cluster C_i, where we sampled a point $x_i \in C_i$ and consider the ball $B_i = \mathsf{ball}(x_i, 2r_i)$. B_i intersects 3 light clusters (C_1, C_2, C_3) with radii $r_1 < r_2 < r_3$. Now $r_{\ell(i)} = r_2$ because $o_2 \in B_i$, while $o_3 \notin B_i$. As previously, we open clusters of two types: (1) for every heavy cluster C_i, a cluster C'_i centered at x_i of radius $2r_i + r_{\ell(i)}$, and (2) the clusters $\{\hat{C}\}_{i \in I'}$ relieving the extra load. Overall, we save a factor of $r_{\ell(i)}$ in the radius of the cluster centered at x_i. Note that this solution yields a 3 approximation w.r.t. the ℓ_∞ norm objective (Capacitated k-Center), and yields a similar improvement w.r.t. other ℓ_p norm objectives.

2.3 Hardness of FPT-approximation for uniform capacities

Our hardness result is based on a polynomial time reduction from Max k-Coverage (Max k-Cov), where, given a universe $\mathcal{G}$ of elements, a positive integer k, and k collections $\{\mathcal{C}_1, \ldots, \mathcal{C}_k\}$ of subsets of G, the task is to find $\{S_1, \ldots, S_k\}$ such that $S_i \in \mathcal{C}_i, i \in [k]$ that maximizes the number of elements covered. It is known that Max k-Cov is NP-hard to approximate to a factor better than $(1 - 1/e)$, even when every set in the collection has precisely $|\mathcal{G}|/k$ elements. Under gap-ETH, there is no $\mathsf{FPT}(k)$ algorithm for Max k-Cov that approximates to a factor better than $(1 - 1/e)$, even when every set in the collection has precisely $|\mathcal{G}|/k$ elements

On a high level, given an instance of Max k-Cov, we create the set-element incidence graph of the instance. We then add edges between the vertices corresponding to the sets of the same collection. Let $G = (V, E)$ be the resulting graph. The points of our CapSoR instance corresponds to the vertices in V, and the distance metric is given by the shortest path distance in G. Finally, we set the uniform capacity $U = |\mathcal{G}|/k + m$. It is easy to see that when there are k sets $\{S_1, \ldots, S_k\}$ such that $S_i \in \mathcal{C}_i, i \in [k]$ that cover $\mathcal{G}$, then we can find a solution for CapSoR with cost k, by selecting the points corresponding to the sets $\{S_1, \ldots, S_k\}$ as the centers. For the No case, observe that any solution to CapSoR must have clusters of size precisely U due to our construction. This simple observation forces the centers to belong to different collections, yielding the result.

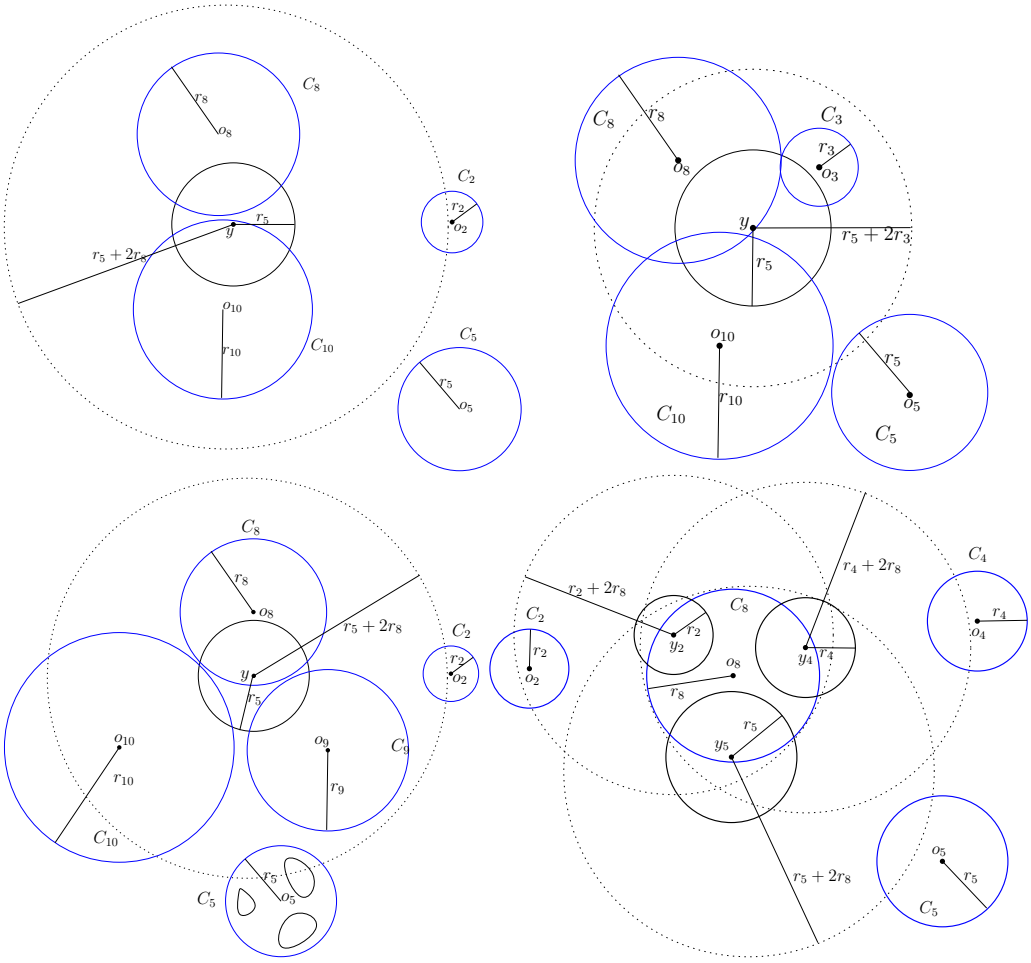

Figure 3 Top-Left figure shows a dense ball $\mathsf{ball}(y, r_5)$, colored in black, that is not good for cluster C_5, because $\mathsf{ball}(y, r_5 + 2r_8)$ is disjoint from C_5. Hence, it is safe to (temporary) delete $\mathsf{ball}(y, r_5 + 2r_8)$ without affecting cluster C_5, and recursively search for good dense ball for C_5 in the remaining points. On the other hand, the $\mathsf{ball}(y, r_5)$ of Top-Right figure is good dense ball for C_5. Furthermore, note that in this case the radius of the anchor $r_3 \leq r_5$, and hence y can serve all the points of C_5 within distance $3r_5 + 2r_3 \leq 5r_5$. In Bottom-left figure, the radius of the anchor is $r_8 > r_5$, and hence the previous argument fails. However, in this case, since $\mathsf{ball}(y,r_5)$ is a good dense ball for C_5, so we can open a new cluster $C_5' \subseteq \mathsf{ball}(y, r_5)$ of appropriate size, instead of serving the points of C_5. Note that, in this case, the new cluster C_5' ends up taking points from clusters C_8, C_9 and C_{10}. However, these clusters can claim back the lost points from the original cluster C_5 (depicted by islands in C_5), which is not too far from them. In this case, we say that C_8, C_9 and C_{10} are partitioned by C_5'. Bottom-right figure shows cluster C_8 partitioned by C_2, C_4 and C_5, and it has to collect its lost points from the respective clusters.

3 Further related work

We begin with further background on the (uncapacitated) Sum of Radii and Sum of Diameters problems. When the point set P is from either ℓ_1 or ℓ_2 there is an exact poly-time algorithm [45], while there is also an EPTAS for the Euclidean (ℓ_2) case [45]. Another interesting case is when the metric between the input points P corresponds to the shortest path metric of an unweighted graph G. Here, assuming the optimal solution does not contain singletons

(clusters with only a single point), there is a polynomial time algorithm finding optimal solution [14]. The Sum of Diameters with fixed k admits exact polytime algorithm [14] (see also [51, 26]). Further, there is a PTAS for Sum of Diameters where the input points are from the Euclidean plane [14]. The Sum of Radii problem was also studied in the fault tolerant regime [17], considering outliers [3], and in an online (competitive analysis) setting [42, 36].

Capacitated k-Center is a special case of capacitated ℓ_p norm of radii when $p = \infty$. The uniform Capacitated k-Center problem has been explicitly studied by Goyal and Jaiswal [50], and is also implicitly captured by the results of [58]. Goyal and Jaiswal design a factor 2 FPT-approximation for the soft assignment setting, where multiple centers can be opened at a single point, enabling it to serve more than U points. For instance, the algorithm can opt to open two centers at a point $p \in P$, thereby allowing up to $2U$ points to be served from location p. In contrast, similar to this paper, [58] focus on the hard assignment scenario, where at most one center can be opened at a given point, and they present a $(4 + \varepsilon)$ FPT-approximation for this case. We are not aware of any approximation preserving subroutines that transform a soft assignment algorithm to a hard assignment algorithm. However, by replacing the chosen center with any other point in the cluster one can obtain a solution with hard assignments while incurring a factor 2 multiplicative loss in approximation. Consequently, the algorithm of [50] can only yield 4 FPT-approximation using this approach, which matches the factor of [58].

Capacitated Max-k-Diameter is a special case of capacitated ℓ_p norm of diameters problem when $p = \infty$. Its uncapacitated version turns out to be computationally very challenging. While there is a simple 2-approximation for Max-k-Diameter [47], it is NP-hard to approximate the problem better than factor 2 in ℓ_∞ metric even for $k = 3$ [69]. Very recently, Fleischmann [41] showed that, even for $k = 3$, the problem is NP-hard to approximate better than factors 1.5 and 1.304 when the points come from ℓ_1 and ℓ_2 metrics, respectively. Given that these hardness results hold for constant k (i.e., even for $k = 3$), they also translate to FPT lower bounds. Thus, these hardness results imply that no FPT algorithm can beat these lower bounds for Max-k-Diameter, unless P = NP. Of course, the corresponding capacitated version of Max-k-Diameter is a generalization of Max-k-Diameter, and hence these FPT-hardness of approximations also hold for the capacitated version. For upper bounds, it is interesting to note that the reduction from Sum of Radii to Sum of Diameters mentioned in Footnote 10 works even when solving Sum of Radii w.r.t. soft assignments. Thus using [50] one can obtain a 4 FPT-approximation for the uniform Capacitated Max-k-Diameter problem, matching our Theorem 5 for this case.

Abstract

In the d-Euclidean Distance Matrix Completion (d-EDMC) problem, one aims to determine whether a given partial matrix of pairwise distances can be extended to a full Euclidean distance matrix in d dimensions. This problem is a cornerstone of computational geometry with numerous applications. While classical work on this problem often focuses on exploiting connections to semidefinite programming typically leading to approximation algorithms, we focus on exact algorithms and propose a novel *distance-from-triviality parameterization* framework to obtain tractability results for d-EDMC.

We identify key structural patterns in the input that capture entry density, including chordal substructures and coverability of specified entries by fully specified principal submatrices. We obtain:

1. The first fixed-parameter algorithm (FPT algorithm) for d-EDMC parameterized by d and the maximum number of unspecified entries per row/column. This is achieved through a novel *compression algorithm* that reduces a given instance to a submatrix on $\mathcal{O}(1)$ rows (for fixed values of the parameters).
2. The first FPT algorithm for d-EDMC parameterized by d and the minimum number of fully specified principal submatrices whose entries cover all specified entries of the given matrix. This result is also achieved through a compression algorithm.
3. A polynomial-time algorithm for d-EDMC when both d and the minimum fill-in of a natural graph representing the specified entries are fixed constants. This result is achieved by combining tools from distance geometry and algorithms from real algebraic geometry.

Our work identifies interesting parallels between EDM completion and graph problems, with our algorithms exploiting techniques from both domains.

1 Introduction

Consider the following problem: given an $n \times n$ symmetric hollow matrix M, and integer d, determine whether M is a Euclidean Distance Matrix (EDM) that is isometrically embeddable into $\mathbb{R}^d$, also said to be *realizable in* $\mathbb{R}^d$. In other words, determine whether there exists a set $P = \{p_1, \ldots, p_n\}$ of n points in $\mathbb{R}^d$ such that $M_{ij} = \|p_i - p_j\|_2^2$, where M_{ij} denotes the (i,j)-th entry of M, and $\|p_i - p_j\|_2$ is the Euclidean distance between p_i and p_j. This question of determining the existence of such a point configuration P (up to congruence) is a central problem in Distance Geometry, whose solution is well understood and dates back to the works of Cayley [13] and Menger [34].

In this paper, we are interested in the version of this problem where the matrix M is *partial*, i.e., some entries may be "unspecified." In this version, called d-EDM Completion (d-EDMC), the goal is to decide whether the missing entries in a matrix can be filled in so that the result is an EDM that can be realized in $\mathbb{R}^d$. In general, such questions of reconstructing point configurations from *partial* distance measurements naturally occur across numerous disciplines. The study of d-EDMC in particular, goes back to mathematicians and mechanical engineers of the nineteenth century – see, for example, the work of Cauchy from 1813 [12] – and is at the heart of rigidity theory. This problem has many applications in different areas, such as molecular conformation in bioinformatics [31, 15, 14], dimensionality reduction in machine learning and statistics, and localization in wireless sensor networks [3, 21, 9].

Saxe [35] and Yemini [40] showed that the d-EDMC problem is already *strongly* NP-hard in dimensions $d = 1$ and $d = 2$. While numerous heuristics for solving d-EDMC under specific structural assumptions on M have been proposed in the literature [23, 39, 8, 11], *theoretical* results with provable performance guarantees are scarce. This lack of rigorous algorithmic understanding of the problem is a primary motivation for us to explore the computational complexity of this problem and in particular, its parameterized complexity.

In this work we adopt the *distance-from-triviality* viewpoint to study the complextity of d-EDMC. Distance-from-triviality is a well-established paradigm in parameterized complexity, where the idea is to introduce a parameter (or a combination of parameters) that measures how far a given instance lies from a class that can be solved efficiently; algorithms then exploit this "distance" to achieve tractability.

What is the notion of "triviality" for d-EDMC*?* Two natural extremal cases suggest themselves.

1. *All entries are unspecified.* If no entry of the matrix is given, *any* Euclidean distance matrix of the appropriate size is a valid completion, so the instance is trivial. Unfortunately, even a very small deviation from this case already yields hardness: Saxe's reduction [35] shows NP-hardness when each row and column contains *exactly two* specified entries. Consequently, parameterizing by distance to the completely unspecified matrix appears unpromising.

2. *All entries are specified.* At the opposite extreme, when every entry is given, one need only test whether the matrix is an EDM that embeds isometrically into $\mathbb{R}^d$, a task solvable in polynomial time. As we show in this paper, distance to this notion of "triviality" is a much more interesting parameter.

We may therefore formulate our main question as follows.

> Which notions of distance to a fully specified matrix can be exploited algorithmically for d-EDMC?

From the standpoint of algorithms with provable guarantees, this question is largely unexplored. A notable exception is the work of Berger, Kleinberg, and Leighton [7]. They show that if, in every row of an $n \times n$ partial matrix M, at least $3n/4+1$ entries are specified, then one can decide in polynomial time whether M can be completed to a 3-EDM. There is, however, a crucial caveat: their theorem assumes that the target point set is in *general position* and that no ten points lie on a quadric surface. We make no such assumptions – the points to be embedded need not be in general position or even distinct – rendering the problem substantially more realistic but also more challenging.

1.1 Our results and methods

We begin by observing that high density of specified entries (or, equivalently, a numerical sparsity of unspecified entries) does not by itself make the problem any easier. To exploit sparsity algorithmically, one must therefore identify and leverage additional *structural properties* that reflect the density of entries.

▶ **Theorem 1.** *$\forall \varepsilon \in (0,1)$, d-EDMC remains strongly* NP*-hard even for instances (M,d) with $d=2$ in which the $n \times n$ matrix M contains at most εn unspecified entries.*

The proof of the theorem is an adaptation of the classic complexity result of Saxe [35]. It also underscores that the general-position assumptions employed by Berger, Kleinberg, and Leighton [7] is essential for their polynomial-time algorithm.

1.1.1 Distance from triviality I

Our first main algorithmic result shows that imposing even a mild structural constraint on the unspecified entries – beyond mere numerical sparsity – makes the problem tractable. Our notion of density of a matrix is expressed by *forbidden t-block patterns*.

▶ **Definition 2** (t-block pattern)**.** For an $n \times n$ matrix M and disjoint sets $I_1, I_2 \subseteq [n]$, we define by $M[I_1, I_2]$ the submatrix of M indexed by the rows in I_1 and the columns in I_2. We say that $M[I_1, I_2]$ is a *t-block pattern* if it is a $t \times t$ submatrix of M where every entry is unspecified. We say that M *excludes* a t-block pattern if there is no I_1 and I_2 such that $M[I_1, I_2]$ is a t-block pattern. See top of Figure 1.

▶ **Example 3.** Consider a partial matrix M. M excludes a 1-block pattern if and only if it is fully specified; if M has at most Δ unspecified entries in total, then M excludes a $\lfloor\sqrt{\Delta+1}\rfloor$-block pattern; if each row of M contains at most Δ unspecified entries, then M excludes a $(\Delta+1)$-block pattern.

We are now ready to state our first tractability result. By *solving* an instance of d-EDMC, we mean deciding[1] whether the answer is yes or no. We also say that an instance (M,d) is *equivalent* to an instance (M',d') if solving both instances leads to the same answer.

▶ **Theorem 4** (Compression for $K_{t,t}$-free complements)**.** *There is a polynomial-time algorithm that, given an instance (M,d) of d-EDMC in which M excludes a t-block pattern for some $t \geq 1$, either solves the problem, or outputs an equivalent instance (M',d), such that M' is a principal submatrix of M with $(d+1)^{\mathcal{O}(t^2)}$ rows and columns.*

[1] As is standard in Computational Geometry, all our algorithms operate under the *real RAM* computational model, assuming that basic operations over real numbers can be executed in unit time.

$$\begin{bmatrix} 0 & * & * & * & * & 2 & * & * & * \\ * & 0 & 1 & * & * & * & * & * & * \\ * & 1 & 0 & * & * & * & * & 2 & * \\ * & * & * & 0 & 1 & * & * & * & 2 \\ * & * & * & 1 & 0 & 1 & * & * & * \\ 2 & * & * & * & 1 & 0 & 1 & * & * \\ * & * & * & * & * & 1 & 0 & * & * \\ * & * & 2 & * & * & * & * & 0 & * \\ * & * & * & 2 & * & * & * & * & 0 \end{bmatrix}$$

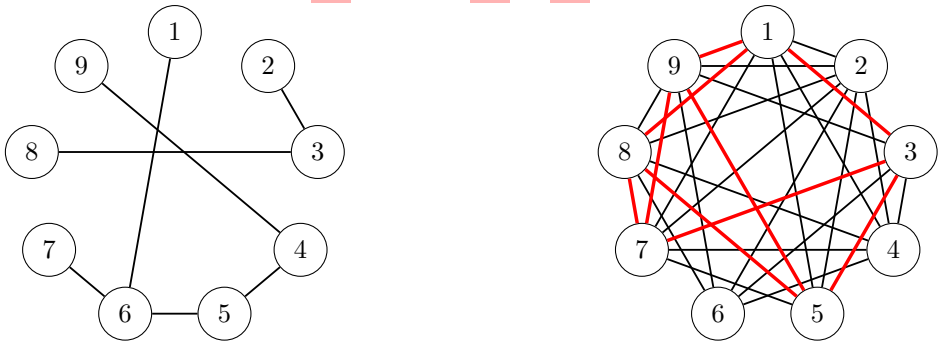

Figure 1 Top: A 9×9 partial matrix M that excludes 4-block pattern. It contains a 3-block pattern formed by rows $\{3, 8, 9\}$ and columns $\{1, 5, 7\}$. Bottom Left: the graph G underlying the partial EDM matrix M. The adjacencies of G are formed by the unspecified entries in the matrix. Bottom Right: the complement graph $\overline{G}$ induced by the unspecified entries of M. The red edges of $\overline{G}$ form $K_{3,3}$, however $\overline{G}$ does not contain $K_{4,4}$.

The algorithm in Theorem 4 compresses the input instance in polynomial time to an equivalent matrix whose size is independent of n. This compression, however, does not guarantee that the numerical entries of the reduced matrix depend only on the parameters t and d; hence it is not a kernel in the strict parameterized complexity sense [17, 25].

Moreover, Theorem 4 by itself does not yield a complete algorithm for solving d-EDMC and we need the following algorithm, which relies on tools from real algebraic geometry.

▶ **Theorem 5.** *There is an algorithm that, given an $n \times n$ partial matrix M and $d \in \mathbb{N}$, runs in time $2^{\mathcal{O}(n^2 \log n)}$ and correctly decides whether (M, d) is a yes-instance of* d-EDMC.

Now, by combining Theorem 4 with Theorem 5, we obtain the following FPT algorithm for d-EDMC with parameters d and t.

▶ **Corollary 6.** *For every $d, t \in \mathbb{N}$, and $n \times n$ partial matrix M excluding a t-block pattern,* d-EDMC *is solvable in time $2^{(d+1)^{\mathcal{O}(t^2)}} + n^{\mathcal{O}(1)}$.*

▶ Remark 7 (Generality of Theorem 4 and Corollary 6). A common way to capture the structure of a partial matrix, see e.g. [2, 7], is to encode it by an underlying graph G as follows. Let G be a graph with vertex set $V(G) = \{1, \ldots, n\}$. An $n \times n$ symmetric hollow partial matrix $M = (m_{ij})$ is said to be a *G-partial* matrix if the entry m_{ij} is specified[2] if and only if $ij \in E(G)$. We refer to G as the *underlying graph* of M, see Figure 1. By studying partial

[2] In this paper, the specified entries of M will always be in $\mathbb{R}_{\geq 0}$.

matrices through a graph-theoretic lens motivated by this defintion, we can identify direct correspondences between their properties and those of their underlying graphs. The condition of Theorem 1 also translates naturally to the property that the average vertex degree of $\overline{G}$ is at most ε. For instance, saying that a partial matrix M excludes a t-block pattern is equivalent to saying that the complement $\overline{G}$ of its underlying graph G does not contain the complete bipartite graph $K_{t,t}$ as a subgraph.

Although Theorem 1 shows that d-EDMC remains intractable even on matrices where the underlying graph's complement has constant average degree, Theorem 4 and Corollary 6 demonstrate that imposing $K_{t,t}$-freeness on the complement of the underlying graph (i.e., excluding a t-block pattern in the input matrix) radically alters the complexity landscape and leads to tractability for a large class of instances.

Many widely studied graph classes with numerous applications can be expressed as $K_{t,t}$-free graphs for a suitable t. In particular, planar graphs are $K_{3,3}$-free by Kuratowski's theorem, graphs excluding a fixed minor H are $K_{t,t}$-free for some t depending on H, graphs of bounded expansion and nowhere dense graphs are $K_{t,t}$-free for an appropriate t, and any graph of maximum degree Δ (or more generally, bounded degeneracy) is $K_{t,t}$-free for $t = \Delta + 1$ or t equal to one plus the degeneracy.

In the rest of the paper, we freely switch between the graph and matrix viewpoints when describing structural properties of partial matrices.

Notice that in the more restricted case when every row of M contains at most Δ unspecified entries, the maximum vertex degree of $\overline{G}$ is at most Δ. In this case, we show that the size of the compression provided by Theorem 4 can be refined as follows.

▶ **Theorem 8.** *There is a polynomial-time algorithm that, given an instance (M, d) of* d-EDMC *such that every row of M has at most Δ unspecified entries, either solves the problem, or outputs an equivalent instance (M', d), such that M' is a principal $n' \times n'$ submatrix of M, where $n' \leq (d+1)(\Delta+1)^2$.*

Combined with Theorem 5, we have the following algorithm.

▶ **Corollary 9.** *For every $d, \Delta \in \mathbb{N}$, and $n \times n$ partial matrix M such that every row of M has at most Δ unspecified entries,* d-EDMC *is solvable in time $2^{\mathcal{O}(d^2 \cdot \Delta^4 \cdot (\log d + \log \Delta))} + n^{\mathcal{O}(1)}$.*

1.1.2 Distance from triviality II

Consider the case where all specified entries of M lie in one fully specified principal submatrix M'. In this case, d-EDMC is polynomial-time solvable: one first determines the minimum dimension d for which M' is isometrically embeddable in $\mathbb{R}^d$ and then assigns values to the remaining entries of M so that the new points lie at appropriate distances. So, a natural definition of distance to this notion of triviality is the least number of fully specified principal submatrices such that their entries cover all specified entries of M. In terms of graphs, if all specified entries of M lie in one fully specified principal submatrix, then the underlying graph G consists of a clique and isolated vertices. Thus all edges of G are covered by one clique. So, when we say that the specified entries in M can be covered by k fully specified principal submatrices, this is equivalent to saying that the underlying graph G admits an *edge clique cover* of size k, that is, the edges of G can be covered by at most k cliques.

▶ Remark 10. A small edge clique cover does *not* imply that $\overline{G}$ is $K_{t,t}$-free for any fixed t. Indeed, the disjoint union of two copies of K_n can be covered by just two cliques, yet its complement contains $K_{n,n}$. Thus, the edge clique cover parameter is *incomparable* with the assumption of $K_{t,t}$-freeness, which motivates the parameterization by edge clique cover.

▶ **Theorem 11.** *There is a polynomial-time algorithm that, given an instance (M, d) of d-EDMC in which M is an $n \times n$ G-partial matrix and the graph G is given together with an edge clique cover $\mathcal{C}$ of size k, either solves the problem, or outputs an equivalent instance (M', d), such that M' is an $n' \times n'$ principal submatrix of M, where $n' \leq (d+1)k^2$.*

▶ **Corollary 12.** *For every $d, k \in \mathbb{N}$, and $n \times n$ partial matrix M such that the specified entries in M can be covered by at most k fully specified principal submatrices, d-EDMC is solvable in time $2^{\mathcal{O}(d^2 \cdot k^4 \cdot (\log d + \log k))} + 2^{2^{\mathcal{O}(k)}} \cdot n^{\mathcal{O}(1)}$.*

Let us next give a brief overview of the proof technique behind Theorem 4, Theorem 8 and Theorem 11. Say that an instance (M, d) of d-EDMC is *efficiently α-reducible* if there is a polynomial-time computable pair comprising a fully specified $\alpha \times \alpha$ principal submatrix indexed by $X \subseteq [n]$ and an element $w \in X$ such that (M, d) is equivalent to $(M - w, d)$. Here, $M - w$ is defined as the matrix obtained from M by removing the row and column indexed by w. The element w is called an *irrelevant* element. Clearly as long as such a pair X and w can be found, we can iteratively reduce the instance by deleting w. To prove these three theorems, we show the following, where G is the underlying graph of M.

- if $\overline{G}$ is $K_{t,t}$-free, then either the instance is solvable in polynomial time or it is already compressed to the claimed size or it is efficiently $d^{\mathcal{O}(t)}$-reducible; and
- if $\overline{G}$ has max-degree at most Δ, then either the instance is solvable in polynomial time or it is already compressed to the claimed size or it is efficiently $\mathcal{O}(d \cdot \Delta)$-reducible; and
- given an edge clique cover of size k for G, either the instance is solvable in polynomial time or it is already compressed to the claimed size or it is efficiently $\mathcal{O}(d \cdot k)$-reducible.

Proving each of the above statements is done along similar lines, but there are certain instance-specific aspects that we exploit in each case. In fact, for the first two statements, we show the existence of an α depending only on the parameters such that the index set of *any* fully specified $\alpha \times \alpha$ principal submatrix must contain an irrelevant element. Then, we can use the sparsity of $\overline{G}$ to infer the existence of such a fully specified principal submatrix of M. For the third statement, we observe that one of the cliques in the given edge clique cover of G must have size at least α (where α depends on the parameters) and then we argue that such a clique contains an irrelevant element.

1.1.3 Distance from triviality III

Our final result concerns a further class of matrices that admit polynomial-time completion algorithms. Recall that a graph G is *chordal* if it has no induced cycles of length greater than 3, see Figure 2. Bakonyi and Johnson [4] proved the following: when G is chordal, a G-partial matrix M can be completed to an EDM that is realizable in $\mathbb{R}^d$ if and only if the submatrix induced by the vertex set of each maximal clique of G is itself an EDM realizable in $\mathbb{R}^d$. Since an n-vertex chordal graph has at most n maximal cliques and these can be listed in polynomial time [27], Laurent [33] observed that this characterization yields a straightforward polynomial-time algorithm for d-EDMC as follows. For each maximal clique of G one checks, in polynomial time, whether the corresponding principal submatrix of M (all of whose entries are specified, by definition) is an EDM realizable in $\mathbb{R}^d$. So, considering partial matrices with chordal underlying graphs as our notion of triviality, let us address the next notion of distance from triviality.

The popular measure of the distance of a graph G to a chordal graph is the *fill-in* of a graph, which is the minimum number of edges that should be added to G to make it chordal. Our next theorem extends the polynomial-time algorithm of Bakonyi and Johnson [4] for chordal graphs to graphs with constant fill-in.

$$\begin{bmatrix} 0 & 1 & 1 & 1 & * & * & * & * & * \\ 1 & 0 & 1 & 1 & * & * & * & * & * \\ 1 & 1 & 0 & 1 & 1 & 1 & 1 & * & * \\ 1 & 1 & 1 & 0 & 1 & 1 & 1 & * & * \\ * & * & 1 & 1 & 0 & 1 & 1 & 1 & * \\ * & * & 1 & 1 & 1 & 0 & 1 & * & 1 \\ * & * & 1 & 1 & 1 & 1 & 0 & 1 & * \\ * & * & * & * & 1 & * & 1 & 0 & 1 \\ * & * & * & * & * & 1 & * & 1 & 0 \end{bmatrix}$$

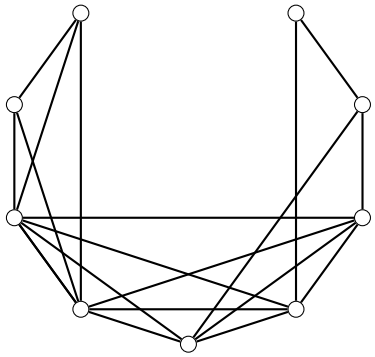

Figure 2 A partial EDM matrix whose underlying graph is chordal.

▶ **Theorem 13.** *Let M be an $n \times n$ G-partial matrix and let $d \in \mathbb{N}$. There is an algorithm that runs in $d^{\mathcal{O}(kd)}\ 2^{\mathcal{O}(k^2)}\ n^{\mathcal{O}(k)}$ time, where k is the size of a minimum fill-in of G, and correctly decides whether (M, d) is a yes-instance of d-EDMC.*

Laurent [33] presented an XP algorithm, that is, polynomial for every fixed k, which decides whether a G-partial matrix can be completed to an EDM realizable in *some* Euclidean space, where k is the minimum size of a fill-in of G. This algorithm, however, does not determine the *smallest* dimension d that suffices, and therefore does not solve d-EDMC. Theorem 13 can thus be viewed as a non-trivial extension of Laurent's result, tailored specifically for embeddability into a prescribed dimension d.

We next give a brief outline of the techniques behind this algorithm. Due to the result of Bakonyi and Johnson [4], it is necessary and sufficient to decide whether a given G-partial matrix M can be extended to a G'-partial matrix M' satisfying the following conditions: (i) G' is chordal, (ii) G' is a supergraph of G, and (iii) for every maximal clique of G', the submatrix of M' induced by the clique's vertex set is an EDM realizable in $\mathbb{R}^d$. For us, G' is defined by a fill-in set X, that is, $G' = G + X$, where X is a set of non-edges of G whose addition to G makes it chordal. Thus, the task reduces to computing M' by assigning values to the entries corresponding to the edges in X, ensuring that condition (iii) is satisfied. To do so, we reduce this task to testing the truth of an existentially quantified statement over a bounded set of polynomial equations and inequalities and then finally invoke an algorithm of Basu, Pollack, and Roy [5]. We note that a similar approach was used in [6], however our case is more complex as the maximal cliques of G' may share edges, requiring us to handle multiple EDMs simultaneously in this reduction.

1.2 Related work

The study of *Euclidean distance matrices* (EDMs) dates back to the pioneering works of Cayley [13] and Menger [34]. Foundational results were later obtained by Schoenberg [36] and by Young and Householder [41]. The subject was further developed in a series of papers by Gower, Critchley, Farebrother, and others [28, 29, 16, 24]. Schoenberg [36] also established the deep connection between EDMs and positive-semidefinite (PSD) matrices. A comprehensive treatment of the vast literature on EDMs lies beyond the scope of this article; we refer the interested reader to the monographs and surveys [10, 15, 19, 32, 18, 2].

2 Preliminaries

For every $x \in \mathbb{N}_{>0}$, we use $[x]$ to denote the set $\{1, \ldots, x\}$.

Distance spaces and matrices. Let X be a set. A function $\rho\colon X \times X \to \mathbb{R}_{\geq 0}$ is a *distance* on X if: (i) ρ is symmetric, that is, for any $x, y \in X$, $\rho(x, y) = \rho(y, x)$, and (ii) $\rho(x, x) = 0$ for all $x \in X$. Then, (X, ρ) is called a *distance space*. A distance space (X, ρ) for a finite $X = \{x_1, \ldots, x_n\}$ can be equivalently defined by the *distance matrix*, in which the value in row i and column j is ρ_{ij}^2, where $\rho_{ij} = \rho(x_i, x_j)$ for $i, j \in \{1, \ldots, n\}$. Throughout the paper we do not distinguish metric spaces and the corresponding distance matrices.

A distance space (X, ρ) is *isometrically embeddable* into $\mathbb{R}^d$ if there is a map, called *isometric embedding*, $\varphi\colon X \to \mathbb{R}^d$ such that $\rho(x, y) = \|\varphi(x) - \varphi(y)\|_2$ for all $x, y \in X$, where $\|p - q\|_2 = \sqrt{\langle p, p\rangle + \langle q, q\rangle - 2\langle p, q\rangle}$ for $p, q \in \mathbb{R}^d$. Notice that we do not require φ to be injective, that is, several points of (X, ρ) may be mapped to the same point of $\mathbb{R}^d$. Throughout the paper, whenever we mention an embedding, we mean an isometric embedding. Moreover, when we use the term d-embedding, we are referring to embedding into $\mathbb{R}^d$. A d-embeddable distance space is *strongly d-embeddable* if it is not $(d-1)$-embeddable. As convention, we assume that the empty set of points is d-embeddable for every d. A symmetric $n \times n$ matrix $D = (d_{ij})$ over $\mathbb{R}_{\geq 0}$ with $d_{ii} = 0$ for all $i \in \{1, \ldots, n\}$ is a *Euclidean distance matrix* (EDM) in $\mathbb{R}^d$ if $D = D(\rho)$ is the distance matrix of a distance space (X, ρ) embeddable in $\mathbb{R}^d$. Suppose that $\mathcal{X} = (X, \rho)$ is embeddable into $\mathbb{R}^d$. The ordered set $P = (p_1, \ldots, p_n)$ of points in $\mathbb{R}^d$ is said to be a *realization* of $\mathcal{X}$ if there is an embedding $\varphi\colon X \to \mathbb{R}^d$ such that $\varphi(x_i) = p_i$ for all $i \in \{1, \ldots, n\}$.

For a d-embeddable distance space (X, ρ), a set $Y \subseteq X$ is a *metric basis* if, given an isometric embedding φ of (Y, ρ) into $\mathbb{R}^d$, there is a unique way to extend φ to an isometric embedding of (X, ρ). Equivalently, if a realization of (Y, ρ) is fixed then the embedding of any point of $X \setminus Y$ in a d-embedding of (X, ρ) is unique. In our paper we also use the embeddablity characterization based on the properties of Cayley-Menger matrices. Towards this, we use terminology and notation from [6]. For $r+1$ points $x_0, x_1, \ldots, x_r$ of distance space (X, ρ) the *Cayley-Menger determinant* $CM(x_0, x_1, \ldots, x_r)$ is the determinant of the matrix obtained from the distance matrix induced by these points by prepending a row and a column whose first element is zero and the other elements are one.

▶ **Proposition 14** ([10, Chapter IV]). *A distance space $\mathcal{X} = (X, \rho)$ with n points is strongly d-embeddable if and only if there exist $d+1$ points, say $X_d = \{x_0, \ldots, x_d\}$, such that:*

1. $(-1)^{j+1} CM(x_0, x_1, \ldots, x_j) > 0$ *for* $1 \leq j \leq d$, *and*
2. *for any* $x, y \in X \setminus X_d$,

$$CM(x_0, x_1, \ldots, x_d, x) = CM(x_0, x_1, \ldots, x_d, y) = CM(x_0, x_1, \ldots, x_d, x, y) = 0.$$

Equivalently (see, for example, [37]), $\mathcal{X}$ is strongly d-embeddable if and only if there is a set of $d+1$ points $X_d = \{x_0, \ldots, x_d\}$ such that $(\{x_0, \ldots, x_j\}, \rho)$ is strongly j-embeddable for all $j \in \{1, \ldots, d\}$, and for every $x, y \in X \setminus X_d$, $(X_d \cup \{x\} \cup \{y\})$ is d-embeddable.

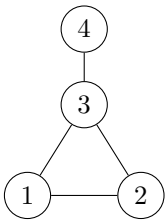
▶ **Proposition 15** ([10, Chapter IV]). *Let (X, ρ) be a d-embeddable distance space, and let $B \subseteq X$ be a metric basis. Then an embedding of B in $\mathbb{R}^d$ is unique up to rigid transformations, and given an embedding φ of (B, ρ) into $\mathbb{R}^d$, there is a unique way to extend φ to an embedding of (X, ρ). Equivalently, if a realization of (B, ρ) is fixed then the embedding of any point of $X \setminus B$ in a d-embedding of (X, ρ) is unique.*

Let (X, ρ) be a distance space. For a nonnegative integer r, we say that $Y \subseteq X$ of size $r+1$ is *independent* if (Y, ρ) is strongly r-embeddable.

▶ **Proposition 16** ([10, Chapter IV]). *Let (X, ρ) be a strongly d-embeddable distance space. Then the following hold:* (i) *any single-element set is independent,* (ii) *if $Y \subseteq X$ is independent, then any $\emptyset \subset Z \subseteq Y$ is independent, and* (iii) *if $Y, Z \subseteq X$ are independent and $|Y| > |Z|$ then there is a $y \in Y \setminus Z$ such that $Z \cup \{y\}$ is independent,* (iv) *the maximum size of an independent set is $d+1$ and any independent set Y of size $d+1$ is a metric basis.*

▶ **Proposition 17** ([10, Chapter IV] and [1, 38]). *Given a distance space $\mathcal{X} = (X, \rho)$ with n points and a positive integer d, in $\mathcal{O}(n^3)$ time, it can be decided whether $\mathcal{X}$ can be embedded into $\mathbb{R}^d$ and, if such an embedding exists, then a metric basis and a realization can be constructed in this running time.*

We remind that by our convention, we do not distinguish metric spaces and the corresponding distance matrices. Thus, we say that an n-tuple of points of $\mathbb{R}^d$ is a realization of an $n \times n$ distance matrix. Furthermore, we say that a subset of indices $X \subseteq \{1, \ldots, n\}$ is a metric basis of the distance matrix meaning that the corresponding points of the distance space compose a metric basis for it. In this spirit, if M is the distance matrix of a (strongly) d-embeddable distance space, then we say that M is a *(strongly) d-embeddable EDM*.



Graphs and matrices. We consider simple finite undirected graphs and refer to [20] for the standard graph-theoretic notation. Given a graph G, we denote by $V(G)$ and $E(G)$ the sets of vertices and edges, respectively. Throughout the paper we use n and m for $|V(G)|$ and $|E(G)|$, respectively, if the graph is clear from the context. A set of pairwise adjacent vertices K of G is called a *clique* and a set of pairwise non-adjacent vertices is *independent*. A family of k cliques $\mathcal{C} = \{C_1, \ldots, C_k\}$ of a graph G is en *edge clique cover* of G if for every edge $uv \in E(G)$, there is $i \in \{1, \ldots, k\}$ such that uv is *covered* by C_i, that is, $u, v \in C_i$. For a vertex $v \in V(G)$, we use $N_G(v)$ to denote the *open neighborhood* of v, that is, the set of adjacent to v vertices. The *degree* $d_G(v) = |N_G(v)|$, and the *maximum degree* of G is $\Delta(G) = \max\{d_G(v) \mid v \in V(G)\}$. For a graph G, its *complement* $\overline{G}$ is the graph with the same set of vertices as G, and two distinct vertices $u, v \in V(G)$ are adjacent to $\overline{G}$ if and only if they are not adjacent in G.

Let A be an $n \times n$ matrix. The matrix obtained from A by deleting $n-k$ rows and $n-k'$ columns (with $1 \leq k, k' \leq n$) is called a $k \times k'$ *submatrix* of A. A *principal submatrix* of A is a square submatrix obtained by deleting the same set of row and column indices; that is, if the i-th row of A is deleted, then the i-th column is also deleted. Let G be a graph with $V(G) = \{1, \ldots, n\}$. An $n \times n$ matrix $A = (a_{ij})$ over $\mathbb{R}_{\geq 0}$ with some unspecified elements is said to be a *G-partial* matrix if (i) the entry a_{ij} is defined (or specified) if and only if $ij \in E(G)$, (ii) $a_{ij} = a_{ji}$ for all $ij \in E(G)$, and $a_{ii} = 0$ for all $i \in \{1, \ldots, n\}$. We also say that G is the *underlying* graph of A. Let A be a G-partial matrix and let d be a positive integer. A matrix D is said to be a d-EDM *completion* of A if:

1. D is d-embeddable, and
2. $d_{ij} = a_{ij}$ for all $ij \in E(G)$.

See Figure 3 for an example.

It is convenient for us to combine graph-theoretic and matrix notation. Let $A = (a_{ij})$ be symmetric $n \times n$ matrix and let G be a graph with $V(G) = [n]$. For a set $X \subseteq [n]$, we use $G[X]$ to denote the subgraph of G induced by X and we use $A[X]$ to denote the principal submatrix indexed by X, that is, the submatrix of A composed by the elements a_{ij} with $i, j \in X$. We also write $G - X$ and $A - X$ to denote the graph obtained by the deletion

$$A = \begin{bmatrix} 0 & 1 & 1.25 & * \\ 1 & 0 & 1.25 & * \\ 1.25 & 1.25 & 0 & 1 \\ * & * & 1 & 0 \end{bmatrix} \qquad D = \begin{bmatrix} 0 & 1 & 1.25 & 4.25 \\ 1 & 0 & 1.25 & 4.25 \\ 1.25 & 1.25 & 0 & 1 \\ 4.25 & 4.25 & 1 & 0 \end{bmatrix}$$

Figure 3 Graph G, G-partial matrix A, and EDM completion D of A. The distance space $\mathcal{X}$ defined by D is embeddable into $\mathbb{R}^2$. For example, a realization φ of $\mathcal{X}$ would map the elements of $\mathcal{X}$ to points $p_1 = (0,0)$, $p_2 = (1,0)$, $p_3 = (0.5,1)$, and $p_4 = (0.5,2)$.

of the vertices of X and the submatrix obtained by the deletion of the rows and columns indexed by X, respectively, that is, $G - X = G[V(G) \setminus X]$ and $A - X = A[V(G) \setminus X]$. For a set $X = \{x\}$, we write $G - x$ and $A - x$ instead of $G - \{x\}$ and $A - \{x\}$, respectively.

We conclude this section with Theorem 1, which shows that for tractability of d-EDMC, it is not sufficient to require high density of the specified element in the input matrix (or, equivalently, high density of the underlying graph G).

▶ **Theorem 1.** *$\forall \varepsilon \in (0,1)$, d-EDMC remains strongly NP-hard even for instances (M,d) with $d = 2$ in which the $n \times n$ matrix M contains at most εn unspecified entries.*

3 Compressing G-partial matrices when G is dense (distance from triviality I and II)

This section is devoted to proving Theorem 4, Theorem 8 and Theorem 11.

Proof of Theorem 4. The main step of the proof is to identify an "irrelevant" vertex of G in polynomial time, that is, a vertex whose deletion does not transform a no-instance into a yes-instance. By exhaustively repeating this step of removing an irrelevant vertex we either solve the problem, or construct an equivalent instance on $(d+1)^{\mathcal{O}(t^2)}$ rows and columns.

Let M be a G-partial matrix, where G excludes a t-block pattern. If $t = 1$, then M is fully specified (i.e., G is complete) and so, we solve the instance (M,d) using Proposition 17. So, we assume that $t > 1$. Let $\eta(d,t) = (d+1)t + (t-1)(d+1)^{t+1} + 1$, and $\rho(d,t) = \binom{2t+\eta(d,t)-2}{2t-1}$.

If $n < \rho(d,t)$, then the desired compression is already achieved and we simply output (M,d). From now on, we assume that $n \geq \rho(d,t)$. Since $\overline{G}$ is $K_{t,t}$-free, it does not contain a clique of size $2t$. By Ramsey's classic theorem [22] $\overline{G}$ must therefore contain an independent set X of size $\eta(d,t)$. Moreover, such a set X can be computed in polynomial time. By definition, X induces a clique in G. Notice that because M is not fully specified, $V(G) \neq X$.

We use Proposition 17 to check in polynomial time whether $M[X]$ is d-embeddable. If not, then we report that (M,d) is a no-instance and stop. For every $v \in V(G) \setminus X$, notice that $C_v = \{v\} \cup (N_G(v) \cap X)$ is a clique of G. So, for every $v \in V(G) \setminus X$ we also check whether $M[C_v]$ is d-embeddable, and report that (M,d) is a no-instance if it is not.

We next iteratively construct disjoint sets $X_1, \ldots, X_t \subseteq X$ of size at most $d+1$ as follows. Assuming that $X_0 = \emptyset$, we select X_i to be a metric basis of $M[X \setminus \bigcup_{j=0}^{i-1} X_j]$ for $i \in \{1, \ldots, t\}$ obtained using Proposition 17. As $|X_i| \leq d+1$ for $i \in \{1, \ldots, t\}$, we have that $|\bigcup_{i=1}^{t} X_i| \leq (d+1)t$. Moreover, since X is large enough, the sets $X_1, \ldots, X_t$ exist.

Consider $Y = \{y \in V(G) \setminus X \colon X_i \setminus N_G(y) \neq \emptyset \text{ for all } i \in \{1, \ldots, t\}\}$. That is, Y consists of all vertices outside X having a non-neighbor in each X_i in G.

▷ Claim 18. $|Y| \leq (t-1)(d+1)^t$.

For every $y \in Y$, we consider the clique $K_y = N_G(y) \cap X$. Since $K_y \subseteq C_y$ and we have already concluded that $M[C_y]$ is d-embeddable, we have that $M[K_y]$ is d-embeddable. We compute a metric basis Z_y of $M[K_y]$ using Proposition 17. Because $|Y| \leq (t-1)(d+1)^t$ by Claim 18 and $|Z_y| \leq d+1$ for $y \in Y$, we have that $|\bigcup_{y \in Y} Z_y| \leq (t-1)(d+1)^{t+1}$. Because $|\bigcup_{i=1}^{t} X_i| \leq (d+1)t$ and $|X| \geq (d+1)t + (t-1)(d+1)^{t+1} + 1$, we have that there is $w \in X \setminus \left(\left(\bigcup_{i=1}^{t} X_i\right) \cup \left(\bigcup_{y \in Y} Z_y\right)\right)$.

▷ Claim 19. The instances (M, d) and $(M - w, d)$ of d-EDMC are equivalent.

We set $M := M - w$ and iterate. In at most n rounds, we either solve the problem or obtain an equivalent instance (M', d), where M' is a $n' \times n'$ submatrix of M with $n' < \binom{2t+\eta(d,t)-2}{2t-1}$. For the running time, note that the construction of the independent set X as well as that of $X_1, \ldots, X_t$ is done in polynomial time by Proposition 17. Then Y and the sets Z_y for $y \in Y$ can also be constructed in polynomial time by Proposition 17. So, an irrelevant vertex can be found in polynomial time. Because the total number of rounds is at most n, the overall running time is polynomial. ◀

As discussed, by combining Theorem 4 with Theorem 5, we obtain the following corollary.

▶ **Corollary 6.** *For every $d, t \in \mathbb{N}$, and $n \times n$ partial matrix M excluding a t-block pattern, d-EDMC is solvable in time $2^{(d+1)^{\mathcal{O}(t^2)}} + n^{\mathcal{O}(1)}$.*

In the remaining part of the section, we show that for some other classes of dense graphs G, we can obtain a better compression for d-EDMC than the one obtained by using Theorem 4 as a black box. The proofs of these results still follow the same lines as the proof of Theorem 4. First, we consider the case when $\overline{G}$ has bounded maximum degree. Since a graph of maximum degree at most Δ does not contain $K_{\Delta+1,\Delta+1}$, in the following theorem, we consider a subclass of matrices considered in Theorem 4.

▶ **Theorem 8.** *There is a polynomial-time algorithm that, given an instance (M, d) of d-EDMC such that every row of M has at most Δ unspecified entries, either solves the problem, or outputs an equivalent instance (M', d), such that M' is a principal $n' \times n'$ submatrix of M, where $n' \leq (d+1)(\Delta+1)^2$.*

Finally in this section, we prove Theorem 11. Notice that Theorem 11 assumes that an edge clique cover is given. However, an edge clique cover of size at most k can be found in FPT in k time (if exists) by the results of Gramm et al. [30].

▶ **Proposition 20** ([30])**.** *Given a graph G and a positive integer k, it can be decided in $2^{2^{\mathcal{O}(k)}} n^{\mathcal{O}(1)}$ time whether G admits an edge clique cover of size at most k. Furthermore, an edge clique cover can be found in the same time if it exists.*

Then we obtain the following corollary.

▶ **Corollary 12.** *For every $d, k \in \mathbb{N}$, and $n \times n$ partial matrix M such that the specified entries in M can be covered by at most k fully specified principal submatrices, d-EDMC is solvable in time $2^{\mathcal{O}(d^2 \cdot k^4 \cdot (\log d + \log k))} + 2^{2^{\mathcal{O}(k)}} \cdot n^{\mathcal{O}(1)}$.*

4 The case of bounded fill-in (distance from triviality III)

In this section, we present our algorithm for d-EDMC for G-partial matrices when G is almost chordal, i.e., it has a small fill-in. Recall that the minimum fill-in of a graph G is the size of a smallest set of non-edges whose addition to G makes it chordal.

▶ **Theorem 13.** *Let M be an $n \times n$ G-partial matrix and let $d \in \mathbb{N}$. There is an algorithm that runs in $d^{\mathcal{O}(kd)}\ 2^{\mathcal{O}(k^2)}\ n^{\mathcal{O}(k)}$ time, where k is the size of a minimum fill-in of G, and correctly decides whether (M, d) is a yes-instance of d-EDMC.*

Towards the proof of this theorem, let us prepare as follows.

▶ **Proposition 21** ([4]). *Every G-partial matrix M where G is chordal can be completed to an EDM in $\mathbb{R}^d$ if every fully specified principal submatrix of M is d-embeddable.*

▶ **Definition 22** ([5]). Let R be a real closed field and $\mathcal{P} \subset R[X_1, \ldots, X_t]$ be a finite set of polynomials. A *$\mathcal{P}$-atom* is one of $P = 0, P \neq 0$, $P \geq 0$, $P \leq 0$, where P is a polynomial in $\mathcal{P}$ and a *quantifier-free $\mathcal{P}$-formula* is a formula constructed from $\mathcal{P}$-atoms together with the logical connectives $\wedge$, $\vee$ and $\neg$. The *R-realization* of a formula F with free variables $x_1, \ldots, x_r$ is a mapping $\nu : \{x_1, \ldots, x_r\} \to R$ so that the sentence resulting from F (denoted by $F[\nu]$) by instantiating each free variable x with $\nu(x)$ is true.

▶ **Proposition 23** (Theorem 13.13, [5]). *Let $s, \ell \in \mathbb{N}$. Let $(\exists X_1) \ldots (\exists X_t) F(X_1, \ldots, X_t)$, be a sentence, where $F(X_1, \ldots, X_t)$ is a quantifier free $\mathcal{P}$-formula where $\mathcal{P} \subset R[X_1, \ldots, X_t]$ is a set of at most s polynomials each of degree at most ℓ. There exists an algorithm to decide the truth of the sentence with complexity[3] $s^{t+1} \cdot \ell^{\mathcal{O}(t)}$ in D where D is the ring generated by the coefficients of the polynomials in $\mathcal{P}_\ell$.*

▶ **Definition 24.** Let M be a G-partial matrix where $V(G) = [n]$ and let Z denote the set of pairs in $\binom{[n]}{2}$ such that every pair in Z indexes a pair of unspecified entries of M, that is, for every $\{i, j\} \in Z$, M_{ij} and M_{ji} are both unspecified. Define the matrix $\hat{M}$ as follows. If $\{i, j\} \notin Z$, then define $\hat{M}_{ij} = M_{ij}$, otherwise define $\hat{M}_{ij} = z_{ij}$ where z_{ij} is an indeterminate.

We have the following adaptation of the notion of Z-augmented Cayley-Menger determinant from [6].

▶ **Definition 25.** Let M and Z be as described in Definition 24. Let $I = \{x_0, \ldots, x_r\} \subseteq [n]$. The *$Z$-Augmented Cayley-Menger determinant indexed by I* is obtained from the Cayley-Menger determinant by replacing each $\rho^2_{x_i, x_j}$ with $\hat{M}_{x_i, x_j}$.

▶ **Lemma 26.** *Let M, Z and $I = \{x_0, \ldots, x_r\}$ be as described in Definition 25. Then, $CM_Z(x_0, x_1, \ldots, x_r)$ is a multi-variate polynomial with real coefficients, over the set $\{z_{ij} \mid \{i, j\} \in Z\}$ of indeterminates where each monomial has degree at most $\min(|I|, 2|Z|)$.*

▶ **Lemma 27.** *There is an algorithm that, given M, I, Z as described in Definition 25, runs in time $|I|^{\mathcal{O}(|I|)} \cdot n^{\mathcal{O}(1)}$ and produces the polynomial representing the Z-Augmented Cayley-Menger determinant indexed by I.*

▶ **Lemma 28.** *Consider an $n \times n$ EDM M and $Y \subseteq [n]$. Let $B \subseteq [n]$ be a metric basis of $M - Y$. Then, there is a metric basis of M that contains B.*

[3] The measure of complexity here is the number of arithmetic operations. Recall that we use the real RAM model.

Proof of Theorem 13. Let the instance (M, d) be given, where M is G-partial and moreover, let X be a set of at most k non-edges of G such that $G' = G + X$ is a chordal graph. It is straightforward to construct G from M and once we have G, we compute X (if it exists) in time $2^{o(k)}n^{\mathcal{O}(1)}$ using the algorithm of Fomin and Villanger [26]. In the rest of the proof, we will only refer to the graph G', so we can refer to the pairs in X as edges. Let $\mathcal{Z}$ denote a set of $2k$ indeterminates, two per edge in X. Formally, for every edge $uv \in X$, $\mathcal{Z}$ contains the indeterminates z_{uv} and z_{vu}. Let $C_1, \ldots, C_t$ be the maximal cliques in G'. It is well-known that $t \leq n$ and these cliques can be computed in polynomial time [27].

1. Do the following for each $i \in [t]$:
   - **a.** Define $\mathcal{Z}_i = \{z_{uv} \mid u, v \in V(C_i)\}$. That is, $\mathcal{Z}_i$ comprises those indeterminates corresponding to those edges in X that have both endpoints in $V(C_i)$.
   - **b.** Define $V_X(C_i) = \{u \mid \exists v : uv \in X \wedge \{u, v\} \subseteq V(C_i)\}$. That is, $V_X(C_i)$ is the set of endpoints of edges in X that are contained in C_i.
   - **c.** Define B_i to be an arbitrary metric basis of $M_i = M[V(C_i) \setminus V_X(C_i)]$. Since by definition, M_i is fully specified, B_i is well-defined. If $|B_i| > d + 1$, then stop and conclude that the input is a no-instance.
   - **d.** For every $Y \subseteq V_X(C_i)$ of size at most $d + 1 - |B_i|$, do the following:
     - **i.** Define $B_i^Y = B_i \cup Y = \{x_0, \ldots, x_r\}$.
     - **ii.** Use Lemma 27 to construct the following set P_i^Y of atoms:
       - **A.** $(-1)^{j+1} CM_{Z_i}(x_0, x_1, \ldots, x_j) > 0$, where $1 \leq j \leq r$.
       - **B.** $CM_{Z_i}(x_0, x_1, \ldots, x_r, x) = 0$ for every $x \in V(C_i) \setminus B_i^Y$.
       - **C.** $CM_{Z_i}(x_0, x_1, \ldots, x_r, x, y) = 0$ for every $x, y \in V(C_i) \setminus B_i^Y$.
       - **D.** $z_{uv} \geq 0$ for each indeterminate $z_{uv} \in Z_i$.
       - **E.** $z_{uv} - z_{vu} = 0$ for each pair z_{uv}, z_{vu} of indeterminates in Z_i.
     - **iii.** Define ϕ_i^Y to be the quantifier-free formula defined as the conjunction of the atoms in P_i^Y.
   - **e.** Define Ψ_i to be the quantifier-free formula defined as the disjunction of the formulas ϕ_i^Y taken over all $Y \subseteq V_X(C_i)$ of size at most $d + 1 - |B_i|$.
2. Define the quantifier-free formula $\Gamma = \bigwedge_{i \in [t]} \Psi_i$.
3. Run the algorithm of Proposition 23 on the sentence obtained by existentially quantifying the indeterminates in $\mathcal{Z}$ and prepending them to Γ. Return the same answer as that produced by this invocation.

▷ Claim 29. (M, d) is a yes-instance of d-EDMC if and only if this algorithm returns Yes.

▷ Claim 30. For each $i \in [t]$ and $Y \subseteq V_X(C_i)$, the atoms in P_i^Y are $\mathcal{P}_i^Y$-atoms, where $\mathcal{P}_i^Y$ is a set of $\mathcal{O}(n^2)$ polynomials each of degree at most $\min(d + 3, 2k)$.

▷ Claim 31. The algorithm runs in time $d^{\mathcal{O}(kd)} \cdot 2^{\mathcal{O}(k^2)} \cdot n^{\mathcal{O}(k)}$.

These three claims complete the proof of the theorem. ◀

5 Concluding remarks and open questions

By Theorem 13, the d-EDMC problem can be solved in polynomial time for every fixed value of d and k. Moreover, for fixed values of k, our algorithm is FPT in d. It is therefore a natural question whether the problem is in FPT with respect to *both* d and k.

Separators for Intersection Graphs of Spheres

Jacob Fox

Jonathan Tidor
Department of Mathematics, Princeton University, NJ, USA

Abstract

We prove the existence of optimal separators for intersection graphs of balls and spheres in any dimension d. One of our results is that if an intersection graph of n spheres in $\mathbb{R}^d$ has m edges, then it contains a balanced separator of size $O_d(m^{1/d}n^{1-2/d})$. This bound is best possible in terms of the parameters involved. The same result holds if the balls and spheres are replaced by fat convex bodies and their boundaries.

1 Introduction

For a graph $G = (V, E)$, a *balanced separator* is a vertex set $\mathcal{X} \subseteq V$ such that each connected component of $G \setminus \mathcal{X}$ contains at most $\frac{2}{3}|V|$ vertices. In 1979, Lipton and Tarjan [15] showed that n-vertex planar graphs have balanced separators of size $O(\sqrt{n})$. There are many different characterizations of planar graphs that each lead to a different extension of the Lipton–Tarjan separator theorem. For example, Wagner's theorem [23] states that a graph is planar if and only if it does not contain K_5 or $K_{3,3}$ as a minor. The family of graphs that can be embedded in a fixed surface has a finite list of forbidden minors by the Robertson–Seymour theorem [19]. Gilbert, Hutchinson, and Tarjan [9] proved that every n-vertex graph which can be embedded in a surface of genus g has a separator of size $O(\sqrt{gn})$. Later, Alon, Seymour, and Thomas [1] proved that for every graph H, every n-vertex graph that does not contain H as a minor has a separator of size at most $O_H(\sqrt{n})$.

Another important characterization of planar graphs is the Koebe–Andreev–Thurston circle packing theorem, which says that a graph is planar if and only if it is the intersection graph of interior-disjoint disks in the plane. (This means that there is a collection of interior-disjoint disks, one corresponding to each vertex, so that two vertices are connected by an edge if and only if the corresponding disks are tangent.) This leads to another way to try to extend the Lipton–Tarjan separator theorem, to intersection graphs of geometric objects. A *string graph* is an intersection graph of arcwise-connected sets in the plane, so planar graphs are string graphs. The Lipton–Tarjan separator theorem has been extended in several works studying separators for string graphs [6, 7, 12, 13, 17], and we now know that every string graph with m edges has a balanced separator of size $O(\sqrt{m})$.

Graphs with a small balanced separator are poor expanders, and one can utilize the separator for many applications, including in fast divide-and-conquer type algorithms for many algorithmically hard graph problems (see, for example, [16]), extremal applications (see, for example, [8, 14]), and enumerative problems (see, for example, [5]).

In this paper, we are interested in finding small separators for intersection graphs of geometric objects in higher dimensions. Miller, Teng, Thurston, and Vavasis [18] proved a separator theorem for the intersection graph of balls in $\mathbb{R}^d$ in which no point is in more than k of the balls. Generalizing this, we prove that every intersection graph of n balls in $\mathbb{R}^d$ with m edges has a balanced separator of size $O_d(m^{1/d}n^{1-2/d})$. This bound is best possible in terms of the parameters involved. (Here and throughout the paper, we use the notation $O_d(\cdot)$ to hide a multiplicative constant that depends only on the dimension d.)

Proving a separator theorem for intersection graphs of spheres turns out to be more challenging as such graphs can have significantly more complicated combinatorial structure. Recently, Davies, Georgakopoulos, Hatzel, and McCarty [3] studied this problem under the constraint that the intersection graph is $K_{t,t}$-free, proving that if an intersection graph of n spheres in $\mathbb{R}^d$ is $K_{t,t}$-free, then it has a balanced separator of size $\tilde{O}_d(t^{10}n^{1-1/(2d+8)})$. We first study the problem in general. Despite their more complicated structure, we show that intersection graphs of spheres have the same size separators as intersection graphs of balls.

▶ **Theorem 1.1.** *An intersection graph of n spheres in $\mathbb{R}^d$ with m edges has a balanced separator of size $O_d(m^{1/d}n^{1-2/d})$.*

As a corollary, we show that every $K_{t,t}$-free intersection graph of n spheres has a separator of size $O_d(t^{1/d}n^{1-1/d})$ (see Corollary 3.9). This verifies a strengthening of a conjecture of Davies, Georgakopoulos, Hatzel and McCarty [3, Conjecture 20]. Both Theorem 1.1 and the corollary are best possible up to the constant factor depending on the dimension d (see Proposition 4.1). We also prove a refinement of Theorem 1.1 which gives a separator whose size depends on the degree sequence of the intersection graph. As a corollary, we prove that every $K_{t,t}$-free intersection graph of spheres in $\mathbb{R}^d$ has average degree $O_d(t)$. It follows that $K_{t,t}$-free intersection graphs of spheres in $\mathbb{R}^d$ have chromatic number $O_d(t)$.

We further study intersection graphs of other geometric objects in Section 4. We generalize our results from balls and spheres to fat convex bodies and their boundaries. Unlike the planar case, we show that both the fatness and convexity assumptions are necessary in dimensions three and larger: no non-trivial separator exists for the intersection graph of general convex bodies or general fat bodies.

Finally, as separators have many algorithmic applications, in Section 5 we show that there are efficient randomized algorithms for finding such separators of intersection graphs of balls or spheres.

2 Separators for intersection graphs of balls

Let $\mathcal{B}$ be a collection of balls in $\mathbb{R}^d$. The *intersection graph* of $\mathcal{B}$, denoted $G(\mathcal{B})$, is the graph with vertex set $\mathcal{B}$ where two balls are adjacent if they intersect. The collection $\mathcal{B}$ is *k-ply* if every point of $\mathbb{R}^d$ is contained in at most k balls. Miller, Teng, Thurston, and Vavasis [18] proved the following separator theorem for intersection graphs of balls.

▶ **Theorem 2.1** ([18])**.** *Let $\mathcal{B}$ be a k-ply collection of n balls in $\mathbb{R}^d$. Then $G(\mathcal{B})$ has a balanced separator of size $O_d(k^{1/d}n^{1-1/d})$.*

A more recent proof of this result was given by Har-Peled [10]. Using his techniques, we are able to give a more refined version of the Miller–Teng–Thurston–Vavasis separator theorem. (Similar techniques also appeared in an earlier work of Smith and Wormald [20].)

Given a collection of balls $\mathcal{B}$, for each point $x \in \mathcal{B}$, the *ply* of x, denoted $p(x)$, is the number of balls in $\mathcal{B}$ which contain x. For each ball $B \in \mathcal{B}$, the *ply* of B, denoted $p(B)$, is the maximum over $p(x)$ over all points $x \in B$. With this definition we strengthen Theorem 2.1 as follows.

▶ **Theorem 2.2.** *Let $\mathcal{B}$ be a collection of n balls in $\mathbb{R}^d$. Then $G(\mathcal{B})$ has a balanced separator of size*

$$O_d\left(\left(\sum_{B\in\mathcal{B}} p(B)^{\frac{1}{d-1}}\right)^{1-\frac{1}{d}}\right).$$

Since every ball has ply at most one more than its degree in the intersection graph, we have the following corollary which bounds the size of the separator in terms of the degree sequence of the graph, or simply its number of edges.

▶ **Corollary 2.3.** *Let $\mathcal{B}$ be a collection of n balls in $\mathbb{R}^d$. Then $G(\mathcal{B})$ has a balanced separator of size*

$$O_d\left(\left(\sum_{B\in\mathcal{B}} \deg(B)^{\frac{1}{d-1}}\right)^{1-\frac{1}{d}}\right).$$

In particular, if $G(\mathcal{B})$ has m edges, then it has a balanced separator of size $O_d(m^{1/d}n^{1-2/d})$.

The second claim follows from the first via an application of Hölder's inequality since

$$\sum_{B\in\mathcal{B}} \deg(B)^{\frac{1}{d-1}} \le \left(\sum_{B\in\mathcal{B}} \deg(B)\right)^{\frac{1}{d-1}} \left(\sum_{B\in\mathcal{B}} 1\right)^{\frac{d-2}{d-1}} = (2m)^{\frac{1}{d-1}} n^{\frac{d-2}{d-1}}.$$

To construct a balanced separator, we first construct a separator with slightly worse quantitative properties and then iterate a bounded number of times to find the desired separator.

▶ **Definition 2.4.** *For a graph $G = (V, E)$ and $c < 1$, a* c-balanced separator *is a vertex set $\mathcal{X} \subseteq V$ such that each connected component of $G \setminus \mathcal{X}$ contains at most $c|V|$ vertices.*

▶ **Lemma 2.5.** *Suppose graph $G = (V, E)$ is such that every induced subgraph has a c-balanced separator of size at most s. Then G has a balanced separator of size at most $\lceil \log_c(2/3) \rceil s$.*

Proof. Set $V_1 = V$. Given a vertex set V_i, let $\mathcal{X}_i$ be a c-balanced separator of $G[V_i]$ of size at most s. Define V_{i+1} to be the set of vertices comprising the largest connected component of $G[V_i] \setminus \mathcal{X}_i$. By definition, $|V_{i+1}| \le c|V_i|$. Furthermore, each other connected components of $G[V_i] \setminus \mathcal{X}_i$ contains at most $\frac{1}{2}|V_i| \le \frac{2}{3}|V|$ vertices. Halt the process at the first $i = r$ satisfying $|V_{r+1}| \le \frac{2}{3}|V|$, so $r \le \lceil \log_c(2/3) \rceil$. Defining $\mathcal{X} = \mathcal{X}_1 \cup \cdots \cup \mathcal{X}_r$, we have $|\mathcal{X}| \le rs \le \lceil \log_c(2/3) \rceil s$. Furthermore, every connected component of $G \setminus \mathcal{X}$ is either equal to V_{r+1}, or is a connected component of $G[V_i] \setminus \mathcal{X}_i$ other than V_{i+1} for some i. Since all of these sets have size at most $\frac{2}{3}|V|$, this implies that $\mathcal{X}$ is a balanced separator for G. ◀

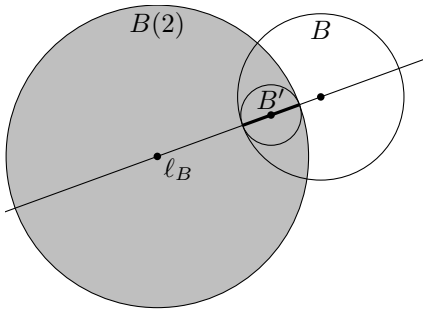

Figure 1 Constructing $\mathcal{B}'$ from $\mathcal{B}$.

Proof of Theorem 2.2. We will give a randomized procedure that produces a $(1-5^{-d})$-balanced separator $\mathcal{X}$ for $G(\mathcal{B})$ of the desired size. By Lemma 2.5, losing another constant factor depending only on d, this suffices to prove the desired result.

Let B_0 be the ball in $\mathbb{R}^d$ with smallest radius that contains at least $5^{-d}n$ centers of balls of $\mathcal{B}$. (B_0 is not necessarily an element of $\mathcal{B}$.) By perturbing B_0 slightly, one can see that B_0 contains exactly $\lceil 5^{-d}n \rceil$ centers. After translating and rescaling the problem appropriately, assume that $B_0 = B(1)$, the origin-centered ball of radius 1.

For some $r \in [1,2]$, let $\mathcal{X}$ be the set of balls $B \in \mathcal{B}$ which intersect the origin-centered sphere of radius r. We claim that for any $r \in [1,2]$, the set $\mathcal{X}$ is a $(1-5^{-d})$-balanced separator for $G(\mathcal{B})$. To see this, note that each connected component of $\mathcal{B} \setminus \mathcal{X}$ consists of balls which are either entirely inside $B(r)$ or entirely outside $B(r)$. Since $B(1) \subseteq B(r)$ contains $\lceil 5^{-d}n \rceil$ centers, there are at most $(1-5^{-d})n$ balls entirely outside $B(r)$. Now $B(2) \supseteq B(r)$ can be covered by 4^d translates of $B(1)$ which, by the minimality of B_0, each contain at most $\lceil 5^{-d}n \rceil$ centers. Thus $B(2)$ contains at most $4^d \lceil 5^{-d}n \rceil \leq (1-5^{-d})n$ centers, so there are at most this many balls entirely inside $B(r)$.

We now show that there is a choice of $r \in [1,2]$ so that $\mathcal{X}$ is small. To do this, pick $r \in [1,2]$ uniformly at random. We now bound the expected size of $\mathcal{X}$. We do this by modifying $\mathcal{B}$ by shrinking those balls that intersect $B(2)$ so that they lie entirely in $B(2)$. For each $B \in \mathcal{B}$ which intersects $B(2)$, let ℓ_B be the line that passes through the origin and the center of B. Let B' be the ball contained in $B(2)$ whose center lies on ℓ_B and which satisfies $\ell_B \cap B' = \ell_B \cap B \cap B(2)$. (See Figure 1.) Define $\mathcal{B}'$ to be the set of these balls B' (the balls in $\mathcal{B}$ that do not intersect $B(2)$ do not have any corresponding ball in $\mathcal{B}'$).

Since each ball $B' \in \mathcal{B}'$ lies inside the corresponding ball $B \in \mathcal{B}$, clearly we have $p_{\mathcal{B}'}(B') \leq p_{\mathcal{B}}(B)$. Write $p(x)$ for the number of balls of $\mathcal{B}'$ which contain the point x. Then $p_{\mathcal{B}'}(B) = \max_{x \in B} p(x)$. We now have

$$\begin{aligned}\operatorname{vol}(B(2)) &\geq \operatorname{vol}\left(\bigcup_{B \in \mathcal{B}'} B\right) = \int_{\bigcup_{B \in \mathcal{B}'} B} p(x) \frac{\mathrm{d}x}{p(x)} = \sum_{B \in \mathcal{B}'} \int_B \frac{\mathrm{d}x}{p(x)} \\ &\geq \sum_{B \in \mathcal{B}'} \int_B \frac{\mathrm{d}x}{p_{\mathcal{B}'}(B)} = \sum_{B \in \mathcal{B}'} \frac{\operatorname{vol}(B)}{p_{\mathcal{B}'}(B)}.\end{aligned}$$

Thus, dividing by $\operatorname{vol}(B(1))$, we conclude that

$$2^d \geq \sum_{B \in \mathcal{B}'} \frac{r(B)^d}{p_{\mathcal{B}'}(B)}.$$

Now for each $B \in \mathcal{B}$, the probability that B is in the separator is at most the length of the interval $\ell_B \cap B \cap B(2)$. In particular, the probability is 0 if B does not intersect $B(2)$. Now if B does intersect $B(2)$, it corresponds to a ball $B' \in \mathcal{B}'$ so that $\ell_B \cap B \cap B(2) = \ell_B \cap B'$ is an interval of length $2r(B')$. Thus by Hölder's inequality we conclude

$$\begin{aligned}\mathbb{E}[|\mathcal{X}|] &\leq 2\sum_{B\in\mathcal{B}'} r(B) \leq 2\left(\sum_{B\in\mathcal{B}'} \frac{r(B)^d}{p_{\mathcal{B}'}(B)}\right)^{1/d} \cdot \left(\sum_{B\in\mathcal{B}'} p_{\mathcal{B}'}(B)^{1/(d-1)}\right)^{(d-1)/d} \\ &\leq 4\left(\sum_{B\in\mathcal{B}'} p_{\mathcal{B}'}(B)^{1/(d-1)}\right)^{(d-1)/d} \leq 4\left(\sum_{B\in\mathcal{B}} p_{\mathcal{B}}(B)^{1/(d-1)}\right)^{(d-1)/d}. \qquad \blacktriangleleft\end{aligned}$$

▶ Remark 2.6. Clearly Theorem 2.2 implies Theorem 2.1. We point out that even the weakest version of Corollary 2.3 is sufficient to imply Theorem 2.1. To see this, let $\mathcal{B}$ be a k-ply collection of balls in $\mathbb{R}^d$. Then the intersection graph $G(\mathcal{B})$ is $O_d(k)$-degenerate. (Recall that a graph is D-degenerate if there exist an ordering of the vertices so that each vertex is adjacent to at most D vertices which appear earlier in the ordering.) To see this, order the balls by radius. One can check that any ball B_j which intersects B_i and has radius satisfying $r_j \geq r_i$ must occupy at least a $(1/3)^d$-fraction of B_i', defined to be the dilate of B_i by a factor of 3. The k-ply assumption shows that there are at most $3^d k$ such balls B_j. Thus $G(\mathcal{B})$ has at most $3^d kn$ edges so Theorem 2.1 follows from Corollary 2.3.

3 Separators for intersection graphs of spheres

The main difficulty in generalizing the results of the previous section to intersection graphs of spheres is that the notion of ply is not useful for sphere intersection graphs. In particular, one can nest spheres so that the corresponding collection of balls would have large ply yet the sphere intersection graph has few or no edges. Furthermore, there are dense graphs (in particular, complete bipartite graphs) that are intersection graphs of spheres but are 2-ply in the sense that no point lies on more than two spheres. (To see this, take two nested families of spheres that are arranged so that every sphere from one family intersects every sphere from the other family.) This shows that no analogue of the argument in Remark 2.6 applies to sphere intersection graphs. Despite these difficulties, we show that separators of the same size exist.

▶ **Theorem 3.1.** *Let $\mathcal{S}$ be a collection of n spheres in $\mathbb{R}^d$. Then $G(\mathcal{S})$ has a balanced separator of size at most*

$$O_d\left(\left(\sum_{S\in\mathcal{S}} \deg(S)^{\frac{1}{d-1}}\right)^{1-\frac{1}{d}}\right).$$

As with Corollary 2.3, this result implies Theorem 1.1 by an application of Hölder's inequality. We start with an elementary lemma that is needed for the proof.

▶ **Lemma 3.2.** *Let $\mathcal{S}$ be a collection of spheres in $\mathbb{R}^d$. Suppose that $G(\mathcal{S})$ has maximum degree at most Δ and that there exists a point $p \in \mathbb{R}^d$ contained in the interior of at least $2s$ spheres. Then there exists a set $\mathcal{X} \subseteq \mathcal{S}$ with $|\mathcal{X}| \leq \Delta$ such that every connected component of $G(\mathcal{S}) \setminus \mathcal{X}$ has size at most $|\mathcal{S}| - s$.*

Proof. Let $\mathcal{S}' \subseteq \mathcal{S}$ be the set of spheres containing p in their interior. For any two spheres $S, S' \in \mathcal{S}'$, either they intersect or one contains the other in its interior. Consider the partial order on $\mathcal{S}'$ defined by containment. Take any linear extension of this poset and let $S_0 \in \mathcal{S}'$

be the median element of this linear extension. This means that there are at least $s-1$ spheres which either intersect S_0 or are contained in its interior and there are at least $s-1$ spheres which either intersect S_0 or contain it in their interior.

Now let $\mathcal{X} = N(S_0)$, the neighborhood of S_0 in $G(\mathcal{S})$, i.e., the set of spheres which intersect S_0. We claim that every connected component of $G(\mathcal{S}) \setminus \mathcal{X}$ has size at most $|\mathcal{S}| - s$. To see this, note that no sphere in $\mathcal{S} \setminus \mathcal{X}$ intersects S_0, so any connected component of $G(\mathcal{S}) \setminus \mathcal{X}$ consists of spheres either entirely inside S_0 or entirely outside S_0. However, we showed that there are at least s spheres that are not of the first type (S_0 and the $s-1$ spheres which follow it in the linear extension) and at least s spheres that are not of the second type. Thus each connected component of $G(\mathcal{S}) \setminus \mathcal{X}$ has size at most $|\mathcal{S}| - s$. ◀

Proof of Theorem 3.1. Set

$$\Sigma = C_d \left(\sum_{S \in \mathcal{S}} \deg(S)^{\frac{1}{d-1}} \right)^{1-\frac{1}{d}}.$$

Choosing $c_d > 0$ small in terms of d and C_d large in terms of c_d, we will construct a $(1-c_d)$-balanced separator for $G(\mathcal{S})$ of size at most Σ. By Lemma 2.5, losing another constant factor depending only on d, this suffices to prove the desired result. Assume $\Sigma < n$, since the result is trivial otherwise.

Through the proof, if we have not already found the desired separator, we will define sets $\mathcal{X}_i \subset \mathcal{S}$ for $i = 1, 2, 3, 4$ with $|\mathcal{X}_i| \leq \Sigma/4$ for each i so that $\mathcal{X}_1 \cup \mathcal{X}_2 \cup \mathcal{X}_3 \cup \mathcal{X}_4$ is the desired separator.

Step 1: First, define $\mathcal{X}_1 \subset \mathcal{S}$ to be the $\Sigma/4$ vertices of highest degree in $G(\mathcal{S})$. Let Δ be the maximum degree of the resulting graph $G(\mathcal{S}) \setminus \mathcal{X}_1$. We claim that $\Delta \leq \Sigma/4$ and $\Delta \leq c_d n$. If the first does not hold, then $G(\mathcal{S})$ would have at least $\Sigma/4$ vertices of degree at least $\Sigma/4$, meaning that

$$\Sigma = C_d \left(\sum_{S \in \mathcal{S}} \deg(S)^{1/(d-1)} \right)^{1-1/d} \geq C_d \left((\Sigma/4)(\Sigma/4)^{1/(d-1)} \right)^{1-1/d} = \frac{C_d}{4}\Sigma.$$

Clearly this is impossible for $C_d > 4$. Similarly, if the second fails then $G(\mathcal{X})$ would have at least $\Sigma/4$ vertices of degree at least $c_d n$, meaning that

$$\Sigma \geq C_d \left((\Sigma/4)(c_d n)^{1/(d-1)} \right)^{1-1/d} = \frac{C_d c_d^{1/d}}{4^{1-1/d}} \Sigma^{1-1/d} n^{1/d} > \frac{C_d c_d^{1/d}}{4^{1-1/d}} \Sigma,$$

where the final inequality holds since $\Sigma < n$. Again, this is impossible for C_d sufficiently large in terms of c_d.

Step 2: Write $\mathcal{S}_1 = \mathcal{S} \setminus \mathcal{X}_1$. The goal of this step is to pass to a subset $\mathcal{S}_2 \subseteq \mathcal{S}_1$ such that every sphere $S \in \mathcal{S}_2$ contains fewer than $4c_d n$ centers of spheres in $\mathcal{S}_2$. Let $S_0 \in \mathcal{S}_1$ be a sphere of minimal radius that contains $4c_d n$ centers of spheres in $\mathcal{S}_1$. (If no such sphere exists, taking $\mathcal{S}_2 = \mathcal{S}_1$ completes this step.) Define $\mathcal{S}_{\supseteq S_0} \subseteq \mathcal{S}_1$ to be the set of spheres which contain S_0 entirely within their interior. First suppose that $|\mathcal{S}_{\supseteq S_0}| \geq 2c_d n$. In this case we can apply Lemma 3.2 to find a separator $\mathcal{X}_2 \subset \mathcal{S}_1$ such that $|\mathcal{X}_2| \leq \Delta \leq \Sigma/4$ and each connected component of $G(\mathcal{S}_1) \setminus \mathcal{X}_2$ has size at most $(1-c_d)n$. Then $\mathcal{X}_1 \cup \mathcal{X}_2$ is a $(1-c_d)$-balanced separator for $G(\mathcal{S})$ of size at most $\Sigma/2$.

Thus we can assume that $|\mathcal{S}_{\supseteq S_0}| < 2c_d n$. In this case, define $\mathcal{X}_2 = N(S_0)$, the neighborhood of S_0 in $G(\mathcal{S})$. Define $\mathcal{S}_2 \subseteq \mathcal{S}_1$ to be the set of spheres which are entirely contained within S_0. Clearly $|\mathcal{X}_2| \leq \Delta \leq \Sigma/4$.

▷ Claim 3.3. If $G(\mathcal{S}) \setminus (\mathcal{X}_1 \cup \mathcal{X}_2)$ has a connected component of size more than $(1 - c_d)n$, then it is also a connected component of $G(\mathcal{S}_2)$.

Proof. Every connected component of $G(\mathcal{S}) \setminus (\mathcal{X}_1 \cup \mathcal{X}_2)$ is either made up of spheres entirely inside S_0 or entirely outside S_0. The former are also connected components of $G(\mathcal{S}_2)$ while the latter are not. There are at least $4c_d n$ centers of spheres of $\mathcal{S}_1$ inside of S_0. Since at most $2c_d n$ of these correspond to spheres surrounding S_0 and at most Δ correspond to spheres which intersect S_0, we see that there are at least $2c_d n - \Delta \geq c_d n$ spheres inside S_0. Therefore any connected component outside of S_0 has size at most $(1 - c_d)n$. ◁

We now construct a separator for $G(\mathcal{S}_2)$. We know that every sphere in $\mathcal{S}_2$ contains fewer than $4c_d n$ centers of spheres in $\mathcal{S}_2$. We can also assume that $|\mathcal{S}_2| \geq (1 - c_d)n$, otherwise $\mathcal{X}_1 \cup \mathcal{X}_2$ is already the desired $(1 - c_d)$-balanced separator.

Step 3: Let B_{in} be a ball of minimal radius which contains at least $4c_d n$ centers of spheres in $\mathcal{S}_2$. Since we showed that no sphere in $\mathcal{S}_2$ contains $4c_d n$ centers, we see that no sphere in $\mathcal{S}_2$ contains B_{in} entirely in its interior. This means that each of the $4c_d n$ spheres whose centers lie in B_{in} also intersect B_{in}.

Write R for the radius of B_{in} and define B_{out} to be the ball with the same center and radius $2R$. By the minimality of B_{in}, we see that B_{out} contains at most $4^d \lceil 4c_d n \rceil$ centers. In particular, choosing c_d sufficiently small, there are at least $c_d n$ sphere centers outside of B_{out}. Let S_{rand} be a sphere with the same center as B_{in} and B_{out} whose radius is chosen uniformly at random in $[R, 2R]$.

For a sphere $S \in \mathcal{S}$, write $r(S)$ for the radius of S. Write $\tilde{r}(S)$ for the radius of the spherical cap formed by intersecting the ball bounded by S with S_{rand}. (The radius of a spherical cap is the minimal $\tilde{r}(S)$ so that the cap is contained in a ball of radius $\tilde{r}(S)$.)

Choose some C'_d sufficiently large in terms of d and let $\mathcal{X}_3$ consist of the spheres $S \in \mathcal{S}_2$ which intersect S_{rand} and which satisfy $\tilde{r}(S) \leq C'_d R(\deg(S)/\Sigma)^{1/(d-1)}$.

▷ Claim 3.4. $\mathbb{E}[|\mathcal{X}_3|] \leq \Sigma/4$.

Proof. We need to upper bound the probability that a sphere S intersects S_{rand} in a spherical cap of radius at most $\tilde{r}$. If $\tilde{r} \leq r(S)$, the probability is upper bounded by

$$\frac{2\left(r(S) - \sqrt{r(S)^2 - \tilde{r}^2}\right)}{R} \leq \frac{2\tilde{r}}{R}.$$

To see this, note that this event is the same as the event that S_{rand} intersects the line connecting the center of B_{in} and the center of S in one of the bold segments in Figure 2.

Now if $\tilde{r} > r(S)$, the probability we need to upper bound is just the probability that S_{rand} and S intersect. This quantity is at most $2r(S)/R < 2\tilde{r}/R$.

Since $\mathcal{X}_3$ is defined with the cutoff $\tilde{r} = C'_d R(\deg(S)/\Sigma)^{1/(d-1)}$, for each $S \in \mathcal{S}_2$ we have the bound

$$\Pr\left[S \text{ intersects } S_{\text{rand}} \text{ and } \tilde{r}(S) \leq C'_d R(\deg(S)/\Sigma)^{1/(d-1)}\right] \leq 2C'_d(\deg(S)/\Sigma)^{1/(d-1)}.$$

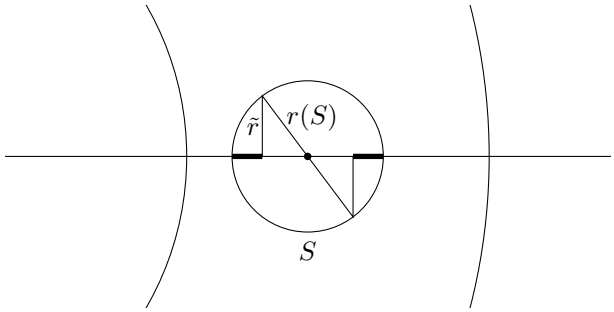

Figure 2 Bounding $\Pr[S \in \mathcal{X}_3]$.

This implies that

$$\mathbb{E}[|\mathcal{X}_3|] \leq \sum_{S \in \mathcal{S}_2} 2C'_d(\deg(S)/\Sigma)^{1/(d-1)} = \frac{2C'_d}{\Sigma^{1/(d-1)} C_d^{d/(d-1)}} \Sigma^{d/(d-1)} \leq \Sigma/4,$$

where the equality is by the definition of Σ and the last inequality holds for C_d chosen appropriately large in terms of C'_d. ◁

Fix some choice of S_{rand} for which $|\mathcal{X}_3| \leq \Sigma/4$.

Step 4: Define $\mathcal{S}_3 = \mathcal{S}_2 \setminus \mathcal{X}_3$. We perform the following iterative process. Start with $\mathcal{X}_4 = \emptyset$ and $\mathcal{S}_4 = \mathcal{S}_3$. We will define spheres $S_1, S_2, \ldots, S_\ell$. Suppose we have defined $S_1, \ldots, S_{i-1}$. Define S_i to be a sphere in $\mathcal{S}_4$ which intersects S_{rand} and has maximal radius among such spheres. Place the neighborhood $N(S_i)$ in $\mathcal{X}_4$ and remove all spheres which intersect the ball bounded by S_i from $\mathcal{S}_4$ (in particular we remove S_i and $N(S_i)$ from $\mathcal{S}_4$). Repeat until no more spheres in $\mathcal{S}_4$ intersect S_{rand}.

We claim that the balls bounded by $S_1, S_2, \ldots, S_\ell$ are disjoint. For $i < j$ we know that $r(S_i) \geq r(S_j)$ and the ball bounded by S_i is disjoint from the sphere S_j. The latter implies that S_i, S_j do not intersect and that S_i does not contain S_j; the former implies that S_j does not contain S_i.

▷ Claim 3.5. $|\mathcal{X}_4| \leq \Sigma/4$.

Proof. By the definition of $\mathcal{X}_3$, every sphere $S \in \mathcal{S}_3$ which intersects S_{rand} also satisfies $\tilde{r}(S) > C'_d R(\deg(S)/\Sigma)^{1/(d-1)}$. Thus

$$|\mathcal{X}_4| \leq \sum_{i=1}^{\ell} \deg(S_i) < \sum_{i=1}^{\ell} \Sigma \left(\frac{\tilde{r}(S_i)}{C'_d R} \right)^{d-1}.$$

Now since the balls bounded by $S_1, \ldots, S_\ell$ are disjoint, we have

$$\sum_{i=1}^{\ell} \tau_{d-1} \tilde{r}(S_i)^{d-1} \leq \sigma_d (2R)^{d-1}$$

where τ_k, σ_k denote the k-volume of the unit ball in $\mathbb{R}^k$ and the $(k-1)$-volume of the unit sphere in $\mathbb{R}^k$, respectively. (In the above inequality, we use the fact that the $(d-1)$-volume of a spherical cap of radius $\tilde{r}$ on any sphere in $\mathbb{R}^d$ is at least the $(d-1)$-volume of a ball of radius $\tilde{r}$ in $\mathbb{R}^{d-1}$.) Thus we conclude that

$$|\mathcal{X}_4| \leq \Sigma \frac{2^{d-1}\sigma_d}{C_d'^{d-1}\tau_{d-1}} \leq \Sigma/4,$$

where the last inequality holds for C'_d chosen sufficiently large in terms of d. ◁

▷ Claim 3.6. $\mathcal{X} = \mathcal{X}_1 \cup \mathcal{X}_2 \cup \mathcal{X}_3 \cup \mathcal{X}_4$ is a $(1 - c_d)$-balanced separator for $G(\mathcal{S})$.

Proof. By Claim 3.3, it suffices to show that each connected component of $G(\mathcal{S}_2) \setminus (\mathcal{X}_3 \cup \mathcal{X}_4)$ has size at most $(1 - c_d)n$. Note that any sphere in $\mathcal{S}_2 \setminus (\mathcal{X}_3 \cup \mathcal{X}_4)$ which crosses S_{rand} must lie in the ball bounded by one of the S_i. Furthermore, no sphere in $\mathcal{S}_2 \setminus (\mathcal{X}_3 \cup \mathcal{X}_4)$ crosses any of the S_i. Therefore any connected component of $G(\mathcal{S}_2) \setminus (\mathcal{X}_3 \cup \mathcal{X}_4)$ must either lie entirely within some sphere S_i, entirely within S_{rand}, or entirely outside of S_{rand}. We chose $\mathcal{S}_2$ so that any sphere in $\mathcal{S}_2$ contains at most $4c_d n$ centers of spheres in $\mathcal{S}_2$. Thus the first type of connected component has size at most $4c_d n$. For the second type, note that S_{rand} is contained within B_{out} which we argued earlier contains at most $4^d \lceil 4c_d n \rceil < (1 - c_d)n$ centers of spheres in $\mathcal{S}_2$. For the third type of connected component, we know that there are at least $4c_d n$ spheres which intersect B_{in}. Since B_{in} is contained in the interior of S_{rand}, we see that there are at most $(1 - 4c_d)n$ spheres outside of S_{rand}, giving the desired bound on the third type of connected component. ◁

Since $|\mathcal{X}| \leq \Sigma$, this completes the proof. ◀

Intersection graphs of spheres are an example of semialgebraic graphs. Using known bounds on the number of edges in $K_{t,t}$-free semialgebraic graphs [21], we deduce the following weak bound for separators in $K_{t,t}$-free sphere intersection graphs.

▶ **Corollary 3.7.** *Let $\mathcal{S}$ be a collection of n spheres in $\mathbb{R}^d$. If $G(\mathcal{S})$ is $K_{t,t}$-free, then it has a balanced separator of size $O_d(t^{2/d(d+2)} n^{1-2/d(d+2)})$.*

Proof. Represent the sphere centered at $x \in \mathbb{R}^d$ with radius r by the point $(x, r) \in \mathbb{R}^{d+1}$. Now two spheres (x, r) and (x', r') intersect if and only if $(r - r')^2 \leq \|x - x'\|^2 \leq (r + r')^2$. These are polynomial inequalities of degree $O(1)$, meaning that $G(\mathcal{S})$ can be represented by a semialgebraic graph in $\mathbb{R}^{d+1}$ of total degree $O(1)$. (See [21, Definition 1.1] for the full definition.)

By [21, Theorem 1.6] (a bound on the Zarankiewicz problem for semialgebraic graphs), if $G(\mathcal{S})$ is $K_{t,t}$-free, then it has $O_d(t^{2/(d+2)} n^{2(d+1)/(d+2)})$ edges. Applying Theorem 1.1 with this bound shows that $G(\mathcal{S})$ has a balanced separator of size

$$O_d\left(\left(t^{2/(d+2)} n^{2(d+1)/(d+2)}\right)^{1/d} n^{1-2/d}\right) = O_d(t^{2/d(d+2)} n^{1-2/d(d+2)}).$$ ◀

We can bootstrap this weak bound to get a better bound on the number of edges in a $K_{t,t}$-free sphere intersection graph. This follows from [6, Lemma 8] which turns a bound on the size of separators into a bound on the number of edges for any hereditary family of graphs. (See [8, Section 3] for another application of this method.)

▶ **Corollary 3.8.** *Let $\mathcal{S}$ be a collection of n spheres in $\mathbb{R}^d$. If $G(\mathcal{S})$ is $K_{t,t}$-free, then it has $O_d(tn)$ edges.*

Proof. We aim to apply [6, Lemma 8]. This result requires a monotone function ϕ so that any n-vertex $K_{t,t}$-free intersection graph of spheres in $\mathbb{R}^d$ contains a balanced separator of size at most $n\phi(n)$. By Corollary 3.7, we can take $\phi(n) = C_d(t/n)^{2/d(d+2)}$ where C_d is the constant in that result. Clearly $\phi(n)$ is monotone.

Set $n_0 = (12C_d)^{d(d+2)/2} t$ so that $\phi(n_0) = 1/12$. Then [6, Lemma 8] implies that every $K_{t,t}$-free intersection graph of spheres in $\mathbb{R}^d$ on $n \geq n_0$ vertices has at most $Cn_0 n/2$ edges where

$$C = \prod_{i=0}^{\infty} \left(1 + \phi\left(\lceil (4/3)^i n_0 \rceil\right)\right).$$

We can bound

$$C \leq \exp\left(\sum_{i=0}^{\infty} \phi\left(\lceil (4/3)^i n_0 \rceil\right)\right) \leq \exp\left(2C_d \sum_{i=0}^{\infty} \left(\left(\frac{3}{4}\right)^i \frac{t}{n_0}\right)^{2/d(d+2)}\right).$$

As $n_0 = O_d(t)$, this geometric series sums to $O_d(1)$, showing that $C = O_d(1)$. This gives the desired bound on the number of edges when $n \geq n_0$.

Note that if $n < n_0$, then we can trivially bound the number of edges by $n^2 < n_0 n = O_d(tn)$. ◀

Combining Theorem 1.1 and Corollary 3.8, we immediately conclude the following strengthening of Corollary 3.7. This result improves upon the sphere separator result of Davies–Georgakopoulos–Hatzel–McCarty [3, Theorem 1], proving a strengthening of [3, Conjecture 20].

▶ **Corollary 3.9.** *Let $\mathcal{S}$ be a collection of n spheres in $\mathbb{R}^d$. If $G(\mathcal{S})$ is $K_{t,t}$-free, then it has a balanced separator of size $O_d(t^{1/d}n^{1-1/d})$.*

▶ Remark 3.10. The same proof also gives Corollaries 3.8 and 3.9 for intersection graphs of balls. However these results actually have significantly easier proofs. For example, let $\mathcal{B}$ be a collection of balls in $\mathbb{R}^d$. If $\mathcal{B}$ is $(2t-1)$-ply, then Theorem 2.1 already implies that $G(\mathcal{B})$ has a balanced separator of size $O_d(t^{1/d}n^{1-1/d})$. Otherwise, there is a point in $2t$ balls of $\mathcal{B}$, implying that $G(\mathcal{B})$ contains K_{2t} which contains $K_{t,t}$.

4 Further results

We start by giving a construction that shows that our main results are asymptotically optimal. We then generalize these results to a larger class of geometric objects.

▶ **Proposition 4.1.** *For each $n, d \geq 1$ and $n \leq m \leq \binom{n}{2}$, there exists an intersection graph of n balls or spheres in $\mathbb{R}^d$ with at most m edges for which every balanced separator has size at least $\Omega_d(m^{1/d}n^{1-2/d})$.*

Proof. Let $V = \{1, \ldots, k\}^d$ for $k = \lfloor n^{1/d} \rfloor$. Define $G = (V, E)$ where $x, y \in V$ are adjacent if $\|x - y\| \leq r$. Choosing $1 \leq r = \Theta_d((m/n)^{1/d})$ appropriately, we can ensure that G has $\Theta_d(m)$ edges. Note that G is both the intersection graph of the radius $r/2$ balls centered at the points of V and the intersection graph of the radius $r/2$ spheres centered at the points of V. We will show that every balanced separator of G has size at least $\Omega_d(m^{1/d}n^{1-2/d})$.

We first handle the case when $r = 1$. Suppose that $\mathcal{X}$ is a balanced separator with $|\mathcal{X}| \leq k^d/3$. Let $A \subset V$ be the union of some connected components of $G \setminus \mathcal{X}$, satisfying $k^d/3 \leq |A| \leq 2k^d/3$. When $r = 1$, the graph G is known as the grid graph on $\{1, \ldots, k\}^d$. Then the isoperimetric inequality on the grid graph [2] implies that there are at least k^{d-1} edges between A and $V \setminus A$. However, all such edges must have one endpoint in $\mathcal{X}$. Since the maximum degree of G is $2d$, we conclude that $|\mathcal{X}| \geq k^{d-1}/2d \geq \Omega_d(n^{1-1/d})$, as desired.

To handle the general case, let $r' = r/(2\sqrt{d})$. For simplicity, assume that r' is an integer that divides k, say $k = r'k'$. Divide $\{1, \ldots, k\}^d$ into $(k')^d$ subcubes of side length r'. Note that every vertex in one subcube is adjacent in G to every vertex in an adjacent subcube. Similar to before, suppose that $\mathcal{X}$ is a balanced separator with $|\mathcal{X}| \leq k^d/12$ and A is a union of connected components of $G \setminus \mathcal{X}$ with $k^d/3 \leq |A| \leq 2k^d/3$. Write $B = V \setminus (\mathcal{X} \cup A)$. We know $|B| \geq k^d/4$. Define $A' \subseteq \{1, \ldots, k'\}^d$ where a point lies in A' if the corresponding

$r' \times \cdots \times r'$ subcube of $\{1, \dots, k\}^d$ contains at least one point of A. Define $B' \subseteq \{1, \dots, k'\}^d$ similarly. First note that A' and B' are disjoint – if they shared a vertex then A, B would contain points in the same subcube which have distance at most $\sqrt{d}r' < r$.

Write $X' = \{1, \dots, k'\}^d \setminus (A' \cup B')$. Note that $|A'| \geq |A|/(r')^d \geq (k')^d/3$ and similarly $|B'| \geq |B|/(r')^d \geq (k')^d/4$. Thus $|A'| \leq (k')^d - |B'| \leq 3(k')^d/4$. Applying the isoperimetric inequality to the grid graph on $\{1, \dots, k'\}^d$, we conclude that there are at least $(k')^{d-1}$ edges between A' and $B' \cup X'$. However, there are no edges between A', B' because any two points in two adjacent subcube are at distance at most $2\sqrt{d}r' = r$. Thus we conclude that $|X'| \geq (k')^{d-1}/(2d)$. Note though that a point lies in X' only if the corresponding subcube lies entirely in $\mathcal{X}$. We thus see that $|\mathcal{X}| \geq (r')^d(k')^{d-1}/(2d) = \Theta_d(m^{1/d}n^{1-2/d})$. ◀

Our main results on ball and sphere separators, Theorems 2.2 and 3.1, hold for more general classes of geometric objects. We say that a set $B \subset \mathbb{R}^d$ is *C-fat* if B contains a ball of radius r and is contained inside a ball of radius Cr for some r. Our results hold for fat convex bodies and for the boundaries of fat convex bodies. (See [11, 4] for related results under slightly different hypotheses.)

▶ **Theorem 4.2.** *Let $\mathcal{B}$ be a collection of n C-fat convex bodies in $\mathbb{R}^d$. Then $G(\mathcal{B})$ has a balanced separator of size at most*

$$O_{d,C}\left(\left(\sum_{B \in \mathcal{B}} p(B)^{\frac{1}{d-1}}\right)^{1-\frac{1}{d}}\right).$$

In particular, if $G(\mathcal{B})$ has m edges, then it has a balanced separator of size $O_d(m^{1/d}n^{1-2/d})$.

Proof. For each $B \in \mathcal{B}$, pick an arbitrary point $p \in \mathrm{int}(B)$ that we call the *center* of B. With this definition, we proceed with the proof of Theorem 2.2 in the same way. The same randomized procedure produces a $(1 - 5^{-d})$-balanced separator.

For each $B \in \mathcal{B}$, let $x_B \subset \mathbb{R}_{\geqslant 0}$ be the set of radii r so that the origin-centered sphere of radius r intersects B. We wish to show that if $x_B \cap [1, 2]$ is non-empty, B contains a genuine ball B' which is contained in $B(2)$ such that $r(B') \geq \Omega_C(|x_B \cap [1, 2]|)$.

First, if $x_B \subseteq [0, 2]$, then B is contained in $B(2)$. Now B contains a point of norm $\max(x_B)$ and a point of norm $\min(x_B)$, i.e., it contains two points at distance at least $\max(x_B) - \min(x_B) \geq |x_B|$. This means that any ball containing B must have radius at least $|x_B|/2$. By hypothesis, B contains a ball of radius $|x_B|/2C$. Letting B' be this ball, we are done since in this case $B' \subseteq B$ is contained in $B(2)$.

Now suppose $x_B \not\subseteq [0, 2]$, but $x_B \cap [0, 2] \neq \emptyset$. By the same argument, B contains some ball (say $\tilde{B}$) of radius $(\max(x_B) - \min(x_B))/2C$ centered at some point p with $\|p\| \leq \max(x_B)$. By assumption, B contains a point q with $\|q\| = \min(x_B) \leq 2$. (See Figure 3.) Then the convexity of B implies that B contains the convex hull of $\{q\} \cup \tilde{B}$. Elementary geometry implies that this convex hull contains a ball B' of radius $\frac{2 - \min(x_B)}{2C+1} \geq \frac{|x_B \cap [1,2]|}{2C+1}$ that is contained in $B(2)$. (To see this, dilate the convex hull of $\{q\} \cup \tilde{B}$ by a factor of $(2 - \|q\|)/(\|p\| + r(\tilde{B}) - \|q\|)$ so that it lies within $B(2)$.)

Thus we have constructed a set $\mathcal{B}'$ contained in $B(2)$ so that $\mathbb{E}[|\mathcal{X}|] \geq \Omega_C\left(\sum_{B \in \mathcal{B}'} r(B)\right)$. Note that $\mathcal{B}'$ consists of genuine balls, so the rest of the proof applies unchanged. ◀

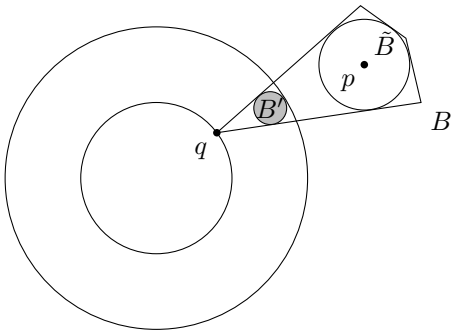

Figure 3 The construction of B' inside of $B \cap B(2)$.

▶ **Theorem 4.3.** *Let $\mathcal{S}$ be a collection of n boundaries of C-fat convex bodies in $\mathbb{R}^d$. Then $G(\mathcal{S})$ has a balanced separator of size at most*

$$O_{d,C}\left(\left(\sum_{S\in\mathcal{S}} \deg(S)^{\frac{1}{d-1}}\right)^{1-\frac{1}{d}}\right).$$

In particular, if $G(\mathcal{S})$ has m edges, then it has a balanced separator of size $O_d(m^{1/d}n^{1-2/d})$.

Proof. For each $S \in \mathcal{S}$, pick an arbitrary point in the interior of S to be its center. Consider the partial order on $\mathcal{S}$ where $S \prec S'$ if S is contained in the interior of S'. Pick an arbitrary linear extension of this partial order. When we talk about the $S \in \mathcal{S}$ of maximal radius (or minimal radius) we mean maximal with respect to this linear extension. With these two definitions, we can proceed with the proof of Theorem 3.1 in the same way. The same randomized procedure produces a $(1 - c_d)$-balanced separator.

The main difference in the analysis is understanding $\mathbb{E}[|\mathcal{X}_3|]$. For each S, define $\tilde{r}(S)$ so that the $(d-1)$-volume of the intersection of the convex body bounded by S and the sphere S_{rand} is $\tau_{d-1}\tilde{r}(S)^{d-1}$. We claim that $\Pr[\tilde{r}(S) \le \tilde{r}] \le O_C(\tilde{r}/R)$.

Fix $\tilde{r}$. Change coordinates so that S_{rand} is centered at the origin. Write B for the convex body with boundary S. Let $r_{\min} = \min_{x\in B} \|x\|$ and $r_{\max} = \max_{x\in B} \|x\|$. Pick $p, q \in B$ with $\|p\| = r_{\min}$ and $\|q\| = r_{\max}$. Since $\|p - q\| \ge r_{\max} - r_{\min}$, we see that the smallest ball that contains B has radius at least $(r_{\max} - r_{\min})/2$. By the C-fat hypothesis, B contains some ball B' centered at a point o with radius $(r_{\max} - r_{\min})/2C$. Now B contains the convex hull of $\{p, q\} \cup B'$ which contains two cones with apexes p, q and with bases some disk of radius $(r_{\max} - r_{\min})/2C$ centered at o. This implies that for each $\epsilon > 0$, the body B contains a ball of radius $\epsilon(r_{\max} - r_{\min})/2C$ centered at a point of distance $r_{\min} + \epsilon(r_{\max} - r_{\min})$ from the origin and another ball of the same radius centered at a point of distance $r_{\max} - \epsilon(r_{\max} - r_{\min})$ from the origin. (See Figure 4.) In particular, if $\epsilon(r_{\max} - r_{\min})/2C \ge \tilde{r}$, then the intersection of B and the spheres of radius $r_{\min} + \epsilon(r_{\max} - r_{\min})$ and $r_{\max} - \epsilon(r_{\max} - r_{\min})$ both contain a spherical cap of radius at least $\epsilon(r_{\max} - r_{\min})/2C \ge \tilde{r}$, so these intersections have $(d-1)$-volume at least $\tau_{d-1}\tilde{r}^{d-1}$. The first inequality holds for $\epsilon \ge 2C\tilde{r}/(r_{\max} - r_{\min})$, so

$$\Pr[\tilde{r}(S) \le \tilde{r}] \le \frac{2(r_{\max} - r_{\min}) \cdot 2C\tilde{r}/(r_{\max} - r_{\min})}{R} = \frac{4C\tilde{r}}{R},$$

as desired.

This gives us the bound $\mathbb{E}[|\mathcal{X}_3|] \le \Sigma/4$ as in Claim 3.4. Then the bound $|\mathcal{X}_4| \le \Sigma/4$ also holds since we defined $\tilde{r}(S)$ so that the proof of Claim 3.5 still goes through. ◀

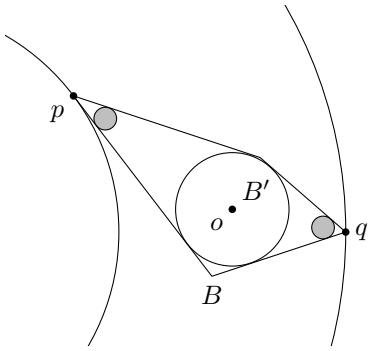

Figure 4 Bounding $\Pr[\tilde{r}(S) \leq \tilde{r}]$.

With these results, Corollary 3.8 also holds for fat convex bodies if the bodies are also semialgebraic sets of bounded description complexity.

We also note that both of the assumptions, convexity and fatness, are necessary. Indeed, for $d \geq 3$, every graph is the intersection graph of convex bodies in $\mathbb{R}^d$ and also every graph is the intersection graph of fat connected bodies in $\mathbb{R}^d$. The former fact is classical (see [22]); we prove the latter fact here.

▶ **Proposition 4.4.** *For $d \geq 3$, $\epsilon > 0$, and any graph G, there exists a collection of $(1+\epsilon)$-fat connected bodies in $\mathbb{R}^d$ whose intersection graph is G.*

Proof. Let B_k be the ball centered at the origin in $\mathbb{R}^d$ of radius $r_k = (2 + 2\epsilon^{-1})^k$. We will define X_k to be a $(1+\epsilon)$-fat connected body that is contained in B_k. The set X_k will be a "balloon" consisting of a large sphere in $\operatorname{int}(B_k) \setminus \operatorname{int}(B_{k-1})$ that is tangent to B_{k-1} at a point p_k and a "string" in B_{k-1}: a curve starting at $p_k \in \partial B_{k-1}$, passing through ∂B_0 at a point q_k, and then continuing into B_0. We will define these sets X_k so that they are disjoint in $\mathbb{R}^d \setminus \operatorname{int}(B_0)$. See Figure 5 for an illustration of this construction.

Suppose we have defined $B_0, \dots, B_{k-1}$ and $X_1, \dots, X_{k-1}$. Let p_k be a point on ∂B_{k-1}. Say B_{k-1} has radius r_{k-1}. Let Y_k be the ball of radius $\epsilon^{-1} r_{k-1}$, centered at $(1+\epsilon^{-1})p_k$. Then $B_{k-1} \cup Y_k$ is contained in the ball of radius $(1+\epsilon)\epsilon^{-1} r_{k-1}$ centered at $\epsilon^{-1} p_k$. Since $r_k = 2(1+\epsilon^{-1}) r_{k-1}$, we see that Y_k is contained in $\operatorname{int}(B_k)$. We will define X_k to be $Y_k \cup \gamma_k$ where γ_k is a curve starting from p_k which is contained in B_{k-1}. Whatever our choice of γ_k, we have ensured that X_k is $(1+\epsilon)$-fat and connected.

Pick q_k to be a point in $\partial B_0 \setminus \{q_1, \dots, q_{k-1}\}$. Let γ_k' be a curve from p_k to q_k whose interior is contained in

$$\operatorname{int}(B_{k-1}) \setminus \left(B_0 \cup \bigcup_{i=1}^{k-1} X_i \right).$$

If $k = 1$, we set $q_1 = p_1$ and let γ_1' have length 0. For $k > 1$, clearly there is enough space in dimension $d \geq 3$ to find such a γ_k'.

Finally, define $\gamma_k = \gamma_k' \cup \delta_k$ where δ_k is a curve starting from q_k whose interior is contained in $\operatorname{int}(B_0)$ such that δ_k and δ_ℓ intersect if and only if k, ℓ are adjacent in G. Again, in dimension $d \geq 3$, this is clearly possible. ◀

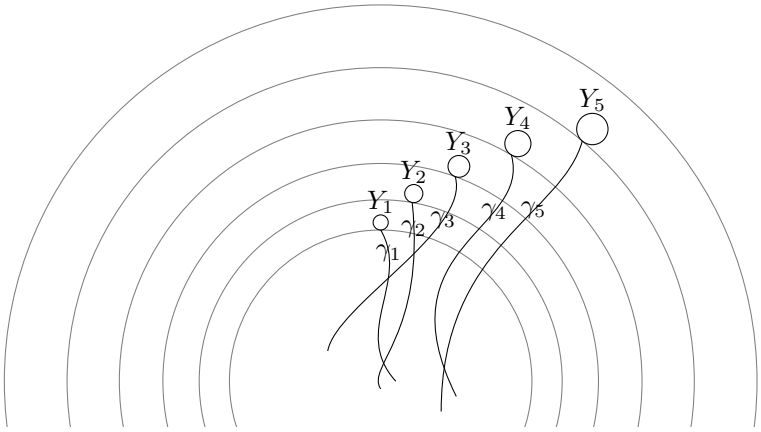

Figure 5 The construction in Proposition 4.4.

5 Algorithmic implementations

Suppose we are given $\mathcal{B}$ as a collection of centers and radii of balls. We give a randomized linear time algorithm that computes a small separator for $G(\mathcal{B})$.

▶ **Theorem 5.1.** *The separator for intersection graphs of balls given in Theorem 2.2 can be computed by a randomized linear time algorithm that succeeds with probability at least* $1/2$.

Proof. Write $\mathcal{P}$ for the centers of the balls of $\mathcal{B}$. Let r be the smallest radius such that there exists a ball B_0 of radius r that contains at least $9^{-d}n$ points of $\mathcal{P}$. Fix such a ball B_0. Then for any $p \in \mathcal{P} \cap B_0$, the ball of radius $2r$ centered at p contains B_0 and thus contains at least $9^{-d}n$ points of $\mathcal{P}$.

Our first goal is to efficiently find an approximation for this ball B_0. Fix a large constant C_d and sample $C_d \cdot 9^d$ points $p_1, p_2, \ldots \in \mathcal{P}$ uniformly at random. For each point p_i, compute the smallest r_i such that the ball of radius r_i centered at p_i contains $9^{-d}n$ points of $\mathcal{P}$. This can be computed in linear time for each p_i. Say we succeed if $\min_i r_i \leq 2r$. By the discussion above, we succeed if some $p_i \in \mathcal{P} \cap B_0$, which occurs with probability at least

$$1 - \left(1 - 9^{-d}\right)^{C_d \cdot 9^d} \geq 1 - e^{-C_d}.$$

Pick $1 \leq i \leq C_d \cdot 9^d$ such that r_i is minimal. As in the proof of Theorem 2.2, pick $r_{\text{rand}} \in [r_i, 2r_i]$ uniformly at random and let $\mathcal{X}$ be the set of balls $B \in \mathcal{B}$ which intersect the sphere of radius r_{rand} centered at p_i. This set can be computed in linear time. Now we still have

$$\mathbb{E}[|\mathcal{X}|] \leq 4 \left(\sum_{B \in \mathcal{B}} p(B)^{\frac{1}{d-1}} \right)^{1-\frac{1}{d}},$$

so by Markov's inequality,

$$\Pr\left[|\mathcal{X}| \leq 4C_d \left(\sum_{B \in \mathcal{B}} p(B)^{\frac{1}{d-1}} \right)^{1-\frac{1}{d}} \right] \geq 1 - C_d^{-1}.$$

Now the set $\mathcal{X}$ is a $(1-9^{-d})$-balanced separator for $G(\mathcal{B})$. To see this, note that the ball of radius r_i centered at p_i contains B_0 which contains $\lceil 9^{-d}n \rceil$ points of $\mathcal{P}$. Furthermore, the ball of radius $2r_i$ centered at p_i can be covered by at most 8^d translates of B_0, so it contains at most $8^d \lceil 9^{-d} \rceil n < (1-9^{-d})n$ points of $\mathcal{P}$.

Thus we have a randomized linear time algorithm which computes a small $(1-9^{-d})$-balanced separator for $G(\mathcal{B})$ with probability at least $1 - C_d^{-1}$. By Lemma 2.5, for C_d sufficiently large, we can iterate this algorithm $\lceil \log_{1-9^{-d}}(2/3) \rceil$ times to produce a $\frac{2}{3}$-balanced separator for $G(\mathcal{B})$ still in linear time with success probability at least $\frac{1}{2}$. ◀

Suppose we are given $\mathcal{S}$ as a list of centers and radii of the spheres. In quadratic time we can compute which pairs of spheres intersect and which pairs are contained in each other. From this we can run the algorithm described in Theorem 3.1 in quadratic time. The only potential difficulty is in selecting the minimal radius ball B_{in}, but this can be handled the same way is in Theorem 5.1.

▶ **Theorem 5.2.** *The separator for intersection graphs of spheres given in Theorem 3.1 can be computed by a randomized quadratic time algorithm that succeeds with probability at least* 1/2.

Abstract

For some geometric graph classes, tractability of testing first-order formulas is precisely characterised by the graph parameter *twin-width*. This was first proved for interval graphs among others in [BCKKLT, IPEC '22], where the equivalence is called *delineation*, and more generally holds for circle graphs, rooted directed path graphs, and H-graphs when H is a forest. Delineation is based on the key idea that geometric graphs often admit natural vertex orderings, allowing to use the very rich theory of twin-width for ordered graphs.

Answering two questions raised in their work, we prove that delineation holds for intersection graphs of non-degenerate axis-parallel unit segment graphs, but fails for visibility graphs of 1.5D terrains. We also prove delineation for intersection graphs of circular arcs.

1 Introduction

The *first-order model checking* problem asks, given a graph G and a first-order (FO) formula ϕ, to test whether G satisfies ϕ. In general this is a difficult problem, known to be $\mathsf{AW}[*]$-hard [8], and subsuming problems such as finding in G an independent set, a dominating set, or any fixed induced subgraph. For a graph class $\mathcal{C}$, one may ask whether this FO model checking problem admits a *fixed parameter tractable* (FPT) algorithm, i.e. one running in time $f(|\phi|) \cdot |G|^{O(1)}$ for some (computable) function f.

Classically, this problem has been studied in sparse graph classes, such as bounded degree graphs [17] and more generally nowhere dense classes [13], which admit such FPT algorithms. A more recent and incomparable development has come from the graph parameter *twin-width* [4]: if $\mathcal{C}$ is a class of bounded twin-width, and witnesses of this (so-called *contraction sequences*) can be efficiently computed, then FO model checking in $\mathcal{C}$ is FPT.

Since bounded twin-width and bounded degree are incomparable, a class with FPT model checking need not have bounded twin-width. Yet a number of remarkable cases exist in which twin-width is exactly the boundary of efficient FO model checking. A fundamental result of [3] is that for any hereditary (i.e. closed under induced subgraphs) class $\mathcal{C}$ of *ordered graphs* (i.e. graphs given with a total ordering of vertices, which formulas can query), model checking in $\mathcal{C}$ is FPT if and only if $\mathcal{C}$ has bounded twin-width[1]. By reducing to ordered graphs using a "nice" vertex ordering, similar results were proved for interval graphs and rooted directed path graphs in [1], where this equivalence is called *delineation*. It also holds for circle graphs [15], H-graphs for any fixed forest H [5], and tournaments [12]. We continue this line of delineation results for geometric intersection graphs:

▶ **Theorem 1.** *Model checking in $\mathcal{C}$ is FPT if and only if $\mathcal{C}$ has bounded twin-width (under the assumption $\mathsf{FPT} \neq \mathsf{AW}[*]$) in the following cases:*

1. *$\mathcal{C}$ is a hereditary subclass of intersection graphs of circular arcs, or*
2. *$\mathcal{C}$ is a hereditary subclass of intersection graphs of non-degenerate, axis-parallel unit segments, given by their geometric representation.*

In the axis-parallel unit segments (APUS) case, we require the geometric representation to be given, as computing it is NP-hard [16]. This is not an issue in circular arc graphs, where representations can be found in polynomial time [18]. We can also prove that relaxing any of the assumptions on non-degenerate APUS breaks delineation.

Finally, we show that delineation fails for visibility graphs of 1.5D-terrains (i.e. polygonal curves formed by an x-monotone sequence of points).

▶ **Theorem 2 (♣).** *There is a class $\mathcal{C}$ of 1.5D-terrain visibility graphs, whose hereditary closure allows FPT model checking, but which has unbounded twin-width.*

The questions of APUS graphs and 1.5D-terrain graphs were both raised in [1].

To further pursue this line of results, one may consider other shapes with unit size: whether unit disks graphs are delineated seems particularly interesting. The difficulty there might be to find the right notion of minimisation. One could also consider unit squares; we expect that our techniques can be used to prove delineation in the case of axis-aligned unit squares, and that delineation fails without the axis-aligned condition.

It may also make sense to consider other parameters than twin-width. Our non-delineated constructions of degenerate APUS graphs and terrain graphs use *merge-width* [10] to obtain FPT model checking. One can ask whether for these graphs, FPT model checking is equivalent to having bounded merge-width. Tackling this question would likely require characterising merge-width through some obstructions, a difficult open problem.

1.1 Proof overview

Let $\mathcal{D}$ be the graph class we are interested in, e.g. the class of all circular-arc graphs. Our goal is the following: for any hereditary[2] subclass $\mathcal{C} \subseteq \mathcal{D}$, there is an FPT model checking algorithm in $\mathcal{C}$ if and only if $\mathcal{C}$ has bounded twin-width. Inspired by [1, 15], we obtain such an equivalence by proving a dichotomy of the following form, for any subclass $\mathcal{C} \subseteq \mathcal{D}$:

[1] Under the assumption $\mathsf{FPT} \neq \mathsf{AW}[*]$, or equivalently that model checking for *all graphs* is not FPT.

[2] The hereditary assumption is necessary to avoid classes in which model checking is easy for trivial reasons, such as graphs of the form: a complex graph on n vertices, plus 2^n isolated vertices as padding.

- Either we can compute in polynomial time a contraction sequence for any $G \in \mathcal{C}$, witnessing that G has bounded twin-width. Then [4] gives FPT model checking in $\mathcal{C}$.
- Or $\mathcal{C}$ is *monadically independent*, which informally means that graphs in $\mathcal{C}$ can be used to encode arbitrary graphs through FO logic (this is formalised by *FO transductions*, see Section 2.4 for the definition). In that case, and if $\mathcal{C}$ additionally is hereditary, then FO model checking on the class of all graphs reduces to FO model checking on $\mathcal{C}$ [9], proving that the latter is hard for the parametrised complexity class $\mathsf{AW}[*]$ [8].

Let us point out that if $\mathcal{C}$ has bounded twin-width, then it is monadically dependent (the opposite of monadically independent). Thus a subclass $\mathcal{C} \subseteq \mathcal{D}$ has bounded twin-width if and only if it is monadically dependent; this is the precise definition of *delineation* in [1]. The above dichotomy is a slight strengthening of delineation, additionally requiring to be able to efficiently find contraction sequences. When $\mathcal{C}$ is hereditary, and assuming $\mathsf{FPT} \neq \mathsf{AW}[*]$, this strengthening gives the equivalence of $\mathcal{C}$ having bounded twin-width, $\mathcal{C}$ being monadically dependent, and $\mathcal{C}$ admitting an FPT model checking algorithm. Let us point out that it is a major conjecture in finite model theory that the last two points are always equivalent:

▶ **Conjecture 3** ([11, Conjecture 8.2]). *For any hereditary class $\mathcal{C}$, there is an FPT FO model checking algorithm for graphs in $\mathcal{C}$ if and only if $\mathcal{C}$ is monadically dependent.*

Our results confirm special cases of this, where twin-width explains the equivalence.

Coming back to the proof overview, let us explain how the previously stated dichotomy is achieved. The starting point is the characterisation of twin-width through obstructions in matrices [4]: given any 0–1 matrix M, one can efficiently find either a contraction sequence for M (witnessing small twin-width), or a *grid*. Given the geometric representation of the graph G, we construct some auxiliary matrix M_G. For instance, for circular arc graphs, we identify the circle with $\{1, \dots, n\}$ modulo n, and the matrix M has a 1 at position (i, j) whenever there is an arc clockwise from i to j. We then prove two facts:

- First, G can be reconstructed from M_G by a sequence of operations that preserve twin-width. Thus if M_G has bounded twin-width, then so does G. This is efficient: a contraction sequence for G can quickly be computed from one for M_G.
- Second, if M_G contains a sufficiently large grid, then G contains a complex structure called a *transversal pair*. It is known that if graphs in $\mathcal{C}$ contain arbitrarily large transversal pairs, then $\mathcal{C}$ is monadically independent [1].

Thus either one can find contraction sequences for the auxiliary matrices $\{M_G : G \in \mathcal{C}\}$, and thus also for $\mathcal{C}$, or these matrices have arbitrarily large grids, hence $\mathcal{C}$ contains arbitrarily large transversal pairs and is monadically independent. The case of APUS graphs requires one additional step: we construct *local* auxiliary matrices, corresponding to 1-by-1 squares in the segment representation. If any such matrix has a grid, then we find a transversal pair; if all local matrices have bounded twin-width, then so does the full graph.

2 Preliminaries

The proofs for results marked with (♣) can be found in the full version. For $n \in \mathbb{N}$, we denote by $[n]$ the interval of integers $\{1, \dots, n\}$.

2.1 Graphs and relational structures

For a graph $G = (V, E)$, we write $V(G) = V$ and $E(G) = E$ for its vertex and edge sets. The set of neighbours of $v \in V(G)$ is $N(v)$. Vertices x, y are *twins* if $N(u) \setminus \{v\} = N(v) \setminus \{u\}$ (xy may or not be an edge). For $X \subseteq V$, $G[X]$ is the subgraph induced by X. When $<$ is a

linear ordering of $V(G)$, we denote by $\mathsf{Adj}(G, <)$ the adjacency matrix with rows and columns ordered by $<$. Similarly, if $<_V$ and $<_E$ are orderings of V and E, then $\mathsf{Inc}(G, <_V, <_E)$ is the incidence matrix with rows and columns ordered by $<_V$ and $<_E$.

More generally, a *binary relational structure* (or simply binary structure) $(V, E_1, \dots, E_\ell)$ consists of a vertex set V, and relations $E_i \subseteq V^2$. It can be viewed as a directed graph with ℓ kinds of edges, where there may be several edges of different kinds between two vertices (but not multiple edges of the same kind). Given a linear ordering $<$ of V, one defines the adjacency matrix of each relation E_i, denoted by $\mathsf{Adj}(E_i, <)$. An *ordered binary structure* is a binary structure in which one of the relations is a linear ordering of the vertex set, normally denoted by $<$. The structure is thus of the form $(V, E_1, \dots, E_\ell, <)$. A special case is *ordered graphs* $(V, E, <)$, where (V, E) is a graph and $<$ a linear ordering of V.

2.2 Grids

The following notion of grids comes from [14]. Given a point $p \in \mathbb{R}^2$, we write $\pi_x(p), \pi_y(p)$ for its x- and y-coordinates. A *t-grid* in the plane is a family of points $(p_{i,j})_{i,j\in[t]}$ satisfying the following for any $i, i', j, j' \in [t]$:

$$\text{if } i < i', \text{ then } \pi_x(p_{i,j}) < \pi_x(p_{i',j'}) \qquad \text{and} \qquad \text{if } j < j', \text{ then } \pi_y(p_{i,j}) < \pi_y(p_{i',j'}).$$

Observe that there are intervals $X_1 < \cdots < X_t$ and $Y_1 < \cdots < Y_t$ of $\mathbb{R}$ such that $p_{i,j} \in X_i \times Y_j$: take X_i to be the smallest interval containing $\pi_x(p_{i,j})$ for all i, and similarly with Y_j.

This extends to 0–1 matrices, interpreting a one at position (i, j) in the matrix M as a point with coordinates (i, j). We say that M contains a t-grid if the point set defined by the ones in M contains a t-grid in the previous sense. Then there are partitions into intervals $\mathcal{R} = \{X_1 < \cdots < X_t\}$ and $\mathcal{C} = \{Y_1 < \cdots < Y_t\}$ of the rows and columns as above. The ordering of rows and columns is crucial, which is why we make it explicit in $\mathsf{Adj}(G, <)$.

The Ramsey property for grids easily follows from the Ramsey theorem on bicliques:

▶ **Lemma 4** (Ramsey theorem for grids, ♣). *There is a function $R(t, k)$ such that if $\mathcal{P}$ is a point set containing an $R(t, k)$-grid, and $\lambda : \mathcal{P} \to [k]$ is any colouring, then $\mathcal{P}$ contains a t-grid consisting only of points of colour c for some $c \in [k]$.*

When the x- and y-coordinates of the grid are indexed by the same set (e.g. in an adjacency matrix), they can be assumed to come from disjoint intervals at a slight cost:

▶ **Lemma 5 (♣).** *Any $2t$-grid $\mathcal{P}$ contains a t-subgrid $\mathcal{P}' \subset \mathcal{P}$ such that the sets $X \coloneqq \pi_x(\mathcal{P}')$ and $Y \coloneqq \pi_y(\mathcal{P}')$ of x- and y-coordinates satisfy either $X < Y$ or $Y < X$.*

The following technical lemma relates grids in incidence and adjacency matrices.

▶ **Lemma 6 (♣).** *Let $E \subseteq V^2$ be a binary relation such that $\mathsf{Adj}(E, <_V)$ has no k-grid. Let $<_{\mathsf{lex}}$ be the lexicographic ordering of E, i.e. $(x, y) <_{\mathsf{lex}} (x', y')$ if either $x <_V x'$, or $x = x'$ and $y <_V y'$. Then $\mathsf{Inc}(E, <_V, <_{\mathsf{lex}})$ has no $4k$-grid.*

2.3 Twin-width

Twin-width [4] is defined by *contraction sequences*: a contraction sequence of width k is a witness that the twin-width $\mathsf{tww}(G)$ is at most k. We omit this definition, as we do not directly manipulate contraction sequences, instead relying on higher level results. It suffices to know that twin-width $\mathsf{tww}(G)$ is well-defined when G is a graph or a binary structure.

We will use the following observation, which is the origin of the name "twin-width".

▶ **Lemma 7** ([4]). *If x, y are twins in G, then* $\mathsf{tww}(G) = \mathsf{tww}(G - y)$.

The fundamental characterisation of twin-width is that it corresponds to ordered graphs whose adjacency matrix excludes some high-rank grid-like structures [3, Theorem 7]. This characterisation is furthermore efficient. It is simple to check that these high-rank grids contain our notion of grid, hence this implies the following.

▶ **Corollary 8** (of [4, Thm. 5.4] or [3, Thm. 7]). *There are functions f, g and an algorithm which, given $(V, E, <)$ an ordered graph whose matrix* $\mathsf{Adj}(E, <)$ *has no k-grid, computes a contraction sequence witnessing that* $\mathsf{tww}(V, E, <) \leq f(k)$ *in time $g(k) \cdot |V|^{O(1)}$.*

Ordered graphs of high twin-width have a Ramsey-like property:

▶ **Theorem 9** ([3]). *There is a function $R(k, \ell)$ such that if $(V, E, <)$ is an ordered graph with $E = E_1 \cup \cdots \cup E_\ell$, and* $\mathsf{tww}(V, E_i, <) \leq k$ *for all i, then* $\mathsf{tww}(V, E, <) \leq R(k, \ell)$.

Proof. This follows from the characterisation of bounded twin-width for ordered graphs by excluding so-called high-rank divisions [3, Theorems 7 and 23], and the Ramsey property for these high-rank divisions [3, Lemma 24]. ◀

It is easy to observe that the twin-width of a graph is the maximum twin-width of its connected components. We will use the following variant of this result for ordered graphs.

▶ **Lemma 10** (♣). *Let $G = (V, E, <)$ be an ordered graph, with V partitioned into intervals $A_1 < \cdots < A_m < B_1 < \cdots < B_m$, such that each edge is between A_i and B_i for some $i \in [m]$, and the subgraphs $(A_i \cup B_i, E, <)$ have twin-width at most k for all i. Then* $\mathsf{tww}(G) \leq 2k + 2$.

2.4 First-order logic

A *relational signature* is a set Σ of *relation symbols* $R \in \Sigma$, each with an arity $r \in \mathbb{N}$. In this work, we will only use *unary* and *binary* symbols, i.e. with arity 1 or 2. A *Σ-structure* S consists of a vertex set $V(S)$, and an interpretation of each symbol $R \in \Sigma$ as a relation $R(S) \subseteq (V(S))^r$ of appropriate arity. Thus a unary symbol U is interpreted as a vertex subset, and a binary symbol as a set of directed edges with loops. For instance, graphs are $\{E\}$-structures, and ordered graphs are $\{E, <\}$-structures (with $E, <$ binary symbols).

FO formulas ϕ over a signature Σ consist of quantifiers over vertices $\forall x, \phi$, $\exists x, \phi$, boolean operators $\vee, \wedge, \neg$, and predicates $R(x_1, \ldots, x_r)$ testing whether $(x_1, \ldots, x_r)$ is a tuple in the interpretation of R, as well as the equality predicate $x = y$. For example,

$$\phi(x, y) = (x = y) \vee E(x, y) \vee \exists z.\ (E(x, z) \wedge E(z, y))$$

is a formula over the signature $\{E\}$ (for graphs) expressing that x, y are at distance at most two. When the formula ϕ has free variables, they are written as arguments of ϕ as above. A formula without free variables is called a *sentence*. If $\phi(x_1, \ldots, x_r)$ is a formula over Σ, S is a Σ-structure, and $v_1, \ldots, v_r \in V(S)$ are vertices, then $S \models \phi(v_1, \ldots, v_r)$ denotes that ϕ is *satisfied* by S, with the variables $x_1, \ldots, x_r$ interpreted as $v_1, \ldots, v_r$ respectively.

The FPT model checking algorithm for twin-width shows the following.

▶ **Theorem 11** ([4, Theorem 1]). *Given a graph G, a contraction sequence of width k for G, and a sentence ϕ, one can test whether $G \models \phi$ in time $f(k, |\phi|) \cdot |V(G)|$.*

Given two signatures Σ, Γ, an *FO interpretation* Φ from Σ to Γ is a map, defined in FO logic, from Σ-structures to Γ-structures. Precisely, Φ is described by giving
1. for each symbol $R \in \Gamma$ of arity r, an FO formula $\phi_R(x_1, \dots, x_r)$ over Σ, and
2. one last FO formula $\phi_V(x)$ again over Σ.

Given a Σ-structure S, its image $\Phi(S)$ is the relational structure where the vertex set is restricted to vertices satisfying ϕ_V, i.e.

$$V(\Phi(S)) = \{x \in V(S) \ : \ S \models \phi_V(x)\},$$

and for each symbol $R \in \Gamma$, the relation set $R(\Phi(S))$ is described by ϕ_R, i.e.

$$R(\Phi(S)) = \{(x_1, \dots, x_k) \in (V(\Phi(S)))^r \ : \ S \models \phi_R(x_1, \dots, x_r)\}.$$

Transductions are a non-deterministic generalisation of interpretations, i.e., a Σ-to-Γ transduction outputs a set of Γ-structures, rather than a single one. Let Σ be a signature, and $U_1, \dots, U_k$ be k unary symbols, disjoint from Σ. The k-colouring is the one-to-many operation which maps a Σ-structure S to all possible extensions of S as $(\Sigma \uplus \{U_1, \dots, U_k\})$-structures S^+, meaning that $V(S) = V(S^+)$ and $R(S) = R(S^+)$ for any $R \in \Sigma$, while the $U_i(S^+)$ are chosen as arbitrary subsets of $V(S^+)$. An *FO transduction* is the composition of a k-colouring (for fixed k), followed by an FO interpretation.

It is folklore that interpretations and transductions can be composed.

▶ **Lemma 12.** *If Φ, Ψ are FO transductions (resp. interpretations) from Σ to Γ and Γ to Δ respectively, then the composition $\Psi \circ \Phi$ is an FO transduction (interpretation) from Σ to Δ.*

Transductions preserve bounded twin-width, and this can be made efficient.

▶ **Theorem 13** ([4, Theorem 8.1])**.** *For any FO transduction Φ, there is a function f such that for any binary structure S and $T \in \Phi(S)$, $\mathsf{tww}(T) \leq f(\mathsf{tww}(S))$.*

Furthermore, given a contraction sequence of width k for S, and the colouring of S used to obtain T through Φ, one can compute in time $g(k) \cdot |S|^{O(1)}$ a contraction sequence of width $f(k)$ for T for some function g depending on Φ.

A graph class $\mathcal{C}$ is called *monadically independent* if it FO transduces the class of all graphs, i.e. if there exists a transduction Φ such that $\Phi(\mathcal{C})$ contains all graphs. If there is no such transduction, then $\mathcal{C}$ is called *monadically dependent*. Theorem 13 implies that bounded twin-width classes are monadically dependent.

▶ **Theorem 14** ([9])**.** *If $\mathcal{C}$ is a hereditary monadically independent class of graphs, then FO model checking in $\mathcal{C}$ is $\mathsf{AW}[*]$-hard.*

To prove that a class $\mathcal{C}$ is monadically independent, we will use the next construction, proposed in [1]. Our definition differs slightly, but the idea and purpose are the same.

▶ **Definition 15.** *A* transversal pair T_k *consists of three sets $A = \{a_i : i \in [k]\}$, $B = \{b_{i,j} : i, j \in [k]\}$ and $C = \{c_j : j \in [k]\}$ with edges $a_i b_{i',j'}$ if and only if $i \leq i'$, and $b_{i,j} c_{j'}$ if and only if $j \leq j'$ (see Figure 1). Edges within A, B, C or between A and C are unconstrained.*

▶ **Lemma 16 (♣).** *Let $\mathcal{C}$ be a graph class such that for any k, some $G \in \mathcal{C}$ contains a transversal pair T_k. Then $\mathcal{C}$ is monadically independent.*

2.5 Geometric graphs

Given a set family $\mathcal{F}$, the *intersection graph* $G_{\mathcal{F}}$ is defined with $\mathcal{F}$ as its vertex set, and an edge between $A, B \in \mathcal{F}$ if and only if $A \cap B \neq \varnothing$. The family $\mathcal{F}$ is a *representation* of $G_{\mathcal{F}}$.

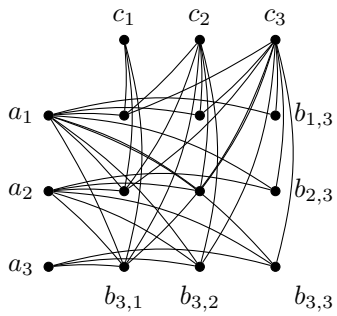

Figure 1 A transversal pair T_3.

Circular arc graphs. A *circular arc graph* is an intersection graph of arcs around a circle. We work with discrete representations in $[n] \coloneqq \{1, ..., n\}$ modulo n: a (discrete) *circular arc* is an interval $[i, j]$ modulo n; explicitly, $[i, j] \coloneqq \{k : i \leq k \leq j\}$ when $i \leq j$, and $[i, j] \coloneqq \{k : k \geq i \text{ or } k \leq j\}$ when $i > j$. Any circular arc representation $\mathcal{F}$ of G can be turned into a discrete circular arcs representation as above for $n = 2|V(G)|$, in time polynomial in the size of the encoding of $\mathcal{F}$. We often identify the vertices of G with the arcs of $\mathcal{F}$. When $I = [i, j]$ is an arc, $\mathsf{left}(I) \coloneqq i$ and $\mathsf{right}(I) \coloneqq j$ denote its endpoints.

▶ **Theorem 17** ([18]). *Given a graph G, one can compute a circular arc representation of G or detect that it is not a circular arc graph in polynomial time.*

Axis-parallel unit segment graphs. An axis-parallel unit segment (APUS) is a segment of length 1 in the plane that is horizontal or vertical. We denote by $\mathsf{Hor}(x, y)$ the horizontal segment from (x, y) to $(x + 1, y)$, and by $\mathsf{Ver}(x, y)$ the vertical one from (x, y) to $(x, y + 1)$. An APUS graph is the intersection graph of a family of APUS. We again work with discrete representations: Any APUS graph G has a representation $\mathcal{F}$ using coordinates that are non-negative multiples of $\eta(\mathcal{F}) = \frac{1}{|\mathcal{F}|}$. This follows from a similar result on unit interval graphs [7], applied to vertical and horizontal coordinates independently.

A family $\mathcal{F}$ of APUS is *non-degenerate* if no two horizontal (resp. two vertical) segments of $\mathcal{F}$ intersect. Intersection graphs of non-degenerate APUS families are called non-degenerate APUS graphs. This is equivalent to G being the intersection graph of an arbitrary family $\mathcal{F}$ of APUS, ignoring intersections between horizontal (vertical) segments (i.e. G has no edge for such intersections). Non-degenerate APUS graphs have a natural bipartition into horizontal and vertical segments. We use the second definition of non-degenerate APUS graphs, that is, degenerate intersections can exist, but are ignored in intersection graphs. The reason is that we will use APUS representations with minimized coordinates (see Section 4).

3 Delineation of circular arc graphs

In this section, we prove Theorem 1 for circular arc graphs.

Given a family $\mathcal{F}$ of circular arcs in $[n]$, we define its *endpoint matrix* $M_{\mathcal{F}}$, where rows and columns are $[n]$, and there is a 1 at position (i, j) if and only if $[i, j] \in \mathcal{F}$.

▶ **Lemma 18.** *There are functions f, g such that if $M_{\mathcal{F}}$ has no k-grid, then one can compute a contraction sequence witnessing that $\mathsf{tww}(G_{\mathcal{F}}) \leq f(k)$ in FPT time $g(k) \cdot |\mathcal{F}|^{O(1)}$.*

Proof. In a first time, let us assume that $\mathcal{F}$ does not contain multiple identical circular arcs.

We identify intervals $[x, y] \in \mathcal{F}$ with pairs (x, y), so that $\mathcal{F}$ describes a binary relation on $[n]$. Its adjacency matrix $\mathsf{Adj}(\mathcal{F}, <)$ with the natural ordering of $[n]$ is exactly $M_{\mathcal{F}}$. It has no k-grid, hence by Lemma 6, the incidence matrix $\mathsf{Inc}(\mathcal{F}, <, <_{\mathsf{lex}})$ has no $4k$-grid, where $<_{\mathsf{lex}}$ is the lexicographic ordering of $[n]^2$.

Construct the following ordered graph $H = (V, E, <_V)$. The vertex set is $V \coloneqq [n] \uplus \mathcal{F}$, ordered with $[n]$ before $\mathcal{F}$, with the natural ordering inside $[n]$, and the lexicographic ordering inside $\mathcal{F}$. In E, each interval $[x, y] \in \mathcal{F}$ is connected to its two endpoints. Thus $\mathsf{Adj}(H, <_V)$ consists of $\mathsf{Inc}(\mathcal{F}, <, <_{\mathsf{lex}})$ and its transpose arranged as diagonal blocks. Since $\mathsf{Inc}(\mathcal{F}, <, <_{\mathsf{lex}})$ has no $4k$-grid, one may check that this implies that $\mathsf{Adj}(H, <_V)$ has no $(4k + 1)$-grid. Using Corollary 8, one can compute in FPT time a contraction sequence of bounded width for H.

To conclude using Theorem 13, we build an FO transduction Φ such that $G_{\mathcal{F}} \in \Phi(H)$:

1. Firstly, add colours to V to distinguish $[n]$ and $\mathcal{F}$, and also to indicate for each interval $[x, y] \in \mathcal{F}$ whether or not $x \leq y$ (this is 3 colours in total).
2. Using these colours, we can write a formula $\phi(v, e)$ testing if $v \in [n]$ belongs to the interval $e \in \mathcal{F}$. Indeed, let $x, y \in [n]$ be the neighbours of e, with $x < y$. Then the interval e is either $[x, y]$ or $[y, x]$, indicated by the colour given to e at step 1. It suffices for $\phi(v, e)$ to check that $x \leq v \leq y$ in the first case, and that $v \leq y \vee x \leq v$ in the second.
   As an extreme case, one could have $e = [x, x]$, which is adjacent to x only. Then x is the only point contained in e. All of the above is easily expressed by a first-order formula.
3. Now, one can test if $e, f \in \mathcal{F}$ intersect with the formula $\psi(e, f) = \exists v.\ \phi(e, v) \wedge \phi(f, v)$.
4. Finally, vertices of $[n]$ are deleted, keeping only $\mathcal{F}$ and the edges defined by ψ.

This is a transduction which, for the choice of colours specified at step 1, yields $G_{\mathcal{F}}$ from H. By Theorem 13, we obtain a contraction sequence for $G_{\mathcal{F}}$ from the one for H in FPT time.

It remains to consider the case where $\mathcal{F}$ has multiple identical arcs. Let $\mathcal{F}'$ be $\mathcal{F}$ with these duplicates removed. Then $M_{\mathcal{F}'} = M_{\mathcal{F}}$, and $G_{\mathcal{F}'}$ is $G_{\mathcal{F}}$ with some twins removed, hence by Lemma 7 $\mathsf{tww}(G_{\mathcal{F}}) = \mathsf{tww}(G_{\mathcal{F}'})$. We conclude using the results for $\mathcal{F}'$. ◀

Say a circular arc representation $\mathcal{F}$ is *minimized* if its circular arcs are inclusion-wise minimal while representing $G_{\mathcal{F}}$, i.e. for any $I \in \mathcal{F}$, removing either endpoint of I would cause it to no longer intersect some other arc $I' \in \mathcal{F}$. A circular arc representation $\mathcal{F}$ can easily be minimized in time polynomial in the size of the encoding of $\mathcal{F}$.

▶ **Lemma 19.** *If $\mathcal{F}$ is a minimized circular arc representation and $I = [i, j] \in \mathcal{F}$ with $i \neq j$, then there exist $I_L, I_R \in \mathcal{F}$ such that $I \cap I_L = \{i\}$ and $I \cap I_R = \{j\}$.*

Proof. If I violates the condition, then it can be shortened by deleting either i or j. ◀

▶ **Lemma 20.** *Let k be a positive integer. Consider a minimized circular arc representation $\mathcal{F}$ of a graph $G_{\mathcal{F}}$. If $M_{\mathcal{F}}$ contains a $(4k + 2)$-grid, then $G_{\mathcal{F}}$ contains a transversal pair T_k.*

Proof. Consider a $(4k + 2)$-grid in $M_{\mathcal{F}}$. It consists of intervals $I_{i,j}$ with $\mathsf{left}(I_{i,j}) < \mathsf{left}(I_{i',j'})$ whenever $i < i'$, and $\mathsf{right}(I_{i,j}) < \mathsf{right}(I_{i',j'})$ whenever $j < j'$. By Lemma 5, a $(2k + 1)$-grid can be extracted so that the x- and y-coordinates belong to disjoint intervals. Thus we assume that $i, j \in [2k + 1]$, and that $\mathsf{left}(I_{i,j}) < \mathsf{right}(I_{i',j'})$ for all i, i', j, j', the case $\mathsf{left}(I_{i,j}) > \mathsf{right}(I_{i',j'})$ being similar.[3]

Let us start constructing the transversal pair T_k. Its central vertices $b_{i,j} \coloneqq I_{2i,2j}$ are obtained by picking every other row and column of the grid. For the left vertices a_i, we first extract auxiliary intervals $x_i \coloneqq I_{2i+1,2k+1}$ for $i \in [k]$. We claim that for all $i, i', j' \in [k]$

[3] This does not reduce the problem to an interval graph, as we will still use arcs other than the $I_{i,j}$s.

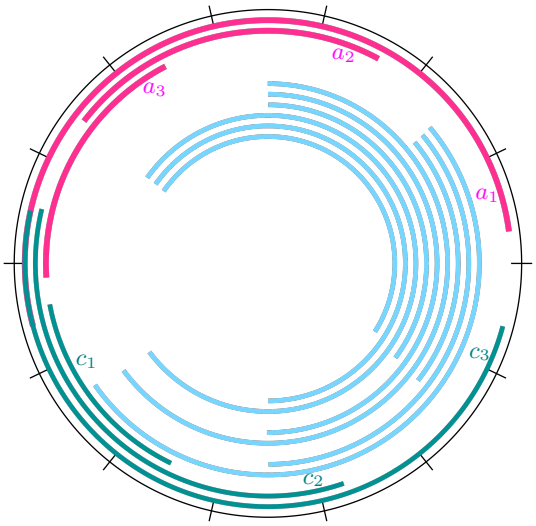

Figure 2 A circular arc representation of a transversal pair T_3 with the tripartition (A, B, C). Magenta circular arcs represent vertices in A, cyan circular arcs in B, and teal circular arcs in C.

$$\text{if } i \geq i', \text{ then } \mathsf{left}(x_i) \in b_{i',j'}, \text{ and} \tag{1}$$

$$\text{if } i < i', \text{ then } b_{i',j'} \subseteq x_i \setminus \{\mathsf{left}(x_i)\}. \tag{2}$$

Indeed, if $i \geq i'$, then $2i + 1 > 2i'$, which gives

$$\mathsf{left}(b_{i',j'}) = \mathsf{left}(I_{2i',2j'}) < \mathsf{left}(I_{2i+1,2k+1}) = \mathsf{left}(x_i). \tag{3}$$

In addition, since all left endpoints are smaller than all right endpoints for intervals of the grid, we also have $\mathsf{left}(x_i) < \mathsf{right}(b_{i',j'})$. Thus $b_{i',j'}$ contains $\mathsf{left}(x_i)$, proving (1). On the other hand, if $i < i'$, then we have $2i + 1 < 2i'$ and $2j' < 2k + 1$, which gives

$$b_{i',j'} = I_{2i',2j'} \subset I_{2i+1,2k+1} = x_i, \tag{4}$$

the inclusion being strict at both endpoints, which implies (2).

Using the minimality of $\mathcal{F}$ and Lemma 19, there is an interval $a_i \in \mathcal{F}$ such that $x_i \cap a_i = \{\mathsf{left}(x_i)\}$. It follows from (1) and (2) that a_i and $b_{i',j'}$ intersect if and only if $i \geq i'$. Symmetrically, we define $y_j = I_{1,2j-1}$, use Lemma 19 to find c_j such that $y_j \cap c_j = \{\mathsf{right}(y_j)\}$, and obtain that c_j and $b_{i',j'}$ intersect if and only if $j \leq j'$. Up to reversing the order of indices, the former description of $a_i, b_{i,j}, c_j$ gives a transversal pair. ◀

Our main theorem for circular arc graphs directly follows from Lemmas 18 and 20.

▶ **Theorem 21.** *Let $\mathcal{C}$ be a subclass of circular arc graphs. Then $\mathcal{C}$ has bounded twin-width if and only if it is monadically dependent. Further, when $\mathcal{C}$ is hereditary, and assuming* FPT $\neq$ AW[$*$]*, these are also equivalent to FO model checking in $\mathcal{C}$ being FPT.*

Proof. For each $G \in \mathcal{C}$, call $\mathcal{F}_G$ the circular arc representation computed by Theorem 17, after minimizing it. Consider the endpoint matrices $\mathcal{M} = \{M_{\mathcal{F}_G} : G \in \mathcal{C}\}$. If matrices in $\mathcal{M}$ have no k-grid for some $k \in \mathbb{N}$, then by Lemma 18 contraction sequences of width $f(k)$ can be computed in FPT time for graphs in $\mathcal{C}$. Thus $\mathcal{C}$ has bounded twin-width (and thus is monadically dependent), and model checking in $\mathcal{C}$ is FPT by Theorem 11.

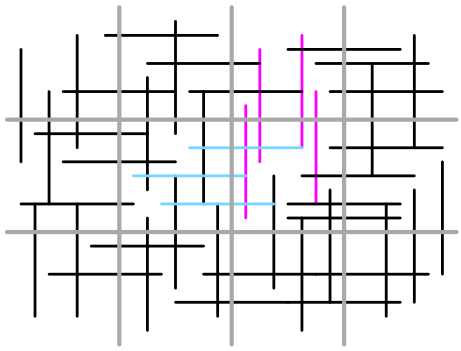

Figure 3 An instance being split along unit squares (drawn in gray). The cyan segments are the set $\mathcal{H}_{s-1,t}$, while the magenta segments are the set $\mathcal{V}_{s,t}$. Together, they form $\mathcal{F}_{s,t,\ulcorner}$.

If however matrices in $\mathcal{M}$ have arbitrarily large grids, then by Lemma 20, $\mathcal{C}$ contains arbitrarily large transversal pairs. Thus $\mathcal{C}$ is monadically independent by Lemma 16. If $\mathcal{C}$ is hereditary, this implies by Theorem 14 that model checking in $\mathcal{C}$ is AW[$*$]-hard. ◀

4 Delineation of axis-parallel unit segment graphs

This section proves Theorem 1 for APUS graphs. Recall that we work with non-degenerate APUS graphs: intersections between two horizontal (resp. vertical) segments are ignored.

As in the circular arc case, we associate the *endpoint matrix* $M_{\mathcal{F}}$ to a family $\mathcal{F}$ of APUS. The columns (resp. rows) are the x- (y-) coordinates of all endpoints of segments in $M_{\mathcal{F}}$, and the entry at position (x, y) is 1 if and only if $\mathsf{Hor}(x, y) \in \mathcal{F}$ or $\mathsf{Ver}(x, y) \in \mathcal{F}$. A variant of Lemma 18 shows that when $M_{\mathcal{F}}$ has no k-grid, then $G_{\mathcal{F}}$ has bounded twin-width. However, the converse fails: even with appropriate minimality conditions on $\mathcal{F}$, a grid in $M_{\mathcal{F}}$ does not imply that $G_{\mathcal{F}}$ has unbounded twin-width. This e.g. fails if the grid is formed by segments that are pairwise at distance more than 1 from each other. The solution, inspired by [1, Lemma 56], is to partition the APUS graph into regions corresponding to unit squares, and look for a grid in each region independently.

4.1 Splitting along unit squares

In an APUS family $\mathcal{F}$, for $s, t \in \mathbb{Z}$, denote by $\mathcal{H}_{s,t}$ the subset of segments $\mathsf{Hor}(x, y)$ where $x \in [s, s+1)$ and $y \in [t, t+1)$, and define $\mathcal{V}_{s,t}$ similarly for vertical segments. Clearly the sets $\mathcal{H}_{s,t}, \mathcal{V}_{s,t}$ for $s, t \in \mathbb{Z}$ partition $\mathcal{F}$. Also, observe that segments in $\mathcal{H}_{s,t}$ and $\mathcal{V}_{s',t'}$ can intersect only if $s' \in \{s, s+1\}$ and $t' \in \{t-1, t\}$. Let $\mathcal{F}_{s,t,\urcorner}$ denote the set $\mathcal{H}_{s,t} \cup \mathcal{V}_{s,t}$, and $E_{s,t,\urcorner}$ the edges of $G_{\mathcal{F}}$ contained in $\mathcal{F}_{s,t,\urcorner}$ that come from segments intersecting in the unit square $[s, s+1) \times [t, t+1)$, for segments coming from the right and top sides of this square (hence $\urcorner$ in the notation). Similarly, define $\mathcal{F}_{s,t,\ulcorner} = \mathcal{H}_{s-1,t} \cup \mathcal{V}_{s,t}$, $\mathcal{F}_{s,t,\lrcorner} = \mathcal{H}_{s,t} \cup \mathcal{V}_{s,t-1}$, and $\mathcal{F}_{s,t,\llcorner} = \mathcal{H}_{s-1,t} \cup \mathcal{V}_{s,t-1}$, as well as $E_{s,t,\ulcorner}, E_{s,t,\lrcorner}, E_{s,t,\llcorner}$ the corresponding edge sets. The sets $E_{s,t,d}$ for $s, t \in \mathbb{Z}$ and $d \in \{\urcorner, \ulcorner, \lrcorner, \llcorner\}$ partition the edge set of $G_{\mathcal{F}}$. We work on each $E_{s,t,d}$ independently with the techniques of Section 3, and show that when all have bounded twin-width, then so does $G_{\mathcal{F}}$. Let us start with the latter.

In general, edge partitions do not preserve bounded twin-width, but they do for ordered graphs (Theorem 9). To use this result, we define an ordering $<_{\mathsf{seg}}$ of segments.

A natural attempt is to take the lexicographic ordering $<_{\mathsf{lex}}$ of segments, i.e. $\mathsf{Hor}(x,y) <_{\mathsf{lex}} \mathsf{Hor}(x',y')$ if and only if $x < x'$, or $x = x'$ and $y < y'$, and similarly for vertical segments. However this works poorly with twin-width: consider a family of segments $\mathcal{F} = \{h_1, \dots, h_n, v_1, \dots, v_n\}$ such that h_i, v_i intersect close to $(0, 2i)$. In particular, h_i, v_j do not intersect for $i \neq j$. By slightly tweaking their x-coordinates, any permutation of $v_1, \dots, v_n$ can be realised as the lexicographic ordering $<_{\mathsf{lex}}$. Thus even for these very simple segment families, the ordered intersection graph $(\mathcal{F}, E, <_{\mathsf{lex}})$ can be an arbitrary ordered matching, which are known to have unbounded twin-width (see e.g. [3]).

The solution is to have two layers of lexicographic ordering, at local and global scales. That is, we first order the sets $\mathcal{H}_{s,t}$ lexicographically by (s,t), and then inside each $\mathcal{H}_{s,t}$ order the segments $\mathsf{Hor}(x,y)$ lexicographically as in $<_{\mathsf{lex}}$. The same ordering applies to vertical segments. Finally, all horizontal segments are placed before all vertical ones. Crucially, in $<_{\mathsf{seg}}$, and unlike $<_{\mathsf{lex}}$, each set $\mathcal{H}_{s,t}$ or $\mathcal{V}_{s,t}$ is an interval.

For an APUS family $\mathcal{F}$ with intersection graph G, denote by $G^{\mathsf{seg}} := (\mathcal{F}, E, <_{\mathsf{seg}})$ the same intersection graph ordered by $<_{\mathsf{seg}}$. Further, for $s,t \in \mathbb{Z}$ and $d \in \{\urcorner, \ulcorner, \lrcorner, \llcorner\}$, let $G^{\mathsf{seg}}_{s,t,d} = (\mathcal{F}_{s,t,d}, E_{s,t,d}, <_{\mathsf{seg}})$ be the restriction to $\mathcal{F}_{s,t,d}$.

▶ **Lemma 22.** *If* $\mathsf{tww}(G^{\mathsf{seg}}_{s,t,d}) \leq k$ *for all* s,t,d*, then* $\mathsf{tww}(G^{\mathsf{seg}}) \leq f(k)$ *for some function* f*.*

Proof. Group the edge sets $E_{s,t,d}$ into 4 classes according to the direction d, i.e. define $\mathcal{E}_d := \bigcup_{s,t} E_{s,t,d}$. The sets $\mathcal{E}_d$ for $d \in \{\urcorner, \ulcorner, \lrcorner, \llcorner\}$ are a partition of the edges, hence by Theorem 9, it suffices to prove that each $(\mathcal{F}, \mathcal{E}_d, <_{\mathsf{seg}})$ has bounded twin-width.

We consider $\mathcal{E}_{\urcorner}$; the other cases are similar. In $\mathcal{E}_{\urcorner}$, vertices of $\mathcal{H}_{s,t}$ are only adjacent to those of $\mathcal{V}_{s,t}$. Also, each $\mathcal{H}_{s,t}$ and $\mathcal{V}_{s,t}$ is an interval of $<_{\mathsf{seg}}$. The intervals $\mathcal{H}_{s,t}$ are ordered lexicographically by (s,t) between themselves, and the corresponding lexicographic ordering is used for the $\mathcal{V}_{s,t}$. Finally, all $\mathcal{H}_{s,t}$ come before all $\mathcal{V}_{s',t'}$. This fits all the requirements of Lemma 10, proving that $(\mathcal{F}, \mathcal{E}_d, <_{\mathsf{seg}})$ has twin-width at most $2k+2$. ◀

4.2 APUS graphs within a unit square

Let us now focus on each $G^{\mathsf{seg}}_{s,t,d}$, to find either bounded twin-width or a transversal pair.

Here, it must be mentioned that the graph $G^{\mathsf{seg}}_{s,t,d}$ is the complement of a circular arc graph, see Figure 4. It is thus not surprising that the techniques of Section 3 can be adapted. The results however cannot be applied as a blackbox: to construct transversal pairs when the matrix $M_{\mathcal{F}_{s,t,d}}$ has a large grid, we may also need segments outside $\mathcal{F}_{s,t,d}$.

We first show that if $M_{\mathcal{F}_{s,t,d}}$ has no k-grid, its intersection graph has bounded twin-width. By symmetry, it is enough to prove the result for $\mathcal{F}_{0,0,\urcorner}$. The only difference with Lemma 18 is that we now care about the ordered graph, with ordering $<_{\mathsf{seg}}$.

▶ **Lemma 23 (♣).** *Let* $\mathcal{F}$ *be a family of APUS consisting of* $\mathsf{Hor}(x,y)$ *or* $\mathsf{Ver}(x,y)$ *with* $x,y \in [0,1)$*. If the matrix* $M_{\mathcal{F}}$ *has no* k*-grid, then* $\mathsf{tww}(G^{\mathsf{seg}}_{\mathcal{F}}) \leq f(k)$ *for some function* f*.*

We now show that when $M_{\mathcal{F}_{s,t,d}}$ does contain a grid, then $G_{\mathcal{F}}$ contains a transversal pair. As in Section 3, this requires some minimality hypothesis. We assume discrete coordinates as in Section 2.5, i.e. in an APUS family $\mathcal{F}$, the coordinates of segments are non-negative multiples of some $\eta(\mathcal{F}) > 0$. Subject to this condition, call $\mathcal{F}$ *minimized* if its segments cannot be pushed towards the bottom-left while preserving the intersection graph. Formally, for a fixed $\eta = \eta(\mathcal{F})$, we say that $\mathcal{F}$ is minimized if there is no other family $\mathcal{F}'$ with the same $\eta = \eta(\mathcal{F}')$ such that there is a bijection $\phi : \mathcal{F} \to \mathcal{F}'$ that preserves the vertical/horizontal orientation and induces an isomorphism of the intersection graphs, and such that the endpoints of $\phi(s)$ are coordinate-wise no larger than that of s.

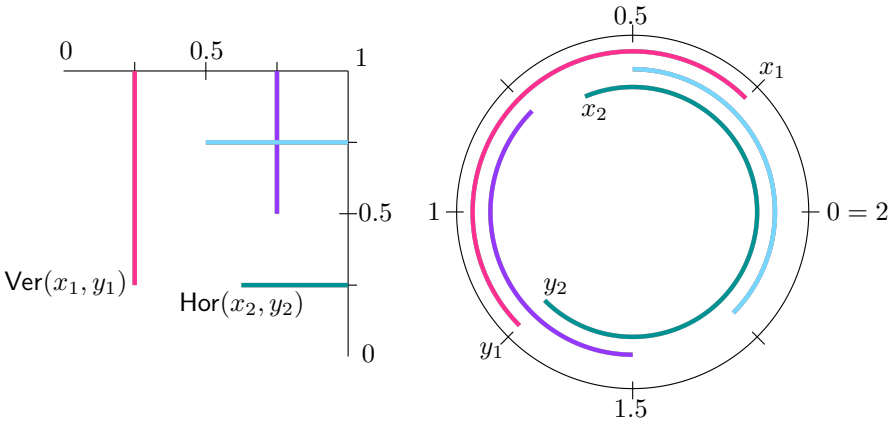

Figure 4 Constructing $G_{0,0,\urcorner}$ as the complement of a circular arc graph: map the segment $\mathsf{Hor}(x, y)$ to the arc $(1 + y, x)$, and $\mathsf{Ver}(x, y)$ to $(x, 1 + y)$ (where the arcs are in $[0, 2)$ modulo 2).

▶ **Lemma 24.** *In a minimized APUS family $\mathcal{F}$, for any horizontal $\mathsf{Hor}(x, y) \in \mathcal{F}$, there are:*
1. *a vertical segment $\mathsf{Ver}(x - \eta, y')$ or $\mathsf{Ver}(x + 1, y')$ with $y' \leq y \leq y' + 1$, unless $x = 0$, and*
2. *a vertical segment $\mathsf{Ver}(x', y - 1 - \eta)$ or $\mathsf{Ver}(x', y)$ with $x \leq x' \leq x + 1$, unless $y = 0$,*

and similarly when flipping the roles of vertical and horizontal, and of x- and y-coordinates.

Proof. If that is not the case, $\mathsf{Hor}(x, y)$ can be moved to the left (in case 1) or the bottom (in case 2) by η without changing the intersection graph, contradicting minimality. ◀

▶ **Lemma 25 (♣).** *Consider a minimized APUS family $\mathcal{F}$, and its restriction $\mathcal{F}_{s,t,d}$ for some $s, t \in \mathbb{Z}$ and $d \in \{\urcorner, \ulcorner, \lrcorner, \llcorner\}$. There is a function $f : \mathbb{N} \to \mathbb{N}$ such that if $M_{\mathcal{F}_{s,t,d}}$ has an $f(k)$-grid, then $G_{\mathcal{F}}$ contains a transversal pair T_k.*

Proof sketch. Consider an $f(k)$-grid $\mathcal{P}$ (for f to be determined) in $M_{\mathcal{F}_{s,t,d}}$, consisting of points $(p_{i,j})_{i,j\in[f(k)]}$ as described in Section 2.2. For each $i, j \in [f(k)]$, $\mathcal{F}$ contains a horizontal segment with $p_{i,j}$ as left endpoint or a vertical segment with $p_{i,j}$ as bottom endpoint.

Using Ramsey's theorem (Lemma 4), when $f(k)$ is chosen large enough, we can find a $2k$-subgrid $\mathcal{P}'$ in which all segments have the same orientation, and their minimality is ensured in the same manner (in the sense of cases (1) or (2) of Lemma 24). Without loss of generality, we assume that segments of $\mathcal{P}'$ are horizontal, denoted as $(h_{i,j})_{i,j\in[2k]}$; with horizontal minimality ensured by line segments on the left that intersect the bottom boundary; and vertical minimality ensured by line segments on the bottom (see Figure 5).

The construction of the transversal pair T_k is now similar to Lemma 20. Pick every other segment of $\mathcal{P}'$ for the central vertices, i.e. define $b_{i,j} = h_{2i-1,2j-1}$. Now consider one of the topmost segments $h_{2i,2k}$, and let a_i be the vertical segment that forbids moving $h_{2i,2k}$ left, which is assumed to intersect the bottom boundary of the square. Then a_i and $b_{i',j'}$ intersect if and only if $i \geq i'$. Similarly, we pick c_j to be the vertical segment blocking $h_{2k,2j}$ from moving down. Up to reversing some indices, this yields a transversal pair of order k. ◀

Our main theorem for APUS graphs follows from Lemmas 22, 23, and 25, along the same lines as Theorem 21, with the additional step of splitting into unit squares (Lemma 22). Since computing APUS representation of graphs is NP-hard [16], some subtleties arise regarding the complexity of FO model checking: we assume graphs to be given by their APUS representation, and use that it is easy to compute an APUS representation of transversal pairs as in Figure 5.

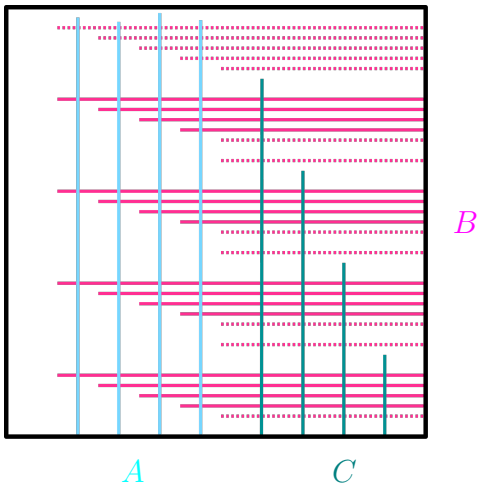

Figure 5 Transversal pair T_4 as APUS graph. The magenta lines are part of an 8-grid. Some of them (solid lines) are picked as B. The others (dotted) are used to define A, C: the cyan (resp. teal) lines forming A (resp. C) ensure horizontal (resp. vertical) minimality of said dotted lines.

▶ **Theorem 26 (♣).** *Let $\mathcal{C}$ be a subclass of non-degenerate APUS graphs. Then $\mathcal{C}$ has bounded twin-width if and only if it is monadically dependent. Further, when $\mathcal{C}$ is hereditary, and assuming* FPT $\neq$ AW[$*$]*, these are also equivalent to FO model checking in $\mathcal{C}$ being FPT, when graphs in $\mathcal{C}$ are given by some APUS representation.*

5 Obstructions to delineation

In this section, we construct graphs with unbounded twin-width, but for which FO model checking is FPT. We use them to show that delineation fails for 1.5D-terrain visibility graphs, and also when relaxing any of the hypotheses of Theorem 26.

Precisely, we construct a class $\mathcal{H}$ of graphs combining half-graphs and paths of slightly more than constant length, and prove that it has unbounded twin-width, but bounded *merge-width* [10]. The latter implies FPT model checking and monadic dependence. The class $\mathcal{H}$ differs significantly from the class of all subcubic graphs used as non-delineation example in [1]: any monadically stable (i.e. that does not transduce all finite linear orders) subclass of $\mathcal{H}$ has bounded twin-width. This is a concrete counter-example to [1, Conjecture 6.6]. Another non-explicit counter-example to this conjecture was given in [6, Corollary 20.10].

Let $\mathfrak{S}_m$ denote the set of permutations of $[m]$. Given $\sigma \in \mathfrak{S}_m$ a length $\ell > 0$, define H_σ^ℓ as follows (see Figure 6). Create vertices a_i, b_i, c_i, d_i for $i \in [m]$, with edges $a_i b_j$ and $c_i d_j$ for all $i \leq j$, thus forming two disjoint half-graphs. Then, connect b_i to $c_{\sigma(i)}$ by a path of length ℓ. For a function $f : \mathbb{N} \to \mathbb{N}$, we define the class of graphs $\mathcal{H}_f := \{H_\sigma^{f(m)} : m \in \mathbb{N},\ \sigma \in \mathfrak{S}_m\}$.

When f grows slowly, we show that $\mathcal{H}_f$ has unbounded twin-width by transducing $f(m)$-subdivisions of cliques of size m, known to have unbounded twin-width [2, Theorem 6.2].

▶ **Fact 27 (♣).** *For $f(m) = o(\log m)$ a positive function, $\mathcal{H}_f$ has unbounded twin-width.*

On the other hand, when f tends to infinity, the class $\mathcal{H}_f$ has bounded merge-width (see full version for the definition and proof). More generally, we prove the following.

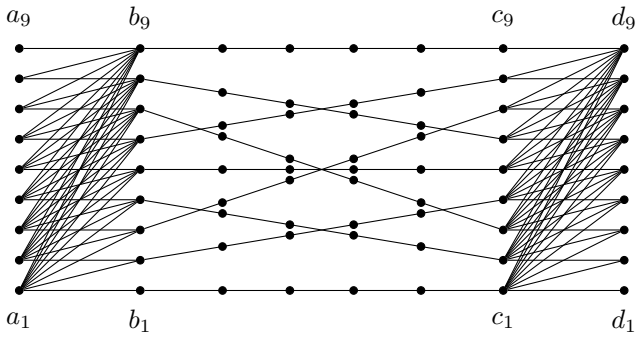

Figure 6 The graph H^5_σ for the permutation $\sigma = 147258369$.

▶ **Lemma 28 (♣).** *Let $\mathcal{C}$ be a class with bounded merge-width, and $f : \mathbb{N} \to \mathbb{N}$ tending to infinity. Call $\mathcal{C}'$ the class of graphs constructed as follows: take $G \in \mathcal{C}$, pick any number of pairs of vertices $(x_1, y_1), \dots, (x_t, y_t)$, and for each add a new path of length more than $f(|V(G)|)$ from x_i to y_i, with fresh internal vertices. Then $\mathcal{C}'$ has bounded merge-width.*

▶ **Fact 29.** *For any function f that tends to infinity, the class $\mathcal{H}_f$ has bounded merge-width.*

Proof. Half-graphs (and disjoint unions thereof) have bounded clique-width, which implies bounded merge-width by [10, Theorem 7.1]. Then, $\mathcal{H}_f$ is obtained from half-graphs by the process described in Lemma 28, hence has bounded merge-width. ◀

Now pick for instance $f(m) \coloneqq \log \log m$, and consider $\mathcal{H} \coloneqq \mathcal{H}_f$.

▶ **Corollary 30.** *The class $\mathcal{H}_f$ has unbounded twin-width, but it is monadically dependent, and FO model checking in $\mathcal{H}_f$ is FPT.*

Proof. The class $\mathcal{H}$ has unbounded twin-width by Fact 27, and bounded merge-width by Fact 29. The latter implies that $\mathcal{H}$ is monadically dependent [10, Theorem 1.12], and has FPT model checking [10, Theorem 1.11]. ◀

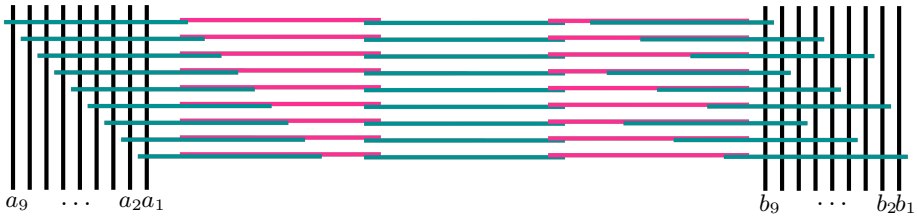

Figure 7 A degenerate APUS whose intersection graph is H^5_σ for $\sigma = 147258369$.

The class $\mathcal{H}_f$ (for any function f with $f(m) \geq 3$) can be constructed as *degenerate* APUS, see Figure 7. Thus the "non-degenerate" assumption in Theorem 26 is necessary. Variants of the construction show that the other hypotheses are necessary too:

▶ **Theorem 31 (♣).** *There are hereditary classes of intersection graphs that have unbounded twin-width but allow FPT FO model checking for the following objects:*

1. *degenerate axis-parallel unit segments,*
2. *axis-parallel segments in general position where segment lengths take only two values,*

3. *axis-parallel segments in general position with lengths in* $[1, 1+\epsilon]$ *for any* $\epsilon > 0$,
4. *unit segments in general position, even when segment slopes are restricted to "vertical", "horizontal plus* ϵ*", and "horizontal minus* ϵ*".*

Case 2 was already known from [1, Figure 8]; we give a different construction based on Figure 7. Finally, a variant of this construction can be used for terrain visibility graphs:

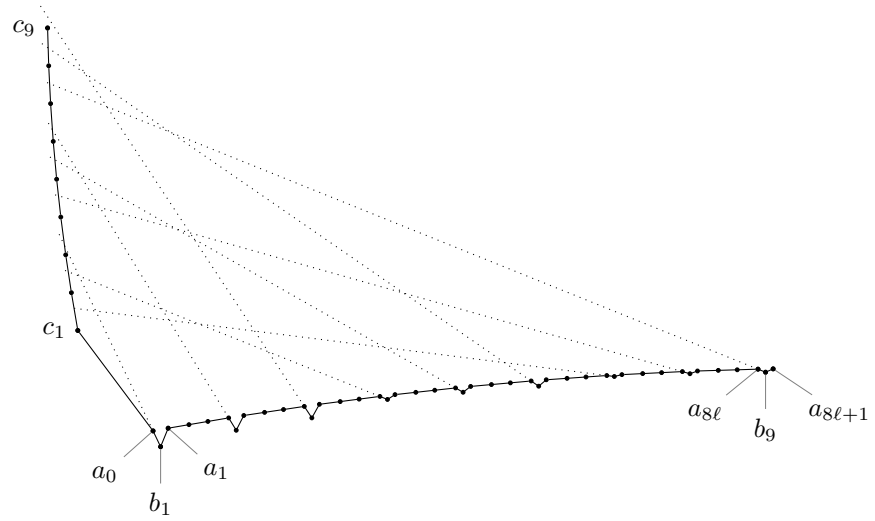

Figure 8 Construction of non-delineated terrain visibility graphs. Dotted lines represent the "horizon" for each b_i, which can be controlled by moving b_i up or down. This allows the half-graph between the b_is and c_js to represent any permutation of the b_is, here 369258147.

▶ **Theorem 2 (♣).** *There is a class* $\mathcal{C}$ *of 1.5D-terrain visibility graphs, whose hereditary closure allows FPT model checking, but which has unbounded twin-width.*

The proof uses one-sided variants of the graphs H^{ℓ}_{σ}, consisting of a long path $a_1, \ldots, a_{\ell n}$, vertices $b_1, \ldots, b_m$ spaced evenly along this path, and a half-graph between $b_1, \ldots, b_m$ and some $c_1, \ldots, c_m$, such that the ordering of $b_1, \ldots, b_m$ from the half-graph can be permuted arbitrarily relative to the path ordering, see Figure 8.

Online Packing of Orthogonal Polygons

Universität Hamburg, Germany

Abstract

While rectangular and box-shaped objects dominate the classic discourse of theoretic investigations, a fascinating frontier lies in packing more complex shapes. Given recent insights that convex polygons do not allow for constant competitive online algorithms for diverse variants under translation, we study orthogonal polygons, in particular of small complexity. For translational packings of orthogonal 6-gons, we show that the competitive ratio of any online algorithm that aims to pack the items into a minimal number of unit bins is in $\Omega(n/\log n)$, where n denotes the number of objects. In contrast, we show that constant competitive algorithms exist when the orthogonal 6-gons are symmetric or small. For (orthogonally convex) orthogonal 8-gons, we show that the trivial n-competitive algorithm, which places each item in its own bin, is best-possible, i.e., every online algorithm has an asymptotic competitive ratio of at least n. This implies that for general orthogonal polygons, the trivial algorithm is best possible.

Interestingly, for packing degenerate orthogonal polygons (with thickness 0), called skeletons, the change in complexity is even more drastic. While constant competitive algorithms for 6-skeletons exist, no online algorithm for 8-skeletons achieves a competitive ratio better than n.

For other packing variants of orthogonal 6-gons under translation, our insights imply the following consequences. The asymptotic competitive ratio of any online algorithm is in $\Omega(n/\log n)$ for strip packing, and there exist online algorithms with competitive ratios in $O(1)$ for perimeter packing, or in $O(\sqrt{n})$ for minimizing the area of the bounding box. Moreover, the critical packing density is positive (if every object individually fits into the interior of a unit bin).

Acknowledgements We thank the anonymous reviewers for their valuable comments and suggestions, which helped to improve the quality of this work. In particular, we thank an anonymous reviewer for the suggestion to use NextFit in the proof of Theorem 6(i) and improving the analysis to obtain a competitive ratio of 2.

1 Introduction

Packing problems not only present us with constant challenges in everyday life, but also find applications in manufacturing industries, logistics, and scheduling. While rectangular and box-shaped objects dominate the classic discourse of theoretic investigations, a fascinating frontier lies in the packing of more complex objects, e.g., convex polygons. The problem of packing convex polygons is particularly interesting when restricting the allowed motions to translations, as allowing for rotations reduces the problem to mere rectangle packing. Across the numerous variants – be it strip packing, bin packing, or perimeter packing – the overall

picture is that constant factor approximations exist for translational packings of convex polygons [7, 8, 1, 41]. However, the landscape changes when we step into the online realm where items arrive sequentially one after the other and decisions have to be made irrevocably without knowing the future items: In this setting, no online algorithm for translational packings of convex polygons has a constant competitive ratio, as recently shown by Aamand, Abrahamsen, Beretta, and Kleist [1]. This is in stark contrast to the case of rectangles, for which constant competitive algorithms exist for various variants, cf. Section 1.1.

In this work, we study the online packing problem of orthogonal polygons which are orthogonally convex, combining relaxed features of both orthogonality and convexity. A polygon is *orthogonally convex* if the intersection with any axis-parallel line has at most one connected component. The simplest yet unresolved setting involves orthogonal 6-gons, which include *L-shapes*. For examples, consider Figure 1.

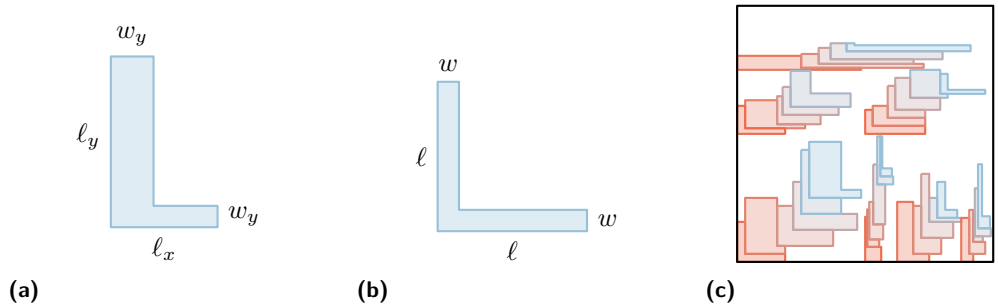

Figure 1 (a) An L-shape, (b) a symmetric L-shape, and (c) a bin packing of L-shapes.

The diverse applications motivate a multitude of interesting packing problems. Among them are bin packing, strip packing, perimeter packing and area packing for various types of objects and allowed motions; for definitions see Section 2. Many variants of these packing problems are known to be computationally difficult. While NP-hardness has usually been known for a long time [5, 28, 35, 43], more recently, some variants were proved to even be $\exists\mathbb{R}$-complete by Abrahamsen, Miltzow, and Seiferth [4]. Adding to this difficulty, we might not have complete information about the objects in advance, e.g., they may appear over time. This is captured by the so called *online setting* where the objects are presented one after another and the next object is only revealed when the previous one has been placed.

In *competitive analysis*, the performance of an online algorithm is measured against the optimal offline solution. While the *absolute competitive ratio* gives the worst-case performance over all possible inputs, the *asymptotic competitive ratio* describes the behavior when the input size goes to infinity. For precise definitions, we refer to Section 2. In the following we present our contributions, see also Tables 1 and 2. Usually, we present lower bounds on the asymptotic competitive ratio and upper bounds on the absolute competitive ratio which imply the statements for both ratios.

Bin Packing of 6-gons. For bin packing of orthogonal polygons, it is natural to consider the variants where the objects can only be translated, and where the objects may be rotated by multiples of 90 degrees. The following proposition shows that even in the latter variant we may restrict our analysis to the translational case. In the problem Ortho-BinPack, we receive orthogonal polygons $P_1, ..., P_n$ which have to be placed into a unit square bin by translation. The goal is to minimize the number of used bins. Ortho-BinPack$_{\text{rot}}$ denotes the variant where the polygons might be rotated by multiples of 90 degrees.

▶ **Proposition 1.** *The best (absolute/asymptotic) competitive ratios for* Ortho-BinPack *and* Ortho-BinPack$_{rot}$ *are within constant factors of each other. The analogous statements hold for the best approximation ratios of the offline variants.*

Proposition 1 allows us to focus on translations only. We start with a lower bound on the competitive ratio of any online algorithm for L-shapes. To this end, let L-BinPack denote the variant of Ortho-BinPack where each polygon is an L-shape.

▶ **Theorem 2.** *The asymptotic competitive ratio of any online algorithm for L-BinPack is in* $\Omega(n/\log n)$.

We obtain this lower bound by reducing from an online sorting problem where natural numbers have to placed in arrays such that the numbers in each array are increasing. Note that the trivial algorithm, which packs each object into its own bin, is n-competitive.

In contrast to Theorem 2, there exist constant competitive algorithms for some interesting subclasses of L-shapes, namely when the L-shapes are either all symmetric or all small. An L-shape is described by four parameters $\ell_x, \ell_y, w_x, w_y \in [0, 1]$. It is *small* if $\ell_x, \ell_y \leq 1/2$, *large* if $\ell_x, \ell_y \geq 1/2$, and *symmetric* if $\ell_x = \ell_y$ and $w_x = w_y$. For illustrations see Figure 1.

▶ **Theorem 3.** *There is an online algorithm for L-BinPack with a constant asymptotic competitive ratio when all L-shapes are symmetric or small. In particular, there exist algorithms that use at most*

(a) $33 \cdot OPT + 2$ *bins when all L-shapes are large and symmetric.*

(b) $8 \cdot OPT + 7$ *when all L-shapes are small.*

(c) $41 \cdot OPT + 9$ *when all L-shapes are symmetric.*

Theorem 3 directly yields algorithms with a constant absolute competitive ratio of 35, 15 and 50, respectively, as in bin packing, we have $\mathrm{OPT} \geq 1$ for any nonempty set of items.

The results for symmetric L-shapes are based on identifying their connection to scheduling problems. Competitive algorithms for two special cases of large and symmetric L-shapes follow directly from previous work on scheduling problems. Precisely, an e-competitive algorithm for objects of equal widths [22] and a 2-competitive algorithm for the case of equal lengths [24] can be deduced, see Subsection 1.1 for explanations. A connection to scheduling problems is also used for the 33-competitive algorithm which builds on a constant competitive algorithm by Devanur et al. [22] for a special machine minimization problem in combination with an online coloring algorithm for intervals graphs by Kierstead and Trotter [39]. For details on the connection to scheduling problems, we refer to Subsection 1.1.

⌐	Z-skeletons	n	[Thm 6]	n	

Other packing variants. Our insights on online bin packing of L-shapes have consequences for other packing variants. In the problem L-PeriPack, we receive L-shapes $L_1, ..., L_n$, and the goal is to place them in the plane such that the perimeter of the bounding box is minimized. In L-AreaPack, the goal is to minimize the area of the bounding box. For a unit square bin and L-shapes with arm lengths ℓ_x, ℓ_y bounded by some constant $t < 1$, the *online critical density* is the largest value of A such that there exists an online algorithm which packs any sequence with total area at most A into the bin.

▶ **Corollary 4.** *The following statements hold for L-shapes with arm lengths in* $[0, 1]$*:*

- **(i)** *The asymptotic competitive ratio of any online algorithm for L-StripPack is in* $\Omega(n/\log n)$.
- **(ii)** *There is an online algorithm for L-PeriPack with absolute competitive ratio in* $O(1)$.
- **(iii)** *There is an online algorithm for L-AreaPack with asymptotic competitive ratio in* $O(\sqrt{n})$.
- **(iv)** *The online critical packing density is positive if the arm lengths of each L-shape are bounded by* $t < 1$. *For* $t = 1$, *the online critical packing density is* 0.

The $O(\sqrt{n})$-competitive algorithm for L-AreaPack is asymptotically best-possible, as a lower bound of $\Omega(\sqrt{n})$ already for rectangles has been shown by Abrahamsen and Beretta [3].

Table 2 Overview on the known upper and lower bounds on the best competitive ratios for the various packing problems.

Variant	▯ rectangles	△ convex polygons	⌙ L-shapes	⌐ ortho polygons
Bin	$\Theta(1)$ [34]	$\Omega\left(\sqrt{\frac{\log n}{\log\log n}}\right)$ [1]	$\Omega\left(\frac{n}{\log n}\right)$ [Thm 2]	n
Strip	$\Theta(1)$ [52]	$\Omega\left(\sqrt{\frac{\log n}{\log\log n}}\right), O(n^{0.59})$ [1]	$\Omega\left(\frac{n}{\log n}\right)$ [Thm 4i]	$\Omega\left(\frac{n}{\log n}\right)$ [Thm 4i]

Orthogonal polygons of higher complexity. For bin packing of orthogonal 8-gons, we show that the trivial algorithm, that places each shape into its own bin, achieves the best possible competitive ratio. Hence, the trivial algorithm is also best possible for Ortho-BinPack.

▶ **Theorem 5.** *There is no online algorithm for Ortho-BinPack that achieves an asymptotic competitive ratio better than* n, *even when restricting to orthogonally convex 8-gons.*

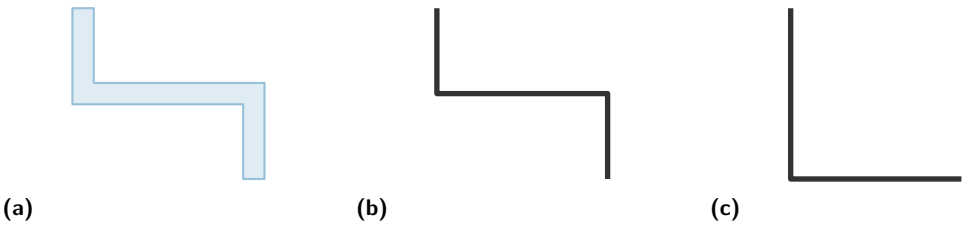

Figure 2 (a) A Z-shape (b) A Z-skeleton (c) An L-skeleton.

We obtain Theorem 5 by considering Z-shapes of equal thickness; Figure 2a depicts an example. Interestingly, we obtain this result via first considering packings of skeletons, which can be viewed as orthogonal polygons of widths 0, see Figures 2b and 2c. In the problem L-Skel-BinPack (Z-Skel-BinPack), L-skeletons (Z-skeletons) shall be packed into a minimum number of bins. In this context, we consider a packing of skeletons as *valid* if any two objects are disjoint, with the exception that either of the two endpoints of one skeleton may touch another; a point of a Z-skeleton is an endpoint if it is a unique extreme point, i.e., topmost, bottommost, leftmost, or rightmost. From L- to Z-skeletons, there is a quite drastic jump in complexity.

▶ **Theorem 6.** *For online bin packing of orthogonal skeletons the following holds.*

(i) *There exists an online algorithm for L-Skel-BinPack with a constant absolute competitive ratio.*

(ii) *No online algorithm for Z-Skel-BinPack has an asymptotic competitive ratio better than n.*

Organization. The remainder of the paper is organized as follows. In Section 1.1, we discuss related work. In Section 2, we give a concise dictionary on crucial notions. In Section 3, we prove Theorem 2, i.e., the lower bound on the competitive ratio for L-BinPack and use our insights to show a lower bound for L-StripPack in Section 4. In Section 5, we consider orthogonal polygons of higher complexity and sketch the proofs of Theorems 5 and 6(ii). Complete proofs of all results can be found in the full version of this paper [30].

1.1 Related work

As the literature on online packing problems is extensive, we refer to the surveys of Christensen, Khan, Pokutta, and Tetali [19], Epstein and van Stee [26], van Stee [49, 50], and Csirik and Woeginger [21] for an overview. Below we discuss the most important results related to the packing problems studied in this paper.

Rectangles. Rectangle packings has been studied for almost 50 years. A straightforward reduction from partition shows that the offline strip packing problem cannot be approximated with an absolute factor better than $3/2$ unless $\mathsf{P} = \mathsf{NP}$, and the best known approximation ratio is $5/3 + \varepsilon$ by Harren, Jansen, Prädel, and Van Stee [35]. For the online variant, first fit shelf algorithms as proposed by Baker and Schwarz [10], are widely studied. The best known competitive ratio of $7/2 + \sqrt{10} \approx 6.66$ is achieved by Ye, Han, and Zhang [52]. Restricting the attention to large instances, the best asymptotic competitive ratio is lower bounded by 1.54 by van Vliet [51] and upper bounded by 1.59 by Han, Iwama, Ye, and Zhang [32].

For *bin packing* of rectangles under translation, there exist approximation algorithms with approximation ratio 2 [34] and asymptotic approximation guarantee 1.4 by Bansal and Khan [14]. For online bin packing of rectangles, the upper bound on the asymptotic competitive ratio for online translational bin packing axis-parallel rectangular pieces into unit square bins has been decreased in a series of papers from 3.25 [20] to about 2.55 by Han, Chin, Ting, Zhang and Zhang [31] and the lower bound has been increased from 1.6 [29] to 1.91 by Epstein [23]. For the special case of squares, the lower bound is approximately 1.75 due to Balogh, Békési, Dósa, Epstein, and Levin [11], while the upper bound is above 2.08 by Epstein and Mualem [25].

For the problem of area minimization, Abrahamsen and Beretta [3] present $O(n)$-competitive algorithms and show a lower bound of $\Omega(n)$ for both versions of rotation allowed and translations only. For perimeter minimization, they gave a 3.98-competitive algorithm for both, translation and rotation, as well as a lower bound on the competitive ratio of $4/3$ for the case of translation and of $5/4$ for the case of rotation.

Convex Polygons. Constant-factor approximations for packing convex polygons exist for many variants [7, 8, 1, 41]; an exception is bin packing where constant approximation factors are only known if the diameter of the items is bounded by a constant. In contrast to these constant guarantees, for online translational packings of convex polygons, Aamand, Abrahamsen, Beretta and Kleist [1] show that strip packing, bin packing, and perimeter packing do not allow for constant competitive online algorithms, even if all pieces have a diameter bounded by an arbitrarily small constant. To this end, they reduce to an online sorting problem which sparked follow-up investigations [2, 9, 47]. Concerning upper bounds, they give an online algorithm with competitive ratio $O(n^{0.59})$ for strip packing. The knapsack problem for convex polygons under rigid motions is studied by Merino and Wiese [45].

Orthogonal Polygons and Scheduling. We identified interesting connections between packings of special L-shapes and scheduling problems such as open end bin packing and machine minimization. These yield algorithms for large and symmetric L-shapes in the case where all L-shapes have equal lengths or equal widths; for an overview see Table 3.

The case of equal lengths is related to open end bin packing. In a variant of classical 1D bin packing known as *ordered open end bin packing*, items of sizes in $(0, 1]$ are presented one by one, and must be assigned to bins in this order. An item can be assigned to any bin for which the current total size is strictly below 1, i.e., the bin can be overloaded by its last packed item. Balogh, Epstein, and Levin [13] present a 2-competitive online algorithm and Epstein [24] designs a 1.5 approximation. As packings of large, symmetric L-shapes of equal lengths can be reduced to open end bin packing, we obtain offline and online algorithms with constant factors. Specifically, for packing L-shapes of length ℓ, we consider open end bins of capacity $1 - \ell$. An L-shape L_i with arm length ℓ and width w_i is associated with a real $r_i := w_i$. It is easy to see that an L_i can be packed into a bin containing $L_1, \ldots, L_k$ (bottom-leftmost) if $\sum_{j=1}^{k} w_j + \ell \leq 1$. Similarly, r_i can be packed into an open bin containing $r_1, \ldots, r_k$ if (and only if) $\sum_{j=1}^{k} r_j \leq 1 - \ell$. As these conditions are equivalent, solutions of open end bin packing translate to (bottom-leftmost) packings of large, symmetric L-shapes of equal lengths. This implies a 2-competitive online algorithm and a 1.5-approximation in this case.

For bin packing of large and symmetric L-shapes with different lengths, we identified a close connection to the *machine minimization* problem: Given a set of jobs, each of which has a release time r, a processing time p and deadline d, the task is to schedule these jobs on a minimum number of machines such that each machine processes at most one job at a time and each job starts not before its release time, and finishes not after its deadline. For large and symmetric L-shapes, we show that the two parameters, length ℓ and width w, translate to a job with release time 0, processing time w, and deadline $1 - \ell$. Therefore, we present relevant work in the context of machine minimization. Yu and Zhang [53] present approximation algorithms for the special cases of equal deadlines and equal processing times. In particular, their 2-approximation algorithm for the special case of equal deadlines translates to a 2-approximation for offline bin packing of large, symmetric L-shapes. Kao, Chen, Rutter, and Wagner [38, Lemmas 1 and 2] present a polynomial algorithm that computes the offline

optimal solution for jobs of unit processing times. This translates to a polyomial time algorithm for offline packings of instances where all L-shapes are large, symmetric, and have equal widths. Devanur, Makarychev, Panigrahi, and Yaroslavtsev [22, Section 2,3] present an e-competitive online algorithm for unit processing times; they also show that the competitive ratio of e is optimal. This result is also implied by Bansal, Kimbrel, and Pruhs [15, Lemmas 4.7 and 4.8]. The insights can be translated to an e-competitive algorithm for packing large, symmetric L-shapes of equal widths. Moreover, Devanur et al. [22] present a 16-competitive online algorithm for the case with equal deadlines; their techniques are the basis of our 33-competitive algorithm for packing large symmetric L-shapes, namely Theorem 3(a).

There are many more results on the general case of machine minimization. However, due to a lower bound of n by Saha [48], most subsequent work allows preemption of the jobs [18, 17, 36], a setting that does not carry over to packings of L-shapes.

Table 3 Upper bounds on the best asymptotic approximation/competitive ratios for L-BinPack with restricted L-shapes.

Critical densities. For a given container of volume C and a class of objects in $\mathbb{R}^d$, the *critical density* is the largest value of V/C such that any sequence of objects of the class with a total volume of at most V can always be packed in the container. For convex bodies of bounded diameter in $\mathbb{R}^3$, Auerbach, Banach, Mazur and Ulam [44] stated (without proof) that the critical density is positive, i.e., there exists a function f such that any sequence of convex bodies in $\mathbb{R}^3$, each of diameter $\leq \delta$ and total volume of at most V, can be packed into a cube with side length $s = f(\delta, V)$ when rotations are allowed. The first proof, even for arbitrary dimension, is given by Kosiński [40]. When rotations are not allowed, Alt, Cheong, Park, and Scharf [6] showed that the critical density of packing convex bodies of bounded diameter into a cube is 0; in particular for packing unit disks in $\mathbb{R}^3$. However, for cubes, Moon and Moser [46] showed that any sequence of cubes in $\mathbb{R}^d$ of total volume $1/2^{d-1}$ can be packed into the unit cube. This bound is the best possible, because for any $\varepsilon > 0$, two cubes with side lengths $1/2 + \varepsilon$ cannot be packed in the unit cube.

The study of critical densities likewise makes sense when the pieces appear in an online fashion. A lower bound on the critical density of online packing squares into the unit square has been improved in a sequence of papers [37, 16, 33, 27] from 5/16 [37] to 2/5 [16]. Interestingly, Januszewski and Lassak [37] proved that in dimension $d \geq 5$, the critical density of online packing cubes into the unit cube is $1/2^{d-1}$, just as in the offline case. Lassak and Zhang [42] showed that for some constant $\delta(d) > 0$, any sequence of axis-parallel boxes of diameter and total area at most $\delta(d)$ can be packed online in the d-dimensional unit hypercube using translations. This implies that the critical packing density for convex bodies is positive for any dimension $d \geq 1$ when rotations are allowed as each body can be rotated so that it has a constant (depending on the dimension) density in its axis-parallel bounding box. In contrast, for translational and online packing convex polygons, Aamand, Abrahamsen, Beretta and Kleist [1] show that the critical packing density is 0.

2 Notions: packing variants, competitive analysis, and objects

We briefly define the packing variants, review the common terminology for competitive analysis, and introduce the considered objects.

Packing variants. Depending on the context, there are numerous packing variants specified by the container and objective. The variants discussed in this paper are as follows. Consider a set (or sequence) of items. Given an unbounded supply of identical unit bins, the goal of *bin packing* is to pack the items into as few bins as possible. Given a horizontal strip of height 1 which is bounded to the left but infinite to the right, the aim of *strip packing* is to place the items in the strip such that the maximum x-coordinate of an occupied point is minimized. In *perimeter packing* or *area packing*, the goal is to find a placement of the items in the plane such that the perimeter or the area of the bounding box is minimized, respectively. All of these variants are interesting as *offline* and *online* problems. In this work we focus on online problems and therefore review competetitive analysis.

Competitive analysis. In an online problem, the input is a sequence $\sigma_1, \ldots, \sigma_n$ of objects, and we need to process object σ_i (in a problem-specific manner) before the next object σ_{i+1} is revealed. In this work, the objects are either natural numbers, orthogonal polygons, or their skeletons. We briefly revisit the standard terminology of competitive analysis for an online algorithm $\mathcal{A}$ of a minimization problem. For an instance I, $\mathrm{OPT}(I)$ denotes the cost of the offline optimum solution and $\mathcal{A}(I)$ denotes the cost of the solution computed by $\mathcal{A}$ for input I. Let $f\colon \mathbb{N} \to \mathbb{R}$ be a function of the size $|I|$ of the instance, in our context typically the number of objects. We say that $\mathcal{A}$ has *(absolute) competitive ratio* $f(|I|)$ if, for all instances I, it holds that $\mathcal{A}(I) \leq f(|I|) \cdot \mathrm{OPT}(I)$. Similarly, $\mathcal{A}$ has *asymptotic competitive ratio* $f(|I|)$ if there exists a constant $\beta > 0$ such that $\mathcal{A}(I) \leq f(|I|) \cdot \mathrm{OPT}(I) + \beta$ for all I.

Objects. We focus on packings of orthogonal polygons that we call *L-shapes* and *Z-shapes*. An *L-shape* is the union of a rectangle of width ℓ_x and height w_y with a rectangle of width w_x and height ℓ_y, with $w_x \leq \ell_x$ and $w_y \leq \ell_y$, such that their lower left corners coincide. Figure 3a presents an example. We describe the placement of an L-shape by specifying the coordinates of its *reference point*, namely its lower left corner.

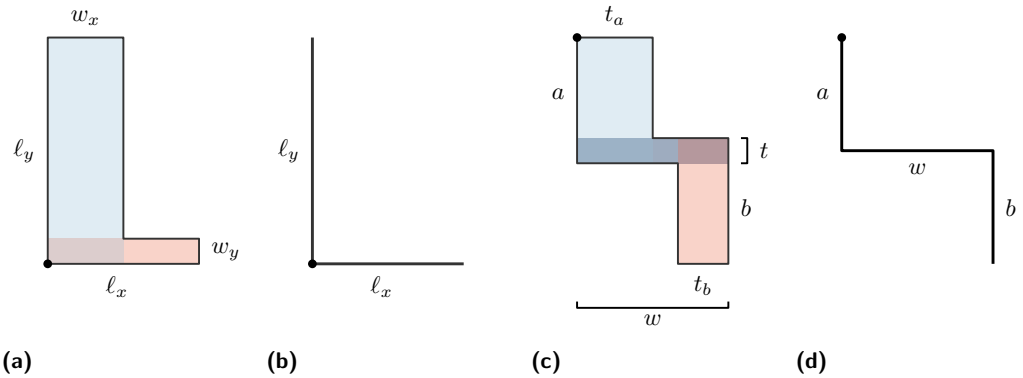

Figure 3 Parameters and the reference point of an (a) L-shape, (b) L-skeleton, (c) Z-shape, and (d) Z-skeleton.

We note that each orthogonal 6-gon is either an L-shape or a rotated L-shape. An L-shape is *small* if $\ell_x, \ell_y \leq 1/2$, *large* if $\ell_x, \ell_y \geq 1/2$, and *symmetric* if $\ell_x = \ell_y$ and $w_x = w_y$.

A *Z-shape* is the union of three rectangles: A base rectangle of height t and width w, and two arm rectangles: One arm (above) of width t_a and height a, whose lower left corner coincides with the lower left corner of the base, and one arm (below) of width t_b and height b such that its upper right corner coincides with the upper right corner of the base, where $t_a, t_b \leq w$, see also Figure 3c. In this paper, we will mostly be concerned with Z-shapes of *equal thickness*, i.e., the case where $t_a = t_b = t$. Note that all L-shapes and Z-shapes are *orthogonally convex*, i.e., the intersection with any axis-parallel line is connected.

L-skeletons and Z-skeletons are the corresponding shapes with zero thickness, i.e., $w_x = w_y = 0$ and $t_a = t_b = t = 0$, respectively. Figures 3b and 3d present examples.

3 Lower bound for bin packing of L-shapes – Proof of Theorem 2

We now prove the lower bound for L-BinPack.

▶ **Theorem 2.** *The asymptotic competitive ratio of any online algorithm for L-BinPack is in* $\Omega(n/\log n)$.

We show this in two steps. We prove that any online algorithm for L-BinPack yields an algorithm for an online sorting problem called BinSorting with the same competitive ratio, and show that every online algorithm for BinSorting has a competitive ratio in $\Omega(n/\log n)$. We start by introducing the problem BinSorting.

3.1 Bin sorting

The online problem BinSorting$[k]$ can be described as a game between two players, Presenter and Algorithm, playing on several arrays with k slots each, in which natural numbers have to be inserted. Within each array, the numbers must be increasing. Presenter presents distinct numbers. When receiving a number, Algorithm has to irrevocably decide in which array and in which slot the number is placed while obeying the rule that the numbers of each array are increasing. The goal of Algorithm is to minimize the number of used arrays, while Presenter wants to maximize it. Figure 4 presents an example of this game.

	2_4	16_1		
4_3	8_2			
		3_5		

Figure 4 An instance of the BinSorting with $k = 5$ for the sequence $16, 8, 4, 2, 3$.

The offline optimum corresponds to the setting where Algorithm knows all numbers in advance and is simple to determine: For n numbers in arrays with k slots, $\lceil n/k \rceil$ arrays are necessary and, as the numbers can be inserted in a sorted manner, also sufficient. Consequently, $\mathrm{OPT} = \lceil n/k \rceil$.

We start by presenting a strategy for Presenter forcing Algorithm to use at most a logarithmic number of slots in each array.

▶ **Lemma 7.** *The asymptotic competitive ratio of any online algorithm for BinSorting$[k]$ is at least* $\lceil n/\lfloor \log(k+1) \rfloor \rceil / \lceil n/k \rceil \in \Omega(k/\log k)$. *For $k = n$, the lower bound is* $n/\lfloor \log(n+1) \rfloor \in \Omega(n/\log n)$.

Proof. We show that PRESENTER has a strategy to present n numbers such that ALGORITHM uses at least $n/\lfloor\log(k+1)\rfloor$ arrays while $\lceil n/k\rceil$ arrays would suffice. The idea is as follows: Consider a partially filled array A. The numbers in A partition it into maximal sections of free slots. If a new number shall be inserted in A, it may be placed into at most one of these sections, since the entries in the array must be increasing. We say that two (possible future) numbers are *similar* with respect to A if they must be placed in the same section. The idea of PRESENTER is to maintain a set of active numbers that are similar for all arrays.

In order to present n natural numbers $a_1, \dots, a_n$, PRESENTER maintains the following invariant: In the beginning of iteration i, it has an *active* set of $2^{n-i+1}-1$ similar numbers. In the very beginning (of iteration 1), the set is $(0, 2^n) := \{1, \dots, 2^n - 1\}$, each array has one section containing all slots, and PRESENTER presents $a_1 = 2^{n-1}$. In iteration $i+1$, PRESENTER determines the next number to be presented based on the action of ALGORITHM in iteration i. ALGORITHM places a_i in a section of some array which results in two smaller sections. If the smaller of the two section lies to the left of a_i, then the active set (l, r) is updated to (l, a_i) and $a_{i+1} = (l + a_i)/2 = a_i - 2^{n-(i+1)}$; otherwise it is updated to (a_i, r) and $a_{i+1} = (a_i + r)/2 = a_i + 2^{n-(i+1)}$. As the new active set is a subset of the previous, ALGORITHM must place numbers presented in the future in (subsets of) the current sections of the active set. By construction, the numbers of the active set remain similar. The active set is non-empty for at least n iterations because it contains $2^{n-i+1} - 1 \geq 1$ numbers if $i \leq n$.

When we restrict our attention to a fixed array with k slots, then the section for the active numbers is (at least) halved each time a number is inserted; this is because we ensure that the active set must be inserted in the smaller section. Therefore, ALGORITHM can place at most $\lfloor \log(k+1) \rfloor$ of the n numbers in each array and thus needs at least $\lceil n/\lfloor\log(k+1)\rfloor\rceil$ bins. This yields a competitive ratio of at least $\lceil n/\lfloor\log(k+1)\rfloor\rceil / \lceil n/k\rceil \in \Omega(k/\log k)$. ◀

We remark that the lower bound of Lemma 7 is tight, that is, there exists an online algorithm BINSORTING$[k]$ that matches this bound.

▶ **Lemma 8.** *There exists an online algorithm for* BINSORTING$[k]$ *with absolute competitive ratio of* $\lceil n/\lfloor\log(k+1)\rfloor\rceil / \lceil n/k\rceil \in O(k/\log k)$.

Proof. For each partially filled array and any number, the valid slots form a consecutive interval. Clearly, in an empty array, all slots are valid. Let $\mathcal{A}$ denote the algorithm that places a new number in the first array with a valid slot, and in particular, in the middle slot of the section. With this choice, the smallest section of an array containing m numbers has length $\geq \lfloor (k+1)/2^m \rfloor - 1$. Therefore each array contains at least $\lfloor\log(k+1)\rfloor$ numbers before a new array is opened. Consequently, $\mathcal{A}$ uses at most $\lceil n/\lfloor\log(k+1)\rfloor\rceil$ arrays while $\mathrm{OPT} = \lceil n/k\rceil$. ◀

3.2 From L-BinPack to BinSorting

We now show how to create instances of L-BINPACK which simulate BINSORTING. The construction is visualized in Figure 5. For fixed $k \in \mathbb{N}$, we consider the family $\mathcal{L}^k = \{L_i\}_{i\in\mathbb{N}}$ of L-shapes with the following parameters:

$$\ell_x(L_i) = 1/2 + 1/2k, \quad w_x(L_i) = 1/2k, \quad \ell_y(L_i) = 1 - 2^{-i-1}, \quad w_y(L_i) = 2^{-i-1}$$

The key idea is that L_i in L-BINPACK mimics the natural number i for BINSORTING. We start with the crucial property that each subset of $\mathcal{L}^k$ packed into a bin is sorted.

▶ **Lemma 9.** *Each set $S \subset \mathcal{L}^k$ packs into one bin if and only if $|S| \leq k$ and the items are placed in descending order of their indices i.*

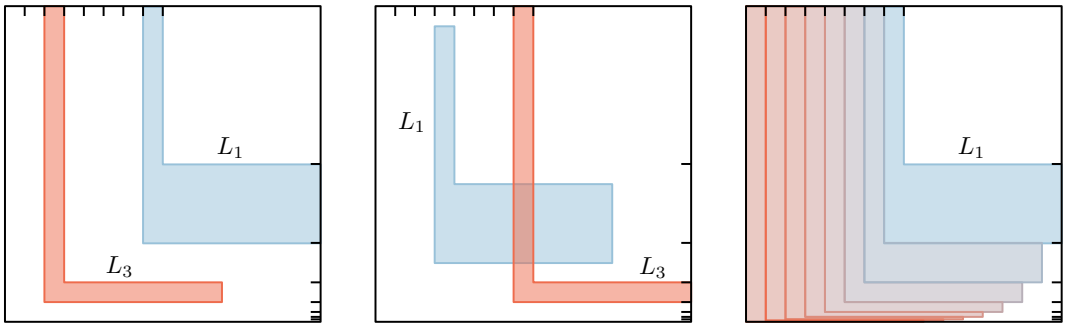

Figure 5 Illustrations for $\mathcal{L}^8$. (a) While L_1 may be placed to the right/above of L_3, (b) L_1 cannot be placed to the left/below of L_3 as $l_x(L_1)+l_x(L_3) > 1$ and $l_y(L_3)+w_y(L_1) = 1-2^{-3-1}+2^{-1-1} > 1$, respectively. (c) A packing of $L_1, \dots, L_k \in \mathcal{L}^k$ for $k = 8$ into one bin.

Proof. By construction up to k items of $\mathcal{L}^k$ fit into one bin in descending order of their indices: With respect to the x-coordinate, exactly k items can be packed next to each other. For the y-coordinate, we note the following. When L_i is placed somewhere in the bin, the free space above is lower bounded by

$$\ell_y(L_i) - w_y(L_i) = (1 - 2^{-i-1}) - 2^{-i-1} = \ell_y(L_{i-1}) \geq \ell_y(L_j) \text{ for } j < i.$$

So when placed in descending order, there is space for k items. Figure 5c depicts an example for $k = 8$. It remains to show that L_i cannot be placed below/left of L_j when $i < j$. It cannot be placed entirely to the left of L_j, because $l_x(L_i) + l_x(L_j) = 2(1/2 + 1/k) > 1$, and it cannot be placed below L_j because $w_y(L_i) + \ell_y(L_j) = 2^{-i-1} + 1 - 2^{-j-1} > 1$. ◀

We now show how an algorithm for L-BinPack yields an algorithm for BinSorting$[k]$.

▶ **Lemma 10.** *An online-algorithm for L-BinPack yields an algorithm for BinSorting$[k]$ with the same (absolute/asymptotic) competitive ratio.*

Proof. Let $\mathcal{A}$ be an α-competitive algorithm for L-BinPack and consider an instance I_S of BinSorting $[k]$ with n numbers. We describe an online algorithm $\mathcal{A}'$ for BinSorting$[k]$ which uses $\mathcal{A}$ as a subroutine. For each presented number i, $\mathcal{A}'$ presents $L_i \in \mathcal{L}^k$ to $\mathcal{A}$. By Lemma 9, at most k L-shapes of $\mathcal{L}^k$ fit into one bin. Let x denote the x-coordinate of the reference point of L_i in the jth bin as assigned by $\mathcal{A}$. Then $\mathcal{A}'$ places number i in the slot $\lfloor x \cdot 2k \rfloor + 1$ of the jth array. As $x \in [0, 1/2 - 1/2k]$, it holds that $\lfloor x \cdot 2k \rfloor + 1 \in [k]$. We shortly argue that this position is valid. Firstly, because all L-shapes have width $1/2k$, the assigned x-values differ by at least $1/2k$ and for any x and x' with $|x - x'| \geq 1/2k$, we have $|\lfloor x \cdot 2k \rfloor - \lfloor x' \cdot 2k \rfloor| \geq 1$. Secondly, as $\mathcal{A}$ guarantees that the numbers of each array are increasing, the same holds for the indices of the L-shapes. Hence, by Lemma 9, the placement is valid. Consequently, we may translate the x-position of L_i in the jth bin to a unique slot in the jth array. The number of used arrays equals the number of used bins. Moreover, the offline optimum is $\lceil n/k \rceil$ in both problems. Hence, $\mathcal{A}'$ is α-competitive. ◀

Together, Lemmas 7 and 10 show the following statement, which proves Theorem 2.

▶ **Corollary 11.** *For each online algorithm $\mathcal{A}$ for L-BinPack and each n, there exists a strategy to present n L-shapes from $\mathcal{L}^n$ (no duplicates) such that they can all be packed into one bin while $\mathcal{A}$ uses at least $n/\log(n+1)$ bins.*

4 Strip packing of L-shapes – Proof of Corollary 4(i)

We now prove Corollary 4(i). To this end, we show how a strip packing algorithm yields a bin packing algorithm.

▶ **Lemma 12.** *An algorithm $\mathcal{A}$ for strip packing a sequence of n L-shapes from $\mathcal{L}^n$ (without duplicates) with asymptotic competitive ratio α yields an algorithm $\mathcal{A}'$ for L-BinPack with asymptotic competitive ratio 2α.*

Proof. Let $\mathcal{A}$ be an asymptotic α-competitive algorithm for L-StripPack and consider an instance of L-BinPack with n objects from $\mathcal{L}^n$. We describe an online algorithm $\mathcal{A}'$ for L-BinPack which uses $\mathcal{A}$ as a subroutine. For each each $L \in \mathcal{L}^n$, $\mathcal{A}'$ presents it to $\mathcal{A}$ and observes its placement in the strip. The idea is to partition the strip into slots of widths $1/2n$; each slot will correspond to a placement in a bin. For an illustration, see Figure 6. We show that objects of n consecutive slots can be packed into one bin. If the reference point of L is placed at (x, y) in the strip, then $\mathcal{A}'$ places it as follows. Let $m, r \in \mathbb{N}$ such that $\lfloor x \cdot 2n \rfloor = mn + r$ and $r < n$. Then $\mathcal{A}'$ places L in the $(m+1)$st bin such that its reference point is at $(x', y') := (r/2n, 1 - \ell_y(L))$.

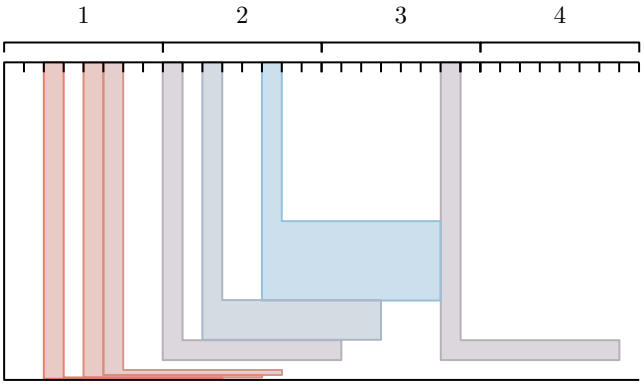

Figure 6 Illustration for the proof of Lemma 12.

We now argue that this yields a valid bin packing. Let L_i and L_j be two L-shapes in a same bin and denote their x-coordinates in the strip by x_i and x_j, and in the bin by x'_i and x'_j, respectively. We assume that $x_i < x_j$. By construction, we have that $|x_i - x_j| \leq 1/2$. The placement $x_i < x_j$ implies that $w_y(L_i) + \ell_y(L_j) \leq 1$ and hence $i \geq j$, i.e., in each bin the L-shapes are non-increasing. Moreover, due to the equal width of $1/2n$, no two L-shapes intersect in the x-direction. Without duplicates, no intersections in the y-direction follow from the definition of $\mathcal{L}^n$. Lastly, if $x'_j - x'_i \leq {}^{n-1}/_{2n}$ then $x'_j + \ell_x(L_i) \leq ({}^{n-1}/_{2n} + x_i) + 1/2 + 1/2k \leq x_i + 1$. Therefore, the y-span of the L-shapes is at most 1.

It remains to check the number of bins. Let OPT_S and OPT_B denote the offline optimum values for L-StripPack and L-BinPack, respectively. Clearly, we have $\mathrm{OPT}_S \leq \mathrm{OPT}_B = 1$; recall that all objects pack into one bin by Lemma 9. As $\mathcal{A}$ is asymptotically α-competitive, there is a constant $\beta > 0$ such that the width of the strip packing is at most $\alpha \cdot \mathrm{OPT}_S + \beta$. The number of bins is $\lceil \lceil 2n(\alpha \cdot \mathrm{OPT}_S + \beta) \rceil / n \rceil \leq 2\alpha \mathrm{OPT}_B + 2\beta + 2$, so $\mathcal{A}'$ is asymptotically 2α-competitive. ◀

Together, Lemma 12 and Corollary 11 imply Corollary 4(i).

5 Orthogonal polygons of higher complexity – Theorems 5 and 6(ii)

As a stepping stone towards a proof of Theorem 5, we first consider Z-skeletons.

▶ **Proposition** (corresponding to Theorem 6(ii)). *No online algorithm for Z-Skel-BinPack has an asymptotic competitive ratio better than n.*

For the proof, we consider an arbitrary online algorithm $\mathcal{A}$ for Z-Skel-BinPack, and use Algorithm 1 to generate a sequence of Z-skeletons such that they can be packed into one bin, but $\mathcal{A}$ is forced to use one bin per Z-skeleton.

Algorithm 1 Strategy to generate a sequence of Z-skeletons for a given algorithm $\mathcal{A}$.

function `GenerateZSkeletons`$(n, \mathcal{A})$
  $b \leftarrow 0, B \leftarrow 1$
  for each $i \in [n]$ **do**
    Present Z_i with $w_i := 1 - 2^{-i-1}$, $b_i := (b + B)/2$ and $a_i := 1 - b_i$.
    $x_i \leftarrow x$-coordinate of Z_i assigned by $\mathcal{A}$
    if $x_i \leq (1 - w_i)/2$ **then** $B \leftarrow b_i$ **else** $b \leftarrow b_i$

▶ **Lemma 13.** *For every online algorithm $\mathcal{A}$ of Z-Skel-BinPack, Algorithm 1 generates a sequence of n Z-skeletons such that $\mathcal{A}$ uses n bins.*

Proof Sketch. For any Z-skeleton Z_i packed by $\mathcal{A}$, Algorithm 1 ensures that all future Z_j it presents cannot be placed into the bin of Z_i. In particular, if $\mathcal{A}$ places Z_i far to the left, all $Z_j, j > i$, have a longer upper arm than Z_i, but are too wide to fit under Z_i, as in Figure 7a. Similarly, if $\mathcal{A}$ places a Z-skeleton far to the right, then all $Z_j, j > i$, have a shorter upper arm than Z_i, but are too wide to fit above Z_i, as in Figure 7b. ◀

(a) (b)

Figure 7 Illustration for the proof of Lemma 13.

In order to expand the Z-skeletons to Z-shapes, we ensure the Z-skeletons can even be packed with some positive distance to each other.

▶ **Lemma 14.** *Let $Z_1, \ldots, Z_n$ be Z-skeletons generated by some execution of Algorithm 1. Then, $Z_1, \ldots, Z_n$ can be packed into one bin, such that all horizontal gaps between the Z-skeletons and the bin boundary have width at least $1/n \cdot 2^{-n-3}$.*

Proof Sketch. First, we show that we may partition the generated Z-skeletons into two subsets $W^{\uparrow}$ and $W^{\downarrow}$, where the parameter w_k grows or shrinks, respectively, as the parameter b_k grows. By induction on k, we show that, given any $\varepsilon > 0$, the shapes of $W^{\uparrow}$ can be packed into the L-shape with parameters $\varepsilon + w_k, \varepsilon, 1, b_k$, depicted in Figure 8a, such that all horizontal gaps have size ε/k.

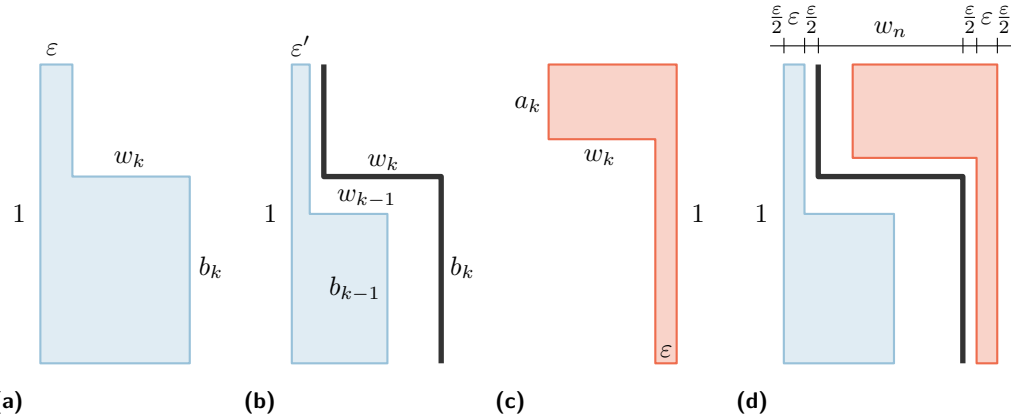

Figure 8 Illustration for Lemma 14.

Similarly, $W^{\downarrow}$ can be packed into a rotated L-shape with parameters $\varepsilon + w_k, \varepsilon, 1, a_k$, illustrated in Figure 8c. Finally, both of these L-shapes can be packed into a unit bin with the desired distances, see Figure 8d. ◀

Lemmas 13 and 14 directly imply Theorem 6(ii). Moreover, the horizontal gap sizes of Lemma 14 allow to expand the Z-skeletons of Algorithm 1 to Z-shapes with thickness $1/n \cdot 2^{-n-3}$. Lemma 14 guarantees that if the Z-skeletons cannot be packed disjointly, the Z-shapes cannot be packed interiorly disjoint. Consequently, there is no online algorithm for Ortho-BinPack of Z-shapes of equal thickness that achieves an asymptotic competitive ratio better than n, which implies the following result.

▶ **Theorem 5.** *There is no online algorithm for Ortho-BinPack that achieves an asymptotic competitive ratio better than n, even when restricting to orthogonally convex 8-gons.*

The similarity to Lemma 13 is in contrast to orthogonal 6-gons, where bounds on the competitive ratios for L-skeletons and L-shapes differ drastically, cf. Theorems 2 and 6(i).

6 Conclusion and open problems

In this work, we investigated various packing problems of orthogonal polygons under translation. For L-shapes, the yet smallest open case, we wondered whether they behave more like rectangles or convex polygons. For bin packing, we provided a surprisingly large lower bound on the competitive ratio of about $n/\log n$ for general L-shapes and n for general orthogonal polygons. That means that the trivial algorithm, which packs each item into its private bin, is worst-case optimal for orthogonal polygons. These lower bounds are much higher than for convex polygons, cf. Table 2. In contrast, for symmetric and small L-shapes there exist constant competitive algorithms. This insight implies that in terms of the competitive ratio, L-shapes behave more like rectangles for perimeter packing, area packing, and the online critical density.

Many interesting problems remain for future work. Most notably, it remains to improve the bounds or even close the gaps for the problems stated in Tables 1 and 2. This includes the problem of determining the best competitive ratio for online bin packing of L-shapes, as it remains open whether it it possible to beat the trivial algorithm for L-BinPack.

Constructing Doppelgängers of Greedy Geometric Spanners in Practice

Anirban Ghosh
University of North Florida, Jacksonville, FL, USA

Abstract

Greedy geometric spanners are considered to be the gold standard for their near-optimal guarantees in terms of sparsity and total weight. However, their inefficient construction poses significant challenges for large-scale geometric networks, especially for low values of stretch factors (< 2). We present Θ-Greedy, a simple and practical parallel algorithm engineered for constructing *doppelgängers* of greedy geometric spanners that empirically resemble the greedy spanners in key structural and performance metrics, including average degree, degree, and lightness. Unlike approximate greedy spanners, *doppelgängers* of greedy spanners are almost indistinguishable from the actual greedy spanners in practice.

In our experiments, Θ-Greedy consistently produced greedy spanner doppelgängers across a broad range of synthetic and real-world datasets, offering the first practical alternative to the computationally intensive greedy spanners. Θ-Greedy can construct a 1.1-spanner on a $128K$-element uniformly distributed point set in well under 5 minutes. In contrast, Bucketing, the most practical greedy spanner algorithm, takes around 3 hours. For million-sized point sets, Θ-Greedy can run to completion in a few hours, making it much faster than Bucketing, which takes days to finish. In extensive experiments on synthetic and real-world datasets, Θ-Greedy delivered speedups of up to 147x over Bucketing while preserving greedy-like sparsity and weight.

For broader uses of the algorithm and reproducibility, we share our engineered C++ code.

1 Introduction

A *geometric spanner* on a set of points P in L_2 metric is a sparse subgraph of the complete Euclidean graph on P that approximately preserves pairwise distances among all point pairs in P. Formally, given a set of n points $P \subset \mathbb{R}^d$ and a *stretch factor* $t \geq 1$, a geometric graph $H := (P, E)$ is a t-spanner if, for all $u, v \in P$, the shortest-path distance in H, denoted by $\delta_H(u, v)$, satisfies $\delta_H(u, v) \leq t \cdot |uv|$, where $|uv|$ denotes the Euclidean distance between u, v. A t-spanner is also a t'-spanner, for all $t' \geq t$. A t-path exists between two points in a geometric graph H if $\delta_H(u, v) \leq t \cdot |uv|$. Therefore, H is a t-spanner if for every point pair in P, a t-path exists in H. The *average degree* of H is defined as $2|E|/|n|$, and its *lightness* is the ratio of the weight of H to the weight of a Euclidean minimum spanning tree of P. For a fixed value of t, lower average degree and lightness are better. The complete Euclidean graph is a 1-spanner with $\binom{n}{2} = \Theta(n^2)$ edges, rendering it impractical for large-scale applications. So, the study of geometric spanners focuses on designing algorithms that construct sparse t-spanners, ideally with $O(n)$ edges, while maintaining desirable geometric and algorithmic properties; see [13, 28, 34] for a comprehensive overview. Spanners play a central role in

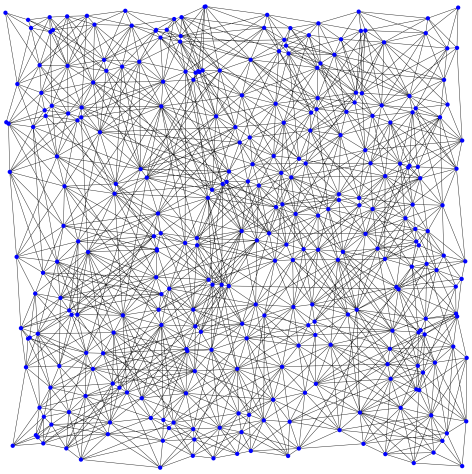
computational geometry and the design of geometric networks. They are widely used in applications such as wireless networks, motion planning, and approximation algorithms, where maintaining low stretch with minimal edge cost is essential [5, 18, 24, 27, 30, 31].

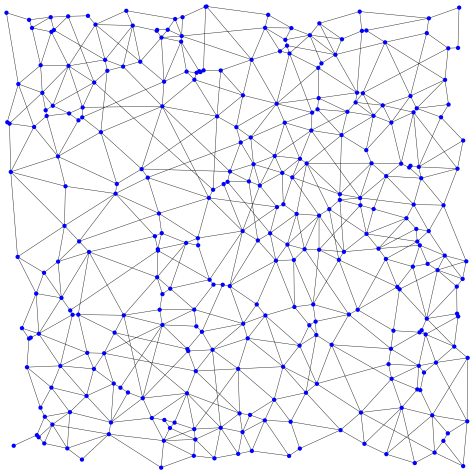


Introduced by Althöfer et al. [4] and also by Chandra et al. [16] more than 30 years ago, the greedy spanner is a cornerstone in the study of geometric spanner networks, offering near-optimal guarantees in terms of sparsity and weight (also lightness) [10, 20, 21, 26, 32]. The greedy spanner is naively constructed by processing all pairs of points in order of increasing Euclidean distance and adding an edge between each pair (u, v) if the current shortest path between them exceeds $t \cdot |uv|$, where $t \geq 1$ is the desired stretch factor. The algorithm, known as Path-Greedy in the literature, is a generalization of the textbook Kruskal's algorithm. Refer to Figure 1 for greedy spanner examples. A straightforward implementation of Path-Greedy runs in $O(n^3 \log n)$ time since there are $\binom{n}{2}$ point pairs, and for every pair, computation of a shortest path takes $O(n \log n)$ time, as greedy spanners are linear-sized spanners. It also uses $\Theta(n^2)$ space to store and sort all point pairs, making it impractical for large point sets. A variant (still using $\Theta(n^2)$ extra space), named FG-Greedy, was introduced by Farshi and Gudmundsson [22], to speed up the algorithm by reducing the number of shortest-path calls. The idea was to memorize the shortest-path lengths obtained by previous single-source shortest-path calls using a matrix, allowing future calls to be avoided using simple lookups. Surprisingly, it was shown in [11] that FG-Greedy runs in $O(n^3 \log n)$ time, although in experiments, it was found to be faster than Path-Greedy; refer to [22]. Das and Narasimhan made the first attempt to approximate greedy spanners in [19], wherein they designed the Approximate-Greedy algorithm that runs in $O(n \log^2 n)$ time. See Table 1. Despite being theoretically novel, experimental studies [22, 32] on spanners found that Approximate-Greedy places substantially more edges compared to actual greedy spanners, rendering them impractical for real-world applications. Bose et al. [12] designed an $O(n^2 \log n)$-time algorithm to construct exact greedy spanners using $\Theta(n^2)$ space, an improvement over Path-Greedy. To see how frustrating quadratic space algorithms are in practice, consider $n = 10^6$. Storing all point pairs, at least $\binom{10^6}{2} \cdot 8$ `bytes` $= 4$ `TB` of space is required, which is impractical. For this reason, we chose not to consider it in our experiments.

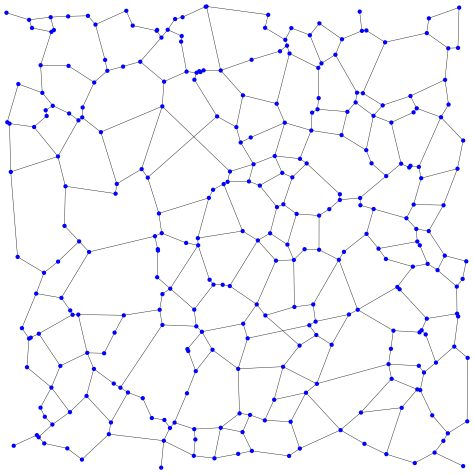
Table 1 A comparison of the popular spanner construction algorithms vs Θ-Greedy (ours), based on the average degree (Δ_{avg}) of the generated spanners. The input was a $128K$-element uniformly distributed point set, and $t = 1.1$.

	Θ-Graph [17]	Sink-Spanner [8]	WSPD-Spanner [14]	Skip-List-Spanner [7]
Δ_{avg}	97.38	123.13	7646.93	192.44

	Appx-Greedy [19]	Fast-Sparse-Spanner [32]	Bucketing [3]	Θ-Greedy
Δ_{avg}	583.40	9.18	9.08	9.08



Alewijnse et al. [2] made the first significant attempt to construct greedy spanners on large point sets, marking a breakthrough. Their algorithm, referred to as WSPD-Greedy in [3], runs in $O(n^2 \log^2 n)$ time using only $O(n)$ space, enabling the construction of geometric spanners on million-point instances for the first time. It avoids storing all pairwise distances by incrementally generating edge candidates via a well-separated pair decomposition (WSPD) [15, 25]. These candidates are processed in order of increasing distance using a priority queue, ensuring that only necessary edges are added while maintaining linear space complexity. The same authors devised an improved algorithm in [3], named Bucketing. It is a distribution-sensitive algorithm for constructing greedy spanners that exploits the geometric structure of point sets. They observed that most short edges can be determined locally, while



(a) $t = 1.05, |E| = 1743$

(b) $t = 1.1, |E| = 1211$

(a) $t = 1.25, |E| = 735$

(b) $t = 2, |E| = 408$

Figure 1 Greedy spanners constructed on a 300-element uniformly distributed point set. The complete graph on the point set has $\binom{300}{2} = 44850$ edges.

long edges can be efficiently identified using the well-separated pair decomposition (WSPD). By leveraging a local characterization of t-spanners, Bucketing achieves subquadratic expected time of $O(n \log^2 n \log^2 \log n)$ on uniform distributions, making it the first such result for greedy spanners on any meaningful class of inputs. Bucketing was observed to be much faster than WSPD-Greedy; see [3] for experimental results. Abu-Affash et al. [1] designed the δ-greedy algorithm that retains the desirable properties of the Path-Greedy spanner, such as low degree, linear number of edges, and near-optimal weight, while significantly reducing the number of shortest path queries. The algorithm runs in $O(n^2 \log n)$ time in the worst case, but achieves expected $O(n \log n)$ time on uniformly random point

sets. The parameter δ controls the trade-off between construction time and similarity to the Path-Greedy spanner; setting $\delta = t$ yields an identical spanner. However, the space complexity is quadratic, making it impractical for large point sets. Therefore, we decided not to include it in our experiments.

Shariful et al. [32] recently observed that Bucketing is slow for large values of n. For instance, when $n = 10^6$, $t = 1.1$, and the points are uniformly distributed inside a square, Bucketing took around five days to generate the spanner. So, they engineered a practical parallel algorithm Fast-Sparse-Spanner, that generated geometric graphs fast and had average degrees close to those of greedy spanners. Fast-Sparse-Spanner could generate a 1.1-spanner for the same above point set in just 55 minutes, making it much faster than Bucketing in practice. They experimentally observed that Fast-Sparse-Spanner consistently generated t-spanners across a wide variety of distributions and real-world point sets. To check for the t-spanner property, they also devised an auxiliary practical stretch factor measurement algorithm, named Fast-Stretch-Factor, since Fast-Sparse-Spanner is not theoretically guaranteed to generate t-spanners. However, the weights and degrees of the generated graphs are far from the actual greedy spanners owing to the presence of long WSPD spanner edges, which form a backbone of their spanners. Despite the average degree of the generated graphs being close to those generated by Bucketing (see Table 1), the degrees and lightness values substantially differed. For the point set used in Table 1, the degrees of graphs generated by Fast-Sparse-Spanner and Bucketing were 78 and 18, respectively, and the lightness values were 16.7196 and 11.0354, respectively.

Despite the progress made by Shariful et al. in [32], practical construction of spanners which closely resemble greedy spanners in terms of average degree, weight, and degree, especially for low t-values (≤ 2), remains an open problem. Note that Delaunay triangulations are 1.998-spanners [35] with $O(n)$ edges that can be constructed in $O(n \log n)$ time (in practice, takes a few seconds even for millions of points). So, constructing t-spanners with t around 2 or more is not considered challenging in practice.

What are doppelgängers of greedy spanners? We introduce the notion of (a, b)-*doppelgänger*. A t-spanner H on a point set P is a (a, b)-*doppelgänger* of the greedy spanner G on P, if its average degree and lightness do not exceed those of G by more than additive constants a and b, respectively. Average degree and lightness are two central measures of spanner quality, and spanners with similar values for these metrics tend to be structurally similar. Thus, smaller values of a and b indicate better doppelgängers. Such doppelgängers are especially appealing to practitioners when they can be constructed significantly faster than the greedy spanner itself. The term "approximation" has not been used in this work intentionally, as the Approximate-Greedy [19] algorithm claims to generate spanners that are approximations of greedy spanners, but, in reality, they are structurally very different from the actual greedy spanners (also, see Table 1).

Our contribution. Motivated by the lack of fast practical algorithm to generate (a, b)-*doppelgängers* of greedy spanners for low values of a and b, we design and engineer Θ-Greedy, a new spanner construction algorithm, based on Θ-Graph. We found Θ-Greedy to be considerably faster than our closest competitor Bucketing, and always produced high quality *doppelgängers* in our experiments. In our experiments, both a and b never exceeded 0.1. To our knowledge, no other known algorithm can achieve this while being fast and scalable in practice. See Figure 2 for a visual comparison between Θ-Greedy and Bucketing.

We use the Θ-Graph as a seed spanner since it can be constructed fast in $O(n \log n)$ time and, as seen in Table 1, excluding Fast-Sparse-Spanner (not guaranteed to produce t-spanners), Θ-Graphs have the lowest average degree and thus the lowest number of edges. We consider its edges by length and place them greedily, akin to Path-Greedy. Finally, we find point pairs that do not have t-paths between them using a quad tree-based approach. For every such point pair, we establish a t-path by placing edges carefully. Our algorithm can leverage multiple cores for speedup.

Θ-Greedy is designed as an engineering solution to a long-standing practical bottleneck in geometric spanner construction rather than as a theoretical breakthrough. While its worst-case complexity is $O(n^3 \log n)$, the algorithm consistently exhibits near-quadratic scaling in practice and uses linear space, enabling it to handle million-point datasets efficiently. It leverages heuristic path checks and shortcut caching to achieve massive speedups, up to $\approx$ 147x faster than Bucketing, while producing spanners that are structurally almost indistinguishable from true greedy spanners in terms of degree and lightness. The focus of Θ-Greedy is on simplicity, scalability, and reproducibility for real-world geometric networks, not on improving asymptotic bounds.

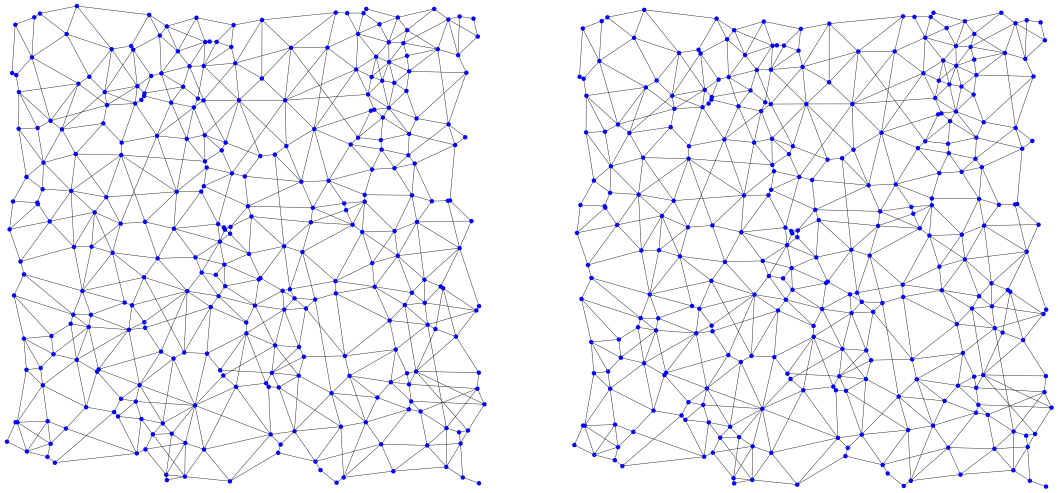


Figure 2 $n = 300, t = 1.25$; the spanners produced by Bucketing (Left) and Θ-Greedy (Right).

Preliminaries. A *region quad tree* is a hierarchical spatial data structure that recursively partitions a two-dimensional region into four congruent quadrants until each subregion is homogeneous or its size falls below a specified threshold ℓ, the maximum leaf size. The root node represents the entire region, and each internal node corresponds to a square subdivided into four child quadrants. A Θ-Graph [28] is a geometric spanner constructed by dividing the plane around each point into k equal-angle cones and connecting the point to the vertex in each cone that minimizes the distance projected onto the cone's bisector. The constructed geometric graph is a t-spanner if $k = \max\left(9, \frac{2\pi}{\Theta}\right)$, where $\Theta = \frac{\arcsin\left(1-\frac{1}{t^2}\right)}{2}$. Θ-Graph can be constructed in $O(n \log n)$ time [28].

2 Description of Θ-Greedy

This section presents the steps of the Θ-Greedy algorithm in order. Let H denote the output spanner constructed on the input point set P of size n. Initially, H is an empty graph.

Step 1. Construct a minimum spanning tree M on P by running Prim's algorithm on the edges of a Delaunay triangulation of P. Place the $n-1$ edges of M in H. Since the Path-Greedy algorithm will place such edges, irrespective of the value of t, we can compute such edges quickly and place them in advance to avoid shortest-path calls.

Step 2. Refer to Algorithm 1. We construct a Θ-Graph t-spanner G_Θ on P. Let E_Θ be the set of edges in G_Θ. Sort the edges in E_Θ in non-decreasing order of length. Then, process them greedily, following the spirit of the Path-Greedy algorithm: For each edge $e = \{u, v\} \in E_\Theta$, if no t-path exists between u and v in H, insert $\{u, v\}$ into H; otherwise, skip the edge.

To check for an t-path between u, v, we first invoke an heuristic algorithm called Greedy-Path, which avoids the use of a priority queue, unlike standard shortest-path algorithms such as A^* or Dijkstra. This heuristic is inspired by the work [32]. We make use of `shortcuts`, as described next, to speed it up. The Greedy-Path performs a walk from u to v in H, aiming to discover a path greedily, whose total length does not exceed $t \cdot |uv|$. At each step, it evaluates candidate next hops drawn from two sources: (i) precomputed t-paths obtained by previous Greedy-Path and A^* calls, stored in `shortcuts`, as described next (also see Algorithm 1), and (ii) the actual graph neighbors of the current vertex. For every candidate, it computes a simple score - the current path length greedily constructed so far plus the edge (or shortcut) cost to that candidate, plus its straight-line (Euclidean) distance to v as an optimistic estimate of continuing via that vertex. It then moves to the candidate with the lowest score, marking visited choices to avoid cycling, and it stops immediately if v is reached. If the accumulated path length exceeds the stretch upper bound, the heuristic declares failure; otherwise, it returns the achieved t-path.

If Greedy-Path finds a t-path, we store it as a shortcut (with its weight) in a structure `shortcuts`, similar to an adjacency list, to accelerate future queries. If Greedy-Path fails, we fall back to the popular A^* algorithm. If A^* also fails, we insert u, v into H; otherwise, we store the discovered t-path in `shortcuts` for future use. Note that to maintain the linear size of `shortcuts`, it is not updated in Steps 3, 4, and 5 of our algorithm.

Step 3. Construct a region quad tree T on P such that the number of points contained inside every leaf is no more than a fixed constant ℓ. In our experiments, we found that $\ell = 1000$ was sufficient. For every leaf $\sigma \in T$, ensure that a t-path exists in H_σ, between all point pairs in σ, where H_σ is a subgraph of H, induced by the points in σ. This is achieved by running Dijkstra from every point in σ. Let S be the set of point pairs from all the leaves that do not have t-paths in H. Sort S, and place edges greedily. Akin to Step 2, we first use Greedy-Path, followed by A^*, if necessary. While adding edges greedily, we check for the existence of t-paths by considering H rather than H_σ.

Step 4. Let E' be an empty set of edges. For every leaf pair $\sigma_i, \sigma_j \in T$, ensure t-paths in H between all point pairs $u \in \sigma_i, v \in \sigma_j$. If a pair $\{u, v\}$ is found not to have a t-path in H, place the edge $\{u, v\}$ in H and add the same to E'. Akin to Step 2, we use Greedy-Path followed by A^*. For a given leaf pair σ_i, σ_j, the t-paths (bridges connecting distant point pairs) found are temporarily stored in a list $\mathcal{B}$. Since $|\sigma_i| \cdot |\sigma_j| \leq \ell^2 = O(1)$, $|\mathcal{B}| = O(1)$. Its use is based on the observation that points from faraway tend to share t-paths. Consequently, we save

Algorithm 1 STEP 2.

t-path computations by first searching for a valid bridge (x, y) in $\mathcal{B}$, where $x \in \sigma_i, y \in \sigma_j$ such that $t \cdot |ux| + |xy| + t \cdot |yv| \leq t \cdot |uv|$. If $|E'| > n$, terminate this step early and go to Step 5. Since every leaf pair is considered independently, a super-linear number of edges could be placed in this step. The following step is a fail-safe step to ensure linearity.

Step 5. If $|E'| > n$, delete all the edges in E' from H. For every leaf pair $\sigma_i, \sigma_j \in T$, find all point pairs $u \in \sigma_i, v \in \sigma_j$, that do not have t-path in H. Similar to Step 4, GREEDY-PATH is used first, followed by A^* (if the former fails to find a t-path). Let X be the set of all such pairs. Sort X, and place edges greedily in H.

Next, we show in Theorem 1 that H is a sparse t-spanner on P.

▶ **Theorem 1.** *For any fixed $t > 1$, H is a t-spanner with $O(n)$ edges.*

Proof. The algorithm begins by inserting the edges of a minimum spanning tree M into H. Since M is connected and contains exactly $n - 1$ edges, H is connected after Step 1. In Step 2, we place $O(n)$ edges since the size of G_Θ is $O(n)$, for fixed t. Step 3 introduces $O(n)$ edges as ℓ is a constant. We insert at most $\binom{\ell}{2} = O(1)$ edges within each leaf of T, and since T has $O(n)$ leaves, the total number of edges added is $O(n)$. If Step 4 places at most n edges, then clearly, H has $O(n)$ edges.

Now, let us assume that the number of edges placed in Step 4 exceeds n (possibly $\omega(n)$). In what follows, we argue that in such a scenario, Step 5 places $O(n)$ edges, thereby proving our sparsity claim for H.

Let u be any vertex of H. We claim that the number of edges placed in Step 5, that are incident on u, is at most $\lceil 2\pi/\alpha \rceil$, such that α satisfies the inequality, $\cos\alpha + t \sin\alpha \leq t$. Assume, for contradiction, that two edges $\{u, v\}$ and $\{u, w\}$ are added in Step 5, where $|uv| \leq |uw|$, and both lie in the same cone (with angle $\theta \leq \alpha$). Since the edge $\{u, v\}$ was processed first, it is already in the graph when $\{u, w\}$ is considered. For the edge $\{u, w\}$ to be prevented from insertion into H, the path $P_{u,w}$ going through v must provide a t-path in H: $|P_{u,w}| \leq t \cdot |uw|$.

We analyze the worst-case geometric configuration where v and w are located on the two distinct bounding rays of the cone, maximizing the distance $|vw|$ for angle α. Refer to Figure 3. An upper bound on $|P_{u,w}|$ can be given by the distance projected onto the ray containing v plus

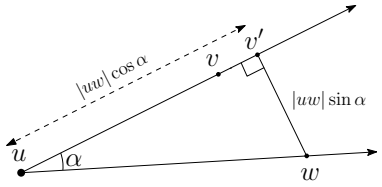

Figure 3 Illustrating the worst case path from u to w.

the stretch factor t applied to the orthogonal component: $|P_{u,w}| \leq |uw|\cos\alpha + t \cdot |uw|\sin\alpha$. To prevent the insertion of the edge $\{u, w\}$ in H, this upper bound must be less than or equal to $t \cdot |uw|$. Thus, $|uw|\cos\alpha + t \cdot |uw|\sin\alpha \leq t \cdot |uw|$. Dividing both sides by $|uw|$, we obtain the necessary angular constraint: $\cos\alpha + t\sin\alpha \leq t$. We conclude that there are at most $\lceil 2\pi/\alpha \rceil$ edges placed that are incident on u in H. For fixed t, $\lceil 2\pi/\alpha \rceil = O(1)$. Hence, Step 5 places $O(n)$ edges.

The t-spanner property of H follows directly from Steps 3, 4, 5. In Step 3, we ensure t-paths between all point pairs inside every leaf of T. In Steps 4 and 5, we ensure t-paths between all point pairs $u, v \in P$ where they belong to distinct leaves of T.

Thus, H is a t-spanner with $O(n)$ edges. ◀

Time complexity. Step 1 runs in $O(n \log n)$ time as Delaunay triangulations can be constructed in $O(n \log n)$ time (via Voronoi diagram) having at most $3n$ edges and Prim's algorithm on $O(n)$ edges runs to completion in $O(n \log n)$ time. Next, the construction of the Θ-Graph G_Θ takes $O(n \log n)$ time [28]. Also, $|E_\Theta| = O(n)$. For every pair $\{u, v\} \in E_\Theta$, verifying the existence of a t-path between u, v takes $O(n) + O(n \log n) = O(n \log n)$ time in the worst-case due to the use of Greedy-Path that runs in $O(n)$ time followed by A^* that runs in $O(n \log n)$ time in the worst-case. For $O(n)$ pairs in E_Θ, the total time taken is $O(n^2 \log n)$. So, Step 2 runs in $O(n^2 \log n)$ time. In Step 3, constructing T takes $O(n^2)$ time in the worst case. The remaining part of this step takes $O(n)$ time since the size of every leaf is at most $\ell = O(1)$. For every leaf of T, there are $O(1)$ point pairs not having t-paths. For $O(n)$ leaves, there are $O(n)$ such point pairs. Detecting such pairs takes $O(n)$ time since the size of every H_σ is $O(1)$. Finally, Steps 4 and 5 each take $O(n^3 \log n)$ time since there are $O(n^2)$ non-empty leaf pairs of T and for every such pair we spend $O(n \log n)$ time for detecting t-paths between $\leq \ell^2 = O(1)$ point pairs. Thus, the overall worst-case time complexity of Θ-Greedy is $O(n^3 \log n)$.

Remark on high time complexity. Although Θ-Greedy has a worst-case complexity of $O(n^3 \log n)$, this bound is highly pessimistic. It assumes that Steps 4 and 5 spend $O(n \log n)$ time for every leaf-pair due to A^* calls. In practice, this scenario rarely occurs. First, A^* is seldom invoked because Greedy-Path successfully finds t-paths in most cases. When Greedy-Path is used, its directional exploration visits only a small fraction of vertices before terminating, making each check extremely fast. Second, when a long t-path is discovered between two distant leaves σ_i, σ_j, it typically suffices for almost all point pairs $p \in \sigma_i, q \in \sigma_j$, greatly reducing the number of subsequent calls. Combined with bridge reuse and shortcut caching, these effects make Steps 4 and 5 far cheaper than the worst-case analysis suggests. As a result, Θ-Greedy exhibits near-quadratic scaling in practice, as confirmed by our experiments on diverse synthetic and real-world datasets in Section 3.

Space complexity. The extra space needed by Prim's algorithm and the Delaunay triangulation construction in Step 1 is $O(n)$. Constructing and storing G_Θ takes $O(n)$ space. Greedy-Path and A^* takes $O(n)$ extra space. The data structure `shortcuts` uses $O(n)$ space since, in the worst case, it can contain one t-path per edge in G_Θ. The quad tree T in Step 4 uses $O(dn)$ space, where d is its height. So, the extra space required by Θ-Greedy is $O(dn+|E'|) = O(dn)$, since $|E'| \leq n$. Thus, Θ-Greedy behaves like a linear-space algorithm in practice, making it possible to generate spanners on point sets where n is as large as 10^6.

3 Experiments

Setup. The algorithms were implemented in `C++23` using `GCC 13` and the `CGAL 6.1` library [33]. The `boost` library was used for common algorithms and data structures. Refer to Table 2. All experiments were conducted on a desktop running `Ubuntu Linux 24.04 LTS`, equipped with an Intel Core `i9-12900K` processor and `32 GB` of RAM. From CGAL, we employed the `CGAL::Exact_predicates_inexact_constructions` kernel. The entire codebase was compiled with the `O3` optimization flag to maximize performance.

Table 2 The algorithms and data structures imported from `CGAL` and `boost`.

Algorithm/Data Structure	Implementation
Graph representation	`boost::adjacency_list`
Delaunay triangulation	`CGAL::Delaunay_triangulation_2`
Prim's algorithm	`boost::prim_minimum_spanning_tree`
Dijkstra's algorithm	`boost::dijkstra_shortest_paths_no_color_map`
Priority queue	`std::priority_queue`
Quad tree	`CGAL::Quadtree`
Quad tree leaf traversal	`CGAL::Orthtrees::Leaves_traversal`
Sorting	`std::ranges::sort`

Synthetic point set distributions. We used five point set distributions to generate random point sets. These distributions were adopted from previous experimental studies [6, 9, 23, 29, 32]. They are named `uni-square`, `normal-clustered`, `grid-random`, `annulus`, and `spokes`. Refer to Figure 4 for an illustration.

The `uni-square` distribution generates points uniformly within a square region using `CGAL::Random_points_in_square_2`. It is the most common distribution used in geometry experiments. The `normal-clustered` distribution places points in randomly positioned clusters, where each cluster follows a normal distribution with a fixed mean and standard deviation. Since the clusters are separated by long distances, shortest-path calls tend to take a long time. Hence, we chose it for our experiments. The `grid-random` distribution scatters points across a non-contiguous grid within a scaled square, with integer coordinates chosen uniformly at random. This distribution is important because of the collinearity present throughout its point sets. In Figure 4, although it resembles `uni-square`, the coordinates of the points are restricted to integers. The `annulus` distribution positions points inside a ring-shaped region defined by inner and outer radii, using real-valued uniform sampling. This distribution is important because of the large hole present inside the point sets. The `spokes` distribution organizes points along five radial spokes emanating from a central point. The vast separation between the collinear spokes is useful for testing spanner algorithms. For each of the above distributions, we considered eight values of n, selected from the set $\{1K, 2K, \ldots, 128K\}$. For every value of n, we sampled five point sets.

Real-world point sets. Real-world point sets are essential because they reflect the actual spatial distributions and irregularities encountered in practical applications. Synthetic datasets, while useful for controlled benchmarking, often assume idealized conditions, such as uniform distributions, perfect clustering, or simplified geometries, that rarely occur in reality. Real-world data introduces challenges, such as uneven point density and non-uniform patterns, which may significantly influence spanner construction time and structural properties. Testing on real-world datasets ensures that algorithms are robust, scalable, and effective under realistic conditions. In our experiments, we used six real-world datasets, as described next.

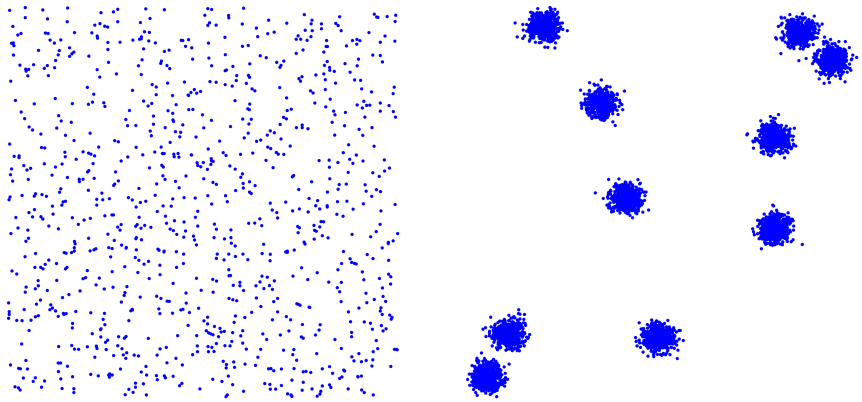

Table 3 The six real-world point sets and their sizes.

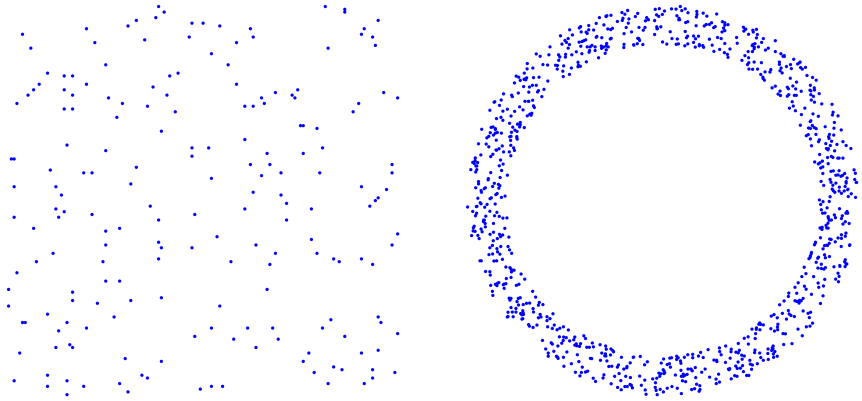
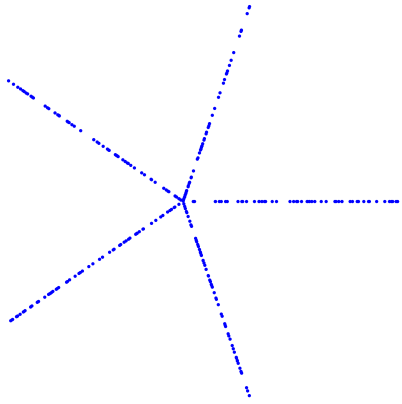
Dataset	`burma`	`birch3`	`monalisa`	`KDDCU2D`	`usa`	`europe`
n	33,708	99,999	100,000	104,297	115,475	168,435



The `burma` dataset consists of 33,708 points representing cities across Burma. The `birch3` dataset contains 99,999 points arranged in random clusters scattered throughout the plane. The `monalisa` dataset is a 100,000-city TSP instance depicting a continuous-line drawing of the Mona Lisa. The `KDDCU2D` dataset includes 104,297 points corresponding to the first two dimensions of a protein dataset. The `usa` dataset represents a large-scale TSP instance with 115,475 cities covering nearly all towns, villages, and cities in the United States. Finally, the `europe` dataset comprises 168,435 points encoding differential coordinates of the European map. Refer to Table 3 for a summary.

Metrics and comparisons. Next, we compare Θ-Greedy with Bucketing using runtime, degree Δ, average degree (Δ_{avg}), and lightness as metrics.



1. *Runtime.* When constructing spanners on large point sets, runtime becomes a critical concern. Guaranteeing a t-path between every pair of points remains a significant challenge. For synthetic point sets, the maximum speedup was observed when $t = 1.05$ (the smallest value used in our experiments) and $n = 128K$. Refer to Figures 5, 6, 7, 8 and 9. For every value of n, the average runtime of five runs is reported. The corresponding speedups were 62.57, 43.18, 49.16, 44.08, and 40.78 for `uni-square`, `normal-clustered`, `grid-random`, `annulus`, and `spokes` respectively. For real-world point sets (Table 4), the highest speedup of 147.59 occurred for the `europe` dataset when $t = 1.1$. As discussed next, Θ-Greedy achieved these speedups while maintaining low values of a and b, ensuring high-quality (a, b)-doppelgängers. We also observed that Bucketing could match the speed of Θ-Greedy when $t = 2$; however, in that case, Θ-Greedy can be easily accelerated further by using additional threads.
   For point sets of size 10^6, Θ-Greedy completed within a few hours (Table 6) using just one thread. Shariful et al. [32] reported that Bucketing requires about five days for the `uni-square` distribution, whereas Θ-Greedy finished in roughly two hours, corroborating its remarkable efficiency. For other distributions, Θ-Greedy consistently performed well, completing within a few hours. The slowest case was the `normal-clustered` point set, which took about four hours due to the presence of long t-paths in the final spanner, causing Greedy-Path and A^* to run slower.
2. *Degree and average degree.* Degree matters for load balancing and hardware constraints. For instance, in computer networks, a node with too many connections consumes more energy and bandwidth. Consequently, a low degree is desired. The average degree metric reflects the overall sparsity and efficiency of a network. A low average degree means fewer edges per vertex, reducing cost and complexity while maintaining connectivity.

(a) `uni-square` (b) `normal-clustered`

(c) `grid-random` (d) `annulus`

(e) `spokes`

Figure 4 The five distributions used to generate random point sets.

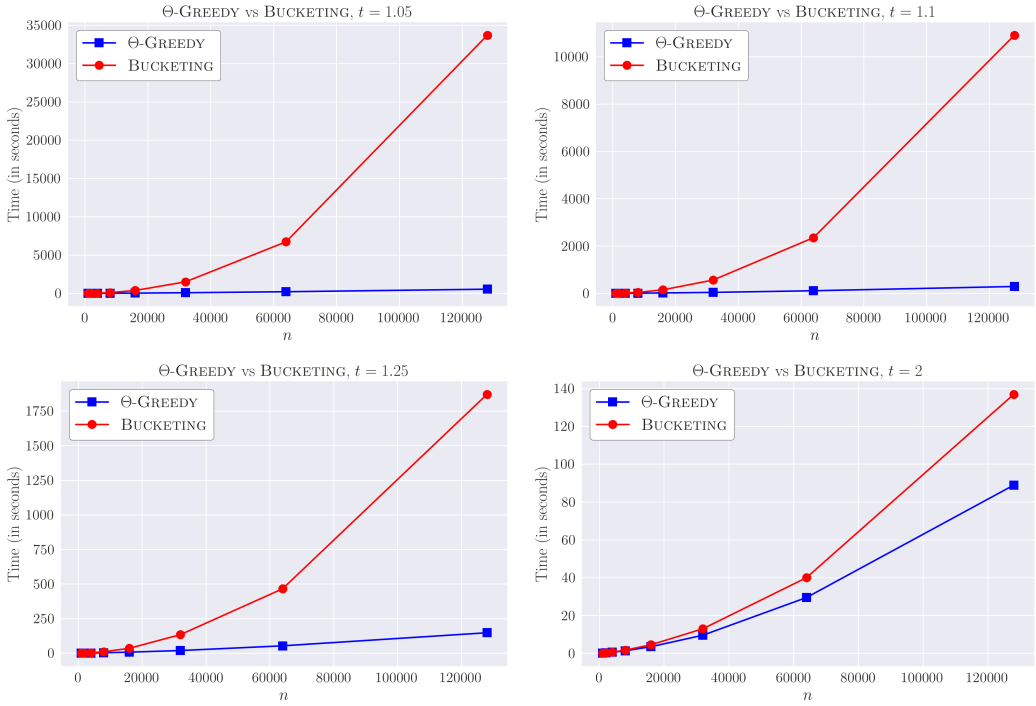


Figure 5 Θ-Greedy vs Bucketing; runtime comparison for the `uni-square` distribution.

According to the definition of (a, b)-doppelgängers, introduced in Section 1, lower values for a and b are desired. We found that for both synthetic and real-world point sets, the maximum value of a did not exceed 0.002, when all four values of t were considered; refer to Table 5. This shows that Θ-Greedy is capable of producing greedy-like sparse spanners. To our knowledge, no other practical algorithm matches this performance.
Regarding the actual difference in degrees, we observe that it is always 0 for the real-world point sets (Table 4) and at most 4 for the synthetic point sets. The maximum value of 4 occurs for the `annulus` instances, whereas for `uni-square` the difference remains 0.

3. *Lightness.* It is crucial because it controls the total cost of connectivity. In real-world networks, such as transportation systems, wireless sensor deployments, or fiber-optic layouts, lower lightness means the network uses short edges while still guaranteeing good connectivity. This translates to lower construction costs, reduced energy consumption, and easier maintenance, making spanners both efficient and practical. As with the average degree, we found that the lightness of Θ-Greedy spanners was very close to that of Bucketing spanners. Refer to Table 5. For the synthetic point sets, the maximum value of b was 0.0875, achieved for the `annulus` distribution. For the real-world point sets, it was 0.06, achieved for the `burma` dataset, when $t = 1.05$; see Table 4.

Multithreaded performance. We now describe how Θ-Greedy is parallelized using OpenMP. The construction of the Θ-Graph is naturally parallelizable, since the edges generated for each point are independent. In Step 2, we process edges from E_Θ in batches of size T, where T is the number of threads. For each batch, we run T instances of Greedy-Path in parallel. Let $T' \leq T$ denote the number of edges in the batch whose endpoints are not connected by a t-path, as determined by Greedy-Path. For these T' edges, A^* is then executed sequentially

Table 5 The maximum observed values for a and b with respect to the spanners produced by Bucketing.

	uni-square	normal-clustered	grid-random	annulus	spokes	real-world
max(a)	0.0000	0.0000	0.0020	0.0010	0.0005	0.0000
max(b)	0.0000	0.0111	0.0056	0.0875	0.0030	0.0600

to find t-paths and insert edges in H whenever required. Since Greedy-Path successfully finds t-paths in most cases where such paths exist in H, calls to A^* are comparatively infrequent. Detection of violating point pairs (i.e., pairs lacking t-paths) in the leaf nodes is independent in Step 3 and therefore parallelizable. In Steps 4 and 5, all leaf pairs (σ, σ_i), where σ is fixed, are also processed in parallel.

The above approach yielded speedups proportional to T, making Θ-Greedy scalable for large point sets. Refer to Figures 10, 11, 12, 13, 14 and Tables 4 and 6. We observed consistent speedups across all values of t used in our experiments.

Comparison with Fast-Sparse-Spanner. Since Fast-Sparse-Spanner [32] was the only previously known practical algorithm for constructing spanners on large point sets, it is natural to compare our algorithm against it. Since one run of Bucketing on a million points takes several days (roughly 5 days for `uni-square`), it is impractical for comparison purposes. However, the trends show that Θ-Greedy spanners are still competitive with Bucketing spanners even for massive point sets. For instance, for the `uni-square` point set, we found the average degree to be 9.1, which is roughly the same as that of the $100K$-element point set used in Section 1 (the reported value for Bucketing is 9.08).

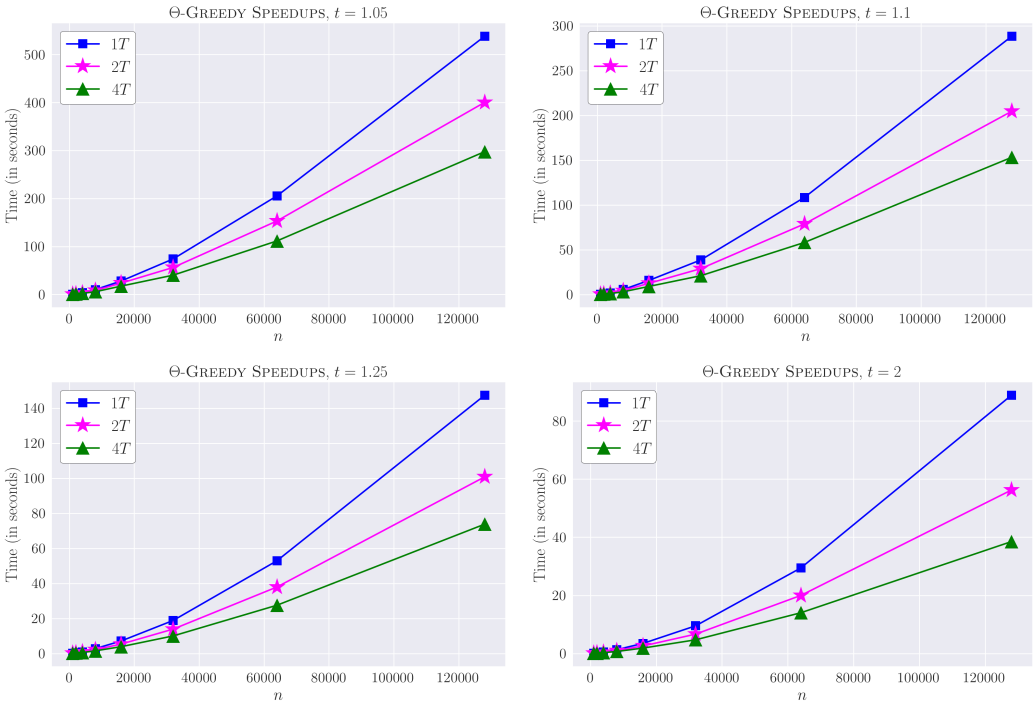

Figure 10 Θ-Greedy: multithreaded runtimes for the `uni-square` distribution.

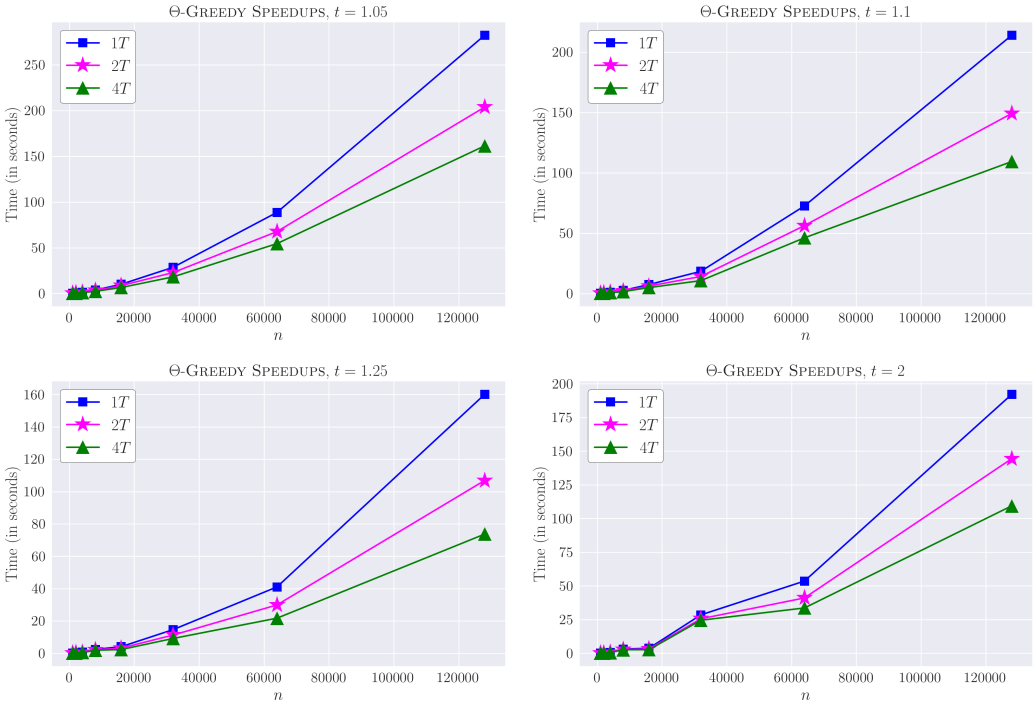

Figure 11 Θ-Greedy: multithreaded runtimes for the `normal-clustered` distribution.

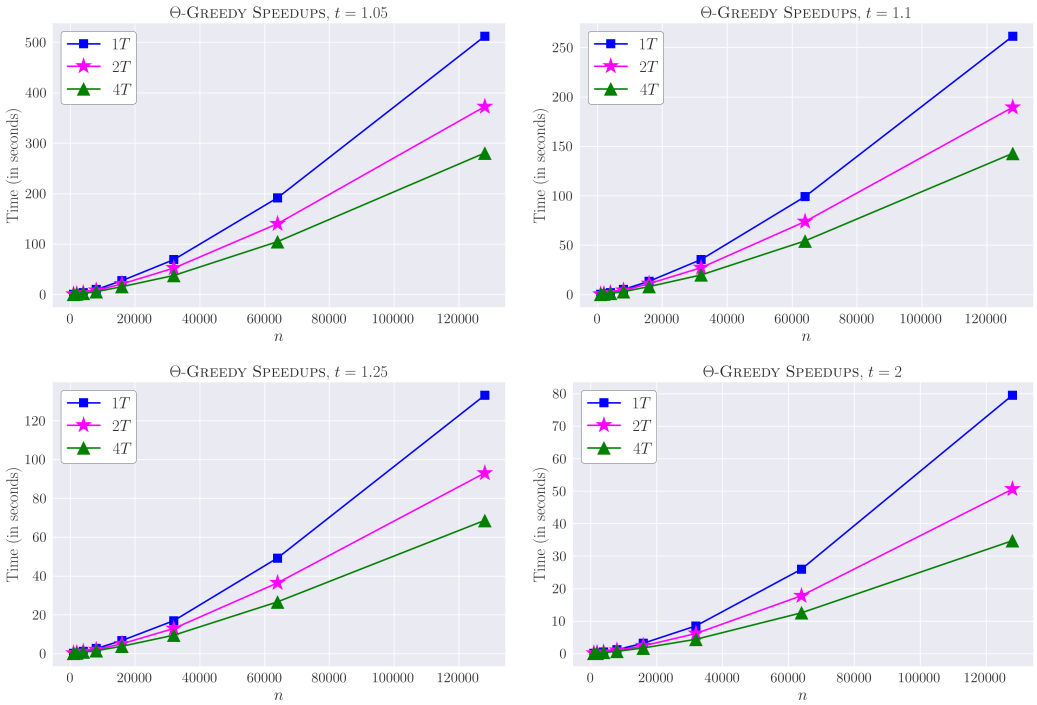

Figure 12 Θ-Greedy: multithreaded runtimes for the `grid-random` distribution.

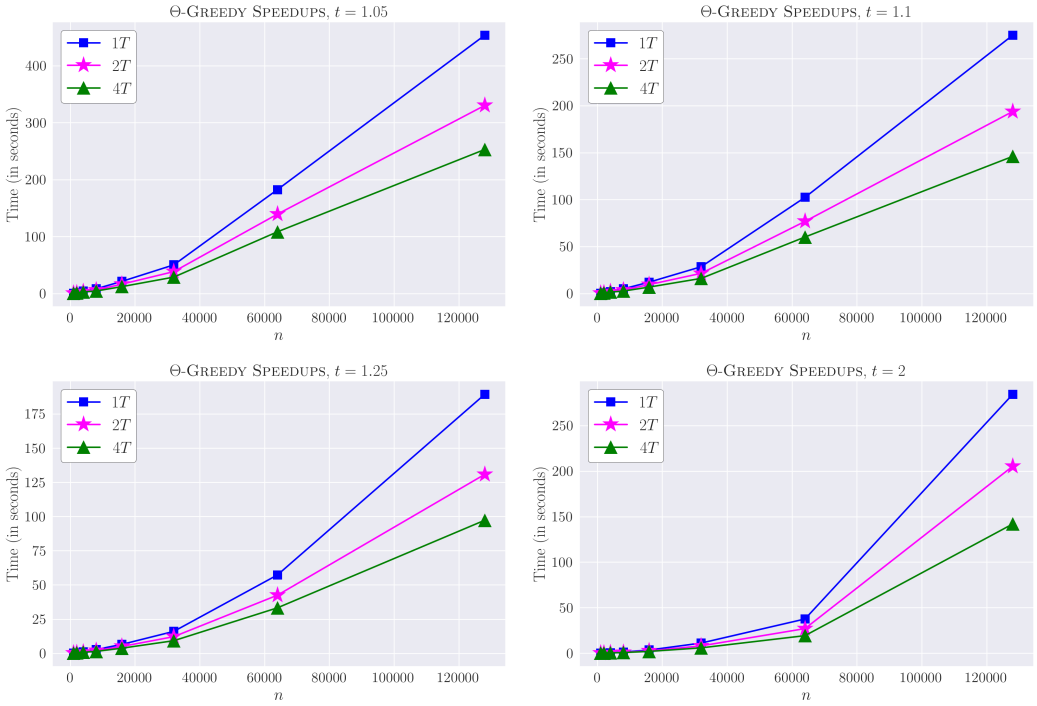

Figure 13 Θ-Greedy: multithreaded runtimes for the `annulus` distribution.

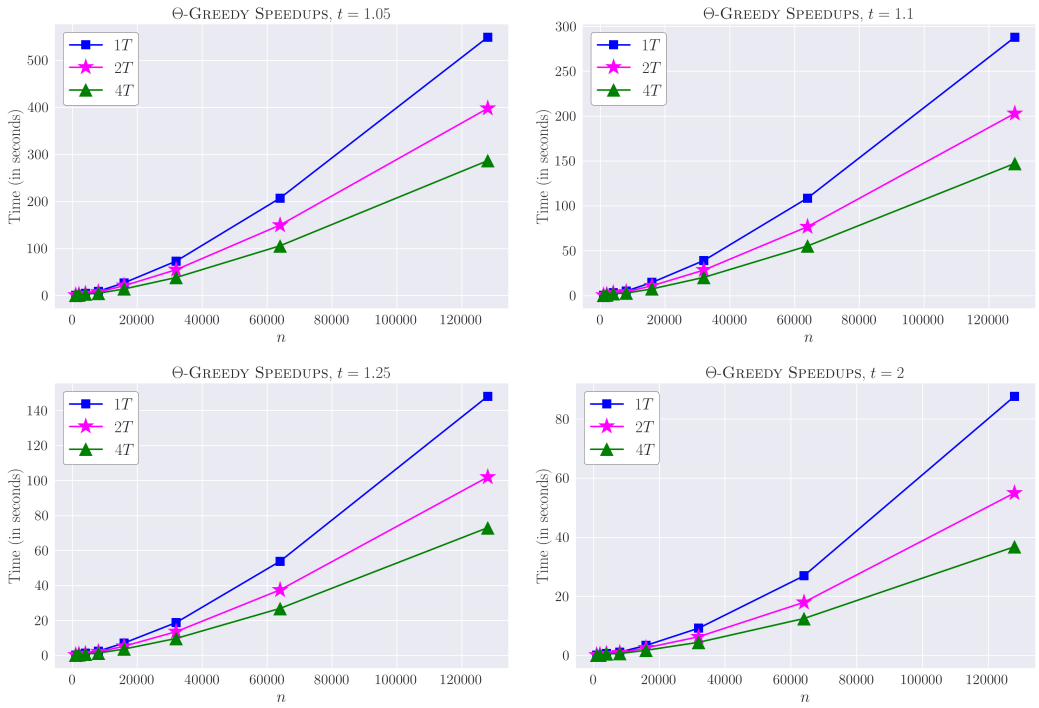

Figure 14 Θ-Greedy: multithreaded runtimes for the `spokes` distribution.

See Table 6, where we set $n = 10^6$ and $t = 1.1$. The spanners produced by Θ-Greedy have significantly lower degrees than those generated by Fast-Sparse-Spanner, indicating that the resulting spanners differ substantially. The biggest differences were achieved for the `uni-square` and `grid-random` point sets. Interestingly, for the $128K$-element `uni-square` point sets, the maximum degree was at most 19 for $t = 1.1$; the same value was observed even when $n = 10^6$. This demonstrates that our algorithm preserves greedy-like degree behavior even for massive point sets.

Although the differences in average degree are modest, the number of edges inserted by Fast-Sparse-Spanner is noticeably higher. For example, on the `uni-square` point set, Fast-Sparse-Spanner added roughly 455,000 more edges than Θ-Greedy. Moreover, the Fast-Sparse-Spanner spanners were substantially heavier than the Θ-Greedy spanners. This is primarily due to the long WSPD-spanner edges that Fast-Sparse-Spanner employs as a backbone. Taken together, these observations clearly demonstrate the superiority of Θ-Greedy over Fast-Sparse-Spanner.

Finally, the lightness of the Θ-Greedy spanners were significantly lower. See Table 6. The largest disparity occurred for the `normal-clustered` point set, where the lightness of the Fast-Sparse-Spanner graph was approximately 320 times greater than that of the Θ-Greedy spanner.

We observe that Fast-Sparse-Spanner is faster than ours in practice. In particular, for `uni-square`, `normal-clustered`, `grid-random`, `annulus`, and `spokes`, the time taken by the algorithm was roughly 55, 18, 57, 53, and 19.07 minutes, respectively, on a system comparable to ours using one thread. Fast-Sparse-Spanner, ran fastest on the `normal-clustered` point set due to the long WSPD-edges connecting distant clusters, owing to which t-path verifications terminated much faster compared to ours. In our case, the opposite happened,

Table 6 Θ-Greedy vs Fast-Sparse-Spanner [32]: runtime (in minutes), degree (Δ) and average degree (Δ_{avg}), when $n = 10^6$ and $t = 1.1$. $1T, 2T, 4T$ stands for $1, 2, 4$ threads, respectively.

$n = 10^6$, $t = 1.1$	uni-square	normal-clustered	grid-random	annulus	spokes
Θ-Greedy $1T$ Runtime	123.69	239.32	124.44	188.76	125.86
Θ-Greedy $2T$ Runtime	89.57	160.6	88.22	125.61	86.73
Θ-Greedy $4T$ Runtime	69.31	108.47	70.51	88.3	65.02
Θ-Greedy Δ	19	19	19	19	18
Fast-Sparse-Spanner Δ	1002	625	1003	573	972
Θ-Greedy Δ_{avg}	9.1	8.84	9.1	9.07	9.1
Fast-Sparse-Spanner Δ_{avg}	9.97	9.15	9.84	9.6	9.88
Θ-Greedy Lightness	11.08	9.88	11.07	11.67	11.07
Fast-Sparse-Spanner Lightness	238.62	3164.69	236.36	164.9	213.22

and we observed that Θ-Greedy was slowest on the same point set and took almost 4 hours to finish due to the presence of much longer t-paths between distant clusters. With the increase in the number of threads (T), Θ-Greedy could accelerate in all five cases.

4 Conclusions

We introduced Θ-Greedy, a practical parallel algorithm for constructing doppelgängers of greedy geometric spanners that are structurally and metrically almost indistinguishable from the actual greedy spanners. Thus, Θ-Greedy spanners serve as practical and reliable alternatives to true greedy spanners. In our experiments, we found that Θ-Greedy consistently achieved almost-greedy sparsity, lightness, and degree distribution while scaling to million-point instances with linear space and significant speedups over Bucketing, the fastest known greedy spanner algorithm. Our results close a long-standing gap between theoretical optimality and practical feasibility for low stretch factors, offering the first engineered solution that combines simplicity, efficiency, accuracy, and scalability for large real-world geometric networks.

An exciting avenue for future work is reducing the worst-case time complexity of Θ-Greedy without sacrificing its ability to produce doppelgängers. Exploring distribution-sensitive optimizations and GPU acceleration could further broaden its applicability. Additionally, extending these ideas to higher dimensions remains a compelling open problem.

Abstract

The Pareto sum of two-dimensional point sets P and Q in $\mathbb{R}^2$ is defined as the skyline of the points in their Minkowski sum. The problem of efficiently computing the Pareto sum arises frequently in bi-criteria optimization algorithms. Prior work establishes that computing the Pareto sum of sets P and Q of size n suffers from conditional lower bounds that rule out strongly subquadratic $O(n^{2-\epsilon})$-time algorithms, even when the output size is $\Theta(n)$. Naturally, we ask: How efficiently can we *approximate* Pareto sums, both in theory and practice? Can we beat the near-quadratic-time state of the art for exact algorithms?

On the theoretical side, we formulate a notion of additively approximate Pareto sets and show that computing an approximate Pareto set is *fine-grained equivalent* to Bounded Monotone Min-Plus Convolution. Leveraging a remarkable $\tilde{O}(n^{1.5})$-time algorithm for the latter problem (Chi, Duan, Xie, Zhang; STOC '22), we thus obtain a strongly subquadratic (and conditionally optimal) approximation algorithm for computing Pareto sums.

On the practical side, we engineer different algorithmic approaches for approximating Pareto sets on realistic instances. Our implementations enable a granular trade-off between approximation quality and running time/output size compared to the state of the art for exact algorithms established in (Funke, Hespe, Sanders, Storandt, Truschel; Algorithmica '25). Perhaps surprisingly, the (theoretical) connection to Bounded Monotone Min-Plus Convolution remains beneficial even for our implementations: in particular, we implement a simplified, yet still subquadratic version of an algorithm due to Chi, Duan, Xie and Zhang, which on some sufficiently large instances outperforms the competing quadratic-time approaches.

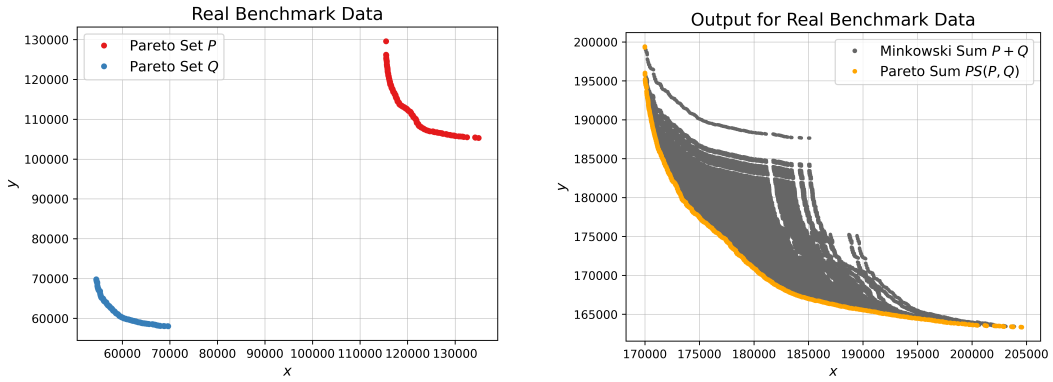

Figure 1 Two Pareto sets P, Q on the left arising from bi-criteria route planning. Depicted on the right is the Minkowski sum $P + Q$ with the Pareto sum $PS(P, Q)$.

1 Introduction

In multi-criteria decision-making processes and in algorithms for multi-objective optimization, a central computational task is to obtain and filter non-dominated solutions. This is essential in order to keep intermediate solution sets interpretable and computationally tractable. Often, partial solutions must be combined in the course of the algorithm, and non-dominated filtering must be applied to the resulting set. This core problem is known as *Pareto sum*: Given two sets $P, Q \subset \mathbb{R}^2$ of non-dominated points[1] (also called skylines or Pareto sets), the Pareto sum $PS(P, Q)$ is defined as the skyline of their Minkowski sum $P + Q := \{p + q \mid \ p \in P, q \in Q\}$.

Recently, exact algorithms have been developed for Pareto sum computation with a running time in $\tilde{O}(n^2)$ [13]. Naturally, the question arises whether this algorithm admits the best-possible time complexity for this problem or whether there is hope for designing asymptotically faster ones. The study of fine-grained complexity has emerged as a powerful framework for understanding the algorithmic complexity of problems within the class P. Using fine-grained reductions, the conjectured intractability of one key problem can be transferred to another problem, yielding a conditional lower bound on how fast the other problem can be solved. For the Pareto sum problem, it was recently shown that an algorithm with a running time in $\mathcal{O}(\min\{n^2, nk\}^{1-\delta})$ for $\delta > 0$, where k denotes the output size, would disprove the 3-SUM hypothesis [15]. The conditional lower bound matches the complexity of known algorithms (up to subpolynomial factors), which renders the existence of subquadratic algorithms for Pareto sum (even with linear output sizes) unlikely.

However, in practical applications, Pareto sum instances of substantial input size n and with output sizes $k \in \Omega(n)$ frequently arise. On such instances, exact computation takes at least quadratic time, which is typically impractical. This motivates our study of approximation algorithms for Pareto sum. We define a point set $\tilde{S}$ to be an approximation of $S := PS(P, Q)$ if for each element s in S there is a point $\tilde{s}$ in $\tilde{S}$ of "similar quality" (specifically, $\tilde{s} \leq s+(\Delta, \Delta)$) and each $\tilde{s} \in \tilde{S}$ is indeed close to a point in $P + Q$ (specifically $p + q \leq \tilde{s} \leq p + q + (\Delta, \Delta)$ for some $p \in P, q \in Q$). This provides an additive approximation guarantee. This definition caters well to many practical applications of Pareto sum computation. For example, in bi-criteria route planning, the goal is to find the set of Pareto-optimal paths between the source and the target node with respect to two metrics. Route planning techniques for this

[1] We call a set S of points non-dominated, if there do not exist distinct vectors $s, s' \in S$ such that $s \leq s'$.

setup heavily rely on Pareto sum computations and the number of resulting skyline points is oftentimes huge [13, 16, 25]. Thus, the goal is to reduce the number of Pareto-optimal paths to be considered within the algorithm and also as an output for the user. Multiplicative approximation algorithms tend to not work well in this scenario, because for paths with a value of zero or close to zero in one metric, even slightly suboptimal paths induce huge approximation factors. Additive approximations do not suffer from the same issue and are also much easier to interpret for a user (for example, if it is guaranteed that the reported route has at most 2 minutes of extra driving time). In this paper, we propose an efficient additive-approximation algorithm that allows one to trade running time against solution quality. We rigorously analyze its theoretical properties and also provide an extensive empirical study of its performance on synthetic and real data sets.

1.1 Related Work

The Pareto sum problem has already been extensively studied from a theoretical and practical perspective. A simple approach follows by computing the Minkowski sum explicitly and then applying general algorithms for skyline computation [17, 10]. In [18], the practical relevance of the problem was emphasized, and novel algorithms were proposed that achieve a subquadratic space consumption for certain input set structures. Algorithms with guaranteed output-sensitive space consumption were proposed in [13]. A simple Sort & Compare algorithm was proven to run in $\mathcal{O}(n^2 \log n)$ on input sets of size n, and a sweep search algorithm to run in $\mathcal{O}(nk + n \log n)$ where k denotes the output size. Experiments on synthetic instances and instances stemming from bi-criteria route planning in road networks confirm that these algorithms outperform those that fully compute the Minkowski sum and also the ones proposed in [18]. In [19], Pareto sum computation is used as a subroutine for multiobjective spanning tree or TSP computation which uses a tree decomposition as basis. For join nodes, an algorithm similar to Sort & Compare is used to obtain the desired combined result. In [14], several additional fine-grained complexity results for Pareto sum are provided. This includes a quadratic lower bound for Pareto sum computation even for $k = \Theta(n)$ under the 3-SUM hypothesis (which is even more believable than the previous min-plus convolution quadratic lower bound by [13], as the min-plus convolution hypothesis implies the 3-SUM hypothesis). Moreover, they established Pareto sum as a complete problem for a wide class of logical and geometric problems, further adding interest to the problem from the side of complexity theory.

1.2 Our Contributions

In this paper, we explore the degree to which the quadratic-time bottleneck for the Pareto sum problem – which is observable both in practice [13] and substantiated by conditional lower bounds [13, 14, 15] – can be circumvented by additively *approximating* Pareto sums. To this end, in Section 3, we formally introduce a natural relaxation of Pareto sums to Δ-approximate Pareto sums: intuitively, $\tilde{S}$ is an approximation of the true Pareto set S of P, Q if for any $s \in S$, we have an approximate point $\tilde{s}$ of "similar quality" (specifically, $\tilde{s} \leq s + (\Delta, \Delta)$). Conversely, any such $\tilde{s} \in \tilde{S}$ is of similar quality to some actual point in $P + Q$ (i.e., there are $p \in P, q \in Q$ with $p + q \leq \tilde{s} \leq p + q + (\Delta, \Delta)$).[2]

[2] In fact, we often even achieve the stronger guarantee that $\tilde{S} \subseteq P + Q$, see Definition 5.

Crucially, our results rely on establishing a certain fine-grained *equivalence* between approximating Pareto sums and Bounded Monotone Min-Plus Convolution, the latter of which has received increasing interest in recent years [9, 11, 4, 6, 12]. This leads to the following theoretical results:

- For any sets P, Q of at most n points in $[0, W]^2$, we can compute an ϵW-approximate Pareto sum $\tilde{S}$ in time $\tilde{O}(n + (1/\epsilon)^{1.5})$. This leverages a remarkable algorithm due to Chi, Duan, Xie and Zhang [11] solving Bounded Monotone Min-Plus Convolution in strongly subquadratic time $\tilde{O}(n^{1.5})$.
- Conversely, we show that any $\tilde{O}(n + (1/\epsilon)^{1.5-\delta})$-time algorithm for computing an ϵW-approximate Pareto sum would give a polynomial-factor improvement for Bounded Monotone Min-Plus Convolution. This establishes a fine-grained equivalence of the approximate Pareto sum and Bounded Min-Plus Convolution. Some approximation problems [8, 7] are known to be fine-grained equivalent to min-plus convolution, but this appears to be the first such connection for bounded monotone min-plus convolution.
- We observe that slightly stronger approximation guarantees can be obtained if a *witness-reporting* version of Bounded Monotone Min-Plus Convolution can be achieved. Indeed, we show that such witnesses can be reported in strongly subquadratic time, by adapting a $\tilde{O}(n^{1.6})$-time algorithm for Bounded Monotone Min-Plus Convolution [11] using techniques due to Alon and Naor [1].

Subsequently, we observe how beneficial our relaxation to approximate Pareto sums can be on realistic input sets. To this end, we empirically fine-tune and evaluate a number of different approaches, leading to the following results:

- On synthetic and realistic inputs, we can approximate Pareto sums significantly more efficiently than computing them exactly. E.g., on generated data sets with 10^6 points and coordinates in $[0, 2 \cdot 10^6]$, computing an additive ($\Delta = 20$)-approximation saves a computation time of up to three orders of magnitude. Furthermore, the size of the returned sets reduces significantly with coarser approximation parameters. Thus, we enable an effective choice of running time/solution size vs. approximation quality.
- We focus on efficiently solving the *Bounded* Pareto sum problem, which denotes the special case in which all coordinates are integer values in $\{0, \dots, W-1\}$ – such instances occur naturally in our approximation algorithms (after a scaling step), but are of independent interest in bi-criteria optimizations with integral cost functions (e.g., in routing). Here, we empirically evaluate and compare several algorithmic approaches: (1) a natural adaptation of the Sort & Compare method of [13] to BucketSort & Compare, (2) a convex-pruning algorithm inspired by a fast algorithm for Near-convex Min-Plus Convolution [5], and (3) an algorithm based on a $\tilde{O}(n^{1.6})$-time algorithm for Bounded Monotone Min-Plus Convolution [11] (which we will refer to as CDXZ algorithm). Perhaps surprisingly, we observe that depending on the class of inputs, either one of these approaches may outperform the others. This indicates that the (theoretical) connection between Pareto sums and Bounded Monotone Min-Plus convolution can also be exploited in practice to obtain practical algorithms (depending on the instances).

We feel that our results add practical evidence (and extend theoretical evidence, e.g. [21, 8, 3]) that studying the connections of geometric (and other) problems with certain formulations of convolution-type problems is beneficial for algorithmic research.

2 Bounded Pareto Sum

In this section, we prove our core reduction which is the basis for developing new algorithms for (approximate) Pareto sum computation. Throughout the paper, we abbreviate $[n] := \{0, 1, \ldots, n-1, n\}$ and use the interval notation $[a, b] := \{a, a+1, \ldots, b-1, b\}$ for some $a, b \in \mathbb{Z}$, with $a \leq b$. We say that a point (x, y) dominates another point (x', y'), if $x \leq x'$ and $y' \leq y$ with at least one coordinate being strictly smaller. A point set is called a Pareto set if it contains no dominated elements. For a point p, we denote by $p.x$ and $p.y$ the x and y-coordinate of p respectively. The Pareto front of a set S, consists of the non-dominated points in S. We are now ready to define the problems of interest.

▶ **Definition 1** (Bounded Pareto Sum). *Given Pareto sets P, Q of size n with integer coordinates in $[W]^2$, compute the set S of non-dominated points in $P+Q := \{p+q \mid p \in P, q \in Q\}$.*

We remark that for bounded Pareto sum, we always have $W \geq n-1$, as in a Pareto set the coordinates per dimension all need to be different.

▶ **Definition 2** (Bounded Monotone Min-Plus Convolution). *Given two monotone decreasing arrays A and B of size n with positive entries bounded by $W = O(n)$. Compute an array C, where for each $k \in [2n-2]$, we have $C[k] := \min_{i \in [n-1]} (A[i] + B[k-i])$.*

The following reduction is also illustrated in Figure 2 on a small Pareto sum instance[3].

▶ **Theorem 3.** *An instance of bounded Pareto Sum with sets P, Q of size n and entries $(x, y) \in [W]^2$ can be reduced in time $\mathcal{O}(W)$ to an instance of bounded monotone min-plus convolution of two sequences A, B of size W with entries in $[W]$.*

Proof. (Sketch.) We first shift all x-coordinates in P and Q so that the minimum x-value becomes 0; this preserves all dominance relations in the Pareto sum.

Next, we construct two sequences A and B of length W, initialized with value W. For each point $(x, y) \in P$ (resp. $(x, y) \in Q$), we set $A[x] = y$ (resp. $B[x] = y$) and then enforce monotonicity by a single left-to-right sweep: each entry is replaced by the minimum seen so far. After this step, $A[i]$ (resp. $B[i]$) equals the smallest y-value among all points of P (resp. Q) with $x' \leq i$. This construction runs in $\mathcal{O}(W)$ time. Computing the min-plus convolution $C[k] = \min_{i+j=k} A[i]+B[j]$ then yields, for each k, exactly the smallest achievable y-coordinate among all pairs $p \in P$, $q \in Q$ with $p.x + q.x = k$. Thus C contains all candidate points of the Pareto sum. A final linear-time sweep removes dominated entries from C, leaving precisely the non-dominated pairs $(k, C[k])$. Hence the Pareto sum of P and Q can be obtained via a bounded monotone min-plus convolution instance computable in $\mathcal{O}(W)$ time. A more detailed proof can be found in the full version of the paper. ◀

According to our theorem, if bounded monotone min-plus convolution can be solved in time $T(n, W)$ for arrays of size n with entries in $[W]$, then we can solve bounded Pareto Sum in time $O(W + T(W, W))$. This makes algorithms for bounded monotone min-plus convolution applicable to Pareto Sum with little overhead to carry out the reduction and the back-transformation of the solution. By applying the algorithm of [11], we get:

▶ **Corollary 4.** *Given two Pareto sets P, Q of size n with integer entries $(x, y) \in [W]^2$, we can compute the Pareto sum of P and Q in time $\tilde{O}(W^{1.5})$.*

[3] A similar construction has been noted by Chan and Lewenstein for the special case that P and Q are connected sets i.e. all points in P and Q have a neighboring point with L_1 distance 1; see [9, Remark 3.4]

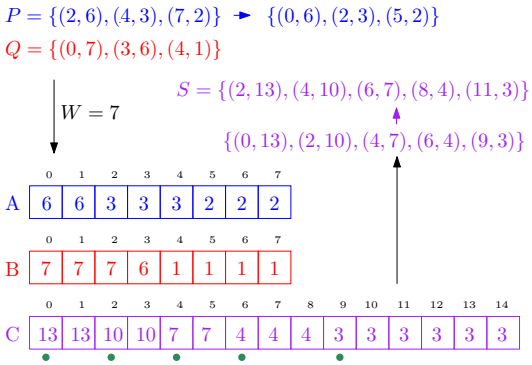

Figure 2 Reduction from Pareto sum to bounded monotone min-plus convolution and back-transformation of the solution on a small example.

3 Additive Approximation of Pareto sum

In this section, we study additive approximation algorithms for Pareto sum with arbitrary real-valued inputs.

To formalize our notion of approximation, observe that the Pareto sum of P and Q can be defined as the set S satisfying the following three conditions: (1) S dominates $P+Q$, i.e.., for every $p \in P$ and $q \in Q$, there exists some $s \in S$ with $s \leq p+q$, (2) $S \subseteq P+Q$ and (3) S is a Pareto set, i.e., pairwise non-dominating. To obtain an *approximate* Pareto set, it is only natural to relax the first condition by allowing an additive slack of $\Delta > 0$ in the domination inequality. Formally, we arrive a the following notion of approximation:

▶ **Definition 5** (Δ-Approximative Pareto sum). *Let $P, Q, \tilde{S} \subseteq \mathbb{R}^2$. We call $\tilde{S}$ a Δ-approximation of the Pareto sum of P, Q if the following conditions hold:*

1. *for all $p \in P, q \in Q$, there exists some $\tilde{s} \in \tilde{S}$ with $\tilde{s} \leq p+q+(\Delta,\Delta)$.*
2. *$\tilde{S} \subseteq P+Q$,*
3. *$\tilde{S}$ is a Pareto set.*

Let us remark that we could have arrived at this definition via slightly adapting the notion of an approximative Pareto front by the authors in [20], which leans on the notion of Papadimitriou and Yannakakis [22]: Let $d_H(S,\tilde{S})$ denote the directed Hausdorff distance between S and $\tilde{S}$ under some "distance" d, i.e., $d_H(S,\tilde{S}) := \max_{s\in S} \min_{\tilde{s}\in\tilde{S}} d(s,\tilde{s})$.

Following [20], we call a set $\tilde{S}$ a Δ-*approximation for the Pareto set* S if $d_H(S,\tilde{S}) \leq \Delta$. As a natural (asymmetric) "distance" measure $d(s,\tilde{s})$ that quantifies the disadvantage of taking $\tilde{s}$ over s (w.r.t domination of other points), we define: $d(s,\tilde{s}) = \max\{0, \tilde{s}.x - s.x, \tilde{s}.y - s.y\}$. Note that this measure is a more suitable definition than using, e.g., $\|\tilde{s}-s\|_\infty$, which would unnaturally punish a point that is worse by $\leq \Delta$ in x-direction, but *much better* (by $\gg \Delta$) in y-direction. With this notion, $\tilde{S}$ is a Δ-approximative Pareto sum of P, Q, if $\tilde{S}$ Δ-approximates S, (2) $\tilde{S} \subseteq P+Q$, and (3) $\tilde{S}$ is a Pareto set.

To obtain such an approximation, we proceed as follows: we first scale down the points of P and Q by dividing the x and y-coordinates by a scaling parameter t, creating the sets P' and Q'. We additionally save a *representative* $\text{rep}(p') \in P, \text{rep}(q') \in Q$ for each (rounded) point $p' \in P'$ and $q' \in Q'$ in the original sets (we choose the one with minimal L_1 norm but any representative works). Then we compute the Pareto sum S' for the sets P' and Q' and determine, from each $s' = p' + q' \in S'$, an approximate point $\tilde{s}$ using the representatives of p' and q', which yields an approximate set $\tilde{S}$. As we shall prove, this simple idea turns out to be conditionally optimal, by devising a fine-grained equivalence with

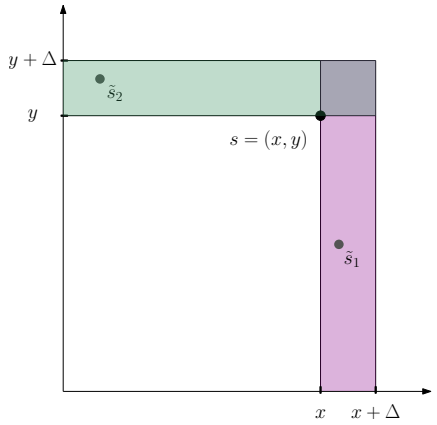

Figure 3 The points $\tilde{s}_1$ and $\tilde{s}_2$ are examples of points with $d(\tilde{s}, s) \leq \Delta$ for the shown $s \in S$. Note that if $s \in S$, then no point in $P + Q$ dominates s (i.e., no point lies to the lower left of s).

bounded $(\min, +)$-convolution. This algorithm is formalized in Algorithm 1, which takes as input P, Q and a scaling factor t, and returns a $2t$-approximation of the Pareto sum of P and Q.

Algorithm 1 ApproximateParetoSum(P, Q, t).

$P' \leftarrow \left\{\left(\lfloor \frac{p.x}{t} \rfloor, \lfloor \frac{p.y}{t} \rfloor\right) \mid p \in P\right\}$
$Q' \leftarrow \left\{\left(\lfloor \frac{q.x}{t} \rfloor, \lfloor \frac{q.y}{t} \rfloor\right) \mid q \in Q\right\}$
for $p' \in P'$ **do**
  $\text{rep}(p') \leftarrow \arg\min_{p \in P} \left\{\|p\|_1 \mid p' = \left(\left\lfloor \frac{p.x}{t} \right\rfloor, \left\lfloor \frac{p.y}{t} \right\rfloor\right)\right\}$
end for
for $q' \in Q'$ **do**
  $\text{rep}(q') \leftarrow \arg\min_{q \in Q} \left\{\|q\|_1 \mid q' = \left(\left\lfloor \frac{q.x}{t} \right\rfloor, \left\lfloor \frac{q.y}{t} \right\rfloor\right)\right\}$
end for
$P' \leftarrow$ Pareto front of P', $Q' \leftarrow$ Pareto front of Q' {*if necessary*}
$S' \leftarrow PS(P', Q')$, where $s' \in S'$ is given as (p', q') with $s' = p' + q'$ and $p' \in P', q' \in Q'$
$Z \leftarrow \{\text{rep}(p') + \text{rep}(q') \mid (p', q') \in S'\}$
return $\tilde{S} \leftarrow$ Pareto front of Z

▶ **Lemma 6.** *For any P, Q and $t > 0$, let S denote $PS(P, Q)$ and let $\tilde{S}$ denote the result of ApproximateParetoSum(P, Q, t). Then $\tilde{S}$ is a $2t$-approximation of the Pareto sum of P, Q.*

Proof. We first argue that the set Z computed in Algorithm 1 satisfies the relaxed domination condition with $\Delta = 2t$, specifically, that for all $p + q$ with $p \in P, q \in Q$, there exists some $z = \text{rep}(p') + \text{rep}(q') \in Z$ with $z \leq p + q + (2t, 2t)$. Indeed, for any $p \in P, q \in Q$, consider their rounded points $p' = \left(\lfloor \frac{p.x}{t} \rfloor, \lfloor \frac{p.y}{t} \rfloor\right) \in P'$, $q' = \left(\lfloor \frac{q.x}{t} \rfloor, \lfloor \frac{q.y}{t} \rfloor\right) \in Q'$. By definition of the Pareto sum S' of P', Q', there must exist some $(\tilde{p} + \tilde{q}) \in S'$ with $\tilde{p} + \tilde{q} \leq p' + q'$. We claim that $z := \text{rep}(\tilde{p}) + \text{rep}(\tilde{q})$ approximately dominates $p + q$, since

$$\begin{aligned} z &= \text{rep}(\tilde{p}) + \text{rep}(\tilde{q}) \leq (t\tilde{p} + (t, t)) + (t\tilde{q} + (t, t)) \\ &= t(\tilde{p} + \tilde{q}) + 2(t, t) \leq t(p' + q') + 2(t, t) \\ &\leq p + q + 2(t, t), \end{aligned}$$

where we used $\text{rep}(x') \leq tx' + (t,t)$ for any rounded point x' in the first line, and $tx' \leq x$ for any x and rounded point x' in the third line. We claim that the lemma follows: Filtering out dominated points in Z ensures that $\tilde{S}$ is a Pareto set (establishing Condition 3.), without affecting the domination condition (if $z \in Z$ dominates $z' \in Z$, then whenever $z' \leq p+q+(t,t)$, then $z \leq z' \leq p+q+(t,t)$, so z' is never needed to ensure the condition). Finally, clearly $\tilde{S} \subseteq Z \subseteq P+Q$ as any element of Z is explicitly given as $\text{rep}(p') + \text{rep}(q')$ for corresponding $\text{rep}(p') \in P$ and $\text{rep}(q') \in Q$. ◀

▶ **Theorem 7.** *Let $T(n,W)$ denote the runtime of monotone min-plus convolution of arrays of size n and entries bounded by W with witness reporting. Given sets P,Q of n points in $\mathbb{R}^2$, we can compute a Δ-approximate Pareto sum in time $\mathcal{O}(n+(W/\Delta)\log(W/\Delta)+T(W/\Delta,W/\Delta))$.*

Proof. Given Lemma 6, it remains to show that $\text{ApproximateParetoSum}(P,Q,t)$ with $t := \Delta/2$ can be computed in the desired running time. After $O(n)$-time preprocessing, the main step in Algorithm 1 is to compute the Pareto sum S' of P', Q'. By our rounding, P', Q' have integer coordinates in $\{0,\dots,\lfloor W/\Delta \rfloor\}$, and Theorem 3 is applicable to obtain S' and thus Z in time $T(\lfloor W/\Delta \rfloor, \lfloor W/\Delta \rfloor)$. Observe that Z is a set of size at most $O(W/\Delta)$. Thus, we can compute its Pareto front in time $O((W/\Delta)\log(W/\Delta))$, concluding the claim. ◀

▶ **Corollary 8.** *Given sets P,Q of n points with real coordinates in $[0,W]^2$ and $\epsilon > 0$, we can compute an ϵW-approximation of the Pareto sum in time $\tilde{\mathcal{O}}\left(n + (1/\epsilon)^{1.6}\right)$.*

Proof. Follows from the $\tilde{O}(n^{1.6})$ time algorithm of [11], and our witness reporting extension, described in the full version of the paper[4]. ◀

Let us also now show a lower bound, which will nicely complement Algorithm 1.

▶ **Theorem 9.** *Let $T_{apx}(n,W,\Delta)$ denote the running time of computing, given Pareto sets P,Q in $\mathbb{R}^2_{\geq 0}$ with maximum coordinate bounded by W, a Δ-approximation of their Pareto sum, with witnesses. If there exists $\alpha \geq 0$ and c such that $T_{apx}(n,W,\Delta) \leq O(n+(W/\Delta)^c)$ whenever $\Delta = \Theta(W^\alpha)$, then bounded monotone min-plus convolution can be computed in time $O(n^c)$, with witnesses.*

Proof. The proof is an adaptation of the reduction from min-plus convolution to Pareto sum given in [13]. Consider an arbitrary min-plus convolution instance $A[0,...,n-1], B[0,...,n-1]$ with monotonicity (specifically, $A[i] > A[i+1], B[i] > B[i+1]$ for all i) and entries in $\{0,\dots,O(n)\}$. We construct the sets of points

$$P := \{(i \cdot (2n^{\frac{\alpha}{1-\alpha}}), A[i] \cdot (2n^{\frac{\alpha}{1-\alpha}})) \mid i \in [n-1]\},$$
$$Q := \{(i \cdot (2n^{\frac{\alpha}{1-\alpha}}), B[i] \cdot (2n^{\frac{\alpha}{1-\alpha}})) \mid i \in [n-1]\}.$$

Consider a Δ-approximation $\tilde{S}$ of the Pareto sum of P,Q with $\Delta = n^{\frac{\alpha}{1-\alpha}}$. By construction of the point sets, if a point $\tilde{s} \in \tilde{S} \subseteq P+Q$ Δ-dominates a point $p+q$, i.e., $\tilde{s} \leq p+q+(\Delta,\Delta)$, then it already dominates $p+q$, i.e., $\tilde{s} \leq p+q$. Thus, $\tilde{S}$ is the true Pareto sum of P,Q, and we can extract the min-plus convolution C of A,B: By construction, for every $k \in [2n-2]$, there must be a point in $PS(P,Q)$ with x-coordinate $k \cdot (2n^{\frac{\alpha}{1-\alpha}})$ and y-coordinate $(\min_{i \in [n-1]} A[i] + B[k-i]) \cdot (2n^{\frac{\alpha}{1-\alpha}})$, revealing $C[k] = \min_{i \in [n-1]}(A[i]+B[k-i])$. The existence of a point with x-coordinate $k \cdot (2n^{\frac{\alpha}{1-\alpha}})$ for every $k \in [2n-2]$ follows by the decreasing values of $C[k]$. Also, witnesses for such points can be transferred.

[4] We remark that it is very plausible that our witness reporting algorithm extends to the $\tilde{O}(n^{1.5})$ algorithm.

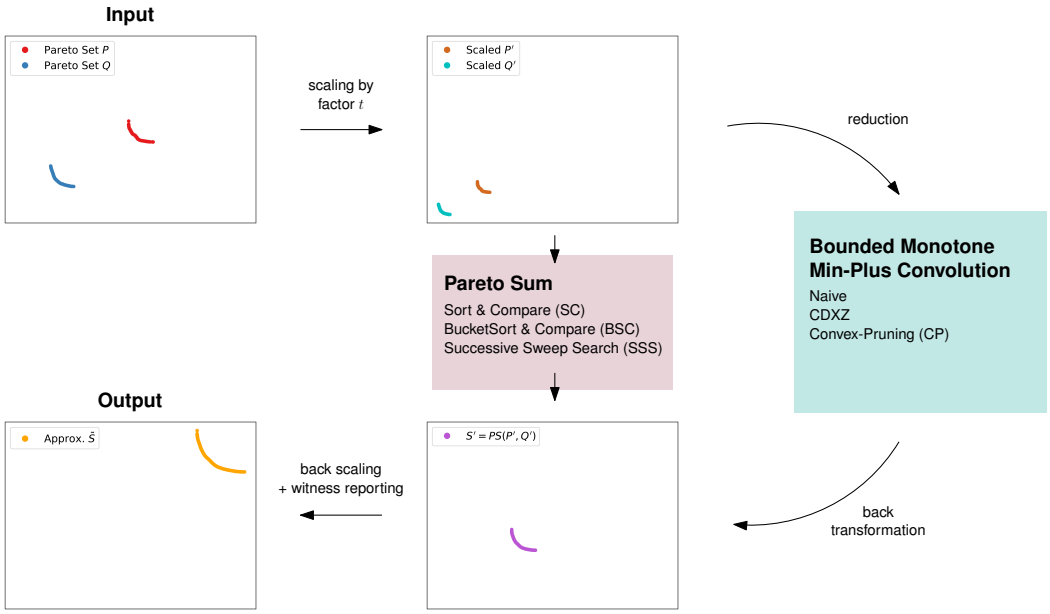

Figure 4 Overview of the main steps of our additive approximation algorithms. An important step is to compute the Pareto sum of the scaled instance. This can either be done directly via a Pareto sum algorithm or by an algorithm for bounded monotone min-plus convolution when applying the proper forward and backward reduction steps.

Note that the constructed instance of Pareto sum Approximation consists of n points in P, Q with coordinates bounded by $W \leq O(n^{1+\frac{\alpha}{1-\alpha}}) = O(n^{\frac{1}{1-\alpha}})$ and $\Delta = n^{\frac{\alpha}{1-\alpha}}$. Thus, if $T_{apx}(n, W, \Delta) \leq O(n + (W/\Delta)^c) = O(n + (n^{\frac{1}{1-\alpha}} - \frac{\alpha}{1-\alpha})^c)$, then we can compute the min-plus convolution of A, B in time $O(n^c)$, with witnesses. ◀

▶ Remark 10. Even without witness reporting, we still get a fine-grained equivalence (for slightly weaker guarantees), by a minor adaptation of Algorithm 1 and Theorem 9. We relax the condition $\tilde{S} \subseteq P + Q$ to the milder condition that each $\tilde{s}$ is in the vicinity of a point $p + q \in P + Q$. More formally, for all $\tilde{s} \in \tilde{S}$ there exist $p \in P$ and $q \in Q$ such that $p + q \leq \tilde{s} \leq p + q + 2(t, t)$. Further details can be found in the full version of the paper.

4 Framework and Implementation

Our proposed additive approximation algorithm, presented in Algorithm 1, consists of scaling down the instance, computing the Pareto sum of the transformed point sets, and then scaling up the solution. The Pareto sum instance after scaling is captured by our definition of bounded Pareto sum. To compute its solution, we can obviously directly apply any Pareto sum algorithm. By virtue of Theorem 3, however, also any algorithm for bounded min-plus convolution translates to an algorithm for bounded Pareto sum when performing the required reduction and back-transformation of the solution. Thus, depending on whether we use an algorithm directly designed for Pareto sum or a convolution algorithm, the computation pipeline needs to be adapted. Figure 4 provides an overview of our framework. In the following, we describe the algorithms of each category in more detail.

4.1 Algorithms for (bounded) Pareto sum

We start with the algorithms designed directly for Pareto sum computation.

Sort & Compare (SC) and Successive sweep search (SSS)

We implemented both state of the art algorithms for (general) Pareto sum computation from [13] as a baseline. In a nutshell, the Sort & Compare algorithm sorts the points in the sumset $P + Q$ lexicographically and performs constant time dominance checks per point based on this ordering. Further details on the baselines can be found in the full version of the paper.

BucketSort & Compare (BSC)

For bounded integral Pareto sum, we can improve the Sort & Compare algorithm, by using bucketsort to sort the points, and then perform a direct update on the minimal y-coordinate for each corresponding x-coordinate. Further details can be found in the full version of the paper.

4.2 Algorithms for min-plus convolution

After the reduction to min-plus convolution, we can of course use the naive quadratic time algorithm for the latter. In the following, we discuss two more sophisticated and (potentially) faster convolution algorithms.

CDXZ Algorithm

We discuss a simplified version of the $\tilde{O}(n^{1.6})$-algorithm [11, Section 4.1] for monotone bounded min-plus convolution in a detailed fashion in the full version of the paper. Using this algorithm in our Pareto sum reduction framework results in a running time of $\mathcal{O}(W^{1.6} \log W)$ for bounded Pareto sum. Let us highlight the main improvements and simplifications we achieved.

- We removed the segment tree data structure. Making use of a simpler enhanced min-plus convolution algorithm instead of using a segment tree with interval updates is simpler and improves the runtime theoretically and practically.
- We improved the bound of b, which was previously ranging from $b \in \{0, 1, 2\}$ to $b \in \{0, 1\}$. The better bound of the constant b, is insignificant in the theoretical analysis of the algorithm, but it plays an important role in the error correction part. Besides the initial polynomial multiplication of P and Q, every other part of the algorithm in the error correction phase will be repeated b-times, thus the better bound on b will result on repeating these costly parts of the algorithm twice instead of thrice.
- As the set T_b can be of expected size $\mathcal{O}(n^{1.6})$ (for the choice of $\beta = 0.4$), we do not save it explicitly like [11] suggests. In order to circumvent storing the set T_b, we make an online computation of the polynomials $R_{p,b}[k](x)$ simultaneously, updating the polynomials after having seen a new pseudo-witness $(i, k - i)$ on the fly.

We implemented the version without witness reporting, as the witness reporting algorithm would be too inefficient in practice. This leads to a weak approximation of the Pareto sum. For the multivariate polynomial multiplication, we perform a standard reduction to the univariate case, by turning P and Q into univariate polynomials. Instead of FFT, we make use of the polynomial multiplication offered by the library FLINT [24], where the univariate

polynomials are kept as lists. Instead of using binary search trees in the computation of T_b, we performed a linear search, after saving for each possible modulo value $i \in [p-1]$ the indices k with $C'[k] + b \mod p = i$. This turned out to be faster in the experiments. The parameters α and β are not fixed as the optimal theoretical runtime suggests. The choice of the parameters α and β are transferred to the choice of the scaling factor n^α and the prime p, which are now inputs of the implementation; see Figure 7 for the influence of these parameters on the runtime.

Convex Pruning (CP) algorithm

Bringmann and Cassis developed an algorithm for min-plus convolution, suited towards the case, where the arrays A and B are near-convex [5]. We implemented two versions of their algorithm with and without witness reporting. Our implementation is close to the descriptions in [5], with the main difference being that we did not use sparse convolutions, but rather an enhanced min-plus convolution computation, which works particularly well when the arrays A and B have few distinct entries. We precomputed groups of entries of the same value in A and B. More details on the enhanced min-plus convolution on the precise changes can be found in the full version of the paper.

4.3 Further engineering

Algorithm 1 has been implemented mostly matching its description, with small changes, which we describe now. When using a convolution algorithm within Algorithm 1, we also perform the needed reduction from bounded Pareto sum to monotone bounded min-plus convolution and the transformation backwards. The reduction closely follows the constructive proof of Theorem 3. At the end of Algorithm 1, instead of computing the Pareto front of the set Z by sorting, we do the following: For each newly inserted point, we look back and remove all points, which are dominated by this new point. This will work fast as the set Z is almost a Pareto set, so few corrections need to be made.

5 Experimental Evaluation

In the following, we evaluate our approximate algorithm with the different choices for bounded Pareto sum computation sketched above. While all algorithms are described for the case that P and Q are of the same size n, they also all work for differing sizes. Our code is written in C++. It was compiled with gcc using -O3. In our implementation of the CDXZ algorithm, we use routines from FLINT (Fast Library for Number Theory) [24]. All experiments were conducted on a single core of an AMD Threadripper 3970 with 256 GB of RAM. We set a time-out of one hour per run. Running times are always averaged over 10 runs.

Benchmarks. We use three types of benchmarks in our evaluation. Two are synthetic to allow us to control instance properties, while the third benchmark consists of real data.

Benchmark 1: Instances with bounded range. First, we use an instance generator that allows us to fix n and W. Here, it is important to ensure $W \geq n-1$ to guarantee that there are enough distinct natural numbers in the range to construct a Pareto set. We use $W = c \cdot n$ for $c \geq 1$. To efficiently create a strictly monotonically increasing sequence, we initialize an array with a counter γ_i for each $i \in [W]$. Then, we increment a randomly selected counter in each of n rounds. Afterwards, we sweep over this array, starting at position 0, and perform

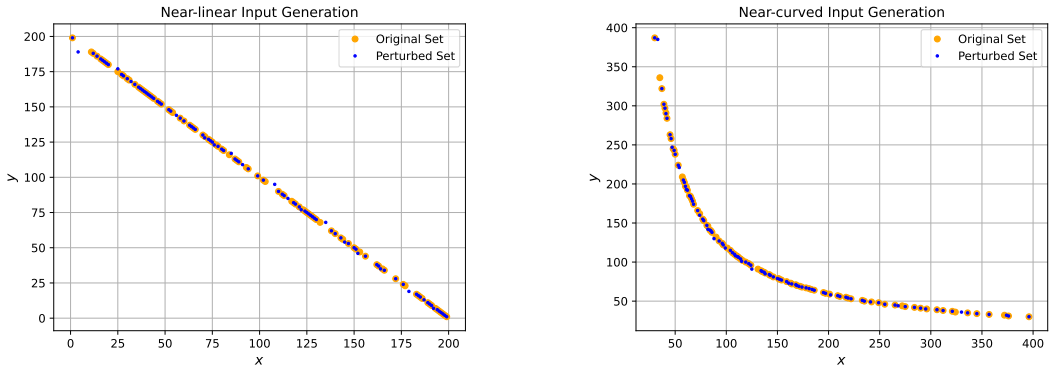

Figure 5 Two different versions of generating input sets with values in the range $[0, 2n]$: Near-linear and near-curved input sets are based on the linear and curve generator, respectively, where we apply perturbation to a subset of the points.

the following operations: If $\gamma_i > 1$, we set $\gamma_i = 1$ and $\gamma_{i+1} = \gamma_{i+1} + \gamma_i - 1$. Here, entry 0 is assumed to be the successor of γ_W. We stop when all entries are 0 or 1 which happens after each entry has been considered at most twice. Then, for all $\gamma_i = 1$, element i is added to the sequence. This produces a valid sequence in time $\mathcal{O}(n + W)$. Pareto sets can then be constructed by using two such sequences, one sorted increasingly for the x-coordinates and the other one decreasingly for the corresponding y-coordinates.

Benchmark 2: Function-based instance generator. For any strictly monotonically decreasing function f defined on $\mathbb{R}^+$, sampling n points $(x, f(x))$ provides us with a Pareto set. We use two base functions: the first uses $f(x) = -x$ and the second $f(x) = \frac{c}{x}$ with a constant $c \in \mathbb{R}^+$. We slightly perturb the points to have more input variability, while guaranteeing that pairwise non-dominance is upheld. We refer to the resulting instances as near-linear or near-curved. See Figure 5 for an illustration. We note that by means of the perturbation, the resulting point sets are no longer convex.

Benchmark 3: Route planning instances. Finally, we also use real-world data sets for evaluation. The instances stem from bi-criteria route planning in line with [13]. Here, given a graph in which the edges are augmented with two cost values (in our case distance in meters and positive height difference in centimeters), the goal is to compute all Pareto-optimal paths from a source node s to a target node t. Using bi-directional search to answer such queries, or constructing a data structure which accelerates query answering [23], demands to combine and filter the set of Pareto-optimal paths from s to some intermediate node v, and from v to the target t. The cost pairs of these two path sets form our inputs P and Q. The benchmark contains roughly 100000 instances based on randomly chosen s, v and t triples in a directed road network with one million nodes and two million edges. Note that the sizes of P and Q might differ significantly in each instance.

Results for Exact Pareto Sum. For a general comparison of the different algorithms for Bounded Pareto sum discussed in this paper, we first applied a scalability study on the range-bound instances with all point coordinates being integers, see Figure 6. We observe huge performance differences. SSS is by far the slowest approach. Its theoretical performance is only subquadratic in case the output size is in $o(n)$. However, for the considered instances there are roughly $4n$ output points. The BSC algorithm performs best and also significantly

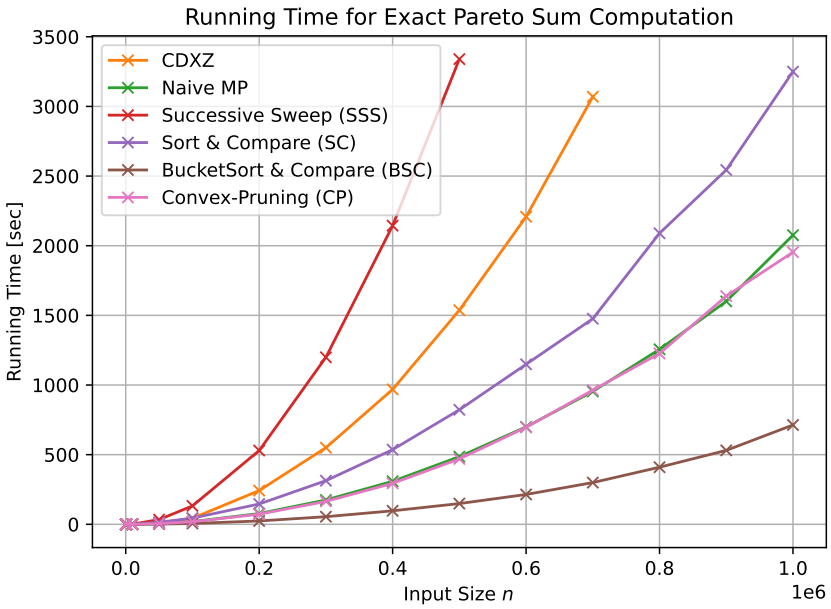

Figure 6 Running times for Pareto sum computation on generated inputs of size up to $n = 100,000$ with values in the range of $[0, 2n]$ and a timeout of 1 hour.

outperforms the plain SC algorithm. Even more remarkably, also the min-plus convolution based algorithms, naive and CP, outperform SC. While CDXZ beats SSS, it is a bit slower than SC on this instance type. As described in Section 4, our implementation of the CDXZ algorithm allows us to choose its parameters. We conducted a series of tests on synthetic instances of different sizes to determine a good parameter choice, see Figure 7 for an example. We observe that the parameter values heavily impact the performance. Across all tested

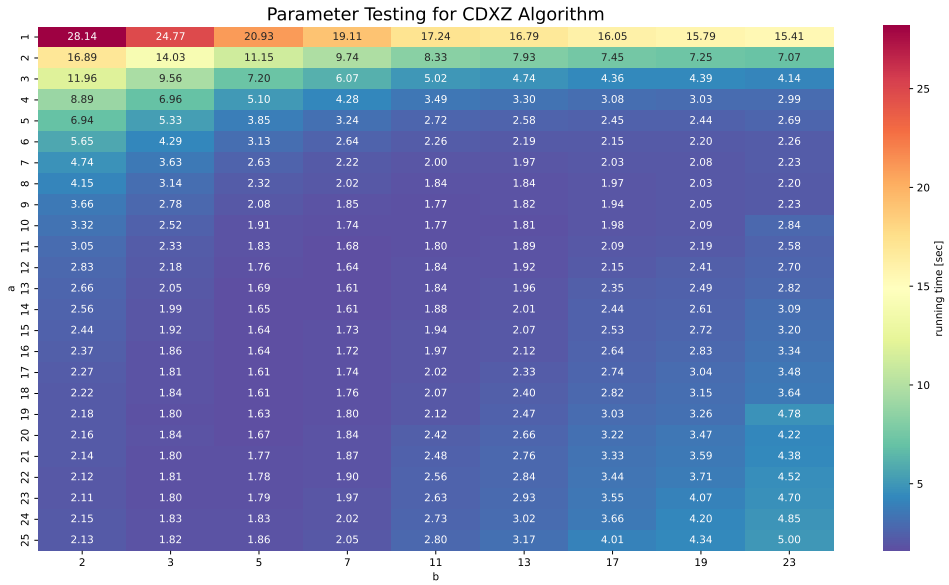

Figure 7 Parameter testing for the CDXZ algorithm on inputs of size $n = 20000$ in the range $2n$.

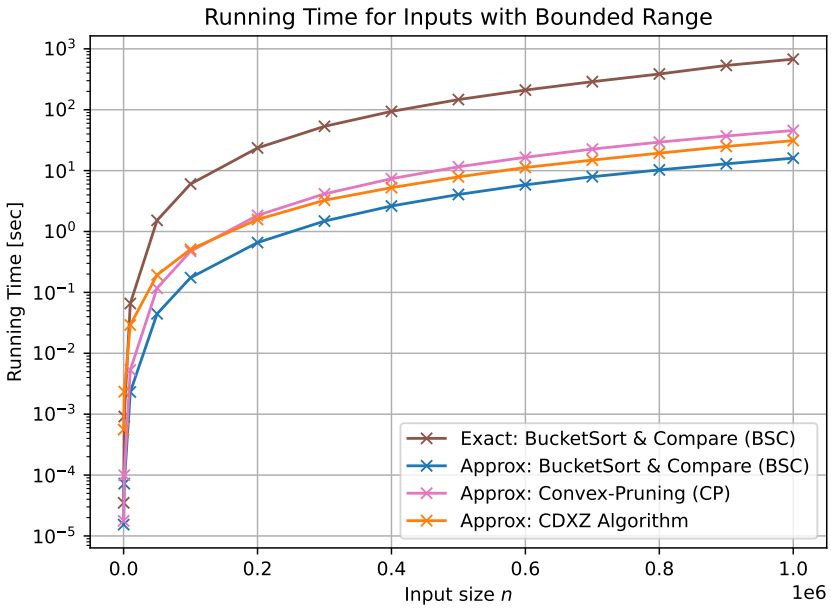

Figure 8 Running time of the approximation variants on inputs generated with bounded range of $2n$ using a scaling factor of $t = 10$.

instances, scaling factors of 25 and $p = 2$ were among the top configurations. We therefore use those values in all subsequent experiments. We remark, though, that additional fine-tuning or choices adaptive to n could potentially further improve the performance.

However, our main interest is in computing approximate solutions. In the following, we investigate how the algorithms perform when used as a plug-in in our approximation framework. In the remainder of the experiments, we focus on the BSC algorithm as well as the convolution based algorithms, as they outperform the baseline algorithms.

Results for Approximate Pareto Sum. Next, we present comparative running time results of our approximation algorithm with different inner methods of Pareto sum computation applied to the scaled down inputs. For fair comparison, we use the non-witness reporting variants for all of them. Figures 8, 9, and 10 depict the results for range-bounded, near-linear and near-curve instances, respectively, using a value range of $2n$ and a scaling factor of $t = 10$. Interestingly, for each input type, another algorithm performs best. For range-bounded instances, BSC is the fastest with CDXZ being second, while on near-linear instances CDXZ outperforms the other two methods. On near-curved instances, however, CP is clearly the best, beating the others by at least an order of magnitude. The performance of CP relies on its ability to prune pairs, which on near-curved instances applies to up to 95% of total point pairs, see Figure 11.

Finally, we consider our third benchmark set, which consists of bi-criteria route planning instances of varying size. Figure 13 shows the running time and approximation quality of our algorithms for different scaling factors. We observe that BSC performs best with CP being a close second, especially for larger values of t. They both improve on exact computation by over an order of magnitude and also stay well below the theoretical additive approximation bound of $2t$. Examples of approximate solutions can be found in Figures 14. One can see that even when choosing a larger t, the Pareto sum is still well represented by the computed

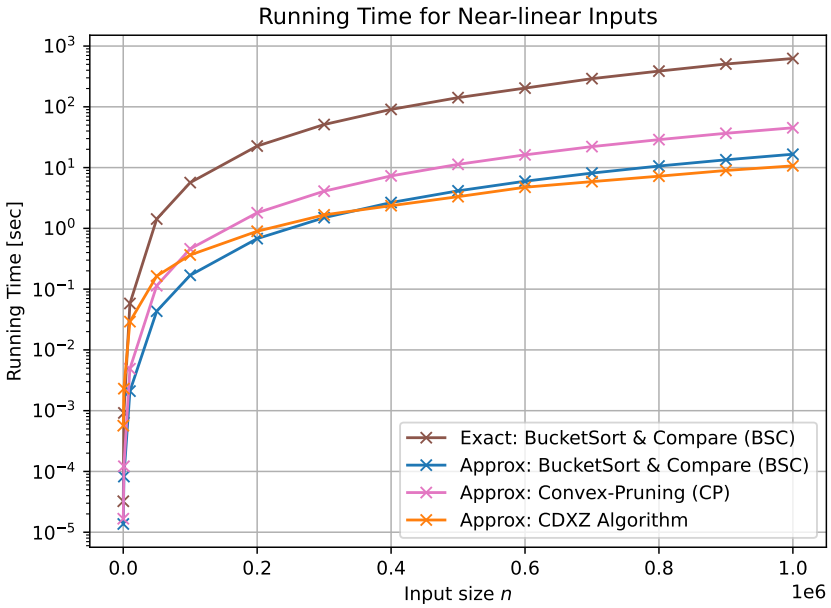

Figure 9 Running time of the approximation variants with a scaling factor of $t = 10$ on near-linear inputs generated in the range of up to $2n$.

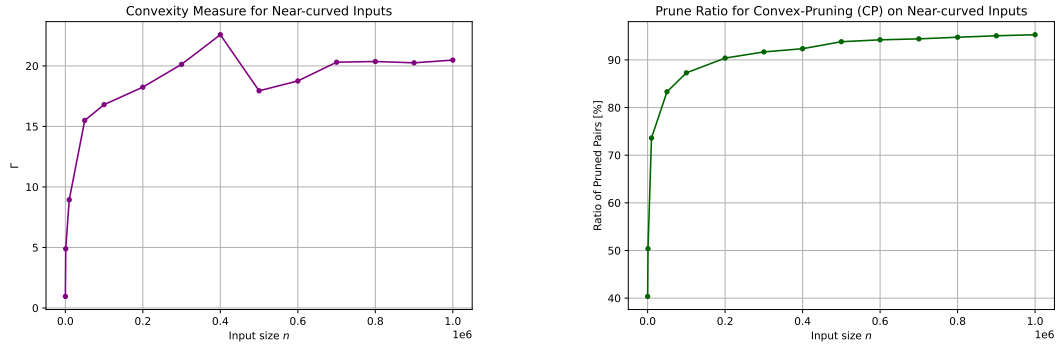

Figure 11 Convexity measure for near-curved inputs (left) and ratios of pruned pairs by the CP algorithm with respect to all available pairs in the index space (right).

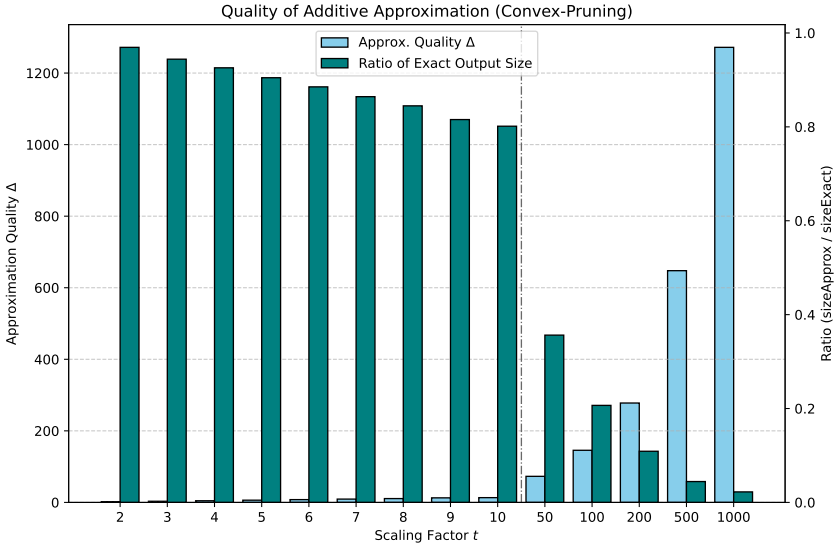

Figure 12 Quality of the approximation using the CP algorithm on real benchmarks for varying scaling factors $t = 2, \ldots, 1000$. We compare the ratio of the output size of the approximation and the exact algorithm to the approximation quality Δ.

solution. Indeed, larger values of t are quite reasonable in our application. For example, a route that is up to 100 meters longer than another one is almost indistinguishable to a user if the total route length is anyway in the orders of kilometers.

Furthermore, the user usually does not want to be presented with hundreds of routing options, but a concise and diverse set of reasonable options. This is achievable with our approach, as we can not only reduce the running time with larger t but also the output size, see Figures 15 and 12. Clearly, our algorithm provides good trade-offs between running time and solution quality, which allows one to choose the best t depending on the application.

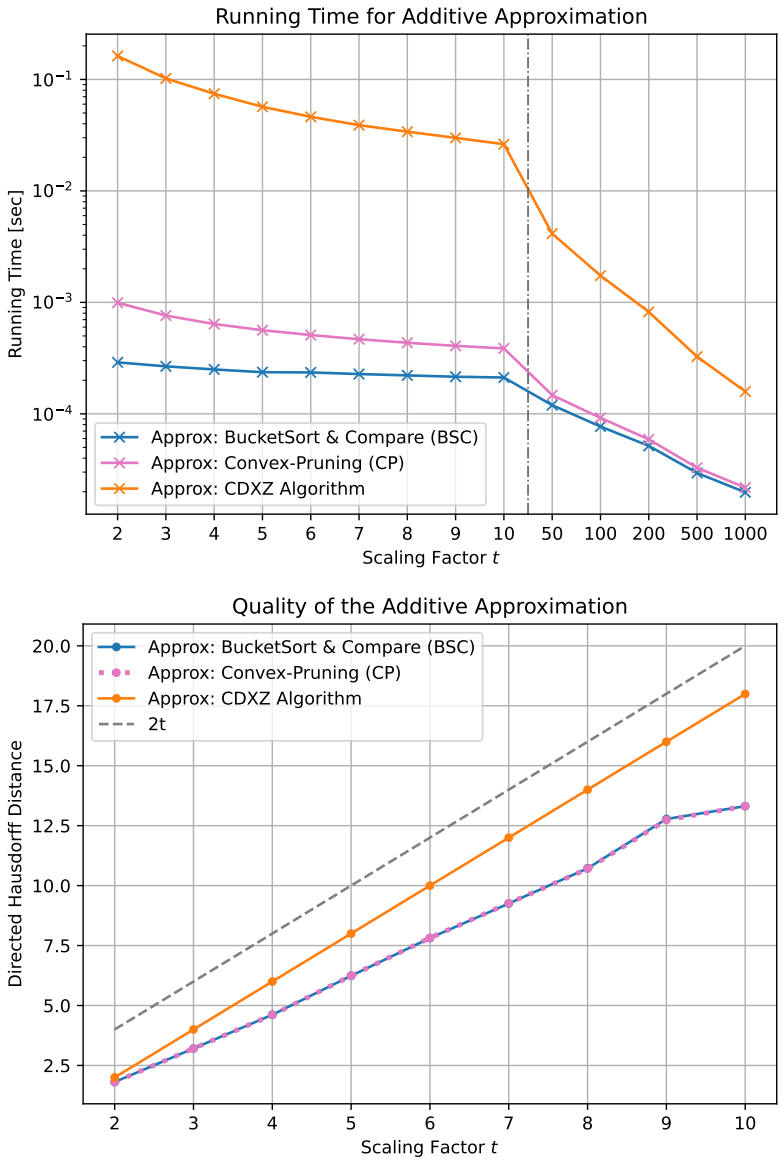

Figure 13 Running time of approximations on real benchmark for varying scaling factors $t = 2, \ldots, 1000$ (top) and solution quality for $t = 2, \ldots, 10$ (bottom). This shows the difference of the quality of approximation with (BSC,CP) and without witness reporting(CDXZ).

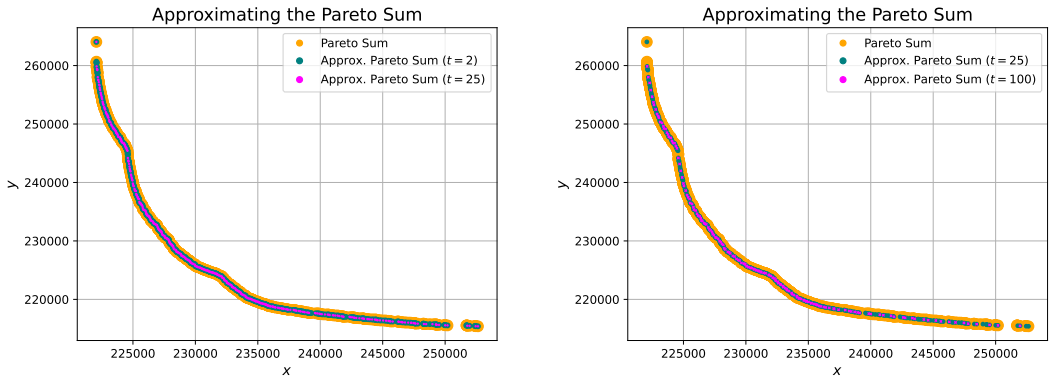

Figure 14 Example for approximate Pareto sum on real benchmark data. The approximative solution for $t = 2$ results in a quality of $\Delta = 2$ (left) whereas for $t = 25$ the quality is $\Delta = 38$ and for $t = 100$ we have $\Delta = 153$ (right).

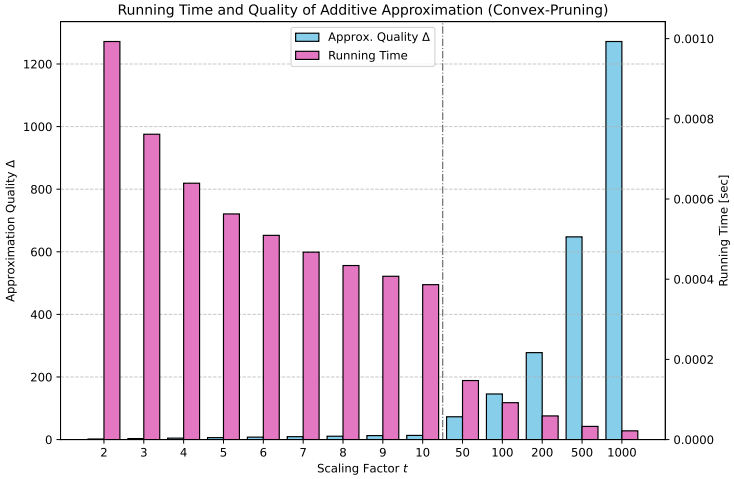

Figure 15 Approximation quality Δ and running time of the approximation using the CP algorithm on real benchmarks with varying scaling factor $t = 2, \ldots, 1000$.

6 Future Work & Discussion

We have established that fine-grained reductions are not only a means to obtain theoretical intractability results, but also a tool to efficiently solve problems via reductions to other problems for which fast algorithms are implemented and engineered. To further foster (bounded monotone) min-plus convolution as a core primitive, it would be interesting to know whether the $\tilde{O}(n^{1.5})$ algorithm [11, Section 4.2], admits an efficient implementation. The main drawback right now is that it needs 9 calls to the monotone bounded min-plus function, and that the constant $b \in [-4, 7]$ is much larger than in the algorithm we implemented. We believe that the CP algorithm can benefit from practical sparse convolution algorithms, especially on near-linear inputs. Is it possible to engineer fast sparse convolution algorithms in practice? Finally, can we leverage our min-plus convolution results to obtain practical improvements for knapsack [4, 6] or the tree sparsity problem [21, 2]?

Abstract

In the celebrated paper of Henzinger, Klein, Rao and Subramanian (1997), it was shown that planar graphs admit a linear time single-source shortest path algorithm. Their algorithm unfortunately does not extend to Euclidean graph classes. We give criteria and prove that any Euclidean graph class satisfying the criteria admits a linear time single-source shortest path algorithm. As a main ingredient, we show that the contracted graphs of these Euclidean graph classes admit sublinear separators.

1 Introduction

Computing shortest paths is a fundamental problem in graph theory and in network analysis. Given a graph with non-negative edge weights, the single-source shortest path (SSSP) problem is to compute the shortest paths from a source vertex to all the other vertices in the graph. The SSSP problem has found numerous applications in transportation networks, geographic information systems, motion planning, social networks, chip design, and so on.

The most well-known SSSP algorithm is Dijkstra's algorithm [2]. Using a Fibonacci heap [8], Dijkstra's algorithm runs in $O(m + n \log n)$ time on graphs with m edges and n vertices. Dijkstra's algorithm has a lower bound of $\Omega(n \log n)$ in the comparison computer model, since the algorithm sorts the vertices of the graph by their distances from the source vertex.

In planar graphs, faster algorithms are known. Frederickson [7] gave an $O(n\sqrt{\log n})$ time SSSP algorithm for planar graphs, using *r-division* and graph contraction. An r-division of a planar graph divides the graph into $O(n/r)$ regions such that each region has $O(r)$ vertices and $O(\sqrt{r})$ boundary vertices. Henzinger, Klein, Rao and Subramanian [12] use *recursive division*, a recursive version of r-division, and an edge-relaxation algorithm on the recursive

division to give an optimal linear-time SSSP algorithm for planar graphs. The algorithms leverage two key properties of planar graphs: (i) the graph class is minor-closed [13], and (ii) the graphs admit a sublinear separator that can be computed in linear time [16]. Tazari and Müller-Hannemann [23] showed how to use knitted H-partition to avoid introducing arbitrarily large minors and extend the linear time algorithm of HKRS [12] to any minor-closed graph class. A natural open problem is to ask: which other graph classes admit a linear time SSSP algorithm?

▶ **Open Problem 1.** *Other than planar graphs and minor-closed graphs, which graph classes admit a linear time single-source shortest path algorithm?*

Practical applications have motivated researchers to study Open Problem 1. For example, road networks are non-planar, and it is unknown if road networks are minor-closed, yet computing shortest paths remains a fundamental problem on road networks.

Le and Than [15] proposed τ-lanky graphs, which are any Euclidean graph where any ball in $\mathbb{R}^d$ with radius r cuts at most τ edges longer than r. Lanky graphs unify several Euclidean graph classes including greedy spanners in $\mathbb{R}^d$ (any fixed d), low-density graphs in $\mathbb{R}^d$ ([1]) and greedy spanners of unit ball graphs in $\mathbb{R}^d$. All these graph classes are $O(1)$-lanky graphs. The low-density graph in $\mathbb{R}^2$ is argued to be a realistic model for road networks [1].

In the conference version of their paper, Le and Than [15] proved that lanky graphs in $\mathbb{R}^d$ admit sublinear separators. They claimed that their (expected) linear time sublinear separator algorithm for lanky graphs implies a linear time SSSP algorithm by applying HKRS's algorithm [12]. Unfortunately, this claim has a gap. While lanky graphs admit sublinear separators, they are not minor-closed. Therefore, HKRS's algorithm does not directly extend to lanky graphs. The SSSP claim is retracted in the full version of the paper [14]. Prior to their paper, Eppstein and Khodabandeh [4] studied the edge crossing patterns of greedy spanners in $\mathbb{R}^2$. They gave an $O(n \log^{(i)} n)$ time SSSP algorithm for greedy spanners in $\mathbb{R}^2$ (Corollary 21), where i is any constant and $\log^{(i)} n$ denotes the i-times iterated logarithm. These efforts raise the following open problem.

▶ **Open Problem 2.** *Is there a linear time SSSP algorithm for τ-lanky graphs in $\mathbb{R}^d$?*

Miller, Teng, Thurston and Vavasis [21, 18, 19] developed a geometric characterization of graphs that have a sublinear separator, using the notion of a *k-ply neighborhood system*. A k-ply neighborhood system is a collection of balls in $\mathbb{R}^d$ such that no point in the space is covered by more than k of the balls. They showed that (the intersection graphs of) k-ply neighborhood systems can model sphere-packings [18], k-nearest neighbor graphs [18] and finite element meshes [20]. They proved that k-ply neighborhood systems in $\mathbb{R}^d$ (and their intersection graphs) admit a sublinear separator that can be computed in linear time [18, 5].

Eppstein and Goodrich [3] use k-ply neighborhood system in $\mathbb{R}^2$ as a model of real-world road networks. They showed how to compute SSSP in randomized linear time, assuming the arrangement of the k-ply disk neighborhood system is given. Besides the assumption, their approach is specific to $\mathbb{R}^2$ and does not extend to higher dimensions. This raises the following open problem.

▶ **Open Problem 3.** *Is there a linear time SSSP algorithm for the intersection graph of a k-ply neighborhood system in $\mathbb{R}^d$, where $d \geq 2$?*

Smith and Wormald [22] considered a collection of cubes in $\mathbb{R}^d$ such that no point in the space is covered by more than κ of the cubes. Here we call the collection of cubes a *κ-thick cubical neighborhood system*. The authors proved that κ-thick cubical neighborhood systems in $\mathbb{R}^d$ (and their intersection graphs) admit a sublinear separator that can be computed in randomized linear time. We consider the following open problem.

▶ **Open Problem 4.** *Is there a linear time SSSP algorithm for the intersection graph of a κ-thick cubical neighborhood system in $\mathbb{R}^d$?*

1.1 Our contribution

Our main technical contribution is to compute a recursive division in linear time, for any Euclidean graph class that satisfies the following **criteria**:

- **(I)** The graph G admits a sublinear separator that can be computed in linear time.
- **(II)** The combinatorially contracted graphs G_i of G (refer to Definition 8) are sparse, i.e., any $\bar{k}$-vertex subgraph of G_i is sparse.
- **(III)** A closed surface in $\mathbb{R}^d$ (such as a Jordan curve in $\mathbb{R}^2$, a sphere in $\mathbb{R}^d$) is used to find the separator in (I). The closed surface cuts a sublinear number of geometrical objects (such as segments, balls) associated with the vertices in G, and these associated vertices form the separator. Moreover, a random closed surface cuts a sublinear number of geometrical objects associated with the vertices in G in expectation.
- **(IV)** The graph class of G is subgraph-closed.

Compared with HKRS [12], criteria (II)-(IV) replace the minor-closed condition, and can be satisfied by a family of non-minor-closed graph classes. Criteria (I)-(IV) are formally stated in Section 3, in which we use criteria (I)-(IV) to compute a recursive division of the Euclidean graph class in linear time. Once we have the recursive division[1], we can apply HKRS's edge-relaxation algorithm on it to compute SSSP in linear time.

In particular, we show that τ-lanky graphs, the intersection graphs of k-ply neighborhood systems and the intersection graphs of κ-thick cubical neighborhood systems all satisfy the above criteria. Thus we can compute a recursive division (and SSSP) for these Euclidean graph classes in linear time. In this way, we answer Open Problems 2, 3 and 4 affirmatively.

Our approach to constructing a recursive division in linear time uses contracted graphs of the Euclidean graph classes. The main technical challenges of using contracted graphs for Euclidean graph classes are:

- Edge contraction for planar or minor-closed graphs is a combinatorial operation. The contracted graphs in HKRS [12] are obtained by such combinatorial edge contractions. In HKRS's approach, the resulting contracted graphs must remain in the original graph class to guarantee that they have sublinear separators. This is not the case for Euclidean graph classes.
- In Euclidean graph classes, vertices are points in $\mathbb{R}^d$ and edges are segments in $\mathbb{R}^d$. Unfortunately, edge contraction *in the Euclidean space* does not preserve geometric properties and seems meaningless. For example, if an edge $(a, b) \in \mathbb{R}^d$ is contracted into a new vertex $c \in \mathbb{R}^d$, any edge e_a or e_b attached to a or b would now be attached to c. There is no way to choose c so that the geometric properties of e_a and e_b (e.g. length, intersections) are preserved.

Although edge contractions in the Euclidean space are incompatible with the geometric properties of straight line embeddings, we overcome this obstacle by performing edge contractions combinatorially and proving that 1) the combinatorially contracted graphs admit sublinear balanced separators, and 2) such balanced separators can be computed in time linear to the size of the contracted graph. These properties are unknown before and we believe that they are of independent interest.

[1] To be precise, the recursive division should satisfy the conditions in Inequalities (1).

1.2 Techniques

A recursive division of a graph divides the graph into regions, then divides the regions into subregions, and so on recursively. There are two approaches to computing a recursive division of planar graph in linear time. The first approach is to adapt Goodrich's [9] recursive separator decomposition algorithm to compute a recursive division of the planar graph in linear time. Goodrich's recursive separator decomposition algorithm emulates Lipton and Tarjan's planar separator algorithm, maintains tree structures used in LT's algorithm and other tree structures dynamically for the divided pieces during decomposition. In this way a separator of the divided piece can be computed in time sublinear to the size of the piece. The second approach, attributed to Frederickson [7] and HKRS [12], is to contract the graph consecutively into a sequence of contracted graphs, then in reverse order divide and expand the contracted graphs to get a recursive division. The first approach relies on specific properties of planar graphs and maintaining spanning trees dynamically. It seems infeasible to use similar ideas on many other graph classes. The second approach relies on edge contraction and the minor-closed property of planar graphs. However, Euclidean graph classes are not minor-closed, yet edge contraction in the Euclidean space seems meaningless.

We compute a recursive division of the Euclidean graph classes by (1) performing edge contractions on the Euclidean graph combinatorially rather than geometrically and (2) proving that the combinatorially contracted graphs have sublinear separators that can be computed in linear time. To prove that the combinatorially contracted graphs have sublinear separators, for each contracted graph we construct an auxiliary Euclidean graph which we call the *representative graph* of the contracted graph. A representative graph of the contracted graph is a sampled subgraph of the original Euclidean graph. Rather than using the contracted graphs, we use (properties of) their representative graphs to prove that the contracted graphs have sublinear separators.

Moreover, to compute an r'-division of the contracted graph (for different contracted graphs the parameter r' is different), it is normally required that any k'-vertex subgraph of the contracted graph has a sublinear separator, for any k'. This is because when dividing the contracted graphs into smaller and smaller pieces, it is required that the smaller pieces still have sublinear separators. However, the contracted graphs of the Euclidean graph classes do not have this property, even if we use their representative graphs to find the separators. Let the contracted graph be G_i and let the accumulated contraction size be the maximum number of vertices in G that are contracted into a vertex in G_i. We resolve this critical issue by requiring the division size r' to be some constant power of the accumulated contraction size. This requirement forces us to use different parameters for contractions and divisions. This is in contrast to the case in HKRS [12]. Despite this modification, we prove that the effect is sufficient by showing that the induced recursive division is still suitable for applying HKRS's edge-relaxation algorithm in linear time.

1.3 Paper Organization

In Section 2 we give preliminaries that are required for later sections. In Section 3 we prove the main theorem. In Sections 4 we consider SSSP in τ-lanky graphs. Due to space limit, we defer the related work section to the full version of the paper. We defer the section of SSSP in the intersection graph of k-ply neighborhood system and the section of SSSP in the intersection graph of κ-thick cubical neighborhood system to the full version of the paper.

2 Preliminaries

▶ **Definition 5** (r-division). *Given any integer $r > 0$, an r-division of an n-vertex graph divides the graph into $O(n/r)$ regions where each region has $O(r)$ vertices (edges) and $O(\sqrt{r})$ boundary vertices. A region consists of its vertices and edges. A vertex is called a boundary vertex if it is contained in multiple regions.*

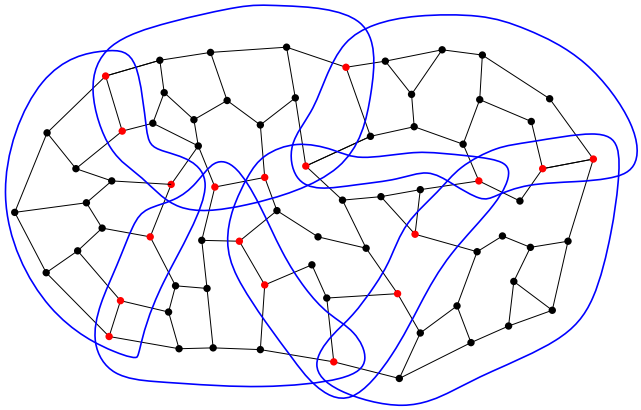

Figure 1 Illustration of r-division. An r-division of the graph divides the graph into regions (enclosed in blue lines) with interior vertices (black) and boundary vertices (red). Modified figure from [7].

▶ **Definition 6** ((r, s)-division). *An (r, s)-division divides an n-vertex graph into $O(n/r)$ regions, such that each region has $r^{O(1)}$ vertices and $O(s)$ boundary vertices.*

A recursive division of a graph divides the graph into regions, then divides the regions into subregions, and so on recursively. Formally, an $(\bar{r}, f)$-recursive division is defined as follows.

▶ **Definition 7** (recursive division [12]). *Let f be a non-decreasing positive integer function and $\bar{r} = (r_0, r_1, \ldots, r_k)$ be a positive integer sequence. An $(\bar{r}, f)$-recursive division of a graph consists of*

- **(i)** *an $(r_k, f(r_k))$-division of the graph, and*
- **(ii)** *an $((r_0, r_1, \ldots, r_{k-1}), f)$-recursive division for each region in the $(r_k, f(r_k))$-division.*

A recursive division can be computed in two phases, the *contraction phase* and the *division phase*. In the contraction phase, a sequence of non-decreasing integers $(z_0, z_1, \ldots, z_I)$ are chosen and a sequence of consecutive contractions are performed. Let $G_0 = G$ and let $\{G_i | 1 \leq i \leq I + 1\}$ be the contracted graphs. Let G_i=Contract(G_{i-1}, z_{i-1}) where the contraction algorithm Contract(G_{i-1}, z_{i-1}) contracts G_{i-1} into G_i. The Contract(G_{i-1}, z_{i-1}) algorithm calls the clustering algorithm in [6] to cluster the vertices of G_{i-1} into $O(n_{i-1}/z_{i-1})$ connected sets (n_{i-1} is the number of vertices in G_{i-1}) with each set containing $O(z_{i-1})$ vertices, then contracts each connected set into a vertex of G_i. The contraction phase ends when the last contracted graph G_{I+1} has at most $n/\log n$ vertices.

▶ **Definition 8.** *Let $G = G_0$ be a graph. We call $\{G_i | 1 \leq i \leq I + 1\}$ the (combinatorially) contracted graphs of G, where $G_i = Contract(G_{i-1}, z_{i-1})$ for some integer z_{i-1}.*

In the division phase, the contracted graphs $G_1, \ldots, G_{I+1}$ are considered in reverse order and a division is obtained for each of the contracted graphs. Let R be an n'-vertex region with a set S of boundary vertices. The Divide(R, S, r) algorithm calls the separator algorithm recursively and computes an (r, s)-division of R (which divides R into subregions). A vertex in a subregion of R is a boundary vertex if it is contained in multiple subregions or it is in S. The division D_{I+1} of G_{I+1} consists of one region, i.e., G_{I+1}. Starting from $i = I$, the division D_i of G_i is obtained from the division D_{i+1} of G_{i+1} by (i) calling Divide(R_{i+1}, S_{i+1}, z_i) for each region R_{i+1} of D_{i+1} and (ii) expanding each vertex of the subregions in R_{i+1} to the connected set in G_i that is contracted into the vertex during the contraction phase. Thus a tree representing the recursive division, called the *recursive division tree*, is obtained.

HKRS's edge-relaxation algorithm. Inspired by Frederickson's work, Henzinger, Klein, Rao and Subramanian [12] developed an optimal $O(n)$ time SSSP algorithm for planar graphs with non-negative edge weights. The algorithm consists of two parts. The first part computes a recursive division of the planar graph in linear time. The second part runs an edge-relaxation algorithm on the recursive division to compute the SSSP. Each node in the recursive division tree represents a region/subregion in the division. Each node (region/subregion) is associated with a heap, whose elements are (the current) distance values to some vertices in the region. The elements in the heap of a region are the min-elements of its subregions' heaps. This forms a hierarchy of heaps. Inside a region, edges are relaxed in analogy to Dijkstra's algorithm, while distance values in the associated heaps are updated. In contrast to Dijkstra's algorithm, the algorithm does not perform edge relaxations for each edge of the region, but only performs a certain number of edge relaxations and then jumps to another region. The numbers of edge relaxations performed inside the regions are carefully coordinated so that (i) when the algorithm terminates, the distance labels of the vertices are the exact distances from the source vertex, (ii) heap operations on large heaps (which are expensive) can be charged to heap operations on small heaps so that the overall heap operations take only $O(n)$ time. In this way the edge-relaxation algorithm correctly computes the distance labels and takes only $O(n)$ time.

A main contribution of HKRS's work is the proof of the following fact. Note that the fact holds for any graph as long as a recursive division satisfying the conditions is given.

▶ **Fact 9** (Section 3 in [12]). *Suppose we are given a graph and an $((r_0, r_1, \ldots, r_k), f)$-recursive division of the graph satisfying*

$$\frac{r_i}{f(r_i)} \geq 8^i f(r_{i-1}) \log r_{i+1} \left(\sum_{j=1}^{i+1} \log r_j \right) \tag{1}$$

for all r_i's exceeding a constant. Then applying the edge-relaxation algorithm on the recursive division takes time linear to the size of the graph.

3 The main theorem

In this section, let G be a Euclidean graph in $\mathbb{R}^d$ that satisfies the following **criteria**:

- **(I)** G admits an $O(c_1 n^{1-1/d})$ balanced separator that can be computed in $O(c_2 n)$ time.
- **(II)** The combinatorially contracted graphs G_i of G are sparse, i.e., any $\bar{k}$-vertex subgraph of G_i has $O(c_3 \bar{k})$ edges.
- **(III)** A closed surface ξ in $\mathbb{R}^d$ (such as a Jordan curve in $\mathbb{R}^2$, a sphere in $\mathbb{R}^d$) is used to find the separator in (I). The closed surface cuts $O(c_4 n^{1-1/d})$ geometrical objects

(such as segments, balls) associated with the vertices in G, and these vertices form the separator. Moreover, a random closed surface cuts $O(c_4 n^{1-1/d})$ geometrical objects (such as segments, balls) associated with the vertices in G in expectation.

(IV) The graph class of G is subgraph-closed.

Here c_1, c_2, c_3 and c_4 are constants. In criteria (I) and (III) we set the exponent of n to be $1 - 1/d$ for ease of exposition. Adapting to any constant < 1 is immediate.

As mentioned in Section 1.2, we will use the edge-relaxation algorithm of HKRS once a recursive division satisfying Inequalities (1) is given. HKRS's edge-relaxation algorithm assumes that the input graph has maximum degree at most 3. Hence, we first transform G into a graph with maximum degree 3. We perform the following transformations on the Euclidean graph G. For each vertex v of degree D greater than 3, let $u_1, \ldots, u_D$ be a cyclic ordering of the vertices adjacent to v. Replace v by a cycle $v_1, \ldots, v_D, v_1$ where each of the vertices v_i $(1 \leq i \leq D)$ is arbitrarily close to v. Replace edge (u_i, v) with new edge (u_i, v_i). Assume that G has $O(c_0 n)$ edges (c_0 is constant), the transformed graph has $O(c_0 n)$ vertices whose maximum degree is 3.

The main task is to compute, in linear time, a recursive division of G that satisfies Inequalities (1). To compute this recursive division, we compute a sequence of combinatorially contracted graphs of G and construct the auxiliary representative graphs of the contracted graphs. In Section 3.1, we use the sparsity of the contracted graphs G_i (criterion (II)) to construct their representative graphs. In Section 3.2 we prove that the (combinatorially) contracted graphs have sublinear separators and such sublinear separators can be found efficiently using their representative graphs. Finally, in Section 3.3, we prove that a recursive division of G satisfying Inequalities (1) can be computed in linear time and conclude the linear time SSSP algorithm.

3.1 The contracted graphs and their representative graphs

Recall that the recursive division can be computed using a two-phase algorithm. In the contraction phase of the recursive division algorithm, the contracted graphs $G_1, G_2, \ldots, G_{I+1}$ are constructed consecutively such that $G_i = Contract(G_{i-1}, z_{i-1})$, $1 \leq i \leq I+1$, where Contract(G_{i-1}, z_{i-1}) is the contraction algorithm. For each contracted graph G_i, $1 \leq i \leq I+1$, we construct its representative graph RG_i.

Each edge of G_i has a *representative edge* in RG_i, which is an edge in G. The representative graph RG_i consists of the representative edges of the edges in G_i and their endpoints. The representative edge of an edge e in G_i is denoted as $rep_{G_i}(e)$. The representative edge of an edge in $G_0 = G$ is the edge itself, and the representative graph of G_0 is G_0.

The representative graph RG_i is constructed from the contracted graph G_{i-1} and its representative graph RG_{i-1}, as follows. Consider a vertex u in G_i and let $cset_{G_{i-1}}(u)$ denote the connected set of vertices in G_{i-1} from which u is contracted. An edge $e = (u, v)$ in G_i corresponds to the set of edges in G_{i-1} between $cset_{G_{i-1}}(u)$ and $cset_{G_{i-1}}(v)$.

Let $REP_{G_i}(e) = \{rep_{G_{i-1}}((u', v')) | u' \in cset_{G_{i-1}}(u), v' \in cset_{G_{i-1}}(v), (u', v') \in E(G_{i-1})\}$ denote the set of the representative edges of the edges in G_{i-1} between $cset_{G_{i-1}}(u)$ and $cset_{G_{i-1}}(v)$. See Figure 2(a) for an illustration. For each edge $e{=}(u, v)$ in $E(G_i)$, choose an arbitrary edge in $REP_{G_i}(e)$ as its representative edge. The chosen representative edges and their endpoints form the representative graph RG_i of G_i.

According to criterion (II), RG_{i-1} has $O(c_3 n_{i-1})$ edges and vertices. It is then observed that RG_i is constructed from G_{i-1} and RG_{i-1} in $O(c_3 n_{i-1})$ time where n_{i-1} is the number of vertices in G_{i-1}. Note that RG_i may not be connected.

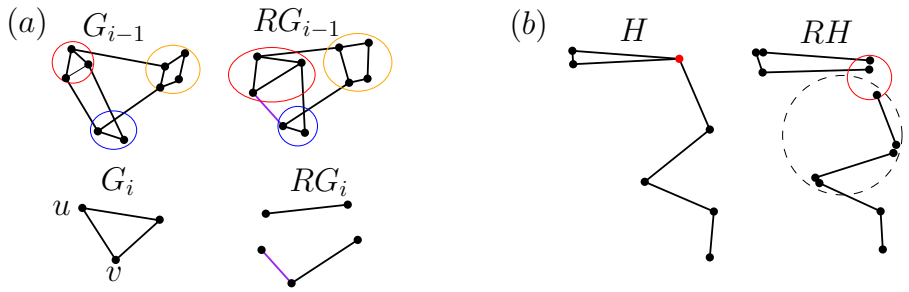

Figure 2 (a) $cset_{G_{i-1}}(u)$ is enclosed in red, $cset_{G_{i-1}}(v)$ is enclosed in blue. The representative edge of (u, v) in G_i is the purple edge. (b) Illustrating the proof of Lemma 11. The closed surface ξ^* is the dashed circle. The red vertex is added to S since its $\Gamma(\cdot)$ has one point inside $\mathbf{b}(o, r^*)$ and two points outside ξ^*.

▶ **Observation 10.** *The representative graph RG_i of G_i can be constructed in $O(c_3 n_{i-1})$ time.*

3.2 Separators of the contracted graphs

The parameters z_i used in the contraction phase, $0 \le i \le I$, are set as in [12]:

$$z_0 = 2, \tag{2}$$

$$z_i = 7^{z_{i-1}^{1/5}}, 1 \le i \le I. \tag{3}$$

Let $\alpha_{i-1} = \prod_{j<i} z_j$ be the accumulated contraction sizes for the contracted graph G_i, and let $\beta_{i-1} = z_{i-1}^{3d-2}$. In [12], parameters z_i $(0 \le i \le I)$ are used for division in the division phase. In contrast, we use β_i in place of z_i as division parameters in the division phase.

A subgraph of G_i with $O(\alpha_{i-1})$ vertices may not admit a sublinear separator. However, the next lemma shows that any subgraph of G_i with $\Omega(\beta_{i-1})$ vertices admit a sublinear separator.

▶ **Lemma 11.** *Let H be any subgraph of G_i with $k = \Omega(\beta_{i-1})$ vertices. A balanced separator of H of size $O((c_1 c_3^{1-1/d} + c_4) k^{(1-\frac{1}{3d-2})})$[2] can be computed in $O(c_2 c_3 k)$ time given H and RH.*

Proof. Let RH denote the representative graph of H, which is a subgraph of RG_i. According to criterion (II), RH has $O(c_3 k)$ vertices. Run the separator algorithm on RH (criterion (I)), noting that RH is a subgraph of G, thus it also admits sublinear separator (criteria (I) and (IV)). Let ξ^* be the closed surface (criterion (III)) used to find the separator of RH. Let S be the desired balanced separator of H, initially being empty. Vertices are added to S in two steps.

(1) For any vertex v in G_i, let $conset_G(v)$ be the (accumulative) connected set of vertices in G that are contracted into v in the contraction phase. For any point p in RG_i, let $rev(p)$ be the vertex v in G_i such that $p \in conset_G(v)$. Note that there is exactly one such vertex v. In the first step, for each geometrical object (criterion (III)) that is cut by ξ^*, add its associated $rev(\cdot)$ to S. For example, if the geometrical object is a ball and p is the ball's center, add $rev(p)$ to S.

[2] We did not try to optimize the size of the separator.

(2) For any vertex v in G_i, let $\Gamma(v)$ be (the set of) endpoints of edges in RG_i that belong to $conset_G(v)$ (we have $\Gamma(v) \subset conset_G(v)$). In the second step, partition the vertices of H into three groups: (i) those such that all points in its $\Gamma(\cdot)$ lie inside ξ^*, (ii) those such that all points in its $\Gamma(\cdot)$ lie outside ξ^*, and (iii) those such that some points in its $\Gamma(\cdot)$ lie inside ξ^* and some points in its $\Gamma(\cdot)$ lie outside ξ^*. Add vertices in group (iii) to S. See Figure 2(b) for an illustration.

We prove that S is a balanced separator of H with $O((c_1c_3^{1-1/d}+c_4)k^{(1-\frac{1}{3d-2})})$ vertices. We first prove the size of S. Since RH is a subgraph of G with $O(c_3k)$ edges and vertices, the closed surface ξ^* cuts $O(c_1(c_3k)^{1-1/d}) = O(c_1c_3^{1-1/d}k^{1-1/d})$ geometrical objects associated with the vertices of RG_i. Since $\Gamma(v)$ is a subset of $conset_G(v)$ and the vertices in $conset_G(v)$ are connected in G, the vertex v belongs to group (iii) only if one or more geometrical objects in (associated with) the subgraph of G induced by vertices in $conset_G(v)$ is cut by ξ^*. Let G_H be the subgraph of G from which H is contracted. G_H has $O(\alpha_{i-1}k)$ vertices where $\alpha_{i-1} = \prod_{j<i} z_j$. Since ξ^* is a random closed surface in G_H, according to criterion (III), ξ^* cuts $O(c_4(\alpha_{i-1}k)^{1-1/d})$ geometrical objects associated with the vertices of G_H in expectation. Since $z_i = 7^{z_{i-1}^{1/5}}$, $\alpha_{i-1} = O(\beta_{i-1}^{\frac{1}{3d-2}}) = O(k^{\frac{1}{3d-2}})$. Thus ξ^* cuts order of

$$c_4(\alpha_{i-1}k)^{1-1/d} \leq c_4k^{(1+\frac{1}{3d-2})(1-1/d)} \tag{4}$$

$$= c_4k^{1-\frac{2d-1}{d(3d-2)}} \leq c_4k^{1-\frac{d}{d(3d-2)}} = c_4k^{1-\frac{1}{3d-2}} \tag{5}$$

geometrical objects associated with G_H. The number of vertices in group (iii) is thus $O(c_4k^{(1-\frac{1}{3d-2})})$. Therefore, the size of S is $O((c_1c_3^{1-1/d}+c_4)k^{(1-\frac{1}{3d-2})})$.

Next, we prove that S is a balanced separator. Let A be the set of vertices in G_i which belong to group (i) and are not added to S. Let B be the set of vertices in G_i which belong to group (ii) and are not added to S. We claim that the removal of S separates A and B. We prove the claim by contradiction.

Each edge in H corresponds to a unique edge in RH. Each vertex v in H corresponds to a set of vertices $\Gamma(v)$ in RH. Let a be a vertex in A and let b be a vertex in B. By the definition of A and B, a is in group (i) so all vertices in $\Gamma(a)$ are inside ξ^* and b is in group (ii) so all vertices in $\Gamma(b)$ are outside ξ^*. If there is an edge in H between a and b, then there is a unique edge (a_r, b_r) in RH such that $a_r \in \Gamma(a)$ and $b_r \in \Gamma(b)$. Since a_r is inside ξ^* and b_r is outside ξ^*, either the geometrical object associated with a_r or the geometrical object associated with b_r would be cut by ξ^*, which implies that either a or b were added to S. A contradiction.

Since ξ^* separates vertices of RH in a balanced way and $|S|$ is sublinear in k, $|A|$ and $|B|$ are proportional to each other. Therefore, S is a balanced separator.

According to criterion (I), running the separator algorithm on RH takes $O(c_2c_3k)$ time. This finishes the proof of the lemma. ◀

3.3 Recursive division

The recursive division of G is computed in two phases. In the contraction phase, the contraction parameters z_i are set as Equations (2) and (3), and the contracted graphs $G_1, \ldots, G_{I+1}$ are computed consecutively by the Contract() algorithm. In the division phase, we choose the parameters for dividing G_i, $1 \leq i \leq I+1$, to be $\beta_{i-1} = z_{i-1}^{3d-2}$. Since the minimum subgraph of G_i that will be divided has $\Omega(\beta_{i-1})$ vertices, we can apply Lemma 11 recursively to obtain the division D_i of G_i.

To analyze the computing time of the recursive division, we analyze the division D_i of G_i, and the division of G it induces. Recall that the division D_i is derived from the division D_{i+1} of G_{i+1}. Let R_{i+1} be a region in D_{i+1}. The Divide$(R_{i+1}, S_{i+1}, \beta_i)$ algorithm divides R_{i+1} into subregions each of which has at most $\beta_i = z_i^{3d-2}$ vertices and has $O((c_1 c_3^{1-1/d} + c_4) z_i^{3d-3})$ boundary vertices. Each expanded subregion, which is a region in D_i, has at most $\beta_i \cdot 3z_i = 3z_i^{3d-1}$ vertices and $O((c_1 c_3^{1-1/d} + c_4) z_i^{3d-2})$ boundary vertices. Let k_i denote the number of regions in the division D_i, $0 \le i \le I+1$, and let n_i be the number of vertices in G_i. We can prove, using similar arguments as in the proof of Lemma 4.1 in [12] that

▶ **Lemma 12.** *The number of regions in the division D_i is $O(n_i / z_i^{3d-1})$.*

From the proof of Lemma 12, we can also prove that the sum of the vertices of all regions in D_i is $O(n_i)$. Now we can analyze the computing time of the recursive division of G.

▶ **Lemma 13.** *Let G be an Euclidean graph in $\mathbb{R}^d$ that satisfies the criteria (I)-(IV) and has $O(c_0 n)$ edges. A recursive division of G can be computed in $O(c_0 c_2 c_3 dn)$ time.*

Proof. We calculate the costs in steps.

1. The number of edges in G_i, $i \ge 1$, is $O(c_3 n_i)$ by criterion (II). Thus, computing the contracted graphs $G_1, \ldots, G_{I+1}$ takes time $O(c_0 n + c_3 n_1 + \ldots + c_3 n_I)$, which is $O(c_0 c_3 n)$.
2. By Observation 10, computing the representative graphs $RG_1, \ldots, RG_{I+1}$ takes $O(c_0 n + c_3 n_1 + \ldots + c_3 n_I) = O(c_0 c_3 n)$ time.
3. For $i \le I$, divide a region R_{i+1} in the division D_{i+1} of G_{i+1} takes $O(c_2 c_3 |R_{i+1}| \log |R_{i+1}|)$ time, by recursively applying Lemma 11.
4. Each region R_{i+1} in D_{i+1} has $O(z_{i+1}^{3d-1})$ vertices. Summing over all regions in D_{i+1}, dividing D_{i+1} takes $O(c_2 c_3 d \sum_{R_{i+1}} |R_{i+1}| \log z_{i+1})$ time, which is $O(c_2 c_3 d n_{i+1} \log z_{i+1})$ by the fact that $\sum_{R_{i+1}} |R_{i+1}|$ is $O(n_{i+1})$.
5. The time to obtain the division D_i of G_i after dividing D_{i+1} is $O(c_3 n_i)$. Computing all the divisions D_i, $1 \le i \le I+1$, thus takes $O(c_2 c_3 d \sum_i n_i \log z_i)$ time. Since $n_i \le n_{i-1}/z_{i-1} \le c_0 n / z_{i-1}$ and $\log z_i$ is $O(z_{i-1}^{1/5})$, $O(c_2 c_3 d \sum_i n_i \log z_i)$ is $O(c_2 c_3 d c_0 n) = O(c_0 c_2 c_3 dn)$.

   Therefore, the total running time is $O(c_0 c_2 c_3 dn)$, which finishes the proof of the lemma. ◀

Finally, we prove that the recursive division satisfies Inequalities (1), which will imply that applying HKRS's edge-relaxation algorithm on it will take $O(c_0 n)$ time.

▶ **Lemma 14.** *The recursive division of G satisfies Inequalities* (1).

Proof. Since $n_j \le n_{j-1}/z_{j-1}$, we have $n_i \le c_0 n / \prod_{j<i} z_j$. Note also that each vertex in G_i expands to at most $\prod_{j<i} 3z_j$ vertices of G.

Consider the division D_i of G_i, and the division of G it induces. The division D_i consists of $O(n_i / z_i^{3d-1})$ regions (Lemma 12), each of which has $O(z_i^{3d-1})$ vertices and $O((c_1 c_3^{1-1/d} + c_4) z_i^{3d-2})$ boundary vertices. Thus it induces a division of G consisting of $O(n_i / z_i^{3d-1})$ regions, each of which has $O(z_i^{3d-1} \prod_{j<i} 3z_j)$ vertices and $O((c_1 c_3^{1-1/d} + c_4) z_i^{3d-2} \prod_{j<i} 3z_j)$ boundary vertices.

Let $r_i = z_i^{3d-1} \prod_{j<i} z_j$, and let

$$f(r_i) = c'(c_1 c_3^{1-1/d} + c_4) z_i^{3d-2} \prod_{j<i} z_j.$$

The induced division of G has $O(c_0 n / r_i)$ regions each having $O(r_i 3^i)$ vertices and $O(f(r_i))$ boundary vertices. Since $3^i \le \prod_{j \le i} z_j$, each region has $O(r_i^2)$ vertices.

We have

$$\frac{r_i}{f(r_i)} = \frac{z_i^{3d-1}}{c'(c_1 c_3^{1-1/d} + c_4) z_i^{3d-2}} = \frac{z_i}{c'(c_1 c_3^{1-1/d} + c_4)}.$$

By the setting of z_i, we have $z_{i-1} = \Theta(\log^5 z_i)$ and $\prod_{j<i} z_j = O(\log^6 z_i)$. Therefore

$$f(r_{i-1}) = c'(c_1 c_3^{1-1/d} + c_4) z_{i-1}^{3d-2} \prod_{j<i-1} z_j = O((c_1 c_3^{1-1/d} + c_4) \log^{5(3d-2)} z_i \log^6 \log z_i).$$

We have $\log r_{i+1} = O(\log z_{i+1}^{3d-1}) = O(d \cdot z_i^{1/5})$ and $\sum_{j=1}^{i+1} \log r_j = O(d \cdot z_i^{1/5})$. Since c_1, c_3, c_4, d are all constants, for a sufficiently large constant $\hat{c}$, Inequalities (1) hold for all r_i exceeding $\hat{c}$. ◀

We have obtained the main theorem of this section.

▶ **Theorem 15.** *Let G be an Euclidean graph in $\mathbb{R}^d$ (d is fixed) that satisfies criteria (I)-(IV) and has $O(c_0 n)$ edges. Then a $(\bar{r}, f)$-recursive division of G satisfying Inequalities* (1) *can be computed in $O(c_0 c_2 c_3 dn)$ time.*

As a corollary,

▶ **Corollary 16.** *Let G be an Euclidean graph in $\mathbb{R}^d$ (d is fixed) that satisfies criteria (I)-(IV) and has $O(c_0 n)$ edges. Single-source shortest path in G can be computed in $O(c_0 c_2 c_3 dn)$ time.*

Note that since edge-relaxation is comparison-based and does not make any assumptions about edge weights, the edge weights of the Euclidean graph can be any nonnegative value, not just the Euclidean distance between the endpoints.

4 SSSP for lanky-graphs

Lanky graphs were introduced by Le and Than [15] when studying sublinear separators of greedy spanners in Euclidean and doubling metrics.

▶ **Definition 17.** *A graph G embedded in an Euclidean or a doubling metric is τ-lanky, if for any $r > 0$ and any ball of radius r, there are at most τ edges of length at least r that are cut by the ball. An edge is cut by a ball if one endpoint of the edge is inside the ball and the other endpoint of the edge is outside the ball.*

A number of graphs are $O(1)$-lanky graphs, including greedy spanners in Euclidean and doubling metrics, low-density graphs in Euclidean [1] and doubling metrics, greedy spanners for point sets in $\mathbb{R}^d$ of low fractal dimension and greedy spanners for unit ball graphs in $\mathbb{R}^d$.

To unify the construction of sublinear separators for lanky graphs in both Euclidean and doubling metrics, Le and Than proposed the (η, d)-packable metric space. We say that a set of points P is r-separated if the distance between any two points in P is at least r.

▶ **Definition 18.** *A* metric (X, δ_X) *is (η, d)-packable if for any $r \in (0, 1]$ and any r-separated set $P \subseteq X$ contained in a unit ball, $|P| \leq \eta(\frac{1}{r})^d$. We call d the packing dimension of the* metric *and η the packing constant of the* metric.

The authors proved the following separator theorem for lanky graphs in an (η, d)-packable metric space.

▶ **Theorem 19** ([15]). *Let (X, δ_X) be an (η, d)-packable metric space and let $G = (V, E, w)$ be a τ-lanky graph in (X, δ_X). G has a $(1 - \frac{1}{\eta 2^{d+1}})$-balanced separator S such that S has size $O(\tau\eta 8^d n^{1-1/d})$. S can be computed in $O((\eta^3 8^d + \tau)n)$ expected time.*

The separator algorithm in the proof of Theorem 19 consists of two steps.

1. Compute a ball $\mathbf{b}(v, r)$ such that $\mathbf{b}(v, r)$ contains at least $\frac{n}{\eta 2^{d+1}}$ vertices of G and the concentric ball $\mathbf{b}(v, 2r)$ contains at most $\frac{n}{2}$ vertices of G, using the randomized algorithm in [11].
2. Choose $r^* = (1 + \sigma)r$ where $\sigma \in (0, 1]$ is chosen uniformly at random. Let $\mathbf{b}(v, r^*)$ be the random ball. Compute the set of edges E^* of G that are cut by $\mathbf{b}(v, r^*)$. Return the endpoints of the edges in E^* as the separator.

With constant probability, E^* has size $O(\tau\eta 8^d n^{1-1/d})$. This is proved by partitioning the edges in E^* into groups of exponentially increasing lengths and summing over the groups. From the proof of Theorem 19, it can be inferred that a random ball $\mathbf{b}(x, y)$ cuts $O(\tau\eta 8^d n^{1-1/d})$ edges of G in expectation.

Until now, we have verified that a τ-lanky graph in an (η, d)-packable metric space satisfies criteria (I) and (III) in Section 3 with $c_1 = \tau\eta 8^d$, $c_2 = \eta^3 8^d + \tau$ and $c_4 = \tau\eta 8^d$. The closed surface ξ used to find the separator is a ball. The geometrical objects cut by ξ are segments, which are edges in G.

From the definition of lanky graphs, it is easy to verify they are subgraph-closed. Thus criterion (IV) is satisfied. It remains to verify criterion (II).

4.1 Sparsity of the contracted graphs

We relate the sparsity of the combinatorially contracted graphs of a lanky graph to the graph-theoretic property *thickness*. The thickness of a graph G' is the minimum number of planar subgraphs that G' can be decomposed into. Let $\theta(G')$ denote the thickness of a graph G'. Determining the thickness of a general graph is NP-hard [17]. However, for graphs with maximum degree Δ, Halton [10] proved that if G' is a graph with maximum degree Δ then $\theta(G') \leq \lceil \Delta/2 \rceil$. It follows from the definition of lanky graph that a τ-lanky graph G has maximum degree τ. Therefore the thickness of G is at most $\lceil \tau/2 \rceil$.

Thus, the τ-lanky graph G can be decomposed into $\lceil \tau/2 \rceil$ planar subgraphs, which we call $H_1, \ldots, H_{\lceil \tau/2 \rceil}$. Let each of $H_1, \ldots, H_{\lceil \tau/2 \rceil}$ have $V(G)$ as its vertex set. Use the clustering inside the Contract(G, z_0) algorithm to cluster vertices in $V(G)$. For each H_j, $1 \leq j \leq \lceil \tau/2 \rceil$, shrink each cluster into a vertex while retaining edges between the clusters (shrunk vertices). Let Shrink(H_j, z_0) be the shrunk graph of H_j. Then Contract(G, z_0) is the union of Shrink(H_j, z_0), $1 \leq j \leq \lceil \tau/2 \rceil$ (removing multi-edges).

Since Shrink(H_j, z_0) is a planar graph, $G_1 = Contract(G, z_0)$ has $O(\tau n_1)$ edges where n_1 is the number of vertices in G_1. Similarly G_i, $i \geq 2$, is the union of the iteratively shrunk graphs of H_j, $1 \leq j \leq \lceil \tau/2 \rceil$, thus has $O(\tau n_i)$ edges where n_i is the number of vertices in G_i.

▶ **Lemma 20.** *The contracted graph G_i of G, $1 \leq i \leq I + 1$, has $O(\tau n_i)$ edges.*

Following similar ideas, we get:

▶ **Corollary 21.** *If H is a subgraph of G_i with $\bar{k}$ vertices then H has $O(\tau\bar{k})$ edges.*

This justifies that a τ-lanky graph satisfies criterion (II) with $c_3 = \tau$.

Since G has maximum degree τ, G has $O(\tau n)$ edges so $c_0 = \tau$. Plugging the constants into Theorem 15, we have

▶ **Theorem 22.** *Let G be a τ-lanky graph in an (η, d)-packable metric space. A $(\bar{r}, f)$-recursive division of G satisfying Inequalities* (1) *can be computed in $O((\tau^2\eta^3 8^d + \tau^3)dn)$ randomized time.*

As a corollary, we get

▶ **Corollary 23.** *Let G be a τ-lanky graph in an (η, d)-packable metric space. Single-source shortest path in G can be computed in $O((\tau^2\eta^3 8^d + \tau^3)dn)$ time.*

Assaf Naor
Department of Mathematics, Princeton University, NJ, USA

Abstract

If $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$ is a unitarily invariant normed space, i.e., $\|\mathsf{UAV}\|_{\mathbf{X}} = \|\mathsf{A}\|_{\mathbf{X}}$ for every matrix $\mathsf{A} \in \mathsf{M}_n(\mathbb{R})$ and every two orthogonal matrices $\mathsf{U}, \mathsf{V} \in \mathsf{M}_n(\mathbb{R})$, then we evaluate up to universal constant factors the smallest $\sigma > 0$ for which there is a probability distribution over partitions of $\mathbf{X}$ into clusters of diameter at most 1 yet for every two matrices $\mathsf{A}, \mathsf{B} \in \mathsf{M}_n(\mathbb{R})$ the probability that they fall into distinct clusters is at most σ times the $\mathbf{X}$-distance between A and B. Specifically, we prove that this infimal σ, which is called the separation modulus of $\mathbf{X}$ and is denoted $\mathsf{SEP}(\mathbf{X})$, satisfies:

$$\mathsf{SEP}(\mathbf{X}) = \Theta\big(\sqrt{n} \cdot \|\mathsf{I}_n\|_{\mathbf{X}} \cdot \mathrm{diam}(B_{\mathbf{X}})\big), \tag{1}$$

where I_n is the n-by-n identity matrix and $\mathrm{diam}(B_{\mathbf{X}})$ is the diameter with respect to the standard Euclidean metric on $\mathsf{M}_n(\mathbb{R})$ of the unit ball $B_{\mathbf{X}}$ of $\mathbf{X}$. Our proof of (1) proceeds through an asymptotic evaluation of the spectral gap of the Laplacian with Dirichlet boundary conditions on $B_{\mathbf{X}}$, which we achieve by exact computations for a Jacobi orthogonal random matrix ensemble. Assuming oracle access to norm evaluations in $\mathbf{X}$, by combining (1) with a new deterministic algorithm for a $O(1)$-approximation of the diameter of convex bodies in $\mathbb{R}^n$ that are given by a weak membership oracle and are symmetric with respect to coordinate permutations and reflections about the standard axes (this task is famously known to be impossible in the absence of such symmetries), we get an oracle polynomial time algorithm whose output is the separation modulus of $\mathbf{X}$ up to universal constant factors. Another example of a consequence of (1) is that for each $m \in \{1, \ldots, n\}$ the separation modulus of the m'th Ky Fan norm on $\mathsf{M}_n(\mathbb{R})$ is bounded from above and from below by universal constant multiples of $m\sqrt{n}$ if $m \geqslant \sqrt{n}$, and of n if $m \leqslant \sqrt{n}$. We also deduce from (1) an upper bound on the Lipschitz extension modulus of $\mathbf{X}$ that improves over the previously best-known bound even in the special case when $\mathbf{X}$ is $\mathsf{M}_n(\mathbb{R})$ equipped with the $\ell_2^n \to \ell_2^n$ operator norm.

1 Introduction

For $\sigma > 0$, a metric space $(\mathcal{M}, d_{\mathcal{M}})$ is said to admit a σ-separating random partition if for every $\Delta > 0$ there is a distribution over random partitions of $\mathcal{M}$ into clusters of diameter at most Δ with the property that for *every* two points $x, y \in \mathcal{M}$ the probability that x and y belong to distinct clusters is at most σ/Δ times the distance between x and y. The smallest σ for which this is possible is called the separation modulus of $\mathcal{M}$ and it is denoted $\mathsf{SEP}(\mathcal{M})$.

Separating random partitions are a well studied clustering primitive which was introduced and investigated in [10] (precursors that considered it implicitly, with a variety of applications, appear in [49, 7, 1, 40]); see e.g. [54, 55] for more on the history. By [10], every n-point metric space $(\mathcal{M}, d_{\mathcal{M}})$ satisfies $\mathsf{SEP}(\mathcal{M}) = O(\log n)$, and there are metric spaces for which this bound is sharp. In [45], a randomized polynomial time algorithm was designed that takes as input a finite metric space $(\mathcal{M}, d_{\mathcal{M}})$ and outputs a factor 2 approximation to $\mathsf{SEP}(\mathcal{M})$. See [11, 20, 41, 31, 46, 24, 47, 45, 8, 54, 55, 43, 56, 44, 57] for an indication of the literature on this topic. The investigation of separating random partitions of finite-dimensional normed spaces, which is what we study herein, originates in [58], motivated by applications to network routing and distributed computing. The work [20] sharpened and generalized the bounds of [58], and influenced later research, e.g. [47, 4, 55]; similar partitioning schemes appeared implicitly in the earlier work [37] on SDP-based algorithms for graph colorings. Applications of separating random partitions to pure mathematics have also been found, notably to metric embeddings [11, 24, 56] and extension of vector-valued Lipschitz functions [47, 55].

In Theorem 1 below we obtain an asymptotic formula (up to universal constant factors) for the separation modulus of $\mathsf{M}_n(\mathbb{R})$ equipped with an arbitrary unitarily invariant matrix norm;[1] we will spell out all of its (standard) notation and terminology right after stating it:

▶ **Theorem 1.** *Let* $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$ *be a unitarily invariant normed space. Then*[2]

$$\mathsf{SEP}(\mathbf{X}) \asymp \sqrt{n}\|\mathsf{I}_n\|_{\mathbf{X}} \operatorname{diam}(B_{\mathbf{X}}), \tag{2}$$

where $\operatorname{diam}(B_{\mathbf{X}}) = \operatorname{diam}_{\mathsf{S}_2^n}(B_{\mathbf{X}})$ *is the diameter with respect to the standard Euclidean metric on* $\mathsf{M}_n(\mathbb{R})$ *of the unit ball* $B_{\mathbf{X}}$ *of* $\mathbf{X}$*, and* $\mathsf{I}_n \in \mathsf{M}_n(\mathbb{R})$ *is the* n*-by-*n *identity matrix.*

A norm $\|\cdot\|$ on the space $\mathsf{M}_n(\mathbb{R})$ of n-by-n matrices with real entries is said to be unitarily invariant if $\|\mathsf{UAV}\| = \|\mathsf{A}\|$ for every $\mathsf{A} \in \mathsf{M}_n(\mathbb{R})$ and every two matrices U, V that belong to the orthogonal group O_n. Norms with this property [71, 64] form a rich class of ways to measure the size of matrices in an intrinsic manner that does not depend on the choice of orthogonal bases of $\mathbb{R}^n$ with respect to which the matrix representation of the corresponding linear operator is formed. As such, unitarily invariant norms are of great importance and utility to a wide range of disciplines, ranging from multiple areas of pure mathematics and theoretical physics, to algorithm design, signal processing, quantum information theory, numerical linear algebra, shape analysis and imaging, statistics, machine learning and data

[1] Formally, when dealing with infinite metric spaces (in particular, in the case of unitarily invariant matrix norms that we study herein), one must impose some measurability requirement for the definition of the separation modulus to make sense. At the very least, one has to demand that for every $x, y \in \mathcal{M}$ the aforementioned event "x and y belong to distinct clusters" is measurable with respect to the underlying probability measure on the space of partitions of $\mathcal{M}$. For the purpose of the present article, it suffices to assume this "minimal" measurability. However, it is beneficial for applications to impose stronger measurability assumptions; such a foundational treatment of random partitions of infinite spaces has been carried out in [47, 55]. One of the applications of Theorem 1 is to deduce an improved extension result for Lipschitz functions (Theorem 2 below), for which the aforementioned stronger measurability assumptions are needed. However, this will be achieved by substituting the ensuing reasoning into the framework of [55], which is shown in [55] to indeed yield the desired measurability. Thus, we do not need to recall stronger measurability requirements as they do not directly pertain to the ensuing discussion. Alternatively, our results are meaningful and new even if one only treats random partitions of finite subsets of $\mathsf{M}_n(\mathbb{R})$ equipped with a unitarily invariant matrix norm rather than random partitions of all of $\mathsf{M}_n(\mathbb{R})$, a setting to which measurability considerations are irrelevant.

[2] In addition to the usual $O(\cdot), o(\cdot), \Omega(\cdot), \Theta(\cdot)$ notation, we will use throughout this text the following conventions for asymptotic notation: Given $a, b > 0$, by writing $a \lesssim b$ or $b \gtrsim a$ we mean that $a \leqslant \kappa b$ for some universal constant $\kappa > 0$, and $a \asymp b$ stands for $(a \lesssim b) \wedge (b \lesssim a)$; when we will need to allow for dependence on parameters, we will indicate it by subscripts.

analysis; we point to this selection [73, 50, 75, 13, 67, 62, 32, 28, 22, 59, 70, 69, 72, 63, 68] of sources for part of the massive and varied literature on this (examining the references therein and those that arise from internet search leads to a cornucopia of additional relevant works).

Non-examples of unitarily invariant norms on matrices include those that consider a matrix $\mathsf{A} = (a_{ij}) \in \mathsf{M}_n(\mathbb{R})$ to merely be a collection of n^2 numbers, e.g., the $\ell_p^{n^2}$ norms

$$\|\mathsf{A}\|_{\ell_p^{n^2}} \stackrel{\text{def}}{=} \Big(\sum_{i=1}^n \sum_{j=1}^n |a_{ij}|^p\Big)^{\frac{1}{p}} \tag{3}$$

for $p \in [1,\infty] \setminus \{2\}$; such measurements of the size of a matrix are of course highly valuable even though they ignore the operator meaning of the arrangement of those numbers as an n-by-n array, and they are *not* what we study herein (for the aforementioned $\ell_p^{n^2}$ norm, the separation modulus has been evaluated up to universal constant factors in [20] when $1 \leqslant p \leqslant 2$ and in [55] when $p > 2$). Examples of unitarily invariant norms include the Schatten von-Neumann trace class S_p^n for every $1 \leqslant p \leqslant \infty$, which are given by setting

$$\forall \mathsf{A} \in \mathsf{M}_n(\mathbb{R}), \qquad \|A\|_{\mathsf{S}_p^n} \stackrel{\text{def}}{=} \Big(\operatorname{Trace}\big((\mathsf{A}\mathsf{A}^*)^{\frac{p}{2}}\big)\Big)^{\frac{1}{p}} = \Big(\sum_{i=1}^n s_i(\mathsf{A})^p\Big)^{\frac{1}{p}},$$

where $s_1(\mathsf{A}) \geqslant \ldots \geqslant s_n(\mathsf{A}) \geqslant 0$ are the singular values of A, i.e., they are the (decreasing rearrangement of the) eigenvalues of the positive semidefinite matrix $|\mathsf{A}| = (\mathsf{A}\mathsf{A}^*)^{1/2}$. If $p = \infty$, then S_∞^n coincides with the space of n-by-n matrices equipped with their operator (a.k.a. spectral) norm, when they are viewed as linear operators from ℓ_2^n to itself, i.e.,

$$\|\mathsf{A}\|_{\mathsf{S}_\infty^n} = \max_{x \in B_{\ell_2^n}} \|\mathsf{A}x\|_{\ell_2^n} = s_1(\mathsf{A}),$$

where $B_{\mathbf{X}} = \{x \in \mathbf{X} : \ \|x\|_{\mathbf{X}} \leqslant 1\}$ denotes the unit ball of a normed space $(\mathbf{X}, \|\cdot\|_{\mathbf{X}})$. Often S_1^n is called the nuclear norm on $\mathsf{M}_n(\mathbb{R})$, and S_2^n is the standard Euclidean (a.k.a. Hilbert–Schmidt or Frobenius) norm on $\mathsf{M}_n(\mathbb{R})$, i.e., it coincides with the case $p = 2$ of (3). Additional examples are furnished [25] by the Ky Fan norms $\|\cdot\|_{\mathsf{K}_1}, \ldots, \|\cdot\|_{\mathsf{K}_n}$ that are defined by:

$$\forall m \in [n] \stackrel{\text{def}}{=} \{1,\ldots,n\}, \ \forall \mathsf{A} \in \mathsf{M}_n(\mathbb{R}), \qquad \|A\|_{\mathsf{K}_m^n} \stackrel{\text{def}}{=} \sum_{i=1}^m s_i(\mathsf{A}). \tag{4}$$

More generally, let $\mathbf{E} = (\mathbb{R}^n, \|\cdot\|_{\mathbf{E}})$ be a symmetric normed space, i.e., the following requirement holds for every vector $x = (x_1,\ldots,x_n) \in \mathbb{R}^n$, every choice of permutation $\pi \in S_n$, and every choice of signs $\varepsilon_1,\ldots,\varepsilon_n \in \{-1,1\}$:

$$\|(\varepsilon_1 x_{\pi(1)},\ldots,\varepsilon_n x_{\pi(n)})\|_{\mathbf{E}} = \|x\|_{\mathbf{E}}. \tag{5}$$

The unitary ideal $\mathsf{S}_{\mathbf{E}}^n$ of $\mathbf{E}$ is defined to be $\mathsf{M}_n(\mathbb{R})$ equipped with the norm that is given by:

$$\forall \mathsf{A} \in \mathsf{M}_n(\mathbb{R}), \qquad \|\mathsf{A}\|_{\mathsf{S}_{\mathbf{E}}^n} = \big\|\big(s_1(\mathsf{A}),\ldots,s_n(\mathsf{A})\big)\big\|_{\mathbf{E}}. \tag{6}$$

A norm $\|\cdot\|$ on $\mathsf{M}_n(\mathbb{R})$ is unitarily invariant iff there is a symmetric norm $\|\cdot\|_{\mathbf{E}}$ on $\mathbb{R}^n$ such that $\|\cdot\| = \|\cdot\|_{\mathsf{S}_{\mathbf{E}}^n}$; see e.g. [53] or [12, Chapter IV] for a justification of this classical fact.

The novel content of Theorem 1 is the upper bound on $\mathsf{SEP}(\mathbf{X})$ in (2), i.e., Theorem 1 provides an improved randomized clustering of $\mathbf{X}$. The matching impossibility result is due to [55, Corollary 79], where it was proved that $\sqrt{n}\|\mathsf{I}_n\|_{\mathbf{X}} \operatorname{diam}(B_{\mathbf{X}}) \lesssim \mathsf{SEP}(\mathbf{X}) \lesssim$

$\sqrt{n\log n}\|\mathsf{I}_n\|_{\mathbf{X}}\operatorname{diam}(B_{\mathbf{X}})$ in the setting of Theorem 1. Therefore, what Theorem 1 achieves is removing the last redundant unbounded lower-order factor, thus obtaining an asymptotic evaluation of $\mathsf{SEP}(\mathbf{X})$ that is optimal up universal constant factors.

For the operator norm, the aforementioned bounds from [55] are $n \lesssim \mathsf{SEP}(\mathsf{S}_\infty^n) \lesssim n\sqrt{\log n}$, and these were the previously best-known estimates on $\mathsf{SEP}(\mathsf{S}_\infty^n)$. By Theorem 1, we now know that $\mathsf{SEP}(\mathsf{S}_\infty^n) \asymp n$.

As another example, it is straightforward to check from (4) that for each $m \in [n]$ the S_2^n-diameter of the unit ball of the m'th Ky Fan norm K_m^n equals $2\sqrt{n+m(m-1)}/m \asymp \max\{1, \sqrt{n}/m\}$, so Theorem 1 demonstrates that $\mathsf{SEP}(\mathsf{K}_m^n)$ is bounded from above and from below by positive universal constant multiples of $m\sqrt{n}$ if $m \geqslant \sqrt{n}$, and of n if $m \leqslant \sqrt{n}$, thus providing an interpolation between the operator norm $\mathsf{K}_1^n = \mathsf{S}_\infty^n$ and the nuclear norm $\mathsf{K}_n^n = \mathsf{S}_1^n$ that somewhat curiously stabilizes (up to universal constant factors) at $m \asymp \sqrt{n}$.

Theorem 1 implies progress on the important and extensively studied classical topic of extending vector-valued Lipschitz functions; see e.g. [19, 55] and the references therein. The Lipschitz extension modulus of a metric space $(\mathcal{M}, d_{\mathcal{M}})$, denoted $\mathsf{e}(\mathcal{M}, d_{\mathcal{M}})$ or simply $\mathsf{e}(\mathcal{M})$ when the underlying metric $d_{\mathcal{M}}$ is clear from the context, is the infimum over those $L \in [1,\infty]$ such that for every subset $\mathcal{C} \subseteq \mathcal{M}$, every Banach space $(\mathbf{Y}, \|\cdot\|_{\mathbf{Y}})$, and every 1-Lipschitz function $f : \mathcal{C} \to \mathbf{Y}$, there exists an L-Lipschitz function $F : \mathcal{M} \to \mathbf{Y}$ whose restriction to $\mathcal{C}$ coincides with f. By [47] we have $\mathsf{e}(\mathcal{M}) \lesssim \mathsf{SEP}(\mathcal{M})$, and the forthcoming work [15] demonstrates that $\mathsf{e}(\mathcal{M}) \gtrsim \sqrt{\mathsf{SEP}(\mathcal{M})}$, so $\mathsf{e}(\mathcal{M}) < \infty$ if and only if $\mathsf{SEP}(\mathcal{M}) < \infty$. A substitution of the former upper bound on $\mathsf{e}(\mathcal{M})$ provides the following extension theorem:

▶ **Theorem 2.** *If $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$ is a unitarily invariant normed space, then:*

$$\mathsf{e}(\mathbf{X}) \lesssim \sqrt{n}\|\mathsf{I}_n\|_{\mathbf{X}}\operatorname{diam}(B_{\mathbf{X}}).$$

The special case $\mathbf{X} = \mathsf{S}_\infty^n$ of Theorem 2 asserts that for every subset $\mathcal{C}$ of $\mathsf{M}_n(\mathbb{R})$ and every Banach space $(\mathbf{Y}, \|\cdot\|_{\mathbf{Y}})$, if $f : \mathcal{C} \to \mathbf{Y}$ is 1-Lipschitz with respect to the operator norm (and the given norm $\|\cdot\|_{\mathbf{Y}}$ on the target $\mathbf{Y}$), then it can be extended to a $\mathbf{Y}$-valued function that is defined on all of $\mathsf{M}_n(\mathbb{R})$ and is L-Lipschitz with respect to the operator norm, where $L \lesssim n$. The previously best-known [55] upper bound on L here was $L \lesssim n\sqrt{\log n}$, and the corresponding best impossibility result that is currently available [55] is that there exist suitably chosen $\mathcal{C}, \mathbf{Y}, f$ as above for which necessarily $L \gtrsim \sqrt{n}$. Thus, we now know that:

$$\sqrt[4]{\dim(\mathsf{S}_\infty^n)} = \sqrt{n} \lesssim \mathsf{e}(\mathsf{S}_\infty^n) \lesssim n = \sqrt{\dim(\mathsf{S}_\infty^n)}. \tag{7}$$

▶ **Problem 3.** It remains an interesting open question to determine the growth rate of $\mathsf{e}(\mathsf{S}_\infty^n)$ as $n \to \infty$. For that matter, there is no unitarily invariant normed space $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$ for which the value of $\mathsf{e}(\mathbf{X})$ is known up to $O(1)$ factors, or even up to lower-order factors. Since $\operatorname{diam}(B_{\mathbf{X}}) \geqslant 2\|\mathsf{I}_n\|_{\mathsf{S}_2^n}/\|\mathsf{I}_n\|_{\mathbf{X}} = 2\sqrt{n}\|\mathsf{I}_n\|_{\mathbf{X}}$, Theorem 2 does not provide an upper bound on $\mathsf{e}_n(\mathbf{X})$ that is $o(n)$. At the same time, the general lower bound on $\mathsf{e}(\mathbf{X})$ in [55, Theorem 96] is at most $\sqrt{n}$, since the Banach–Mazur distance between $\mathbf{X}$ and an n^2-dimesnional Hilbert space is at most $\sqrt{n}$, as seen by applying John's theorem [33] to the symmetric space $\mathbf{E} = (\mathbb{R}^n, \|\cdot\|_{\mathbf{E}})$ for which $\mathbf{X} = \mathsf{S}_{\mathbf{E}}^n$. Thus, the bounds in (7) are the best one could hope for using the current state of the art even when S_∞^n is replaced by any unitarily invariant norm on $\mathsf{M}_n(\mathbb{R})$. It seems that a substantial new idea will be needed in order to improve either the upper or lower estimate in (7).

As another application of Theorem 1, if we are given oracle access to (approximate) norm computations in a unitarily invariant normed space $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$, then we obtain a (deterministic) algorithm that evaluates its separation modulus $\mathsf{SEP}(\mathbf{X})$ up to universal constant factors in oracle polynomial time.[3]

Theorem 1 reduces the above task to devising an algorithm that outputs a $O(1)$-factor approximation to $\mathrm{diam}(B_{\mathbf{X}})$ in oracle polynomial time. Write $\mathbf{X} = \mathsf{S}_{\mathbf{E}}^n$ for a symmetric normed space $\mathbf{E} = (\mathbb{R}^n, \|\cdot\|_{\mathbf{E}})$. The S_2^n-diameter of $B_{\mathbf{X}}$ is equal to the diameter $\mathrm{diam}_{\ell_2^n}(B_{\mathbf{E}})$ of $B_{\mathbf{E}} \subseteq \mathbb{R}^n$ in ℓ_2^n. And, $\mathbf{X}$ has the desired oracle if and only if $\mathbf{E}$ does.[4] So, the goal is obtaining an oracle polynomial time $O(1)$-factor approximation algorithm to $\mathrm{diam}_{\ell_2^n}(B_{\mathbf{E}})$.

A reduction to efficient Euclidean diameter estimation should give one pause, as the latter task cannot be achieved for general convex bodies, i.e., there is no oracle polynomial time algorithm that outputs a $O(1)$-factor approximation to the ℓ_2^n-diameter of an arbitrary convex body K in $\mathbb{R}^n$ that is given by a weak membership oracle; for deterministic algorithms, this impossibility result was proved in [9], and randomized algorithms were ruled out in [17, 18]. Such hardness of approximation is also proved in [18] for the problem of computing the diameter $\mathrm{diam}_{\ell_p^n}(\cdot)$ in ℓ_p^n for every $1 \leqslant p < \infty$ (see Remark 10 below for a description of the known inapproximability factors). Nevertheless, in the presence of additional symmetries, we will prove the following theorem, which yields the aforementioned algorithm for approximating $\mathsf{SEP}(\mathbf{X})$ using Theorem 1:

▶ **Theorem 4.** *For every $n \in \mathbb{N}$, $D \geqslant 1$ and $0 < \delta \leqslant \frac{1}{2}$, there is $d = d(D, \delta) \in \mathbb{N}$ satisfying*

$$d \lesssim D + \frac{\log\left(\frac{1}{\delta}\right)}{\delta}, \tag{8}$$

such that for every $1 \leqslant p \leqslant \infty$ there exists a deterministic algorithm Alg_p that takes as input n, D, ε and a symmetric normed space $\mathbf{E} = (\mathbb{R}^n, \|\cdot\|_{\mathbf{E}})$ whose unit ball is given by a weak membership oracle and satisfies

$$\frac{1}{e^{n^D}} \leqslant \|e_1\|_{\mathbf{E}} = \ldots = \|e_n\|_{\mathbf{E}} \leqslant e^{n^D}. \tag{9}$$

The algorithm Alg_p outputs in oracle time n^d a number $\mathrm{Alg}_p(n, D, \delta, \mathbf{E})$ that satisfies

$$(1-\delta)\,\mathrm{diam}_{\ell_p^n}(B_{\mathbf{E}}) \leqslant \mathrm{Alg}_p(n, D, \delta, \mathbf{E}) \leqslant (1+\delta)\,\mathrm{diam}_{\ell_p^n}(B_{\mathbf{E}}). \tag{10}$$

1.1 Reverse Faber–Krahn

The new ingredient of our proof of Theorem 2 is an asymptotic evaluation of the spectral gap of the Laplacian with Dirichlet boundary conditions on the unit ball $B_{\mathbf{X}} \subseteq \mathsf{M}_n(\mathbb{R})$ of any unitarily invariant norm $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$. We will next describe this; all of the relevant (classical and rudimentary) background on the spectral properties of the Dirichlet Laplacian can be found in [60, 21].

[3] A weak membership oracle suffices here (one can obtain from such a membership oracle a norm evaluation oracle by binary search of possible upper bounds on the norm of the queried vector). See [30] for the relevant (standard) background in algorithmic convex geometry. In particular, "oracle polynomial time" means that the algorithm consists of a binary Turing machine that is augmented by the given oracle, and its running time is polynomial in the usual sense, with the understanding that the time required by each call to the oracle is only what is needed to write the question onto, and read the answer from, a tape of the Turing machine. Thus, here we demand that the algorithm outputs a number that is guaranteed to be bounded from above and from below by positive universal constant multiples of $\mathsf{SEP}(\mathbf{X})$, yet it performs only $n^{O(1)}$ norm evaluations.

[4] We will use here only the trivial direction of this equivalence, which is simply restricting the oracle for $\mathbf{X}$ to diagonal matrices. The reverse direction incurs the $n^{O(1)}$- time overhead of computing the singular values of the query matrix.

Fix $n \in \{2,3,\ldots\}$. For a bounded domain $\Omega \subseteq \mathbb{R}^n$, let $\lambda(\Omega)$ be the smallest $\lambda > 0$ such that there exists a function $f : \Omega \to \mathbb{R}$ that is smooth on the interior of Ω, vanishes on the boundary $\partial\Omega$ of Ω, and satisfies $\Delta f = -\lambda f$ on the interior of Ω, where $\Delta = \sum_{i=1}^n \partial^2/(\partial x_i^2)$ is the standard Laplacian on $\mathbb{R}^n$. Set $\lambda(\mathbf{Y}) = \lambda(B_{\mathbf{Y}})$ for each normed space $\mathbf{Y} = (\mathbb{R}^n, \|\cdot\|_{\mathbf{Y}})$. Here, we obtain the following result:

▶ **Theorem 5.** *Every unitarily invariant normed space* $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$ *satisfies:*

$$\lambda(\mathbf{X}) \asymp n^3 \|\mathsf{I}_n\|_{\mathbf{X}}^2. \tag{11}$$

In the setting of Theorem 5, the following asymptotic equivalence is a different way to express (11):

$$\lambda(B_{\mathbf{X}}) \mathrm{vol}_{\dim(\mathbf{X})}^{\frac{2}{\dim(\mathbf{X})}}(B_{\mathbf{X}}) \asymp \dim(\mathbf{X}), \tag{12}$$

where for $m \in \mathbb{N}$ and $0 \leqslant \alpha \leqslant m$ the α-dimensional Hausdorff measure on $\mathbb{R}^m$ is denoted $\mathrm{vol}_\alpha(\cdot)$; the only values of α that occur herein are $\alpha \in \{m, m-1\}$ (Lebesgue measure and surface area measure, respectively). To see that (12) and (11) coincide, note that $\dim(\mathbf{X}) = n^2$ and by [65, equation (2.2)] we have:

$$\mathrm{vol}_{n^2}(B_{\mathbf{X}})^{\frac{1}{n^2}} \asymp \frac{1}{\sqrt{n}\|\mathsf{I}_n\|_{\mathbf{X}}}. \tag{13}$$

The Faber–Krahn inequality [23, 42] (originally conjectured in [61]) states that the left hand side of (12) is minimized when $B_{\mathbf{X}}$ is replaced by the unit ball of the standard Euclidean metric (in our case S_2^n, though the analogous statement holds if $\mathsf{M}_n(\mathbb{R})$ is replaced by $\mathbb{R}^m$ of any dimension). By a direct computation (see e.g. [55, page 32]), this classical extremal statement implies that the left hand side of (12) is bounded from below by a positive universal constant multiple of $\dim(\mathbf{X})$.

The new content of (12) is thus the reverse inequality, i.e., the estimate $\lambda(\mathbf{X}) \lesssim n^3\|\mathsf{I}_n\|_{\mathbf{X}}^2$ in Theorem 5. This confirms for (unit balls of) unitarily invariant matrix norms the following much more general (and still open) reverse Faber–Krahn phenomenon that was conjectured in [55]:

▶ **Conjecture 6** (reverse Faber–Krahn)**.** *For every origin-symmertric convex body* $K \subseteq \mathbb{R}^m$ *(thus,* $x \in K$ *if and only if* $-x \in K$*) there exists a volume-preserving linear transformation* $S \in \mathsf{SL}_m(\mathbb{R})$ *with* $\lambda(SK)\mathrm{vol}_m(K)^{2/m} \asymp m$*.*

Theorem 5 demonstrates that Conjecture 6 holds for any unitarily invariant norm on $\mathsf{M}_n(\mathbb{R}) \cong \mathbb{R}^{n^2}$ with the matrix S being the (n^2-by-n^2) identity on $\mathsf{M}_n(\mathbb{R})$; this too was conjectured in [55] (see Conjecture 50 there, as well as [55, Problem 44] and [55, Remark 172]).

1.2 Weak isomorphic reverse isoperimetry

It was proved in [55] that Theorem 5 implies Theorem 1. The link between these two results is Theorem 7 below. For its formulation, recall that the isoperimetric quotient of a convex body $K \subseteq \mathbb{R}^m$ is defined to be $\mathrm{iq}(K) = \mathrm{vol}_{m-1}(\partial K)/\mathrm{vol}_m(K)^{1-1/m}$.

▶ **Theorem 7.** *For every* $n \in \mathbb{N}$*, if* $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$ *is a unitarily invariant normed space, then there exists an origin-symmetric convex body* $L \subseteq B_{\mathbf{X}}$ *such that:*

$$\mathrm{vol}_{n^2}(L)^{\frac{1}{n^2}} \gtrsim \mathrm{vol}_{n^2}(B_{\mathbf{X}})^{\frac{1}{n^2}} \qquad \text{yet} \qquad \mathrm{iq}(L) \lesssim n. \tag{14}$$

It was proved in [55, Section 1.6.2] that for each unitarily invariant normed space $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$, the validity of Theorem 5 for $\mathbf{X}$ is equivalent to the validity of Theorem 7 for $\mathbf{X}$; see specifically the explanation why [55, Conjecture 49] and [55, Conjecture 50] are equivalent that appears in [55, page 43], for which equation (1.62) of [55] is crucial input, as well as the convexity and uniqueness of the so-called Cheeger body (see page 31 of [55]), per [2]. Therefore, by proving Theorem 5 we will also establish Theorem 7, but we will next briefly explain the meaning of Theorem 7 and its utility for proving Theorem 1.

For $m \in \mathbb{N}$, the isoperimetric theorem implies that the isoperimetric quotient of a convex body $K \subseteq \mathbb{R}^m$ is at least the isoperimetric quotient of the ℓ_2^m-ball. Direct computation shows that the latter is bounded from above and from below by positive universal constant multiples of $\sqrt{m}$. Thus, Theorem 7 says that one can inscribe in $B_{\mathbf{X}}$ an origin-symemtric convex body L that is large in the sense that the first inequality in (14) holds, yet its isoperimetric quotient is as small as possible up to universal constant factors, i.e., $\mathrm{iq}(L)$ has the same order of magnitude as the isoperimetric quotient of the Hilbert–Schmidt unit ball in $\mathsf{M}_n(\mathbb{R})$. This confirms for (unit balls of) unitarily invariant matrix norms the following much more general (and still open) phenomenon that was conjectured in [55]:

▶ **Conjecture 8** (weak isomorphic reverse isoperimetry).[5] *For every origin-symmetric convex body $K \subseteq \mathbb{R}^m$ there exist $\mathsf{S} \in \mathsf{SL}_m(\mathbb{R})$ and an origin-symmetric convex body $L \subseteq \mathsf{S}K$ that satisfies:*

$$\mathrm{vol}_m(L)^{\frac{1}{m}} \gtrsim \mathrm{vol}_m(B_{\mathbf{X}})^{\frac{1}{m}} \qquad \text{yet} \qquad \mathrm{iq}(L) \lesssim \sqrt{m}.$$

Analogously to the discussion in Section 1.1, Theorem 7 demonstrates that Conjecture 8 holds for any unitarily invariant norm on $\mathsf{M}_n(\mathbb{R})$ with the matrix S being the identity on $\mathsf{M}_n(\mathbb{R})$; this too was conjectured in [55] (see specifically Conjecture 49 there).

By [55], the upper bound on $\mathsf{SEP}(\mathbf{X})$ of Theorem 1 (which, as we explained earlier, is the part of Theorem 1 that remained to be proved because the matching lower bound is due to [55]) follows from Theorem 7; specifically, combine [55, Corollary 79] with equation (2.2) of [65], which is reproduced as equation (6.131) in [55]. The resulting construction in [55] of the random partition of $\mathbf{X}$ can be illustrated informally as follows. Let $L \subseteq B_{\mathbf{X}}$ be the auxiliary convex body that Theorem 1 provides. Iteratively remove random translates[6] of L from $\mathsf{M}_n(\mathbb{R})$; this yields almost surely a random partition of $\mathsf{M}_n(\mathbb{R})$ into sets (translates of L minus the union of those translates from the preceding steps of this random iterative removal) that are of $\mathbf{X}$-diameter at most 1, as $L \subseteq B_{\mathbf{X}}$, and [55] demonstrates that the desired estimate on the separation probability holds thanks to the upper bound on the isoperimetric quotient of L in (14).

▶ Remark 9. While the above procedure yields a random partition of $\mathbf{X}$ whose separation modulus is optimal up to universal constant factors, it is not entirely constructive. From the algorithmic perspective it suffices to bound $\mathsf{SEP}(\mathbf{X})$ from above, per Theorem 4 and the discussion that precedes its statement, as by [45] there is a randomized polynomial time algorithm that takes as input any finite subset $\mathcal{C}$ of $\mathbf{X}$ and outputs a $2\mathsf{SEP}(\mathbf{X})$-separating partition of $\mathcal{C}$. One could hope to extract more algorithmic information by assuming that

[5] The adjective "weak" was used in [55] to describe this conjecture because in [55] a stronger phenomenon was also conjectured; we do not need to recall that stronger conjecture because the present work does not address it, and furthermore its weaker variant that we establish herein suffices for proving Theorem 1.

[6] One must define a suitable distribution of those random shifts here; for the purpose of the present sketch, one could aim instead to obtain a separated partition of an arbitrarily large bounded domain in $\mathsf{M}_n(\mathbb{R})$, in which case the shifts can be chosen Lebesgue-uniformly at random.

$B_{\mathbf{X}}$ has a weak membership oracle and aiming to obtain a convex body L as in Theorem 1 which also has a weak membership oracle that is allowed to make $n^{O(1)}$ calls to the oracle of $B_{\mathbf{X}}$ and $n^{O(1)}$ additional Turing machine operations. We do not currently have this because the body L of Theorem 1 is defined implicitly as the solution of a variational problem. We expect that the aforementioned task could be achieved by computing in oracle polynomial time a sufficiently good approximation to the first nontrivial eigenfunction $\varphi : B_{\mathbf{X}} \to \mathbb{R}$ of the Dirichlet Laplacian on $B_{\mathbf{X}}$, i.e., φ is smooth on the interior of $B_{\mathbf{X}}$, it vanishes on $\partial B_{\mathbf{X}}$, and $-\Delta\varphi = \lambda(\mathbf{X})\varphi$ point-wise. By [14] we know that φ is a log-concave function, whence its sub-level sets are convex. We could then repeat the above procedure with L replaced a suitable sub-level set of φ. We conjecture that this will yield an optimal separating partition of (a large bounded domain of) $\mathbf{X}$, and it remains open to implement the above strategy efficiently.

The above proposal is an (especially interesting) instance of a general program to estimate efficiently (in oracle polynomial time) solutions of geometrically meaningful partial differential equations; another important example is the first nontrivial eigenfunction of the Laplacian on a convex body with Neumann boundary conditions, which controls the Kannan–Lovász–Simonovits conjecture [36]; see [52, 48].

2 Proof of Theorem 5

Proof. Fix $n \in \mathbb{N}$. It was proved in [55, Remark 172] that if Theorem 7 holds for S_∞^n, then Theorem 7 holds for every unitarily invariant normed space $\mathbf{X} = (\mathsf{M}_n(\mathbb{R}), \|\cdot\|_{\mathbf{X}})$. By the equivalence of Theorem 5 and Theorem 7 that was proved in [55] and we discussed in Section 1.2, it therefore suffices to prove Theorem 5 when $\mathbf{X} = \mathsf{S}_\infty^n$, where we recall that S_∞^n is $\mathsf{M}_n(\mathbb{R})$ equipped with the $\ell_2^n \to \ell_2^n$ operator norm. So, our goal in the rest of this section will be to demonstrate that $\lambda(\mathsf{S}_\infty^n) \asymp n^3$. Only the upper bound

$$\lambda(\mathsf{S}_\infty^n) \lesssim n^3 \tag{15}$$

remains to be proved, thanks to the Faber–Krahn inequality, as we explained in Section 1.1.

For every $p, n \in \mathbb{N}$ define a function $f_n^p : B_{\mathsf{S}_\infty^n} \to [0,\infty)$ by setting:

$$\forall \mathsf{A} \in B_{\mathsf{S}_\infty^n}, \qquad f_n^p(\mathsf{A}) \stackrel{\mathrm{def}}{=} \det\left(\mathsf{I}_n - \mathsf{A}\mathsf{A}^*\right)^p = \prod_{k=1}^n \left(1 - s_k(\mathsf{A})^2\right)^p. \tag{16}$$

Then, f_n^p is smooth (in fact, it is a polynomial in the entries of A), and the second equality in (16) makes it evident that f_n^p vanishes on $\partial B_{\mathsf{S}_\infty^n} = \{\mathsf{A} \in \mathsf{M}_n(\mathbb{R}) : \ s_1(\mathsf{A}) = 1\}$. The standard (see e.g. [21]) Rayleigh quotient characterization of the smallest nonzero Dirichlet eigenvalue of $(-\Delta)$ therefore gives:

$$\lambda(\mathsf{S}_\infty^n) \leqslant \frac{\int_{B_{\mathsf{S}_\infty^n}} \|\nabla f_n^p(\mathsf{A})\|_{\mathsf{S}_2^n}^2 \,\mathrm{d}\mathsf{A}}{\int_{B_{\mathsf{S}_\infty^n}} f_n^p(\mathsf{A})^2 \,\mathrm{d}\mathsf{A}}. \tag{17}$$

Theorem 5 will thus be proven if we will evaluate exactly the right hand side of (17) as follows:

$$\frac{\int_{B_{\mathsf{S}_\infty^n}} \|\nabla f_n^p(\mathsf{A})\|_{\mathsf{S}_2^n}^2 \,\mathrm{d}\mathsf{A}}{\int_{B_{\mathsf{S}_\infty^n}} f_n^p(\mathsf{A})^2 \,\mathrm{d}\mathsf{A}} = \frac{pn^2(4p+n)^2}{2(2p-1)(4p+1)}. \tag{18}$$

Indeed, the right hand side of (18) is bounded from above and from below by positive universal constant multiples of $n^2 \max\{n^2/p, p\}$. Therefore, up to universal constant factors setting $p = n$ minimizes the right hand side of (18). For this choice of p, the Rayleigh quotient estimate (17) becomes $\lambda(\mathsf{S}^n_\infty) \lesssim n^3$, which is our current goal (15). Observe that the above reasoning shows that any choice of p other than $p \asymp n$ does not yield the desired estimate (15) . The rest of this section will be devoted to establishing (18).

Given $n \in \mathbb{N}$, we will denote by $V_n : \mathbb{R}^n \to [0,\infty)$ the following (Vendermunde determinant) function:

$$\forall x = (x_1,\ldots,x_n) \in \mathbb{R}^n, \qquad V_n(x) \stackrel{\mathrm{def}}{=} \prod_{i=1}^{n-1} \prod_{j=i+1}^{n} |x_i - x_j|. \tag{19}$$

Define a probability density $\mathfrak{J}^p_n : [0,1]^n \to [0,\infty)$ by setting:

$$\forall x = (x_1,\ldots,x_n) \in [0,1]^n, \qquad \mathfrak{J}^p_n(x) \stackrel{\mathrm{def}}{=} \frac{V_n(x)}{Z_n(p)} \prod_{r=1}^{n} \frac{x_r^{2p}}{\sqrt{1-x_r}}, \tag{20}$$

where $Z_n(p) > 0$ denotes the normalization factor such that $\int_{[0,1]^n} \mathfrak{J}^p_n(x)\,\mathrm{d}x = 1$, i.e.,

$$Z_n(p) \stackrel{\mathrm{def}}{=} \int_{[0,1]^n} V_n(x) \prod_{r=1}^{n} \frac{x_r^{2p}}{\sqrt{1-x_r}}\,\mathrm{d}x = \frac{n!}{\pi^{\frac{n}{2}}} \prod_{s=1}^{n} \frac{\Gamma\big(2m + \frac{1}{2}(s+1)\big)\Gamma\big(\frac{1}{2}s\big)^2}{\Gamma\big(2m + \frac{1}{2}(n+s+1)\big)}. \tag{21}$$

The second equality in (21) is a special case of the classical Selberg integral formula [66]. The parameter $Z_n(p)$ is commonly denoted in the literature (see e.g. [27]) as $S_n(\alpha,\beta,\gamma)$ for the setting of parameters $(\alpha,\beta,\gamma) = (2p+1, 1/2, 1/2)$; using the ad hoc shorter notation $Z_n(p)$ is beneficial here since we will not need to consider probability densities other than $\mathfrak{J}^p_n$. Also, we chose to use the letter $\mathfrak{J}$ for the probability density on $[0,1]^n$ in (20) to indicate that it belongs to the 3-parameter family of densities of Jacobi random n-by-n matrix ensembles; specifically, using the parametrization of [3, equation (4.1.5)], the relevant setting of parameters in the present case are $(\beta, r, s) = (1, 4p+1, 0)$.

There exists $c_n > 0$ such that for every Borel-measurable function $f : [0,\infty)^n \to [0,\infty)$ that is invariant under permutations of the coordinates, i.e., $f(s_{\pi(1)},\ldots,s_{\pi(n)}) = f(s)$ for every permutation $\pi \in S_n$ and every point $s = (s_1,\ldots,s_n) \in [0,\infty)^n$, the following identity holds:

$$\int_{\mathsf{M}_n(\mathbb{R})} f\big(s_1(\mathsf{A}),\ldots,s_n(\mathsf{A})\big)\,\mathrm{d}A = c_n \int_{[0,\infty)^n} f(s) \prod_{i=1}^{n-1} \prod_{j=s+1}^{n} \big|s_i^2 - s_j^2\big|\,\mathrm{d}s. \tag{22}$$

(22) is a special case of the Weyl integration formula [74]; see e.g. [3, Proposition 4.1.3]. The exact value of the parameter c_n will not have any role in the ensuing reasoning (it will cancel out in our computations), but it is worthwhile to note in passing that $c_n^{1/n^2} \asymp 1/\sqrt{n}$; see e.g. [26] for much more on such matters. Thanks to (22), the denominator in the left hand side of (18) can be evaluated as follows:

$$\int_{B_{\mathsf{S}^n_\infty}} f_n^p(\mathsf{A})^2\,\mathrm{d}\mathsf{A} \stackrel{(16)\wedge(22)}{=} c_n \int_{[0,1]^n} \prod_{r=1}^{n} \big(1-s_r^2\big)^{2p} \prod_{i=1}^{n-1} \prod_{j=s+1}^{n} \big|s_i^2 - s_j^2\big|\,\mathrm{d}x \stackrel{(21)}{=} \frac{c_n}{2^n} Z_n(p), \tag{23}$$

where for the last step of (23) we applied the change of variable $s = (\sqrt{1-x_1},\ldots,\sqrt{1-x_n})$, whose Jacobian is $(-1)^n/(2^n \prod_{r=1}^n \sqrt{1-x_r})$.

We need to understand the Hilbert–Schmidt norm of the gradient of $(\mathsf{A} \in B_{\mathsf{S}_\infty^n}) \mapsto f_n^p(\mathsf{A})$. For this, as a special case of [51, Theorem 7.1] we see that if we define $g_n^p : \mathbb{R}^n \to \mathbb{R}$ by

$$\forall x \in \mathbb{R}^n, \qquad g_n^p(x) \stackrel{\text{def}}{=} \prod_{i=1}^n \big(1 - x_i^2\big)^p, \tag{24}$$

then for any matrix A in the interior of $B_{\mathsf{S}_\infty^n}$ there are $\mathsf{U} = \mathsf{U}_{\mathsf{A},n,p}, \mathsf{V} = \mathsf{V}_{\mathsf{A},n,p} \in \mathsf{O}_n$ such that

$$\nabla f_n^p(\mathsf{A}) = \mathsf{U} \begin{pmatrix} \frac{\partial g_n^p}{\partial x_1}\big(s_1(\mathsf{A}), \dots, s_n(\mathsf{A})\big) & 0 & \dots & 0 \\ 0 & \frac{\partial g_n^p}{\partial x_2}\big(s_1(\mathsf{A}), \dots, s_n(\mathsf{A})\big) & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \dots & 0 & \frac{\partial g_n^p}{\partial x_n}\big(s_1(\mathsf{A}), \dots, s_n(\mathsf{A})\big) \end{pmatrix} \mathsf{V}.$$

By substituting the definition (24) of g_n^p, we thus have:

$$\nabla f_n^p(\mathsf{A}) = 2p \prod_{i=1}^n \big(1 - s_i(\mathsf{A})^2\big)^p \mathsf{U} \begin{pmatrix} \frac{s_1(\mathsf{A})}{1-s_1(\mathsf{A})^2} & 0 & \dots & 0 \\ 0 & \frac{s_2(\mathsf{A})}{1-s_2(\mathsf{A})^2} & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \dots & 0 & \frac{s_n(\mathsf{A})}{1-s_n(\mathsf{A})^2} \end{pmatrix} \mathsf{V}.$$

Since U and V are orthogonal matrices, we therefore have:

$$\|\nabla f_n^p(\mathsf{A})\|_{\mathsf{S}_2^n}^2 = 4p^2 \prod_{r=1}^n \big(1 - s_r(\mathsf{A})^2\big)^{2p} \sum_{k=1}^n \frac{s_k(\mathsf{A})^2}{\big(1 - s_k(\mathsf{A})^2\big)^2}. \tag{25}$$

Consequently, the numerator in the left hand side of (18) can be evaluated as follows:

$$\begin{aligned} &\int_{B_{\mathsf{S}_\infty^n}} \|\nabla f_n^p(\mathsf{A})\|_{\mathsf{S}_2^n}^2 \,\mathrm{d}\mathsf{A} \\ &\quad \stackrel{(22)\wedge(25)}{=} 4p^2 c_n \int_{[0,1]^n} \left(\sum_{k=1}^n \frac{s_k^2}{\big(1 - s_k^2\big)^2} \right) \prod_{r=1}^n \big(1 - s_r^2\big)^{2p} \prod_{i=1}^{n-1} \prod_{j=s+1}^n \big|s_i^2 - s_j^2\big| \,\mathrm{d}x \\ &\quad \stackrel{(20)}{=} \frac{c_n Z_n(p)}{2^n} 4p^2 \int_{[0,1]^n} \sum_{k=1}^n \frac{1 - x_k}{x_k^2} \mathfrak{J}_n^p(x) \,\mathrm{d}x \\ &\quad = \frac{c_n Z_n(p)}{2^n} 4p^2 n \bigg(\int_{[0,1]^n} \frac{\mathfrak{J}_n^p(x)}{x_n^2} \,\mathrm{d}x - \int_{[0,1]^n} \frac{\mathfrak{J}_n^p(x)}{x_n} \,\mathrm{d}x \bigg), \end{aligned} \tag{26}$$

where the second step of (26) makes the same change of variable $s = (\sqrt{1 - x_1}, \dots, \sqrt{1 - x_n})$ as above. By combining (23) and (26) we obtain the following expression for the Rayleigh quotient in (18):

$$\begin{aligned} \frac{\int_{B_{\mathsf{S}_\infty^n}} \|\nabla f_n^p(\mathsf{A})\|_{\mathsf{S}_2^n}^2 \,\mathrm{d}\mathsf{A}}{\int_{B_{\mathsf{S}_\infty^n}} |f_n^p(\mathsf{A})|^2 \,\mathrm{d}\mathsf{A}} &= 4p^2 \int_{[0,1]^n} \Big(\sum_{s=1}^n \frac{1 - x_s}{x_s^2} \Big) \mathfrak{J}_n^p(x) \,\mathrm{d}x \\ &= 4p^2 n \bigg(\int_{[0,1]^n} \frac{\mathfrak{J}_n^p(x)}{x_n^2} \,\mathrm{d}x - \int_{[0,1]^n} \frac{\mathfrak{J}_n^p(x)}{x_n} \,\mathrm{d}x \bigg). \end{aligned} \tag{27}$$

To evaluate the right hand side of (27), consider the following symmetric polynomial $P \in \mathbb{Q}[x_1, \ldots x_n]$:

$$P(x) \stackrel{\text{def}}{=} \sum_{s=1}^{n} \prod_{t \in [n] \setminus \{s\}} x_t^2 + \frac{2}{3} \sum_{s=1}^{n-1} \sum_{t=s+1}^{n} x_s x_t \prod_{k \in [n] \setminus \{s,t\}} x_k^2, \tag{28}$$

where in (28), and throughout, we use the common notation $[n] \stackrel{\text{def}}{=} \{1, \ldots, n\}$. Thus,

$$\begin{aligned} &\frac{1}{Z_n(p)} \int_{[0,1]^n} P(x) V_n(x) \prod_{s=1}^{n} \frac{x_s^{2p-2}}{\sqrt{1-x_s}} \, \mathrm{d}x \\ &\qquad \stackrel{(20)}{=} n \int_{[0,1]^n} \frac{\mathfrak{J}_n^p(x)}{x_n^2} \, \mathrm{d}x + \frac{n(n-1)}{3} \int_{[0,1]^n} \frac{\mathfrak{J}_n^p(x)}{x_{n-1} x_n} \, \mathrm{d}x. \end{aligned} \tag{29}$$

The final integral that appears in (29) can be evaluated as follows:

$$\begin{aligned} &\int_{[0,1]^n} \frac{\mathfrak{J}_n^p(x)}{x_{n-1} x_n} \, \mathrm{d}x \\ &\qquad \stackrel{(20)}{=} \frac{1}{Z_n(p)} \int_{[0,1]^n} V_n(x) \Bigg(\prod_{t=1}^{n-2} x_t \Bigg) \prod_{s=1}^{n} \frac{x_s^{2p-1}}{\sqrt{1-x_s}} \, \mathrm{d}x = \frac{(4p+n)(4p+n+1)}{4p(4p+1)}, \end{aligned} \tag{30}$$

where the second equality that appears in (30) is an instantiation of the Aomoto integral formula [6] (see also e.g. [5, Theorem 8.1.2]). To evaluate the integral that appears in the left hand side of (29), observe that the polynomial P that is defined in (28) coincides with the Jack polynomial that is denoted in [27] by $P_\lambda^{(1/\gamma)}$, where $\gamma = 1/2$ and λ is the vector in $\mathbb{Z}^n$ whose first $n-1$ coordinates equal 2 and the whose last coordinate equals 0; this is seen by substituting the aforementioned parameters γ, λ into equations (3.2) and (3.10) of [27]. The Kadell integral formula [35], which appears in [27] as equation (3.13) thus gives:

$$\frac{1}{Z_n(p)} \int_{[0,1]^n} P(x) V_n(x) \prod_{s=1}^{n} \frac{x_s^{2p-2}}{\sqrt{1-x_s}} \, \mathrm{d}x = \frac{n(n+2)(4p+n)(4p+n-2)}{24p(2p-1)}. \tag{31}$$

The first integral that appears in the right hand side of (27) is therefore evaluated as follows:

$$\begin{aligned} &\int_{[0,1]^n} \frac{\mathfrak{J}_n^p(x)}{x_n^2} \, \mathrm{d}x \\ &\qquad \stackrel{(29) \wedge (30) \wedge (31)}{=} \frac{(n+2)(4p+n)(4p+n-2)}{24p(2p-1)} - \frac{(n-1)(4p+n)(4p+n+1)}{12p(4p+1)}. \end{aligned} \tag{32}$$

Now, the second integral that appears in the right hand side of (27) can be evaluated as follows:

$$\int_{[0,1]^n} \frac{\mathfrak{J}_n^p(x)}{x_n} \, \mathrm{d}x \stackrel{(20)}{=} \frac{1}{Z_n(p)} \int_{[0,1]^n} V_n(x) \Bigg(\prod_{t=1}^{n-1} x_t \Bigg) \prod_{s=1}^{n} \frac{x_s^{2p-1}}{\sqrt{1-x_s}} \, \mathrm{d}x = \frac{4p+n}{4p}, \tag{33}$$

where the second step of (33) is another instantiation of the Aomoto integral formula. The desired identity (18) follows by substituting (32) and (33) into (27), and then simplifying the resulting expression. ◀

3 Proof of Theorem 4

Proof. Observe that every $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$ satisfies the following estimate:

$$\|x\|_{\mathbf{E}} \overset{(5)}{=} \max_{s\in[n]} \frac{\|x\|_{\mathbf{E}} + \|(-x_1, \ldots, -x_{s-1}, x_s, -x_{s+1}, \ldots, -x_n)\|_{\mathbf{E}}}{2}$$
$$\geqslant \max_{s\in[n]} |x_s| \cdot \|e_s\|_{\mathbf{E}} \overset{(9)}{\geqslant} \frac{\|x\|_{\ell_2^n}}{\sqrt{n}e^{n^D}}, \tag{34}$$

where the penultimate step of (34) is an application of the covexity of $\|\cdot\|_{\mathbf{E}}$. Furthermore:

$$\|x\|_{\mathbf{E}} \leqslant \sum_{s=1}^n |x_s| \cdot \|e_s\|_{\mathbf{E}} \overset{(9)}{\leqslant} e^{n^D} \sum_{s=1}^n |x_s| \leqslant \sqrt{n}e^{n^D} \|x\|_{\ell_2^n}, \tag{35}$$

where the first step of (35) is an application of the triangle inequality for $\|\cdot\|_{\mathbf{E}}$ and last step of (35) is an application of Cauchy–Schwarz. Therefore:

$$\frac{1}{\sqrt{n}e^{n^D}} B_{\ell_2^n} \overset{(35)}{\subseteq} B_{\mathbf{E}} \overset{(34)}{\subseteq} \sqrt{n}e^{n^D} B_{\ell_2^n}. \tag{36}$$

Using the terminology of [30], the inclusions (36) mean that $B_{\mathbf{E}}$ is well–bounded and centered. Since in Theorem 4 we are assuming that $B_{\mathbf{E}}$ is given by a weak membership oracle, the Judin–Nemirovskiĭ theorem [34] (see [30, Section 4.3]), which is a striking application of the Shallow-Cut Ellipsoid Method [34] (see [30, Section 3.3]), implies it is possible to optimize linear functionals efficiently on $B_{\mathbf{E}}$. In particular, since the dual norm $\|\cdot\|_{\mathbf{E}^*}$ is given by $\|x\|_{\mathbf{E}^*} = \max_{y\in B_{\mathbf{E}}} \langle x, y\rangle$ for every $x \in \mathbb{R}^n$, where $\langle\cdot,\cdot\rangle : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$ denotes the standard scalar product on $\mathbb{R}^n$, it follows that there is an algorithm $\mathrm{Eval}_{\mathbf{E}^*}$ which takes as input $x \in \mathbb{R}^n$ and outputs in oracle time that is polynomial in both $\log(1/\delta)$ and n^D a number $\mathrm{Eval}_{\mathbf{E}^*}(x) \in [0, \infty)$ that is guaranteed to satisfy the following estimates:

$$\Big(1 - \frac{\delta}{2}\Big)\|x\|_{\mathbf{E}^*} \leqslant \mathrm{Eval}_{\mathbf{E}^*}(x) \leqslant \Big(1 + \frac{\delta}{2}\Big)\|x\|_{\mathbf{E}^*}. \tag{37}$$

Define $q = p/(p-1)$ if $p > 1$, and $q = \infty$ if $p = 1$. By [29, Lemma 2], if we denote

$$K_q^n \overset{\mathrm{def}}{=} \big\{a = (a_1, \ldots, a_n) \in \mathbb{R}^n : \ \|a\|_{\ell_q^n} \leqslant 1 \text{ and } a_1 \geqslant a_2 \geqslant \cdots \geqslant a_n \geqslant 0\big\}, \tag{38}$$

then for every $0 < \delta < 1$ there exists a subset $\mathcal{G}(n, q, \delta)$ of K_q^n such that:

$$\forall x \in K_q^n, \quad d_{\ell_q^n}\big(x, \mathcal{G}(n, q, \delta)\big) = \min_{a\in\mathcal{G}(n,q,\delta)} \|x - a\|_{\ell_q^n} \leqslant \frac{\delta}{2}, \tag{39}$$

i.e., $\mathcal{G}(n, q, \delta)$ is $(\delta/2)$-dense in K_q^n with respect to the ℓ_q^n norm, yet its size satisfies:

$$|\mathcal{G}(n, q, \delta)| \leqslant n^{\frac{2\log\left(\frac{30}{\delta}\right)}{\log\left(1+\frac{\delta}{6}\right)}}. \tag{40}$$

So, by (40) for fixed δ the size of $\mathcal{G}(n, q, \delta)$ grows like a fixed power of n, in marked contrast to the fact (which is a straightforward consequence of volume comparison) that every $(\delta/2)$-dense subset of a unit ball of an n-dimensional normed space must have size at least $(2/\delta)^n$.

The algorithm Alg_p of Theorem 4 evaluates $\mathrm{Eval}_{\mathbf{E}^*}(a)$ for each $a \in \mathcal{G}(n, q, \delta)$ and outputs the number:

$$\mathrm{Alg}_p(n, D, \delta, \mathbf{E}) \overset{\mathrm{def}}{=} 2 \max_{a\in\mathcal{G}(n,q,\delta)} \mathrm{Eval}_{\mathbf{E}^*}(a). \tag{41}$$

The oracle running time of this simple procedure is a polynomial in both $\log(1/\delta)$ and n^D times the size of $\mathcal{G}(n,q,\delta)$, so by (40) it is at most n^d where the degree d satisfies the desired bound (8). Furthermore:

$$\operatorname{diam}_{\ell_p^n}(B_{\mathbf{E}}) = 2\sup_{x\in B_{\mathbf{E}}}\|x\|_{\ell_p^n} = 2\sup_{x\in B_{\mathbf{E}}}\sup_{y\in B_{\ell_q^n}}\langle x,y\rangle = 2\sup_{y\in B_{\ell_q^n}}\sup_{x\in B_{\mathbf{E}}}\langle x,y\rangle = 2\sup_{y\in B_{\ell_q^n}}\|x\|_{\mathbf{E}^*}. \quad (42)$$

Since $\mathcal{G}(n,q,\delta)$ is a subset of $B_{\ell_q^n}$, this implies in particular that the following a priori upper bound on the output of Alg_p holds, which gives the second inequality in the desired conclusion (10) of Theorem 4:

$$\begin{aligned}\mathrm{Alg}_p(n,D,\delta,\mathbf{E}) &\overset{(37)\wedge(41)}{\leqslant} 2\max_{a\in\mathcal{G}(n,q,\delta)}\Big(1+\frac{\delta}{2}\Big)\|a\|_{\mathbf{E}^*}\\ &\leqslant 2\Big(1+\frac{\delta}{2}\Big)\sup_{y\in B_{\ell_q^n}}\|x\|_{\mathbf{E}^*} \overset{(42)}{\leqslant} \Big(1+\frac{\delta}{2}\Big)\operatorname{diam}_{\ell_p^n}(B_{\mathbf{E}}).\end{aligned}$$

Define $\mathcal{D}(n,q,\delta)\subseteq B_{\ell_q^n}$ by:

$$\mathcal{D}(n,q,\delta) \overset{\text{def}}{=} \Big\{\big(\varepsilon_1 a_{\pi(1)},\varepsilon_2 a_{\pi(2)},\ldots,\varepsilon_n a_{\pi(n)}\big) : (\pi,(\varepsilon_1,\ldots,\varepsilon_n),a)\in S_n\times\{-1,1\}^n\times\mathcal{G}(n,q,\delta)\Big\}. \quad (43)$$

Then, $\mathcal{D}(n,q,\delta)$ is $(\delta/2)$-dense in $B_{\ell_q^n}$. Indeed, for each $x=(x_1,\ldots,x_n)\in B_{\ell_q^n}$ fix a permutation $\pi=\pi^x\in S_n$ such that $|x_{\pi(1)}|\geqslant|x_{\pi(2)}|\geqslant\ldots\geqslant|x_{\pi(n)}|$. Denoting $\varepsilon_i=\varepsilon_i^x=\operatorname{sign}(x_i)\in\{-1,1\}$ for each $i\in[n]$, the vector $y=(\varepsilon_{\pi(1)}x_{\pi(1)},\ldots,\varepsilon_{\pi(n)}x_{\pi(n)})=(|x_{\pi(1)}|,\ldots,|x_{\pi(n)}|)$ belongs K_q^n, by (39). Now, use (39) to get a point $a\in\mathcal{G}(n,q,\delta)$ with $\|y-a\|_{\ell_q^n}\leqslant\delta/2$, so that the point $b=(\varepsilon_1 a_{\pi^{-1}(1)},\ldots,\varepsilon_n a_{\pi^{-1}(n)})$ belongs to $\mathcal{D}(n,q,\delta)$ by (43), and satisfies $\|x-b\|_{\ell_q^n}=\|y-a\|_{\ell_q^n}\leqslant\delta/2$.

Observe that the convex hull $\operatorname{conv}(\mathcal{D}(n,q,\delta))$ of $\mathcal{D}(n,q,\delta)$ satisfies the following inclusion:

$$\operatorname{conv}\left(\mathcal{D}(n,q,\delta)\right)\supseteq\Big(1-\frac{\delta}{2}\Big)B_{\ell_q^n}. \quad (44)$$

In fact, more generally, for any normed space $\mathbf{X}=(\mathbb{R}^n,\|\cdot\|_{\mathbf{X}})$, if $\mathcal{C}\subseteq B_{\mathbf{X}}$ is $(\delta/2)$-dense in $B_{\mathbf{X}}$ with respect to the metric induced by $\|\cdot\|_{\mathbf{X}}$, then $\operatorname{conv}(\mathcal{C})\supseteq(1-\delta/2)B_{\mathbf{X}}$. Indeed, suppose contrapositively that there exists $x\in(1-\delta/2)B_{\mathbf{X}}\setminus\operatorname{conv}(\mathcal{C})$. Then, by the separation theorem we can fix $y^*\in\mathbb{R}^n$ with $\|y^*\|_{\mathbf{X}^*}=1$ such that $\langle y^*,x\rangle>\langle y^*,c\rangle$ for every $c\in\mathcal{C}$. By the Hahn–Banach theorem, we can fix $y\in B_{\mathbf{X}}$ such that $\langle y^*,y\rangle=1$. Finally, because $\mathcal{C}$ is $(\delta/2)$-dense in $B_{\mathbf{X}}$, we can fix $c_y\in\mathcal{C}$ such that $\|y-c_y\|_{\mathbf{X}}\leqslant\delta/2$. We now arrive at the desired contradiction as follows:

$$1-\frac{\delta}{2}\geqslant\|x\|_{\mathbf{X}}\geqslant\langle y^*,x\rangle>\langle y^*,c_y\rangle=\langle y^*y\rangle-\langle y^*,c_y-y\rangle\geqslant 1-\|c_y-y\|_{\mathbf{X}}\geqslant 1-\frac{\delta}{2}, \quad (45)$$

where the second and the penultimate steps of (45) use the fact that y^* has norm 1 as a linear functional in $\mathbf{X}^*$, the first step of (45) uses the assumption $x\in(1-\delta/2)B_{\mathbf{X}}$, the third step of (45) uses the assumed property of the separating functional y^* for $c=c_y\in\mathcal{C}$, and the final step of (45) uses the choice of c_y.

We can now justify the first inequality of the desired conclusion (10) of Theorem 4 as follows:

$$\begin{aligned}
\mathrm{Alg}_p(n, D, \delta, \mathbf{E}) &\overset{(37)\wedge(41)}{\geqslant} 2 \max_{a \in \mathcal{G}(n,q,\delta)} \Big(1 - \frac{\delta}{2}\Big) \|a\|_{\mathbf{E}^*} \\
&\overset{(43)}{=} 2 \max_{a \in \mathcal{D}(n,q,\delta)} \Big(1 - \frac{\delta}{2}\Big) \|a\|_{\mathbf{E}^*} \qquad (46) \\
&= 2\Big(1 - \frac{\delta}{2}\Big) \max_{x \in \mathrm{conv}\left(\mathcal{D}(n,q,\delta)\right)} \|x\|_{\mathbf{E}^*} \qquad (47) \\
&\overset{(44)}{\geqslant} 2\Big(1 - \frac{\delta}{2}\Big) \max_{x \in \left(1-\frac{\delta}{2}\right) B_{\ell_q^n}} \|x\|_{\mathbf{E}^*} \\
&= 2\Big(1 - \frac{\delta}{2}\Big)^2 \max_{x \in B_{\ell_q^n}} \|x\|_{\mathbf{E}^*} \\
&\overset{(42)}{=} \Big(1 - \frac{\delta}{2}\Big)^2 \mathrm{diam}_{\ell_p^n}(B_{\mathbf{E}}) \\
&> (1 - \delta)\, \mathrm{diam}_{\ell_p^n}(B_{\mathbf{E}}),
\end{aligned}$$

where (46) is the step in which the assumption that $\|\cdot\|_{\mathbf{E}}$ is a symmetric norm is used, as this implies (by definition) that its dual $\|\cdot\|_{\mathbf{E}^*}$ is also a symmetric norm, and (47) holds since $\|\cdot\|_{\mathbf{E}^*}$ is a convex function. ◀

▶ Remark 10. In the Introduction we stated the contrast between Theorem 4 and the known nonexistence of any oracle polynomial time algorithm that computes a $O(1)$-factor approximation to the ℓ_p^n-diameter of an arbitrary (so, not necessarily symmetric, as in Theorem 4) convex body in $\mathbb{R}^n$ that is given by a weak membership oracle, where $1 \leqslant p < \infty$ is fixed. This contrast is even more severe because the known impossibility results rule out approximation factors that tend to ∞ with n, as we will next recall.

For $n \in \mathbb{N}$, $h \geqslant 3$ and $1 \leqslant p < \infty$, let $D_p^h(n)$ be the smallest $\alpha \geqslant 1$ for which there is a deterministic algorithm that takes as input a convex body $K \subseteq \mathbb{R}^n$ given by a weak membership oracle, and outputs in oracle time at most n^h a number $\Delta_p(K)$ satisfying $\mathrm{diam}_{\ell_p^n}(K) \leqslant \Delta_p(K) \leqslant \alpha\, \mathrm{diam}_{\ell_p^n}(K)$. Similarly, let $R_p^h(n)$ denote the smallest $\alpha \geqslant 1$ for which there is a randomised algorithm that outputs in oracle time at most n^h a number $\Delta_p(K)$ satisfying $\mathrm{diam}_{\ell_p^n}(K) \leqslant \Delta_p(K) \leqslant \alpha\, \mathrm{diam}_{\ell_p^n}(K)$ with probability at least, say, $1/3$.

Using the above notations, for $2 \leqslant p < \infty$ we have $D_p^h(n) \asymp_h R_p^h(n) \asymp_h (n/\log n)^{1/p}$; when $p = 2$ these bounds on $D_2^h(n)$ are due to [9], and these bounds for both $D_p^h(n)$ and $R_p^h(n)$, and arbitrary $2 < p < \infty$, are due to [17, 18]. If $1 \leqslant p < 2$, then $R_p^h(n) \asymp_h \sqrt{n/\log n}$ by [38, 39], improving by unbounded polylog factor over the corresponding bounds of [17, 18]. For deterministic algorithms, when $1 \leqslant p < 2$ we have $D_p^h(n) \lesssim_h \sqrt{n}/(\log n)^{1-1/p}$ by [17, 18], and the best-known lower bound is $D_p^h(n) \gtrsim_h \sqrt{n/\log n}$, which follows from the trivial lower bound $D_p^h(n) \geqslant R_p^h(n)$ and the aforementioned asymptotic evaluation of $R_p^h(n)$. Thus, for fixed $1 \leqslant p < 2$ there remains a gap of $(\log n)^{1/p-1/2}$, which tends to ∞ with n, between the best-known upper and lower bounds on the deterministic approximation ratio $D_p^h(n)$. While it seems reasonable to expect that this gap (noted in [17, 18, 16]) could be closed using available methods, to the best of our knowledge this has not yet been carried out, even though it would be worthwhile to do so.

Abstract

We present an exact and efficient algorithm for computing the Reeb space of a bivariate PL map. The Reeb space is a topological structure that generalizes the Reeb graph to the setting of multiple scalar-valued functions defined over a shared domain, a situation that frequently arises in practical applications. While the Reeb graph has become a standard tool in computer graphics, shape analysis, and scientific visualization, the Reeb space is still in the early stages of adoption. Although several algorithms for computing the Reeb space have been proposed, none offer an implementation that is both exact and efficient, which has substantially limited its practical use. To address this gap, we introduce *singular arrange and traverse*, a new algorithm built upon the *arrange and traverse* framework [26]. Our method exploits the fact that, in the bivariate case, only singular edges contribute to the structure of Reeb space, allowing us to ignore many regular edges [40]. This observation results in substantial efficiency gains on datasets where most edges are regular, which is common in many numerical simulations of physical systems. We provide an implementation of our method and benchmark it against the original *arrange and traverse* algorithm, showing performance gains of up to four orders of magnitude on real-world datasets.

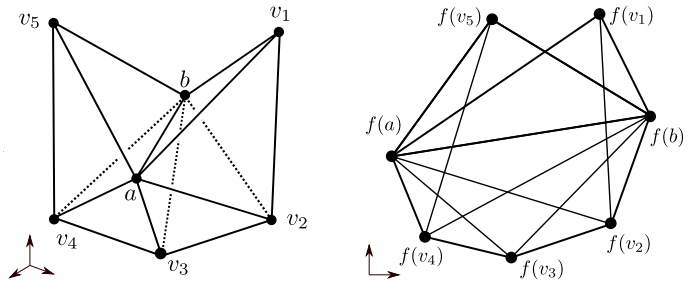
1 Introduction

Visualizing and analyzing the structure of scalar-valued functions is fundamental across many disciplines, including physics [38], chemistry [3, 21], atmosphere science [29, 42], biology [32, 34], computer graphics [4, 22], and machine learning [12, 31]. Topological tools such as persistent homology, the Morse-Smale complex, and the Reeb graph are state-of-the-art methods for extracting meaningful features from scalar fields [23]. Their widespread adoption is largely due to the fact that they can be computed *robustly* and *efficiently*.

The multivariate setting, where multiple scalar functions are defined over a shared domain, is considerably more complex. In this context, the interrelated structure between the functions cannot be captured adequately by scalar field techniques. To address this limitation, the Reeb graph can be generalized to the Reeb space [18]. The Reeb space is a quotient space that contracts the components of all preimages of points, also called *fibers*. The Reeb space of a bivariate PL map over a compact PL manifold can be represented as a two-dimensional cell complex [18, 27], where the 2-cells, referred to as sheets, represent features in data.

Four algorithms have been proposed for computing the Reeb space of a PL map. The first algorithm [18] segments the domain into regions where fibers have uniform connectivity and then glues those regions appropriately to form the sheets of the Reeb space. The Jacobi fiber surfaces algorithm [40] significantly improves practical performance in the bivariate case by computing these regions only for the singular (or Jacobi) edges in the domain, where fibers can change their connectivity. The third algorithm uses a hierarchical decomposition-based approach [10] to compute the Reeb space of a bivariate PL map from a sequence of nested Reeb graphs. Finally, the arrange and traverse algorithm [26] computes combinatorial descriptions of fibers called preimage graphs and determines their topological correspondence to obtain regions of uniform fiber connectivity that match the sheets of the Reeb space.



While all four Reeb space algorithms have close to quadratic algorithmic complexity in the bivariate case, their implementations suffer from either efficiency or robustness issues. The arrange and traverse algorithm [26] provides a robust implementation [24] in the bivariate case with CGAL's exact implementation of arrangements of 2D line segments [19]. However, due to its slow running time, it cannot handle real-life datasets without significant downsampling. The Jacobi fiber surfaces algorithm [40] offers better performance, but, as has been noted [10], its implementation is not exact without additional care in handling Jacobi fiber surface intersections. This paper aims to combine the strengths of these two approaches to provide a Reeb space algorithm with an implementation that is both efficient and robust.

We propose the *singular arrange and traverse* algorithm for computing the Reeb space of a generic bivariate PL map $f : |K| \to \mathbb{R}^2$, defined over a triangulation of a 3-manifold K. This is a specialization of the arrange and traverse algorithm that does not require the arrangement of the images of all edges of K in the range, only the singular ones, where the connectivity of the fibers can change. Using red-blue line segment intersection on the images of regular and singular edges, our algorithm computes the Reeb space from a subset of all preimage graphs, which we call *essential*. The worst-case running time of our algorithm is $O(N_s N_t \log N_t)$, where N_s is the number of singular edges and N_t is the number of triangles. This is a significant improvement because datasets with a low proportion of singular edges are common in practice. We provide an exact implementation and benchmark it against the arrange and traverse algorithm, the only other exact implementation known to the authors, achieving up to four orders of magnitude improvement in running time and memory footprint.

This paper is structured as follows: in Section 2, we introduce the background relevant to Reeb spaces of PL maps; in Section 3, we present the singular arrange and traverse algorithm; in Section 4, we prove its correctness and worst-case complexity; in Section 5 we describe our implementation, which we benchmark in Section 6. We conclude in Section 7.

2 Preliminaries

Let K be a triangulation of a 3-manifold and let $f : |K| \to \mathbb{R}^2$ be a piecewise linear (PL) map [35, 17]; see Figure 1. We will refer to f as a *bivariate* PL map because it can be decomposed into two scalar PL maps $f = (f_1, f_2)$, where $f_1, f_2 : |K| \to \mathbb{R}$. We assume that f is *generic*, in the sense that the images of no three vertices are collinear and the images of no three edges intersect at a single point in their interiors [25]. We refer to the images of edges under f in the range as *segments* and to the image of vertices under f as *vertex points*. For an edge e with endpoints a and b, we will also refer to e as ab.

(a) Tetrahedral mesh. **(b)** Image in the range.

Figure 1 Example tetrahedral mesh (a) and its image in the range under a bivariate PL map (b).

The *upper link* of an edge ab is a sub-complex of the link of ab induced by the vertices v in the link, whose vertex points $f(v)$ have a positive orientation with respect to $f(a)$ and $f(b)$ [27]. The *lower link* is defined analogously by the vertex points with negative orientation. In general we will assume that the endpoints of an edge or a segment are ordered lexicographically in order to establish a canonical orientation. For example, the upper link of ab in Figure 1 is $\{v_1, v_5\}$ and the lower link is $\{v_2, v_3, v_4, v_2v_3, v_3v_4\}$.

An edge is *regular* if both its lower and upper links have one simply connected component. Otherwise, that edge is *singular*, or Jacobi [16]. A vertex is *singular* if it is incident to at least one singular edge and *regular* otherwise. We call the images of singular edges and vertices in the range *singular segments and vertex points* respectively. The collection of singular edges and vertices is a one-dimensional subcomplex of K, which we call the *singular set* S_f.

A *fiber* is the preimage of a point $f^{-1}((x_1, x_2)) \subset |K|$ for $(x_1, x_2) \in \mathbb{R}^2$, which we call a *fiber point* (see Figure 2). A simplex intersected by a fiber is called *active* with respect to that fiber. We refer to the connected components of fibers as *fiber components*. Since fiber components can change their connectivity only at the singular set [27, 40], those that intersect S_f are called *singular*, and those that do not are called *regular*. Regular fiber components are polylines, while singular fiber components are either an isolated point or a number of polylines glued together at exactly one or two points [24]. Fibers with only regular components are *regular*, otherwise, they are *singular*.

Singular edges, analogous to critical points in the univariate case, can be categorized in the following way: *definite* edges create or destroy fiber components (analogous to minima and maxima) and *indefinite* edges merge or split fiber components (analogous to saddles) [27, 26]. Indefinite edges that split or merge exactly two components are referred to as *simple*. The singular set is called *simple* [18, 10] when it is a collection of polylines and all indefinite edges are simple. Non-simple singular edges can be unfolded into multiple simple ones (like monkey saddles), but that requires the addition of new simplices to the input mesh [16].

The *Reeb space* R_f of a PL map f is a topological structure that contracts each fiber component to a single point. It is the quotient space of $|K|$ with respect to the equivalence relation $\sim$, where $x \sim y$ if and only if x and y belong to the same fiber component. The

Reeb space is a part of the Stein factorization $f = \pi \circ q$, where $q : |K| \to R_f$ is the quotient map with respect to $\sim$ and π is the natural map such that the diagram commutes [30]. For computational purposes, the Reeb space of a bivariate PL map can be represented as a two-dimensional cell complex whose 2-cells, referred to as *sheets*, are glued together along the image of the singular set under q [9]. For an example see Figure 2.

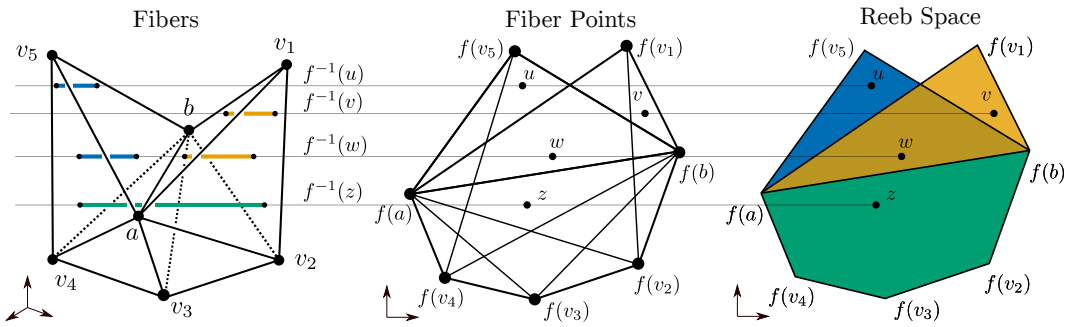


Figure 2 Examples of the change of connectivity of four fibers at the indefinite edge ab and the definite edges av_1 and bv_5. The Reeb space of f has three sheets (blue, yellow and green) – one for each fiber component. To visualize the Reeb space we map its sheets to the range and overlay them.

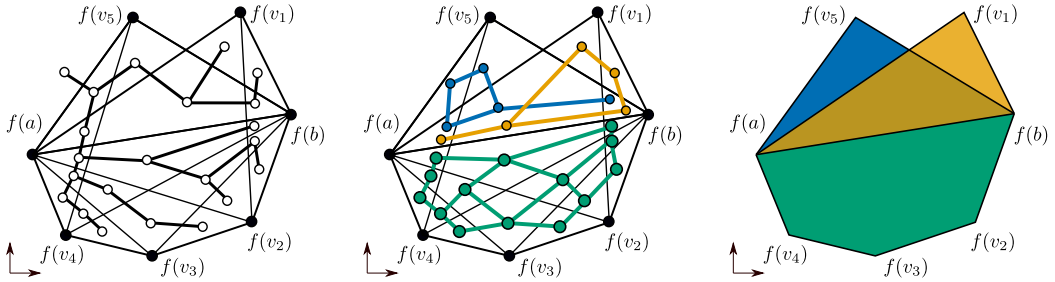


2.1 Arrange and Traverse Algorithm

The Reeb space of a PL map can be computed with four different approaches, which we outlined in Section 1. We will review the *arrange and traverse* algorithm [26] in detail because it forms the foundation for our new approach. The *arrange and traverse* algorithm computes the Reeb space by combinatorially representing fibers and tracking how their connectivity changes as they intersect the edges of K. Fibers are represented combinatorially with a preimage graph, similar to Parsa's optimal Reeb graph algorithm [33]. The *preimage graph* of a fiber $f^{-1}((x_1, x_2)) \subset |K|$ for a point $(x_1, x_2) \in \mathbb{R}^2$, which is not in the image of an edge or vertex, is a graph whose vertices are the active triangles with respect to that fiber and whose edges connect triangles which are both the faces of the same tetrahedron.

In the first stage of this algorithm, the edges of K are mapped to the range via f, and their geometric arrangement A is computed (see Section 2.2). Within each face F of A, all fibers have the same active triangles, so they can all be represented by a single *preimage graph*. In the second stage, the faces of A are traversed in order to compute their preimage graphs. The difference in the connectivity of the preimage graphs of two faces F_1 and F_2, which are incident via a segment $f(ab)$, where ab is an edge of K, is locally determined by the upper and lower link of ab. Assume that we cross from F_1 to F_2 via $f(ab)$ by crossing from the half-plane with negative orientation with respect to $f(a)$ and $f(b)$ to the half-plane with positive orientation. Then all triangles abv, where v is in the lower link of ab, are removed from the preimage graph of F_1, and all triangles abv', where v' is in the upper link of ab, are added to the preimage graph of F_1 to form the preimage graph of F_2. For the opposite direction of travel, all triangles abv are added and all triangles abv' are removed.

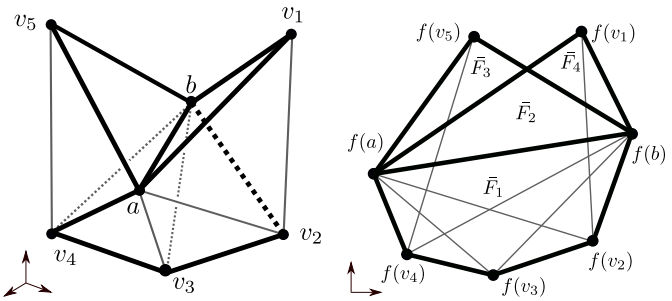
Once all preimage graphs are computed, the *correspondence graph* H is constructed. The vertices of the correspondence graph are the fiber components of the preimage graphs of all faces. Edges connect vertices representing fiber components when there is a correspondence between them – that is, when a fiber component passes from one face to another without any change in connectivity. Each sheet in the Reeb space is a collection of faces such that the connected components of the preimage graphs of those faces are in the same connected component in the correspondence graph. The adjacency of the sheets in the Reeb space is determined by the adjacency of the faces that comprise them.

For an example of stages of the arrange and traverse algorithm refer to Figure 3. In the bivariate case, the only geometric computations performed by this algorithm are in 2D – computing the arrangement and orientation tests for upper and lower links. The rest of the computation is entirely combinatorial. This is a significant advantage over other Reeb space algorithms, as it allows the use of only 2D geometric predicates [25]. An exact open-source implementation using CGAL can be found on GitHub [24]. Finally, this algorithm can be extended to higher dimensional domains K^d and ranges $\mathbb{R}^k$ such that $d > k$.

(a) Arrangement traversal. **(b)** Correspondence graph. **(c)** Reeb space.

Figure 3 The key stages of the arrange and traverse algorithm [26] for Figure 1.

2.2 Segment Intersections and Arrangements



The intersections of n line segments in the plane can be computed in time $O(n \log n + k)$, where k is the number of intersections [11, 2]. A subdivision of the plane by segments into vertices, edges, and faces is called an *arrangement* and can be computed in $O(n \log n + k \log n)$ time [14, 20] and represented with a *doubly connected edge list (DCEL)*. The special case of reporting the intersections between two sets of segments, typically labeled *red* and *blue*, can be solved in $O(n \log n + t)$ time, where t is the number of intersections between the two sets.

3 Singular Arrange and Traverse Algorithm

The *key idea* of the algorithm we propose is that *not all faces and preimage graphs are needed* to compute the Reeb space in the arrange and traverse algorithm (see Section 2.1). The only faces where the connectivity of fibers can change are the ones that are incident to at least one singular segment or singular vertex point. We call these faces *essential* because they outline a part of the boundary of at least one sheet of the Reeb space. More precisely, they outline the images of sheets in the plane under π. We refer to all other faces as *nonessential* because they do not contribute to the shape of the sheets. Our goal is to compute the Reeb space by *using only the essential faces* and their preimage graphs.

3.1 Definitions

Let K be a triangulation of a 3-manifold and let $f : |K| \to \mathbb{R}^2$ be a generic PL map. Let S_f be the singular set of f and let R_f be the Reeb space of f (see Section 2). We *do not* assume that the singular set is simple. For clarity of exposition, we will assume that $f(S_f)$ is connected – we will deal with the case where it is not in Section 3.3. We will refer to preimage graphs as *fiber graphs*, since fibers are defined as preimages of points under f. Let $A = \text{Arrangement}(f(K^{(1)}))$, where $K^{(1)}$ is the 1-skeleton of K, be the arrangement of all segments, and let $\bar{A} = \text{Arrangement}(f(S_f))$ be the arrangement of all singular segments. We will refer to A and $\bar{A}$ as the *full* and *singular* arrangement respectively (see Figure 4).

(a) Singular edges (in bold). **(b)** Singular segments (in bold).

Figure 4 The singular set (a) of Figure 1 and its image in the range (b). The arrangement $\bar{A}$ of the singular segments has four bounded faces, each subdivided by the faces of the full arrangement.

Consider a face of the singular arrangement $\bar{F} \in \bar{A}$. The fibers that correspond to points in the interior of $\bar{F}$ are homeomorphic to one another because they are all regular – no change in connectivity happens to any of them. Since $\bar{A}$ is an arrangement of a subset of the segments used in A, $\bar{F}$ is subdivided into a set of faces in A such that $\bar{F} = \cup_i F_i$, where $F_i \in A$. We describe the connectivity of fibers inside $\bar{F}$ by grouping the fiber graphs of all faces that subdivide $\bar{F}$ into a fiber graph class.

▶ **Definition 1** (Fiber Graph Class). *Let $\bar{F}$ be a face of the singular arrangement $\bar{A}$ and let $\{F_i\}_i$ be the set of faces of the full arrangement that are in $\bar{F}$. The fiber graph class $\bar{G}_{\bar{F}}$ of $\bar{F}$ is the set of fiber graphs $\bar{G}_{\bar{F}} = \{G_{F_i}\}_i$, where G_{F_i} is the fiber graph of F_i.*

Fiber graph classes allow us to *bundle* together fibers with the same topology to examine their connectivity in bulk. For an example see Figure 5. In order to examine that connectivity, we define the notion of a component of a fiber graph class.

▶ **Definition 2** (Fiber Graph Class Component). *Let $\bar{G}_{\bar{F}} = \{G_{F_i}\}_i$ be the fiber graph class of a face $\bar{F}$ of $\bar{A}$. A component $\bar{C}$ of a fiber graph class $\bar{G}_{\bar{F}}$ is a set $\{C_i\}_i$, where each C_i is a connected component of G_{F_i}, such that any two connected components C_i and C_j of $\bar{C}$ correspond to each other (see correspondence in Section 2.1).*

The connected components of fiber graphs within a single fiber graph class component are in the same connected component of the correspondence graph H. In order to determine how the components of fiber graph classes change their topology across the faces of the singular arrangement we define their correspondence.

▶ **Definition 3** (Fiber Graph Class Component Correspondence). *Two components $\bar{C}$ and $\bar{C}'$ of two fiber graph classes $\bar{G}_{\bar{F}}$ and $\bar{G}_{\bar{F}'}$ correspond to each other if there exist two connected components $C \in \bar{C}$ and $C' \in \bar{C}'$ that correspond to each other.*

We can describe the connectivity of fiber graph class components across all faces of the singular arrangement with the singular correspondence graph.

▶ **Definition 4** (Singular Correspondence Graph). *The singular correspondence graph $\bar{H}$ is a graph whose vertices are the set of all fiber graph class components and whose edges connect corresponding ones (see Definition 3).*

The sheets of the Reeb space have a one-to-one matching with the connected components of the singular correspondence graph. The geometry of a sheet of the Reeb space, or its image in the plane via π, is then the union of all faces $\cup_i \bar{F}_i$ whose fiber graph classes have components that span the connected component of $\bar{H}$ that matches that sheet.

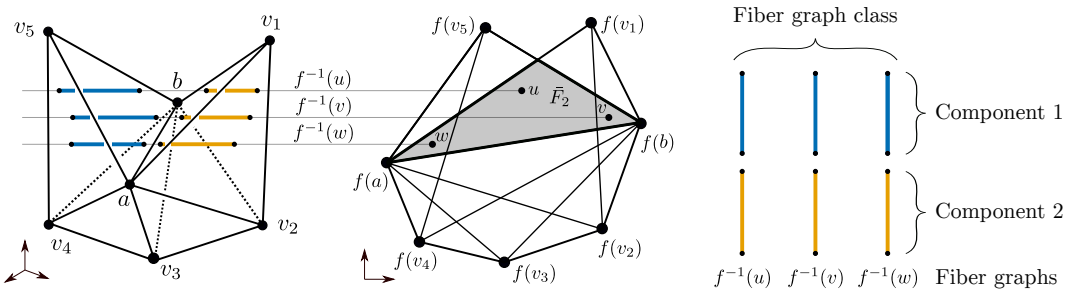


Figure 5 The fiber graph class of the face $\bar{F}_2$ is the collection of the fiber graphs of faces of the full arrangement that are in $\bar{F}_2$. All yellow (and respectively blue) fiber components correspond to one another; they change continuously from one to another as a fiber point moves around $\bar{F}_2$. All corresponding fiber graph components form a component of the fiber graph class of $\bar{F}_2$.

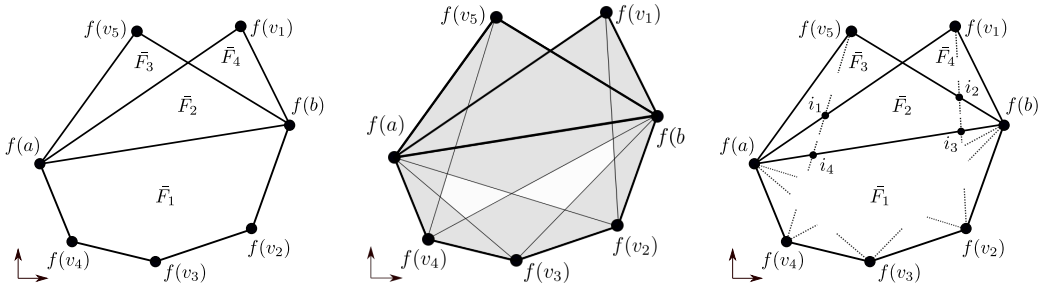
By reframing the computation of the Reeb space in terms of fiber graph classes, their components, and the singular correspondence graph $\bar{H}$, we can optimize running time and memory efficiency in several ways. First, we can completely skip the computation of all nonessential fiber graphs because the correspondence between two fiber graph class components can only be established with components of essential fiber graphs. Second, we can save a significant amount of memory, which is the primary bottleneck of the arrange and traverse algorithm, by representing every fiber graph class component as a single vertex in $\bar{H}$. Finally, since all essential faces are incident to singular segments, we do not have to compute the full arrangement A, only the singular one $\bar{A}$. Then we can identify the essential faces by finding the intersections between $\bar{A}$ and the regular segments.

3.2 Algorithm Description



We describe the *singular arrange and traverse algorithm* in three stages. First, we compute all essential faces in the *geometric preprocessing stage*. Then, we compute their fiber graphs and the singular correspondence graph in the *topological traversal stage*. Finally, we compute the geometry of the sheets and their adjacency in the *geometric postprocessing stage*.

Stage I. Geometric Preprocessing

In the first stage, we compute all essential faces *implicitly* without using the full arrangement A. To do so, we compute the singular set S_f, then map it to the range to compute the singular arrangement $\bar{A}$, and finally we compute the intersection of $\bar{A}$ and the regular segments. We store all regular segments that intersect the boundary $\partial\bar{F}$ of each face $\bar{F}$ of $\bar{A}$ in a *circular counterclockwise ordered list* $Q_{\bar{F}}$.

When two regular segments intersect the interiors of two different half-edges or vertices of $\bar{F}$ we use the counterclockwise order defined on the boundary of $\bar{F}$ by the DCEL data structure of $\bar{A}$. When two regular segments intersect the interior of the same half-edge of $\bar{F}$, we compare the barycentric coordinates of the points of intersection. When two regular segments share a vertex of $\bar{F}$ as a common endpoint, we use their radial ordering. We use our running example to illustrate this in Figure 6, where $Q_{\bar{F}_2} = \{f(v_1v_2), f(v_1v_2), f(v_4v_5), f(v_4v_5)\}$.

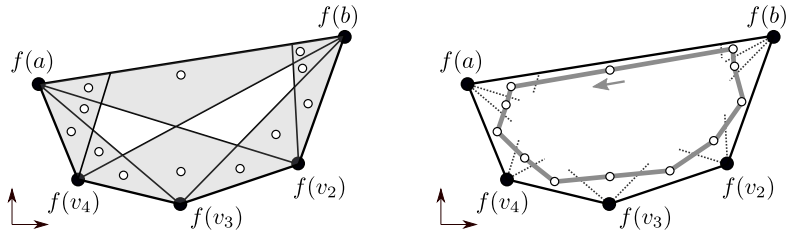
Each essential face $F \subseteq \bar{F}$ is implicitly represented with the part of its boundary that intersects $\partial\bar{F}$. This can be identified by pairs of consecutive regular segments in $Q_{\bar{F}}$. Note also that an essential face may be represented multiple times when $\partial F \cap \partial\bar{F}$ has multiple connected components. Such is the case for the essential face whose boundary vertices include i_1, i_2, i_3 and i_4 in the middle of face $\bar{F}_2$ in Figure 6c.

(a) Singular arrangement. **(b)** Essential faces (shaded). **(c)** Regular segment intersections.

Figure 6 Our algorithm computes the arrangement $\bar{A}$ of all singular segments (a), then idenfities all essential faces (b) by computing the intersections between $\bar{A}$ and all regular segments (c).

Stage II. Topological Traversal

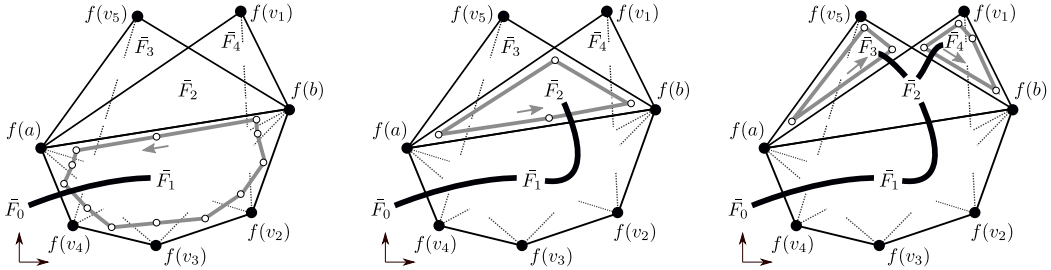
In the second stage, we traverse the faces of the singular arrangement along their shared segments using breadth-first search (BFS) to compute the essential fiber graphs and the singular correspondence graph $\bar{H}$. Starting with the unbounded face outside $\bar{A}$, whose fiber graph is empty, we visit one of its incident bounded faces $\bar{F}$ via a segment $f(ab)$, where ab is an edge in K. The edge ab is definite (see Section 2) because $f(ab)$ is on the boundary of $\bar{A}$, so we add the triangles abv, where v is in the upper (or lower, depending on the direction of travel) link of ab, to the first essential fiber graph in the fiber graph class of $\bar{F}$.



Next, we compute all other essential fiber graphs of $\bar{F}$ with a loop operation. A *loop operation* implicitly loops around the inner boundary of $\bar{F}$ to visit all essential faces in $\bar{F}$ using the order $Q_{\bar{F}}$ we have established in the geometric preprocessing stage. During the loop of $\bar{F}$, we cross from one essential face to the next via the regular segments listed in $Q_{\bar{F}}$. We add and remove the appropriate triangles related to the upper and lower links of the edges that map to those segments (see Section 2.1).

After we have computed the essential faces of $\bar{F}$, we visit its neighboring faces. We compute the new fiber graphs by adding and removing triangles according to the upper and lower links of the singular edges that map to shared segments on the boundaries of incident singular faces. We continue to loop each face as we visit it in the BFS traversal until we have computed the fiber graphs of all essential faces. For an example of the loop operation, see Figure 7, and for an example of the overall traversal, see Figure 8.

Finally, we construct the singular correspondence graph $\bar{H}$. Let $\bar{F}$ and $\bar{F}'$ be two singular faces which are incident via the segment $f(ab)$, and let F and F' be any two essential faces in $\bar{F}$ and $\bar{F}'$ respectively, which are also incident via $f(ab)$. We use the upper and lower links of ab to determine which components in the fiber graphs of F and F' are not affected by the transition from F to F' via $f(ab)$ and establish correspondence between them [26]. This allows us to establish correspondence between the components of the fiber graph classes of $\bar{F}$ and $\bar{F}'$. We do this for all pairs of incident singular faces.



Stage III. Geometric Postprocessing

Once we have computed the singular correspondence graph, we can compute the geometry and adjacency of the sheets of the Reeb space R_f. By the geometry of a sheet of the Reeb space, we mean its image into the plane via $\pi : R_f \to \mathbb{R}^2$. Let L be a sheet that matches a connected component of $\bar{H}$. Then, the geometry of L is exactly the union of faces in the singular arrangement whose fiber graph class components span that component of

(a) Essential fiber graphs of $\bar{F}_1$. **(b)** Looping all essential fiber graphs.

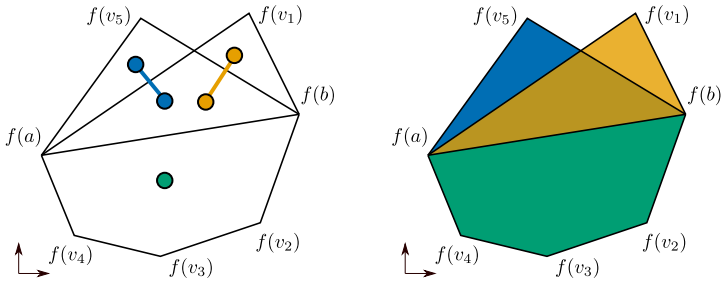
$\bar{H}$. Sheets are adjacent when they have incident faces in the singular arrangement. The singular correspondence graph and the Reeb space of our running example are given in Figure 9. Notice how much smaller the singular correspondence graph is compared to the correspondence graph in Figure 3b.



3.3 Nested Faces

We now address the case where the image of the singular set is *not* connected. In this case, either the unbounded face of the singular arrangement has more than one hole, or some bounded face has at least one hole, or both. If the unbounded face of the arrangement has multiple holes, we can traverse them independently. If a bounded face $\bar{F}_1$ has a nested face $\bar{F}_2$ (a hole), we find the shortest path in the 1-skeleton of K that connects a vertex that maps to $\partial\bar{F}_1$ to a vertex that maps to $\partial\bar{F}_2$. We mark the regular edges on this path as *pseudo-singular* and compute the arrangement of all singular and pseudo-singular segments, which is now guaranteed to be connected. After this, our algorithm proceeds as usual.

Note that this may introduce additional faces in the singular arrangement, such as $\bar{F}_3$ in Figure 10, whose nonessential fiber graphs will be computed by our algorithm. We will demonstrate that this is not an issue in practice and that only a negligible number of pseudo-singular edges are added for real-life datasets we evaluate in Section 6.

3.4 Higher Dimensional Domains

Finally, we describe an extension of our algorithm for computing the Reeb space of a PL map $f : |K| \to \mathbb{R}^2$, where K is a triangulation of a d-manifold with $d > 3$. Due to the skeleton lemma [18], the Reeb space of $f : |K| \to \mathbb{R}^2$ is homeomorphic to the Reeb space of $f' : K^{(3)} \to \mathbb{R}^2$, which is the restriction of f to the 3-skeleton of K. In order to compute the Reeb space of f', we compute all singular edges of K [16] and discard all simplices

(a) Correspondence graph. **(b)** Reeb space.

Figure 9 Singular correspondence graph and Reeb space of the toy example from Figure 1.

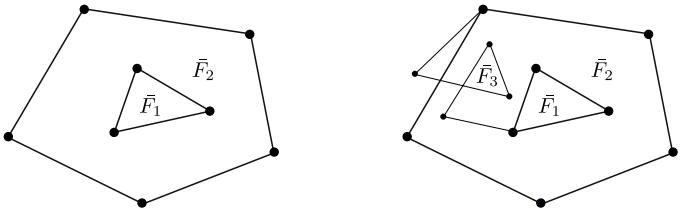


Figure 10 Connecting nested faces by adding pseudo-singular segments.

of dimension bigger than three from K. Then, we map the singular edges to the plane, compute their arrangement, and traverse it to compute the singular correspondence graph. The only difference is that we need a new subroutine to track the connectivity of fiber graphs. This is because the regular fibers of f' are not PL curves but the 1-skeleton of triangulated $(d-2)$-manifolds. This requires more involved data structures for dynamic graph connectivity tracking, similar to how Reeb graph algorithms handle the scalar case [15, 33].

4 Proofs

In this section we prove the correctness and worst-case running time of our algorithm using our definitions from the start of Section 3.

4.1 Correctness

First, we prove the correctness of each stage in our algorithm (see Section 3.2).

▶ **Lemma 5** (Essential Faces). *The singular arrange and traverse algorithm correctly identifies all essential faces.*

Proof. Let F be an essential face of the full arrangement A, and let $\bar{F}$ be the face of the singular arrangement $\bar{A}$ that contains F. The case when $F = \bar{F}$ is trivial because then F is already correctly represented in $\bar{A}$. Suppose that $F \subset \bar{F}$. Let B be a connected component of $\partial F \cap \partial \bar{F}$. Then B is a path from i_1 to i_2, where i_1 and i_2 are the intersection points of two regular segments s_1 and s_2 with $\partial \bar{F}$.

First, we examine the case where $B = i_1 = i_2$. In the DCEL of the full arrangement A, the half-edges of the boundary cycle of F that originate from s_1 and s_2 must be consecutive. This means that no other regular segment comes between s_1 and s_2 in the counterclockwise order of segments around i_1 in A. Otherwise, that other segment would be on the boundary of F. Therefore, the segments s_1 and s_2 are present as a consecutive pair in the circular list

$Q_{\bar{F}}$ of regular segments of $\bar{F}$. If on the other hand $i_1 \neq i_2$, then B is subdivided into at least one half-edge in the DCEL of A. No other regular segment intersects the interior of B, because then the essential face F would have been subdivided differently in A. Similarly to the previous case, other regular segments whose endpoint is either i_1 or i_2 are either before s_1 or after s_2 in the counterclockwise order of segments around those vertex points. Therefore, s_1 and s_2 are consecutive in $Q_{\bar{F}}$.

Conversely, we can use a similar argument to show that each consecutive pair of regular segments in $Q_{\bar{F}}$ can be uniquely identified with an essential face. ◀

▶ **Lemma 6** (Essential Fiber graphs). *The singular arrange and traverse algorithm correctly computes all essential fiber graphs.*

Proof. Since all essential faces are identified correctly by Lemma 5, our algorithm can traverse them, analogously to the arrange and traverse algorithm, but in a different order. To see why this does not affect the correctness, consider a path P in the range that only intersects regular or singular segments, from the unbounded outside face to an essential face. Any such path gives rise to a sequence of additions and removals of triangles, based on the upper and lower links of edges whose segments P intersects. This sequence can be used to build the fiber graph of the essential face, which is the same as the fiber graph computed by our algorithm. Additional pseudo-singular segments in $\bar{A}$ (see Section 3.3) do not affect the correctness because our algorithm still identifies such a path P correctly. ◀

▶ **Lemma 7** (Singular Correspondence Graph). *The connected components of the singular correspondence graph correctly represent the sheets of the Reeb space.*

Proof. The singular correspondence graph $\bar{H}$ can be obtained from the correspondence graph H by contracting all vertices that are associated with the components of fiber graphs within the same fiber graph class. A contraction of a graph does not affect its connectivity. Each vertex of $\bar{H}$ simply represents a larger area in the range of fiber points whose fibers have the same topology. The singular correspondence graph can be computed correctly by establishing correspondence only between the essential fiber graphs because nonessential fiber graphs do not introduce correspondences with new fiber graph classes. They only correspond directly to other components within their own class, and it is precisely these correspondences that are lost in the contraction of H to H'. The correctness of the correspondence procedure between fiber graphs is proven in the original arrange and traverse algorithm [26]. ◀

▶ **Corollary 8** (Reeb space). *The singular arrange and traverse algorithm correctly computes the Reeb space of a generic PL map $f : |K| \to \mathbb{R}^2$, where K is a triangulation of a 3-manifold.*

Proof. By Lemma 5 and Lemma 6, the essential faces and essential fiber graphs are computed correctly. By Lemma 7, the singular correspondence graph represents the sheets of the Reeb space and is computed correctly. Therefore, the singular arrange and traverse algorithm correctly computes the Reeb space of f. ◀

4.2 Complexity

Let N_e and N_t be the number of edges and triangles in K respectively. Let N_s be the number of singular edges. Let k_s be the number of intersections between all singular segments, and let k_r be the number of intersections between all regular and singular segments. First, we compute the arrangement of all singular segments in time $O((N_s + k_s) \log N_s)$. Next, we compute the number of intersections between all regular and singular segments and

their relative order in time $O((N_e + k_r) \log N_e)$. We use a red-blue segment intersection algorithm (see Section 2.2) and sort the intersection points along each singular segment using their barycentric coordinates. This concludes the geometric part of our computation. What remains is the complexity of computing the essential fiber graphs and the singular correspondence graph, which we demonstrate with the following lemma.

▶ **Lemma 9.** *Computing the essential fiber graphs and the singular correspondence graph has worst-case running time* $O(N_s N_t \log N_t)$.

Proof. Let $k(e)$ be the number of times an edge $e \in K$ is visited by the algorithm. A visit can mean either crossing a singular segment in the traversal from one face to another in the singular arrangement, or crossing a regular segment in the looping of a single face. When we visit an edge with degree $\deg(e)$, where we define the degree of an edge as the number of its incident triangles, we add and remove at most $\deg(e)$ triangles from the relevant fiber graphs, and perform at most $\deg(e)$ connectivity queries. Each of those operations takes at most $O(\log N_t)$ time if we represent each fiber graph with a balanced search tree [13].

The overall worst-case running time can then be obtained by summing the costs of all visits across all edges $O\big(\sum_{e \in E} k(e) \deg(e) \log(N_t)\big)$, where E is the set of edges in K. Since we do not consider any intersections between regular segments, each segment is intersected, and hence visited, at most N_s times. Using $k(e) \leq N_s$ we obtain $O\big(N_s \log(N_t) \sum_{e \in E} \deg(e)\big)$. Using a straightforward counting argument, we can show that $\sum_{e \in E} \deg(e) = 3N_t$. This leads to a worst-case running time of $O(N_s N_t \log N_t)$. ◀

Computing the connected components of $\bar{H}$ can be done in linear time in its size with a graph search. The geometry of the sheets of the Reeb space can be obtained by combining all faces of the singular arrangement that belong to each sheet. Thus, *the overall complexity of our algorithm is* $O(N_s N_t \log N_t)$. Note that, practical performance depends primarily on k_s and k_r, which determine how many times an edge is actually visited.

When $O(N_s) = O(N_e)$ our algorithm has the same running time as arrange and traverse. However, our algorithm is significantly more efficient for practical data sets where the number of singular edges is orders of magnitude less than the number of regular edges, as we will demonstrate in our evaluation in Section 6.

5 Implementation

We provide an open-source implementation of the singular arrange and traverse algorithm in C++. The input is a tetrahedral mesh with two scalar values defined at each vertex, represented in the `.vtu` file format with VTK [36]. For the geometric preprocessing operations we used CGAL 6.0.2 [39] with the exact predicates and exact constructions kernel [5]. We compute the red-blue intersections with CGAL's `box_intersection_d` [28], which has quadratic complexity. While, this is not optimal, it has an efficient implementation.

We track changes in the connectivity of fiber graphs with a graph search over the affected [26] fiber components. While this operation is not logarithmic in the size of the fiber, in practice most of the connectivity computations are done within the loop operation for a face of the singular arrangement, so all triangles can be directly added or removed from the same fiber graph component without affecting the connectivity.

Another important practical optimization, similar to arrange and traverse, is to only keep the fiber graphs at the wave front of the BFS search in memory since those are the only ones needed to establish correspondence to create the singular correspondence graph [26]. While

degenerate cases, which occur when the input PL map is not generic (see Section 2), can be handled robustly with simulation of simplicity [25], random numerical perturbation with double floating-point precision was sufficient for our tests.

6 Evaluation

In this section, we perform a practical evaluation of the efficiency of our algorithm in terms of running time and memory. We benchmark our algorithm against the arrange and traverse algorithm [26], since that is the only other open-source exact Reeb space implementation known to the authors. Our tests were performed on a PC with two Intel Xeon Gold 6130 processors with 32 cores clocked at 2.1GHz and 384GB memory with Rocky Linux 9.6. We measured execution time using the C++ `chrono` library and estimated memory usage via the process's resident set size by reading `/proc/self/status`.

We benchmark our algorithm on three numerical simulation datasets – MVK [8, 37], ethane-diol [7, 41] and enzo [6, 7]. MVK comes from a quantum chemistry simulation studying photo-induced changes in electron transition orbitals. Ethane-diol is a molecular dynamics simulation of a molecule's electron density field and its reduced gradient. Lastly, the origin of Enzo is cosmological simulation of the universe's expansion; here, the bivariate field represents matter and dark matter concentration. Each dataset is given on a three-dimensional regular grid and then tetrahedralized using Paraview's [1] default filter.

We summarize our results in Table 1. Columns labeled $\times$ show the speedup of our algorithm over arrange and traverse. In the time columns, this indicates how many times faster it is; in the memory columns, how much less memory it uses. The timings for the geometric preprocessing stage are given in the *Prep.* column and the timings for the topological traversal stage are given in the R_S column. The timings for the geometric postprocessing stage are omitted, as the computation time is negligible compared to the first two stages and depends on how the Reeb space will be used in downstream tasks. Each entry is rounded to the nearest whole number. We downsampled each dataset multiple times to obtain a wide range of data sizes and proportion of the number singular edges, ranging from 0.20% for MVK to 3.73% for ethane-diol and finally 43.78% for enzo. The enzo datasets and ethane-diol with 3,150K tetrahedra required the use of perturbation with strength 0.0001.

Our *primary result* is that the singular arrange and traverse algorithm is up to four orders of magnitude faster for MVK at 189K tetrahedra. For this dataset, arrange and traverse requires over 13 hours of computation time and about 100 GB of memory. Singular arrange and traverse not only takes less than 3 seconds and uses less than 700 MB of memory, but is also able to compute the Reeb space at full resolution (1,540K tetrahedra) in less than 10 seconds and 6 GB of memory. This speedup is due to the small number of singular edges, which our algorithm can successfully exploit.

Although the two other datasets have a larger singular set, we still see a significant speedup – at least two orders of magnitude for ethane-diol and at least one for enzo. Note that even though the number of singular edges in enzo is about half the total number of edges, we still see a significantly higher speedup – not just two-fold but up to 23x. This is due to the fact that the singular arrange and traverse algorithm not only allows us to avoid computing nonessential faces, but also allows us to group the computation of regular fiber graphs and significantly reduce the size of the correspondence graph.

In the case of MVK and ethane-diol, we are able to compute the Reeb space of their original non-downsampled resolution. This is something that would have been extremely difficult with arrange and traverse. The enzo dataset, however, has 83 million tetrahedra in its non-downsampled resolution and a high proportion of singular edges, which makes it difficult for our algorithm to handle.

Table 1 Performance metrics for real-life datasets. We report the number of input tetrahedra N_T, the percentage of singular edges N_s relative to all edges N_e, computation times, and memory usage for both preprocessing and Reeb space computations, including scaling factors (×) relative to arrange and traverse. Runs with over a day of compute were terminated and marked with "–".

	N_T	N_s/N_e	Time				Memory

We verified the correctness of our algorithm by comparing the sheets it outputs against arrange and traverse. For all datasets for which we could compute arrange and traverse, the outputs of both algorithms were identical. Finally, we note that the amount of additional computation needed to connect the nested faces was negligible. In the MVK datasets our algorithm added one to two additional pseudosingular edges to connect the arrangement and avoid nested faces. In the ethane-diol datasets that number was from 20 to 94.

The geometric preprocessing stage of our algorithm is significantly faster for MVK and ethane-diol and uses substantially less memory. Our memory usage improvement holds for enzo as well, but it takes up to 10 times longer to compute, even though arrange and traverse computes the arrangement of all segments. This may be addressed by implementing a more efficient algorithm for red-blue segment intersection.

7 Conclusion

In this paper, we presented the singular arrange and traverse algorithm for the exact and efficient computation of Reeb spaces of bivariate PL maps. This algorithm takes advantage of the fact that datasets with a small number of singular edges, relative to the total number of edges, have smaller Reeb spaces, which allows us to avoid nonessential computation from previous Reeb space algorithms such as arrange and traverse [26].

We presented a reformulation of the computation in terms of fiber graph classes and the singular correspondence graph, enabling the collective treatment of many related fiber graphs and thereby improving efficiency. We further provided an exact implementation of this approach and benchmarked it against the original arrange and traverse algorithm, demonstrating speedups ranging from one to four orders of magnitude across multiple real-world datasets derived from numerical simulations.

Future work will focus on optimising the running time through parallelisation as well as simplification for datasets with large singular sets. Other open problems include non-heuristic methods for dealing with nested faces and extensions to higher dimensional ranges.

On Sparse Representations of 3-Manifolds

Kristóf Huszár
Institute of Geometry, Graz University of Technology, Austria

Clément Maria
Inria d'Université Côte d'Azur, Sophia Antipolis, France

Abstract

3-manifolds are commonly represented as triangulations, consisting of abstract tetrahedra whose triangular faces are identified in pairs. The combinatorial sparsity of a triangulation, as measured by the treewidth of its dual graph, plays a fundamental role in the design of parameterized algorithms. In this work, we investigate algorithmic procedures that transform or modify a given triangulation while controlling specific sparsity parameters. First, we revisit a standard, linear-time algorithm that converts a given triangulation into a Heegaard diagram of the underlying 3-manifold, showing that the construction preserves treewidth. We apply this construction to exhibit a fixed-parameter tractable framework for computing Kuperberg's quantum invariants of 3-manifolds. Second, we present a quasi-linear-time algorithm that retriangulates a given triangulation into one with maximum edge valence of at most nine, while only moderately increasing the treewidth of the dual graph. Combining these two algorithms yields a quasi-linear-time algorithm that produces, from a given triangulation, a Heegaard diagram in which every attaching curve intersects at most nine others.

2012 ACM Subject Classification Mathematics of computing → Geometric topology; Theory of computation → Fixed parameter tractability

Keywords and phrases computational 3-manifold topology, fixed-parameter tractability, Heegaard splittings and diagrams, triangulations, edge valence, treewidth, quantum invariants, tensor networks

1 Introduction

Structural properties of triangulations – which are commonly used to encode 3-manifolds both in theory and in practice – can dramatically affect the feasibility of computations. Over the past decade, several fixed-parameter tractable (FPT) algorithms have been developed that efficiently solve provably hard problems on 3-manifolds, provided they are represented by triangulations that are sufficiently "thin" [5, 6, 7, 8, 9].[1] On input triangulations with bounded *treewidth*[2] these algorithms run in time polynomial in the number of tetrahedra.

Motivated by these algorithms, several recent papers have investigated the quantitative relationship between the treewidth (and other width parameters) of triangulations and the corresponding quantities in various related representations of 3-manifolds. It has been shown that 3-manifolds with small Heegaard genus [14, 19], as well as hyperbolic 3-manifolds with small volume [17, 30], admit triangulations with small treewidth. At the same time, for certain 3-manifolds, a large Heegaard genus or a "complicated" JSJ decomposition can entirely preclude the existence of triangulations with small treewidth [20, 21].[3]

[1] See [3, 27, 28, 29] for related FPT algorithms in knot theory, and the survey [25] for a broader context.
[2] Treewidth is a graph parameter that quantifies the similarity of a given graph to any tree. We define the treewidth of a triangulation $\mathcal{T}$ as the treewidth of its dual graph $\Gamma(\mathcal{T})$. See Section 2 for details.
[3] See [11, 26] for related structural results about knots and links and their diagrams.

In this work, we also focus on algorithmic transformations of 3-manifold triangulations with a view toward parameterized algorithms and sparsity. We provide two main contributions. First, we revisit and analyze a classical construction that turns a triangulation $\mathcal{T}$ of a closed 3-manifold $\mathcal{M}$ into a Heegaard splitting[4] and show that it yields a Heegaard diagram of $\mathcal{M}$, whose size and treewidth are linearly bounded by those of $\mathcal{T}$. More concretely, we prove

▶ **Theorem 1.** *Let $\mathcal{T}$ be a triangulation of a closed, orientable 3-manifold $\mathcal{M}$ with n tetrahedra and dual graph $\Gamma(\mathcal{T})$. Let $\mathcal{D} := \mathcal{D}(\mathcal{T})$ be the Heegaard diagram of $\mathcal{M}$ induced by $\mathcal{T}$. Then, for the number of vertices and for the treewidth[5] of $\mathcal{D}$ and $\Gamma(\mathcal{T})$ we have*

$$|V(\mathcal{D})| = 6n \quad \text{(1a)} \qquad \text{and} \qquad \operatorname{tw}(\mathcal{D}) \leq 12\operatorname{tw}(\Gamma(\mathcal{T})) + 11. \quad \text{(1b)}$$

Moreover, given $\mathcal{T}$, the induced Heegaard diagram $\mathcal{D}$ can be constructed in $O(n)$ time.

Guided by this result, in Section 5 we investigate the complexity of computing Kuperberg's quantum invariants of oriented 3-manifolds [23], which are obtained from a Heegaard diagram by evaluating an associated tensor network. First, we show that this construction is width-preserving (Lemma 18). This insight, combined with Theorem 1 and results on the complexity of evaluating tensor networks [31, 34] (cf. Theorem 19), provides a framework for computing Kuperberg's invariants from triangulations that is FPT in the treewidth (Theorem 15).

▶ Remark. The converse of Theorem 1, i.e., building a triangulation from a given Heegaard splitting in a width-preserving way, has been studied in [19] and, very recently, in [14], where an explicit algorithm for constructing a triangulation from a Heegaard diagram is provided.

Our second contribution investigates the interplay between the *maximum edge valence* and the treewidth of a 3-manifold triangulation $\mathcal{T}$. Analogous to the notion of vertex degree in graphs, the *valence of an edge* in $\mathcal{T}$ is defined as the number of tetrahedra in $\mathcal{T}$ that contain it. While treewidth can be viewed as a measure of *global* sparsity, the maximum edge valence captures *local* sparsity. The maximum edge valence of a triangulation can also provide valuable insights into geometric properties of the underlying 3-manifold [13, Sec. 3.6]. Having a triangulation $\mathcal{T}$ with small maximum edge valence can be computationally advantageous even when $\mathcal{T}$ already has small treewidth; see the full version [18] for a discussion.

Every closed orientable 3-manifold has a triangulation with maximum edge valence at most six [2]. Frick has shown by an explicit construction that any triangulation $\mathcal{T}$ can be modified into a triangulation $\mathcal{T}^\dagger$ of the same manifold with edge valences at most nine [13, Theorem 3.36]. However, this construction may significantly increase the treewidth of the resulting triangulation, because if $\mathcal{T}$ contains edges with large valence, the retriangulation procedure introduces large grid-like structures in $\mathcal{T}^\dagger$. In Section 4, we show how to circumvent this and obtain a different retriangulation $\mathcal{T}^*$ that also achieves $\Delta(\mathcal{T}^*) \leq 9$, while controlling the increase in treewidth by a polylogarithmic factor of the maximum edge valence of $\mathcal{T}$.

▶ **Theorem 2.** *There is an algorithm which, given a triangulation $\mathcal{T}$ of a closed 3-manifold $\mathcal{M}$ with n tetrahedra, $\mathbf{v}$ vertices, $\operatorname{tw}(\Gamma(\mathcal{T})) = \mathbf{tw}$, and maximum edge valence $\Delta(\mathcal{T}) = \boldsymbol{\Delta}$, constructs a triangulation $\mathcal{T}^*$ of $\mathcal{M}$ with $O((n+\mathbf{v}) \cdot \operatorname{poly}(\log_2(\boldsymbol{\Delta})))$ vertices and tetrahedra, $\operatorname{tw}(\Gamma(\mathcal{T}^*)) \leq \mathbf{tw} \cdot \operatorname{poly}(\log_2(\boldsymbol{\Delta}))$, and $\Delta(\mathcal{T}^*) \leq 9$. The algorithm runs in $O(n \log\log n)$ time.*

[4] A Heegaard splitting is a decomposition of a 3-manifold into two identical handlebodies, cf. Section 2.2.

[5] The number $V(\mathcal{D})$ of vertices and the treewidth $\operatorname{tw}(\mathcal{D})$ of a Heegaard diagram $\mathcal{D} = (\mathcal{S}, \boldsymbol{\alpha}, \boldsymbol{\beta})$ are, by definition, respectively equal to those of its underlying graph, which is the 4-regular multigraph geometrically obtained by taking the union of the α- and β-curves and placing a vertex at each crossing.

Finally, the execution of the algorithms in Theorem 2 and Theorem 1 (in this order) yields the following corollary, which we believe to be of independent interest.

▶ **Corollary 3.** *There is a quasi-linear time algorithm that, given a triangulation $\mathcal{T}$ of a closed, orientable 3-manifold $\mathcal{M}$ with n tetrahedra, $\mathrm{tw}(\Gamma(\mathcal{T})) = \mathbf{tw}$, and maximum edge valence $\Delta(\mathcal{T}) = \boldsymbol{\Delta}$, constructs a Heegaard diagram $\mathcal{D} = (\mathcal{S}, \boldsymbol{\alpha}, \boldsymbol{\beta})$ of $\mathcal{M}$ of size and genus $O(n\,\mathrm{poly}(\log(\boldsymbol{\Delta})))$, treewidth $O(\mathbf{tw} \cdot \mathrm{poly}(\log(\boldsymbol{\Delta}))$, where any α-curve intersects at most 9 β-curves, and any β-curve intersects at most 3 α-curves.*

2 Preliminaries

2.1 Graphs and their treewidth

By a *graph* we generally mean a *multigraph* $G = (V, E)$ with a finite set $V = V(G)$ of *vertices* and of a multiset $E = E(G)$ of two-element submultisets of V called *edges*. A *loop* is an edge of the form $\{v, v\}$, and a *multiedge* is an edge with multiplicity larger than one. A graph without loops or multiedges is *simple*. The *degree* $\deg(v)$ of $v \in V$ is the number of edges containing v, counted with multiplicity. A graph is *k-regular* if $\deg(v) = k$ for all $v \in V$.

Introduced in [36] (cf. [12]), the *treewidth* of a graph measures its similarity to any tree. A *tree decomposition* $\mathcal{X}$ of a graph $G = (V, E)$ is a pair $\mathcal{X} = (T, \mathcal{B})$ of a tree $T = (I, F)$ and a collection $\mathcal{B} = \{B_i : i \in I\}$ of *bag*s, where $B_i \subseteq V$ and the following three properties hold: **1.** $\bigcup_{i\in I} B_i = V$ (vertex coverage), **2.** for every $\{u, v\} \in E$ there exists $i \in I$ with $\{u, v\} \subseteq B_i$ (edge coverage), and **3.** for every $v \in V$, the set $T_v = \{i \in I : v \in B_i\}$ spans a connected subtree of T (subtree property). The *width* of the tree decomposition $\mathcal{X}$ equals $\max_{i\in I} |B_i| - 1$, and the *treewidth* $\mathrm{tw}(G)$ is defined as the smallest width of any tree decomposition of G.

2.2 3-Manifolds and their representations

A *d-dimensional topological manifold with boundary* (hereafter *d-manifold*) $\mathcal{M}$ is a topological space[6] locally homeomorphic to $\mathbb{R}^d$, i.e., every point of $\mathcal{M}$ has a neighborhood homeomorphic to $\mathbb{R}^d$ or to the upper half-space $\{(x_1, \ldots, x_d) \in \mathbb{R}^d : x_d \geq 0\}$. The *boundary* $\partial\mathcal{M}$ of $\mathcal{M}$ consists of all points of $\mathcal{M}$ that have no open neighborhood homeomorphic to $\mathbb{R}^d$. In this paper we only consider compact, orientable d-manifolds with $d \leq 3$. A manifold $\mathcal{M}$ is *closed* if it is compact and $\partial\mathcal{M} = \emptyset$. A *surface* is just a 2-manifold. We consider manifolds up to homeomorphism. See [39] for general background on 3-manifolds.

Triangulations and their dual graphs. As is common in algorithmic topology, we define a (3-dimensional) *triangulation* as a quotient space $\mathcal{T} = \Sigma/\Phi$, where $\Sigma = \{\sigma_1, \ldots, \sigma_n\}$ is a set of labeled and vertex-labeled abstract tetrahedra, and $\Phi = \{\varphi_1, \ldots, \varphi_m\}$ is a set of simplicial isomorphisms, called *gluing maps*, each of which identifies two triangles of the simplices in Σ.[7] For $i \in \{0, 1, 2, 3\}$, let $\mathcal{T}(i)$ denote the set of i-dimensional faces of the resulting quotient $\mathcal{T}$, and let $\mathcal{T}^{(i)}$, its *i-skeleton*, be $\mathcal{T}^{(i)} := \cup_{j=0}^{i} \mathcal{T}(j)$. The *valence* $\mathrm{val}(e)$ of an edge $e \in \mathcal{T}(1)$ is the number of tetrahedra in $\mathcal{T}$ that contain it and $\Delta(\mathcal{T}) := \max_{e\in\mathcal{T}(1)} \mathrm{val}(e)$. $\mathcal{T}$ *triangulates* the manifold $\mathcal{M}$ if the geometric realization of $\mathcal{T}$ is homeomorphic to $\mathcal{M}$. Triangulations of surfaces are defined analogously. Every surface and 3-manifold has a triangulation [33, 35].

[6] Some technical requirements about the space are intentionally omitted here, cf. [39, Definition 1.1.1].

[7] Each triangle is identified with at most one other triangle. We allow two pairs of triangles to be glued between the same pair of tetrahedra, as well as gluing two triangles within a single tetrahedron. Hence the triangulations considered here are not simplicial complexes but *regular simplicial cell complexes*. Nevertheless, the second barycentric subdivision $\mathcal{T}''$ of any triangulation $\mathcal{T}$ is always a simplicial complex.

Given a triangulation $\mathcal{T} = \Sigma/\Phi$, its *dual graph* (or *face-pairing graph*) $\Gamma(\mathcal{T})$ is the graph with $V(\Gamma(\mathcal{T})) = \Sigma$, and $\{\sigma_1, \sigma_2\} \in E(\Gamma(\mathcal{T}))$ if and only if there is a gluing map $\varphi \in \Phi$ that identifies a triangle of σ_1 with a triangle of σ_2 (where σ_1 and σ_2 may coincide). See Figure 1. We define the *treewidth of a triangulation* $\mathcal{T}$ as the treewidth of its dual graph $\Gamma(\mathcal{T})$.

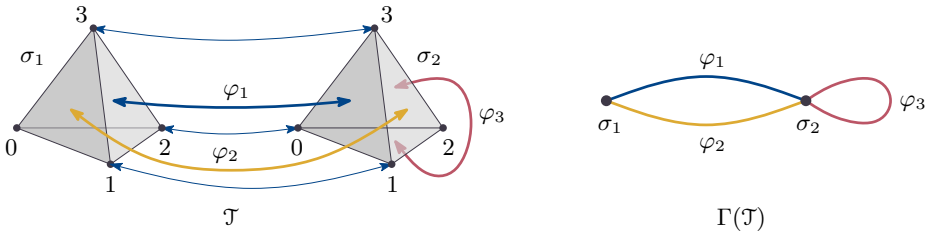

Figure 1 A triangulation $\mathcal{T} = \Sigma/\Phi$ with tetrahedra $\Sigma = \{\sigma_1, \sigma_2\}$, gluing maps $\Phi = \{\varphi_1, \varphi_2, \varphi_3\}$ and dual graph $\Gamma(\mathcal{T})$. φ_1 is explicitly defined as $\sigma_1(123) \leftrightarrow \sigma_2(103)$. Based on [20, Figure 1].

Handlebodies and Heegaard splittings. A *handlebody* $\mathcal{H}$ is a compact 3-manifold homeomorphic to a regular neighborhood of a bouquet of circles embedded in $\mathbb{R}^3$. Every closed, orientable 3-manifold $\mathcal{M}$ admits a *Heegaard splitting* [15, 16], i.e., a decomposition into two homeomorphic handlebodies $\mathcal{H}_1$ and $\mathcal{H}_2$ with a shared boundary. That is, $\mathcal{M} = \mathcal{H}_1 \cup \mathcal{H}_2$ and $\mathcal{H}_1 \cap \mathcal{H}_2 = \partial\mathcal{H}_1 = \partial\mathcal{H}_2 = \mathcal{S}$. The surface $\mathcal{S}$ is called a *splitting surface*, and its genus $g(\mathcal{S})$ is referred to as the *genus of the Heegaard splitting*. The minimum genus of any Heegaard splitting of $\mathcal{M}$ is called the *Heegaard genus* of $\mathcal{M}$. We refer to [38] for an extensive survey.

Heegaard diagrams. Heegaard diagrams were developed alongside Heegaard splittings to describe them. They also provide the basis for computing Kuperberg's invariants (Section 5). We follow the definitions of [23, Section 4]. In particular, we consider Heegaard diagrams in a sense more flexible than usual. A *handlebody diagram* is an ordered pair $(\mathcal{S}, \boldsymbol{\gamma})$ of a closed orientable surface $\mathcal{S}$ and a collection $\boldsymbol{\gamma} = \{\gamma_1, \ldots, \gamma_\ell\}$ of pairwise disjoint simple closed curves embedded in $\mathcal{S}$ that divide $\mathcal{S}$ into planar regions.[8] (Figure 2). A handlebody diagram $(\mathcal{S}, \boldsymbol{\gamma})$

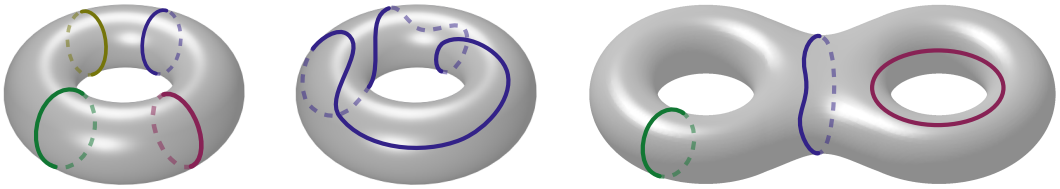

Figure 2 Illustrations of some handlebody diagrams. The surfaces are meant to be hollow.

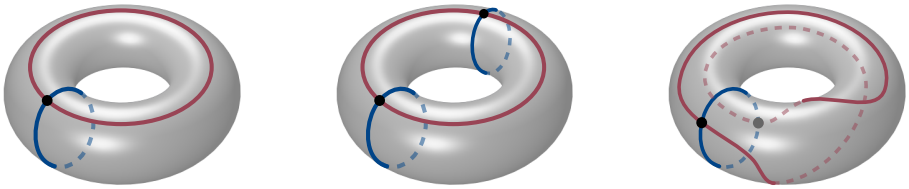
can be seen as a prescription for gluing a handlebody to one side of $\mathcal{S}$. Specifically, consider the thickening $\mathcal{S} \times [0, 1]$, and for each $i \in \{1, \ldots, \ell\}$ attach to its *upper boundary* $\mathcal{S} \times \{1\}$ a thickened disk (called a 2-*handle*) along the curve γ_i.[9] Because of the assumption about $\boldsymbol{\gamma}$, each resulting new boundary component is a 2-sphere, each of which we fill in with a 3-ball. (Importantly, these fillings are unique up to isotopy; see [39, Lemma 2.5.3].) The union of the attached 2-handles and the filling 3-balls is a handlebody $\mathcal{H}$, which we have just glued to $\mathcal{S}$.

[8] Because of this requirement the number ℓ of curves in $\boldsymbol{\gamma}$ is at least the genus $g(\mathcal{S})$ of the surface $\mathcal{S}$, and $\ell = g(\mathcal{S})$ is commonly assumed in the literature. However, we will generally have $\ell > g(\mathcal{S})$.

[9] More precisely, we attach the 2-handle along the copy of γ_i in $\mathcal{S} \times \{1\}$.

With that, a *Heegaard diagram* is a triple $\mathcal{D} = (\mathcal{S}, \boldsymbol{\alpha}, \boldsymbol{\beta})$ such that $(\mathcal{S}, \boldsymbol{\alpha})$ and $(\mathcal{S}, \boldsymbol{\beta})$ are handlebody diagrams relative to different sides of $\mathcal{S}$. That is, the 2-handles corresponding to $\boldsymbol{\alpha}$ (resp. $\boldsymbol{\beta}$) are attached to the upper boundary $\mathcal{S} \times \{1\}$ (resp. the *lower boundary* $\mathcal{S} \times \{0\}$) of the thickening $\mathcal{S} \times [0, 1]$. We refer to the curves in $\boldsymbol{\alpha}$ (resp. $\boldsymbol{\beta}$) as *α-curves* (resp. *β-curves*) and assign the same color to each family in illustrations; see Figure 3. A Heegaard diagram $\mathcal{D}$ can naturally be viewed as a 4-regular, surface-embedded graph, obtained geometrically by taking the union of the α- and β-curves and placing a vertex at each crossing.



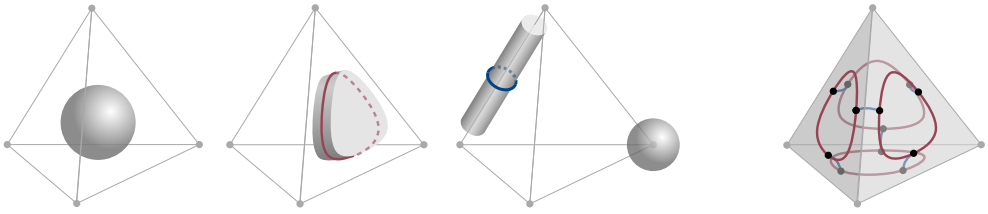


Figure 3 Two Heegaard diagrams of the 3-sphere, and one of the real projective 3-space $\mathbb{RP}^3$.

3 From triangulations to Heegaard diagrams

In this section, we revisit a classical construction that converts a triangulation $\mathcal{T}$ into a corresponding Heegaard diagram $\mathcal{D} = (\mathcal{S}, \boldsymbol{\alpha}, \boldsymbol{\beta})$. We prove that this construction preserves both size and width up to a constant factor, as stated in Theorem 1. Moreover, using standard data structures, the conversion $\mathcal{T} \rightsquigarrow \mathcal{D}$ can be performed in time linear in the size of $\mathcal{T}$. We first review the construction via handles, then prove the inequalities (1a) and (1b) in Theorem 1, and finally discuss the algorithmic aspects of the construction.

Handle decompositions. Any triangulation $\mathcal{T}$ of a 3-manifold $\mathcal{M}$ induces a *canonical handle decomposition* $\mathrm{chd}(\mathcal{T})$ of $\mathcal{M}$, in which the *k-handles* (all 3-balls) correspond to the $(3-k)$-simplices of $\mathcal{T}$. Informally, $\mathrm{chd}(\mathcal{T})$ is the "thickening" of $\mathcal{T}$ (see Figure 4a). For each tetrahedron $\sigma \in \mathcal{T}(3)$, take a 0-handle centered at its barycenter. For each triangle $t \in \mathcal{T}(2)$, attach a 1-handle along a pair of disjoint disks connecting the 0-handles of the tetrahedra incident to t. For each edge $e \in \mathcal{T}(1)$, attach a 2-handle along an annulus to the union of the 0- and 1-handles corresponding to the tetrahedra and triangles incident to e. Finally, for each vertex $v \in \mathcal{T}(0)$, attach a 3-handle along a 2-sphere to fill the void surrounding v.

(a) The building blocks of the canonical handle decomposition $\mathrm{chd}(\mathcal{T})$. Meridian curves of the 1- and the 2-handle are also drawn.

(b) The α- and β-curves of $\mathcal{D}(\mathcal{T})$ restricted to a tetrahedron σ of $\mathcal{T}$.

Figure 4 The canonical handle decomposition and the induced Heegaard diagram.

The Heegaard diagram induced by $\mathcal{T}$. The union $\mathcal{H}_1$ of the 0- and 1-handles and the union $\mathcal{H}_2$ of the 2- and 3-handles of $\mathrm{chd}(\mathcal{T})$ are both handlebodies that together form a Heegaard splitting of the 3-manifold triangulated by $\mathcal{T}$. Letting $\mathcal{S} := \mathcal{H}_1 \cap \mathcal{H}_2$ and taking the meridional curves of the 2-handles and those of the 1-handles as α- and β-curves, respectively (Figure 4a), we obtain the Heegaard diagram $\mathcal{D}(\mathcal{T}) = (\mathcal{S}, \boldsymbol{\alpha}, \boldsymbol{\beta})$, where $\boldsymbol{\alpha} = \{\alpha_e : e \in \mathcal{T}(1)\}$ and $\boldsymbol{\beta} = \{\beta_t : t \in \mathcal{T}(2)\}$. We call $\mathcal{D}(\mathcal{T})$ the *Heegaard diagram induced by the triangulation* $\mathcal{T}$.

Proof of inequalities (1a) and (1b) in Theorem 1. For (1a), note that each triangle of $\mathcal{T}$ contains exactly three vertices of the Heegaard diagram $\mathcal{D} := \mathcal{D}(\mathcal{T})$ induced by $\mathcal{T}$ (Figure 4b), and each tetrahedron has four triangular faces identified in pairs, hence $|V(\mathcal{D})| = 3 \cdot 4n/2 = 6n$. To show (1b), take an optimal tree decomposition $\mathcal{X} = (T, \mathcal{B})$ of $\Gamma(\mathcal{T})$, where $T = (I, F)$ is a tree, $\mathcal{B} = \{B_i : i \in I\}$ is the corresponding set of bags, and $\max\{|B_i| : i \in I\} = \mathrm{tw}(\Gamma(\mathcal{T})) + 1$. We turn $\mathcal{X}$ into a tree decomposition $\mathcal{X}' = (T', \mathcal{B}')$ of $\mathcal{D}$ as follows.

- $T' = T$, i.e., the tree structure of the decomposition remains the same.
- $\mathcal{B}' = \{B'_i : i \in I\}$ and for each $i \in I$, the bag B'_i is obtained from B_i by replacing each $\sigma \in B_i$ with the (at most) 12 vertices of $\mathcal{D}$ incident to σ, see Figure 4b.

Clearly, $|B'_i| \leq 12\,|B_i|$. We now check that $\mathcal{X}' = (T', \mathcal{B}')$ is a tree decomposition of $\mathcal{D}$.

Vertex coverage. Consider a vertex $v \in V(\mathcal{D})$. By construction, there exists a tetrahedron $\sigma \in \mathcal{T}$, such that v is incident to σ. Thus, for any $i \in I$, $v \in B'_i \Leftrightarrow \sigma \in B_i$. However, since $\bigcup_{i \in I} B_i = V(\Gamma(\mathcal{T}))$, this implies $\bigcup_{i \in I} B'_i = V(\mathcal{D})$ as well.

Edge coverage. Let $e = \{u, v\} \in E(\mathcal{D})$ be any arc of the diagram. Again, by construction of $\mathcal{D}$, there exists a tetrahedron $\sigma \in \mathcal{T}$ that entirely contains e. Let B_i be a bag that contains σ. Then B'_i must contain both u and v.

Subtree property. Fix a vertex $v \in V(\mathcal{D})$ and consider $I'_v := \{i \in I : v \in B'_i\}$. We need to show that I'_v spans a connected subtree of $T' = T$. Let $\sigma, \tau \in \mathcal{T}$ be the tetrahedra containing v on their common triangular face (note that σ and τ may coincide) and define $I_\sigma := \{i \in I : \sigma \in B_i\}$ and $I_\tau := \{i \in I : \tau \in B_i\}$. From the definition of $\mathcal{B}'$ it follows that $I'_v = I_\sigma \cup I_\tau$. Since $\mathcal{X}$ is a tree decomposition of $\Gamma(\mathcal{T})$, each of I_σ and I_τ spans a connected subtree in T'. Moreover, $I_\sigma \cap I_\tau \neq \emptyset$: either $\sigma = \tau$, or $\{\sigma, \tau\} \in E(\Gamma(\mathcal{T}))$, so there exists a bag B_j containing both σ and τ. Thus, the connected subtrees spanned by I_σ and I_τ overlap, hence their union I'_v spans a connected subtree as well. ◀

Algorithmic aspects of Theorem 1. We briefly comment on the computational cost of extracting the Heegaard diagram $\mathcal{D}(\mathcal{T})$ from a given triangulation $\mathcal{T}$ with n tetrahedra. Recall that for an *abstract simplicial complex* $\mathcal{C}$, its barycentric subdivision $\mathcal{C}'$ is the simplicial complex whose ground set is $\mathcal{C}$, and a collection $\{\tau_0, \ldots, \tau_k\}$ forms a k-simplex in $\mathcal{C}'$ precisely when the simplices $\tau_i \in \mathcal{C}$ are nested, that is, when $\tau_0 \subset \cdots \subset \tau_k$. Although a triangulation $\mathcal{T}$ is generally not a simplicial complex, we can still form its barycentric subdivision by first subdividing each tetrahedron and then applying the gluing maps to identify the subdivided triangular faces. Performed twice, the resulting complex $\mathcal{T}''$ naturally contains both the canonical handle decomposition $\mathrm{chd}(\mathcal{T})$ and the induced Heegaard diagram $\mathcal{D}(\mathcal{T})$. As the barycentric subdivision of a tetrahedron contains 24 tetrahedra, $|\mathcal{T}''| = 24^2 |\mathcal{T}| = 576 |\mathcal{T}|$.

Extracting $\mathrm{chd}(\mathcal{T})$ from $\mathcal{T}''$. Every vertex v of $\mathcal{T}'$ is of the form $v = \{\tau\}$ for some simplex $\tau \in \mathcal{T}$. Let $\iota \colon \mathcal{T}'(0) \hookrightarrow \mathcal{T}''(0)$ be the natural inclusion defined by $\iota(\{\tau\}) = \{\{\tau\}\}$. For every $w \in \mathrm{im}(\iota)$, let h_w be the smallest subcomplex of $\mathcal{T}''$ containing all 3-faces incident to w. If w corresponds to a simplex $\sigma \in \mathcal{T}$ of dimension $3 - k$, then h_w is regarded as a k-handle. The collection $\{h_w : w \in \mathrm{im}(\iota)\}$ forms the canonical handle decomposition $\mathrm{chd}(\mathcal{T})$. See Figure 5.

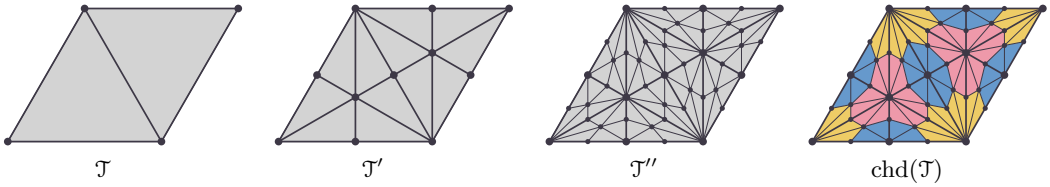

Figure 5 A 2-dimensional triangulation $\mathcal{T}$ with two triangles, its first and second barycentric subdivisions $\mathcal{T}'$ and $\mathcal{T}''$ (regarded geometrically), and the canonical handle decomposition chd($\mathcal{T}$).

Extracting $\mathcal{D}(\mathcal{T})$ from $\mathcal{T}''$. To extract the induced Heegaard diagram $\mathcal{D}(\mathcal{T})$ from $\mathcal{T}''$, we need to pinpoint its α- and β-curves, as well as the splitting surface $\mathcal{S}$ in $\mathcal{T}''$. We illustrate this via concrete examples; see Figure 6. We start with the α-curves. Let $e \in \mathcal{T}(1)$ be an edge of $\mathcal{T}$, and assume that e is contained in four distinct tetrahedra $\sigma_1, \sigma_2.\sigma_3, \sigma_4$ of $\mathcal{T}$. Let t_{ij} denote the triangular face shared by σ_i and σ_j. Consider the subcomplex C_e of $\mathcal{T}'$ spanned by the nine vertices $\{e\}, \{\sigma_1\}, \{\sigma_2\}, \{\sigma_3\}, \{\sigma_4\}, \{t_{12}\}, \{t_{23}\}, \{t_{34}\}$, and $\{t_{14}\}$. This complex C_e triangulates the *dual 2-cell transverse to* e (Figure 6, top left). Taking the second barycentric subdivision $\mathcal{T}''$ (Figure 6, top middle), we see that the α-curve α_e corresponding to e is readily obtained as the polygonal curve spanned by the vertices of C'_e adjacent to $\{\{e\}\}$ (Figure 6, top right). The β-curves can be located analogously (Figure 6, bottom row).

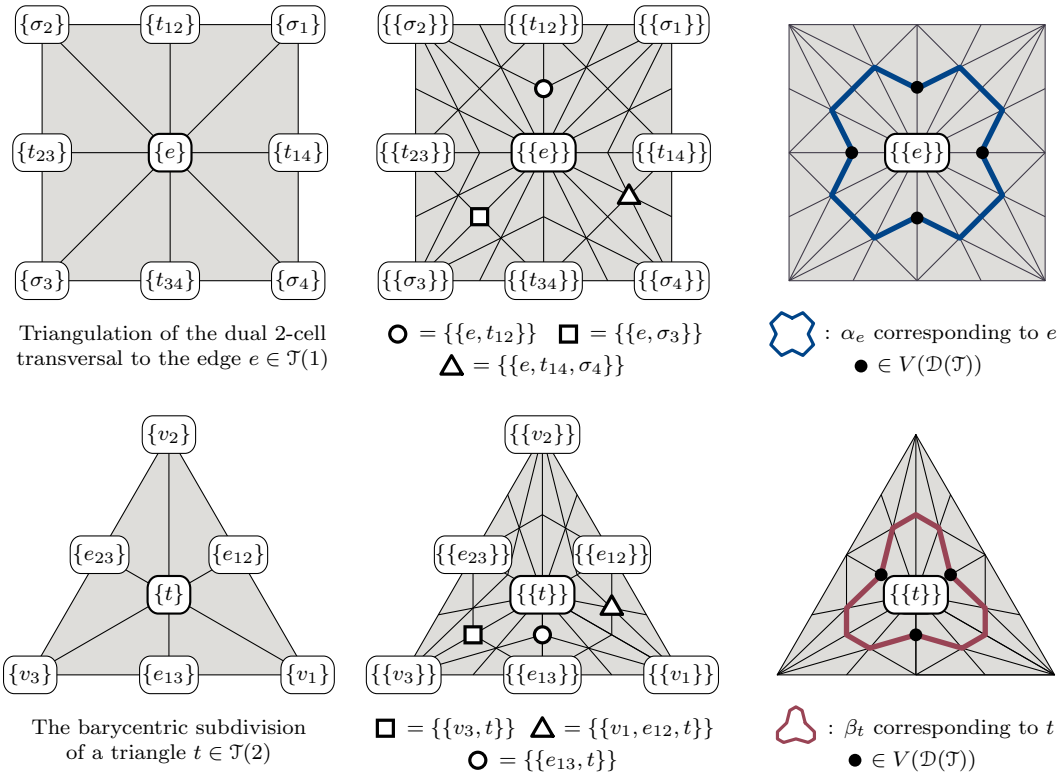

Figure 6 Locating the α- and β-curves $\mathcal{D}(\mathcal{T})$ in the second barycentric subdivision $\mathcal{T}''$ of $\mathcal{T}$.

A triangulation of the splitting surface $\mathcal{S}$ can also be readily obtained as the boundary of the subcomplex of $\mathcal{T}''$ formed by the union of the triangulated 2- and 3-handles of chd($\mathcal{T}$). Using standard data structures to represent these objects (such as in `Regina` [4]), all of these operations can be performed in linear time in terms of $n = |\mathcal{T}|$.

▶ Remark 4. Often it is assumed – and in certain applications even required, cf. [24] – that a Heegaard diagram $\mathcal{D} = (\mathcal{S}, \boldsymbol{\alpha}, \boldsymbol{\beta})$ be *minimal*, i.e. $|\boldsymbol{\alpha}| = |\boldsymbol{\beta}| = g(\mathcal{S})$. In our setting, we can ensure this by first choosing arbitrary spanning trees T_1 and T_2 for the 1-skeleton $\mathcal{T}^{(1)}$ and the dual graph $\Gamma(\mathcal{T})$ of $\mathcal{T}$, respectively, and then retaining only those α-curves (resp. β-curves) that correspond to edges of $\mathcal{T}^{(1)}$ (resp. $\Gamma(\mathcal{T})$) *not* contained in T_1 (resp. T_2).

4 Retriangulating with constant edge valence and controlled treewidth

In this section, we describe and analyze a quasi-linear time procedure that retriangulates any 3-manifold triangulation $\mathcal{T}$ into a triangulation $\mathcal{T}^*$ with maximum edge valence at most 9 and treewidth increased only by a polylogarithmic factor of the original maximum edge valence.

▶ **Theorem 5** (Theorem 2; with explicit polylog-factors)**.** *There is an algorithm which, given a triangulation $\mathcal{T}$ of a closed 3-manifold $\mathcal{M}$ with n tetrahedra, $\mathbf{v}$ vertices, $\mathrm{tw}(\Gamma(\mathcal{T})) = \mathbf{tw}$, and maximum edge valence $\Delta(\mathcal{T}) = \boldsymbol{\Delta}$, yields a triangulation $\mathcal{T}^*$ of $\mathcal{M}$ with $O((n+\mathbf{v})\log_2(\boldsymbol{\Delta})^{5.32})$ vertices and tetrahedra, $\mathrm{tw}(\Gamma(\mathcal{T}^*)) < (\mathbf{tw}+1)\cdot\log_2(\boldsymbol{\Delta})^{5.17}$, and $\Delta(\mathcal{T}^*) \leq 9$. The algorithm runs in $O(n \log\log n)$ time.*

The construction in Theorem 5 is based on an iterative application of the following result.

▶ **Theorem 6.** *There is an algorithm which, given a triangulation $\mathcal{T}$ of a closed 3-manifold $\mathcal{M}$ with n tetrahedra, $\mathbf{v}$ vertices, $\mathrm{tw}(\Gamma(\mathcal{T})) = \mathbf{tw}$, and $\Delta(\mathcal{T}) = \boldsymbol{\Delta}$, constructs a triangulation $\mathcal{T}^*$ of $\mathcal{M}$ with at most $(28+4\sqrt{6})n + (16+4\sqrt{6})\mathbf{v}$ tetrahedra, $(6+\sqrt{6})(n+\mathbf{v})$ vertices, $\Delta(\mathcal{T}^*) \leq \max\{\lfloor\sqrt{\boldsymbol{\Delta}}\rfloor + 4, 9\}$, and $\mathrm{tw}(\Gamma(\mathcal{T}^*)) \leq 36\cdot\mathbf{tw}$. The algorithm runs in $O(n)$ time.*

The proof of Theorem 6 is the core of this section. We prove Theorem 5 at the end of it.

Setup. Let us fix a triangulation $\mathcal{T}$ of a closed 3-manifold $\mathcal{M}$ with n tetrahedra, $|\mathcal{T}(0)| = \mathbf{v}$ vertices, treewidth $\mathrm{tw}(\Gamma(\mathcal{T})) = \mathbf{tw}$, and maximum edge valence $\Delta(\mathcal{T}) = \boldsymbol{\Delta}$. Let $S = S(\mathcal{T})$ be the *spine of* $\mathcal{M}$ *dual to* $\mathcal{T}$. It is a 2-dimensional polyhedral cell complex whose 1-skeleton $S^{(1)}$ is the dual graph $\Gamma(\mathcal{T})$, and for each edge $e \in \mathcal{T}(1)$, S contains a polygonal 2-face F_e glued along the cycle in $\Gamma(\mathcal{T})$ formed by the vertices corresponding to the tetrahedra that contain e. Locally, at each tetrahedron of $\mathcal{T}$, the spine S looks like the configuration shown in Figure 7.

▶ Remark. Spines, and in particular *special spines*, offer a perspective on 3-manifolds that is dual to that provided by triangulations. We refer to [32, Chapter 1] and [37] for details.

Overall strategy. Note that, given the spine S, we can recover $\mathcal{M}$ by first thickening S and then filling in the resulting 2-sphere boundary components with 3-balls (which may be viewed as centered at the vertices of $\mathcal{T}$). In what follows, we triangulate S and fill in these missing balls combinatorially. Throughout, the term 2-*face* refers to the faces of the spine S, whereas *triangle* refers to the faces of the triangulation. Our strategy is similar to that of [13, Theorem 3.36], but we employ a different – and necessarily more intricate – triangulation of the 2-faces of S in order to control the treewidth of the resulting triangulation.

Triangulating the faces of S. Consider a 2-face $F := F_e$ of the spine S transverse to an edge $e \in \mathcal{T}(1)$. This face F is a k-gon, where $k = \mathrm{val}(e)$, whose vertices are the centers of the tetrahedra of $\mathcal{T}$ containing e. We triangulate F as follows (see Figure 8). If $k \leq 9$, we add a vertex w at the center of F and connect it to all boundary vertices, as in Figure 8 (left). If $k > 9$, we proceed as follows. Fix an arbitrary orientation of the boundary of F, and choose positive integers $m := m_F$ and $d := d_F$ such that $k \leq m(d-1)$. Label the boundary vertices

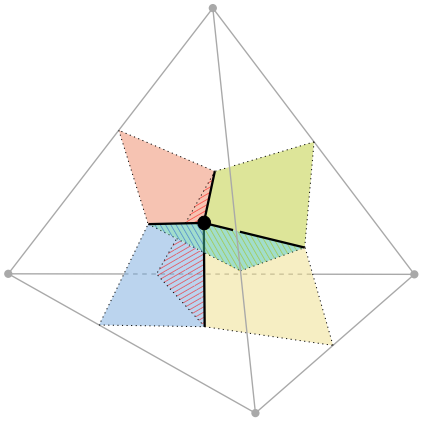

Figure 7 The intersection of the spine S with a tetrahedron of $\mathcal{T}$. The vertices of S bijectively correspond to the centers of tetrahedra of $\mathcal{T}$, and each 2-face of S is transverse to an edge of $\mathcal{T}$.

$u_0, \dots, u_{k-1}$ in accordance with this orientation. Introduce a ring of m interior vertices $v_0, \dots, v_{m-1}$, and connect each v_i to v_{i-1} and v_{i+1} (indices $\mod m$). For each $0 \le i < m-1$, connect v_i to the boundary vertices $u_{i(d-1)}, \dots, u_{(i+1)(d-1)}$. The final interior vertex v_{m-1} is connected to $u_{(m-1)(d-1)}, \dots, u_{k-1}, u_0$. The inequalities $(m-1)(d-1) < k \le m(d-1)$ ensure that the vertices u_i and v_ℓ, together with these edges, form a triangulated annulus. Finally, we place a central vertex w inside F and connect it to all v_i, see Figure 8 (right).

The next proposition follows directly from this construction; k, m, and d are as above.

▶ **Proposition 7.** *The triangulation of the 2-face F described above consists of $k + 2m$ triangles. Each boundary vertex u_i is incident to 3 or 4 edges, each interior vertex v_j is incident to at most $d+3$ edges, and the central vertex w is incident to m edges. In particular, the maximum degree of a vertex in the 1-skeleton of F is $\max\{m, d+3\}$.*

Building the triangulation $\mathcal{T}^*$ in Theorem 6. Let $\mathcal{T}_S$ denote the triangulation of the spine S obtained by triangulating each 2-face F of S as described above. We construct the triangulation $\mathcal{T}^*$ by first taking $\mathcal{T}_S$, considered as embedded in the geometric realization $\|\mathcal{T}\|$ of $\mathcal{T}$, and then adding the vertices $\mathcal{T}(0)$. Each vertex $a \in \mathcal{T}(0)$ lies in the interior of a connected component of $\|\mathcal{T}\| \setminus S$, which is an open 3-ball denoted by B_a. Its boundary $\partial B_a := \overline{B_a} \setminus B_a$ is a subpolyhedron of S comprised of certain 2-faces of S. Let $\mathcal{T}_{\partial B_a}$ denote the subtriangulation of $\mathcal{T}_S$ formed by the union of the triangulations of these 2-faces of S. To complete the construction, for each $a \in \mathcal{T}(0)$ we cone over $\mathcal{T}_{\partial B_a}$ from the vertex a. We denote the resulting triangulation by $\mathcal{T}^*$. By construction, $\mathcal{T}^*$ triangulates $\mathcal{M}$.

▶ Remark. In the above construction, for each 2-face F we fix integers $m = m_F$ and $d = d_F$ that depend solely on the number of boundary vertices u_i of F in S, or equivalently, on the valence of the edge of $\mathcal{T}$ transverse to F. When the context requires, we write d_F and m_F.

▶ **Definition 8** (type of a vertex of $\mathcal{T}^*$)**.** *The vertices of $\mathcal{T}^*$ fall into the following three* types. **1.** *vertices $a \in \mathcal{T}(0)$,* **2.** *vertices u_i lying on the boundary of exactly six 2-faces of S, and* **3.** *vertices v_ℓ and w lying in the interior of exactly one 2-face of S.*

We proceed with investigating the maximum edge valence and the treewidth of $\mathcal{T}^*$.

▶ **Lemma 9.** *The triangulation $\mathcal{T}^*$ has edge valences at most $\max_{F \in S} \max\{d_F + 3, m_F, 9\}$.*

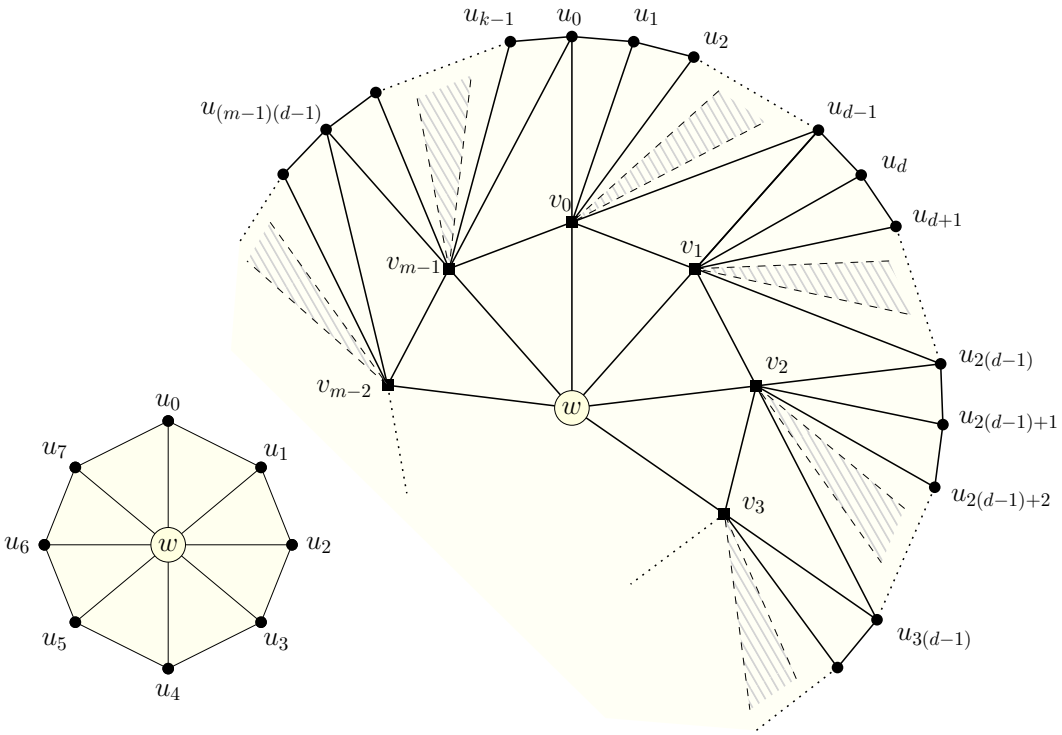

Figure 8 Triangulating a 2-face F (a k-gon) of the spine S of $\mathcal{T}$ if $k \leq 9$ (left) and if $k > 9$ (right).

Proof. We consider, case by case, the different types of edges in $\mathcal{T}^*$. Let a denote a vertex of $\mathcal{T}(0)$, and let u_i, v_ℓ, and w denote vertices in a 2-face F, see Figure 8. (We keep this labeling convention throughout this section.) The next valence-bounds follow from Proposition 7.

Type $\{a, w\}$. The valence of the edge of this type is equal to the degree of w in the triangulation of the 2-face, i.e., $\mathrm{val}(\{a, w\}) = m$.

Type $\{a, v_\ell\}$. The valence of the edge of this type is equal to the degree of v_ℓ in the triangulation of the 2-face, i.e., $d + 3$.

Type $\{a, u_i\}$. is incident to at most 3 tetrahedra per 2-face containing u_i, and there are at most three 2-faces containing u_i and bounding the ball containing a, so $\mathrm{val}(\{a, u_i\}) \leq 9$.

Type $\{w, v_\ell\}$ or $\{v_\ell, u_i\}$. are incident to at most 4 tetrahedra, two on either side of F,

Type $\{u_i, u_{i+1}\}$. is incident to one tetrahedra $\{a, v_\ell, u_i, u_{i+1}\}$ per 2-face that contains it, and is contained in at most three 2-faces, therefore $\mathrm{val}(\{u_i, u_{i+1}\}) \leq 3$.

Hence, for the maximum edge valence of $\mathcal{T}^*$ we have $\Delta(\mathcal{T}^*) \leq \max\{d_F + 3, m_F, 9\}$. ◀

▶ **Lemma 10.** *The dual graph of the triangulation $\mathcal{T}^*$ has treewidth* $\mathrm{tw}(\Gamma(\mathcal{T}^*)) < 36 \cdot (\mathbf{tw} + 1)$.

Proof. Consider a tree decomposition $\mathcal{X} = (T, \mathcal{B})$ of the graph $\Gamma(\mathcal{T})$ with optimal width $\mathbf{tw}$.

By construction, every tetrahedron of $\mathcal{T}^*$ contains a vertex of $\mathcal{T}(0)$ and at least one triangle from the triangulation of a 2-face F of S. Following the notation of Figure 8, these triangles are of the form $\{v_\ell, u_{i-1}, u_i\}$, $\{v_{\ell-1}, u_{\ell(d-1)}, v_{\ell+1}\}$, or $\{w, v_{\ell-1}, v_\ell\}$. For any 2-face of S, the boundary vertices $u_0, \ldots, u_{k-1}$ correspond to nodes of the graph $\Gamma(\mathcal{T})$, and consequently each of them appears in some bag of this tree decomposition $\mathcal{X}$.

We now construct a tree decomposition $\mathcal{X}' = (T, \mathcal{B}')$ for the dual graph of $\mathcal{T}^*$, with the same underlying tree T as for $\mathcal{X}$ and $\mathcal{B}' = \{B'_\tau : \tau \in V(T)\}$. We initialize B'_τ as $B'_\tau = \emptyset$ for all $\tau \in V(T)$, and consider all types of tetrahedra σ in $\mathcal{T}^*$:

1. If σ has a triangular face $\{v_\ell, u_{i-1}, u_i\}$, then add σ to all bags B'_τ such that $u_{i-1} \in B_\tau$.
2. If σ has a face $\{v_{\ell-1}, u_{\ell(d-1)}, v_{\ell+1}\}$, then add σ to all bags B'_τ such that $u_{\ell(d-1)} \in B_\tau$. Similarly, for $\sigma = \{a, v_{m-1}, u_0, v_0\}$, add σ to all bags B'_τ such that $u_0 \in B_\tau$.
3. If σ has a face $\{w, v_{\ell-1}, v_\ell\}$, then add σ to all bags B'_τ such that B_τ contains any u_i with $\ell(d-1) \le i < \max\{(\ell+1)(d-1), k-1\}$.

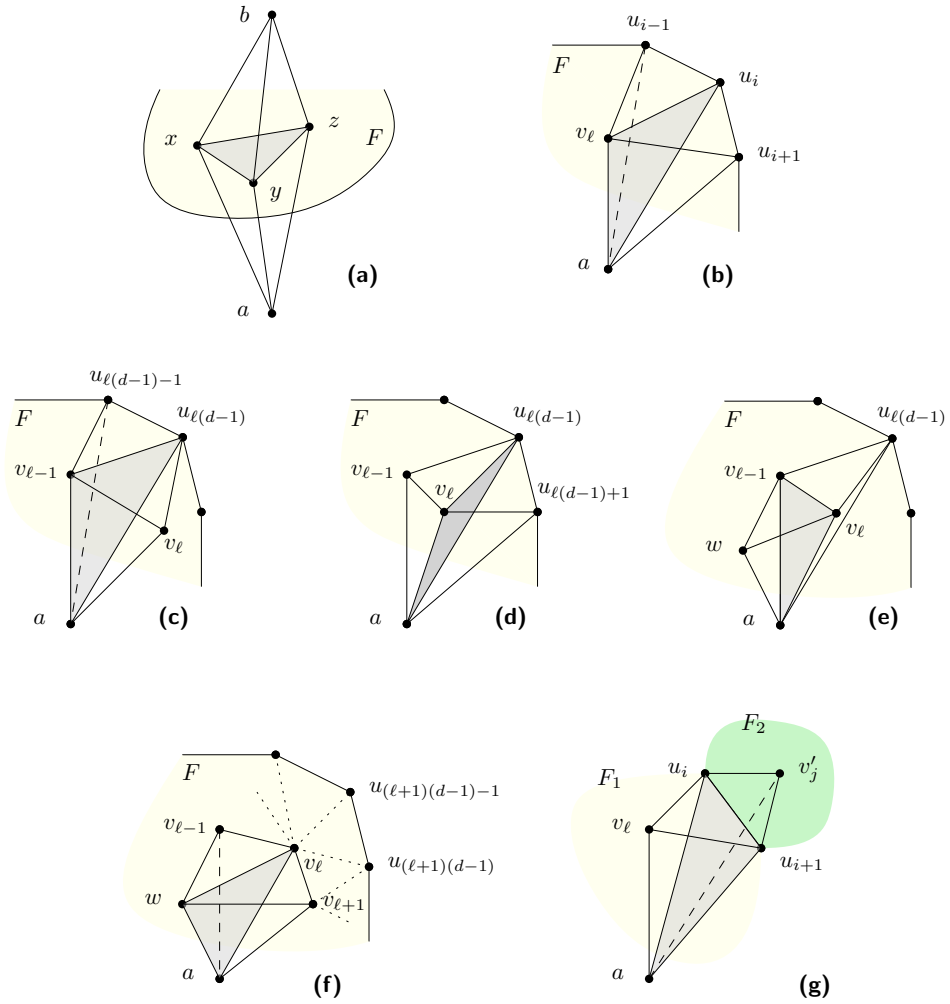

Figure 9 Illustrations of 7 possible triangles shared by tetrahedra in $\mathcal{T}^*$ from the proof of Claim 11.

▷ Claim 11. $\mathcal{X}' = (T, \mathcal{B}')$ is a valid tree decomposition of the dual graph $\Gamma(\mathcal{T}^*)$ of $\mathcal{T}^*$.

Proof. We verify the three defining properties of a tree decomposition (Section 2.1).

Vertex coverage. By construction, any tetrahedron of $\mathcal{T}^*$ contains a triangle from a 2-face F of the spine S, and in consequence appears in some bag of $\mathcal{X}' = (T, \mathcal{B}')$.

Edge coverage. Showing that every edge of $\mathcal{T}^*$ is contained in some bag of $\mathcal{X}'$ can be carried out by a tedious case analysis. In the triangulation $\mathcal{T}^*$, two tetrahedra may be adjacent

along seven types of shared triangles, classified by the types of the triangle's vertices; all possible configurations are shown in Figure 9. See the full version [18] for all the details.

Subtree property. By **1** and **2**, tetrahedra of type $\{a, v_\ell, u_i, u_{i+1}\}$, $\{a, v_{\ell-1}, u_{\ell(d-1)}, v_\ell\}$ and $\{a, v_{m-1}, u_0, v_0\}$ appear exactly in the bags B'_τ such that B_τ contain a certain fixed tetrahedron (respectively u_i, $u_{\ell(d-1)}$, and u_0); the bags containing them are consequently connected in σ. By **3**, a tetrahedron σ of type $\{a, w, v_{\ell-1}, v_\ell\}$ is inserted in all bags B'_τ such that B_τ contains any u_i with $\ell(d-1) \leq i < (\ell+1)(d-1)$. Call T_i the subtree of T spanned by the nodes τ such that $u_i \in B_\tau$ in $\mathcal{X}$. The subtree of T spanned by the nodes τ in $\mathcal{X}'$ such that $\sigma \in B_\tau$ is, in consequence, $\cup_{\ell(d-1)\leq i<(\ell+1)(d-1)} T_i$. Because $\mathcal{X}$ is a tree decomposition, each T_i is connected. Additionally, for any i, u_i and u_{i+1} are adjacent, and must consequently appear in a common bag of $\mathcal{X}$. Hence $T_i \cap T_{i+1} \neq \emptyset$. In consequence, $\cup_{\ell(d-1)\leq i<(\ell+1)(d-1)} T_i$ is a connected subtree of σ. ◁

▷ Claim 12. $\mathcal{X}' = (T, \mathcal{B}')$ has width less than $36 \cdot (\mathbf{tw} + 1)$.

Proof. Let B_τ be a bag of $\mathcal{X}$ of size r. Every occurrence of a tetrahedron u_i in B_τ will induce the insertion of at most 6 tetrahedra in B'_τ, per 2-face incident to u_i, namely tetrahedra $(\star, v_\ell, u_i, u_{i+1}\}$, tetrahedra $(\star, v_\ell, u_i, v_{\ell+1}\}$ if $i = \ell(d-1)$ or $i = 0$, and tetrahedra $(\star, w, v_{\ell-1}, v_\ell\}$ with $\ell(d-1) \leq i \leq \max\{(\ell+1)(d-1)-1, k-1\}$; where $\star$ indicates at most two possible vertices a and b of $\mathcal{T}(0)$, on either side of the 2-face. Adding the fact that at most six 2-faces are incident to a given tetrahedron u_i, the size of a bag B'_τ is at most 36 times the size of B_τ. In consequence, the width of $\mathcal{X}'$ is at most $36 \cdot (\mathbf{tw} + 1) - 1$. This concludes the proofs of Claim 12 and Lemma 10. ◁

From now on, for the 2-face F_e transverse to the edge $e \in \mathcal{T}(1)$ with valence $k = \mathrm{val}(e)$, we set $m := \lfloor\sqrt{\mathrm{val}(e)}\rfloor + 4$ and $d := \lfloor\sqrt{\mathrm{val}(e)}\rfloor + 1$, which satisfy the condition $k \leq m(d-1)$ whenever $\mathrm{val}(e) > 6$. The next two lemmas provide bounds on the number of tetrahedra (Lemma 13) and the number of vertices (Lemma 14) in $\mathcal{T}^*$. These rely on standard counting arguments for triangulations; see the full version [18].

▶ **Lemma 13.** *The triangulation $\mathcal{T}^*$ has at most $(28 + 4\sqrt{6})n + (16 + 4\sqrt{6})\mathbf{v}$ tetrahedra.*

Proof. Each 2-face, transversal to an edge e of valence $\mathrm{val}(e)$, contributes to $2(k + 2m) = 2\,\mathrm{val}(e) + 4(\lfloor\sqrt{\mathrm{val}(e)}\rfloor + 4)$ tetrahedra ($k + 2m$ triangles in the transversal 2-face F, holding a tetrahedron on either side of F). In consequence,

$$\sum_{e\in\mathcal{T}(1)} (2\,\mathrm{val}(e) + 4(\lfloor\sqrt{\mathrm{val}(e)}\rfloor + 4)) \underbrace{\leq}_{\text{[18, Lem. 24, Cor. 25]}} 12n + 16(n+\mathbf{v}) + 4\sum_e \sqrt{\mathrm{val}(e)} \underbrace{\leq}_{\text{[18, Lem. 26]}} 12n + 16(n+\mathbf{v}) + 4\sqrt{6}(n+\mathbf{v}).$$

◀

▶ **Lemma 14.** *The triangulation $\mathcal{T}^*$ has at most $(6 + \sqrt{6})(n + \mathbf{v})$ vertices.*

Proof. By construction, the vertex set $\mathcal{T}^*(0)$ consist of the vertices $\mathcal{T}(0)$, the vertices u_i (lying on the boundaries of the 2-faces), and, for each $e \in \mathcal{T}(1)$, the $\lfloor\sqrt{\mathrm{val}(e)}\rfloor + 5$ interior vertices on the triangulated 2-face F_e. The vertices u_i are in bijection with the tetrahedra of $\mathcal{T}$, hence there are exactly n of them. The total number of interior vertices over all 2-faces is

$$\sum_{e\in\mathcal{T}(1)} \left(\lfloor\sqrt{\mathrm{val}(e)}\rfloor + 5\right) \underbrace{\leq}_{\text{[18, Lemmas 24, 26]}} (\sqrt{6}+5)(n+\mathbf{v}).$$

With $|\mathcal{T}(0)| = \mathbf{v}$ and the n vertices u_i, this gives at most $(6 + \sqrt{6})(n + \mathbf{v})$ vertices in $\mathcal{T}^*$. ◀

We are now ready to prove the main theorems of this section.

Proof of Theorem 6. If the maximum edge valence of $\mathcal{T}$ is at most 9, the algorithm simply returns $\mathcal{T}^* := \mathcal{T}$. Otherwise, we apply the construction described above; the bounds on the number of tetrahedra, the number of vertices, the treewidth, and the edge valence follow from Lemmas 13, 14, 10, and 9, respectively. Note that the construction runs in time linear in the size of $\mathcal{T}^*$, which is $O(n)$. ◀

Finally, the proof of Theorem 5 relies on standard calculations involving geometric series and iterated radicals, as detailed in the full version [18].

Proof of Theorem 5. If the maximum edge valence of $\mathcal{T}$ satisfies $\Delta(\mathcal{T}) \leq 9$, we are done. Otherwise, we construct a sequence of triangulations $\mathcal{T} = \mathcal{T}_0, \mathcal{T}_1, \ldots, \mathcal{T}_p$ by iterating the construction of Theorem 6. The triangulation $\mathcal{T}_r$ has $O((30+4\sqrt{6})^r(n+\mathbf{v}))$ tetrahedra and vertices [18, Lemma 23], treewidth $\mathrm{tw}(\Gamma(\mathcal{T}_r)) < 36^r \cdot (\mathbf{tw}+1)$ (Lemma 10), and maximum edge valence $\Delta(\mathcal{T}_r) \leq \max\{a_r, 9\}$ (Lemma 9, with $m = \lfloor\sqrt{\mathrm{val}(e)}\rfloor + 4$ and $d = \lfloor\sqrt{\mathrm{val}(e)}\rfloor + 1$), where $(a_r)_{r\in\mathbb{N}}$ is the sequence of iterated radicals of [18, Lemma 21], with $a_0 = \mathbf{\Delta}$, $c = 4$, and $L < 6.32$. By [18, Lemma 22], choosing $p = \log_2 \log_2(\mathbf{\Delta})$ ensures that the edge valence of $\mathcal{T}_p$ is at most 9. We therefore set $\mathcal{T}^* := \mathcal{T}_p$. Since $\log_2(30+4\sqrt{6}) < 5.32$ and $\log_2(36) < 5.17$, the triangulation $\mathcal{T}^*$ has $O((n+\mathbf{v})\log_2(\mathbf{\Delta})^{5.32})$ tetrahedra and vertices, treewidth at most $(\mathbf{tw}+1)\cdot\log_2(\mathbf{\Delta})^{5.17}$, and edge valence at most 9. The algorithm performs $O(\log\log(n))$ iterations of the algorithm of Theorem 6, yielding the stated complexity bound. ◀

5 Efficient evaluation of Kuperberg's tensor networks

In this section we present a fixed-parameter tractable (FPT) scheme for computing Kuperberg's quantum invariants $\sharp(\vec{\mathcal{D}}, \mathcal{H})$ of closed, oriented[10] 3-manifolds [23]. This quantity depends on an oriented Heegaard diagram[11] $\vec{\mathcal{D}} = (\vec{\mathcal{S}}, \vec{\boldsymbol{\alpha}}, \vec{\boldsymbol{\beta}})$ and a finite-dimensional involutory Hopf algebra $\mathcal{H}$ over a field $\mathbb{F}$, which is considered fixed. By construction, $\sharp(\vec{\mathcal{D}}, \mathcal{H}) \in \mathbb{F}$.

▶ Remark. We emphasize that understanding the results in this section does **not** require knowledge of Hopf algebras or tensors, since the following proofs are purely graph theoretical. Nevertheless, we provide some basic definitions and examples in the full version [18]. We refer to Kuperberg's paper [23] (cf. its open-access version [22]) for further details.

Even if $\sharp(\vec{\mathcal{D}}, \mathcal{H})$ is originally derived from an oriented Heegaard diagram, it can also be computed from an oriented triangulation. This is briefly hinted at in [23, Section 4], however, with the machinery developed in Section 3 we can make it fully explicit: Any triangulation $\mathcal{T}$ of a 3-manifold $\mathcal{M}$ gives rise to a Heegaard diagram $\mathcal{D} = (\mathcal{S}, \boldsymbol{\alpha}, \boldsymbol{\beta})$ of $\mathcal{M}$, moreover, in a width-preserving way (Theorem 1). Picking an orientation for $\mathcal{T}$ induces an orientation also for $\mathcal{S}$. Then choosing orientations for the α- and β-curves arbitrarily yields an oriented diagram $\vec{\mathcal{D}}$. Next, from $\vec{\mathcal{D}}$ we build a *tensor network* $\mathcal{K}$ following Kuperberg's construction [23, Section 5], which we finally *evaluate* to obtain $\sharp(\vec{\mathcal{D}}, \mathcal{H})$. From now on, we will use the notation $\sharp(\vec{\mathcal{T}}, \mathcal{H}) := \sharp(\vec{\mathcal{D}}, \mathcal{H})$ to indicate when we regard the invariant as computed from a triangulation, where $\vec{\mathcal{D}}$ denotes the oriented Heegaard diagram induced by $\vec{\mathcal{T}}$.

[10] In this section we assume $\mathcal{M}$ to be an *oriented*, not merely orientable, 3-manifold.

[11] An *oriented Heegaard diagram* is a Heegaard diagram $\mathcal{D} = (\mathcal{S}, \boldsymbol{\alpha}, \boldsymbol{\beta})$ together with an orientation for the surface $\mathcal{S}$ and for each of the α- and β-curves. The quantity $\sharp(\vec{\mathcal{D}}, \mathcal{H})$ does not depend on the choice of orientation for the α- and β-curves, however, it generally does depend on the chosen orientation for $\mathcal{S}$.

Building on Theorem 1 and bounding the treewidth of the tensor network $\mathcal{K}$ (Lemma 18), together with work of O'Gorman [34] (cf. Markov–Shi [31]) we prove the following result:

▶ **Theorem 15.** *Let $\mathcal{H}$ be a fixed finite-dimensional involutory Hopf algebra over a field $\mathbb{F}$. Let $\vec{\mathcal{T}}$ be an oriented triangulation of a closed oriented 3-manifold with n tetrahedra and treewidth $\mathrm{tw}(\vec{\mathcal{T}}) := \mathrm{tw}(\Gamma(\vec{\mathcal{T}})) = t$. The invariant $\sharp(\vec{\mathcal{T}}, \mathcal{H})$ can be computed in time $O(2^{O(t)}n)$.*

Before discussing the proof of Theorem 15 in detail, we provide an overview on Figure 10.

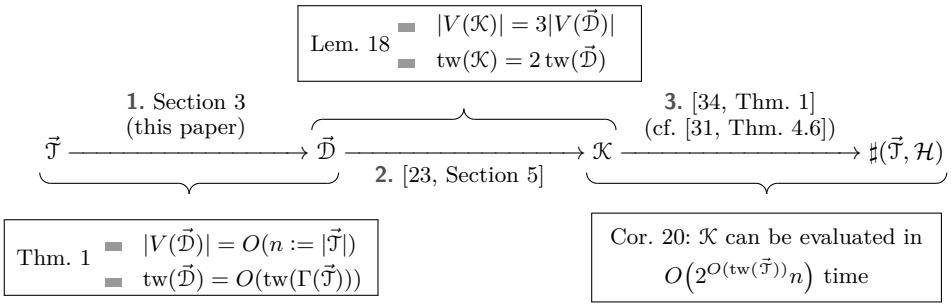

Figure 10 The algorithmic pipeline of computing $\sharp(\vec{\mathcal{T}}, \mathcal{H})$ from an oriented triangulation $\vec{\mathcal{T}}$. The references on the arrows provide the theoretical backbone, and the framed results indicate our contributions. The running time of the computation is dominated by that of step **3.** $\mathcal{K} \longrightarrow \sharp(\vec{\mathcal{T}}, \mathcal{H})$.

▶ Remark 16. Theorem 15 asserts that computing $\sharp(\vec{\mathcal{T}}, \mathcal{H})$ is FPT in the treewidth of $\vec{\mathcal{T}}$. In particular, for bounded-treewidth triangulations it can be computed in linear time. However, since tensor network contraction – the last part of the computation – is generally $\sharp\mathbf{P}$-hard [10], we expect this to hold for computing $\sharp(\vec{\mathcal{T}}, \mathcal{H})$ for general triangulations as well.

As motivation, let us recall the formula for the invariant $\sharp(\vec{\mathcal{D}}, \mathcal{H})$ from [23, Section 5]:

$$\sharp(\vec{\mathcal{D}}, \mathcal{H}) := \mathcal{Z}(\vec{\mathcal{D}}, \mathcal{H}) \cdot \dim_{\mathbb{F}}(\mathcal{H})^{g(\mathcal{S})-|\boldsymbol{\alpha}|-|\boldsymbol{\beta}|}. \tag{2}$$

Here $g(\mathcal{S})$ is the genus of the surface $\mathcal{S}$, and $|\boldsymbol{\alpha}|$ and $|\boldsymbol{\beta}|$ denote the number of α- and β-curves of $\vec{\mathcal{D}}$, respectively. The "complicated" term $\mathcal{Z}(\vec{\mathcal{D}}, \mathcal{H}) \in \mathbb{F}$ is defined as the *evaluation* $\mathcal{Z}(\mathcal{K})$ of a specific *tensor network* $\mathcal{K}$ associated to $\vec{\mathcal{D}}$, built from (several copies of) the *structure tensors* of the Hopf algebra $\mathcal{H}$. We now very briefly and selectively review these notions.

Hopf algebras and their structure tensors. A *Hopf algebra* $\mathcal{H}$ is a vector space $\boldsymbol{H}$ over a field $\mathbb{F}$ together with three $\mathbb{F}$-linear maps $\mathsf{M}\colon \boldsymbol{H} \otimes \boldsymbol{H} \to \boldsymbol{H}$ (*multiplication*), $\Delta\colon \boldsymbol{H} \to \boldsymbol{H} \otimes \boldsymbol{H}$ (*comultiplication*) and $\mathsf{S}\colon \boldsymbol{H} \to \boldsymbol{H}$ (*antipode*) satisfying certain axioms (cf. [23, Section 3]). We will assume that $\dim_{\mathbb{F}}(\boldsymbol{H}) < \infty$ and $\mathcal{H}$ is *involutory*, i.e., $\mathsf{S} \circ \mathsf{S} = \mathrm{id}_{\boldsymbol{H}}$. The maps M, Δ and S can be regarded as tensors of type $(1,2)$, $(2,1)$ and $(1,1)$, respectively, see Figure 11.

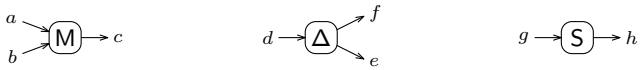

Figure 11 The multiplication, comultiplication and antipode tensors represented as *coupons*.

▶ **Example 17.** The *group algebra* $\mathcal{G} = \mathbb{F}G$ of a finite group G is naturally a Hopf algebra: the multiplication is defined as $\mathsf{M}(g \otimes h) = gh$, the comultiplication as $\Delta(g) = g \otimes g$, and the antipode as $\mathsf{S}(g) = g^{-1}$. In [23, Sections 1 and 6] it is shown that $\sharp(\vec{\mathcal{D}}, \mathcal{G})$ equals the number of homomorphisms $\pi_1(\mathcal{M}) \to G$ from the fundamental group of the 3-manifold $\mathcal{M}$ described by $\vec{\mathcal{D}}$ to the group G. (In this case $\sharp(\vec{\mathcal{D}}, \mathcal{G})$ is independent of the chosen orientation for $\mathcal{D}$.)

5.1 Kuperberg's construction and the proof of Theorem 15

Following [23, Section 5], first we explain how the tensor network $\mathcal{K}$ – whose evaluation $\mathcal{Z}(\mathcal{K}) =: \mathcal{Z}(\vec{\mathcal{D}}, \mathcal{H})$ appears in (2) – is constructed from an oriented Heegaard diagram $\vec{\mathcal{D}}$. Then we prove Lemma 18, which – together with Theorem 19 – implies Theorem 15.

The construction of $\mathcal{K}$. As already mentioned, the building blocks of $\mathcal{K}$ are the structure tensors M, Δ and S of the Hopf algebra $\mathcal{H}$ (Figure 11). The shorthands in Figure 12 – which are justified by the fact that both abbreviated tensor networks, called the *tracial product* and *tracial coproduct* in [23], are cyclically symmetric[12] – will be useful:

Figure 12 Diagrammatic abbreviations of the *tracial product* and *tracial coproduct* tensors.

Let $\vec{\mathcal{D}} = (\vec{\mathcal{S}}, \vec{\boldsymbol{\alpha}}, \vec{\boldsymbol{\beta}})$ be an oriented Heegaard diagram. For every oriented α-curve $\vec{\alpha}_i \in \vec{\boldsymbol{\alpha}}$, we take a copy of the tracial product tensor  , where the abstract indices $c_1, \ldots, c_p$ correspond to the crossings on $\vec{\alpha}_i$ (with the β-curves of $\vec{\mathcal{D}}$) in the order they are encountered when traversing $\vec{\alpha}_i$ following its orientation. We assign a copy  of the tracial coproduct tensor to each oriented β-curve $\vec{\beta}_j \in \vec{\boldsymbol{\beta}}$ analogously. Note that each crossing c between an α- and a β-curve of $\vec{\mathcal{D}}$ appears exactly twice as an abstract index of the above tensors: once at a product and once at a coproduct. The construction of $\mathcal{K}$ is concluded by contracting these indices (i.e., joining the respective arrows with *wires*) with a caveat: if the tangent vectors of the β- and α-curves intersecting at c form (in that order) a negatively oriented basis of the tangent space $T\vec{\mathcal{S}}$, then the antipode tensor is interposed before contracting (Figure 13).

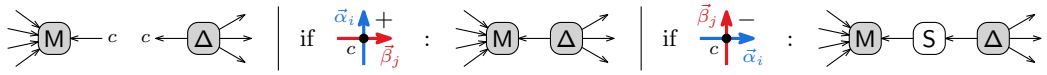

Figure 13 Instruction manual for assembling the tensor network $\mathcal{K}$ from its building blocks.

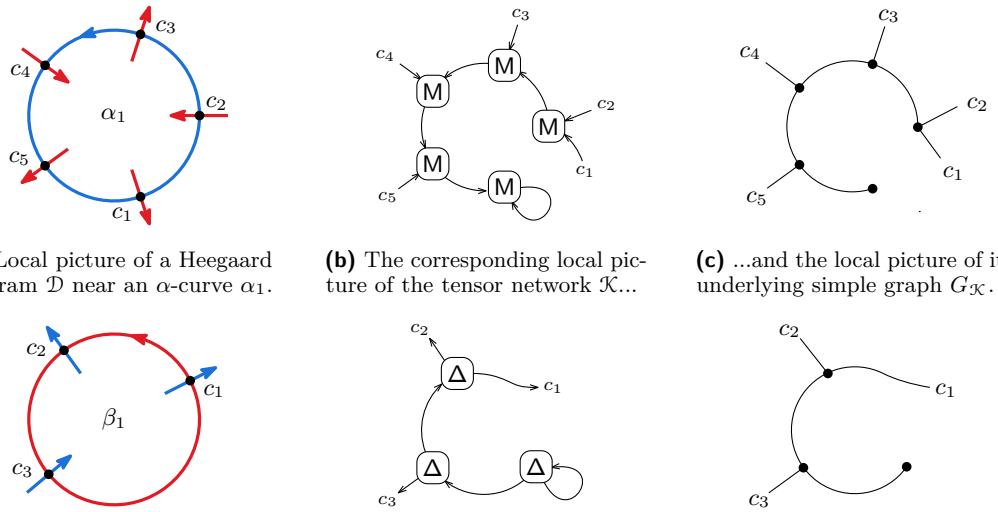

A fully contracted tensor network $\mathcal{N}$ (such as $\mathcal{K}$) can be seen as a graph $(V(\mathcal{N}), E(\mathcal{N}))$ in the obvious way: $V(\mathcal{N})$ corresponds to the coupons of $\mathcal{N}$, whereas $E(\mathcal{N})$ to its wires. (We emphasize that $\mathcal{N}$ is considered here without any diagrammatic abbreviations.)

▶ **Lemma 18.** *Let $\vec{\mathcal{D}}$ be an oriented Heegaard diagram and $\mathcal{K}$ be the Kuperberg tensor network induced by $\vec{\mathcal{D}}$. Then, the number of vertices and the treewidth of $\vec{\mathcal{D}}$ and $\mathcal{K}$ satisfy*

$$|V(\mathcal{K})| \leq 3|V(\vec{\mathcal{D}})| \qquad \text{(3a)} \qquad \textit{and} \qquad \operatorname{tw}(\mathcal{K}) \leq 2\operatorname{tw}(\vec{\mathcal{D}}). \qquad \text{(3b)}$$

Proof. Both inequalities (3a) and (3b) follow directly from the construction of $\mathcal{K}$. In fact, the local configurations shown in Figure 14 already reveal the close structural relationship between $\vec{\mathcal{D}}$ and $\mathcal{K}$. We refer to the full version [18] for the complete proof. ◀

[12] This is analogous to the fact that $\operatorname{Tr}(A_1 A_2 \cdots A_n) = \operatorname{Tr}(A_n A_1 \cdots A_{n-1})$ for the trace of matrices.

(a) Local picture of a Heegaard diagram $\mathcal{D}$ near an α-curve α_1.

(b) The corresponding local picture of the tensor network $\mathcal{K}$...

(c) ...and the local picture of its underlying simple graph $G_{\mathcal{K}}$.

(d) Local picture of a Heegaard diagram $\mathcal{D}$ near an β-curve β_1.

(e) The corresponding local picture of the tensor network $\mathcal{K}$...

(f) ...and the local picture of its underlying simple graph $G_{\mathcal{K}}$.

Figure 14 The local structural correspondence between a Heegaard diagram $\mathcal{D}$ and the induced Kuperberg tensor network $\mathcal{K}$.

Proof of Theorem 15. With Theorem 1 and Lemma 18 at hand, Theorem 15 is a consequence of the following general result about the computational cost of evaluating tensor networks.

▶ **Theorem 19** ([34, Theorem 1], cf. [31, Theorem 4.6]). *Any tensor network $\mathcal{N}$ with n tensors can be evaluated in $O\big(2^{O(\mathrm{vc}(\mathcal{N}))}n\big)$ time, where $\mathrm{vc}(\mathcal{N})$ denotes the* vertex congestion *of $\mathcal{N}$.*

Vertex congestion is a graph parameter similar to treewidth, discussed in [1, p. 135]. For a graph G with maximum degree Δ, we have $\mathrm{vc}(G) \leq (3/2)\cdot\Delta\cdot(\mathrm{tw}(G)+1)$, see [1, Theorem 1 and Remark 3]. Since Kuperberg's tensor networks are 3-regular graphs, we have

▶ **Corollary 20.** *Any Kuperberg tensor network $\mathcal{K}$ can be evaluated in time $O\big(2^{O(\mathrm{tw}(\mathcal{K}))}|\mathcal{K}|\big)$, where $\mathrm{tw}(\mathcal{K})$ denotes the treewidth and $|\mathcal{K}|$ the number of tensors of $\mathcal{K}$.*

Now, if $\mathcal{K}$ is induced by an oriented triangulation $\vec{\mathcal{T}}$ with n tetrahedra, then $|\mathcal{K}| \leq 3|V(\vec{\mathcal{D}})|$ and $\mathrm{tw}(\mathcal{K}) \leq 2\,\mathrm{tw}(\vec{\mathcal{D}})$ by Lemma 18, and $|V(\vec{\mathcal{D}})| \leq 6$ and $\mathrm{tw}(\vec{\mathcal{D}}) \leq 12\,\mathrm{tw}(\vec{\mathcal{T}})+11$ by Theorem 1. Combining these inequalities with Corollary 20, the Theorem 15 follows. ◀

Improved Bound for the k-Variate Elekes–Rónyai Theorem

Yaara Jahn
Hebrew University of Jerusalem, Israel

Orit E. Raz
Ben-Gurion University, Be'er-Sheva, Israel

Abstract

Let $f \in \mathbb{R}[x_1, \ldots, x_k]$, for $k \geq 2$. For any finite sets $A_1, \ldots, A_k \subset \mathbb{R}$, consider the set

$$f(A_1, \ldots, A_k) := \{f(a_1, \ldots, a_k) \mid (a_1, \cdots, a_k) \in A_1 \times \cdots \times A_k\},$$

that is, the image of $A_1 \times \cdots \times A_k$ under f. Extending a theorem of Elekes and Rónyai, which deals with the case $k = 2$, and the result of Raz, Sharir, and De Zeeuw [9], dealing with the case $k = 3$, it is proved in Raz and Shem Tov [10], that for every choice of finite $A_1, \ldots, A_k \subset \mathbb{R}$, each of size n, one has

$$|f(A_1, \ldots, A_k)| = \Omega(n^{3/2}), \tag{1}$$

unless f has some degenerate special form.

In this paper, we introduce the notion of a *rank* of a k-variate polynomial f, denoted as $\mathrm{rank}(f)$. Letting $r = \mathrm{rank}(f)$, we prove that

$$|f(A_1, \ldots, A_k)| = \Omega\left(n^{\frac{5r-4}{2r}-\varepsilon}\right), \tag{2}$$

for every $\varepsilon > 0$, where the constant of proportionality depends on ε and on $\deg(f)$. This improves the lower bound (1), for polynomials f for which $\mathrm{rank}(f) \geq 3$.

We present an application of our main result, to lower bound the number of distinct d-volumes spanned by $(d+1)$-tuples of points lying on the moment curve in $\mathbb{R}^d$.

1 Introduction

In many cases in combinatorial geometry, counting questions involving distances, slopes, collinearity, etc., can be reformulated as analogous counting questions involving grid points lying on certain algebraic varieties. A unified study of such problems began with a question of Elekes [3] about expansion of bivariate real polynomials $f(x, y)$. Specifically, he asked: For a bivariate polynomial $f \in \mathbb{R}[x, y]$ and given finite sets $A, B \subset \mathbb{R}$, how small can be the image set

$$f(A, B) = \{f(a, b) \mid a \in A, b \in B\}.$$

Elekes conjectured that the image of f on a $n \times n$ Cartesian product must be of cardinality superlinear in n, unless f has a very concrete *special form*. This was confirmed in 2000 by Elekes and Rónyai [4] who proved the following dichotomy: Either f has one of the forms

$$f(x, y) = h(p(x) + q(y)) \quad \text{or}$$
$$f(x, y) = h(p(x)q(y)), \tag{3}$$

© Yaara Jahn and Orit E. Raz;

for some univariate real polynomials p, q, h, or, otherwise, for every finite $A, B \subset \mathbb{R}$, each of size n, we have

$$|f(A,B)| = \omega(n). \tag{4}$$

In case f is not one of the forms in (3), the lower bound on $|f(A,B)|$ was improved in [8] to be $\Omega(n^{4/3})$, and further improved in [13] to be $\Omega(n^{3/2})$, which is currently the best known lower bound for bivariate polynomials that are not special.

An analogue of the Elekes–Rónyai problem can be formulated for polynomials in more than two variables. The trivariate case was studied by Raz, Sharir, and De Zeeuw [9], and the general k-variate case was established by Raz and Shem Tov [10]. They obtain the following result.

▶ **Theorem 1** ([9, 10]). *Let $k \geq 3$ and let $f \in \mathbb{R}[x_1, \ldots, x_k]$. Then one of the following holds:*

(i) *For every $A_1, \ldots, A_k \in \mathbb{R}$ each of size n one has*

$$|f(A_1, \ldots, A_k)| = \Omega\left(n^{3/2}\right)$$

(ii) *f is of one of the forms:*

$$\begin{aligned} f(x_1, \ldots, x_k) &= h(p_1(x_1) + \cdots + p_k(x_k)) \\ f(x_1, \ldots, x_k) &= h(p_1(x_1) \cdot \ldots \cdot p_k(x_k)) \end{aligned} \tag{5}$$

Note that the bound in Theorem 1, for non-special polynomials f, is independent of k, and in particular coincides with the bound for $k = 3$. At first glance this may appear to be merely a consequence of the proof. Indeed, the argument in [10] reduces the k-variate case for $k \geq 4$ to the trivariate case by fixing values for $k-3$ of the variables. They then show that if fixing any such subset of $k-3$ variables yields a special trivariate polynomial, then f itself, as a k-variate polynomial, must be special in the sense of (5).

It is natural to expect that increasing the number of variables should force the image of f to grow faster. However, certain polynomials in many variables can in effect behave like polynomials in fewer variables. For example, consider the $(k+2)$-variate polynomial

$$f(x, y, z_1 \ldots, z_k) = xy + z_1 + z_2 + \cdots + z_k.$$

Let $A, B, C_1, \ldots, C_k \subset \mathbb{R}$, where A, B are arbitrary finite sets of size n and $C_1 = \cdots = C_k = [n]$. Let

$$C := C_1 + \cdots + C_k = \{k, k+1, \ldots, kn\}.$$

Then $|C| = \Theta(n)$, and letting $g(x, y, z) := xy + z$, we have

$$f(A, B, C_1, \ldots, C_k) = g(A, B, C).$$

In this case, with the current techniques, it is unclear how to obtain a bound on the expansion of f that improves upon the trivariate result for g.

Our results

In this paper, we recognize k-variate polynomials that are, in a precise sense, truly k-variate, and we improve the corresponding expansion bounds for them. More precisely, for a k-variate polynomial f, we introduce the notion of the *rank* of f. If f has rank r, then, in a rigorous sense, it is essentially $(r+1)$-variate, and the bound on the size of its image can be improved with an exponent that grows with r.

We now define the rank of a polynomial and then state our main result.

Let $f \in \mathbb{R}[x_1, \ldots, x_k]$ and let d_{x_1} stand for the degree of f with respect to the variable x_1. Write

$$f(x_1, \ldots, x_k) = \sum_{i=0}^{d_{x_1}} \alpha_i(x_2, \ldots, x_k)\, x_1^i.$$

We consider the *coefficient map* $T = T_{f,x_1} : \mathbb{R}^{k-1} \to \mathbb{R}^{d_{x_1}+1}$ given by

$$(x_2, \ldots, x_k) \mapsto \left(\alpha_0(x_2, \ldots, x_k), \ldots, \alpha_{d_{x_1}}(x_2, \ldots, x_k)\right).$$

We define the rank of f with respect to the variable x_1 to be

$$\operatorname{rank}_{x_1}(f) := \operatorname{rank}(J_T),$$

where J_T stands for the Jacobian matrix of T; here we consider the rank over the field of rational functions in $x_2, \ldots, x_k$ over $\mathbb{R}$, which is equivalent to evaluating the rank at a generic point $(x_2, \ldots, x_k) \in \mathbb{R}^{k-1}$. Note that

$$0 \le \operatorname{rank}_{x_1}(f) \le k - 1.$$

Similarly, define $\operatorname{rank}_{x_i}(f)$, for every $i = 2, \ldots, k$, where x_i plays the role of x_1.

Finally, define the *rank* of the polynomial f to be

$$\operatorname{rank}(f) := \max_{1 \le i \le k} \operatorname{rank}_{x_i}(f).$$

▶ **Example 2.** Let

$$f(x_1, x_2, \ldots, x_k) = x_1 x_k + x_2 x_k^2 \cdots + x_{k-1} x_k^{k-1}.$$

Then $\operatorname{rank}(f) = \operatorname{rank}_{x_k}(f) = k - 1$.

▶ **Example 3.** Let

$$f(x_1, x_2, \ldots, x_k) = p_1(x_1)x_k + p_2(x_1, x_2)x_k^2 + \cdots + p_{k-1}(x_1, \ldots, x_{k-1})x_k^{k-1},$$

where p_i is an i-variate polynomial that depends non-trivially on x_i. Then $\operatorname{rank}(f) = \operatorname{rank}_{x_k}(f) = k - 1$. Indeed, in this case the matrix $J_{T_{f,x_k}}$ is upper-triangular.

▶ **Example 4.** Let $f(x_1, \ldots, x_k) = p_1(x_1) + p_2(x_2) + \cdots + p_k(x_k)$. The coefficient map T_{f,x_1} maps $(x_2, \ldots, x_k)$ to the coefficients of $p_1(x_1)$, which consist only of a single term depending on the other variables. The Jacobian matrix consists almost entirely of zeros, yielding $\operatorname{rank}(f) = 1$. This aligns perfectly with the special degenerate forms described in Theorem 1.

We prove the following main result of the paper.

▶ **Theorem 5.** *Let $k \ge 3$ and let $f \in \mathbb{R}[x_1 \ldots, x_k]$. Assume that $\operatorname{rank}(f) = r \ge 2$. Then, for every $\varepsilon > 0$, the following holds: Let $A_1, \ldots, A_k \subseteq \mathbb{R}$ be finite, each of size n. Then*

$$|f(A_1, \ldots, A_k)| = \Omega\left(n^{\frac{5r-4}{2r} - \varepsilon}\right),$$

where the constant of proportionality depends on $\deg(f)$, on r, and on ε.

Observe that for a generic k-variate polynomial, the rank is maximal, meaning $r = k-1$. In this case, Theorem 5 yields a lower bound of $\Omega(n^{\frac{5k-9}{2k-2}-\epsilon})$. Notably, this relates to Conjecture 1.3 of de Zeeuw [2], which posits that a generic bivariate polynomial has at least $\Omega(n^{2-\epsilon})$ distinct values. Our theorem pushes towards this super-quadratic growth and currently provides the best known lower bound for the minimal number of distinct values taken by generic k-variate polynomials for $k \geq 4$.

We observe that $\operatorname{rank}(f) = 1$ corresponds to the special forms from Theorem 1. Indeed, we have the following theorem.

▶ **Theorem 6.** *Let $k \geq 3$ and let $f \in \mathbb{R}[x_1 \ldots, x_k]$. Assume that f depends non-trivially on each of its variables and that*

$$\operatorname{rank}(f) = 1.$$

Then f has one of the forms

$$\begin{aligned} &f(x_1, \ldots, x_k) = h(p_1(x_1) + \cdots + p_k(x_k)) \quad \text{or} \\ &f(x_1, \ldots, x_k) = h(p_1(x_1) \cdot \ldots \cdot p_k(x_k)), \end{aligned} \tag{6}$$

for some univariate real polynomials $h(x), p_1(x), \ldots, p_k(x)$.

Finally, we present an application of our results to the following Erdős-type combinatorial geometric problem. Let ν denote the moment curve in $\mathbb{R}^d$, parameterized by

$$\nu(t) = (t, t^2, \ldots, t^d), \quad t \in \mathbb{R}.$$

Let $P \subset \nu$ be a finite set of n points. For any distinct $p_1, \ldots, p_{d+1} \in \nu$, let $\sigma = \sigma(p_1, \ldots, p_{d+1})$ denote the d-simplex which is the convex hull of $p_1, \ldots, p_{d+1}$ in $\mathbb{R}^d$, and let $\operatorname{vol}(\sigma)$ denote its d-dimensional volume. Define

$$\Delta(P) = \{\operatorname{vol}(\sigma(p_1, \ldots, p_{d+1})) \mid p_1, \ldots, p_{d+1} \in P\}.$$

We have the following theorem.

▶ **Theorem 7.** *Let ν be the moment curve in $\mathbb{R}^d$ and let $P \subset \nu$ be any finite set of size n. Then, for every $\varepsilon > 0$,*

$$|\Delta(P)| = \Omega\left(n^{\frac{5d-4}{2d}-\varepsilon}\right),$$

where the implicit constant depends only on ε and on d.

Theorem 7 is obtained by identifying a $(d+1)$-variate polynomial f whose expansion over a certain $n \times \cdots \times n$ grid in $\mathbb{R}^{d+1}$ corresponds to the number of distinct volumes of d-simplices spanned by P. We then show that f has rank d and apply our main Theorem 5.

Organization of the paper

The paper is organized as follows. In Section 2 we recall an incidence bound that will serve as a key tool in our arguments. In Section 3, we establish a special case of our main result, Theorem 5, and in Section 4, we complete its proof. The proof of Theorem 6 is provided in Section 5. Finally, Section 6 contains the proof of Theorem 7.

2 Incidences between points and algebraic curves

For a finite set of points $\mathcal{P} \subset \mathbb{R}^2$ and a finite set of planar curves $\mathcal{C}$, we let $I(\mathcal{P},\mathcal{C})$ denote the set of point-curve incidences; that is

$$I(\mathcal{P},\mathcal{C}) = \{(p,\gamma) \in \mathcal{P} \times \mathcal{C} \mid p \in \gamma\}.$$

The classical Szemerédi–Trotter theorem [14] asserts that, for the special case where $\mathcal{C}$ is a set of lines, and putting $m := |\mathcal{P}|$ and $n := |\mathcal{C}|$, one has

$$|I(\mathcal{P},\mathcal{C})| = O\left(m^{2/3}n^{2/3} + m + n\right).$$

Since the Szemerédi–Trotter result, many alternative proofs and analogue problems have been studied. Today incidence problems play a fundamental role in combinatorial geometry. For our result we will need an extension of the Szemerédi–Trotter theorem to point-curve incidence problems, where the curves are algebraic and come from an s-dimensional family of curves. We now present the definition from Sharir–Zahl [12].

A bivariate polynomial $h \in \mathbb{R}[x,y]$ of degree at most D is a linear combination of the form

$$h(x,y) = \sum_{0 \le i+j \le D} c_{ij} x^i y^j.$$

Note that the number of monomials $x^i y^j$ such that $0 \le i+j \le D$ is $\binom{D+2}{2}$. In this sense, every point $\vec{c} \in \mathbb{R}^{\binom{D+2}{2}}$ (other than the all-zero vector) can be associated with a curve in $\mathbb{R}^2$, given by the zeroset of the bivariate polynomial whose coefficients are the entries of $\vec{c}$. If $\lambda \neq 0$, then f and λf have the same zero-set. Thus, the set of algebraic curves that can be defined by a polynomial of degree at most D in $\mathbb{R}^2$ can be identified with the points in the projective space $\mathbf{P}\mathbb{R}^{\binom{D+2}{2}}$.

In [12], Sharir and Zahl defined an *s-dimensional family of plane curves of degree at most D* to be an algebraic variety $F \subset \mathbf{P}R^{\binom{D+2}{2}}$ such that $\dim(F) = s$. We will call the degree of the variety F the *complexity of the family*.

They then proved the following incidence bound:

▶ **Theorem 8** (Sharir–Zahl [12]). *Let $\mathcal{F}$ be an s-dimensional family of plane curves of degree at most D and complexity at most K. Let $\mathcal{P}$ be a set of m points in the plane and let $\mathcal{C} \subset \mathcal{F}$ be a set of n plane curves. Suppose that no two of the curves in $\mathcal{C}$ share a common irreducible component. Then for every $\varepsilon > 0$, we have*

$$I(\mathcal{P},\mathcal{C}) = O_\varepsilon\left(m^{\frac{2s}{5s-4}} n^{\frac{5s-6}{5s-4}+\varepsilon}\right) + O\left(m^{2/3}n^{2/3} + m + n\right),$$

where the constant of proportionality depends on s, K, D and in the first term also on ε.

3 A special case

In this section we prove the special case of Theorem 5 with $r = k-1$. This will serve as a key ingredient for the proof of the general result.

▶ **Proposition 9.** *Let $k \ge 3$, $f \in \mathbb{R}[x_1 \ldots, x_k]$, and assume that* $\operatorname{rank}(f) = k-1$. *Then, for every $\varepsilon > 0$, the following holds: Let $A_1, \ldots, A_k \subseteq \mathbb{R}$ be finite, each of size n. Then*

$$|f(A_1, \ldots, A_k)| = \Omega\left(n^{\frac{5(k-1)-4}{2(k-1)}-\varepsilon}\right),$$

where the constant of proportionality depends on $\deg(f)$, *on k, and on ε.*

Proof. Let $f, A_1, \ldots, A_k$ be as in the statement. Up to renaming of the variables, we may assume without loss of generality that $\operatorname{rank}_{x_1}(f) = k-1$. Put

$$B = f(A_1, \ldots, A_k)$$

We aim to lower bound $|B|$. For this, consider:

$$S = \{(x_1, x_2, \ldots, x_k, y) \in A_1 \times A_2 \times \cdots \times A_k \times B \mid y = f(x_1, \ldots, x_k)\}.$$

Notice that, for every $(a_1 \ldots, a_k) \in A_1 \times \ldots \times A_k$, we have that $(a_1 \ldots, a_k, f(a_1, \ldots, a_k)) \in S$, and so

$$|S| = n^k. \tag{7}$$

We claim that, for every $\varepsilon > 0$, one has

$$|S| = O\left(|B|^{\frac{2(k-1)}{5(k-1)-4}} n^{(k-1)(1+\varepsilon)}\right), \tag{8}$$

where the constant of proportionality depends on ε, k, and $\deg(f)$. Combining (7) and (8), we get

$$n^k = O\left(|B|^{\frac{2(k-1)}{5(k-1)-4}} n^{(k-1)(1+\varepsilon)}\right)$$

or

$$|B| = \Omega\left(n^{\frac{5(k-1)-4}{2(k-1)} - \varepsilon'}\right),$$

where $\varepsilon' = \frac{5(k-1)-4}{2}\varepsilon$, which proves the proposition.

So in order to complete the proof of Proposition 9 we only need to prove (8). Let $T = T_{f,x_1}$ be the coefficient map defined in the introduction. By assumption, $\operatorname{rank}(J_T) = k-1$. Thus, there exist indices $(i_1, \ldots, i_{k-1})$ such that for

$$\hat{T} : (x_2 \ldots, x_k) \mapsto (\alpha_{i_1}(x_2 \ldots, x_k), \ldots, \alpha_{i_{k-1}}(x_2 \ldots, x_k)),$$

we have

$$\det J_{\hat{T}} \not\equiv 0.$$

Define

$$S_0 = \left\{(a_1, \ldots, a_k, b) \in S \mid \det J_{\hat{T}}(a_2, \ldots, a_k) = 0\right\},$$
$$S' = S \setminus S_0.$$

Clearly $|S| = |S_0| + |S'|$.

Observe that,

$$|S_0| = |A_1| \cdot \left|(A_2 \times \cdots \times A_k) \cap \left\{\det J_{\hat{T}} = 0\right\}\right| \leq n \cdot \deg(\det J_{\hat{T}}) n^{k-2},$$

where the inequality is due to the Schwartz–Zippel Lemma (see [11, 16]). Thus, we get

$$|S_0| = O(n^{k-1}), \tag{9}$$

where the constant of proportionality depends on $\deg(f)$ and on k.

We now bound $|S'|$. For this, we reduce the problem into a point-curve incidence problem in the plane as follows. With each $(a_2, \ldots, a_k) \in A_2 \times \cdots \times A_k$ for which $\det J_{\hat{T}}(a_2, \ldots, a_k) \neq 0$, we associate a curve $\gamma_{a_2,\ldots,a_k}$ in $\mathbb{R}^2$ given by the equation

$$y = f(x, a_2, \ldots, a_k).$$

Note that $\gamma_{a_2,\ldots,a_k}$ is irreducible for every $(a_2, \ldots, a_k) \in A_2 \times \cdots \times A_k$, because it is defined by an equation of the form $y = P(x)$, making it the graph of a polynomial. Let

$$\mathcal{P} = A_1 \times B,$$
$$\mathcal{C} = \left\{\gamma_{a_2,\ldots,a_k} \mid \det J_{\hat{T}}(a_2, \ldots, a_k) \neq 0\right\};$$

note that curves in $\mathcal{C}$ are taken without multiplicity. Let $I(\mathcal{P}, \mathcal{C})$ denote the set of point-curve incidences between $\mathcal{P}$ and $\mathcal{C}$.

▷ Claim 10. We have

$$|S'| = \Theta\left(|I(\mathcal{P}, \mathcal{C})|\right), \tag{10}$$

where the constant of proportionality depends only on $\deg f$ and on k.

Proof. By definition, if $(a_1, a_2, \ldots, a_k, b) \in S'$ then $((a_1, b), \gamma_{a_2,\ldots,a_k}) \in I(\mathcal{P}, \mathcal{C})$. So, to prove the claim, it suffices to show that every $(p, \gamma) \in I(\mathcal{P}, \mathcal{C})$ corresponds to at most $O(1)$ elements of S'.

For $\gamma \in \mathcal{C}$, write

$$m(\gamma) = \left\{(a_2, \ldots, a_k) \mid \gamma_{a_2,\ldots,a_k} = \gamma \text{ and } \det J_{\hat{T}}(a_2, \ldots, a_k) \neq 0\right\}.$$

We need to prove that

$$|m(\gamma)| = O(1), \tag{11}$$

with constant of proportionality that depends only on $\deg(f)$ and on k.

By the definition of the set $\mathcal{C}$, we have that γ is given by an equation of the form

$$y = \sum_{i=0}^{d_{x_1}} c_i x^i,$$

for some coefficients $c_0, \ldots, c_{d_{x_1}} \in \mathbb{R}$. Let V denote the algebraic variety which is given by the system of equations

$$\begin{aligned} \alpha_{i_1}(x_2, \ldots, x_k) &= c_{i_1} \\ \alpha_{i_2}(x_2, \ldots, x_k) &= c_{i_2} \\ &\vdots \\ \alpha_{i_{k-1}}(x_2, \ldots, x_k) &= c_{i_{k-1}}. \end{aligned} \tag{12}$$

Then

$$m(\gamma) \subset V.$$

Write $V = V_0 \cup V_+$, where V_0 is the union of all 0-dimensional irreducible components of V, and V_+ is the union of all other irreducible components of V. Recall that, by properties of real algebraic varieties, we have that V_0 is finite, and

$$|V_0| = O(1),$$

with a constant that depends only of $\deg(f)$ and on k (see e.g. [1, 6, 15] for a bound on the number of connected components of a real algebraic variety).

Thus, to prove (11), it suffices to show that $m(\gamma) \subset V_0$. Assume, for contradiction, that this is not the case. That is, there exists $(a_2, \ldots, a_k) \in m(\gamma) \cap V_+$. Then, by definition, we have

$$\hat{T}(a_2, \ldots, a_k) = (c_{i_1}, \ldots, c_{i_{k-1}})$$
$$\det J_{\hat{T}}(a_2, \ldots, a_k) \neq 0.$$

By the inverse function theorem, there exists an open neighborhood, N, of $(a_2, \ldots, a_k)$ such that $\hat{T}$ restricted to N is invertible. In particular,

$$N \cap \hat{T}^{-1}\{(c_{i_1}, \ldots, c_{i_{k-1}})\} = \{(a_2, \ldots, a_k)\}.$$

On the other hand,

$$N \cap \hat{T}^{-1}(c_{i_1}, \ldots, c_{i_{k-1}}) = N \cap V.$$

Since N is a neighborhood of $(a_1, \ldots, a_{k-1})$ and the latter lies on an irreducible component of V of dimension at least 1, the intersection $N \cap V$ must be infinite. This leads to a contradiction, and thus $m(\gamma) \subset V_0$. This completes the proof of Claim 10. ◁

In view of Claim 10, in order to bound $|S'|$ it suffices to bound $|I(\mathcal{P}, \mathcal{C})|$. We have $|\mathcal{P}| = n|B|$ and $|\mathcal{C}| \leq n^{k-1}$. Since the curves in $\mathcal{C}$ are irreducible, every two distinct curves γ, γ' in $\mathcal{C}$ intersect in at most $d_{x_1}^2$ points, by Bezout's Theorem (see e.g. [5, Corollary 7.8]). We can therefore apply Theorem 8. In our context, the family of curves $\mathcal{F}$ is parameterized by the $k-1$ variables from $A_2 \times \cdots \times A_k$, so the dimension is $s \leq k-1$. The degree $D \leq \max(\deg(f), 1)$ and the complexity $K = O(1)$ depend strictly on k and $deg(f)$, and crucially, are independent of n. This gives

$$|I(\mathcal{P}, \mathcal{C})| = O\left((|B| \cdot n)^{\frac{2(k-1)}{5(k-1)-4}} n^{(k-1)\left(\frac{5(k-1)-6}{5(k-1)-4}+\varepsilon\right)} + (|B|n)^{2/3}(n^{k-1})^{2/3} + |B|n + n^{k-1} \right).$$

or

$$|I(\mathcal{P}, \mathcal{C})| = O\left(|B|^{\frac{2(k-1)}{5(k-1)-4}} n^{(k-1)(1+\varepsilon)} + |B|^{\frac{2}{3}} n^{\frac{2k}{3}} + |B|n + n^{k-1} \right).$$

Note that we may assume without loss of generality that the first summand is dominant. Indeed, the second summand is dominant if

$$|B|^{\frac{2(k-1)}{5(k-1)-4}} n^{(k-1)(1+\varepsilon)} \leq |B|^{\frac{2}{3}} n^{\frac{2k}{3}}$$

or

$$|B| \geq n^{\frac{5(k-1)-4}{4}+O(\varepsilon)},$$

which is stronger than the lower bound we wish to prove on $|B|$, for every $k \geq 3$. Similarly, the third summand is dominant if

$$|B|^{\frac{2r}{5r-4}} n^{r(1+\varepsilon)} \leq |B|n$$

or

$$|B| \geq n^{\frac{(k-2)(5(k-1)-4)}{3(k-1)-4}+\varepsilon\frac{(k-1)(5(k-1)-4)}{3(k-1)-4}},$$

which is better than the lower we want to prove on $|B|$ for every k, as is easy to verify. Finally, the fourth summand is always subsumed by the first one.

Hence, either the conclusion of Proposition 9 holds, or we obtain

$$|I(\mathcal{P},\mathcal{C})| = O\left(|B|^{\frac{2(k-1)}{5(k-1)-4}} n^{(k-1)(1+\varepsilon)}\right).$$

In view of Claim 10 and combined with (9), the inequality (8) follows. This completes the proof Proposition 9. ◀

4 Proof of Theorem 5

The following lemma shows that the main Theorem 5 can in fact be reduced to the statement of Proposition 9.

▶ **Lemma 11.** *Let $f \in \mathbb{R}[x_1 \ldots, x_k]$ and assume that $\operatorname{rank}_{x_1}(f) = r < k-1$. Then, up to renaming of the variables $x_2, \ldots, x_k$, we have that*

$$g(x_1, \ldots, x_{r+1}) := f(x_1, x_2, \ldots, x_{r+1}, y_{r+2}, \ldots, y_k)$$

is a $(r+1)$-variate polynomial in $\mathbb{R}[x_1, \ldots, x_{r+1}]$ with $\operatorname{rank}_{x_1}(g) = r$, for all $(y_{r+2}, \ldots, y_k) \in \mathbb{R}^{k-r-1} \setminus Z_0$, where Z_0 is some subvariety of $\mathbb{R}^{k-r-1}$ of codimension at least 1 and degree depending only on k and $\deg(f)$.

Proof. Let f be as in the statement. Let $T = T_{f,x_1}$ be the corresponding coefficient map. By assumption

$$\operatorname{rank}(J_T) = r < k-1. \tag{13}$$

Up to renaming the variables, we may assume without the loss of generality, that the first r columns of J_T, corresponding to the variables $x_2, \ldots, x_{r+1}$, are independent. Observe that the matrix composed of the first r columns of J_T, is in fact the Jacobian matrix of the coefficient map T_{g,x_1}, where g is the $(r+1)$-variate polynomial given by

$$g(x_1, x_2, \ldots, x_{r+1}) := f(x_1, x_2, \ldots, x_{r+1}, y_{r+2}, \ldots, y_k);$$

here $x_2, \ldots, x_{r+1}$ are regarded as constant parameters.

Our goal is to show that for $J_{T_{g,x_1}}$, treated as a matrix with entries in $\mathbb{R}(x_1, \ldots, x_{r+1})$, we have that $\operatorname{rank}(J_{T_{g,x_1}}) = r$, for every generic choice of $(y_{r+2}, \ldots, y_k) \in \mathbb{R}^{k-r-1}$.

Let Δ denote the polynomial corresponding to the sum of squares of the determinants of all the $r \times r$ submatrices of $J_{T_{g,x_1}}$. So Δ is a multivariate polynomial, and we can write

$$\Delta(x_2, \ldots, x_{r+1}, y_{r+2}, \ldots, y_k) = \sum_i \beta_i(y_{r+2}, \ldots, y_k) g_i(x_2, \ldots, x_{r+1}),$$

with $g_i \in \mathbb{R}[x_2, \ldots, x_{r+1}]$ and $\beta_i \in \mathbb{R}[y_{r+2}, \ldots, y_k]$. By the definition of Δ we have

$$\operatorname{rank}(J_{T_{g,x_1}}(x_2, \ldots, x_{r+1}, y_{r+2}, \ldots, y_k)) < r \text{ if and only if } \Delta(x_2, \ldots, x_{r+1}, y_{r+2}, \ldots, y_k) = 0.$$

Thus, in view of (13), we have $\Delta \not\equiv 0$. In particular, the polynomials β_i are not all zero. Thus, letting

$$Z_0 := \{(y_{r+2}, \ldots, y_k) \mid \forall i \ \beta_i(y_{r+2}, \ldots, y_k) = 0\},$$

we see that Z_0 has codimension at least 1. This completes the proof of the lemma. ◀

We can now complete the proof of our main Theorem 5.

Proof of Theorem 5. Let $f \in \mathbb{R}[x_1, \ldots, x_k]$ and assume without loss of generality that $\deg_{x_1}(f) = r \leq k-2$. Apply Lemma 11 to f. Then, up to renaming of the variables, there exists an algebraic variety $Z_0 \subset \mathbb{R}^{k-r-1}$, of codimension at least one, and of degree $O(1)$, such that for every $(y_{r+2}, \ldots, y_k) \in \mathbb{R}^{k-r-1} \setminus Z_0$ we have that the polynomial

$$(x_1, \ldots, x_{r+1}) \mapsto f(x_1, \ldots, x_{r+1}, y_{r+2}, \ldots, y_k)$$

is an $(r+1)$-variate polynomial of rank r.

Observe that, by the Schwartz–Zippel lemma, there exists $(a_{r+2}, \ldots, a_k) \in (A_{r+2} \times \ldots \times A_k) \setminus Z_0$. Thus

$$g(x_1, \ldots, x_{r+1}) := f(x_1, \ldots, x_{r+1}, a_{r+2}, \ldots, a_k)$$

satisfies $\operatorname{rank}_{x_1}(g) = r$. Thus, by Proposition 9, we have that

$$|g(A_1, \ldots, A_{r+1})| = \Omega\left(n^{\frac{5r-4}{2r}-\varepsilon}\right).$$

Noting that

$$g(A_1, \ldots, A_{r+1}) = f(A_1, \ldots, A_{r+1}, \{a_{r+2}\}, \ldots, \{a_k\}) \subset f(A_1, \ldots, A_k),$$

this completes the proof of the theorem. ◀

5 Characterization of rank-1 polynomials

In this section we prove Theorem 6. For the proof we will use the following lemma from Raz and Shem Tov [10].

▶ **Lemma 12** (Raz–Shem Tov [10, Lemma 2.3]). *Let $f \in \mathbb{R}[x_1, \ldots, x_k]$. Assume that*

$$\frac{\frac{\partial f}{\partial x_1}(x_1, \ldots, x_k)}{r_1(x_1)} = \cdots = \frac{\frac{\partial f}{\partial x_k}(x_1, \ldots, x_k)}{r_k(x_k)}, \tag{14}$$

for some univariate real polynomials $r_1, \ldots, r_k$. Then, f is one of the forms

$$f(x_1, \ldots, x_k) = h(p_1(x_1) + \cdots + p_k(x_k)) \quad \text{or}$$
$$f(x_1, \ldots, x_k) = h(p_1(x_1) \cdot \cdots \cdot p_k(x_k)),$$

for some univariate real polynomials $h(x), p_1(x), \ldots, p_k(x)$.

Proof of Theorem 6. Let f be as in the statement. Since f depends non-trivially on each of its variables, we have in particular that

$$\operatorname{rank}_{x_i}(f) = 1, \quad \text{for each } i = 1, \ldots, k. \tag{15}$$

In view of Lemma 12, it suffices to show that f satisfies the differential equation (14), for some univariate polynomials $r_1, \ldots, r_k$. By symmetry, it suffices to prove that

$$\frac{\frac{\partial f}{\partial x_1}(x_1, \ldots, x_k)}{r_1(x_1)} = \frac{\frac{\partial f}{\partial x_2}(x_1, \ldots, x_k)}{r_2(x_2)} \tag{16}$$

We write

$$f(x_1, \ldots, x_k) = \sum_{i=0}^{d_{x_1}} \alpha_i^{(1)}(x_2, \ldots, x_k)\, x_1^i = \cdots = \sum_{i=0}^{d_{x_k}} \alpha_i^{(k)}(x_1, \ldots, x_{k-1})\, x_k^i, \tag{17}$$

where d_{x_j} stands for the degree of f as a univariate polynomial in the variable x_j. Then for every $j, \ell \in \{1, \ldots, k\}$, such that $j \neq \ell$, we have

$$\frac{\partial f}{\partial x_j}(x_1, \ldots, x_k) = \sum_{i=0}^{d_{x_\ell}} \frac{\partial \alpha_i^{(\ell)}(x_1, \ldots, \widehat{x_\ell}, \ldots, x_k)}{\partial x_j} x_\ell^i. \tag{18}$$

We next show that

$$\frac{\frac{\partial f}{\partial x_1}}{\frac{\partial f}{\partial x_2}} = u(x_1, x_2), \tag{19}$$

where u is some rational function over $\mathbb{R}$.

In other words, we need to show that $\frac{\partial f}{\partial x_1} / \frac{\partial f}{\partial x_2}$ is independent of x_i, for every $i \neq 1, 2$. By symmetry it suffices to show that this ratio is independent of the variable x_3. Consider the first two columns of $J_{T_{f,x_3}}$, corresponding to derivatives with respect to x_1 and to x_2. Namely,

$$\begin{pmatrix} \frac{\partial \alpha_0^{(3)}}{\partial x_1} & \frac{\partial \alpha_0^{(3)}}{\partial x_2} \\ \frac{\partial \alpha_1^{(3)}}{\partial x_1} & \frac{\partial \alpha_1^{(3)}}{\partial x_2} \\ \vdots & \vdots \\ \frac{\partial \alpha_{d_{x_3}}^{(3)}}{\partial x_1} & \frac{\partial \alpha_{d_{x_3}}^{(3)}}{\partial x_2} \end{pmatrix}.$$

Note that neither of the columns is zero, since f depends non-trivially in each of its variables. Moreover, since $\operatorname{rank}(J_{T_{f,x_3}}) = 1$, by (15), and using the fact that the entries of $J_{T_{f,x_3}}$ are independent of x_3, we get that there exists a rational function $u(x_1, x_2, x_4, \ldots, x_k)$ such that

$$\frac{\partial \alpha_i^{(3)}}{\partial x_1} = u(x_1, x_2, x_4, \ldots, x_k) \frac{\partial \alpha_i^{(3)}}{\partial x_2}, \quad \text{for } i = 0, \ldots, d_{x_3}.$$

Using the identity (18), this implies that

$$\frac{\frac{\partial f}{\partial x_1}}{\frac{\partial f}{\partial x_2}} = u(x_1, x_2, x_4, \ldots, x_k);$$

that is, this ratio is independent of x_3. This proves (19).

Repeating the analysis symmetrically for the pair x_1, x_3 and then to the pair x_2, x_3 we conclude that there exist real rational functions $v(x_1, x_3)$ and $w(x_2, x_3)$ such that

$$\frac{\frac{\partial f}{\partial x_1}}{\frac{\partial f}{\partial x_3}} = v(x_1, x_3)$$

$$\frac{\frac{\partial f}{\partial x_2}}{\frac{\partial f}{\partial x_3}} = w(x_2, x_3).$$

But then

$$\frac{\frac{\partial f}{\partial x_1}}{\frac{\partial f}{\partial x_2}} = \frac{v(x_1, x_3)}{w(x_2, x_3)} = u(x_1, x_2),$$

meaning in particular that the ratio of v, w is independent of x_3. Thus, setting an arbitrary value for x_3, we get that

$$\frac{\frac{\partial f}{\partial x_1}}{\frac{\partial f}{\partial x_2}} = \frac{v(x_1, 0)}{w(x_2, 0)}.$$

Thus, letting $r_1(x_1) := v(x_1, 0)$ and $r_2(x_2) := w(x_2, 0)$, this proves (16), and hence completes the proof of the lemma. ◀

6 Distinct d-volumes on the moment curve in $\mathbb{R}^d$

In this section we prove Theorem 7.

Proof of Theorem 7. The *moment curve* in $\mathbb{R}^d$ is defined by $\nu(x) = (x, x^2, \ldots, x^d)$. Consider $d+1$ point on ν given by the parameters $x_1, \ldots, x_{d+1} \in \mathbb{R}^d$, and let $\sigma(x_1, \ldots, x_{d+1})$ denote the simplex spanned by these points. Define

$$f(x_1, \ldots, x_{d+1}) := \mathrm{vol}\sigma(x_1, \ldots, x_{d+1}).$$

It suffices to prove that

$$\mathrm{rank}_{x_{d+1}}(f) = d. \tag{20}$$

Indeed, assume that (20) is true and let $P \subset \nu$ be a set of size n. Let A denote the x_1-coordinate of the points in P. Then $\Delta(P) = f(A, \ldots, A)$. By Theorem 5, for every $\varepsilon > 0$, we have

$$|\Delta(P)| = |f(A, \ldots, A)| = \Omega\left(n^{\frac{5d-4}{2d} - \varepsilon}\right),$$

as needed.

So we only need to prove (20). We have

$$f(x_1, \ldots, x_{d+1}) = \frac{1}{d!} \det \begin{pmatrix} 1 & x_1 & x_1^2 & \ldots & x_1^d \\ 1 & x_2 & x_2^2 & \ldots & x_2^d \\ \vdots & \vdots & \vdots & & \vdots \\ 1 & x_{d+1} & x_{d+1}^2 & \ldots & x_{d+1}^d \end{pmatrix},$$

which is the determinant of the $(d+1) \times (d+1)$-*Vandermonde matrix*. Thus

$$\begin{aligned} f(x_1, \ldots, x_{d+1}) &= \frac{1}{d!} \prod_{1 \le i < j \le d+1} (x_j - x_i) \\ &= \frac{1}{d!} \prod_{1 \le i < j \le d} (x_j - x_i) \prod_{k=1}^{d} (x_{d+1} - x_k) \\ &= g(x_1, \ldots, x_d) \hat{f}(x_1, \ldots, x_{d+1}), \end{aligned}$$

where $g(x_1, \ldots, x_d) := \frac{1}{d!} \prod_{1 \le i < j \le d} (x_j - x_i)$ is independent of x_{d+1} and $\hat{f}(x_1, \ldots, x_{d+1}) := \prod_{k=1}^{d} (x_{d+1} - x_k)$. Note that $\hat{f}$ can be written as

$$\hat{f}(x_1, \ldots, x_{d+1}) = \sum_{\ell=0}^{d} s_\ell(x_1, \ldots, x_d) x_{d+1}^\ell,$$

where

$$\begin{aligned} s_0(x_1, \ldots, x_d) &= (-1)^d x_1 \cdots x_d \\ s_1(x_1, \ldots, x_d) &= (-1)^{d-1} (x_2 \cdots x_d + x_1 x_3 \cdots x_d + \cdots + x_1 \cdots x_{d-1}) \\ &\ldots \\ s_{d-1}(x_1, \ldots, x_d) &= -x_1 - \cdots - x_d \\ s_d(x_1, \ldots, x_d) &= 1, \end{aligned}$$

are the symmetric polynomials.

▷ Claim 13. Let M be the $d \times d$ matrix $M = (M_{i,j})_{0 \le i \le d-1,\ 1 \le j \le d}$ given by

$$M_{i,j} = \frac{\partial s_i}{\partial x_j} \qquad (0 \le i \le d-1,\ 1 \le j \le d).$$

Then $\operatorname{rank}(M) = d$.

The strategy for this proof is adapted from the proof of [[7], section 4].

Proof. We prove that $\det M$ is not the zero polynomial. Consider the function

$$P(x_1, \dots, x_d, t) = \prod_{k=1}^{d} (t - x_k) = \sum_{k=0}^{d} s_k\, t^k,$$

which is a monic polynomial in t.

For $1 \le j \le d$ we have

$$\frac{\partial P}{\partial x_j}(t) = -\prod_{\substack{k=1 \\ k \ne j}}^{d} (t - x_k) = \sum_{k=0}^{d-1} \frac{\partial s_k}{\partial x_j}\, t^k$$

Evaluating at $t = x_i$ yields

$$\frac{\partial P}{\partial x_j}(x_i) = \sum_{k=0}^{d-1} \frac{\partial s_k}{\partial x_j}\, x_i^k = \begin{cases} 0, & i \ne j, \\ -\prod_{k \ne j} (x_j - x_k), & i = j. \end{cases} \tag{21}$$

The identity (21) implies

$$\begin{pmatrix} 1 & x_1 & x_1^2 & \dots & x_1^{d-1} \\ 1 & x_2 & x_2^2 & \dots & x_2^{d-1} \\ \vdots & \vdots & \vdots & & \vdots \\ 1 & x_d & x_d^2 & \dots & x_d^{d-1} \end{pmatrix} M = \operatorname{diag}\left(\frac{\partial P}{\partial x_1}(x_1), \dots, \frac{\partial P}{\partial x_d}(x_d) \right).$$

Thus

$$\begin{aligned} \det(M) &= \frac{(-1)^d \prod_{j=1}^{d} \prod_{i \ne j} (x_j - x_i)}{\prod_{1 \le i < j \le d} (x_j - x_i)} \\ &= \frac{(-1)^d \prod_{1 \le i \ne j \le d} (x_j - x_i)}{\prod_{1 \le i < j \le d} (x_j - x_i)} \\ &= \prod_{1 \le i < j \le d} (x_j - x_i). \end{aligned}$$

This completes the proof of Claim 13. ◁

We are now ready to prove (20). Write

$$f(x_1, \dots, x_{d+1}) = \sum_{i=0}^{d} \alpha_i(x_1, \dots, x_d) x_{d+1}^i.$$

By the above we have

$$\alpha_i = g(x_1, \dots, x_d) s_i(x_1, \dots, x_d), \text{ for } i = 0, \dots, d$$

Let $T = T_{f,x_{d+1}}$. Denoting partial derivatives with subscripts (e.g., $g_{x_1} = \frac{\partial g}{\partial x_1}$), we have

$$J_T = \begin{pmatrix} g_{x_1}s_0 + gs_{0x_1} & g_{x_2}s_0 + gs_{0x_2} & \cdots & g_{x_d}s_0 + gs_{0x_d} \\ \vdots & \vdots & & \vdots \\ g_{x_1}s_{d-1} + gs_{d-1x_1} & g_{x_2}s_{d-1} + gs_{d-1x_2} & \cdots & g_{x_d}s_{d-1} + gs_{d-1x_{d-1}} \\ g_{x_1} & g_{x_2} & \cdots & g_{x_d} \end{pmatrix}.$$

Applying row operation to the first d rows, namely, $R_i \leftarrow R_i - s_i R_d$ we get

$$\begin{aligned} \operatorname{rank} J_T &= \operatorname{rank} \begin{pmatrix} gs_{0x_1} & gs_{0x_2} & \cdots & gs_{0x_d} \\ \vdots & \vdots & & \vdots \\ gs_{d-1x_1} & gs_{d-1x_2} & \cdots & gs_{d-1x_{d-1}} \\ g_{x_1} & g_{x_2} & \cdots & g_{x_d} \end{pmatrix} \\ &= \operatorname{rank} \begin{pmatrix} s_{0x_1} & s_{0x_2} & \cdots & s_{0x_d} \\ \vdots & \vdots & & \vdots \\ s_{d-1x_1} & s_{d-1x_2} & \cdots & s_{d-1x_{d-1}} \\ g_{x_1}/g & g_{x_2}/g & \cdots & g_{x_d}/g \end{pmatrix}. \end{aligned}$$

Note that first d rows of the above matrix are exactly the matrix M from Claim 13. This completes the proof of Theorem 7 ◀

Space-Efficient Approximate Spherical Range Counting in High Dimensions

Andreas Kalavas
Carnegie Mellon University, Pittsburgh, PA, USA

Ioannis Psarros
Archimedes, Athena Research Center, Greece

Abstract

We study the following range searching problem in high-dimensional Euclidean spaces: given a finite set $P \subset \mathbb{R}^d$, where each $p \in P$ is assigned a weight w_p, and radius $r > 0$, we need to preprocess P into a data structure such that when a new query point $q \in \mathbb{R}^d$ arrives, the data structure reports the cumulative weight of points of P within Euclidean distance r from q. Solving the problem exactly seems to require space usage that is exponential to the dimension, a phenomenon known as the curse of dimensionality. Thus, we focus on approximate solutions where points up to $(1+\varepsilon)r$ away from q may be taken into account, where $\varepsilon > 0$ is an input parameter known during preprocessing. We build a data structure with near-linear space usage, and query time in $n^{1-\Theta(\varepsilon^4/\log(1/\varepsilon))} + t_q^{\varrho} \cdot n^{1-\varrho}$, for some $\varrho = \Theta(\varepsilon^2)$, where t_q is the number of points of P in the ambiguity zone, i.e., at distance between r and $(1+\varepsilon)r$ from the query q. To the best of our knowledge, this is the first data structure with efficient space usage (subquadratic or near-linear for any $\varepsilon > 0$) and query time that remains sublinear for any sublinear t_q. We supplement our worst-case bounds with a query-driven preprocessing algorithm to build data structures that are well-adapted to the query distribution.

1 Introduction

Range searching is a fundamental problem with wide applications in areas such as computational geometry [13], databases [36], geographic information systems (GIS) [25], and computer graphics [4]. One fundamental variant of range searching is that of *range counting*, where given a dataset P, we need to preprocess it into a data structure so that for a query range R_q, we can efficiently estimate $|R_q \cap P|$. Primary examples of types of query ranges include rectangles, balls, halfspaces, and simplices.

In this paper, we study the special case of range counting queries for Euclidean balls of fixed radius. Solving the problem exactly seems to require space usage that is exponential to the dimension, a phenomenon known as the curse of dimensionality. Therefore, aiming for solutions that scale well with the dimension, we focus on approximate solutions where points up to $(1+\varepsilon)r$ away from q may be considered, where $\varepsilon > 0$ is an input parameter known during preprocessing. Formally, given as input a dataset $P \subseteq \mathbb{R}^d$, such that each point $p \in P$

© Andreas Kalavas and Ioannis Psarros;
licensed under Creative Commons License CC-BY 4.0

is assigned a weight $w_p \in \mathbb{R}$, search radius $r > 0$, and approximation parameter $\varepsilon > 0$, the *approximate spherical range counting* problem is to preprocess P into a data structure that given any query point $q \in \mathbb{R}^d$, it reports $w_S = \sum_{p \in S} w_p$, where $S \subseteq P$ is a subset such that $B(q, r) \cap P \subseteq S \subseteq B(q, (1 + \varepsilon)r) \cap P$, where, for any $x \in \mathbb{R}^d$, $r > 0$, $B(x, r)$ denotes the Euclidean ball of radius r centered at x. Since we can uniformly rescale the dataset, we assume throughout the paper that the search radius is 1.

Related work. We juxtapose the above problem definition with a different notion of approximate counting, adapted for example by Aronov and Har-Peled [10], where one is interested in approximating the number of points inside a query range. Given a query range R_q, the data structure shall return a value ν such that $(1-\varepsilon)|R_q \cap P| \leq \nu \leq (1+\varepsilon)|R_q \cap P|$. Aronov and Har-Peled [10] show that one can reduce such a counting query to a sequence of "emptiness" queries, determining if the query range is empty or not, of length polynomial in $\log |P|$ and ε^{-1}. In contrast, our definition asks for an *exact* aggregate over a set whose geometry is allowed to vary within the annulus $B(q, 1+\varepsilon) \setminus B(q, 1)$. This definition has been used, e.g., by Arya and Mount [11], although they study solutions in the low-dimensional regime.

In terms of known solutions, approximate spherical range counting in high dimensions is not clearly distinguished from other variants of approximate range searching. Perhaps the most promising approach for related problems in high dimensions is locality sensitive hashing (LSH) (see [26, 20, 6, 8]), which maps the points to buckets with the promise that near (resp. far) points are more (resp. less) likely to be mapped together. It is not clear how one could use an LSH-based approach to solve the counting variant without paying at least the cost of exploring all points in $B(q, 1)$. This suggests that, within LSH-based frameworks, counting is unlikely to admit a fundamentally more efficient solution than reporting. In this work, we focus on designing solutions better suited to the counting variant.

Our Results. Our main contribution is to design a data structure for the approximate range counting problem in high-dimensional Euclidean spaces. For any constant approximation parameter $\varepsilon \in (0, 1)$, our data structure uses near-linear space, polynomial preprocessing time, and query time that is sublinear for any sublinear number of points in the ambiguity zone, i.e., for any sublinear $t_q = |\left(B(q, 1+\varepsilon) \setminus B(q, 1)\right) \cap P|$ the query time is sublinear.

Our approach is reminiscent of classic results for the *exact* range searching problem in low-dimensional Euclidean spaces. In particular, a central notion of our approach is that of partition trees [32, 14]. We adapt well-studied relations between spanning trees with low stabbing numbers (which also appears as "crossing" in previous works) and partition trees (see, e.g., [15]) to our approximate setting. A key difference in our setting is that we use a stronger notion of stabbing; we say that a point q ε-stabs a set S if $\exists x \in S : \|x - q\| \leq 1$ and $\exists y \in S : \|y - q\| \geq 1 + \varepsilon$ (classic stabbing would correspond to the case where $\varepsilon = 0$). An important step in our preprocessing algorithm is finding a "light" edge, i.e., a pair of input points that is ε-stabbed by a *polynomial in d* ratio of the relevant queries. Then, using the multiplicative weight update (MWU) method in a similar manner as [38, 15, 39], we are able to show that we can compute a spanning tree with low ε-stabbing number, implying that we can build a partition tree such that for any query, we only need to visit a bounded number of nodes. To traverse the partition tree, we need to be able to decide for each internal node if the corresponding subset is ε-stabbed by the query. We can only do this approximately, meaning that we may also explore nodes that are almost ε-stabbed, but the overall cost of this exploration is proportional to t_q.

▶ **Theorem 1** (Simplified version of Theorem 17). *Given a set of n points in $\mathbb{R}^d$, we can build a randomized data structure for the approximate range counting problem, with space usage in $\tilde{O}(n)$, preprocessing time in $O(dn) + n^{\mathsf{poly}(1/\varepsilon)}$ and sublinear query time if t_q is also sublinear.*

Our data structure is the first to achieve space usage that is near-linear in n and polynomial in d, and query time that is sublinear in n and polynomial in d for any sublinear t_q. In Table 1, we juxtapose our result with previous known results that even implicitly solve the same problem. While LSH is originally proposed for the approximate near neighbor problem, where the data structure is only required to report one witness point within distance $1 + \varepsilon$, Ahle et al. [2] proposed an LSH-based solution for the problem of reporting all points. Their data structure is adaptive; while building time and space can be that of an LSH table prepared for worst-case inputs (parameter ρ in Table 1), query time is that of the best LSH parameters for the query/instance (parameter b). Moreover, LSH tuned for near-linear space [8] can solve the reporting problem with only a logarithmic overhead in space and query time, since we can amplify the probability that every near neighbor will eventually be encountered. Since both LSH-based methods can solve the reporting variant, they can also solve the counting problem. However, it is not clear whether one can modify such an approach to avoid looking into all near points. Although our result does not guarantee sublinear query time in the worst case, it advances prior space-efficient work in high dimensions by making the complexity depend on the number of points in the annulus rather than on all points inside the entire ball. Trivially, the bucketing method, when combined with a Johnson-Lindenstrauss dimension reduction (as in [20]), can solve the counting problem; after reducing the dimension, one can store the relevant information in grid cells near the dataset. Such methods that discretize the query space, while providing efficient query times, unavoidably have huge space requirements. Finally, when the dimension is constant, partition trees [14] solve the problem exactly, while BBD-trees [11] leverage improved query times for approximate solutions (although still exponential in d).

In addition to our worst-case guarantees, we present an algorithm inspired by learning theory. Specifically, this algorithm is query-driven, i.e., it receives a number of query samples and aims to construct the data structure that yields the best expected query runtime for the distribution of the queries. This way, we design a much faster preprocessing algorithm (from $n^{\mathsf{poly}(1/\varepsilon)}$, the complexity falls to $n^{O(1)}$), which gives us similar bounds for the average case.

Our approach is motivated by the viewpoint of analyzing algorithms through the lens of statistical learning (e.g., [19, 12]). While this has been influential in optimization and mechanism design, to the best of our knowledge, a similar treatment for data structures is absent. Although related ideas appear in learned index structures [31], LSH trees whose cutting rules are optimized with respect to the given dataset [7], learning-augmented binary trees with optimized search assuming access to advice from a frequency estimation oracle [30], these works do not directly cast the data structure construction itself as a PAC learning problem. We also remark that the related notions of self-improving [3] and instance-optimal algorithms [1] address different guarantees. A simplified version of our result follows:

▶ **Theorem 2** (Simplified version of Theorem 20). *Given a set of n points in $\mathbb{R}^d$ and a sample of $O(nd \log n)$ queries from a query distribution $\mathcal{D}_Q$, we can compute a partition tree $\tilde{\mathcal{T}}$ with near-optimal expected visiting number for $\mathcal{D}_Q$ in $O(n^3 d \log n)$ time with high probability.*

We believe this is a neat way to use tools from other areas to design efficient algorithms for difficult problems or problems with only existence guarantees, and it would be interesting to see what other data-structure problems might benefit from this viewpoint.

Organization. In Section 2 we present notation and useful known results and prove auxiliary lemmas that will be used later. In Section 3 we analyze a data structure that supports approximate stabbing queries. Subsequently, in Section 4 we prove that a spanning tree with sublinear ε-stabbing number exists and can be computed in polynomial time, which we then use to prove that a partition tree with sublinear query time can be efficiently constructed in Section 5. In Section 6 we present our data-driven algorithm for building a partition tree with near-optimal expected visiting number. Missing proofs can be found in the full version.

Table 1 Existing solutions for the approximate range counting problem. k denotes the number of points within distance $1+\varepsilon$ from the query, whereas $t \leq k$ denotes the number of points at distance between 1 and $1+\varepsilon$ from the query. Adaptive LSH uses a worst-case choice of LSH exponent ρ, but answers queries with an instance-best LSH exponent b.

Method	Space	Prep. time	Query time
LSH [8]	$n^{1+o(1)}$	$n^{1+o(1)}$	$n^{1-\Theta(\varepsilon^2)+o(1)} + kn^{o(1)}$
Adaptive LSH [2]	$\tilde{O}(n^{1+\rho})$	$\tilde{O}(n^{1+\rho})$	$O(k(n/k)^b)$
Bucketing + JL [20]	$n^{\mathrm{poly}(1/\varepsilon)}$	$n^{\mathrm{poly}(1/\varepsilon)}$	$O(\varepsilon^{-2}\log n)$
BBD-Trees [11]	$O(dn)$	$O(dn\log n)$	$O(\log n) + O(1/\varepsilon)^{d-1}$
Partition trees [14]	$O(dn)$	$O(dn)$	$O(n^{1-1/d})$
Theorem 20	$\tilde{O}(n)$	$n^{\mathrm{poly}(1/\varepsilon)}$	$n^{1-\Theta(\varepsilon^4/\log(1/\varepsilon))} + t^{\Theta(\varepsilon^2)} \cdot n^{1-\Theta(\varepsilon^2)}$

2 Preliminaries

We use the $\tilde{O}$ notation to hide the dependence on $\mathrm{poly}(\log n, \log(1/\varepsilon))$. For any $\delta \in \mathbb{R}_{>0}$, let $\mathcal{G}_\delta^d = \{\delta \cdot v \mid v \in \mathbb{Z}^d\}$ be the grid of side length δ. Unless stated otherwise, $\|\cdot\|$ denotes the Euclidean norm $\|\cdot\|_2$. For any $p \in \mathbb{R}^d$ and $r > 0$, $B(p,r)$ denotes the Euclidean ball centered at p, i.e., $B(p,r) = \{x \in \mathbb{R}^d \mid \|x-p\| \leq r\}$.

We say that a set of points P is (ε, r)-*stabbed* by a point p, if and only if there exists a point $x \in P$ such that $\|x-p\| \geq (1+\varepsilon)r$ and there exists a point $y \in P$ such that $\|y-p\| \leq r$. We say that a pair of points x, y (or an edge formed by them) is (ε, r)-stabbed by p, if and only if $\{x, y\}$ is (ε, r)-stabbed by p. For brevity, when $r = 1$, we say that a pair x, y is ε-stabbed by p if and only if it is $(\varepsilon, 1)$-stabbed by p. Given some $P \subset \mathbb{R}^d$ and an edge set G (if G is a graph, we refer to its edges), $\sigma(q, G)$ denotes the *ε-stabbing number* of q on G, i.e., the number of edges in G that are ε-stabbed by q.

A *partition tree* $\mathcal{T}$ built on a set of points P is a tree where each node v is associated with a subset $P_v \subseteq P$, and for each node v with children $u_1, \ldots, u_\ell$, we have $P_v = \bigcup_i P_{u_i}$ and $\forall i \neq j \; P_{u_i} \cap P_{u_j} = \emptyset$. For a partition tree $\mathcal{T}$, and a query q, the *visiting number* of $\mathcal{T}$ w.r.t. q, denoted by $\zeta(q, \mathcal{T})$ is the number of nodes v in $\mathcal{T}$ which are either root of $\mathcal{T}$ or their parent u satisfies one of the following:

- P_u is ε-stabbed by q, or
- $P_u \cap (B(q, 1+\varepsilon) \setminus B(q,1)) \neq \emptyset$ and $P_u \subseteq B(q, 1+\varepsilon)$, or
- $P_u \cap (B(q, 1+\varepsilon) \setminus B(q,1)) \neq \emptyset$ and $P_u \cap B(q,1) = \emptyset$.

Intuitively, the visiting number is an upper-bound estimate of the number of nodes that will be visited to answer a query approximately.

2.1 Range spaces

Fix a countably infinite domain set X. The so-called Vapnik-Chernovenkis dimension [34, 35, 37] (VC dimension) of a set $\mathcal{F}$ of functions from X to $\{0,1\}$, denoted by $VCdim(\mathcal{F})$, is the largest d such that there is a set $S = \{x_1, \ldots, x_d\} \subseteq X$, for which, for any $s \in 2^S$ there

is a function $f \in \mathcal{F}$ such that $p \in s \iff f(p) = 1$. A *range space* is defined as a pair $(X, \mathcal{F})$ where X is the domain and $\mathcal{F}$ is a set of functions from X to $\{0, 1\}$, or equivalently a pair of sets $(X, \mathcal{R})$, where X is the domain and $\mathcal{R}$ is a set of ranges, i.e., subsets of X. The dual range space of a range space defined by sets $(X, \mathcal{R})$ is a range space defined by sets $(\mathcal{R}, \mathcal{X})$, where $\mathcal{X} = \{\{R \in \mathcal{R} \mid x \in R\} \mid x \in X\}$. The dual VC dimension of a range space is the VC dimension of its dual. A set $N \subseteq X$ is an ε-net if $\forall R \in \mathcal{R} : \ |R \cap X| \geq \varepsilon |X| \ \Rightarrow \ N \cap R \neq \emptyset$.

▶ **Theorem 3** (ε-net theorem [24]). *Let $(X, \mathcal{R})$ be a range space of VC-dimension $D < \infty$, where X is a finite set. There exists a constant $C > 0$ such that for any $\varepsilon \in (0, 1)$ if we sample a set of m points (independent picks with uniform probability) from X, where*

$$m \ \geq \ C \frac{1}{\varepsilon} \Big(D \log \tfrac{1}{\varepsilon} \ + \ \log \tfrac{1}{\delta} \Big),$$

then, with probability at least $1 - \delta$, the resulting set is an ε-net for $(X, \mathcal{R})$.

For any $S = (x_1, \ldots, x_m) \in X^m$ let $\mu_f(S) = m^{-1} \cdot \sum_{i=1}^{m} f(x_i)$. For any $\eta > 0, r \geq 0, s \geq 0$, let $d_\eta(r, s) = \frac{|r-s|}{\eta + r + s}$. By properly adjusting the parameters in Theorem 3.1 of [29], we obtain the following corollary. A similar result is obtained in [23].

▶ **Corollary 4.** *Let X be a countably infinite domain. Let $\mathcal{F}$ be a set of functions from X to $\{0, 1\}$ with VC dimension D and let $\mathcal{D}$ be a probability distribution over X. Also, let $\delta, \eta \in (0, 1)$. There is a universal constant c such that if $m \geq \frac{c}{\eta} \cdot \left(D \log \left(\frac{1}{\eta} \right) + \log \left(\frac{1}{\delta} \right) \right)$ then if we sample $S = \{x_1, \ldots, x_m\}$ independently at random according to $\mathcal{D}$, then with probability at least $1 - \delta$, for any $f \in \mathcal{F}$,*

$$|\mu_f(S) - \mathbb{E}_{p \sim \mathcal{D}}[f(p)]| \leq (3/8) \cdot \max\{\mathbb{E}_{p \sim \mathcal{D}}[f(p)], \eta\}.$$

A key requirement in building our data structures is to be able to efficiently sample from a multiset, which can also be updated. A multiset can be seen as a weighted set where weights correspond to multiplicities. In the following lemma, we show that one can maintain a multiset in a data structure that supports sampling and updates on the multiplicities.

▶ **Lemma 5.** *[Multiset sampling data structure] Let $P = \{p_1, \ldots, p_n\} \subset \mathbb{R}^d$, and let $\varepsilon \in (0, 1)$. Let $\Gamma = \{\gamma_1, \ldots, \gamma_n\} \subset \mathbb{N}$ be weights associated with the points of P. There is an algorithm that preprocesses Γ, P into a data structure, in $O(n \log n)$ time, using $O(n \log n)$ space, which supports the following operations:*

1. *sampling of a point $p_i \in P$ with probability $\frac{\gamma_i}{\sum_{i \in [n]} \gamma_i}$ in $O(\log(n))$ time,*
2. *update of the weight γ_i of a point $p_i \in P$, in $O(\log n)$ time.*

Sampling uses $O\left(\log\left(\sum_{i \in [n]} \gamma_i\right)\right)$ random bits. If bit-complexity were taken into account, both preprocessing and updates would incur an additional $O\left(\log\left(\sum_{i \in [n]} \gamma_i\right)\right)$ bit-cost per arithmetic operation.

2.2 Embeddings

We use the following version of the Johnson-Lindenstrauss (JL) lemma [28], as expressed for a single vector and Gaussian matrices.

▶ **Theorem 6** ([27]). *Let $x \in \mathbb{R}^d$ be fixed and let $k \in \mathbb{N}$. Draw a random matrix $A \in \mathbb{R}^{k \times d}$ with i.i.d. entries $A_{ij} \sim \mathcal{N}(0, 1/k)$. Then for any $\varepsilon \in (0, 1)$,*

$$\Pr\left[\left| \|Ax\|_2^2 - \|x\|_2^2 \right| > \varepsilon \|x\|_2^2 \right] \ \leq \ 2 \cdot exp\left(-\frac{\varepsilon^2 k}{8} \right).$$

We also make use of the following result on terminal embedding for Euclidean spaces.

▶ **Theorem 7** ([33]). *Let $T \subset \mathbb{R}^d$ be a finite set of* terminals. *For every $\varepsilon \in (0,1)$ there exists a mapping $f : \mathbb{R}^d \to \mathbb{R}^k$ with $k = O(\varepsilon^{-2} \log |T|)$ such that for all $q \in T$ and all $p \in \mathbb{R}^d$,*

$$(1-\varepsilon)\,\|q-p\|_2 \;\le\; \|f(q)-f(p)\|_2 \;\le\; (1+\varepsilon)\,\|q-p\|_2.$$

For any T, and any $c > 0$, we can compute a mapping f in $\mathrm{poly}(|T|)$ *time such that the above property holds with probability at least $1 - n^{-c}$. Moreover, for any $p \in \mathbb{R}^d$, $f(p)$ can be computed in* $\mathrm{poly}(|T|)$ *time.*

2.3 Model

We assume that our algorithms operate in the Real-RAM model with the additional assumption that the floor function can be computed in constant time. While it is known that this model is strictly more powerful than the classical word-RAM [16], it is often used in the Computational Geometry literature [22]. We stress that we do not use encodings that pack superpolynomial information into a single machine word or real number, and our use of $\lfloor \cdot \rfloor$ is purely for convenience (e.g., discretization and bucketing).

One building block of our algorithms is a data structure known as the dictionary. A *dictionary* is a data structure which stores a set of (key, value) pairs and when presented with a key, either returns the corresponding value, or returns that the key is not stored in the dictionary. In our case, keys are typically vectors in $\mathbb{Z}^d$ and values are pointers to lists. In the Real-RAM model, we can use a balanced binary tree to build a dictionary with n values, using $\tilde{O}(dn)$ preprocessing time and storage and $\tilde{O}(d)$ query time.

3 Approximate stabbing queries

In this section, we design a solution for our main subproblem, that is, the problem of preprocessing a set of points to support queries that ask to determine if a query ε-stabs the given pointset. In particular, the data structure is required to determine if the query ε-stabs the pointset, if all points are near the query, or if all points are far from the query. The resulting data structure returns approximate answers, meaning that it allows for wrong decisions when the pointset is "nearly" ε-stabbed, as formalized in Theorem 10. This is sufficient for our purposes, which are building these data structures in internal nodes of a partition tree to assist in traversing the tree to answer a query.

Our main technical ingredient is a randomized embedding to the Hamming metric, which is implemented using LSH to partition the space into buckets and then applying random binarization of the buckets. A similar argument has been used in Alman et al. [5], where they first embed the points to ℓ_1 and then use an LSH function to partition points into buckets; each bucket is then assigned to a random bit. Repeating the above sufficiently many times gives the desired embedding. We obtain a slightly more direct construction that does not need to embed the points in ℓ_1, but instead uses the LSH family of Datar et al. [18]. The final embedding succeeds in preserving distances with respect to a single scale; distances considered small with respect to a given threshold remain small, and large distances remain large. This is formally stated in the following lemma.

▶ **Lemma 8.** *For any $\delta, \varepsilon \in (0,1)$, there exists a randomized embedding $f : \mathbb{R}^d \to \{0,1\}^{d'}$, and specific $\theta \in [d']$, such that, for any $p, q \in \mathbb{R}^d$, with probability at least $1-\delta$,*

- *if $\|p-q\| \le 1$ then $\Pr[\|f(p)-f(q)\|_1 > \theta] \le e^{-\frac{\varepsilon^2 d'}{19200}}$*
- *if $\|p-q\| \ge (1+\varepsilon)$ then $\Pr[f\|(p)-f(q)\|_1 < \theta + \varepsilon d'] \le e^{-\frac{\varepsilon^2 d'}{19200}}$.*

Moreover, for any $p \in \mathbb{R}^d$, $f(p)$ can be computed in $O(d)$ running time.

We aim to build a data structure that supports approximate "stabbing queries". Given a query point q we need to identify if there exists a pair of points in the input pointset that are (approximately) ε-stabbed by q. Using the embedding of Lemma 8, we map points to keys in $\{0,1\}^{d'}$, and we store them in a dictionary, where each bucket is assigned the list of points mapped to it. We set d' slightly below $\log n$ to balance the number of buckets $2^{d'}$ with the number of arbitrarily distorted distances from q, in a way that both remain sublinear. To answer a query, we search the dictionary for an approximate near neighbor, i.e., a point within distance $1+\varepsilon$, and an approximate far neighbor, i.e., a point at a distance of at least 1. The following lemma indicates that a simple search over the buckets of a single dictionary is sufficient to guarantee that if there is a point within distance 1, we will find a point within distance $1+\varepsilon$ with constant probability, and if there is a point at distance at least $1+\varepsilon$, we will find a point at distance at least 1 with constant probability. We remark that for finding an approximate near neighbor, one could instead use the data structure of Andoni et al. [8] that provides near-linear space with comparable query time. However, we are not aware of a comparable result for computing an approximate far neighbor (which we also need and do).

▶ **Lemma 9.** *Let $P=\{p_1,\ldots,p_n\}\subset\mathbb{R}^d$ and let $\varepsilon\in(0,1)$. We can build a randomized data structure with preprocessing time and space in $\tilde{O}(dn)$ and query time in $\tilde{O}(dn^{1-\frac{\varepsilon^2}{19200(1+\varepsilon^2)}})$, such that for any query $q\in\mathbb{R}^d$, it reports $\mathcal{I}$, $|\mathcal{I}|\leq 2$, as follows:*

- *if $\exists x\in P:\ \|x-q\|\leq 1$ then $\Pr[\exists i\in\mathcal{I}$ such that $\|q-p_i\|\leq 1+\varepsilon]\geq 0.95$,*
- *if $\exists y\in P:\ \|y-q\|\geq 1+\varepsilon$ then $\Pr[\exists j\in\mathcal{I}$ such that $\|q-p_j\|\geq 1]\geq 0.95$,*

where the probabilities are taken over the randomness during preprocessing.

Now using Lemma 9, we can prove the main result of this section, namely, a data structure that determines, with high probability, if a query point ε-stabs the preprocessed pointset, if it is near the entire pointset (the pointset is *covered* by q), or if it is far from the entire pointset (the pointset is *disjoint* from q). The data structure gives approximate answers in the following sense: if all points are within distance $1+\varepsilon$, and there is at least one point at a distance at most 1, it can falsely report that the pointset is ε-stabbed. Similarly, if all points are at a distance larger than 1, and there is at least one point at a distance of at least $1+\varepsilon$, it can falsely report that the pointset is ε-stabbed. If all points lie in the annulus $\{x\in\mathbb{R}^d \mid \|x-q\|\in(1,1+\varepsilon)\}$ then any answer is possible. Additionally, the success probability of the preprocessing is for each query individually, i.e., it is not for all queries simultaneously. Copies of this structure will be used as parts of the final data structure for the approximate spherical range counting problem.

▶ **Theorem 10.** *Let $P\subset\mathbb{R}^d$ be a set of n points and let $\varepsilon\in(0,1)$. We can build a randomized data structure such that for any query $q\in\mathbb{R}^d$, it reports as follows:*

- *if $\exists x\in P:\ \|x-q\|\leq 1$ and $\exists y\in P:\ \|y-q\|\geq 1+\varepsilon$ then it returns "stabbed",*
- *if $\forall y\in P:\ \|y-q\|\leq 1$ then it returns "covered"*
- *if $\forall x\in P:\ \|x-q\|\geq 1+\varepsilon$ then it returns "disjoint",*
- *if $\exists x\in P:\ \|x-q\|\leq 1$ and $\forall y\in P:\ \|y-q\|<1+\varepsilon$ then it can return "stabbed", or "covered", and*
- *if $\exists x\in P:\ \|x-q\|\geq 1+\varepsilon$ and $\forall y\in P:\ \|y-q\|>1$ then it can return "stabbed", or "disjoint".*
- *if $\forall x\in P:\ \|x-q\|\in(1,1+\varepsilon)$ then it can return "stabbed", or "disjoint", or "covered".*

For each query and for any constant $c>0$, the preprocessing of the data structure succeeds with probability $1-n^{-c}$, has $\tilde{O}(dn)$ preprocessing time and space and the query time is $\tilde{O}(dn^{1-\frac{\varepsilon^2}{19200(1+\varepsilon^2)}})$.

Proof. We build $L = c \log n$ independent data structures as in Lemma 9. For any query point $q \in \mathbb{R}^d$, we query the data structures, and we report as follows. If we find a point x such that $\|x - q\| \leq 1 + \varepsilon$ and a point y such that $\|y - q\| \geq 1$ we return "stabbed". Otherwise, if all returned points are within distance $1 + \varepsilon$, we return "covered". Else, we return "disjoint".

If there is a pair x, y in P such that $\|x - q\| \leq 1$ and $\|y - q\| \geq 1 + \varepsilon$ then the probability that all L data structures fail to return a point x' such that $\|x' - q\| \leq 1 + \varepsilon$ or a point y' such that $\|y' - q\| \geq 1$ is by union bound at most $2 \cdot 0.05^L \leq n^{-c}$. Moreover, if all points of P are within distance 1 from q (resp. at a distance of at least $1 + \varepsilon$), then all returned points are within distance $1 + \varepsilon$ from q (resp. at a distance of at least 1), implying that the query algorithm correctly identifies "covered" (resp. "disjoint"). ◀

4 Spanning trees with low ε-stabbing number

The ε-stabbing number of a spanning tree (or of a set of edges in general) is the maximum number of edges of that tree (or that set) that are ε-stabbed by any query range. Chazelle and Welzl showed in [15] a close relationship between the stabbing number of a spanning tree (the stabbing number is the special case of ε-stabbing number where $\varepsilon = 0$) and the maximum number of nodes visited, during a worst-case query, in a corresponding partition tree. Motivated by this, we wish to extend this notion to the ε-stabbing number and to achieve similar results, but without exponential dependency on d as we deal with the approximation scheme. In this section, we show that a spanning tree with sublinear ε-stabbing number exists, and can be computed in polynomial time. Following [15], we use MWU to find a spanning tree with small ε-stabbing number. We remark that there are other alternatives [17, 21] in the literature for computing spanning trees with low stabbing numbers. While it is plausible that they can be modified to support our notion of ε-stabbing, they all share the same bottleneck, i.e., they depend at least linearly on the number of ranges.

Similarly, to [15], we start by showing that for any set of ball queries, we can always find a pair of points that is not ε-stabbed many times.

▶ **Lemma 11.** *Let $P \subset \mathbb{R}^d$ be a set of n points and let Q be a multiset consisting of m points from a universe set $U \subset \mathbb{R}^d$. Let $\varepsilon \in (0, 1)$. There exists a pair of points in P which is not ε-stabbed by more than $O\left(m \cdot \frac{d}{n^\rho}\right)$ points of Q, where $\rho = \Theta(\varepsilon^2 / \log(1/\varepsilon))$.*

If Q is stored in a multiset sampling data structure as in Lemma 5, then for any constant c, we can find such a pair of points in $\mathrm{poly}(n, d, \frac{1}{\varepsilon}) \cdot O(\log |U|)$ time with probability $1 - n^{-c}$.

Proof. If $d \geq n^\rho$, then the statement trivially holds, since $|Q| = m$. Thus, we assume $d < n^\rho$. For any two points x, y, let $S_{x,y}$ be the set of points in $\mathbb{R}^d$ that ε-stab x, y. We define a range space $\mathcal{R} = (\mathbb{R}^d, \{S_{x,y} \mid x, y \in \mathbb{R}^d, x \neq y\})$. Notice that for any point $p \in \mathbb{R}^d$, determining if $p \in S_{x,y}$ reduces to evaluating the signs of the following four polynomials of degree 2 in d variables: $\|p - x\|^2 - 1$, $\|p - x\|^2 - (1 + \varepsilon)^2$, $\|p - y\|^2 - 1$, $\|p - y\|^2 - (1 + \varepsilon)^2$. This implies (see, e.g., [9][Theorem 8.3]) that the VC dimension of $\mathcal{R}$ is $O(d)$. Hence, by Theorem 3, for any $\delta < 1$ and constant $c > 0$, a random sample N_δ of $O\left(\frac{d}{\delta}\left(\log\left(\frac{1}{\delta}\right) + \log n\right)\right)$ points of Q is a δ-net for $\mathcal{R}$ with probability $1 - n^{-c-1}$. Moreover, we can find such a δ-net by randomly sampling from Q, using the assumed multiset sampling data structure of Lemma 5, in $\tilde{O}(\frac{d}{\delta} \log n) \cdot O(\log |U|)$ time.

By Theorem 7, there exists a terminal embedding f to dimension $d' = O(\varepsilon^{-2} \log |N_\delta|)$ such that $\forall p \in N_\delta, q \in \mathbb{R}^d$, $\|f(p) - f(q)\| \in (1 \pm \varepsilon/20)\|p - q\|$. The time needed to compute $f(P)$ is in $O(n) \cdot \mathrm{poly}(|N_\delta|)$ for the probability of success to be at least $1 - n^{-c-1}$.

Now let $x, y \in P$ be ε-stabbed by some $q \in Q$, and further assume wlog that $\|x - q\| \leq 1$ and $\|y - q\| \geq 1 + \varepsilon$. We obtain $\|f(x) - f(q)\| \leq 1 + \varepsilon/20$ and $\|f(y) - f(q)\| \geq (1 + \varepsilon)(1 - \varepsilon/20) \geq 1 + 3\varepsilon/4$. Hence, $f(x), f(y)$ are $(\varepsilon/2, 1 + \varepsilon/20)$-stabbed by $f(q)$. Moreover, by the triangle

inequality, $\|f(x) - f(y)\| \geq \varepsilon/2$. Now consider the grid of side-length $\varepsilon/(4\sqrt{d'})$ in $\mathbb{R}^{d'}$ and let U_B be the set of all grid cells that intersect with at least one ball of radius $1+\varepsilon$ centered at a point of $f(N_\delta)$. There are

$$n_{\varepsilon,d'} = |N_\delta| \cdot O(1/\varepsilon)^{d'} = |N_\delta| \cdot O(1/\varepsilon)^{O(\varepsilon^{-2} \cdot \log|N_\delta|)} = |N_\delta|^{O(\varepsilon^{-2}\log(1/\varepsilon))}$$

such cells, where $|N_\delta| = O\left(\frac{d}{\delta}\left(\log\left(\frac{1}{\delta}\right) + \log n\right)\right)$. Now let $\delta = \frac{d}{n^\rho}$ where $\rho = \Theta(\varepsilon^2/\log(1/\varepsilon))$ is chosen sufficiently small (in terms of the hidden constants) so that $|N_\delta|^{O(\varepsilon^{-2}\log(1/\varepsilon))} \leq (n^\rho \log n)^{O(\varepsilon^{-2}\log(1/\varepsilon))} < n-2$. By the pigeonhole principle, there is either a pair of points of P mapped to the same cell of U_B, under f, or there is a pair of points of P that are not mapped to U_B. In either case, the two points are not $(\varepsilon/2, 1+\varepsilon/20)$-stabbed by any point of $f(N_\delta)$. To see this, notice that if the two points are in the same cell, then they are within distance $\varepsilon/4$ from each other, contradicting the fact that they are $(\varepsilon/2, 1+\varepsilon/20)$-stabbed (which would mean they are separated by a distance of at least $\varepsilon/2$). If they are not mapped in U_B then neither of them is within distance $1+\varepsilon/20$ from any point of $f(N_\delta)$, also implying that they cannot be $(\varepsilon/2, 1+\varepsilon/20)$-stabbed by any point of $f(N_\delta)$. Since the two points are not $(\varepsilon/2, 1+\varepsilon/20)$-stabbed by any point of $f(N_\delta)$ in the mapped space, their pre-images (under f) are not ε-stabbed by any point of N_δ. Since N_δ is a δ-net, it must be that at most δm points of Q ε-stab those two points.

We now focus on the running time needed to find a pair of points as above. By Theorem 7, we can map points under f in $\text{poly}(n)$ time. To compute the two points, we essentially use the bucketing method (see, e.g., [20]) for balls centered at $f(N_\delta)$. We first store all cells of U_B in a dictionary data structure. Then, for each point $x \in f(P)$, we query the data structure to see if its cell C_x is stored, i.e., $C_x \in U_B$. If $C_x \in U_B$ then we store x in a linked list in the bucket of C_x. We can stop and output any two points stored in the same linked list, or any two points whose cells do not belong to U_B. Iterating over all points of $f(P)$ costs $\tilde{O}(dn)$ assuming that the dictionary is implemented using balanced binary trees. The overall probability of success follows from a union bound over failure events of the random sampling for computing N_δ and the failure event of computing the terminal embedding f. ◀

Knowing that a good pair exists, and that we can find it, we repeat the process $n/2$ times, in order to build a good forest, in the sense that it has a small ε-stabbing number. We use the MWU technique introduced in the context of trees with low stabbing number in [15].

▶ **Lemma 12.** *Let $P \subset \mathbb{R}^d$ be a set of n points and let $\varepsilon \in (0,1)$. There is a forest of trees on P with at least $n/2$ edges, such that every point of $\mathcal{G}_\gamma^d$ ε-stabs $\tilde{O}(dn^{1-\rho})$ edges, where $\gamma = \Theta(\varepsilon/\sqrt{d})$, $\rho = \Theta(\varepsilon^2/\log(1/\varepsilon))$. For any $c > 0$, we can compute such a forest in $\text{poly}(n, d, \frac{1}{\varepsilon})) + \tilde{O}(n) \cdot O(1/\varepsilon)^d$ time, with probability of success $1 - n^{-c}$.*

We conclude with the main result of this section, the tractability of a spanning tree with a sublinear ε-stabbing number. This follows from $O(\log n)$ iterative applications of Lemma 12.

▶ **Theorem 13.** *Let $P \subset \mathbb{R}^d$ be a set of n points. There is a spanning tree on P such that every point of $\mathcal{G}_\gamma^d$ ε-stabs $\tilde{O}(dn^{1-\rho})$ edges, where $\gamma = \Theta(\varepsilon/\sqrt{d})$, $\rho = \Theta(\varepsilon^2/\log(1/\varepsilon))$.*

Moreover, for any $c > 0$, we can compute such a spanning tree in $\text{poly}(n, d, \frac{1}{\varepsilon}) + \tilde{O}(n) \cdot O(1/\varepsilon)^d$ time, with probability of success $1 - n^{-c}$.

5 Spherical range counting

In this section, we show how to construct a partition tree for the approximate spherical range counting problem with sublinear query time. We first show how to get a partition tree with a sublinear visiting number given a spanning tree with a sublinear ε-stabbing number, by

extending the procedure in [15] to accommodate the approximation scheme. Subsequently, we incorporate the data structures of Section 3 in the inner nodes of the partition tree to get sublinear worst-case guarantees.

We start by proving that having a spanning tree with low ε-stabbing number can give us a spanning path with low ε-stabbing number, which we then use to construct a partition tree with low visiting number. Lemmas 14 and 15 are adapted from [15] for ε-stabbing numbers, and the bounds become dependent on the ambiguity zone of the query.

▶ **Lemma 14.** *Given a spanning tree T on a pointset $P \subset \mathbb{R}^d$, we can build a spanning path $\mathcal{P}$ on P, in $O(dn)$ time, such that for any point q, $\sigma(q, \mathcal{P}) \leq 2\sigma(q, T) + 2t_q$, where $t_q = |\,(B(q, 1+\varepsilon) \setminus B(q, 1)) \cap P|$.*

▶ **Lemma 15.** *Given a spanning path $\mathcal{P}$ on a pointset $P \subset \mathbb{R}^d$ we can build a binary partition tree $\mathcal{T}$ on P, in $(dn \log n)$ time, such that for any point q, we have $\zeta(q, \mathcal{T}) \leq 2[\sigma(q, \mathcal{P}) + t_q] \cdot \log n + 1$, where $t_q = |\,(B(q, 1+\varepsilon) \setminus B(q, 1)) \cap P|$.*

We combine these results to get a bound on the visiting number of a partition tree.

▶ **Corollary 16.** *Let $P \subset \mathbb{R}^d$ be a set of n points. For any $c > 0$, we can build a binary partition tree $\mathcal{T}$ on P, in $\mathrm{poly}(n, d, \frac{1}{\varepsilon}) + \tilde{O}(n) \cdot O(1/\varepsilon)^d$ time such that with probability $1 - 1/n^c$ every $q \in \mathcal{G}_\gamma^d$, with $\gamma = \varepsilon/\sqrt{d}$, visits $\zeta(q, \mathcal{T}) = \tilde{O}(dn^{1-\rho} + t_q)$ nodes, where $t_q = |\,(B(q, 1+\varepsilon) \setminus B(q, 1)) \cap P|$ and $\rho = \Theta(\varepsilon^2 / \log(1/\varepsilon))$.*

Finally, we present the main contribution of our paper, which states that for the approximate spherical range counting problem, we can build a data structure in polynomial time that supports sublinear queries (if t_q is also sublinear) and takes near-linear space. In our proof, we make use of Theorems 10 and 13 and Lemma 15.

▶ **Theorem 17.** *Let $P \subset \mathbb{R}^d$ be a set of n points, such that each $p \in P$ is assigned a weight $w_p \in \mathbb{R}$, and let $\varepsilon \in (0, 1)$. We can build a data structure for the approximate range counting problem with input P, $\{w_p \mid p \in P\}$, ε, that uses space in $\tilde{O}(n)$, needs preprocessing time in $O(dn) + n^{O(\varepsilon^{-2} \log(1/\varepsilon))}$ and for each query $q \in \mathbb{R}^d$, it returns an answer in $n^{1-\Theta(\varepsilon^4/\log(1/\varepsilon))} + t_q^{\varrho} \cdot n^{1-\varrho}$ time, where $\varrho = \Theta(\varepsilon^2)$ and $t_q = |\,(B(q, 1+\varepsilon) \setminus B(q, 1)) \cap P|$. For each query, the preprocessing succeeds with probability $1 - n^{-c}$, where $c > 0$ is a constant hidden in the aforementioned time and space complexities.*

Proof. We first apply a JL transformation [28] to reduce the dimension to $O(\varepsilon^{-2} \log n)$. By Theorem 6, and by applying a union bound over n vectors, for any $c > 0$ and any query $q \in \mathbb{R}^d$, with probability $1 - 1/n^c$, all distances from P are approximately preserved within factors $1 \pm \varepsilon/10$. This initial step costs $O(dn)$ time. For the rest of the proof, we assume that all points lie in $\mathbb{R}^{O(\varepsilon^{-2} \log n)}$. Then, we assume that queries are snapped to the grid $\mathcal{G}_\gamma^d$, $\gamma = \varepsilon/(10\sqrt{d})$. This induces an additive $\pm\varepsilon/10$ error to the distances between P and the query. Hence, points within distance 1 from the query may be moved to a distance up to $1 + \varepsilon/5$, and points at a distance of at least $1 + \varepsilon$ may be moved to a distance of at least $1 + 4\varepsilon/5$. Notice that $1 + \varepsilon/2 \leq \frac{1+4\varepsilon/5}{1+\varepsilon/5}$, hence it suffices to use a more refined error of $\varepsilon/2$ for the rest of the construction and assume that the space is rescaled by a factor $1/(1 + \varepsilon/5)$.

We build a binary partition tree $\mathcal{T}$ on the input with error parameter $\varepsilon/2$ using Corollary 16. The construction of $\mathcal{T}$ can be done in $n^{O(\varepsilon^{-2} \log(1/\varepsilon))}$ time and be successful for a fixed q, in that $\zeta(q, \mathcal{T}) \leq n^{1-\Theta(\varepsilon^2/\log(1/\varepsilon))} + t_q$, with probability $1 - 1/n^c$ for any constant $c > 0$. For each internal node v, let P_v be the set of points in the leaves of the subtree rooted at v. In each internal node v, we build a data structure $\mathcal{D}_v$ as in Theorem 10 on P_v with error

parameter $\varepsilon/2$, and we store the cumulative weight s_v of the points in P_v, i.e., $s_v = \sum_{p \in P_v} w_p$. By Theorem 10, each construction of a data structure $\mathcal{D}_v$, can be done in $\tilde{O}(d|P_v|)$ time and be successful with probability $1 - 1/n^c$ for any constant $c > 0$. By a union bound over all inner nodes, we claim that all data structures $\mathcal{D}_v$ are also successful for q with probability $1 - \Theta\left(\frac{n \log n}{n^c}\right)$. By Theorem 10, the time and space needed to build data structures for the inner nodes is near-linear per level of the tree (since each level defines a partition).

To answer a query $q \in \mathbb{R}^d$, we traverse the tree and collect all cumulative weights s_v in each internal node v, whose associated data structure $\mathcal{D}_v$ returns "covered". We continue traversing the children of a node v if and only if $\mathcal{D}_v$ returns "stabbed". By Corollary 16, assuming that the tree has been constructed correctly for $q \in \mathbb{R}^d$, the number of nodes visited during the query algorithm for input $q \in \mathbb{R}^d$ is $\tilde{O}(n^\alpha + t_q)$, where $\alpha = 1 - \Theta(\varepsilon^2/\log(1/\varepsilon))$. By Theorem 10, the time needed to query a data structure $\mathcal{D}_v$ in an internal node v is $\tilde{O}(|P_v|^\beta)$, where $\beta = 1 - \Theta(\varepsilon^2)$. At each level i of $\mathcal{T}$, the number of nodes whose data structures are queried is upper bounded by both 2^i and $\zeta(q, \mathcal{T})$. Hence, the running time at level i for query q is $\tilde{O}(T_i^q(n))$, where $T_i^q(n)$ is defined as follows:

$$T_i^q(n) = \min\left\{2^i,\ n^\alpha + t_q\right\} \cdot \left(\frac{n}{2^i}\right)^\beta \leq (n^\alpha + t_q)^{1-\beta} \cdot n^\beta,$$

because if $i \leq \log(n^\alpha + t_q)$ then $\min\left\{2^i,\ n^\alpha + t_q\right\} = 2^i$ and if $i > \log(n^\alpha + t_q)$ then $\min\left\{2^i,\ n^\alpha + t_q\right\} = n^\alpha + t_q$. Now, since $1 - \beta < 1$,

$$T_i^q(n) \leq n^{\alpha(1-\beta)+\beta} + t_q^{1-\beta} \cdot n^\beta = n^{1-\Theta(\varepsilon^4/\log(1/\varepsilon))} + t_q^\varrho \cdot n^{1-\varrho},$$

where $\varrho = 1 - \beta$. We observe that the query algorithm will not explore any descendants of an internal node v if $\mathcal{D}_v$ returns "disjoint" when $\min_{x \in P_v} \|x - q\| > 1$, or if $\mathcal{D}_v$ returns "covered" when $\max_{x \in P_v} \|x - q\| \leq 1 + \varepsilon/2$, in which case it takes into account s_v. Thus, the answer is calculated by summing over cumulative weights $s_{v_1}, \ldots, s_{v_\ell}$ of nodes corresponding to subsets $P_{v_1}, \ldots, P_{v_\ell}$ such that $B(q, 1) \cap P \subseteq \bigcup_{i \in [\ell]} P_{v_i} \subseteq B(q, 1 + \varepsilon/2) \cap P$. ◀

6 Data-driven range searching

As we saw in the previous section, we can construct the partition tree in polynomial time. However, the exponent depends on $1/\varepsilon$, which we would like to avoid. In this section, we present an algorithm inspired by learning theory that constructs a partition tree with near-optimal visiting number in expectation, over the distribution of queries. Specifically, the algorithm will have access to a number m of sample queries, and will construct a partition tree that is optimal for that sample - thus the algorithm is data-driven. Showing that uniform convergence is achieved, we prove that this partition tree is nearly optimal, in that its expected visiting number is nearly minimal.

In the next lemma, we show that using only a near-linear number of queries we can achieve uniform convergence for the expected ε-stabbing number, i.e., for any spanning tree, the estimation of the ε-stabbing number using only these queries is close to its real expected ε-stabbing number.

▶ **Lemma 18.** *Let P be a set of n points in $\mathbb{R}^d$ and let $\mathcal{D}_Q$ be a ball query distribution having as support a countably infinite set $\mathcal{R}$. It suffices to sample $m \in O(n \cdot (d \log n + \log(1/\delta)))$ queries S independently from $\mathcal{D}_Q$, so that with probability at least $1 - \delta$, for any spanning tree T of P, $m^{-1} \cdot \sum_{q \in S} \sigma(q, T)$ is in $\left[\frac{5}{8} \cdot \mathbb{E}_{q \sim \mathcal{D}_Q}[\sigma(q, T)] - \frac{3}{8}, \frac{11}{8} \cdot \mathbb{E}_{q \sim \mathcal{D}_Q}[\sigma(q, T)] + \frac{3}{8}\right]$.*

The next lemma states that the number of nodes of a partition tree visited during a query search consists an upper bound on the ε-stabbing number of a corresponding spanning path of the points for the same query. Its proof is a straightforward adaptation of the third item of [15, Lemma 3.1].

▶ **Lemma 19.** *If $\mathcal{T}$ is a partition tree for P, then there exists a spanning path $\mathcal{P}$ whose ε-stabbing number does not exceed the visiting number of $\mathcal{T}$.*

We now prove the main result of this section.

▶ **Theorem 20.** *Let P be a set of n points in $\mathbb{R}^d$ and let $\mathcal{D}_Q$ be a ball query distribution having as support a countably infinite set $\mathcal{R}$. It suffices to sample a set S of $m \in O(n \cdot (d \log n + \log(1/\delta)))$ queries independently from $\mathcal{D}_Q$, so that with probability at least $1-\delta$, we can compute a partition tree $\tilde{\mathcal{T}}$ such that*

$$\mathbb{E}_{q\sim\mathcal{D}_Q}\left[\zeta(q,\tilde{\mathcal{T}})\right] = O\left(\left[\min_{\mathcal{T}} \mathbb{E}_{q\sim\mathcal{D}_Q}[\zeta(q,\mathcal{T})] + t_q\right] \cdot \log n\right),$$

where $t_q = |\,(B(q,1+\varepsilon) \setminus B(q,1)) \cap P|$. Moreover, given S, the running time to compute $\tilde{\mathcal{T}}$ is in $O(n^3(d\log n + \log(1/\delta))$.

Proof. By Lemma 18, with probability at least $1-\delta$, for any spanning tree T of P, $m^{-1} \cdot \sum_{q\in S} \sigma(q,T)$ is in

$$\left[\frac{5}{8} \cdot \mathbb{E}_{q\sim\mathcal{D}_Q}\left[\sigma(q,T)\right] - \frac{3}{8}, \frac{11}{8} \cdot \mathbb{E}_{q\sim\mathcal{D}_Q}\left[\sigma(q,T)\right] + \frac{3}{8}\right].$$

Now, let $E(T)$ denote the edges of spanning tree T and $\tilde{T} = \arg\min_T\{m^{-1} \cdot \sum_{q\in S} \sigma(q,T)\}$. Notice that $\sum_{q\in S} \sigma(q,T) = \sum_{q\in S} \sum_{e\in E(T)} \sigma(q,\{e\}) = \sum_{e\in E(T)} \sum_{q\in S} \sigma(q,\{e\})$ for any spanning tree T. Hence, we can compute $\tilde{T}$, by first constructing a complete weighted graph on P where we assign weight $\sum_{q\in S} \sigma(q,\{e\})$ to each edge $e \in \binom{P}{2}$, and then computing the minimum spanning tree on that graph, using Kruskal's algorithm. The running time of this step is $O(n^2 m)$, which corresponds to the step of building the graph.

Let T^* be the spanning tree that minimizes $\mathbb{E}_{q\sim\mathcal{D}_Q}[\sigma(q,T)]$ over all spanning trees T of P. By Lemma 19 we get $\mathbb{E}_{q\sim\mathcal{D}_Q}[\sigma(q,T^*)] \le \min_{\mathcal{T}} \mathbb{E}_{q\sim\mathcal{D}_Q}[\zeta(q,\mathcal{T})]$ and by Lemma 18 we get:

$$\Omega(1) \cdot \mathbb{E}_{q\sim\mathcal{D}_Q}[\sigma(q,\tilde{T})] \le m^{-1} \sum_{q\in S} \sigma(q,\tilde{T}) \le m^{-1} \sum_{q\in S} \sigma(q,T^*) \le O(1) \cdot \mathbb{E}_{q\sim\mathcal{D}_Q}[\sigma(q,T^*)]$$

Hence $\mathbb{E}_{q\sim\mathcal{D}_Q}[\sigma(q,\tilde{T})] \subseteq O\left(\min_{\mathcal{T}} \mathbb{E}_{q\sim\mathcal{D}_Q}[\zeta(q,\mathcal{T})]\right)$. Given $\tilde{T}$, by Lemmas 14 and 15 we can construct a binary partition tree $\tilde{\mathcal{T}}$ of P such that

$$\begin{aligned}\mathbb{E}_{q\sim\mathcal{D}_Q}[\zeta(q,\tilde{\mathcal{T}})] &= O\left(\left[\mathbb{E}_{q\sim\mathcal{D}_Q}[\sigma(q,\tilde{T})] + t_q\right] \cdot \log n\right) \\ &= O\left(\left[\min_{\mathcal{T}} \mathbb{E}_{q\sim\mathcal{D}_Q}[\zeta(q,\mathcal{T})] + t_q\right] \cdot \log n\right)\end{aligned}$$

in $O(n)$ time. Thus, the overall running time is $O(n^2 m) \subseteq O(n^3(d\log n + \log(1/\delta))$. ◀

Complements of Finite Unions of Convex Sets

Chaya Keller

Abstract

Finite unions of convex sets are a central object of study in discrete and computational geometry. In this paper we initiate a systematic study of *complements* of such unions – i.e., sets of the form $S = \mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$, where K_i are convex sets. In the first part of the paper we study isolated points in S, whose number is related to the Betti numbers of $\cup_{i=1}^n K_i$ and to its non-convexity properties. We obtain upper bounds on the number of such points, which are sharp for $n = 3$ and significantly improve previous bounds of Lawrence and Morris (2009) for all $n \ll \frac{2^d}{d}$. In the second part of the paper we study coverings of S by well-behaved sets. We show that S can be covered by at most $g(d, n)$ flats of different dimensions, in such a way that each $x \in S$ is covered by a flat whose dimension equals the "local dimension" of S in the neighborhood of x. Furthermore, we determine the structure of a minimum cover that satisfies this property. Then, we study quantitative aspects of this minimum cover and obtain sharp upper bounds on its size in various settings.

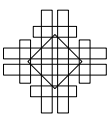
1 Introduction

The complexity of finite unions of convex sets has been a prolific research area in the last decades, due to intrinsic deep discrete-geometric questions pertaining to it and to applications to optimization, robotics, motion planning and other areas (see, e.g., the survey [1]). In some of these questions and applications, the structure of the complement plays an important role, and as a result, various structural questions regarding complements of such finite unions were studied in different works over the years.



One well-studied question is determining the maximum possible number of *bounded connected components* in $S = \mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$ (also known as *voids* in $K = \cup_{i=1}^n K_i$), where $\{K_i\}$ are convex. Asked by Fejes Tóth in the plane, and independently by Vitushkin (1958) in $\mathbb{R}^d$, this question was studied both in full generality and for specific families of convex sets, such as translates of the same convex set (see, e.g., [2, 9]). As the number of voids is equal to the $(d-1)$'st Betti number of $\cup_{i=1}^n K_i$, bounding its maximum size is the first step toward understanding the statistical behavior of the Betti numbers of such unions (see [8]).

A related question is determining the maximum possible number of *all* connected components (including unbounded ones). Kovalev [11] proved that the maximum is $\sum_{i=0}^{d} \binom{n}{i}$, and that it is attained if and only if K_i are either hyperplanes in general position, or layers between parallel hyperplanes. Bei, Chen and Zhang [5] provided a different proof, and applied the result to analyze the complexity of an algorithm they proposed for solving linear programming problems with only partial knowledge of the constraints.

In the case where $\{K_i\}$ are polyhedra, the combinatorial complexity of S plays an important role in motion planning, and was studied, e.g., by Aronov and Sharir in [3, 4].

The case where S is finite was studied by Lawrence and Morris [12], who obtained upper bounds on $|S|$ (which, in this case, is equal to the number of *one-point holes* in K) in terms of n. As was shown much earlier by Matoušek and Valtr [13, Thm. 1.1(ii)], bounds on the number of one-point holes allow bounding the *convexity number* of K in terms of its *invisibility number* (see also [7, Theorem 1]).

In this paper we initiate a systematic study of the structural properties of such sets S. We concentrate on two types of questions – isolated points in S (which were studied in the special case where S is finite by Lawrence and Morris [12]), and covering of S by flats (i.e., affine subspaces of $\mathbb{R}^d$).

Isolated points in S. For the sake of convenience, we use the following definition:

▶ **Definition 1.** *A point $p \in \mathbb{R}^d$ is* encapsulated *by the convex sets $K_1, \ldots, K_n \subset \mathbb{R}^d$ if for some $\epsilon > 0$, $B(p,\epsilon) \setminus (\cup_{i=1}^n K_i) = \{p\}$, where $B(p,\epsilon)$ is the open ball of radius ϵ centered at p. In other words, $p \in \mathbb{R}^d$ is* encapsulated *by $K_1, \ldots, K_n \subset \mathbb{R}^d$ if these convex sets cover a pointed neighborhood of p.*

Lawrence and Morris [12] studied the case $|S| < \infty$, in which every $p \in S$ is encapsulated by the convex sets $K_1, \ldots, K_n$. In the case where all $\{K_i\}$ are open, they used a classical theorem of Björner and Kalai [6] to show that $|S| \leq \binom{n-1}{d}$. On the other hand they showed the existence of such a set S with $(\lfloor \frac{n}{d} \rfloor - 1)^d \leq |S|$. With no additional assumption on $\{K_i\}$ (except for convexity), but assuming that S affinely spans $\mathbb{R}^d$, they obtained the upper bound $|S| \leq (n-1)(\binom{n}{\lfloor \frac{n}{2} \rfloor})^{d-1}$.

We consider the general case, where no additional assumptions on S and $\{K_i\}$ are made. First, we obtain the following tight bound on the number of points encapsulated by 3 convex sets:

▶ **Theorem 2.** *Let $K_1, K_2, K_3 \subset \mathbb{R}^d$ be 3 convex sets. Denote by S the set of points of $\mathbb{R}^d$ encapsulated by $K_1 \cup K_2 \cup K_3$. Define $f(d) = \lfloor \frac{3d}{2} \rfloor + 1$. Then:*

(a) $|S| \leq f(d)$;

(b) If $|S| = f(d)$ then the sets K_1, K_2, K_3 are pairwise disjoint;

(c) The sets K_1, K_2, K_3 can be chosen in such a way that $|S| = f(d)$ and $\mathbb{R}^d \setminus (K_1 \cup K_2 \cup K_3) = S$.

For larger numbers of convex sets, let $f(d,n)$ be the maximal number of points that can be encapsulated by n convex sets in $\mathbb{R}^d$. It is easy to see[1] that for $d \geq 1$, $f(d,1) = 0$, $f(d,2) = 1$, for all $n \geq 1$ we have $f(1,n) = n-1$ and by Theorem 2, $f(d,3) = \lfloor \frac{3d}{2} \rfloor + 1$. The following recursive bound can be proved inductively, by determining arbitrarily $f(0,n) = 1$.

▶ **Theorem 3.** *For every $n > 3, d \geq 2$,*

$$f(d,n) \leq \sum_{i=2}^{n-1} \left(\binom{n}{i} f(d,i) \right) + f(d-2,n),$$

and consequently,

$$f(d,n) \leq 2d^{n-2}n!.$$

[1] See also Theorem 9 below.

Note that for a constant n, the bound we obtain is polynomial in d, whereas the bound of [12] is exponential in d. Furthermore, a direct calculation shows that our bound is superior as long as $n \ll \frac{2^d}{d}$.

In addition, we prove a sharp bound in the plane, under the additional assumptions that S is finite and the sets K_i are pairwise disjoint. It turns out that while in $\mathbb{R}^1$ and for three sets in $\mathbb{R}^2$, the maximal size of S is obtained where the convex sets are pairwise disjoint, in the general case the disjointness assumption leads to a much smaller bound on $|S|$ – even in the plane, where the upper bound is linear in n (compared to a quadratic lower bound without this restriction, see [10, Appendix A]).

▶ **Proposition 4.** *Let $S = \mathbb{R}^2 \setminus (\cup_{i=1}^n K_i)$ where $n \geq 3$ and $\{K_i\}$ are pairwise disjoint convex sets. Assume that $|S| < \infty$. Then $|S| \leq 5n - 11$, and this bound is sharp.*

Covering S by flats. For the sake of convenience, we use the following definition.

▶ **Definition 5.** *For $S \subset \mathbb{R}^d$, the* flat-dimension *of S, $dm(S)$, is*

$$\mathrm{dm}(S) = max\{k : S \text{ includes a } k\text{-simplex}\},$$

where a k-simplex (for $k \geq -1$) is the convex hull of $k+1$ affinely independent points in $\mathbb{R}^d$.

The local dimension $\mathrm{dm}(S, p)$ *of S at $p \in S$ is*

$$\mathrm{dm}(S, p) = \min_{\epsilon > 0} \mathrm{dm}(S \cap B(p, \epsilon)).$$

Our main result in this part is the following theorem:

▶ **Theorem 6.** *For any $n, d \in \mathbb{N}$, there exists a number $g = g(n, d)$ such that the following holds. Let $S = \mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$, where $\{K_i\}$ are convex sets. Then S can be covered by at most g flats, in such a way that each $p \in S$ is covered by a flat of dimension $\mathrm{dm}(S, p)$. Furthermore, there exists a unique such cover $\mathcal{C}$ that is minimal with respect to inclusion.*

Actually, the proof of Theorem 6 provides significant structural information on $\mathcal{C}$: Suppose $p \in S, \mathrm{dm}(S, p) = k$, and let L be a flat. If $S \cap W = L \cap W$ for some neighborhood W of p, then L is the k-flat in $\mathcal{C}$ that covers p.

On the quantitative side, the bound on $g(d, n)$ which follows from the proof is rather large, and in particular, the maximum numbers of flats of each dimension in $\mathcal{C}$ seem difficult to compute in general. Hence, we focus on special cases where effective bounds can be obtained. The following natural definition will be convenient.

▶ **Definition 7.** *For $S = \mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$, where $\{K_i\}$ are convex sets, and for $k = 0, 1, \ldots, d$, denote by $\nu_k(S)$ the number of k-flats in the cover $\mathcal{C}$ of S. Denote by $\nu_k(d, n)$ the maximum of $\nu_k(S)$ over all such sets S, where d, n, k are fixed.*

Theorems 2 and 3 above provide upper bounds on $\nu_0(d, n)$ (i.e., on the maximal number of 0-dimensional flats in $\mathcal{C}$), as by definition, the flat which covers each isolated point in S must be the point itself. At the other end of the spectrum, it is clear that $\nu_d(d, n) = 1$. Regarding $(d-1)$-flats, we determine $\nu_{d-1}(d, n)$ completely.

▶ **Theorem 8.** *We have*

$$\nu_1(2, n) = t(n, 4) = (\tfrac{3}{4} + o(1))\binom{n}{2}, \quad \text{and} \quad \nu_{d-1}(d, n) = \binom{n}{2}, \quad \forall d \geq 3,$$

where $t(n, 4)$ is the Turán number.

Finally, in the case $n = 2$, i.e., where there are only two convex sets, we completely determine the numbers of k-flats that can appear in the cover $\mathcal{C}$ of $S = \mathbb{R}^d \setminus (K_1 \cup K_2)$, for each $0 \leq k \leq d$.

▶ **Theorem 9.** *Let K_1, K_2 be convex sets in $\mathbb{R}^d$ ($d \geq 1$), and let $\mathcal{C}$ be the cover of $S = \mathbb{R}^d \setminus (K_1 \cup K_2)$ discussed above. Then any two flats $I, J \in \mathcal{C}$ satisfy $J \subset I$ or $I \subset J$. Consequently, $\mathcal{C}$ contains at most one k-flat for each $0 \leq k \leq d$.*

Moreover, for any subset T of $\{0, 1, \ldots, d\}$ we can find $K_1, K_2 \subset \mathbb{R}^d$ such that $\mathcal{C}$ contains a k-flat if and only if $k \in T$.

The rest of the paper is organized as follows. In Section 2 we study isolated points in S, proving Theorems 2 and 3. In Section 3 we study the qualitative question of covering S by flats, proving Theorem 6. In Sections 4 and 5 we study quantitative aspects of covering S by flats and present the proofs of Theorems 8 and 9.

2 Bounding the number of points encapsulated by convex sets

Recall that $f(d, n)$ is the maximal number of points that can be encapsulated by n convex sets in $\mathbb{R}^d$. It is easy to see that for every $n > 0$, $f(1, n) = n - 1$ and that for every $d > 0$, $f(d, 2) = 1$. After introducing a few definitions and an observation in Section 2.1, we determine $f(d, 3)$ exactly in Section 2.2. Then, in Section 2.3 we obtain by an inductive argument an upper bound on $f(d, n)$ for $n > 3$.

2.1 Preliminaries

For a set $S \subset \mathbb{R}^d$, denote by $\mathrm{cl}(S)$ and $\mathrm{int}(S)$ the topological closure and interior of S, respectively. The convex hull of S is denoted by $\mathrm{conv}(S)$. For $d \in \mathbb{N}$ and $0 \leq k \leq d$, a k-flat $\pi \subset \mathbb{R}^d$ is a k-dimensional affine subspace of $\mathbb{R}^d$.

▶ **Definition 10.** *For $K \subset \mathbb{R}^d, p \in \mathbb{R}^d$, we say that p touches K (or K touches p), if $p \in cl(K) \setminus K$.*

The following observation will be used several times in the sequel.

▶ **Observation 11.** *Let $K_1, \ldots, K_n \subset \mathbb{R}^d$ be convex sets, and let B be a d-dimensional ball $B \subset K_1 \cap \ldots \cap K_n$. Let $p_0 \notin K_1 \cup \ldots \cup K_n$. Consider the double cone with apex p_0 spanned by B. Then the other side of this cone (the dark area in Figure 1) is disjoint to $K_1, \ldots, K_n$.*

Indeed, for each x in the other side of the cone above, p_0 lies inside a segment that connects x to a point in each K_i.

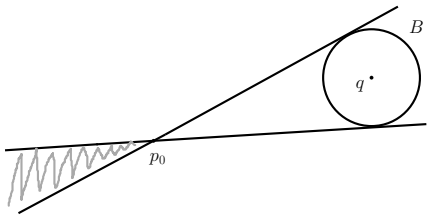

Figure 1 A cone with a vertex in p_0 that is tangent to a ball B.

2.2 The number of points encapsulated by 3 convex sets in $\mathbb{R}^d$

The following theorem implies that $f(d,3) = \lfloor \frac{3d}{2} \rfloor + 1$. For the sake of simplicity, we denote by S the set of encapsulated points, instead of the entire set $\mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$. The reason for abusing notation is that in the proof of this theorem, elements of $\mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$ other than encapsulated points do not make any difference. Hence, we implicitly assume that there are no such elements, and thus, $\mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$ is equal to the set of encapsulated points.

Proof of Theorem 2. We prove the first two statements together by induction on d. The cases $d = 0, 1$ are trivial. For $d \geq 2$ and for every $p \in S$, let

$$touch(p) = \{i : 1 \leq i \leq 3, \text{ and } p \textit{ touches } K_i\}.$$

We shall use the following observations.

▶ **Observation 12.** *If p is encapsulated by K_1, K_2, K_3 then $|touch(p)| \geq 2$, and if $touch(p) = \{i, j\}$ then $K_i \cap K_j = \emptyset$.*

Indeed, if $q \in K_i \cap K_j$ then all the points on the line $\ell(p, q)$ that are separated from q by p, are not in $K_i \cup K_j$. Since there exist such points arbitrarily close to p, this contradicts the assumption on p.

▶ **Observation 13.** *If for $p \in S$, $touch(p) = \{i, j\}$ then each of the cones $cone(p, K_i) = \{(1-\lambda)p + \lambda x : \lambda > 0, x \in K_i\}, cone(p, K_j)$ is a semi-space[2]. Moreover, there is no other point $p' \in S$ with $touch(p') = \{i, j\}$. (See Figure 2.)*

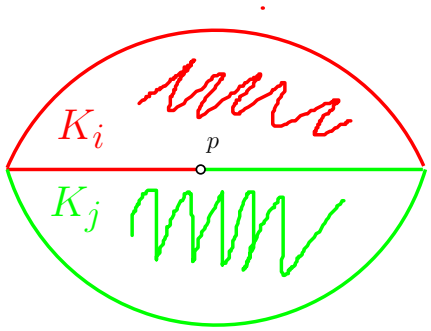

Figure 2 An illustration for Observation 13 in $\mathbb{R}^2$ where $touch(p) = \{i, j\}$. The set K_i is colored with red and K_j is colored with green. In this case $cone(K_i)$ is the upper half-plane, and $cone(K_j)$ is the lower half-plane.

By Observation 13, there is at most one point $p_{12} \in S$ with $touch(p_{12}) = \{1, 2\}$, at most one point $p_{13} \in S$ with $touch(p_{13}) = \{1, 3\}$, and at most one point $p_{23} \in S$ with $touch(p_{23}) = \{2, 3\}$. By Observation 12, all other points in S touch all three convex sets K_1, K_2, K_3. Let $S' = \{p \in S : |touch(p)| = 3\}$ and let $J = \text{aff}(S')$ be the flat spanned by S'. If $S' = J = \emptyset$ then we are done. Otherwise, by Observation 11, J cannot contain a d-dimensional ball, and hence, $\dim(J) < d$.

[2] In the plane, this means that each of $cone(p, K_i), cone(p, K_j)$ is a half-open half-space. In general dimension, this means that there exists a unique orthonormal base $B = \{e_1, \ldots, e_d\}$ of $\mathbb{R}^d$ such that with respect to B, $cone(p, K_i)$ is the set of all points that are lexicographically smaller than p, and $cone(p, K_j)$ is the set of all points that are lexicographically larger than p.

Consider $S \cap J$. This set includes S' and maybe some of the points p_{ij} defined above. Every point in $S \cap J$ is encapsulated (w.r.t. J) by the three convex sets $K_i \cap J$ $(1 \leq i \leq 3)$. Hence, by the induction hypothesis, $|S \cap J| \leq f(\dim(J))$. There are 3 cases:

Case 1: $\dim(J) = d - 2$. Then $|S'| \leq f(d-2)$, and since S contains at most three points that are not in S' (i.e., the p_{ij}'s above), we have

$$|S| \leq |S'| + 3 \leq f(d-2) + 3 = f(d).$$

If all inequalities hold with equality, then all three points p_{12}, p_{13} and p_{23} exist, and by Observation 12, the K_i's are pairwise disjoint.

Case 2: $\dim(J) < d - 2$. Then

$$|S| \leq |S'| + 3 \leq f(\dim J) + 3 < f(d).$$

Case 3: $\dim(J) = d - 1$. In this case we prove that the points p_{12}, p_{13} and p_{23} (if exist) are in J, and therefore, $|S| \leq f(d-1) < f(d)$, and we are done.

Indeed, assume to the contrary (w.l.o.g.) that p_{12} exists and $p_{12} \notin J$. Then $\dim(\mathrm{conv}(S' \cup \{p_{12}\})) = d$. Moreover, since all the points in S' touch both K_1 and K_2, we have

$$\mathrm{conv}(S' \cup \{p_{12}\}) \subset \mathrm{cl}(K_1) \cap \mathrm{cl}(K_2).$$

Therefore, $\dim(\mathrm{cl}(K_1) \cap \mathrm{cl}(K_2)) = d$, hence $K_1 \cap K_2 \neq \emptyset$, in contradiction to Observation 12. This completes the proof of parts (a) and (b) of the theorem.

For the proof of (c) we need the following claim:

▷ Claim 14. Let $A, B \subset \mathbb{R}^d$ be convex sets such that $A \cap B = \emptyset$, and let $z \in \mathbb{R}^d \setminus (A \cup B)$. Then there exist two convex sets $\tilde{A}, \tilde{B} \subset \mathbb{R}^d$ such that

- $A \subset \tilde{A}, B \subset \tilde{B}$,
- $\tilde{A} \cap \tilde{B} = \emptyset$, and
- $\tilde{A} \cup \tilde{B} = \mathbb{R}^d \setminus \{z\}$,

if and only if

$$A \cap (\mathrm{conv}(B \cup \{z\})) = \emptyset \text{ and } B \cap (\mathrm{conv}(A \cup \{z\})) = \emptyset. \tag{1}$$

Proof of Claim 14. The direction $(\Rightarrow)$ is trivial, since if (w.l.o.g.) $B \cap (\mathrm{conv}(A \cup \{z\})) \neq \emptyset$ then there exist $a \in A$ and $b \in B$ such that b in contained in the open segment (a, z). But in this case, no point on the opposite ray $\{(1+\lambda)z - \lambda a : \lambda > 0\}$ can belong to $\tilde{A}$ or to $\tilde{B}$, a contradiction.

For the opposite direction, assume for the sake of convenience that $z = 0$ and that (1) is satisfied. An equivalent formulation of (1) is:

$$\text{Each ray from 0 meets at most one of the sets } A, B. \tag{2}$$

We shall now construct $\tilde{A}$ and $\tilde{B}$. First, let $A^+ = \bigcup_{\lambda>0}(\lambda A)$ (resp., $B^+ = \bigcup_{\lambda>0}(\lambda B)$) be the union of all open rays from 0 via A (resp., B). The sets A^+, B^+ are convex and $A \subset A^+, B \subset B^+$. Since each ray from the origin intersects A if and only if it intersects A^+, and similarly for B, the condition (2) is satisfied also for A^+, B^+. Therefore, A^+, B^+ are disjoint convex sets that are closed under addition and multiplication by a positive scalar. Let

$$\mathcal{D} = \{F \subset \mathbb{R}^d \setminus \{0\} : F \text{ is closed under addition and multiplication by a positive scalar}\},$$

and consider the family

$$\mathcal{F} = \{(A', B') : A', B' \in \mathcal{D}, A' \cap B' = \emptyset, A^+ \subset A', B^+ \subset B'\}.$$

Define a partial order on $\mathcal{F}$ by $(A', B') \leq (A'', B'')$ iff $A' \subseteq A''$ and $B' \subseteq B''$. Since each chain

$\{(A'_i, B'_i)\}$ is bounded from above by $(\cup_i A'_i, \cup_i B'_i)$, by Zorn's lemma, $\mathcal{F}$ contains a maximal element $(\tilde{A}, \tilde{B})$. Clearly $\tilde{A}, \tilde{B}$ are disjoint convex sets, $A \subset \tilde{A}, B \subset \tilde{B}$. It remains to prove that $\tilde{A} \cup \tilde{B} = \mathbb{R}^d \setminus \{0\}$. Assume on the contrary that there exists a point $w \in \mathbb{R}^d \setminus (\tilde{A} \cup \tilde{B} \cup \{0\})$. Then by the maximality of $(\tilde{A}, \tilde{B})$, the cone $\{\tilde{A} + \lambda w : \lambda > 0\}$ meets $\tilde{B} \cup \{0\}$. Therefore there exist $a \in \tilde{A}$ and $b' \in \tilde{B} \cup \{0\}$ such that $w + a = b'$. Similarly, there exist $b \in \tilde{B}$ and $a' \in \tilde{A} \cup \{0\}$ such that $w + b = a'$. Hence $b' - a = a' - b$ and it follows that $a + a' = b + b' \in \tilde{A} \cap \tilde{B}$, a contradiction. This completes the proof of Claim 14. ◁

Claim 14 implies the following consequence:

▶ **Corollary 15.** *Let $H \subset \mathbb{R}^d$ be a $(k+1)$-flat and let $J \subset H$ be a k-flat. Let $A, B \subset J$ be disjoint convex sets. Assume that J separates H into two open half-flats H^+, H^- and that $z \in H^+$. Then there exist two disjoint convex sets $\tilde{A}, \tilde{B}$ such that $A \subset \tilde{A}, B \subset \tilde{B}$ and $\tilde{A} \cup \tilde{B} = H \setminus \{z\}$ (see Figure 3). Moreover, the sets $\tilde{\tilde{A}} = (\tilde{A} \cap H^+) \cup A, \tilde{\tilde{B}} = (\tilde{B} \cap H^+) \cup B$ are disjoint convex sets such that $\tilde{\tilde{A}} \cap J = A, \tilde{\tilde{B}} \cap J = B$ and $(\tilde{\tilde{A}} \cup \tilde{\tilde{B}}) \cap H^+ = H^+ \setminus \{z\}$.*

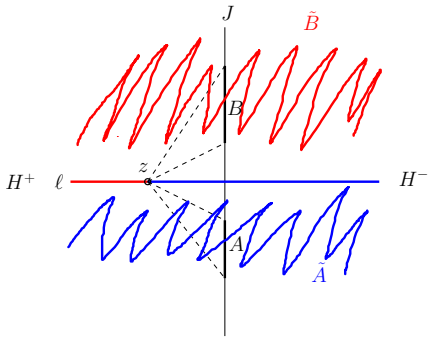

Figure 3 An illustration for Corollary 15 where $H = \mathbb{R}^2$ and J is a line. A and B are two segments, as illustrated in the figure. $\tilde{B}$ is the red half-open upper half-plane supported by ℓ, and $\tilde{A}$ is the blue half-open lower half-plane supported by ℓ.

Now we are ready to prove part (c) of Theorem 2. We prove the construction by induction on d. Given a construction in $\mathbb{R}^{d-2}$ of 3 convex sets that encapsulate $f(d-2)$ points, we extend each of the three convex sets to $\mathbb{R}^d$ in such a way that the previously encapsulated points are still encapsulated, and three more encapsulated points are formed. Since $f(d) = f(d-2) + 3$, such a construction completes the proof.

For the basic case, in $\mathbb{R}^0$ we can take $K_1 = K_2 = K_3 = \emptyset$, and in $\mathbb{R}^1$ the convex sets can be $K_1 = (-\infty, 0), K_2 = (0, 1)$ and $K_3 = (1, \infty)$. The construction for $d = 2$ is illustrated in Figure 4 (though it can be also obtained by the inductive argument).

In the induction step, let $J \subset \mathbb{R}^d$ be a $(d-2)$-flat. By the induction hypothesis there exist three pairwise disjoint convex sets $K'_1, K'_2, K'_3 \subset J$ such that $|J \setminus (K'_1 \cup K'_2 \cup K'_3)| = f(d-2)$. Let $\pi \subset \mathbb{R}^d$ be a plane orthogonal to J, hence $\pi \cap J$ is a point. W.l.o.g., assume that $\pi \cap J = \{0\}$. Consider 3 points $x_1, x_2, x_3 \in \pi$ equally distributed around 0 (see Figure 5). Consider the $(d-1)$-flat $H_1 = \mathrm{aff}(J, x_1)$, and let H_1^+ be the open half-flat of H_1 supported by J that contains x_1. (Formally, $H_1^+ = \{y + \lambda x_1 : y \in J, \lambda > 0\}$.) Define H_2^+, H_3^+ similarly.

We are supposed to produce three pairwise disjoint convex sets K_1, K_2, K_3, such that $K'_i \subset K_i$ for $i = 1, 2, 3$ and $\mathbb{R}^d \setminus (K_1 \cup K_2 \cup K_3) = J \setminus (K'_1 \cup K'_2 \cup K'_3) \cup \{x_1, x_2, x_3\}$. By Corollary 15, K'_1 and K'_2 can be extended to two disjoint convex sets K_1^3 and K_2^3 such that $K_1^3 \cap J = K'_1$, $K_2^3 \cap J = K'_2$ and $K_1^3 \cup K_2^3 = K'_1 \cup K'_2 \cup H_3^+ \setminus \{x_3\}$. Similarly, K'_1 and K'_3 can be extended to two disjoint convex sets K_1^2 and K_3^2 such that $K_1^2 \cap J = K'_1$, $K_3^2 \cap J = K'_3$ and

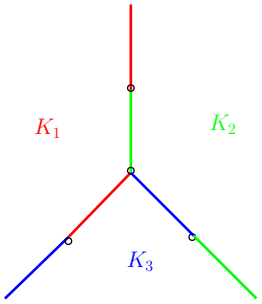

Figure 4 An illustration for the basic case $d = 2$ in the proof of Theorem 2(c).

$K_1^2 \cup K_3^2 = K_1' \cup K_3' \cup H_2^+ \setminus \{x_2\}$. K_2^1 and K_3^1 are obtained in the same way. Finally, we define $K_1 = K_1^2 \cup K_1^3 \cup \text{int}(\text{conv}(H_2^+ \cup H_3^+))$ and similarly, $K_2 = K_2^1 \cup K_2^3 \cup \text{int}(\text{conv}(H_1^+ \cup H_3^+))$ and $K_3 = K_3^1 \cup K_3^2 \cup \text{int}(\text{conv}(H_1^+ \cup H_2^+))$. The sets K_1, K_2 and K_3 encapsulate all the $f(d-2)$ points that were originally encapsulated by K_1', K_2', K_3' in J, and additionally encapsulate x_1, x_2, x_3. Therefore, we obtain $f(d-2)+3 = f(d)$ points that are encapsulated by 3 convex sets in $\mathbb{R}^d$. This completes the proof of part (c) of Theorem 2, and hence the proof of Theorem 2. ◀

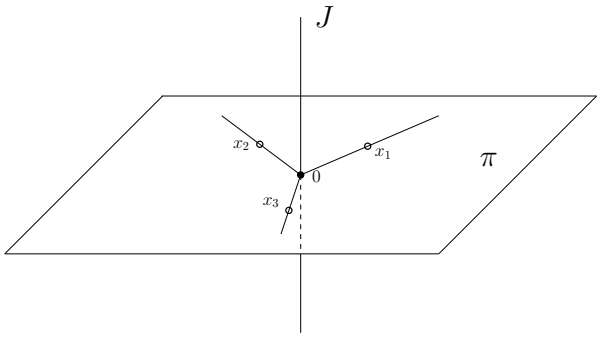

Figure 5 An illustration for the induction step in the proof of Theorem 2(c).

2.3 The number of points encapsulated by n convex sets in $\mathbb{R}^d$

Recall that $f(d,n)$ is the maximal number of points that can be encapsulated by n convex sets in $\mathbb{R}^d$. Clearly[3], for $d \geq 1$, $f(d,1) = 0, f(d,2) = 1$, and for all $n \geq 1$ we have $f(1,n) = n-1$. Define arbitrarily $f(0,n) = 1$. After obtaining the value $f(d,3) = \lfloor \frac{3d}{2} \rfloor + 1$, the following theorem yields a recursive upper bound on the function $f(d,n)$ in general.

▶ **Theorem 3** (Restatement). *For every $n > 3, d \geq 2$*

$$f(d,n) \leq \sum_{i=2}^{n-1} \left(\binom{n}{i} f(d,i) \right) + f(d-2,n). \tag{3}$$

Consequently,

$$f(d,n) \leq 2d^{n-2}n!. \tag{4}$$

[3] See also Theorem 9 below.

Proof. The proof of the recursive formula is by a double induction on n and d, where the basic cases $f(1,n)$, $f(d,2)$ and $f(d,3)$ have already been proved above. In the induction step, note that for each of the $\binom{n}{i}$ i-subsets of $K_1,\ldots,K_n$, the points of $\mathbb{R}^d \setminus \bigcup_{i=1}^n K_i$ that touch exactly this subset, are encapsulated by this subset, and by the induction hypothesis their number is bounded by $f(d,i)$. Therefore it remains to prove that the number of points that touch all n sets is at most $f(d-2,n)$.

Indeed, Let S' be the set of points that touch $K_1,\ldots,K_n$, and let $J = \mathrm{aff}(S')$. By Observation 11, $\dim(J) < d$. If $\dim(J) \le d-2$, we are done.

Otherwise, $\dim(J) = d-1$. In this case, as in the argument of Case 3 in the proof of Theorem 2, no point that is encapsulated by some subset of $K_1,\ldots,K_n$ lies outside J. Indeed, otherwise there exists $T \subset [n]$ and a point $p \in \mathbb{R}^d \setminus J$ that touches each K_i for $i \in T$ and no K_j for $j \notin T$. Then $\dim(\mathrm{conv}(S' \cup \{p\})) = d$, and since all the points in S' touch all the K_i's for $i \in T$, we have $\mathrm{conv}(S' \cup \{p\}) \subset \bigcap_{i\in T} \mathrm{cl}(K_i)$, and $\bigcap_{i\in T} K_i$ is d-dimensional. But then by Observation 11, p is not encapsulated by $\bigcup_{i\in T} K_i$.

Consequently, for every $T \subset [n]$, all the points that are encapsulated by $\bigcup_{i\in T} K_i$ are in J, and the bound $f(d-1,n)$, which is smaller than the right hand side of (3) by the induction hypothesis on d, follows.

The upper bound (4) follows from the recursive formula (3) by induction on n, for every fixed $d \ge 2$. The induction bases are the bounds $f(d,2) = 1$ and $f(d,3) \le \lfloor \frac{3d}{2} \rfloor + 1 \le 2d$, proved above. Assume that (4) holds for all $f(d,n')$, $n' < n$. Hence, by (3) we have

$$f(d,n) \le \sum_{i=2}^{n-1} \left(\binom{n}{i} f(d,i) \right) + f(d-2,n) \le \sum_{i=2}^{n-1} \left(\binom{n}{i} \cdot 2d^{i-2} i! \right) + 2(d-2)^{n-2} n!.$$

Define $h_{d,n}(i) = \binom{n}{i} \cdot 2d^{i-2} i!$. Note that for any $d \ge 2$, $n \ge 4$, $2 \le i \le n-2$,

$$\frac{h_{d,n}(i+1)}{h_{d,n}(i)} = \frac{\binom{n}{i+1} \cdot 2d^{i-1}(i+1)!}{\binom{n}{i} \cdot 2d^{i-2} i!} = \frac{n-i}{i+1} \cdot d(i+1) = (n-i)d \ge 2.$$

Hence, $\sum_{i=2}^{n-1} h_{d,n}(i) \le 2h_{d,n}(n-1)$. Thus, we have

$$\begin{aligned} f(d,n) &\le \sum_{i=2}^{n-1} \left(\binom{n}{i} \cdot 2d^{i-2} i! \right) + 2(d-2)^{n-2} n! \le 2nd^{n-3}(n-1)! + 2(d-2)^{n-2} n! \\ &= 2n! d^{n-2} \left(\tfrac{2}{d} + (\tfrac{d-2}{d})^{n-2} \right) \le 2n! d^{n-2}. \end{aligned}$$

This completes the proof of (4) by induction. ◀

We note that the upper bound (4) can be improved further with no much effort. However, it is not far from the best one can get from the recursion (3). Indeed, it is easy to see that for n constant, the dependence on d in (3) is $\Omega(d^{n-2})$, and that for d constant, the dependence on n in (3) is super-exponential.

3 Covering the complement of finite unions of convex sets by flats

In this section we study covering of $S = \mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$ by flats – i.e., affine subspaces of $\mathbb{R}^d$. The main result we prove is Theorem 6 which asserts that there exists a covering of S by $g(n,d)$ flats such that any $p \in S$ is covered by a flat whose dimension is $\mathrm{dm}(S,p)$.

3.1 Preliminaries

Recall that by Def. 5, the flat-dimension of S is $\mathrm{dm}(S) = \max\{k : S \text{ includes a } k\text{-simplex}\}$, and the local dimension of $p \in S$ is $\mathrm{dm}(S,p) = \min_{\epsilon>0} \mathrm{dm}(S \cap B(p,\epsilon))$.

Define $\mathrm{dm}(\emptyset) = -1$. Note that $\mathrm{dm}(S) = 0$ iff S is non-empty, but does not include a non-degenerate straight line segment, and $\mathrm{dm}(S) = d$ iff $\mathrm{int}(S) \neq \emptyset$. Note that for general sets $S \subset \mathbb{R}^d$, $\mathrm{dm}(S)$ does not necessarily coincides with the topological dimension of S, nor with the dimension of its affine hull, $\dim(\mathrm{aff}(S))$.

As for the local dimension, $\mathrm{dm}(S,p) = k$ if the intersection of S with every neighborhood of p includes a k-simplex, but the intersection of S with some neighborhood of p does not include a $(k+1)$-simplex. Refer to Figure 6 (and also to Figure 12 below) for an example of the local dimension. Note that if $\mathrm{dm}(S,p) = 0$ then there exists some neighborhood U of p such that $S \cap U$ contains no segment. In this case p is an isolated point of S, since by Theorem 6, S can be covered by finitely many points, hence $S \cap U$ is finite and therefore p is isolated.

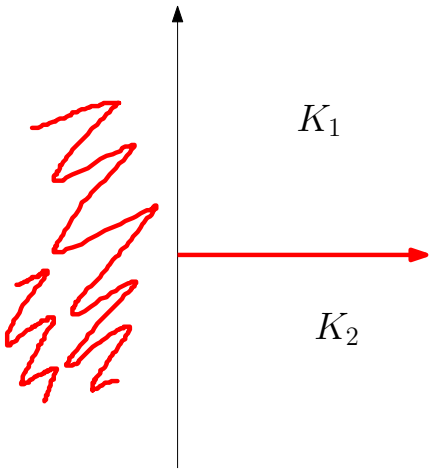

Figure 6 In the figure, the red-colored area is $S = \{(x,y) : x < 0\} \cup \{(x,0) : x \geq 0\} = \mathbb{R}^2 \setminus (K_1 \cup K_2)$, where $K_1 = \{(x,y) : x \geq 0, y > 0\}$ and $K_2 = \{(x,y) : x \geq 0, y < 0\}$. In this case, $\mathrm{dm}(S,(0,0)) = 2$ and $\mathrm{dm}(S,(1,0)) = 1$. The point $(1,0)$ is an ordinary point of S (with the x-axis as the corresponding 1-flat), while $(0,0)$ is not.

Ordinary points and ordinary flats.

▶ **Definition 16.** *The point p is a k-ordinary point of S ($p \in S \subset \mathbb{R}^d$) if*

1. $\mathrm{dm}(S,p) = k$.
2. *For some k-flat $H \subset \mathbb{R}^d$ and for some open neighborhood U of p, $S \cap U = H \cap U$.*

We call H a k-ordinary flat of S. Moreover, p is called an ordinary point of S if it is k-ordinary for some $0 \leq k \leq d$. Similarly for flats.

The set of k-ordinary points of S is a relatively open subset of S. Indeed, if p is a k-ordinary point of S and U, H are as in Definition 16, then every point $x \in S \cap U$ is k-ordinary as well with the same k-flat H. Note that if Definition 16 holds for U then it clearly holds for any smaller neighborhood $p \in U' \subset U$. Moreover, the flat H is determined by the point p, $H = \mathrm{aff}(U \cap S)$, for an appropriate neighborhood U as in Definition 16.

▶ Remark 17. If S' is relatively open subset of S, (i.e., $S' = S \cap U$ where U is an open subset of $\mathbb{R}^d$) then for every point $p \in S'$, $\mathrm{dm}(S,p) = \mathrm{dm}(S',p)$. Moreover, p is a k-ordinary point of S iff it is a k-ordinary point of S' (with the same k-ordinary flat.)

Strong covers.

▶ **Definition 18.** *Let $S \subset \mathbb{R}^d$. A collection $\mathcal{C}$ of flats in $\mathbb{R}^d$ is a strong cover of S, if:*

1. $|\mathcal{C}| < \infty$
2. *Each point $p \in S$ belongs to some k-flat $H \in \mathcal{C}$, where $k = \mathrm{dm}(S,p)$.*
3. *$\mathcal{C}$ is minimal, i.e., no proper subcollection of $\mathcal{C}$ satisfies (2).*

3.2 Proof of Theorem 6

Our main result in this section is the following restatement of Theorem 6 (where the value of the function g from the original statement follows from the proof).

▶ **Theorem 6** (Restatement). *Let $K_1, \ldots, K_n$ be convex subsets of $\mathbb{R}^d$ and let $S = \mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$. Then S admits a unique strong cover $\mathcal{C}$. Actually, $\mathcal{C}$ is the collection of all ordinary flats with respect to S.*

Note that p is encapsulated by $K_1, \ldots, K_n$ if and only if $\{p\}$ is an 0-ordinary flat w.r.t. $\mathbb{R}^d \setminus (K_1 \cup \ldots \cup K_n)$. Hence, both Theorems 2 and 3 above, supply quantitative bounds for special cases of Theorem 6.

It is easy to see that any strong cover $\mathcal{C}$ of S must contain all ordinary flats of S. Indeed, given a k-ordinary flat H, there exists some k-ordinary point $p \in S$ and some open neighborhood U of p, such that $S \cap U = H \cap U$. If $H \notin \mathcal{C}$ then consider all the k-flats $H' \in \mathcal{C}$. Since for any such H', $H \neq H'$, it follows that $\dim(H \cap H') < k$, therefore the neighborhood U is not covered by these (finitely many) k-flats H'. But as mentioned above, each point in $S \cap U$ is a k-ordinary point of S – a contradiction.

Therefore, in order to prove Theorem 6 we show that there are only finitely many ordinary flats with respect to S, and that condition (2) of Definition 16 is satisfied not only for the ordinary points of S (which is trivial), but also for the non-ordinary points of S.

Proof of Theorem 6. The proof is by a primary induction on d and a secondary induction on n. For the induction basis, let $p \in S \subset \mathbb{R}^d$ with $\mathrm{dm}(S,p) = k$. If $k = d$ then no inductive argument is needed since $p \in \mathrm{cl}(\mathrm{int}(S))$, and then the corresponding d-flat is $\mathbb{R}^d$. The case $d = 0$ is trivial. If $d = 1$ and $k = 0$ then p is an isolated point of S and the number of such points p is at most $n - 1$. The corresponding 0-flat in this case is clearly $\{p\}$. If $d = 1$ and $k = 1$ then $\mathbb{R}^1$ is the corresponding 1-flat. If $n = 1$ then for any $p \in S$, $\mathrm{dm}(S,p) = d$ and $\mathbb{R}^d$ is the d-ordinary flat.

For larger values of n and d we shall prove by induction the following:

1. For any $0 \leq k \leq d$, there are finitely many k-ordinary flats w.r.t. S.
2. For any $p \in S$ with $\mathrm{dm}(S,p) = k$ and for any $\epsilon > 0$, there is a k-ordinary point $q \in S$ such that $||p - q|| < \epsilon$.

▶ Remark 19. The second statement implies the existence of a k-ordinary flat J such that $p \in J$. Indeed, by the statement p is in the closure of the k-ordinary points of S, each of which is contained in a k-ordinary flat. But these flats form a closed set, hence p is contained in at least one of these k-ordinary flats.

The sets to which we apply the induction hypothesis are as follows:

- $S^i = \mathbb{R}^d \setminus \bigcup_{j \neq i} K_j$, $(i = 1, 2, \ldots, n)$, to which we apply the induction hypothesis with the same d and $n-1$ convex sets.
- For a flat H (to be specified later) with $\dim(H) < d$, consider $S^H = H \setminus (\bigcup_{j=1}^{n}(K_j \cap H))$, that is, the restriction[4] of the original system to H. Here we apply the induction hypothesis with the dimension $\dim(H)$.

We will prove that any k-ordinary flat w.r.t. S is either a k-ordinary flat w.r.t. some S^i or a k-ordinary flat for some S^H with $\dim(H) < d$. Hence we will be able to apply the induction hypothesis either to S^i or to S^H.

Let $p \in S$ with $\mathrm{dm}(S, p) = k$. There are two options:

- **Case 1:** For some $1 \leq i \leq n$, p does not touch K_i.
- **Case 2:** p touches all sets K_i, $1 \leq i \leq n$.

We handle each case separately.

Case 1: Since p does not touch K_i, it follows that $p \in \mathrm{int}(\mathbb{R}^d \setminus K_i)$, and thus, p has a positive distance from K_i. Let U be a neighborhood of p in $\mathbb{R}^d$ that satisfies $U \subset \mathrm{int}(\mathbb{R}^d \setminus K_i)$. Then $S \cap U = S^i \cap U$ and $\mathrm{dm}(S^i, p) = \mathrm{dm}(S, p) = k$. Moreover, for every corresponding k-flat J with $J \cap U = S \cap U$ we have $J \cap U = S^i \cap U$. Hence, the set of k-ordinary flats w.r.t. S that correspond to a point p as in case 1, is included in the union of the sets of k-ordinary flats w.r.t. S^i, $1 \leq i \leq n$, and we are done by the induction hypothesis on the S^i's.

Case 2: Let $G = \{p \in S : p \text{ touches all } K_i\text{'s}\}$ and let $H = \mathrm{aff}(G)$ be the flat that is spanned by G. If $H = \mathbb{R}^d$ then $\mathrm{conv}(G)$ is d-dimensional and $\mathrm{int}(\mathrm{conv}(G)) \subset \bigcap_{1 \leq i \leq n} K_i$. Then $\mathrm{dm}(p, S) = d$ holds for all $p \in G$, and the corresponding d-flat is $\mathbb{R}^d$. From now on we assume $\dim(H) < d$.

Clearly $\mathrm{dm}(S^H, p) \leq k$, and every neighborhood of p in S includes a k-simplex. We distinguish between two cases:

Case 2a: Any neighborhood U of p includes a k-simplex that is not included in H. In this case, in each sufficiently small neighborhood $U = B(p, \frac{1}{m})$ of p we can find a point q_m with $\mathrm{dm}(S, q_m) = k$ and $q_m \notin H$. By the definition of H, this means that for some $1 \leq i \leq n$, q_m does not touch K_i. By passing to a subsequence $\{q_{m_r}\}_{r=1}^{\infty}$ we can assume that for a fixed $1 \leq i \leq n$, each q_{m_r} does not touch K_i. By the induction hypothesis on S^i, each q_{m_r} is contained in a k-ordinary flat w.r.t. S^i, where the number of such flats is finite. By passing again to a subsequence, we can restrict ourselves to only one such k-ordinary flat, J. Therefore, we obtain in this flat a sequence of k-ordinary points that tend to p and by the closedness of J, $p \in J$.

Case 2b: There exists a neighborhood U of p such that every k-simplex in $S \cap U$ is contained in H. In this case, $\mathrm{dm}(S^H, p) = k$ and we can apply the induction hypothesis to S^H, since we have already assumed $\dim(H) < d$. By this induction hypothesis there exists a k-ordinary flat J' (w.r.t S^H) that contains p, and a sequence of k-ordinary points in $J' \cap S^H$ that tends to p.

The only thing that is left to prove is that J' is ordinary not only w.r.t. $S^H \subset H$ but also w.r.t. $S \subset \mathbb{R}^d$. Indeed, let $U' \subset U$ be a neighborhood of p such that $U' \cap J' = U' \cap S^H$. If some point $q \in U'$ is the limit of a sequence of points from S outside H, each point in the

[4] Note that along the proof, when considering S^H, we treat S^H as a subset of H (and not as a subset of $\mathbb{R}^d$).

sequence does not touch some K_i, and by passing to a subsequence, we can assume that all its elements do not touch K_i for a fixed i. Then, by the induction hypothesis on S^i, the whole sequence is contained in finitely many $(\leq k)$-flats, none of them is J'. The union of all these $(\leq k)$-flats, intersects J' in a $(<k)$-dimensional set, hence we can find $U'' \subset U'$ s.t. $U'' \cap J' = U'' \cap S$, namely, J' is k-ordinary also w.r.t. S. ◀

4 Bounding the number of ordinary hyperplanes

In this section we present the proof of Theorem 8 which essentially determines the maximal possible number of hyperplanes in the strong cover $\mathcal{C}$ of $S = \mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$, whose existence was proved in Theorem 6. In Theorem 20 we prove the assertion of the theorem for $d \geq 3$, and in Theorem 21 we prove it for $d = 2$. We formulate these theorems using the notion of *ordinary hyperplanes*, whose number is equal, by the proof of Theorem 6, to the notion ν_{d-1} used in the formulation of Theorem 8.

▶ **Theorem 20.** *Let $d \geq 3$ and let $S = \mathbb{R}^d \setminus (\cup_{i=1}^n K_i)$, where $\{K_i\}$ are convex sets. Then the number of ordinary hyperplanes (i.e., $(d-1)$-flats) w.r.t. S is at most $\binom{n}{2}$. On the other hand, the value $\binom{n}{2}$ is attained for some $K_1, \ldots, K_n$.*

Due to space limit, the proof is presented in [10, Theorem 4.1].

In the case $d = 2$, we prove an upper bound of $(\frac{3}{4} + o(1))\binom{n}{2}$, and provide a construction for which this value is obtained.

▶ **Theorem 21.** *Let $S = \mathbb{R}^2 \setminus (\cup_{i=1}^n K_i)$, where $\{K_i\}$ are convex sets. Then the maximum possible number of ordinary lines w.r.t. S is the Turán number $t(n,4) = (\frac{3}{4} + o(1))\binom{n}{2}$. On the other hand, this value is attained for some $K_1, \ldots, K_n$.*

Proof. For the upper bound we consider the geometric graph G, whose vertices are n arbitrary points $x_i \in \operatorname{int}(K_i)$ $(1 \leq i \leq n, \forall i \neq j : x_i \neq x_j)$, and whose edges are defined as follows: For each ordinary line ℓ that corresponds to a 1-ordinary point p_ℓ, there exist (as in the proof of Theorem 20) K_i, K_j with $\dim K_i = \dim K_j = 2$, such that ℓ is the only line that weakly separates K_i and K_j, $p \in \operatorname{cl}(K_i) \cap \operatorname{cl}(K_j)$. (Clearly, $\operatorname{int}(K_i) \cap \operatorname{int}(K_j) = \emptyset$.) We connect x_i to x_j in G by a two-edges polygonal path $[x_i, p_\ell, x_j]$.

By the disjointness of $\operatorname{int}(K_i)$ and $\operatorname{int}(K_j)$, the graph G (though not necessarily planar) does not include K_5, since otherwise there exist 5 pairwise disjoint open convex sets whose closures are pairwise intersecting, which is impossible since the restriction of G to the corresponding vertices is planar by the disjointness of the 5 $\operatorname{int}(K_i)$'s. Hence, by Turán's Theorem, $|E(G)| \leq t(n,4) = (\frac{3}{4} + o(1))\binom{n}{2}$, and the upper bound on the number of ordinary lines follows.

On the other hand, we present a construction that realizes every complete 4-partite graph K_{n_1,n_2,n_3,n_4} with $n_1 + n_2 + n_3 + n_4 = n$, in particular Turán's graph. The construction is a bit complicated, hence we present it in five steps accompanied by illustrations.

Step 1. First consider four closed convex sets K_1, K_2, K_3, K_4 as in Figure 7. Let $e_{ij} = K_i \cap K_j$ for $1 \leq i < j \leq 4$. Each segment e_{ij} on the line that separates K_i from K_j.

Our goal is to construct for each $1 \leq i \leq 4$, n_i open convex sets $K_i^1, \ldots, K_i^{n_i}$, each of which is a subset of a tiny perturbation of K_i. This construction has the property that for every $1 \leq i < j \leq 4$, and for every $1 \leq \ell_i \leq n_i, 1 \leq \ell_j \leq n_j$, there exists an ordinary line separating $K_i^{\ell_i}$ from $K_j^{\ell_j}$. By taking the n_i's $(1 \leq i \leq 4)$ as equal as possible and satisfying $n_1 + n_2 + n_3 + n_4 = n$, we obtain in this way n convex sets with $\Sigma_{i<j} n_i n_j = t(n,4)$ ordinary lines as asserted.

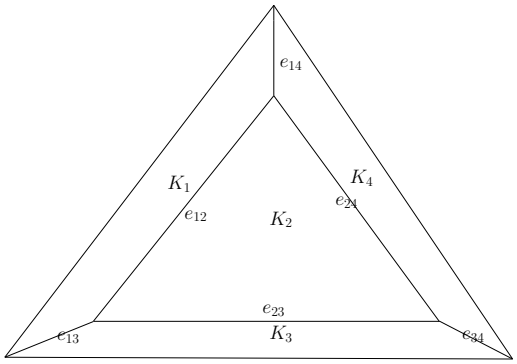

Figure 7 An illustration for step 1 in the proof of Theorem 21.

Step 2. For every $1 \leq i < j \leq 4$, draw a circular arc γ_{ij} through the endpoints of e_{ij} inside K_i (see Figure 8).

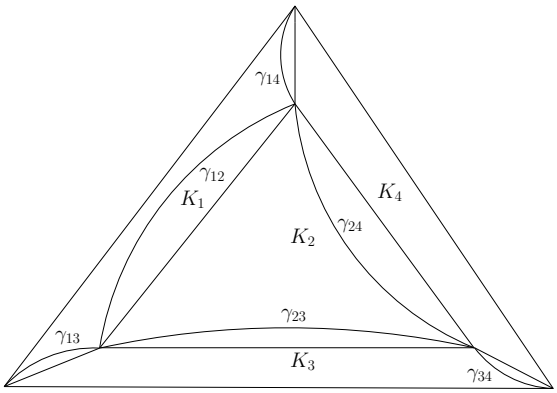

Figure 8 An illustration for step 2 in the proof of Theorem 21.

The radius of the circle associated with this arc, should be very large (in a sense to be clarified later). Note that in Figures 8-11 this radius is not large enough, just to make the illustration easier to follow.

Step 3. For every $1 \leq i < j \leq 4$, split γ_{ij} by $n_i + 1$ points into $n_i + 2$ parts. Let the edges of the polygonal path through these points (and the endpoints of e_{ij}) be $a_0^{ij}, a_1^{ij}, \ldots, a_{n_i+1}^{ij}$. See Figure 9, in which the polygonal paths corresponding to γ_{12}, γ_{23} and γ_{24} are illustrated. In this figure, $n_1 = 2$ and $n_2 = 3$.

Step 4. For every $1 \leq i < j \leq 4$, and $1 \leq t \leq n_i$, draw an arc δ_t^{ij} through the endpoints of a_t^{ij} to the side of K_j. Again, the radius of the circle associated with δ_t^{ij} should be very large (as will be determined later), much larger than in Figure 10 (in which still $n_1 = 2$ and $n_2 = 3$). Partition δ_t^{ij} into $n_j + 2$ sub-arcs by adding $n_j + 1$ points on it, and let the edges of the polygonal path through these points (and the endpoints of a_t^{ij}) be $b_{t,0}^{ij} \ldots, b_{t,n_j+1}^{ij}$. In Figure 11, these polygonal paths are illustrated, where $n_1 = n_3 = n_4 = 2$, and $n_2 = 3$.

Step 5. Let $1 \leq i \leq 4$. In this step we construct n_i open convex sets $K_i^1, \ldots, K_i^{n_i}$, each of which is a subset of a tiny perturbation of K_i. Each of these n_i convex sets will be the interior of the convex hull of several segments, and the radii of the circles mentioned in steps

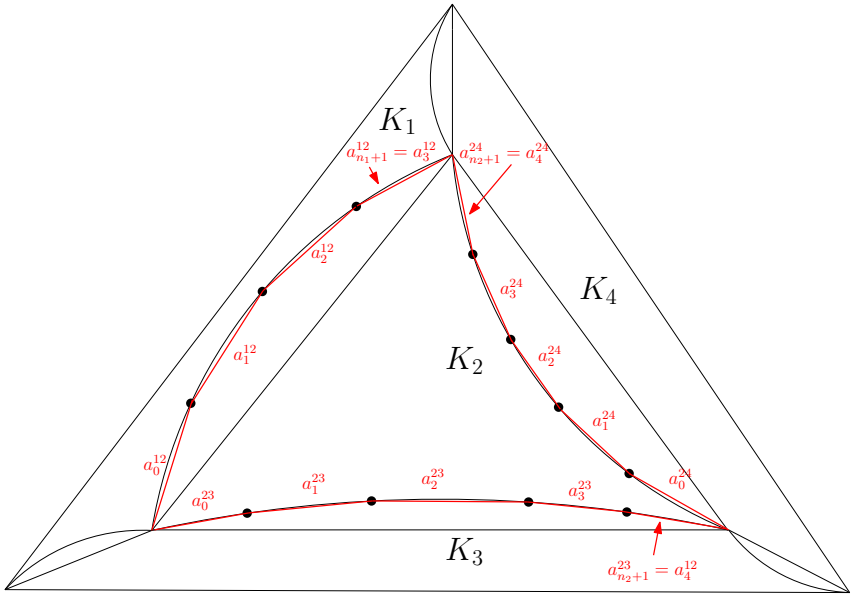

Figure 9 An illustration for step 3 in the proof of Theorem 21. Here $n_1 = 2, n_2 = 3$.

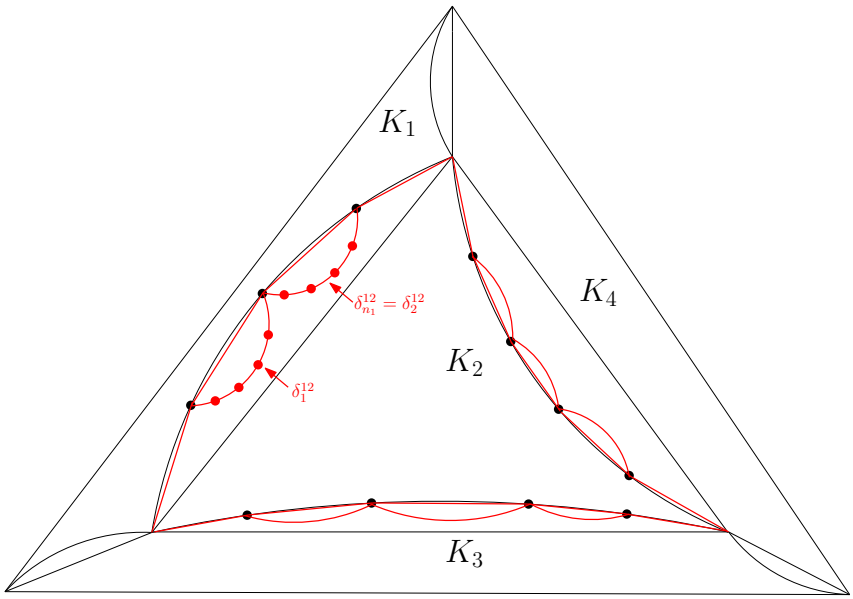

Figure 10 An illustration for step 4 in the proof of Theorem 21. Here $n_1 = n_3 = n_4 = 2, n_2 = 3$.

2 and 4 should be so large, such that all the segments that are involved in the construction of each K_i^ℓ $(1 \le \ell \le n_i)$ will be on the boundary of $\mathrm{cl}(K_i^\ell)$. Note that each K_i^ℓ is an open convex polygon[5].

[5] This is the reason why in the construction we omit the first and the last segments of each arc.

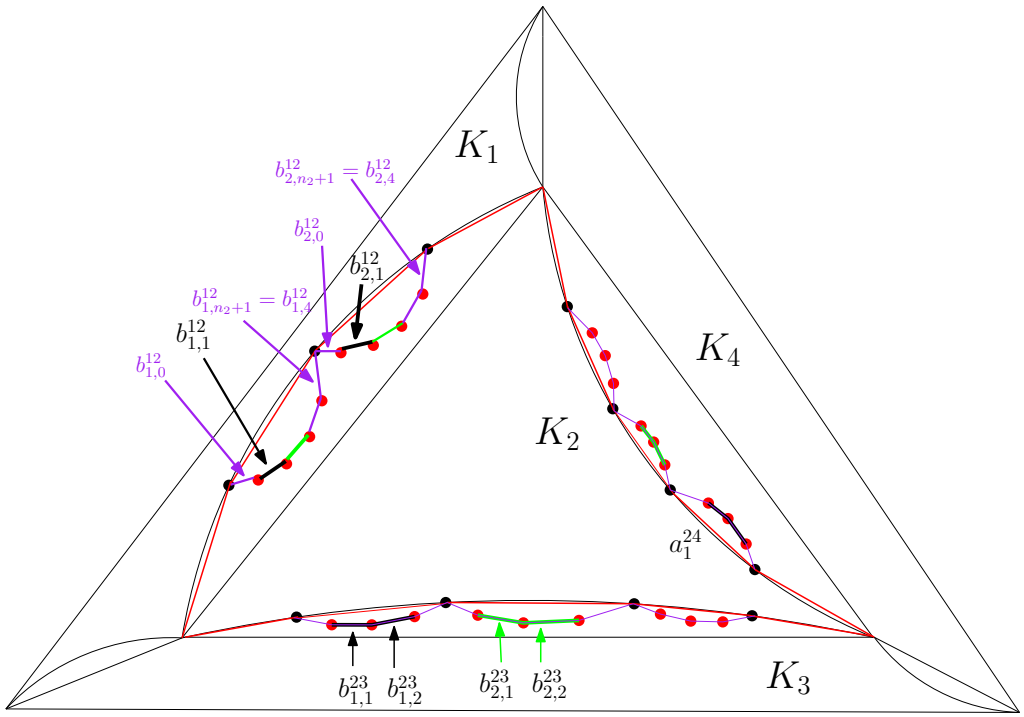

Figure 11 An illustration for steps 4-5 in the proof of Theorem 21. Here $n_1 = n_3 = n_4 = 2, n_2 = 3$.

The first such set, K^1_i, is the interior of the convex hull of the following segments:

$$\begin{cases} b^{ij}_{1,1}, b^{ij}_{2,1}, \ldots b^{ij}_{n_j,1} & : 1 \le j < i \\ b^{ij}_{1,1}, b^{ij}_{1,2}, \ldots b^{ij}_{1,n_j} & : i < j \le 4 \end{cases}$$

In Figure 11 (that still demonstrates the case where $n_1 = 2, n_2 = 3$), the segments that form K^1_2 are colored black. Roughly speaking, from the arcs inside K_i we take consecutive "b" edges whose endpoints lie on the first "δ"-arc corresponding to each edge of K_i, and from the arcs out of K_i that correspond to an edge of K_i, we take the first "b"-edge from each "δ"-arc. Recall that the radii of all arcs involved are so large, that (unlike the drawing in Figures 8 -11) all these "b"-edges that form each K^ℓ_i are in convex position.

The second such set, K^2_i, is the interior of the convex hull of the following segments, colored by green in Figure 11:

$$\begin{cases} b^{ij}_{1,2}, b^{ij}_{2,2}, \ldots b^{ij}_{n_j,2} & : 1 \le j < i \\ b^{ij}_{2,1}, b^{ij}_{2,2}, \ldots b^{ij}_{2,n_j} & : i < j \le 4 \end{cases}$$

In general, for each $1 \le \ell \le n_i$, the set K^ℓ_i is the interior of the convex hull of the following segments:

$$\begin{cases} b^{ij}_{1,\ell}, b^{ij}_{2,\ell}, \ldots b^{ij}_{n_j,\ell} & : 1 \le j < i \\ b^{ij}_{\ell,1}, b^{ij}_{\ell,2}, \ldots b^{ij}_{\ell,n_j} & : i < j \le 4 \end{cases}$$

In this way, as was mentioned just after Step 1, we construct n open convex sets with $\Sigma_{i<j} n_i n_j$ distinct ordinary lines. This completes the proof of Theorem 21. ◀

5 The complement of the union of two convex sets

In this section we present the proof of Theorem 9, which fully characterizes the set of possible vectors $(v_0, \ldots, v_d)$ attainable as the numbers of ordinary k-flats of $S = \mathbb{R}^d \setminus (K_1 \cup K_2)$, where $K_1, K_2 \subset \mathbb{R}^d$ are convex sets. The theorem follows immediately from Claims 22, 23 below.

A construction for $d = 2$, in which a strong cover of S consists of exactly one k-ordinary flat for every $0 \leq k \leq d$ (or in other words, a construction which corresponds to the vector $(v_0, v_1, v_2) = (1, 1, 1)$) is presented in Figure 12.

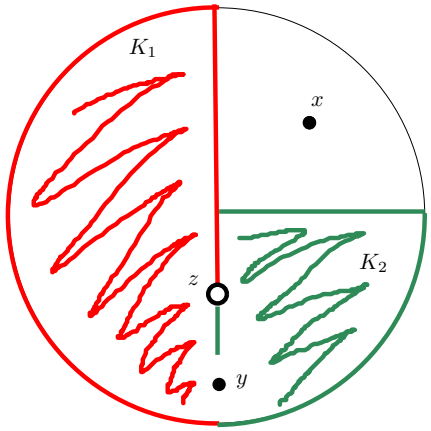

Figure 12 The circle in this figure is centered at the origin. The sets K_1 and K_2 are colored with red and green, respectively. The set K_1 contains the left half circle (including its arc) and the segment $[(0, 1), (0, -\frac{1}{3}))$, and K_2 contains the quarter right-bottom circle and the segments $[(0, 0), (1, 0)]$ and $((0, -\frac{1}{3}), (0, -\frac{2}{3})]$. The point $x \in S = \mathbb{R}^2 \setminus (K_1 \cup K_2)$ is of local dimension $d = 2$ and the corresponding 2-ordinary flat is $\mathbb{R}^2$. The point y is of local dimension 1 and the corresponding 1-ordinary flat is the y-axis. The point z is of local dimension 0 and the corresponding 0-ordinary flat is $\{z\}$ itself.

The following claim implies that for every $0 \leq k \leq d$, a strong cover of S contains at most one k-ordinary flat.

▷ Claim 22. Let $K_1, K_2 \subset \mathbb{R}^d$ be convex sets, and let $S = \mathbb{R}^d \setminus (K_1 \cup K_2)$. If J_1, J_2 are k-ordinary flats w.r.t. S then $J_1 \subset J_2$ or $J_2 \subset J_1$.

Due to space limit, the proof of Claim 22 is presented in [10, Claim 5.1].

On the other hand, for any subset T of $\{0, 1, \ldots, d\}$ we can find $K_1, K_2 \subset \mathbb{R}^d$ such that $\mathcal{C}$ contains a k-flat if and only if $k \in T$.

▷ Claim 23. Let $f : \{0, \ldots, d\} \to \{0, 1\}$. Then there exist convex sets $K_1, K_2 \subset \mathbb{R}^d$ such that the number of k-ordinary flats in a strong cover of $S = \mathbb{R}^d \setminus (K_1 \cup K_2)$ is $f(k)$.

The proof of Claim 23 is presented in [10, Claim 5.2].

Computing the Bottleneck Distance Between Persistent Homology Transforms

Michael Kerber

University of Fribourg, Switzerland

Abstract

The Persistent Homology Transform (PHT) summarizes a shape in $\mathbb{R}^m$ by collecting persistence diagrams obtained from linear height filtrations in all directions on $\mathbb{S}^{m-1}$. It enjoys strong theoretical guarantees, including continuity, stability, and injectivity. A natural way to compare two PHTs is to use the bottleneck distance between their diagrams as the direction varies. Prior work has either compared PHTs by sampling directions or, in 2D, computed the exact *integral* of bottleneck distance over all angles via a kinetic data structure. We improve the integral objective to $\tilde{O}(n^5)$ in place of the earlier $\tilde{O}(n^6)$ bound, where n denotes the number of simplices. For the *max* objective, we give an $\tilde{O}(n^3)$ expected-time algorithm in $\mathbb{R}^2$ and an $\tilde{O}(n^5)$ expected-time algorithm in $\mathbb{R}^3$.

1 Introduction

Persistent homology captures the multiscale evolution of homology classes along a filtration induced by a real-valued function on a space. It has proved useful across fields such as materials science [9, 14], computational biology [12, 19], as well as machine learning [3, 13], providing robust descriptors for high-dimensional data. A persistence diagram is a concise multiset summary of persistent homology, recording the birth–death times of features. Similarity between objects is then assessed by comparing their diagrams, most commonly via the bottleneck distance. Computationally, this reduces to a minimum-bottleneck perfect matching on a bipartite graph with diagonal copies, and algorithms for this problem have been studied extensively in both theory and practice [2, 6, 10, 15, 16].

Since a single diagram depends on the chosen filter and may miss geometry, the Persistent Homology Transform (PHT) collects diagrams from all directions to retain fuller information [20]. It assigns to a shape in $\mathbb{R}^m$ the collection of persistence diagrams obtained from linear height filtrations over all directions on $\mathbb{S}^{m-1}$. It possesses many desirable theoretical properties such as continuity, stability, and injectivity [5, 11, 20]. These properties make the PHT an effective topological descriptor for applications. However, unlike other directional-transform–based signatures such as the Euler Characteristic Transform, the PHT lacks efficient comparison algorithms, limiting its practical use. A natural way to compare PHTs is to sample directions and compute the bottleneck distance only at those angles. This

inevitably leads to information loss. To integrate the bottleneck distance over the parameter domain (e.g., $\mathbb{S}^{m-1}$), prior work by Munch, Wang, and Wenk introduced a kinetic "hourglass" approach that maintains matchings as the parameter moves. It computes this integral with an $\tilde{O}(n^6)$ bound for data in $\mathbb{R}^2$ [18]. In this work, we focus on the max variant, which we define as the supremum of the bottleneck distance over all directions.

Our Contributions. We provide an $\tilde{O}(n^3)$ expected-time algorithm to compute the max bottleneck distance between PHTs of shapes in $\mathbb{R}^2$ and an $\tilde{O}(n^5)$ expected-time algorithm in $\mathbb{R}^3$, where $\tilde{O}$ means the logarithmic factor is ingored. Additionally, we improve the computation of the integral distance from the previous $\tilde{O}(n^6)$ bound to $\tilde{O}(n^5)$ in $\mathbb{R}^2$.

For the max bottleneck distance, we use techniques from computational geometry and topology and inspired by the strategy of Bjerkevik and Kerber for computing the matching distance for two-parameter modules [1]. At a high level, the solution for 2D and 3D are similar. We first reformulate the problem as a decision problem: given a threshold λ, we determine whether the max bottleneck distance is at most λ. To solve this, we sweep the direction parameter around the sphere while maintaining the bottleneck matching between the two persistence diagrams. The key insight is that this matching changes only at discrete "events": points where persistence diagrams change combinatorially or where edge weights cross the threshold λ. At each event, we update the matching using a single augmenting path search in the geometric bipartite graph, exploiting the fact that only local changes occur.

We then identify that the maximum bottleneck distance must occur at one of a finite set of candidate values, corresponding to critical points and intersections of the difference functions between simplices. While there are $O(n^4)$ candidates in 2D and $O(n^6)$ in 3D, we avoid exhaustive enumeration through a randomized incremental construction. We maintain a band containing the true maximum and iteratively refine it by processing simplices in random order, testing whether their associated candidates lie within the current band. The randomization ensures that we expect only $O(\log n)$ refinements, reducing the expected complexity to $\tilde{O}(n^3)$ in 2D and $\tilde{O}(n^5)$ in 3D.

Outline. We begin in Section 2 with a brief overview of persistent homology, persistence diagrams, and the PHT, and we formalize the problem. Section 3 presents our $\mathbb{R}^2$ algorithm: first at a high level, then with full technical details. The improvement for the integral distance is shown in Section 4. Section 5 extends the approach to $\mathbb{R}^3$ before concluding in Section 6.

2 Preliminary

2.1 Persistent homology

Persistent homology is a multi-scale summary of the connectivity of objects in a nested sequence of subspaces; see [7, 8] for an introduction. For the purposes of this section, we define a *persistence diagram* to be a finite collection of points $\{(b_i, d_i)\}_i$ with $d_i \geq b_i$ for all i.

Given two persistence diagrams X and Y, a partial matching is a bijection $\eta : X' \to Y'$ on a subset of the points $X' \subseteq X$ and $Y' \subseteq Y$; we denote this by $\eta : X \rightleftharpoons Y$. The cost of a partial matching is the maximum over the L_∞-norms of all pairs of matched points and the distance between the unmatched points to the diagonal:

$$c(\eta) = \max\left(\{\|x - \eta(x)\|_\infty \mid x \in X'\} \cup \{\tfrac{1}{2}|z_2 - z_1| \mid (z_1, z_2) \in (X \setminus X') \cup (Y \setminus Y')\}\right) \quad (1)$$

and the bottleneck distance is defined as $d_B(X, Y) = \inf_{\eta : X \rightleftharpoons Y} c(\eta)$.

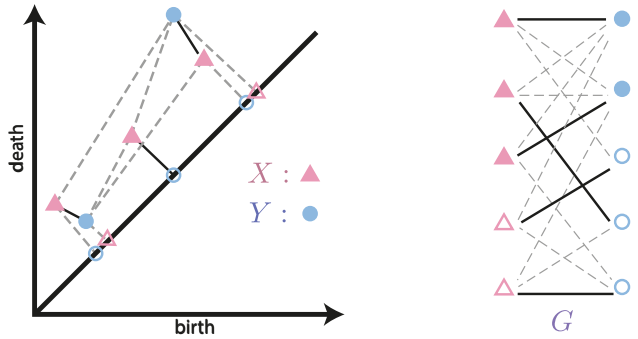

Figure 1 Construction of the bipartite graph G based on the persistence diagrams X and Y.

We can reduce finding the bottleneck distance between persistence diagrams to the problem of finding the bottleneck cost of a bipartite graph. Let X and Y be two persistence diagrams given as finite lists of off-diagonal points. For any off-diagonal point $z = (z_1, z_2)$, the orthogonal projection to the diagonal is $z' = ((z_1 + z_2)/2, (z_1 + z_2)/2)$. Let $\overline{X}$ (resp. $\overline{Y}$) be the set of orthogonal projections of the points in X (resp. Y). Set $U = X \sqcup \overline{Y}$ and $V = Y \sqcup \overline{X}$. We define the complete bipartite graph $G = (U \sqcup V, U \times V, \mathrm{c})$, where for $u \in U$ and $v \in V$, the weight function c is given by

$$\mathrm{c}(uv) = \begin{cases} \|u - v\|_\infty & \text{if } u \in X \text{ or } v \in Y \\ 0 & \text{if } u \in \overline{X} \text{ and } v \in \overline{Y}. \end{cases}$$

An example of the bipartite graph construction is shown in Figure 1. This graph can be used to compute the bottleneck distance of the input diagrams because of the following lemma.

▶ **Lemma 1** (Reduction Lemma [8]). *For the above construction of G, $d_B(G) = d_B(X, Y)$.*

2.2 Persistent homology transform

Let K be a finite simplicial complex embedded in $\mathbb{R}^m$. For any direction $\omega \in \mathbb{S}^{m-1}$, the height function $h_\omega : |K| \to \mathbb{R}$ is defined by $h_\omega(x) = \langle x, \omega \rangle$. The lower-star filtration induced on the abstract complex K is given by:

$$h_\omega(\sigma) = \max\{h_\omega(v) \mid v \in \sigma\},$$

and the sublevelset at height a is the full subcomplex induced by vertices $\{v \in K \mid h_\omega(v) \leq a\}$. Filtering K by h_ω produces a persistence diagram $\mathrm{Dgm}_k(h_\omega^K)$. We focus on $k = 0, 1$ for $m = 2$, and $k = 0, 1, 2$ for $m = 3$.

The *persistent homology transform (PHT)* is defined as:

$$\mathrm{PHT}(K) : \mathbb{S}^{m-1} \to \mathcal{D}, \quad \omega \mapsto \mathrm{Dgm}(h_\omega^K),$$

where $\mathcal{D}$ is the space of persistence diagrams. The PHT is injective [20, 5], making it a faithful shape representation.

2.3 Maximum bottleneck distance

In this work, we are interested in comparing two finite embedded simplicial complexes, $K, K' \in \mathbb{R}^m$, $m = 2$ or 3, by comparing their PHTs. We define the *maximum bottleneck distance* between K and K' to be:

$$d_\infty(\mathrm{PHT}(K), \mathrm{PHT}(K')) = \max_{\omega \in \mathbb{S}^{m-1}} d_B\left(\mathrm{Dgm}(h_\omega^K), \mathrm{Dgm}(h_\omega^{K'})\right).$$

This distance is a variant of a similar integral distance that has been studied previously by Munch, Wang, and Wenk [18]:

$$d_1(\mathrm{PHT}(K), \mathrm{PHT}(K')) = \int_{\mathbb{S}^{m-1}} d_B\left(\mathrm{Dgm}(h_\omega^K), \mathrm{Dgm}(h_\omega^{K'})\right) d\omega.$$

Both d_∞ and d_1 inherit stability from the bottleneck distance. However, they differ from a computational perspective. Computing d_1 requires full knowledge of the whole domain, which is inevitably expensive. Our d_∞ metric seeks the maximum value, which allows us to reformulate the problem as finding the supremum over a finite set of candidate values rather than tracking the bottleneck distance continuously.

A key property that makes our algorithmic approach feasible is that the bottleneck distance function is Lipschitz continuous, which is a direct consequence of the stability of the bottleneck distance (see the full version for a complete proof):

▶ **Lemma 2.** *Let $H(\omega) := d_B\big(\mathrm{Dgm}(h_\omega^K), \mathrm{Dgm}(h_\omega^{K'})\big)$ denote the bottleneck distance between persistence diagrams. Then the function $H : \mathbb{S}^{m-1} \to \mathbb{R}$ is Lipschitz continuous with constant $R_K + R_{K'}$, where $R_K = \max_{v \in K^{(0)}} \|v\|$ and $R_{K'} = \max_{v \in (K')^{(0)}} \|v\|$.*

3 Computing d_∞ in $\mathbb{R}^2$

Our setup in this section is as follows: we are given two geometric simplicial complexes K, K' in $\mathbb{R}^2$ with at most n simplices each. The goal is to compute d_∞: we first introduce the necessary notation, then give a high-level overview, and finally present the technical details.

3.1 Events

For each simplex $\alpha \in K \cup K'$, we define an insertion curve $I_\alpha(\omega)$. These curves record the height at which each simplex enters the sublevel-set filtration induced by direction $\omega \in S^1$. Explicitly, if the k-simplex α has vertices $\{v_0, \ldots, v_k\} \subseteq V(K)$, its insertion curve is

$$I_\alpha(\omega) := \max_{0 \le i \le k} h_\omega(v_i), \quad h_\omega(x) = \langle x, \omega \rangle.$$

Each I_α is a piecewise-trigonometric function on S^1.

There are at most $2n$ such curves. We now define *difference curves* that capture both matched and unmatched contributions to the bottleneck distance. For distinct simplices α, σ:

$$\Delta_{\alpha,\sigma}(\omega) := \begin{cases} |I_\alpha(\omega) - I_\sigma(\omega)| & \text{if } \alpha, \sigma \text{ are from different complexes} \\ \frac{1}{2}|I_\alpha(\omega) - I_\sigma(\omega)| & \text{if } \alpha, \sigma \text{ are from the same complex} \end{cases}$$

These are real-valued functions on S^1; geometrically, one can picture their graphs as curves in $S^1 \times \mathbb{R}_{\ge 0}$. The factor of $\frac{1}{2}$ corresponds to the contribution of unmatched points to the bottleneck distance, see Equation 1. There are $O(n^2)$ such curves for $|K|, |K'| = O(n)$. We call the vertex v_i achieving $\max_{0 \le j \le k} \langle v_j, \omega \rangle$ the *active vertex* of α at ω. As ω varies, the active vertex changes at discrete directions where two vertices achieve the same height. Within any interval where the active vertices remain fixed, the difference curve simplifies to either $|\langle u - w, \omega \rangle|$ (for different complexes) or $\frac{1}{2}|\langle u - w, \omega \rangle|$ (for same complex), which is a simple trigonometric function. See Figure 2 for an example. The insertion and difference curves are both well-behaved. See Figure 3 for an example.

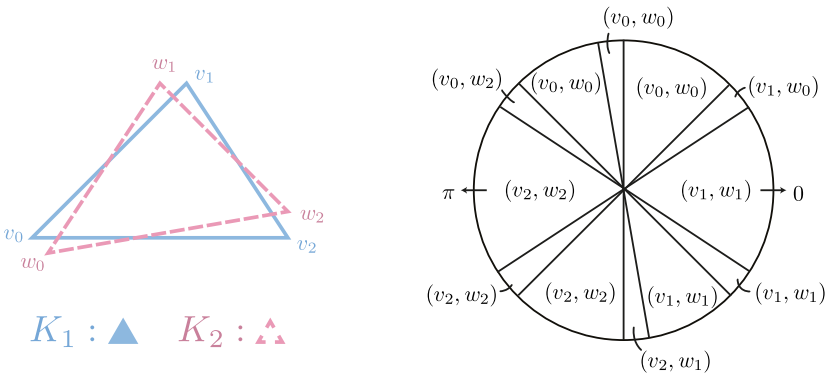

Figure 2 On the left are two simplices with vertices $v_{0,1,2}$ and $w_{0,1,2}$ respectively. On the right is $\mathbb{S}^1$ partitioned into regions with the same active vertex pairs (v_i, w_j).

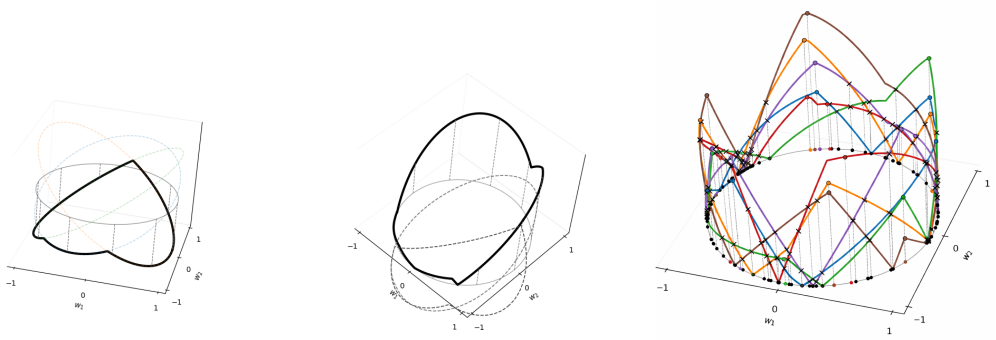
▶ **Lemma 3.** *Each difference curve $\Delta_{\alpha,\sigma}$ crosses any horizontal line $y = \lambda$ at most $O(1)$ times as ω varies over $[0, 2\pi]$. Since there are $O(n^2)$ difference curves in total, this yields $O(n^2)$ crossings with any horizontal line. In particular, there are $O(n^2)$ insertion-curve intersections, as these correspond to difference curves crossing the line $y = 0$.*

The bound on insertion-curve intersections follows immediately since we have $O(n)$ curves total, giving at most $\binom{O(n)}{2} = O(n^2)$ pairwise intersections. For threshold crossings, each difference curve $\Delta_{\alpha,\sigma}$ is piecewise trigonometric with $O(1)$ pieces (as simplices in $\mathbb{R}^2$ have at most 3 vertices), and crosses any threshold λ at most $O(1)$ times. With $O(n^2)$ pairs total, this yields $O(n^2)$ threshold crossings. The detailed geometric analysis is in the full version.

In each direction ω, the bottleneck distance is realized by the value of a difference curve $\Delta_{\alpha,\sigma}(\omega)$. When this maximum is unique in a neighborhood of ω, the continuity of the bottleneck function $H(\omega) := d_B\left(\mathrm{Dgm}(h^K_\omega), \mathrm{Dgm}(h^{K'}_\omega)\right)$ ensures that the same curve or persistence value realizes the bottleneck distance in an ε-neighborhood. We call the points in S^1 where the realizing curve or value changes locally *events*, and the values H attains at events are the *candidate values*.



▶ **Theorem 4** (Events for d_∞ in $\mathbb{R}^2$)**.** *The direction ω^* attaining d_∞ occurs at either*

1. *a local maximum of a difference curve $\Delta_{\alpha,\sigma}$, or*
2. *an intersection of two difference curves. See Figure 3 for an illustration.*

Proof. Let ω^* be the direction that attains d_∞. By Lemma 2, if the bottleneck distance at ω^* is realized by a unique difference curve in a neighborhood, then ω^* must be a local maximum of that difference curve, giving case (1). This includes both matched pairs (when $\alpha \in K, \sigma \in K'$) and unmatched point persistence (when α, σ are from the same complex). Otherwise, at least two curves achieve the same maximum value at ω^*, giving case (2). Note that intersections of insertion curves (where the persistence diagram changes combinatorially) form a special case of (2), as when two insertion curves I_α, I_β from the same complex coincide, all difference curves of the form $\Delta_{\alpha,\sigma}$ and $\Delta_{\beta,\sigma}$ are equal. ◀

▶ Remark 5. When we refer to "intersections" of difference curves, we mean isolated transverse crossings, not intervals of coincidence. Endpoints of overlaps also count as intersections, since the realizing curve may change at those boundaries.

▶ **Corollary 6.** *There are $O(n^4)$ candidate values where d_∞ may be attained.*

(a) (b) (c)

Figure 3 (a) An insertion curve $I_\alpha(\omega)$. (b) A difference curve $\Delta_{\alpha,\sigma}(\omega)$. (c) Arrangement of four difference curves; local maxima and pairwise intersections mark the candidate values of Theorem 4.

Proof. There are $O(n^2)$ difference curves: $O(n^2)$ from pairs $(\alpha, \sigma) \in K \times K'$, plus $O(n^2)$ from pairs within the same complex. Each has $O(1)$ local maxima (see the full version for the explicit bound), contributing $O(n^2)$ type-(1) candidates. For type-(2) candidates, each pair of difference curves intersects at $O(1)$ heights, giving $\binom{O(n^2)}{2} = O(n^4)$ intersections total. Thus the total number of candidates is $O(n^4)$. ◀

▶ Remark 7. When simplices share vertices, their difference curves may partially coincide. For instance, if $\alpha, \beta \in K$ share vertex v and $\sigma, \tau \in K'$ share vertex w, then $\Delta_{\alpha,\sigma}$ and $\Delta_{\beta,\tau}$ coincide in regions where v and w are simultaneously active. Despite these overlaps, each difference curve retains a unique identity at the combinatorial level through its defining simplex pair. In particular, our candidate enumeration remains valid: if the maximum bottleneck distance is achieved at direction ω^*, then at least one combinatorially distinct difference curve must realize this maximum, and this curve's critical points and intersections are in our candidate set. The full technical detail is in the full version.

3.2 Overview of the algorithm

We describe the high-level structure of our algorithm next. On this level, our approach is similar to the algorithm of Bjerkevik and Kerber to compute the matching distance [1]. However, the approaches differ in the technical realization of the predicates which are described in the subsequent subsections.

Decision procedure. Given a threshold $\lambda \geq 0$, we decide whether $d_\infty \leq \lambda$ by sweeping ω around $\mathbb{S}^1$ and maintaining a bottleneck matching. As ω rotates, we update the persistence diagrams at $O(n^2)$ insertion-curve intersections and perform single augmenting-path updates whenever an edge weight crosses the threshold. This decision procedure runs in $\tilde{O}(n^3)$ time.

Basic algorithm. By Theorem 4, d_∞ is attained at one of $O(n^4)$ candidate values corresponding to intersections of difference curves and their local maxima. These candidates can be enumerated and sorted in $O(n^4 \log n)$ time. Combined with binary search using our decision procedure, this yields an $O(n^4 \log n + n^3 \operatorname{polylog}(n)) = \tilde{O}(n^4)$ algorithm.

Improved algorithm via band refinement. By Theorem 4, there are $O(n^4)$ total candidates where d_∞ could be attained. To achieve $\tilde{O}(n^3)$ time, we avoid enumerating all candidates.

We call a candidate an α-candidate if it arises from a difference curve $\Delta_{\alpha,\sigma}$ for some σ (when $\alpha \in K$), from $\Delta_{\tau,\alpha}$ for some τ (when $\alpha \in K'$), or from $|I_\alpha(\omega) - I_\beta(\omega)|/2$ for some β in the same complex as α.

We maintain a height band $(\lambda_1, \lambda_2]$ satisfying $d_\infty > \lambda_1$ and $d_\infty \leq \lambda_2$. We process simplices from both complexes in random order. For each simplex α, we apply:

1. Existence predicate: Tests if any α-candidate lies in $(\lambda_1, \lambda_2]$ in $O(n^2 \operatorname{polylog}(n))$ time. If no candidate exists in the band, we skip to the next simplex.
2. Band-refinement predicate: If the existence test is positive, we enumerate all $O(n^3)$ α-candidates in the band and refine via binary search in $O(n^3 \operatorname{polylog}(n))$ time.

The resulting total running time is $O(n \cdot n^2 \operatorname{polylog}(n) + C \cdot n^3 \operatorname{polylog}(n))$, where C is the number of band-refinement calls. As we will show, processing the simplices in a random order ensures $\mathbb{E}[C] = O(\log n)$, yielding expected time $\tilde{O}(n^3)$.

3.3 Decision problem

We now describe how to decide whether $d_\infty \leq \lambda$ for a given threshold $\lambda \geq 0$. The key idea is to sweep the direction ω around S^1 and check if the bottleneck distance ever exceeds λ.

By Lemma 1, at each direction ω, the bottleneck distance d_B equals the cost of a minimum-bottleneck matching in a bipartite graph $G(\omega)$ constructed from the two persistence diagrams $X = \operatorname{Dgm}(h^K_\omega)$ and $Y = \operatorname{Dgm}(h^{K'}_\omega)$ with diagonal copies. Define the subgraph $G_\lambda(\omega)$ to contain only those edges of $G(\omega)$ whose weights are $\leq \lambda$. Then $d_B(X, Y) \leq \lambda$ if and only if $G_\lambda(\omega)$ admits a perfect matching.

Our strategy is to maintain a perfect matching in $G_\lambda(\omega)$ as ω sweeps from 0 to 2π. If at any point no perfect matching exists, we conclude $d_\infty > \lambda$; otherwise, if the sweep completes with a valid matching at every direction, then $d_\infty \leq \lambda$.

Sweep algorithm. We initialize at $\omega = 0$ by computing a perfect matching in $G_\lambda(0)$ using Hopcroft-Karp in $O(n^{2.5})$ [15]; if none exists, $d_\infty > \lambda$.

As ω increases from 0 to 2π, the bipartite graph $G_\lambda(\omega)$ changes only at discrete events:

- Diagram changes: At intersections of insertion curves, points move to or from the diagonal in the persistence diagrams, updating the bipartite graph structure.
- Threshold crossings: When a difference curve $\Delta_{\alpha,\sigma}(\omega)$ crosses the threshold λ, the corresponding edge enters or leaves $G_\lambda(\omega)$.

Maintaining the matching. A matching M is maintained across the sweep. At each event:

- If a new edge enters $G_\lambda(\omega)$ (weight decreases below λ), M remains valid.
- If an edge leaves $G_\lambda(\omega)$ (weight exceeds λ) and is not in M, then M remains valid.
- If an edge $(u, v) \in M$ becomes invalid, Hall's theorem guarantees that a new perfect matching exists if and only if there is an augmenting path from the newly exposed vertices. We search for such a path in $O(n \log n)$ time using the geometric structure [10]. If found, we augment along this path to restore a perfect matching. If no augmenting path exists, then $G_\lambda(\omega)$ has no perfect matching, so $d_B > \lambda$ at this ω, implying $d_\infty > \lambda$.

At diagram change events (insertion curve intersections), we update the persistence diagrams using the vineyard algorithm [4]. When two insertion curves I_α and I_β from the same complex intersect, the relative order of exactly two simplices changes in the filtration. Following Bjerkevik and Kerber [1], this corresponds to a single transposition in the barcode pairing, which can be updated in $O(n)$ time.

If the sweep completes with a valid perfect matching at every ω, then $d_\infty \leq \lambda$.

▶ **Lemma 8.** *The decision procedure runs in $\tilde{O}(n^3)$ time.*

Proof. At each event, we either update the diagram structure in $O(n)$ time (vineyard update for insertion curve intersections) or search for a single augmenting path in $O(n \log n)$ time (for threshold crossings). With $O(n^2)$ total events from Lemma 3, the total time is $\tilde{O}(n^3)$. ◀

3.4 Candidate pruning via band refinement

Recall that we have $O(n^4)$ total candidates where d_∞ may be attained. To find d_∞ efficiently, we maintain a height band $(\lambda_1, \lambda_2]$ containing d_∞ and iteratively shrink it by processing simplices from both complexes in random order.

We distinguish between two types of intersections between difference curves. *Intra-intersections* occur when two difference curves share a common simplex: either Δ_{α,σ_1} and Δ_{α,σ_2} sharing simplex α, or $\Delta_{\beta_1,\tau}$ and $\Delta_{\beta_2,\tau}$ sharing simplex τ. *Inter-intersections* occur when $\Delta_{\alpha,\sigma}$ and $\Delta_{\beta,\tau}$ meet with all four simplices distinct: $\alpha \neq \beta$ and $\sigma \neq \tau$.

Pre-refinement. Before processing individual simplices, we refine the band to exclude certain events from its interior: let S be the set containing all local maxima of difference curves $\Delta_{\alpha,\sigma}$ for all pairs (including both different-complex and same-complex pairs), all intra-α intersections where $\Delta_{\alpha,\sigma_1}(\omega) = \Delta_{\alpha,\sigma_2}(\omega)$ for some $\omega \in \mathbb{S}^1$ and distinct σ_1, σ_2, and all intra-τ intersections where $\Delta_{\beta_1,\tau}(\omega) = \Delta_{\beta_2,\tau}(\omega)$ for distinct β_1, β_2.

Since there are $O(n^2)$ difference curves, each with $O(1)$ local maxima, we have $O(n^2)$ maxima total. For intra-intersections, each of the $O(n)$ simplices in K contributes $\binom{O(n)}{2} = O(n^2)$ pairs of curves that could intersect, with $O(1)$ intersection points each, giving $O(n^3)$ intra-α intersections. Similarly for intra-τ intersections. Thus $|S| = O(n^3)$.

We binary search with the decision procedure to find the largest value in S below d_∞ and the smallest at or above it, setting these as λ_1 and λ_2. The resulting band $(\lambda_1, \lambda_2]$ contains no intra-events in its interior. This takes $O(n^3 \operatorname{polylog} n)$ time.

3.4.1 Predicate 1: Existence test

After pre-refinement, we process simplices to detect inter-intersections.

▶ **Lemma 9.** *For fixed $\alpha \in K$, determining whether any inter-intersection involving α lies in $(\lambda_1, \lambda_2]$ takes $O(n^2 \log n)$ time.*

Proof. We seek intersections of the form $\Delta_{\alpha,\sigma} \cap \Delta_{\beta,\tau}$ where $\beta \neq \alpha$. For each $\tau \in K'$, we define the *red curves* $R_\alpha = \{\Delta_{\alpha,\sigma} : \sigma \neq \alpha\}$ as all curves involving simplex α, and the *blue curves* $B_\tau = \{\Delta_{\beta,\tau} : \beta \neq \tau\}$ as all curves involving simplex τ. (See Figure 2 for the geometric setting; the red and blue curves are real-valued functions on S^1, and we detect their intersection as real-valued crossing events while sweeping around S^1.)

The key insight from pre-refinement is that within the band $(\lambda_1, \lambda_2]$, no two red curves can intersect (these would be intra-α intersections), and no two blue curves can intersect (these would be intra-τ intersections).

Each difference curve $\Delta_{\alpha,\sigma}(\omega)$ consists of $O(1)$ trigonometric pieces, switching between different expressions at directions where the active vertex changes. Since simplices in $\mathbb{R}^2$ have at most 3 vertices, there are $O(1)$ such transition points. When we clip to the band $[\lambda_1, \lambda_2]$, each curve crosses the boundary at $O(1)$ points, subdividing into $O(1)$ monotone arcs within the band.

We apply the standard Bentley-Ottmann sweep-line algorithm to all $O(n)$ arcs. Since red arcs do not intersect each other and blue arcs do not intersect each other (by pre-refinement), any intersection must be between a red and blue arc. We terminate immediately upon detecting the first such intersection. This takes $O(n \log n)$ time per choice of τ. Testing all $O(n)$ choices of $\tau \in K'$ takes $O(n^2 \log n)$ total time for fixed α. ◀

3.4.2 Predicate 2: Band refinement

When the existence test detects an inter-intersection, we must enumerate all candidates involving α to refine the band.

▶ **Lemma 10.** *When an inter-intersection involving α is detected, we can enumerate all $O(n^3)$ α-candidates in $(\lambda_1, \lambda_2]$ and compute a refined band with no α-candidates in its interior in $O(n^3 \operatorname{polylog} n)$ time.*

Proof. After pre-refinement, only inter-intersections remain in the band's interior. For simplex α, there are $O(n^3)$ such intersections (choosing σ, β, τ with $O(n)$ choices each). We enumerate these candidates, sort them, and refine the band using binary search with the decision procedure, taking $O(n^3 \operatorname{polylog} n)$ time. ◀

▶ **Theorem 11.** *After global pre-refinement, processing each simplex α takes $O(n^2 \log n + \mathbb{1}_\alpha n^3 \operatorname{polylog} n)$ total time, where $\mathbb{1}_\alpha$ is the indicator function of the existence test.*

Proof. This follows directly from Lemma 9 and 10. ◀

3.4.3 Randomized analysis

▶ **Theorem 12.** *Processing simplices from both K and K' in uniformly random order yields $\mathbb{E}[C] = O(\log n)$ refinements, where C counts positive existence tests.*

Proof. For each simplex α, define x_α as the smallest α-candidate that is $\geq d_\infty$ and y_α as the largest α-candidate that is $< d_\infty$. Since d_∞ is realized by at least one candidate, for some simplex α^* we have $x_{\alpha^*} = d_\infty$. Every interval $(y_\alpha, x_\alpha]$ contains d_∞, so our maintained band always has the form $(y_{\alpha_i}, x_{\alpha_j}]$ for some processed simplices α_i, α_j.

When processing simplices in random order, we obtain random permutations of the sequences $\{x_\alpha\}$ and $\{y_\alpha\}$. Simplex α passes the existence test and the refinement is triggered if and only if there exists an α-candidate in the current band. This occurs when x_α is smaller than all previously seen $x_{\alpha'}$ values (making it a left-to-right minimum), or y_α is larger than all previously seen $y_{\alpha'}$ values (making it a left-to-right maximum).

Indeed, if x_α is not a minimum, then some previously processed α' satisfies $x_{\alpha'} \leq x_\alpha$, so the band's upper bound is already at most x_α, excluding all α-candidates with value $\geq x_\alpha$. Likewise, if y_α is not a maximum, the band's lower bound already exceeds y_α, excluding all α-candidates with value $\leq y_\alpha$. Thus, when neither x_α nor y_α improves the band boundaries, every α-candidate lies outside (y_α, x_α), and none can fall in the current band.

By a classical result on random permutations [17]: in a uniformly random ordering of n distinct values, the i-th element is a left-to-right minimum with probability $1/i$ (being the smallest of the first i elements). By linearity of expectation, the expected number of left-to-right minima is $H_n = \sum_{i=1}^{n} \frac{1}{i} = O(\log n)$. The same bound holds for maxima. Therefore, the expected number of refinements is at most the expected number of minima in $\{x_\alpha\}$ plus the expected number of maxima in $\{y_\alpha\}$, giving $\mathbb{E}[C] \leq O(\log n) + O(\log n) = O(\log n)$. ◀

▶ **Corollary 13.** *The candidate pruning algorithm runs in expected time*

$$O(n \cdot n^2 \log n + \log n \cdot n^3 \operatorname{polylog}(n)) = \tilde{O}(n^3).$$

Proof. We process $O(n)$ simplices from both complexes. Each requires an $O(n^2 \log n)$ existence test. In expectation, only $O(\log n)$ trigger the $O(n^3 \operatorname{polylog}(n))$ band refinement. The refinement cost dominates, giving $\tilde{O}(n^3)$ expected time. ◀

4 Computing d_1 in $\mathbb{R}^2$

Our framework also improves the computation of the integral bottleneck distance d_1 from the previous $\tilde{O}(n^6)$ bound [18] to $\tilde{O}(n^5)$.

The integral requires maintaining the bottleneck matching as ω sweeps around $\mathbb{S}^1$. As ω varies, the bottleneck distance $H(\omega)$ changes only at the $O(n^4)$ difference curve intersection events identified in Section 3. At each event, we update the matching in $O(n \log n)$ time via an augmenting path search to identify which difference curve realizes the new bottleneck. Between consecutive events at angles ω_i and ω_{i+1}, the bottleneck distance is given by a single difference curve that can be integrated analytically.

Thus the integral distance can be computed in $\tilde{O}(n^5)$ total time: $O(n^4)$ events, each requiring $O(n \log n)$ processing. This improves upon the hourglass data structure approach of [18], which maintained two kinetic heaps and required $\tilde{O}(n^6)$ time.

5 Computing d_∞ in $\mathbb{R}^3$

We now consider embedded complexes in $\mathbb{R}^3$. Directions range over the sphere $\mathbb{S}^2$, difference curves become surfaces, and intersections occur along curves rather than at points. The algorithm follows the same framework as 2D, but requires traversing an arrangement on $\mathbb{S}^2$ via an Euler tour rather than sweeping a circle. This yields expected complexity $\tilde{O}(n^5)$.

5.1 Events

Let $K, K' \subset \mathbb{R}^3$ be finite simplicial complexes with at most n simplices each. For each simplex $\alpha \in K \cup K'$, $\omega \in S^2$, the *insertion surface* is:

$$I_\alpha : S^2 \to \mathbb{R}, \quad I_\alpha(\omega) := \max_{v \in \alpha} \langle v, \omega \rangle$$

Each I_α is the upper envelope of at most 4 trigonometric forms on S^2. The loci where the maximizing vertex changes are great circles $\{\omega \in S^2 : \langle v_i - v_j, \omega \rangle = 0\}$.

For distinct simplices α, σ, the *difference surface* is a real-valued function on $\mathbb{S}^2$:

$$\Delta_{\alpha,\sigma}(\omega) := \begin{cases} |I_\alpha(\omega) - I_\sigma(\omega)| & \text{if } \alpha, \sigma \text{ are from different complexes} \\ \frac{1}{2}|I_\alpha(\omega) - I_\sigma(\omega)| & \text{if } \alpha, \sigma \text{ are from the same complex} \end{cases}$$

Within each region where the active vertices are fixed, $\Delta_{\alpha,\sigma}$ simplifies to $|\langle u - w, \omega \rangle|$ for active vertices $u \in \alpha$ and $w \in \sigma$. Two difference surfaces $\Delta_{\alpha,\sigma}$ and $\Delta_{\beta,\tau}$ intersect along curves on $\mathbb{S}^2$ where $\Delta_{\alpha,\sigma}(\omega) = \Delta_{\beta,\tau}(\omega)$.

▶ **Lemma 14.** *For simplicial complexes in $\mathbb{R}^3$:*

1. *Each pair of insertion surfaces intersects along $O(1)$ great circle arcs on $\mathbb{S}^2$.*
2. *Each pair of difference surfaces intersects along $O(1)$ great circle arcs on $\mathbb{S}^2$.*
3. *Each intersection curve between difference surfaces has $O(1)$ local maxima.*
4. *Each difference surface crosses any threshold λ along $O(1)$ curves on $\mathbb{S}^2$.*

The proof follows from the piecewise structure: since simplices in $\mathbb{R}^3$ have at most 4 vertices, each insertion surface has $O(1)$ regions of fixed active vertex. Within each region, the surfaces are trigonometric forms and their intersections are great circles. The detailed geometric analysis is in the full version.

▶ **Theorem 15** (Events for d_∞ in $\mathbb{R}^3$). *The direction ω^* attaining d_∞ occurs at one of:*

1. *A local maximum of a difference surface $\Delta_{\alpha,\sigma}$*
2. *A local maximum along an intersection curve on $\mathbb{S}^2$ where two difference surfaces meet*
3. *A triple intersection point where three difference surfaces meet*

Proof. The bottleneck distance function $H(\omega)$ is continuous on S^2. At any $\omega^* \in S^2$ where d_∞ is attained, consider the difference surfaces achieving the maximum value $H(\omega^*)$.

If a unique surface $\Delta_{\alpha,\sigma}$ achieves this maximum in a neighborhood of ω^*, then by continuity, ω^* must be a local maximum of that surface (case 1). This covers both matched pairs and unmatched persistence. If exactly two surfaces achieve the maximum at ω^* but no other surface does so nearby, then ω^* lies on their intersection curve on $\mathbb{S}^2$. Since H is locally determined by these two surfaces along the curve, ω^* must be a local maximum along this curve (case 2). If three or more surfaces achieve the maximum at ω^*, then generically three surfaces meet at isolated points, giving case 3. ◀

▶ **Corollary 16.** *There are $O(n^6)$ candidate values where d_∞ may be attained.*

Proof. We count candidates by type. Type 1 has $O(n^2)$ difference surfaces (including both between-complex and within-complex pairs), each having $O(1)$ maxima, contributing $O(n^2)$ candidates. Type 2 consists of $\binom{O(n^2)}{2} = O(n^4)$ pairs with $O(1)$ maxima per intersection curve, giving $O(n^4)$ candidates. Type 3 is $\binom{O(n^2)}{3} = O(n^6)$ triple intersection points. This gives us the total of $O(n^6)$ candidates. ◀

5.2 Overview of algorithm

Decision procedure. Given threshold λ, we decide whether $d_\infty \leq \lambda$ by traversing an arrangement on $\mathbb{S}^2$. Similar to the 2D case, we track two types of events:

- Diagram changes: $O(n^2)$ intersection curves between insertion surfaces where the persistence diagrams change combinatorially;
- Threshold crossings: $O(n^2)$ curves on $\mathbb{S}^2$ where difference surfaces cross the threshold λ.

Overlaying these curves yields an arrangement of $O(n^4)$ complexity on $\mathbb{S}^2$. We traverse the dual of this arrangement via an Euler tour by traversing each edge twice, maintaining a bottleneck matching throughout. Each diagram change requires $O(n)$ time to update the barcode pairing using the vineyard algorithm, while each threshold crossing may require $O(n \log n)$ time for augmenting path search. The total complexity is $\tilde{O}(n^5)$.

Improved algorithm via band refinement. We maintain a band $(\lambda_1, \lambda_2]$ containing d_∞ and process simplices in random order. For each simplex α:

1. Existence predicate: Test if any α-candidate lies in the band. Following the approach from 2D adapted to surfaces: for fixed α and $\sigma \in K'$, consider the surface $\Delta_{\alpha,\sigma}$. For each $\beta \in K \setminus \{\alpha\}$, compute intersection curves with all $\Delta_{\beta,\tau}$ surfaces. Within the band, these $O(n)$ curves form disjoint arcs on $\mathbb{S}^2$ (no intra-β intersections after pre-refinement). Similarly get $O(n)$ disjoint arcs from surfaces involving $\gamma \in K \setminus \{\alpha, \beta\}$. Check for red-blue intersections in $O(n \log n)$ time. Testing all combinations takes $O(n^4 \log n)$.

2. Band refinement: If positive, enumerate all α-candidates in the band: $O(n^5)$ triple intersections, $O(n^3)$ curve maxima, $O(n)$ surface maxima. Then refine via binary search in $\tilde{O}(n^5)$ time.

Using the same randomization analysis as 2D, we expect $O(\log n)$ refinements. This results in total expected complexity of $O(n \cdot n^4 \log n + \log n \cdot n^5 \operatorname{polylog} n) = \tilde{O}(n^5)$.

5.3 Decision problem

Given threshold $\lambda \geq 0$, we decide whether $d_\infty \leq \lambda$ by constructing and traversing an arrangement on $\mathbb{S}^2$. Unlike the 2D case where we sweep around a circle, here we must systematically explore the entire sphere.

We first construct an arrangement $\mathcal{A}$ on $\mathbb{S}^2$ consisting of:

- $O(n^2)$ curves from insertion surface intersections (where persistence diagrams change)
- $O(n^2)$ curves where difference surfaces equal λ (threshold crossings)

Each insertion surface is piecewise trigonometric with $O(1)$ pieces, so pairs intersect along $O(1)$ curves each. Similarly, each difference surface crosses the threshold λ along $O(1)$ curves. The overlay of all these curves forms an arrangement with $O(n^4)$ vertices, edges, and faces.

▶ **Theorem 17.** *Whether $d_\infty \leq \lambda$ can be decided in $\tilde{O}(n^5)$ time.*

Proof. We construct the arrangement $\mathcal{A}$ and compute an Euler tour of its dual graph, treated as a planar graph embedded on $\mathbb{S}^2$. The tour visits each edge twice, once in each direction.

Starting from an arbitrary face with a perfect matching in $G_\lambda(\omega)$, we traverse the tour and maintain the matching throughout. At insertion curve crossings where the persistence diagram changes, we update the barcode pairing via a single transposition in $O(n)$ time using the vineyard algorithm. At threshold crossings where an edge weight exceeds λ, we search for an augmenting path in $O(n \log n)$ time. If no augmenting path exists, we conclude $d_\infty > \lambda$ and terminate. If the tour completes with valid matchings maintained throughout, then $d_B(\omega) \leq \lambda$ for all $\omega \in \mathbb{S}^2$, hence $d_\infty \leq \lambda$.

The arrangement has $O(n^4)$ edges in total. The $O(n^4)$ diagram changes contribute $O(n^5)$ total time at $O(n)$ each, while the $O(n^2)$ threshold crossings contribute $\tilde{O}(n^3)$ at $O(n \log n)$ each. However, the bottleneck arises from traversing all $O(n^4)$ edges of the arrangement, where at each edge crossing we may need to update the matching. Since each edge crossing potentially requires $O(n \log n)$ time for augmenting path search, the total complexity is $O(n^4 \cdot n \log n) = \tilde{O}(n^5)$. ◀

5.4 Candidate pruning via band refinement and complexity analysis

As in the 2D case, we maintain a band $(\lambda_1, \lambda_2]$ containing d_∞ and process simplices in random order. We first apply a pre-refinement to exclude all intra-events from the band.

Pre-refinement. Before processing individual simplices, we refine the band to exclude all intra-events from its interior. We call a triple intersection point $\Delta_{\alpha,\sigma} \cap \Delta_{\beta,\tau} \cap \Delta_{\gamma,\rho}$ an *intra-event* if any two of the six involved simplices are equal. Let S be the set containing all $O(n^2)$ local maxima of difference surfaces, all $O(n^4)$ local maxima along surface intersection curves, and all intra-event triple intersections. Since there are $O(n^5)$ ways to choose 5 distinct simplices and $O(1)$ ways to make two of them equal, we have $|S| = O(n^5)$. We use binary search with the decision procedure to find the largest value in S that is $< d_\infty$ (setting λ_1) and the smallest value in S that is $\geq d_\infty$ (setting λ_2), yielding the band $(\lambda_1, \lambda_2]$ that contains d_∞ but excludes all values of S from its interior. This takes $O(n^5 \operatorname{polylog} n)$ time.

▶ **Lemma 18.** *For fixed $\alpha \in K$, we can test whether any inter-intersection involving α lies in the band $(\lambda_1, \lambda_2]$ in $O(n^4 \log n)$ time.*

Proof. Fix $\alpha \in K$ and $\sigma \in K'$, giving the difference surface $\Delta_{\alpha,\sigma}$. We seek triple intersection points of the form $\Delta_{\alpha,\sigma} \cap \Delta_{\beta,\tau} \cap \Delta_{\gamma,\rho}$ where $\beta, \gamma \in K \setminus \{\alpha\}$ and $\tau, \rho \in K'$, with the intersection value lying in $(\lambda_1, \lambda_2]$.

For fixed $\beta \in K \setminus \{\alpha\}$, compute the intersection curves between $\Delta_{\alpha,\sigma}$ and all surfaces $\Delta_{\beta,\tau}$ for $\tau \in K'$. Each pair of surfaces intersects along great circle arcs on $\mathbb{S}^2$ where $\Delta_{\alpha,\sigma}(\omega) = \Delta_{\beta,\tau}(\omega)$. We obtain $O(n)$ intersection curves on $\mathbb{S}^2$.

The crucial observation is that when we restrict to the band $\{\omega : \lambda_1 < \Delta_{\alpha,\sigma}(\omega) \leq \lambda_2\}$, these $O(n)$ curves become disjoint arcs. Any intersection between curves $\Delta_{\alpha,\sigma} \cap \Delta_{\beta,\tau_1}$ and $\Delta_{\alpha,\sigma} \cap \Delta_{\beta,\tau_2}$ would yield a triple point where $\Delta_{\alpha,\sigma} = \Delta_{\beta,\tau_1} = \Delta_{\beta,\tau_2}$. This is an intra-event (two surfaces share β), excluded from the band's interior via pre-refinement.

Similarly, for fixed $\gamma \in K \setminus \{\alpha, \beta\}$, the intersection curves between $\Delta_{\alpha,\sigma}$ and all $\Delta_{\gamma,\rho}$ surfaces yield another set of $O(n)$ disjoint arcs within the band. We now have two collections of arcs on the restricted domain of $\Delta_{\alpha,\sigma}$: the "red" arcs from β-surfaces and the "blue" arcs from γ-surfaces. A red-blue intersection corresponds to a triple point $\Delta_{\alpha,\sigma} \cap \Delta_{\beta,\tau} \cap \Delta_{\gamma,\rho}$, which is an inter-intersection involving α.

To detect red-blue intersections, we apply stereographic projection from the north pole of $\mathbb{S}^2$ to map the band region to a planar domain and use a sweep-line algorithm. As shown in the full version, the projection preserves the disjointness of red and blue arc families while mapping great circle arcs to well-behaved curves (circles and lines) that intersect $O(1)$ times. The sweep-line algorithm thus detects all red-blue intersections in $O(n \log n)$ time.

Iterating over all choices of $\sigma \in K'$, $\beta \in K \setminus \{\alpha\}$, and $\gamma \in K \setminus \{\alpha, \beta\}$ gives total complexity $O(n \cdot n \cdot n \cdot n \log n) = O(n^4 \log n)$. ◀

▶ **Lemma 19.** *When the existence test is positive for simplex α, we can enumerate all $O(n^5)$ candidates involving α that lie in $(\lambda_1, \lambda_2]$.*

Proof. For each α, the pre-refinement step excludes the $O(n)$ local maxima of difference surfaces and $O(n^2)$ local maxima of intersection curves. We only need to consider triple intersection points $\Delta_{\alpha,\sigma} \cap \Delta_{\beta,\tau} \cap \Delta_{\gamma,\rho}$: with $O(n)$ choices each for $\sigma, \beta, \tau, \gamma, \rho$, and $O(1)$ intersection points per triple, we get $O(n^5)$ candidates. Total enumeration takes $O(n^5)$ time. Binary search with the decision procedure then refines the band in $\tilde{O}(n^5)$ time. ◀

▶ **Theorem 20** (Total complexity in 3D)**.** *The algorithm runs in expected time $\tilde{O}(n^5)$.*

Proof. We process $O(n)$ simplices from both complexes. For each simplex α, we perform the existence test in $O(n^4 \log n)$ time. If positive, we enumerate and refine in $\tilde{O}(n^5)$ time. We expect $O(\log n)$ refinements using the same analysis as in 2D. The total expected complexity is therefore $O(n \cdot n^4 \log n + \log n \cdot n^5 \operatorname{polylog} n) = \tilde{O}(n^5)$. ◀

6 Conclusion

We have presented the first algorithms for computing the maximum bottleneck distance between Persistent Homology Transforms, achieving expected time complexity of $\tilde{O}(n^3)$ in $\mathbb{R}^2$ and $\tilde{O}(n^5)$ in $\mathbb{R}^3$. As a byproduct, our framework also improves the integral bottleneck distance computation from $\tilde{O}(n^6)$ to $\tilde{O}(n^5)$ in 2D. Using similar techniques, the integral version in $\mathbb{R}^3$ can be computed in $\tilde{O}(n^7)$ time by maintaining matchings across all $O(n^6)$ events, though we leave the technical details for future work.

Our adaptation of the framework introduced by Bjerkevik and Kerber [1] reveals a broader principle: directional transforms that vary continuously over parameter spaces can often be optimized through event-driven algorithms and randomized candidate pruning. This suggests potential applications beyond the PHT to other parametric problems in computational topology, such as the Euler Characteristic Transform or persistence-based shape signatures.

From a practical perspective, the cubic complexity in 2D makes exact PHT comparison feasible for moderate-sized datasets, potentially enabling new applications in shape matching and retrieval where sampling-based approximations were previously necessary. However, significant challenges remain: extending to the Wasserstein distance would require fundamentally different techniques due to its non-combinatorial nature, and handling higher-dimensional ambient spaces faces steep complexity barriers.

Abstract

Let $C_{s,t}$ be the complete bipartite geometric graph, with s and t vertices on two distinct parallel lines respectively, and all st straight-line edges drawn between them. In this paper, we show that every complete bipartite simple topological graph, with parts of size $2(k-1)^4+1$ and $2^{k^{5k}}$, contains a topological subgraph weakly isomorphic to $C_{k,k}$. As a corollary, every n-vertex simple topological graph not containing a plane path of length k has at most $O_k(n^{2-8/k^4})$ edges. When $k=3$, we obtain a stronger bound by showing that every n-vertex simple topological graph not containing a plane path of length 3 has at most $O(n^{4/3})$ edges. We also prove that x-monotone simple topological graphs not containing a plane path of length 3 have at most a linear number of edges.

1 Introduction

A *topological graph* is a graph drawn in the plane such that its vertices are represented by points and its edges are represented by non-self-intersecting arcs connecting the corresponding points. No edge is allowed to pass through any point representing a vertex other than its endpoints. Tangencies between the edges are not allowed. That is, if two edges share an interior point, then they must properly cross at this point. A topological graph is called *plane* if there are no crossing edges. Given a topological graph G, we say that H is a *topological subgraph* of G if $V(H) \subset V(G)$ and $E(H) \subset E(G)$. We say that G and H are

weakly isomorphic if there is an incidence preserving bijection between the vertices and edges of G and H such that two edges of G cross if and only if the corresponding edges in H cross as well. A topological graph is *simple* if every pair of its edges intersect at most once: at a common endpoint or at a proper crossing. Simple topological graphs are also known as *simple drawings*. If the edges of a topological graph are drawn with straight-line segments, then it is called *geometric*. We call a geometric graph *convex* if its vertices are in convex position.

In this paper, we are interested in finding large unavoidable patterns in dense simple topological graphs, and in particular, finding large plane paths. Let us emphasize here that a *path of length* k consists of $k+1$ distinct vertices and k edges. It is not hard to see that the simple condition here is necessary for plane paths, as one can easily draw K_n in the plane such that every pair of edges cross. Moreover, a construction due to Pach and Tóth [19] shows that there is a drawing of K_n in the plane such that every pair of edges crosses exactly once or twice. In 2003, Pach, Solymosi, and Tóth [20] showed that every complete n-vertex simple topological graph contains a topological subgraph on $\Omega(\log^{1/8}(n))$ vertices that is weakly isomorphic to either a complete convex geometric graph or a so-called complete twisted graph. This bound was later improved by Suk and Zeng [27] to $(\log n)^{1/4-o(1)}$. In 1998, Negami proved a bipartite analogue of this theorem. Let $C_{s,t}$ be a complete bipartite geometric graph with vertex sets U and V, where $|U| = s$ and $|V| = t$, such that the vertices in U lie on the y-axis and the vertices in V lie on the vertical line $x = 1$. (It is easy to see that $C_{s,t}$ is determined up to weak isomorphism independent of the exact placement of the vertices on these vertical lines.) In [18], Negami showed that for every $k > 1$, there is a minimum integer $n = n(k)$ such that every complete bipartite simple topological graph with n vertices in each part contains a topological subgraph weakly isomorphic to $C_{k,k}$. The proof in [18] is based on 4-uniform hypergraph Ramsey theory and no explicit bound for $n(k)$ is given. By applying more geometric arguments, we establish the following stronger result.

▶ **Theorem 1.** *Every complete bipartite simple topological graph with vertex sets U and V, where $|U| > 2(k-1)^4$ and $|V| \geq 2^{k^{5k}}$, contains a topological subgraph weakly isomorphic to $C_{k,k}$.*

We suspect that Theorem 1 still holds if $|V|$ is at least single exponential in a power of k, rather than double exponential in $\Omega(k \log k)$. On the other hand, our next result shows that the size of $U \cup V$ needs to be at least exponential in $k/2$.

▶ **Proposition 2.** *For every positive integer k there exists a complete simple topological graph on $2^{\lfloor k/2 \rfloor}$ vertices that does not contain a topological subgraph weakly isomorphic to $C_{k,k}$.*

Very recently, Balogh, Parada, and Salazar [5] extended Negami's result to complete multipartite simple topological graphs. Let us remark that our quantitative bound for the bipartite case, i.e. Theorem 1, is particularly interesting, because we can combine it with the celebrated Kővári-Sós-Turán theorem to conclude the following statement.

▶ **Theorem 3.** *Every n-vertex simple topological graph without a topological subgraph weakly isomorphic to $C_{k,k}$ has at most $O_k(n^{2-\epsilon(k)})$ edges with $\epsilon(k) = (2(k-1)^4 + 1)^{-1}$.*

It is an interesting open question to determine the optimal value of $\epsilon(k)$ in the theorem above.

An old conjecture due to Rafla [23] predicts that every complete n-vertex simple topological graph contains a plane Hamiltonian cycle for $n \geq 3$. This has been verified for small n and is open for $n \geq 10$ (see [1]). The much weaker conjecture of finding a linear size plane matching

in a complete n-vertex simple topological graph has been extensively studied [26, 3, 25]. The best known result for this problem is due to Aichholzer–García–Tejel–Vogtenhuber–Weinberger [3], who showed the existence of a plane matching of size $\Omega(\sqrt{n})$. Even less is known about plane paths. Recently, it is proved [3, 27] that every complete n-vertex simple topological graph contains a plane path of length $\Omega(\log n/\log\log n)$. Since one can easily find a plane path of length k in $C_{\lceil k/2\rceil,\lceil k/2\rceil}$, we can apply Theorem 3 to obtain the following corollary.

▶ **Corollary 4.** *Every n-vertex simple topological graph not containing a plane path of length k has at most $O_k(n^{2-8/k^4})$ edges.*

Next, we concentrate on the case of Corollary 4 when $k = 3$, that is, on simple topological graphs with no plane path of length 3. Such graph drawings can be regarded as a local variant of the so-called thrackles. A *thrackle* is a simple topological graph such that every pair of edges that do not share a vertex must cross. The famous thrackle conjecture of Conway states that a thrackle with n vertices has at most n edges, see [22] for a detailed history of the problem. For the special case of geometric graphs, the thrackle conjecture is proved by Erdős, and later, a short proof is given by Perles (see [22]). The proof of Perles also works if the drawing is outerplanar [7], i.e., if the points lie on the boundary of a disk and the edges lie inside this disk. The case that the edges are x-monotone is settled by Pach and Sterling [22]. In general, after a long series of improvements (Lovász–Pach–Szegedy [17] proved $2n$, Cairns–Nikolayevsky [6] proved $1.5n$, improved further by Fulek–Pach [11, 12] and Goddyn–Xu [13]), the current best upper bound on the number of edges of an n-vertex thrackle is $1.393(n-1)$ by Xu [30]. Apart from improvements on the upper bound, several papers consider variations of thrackles, in particular generalized thrackles [6], superthrackles [8], thrackles on surfaces [14], and thrackles of convex sets [4, 15].

We call a simple topological graph with no plane path of length 3 a *local thrackle*. Note that every thrackle is a local thrackle, but the two notions do differ. For example, consider the graph G on 6 vertices and 7 edges obtained from two disjoint copies of K_3 and an edge between them. Then G does not have a thrackle drawing (see, e.g., [29]), but G does have a local thrackle drawing (see full version for such a drawing [16]). However, our next result shows that the number of edges in a local thrackle with straight-line edges cannot be larger than n, just like in the case of thrackles.

▶ **Proposition 5.** *A local thrackle on n vertices and with straight-line segments as edges has at most n edges.*

Our proof in fact gives a characterization of the graphs that have a local thrackle drawing with segments. On the other hand, already with x-monotone edges one can draw a local thrackle with more than n edges, unlike in the case of thrackles.

▶ **Proposition 6.** *A local thrackle on n vertices and with x-monotone edges has at most $\frac{4}{3}n$ edges, while there exist local thrackles on n vertices with x-monotone edges and with $\frac{6}{5}n - O(1)$ edges.*

For the general case, we have a slightly better construction and an upper bound which improves the bound that comes from Corollary 4.

▶ **Proposition 7.** *A local thrackle on n vertices has at most $O(n^{4/3})$ edges, while there exist local thrackles on n vertices and with $2n - O(\sqrt{n})$ edges.*

Notice that the lower bound construction for the general case has more edges than the upper bound for the x-monotone case.

Our paper is organized as follows. In the next section, we prove Theorem 1 and Proposition 2. In Section 3, we establish our results on local thrackles, proving Propositions 5, 6, and 7. Finally, in Section 4, we give some concluding remarks. We systematically omit floors and ceilings whenever they are not crucial for the sake of clarity in our presentation. All logarithms are in base 2.

2 Unavoidable patterns in complete bipartite topological graphs

In this section, we prove Theorem 1. We will need the following combinatorial lemmas. Let G be an ordered graph with vertex set $U = \{u_1, u_2, \dots, u_n\}$. We say that G contains a *monotone path* of length k if there are $k+1$ indices $1 \le i_0 < i_1 < \cdots < i_k \le n$ such that $u_{i_j}u_{i_{j+1}} \in E(G)$ for all $0 \le i < k$. We say that G is *transitive* if for any $1 \le i_1 < i_2 < i_3 \le n$, the condition $u_{i_1}u_{i_2}, u_{i_2}u_{i_3} \in E(G)$ implies that $u_{i_1}u_{i_3} \in E(G)$. We will need the following three simple observations. The first is self evident, for the second we provide a simple proof to be self contained. The last one is a well known estimate of the multicolor Ramsey numbers.

▶ **Lemma 8.** *The vertices of a monotone path induce a clique in a transitive ordered graph.*

▶ **Lemma 9.** *Let t and m be positive integers. If G is a complete ordered graph on $n > tm^4$ vertices whose edges are colored with five colors, then either there exists an m-edge monochromatic monotone path in G in one of the first four colors, or there exists a monochromatic clique of size $t+1$ in the fifth color.*

Proof. Label each vertex v of G by the four-tuple (l_1, l_2, l_3, l_4), where l_i is the edge number of the longest monotone path in color i ending at v. If any of these paths have at least m edges we are done. If this is not the case, then all the labels are from $\{0, \dots, m-1\}^4$, so by the pigeonhole principle, some $t+1$ vertices must share the same label. We claim that these vertices induce a monochromatic clique in the fifth color. Indeed, assume the vertex u precedes vertex v in the vertex order and the edge uv receives color i. Consider the longest monotone path in color i ending at u. Extending this path with the uv edge we get a longer monotone path in color i ending at v showing that u and v cannot share the same label unless $i = 5$. This proves the lemma. ◀

Let $r(k; r)$ be the minimum integer n such that every r-coloring of the edges of the complete graph on n vertices contains a monochromatic clique on k vertices. The existence of $r(k; r)$ follows by the famous theorem of Ramsey [24], and following the arguments of Erdős–Szekeres [9], we have

▶ **Lemma 10.** $r(k; r) < r^{rk}$.

Proof of Theorem 1. Let G be a complete bipartite simple topological graph whose vertex set is $U \cup V$, where $|U| = m > 2(k-1)^4$ and $|V| = n \ge 2^{k^{5k}}$. We assume without loss of generality that $m = 2(k-1)^4 + 1$ (otherwise we simply ignore the extra vertices in U). There is nothing to prove when $k = 1$. When $k = 2$, since $K_{3,3}$ is not planar, we can find a pair of crossing edges u_1v_1 and u_2v_2 in G, and as G is simple, the induced topological subgraph on u_1, u_2, v_1, v_2 is weakly isomorphic to $C_{2,2}$. Therefore, we assume $k \ge 3$ for the rest of this proof.

By arbitrarily ordering the elements in U and V, we have $U = \{u_1, \dots, u_m\}$, and $V = \{v_1, \dots, v_n\}$. For each 4-tuple $u_i, u_j \in U$ and $v_s, v_t \in V$, where $i < j$ and $s < t$, let us consider the drawing of $K_{2,2}$ induced on these vertices. Note that as we have a simple topological graph, only non-adjacent edges can cross, that is, u_iv_s may cross u_jv_t or u_iv_t may

cross u_jv_s. If both of these pairs of edges cross, then we obtain a thrackle drawing of C_4 and a small case-analysis shows that such a drawing does not exist. So we have three possibilities, either the first pair cross, or the second pair, or it is a plane drawing. We further refine this classification according to the orientation of the vertices around the crossing point obtaining the following five *order types*. When speaking about the order of the vertices around the crossing point we mean the cyclic order of the edge-segments going to these vertices.

1. The 4-tuple $\{u_i, u_j, v_s, v_t\}$ is of *type 1* if edge u_iv_t crosses edge u_jv_s, and moreover, vertices (u_i, v_s, v_t, u_j) appear in clockwise order from the crossing point of u_iv_t and u_jv_s.
2. The 4-tuple $\{u_i, u_j, v_s, v_t\}$ is of *type 2* if edge u_iv_t crosses edge u_jv_s, and moreover, vertices (u_i, u_j, v_t, v_s) appear in clockwise order from the crossing point of u_iv_t and u_jv_s.
3. The 4-tuple $\{u_i, u_j, v_s, v_t\}$ is of *type 3* if edge u_iv_s crosses edge u_jv_t, and moreover, vertices (u_i, v_t, v_s, u_j) appear in clockwise order from the crossing point of u_iv_s and u_jv_t.
4. The 4-tuple $\{u_i, u_j, v_s, v_t\}$ is of *type 4* if edge u_iv_s crosses edge u_jv_t, and moreover, vertices (u_i, u_j, v_s, v_t) appear in clockwise order from the crossing point of u_iv_s and u_jv_t.
5. The 4-tuple $\{u_i, u_j, v_s, v_t\}$ is of *type 5* if it induces a plane drawing of $K_{2,2}$.

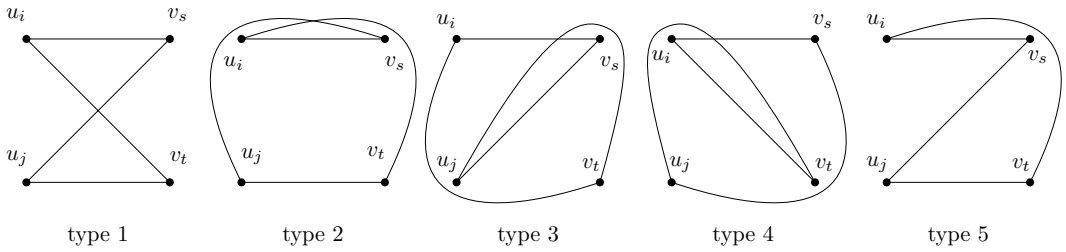

Figure 1 A drawing of each of the five types of C_4's.

See Figure 1. For $v_s, v_t \in V$ and $w \in \{1, 2, 3, 4, 5\}$, let $G^{(w)}_{s,t}$ be the ordered graph whose vertex set is U, and edges are pairs of vertices $\{u_i, u_j\}$ such that the 4-tuple $\{u_i, u_j, v_s, v_t\}$ is of type w.

We claim that the ordered graph $G^{(w)}_{s,t}$ is transitive for $w \in \{1, 2, 3, 4\}$, that is, with respect to the first four order types. We verify the statement for $G^{(1)}_{s,t}$. For $i < j < \ell$, suppose that $\{u_i, u_j\}$ and $\{u_j, u_\ell\}$ are edges in $G^{(1)}_{s,t}$. Consider the drawing of $K_{2,2}$ induced by the 4-tuple $\{u_i, u_j, v_s, v_t\}$, specifically the "triangle" formed by u_j, v_t and the crossing point between u_jv_s and u_iv_t. Since (u_j, v_s, v_t, u_ℓ) must appear in clockwise order from the crossing point of u_jv_t and $u_\ell v_s$, we must exit the "triangle" at this crossing point as we travel along $u_\ell v_s$ from v_s to u_ℓ. This implies that $u_\ell v_s$ crosses both u_jv_t and u_iv_t. Further, u_ℓ, v_s, and v_t must appear in the same cyclic order from the crossing point of u_jv_t and $u_\ell v_s$ as well as from the crossing point of u_iv_t and $u_\ell v_s$. The former is clockwise order from the assumption $\{u_j, u_\ell\} \in E(G^{(1)}_{s,t})$, so the latter also clockwise implying $\{u_i, u_\ell\} \in E(G^{(1)}_{s,t})$ as claimed. See Figure 2. The transitivity property of $G^{(2)}_{s,t}, G^{(3)}_{s,t}$, and $G^{(4)}_{s,t}$ can be argued similarly, or be reduced to the case of $G^{(1)}_{s,t}$ by reversing the vertex orders on U or V. For example, a type 3 quadruple $\{u_i, u_j, v_s, v_t\}$ would have been type 1 if we had ordered the vertices in U the same but in V reversely.

Since $|U| > 2(k-1)^4$, by combining Lemmas 8, 9, and the fact that $G^{(w)}_{s,t}$ is transitive when $w \in \{1, 2, 3, 4\}$, we have the following observation.

▷ Claim 11. For each pair $v_s, v_t \in V$, there is a subset $S \subset U$ such that either

1. $|S| = k$, and S induces a clique in $G^{(w)}_{s,t}$ for some $w \in \{1, 2, 3, 4\}$, or
2. $|S| = 3$, and S induces a clique (i.e., a triangle) in $G^{(5)}_{s,t}$.

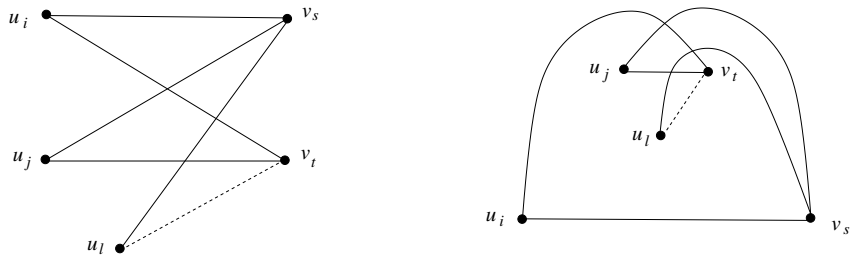

Figure 2 Proof of transitivity of $G^{(1)}_{s,t}$.

This claim implies that we can label the edge v_sv_t of the complete graph on V with a pair (S, i), where $i \in \{1, \dots, 5\}$ and $S \subset U$ is a clique in $G^{(i)}_{s,t}$ of size 3 if $i = 5$ or of size k otherwise. In case there are more possible labels we choose arbitrarily. For $k \geq 7$, using $|U| = 2(k-1)^4 + 1 \leq 2k^4$, the number of distinct labels we use on the edges is at most

$$r(k) := 4\binom{|U|}{k} + \binom{|U|}{3} \leq 5\binom{2k^4}{k} \leq 5(2ek^3)^k \leq k^{4k}.$$

And we can further estimate using $k \geq 7$

$$r(k)^{r(k)\cdot k} < 2^{k^{5k}}.$$

For $k = 3, 4, 5, 6$, the upper bound for $r(k)$ is too crude, but we can verify the previous inequality by direct computation.

Applying Lemma 10 together with $|V| \geq 2^{k^{5k}}$, there is a subset $T \subset V$ of size k such that every pair in T has the same label (S, i). Let us consider the topological subgraph G' induced on $S \cup T$. The proof now falls into the following cases.

Case 1. Suppose $|S| = k$ and $i \in \{1, 2, 3, 4\}$. We can assume that $i = 1$, since a symmetric argument would follow otherwise. Then for $u_i, u_j \in S$ and $v_s, v_t \in T$, where $i < j$ and $s < t$, $\{u_i, u_j, v_s, v_t\}$ is of type 1, and therefore, u_iv_t crosses u_jv_s. Hence, G' is weakly isomorphic to $C_{k,k}$.

Case 2. Suppose $|S| = 3$ and $i = 5$. Then G' is a plane drawing of $K_{3,k}$. This is impossible as $k \geq 3$. ◀

2.1 Construction: Proof of Proposition 2

Here we show that one needs exponentially many vertices in a simple topological graph – even in a simple complete topological graph – to ensure the presence of a subgraph weakly isomorphic to $C_{k,k}$. Note however, that this lower bound does not match the doubly exponential bound in Theorem 1.

Fix $k \geq 3$. We construct a large random simple complete topological graph as follows, and show that with positive probability it has no subgraph weakly isomorphic to $C_{k,k}$. Set $n = 2^{\lfloor k/2 \rfloor}$. Let U be a set of n points placed on the x-axis. This will be the vertex set of the graph we construct. For each pair $u, v \in U$, draw an edge connecting u and v as a half-circle in the upper or lower half of the plane uniformly at random and independently for each pair (u, v). Clearly, this will result in a simple drawing of K_n in the plane.

Consider four vertices $u_1, u_2, u_3, u_4 \in U$ that appear in this order on the x axis. These vertices induce a drawing of K_4 in which only the edges u_1u_3 and u_2u_4 cross if and only if they are drawn in the same half plane. If these two edges are drawn in distinct half planes we obtain a plane drawing of K_4.

Let $S, T \subseteq U$ be disjoint sets of size k and let us calculate the probability that the edges between S and T form a subgraph weakly isomorphic to $C_{k,k}$. First note that $C_{k,k}$ has no subgraph that is a plane drawing of C_4, so for the weak isomorphism we need that for every $u \neq u' \in S$ and $v \neq v' \in T$ some two edges between $\{u, u'\}$ and $\{v, v'\}$ cross. This implies that the order on x axis cannot alternate between the vertices in S and the vertices of T, because in that case the subgraph is a plane drawing with probability one. This implies that either S can be split into two sets S_1 and S_2, so that all vertices in S_1 are to the left of the vertices of T and all vertices in S_2 are to the right of the vertices in T, or T can be split in two sets, one to the left and one to the right of S. We call such pairs *separated*.

Now let S and T be two separated k-element set of vertices. We may assume that S splits into S_1 and S_2 as above and S_1 is not empty (otherwise, switch the roles of S and T). Let v_0 and v_1 be the leftmost and rightmost vertices in T, respectively, while u_1 is the rightmost vertex in S_1 and u_0 is the leftmost vertex in S_2, or in case S_2 is empty, then u_0 is the leftmost vertex in S_1. We claim that the subgraph formed by the edges between S and T is weakly isomorphic to $C_{k,k}$ if and only if all of its edges, with the possible exception of u_1v_0 and u_0v_1, are drawn in the same (upper or lower) half plane. The if part of this equivalence is easy to check (and strictly speaking, not even needed for our argument). For the only if part assume without loss of generality that u_1v_1 is drawn in the upper half plane. Now consider two other vertices: $u_1 \neq u \in S$ and $v_1 \neq v \in T$. If uv is drawn in the lower half plane, then the 4-cycle u_1v_1uv is a plane drawing, so we do not have the desired weak isomorphism. So the weak isomorphism implies that all of these edges are drawn in the upper half plane including the edge u_0v_0. But then a similar argument shows that all the edges uv with $u_0 \neq u \in S$ and $v_0 \neq v \in T$ must also be drawn in the upper half plane. This covers all the edges mentioned in the claim.

As a result, the probability that the edges between the separated sets S and T form a subgraph weakly isomorphic to $C_{k,k}$ is exactly 2^{-k^2+3} and therefore the expected number of subgraphs weakly isomorphic to $C_{k,k}$ is exactly

$$k\binom{n}{2k}2^{-k^2+3}.$$

By our choice of $n = 2^{\lfloor k/2 \rfloor}$ and $k \geq 3$, this is less than 1, so the random drawing of K_n contains no subgraph weakly isomorphic to $C_{k,k}$ with positive probability.

3 Local thrackles

We say that a graph G is *thrackleable* (*local thrackleable*) if G has a thrackle drawing (local thrackle drawing). Likewise, we say that G is *geometric local thrackleable* if there is a drawing of G with straight-line edges that is a local thrackle.

Let us first consider the case when edges are drawn as straight-line segments. In this case, we can even classify all geometric local thrackleable graphs following the arguments of Woodall [29]. We prove Proposition 13 below which implies Proposition 5. A *caterpillar* is a tree in which each vertex is adjacent to at most two non-leaf vertices. A *spiked cycle* is a connected graph with one cycle such that every vertex not on this cycle has degree one. The *length* of a spiked cycle is the length of its unique subgraph that is a cycle. Let us first recall Woodall's characterization of geometric thrackles [29] using these definitions:

▶ **Theorem 12.** *A graph can be drawn as a thrackle with straight-line segments as edges if and only if either it is a union of disjoint caterpillars, or it is a spiked cycle of odd length with some additional isolated vertices.*

Our characterization of geometric local thrackles is the following:

▶ **Proposition 13.** *A graph can be drawn as a local thrackle with straight-line segments as edges if and only if it is the disjoint union of caterpillars, spiked cycles of odd length and spiked cycles of even length at least eight.*

Proof. First, we argue that if a graph G contains a vertex v with at least three non-leaf neighbors, then G is not geometric local thrackleable. See Figure 3 for two such graphs with G_1 already covered in [29]. Indeed, if v has three non-leaf neighbors, then in any straight line drawing, one of them "splits" the neighborhood of v, that is, v has neighbors in both sides of the line of the edge vw for some non-leaf neighbor w. But as w is no leaf it has another neighbor $w' \neq v$ and in any local thrackle drawing ww' intersects (crosses or has a common endpoint with) every edge incident to v, which is only possible if w does not split the neighborhood, a contradiction.

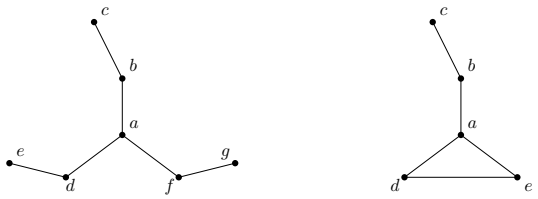

Figure 3 Two forbidden subgraphs G_1 (left) and G_2 (right) for geometric local thrackles.

Let us remove all the leaves of a geometric local thrackleable graph G. The observation above implies that the remaining graph has maximum degree at most 2, so it is the disjoint union of paths and cycles. This implies that G is the disjoint union of caterpillars and spiked cycles. To finish the only if part of the proposition we are left to show that C_4 and C_6 are not geometric local thrackleable. It is easy to see that if C_4 is drawn as a local thrackle, then this drawing must be a thrackle. The same holds true for C_6 as we shall prove in Lemma 15 (although for straight line drawings the case analysis could be shortened). On the other hand, it follows from Theorem 12 that even cycles are not geometric thrackleable (C_4 is not even thrackleable), hence C_4 and C_6 are not geometric local thrackleable.

For the if part of proposition, notice that the components of G can be drawn pairwise disjointly, so it is enough to prove that caterpillars, odd spiked cycles and even spiked cycles of length at least 8 are geometric local thrackleable. The first two cases are already handled by Theorem 12 (as those graphs are geometric thrackleable), so here we concentrate on even spiked cycles. Let $n \geq 8$ be even. We first place vertices $v_1, v_2, \ldots, v_{n-3}$ on the circle according to the following clockwise order: $v_1, v_3, v_5, \ldots, v_{n-3}$, $v_2, v_4, \ldots, v_{n-4}$. Then we put v_{n-2} on the clockwise arc v_1v_3, v_{n-1} on the clockwise arc v_2v_4, and v_n on the clockwise arc $v_{n-5}v_{n-3}$. Observe that we obtain a geometric local threackle drawing of C_n by connecting v_iv_{i+1} using straight-line segments. See Figure 4 for an illustration. Finally, we can choose an interval on the cycle for each v_i such that if we place the leaf neighbors of v_i on this intervals the resulting drawing is still a local thrackle. ◀

We continue with the case when edges are drawn x-monotone.

Proof of Proposition 6. For the lower bound we give a construction with $6/5n - O(1)$ edges. See Figure 5. First, we draw a path as seen on the top of Figure 5 as a local thrackle. Then we make a translated copy of this path as seen on the middle of Figure 5, this is clearly still a local thrackle. Finally, we add further paths of length 2, one of them is drawn blue on the

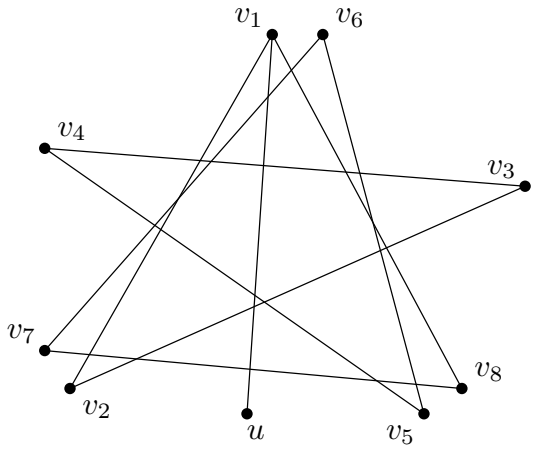

Figure 4 C_8 can be drawn as a linear local thrackle, and with a spike u attached to v_1.

middle of Figure 5, and moreover, one can check that adding this one path maintained that the drawing is a local thrackle. All such blue paths are drawn on the bottom of Figure 5, where it is not hard to check that the drawing gives a simple topological graph and also it is still a local thrackle (the blue 2-paths are far enough in the graph, thus no planar 3-path can be created when adding all blue 2-paths, if adding one did not create a planar 3-path), finishing the construction. Note that we connected using a 2-path every second vertex of one path with the corresponding vertex of the second path, thus when extending the construction with 2 vertices on each path plus a vertex to add the 2-path joining, we added 5 vertices and 6 edges. Thus, the number of edges is $6/5n - O(1)$ (the constant error comes from the fact that close to the two ends of the two paths some edges are missing).

For the upper bound, let G be a local thrackle with x-monotone edges. We may assume that every vertex has degree at least one. We distinguish three types of vertices. A vertex that has no edges going to the left (resp. right) is called a *left-vertex* (resp. *right-vertex*). A vertex that has edges in both directions is called a *middle-vertex*. Assume there are l left-vertices, r right-vertices and m middle-vertices, $l + r + m = n$.

At each left-vertex, delete the incident edge that leaves highest at this vertex. Delete at each right-vertex the incident edge that leaves lowest at this vertex. We have deleted at most $l + r$ edges. Notice that if there is a remaining edge between a left-vertex and a right-vertex, then together with the 2 deleted edges incident to these vertices, we get a plane 3-path, a contradiction. Therefore, no edge is left between a left- and a right-vertex. Similarly, if a middle-vertex is connected to two left-vertices in the remaining graph, then adding the deleted edge of the left-vertex on the higher of these two edges, we obtain a plane 3-path. The contradiction shows that every middle vertex is connected to at most one left-vertex in the remaining graph.

Next, we claim that the remaining edges connecting the left-vertices and middle-vertices form a matching. After the observation above it is enough to show that any left-vertex has at most one middle-vertex neighbor. Indeed, otherwise take two edges from a left-vertex to middle-vertices and two more edges going right from these middle-vertices. It is easy to see that one of the 3-paths in the obtained 4-path or 4-cycle must be plane, a contradiction. Therefore, the number of remaining edges connecting left- and middle vertices is at most $\min(l, m)$.

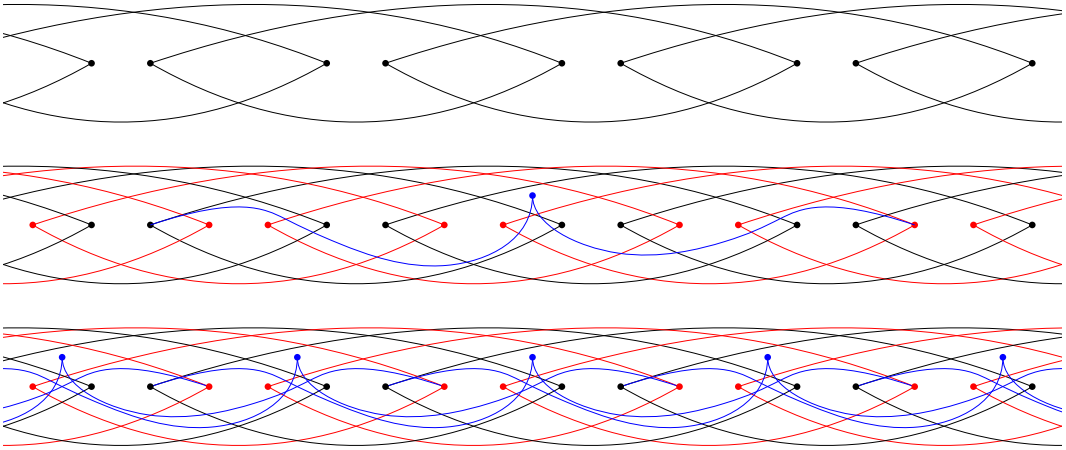

Figure 5 Two paths (black and red) joined by additional 2-paths (blue) drawn as a local thrackle with x-monotone edges.

Similarly, there are at most $\min(r, m)$ edges between the right-vertices and middle-vertices left in the graph. No edge connects two middle-vertices because that would lead to an x-monotone (therefore plane) 3-path. Putting everything together, our original graph has at most $l + r + \min(l, m) + \min(r, m)$ edges. Assume without loss of generality that $r \leq l$. Then this is at most $l + r + m + \min(l, r, m) = n + \min(l, r, m) \leq n + n/3 = 4n/3$. ◀

For the case of general local thrackles we need the following statements. Let Θ_3 denote a graph consisting of two vertices connected by three internally-disjoint paths of length three. That is, Θ_3 is a graph with 8 vertices and 9 edges.

▶ **Theorem 14** ([10]). *A graph that does not contain Θ_3 as a subgraph has at most $O(n^{4/3})$ edges.*

▶ **Lemma 15.** *Any local thrackle drawing of C_6 is also a thrackle drawing of C_6.*

Proof. Fulek and Pach [11] invented a computational approach to check whether a given graph is thrackleable. In fact, as we shall describe, their method is more general and can check whether any crossing pattern can be realized as a simple drawing or not. Let $G = (V, E)$ be an oriented graph. (We need the orientation for reference purposes only.) Suppose we are given an ordered list $\ell(e)$ consisting of elements in $E \setminus e$ for each $e \in E$, with the property that $f \in \ell(e)$ if and only if $e \in \ell(f)$, then we can construct an auxiliary graph H through the following procedure:

1. (Planarization) For every $e \in E$ directed from u to v, we replace the edge $e = \{u, v\}$ by a path from u to v, through the vertices named as $\{e, f\}$ with $f \in \ell(e)$ following the order of $\ell(e)$. Here, we introduce new vertices $\{e, f\}$ if necessary.
2. (Subdivision) For each edge between two new vertices created in the planarization step, we replace it with a path of length two, by inserting an additional vertex.
3. (Bracing) For each new vertex $v = \{e, f\}$ created in the planarization step, there will be exactly four vertices a, b, c, d adjacent to v (they may be original vertices in V or new vertices introduced in subdivision step), where a, b are adjacent to v along segments of of e and c, d are adjacent to v along segments of f. We create the edges $\{a, c\}$, $\{a, d\}$, $\{b, c\}$, and $\{b, d\}$.

We remark that here $\{e, f\}$ is unordered, so it will be considered in the planarization steps for e and f respectively, which will give it exactly four neighbors.

▷ Claim 16. The following two statements are equivalent: (i) There exists a drawing of G where the crossings on each edge e, along its direction, are exactly those between e and f with $f \in \ell(e)$ in this order. (ii) The graph H constructed above according to G and ℓ is planar.

We give a brief explanation to this claim. Suppose G has such a drawing, then we can turn it into a plane drawing by turning each crossing point into a new vertex (planarization). Next, we can subdivide each edge between the crossing points once (subdivision). Finally, we connect the neighbors of each crossing point in their cyclic order (bracing). This can be done easily such that the resulting drawing is still plane, implying that H is planar; On the other hand, suppose we have a plane drawing of H, we can draw any edge e of G, directed from u to v, along the path from u to v in H created in planarization. The vertices created in the subdivision step serve as a guide on which path to follow at a crossing point. The bracing structures will enforce the edges drawn to cross properly without tangencies. This will give a drawing of G as wanted.

Following this approach, we used a computer program to verify Lemma 15. To prove this lemma, it suffices for us to take $G = C_6$, direct its edges arbitrarily, create every possible crossing list ℓ that obeys the local thrackle condition, construct H and test for its planarity. If all such H except for those corresponding to thrackles are not planar, then we can conclude the proof. A source code for such a computer program is given in the full version of this paper [16]. ◀

▶ **Theorem 17** (Theorem 5.1 in [17]). *A thrackleable graph cannot contain Θ_3 as a subgraph.*

We show the following strengthening of the above theorem:

▷ Claim 18. A local thrackleable graph cannot contain Θ_3 as a subgraph.

Proof. Assume on the contrary, then Θ_3 can be drawn as a local thrackle. By Theorem 17 this is not a thrackle, therefore there are two independent edges that do not cross. The only way this can happen is that there is a subgraph C_6 drawn such that a pair of opposite edges do not cross. This is a local thrackle drawing of a C_6 which is not a thrackle drawing, contradicting Lemma 15, finishing the proof. ◁

▷ Claim 19. The 1-subdivision of the complete graph $K_{n,n}$ is local thrackleable.

Proof. First we show that a 1-subdivision of a star S_n is local thrackleable. For that see Figure 6. Note that outside of an area that can be made arbitrarily small (the inside of the dotted circle on the figure), the edges incident to the center can be drawn close to each other and the edges incident to the leaves can be drawn parallel. That is, every 2-path starting at v_1 goes very close to a given 2-path (say the one joining v_1 to w_1) and only in a small vicinity of the middle vertex of this given 2-path do these 2-paths intersect each other. Note that the cyclic order of the paths around v_i is reversed by the time they reach the w_i's.

We have a drawing of the 1-subdivision of the star S_n with center v_1 and leaves $W = \{w_1, \dots, w_n\}$. Now we draw n copies of this graph so that the leaves are identified to get the drawing of the graph G which is the 1-subdivision of $K_{n,n}$. The way we do it is that we put $n-1$ more vertices, $v_2, \dots, v_n$, close to v_1 and draw the new edges in the following way. For each w_i, we had one 2-path going to v_1 and we need $n-1$ more 2-paths going to $v_2, \dots, v_n$. We draw them the same way as we created the original star, just now w_i is the center and the 2-path from w_i to v_1 is the 2-path close to which all the other 2-paths go (and they only intersect in a small vicinity of the middle vertex of the 2-path from w_i to v_1). We denote $V = \{v_1, \dots v_n\}$.

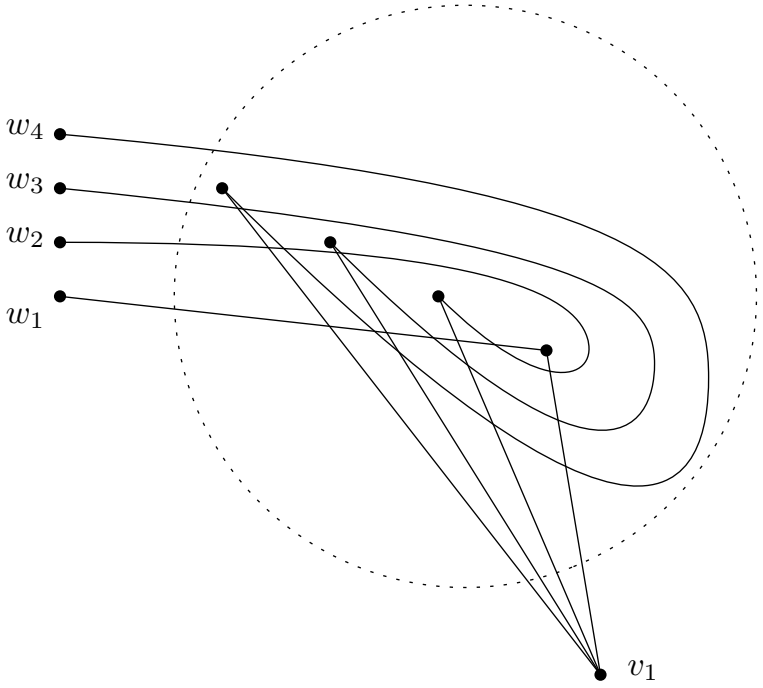

Figure 6 The 1-subdivision of a star drawn as a local thrackle.

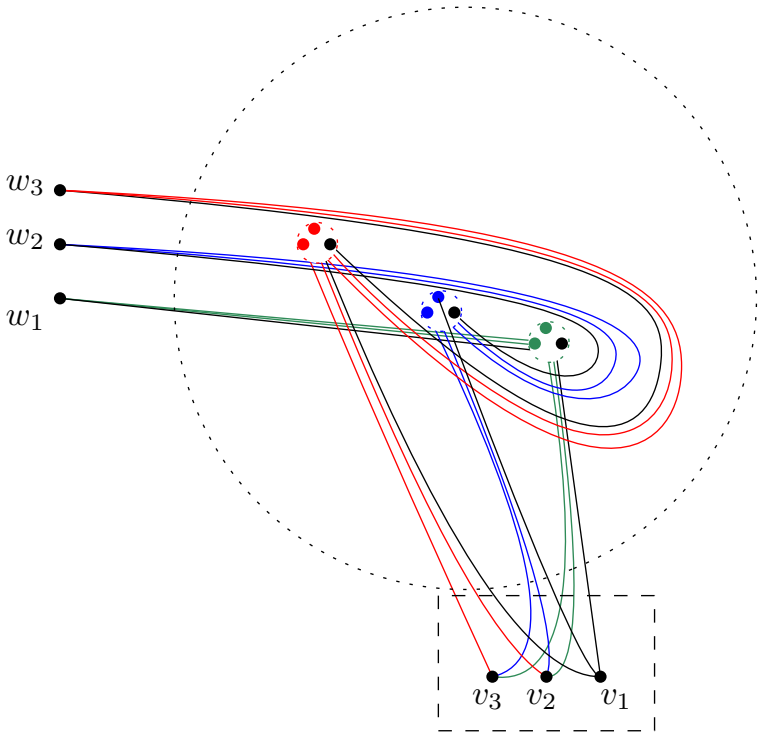

Figure 7 Subdivided $K_{3,3}$ drawn as a local thrackle. The intersections among the edges of the subdivided stars centered at w_i are hidden inside the dotted circles, each of them hiding a drawing that looks like the drawing on Figure 6 (with w_i and V on this figure playing the role of v_1 and W on Figure 6, respectively).

We draw the edges in the vicinity of v_1 such that they intersect pairwise at most once and two edges with a common endpoint v_i do not cross. See Figure 7, the dashed rectangle is the vicinity of v_1 where such crossings happen.

Finally, we are left to prove that this is a local thrackle. It is easy to check we have a simple drawing. It remains to check that no 3-edge path is planar. For this, notice that any 3-path contains exactly one vertex from V and W respectively. This implies that the 3 edges of any 3-path belong to a 1-subdivision of a star that was drawn as a local thrackle. For v_1 this follows from our drawing of S_n, for other v_i it follows from the fact that these edges go close to the respective edge from v_1, and for w_i it again follows from the fact that at w_i we drew the edges in distance two as a local thrackle. ◁

Proof of Proposition 7. The upper bound directly follows from Theorem 14 and Claim 18. The lower bound follows from Claim 19 by observing that in a 1-subdivision of $K_{n,n}$ we have $n^2 + 2n$ vertices and $2n^2$ edges. ◀

Note that Claim 19 implies that the 3-subdivision of K_n is local thrackleable, which implies that the 3-subdivision of any graph is local thrackleable. Therefore arguments that rely on forbidden subdivided copies of some graph (e.g., planarity arguments) won't work when trying to improve the upper bound in Proposition 7.

In the full version of this paper [16] we give further examples of local thrackles.

4 Related problems and concluding remarks

1. A *dual* version of Proposition 6 was obtained by Pach, Pinchasi, Tardos, and Tóth in [21], who proved that every n-vertex x-monotone simple topological graph with no self-intersecting path of length 3 has at most $O(n \log n)$ edges. Moreover, they showed that this bound is asymptotically tight. For fixed $k \geq 3$, a construction due to Tardos [28] shows that there are geometric graphs with no self-intersecting path of length k and with a superlinear number of edges. Pach, Pinchasi, Tardos, and Tóth in [21] also showed that every n-vertex topological graph (not necessarily simple) with no self-intersecting path of length 3 has at most $O(n^{3/2})$ edges. In the full version of the paper [16], we give a short proof of the following variant.

▶ **Theorem 20.** *Every n-vertex simple topological graph G with no self-intersecting path of length 4 has at most $O(n \log^2 n)$ edges.*

2. Two topological graphs G and H are *isomorphic* if there is a homeomorphism of the sphere that transforms G to H, where this sphere is the one-point compactification of the plane we draw the graphs on. The proof of Theorem 1 finds more than a weak-isomorphic copy of $C_{k,k}$ any simple drawing of a large enough complete graph. The drawing of $K_{k,k}$ we find as a subgraph agrees with $C_{k,k}$ in its *extended rotation system*, that is, the cyclic orders of edges emanating from all vertices and crossings. According to Theorem 1 in the recent paper [2], this determines H up to triangle flips followed by an isomorphism. Here, a *triangle flip* refers to the operation of moving one edge of a triangular cell formed by three pairwise crossing edges over the opposite crossing of the two other edges.

3. The following 4-uniform hypergraph Ramsey problem was also studied independently by Negami [18] and Mathias Schacht (private communication). Let $S_{a,b} = (U, V, E)$ be the 4-uniform hypergraph with the vertex set the disjoint union of U and V, where $|U| = a$ and $|V| = b$, such that $E(S_{a,b}) = \{\{x, y, z, w\} : x \neq y, z \neq w, x, y \in U, \text{ and } z, w \in V\}$. What is the minimum integer $r(S_{n,n}) = N$ such that for any red/blue coloring of the edges of

$S_{N,N}$, there is a monochromatic copy of $S_{n,n}$? Following the arguments given in Section 2, one can show that $r(S_{n,n}) < 2^{2^{O(n^2)}}$, while a standard probabilistic argument shows that $r(S_{n,n}) > 2^{\Omega(n^3)}$.

Abstract

We give an approximation scheme for the TSP in d-dimensional hyperbolic space that has optimal dependence on ε under Gap-ETH. For any fixed dimension $d \geq 2$ and for any $\varepsilon > 0$ our randomized algorithm gives a $(1+\varepsilon)$-approximation in time $2^{O(1/\varepsilon^{d-1})} n^{1+o(1)}$. We also provide an algorithm for the hyperbolic Steiner tree problem with the same running time.

Our algorithm is an Arora-style dynamic program based on a randomly shifted hierarchical decomposition. However, we introduce a new hierarchical decomposition called the hybrid hyperbolic quadtree to achieve the desired large-scale structure, which deviates significantly from the recently proposed hyperbolic quadtree of Kisfaludi-Bak and Van Wordragen (JoCG'25). Moreover, we have a new non-uniform portal placement, and our structure theorem employs a new weighted crossing analysis. We believe that these techniques could form the basis for further developments in geometric optimization in curved spaces.

1 Introduction

The metric traveling salesman problem (TSP) is easily stated: given a set of n points in some metric space, find a cyclic permutation of points that minimizes the sum of lengths between consecutive points. A very commonly studied variant is when the underlying space is d-dimensional Euclidean space (henceforth denoted by $\mathbb{R}^d$), and admits $(1+\varepsilon)$-approximations in polynomial time (PTAS) for any fixed $\varepsilon > 0$ [1, 38]. The PTAS of Arora [1] for Euclidean TSP has been tirelessly improved, generalized, and optimized throughout the past decades by researchers working on geometric optimization. Today, we have Gap-ETH-tight running times in Euclidean space, and have working approximation schemes in any so-called doubling space to many related problems [3, 4, 5, 10, 31, 40, 42]. Moreover, many components of an Arora-style scheme can also be used in other important optimization problems related to network design, clustering, and facility location [2, 16, 17, 18, 20, 48, 22].

The key components of Arora's scheme [1] involve a hierarchical decomposition of the space (a quadtree) where the space is decomposed into fat[1] regions called *cells*, each of which in turn is decomposed into $f(d)$ smaller fat cells, where d is the dimension of the space. One can then argue that using small modifications, called *patching* on the tour, we can find a $(1+\varepsilon)$-approximate tour that crosses between neighboring cells of the decomposition only $g(\varepsilon, d)$ times (or, in some cases, $f(\varepsilon, d) \cdot \text{poly}(\log n)$ times), and these crossings come from a fixed set of points called *portals*. However, this argument cannot be made for a fixed hierarchical decomposition; one needs to apply a randomized decomposition and ensure that the number of crossings is small in expectation. Finally, one can employ a bottom-up dynamic programming algorithm on the hierarchy to compute partial solutions for each possible connection pattern of the cell's portals. Crucially, the running time depends on the number of portals used by the approximate tour as well as the number of children a cell can have, as both of these terms appear in the exponent of the dynamic programming algorithm.

In the Euclidean case, the hierarchical decomposition is a quadtree whose nodes correspond to axis-aligned hypercubes whose side length is a power of 2. The entire quadtree is shifted randomly, ensuring that in expectation the hypercube boundaries avoid hitting many short segments of the tour.

Doubling spaces are those metric spaces where for all $r \geq 0$ it holds that all balls of radius r can be covered by constantly many balls of radius $r/2$. The above techniques have been successfully generalized to this much more general setting, where randomized net-trees and padded decompositions take over the role of randomly shifted quadtrees [12, 15, 23, 28, 36, 44].

However, generalizing beyond the doubling space setting has been difficult. A natural target of extensions into the non-doubling setting is hyperbolic space, where the local structure is (almost) Euclidean, but at super-constant scale the space expands exponentially. Moreover, the exponential expansion leads to a tree-like behavior that can be exploited algorithmically.

Geometric optimization in hyperbolic space is still in its infancy, but there is reason to believe that even low-dimensional hyperbolic space is highly relevant from the practical perspective [7, 8, 11, 24, 25, 26, 39, 41, 43, 46, 47], and establishing the basic tools of geometric optimization in this setting will be widely useful for future algorithmic developments in both theory and practice. Thus, it would be prudent to explore the following problem.

▶ **Problem 1.** *Adapt algorithms from Euclidean geometric optimization to negatively curved (non-doubling) spaces, or prove lower bounds that rule out such adaptations.*

Krauthgamer and Lee [35] showed the existence of a PTAS for TSP in a more general setting: in so-called geodesic, visual and Gromov-hyperbolic spaces. This implies the existence of a PTAS in d-dimensional hyperbolic space (henceforth denoted by $\mathbb{H}^d$); however, the running time dependencies on d and ε are not explicit in their work. Their paper relies on doubling space results that bring factors $1/\varepsilon^{O(d)}$ to the exponent of the running time, thus Gap-ETH-tight running times cannot result from their approach. (Nonetheless, we include a more direct overview of their techniques and achieved running times to ours, see Section 1.2.)

In order to obtain tight running times, we need to make a more explicit analysis and not rely on generic doubling space results.

▶ **Problem 2.** *Is it possible to solve TSP in $\mathbb{H}^d$ as fast as in $\mathbb{R}^d$?*

A natural starting point is the recent work on hierarchical decompositions in hyperbolic space and the newly introduced hyperbolic quadtree of Kisfaludi-Bak and Van Wordragen [34].

[1] An object (a point set) is *α-fat* if the radius of the minimum circumscribed ball divided by the radius of the maximum inscribed ball is at least α. It is *fat* if it is α-fat for some fixed constant $\alpha > 0$.

In fact, García-Castellanos, Medbouhi, Marchetti, Bekkers, and Kragic [26] recently raised the question if a quadtree-based PTAS for hyperbolic Steiner tree is possible. We answer both the question of Problem 2 and of [26] affirmatively.

1.1 Our results

In this paper, we show that explicit Arora-style approximation schemes are possible in hyperbolic space, and we can match the efficiency of Euclidean approximation schemes apart from a factor of poly$(\log n)$.

▶ **Theorem 1.** *For any fixed $d \geq 2$ and any $\varepsilon > 0$, there is a randomized $(1+\varepsilon)$-approximation for TSP and Steiner tree in d-dimensional hyperbolic space in $2^{O(1/\varepsilon^{d-1})} n(\log n)^{2d(d-1)}$ time.*

To make our algorithm work, we need to introduce three new key components compared to earlier work in hyperbolic and Euclidean spaces:

- We need to change the hyperbolic quadtree of Kisfaludi-Bak and Van Wordragen [34] into a so-called hybrid hyperbolic quadtree (in short, hybrid tree). We create a hyperbolic shifting technique.
- We introduce a new portal placement for the cells of this hybrid tree. The portal placement is non-uniform, in stark contrast with all earlier algorithms.
- The proof of our structure theorem is built on a new amortized *weighted* crossing analysis.

Our techniques readily generalize to the Steiner tree problem and achieve the same running time. This resolves a recent question posed in [26] about hyperbolic Steiner tree. Our result can be considered as an important step toward geometric approximation schemes in non-doubling spaces of negative curvature, and hopefully a first step toward geometric optimization in more general (non-doubling) Riemannian manifolds.

It is important to note that due to our modified shifting technique, there is no polynomial time derandomization for this algorithm for general hyperbolic point sets, again deviating from the Euclidean setting. However, derandomization is possible in case the input has at most constant diameter, and it multiplies the running time by n^d in this case. Our derandomization can be stated as follows.

▶ **Corollary 2.** *For any fixed $d \geq 2$ and any $\varepsilon > 0$, there is a deterministic $(1+\varepsilon)$-approximation for TSP and Steiner tree in $\mathbb{H}^d$ in $2^{O(\operatorname{diam}(P)+1/\varepsilon^{d-1})} n^{d+1} (\log n)^{2d(d-1)}$ time, where $\operatorname{diam}(P)$ is the diameter of the input point set $P \subset \mathbb{H}^d$.*

The achieved dependence on ε is identical to the fastest Euclidean algorithm [31, 40], which is best possible under the so-called Gap Exponential Time Hypothesis (Gap-ETH) [21, 37]. Since a instance in $\mathbb{R}^d$ can be scaled to a small neighborhood and embedded in $\mathbb{H}^d$ with infinitesimally small distortion, any lower bound in $\mathbb{R}^d$ readily applies in $\mathbb{H}^d$.

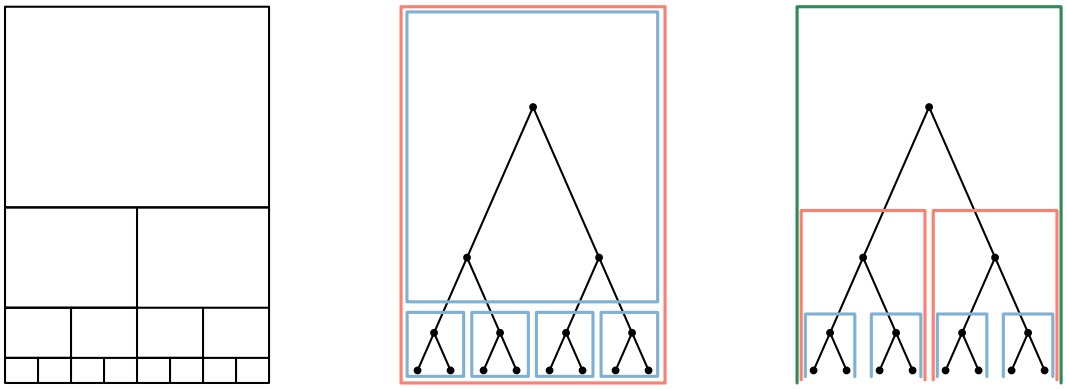
▶ **Corollary 3** (Embedding the lower bound construction of [31])**.** *For any fixed integer $d \geq 2$ there is a $\gamma > 0$ such that there is no $2^{\gamma/\varepsilon^{d-1}} \operatorname{poly}(n)$ time $(1+\varepsilon)$-approximation algorithm for TSP in $\mathbb{H}^d$ under Gap-ETH.*

In particular, this means that our running time for TSP is Gap-ETH-tight for any constant d. However, it remains an open problem whether a *deterministic* running time of $2^{O(1/\varepsilon^{d-1})} n^{O(1)}$ is possible in $\mathbb{H}^d$ for point sets of super-constant diameter.

1.2 Overview of our techniques, comparison with earlier work

The techniques of Krauthgamer and Lee [35]. The main idea in the TSP algorithm of Krauthgamer and Lee [35] is to use a randomized embedding of the space into a distribution of trees. This exploits the tree-likeness of hyperbolic spaces at larger scales. At the same time, they propose an Arora-style approach inside balls of radius τ. Roughly, the space is partitioned into ball-like regions of radius τ in a randomized fashion, then embedded into a tree whose nodes correspond to partition classes.

The value of τ and the obtained running times are not explicit in [35]. Here we will briefly speculate about the resulting running time for the sake of comparison. When embedding into a tree with edges of length at least $\tau = \Omega_\delta(1/\varepsilon)$ one can observe that the tree distance and the true hyperbolic distance will differ by at most $O(\delta) = O(1)$, which is at most $(1 + O(\varepsilon))\tau$, i.e., measuring distances between different classes along the tree leads to only $1 + O(\varepsilon)$ multiplicative error.



Within the partition classes of diameter τ, Krauthgamer and Lee must apply doubling space or Arora-style techniques [35]. However, even with newer doubling space algorithms, e.g. [5, 44], the doubling dimension of this neighborhood appears in the second level exponent. Since the doubling dimension of a τ-radius ball is *exponential in* τ, this leads to an at least triple-exponential algorithm in $1/\varepsilon$. Similarly, using some version of Arora's algorithm [1] on a distorted Euclidean instance would have to have the solution quality depend on the distortion of the τ-neighborhood, which is again exponential in τ. Thus, Arora's algorithm would have to be invoked with precision at least $\varepsilon' = 2^{-\tau}$, leading to a running time that is at least double-exponential in $\tau = \Omega(1/\varepsilon)$.

Overcoming exponential expansion. In a more explicit Arora-style algorithm, we have some challenges to overcome, in particular the following.

Ch1 Euclidean quadtrees (and net-trees in doubling spaces) have growth rates that depend only on the dimension, i.e., each cell has $f(d)$ children cells for some fixed function f. This is important as the dynamic program must take into account all portal placements of all children, and in particular, the running time has the number of children in the exponent. Due to the exponential expansion of hyperbolic spaces, no hierarchical decomposition matching the following properties is possible: (a) cells are fat, (b) cells of level ℓ have diameter $2^{\Theta(\ell)}$ and (c) each cell is partitioned into $f(d)$ children cells for some fixed function f. This issue was already observed by [34].

This property means that the hyperbolic quadtree of [34] is not suitable for our purposes: the number of children a cell can have is unbounded. Instead, we propose a new structure, called *hybrid hyperbolic quadtree*, or just *hybrid tree* for short, that has "open" cells at positive levels, and it fails the diameter property, but keeps fatness, and the number of children for cells is now bounded by 2^d. At the same time, we can still use the quadtree of [34] for its negative levels; these resemble a slightly distorted d-dimensional Euclidean quadtree, which is only defined now up to cells of diameter $O(1)$.

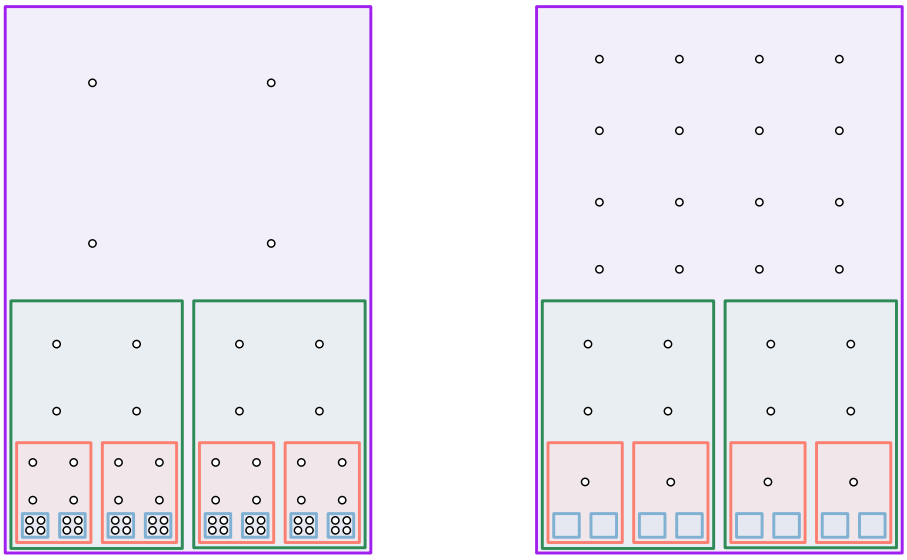
The binary tiling [13, 14] is a binary tree-like decomposition of the hyperbolic plane into isometric fat tiles. The tiling has a structure that resembles a binary tree: below each tile there are two other tiles, see the illustration in the half-plane model of $\mathbb{H}^2$ in Figure 1. For the sake of a simpler description, we compare the quadtree of [34] and our hybrid tree via this binary tree T. In the quadtree of [34], a cell of level ℓ will correspond to a subtree of T of height 2^ℓ, which can naturally be cut at half its depth into trees of height $2^{\ell-1}$, all the way until the tiling at level 0 is obtained consisting of subtrees of height 1 (i.e., the vertices of T). In our hybrid tree, a so-called *cell* of level $\ell > 0$ simply corresponds to a subtree of

(i) (ii) (iii)

Figure 1 (i) The binary tiling of $\mathbb{H}^2$ with isometric tiles. (ii) The cells of various positive levels of the corresponding quadtree illustrated on the binary tree T. (iii) Cells of the new hybrid tree of various positive levels illustrated on T.

height ℓ. Here we only allow subtrees whose leaves are also leaves of T. The corresponding cell diameter is not exponential in h, but each cell naturally has 2 children that are cells, plus a single child that is a cell of the binary tiling.

Notice that the resulting cells are "open" from the leaves' side, i.e., there is no cell below these cells. In particular, we place no portals on the bottom sides of cells of level $\ell \geq 1$.



Our algorithm. Handling the hybrid tree in a black box fashion, our algorithm proceeds similarly to Arora's scheme. We first round our input points to centers of cells of size $\varepsilon \cdot \text{OPT}/n$. The level of these cells is $\ell_{\min}$, and it is useful to think of $\ell_{\min} < 0$ for this section.

We apply a random shift on the hybrid tree using the Euclidean vectors in the half-plane model. The shifting is very similar to the Euclidean shifting, with horizontal shifts corresponding to vertical cell boundaries in the bottom layer of the lowest level cells. On the vertical axis, the shifting has only constant range. While the shifting is easy to describe and somewhat natural, it is significantly different from the grid-based shifting in Euclidean space.

The main difficulty, as with all algorithms of this type, is the structure theorem: we need to prove that there exists a $(1+\varepsilon)$-approximate tour that intersects the cell boundaries only at a few pre-defined portals. In the Euclidean setting, one can prove that the number of intersections between the optimum tour and all grid hyperplanes is $O(\text{OPT})$ (assuming a minimum edge length of one), and then one can show that the patching cost incurred at each of these intersection points is $O(\varepsilon)$ in expectation. Since hyperbolic spaces are not vector spaces, most of the steps of the analysis fail and need new ideas: we already fail to bound the number of crossings in the same manner, as there is no convenient collection of hyperplanes that could play the role of grid hyperplanes in the Euclidean analysis.

The number of crossings, weighted portal analysis. In Arora's algorithm [1], grid lines parallel to each coordinate axis are analyzed in the same uniform manner. However, in a binary tiling, the vertical lines can intersect cells at larger heights and have a non-uniform behaviour. The main challenges with vertical lines (and in higher dimensions, vertical hyperplanes) are as follows:

Ch2 The vertical lines corresponding to our shifts can intersect the optimum tour an unbounded number of times, while in the Euclidean setting, the number of intersections with vertical grid lines is (up to constant factors) equal to the tour length.

(i) (ii)

Figure 2 Illustration of (i) uniform (naïve) portal placement and (ii) non-uniform portal placement, on a Side facet of a 3-dimensional cell of the hybrid tree. For simplicity, Figure (ii) uses a scaling factor of 2, although the true scaling factor is $2^{1-1/d}$. The empty circles represent the portals.

We overcome this via weighing the intersection points by the inverse of their z-coordinates. This allows us to have an absolute bound (for every shift) on the number of intersections between the tour and the vertical lines as a function of the length of the optimum tour.

Ch3 In dimension $d \geq 3$, a side facet of a cell is itself a cell whose structure resembles that of a binary tree. In particular, its surface area is an exponential function of its diameter. This is a very significant problem, as all known algorithms rely on placing portals in a grid-like fashion, ensuring that the distance from a grid point to the nearest portal is at most ε times the diameter of the facet. In Euclidean space, this requires the placement of $O(1/\varepsilon^{d-1})$ portals inside the hypercube-shaped facet. Here, this would lead to placing a number of portals that is exponential in $1/\varepsilon$, thus it would lead to a double-exponential running time as a function of $1/\varepsilon$. Since the number of portals is in the exponent of the running time of Arora-style algorithms, this would lead to a double-exponential dependence on $(1/\varepsilon)$.

We overcome this challenge via an elaborate portal placement. First, we observe that the probability that an intersection point ends up in a very large cell facet is exponentially small. Thus, we can afford to pay a large patching cost for certain crossings near the bottom of the bounding box with an exponentially small probability. Moreover, we must ensure that the patching cost gets progressively smaller as we get closer to the top of the side facets, as we need to counterbalance the weighted analysis used for the number of crossings. This leads to a non-uniform portal placement. For an illustration of the portal placement on a 2-dimensional Side facet of a 3-dimensional cell of the hybrid tree, see Figure 2(ii).

The dynamic programming: a banyan for hyperbolic Steiner tree. The dynamic programming algorithm for hyperbolic TSP can proceed in a bottom-up manner on the hybrid tree, as seen in previous algorithms [1, 31]. In fact, the same structure theorem readily works for

the Steiner tree problem, however, there is one difficulty: in the leaf cells (and in compressed cells) of the hybrid tree, the part of the optimum falling there is some Steiner forest, and such a forest can have Steiner points inside these cells. It is non-trivial to find these Steiner points in such a way as to preserve the approximation ratio. In the Euclidean setting, the standard solution is to use a so-called *banyan* of the portals of the cell.

A $(1+\varepsilon)$-*banyan* of the point set P is a geometric graph G on some set $P \cup Q$ such that for any subset $S \subseteq P$ there is a Steiner tree in G for S whose length is at most $1+\varepsilon$ times longer than the optimum Steiner tree of S in the ambient space. In the Euclidean setting of leaf cells, one can take Q to be a dense grid and G to be a complete geometric graph on $P \cup Q$: this will lead to a solution of size $\text{poly}(1/\varepsilon)$. However, due to the exponential volume growth in the hyperbolic setting, this is not a viable solution in hyperbolic space at larger distance scales: in this case, we show that it suffices to place potential Steiner points along all edges of a (d-dimensional) triangulation of portals and input points.

2 Preliminaries

Here we only give concise preliminaries for topics handled in the main text; for further details see the full version [32]. Let $\mathbb{H}^d$ and $\mathbb{R}^d$ denote d-dimensional hyperbolic space (of sectional curvature -1) and d-dimensional Euclidean space, respectively, with distance functions $\text{dist}_{\mathbb{H}}$ and $\text{dist}_{\mathbb{R}}$. For a given set of points $P = \{p_1, p_2, \ldots, p_n\}$, a tour is defined to be a cycle π that visits each point and returns to its starting point. Let $\text{len}_{\mathbb{R}}(\pi)$ denote its total Euclidean length and $\text{len}_{\mathbb{H}}(\pi)$ its total hyperbolic length. In the *hyperbolic Traveling Salesman problem*, the goal is to determine the hyperbolic length $\text{OPT}_{\mathbb{H}}$ of the shortest such tour passing through P. We also let $\text{OPT}_{\mathbb{R}}$ denote the Euclidean length of an optimal Euclidean tour. A *hyperbolic Steiner tree* of a point set $P \subseteq \mathbb{H}^d$ is a connected geometric graph whose vertex set includes P. The aim of the *hyperbolic Steiner Tree problem* is to compute a Steiner tree of P with minimum total hyperbolic length. Throughout this paper, we use log for the base-2 logarithm and ln for the natural logarithm. For a positive integer n, we use $[n]$ to denote the set $\{1, \ldots, n\}$. For $X \subset \mathbb{H}^d$, we write $\text{diam}(X)$ for the largest hyperbolic distance between any two points of X. For $\delta > 0$, a set N is a δ-*cover* of X if every $x \in X$ lies within distance δ of some $y \in N$.

Poincaré upper half-space model. The *Poincaré upper half-space model* maps hyperbolic space $\mathbb{H}^d$ to the Euclidean upper half-space, where each point $p \in \mathbb{H}^d$ is represented as $(x(p), z(p)) \in \mathbb{R}^{d-1} \times \mathbb{R}_{>0}$. In this model, the geodesic (shortest path) between p and q is either a vertical Euclidean line segment (when $x(p) = x(q)$), or an arc from a Euclidean circle that is perpendicular to the Euclidean hyperplane $z = 0$. The results in this paper are presented in the upper half-space model. We think of the z-direction as going "up" and the x-directions as going "sideways". For more details, see [14] or the textbooks [6, 29, 45].

Binary tiling. Let us first define the relevant notation from [34]. In the upper half-space model, an *axis-aligned horobox* B is a Euclidean axis-aligned box specified by its lexicographically minimal and maximal corner points $(x_{\min}(B), z_{\min}(B))$ and $(x_{\max}(B), z_{\max}(B))$. A *cube-based horobox* B is an axis-aligned horobox with $z_{\max}(B)/z_{\min}(B) = 2^h$ and $(x_{\max}(B) - x_{\min}(B))/z_{\min}(B) = (w, \ldots, w)$, where w is the *width* of B and h is the *height* of B.

To define the binary tiling, we begin with the cube-based horobox C such that $x_{\min}(C) = (0, \ldots, 0)$ and $z_{\min} = 1$, $w(C) = 1/\sqrt{d-1}$ and $h(C) = 1$. For $\sigma > 0$ and $\tau \in \mathbb{R}^{d-1}$, let $T_{\sigma,\tau}(x, z) = \sigma \cdot (x + \tau, z)$ be a family of transformations. The *binary tiling* is obtained by applying transformations $T_{\sigma,\tau}$, where $\sigma = 2^k$ for integers k, and $\tau \in \mathbb{Z}^{d-1}$, to the horobox C. This yields a tiling of $\mathbb{H}^d$ into isometric cells that are cube-based horoboxes; see Figure 1(i).

Euclidean tools from [1] and [31]. For small distances, our structure theorem relies on the Euclidean structure theorems of [1] and [31]. For the necessary definitions and the formal statement of these Euclidean structure theorems, we refer the reader to the full version of the paper [32] and to [1, 31].

3 Hybrid Hyperbolic Quadtree and Portals

The *hybrid hyperbolic quadtree* is a tree whose nodes, called cells, are cube-based horoboxes. Each cell is the disjoint union of its children in the tree and has an integer level such that same-level cells are (almost) isometric. A cell of level 0 is a cell of the binary tiling. A cell of level $\ell > 0$ is the union of its children, which are a cell C from the binary tiling and the 2^{d-1} cells of level $\ell - 1$ directly below C (for an illustration in $\mathbb{H}^2$, see Figure 1(iii)). Equivalently, a cell C of level $\ell \geq 0$ is a portion of the binary tiling resembling a complete 2^{d-1}-ary tree of height ℓ, whose subtrees of height $\ell' > 0$ are exactly the level-ℓ' descendants of C (see Figure 1(iii)). Note that all the cells of the same positive level are isometric. Cells of levels $\ell < 0$ are defined by splitting a binary tiling cell using Euclidean quadtree splits as in the hyperbolic quadtree of [34].

We can also define a *compressed hybrid hyperbolic quadtree* (shown in Figure 3) analogously to the compressed Euclidean quadtree; the details for this are in [32]. From this point onward, we refer to the hybrid hyperbolic quadtree as the *hybrid tree* and to the compressed hybrid hyperbolic quadtree as the *compressed hybrid tree*.

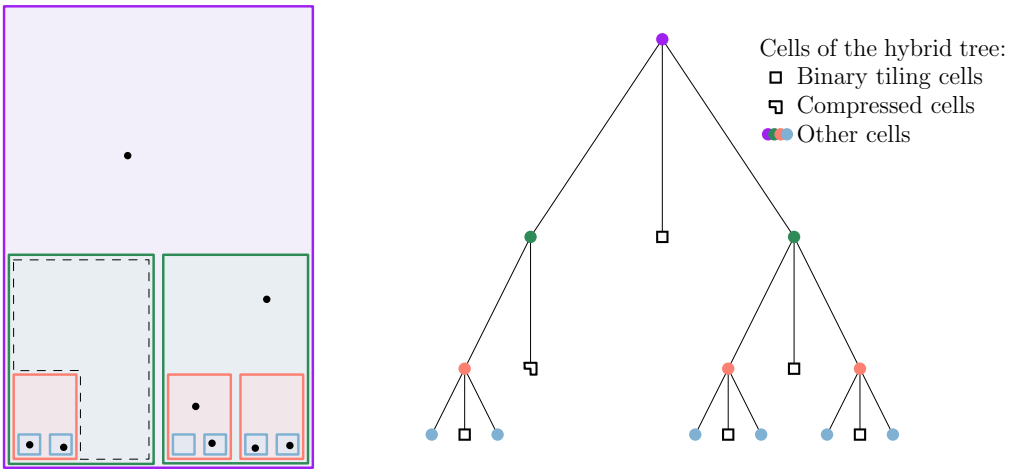


Figure 3 The compressed hybrid tree. (i) A point set and the cells of its compressed hybrid tree (A compressed cell is depicted in dashed lines). (ii) The tree structure of the hybrid tree.

Throughout the paper, the proofs of statements marked with ($\star$) can be found in the full version of the paper [32].

▶ **Lemma 4** ($\star$). *Let P be a set of n points in $\mathbb{H}^d$. There exists an $O(2^d n + dn \log n)$ time algorithm to build a compressed hybrid tree on P.*

Bounding box. Let B be the smallest Euclidean axis-aligned bounding box containing P. We first apply the same isometry $T_{\sigma,\tau}$ to both P and B so that $x_{\min}(B) = (0, \ldots, 0)$ and $z_{\min}(B) = 1$. Let s be the largest of the distances between non-adjacent facets of B.

▶ **Lemma 5** (⋆). $\operatorname{diam}(B) \leq (d+1)s$.

Since B is the smallest bounding box, $\textsc{opt}_{\mathbb{H}} \geq s$. Now, due to Lemma 5, $\textsc{opt}_{\mathbb{H}} \geq (1/(d+1)) \cdot \operatorname{diam}(B)$. Set $\ell_{\min}$ to be the minimum of 0 and the largest level where twice the diameter of a cell at that level is less than $(\varepsilon/(d+1)n) \cdot \operatorname{diam}(B)$. Define $\ell_{\max} - 1$ as the smallest hybrid tree level at which some cell C fully contains B, then let B^* denote the level $\ell_{\max}$ hybrid tree cell whose lexicographically minimal child cell is C.

Perturbation. Similar to Arora [1], our algorithm perturbs the instance by snapping each point in P to the center of level $\ell_{\min}$ cells (horobox) that contain them. Specifically, each point lying strictly inside a cell is mapped to the center of that cell, while points located on the boundaries of cells are assigned arbitrarily to the center of one of the adjacent cells. After snapping, we introduce an infinitesimal perturbation by adding the offset $\mu \cdot (1, 1, \ldots, 1)$ to each perturbed point in that cell, for an arbitrarily small $\mu > 0$. This ensures that, under every possible shift of the grid, no perturbed point lies exactly on a cell boundary.

▶ **Lemma 6** (⋆). *The length of an optimal tour over the perturbed points is at most* $(1+\varepsilon)\textsc{opt}_{\mathbb{H}}$.

3.1 Shifting of the hybrid tree

Similarly to Euclidean approximation schemes for TSP, we will use random shifting, though it is worth noting that our "shift" will not be an isometry. Let $\mathcal{C}_{\min}$ denote the cells of level $\ell_{\min}$ that lie in the lexicographically minimal child cell of B^*. We pick $\mathbf{a}_x \in \{x_{\min}(C) \mid C \in \mathcal{C}_{\min}\}$ and $\mathbf{a}_z \in \{z_{\min}(C) \mid C \in \mathcal{C}_{\min}\} \cap [1, 2)$ uniformly at random, then apply the transformation $(x, z) \mapsto (x - \mathbf{a}_x, z/\mathbf{a}_z)$ to the hybrid tree. This would be an isometry if $\mathbf{a}_z$ rescaled all coordinates; however, since it only rescales the z-coordinate, the distances are distorted by a factor of at most $\mathbf{a}_z \in [1, 2)$. Consequently, the transformed compressed hybrid tree has slightly different properties from the original hybrid tree, but we can still talk about cells and their children. We denote the shifted compressed hybrid tree under shift $\mathbf{a} = (\mathbf{a}_x, \mathbf{a}_z)$ by $Q_{\mathbf{a}}(P)$. We stop splitting once cells reach level $\ell_{\min}$, even if they still contain multiple points.

▶ **Lemma 7** (⋆). *Any level $\ell_{\min}$ cell of $Q_{\mathbf{a}}(P)$ contains at most 2^{d-1} distinct perturbed points.*

▶ **Lemma 8** (⋆). *Let C be a cell of level 0 in $Q_{\mathbf{a}}(P)$. There is a bijection $\phi : C \to [0, 1]^d$ such that $\phi(C)$ is a Euclidean unit hypercube that is split in $Q_{\mathbf{a}}(P)$ exactly as a Euclidean (compressed) quadtree. Additionally, ϕ is bi-Lipschitz: for any $p, q \in C$,*

$$\Omega(dist_{\mathbb{H}}(p, q)) \leq \operatorname{dist}_{\mathbb{R}}(\phi(p), \phi(q)) \leq O\Big(\sqrt{d} \cdot \operatorname{dist}_{\mathbb{H}}(p, q)\Big).$$

3.2 Portal placement

For any pair of sibling cells in $Q_{\mathbf{a}}(P)$, we now define a set of portals to be placed on their shared boundary. The placement depends on the level ℓ of these siblings.

Negative levels. When $\ell < 0$, we place the portals as in the Euclidean case [31] with a slight modification described below. In the Euclidean setting, the optimal tour consists of n line segments. Each segment crossing between two adjacent (Euclidean) quadtree cells must intersect their common facet. In the hyperbolic setting, however, tour segments can have endpoints in two adjacent negative-level cells but still avoid intersecting their common facet. To address this, we slightly modify the height of the common facet by extending it in the

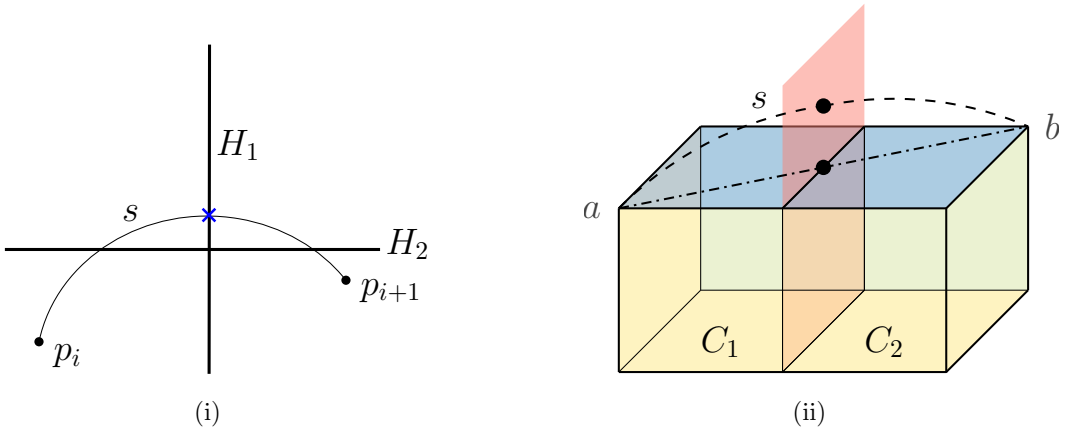

Figure 4 (i) The geodesic s has a crossing with the hyperplane H_1, but not with the hyperplane H_2: although s intersects H_2 twice, its endpoints lie on the same side. (ii) Two adjacent negative-level hybrid tree cells C_1 and C_2 share a common facet F. Extending F upward by a factor of 4 yields F', which is intersected by any geodesic s joining points $a \in C_1$ and $b \in C_2$.

z-direction. This ensures that every geodesic intersects the extended facet; see Figure 4(ii). Correspondingly, for a (hyperbolic or Euclidean) hyperplane H, we say here that a point $q \in H \cap \pi$ is a *crossing* of the tour π, if there exists $i \in [n]$ such that q lies on geodesic $p_i p_{i+1}$ and the endpoints p_i and p_{i+1} lie on different sides of H; see Figure 4(i).

▶ **Lemma 9** (⋆). *Let C_1 and C_2 be two adjacent level-ℓ ($\ell < 0$) hybrid tree cells sharing a common facet F of Euclidean height $\Delta = 2^{2^\ell} - 1$. If we extend this facet upward by a factor of 4, then every geodesic with endpoints in C_1 and C_2 intersects the extended facet F'.*

Non-negative levels. We now consider the case $\ell \geq 0$. Here, even the previously modified Euclidean portal placement cannot be applied directly, as it would result in an exponential blow-up in the number of portals and thus fail to achieve the desired result. To overcome this, we introduce a different portal placement strategy, described below. Note that a boundary facet shared between two sibling cells of level ℓ can be of two types:

Top: Facets that lie in horizontal Euclidean hyperplanes (hyperbolically these are horospheres). Each such facet is the top boundary of some binary tiling cell.

Side: Facets that lie in vertical hyperplanes. These are in fact $(d-1)$-dimensional cells, so each such facet corresponds to a cell in some $(d-1)$-dimensional hybrid tree.

Since Top facets come from binary tiling cells, Lemma 8 means we have constant distortion compared to Euclidean space. Consequently, we can simply construct a $(1/r)$-cover of the facet by placing a grid of $r^{d-1} \cdot d^{O(d)}$ equally-spaced portals.

For a Side facet σ, recall that σ is a cell of some $(d-1)$-dimensional hybrid tree and can therefore be seen as a complete 2^{d-2}-ary tree T_σ of binary tiling cells. We consider each cell F in T_σ individually and give a portal placement based on its (hop) distance h to the root of T_σ. Let $b = 2^{1-1/d}$. If $b^h \leq r$, we place portals according to a (b^h/r)-cover in F. Due to Lemma 8, this means we place $d^{O(d)} \cdot (r/b^h)^{d-1}$ portals. Otherwise, we do not place any portals. Now, the total number of portals placed for a Side facet is bounded by

$$\sum_{h=0}^{\infty} 2^{h(d-2)} \cdot d^{O(d)} \cdot (r/b^h)^{d-1} = d^{O(d)} \cdot r^{d-1} \sum_{h=0}^{\infty} 2^{-h/d} = d^{O(d)} \cdot r^{d-1}.$$

▶ **Observation 10.** *For any* Top *or* Side *facet, we place* $r^{d-1} \cdot d^{O(d)}$ *portals.*

4 Structure Theorem

Now we discuss and prove the structure theorem that allows us to develop a dynamic programming algorithm to solve the Hyperbolic TSP and Steiner Tree problem. We start by adapting the definitions for r-simple geometric graphs and r-simplifications from the Euclidean case [31] to our hyperbolic setting.

▶ **Definition 11** (r-simple geometric graph)**.** *Given a* $(d-1)$*-dimensional Euclidean box* F*, let* F^* *denote* F *with its* 2^{d-1} *corners removed. A geometric graph* π *is called* r-simple *if, for each facet* F *shared by a pair of sibling cells in* $Q_{\mathbf{a}}(P)$*,*

- *if* F *belongs to a non-negative level of the compressed hybrid tree, then the geometric graph* π *crosses* F *only through the portal points defined in* F*; or*
- *if* F *belongs to a negative level of the compressed hybrid tree, then either* π *crosses* F *at any number of its corner points and exactly one point of* F^**, or* π *crosses* F *only through the points from the uniform grid of size* g *on* F*, for some* $2^{d-1} \leq g \leq r^{2(d-1)}/|\pi \cap F^*|$*.*

▶ **Definition 12** (r-simplification)**.** *A geometric graph* π' *is called an* r-simplification *of a geometric graph* π *if* π' *is* r*-simple, and in each facet* F *of a negative level where* $|\pi \cap F^*| = 1$*, the single non-corner crossing of* π' *is the point in* $\pi \cap F^*$*.*

Having these definitions, we are now ready to state our main theorem.

▶ **Theorem 13** (hyperbolic structure theorem)**.** *Let* $\boldsymbol{a}$ *be a random shift and let* π *be a tour (or Steiner tree) of the point set* $P \subset \mathbb{H}^d$*. Then for* $r > 0$*, there is a tour (resp. Steiner tree)* π' *of* P *that is an* r*-simplification of* π *such that*

$$\mathbb{E}_{\mathbf{a}}[\mathrm{len}_{\mathbb{H}}(\pi') - \mathrm{len}_{\mathbb{H}}(\pi)] \leq O(d^3) \cdot \frac{\mathrm{len}_{\mathbb{H}}(\pi)}{r}.$$

In order to prove Theorem 13, we start by proving a bound on the patching cost of the negative levels of the compressed hybrid tree. Note that we state and prove everything for a tour, but every step works identically for a Steiner tree.

▶ **Lemma 14** ($\star$)**.** *Let* π_C *be the part of a tour* π *inside a cell* C *of the binary tiling. Then there exists a tour* π'_C *in* C *containing* $C \cap P$ *and connecting* $a, b \in \partial C$ *with a path if and only if* $a, b \in \partial C$ *are connected in* π_C *such that* π'_C *is either*

- *an* r*-simplification with respect to the negative levels and patched to the portals of [31] or*
- r*-simple with respect to the negative levels and patched to the portals of Arora [1],*

and π'_C *has expected length* $(1 + O(d^3/r))\mathrm{len}_{\mathbb{H}}(\pi_C)$*.*

Now, we prove our structure theorem.

Proof of Theorem 13. We describe a patching procedure for negative and non-negative levels of our shifted compressed hybrid tree separately.

Patching negative levels. We first modify the optimum tour π to get a tour π_1 that is slightly longer in expectation, and only crosses the shared boundaries of negative-level sibling cells through portals. In each binary tiling cell C, we apply Lemma 14 on $\pi_C = \pi \cap C$. As a result, we get a collection π'_C of paths in C whose expected length is $(1+O(d^3/r))\mathrm{len}_{\mathbb{H}}(\pi \cap C)$. Let π_1 denote the union of π'_C over all binary tiling cells C. Notice that $\pi_1 \cap C$ connects two points of ∂C if and only if the same points are connected by π, and π_1 covers the same set of input points; thus π_1 is a tour of P of expected length $(1 + O(d^3/r))\mathrm{len}_{\mathbb{H}}(\pi)$.

Patching non-negative levels. We further modify the tour π_1 to get a tour π_2 that is slightly longer in expectation, and only crosses the cell boundaries between non-negative level siblings of the compressed hybrid tree through portals. This can be achieved as follows. For each crossing point x of π_1 with a shared facet F of cell siblings of level at least 0, we add two hyperbolic segments on each side of the facet connecting a copy of x and the portal that is closest to x. (Technically, the segments are added at some infinitesimal distance from the facet.) This operation transfers all crossings to the nearest portals. Next, if some portal v is used at least three times by the tour, then by the patching lemma [1, Lemma 3] the tour can be simplified to go through the portal at most twice.

Patching costs on non-negative levels. To bound the patching cost, we want to give deterministic bounds on the number of intersections between the tour π and the hyperplanes used by the cells at level $\ell_{\min}$, then combine this with the expected cost for each intersection under random shifts $\mathbf{a}$. We do this separately for the vertical hyperplanes and the horizontal ones, since their behavior and portal placement differ.

Let $\mathcal{V}$ be the set of all vertical hyperplanes obtained by extending the vertical facets of the cells at level $\ell_{\min}$ in the unshifted hybrid tree. Let δ be the (maximum) diameter of all level $\ell_{\min}$ cells. Since these cells are $\Omega(1/\sqrt{d})$-fat [34, Theorem 7], we observe the following.

▶ **Observation 15.** *After perturbation, the distance between two distinct points is* $\Omega(\delta/\sqrt{d})$.

Decompose π into consecutive segments $\pi^1, \dots, \pi^n$. Let I denote the set of intersection points of π and all hyperplanes in $\mathcal{V}$. To bound the patching cost of the vertical intersections of the tour π, we use a weighted portal analysis. We assign each $q \in I$ a weight equal to $1/z(q)$. To bound the expected patching cost of the Side facets, we start by bounding the total weight of intersections in I as follows.

▷ Claim 16. $\sum_{p\in I} \frac{1}{z(p)} \le O\Big(\frac{d\sqrt{d}}{\delta} \cdot \mathrm{len}_{\mathbb{H}}(\pi)\Big)$.

Proof. We consider each of the $d-1$ horizontal axes separately; let $\mathcal{V}'$ be a set of hyperplanes perpendicular to one of these axes. For each $j \in [n]$, let $I^j = \{p_1^j, \dots, p_{k_j}^j\}$ be the ordered set of intersection points of π^j with $\mathcal{V}'$, and $I' = \bigcup_{j\in[n]} I^j$. For $i \in [k_j - 1]$, let $z_i^j = \min\{z(p_i^j), z(p_{i+1}^j)\}$. The Euclidean distance between adjacent hyperplanes from $\mathcal{V}'$ is given by the horobox width of level-$\ell_{\min}$ cells, which is $w \coloneqq \Theta(\delta/\sqrt{d})$ according to [34, Lemma 6]. By [34, Observation 11], the distance from a point $(w, 0, \dots, 0, z_i^j)$ to hyperplane $x_1 = 0$ is $\operatorname{arsinh}\frac{w}{z_i^j}$. Since $\operatorname{arsinh} x = \Omega(x)$ for $x = O(1)$, $\mathrm{len}_{\mathbb{H}}(p_i^j p_{i+1}^j) = \Omega\Big(\frac{\delta}{z_i^j\sqrt{d}}\Big)$. Summing this over $i \in [k_j - 1]$ yields

$$\mathrm{len}_{\mathbb{H}}(\pi^j) \ge \sum_{i\in[k_j-1]} \mathrm{len}_{\mathbb{H}}(p_i^j p_{i+1}^j) \ge \sum_{i\in[k_j-1]} \Omega\left(\frac{\delta}{z_i^j\sqrt{d}}\right).$$

Since $1/(z_i^j) = \max\{1/z(p_i^j), 1/z(p_{i+1}^j)\}$, we have $\sum_{i\in[k_j-1]} \frac{1}{z_i^j} \ge \frac{1}{2}\sum_{p\in I^j} \frac{1}{z(p)}$. Hence, $\sum_{p\in I^j} \Omega\Big(\frac{\delta}{\sqrt{d}\cdot z(p)}\Big)$ is a lower bound for $\mathrm{len}_{\mathbb{H}}(\pi^j)$. If $k_j \le 1$ (that is π^j intersects $\mathcal{V}'$ at most once), the lower bound follows from Observation 15. Summing over $j \in [n]$, we have

$$\mathrm{len}_{\mathbb{H}}(\pi) \ge \sum_{j\in[n]} \sum_{p\in I^j} \Omega\left(\frac{\delta}{\sqrt{d}\cdot z(p)}\right) = \frac{\delta}{\sqrt{d}} \sum_{p\in I'} \Omega\left(\frac{1}{z(p)}\right).$$

Hence, $\sum_{p\in I'} \frac{1}{z(p)} \le O\Big(\frac{\sqrt{d}}{\delta} \cdot \mathrm{len}_{\mathbb{H}}(\pi)\Big)$ and summing over all axes gives the claim. ◁

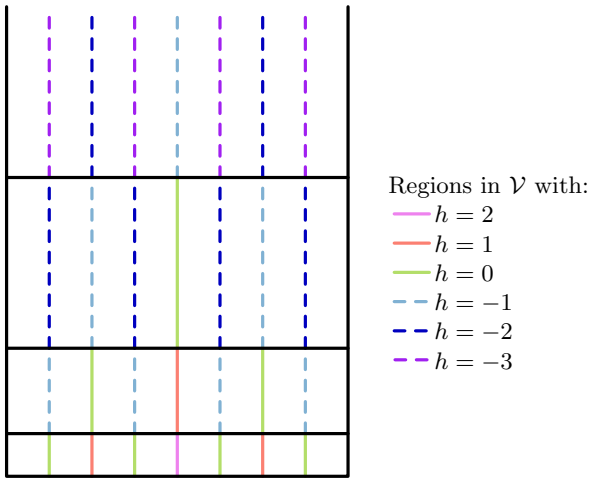

Figure 5 Distribution of the value h used in Claim 17 (here $\ell_{\min} = 0$). Note that the solid lines give the binary tiling.

Next, we state a bound for the expected patching cost of vertical intersections.

▷ Claim 17. Let $p \in I$. Then $\mathbb{E}_{\mathbf{a}}[\text{patching cost for } p] = O\left(\frac{d \cdot \delta}{r \cdot z(p)}\right)$.

Proof. For any vertical hyperplane $V \in \mathcal{V}$, partition it into regions $(V_h)_{h \in \mathbb{Z}}$ with the horizontal Euclidean hyperplanes $z = 2^i/\mathbf{a}_z$ (for all $i \in \mathbb{Z}$, unrelated to h) used by the shifted binary tiling. Here, V_0 denotes the highest region of V that still separates two cells from the shifted binary tiling, and V_{h+1} is the region directly below region V_h, as shown in Figure 5. Note that for $h \geq 0$, any two regions V_h and V'_h (with $V \neq V'$ but the same h) have the same portal placement: if $b^h \leq r$ the portals form a (b^h/r)-cover and otherwise there are no portals. For the given point p, we now let the random variable H be such that $p \in V_H$ for some $V \in \mathcal{V}$, and calculate the expected patching cost based on the behavior of H.

Note that H depends on the shift $\mathbf{a}$ as well as $z(p)$. Let us first determine the probability distribution of H at the bottom row $z(p) = 1/\mathbf{a}_z$. Note that the number of shifts $\mathbf{a}_x$ giving $H = h$ is twice the number giving $H = h + 1$. Thus, if we have k shifts that give $H = \ell_{\min}$ then $\lfloor k \cdot 2^{\ell_{\min} - h - 1} \rfloor$ shifts give $H = h$. Seeing as we have $2k - 1$ shifts in total,

$$\mathbb{P}(H = h) = O(2^{\ell_{\min} - h}) = O(\delta/2^h).$$

For general $z(p)$, note that H decreases by one every time $z(p)$ doubles and hence

$$\mathbb{P}(H = h) = O\left(\delta/2^{h + \log \frac{z(p)}{\mathbf{a}_z}}\right) = O\left(\frac{\delta}{2^h z(p)}\right),$$

since $\mathbf{a}_z \in [1, 2)$. For convenience, let $t = O(\delta/z(p))$ to simplify this to $\mathbb{P}(H = h) \leq t/2^h$.

When $H \geq 0$ and $b^H \leq r$, the patching cost will be at most $2b^H/r$. If $b^H > r$, we can still route through some other portal on the facet, which will be within distance $O(H - \log_b r)$. If $H < 0$, then the patching cost is zero. Therefore, we have

$$\begin{aligned}
\mathbb{E}_{\mathbf{a}}[\text{patching cost for } p] &\leq \sum_{h=0}^{\log_b r} 2b^h t/(r\cdot 2^h) + \sum_{h=\log_b r}^{\infty} O(h-\log_b r)\cdot t/2^h \\
&< \frac{2t}{r}\sum_{h=0}^{\infty}(b/2)^h + O(t/2^{\log_b r})\sum_{h=0}^{\infty} h/2^h \\
&= \frac{2t}{r}\cdot\frac{1}{1-b/2} + O(t/2^{\log_b r}) \\
&= \frac{2t}{r}\cdot\frac{1}{1-2^{-1/d}} + O(t/r^{\frac{1}{1-1/d}}) \\
&= O(dt/r). \\
&\qquad\qquad \text{(since } (1+x)^r \leq 1+rx \text{ for reals } 0\leq r\leq 1 \text{ and } x\geq -1.)
\end{aligned}$$

Hence, the claim follows. ◁

Consider the crossings of π_1 with Side facets. By Claim 16 and Claim 17, we have

$$\sum_{p\in I}\mathbb{E}_{\mathbf{a}}[\text{patching cost for } p] = O\left(\frac{d\delta}{r}\right)\sum_{p\in I}\frac{1}{z(p)} = O\left(\frac{d^2\sqrt{d}}{r}\right)\text{len}_{\mathbb{H}}(\pi_1).$$

To bound the number of crossings with Top facets, we have the following claim.

▷ Claim 18 (⋆). Let Λ be the number of intersections of π with Top facets of non-negative level cells. We have $\mathbb{E}_{\mathbf{a}}[\Lambda] = O(\text{len}_{\mathbb{H}}(\pi)\sqrt{d})$.

For Top facets, the patching cost is always at most $2/r$ by construction, thus by Claim 18 their expected total patching cost is $O\left(\frac{\sqrt{d}}{r}\right)\text{len}_{\mathbb{H}}(\pi_1)$. Combining the two contributions, the expected total patching cost is $O\left(\frac{d^2\sqrt{d}}{r}\right)\text{len}_{\mathbb{H}}(\pi_1)$. Finally, using $\text{len}_{\mathbb{H}}(\pi_1) = (1+O(1/r))\text{len}_{\mathbb{H}}(\pi)$ to express the bound in terms of π, we obtain $\mathbb{E}_{\mathbf{a}}\left[\text{len}_{\mathbb{H}}(\pi_2) - \text{len}_{\mathbb{H}}(\pi_1)\right] = O\left(\frac{d^2\sqrt{d}}{r}\right)\text{len}_{\mathbb{H}}(\pi)$, as required. We conclude the proof by observing that $\pi' := \pi_2$ is an r-simplification of π and has the desired length. ◀

5 Conclusion

In this paper we have obtained approximation schemes for d-dimensional hyperbolic TSP and hyperbolic Steiner tree with running time $2^{O(1/\varepsilon^{d-1})}n\,\text{poly}(\log n)$ (our approximation schemes follow from the structure theorem, mostly using standard techniques; we go into this in the full version [32]). Some interesting open questions remain for future work.

- The reason why we do not yet match the running times of [31] is because the faster algorithms rely on light Euclidean spanners, while no light (Steiner) spanners exist for hyperbolic point sets as of yet. Are there Steiner spanners of lightness $\text{poly}(1/\varepsilon)$ in $\mathbb{H}^d$? What about light banyans?
- Is it possible to use the techniques of [40] to get a linear dependence on n?
- Is there a deterministic algorithm for hyperbolic TSP without dependence on the diameter of the input?
- It has been observed on several occasions that the complexity of optimization problems in hyperbolic space decreases as points are at larger distance from each other [9, 30, 33]. In line with this, one can embed any hyperbolic point set into an edge-weighted tree

with additive error $O(\log n)$ [27, Chapter 6] in time $O(n^2)$ [19], which already implies an $O(n^2)$ time TSP algorithm when $\text{OPT}_{\mathbb{H}} = \Omega(n \log n/\varepsilon)$. Can we already achieve milder dependence on ε for smaller $\text{OPT}_{\mathbb{H}}$, or keep near-linear dependence on n?

Abstract

We consider Steiner spanners in Euclidean and non-Euclidean geometries. In the Euclidean setting, a recent line of work initiated by Le and Solomon [FOCS'19] and further improved by Chang et al. [SoCG'24] obtained Steiner $(1+\varepsilon)$-spanners of size $O_d(\varepsilon^{(1-d)/2}\log(1/\varepsilon)n)$, nearly matching the lower bound $\Omega_d(\varepsilon^{(1-d)/2}n)$ of Bhore and Tóth [SIDMA'22].

We obtain Steiner $(1+\varepsilon)$-spanners of size $O_d(\varepsilon^{(1-d)/2}\log(1/\varepsilon)n)$ not only in d-dimensional Euclidean space, but also in d-dimensional spherical and hyperbolic space. For any fixed dimension d, the obtained edge count is optimal up to an $O(\log(1/\varepsilon))$ factor in each of these spaces. Unlike earlier constructions, our Steiner spanners are based on simple quadtrees, and they can be dynamically maintained, leading to efficient data structures for dynamic approximate nearest neighbours and bichromatic closest pair.

In the hyperbolic setting, we also show that 2-spanners in the hyperbolic plane must have $\Omega(n\log n)$ edges, and we obtain a 2-spanner of size $O_d(n\log n)$ in d-dimensional hyperbolic space, matching our lower bound for any constant d. Finally, we give a Steiner spanner with *additive* error ε in hyperbolic space with $O_d(\varepsilon^{(1-d)/2}\log(\alpha(n)/\varepsilon)n)$ edges, where $\alpha(n)$ is the inverse Ackermann function.

Our techniques generalize to closed orientable surfaces of constant curvature as well as to some other quotient spaces.

1 Introduction

Given a set of points in some metric space, what is the most efficient way to represent all pairwise distances? One can use a complete geometric graph: the vertices are the given points, and the edges are weighted by the corresponding distance. A *t-spanner* is some small subgraph G of this complete graph such that the shortest path in G among any pair of points is at most t times longer than their distance. In Euclidean space, one can obtain $(1+\varepsilon)$-spanners of linear size for any fixed constant $\varepsilon > 0$ [20, 35]. Spanners are not only interesting in their own right, but they are also used in a plethora of algorithmic applications, and they lie at the heart of many approximation algorithms [54, 41, 24, 3, 39]. There is an ongoing research effort to study spanners in more general settings, and to establish optimal trade-offs between their stretch ($t = 1+\varepsilon$) and their size (edge count).

Spanners and dynamic spanners have been studied extensively in Euclidean spaces [49, 19, 2, 21] as well as in the more general setting of spaces with bounded doubling dimension [28, 30, 13, 56, 14]. The *doubling dimension* of a metric space is the minimum k such that any ball in the metric space can be covered by 2^k balls of half its radius. Today, we understand the optimal trade-offs between stretch and spanner size in Euclidean and doubling spaces. In Euclidean space, several techniques for spanner constructions, such as greedy spanners [1, 49] and locality-sensitive orderings [15, 29] yield $(1+\varepsilon)$-spanners of size (near) $\mathcal{O}_d(\varepsilon^{1-d}n)$, which is optimal for any fixed dimension d [47]. Well-separated pair decompositions (WSPDs) [10] give a slightly worse edge count of $\mathcal{O}_d(\varepsilon^{-d}n)$, but have a simpler construction and analysis.

Many of these techniques have been ported to doubling spaces, and have been used successfully to create spanners (and approximation algorithms). Net trees [33] play the role of a hierarchical decomposition of the space rather than quadtrees, and one can build WSPDs [59, 33], greedy spanners [58], and locality-sensitive orderings [15, 26, 44]. Gottlieb and Roditty [31] provide dynamic spanners in doubling spaces of dimension d with $\varepsilon^{-\mathcal{O}(d)}n$ edges and update time $\varepsilon^{-\mathcal{O}(d)}\log n$. Note here that the doubling dimension of Euclidean space is already (a constant fraction) more than d which makes it difficult to match Euclidean results, and moreover spanners have a worse lower bound of $\Omega_d(\varepsilon^{-d}n)$ edges [45].

While the above spanners are already useful, one can obtain even smaller (sparser) spanners if we allow so-called Steiner points in the spanner graph, that is, new points from the ambient space. More precisely, a *Steiner* $(1+\varepsilon)$*-spanner* of a point set P in a metric space (X, dist) is a subgraph G of the complete geometric graph on $P \cup S$ (for some set $S \subset X \setminus P$) that has the spanner property on P: $\mathrm{dist}_G(u,v) \leq (1+\varepsilon)\,\mathrm{dist}(u,v)$ for all $u, v \in P$. The points in S are called *Steiner points*. In d-dimensional Euclidean space (henceforth denoted by $\mathbb{E}^d$) it is possible to obtain Steiner $(1+\varepsilon)$-spanners of size $\mathcal{O}_d(\varepsilon^{(1-d)/2}\log(1/\varepsilon)n)$ [17]. This is almost matched by a lower bound of [6], who prove that $\Omega_d(\varepsilon^{(1-d)/2}n)$ edges are required.

In this paper, we attempt to generalise Euclidean (Steiner) spanners to curved (non-Euclidean) spaces. In particular, we study the following question.

▶ **Question 1.** *What is the optimal trade-off between the stretch and the size of a (Steiner)* $(1+\varepsilon)$*-spanner in non-Euclidean spaces?*

To begin our investigation with the simplest non-Euclidean spaces, let us consider the two other geometries of constant curvature: spherical geometry,[1] representing constant positive (sectional) curvature, and hyperbolic geometry, representing constant negative (sectional) curvature. We note that spanner results apply regardless of the constant positive curvature of the spherical space, as a scaling of the metric can generate the same result for any other spherical space. The same observation holds in the hyperbolic setting. For these reasons, we work in d-dimensional spherical and hyperbolic space of sectional curvature 1 and -1, and denote them by $\mathbb{S}^d$ and $\mathbb{H}^d$, respectively.

Spherical space is naturally modelled by a d-dimensional sphere in $(d+1)$-dimensional Euclidean space, where distances are measured along the sphere. Due to its positive curvature, spherical space grows more slowly than Euclidean space, especially at larger distances (e.g., the area of a disk of radius r is $2\pi(1-\cos r)$ rather than πr^2). In contrast, hyperbolic space grows more quickly than Euclidean space (e.g., the area of a disk of radius r is now $2\pi(\cosh r - 1)$, which is $\Theta(e^r)$ for superconstant r). It is commonly visualised using

[1] Arguably, elliptic geometry is more appropriate, but less readily perceived. Our results also extend to elliptic geometry with a simple trick, which is presented in the full version.

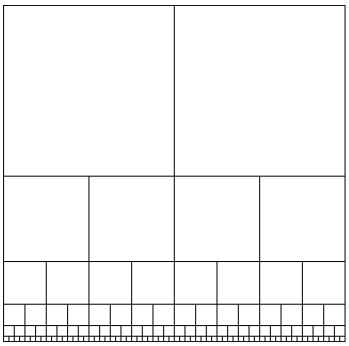

Figure 1 A patch of the binary tiling shown in the half-plane model. Note that all tiles are isometric.

models that map it to Euclidean space with heavily distorted distances, similar to e.g. the stereographic and gnomonic projection used for spheres. See for example Figure 1, which shows a tiling of the hyperbolic plane with tiles that are, importantly, isometric. Note the strong similarity to a binary tree.

One of the main motivations for studying curved spaces is that certain types of data can be much more accurately and efficiently modelled in a curved space than in (flat) Euclidean space. In particular, constant-dimensional hyperbolic space already allows for exponential growth and unbounded doubling dimension, giving good embeddings for graphs with an inherent hierarchy, such as those based on the internet [57] and social networks [62]. This has attracted the attention of, for example, the machine learning [50, 27, 12, 52], graph visualisation [46] and complex network modelling [43] communities. From a more theoretical standpoint, negative curvature is one of the simplest ways a geometric space can be non-doubling. Properly dealing with this requires new approaches that do not rely on doubling dimension and could inspire future work in other non-doubling spaces. Additionally, every closed surface can be assigned constant curvature, making especially hyperbolic geometry a useful tool in computational topology [23, 18, 22].

Both $\mathbb{S}^d$ and $\mathbb{H}^d$ are locally Euclidean spaces, meaning that a small radius ball in each space can be embedded into $\mathbb{E}^d$ with very small distortion. On a larger scale however, they have a very different behaviour. In $\mathbb{S}^d$, we can still bound the doubling dimension by $\mathcal{O}(d)$, and thus doubling metric results apply, yielding spanners of size $\varepsilon^{-\mathcal{O}(d)}n$. One would expect that the stronger Euclidean spanner and Steiner spanner constructions (of size $\mathcal{O}_d(\varepsilon^{1-d}n)$ and $\mathcal{O}_d(\varepsilon^{(1-d)/2}\log(1/\varepsilon)n)$) should be possible in $\mathbb{S}^d$, however, proving it is non-trivial: the geometric transformations to convert between these cases introduce constant multiplicative error, thus a spanner property in $\mathbb{E}^d$ does not imply the spanner property in $\mathbb{S}^d$. Note that spanners of $\mathbb{S}^d$ with the same guarantees as the Euclidean constructions would be (nearly) optimal in $\mathbb{S}^d$, as the Euclidean lower-bound constructions of Bhore and Tóth [6] can be ported to $\mathbb{S}^d$ inside a small neighbourhood. (Naturally, the Euclidean lower bounds hold in $\mathbb{H}^d$ for the same reason.)

In d-dimensional hyperbolic space ($\mathbb{H}^d$), the landscape is very different. First of all, $\mathbb{H}^d$ is not a doubling space, so doubling space results do not apply. Second, as observed by [42, 38], there do not exist t-spanners for any $t < 2$ of size less than $\binom{n}{2}$. In fact, many of the important techniques such as WSPDs and locality sensitive orderings are known to fail [38]. However, Krauthgamer and Lee [42] obtained a Steiner $(1+\varepsilon)$-spanner with $\varepsilon^{-\mathcal{O}_d(1)}n$ edges in a more general setting of visual geodesic Gromov-hyperbolic spaces. Their

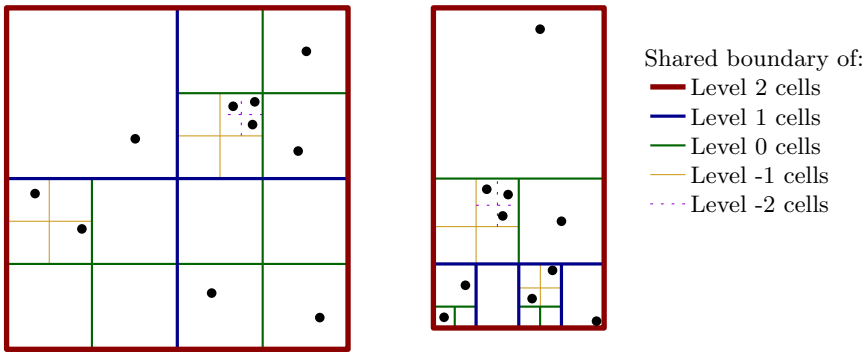

Figure 2 A Euclidean quadtree and the hyperbolic quadtree of [38].

technique is based on the observation that over shorter distances, hyperbolic space has bounded doubling dimension and thus one can use doubling space techniques, while at larger distances hyperbolic space is sufficiently "tree-like" and one can obtain additive Steiner spanners. In an *additive* (Steiner) spanner, the distance in the spanner is at most ℓ longer than the hyperbolic distance. Recently, Park and Vigneron [51] gave a Steiner spanner in $\mathbb{H}^d$ with additive error $\mathcal{O}(k \log d)$ and $2^{\mathcal{O}(d)} n\lambda_k(n)$ edges, where $\lambda_k(n)$ is an extremely slow-growing k-th row inverse Ackermann function. Finally, Kisfaludi-Bak and Van Wordragen [38] gave a dynamic Steiner $(1+\varepsilon)$-spanner in $\mathbb{H}^d$ with $\mathcal{O}(\varepsilon^{-d} \log(1/\varepsilon)n)$ edges based on the construction of a new hyperbolic quadtree. Their quadtree is shown in Figure 2. In short, it splits cells that are sufficiently small the same way as a Euclidean quadtree, while splitting larger cells into one top cell and a possibly unbounded number of bottom cells. From their Steiner spanner, [38] also obtain linear size $(2+\varepsilon)$-spanners, leaving the matter of 2-spanners open.

▶ **Question 2.** *Are there 2-spanners of size $\mathcal{O}_d(n)$ in $\mathbb{H}^d$?*

Hyperbolic spaces can exhibit very different behaviours than Euclidean spaces due to their non-doubling nature at larger scales. The tree-likeness of hyperbolic spaces has been used to obtain stronger structural and algorithmic results for several geometric problems [36, 37, 7] in $\mathbb{H}^d$ than what is possible in $\mathbb{E}^d$. It is thus natural to ask the following question.

▶ **Question 3.** *Are there (Steiner) spanners in $\mathbb{H}^d$ that have even stronger guarantees than their Euclidean counterparts for points that are pairwise distant?*

The existence of additive Steiner spanners already answers this question affirmatively, but finding the best trade-off between the additive error of a Steiner spanner and its edge count remains open.

Outside the specific hyperbolic setting, there is growing interest in obtaining spanners in other non-doubling spaces, in particular, metric spaces induced by planar, minor-free, or bounded treewidth graphs as well as polyhedral terrains or surfaces. In recent work, the technique of *tree covers* has gained momentum. A tree cover can be thought of as a set of weighted trees whose union gives a (Steiner) spanner. More precisely, set $\mathcal{T}$ is a tree cover for a point set P in metric space X if for any pair of points in P there is a tree in $\mathcal{T}$ where their distance is at most $1+\varepsilon$ times larger than their distance in X, while their distance in all trees of $\mathcal{T}$ is at least that in X. In geometric settings, the trees are typically required to be geometric graphs, i.e. any Steiner points are points in X and the edge weights match the distances in X. Chang et al. [16] gave (Steiner) tree covers in planar and treewidth t metrics, which yield Steiner $(1+\varepsilon)$-spanners of size $\mathcal{O}\big(\varepsilon^{-3} \log \frac{1}{\varepsilon} n\big)$ for planar metrics and

$2^{(t/\varepsilon)^{\mathcal{O}(t)}}n$ for treewidth-t metrics. Even more recently, Bhore et al. [5] obtained a Steiner $(1+\varepsilon)$-spanner on planar metrics and on 2-dimensional polyhedral surfaces of bounded genus with $\mathcal{O}\left(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\cdot\log\frac{\alpha(n)}{\varepsilon}\cdot n\right)$ edges, where $\alpha(n)$ is the inverse Ackermann function. These settings vastly generalize the finite metrics induced by point sets in $\mathbb{H}^2$ and thus the trade-offs in these settings are not directly comparable. However, the hyperbolic plane does have many of the important properties of more general planar metrics: for example, there is a natural lower bound of 2 for the stretch of (non-Steiner) spanners of subquadratic size both in planar metrics and in $\mathbb{H}^2$ [5, 38].

Limitations of previous Steiner spanner constructions. Before stating the new contribution, let us first examine why the ideas behind the existing Steiner spanner constructions in $\mathbb{H}^d$ are insufficient to get optimal sparsity. First, the Steiner spanner of Krauthgamer and Lee [42] considers a more general setting than $\mathbb{H}^d$, which among other things means they get a dependence on the local doubling dimension and consequently dependencies on d will always be of the form $\mathcal{O}(d)$. Since we care about the exact constants in the exponent of ε, this makes it unsuitable. Kisfaludi-Bak and Van Wordragen [38] place Steiner points at distance ε in a d-dimensional volume, which naturally gives a dependence ε^{-d}. It is not obvious how one can place Steiner points only at distance $\sqrt{\varepsilon}$ and along $(d-1)$-dimensional boundaries to get the optimal dependence $\varepsilon^{(1-d)/2}$. Moreover, they never have edges between two Steiner points (giving a "bipartite" Steiner spanner) and we show in Lemma 10 that such edges are necessary to get a Steiner spanner with optimal sparsity. Finally, Park and Vigneron [51] give a Steiner spanner with additive error $\mathcal{O}(\log d)$, which is good for large distances but does not help with the most challenging regime of distances between 1 and $\frac{1}{\varepsilon}$.

Our contribution. Our main contribution is the following theorem.

▶ **Theorem 1** (Main theorem). *Let $\varepsilon\in(0,\frac{1}{2}]$ and P be a set of n points in d-dimensional Euclidean, hyperbolic or spherical space. There is a Steiner $(1+\varepsilon)$-spanner for P with $\mathcal{O}_d\left(\varepsilon^{(1-d)/2}\log\frac{1}{\varepsilon}\cdot n\right)$ edges. We can maintain it dynamically, such that each point insertion or deletion takes $\mathcal{O}_d\left(\varepsilon^{(1-d)/2}\log\frac{1}{\varepsilon}\cdot\log n\right)$ time.*

Our edge count nearly matches the lower bound $\Omega\left(\varepsilon^{(1-d)/2}n\right)$ given by Bhore and Tóth [6] for Euclidean Steiner spanners, up to the factor $\log\frac{1}{\varepsilon}$. Our $\mathcal{O}_d$ notation hides a factor of $d^{\mathcal{O}(d)}$. Note that the Euclidean lower bound is also a valid lower bound in $\mathbb{S}^d$ and $\mathbb{H}^d$, as both spaces are locally Euclidean, meaning that any hard instance in $\mathbb{E}^d$ can be embedded both in $\mathbb{S}^d$ and $\mathbb{H}^d$ with arbitrarily small distortion.

Thus, we nearly settle Question 1 in the three geometries cases of constant dimension, up to the $\log 1/\varepsilon$ term. In Euclidean space our edge count matches a recent result of Chang et al. [17], however, our technique is completely different and arguably simpler. The main advantage is that our spanner can be maintained dynamically when points are added to P or deleted from P, using $\mathcal{O}_{d,\varepsilon}(\log n)$ time updates. As a result of the dynamicity and the simple structure, our spanner can readily act as a data structure for classic query problems such as dynamic approximate nearest neighbours and (dynamic approximate) bichromatic closest pair. From the Steiner spanner constructions, one can also directly get (dynamic) Steiner tree covers of size $\mathcal{O}_d\left(\varepsilon^{(1-d)/2}\log\frac{1}{\varepsilon}\right)$, which generalise the result of [17].

The main challenge in establishing Theorem 1 lies in the hyperbolic variant. While our spanner for $\mathbb{S}^d$ can be relatively easily derived from our Euclidean construction using geometric transformations, our spanner for $\mathbb{H}^d$ is substantially different. In our approach,

we use Euclidean (doubling space) ideas for small distances and tree-based ideas (constant-additive spanner) for sufficiently large distances, but in the hyperbolic setting, this leaves a gap for point pairs at distances between 1 and $\frac{1}{\varepsilon}$. This is the most challenging regime and requires mixing ideas from both approaches, as well as new ideas. As a result, we obtain a significantly smaller hyperbolic Steiner spanner compared to the state of the art, which had size $\mathcal{O}_d(\varepsilon^{-d}\log(1/\varepsilon)n)$ [38].

Note that the spanners of Theorem 1 are bipartite in case of $\mathbb{E}^d$ and $\mathbb{S}^d$, and we are also able to design bipartite Steiner spanners in $\mathbb{H}^d$ for any $d \geq 3$ with the same properties as stated in Theorem 1. Surprisingly, we prove that a bipartite Steiner spanner of size $o(n/\varepsilon)$ does not exist in $\mathbb{H}^2$. As a corollary of this lower bound, we obtain an $\Omega(n\log n)$ lower bound for the edge count of a hyperbolic (non-Steiner) 2-spanner in the plane. We prove that there exist 2-spanners in $\mathbb{H}^d$ of size $\mathcal{O}_d(n\log n)$, matching our lower bound, and settling Question 2.

▶ **Theorem 2.** *Let $P \subset \mathbb{H}^d$ be a set of n points. We can construct a 2-spanner for P with $d^{\mathcal{O}(d)} \cdot n\log n$ edges in $d^{\mathcal{O}(d)} \cdot n\log n$ time.*

By incorporating so-called *transitive closure spanners* [55] on certain trees obtained from hyperbolic quadtrees, we are also able to get Steiner spanners with ε *additive* error for any $\varepsilon > 0$ whose size is very close to linear in n: it has size $\mathcal{O}_{\varepsilon,d}(n\log\alpha(n))$, where α is the inverse Ackermann function.

▶ **Theorem 3.** *Let $\varepsilon \in (0, \frac{1}{2}]$ and P be a set of n points in $\mathbb{H}^d$. An ε-additive Steiner spanner for P with $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2}\log\frac{\alpha(n)}{\varepsilon}\cdot n$ edges can be found in $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2}\log\frac{\alpha(n)}{\varepsilon}\cdot n\log n$ time.*

While no direct lower bounds are known for additive hyperbolic spanners, this stronger variant of an additive spanner is in stark contrast with the Euclidean setting where no subquadratic-size additive (Steiner) spanners can exist: indeed, in the Euclidean case one can scale any point set, so a scale-invariant spanner construction cannot give constant additive error. In the hyperbolic setting, no scaling transformation exists, and the thin triangle property [32] allows the construction of Steiner spanners with constant additive error. In terms of Question 3, this is further evidence that pairwise distant points in $\mathbb{H}^d$ are structurally simpler than their Euclidean counterparts. It is an interesting open question whether one can improve the edge count by removing the $\log\alpha(n)$ term from the bound of Theorem 3.

Finally, we apply our spanners to two different problems. First, we observe that our spanner construction easily extends to certain closed Riemannian manifolds of constant curvature: in particular, closed constant-curvature orientable surfaces and higher-dimensional manifolds obtained as a quotient of the three base geometries using a finite isometry group.

Next, we demonstrate the usefulness of our spanners by establishing *dynamic* data structures for approximate nearest neighbours (ANN) and bichromatic closest pair. Hyperbolic ANN algorithms have already been proposed and implemented, albeit without worst-case guarantees on the running time [63, 53]. In the $(1+\varepsilon)$-approximate bichromatic closest pair problem, we are given two point sets R and B and wish to find a pair $(r,b) \in R \times B$ whose distance is at most $1+\varepsilon$ more than that of the closest pair between R and B. The dynamic version requires that the approximate bichromatic closest pair can be recalculated efficiently after point insertions and removals in R and B. Here, we improve over the result of [29] in Euclidean space, which uses $\mathcal{O}_d\big(\varepsilon^{1-d}\log(1/\varepsilon)n\big)$ space and handles updates in $\mathcal{O}_d\big(\varepsilon^{1-d}\log(1/\varepsilon)\log n\big)$ time, with a data structure that uses $\mathcal{O}_d\big(\varepsilon^{(1-d)/2}\log(1/\varepsilon)n\big)$ space and handles updates in $\mathcal{O}_d\big(\varepsilon^{(1-d)/2}\log(1/\varepsilon)\log n\big)$ time. We also improve on the result of [38] in hyperbolic space, where the factors ε^{-d} are improved to $\varepsilon^{(1-d)/2}$ in both the running

time and space usage bounds. To the best of our knowledge we give the first data structure for approximate bichromatic closest pair that is explicitly for spherical space. We obtain analogous improvements compared to the state of the art for (dynamic) ANN in hyperbolic and spherical space.

Organisation. Complete details are available in the full version; we give abridged preliminaries in Section 2 and an overview of the main ideas and constructions in Section 3. Finally, Section 4 concludes the paper by proposing some intriguing open problems.

2 Preliminaries

Throughout the paper, we will use pq to denote the shortest curve (*segment*) connecting p and q in the current geometry. In particular, this means it may not appear as a straight line segment in the used model of that geometry. Additionally, we use $|pq|$ for the length of this segment, again measured in the current geometry.

Our algorithmic results rely on compressed quadtree operations and therefore require access to floor and bitwise operations. Apart from that, they hold both in the real RAM and word RAM model. In particular, we do not need (hyperbolic) trigonometric functions despite these showing up in the distance formulas for spherical and hyperbolic space, since we only ever compare two distances between pairs of input points to each other. (In case of word RAM, we need to assume that points of $\mathbb{H}^d$ are given with coordinates in the half-space model, as we do not have the capacity to convert between different models of hyperbolic geometry.) In $\mathbb{S}^d$, any reasonable representation[2] of points can work with our algorithm. We will have the points represented in polar coordinates.

Hyperbolic geometry. In this paper we use the half-space model of hyperbolic geometry (for more details, refer to for example [11] or the textbooks [34, 61, 4]). This assigns any point $p \in \mathbb{H}^d$ coordinates $(x(p), z(p)) \in \mathbb{R}^{d-1} \times \mathbb{R}_{>0}$ in the upper half-space, which also lets us refer to the positive z-direction as "up". Important to note is that hyperbolic distances are not given by the Euclidean distances in the model, which also means that the shortest curve pq between points $p, q \in \mathbb{H}^d$ is often not a Euclidean segment. In general, pq is modelled by an arc from a Euclidean circle perpendicular to the Euclidean hyperplane $z = 0$ (in particular its centre lies at $z = 0$) and pq has hyperbolic length

$$|pq| = 2 \operatorname{arsinh} \sqrt{\frac{\|x(p) - x(q)\|^2 + (z(p) - z(q))^2}{4z(p)z(q)}},$$

but if $x(p) = x(q)$ then pq is a vertical Euclidean line segment and $|pq| = \left|\ln \frac{z(p)}{z(q)}\right|$. Note here that applying any isometry of $\mathbb{E}^{d-1}$ to $x(p)$ and $x(q)$ yields the same distance, as does multiplying all of $x(p), x(q), z(p)$ and $z(q)$ by the same positive factor. Vertical Euclidean hyperplanes are also hyperbolic hyperplanes (as with vertical segments), but horizontal ones are not. These are *horospheres*, but we will not directly use any property of horospheres other than them being distinct from hyperplanes.

[2] Note that unlike $\mathbb{H}^d$, the conversions between different representations of $\mathbb{S}^d$ and distance computations can typically be carried out with exponentially small error, which is sufficient for constructing $(1+\varepsilon)$-spanners.

Hyperbolic quadtree. Here we describe the quadtree of [38] while introducing new notation that will be useful throughout this paper. Instead of being based on hypercubes, its cells are *cube-based horoboxes*. In the half-space model, a cube-based horobox C is a Euclidean axis-parallel box with corners $(x_{\min}(C), z^{\downarrow}(C))$ and $(x_{\max}(C), z^{\uparrow}(C))$ with its *width* given by $\frac{x_{\max}(C)-x_{\min}(C)}{z^{\downarrow}(C)} = (w(C), \dots, w(C))$ and *height* $h(C) = \log \frac{z^{\uparrow}(C)}{z^{\downarrow}(C)}$. This definition ensures that any two cube-based horoboxes with the same width and height are isometric. Just like any box can tile Euclidean space, any horobox can tile hyperbolic space.

Instead of being based on the grid (the tiling of $\mathbb{E}^d$ with isometric hypercubes) like the Euclidean quadtree, the hyperbolic quadtree is based on the *binary tiling*. To construct a binary tiling, we start with the cube-based horobox C with $x_{\min}(C) = (0, \dots, 0)$, $z^{\downarrow}(C) = 1$, $w(C) = \frac{1}{\sqrt{d-1}}$ and $h(C) = 1$. Now we apply the isometry $T_{\sigma,\tau}(x, z) = \sigma \cdot (x + \tau, z)$ for all values $\tau = a/\sqrt{d-1}$ with $a \in \mathbb{Z}^{d-1}$ and $\sigma = 2^b$ with $b \in \mathbb{Z}$. This gives a tiling that covers all of $\mathbb{H}^d$ with isometric tiles; see Figure 1. Note that the two-dimensional tiling resembles a binary tree, hence the name. In general the d-dimensional tiling bears resemblance to a $(d-1)$-dimensional Euclidean quadtree, where each "layer" of the tiling at a fixed z value is a level of this quadtree.

We formalise this tree structure by thinking of the binary tiling as the infinite arborescence T^0, which has the tiles as its vertices and a directed edge from any tile to the tile directly above it. We can then also generalise this to T^ℓ for $\ell \in \mathbb{N}$. The tiling for T^ℓ is constructed by taking the cube-based horobox C with again $x_{\min}(C) = (0, \dots, 0)$ and $z^{\downarrow}(C) = 1$, but now $w(C) = 2^{2^\ell - 1}/\sqrt{d-1}$ and $h(C) = 2^\ell$. Then, we apply $T_{\sigma,\tau}$ for all values $\tau = a \cdot w(C)$ with $a \in \mathbb{Z}^{d-1}$ and $\sigma = 2^{b \cdot h(C)}$ with $b \in \mathbb{Z}$. The arborescence T^ℓ follows as before, where it is worth noting that the in-degree of vertices of T^ℓ has grown from 2^{d-1} to $2^{(d-1)\cdot 2^\ell}$.

The tiles are chosen exactly so that each tile of $T^{\ell+1}$ is the union of a tile of T^ℓ with its children. Thus, the tilings for T^ℓ can be used to define the hyperbolic quadtree for levels $\ell \geq 0$. Levels $\ell < 0$ are now constructed by splitting each cell at level $\ell + 1$ up with a Euclidean quadtree split. See Figure 2 for an illustration.

Since we will make frequent use of trees and arborescences, we also introduce some related notation for an arbitrary tree or arborescence of cells T. Given two cells $C, C' \in V(T)$, we let $\mathrm{lca}(C, C', T)$ denote their lowest common ancestor in T. Given a point $p \in \mathbb{H}^d$, we let $\mathrm{cell}(p, T)$ denote the cell of T containing p, and given a second point $q \in \mathbb{H}^d$ we use the shorthand $\mathrm{lca}(p, q, T) = \mathrm{lca}(\mathrm{cell}(p, T), \mathrm{cell}(q, T), T)$.

3 Technical overview and key ideas

All of our results are built on quadtrees. A quadtree is a simple hierarchical decomposition that is often used for geometric approximation in Euclidean space. More precisely, each of our spanners are built on $\mathcal{O}(d)$ different shifted quadtrees. It is a well-known fact that in Euclidean space, one can find $\mathcal{O}(d)$ shifts with the following key property.

(*) Any pair of points p, q is contained in a cell of diameter $|pq| \cdot \mathcal{O}(d\sqrt{d})$.

To get a set of shifted quadtrees in spherical space, we take two stereographic projections and construct shifted Euclidean quadtrees in both of these projections. For a pair of points that are not too distant, one of the stereographic projections will always give constant distortion compared to Euclidean space, and Property (*) can be achieved in one of the shifts for this projection. In hyperbolic space we use the quadtree of [38] that already comes with the required guarantee. For small enough distances, hyperbolic space also has a constant distortion compared to Euclidean space and as a result, the quadtrees share most of the properties of the Euclidean quadtree in constant-size neighbourhoods.

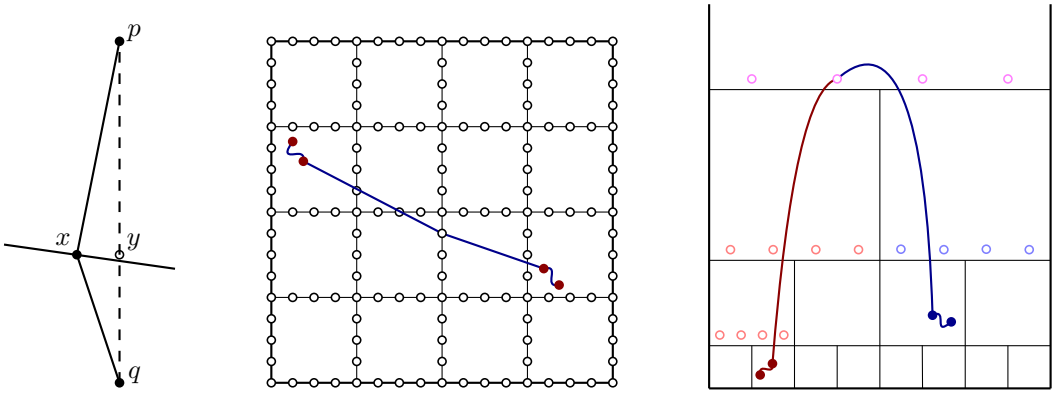

Figure 3 Left: if distance $|xy| \approx |pq|\sqrt{\varepsilon}$, then the detour from p to q through x only adds a factor $1+\varepsilon$. Middle: the Steiner spanner in $\mathbb{E}^2$. Right: the bipartite Steiner spanner in $\mathbb{H}^2$.

While constant distortion is enough to get constant-approximations, it is not enough for a $(1+\varepsilon)$-approximation. For this, we prove in Lemma 4 that a simple approximation result in Euclidean space also carries through to spherical and hyperbolic space. The following lemma is what any Euclidean Steiner spanner fundamentally relies on to get a dependency of $\varepsilon^{(1-d)/2}$ rather than ε^{1-d}. Namely, it means that for two points p, q separated by a hyperplane that has distance $\Omega(|pq|)$ from both, we can afford to go through a point x on that hyperplane with distance $\mathcal{O}(\sqrt{\varepsilon}|pq|)$ to pq; see the left-hand side of Figure 3. We generalise the lemma to spherical and small-distance hyperbolic geometry.

▶ **Lemma 4.** *Let $p, q, x \in \mathbb{X}^d$ for $\mathbb{X} \in \{\mathbb{H}, \mathbb{E}, \mathbb{S}\}$ and let y be the closest point to x on the segment pq. Assume $\varepsilon \in (0, 1]$. If $|xy| \leq \sqrt{\varepsilon}\min\{|py|, |qy|\}$, then (i) $|px| + |xq| \leq (1+\varepsilon)|pq|$ if $\mathbb{X} \in \{\mathbb{E}, \mathbb{S}\}$ and (ii) $|px| + |xq| \leq (1 + e^{\Delta}\varepsilon)|pq|$ if $\mathbb{X} = \mathbb{H}$ and $|pq| \leq \Delta$.*

With this lemma at hand, we can now give a Steiner $(1+\varepsilon)$-spanner. For any two points p and q, we consider the shifted quadtree where the cell satisfying property (*) is found. We ensure that within this cell, both p and q have some point nearby, say p' and q', respectively, such that p' and q' are both connected to a Steiner point that is chosen from a grid-like point set on a cell boundary separating p' and q'. This Steiner spanner proves Theorem 1 for $\mathbb{S}^d$, $\mathbb{E}^d$ and small-diameter point sets in $\mathbb{H}^d$.

▶ **Theorem 5.** *Let $\varepsilon \in (0, \frac{1}{2}]$ and P be a set of n points in $\mathbb{E}^d$ or $\mathbb{S}^d$, or in a quadtree cell in $\mathbb{H}^d$ of level $4 + \log\log d$. There is a Steiner $(1+\varepsilon)$-spanner for P with Steiner vertex set Q, that is bipartite on P and Q, and where each point $p \in P$ has degree $d^{\mathcal{O}(d)} \cdot \varepsilon^{(1-d)/2}\log\frac{1}{\varepsilon}$. We can maintain it dynamically such that each point insertion or deletion takes $d^{\mathcal{O}(d)} \cdot \varepsilon^{(1-d)/2}\log\frac{1}{\varepsilon} \cdot \log n$ time.*

By construction this is a *bipartite* Steiner spanner (i.e. every edge is between an input point and a Steiner point). This makes it easy to turn it into a spanner without Steiner points. For that, we take each Steiner point s and connect all input points that were connected to s to each other instead. This maintains the same bound on the stretch, but adds more edges based on the degrees of the Steiner points. In this case, the Steiner points have small degree, which leads to a total of $\mathcal{O}_d(n/\varepsilon^d)$ edges in Theorem 6.

▶ **Theorem 6.** *Let $\varepsilon \in (0, \frac{1}{2}]$ and P be a set of n points in $\mathbb{E}^d$ or $\mathbb{S}^d$, or in a quadtree cell in $\mathbb{H}^d$ of level $4 + \log\log d$. In $d^{\mathcal{O}(d)} \cdot \varepsilon^{-d} \log \frac{1}{\varepsilon} \cdot n \log n$ time, we can construct a $(1+\varepsilon)$-spanner (i.e., without Steiner points) for P with maximum degree $d^{\mathcal{O}(d)} \cdot \varepsilon^{-d} \log \frac{1}{\varepsilon}$.* [3]

Near-optimal bipartite Steiner spanner in hyperbolic space. Our first challenge here is that for super-constant hyperbolic distances the hyperbolic quadtree gets meaningfully different from a Euclidean quadtree. This was already dealt with to get a bipartite Steiner spanner in [38], but we need new insights to get near-optimal dependence on ε. The results that made the construction for small distances work are not enough, as the exponential expansion of hyperbolic space causes them to break down. In particular, Lemma 4 is false for super-constant hyperbolic distances: as the distances grow the hyperbolic Pythagorean theorem converges to the triangle inequality, which precludes us from proving something stronger for large hyperbolic distances. At medium hyperbolic distances (between 1 and $1/\varepsilon$), we give a result reminiscent of Lemma 4 to enable dependences $\varepsilon^{(1-d)/2}$ instead of ε^{1-d}.

▶ **Lemma 7.** *Let $p, q \in \mathbb{H}^d$ be separated from each other by hyperplane H that has distance at least 2 from both. For a point $x \in H$ at distance δ from pq, we get $|px| + |xq| \leq |pq| + \delta^2$.*

Note that when $|pq| = \Theta(1)$ and $\delta = \sqrt{\varepsilon}|pq|$ this is very similar to Lemma 4, while when $|pq| = \Theta(1/\varepsilon)$ and $\delta = \varepsilon|pq|$ we get the same guarantee as from the triangle inequality; the most interesting regime of the lemma is in between these two values. The hyperbolic bipartite Steiner spanner now follows from a similar construction as the one for smaller distances, with two major changes. First, we replace Lemma 4 with Lemma 7. Second, we only connect each point to its "ancestors" in the tiling (here one should think of ancestors in the binary tree), as opposed to all tiles, because in the hyperbolic quadtree there can be unboundedly many sibling tiles inside a parent cell. With this Steiner spanner we can prove Theorem 1 for all cases except for super-constant distances in $\mathbb{H}^2$.

▶ **Theorem 8.** *Let $\varepsilon \in (0, \frac{1}{2}]$ and P be a set of n points in $\mathbb{H}^d$. There is a Steiner $(1+\varepsilon)$-spanner for P with Steiner vertex set Q that is bipartite on P and Q. Each point in P has degree at most $d^{\mathcal{O}(d)} \cdot \varepsilon^{(1-d)/2} \log \frac{1}{\varepsilon}$ when $d \geq 3$ and at most $\mathcal{O}\big(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\big)$ when $d = 2$.*

The coming lower bound shows that, surprisingly, having a weaker result for specifically $\mathbb{H}^2$ is unavoidable unless we go for a very different, non-bipartite construction. First, Observation 9 gives a simple alternative procedure to turn a bipartite Steiner spanner into a spanner without Steiner points (as already observed by [38]). The procedure maintains the same edge bound, but in the worst case it doubles the stretch from $(1+\varepsilon)$ to $2+2\varepsilon$. As a result, we improve the $(2+\varepsilon)$-spanner of [38], but perhaps more importantly it lets us apply the coming spanner lower bound to bipartite Steiner spanners. Moreover, we will later use the same strategy to make a (non-Steiner) 2-spanner.

▶ **Observation 9** (Corollary 17 of [38]). *Given a point set P in some metric space (X, dist) and a bipartite Steiner $(1+\varepsilon)$-spanner for P with $|E|$ edges, there is also a $(2+2\varepsilon)$-spanner for P with at most $|E|$ edges.*

Lower bound. For the lower bound, we show that a $(2 + \frac{1}{\ln n})$-spanner for a set of n evenly spaced points on a circle of radius $3 \ln n$ already requires $\Omega(n \log n)$ edges. This implies three things for these point sets:

[3] Note that we do not get optimal edge count $\mathcal{O}_d\big(n/\varepsilon^{d-1}\big)$, so one can likely improve on this by adapting for example [29].

- a $(2+\varepsilon)$-spanner needs $\Omega(n/\varepsilon)$ edges,
- a bipartite Steiner $(1+\varepsilon)$-spanner needs $\Omega(n/\varepsilon)$ edges (through Observation 9), and
- a 2-spanner needs $\Omega(n \log n)$ edges.

▶ **Lemma 10.** *For any $n \geq 2$, let $\varepsilon \in [0, \frac{1}{2 \ln n}]$ and $P \subset \mathbb{H}^2$ be a set of n points equally spaced around a circle of radius $3 \ln n$. Any $(2+\varepsilon)$-spanner for P must have $\Omega(n \log n)$ edges.*

Proof sketch. First of all, the smallest and largest distance among the points differ only by a multiplicative factor close to $\frac{3}{2}$, which lets us conclude that the path between any two points p and q in the $(2+\frac{1}{\ln n})$-spanner can have at most 2 hops. We denote by m the middle vertex of the 2-hop path. Next, we observe that the location of m is highly constrained: the number of points on the circle separating m from p and q must be at most a constant times larger than the number of points separating p from q. This observation lets us partition all *pairs* of points into classes based on the number of points separating them, of the form $[51^i, 51^{i+1})$. We prove that for any pair of points, the longer edge on the path connecting them can only be shared with one disjoint pair of the same class. Thus, we require $\Theta(n)$ edges per class, and get the $\Omega(n \log n)$ lower bound from having $\Theta(\log n)$ classes. ◀

Non-bipartite Steiner spanners. To bypass the lower bound, we then work towards a non-bipartite Steiner spanner (i.e., one where Steiner points can be connected to Steiner points). The key to making this spanner work is to make use of the exponential divergence of lines in hyperbolic space: two long segments whose endpoints lie close together get exponentially close near their middle. We capture this property in Lemma 11.

▶ **Lemma 11.** *Let C be a cell of $T^{1+\log\log(1/\varepsilon)}$, let p be a point that lies in C or one of its descendant cells, and let q be a point that lies in an ancestor cell of the parent C_1 of C. Then, pq passes within distance ε of $s_C = \left(\frac{x_{\min}(C)+x_{\max}(C)}{2}, \sqrt{z^{\downarrow}(C_1) z^{\uparrow}(C_1)}\right)$.*

Directly from Lemma 11, we get Lemma 12 which gives a quasi-isometric embedding of any hyperbolic point set into a *union* of $\mathcal{O}(d)$ trees, similar to the much more involved quasi-isometric embedding of any hyperbolic metric space into a *product* of d trees [8, 9]. For our purposes, it implies a Steiner $(1+\mathcal{O}(\varepsilon))$-spanner with only $\mathcal{O}(dn)$ edges for hyperbolic point sets with minimum distance $\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}$.

▶ **Lemma 12.** *Let $\varepsilon \in (0, \frac{1}{2}]$ and P be a set of points in $\mathbb{H}^d$. There is a set of $\mathcal{O}(d)$ trees with P as the leaves whose union is a Steiner spanner for P with multiplicative distortion $1+\varepsilon$ and additive distortion $\mathcal{O}\left(\log\frac{1}{\varepsilon}\right)$. In particular, if all points in P have distance at least $\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}$ to each other, this is a Steiner $(1+\mathcal{O}(\varepsilon))$-spanner.*

To obtain a Steiner spanner for smaller distances, we need to eliminate the additive distortion. This comes from the sharp turn at the highest node on paths in these trees. We avoid this with ideas from Theorem 8. Namely, we consider the tiling $T^{4+\log\log d}$ and connect each (input and Steiner) point from the trees of Lemma 12 to $\mathcal{O}_d\left(\varepsilon^{(1-d)/2}\right)$ Steiner points placed for the $2\log\frac{1}{\varepsilon}$ cells above it. This gives more options for a gradual turn and with that finally proves that our main theorem Theorem 1 holds in all cases.

▶ **Theorem 13.** *Let $\varepsilon \in (0, \frac{1}{2}]$ and P be a set of n points in $\mathbb{H}^d$. There is a Steiner $(1+\varepsilon)$-spanner for P with $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2}\log\frac{1}{\varepsilon}\cdot n$ edges. We can maintain it dynamically, such that each point insertion or deletion takes $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2}\log\frac{1}{\varepsilon}\cdot\log n$ time.*

We can also get a Steiner spanner with *additive* error ε by using the same general idea as in Theorem 13. One of the issues here is that we accumulate some error in each hop along a spanner path, and we do not have a bound on the number of hops a spanner path might need to take. This problem can be mitigated by using the transitive closure spanner of Thorup [60] to reduce the number of hops to $\mathcal{O}(\alpha(n))$, and get the same error no matter how (hop-)distant two points are.

▶ **Theorem 3.** *Let $\varepsilon \in (0, \frac{1}{2}]$ and P be a set of n points in $\mathbb{H}^d$. An ε-additive Steiner spanner for P with $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2} \log \frac{\alpha(n)}{\varepsilon} \cdot n$ edges can be found in $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2} \log \frac{\alpha(n)}{\varepsilon} \cdot n \log n$ time.*

2-spanner. We match the lower bound of Lemma 10 with a 2-spanner that has $\mathcal{O}_d(n \log n)$ edges (in hyperbolic space of any dimension). To get the 2-spanner, we use two ways of getting a spanner from a Steiner spanner. For small distances we can get a $(1+\varepsilon)$-spanner from Theorem 6. For larger distances, we first construct a new bipartite Steiner spanner that gives constant additive error and has $\mathcal{O}_d(n \log n)$ edges. For this, we essentially take the trees of Lemma 12 for $\varepsilon = 1/d^8$, then connect each input point to $\mathcal{O}(\log n)$ nodes in each tree such that any pair of points is connected to a common node. This avoids the multiplicative distortion and makes the Steiner spanner bipartite. We then turn this into a 2-spanner with the approach of Observation 9, but we bound the stretch more precisely using the specific geometric configuration to avoid the additive error.

▶ **Theorem 2.** *Let $P \subset \mathbb{H}^d$ be a set of n points. We can construct a 2-spanner for P with $d^{\mathcal{O}(d)} \cdot n \log n$ edges in $d^{\mathcal{O}(d)} \cdot n \log n$ time.*

Dynamic data structures. We can maintain our three multiplicative Steiner spanners dynamically by using the so-called Z-order [48] or L-order [38] for each of our shifted quadtrees. These are specific orderings of the input point set based on post-order traversals of the respective quadtree, i.e., our data structure is essentially $\mathcal{O}(d)$ differently ordered lists of our n input points, as seen in locality-sensitive orderings [15, 29].

Comparing two points based on such an order is equivalent to asking which comes first if we add both to a quadtree and do a depth-first traversal of it, but these comparisons can be done in $\mathcal{O}(d)$ time without explicitly computing the quadtree. The multiplicative Steiner spanner constructions are such that for any input point, the edges connected to it purely depend on its neighbours in the Z- or L-order, which allows for efficient updates.

The results below follow directly from having dynamic bipartite Steiner spanners.

▶ **Theorem 14** (Dynamic approximate nearest neighbours)**.** *For n points in $\mathbb{S}^d$, $\mathbb{E}^d$ or $\mathbb{H}^d$ with $d \geq 3$, there is a data structure using $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2} \log \frac{1}{\varepsilon} \cdot n$ space, that can answer queries for a $(1+\varepsilon)$-approximate nearest neighbour in $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2} \log \frac{1}{\varepsilon} + \mathcal{O}\big(d^2 \log n\big)$ time and perform updates (point insertions and removals) in $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2} \log \frac{1}{\varepsilon} \cdot \log n$ time.*

▶ **Theorem 15** (Dynamic approximate bichromatic closest pairs)**.** *For n points in $\mathbb{S}^d$, $\mathbb{E}^d$ or $\mathbb{H}^d$ with $d \geq 3$, there is a data structure using $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2} \log \frac{1}{\varepsilon} \cdot n$ space, that can maintain an $(1+\varepsilon)$-approximate bichromatic closest pair while allowing updates (point insertions and removals) in $d^{\mathcal{O}(d)}\varepsilon^{(1-d)/2} \log \frac{1}{\varepsilon} \cdot \log n$ time.*

Quotient spaces. Finally, we note that we also get results for specific manifolds of the form $\mathbb{X}^d/\Gamma$ for $\mathbb{X} \in \{\mathbb{H}, \mathbb{E}, \mathbb{S}\}$, where points $p, q \in \mathbb{X}^d$ are unified if some isometry from Γ maps p to q. If Γ is finite, then we simulate this by simply replacing every point $p \in P$ by $|\Gamma|$ copies.

▶ **Corollary 16.** *For any set P of n points on a manifold isometric to $\mathbb{S}^d/\Gamma$, $\mathbb{E}^d/\Gamma$ or $\mathbb{H}^d/\Gamma$ for some finite isometry group Γ, there is a Steiner $(1+\varepsilon)$-spanner with $d^{\mathcal{O}(d)} \cdot \varepsilon^{(1-d)/2} \log \frac{1}{\varepsilon} \cdot n|\Gamma|$ edges.*

A similar approach works for constant curvature surfaces of any genus g that are closed, orientable and connected, since these are always isometric to manifolds of the form $\mathbb{X}^2/\Gamma$. Here, we use an idea from Despré, Kolbe and Teillaud [25] to represent each point in $\mathbb{X}^2/\Gamma$ by $g^{\mathcal{O}(g)}$ points in $\mathbb{X}^2$.

▶ **Theorem 17.** *Let S be a constant curvature surface of genus g that is closed, orientable and connected. For any set P of n points on S, there is a Steiner $(1+\varepsilon)$-spanner with $\mathcal{O}\left(\frac{1}{\sqrt{\varepsilon}} \log \frac{1}{\varepsilon} \cdot n g^{\mathcal{O}(g)}\right)$ edges.*

4 Conclusion

We have given spanners of size $\mathcal{O}_d(\varepsilon^{(1-d)/2}n)$ in d-dimensional spaces of constant curvature, most importantly, even in the non-doubling hyperbolic setting. Our results raise several natural questions. We believe that the following are especially promising open problems for future work:

- Let $\mathcal{R}$ be a fixed d-dimensional Riemannian manifold (of non-constant curvature). Can one construct a Steiner spanner for any set of n points in $\mathcal{R}$ that has size $\widetilde{\mathcal{O}}_{\mathcal{R}}(\varepsilon^{(1-d)/2}n)$?
- Can we get a polynomial dependence on the genus g for Steiner spanners on (constant-curvature) surfaces?
- Is there a near-linear size ε-additive Steiner spanner in hyperbolic space that is dynamic? Can we remove the $\alpha(n)$ factor in its edge count?
- Can we strengthen Lemma 12, for example by getting a smaller number of trees or already getting a Steiner $(1+\varepsilon)$-spanner with $\mathcal{O}(dn)$ edges at distances $o(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon})$?

Nir Petruschka
Weizmann Institute of Science, Rehovot, Israel

Abstract

The Nearest Neighbor Search (NNS) problem asks to design a data structure that preprocesses an n-point dataset X lying in a metric space $\mathcal{M}$, so that given a query point $q \in \mathcal{M}$, one can quickly return a point of X minimizing the distance to q. The efficiency of such a data structure is evaluated primarily by the amount of space it uses and the time required to answer a query. We focus on the fast query-time regime, which is crucial for modern large-scale applications, where datasets are massive and queries must be processed online, and is often modeled by query time $\mathrm{poly}(d \log n)$ when $\mathcal{M}$ is a d-dimensional normed space. Our main result is such a randomized data structure for NNS in ℓ_p^d spaces, $p > 2$, that achieves $p^{O(1)+\log\log p}$ approximation with fast query time and $\mathrm{poly}(dn)$ space. Our data structure improves, or is incomparable to, the state-of-the-art for the fast query-time regime from [Bartal and Gottlieb, TCS 2019] and [Krauthgamer, Petruschka and Sapir, FOCS 2025].

1 Introduction

The Nearest Neighbor Search (NNS) problem asks to design a data structure (also called a scheme) that preprocesses an n-point dataset X lying in a metric space $\mathcal{M}$, so that given a query point $q \in \mathcal{M}$, one can quickly return a point of X minimizing the distance to q (or approximately minimizing it in the approximate version). The efficiency of such a data structure is evaluated primarily by the amount of space it uses and the time required to answer a query. The preprocessing time is a secondary measure and is usually comparable to the space usage. Because of its central role in areas such as machine learning, data analysis, and information retrieval, NNS has been the subject of extensive research, both practical and theoretical (see, e.g., the surveys [1, 6]).

It is well known that approximate NNS can be reduced to solving $\mathrm{polylog}(n)$ instances of the approximate *near* neighbor problem [18]. For this reason, we restrict attention to the latter.

▶ **Definition 1.1.** *The Approximate Near Neighbor problem for a metric space $(\mathcal{M}, d_{\mathcal{M}})$ and parameters $c \geq 1$, $r > 0$, abbreviated (c, r)-ANN, is the following. Design a data structure that preprocesses an n-point subset $X \subseteq \mathcal{M}$, so that given a query $q \in \mathcal{M}$ with $d_{\mathcal{M}}(q, X) \leq r$,*[1] *it reports $x \in X$ such that*

$$d_{\mathcal{M}}(q, x) \leq cr.$$

In a randomized data structure, the reported $x \in X$ satisfies this with probability at least $2/3$.

We focus on the fast query-time regime, which is crucial for modern large-scale applications where datasets are massive and queries must be processed online, and is often modeled by query time $\mathrm{poly}(d \log n)$ when $\mathcal{M}$ is a d-dimensional normed space. We study the metric spaces ℓ_p^d, which refer to $\mathbb{R}^d$ with distances defined by the ℓ_p norm, and we may omit the dimension d when it is clear from the context. In ℓ_p spaces, ANN in this regime is well understood for $1 \leq p \leq 2$ [19, 25, 18] and for $p = \infty$ [20, 4, 21]. For $2 < p < \infty$, the situation is less clear: there exists a handful of data structures, each suitable for a different range of p, as detailed in Table 1. We present a new scheme for ANN in ℓ_p, $p > 2$, with fast query time, that offers an improved tradeoff between approximation and space, as follows.

▶ **Theorem 1.2.** *Let $p > 2$, $d \geq 1$. Then for every $r > 0$, there is a randomized data structure for (c, r)-ANN in ℓ_p^d, where $c = p^{O(1)+\log\log p}$, that has query time $\mathrm{poly}(d \log n)$ and preprocessing (both space and time) $\mathrm{poly}(dn)$.*[2]

Studying ANN in ℓ_p, $p > 2$, is important both practically and theoretically. Real-world data and applications may motivate norms that emphasize outliers, e.g., for anomaly detection, or alter the presence of "hubs", e.g., to affect classification; such data structures were indeed used for time-series classification [28], see [14] for additional references. From a theoretical perspective, the geometry of ℓ_p spaces undermines existing algorithmic techniques and requires developing new ones. A key challenge is to bridge between $p = 2$ and $p = \infty$. In the fast query-time regime, this means interpolating between the classical $(O(1), r)$-ANN in ℓ_2 [18] and the $(O(\log\log d), r)$-ANN in ℓ_∞ [20], which both use only $\mathrm{poly}(dn)$ space. It is natural to conjecture that $2 < p < \infty$ exhibits an interpolation between these two guarantees, and since ℓ_∞^d is $O(1)$-equivalent to $\ell_{\log d}^d$ by Hölder's inequality, this interpolated data structure is conjectured to achieve $O(\log p)$ approximation using $\mathrm{poly}(nd)$ space. The first step towards this conjecture, in [2, 3], devised a reduction from ℓ_p to ℓ_∞, and obtained a data structure with $O(\log^{1/p} n \log\log d)$-approximation, which is mainly suited for large values of p. A nontrivial reduction, devised in [14], reduced ℓ_p to ℓ_2 and obtains $2^{O(p)}$-approximation, which is a major improvement for small values of p, although it is doubly-exponentially worse than the conjecture. A more sophisticated reduction, that was devised recently in [23], achieves approximation $\mathrm{poly}(p)$, which is an exponential improvement. However, it goes through multiple intermediate ℓ_t spaces ($2 \leq t < p$) via a recursive argument that increases the space to $n^{O(\log p)}$, much higher than conjectured. Our Theorem 1.2 essentially completes the improvement of [23], by decreasing the space complexity back to the conjectured $\mathrm{poly}(dn)$, albeit slightly increasing the approximation to $p^{\log\log p}$. In particular, it resolves a question posed in [23], of whether the recursion can avoid this higher space complexity.

The proof of Theorem 1.2 is based on a simple yet powerful enhancement of the known NNS schemes from [14, 23], which utilizes classical results from [11, 12] about sparse covers. We provide an overview of the algorithms of [14, 23] in Section 3, along with an intuitive explanation of our approach at the beginning of Section 4.

---

[1] If $d_{\mathcal{M}}(q, X) > r$, it may report anything, where as usual, $d_{\mathcal{M}}(q, X) := \min_{x^* \in X} d_{\mathcal{M}}(x^*, q)$.

[2] The time and space bounds are independent of p.

Table 1 Known data structures for ANN in ℓ_p, $p > 2$, in the fast query time regime.

Approximation	Space	Reference
$O(\log^{1/p} n \log\log d)$	$\text{poly}(nd)$	[2, 3]
$2^{O((\log d)^{2/3}(\log\log d)^{1/3})}$	$\text{poly}(nd)$	[8]
$2^{O(p)}$	$\text{poly}(nd)$	[14]
$p^{O(1)}$	$n^{O(\log p)}$	[23]
c	$n^{O(p/c)\cdot\log\log n}$	[13]
$p^{O(1)+\log\log p}$	$\text{poly}(nd)$	Theorem 1.2

Related Work

Many of the existing results on approximate nearest neighbor search in ℓ_p spaces focus on the case $1 \le p \le 2$ [25, 19, 18, 17, 5, 3, 27]. In this setting, $O(1)$-approximation can be achieved with $\text{poly}(dn)$ preprocessing (space and time), and query time polynomial in $d \log n$ [25, 18].

In recent years, significant progress has been made for the case $p \in (2, \infty)$, and current results can be broadly divided into three regimes. The first regime consists of data structures that achieve moderate approximation and query time using near-linear space [3, 7, 8, 9, 24, 10]. The second regime has small approximation factor, say $O(1)$ or even $1 + \varepsilon$, in which case both the query time and the preprocessing requirements (space and time) are typically very large [14, 13]. The third regime, which is the focus of our work, has fast query time, namely, $\text{poly}(d \log n)$, and existing results either achieve $2^{O(p)}$-approximation with $\text{poly}(dn)$ space [14], or better approximation $o(2^p)$ at the cost of a much bigger $n^{\omega(1)}$ space [13, 23]. Our result is the first to obtain both $o(2^p)$ approximation and $\text{poly}(dn)$ space. Table 1 provides a comparison of all known data structures in this regime.

We point out that the recursive embedding technique from [23], which is used here, has been applied successfully also to other problems involving ℓ_p spaces, such as the construction of Lipschitz decompositions [22, 23, 26], geometric spanners [22, 23], and low-distortion embeddings [23, 26].

2 Preliminaries

Given a metric space $\mathcal{M} = (X, d_{\mathcal{M}})$, we denote by $B_{d_{\mathcal{M}}}(x, r) := \{y \in X : d_{\mathcal{M}}(x, y) \le r\}$ the ball of radius $r > 0$ centered at a point $x \in \mathcal{M}$.

For every $p, q \in [1, \infty)$, the Mazur map $M_{p,q} : \ell_p^d \to \ell_q^d$ is computed by taking, in each coordinate, the absolute value raised to power p/q, but keeping the original sign. Our algorithm crucially relies on the following property of this map.

▶ **Theorem 2.1** ([15, 14]). *Let $1 \le q < p < \infty$ and $C_0 > 0$, and let M be the Mazur map $M_{p,q}$ scaled down by factor $\frac{p}{q} C_0^{p/q-1}$. Then for all $x, y \in \ell_p^d$ such that $x, y \in B_{\ell_p}(0, C_0)$,*

$$\tfrac{q}{p}(2C_0)^{1-p/q}||x - y||_p^{p/q} \le ||M(x) - M(y)||_q \le ||x - y||_p.$$

3 Overview of Algorithms from [14, 23]

In this section, we review the algorithms of [14] and [23] for ANN in ℓ_p, $p > 2$. For the rest of the section, fix a dataset $X \subset \ell_p^d$ with $|X| = n$ for some $p > 2$.

3.1 $(2^{O(p)}, r)$-ANN with $\mathrm{poly}(dn)$ Space [14]

In the preprocessing stage, consider a set of $k = \frac{p}{2} \cdot O(\log\log d)$ possible approximation factors $\hat{\mathcal{C}} = \{\hat{c}_i\}_{i=0}^{k}$, where $\mathrm{poly}(d) = \hat{c}_0 \geq \hat{c}_1 \geq \cdots \geq \hat{c}_k = 2^{O(p)}$. First, compute for X an initial NNS data structure A_{init} using [16], which provides approximation $\hat{c}_0 = \mathrm{poly}(d)$ using query time $\mathrm{poly}(d \log n)$ and space $\mathrm{poly}(d)\tilde{O}(n)$.[3] Then, for every data point $x \in X$ and every approximation $\hat{c} \in \hat{\mathcal{C}}$, compute a (scaled) Mazur map $M_{x,\hat{c}} : \ell_p^d \to \ell_2^d$ for the points in the set $B_{\ell_p}(0, \hat{c}r) \cap (X - x)$. Finally, compute for the image points in ℓ_2^d the $(2, r)$-ANN data structure $A_{x,\hat{c}}$ from [18], which uses $\mathrm{poly}(d \log n)$ query time and $\mathrm{poly}(dn)$ space. We have this data structure for each point $x \in X$ and each approximation factor $\hat{c} \in \hat{\mathcal{C}}$, and clearly $|B_{\ell_p}(x, \hat{c}r)| \leq n$, hence the total space requirement is $O(p \cdot \log\log d)n \cdot \mathrm{poly}(dn) = \mathrm{poly}(dn)$.

At query time, given a query point $q \in \ell_p^d$, find a $\hat{c}_0$-approximate solution x_0 using A_{init}. The crucial observation is that since the Mazur map ensures a distortion that depends on the diameter of the point set (Theorem 2.1), the answer from $A_{x_0 \cdot \hat{c}_0}$ is a $\hat{c}_1$-approximate solution x_1. Applying this procedure iteratively, the approximation factor decreases even faster than geometrically, roughly as $\hat{c}_i = \hat{c}_{i-1}^{1-2/p}$. Hence, after $k = O(p \log\log c_0)$ iterations we obtain an approximate solution x_k with $\hat{c}_k = 2^{O(p)}$, where the approximation factor does not improve further.

3.2 $(\mathrm{poly}(p), r)$-ANN with $\mathrm{poly}(d)n^{O(\log p)}$ Space [23]

In [23], the image space of the Mazur map is changed from ℓ_2 to ℓ_t for general $1 \leq t < p$. Generalizing the results from [14], a (c_t, r)-ANN data structure in ℓ_t^d with query time $Q(n)$ and space $S(n)$ is used to construct a $(2^{O(p/t)} \cdot c_t, r)$-ANN data structure for ℓ_p^d with query time $O(d) + \frac{p}{t}O(\log\log d)Q(n)$ and space $\frac{p}{t}O(\log\log d)n \cdot S(n)$. Using the above result with $t = p/2$, and applying it recursively to decrease p to 2 (which is actually a double recursion, because we also iterate over the $\hat{c}_i$'s), yields a $(\mathrm{poly}(p), r)$-ANN data structure with query time $\mathrm{poly}(d \log n)$. The caveat is that every application of the recursive step multiplies the space of the data structure by factor n, which yields a data structure with space $\mathrm{poly}(d)n^{O(\log p)}$.

4 $(2^{\tilde{O}(\log p)}, r)$-ANN with $\mathrm{poly}(dn)$ Space

In this section, we give the proof of Theorem 1.2. We first explain the intuition, and for simplicity we restrict this discussion to reducing the space requirement of [14]; reducing the space requirements of [23] is similar in spirit, although more technical.

Revisiting Section 3.1, the final solution x_k is obtained by finding iteratively a sequence of intermediate solutions $x_0, x_1, \ldots, x_{k-1}$. Each iteration $i < k$ makes progress by finding a point x_i and restricting the search region to $B_{\ell_p}(x_i, \hat{c}_i r)$, which has bounded diameter, and thus applying a Mazur map on this region has distortion guarantees. It follows that querying the data structure $A_{x_i,\hat{c}_i}$ (computed over $B_{\ell_p}(x_i, \hat{c}_i r) \cap X$) finds a point x_{i+1} and we can restrict the search region even further, to diameter $\hat{c}_{i+1} r$.

The preprocessing phase prepares for the possibility that each point $x \in X$ will serve (at query time) the $\hat{c}_i$-approximate solution, i.e., the search region will be restricted to $B_{\ell_p}(x, \hat{c}_i r)$. To make progress and restrict the search region even further, a data structure $A_{x,\hat{c}_i}$ is constructed for (the points in) this region. Our key idea in Theorem 1.2 is that, rather

[3] Throughout, the notation $\tilde{O}(f)$ hides factors that are logarithmic in f.

than preparing a *separate* data structure for each search region, the algorithm constructs one *global* collection of data structures that together cover all the possible search regions. For every $\hat{c}_i$, the algorithm constructs a set of ANN data structures computed on a collection of subsets $\mathcal{S} \subseteq 2^X$, such that for every point $x \in X$ there is some $S \in \mathcal{S}$ that contains the search region $B_{\ell_p}(x, \hat{c}_i r) \cap X$. In addition, every $S \in \mathcal{S}$ has diameter at most $\beta \hat{c}_i r$ for some $\beta > 1$. We also want the total number of points in $\mathcal{S}$ (counting repetitions) to be small. The preprocessing algorithm simply stores for every $x \in X$ a reference to a set $S_x \in \mathcal{S}$ with $B_{\ell_p}(x, \hat{c}_i r) \cap X \subseteq S_x$, and at query time, if x serves as a $\hat{c}_i$-approximate solution, the algorithm queries the ANN data structure constructed for S_x. Since S_x has a diameter at most $\beta \hat{c}_i r$, this will still cause the search region's diameter to shrink in the next iteration (although by a slightly smaller factor). Since the total number of points in $\mathcal{S}$ is small, the total memory used by all the ANN data structures will be small too.

It remains to show that the preprocessing phase can indeed find efficiently a collection of subsets of X with the above properties. Fortunately, this was shown to be possible in [11, 12], and has become a fundamental algorithmic tool with numerous applications in distributed computing, network design, routing, graph algorithms, and metric embeddings.

▶ **Definition 4.1** (Sparse Neighborhood Cover [11, 12]). *A (β, r)-sparse cover of a metric space $\mathcal{M} = (X, d_{\mathcal{M}})$ is a collection of subsets (called clusters) $\mathcal{S} \subseteq 2^X$, each of diameter at most βr, such that for every $x \in X$ there exists $S \in \mathcal{S}$ with $B_{d_{\mathcal{M}}}(x, r) \subseteq S$. The total number of points $\sum_{S \in \mathcal{S}} |S|$ is called the* sparsity *of $\mathcal{S}$.*

▶ **Theorem 4.2** ([12]). *There is an algorithm that, given an n-point metric space $\mathcal{M}$ and parameters $\beta > 1$ and $r > 0$, outputs a (β, r)-sparse cover of $\mathcal{M}$ of sparsity $O(n^{1+1/\beta})$, and runs in $O(\beta n^{2+2/\beta})$ time.*

We are now ready to prove Theorem 1.2, largely following the proof structure of [23, Theorem 1.8].

Proof of Theorem 1.2. Let $X \subset \ell_p^d$ be an n-point dataset for some $p \in (2, \infty)$. For clarity of exposition, we assume that p is a power of 2, which can be easily resolved, see [23, Theorem 1.2]. Also, by an application of Hölder's inequality, we may assume that $p \leq \log d$.

We construct the ANN scheme using a doubly-recursive procedure. The first recursion assumes access to an ANN scheme for ℓ_p^d that achieves approximation factor c_{base}, and provides a new ANN scheme for ℓ_p^d that achieves improved (smaller) approximation c_{new}. This step crucially relies on access to yet another ANN data structure, for ℓ_t^d, for $t = p/2$, that is actually constructed by the same method. This leads to a second recursion, of constructing ANN data structures for intermediate spaces $\ell_p^d, \ell_{p/2}^d, \ldots, \ell_2^d$, where the space ℓ_2^d is known to have ANN data structures with $O(1)$ approximation.

We next describe the first recursion, i.e., how to construct an improved (c_{new}, r)-ANN scheme for ℓ_p^d given a (c_{base}, r)-ANN scheme for ℓ_p^d and a (c_t, r)-ANN scheme for ℓ_t^d, where $t < p$. In the preprocessing phase, use Theorem 4.2 to construct for X a $(\beta, 2c_{\text{base}} r)$-cover $\mathcal{S}$ with sparsity $\tilde{O}(n^{1+1/\beta})$ for $\beta = \log p$. During the construction of $\mathcal{S}$, store for every $x \in X$ a reference to a set $S_x \in \mathcal{S}$ that "covers" it, i.e., $B_{\ell_p}(x, 2c_{\text{base}} r) \cap X \subseteq S_x$, which is guaranteed to exist in a sparse cover. In addition, for every $S \in \mathcal{S}$ designate (arbitrarily) a center point $y \in S$, apply a Mazur map $M^y : \ell_p^d \to \ell_t^d$ scaled down by factor $\frac{p}{t} \cdot (2\beta c_{\text{base}} r)^{p/t-1}$ on $B_{\ell_p}(0, 2\beta c_{\text{base}} r) \cap (X - y)$, and construct for these image points a (c_t, r)-ANN scheme A_S. Finally, construct a (c_{base}, r)-ANN scheme A_{base} for X, and amplify the success probabilities of both data structures to $5/6$ by the standard method of independent repetitions. Given a query $q \in \ell_p^d$ that is guaranteed to have $x^* \in X$ with $\|x^* - q\|_p \leq r$, query A_{base}

for the point q and obtain an answer $x_{\text{base}} \in X$. Then find its cluster $S_{x_{\text{base}}}$ and this cluster's designated center y, query $A_{S_{x_{\text{base}}}}$ for the point $M^y(q-y) \in \ell_t^d$, and use its answer $M^y(z_{\text{out}} - y) \in M^y(X-y)$ to output the corresponding $z_{\text{out}} \in X$.

The next claim is analogous to [23, Claim 4.1], and the main difference is using the sparse cover.

▷ Claim 4.3. With probability at least 2/3, we have $\|z_{\text{out}} - q\|_p \le c_{\text{new}} r$, where $c_{\text{new}} = (\frac{p}{t})^{t/p}\, c_t^{t/p}\, (4\beta c_{\text{base}})^{1-t/p}$.

Proof. With probability at least $\frac{5}{6}$, the data structure A_{base} outputs a point x_{base} with $\|x_{\text{base}} - q\|_p \le c_{\text{base}} r$. Let $S_{x_{\text{base}}}$ be the set in the cover referenced by x_{base}, and let $y \in S_{x_{\text{base}}}$ be its designated center point. Since

$$\|x^* - x_{\text{base}}\|_p \le \|x^* - q\|_p + \|q - x_{\text{base}}\|_p \le 2c_{\text{base}} r,$$

we get that $x^* \in B_{\ell_p}(x_{\text{base}}, 2c_{\text{base}} r) \cap X \subseteq S_{x_{\text{base}}}$. Observe that by Theorem 2.1, $\|M^y(x^*) - M^y(q)\|_t \le r$, and thus with probability at least $\frac{5}{6}$, querying $A_{S_{x_{\text{base}}}}$ finds a point $M^y(z_{\text{out}}) \in M^y(S_{x_{\text{base}}}) \subseteq M^y(X)$ with $\|M^y(z_{\text{out}}) - M^y(q)\|_t \le c_t r$. Applying a union bound, we see that with probability at least 2/3, both events hold. In this case, we have by Theorem 2.1, that

$$\frac{t}{p} \cdot (4\beta c_{\text{base}} r)^{1-p/t} \cdot \|z_{\text{out}} - q\|_p^{p/t} \le \|M^y(z_{\text{out}}) - M^y(q)\|_t \le c_t r,$$

and by rearranging, we obtain $\|z_{\text{out}} - q\|_p \le (\frac{p}{t})^{t/p}\, c_t^{t/p}\, (4\beta c_{\text{base}})^{1-t/p} r = c_{\text{new}} r$. ◁

Denote by $\hat{c}_i$ the approximation of the ANN scheme obtained by i applications of Claim 4.3, where the initial ANN scheme is the one from [16], with approximation $\hat{c}_0 = \text{poly}(d)$. We also denote by c_t the approximation of an ANN scheme for ℓ_t, that is constructed by the same method (i.e., recursively), except that for ℓ_2^d we use a $(2,r)$-ANN scheme from [18] with $\text{poly}(d \log n)$ query time and $\text{poly}(dn)$ space and preprocessing time. Using Claim 4.3 with $t = p/2$, and furthermore applying this recursively $k = \lceil \log(\log \hat{c}_0) \rceil = O(\log \log d)$ times, we obtain

$$\hat{c}_k \le \sqrt{8\beta c_{p/2} \hat{c}_{k-1}} \le \sqrt{8\beta c_{p/2} \sqrt{8\beta c_{p/2} \hat{c}_{k-2}}} \le \ldots \le 8\beta c_{p/2} \cdot \hat{c}_0^{1/2^k} \le 16\beta c_{p/2},$$

i.e., this scheme has approximation $c_p = \hat{c}_k \le 16\beta c_{p/2}$. We can amplify the success probability of this scheme to $1 - \frac{1}{3\log p}$ by the standard method of $O(\log \log p) = O(\log \log \log d)$ independent repetitions. Now by recursion over p for $\log p$ levels, we get that

$$c_p \le (16\beta)^{\log p} = (16 \log p)^{\log p} = p^{4 + \log \log p},$$

and the overall success probability is at least $\frac{2}{3}$ by a union bound.

We are left to analyze the query time of the algorithm, and its space and preprocessing time. Each level of the second recursion makes a total of $k \cdot O(\log \log p) = \tilde{O}(\log \log d)$ calls to an ANN scheme for ℓ_t, for different intermediate values of t. Since the $(2,r)$-ANN for ℓ_2 from [18] has query time $\text{poly}(d \log n)$, and recalling that $p \le \log d$, the overall query time is $\tilde{O}(\log \log d)^{\log p} \cdot \text{poly}(d \log n) = \text{poly}(d \log n)$.

To analyze the space and preprocessing time, we prove the following claim.

▷ Claim 4.4. There exists an absolute constant $D > 2$ such that when the data structure for ℓ_t^d, $t = 2^i$, is computed on m points, it uses total space and preprocessing time $\tilde{O}(\log \log d)^i\, \text{poly}(d) O(m)^{D + i/\log p}$.

Proof. We only analyze the space usage of the data structure; the analysis of the preprocessing time follows similarly, as it takes $O(d)$ time to compute a Mazur map and $O(\log p \cdot m^{2(1+1/\log p)}) \leq O(\log\log d \cdot m^{2(1+1/\log p)})$ time to compute a sparse cover.

The proof proceeds by induction on $i \geq 0$. For $i = 0$, the claim follows because the $(2, r)$-ANN from [18], when computed on m points, uses at most $\mathrm{poly}(d)m^D$ space for some absolute constant $D > 1$. Now, assume the claim holds for $i - 1 \geq 0$. The ANN scheme at level i of the recursion consists of two types of ANN schemes. The first type is an ANN scheme from [16] computed on all m points, which uses $\mathrm{poly}(d)\tilde{O}(m) \leq \mathrm{poly}(d)O(m)^{D(1+1/\log p)}$ space. The second type are multiple ANN schemes at level $i - 1$ that are computed on different subsets of the m points. For every $j = 0, 1, \ldots, k = \tilde{O}(\log\log d)$, let $\mathcal{S}^j$ be the sparse cover of sparsity $O(m^{1+1/\log p})$ computed for the points at the j-th level of the first recursion. For every level j of the first recursion and cluster $S \in \mathcal{S}^j$, the algorithm computes a data structure of level $i - 1$ on S. By the induction hypothesis, the space of this data structure is bounded by $\tilde{O}(\log\log d)^i \,\mathrm{poly}(d)O(m)^{D+i/\log p}$. Observe that the function $f : x \mapsto \tilde{O}(\log\log d)^i \,\mathrm{poly}(d)x^{D+i/\log p}$ satisfies that $f(a) + f(b) \leq f(a + b)$ for all $a, b \geq 1$, and, since every data structure is constructed over some $S \in \mathcal{S}^j$ containing at most m points, we can bound the contribution of every point $p \in S$ to the total space usage of the data structure by $\frac{f(m)}{m}$. Since for every j the sparsity of $\mathcal{S}^j$ is at most $O(m^{1+1/\log p})$, the total space usage of all ANN schemes computed over all clusters of $\mathcal{S}^j$ is at most

$$O(m^{1+1/\log p})\frac{f(m)}{m} \leq \tilde{O}(\log\log d)^i \,\mathrm{poly}(d)O(m)^{D+(i+1)/\log p}.$$

Hence, the total space usage is

$$\begin{aligned}&\tilde{O}(\log\log d) \cdot \left(\tilde{O}(\log\log d)^i \cdot \mathrm{poly}(d) \cdot O(m)^{D+(i+1)/\log p}\right) + \mathrm{poly}(d) \cdot \tilde{O}(m)\\ &\leq \tilde{O}(\log\log d)^{i+1} \cdot \mathrm{poly}(d) \cdot O(m)^{D+(i+1)/\log p},\end{aligned}$$

completing the proof. ◁

Finally, we use Claim 4.4 for $m = n$ and $i = \log p$, and obtain that the space usage of the entire ANN data structure is bounded by

$$\tilde{O}(\log\log d)^{\log p} \,\mathrm{poly}(d) \cdot n^{D+\log p/\log p} \leq \mathrm{poly}(d) \cdot n^{D+1} \leq \mathrm{poly}(dn),$$

which completes the proof of Theorem 1.2. ◀

▶ Remark 4.5. Modifying the parameter β of the sparse cover in the proof of Theorem 1.2 from $\log p$ to $\frac{\log p}{\delta}$ for $0 < \delta < 1$ yields a data structure with a slightly larger approximation factor $p^{O(1)+\log(1/\delta)+\log\log p}$, but space requirement that matches that of [18] up to subpolynomial factors in d and an additional n^δ term.

▶ Remark 4.6. The same technique used in the proof of Theorem 1.2, namely applying Theorem 4.2 to construct covers in the preprocessing phase, can also be used to improve the space requirement of ANN for general normed spaces from [8, Theorem 3]. More specifically, for every $0 < \delta < 1$, one can shave an $\Omega(n^{1-\delta})$ factor from the space of their data structure, at the cost of an additional $O(\delta^{-1})$ factor in the approximation.

Non-Dissective Coverings by Planks

Abstract

A *plank* is the part of space between two parallel planes. The following open problem, posed 45 years ago, can be viewed as the converse of Tarski's plank problem (Bang's theorem): Is it true that if the total width of a collection of planks is sufficiently large, then the planks can be individually translated to cover a unit ball B?

A translative covering of B by planks is said to be *non-dissective* if the planks can be added one by one, in some order, such that the uncovered part remains connected at each step and is empty at the end. Improving a classical result of Groemer, we show that every set of $C/\epsilon^{7/4}$ planks of width ϵ admits a non-dissective translative covering of a 3-dimensional ball B^3, provided C is large enough. Our proof yields a low-complexity algorithm. We also show that $c/\epsilon^{4/3}$ planks are, in general, insufficient for a non-dissective covering of B^3. This provides the first non-trivial lower bound for this problem.

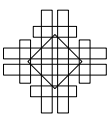
1 Introduction



A *plank of width* ϵ in $\mathbb{R}^d$ is a closed region P bounded by two parallel hyperplanes at distance ϵ from each other. The distance between these two hyperplanes is called the *width* of P.

In 1932, Tarski [17] posed the question now known as the *plank problem*: if a convex body K in $\mathbb{R}^d$ is covered by a collection of planks, is it true that the sum of their widths is at least as large as the minimal *width* of K, that is, the minimum width of a plank that contains K? Twenty years later, this question was answered affirmatively by Bang [3, 4]; see also Fenchel [8] for an alternative proof. Bang also conjectured that a similar statement is true with "relative widths" with respect to K. This was proved by Ball [2] for centrally symmetric bodies, but in the general case the problem is open. A spherical analogue of the plank problem, raised by L. Fejes Tóth [7], was settled by Jiang and Polyanskii [12] (see also Ortega-Moreno [16]). A. Bezdek [5] conjectured that the following planar variant of Tarski's conjecture is also true: the total width of a set of planks that cover a unit disk with a small circular hole around its center is at least 2; see also [19, 1]. For many other related open problems, consult [6], Section 3.4. For a recent survey on the topic, see [18].

The following natural question was asked independently by Groemer [9] and Makai-Pach [15]. Can one reverse Bang's theorem? Is it true that if the total width of a collection of planks $P_1, P_2, \ldots$ in $\mathbb{R}^d$ is large enough, then each P_i can be translated into a new position

P_i' such that $P_1', P_2', \ldots$ together cover, say, a ball B^d of *unit radius*? In other words, does there exist a constant C_d such that any collection of planks of total width at least C_d permits a *translative covering* of the unit ball B^d? In the plane, this was proved independently by Makai-Pach [15] and Erdős-Straus (unpublished); see also [10, 11]. For $d \geq 3$, the problem is open. In particular, we have the following.

▶ **Conjecture 1** ([15]). *For every $d \geq 3$, there exists a constant C_d such that every collection of $C_d\epsilon^{-1}$ planks of width ϵ in $\mathbb{R}^d$ permits a translative covering of the unit ball.*

For a long time, the best known result was due to Groemer [9], who designed a greedy algorithm to construct a translative covering of the unit ball for any collection of $O(\epsilon^{-(d+1)/2})$ planks of width ϵ in $\mathbb{R}^d$. Kupavskii and Pach [13, 14] came close to proving Conjecture 1: they showed that the statement is true for any system of only $O(\epsilon^{-1}\log(\epsilon^{-1}))$ planks.

Nevertheless, Groemer's algorithm had a very interesting additional feature. Given a sequence of planks $P_1, \ldots, P_f$, by a simple greedy method, one can find suitable translates P_i' of P_i $(i = 1, \ldots, f)$, with the property that

$$B^d \setminus \cup_{i=1}^{j} P_i'$$

is a *connected* set for every $j \geq 1$. Moreover, Groemer showed that if we insist on this property and we also fix the order of the planks, then the bound $O(\epsilon^{-(d+1)/2})$ is essentially best possible.

▶ **Definition 2.** We say that a collection of planks $P_1, \ldots, P_f$ permits a *non-dissective translative covering* of a convex body K in $\mathbb{R}^d$ if there exist a permutation

$$\sigma : \{1, \ldots, f\} \to \{1, \ldots, f\}$$

and suitable translates P_i' of P_i with the property that

$$K \setminus \cup_{i=1}^{j} P_{\sigma(i)}'$$

is a *connected* set for $j = 1, \ldots, f$, and is empty for $j = f$.

In the present paper, we study the following variant of the problem addressed in Conjecture 1.

▶ **Problem 3.** *What is the smallest integer $f = f(d, \epsilon)$ such that every collection of f planks of width ϵ in $\mathbb{R}^d$ permits a non-dissective translative covering of the unit ball $\mathbb{R}^d$?*

The Makai–Pach covering [15] is non-dissective, and thus we have $f(2, \epsilon) = \Theta(1/\epsilon)$. For every $d \geq 3$, we have

$$c_d\epsilon^{-1} \leq f(d, \epsilon) \leq C_d\epsilon^{-(d+1)/2}. \tag{1}$$

Here, we concentrate on the first open case $d = 3$. Our main theorem improves both the lower and upper bounds in (1).

▶ **Theorem 4.** *There exist constants $c, C > 0$ such that*

$$c\epsilon^{-4/3} \leq f(3, \epsilon) \leq C\epsilon^{-7/4}.$$

In particular, the lower bound shows that Conjecture 1 does not remain true if we restrict our attention to non-dissective coverings.

In the next two sections, we establish the lower and upper bounds in Theorem 4, respectively. We conclude this note with a few remarks (see Section 5).

2 Proof of Theorem 4 – Lower bound

In this section, we establish the lower bound in Theorem 4. Consider $k = \Omega(\epsilon^{-4/3})$ points on the sphere such that the angular distance between any two of them is at least $10\epsilon^{2/3}$, and each point is within angle 1° from the north pole.

Let $P_1, \dots, P_k$ be a sequence of planks of width ϵ, whose normal vectors correspond to the above k points. Consider a non-dissective covering of the unit ball B^3 using planks P_i in the order of increasing i. Since all planks are almost horizontal, we may talk about their "upper" and "lower" boundary planes. Formally, the z-coordinate of the intersection of the upper boundary plane with the z-axis is larger than that for the lower boundary plane.

Let $K_0 = B^3$ and, for all i, $1 \le i \le k$, let $K_i := K_{i-1} \setminus P'_i$, where P'_i is a suitable translate of P_i used for the covering. By the assumption that the covering is non-dissective, K_i is a connected set for every i. As soon as we cover a point of B^3 within angular distance 1° from the equator, we stop the covering process, and we declare that the covering was *successful*. We want to show that the number of planks used up to this moment is $\Omega(\epsilon^{-4/3})$.

We may assume recursively that P'_{i+1}, the translate of P_{i+1} that we use for the covering, satisfies one of the following two conditions:

1. either the upper boundary plane of P'_{i+1} coincides with the upper supporting plane of K_i,
2. or the lower boundary plane of P'_{i+1} coincides with the lower supporting plane of K_i.

Assume without loss of generality that the first plank that covers a point at distance at most 1° from the equator satisfies condition 1 above. Note that this implies that at this moment we have already covered a portion of the upper half of B^3 whose volume is $\Omega(1)$. Slightly abusing notation, we denote the planks that were used for the covering of the upper hemisphere also by $P'_1, \dots, P'_k$.

Note that the normal vectors at the boundary of the part of K_i covered by P'_{i+1} have angle at most 90° with the normal vector defining P'_{i+1}. This holds for all flat faces since all P'_j have normals within angle 1° from the north pole. This also holds for the parts of the boundary coming from B^3 since in the covering procedure we only cover points that are more than 1° from the equator. Using this, we can bound the volume of K_i that is covered by P'_{i+1}: it is at most ϵ times the area of the face of K_{i+1} lying on the boundary of the plank P'_{i+1}. Note that this face is the intersection of the lower boundary plane π^L of P'_{i+1} with K_i. Let X denote this intersection.

▶ **Lemma 5.** *X does not contain a disk of radius $10\epsilon^{1/3}$.*

The lemma implies the lower bound as follows. The diameter of X is at most 2, which is the diameter of B^3. Combining this fact with Lemma 5, we obtain that the area of X is $O(\epsilon^{1/3})$. This, in turn, implies that, for every i, $1 \le i \le k$, the volume of the intersection $P'_{i+1} \cap K_i$ is $O(\epsilon^{4/3})$. The volume of the upper part of B^3 that we need to cover is $\Omega(1)$. Hence, we need $\Omega(\epsilon^{-4/3})$ planks to exhaust this volume. We note that Lemma 5 is one part of the proof that is specific to the non-dissective case.

Proof of Lemma 5. Let n stand for the normal vector to π^L. For any point w in X, we denote by w' the point on the boundary of K_i that is obtained from w by translating it parallel to n inside P'_{i+1}. Note that w' and w are at most ϵ apart.

Let us show that X does not contain a disk D of radius $10\epsilon^{1/3}$. See Figure 1. Assume the contrary, and let v be the center of such a disk D.

Consider the circle C in π^L, concentric to D and of radius $5\epsilon^{1/3}$. Take a point $w \in C$. Consider the normal vector $n_{w'}$ of a supporting plane for K_i at w', whose choice we explain below. If w' lies on the boundary of, potentially, several planks P'_j with $j \le i$, then take a supporting hyperplane of one of these planks P'_j. Otherwise, w' must lie on the boundary of the initial ball B^3, and then we simply take the unique supporting plane to the ball at w'.

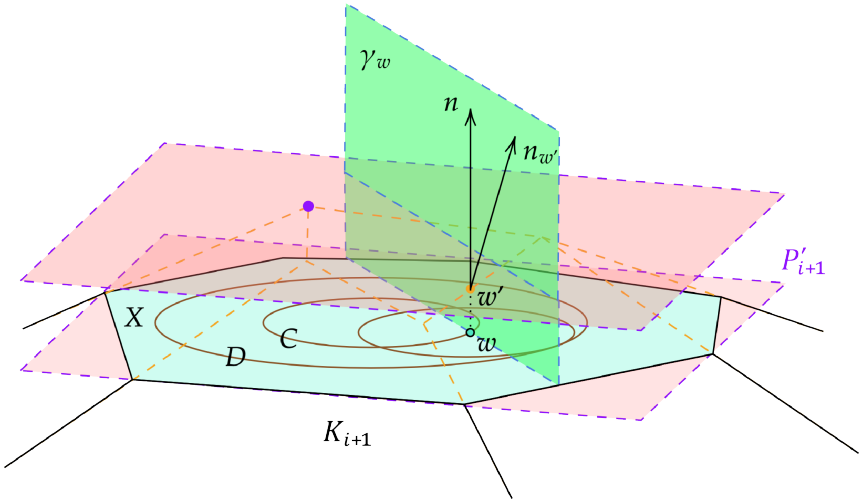

Figure 1 Discs D, C on the face X of the set K_{i+1}. The plank P'_{i+1} is shown by two parallel planes in semi-transparent red. The part of K_i that was cut off by P'_{i+1} is indicated in dashed orange. The plane γ_w containing w, w' and normal vectors $n, n_{w'}$ is semi-transparent green.

Consider the intersection Q of $K_i \cap P'_{i+1}$ with the plane γ_w spanned by n and $n_{w'}$ and passing through w. By our assumption, X contains a disk of radius $5\epsilon^{1/3}$ centered at w. Thus, Q is a convex set of height at most ϵ and with the "base" being a straight line segment orthogonal to n that passes through w and has length at least $5\epsilon^{1/3}$ in each direction from w. Thus, the angle between n and $n_{w'}$ is at most $\epsilon^{2/3}$: otherwise, the supporting line at w' corresponding to $n_{w'}$ will hit the base segment at distance at most $\epsilon \cdot \cot(\epsilon^{2/3}) < 2\epsilon^{1/3}$ from w, which is a contradiction. See Figure 2.

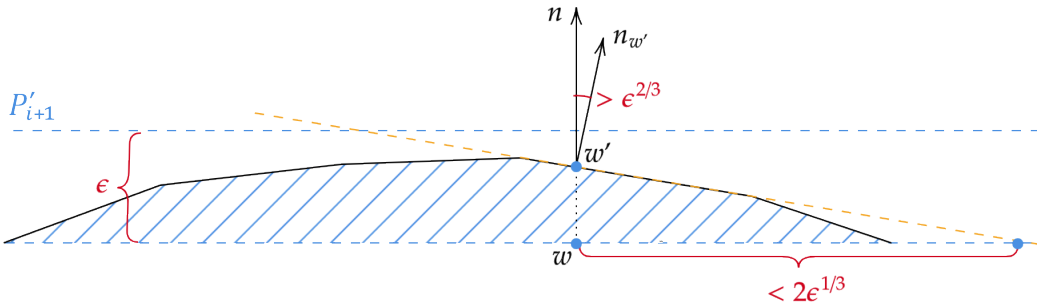

Figure 2 An illustration to the proof of Lemma 5: If the angle between n and $n_{w'}$ is greater than $\epsilon^{2/3}$, then the supporting line at w' hits the "base" $\pi^L \cap \gamma_w$ at distance at most $2\epsilon^{1/3}$.

We conclude that $n_{w'}$ has angle at most $\epsilon^{2/3}$ with n for any $w \in C$. Since the angle between the normal vectors of any two planks is at least $10\epsilon^{2/3}$, $n_{w'}$ cannot be a normal vector to any other plank. Running the same argument for each point $w \in C$, we conclude that the set $C' := \{w' : w \in C\}$ lies on the boundary of B^3. But then the angle between the normal vectors at two points of C' corresponding to the opposite points of C is $\Omega(\mathrm{diam}(C)) = \Omega(\epsilon^{1/3})$, a contradiction with the fact that each of them has angle at most $\epsilon^{2/3}$ with n. ◀

3 Proof of Theorem 4 – Upper bound

Consider k planks of width ϵ, and write k in the form $k = \epsilon^{-\beta}$ for some $\beta > 0$. Let $\alpha > 0$ be a constant to be specified later. By averaging over all directions, we can find a vector n such that there are $\Theta(\epsilon^{2\alpha-\beta})$ planks whose normal vectors form an angle of at most ϵ^α with n. Let these planks be $P_1, \dots, P_m$. (At the end of the proof we will see that for our arguments to work, the optimal choice of the parameters will be $\beta \approx 7/4$ and $\alpha \approx 3/4$.)

Choose a coordinate system in which the direction of the positive z-axis, pointing upwards, is n. Since the normal vectors of the planks $P_1, \dots, P_m$ are very close to n, we can call these planks "almost horizontal", and we can talk about their "upper" and "lower" boundary planes.

Given a convex body K, the *(outer) parallel body* of K at distance 1 is defined as

$$B(K) := \{v \in \mathbb{R}^3 : \inf_{w \in K} \|v - w\| \le 1\}.$$

Clearly, $B(K)$ is a smooth body, hence in every direction it has precisely two supporting planes.

We are going to process the planks one by one. Set $K_0 = B^3$. Let P_1' denote the translate of P_1 whose upper boundary plane is tangent to K_0 from above. Informally, this means that we move P_1 from above as long as we can, preserving the property that $K_0 \setminus P_1'$ remains connected. Since $K_0 = B^3$, we have $B(K_0) = 2B^3$. Denote by P_1'' the translate of P_1 whose upper boundary plane is tangent from above to $B(K_0)$.

Next, we set $K_1 := K_0 \setminus P_1'$. Let P_2' denote the translate of P_2 whose upper boundary plane is tangent to K_1 from above. Analogously, denote by P_2'' the translate of P_2 whose upper boundary plane is tangent to $B(K_1)$ from above. Let $K_2 := K_1 \setminus P_2'$. Proceeding like this, after performing j steps ($j \le m$), we obtain a sequence of convex bodies $K_0 = B^3 \supset K_1 \supset K_2 \supset \dots \supset K_j$, and two sequences of planks, $P_1', \dots, P_j'$ and $P_1'', \dots, P_j''$ with the following properties:

1. $B(K_0) \supset B(K_1) \supset \dots \supset B(K_j)$
2. For every i, $1 \le i \le j$, the distance between the lower (resp. upper) boundary planes of P_i' and P_i'' is 1.
3. If $K_j = K_{j-1} \setminus P_j'$ is *empty*, we terminate the process.

By definition, for every j, we have $K_j = K_0 \setminus \cup_{i=1}^j P_i'$. We will keep track of the (decreasing) sequence of volumes Vol $B(K_i)$. If for some j, we have

$$\text{Vol } B(K_j) < \text{Vol } B^3, \tag{2}$$

then we can conclude that K_j is empty, i.e., the initial ball B^3 is completely covered by the planks $\cup_{i=1}^j P_i'$.

We need some easy observations.

▶ **Proposition 6.** *Let π_i', π_i'' be the lower boundary planes of P_i', P_i'', respectively, and let Π_i be the upper half-space bounded by the π_i''.*

Then, for $i = 1, 2, \dots$, we have

$$B(K_i) = B(K_{i-1} \setminus P_i') \subset B(K_{i-1}) \setminus \Pi_i \subset B(K_{i-1}) \setminus P_i''.$$

Proof. We start by verifying the first inclusion. Let v be any point of $B(K_{i-1} \setminus P_i')$. By definition, there exists $w \in K_{i-1} \setminus P_i'$ with $\|v - w\| \le 1$. Thus, v also belongs to $B(K_{i-1})$. We only have to argue that v does not lie inside the half-space Π_i. If it did, by property 2

above, it would be farther away than 1 from the lower boundary plane of P_i', which separates $K_{i-1} \setminus P_i'$ from v. This would contradict our assumption that $v \in B(K_{i-1} \setminus P_i')$.

The second inclusion holds since $P_i'' \subset \Pi_i$. ◀

Recall that, according to our conventions, the direction of the positive z-axis of the coordinate system coincides with the vector n. At the beginning, we fixed a vertical direction n, but in the sequel we will also use the following simple fact in other scenarios.

▶ **Proposition 7.** *Let K be a convex body and let s be a boundary point of the parallel body $B(K)$ such that the z-coordinate of s is maximum.*

Then $B(K)$ contains a ball U of unit radius *that touches the boundary of $B(K)$ at s.* ◀

Now we quickly outline our proof strategy for the upper bound in Theorem 4. Recall that we selected a "dense" subset of almost parallel directions, in terms of two constants α and β. Our first and main goal is to bound from below the volume of the parallel body $B(K_j)$ of the part of B that we cover with the first j planks corresponding to the chosen directions. To get this lower bound, we will have two cases to consider, and the parameter α is chosen to balance the bound in the two cases. We cover a substantial part of $K_0 = B^3$ using these planks, and remove them. This constitutes the first stage of our covering algorithm.

At the second stage, we repeat the same procedure. This time, in the remaining set of directions we find a "dense" subset (using the same α), and we use the corresponding almost parallel planks to cover the remaining part of the ball. While at stage 1, we started with $K_0 = B^3$, at stage 2 we start where we left off at stage 1. That is, our new initial body $K_0^{(2)}$ will be identical to the last K_j at stage 1. Again, we bound from below the volumes of the parallel bodies of the new shrinking sequence

$$K_0^{(2)} \supset K_1^{(2)} \supset K_2^{(2)} \supset \cdots$$

of uncovered bodies. Because of our choice of parameters, it is guaranteed that after performing this procedure a bounded number of times, at some stage we reach a point where (2) holds. At this point, we can be sure that B^3 is entirely covered.

Apply Proposition 7 with $K_0 = B^3$ to obtain a ball $U \subset B(K_0)$ of unit radius that touches the boundary of $B(K_0)$ at its highest point in the vertical direction n. Let ℓ be the vertical line passing through the center of U (which is the highest point of B^3).

We distinguish two cases.

Case A: There is a set of indices $A \subset \{1, \ldots, m\}$ with $|A| \geq m/2$ such that for any $i \in A$, the intersection of ℓ with $B(K_i)$ is at least $\epsilon/2$ shorter than the intersection of ℓ with $B(K_{i-1})$.

Case B: There is a set of indices $Z \subset \{1, \ldots, m\}$ with $|Z| \geq m/2$ such that for any $i \in Z$, the intersection of ℓ with $B(K_i)$ is less than $\epsilon/2$ shorter than the intersection of ℓ with $B(K_{i-1})$.

In **Case A**, we start our argument as follows. To simplify the notation, assume that $m \in A$. Suppose that the center of U is inside $B(K_m)$ and we have $m\epsilon = o(1)$. Using Proposition 6, we obtain that

$$B(K_m) \subset B(K_{m-1}) \setminus \Pi_m \subset B(K_0) \setminus \Pi_m.$$

Since $U \subset B(K_0)$, we also have that

$$U \cap \Pi_m \subset B(K_0) \cap \Pi_m.$$

By the above inclusions, we can bound from below the difference between the volumes of $B(K_m)$ and $B(K_0)$.

$$\begin{aligned}\text{Vol } B(K_0) - \text{Vol } B(K_m) &\geq \text{Vol } B(K_0) - \text{Vol } \big(B(K_0) \setminus \Pi_m\big)\\ &= \text{Vol } \big(B(K_0) \cap \Pi_m\big)\\ &\geq \text{Vol } \big(U \cap \Pi_m\big) = \Omega(m^2\epsilon^2).\end{aligned}$$

We explain the last equality. The set $U \cap \Pi_m$ is a spherical cap that contains a section of the vertical line ℓ of length at least $m\epsilon/4$. The lower boundary plane π''_m of P''_m is almost horizontal: its normal vector has an angle of at most ϵ^α with ℓ. Thus, $U \cap \Pi_m$ contains a spherical cap and, hence, a cone whose height is roughly the same as the length of the portion of ℓ contained in $U \cap \Pi_m$, which is $\Omega(m\epsilon)$. The radius of the circular base of this cone (and of the cap) is $\Omega(\sqrt{m\epsilon})$ (here is where we use the $m\epsilon = o(1)$ assumption). The volume of this cone is $\Omega(m^2\epsilon^2)$, as claimed.

If the center of U is outside $B(K_m)$ or if $m\epsilon = \Omega(1)$, then we have

$$\text{Vol } B(K_0) - \text{Vol } B(K_m) = \Omega(1).$$

Recall that $m = \Theta(\epsilon^{2\alpha-\beta})$. Thus, the volume that we managed to cover in this case is at least

$$\min\big\{\Omega\big(m^2\epsilon^2\big), \Omega(1)\big\} = \min\big\{\Omega\big(\epsilon^{4\alpha-2\beta+2}\big), \Omega(1)\big\}. \tag{3}$$

In **Case B**, we proceed as follows. In view of Proposition 6, the condition implies that for any $i \in Z$, the intersection of ℓ with $B(K_{i-1}) \setminus \Pi_i$ is less than $\epsilon/2$ shorter than that of $B(K_{i-1})$.

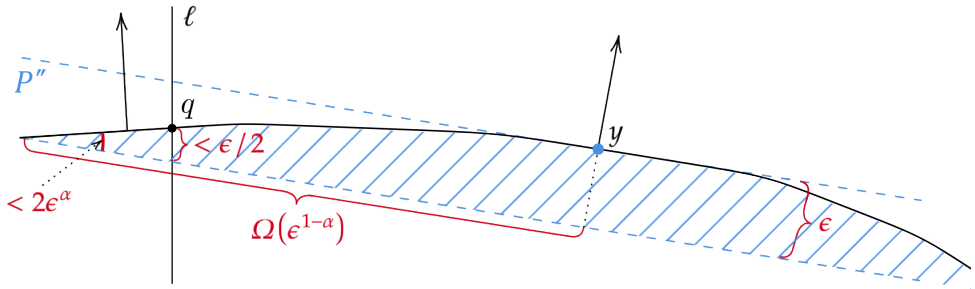

Figure 3 An illustration for the proof of the upper bound in Case B. The convex curve is a portion of the boundary of the intersection of $B(K_{i-1})$ with γ. The shaded area is the part of this intersection covered by the plank P''_i, denoted by Q.

Consider the plane γ spanned by ℓ and a point y at which the upper boundary plane of P''_i touches $B(K_{i-1})$. Set

$$Q := \gamma \cap B(K_{i-1}) \cap P''_i.$$

See Figure 3. If Q intersects ℓ, then let q denote the upper intersection point of the boundary of Q with ℓ. If Q does not intersect ℓ, then let q be the point of Q closest to ℓ, i.e., the endpoint of the "base" of Q closer to ℓ. In both cases, the angle between the normal vector to the boundary of $\gamma \cap B(K_{i-1})$ at q and the normal at y is at most $2\epsilon^\alpha$, because the normal

vectors of all planks $P_1, \dots, P_m$ are within an angle of at most ϵ^α from the vertical direction n (which is the same as the direction of ℓ). The *height* of Q at y, i.e., the intersection of Q with a vertical line through y, is at least ϵ, while its height at q is at most $\epsilon/2$, by the assumption of Case B. This implies that the base of Q has length $\Omega(\epsilon^{1-\alpha})$.

Stepping out of the plane γ, we find that the intersection of P_i'' with $B(K_{i-1})$ cuts out a whole 2-dimensional face. This face contains a disk of radius $\Omega(\epsilon^{1/2})$, since, as before, $B(K_{i-1})$ contains a unit ball that is tangent to the boundary of $B(K_{i-1})$ at the point y. Combining the last two facts, we obtain that the area of the face cut out by P_i'' is $\Omega(\epsilon^{1-\alpha}) \cdot \Omega(\epsilon^{1/2}) = \Omega(\epsilon^{3/2-\alpha})$. Thus, $B(K_{i-1}) \cap P_i''$ contains a cone with base of area $\Omega(\epsilon^{3/2-\alpha})$ and height ϵ. This implies that

$$\text{Vol}\,(B(K_{i-1}) \cap P_i'') = \Omega(\epsilon^{5/2-\alpha}).$$

Therefore, in Case B, we have that

$$\text{Vol}\, B(K_0) - \text{Vol}\, B(K_m) \geq \Omega(m\epsilon^{5/2-\alpha}) = \Omega(\epsilon^{5/2+\alpha-\beta}). \tag{4}$$

To complete the proof of the upper bound in Theorem 4, we iterate the above procedure. Let $k = \epsilon^{-\beta}$. As before, by averaging over directions, for any collection of M planks there exists a direction n such that at least $c\epsilon^{2\alpha}M$ of them have normals within angle ϵ^α of n. In particular, at the first stage we find a subcollection of size $\Theta(\epsilon^{2\alpha-\beta})$ and apply the argument of Cases A and B.

After removing the planks used in this stage, we repeat the same argument on the remaining family. As long as the number of remaining planks is at least $k/2$, the same averaging argument yields at each stage a subcollection of size $\Theta(\epsilon^{2\alpha-\beta})$, so the bounds obtained above apply for each such subcollection.

Since each stage removes at most $O(\epsilon^{2\alpha-\beta})$ planks, after t stages the total number removed is $O(t\epsilon^{2\alpha-\beta})$. Choosing $t = \Omega(\epsilon^{-2\alpha})$ sufficiently small in the constant factor, we ensure that at least $k/2$ planks remain throughout. Thus the procedure can be repeated $\Omega(\epsilon^{-2\alpha})$ times.

Combining (3) and (4), each stage removes volume at least

$$\min\left\{\epsilon^{2+4\alpha-2\beta}, 1, \epsilon^{2\alpha-\beta+5/2-\alpha}\right\}.$$

Therefore the total removed volume of $B(B^3)$ is at least

$$\Omega(\epsilon^{-2\alpha}) \cdot \min\left\{\epsilon^{2+4\alpha-2\beta}, 1, \epsilon^{2\alpha-\beta+5/2-\alpha}\right\} = \Omega\big(\min\left\{\epsilon^{2+2\alpha-2\beta}, \epsilon^{-2\alpha}, \epsilon^{5/2-\beta-\alpha}\right\}\big).$$

Choose α such that $2 + 2\alpha - 2\beta = 5/2 - \alpha - \beta$, that is, $\alpha = \frac{1}{6} + \frac{1}{3}\beta$. Then the above minimum is equal to $\Omega(\min\{\epsilon^{\frac{7}{3}-\frac{4}{3}\beta}, \epsilon^{-\frac{1}{3}-\frac{2}{3}\beta}\})$. In view of (2), if this value is bigger than the volume of $B(B^3)$, then we must have covered the entire ball B^3, and we are done. If we put $\beta = \frac{7}{4}$, then this quantity is $\Omega(1)$. This means that taking $k = C\epsilon^{-7/4}$ with a sufficiently large C is enough to cover B^3.

This completes the proof of the theorem. ◀

4 Concluding remarks

1. In the present note, we focused on the non-dissective covering problem in three dimensions. For $d > 3$, the same lower bound remains valid: indeed, in order to cover a ball in $\mathbb{R}^d$, one needs to cover any of its 3-dimensional sections. One may try to go into the proof and adapt

the lower bound argument to the d-dimensional case. We should then take $\Omega(\epsilon^{-2(d-1)/d})$ points on the sphere with pairwise distances at least $10\epsilon^{2/d}$. The same analysis should lead to a slightly stronger lower bound $\epsilon^{-2(d-1)/d}$. The exponent in the bound does not grow linearly with d, because Lemma 5 guarantees only one "short" direction in the intersection of a plank and the remaining body.

2. The proof of the upper bound can also be extended to $d > 3$, and the resulting bound would be $C_d\epsilon^{-\frac{d+1}{2}+\frac{d-1}{d^2-d+2}}$, which is better than (1), albeit by an additive term in the exponent that tends to 0 as d grows. We believe that neither the lower nor the upper bound is tight.

3. The proof of the upper bound extends to $d > 3$ with only minor changes. Let $k = \epsilon^{-\beta}$ and fix $\alpha > 0$. By averaging over S^{d-1}, there exists a direction n such that at least

$$m = \Theta\left(\epsilon^{(d-1)\alpha-\beta}\right)$$

planks have normals within angle ϵ^α of n, since a spherical cap of angular radius ϵ^α has measure $\Theta(\epsilon^{(d-1)\alpha})$.

We proceed as in Section 3, distinguishing Cases A and B.

Case A. As before, if at least $m/2$ steps reduce the intersection of ℓ with $B(K_i)$ by at least $\epsilon/2$, then we remove from the unit ball a cap of height $\Omega(m\epsilon)$. For $m\epsilon = o(1)$, such a cap has volume $\Omega((m\epsilon)^{(d+1)/2})$. Hence

$$\text{Vol } B(K_0) - \text{Vol } B(K_m) \geq \min\left\{\Omega\left((m\epsilon)^{(d+1)/2}\right), \Omega(1)\right\} = \min\left\{\Omega\left(\epsilon^{\frac{d+1}{2}(1+(d-1)\alpha-\beta)}\right), \Omega(1)\right\}.$$

Case B. The planar argument in γ is unchanged and yields a segment of length $\Omega(\epsilon^{1-\alpha})$. Passing to d dimensions, the boundary of $B(K_{i-1})$ contains a $(d-2)$-dimensional ball of radius $\Omega(\epsilon^{1/2})$, hence the exposed $(d-1)$-dimensional face has measure $\Omega(\epsilon^{d/2-\alpha})$. Therefore

$$\text{Vol } (B(K_{i-1}) \cap P_i'') = \Omega\left(\epsilon^{d/2+1-\alpha}\right),$$

and summing over the m steps gives

$$\text{Vol } B(K_0) - \text{Vol } B(K_m) \geq \Omega\left(m\epsilon^{d/2+1-\alpha}\right) = \Omega\left(\epsilon^{d/2+1+(d-2)\alpha-\beta}\right).$$

Repeating the argument $\Omega(\epsilon^{-(d-1)\alpha})$ times, we obtain a total contribution of order

$$\min\left\{\epsilon^{\frac{d+1}{2}-\frac{d+1}{2}\beta+\frac{(d-1)^2}{2}\alpha}, \epsilon^{-(d-1)\alpha}, \epsilon^{\frac{d}{2}+1-\beta-\alpha}\right\}.$$

Balancing the first and third exponents gives

$$\alpha = \frac{1+(d-1)\beta}{d^2-2d+3}.$$

Substituting and setting the exponent to zero yields

$$\beta = \frac{d+1}{2} - \frac{d-1}{d^2-d+2}.$$

Thus

$$f(d,\epsilon) \leq C_d\,\epsilon^{-\frac{d+1}{2}+\frac{d-1}{d^2-d+2}}.$$

This improves (1), although only by an additive term in the exponent that tends to 0 as $d \to \infty$. We believe that neither the lower nor the upper bound is tight.

4. Our upper bound argument in Section 3 can be easily turned into a polynomial-time algorithm for constructing a cover. Take $k = C\epsilon^{-7/4}$ planks of width ϵ. We first iteratively construct an ordering of the planks which will turn out to guarantee that we end up with a cover. For this, first we (approximately) compute the angle between any two normal vectors and construct a graph G whose vertices are the selected k planks. Two vertices are joined by an edge if the angle between the normal vectors of the corresponding planks is smaller than $\epsilon^\alpha = \epsilon^{3/4}$. Then, at each step, we

(a) find a vertex v whose degree is at least the average degree in G;

(b) include v and its neighbors in the ordering (the order within this set is arbitrary);

(c) modify G by deleting v and its neighbors from G.

In the proof of the upper bound, at each step, we actually work with a chunk of vectors that were included in the ordering in one step.

Finally, we construct the covering, i.e., we find suitable translates of the planks that cover the ball, as follows. For the i-th plank in the ordering, we need to find the maximum (or an approximate maximum) of a linear function over the convex set K that remains from the original ball after removing all points covered by the first $i-1$ planks. Then we modify the set K by including an extra linear inequality in its definition, and repeat the whole procedure, if necessary.

Abstract

It is known that any n-point set in the d-dimensional Euclidean space $\mathbb{R}^d$, for $d = O(1)$, admits:

1. A $(1+\varepsilon)$-spanner with maximum degree $\tilde{O}(\varepsilon^{-d+1})$ and with lightness $\tilde{O}(\varepsilon^{-d})$, for any $\varepsilon > 0$.[1]
2. A $(1+\varepsilon)$-tree cover with $\tilde{O}(n \cdot \varepsilon^{-d+1})$ trees and maximum degree of $O(1)$ in each tree.

Moreover, all the parameters in these constructions are optimal: For any $2 \leq d = O(1)$, there exists an n-point set in $\mathbb{R}^d$, for which any $(1+\varepsilon)$-spanner has $\tilde{\Omega}(n \cdot \varepsilon^{-d+1})$ edges and lightness $\tilde{\Omega}(\varepsilon^{-d})$.

The upper bounds for Euclidean spanners rely heavily on the spatial property of *cone partitioning* in $\mathbb{R}^d$, which does not seem to extend to the wider family of *doubling metrics*, i.e., metric spaces of constant *doubling dimension*. In doubling metrics, a **simple spanner construction from two decades ago, the *net-tree spanner***, has $\tilde{O}(n \cdot \varepsilon^{-d})$ edges, and it could be transformed into a spanner of maximum degree $\tilde{O}(\varepsilon^{-d})$ and lightness $\tilde{O}(n \cdot \varepsilon^{-(d+1)})$ by pruning redundant edges. Moreover, a careful refinement of the net-tree spanner yields a $(1+\varepsilon)$-tree cover with $\tilde{O}(\varepsilon^{-d})$ trees.

Despite a large body of work, the problem of obtaining tight bounds for spanners and tree covers in the wider family of *doubling metrics* has remained elusive. We resolve this problem by presenting:

1. A surprisingly simple and tight lower bound, which shows that the net-tree spanner and its pruned version are optimal with respect to all the involved parameters.
2. A new construction of $(1+\varepsilon)$-tree covers with $\tilde{O}(n \cdot \varepsilon^{-d})$ trees, with maximum degree $O(1)$ in each tree. This construction is optimal with respect to the number of trees and maximum degree.

1 Introduction

1.1 Low-Dimensional Euclidean Spaces

1.1.1 Euclidean Spanners

Let P be a set of n points in the Euclidean space $\mathbb{R}^d, d \geq 2$, and consider the complete weighted graph $G_P = (P, \binom{P}{2}, \|\cdot\|)$ induced by P, where the weight of any edge $(x, y) \in \binom{P}{2}$ is the Euclidean distance $\|xy\|$ between its endpoints. We say that a spanning subgraph $H = (P, E, \|\cdot\|)$ of G_P (with $E \subseteq \binom{P}{2}$) is a *t-spanner* for P, for a parameter $t \geq 1$ that is called the *stretch* of the spanner, if $d_H(x, y) \leq t \cdot \|xy\|$ holds $\forall x, y \in P$. Spanners for Euclidean spaces, or *Euclidean spanners*, were introduced in the pioneering work of Chew [14] from 1986, which gave an $O(1)$-spanner with $O(n)$ edges. The first constructions of Euclidean $(1+\varepsilon)$-spanners, for any parameter $\varepsilon > 0$, were given in the seminal works of [15, 34, 35]) that introduced the *Θ-graph* in 2 and 3-dimensional Euclidean spaces, which was generalized for any Euclidean space $\mathbb{R}^d$ in [45, 2]. The Θ-graph is a natural variant of the *Yao graph*, introduced by Yao [49] in 1982, and can be described as follows.

> **Yao graph:** $\forall p \in P$, the space $\mathbb{R}^d$ around p is partitioned into *cones* of angle Θ each ($O(\Theta^{-d+1})$ cones for $d = O(1)$), and then edges are added between point p and its closest point in each of these cones.

The Θ-graph is defined similarly to the Yao graph: instead of connecting p to its closest point in each cone, connect it to a point whose *orthogonal projection* to some fixed ray contained in the cone is closest to p. Taking Θ to be $c\varepsilon$, for small enough constant c, one can show that the stretch of the Θ and Yao graphs is at most $1+\varepsilon$. Since the number of cones is asymptotically ε^{-d+1} (for $d = O(1)$), the *maximum degree* is $O(\varepsilon^{-d+1})$, leading to a total of $O(n \cdot \varepsilon^{-d+1})$ edges.

The tradeoff between stretch $1+\varepsilon$ and $O(n \cdot \varepsilon^{-d+1})$ edges (and maximum degree $O(\varepsilon^{-d+1})$) is also achieved by other constructions, including the *greedy spanner* [2, 12, 43] and the gap-greedy spanner [46, 4]. The spatial cone partitioning of $\mathbb{R}^d$ is key to attaining the size bound $O(n \cdot \varepsilon^{-d+1})$ in these constructions, either in the constructions themselves or in their analysis. In 2019, Le and Solomon [38] showed that this stretch-size tradeoff is *existentially*

tight: For any constant $d \geq 2$, there exists an n-point set in $\mathbb{R}^d$ (basically a set of evenly spaced points on the d-dimensional sphere), for which any $(1+\varepsilon)$-spanner has $\Omega(n \cdot \varepsilon^{-d+1})$ edges.

Light spanners. Another basic property of spanners is *lightness*, defined as the ratio of a spanner's total weight to the weight of the Minimum Spanning Tree of P. A long line of work [2, 16, 18, 44, 43, 6, 38], starting from the paper of Das et al. [16] in 1993, showed that for any point set in $\mathbb{R}^d$, the greedy $(1+\varepsilon)$-spanner of [2] has constant (depending on ε and d) lightness. The exact dependencies on ε and d in the lightness bound were not explicated in [2, 16, 18]. In their seminal work on approximating TSP in $\mathbb{R}^d$ using light spanners, Rao and Smith [44] showed that the greedy spanner has lightness $\varepsilon^{-O(d)}$, and they raised the question of determining the exact constant hiding in the exponent of their upper bound. The proofs in [2, 16, 18, 44] were incomplete; the first complete proof was given in [43], where a lightness bound of $O(\varepsilon^{-2d})$ was established. This line of work culminated with the work of Le and Solomon [38], which improved the lightness bound to $\tilde{O}(\varepsilon^{-d})$, where we shall use the $\tilde{O}$ and $\tilde{\Omega}$ notations to suppress $\texttt{polylog}(\varepsilon^{-1})$ terms. The exact lightness bound here is $O(\varepsilon^{-d} \cdot \log(1/\varepsilon))$, but for the sake of brevity we will mostly disregard $\texttt{polylog}(\varepsilon^{-1})$ terms from now on. They [38] also showed that this stretch-lightness tradeoff is *existentially tight* (up to a $\log(\varepsilon^{-1})$ factor): for any constant $d \geq 2$, there exists an n-point set in $\mathbb{R}^d$ (the same set of evenly spaced points on the d-dimensional sphere), for which any $(1+\varepsilon)$-spanner has lightness $\Omega(\varepsilon^{-d})$.

1.1.2 Euclidean Tree Covers

A more structured variant of spanners is the *tree cover*, defined as a collection $\mathcal{T}$ of trees for a given graph or metric space such that, for every pair of vertices, there exists a tree in $\mathcal{T}$ that preserves their distance up to a given stretch factor, without shortening distances. Due to their strong structural properties, tree covers play a pivotal role in routing, (path-reporting) distance oracles, and various other algorithmic applications. The first tree cover construction for a graph or metric family was given by Arya et al. [3] – known as the "Dumbbell Theorem" – asserting that any low-dimensional Euclidean space admits a $(1+\varepsilon)$-stretch tree cover of size $O(\varepsilon^{-d} \cdot \log(1/\varepsilon))$, for any $\varepsilon > 0$. The lower bound by Le and Solomon [37] on the size of spanners directly implies that any $(1+\varepsilon)$-stretch tree cover must have size at least $\Omega(\varepsilon^{-d+1})$. Recently, Chang et al. [13] closed this longstanding gap between the upper and lower bounds on the size of tree covers, up to a $\log(1/\varepsilon)$ factor, by improving the size upper bound to $O(\varepsilon^{-d+1} \cdot \log(1/\varepsilon))$. Another important quality measure of tree covers is the maximum degree of a vertex in any tree; in particular, a constant degree tree cover enables compact routing schemes with small routing tables [13]. Chang et al. constructed a constant degree tree cover without increasing the size beyond $O(\varepsilon^{-d+1} \cdot \log(1/\varepsilon))$. Whether the $\log(1/\varepsilon)$ factor separating this upper bound from the lower bound is necessary remains an open problem.

1.2 Doubling Metrics

1.2.1 Doubling Spanners

Euclidean spanners have been extensively studied over the years [34, 35, 2, 17, 3, 18, 4, 44, 26, 22, 1, 7, 24, 9, 19, 48, 20, 38], with a plethora of applications, such as in geometric approximation algorithms [44, 27, 30, 28], geometric distance oracles [27, 30, 29, 28], network design [32, 42] and machine learning [25]. (See the book [43] for an excellent account on

Euclidean spanners and their applications.) There is a growing body of work on *doubling spanners*, i.e., spanners for the wider family of *doubling metrics*;[2] see [22, 8, 7, 31, 23, 24, 47, 10, 20, 11, 48, 6, 41, 33, 40], and the references therein. **A common theme in this line of work is to devise constructions of spanners for doubling metrics that are just as good as the analog Euclidean spanner constructions**. Alas, this may not always be possible, as doubling metrics do not possess the spatial properties of Euclidean spaces – and in particular the spatial property of *cone partitioning*, which is key to achieving the aforementioned stretch-size and stretch-lightness upper bounds. Despite this shortcoming, the basic *packing bound* in doubling metrics can be used to construct, via a simple greedy procedure, a *hierarchy of nets*, which induces the so-called *net-tree* [31, 22, 8]. (See Section 2 for the packing bound and other definitions.) Equipped with such a hierarchy of nets, a $(1+\varepsilon)$-spanner with $\tilde{O}(n \cdot \varepsilon^{-d})$ edges is constructed as follows [31, 22, 8].

Net-tree spanner [31, 22, 8]: Let $X = N_0 \supseteq N_1 \supseteq N_2 \supseteq \ldots \supseteq N_{\lceil \log \Delta \rceil}$ be a hierarchy of nets of a doubling metric (X, d_X) with minimum distance 1 and maximum distance Δ, where N_i is a 2^i-net for N_{i-1}, $1 \leq i \leq \lceil \log \Delta \rceil$.
Let $E_{-1} = \emptyset$ and for each $0 \leq i \leq \lceil \log \Delta \rceil$:

$$E_i = \left\{ (x,y) \mid x,y \in N_i, d_X(x,y) \leq \left(4 + \frac{32}{\varepsilon}\right) 2^i \right\} \setminus E_{i-1} \tag{1}$$

Then $(X, \cup_{0 \leq i \leq \lceil \log \Delta \rceil} E_i, d_X)$ is a $(1+\varepsilon)$-spanner of (X, d_X).

The net-tree spanner is a simple and basic spanner construction from over 20 years ago, and it provides the state-of-the-art size bound, $O(n \cdot \varepsilon^{-d} \cdot \log(1/\varepsilon))$. Le and Solomon [39] presented a unified framework for transforming sparse spanners into light spanners by carefully pruning redundant edges. In particular, for doubling metrics, the framework of [39] provides a pruned spanner, with a lightness bound of $\tilde{O}(\varepsilon^{-(d+1)})$, which is the state-of-the-art lightness bound for doubling metrics. Interestingly, these upper bounds on the size and lightness in doubling metrics exceed the respective Euclidean bounds by a factor of ε^{-1}. Despite a large body of work in the area, it has remained a longstanding open question whether the superior Euclidean bounds of $\tilde{O}(n \cdot \varepsilon^{-d+1})$ edges and lightness $\tilde{O}(\varepsilon^{-d})$ could be achieved also in doubling metrics.

▶ **Question 1.** *Can one get a construction of $(1+\varepsilon)$-spanners in doubling metrics with $\tilde{O}(n \cdot \varepsilon^{-d+1})$ edges and/or lightness $\tilde{O}(\varepsilon^{-d})$?*

This question is related to a possibly deeper question, regarding the (im)possibility to generalize the spatial cone partitioning in $\mathbb{R}^d$ to arbitrary doubling metrics.

1.2.2 Doubling Tree Covers

Bartal et al. [5] constructed a tree cover of size $O(\varepsilon^{-d} \cdot \log(1/\varepsilon))$ using the net-tree by redistributing cross edges at each level into color classes. However, in their construction, a vertex in one of the trees may have many children, resulting in unbounded degree, potentially as large as $\log(\Delta)$, where Δ is the aspect ratio. Motivated by the Euclidean setting, it is natural to ask whether one can obtain a tree cover with bounded degree in doubling metrics.

[2] The *doubling dimension* of a metric space is the smallest value d such that every ball B in the metric can be covered by at most 2^d balls of half the radius of B; a metric space is called *doubling* if its doubling dimension is constant. The doubling dimension generalizes the standard Euclidean dimension, as the doubling dimension of the Euclidean space $\mathbb{R}^d$ is $\Theta(d)$.

▶ **Question 2.** *Can one construct a $(1+\varepsilon)$-tree cover in doubling metrics whose maximum degree is an absolute constant, i.e., $O(1)$, while having size $\tilde{O}(\varepsilon^{-d})$?*

1.3 Our contribution

We give a negative answer to Question 1 by a **surprisingly simple** and tight lower bound.

▶ **Theorem 1.** *For any integer constant $d \geq 1$, parameter $\varepsilon \in (0,1)$, and $n \in \mathbb{Z}^+$ satisfying $\varepsilon^{-d} = O(n)$, there exists an n-point ultrametric space (X, d_X) of doubling dimension d such that any $(1+\varepsilon)$-spanner $G = (X, E, w)$ for X has $\Omega(n \cdot \varepsilon^{-d})$ edges and lightness $\tilde{\Omega}(\varepsilon^{-(d+1)})$.*

Since the net-tree spanner has sparsity [3] $O(\varepsilon^{-d})$ [22], our lower bound shows, in particular, that **the net-tree spanner is optimal**; this is our **key conceptual contribution**.

Second, **as our main technical contribution**, we show that a tree cover with constant degree and nearly optimal size is achievable, resolving Question 2 affirmatively.

▶ **Theorem 2.** *For any metric (X, d_X) with doubling dimension d, parameter $0 < \varepsilon < 1$, there exists a $(1+\varepsilon)$-stretch tree cover $\mathcal{T}$ of size $\tilde{O}\left(\varepsilon^{-d}\right)$, where each tree in $\mathcal{T}$ has maximum vertex degree $O(1)$.*

To complement our result, Theorem 3 shows that it is impossible to eliminate the $\mathsf{polylog}(1/\varepsilon)$ factor from the size of any constant-degree tree cover (the detailed proof is provided in Appendix A of the full version of this paper).

▶ **Theorem 3.** *For any integer constant $d \geq 1$, any parameter $\varepsilon \in (0,1)$, and any $n \in \mathbb{Z}^+$ satisfying $\varepsilon^{-d} = O(n)$, there exists an n-point ultrametric space (X, d_X) of doubling dimension d such that any $(1+\varepsilon)$-spanner $G = (X, E, w)$ for X has maximum degree $\Omega(\log(1/\varepsilon) \cdot \varepsilon^{-d})$.*

Theorem 3 demonstrates an inherent multiplicative gap of $\log(1/\varepsilon)$ between the maximum degree and the optimal sparsity of $(1+\varepsilon)$-spanners in doubling metrics, a gap that does not appear in Euclidean spaces. Although Theorem 3 is not the main focus of our work, it provides an interesting separation between Euclidean and doubling metrics. Moreover, it shows that the $\mathsf{polylog}(1/\varepsilon)$ term in Theorem 2 (hidden via the $\tilde{O}$-notation) is unavoidable in doubling metrics, whereas its necessity in Euclidean spaces remains an open question.

1.4 Technical Overview

Our tree cover construction provides the key technical contribution of this work. In what follows, we provide a technical overview of this construction.

Our tree cover construction relies on a hierarchical structure – specifically, the standard *net-tree* – and builds a tree cover so that every cross edge e (i.e., every edge in E_i) is contained in some tree. For every pair of points (u, v), there exists a cross edge (u', v') such that the path from u to v that goes through (u', v') provides a good approximation of $d_X(u, v)$. The distance between u and v is then preserved by the tree T that contains (u', v'); in this case, we say that (u, v) is covered by T.

The construction proceeds in two phases. In Phase 1, we partition the cross edges into congruent classes according to their levels modulo $\log(1/\varepsilon)$, and handle each class independently. For each class, we distribute the cross edges into each tree in our tree cover. Note that after Phase 1, we already obtain a tree cover of stretch $(1+\varepsilon)$ and size $\tilde{O}(\varepsilon^{-d})$.

[3] The *sparsity* of a spanner H is the ratio between number of edges in H over $n-1$, for $n > 1$.

In Phase 2, for a fixed level, we replace edges in a controlled manner to obtain the required bounded degree property, without significantly increasing the stretch. The desired $(1+\varepsilon)$ stretch bound can then be recovered by a simple scaling argument.

Our Phase 2 is inspired by the degree-reduction procedure of [13]. To achieve constant degree, we proceed in two steps. First, using the technique in [8], we reroute the edges in each tree T in the cover produced by Phase 1, obtaining trees of maximum degree $\varepsilon^{-O(d)}$, while the stretch increases only to $1+O(\varepsilon)$. Second, we use the rerouting technique in [13] to obtain absolute constant maximum degree. For each vertex u in each such tree T, we replace the edges connecting u to its children by a binary tree. Suppose that l is the maximum distance from (the representative of) u to its children, this step incurs an additive distortion of $\Theta(\log(\varepsilon^{-d})\cdot l)$ for every pair of points covered by T.

A key technical challenge in integrating Phase 2 into Phase 1 is that the edges replaced by binary trees must be sufficiently short relative to the cross edges at the same level. Otherwise, the additive distortion for a pair (u,v) might become comparable to $d(u,v)$ itself, producing a stretch larger than 2. In the construction of [5], a point u in a tree T may be incident to ε^{-d} cross edges of nearly equal length; applying Phase 2 on top of [5] would therefore not yield a tree cover with good stretch.

Our first idea is to ensure that, in Phase 1, for every level we partition the cross edges into $O(\varepsilon^{-d})$ sets such that in each tree of the resulting cover, every point u is incident to *at most one* edge from each set. This motivates partitioning E_i into sets of *matchings*.

We implement Phase 1 as follows. We initialize tree cover $\mathcal{T}$ with $\tilde{O}(\varepsilon^{-d})$ empty forests. For each congruent class modulo $\log(1/\varepsilon)$, we process the levels in increasing order. For each level i, we partition E_i into sets of matchings $\mathcal{M}_i$. For each matching $M\in\mathcal{M}_i$, we assign M to forest $F\in\mathcal{T}$, and add all edges in M to F. We continue this process until the top level.

A second challenge is ensuring that the graph F remains a forest after inserting the edges of M. Specifically, we guarantee that for any two edges (u,v) and (u',v') in M, there is no tree in the forest F containing both u and u'. This leads to our second idea: each matching M must be *pairwise far*. That is, for every $M\in\mathcal{M}_i$ and every two distinct edges $e,e'\in M$, the distance between (any two endpoints of) e and e' must be at least $\Theta(2^i)$. Under this condition, an inductive argument shows that every tree in each forest F has small diameter $(<2^i)$; thus, after connecting each tree to an edge in M, a sufficient separation still remains, ensuring that the resulting graph is indeed a forest. Such matchings, also known as *red–blue matchings*, were also used by [21, 36] in different contexts.

2 Preliminaries

Let (X,d_X) be a metric space. The *aspect ratio* Δ of X is the ratio of its largest to smallest pairwise distances. The following definitions are crucial for our construction and proofs.

▶ **Definition 4** (r-net). *For a metric space (X,d_X), an r-net $N\subseteq X$ is a set satisfying:*
1. ***[Packing]*** *for every distinct $u,v\in N$, $d_X(u,v)>r$*
2. ***[Covering]*** *for every $x\in X$, there exists $u\in N$ such that $d_X(u,x)\le r$.*

▶ **Definition 5** ((α,β)-Net Tree). *An (α,β)-net tree τ is induced by a hierarchy of nets $N_{-1}=X,N_0,N_1,\ldots,N_{\log\Delta}$ at levels $-1,0,1,\ldots,\log\Delta$ of τ resp., satisfying the following:*
1. *(Hierarchy) $N_i\subseteq N_{i-1}$ for every $i\in[\log\Delta]$.*
2. *(Net) For every $i\in\{0,1,\ldots,\log\Delta\}$, N_i is an $(\alpha\cdot\beta^i)$-net of N_{i-1}.*

The following lemma gives the basic packing bound of doubling metrics.

▶ **Lemma 6** (Packing Lemma). *Metric (X, d_X) has doubling dimension d. If $S \subseteq X$ is a subset with pairwise distance at least r that is contained in a ball of radius R, then $|S| \leq \left(\frac{4R}{r}\right)^d$.*

▶ **Definition 7** (Ultrametric). *An* ultrametric *(X, d_X) is a metric space that satisfies the strong triangle inequality, i.e., for any $u, v, w \in X$, we have $d_X(u, w) \leq \max\{d_X(u, v), d_X(v, w)\}$.*

▶ **Definition 8** (k-HST). *Let $k > 1$ be a fixed constant. A metric space (X, d_X) is a k-*hierarchical well-separated tree (k-HST) *if there exists a bijection ϕ from X to leaves of a rooted tree T in which:*

1. *Each node $v \in T$ is associated with a label $\Gamma(v)$ such that $\Gamma(v) = 0$ if v is a leaf, and $\Gamma(v) \geq k \cdot \Gamma(u)$ $(\Gamma(v) > 0)$ if v is an internal node and u is a child of v.*
2. *$d_X(x, y) = \Gamma(\texttt{LCA}(\phi(x), \phi(y)))$, where $\texttt{LCA}(u, v)$ is the lowest common ancestor of u, v.*

Lastly, we defer some proofs of lemmas/claims (marked by $(\star)$) to the appendix of the full version.

3 Sparsity and Lightness Lower Bounds for $(1 + \varepsilon)$-Spanners.

This section is devoted to the proof of Theorem 1. We state it again below:

▶ **Theorem 1.** *For any integer constant $d \geq 1$, parameter $\varepsilon \in (0, 1)$, and $n \in \mathbb{Z}^+$ satisfying $\varepsilon^{-d} = O(n)$, there exists an n-point ultrametric space (X, d_X) of doubling dimension d such that any $(1 + \varepsilon)$-spanner $G = (X, E, w)$ for X has $\Omega(n \cdot \varepsilon^{-d})$ edges and lightness $\tilde{\Omega}(\varepsilon^{-(d+1)})$.*

We begin by constructing an ultrametric space (X, d_X) for which we later prove that any $(1 + \varepsilon)$-spanner must satisfy the size and lightness lower bound.

Without loss of generality, assume that n is a power of 2^d. More specifically, if n is not a power of 2^d, let $\tilde{n} = (2^d)^\ell$ be the largest integer power of 2^d before n, with $\tilde{n} \geq n/2^d$, and apply the argument to $\tilde{n}$ instead of n. The size lower bound will decrease by at most an $O(1)$ factor 2^d and the lightness lower bound will remain the same.

We define the following 2-HST (X, d_X). Let T be a rooted perfect 2^d-ary tree with n leaf nodes: all leaf nodes are at the same depth $\log_{2^d} n = \frac{\log_2 n}{d}$ and each internal node has 2^d children. The *height* of a node is its distance to the closest leaf, so the leaf nodes have height 0, their parents have height 1, and so on, until reaching the root, at height $\frac{\log_2 n}{d}$. For each node v in the tree we assign a label, denoted by $\Gamma(v)$. Each leaf node is assigned label 0, and each node of height $i = 1, \ldots, \frac{\log_2 n}{d}$ is assigned label 2^i. For any $x, y \in T$, we denote the *lowest common ancestor* of x and y by $\texttt{LCA}(x, y)$. Let ψ be any arbitrary bijection mapping X to the leaf nodes of T. For any $u, v \in X$, we define $d_X(u, v)$ to be $\Gamma(\texttt{LCA}(\psi(u), \psi(v)))$.

We start with the following basic observation in Claim 9. Although to the best of our knowledge, this precise statement does not appear in previous work, weaker (though similar) versions of this statement can be found in [7, 21].

▷ Claim 9. (X, d_X) is an ultrametric space of doubling dimension d.

Proof. First, we argue that (X, d_X) is an ultrametric space. By the definition of d_X, we have $d_X(u, v) = 0$ iff $u = v$. Further, $d_X(u, v) = d_X(v, u)$ holds for any $u, v \in X$ since $\texttt{LCA}(\psi(u), \psi(v)) = \texttt{LCA}(\psi(v), \psi(u))$. It remains to show $d_X(u, v) \leq \max\{d_X(u, w), d_X(w, v)\}$, for any $u, v, w \in X$. Let T_u (T_v) denote the subtree rooted at the child node of $\texttt{LCA}(\psi(v), \psi(u))$ that contains $\psi(u)$ $(\psi(v))$. Note that for any $w \in X$, $\psi(w)$ cannot belong to both T_u and T_v, so either $\texttt{LCA}(\psi(v), \psi(w))$ is not contained in T_v, or $\texttt{LCA}(\psi(u), \psi(w))$ is not contained in T_u. Thus, $d_X(u, v) \leq \max\{d_X(u, w), d_X(w, v)\}$ holds.

Second, we prove that (X, d_X) has doubling dimension d.

We first show that the doubling dimension is no smaller than d. Let $B(u, r)$ be a ball centered at $u \in X$ with radius $r \in \mathbb{R}^+$. Let $\psi(f_u)$ be the parent of $\psi(u)$ in T. Consider $r = 2$. By the construction of T, every point $v \in X$ corresponding to a child of $\psi(f_u)$ satisfies $d_X(u, v) = \Gamma(\psi(u), \psi(v))$. Hence, $B(u, 2)$ contains all points corresponding to the children of $\psi(f_u)$, and contains at least 2^d distinct points. On the other hand, for any $v \in X$, the ball $B(v, 1)$ contains only the single point v. Hence, covering $B(u, 2)$ requires at least 2^d balls of radius 1. This implies that the doubling dimension is no smaller than d.

Then, we show that the doubling dimension of (X, d_X) is no bigger than d. When $r < 2$, $B(u, r)$ contains only one point u and is covered by $B(u, \frac{r}{2})$. When $2^i \leq r < 2^{i+1}$ for some integer $i \geq 1$, let ω be the ancestor of $\psi(u)$ of height i in T and let T_ω be the subtree rooted at ω. By the construction of T, all pairwise distances between the points corresponding to the leaf nodes of T_ω are no larger than the label 2^i of ω. On the other hand, the distance between u and any point corresponding to a leaf node outside T_ω is no smaller than the label 2^{i+1} of the parent node of ω, as their lowest common ancestor is outside T_ω. Thus, $B(u, r)$ consists of the $(2^d)^i = 2^{d \cdot i}$ points that correspond to the leaf nodes of T_ω. Let L_j be the set of points corresponding to the leaves of the subtree rooted at the jth child of ω, for each $j \in [2^d]$, and let v_j be an arbitrary point in L_j. Since all children of ω have label 2^{i-1}, all pairwise distances between the points in L_j are no larger than 2^{i-1}. So $B(v_j, \frac{r}{2}) \supseteq B(v_j, 2^{i-1})$ covers all $(2^d)^{i-1} = 2^{d \cdot (i-1)}$ points in L_j, for each $j \in [2^d]$, implying that the ball $B(u, r)$ can be covered by the 2^d balls $B(v_j, \frac{r}{2}), j \in [2^d]$. ◁

Then, we demonstrate the following property of (X, d_X) in Claim 10 that will be crucial for proving the size and lightness lower bounds.

▷ Claim 10. Let $G = (X, E, w)$ be an arbitrary $(1 + \varepsilon)$-spanner for (X, d_X). For any point pair $u, v \in X$ such that $d_X(u, v) < \frac{2}{\varepsilon}$, edge (u, v) must be in G.

Proof. Consider any pair $u, v \in X$. We first argue that if edge (u, v) is not in G, then $d_G(u, v) \geq d_X(u, v) + 2$. In this case, consider a shortest path from u to v in G, and note that it traverses an intermediate point $w \in X$. By the triangle inequality, $d_G(u, v) \geq d_G(u, w) + d_G(w, v) \geq d_X(u, w) + d_X(w, v)$. Since the minimum pairwise distance is 2 and (X, d_X) is an ultrametric, $d_G(u, v) \geq d_X(u, w) + d_X(w, v) = \max\{d_X(u, w), d_X(w, v)\} + \min\{d_X(u, w), d_X(w, v)\} \geq d_X(u, v) + 2$.

We conclude that if $d_X(u, v) < \frac{2}{\varepsilon}$, then edge (u, v) must be in G, otherwise by the above assertion we would get $d_G(u, v) \geq d_X(u, v) + 2 > (1 + \varepsilon) d_X(u, v)$, which is a contradiction to G being a $(1 + \varepsilon)$-spanner for (X, d_X). ◁

In the following subsections, we apply Claim 10 to prove the size and lightness lower bounds of any $(1 + \varepsilon)$-spanner $G = (X, E, w)$ for (X, d_X).

Size lower bound. Let $D_{\max}$ be the largest label among nodes in T that is strictly smaller than $\frac{2}{\varepsilon}$. Since the labels in T grow geometrically by a factor of 2, there exists a label in $\left[\frac{1}{\varepsilon}, \frac{2}{\varepsilon}\right)$, hence $\frac{1}{\varepsilon} \leq D_{\max} < \frac{2}{\varepsilon}$. Let $i_{\max} = \log(D_{max}) \geq \log(\frac{1}{\varepsilon})$ be the height of nodes with label D_{max}. Each subtree of height $i_{\max}$ has $(2^d)^{i_{\max}} \geq \varepsilon^{-d}$ leaf nodes (this is where the restriction $\varepsilon^{-d} = O(n)$ comes into play) and the pairwise distances between the corresponding points are bounded by $D_{max} < \frac{2}{\varepsilon}$, hence Claim 10 implies that the spanner G connects all these points by a clique. Thus each point in X has a degree of at least $\varepsilon^{-d} - 1$ in G, and so G contains at least $n(\varepsilon^{-d} - 1)/2 = \Omega(n \cdot \varepsilon^{-d})$ edges, which proves the size lower bound.

Lightness lower bound. We begin by giving the lower bound on the weight of G. Consider an arbitrary point $u \in X$ and denote the subtree rooted at the ancestor of $\psi(u)$ at level $i_{\max}$ as $T_{i_{\max}}(u)$. We have shown that u is connected to all $(2^d)^{i_{\max}} \geq \varepsilon^{-d}$ points corresponding to the leaf nodes in $T_{i_{\max}}(u)$. Note also that only $(2^d)^{i_{\max}-1}$ points among those may belong to the child subtree of $T_{i_{\max}}(u)$ that contains $\psi(u)$, while the remaining $(2^d)^{i_{\max}} - (2^d)^{i_{\max}-1} \geq \varepsilon^{-d}/2$ points belong to other child subtrees of $T_{i_{\max}}(u)$, and are therefore at distance $D_{max} = 2^{i_{\max}} \geq 1/\varepsilon$ from u. Thus the total weight of edges incident on any point $u \in X$ in G is at least $\varepsilon^{-d}/2 \cdot (1/\varepsilon) = \varepsilon^{-(d+1)}/2$, and so the weight of G is at least $n \cdot \varepsilon^{-(d+1)}/4 = \Omega(n \cdot \varepsilon^{-(d+1)})$.

Claim 11 concludes the proof of the lightness lower bound for $d \geq 2$. As for $d = 1$, Claim 11 is not enough, since we need $w(\mathrm{MST}_X)$ to be $O(n \cdot \log(\varepsilon^{-1}))$ rather than $O(n \log n)$ to obtain the required lightness bound; we will handle this issue after the proof of Claim 11.

▷ Claim 11. $w(\mathrm{MST}_X) = O(n)$ for any $d \geq 2$ and $w(\mathrm{MST}_X) = O(n \log n)$ for $d = 1$.

Proof. Let P_X be the Hamiltonian path of X that traverses the points of X according to the induced left-to-right ordering in T of the corresponding leaves. To prove the claim, we will show that $w(P_X) = O(n)$ for any $d \geq 2$ and $w(P_X) = O(n \log n)$ for $d = 1$. (It can be shown that $P_X = \mathrm{MST}_X$, but there is no need for that, since we only need to upper bound $w(\mathrm{MST}_X)$ and we have $w(P_X) \geq w(\mathrm{MST}_X)$.)

Denote the root of T by r, and note that $\Gamma(r) = 2^{\frac{\log_2 n}{d}} = n^{1/d}$. Observe that the number of edges in P of weight $\Gamma(r) = n^{1/d}$ is exactly one less than the number of children, i.e., $2^d - 1$. In general, note that the number of edges in P of weight $\frac{\Gamma(r)}{2^i} = \frac{n^{1/d}}{2^i}$ is $2^{d \cdot i}(2^d - 1)$, for each $i \in [0, \frac{\log_2 n}{d} - 1]$. It follows that

$$w(P_X) = \sum_{i=0}^{\frac{\log_2 n}{d}-1} 2^{d \cdot i}(2^d - 1) \cdot \frac{n^{1/d}}{2^i} = (2^d - 1) \cdot n^{1/d} \cdot \sum_{i=0}^{\frac{\log_2 n}{d}-1} (2^{d-1})^i.$$

If $d = 1$, we get that $w(P_X) = n \cdot \log_2 n$.
If $d \geq 2$, then $\sum_{i=0}^{\frac{\log_2 n}{d}-1} (2^{d-1})^i$ is a geometric sum with rate $2^{d-1} \geq 2$, hence we have

$$\sum_{i=0}^{\frac{\log_2 n}{d}-1} (2^{d-1})^i \leq 2 \cdot 2^{(d-1)\cdot(\frac{\log_2 n}{d}-1)} = 2 \cdot 2^{\log_2 n - d - \frac{\log_2 n}{d} + 1} = 4 \cdot \frac{n}{2^d \cdot n^{1/d}},$$

and we get that $w(P_X) = (2^d - 1) \cdot n^{1/d} \cdot \sum_{i=0}^{\frac{\log_2 n}{d}-1} (2^{d-1})^i \leq 4n$. ◁

Finally, consider the case $d = 1$. Claim 11 gives $w(\mathrm{MST}_X) = O(n \log n)$, but to get the required lightness bound we need an upper bound of $w(\mathrm{MST}_X) = O(n \cdot \log(\varepsilon^{-1}))$.

Without loss of generality, we may assume that $n = n'$ and that $n' = \Theta(\varepsilon^{-1})$. In this case, Claim 11 implies that $w(\mathrm{MST}_X) = O(n' \log n') = O(n' \log(\varepsilon^{-1}))$, and the lightness of G is $\Omega(\frac{\varepsilon^{-2}}{\log(\varepsilon^{-1})})$, as required. We introduce two different reductions justifying this assumption.

First, one can simply take the same ultrametric as before on top of n' points (instead of n) as leaves, and then add $n - n'$ points that are arbitrarily close to one of the n' points, to get a metric space with n points and basically the same MST weight; while this reduction provides the required lightness lower bound, it does not preserve the size lower bound.

To get a single instance for which both lower bounds apply, one can do the following. Create n/n' vertex-disjoint copies of the same ultrametric (X, d_X) as before, each on top of n' points as leaves, denoted by $(X^{(j)}, d_{X^{(j)}})$, for each $j \in [n/n']$, and place these copies "on a line", so that neighboring copies $(X^{(j)}, d_{X^{(j)}})$ and $(X^{(j+1)}, d_{X^{(j+1)}})$ are at distance say $2n'$ from each other. Since any two copies are sufficiently spaced apart from each other

(w.r.t. the maximum pairwise distance in each copy, namely n'), any $(1+\varepsilon)$-spanner edge between two points in the same copy must be contained in that copy, hence we can apply the aforementioned size and weight spanner lower bounds on each of the copies separately, and then aggregate their size and weight bounds to achieve the same size and weight lower bounds as before, namely $\Omega(n \cdot \varepsilon^{-1})$ and $\Omega(n \cdot \varepsilon^{-2})$, respectively, for the entire spanner. Since each copy has weight $O(n' \log n')$ by Claim 11 and as neighboring copies are sufficiently close to each other, the MST weight of this metric is bounded by $O(n' \log n') \cdot (n/n') = O(n \cdot \log(\varepsilon^{-1}))$, which proves the required lightness lower bound $\Omega(\frac{\varepsilon^{-2}}{\log(\varepsilon^{-1})})$.

4 Bounded Degree Tree Cover

▶ **Theorem 2.** *For any metric (X, d_X) with doubling dimension d, parameter $0 < \varepsilon < 1$, there exists a $(1+\varepsilon)$-stretch tree cover $\mathcal{T}$ of size $\tilde{O}(\varepsilon^{-d})$, where each tree in $\mathcal{T}$ has maximum vertex degree $O(1)$.*

4.1 Phase 1: Unbounded Degree Tree Cover

▶ **Lemma 12.** *For any metric (X, d_X) with doubling dimension d, and any parameter $0 < \varepsilon < 1$, there is a $(1+\varepsilon)$-stretch tree cover $\mathcal{T}$ of size $O\left(\varepsilon^{-d} \cdot \log(1/\varepsilon)\right)$, where the maximum degree of a vertex in each of the trees in $\mathcal{T}$ is $O(\varepsilon^{-d} \log_{1/\varepsilon} \Delta)$.*

We first give a construction of a tree cover with maximum degree $O(\varepsilon^{-d} \log_{1/\varepsilon} \Delta)$. Later, in Section 4.2, we modify this tree cover to get constant degree bound.

1. **Creating intra-level edge matchings.** Let $\delta_p = 2^p$ for $p \in \{0, \ldots, \lfloor \log(1/\varepsilon) \} \rfloor$, and let τ_{δ_p} be a $(\delta_p, \varepsilon^{-1})$-net tree (see Definition 5) of X and N_i be the $\delta_p \varepsilon^{-i}$-net in τ_{δ_p}. For each p, construct graph G_p, where $V(G_p) = \{u_i \mid u \in N_i\}_{\forall i \in \mathbb{N}}$ and $E(G_p) = \emptyset$. Define a set of *cross edges* $E_c = \{(u_i, v_i) \mid d_X(u,v) \in (\frac{\delta_p}{3\varepsilon^{i+1}}, \frac{4 \cdot \delta_p}{3\varepsilon^{i+1}})\}_{\forall i}$. Partition E_c into $\gamma = O(\varepsilon^{-d})$ matchings $\mathcal{M} = \{M_1, \ldots, M_\gamma\}$, with the property that in each $M \in \mathcal{M}$, $d_X(u_i, v_i) > \frac{14\delta_p}{\varepsilon^i}$, for all matched u_i, v_i. Initialize $T_k^p = (V(G_p), M_k)$ for $k \in \{1, \ldots, \gamma\}$.
2. **Creating inter-level edges.** For each $T = T_k^p$, construct edges between levels i and $(i-1)$ in the order $i = 0, 1, \ldots$. Create a relabel function $\Phi_i^T : N_i \to N_i$, initialized as $\Phi_i^T(u_i) = u_i$ for all $u_i \in N_i$. At each level i, process vertices in the order specified below:
   a. **Matched vertices.** For each matched u_i in M_k, add (u_i, u_{i-1}). For $v \in B_X(u, \frac{4\delta_p}{\varepsilon^i})$ such that v_{i-1} exists, add (u_i, v_{i-1}) if either v_{i-1} is unmatched, or $(v_{i-1}, x_{i-1}) \in M_k$ and x_{i-1} does not have a parent at level i.
   b. **Unmatched vertices.** For each unmatched u_i: enumerate its child nodes in net-tree τ_{δ_p}, denoted by $C_{u_i} = \{a_{i-1}^0, a_{i-1}^1, \ldots, a_{i-1}^\eta\}$. For every $a_{i-1} \in C_{u_i}$:
      - Add $(\Phi_i^T(u_i), a_{i-1})$ in the following cases: 1) a_{i-1} is unmatched and does not have a parent, and 2) $(a_{i-1}, b_{i-1}) \in M_k$ and both a_{i-1}, b_{i-1} do not have parents at level i.
      - Otherwise, if a_{i-1} has a parent x_i, or $(a_{i-1}, b_{i-1}) \in M_k$ and b_{i-1} has a parent x_i, merge x_i with $\Phi_i^T(u_i)$. Set $\Phi_i^T(x_i) = \Phi_i^T(u_i)$ if u_{i+1} exists, otherwise set $\Phi_i^T(u_i) = x_i$. (Note that a_{i-1} and b_{i-1} will not have parents at the same time.)
3. **Contraction.** Contract all vertices sharing label u. $\mathcal{T} = \{T_k^p\}_{p,k}$ forms a tree cover.

Throughout the construction (even after relabeling), the weight of any edge, $w_T(u_i, v_j) = d_X(u, v)$. In Step 2, we slightly abuse the notation, setting $\Phi_i^T(u_i) = x_i$, instead of $\Phi_i^T(\Phi_i^T(u_i)) = x_i$. This is fine, since a node undergoes relabeling at most once. This finishes the construction of the tree cover.

Unless stated otherwise, we refer to the intermediate trees just prior to Step 3 as the tree cover $\mathcal{T}$ and prove our bounds on them. This works since the contraction of only 0-weight edges in Step 3 does not affect the stretch.

We first prove that each T in $\mathcal{T}$, after contraction, is a tree (see Corollary 16). Then, we bound the number of trees in $\mathcal{T}$ (see Lemma 17). Finally, we use Claim 18 and Claim 19 to bound the final stretch in Lemma 20 (proof deferred to the Appendix B of the full version).

We first require the following combinatorial lemma of [21], used in Step 1 of our construction.

▶ **Lemma 13** (Lemma 6 of [21]). *Consider a graph $G = (V, E_b \cup E_r)$ with disjoint sets of blue edges E_b and red edges E_r, such that the maximum blue degree is $\delta_b \geq 1$, and the maximum red degree is $\delta_r \geq 1$. Then there is a set of at most $\gamma = O(\delta_b \delta_r)$ matchings $\mathcal{M} = \{M_1, \ldots, M_\gamma\}$ of G such that:*

1. *$E_b \subseteq \cup_{i=1}^{\gamma} M_i$, and*
2. *for every matching $M \in \mathcal{M}$, there is no red edge whose both endpoints are matched by M.*

▶ Remark 14. Note that we apply this lemma in Step 1 of the construction. More specifically, $E_b = E_c = \{(u_i, v_i) \mid d_X(u, v) \in (\frac{\delta_p}{3\varepsilon^{i+1}}, \frac{4\delta_p}{3\varepsilon^{i+1}})\}_{\forall i}$, and $E_r = \{(u_i, v_i) \mid d_X(u, v) \leq \frac{14\delta_p}{\varepsilon^i}\}$. In each $M \in \mathcal{M}$, $d_X(u_i, v_i) > \frac{14\delta_p}{\varepsilon^i}$ holds for all matched u_i, v_i.

We begin by proving that each $T_k^p \in \mathcal{T}$ is a tree. We rely on the following inductive invariant: after processing the i^{th} level, every level-i subtree has a diameter at most $O(\varepsilon)$ factor of the newly added level-i cross edge. This large separation ensures that the forest remains a forest.

▶ **Lemma 15.** *Each $T_k^p \in \mathcal{T}$ is a tree.*

Proof. Let $T = T_k^p$. We will prove the following two properties. First, each vertex at level-i is connected to at most one vertex at level-$(i+1)$. Second, for every level-i cross edge, at most one of the end points is connected to a level-$(i+1)$ vertex. These two arguments are sufficient condition for T to be acyclic since all cross edges are mutually vertex-disjoint.

We begin by proving that these two properties hold in Step 2a. For any vertex $v_{i-1} \in B_X(u, \frac{4\delta_p}{\varepsilon^i})$ and u_i is a matched vertex of T, v_i cannot also be a matched vertex of T since $d_X(u, v) > \frac{14\delta_p}{\varepsilon^i}$ should hold by Lemma 13. Hence, any vertex v_{i-1} is connected to at most one vertex at level-$(i+1)$. For any matched cross edge $(u_{i-1}, v_{i-1}) \in T$, we have $d_X(u, v) \in (\frac{\delta_p}{3\varepsilon^i}, \frac{4\delta_p}{3\varepsilon^i})$, in which case u_i and v_i cannot both be matched vertices in level-i since this requires $d_X(u, v) > \frac{14\delta_p}{\varepsilon^i}$. Thus, (u_i, u_{i-1}) and (v_i, v_{i-1}) will not be added at the same time, and (u_{i-1}, v_{i-1}) cannot have parents at both endpoints. Next, by construction (Step 2b), the two properties hold. This is because an edge between some a_{i+1} and b_i is created only when either b_i is unmatched and does not have a parent, or some (b_i, c_i) exists and neither of b_i or c_i have a parent. At each level of the net tree τ_{δ_p}, we go over all vertices.

Let rt be the vertex at the highest level of T. For any two vertices $u, v \in V(T)$, we know that there is a path from u to rt, and from v to rt in T. This holds because each vertex is either connected to a vertex one level above, or to another vertex at the same level via a cross edge (since each such vertex is enumerated in Step 2b). Hence, there is a walk between u and v via rt in T. This implies that T is connected. ◀

▶ **Corollary 16.** ($\star$) *After the contraction procedure, each T_k^p in $\mathcal{T}$ remains a tree.*

▶ **Lemma 17.** *The number of trees in $\mathcal{T}$ is $O(\varepsilon^{-d} \log(1/\varepsilon))$.*

Proof. For each G_p ($p \in \{0, 1 \ldots, \lfloor \log(1/\varepsilon) \rfloor\}$, we take $V = V(G_p)$, $E_b = E_c$. We define a set of dummy edges in G_p: $E_r = \{(u_i, v_i) \mid d_X(u, v) \leq \frac{14\delta_p}{\varepsilon^i}\}_{\forall i}$. By packing lemma, the maximum degree in E_b at each level i is $O((\delta_p\varepsilon^{-(i+1)}/\delta_p\varepsilon^{-i})^d) = O(\varepsilon^{-d})$.

Similarly, the maximum degree in E_r is $O(14\delta_p\varepsilon^{-i}/\delta_p\varepsilon^{-i})^d = c^d$ for some constant c. We can now invoke Lemma 13 on $G = (V, E_b \cup E_r)$ with $\delta_b = O(\varepsilon^{-d})$ and $\delta_r = c^d$ to get $O((c\varepsilon^{-1})^d) = O(\varepsilon^{-d})$ matchings (each corresponding to a tree) with the required properties. Hence, the total number of trees in $\mathcal{T}$ is $O(\gamma \cdot \log(1/\varepsilon)) = O(\varepsilon^{-d} \log(1/\varepsilon))$. ◀

▷ Claim 18. ($\star$) Let $T = T_k^p$. Let (a_i, b_i) be a cross edge and (c_i, d_{i-1}) be an inter-level edge in T. For $\varepsilon < 1/156$, we have

$$\frac{\delta_p}{4\varepsilon^{i+1}} \leq d_T(a_i, b_i) \leq \frac{3\delta_p}{2\varepsilon^{i+1}}, \quad \text{and} \quad d_T(c_i, d_{i-1}) \leq \frac{27}{2}\frac{\delta_p}{\varepsilon^i}.$$

▷ Claim 19. ($\star$) For any $T_k^p \in \mathcal{T}$, the distance from a leaf node u_0 to any of its ancestors at level i is at most $2\delta_p\varepsilon^{-(i+1)}$.

▶ **Lemma 20.** ($\star$) *For every $u, v \in X$, there exists a tree T in the tree cover $\mathcal{T}$ such that: $d_T(u, v) \leq (1 + \varepsilon)d_X(u, v)$.*

4.2 Phase 2: Bounding the Degree

The algorithm in Section 4.1 builds the tree cover $\mathcal{T}$ of size $O(\varepsilon^{-d} \log(1/\varepsilon))$. In this section, we focus on adjusting edges of these trees to achieve constant degree bound. We state the main algorithm and refer to the Appendix B of the full version for the detailed analysis of this section.

Let T denote a tree in the tree cover $\mathcal{T}$ constructed before Step 3 (contraction). Let $l(x)$ be the highest level of x in the net tree τ_{δ_p}. We assign a direction to each edge of T based on the levels of its endpoints in τ_{δ_p}. An edge $e = (a_i \to b_j)$ is going out from a_i to b_j if $l(a) \leq l(b)$. If $l(a) = l(b)$, we assign the direction arbitrarily. Similar to Phase 1, we categorize the set of directed edges into two categories:

1. An edge $(x_i \to p_{i+1})$ is an *inter-level edge at level i* if $x \in N_i \setminus N_{i+1}$ and $p \in N_{i+1}$. Let D_i be the set of inter-level edges at level i. We denote the set of points p_{i+1} incident to an inter-level edge $(x_i \to p_{i+1})$ at level i by $D_i^-(x)$, and the set of points w_i incident to an inter-level edge $(w_i \to x_{i+1})$ at level i by $D_i^+(x)$.
2. An edge $(x_i \to y_i)$ is a *cross edge at level i* if $x, y \in N_i$. Let C_i be the set of all cross edges at level i. Given a point x_i, we denote the set of all points y_i having a cross edge $(y_i \to x_i)$ by $C_i^+(x)$, and the set of all points z_i having a cross edge $(x_i \to z_i)$ by $C_i^-(x)$.

By our Phase 1 construction, we observe the following bounds:

▶ **Observation 21.** *Given a fixed level i, for every vertex $x \in N_i$, $|D_i^+(x)| = O(\varepsilon^{-d})$, $|D_i^-(x)| \leq 1$, $|C_i^+(x)| \leq 1$, $|C_i^-(x)| \leq 1$. Furthermore, for every point x, we have $\sum_i |D_i^-(x)| \leq 1$, and $\sum_i |C_i^-(x)| \leq 2$.*

We use the degree reduction technique of [8] to reduce degree associated with both cross edges and inter-level edges. The input and output of this technique are specified in Remark 22 and Lemma 23, respectively.

▶ Remark 22. The input tree T must be a tree in the tree cover, and we consider a subset E of edges in T. Let E_i denote the edges in E at level i, and $E_i^+(x)$ (resp., $E_i^-(x)$) denote the set of points connected to x by incoming (resp., outgoing) edges in E_i. The subset E must satisfy the following degree constraints for every point x: 1) $O(1)$ in-coming edges at every level, 2) at most one out-going edge at every level, and 3) totally $O(1)$ out-going edges over all levels. Formally, $|E_i^+(x)| \le d_{in}$, $|E_i^-(x)| \le 1$ and $\sum_i |E_i^-(x)| \le d_{out}$, where $d_{in} > 0$ and $d_{out} > 0$ are constants.

▶ **Lemma 23.** *Given a tree cover $\mathcal{T}$, let T be a tree in $\mathcal{T}$ that satisfies Remark 22. There exists an algorithm redirecting edges in E of T to obtain a tree T' with a new edge set E' such that:*

- *(Bounded degree.) Every point has at most $2 + 2d_{in} + d_{out}$ edges in E'.*
- *(Small stretch.) For every edge (y, x) in E of T, there exist a path π in T' from y to x such that π contains edges in E', and $d_{T'}(y, x) \le (1 + O(\varepsilon)) \cdot d_X(y, x)$.*

Algorithm. We use two operations: redirect cross edges and redirect inter-level edges.

- **Step 1. Redirecting cross edges.** We apply Lemma 23 to re-direct cross edges, where $E = \bigcup_i C_i$. E_i^- and E_i^+ in Remark 22 will respectively be C_i^- and C_i^+, where $|C_i^+(x)| \le 1, |C_i^-(x)| \le 1, \sum_t |C_t^-(x)| \le 2$ for every point x and every level i (by Observation 21).
- **Step 2. Redirecting inter-level edges.**
  - **Step 2.1.** We visit levels from the bottom to top. Let Q_i be the set of new edges at level i created by this step. Initialize $Q_i = \emptyset$. Let $Q_i^-(p)$ be the set of points q having an edge $(p \to q)$ in Q_i. Let $Q_i^+(p)$ be the set of points q having an edge $(q \to p)$ in Q_i. Given a fixed level i, for every vertex $x_{i+1} \in N_{i+1}$, recall that the set of in-coming inter-level edges at level i of x is $D_i^+(x) = \{w_i^{(1)}, w_i^{(2)}, \ldots\}$, we know $|D_i^+(x)| \le O(\varepsilon^{-d})$. We sort D_i^+ by increasing order of distances to x_{i+1}. Consider $w_i^{(j)} \in D_i^+(x)$:
    - If $j \le 2$: keep $(w_i^{(j)} \to x)$.
    - If $j > 2$: let $j^* = \lfloor (j-1)/2 \rfloor$; remove $(w_i^{(j)} \to x_{i+1})$ and create edge $(w_i^{(j^*)} \to w_i^{(j)})$ with weight $d_X(w_i^{(j^*)}, w_i^{(j)})$. We add $(w_i^{(j^*)} \to w_i^{(j)})$ to Q_i.
  - **Step 2.2.** We apply Lemma 23 to re-direct inter-level edges remaining after Step 2.1, where $E = \bigcup_i D_i$. E_i^- and E_i^+ in Remark 22 will be D_i^- and D_i^+ respectively, where $|D_k^+(p)| \le 2, |D_k^-(p)| \le 1, \sum_t |D_t^-(p)| \le 1$ for every point p and level k. These bounds hold by Observation 21 and by Step 2.1 (when $j \le 2$).
  - **Step 2.3.** We apply Lemma 23 to re-direct $E = \bigcup_i Q_i$ created by Step 2.1. E_i^- and E_i^+ in Remark 22 will be respectively Q_i^- and Q_i^+.

This finishes the construction of the bounded degree tree cover.

Abstract

We present efficient data structures for approximate nearest neighbor searching and approximate 2-point shortest path queries in a two-dimensional polygonal domain P with n vertices. Our goal is to store a dynamic set of m point sites S in P so that we can efficiently find a site $s \in S$ closest to an arbitrary query point q. We will allow both insertions and deletions in the set of sites S. However, as even just computing the distance between an arbitrary pair of points $q, s \in P$ requires a substantial amount of space, we allow for approximating the distances. Given a parameter $\varepsilon > 0$, we build an $O(\frac{n}{\varepsilon} \log n)$ space data structure that can compute a $1+\varepsilon$-approximation of the distance between q and s in $O(\frac{1}{\varepsilon^2} \log n)$ time. Building on this, we then obtain an $O(\frac{n+m}{\varepsilon} \log n + \frac{m}{\varepsilon} \log m)$ space data structure that allows us to report a site $s \in S$ so that the distance between query point q and s is at most $(1+\varepsilon)$-times the distance between q and its true nearest neighbor in $O(\frac{1}{\varepsilon^2} \log n + \frac{1}{\varepsilon} \log n \log m + \frac{1}{\varepsilon} \log^2 m)$ time. Our data structure supports updates in $O(\frac{1}{\varepsilon^2} \log n + \frac{1}{\varepsilon} \log n \log m + \frac{1}{\varepsilon} \log^2 m)$ amortized time.

1 Introduction

Nearest neighbor searching is a fundamental problem in which the goal is to store a set S of m point sites so that given a query point q one can quickly report a site in S that is closest to q. For example, the set S may be a set of (locations of) shops, and we may wish to efficiently find the shop closest to our current location. In addition, nearest neighbor searching shows up as an important subroutine in several other fundamental problems. For example, in computing closest pairs [7] and matchings [15]. In these applications, there are often two (additional) difficulties: (i) the point sites are typically embedded in some constrained domain, and (ii) the set of sites may change over time, and hence it may be necessary to insert and delete sites. In the example problem above other buildings, roads, and lakes etc. act as obstacles, and thus we actually have to measure the distance $d(q, s)$ between two points q and s in terms of the length of a shortest obstacle avoiding path $\pi(q, s)$. Furthermore, shops may open and close (or may be too crowded or out of products etc.), and hence we want to consider only the currently open or available shops when querying.

In this paper, we consider dynamic nearest neighbor searching among a set S of m sites in a two-dimensional polygonal domain P with n vertices. We will allow both insertions and deletions in the set of sites S. Agarwal, Arge, and, Staals [1] presented a near linear space data structure for this problem that allows efficient (polylogarithmic) queries and updates, provided that P contains no holes; i.e. it is a simple polygon. However, extending these

results to arbitrary polygonal domains seems to be far out of reach. It seems we need to at least be able to efficiently compute the (geodesic) distance $d(q, s)$ between two arbitrary query points q and s in P. Currently, the best data structures that support such queries in polylogarithmic time use $O(n^9)$ space [11] (and it seems unlikely we can determine the site closest to q without actually evaluating geodesic distances). Hence, we settle on answering queries approximately. Let $\varepsilon > 0$ be some parameter, and let s^* be the site in S closest to a query point q, then our goal is to report a site $s \in S$ whose distance to q is at most $(1 + \varepsilon)d(q, s^*)$. We will say that s is *ε-close* to q. Our main result is then:

▶ **Theorem 1.** *Let P be a polygonal domain with n vertices, let S be a dynamic set of m point sites in P, and let $\varepsilon > 0$ be a parameter. There is an $O(\frac{n+m}{\varepsilon} \log n + \frac{m}{\varepsilon} \log m)$ space data structure that can*

- *compute a site in S that is ε-close to a query $q \in P$ in $O(\frac{1}{\varepsilon^2} \log n + \frac{1}{\varepsilon} \log n \log m + \frac{1}{\varepsilon} \log^2 m)$ time,*
- *support insertions of sites into S in $O(\frac{1}{\varepsilon^2} \log n + \frac{1}{\varepsilon} \log n \log m + \frac{1}{\varepsilon} \log^2 m)$ amortized time,*
- *and support deletions of sites from S in $O(\frac{1}{\varepsilon} \log n \log m + \frac{1}{\varepsilon} \log^2 m)$ amortized time.*

Constructing the initially empty data structure takes $O(\frac{n}{\varepsilon^2} \log^2 n)$ time.

The crucial ingredient in our data structure is a data structure for $(1 + \varepsilon)$-approximate 2-point shortest path queries. Thorup [19] presents an $O(\frac{n}{\varepsilon} \log n)$ space data structure that, given two arbitrary query points s, t in the polygonal domain P, can compute an estimate $\hat{d}(s, t)$ of their distance so that $d(s, t) \leq \hat{d}(s, t) \leq (1 + \varepsilon)d(s, t)$ in $O(\frac{1}{\varepsilon^3} + \frac{\log n}{\varepsilon \log \log n})$ time. Thorup's solution however assumes that distances are encoded as floating point numbers whose bits we can manipulate. This is inconsistent with the Real-RAM model of computation usually assumed in computational geometry. We stick to the Real-RAM model, and show that we can still compute approximate distances efficiently. We can actually improve the dependency on ε, and obtain:

▶ **Theorem 2.** *Let P be a polygonal domain with n vertices, and let $\varepsilon > 0$ be a parameter. In $O(\frac{n}{\varepsilon^2} \log^2 n \log \frac{n}{\varepsilon})$ time we can construct an $O(\frac{n}{\varepsilon} \log n)$ space data structure that, given query points $s, t \in P$ returns an $(1 + \varepsilon)$-approximation of $d(s, t)$ in $O(\frac{1}{\varepsilon^2} \log n)$ time.*

Our overall approach is actually the same as in Thorup's approach: we recursively construct a separator, and estimate distances by going via a discrete set of anchor points on this separator. However, our approach provides stronger guarantees on these anchor points. We believe this may be useful for other problems as well. Indeed, it allows us to efficiently answer (approximate) nearest neighbor queries as well. This also still requires several additional ideas, as simply evaluating the distance between a query point and every site would only give us query time linear in m.

Related Work. Dynamic nearest neighbor searching in the Euclidean plane has a long history, with early results by Agarwal and Matoušek [2]. Chan [6] was the first to achieve expected polylogarithmic update and query times. Following a sequence of improvements, the best structure at this time uses $O(m)$ space, allows for $O(\log^2 m)$ time queries, and for updates in deterministic, amortized $O(\log^4 m)$ time [15, 8]. For more general (constant complexity) distance functions, one can similarly achieve expected polylogarithmic query and update times [15, 16]. When the domain is a simple polygon P with n vertices, Oh and Ahn [17] presented a solution using $O(n + m)$ space achieving $O(\sqrt{m} \log(n + m))$ query time, and $O(\sqrt{m} \log m \log^2 n)$ update time. Agarwal, Arge, and, Staals [1] then showed how to achieve $O(\log^2 n \log^2 m)$ query time and expected $O(\text{polylog}(nm))$ update time using

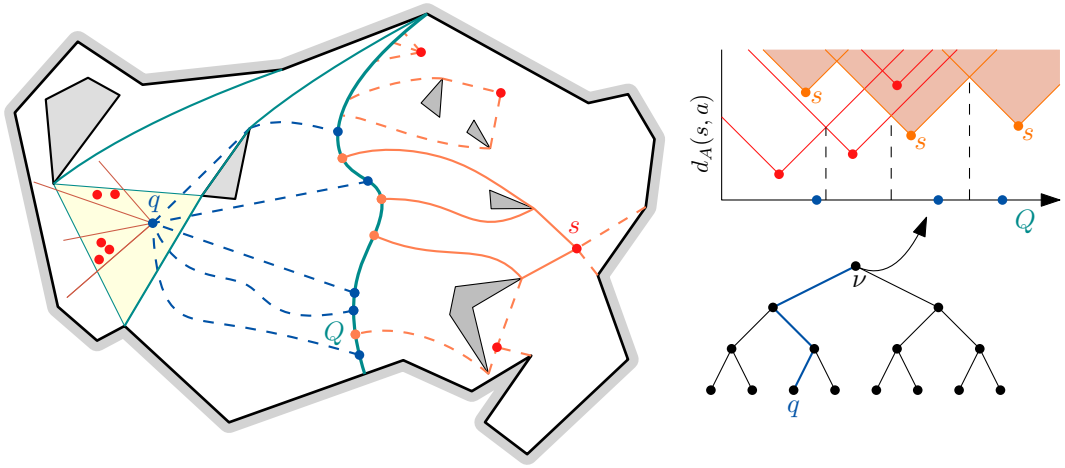

Figure 1 An overview of our approach. We use shortest paths to recursively subdivide P into subpolygons. If s^* lies in the same triangle as q, we can directly compute an ε-close site. Otherwise, the shortest path must cross a shortest path Q, and we find a site s that is sufficiently close to q whose path goes via an anchor point on Q.

$O(n + m \log^3 m \log n)$ space. When the domain may have holes and the set of sites is static, there is an $O(n + m)$ space data structure that allows querying the (exact) nearest neighbor in $O(\log(n + m))$ time [14]. Constructing the data structure uses $O(n \log n)$ time. Wang [21] recently showed that if P is triangulated, the shortest path map of a single site can be computed in $O(n + h \log h)$ time, where h is the number of holes in P. Conceivably, his algorithm could be extended to handle multiple sites (as is the case in the algorithm by Hershberger and Suri). We are not aware of any results that allow updating sites. Even the case where we allow only insertions is challenging: we cannot easily apply a static-to-dynamic transformation [3] since rebuilding the static structure may require $\Omega(n)$ time.

2 Global Approach

We first present an overview of our data structure. See also Figure 1. We start by briefly reviewing the ε-approximate 2-point shortest path query data structure by Thorup [19].

Computing approximate shortest paths. Thorup's approach recursively partitions the domain P using *separators* such that: each separator consists of at most three shortest paths, and the resulting subpolygons are of roughly the same size. This results in a balanced binary tree $\mathcal{T}$ of height $O(\log n)$ in which each node ν corresponds to some subpolygon P_ν that is further subdivided using a separator Q_ν.

Consider the separator Q of the root of this tree $\mathcal{T}$, and let $k = \lceil 1/\varepsilon \rceil$. The main idea is that each polygon vertex v generates a set $A_Q(v)$ of $O(k)$ so called *anchor points*[1] on Q, so that for any point $q \in Q$ the distance via one of these anchor points $A_Q(v)$ to v is at most $(1 + \varepsilon)$ times the true distance $d(q, v)$. So, if a shortest path $\pi(u, v)$ between two vertices u and v intersects Q then there is a path from u to v via two anchor points $a \in A_Q(u)$ and $a' \in A_Q(v)$ (and the subcurve $Q[a, a']$ of Q) of length $(1 + \varepsilon)d(u, v)$. Given the anchor points

[1] Thorup calls these points connections, but we use anchor points to avoid confusion with the paths connecting v to these points.

(and the distances to their defining vertices) we can find the length of such a path in $O(k)$ time. If the path $\pi(u, v)$ does not intersect Q, it is contained in one of the subpolygons of the children of the root, and hence we can compute a $(1 + \varepsilon)$-approximation of the distance $d(u, v)$ in the appropriate subpolygon. As each vertex defines $O(k)$ anchor points on Q, and appears in $O(\log n)$ levels of the recursion. The total space used is $O(nk \log n)$.

To compute the anchor points efficiently, Thorup's actual algorithm uses a graph G in which the distance $d_G(u, v)$ between u and v in the graph is already an $(1+\varepsilon_1)$-approximation of the true distance $d(u, v)$. Using the above approach with parameter ε_0 then actually gives a path in P with total length at most $(1 + \varepsilon_0)(1 + \varepsilon_1)d(u, v)$. Setting $\varepsilon_0 = \varepsilon_1 = \varepsilon/3$ then gives a ε-approximation of the distances as desired.

However, using the graph G results in slightly different (generally weaker) properties compared to the ideal case sketched above. In particular, his approach now guarantees that the distances from vertex v are within a factor $1 + \varepsilon$ of the true distance only for a discrete subset of points on Q. For querying the distances between pairs of vertices this is not an issue. Thorup's data structure can handle such queries in only $O(k)$ time. To support queries between arbitrary points $s, t \in P$, his algorithm connects s and t to $O(k)$ vertices in G each, and then queries the all these pairs. This leads to the query time $O(k^3 + k \log n/ \log \log n)$.

Reducing the query time. Ideally, we would treat s and t identical to polygon vertices, so that we get $O(k)$ anchor points on a separator Q. However, as such a candidate anchor point $p \in Q$ may lie anywhere on Q (in particular, it is not necessarily a vertex of G yet), we may not have the required ε_1-approximation of the distance to such a point yet.

We will show that we can use a slightly different graph G^Q that includes additional "Steiner" points on Q. This leads to a different set of anchor points compared to Thorup's approach, but *does* guarantee that for any vertex v, and *any* point q on Q, the distance to v is at most $(1 + \varepsilon)d(q, v)$. Furthermore, we show that we can efficiently compute an initial set of $O(k^2)$ candidate anchor points for an arbitrary point s, which we then reduce to $O(k)$. This results in $O(k^2 \log n)$ query time for an arbitrary pair of query points $s, t \in P$.

Answering nearest neighbor queries. As in the approximate 2-point shortest path data structure above, we construct a tree $\mathcal{T}$ of separators. We associate every site $s \in S$ with a root-to-leaf path in this tree. Namely, the nodes ν for which s is contained in the subpolygon P_ν. For each node ν on this path, we will additionally maintain a set of anchor points $A_Q(s)$ on the separator $Q = Q_\nu$ corresponding to this node. In particular, we consider Q as a one dimensional space, and maintain an additively weighted Voronoi diagram $Vor(A_Q)$ on Q. The set of sites $A_Q = \bigcup_{s \in S \cap P_\nu} A_Q(s)$ is the set of all anchor points of all sites that appear in P_ν. The weight of an anchor point $a \in A_Q(s)$ is the distance estimate from a to s.

If a shortest path between a query point q and its closest site $s^* \in S$ intersects Q, then there is a sufficiently short path via one of the anchor points of s^* and q on Q. We can then find a sufficiently close site s by querying the Voronoi diagram $Vor(A_Q)$ with all anchor points of q. This leads to an overall query time of $O(k^2 \log n + k \log n \log m + k \log^2 m)$, as we perform such queries in $O(\log n)$ nodes in $\mathcal{T}$.

The graph of the function that expresses the distance from a site $s \in S$ to a point p on Q via a given anchor point $a \in A_Q(s)$ is nicely "V-shaped". Hence, we can maintain $Vor(A_Q)$ by maintaining the lower envelope of these functions. This allows us to insert and remove sites in $O(k \log^2(km))$ time. This leads to an overall update time of $O(k^2 \log n + k \log n \log m + k \log^2 m)$. Our structure uses $O(nk \log n + mk \log n + mk \log m)$ space.

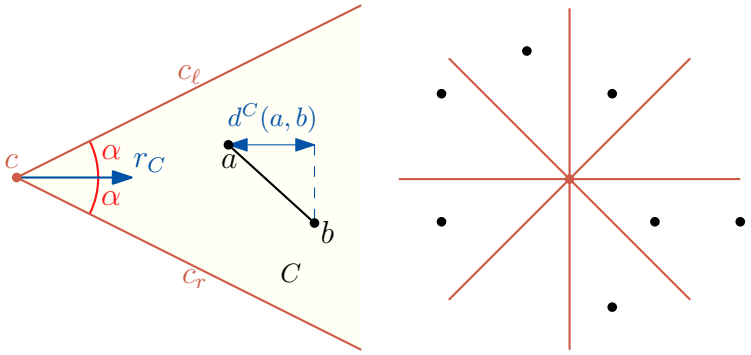

Figure 2 (a) A cone C with apex c, cone direction r_C, and angle α, and an illustration of the cone distance $d^C(a,b)$ between two points $a,b \in C$. (b) A family of cones with angle $2\alpha = 45$ degrees.

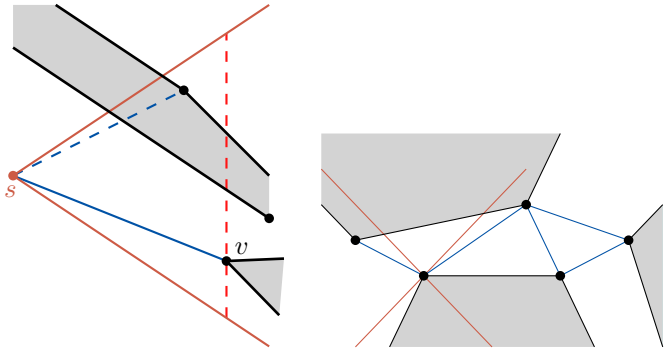

Figure 3 (a) A point s, which has an outgoing cone edge to a vertex v w.r.t the pictured cone C. Hence, there are no visible vertices in C to the left of the red dashed line. (c) An example cone graph G (for a very large ε).

Organization. In Section 3, we define our graph G^Q, and prove that it allows us to accurately estimate distances between any pair of points s,t whose shortest path intersects Q. We then use this to construct our approximate 2-point shortest path data structure in Section 4. Finally, in Section 5 we describe our lower envelope data structure and the remaining tools needed for an efficient dynamic data structure for approximate nearest neighbor searching. Omitted proofs are in the full version [20].

3 Estimating distances using a graph

In this section we discuss how to approximate distances within a polygon P. Our results are based on Clarkson's cone graph [10] on which we can efficiently compute approximate distances between vertices. We review this result in Section 3.1. In Section 3.2 we then extend this approach so that we can represent the distance from any vertex of P to any point on a given shortest path Q in P. This involves computing the anchor points for each vertex of P. Finally, in Section 3.3, we further augment the graph to also represent distances from a set S of arbitrary point sites to (and via) the shortest path Q, and show how to compute the anchor points for such an arbitrary point $s \in S$ efficiently.

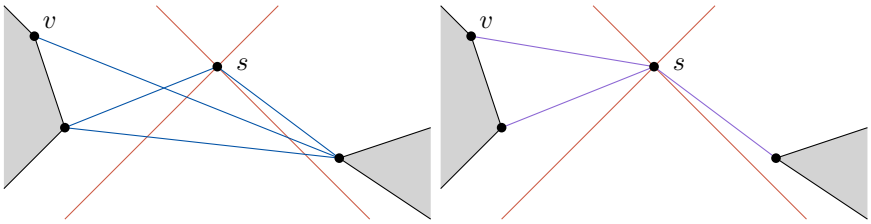

Figure 4 (a) The graph $G[s]$, where only outgoing cone edges from s have been added. (b) The cone graph on $V \cup \{s\}$. Observe that the edge set of neither graph is a subset of the other.

3.1 Clarkson's cone graph

Clarkson [10]'s graph is based on cones. A *cone* C is characterized by an apex point c, a cone direction r_C which is a unit length vector and an angle $\alpha \leq \pi/2$. The boundary of the cone consists of two half lines c_ℓ, c_r who both start at c and the difference in angle compared to r_C is $\alpha/2$ and $-\alpha/2$ respectively. We use C_c to denote a cone C to have its apex at point c. A *cone family* $\mathcal{F}$ is a set of cones that all have their apex at the origin, such that any point in $\mathbb{R}^2$ is contained in at least one cone $C \in \mathcal{F}$. See Figure 2(b) for an example.

Let $\varepsilon > 0$ be a parameter. Clarkson then defines a cone family $\mathcal{F}_\varepsilon$ consisting of $O(k) = O(1/\varepsilon)$ cones, each with angle at most $\varepsilon/8$, and a *cone graph* G based on $\mathcal{F}_\varepsilon$.

Let V be the set of vertices of P. A vertex $b \in V$ is a *minimal cone neighbor* of a point $a \in P$ if and only if there exists a cone $C \in \mathcal{F}_\varepsilon$, so that $b \in S$ is the vertex in the translated cone C_a with minimum *cone-distance* $d^C(a,b) = |r_C \cdot (b-a)|$ to a among all vertices that are visible from a (i.e. for which the line segment $\overline{ab}$ is contained in P). We will also say that a has an *outgoing cone edge* to b w.r.t the cone C. Let $N(a)$ denote the set of these minimal cone neighbors of a over all cones in $\mathcal{F}_\varepsilon$. See Figure 3(a) for an example.

The cone graph $G = (V, E)$ then has an edge $(u, v) \in E$ between two (polygon) vertices $u, v \in V$ if and only if u had v as its *minimal cone neighbor* or vice versa, i.e. $v \in N(u)$ or $u \in N(v)$. Each vertex u has at most $O(k)$ outgoing cone neighbors, and thus the total number of edges in G is at most $O(nk)$. Let $d_G(u, v)$ denote the length of a shortest path $\pi_G(u, v)$ between vertices u, v in G.

▶ **Lemma 3** (Clarkson [10]). *For every pair of vertices u, v in the cone graph G, there is a path $\pi_G(u, v)$ of length $d_G(u, v)$ so that*

$$d(u, v) \leq d_G(u, v) \leq (1 + \varepsilon)d(u, v).$$

In $O(nk \log n)$ time we can build a data structure of size $O(nk)$ so that for any point $s \in P$ one can compute $N(s)$ in $O(k \log n)$ time. Hence, G can be constructed in $O(nk \log n)$ time.

Extending the cone graph. Let $s \in P$ be a point, we define the *extended cone graph* $G[s] = (V \cup \{s\}, E \cup \{(s, v) \mid v \in N(s)\})$ by adding s as a vertex, and connecting it to all of its outgoing cone neighbors. Note that this graph is different from Clarkson's cone graph on $V \cup \{s\}$. See Figure 4 for an illustration. Using essentially same argument as in Lemma 3, we can still prove that $G[s]$ provides an ε-approximation of the distances to and from s.

3.2 Continuous ε-approximation graphs

Let Q be a shortest path between two vertices in P. Our goal is to define and compute, for each vertex v of P, a small set of weighted anchor points $A_Q(v)$ on Q, so that for any point q on Q there is an obstacle avoiding path between q and v of length at most $(1 + \varepsilon)d(q, v)$

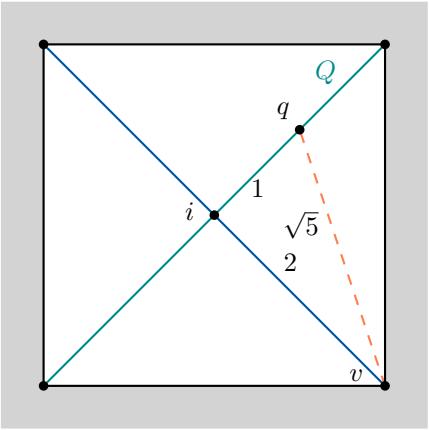

Figure 5 An example that shows that there may be points q on Q (shown in green) for which the graph G' (black, blue and green edges) considered by Thorup does not yield a ε-approximation. For any $\varepsilon \leq 1/10$, Thorup's anchor points give us distance estimate of 3, while the true distance is $\sqrt{5}$. Hence, this is only a $3/\sqrt{5} \geq 1.34$-approximation, not an $(1+\varepsilon)$-approximation.

via one of these anchor points. More specifically, let $\hat{d}_a$ be the weight of an anchor point a. We then want that there is an obstacle avoiding path $\hat{\pi}_a$ from v to a of length $\hat{d}_a$, and that $d_G(v, A_Q(v), q) := \min_{a \in A_Q(v)} d_G(a, q) + \hat{d}_a$ is at most $(1+\varepsilon)d(q, v)$.

Thorup [19] argues that such a set of $O(k)$ anchor points exists. Although his argument (Lemma 5 in his paper) is constructive, it is unclear how to efficiently construct such a set of anchor points. So, he constructs a set of anchor points with respect to Clarkson's cone graph instead. In particular, let $G = (V, E)$ be a cone graph constructed with parameter $\varepsilon_1 = \varepsilon/3$. Thorup defines the graph G' by subdividing every edge in G that intersects Q (at the intersection point), and connecting consecutive vertices along Q, and proves

▶ **Lemma 4** (Thorup [19]). *Let $H = (V, E)$ be an undirected weighted graph, let Q be a shortest path in H, and let $k' \in \mathbb{N}$ be a parameter. For each vertex $u \in H$, we can compute a set $A_Q(u) \subseteq V$ of $O(k')$ discrete anchor points on Q, so that for any vertex $v \in Q$ we have*

$$d_H(u, v) \leq d_H(u, A_Q(u), v) \leq (1 + 1/k')d_H(u, v).$$

Computing all sets of anchor points takes a total of $O\left(k' \log |Q| \left(|V| \log |V| + |E|\right)\right)$ time.

By choosing $1/k' = \varepsilon/3$ and applying Lemma 4 on the graph G' this then allows him to efficiently estimate the distances between the *vertices* of G'. In particular, if the shortest path in G' between two vertices $u, v \in G'$ intersects Q then one can find an $(1+\varepsilon)$-approximation of their distance $d(u, v)$ in P using one of the constructed anchor points in $O(k)$ time.

However, we want an $(1+\varepsilon)$-approximation for the distance between any vertex in G and *any point* on Q; i.e. not just the vertices of Q and the intersection points of Q with edges of G. Thorup's construction does not immediately provide that, see for example Figure 5.

A continuous graph G^Q. We will instead define a slightly different graph G^Q that includes additional "Steiner" points on Q. This *does* allow us to accurately estimate the distance to *any* point on Q, and thus compute appropriate anchor points. We actually construct the cone graph G with parameter $\varepsilon_1 = \varepsilon/9$, and then extend it into a *continuous graph* $G^Q = (V^Q, E^Q)$ (see below). We obtain G^Q from G and Q as follows:

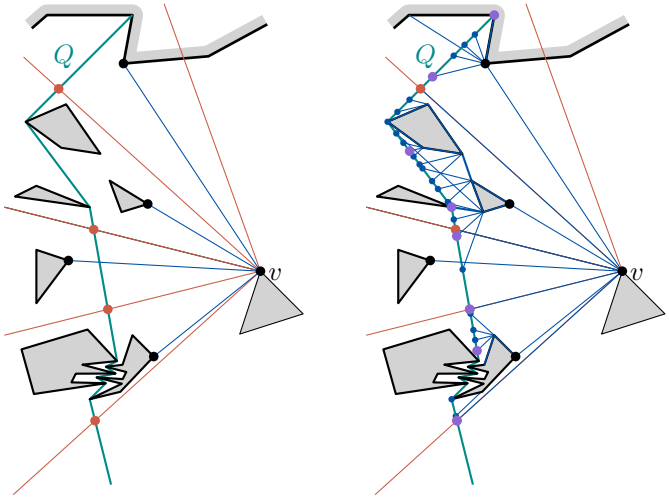

Figure 6 (a) The minimal cone neighbors $N(v)$ of vertex v, and the additional vertices $X_Q(v)$ (brown). (b) We compute a set of anchor points $A_Q(v)$ (purple) on Q based on G^Q (partially drawn).

- We include all vertices of G and of Q as vertices of G^Q.
- For each vertex $v \in G$ we consider the cones in the cone family centered at v. For each cone boundary ρ, we consider the first intersection point q of ρ with Q; if the resulting line segment $\overline{vq}$ lies inside P (i.e. the ray does not intersect the boundary of P before reaching q), we add q as a vertex, and (v, q) as an edge. Let $X_Q(v)$ denote the set of vertices added by v in this way. See Figure 6(a) for an illustration.
- We add all edges of G, and connect each pair of vertices that is consecutive along Q.

Observe that G^Q still has size $O(nk)$; as each vertex in G adds $O(k)$ additional vertices and edges, and Q also has at most $O(n)$ vertices. It is straightforward to construct G^Q from G in $O(nk \log n)$ time, using data structures for fixed-directional ray shooting queries [18].

▶ **Lemma 5.** *In $O(nk \log n)$ time we can construct a data structure of size $O(nk)$ so that for any point $s \in P$ we can compute the extra vertices $X_Q(s)$ in $O(k \log n)$ time. Hence, G^Q can be constructed in $O(nk \log n)$ time.*

Next, we argue that G^Q indeed allows us to ε_1-approximate the distances. We actually interpret G^Q as a *continuous graph* [5]. Every edge $(u, v) \in E^Q$ is a line segment $\overline{uv}$ in P, so we can extend the (graph) distance d_{G^Q} to points in the interior of edges. In particular, for points p, q on the same edge $\overline{uv}$ we define $d_{G^Q}(p, q) = \|p - q\|$ to simply be their Euclidean distance, and for $p \in \overline{uv} \in E^Q$ and $q \in \overline{wz} \in E^Q$ in the interior of different edges we have $d_{G^Q}(p, q) = \min_{u' \in \{u,v\}} \min_{w' \in \{w,z\}} \|p - u'\| + d_{G^Q}(u', w') + \|w' - q\|$. We are only interested in points in the interior of edges of Q. Hence, we prove:

▶ **Lemma 6.** *Let $u, v \in V$ be two polygon vertices in G^Q. Then we have that*

$$d(u, v) \leq d_{G^Q}(u, v) \leq (1 + \varepsilon_1) d(u, v).$$

Furthermore, for any point $q \in Q$ and any vertex $v \in G^Q$ we have that

$$d(v, q) \leq d_{G^Q}(v, q) \leq (1 + \varepsilon_1) d(v, q).$$

Computing and storing anchor points. We can now compute the distances in G^Q, and use them to construct an appropriate set of anchor points. See Figure 6(b). Due to Lemma 6 we can now actually just reuse Thorup's approach (i.e. Lemma 4) again:

▶ **Lemma 7.** *For every vertex v of P, we can compute a set $A_Q(v)$ of $O(k)$ anchor points on Q such that for any point q on Q we have $d(v,q) \leq d_{G^Q}(v, A_Q(v), q) \leq (1+\varepsilon)d(v,q)$.*

This takes $O(nk^2 \log n \log(kn))$ time in total.

3.3 The augmented cone graph

Let S be a dynamic set of point sites inside P. As we are interested in distances to (and between) the points in S, we also want to define and compute anchor points on Q for the points in S. The most straightforward approach would be to just build the above continuous graph G^Q on the set of points (vertices) $V \cup S$ rather than just the polygon vertices V. However, as computing the anchor points involves computing shortest paths in this graph, we cannot easily compute the anchor points for a single new site s. Similarly, maintaining (the distances in) the graph as S changes will be difficult. So, we argue that we can compute suitable anchor points for these new sites using a slightly different method instead.

Let $s \in P$ be a new point site. Similar to Section 3.1, we now consider the (continuous) graph $G^Q[s]$ that we obtain from G^Q by introducing $\{s\} \cup X_Q(s)$ as additional vertices, connecting s to every minimal cone neighbor in $N(s)$ and to every point in $X_Q(s)$, and subdividing the edges of Q to account for the additional vertices in $X_Q(s)$. This (continuous) graph still has $O(nk)$ vertices and $O(nk)$ edges. Moreover, we can use this graph to accurately estimate distances from s to any point on Q.

▶ **Lemma 8.** *Let s be a point in P. For any vertex w of P there is a path from s to w in $G^Q[s]$ of length $d(s,w) \leq d_{G^Q[s]}(s,w) \leq (1+\varepsilon_1)d(s,w)$ that passes through a cone neighbor $v \in N(s)$. Furthermore, for any point $q \in Q$ we have*

$$d(s,q) \leq d_{G^Q[s]}(s,q) \leq (1+\varepsilon_1)d(s,q).$$

Defining anchor points. Our goal is to define a set $A_Q(s)$ of anchor points on Q for point s. To this end, we first define a set of candidate points $X'_Q(s) = X_Q(s) \cup \bigcup_{v \in N(s)} A_Q(v)$ on Q. We can prove that if we assign appropriate weights to this set of $O(k^2)$ points it is indeed a set of anchor points. However, as we argue next, a subset of $O(k)$ of these points suffices.

Let $H = (V', E')$ be an undirected weighted graph with vertex set $V' = \{s\} \cup X'_Q(s)$. Vertex s is connected to each vertex $p \in X_Q(s)$ with an edge of length $\|s-p\| = d_{G^Q[s]}(s,p)$, and to $p \in A_Q(v)$ by an edge of length $\|s-v\| + d_{G^Q}(v,p)$. We connect vertices $u, w \in X'_Q(s)$ that appear consecutively on Q by an edge of length $d(u,w)$ (which is the length of the subpath along Q). Observe that the vertices of $X'_Q(s)$ form a shortest path in the graph H.

▶ **Lemma 9.** *Let $\varepsilon_2 > 0$ be a parameter such that $O(1/\varepsilon_2) = O(k)$. In $O(k^2)$ time we can compute a set $A_Q(s)$ of $O(k)$ discrete anchor points for H, i.e. so that for any $p \in X'_Q(s)$*

$$d_H(s,p) \leq d_H(s, A_Q(s), p) \leq (1+\varepsilon_2)d_H(s,p).$$

We use Lemma 9 with $\varepsilon_2 := \varepsilon/9$ to compute a set $A_Q(s)$ of $O(k)$ anchor points for s with respect to H. Hence, for each point $p \in X'_Q(s)$ (so in particular for those in a set $A_Q(v)$) there is a path of length $(1+\varepsilon_2)d_H(s,p) \leq (1+\varepsilon_2)(\|s-v\| + d_{G^Q}(v,p))$ via an anchor point in $A_Q(s)$. Next, we argue that this set is a valid set of anchor points for any point on Q.

▶ **Lemma 10.** *Let s be a point in P. In $O(k \log n + k^2)$ time, we can compute a set $A_Q(s)$ of $O(k)$ anchor points, so that for any point $q \in Q$ we have*

$$d(s,q) \leq d_{G^Q[s]}(s, A_Q(s), q) \leq (1+\varepsilon)d(s,q).$$

Estimating distances via the shortest path Q. Given a shortest path Q, and points $s, t \in P$ whose shortest path $\pi(s,t)$ in P intersects Q, we can use the above tools to accurately estimate the distance between s and t. More specifically, we compute G^Q and the anchor points as defined above. Additionally, we fix an endpoint u of Q and compute and store, for each vertex w of Q the distance to u (i.e. the path length along Q). This can easily be done in $O(n)$ additional time. Given a pair of points a, b on Q (and the edges that contain a and b, respectively) we can then compute their distance $d(a,b)$ (i.e. the length of the subpath $Q[a,b]$) in constant time.

Let $a \in A_Q(s)$ and $b \in A_Q(t)$ be anchor points of s and t on Q, respectively. The subpath $\hat{\pi}_a$ from s to a in $G^Q[s]$ corresponds to an obstacle avoiding path in P. Similarly, the subpath $\hat{\pi}_b$ from b to t is obstacle avoiding. Furthermore, since Q is a shortest (obstacle-avoiding) path in P, so is its subpath $Q[a,b]$ from a to b. So, the concatenation of $\hat{\pi}_a$, $Q[a,b]$, and $\hat{\pi}_b$ connects s and t and is obstacle avoiding, and has length $\hat{d}_a + \hat{d}_b + d(a,b)$. Now define

$$\hat{d}_Q(s,t) = \min_{a \in A_Q(s), b \in A_Q(t)} \hat{d}_a + \hat{d}_b + d(a,b)$$

to be the length of a shortest such obstacle avoiding path $\hat{\pi}_Q(s,t)$. We then have:

▶ **Lemma 11.** *Let P be a polygonal domain with n vertices, and let Q be a shortest path in P. In $O(nk^2 \log n \log(kn))$ time, we can construct a data structure on P and Q of size $O(nk)$ that can answer the following queries in $O(k \log n + k^2)$ time: given any pair of points $s, t \in P$ for which a shortest path $\pi(s,t)$ intersects Q, return the length $\hat{d}_Q(s,t)$ of an obstacle avoiding path $\hat{\pi}_Q(s,t)$ so that $d(s,t) \leq \hat{d}_Q(s,t) \leq (1+\varepsilon)d(s,t)$.*

4 A data structure for answering distance queries

In this section we develop an $O(nk \log n)$ space data structure that stores the polygonal domain P, so that given a pair of query points s, t we can compute an $(1+\varepsilon)$-approximation of the distance $d(s,t)$ in $O(k^2 \log n)$ time. Our data structure is essentially a balanced hierarchical subdivision of the polygonal domain combined with the graph-based approach to estimate distances from the previous section.

A balanced hierarchical subdivision for polygonal domains. A balanced hierarchical subdivision [9] is a recursive subdivision of a simple polygon into subpolygons. It is a crucial ingredient to obtain efficient solutions to many problems involving simple polygons [1, 13]. As was also recently observed [12], Thorup's approach [19] essentially provides a balanced hierarchical subdivision for polygonal domains. The following lemma summarizes this result:

▶ **Lemma 12** ([19, 12])**.** *Let P be a polygonal domain with n vertices. In $O(n \log n)$ time, one can compute a tree $\mathcal{T}$ so that*

1. *the leaves of $\mathcal{T}$ correspond to triangles in a triangulation of P,*
2. *each node ν of T corresponds to a subpolygon P_ν,*
3. *each internal node ν also corresponds to a set $\mathcal{Q}_\nu$ of shortest paths so that:*
   a. *$\mathcal{Q}_\nu$ consists of at most three shortest paths (see Figure 7),*
   b. *every shortest path $Q \in \mathcal{Q}_\nu$ is also a shortest path in P_ν, and*
   c. *the paths in $\mathcal{Q}_\nu$ partition P_ν into P_μ and P_ω, corresponding to the children of ν,*

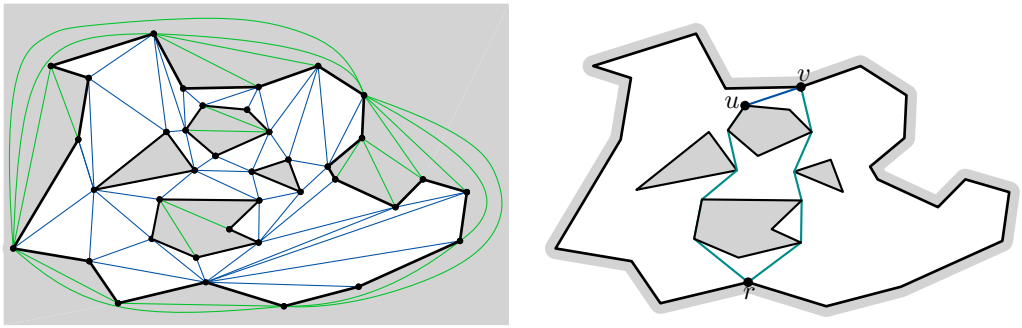

Figure 7 One step in the construction of the balanced hierarchical separator.

4. *the height of the tree is* $O(\log n)$*, and*
5. *the total complexity of the subpolygons* P_ν *on each level of* $\mathcal{T}$ *is* $O(n)$*, and thus the total complexity of* $\mathcal{T}$ *is* $O(n \log n)$*.*

The data structure. Our data structure now stores the balanced hierarchical subdivision $\mathcal{T}$ from Lemma 12. We build a point location data structure [18] on the triangulation induced by the leaves of $\mathcal{T}$. Additionally, for each edge e of this triangulation, let ν be the highest node in $\mathcal{T}$ for which the edge appears on a shortest path $Q \in \mathcal{Q}_\nu$ (if such a node exists). We store a pointer from edge e to this shortest path. We can easily compute these pointers during the construction of $\mathcal{T}$.

Consider a node ν. For each of the $O(1)$ shortest paths $Q \in \mathcal{Q}_\nu$ we will construct the data structure from Lemma 11 (i.e. the graph G^Q and the sets of anchor points) with respect to the subpolygon P_ν. Since the total size of all subpolygons P_ν on each level of the tree is $O(n)$, the total size of all of these data structures on a given level of $\mathcal{T}$ is $O(kn)$, and thus $O(nk \log n)$ in total. Similarly, the total preprocessing time is $O(nk^2 \log^2 n \log(kn))$.

Query. Given a pair of query points s, t we find the leaf triangles Δ_s and Δ_t that contain points s and t, respectively. If s and t lie in the same triangle, we can trivially report the length $\overline{st}$ as their shortest path. Otherwise, a shortest path from s to t must intersect one of the shortest paths $Q \in \mathcal{Q}_\nu$ for a common ancestor ν of the two leaves. In particular, let μ be the highest node of $\mathcal{T}$ for which $\pi(s,t)$ intersects a shortest path $Q \in \mathcal{Q}_\mu$. It follows that the shortest path $\pi(s,t)$ lies inside P_μ, and thus we can use the Lemma 11 data structure for Q to obtain a path of length at most $(1+\varepsilon)d(s,t)$. Unfortunately, we cannot easily find this node μ, so we query all Lemma 11 data structures for all shortest paths $Q \in \mathcal{Q}_\nu$, for all common ancestors ν of the leaves representing Δ_s and Δ_t, and report the shortest distance found. If either s or t lies on an edge e of the boundary of some triangle that is part of some shortest path $Q \in Q_\nu$, we use the pointer stored at e to jump to the highest such node, and query only the common ancestors of these nodes instead. Since every query returns the length of an obstacle-avoiding path, the returned estimate $\hat{d}(s,t)$ satisfies $d(s,t) \leq \hat{d}(s,t) \leq (1+\varepsilon)d(s,t)$ as desired. Since each query takes $O(k \log n + k^2)$ time, the total query time is $O(k \log^2 n + k^2 \log n)$.

Improving the query time. The $O(k \log^2 n)$ term in the query time is only due to computing the ray shooting queries needed to compute the sets $X_Q(s)$ for each shortest path Q considered. Next, we argue that we can compute these sets in only $O(k \log n)$ time by building an additional $O(nk \log n)$ space data structure. The overall space usage thus remains the same, and the final query time becomes $O(k^2 \log n)$ as claimed.

▶ **Lemma 13.** *In $O(nk \log n)$ time, we can build an $O(nk \log n)$ space data structure that given a query point s, allows us to compute the sets $X_Q(s)$ for all shortest paths $Q \in \bigcup_{\nu \in \mathcal{T}(s)} \mathcal{Q}_\nu$, where $\mathcal{T}(s)$ is the path in $\mathcal{T}$ from the root to the leaf triangle containing s.*

Finally, we plug in that $k = \lceil \frac{1}{\varepsilon} \rceil$, which establishes Theorem 2.

▶ Remark 14. Thorup's final approach [19] uses one additional idea: that one can guarantee that the boundary of a subgraph G_ν (used during the construction in Lemma 12) intersects only $O(1)$ shortest paths from ancestor separator paths. Therefore, he can also store anchor points on these paths, and query only the shortest paths of the lowest common ancestor of the leaves corresponding to s and t. It is not clear to us if this idea is still applicable with our approach. For a shortest path B on the boundary of some subpolyon P_ν, it is not clear in which (sub)polygon to place the path B so that we can invoke Lemma 11.

5 Dynamic nearest neighbor searching

In this section, we develop our data structure for approximate nearest neighbor searching with a dynamic set of sites S in a polygonal domain P. In Section 5.1 we first develop a simple solution for when S is simply a set of sites in the plane. In Section 5.2 we consider how to solve a restricted case in which we are given a shortest path Q in P, and we have to only answer queries q for which the shortest path between q and any site in S intersects Q. Then finally, in Section 5.3 we combine these results with the balanced hierarchical subdivision to obtain our data structure for the general problem.

5.1 Dynamic Euclidean ε-close neighbor searching

Let S be a dynamic set of m points in $\mathbb{R}^2$. We present a simple $O(km \log m)$ space data structure that given a query point q can report a site s for which the distance $d(q, s)$ is at most $(1+\varepsilon)d(q, s^*)$ in $O(k \log m)$ time. Here, s^* is a site in S closest to q. Our data structure supports insertions and deletions in $O(k \log m)$ time as well. Our data structure essentially uses the cone based approach from Section 3.1; i.e. for each cone C in the cone family $\mathcal{F}_\varepsilon$, we build a dynamic data structure that can report the site $s \in S \cap C_q$ with minimum cone distance. By the argument from Lemma 3 it follows that this then yields an ε-close site.

▶ **Lemma 15.** *Let S be a set of m sites in $\mathbb{R}^2$. There is an $O(km \log m)$ space data structure that, given a query point $q \in \mathbb{R}^2$ can report an $1/k$-close site from S in $O(k \log^2 m)$ time. Insertions and deletions of sites are supported in amortized $O(k \log^2 m)$ time.*

5.2 Maintaining an additively weighted Voronoi diagram

Let S be the set of m sites in the polygonal domain P, and let Q be a shortest path. We describe a dynamic data structure that, given a query point $q \in P$ can report an ε-close site $s \in S$, provided that the shortest path from q to the closest site $s^* \in S$ intersects Q. More specifically, our goal is to compute a site s which achieves the following minimum

$$\min_{s \in S} \hat{d}_Q(q, s) = \min_{s \in S} \min_{a \in A_Q(q), b \in A_Q(s)} \hat{d}_a + \hat{d}_b + d(a, b). \tag{1}$$

If the shortest path between s^* and q intersects Q, then by Lemma 11 this value is indeed at most $(1+\varepsilon)d(s^*, q)$, and thus the site s that achieves this minimum is ε-close to q. We rewrite Equation 1 to $\min_{a \in A_Q(q)} L_Q(a)$, where we define $L_Q(a) := \hat{d}_a + \min_{s \in S, b \in A_Q(s)} \hat{d}_b + d(a, b)$. Finding the optimal b for the evaluation of $L_Q(a)$ is essentially the closest site problem

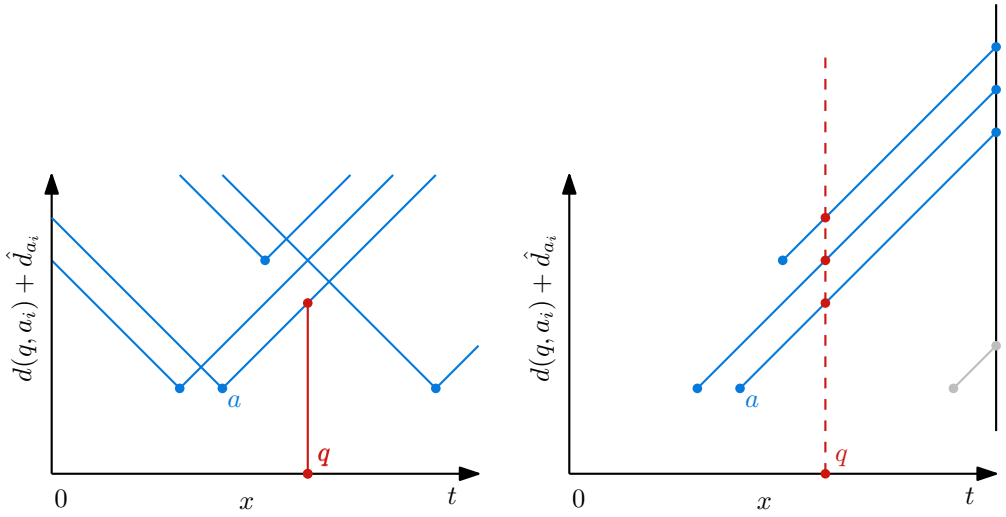

Figure 8 (a) For a query q we want to find the lowest intersection of the line at $q = x$ with the graph of the function $d(a, \cdot)$ of an anchor point $a \in A_Q(s)$. (b) The right half-lines of our V-functions. Note that the half lines intersect the vertical line at q in the same order as at t. Our data structure would find the site to the left of $q = x$ which makes the lowest intersection with $x = t$.

with additive weights $\hat{d}_b$. Furthermore, we only have to consider a 1-dimensional closest site problem as all anchor points lie on a shortest path $Q = \pi(u, v)$. This means we can map the coordinates of each point $a \in Q$ to the one-dimensional coordinate $a_x = d(u, a)$, this preserves distances as for all $a, b \in \pi(u, v)$ we have $d(a, b) = |d(u, b) - d(u, a)| = d(a_x, b_x)$.

Since these functions a have nice structure (see Figure 8), we can relatively easily maintain and query L_Q using priority search trees [4]. We store all $O(mk)$ anchor points (constructed using Lemma 11) and obtain:

▶ **Lemma 16.** *Let P be a polygonal domain with n vertices, let Q be a shortest path in P, and let S be a set of m sites in P. There is an $O(nk + mk)$ space data structure such that:*

- *For any point $q \in P$ we can find $\min_{s \in S} \hat{d}_Q(q, s)$ and the site which achieves this minimum in $O(k \log n + k^2 + k \log(mk))$ time.*
- *We can insert sites in amortized $O(k \log n + k^2 + k \log(mk))$ time, and delete sites in amortized $O(k \log(mk))$ time.*

Constructing an initially empty data structure takes $O(nk^2 \log n \log(kn))$ time.

5.3 The final data structure

Our data structure for general approximate nearest neighbor queries uses the same approach as in Section 4. Our data structure consists of the balanced hierarchical separator $\mathcal{T}$ from Lemma 12, in which we store associated structures at each node. We again preprocess the triangulation formed by the leaves for efficient point location, and store a pointer from each edge e to the highest shortest path Q in some $\mathcal{Q}_\nu$ that uses edge e.

For each internal node ν, and for each shortest path $Q \in \mathcal{Q}_\nu$, we now build an associated Lemma 16 data structure on Q. This structure will store a subset $S_{\nu,Q}$ of the sites. In particular, the sites in $S \cap P_\nu$ that did not lie on shortest paths of ancestors of ν.

For each leaf ν of $\mathcal{T}$, which represents some triangle P_ν, we store (a subset S_ν of) the sites in $S \cap P_\nu$ in the data structure from Lemma 15. We again store only the sites that did not already appear on shortest paths stored at ancestors of ν.

Finally, we build the data structure from Lemma 13 that allows us to efficiently compute the sets $X_Q(s)$ on any root-to-leaf path.

Space and construction time. Since the total complexity of all polygons associated with $\mathcal{T}$ is $O(n \log n)$, it readily follows that the total space of all Lemma 16 data structures is $O(nk \log n + mk \log n)$. As each site also appears in at most one leaf, it then follows that we use a total of $O(nk \log n + mk \log n + mk \log m)$ space. Similarly, constructing an empty data structure takes $O(nk^2 \log^2 n \log(kn))$ time.

Answering a query. Our goal is to report a site $s \in S$ that is ε-close to a query $q \in P$.

We point locate to find a triangle Δ_q that contains q, and compute the sets $X_Q(s)$ for all nodes on the path $\mathcal{T}(q)$ towards this leaf using the Lemma 13 data structure. For each shortest path $Q \in \mathcal{Q}_\nu$ of each node $\nu \in \mathcal{T}(q)$ along this path, we then query the Lemma 16 data structure. Each such query returns a site $s_{\nu,Q}$ that minimizes $\hat{d}_Q(q, s_{\nu,Q})$ among the sites in $S_{\nu,Q}$ (as well as the actual distance estimate $\hat{d}_Q(q, s_{\nu,Q})$). Finally, we query the Lemma 15 data structure of the leaf triangle Δ_q, to compute an ε-close site from the subset of sites stored there. We report the site s with overall minimum distance estimate.

Let s^* be site in S closest to q. We now argue that the site s and the distance estimate $\hat{d}(s, q)$ that we return indeed satisfies $d(q, s^*) \leq d(q, s) \leq \hat{d}(s, q) \leq (1 + \varepsilon)d(q, s^*)$.

If s^* also lies in Δ_q, then Lemma 15 guarantees that s is within distance $(1 + \varepsilon)d(q, s^*)$. Otherwise, the shortest path $\pi(q, s^*)$ from q to s^* must intersect one of the shortest paths $Q \in \mathcal{Q}_\nu$ on one of the nodes on the root-to-leaf path $\mathcal{T}(q)$. In particular, consider a shortest path of the highest such node ν. It follows that s^* is one of the sites in $S_{\nu,Q}$, and thus Lemma 16 guarantees that the candidate $s_{\nu,Q}$ has the minimum $\hat{d}_Q(q, s_{\nu,Q})$ value among all sites in $S_{\nu,Q}$. Hence, our distance estimate satisfies $\hat{d}(q, s) \leq \hat{d}_Q(q, s_{\nu,Q}) \leq \hat{d}_Q(q, s^*)$. Lemma 11 tells us that $\hat{d}_Q(q, s^*) \leq (1 + \varepsilon)d(q, s^*)$ as desired. Finally, since our distance estimate $\hat{d}(q, s)$ corresponds to the length of an obstacle avoiding path, we also have $d(s, q^*) \leq d(s, q) \leq \hat{d}(q, s)$, and thus s is indeed ε-close to q.

Finding the triangle containing q, and traversing the root-to-leaf path corresponding to this triangle takes $O(\log n)$ time. Querying all $O(\log n)$ Lemma 16 data structures along this path would take a total of $O(k \log^2 n + k^2 \log n + k \log(mk) \log n)$ time. Finally, the query to the Lemma 15 data structure stored at the leaf takes $O(k \log^2 m)$ time. As before, the $O(k \log^2 n)$ term in the query time is only due to computing the sets $X_Q(s)$ in every node separately. By querying the Lemma 13 data structure, we can again reduce this term to $O(k \log n)$. This reduces the total time required to query the Lemma 16 data structures to $O(k^2 \log n + k \log(mk) \log n + k \log^2 m)$, which simplifies to $O(k^2 \log n + k \log n \log m + k \log^2 m)$. As this term still dominates the other terms, this is also the final query time.

Updates. We first describe the process for inserting a new site s into S. We point locate to find a triangle P_ν that contains s. When s lies in the interior of such a triangle, then it must lie in the interior of all ancestor subpolygons P_μ as well, so we insert s into the Lemma 15 data structure of the leaf ν, and the Lemma 16 data structures along the root-to-leaf path. If s lies on an edge e of P_ν that is also an edge in a shortest path in one of the separators, we use the pointer stored at this edge to jump to the shortest path $Q \in \mathcal{Q}_{\nu'}$ of the highest such node ν', and insert s in the Lemma 16 data structures of ν' and its ancestors.

We have to insert s into at most one Lemma 15 data structure, (in $O(k \log^2 m)$ time), and at most $O(\log n)$ Lemma 16 data structures. Naively inserting them into every such structure then gives a total insertion time of $O(k \log^2 n + k^2 \log n + k \log(mk) \log n + k \log^2 m)$. As with the queries, we can compute the sets $X_Q(s)$ in $O(k \log n)$ time in total using Lemma 13. This then gives us a total insertion time of $O(k^2 \log n + k \log n \log m + k \log^2 m)$.

When we delete a site, we simply delete the site from all places where it was inserted. This takes a total of $O(k \log n \log m + k \log^2 m)$ time. Plugging in $k = \lceil 1/\varepsilon \rceil$ gives us Theorem 1.

Abstract

Sparse *shortcuttings* of trees – equivalently, sparse 1-spanners for tree metrics with bounded *hop-diameter* – have been studied extensively (under different names and settings), since the pioneering works of [24, 14, 2, 7], initially motivated by applications to range queries, online tree product, and MST verification, to name a few. These constructions were also lifted from trees to other graph families using known low-distortion embedding results. The works of [24, 14, 2, 7] establish a tight tradeoff between *hop-diameter* and sparsity (or average degree) for tree shortcuttings and imply constant-hop shortcuttings for n-node trees with sparsity $O(\log^* n)$. Despite their small sparsity, **all known constant-hop shortcuttings contain dense subgraphs** (of sparsity $\Omega(\log n)$), which is a significant drawback for many applications.

We initiate a systematic study of constant-hop tree shortcuttings that are "tree-like". We focus on two well-studied graph parameters that measure how far a graph is from a tree: *arboricity* and *treewidth*. Our contribution is twofold.

- **New upper and lower bounds for tree-like shortcuttings of trees**, including an *optimal* tradeoff between hop-diameter and treewidth for all hop-diameter up to $O(\log \log n)$. We also provide a lower bound for larger values of k, which together yield hop-diameter $\times$ treewidth $= \Omega((\log \log n)^2)$ *for all values of hop-diameter*, resolving an open question of [16, 19].
- **Applications of these bounds**, focusing on low-dimensional Euclidean and doubling metrics. A seminal work of Arya et al. [4] presented a $(1+\epsilon)$-spanner with constant hop-diameter and sparsity $O(\log^* n)$, but with large arboricity. We show that constant hop-diameter is sufficient to achieve arboricity $O(\log^* n)$. Furthermore, we present a $(1+\epsilon)$-stretch routing scheme in the *fixed-port* model with 3 hops and a local memory of $O(\log^2 n / \log \log n)$ bits, resolving an open question of [18].

1 Introduction

Given a tree $T = (V, E)$ and an integer $k \geq 1$, a *tree shortcutting* of T with hop-diameter k is a graph $G = (V, E')$ such that for every two vertices $u, v \in V$, there is a path in G consisting of at most k edges such that $\delta_G(u, v) = \delta_T(u, v)$, where $\delta_G(u, v)$ represents the distance between u and v in G. The problem of constructing sparse tree shortcuttings with small hop-diameter has been studied extensively (under different names and settings) since the pioneering works of [24, 14, 2, 7]. The optimal tradeoff is hop-diameter k with $\Theta(n\alpha_k(n))$ edges, where $\alpha_k(n)$ is a very slowly-growing inverse Ackermann function, $\alpha_2(n) = \lceil \log n \rceil$, $\alpha_3(n) = \lceil \log \log n \rceil$, $\alpha_4(n) = \log^* n$, etc.[1] (See the full version of the paper for a formal definition.)

Tree shortcutting has many applications, for example, finding max-flow [23], MST verification [23], maintaining MST under edge weight increases [23], computing semigroup product along paths and trees [24, 2], to name a few. In these applications, the shortcut graph serves as a compact data structure where k determines the query time, and the number of edges is the space. Tree shortcutting is a key subroutine in constructing low-hop $(1 + \epsilon)$-spanners for Euclidean [4, 22, 21] and doubling metrics [9, 18]. (See Section 2 for a formal definition.)

The fundamental drawback of sparse tree shortcuttings is that they are not uniformly-sparse – all of the aforementioned tree shortcutting constructions contain subgraphs with average degree of $\Omega(\log n)$ for $k = 2$ and $\Omega(\sqrt{n})$ for $k = 3$. As k increases, the (global) sparsity of the shortcutting reduces substantially, but the uniform sparsity remains $\Omega(\log n)$. Motivated by this, we initiate a systematic study of low-hop tree shortcuttings that are "tree-like". In particular, we are interested in two notions that capture uniform sparsity: *treewidth* and *arboricity*. (See Section 2 for formal definitions.)

Low-treewidth shortcutting. Low-treewidth shortcutting was introduced in the context of low-treewidth embedding of planar metrics. Specifically, Filtser and Le [16] showed that if one can construct a tree shortcutting with hop-diameter k and treewidth t, then one obtains an embedding of planar metrics into graphs of treewidth $O(kt/\epsilon)$ and additive distortion $+\epsilon D$, where D is the diameter of the input metric. They constructed a tree shortcutting with hop-diameter $k = O(\log \log n)$ and treewidth $t = O(\log \log n)$, and hence obtained an embedding with treewidth $O((\log \log n)^2/\epsilon)$. This bound does not seem to be optimal – other works [17, 11] used different embedding techniques to remove the dependency on n but at the cost of a (much) higher dependency on $1/\epsilon$. If one can construct a shortcutting with hop-diameter $k = O(1)$ and treewidth $t = O(\alpha_k(n))$ (which matches the sparsity bound), then one gets an embedding of planar metrics with treewidth $O(\alpha_k(n)/\epsilon) = O(\log^*(n)/\epsilon)$, which is almost as good as $O(1/\epsilon)$. The linear dependency on $1/\epsilon$ is optimal [16], whereas the other embedding techniques [17, 11] have an inherent $\Omega(1/\epsilon^2)$ barrier. Motivated by this observation, Filtser and Le [16] asked:

[1] Throughout the paper, we use $\log(x) \coloneqq \log_2(x)$.

▶ **Question 1** ([19, 16]). *Is there a tree shortcutting with treewidth t and hop-diameter k such that $k \cdot t = o((\log\log n)^2)$? Furthermore, is it possible for $k \cdot t$ to approach $O(1)$?*

In this work, we seek to answer a **broader question**: *What is the exact tradeoff between the hop-diameter k and the treewidth t of tree shortcuttings?* Understanding the full tradeoff would not only answer Question 1 but could also be useful for other applications that require a different hop-diameter. Specifically, in this paper, we use our construction for $k = 3$ to resolve an open problem posed by Kahalon et al. [18] regarding compact routing schemes.

Low-arboricity shortcutting. Given a set of points P in an Euclidean (or doubling) space of dimension d, one can construct a sparse $(1+\epsilon)$-spanner with a small hop-diameter. This is achieved via tree covers. (See Section 2 for a definition.) Known tree cover constructions for Euclidean and doubling metrics achieve stretch $1+\epsilon$ using $\epsilon^{-O(d)}$ trees [4, 5, 12]. By constructing a k-hop shortcutting G_T for each tree T in the cover $\mathcal{T}$, the union $\cup_{T\in\mathcal{T}} G_T$ is a k-hop $(1+\epsilon)$-spanner. For a constant ϵ and d, the sparsity is only $O(1)$ times worse than the sparsity of the shortcuttings, which is $O(\alpha_k(n))$. However, if G_T has low treewidth for every tree T, the union $\cup_{T\in\mathcal{T}} G_T$ might have a very large treewidth. A recent work on low-treewidth Euclidean spanners by Buchin, Rehs, and Scheele [8] showed that treewidth-t spanners must have stretch $\Omega(n/t^{d/(d-1)})$. That is, if the stretch is $O(1)$, the treewidth has to be very large: $\Omega(n^{1-1/d})$.

While the treewidth grows substantially under taking union, the arboricity does not: if G_T has arboricity at most β for every $T \in \mathcal{T}$, then $\cup_{T\in\mathcal{T}} G_T$ has arboricity $|\mathcal{T}|\beta$, which is $O(\beta)$ for constant ϵ and d. This makes arboricity an appealing tree-like measure. Specifically, one could hope to construct a low-arboricity Euclidean (or doubling) $(1+\epsilon)$-spanner with small hop-diameter using low-arboricity tree shortcuttings.

1.1 Our contribution

Our key **conceptual contribution** is in identifying the power of tree-like shortcuttings of trees, in particular in the regime of very small hop-diameter. We employ the low-treewidth construction with hop-diameter 3 to improve the state-of-the-art on low-hop compact routing schemes in tree and doubling metrics. Using the low-arboricity shortcuttings, we devise a $(1+\epsilon)$-spanner with arboricity $O(\log^* n)$ and hop-diameter 6 for doubling metrics. We also fully resolve Question 1 in the negative, which is our **main technical contribution**.

Treewidth. Our main technical contribution is a lower bound on the treewidth t of tree shortcuttings for any hop-diameter k, which holds even when the underlying graph is a path. This result fully resolves Question 1 in the negative.

▶ **Theorem 2.** *For every $n \geq 1$, every shortcutting with hop-diameter k for an n-point path must have treewidth:*

- $t = \Omega(k \log^{2/k} n)$ *for even k and* $t = \Omega(k(\frac{\log n}{\log\log n})^{2/(k-1)})$ *for odd $k \geq 3$, whenever* $k \leq \frac{2}{\ln(2e)} \ln\ln n$;
- $t = \Omega((\log\log n)^2/k)$ *whenever* $k > \frac{2}{\ln(2e)} \ln\ln n$.

Specifically, Theorem 2 implies that $t \cdot k = \Omega((\log\log n)^2)$, and therefore, the artificially looking upper bound by Filtser and Le [16] is indeed optimal.

We prove Theorem 2 by constructing a large clique minor K_t in any given shortcutting H with hop-diameter k. Such a clique minor is a certificate that the treewidth of G is at least t. Our lower bound instance is an n-vertex path, and the proof is by induction on

k. We observe that when $k = 2$, shortcutting H contains the clique $K_{\lfloor \log n \rfloor + 1}$ as a minor. For a higher even value of $k \geq 4$, we use the induction hypothesis for $k - 2$. We divide the path into equally sized subpaths and consider two cases. If there is a subpath where every vertex has an edge going out of it, we can readily construct a large minor using this subpath. Otherwise, each subpath P has at least one vertex without an edge going out of P. This allows us to use the induction hypothesis for $k - 2$ on a graph obtained by contracting each subpath into a single vertex. The argument for odd values of k is analogous. Although the method of constructing the minor is simple to describe, the analysis is much more intricate, specifically handling the dependency between k and n in the recurrences. See Section 3 for details.

We also give an upper bound construction that matches the lower bound when $k = O(\log \log n)$, which arguably is the most interesting regime. Our construction is a rather natural adaptation of the known result by Filtser and Le [16]. The difference is that when we shortcut a set of "cut vertices" recursively, we set the hop bound to be $k - 2$. This requires some technical work; the proofs are deferred to the full version. The following theorem summarizes the construction.

▶ **Theorem 3.** *For every $n \geq 1$ and every $k = O(\log \log n)$, every n-vertex tree admits a shortcutting with hop-diameter k and treewidth $O(k \log^{2/k} n)$ for even k and $O(k(\frac{\log n}{\log \log n})^{2/(k-1)})$ for odd $k \geq 3$.*

In Section 5, we use this construction to devise a 3-hop routing scheme for tree metrics with stretch 1 and $O(\log^2 n / \log \log n)$ bits per vertex. This answers the open question from [18]: "Whether or not one can use a spanner of larger (sublogarithmic and preferably constant) hop-diameter for designing compact routing schemes with $o(\log^2 n)$ bits is left here as an intriguing open question." In the full version of the paper, we prove that the bound is tight. Using tree covers, we obtain a 3-hop routing scheme with stretch $(1 + \epsilon)$ that uses $\epsilon^{-\tilde{O}(d)} \log^2 n / \log \log n$ bits per vertex for every n-point metric with doubling dimension d. (See Section 5.)

▶ **Theorem 4.** *For every n and every n-point metric with doubling dimension d, there is a 3-hop routing scheme with stretch $(1 + \epsilon)$ that uses $\epsilon^{-\tilde{O}(d)} \cdot \log^2 n / \log \log n$ bits per vertex.*

This provides the first routing scheme in Euclidean and doubling metrics, where the number of hops is $o(\log n)$, and the labels consist of $o(\log^2 n)$ bits.

Arboricity. In Section 4 we focus on low-arboricity shortcuttings. We show how to construct shortcuttings of *hierarchically separated trees (HSTs)* where the arboricity grows proportionally to an inverse Ackermann function.

Our starting point is a sparse shortcutting of an n-vertex path. We use the well-known fact about arboricity – if the edges of a given graph can be oriented so that the in-degree is bounded by β, then the arboricity is at most $\beta + 1$. Our key observation is that one can split every edge (u, v) of a sparse shortcutting into two edges (u, w) and (w, v) in order to reduce the in-degrees of u and v. By carefully choosing vertex w for every edge (u, v), we show that the arboricity can be bounded by $\alpha_{k/2+1}(n)$ when the hop-diameter is k. Roughly speaking, we achieve the same sparsity bound with a twice as large hop-diameter, which is the consequence of splitting each edge into two. Our construction for paths is then readily applicable to HSTs. Using the known HST cover [15], we obtain the following theorem. See Section 4 for details.

▶ **Theorem 5.** *Let k be an even integer and let $\epsilon \in (0, 1/6)$ be an arbitrary parameter. Then, for every positive integer n, every n-point metric with doubling dimension d admits a $(1+\epsilon)$-spanner with hop-diameter k and arboricity $\epsilon^{-O(d)}\alpha_{k/2+1}(n)$.*

This significantly strengthens the construction of Arya et al. [4], by providing a uniformly sparse (rather than just sparse) construction with constant hop-diameter: For hop-diameter k, we transition from sparsity $\epsilon^{-O(d)}\alpha_k(n)$ to arboricity $\epsilon^{-O(d)}\alpha_{k/2+1}(n)$. In particular, we get arboricity $O(\log^* n)$ with a hop-diameter of 6. Recall that, in contrast to arboricity, one cannot achieve similar dependencies on the treewidth.

For general trees, we obtain a k-hop shortcutting with arboricity $O(\log^{12/(k+4)} n)$. While the arboricity is larger than that of ultrametrics (cf. Lemma 16), it is smaller than the treewidth in Theorem 3 by about a factor of k (at a cost of some slack to the exponent of $\log n$). Specifically, when $k = \Theta(\log\log n)$, the arboricity is $O(1)$, while the treewidth is $\Omega(\log\log n)$. Using this result and the known tree cover constructions [10, 11, 5, 20], we obtain low-hop spanners for planar, minor-free, and general metrics with small arboricity. See the full version for details.

2 Preliminaries

Treewidth. A tree decomposition of $G = (V, E)$ is a tree T where each node is associated with a subset of V called a bag. The bags $X_1, \ldots, X_\ell$ satisfy: (i) $\cup_{i=1}^{\ell} X_i = V$, (ii) for every vertex $v \in V$, the collection of bags containing it forms a connected subtree of T, and (iii) for every edge $(u, v) \in E$, there is a bag containing u and v. The width of T is $\max_{i=1}^{\ell} |X_i| - 1$; the treewidth of G is the minimum width among all possible tree decompositions of G. If a graph G contains K_h as a minor, then the treewidth of G is at least $h - 1$.

Arboricity. The arboricity of $G = (V, E)$ is defined as $\max\lceil \frac{|E(H)|}{|V(H)|-1} \rceil$, where the maximum is taken over all subgraphs H of G with at least two vertices.

Spanners. Given a metric space $M_X = (X, \delta)$, which we view as a complete graph $(X, \binom{X}{2})$, a *t-spanner* of M_X is a subgraph $H = (X, E)$ with $E \subseteq \binom{X}{2}$, such that for every two vertices $x, y \in X$, their distance in H is at most $t \cdot \delta(x, y)$. The path $P_{x,y}$ realizing this distance is called a t-spanner path. The *hop-diameter* of a spanner is the minimum k such that between every two vertices $x, y \in X$ there is a t-spanner path with at most k edges.

Tree covers. Given a metric space $M_X = (X, \delta)$, a tree cover of M_X with stretch t is a collection of trees such that for every two vertices $x, y \in X$ we have $\delta(x, y) \le \min_{T \in \mathcal{T}} \delta_T(x, y) \le t \cdot \delta(x, y)$, where $\delta_T(x, y)$ is the distance between x and y in T.

3 Low-treewidth shortcuttings of trees: lower bound

In this section, we prove Theorem 2, restated below for the reader's convenience.

▶ **Theorem 2.** *For every $n \ge 1$, every shortcutting with hop-diameter k for an n-point path must have treewidth:*

- *$t = \Omega(k \log^{2/k} n)$ for even k and $t = \Omega(k(\frac{\log n}{\log\log n})^{2/(k-1)})$ for odd $k \ge 3$, whenever $k \le \frac{2}{\ln(2e)} \ln\log n$;*
- *$t = \Omega((\log\log n)^2/k)$ whenever $k > \frac{2}{\ln(2e)} \ln\log n$.*

Given an arbitrary integer n, our instance is the n-point path. We argue that any shortcutting of the path has a large minor. Due to the inductive nature of our argument, we prove a stronger version of the statement, which considers shortcuttings that could potentially use points outside of the given path. We start with the proof for hop-diameter $k = 2$.

▶ **Lemma 6.** *For every $n \geq 1$ and every n-vertex path L, every shortcutting with hop-diameter 2 has $K_{\lfloor \log n \rfloor + 1}$ as a minor.*

Proof. We prove the claim by complete induction over n. For the base case, we use $n = 1$, where the claim holds vacuously. Let H be a shortcutting for L with hop-diameter 2. Split L into two consecutive parts, L_1 and L_2, of sizes $\lfloor n/2 \rfloor$ and $\lceil n/2 \rceil$, respectively. Let H_1 and H_2 be subgraphs of H induced on L_1 and L_2, respectively. From the induction hypothesis, H_1 and H_2 have $K_{\log \lfloor n/2 \rfloor + 1}$ and $K_{\log \lceil n/2 \rceil + 1}$ as minors, respectively. Consider the case where every point of L_1 has an edge in H to some point in L_2. Then $K_{\log \lfloor n/2 \rfloor} \cup \{H_2\}$ induces a clique minor of size $\log \lfloor n/2 \rfloor + 1$. Consider the complementary case where L_1 has a point p that does not have an edge in H to any point in L_2. Then, every point in L_2 has a neighbor in L_1 because H has hop-diameter 2. Thus, $K_{\log \lceil n/2 \rceil} \cup \{H_1\}$ induces a clique minor of size $\log \lceil n/2 \rceil + 1$. Hence, the minor size satisfies recurrence $W_2(n) \geq W_2(\lfloor n/2 \rfloor) + 1$, with a base case $W_2(1) = 1$. The solution is given by $W_2(n) = \lfloor \log n \rfloor + 1$. ◀

We next give a proof for even values of k such that $4 \leq k \leq \frac{2}{\ln(2e)} \ln \log n$ in Lemma 7. The proof for odd values is analogous. The proof for $k > \frac{2}{\ln(2e)} \ln \log n$ is given in Lemma 8. We will need some auxiliary claims (Claims 9–11) in the proofs of Lemmas 7 and 8, as well as in the upper bound proof of Theorem 3. These claims are deferred to the end of this section.

▶ **Lemma 7.** *For every $n \geq 1$, every even k such that $4 \leq k \leq \frac{2}{\ln(2e)} \ln \log n$, and every n-vertex path L, every shortcutting with hop-diameter k has treewidth at least $c_1 k \log^{2/k} n - 1$, where c_1 is an absolute constant.*

Proof. We prove the statement by complete induction over n and k. For the base case, we take $n = 1$, and $W_k(1) = 1 > c_1 k \log^{2/k} n - 1$. Otherwise, let ℓ_k be such that $\log \ell_k = (\frac{k}{k-2})^{(k-2)/2} (\log n)^{(k-2)/k}$ for even values of k. (The proof for odd values is similar. There, we choose ℓ_k so that $\log \ell_k = (\frac{k}{k-2})^{(k-2)/2} (\log n / \log \log n)^{(k-2)/k}$.) By Claim 10, we have that $\ell_k \leq \sqrt{n}$, whenever $k \leq \frac{2}{\ln(2e)} \ln \log n$.

Split L into consecutive sets of points $L_1, L_2, \ldots, L_{\ell_k}$ of size $\lfloor n/\ell_k \rfloor$ each and ignore the remaining points. Let H be a shortcutting with hop-diameter k for L. Our goal is to show that the size of a clique minor of H can be lower bounded by the following recurrence.

$$W_k(n) \geq \min(W_{k-2}(\ell_k), W_k(n/(2\ell_k)) + 1) \text{ and } W_k(1) = 1 \tag{1}$$

We say that a point in L_i is *global* if it has an edge to a point outside L_i and *non-global* otherwise. We say that L_i is global if all of its points are global and *non-global* otherwise.

Case 1: Every L_i is non-global. See Figure 1 for an illustration. For every L_i and L_j the path between a non-global point in L_i and a non-global point in L_j must have the first (resp., last) edge inside L_i (resp., L_j). Let H' be obtained from H by contracting each L_i into a single vertex. (Clearly, $H[L_i]$ is connected.) Let L' be the path obtained from L by contracting every L_i into a single point. Then H' is a $(k-2)$-hop spanner of L' with stretch 1. Thus, H' has a minor of size $W_{k-2}(\ell_k) \geq c_1(k-2) \log^{2/(k-2)} \ell_k - 1 = c_1 k \log^{2/k} n - 1$.

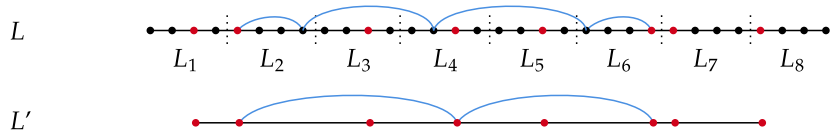

Figure 1 An illustration of Case 1. Every set L_i contains a non-global point. Any k-hop path between two non-global points must have the first and the last edge inside the corresponding sets. By contracting every L_i into a single point, we obtain a new path L'. Any shortcutting with hop-diameter k for L must have hop-diameter $k-2$ for L'. This allows us to use the induction hypothesis for $k-2$. In the illustration above the blue path consisting of 4 hops in L becomes a 2-hop path in L'.

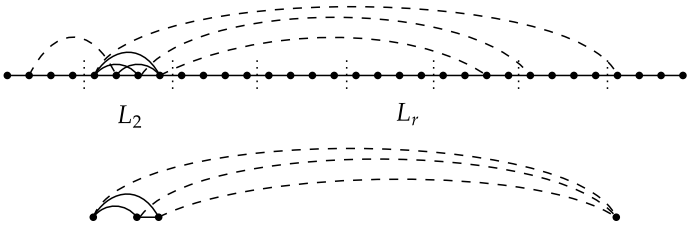

Figure 2 An illustration of Case 2. L_2 is global, meaning that every vertex is adjacent to an edge going outside of L_2. At least half of these edges are adjacent on the vertices in L_r. By contracting L_r and using the clique minor of L_2, we obtain the desired clique minor.

Case 2: Some L_i is global. See Figure 2 for an illustration. Let $\{L_l, L_r\} = L \setminus L_i$, so that L_l (resp., L_r) is on the left (resp., right) of L_i. (Possibly $L_l = \emptyset$ or $L_r = \emptyset$.) At least $|L_i|/2$ points in L_i have edges to either L_l or L_r. Without loss of generality, we assume the latter. Let $L_i' \subseteq L_i$ be the subset of points that have edges to L_r and let H_i be a subgraph of H which is a shortcutting of L_i with hop-diameter k. Inductively, H_i has a clique minor of size at least $W_k(n/(2\ell_k))$. (Since H_i is a 1-spanner, it does not include any point outside of L_i.) Then H_i and L_r are vertex-disjoint (because we are considering 1-spanners) and hence their union has a clique minor of size $W_k(n/(2\ell_k)) + 1$. Thus, $W_k(n)$ satisfies Equation (1), which we lower bound next.

$$
\begin{aligned}
W_k(n) &\geq \min(c_1 k(\log n)^{2/k} - 1, W_k(n/(2\ell_k)) + 1) \\
&\geq \min(c_1 k(\log n)^{2/k} - 1, c_1 k(\log n - \log \ell_k - 1)^{2/k}) \\
&\geq \min\left(c_1 k(\log n)^{2/k} - 1, c_1 k\left(\log n - \left(\frac{k}{k-2}\right)^{\frac{k-2}{2}} \cdot (\log n)^{(k-2)/k} - 1\right)^{2/k}\right) \\
&\geq \min\left(c_1 k(\log n)^{2/k} - 1, c_1 k(\log n)^{2/k} - 1\right)
\end{aligned}
$$

The last inequality follows from Claim 9 by replacing $c_1 = 1/\gamma$, $x = \log n$ and $\alpha = 1$. ◀

▶ **Lemma 8.** *For every $n \geq 1$, every $k > \frac{2}{\ln(2e)} \ln\log n$, every shortcutting with hop-diameter k for an n-vertex path has treewidth at least $c_2(\log\log n)^2/k$, for an absolute constant c_2.*
