Proof. We set ℓ_k so that $\log\log \ell_k = \sqrt{\frac{k-2}{k}} \log\log n$. (We use $\log(\cdot) \coloneqq \log_2(\cdot)$.) For the clarity of exposition, we ignore the rounding issues. We note that $1 \leq \ell_k \leq n$. Using the same argument as in Lemma 7, we have $W_k(n) \geq \min(W_{k-2}(\ell_k), W_k(n/(2\ell_k)) + 1)$. We prove the lemma by induction, where the base case is Lemma 7 whenever $k < \frac{2}{\ln(2e)} \ln\log n$. Our goal is to prove that $W_{k-2}(\ell_k) \geq c_2(\log\log n)^2/k$ and $W_k(n/(2\ell_k)) + 1 \geq c_2(\log\log n)^2/k$. For the first inequality we distinguish two cases. If $k - 2 \leq \frac{2}{\ln(2e)} \ln\log(\ell_k)$, then by Lemma 7 we have

$$\begin{aligned} W_{k-2}(\ell_k) &\geq c_1(k-2)\log^{\frac{2}{k-2}} \ell_k - 1 \geq c_1(k-2)\log^{\frac{\ln(2e)}{\ln\log \ell_k}} \ell_k - 1 = 2ec_1(k-2) - 1 \\ &\geq ec_1 k - 1 \geq ec_1 \cdot \left(\frac{2}{\ln(2e)}\right)^2 \frac{(\ln\log \ell_k)^2}{k} - 1 \geq c_2 \frac{(\log\log \ell_k)^2}{k-2} \end{aligned}$$

The penultimate inequality holds because $k \geq \frac{2}{\ln(2e)} \ln\log(n) \geq \frac{2}{\ln(2e)} \ln\log(\ell_k)$. The last inequality holds for a proper choice of constant c_2. If $k - 2 > \frac{2}{\ln(2e)} \ln\log(\ell_k)$, we have $W_{k-2}(\ell_k) \geq c_2 \frac{(\log\log \ell_k)^2}{k-2}$ by the induction hypothesis. Hence, in both cases, we have:

$$W_{k-2}(\ell_k) \geq c_2 \cdot \frac{(\log\log \ell_k)^2}{k-2} = c_2 \cdot \frac{\left(\sqrt{\frac{k-2}{k}} \log\log n\right)^2}{k-2} = c_2 \cdot \frac{(\log\log n)^2}{k}$$

For the second inequality, let $x = \log n$. We have $\log \ell_k = x^{\sqrt{(k-2)/k}}$. Since $\frac{n}{2\ell_k} < n$, we have that $k > \frac{2}{\ln(2e)} \ln\log \frac{n}{2\ell_k}$ and the induction hypothesis gives the following.

$$W_k\left(\frac{n}{2\ell_k}\right) + 1 \geq \frac{c_2 \left(\log\log\left(\frac{n}{2\ell_k}\right)\right)^2}{k} + 1 = \frac{c_2 \log^2\left(x - x^{\sqrt{(k-2)/k}} - 1\right)}{k} + 1$$

To show that the right-hand side is at least $c_2 \log^2(x)/k$, it suffices to show the following:

$$\log^2\left(x - x^{\sqrt{(k-2)/k}} - 1\right) + \frac{k}{c_2} \geq \log^2 x \tag{2}$$

From Claim 11 we have $x^{\sqrt{(k-2)/k}} \leq x - \frac{x \ln x}{k} + \frac{x \ln^2 x}{k^2}$.

$$x - x^{\sqrt{(k-2)/k}} - 1 \geq x - \left(x - \frac{x \ln x}{k} + \frac{x \ln^2 x}{k^2}\right) - 1 = \frac{x \ln x}{k}\left(1 - \frac{\ln x}{k}\right) - 1 > \frac{x \ln x}{10k} - 1$$

The last inequality holds because $k > \frac{2}{\ln(2e)} \ln(x)$. We next consider two cases. If $\frac{x \ln x}{10k} < 2$, then $\frac{k}{c_2} > \frac{x \ln x}{20c_2} \geq \log^2 x$ and Equation (2) is proved. Otherwise, we proceed as follows.

$$\begin{aligned} \log^2\left(\frac{x \ln x}{10k} - 1\right) + \frac{k}{c_2} &\geq \log^2\left(\frac{x \ln x}{20k}\right) + \frac{k}{c_2} = \left(\log x + \log\frac{\ln x}{20k}\right)^2 + \frac{k}{c_2} \\ &= \log^2 x + 2(\log x)\log\frac{\ln x}{20k} + \log^2\frac{\ln x}{20k} + \frac{k}{c_2} \geq \log^2 x \end{aligned}$$

The last inequality holds for any $c_2 \leq 1/10$. ◀

We conclude the section by proving the auxiliary claims used in the lemmas above.

▷ Claim 9. There is an absolute constant γ such that for $\alpha \in \{0,1\}$, every integer $k \geq 4$ and every $x > 1$ where the expression is defined, it holds

$$\frac{2}{k} < x^{2/k} - \left(x - \left(\frac{k}{k-2}\right)^{(k-2)/2} \cdot x^{(k-2)/k} - \alpha\right)^{2/k} < \frac{\gamma}{k}$$

Proof. We rewrite the expression as follows.

$$x^{2/k}\left(1 - \left(1 - \left(\frac{k}{k-2}\right)^{(k-2)/2} \cdot x^{-2/k} - \alpha x^{-1}\right)^{2/k}\right) \tag{3}$$

Using Maclaurin expansion, we have that $(1+y)^{2/k} = 1 + \frac{2}{k}y + \frac{2-k}{k^2} \cdot (1+\zeta)^{\frac{2}{k}-2} \cdot y^2$, where ζ is a number between 0 and y. We set $y = -\left(\frac{k}{k-2}\right)^{(k-2)/2} \cdot x^{-2/k} - \alpha x^{-1}$.

$$\left(1 - \left(\frac{k}{k-2}\right)^{(k-2)/2} \cdot x^{-2/k} - \alpha x^{-1}\right)^{2/k} = \tag{4}$$

$$1 - \frac{2}{k}\left(\left(\frac{k}{k-2}\right)^{\frac{k-2}{2}} x^{-\frac{2}{k}} + \alpha x^{-1}\right) - \frac{k-2}{k^2}(1+\zeta)^{\frac{2}{k}-2}\left(\left(\frac{k}{k-2}\right)^{\frac{k-2}{2}} \cdot x^{-\frac{2}{k}} + \alpha x^{-1}\right)^2 \tag{5}$$

Plugging Equation (4) into Equation (3), we obtain the following.

$$x^{2/k}\left(1 - \left(1 - \left(\frac{k}{k-2}\right)^{\frac{k-2}{2}} \cdot x^{-2/k} - \alpha x^{-1}\right)^{2/k}\right) =$$

$$\frac{2}{k}\left(\left(\frac{k}{k-2}\right)^{\frac{k-2}{2}} + \alpha x^{-\frac{k-2}{k}}\right) + \frac{k-2}{k^2}(1+\zeta)^{\frac{2}{k}-2}\left(\left(\frac{k}{k-2}\right)^{\frac{k-2}{2}} \cdot x^{-1/k} + \alpha x^{-\frac{k-1}{k}}\right)^2$$

The lower bound in Claim 9 holds because $-1 < y < \zeta < 0$ and $x > 1$. Next we prove the upper bound.

$$\frac{2}{k}\left(\left(\frac{k}{k-2}\right)^{\frac{k-2}{2}} + \alpha x^{-\frac{k-2}{k}}\right) + \frac{k-2}{k^2}(1+\zeta)^{\frac{2}{k}-2}\left(\left(\frac{k}{k-2}\right)^{\frac{k-2}{2}} \cdot x^{-1/k} + \alpha x^{-\frac{k-1}{k}}\right)^2 <$$

$$\frac{2(e + x^{-(k-2)/k}) + (ex^{-1/k} + x^{-(k-1)/k})^2}{k}$$

The right-hand side is decreasing with x in the whole domain and we can upper bound it by taking $x = 1$.

$$\frac{2(e + x^{-(k-2)/k}) + (ex^{-1/k} + x^{-(k-1)/k})^2}{k} < \frac{(e+1)(e+3)}{k}$$

Letting $\gamma = (e+1)(e+3)$, the upper bound from Claim 9 follows. ◁

▷ Claim 10. For every $3 \leq k \leq \frac{2}{\ln(2e)} \ln\log n$, it holds that $(\frac{k}{k-2})^{(k-2)/2}(\log n)^{(k-2)/k} \leq (\log n)/2$.

Proof. We have that $k \leq \frac{2}{\ln(2e)} \ln\log n$. Rearranging the last inequality, we have that $e(\log n)^{(k-2)/k} \leq (\log n)/2$. The proof is completed by observing that $(\frac{k}{k-2})^{(k-2)/2}$ is monotonically increasing for $k \geq 3$ and $\lim_{k\to\infty}(\frac{k}{k-2})^{(k-2)/2} = e$. ◁

▷ Claim 11. For every $x \geq 1$ and $k \geq 4$, $x^{\sqrt{(k-2)/k}} \leq x - \frac{x \ln x}{k} + \frac{x \ln^2 x}{k^2}$

Proof. Let $p := 1/k$. Then, $x^{\sqrt{(k-2)/k}} = x^{\sqrt{1-2p}}$. Using Taylor series around $p = 0$, we have that $x^{\sqrt{1-2p}} = x - px \ln x + R(p)$. The term $R(p)$ has the following form for $0 < \xi < p$.

$$R(p) = \frac{p^2}{2} \cdot x^{\sqrt{1-2\xi}} \ln x \left(\frac{\ln x}{1-2\xi} - (1-2\xi)^{-3/2} \right) \leq \frac{p^2}{2} \cdot x^{\sqrt{1-2\xi}} \ln x \cdot \frac{\ln x}{1-2\xi} \leq p^2 x \ln^2 x$$

To complete the proof, we replace p by $1/k$. ◁

4 Low-arboricity shortcuttings

In this section, we prove Theorem 5.

▶ **Theorem 5.** *Let k be an even integer and let $\epsilon \in (0, 1/6)$ be an arbitrary parameter. Then, for every positive integer n, every n-point metric with doubling dimension d admits a $(1+\epsilon)$-spanner with hop-diameter k and arboricity $\epsilon^{-O(d)} \alpha_{k/2+1}(n)$.*

We first describe the shortcutting on paths (Section 4.1) and then adapt it to HSTs via an analogous argument (Section 4.2). Instead of directly arguing about the arboricity, we show that the shortcutting can be oriented so that it has a bounded in-degree. The connection is provided by the following fact.

▶ **Fact 12.** *If the edges of a graph $G = (V, E)$ can be oriented such that the maximum in-degree of every vertex is at most d, then the arboricity of G is at most $d + 1$.*

4.1 Paths

The main intuition of this part of the proof is given in Figure 3. We shall use a modification of the following well-known result.

▶ **Theorem 13** (Cf. [3, 7, 22])**.** *For every $n \geq 2$ and $k \geq 2$, every n-point tree metric admits a shortcutting with hop-diameter k and $O(n\alpha_k(n))$ edges.*

We next prove a slightly modified version of this theorem.

▶ **Lemma 14.** *Let $n \geq 1$ and $k \geq 1$ be two arbitrary integers. Let L be a line metric induced by a set of n points on a line so that between every two points there are $\alpha_k(n)$ Steiner points for $k \geq 2$ and n^2 points for $k = 1$. Then, L admits a Steiner 1-spanner with hop-diameter $2k$ such that the Steiner points belong to S and every vertex in $L \cup S$ has a constant in-degree.*

Proof. We prove the lemma by induction over k. For $k = 1$, we interconnect the vertices in L by a clique. Consider an arbitrary clique edge (u, v) and split it into two using a Steiner point w. Orient the edges (u, w) and (w, v) into w. By using a fresh Steiner point for every clique edge, we obtain the guarantees from the statement. For $k = 2$, we take a central vertex c in L and connect it to every other point in L; orient the edges outwards from c. Proceed recursively with the two halves. This way we obtain a 1-spanner for L with hop-diameter 2. Denote by E the edge set of this spanner. The depth of the recursion in the construction is $O(\log n)$, and the size of S is $n\alpha_2(n) = n \log n$. Every vertex in L has in-degree 1 per recursion level. We can split every such edge into two using a fresh Steiner point for each recursion level. This concludes the proof for $k = 2$.

Consider now an arbitrary k. Divide L into intervals of size $\alpha_{k-2}(n)$ using $n/\alpha_{k-2}(n)$ cut vertices. Denote by C the set of cut vertices and invoke the induction hypothesis on C with parameter $k - 2$. Let E' be the obtained set of edges. Let E_C be obtained by connecting

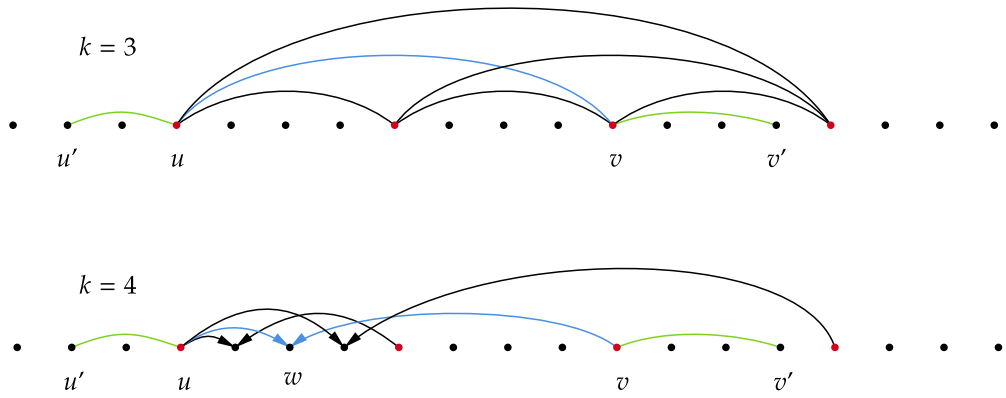

Figure 3 An illustration of the shortcutting with hop-diameter 4 and arboricity $O(\log\log n)$. We start by a well-known 3-hop construction [2, 7]. Split the path into subpaths using $\sqrt{n}$ cut vertices (red) so that every subpath contains $\sqrt{n}$ vertices. The shortcutting is obtained by: *(i)* interconnecting the cut vertices by a clique, *(ii)* connecting every cut vertex to the points in its two adjacent subpaths (in the illustration, only two such edges, (u', u) and (v, v'), are shown in green), and *(iii)* applying the recursive construction to each of the subpaths. This construction readily gives hop-diameter 3 (see, e.g., the path between u' and v'), but it suffers from having arboricity $\Omega(\sqrt{n})$ due to the clique on the cut vertices. To remedy this, we split every clique edge (u, v) into two edges, (u, w) and (w, v). This allows us to reduce the in-degree of every point to $O(1)$ per recursion level, at a cost of increasing the hop-diameter to 4. Overall, the number of recursion levels is $O(\log\log n)$, yielding the desired bound on the arboricity.

every cut vertex to every point in the two neighboring intervals; the edges are oriented out of E_C. Proceed recursively with parameter k on each of the intervals.

To analyze the in-degree, we observe that the depth of the recursion with parameter k is $O(\alpha_k(n))$, which coincides with the number of Steiner vertices between every two consecutive points in L. One level of recursion contributes a constant in-degree to each vertex in the construction. This means that we can split all such vertices into two and use a fresh Steiner point at each recursion level. This concludes the proof. ◀

▶ **Proposition 15.** *For every $n \geq 1$ and every even $k \geq 2$, every n-point path admits a shortcutting with hop-diameter k and arboricity $O(\alpha_{k/2+1}(n))$.*

Proof. Let L_n be an arbitrary line metric. For an integer $k' \geq 2$, we describe a construction of a shortcutting H for L_n with hop-diameter $4k' - 2$ and arboricity $O(\alpha_{2k'}(n))$.

Consider a set of $n' = n/\alpha_{2k'-2}(n)$ equally-spaced *cut vertices* dividing L_n into subpaths consisting of $\alpha_{2k'-2}(n)$ points. To construct the shortcutting H, we connect every cut vertex to all the vertices in its two neighboring intervals. Denote the corresponding edge by E_C. Let C be the set of cut vertices. Let E' be obtained by invoking Lemma 14 with parameter $2k' - 2$ on C using $L_n \setminus C$ as Steiner points. Proceed recursively with each of the intervals.

To analyze the arboricity, we will show that the edges in E_C and E' can be oriented so that the in-degree of every vertex is constant. Orient every edge in E_C so that it goes out of the corresponding cut vertex. Since every interval is adjacent to at most two cut vertices, the in-degree of every point with respect to E_C is at most 2. By Lemma 14, the edges in E' have a constant in-degree on L_n. In conclusion, E_C and E' contribute $O(1)$ to the in-degree of each vertex in L_n. The number of recursion levels $\ell(n)$ satisfies the recurrence $\ell(n) = \ell(\alpha_{2k'-2}(n)) + O(1)$, which has solution $\ell(n) = \alpha_{2k'}(n)$. Every recursion

level contributes $O(1)$ to the in-degree of vertices, meaning that the overall in-degree in H is $O(\alpha_{2k'}(n))$. The hop-diameter of H is $2 + 2 \cdot (2k' - 2) = 4k' - 2$. This concludes the description of a shortcutting with hop-diameter $4k' - 2$ and arboricity $O(\alpha_{2k'}(n)$.

Note that we have only shown how to get a tradeoff of hop-diameter $4k' - 2$ and arboricity $O(\alpha_{2k'}(n))$. We could similarly get a construction with hop-diameter $4k'$ and arboricity $O(\alpha_{2k'+1}(n))$ for a parameter $k' \geq 1$. Specifically, we divide L_n into intervals of size $\alpha_{2k'-1}(n)$. The cut vertices are interconnected using Lemma 14 with hop-diameter $2k' - 1$. The hop-diameter is $2 + 2(2k' - 1) = 4k'$ and the arboricity is $O(\alpha_{2k'+1}(n))$ using a similar argument. ◀

4.2 Ultrametrics and doubling metrics

A metric (X, d_X) is an *ultrametric* if it satisfies a strong form of the triangle inequality: for every x, y, z, $d_X(x, z) \leq \max\{d_X(x, y), d_X(y, z)\}$. It is well known that an ultrametric can be represented as a *hierarchical well-separated tree* (HST). More precisely, an (s, Δ)-*HST* is a tree T where *(i)* each node v is associated with a label Γ_v such that $\Gamma_v \geq s \cdot \Gamma_u$ whenever u is a child of v and *(ii)* each internal node v has at most Δ children. Parameter s is called the *separation* while Δ is called the *degree* of the HST. Let L be the set of leaves of T. The labels of internal nodes in T induce a metric (L, d_L) on the leaves, called leaf-metric, where for every two leaves $u, v \in L$, $d_L(u, v) = \Gamma_{\text{lca}(u,v)}$ where $\text{lca}(u, v)$ is the lowest common ancestor of u and v. It is well-known, e.g., [6], that (L, d_L) is an ultrametric, and that any ultrametric is isomorphic to the leaf-metric of an HST.

Chan and Gupta [9] showed that any $(1/\epsilon, 2)$-HST can be embedded into the line metric with (worst-case) distortion $1 + O(\epsilon)$. Therefore, by applying Proposition 15, we obtain a $(1 + O(\epsilon))$-spanner with hop diameter k and arboricity $O(\alpha_{k/2+1}(n))$ for $(1/\epsilon, 2)$-HSTs. In our setting, we are interested in large-degree (s, Δ)-HSTs where $s = 1/\epsilon$ and $\Delta = \text{poly}(1/\epsilon)$; the embedding result by Chan and Gupta [9] no longer holds for these HSTs. Instead, we directly apply our technique for the line metric to get a $(1 + O(\epsilon))$-spanner with low-hop diameter. We describe the modifications of Proposition 15 required to prove Lemma 16.

▶ **Lemma 16.** *Let $\epsilon \in (0, 1)$, $\Delta > 0$ be parameters, and k be an even positive integer. Then, any $(\Theta(1/\epsilon), \Delta)$-HST with n leaves admits a $(1 + \epsilon)$-spanner with hop-diameter k and arboricity $O(\alpha_{k/2+1}(n))$.*

Proof. Let T be the $(1/\epsilon, \Delta)$-HST and let M_T be the metric induced by T. For an integer $k' \geq 2$, we describe a construction of a $(1 + O(\epsilon))$-spanner for M_T with hop-diameter $4k' - 2$ and arboricity $O(\alpha_{2k'}(n))$. The construction is similar to that in Proposition 15.

Let C be the set of internal nodes of T, called *cut vertices*, such that the subtrees rooted at these nodes has size $\alpha_{2k'-2}(n)$. The number of cut vertices is $|C| \leq n/\alpha_{2k'-2}(n)$. First, connect every cut vertex to all of its descendants in T and let the corresponding set of edges be E_C. Next, let E be the set of edges interconnecting the cut vertices using Theorem 13 with hop-diameter $2k' - 2$ and $O(n'\alpha_{2k'-2}(n')) = O(n)$ edges. We construct a set E' by subdividing every edge $(u, v) \in E$ into two edges using a vertex, say x, in the subtree rooted at u. The spanner H is obtained using the edges in E_C and those in E'. Finally, the recursive construction is applied to each subtree rooted at a vertex in C. This concludes the description of the recursive construction of H. The same argument in Proposition 15 implies that the arboricity is $O(\alpha_{2k'}(n))$. The stretch is $(1 + O(\epsilon))$ since the path $u \to x \to v$ between two cut vertices u and v has stretch $(1 + O(\epsilon))$. ◀

To construct a low-hop spanner with small arboricity for doubling metrics (Theorem 5), we will rely on the ultrametric cover by Filtser and Le [15]. Following their notation, for a given metric space (X, d_X), we say that a collection $\mathcal{T}$ of at most τ different (s, Δ)-HSTs

such that (i) for every HST $T \in \mathcal{T}$, points in X are leaves in T, and (ii) for every two points $x, y \in X$, $d_X(x,y) \leq d_T(x,y)$ for every $T \in \mathcal{T}$, and there exists a tree $T_{xy} \in \mathcal{T}$ such that $d_X(x,y) \leq \rho \cdot d_{T_{xy}}(x,y)$.

▶ **Theorem 17** (Cf. Theorem 3.4 in [15]). *For every $\epsilon \in (0, 1/6)$, every metric with doubling dimension d admits an $(\epsilon^{-O(d)}, 1+O(\epsilon), 1/\epsilon, \epsilon^{-O(d)})$-ultrametric cover.*

Let $\mathcal{T}$ be the $(\epsilon^{-O(d)}, 1+O(\epsilon), 1/\epsilon, \epsilon^{-O(d)})$-ultrametric cover in Theorem 17 for the input doubling metric. We construct the spanner from Lemma 16 on each of $(1/\epsilon, \epsilon^{-O(d)})$-HST in $\mathcal{T}$ and take the union of them. This concludes the proof of Theorem 5.

5 Routing schemes

A compact routing scheme is a distributed algorithm that uses local information (routing tables and unique labels) to deliver packets between any source and destination node in a network. In this section, we prove Theorem 4.

▶ **Theorem 4.** *For every n and every n-point metric with doubling dimension d, there is a 3-hop routing scheme with stretch $(1+\epsilon)$ that uses $\epsilon^{-\tilde{O}(d)} \cdot \log^2 n / \log\log n$ bits per vertex.*

Our starting point is the routing scheme for the trees.

▶ **Theorem 18.** *For every n and every n-vertex tree T, there is a 3-hop routing scheme in the fixed-port model for the metric M_T induced by T with stretch 1 that uses $O(\log^2 n / \log\log n)$ bits per vertex.*

Proof. Given an n-vertex tree T, our routing scheme operates on top of a shortcutting with hop-diameter 3 and treewidth $O(\log n / \log\log n)$. We start by sketching this construction. Note that the routing scheme does not rely on the treewidth bound itself, but on the fact that the edges of the shortcutting can be oriented so that every vertex has an in-degree bounded by $O(\log n / \log\log n)$.

Let X be a set of vertices of T such that: *(i)* every component of $T \setminus X$ is of size $O(n \log\log n / \log n)$, *(ii)* the size of X is $O(\log n / \log\log n)$, *(iii)* every component of $T \setminus X$ has at most 2 edges adjacent to X, and *(iv)* if a component C has 2 edges adjacent to some $x, y \in X$, then x and y are in ancestor/descendant relation. Connect the vertices of X by a clique and do the following for every subtree T' in $T \setminus X$. Let u and v be two vertices from X adjacent to T'. Connect u and v to every vertex in T' and proceed recursively with T'. When $n \leq 3$, connect the vertices by a clique. This concludes the description of the shortcutting. The constructions of low-treewidth shortcuttings for general values of hop-diameter are more technical (and not needed for this section). See the full version for the details.

Our routing scheme is constructed on top of a 3-hop shortcutting H_3 described above. For a vertex $u \in T$, let table(u) denote its routing table and label(u) its label. First, assign a unique identifier $ID(u) \in \{1, \ldots, n\}$ to every vertex u in T and add it to table(u) and label(u). Equip the routing table and a label of every vertex $u \in T$ with an ancestor label anc(u) as in [1]. Using this ancestor labeling scheme, we can determine, given two vertices u and v, whether they are in ancestor-descendant relation, and if so, whether u is the ancestor of v or not. This adds $O(\log n)$ bits of memory per vertex.

Recall the recursive construction of the shortcutting. Assign to each recursive call a unique integer r_T. For every vertex in $u \in X$, add to table(u) the information consisting of $C(u) = \langle r_T, \{\langle ID(v), \text{port}(u,v), \text{anc}(v)\rangle \mid v \in X \setminus \{x\}\}\rangle$. The memory occupied per every vertex in X is $O(\log^2 n / \log\log n)$. (Note that the construction of H_3 guarantees that

every vertex belongs to such a clique exactly once across all the recursive calls, meaning that table(u) contains only one such $C(u)$.) Let T' be a subtree in $T \setminus X$. Let u and v be two vertices from X to which T' has outgoing edges. For every vertex $x \in T'$, add to table(x) the following: $\langle r_T, ID(u), \text{port}(x,u)\rangle$ and $\langle r_T, ID(v), \text{port}(x,v)\rangle$. Similarly, add to label(x) the following: $\langle r_T, ID(u), \text{port}(u,x)\rangle$ and $\langle r_T, ID(v), \text{port}(v,x)\rangle$. This information takes $O(\log n)$ bits per recursive call r_T. The construction proceeds recursively with T'; the number of recursive calls every vertex participates in is at most $O(\log n/\log\log n)$.

Next we describe the routing algorithm. Let u be the source and v be the destination. First, check if $C(u)$ contains routing information leading directly to v. In this case, the algorithm outputs port(u,v) and the routing is complete. (This case happens when u and v are in the same clique during the construction.) Otherwise, go over table(u) and label(v) and find the last recursive call r_T which is common to both u and v. Next, consider label(v) and the two entries consisting $\langle r_T, ID(v_1), \text{port}(v_1,v)\rangle$ and $\langle r_T, ID(v_2), \text{port}(v_2,v)\rangle$, corresponding to r_T. If v_1 and v_2 are in $C(u)$, use anc(u), anc(v_1), anc(v_2), and anc(v) to decide whether to output port(u,v_1) or port(u,v_2). (This case happens when u, v_1, and v_2 are in X in the recursive call r_T and v is not in it.) Finally, let $\langle r_T, ID(u_1), \text{port}(u,u_1)\rangle$ and $\langle r_T, ID(u_2), \text{port}(u,u_2)\rangle$ be the two entries corresponding to r_T in table(u). Use anc(u) and anc(v) to decide whether to output port(u,u_1) or port(u,u_2). (This case happens when u is not in X.) ◀

In what follows, we extend the routing result for tree metrics to the metrics with doubling dimension d. We first construct a tree cover using the tree cover theorem from [13].

▶ **Theorem 19** ([13]). *Given a point set P in a metric of constant doubling dimension d and any parameter $\epsilon \in (0,1)$, there exists a tree cover with stretch $(1+\epsilon)$ and $\epsilon^{-\tilde{O}(d)}$ trees. Furthermore, every tree in the tree cover has maximum degree bounded by $\epsilon^{-O(d)}$.*

We use this specific tree cover theorem, since the authors also provide an algorithm for determining the "distance-preserving tree" given the labels of any two metric points.

▶ **Lemma 20** ([13]). *Let $\epsilon \in (0,1)$. Let $T = \{T_1, \ldots, T_k\}$ be the tree cover for P constructed by Theorem 19, where $k = \epsilon^{-\tilde{O}(d)}$. There is a way to assign $\epsilon^{-\tilde{O}(d)} \log n$-bit labels to each point in P so that, given the labels of two vertices x and y, we can identify an index i such that tree T_i is a "distance-approximating tree" for u and v; that is, $\delta_{Ti}(x,y) \le (1+\epsilon)\delta_P(x,y)$. This decoding can be done in $O(d \cdot \log(1/\epsilon))$ time.*

We equip each tree in the cover with the stretch-1 routing scheme from Theorem 18. This consumes overall $\epsilon^{-\tilde{O}(d)} \log^2 n/\log\log n$ bits per point in P. In addition, we add $\epsilon^{-\tilde{O}(d)} \log n$-bit labels to each point in P as stated in Lemma 20. Given two points $x, y \in P$, we first employ the algorithm from Lemma 20 to find the tree in which the routing should proceed. Then, the routing proceeds on that specific tree using the routing algorithm from Theorem 18. This concludes the proof of Theorem 4.

Abstract

For a weighted graph $G = (V, E, w)$ and a designated source vertex $s \in V$, a spanning tree that simultaneously approximates a *shortest-path tree* w.r.t. source s and a *minimum spanning tree* is called a *shallow-light tree (SLT)*. Specifically, an (α, β)-SLT of G w.r.t. $s \in V$ is a spanning tree of G with *root-stretch* α (preserving all distances between s and all other vertices up to a factor of α) and *lightness* β (its *weight* is at most β times the weight of a minimum spanning tree of G).

It was shown in the early 1990s that (1) for any graph, any source, and any $\epsilon > 0$, there is a $(1+\epsilon, O(1/\epsilon))$-SLT, and (2) there *exist* graphs for which $\beta = \Omega(1/\epsilon)$ for any $(1+\epsilon, \beta)$-SLT.

The focus of this work is on SLTs in *low-dimensional Euclidean spaces*, which are of special interest for some applications of SLTs, in geometric network optimization problems. The aforementioned existential lower bound applies to Euclidean plane, as well. It was shown more than a decade ago that (1) by using *Steiner points*, one can reduce the lightness bound from $O(1/\epsilon)$ to $O(\sqrt{1/\epsilon})$, and (2) there exist point sets in the plane for which $\beta = \Omega(\sqrt{1/\epsilon})$ for any Steiner $(1+\epsilon, \beta)$-SLT.

These *tight existential bounds* for the Euclidean case yield *approximation factors* of $O(1/\epsilon)$ and $O(\sqrt{1/\epsilon})$ on the minimum weight of any non-Steiner and Steiner tree with root-stretch $1+\epsilon$, respectively. Despite the large body of work on SLTs, the basic question of whether a better approximation algorithm exists was left untouched to date, and this holds in any graph family. This paper makes a first nontrivial step towards resolving this question by presenting two *bicriteria approximation* algorithms. For any $\epsilon > 0$, a set P of n points in constant-dimensional Euclidean space and a source $s \in P$, our first (respectively, second) algorithm returns, in $O(n \log n \cdot \mathrm{polylog}(\epsilon^{-1}))$ time, a non-Steiner (resp., Steiner) tree with root-stretch $1 + O(\epsilon \log \epsilon^{-1})$ and weight at most $O(\mathsf{opt}_\epsilon \cdot \log^2 \epsilon^{-1})$ (resp., $O(\mathsf{opt}_\epsilon \cdot \log \epsilon^{-1})$), where opt_ϵ denotes the minimum weight of a non-Steiner (resp., Steiner) tree with root-stretch $1+\epsilon$.

1 Introduction

A *shortest-path tree (SPT)* of an undirected edge-weighted n-vertex graph $G = (V, E, \mathbf{w})$ with respect to a designated *source* or *root* vertex $s \in V$, denoted by $\mathsf{SPT}(G, s)$ is a spanning tree T rooted at s that preserves all distances from s, i.e., for every vertex $v \in V$, the distance $d_T(s, v)$ between s and v in T equals their distance $d_G(s, v)$ in G. For a parameter $\alpha \geq 1$, an *α-shallow tree (α-ST)* is a spanning tree T of G of *root-stretch* at most α, i.e., for every $v \in V$, $d_T(s, v) \leq \alpha \cdot d_G(s, v)$. A *minimum spanning tree (MST)* of G, denoted by $\mathsf{MST}(G)$, is a spanning tree T of G of minimum weight. For a parameter $\beta \geq 1$, a *β-light tree (β-LT)* is a spanning tree T of G of *lightness* β, i.e., $\mathbf{w}(T) \leq \beta \cdot \mathbf{w}(\mathsf{MST}(G))$. The SPT and the MST, including their approximate versions, are among the most fundamental graph constructs and have been extensively studied over decades.

A single tree that simultaneously approximates the SPT and the MST is called a *shallow-light tree (SLT)*. For a pair of parameters $\alpha, \beta \geq 1$, a (α, β)-SLT of graph G w.r.t. a designated source $s \in V$ is a spanning tree of G that is both a α-ST and a β-LT. The notion of SLTs was introduced in the pioneering works of Awerbuch et al. [2, 3] and Khuller et al. [18] (see also [8]). They showed that for every $\epsilon > 0$, a $(1 + \epsilon, O(\frac{1}{\epsilon}))$-SLT can be constructed in linear time for every graph G if an SPT and an MST are given. Khuller et al. [18] also showed that this tradeoff is tight, by presenting a *planar* graph for which $\beta = \Omega(\frac{1}{\epsilon})$ for any $(1 + \epsilon, \beta)$-SLT.

The balance between the useful properties of an MST, which provides a light-weight network, and of an SPT, which provides short paths from a designated source to all other vertices, has led to a wide variety of applications across diverse domains. This includes applications in routing [1, 5, 16, 19, 21, 27, 32] and in network and VLSI-circuit design [7, 8, 14, 26], for data gathering and dissemination tasks in overlay networks [17, 20, 30], in the message-passing model of distributed computing [2, 3], and in wireless and sensor networks [31, 4, 9, 23, 22, 28]. Additionally, SLTs are used as building blocks in other related graph structures, such as *light approximate routing trees* [32], *shallow-low-light trees* [11, 12], *light spanners* [3, 25], and others [26, 23, 22]. In particular, in real-world applications, such as VLSI-design and wireless communication networks, the vertices are embedded in Euclidean space, and the edge weights correspond to the metric distances between the nodes.

Low-dimensional Euclidean spaces. Khuller et al. [18] asked whether a better construction of SLTs can be achieved in Euclidean plane, *which is the focus of this work*. Euclidean space $\mathbb{R}^d$, $d \geq 1$, can be modeled as a complete edge-weighted graph $G = (V, E, \mathbf{w})$ induced by a finite set P of points in $\mathbb{R}^d$ with $V = P$, $E = \binom{P}{2}$, and $\mathbf{w} = \|\cdot\|_2$. Elkin and Solomon [13] showed that the upper bound of $(1 + \epsilon, O(\frac{1}{\epsilon}))$-SLTs in general graphs [2, 3, 18] is asymptotically tight even in Euclidean plane: For a set C of $\lceil 1/\epsilon \rceil$ evenly spaced points on a circle, any $(1 + \epsilon, \beta)$-SLT for C for any source $s \in C$ must have $\beta = \Omega(\frac{1}{\epsilon})$. Solomon [29] showed that allowing *Steiner points* lead to substantial improvement in Euclidean plane: For

every set $P \subset \mathbb{R}^2$ and source $s \in P$, one can construct a *Steiner* $(1+\epsilon, O(\sqrt{1/\epsilon}))$-SLT in linear time. Moreover, this bound is asymptotically tight: For the same set C of $\lceil 1/\epsilon \rceil$ evenly spaced points on a circle (in fact, here $\lceil \sqrt{1/\epsilon} \rceil$ evenly spaced points suffice), any Steiner $(1+\epsilon, \beta)$-SLT for C for any source $s \in C$ must have $\beta = \Omega(\sqrt{1/\epsilon})$ [13, 29].

Approximation algorithms and hardness. The aforementioned results provide *tight existential bounds* on the tradeoff between root-stretch and lightness of SLTs in general graphs as well as in planar graphs and in Euclidean plane; moreover, as mentioned above, tight bounds were established also for *Steiner* SLTs in Euclidean plane. However, these algorithms do not necessarily provide instance-optimal SLTs: We present point sets $P \subset \mathbb{R}^2$ for which any previous SLT algorithm in [2, 3, 18] returns a $(1+\epsilon)$-ST of weight $O(\frac{1}{\epsilon}) \cdot \mathbf{w}(\mathsf{MST}(P))$, Solomon [29] constructs a Steiner $(1+\epsilon)$-ST of weight $O(\sqrt{1/\epsilon}) \cdot \mathbf{w}(\mathsf{MST}(P))$, but the minimum weight of a $(1+\epsilon)$-ST is only $O(1) \cdot \mathbf{w}(\mathsf{MST}(P))$. Despite the large body of work on SLTs, very little is known about SLTs from the perspective of optimization and approximation algorithms.

In the *$(1+\epsilon)$-SLT problem*, we are given a parameter $\epsilon \geq 0$ and an edge-weighted graph G, and the goal is to find a $(1+\epsilon)$-ST for G of minimum weight. Khuller et al. [18] showed that for any $\epsilon > 0$, the $(1+\epsilon)$-SLT problem is NP-hard (via a reduction from 3SAT), while the case $\epsilon = 0$ can be solved in near-linear time. Cheong and Lee [6] showed that it is NP-hard in Euclidean plane, as well (via a reduction from Knapsack). A κ-approximation algorithm for the problem should return a $(1+\epsilon)$-ST for G whose weight is at most κ times that of a minimum weight $(1+\epsilon)$-ST. One can also consider a *bicriteria approximation*: a (κ_1, κ_2)-approximation for the problem should return a $(1+\kappa_1 \cdot \epsilon)$-ST for G whose weight is at most κ_2 times that of a minimum-weight $(1+\epsilon)$-ST.

The *tight existential bounds*, mentioned above, yield *approximation factors* of $O(1/\epsilon)$ and $O(\sqrt{1/\epsilon})$, respectively, for the $(1+\epsilon)$-SLT problem on general edge-weighted graphs and in Euclidean plane, respectively. To the best of our knowledge, no other approximation algorithm or hardness result is known for this problem, even for basic graph families such as the complete graph with Euclidean edge weights. (In our full version, we discuss a related problem, for which both approximation algorithms and hardness results are known.)

In Euclidean spaces, one can define the *Steiner $(1+\epsilon)$-SLT problem*: For a parameter $\epsilon \geq 0$ and an input point set $P \subset \mathbb{R}^d$, $d \in \mathbb{N}$, the goal is to find a Steiner $(1+\epsilon)$-ST for P of minimum weight. We note that a minimum weight Steiner $(1+\epsilon)$-ST may be significantly lighter than a minimum weight non-Steiner $(1+\epsilon)$-ST. For example, for a set C of $\lceil 1/\epsilon \rceil$ evenly spaced points on a circle, the ratio between the weights of minimum weight non-Steiner and Steiner $(1+\epsilon)$-STs is $\Theta(\sqrt{1/\epsilon})$.

1.1 Our Contribution

We provide a bicriteria approximation for the $(1+\epsilon)$-SLT problem, where $0 < \epsilon \ll 1$ is an arbitrary parameter, in any constant-dimensional Euclidean space. (We shall assume throughout that ϵ is a sub-constant parameter. If $\epsilon > 0$ is a constant, the algorithm in [18] already provides a constant approximation in linear time.)

▶ **Theorem 1.** *There is an $O(n \log n \cdot \mathrm{polylog}(\epsilon^{-1}))$-time algorithm that, given $\epsilon > 0$, a finite set P of n points in Euclidean plane, including a source $s \in P$, returns a Steiner $(1 + O(\epsilon \log \epsilon^{-1}))$-ST of weight at most $O(\mathsf{opt}_\epsilon \cdot \log \epsilon^{-1})$, where opt_ϵ denotes the minimum weight of a Steiner $(1+\epsilon)$-ST. The result extends without any loss in parameters to Euclidean space $\mathbb{R}^d$, for any constant $d \geq 3$.*

Interestingly, our bicriteria approximation algorithm of Theorem 1 incurs the same $O(\log \epsilon^{-1})$ ratio for both the stretch approximation (to the additive ϵ term) and the weight approximation. With some additional effort and another $\log \epsilon^{-1}$ factor in the weight approximation ratio, our result generalizes to the setting without Steiner points in the plane.

▶ **Theorem 2.** *There is an $O(n \log n \cdot \text{polylog}(\epsilon^{-1}))$-time algorithm that, given $\epsilon > 0$, a finite set P of n points in Euclidean plane, including a source $s \in P$, returns a $(1+O(\epsilon \log \epsilon^{-1}))$-ST of weight at most $O(\mathsf{opt}_\epsilon \cdot \log^2 \epsilon^{-1})$, where opt_ϵ denotes the minimum weight of a $(1+\epsilon)$-ST. The result extends to Euclidean space $\mathbb{R}^d$, for any constant $d \geq 3$, with approximation ratio increasing by a factor of $O(\log \epsilon^{-1})$ and the running time increasing by a factor of $\mathsf{poly}(\epsilon^{-1})$.*

To complement our results, we show that the approximation ratio of our algorithms (with or without using Steiner points) is significantly better than the state-of-the-art algorithms at the instance level. Specifically, we design point sets in Euclidean plane for which any previous algorithm returns a $(1+\epsilon)$-ST of approximation ratio at least $\Omega(\sqrt{1/\epsilon})$ with Steiner points and $\Omega\left(\frac{1}{\epsilon}\right)$ without Steiner points.

▶ **Theorem 3.** *For every $\epsilon > 0$, there exists a set $P \subseteq \mathbb{R}^2$ and a source $s \in P$ such that the minimum weight of a $(1+\epsilon)$-ST (resp., Steiner $(1+\epsilon)$-ST) is $O(1) \cdot \mathbf{w}(\mathsf{MST}(P))$, but any previous algorithm in [2, 3, 18] returns a $(1+\epsilon)$-ST of weight $\Omega(\frac{1}{\epsilon}) \cdot \mathbf{w}(\mathsf{MST}(P))$, and the algorithm in [29] returns a Steiner $(1+\epsilon)$-ST of weight $\Omega(\sqrt{1/\epsilon}) \cdot \mathbf{w}(\mathsf{MST}(P))$.*

To prove Theorem 1 and Theorem 2, we reduced the problem to a set of points, called centered ϵ-net, in a region in a cone with aperture $\sqrt{\epsilon}$, within $\Theta(1)$ distance from the root. The classical lower-bound construction for this problem consists of a set P of uniformly distributed points along a circle of unit radius centered at the root s. However, if P is the subset of points in a cone of angle $\sqrt{\epsilon}$, then there exists a Steiner $(1+\epsilon)$-ST of weight $O(1) \cdot \mathbf{w}(\mathsf{MST}(P))$ [29]. This raises the question: What is the maximum lightness of a Steiner $(1+\epsilon)$-ST for points in a cone of aperture $\sqrt{\epsilon}$? We give a lower bound on the maximum lightness of a minimum-weight Steiner $(1+\epsilon)$-ST for points in a cone of aperture $\sqrt{\epsilon}$.

1.2 Technical Overview

Given a set P of n points in the plane, including a source $s \in P$, and a parameter $\epsilon > 0$, we describe $O(n \log n \cdot \text{polylog}(\epsilon^{-1}))$-time algorithms to construct a (Steiner) $(1+\epsilon \cdot \log \epsilon^{-1})$-ST rooted at s, and then analyze its weight compared to the minimum weight $(1+\epsilon)$-ST rooted at s. We note that, since $(1+\epsilon)$-STs do not have a recursive substructure, the stretch between two arbitrary points in P may be unbounded. Yet, we can apply a divide-and-conquer strategy by clustering nearby points together, based on their position w.r.t. the source s.

In Section 3, we partition the plane into trapezoid tiles, and show that the union of bicriteria approximate SLTs for the point sets in the tiles is a bicriteria approximation for the entire point set for both the Steiner and non-Steiner settings (Theorem 6). We construct a tiling based on geometric considerations. The diameter of each tile τ is proportional to the distance $\text{dist}(s, \tau)$, and the shape of τ is roughly $A \times (A \cdot \sqrt{\epsilon})$ for $A = \text{dist}(s, \tau)$; see Figure 1. That is, we choose the aspect ratio of every tile to be roughly $\sqrt{\epsilon}$ for the following reason: The triangle inequality implies that every ps-path of weight at most $(1+\epsilon) \cdot d(p, s)$ lies in an ellipse $\mathcal{E}_{ps}$ with foci p and s, and aspect ratio roughly $\sqrt{\epsilon}$; see Section 2. Therefore, the union of all ellipses $\mathcal{E}_{ps}$, for all points $p \in P \cap \tau$, will be similar to the tile τ in the sense that the aspect ratio of its bounding box is roughly $\sqrt{\epsilon}$. The shape of the tiles is crucial for the proof of the reduction (Theorem 6).

For all points in a tile $P \cap \tau$, the distance $d(p, s)$ to s is the same up to constant factors. We can further partition the set of points in each tile into cluster by approximating $d(p, s)$ up to a $(1 + \epsilon)$-factor. Recall that a classical ϵ-*net* in a metric space (X, d) is a set $N \subset X$ such that the points in N are at least ϵ distance apart, and the ϵ-neighborhood of every point $x \in X$ contains a net point in N. In Section 3, we define a *centered ϵ-net* N, where points $a, b \in N$ are at least $\epsilon \cdot \max\{d(a, s), d(b, s)\}$ apart, and the $(\epsilon \cdot d(p, s))$-neighborhood of every point $p \in P$ contains a net point in N. We show that a bicriteria approximate STs for a centered ϵ-net can be extended to bicriteria ST for the entire point set, using $O(1)$-spanners in the neighborhoods of the net points (Lemma 7). Interestingly, we reduce the $(1 + \epsilon)$-SLT problem for P to a variant of the Steiner $(1 + \epsilon)$-SLT problem for the net $N \subset P$, where all Steiner points must be in the original set P. We note that although the reduction steps in Section 3 are new and essential to our approach, they are based mainly on standard techniques.

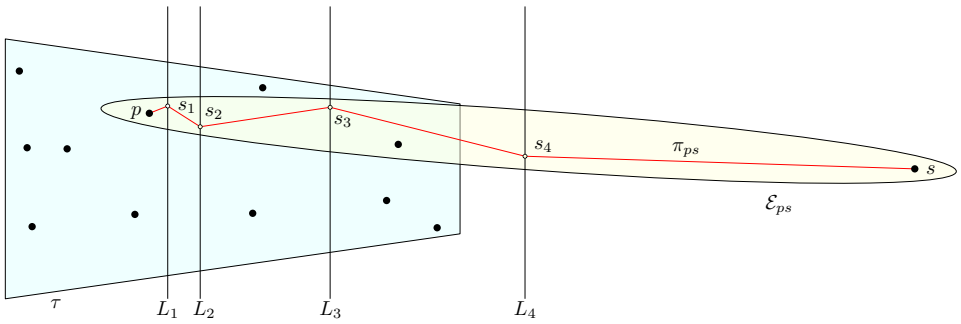

Figure 1 Points in a trapezoid tile τ, and Steiner points $s_1, \ldots, s_4 \in \mathcal{E}_{ps}$ on parallel lines.

The core technical contributions of our work appear in Sections 4 and 5, where we construct a Steiner ST for a centered ϵ-net in Section 4 and then extend the construction to the non-Steiner setting in Section 5. The Steiner setting is easier to work with because we can control the location of Steiner points. We begin with a brief overview of the Steiner construction; refer to Figure 1. From the perspective of a single point $p \in P \cap \tau$, the construction is similar to the Steiner SLT construction by [29], which gave an existentially tight bound: We choose Steiner points $s_1, s_2, \ldots, s_{k-1}$ in the ellipse $\mathcal{E}_{ps}$ on parallel lines $L_1, \ldots, L_{k-1}$ at distance $4^i \epsilon \cdot d(p, s)$ from p, where $k = O(\log \epsilon^{-1})$. Solomon [29] shows that one can carefully choose Steiner points so that the stretch of the path $\pi_{ps} = (p, s_1, \ldots, s_{k-1}, s)$ is at most $1 + \epsilon$. However, geometric calculations show that even if we choose arbitrary points $s_i \in L_i \cap \mathcal{E}_{ps}$ for $i = 1, \ldots, k - 1$, then each edge $s_{i-1}s_i$ still contributes only $O(\epsilon)$ to the stretch (more precisely, $\mathbf{w}(s_{i-1}s_i)$ exceeds the length of its orthogonal projection to the line ps by $O(\epsilon) \cdot d(p, s)$). In other words, arbitrary Steiner points $s_i \in L_i \cap \mathcal{E}_{ps}$, for $i = 1, \ldots, k - 1$, guarantee a root-stretch $1 + O(\epsilon \cdot \log \epsilon^{-1})$.

For a point set $P_\tau = P \cap \tau$ in a tile τ, we follow the above strategy, but we synchronize the lines $L_1, \ldots, L_k$ chosen for different points in P_τ. Then each line L_i corresponds to many points $p \in P_\tau$, and intersects their ellipses $\mathcal{E}_{ps}$. We use a *minimum hitting set* for the intervals $L_i \cap \mathcal{E}_{ps}$, to choose the minimum number of Steiner points that serve all associated ellipses. The weight analysis uses the fact that each ellipse $\mathcal{E}_{ps}$ contains a ps-path that crosses all lines $L_1, \ldots, L_k$.

In Section 5, we adapt the Steiner ST algorithm to the non-Steiner setting. However, both the algorithm design and its analysis are more challenging. Instead of creating Steiner points s_i in a line L_i of our choice, now all points s_i must be in P. We use the lines $L_1, \ldots, L_k$ to

cover the ellipse $\mathcal{E}_{ps}$ with axis-aligned rectangles whose corners are on two consecutive lines L_i and L_{i+1}; and then choose *minimum hitting sets* from P for the *nonempty* rectangles. Some of the rectangles R_i might be *empty* (i.e., $R_i \cap P = \emptyset$). This means that we cannot choose a point $s_i \in P$ in R_i for some ps-path (our algorithm simply skips R_i), but it also means that an optimal ST OPT does not have any vertices in R_i, to the ps-path in OPT contains an edge that traverses R_i whose weight is proportional to the width of R_i. This is a crucial observation for the weight analysis. The root-stretch analysis also requires more work in the non-Steiner setting: In the Steiner case, the Steiner points s_{i-1} and s_i are on the lines L_{i-1} and L_i, so we can control the distance between s_{i-1} and s_i. However, when are limited to points $s_{i-1}, s_i \in P$ in rectangles R_{i-1} and R_i, it is possible that s_{i-1} and s_i are too close to each other, and their contribution to the root-stretch is too large. In such cases, we modify the ps-paths by skipping s_{i-1} or s_i. This ensures that the distances between consecutive points of the ps-paths are sufficiently large, and we prove that the weight increases by at most a constant factor. We show that our algorithms (for both the Steiner and non-Steiner settings) extend naturally to higher dimensions using cone partitioning and approximate high-dimensional hitting sets. For the Steiner version, the approximation guarantee remains unchanged. However, the non-Steiner algorithm incurs an additional $\log(\varepsilon^{-1})$ factor in its approximation ratio. Its running time also increases by an additional $\mathsf{poly}(\varepsilon^{-1})$ factor.

2 Preliminaries

Let $p, s \in \mathbb{R}^2$, and $\epsilon > 0$. If π_{ps} is a ps-path of weight at most $(1+\epsilon) \cdot d(p,s)$, then every point $q \in \pi_{ps}$, we have $d(p,q) + d(q,s) \leq \mathbf{w}(\pi_{ps}) \leq (1+\epsilon) \cdot d(p,s)$. This implies that π_{ps} is contained in the ellipse $\mathcal{E}_{ps}$ with foci p and s, and major axis $(1+\epsilon)d(p,s)$; see Figure 2. The ellipse $\mathcal{E}_{ps}$ is contained in a rectangle spanned by its major and minor axes. The length of its minor axis is $\sqrt{(1+\epsilon)^2 - 1} \cdot d(p,s) = \sqrt{2\epsilon + \epsilon^2} \cdot d(p,s) < 2\sqrt{\epsilon} \cdot d(p,s)$ if $\epsilon < 2$.

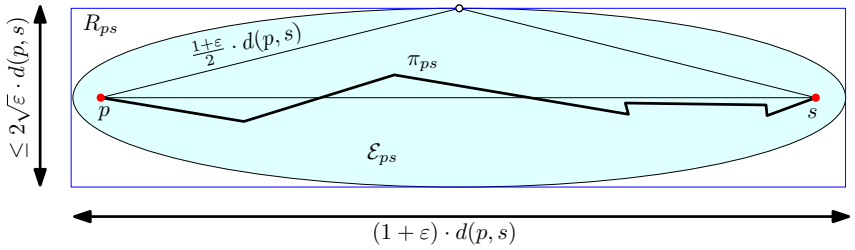

Figure 2 The ellipse $\mathcal{E}_{ps}$ with foci p and s and major axis of length $(1+\epsilon) \cdot d(p,s)$.

For analyzing the weight of an ST, we consider a ps-path π_{ps} as a polyline (i.e., a subset of the plane). In particular, for any region $R \subset \mathbb{R}^2$, the intersection $\pi \cap R$ is the part of the polyline contained in R.

Slopes, slack, and stretch. The *slope* of a line segment ab is $\text{slope}(ab) = \frac{y(b)-y(a)}{x(b)-x(a)}$ if $x(a) \neq x(b)$, and $\text{slope}(ab) = \infty$ if $x(a) = x(b)$. For a line segment ab in the plane, we denote by $\text{proj}(ab)$ the orthogonal projection of ab to the x-axis. Note that $|\text{proj}(ab)| = |x(b) - x(a)|$. We define the *slack* of ab as $\text{slack}(ab) = d(a,b) - |\text{proj}(ab)|$. In our paper, all proofs of theorems, lemmas, corollaries, and observations marked with a $\star$ are in our full version.

▶ **Lemma 4** (⋆). *For any line segment ab with $\text{slope}(ab) \neq \infty$, we have*

$$|\text{proj}(ab)| \cdot \left(1 + \frac{1}{3} \cdot |\text{slope}(ab)|^2\right) \leq d(a,b) \leq |\text{proj}(ab)| \cdot \left(1 + \frac{1}{2} \cdot |\text{slope}(ab)|^2\right) \quad (1)$$

$$\frac{1}{3} \cdot |\text{slope}(ab)|^2 \leq \frac{\text{slack}(ab)}{|\text{proj}(ab)|} \leq \frac{1}{2} \cdot |\text{slope}(ab)|^2. \quad (2)$$

It is known that a x-monotone path (i.e., a path in which the x-coordinates of the points along the path are monotone increasing) with edges of bounded slopes have small stretch.

▶ **Lemma 5.** *Let $\pi = (v_0, v_1, \ldots, v_k)$ be a x-monotone polygonal path in $\mathbb{R}^2$ such that $|\text{slope}(v_{i-1}v_i)| \leq \varrho$ for all $i \in [1,k]$. Then $|\text{slope}(v_0v_k)| \leq \varrho$; and $\frac{\mathbf{w}(\pi)}{d(v_0,v_k)} \leq \sqrt{1+\varrho^2} < 1 + \frac{\varrho^2}{2}$.*

For two points $a, b \in \mathbb{R}^2$ and a parameter $\epsilon > 0$, let $\mathcal{E}_{ab,\epsilon}$ denote the ellipse with foci a and b and major axis $(1+\epsilon) \cdot d(a,b)$, that is, $\mathcal{E}_{ab,\epsilon} = \{p \in \mathbb{R}^2 : d(a,p) + d(p,b) \leq (1+\epsilon) \cdot d(a,b)\}$.

3 Reduction to Net Points in a Trapezoid

In this section, we reduce the problem of constructing a bicriteria approximation for the minimum weight (Steiner) $(1+\epsilon)$-ST to the special case where all points, except the source s, lie in a trapezoid, and the point set is sparse (i.e., form a centered ϵ-net, defined below).

Given a source $s \in \mathbb{R}^2$ and $\epsilon > 0$, define a *tiling* of the plane into a set $\mathcal{T}$ of trapezoids as follows; refer to Figure 3. Let C be a circle of unit radius centered at s. Let O_1 be a regular k-polygon with inscribed circle C, where k is the minimum integer such that the side length of O_1 is less than $\sqrt{\epsilon}$. For all integers $i \in \mathbb{Z}$, let $O_i = 2^i \cdot O_1$, that is, a scaled copy of O_1, centered at s. Finally, add k rays emanating from s that pass through the vertices of the polygons O_i, $i \in \mathbb{Z}$. Polygons O_i, $i \in \mathbb{Z}$, and the k rays subdivide the plane into a set $\mathcal{T}$ of trapezoids: Each trapezoid $\tau \in \mathcal{T}$ lies between two consecutive polygons O_i and O_{i+1}, and two consecutive rays.

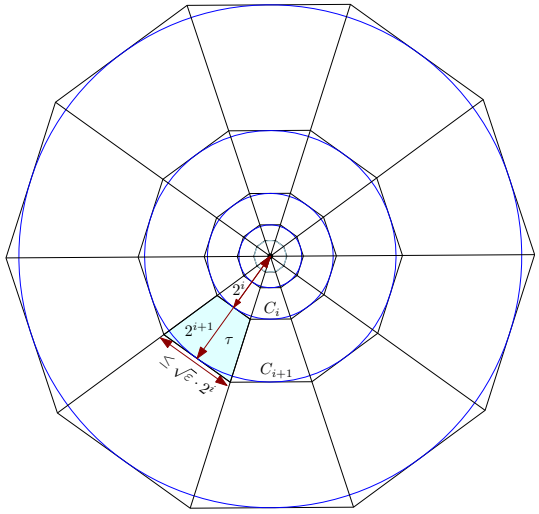

Figure 3 A section of the trapezoid tiling of the plane.

Let P be a set of n points in the plane, and let $\tau_1, \ldots, \tau_m \in \mathcal{T}$ be a finite set of tiles that cover P, and let $P_i := P \cap \tau_i$. For a tile $\tau_i \in \mathcal{T}$, we define a *tile-restricted* $(1+\epsilon)$-*ST* (for short, $(1+\epsilon)$-*tST*) as a tree $T = (V, E)$ such that $P_i \cup \{s\} \subseteq V(T) \subseteq P$, and T contains a ps-path of weight at most $(1+\epsilon) \cdot d(p,s)$ for every $p \in P_i$. In other words, a tile-restricted $(1+\epsilon)$-*ST* is a Steiner $(1+\epsilon)$-ST for $P_i \cup \{s\}$ rooted at s, where all Steiner points are in P.

▶ **Theorem 6** (⋆). *Given a set $P \subset \mathbb{R}^2$ of n points, a source $s \in \mathbb{R}^2$, a parameter $\epsilon > 0$, and two real functions $f(.)$ and $g(.)$. Let $\tau_1, \ldots, \tau_m$ be the set of tiles in $\mathcal{T}$, where $P_i := P \cap \tau_i \neq \emptyset$. Let G_i be a tile-restricted $(1 + f(\epsilon) \cdot \epsilon)$-ST (resp., Steiner $(1 + f(\epsilon) \cdot \epsilon)$-ST) for $P_i \cup \{s\}$ of weight $\mathbf{w}(G_i) \leq O(g(\epsilon) \cdot \mathsf{opt}_{\epsilon,i})$, where $\mathsf{opt}_{\epsilon,i}$ is the minimum weight of a $(1+\epsilon)$-ST for $P_i \cup \{s\}$, for all $i = 1, \ldots, m$. Then, a shortest-path tree of the graph $G := \bigcup_{i=1}^{m} G_i$, rooted at s, is a $(1+f(\epsilon)\cdot\epsilon)$-ST (resp., Steiner $(1+f(\epsilon)\cdot\epsilon)$-ST) for $P \cup \{s\}$ and $\mathbf{w}(G) \leq O(g(\epsilon)\cdot \mathsf{opt}_\epsilon)$, where opt_ϵ is the minimum weight of a $(1+\epsilon)$-ST for $P \cup \{s\}$.*

For the purpose of a $(1+\epsilon)$-ST, with a source (or center) $s \in P$, we define a variation of ϵ-nets where the density of the net depends on the distance from s: A *centered ϵ-net* (for short, *ϵ-cnet*) with center s is a subset $N \subset P$ such that

- for all $a, b \in N$, $a \neq b$, we have $d(a,b) > \epsilon \cdot \min\{d(a,s), d(b,s)\}$ and
- for every $p \in P$, there exists a point $a \in N$ such that $d(p,a) \leq \epsilon \cdot d(p,s)$.

Given a point set $P \subset \mathbb{R}^2$, including $s \in P$, a parameter $\epsilon > 0$ and a subset P, we also define a *net-restricted $(1+\epsilon)$-ST for $N \subset P$* as a tree $T = (V, E)$ such that $N \cup \{s\} \subseteq V(T) \subseteq P$, and T contains a ps-path of weight at most $(1+\epsilon) \cdot d(p,s)$ for every $p \in N$. This means that T is a Steiner $(1+\epsilon)$-ST rooted at s for the ϵ-cnet N, where all Steiner points are in P. We claim that it suffices to find a net-restricted (resp., Steiner) $(1+\epsilon)$-ST for a ϵ-cnet with center s.

▶ **Lemma 7** (⋆). *Let P be a set of n points in the plane, $s \in P$, $\epsilon \in (0, \frac{1}{9})$, and $N \subset P$ a ϵ-cnet for P. Let $f(.)$ and $g(.)$ be real functions such that $f(x) \geq x$ and $g(x) \geq x$ for all $x \geq 0$. Assume that in $O(|N| \log |N|)$ time, we can compute a net-restricted (resp., Steiner) $(1+f(\epsilon)\cdot\epsilon)$-ST T_N for N of weight $O(g(\epsilon)) \cdot \mathsf{opt}_\epsilon(N)$, where $\mathsf{opt}_\epsilon(N)$ is the minimum weight of a net-restricted (resp., Steiner) $(1+\epsilon)$-ST for N. Then, in $O(n \log n)$ time, we can compute a (Steiner) $(1+O(f(\epsilon)\cdot\epsilon))$-ST T_P for P of weight $O(g(\epsilon)) \cdot \mathsf{opt}_\epsilon(P)$, where $\mathsf{opt}_\epsilon(P)$ is the minimum weight of a (Steiner) $(1+\epsilon)$-ST for P.*

4 Steiner Shallow Trees for Points in a Tile

In this section, we prove Theorem 1. By Theorem 6 and Lemma 7, we may assume that P is a set of points in a trapezoid $\tau \in \mathcal{T}$ (defined in Section 3), and P is a centered ϵ-net w.r.t. center $s \in P$. We may further assume w.l.o.g. that $\tau \subset [0,1] \times [-\sqrt{\epsilon}, \sqrt{\epsilon}]$ and $s = (2,0)$; see Figure 4. We first present an algorithm that constructs a Steiner tree T for $P \cup \{s\}$, rooted at s. Then we show that T is a $(1+O(\epsilon \log \epsilon^{-1}))$-ST and its weight is $O(\mathsf{opt}_\epsilon \cdot \log \epsilon^{-1})$, where opt_ϵ denotes the minimum weight of a Steiner $(1+\epsilon)$-ST for P rooted at s; and let OPT_ϵ be one such Steiner $(1+\epsilon)$-ST.

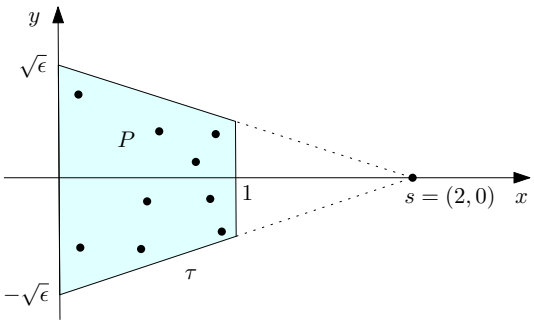

Figure 4 A point set P in a trapezoid τ and a source $s = (2,0)$.

Steiner shallow tree construction: Overview. We start with a brief overview of the ST construction and then present the algorithm in detail. We construct a Steiner graph G on $P \cup \{s\}$ (which is not necessarily a tree), and then let T be the shortest path tree of G rooted at s (that is, the single-source shortest path tree of G with s as the source). We can analyze the root-stretch in the graph G, and the weight of T is upper-bounded by the weight of G.

For each point $p \in P$, we know that OPT_ϵ contains a ps-path of length at most $(1+\epsilon)\cdot d(p,s)$ in the ellipse $\mathcal{E}_{ps}$ with major axis $(1+\epsilon)\cdot d(p,s)$. We associate each point $p \in P$ with vertical lines $L_0(p), \ldots, L_{k-1}(p)$, where $k = O(\log \epsilon^{-1})$. For $i = 0, 1, \ldots, k-1$, we choose a Steiner point s_i in the line segments $\mathcal{E}_{ps} \cap L_i(p)$, and add the path $\pi_{ps} = (p, s_0, \ldots, s_{k-1}, s)$ to the graph G. We show (Lemma 12) that if the distances between the vertical lines $L_1, \ldots, L_k$ increase exponentially, then $\mathbf{w}(\pi_{ps}) = (1 + O(\epsilon \log \epsilon^{-1})) \cdot d(p,s)$.

Importantly, each line L_i is associated with multiple points in P, and each Steiner point $s_i \in L_i$ also serves multiple points in P. For each line L_i, we choose the Steiner points in L_i as a minimum hitting set for the line segments $\mathcal{E}_{ps} \cap L_i$ over all points $p \in P$ associated with line L_i. Since the intersection $\mathsf{OPT}_\epsilon \cap L_i$ is a hitting set for these intervals, we can charge the weight of G to the weight of OPT_ϵ. The approximation factor $O(\log \epsilon^{-1})$, in the stretch and the weight, is the result of using $O(\log \epsilon^{-1})$ Steiner points, one in each line L_i, for $i = 1, \ldots, k$.

Steiner shallow tree construction: Details. Assume w.l.o.g. that $\epsilon = 4^{-(k+1)}$ for some $k \in \mathbb{N}$. Each ellipse $\mathcal{E}_{ps}$ is contained in an ellipse $\mathcal{E}_{pb(p),2\epsilon}$ ($\star$), where the segment $pb(p)$ is horizontal and $d(p,b(p)) \le 2 \cdot d(p,s)$. As a shorthand notation, we use $\mathcal{E}_p := \mathcal{E}_{pb(p),2\epsilon}$.

We define families of vertical lines. For every integer $i \ge 0$, let

$$\mathcal{L}_i = \{x = j4^i \cdot \epsilon : j \in \mathbb{Z}\}, \tag{3}$$

that is, the distance between two consecutive vertical lines in $\mathcal{L}_i$ is $4^i \cdot \epsilon$. For every point $p \in P$, we recursively choose $L_i(p) \in \mathcal{L}_i$ for $i = 0, 1, \ldots, k-1$, as follows. Let $L_0(p)$ be the second line in $\mathcal{L}_0$ to the right of p. For $i = 1, \ldots, k-1$, if $L_{i-1}(p)$ has already been chosen, let $L_i(p)$ be the second line in $\mathcal{L}_i$ to the right of $L_{i-1}(p)$. (We choose the second line in $\mathcal{L}_i$, rather than the first one, to ensure that the gaps between $L_{i-1}(p)$ and $L_i(p)$ grow exponentially in i; cf. Observation 8.)

Now consider a line $L \in \mathcal{L}_i$, and let $P(L)$ be the set of all points in P associated with L. Formally, we put $P(L) = \{p \in P : L_i(p) = L\}$. Consider the set of intervals $I(L) = \{L \cap \mathcal{E}_p : p \in P(L)\}$. Let $H(L)$ be a *minimum hitting set* (a.k.a., piercing set, stabbing set, or transversal) for $I(L)$: It is a minimum subset of L that contains at least one point in each interval in $I(L)$; it can be computed in $O(|I(L)| \log |H(L)|)$ time [10, 15, 24].

Finally, we construct the Steiner graph G as follows. The vertex set of G comprises P, s, and the points $H(L)$ for all $L \in \mathcal{L}_i$, $i = 0, \ldots, k-1$. The edges are defined as follows. For each point $p \in P$, consider the lines $L_0(p), \ldots, L_{k-1}(p)$ associated with p. For $i = 0, 1, \ldots, k-1$ let $s_i(p)$ be an arbitrary point in $H(L_i(p)) \cap \mathcal{E}_p$. Add the edges of the path $\pi_{ps} = (p, s_0(p), \ldots, s_{k-1}(p), s)$ to G. We output the shortest path tree T of G rooted at s.

▶ **Observation 8.** *For $i \in [1, k-1]$, $\mathsf{dist}(L_{i-1}(p), L_i(p))$ is within $[4^i\,\epsilon, 2 \cdot 4^i\,\epsilon]$.*

From Observation 8, using a geometric series, we obtain the following corollary:

▶ **Corollary 9** ($\star$). *For $i \in [1, k-1]$, $\mathsf{dist}(p, L_i(p))$ is within $[4^i\,\epsilon, \frac{32}{3} \cdot 4^i\,\epsilon]$.*

Root stretch analysis. It is enough to analyze the root stretch in the graph G. Recall that in the construction of G, we have already built a path $\pi_{ps} = (p, s_0(p), \ldots, s_{k-1}(p), s)$. We show that $\mathbf{w}(\pi_{ps}) \leq (1 + O(\epsilon \log \epsilon^{-1})) \cdot d(p, s)$ (Lemma 12). We first need to estimate the slopes of the edges of π_{ps}. We start with the following lemma.

▶ **Lemma 10.** *For every point $p \in P$ if a vertical line L is to the right of p at distance $x \in [0, \frac{2}{3}]$ from p, then $\mathbf{w}(L \cap \mathcal{E}_p) = \Theta(\sqrt{\epsilon\, x})$. In particular, for every $i = 0, \ldots, k-1$, we have $\mathbf{w}(L_i(p) \cap \mathcal{E}_p) = \Theta(2^i \cdot \epsilon)$.*

Proof. Consider the unit disk $D = \{(x, y) \in \mathbb{R}^2 : x^2 + y^2 = 1\}$ and the line $L : x = -1 + \varrho$ for $0 \leq \varrho \leq 1$; see Figure 5. Then for $\varrho \in [0, 1]$, we obtain

$$\mathbf{w}(D \cap L) = 2 \cdot \sqrt{1^2 - (1-\varrho)^2} = 2 \cdot \sqrt{2\varrho - \varrho^2} = 2^{3/2} \cdot \sqrt{\varrho - \frac{\varrho^2}{2}} = \Theta(\sqrt{\varrho}).$$

The ellipse $\mathcal{E}_p = \mathcal{E}_{pb,2\epsilon}$ is an affine image of the unit disk D: The affine transformation $f(x, y) = (\frac{M}{2}x, \frac{m}{2}y)$ takes D to $\mathcal{E}_p$, where M and m are the major and minor axes of $\mathcal{E}_p$. We estimate M and m up to constant factors. Since $P \subset [0, 1] \times [-\sqrt{\epsilon}, \sqrt{\epsilon}]$ and $s = (2, 0)$, then we have $1 \leq |x(p) - x(s)| \leq 2$. We have $1 \leq d(p, b(p)) \leq 4$ $(\star)$. The major axis of $\mathcal{E}_p$ is $M = (1 + 2\epsilon) \cdot d(p, b(p))$ so $1 < M \leq 4 + 8\epsilon$; and its minor axis is $m = 2 \cdot \sqrt{(1 + 2\epsilon)^2 - 1} \cdot d(p, b(p)) = 4 \cdot \sqrt{\epsilon + \epsilon^2} \cdot d(p, b(p))$, and so $4 \cdot \sqrt{\epsilon} \leq m \leq 16 \cdot \sqrt{\epsilon + \epsilon^2} \leq 16\sqrt{2} \cdot \sqrt{\epsilon}$.

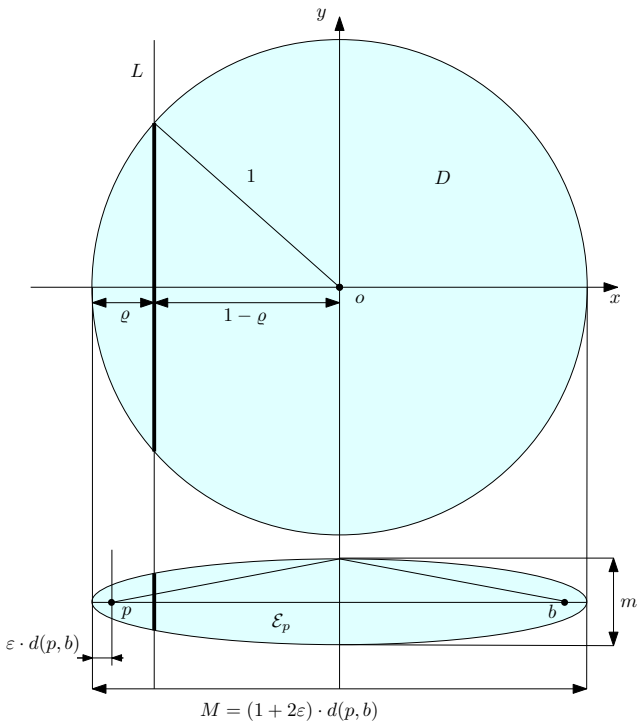

Figure 5 A unit disk D, a cross section $L \cap D$, and an affine transformation to the ellipse $\mathcal{E}_p$.

The focus p is at distance $\epsilon \cdot d(p, b(p))$ from the leftmost point of $\mathcal{E}_p$, where $\epsilon \leq \epsilon \cdot d(p, b(p)) \leq 4\epsilon$. By Corollary 9, the distance between $L_i(p)$ and the leftmost point of $\mathcal{E}_p$ is at least $\epsilon + 4^i\epsilon = \Omega(4^i\epsilon \cdot M)$ and at most $4\epsilon + \frac{32}{3} \cdot 4^i\epsilon = O(4^i\epsilon \cdot M)$. Overall, this distance is $\Theta(4^i\epsilon \cdot M)$.

The inverse transformation f^{-1} takes $\mathcal{E}_p$ to the unit disk D, and the line $L_i(p)$ to a vertical line $L : x = -1 + \varrho$, where $\varrho = \Theta(4^i\epsilon)$. As noted above, we have $\mathbf{w}(L \cap D) = \Theta(\sqrt{\varrho}) = \Theta(2^i \cdot \sqrt{\epsilon})$, consequently $\mathbf{w}(L_i(p) \cap \mathcal{E}_p) = \Theta(m \cdot \sqrt{\varrho}) = \Theta(\sqrt{\epsilon} \cdot 2^i \cdot \sqrt{\epsilon}) = \Theta(2^i \cdot \epsilon)$. ◀

Combining Observation 8 and Lemma 10, we have the following corollary:

▶ **Corollary 11** (⋆). *For every $p \in P$, consider the path $\pi_{ps} = (p, s_0, \ldots, s_{k-1}, s)$. For all $i = 1, \ldots, k-1$, we have $|\text{slope}(s_{i-1}s_i)| \le O(2^{-i})$.*

▶ **Lemma 12.** *For every $p \in P$, we have $\mathbf{w}(\pi_{ps}) \le (1 + O(\epsilon \log \epsilon^{-1})) \cdot d(p, s)$.*

Proof. By construction, we have $\pi_{ps} = (p, s_0, s_1, \ldots s_{k-1}, s)$. We partition π_{ps} into three parts: ps_0, $(s_0, s_1, \ldots s_{k-1})$ and $s_{k-1}s$, and bound the weight of each part separately.

First we estimate the weight of the first edge ps_0. Recall that $p \in [0,1] \times [-\sqrt{\epsilon}, \sqrt{\epsilon}]$ and $s = (2, 0)$. By construction, we have $|x(p) - x(s_0)| \le \epsilon$, and Lemma 10 gives $|y(p) - y(s_0)| \le O(\epsilon)$. Therefore, we have $\mathbf{w}(ps_0) = O(\epsilon) \le O(\epsilon) \cdot d(p, s)$. We can now bound the weight of the subpath $(s_0, s_1, \ldots, s_{k-1})$ of π_{ps}. By Lemma 4, Observation 8, and Corollary 11,

$$\begin{aligned}
\mathbf{w}((s_0, s_1, \ldots, s_{k-1})) &= \sum_{j=1}^{k} \mathbf{w}(s_{j-1}s_j) \le \sum_{j=1}^{k-1} \left(1 + \frac{(\text{slope}(s_{j-1}s_j))^2}{2}\right) \cdot |\text{proj}(s_{j-1}s_j)| \\
&= \sum_{j=1}^{k-1} |\text{proj}(s_{j-1}s_j)| + \sum_{j=1}^{k-1} O(4^{-j}) \cdot |\text{proj}(s_{j-1}s_j)| \\
&\le |\text{proj}(s_0 s_{k-1})| + \sum_{j=1}^{k-1} O(4^{-j}) \cdot 2 \cdot 4^j \cdot \epsilon = |\text{proj}(s_0 s_{k-1})| + O(k\epsilon) \\
&= |\text{proj}(s_0 s_{k-1})| + O\left(\epsilon \log \epsilon^{-1}\right) = |\text{proj}(s_0 s_{k-1})| \left(1 + O\left(\epsilon \log \epsilon^{-1}\right)\right).
\end{aligned}$$

Finally, we estimate the weight of the last edge, $s_{k-1}s$, of π_{ps}. We have

$$\text{dist}(p, L_{k-1}(p)) < \frac{32}{3} \cdot 4^{k-1} \cdot \epsilon = \frac{2}{3\epsilon} \cdot \epsilon = \frac{2}{3}. \qquad \text{(by Corollary 9 and } \epsilon = 4^{-(k+1)}) \qquad (4)$$

Since $x(p) \in [0, 1]$ and $s = (2, 0)$, then $|x(s_{k-1}) - x(s)| \ge \frac{1}{3}$. Lemma 10 gives $|y(s_{k-1}) - y(s)| = |y(s_{k-1})| \le O(2^{k-1} \cdot \epsilon) = O\left(\frac{1}{\sqrt{\epsilon}} \cdot \epsilon\right) = O(\sqrt{\epsilon})$. Consequently, $\text{slope}(s_{k-1}s) = O(\sqrt{\epsilon})$, and Lemma 4 yields $\mathbf{w}(s_{k-1}s) \le (1 + O(\epsilon)) \cdot |\text{proj}(s_{k-1}s)|$.

The sum of the weights of the three parts is

$$\begin{aligned}
\mathbf{w}(\pi_{ps}) &= \mathbf{w}(ps) + \mathbf{w}((s_0, s_1, \ldots, s_{k-1})) + \mathbf{w}(s_{k-1}s) \\
&\le O(\epsilon) \cdot d(p, s) + \left(1 + O\left(\epsilon \log \epsilon^{-1}\right)\right) |\text{proj}(s_0 s_{k-1})| + (1 + O(\epsilon)) \cdot |\text{proj}(s_{k-1}s)| \\
&\le O(\epsilon) \cdot d(p, s) + \left(1 + O\left(\epsilon \log \epsilon^{-1}\right)\right) |\text{proj}(s_0 s)| \le \left(1 + O\left(\epsilon \log \epsilon^{-1}\right)\right) d(p, s).
\end{aligned}$$

◀

Weight analysis. We give an upper bound for $\mathbf{w}(G)$. Similarly to the root stretch analysis, we decompose π_{ps} into three parts, ps_0, $(s_0, s_1, \ldots, s_{k-1})$, and $s_{k-1}s$, and then bound the weight of the union of each.

We first analyze the total weight of the union of edges $s_{i-1}(p)\, s_i(p)$ of the paths π_{ps} over all $p \in P$. For lines $L_a \in \mathcal{L}_{i-1}$ and $L_b \in \mathcal{L}_i$, let $G(L_a, L_b)$ denote the set of all edges $uv \in E(G)$ such that $u \in I(L_a)$ and $v \in I(L_b)$. Recall that OPT_ϵ is a minimum-weight Steiner $(1+\epsilon)$-ST for $P \cup \{s\}$ rooted at s ($\mathbf{w}(\mathsf{OPT}_\epsilon) = \mathsf{opt}_\epsilon$). We denote by $\mathsf{OPT}_\epsilon \cap [\![L_a, L_b]\!]$ the part of OPT_ϵ clipped in the vertical strip $[\![L_a, L_b]\!]$. Our main lemma is as follows.

▶ **Lemma 13.** *For every $p \in P$ and $i \in \{1, \dots, k-1\}$, we have*

$$\mathbf{w}(G(L_{i-1}(p), L_i(p))) \leq O(\mathbf{w}(\mathsf{OPT}_\epsilon \cap [\![L_{i-1}(p), L_i(p)]\!])).$$

Before the proof of Lemma 13, we observe that it implies the bound on the total weight of the interior edges of the paths π_{ps} over all $p \in P$.

▶ **Corollary 14** (⋆). $\mathbf{w}\left(\bigcup_{p \in P}(s_0(p), \dots, s_{k-1}(p))\right) \leq O(\log \epsilon^{-1} \cdot \mathsf{opt}_\epsilon)$.

It remains to prove Lemma 13. We do this in a sequence of lemmas, using geometric properties of ellipses and interval graphs. We start with an easy observation.

▶ **Observation 15** (⋆). *For every $p \in P$ and every $i \in \{1, \dots, k-1\}$, we have*

$$\mathbf{w}(\mathsf{OPT}_\epsilon \cap [\![L_{i-1}(p), L_i(p)]\!] \cap \mathcal{E}_p) \geq \mathrm{dist}(L_{i-1}(p), L_i(p)).$$

▶ **Lemma 16.** *For every $i \in \{1, \dots, k-1\}$ and every $p \in P$, there exists a set $Q \subset P(L_{i-1}(p))$ of size $|Q| \geq \Omega(|H(L_i(p))|)$ such that the regions in $\{\mathcal{E}_q \cap [\![L_{i-1}(p), L_i(p)]\!] : q \in Q\}$ are disjoint.*

Proof. Each interval in $I(L_i(p))$ has weight $\Theta(2^i \cdot \epsilon)$ by Lemma 10. Let $c \geq 1$ be the ratio of the maximum to the minimum weight of an interval in $I(L_i(p))$. Each interval in $I(L_i(p))$ is of the form $L_i(p) \cap \mathcal{E}_r$ for some point $r \in P(L_i(p))$. For every $r \in P(L_i(p))$, let B_r be the axis-aligned bounding box of $\mathcal{E}_r \cap [\![L_{i-1}(p), L_i(p)]\!]$; see Figure 6. Note that the major axis of $\mathcal{E}_r$ is horizontal, and its minor axis is to the right of L_i by Equation (4). Consequently, for every vertical line $L \subset [\![L_{i-1}(p), L_i(p)]\!]$, we have $\mathbf{w}(L \cap \mathcal{E}_r) \leq \mathbf{w}(L_i(p) \cap \mathcal{E}_r)$, which holds with equality for $L = L_i(p)$. In particular, the height of B_r is $\mathbf{w}(L_i(p) \cap \mathcal{E}_r) = \Theta(2^i \cdot \epsilon)$.

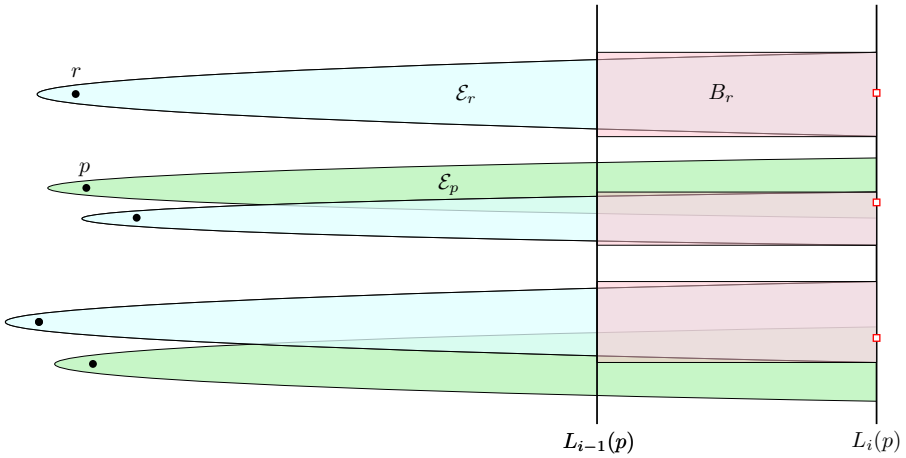

Figure 6 A point $p \in P$ and ellipses $\mathcal{E}_r$ for five points in $P(L_{i-1}(p))$. The boxes B_r corresponding to the three light blue ellipses are disjoint. A minimum hitting set $H(L_i(p))$ has size 3.

Now consider a maximum set $Q_0 \subset P(L_i(p))$ such that the intervals $\{L_i(p) \cap \mathcal{E}_q : q \in Q_0\}$ are disjoint. Note that $|Q_0| = |H(L_i(p))|$, that is, the maximum independent set has the same size as a hitting set for intervals in a line.

A set of disjoint intervals along the line $L_i(p)$ have a well-defined total order, which defines a total order on Q_0. Let $Q \subset Q_0$ be the subset that corresponds to the first and every $\lceil c \rceil$-th interval. Then $|Q_0| = \Theta(|Q|) = \Theta(|H(L_i(p))|)$. Furthermore, the intervals $\{L_i(p) \cap \mathcal{E}_q : q \in Q\}$ are disjoint. This, in turn, implies that the boxes $\{B_q : q \in Q\}$ are disjoint. Thus, the regions $\{\mathcal{E}_q \cap [\![L_{i-1}(p), L_i(p)]\!] : q \in Q\}$ are also disjoint. ◀

Observation 15 and Lemma 16 imply the following corollary.

▶ **Corollary 17** (⋆). *For every $p \in P$ and $i \in \{1, \dots, k-1\}$, we have*

$$\Omega(|H(L_i(p))|) \cdot \mathrm{dist}(L_{i-1}(p), L_i(p)) \leq \mathbf{w}\big(\mathsf{OPT}_\epsilon \cap [\![L_{i-1}(p), L_i(p)]\!]\big).$$

▶ **Lemma 18.** *For every $p \in P$ and $i \in \{1, \dots, k-1\}$, we have*

$$\mathbf{w}(G(L_{i-1}(p), L_i(p))) \leq O(|H(L_i(p)|) \cdot \mathrm{dist}(L_{i-1}(p), L_i(p)).$$

Proof. We first show that every edge in $G(L_{i-1}(p), L_i(p))$ has weight $\Theta(\mathrm{dist}(L_{i-1}(p), L_i(p)))$. Every edge of $G(L_{i-1}(p), L_i(p))$ is the edge $s_{i-1}(r)s_i(r)$ of π_{rs} for some point $r \in P(L_{i-1}(p))$. By Corollary 11, $|\mathrm{slope}(s_{i-1}(r)s_i(r))| \leq O(2^{-i})$, where $i = O(\log_4 \epsilon^{-1})$. Consequently, we have $|\mathrm{slope}(s_{i-1}(r)s_i(r))| \leq O(1)$ for all $i = 1, \dots, k-1$. Therefore,

$$\mathbf{w}(s_{i-1}(r)s_i(r)) \leq O(1) \cdot |\mathrm{proj}(s_{i-1}(r)s_i(r))| \leq O(\mathrm{dist}(L_{i-1}(p), L_i(p))).$$

Next, we show that every vertex $v \in H(L_i(p))$ of $G(L_{i-1}(p), L_i(p))$ has $O(1)$ degree. Lemma 10 gives $\mathbf{w}(L_{i-1}(p) \cap \mathcal{E}_r) = \Theta(2^i)$ and $\mathbf{w}(L_i(p) \cap \mathcal{E}_r) = \Theta(2^{i-1})$ for all $r \in P(L_{i-1}(p))$. Note also that both $L_{i-1}(p) \cap \mathcal{E}_r$ and $L_i(p) \cap \mathcal{E}_r$ have a reflection symmetry in the horizontal major axis of $\mathcal{E}_r$, implying $\bigcup\{L_i(p) \cap \mathcal{E}_r : r \in P(L_i(p)) \text{ and } v \in \mathcal{E}_r\}$ is contained in an interval of length $2 \cdot \Theta(2^i) = \Theta(2^i)$ centered at v. Similarly, $\bigcup\{L_{i-1}(p) \cap \mathcal{E}_r : r \in P(L_{i-1}(p)) \text{ and } v \in \mathcal{E}_r\}$ is contained in an interval $I \subset L_{i-1}$ of length $2 \cdot \Theta(2^{i-1}) = \Theta(2^i)$. Since $\mathbf{w}(L_{i-1}(p) \cap \mathcal{E}_r) = \Theta(2^i)$ for all $r \in P(L_{i-1}(p))$, then the hitting set $H(L_{i-1}(p))$ contains $O(1)$ points in the interval I. In the graph $G(L_{i-1}(p), L_i(p))$, all neighbors of vertex v are in the interval I and in $H(L_{i-1}(p))$. This proves that v has $O(1)$ neighbors in $G(L_{i-1}(p), L_i(p))$.

Overall, every edge of $G(L_{i-1}(p), L_i(p))$ has weight $\Theta(\mathrm{dist}(L_{i-1}(p), L_i(p)))$; and every vertex $v \in H(L_i(p))$ of $G(L_{i-1}(p), L_i(p))$ has $O(1)$ degree. Since $G(L_{i-1}(p), L_i(p))$ is a bipartite graph with partite sets $H(L_{i-1}(p))$ and $H(L_i(p))$, then the total weight of $G(L_{i-1}(p), L_i(p))$ is $O(|H(L_i(p)|) \cdot \mathrm{dist}(L_{i-1}(p), L_i(p))$, as claimed. ◀

Combining Lemma 18 and Corollary 17, we obtain Lemma 13. We conclude:

▶ **Lemma 19.** *For a ϵ-cnet $P \subset [0,1] \times [-\sqrt{\epsilon}, \sqrt{\epsilon}]$ and $s = (0,2)$, the weight of G is $O(\log \epsilon^{-1}) \cdot \mathsf{opt}_\epsilon$, where opt_ϵ denotes the minimum weight of a Steiner $(1+\epsilon)$-ST for P.*

Proof. We have shown that for every $p \in P$, the first edge of π_{ps} has weight $O(\epsilon)$. Consequently, the total weight of the union of first segments of π_{ps} over all $p \in P$ is $O(\epsilon \cdot |P|)$. Since P is a ϵ-cnet, then this is bounded by $O(\mathsf{opt}_\epsilon)$. By Corollary 14, the total weight of the interior edges of the paths π_{ps} over all $p \in P$, namely, $\mathbf{w}\left(\bigcup_{p \in P}(s_0(p), \dots, s_{k-1}(p))\right)$ is bounded by $O(\log \epsilon^{-1}) \cdot \mathsf{opt}_\epsilon$.

Finally, we bound the total weight of the last edges of the paths $\pi_{ps} = (p, s_0(p), \dots, s_{k-1}(p), s)$ for all $p \in P$. By Observation 8, there are $O(1)$ vertical lines in $\mathcal{L}_{k-1}$ between $o = (0,0)$ and $s = (2,0)$. By Corollary 11, we have $\mathbf{w}(\mathcal{E}_p \cap L_{k-1}(p)) = \Theta(\sqrt{\epsilon})$. Consequently, each piercing set $H(L_{k-1}(p))$ has $O(1)$ size. Overall, there are $O(1)$ distinct segments in $\{s_{k-1}(p)s : p \in P\}$, and the weight of each segment is $O(1)$. Consequently, the total weight of these segments is also $O(1)$. Since $\mathrm{dist}(P, s) \geq 1$, then $\mathbf{w}(OPT_\epsilon) \geq 1$, and so $\mathbf{w}(\{s_{k-1}(p)s : p \in P\}) \leq O(1) \leq O(\mathbf{w}(\mathsf{OPT}_\epsilon))$. ◀

Running time. The running time is $O(n \log n \cdot \mathrm{polylog}(\epsilon^{-1}))$.

5 Shallow Trees for Points in a Tile

In this section, we prove Theorem 2. By Theorem 6 and Lemma 7, we may reduce to the problem of finding a tile-restricted $(1+\epsilon)$-ST for points in a tile τ. Let P be a set of n points in the plane, $\tau \in \mathcal{T}$ be a tile, and N_τ an ϵ-cnet for the point set $P \cap \tau$. We present an algorithm constructing a net-restricted ST T for N_τ. Then we show that T is a net-restricted $(1+O(\epsilon \log \epsilon^{-1}))$-ST and its weight is $O(\mathsf{opt} \cdot \log^2(\epsilon^{-1}))$, where opt denotes the minimum weight of a net-restricted $(1+\epsilon)$-ST for $N_\tau \subset P$; and let OPT be one such a $(1+\epsilon)$-ST.

▶ **Lemma 20** (⋆). *Let $\mathsf{opt}(\tau)$ be the weight of the lightest net-restricted $(1+\epsilon)$-ST for $N_\tau \cup \{s\}$. There is a polynomial time algorithm returns a net-restricted $(1+\epsilon \cdot \log(\epsilon^{-1}))$ ST T for $N_\tau \cup \{s\}$ of weight $O(\log^2(\epsilon^{-1}) \cdot \mathsf{opt}(\tau))$.*

Shallow tree construction algorithm. Similar to Section 4, we assume that $\tau \subset [0,1] \times [-\sqrt{\epsilon}, \sqrt{\epsilon}]$ and $s = (2,0)$ (see Figure 4). For each point $p \in N_\tau$, we use the same set of vertical lines $L_0(p), L_1(p), \ldots$ defined in Equation (3). For each point p and each integer i, let $\mathcal{E}_p(i)$ denote the intersection of $\mathcal{E}_{ps}$ with the strip between the two lines $L_i(p)$ and $L_{i+1}(p)$ and $B_i(p)$ be the smallest axis-parallel rectangle containing $\mathcal{E}_p(i)$. The point p is associated with the rectangles $B_0(p), B_1(p), \ldots, B_k(p)$ with $k = O(\log \epsilon^{-1})$. A rectangle R *lies on* two distinct vertical lines L_1 and L_2 if two of its vertical sides are contained in L_1 and L_2.

We construct minimum hitting sets in k iterations. Starting from $i = 0$, let $\mathcal{R}_i$ be the set of rectangles $\{B_i(p) : p \in P_\tau\}$. Consider every pair of lines $L_i \in \mathcal{L}_i, L_{i+1} \in \mathcal{L}_{i+1}$ such that there are some rectangles in $\mathcal{R}_i$ lying on L_i and L_{i+1}. Let $\mathcal{R}_i(L_i, L_{i+1})$ be the set of rectangles in $\mathcal{R}_i$ lying on L_i and L_{i+1} that have nonempty intersection with P. We find the minimum hitting set of $\mathcal{R}_i(L_i, L_{i+1})$ from P. For each point u in the hitting set, let $\mathsf{iter}_p(u) = i$ for every $p \in P(L_i)$ (and define $\mathsf{iter}_p(s) := k+1$ for all $p \in P_\tau$).

We build a graph G on P as follows: For every point $p \in N_\tau$, let $s_0, s_1, \ldots s_h$ be a sequence of hitting points so that for $i = 0, 1, \ldots h$, if $B_i(p) \cap P \neq \emptyset$, then we choose an arbitrary point from the minimum hitting set of $\mathcal{R}(L_i(p), L_{i+1}(p))$ that hits $B_i(p)$ (otherwise no point is chosen from $B_i(p)$. We add the path $(p, s_0, s_1, \ldots, s_h, s)$ to G. The path $(p, s_0, s_1, \ldots, s_h, s)$ is called the *candidate path* of p in G.

For each point $p \in N_\tau$, let $H(p) = (p, s_0, s_1, \ldots s_h, s)$ be the candidate path of p in G. We prune the path $H(p)$ to eliminate some of the vertices: Initialize $H'(p) := H(p)$. While there exist two consecutive interior vertices v and v' in $H'(p)$ such that $\mathsf{iter}_p(v') = \mathsf{iter}_p(v) + 1$, then let the first such pair be v, v' and eliminate v' from $H'(p)$. Assume that $H'(p) = (p, s'_0, s'_1, \ldots s'_l, s)$ is the result of the pruning process. Observe that $H'(p)$ is a path from p to s. We call $H'(p)$ the *approximate path* of p. Let G' be the union of paths $H'(p)$ for all $p \in N_\tau$. We return the shortest-path tree $\mathsf{SPT}(G')$ of G' rooted at s.

▶ **Lemma 21** (⋆). *Let p be a point in N_τ, and let $\pi = (p, s_0, s_1, \ldots, s_{h-1}, s)$ be the approximate path of p in G', we have $\mathbf{w}(\pi) \leq (1 + \epsilon \log \epsilon^{-1})\, d(u, s)$.*

The proof of Lemma 21 is similar to the one with Steiner points. Since $\mathsf{SPT}(G')$ is the shortest-path tree of G', it contains ps-paths of weight $(1+O(\epsilon \log \epsilon^{-1}))\, d(p,s)$ for all $p \in N_\tau$.

Weight Analysis. We show that $\mathbf{w}(G) \leq O(\mathsf{opt} \cdot \log \epsilon^{-1})$, and then prove that $\mathbf{w}(G') \leq O(\mathbf{w}(G) \cdot \log \epsilon^{-1})$. Combined with the trivial bound $\mathbf{w}(\mathsf{SPT}(G')) \leq \mathbf{w}(G')$, we obtain $\mathbf{w}(\mathsf{SPT}(G')) \leq O(\mathsf{opt} \cdot \log^2 \epsilon^{-1}))$, as required.

Proof Overview. To bound the weight of G, we partition its edges into two types: local edges, which connect vertices in consecutive strips, and crossing edges, which connect vertices

in non-consecutive strips. The contribution of local edges can be bounded using the number of paths in OPT that intersect the upper strip. For crossing edges, we charge each such edge to an appropriate representative edge of OPT. The key observation is that if G contains a long edge e, then there must exist an edge $e' \in \mathsf{OPT}$ whose length is at least $\mathbf{w}(e)$, and we charge e to this e'. Because the lengths at different scale differ by exponential factors, each edge of OPT can be charged only by $O(\log(1/\varepsilon))$ edges of G at the same scale. Therefore, each such representative edge e' is charged at most $\log(1/\varepsilon)$ times, which yields the desired bound. The bound on the weight of G' follows from the fact that each consecutive edge can appear in at most $O(\log(1/\varepsilon))$ candidate paths in G.

Abstract

Topological simplification is the process of reducing complexity of a function while maintaining its essential features. Its goal is to find a new filter function, which reorders cells of the input complex in a way which eliminates some persistent homological features, without affecting the rest. We present a new approach to simplification based on the concept of *forbidden regions* and combinatorial dynamics. It allows us to reorder and cancel critical values, whose cancellation is not possible using existing methods because they are not consecutive in the total order. Each such cancellation takes $O(c \cdot n)$ time in the worst case, where c is the number of birth-death pairs and n is the size of the input complex.

1 Introduction

Simplification of real-valued functions is one of the central topics in Morse theory. In the classical (smooth) setting, one of the most notable examples of such simplifications is performed throughout the proof of the h-cobordism theorem [25, 24]. In the discrete

setting, Forman's theory [18, 17] studies the reversal of a *unique* combinatorial path between two critical points as a way of reducing the total number of critical points and, therefore, simplifying the Morse complex.

More recently, simplification has been studied in the context of persistent homology. The authors of [14] introduced the problem of persistence-sensitive simplification – asking to simplify all pairs with persistence below a given threshold – and gave an algorithm for 2-manifolds. Their solution was later improved to linear time [1]. Another approach, based on Forman's combinatorial vector fields, was presented in [3]. This work drew connection to the cancellation procedure by observing that whenever the unique path connects two critical points with locally lowest difference in function values, their cancellation does not affect the remaining part of the persistence diagram [3]. These *apparent pairs* have also been called *close pairs* [9] and *shallow pairs* [15].

This observation further helped in optimization of (persistent) homology computation [2] and shape reconstruction [4]. The idea of pruning pairs of critical cells, following Forman's approach, has been extensively studied in data visualization [6, 7, 10, 16, 21, 22, 27]. Recent works on topological optimization [20, 26] offer an alternative, albeit less controlled approach to simplification.

But there remains a critical gap. The works that are able to rigorously control the changes in persistent homology [14, 1, 3] are only able to simplify 0-dimensional persistent homology (as well as codimension-1, by duality). Meanwhile, the middle dimensions – e.g., 1-dimensional homology on 3-manifolds – are important in practice.

In this work, we study how relations between persistence pairs calculated by the standard lazy reduction algorithm [11, 5] can guide us in simplifying a discrete Morse function h, while controlling the changes in its persistence diagram *in any dimension* and the overall gradient structure. These relations organize persistence pairs in a hierarchical structure called a *depth poset* [12]. As observed in [13, 26], these relations describe the obstacles to modifying a function without changing its persistence diagram.

Concretely, for a given persistence pair α, we define *forbidden regions* for its death and birth cells, which describe the parts of the persistence diagram that α cannot move to without changing the persistence pairing. Conversely, when the forbidden regions leave a gap – a path from α to the diagonal – we can construct a homotopy that brings α to the diagonal without changing the rest of the persistence pairs and the gradient structure. This allows us to identify a broader family of persistence pairs, possibly with high persistence, that can be safely and selectively removed. We summarize our main contribution in the following theorem, where $\mathrm{BD}(h)$ denotes the set of birth-death pairs induced by a discrete Morse function h, and $\mathrm{Crit}(\mathcal{V}_h)$, the set of critical cells for h.

▶ **Theorem 1.** *Let h be a discrete Morse function on a Lefschetz complex X. If $\alpha \in \mathrm{BD}(h)$ is a persistence pair such that forbidden regions of its death and birth cells do not intersect, and there exists exactly one gradient path between the paired critical cells, then there exists a discrete Morse function h' on X such that $\mathrm{BD}(h') = \mathrm{BD}(h) \setminus \{\alpha\}$ and $h(x) = h'(x)$ for all $x \in \mathrm{Crit}(\mathcal{V}_{h'})$.*

We present a constructive proof to this theorem, which provides an algorithm explicitly tracking all changes in relations throughout the homotopy and the final path reversal. As a result, we obtain already computed relations between pairs in $\mathrm{BD}(h')$, which enables iterative simplification.

2 Preliminaries

▶ **Definition 2.** *A* Lefschetz complex *is a triplet* $(X, \dim, D)$*, where* X *is a finite set of elements called cells,* $\dim : X \to \mathbb{N}$ *is a map assigning a dimension to each cell, and* $D : X \times X \to \mathbb{Z}_2$ *is the boundary coefficient such that* $D(x, y) \neq 0$ *implies* $\dim x + 1 = \dim y$*, in which case we say* x *is a* facet *of* y*. Additionally, we require that for any* $x, y \in X$ *we have* $\sum_{z \in X} D(x, z) \cdot D(z, y) = 0$*. We also define the coboundary coefficient as* $D^{\perp}(y, x) \coloneqq D(x, y)$*.*

Lefschetz complexes generalize simplicial, cubical, and cellular complexes while remaining concrete enough to define persistent homology. When it does not lead to confusion, we shorten the notation and refer to the set of cells, X, as the Lefschetz complex. We often interpret D and $D^{\perp}$ as a matrix, in which case we put the arguments in the square brackets for emphasis, e.g., $D[x, y]$. We write X_n for the set of n-dimensional cells of X, and D_n, $D_n^{\perp}$ for the n-th boundary and coboundary matrix, respectively.

▶ **Definition 3** (Discrete Morse function)**.** *Let* X *be a Lefschetz complex. A map* $h : X \to \mathbb{R}$ *is called a* discrete Morse function *(dMf, for short) if the following conditions are satisfied for all* $x, y \in X$*.*

- **(i)** *if* $D(x, y) = 1$ *then* $h(x) \leq h(y)$ *(weak monotonicity),*
- **(ii)** *if* $h(x) = h(y)$ *then either* $D(x, y) = 1$ *or* $D(y, x) = 1$ *(pairing),*
- **(iii)** *for every* $y \in \mathbb{R}$*, we have* $\#h^{-1}(y) \leq 2$ *(almost injective).*

In particular, we say that X is *filtered* by h. It also induces an h-order on X:

$$x <_h y \iff \big(h(x) < h(y)\big) \text{ or } \big(h(x) = h(y) \text{ and } \dim x < \dim y\big).$$

If X is filtered by a dMf h, then we always assume that rows and columns of D_n are ordered by the h-order, and those of $D_n^{\perp}$ by the reversed h-order.

To calculate persistent homology, we use the original version of the persistence algorithm [11], called *lazy reduction algorithm*, described in the form we need in [26]. The algorithm relies on an auxiliary function low, which, for a given column, returns the index of the row containing the lowest non-zero entry in that column. For a given (co)boundary matrix D_n, Algorithm 1 performs successive column additions, which results in a decomposition $D_n = R_n U_n$ with U_n invertible and upper triangular. Moreover, if $x \neq y$ and $U_n[x, y] \neq 0$, then column $R_n[:, x]$ was added to $R_n[:, y]$ by the algorithm. Observe that in D_n the rows are indexed by $(n-1)$-dimensional cells and the columns by n-dimensional cells. The same holds for R_n; however, both the rows and columns of U_n are indexed by n-dimensional cells. Similarly, we obtain $D^{\perp} = R^{\perp} U^{\perp}$ decomposition by applying $D^{\perp}$ to the algorithm.

Algorithm 1 Lazy reduction of the matrix over $\mathbb{Z}_2$.

```
R_n=D_n,   U_n=I
for y over the columns of R_n (left to right) do
    while R_n[:, y] ≠ 0 and there exists a preceding column x with
      low(R_n[:, x]) = low(R_n[:, y]) do
        R_n[:, y] ← R_n[:, y] + R_n[:, x]
        U_n[x, :] ← U_n[x, :] + U_n[y, :]
```

We say that $\alpha = (\alpha^{\circ}, \alpha^{\times})$ is an (n-dimensional) *birth-death* pair if α° is a low of $R_{n+1}[:, \alpha^{\times}]$. α is an (n-dimensional) birth-death pair if and only if $\alpha^{\times}$ is a low of $R_n^{\perp}[:, \alpha^{\circ}]$ [8]. We refer to α° and $\alpha^{\times}$ as *birth* and *death* cells, respectively. The *dimension* of a birth-death pair is

the dimension of its birth cell. We denote the set of all birth-death pairs by $\mathrm{BD}(h)$ and the set of all n-dimensional birth-death pairs by $\mathrm{BD}_n(h)$. The cells in dimension n that are not paired at all – their columns in R_n are zero, and there are no columns in R_{n+1} that have them as the lowest non-zero entry – are *n-dimensional homology generators*. It is convenient to assume that these generators also belong to some birth-death pair, even if its second component is undefined.

Let $x, y \in X_n$. If $U_n[x, y] = 1$, we say that there is a *homological relation* between x and y and denote this fact by $x \xrightarrow{\times} y$. Dually, if $U_n^{\perp}[x, y] = 1$, we write $x \xrightarrow{\circ} y$ to indicate a *cohomological relation*. If the relation type is not important, we simply write $x \to y$. If x and y are unrelated, we write $x \nrightarrow y$, adding a superscript to specify the missing relation type, e.g., $x \overset{\times}{\not\to} y$ if $U[x, y] = 0$. Observe that if $x \xrightarrow{\times} y$, then x must be a death cell, whereas y may be either a death cell or birth cell. Similarly if $x \xrightarrow{\circ} y$ then x has to be a birth cell, while the type of y remains unspecified. We extend these notions to birth-death pairs: $\beta \xrightarrow{\times} \alpha$ whenever $\beta^{\times}$ is homologically related to any component of α; similarly for other kinds of arrows. As rows and columns of D_n and $D_n^{\perp}$ are ordered with respect to the h-order and the reversed h-order, so are R_n, $R_n^{\perp}$, U_n and $U_n^{\perp}$. We emphasize that $R_n^{\perp}$ and $U_n^{\perp}$ are not transposed matrices R_n and U_n, but components of lazy decomposition $D_n^{\perp} = R_n^{\perp} U_n^{\perp}$.

The persistence diagram is a set of two dimensional points $(h(\alpha^{\circ}), h(\alpha^{\times}))$ for $\alpha \in \mathrm{BD}(h)$. When we visualize a persistence diagram (see Figure 2), it is convenient to add the *diagonal*, i.e., all points (x, x) for $x \in \mathbb{R}$, and to annotate the arrows with the type of the relation. Since a dMf is not injective in general, it can generate birth-death pairs on the diagonal of the persistence diagram. We denote the set of such diagonal pairs by $\overline{\mathrm{BD}}(h)$ and use notation $\hat{\mathrm{BD}}(h)$ for the pairs above the diagonal.

▶ **Observation 4.** *If pairs $\alpha, \beta \in \mathrm{BD}_n(h)$ and $\beta \to \alpha$, then $h(\beta^{\circ}) > h(\alpha^{\circ})$ and $h(\beta^{\times}) < h(\alpha^{\times})$. (see [26, Lemma 2.1])*

The preceding observation means that if we depict every relation between the birth-death pairs of the same dimension as arrows in the persistence diagram, then every such arrow points up and to the left.

▶ **Definition 5.** *Let X be a Lefschetz complex and let $h\colon X \to \mathbb{R}$ be a dMf. A* topological simplification of h *is a discrete Morse function h' such that $\hat{\mathrm{BD}}(h') \subset \hat{\mathrm{BD}}(h)$ and $h'(\alpha^{\circ}) = h(\alpha^{\circ})$ and $h'(\alpha^{\times}) = h(\alpha^{\times})$, whenever $\alpha \in \hat{\mathrm{BD}}(h')$.*

In words, a topological simplification removes some off-diagonal persistence pairs and preserves the rest.

▶ **Definition 6.** *A* combinatorial vector field *(or a vector field, for short) on a Lefschetz complex X is a partition $\mathcal{V}$ of X into singletons, called* critical cells*, and facet–cofacet pairs, called* vectors*. $\mathrm{Crit}(\mathcal{V})$ denotes the family of all critical cells of $\mathcal{V}$; $\mathrm{Vec}(\mathcal{V})$, the family of all vectors. We use the convention that the dimension of a vector is the smaller dimension of its two components.*

A combinatorial vector field $\mathcal{V}$ induces a digraph $G_{\mathcal{V}} = (X, E)$. Every edge $(x, y) \in E$ is either an *explicit arc* when $(x, y) \in \mathcal{V}$ or an *implicit arc* when $D(y, x) = 1$ and $(x, y) \notin \mathcal{V}$. A path ρ has *dimension* k if it consists only of cells of dimension k and $k + 1$. In particular, any path from y to x, where $x, y \in \mathrm{Crit}(\mathcal{V})$ and $k = \dim(x) = \dim(y) - 1$ is of dimension k and alternates between k and $k + 1$ dimensional cells.

A combinatorial vector field $\mathcal{V}$ is called *gradient* if $G_{\mathcal{V}}$ is acyclic. If there is a path between vertices y and x, then we write $y \overset{\mathcal{V}}{\rightsquigarrow} x$, omitting the superscript when the vector field is clear from the context. $\mathcal{V}^k$ denotes the union of all k-dimensional vectors and critical

cells of dimension k and $k+1$. Finally, note that for a given discrete Morse function h, the non-empty preimages $\mathcal{V}_h \coloneqq \{h^{-1}(a) \mid a \in \mathbb{R},\ h^{-1}(a) \neq \emptyset\}$ form a combinatorial gradient vector field.

The *Morse complex* connects homological and dynamical perspectives on scalar functions. It is not required to carry out the reasoning we need, but it will simplify it considerably.

▶ **Definition 7** (Morse complex). *Let $\mathcal{V}$ be a combinatorial gradient vector field on X. The* Morse complex *of $\mathcal{V}$ is a Lefschetz complex, denoted by $\mathcal{M}(\mathcal{V})$, consisting of the set of critical cells of $\mathcal{V}$ along with the restriction of* dim*. The boundary coefficient $D_{\mathcal{M}}(x,y)$ is given by the number of paths in $G_{\mathcal{V}}$ from y to $x \pmod 2$, provided $\dim y = \dim x + 1$ and 0 otherwise.*

The most useful properties of Morse complexes for our work is that they describe the off-diagonal birth-death pairs. Indeed, if $\mathcal{V}_h$ is a gradient vector field of some dMf h, its restriction to $\mathcal{M}(\mathcal{V}_h)$, denoted by $h_{\mathcal{M}}$, is an injective dMf. The next observation follows from [15, Theorem 4.3].

▶ **Corollary 8.** *Let X be filtered by dMf h. Then $\mathrm{BD}(h_{\mathcal{M}}) = \hat{\mathrm{BD}}(h)$ and $U_{\mathcal{M}}$, $U_{\mathcal{M}}^{\perp}$ are restrictions of U and $U^{\perp}$ to the critical cells.*

It follows that we can identify the components of the pairs in $\hat{\mathrm{BD}}(h)$ with elements of $\mathrm{Crit}(\mathcal{V}_h)$, while the vectors are the diagonal pairs, $\mathrm{Vec}(\mathcal{V}_h) = \overline{\mathrm{BD}}(h)$. This perspective enables us to apply the following classical theorem.

▶ **Theorem 9** ([19, Theorem 9.1]). *Let x be a k-dimensional critical cell and y be a $k+1$ dimensional critical cell of a gradient vector field $\mathcal{V}$. If there exists a unique path ρ from y to x, then reversing it in $\mathcal{V}$ produces another gradient vector field, which we denote $\mathcal{V}^{-\rho}$. The critical cells of $\mathcal{V}^{-\rho}$ are exactly the critical cells of $\mathcal{V}$ apart from x and y.*

We say that $\alpha \in \hat{\mathrm{BD}}(h)$ is *reversible* if there exists exactly one path between $\alpha^{\times}$ and α° in $\mathcal{V}_h$. However, the theorem alone gives no guarantee that elimination of a pair of critical cells will not affect the remaining pairs in $\hat{\mathrm{BD}}(h)$. Identifying those pairs that can be safely removed is therefore a key challenge.

▶ **Definition 10.** *Let X be a Lefschetz complex filtered by dMf h. A pair $(x,y) \in X \times X$ such that $D(x,y) = 1$ is a* shallow pair *if $h(x)$ is the maximum among facets of y and $h(y)$ is the minimum among cofacets of x.*

Observe that every shallow pair is a birth-death pair. Shallow pairs were introduced as apparent pairs in [2] and as close pairs in [9]. Since the theory behind them was later developed in the framework of the *depth posets* [13], we adopt the name from that setting. Shallow pairs are closely related to an algebraic operation called *Lefschetz cancelation*.

▶ **Definition 11.** *Let $(s,t) \in X \times X$ be a pair in a Lefschetz complex such that s is a facet of t. A* cancellation *of (s,t) produces a* quotient*, another Lefschetz complex $(\hat{X}, \hat{\dim}, \hat{D})$ such that $\hat{X} = X \setminus \{s,t\}$, $\hat{\dim}$ is a restriction of* dim *to $\hat{X}$ and $\hat{D}(x,y) = D(x,y) + D(s,y) \cdot D(x,t)$.*

The boundary map in the quotient can be written in matrix form: if $\dim t = n$ and $\hat{D}_n$ is the n-th boundary matrix of $\hat{X}$, then $\hat{D}_n[:,y] = D_n[:,y] + D_n[s,y] \cdot D_n[:,t]$, after erasing row s and column t. Throughout this paper, we often refer to small modifications of matrices based on their previous state. In such cases, any matrix M after modification is denoted $\hat{M}$.

▶ **Theorem 12** ([12, Theorem 3.2]). *Let X be filtered by a dMf h. Fix a shallow pair α. Then birth-death pairs of quotient of X after Lefschetz cancelation of α are exactly $\mathrm{BD}(h) \setminus \{\alpha\}$, and every shallow pair of h distinct from α remains shallow in the quotient, which may in addition contain new shallow pairs not present in X.*

In other words, performing a Lefschetz cancellation on a shallow pair does not change the pairing between the rest of the cells. It is convenient to characterize shallow pairs in terms of the relations between cells.

▶ **Observation 13.** *An n-dimensional birth-death pair α is shallow if and only if $U_{n+1}[:, \alpha^\times]$ and $U_n^\perp[:, \alpha^\circ]$ are zero except $U_{n+1}[\alpha^\times, \alpha^\times]$ and $U_n^\perp[\alpha^\circ, \alpha^\circ]$. Equivalently, α is shallow iff $\beta \nrightarrow \alpha$ for any birth-death pair β.*

It is important to note that a Lefschetz cancellation leaves intact not only the pairing, but also the relations between cells.

▶ **Theorem 14.** *Let D_n be a boundary matrix, and $\hat{D}_n$, a boundary matrix of the quotient after cancellation of the $(n-1)$-th dimensional shallow pair α. Let R_nU_n and $\hat{R}_n\hat{U}_n$ be their respective decompositions obtained via the lazy reduction. Then, $U_n[x, y] = \hat{U}_n[x, y]$ for all x, y different than $\alpha^\times$. Moreover, symmetrically $U_{n-1}^\perp[x, y] = \hat{U}_{n-1}^\perp[x, y]$ for all x, y different than α°.*

The above theorem can be rephrased as follows.

▶ **Observation 15.** *Let X be filtered by a dMf and α be a shallow birth-death pair. If $\beta \to \gamma$ in X, then the same relation holds in the quotient $\hat{X}$ obtained after the cancellation of α, for all $\beta \neq \alpha$.*

Due to Observation 13 above, we introduce *critical shallow pairs*. An off-diagonal birth-death pair α is a critical shallow pair if there does not exist an off-diagonal birth-death pair β such that $\beta \to \alpha$. It is easy to see that critical shallow pairs are exactly the shallow pairs of the Morse complex, although they need not be shallow pairs in the original complex. Equivalently, a pair α is critically shallow if for every $\beta \to \alpha$, the pair β is a vector in $\mathcal{V}_h$.

▶ **Theorem 16.** *Let $\mathcal{V}$ be a combinatorial vector field on X and let $s, t \in \mathrm{Crit}(\mathcal{V})$ be such that $\dim s + 1 = \dim t$. Assume that there exists a unique path ρ from t to s. Then $\mathcal{M}(\mathcal{V}^{-\rho})$ is isomorphic to the quotient of $\mathcal{M}(\mathcal{V})$ after cancelling the pair (s, t). (See example in Figure 1.)*

So to find a topological simplification of h, one can find a critical shallow pair α that is reversible. Then, one has to invert the unique path ρ between $\alpha^\times$ and α°, and find h' with the property that $\mathcal{V}^{-\rho} = \mathcal{V}_{h'}$ and $h_{|\,\mathrm{Crit}(\mathcal{V}^{-\rho})} = h'_{|\,\mathrm{Crit}(\mathcal{V}^{-\rho})}$. Unfortunately, it may happen that there is no pair that is both shallow and reversible. One of the goals of this paper is to remedy this problem.

3 Homology and cohomology relations in the filter

To understand how birth-death pairs and the relationships between them change during changes of the dMf, one must study how they change upon transposition of two adjacent cells in the boundary matrix. This problem is well-studied; see [5] and [13]. Observing that the depth poset can be constructed from the union of homological and cohomological relations between birth-death pairs (see Theorem 4.8 in [12]), we reformulate the results from [13] in the language of this paper. First, we introduce two additional objects.

▶ **Lemma 17** ([13, Lemma 3.2])**.** *Fix a birth-death pair $\alpha \in \mathrm{BD}(h)$. If we remove all birth-death pairs below and to the right of α – in the region $(h(\alpha^\circ), +\infty] \times [-\infty, h(\alpha^\times))$ – by iteratively canceling shallow pairs, we get the same boundary matrix regardless of the order of cancellations.*

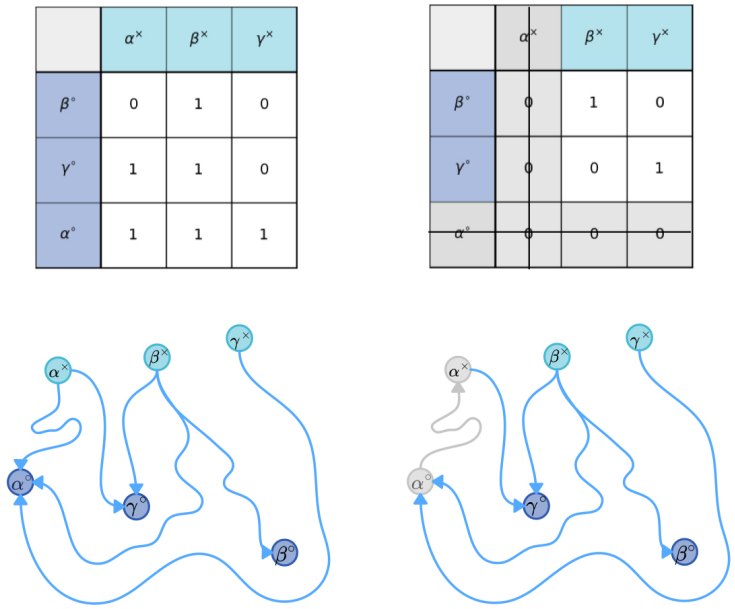

Figure 1 Two vector fields differing by a reversal of the path between components of a birth-death pair α. Critical cells are shown with colored nodes, and arrows between them symbolize paths created by vectors. Above each vector field is the boundary matrix of the corresponding Morse complex. Reversing the path between components of α gives the same boundary matrix as performing the Lefschetz cancelation.

Lemma 17 proves that the following definition is unambiguous.

▶ **Definition 18.** *Fix $\alpha, \beta \in \mathrm{BD}_n(h)$ such that the components of these pairs are consecutive columns in D_{n+1} or in $D_n^\perp$. Define $D_{n+1}^{\alpha,\beta}$ to be the matrix obtained by performing Lefschetz cancellations, always canceling shallow pairs, for all pairs lying in the bottom-right quadrant of α (excluding β if it eventually lies in this region) and for all pairs lying in the bottom-right quadrant of β (excluding α if it eventually lies in this region).*

Note that in the above definition, we can cancel all pairs in the bottom-right quadrants because, from Observation 4, there is no $\gamma \in \mathrm{BD}_n(h)$ such that $\beta \to \gamma \to \alpha$. After the cancellations, we have either (i) both α and β are shallow, or (ii) $\beta \to \alpha$ and β is shallow, or (iii) $\alpha \to \beta$ and α is shallow.

Now we are ready to utilize results from [13] in a series of theorems.

▶ **Theorem 19** (Result of death-cells transposition [13, Lemma 3.4])**.** *Let α, β be n-dimensional birth-death pairs such that $h(\alpha^\circ) < h(\beta^\circ)$. Then the transposition of $\alpha^\times$ and $\beta^\times$ does not change the values in U_{n+1}, while the changes in $U_n^\perp$ follow these rules:*

(1) *If $\beta \overset{\times}{\not\to} \alpha$ and $\left(\beta \overset{\circ}{\to} \alpha \text{ or } D_{n+1}^{\alpha,\beta}[\alpha^\circ, \beta^\times] = 1\right)$, then the pairing is unaffected and the row β° of the matrix $U_n^\perp$ changes according to the formula:*

$$\hat{U}_n^\perp[\beta^\circ, :] = U_n^\perp[\beta^\circ, :] + U_n^\perp[\alpha^\circ, :], \tag{1}$$

(2) *If $\beta \overset{\times}{\to} \alpha$, then the pairs $(\alpha^\circ, \alpha^\times), (\beta^\circ, \beta^\times)$ turn into $(\alpha^\circ, \beta^\times)$ and $(\beta^\circ, \alpha^\times)$ and $U_n^\perp$ changes as in (1).*

(3) *Otherwise, $U_n^\perp$ and the pairing remain unchanged.*

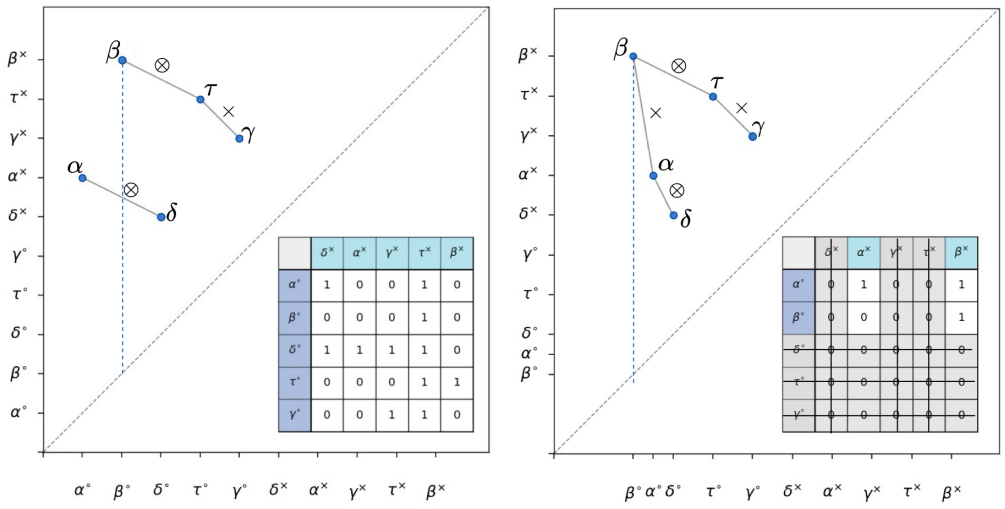

Figure 2 Left: $(n-1)$-st dimensional persistence diagram of some complex X, with D_n in the bottom-right corner. In the diagram, we denote by $\times$ homological relations between pairs, and by $\otimes$ relations which are homological and cohomological at the same time. To decide if moving β° past α° changes the relations between cells, as determined by Equation (1) in Theorem 20, we need to calculate $D_n^{\alpha,\beta}$. Right: The persistence diagram with the updated relation after the transposition of α° and β°. In the bottom-right corner, we show $D_n^{\alpha,\beta}$ before the transposition. The cells deleted by the Lefschetz cancellations are crossed out.

▶ **Theorem 20** (Result of birth-cells transposition [13, Lemma 3.3])**.** *Let α and β be n-dimensional birth-death pairs such that $h(\beta^\times) < h(\alpha^\times)$. Then the transposition of α° and β° does not change the values in $U_n^\perp$, while the changes in U_{n+1} follow these rules:*

(1) *If $\beta \not\xrightarrow{\circ} \alpha$ and $\left(\beta \xrightarrow{\times} \alpha \text{ or } D_{n+1}^{\alpha,\beta}[\beta^\circ, \alpha^\times] = 1\right)$, then the pairing is unaffected and the row $\beta^\times$ of the matrix U_{n+1} changes according to the formula:*

$$\hat{U}_{n+1}[\beta^\times, :] = U_{n+1}[\beta^\times, :] + U_{n+1}[\alpha^\times, :] \tag{2}$$

(2) *If $\beta \xrightarrow{\circ} \alpha$, then U_{n+1} changes as in (2), and pairs $(\alpha^\circ, \alpha^\times), (\beta^\circ, \beta^\times)$ turn into $(\beta^\circ, \alpha^\times)$ and $(\alpha^\circ, \beta^\times)$.*

(3) *Otherwise U_{n+1} and the pairing remain unchanged.*

▶ **Theorem 21** (Result of birth-death transposition [13, Lemma 3.5])**.** *A transposition between a birth and a death cell, which is a result of increasing birth, or decreasing death does not affect pairing or relations between birth-death pairs.*

Figure 2 presents an example of how a transposition affects the relationship between birth-death pairs. Now we introduce our own propositions, which will be useful later.

▶ **Proposition 22.** *Fix a pair $\alpha \in \mathrm{BD}_{(n-1)}(h)$. A transposition that increases the value of α° or decreases the value of $\alpha^\times$ and does not cause a switch cannot create a relation $\beta \to \alpha$ for any pair β.*

Note that a transposition may involve skipping two columns and rows when bypassing a combinatorial vector. The following proposition helps decrease complexity of the final algorithm.

▶ **Proposition 23.** *Let h, h' be two dMfs such that $\mathcal{V}_h = \mathcal{V}_{h'}$ and the difference between h-order and h'-order is a transposition between a critical cell and a vector. Then h and h' generate the same off-diagonal birth-death pairs and relations between them.*

Proof. As this process does not change the (co)boundary matrix of $\mathcal{M}(\mathcal{V}_h)$, it cannot change the pairing or relations between critical cells. ◀

Finally, the following two corollaries give us an opportunity to focus only on specific cases during the construction of the homotopy below.

▶ **Corollary 24.** *Take a pair $\alpha \in \mathrm{BD}_n(h)$. If x is a cell such that $\alpha^\circ <_h x$ and also $x \xrightarrow{\circ} \alpha^\circ$, then x is an n-dimensional birth cell. Analogously, if $y <_h \alpha^\times$ and $y \xrightarrow{\times} \alpha^\times$, then y is an $(n+1)$-dimensional death cell.*

Proof. Because $y \xrightarrow{\times} \alpha^\times$, the column indexed by y was added to column $\alpha^\times$ during the lazy reduction of matrix D_{n+1}. Because lazy reduction never adds zero columns, column y in R_{n+1} has a unique low, so it is a death cell. Analogously, if $x \xrightarrow{\circ} \alpha^\circ$, then column x was added to column α° in $D_n^\perp$, so x is a birth cell. ◀

4 Constructing the homotopy

4.1 Homotopy

Recall that a linear homotopy between two maps f_0 and f_1 is a family of maps $f_t(x) := H(t,x) = (1-t)f_0(x) + tf_1(x)$ for $t \in [0,1]$.

We say that $A \subset X$ is *connected* if it Hasse diagram – the graph whose vertices are the cells of A with an edge for every boundary relation – is connected. An *f-induced partition* is a partition $\mathcal{A}$ of X into maximal, with respect to inclusion, sets A, such that f is constant on A, and every A is connected.

▶ **Theorem 25.** *Let f_0 and f_1 be two dMfs defined on X such that $\mathcal{V}_{f_0} = \mathcal{V}_{f_1}$. Let $f_t(x) := H(t,x)$ be the linear homotopy between f_0 and f_1. Let $\mathcal{V}_{f_t}$ denote the f_t-induced partition of X. Then, $\mathcal{V}_{f_t} = \mathcal{V}_{f_0}$ for every $t \in [0,1]$.*

Using this theorem, we can represent our homotopy as a finite series of transpositions, allowing us to analyze only a finite number of time steps. Indeed, along a homotopy $(f_t)_{t\in[0,1]}$ there are only finitely many parameters t at which f_t fails to be a dMf. On each open interval between two such parameters, the induced f_t-order is well-defined and remains constant (in particular, it does not depend on t). Consequently, for a sufficiently fine discretization of $[0,1]$, consecutive f_t-orders differ by exactly one transposition.

4.2 Journey to the diagonal

Consider an example in Figure 3 and assume that our goal is to reduce the lifetime of the pair α to be arbitrarily small, without changing the pairing or the vector field. To reduce the lifetime, we may increase the value of α° and decrease the value of $\alpha^\times$, along with a set of vectors. We may implement this as a series of "moves" of the birth-death pair to the right and down in the persistence diagram.

Unfortunately, our moves are constrained: if we want to preserve the original vector field, then we cannot decrease $\alpha^\times$ below β° as $\alpha^\times \rightsquigarrow \beta^\circ$, and similarly, α° cannot increase above $\gamma^\times$. Moreover, as $\beta^\times \xrightarrow{\times} \alpha^\times$ and $\gamma^\times \xrightarrow{\times} \alpha^\times$, we also cannot decrease $\alpha^\times$ below these levels, without switches in pairing. Even worse, because $\xi^\circ \xrightarrow{\circ} \alpha^\circ$, α° cannot increase above ξ° without another switch.

This appears to be a serious obstacle. However, when we examine the persistence diagram (see bottom part of the Figure 3), we notice, following Observation 4, that increasing α° above β° breaks both homological relations of $\alpha^\times$ without changing the pairing. Afterwards, we are able to decrease $\alpha^\times$ as close to α° as we want. This motivates our central notion of forbidden regions, which describe the allowed "moves" in the persistence diagram.

▶ **Definition 26** (Forbidden regions). *For an off-diagonal pair $\alpha \in \hat{\mathrm{BD}}(h)$, we say that:*
(1) Forbidden region for $\alpha^\times$ *is defined as*

$$\mathcal{R}_h^{\urcorner}(\alpha) := \bigcup_{\substack{\beta \xrightarrow{\times} \alpha \\ \beta \in \hat{\mathrm{BD}}_n(h)}} [-\infty, h(\beta^\circ)] \times [-\infty, h(\beta^\times)] \;\cup \bigcup_{\substack{\alpha^\times \rightsquigarrow x \\ x \in \mathrm{Crit}(\mathcal{V}_h)}} [-\infty, h(x)] \times [-\infty, h(x)].$$

(2) Forbidden region for α° *is defined as*

$$\mathcal{R}_h^{\llcorner}(\alpha) := \bigcup_{\substack{\beta \xrightarrow{\circ} \alpha \\ \beta \in \hat{\mathrm{BD}}_n(h)}} [h(\beta^\circ), +\infty] \times [h(\beta^\times), +\infty] \;\cup \bigcup_{\substack{y \rightsquigarrow \alpha^\circ \\ y \in \mathrm{Crit}(\mathcal{V}_h)}} [h(y), +\infty] \times [h(y), +\infty].$$

Once we have the notion of forbidden regions, we can define a set of safe transformations, which we call *allowed moves*.

▶ **Definition 27** (Allowed moves). *Let h be a dMf, $\alpha \in \hat{\mathrm{BD}}(h)$ and $c \in \alpha$. A* pre-allowed move *of α is a new dMf h' such that:*
(1) *$\mathcal{V}_h = \mathcal{V}_{h'}$ and for all $x \in \mathrm{Crit}(\mathcal{V}_h) \setminus \{c\}$ we have $h(x) = h'(x)$,*
(2) *If c is a birth cell, then $h'(c) > h(c)$; if c is a death cell, then $h'(c) < h(c)$,*
(3) *h-order and h'-order restricted to $\mathrm{Crit}(\mathcal{V}_h)$ differ by a single transposition at most.*
If a pre-allowed move h' is such that $\mathrm{BD}(h) = \mathrm{BD}(h')$, then we say that h' is an allowed move.

A pre-allowed move pushes the pair α containing c toward the diagonal either by increasing birth or decreasing death without affecting the vector field. A single pre-allowed move bypasses at most one other critical cell. We note that multiple vectors can change their value and position in the h'-order – as long as the gradient structure is preserved. We will use the allowed moves to construct the homotopy bringing a persistent pair to the diagonal.

▶ **Corollary 28.** *If h' is a pre-allowed move for h, then the change in persistence pairing can only result from transpositions of critical cells.*

Proof. The linear homotopy from h to h' may be expressed as a series of transpositions in h-order, given by specific times $t \in [0, 1]$ and h_t-orders. By Theorem 25, the transpositions do not change the vector field, and thus, the diagonal pairs. Therefore, by Proposition 23, the change in persistence pairing can only result from transpositions of critical cells. ◀

Observe that for an X filtered by dMf h, for every cell x and interval $[a, b]$ such that $h(x) \in [a, b]$, we can find $t \in [0, 1]$ such that $h(x) = at + (1 - t)b$. We call it the *linear coefficient of x* on $[a, b]$. We now show that, for a fixed h, one can construct a pre-allowed move that pushes the chosen birth-death pair to the right, and another one that pushes it downward.

▶ **Proposition 29** (Increasing birth – moving right). *Let X be filtered by a dMf h. Let $\alpha \in \hat{\mathrm{BD}}(h)_k$ be an off-diagonal pair, and δ, ξ be real values such that $h(\alpha^\circ) < \delta < \xi < h(\alpha^\times)$, and there is at most one $e \in \mathrm{Crit}(\mathcal{V}_h)$ such that $h(e) \in (h(\alpha^\circ), \delta)$. Additionally, assume that $e \not\rightsquigarrow \alpha^\circ$ and $h^{-1}([\delta, \xi]) = \emptyset$. Define*

$$h'(x) = \begin{cases} t_x\delta + (1-t_x)\xi & \text{when } h(x) \in [h(\alpha^\circ), \xi] \text{ and } x \overset{\mathcal{V}_h}{\rightsquigarrow} \alpha^\circ \text{ and } x \notin \mathrm{Crit}(\mathcal{V}_h) \setminus \{\alpha^\circ\}, \\ h(x) & \text{otherwise,} \end{cases}$$

where t_x is the linear coefficient of x on the interval $[h(\alpha^\circ), \xi]$. Then h' is a pre-allowed move of α with respect to h.

▶ **Proposition 30** (Decreasing death – moving down). *Let X be filtered by dMf h. Let $\alpha \in \hat{\mathrm{BD}}(h)_k$ be an off-diagonal pair, and ξ, δ be real values such that $h(\alpha^\circ) < \xi < \delta < h(\alpha^\times)$, and there is at most one $e \in \mathrm{Crit}(\mathcal{V}_h)$ such that $h(e) \in (\delta, h(\alpha^\times))$. Additionally, assume $\alpha^\times \not\rightsquigarrow e$ and at the same time $h^{-1}([\xi, \delta]) = \emptyset$. Define*

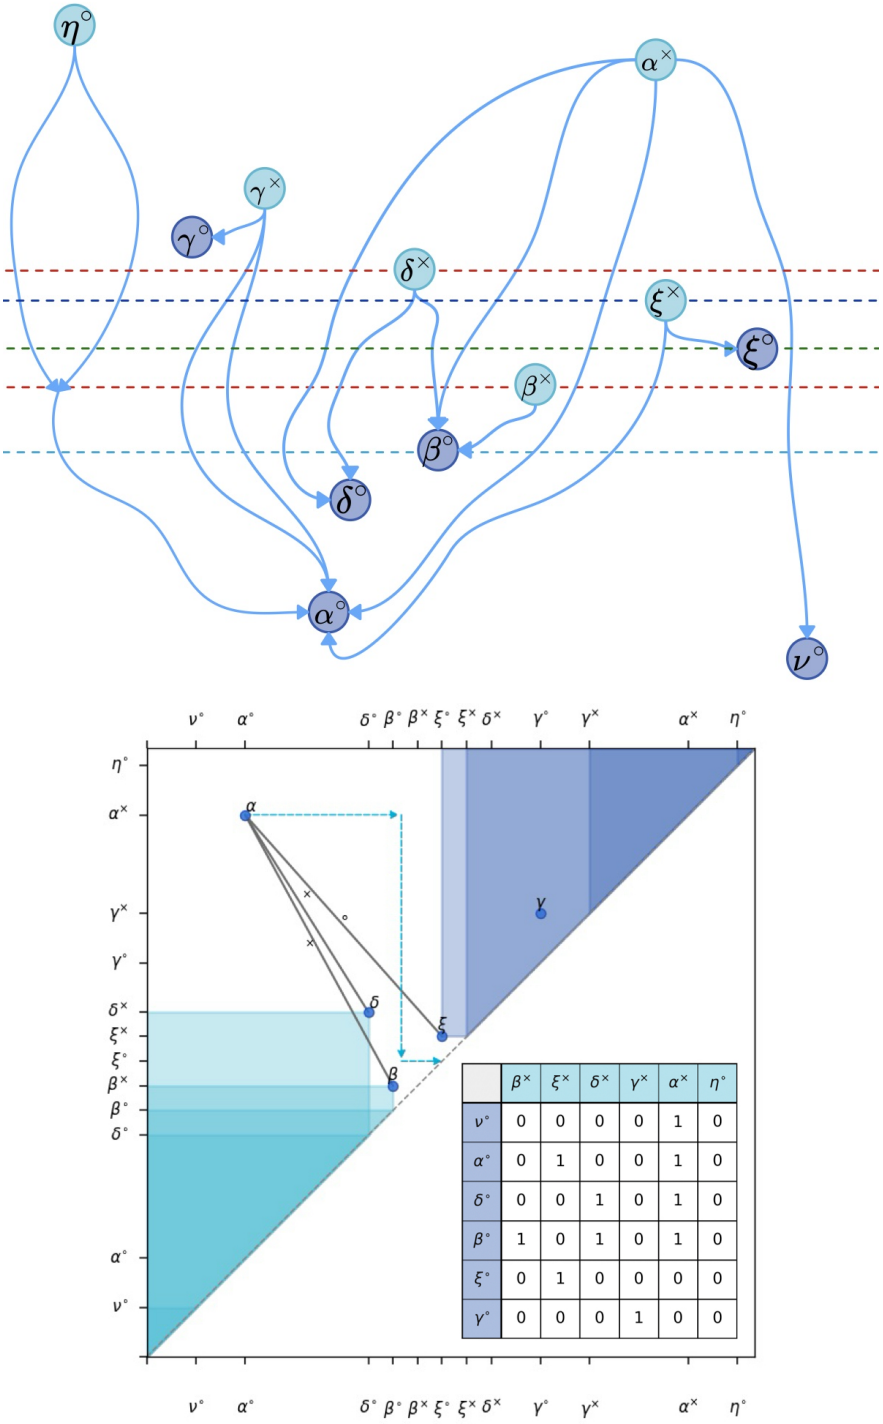
$$h'(x) = \begin{cases} t_x\xi + (1-t_x)\delta & \text{when } h(x) \in [\xi, h(\alpha^\times)] \text{ and } \alpha^\times \overset{\mathcal{V}_h}{\rightsquigarrow} x \text{ and } x \notin \mathrm{Crit}(\mathcal{V}_h) \setminus \{\alpha^\times\}, \\ h(x) & \text{otherwise,} \end{cases}$$

where t_x is the linear coefficient of x on the interval $[\xi, h(\alpha^\times)]$. Then h' is a pre-allowed move of α with respect to h.

Now observe that an allowed move of α does not introduce new forbidden regions.

▶ **Lemma 31.** *Let h' be an allowed move of $\alpha \in \hat{\mathrm{BD}}(h)$. Then $\mathcal{R}^{\urcorner}_{h'}(\alpha) \subset \mathcal{R}^{\urcorner}_{h}(\alpha)$ and $\mathcal{R}^{\llcorner}_{h'}(\alpha) \subset \mathcal{R}^{\llcorner}_{h}(\alpha)$.*

Proof. The statement follows directly from Proposition 22 and the fact that $\mathcal{V}_h = \mathcal{V}_{h'}$, and we are changing the value of only one component of α. ◀



It follows that if we know the initial forbidden regions, we can design a sequence of allowed moves that brings α arbitrarily close to the diagonal.

▶ **Theorem 32.** *Let X be filtered by a dMf h_1 and $\alpha \in \hat{\mathrm{BD}}_k(h)$ be such that $\mathcal{R}^{\llcorner}_{h_1}(\alpha) \cap \mathcal{R}^{\urcorner}_{h_1}(\alpha) = \emptyset$, then there exists a sequence of dMfs $h_1, h_2, \ldots, h_n$ such that h_{i+1} is an allowed move of $\alpha \in \mathrm{BD}(h_i)$, and $h_n(\alpha^\times) - h_n(\alpha^\circ)$ is arbitrarily small.*

Proof. We begin by showing that we are able to construct from h_i an allowed move h_{i+1} such that α° and $\alpha^\times$ are closer in h_{i+1}-order than in h_i-order, where both orders are restricted to the critical cells. Due to Corollary 28, to show that $\mathrm{BD}(h_i) = \mathrm{BD}(h_{i+1})$, we can focus only on transpositions between critical cells. Define x and y as critical cells such that in h_i-order, we have $\alpha^\circ <_{h_i} x <_{h_i} \ldots <_{h_i} y <_{h_i} \alpha^\times$.

If $x \not\rightsquigarrow \alpha^\circ$, then if x is a death cell or $x \overset{\circ}{\not\to} \alpha^\circ$, we use Proposition 29 to construct h_{i+1}, which increases the value of α° with the values of δ and ξ in the proposition larger than $h_i(x)$. Analogously, if $\alpha^\times \not\rightsquigarrow y$, then if y is a birth cell or $y \overset{\times}{\not\to} \alpha^\times$, then use Proposition 30 to construct h_{i+1}, which decreases the value of $\alpha^\times$ to bypass y. From Theorems 19, 20 and 21, we get that these are indeed allowed moves.

If $x \rightsquigarrow \alpha^\circ$ and $\alpha^\times \rightsquigarrow y$, then x generates forbidden regions bounded by a vertical line and y generates forbidden region bounded by a horizontal line. Because $x <_{h_i} y$, they intersect. We get the same argument if $x \rightsquigarrow \alpha^\circ$ and $y \overset{\times}{\to} \alpha^\times$, or $\alpha^\times \rightsquigarrow y$ and $x \overset{\circ}{\to} \alpha^\circ$. If $x \overset{\circ}{\to} \alpha^\circ$ and

	$\beta^\times$	$\xi^\times$	$\delta^\times$	$\gamma^\times$	$\alpha^\times$	η°
ν°	0	0	0	0	1	0
α°	0	1	0	0	1	0
δ°	0	0	1	0	1	0
β°	1	0	1	0	1	0
ξ°	0	1	0	0	0	0
γ°	0	0	0	1	0	0

Figure 3 Top: Schematic picture of $\mathcal{V}_h^k$. Node heights encode values of dMf, critical cells are labeled by Greek letters with superscripts. Several important sublevels are highlighted with dashed lines. Bottom: Boundary matrix and the persistence diagram of the Morse complex induced by $\mathcal{V}_h^k$ with the two kinds of forbidden regions highlighted, and relations involving the birth-death pair α shown as edges. The forbidden regions for $\alpha^\times$ are shown in light blue; those for α°, in darker blue. The dashed arrows illustrate a possible homotopy, which moves the point to the diagonal.

$y \xrightarrow{\times} \alpha^\times$, then due to Corollary 24, there has to exist $(x, \beta^\times), (\gamma^\circ, y) \in \mathrm{BD}_k(h_i)$. It follows from Observation 4 that they are in the bottom-right quadrant of the pair α. Therefore, they generate forbidden $\alpha^\times$ and α° regions, which intersect.

It follows from Lemma 31 that if $\mathcal{R}^{\urcorner}_{h_i}(\alpha) \cap \mathcal{R}^{\llcorner}_{h_i}(\alpha) \neq \emptyset$, then $\mathcal{R}^{\urcorner}_{h_1}(\alpha) \cap \mathcal{R}^{\llcorner}_{h_1}(\alpha) \neq \emptyset$.

Accordingly, we can construct a series of allowed moves, such that h_j is the last one, and α° and $\alpha^\times$ are consecutive in the h_j-order restricted to the critical cells. Then, by Proposition 29, we construct a final pre-allowed move such that the value gap between the cells of α can be made arbitrarily small. Since no critical cell is bypassed during this deformation, the move is allowed. ◀

4.3 Reversing the path

In the previous subsection, we showed that if the forbidden regions of the birth and the death cell of a (reversible) pair α do not intersect, then we can reduce its lifetime arbitrarily close to zero. In particular, we can make it a critical shallow pair. It follows from Theorem 16 that we can safely – that is, without introducing changes in the pairing or in the relations – reverse the path between the components of α. The reversal is the final step of the construction, which corresponds to α entering the diagonal. To make the homotopy fully explicit we construct the final dMf inducing the vector field with reversed path.

▶ **Proposition 33.** *Let $\alpha \in \mathrm{BD}_n(h)$ be a reversible pair such that the unique path between $\alpha^\times$ and α° is ρ. If $h^{-1}([h(\alpha^\circ), h(\alpha^\times)]) = \rho = (\alpha^\circ = x_0, x_1, x_2, \ldots, x_m = \alpha^\times)$, then the function h', defined as*

$$h'(x) = \begin{cases} h(x_{m-2\lfloor i/2 \rfloor}) & \text{when } x \in \rho \text{ and } x = x_i, \\ h(x) & \text{otherwise,} \end{cases}$$

is a dMf which generates $\mathcal{V}^{-\rho}$ and does not change the value of the critical cells other than the components of α.

5 Final algorithm and summary

5.1 Final algorithm

We summarize the entire construction in the form of an algorithm that produces a topological simplification of a given dMf.

Input. A Lefschetz complex X filtered by a dMf h; the combinatorial vector field $\mathcal{V}_h$; the set $\mathrm{BD}(h)$ of birth–death pairs; all homology/cohomology relations among the off-diagonal pairs; and a reversible, k-dimensional birth-death pair α, such that $\mathcal{R}^{\urcorner}_h(\alpha) \cap \mathcal{R}^{\llcorner}_h(\alpha) = \emptyset$.

(1) Following the procedure described in Theorem 32, move α so close to the diagonal that $h^{-1}((h(\alpha^\circ), h(\alpha^\times)) = \rho$, where ρ is a unique path between the components of α. During this process, update the relations between the critical cells of $\mathcal{V}_h$ using Theorems 19, 20.

(2) Reverse the path ρ between $\alpha^\times$ and α° in the vector field, constructing a new dMf as described in Proposition 33.

Output. A Lefschetz complex X filtered by a dMf h'; the combinatorial vector field $\mathcal{V}_{h'}$; the set $\mathrm{BD}(h')$ of birth-death pairs; all homology/cohomology relations among the off-diagonal pairs.

Figure 4 illustrates an example of a topological simplification obtained by this procedure.

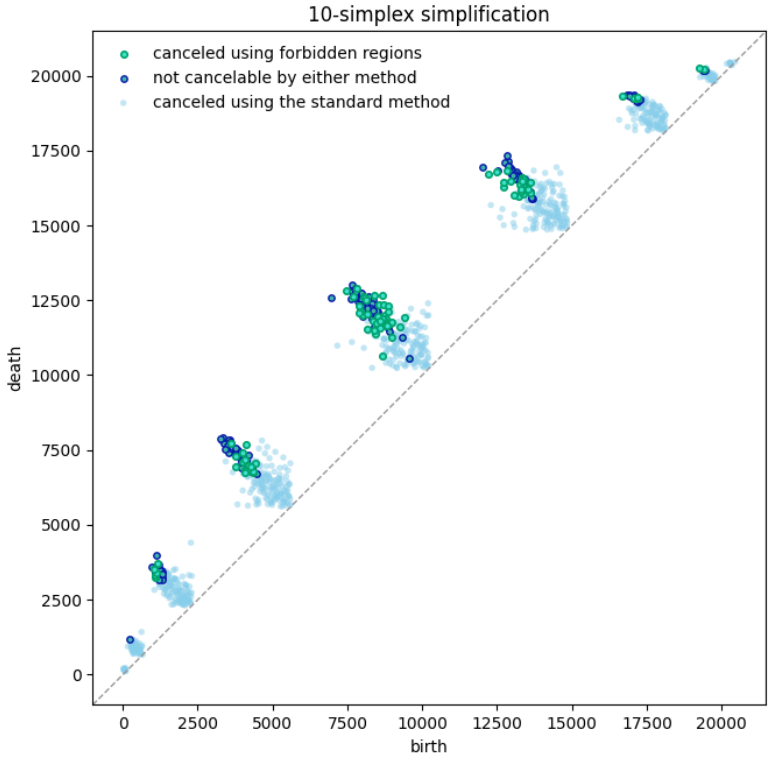


Figure 4 Persistence diagram of the 10-simplex, filtered by a random injective dMf such that every birth-death pair of dimension n is separated from pairs of dimensions $n+1$ and $n-1$. We apply a procedure that first simplifies dMf by the standard method, i.e., path reversing between shallow pairs. When there is no reversible shallow pair left, we continue using the algorithm described in this paper. We made multiple passes canceling any pair that met the algorithm's assumptions. We stopped when there was no reversible pair with a path between forbidden regions. Pairs of different types (canceled by the standard method, canceled using forbidden regions, not cancelable) are denoted by different colors. Figure 5 zooms-in on the pairs in dimension 4.

▶ **Theorem 34.** *The algorithm above returns a topological simplification h' for a dMf h. Moreover, the output of the algorithm contains the updated vector field and homology/cohomology relations for h'.*

Proof. We start by showing that $\hat{\mathrm{BD}}(h') = \hat{\mathrm{BD}}(h) \setminus \{\alpha\}$. Step 1 does not cause any changes in the pairing by Theorem 32. A dMf constructed in Step 2 has the same off-diagonal pairs as the previous one, except α, due to Theorem 16 and Theorem 12.

Proposition 23 and Theorem 16 imply that it suffices to apply the update pattern and check its conditions only during transpositions of critical cells in Step 1. This results in the updated relations among critical cells at the end of the algorithm.

After the update, the new vector field $\mathcal{V}_{h'} = \mathcal{V}^{-\rho}$, where ρ is a unique path. We know the birth-death pairs $\mathrm{BD}(h')$, as well as all relations between critical cells after the application of the update patterns. ◀

The proof of Theorem 34 also proves Theorem 1. For an iterative execution of the algorithm, we can use its output as an input for the next run; one only needs to provide the next eligible pair. Finally, we consider how much the new constructed dMf h' differs from the original one.

▶ **Proposition 35.** *Let X be filtered by a dMf h, and h' be its topological simplification constructed by our algorithm, which removes pair α. Then, the difference between h' and h is bounded by the lifetime of α, that is* $\max_{x \in X} |h(x) - h'(x)| \leq (h(\alpha^{\times}) - h(\alpha^{\circ}))$.

Proof. It follow directly from the fact that in Propositions 29, 30 and 33, we change only the values of the cells between $h(\alpha^{\circ})$ and $h(\alpha^{\times})$, and if the value of the dMf is changed on x, then the resulting value also lies between $h(\alpha^{\circ})$ and $h(\alpha^{\times})$. ◀

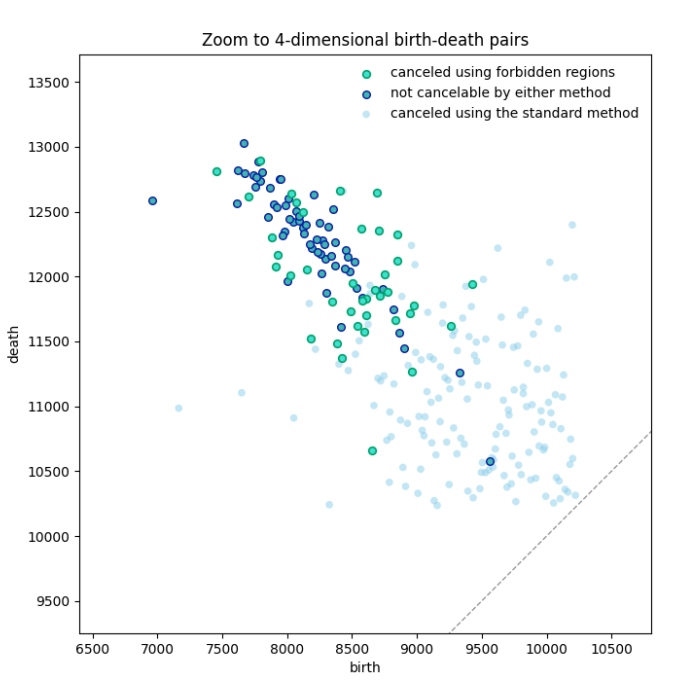

Figure 5 Birth-death pairs in dimension 4 from Figure 4.

5.2 Complexity

We note that checking if a pair α can serve as an input to the algorithm takes $\mathcal{O}(n \log n)$ time, see [23]; there are at most c such pairs to check. The complexity of the algorithm is dominated by the cost of checking if moving pair α past pair β requires updating relations between birth-death pairs, whenever $\beta \nrightarrow \alpha$. Computing $D_{n+1}^{\alpha,\beta}$ can clearly be done in $\mathcal{O}(n^2)$

time; however, in the full version of the paper (see [23]) we show that it can be reduced to $\mathcal{O}(n)$. Therefore, the worst case running time is $\mathcal{O}(c \cdot n)$, where c is the number of birth-death pairs, and n is the number of cells in the complex.

5.3 Summary

We presented a new criterion for removing a fixed birth-death pair. We have also shown that for every pair that satisfies this criterion, it is possible to construct a homotopy, which moves this pair into the diagonal. The paper opens a number of questions.

(1) How does the order of cancellations affect the possibility of canceling the remaining pairs? Is there an optimal order? Can we find a hierarchy of cancellations using this order?
(2) Is the criterion exhaustive? That is, are there other removable pairs that are not captured by the criterion?
(3) Is it possible to weaken the criterion by proper manipulation of the pairs generating the forbidden regions? For example, if forbidden region of α° and forbidden region of $\alpha^\times$ intersect, is it possible to manipulate other cells to clear a path to the diagonal for α, and restore their values after the cancellation?
(4) Is it possible to parallelize the cancellation process? If so, for which pairs?

The Complete 10-Tetrahedra Census of Orientable Cusped Hyperbolic 3-Manifolds

Shana Yunsheng Li
Dept. of Math., University of Illinois Urbana-Champaign, IL, USA

Abstract

We extend the complete census of orientable cusped hyperbolic 3-manifolds to 10 tetrahedra, giving the next 150,730 manifolds and their 496,638 minimal ideal triangulations. As applications, we find the precisely 439,898 exceptional Dehn fillings on them, revealing the next 1,849 simplest hyperbolic knot exteriors in S^3. We also give the simplest example of an orientable cusped hyperbolic 3-manifold containing a closed totally geodesic surface.

1 Introduction

The enumeration of examples has been of fundamental importance in the study of low-dimensional topology ever since Tait gave the first knot table in 1884 [41]. The censuses of knots have been extensively explored over the years, all the way to approximately the first 2 billion knots [28, 8, 43]. However, the censuses of orientable cusped hyperbolic 3-manifolds, initiated by Hildebrand and Weeks [25], have seen no progress after the 44,250 manifolds whose minimal ideal triangulations consist of 9 tetrahedra were given by Burton in 2014 [7]. In this paper, we extend the census by giving the 150,730 manifolds whose minimal ideal triangulations consist of 10 tetrahedra. Table 1 summarizes the timeline of the development of censuses of orientable cusped hyperbolic 3-manifolds.

By hyperbolic 3-manifolds, we mean 3-manifolds with Riemannian metrics of constant curvature -1 that are complete as metric spaces; in particular their geodesics can be extended indefinitely in length. A hyperbolic 3-manifold is *cusped* if it has a topological end that is of finite volume. An orientable cusped finite-volume hyperbolic 3-manifold is homeomorphic to the interior of a compact 3-manifold whose boundary is a non-empty union of tori. Our main result is the following:

▶ **Theorem 1.** *There are precisely* 150,730 *orientable cusped hyperbolic* 3*-manifolds whose minimal ideal triangulations consist of* 10 *tetrahedra. Moreover, there are precisely a total of* 496,638 *minimal ideal triangulations of these manifolds.*

6 7	s000 ∼ s961 v0000 ∼ v3551	1999	Callahan, Hildebrand & Weeks [11]
8	t00000 ∼ t12845	2010	Thistlethwaite [42]
9	o9_00000 ∼ o9_44249	2014	Burton [7]
10	o10_000000 ∼ o10_150729	2025	L.

Table 5 in [33, Appendix A.2] gives the counts of manifolds in Theorem 1 by cusp number.

We highlight here that in order to obtain Theorem 1, we applied a new core technique, the verified canonical triangulations. We anticipate that a mixture of this technique with traditional ones would suffice for further extension of the census, provided successful generation of the candidates; see Sections 3.1 and 3.5 for more detailed discussions.

Throughout this paper, we assume triangulations consist of finitely many tetrahedra. If a cusped hyperbolic 3-manifold admits an ideal triangulation, each tetrahedron has finite volume [15, §2.5], hence the volume of the manifold is finite. Conversely, any cusped finite-volume hyperbolic 3-manifold has an ideal triangulation given by a refinement of the Epstein–Penner cellulation [37, §5]. Therefore, for cusped hyperbolic 3-manifolds, being finite-volume is equivalent to admitting ideal triangulations, hence we drop the term finite-volume when talking about cusped hyperbolic 3-manifolds admitting ideal triangulations.

In general, it is unknown whether all cusped finite-volume hyperbolic 3-manifolds admit geometric triangulations in the sense of Section 2.1 below [36]. However, when certifying hyperbolicity, `SnapPy` returns true if and only if it finds a geometric triangulation. Therefore an immediate corollary of this paper is that

▶ **Corollary 2.** *All cusped hyperbolic* 3*-manifolds ideally triangulable by at most* 10 *tetrahedra admit geometric triangulations.*

Note that nonorientable manifolds are included here since they are included in Theorem 7. For orientable manifolds, the above result can be strengthened to Proposition 11.

We briefly review the needed terminologies in Section 2, then give detailed discussions in Section 3 for the creation of the 10-tetrahedra census, after which we give some applications of the extended census in Section 4. All corresponding code and data are available at [34].

2 Preliminaries

2.1 Triangulations

A *(generalised) triangulation* $\mathcal{T}$ is a disjoint union of finitely many tetrahedra, with some or all faces identified in pairs via simplicial maps, and we avoid identifications where an edge is identified with itself in reverse. Note that $\mathcal{T}$ is not necessarily a simplicial complex, as identifications of two faces of the same tetrahedron are allowed.

Quotienting by the identifications, $\mathcal{T}$ can be seen as a topological space, along with a cellular structure induced by the tetrahedra. A *vertex* in $\mathcal{T}$ is a 0-cell in this cellular structure, and an *edge* is a 1-cell. The *link* of a vertex in $\mathcal{T}$ is the frontier of a small regular neighborhood of that vertex. A vertex is *internal* if its link is a sphere, and is *ideal* if its link is some other closed surface. For an edge e in $\mathcal{T}$, its *degree* is the cardinality of the set

$$\mathcal{S}_e \coloneqq \bigcup_{t \in \{\text{3-cells of } \mathcal{T}\}} \{\text{(nonempty) connected components of } \mathcal{N}_e \cap t\},$$

where $\mathcal{N}_e$ is a small regular neighborhood of the midpoint of e.

▶ **Definition 3.** *Let M be the interior of a compact 3-manifold with boundary. A triangulation $\mathcal{T}$ is an ideal triangulation of M if it is homeomorphic to M after removing its ideal vertices, and is minimal if no ideal triangulation of M with fewer tetrahedra exists.*

It follows that every vertex of an ideal triangulation is either internal or ideal. Note that an ideal triangulation itself is not a manifold and has at least one ideal vertex.

If M is a cusped hyperbolic 3-manifold, an ideal triangulation $\mathcal{T}$ of M is *geometric* if all vertices are ideal, all edges are geodesics, all 2-cells are parts of geodesic planes, and no flat or negatively oriented tetrahedron (i.e. with zero or negative volume) exists.

The following results were proven in Section 3 of [7]:

▶ **Lemma 4** (Burton). *Let $\mathcal{T}$ be a minimal ideal triangulation of a cusped hyperbolic 3-manifold. Then $\mathcal{T}$ contains no internal vertices.*

▶ **Lemma 5** (Burton). *Let $\mathcal{T}$ be a minimal ideal triangulation of a cusped hyperbolic 3-manifold. Then $\mathcal{T}$ has no edges of degree 1 or 2, and $\mathcal{T}$ has no edges of degree 3 that are contained in three distinct tetrahedra.*

2.2 Normal surfaces

In a tetrahedron, an arc α properly embedded in one of its faces is *normal* if the endpoints of α are in the interior of distinct edges. A properly embedded disk is a *triangle* if its boundary consists of three normal arcs in distinct faces, and is a *square* if its boundary consists of four normal arcs in distinct faces.

Let $\mathcal{T}$ be a triangulation. A properly embedded compact surface in $\mathcal{T}$ is *normal* if its intersection with every tetrahedron in $\mathcal{T}$ (with the identifications undone) is a properly embedded surface whose connected components consist of only triangles and squares.

An isotopy of $\mathcal{T}$ is normal if it preserves the cellular structure of $\mathcal{T}$. Up to normal isotopy, there are 4 triangles and 3 squares in a tetrahedron. Multiple copies of triangles or squares in the same normal isotopy class may appear in the intersection of a normal surface and a tetrahedron. It follows that a normal surface in a triangulation of n tetrahedra is uniquely determined by a vector in $\mathbb{N}^{7n}$ up to normal isotopy, where $\mathbb{N} \coloneqq \{k \in \mathbb{Z} \mid k \geq 0\}$.

The subset $\mathcal{N} \coloneqq \{\boldsymbol{v} \in \mathbb{N}^{7n} \mid \boldsymbol{v} \text{ represents a normal surface}\}$ consists of integral vectors in a certain non-convex subset of a polyhedral cone in $\mathbb{R}^{7n}$ [29]. The *standard vertex normal surfaces* correspond to vertices of a cross-section of this polyhedral cone, and can be viewed as forming a finite basis for $\mathcal{N}$.

The following result was proven in Section 3 of [7]:

▶ **Lemma 6** (Burton). *Let $\mathcal{T}$ be a minimal ideal triangulation of a cusped hyperbolic 3-manifold. Then no standard vertex normal surface in $\mathcal{T}$*

- *has positive Euler characteristic; or*
- *has zero Euler characteristic, is not a vertex link, and in addition*
  - *is one-sided; or*
  - *is two-sided, and if we cut $\mathcal{T}$ open along it then no component of the resulting space is a solid torus or solid Klein bottle.*

3 Creating the 10-tetrahedra census

3.1 Overview

To build a census (of knots, manifolds, etc), the procedure generally follows a 3-step outline:

(i) Generate all candidates for the census.

(ii) Decide the eligibility of each candidate.

(iii) Group eligible candidates into isomorphism classes and certify that the isomorphism classes are all distinct.

As long as the candidate generation is performed exhaustively and the eligibility for each candidate is decided correctly, the census obtained is guaranteed to contain all wanted objects. With step (iii), the resulting census will contain no duplicates. We say that a census is *complete* if it contains all wanted objects without any duplicated ones.

For censuses of cusped hyperbolic 3-manifolds, the candidates will be ideal triangulations consisting of a given number of tetrahedra, and the eligibility conditions will be minimality (of triangulations) and hyperbolicity (of manifolds the triangulations represent). For certifying distinctness, algebraic invariants were widely applied for both the census of hyperbolic 3-manifolds [7] and the census of knots [28, 8, 43]. However, it is unknown whether algebraic methods will indeed separate all given isometry classes within a given scope, consequently they cannot be used to certify if two isometry classes are indeed the same, and other methods will be required for that purpose. Here we propose an alternative approach for cusped hyperbolic 3-manifolds, using a geometric invariant, the *canonical triangulation*, built upon the Epstein–Penner canonical cellulation [21] by Weeks [44], whose rigorous computation was implemented by Goerner [24]. An introduction to these can be found in [22], and we review them briefly in Section 3.3.1. The canonical triangulation, when computed rigorously, is a complete invariant of cusped hyperbolic 3-manifolds, and we applied it to deduplicate a majority of triangulations in the 10-tetrahedra census in Section 3.3.3.

Our approaches for steps (i) and (ii) largely overlap with those in [7]. For completeness, we briefly describe them in Section 3.2, and kindly refer the reader to [7] for more details. For step (iii), detailed discussions will be given in Section 3.3.

3.2 Candidate generation and eligibility tests

Let us start by looking at Table 2. The steps proceed from top to bottom. Each row consists of the name of the step, the number of remaining candidates whose hyperbolicity is unknown, the numbers of candidate discarded within that step due to ineligibility, and the number of candidates kept to be dealt with later in Section 3.3.3.

For candidate generation, we used `Regina`'s utility command `tricensus` to generate all ideal triangulations consisting of 10 tetrahedra except those that are obviously nonminimal or non-hyperbolic. More precisely, we obtained:

▶ **Theorem 7.** *Up to relabelling, there are* 8,373,308 *ideal triangulations with* 10 *tetrahedra, in which every vertex is ideal, there are no edges of degree* 1 *or* 2*, and there are no edges of degree* 3 *that belong to three distinct tetrahedra.*

Due to Lemmas 4 and 5, the triangulations described in Theorem 7 contain all minimal ideal triangulations of cusped hyperbolic 3-manifolds whose minimal ideal triangulations consist of 10 tetrahedra. Note that triangulations representing nonorientable manifolds are also included and carried through the tests, though we will discard them in Section 3.3.

Table 2 The steps of filtering candidates for the 10-tetrahedra census.

Step	Candidates	Discarded	Kept
Candidate generation	8,373,308	0	0
Greedy nonminimality	1,946,782	6,426,526	0
Certify hyperbolicity ($r = 1$)	1,072,874	0	873,908
Exhaustive nonminimality ($h = 2$)	698,650	374,224	0
Special surfaces	33,807	664,843	0
Certify hyperbolicity ($r = 60$)	3,269	0	30,538
Exhaustive nonminimality ($h = 5$)	12	3,257	0
Exhaustive nonminimality ($h = 6$)	6	6	0
Certify hyperbolicity ($r = 1000$)	0	0	6
Total	8,373,308	7,468,856	904,452

With the candidates generated, we proceed to determine their eligibilities. For an ideal triangulation to remain in the census, it must be both minimal and representing a cusped hyperbolic 3-manifold. Hence an ideal triangulation is discarded immediately if it is certified to be nonminimal or representing a non-hyperbolic 3-manifold. If an ideal triangulation is certified to represent a cusped hyperbolic 3-manifold, we temporarily keep it, and decide whether it is minimal by checking if it represents a manifold that has already appeared in censuses with fewer tetrahedra, which we discuss in Section 3.3.

Four tests were used in Table 2, which we describe below:

Greedy nonminimality: we use `Regina`'s highly efficient simplification algorithm [5] to try converting each candidate into an ideal triangulation with fewer tetrahedra, while representing the same 3-manifold. If such a triangulation with fewer tetrahedra is found, then the candidate is nonminimal.

Exhaustive nonminimality: given an integer parameter $h > 0$, for each candidate with n tetrahedra ($n = 10$ in our settings), enumerate all triangulations that can be reached via 2-3 and 3-2 Pachner moves without ever exceeding $n + h$ tetrahedra. If a triangulation with fewer than n tetrahedra is found during the process, the candidate is nonminimal.

Special surfaces: for each candidate $\mathcal{T}$, enumerate all standard vertex normal surfaces in it, and check if any of them

- has positive Euler characteristic; or
- has zero Euler characteristic, is not a vertex link, and in addition
  - is one-sided; or
  - is two-sided, and if we cut $\mathcal{T}$ open along it then no component of the resulting space is a solid torus or solid Klein bottle.

If any such surface is found, then by Lemma 6, $\mathcal{T}$ is either nonminimal or does not represent a cusped hyperbolic 3-manifold.

Certify hyperbolicity: given an integer parameter $r > 0$, for each candidate $\mathcal{T}$, we randomize it by doing random Pachner moves, and ask `SnapPy` to try finding a complete hyperbolic structure on $\mathcal{T}$, which uses an algorithm similar to HIKMOT's [27], where affirmative answers are rigorous [24]. If the answer is not affirmative, we randomize $\mathcal{T}$ and try again, until an affirmative answer is achieved or the number of attempts reaches r.

We summarize the tests along with their core functions in Table 4 in [33, Appendix A.1].

As is presented in Table 2, for each candidate, an affirmative answer was given by one of the above four tests. A candidate was kept if and only if the affirmative answer was given by the certify hyperbolicity test, and was discarded otherwise. As such, we obtained 904,452 triangulations certified to represent cusped hyperbolic 3-manifolds at the bottom of Table 2, with all others discarded.

3.3 Grouping and Separating

In this section, we discuss the procedure for step (iii) described in Section 3.1. A central tool for it, in both [7] and our method, is the *canonical triangulation* of cusped finite-volume hyperbolic 3-manifolds.

3.3.1 Canonical triangulation

We review the definition and computation of canonical triangulations very briefly, and refer the reader to [22] for more details.

Consider the $(3+1)$-Minkowski space $\mathbb{E}^{3,1} \coloneqq \mathbb{R}^4$ whose inner product $\langle \cdot, \cdot \rangle$ is defined by $\langle \boldsymbol{x}, \boldsymbol{y} \rangle \coloneqq \sum_{i=0}^{2} x_i y_i - x_3 y_3$. The hyperboloid $S^+ \coloneqq \{\boldsymbol{x} \in \mathbb{E}^{3,1} \mid x_3 > 0, \quad \langle \boldsymbol{x}, \boldsymbol{x} \rangle = -1\}$ is isometric to $\mathbb{H}^3$. Given a cusped hyperbolic 3-manifold M, for each cusp of M we choose a horotorus cusp neighborhood of the same volume; each neighborhood is bounded by a torus, which lifts to horospheres in $\mathbb{H}^3 \cong S^+$. For each horosphere $\mathcal{H} \subset S^+$, its normal vector $\boldsymbol{v}$ in $\mathbb{E}^{3,1}$ satisfies $\langle \boldsymbol{v}, \boldsymbol{v} \rangle = 0$, and we normalize it so that $\langle \boldsymbol{v}, \boldsymbol{w} \rangle = -1$ for any $\boldsymbol{w} \in \mathcal{H}$. Therefore we obtain a family $\{\boldsymbol{v}\}_M$ of such vectors associated to a cusped hyperbolic 3-manifold M.

▶ **Definition 8.** *The Epstein–Penner cellulation of M is given by the radial projection of the polygonal faces of the convex hull of $\{\boldsymbol{v}\}_M$ onto S^+.*

The Epstein–Penner cellulation is invariant under the choice of the volume of cusp neighborhoods, hence it is an invariant of cusped hyperbolic 3-manifolds [21]. It is generically a triangulation, but not always so. Given a polygonal cellulation of a 3-manifold, one can subdivide it into the triangulation induced by the following refinement of its 1-skeleton:

- add a vertex in the interior of each 2-cell and 3-cell;
- for each 2-cell or 3-cell e, let v be the vertex added to its interior:
  - for each vertex u originally in e, add an edge connecting v and u;
  - if e is a 3-cell, for each 2-cell e_2 on the boundary of e, add an edge connecting v and the vertex added to the interior of e_2.

▶ **Definition 9.** *The canonical triangulation of M is the Epstein–Penner cellulation of M if the latter is a triangulation, and the subdivision of the Epstein–Penner cellulation described above otherwise.*

Weeks established a heuristic procedure which, given a geometric triangulation, computes the Epstein–Penner cellulation of the corresponding cusped hyperbolic 3-manifold via local modifications, doing 2-3 and 3-2 Pachner moves wherever tetrahedra meet concavely at faces or edges [44]. The canonical triangulation can then be easily computed from the Epstein–Penner cellulation. The methods for both were implemented in `SnapPea` in the 1990s, and later inherited by its successor `SnapPy` [13]. In their original implementations, the hyperbolic structures used were only recorded numerically, hence accuracy issues may come into play, which we discuss in the following two sections.

3.3.2 Burton's method: algebraic certification

Let us briefly review the method Burton used in [7], which can be summarized as:

1. For each ideal triangulation, compute its canonical triangulation numerically using `SnapPea`, and partition them into classes by the canonical triangulations computed.
2. For triangulations in each class, perform an exhaustive search through 2-3 and 3-2 Pachner moves, attempting to identify classes that should have been merged in step 1, but were not due to numerical accuracy issues, thus refining the partitioning.
3. For each class, compute the list $\{\text{orientability}, H_1 = \pi_1^{\text{ab}}, S_2^{\text{ab}}(\pi_1), \dots, S_k^{\text{ab}}(\pi_1)\}$ of algebraic invariants to certify that all groups are distinct, increasing k if necessary, where $S_i^{\text{ab}}(G)$ is the multi-set of abelianisations of index i subgroups of G, one subgroup for each conjugacy class. For the 9-tetrahedra census, $k = 11$ was required and sufficed.

Note that to confirm the completeness of previous censuses, Burton dealt with all candidates with no more than 9 tetrahedra at once, hence triangulations that were grouped with triangulations with fewer tetrahedra were discarded immediately due to nonminimality.

There are several aspects where numerical computation could cause issues in step 1:

- A quantity *tilt* is used to characterize whether tetrahedra meet concavely, parallelly or convexly, each corresponding to the tilt being positive, zero, or negative respectively [44, 40]. When the absolute value of tilt is small, the numerical computation may falsely recognize the sign of tilt, resulting in an incorrect canonical triangulation.
- Flat tetrahedra being falsely recognized as non-flat, which would then be incorrectly dealt with when subdividing Epstein–Penner triangulations into canonical triangulations.

When the above issues arise in step 1, `SnapPea`/`SnapPy` fails to find the correct canonical triangulation and arrives at an incorrect one, while still representing the same manifold as the input triangulation. Hence steps 2 and 3 were necessary to spot and resolve these miscomputed cases. However, steps 2 and 3 can be very expensive to perform, and require back-and-forth adjustments of parameters. Furthermore, although successful for censuses with at most 9 tetrahedra, it is unknown whether step 3 will separate all cases within a computable scope, or even if it will separate all of them in theory [23].

▶ Remark 10. We remark here that the subdividing algorithm Weeks implemented in `SnapPea`/`SnapPy` does not work for refinements of Epstein–Penner cellulations containing flat tetrahedra. This led to the miscomputed example x101 found by Burton [6] and mentioned in [22, Remark 3.6]. The cause of the miscomputation was not located at the time of [22]. During the course of this project, the author found another such example, o9_43806 and located the said cause. This bug has been fixed in `SnapPy 3.3` by forcing it to find a refinement that does not contain flat tetrahedra before proceeding to subdividing it. After the fix, the numerical computation gives correct results for all minimal triangulations in the orientable cusped censuses of at most 10 tetrahedra, which we confirmed using the verified computation explained in Section 3.3.3 (as long as successfully computed).

3.3.3 Our method: verified computation

Instead of making up for the mistakes caused by numerical computation of canonical triangulations using other methods, we enhance the computation itself to avoid the mistakes directly. With the accuracy issues described in the previous section, this requires us to:

(a) given two supposedly different quantities, rigorously tell which one is larger;

(b) given two supposedly equal quantities, prove that they are equal.

For (a), we use interval arithmetics, which can be thought of as computation with controlled errors. If two quantities are different, with sufficiently small error the lower bound of one will be strictly larger than the upper bound of another, revealing the larger quantity. Similar approach was also used in HIKMOT's rigorous certification of hyperbolicity [27].

For (b), we use the LLL algorithm [32] to symbolically solve the trace field of hyperbolic structure, representing it as a number field. We then express the quantities as elements in the number field, hence they are equal if and only if their difference is the zero element.

The above enhanced computation was implemented in `SnapPy` by M. Goerner [24], and is called verified computation. We refer the reader to [20, 22] for more detailed discussions.

Canonical triangulations obtained with verified computation are thus provably correct. Let us call a supposedly canonical triangulation obtained by `SnapPy` a *verified canonical triangulation* if it was obtained with verified computation, and an *unverified canonical triangulation* if the computation was performed purely numerically.

Let $\{\mathcal{T}\}$ be the set of ideal triangulations representing cusped hyperbolic 3-manifolds and $\{\mathcal{M}\}$ be the set of cusped finite-volume hyperbolic 3-manifolds. Let $\iota\colon \{\mathcal{T}\} \to \{\mathcal{M}\}$ be the function that maps an ideal triangulation to the manifold it represents. The unverified canonical triangulation can thus be seen as a multi-valued function $c_u\colon \{\mathcal{M}\} \to \{\mathcal{T}\}$ which is a right inverse of ι; in other words, the following diagram commutes:

$$\begin{array}{ccc} \{\mathcal{T}\} & \xrightarrow{\ \iota\ } & \{\mathcal{M}\} \\ & {\scriptstyle c_u}\nwarrow \quad \uparrow{\scriptstyle 1_{\{\mathcal{M}\}}} & \\ & \{\mathcal{M}\} & \end{array} \tag{1}$$

In particular, c_u is injective. The verified canonical triangulation is then a branch of c_u, a single-valued function $c_v\colon \{\mathcal{M}\} \to \{\mathcal{T}\}$. Since c_u is injective, c_v is also injective, hence restricts to a bijection between $\{\mathcal{M}\}$ and its image. Therefore the verified canonical triangulation is a complete invariant of cusped finite-volume hyperbolic 3-manifolds.

Although the definition of canonical triangulation does not require the manifold to be orientable, the current implementation of verified computation for canonical triangulations in `SnapPy` does not work for nonorientable ones with multiple cusps. Hence we discard the nonorientable candidates and deal with the remaining 608,918 orientable ones.

We successfully computed the verified canonical triangulations for all except 16 of the 608,918 orientable candidates. The 16 cases failed due to their trace fields being too complicated; we remark that this very nature intrinsically separates them from the others, though further investigation is still required to prove it. By comparing the results with the verified canonical triangulations of all manifolds in censuses of at most 9 tetrahedra, we obtained 496,622 minimal triangulations of 10 tetrahedra, which, grouped by their verified canonical triangulations, give 150,724 distinct manifolds. For the 16 candidates whose verified canonical triangulations were not computed, we computed the first 60 digits of their hyperbolic volumes using interval arithmetics [24] and their first homology groups, which separated them from all manifolds in censuses up to 9 tetrahedra plus the 150,724 ones, and grouped them into 6 classes; within each class, the triangulations were confirmed to all represent the same manifold as their unverified canonical triangulations are the same.

Therefore, we conclude that there are exactly 150,730 isometry classes in the 10-tetrahedra census, containing a total of 496,638 minimal triangulations, obtaining Theorem 1.

3.4 Finalizing the census

For each of the 150,730 isometry classes obtained in Section 3.3, we select a representative triangulation by the following procedure:

(1) If the verified canonical triangulation is in the isometry class, let it be the representative.
(2) Otherwise, consider the subset of triangulations that are geometric, which turns out to be never empty. If there is only one triangulation in the class, let it be the representative.
(3) If there are multiple triangulations in that subset, let the triangulation with the most self-isomorphisms, i.e. cellular homeomorphisms onto itself, be the representative.
(4) If there are multiple triangulations with the most self-isomorphisms, choose the one with the "fattest" tetrahedra, i.e. the one with the largest minimum imaginary part of tetrahedron shape parameters.
(5) If there are still multiple options left, choose the one with the smallest triangulation signature (as defined in [4]) under the lexicographical order.

With the representative triangulations chosen as above, we set their peripheral curves to be the shortest. We then ordered them by volume, named them as displayed in Table 1, saved and published the data in [34]. The data now comes automatically with `SnapPy 3.3`.

Note that verified canonical triangulations, by construction, are always geometric [22]. Hence due to the geometric requirement in step (2), we obtained

▶ **Proposition 11.** *Every cusped hyperbolic* 3*-manifold in the* 10*-tetrahedra census admits a minimal triangulation that is geometric.*

We remark that the above proposition also holds for all (orientable) censuses with fewer tetrahedra, which we checked using Burton's data from [7].

3.5 Obstructions on further extending the census

As is discussed in Section 3.1, there are essentially three steps for creating a complete census. For the census of (orientable) cusped hyperbolic 3-manifolds, step (ii) should not be a problem, as there are several other tests proposed in [7], but were not used when creating the 10-tetrahedra census. For step (iii), the verified computation has a chance of failing only when the LLL algorithm is invoked, which happens only when a tilt that is extremely close to zero is encountered during computation. This essentially implies that the Epstein–Penner cellulation is not a triangulation, which is the case for only 986 triangulations out of the 608918 orientable candidates mentioned in Section 3.3.3, a frequency less than 0.2%. Therefore, it is promising that a combination of verified canonical triangulations with algebraic methods would suffice in the foreseeable future, where the former separates most manifolds, and the latter deals with the rest.

The main obstruction thus lives in step (i), where an exponential growth rate of the computational power is needed, with a much larger base compared to tabulating knots [39]. If one were to include nonorientable candidates during generation (as we did in Theorem 7), even though the algorithm established in [7] is already extremely efficient, it still takes approximately 2 years to generate all candidates with 10 tetrahedra in a single thread of 2.6 GHz, about 50 times longer than to generate all candidates with 9 tetrahedra; we accelerated the process by parallelizing it in 300 threads. Thus, assuming the same growth rate, it will take approximately 100 years to generate all candidates with 11 tetrahedra with a single thread of 2.6 GHz, and hence 4 months in 300 threads.

The time consumption and growth rate can both be lowered by excluding nonorientable candidates during generation, as half of identifications of each face will be excluded from the beginning. It takes 2 months to enumerate all orientable candidates with 10 tetrahedra in a

single thread, about 25 times longer than for 9 tetrahedra. We successfully generated all orientable candidates with 11 tetrahedra, which took about 6 years in a single thread, giving Theorem 12. We have now completed the 11-tetrahedra orientable census, with a preliminary `SnapPy` module available at [35], and full details to appear in a future publication.

▶ **Theorem 12.** *Up to relabelling, there are* 27,794,289 *ideal triangulations of orientable* 3*-manifolds with* 11 *tetrahedra, in which every vertex is ideal, there are no edges of degree* 1 *or* 2*, and there are no edges of degree* 3 *that belong to three distinct tetrahedra.*

4 Applications

A substantial amount of follow-up work can be done with the extended census. We describe several of them in this section.

4.1 Extending the census of exceptional Dehn fillings

Let $\overline{M}$ be a compact orientable 3-manifold whose interior M is a 1-cusped hyperbolic 3-manifold; in particular $\partial\overline{M}$ is a torus, and M has finite volume. Dehn fillings on M are characterized by slopes on $\partial\overline{M}$, which are unoriented isotopy classes of simple closed curves on the torus. For a slope α, we denote by $M(\alpha)$ the closed manifold obtained by Dehn filling on M so that α bounds a disk in the attached solid torus $D^2 \times S^1$.

▶ **Definition 13.** *A slope α is exceptional if $M(\alpha)$ is not hyperbolic.*

The census of exceptional Dehn fillings will consist of pairs (M, α), where α is exceptional.

By deleting a cusp neighborhood N of M, we obtain a compact 3-manifold $M \setminus N$ with torus boundary which is isotopic to $\overline{M}$. Slopes on $\partial\overline{M}$ can thus be carried by the isotopy onto $\partial(M \setminus N) \subset M$. By taking N to be maximal, we define the length of a slope to be the minimum length of all curves in its isotopy class on $\partial(M \setminus N)$.

Agol [1] and Lackenby [31] independently proved that lengths of exceptional slopes cannot exceed 6. It follows that there are only finitely many exceptional fillings on a 1-cusped finite-volume hyperbolic 3-manifold. Therefore it is possible to give complete lists of exceptional Dehn fillings on 1-cusped hyperbolic 3-manifolds in the censuses. For censuses of at most 9 tetrahedra, this has been done by Dunfield [17]. For the 10-tetrahedra census, we obtained:

▶ **Theorem 14.** *There are precisely* 439,898 *exceptional Dehn fillings on orientable* 1*-cusped hyperbolic* 3*-manifolds in the* 10*-tetrahedra census.*

Table 3 outlines the procedure for obtaining Theorem 14. There are 144,016 1-cusped hyperbolic 3-manifolds in the 10-tetrahedra census. For each of them, we enumerated all slopes with length no more than 6, obtaining a total of 800,447 candidates for the exceptional census. As no duplicate slopes were enumerated for a given manifold, all candidates are distinct, and we only need to decide the hyperbolicity for each of them.

For each candidate (M, α), we consider its filled manifold $M(\alpha)$. Several rounds of certifying the hyperbolicity of $M(\alpha)$ with `SnapPy` reduced the remaining list by nearly a half. For Regina census lookup, we cut $M(\alpha)$ into connected sum summands and used `regina.Census.lookup` to try obtaining a name classifying it, which then tells us whether $M(\alpha)$ is hyperbolic or not. For those whose names were not obtained, we check whether they have fundamental normal surfaces which are essential S^2 or tori; if they do, they are not hyperbolic. Only 11 candidates remain undetermined after this, and their filled manifolds were all identified as m135(1,3) by `SnapPy`. m135(1,3) is isometric to m412(1,-3)(-3,1) whose triangulation in `SnapPy` is certified to be geometric, hence m135(1,3) is hyperbolic.

Table 3 The steps for creating the 10-tetrahedra exceptional census.

Step	Candidates	Discarded	Confirmed
Candidate generation	800,447	0	0
Certify hyperbolicity	439,933	360,514	0
Regina census lookup	11,540	24	428,369
Essential S^2 or torus	11	0	11,529
Identified to be m135(1,3)	0	11	0
Total	800,447	360,549	439,898

Applying `regina.Triangulation3.isSphere` on fillings in Theorem 14 reveals that

▶ **Theorem 15.** *There are precisely* 1,849 *manifolds in the* 10*-tetrahedra census that are exteriors of knots in* S^3*.*

For censuses of at most 9 tetrahedra, similar work have been done by Callahan, Dean and Weeks [10], Champanerkar, Kofman and Patterson [12] and Dunfield [17].

Many conjectures and results mentioned in [17] can be tested and updated against the extended exceptional census. We plan to address these in a future publication.

4.2 Thurston norm and twisted Alexander polynomial

Given an orientable cusped hyperbolic 3-manifold M with Betti number $b_1(M) = 1$ and an $\mathrm{SL}(2,\mathbb{C})$-lift $\tilde{\rho}$ of its holonomy representation $\rho\colon \pi_1(M) \to \mathrm{PSL}(2,\mathbb{C})$, we consider its twisted Alexander polynomial $\tau_{2,\tilde{\rho}}(M) \in \mathbb{C}[t^{\pm 1}]$, defined by Dunfield, Friedl and Jackson [18, §2]. It was proved in [18] that

$$x(M) \geq \frac{1}{2} \deg \tau_{2,\tilde{\rho}}(M), \tag{2}$$

where $x(M)$ is the Thurston norm of a generator of $H^1(M;\mathbb{Z})$, and Equation (2) is an equality if M fibers over S^1. Moreover, if M fibers over S^1, then $\tau_{2,\tilde{\rho}}(M)$ is monic.

In [19], Dunfield, Garoufalidis and Yoon asked whether for any orientable cusped hyperbolic 3-manifold with $b_1(M) = 1$, there is at least one lift $\tilde{\rho}$ such that Equation (2) is an equality. An affirmative answer was then experimentally given for all such manifolds in the censuses of at most 9 tetrahedra, a sample size of 59,068 manifolds.

We extended the experimentation to the 10-tetrahedra census. There are 143,919 manifolds in the 10-tetrahedra census with $b_1(M) = 1$. By applying the code in [14], we were able to compute the Thurston norms for all except the following 21 of them:

$$\begin{array}{lllllll} o10_077959 & o10_076513 & o10_091925 & o10_073669 & o10_067720 & o10_102779 & o10_142965 \\ o10_141638 & o10_146022 & o10_140310 & o10_091511 & o10_122772 & o10_147820 & o10_127911 \\ o10_120303 & o10_145417 & o10_136855 & o10_136895 & o10_148034 & o10_143501 & o10_138268 \end{array} \tag{3}$$

Out of the 21 manifolds in Equation (3), the following 9 were confirmed to not fiber over S^1, as their twisted Alexander polynomials are not monic:

$$\begin{array}{lllll} o10_076513 & o10_091925 & o10_142965 & o10_091511 & o10_136855 \\ o10_136895 & o10_148034 & o10_143501 & o10_138268 & \end{array} \tag{4}$$

For the remaining 143,898 manifolds whose Thurston norms were successfully computed, we numerically computed their twisted Alexander polynomials of all $\mathrm{SL}(2,\mathbb{C})$-lifts. After taking the maximum degrees, we found that Equation (2) is an equality for all of them.

4.3 Homology 3-spheres and the L-space conjecture

The L-space conjecture asserts that for an irreducible $\mathbb{Q}$-homology 3-sphere Y, the following are equivalent:

(a) $\pi_1(Y)$ is left-orderable;
(b) Y has non-minimal Heegaard Floer homology;
(c) Y admits a taut foliation.

The equivalence of (a) and (b) was proposed by Boyer, Gordon and Watson [3]. The equivalence of (b) and (c) was asked by Ozsváth and Szabó [38] after they proved that (c) implies (b), and upgraded to a conjecture by A. Juhász [30]. For $\mathbb{Z}$-homology spheres, Calegari and Dunfield [9] proved that (c) implies (a).

Dunfield [16] showed that the L-space conjecture holds on at least 62.2% of 307,301 hyperbolic $\mathbb{Q}$-homology 3-spheres, obtained by Dehn fillings on orientable 1-cusped hyperbolic 3-manifolds in censuses of at most 9 tetrahedra. It was conjectured in [16] that these are precisely the filled manifolds from those censuses with lengths of systoles being at least 0.2.

While there are infinitely many hyperbolic $\mathbb{Q}$-homology 3-spheres obtained by Dehn fillings on a finite set of orientable 1-cusped hyperbolic 3-manifolds, a finite list is obtained if we bound the list by the length of systoles, i.e. the shortest geodesics, from below, as the following result was shown by Hodgson and Kerckhoff [26]:

▶ **Lemma 16** (Hodgson & Kerckhoff). *Let $\overline{M}$ be a compact orientable 3-manifold with torus boundary whose interior M is hyperbolic, and α be a slope on $\partial\overline{M}$. If $M(\alpha)$ is hyperbolic with systole length at least 0.163, then the normalized length of α is no more than 7.515.*

Here, the *normalized length* of α is the length of α divided by the area of $\partial(M \setminus N)$.

Similarly to Section 4.1, for the 1-cusped hyperbolic 3-manifolds in the 10-tetrahedra census, by enumerating all slopes with normalized length no more than 7.515, excluding all exceptional slopes, and filtering by the length of systole, we obtained a list of 1,899,974 fillings containing all pairs (M,α) such that $M(\alpha)$ is a hyperbolic $\mathbb{Q}$-homology 3-sphere with length of systole at least 0.163. Therefore,

▶ **Theorem 17.** *There are precisely 1,899,974 pairs (M,α) where M is a 1-cusped hyperbolic 3-manifold in the 10-tetrahedra census and α is a slope such that $M(\alpha)$ is a hyperbolic $\mathbb{Q}$-homology 3-sphere with length of systole at least 0.163.*

Changing $\mathbb{Q}$ to $\mathbb{Z}$ in Theorem 17, the number of pairs becomes 10,729.

Note that, although the pairs (M,α) in Theorem 17 are all distinct, the filled manifolds $M(\alpha)$ are not; for instance, there are at least 22 pairs in the list such that $M(\alpha)$ is identical to m007(3,1). It remains to group the pairs into distinct isometry classes by $M(\alpha)$, compare the grouped list against the list of 307,301 manifolds in [16], and test the L-space conjecture on it. We wish to address these in a future publication.

4.4 Closed totally geodesic surfaces

An embedded surface S in a hyperbolic 3-manifold M is called *totally geodesic* if every geodesic in S is also a geodesic in M. The existence of closed totally geodesic surfaces is of particular interest.

An algorithm that is guaranteed to find all closed totally geodesic surfaces (up to isotopy) in a given orientable cusped finite-volume hyperbolic 3-manifold was built and used to find several examples of cusped hyperbolic 3-manifolds with closed totally geodesic surfaces by Basilio, Lee and Malionek [2]; however, none was found in the censuses of at most 9 tetrahedra. By applying their algorithm to the 10-tetrahedra census, we found that

▶ **Theorem 18.** *The* 2*-cusped manifold o10_143602, whose volume is approximately* 9.1345 *and first homology group is* $\mathbb{Z}^2 \oplus \mathbb{Z}_6$*, is the only manifold containing closed totally geodesic surfaces in the orientable cusped hyperbolic censuses of at most* 10 *tetrahedra. Moreover, o10_143602 contains exactly one such surface up to isotopy, which is nonorientable with Euler characteristic* -1*.*

In particular, among all orientable cusped hyperbolic 3-manifolds containing closed totally geodesic surfaces, o10_143602 is the one whose minimal triangulations have the fewest tetrahedra; in other words, it is the simplest such example.

Manifolds of Positive Reach, Differentiability, Tangent Variation, and Attaining the Reach

André Lieutier

Mathijs Wintraecken
Inria Centre d'Université Côte d'Azur, Sophia Antipolis, France

Abstract

This paper contains three main results.

Firstly, we give an elementary proof of the following statement: Let $\mathcal{M}$ be a topological manifold without boundary embedded in $\mathbb{R}^d$. If $\mathcal{M}$ has positive reach, then $\mathcal{M}$ can locally be written as the graph of a $C^{1,1}$ function from the tangent space to the normal space. Conversely if $\mathcal{M}$ can locally be written as the graph of a $C^{1,1}$ function from the tangent space to the normal space, then $\mathcal{M}$ has positive reach. The result was hinted at by Federer when he introduced the reach, and proved by Lytchak. Lytchak's proof relies heavily on CAT(k)-theory. The proof presented here uses only basic results on homology.

Secondly, we give optimal Lipschitz-constants for the derivative, in other words we give an optimal bound for the angle between tangent spaces in term of the distance between the points. We stress that Lytchak did not provide any bound, let alone an optimal one, making his proof, although interesting from a mathematical perspective, ineffectual in an algorithmic setting. To provide precise and optimal bounds on the angle between tangent spaces, we formally introduce the local reach for sets of positive reach, based on Aamari et al.'s discussion for C^2 manifolds. We prove that the local reach of a manifold is completely characterized by the variation of tangent spaces. This improves earlier results, that were either suboptimal or assumed that the manifold was C^2.

Thirdly, we show that the value of the reach is equals minimum of the local reach of the set and a global bottleneck for any set. This generalizes a result by Aamari et al. which explains how the reach is attained for C^2 manifolds.

1 Introduction

In [13] Federer introduced the reach of a closed set $\mathcal{S} \subset \mathbb{R}^d$ as the minimum of the distance from $\mathcal{S}$ to the medial axis $\mathrm{ax}(\mathcal{S})$, i.e. the set of points in $\mathbb{R}^d$ for which the closest point in $\mathcal{S}$ is not unique. Assumptions on the reach (and its local version the local feature size [4]) underpin the correctness of many algorithms in computational geometry and topology. In

this paper we consider the differentiability class of manifolds of positive reach and give tight bounds on the angle between nearby tangent spaces for general manifolds of positive reach. For arbitrary sets of positive reach we give a geometrical explanation on how the reach in attained.

Previous work

Differentiability. Federer proved that the reach is stable under $C^{1,1}$-diffeomorphisms of the ambient space. Here we write $C^{1,1}$ to indicate C^1 maps whose derivative is Lipschitz, and by a $C^{1,1}$-diffeomorphism we mean that both the diffeomorphism and its inverse are $C^{1,1}$. Federer [13, Remark 4.20] furthermore mentioned (without going into much detail on one direction of the implication) that the graph of a function has positive reach if and only if it is $C^{1,1}$. Lytchak [21, 22] proved that a topologically embedded manifold without boundary has positive reach if and only if it is $C^{1,1}$, without a quantitative bound on the Lipschitz constant. This statement is quantified in our Theorem 1 below. We emphasize that quantifying these constants is essential for the result to allow us to formulate sampling criteria that guarantee the correctness of algorithms.

Lytchak's proof requires significant background in CAT(k)-theory. Lytchak, motivated by bounds on intrinsic curvature, does not give any quantified bound on the extrinsic curvature, which play an important role in this paper.

Scholtes [27] also gave a proof that a hypersurface has positive reach if and only if it is $C^{1,1}$, using different techniques from both the ones employed by Lytchak and in this paper. Scholtes' method uses the fact that the manifold has codimension one in an essential way.

Rataj and Zajíček [26] prove that if a Lipschitz manifold has positive reach, then it is $C^{1,1}$. They also use Lemma 17, however the assumption that the manifold is already Lipschitz simplifies the matter considerably, in particular they can skip the topological analysis. Moreover, again, they do not quantify their results in the way that we do and is essential for guarantees for algorithms. Recently, Leobacher and Steinicke [18] also reproved Lytchak's result, but once more the result was not quantified. We further stress that the bounds that we provide on the Lipschitz constants are tight, as we'll discuss in more detail below.

Geometric bounds and tangent variation. Bounding the tangent angle variation on smooth manifolds is crucial for establishing constants in the context manifolds reconstruction and meshing [4, 10, 12, 7]. If we now focus on more recent results, some authors consider angle variation bounds for a given local feature size bound [17]. Other authors, including the ones of the present paper, give angle variation bounds based on the reach [8]. Assuming the surface to be smooth, more specifically C^2 smooth, allows using standard differential geometry tools such as second fundamental forms, curvatures and Riemannian geometry, while, as hinted at by Federer's and Lytchak's results, the weaker positive reach assumption is sufficient for many properties to hold.

For example, in [8], the angle variation bound given for C^2 manifolds are clearly optimal (the bound is attained on spheres) while only suboptimal bounds are derived for $C^{1,1}$, or positive reach, manifolds.

Attaining the reach. In [1, Theorem 3.4], Aamari et al. make the following observation for C^2 manifolds: The reach of a submanifold of Euclidean space can be expressed as the minimum of a global quantity, realized at so called "bottlenecks", and a local quantity, the inverse of the maximal extrinsic curvature. These "bottlenecks" can be formally related to a

global reach and the local quantity with a local reach, which we'll do in this paper. We stress that the concepts of the local and global reach are mentioned once in the introduction of [1], no formal definition was given in that paper. Moreover, while this assumption is somewhat implicit in the proof of [1, Theorem 3.4], the analysis uses the context of Riemannian geometry, assuming the C^2 regularity of the manifold. We further emphasize that [1] focused uniquely on manifolds, which contrasts with the definition for global reach and local reach for any set of positive reach in this paper.

These results explain how the reach is attained, see Figure 1. This gives insight in which parts of a set of positive reach present the "difficult" parts for algorithms, in the examples we'll discuss now.

Motivation and related work

The assumption of positive reach is central to almost all triangulation algorithms, see for example [10, 12, 7], manifold learning, see for example [15, 14, 2, 28], and homotopy inference, see for example [24, 29]. Closing the gap between C^2 and positive reach manifolds significantly extends the applications domains. This extension is necessary to include for example the boundary of objects that have been designed by computer aided design software. These boundaries are generically tangent continuous and have bounded curvature (e.g. two planar faces connected through a cylindrical fillet surface), but don't have continuous curvature.

The main result of this paper makes precise what it means for a topologically embedded submanifold of Euclidean space to have positive reach: The embedding is necessarily $C^{1,1}$-smooth (Theorem 1) and we give a tight bound on the (generalized) extrinsic curvature of the submanifold (Theorem 4).

Generalized tangent and normal spaces. Federer showed that although sets of positive reach are more general than smooth manifolds, they still posses generalized tangent and normal spaces, which are convex cones instead of just linear spaces. Roughly speaking, the normal cone at a point p of a set with positive reach determines the topological "link" of point p in the set, that is the local topology.

To prove the Theorem 1 it is essential to show that the normal cone at any point of a positive reach, topologically embedded n-manifold is a $(d-n)$-dimensional vector space. In the proofs of [21, 22] the relation between the normal cone at a point p of a topologically embedded manifold with positive reach and the "link" of p is established using CAT(k)-theory. In contrast, our (short) proof (see the overview in Section 3 and Lemma 31 of [20]) is based on elementary properties of (the homology of) convex cones makes this correspondence more transparent in our opinion.

We further extend the results of [21, 22] by giving an optimal bound on the angle variation of tangent spaces. This also extends the same bound obtained in the particular context of C^2 manifolds [8]. We even obtain a significantly stronger result, that is, we characterize the local reach of a manifold completely by the tangent variation.

Contribution. In this paper we give an elementary proof of the following characterizations of manifolds of positive reach. Moreover the statement is quantified with optimal constants. Here we write $B(p,r)$ or $B^\circ(p,r)$ for the closed or open ball centred at p with radius r.

▶ **Theorem 1.** *If $\mathcal{M}$ is a topologically embedded manifold with positive reach and p a point in $\mathcal{M}$, then $\mathcal{M} \cap B^\circ(p, \sqrt{2}\operatorname{rch}(\mathcal{M})) \cap \pi^{-1}_{T_p\mathcal{M}}(B^\circ(0, \operatorname{rch}(\mathcal{M})))$ is the graph of a $C^{1,1}$ function above the open domain $B^\circ(0, \operatorname{rch}(\mathcal{M})) \subset T_p\mathcal{M}$.*

We also generalize the notations of local and global reach from C^2 submanifolds [1] to arbitrary compact sets (of positive reach):

▶ **Definition 2** (Local and global reach). *For a closed set $\mathcal{S} \subset \mathbb{R}^d$, we define the local* $\mathrm{rch}_{loc.}(\mathcal{S})$ *and global* $\mathrm{rch}_{glob.}(\mathcal{S})$ *reach as:*

$$\mathrm{rch}_{glob.}(\mathcal{S}) \underset{def.}{=} \inf\left\{ \frac{|a-b|}{2} \,\middle|\, \exists\, a,b \in \mathcal{S}, B^\circ\left(\frac{a+b}{2}, \frac{|a-b|}{2}\right) \cap \mathcal{S} = \emptyset \right\} \tag{1}$$

$$\mathrm{rch}_{loc.}(p,\mathcal{S}) \underset{def.}{=} \lim_{\substack{\rho \to 0 \\ \rho > 0}} \mathrm{rch}\big(\mathcal{S} \cap B(p,\rho)\big) \in [0,+\infty] \tag{2}$$

$$\mathrm{rch}_{loc.}(\mathcal{S}) \underset{def.}{=} \inf_{p \in \mathcal{S}} \mathrm{rch}_{loc.}(p,\mathcal{S}) \in [0,+\infty], \tag{3}$$

where $\inf(\emptyset) = +\infty$.

▶ Remark 3. If $\mathrm{rch}(\mathcal{S}) > 0$, then $\rho \mapsto \mathrm{rch}\big(\mathcal{S} \cap B(p,\rho)\big)$ is non-increasing (this follows from Theorem 16 because $\mathcal{S} \cap B(p,\rho)$ is geodesically convex [8, Corollary 1] for all $\rho < \mathrm{rch}(\mathcal{S})$ so that the set of bounds that need to be satisfied in (9) is larger, c.f. [6, Lemma 5]) as soon as $\rho < \mathrm{rch}(\mathcal{S})$, so that the limit in (2) exists. Moreover, since for any p one has $\mathrm{rch}_{loc.}(p,\mathcal{S}) \geq \mathrm{rch}(\mathcal{S})$, we get that:

$$\mathrm{rch}_{loc.}(\mathcal{S}) \geq \mathrm{rch}(\mathcal{S}). \tag{4}$$

To be able to give the bounds on the tangent variation/extrinsic curvature we need to introduce some notation.

We write $\mathrm{Gr}(n,\mathbb{R}^d)$ for the Grassmannian, that is the space of n-linear subspaces of $\mathbb{R}^d$ with metric given by the sine of the maximum angle. We recall that the maximum angle is given by

$$\angle A, B \underset{\text{def.}}{=} \max_{a \in A \setminus \{0\}} \min_{b \in B \setminus \{0\}} \angle a, b = \max_{b \in B \setminus \{0\}} \min_{a \in A \setminus \{0\}} \angle a, b. \tag{5}$$

We use this maximal angle as our metric. It is not that difficult to establish that this is indeed a metric, see [30] or [25] for a far reaching generalization.[1]

▶ **Theorem 4.** *If $\mathcal{M} \subset \mathbb{R}^d$ is a topologically embedded n-manifold with reach at least $R > 0$, then tangent spaces and normal spaces to $\mathcal{M}$ are linear spaces at any point $p \in \mathcal{M}$ and the maps* $\mathrm{Tan} : \mathcal{M} \to \mathrm{Gr}(n,\mathbb{R}^d)$ *and* $\mathrm{Nor} : \mathcal{M} \to \mathrm{Gr}(d-n,\mathbb{R}^d)$ *are Lipschitz.*

Moreover, the smallest Lipschitz constant satisfied by $p \mapsto \mathrm{Tan}(p,\mathcal{S})$ is $\frac{1}{\mathrm{rch}_{loc.}(\mathcal{M})}$:

$$\sup_{\substack{p,q \in \mathcal{M} \\ p \neq q}} \frac{\angle\, \mathrm{Tan}(p,\mathcal{M}), \mathrm{Tan}(q,\mathcal{M})}{d_{\mathcal{M}}(p,q)} = \frac{1}{\mathrm{rch}_{loc.}(\mathcal{M})}, \tag{6}$$

where $d_{\mathcal{M}}$ denotes the geodesic distance on $\mathcal{M}$ and we say that $d_{\mathcal{M}}(p,q) = \infty$ when p and q are not connected by any path in $\mathcal{M}$ and that $1/\infty = 0$.

[1] The sine of this angle also defines a metric on the Grassmannian as can be found in e.g. [16, Chapter IV, Section 2.1] or [3, Section 34], see Appendix B of [20] for a more extensive description. It seems that in a number of fields the sine of the angles is a more common metric, but it is suboptimal in this context. We further stress that neither of these metrics equal the standard Riemannian metric on the Grassmannian, which is given by the sum of the squares of the principal angles, see e.g. [31].

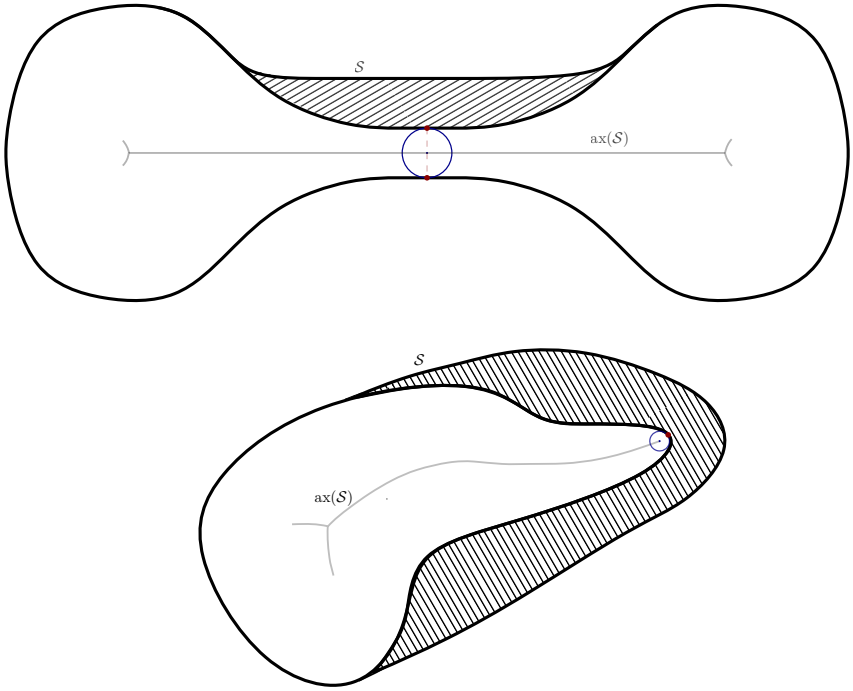

Figure 1 In this figure we see the two ways in which the reach can be attained for a general set of positive reach, by means of the global reach (top) or local reach (bottom), for two sets of positive reach in the plane. The shading indicates a solid set. The points (red) and the circle (blue) in which the reach is attained are indicated.

▶ Remark 5. If $\mathcal{M} \subset \mathbb{R}^d$ is a manifold with boundary then the results of Theorem 4 still hold as long as there is a shortest path geodesic between p and q that lies completely in the interior of $\mathcal{M}$.

Next theorem is a generalization of [1, Theorem 3.4] which was formulated in the particular situation where $\mathcal{S}$ is a C^2 embedded manifold, in which case $\mathrm{rch}_{loc.}(\mathcal{S})$ is also the supremum of extrinsic curvature.

▶ **Theorem 6.** *If $\mathcal{S}$ is a compact subset of $\mathbb{R}^d$, then:*

$$\mathrm{rch}(\mathcal{S}) = \min(\mathrm{rch}_{glob.}(\mathcal{S}), \mathrm{rch}_{loc.}(\mathcal{S}))$$

We refer to Figure 1 for an illustration.

2 Preliminaries

In this section we first recall some results and definitions concerning sets of positive reach. The results concerning the reach are mainly taken from [13] and [8].

2.1 Sets of positive reach

Throughout this paper we will write $\mathcal{S}$ for a general closed set (mostly with positive reach) and $\mathcal{M}$ for a manifold (mostly without boundary) and in some (rare) cases $\partial\mathcal{M}$ for its boundary (if it exists).

The concept of a tangent space of a smoothly embedded manifold has been generalized by Federer to tangent cones in the following manner:

▶ **Definition 7** (Generalized tangent spaces, Definitions 4.3 and 4.4 of [13]). *If $\mathcal{S} \subset \mathbb{R}^d$ and $p \in \mathcal{S}$, then the generalized tangent space*

$$\mathrm{Tan}(p, \mathcal{S})$$

is the set of all tangent vectors of $\mathcal{S}$ at p consists of all those $u \in \mathbb{R}^d$, such that either $u = 0$ or for every $\epsilon > 0$ there exists a point $q \in \mathcal{S}$ with

$$0 < |q - p| < \epsilon \qquad \text{and} \qquad \left| \frac{q-p}{|q-p|} - \frac{u}{|u|} \right| < \epsilon.$$

The set

$$\mathrm{Nor}(p, \mathcal{S})$$

of all normal vectors of $\mathcal{S}$ at p consists of all those $v \in \mathbb{R}^d$ such that $v \cdot u \leq 0$ for all $u \in \mathrm{Tan}(p, \mathcal{S})$.

▶ **Definition 8.** *We write $\pi_{\mathcal{S}}$ for the closest point projection on $\mathcal{S}$.*

Although it is possible to define a set valued version of $\pi_{\mathcal{S}}$, we only use the projection map outside the medial axis, that is at those points where there is a single closest point.

For the remainder of this subsection we will recall the properties of this map and sets of positive reach that are essential for this paper.

▶ **Lemma 9** (Angle with tangent space, Theorem 4.8(7) of [13]). *Suppose that $\mathcal{S}$ is a set positive reach $\mathrm{rch}(\mathcal{S})$. Let $p, q \in \mathcal{S} \subset \mathbb{R}^d$ such that $|p - q| < \mathrm{rch}(\mathcal{S})$. We have*

$$\sin \angle(q - p, \mathrm{Tan}(p, \mathcal{S})) \leq \frac{|p - q|}{2\,\mathrm{rch}(\mathcal{S})}. \tag{7}$$

Moreover, a variant of the previous lemma characterizes the reach for arbitrary closed sets, that is:

▶ **Lemma 10** (Distance to tangent space characterizes the reach, Theorem 4.18 of [13]). *For a closed subset $\mathcal{S}$ of Euclidean space $\mathbb{E} = \mathbb{R}^d$, one has:*

$$\mathrm{rch}(\mathcal{S}) = \inf_{\substack{p,q \in \mathcal{S} \\ p \neq q}} \frac{|p - q|^2}{2 d_{\mathbb{E}}(q,\ p\ + \mathrm{Tan}(p, \mathcal{M}))} \tag{8}$$

▶ **Lemma 11** (Theorem 4.8 (4) of [13]). *$\pi_{\mathcal{S}}$ is continuous on $\mathbb{R}^d \setminus \mathrm{ax}(\mathcal{S})$.*

In fact the following lemma strengthens the previous.

▶ **Lemma 12** (Theorem 4.8 (8) of [13]). *If $x, y \in \mathbb{R}^d$, and*

$$\max\{|x - \pi_{\mathcal{S}}(x)|, |y - \pi_{\mathcal{S}}(y)|\} = \mu \leq \mathrm{rch}(\mathcal{S}),$$

then

$$|\pi_{\mathcal{S}}(x) - \pi_{\mathcal{S}}(y)| \leq \frac{\mathrm{rch}(\mathcal{S})}{\mathrm{rch}(\mathcal{S}) - \mu} |x - y|$$

▶ **Lemma 13** (Theorem 4.8 (12) of [13]). *If $p \in \mathcal{S}$ and $lfs(p) > \rho > 0$, then*

$$\mathrm{Nor}(p, \mathcal{S}) = \{\lambda v \mid \lambda \geq 0, |v| = \rho, \pi_{\mathcal{S}}(p + v) = p\}.$$

$\mathrm{Tan}(p, \mathcal{S})$ *is the convex cone dual to* $\mathrm{Nor}(p, \mathcal{S})$*, and*

$$\lim_{t \to 0^+} t^{-1} d(p + tu, \mathcal{M}) = 0,$$

for $u \in \mathrm{Tan}(p, \mathcal{S})$, where d is the Euclidean distance.

▶ **Lemma 14** (Remark 4.15 (1) of [13]). *If $p \in \mathcal{S}$ and $lfs(p) > \rho > 0$, then $\mathcal{S} \cap B(p, \rho)$ is contractible.*

2.1.1 Geodesics

We also recall a result from the second paragraph of Part III, Section 1: "Die Existenz geodätischer Bogen in metrischen Räumen" in [23]:

▶ **Lemma 15** (Menger's existence of geodesics). *For a closed set $\mathcal{S} \subset \mathbb{R}^d$, $d_{\mathcal{S}}$ denotes the geodesic distance in $\mathcal{S}$, i.e. $d_{\mathcal{S}}(a, b)$ is the infimum of lengths of paths in $\mathcal{S}$ between a and b. If there is at least one path between a and b with finite length, then it is known that a minimizing geodesic, i.e. a path with minimal length connecting a to b exists. When no such path between a and b with finite length exists, we write $d_{\mathcal{S}}(a, b) = \infty$.*

We'll be using the metric characterization of the reach from [8] quite often in this paper.

▶ **Theorem 16** (Theorem 1 of [8]). *If $\mathcal{S} \subset \mathbb{R}^d$ is a closed set, then*

$$\operatorname{rch} \mathcal{S} = \sup \left\{ r > 0,\ \forall a, b \in \mathcal{S},\ |a - b| < 2r \Rightarrow d_{\mathcal{S}}(a, b) \leq 2r \arcsin \frac{|a - b|}{2r} \right\}, \tag{9}$$

where the sup *over the empty set is* 0*.*

2.2 Embeddings and atlases

We consider below an embedded, compact n-manifold $\mathcal{M} \subset \mathbb{R}^d$ with an atlas associated with an open cover $(U_i)_{i \in I}$:

$$\mathcal{M} = \bigcup_{i \in I} U_i$$

and charts $f_i : U_i \to \mathbb{R}^n$ that are homeomorphisms on their images, where the topology on $\mathcal{M}$ is the one induced by the ambient metric of $\mathbb{R}^d$.

Note that, topologically[2] embedded manifold does not exclude wild embeddings [11] but, as seen below, the positive reach assumption does, because the embedding is proven to be $C^{1,1}$.

[2] We say that an embedding is topological to stress that we don't make any assumption beyond the assumption that it is a homeomorphism onto its image, in particular no assumptions on differentiability are made.

3 Overview of the first two main results: Manifolds of positive reach, differentiability, and tangent variation

In this section we provide an overview of the proof of the first two main results of this paper Theorems 1 and 4. We discuss this in complete detail with full proofs of the statements in the appendix of the full version of this paper, that is [20].

A topologically embedded manifold with positive reach is differentiably embedded. Consider a topologically embedded manifold with positive reach. That is, we don't assume anything on the embedding of the manifold except that it is a homeomorphism with its image. However, the assumption that the manifold has positive reach yields that the generalized tangent spaces (see Definition 7) are cones.

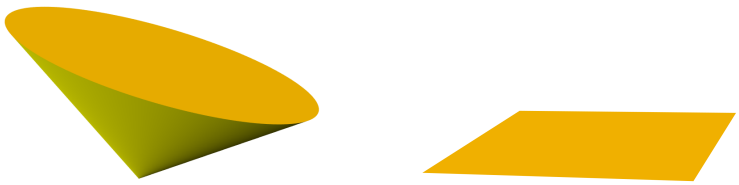

Figure 2 Convex cones come in two variants, a tapering object or a half space on the one hand and vector spaces on the other.

We characterize convex cones by topological means (roughly speaking) as follows. We recall that a convex cone is a subset of $\mathbb{R}^d$ that is convex and for each v in the set we have that λv is also in the set for $\lambda \in \mathbb{R}_{\geq 0}$. By this we mean that, roughly speaking, convex cones A come into two classes:

1. The convex cone is defined by

   $$A = \{\lambda a | \lambda \geq 0, a \in \tilde{A}\},$$

   where $\tilde{A}$ is a contractible subset of $\mathbb{S}^{d-1}$. Note that $\tilde{A} = A \cap \mathbb{S}^{d-1}$. In this case A is (again roughly speaking) either a tapering object or a half space.
2. The convex cone is defined by

   $$A = \{\lambda a | \lambda \geq 0, a \in \tilde{A}\},$$

   where $\tilde{A}$ is a (k dimensional, with $0 \leq k \leq d-1$) geodesic sphere in $\mathbb{S}^{d-1}$. In this case A is a vector space.

These two classes are characterized by the homology of $B(0,1) \setminus A^{\perp}$. The contractibility of $\tilde{A}$ is the key ingredient, see Lemma 30 of [20]. More precisely, we'll use that $\tilde{A}$ is contractible on the sphere if and only if A isn't a vector space.

In Section A.2 of the appendix of [20] we'll establish, based on the characterization of Appendix A.1 of [20], that for topologically embedded manifolds the tangent cones are in fact tangent spaces. The proof proceeds in two steps:

- In Lemma 31 of [20], we'll see that $B(p,\rho) \setminus \big(p + \mathrm{Nor}(p,\mathcal{S})\big)$ has the same homology as $\mathcal{S} \cap B(p,\rho) \setminus \{p\}$, see Figure 3. This result will rely on the deformation retract along the closest point projection of sets of positive reach and its continuity as established by Federer [13]. We stress that the normal cone $\mathrm{Nor}(p,\mathcal{S})$ is the dual of the tangent cone $\mathrm{Tan}(p,\mathcal{S})$, which explains the link with Lemma 30 of [20].

- In the proof of Lemma 32 of [20], we'll see that if $\mathcal{M}$ is manifold, then $\mathcal{M} \cap B(p,\rho) \setminus \{p\}$ has the homology of a sphere of dimension $n-1$, which with the previous lemma allows us to conclude that $\mathrm{Tan}(p,\mathcal{M})$ is a vector space. The proof combines topological reasoning with arguments based on the charts of the manifold $\mathcal{M}$.

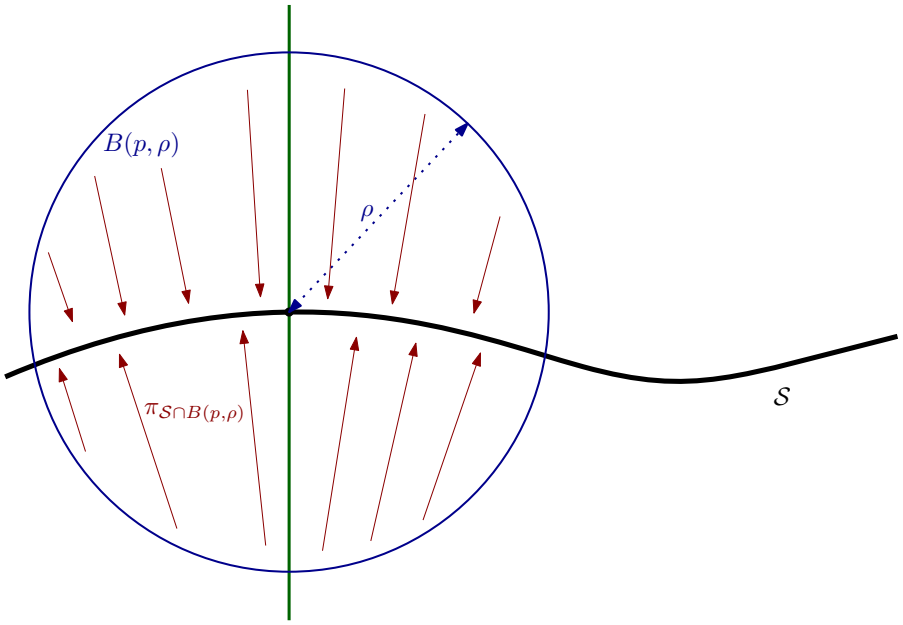

Figure 3 Sketch of the proof of Lemma 31 of [20]. We establish a homotopy between $B(p,\rho) \setminus \big(p + \mathrm{Nor}(p,\mathcal{S})\big)$ and $\mathcal{S} \cap B(p,\rho) \setminus \{p\}$ by deformation retract induced by the map $\pi_{\mathcal{S}\cap B(p,\rho)}$.

By definition we have that if a manifold has a tangent space it is differentiably embedded, but that does not mean that the manifold has to be continuously differentiably embedded, this is what will be the topic we'll address next.

Semi-continuity of normal cones and C^1 embeddings. In Section A.3 of [20] we will first prove a more general statement (Lemma 33 of [20]), namely semi-continuity of the normal cones for general sets of positive reach. By this we mean that given a point p and its normal cone $\mathrm{Nor}(p,\mathcal{S})$, for all ϵ there exists a neighbourhood of p such that for all p' in this neighbourhood, we have that the normal cone $\mathrm{Nor}(p',\mathcal{S})$ makes only an ϵ angle with some subset of $\mathrm{Nor}(p,\mathcal{S})$. The proof is elementary, but rather technical, and relies on compactness arguments and the manipulation of offsets.

Lemma 33 of [20] together with the observation that the tangent spaces are k-dimensional vector spaces the one sided bound on the angle between the normal cones above is in fact a two-sided bound, see Lemma 34 of [20], yields that the manifold is C^1, that is continuously differentiable. Lemma 35 of [20] strengthens this even further and explains that $\mathcal{M}$ can locally be written as the graph of a function. To put it differently, using some geometrical and analytical arguments we see that the manifold (locally) projects injectively on its tangent cone (which is an affine space by Lemma 32 of [20]). This then allows us to identify it, locally, as the graph of a differentiable map from the tangent space to the normal space.

From C^1 to $C^{1,1}$ embeddings. Appendix A.4 of [20] proves the majority of the main statements of the paper, namely that manifolds with positive reach are $C^{1,1}$ and characterizes the Lipschitz constants of the derivative in terms of the local reach. It is the most technical section and relies heavily on the theory of semiconcave functions. Most crucially we'll use the following result, namely Corollary 3.3.8 of [9]:

▶ **Lemma 17.** *Let $F : U \to \mathbb{R}$ be a function defined on a convex open set $U \subset \mathbb{R}^n$. Then the following properties are equivalent:*

- *F is of class $C^{1,1}$ with 1-Lipschitz derivative.*
- *both $x \to 1/2\, x^2 - F(x)$ and $x \to 1/2\, x^2 + F(x)$ are convex functions.*

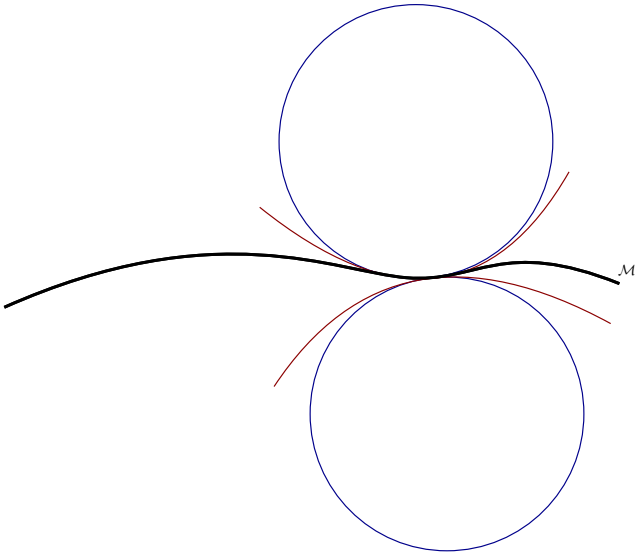

Figure 4 A manifold with empty tangent balls (blue) and (locally) empty tangent parabola (red).

Although that the precise technical way that this result is used is too intricate to explain in a paragraph or two, the link between sets of positive reach and Lemma 17 can be explained in geometrical terms. Assume for the moment that $\mathcal{M}$ has reach 1. As a consequence of Lemma 13 the interior of every ball that is tangent to a manifold $\mathcal{M}$, that has radius less or equal to 1 (the reach of $\mathcal{M}$) does not intersect $\mathcal{M}$ itself. Geometrically speaking the fact that $x \to 1/2\, x^2 - F(x)$ and $x \to 1/2\, x^2 + F(x)$ are convex functions can be expressed by the fact that (locally) the interior of parabolae that are tangent to the manifold have an empty interior, see Figure 4. Of course these parabolae are just second order approximations of the spheres. Because we are just interested in the Lipschitz constants of the derivative this approximation suffices.

Using Lemma 17 we do not directly prove our bound on the angle between nearby tangent spaces, instead we first establish the bound

$$\left\|D\phi(y_2) - D\phi(y_1)\right\| \leq \frac{1}{(\mathrm{rch}_{loc.}(p, \mathcal{M}) - \epsilon)} |y_2 - y_1|,$$

see Lemma 39 of [20], where ϕ is the local function (from the tangent to normal space) of which $\mathcal{M}$ is locally the graph and $\|\cdot\|$ denotes the operator two norm, in other words we regard the Jacobians as matrices depending on y and bound their Lipschitz constant in a way that is ϵ close to optimal.

From the result of Lemma 39 of [20] it is not very difficult to derive a local bound between tangent spaces, which is done in Lemma 40 of [20]. This local bound can then be extended (Lemma 41 of [20]) to a non-local statement by gluing the local estimates on the angle between tangent spaces along a geodesic, which exists thanks to Lemma 15. This allows us to establish one of the main results, the characterization of the local reach in terms of the tangent variation in Theorem 4, whose proof requires a significant amount of computation. The optimal size of the domain (in a fixed tangent space) such that $\mathcal{M}$ can be written as the graph of a function from a (fixed) tangent space to its normal space is then given in Theorem 1. The proof can be sketched as follows: By combining Theorems 4 and 16 with the submersion theorem we can establish a local diffeomorphism. The global diffeomorphism is established by proving that the covering number is one.

4 Global and local reach

In this section we stablish the third main result of the paper, that is Theorem 6. This theorem generalizes the results of [1] on how the reach is attained from C^2 manifolds to arbitrary sets of positive reach. It states that the reach is a consequence of either curvature maxima or so-called bottlenecks. In our result we replace the curvature by the local reach, which in turn is defined using local metric distortion, while the bottlenecks are similar in nature. In a number of cases we will have to assume that the set is bounded/compact.

Athough some of the details of the proof of Theorem 6 are a bit technical, the main idea is not that complicated. In fact we provide a sketch of the proof in Figure 5 and its caption.

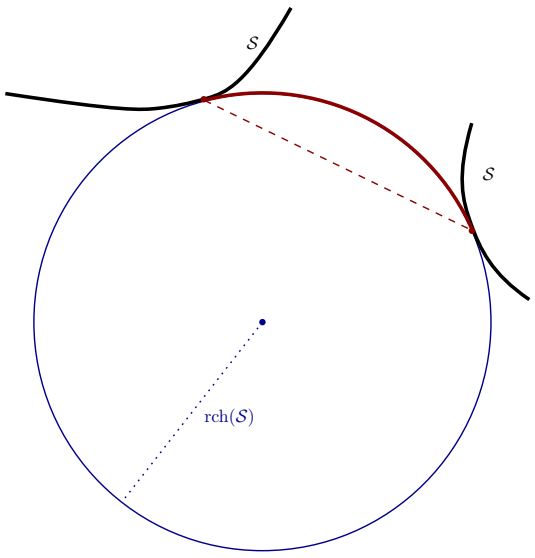

Figure 5 To derive a contradiction assume that $\mathrm{rch}(\mathcal{S}) < \mathrm{rch}_{loc.}(\mathcal{S})$ and $\mathcal{S}$ is tangent to the ball with radius $\mathrm{rch}(\mathcal{S})$ (blue) in two distinct points (red) that are closer than $2\mathrm{rch}(\mathcal{S})$, and therefore not antipodal. Consider the cord connecting these two points (dashed red), then Theorem 16 yields that the length of the geodesic is at most equal to part of the circle indicated in red, however that is the only curve of that length (or less) that connects the two red points that does not intersect the interior of the ball of radius $\mathrm{rch}(\mathcal{S})$. This implies that this curve has to lies inside $\mathcal{S}$, moreover this curve has local reach $\mathrm{rch}(\mathcal{S})$. Combining these observations yields that $\mathrm{rch}(\mathcal{S}) \geq \mathrm{rch}_{loc.}(\mathcal{S})$.

We recall the definition from the introduction:

▶ **Definition 2** (Local and global reach)**.** *For a closed set $\mathcal{S} \subset \mathbb{R}^d$, we define the local* $\mathrm{rch}_{loc.}(\mathcal{S})$ *and global* $\mathrm{rch}_{glob.}(\mathcal{S})$ *reach as:*

$$\mathrm{rch}_{glob.}(\mathcal{S}) \underset{def.}{=} \inf\left\{ \frac{|a-b|}{2} \,\middle|\, \exists\, a,b \in \mathcal{S}, B^\circ\left(\frac{a+b}{2}, \frac{|a-b|}{2}\right) \cap \mathcal{S} = \emptyset \right\} \tag{1}$$

$$\mathrm{rch}_{loc.}(p,\mathcal{S}) \underset{def.}{=} \lim_{\substack{\rho\to 0\\ \rho>0}} \mathrm{rch}\big(\mathcal{S}\cap B(p,\rho)\big) \in [0,+\infty] \tag{2}$$

$$\mathrm{rch}_{loc.}(\mathcal{S}) \underset{def.}{=} \inf_{p\in\mathcal{S}} \mathrm{rch}_{loc.}(p,\mathcal{S}) \in [0,+\infty], \tag{3}$$

where $\inf(\emptyset) = +\infty$.

▶ **Lemma 18.** *The map $p \mapsto \mathrm{rch}_{loc.}(p,\mathcal{S})$ defined over $\mathcal{S}$ is lower semi-continuous, in other words:*

$$\mathrm{rch}_{loc.}(p,\mathcal{S}) = \lim_{\substack{\rho\to 0\\ \rho>0}} \inf_{q\in\mathcal{S}\cap B^\circ(p,\rho)} \mathrm{rch}_{loc.}(q,\mathcal{S}).$$

Proof. By definition of $\mathrm{rch}_{loc.}(p,\mathcal{S})$, we have that for any $\epsilon > 0$ there is $\rho > 0$ such that:

$$\mathrm{rch}(p, \mathcal{S}\cap B(p,\rho)) > \mathrm{rch}_{loc.}(p,\mathcal{S}) - \epsilon. \tag{10}$$

One gets

$$\begin{aligned}
\mathrm{rch}_{loc.}(p,\mathcal{S}) &\geq \inf_{q\in\mathcal{S}\cap B^\circ(p,\rho)} \mathrm{rch}_{loc.}(q,\mathcal{S}) \\
&= \inf_{q\in\mathcal{S}\cap B^\circ(p,\rho)} \mathrm{rch}_{loc.}(q, \mathcal{S}\cap B(p,\rho)) \\
&\geq \mathrm{rch}_{loc.}(\mathcal{S}\cap B(p,\rho)) && \text{(by (3) applied to the set } \mathcal{S}\cap B(p,\rho)) \\
&\geq \mathrm{rch}(\mathcal{S}\cap B(p,\rho)) && \text{(by (4))} \\
&> \mathrm{rch}_{loc.}(p,\mathcal{S}) - \epsilon. && \text{(by (10))}
\end{aligned}$$

Because this inequality holds for any positive ϵ, the equality follows. ◀

▶ Remark 19. As a consequence, when $\mathcal{S}$ is compact, the inf in (3) is a min, in other words there exists at least one point $p \in \mathcal{S}$ such that $\mathrm{rch}_{loc.}(p,\mathcal{S}) = \mathrm{rch}_{loc.}(\mathcal{S})$.

▶ **Definition 20.** *A bottleneck is a pair of points $(a,b) \in \mathcal{S}^2$ such that*

$$B^\circ\left(\frac{a+b}{2}, \frac{|a-b|}{2}\right) \cap \mathcal{S} = \emptyset.$$

We have the following variant of Lemma 12 of [8], which in turn is a relatively straightforward generalization to arbitrary dimension of Property I of [5]:

▶ **Lemma 21.** *If a geodesic (or more generally a curve) γ parametrized according to arc length on the interval $[0,\ell]$ satisfies*

$$\angle\dot\gamma(s_1), \dot\gamma(s_2) \leq \frac{1}{R}|s_2 - s_1|, \tag{11}$$

then as long as $\ell \leq 2\pi R$,

$$|q-p| \geq 2\,\mathrm{rch}(\mathcal{M}) \sin\left(\frac{\ell}{2R}\right),$$

where $p = \gamma(0)$ and $q = \gamma(\ell)$.

Proof. The length of γ in the direction $\dot\gamma(\frac{\ell}{2})$ is

$$\begin{aligned}\left\langle q-p, \dot\gamma\left(\frac{\ell}{2}\right)\right\rangle &= \int_0^\ell \langle \dot\gamma(s), \dot\gamma(\ell/2)\rangle \mathrm{d}s \\ &= \int_0^{\ell/2} \langle \dot\gamma(s), \dot\gamma(\ell/2)\rangle \mathrm{d}s + \int_{\ell/2}^{\ell} \langle \dot\gamma(s), \dot\gamma(\ell/2)\rangle \mathrm{d}s \\ &\geq \int_0^{\ell/2} \cos\frac{|s-\ell/2|}{R}\mathrm{d}s + \int_{\ell/2}^{\ell} \cos\frac{|s-\ell/2|}{R}\mathrm{d}s \\ &= 2\,R \sin\left(\frac{\ell}{2R}\right).\end{aligned}$$

where, in the above inequality, we use the assumption $\ell \leq 2\pi R$ and the fact that $\theta \mapsto \cos\theta$ is decreasing on $[0,\pi]$.

Because $|q-p| \geq \langle q-p, \dot\gamma(\frac{\ell}{2})\rangle$, we see that

$$|q-p| \geq 2\,R \sin\left(\frac{\ell}{2R}\right). \qquad \blacktriangleleft$$

Combining Lemmas 42 of [20] and 21 we get:

▶ **Corollary 22.** *If γ is a geodesic in $\mathcal{S}$ with length $\ell \leq 2\pi \mathrm{rch}_{loc.}(\mathcal{S})$, then*

$$\ell \leq 2\mathrm{rch}_{loc.}(\mathcal{S}) \arcsin \frac{|p-q|}{2\mathrm{rch}_{loc.}(\mathcal{S})}.$$

The Lemma 23 below is a special case of [19, Lemma 4.6], we still provide a proof for completeness.

▶ **Lemma 23.** *Let $x \notin \mathrm{ax}(\mathcal{S})$ and denote by $\tilde x$ the unique point closest to x in $\mathcal{S}$. Then, for any $\epsilon > 0$, there is $\alpha > 0$ such that,*

$$|y-x| < \alpha \Rightarrow \{z \in \mathcal{S} \mid d(y,z) = d(y,\mathcal{S})\} \subset B^\circ(\tilde x, \epsilon). \tag{12}$$

Proof. Consider the closed set $\mathcal{S}' := \mathcal{S} \setminus B^\circ(\tilde x, \epsilon)$. The minimum distance $d(x,\mathcal{S}')$ to x is attained at least at some point z in $\mathcal{S}'$ so that

$$d(x,\mathcal{S}') = d(x,z) > d(x,\tilde x) = d(x,\mathcal{S}).$$

Taking

$$\alpha := \frac{d(x,\mathcal{S}') - d(x,\mathcal{S})}{2},$$

we get, for any y such that $|y-x| < \alpha$ and $z \in \mathcal{S}'$ that:

$$\begin{aligned} d(y,z) &\geq d(y,\mathcal{S}') \geq d(x,\mathcal{S}') - d(y,x) \\ &= d(x,\mathcal{S}) + 2\alpha - d(y,x) = d(x,\tilde x) + 2\alpha - d(y,x) \\ &> d(x,\tilde x) + d(y,x) \geq d(y,\tilde x) \geq d(y,\mathcal{S}). \end{aligned}$$

We have shown that if $z \in \mathcal{S}'$, then $d(y,z) > d(y,\mathcal{S})$. It follows that any closest point to y in $\mathcal{S}$ is in $\mathcal{S} \setminus \mathcal{S}' = \mathcal{S} \cap B^\circ(\tilde x, \epsilon)$ which is (12). ◀

▶ **Theorem 6.** *If $\mathcal{S}$ is a compact subset of $\mathbb{R}^d$, then:*

$$\mathrm{rch}(\mathcal{S}) = \min(\mathrm{rch}_{glob.}(\mathcal{S}), \mathrm{rch}_{loc.}(\mathcal{S}))$$

Proof. We consider first the situation where $\mathrm{rch}(\mathcal{S}) = 0$. In this case, since $\mathcal{S}$ is bounded, there exists some point $p \in \overline{\mathrm{ax}(\mathcal{S})} \cap \mathcal{S}$. Then, for any $\rho > 0$, there is some $p' \in \mathrm{ax}(\mathcal{S})$ such that $d(p', p) < \rho/2$, so that there are at least two points in $\mathcal{S} \cap B(p, \rho)$ closest to p'. Thus, $\mathrm{rch}(\mathcal{S} \cap B(p, \rho)) < \rho/2$, and, since this holds for any $\rho > 0$, we get that $\mathrm{rch}_{loc.}(p, \mathcal{S}) = 0$ and as a direct consequence $\mathrm{rch}_{loc.}(\mathcal{S}) = \inf_{q \in \mathcal{S}} \mathrm{rch}_{loc.}(q, \mathcal{S}) = 0$.

We assume now that $\mathrm{rch}(\mathcal{S}) > 0$.

As we have seen in Equation (4) of Remark 3, we have that $\mathrm{rch}(\mathcal{S}) \leq \mathrm{rch}_{loc.}(\mathcal{S})$. Therefore it suffices to prove that, if $\mathrm{rch}(\mathcal{S}) < \mathrm{rch}_{loc.}(\mathcal{S})$, then $\mathrm{rch}(\mathcal{S}) = \mathrm{rch}_{glob.}(\mathcal{S})$. So let us assume now that $\mathrm{rch}(\mathcal{S}) < \mathrm{rch}_{loc.}(\mathcal{S})$.

Since $\mathcal{S}$ is compact and thus bounded, which implies that a closed $\mathrm{rch}(\mathcal{S})$-neighbourhood of $\mathcal{S}$ is also bounded, there must exist $x \in \overline{\mathrm{ax}(\mathcal{S})}$, where $\overline{\mathrm{ax}(\mathcal{S})}$ is the closure of the medial axis $\mathrm{ax}(\mathcal{S})$, such that $d(x, \mathcal{S}) = \mathrm{rch}(\mathcal{S})$.

If $x \in \overline{\mathrm{ax}(\mathcal{S})} \setminus \mathrm{ax}(\mathcal{S})$, in particular $x \notin \mathrm{ax}(\mathcal{S})$ and there is a unique point $\tilde{x}$ closest to x in $\mathcal{S}$. Choose some $0 < \epsilon < \mathrm{rch}(\mathcal{S})$ and, as in Lemma 23, take $\alpha > 0$ so that (12) holds and, moreover, such that

$$\alpha < \mathrm{rch}_{loc.}(\mathcal{S}) - \mathrm{rch}(\mathcal{S}).$$

Since $x \in \overline{\mathrm{ax}(\mathcal{S})}$, there exists $y \in \mathrm{ax}(\mathcal{S}) \cap B^\circ(x, \alpha))$, and therefore Lemma 23 yields that there exists at least two points $p, q \in B^\circ(\tilde{x}, \epsilon)$ such that $d(y, p) = d(y, q) = d(y, \mathcal{S})$.

Because $d(p, q) < 2\epsilon < 2\mathrm{rch}(\mathcal{S})$, by Theorem 16, there is a geodesic from p to q of length at most $\pi\mathrm{rch}(\mathcal{S})$, which is less that $2\pi\mathrm{rch}_{loc.}(\mathcal{S})$. But then one can apply Corollary 22, which implies that the length of a geodesic from p to q is at most

$$\ell_{\max} = 2\mathrm{rch}_{loc.}(\mathcal{S}) \arcsin \frac{|p - q|}{2\mathrm{rch}_{loc.}(\mathcal{S})}.$$

However, since projecting a curve outside a given sphere onto the given sphere only decreases its length, a curve from p to q outside the ball centered at y whose radius is at most $\mathrm{rch}(\mathcal{S}) + |y - x| < \mathrm{rch}(\mathcal{S}) + \alpha < \mathrm{rch}_{loc.}(\mathcal{S})$ must have length strictly greater than $\ell_{\max}$, a contradiction.

We have so far proven that when $\mathrm{rch}(\mathcal{S}) < \mathrm{rch}_{loc.}(\mathcal{S})$, then the reach cannot be realized in $\overline{\mathrm{ax}(\mathcal{S})} \setminus \mathrm{ax}(\mathcal{S})$. One must then have $x \in \mathrm{ax}(\mathcal{S})$ and there are at least two points $p \neq q$ closest points to x on $\mathcal{S}$.

If $|p - q| < 2\mathrm{rch}(\mathcal{S})$ then by Theorem 16 one has that $d_{\mathcal{S}}(p, q) \leq 2\mathrm{rch}(\mathcal{S}) \arcsin \frac{|p-q|}{2\mathrm{rch}(\mathcal{S})}$ which is less than $2\pi\mathrm{rch}_{loc.}(\mathcal{S})$. Again, Corollary 22 implies that the length of a geodesic from p to q is a most $2\mathrm{rch}_{loc.}(\mathcal{S}) \arcsin \frac{|p-q|}{2\mathrm{rch}_{loc.}(\mathcal{S})}$, which, again, is impossible without entering the ball centered at x with radius $\mathrm{rch}(\mathcal{S}) < \mathrm{rch}_{loc.}(\mathcal{S})$.

Since $|p - q| \leq 2\mathrm{rch}(\mathcal{S})$, the only possibility is that $|p - q| = 2\mathrm{rch}(\mathcal{S})$, i.e. $x = (p + q)/2$, a bottleneck. ◀

Geodesics of Length Less Than πR in a Set of Reach R Are Unique and Continuous with Respect to the Endpoints

Abstract

Positive reach underpins many results in computational geometry and topology. It is used for triangulation criteria, topological inference, and manifold learning. The geometric properties of these sets have therefore been studied intensely. Here we focus on the shortest paths or minimizing geodesics in these sets. Our main result states that minimizing geodesics of length strictly less than πR in a set of reach R are unique. This in turn implies that such minimizing geodesics are continuous with respect to the endpoints.

1 Introduction

Federer [14] introduced the reach of a closed set $\mathcal{S} \subset \mathbb{R}^d$ as the infimum of the distance from $\mathcal{S}$ to the medial axis $\mathrm{ax}(\mathcal{S})$, i.e. the set of points in $\mathbb{R}^d$ for which the closest point in $\mathcal{S}$ is not unique. Assumptions on the reach (and its local version the local feature size [3]) underpin the correctness of many algorithms in computational geometry and topology. In this paper we consider minimizing geodesics in this space and show that they are both unique and depend continuously on the endpoints if the geodesics are sufficiently short. Moreover, the bound on the length of the minimizing geodesics that implies uniqueness (and therefore continuity) is in fact tight, because it is attained on the sphere.

1.1 Motivation

Triangulation algorithms. The assumption of positive reach is central to almost all triangulation algorithms, see for example [10, 12, 5], as well as manifold learning, see for example [16, 15, 2, 30]. However these algorithms often consider manifolds of positive reach instead general sets of positive reach. If we want to extend our algorithm beyond the realm

© André Lieutier and Mathijs Wintraecken;
licensed under Creative Commons License CC-BY 4.0

of manifolds to more general stratified spaces, starting with "well behaved" sets of positive reach[1] or at least sets of which the strata have positive (local [24]) reach understanding the geometry of those sets seems essential.

Metric learning. Another motivation comes from metric learning. In [1] this is explained as follows:

"In the data analysis area, metric learning refers to the problem of finding a distance d over the space of observations that is relevant for a given task at stake [35, 32]. For instance, in a supervised framework where one is provided with tuples of allegedly similar or dissimilar observations, the goal is to find a distance that is small on the similar tuples and large on the dissimilar ones. There is a wide range of existing methods in the literature, ranging from parametric (LSI [34], MCML [18], LDML [21] among others) to nonparametric (DMLMJ [29], kernel methods [23, 9], to cite a few).

In an unsupervised setting, metric learning aims at finding a metric that takes into account the underlying geometry of the data. That is, it amounts to estimating the shortest-path (or geodesic) distance. Often, this is done via a dimension reduction technique: any low-dimensional embedding of the data gives rise to a new distance over the data in the embedded space. Existing algorithms include PCA, t-SNE [22], MDS [11], Isomap [33], or MVU [4]. See [32] for a thorough overview of the field."

And indeed in [1] geodesics play a crucial role in establishing optimal bounds.

1.2 Contribution

This paper focusses on the following result:

▶ **Theorem 1.** *Let $\mathcal{S}$ be a set of positive reach R, then for any two points $a, b \in \mathcal{S}$ such that the geodesic distance on $\mathcal{S}$ satisfies $d_{\mathcal{S}}(a, b) < \pi R$ there is a unique minimizing geodesic in $\mathcal{S}$ connecting a and b.*

We stress that in the context of sets of positive reach a minimizing geodesic is a curve of minimal length connecting the two points. In this paper we only consider minimizing geodesics and therefore will not explicitly repeat "minimizing" everywhere. More generally, a geodesic is a curve such that it is locally a minimizing geodesic (between the endpoints of a subsegment). In particular more than half of great circle on a sphere, is NOT a minimizing geodesic, although they are geodesics in the more general and Riemannian setting.

The following corollary to the main theorem is perhaps even more important for applications:

▶ **Corollary 2.** *Let $\mathcal{S}$ be a set of positive reach R, then the geodesic connecting any two points $a, b \in \mathcal{S}$ is continuous (in the C^0 sense) with respect to the endpoints provided that $d_{\mathcal{S}}(a, b) < \pi R$.*

Both results are tight, because the bound is attained on the sphere.

[1] Sets of positive reach are stratified spaces [14], where the stratification is understood in a weak sense. However, it is not clear that sets of positive reach are triangulable in general or additional assumptions are needed. This having been said, there are compact sets of (arbitrarily large) positive reach that are not (piecewise smoothly/linearly) homeomorphic to a finite simplicial complex, which puts this outside of the realm of computation.

1.3 Previous work

CAT(k) spaces. The terminology CAT(k) was introduced by Gromov [20] for metric spaces that satisfy some weak form of curvature bound. We'll now give a rough definition of CAT(k) spaces, but refer to [7] for a precise introduction, see Section II.1. Let $(\mathcal{M}, d_{\mathcal{M}})$ be a geodesic metric space, that is a space where the length between two points is defined as the minimum of all lengths of continuous (rectifiable) curves connecting the two points, i.e. the minimum is attained. Such a minimizing curve is called a geodesic. A geodesic triangle in such a space consists of three points and the geodesics connecting those points. We can then consider a geodesic triangle with the same edge lengths in a (simply connected) space of constant curvature k (that is a sphere, Euclidean space, or hyperbolic space). This triangle is called a comparison triangle. We say that the diameter of a simply connected space of constant curvature is $\pi/\sqrt{k}$ if $k > 0$ and ∞ otherwise. We also refer to this as the diameter of the comparison space. This geodesic triangle in $\mathcal{M}$ satisfies the CAT(k) inequality if the distances between the points on the triangle are less than the corresponding distances between points on the comparison triangle in a space of constant curvature k. If this holds for any geodesic triangle of diameter less than the diameter of the comparison space, then we say that the entire space is CAT(k).

Sets of positive reach as CAT(k) spaces. Lytchak [25, 26] proved sets of positive reach are CAT(k), for some k. Because in (simply connected) spaces of constant curvature, geodesic triangles with small diameter and one edge length equal to zero consist of two coinciding edges, the uniqueness of sufficiently small geodesics follows directly from Lytchak's result. However, from a computational perspective the result of Lytchak is ineffective, because we only know that such a constant exists and not what this constant may be.

Another way that this paper distinguishes itself compared to the literature, is that the results are all completely elementary, in the sense that we only need some results by Federer [14] and Euler-Lagrange theory [31].

1.4 Further motivation and future work

Many questions on the geometry of sets of positive reach and the behaviour of geodesics in sets of positive reach of course remain open. Determining the k for which a set of reach R is CAT(k), would be an important next step, which in fact motivated this work to a large extent. We conjecture that $k = 1/R^2$.

If we may engage in some speculation, establishing the CAT(k) property would potentially:

- Help establish bounds on angles between tangent cones of sets of positive reach, beyond the manifold setting, which is in turn essential for stratification learning.
- Help establish convergence rates for algorithms to compute geodesics in sets of positive reach.

2 Result

2.1 Notation

We'll denote sets of positive reach by $\mathcal{S}$ and the closest point projection by $\pi_{\mathcal{S}}$. We use the notation $B(c, r)$ for a ball in Euclidean spaces with centre c and radius r. Curves are generally denoted by γ and most importantly:

We'll use Newton's notation for the derivatives of curves that is, $\dot{\gamma} = \frac{d}{dt}\gamma$.

2.2 Uniqueness

The main idea of the proof is the following: Suppose that there are two geodesics γ_1 and γ_2 connecting two points is not unique then we can move the geodesic γ_1 a little in the direction γ_2, shortening the geodesic and thus yielding a contradiction. This perturbed geodesic, of course, needs to lie on the set of positive reach, which will be achieved by closest point projection onto the set of positive reach. We commence our proof with a couple of lemmas that will be instrumental in dealing with this projection.

We first recall a convexity result from [6]. We recall that a set C is geodesically convex if for any two points $c, c' \in C$ the geodesic connecting c and c is contained in C.

▶ **Corollary 3** (Corollary 1 of [6]). *Let $\mathcal{S} \subset \mathbb{R}^d$ be a closed set with positive reach $R > 0$. Then, for any $r' < R$ and any $x \in \mathbb{R}^d$ then $\mathcal{S} \cap B(x, r')$ is geodesically convex in $\mathcal{S}$.*

▶ **Lemma 4.** *Let $\mathcal{S}$ have reach R and assume $p, q \in \mathcal{S}$ with $|p - q| \leq 2R$. Define $x = \lambda p + (1 - \lambda)q$. We have that*

$$\begin{aligned} d(x, \mathcal{S}) &= |x - \pi_{\mathcal{S}}(x)| \\ &\leq R - \sqrt{R^2 - \lambda(1-\lambda)|p-q|^2} \\ &\leq \frac{\lambda(1-\lambda)|p-q|^2}{2R} + \mathcal{O}\left(\left(\frac{\lambda(1-\lambda)|p-q|^2}{2R}\right)^2\right), \end{aligned}$$

with d the Euclidean distance.

Proof. Corollary 3 implies that the geodesic connecting p and q is contained in the intersection of all balls of radius less than the reach that contain p and q so that in particular the geodesic is contained in the spindle (the intersection of all balls of radius R in Euclidean space that contain p and q), as depicted in Figure 1. This implies in turn that $|x - \pi_{\mathcal{S}}(x)|$ less than or equal to the distance from x to the boundary of the spindle. Let's restrict ourselves to the plane given by p, q, and $\pi_{\mathcal{S}}(x)$ and consider a circle of radius R with centre c that yields the boundary of the spindle in this plane, see again Figure 1. By the cosine rule have that

$$|c - \lambda p - (1-\lambda)q|^2 = R^2 + \lambda^2|p-q|^2 - 2R\lambda|p-q|\cos\theta,$$

where $\cos\theta = \frac{|p-q|}{2R}$ (the value for θ follows by inspection of the triangle with vertices p, c, and $\frac{1}{2}(p+q)$). So that

$$\begin{aligned} |c - \lambda p - (1-\lambda)q|^2 &= R^2 + \lambda^2|p-q|^2 - \lambda|p-q|^2 \\ &= R^2 - (1-\lambda)\lambda|p-q|^2. \end{aligned}$$

The first inequality now follows by observing that the distance from x to the spindle is given by $R - |c - \lambda p + (1-\lambda)q|$, see Figure 1. The second inequality follows from the standard observation that $\sqrt{1-t} = 1 - \frac{t}{2} - \mathcal{O}(t^2)$, which in turn follows by Taylor's theorem. ◀

We'll need the following corollary of [14, Theorem 4.8(8)]. Theorem 4.8(8) of [14] says the closest point projection $\pi_{\mathcal{S}}$ at a point x is $\frac{1}{1-d(x,\mathcal{S})/R}$-Lipschitz. We therefore immediately have:

▶ **Corollary 5.** *If $\gamma : [0, \ell] \to \mathbb{R}^d$ is a C^1 curve, then the length of $\pi_{\mathcal{S}}(\gamma)$ is upper bounded as follows*

$$\text{length}(\pi_{\mathcal{S}}(\gamma)) \leq \int_0^\ell \frac{1}{1 - d(\gamma(t), \mathcal{S})/R} |\dot{\gamma}(t)| dt. \tag{1}$$

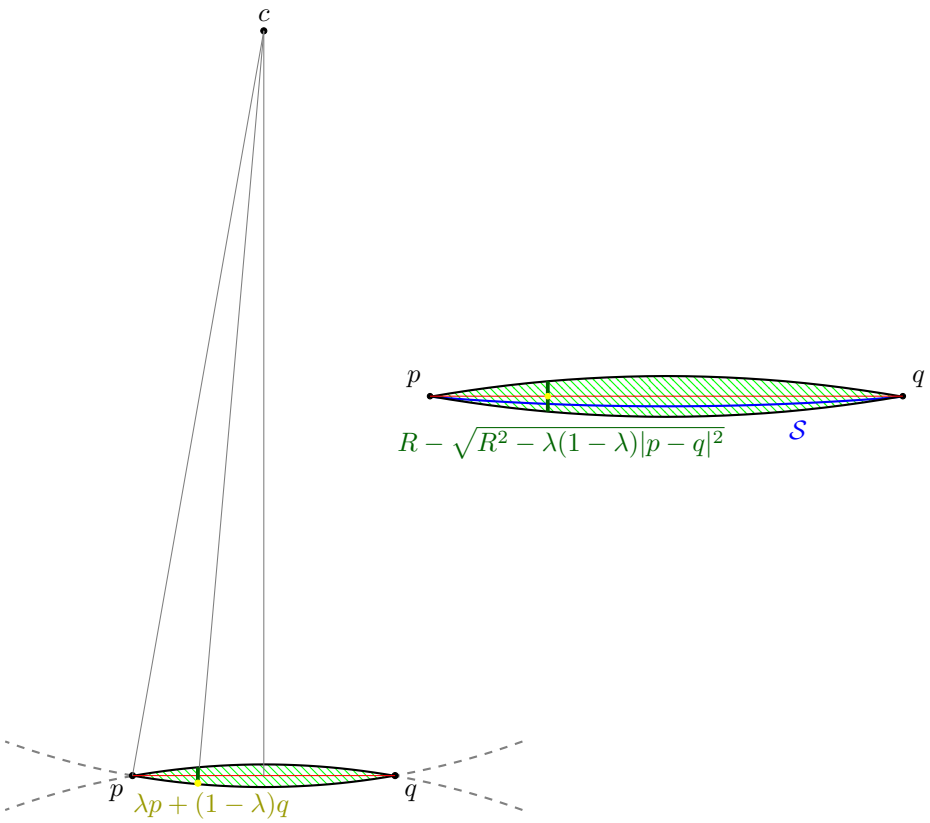

Figure 1 Left: The region in which the geodesic connecting p and q lies is indicated in green, the grey dashed circles have radius R. Right: A zoom in on the spindle with the distance from the yellow point $(\lambda p + (1-\lambda)q)$ to the boundary of the spindle indicated in dark green. The geodesic connecting p and q (which is a part of $\mathcal{S}$) within the spindle is indicated in blue. Because the union of the two dark green line segments (which are almost collinear in the figure, in higher dimensions it is a cone or in other words, the join of a sphere and a point), separates the spindle into two halves and the geodesic is continuous the dark green set intersect the geodesic. This implies that the distance from the grey point to the boundary upper bounds the distance to $\mathcal{S}$.

The following simple but very useful bound will be instrumental in the proof below.

▶ **Lemma 6.** *If a and b are two unit vectors we have that*

$$|\lambda a + (1-\lambda)b|^2 = 1 - (1-\lambda)\lambda|a-b|^2.$$

For vectors of arbitrary length we have

$$|\lambda a + (1-\lambda)b|^2 = \lambda|a|^2 + (1-\lambda)|b|^2 - \lambda(1-\lambda)|a-b|^2.$$

Proof. We have that for any two unit vectors a, b that:

$$\begin{aligned} |\lambda a + (1-\lambda)b|^2 &= \lambda^2|a|^2 + (1-\lambda)^2|b|^2 + 2\lambda(1-\lambda)a\cdot b && (2)\\ &= \lambda^2 + (1-\lambda)^2 + 2\lambda(1-\lambda)a\cdot b && \text{(using that } |a| = |b| = 1)\\ &= 1 - (1-\lambda)\lambda\,(2 - 2a\cdot b) \\ |a-b|^2 &= |a|^2 + |b|^2 - 2a\cdot b && (3)\\ &= 2 - 2a\cdot b && \text{(using that } |a| = |b| = 1) \end{aligned}$$

and thus

$$|\lambda a + (1-\lambda)b|^2 = 1 - (1-\lambda)\lambda|a-b|^2.$$

For a, b of arbitrary length we combine (2) and (3) as follows

$$\begin{aligned}|\lambda a + (1-\lambda)b|^2 &= \lambda^2|a|^2 + (1-\lambda)^2|b|^2 + \lambda(1-\lambda)\left(|a|^2 + |b|^2 - |a-b|^2\right)\\ &= \lambda|a|^2 + (1-\lambda)|b|^2 - \lambda(1-\lambda)|a-b|^2.\end{aligned}$$

◀

▶ **Theorem 1.** *Let $\mathcal{S}$ be a set of positive reach R, then for any two points $a, b \in \mathcal{S}$ such that the geodesic distance on $\mathcal{S}$ satisfies $d_{\mathcal{S}}(a,b) < \pi R$ there is a unique minimizing geodesic in $\mathcal{S}$ connecting a and b.*

Overview of the proof. The core idea of the proof is the following: Given two geodesics γ_1 and γ_2 connecting a, b that are parametrized by arc length we have that $\lambda\gamma_1 + (1-\lambda)\gamma_2$ is shorter than γ_1 and γ_2 because $|\lambda\dot{\gamma}_1 + (1-\lambda)\dot{\gamma}_2| < 1$, if $\lambda \in (0,1)$. So[2] if $\lambda\gamma_1 + (1-\lambda)\gamma_2 \subset \mathcal{S}$ we would find a contradiction, because there would be a curve connecting a and b that would be shorter than a geodesic. The main difficulty of the proof is that $\lambda\gamma_1 + (1-\lambda)\gamma_2$ is generally not in $\mathcal{S}$, but we need to project on $\mathcal{S}$ to find a curve that is. The technical difficulty lies with dealing with this projection.

The proof, perhaps surprisingly, also relies on a result from mathematical physics. Consider the Lagrangian of the (real) harmonic oscillator:

$$\mathcal{L}_{\mathrm{HO}} = |\dot{x}|^2 - \frac{|x|^2}{R^2}$$

Write S_{HO} for the action, that is

$$S_{\mathrm{HO}} = \int_0^\tau \mathcal{L}_{\mathrm{HO}} dt. \tag{4}$$

The Euler-Lagrange equation,

$$\frac{d}{dt}\frac{\partial \mathcal{L}}{\partial \dot{x}} = \frac{\partial \mathcal{L}}{\partial x},$$

in this case yields

$$\ddot{x}(t) = -\frac{x(t)}{R^2},$$

with the familiar solutions $c_1 \sin(t/R) + c_2 \cos(t/R) = c_4 \sin\left(\frac{t-t_0}{R}\right)$. We have the following, see [19, Section V], [28] for this specific result[3] and [17] for general theory:

▶ **Theorem 7** (Adjusted from [19] and [28])**.** *The solution to the Euler-Lagrange equation of the harmonic oscillator is a global minimum of the action* (4) *provided that $\tau < \pi R$.*

This means in particular that:

[2] Here abuse notation a little bit because we do not distinguish the notation for a geodesic and its parametrization.

[3] Note that our the Lagrangian of a high dimensional harmonic oscillator (with constant potential) is the sum of one-dimensional harmonic oscillators.

▶ **Corollary 8.** *Let c_4 be a constant. If $\tau < \pi R$ and $x(t)$ is a function that satisfies $x(0) = 0$ and $x(\tau) = c_4 \sin\left(\frac{\tau}{R}\right)$, then we have that*

$$\begin{aligned} S_{HO}(x) &= \int_0^\tau |\dot{x}|^2 - \frac{|x|^2}{R^2} dt \\ &\geq \int_0^\tau \left(\frac{c_4^2 \cos^2\left(\frac{t}{R}\right) - c_4^2 \sin^2\left(\frac{t}{R}\right)}{R^2} \right) dt \\ &= \int_0^\tau \frac{c_4^2}{R^2} \cos\left(\frac{2t}{R}\right) dt \\ &= \frac{c_4^2}{2R} \sin\left(\frac{2\tau}{R}\right). \end{aligned}$$

Proof of Theorem 1. Because $d_S(a,b) < \pi R$ the geodesic distance between a and b is finite, which means that there exists a path of finite length connecting a and b in $\mathcal{S}$. Moreover, thanks to the second paragraph of part III, section 1: "Die Existenz geodätischer Bogen in metrischen Räume" in [27], we have that: If there is at least one path between a and b with finite length, then a minimizing geodesic, i.e. a path with minimal length connecting a to b, exists. Therefore the set of minimizing geodesics is not empty.

Let $\gamma_1, \gamma_2 : [0, \ell] \to S$ be two length minimizing paths from a to b, parametrized by arc length, with same length: $\text{length}(\gamma_1) = \text{length}(\gamma_2) = \ell := d_S(a,b)$.

Denote by ϵ the maximal distance between $\gamma_1(t)$ and $\gamma_2(t)$, i.e.

$$\epsilon := \max_{t\in[0,\ell]} |\gamma_1(t) - \gamma_2(t)|, \tag{5}$$

and let $t_{\max} \in [0, \ell]$ be a parameter for this distance is attained, that is,

$$d\big(\gamma_1(t_{\max}), \gamma_2(t_{\max})\big) = \epsilon.$$

Without loss of generality, we assume that $t_{\max} \leq \ell/2$.

We now consider the two families of curves

$$\gamma_\lambda^{\mathbb{E}}(t) = \lambda\gamma_1(t) + (1-\lambda)\gamma_2(t)$$

and

$$\gamma_\lambda^{\mathcal{S}}(t) = \pi_{\mathcal{S}}(\gamma_\lambda^{\mathbb{E}}(t)).$$

We now upper bound the length $\gamma_\lambda^{\mathcal{S}}(t)$. By Lemma 4 we have that

$$d(\gamma_\lambda^{\mathbb{E}}(t), \mathcal{S}) \leq R - \sqrt{R^2 - \lambda(1-\lambda)|\gamma_1(t) - \gamma_2(t)|^2}.$$

Using Corollary 5 this yields that

$$\begin{aligned} &\text{length}(\gamma_\lambda^{\mathcal{S}}(t)) \\ &\leq \int_0^\ell \frac{1}{1 - (1 - \sqrt{1 - \lambda(1-\lambda)|\gamma_1(t) - \gamma_2(t)|^2/R^2})} |\lambda\dot{\gamma}_1(t) + (1-\lambda)\dot{\gamma}_2(t)| dt. \end{aligned} \tag{6}$$

We now focus on the second term in the product in the integral.

With Lemma 6 we find the following bound on (6):

$$\text{length}(\gamma_\lambda^{\mathcal{S}}(t)) \leq \int_0^\ell \frac{\sqrt{1 - (1-\lambda)\lambda(|\dot{\gamma}_1(t) - \dot{\gamma}_2(t)|^2)}}{\sqrt{1 - \lambda(1-\lambda)|\gamma_1(t) - \gamma_2(t)|^2/R^2}} dt. \tag{7}$$

Assuming that $(1-\lambda)\lambda$ is very small (more precisely we'll show that the length decreases in first order near $\lambda = 0$ or $\lambda = 1$) yields that

$$\begin{aligned}
&\int_0^\ell \frac{\sqrt{1-(1-\lambda)\lambda(|\dot\gamma_1(t)-\dot\gamma_2(t)|^2)}}{\sqrt{1-\lambda(1-\lambda)|\gamma_1(t)-\gamma_2(t)|^2/R^2}}dt. \\
&= \int_0^\ell \left(1+\lambda(1-\lambda)\frac{|\gamma_1(t)-\gamma_2(t)|^2}{2R^2}\right)\left(1-\frac{1}{2}(1-\lambda)\lambda(|\dot\gamma_1(t)-\dot\gamma_2(t)|^2)\right)dt \\
&\quad + \mathcal{O}\left(\lambda^2(1-\lambda)^2\right) \qquad \text{(by Taylor)} \\
&= \int_0^\ell 1+\lambda(1-\lambda)\frac{|\gamma_1(t)-\gamma_2(t)|^2}{2R^2} - \frac{1}{2}(1-\lambda)\lambda(|\dot\gamma_1(t)-\dot\gamma_2(t)|^2)dt \\
&\quad + \mathcal{O}\left(\lambda^2(1-\lambda)^2\right) \\
&= \int_0^\ell 1-\frac{1}{2}(1-\lambda)\lambda\left(|\dot\gamma_1(t)-\dot\gamma_2(t)|^2 - \frac{|\gamma_1(t)-\gamma_2(t)|^2}{R^2}\right)dt \\
&\quad + \mathcal{O}\left(\lambda^2(1-\lambda)^2\right). \qquad (8)
\end{aligned}$$

Now writing $\Delta(t) = \gamma_1(t) - \gamma_2(t)$ and thus $\dot\Delta(t) = \dot\gamma_1(t) - \dot\gamma_2(t)$, this integral (ignoring the higher order terms) takes the form of a familiar Lagrangian integral or action

$$\int_0^\ell \mathcal{L}\,dt = \int_0^\ell 1-\frac{1}{2}(1-\lambda)\lambda\left(|\dot\Delta(t)|^2 - \frac{|\Delta(t)|^2}{R^2}\right)dt, \qquad (9)$$

which we recognize (up to global additive and multiplicative factors) as the action integral of the harmonic oscillator. To achieve better bounds we'll now split this into two integrals

$$\int_0^\ell \mathcal{L}\,dt = \int_0^{\ell/2} \mathcal{L}\,dt + \int_{\ell/2}^\ell \mathcal{L}\,dt.$$

We'll only concentrate on the first integral, the second one can be treated in a completely symmetrical manner.

We now invoke Theorem 7 and Corollary 8, with $\tau = \ell/2$, together with (7), (8), and (9), to find that

$$\begin{aligned}
\text{length}(\gamma_\lambda^{\mathcal{S}}(t)) &\le \int_0^\ell 1-\frac{1}{2}(1-\lambda)\lambda\left(|\dot\gamma_1(t)-\dot\gamma_2(t)|^2 - \frac{|\gamma_1(t)-\gamma_2(t)|^2}{R^2}\right)dt \\
&\quad + \mathcal{O}\left(\lambda^2(1-\lambda)^2\right) \\
&= \left(\int_0^{\ell/2} + \int_{\ell/2}^\ell\right)\left(1-\frac{1}{2}(1-\lambda)\lambda\left(|\dot\gamma_1(t)-\dot\gamma_2(t)|^2 - \frac{|\gamma_1(t)-\gamma_2(t)|^2}{R^2}\right)\right)dt \\
&\quad + \mathcal{O}\left(\lambda^2(1-\lambda)^2\right) \\
&\le 2\left(\ell/2 - \frac{1}{2}(1-\lambda)\lambda\frac{c_4^2}{2R}\sin\left(\frac{\ell}{R}\right)\right) + \mathcal{O}\left(\lambda^2(1-\lambda)^2\right), \\
&\qquad \text{(the } \le \text{ follows because } -\tfrac{1}{2}(1-\lambda)\lambda \text{ is negative)}
\end{aligned}$$

where c_4 is some constant. This is strictly less than ℓ, as long as $\ell < \pi R$. This contradicts the assumption that the geodesics have length ℓ (which is the sum of the integral from 0 to $\ell/2$ and the integral from $\ell/2$ to ℓ), because now we found a curve that is shorter up to first order. ◀

2.3 Continuity

The uniqueness of the geodesics of length less than πR implies continuity for geodesics under the same restriction. The proof of the continuity will rely heavily on the Arzelà-Ascoli theorem, see e.g. [13]. To this end we have to recall some nomenclature: A sequence

$\{\gamma_n\}_{n\in\mathbb{Z}_{\geq 0}}$ of continuous functions on an interval $I \subset \mathbb{R}$ is uniformly bounded if for all n and all $t \in I$, we have that $|\gamma_n(x)| \leq C$, with C some (universal) constant. The sequence $\{\gamma_n\}_{n\in\mathbb{Z}_{\geq 0}}$ is uniformly equicontinuous if, for every $\epsilon > 0$ there exists a $\delta > 0$, such that for all t, t' satisfying $|t - t'| \leq \delta$ and all n we have that

$$|\gamma_n(t) - \gamma_n(t')| \leq \epsilon.$$

The theorem can now be stated as

▶ **Theorem 9** (Arzelà-Ascoli). *Let $\{\gamma_n\}_{n\in\mathbb{Z}_{\geq 0}}$ be a sequence of real-valued uniformly bounded, equicontinuous functions on a compact interval I. Then there exists a subsequence $\{\gamma_{n_k}\}_{k\in\mathbb{Z}_{\geq 0}}$ that converges uniformly.*

With these preliminaries out of the way we can state the second contribution of the paper:

▶ **Corollary 2.** *Let $\mathcal{S}$ be a set of positive reach R, then the geodesic connecting any two points $a, b \in \mathcal{S}$ is continuous (in the C^0 sense) with respect to the endpoints provided that $d_{\mathcal{S}}(a, b) < \pi R$.*

We provide two proofs, one here and another in the appendix. Although they share a fair number of common techniques they differ significantly on the way that they treat the length of the limit curve. Moreover, the proof here is shorter, but requires some familiarity with using the Arzelà-Ascoli theorem, while the proof in the appendix discusses this in greater detail.

Proof. Let a_n, b_n be a pair of sequences of points in $\mathcal{S}$, where $\lim_{n\to\infty} a_n = a$ and $\lim_{n\to\infty} b_n = b$, as well as a sequence of geodesics γ_n, connecting a_n and b_n. Let γ be the minimizing geodesic connecting a and b.

We want to prove that $\lim_{n\to\infty} \|\gamma - \gamma_n\|_{\sup} = 0$, where $\|\cdot\|_{\sup}$ denotes the C^0 norm (i.e. sup norm). In other words, we have to prove that, for any $\epsilon > 0$, the cardinal of the set:

$$\Gamma_\epsilon := \{\gamma_n \mid \|\gamma - \gamma_n\|_{\sup} \geq \epsilon\}$$

is finite.

Assume to achieve a contradiction that the cardinal of Γ_ϵ is infinite. Since the set of functions in Γ_ϵ is bounded and equicontinuous (because they admit a uniform Lipschitz constant), we can apply Arzelà-Ascoli theorem and find a subsequence $\{\gamma_{n_k}, k \in \mathbb{N}\} \subset \Gamma_\epsilon$ converging to a curve γ' in $\mathcal{S}$. Since $|\text{length}(\gamma) - \text{length}(\gamma_{n_k})| = |d_{\mathcal{S}}(a, b) - d_{\mathcal{S}}(a_{n_k}, b_{n_k})| \leq d_{\mathcal{S}}(a, a_{n_k}) + d_{\mathcal{S}}(b, b_{n_k})$.) one has $\lim_{k\to\infty} \text{length}(\gamma_{n_k}) = \text{length}(\gamma)$.

By a classical result [8, Claim 5.8, page 19], the length of the limit cannot be larger than the limit inf of lengths which yields $\text{length}(\gamma') \leq \lim_{k\to\infty} \text{length}(\gamma_{n_k}) = \text{length}(\gamma)$. Therefore, γ' would be a geodesic between a and b with $\|\gamma - \gamma'\|_{\sup} \geq \epsilon$ which contradicts the unicity of geodesics stated in Theorem 1. ◀

Corollary 2 has itself another consequence which is worth pointing out.

▶ **Corollary 10.** *A geodesic ball of radius less than πR is contractible.*

Proof. Write $B_{\mathcal{S}}(c, r)$, for the geodesic ball in $\mathcal{S}$ with centre c and radius r, where $r < \pi R$. Let $x \in B_{\mathcal{S}}(c, r)$, and let $\gamma_{xc}(t)$ be the geodesic parametrized by $[0, 1]$ with constant arclength with $\gamma_{xc}(1) = x$ and $\gamma_{xc}(0) = c$. Thanks to Corollary 2 the geodesics are continuous under the sup-norm, with respect to endpoint x. This means that the map $H : [0, 1] \times B_{\mathcal{S}}(c, r) : (\lambda, x) \mapsto \gamma_{xc}(\lambda)$ is a (continuous) homotopy. ◀

A Alternative proof

Alternative proof of Corollary 2. Assume that the geodesics are not continuous with respect to the endpoints, then there exist an $\epsilon > 0$ and a pair of sequences of points a_n, b_n, where $\lim_{n\to\infty} a_n = a$ and $\lim_{n\to\infty} b_n = b$, as well as a sequence of geodesics γ_n, connecting a_n and b_n such that

$$\sup_{t\in I} |\gamma_n(t) - \gamma(t)| \geq \epsilon,$$

where γ is the geodesic connecting a and b. We stress that here we parametrize the geodesics on the unit interval $[0, 1]$, with constant norm of the tangent vector, i.e. $|\dot{\gamma}_n| = d_{\mathcal{S}}(a_n, b_n)$.

We further note that thanks to the metric characterization of sets of positive reach [6, Theorem 1] convergence in the Euclidean and geodesic sense are equivalent.

Again, thanks to the metric characterization of sets of positive reach [6, Theorem 1] we know that geodesics are themselves sets of (at least) the same reach as the set in which they lie. We also know that manifolds of positive reach are $C^{1,1}$ where the Lipschitz constant of the derivative is bounded by $1/R$, see [24]. This implies that the tangent vectors $\dot{\gamma}_n$ are uniformly Lipschitz, that is Lipschitz with the same Lipschitz constant for all n. This

uniform Lipschitz constant implies by definition uniform equicontinuity of $\dot{\gamma}_n$. Because all geodesics are parametrized according to arclength, with $|\dot{\gamma}_n| = d_{\mathcal{S}}(a_n, b_n)$, and $d_{\mathcal{S}}(a_n, b_n)$ is bounded by assumption, $\dot{\gamma}_n$ is also bounded.

We now observe that by passing to a subsequence we can assume that there is one $t^* \in I$ such that

$$|\gamma_n(t^*) - \gamma(t^*)| \geq \epsilon/2. \tag{10}$$

This can be seen as follows: Because I is compact the supremum must be attained at some point t_n^* for each $(\gamma_n - \gamma)(t)$. Again because I is compact this sequence of points must have a convergent subsequence n_m with limit t^* because of smoothness (more precisely, the fact that $|\dot{\gamma}_n|$ is bounded) of $(\gamma_n)(t)$, we have that for m sufficiently large and $|t - t^*|$ sufficiently small, we have $|\gamma_{n_m}(t) - \gamma(t)| \geq \epsilon/2$. This implies that (10) holds.

Now we can invoke the Arzelà-Ascoli theorem to conclude that there exist a $\dot{\gamma}'$, which is the limit of a convergent subsequence of $\dot{\gamma}_n$. We write $\gamma'(t) = \int_0^t \dot{\gamma}' \mathrm{d}s$. With this notation we can formulate the following observations:

- The lengths of γ_n converge to the length of γ'.
- The geodesic γ_n has to converge to the geodesic distance between a and b, because by the triangle inequality we have that

  $$|\text{length}(\gamma) - \text{length}(\gamma_n)| = |d_{\mathcal{S}}(a, b) - d_{\mathcal{S}}(a_n, b_n)| \leq d_{\mathcal{S}}(a, a_n) + d_{\mathcal{S}}(b, b_n).$$

  And hence, γ and γ' both are geodesics, that is their lengths equal the geodesic distance between the endpoints.
- $|\gamma(t^*) - \gamma'(t^*)| \geq \epsilon/2$, in particular $\gamma \neq \gamma'$.

This yields a contradiction with the uniqueness of the geodesics, that is Theorem 1. ◀

A Fast Algorithm for the Hecke Representation of the Braid Group, and Applications to the Computation of the HOMFLY-PT Polynomial and the Search for Interesting Braids

Abstract

Knot theory is an active field of mathematics, in which combinatorial and computational methods play an important role. One side of computational knot theory, that has gained interest in recent years, both for complexity analysis and practical algorithms, is quantum topology and the computation of topological invariants issued from the theory.

In this article, we leverage the rigidity brought by the representation-theoretic origins of the quantum invariants for algorithmic purposes. We do so by exploiting braids and the algebraic properties of the braid group to describe, analyze, and implement a fast algorithm to compute the Hecke representation of the braid group. We apply this construction to design a parameterized algorithm to compute the HOMFLY-PT polynomial of knots, and demonstrate its interest experimentally. Finally, we combine our fast Hecke representation algorithm with Garside theory, to implement a reservoir sampling search and find non-trivial braids with trivial Hecke representations with coefficients in $\mathbb{Z}/p\mathbb{Z}$. We find explicitly several such braids, for the 4-strand and 5-strand braid groups.

1 Introduction

Geometrically, a *braid* on n strands is the embedding of n non-intersecting paths in the 3-dimensional space $\mathbb{R}^2 \times [0,1]$, such that every path connects a point $(i,0,0), i \in \{1,\dots,n\}$ in the bottom plane to a point $(j,0,1), j \in \{1,\dots,n\}$ in the top plane, and every path grows monotonically along the z-axis. Two braids are *equivalent* if there is an ambient isotopy of

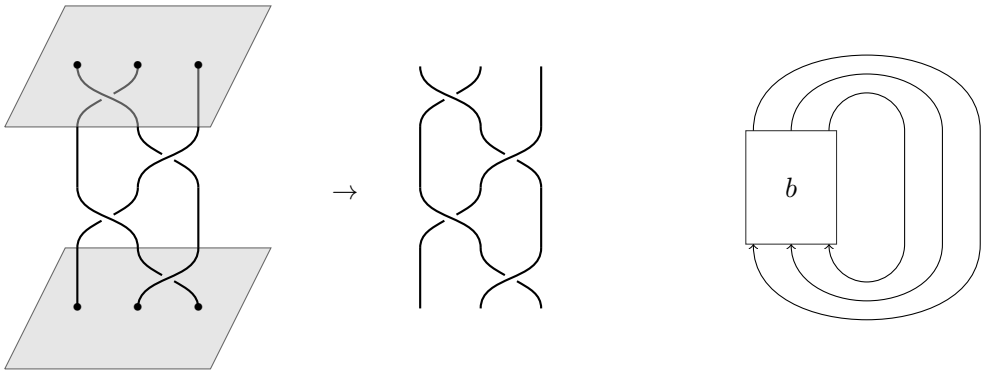

Figure 1 Left: Geometric braid on 3 strands in $\mathbb{R}^2 \times [0;1]$, and natural diagram (projection on xz-plane). Right: Braid closure $\widehat{b}$ of braid b.

$\mathbb{R}^2 \times [0,1]$ fixing the bottom and top planes and taking one braid to the other. Braids are generally represented by *braid diagrams*, that are planar projections of a braid along the y-axis, keeping track of upper and under crossings; see Figure 1.

Braids are notably important in knot theory, as any link can be represented as the closure of a braid [1]. Knots have been studied extensively under the algorithmic lens. A famous problem is the computational complexity of recognizing the *trivial knot* from an input diagram, which is known to be in the complexity classes **NP** [19] and **coNP** [24], for which the best known worst case algorithm is exponential [19], but which experimentally exhibits a fast polynomial time behavior [11] with optimized implementation. In particular, the experimental aspects of computational knot theory play a fundamental role in the field, where mathematicians and computer scientists use efficient software, such as `Regina` [6, 9] and `SnapPy` [12], as well as computer-constructed census of knots [8], to guess and challenge profound conjectures, *e.g.*[5, 14, 16]. Consequently, an important side of computational knot theory is the design and implementation of fast, highly optimized algorithms.

Motivated by a finer understanding of the complexity of problems related to knots as well as practically fast computation, a recent route of research uses tools from *parameterized complexity* to compute *topological invariants* of knots. This approach has been particularly successful for invariants constructed via *quantum topology*, a field of topology using tools from quantum mechanics. In particular, the *treewidth* of a graph is a parameter measuring how close the graph is to a tree and, similarly, the *pathwidth* measures the proximity to a path. They can be extended to knot theory by considering the graph obtained from a diagram by putting a vertex on each crossing and an edge for each strand connecting crossings.

These are important parameters capturing a certain notion of sparsity of the input, and they can be combined with algorithmic techniques such as *dynamic programming* to design algorithms whose complexity depends exponentially on the tree/pathwidth and only polynomially in the size of the input: in quantum topology, such algorithms have been designed for the Jones and Kauffman polynomials [27], the Reshetikhin-Turaev invariants [28], and the HOMFLY-PT polynomial [7], which are **#P-hard** to compute in general [23]. Note that these quantum invariants, together with theoretically and practically fast algorithms, have been applied to construct knot censuses [8].

Contrary to knots, braids on n-strands have a natural algebraic description as a group, the *braid group* B_n, yielding rich algebraic properties that we exploit heavily in the following.

Our results. The goal of this article is to describe fast algorithms and data structures for braids and the braid group, related to quantum topology, and to apply them to computational knot theory and experimental mathematics. As opposed to algorithms on knots mentioned above, these algorithms rely heavily on the algebraic structure of the braid group.

Our starting point is to consider the *Hecke representation* of a braid. The *Hecke algebra* $\mathcal{H}_n$ is a fundamental concept in modern mathematics [30], deeply connected to group theory, number theory, and knot theory. The braid group B_n admits a representation into the Hecke algebra $\mathcal{H}_n$, *i.e.*, a map $B_n \to \mathcal{H}$ respecting the group structure. Knowing whether this map (with $\mathbb{Z}$-coefficients) is *faithful* (*i.e.*, only the trivial braid has a trivial image) is a major open question [35, 21, 25, 4], related to the detection of the unknot by the Jones polynomial [20].

Our algorithm scans an input braid diagram from bottom to top, and updates its representation in a basis of $\mathcal{H}$. This strategy was already used by Morton and Short in the 80's [32]; the program we wrote can be seen as an optimized and parallelized version of theirs.

▶ **Theorem 1** (see Theorem 10). *Given a braid $b \in B_n$ on n strands and with N crossings, there is an algorithm to compute its Hecke representation in $O(n!(n \log n) \times N)$ operations and $O(n! \times N)$ algebraic operations, storing at most $n! + O(1)$ algebraic elements over the computation.*

Every knot or link can be obtained from the braid closure of a braid [1]; see Figure 1. Additionally, the HOMFLY-PT polynomial of the knot/link obtained from the braid closure can be computed from the Hecke representation of the braid by taking a *trace*. This is an alternative, more algebraic approach, to the usual definition of quantum invariants used in parameterized algorithms in the literature, relying either on *state sums* [10], *tensor networks* [28], or skein relations [7]. Here, we exploit the rigidity provided by the algebraic or representation-theoretic point of view to design more efficient algorithmic processes. In particular, the morphism spaces between representations are of much lower dimension than those between the underlying vector spaces, which helps reducing the algorithmic complexity.

We describe a fast implementation of the trace operation in the single pass of the coordinate vector representing the Hecke element associated to the braid.

▶ **Theorem 2** (see Theorem 19). *Given a braid $b \in B_n$ with m crossings, there is an algorithm to compute its HOMFLY-PT polynomial with the same complexity as Theorem 1.*

We compare experimentally this algorithm against Burton's implementation [7, 9] on large families of braid closures, and demonstrate its practical interest.

Finally, we use these fast implementations in experimental mathematics, running an extensive search for counter-examples to the Hecke faithfulness question in the case of Hecke representation with $\mathbb{Z}/p\mathbb{Z}$ coefficients.

Taking inspiration from earlier works [2, 3, 18], we have implemented a random algorithm to find counter-examples to faithfulness in the braid groups B_4 and B_5, for different coefficients $\mathbb{Z}/p\mathbb{Z}$. Exploiting the favorable algebraic properties of braids, we have used *Garside theory* to generate increasingly complicated, non-trivial, braids for the search, running on each of them the algorithm from Theorem 10 in order to find braids whose Hecke representation was getting increasingly close to the trivial one. We have found explicit non-trivial braids in B_4 whose Hecke image is trivial in coefficients $\mathbb{Z}/2\mathbb{Z}$, $\mathbb{Z}/3\mathbb{Z}$ and $\mathbb{Z}/4\mathbb{Z}$. The non-faithfulness of the Hecke representation was known abstractly in these cases, using the explicit decomposition into simpler representations [21, Sections 5.7, 8.5], but our algorithm provides an efficient way to find examples of elements in the kernel. Similarly, we have explicitly found a non-trivial braid in B_5 whose Hecke image modulo 2 is trivial, while the status of the faithfulness of the Hecke representation of B_5 only relies on embedding B_4 into B_5.

The code is available as part of the `KumQuAT` library [36].

Comparison with the literature. The HOMFLY-PT polynomial is a powerful topological invariants, and its computation has attracted the attention of mathematicians. For a knot diagram with N crossings, Kauffman gave a fast $O(2^N)$ skein template algorithm [22]. More recently, starting from Kauffman's work, Burton [7] designed the first fixed parameter tractable algorithm in the treewidth of the knot diagram, running in $O((2\,\mathrm{tw})!^4 \cdot \mathrm{poly}(N))$, and implemented it in the software `Regina` [9]. This complexity bound should be compared to our bound from Theorem 1.

While treewidth, over all possible diagrams of a knot, is a generally smaller parameter than the braid index, it is common for them to be essentially equal, and the diagrams minimizing the treewidth are braid closures ; this is the case for *torus knots* for example [34, 26]. On the other hand, the complexity dependence of our algorithm in the number of strands is much lower than Burton's dependence in the treewidth, which proves an advantage in practice on particular families of examples where treewidth and braid index are close.

Our approach to find counter-examples to the faithfulness of the Hecke representation is inspired from recent works [18] in computational mathematics, which have used a combination of curve-based random search with Garside theory to study the faithfulness of the *Burau representation* of the braid group, and in particular to find braids with trivial representations. However, the Burau representation of a braid is significantly less costly to compute, with a (small) polynomial dependence in both number of strands and number of crossings, while all known algorithms for the HOMFLY-PT polynomial, including this work, have a super-exponential dependence in the number of strands.

2 Preliminaries

2.1 Permutations and compact encoding

The *symmetric group* Σ_n is the group of permutations of n elements $\{1, \dots, n\}$. The group Σ_n is generated by the *transpositions*, *i.e.*, the permutations s_i of the two consecutive elements at index i and $i+1$, for $1 \leq i \leq n-1$. Every permutation $w \in \Sigma_n$ can be represented either by a unique *one-line word* $w(1)w(2)\cdots w(n)$, where $w(i)$ is the image of i under the permutation w, or by a non-unique product of generators $w = s_{i_k} \cdots s_{i_1}$.

An *inversion* in a permutation w is a pair of indices (i, j) such that $i < j$ and $w(i) > w(j)$. The *(Coxeter) length* of a permutation w, denoted by $\ell(w)$, is its total number of inversions.

The *Lehmer code* $L(w)$ of a permutation $w = w(1)w(2)\cdots w(n)$ is the sequence of positive integers $L(w) := (L(w)_1, \dots, L(w)_n)$ such that:

$$L(w)_i := \#\{j > i : w(j) < w(i)\},$$

i.e., $L(w)_i$ counts the number of inversions happening to the right of index i. In particular, $0 \leq L(w)_i \leq n - i$. Permutations are in bijection with their Lehmer code.

This last property allows us to represent a permutation with a single number, using the *factorial number system*. Specifically, given a sequence of numbers $\mathbf{a} = (a_1, \dots, a_n)$ such that $0 \leq a_i \leq n - i$ for all i, one can write uniquely the sequence as a single positive integer:

$$(a_1, \dots, a_n) \to F_{\mathbf{a}} = \sum_{i=1}^{n} a_i \times (n-i)! \tag{1}$$

In particular, the application $\Sigma \to \{0, \dots, n! - 1\}$ sending $w \mapsto F_{L(w)}$ is a bijection. In the following, we call the number $F_{L(w)}$ the *index of the permutation* w.

We prove, in the long version [29], the following basic facts about the encoding:

▶ **Lemma 3.**

(i) *Given an index $F_{L(w)} \in \{0, \dots, n!-1\}$, there is an $O(n \log n)$ time algorithm to compute a one-line word presentation of w,*

(ii) *Given a permutation w represented as a one-line word $w(1) \cdots w(n)$, there is an $O(n \log n)$ time algorithm to compute its index $F_{L(w)}$,*

(iii) *Let $w, w' \in \Sigma_n$ be permutations, then:*

$$w(1) \cdots w(n) \leq_{\text{lex}} w'(1) \cdots w'(n) \text{ iff } F_{L(w)} \leq F_{L(w')},$$

where $\leq_{\text{lex}}$ denotes the lexicographic order.

2.2 Braids and Garside structure

We consider B_n the braid group on n strands:

$$B_n = \left\langle \sigma_1, \dots, \sigma_{n-1} \;\middle|\; \begin{cases} \sigma_i \sigma_{i+1} \sigma_i = \sigma_{i+1} \sigma_i \sigma_{i+1} \\ \sigma_i \sigma_j = \sigma_j \sigma_i \text{ if } |i-j| > 1 \end{cases} \right\rangle.$$

The generators $\{\sigma_i^{\pm 1}\}_i$ are called the *Artin generators* of the braid group. The monoid with the same presentation, *i.e.*, generated by the $\{\sigma_i^{+1}\}_i$, is denoted by B_n^+.

For some of our applications, we are interested in producing braids that we want to make sure get more and more complicated. The notion of Garside structure is instrumental, by providing us with an algorithmic-friendly normal form. We very briefly review the most important aspects, but refer to [13] for details.

Let us denote $[1, \Delta]$ the braids that realize positive lifts (that is, in B_n^+) of reduced words from the symmetric group. For example, $s_1 s_2 s_1 = s_2 s_1 s_2 \in \Sigma_n$ lifts to $\sigma_1 \sigma_2 \sigma_1 = \sigma_2 \sigma_1 \sigma_2 \in B_n$. It is a classical result that the map is well-defined (independent on the choice for the starting word). The half-twist $\Delta = \sigma_1 \cdots \sigma_{n-1} \sigma_1 \cdots \sigma_{n-2} \cdots \sigma_1$ is the so-called *Garside element*. One has a lattice structure [17, 13] on $[1, \Delta]$, extending to B_n^+, with left divisibility given by:

$$b_1 \leq_L b_2 \;\Leftrightarrow\; \exists b_3 \in B_n^+,\; b_1 b_3 = b_2.$$

Similarly, one can define a notion of right divisibility, $\leq_R$. We are now ready to obtain the normal form $b_k \cdots b_1$ of a braid $b \in B_n^+$ by inductively defining:

$$b_i := \sup\{b' \in [1, \Delta],\; b' \leq_R (b b_1^{-1} \cdots b_{i-1}^{-1})\}.$$

If one adds the fact that any braid $b \in B_n$ can be written as $\Delta^r b^+$ with $b^+ \in B_n^+$, then one has a preferred expression for any braid.

At some point, we will be interested in using the Garside normal form to generate complicated braids. This will be made algorithmic thanks to the following lemma.

▶ **Lemma 4.** *The word $b_k \cdots b_1$ with $b_i \in [1, \Delta]$ is under normal form if and only if the following condition holds:*

$$\forall i \geq 2, \forall j, \quad \sigma_j \leq_R b_i \Rightarrow \sigma_j \leq_L b_{i-1}.$$

The divisibility in $[1, \Delta]$ being controlled by Σ_n, the computations can be made in the symmetric group. More details about the underlying automaton appear in Section 5.3.

2.3 Hecke algebra

The Hecke algebra is an ubiquitous object in representation theory. We introduce it as a quotient of the braid group, which makes it most natural for the computations we care about, and we refer to [29] and to Mathas' book [30] for further details and context.

▶ **Definition 5.** *Let $\mathcal{H}_n$ be the $\mathbb{Z}[q^{\pm 1}]$ module obtained from the group algebra of the braid group as follows:*

$$\mathcal{H}_n = \frac{\mathbb{Z}[q^{\pm 1}][B_n]}{\langle (\sigma_i - 1)(\sigma_i + q^2) \rangle}$$

We denote by $\psi : B_n \to \mathcal{H}_n$ the natural induced map. We quickly review some useful basic properties of the Hecke algebra that will be instrumental to us.

▶ **Lemma 6.** *Denote by T_{s_i} the image of the i-th generator $\sigma_i \in B_n$. Then there is a* well-defined *map (of sets):*

$$\Sigma_n \to \mathcal{H}_n \qquad\qquad s = s_{i_1} \cdots s_{i_k} \mapsto T_s := T_{s_{i_1}} \cdots T_{s_{i_k}}.$$

Furthermore the image $\{T_s\}_{s \in \Sigma_n}$ is a basis of the Hecke algebra as a $\mathbb{Z}[q^{\pm 1}]$-module.

The content of the above lemma is that the image of s does not depend on the word chosen to write it. This is simply because the T_s satisfy the same braiding relations as the elements in the symmetric group. To our eyes, the key property is that we have a basis indexed by permutations, which can be efficiently handled. For computation purposes, we also take advantage of the fact that the structure constants of this basis are quite simple, as expressed in the following classical lemmas [30, Theorem 1.11].

▶ **Lemma 7.**

$$\forall w \in \Sigma_n,\ \forall i,\ T_{s_i} T_w = \begin{cases} T_{s_i w} & \text{if} \quad \ell(s_i w) > \ell(w); \\ (1-q^2)T_w + q^2 T_{s_i w} & \text{if} \quad \ell(s_i w) < \ell(w). \end{cases}$$

▶ **Lemma 8.**

$$\forall w \in \Sigma_n,\ \forall i,\ T_{s_i}^{-1} T_w = \begin{cases} (1-q^{-2})T_w + q^{-2} T_{s_i w} & \text{if} \quad \ell(s_i w) > \ell(w); \\ T_{s_i w} & \text{if} \quad \ell(s_i w) < \ell(w). \end{cases}$$

When we compute knot invariants, it is convenient to take braid closures of braids. Assuming that P is a knot invariant, it is clear that $P(\widehat{b_1 b_2}) = P(\widehat{b_2 b_1})$. This remark motivates the introduction of an intermediary object $\mathrm{Tr}(\mathcal{H}_n)$ which is obtained from $\mathcal{H}_n$ by formally adding the relation $b_1 b_2 = b_2 b_1$. This makes it possible to break the computation into a first step $\mathcal{H}_n \to \mathrm{Tr}(\mathcal{H}_n)$, where elements are reduced as much as possible using the trace relation $b_1 b_2 = b_2 b_1$, before using information about the specific invariant we want to compute to go from $\mathrm{Tr}(\mathcal{H}_n)$ to $\mathbb{Z}[q^{\pm 1}]$. Note that because $\psi \colon B_n \to \mathcal{H}_n$ is a representation, for any two braids $b_1, b_2 \in B_n$, we have $\mathrm{Tr}(\psi(b_1 b_2) = \mathrm{Tr}(\psi(b_1)\psi(b_2)) = \mathrm{Tr}(\psi(b_2)\psi(b_1)) = \mathrm{Tr}(\psi(b_2 b_1))$.

Finally, when searching for counterexamples, we measure how far an element of $\mathcal{H}_n$ is from the identity. We use the following notion, that we adapt from [18].

▶ **Definition 9.** *Let $x = \sum_w a_w T_w \in \mathcal{H}_n$. We define its* projective length*:*

$$\mathrm{projlength}(x) = \max\{\deg(a_w),\ w \in \Sigma_n\} - \min\{\mathrm{val}(a_w),\ w \in \Sigma_n\},$$

where deg *and* val *are the degree and valuation of a Laurent polynomial in the variable q.*

Most of the notions we have defined here enjoy similar definitions with $\mathbb{Z}/p\mathbb{Z}$ in place of $\mathbb{Z}$. We use this context in Section 5.

3 Computing the Hecke representation of the braid group

The goal of the algorithm is to compute the image $\psi(b)$ in the Hecke algebra $\mathcal{H}_n$ of a braid $b = \sigma_{i_c}^{\epsilon_c} \cdots \sigma_{i_1}^{\epsilon_1} \in B_n$, given as an expression of the braid in the generators $\{\sigma_i\}$ of B_n.

Our algorithm is iterative, and maintains at step j the image in $\mathcal{H}_n$ of the braid $b_{(j)} := \sigma_{i_j}^{\epsilon_j} \cdots \sigma_{i_1}^{\epsilon_1}$, made of the first j crossings of the input braid.

3.1 Data structure and initialization

For a braid in B_n, we represent its image in $\mathcal{H}_n$ by an array of coordinates (Laurent polynomials) in the basis $\{T_w\}$. Specifically, a vector $x = \sum_{w\in\Sigma_n} a_w T_w \in \mathcal{H}_n$, with $a_w \in \mathbb{Z}[q^{\pm 1}]$, is represented by a length $n!$ array `hecke`, such that `hecke`$[j] = a_w$ whenever the permutation w has index $F_{L(w)} = j$.

Recall that the one-line word $w(1)\cdots w(n)$ of a permutation w, and its index $F_{L(w)}$ can be obtained from one another in $O(n \log n)$ operations. Note also that the maximal value $n! - 1$ of an index is below 2^{64} when $n \leq 20$, which will always be the case in this article ; permutation indices are stored as standard integers.

The image of σ_{i_1} is $T_{s_{i_1}} \in \mathcal{H}_n$, and Lemma 8, shows that the image of $\sigma_{i_1}^{-1}$ is $q^{-2}T_{s_{i_1}} + (1 - q^{-2}) \in \mathcal{H}_n$. Consequently, if $\epsilon_1 = 1$, at the initialization, only the coefficient corresponding to s_{i_1} is 1, all other ones being 0. If $\epsilon_1 = -1$, then we have the coefficient $1 - q^{-2}$ at index 0, q^{-2} at the index representing s_{i_1}, and 0 elsewhere.

3.2 Inductive step

We suppose that at the beginning of step j of the algorithm, `hecke` stores the coordinates of the image of $\sigma_{i_{j-1}}^{\epsilon_{j-1}} \cdots \sigma_{i_1}^{\epsilon_1}$, that we update with the next generator $\sigma_{i_j}^{\epsilon_j}$.

Since ψ is a group homomorphism, we have $\psi(b_{(j)}) = T_{\sigma_{i_j}}^{\epsilon_j} \psi(b_{(j-1)})$. We consequently need to update the coordinates of `hecke` following the local relations described in Lemmas 7 and 8. We do so in the single pass through `hecke`, without allocating more than $O(1)$ Laurent polynomials in memory:

Algorithm 1 From `hecke` representing $\psi(b_{(j-1)})$ to representing $\psi(b_{(j)})$.

for $i \leftarrow 0$ **to** $n! - 1$ **do**
  compute w such that $F_{L(w)} = i$;
  if $\ell(s_{i_j} w) > \ell(w)$ **then**
    set $\text{idx}_w \leftarrow F_{L(w)}$; $\text{idx}_{s_{i_j} w} \leftarrow F_{L(s_{i_j} w)}$; $a_w \leftarrow$ `hecke`$[\text{idx}_w]$;
     $a_{s_{i_j} w} \leftarrow$ `hecke`$[\text{idx}_w]$;
    if $\epsilon_j = +1$ **then**
      set `hecke`$[\text{idx}_w] \leftarrow q^2 a_{s_{i_j} w}$; set `hecke`$[\text{idx}_{s_{i_j} w}] \leftarrow a_w + (1 - q^2) a_{s_{i_j} w}$;
    end
    else
      set `hecke`$[\text{idx}_w] \leftarrow (1 - q^{-2}) a_w + a_{s_{i_j} w}$; set `hecke`$[\text{idx}_{s_{i_j} w}] \leftarrow q^{-2} a_w$;
    end
  end
end

3.3 Correctness

The correctness of the initialization phase is guaranteed by Lemmas 7 and 8. We focus on the inductive step. Consider any permutation $w \in \Sigma$. According to Lemmas 7 and 8, both $T_{s_{i_j}}^{\pm 1} T_w$ and $T_{s_{i_j}}^{\pm 1} T_{s_{i_j} w}$ give linear combinations of T_w and $T_{s_{i_j} w}$, because $s_{i_j}(s_{i_j} w) = w$. Additionally, for any permutation $w' \notin \{w, s_{i_j} w\}$, the product $T_{s_{i_j}}^{\pm 1} T_{w'}$ contains no term T_w or $T_{s_{i_j} w}$. Thus the pair of coordinates of `hecke` corresponding to permutations w and $s_{i_j} w$ can be updated independently from the rest of the array, and their new values is a combination of their previous values. We update them at once in the core of the (outer) `if` loop of Algorithm 1.

Finally, the condition of the (outer) `if` loop guarantees that we proceed to the update once. Indeed, the length ℓ being the number of inversions, we have $\ell(s_{i_j} w) \in \{\ell(w) - 1, \ell(w) + 1\}$. In consequence, considering the two permutations w and $(s_{i_j} w)$, multiplying by s_{i_j} exactly increases the length once and decreases the length once.

In light of the above, the induction algorithm does compute $\psi(b_{(j)})$ from $\psi(b_{(j-1)})$ and, at the end of the algorithm, we are left with $\psi(b) = \sum_{w \in \Sigma_n} a_w T_w$.

3.4 Complexity

▶ **Theorem 10.** *Given $b \in B_n$ represented by N generators (N crossings), the algorithm above computes the Hecke representation $\psi(b) = \sum_{w \in \Sigma_n} a_w T_w$ in $O(n!(n \log n) \times N)$ operations and $O(n! \times N)$ algebraic operations in $\mathbb{Z}[q^{\pm 1}]$, storing at most $n! + O(1)$ Laurent polynomials in memory over the computation.*

Proof. The initialization of the vector `hecke` requires $O(n!)$ operations, and parsing the first crossing requires $O(n \log n)$ operations to convert permutations into their indices, and $O(1)$ arithmetic operations in $\mathbb{Z}[q^{\pm 1}]$ to initialize a constant number of entries in `hecke`. The induction step reads the array `hecke` (of length $n!$) once, and every time converts a constant number of permutations into their indices ($O(n \log n)$) and performs at most $O(1)$ operations in $\mathbb{Z}[q^{\pm 1}]$. Finally, we run the induction exactly n times. ◀

▶ Remark 11. Note that the algorithm above is rather simple, and the constant hidden by the big-O notation is rather small. This matters for running times in practice ; see Section 4.3.

▶ Remark 12. Note that the main **for** loop of Algorithm 1 can be naturally parallelized, considering that pairs of indices in `hecke`, corresponding to permutations w and $s_{i_j} w$, where s_{i_j} is the transposition corresponding to the new braid generator $\sigma_{i_j}^{\epsilon_j}$, are treated independently from other entries. We use a parallel and a non-parallel implementation of the **for** loop in Section 4.3.

4 Computing the HOMFLY-PT polynomial

4.1 The HOMFLY-PT polynomial

The HOMFLY-PT polynomial [15, 33] is a famous 2-variable knot invariant, that can be specialized to both the Jones polynomial and the Alexander polynomial. If one starts from a knot presented as a braid closure $\widehat{b}$ (see Figure 1), then, up to renormalization, the invariant is computed by taking a trace of the image of the braid b in the Hecke algebra. We now make this more precise, and we refer to the long version [29] for another presentation of the invariant.

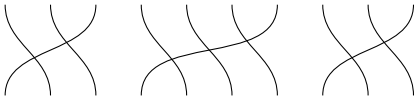

Figure 2 An annularly reduced element in Σ_{10}.

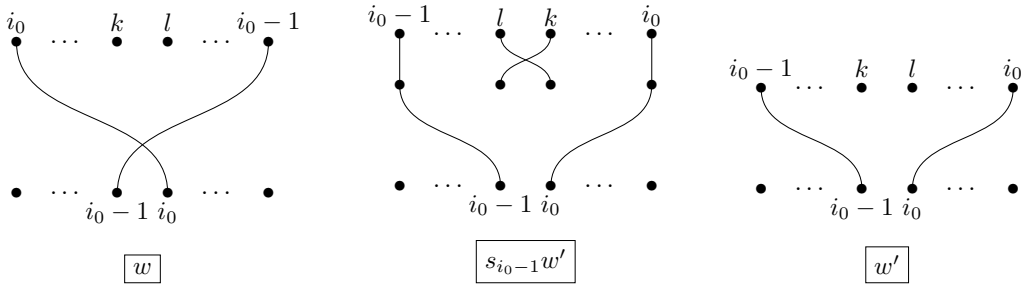
As in Section 3, we start from a braid $b = \sigma_{i_c}^{\epsilon_c} \cdots \sigma_{i_1}^{\epsilon_1}$, and pre-compute the array `hecke` encoding the Hecke representation $\psi(b) = \sum_{w \in \Sigma_n} a_w T_w$ with the algorithm of Theorem 10.

Our strategy is to simplify, in a single pass through `hecke`, the entries of the array, using the defining property of the trace, *i.e.*, $\mathrm{Tr}(\psi(bb')) = \mathrm{Tr}(\psi(b'b))$ for b, b' braids in B_n. We do not simplify the array all the way down, but instead only keep entries corresponding to permutations w with a simple form (called *annularly reduced*), and for which we know how to compute the participation to the final HOMFLY-PT polynomial.

Before describing the algorithm, we introduce some definitions and lemmas.

▶ **Definition 13.** *An element $w \in \Sigma_n$ is said to be* annularly reduced *(see Figure 2) if it is a product of disjoint cycles r_i so that:*

- *r_i has support $(j_i, j_i + 1, \cdots, j_i + l_i)$ for some j_i and l_i;*
- *$r_i = (j_i + l_i, j_i, j_i + 1, \cdots, j_i + l_i - 1)$.*



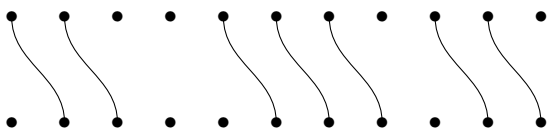
Our algorithm reduces braids to annularly reduced ones, using the following lemma.

▶ **Lemma 14.** *Consider $w \in \Sigma_n$, and define, if it exists:*

$$i_0 := \min\{i \mid w(i) < w(i) - 1\}.$$

Then $s_{i_0-1} w s_{i_0-1}$ and $w s_{i_0-1}$ are lower than w in the lexicographic order.

Proof. We first argue that $w = w' s_{i_0-1}$ as a reduced word. Indeed, from the definition of i_0, $w(i_0 - 1) \geq i_0 - 2$ and thus $w(i_0 - 1) \geq w_{i_0}$. The relative order of $i_0 - 1$ and i_0 is exchanged under w and thus $w = w' s_{i_0-1}$ with $\ell(w) = \ell(w') + 1$. We are thus in the following situation:



In both cases the lexicographic order gets lowered. ◀

The second piece of argument we need is the following one.

▶ **Lemma 15.** *If $w \in \Sigma_n$ is so that $w(i) \geq i - 1$ for all i, then w is annularly reduced.*

Proof. One first considers only the strands that move to the left. By hypothesis, those can only move one step to the left:

We are left with relating free ends with strands that can only go straight up or right. There is a unique solution, that consists of pairing the leftmost free end at the bottom with the leftmost free end at the top, and so on, which yields an annularly reduced element. ◀

We refer to the long version [29] for a precise definition of the HOMFLY-PT polynomial P. For our purpose, it suffices to say that the polynomial $P(\widehat{b})$ can be obtained from the vector `hecke` by:

- reducing the vector `hecke` in $\mathrm{Tr}(\mathcal{H}_n)$ using trace moves $b_1 b_2 = b_2 b_1$. This leaves us with $\sum_{w\in\mathcal{A}} a'_w T_w$ where $\mathcal{A}$ denotes the set of annularly reduced words in Σ_n from Definition 13;
- evaluating annularly reduced elements on $\prod_i (a^{1-l_i} q^{l_i-1} \frac{a-a^{-1}}{q-q^{-1}})$ (with the notations of Definition 13). See [29] for a justification.

4.1.1 Simplifying the trace

We now want to simplify the vector `hecke` in a trace process. Given a basis element T_w, we want, when possible, to simplify its image $\mathrm{Tr}(T_w) \in \mathrm{Tr}(\mathcal{H}_n)$. We do that by ordering elements in w by the lexicographic order $\leq_{\mathrm{lex}}$ of their one-line word $w(1)\cdots w(n)$, so that the simplification can be achieved in one scan through the set $\{T_w\}_{w\in\Sigma_n}$.

▶ Remark 16. Two elements that are annularly reduced might still be conjugate: the order of the cycles can be permuted. This results in keeping more non-zero entries in the vector we consider than necessary, but has the advantage of yielding a particularly simple algorithm.

We traverse the array `hecke` from right to left, *i.e.*, considering permutations w with *decreasing* position in lexicographic order: for every such w,

1. look for the first i_0 so that $w(i_0) < i_0 - 1$.
2. If there is no such i_0 then w is already annularly reduced (Lemma 15).
3. Otherwise it can be written $w = w' s_{i_0-1}$. Replace T_w by $T_{i_0-1} T'_w$ which expresses as a single or a sum of two basis elements (Lemma 7). In both cases, the elements that appear are strictly lower in the lexicographic order (Lemma 14), and the coefficient of $T_{i_0-1} T'_w$ is removed and added to entries of `hecke` to the left of w.

4.1.2 Evaluating the polynomial

We now are left with $v = \sum_{w\in\mathcal{A}} a'_w T_w$. The result we are looking for is:

$$P(\widehat{b}) = \sum_{w\in\mathcal{A}} a'_w P(\widehat{b_w}) \text{ (b_w is the positive lift of } w \in B_n).$$

The value for $P(\widehat{b_w})$ above is recorded in the following lemma.

▶ **Lemma 17.** *The HOMFLY-PT polynomial of an annularly reduced braid with cycles of lengths $l_1, \cdots, l_k$ is $\prod_{i=1}^{k} (a^{1-l_i} q^{l_i-1} \frac{a-a^{-1}}{q-q^{-1}})$.*

Proof. The computation consists of taking the product of each cycle value, as computed in the long version [29]. ◀

The last step of the algorithm thus consists in replacing T_w by the product of the values of the HOMFLY-PT polynomial on the cycles of T_w, and taking the sum for all w's, in a single pass through the array `hecke`.

4.2 Complexity and correctness

The correctness of the algorithm is guaranteed by the diverse lemmas proved along the way.

▶ **Theorem 18.** *Let* `hecke` *be the vector of (Laurent polynomials) coordinates of the Hecke representation of a braid $b \in B_n$, expressed in the $\{T_w\}_w$ basis. Given* `hecke`*, evaluating the HOMFLY-PT polynomial of b takes $O(n!(n \log n))$ operations and $O(n! \cdot n)$ algebraic operations, storing at most $n! + O(1)$ algebraic elements over the computation.*

Proof. Recall from Section 4.1.1 that we reduce the vector to only keep annularly reduced elements in a single pass on the array `hecke` of length $n!$. Computing w from its index and finding the first i_0 so that $w(i_0) < i_0 - 1$ takes $O(n \log n)$ operations. Then one finds w' so that $w = w' s_{i_0-1}$. This amounts to computing $w s_{i_0-1}$, which costs $O(1)$ operations. Then computing $T_{i_0-1} T_{w'}$ costs two multiplications in $\mathbb{Z}[q^{\pm 1}]$. In total, for this phase, we use $O(n! n \log n)$ combinatorial operations and $O(n!)$ arithmetic operations in $\mathbb{Z}[q^{\pm 1}]$.

Finally, thanks to Lemma 17, if suffices to know the number of cycles and their lengths to evaluate an annularly reduced element in $O(n)$ arithmetic operations in $\mathbb{Z}[q^{\pm 1}]$ at most (there are at most n disjoint cycles). Identifying cycles and their lengths is done directly by reading the one-line word of a permutation w ($O(n \log n)$ operations to compute the one-line word from w's index, then $O(n)$ to identify cycles), yielding a last step in $O(n! \cdot n \log n)$ combinatorial operations and $O(n! \cdot n)$ arithmetic operations in $\mathbb{Z}[q^{\pm 1}]$. Summing the complexity gives the theorem. ◀

▶ **Theorem 19.** *Given a braid $b \in B_n$ with N crossings, the above algorithm computes its HOMFLY-PT polynomial in $O(n!(n \log n) \times N)$ operations and $O(n! \times N)$ algebraic operations, storing $n! + O(1)$ algebraic elements.*

Proof. Summing the complexity of Theorem 10 and Theorem 18, all steps of the algorithm are covered; assuming $n \leq N$, Theorem 10 dominates the computation. ◀

4.3 Experimental performance

We have compared our code with the advanced `C++` library `Regina` [9], implementing Burton's state of the art algorithm [7] for the HOMFLY-PT polynomial. We have run our experiments on an 8 cores, 32Gb RAM computer; parallel implementations use the library `Intel::TBB`. We restrict our attention to braids whose closures lead to knots. The computation of the Hecke representation, which largely dominates the timings for our computation of the HOMFLY-PT polynomial, can be implemented in parallel, as described in Remark 12, while `Regina` does not admit a parallel implementation and the algorithm it implements may not parallelize as naturally as ours.

We have generated p-strands torus braids $T_{p,q}$ and p-strands weaving braids $W_{p,q}$, in their standard form (see Figure 3), keeping only those parameters q for which the closure is a knot. We have used them as is in our algorithm. `Regina` working with knot diagrams and treewidth, we have run simplification heuristics and the construction of the tree decomposition, before computing the HOMFLY-PT polynomial (and before starting the timer). However, for these knots, the braid presentation is expected to be minimal for both size and parameter.

In Figure 4 we compare the running time of our algorithm *not using parallelism*, against the algorithm from `Regina` for torus braids $T_{p,q}$ and weaving braids $W_{p,q}$, for $3 \leq p < 6$ and all values of $q = p + 1, \ldots, q_{\max}$, such that the closures of the braids lead to knots (*i.e.*, $\gcd(p, q) = 1$), with $q_{\max}$ picked such that the braids $T_{p,q_{\max}}$ and $W_{p,q_{\max}}$ have approximately

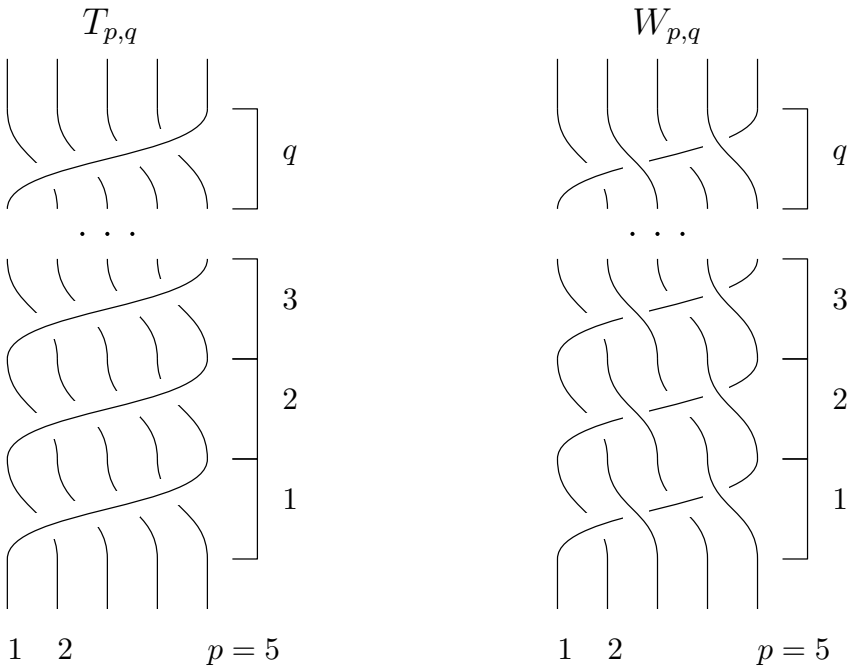


Figure 3 Torus braid $T_{p,q}$ and weaving braid $W_{p,q}$.

600 crossings. The results are very similar for torus and weaving braids, highlighting the fact that the running times depends mostly on the combinatorics of the input diagrams, and not so much on the algebraic computations. Our implementation consistently outperforms `Regina` on braids with more than 4 strands, by a factor ranging from 3 (shorter braids) to 9 (longer braids) for braids on 4 strands, a factor ranging from 3 to 4 for 5-braids.

In Figure 4, `Regina` is faster on the smaller 3-strands examples, by a factor 3 on shorter braids, and a smaller factor 1.3 on the larger braids ; all these timings are below 0.3 seconds, and may be explained by a slower initialization of data on our side. The global tendency is that our algorithm, even on its non-parallel form, gets better on longer braids (the slopes α of interpolating lines is $0.78 \leq \alpha \leq 0.8$ on all examples) and on braids with more strands.

On braids with ≥ 6 strands, `Regina` starts to `swap` due to excessive memory consumption, leading to impractical running times ; to the contrary, our implementation continues to be practical, Table 1 and see Figure 5 for much larger examples.

In Figure 5, we compare the performance of our implementation with and without parallelism. Recall that the parallelization is on the array `hecke` of length $n!$ (working with an n-strands braid). In consequence, we see the gain of parallelism increasing with the number of strands: first, the gain range from a factor 1.6 to 2.4 on 3-strands, from 3.3 to 4.54 4-strands, and from 3.8 to 6.25 on 5-strands. On braids with $6, 7, 8$-strands, the gain ranges between a factor 5 to 7.14, near the optimal 8 (on 8 cores); see Figure 5.

Finally, the memory consumption of our implementation is much more frugal than `Regina`, and remains very applicable for large number of strands. The memory cost depends mostly on the number of strands; however, for a fixed number of strands, longer braids tend to consume slightly more memory because the Laurent polynomials stored in the array `hecke` become more complicated; the memory consumption of longer braids is shown in Table 1).

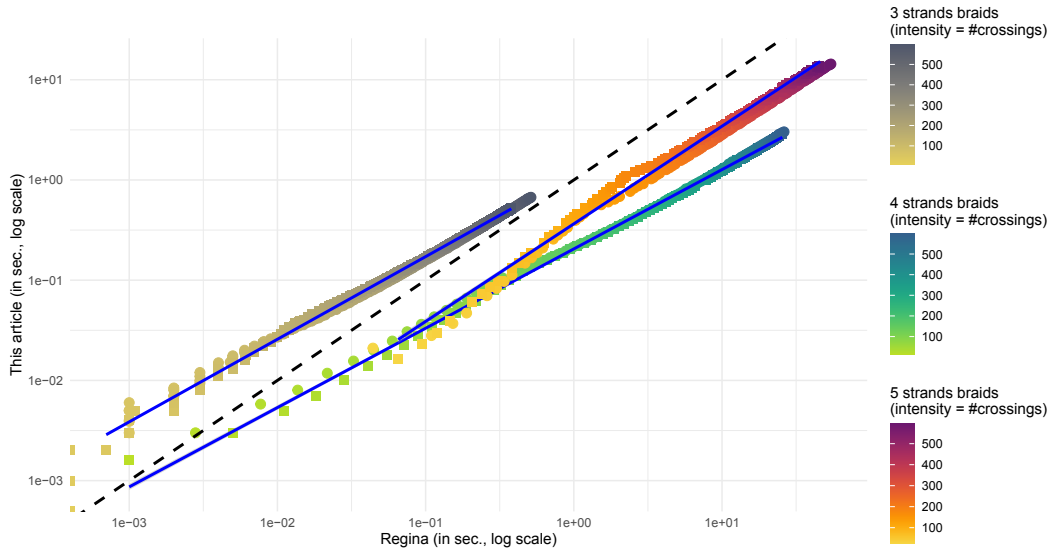

Figure 4 Timings of our algorithm (without parallelism) and `Regina`. Circle points represent torus braids, and square points represent weaving braids. The dashed line is $x = y$.

Table 1 Timing and peak memory usage of our algorithm using parallelism on large torus braids (similar results are found for weaving braids).

Braid	Num. of crossings	Timing parallel (8 cores)	Timing non-parallel	Peak memory
$T_{6,41}$	205	1.6 sec.	9.6 sec.	8.1 Mb
$T_{6,119}$	595	13.4 sec.	95.1 sec.	23.5 Mb
$T_{7,36}$	216	10.8 sec.	74 sec.	45.6 Mb
$T_{7,99}$	594	88.9 sec.	643 sec.	109 Mb
$T_{8,29}$	203	74.5 sec.	502 sec.	257 Mb
$T_{8,49}$	343	272 sec.	2265 sec.	435 Mb

In conclusion, our implementation is very competitive for knots represented by braids, even with a fairly large number of strands. It also combines very well with parallelism. We apply our parallel implementation in experimental mathematics in Section 5 to investigate algebraic properties of the Hecke algebra.

5 Proving the non-faithfulness of the Hecke representation in $\mathbb{Z}/m\mathbb{Z}$

With a bucket search procedure, coupled with the fast algorithm described in Section 3, we have been looking for non-trivial braids with trivial Hecke representation in several contexts.

Following [3, 18, 2], we generate a sample of non-trivial braids from B_n in Garside normal form, and store them in *buckets* of bounded size, one for each represented value of *augmented projlength* (see below). At iteration k of the search, the buckets store braids of Garside length k. For initialization, the Garside length 1 braids are in bijection with permutations in $\Sigma_n \setminus \{\mathrm{id}, \Delta\}$, and we store them in the buckets. Inductively, if we have generated a sample of Garside length k braids, we attempt to extend each of them into Garside length $k+1$ braids by appending an extra compatible Garside letter. Note that, when attempting to insert a new generated braid, we use a *reservoir sampling* [37] approach to guarantee that we extract an iid sample. In Section 5.3, we describe details on the optimized extension of

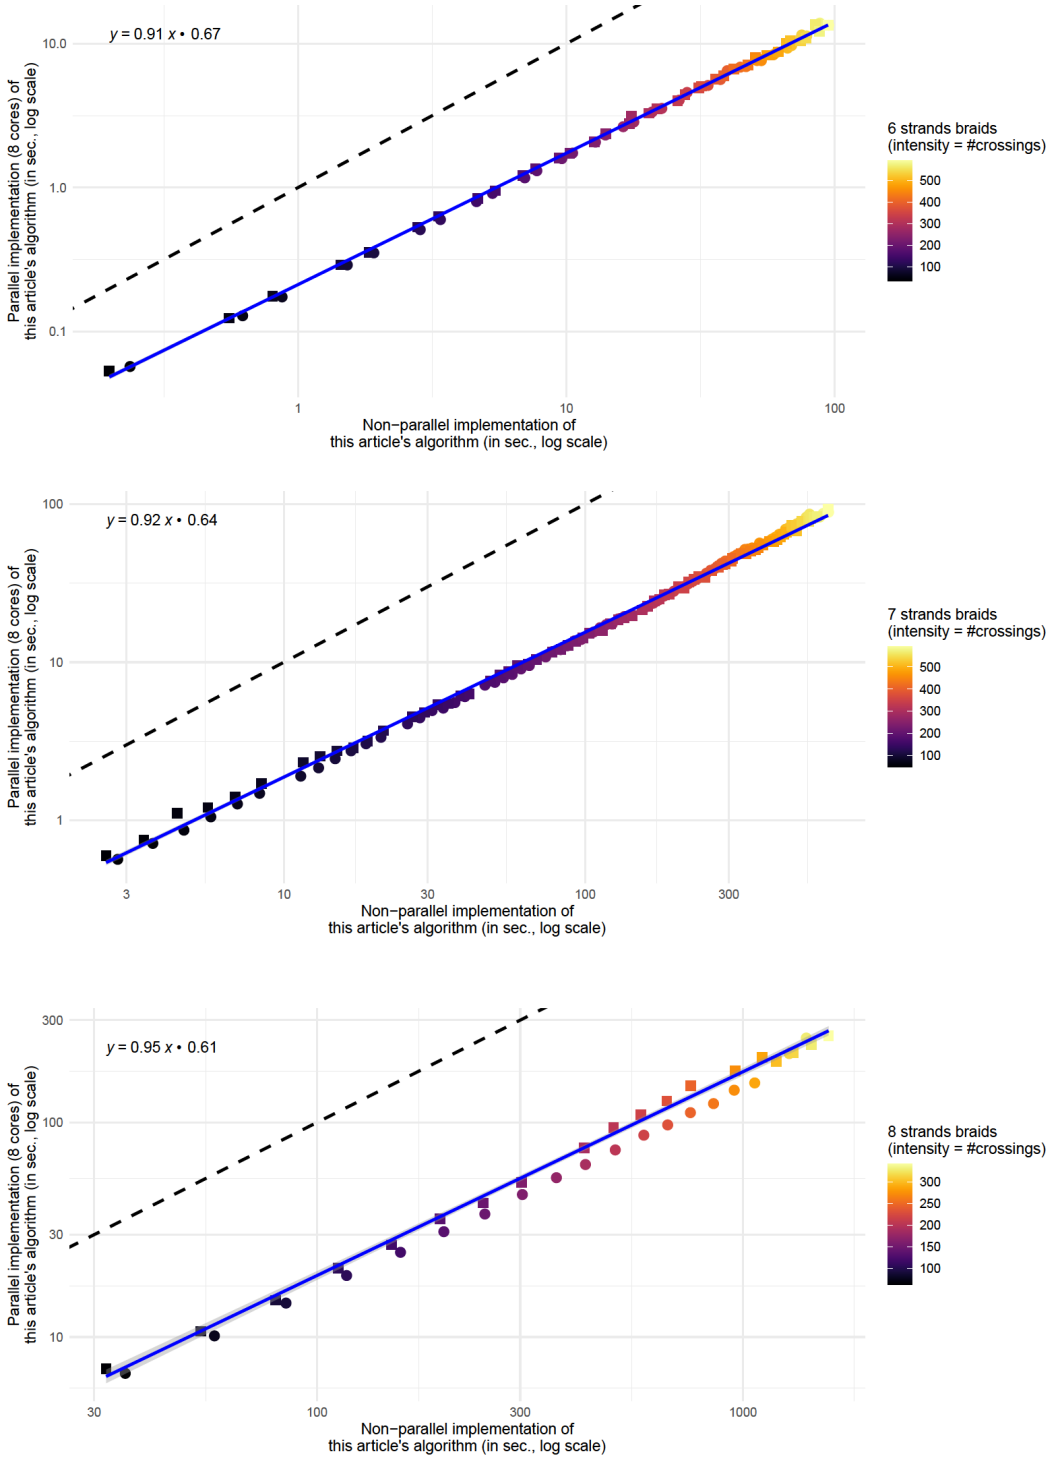

Figure 5 Timings of our algorithm with parallelism against our algorithm without parallelism. The interpolation line are near $x = y/7.14$ (we use 8 cores).

Garside normal forms we have implemented. In particular, we prove,

▶ **Lemma 20.** *Given a braid $b = b_k \dots b_1 \in B_n$ in Garside normal form, there is an $O(n \log n)$ algorithm to pick a Garside letter b_{k+1}* iid *among all Garside letters compatible with b_k.*

We define the *augmented projlength* of a positive braid b to be

$$\widehat{\text{projlength}}(b) : \sup_{k \leq 0}\{\text{projlength}(\psi(\Delta^k b))\},$$

and we try to minimize this quantity over the search. To avoid computing the projlength for infinitely many negative powers of Δ, we (heuristically) stop the computation of $\widehat{\text{projlength}}(b)$ when we encounter a power $k_0 < 0$ for which $\psi(\Delta^k b)$ has a coordinate with negative degree.

The bucket search algorithm, if successful, finds positive braids b (not of the form Δ^l) such that there exists of negative power k of Δ satisfying: $\Delta^k \cdot b$ has projlength $= 0$. In all cases where we found such braids, they had an image in the Hecke algebra (in the basis used from Lemma 6) with a single non-trivial coordinate idx equal to 1. This coordinate corresponding to the positive permutation s^{-1}, the braid $s^{-1} \cdot \Delta^k \cdot b$ has trivial Hecke representation.

We have run our searches in parallel on a cluster of 2 CPUs, 128 cores/CPU, and 1024GB RAM.

5.1 Non-faithful Hecke representations of B_4

The decomposition of $\mathcal{H}_4$ into irreducible B_4 representations only contains the Burau representation as possibly faithful summand. The latter being not faithful at $p = 2, 3, 5$ implies the same for the Hecke representation. We indeed found such counterexamples for $p = 2$ and 3, as well as with $p = 4$, that we present in the long version [29].

5.2 Non-faithful Hecke representations of B_5

The same search performed on B_5 with base ring $\mathbb{Z}/2\mathbb{Z}$ also yielded a counterexample to faithfulness. In this case, non-faithfulness follows by including the B_4 kernel into B_5. Here we could run a direct search in B_5 to find *explicit* counterexamples.

▶ **Theorem 21.** *The braid $s_9^{-1}\Delta^{-9}b$ is in the kernel of the Hecke representation of B_5 with coefficients in $\mathbb{Z}/2\mathbb{Z}[q^{\pm 1}]$, with:*

$$\begin{aligned} b =& \sigma_3\sigma_4\sigma_2\sigma_3\sigma_1\sigma_2\sigma_2\sigma_4\sigma_2\sigma_3\sigma_1\sigma_2\sigma_4\sigma_2\sigma_3\sigma_3\sigma_2\sigma_3\sigma_1\sigma_3\sigma_1\sigma_2\sigma_2\sigma_3\sigma_1\sigma_3\sigma_1\sigma_2\sigma_2\sigma_3\sigma_1\sigma_3\sigma_1\sigma_2\sigma_4\sigma_3 \\ & \sigma_2\sigma_3\sigma_4\sigma_1\sigma_4\sigma_3\sigma_2\sigma_1\sigma_2\sigma_3\sigma_4\sigma_4\sigma_3\sigma_2\sigma_3\sigma_1\sigma_2\sigma_3\sigma_3\sigma_2\sigma_3\sigma_4\sigma_1\sigma_2\sigma_3\sigma_4\sigma_4\sigma_3\sigma_4\sigma_2\sigma_1\sigma_2\sigma_3\sigma_3\sigma_4\sigma_2 \\ & \sigma_1\sigma_2\sigma_3\sigma_4\sigma_4\sigma_3\sigma_4\sigma_1\sigma_2\sigma_3\sigma_3\sigma_4\sigma_2\sigma_3\sigma_4\sigma_1\sigma_4\sigma_3\sigma_4\sigma_1\sigma_2 \\ s_9^{-1} =& \sigma_2^{-1}\sigma_3^{-1}\sigma_4^{-1}, \qquad \Delta^{-1} = \sigma_4^{-1}\sigma_3^{-1}\sigma_2^{-1}\sigma_1^{-1}\sigma_4^{-1}\sigma_3^{-1}\sigma_2^{-1}\sigma_4^{-1}\sigma_3^{-1}\sigma_4^{-1}. \end{aligned}$$

b is of Garside length 19*, and the resulting counterexample is a braid with* 186 *crossings.*

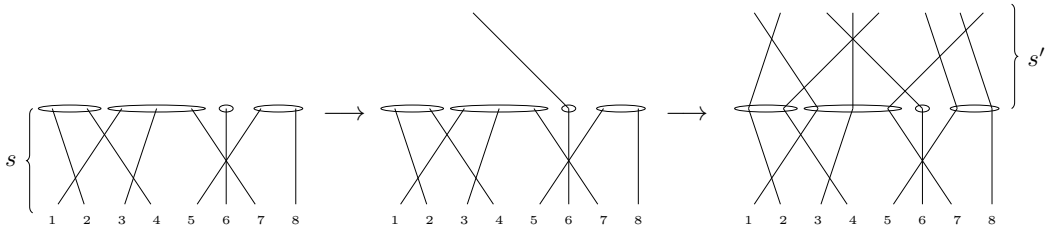
5.3 Garside automaton

To generate braids, we use the following finite state automaton.

▶ **Definition 22.** *Let* **Garside** *be the finite state automaton with:*

- *states, permutations s in Σ_n (or equivalently elements in $[1, \Delta]$);*
- *s'-labeled arrows $s \to s'$ if $\forall s_j \leq_R s'$ then $s_j \leq_L s$.*

We create increasingly complicated braids by applying to a Garside normal form $b_k \cdots b_1$ any (possibly randomly chosen) letter from $\mathbf{Garside}(b_k)$. The construction of the automaton can be made very efficient thanks to the following observation.



▶ **Lemma 23.** *Given $s = (s(1), \cdots, s(n))$ and $s' = (s'(1), \cdots, s'(n))$, s' can be applied at the state s if and only if the following property holds:*

$s' \neq \mathrm{id}$ *and* $\forall i \in [\![1, n]\!]$ *with* $s'(i) > s'(i+1),\ s^{-1}(i) > s^{-1}(i+1)$.

Proof. This restates the fact that right descents from s' need to be left descents of s. ◀

From a state s, we want to generate admissible arrows s'. All pairs $\{(i_r, i_r + 1) \mid \exists l < k,\ i_r = s(k),\ i_r + 1 = s(l)\}$ partition $[\![1, n]\!]$ into intervals $[\![i_r + 1, i_{r+1}]\!]$. Lemma 23 prevents two entries from the same interval to cross in s'. This suggests the following (see Figure 6):

- for length 1 intervals ($i_r + 1 = i_{r+1}$), freely choose $s'(i_r)$ in $[\![1, n]\!]$ (forming S_{free});
- images of the other intervals are disjoint ordered subsets of $[\![1, n]\!] \setminus S_{free}$. These choices can be made one interval at a time in any order. Starting from the first interval $[\![i_r + 1, i_{r+1}]\!]$ of length $p' > 1$, one chooses a random ordered subset $S_{p'}$ of p' elements in $[\![1, n - p]\!]$, and then decide that $s'(i_r + k)$ is the $S_{p'}(k)$-th element in $[\![1, n]\!] \setminus S_{free}$. Then one replaces S_{free} by $S_{free} \cup S_{p'}$ and goes to the next interval of size greater than 1.

Start from s. Choose S_{free}. Choose the other images so that no strands coming out of the same ellipse cross.

Figure 6 Generating descents.

A major advantage of the above construction is the following.

▶ **Lemma 24.** *Given a braid $b \in B_n$ in Garside normal form $b_k \dots b_1$, there is an $O(n \log n)$ algorithm to pick a Garside letter b_{k+1} iid among all Garside letters compatible with b_k.*

Proof. If one can make uniform random choices of p unordered elements in $[\![1, n]\!]$, and uniform random choices of p ordered elements in $[\![1, p']\!]$, then the procedure described above the lemma produces uniform choices in $\mathbf{Garside}(s)$. Picking iid random subsets can be done in time $O(n \log n)$ using, for example, a reservoir sampling algorithm. ◀

Abstract

We study the design of robust subexponential algorithms for classical connectivity problems on intersection graphs of similarly sized fat objects in $\mathbb{R}^d$. In this setting, each vertex corresponds to a geometric object, and two vertices are adjacent if and only if their objects intersect. We introduce a new tool for designing such algorithms, which we call a *λ-linked partition*. This is a partition of the vertex set into groups of highly connected vertices. Crucially, such a partition can be computed in polynomial time and does not require access to the geometric representation of the graph.

We apply this framework to problems related to paths and cycles in graphs. First, we obtain the first *robust ETH-tight* algorithms for Hamiltonian Path and Hamiltonian Cycle, running in time $2^{O(n^{1-1/d})}$ on intersection graphs of similarly sized fat objects in $\mathbb{R}^d$. This resolves an open problem of de Berg *et al.* [STOC 2018] and completes the study of these problems on geometric intersection graphs from the viewpoint of ETH-tight exact algorithms.

We further extend our approach to the parameterized setting and design the first robust subexponential parameterized algorithm for Long Path in any fixed dimension d. More precisely, we obtain a randomized robust algorithm running in time $2^{O(k^{1-1/d}\log^2 k)}\, n^{O(1)}$ on intersection graphs of similarly sized fat objects in $\mathbb{R}^d$, where k is the natural parameter. Besides λ-linked partitions, our algorithm also relies on a low-treewidth pattern covering theorem that we establish for geometric intersection graphs, which may be viewed as a refinement of a result of Marx-Pilipczuk [ESA 2017]. This structural result may be of independent interest.

1 Introduction

Given a set $\mathcal{F}$ of objects in $\mathbb{R}^d$, the *intersection graph* of $\mathcal{F}$ is defined as the graph having one vertex for each object in $\mathcal{F}$, and an edge between two vertices whenever the corresponding objects intersect. One of the most extensively studied classes of intersection graphs are the *unit disk graphs*, obtained when the objects are disks in $\mathbb{R}^2$ of identical radius. In this work, we consider families $\mathcal{F}$ of *similarly sized β-fat* objects in $\mathbb{R}^d$ (for some constants $d, \beta \geq 1$) which means that for every object $O \in \mathcal{F}$, there are two balls B_{in} and B_{out} of $\mathbb{R}^d$ such that $B_{\text{in}} \subseteq O \subseteq B_{\text{out}}$, where B_{in} has radius 1 and B_{out} has radius β.

In their seminal work, de Berg *et al.* [4] introduced a general framework for deriving algorithms with running times that are tight under the Exponential Time Hypothesis (ETH) for a broad range of classical problems on intersection graphs of similarly sized fat objects. Their framework encompasses problems such as Maximum Independent Set, Dominating Set, Steiner Tree, and Hamiltonian Cycle. The key idea of their approach is the construction of a partition $\mathcal{P} = (V_1, \ldots, V_t)$ of the vertex set of the input graph G satisfying the following properties:

- **(i)** each induced subgraph $G[V_i]$ can be further partitioned into at most κ cliques, and
- **(ii)** the quotient graph of the parts, denoted $G_{\mathcal{P}}$, has bounded degree and treewidth $O(n^{1-1/d})$.

Notice that $\mathcal{P}$ can be computed *without* access to the geometric representation of F, and is enough to solve all the aforementioned problems except for Hamiltonian Cycle. Algorithms of this type, which operate solely on the intersection graph and do not require a geometric representation, are referred to as *robust* algorithms. We stress here that robustness is a substantial advantage since for many classes of intersection graphs such as unit disk graphs, computing a representation is $\exists\mathbb{R}$-complete [10].

However, the algorithm of [4] solving Hamiltonian Cycle requires one additional step: computing a partition of each V_i into a bounded number of cliques. For this step, de Berg *et al.* used the geometric representation. They explicitly left open the question of whether a robust ETH-tight algorithm for Hamiltonian Cycle could be obtained. One possible direction toward such a result would be to design a robust algorithm that computes a partition into a constant number of cliques whenever the input graph is known to contain one. Unfortunately, recent advances on clique partitions of geometric graphs suggest that this task is likely to be difficult [11].[1] It is worth noting that, in the case of unit disk graphs, such a clique partition can be obtained using the approach of [13].

We circumvent this problem by using a new type of partition into highly connected subgraphs called λ-*linked partitions*. We show the two following crucial properties : these partitions can be used to solve the considered problems (instead of partitions into cliques) and they can be computed in polynomial time (and, importantly, without relying on the geometric representation) in graphs known to admit a partition into a constant number of cliques.

Combining these findings with the framework of de Berg *et al.*, we obtain the following.

▶ **Theorem 1.** *For every constants $d \geqslant 1$ and $\beta \geqslant 1$ there is a robust algorithm solving Hamiltonian Path (resp. Hamiltonian Cycle) in time $2^{O\left(n^{1-1/d}\right)}$ on intersection graphs of similarly sized β-fat objects in $\mathbb{R}^d$.*

This result matches the ETH-based lower bound of [4] and resolves an open problem from the same paper.

To further demonstrate the applicability of our techniques, we show in a second part of the paper how they can be used to deal with parameterized version of Hamiltonian Path, that is, Long Path parameterized by the length of the path. For this problem and for Long Cycle, Fomin *et al.* proved in [16] that there are algorithms running in time $2^{O(\sqrt{k})} \cdot n^{O(1)}$ on intersection graphs of similarly sized fat objects in $\mathbb{R}^2$. Their approach relies on computing a *clique partition* of the vertex set and analyzing the resulting *clique-grid graph*. The idea of using clique partitions in the context of subexponential parameterized algorithms was

[1] There is no $2^{o(n)}$-time algorithm for this problem in unit ball graphs of $\mathbb{R}^5$, unless the ETH fails [11].

introduced in [8] and has since become a central tool in the area [15]. However, the clique-grid graph is typically defined using a geometric representation of the input graph. Designing a robust subexponential parameterized algorithm for Long Path in dimensions $d \geqslant 3$ has remained an open problem. Indeed, while the bidimensionality-based approach of [16] does not generalize to higher dimensions, the approach of [8], based on Baker's technique [5], again requires access to the geometric representation.

We show that this dependency can be removed by combining two key techniques. The first consists, as in the case of the Hamiltonian Path problem, in replacing the clique partition with a partition into highly connected parts. The second is an adaptation of the *low-treewidth pattern covering* technique, introduced by Fomin *et al.* [7] for planar graphs and later extended to graphs of polynomial growth by Marx and Pilipczuk [12]. Formally, we prove that there exists a randomized polynomial-time algorithm which, given an intersection graph of similarly sized objects in $\mathbb{R}^d$ with bounded degree and an integer k, outputs a vertex set $A \subseteq V(G)$ such that $G[A]$ has treewidth $O(k^{1-1/d} \log k)$, and for every set $X \subseteq V(G)$ of size at most k, we have $X \subseteq A$ with probability at least $2^{-\Omega(k^{1-1/d} \log^2 k)}$. This result can be viewed as a strengthening of that of Marx and Pilipczuk [12] in the case where the input graph has additional geometric structure rather than merely polynomial growth. Combined together, these techniques yield the first robust subexponential FPT algorithm for Long Path.

▶ **Theorem 2.** *For every constants $d \geqslant 1$ and $\beta \geqslant 1$, there is a robust randomized parameterized algorithm solving Long Path in time $2^{O(k^{1-1/d} \log^2 k)} n^{O(1)}$ on intersection graphs of similarly sized β-fat objects of $\mathbb{R}^d$.*

2 Preliminaries

2.1 Graph Theory

Unless otherwise specified we use standard graph theory terminology. All graphs considered in this paper are simple, undirected, and finite. For a graph G, we denote by $V(G)$ and $E(G)$ its vertex set and edge set, respectively. We write $n = |V(G)|$ and $m = |E(G)|$ its number of vertices and edges when G is clear from the context. For a vertex $v \in V(G)$, we write $N_G(v)$ for its *open neighborhood*, that is, the set of vertices adjacent to v, and $N_G[v] = N_G(v) \cup \{v\}$ for its *closed neighborhood*. For $X \subseteq V$, we denote by $G[X]$ the subgraph of G induced by X, and by $G - X$ the subgraph induced by $V \setminus X$. The *degree* of a vertex v is $d_G(v) = |N_G(v)|$, and the maximum degree of G is denoted by $\Delta(G)$. An *independent set* $I \subseteq V(G)$ is a subset of pairwise non-adjacent vertices of G. The *independence number* of G, denoted by $\alpha(G)$, is the maximum size of an independent set of G.

A *path* in a graph G is a sequence of distinct vertices $(v_1, v_2, \ldots, v_k)$ such that any two consecutive vertices are adjacent in G. A *cycle* is also a sequence of vertices $(v_1, v_2, \cdots v_k)$ such that any two consecutive vertices are adjacent in G, and $v_k v_1 \in E(G)$. Given a path P (resp. a cycle), we denote by $V(P)$ the set of vertices appearing in the sequence.

For two vertices u, v of a graph G, the *distance* between u and v, denoted by $\mathrm{dist}_G(u, v)$, is the minimum number of edges on a path from u to v in G. For an integer r, and a vertex $v \in V(G)$, we define $B_G(v, r) = \{ w \in V(G) : \mathrm{dist}_G(v, w) < r \}$, that is, the set of vertices at distance strictly less than r from v in G. Similarly, we let $\partial B_G(v, r) = \{ w \in V(G) : \mathrm{dist}_G(v, w) = r \}$ denote the set of vertices at distance exactly r from v.

2.2 Treewidth, κ-partition and $\mathcal{P}$-contraction

A *tree decomposition* of a graph $G = (V, E)$ is a pair $(T, \{X_t\}_{t \in V(T)})$ where T is a tree, $\{X_t\}_{t \in V(T)}$ is a collection of subsets of $V(G)$ (called *bags*), and satisfying the following:

(i) $\bigcup_{t \in V(T)} X_t = V(G)$,
(ii) for every edge $uv \in E(G)$, there exists a bag X_t containing both u and v, and
(iii) for every vertex $v \in V$, the set $\{t \in V(T) \mid v \in X_t\}$ induces a connected subtree of T.

Given a graph G and a weight function $\gamma : V(G) \to \mathbb{R}_{\geqslant 0}$, the *weighted width* of a tree decomposition $(T, \{X_t\})$ is $\max_{t \in V(T)} \sum_{v \in X_t} \gamma(v)$. The *weighted treewidth of* G (w.r.t. a given weight function) is the minimum weighted treewidth over all tree decompositions of G [14].

In [4], de Berg *et al.* introduced the notion of a κ-partition as a generalization of a clique partition, in order to obtain separator theorems for intersection graphs of similarly sized fat objects in $\mathbb{R}^d$.

▶ **Definition 3** (κ-partition [4]). *Let G be a graph and let $\kappa \geqslant 1$ be an integer. A* κ-partition *of G is a partition $\mathcal{P} = (V_1, \ldots, V_t)$ of $V(G)$ such that each class V_i induces a connected subgraph $G[V_i]$ whose vertex set can be partitioned into at most κ cliques. If $\kappa = 1$, $\mathcal{P}$ is called a* clique partition *of G.*

▶ **Definition 4** ($\mathcal{P}$-contraction [4]). *Given a graph G and a partition $\mathcal{P} = (V_1, \ldots, V_t)$ of $V(G)$, the* $\mathcal{P}$-contraction *of G, denoted by $G_{\mathcal{P}}$, is the (simple) graph whose vertex set is $\{V_1, \ldots, V_t\}$, where V_iV_j is an edge if and only if there is an edge in G between a vertex of V_i and a vertex of V_j. The* degree *of the partition $\mathcal{P}$ refers to the maximum degree of $G_{\mathcal{P}}$. Given a weight function $\gamma : \mathbb{R} \to \mathbb{R}$, we define the weighted treewidth of $G_{\mathcal{P}}$ (w.r.t. γ) by assigning to each vertex $V_i \in V(G_{\mathcal{P}})$ the weight $\gamma(|V_i|)$.*

The following result shows that for intersection graphs of similarly sized fat objects, it is possible to construct a κ-partition for which $G_{\mathcal{P}}$ has bounded maximum degree and sublinear weighted treewidth.

▶ **Theorem 5** (de Berg *et al.* [4, Theorem 12]). *Let $d \geqslant 2$, $\beta \geqslant 1$ and $\varepsilon > 0$ be constants, and let γ be a weight function satisfying $1 \leqslant \gamma(x) = O(x^{1-1/d-\varepsilon})$. There exist constants κ and Δ such that the following holds :*

- *Any intersection graph G of similarly-sized β-fat objects in $\mathbb{R}^d$ has a κ-partition $\mathcal{P}$ such that $G_{\mathcal{P}}$ has weighted treewidth $O(n^{1-1/d})$ (with respect to γ) and maximum degree Δ.*
- *There is a polynomial-time algorithm that, given such a graph G (without the representation), returns such a κ-partition, and a $2^{O(n^{1-1/d})}$-time algorithm which returns the corresponding tree decomposition.*

▶ Remark 6. We provide here a few additional observations regarding the construction and properties of the κ-partition.

- The κ-partition can be obtained in a *greedy manner* as follows: consider a maximal independent set S of G and create one part for each vertex of this independent set. By maximality, every vertex $v \in V(G) \setminus S$ has a neighbor in S. We pick any $u \in N(v) \cap S$ and add v to the same part as u. As a consequence, in any geometric representation of G with similarly sized β-fat objects, two objects belonging to the same part of a κ-partition can be assumed to be at distance at most 2β (see Figure 1).
- The graph $G_{\mathcal{P}}$ defined in the theorem above has (unweighted) treewidth $O(n^{1-1/d})$ when γ is the unit function.

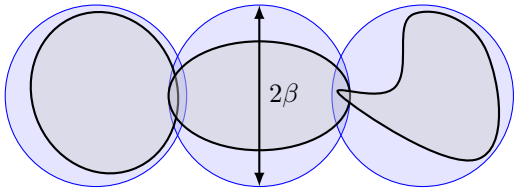

Figure 1 An example of 3 fat objects, the blue disks representing the enclosing disks of each object. The objects on left and right intersect the same object so there are at distance at most 2β.

2.3 Hamiltonicity and Connectivity

A path (or cycle) is said to be *Hamiltonian* if it contains all vertices of the graph. The Hamiltonian Path (resp. Cycle) problem asks, given a graph G, whether G has a Hamiltonian path (resp. cycle). The Long Path problem asks, given a graph G and a parameter k, whether G has a path on k vertices.

Since the problems we study are either trivially infeasible on disconnected graphs, or can be handled by considering each connected component independently, we restrict our attention to connected graphs throughout the paper.

A *vertex separator* in a connected graph G is a subset $A \subseteq V(G)$ such that $G - A = G[V(G) \setminus A]$ is disconnected. The *vertex connectivity* of G, denoted by $c_v(G)$, is the size of a minimum vertex separator of G, or $|V(G)| - 1$ if G is complete. Since we will not consider edge connectivity, we simply refer to $c_v(G)$ as the *connectivity* of G. A graph G is said ℓ-connected whenever $\ell \leqslant c_v(G)$.

A graph G is said to be *ℓ-linked* if $|V(G)| \geqslant 2\ell$ and, for every collection of ℓ disjoint pairs of distinct vertices $(s_1, t_1), (s_2, t_2), \ldots, (s_\ell, t_\ell)$, there exist ℓ vertex-disjoint paths $P_1, \ldots, P_\ell$ such that each P_i connects s_i to t_i. The graph G is *Hamiltonian-ℓ-linked* if there are such paths that, in addition, span all the vertices of G.

Let H and G be graphs. A *topological minor embedding* (or *TM-embedding*) of H into G is a pair (M, f), where M is a subgraph of G and $f : V(H) \to V(M)$ is an injective mapping such that, for every edge $\{u, v\} \in E(H)$, there exists a path P_{uv} in M connecting $f(u)$ and $f(v)$, and all these paths are pairwise internally vertex-disjoint. We say that H is a *topological minor* of G if such a TM-embedding exists. Moreover, when $V(G) = \bigcup_{uv \in E(H)} V(P_{u,v})$, we say that the TM-embedding is *spanning* all vertices of G.

The following lemma, due to Fomin *et al.* [6], establishes that in highly connected graphs, either a given small graph H can be TM-embedded in a spanning way, or there exists a large independent set.

▶ **Lemma 7** ([6, Lemma 4]). *Let H and G be graphs, with H non-empty. Let $f : V(H) \to V(G)$ be an injective mapping, and let k be a positive integer. Assume that G is $(\max\{k+2, 10\} \cdot h)$-connected, where $h = |V(H)| + |E(H)|$. Then there exists an algorithm with running time $2^{(h+k)^{O(k)}} + |G|^{O(1)}$ that computes either a subgraph $M \subseteq G$ such that (M, f) is a TM-embedding of H in G spanning all vertices of G, or an independent set of size k in G.*

Note that when H is the disjoint union of ℓ edges and $k > \alpha(G)$, Lemma 7 implies that the algorithm returns a TM-embedding of H spanning all vertices of G, regardless of the choice of the injective mapping f. It is straightforward to observe that in this case, H is Hamiltonian-ℓ-linked.

▶ **Lemma 8** (Consequence of Lemma 7). *Let G be a graph and let $\ell \geq 1$ be an integer. If G is $(\max\{\alpha(G) + 3, 10\} \cdot 3\ell)$-connected, then G is Hamiltonian-ℓ'-linked for all $\ell' \leqslant \ell$. Moreover, there exists an algorithm with running time $g(\alpha(G), \ell) \cdot |G|^{O(1)}$ (for some computable function*

g) which, given a graph G and 2ℓ distinct vertices $\{s_i, t_i\}_{1 \leqslant i \leqslant \ell}$, constructs ℓ vertex-disjoint paths $P_1, \ldots, P_\ell$ such that each P_i connects s_i to t_i, and the union of these paths spans all vertices of G.

3 A Robust Algorithm for Hamiltonian Path and Cycle

This section is devoted to our main tool, namely λ-linked partitions of intersection graphs of similarly sized fat objects, and to their application in proving Theorem 1.

3.1 Linked Partitions

We now generalize the notion of κ-partition to the concept of a *λ-linked partition*, where each part has to be highly connected.

▶ **Definition 9** (λ-linked partition). *Let G be a graph and let $\lambda \geqslant 1$ be an integer. A* λ-linked partition *of G is a partition $\mathcal{P} = (V_1, \ldots, V_t)$ of $V(G)$ such that each part V_i either induces a clique or a Hamiltonian λ-linked graph.*

▶ **Theorem 10.** *Let $d \geqslant 2$ and $\beta \geqslant 1$ be constants. There exists a constant Δ such that for every $c \geqslant 1$ and $\lambda \geqslant \Delta + c$, the following holds:*

- *Any intersection graph G of similarly-sized β-fat objects in $\mathbb{R}^d$ has a λ-linked partition $\mathcal{P}$ of G such that $G_{\mathcal{P}}$ has treewidth $O(n^{1-1/d})$ and maximum degree Δ.*
- *There is a $2^{O(n^{1-1/d})}$-time algorithm that, given such a graph (without a representation), returns such a partition as well as the corresponding tree decomposition.*

Moreover, the difference between λ and Δ can be made arbitrarily large.

Proof. Let $\mathcal{P}_0 = (V_1^0, \ldots, V_t^0)$ be the κ-partition obtained in Theorem 5, so that $G_{\mathcal{P}_0}$ has maximum degree Δ and treewidth $O(n^{1-1/d})$. This partition can be computed in polynomial time, and a tree decomposition of width $O(n^{1-1/d})$ in time $2^{O(n^{1-1/d})}$. We now refine each part V_i^0 of $\mathcal{P}_0$ using the following key claim. Let $g : \mathbb{N} \to \mathbb{N}$ be a function to be set later.

▷ Claim 11. Let $X \subseteq V(G)$ be a vertex set such that X admits a (unknown) clique partition of size κ. Then X can be partitioned into at most 2κ subsets, each of which either induces a clique or a $g(\kappa)$-connected subgraph, and such a partition can be found in polynomial-time.

Proof. We first construct a *separator tree* T for $G[X]$. This is a rooted tree defined as follows. If $G[X]$ has no vertex separator of size at most $g(\kappa)$, then T consists of a single leaf, which is also the root, and whose label is X. Otherwise, let $S \subseteq X$ be a vertex separator of $G[X]$ of size at most $g(\kappa)$, and let $X_1, \ldots, X_\ell$ be the vertex sets of the connected components of $G[X \setminus S]$, where $\ell \geq 2$. For each $i \in \{1, \ldots, \ell\}$, recursively construct a separator tree T_i for $G[X_i]$. Then T is obtained by creating a new root node labelled with S and making it adjacent to the roots of $T_1, \ldots, T_\ell$.

By construction, every leaf of T is labelled with a set $C \subseteq X$ such that $G[C]$ has no separator of size at most $g(\kappa)$; that is, each $G[C]$ is $g(\kappa)$-connected.

Furthermore, T has at most κ leaves. Indeed, suppose for contradiction that T had at least $\kappa + 1$ leaves $C_1, \ldots, C_{\kappa+1}$. Since the labels of distinct leaves lie in distinct connected components after removing all separators encountered on their respective root–leaf paths, they are pairwise non-adjacent. Thus picking one vertex from each C_i yields an independent set of size $\kappa + 1$, which is a contradiction with the existence of a clique partition of size κ.

Since every internal node has at least two children and the tree has at most κ leaves, it follows that T has at most $\kappa - 1$ internal nodes. Each internal node is labelled with a separator of size at most $g(\kappa)$, so the union X' of those labels satisfies $|X'| \leqslant (\kappa - 1)g(\kappa)$.

Finding a vertex separator of size at most $g(\kappa)$ can be done in time $|X|^{g(\kappa)}$. Since T contains at most $2\kappa - 1$ nodes, this operation is performed at most $2\kappa - 1$ times. Hence the total running time for constructing T is $(2\kappa - 1)\,|X|^{g(\kappa)}$. Since $X' \subseteq X$, the set X' admits a partition into at most κ cliques. As $|X'| \leqslant (\kappa - 1)g(\kappa)$, one can find such a partition by brute force in time $\kappa^{(\kappa-1)g(\kappa)}$, by enumerating all partitions of X' into κ (possibly empty) parts. Finally, note that the leaf labels of T, together with the clique partition of X', yield a partition of X into at most 2κ parts, each of them being either a clique or $g(\kappa)$-connected. ◁

Applying Claim 11 to each V_i^0 yields a refined partition of $V(G)$ into at most 2κ subsets per class, each of which induces a clique or a $g(\kappa)$-connected subgraph. Let $\mathcal{P}$ denote the resulting partition of $V(G)$, and consider the contraction $G_{\mathcal{P}}$.

Since each V_i^0 was replaced by at most 2κ subsets, $G_{\mathcal{P}}$ has maximum degree at most $\Delta' := (\Delta + 1) \cdot 2\kappa$. Moreover, its treewidth remains $O(n^{1-1/d})$, since κ is a constant.

Finally, fix $\lambda > \Delta'$ as large as desired (but constant), and fix $g(\kappa)$ large enough such that $g(\kappa) \geqslant \max(\kappa + 3, 10) \cdot 3\lambda$. Then each part of $\mathcal{P}$ is either a clique or Hamiltonian λ-linked by Lemma 8, which proves the theorem.

Note that $\mathcal{P}$ can be computed in polynomial time: the partition $\mathcal{P}_0$ is obtained in polynomial time, and by Claim 11, the refinement of each $V_i^0 \in \mathcal{P}_0$ can also be computed in polynomial time. Moreover, a tree decomposition of $G_{\mathcal{P}}$ of treewidth $O(n^{1-1/d})$ can be obtained from a tree decomposition of $G_{\mathcal{P}_0}$ by replacing each vertex V_i^0 with the vertices of its refinement in $\mathcal{P}$. Since the treewidth remains $O(n^{1-1/d})$, such a decomposition can be computed in time $2^{O(n^{1-1/d})}$. ◀

▶ Remark 12. Given a graph G, the partition $\mathcal{P} = (V_1, ..., V_t)$ of $V(G)$ obtained in Theorem 10 is a refinement of the partition $\mathcal{P}_0$ obtained from Theorem 5. By Remark 6, in any representation $\mathcal{O} = \{O_v\}_{v \in V(G)}$ of G with similarly sized β-fat objects in $\mathbb{R}^d$, two objects O_u and O_v are at distance at most 2β whenever $u, v \in V_i$ for some $1 \leqslant i \leqslant t$.

3.2 The Algorithm

We begin by adopting the technique introduced by Ito and Kadoshita, who observed that when looking for a Hamiltonian cycle in a graph G admitting a clique partition $\mathcal{P}$ such that the $\mathcal{P}$-contraction has bounded degree, it is sufficient to consider only a constant number of vertices from each clique. In particular, they proved that there always exists a Hamiltonian cycle that uses only a bounded number of edges between any two fixed cliques of the partition.

▶ **Lemma 13** ([9, Lemmas 3.2 and 3.3]). *Let G be a graph and $\mathcal{P} = (Q_1, \ldots, Q_t)$ a clique partition of G such that $G_{\mathcal{P}}$ has maximum degree Δ. There is a family $\{E_{i,j}\}_{1 \leqslant i < j \leqslant t}$ of edge sets such that the two following points hold:*

- **(i)** *for every i, j such that $1 \leqslant i < j \leqslant t$, $E_{i,j} \subseteq E(G) \cap (Q_i \times Q_j)$ and $|E_{i,j}| \leqslant 4(2\Delta - 1)^2$;*
- **(ii)** *G admits a Hamiltonian cycle if and only if it admits a Hamiltonian Cycle C that, for every i, j as above, uses at most two edges from $(Q_i \times Q_j)$, all belonging to $E_{i,j}$.*

Moreover, the sets $\{E_{i,j}\}$ can be computed in polynomial time.

In addition, we will use as a black box the FPT algorithms for Hamiltonian Path and Hamiltonian Cycle, both running on a graph G in time $2^{O(\mathrm{tw}(G))} \cdot |G|^{O(1)}$, where $\mathrm{tw}(G)$ denotes the treewidth of G.

▶ **Theorem 14** ([1, 3]). *Given a graph G together with a tree decomposition of width w, there exists an algorithm that solves Hamiltonian Cycle in time $2^{O(w)} \cdot n^{O(1)}$.*

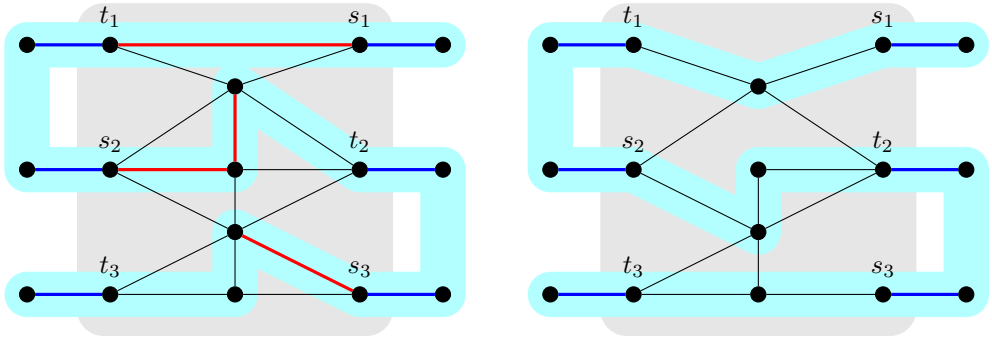

Figure 2 Illustration of the proof of Theorem 1, when turning a Hamiltonian cycle C in H (left) to a Hamiltonian cycle in G (right), focusing on a part V_i. In both figures, the grey box represents the set V_i, and the blue box represents the (partial) Hamiltonian cycle going through V_i. Left: C uses blue edges to enter and leave V_i, and uses edges from G as well as red edges inside V_i (notice that we only represented the red edges which are used by C). Right: since $G[V_i]$ is Hamiltonian-λ-linked, the (s_i, t_i)-paths which were using red edges in H can be replaced by actual paths in G.

We are now ready to prove the main result of this section.

Proof of Theorem 1. We give here an algorithm for Hamiltonian Cycle and explain at the end how to obtain that for Hamiltonian Path. According to Theorem 10, for some constants Δ and λ with $\Delta < \lambda$ we can compute a λ-linked partition $\mathcal{P} = (V_1, \ldots, V_t)$ of G and a tree decomposition of $G_{\mathcal{P}}$ in time $2^{O(n^{1-1/d})}$. In order to be able to apply Lemma 13, we define $G^\times$ as the graph obtained by turning each V_i into a clique (i.e., by adding all missing edges inside each V_i). We call the edges of $E(G^\times) \setminus E(G)$ the *red edges*.

Compute the edge sets $\{E_{i,j}\}_{1 \leqslant i < j \leqslant k}$ from Lemma 13, and call these *blue edges*. Let H be the graph obtained from $G^\times$ by removing every vertex not incident to a blue edge, except for one special vertex v_i per part V_i (if such a vertex exists). Denote by V_i^H the set of vertices of V_i that remain in H. Since $G_{\mathcal{P}}$ has maximum degree at most Δ, at most $4\Delta(2\Delta-1)^2$ vertices from each V_i are incident to blue edges, so $|V_i^H| \leqslant 4\Delta(2\Delta-1)^2 + 1$. Observe that H is a subgraph of the lexicographic product of $G_{\mathcal{P}}$ with a clique of constant size (depending on d only), hence its treewidth is $O(n^{1-1/d})$.

We now prove that G admits a Hamiltonian cycle if and only if H does.

Suppose that G has a Hamiltonian cycle. Then so does $G^\times$ as it is a supergraph of G. By Lemma 13, $G^\times$ admits a Hamiltonian cycle C that uses at most two blue edges between any V_i and V_j, that belong to $E_{i,j}$. Removing from C any vertex $v \in V_i \setminus V_i^H$ preserves Hamiltonicity in H (as V_i^H is a clique in H, and the neighbors of v in C must belong to V_i, otherwise v would be adjacent to a blue edge), hence H has a Hamiltonian cycle.

Conversely, suppose that H has a Hamiltonian cycle C. We reconstruct a Hamiltonian cycle of G as follows. For each $i \in [t]$, if $G[V_i]$ is a clique, we can insert the missing vertices of $V_i \setminus V_i^H$ along C. Indeed, if V_i^H contains a special vertex v_i, then C must contain an edge uv_i with $u \in V_i$, and thus all vertices of $V_i \setminus V_i^H$ can be inserted between u and v_i in C. If V_i^H do not contain a special vertex, then $V_i^H = V_i$ and C already contain all vertices of V_i.

If instead $G[V_i]$ is Hamiltonian-λ-linked, fix an orientation of C and let $s_1, \ldots, s_m$ be the vertices of V_i where C enters V_i, and $t_1, \ldots, t_m$ where it exits. Observe that $2m \leqslant 2\Delta$ as one can map each s_j (resp. t_j) to the unique blue edge that C uses to enter (resp. exit) V_i^H, and C uses at most 2Δ blue edges adjacent to V_i^H (at most two blue edges per adjacent part of V_i in $G_{\mathcal{P}}$). Since $G[V_i]$ is Hamiltonian-λ-linked with $\lambda > \Delta$, there exist m vertex-disjoint paths in $G[V_i]$ covering V_i and connecting each s_j to t_j. Replacing the subpaths of C within V_i by these paths yields a Hamiltonian cycle of G. See Figure 2 for an illustration.

To sum up, we reduced the problem to that of deciding whether H has a Hamiltonian cycle. Recall that H has treewidth $O(n^{1-1/d})$. This can be done in time $2^{O(n^{1-1/d})}$ using Theorem 14 on the tree decomposition of H computed above. Each local reconstruction inside a part V_i can be carried out using the algorithm of Lemma 8 in polynomial time.

With minor adjustments, Lemma 13 also applies to the Hamiltonian Path problem. More precisely, if G admits a Hamiltonian path, one can construct a graph G' by adding a special edge between the two endpoints of that path. The resulting graph G' admits a clique partition of bounded degree, and thus Lemma 13 applies to it. The Hamiltonian cycle obtained in G' may include the special edge; removing this edge then yields a Hamiltonian path in the original graph G. Then, the very same proof carries over to Hamiltonian Path, yielding an algorithm with identical running time. ◀

4 A Subexponential FPT algorithm for Long Path

This section is dedicated to the proof of Theorem 2. We first present a low-treewidth pattern covering technique adapted to geometric graphs, and then solve the Long Path problem using both this technique with λ-linked partitions.

4.1 Low-Treewidth Pattern Covering

We say that a graph class $\mathcal{G}$ has *growth* at most f if for every $G \in \mathcal{G}$ and $v \in V(G)$, the ball $B_G(v, r)$ contains at most $f(r)$ vertices. The next lemma shows that intersection graphs of similarly sized fat objects of bounded maximum degree have growth at most a polynomial function.

▶ **Lemma 15.** *For every constants $d \geqslant 2$, $\beta \geqslant 1$ and $\Delta > 0$, any intersection graph of similarly sized β-fat objects in $\mathbb{R}^d$ has growth $O(r^d)$.*

Proof. Let $\{O_v\}_{v \in V(G)}$ be a representation of G with similarly sized β-fat objects in $\mathbb{R}^d$. Let $v \in V(G)$. Observe than since the object associated to every neighbor of v intersects O_v, and these objects are β-fat, there is a d-dimensional hypercube of side length 6β that delimits a region containing the objects of v and all its neighbors. More generally for any integer $r \geqslant 1$, all the vertices at distance at most r from v in G have their objects in the region of $\mathbb{R}^d$ enclosed by a d-dimensional hypercube of side length $c_\beta r$, for some constant c_β depending only on β.

This hypercube can be partitioned into at most $c_\beta^d r^d$ smaller hypercubes of unit side length. Since the objects are β-fat, the object O_u associated to each $u \in V(G)$ contains a ball of radius 1. Let us denote by z_u the center of such a ball. Observe that if a smaller hypercube contains z_u and $z_{u'}$ for some $u, u' \in V(G)$, then O_u and $O_{u'}$ intersect and so u and u' are adjacent. Hence each such smaller hypercube contains at most $\Delta + 1$ points of the form z_u for $u \in V(G)$ (whose associated vertices form a clique of order at most $\Delta + 1$). Therefore, the ball $B_G(v, r)$ contains at most $c_\beta^d(\Delta + 1) \cdot r^d$ vertices, as claimed. ◀

▶ Remark 16. As a consequence of the previous lemma and the algorithm of [12], there exists a randomized algorithm that solves Long Path in time $2^{O(n^{1-1/(d+1)})}$ in intersection graphs of similarly sized fat objects in $\mathbb{R}^d$, provided that the maximum degree is constant.

We will use the following lemma showing that in graphs of polynomial growth, one can select a subset of vertices inducing connected components of radius $O(k \log k)$ and that has good probability of containing an unknown subset $X \subseteq V(G)$ of size at most k.

▶ **Lemma 17** ([12, Lemma 2.1]). *Let $\mathcal{G}$ be a graph class of growth $O(r^\delta)$. There exists a constant $c > 0$ and a polynomial-time randomized algorithm that, given $G \in \mathcal{G}$ and an integer $k \geqslant 4$, outputs a subset $A \subseteq V(G)$ satisfying:*

1. *every connected component of $G[A]$ has radius at most $ck \log k$;*
2. *for every set $X \subseteq V(G)$ of size at most k, the probability that $X \subseteq A$ is at least $\frac{17}{256}$.*

We then give a low-treewidth pattern covering lemma for intersection graphs of similarly sized fat objects and bounded maximum degree, with diameter polynomial in k. The proof, available in the long version, follows essentially the same clustering procedure as in [12]. Roughly speaking, the idea is to construct a collection of disjoint *clusters* in the graph, where each cluster induces a subgraph of small treewidth, and then add a small number of vertices that are adjacent to these clusters in order to ensure connectivity between them. The main difference with [12] lies in the analysis of the treewidth of the clusters, which can be improved in the case of geometric graphs.

▶ **Lemma 18** (✂). *For every constants $d \geqslant 2$, $\beta \geqslant 1$, $\Delta \geqslant 1$ and $c > 0$, there exists a constant $c' > 0$ and a polynomial-time randomized algorithm that, given $k \geqslant 4$ and a connected intersection graph G of similarly-sized β-fat objects in $\mathbb{R}^d$ of maximum degree Δ and radius at most $ck \log k$, outputs a subset $A \subseteq V(G)$ such that:*

1. *the treewidth of $G[A]$ is $O(k^{1-1/d} \log k)$;*
2. *for every set $X \subseteq V(G)$ of size at most k, the probability that $X \subseteq A$ is at least $2^{-c'(|X|+k)k^{-1/d}\log^2 k}$.*

4.2 Robust Subexponential FPT algorithm for Long Path

Recall that there exists an algorithm solving Long Path and Long Cycle in subexponential FPT time $2^{O(\sqrt{k})} \cdot n^{O(1)}$ in unit-disk graphs [16], and that this running time is tight under the Exponential Time Hypothesis (ETH). The approach to obtain this algorithm is very similar that used to obtain a subexponential algorithm running in time $2^{O(\sqrt{n})}$.

The key idea is to view G as a *clique-grid* graph. Informally, a clique-grid graph is a graph equipped with a mapping $f : V(G) \to [t]^2$ such that, for all $(i, j) \in [t]^2$, the preimage $f^{-1}(i, j)$ induces a clique, and edges between vertices in $f^{-1}(i, j)$ and $f^{-1}(i', j')$ exist only if the distance between the cells (i, j) and (i', j') is less than a fixed constant. The algorithm can then be seen as consisting of two main steps:

- **(i)** marking a constant number of vertices in each clique such that the path only traverses the cliques via these marked vertices, and
- **(ii)** applying bidimensionality techniques to solve a weighted version of Long Path on the subgraph induced by the marked vertices in time $2^{O(\sqrt{k})} \cdot n^{O(1)}$.

The mapping f is straightforward to obtain when a geometric representation of the underlying objects is available. However, at the time of writing, it is not know how to do so without the representation. Importantly, the marking scheme does not fundamentally rely on G being a clique-grid graph, but only on the existence of a clique partition $\mathcal{P}$ such that $G_{\mathcal{P}}$ has bounded degree. The following lemma is a straightforward rewriting of the marking scheme of [16]. It can be viewed as a generalization of Lemma 13, which additionally handles the case where the path is not necessarily Hamiltonian.

▶ **Lemma 19** (Reformulation of [16, Lemma 14]). *Let G be a graph and $\mathcal{P} = (Q_1, \ldots, Q_t)$ a clique partition of G such that the $\mathcal{P}$-contraction $G_{\mathcal{P}}$ has degree at most Δ. There exists a family of vertex subsets $\{\mathsf{M}(i)\}_{1 \leqslant i \leqslant t}$ with $\mathsf{M}(i) \subseteq Q_i$ for every $i \in \{1, \ldots, t\}$ and satisfying*

the following property. If G contains a path with k vertices, then it also contains a path P with endpoints x, y such that, for every $1 \leqslant i \leqslant t$,

1. *either $V(P) \subseteq Q_i$, or*
2. *$V(P) \cap (Q_i \setminus \mathsf{M}(i)) = \emptyset$, or*
3. *there exist distinct vertices $u, v \in (V(P) \cap \mathsf{M}(i)) \cup (\{x, y\} \cap Q_i)$ such that the set of internal vertices of the subpath of P between u and v is precisely*

$$(V(P) \cap Q_i) \setminus (\mathsf{M}(i) \cup \{u, v\}).$$

In addition, M can be computed in polynomial time, and $|\mathsf{M}(i)| = \Delta^{O(1)}$ for any $1 \leqslant i \leqslant t$.

In the Weighted Long Path problem, the input is a graph G, a weight function $w : V(G) \to \mathbb{N}$ and an integer W, and the goal is to find a path $(u_1, \ldots, u_q)$ in G ($q > 0$), such that $\sum_{i \in [q]} w(u_i) \geqslant W$. Adapting the classical dynamic programming algorithm for Long Path on graphs with bounded treewidth [2], we can obtain the following result.

▶ **Proposition 20** (see [2]). *Weighted Long Path is solvable in time $2^{O(w)} \cdot n^{O(1)}$ on n-vertex graphs of treewidth at most w.*

We are now ready to prove the main result of this section.

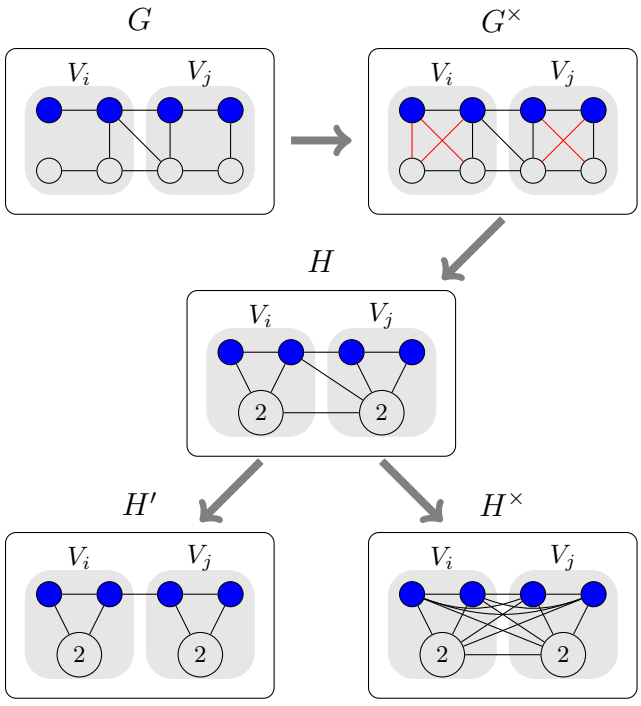

Figure 3 Illustration of the five graphs of the proof of Theorem 2.

Proof of Theorem 2. We begin by computing, in polynomial time, the λ-linked partition $\mathcal{P} = (V_1, \ldots, V_t)$ guaranteed by Theorem 10, such that $G_{\mathcal{P}}$ has maximum degree Δ, for some constants λ and Δ such that $\Delta < \lambda$. Let $G^\times$ denote the graph obtained from G by turning each V_i into a clique, that is, by adding all missing edges inside each V_i. Again, the edges in $E(G^\times) \setminus E(G)$ are called *red edges*.

We apply Lemma 19 to the pair $(G^\times, \mathcal{P})$, yielding the marking function M defined on $V(G^\times)$. From this, we build the weighted graph H as follows: for each $1 \leqslant i \leqslant t$, let $U_i := V_i \setminus \mathsf{M}(i)$, and contract all vertices in U_i into a single vertex v_i with weight $w_i := |U_i|$. Whenever $U_i \neq \emptyset$, define $Q_i := \mathsf{M}(i) \cup \{v_i\}$. If $U_i = \emptyset$, do not create vertex v_i and define $Q_i := \mathsf{M}(i)$. All remaining vertices (the marked ones) receive weight 1. Note that Q_i is a clique in H for all $1 \leqslant i \leqslant t$.

We now define two auxiliary graphs derived from H:

1. H' is obtained from H by deleting every edge $v_i u$ with $u \in V_j$ and $j \neq i$.
2. $H^\times$ is obtained from H by adding, for every $1 \leqslant i < j \leqslant t$, all edges between Q_i and Q_j whenever there exists an edge $uv \in E(H')$ with $u \in Q_i$ and $v \in Q_j$. Note that, for any $u, v \in Q_i$, u and v are *true twins* in $H^\times$, meaning that $N_{H^\times}[u] = N_{H^\times}[v]$. Moreover, H' is a subgraph of $H^\times$.

See Figure 3 for an illustration of the graphs G, $G^\times$, H, H' and $H^\times$. We first prove that $H^\times$ is the intersection graph of similarly sized fat objects in $\mathbb{R}^d$.

▷ Claim 21. There exist constants β' and Δ' such that $H^\times$ is the an intersection graph of similarly-sized β'-fat objects in $\mathbb{R}^d$, and has maximum degree at most Δ'.

Proof. Let $\mathcal{O} = \{O_v\}_{v \in V(G)}$ be a geometric representation of G with d-dimensional similarly sized β-fat objects. For each i, let $O_i = \bigcup_{v \in V_i} O_v$. Since V_i is λ-linked, the diameter of O_i is bounded by $O(\beta)$ by Remark 12, and O_i contains a ball of radius 1 (as each O_v does). We represent every vertex $u \in Q_i$ by the same object O_i.

Note that for each $1 \leqslant i \leqslant t$, the objects representing Q_i pairwise intersect, since they are all represented by the same geometric object. Moreover, for any $1 \leqslant i < j \leqslant t$, the objects O_i and O_j intersect whenever there exist vertices $u \in V_i$ and $v \in V_j$ such that O_u and O_v intersect. It follows that $H^\times$ is indeed the intersection graph of $\{O_u : u \in V(H^\times)\}$. In addition, its degree is bounded by $\Delta' = \Delta^{O(1)}$, as each O_i intersects only a bounded number of other regions corresponding to adjacent parts in $G_{\mathcal{P}}$. ◁

We now show that G has a long path if and only if H' does.

▷ Claim 22. G has a path on at least k vertices if and only if H' has a weighted path of total weight at least k. Moreover, given such a path in H', one can construct a path in G with at least the same number of vertices in polynomial time.

Proof. Suppose that G contains a path P on k vertices with endpoints x and y. Since G is a subgraph of $G^\times$, P is also a path in $G^\times$. By Lemma 19, P can be modified into a path P' such that for each i, P' contains all vertices in $(V(P) \cap V_i) \setminus \mathsf{M}(i)$ consecutively along P', and we call P_i such a subpath. By contracting each such P_i into a single vertex v_i, we obtain a path P_H in H' whose total weight equals $|V(P)| \geqslant k$.

Conversely, let P_H be a weighted path in H' of total weight at least k. For each contracted vertex v_i of weight w_i, we expand it into an arbitrary path of w_i distinct vertices from U_i. The two vertices (if they exist) adjacent to v_i in P_H must belong to $\mathsf{M}(i)$ by definition of H', so the resulting expanded path P' exists in $G^\times$ and has at least k vertices.

It remains to transform the path P' in $G^\times$ into a path in G. Currently, P' may use red edges inside some V_i that is not a clique in G, but each $G[V_i]$ is Hamiltonian λ-linked. Fix i such that $G[V_i]$ is Hamiltonian λ-linked, and let $s_1, \ldots, s_m$ be the vertices of V_i where P' enters V_i, and $t_1, \ldots, t_m$ the vertices where it exits. Since P' must enter and exit through marked vertices, we have $m = \Delta^{O(1)}$. If λ is chosen so that $\lambda > m$, there exist m vertex-disjoint paths $\{P_{i,j}\}_{1 \leqslant j \leqslant m}$ covering all vertices of V_i, each connecting s_j to t_j. Replacing each subpath between s_j and t_j in P' by $P_{i,j}$ yields a new path with at least the same

number of vertices, and without using red edges. Performing this replacement for every part V_i such that $G[V_i]$ is Hamiltonian λ-linked yields a path on at least k vertices in G. This construction can be carried out in polynomial time by Lemma 8. ◁

We now describe the algorithm. Suppose that G has a path P with k vertices. We apply successively Lemma 17 and Lemma 18 to $H^\times$ (which, by the previous claim, is the intersection of similarly-sized fat objects in $\mathbb{R}^d$, and has bounded maximum degree) to obtain a set $A \subseteq V(H^\times)$ such that:

1. the treewidth of $H^\times[A]$ is $O(k^{1-1/d} \log k)$;
2. with probability at least $2^{-O(k^{1-1/d} \log^2 k)}$, we have $V(P) \subseteq A$.

Since H' is a subgraph of $H^\times$, $H'[A]$ also has treewidth $O(k^{1-1/d} \log k)$. Then, one can find a path on k vertices in $H'[A]$ using Proposition 20 in time $2^{O(k^{1-1/d} \log k)} \cdot n^{O(1)}$. Repeating this process $2^{O(k^{1-1/d} \log^2 k)}$ times ensures constant success probability. If a path on k vertices is found in H', we construct in polynomial time a path on k vertices of G using Claim 22. If no such path is found after all repetitions, the algorithm reports that G has no path on k vertices. ◀

5 Conclusion

In this paper we have presented a robust algorithm for solving Hamiltonian Path and Hamiltonian Cycle in intersection graphs of similarly sized fat objects in $\mathbb{R}^d$ in time $2^{O(n^{1-1/d})}$, which is tight under ETH. In addition, we extended our method to obtain a robust randomized FPT algorithm for Long Path, running in time $2^{O(k^{1-1/d} \log^2 k)}$. We conclude with two open questions:

- Is it possible to remove the $\log^2 k$ factor in the exponent of our algorithm for Long Path, and to make the algorithm deterministic?
- Our method does not directly yield a robust subexponential FPT algorithm for Long Cycle. Is it possible to obtain one using a different approach?

Abstract

The vast chemical space, encompassing virtually innumerable molecules and materials, presents both immense opportunities and significant challenges. The design and discovery of novel drugs and functional materials may be viewed as a search within this space; however, the sheer scale of potential candidates renders exhaustive exploration infeasible. To address this, we introduce *Chemical Mapper*, a framework that integrates topological data analysis with deep learning to enable the visual exploration and analysis of chemical latent spaces. At its core, *Chemical Mapper* employs mapper, a widely used tool in topological data analysis, to investigate the organizational principles of chemical latent spaces defined by molecular representations learned by geometric deep learning models. In doing so, *Chemical Mapper* not only highlights groups of molecular representations but also uncovers the relationships among them through linkages and branching structures. Our results show that *Chemical Mapper* reveals intrinsic patterns associated with molecular scaffolds, functional groups, and chemical properties, as well as the structural and functional evolutions of the molecules.

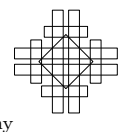
1 Introduction



Navigating chemical space, which encompasses the immense number of compounds formed by all possible atomic combinations, is both challenging and full of promise [10, 24, 42, 41]. For example, the GDB-17 dataset, which includes molecules composed of up to 17 atoms

[1] Corresponding author

licensed under Creative Commons License CC-BY 4.0

of C, N, O, S, and halogens, already enumerates 166.4 billion structures [41]. Estimates suggest that more than 10^{60} molecules could satisfy Lipinski's rule-of-five and thus represent potential drug candidates. Even restricting attention to drug candidates of up to 30 atoms yields a chemical space of about 10^{20}–10^{24} compounds. This staggering diversity provides an effectively unlimited reservoir of opportunities for novel drugs, functional materials, and green technologies [24, 42]. Indeed, chemical space is widely regarded as the ultimate frontier for drug discovery, as all approved drugs originate from exhaustive screening and refinement of candidates within this vast molecular universe [42].

Understanding and navigating the vast landscape of chemical space is essential for advancing drug discovery, materials science, and chemical engineering [3, 13, 24, 29, 44, 50, 52]. Broadly, there are two principal approaches for the visualization and analysis of chemical space: *global clustering* and *local topology*.

Global clustering models are frequently built on dimensionality reduction techniques [14, 23]. For instance, the *Chemical Space Project* [41] employs PCA [34] to illustrate chemical diversity, whereas *ChemPlot* [46], a Python library for chemical space visualization, supports PCA, t-SNE [47], as well as UMAP [28]. *Drug Discovery Maps* (DDM) [20] applies t-SNE to visualize the molecular similarity of experimental drugs in chemical space. More recently, AI-driven approaches have been adopted to study the chemical latent space, which embeds molecule structures into a mathematical space defined by molecular features. This chemical latent space captures structural diversity within chemical libraries and supports the exploration of broader chemical space for designing novel drug candidates [32]. Variational autoencoders (VAEs) have been widely used for both learning [15] and constructing chemical latent spaces [32]. The overarching idea is to transform chemical structures into low-dimensional or latent representations that preserve key structural and functional properties, thereby enabling visualization, clustering, and analysis. A variety of clustering methods [18, 19, 33] have been applied in this context. For example, Cheng et al. [9] used unsupervised clustering with Gaussian mixture models (GMMs) to partition chemical space, while Hadipour et al. [16] applied K-means [26] and BIRCH [51] – a scalable hierarchical clustering algorithm – to group VAE-based molecular representations. A recent extension, BitBIRCH [35], was shown to cluster 450,000 molecules in around 2.2 minutes.

In contrast, local topology models highlight connections at the level of individual compounds [25, 27, 36, 43]. For example, interaction networks among proteins, ligands, RNAs, DNAs, and other molecules are widely used to model chemical space. Beyond direct interactions, molecular graphs can also be constructed based on structural similarity. While these graph models can also support visualization and clustering, their key strength lies in preserving local molecular connectivity, which is particularly valuable for molecular search, optimization, and modification under structural or functional constraints.

The mapper construction [45] is a central tool in topological data analysis, offering a topological summary that balances global clustering with local structure. As a discrete analogue of the Reeb graph [2, 40], mapper provides a versatile framework for exploring and analyzing high-dimensional data [4, 7, 30]. Unlike conventional clustering methods, it not only identifies clusters but also encodes their interrelationships. Crucially, mapper preserves the intrinsic topology of the data space, enabling the detection of subtle structural features such as branches, chains, and loops that are often overlooked by dimensionality reduction techniques. In its simplest form, the *mapper graph* represents clusters as nodes and their overlaps as edges. Recently, mapper graphs have emerged as powerful tools for interpreting the structure of deep learning activation spaces [5, 37, 38, 54, 55] and exploring the topology of word embeddings [39].

We present *Chemical Mapper*, a mapper framework for the visual exploration and analysis of chemical latent space. The central idea is to employ mapper graphs to investigate the organizational principles of chemical latent spaces learned by deep learning models. Specifically, we focus on chemical latent space defined by molecular representations learned from geometric deep learning models such as GEM (Geometry-Enhanced Molecular representation learning, also referred to as the Geometry Embedding Model) [13], GraphMAE [17], and Mole-BERT [48]. From these latent representations, we construct a mapper graph in which each node denotes a cluster of molecule representations and each edge encodes the overlap between clusters. Our analysis shows that edges in the mapper graph capture shared motifs, substructures, or scaffold types, while topological patterns such as branches and chains reveal systematic variations in functional groups and chemical properties.

In addition, *Chemical Mapper* enables the characterization of how molecular representations evolve during the pre-training and fine-tuning phases of deep learning models. By comparing mapper graphs across training stages, we trace the progression of molecular representations and assess their ability to generalize chemical properties. This provides new insight into the latent chemical structures learned by deep models.

Overall, this work advances topology-driven molecular analysis, highlighting the value of mapper graphs for both chemical space exploration and the interpretation of deep learning models. Our findings emphasize the importance of integrating topological data analysis with machine learning to achieve structured, interpretable molecular representations, thereby paving the way for future developments in computational chemistry, materials discovery, and AI-driven chemical modeling.

The source code and datasets associated with *Chemical Mapper* are publicly available at `https://doi.org/10.5281/zenodo.19241865`, along with supplementary videos that demonstrate its interactive exploration capabilities.

2 Materials and Methods

2.1 Datasets

To demonstrate the adaptability of our *Chemical Mapper* framework in exploring diverse chemical latent spaces, we employ three chemical datasets in this study: (1) PubChem, a large-scale molecular repository; (2) a toxicity dataset containing rat oral acute toxicity data; and (3) a water solubility dataset with $logS$ values that quantify how readily compounds dissolve in water.

First, to illustrate the representational capability of mapper in capturing molecular distributions, we focus on a randomly selected subset of two million chemical structures from the PubChem database [21], a comprehensive repository of small molecules. Second, to highlight the ability of *Chemical Mapper* to capture both molecular structures and associated physicochemical properties, we incorporate two additional datasets from Deep-PK [31], which focus on toxicity and water solubility. The toxicity dataset contains 10,130 molecules and measures acute oral toxicity in rats, typically expressed as the lethal dose for 50% of test animals (LD_{50}). The water solubility dataset comprises 9,964 molecules, each labeled with the logarithm of water solubility (logS) at 20-25°C, expressed in log mol/L.

2.2 AI-Enhanced Chemical Structural Representations

For structural analyses using *Chemical Mapper* (Section 3.2), we employ GEM [13] as the primary model for generating molecular structural representations. GEM utilizes a geometry-based graph neural network (GNN) architecture enhanced with self-supervised learning

strategies designed to capture fine-grained molecular geometry. Molecular representations are produced using a pre-trained GEM model for two million molecules, each represented as a 32-dimensional real-valued vector.

To further examine the training behavior of other geometric deep learning models, we also evaluate GraphMAE [17] and Mole-BERT [48] under pre-trained and fine-tuned conditions (Section 3.3). GraphMAE, inspired by masked autoencoding techniques in natural language processing, learns effective graph representations through self-supervised learning by masking portions of node features and training the network to reconstruct them. In contrast, Mole-BERT adopts a transformer-based architecture to capture rich structural and chemical information. Drawing inspiration from BERT, it employs masking strategies to model contextual relationships within molecular graphs, enabling more flexible and comprehensive molecular feature learning.

2.3 Mapper Algorithm

The mapper construction is a powerful topological data analysis technique that captures the intrinsic shape of high-dimensional datasets [45]. Its 1D form, the mapper graph, provides a simplified graphical summary of complex point clouds, where nodes represent clusters and edges capture overlapping relationships among them. When applied to chemical space, the mapper graph enables hierarchical exploration of molecular scaffolds, functional groups, and properties, revealing meaningful topological patterns and chemical insights.

The mapper algorithm takes as input a high-dimensional point cloud $\mathbb{X}$ equipped with a real-valued function $f : \mathbb{X} \to \mathbb{R}$, referred to as a *filter function*. It produces a graphical summary of $\mathbb{X}$ in the form of a *mapper graph*, where each node represents a cluster interpreted as a topological neighborhood, and an edge connects two nodes if their corresponding neighborhoods overlap.

We illustrate the construction of a mapper graph using a 1D point cloud $\mathbb{X}$ sampled from the letter $\mathcal{Y}$, rendered in a mathematical script font. As shown in Figure 1 (left), $\mathbb{X}$ is equipped with a height function f, which serves as the filter function. To obtain a topological summary of $\mathbb{X}$, we begin with a finite cover $\mathcal{V} = \{V_1, V_2, \dots\}$ of $f(\mathbb{X})$, formed by a set of partially overlapping intervals such that $f(\mathbb{X}) \subseteq \bigcup_j V_j$ (see Figure 1, middle). For each interval V_j, we consider the clusters induced by points in $f^{-1}(V_j)$; these clusters form a finite cover $\mathcal{U} = \{U_1, U_2, \dots\}$ of $\mathbb{X}$ such that $\mathbb{X} \subseteq \bigcup_j U_j$, highlighted by rectangles. For example, points in $f^{-1}(V_1)$ form two clusters, U_1 and U_2, while those in $f^{-1}(V_2)$ yield four. The 1D *nerve* of $\mathcal{U}$ defines the *mapper graph* in Figure 1 (right), where each cluster U_i corresponds to a node i, and an edge connects nodes i and j whenever clusters U_i and U_j have a nonempty intersection. For example, an edge connects the nodes representing clusters U_2 and U_3. The resulting mapper graph captures key topological features of the letter $\mathcal{Y}$, including its branching and looping structures.

In our study, we use the l^2-norm as the filter function, which quantifies how strongly a model is activated by an input molecule and has been shown to yield meaningful insights when analyzing latent representations in deep learning [38, 39]. Given a fixed filter function, the mapper graph construction is determined by: (1) the number of intervals and their overlap, which control the resolution of the cover; and (2) the parameters of the clustering algorithm. The overlap among cover elements is crucial for maintaining connectivity among topological neighborhoods at a given resolution, thereby revealing both local and global topological structure. In practice, we employ DBSCAN [12] for clustering, with parameters ϵ and `minPts`, where ϵ defines the neighborhood radius determining how close points must be to belong to the same cluster, and `minPts` specifies the minimum number of points required to form a dense cluster. See Section 4.1 for a discussion on parameter turning.

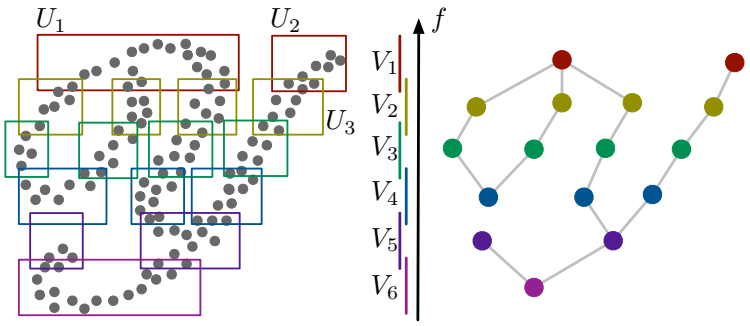

Figure 1 A simple illustration of mapper graph construction. Left: a point cloud $\mathbb{X}$ is equipped with a height function f. Middle: a cover $\mathcal{U} = \{U_1, U_2 \dots\}$ of $\mathbb{X}$ is induced by a cover $\mathcal{V} = \{V_1, V_2, \dots\}$ of $f(\mathbb{X})$ consisting of 6 intervals with 25% overlap. Right: the 1D nerve of $\mathcal{U}$ yields the mapper graph.

3 Results

3.1 Topological Data Analysis with Mapper

The mapper construction offers a key advantage in its ability to integrate topological structure into clustering analysis. As an initial study, we compare t-SNE [47] and mapper [45] for visualizing the chemical space of molecular representations.

Our study uses two million chemical structures from the PubChem database [22], comprising ten distinct scaffolds (i.e., core molecular frameworks), each represented by 200,000 molecules. Each chemical graph is converted into a 32-dimensional feature vector using the pre-trained GEM model. Detailed experimental settings are provided in Section 2.

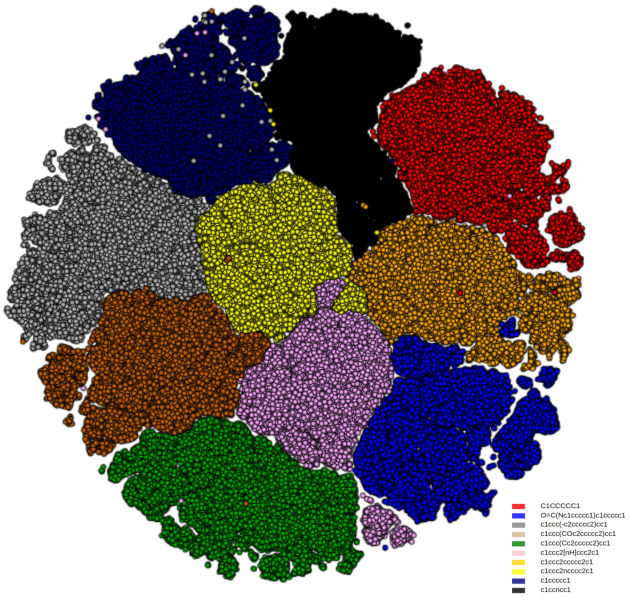

Figure 2 Application of t-SNE to two million chemical structures from the PubChem database. The embedding reveals scaffold-based clusters but offers limited insight into both intra- and inter-cluster relationships.

In the t-SNE visualization shown in Figure 2, each data point is colored by its chemical scaffold. In contrast, the mapper graphs used throughout this work represent each node as a group of molecular representations, visualized as a pie chart whose color proportions reflect the distribution of scaffolds within the node (see Figures 10 and 11), except in Section 3.2.3. Nodes rendered in a single color indicate high purity, meaning all molecules share the same scaffold (e.g., the mapper graph in Figure 5 contains only one impure node out of 5,104 total nodes). Although nodes are displayed with a uniform size by default, they may contain varying numbers of molecules, and their sizes can be adjusted if needed. The corresponding scaffold colormap, along with representative molecular structures, is shown in Figure 3.

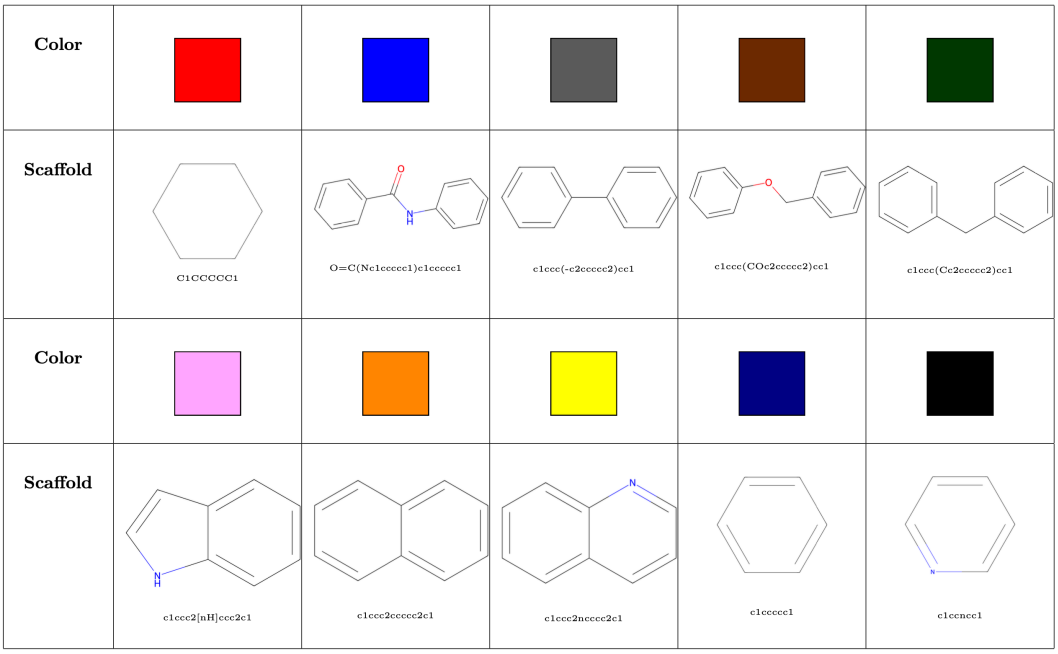

Figure 3 Scaffold colormap with representative molecular structures.

While t-SNE organizes molecular representations into ten well-separated clusters, it does not capture relationships among them. In contrast, the mapper graph in Figure 5 reveals both inter- and intra-cluster connectivity and exposes finer-grained topological features – such as branches, chains, and loops – that capture meaningful structural distinctions within the chemical space. By capturing both local and global organization, the mapper graph offers a more comprehensive view of molecular structure, surpassing the representational capacity of conventional clustering methods. In subsequent sections, our results demonstrate that the mapper graph effectively uncovers topological organization within the chemical space, revealing clusters and their relationships and providing deeper insights into molecular structure and function (see Sections 3.2 and 3.3 for details).

3.2 Mapping GEM Chemical Latent Space with Mapper

We integrate molecular representations learned from geometric deep learning models into the mapper algorithm to create an exploratory framework, *Chemical Mapper*. As illustrated in Figure 4, the workflow begins with molecular datasets from which latent representations are extracted using deep learning models. These representations form a high-dimensional point cloud that is analyzed using the mapper algorithm. The resulting mapper graph

captures relationships among scaffolds, functional groups, and molecular properties. Downstream analyses leverage this graph to reveal structural patterns and property distributions, highlighting the framework's capacity to uncover organizational principles within chemical latent space.

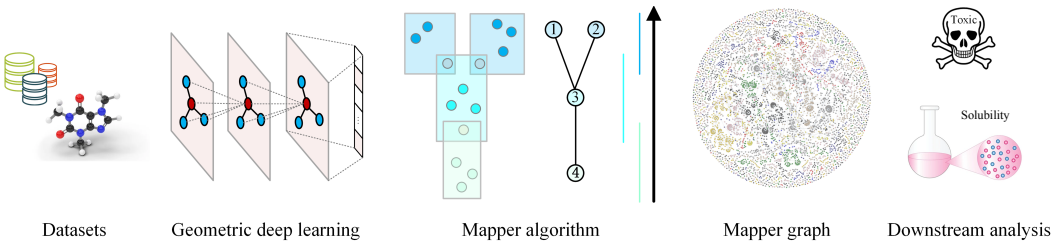

Figure 4 The workflow of the AI-enhanced *Chemical Mapper* for chemical space analysis. From left to right: input of molecular structures; extraction of molecular representations using geometric deep learning models; application of the mapper algorithm to the resulting chemical latent space to construct a mapper graph; and downstream analysis of chemical structures and properties (such as solubility and toxicity) informed by the topology of the mapper graph.

We analyze a large-scale dataset of two million molecules spanning ten scaffolds from the PubChem database [22]. Each molecule is embedded into a 32-dimensional latent space using a pre-trained GEM model. Figure 5 shows the mapper graph constructed from these representations using 100 intervals with 50% overlap, $\epsilon = 1$, and `minPts` $= 10$.

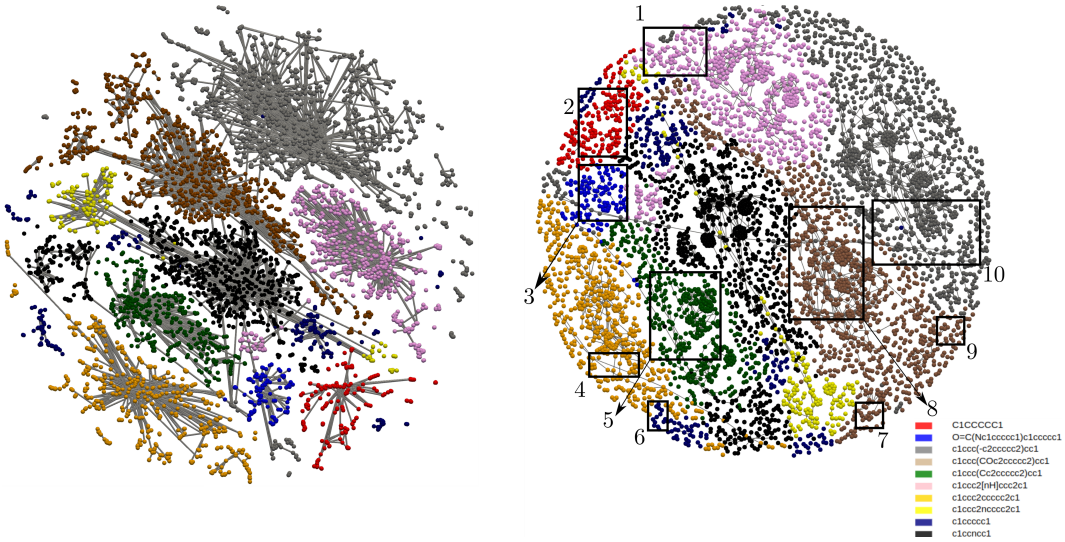

Figure 5 Mapper graph of two million molecular representations from a pre-trained GEM model. The left visualization uses an anchored layout, while the right shows the same graph with a force-directed layout. Numbered regions on the right are examined in detail in subsequent sections.

In Figure 5(left), the mapper graph is drawn using an anchored layout, where each node is initialized at the mean of the 2D t-SNE coordinates of its assigned data points, effectively grounding the graph in the underlying embedding. Figure 5(right) shows the corresponding force-directed layout, which refines this initialization by iteratively adjusting node positions through attractive forces along edges and repulsive forces between nodes to improve separation and reduce visual clutter. For the remainder of the paper, we use the force-directed layout, as it yields clearer and more interpretable visualizations.

We analyze the topological structure of this graph and its relationship to variations in the chemical latent space, focusing on connected components (Section 3.2.1) and branches (Section 3.2.2). We further examine how the graph organization correlates with chemical functions and properties such as toxicity and solubility (Section 3.2.3).

3.2.1 Exploring Connected Components in Chemical Latent Space

As illustrated in Figure 5, the mapper graph consists of multiple connected components, each corresponding to a group of molecules sharing a common scaffold in the latent space. Within a given scaffold, molecules further partition into components of varying sizes, revealing finer-grained structural distinctions.

Figure 6 highlights four connected components, each containing representative molecules drawn from a shared scaffold but distinguished by their functional groups. The top-left component is enriched with molecules featuring amide bonds (O=C–NH–), whereas the bottom-left component consists exclusively of molecules containing sulfate groups (O=S=O). On the right, the top component contains molecules that consistently feature a combination of carboxylic acid (O=C–OH), epoxide (–C–O–C–), and halide substituents. The bottom-right component similarly comprises molecules that simultaneously contain nitro groups (O–N(=O)–O), carboxylic acid, and halide substitutions. This demonstrates that a component can be characterized by a set of functional groups rather than a single one. Together, these topological patterns indicate that the GEM model has learned not only to separate molecules by their underlying scaffolds but also to organize them hierarchically according to their functional groups.

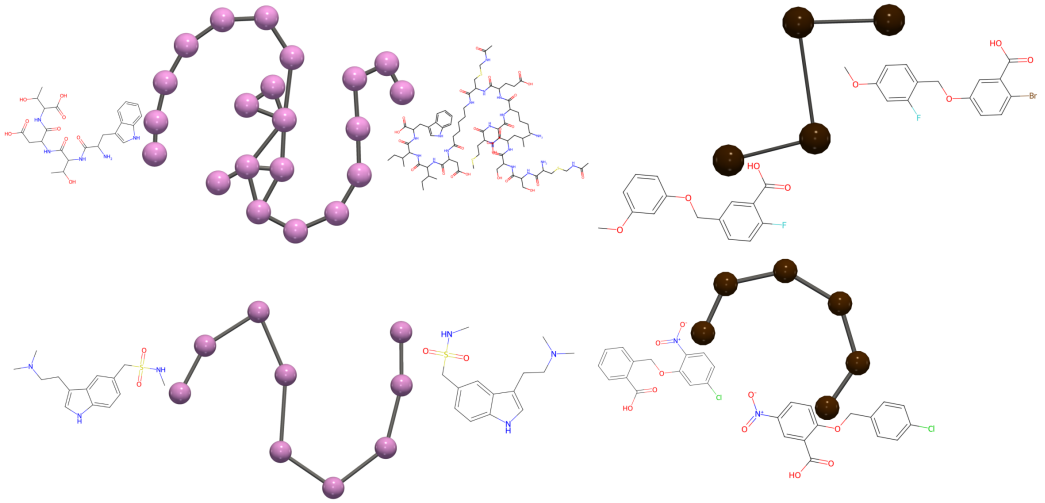

Figure 6 Four chain-like connected components with representative molecules identified by *Chemical Mapper* on the pre-trained GEM model. The components on the left are extracted from region 1 in Figure 5 (right), while the components on the right correspond to regions 9 (top) and 7 (bottom), respectively.

3.2.2 Exploring Chains and Branches in Chemical Latent Space

A *chain* in a mapper graph refers to a linear arrangement of nodes forming a sequential, chain-like structure, whereas *branches* are chains that emerge from a common source node. We investigate the evolution of chemical structures across mapper edges in the latent space by analyzing these chains and branches in the mapper graph.

The components shown in Figure 6 exhibit chain-like topologies, each consisting of a nearly linear sequence of nodes. In the top-left component, the number of amide bonds (O=C–NH–) within the molecules gradually increases from one end of the chain to the other. The GEM model not only groups molecules with a dominant presence of amide bonds into the same component but also differentiates them according to the number of such bonds. This represents a specific instance of a broader pattern in the chemical space, where similar trends are observed across multiple regions of the mapper graph.

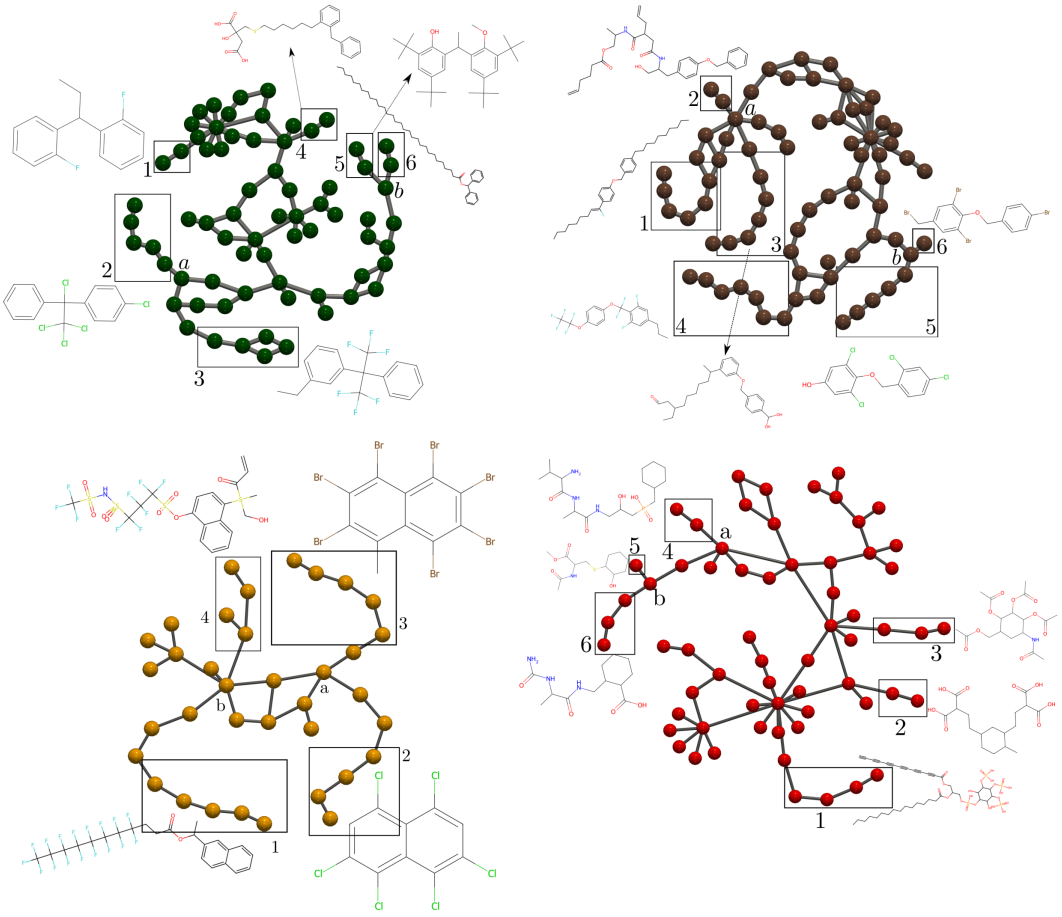

Figure 7 Four connected components with prominent branching structures identified by *Chemical Mapper* on the GEM model. The components are extracted from region 5 (top-left), region 8 (right), region 4 (bottom-left), and region 2 (bottom-right) in Figure 5 (right). Branches are highlighted using numbered boxes, and representative molecules are displayed adjacent to their corresponding branches or indicated with arrows.

In contrast, branches in the mapper graph represent bifurcations that correspond to distinct functional groups. As shown in Figure 7, the numbered branches (highlighted by boxes) reveal fine-scale structural variations among molecular clusters. The top-left component features multiple branches that share the same scaffold (c1ccc(Cc2ccccc2)cc1) but differ in their functional groups. Specifically, branch 1 contains molecules with fluoride groups (–F), whereas branch 4 includes molecules with carboxylic groups (COOH). Branches 5 and 6 emerge from the branching node b, with branch 5 comprising molecules rich in quaternary carbon groups and branch 6 containing molecules with long carbon chains.

These bifurcations not only distinguish functional groups with markedly different chemical structures but also separate those with closely related frameworks that differ only by atomic composition. For instance, from the branching node a, branch 2 primarily contains molecules with chloride (–Cl) and trichloride ($–CCl_3$) groups, whereas branch 3 consists of molecules featuring trifluoride ($–CF_3$) groups.

Similarly, the top-right component in Figure 7 displays multiple branches that reflect comparable bifurcation patterns of functional groups. Branches 1, 2, and 3 originate from node a, containing molecules characterized by long carbon chains, amides (O=C–NH–), and alcohols (–OH), respectively. Branches 5 and 6 bifurcate from node b, with branch 5 including molecules containing chlorides (–Cl) and branch 6 those containing bromides (–Br). Branch 4 comprises molecules with a prominent presence of fluoride (e.g., –F, $–CF_5$) groups.

Similarly, the bottom-left component of Figure 7 is composed of molecules with a high halogen content, and it is notable that all halogen-bearing molecules cluster together within a single component. Within this component, the mapper graph indicates a hierarchical separation of molecules according to the specific halogen substituent. Branch 1 consists of molecules featuring fluorine (–F), branch 2 contains molecules with chloride (–Cl), and branch 3 includes those with bromine (–Br). Notably, branches 2 and 3 both emerge from node a. Although they differ in the halogen substituent, their molecules remain structurally similar because the halogens are directly attached to the underlying aromatic scaffold. Branch 4 comprises molecules that contain both fluorine (–F) and sulfone (O=S=O) groups. Branches 1 and 4 originate from node b, reflecting their shared fluorine-containing molecules.

A similar pattern of organization appears in the bottom-right component of Figure 7. Branches 1, 2, and 3 contain molecules enriched in phosphate (PO_4) and long carbon chains, carboxylic acid (O=C–OH), and aldehyde (O=CH) functional groups, respectively. In contrast, branches 4, 5, and 6 all contain amide functional groups (O=C–NH–). Rather than forming a single branch, these three branches diverge hierarchically, reflecting additional chemical variations among the molecules. Branch 4 diverges first at node a, indicating the presence of a prominent phosphoryl functional group (PO_2), in addition to the amide group. From the remaining branch emerging from node a, a further split occurs at node b. This subsequent bifurcation reflects an additional layer of chemical variation: branch 5 contains molecules featuring sulfur substituents (–S–), whereas branch 6 includes molecules enriched in carboxylic acid functional groups (O=C–OH). This hierarchical branching structure shows how the mapper graph progressively separates molecules based on both their dominant and secondary functional groups.

3.2.3 Mapper for Chemical Function Analysis

Given the strong relationship between molecular structure and chemical function, mapper graphs provide a powerful framework for interpreting chemical properties. We use the water solubility and toxicity datasets from Deep-PK [31], comprising 9,964 molecules with solubility labels and 10,130 molecules with toxicity labels. Both properties are reported on a logarithmic scale. Using these datasets, we train the GEM model [13] to predict properties for the two million molecules analyzed in this study. Specifically, 90% of the labeled data are used for training and the remaining 10% for validation, with model parameters optimized based on validation performance. Once the GEM model reaches its optimal accuracy, it is employed to predict water solubility and toxicity for unlabeled molecules, thereby assigning property labels to previously uncharacterized chemical structures for downstream analysis.

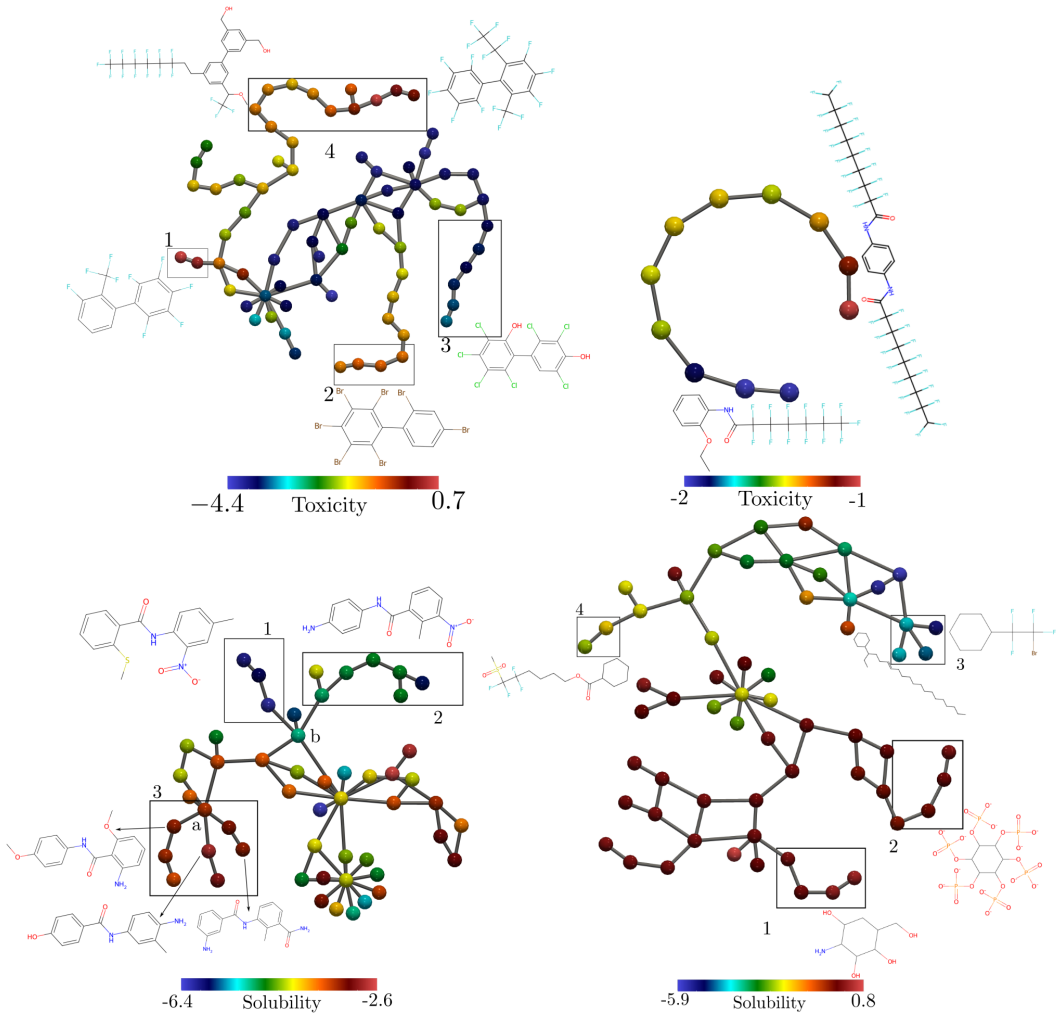

Figure 8 Four connected components with prominent branching structures or chains identified by *Chemical Mapper* and colored according to averaged chemical properties. The components are extracted from region 10 (top-left), region 6 (top-right), region 3 (bottom-left), and region 2 (bottom-right) in Figure 5 (right). Branches are highlighted with numbered boxes, and representative molecules are displayed adjacent to their corresponding branches or indicated with arrows.

Our key finding is that the mapper graph effectively visualizes the organization of molecules with similar chemical properties into cohesive regions, while molecules spanning different property ranges are distributed across distinct branches. This organization aligns closely with structural characteristics: the branching patterns in the mapper graph reflect variations in functional groups, the primary determinants of chemical behavior.

Figure 8 illustrates four connected components from the mapper graph in Figure 5. In the top panel, nodes are colored by molecular toxicity, and in the bottom, by water solubility; colormaps are adjusted for each component to better highlight diversity. In both cases, nodes within each branch share similar colors or exhibit gradual color transitions, indicating smooth variation in the corresponding property. In Figure 8 (top-left), branch 1 contains highly toxic molecules, likely due to the strong presence of fluoride groups (–F). Branch 2, which shows higher toxicity than branch 3, is enriched with bromide-containing (–Br) molecules, while

branch 3 is characterized by chloride (–Cl) substitution. Branch 4 is particularly notable: toxicity increases progressively along the branch. Although all molecules in this branch contain fluoride groups, the less toxic end includes additional functional groups, whereas the highly toxic end consists solely of fluoride-bearing (–F) molecules. Representative molecular structures are displayed alongside each branch.

In Figure 8 (top-right), the component forms a single linear chain in which toxicity increases steadily along its length. This gradual rise in toxicity parallels the chemical trend observed in the structures: all molecules in the chain contain fluorine substituents (–F), but the number of fluorine functional groups increases progressively from one end of the chain to the other. As a result, molecules at the high-toxicity end exhibit a substantially heavier fluorine presence compared to those at the low-toxicity end.

A similar pattern is observed in the component in Figure 8 (bottom-right). Within each branch, nodes display uniform or gradually changing colors. Branch 1 consists of highly soluble molecules, primarily due to the presence of alcohol (–OH) and amine (–NH_2) groups. Branch 2 also contains highly soluble molecules, likely attributable to phosphate (–PO_4) groups. This is interpretable, as phosphate-containing molecules (–PO_4) appear in high-solubility regions, due to their charged and polar nature. These functional groups correspond to identifiable subgraphs (C–O–H and P–O–O patterns) that the GEM model learns to encode, forming distinct branches in the mapper graph. In Area 3, the branches are dominated by molecules with halide substitutions (e.g., –Br, –F) or very long carbon chains (–$(CH_2)_n$–), which generally correspond to low water solubility. Branch 4 contains molecules of moderate solubility, as they appear to contain sulfone (–SO_2–) groups that increase solubility, but also halides that reduce it, resulting in an intermediate solubility profile.

A comparable pattern emerges in Figure 8 (bottom-left) component, where each branch contains molecules with either uniform or smoothly varying solubility levels. Branch 1 consists of molecules with low solubility, primarily due to the presence of nitro groups (–NO_2). Branch 2, which also contains nitro-bearing (–NO_2) molecules, exhibits moderately higher solubility because these molecules additionally feature amine functional groups (–NH_2), which enhance aqueous solubility. Note, branches 1 and 2 diverge from node b, reflecting their shared nitro substitution. Area 3 contains three branches, each composed of molecules with high solubility. These molecules predominantly feature epoxide (–C–O–C–), alcohol (–OH), or amide (O=C–NH–) functional groups. All three branches emerge from node a, consistent with the fact that their molecular structures are closely related, differing mainly in the specific solubility-enhancing functional group present.

Finally, for completeness, we present the full mapper graph of the chemical latent space from the pre-trained GEM model, where nodes are colored according to predicted toxicity (left) and solubility (right) in Figure 9.

3.3 Exploring Chemical Latent Spaces from Different Learning Models

In this section, we demonstrate how mapper graphs can serve as a powerful tool for characterizing and evaluating molecular representations learned by geometric deep learning models such as GraphMAE and Mole-BERT. We further show that mapper graphs enable qualitative comparisons of the learning capabilities between pre-trained and fine-tuned models.

Following the procedure for the GEM model (Section 3.2), we apply *Chemical Mapper* to the molecular representations of the same two million molecules from the PubChem database [22], learned by the pre-trained GraphMAE model. A subgraph of the resulting mapper graph is shown in Figure 10 (left), where each node is represented as a pie chart

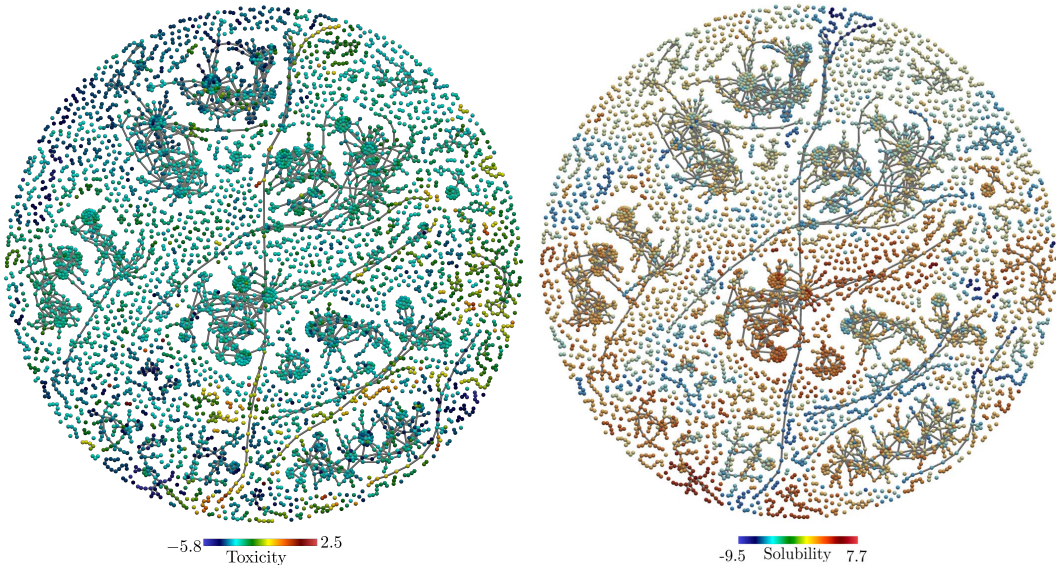

Figure 9 Mapper graphs of molecular representations from the pre-trained GEM model, computed using the same experimental settings as in Figure 5. Nodes are colored according to molecular toxicity (left) and solubility (right), as discussed in Section 3.2.3 and Section 2.

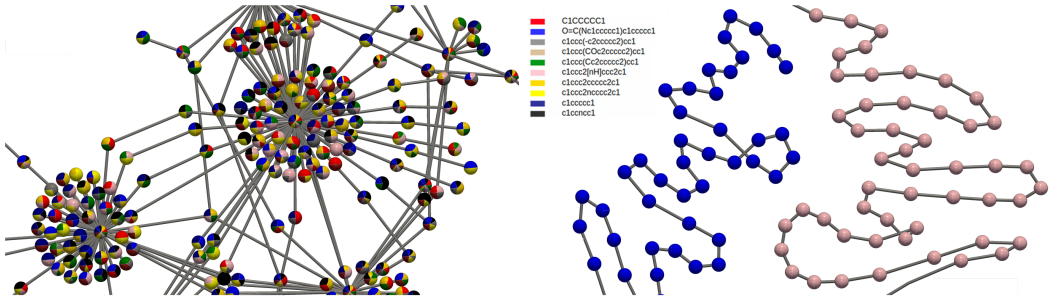

Figure 10 Partial views of mapper graphs derived from latent representations of the pre-trained (left) and fine-tuned (right) GraphMAE models. Fine-tuning refines and restructures the latent space, revealing its evolution during training. Both graphs are computed with 500 intervals, 40% overlap, and DBSCAN parameters $\epsilon = 5$ and `minPts` $= 5$.

indicating the distribution of molecular scaffolds within that node. Each node clearly contains a mixture of scaffolds, suggesting that the pre-trained GraphMAE model does not separate the chemical space according to scaffold structure (cf. Section 3.2.1). Moreover, the mapper graph exhibits no clear branching patterns, in contrast to the structured branches observed for the GEM model (Section 3.2.2).

Subsequently, the pre-trained GraphMAE model is fine-tuned on the task of predicting molecular scaffolds, and representations for the same two million molecules are extracted from the fine-tuned model. Using identical parameters, a new mapper graph is constructed. Figure 10 (right) shows a portion of this graph, where the nodes are noticeably more homogeneous, with molecules sharing the same scaffold clustering together. Fine-tuning the GraphMAE model, therefore, induces a clearer partitioning of the chemical space according to molecular scaffolds. The resulting mapper graph contains 1,606 nodes – a substantial

increase from the 420 nodes in the mapper graph of the pre-trained model – indicating that fine-tuning expands the representational space and more effectively separates molecules with different scaffolds.

Furthermore, the mapper graph derived from the fine-tuned model consists predominantly of chains and exhibits few branches. As discussed in Section 3.2.2, branching in the chemical space reflects distinctions among functional groups. Because the fine-tuning task focuses solely on scaffold prediction and does not consider functional groups, the lack of branching suggests that the chemical space is organized primarily around scaffold structure rather than functional group variation.

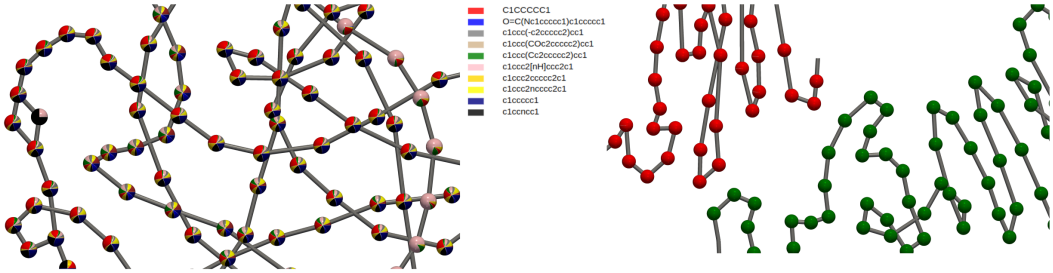

Figure 11 Partial views of mapper graphs of molecular representations from the pre-trained (left) and fine-tuned (right) Mole-BERT model. Nodes are colored by scaffolds.

We conduct a similar experiment with Mole-BERT on the same two million PubChem molecules, obtaining results qualitatively consistent with GraphMAE. Figure 11 compares mapper graphs from the pre-trained (left) and fine-tuned (right) Mole-BERT models for the scaffold classification task.

For completeness, we may also compare the pre-trained and fine-tuned GEM model. Figure 12 shows the complete mapper graph of the chemical latent space derived from the GEM model fine-tuned on the scaffold classification task, with nodes colored by molecular scaffolds. We perform a comparative analysis between the pre-trained and fine-tuned GEM models. As shown in Figure 5 and Figure 12, the mapper graph of the fine-tuned GEM model exhibits the same qualitative trends observed in the pre-trained model (Section 3.2): molecules with different scaffolds remain clearly separated into distinct connected components, and branching structures continue to reflect variations in functional groups.

Because the chemical space produced by the pre-trained GEM model already partitions molecules according to scaffolds (as shown in Figure 5), fine-tuning on this task does not substantially affect the purity of the cluster nodes. However, comparing the mapper graphs in Figure 5 and Figure 12 reveals notable topological changes. Certain scaffold classes become more dispersed, exhibiting a larger number of isolated nodes and fewer interconnections (e.g., c1ccccc1), whereas others contract significantly (e.g., c1ccc(-c2ccccc2)cc1 and c1ccc(COc2ccccc2)cc1). Investigating the causes and implications of these topological changes represents an important direction for future research.

4 Conclusion, Discussion and Future Work

In conclusion, the immense size and complexity of chemical space present substantial challenges for analysis and discovery. In this work, we introduce *Chemical Mapper*, a mapper framework that enables effective visualization, search, exploration, and interpretation of chemical latent spaces. Our approach offers several key advantages. First, similar to tradi-

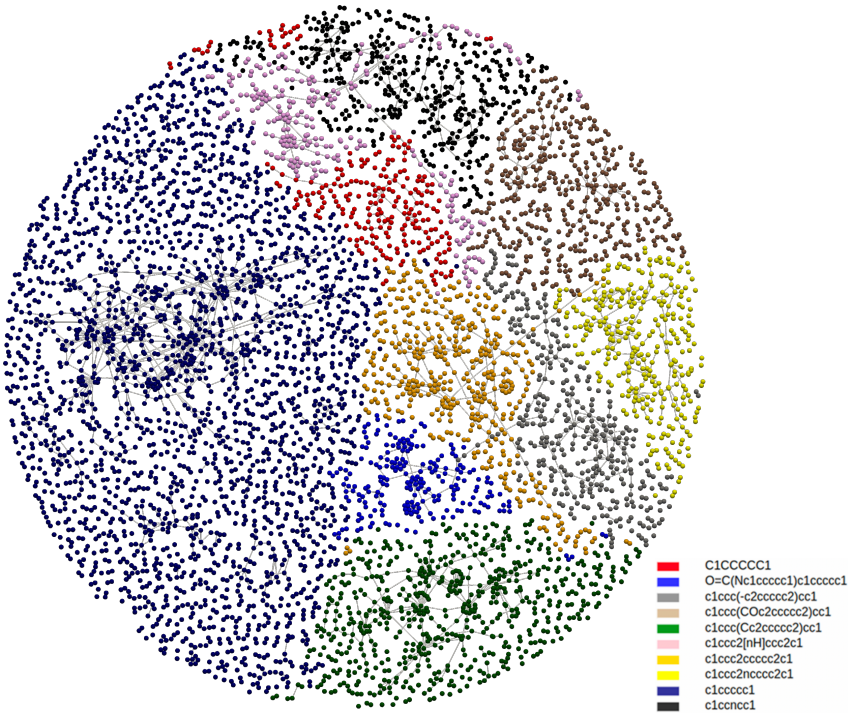

Figure 12 Mapper graph of molecular representations from the fine-tuned GEM model, colored by molecular scaffolds.

tional clustering methods, the mapper graph organizes molecules with similar properties into coherent groups. Second, beyond simple clustering, the graph's topological structures, such as connected components and branches, capture the continuous variations and evolution among molecular structures. Third, by jointly encoding both structural clustering and topological organization, mapper graphs provide a powerful lens for understanding chemical functions and properties. Finally, *Chemical Mapper* serves not only as an analysis tool but also as a diagnostic framework for evaluating chemical representations: it allows qualitative assessment of how well deep learning models capture meaningful chemical patterns.

Our framework provides a principled and interpretable approach for navigating chemical latent space, revealing its intrinsic organization and supporting both the development and evaluation of molecular deep learning methods. We conclude with a discussion of parameter tuning, stability, extensibility, and opportunities for enhanced human–AI collaboration.

4.1 Parameter Tuning

The *Chemical Mapper* framework involves several key parameters: the number of intervals m, the percentage of overlap p, and the DBSCAN clustering parameters, including the neighborhood radius ϵ and the minimum number of points `minPts` required to form a core point. These parameters are collectively denoted as $(m, p, \epsilon, \texttt{minPts})$. In practice, they are often hand-tuned (as in this study), with best practice being to select values within ranges where the mapper graph structures (such as branches, loops, and connected components) remain stable. Prior works have investigated automated parameter selection for mapper graphs [1, 6, 7, 8], and ϵ can be estimated using the elbow method [12, 53].

4.2 Stability

Theoretical studies have investigated the structural stability of mapper graphs [4, 7] and their multiscale variants [11]. In particular, mapper graphs are stable under perturbations of the data $(\mathbb{X}, f)$, with stability depending on how the cover $\mathcal{U}$ aligns with the critical values of f [4]. However, these theoretical guarantees rely on statistical assumptions that are often not satisfied in real-world datasets. Motivated by this gap, we provide empirical evidence of stability in Figure 13.

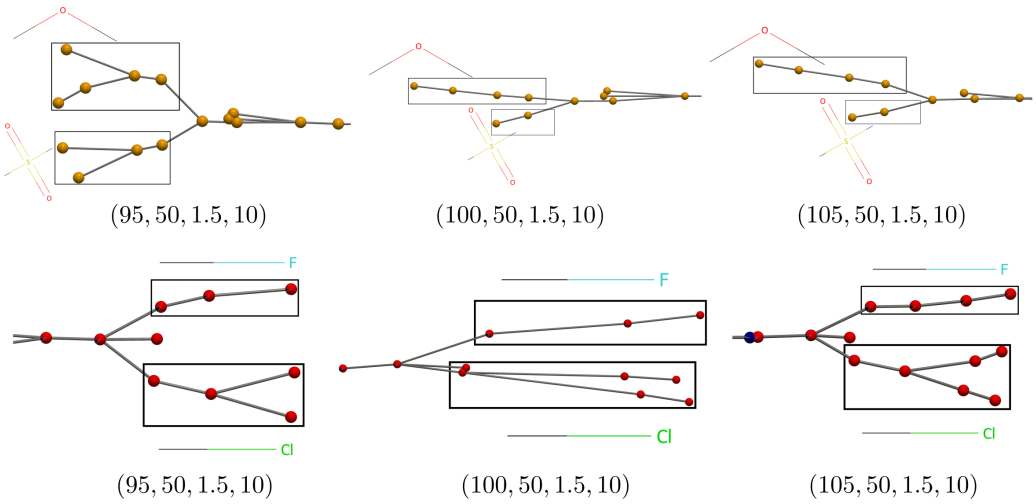

Figure 13 Two examples of local branches in mapper graphs generated under varying parameter settings $(m, p, \epsilon, \texttt{minPts})$, where p, ϵ, and `minPts` are fixed and m varies from 95 to 105. In both top and bottom cases, a component with the same branching structure and the same set of molecules persists across different m values, illustrating the stability of the mapper construction.

Building on these findings, we examine the stability of mapper graphs under varying parameter configurations using two million molecular representations from PubChem, generated by the pre-trained GEM model (same as the dataset used in Section 3). As shown in Figure 13, local branches in the mapper graphs remain consistent across suitable ranges of m, where each branch corresponds to molecules sharing a functional group, indicated alongside the branch. In particular, the first row in Figure 13 highlights connected components containing molecules with –O– and –(O=S=O)– functional groups, exhibiting the same bifurcation pattern across three values of m. Similarly, the second row in Figure 13 shows a bifurcation between molecules containing –F and –Cl groups across different interval numbers.

Overall, this experiment provides an initial demonstration of the robustness of the mapper framework in capturing chemically meaningful topological structures across parameter settings. Although parameter variations affect the granularity of branching, the key separations corresponding to distinct functional groups remain stable. Future work should investigate how chemical semantics relate to parameter choices, guiding principled parameter selection and further enhancing the mapper's interpretability and applicability in cheminformatics.

4.3 Extendability and Human-AI Collaboration

We plan to extend *Chemical Mapper* to study structural motifs beyond scaffolds, including functional groups as well as aromatic and reactivity motifs. The recent Explainable Mapper framework [49] provides an effective strategy for analyzing high-dimensional latent spaces

by integrating topological representations with agentic large language model (LLM)–based explanations. In the chemical domain – where latent spaces may encode relationships among molecular structure, reactivity, and function – this approach opens up rich opportunities for human–AI collaboration. In such a setting, rather than relying solely on human experts to explain mapper elements (Section 3.2), agents powered by LLMs or VLMs (Vision–Language Models) can propose distinguishing descriptors (e.g., fingerprints, substructures, or property ranges) and generate hypotheses about the chemical attributes that unify a given mapper element – such as the connected components, chains, and branches described in Section 3.2. Human experts can then validate or refine these hypotheses using their domain knowledge. We leave this direction for future work.

Abstract

End-to-end topological learning using 1-parameter persistence is well-known. We show that the framework can be enhanced using 2-parameter persistence by adopting a recently introduced 2-parameter persistence based vectorization technique called GRIL. We establish a theory for gradient *descent* on GRIL producing D-GRIL. We show that D-GRIL can be used to learn a bifiltration function on benchmark graph datasets. Further, we exhibit that this framework can be applied in the context of bio-activity prediction in drug discovery.

1 Introduction

In recent years, persistent homology, one of the flagship concepts of Topological Data Analysis (TDA), has found its use in many fields such as neuroscience, material science, sensor networks, shape recognition, gene expression data analysis and many more [12, 25]. The performance of machine learning models such as Graph Neural Networks (GNNs) can be improved by augmenting topological information captured by persistent homology [8, 15, 29, 30]. Classical persistent homology, also known as 1-parameter persistence, captures the evolution of topological structures in a simplicial complex K following a filter function $f\colon K \to \mathbb{R}$. The evolution of topological structures, in this case, can be completely characterized and compactly represented as *persistence diagrams* or equivalently *barcodes* [21, 50]. These

[1] Equal contribution

persistence diagrams or barcodes can be vectorized [1, 2, 8, 28, 31, 42] and used in machine learning pipelines. In most applications, the simplicial complex K is given and the choice of the filter function f depends on the application. Choosing an appropriate filter function can be challenging. To avoid this, in [27], the authors proposed an end-to-end learning framework to learn the filter function rather than relying on making the right choice. They showed that learning the filter function performs better than the standard choices of filter functions on many graph datasets.

To obtain richer topological information, we can consider an $\mathbb{R}^n$-valued filter function instead of a scalar filter function. This leads to the structure of a multiparameter persistence module instead of 1-parameter persistence module. Multiparameter persistence modules, unlike their 1-parameter counterparts, can *not* be classified completely using a discrete invariant [5]. Consequently, vectorizing multiparameter persistence modules while retaining as much topological information as possible has become a challenging problem. There are many recent works in this direction which use incomplete invariants such as *rank invariant* [5] or equivalently *fibered barcodes* [33], multiparameter persistence images [6], multiparameter persistence landscapes [45], multiparameter persistence kernel [11], vectorization of signed barcodes [35], topological fingerprinting for virtual screening using multidimensional persistence [16], effective multidimensional persistence [10] or *generalized rank invariant* [48]. The authors, in all these works, show that 2-parameter persistence methods perform better than 1-parameter persistence methods on many graph and time-series datasets, suggesting that an $\mathbb{R}^2$-valued filter function, indeed, captures richer topological information than a scalar filter function. However, in all these works, one needs to make a suitable choice for an $\mathbb{R}^2$-valued filter function. Akin to the 1-parameter setup, learning the filter function rather than choosing a filter function can prove to be more informative and beneficial for the task at hand.

In this paper, we propose an end-to-end learning framework using 2-parameter persistent homology based on the vectorization Gril introduced by [48]. We show that Gril is piecewise affine and give an explicit formula for the differential of Gril. The results discussed in [7, 14] help us to show the convergence of stochastic sub-gradient descent on Gril. We use these results to build a differentiable topological layer D-Gril, consequently an end-to-end learning pipeline. We use D-Gril for bio-activity prediction and provide experimental results. One of the key advantages of using TDA in the context of bio-activity prediction is its ability to capture and analyze the shape and structural characteristics of molecules in a manner that traditional methods might overlook. Molecules possess intricate shapes and topological features that directly influence their interactions with biological targets. TDA can uncover these subtleties, allowing for a deeper understanding of structure-activity relationships. We also show that D-Gril can be used, more generally, for bifiltration learning on graphs and provide experimental results where we compare with existing multiparameter persistence methods on benchmark graph datasets.

In a recent work, authors of [44] present an end-to-end topological learning method by developing a general framework suitable for a class of invariants of multiparameter persistence. Our approach though specific to Gril is more direct, uses simpler arguments, and is faster for training.

2 Overview

Our main construct is Gril, introduced in [48] for vectorizing a 2-parameter persistence module. Gril is defined in the same spirit as persistence landscapes [2], introduced for 1-parameter persistence. The landscape uses the rank function over the interval decomposition known for 1-parameter persistence modules. To extend the concept to 2-parameter persistence

modules, one faces two main challenges: (i) in general, persistence modules beyond 1-parameter may not decompose into intervals, (ii) the usual rank function cannot be defined for intervals that are not rectangular. GRIL solves (i) by defining the landscape function over a fixed set of two-dimensional intervals called ℓ-*worms* instead of the support of the indecomposables of the modules, and solves (ii) by considering a generalized version of the rank function termed as *generalized rank* (Definition 3).

An interesting property of the generalized rank over intervals is that it monotonically decreases as the intervals get larger. Thus, given fixed parameters $k > 0$ and $\ell > 0$, the width d of an ℓ-worm can be increased until the generalized rank over the worm drops below k. The maximum value of the width thus obtained, $d_{\mathbf{p}}$, is the value of GRIL at the worm center point $\mathbf{p}$ for k and ℓ.

GRIL yields a vector representation of the 2-parameter persistence module formed from a given simplicial complex and a bifiltration function (formally defined in section 3). However, there is no provision to learn this bifiltration function. To learn a suitable bifiltration function, we build a differentiable layer called D-GRIL. We show in section 6 that the learnt bifiltration function performs better than some of the popular bifiltration functions known in TDA supporting the need for end-to-end learning.

3 Background

We review and recall some definitions and results in this section. Section 3.1 primarily consists of concepts in multiparameter persistent homology. Section 3.3 consists of concepts and results that establish the conditions required for the convergence of stochastic sub-gradient descent. Section 3.2 contains some background which is required to prove that GRIL satisfies these conditions.

3.1 Multiparameter persistent homology

In this subsection, we briefly review the concepts in multiparameter persistent homology. We focus, primarily, on 2-parameter persistent homology. For detailed definitions, refer [20, 22]. We begin by recalling the definition of a simplicial complex. Given a finite vertex set V, a simplicial complex $K = K(V)$ defined on this vertex set is a collection of subsets of V such that if a subset $\sigma \subseteq V$ is in K, then all proper subsets $\tau \subset \sigma$ are also in K. Each element in K with cardinality $k+1$ is called a k-simplex or simply a simplex. A graph is a simplicial complex where V is the vertex set of the graph and K consists of edges and vertices of the graph. A *filtration* is a collection of simplicial complexes $\{K_{\mathbf{x}}\}_{\mathbf{x}\in\mathbb{R}}$ indexed by the reals, with the property that $K_{\mathbf{x}} \subseteq K_{\mathbf{y}}$ for each $\mathbf{x} \leq \mathbf{y}$. Extending this definition to collections of complexes indexed by $\mathbb{R}^2$ with the product partial order ($\mathbf{x} \leq \mathbf{y} \in \mathbb{R}^2$ if $x_1 \leq y_1$ and $x_2 \leq y_2$), we get a *bifiltration*.

▶ **Definition 1** (Bifiltration). *A bifiltration is a collection of simplicial complexes* $\{K_{\mathbf{x}}\}_{\mathbf{x}\in\mathbb{R}^2}$ *where* $K_{\mathbf{x}} \subseteq K_{\mathbf{y}}$ *for all comparable* $\mathbf{x} \leq \mathbf{y} \in \mathbb{R}^2$.

Let K be a simplicial complex and $f\colon K \to \mathbb{R}^2$ be a map with the property that $f(\sigma) \leq f(\tau) \in \mathbb{R}^2$ for all $\sigma \subseteq \tau$. For each $\mathbf{x} \in \mathbb{R}^2$, let $K_{\mathbf{x}} \coloneqq \{\sigma \in K\colon f(\sigma) \leq \mathbf{x}\}$. Clearly, $K_{\mathbf{x}} \subseteq K_{\mathbf{y}}$ for all comparable $\mathbf{x} \leq \mathbf{y} \in \mathbb{R}^2$. The resulting bifiltration, denoted $\{K^f_{\mathbf{x}}\}_{\mathbf{x}\in\mathbb{R}^2}$, is called the *sub-level set* bifiltration of the *bifiltration function* f.

A filtration in the 1-parameter case induces a persistence module, obtained by considering the inclusion-induced linear maps between the vector spaces given by the homology groups of the simplicial complexes comprising the filtration. Similarly, we obtain a 2-parameter persistence module from a bifiltration.

▶ **Definition 2** (2-parameter persistence module). *A 2-parameter persistence module is an assignment of finite-dimensional vector spaces $M_{\mathbf{x}}$ for each $\mathbf{x} \in \mathbb{R}^2$, and of linear maps $M_{\mathbf{x}\leq\mathbf{y}} \colon M_{\mathbf{x}} \to M_{\mathbf{y}}$ for all comparable $\mathbf{x} \leq \mathbf{y} \in \mathbb{R}^2$, with the properties that $M_{\mathbf{x}\leq\mathbf{x}} = id$ and $M_{\mathbf{y}\leq\mathbf{z}} \circ M_{\mathbf{x}\leq\mathbf{y}} = M_{\mathbf{x}\leq\mathbf{z}}$ for all $\mathbf{x} \leq \mathbf{y} \leq \mathbf{z} \in \mathbb{R}^2$.*

Readers familiar with category theory can recognize that a 2-parameter persistence module is a functor $M \colon \mathbb{R}^2 \to \mathbf{vec}_{\mathbb{F}}$ where the poset $\mathbb{R}^2$ is regarded as a category and $\mathbf{vec}_{\mathbb{F}}$ denotes the category of finite-dimensional vector spaces over a field $\mathbb{F}$.

Given a bifiltration $\{K_{\mathbf{x}}\}_{\mathbf{x}\in\mathbb{R}^2}$, we consider $H_i(K_{\mathbf{x}})$, the ith homology group of the simplicial complex $K_{\mathbf{x}}$ over a field F, say $\mathbb{Z}_2$. Then, for each inclusion $K_{\mathbf{x}} \subseteq K_{\mathbf{y}}$, we get an induced linear map $H_i(K_{\mathbf{x}}) \to H_i(K_{\mathbf{y}})$. By this assignment, we get a 2-parameter persistence module.

Let $\{K^f_{\mathbf{x}}\}_{\mathbf{x}\in\mathbb{R}^2}$ be a sub-level set bifiltration. Then the 2-parameter persistence module M obtained by the homology assignment is called the 2-parameter persistence module induced by f, and we denote it as M_f.

As mentioned in Section 2, GRIL vectorization uses the concept of generalized rank introduced by [32], which we define below formally.

▶ **Definition 3** (Generalized Rank). *Let M be a 2-parameter persistence module. The restriction of M to an interval I of $\mathbb{R}^2$, denoted by $M|_I$, is the diagram formed by the collection of vector spaces $M_{\mathbf{x}}$ for $\mathbf{x} \in I$ and linear maps $M_{\mathbf{x}\leq\mathbf{y}}$ for all comparable $\mathbf{x} \leq \mathbf{y} \in I$. Then, the generalized rank of M over I is defined as the rank of the canonical map from the limit $\varprojlim M|_I$ to colimit $\varinjlim M|_I$:*

$$\mathsf{rk}^M(I) := rank\left(\varprojlim M|_I \to \varinjlim M|_I\right).$$

We refer the reader to [36] for the definitions of limit, colimit, and the construction of the canonical limit-to-colimit map. Intuitively, generalized rank captures the number of independent topological features supported over the interval I. It can be computed efficiently for 2-parameter persistence modules [18] using zigzag persistence [17].

▶ Remark 4. In the special case where I is a rectangle, $\mathsf{rk}^M(I)$ is the rank of the linear map $M_{\mathbf{u}\leq\mathbf{v}}$ from the lower left corner $\mathbf{u}$ of the rectangle to the upper right corner $\mathbf{v}$.

3.2 o-minimal geometry

We recall the definitions of o-minimal structure and definable function here.

▶ **Definition 5** (o-minimal structure). *An o-minimal structure on $\mathbb{R}$ is a collection $\{S_n\}_{n\in\mathbb{N}}$ where each S_n is a set of subsets of $\mathbb{R}^n$ such that:*

1. *S_1 is exactly the collection of finite union of points and intervals.*
2. *S_n contains all the sets of the form $\{\mathbf{x} \in \mathbb{R}^n \colon p(\mathbf{x}) = 0\}$ where p is a polynomial on $\mathbb{R}^n$.*
3. *S_n is a Boolean sub-algebra of $\mathbb{R}^n$ for all n.*
4. *If $A \in S_n$ and $B \in S_m$, then $A \times B \in S_{n+m}$.*
5. *If $\pi \colon \mathbb{R}^{n+1} \to \mathbb{R}^n$ is the canonical projection onto the first n-coordinates, then for $A \in S_{n+1}$, $\pi(A) \in S_n$.*

A subset $A \in S_n$ for some $n \in \mathbb{N}$ is known as a *definable set* in the o-minimal structure. Let $A \in S_n$ be given. A function $f \colon A \to \mathbb{R}^m$ is said to be *definable* if the graph of the function in $\mathbb{R}^{n+m}$ is a definable set.

We note that all semi-algebraic functions are definable. In fact, the author in, [47], shows that there exists an o-minimal structure that simultaneously contains all semi-algebraic sets and the graph of the exponential function. The authors in [14] use this result to show that a

neural network, being a composition of definable functions, is definable (Corollary 5.11 [14]). For readers not familiar with the notion of definable functions, it is sufficient to know that a piecewise affine map is definable.

3.3 Stochastic sub-gradient descent

In this subsection, we briefly review the result and the conditions under which stochastic sub-gradient descent converges as shown in [14]. In [7], authors use this result in the setting of 1-parameter persistent homology and show that stochastic sub-gradient descent converges in that case. We begin by reviewing the definition of Clarke subdifferential. Given a locally Lipschitz function $f\colon \mathbb{R}^n \to \mathbb{R}$, the Clarke subdifferential of f at a point x is defined as:

$$\partial f(x) \coloneqq \mathbf{Co}\left\{s \in \mathbb{R}^n \colon \exists x^k \to x, \nabla f(x^k) \text{ exists, and } \nabla f(x^k) \to s\right\},$$

where **Co** denotes the convex hull of the set.

Now, given a loss function $\mathcal{L}$ with the objective of minimizing it, consider the differential inclusion

$$\dot{\mathbf{z}}(t) \in -\partial\mathcal{L}(\mathbf{z}(t)) \quad \text{for almost every } t,$$

where $\partial\mathcal{L}(\mathbf{z}(t))$ denotes the Clarke subdifferential of the function $\mathcal{L}$ at the point $\mathbf{z}(t)$. The solutions $\mathbf{z}(t)$ are the trajectories of the sub-gradient of $\mathcal{L}$ which can be approximated by the standard stochastic sub-gradient descent method given by:

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha_k(\mathbf{y}_k + \zeta_k), \quad \mathbf{y}_k \in \partial\mathcal{L}(\mathbf{x}_k), \tag{1}$$

where the sequence $(\alpha_k)_k$ is the learning rate and $(\zeta_k)_k$ is a sequence of random variables or "noise". [14] establish that under mild technical assumptions (stated below) on these two sequences, the stochastic sub-gradient method converges almost surely to critical points of $\mathcal{L}$ if $\mathcal{L}$ is locally Lipschitz and definable.

Consider the following assumptions (Assumption C in [14]):

1. for any k, $\alpha_k \geq 0$, $\Sigma_{k=1}^{\infty} = \infty$ and $\Sigma_{k=1}^{\infty}\alpha_k^2 < \infty$;
2. $\sup_k ||x_k|| < \infty$, almost surely;
3. denoting by $\mathcal{F}_k$ the increasing sequence of σ-algebras $\mathcal{F}_k = \sigma(x_j, y_j, \zeta_j, j < k)$, there exists a function $p\colon \mathbb{R}^d \to \mathbb{R}$ which is bounded on bounded sets such that almost surely, for any k,

$$\mathbb{E}\left[\zeta_k|\mathcal{F}_k\right] = 0 \text{ and } \mathbb{E}\left[||\zeta_k||^2|\mathcal{F}_k\right] < p(x_k).$$

▶ **Proposition 6** (Corollary 5.9 [14]). *Let $f\colon \mathbb{R}^d \to \mathbb{R}$ be a locally Lipschitz definable function*[1]*. Consider the iterates $\{\mathbf{x}_k\}_{k\geq 1}$ produced by the stochastic sub-gradient method (Eq (1)) and suppose Assumption C of [14] holds. Then, almost surely, every limit point of the iterates $\{\mathbf{x}_k\}_{k\geq 1}$ is critical for f and the function values $\{f(\mathbf{x}_k)\}_{k\geq 1}$ converge.*

4 Differentiability of GRIL

We begin this section by proving that Gril is a piecewise affine map in section 4.1. Gril being piecewise affine leads to stochastic sub-gradient converging almost surely on Gril, discussed in section 4.2. In section 4.3, we give an explicit formula for differential of Gril.

[1] The authors in [14] show that the result holds for a more general class of C^d-stratifiable functions.

4.1 GRIL as a piecewise affine map

We begin by recalling the definitions of ℓ-worm and GRIL.

▶ **Definition 7** (discrete ℓ-worm, [48]). *Let* $\boxed{\mathbf{p}}_d \coloneqq \{\mathbf{w} : \|\mathbf{p} - \mathbf{w}\|_\infty \leq d\}$ *be the* d*-square centered at* $\mathbf{p} \in \mathbb{R}^2$ *with side* $2d$*. Given* $\ell \geq 1$ *and* $d > 0$*, the* ℓ-worm, $\boxed{\mathbf{p}}_d^\ell$*, is defined as the union of all* d*-squares* $\boxed{\mathbf{q}}_d$ *centered at some point* $\mathbf{q}$ *on the off-diagonal line segment* $\mathbf{p} \pm \alpha \cdot (1, -1)$ *with* $\alpha = j \cdot d$ *where* $j \in \{1, \ldots, \ell - 1\}$.

Refer to Figure 1 for a 2-worm.

▶ **Definition 8** (GRIL, [48]). *For a 2-parameter persistence module* M*, the Generalized Rank Invariant Landscape (GRIL) is a function* $\lambda^M : \mathbb{R}^2 \times \mathbb{N}_+ \times \mathbb{N}_+ \to \mathbb{R}$ *defined as*

$$\lambda^M(\mathbf{p}, k, \ell) \coloneqq \sup\left\{d \geq 0 \colon \mathsf{rk}^M\left(\boxed{\mathbf{p}}_d^\ell\right) \geq k\right\}.$$

Fixing the bifiltration function f and k, ℓ, the landscape λ^M provides a function $\lambda^{M_f}_{k,\ell} : \mathbb{R}^2 \to \mathbb{R}$, $\mathbf{p} \mapsto \lambda^{M_f}(\mathbf{p}, k, \ell)$. The GRIL vector is the vector of values of $\lambda^{M_f}_{k,\ell}$ evaluated at a set of chosen sample points $\{\mathbf{p}_1, \ldots, \mathbf{p}_s\} \subset \mathbb{R}^2$.

Let K be a simplicial complex with n simplices, labelled $\sigma_1, \sigma_2, \ldots, \sigma_n$. A bifiltration function $f \colon K \to \mathbb{R}^2$ can be viewed as a vector $\mathbf{v}_f \in \mathbb{R}^{2n}$ where, for $k = 1, \ldots, n$, $\mathbf{v}_f[2k-1] = f_x(\sigma_k)$ and $\mathbf{v}_f[2k] = f_y(\sigma_k)$. Here, $f_x(\sigma)$ and $f_y(\sigma)$ denote the x- and y-coordinates of the vector $f(\sigma)$ respectively. Notice that the vectors in $\mathbb{R}^{2n}$ that correspond to a valid bifiltration function form a convex cone. We work with this set of vectors in $\mathbb{R}^{2n}$. In this setting, the authors in [48] show that GRIL is Lipschitz continuous in the following sense.

▶ **Proposition 9.** *Let* X *be a discrete space with* $|X| = n$*. For fixed* $k, \ell, \mathbf{p}$*, let* $\Lambda^{\mathbf{p}}_{k,\ell} \colon \mathbb{R}^{2n} \to \mathbb{R}$ *be the map* $\mathbf{v}_f \mapsto \lambda^{M_f}_{k,\ell}(\mathbf{p})$*. Then,* $\Lambda^{\mathbf{p}}_{k,\ell}$ *is Lipschitz continuous.*

By Rademacher's theorem [23], $\Lambda^{\mathbf{p}}_{k,\ell}$ is differentiable almost everywhere.

Let $\mathcal{G}_{k,\ell} \colon \mathbb{R}^{2n} \to \mathbb{R}^s$ be the map defined as:

$$\mathcal{G}_{k,\ell}(v_f) = \left[\Lambda^{\mathbf{p}_1}_{k,\ell}(\mathbf{v}_f), \Lambda^{\mathbf{p}_2}_{k,\ell}(\mathbf{v}_f), \ldots, \Lambda^{\mathbf{p}_s}_{k,\ell}(\mathbf{v}_f)\right]^T \tag{2}$$

where $\{\mathbf{p}_j\}_{j=1}^s$ are the s sampled center points. We drop the k, ℓ and refer to $\mathcal{G}_{k,\ell}$ as $\mathcal{G}$ whenever k, ℓ are well understood. We note that $\mathcal{G}$ is also a function of the center points $\mathbf{p}_j$ for all j. We show that $\mathcal{G}$ is piecewise affine.

For notational convenience, in what follows we denote $f_x(\sigma)$ as σ^x and $f_y(\sigma)$ as σ^y, and we call them the *simplex coordinates* of σ. Similarly, we denote the x-coordinate and y-coordinate of $\mathbf{p}$ as $\mathbf{p}^x$ and $\mathbf{p}^y$ respectively.

We observe that, if there are two simplices σ_i, σ_j such that for some $\rho \in \mathbb{Z}$ and $0 \leq \rho \leq \ell$ and $a, b \in \{x, y\}$, one has $|\sigma_i^a - \mathbf{p}_t^a| = \rho \cdot |\sigma_j^b - \mathbf{p}_t^b|$ then, say for $a = x$ and $b = y$, the point representing the vector $\mathbf{v}_f$ lies on a hyperplane in $\mathbb{R}^{2n}$:

$$\left\{\mathbf{v} \in \mathbb{R}^{2n} \colon\ |\mathbf{v}[2i-1] - \mathbf{p}_t^x| = \rho \cdot |\mathbf{v}[2j] - \mathbf{p}_t^y|\right\}.$$

Corresponding to each such pair of simplex coordinates, we get one hyperplane. Here, in the example, we chose one simplex coordinate to be x-coordinate and the other to be y-coordinate. This, however, need not always be the case: we can have all four possible combinations of x- and y-coordinates, corresponding to each of which we get a hyperplane. We refer the reader to Appendix A in [40] for the exact formula of all such hyperplanes. Combining all

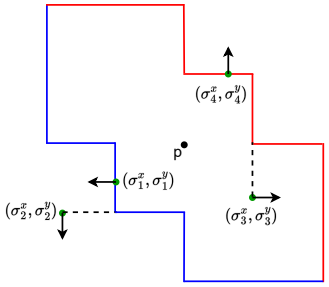

Figure 1 A 2-worm with lower boundary colored in blue and upper boundary colored in red. The figure also shows the possible cases of **constraining simplex coordinates**; σ_1 is a *lower x-constraining* simplex coordinate because the x-coordinate σ_1^x constrains the lower boundary of the worm and prevents the worm from expanding to the left; σ_2 shows a *lower y-constraining* simplex coordinate because σ_2^y also constrains the lower boundary of the worm and prevents the worm from expanding downwards. Similarly, σ_3 and σ_4 are *upper x-constraining* and *upper y-constraining* respectively. The arrows depict the gradient directions as described in Theorem 13.

these hyperplanes, we get an *arrangement $\mathcal{H}$ of hyperplanes* in $\mathbb{R}^{2n}$ [26]. The arrangement $\mathcal{H}$ partitions $\mathbb{R}^{2n}$ into *relatively open* r-cells, $r \in \{0, \ldots, 2n\}$. We observe that this arrangement induces an affine stratification $\mathcal{S}_{\mathcal{H}}$ (refer [34] for the formal definition) of $\mathbb{R}^{2n}$ where the r-dimensional strata are precisely the r-cells.

In the following we prove that $\mathcal{G}$ is a piecewise affine map relative to this arrangement, meaning that it is affine on each stratum of $\mathcal{S}_{\mathcal{H}}$. To this end, we introduce the notions of *upper boundary*, *lower boundary*, and *constraining simplex coordinate* for an ℓ-worm which will allow us to characterize the strata of $\mathcal{S}_{\mathcal{H}}$ in terms of conditions on the bifiltration function. We give an intuitive explanation of these concepts using Figure 1. We refer the reader to Appendix A in [40] for the formal definitions.

In Figure 1, a 2-worm is shown with its lower boundary colored in blue and its upper boundary in red. As depicted, the *lower boundary* consists of the part of the boundary that is in the lower half of the worm, while the *upper boundary* consists of the rest of the boundary, i.e., a point belongs to the lower boundary (resp. upper boundary) if the open lower-set (resp. upper-set) of the point does not intersect the worm.

For an intuitive understanding of *constraining simplex coordinate*, consider the Gril value d of an ℓ-worm centered at $\mathbf{p}$ for a given rank k. It follows from Definition 8 that there exists at least one simplex σ such that σ^x or σ^y prevents the worm from expanding any further to have a Gril value more than d at $\mathbf{p}$. The coordinate in question (either σ^x or σ^y) is called a *constraining simplex coordinate* for the ℓ-worm centered at $\mathbf{p}$. Here, by preventing the worm from expanding, we mean that if the worm were to expand then the value of the generalized rank over the worm would drop below the given value of rank k. Note that an ℓ-worm can have multiple constraining simplex coordinates, including some coming from the same simplex σ.

We can characterize the top-dimensional ($2n$-dimensional) strata of $\mathcal{S}_{\mathcal{H}}$ in terms of conditions on constraining simplex coordinates for ℓ-worms, and consequently, in terms of conditions on the bifiltration functions.

▶ **Proposition 10.** *The top-dimensional strata of $\mathcal{S}_{\mathcal{H}}$ consist precisely of those bifiltration functions that have a unique constraining simplex coordinate for each ℓ-worm.*

We state the main theorem of this subsection.

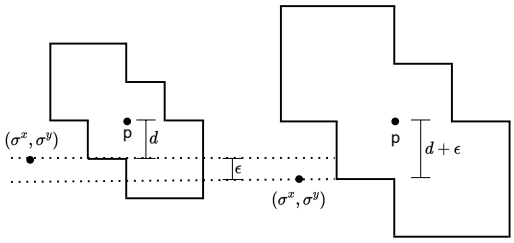

Figure 2 An intuitive understanding of the gradient assignment described in Theorem 13. The y-coordinate σ^y is at a distance of d from the y-coordinate of $\mathbf{p}$ in the left figure; σ is the only constraining simplex for the 2-worm. In the figure on the right, σ^y has *reduced* by ϵ and is now at a distance $d+\epsilon$ from $\mathbf{p}^y$. As a consequence, the value of GRIL increases from d to $d+\epsilon$. Thus, $\frac{\partial \Lambda^{\mathbf{P}}_{k,\ell}(\mathbf{v}_f)}{\partial \sigma^y} = -1$.

▶ **Theorem 11.** *Let K be a simplicial complex with n simplices. Let $k, \ell \in \mathbb{N}$, and let $\{\mathbf{p}_j\}_{j=1}^s$ be the s sampled center points for the ℓ-worms. Then, $\mathcal{G}$, as defined in Eq.*(2)*, is a piecewise affine map relative to the arrangement $\mathcal{H}$.*

Overview of the proof: $\mathcal{G}$ depends affinely on the simplex coordinates in each top-dimensional stratum, because there is a unique constraining simplex coordinate for each ℓ-worm. By continuity of $\mathcal{G}$ (Proposition 9), the restriction of $\mathcal{G}$ to each (affine) lower dimensional stratum is affine.

4.2 Stochastic sub-gradient descent

In our machine learning pipeline, the GRIL map $\mathcal{G}$ is post-composed with a loss function $N\colon \mathbb{R}^s \to \mathbb{R}$, derived e.g. from some neural network. In the corollary below, we give sufficient conditions on N that ensure the convergence of stochastic sub-gradient descent on $N \circ \mathcal{G}$.

▶ **Corollary 12.** *If $N\colon \mathbb{R}^s \to \mathbb{R}$ is definable and locally Lipschitz continuous, then, under the assumptions of Proposition 6 and Theorem 11, stochastic sub-gradient descent on $N \circ \mathcal{G}$ converges almost surely to critical points of $N \circ \mathcal{G}$.*

Overview of the proof: In the discussion towards the end of section 3.3, we saw that any piecewise affine map is definable. Since $\mathcal{G}$ is piecewise affine, it is locally Lipschitz and definable. We know that the composition of two definable functions is definable, and that the composition of two locally Lipschitz functions is locally Lipschitz. These facts, put together with Proposition 6, immediately lead to the fact that stochastic sub-gradient descent converges almost surely to critical points of $N \circ \mathcal{G}$.

4.3 Differential of GRIL

In order to back-propagate gradients through the GRIL computation, we need an explicit formula for the differential of $\mathcal{G}$. Such a formula is needed only in the top-dimensional strata, where $\mathcal{G}$ is actually smooth. In lower-dimensional strata, sub-gradients can be approximated using, e.g., gradient sampling [3].

In section 4.1, we saw that $\mathcal{G}$ is piecewise affine, which implies that its differential is constant in each top-dimensional stratum. In order to compute it, we need to determine the sign of the gradient at different simplex coordinates. To do so, given a worm, we distinguish between simplex coordinates that constrain the lower boundary of the worm and those that constrain its upper boundary. Since each simplex has two coordinates, x and y, and these can

be constraining either the upper boundary or the lower boundary, we get four different cases: *lower x-constraining, lower y-constraining, upper x-constraining* and *upper y-constraining.* All these cases are shown in Figure 1.

We deduce an explicit formula for the differential of $\mathcal{G}$ in the top-dimensional strata.

▶ **Theorem 13.** *Let K be a simplicial complex with n simplices. Let $k, \ell \in \mathbb{N}$ and $\{\mathbf{p}_j\}_{j=1}^{s}$ be the s sampled center points for the ℓ-worms. Then, the differential of $\mathcal{G}$ at any $\mathbf{v}_f$ in a top-dimensional stratum is given by:*

$$\begin{pmatrix} \frac{\partial \Lambda^{\mathbf{p}_1}_{k,\ell}(\mathbf{v}_f)}{\partial \sigma^x_1} & \frac{\partial \Lambda^{\mathbf{p}_1}_{k,\ell}(\mathbf{v}_f)}{\partial \sigma^y_1} & \frac{\partial \Lambda^{\mathbf{p}_1}_{k,\ell}(\mathbf{v}_f)}{\partial \sigma^x_2} & \cdots & \frac{\partial \Lambda^{\mathbf{p}_1}_{k,\ell}(\mathbf{v}_f)}{\partial \sigma^y_n} \\ \vdots & & & & \vdots \\ \frac{\partial \Lambda^{\mathbf{p}_s}_{k,\ell}(\mathbf{v}_f)}{\partial \sigma^x_1} & \cdots & \cdots & & \frac{\partial \Lambda^{\mathbf{p}_s}_{k,\ell}(\mathbf{v}_f)}{\partial \sigma^y_n} \end{pmatrix}_{s \times 2n}$$

where,

$$\frac{\partial \Lambda^{\mathbf{p}_j}_{k,\ell}(\mathbf{v}_f)}{\partial \sigma^x_i} = \begin{cases} -1, & \text{if } \sigma_i \text{ is lower } x\text{-constraining for } \boxed{\mathbf{p}_j}^{\ell}_{d_j}, \\ +1, & \text{if } \sigma_i \text{ is upper } x\text{-constraining for } \boxed{\mathbf{p}_j}^{\ell}_{d_j}, \\ 0, & \text{otherwise,} \end{cases}$$

$$\frac{\partial \Lambda^{\mathbf{p}_j}_{k,\ell}(\mathbf{v}_f)}{\partial \sigma^y_i} = \begin{cases} -1, & \text{if } \sigma_i \text{ is lower } y\text{-constraining for } \boxed{\mathbf{p}_j}^{\ell}_{d_j} \\ +1, & \text{if } \sigma_i \text{ is upper } y\text{-constraining for } \boxed{\mathbf{p}_j}^{\ell}_{d_j} \\ 0, & \text{otherwise,} \end{cases}$$

and d_j is the GRIL *value at $\mathbf{p}_j$.*

Recall that each $\mathbf{v}_f$ in a top-dimensional stratum of $\mathcal{S}_{\mathcal{H}}$ corresponds to a bifiltration function f with a unique constraining simplex. Refer to Figure 2 for an intuitive explanation about the sign of the gradient and the different cases in Theorem 13, as shown by the arrows in Figure 1.

▶ **Corollary 14.** *Given the conditions of Theorem 13, partial derivatives of $\mathcal{G}$ with respect to $\mathbf{p}^x_j$ and $\mathbf{p}^y_j$ also exist and are given by:*

$$\frac{\partial \Lambda^{\mathbf{p}_j}_{k,\ell}(\mathbf{v}_f)}{\partial \mathbf{p}^x_j} = \begin{cases} +1, & \text{if there exists a lower } x\text{-constraining} \\ & \text{simplex for } \boxed{\mathbf{p}_j}^{\ell}_{d_j}, \\ -1, & \text{if there exists an upper } x\text{-constraining} \\ & \text{simplex for } \boxed{\mathbf{p}_j}^{\ell}_{d_j}, \\ 0, & \text{otherwise,} \end{cases}$$

$$\frac{\partial \Lambda^{\mathbf{p}_j}_{k,\ell}(\mathbf{v}_f)}{\partial \mathbf{p}^y_j} = \begin{cases} +1, & \text{if there exists a lower } y\text{-constraining} \\ & \text{simplex for } \boxed{\mathbf{p}_j}^{\ell}_{d_j}, \\ -1, & \text{if there exists an upper } y\text{-constraining} \\ & \text{simplex for } \boxed{\mathbf{p}_j}^{\ell}_{d_j}, \\ 0, & \text{otherwise.} \end{cases}$$

5 Experimental setup

In this section, we outline the overall experimental setup. We first describe some practical considerations involved in implementing D-Gril, and then describe the architecture used across all experiments.

5.1 Practical considerations

In section 4.1 we saw that $\mathcal{G}$ is piecewise affine and in section 4.2 we deduced that stochastic sub-gradient descent converges almost surely to critical points of $N \circ \mathcal{G}$ for any definable and locally Lipschitz loss function N. We gave an explicit formula for the differential of Gril in the top-dimensional strata in section 4.3, and at the beginning of that section we argued that gradient sampling can be used to approximate sub-gradients in lower-dimensional strata. In practice, for the sake of computational efficiency, we use a simple variant of gradient sampling, which consists of sampling a single nearby point and taking its gradient.

So far, we considered a bifiltration function on the entire simplicial complex K. However, in practice, we may need to extend the filtration function to the entire simplicial complex based on filtration function values on certain simplices. For example, in a lower-star filtration, the filtration function values on the higher dimensional simplices are dictated by the filtration function values on the vertices of the simplicial complex. In a Rips filtration, the filtration function values on the vertices are 0, while the filtration function values on higher dimensional simplices are dictated by the filtration function values on the edges.

In such scenarios, the bifiltration function f is given on a subcomplex L of the simplicial complex K. This is extended to a bifiltration function $\bar{f}$ on the entire simplicial complex in a piecewise constant manner. We use the example of lower-star bifiltration to show how our framework fits to this type of scenario. Let $f\colon K^0 \to \mathbb{R}^2$ be a function on the vertices of the simplicial complex K with m vertices and n simplices. The map f is extended to a piecewise constant map $\bar{f}\colon K \to \mathbb{R}^2$ as follows: for an edge $e = (u, v)$, we let $\bar{f}_x(e) = \max\{f_x(u), f_x(v)\}$ and $\bar{f}_y(e) = \max\{f_y(u), f_y(v)\}$; the values on higher dimensional simplices are defined inductively. Notice that for each simplex $\sigma \in K$, there is a *maximal x-vertex* and a *maximal y-vertex*, the vertices that give the x and y-values to the simplex respectively. We know that f can be represented as a vector $\mathbf{v}_f \in \mathbb{R}^{2m}$ and $\bar{f}$ as a vector $\mathbf{v}_{\bar{f}} \in \mathbb{R}^{2n}$ after ordering the simplices of K. Consider the map $q\colon \mathbb{R}^{2m} \to \mathbb{R}^{2n}$ given by $q(\mathbf{v}_f) = \mathbf{v}_{\bar{f}}$. The map q is piecewise affine and thus, $\mathcal{G} \circ q$ is piecewise affine as well. Therefore, we can apply stochastic sub-gradient descent on $N \circ \mathcal{G} \circ q$ with analogous convergence guarantees.

Observe that we get an arrangement of hyperplanes on $\mathbb{R}^{2m}$, $\mathcal{H}_q$, analogous to $\mathcal{H}$ on $\mathbb{R}^{2n}$ that we saw in the previous subsections. On the top-dimensional cells of $\mathcal{H}_q$, the differential of q is well-defined and constant and expressions analogous to the ones in Theorem 13 can be derived, and the chain rule can be used for back-propagating gradients. As mentioned previously, we use a simple form of gradient sampling to approximate sub-gradients when the gradient is not well-defined. For the experimental section that follows, N is a neural network with one of the standard choices for loss functions, which is definable as discussed towards the end of section 3.2.

We observe that if the bifiltration f is extended to $\bar{f}$ as described above , then we end up in a scenario where multiple simplices have the same x or y-values. This is a degenerate scenario with respect to the assumptions in Theorem 11. To avoid this, in practice, we add an infinitesimal perturbation to the higher dimensional simplices to ensure the values are not exactly the same. We note that this is, in spirit, similar to gradient sampling.

5.2 Model architecture

Every instance in each dataset is an attributed graph with a label associated with it. We use a Graph Isomorphism Network (GIN) [49], as a candidate GNN architecture, to obtain a bifiltration function over the vertices. We consider the lower-star bifiltration of this function. This gives us a bifiltration function on the entire graph, which we denote as f. Let $\mathbf{v}_f$ denote the vector representation of f which we get after ordering the n simplices of the graph. We divide the range of f into a grid of size 100×100. We randomly initialize the s center points from this grid and compute the vector $\mathcal{G}_{k,\ell}(\mathbf{v}_f)$ (Eq. (2)) for $k = 1, 2, 3$ and $\ell = 2$ at these center points. This vector $\mathcal{G}_{k,\ell}(\mathbf{v}_f)$ is fed to a 3-layer Multilayer Perceptron (MLP) classifier and the loss is back-propagated through the GRIL computation according to the gradient described in Section 4. Refer to Figure 3 for an illustration. Note that the positions of the s center points are also optimized as the gradient can be back-propagated to the coordinates of the center points as well. We refer the reader to Appendix B in [40] for additional details.

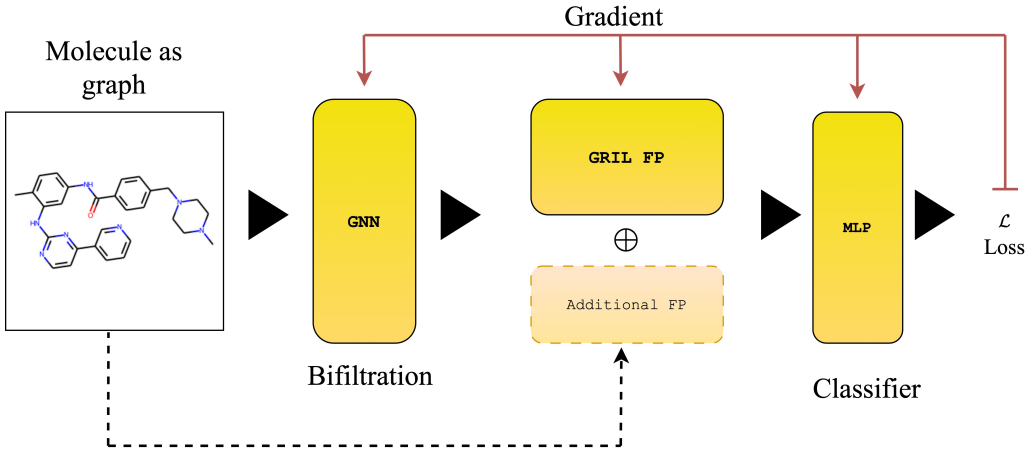

Figure 3 Architecture choice for bio-activity prediction; the bifiltration fuction f is learnt compared to the standard multiparameter pipeline; $\oplus$ denotes concatenation of vectors.

6 Experimental results

In this section, we present the experimental results on various bio-activity prediction datasets and benchmark graph datasets. We begin the section with a brief description of bio-activity prediction datasets followed by experimental results on those datasets. Then, in section 6.2, we show that D-GRIL can be, more generally, applied in the context of bifiltration learning on standard benchmark graph datasets. We compare with existing multiparameter persistent homology methods on these datasets. All the reported accuracy/ROC-AUC scores, in this section, are 5-fold cross-validated scores.

6.1 Bio-activity prediction datasets

The data is extracted from the ChEMBL database [24, 13]. Each dataset contains the SMILES [46] encoding of a novel drug (compound), and activity pairs for a target of interest. For example, the EGFR dataset contains all the molecules that have been tested against epidermal growth factor receptor (EGFR) kinase, and their measured bio-activity. The

Table 1 Test ROC-AUC on ChEMBL datasets. D-GRIL performs better than GIN with *sum* pooling and GRIL with bifiltration obtained from pre-trained GIN.

Dataset	GIN	GIN-GRIL	GIN-MPSM	D-GRIL
EGFR	55.60 ± 8.61	58.39 ± 2.51	$\mathbf{66.97 \pm 1.87}$	65.38 ± 5.34
ERBB2	57.06 ± 8.58	61.28 ± 3.66	68.75 ± 1.98	$\mathbf{69.24 \pm 5.06}$
CHEMBL1163125	58.48 ± 4.37	54.13 ± 1.09	61.23 ± 2.47	$\mathbf{65.69 \pm 1.57}$
CHEMBL2148	52.88 ± 0.91	50.24 ± 0.18	51.45 ± 0.87	$\mathbf{53.13 \pm 3.70}$
CHEMBL4005	55.90 ± 4.63	51.85 ± 3.55	$\mathbf{61.35 \pm 1.49}$	59.34 ± 5.70

SMILES encodings of the molecules are then converted to graphs with MOLFEAT [41]. Bio-activity is measured in *half maximal inhibitory concentration* (IC_{50}), which qualitatively indicates how much a drug is needed, *in vitro*, to inhibit a particular process by 50%. To facilitate the comparison of IC_{50} values, it is common practice to convert IC_{50} to $pIC_{50} = -\log_{10}(IC_{50})$, expressed in molar units. Threshold for activity cutoff $pIC_{50} = 6.3$ is used throughout the paper. We refer the reader to Appendix B in [40] for additional details.

In the first set of experiments, we compare D-GRIL with (i) a standard GNN model– GIN with sum-pooling, (ii) with GIN and GRIL as a readout layer and with (iii) GIN and MPSM [44]. Note that for the results on GIN-GRIL, GRIL is used as a passive readout layer, i.e., we obtain a bifiltration function from a pre-trained GIN (pre-trained for graph classification on the same dataset) and compute GRIL on it. We use the exact same pipeline as GIN-GRIL and train it end-to-end using D-GRIL and GIN-MPSM and report the results. The classifier, 3-layer MLP, is the same for all the experiments. Refer to Figure 3 for the pipeline. From Table 1, we can see that adding topological information after GIN has been trained can improve the performance in some cases and need not be beneficial in others. However, it is clear that adding topological information in an end-to-end framework appears to be beneficial for bio-activity prediction. D-GRIL has comparable performance to MPSM.

Further, we perform a series of experiments where we augment other popular molecular fingerprints such as ECFP and Morgan3 [43, 37] with the D-GRIL framework. In these experiments, we compare the performance of the model with and without D-GRIL augmentation. We report the results in Table 2. We see from the table that augmenting with D-GRIL seems to, generally, increase the performance of the model. Fingerprints such as ECFP and Morgan3 can essentially represent an infinite number of different molecular features, including stereochemical information [43] but they are not effective in capturing global features of molecules such as size and shape [4]. Combining D-GRIL with these fingerprints augments the model with topological information, yielding an improved performance.

6.2 Benchmark graph datasets

D-GRIL can be used more generally for filtration learning on graph datasets. We perform a series of experiments with benchmark graph datasets such as MUTAG, PROTEINS, DHFR, COX2 [38] and compare with existing multiparameter persistence methods. Details about the datasets are given in Appendix B in [40]. We report the results in Table 3. For a valid comparison, we use a 3-layer MLP as the classifier for all the multiparameter signatures. Hence, the numbers reported look different from the ones in [48], [6] where the authors consider XGBoost [9]. In fact, in [48], the authors show that XGBoost performs much better than a 3-layer MLP classifier for GRIL vectors on these datasets. We can see from the table that learning the bifiltration function seems to perform better than multiparameter

Table 2 Test ROC-AUC scores on ChEMBL datasets; augmenting ECFP and Morgan3 fingerprints with D-GRIL increases the classification performance for most of the datasets.

persistence methods on popular choices of bifiltration functions on most datasets. We can also see that D-GRIL performs better than GRIL, supporting our argument for an end-to-end learning framework. We also see that D-GRIL performs better than MPSM. The training times for the two end-to-end learning methods, D-GRIL and MPSM are reported in Table 4. We can see that the training times for D-GRIL are improved by about 40% compared to the ones of MPSM. We refer the reader to Figure 4 [40] for visualizations of bifiltration functions learnt by D-GRIL.

Additionally, we performed experiments where we added a fusion layer to combine the representation power of both D-GRIL and MPSM. We present the results in Table 5. We see from the table that combining the representations leads to a better overall performance, which includes a generally higher mean and a lower standard deviation. Thus, D-GRIL can also be used with existing vectorization methods in a complementary manner to capture additional topological information.

7 Conclusions

In this paper, we propose a differentiable framework using Gril. We show that stochastic sub-gradient descent converges almost surely on Gril, and we compute an explicit formula for the differential of Gril. We use this formula to back-propagate gradients through the Gril computation, yielding the differentiable framework D-Gril. We use D-Gril to show that adding topological information in an end-to-end manner is beneficial for bio-activity prediction. Further, we show that D-Gril can be used in a more general setting, for filtration learning on graphs. Moreover, we show that D-Gril is faster and lighter, both in theory and in practice, than Mpsm. Our results indicate that learnt bifiltration functions on graphs, generally, give a better performance than the standard choices for bifiltration functions. Recently, the Gril framework has been extended to a variant of 2-parameter persistence called *quasi-zigzag* persistence [19]. The results in this paper may shed light on the question of differentiability in the quasi-zigzag framework.

Hardness of High-Dimensional Linear Classification

Alexander Munteanu

Abstract

We establish new exponential in dimension lower bounds for the Maximum Halfspace Discrepancy problem, which models linear classification. Both are fundamental problems in computational geometry and machine learning in their exact and approximate forms. However, only $O(n^d)$ and respectively $\tilde{O}(1/\varepsilon^d)$ upper bounds are known and complemented by polynomial lower bounds that do not support the exponential in dimension dependence. We close this gap up to polylogarithmic terms by reduction from widely-believed hardness conjectures for Affine Degeneracy testing and k-Sum problems. Our reductions yield matching lower bounds of $\tilde{\Omega}(n^d)$ and respectively $\tilde{\Omega}(1/\varepsilon^d)$ based on Affine Degeneracy testing, and $\tilde{\Omega}(n^{d/2})$ and respectively $\tilde{\Omega}(1/\varepsilon^{d/2})$ conditioned on k-Sum. The first bound also holds unconditionally if the computational model is restricted to make *sidedness* queries, which corresponds to a widely spread setting implemented and optimized in many contemporary algorithms and computing paradigms.

1 Introduction

Linear Classification. One of the most fundamental tasks in machine learning is the minimum mislabeling linear classification problem. We formulate it as follows. Consider two point sets $R, B \subset \mathbb{R}^d$ (for red R and blue B points) so $|R \cup B| = n$. Let $\mathcal{H}_d$ be the set of all halfspaces parameterized by $w, \xi \in \mathbb{R}^d \times \mathbb{R}$. So the *halfspace* $h_{w,\xi} \in \mathcal{H}_d$ is the set of points $h_{w,\xi} := \{x \in \mathbb{R}^d \mid \langle w, x\rangle - \xi \geq 0\}$, where $\langle w, x\rangle = \sum_{j=1}^d w_j \cdot x_j$ denotes the standard Euclidean dot-product. Now given fixed input sets $R, B \subset \mathbb{R}^d$ and a halfspace $h \in \mathcal{H}_d$ define

$$\phi(h) = \phi_{R,B}(h) = |h \cap R| - |h \cap B|.$$

as the number of red points in h, minus the number of blue points in h. Then the fraction of misclassifications may be written as

$$\psi(h) = \frac{|R| - (|h \cap R| - |h \cap B|)}{|R \cup B|} = 1 - \frac{|B|}{|R \cup B|} - \frac{1}{n}\phi(h).$$

© Alexander Munteanu, Simon Omlor, and Jeff M. Phillips;

So maximizing ϕ is equivalent to minimizing ψ. For historical reasons we write the aim to minimize the misclassification rate $\psi(h)$ as the following maximization problem and its approximate version:

- MaxHalfspace: For $R, B \subset \mathbb{R}^d$ with $|R \cup B| = n$, find $h^* = \arg\max_{h \in \mathcal{H}_d} \phi(h)$.
- ε-MaxHalfspace: Consider $R, B \subset \mathbb{R}^d$ with $|R \cup B| = n$ with $h^* = \arg\max_{h \in \mathcal{H}_d} \phi(h)$. For an error tolerance $\varepsilon \in (0, 1)$, find some $\hat{h} \in \mathcal{H}_d$ so that $\phi(h^*) - \phi(\hat{h}) \leq \varepsilon n$.

While it is common in machine learning to replace ψ with a convex loss function (such as logistic loss) which allows for a solution with gradient descent, the most classic formulations by Vapnik [57, 56], which begat much of the foundations of statistical learning theory, have this combinatorial form and result in strong generalization guarantees.

If $R \cup B$ is drawn i.i.d. from a distribution Π, then we can use $\psi(h)$ to predict how accurate h would be on a new data point $x \sim \Pi$. In particular, for $\varepsilon, \delta \in (0, 1)$, if $|R \cup B| = \Theta(\varepsilon^{-2}(d + \log(1/\delta)))$, then with probability at least $1 - \delta$ over the sample, we get a guarantee that the probability that any h correctly classifies a new point $x \sim \Pi$ is within ε to the finite sample fraction $\psi(h)$ [56, 43, 53]. Thus maximizing $\phi(h)$ on a small sample gives a classifier which is within ε to the best possible generalization guarantee for new data. Notably, this generalization rate guarantee is only accurate up to an additive $\varepsilon \in (0, 1)$. So solving for the exact optimum $h^* = \arg\max_{h \in \mathcal{H}_d} \phi(h)$ (as in MaxHalfspace) may be unnecessary. In such cases, it is sufficient to find some $\hat{h}$ satisfying ε-MaxHalfspace (and it can be randomized, succeeding with probability $1 - \delta$), to achieve the same asymptotic guarantees.

Conditional Hardness. Conditional hardness results in computational geometry are often obtained by reduction from base problems that are believed to be hard. The main problems we reduce from are k-Sum and AffineDegeneracy testing. We discuss key variants and known results starting from the classic 3-Sum [31].

Consider the k-Sum decision problem: Given $n \geq k$ integers $a_i \in \mathbb{Z}$, decide whether there exists a (multi)set $S \subseteq \{a_1, \ldots, a_n\}$ of $|S| = k$ integers that add up to 0.

The problem can be solved in time $O(n^{\lceil k/2 \rceil})$ by comparing $k/2$-tuples from one half of the input to the other half, known as the *meet in the middle* approach [39]. Despite polylogarithmic improvements for constant k [10], $\Omega(n^{\lceil k/2 \rceil})$ lower bounds hold against algorithms in certain restricted models of computation [27, 4] and in general the problem is conjectured to not admit $O(n^{\lceil k/2 \rceil - c})$ time algorithms for any $c > 0$, cf. [1].

▶ **Conjecture 1** (k-Sum conjecture). *For $k \geq 2$, there does not exist a randomized algorithm that succeeds (with high probability) in solving k-Sum in time $O(n^{\lceil k/2 \rceil - c})$ for any $c > 0$.*

Consider the AffineDegeneracy problem: Given n points in $\mathbb{Z}^d$, decide whether there exists a set of $(d + 1)$ points that lie on a common affine hyperplane in d dimensions.

If the algorithm is restricted to *sidedness* queries that return whether a given point lies above, below, or on a given affine hyperplane, then Erickson and Seidel [28] prove a $\Omega(n^d)$ lower bound matching the $O(n^d)$ complexity of any existing algorithm for the problem [15, 25, 24, 26]. Recent research by Cardinal and Sharir [12] has explored lower-order improvements in the exponent to $O(n^{k-1+o(1)})$ in the case of constant-degree polynomials in one dimension. Their result thus indicates that lifting the polynomial degree is slightly simpler than lifting to higher dimensions. The general case of AffineDegeneracy in d dimensions remains a major open problem in the real RAM model, for which it is conjectured that there exists no algorithm that runs in time $O(n^{d-c})$ for any $c > 0$, cf. [36, 13, 12].

▶ **Conjecture 2** (Affine Degeneracy conjecture). *There does not exist an algorithm that solves AffineDegeneracy in d dimensions in time $O(n^{d-c})$ for any $c > 0$.*

1.1 Our Results

We provide hardness results for exact and approximate versions of the MaxHalfspace problem that hold conditionally on the aforementioned widely believed hardness conjectures in the real RAM model of computation and unconditionally in a more restricted computational model that counts only $\text{sign}(x^T y) \in \{-1, 0, +1\}$ queries, referred to as *sidedness* query model or (ternary) k-linear decision tree model in the literature. For an overview, we only state our bounds slightly informally for the case d is a constant, and so for instance $2(d+1)^d$ is also a constant. The exact bounds are stated in the formal part in Section 2.

k-Sum Hardness. Our first reduction is from k-Sum to MaxDiscrepancy. This generalizes the previous 3-Sum reduction [31, 46] that gave quadratic lower bounds to an arbitrary $k \geq 2$ and hereby improves the exponents in the lower bounds to depend on the dimension. Our reduction yields the following theorem:

▶ **Theorem 3** (informal version of Theorem 6). *Assume that there exists no algorithm that solves k-Sum on n items within runtime $O(n^{\lceil k/2 \rceil - c})$ for any $c > 0$. Then there exist sets $R, B \subset \mathbb{R}^d, d = k - 1$, each of size $n/2$, for which there is no algorithm that solves either*

- MaxHalfspace *in time $O(n^{\lceil (d+1)/2 \rceil - c})$, or*
- ε-MaxHalfspace *in time $O(1/\varepsilon^{\lceil (d+1)/2 \rceil - c})$.*

Affine Degeneracy Testing Hardness. Our second reduction is from AffineDegeneracy testing to MaxDiscrepancy and yields the following theorems:

▶ **Theorem 4** (informal version of Theorem 8). *Assume that there exists no algorithm for AffineDegeneracy on n points with runtime $O(n^{d-c})$ for any $c > 0$. Then there exist sets $R, B \subset \mathbb{R}^d$, each of size $n/2$, for which there is no algorithm that solves either*

- MaxHalfspace *in time $O(n^{d-c})$, or*
- ε-MaxHalfspace *in time $O(1/\varepsilon^{d-c})$.*

▶ **Theorem 5.** *There exist sets $R, B \subset \mathbb{R}^d$, each of size $n/2$, for which any algorithm that uses only sidedness queries requires*

- $\Omega(n^d)$ *such queries to solve* MaxHalfspace, *and*
- $\Omega(1/\varepsilon^d)$ *such queries to solve* ε-MaxHalfspace.

We remark that lower bounds of the form $1/\varepsilon^d$ do not rule out $2^{1/\varepsilon}\,\text{poly}(d)$ algorithms. The latter two results are of special importance since either under the hardness conjecture or in the sidedness query model they match the best exact and approximate algorithms for this problem up to lower order polylogarithmic terms. The exact version, MaxHalfspace, has a $O(n^d)$ complexity [21, 22], and for the approximate version, ε-MaxHalfspace, there is an $O(\frac{1}{\varepsilon^d} \log^4 \frac{1}{\varepsilon})$ time algorithm (after preprocessing the input in $O(n)$ time) in [46]. Notably, this is based on a range counting data structure that can be implemented to work in the sidedness query model as well. The sidedness query model may seem restrictive at first glance and indeed it does not rule out simple comparisons between values (rather than signs) of dot products and determinants which may be exploited to break such lower bounds.

However, we stress that basically all known algorithms rely exactly on that type of subroutines, see related work below, and especially the discussion in [28]. Now, 30 years later, the core sidedness query operation is precisely the heavily optimized $\text{sign}(x^T y)$ operation which can be vectorized, optimized and accelerated on GPUs. Additionally, the study of big data models have brought up a paradigm that discretizes and reduces the search space to a

few candidate solutions and then brute forces that subset using simple queries as in [46]. This underlines that the sidedness query model is even more relevant in today's age of AI/ML and big data, than it probably was when Erickson and Seidel [28] studied it.

The hardness conjecture of AffineDegeneracy extends the same lower bound to the real RAM model in any dimension. In the Turing model, our reduction holds only in any constant dimension, due to the bit complexity of representing and adjusting small scalars.

1.1.1 Technical Overview

Reduction from k-Sum

Given an input $a_1, \ldots, a_n \in \mathbb{Z}$ for the k-Sum decision problem, the idea behind our construction is as follows: we construct for any $i \in [n]$ and $j \in [k]$ a point $x_{i,j} \in \mathbb{R}^{k-1}$. The points are constructed in such a way, that[1] the first coordinate of each $x_{i,j}$ corresponds to the input a_i, and for $j \in [1, \ldots, d-1]$, the remaining coordinates are the standard basis vectors e_j, whose coordinates are all 0 except for coordinate j which is 1. The remaining vectors are $x_{i,0}$ and $x_{i,d}$. Both have their first coordinate set to $-a_i$ (times a constant), then $x_{i,0}$ has all remaining coordinates set to 0, and $x_{i,d}$ has all remaining coordinates are set to 1.

The idea behind this construction is that a solution $a_1, \ldots, a_k$ to k-Sum corresponds to a hyperplane that crosses a specific selection of points, including an ancillary point that acts as an intercept term. Hence, there exists a linear combination of these points such that their first coordinates resemble the equation $a_1 + \ldots + a_{k-1} = -a_k$, while the other coordinates enforce constraints that ensure we make the right geometric selection of points, such that on these coordinates we have $e_1 + e_2 + \ldots + e_{k-1} = \mathbf{1}$, i.e., the selected unit basis vectors sum up to the vector $\mathbf{1}$ that comprises only 1s. By construction, a linear combination of these points whose coefficients parametrize a hyperplane also implies the existence of a k-Sum solution.

Now, we reduce to the MaxHalfspace problem. To this end, we copy each of the constructed points twice to create nk red points $r_{i,j} = x_{i,j} + \gamma e_1 \in R$, and another nk blue points $b_{i,j} = x_{i,j} - \gamma e_1 \in B$. That means the two colored point sets to be separated are simply copies of the previously constructed points but shifted by a tiny amount γ in opposite directions along their first coordinate. Note that this affects only the coordinate that corresponds to the original k-Sum input, not the additional gadgets.

Now if $||h \cap R| - |h \cap B|| \geq k$ then there exists a hyperplane that passes through the tiny gaps between at least k pairs of points $(r_{i,j}, b_{i,j})$. Using the constraints imposed by the gadgets this enforces a certain parameterization of the hyperplane. Applying this parameterization only to the first coordinates of the points and choosing $\gamma \leq 1/k$, we can bound $|a_1 + \ldots + a_k| \leq (k-1)\gamma < 1$. Since all a_i are integers, it follows that $a_1 + \ldots + a_k = 0$.

For the other direction $a_1 + \ldots + a_{k-1} = -a_k$ implies, as explained above, that there exists a linear combination of k original points $x_{i,j}$ that equals zero. Now note that the shifted versions $r_{i,j}, b_{i,j}$ of these k points each lie above (respectively below) the hyperplane, so each of them contributes 1 to the cost. Other points can only increase this number above k, or their red and blue contributions cancel in case they both lie on the same side. It thus follows that $||h \cap R| - |h \cap B|| \geq k$.

[1] up to technical scalars that are specified in the formal proof, see Section 2.1.

Reduction from AffineDegeneracy

This construction is more direct: given n points $x_i \in \mathbb{Z}^d$ as input for the AffineDegeneracy testing problem, we simply create n red points $r_i = x_i + \gamma e_1 \in R$, and another n blue points $b_i = x_i - \gamma e_1 \in B$. The two colored point sets to be separated are simply copies of the original points shifted by a tiny amount γ in opposite directions along their first coordinate.

If there exist $d+1$ points that lie on a common affine hyperplane, then the number of red points minus the number of blue points of the transformed input that lie in the halfspace h is clearly at least $||h \cap R| - |h \cap B|| \geq d+1$. To see this, note that for any of the original points on the hyperplane, we have one red point that lies above, and one blue point that lies below. Other points can only increase this number, or their red and blue contributions cancel if both lie on the same side.

The other direction is considerably more sophisticated and technical to prove: if $||h \cap R| - |h \cap B|| \geq d+1$ then there exist at least $d+1$ pairs (r_i, b_i) of corresponding red and blue points, such that the hyperplane passes through some points x'_i located in the tiny gap of size 2γ between r_i and b_i. Relabel these points $x'_1, \ldots, x'_{d+1}$. Our claim is that the corresponding $d+1$ original points $x_1, \ldots, x_{d+1}$ lie on a common affine hyperplane. Since any collection of d points such as $x_1, \ldots, x_d$ lie on a common hyperplane, the task reduces to show that x_{d+1} also lies on the same hyperplane.

Reframing this in terms of linear algebra, we collect the vectors $x'_1, \ldots, x'_d$ into a matrix $X' \in \mathbb{R}^{d \times d}$, and similarly $x_1, \ldots, x_d$ into $X \in \mathbb{Z}^{d \times d}$. Let $\mathbf{1} \in \mathbb{R}^d$ be the vector whose coordinates are all equal to one. We can now calculate the vector of coefficients of the hyperplane as $b' = X'^{-1}\mathbf{1}$. And for this instance, we know that $\langle b', x'_{d+1} \rangle - 1 = 0$. Similarly, we get for the original points $b = X^{-1}\mathbf{1}$, and our task is to prove that $\langle b, x_{d+1} \rangle - 1 = 0$ holds as well. To this end, we prove the following two claims:

(i) we have that $\langle b, x_{d+1} \rangle - 1$ is an integer multiple of $1/N_0$, for some integer $N_0 \neq 0$, and
(ii) it holds that

$$|\langle b, x_{d+1} \rangle - 1| = |\langle b, x_{d+1} \rangle - \langle b', x'_{d+1} \rangle + \langle b', x'_{d+1} \rangle - 1| = |\langle b, x_{d+1} \rangle - \langle b', x'_{d+1} \rangle| < 1/N_0.$$

Combining claims (i) and (ii) clearly implies our goal $\langle b, x_{d+1} \rangle - 1 = 0$.

At this point of the proof, especially bounding $|\langle b, x_{d+1} \rangle - \langle b', x'_{d+1} \rangle| < 1/N_0$ becomes very technical and requires bounding the effect of the remainder of matrix inverses $(X^{-1} - X'^{-1})$ along the shift direction e_1, as well as along x_{d+1}. Crucial steps involve showing that the determinants of X and its minors must be non-zero integers. Then we note that X' can be seen as a rank-one update of X, and apply the Sherman-Morrison formula to express the required remainder term in closed form. We further use Hadamard's bound on the determinants of minors of X in terms of the largest integer that appears in X. Choosing the shift size parameter γ small enough to cancel all but a factor $1/\det(X)$ yields the bounds that we require to conclude the proof. We refer the reader to Section 2.2 for the full details.

1.2 Implications Beyond Machine Learning

A number of other settings consider range space maximization, where the key unit of measure is the fraction of red points $\mu_R(h) = \frac{|h \cap R|}{|R|}$ and of blue points $\mu_B(h) = \frac{|h \cap B|}{|B|}$ in a halfspace.

- **discrepancy:** $\phi_{\|}(h) = |\mu_R(h) - \mu_B(h)|$
  This relates to discrepancy theory [49, 14, 9, 3] where one often seeks to find a coloring of a set $X \subset \mathbb{R}^d$ so each $x \in X$ is assigned to R or to B, and so $\max_{h \in \mathcal{H}} \phi_{\|}(h)$ is minimized over any choice of R, B. Then taking R, B as input, the optimization $\max_{h \in \mathcal{H}} \phi_{\|}(h)$

amounts to evaluating how well the chosen coloring works. In particular, many of the algorithms are Monte Carlo randomized, so to transform them into a Las Vegas style algorithm this verification step would be required. Moreover, iteratively applying discrepancy leads to coresets, which achieve additive $\varepsilon|X|$ error on ϕ or range counting queries; hence the approximate version is often sufficient.

In minimizing discrepancy, one often seeks $|R| = |B|$, in which case $\phi_{\|}(h) = \frac{2}{n}|\phi(h)|$. Further note that the absolute value $|\cdot|$ takes the maximum value between $\phi(h)$ and when reversing the roles of R and B. Our constructions will be symmetric in R and B with $|R| = |B|$. So our hardness results will hold for the most common case in discrepancy maximization in high dimensions.

- **Poisson:** $\phi_P(h) = \mu_R(h) \log \frac{\mu_R(h)}{\mu_B(h)} + (1 - \mu_R(h)) \log \frac{1-\mu_R(h)}{1-\mu_B(h)}$

  This relates to the spatial scan statistic model under a Poisson point process, as described by [42]. The maximizing $h \in \mathcal{H}$ corresponds to the most anomalous region under a statistical hypothesis test where the null hypothesis $\mathtt{H}_0$ models that there is a consistent Poisson process for all of the data, and the $\mathtt{H}_1$ hypothesis models that the Poisson rate is different in h than outside h. Then ϕ_P is the negative log-likelihood ratio of these two scenarios, also known as the KL divergence between the two distributions $(\mu_R(h), 1 - \mu_R(h))$ and $(\mu_B(h), 1 - \mu_B(h))$. The score $\phi_P(h^*)$ of the maximizing $h^* = \arg\max_{h \in \mathcal{H}} \phi_P(h)$ is the individually most powerful statistic for evaluating this sort of anomaly. Moreover, efficient ε-approximate algorithms [47] retain high statistical power. One can cover the relevant part of ϕ_P with $O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ linear functions $\phi_\alpha(h) = \alpha|h \cap R| + (1 - \alpha)|h \cap B|$, so returning the maximum h over any function ε-approximately maximizes ϕ_P. And by changing the weight of points in R and B to α and $(1 - \alpha)$ our results provide hardness for any of these linear instances.

  In spatial scan statistics, it is common to search over balls [42, 47] instead of halfspaces (although halfspaces are considered [48]), and procedurally, a Veronese map from balls in $\mathbb{R}^{d-1}$ to halfspaces in $\mathbb{R}^d$ reduces this to a halfspace problem. All known methods with provable runtime and error guarantees [47, 46] either explicitly use or are isometric to using this transformation.

1.3 Additional Related Work

Maximum Discrepancy Classification. Exact algorithms are known that compute halfspace discrepancy in $O(n^d)$ time in any dimension $d \geq 2$ [21, 22, 23].

It was shown in [46] that the ε-MaxHalfspace problem can be solved in $O(\frac{1}{\varepsilon^d} \log^4 \frac{1}{\varepsilon})$ time (plus a linear scan over the data in time $O(n)$). This was complemented by conditional lower bounds in 2 dimensions: an exact solution requires $\Omega(n^{3/2})$ time conditioned on the conjecture that the all-pairs-shortest-paths problem (APSP) requires $\Omega(n^3)$ time to be solved. An approximate solution requires $\Omega(1/\varepsilon^2)$ by reduction from 3-Sum under the special case $k = 3$ of the aforementioned k-Sum conjecture detailed in Section 1.

Previous results by the same authors [45] gave $O(\frac{1}{\varepsilon^{d+1/3}} \log^{2/3} \frac{1}{\varepsilon})$ for ε-MaxHalfspace. They also studied a version that considered rectangular ranges instead of halfspaces, and provided an $O(n + \frac{1}{\varepsilon^2} \log\log \frac{1}{\varepsilon})$ algorithm and an $\Omega(1/\varepsilon^2)$ lower bound leveraging a previous $\Omega(n^2)$ lower bound of [6] for the exact rectangle variant. These lower bounds were again conditioned on the conjecture that APSP requires $\Omega(n^3)$ time to be solved.

More Connections to Learning Theory. Aside for the classic work described above, the hardness of classification has been studied in computational learning theory from other perspectives. A touchstone result by Guruswami and Raghvendra [34] showed it was NP-Hard in the dimension d to distinguish between instances where there exist halfspaces which

agree on at least a $(1-\varepsilon)$ fraction of the labels and ones where no halfspace agrees on more than a $(1/2+\xi)$ fraction of the data. Their work, and many others in this line (c.f. [30]), consider data from $\{0,1\}^d$, and since $O(d/\varepsilon^2)$ samples are sufficient to attain this ε-error, the number of points n does not show up separately in this analysis. But this work does not for instance control the constant in the exponent of the runtime; it does not rule out algorithms with runtime $1/\varepsilon^{\max\{2,d/1{,}000{,}000\}}$. Also, algorithms with runtime polynomial in $1/\varepsilon$ and d are possible with stronger noise like Massart noise [19].

A very recent and independent work by Pinto, Palit, and Raskhodnikova [52] approaches these problems from the property testing perspective, and conditioned on k-Sum, attains lower bound on the runtime for ε-MaxHalfspace of $\Omega(1/\varepsilon^{\lceil (d+1)/2\rceil - c})$. The core of their argument and construction is basically the same as our k-Sum hardness result.

No-Dimensional Results in Computational Geometry and Classification. Computational geometry has recently witnessed a number of "no-dimensional" or "dimension-free" results. These are often approximate solutions to problems in $\mathbb{R}^d$ where the core aspect of the problem does not depend on the dimension d. It may take $O(d)$ time to read or process each data point, so they are not independent of the dimension d, but importantly, these sorts of results prevent exponential dependence. Arguably this expedition started with approximate minimum enclosing ball and geometric median problems [8, 7, 40], which only require $O(1/\varepsilon)$ resp. $O(1/\varepsilon^2)$ points to approximate within a relative $(1+\varepsilon)$. This sort of analysis led to more general analyses of Frank-Wolfe style greedy algorithms [17], which induced no-dimensional results for the approximate polytope distance problem [33]. Also, classical combinatorial geometric consequences of convexity such as Carathéodory, Helly, and Tverberg theorems can be made no-dimensional when the diameter is bounded [2]. And this led to improved centerpoint and ε-net results [16, 37].

These geometric insights have led to improvements in sublinear and no-dimensional algorithms for classic linear classification problems [18, 20]. These analyses, and the above mentioned analysis of polytope distance [33], are refinements of Novikoff's classic analysis of the perceptron for linear classifiers, which is also no-dimensional. In particular, it requires that there exists a perfect classifier with no mistakes, and depends on the ratio between the distance between classes, and the diameter of the input set, cf. [38, 35]. The linear classification problem which optimizes an often convex loss function (e.g., logistic regression) requires additional assumptions to be made no-dimensional. Classic sparsity assumptions do not prevent from mild $\Theta(\log(d)/\varepsilon^2)$ dependence [44]. Strictly dimension-free bounds can be achieved if one uses a regularization term and also assumes the diameter is bounded (in expectation) [5]. These results $(1+\varepsilon)$-approximate typical classification loss functions with $O(1/\varepsilon^2)$ samples and an additional dependence that relies solely on the amount and type of regularization. Apart from classification there is a plethora of no-dimensional results in the clustering regime. The first dimension-free bounds for k-means/median clustering objectives appeared in [29, 54]. Recent developments extend the classic finite data setting to learning-theoretical dimension-free bounds for center based clustering and classification of points and polygonal curves [11, 41, 5].

Impossibility of No-Dimensional Results. In the context of these numerous no-dimensional results, it may be surprising that the geometric linear classification problem, and especially the approximately optimized variant tackled in this paper, is shown to require time exponential in d under conditional hardness assumptions. What is different in our setting? First, the perceptron-based results require separability, so $\psi(h^*)=0$; our constructions do not consider

this case, and have $\psi(h^*)$ fairly large. Second, these results mostly consider a bounded diameter of the point set, and also a structural term that prevents affine scaling, which could be the margin or the regularization term that has a similar effect. While we could affinely scale our constructions to be within a unit ball, it would make these other structural parameters (e.g., the margin between the properly separated points) proportionally small. Third, while no-dimensional ε-nets [37] and ε-covers [51] exist – and these play a crucial role in the best algorithms for our variant of classification [45, 46] – these results apply for bounded-radius balls or kernels, and not the halfspaces we study.

Hence, we hope our conditional hardness results help the community identify when these high-dimensional geometric problems relevant for data analysis can, *and cannot*, be solved in a dimension-efficient way. Our work provides recipes to show that even when approximation is allowed, exponential dependence on the dimension can be unavoidable.

2 Improved Halfspace Discrepancy Lower Bounds

2.1 k-Sum Hardness

We reduce from the k-Sum decision problem.

▶ **Theorem 6.** *Assume that there exists no algorithm that solves k-Sum on n items within runtime $O(n^{\lceil k/2\rceil - c})$ for any $c > 0$. Then there exist sets $R, B \subset \mathbb{R}^d$, for $d = k-1$, each of size $n/2$, for which there is no algorithm that solves either*

- MaxHalfspace *in time $O((n/(2(d+1))^{\lceil (d+1)/2\rceil - c})$, or*
- ε-MaxHalfspace *in time $O((1/(2(d+1)\varepsilon))^{\lceil (d+1)/2\rceil - c})$.*

Proof. We reduce k-Sum to MaxHalfspace with $d = k-1$ as follows. Let $A = \{a_1, \ldots, a_n\}$ for integers $a_i \in \mathbb{Z}$ be an instance of k-Sum. We will transform this input into a set of $2nk$ points in $\mathbb{R}^d$ where the solution to MaxHalfspace will resolve the k-Sum instance on A.

The Construction. For any integer $a_i, i \in [n]$ consider the following $k = d+1$ points in $\mathbb{R}^d$: Let $z_{i,0} := (-a_i/(2d-3), 0, \ldots, 0)$ and for each $j \in [d-1]$, let $z_{i,j} = (a_i/2, 0, \ldots, 0, 1, 0 \ldots, 0)$ which has a single 1 entry at position $j+1$. Further we create the point $z_{i,d} = (-a_i, 2, 2, \ldots, 2)$.

Further for each point $z_{i,j}$ we create two points: one point, which we place in R and one point, which we place in B. For $j \in \{0, \ldots, d\}$ we define $x_{i,j} \in R$ by $x_{i,j} = z_{i,j} + \gamma e_1$ and $y_{i,j} \in B$ by $y_{i,j} = z_{i,j} - \gamma e_1$ where γ is a sufficiently small number (for instance $\gamma < 1/(4d)$) and e_1 denotes the first standard basis vector in $\mathbb{R}^d$.

Restricting $R - B$ Difference to at least k. First, assume that there is h with $\mu_R|R| - \mu_B|B| \geq k$. Consider a set of $k = d+1$ lines defined by $l_0(t) = (t, 0, \ldots, 0)$, $l_j(t) = (t, 0, \ldots, 0, 1, 0, \ldots, 0)$, for $j \in [d-1]$, and $l_d(t) = (t, 2, \ldots, 2)$. Observe that all points in R and B lie on these lines. Let v_j be the point where h crosses the line l_j, for $j \in \{0, \ldots, d\}$.

Note, since the $z_{i,j}$ points are further apart than 2γ, then the number of points $x_{i,j}$ or $y_{i,j}$ on each of the lines that lie above h in R can differ by at most 1 from the number of points above h in B.

Thus, there cannot be any hyperplane with $\mu_R|R| - \mu_B|B| > k$ and in order to achieve $\mu_R|R| - \mu_B|B| = k$, the hyperplane h must cross each line l_j at a point $v_j = (\beta_{j+1}, \ldots)$ that for some $i_j \in [n]$, lies between the points $z_{i_j,j} - \gamma e_1$ and $z_{i_j,j} + \gamma e_1$. Equivalently, we have that $\beta_{j+1} \in [e_1^T z_{i,j} - \gamma, e_1^T z_{i,j} + \gamma]$. To simplify notation, we define $\alpha_{i,j} := e_1^T z_{i,j-1}$ for all $(i,j) \in [n] \times [k]$, where $k = d+1$. With this substitution, we get that $\beta_j \in [\alpha_{i,j} - \gamma, \alpha_{i,j} + \gamma]$.

Showing k-Separation implies k-Sum. Consider the points $w_j = v_j - v_0$, for $j \in [d]$. Since these are d points in $\mathbb{R}^d$, they must lie on a common linear hyperplane and the only way to align the upper $d-1$ coordinates is by setting $w_d = 2\sum_{j=1}^{d-1} w_j$.

This is equivalent to $0 = v_0 - v_d + 2\sum_{j=1}^{d-1}(v_j - v_0) = -(2d-3)v_0 + (2\sum_{j=1}^{d-1} v_j) - v_d$, implying in particular for the first coordinate that

$$-(2d-3)\beta_1 + \left(2\sum_{j=2}^{k-1}\beta_j\right) - \beta_k = 0. \tag{1}$$

Now, since for all $j \in [k]$ there exists some $i_j \in [n]$ such that $|\alpha_{i_j,j} - \beta_j| \le \gamma$, we get that

$$\begin{aligned}
&|a_{i_1} + \ldots + a_{i_k}| \\
&\overset{Eq.\ (1)}{=} \left| a_{i_1} + \ldots + a_{i_k} - \left(-(2d-3)\beta_1 + \left(2\sum_{j=2}^{k-1}\beta_j\right) - \beta_k\right)\right| \\
&= \left|-(2d-3)\alpha_{i_1,1} + \left(2\sum_{j=2}^{k-1}\alpha_{i_j,j}\right) - \alpha_{i_k,k} - \left(-(2d-3)\beta_1 + \left(2\sum_{j=2}^{k-1}\beta_j\right) - \beta_k\right)\right| \\
&\le (2d-3)|\alpha_{i_1,1} - \beta_1| + \left(\sum_{j=2}^{k-1} 2|\alpha_{i_j,j} - \beta_j|\right) + |\alpha_{i_k,k} - \beta_k| \le 4d\gamma < 1\,,
\end{aligned}$$

where we used the triangle inequality and the choice $\gamma < 1/(4d)$. Since all a_i are integers, it follows that $a_{i_1} + \ldots + a_{i_k} = 0$.

Showing k-Sum implies k-Separation. For the other direction, assume that $a_{i_1} + \ldots + a_{i_k} = 0$ or equivalently $a_{i_1} + \ldots + a_{i_{k-1}} = -a_{i_k}$. Then the points $z_{i_1,0}, \ldots, z_{i_k,d}$ lie on a hyperplane h. To prove this, note that any set of d points in d dimensions lie on a hyperplane. We need to show that the remaining point $z_{i_k,d}$ lies on the same hyperplane as the others. By a similar calculation as above, we get

$$\begin{aligned}
z_{i_k,d} = (-a_{i_k}, 2, \ldots, 2) &= (a_{i_1} + \ldots + a_{i_{k-1}}, 2, \ldots, 2) \\
&= -(2d-3)z_{i_1,0} + 2\sum_{j=1}^{d-1} z_{i_{j+1},j} = z_{i_1,0} + 2\sum_{j=1}^{d-1}(z_{i_{j+1},j} - z_{i_1,0}).
\end{aligned}$$

For this hyperplane it holds that $|\mu_R|R| - \mu_B|B|| \ge k$, since for any point $z_{i,l}$, for $l \in \{0, \ldots, d\}$ that lies on the hyperplane, the corresponding $x_{i,l}$ (and $y_{i,l}$) lie above (respectively below) the hyperplane, all counting for one of the two classes. If it does not lie on the hyperplane, then by construction and for sufficiently small γ as above, both $x_{i,l}$, and $y_{i,l}$ lie on the same side of the hyperplane and thus both contribute 0 or cancel each other.

Exact Bound. The number of points is $2nk = 2n(d+1)$, and so any algorithm with runtime $O((\beta n)^\alpha)$ for MaxHalfspace yields an algorithm with runtime $O((\beta n)^\alpha)$ for k-Sum. Set $\beta = 1/(2(d+1))$ and $\alpha = \lceil k/2 \rceil - c = \lceil (d+1)/2 \rceil - c$. Now using the Lemma's assumption on k-Sum hardness, there cannot be an algorithm for MaxHalfspace within runtime $O((\beta n)^\alpha) = O((n/(2(d+1))^{\lceil (d+1)/2 \rceil - c})$.

Cost of Reduction with Error ε. Similar to the reduction for MaxHalfspace, we now set $\varepsilon = 1/(2n(d+1))$, and any algorithm with runtime $O((\beta/\varepsilon)^\alpha)$ for ε-MaxHalfspace yields an algorithm with runtime $O((\beta/\varepsilon)^\alpha) = O(2n(d+1)\beta)^\alpha)$ for k-Sum. We again set $\beta = 1/(2(d+1))$ and $\alpha = \lceil k/2 \rceil - c = \lceil (d+1)/2 \rceil - c$. Thus, assuming the k-Sum hardness conjecture as in the statement of the lemma, there cannot be any algorithm that solves ε-MaxHalfspace within runtime $O(1/(2(d+1)\varepsilon)^{\lceil (d+1)/2 \rceil - c})$. We note that the time for the reduction from k-Sum to MaxHalfspace is $O(nk^2) \subseteq O(n^\alpha)$. ◀

2.2 Affine Degeneracy Hardness

The next lower bound is derived by reduction from the AffineDegeneracy problem. We first need a review of some basic linear algebra facts that are used in our proof.

2.2.1 Preliminaries and Review of Linear Algebra

Let $[d] = \{1, \ldots, d\}$ denote the positive integers up to d. Let $\mathbb{Z}_N = \{-N, \ldots, N\}$ be the set of integers between $-N$ and N. Given a square $d \times d$ matrix X, we denote its i,j-th entry for $i,j \in [d]$ by $X_{i,j}$ and its i-th row vector by X_i. Further, let its (i,j)-minor be the $(d-1) \times (d-1)$ submatrix denoted by $X^{\setminus(i,j)}$ that results from X by removing its i-th row and j-th column. We denote by I the $d \times d$ identity matrix and by e_i its i-th column vector.

Our reduction involves the analysis of the *determinant* $\det(X)$ and the *adjugate* matrix $\operatorname{adj}(X)$, whose entries are defined as $\operatorname{adj}(X)_{i,j} = (-1)^{i+j} \cdot \det(X^{\setminus(j,i)})$. We summarize certain well-known facts about these quantities and their relationships.

▶ **Fact.** *Let $X \in \mathbb{Z}_N^{d \times d}$ with linearly independent rows and columns. We remind of the following facts from linear algebra:*

1. $\det(X) \in \mathbb{Z}$
2. $1 \leq |\det(X)| \leq d^{d/2} N^d$
3. $X^{-1} = \det(X)^{-1} \operatorname{adj}(X)$
4. $\operatorname{adj}(X) \in \mathbb{Z}^{d \times d}$
5. *Let $u, v \in \mathbb{R}^d$. If X is invertible and $1 + u^T X^{-1} v \neq 0$, then*

$$X^{-1} - (X + u^T v)^{-1} = \frac{X^{-1} u v^T X^{-1}}{1 + u^T X^{-1} v}\,.$$

Proof. By Leibnitz' formula, also known as the *big formula* [55], the determinant of X can be written as a signed sum over products of the entries of X. Since each $X_{i,j} \in \mathbb{Z}_N \subset \mathbb{Z}$, these products are again in $\mathbb{Z}$ and signed sums of the products are again integers in $\mathbb{Z}$. We thus get Fact 1.

Next we have by linear independence, that $\det(X) \neq 0$. From this and Fact 1 it follows that $1 \leq |\det(X)|$. Hadamard's determinant bound [32] together with $X_{i,j} \in \mathbb{Z}_N$ yields that

$$1 \leq |\det(X)| \leq \prod_{j \in [d]} \left(\sum_{i \in [d]} X_{i,j}^2 \right)^{1/2} \leq \prod_{j \in [d]} (dN^2)^{1/2} = d^{d/2} N^d\,.$$

We thus conclude Fact 2.

Applying the Laplace expansion of the determinant, also known as *cofactor formula* [55], to every row of X it follows that $X \operatorname{adj}(X) = \det(X) I$. We recall that by linear independence, X is invertible. Left multiplication with X^{-1} thus yields $\operatorname{adj}(X) = X^{-1} X \operatorname{adj}(X) = X^{-1} \det(X) I$. By Fact 2, we have $\det(X) \neq 0$ and thus dividing both sides by $\det(X)$ concludes Fact 3, i.e., $X^{-1} = \det(X)^{-1} \operatorname{adj}(X)$.

Note that each (i,j)-minor of $X \in \mathbb{Z}_N^{d\times d}$ for $i,j \in [d]$ is a submatrix $X^{\setminus(i,j)} \in \mathbb{Z}_N^{(d-1)\times(d-1)}$. Then Fact 4 follows from Fact 1 since then $\operatorname{adj}(X)_{i,j} = (-1)^{i+j} \cdot \det(X^{\setminus(j,i)}) \in \mathbb{Z}$.

Fact 5 is a rearrangement of the Sherman-Morrison formula [55] to isolate the remainder term of the inverse under a rank-1 update $X^{-1} - (X + u^T v)^{-1}$. ◀

We will also need a bound on the coordinates of the inverse matrix multiplied by an arbitrary vector in the unit ℓ_∞ ball. To this end, we show that if X has integer coordinates bounded between $-N$ and N, then the coordinates in the following inverse term can be controlled in terms of N and d.

▶ **Lemma 7.** *Let $\lambda \in [-1,1]^d$ and $X \in \mathbb{Z}_N^{d\times d}$. Then for each coordinate $i \in [d]$ we have that*

$$|(X^{-1}\lambda)_i| \leq \frac{1}{|\det(X)|} \cdot d^{(d+1)/2} N^{d-1}.$$

Proof. By Hoelder's inequality, the fact that $\|\lambda\|_\infty \leq 1$, and using Hadamard's determinant bound (Fact 2), we have that

$$\begin{aligned}
|(X^{-1}\lambda)_i| &\overset{Fact\ 3}{=} |(\det(X)^{-1} \operatorname{adj}(X)\lambda)_i| = \frac{1}{|\det(X)|} \cdot |(\operatorname{adj}(X)\lambda)_i| \\
&\overset{Hoelder}{\leq} \frac{1}{|\det(X)|} \cdot \|\operatorname{adj}(X)_i\|_1 \|\lambda\|_\infty \leq \frac{1}{|\det(X)|} \cdot \sum_{j=1}^{d} \left|\det(X^{\setminus(j,i)})\right| \\
&\overset{Fact\ 2}{\leq} \frac{1}{|\det(X)|} \cdot d \cdot (d-1)^{(d-1)/2} N^{d-1} \leq \frac{1}{|\det(X)|} \cdot d^{(d+1)/2} N^{d-1}.
\end{aligned}$$

◀

2.2.2 Main Problem Reduction

We are now ready to prove the main result of this section.

▶ **Theorem 8.** *Assume that there exists no algorithm for* AffineDegeneracy *on n points with runtime $O(n^{d-c})$ for any $c > 0$. Then there exist sets $R, B \subset \mathbb{R}^d$, each of size $n/2$, for which there is no algorithm that solves either*

- MaxHalfspace *in time $O((n/2)^{d-c})$, or*
- ε-MaxHalfspace *in time $O(1/\varepsilon^{d-c})$.*

Proof. Let $X_n = \{x_1, \ldots, x_n\} \subset \mathbb{Z}_N^d$ be an instance of AffineDegeneracy. We construct an instance of MaxHalfspace by splitting each point into two points.

The Construction. For each $i \in [n]$ we create one point $y_i = x_i + \gamma e_1 \in R$ and one point $z_i = x_i - \gamma e_1 \in B$ where γ is sufficiently small (yet to be determined). Now, we claim that there exists a solution with $\mu_R|R| - \mu_B|B| \geq d+1$ if and only if there exists a set $X' \subseteq X_n$ of $|X'| = d+1$ points that lie on a common d-dimensional hyperplane.

First note that if there exists a set $X' \subseteq X_n$ of $|X'| = d+1$ points that lie on a common d-dimensional hyperplane h, then this hyperplane is a solution to MaxHalfspace with $\mu_R|R| - \mu_B|B| \geq d+1$ because for each $x \in X'$, the corresponding point $y \in R$ lies above h, whereas $z \in B$ lies below h.

For the other direction, assume that there exists a hyperplane h with $\mu_R|R| - \mu_B|B| \geq d+1$. Then there must be a set $S \subseteq [n]$ of $|S| = d+1$ indices such that for any $i \in S$ this hyperplane crosses $x_i' = x_i + \lambda_i \gamma e_1$ for some $\lambda_i \in [-1,1]$, i.e., it passes between $y_i \in R$ and $z_i \in B$ corresponding to x_i. Assume w.l.o.g. that $S = [d+1]$. It remains to show that $x_1, \ldots, x_{d+1}$ lie on a common hyperplane. The key will be leveraging that the coordinates of input points are integers to ensure that the solution to a satisfying halfspace must have x_{d+1} very close. Setting γ sufficiently small will imply the distance is actually 0.

Reframing the Problem in Linear Algebra. We assume w.l.o.g. that $x_1, \dots, x_d$ and $x'_1, \dots, x'_d$ are linearly independent, otherwise the proof continues verbatim in the largest dimension $d' < d$ for which the assumption is true, without affecting the hardness in d. Then $x'_1, \dots, x'_d$ lie on a common hyperplane and in particular there exists $b' \in \mathbb{R}^d$ such that for all $i \in [d]$, it holds that $\langle b', x'_i \rangle - 1 = 0$. We set $X \in \mathbb{Z}^{d \times d}$ to be matrix whose i-th row equals x_i^T, for $i \in [d]$, and $X' \in \mathbb{R}^{d \times d}$ to be matrix whose i-th row equals $x_i'^T$, for $i \in [d]$. Let $\mathbf{1} \in \mathbb{R}^d$ be the vector whose coordinates are all equal to one. Then we have that $X'b' = \mathbf{1}$, which implies $b' = X'^{-1}\mathbf{1}$. Similarly, we set $b = X^{-1}\mathbf{1}$.

Now, we show that $x_1, \dots, x_{d+1}$ lie on a common hyperplane by proving the following two claims, which clearly imply that $\langle b, x_{d+1} \rangle - 1 = 0$:

(i) we have that $\langle b, x_{d+1} \rangle - 1$ is a multiple of $1/N_0$, for some integer $N_0 \geq 1$, and

(ii) it holds that

$$|\langle b, x_{d+1} \rangle - 1| = |\langle b, x_{d+1} \rangle - \langle b', x'_{d+1} \rangle + \langle b', x'_{d+1} \rangle - 1| = |\langle b, x_{d+1} \rangle - \langle b', x'_{d+1} \rangle| < 1/N_0.$$

(i) Showing Integrality. For the first claim (i), note that $\langle b, x_{d+1} \rangle = (X^{-1}\mathbf{1})^T x_{d+1}$. Since X comprises only integer entries, $\det(X)$ is also an integer by Fact 1. By Fact 2, we also have that $|\det(X)| \geq 1$. We know from Fact 3 that $X^{-1} = \operatorname{adj}(X)/\det(X)$ and the entries of $\operatorname{adj}(X)$ are again integers by Fact 4. Finally, each coordinate $i \in [d]$ of $\operatorname{adj}(X)\mathbf{1}$ is a sum over the integer entries of $\operatorname{adj}(X)_i$. The vector x_{d+1} again consists only of integers. Taking their dot product thus retains the property of being integers, i.e., $(\operatorname{adj}(X)\mathbf{1})^T x_{d+1} \in \mathbb{Z}$.

We set $N_0 \coloneqq |\det(X)|$ and conclude that there exists $k \in \mathbb{Z}$ such that $\langle b, x_{d+1} \rangle - 1 = \frac{k}{N_0}$.

(ii) Controlling the Deviations. For the second claim (ii), let $R = X^{-1} - X'^{-1}$. To bound the remainder term R, we first express X' as a rank-1 update of X as follows. Let $u = \gamma\lambda$, and let $v = e_1$. Then $X'^{-1} = (X + uv^T)^{-1}$. Plugging in the definitions of u and v, the Sherman-Morrison formula yields

$$R = X^{-1} - X'^{-1} \overset{Fact\ 5}{=} \frac{X^{-1}uv^TX^{-1}}{1 + v^TX^{-1}u} = \frac{X^{-1}\lambda\gamma e_1^TX^{-1}}{1 + e_1^TX^{-1}\gamma\lambda} = \frac{X^{-1}\lambda\gamma e_1^TX^{-1}}{1 + (X^{-1}\lambda)^T\gamma e_1}\,.$$

We will see below that the denominator is non-zero, so the remainder term is well-defined. Now, recall that $X^{-1}\mathbf{1} = b$. Similarly, we set $\beta \coloneqq X^{-1}\lambda$. Using these substitutions, we get

$$R\mathbf{1} = (X^{-1} - X'^{-1})\mathbf{1} = \left(\frac{X^{-1}\lambda\gamma e_1^TX^{-1}\mathbf{1}}{1 + (X^{-1}\lambda)^T\gamma e_1}\right) = \left(\frac{\beta\gamma e_1^Tb}{1 + \beta^T\gamma e_1}\right) = \left(\frac{\gamma b_1}{1 + \gamma\beta_1}\right)\beta\,. \tag{2}$$

We choose $\gamma \coloneqq (6d^{d+2}N^{2d})^{-1} > 0$. In particular, with our coordinate bound (Lemma 7) this implies that $\gamma|\beta_1| \ll 1/2$, such that the denominator in the remainder term of Equation (2) is non-zero and bounded in the interval $[1/2, 3/2]$. By Lemma 7, we can bound the coordinates of β as $|\beta_i| = |(X^{-1}\lambda)_i| \leq \frac{1}{|\det(X)|} \cdot d^{(d+1)/2}N^{d-1}$. Since $\mathbf{1} \in [-1, 1]^d$ the same bound holds for all coordinates $|b_i|$ of b. These arguments yield the following bound

$$\begin{aligned}
\left|(R\mathbf{1})^T x_{d+1}\right| &\overset{Eq.\ (2)}{=} \left|\left(\frac{\gamma b_1}{1 + \gamma\beta_1}\right)\beta^T x_{d+1}\right| \overset{Hoelder}{\leq} \gamma\left|\left(\frac{1}{1 + \gamma\beta_1}\right)\right| |b_1| \|\beta\|_\infty \|x_{d+1}\|_1 \\
&\overset{Lem.\ 7}{\leq} \gamma\left|\left(\frac{1}{1 + \gamma\beta_1}\right)\right| \cdot \frac{1}{|\det(X)|^2} \cdot d^{d+1}N^{2d-2} \cdot dN \\
&< \quad 2\gamma \cdot \frac{1}{|\det(X)|} \cdot d^{d+2}N^{2d-1} < \frac{1}{3 \cdot |\det(X)|}\,.
\end{aligned} \tag{3}$$

With almost the same calculation, we also have that

$$\begin{aligned}\left|(R\mathbf{1})^T e_1\right| &\overset{Eq.\ (2)}{=} \left|\left(\frac{\gamma b_1}{1+\gamma\beta_1}\right)\beta_1\right| \leq \gamma\left|\left(\frac{1}{1+\gamma\beta_1}\right)\right||b_1||\beta_1| \\ &\overset{Lem.\ 7}{\leq} \gamma\left|\left(\frac{1}{1+\gamma\beta_1}\right)\right| \cdot \frac{1}{|\det(X)|^2}\cdot d^{d+1}N^{2d-2} \\ &< \quad 2\gamma\cdot\frac{1}{|\det(X)|}\cdot d^{d+1}N^{2d-2} < \frac{1}{3\cdot|\det(X)|}\,. \end{aligned} \tag{4}$$

Now, by combining the triangle inequality, Equation (4), Lemma 7, and our choice of $\gamma = (6d^{d+2}N^{2d})^{-1} \leq 1$, we get that

$$\begin{aligned}\gamma\left|(R\mathbf{1})^T e_1 - (X^{-1}\mathbf{1})^T e_1\right| &\leq \gamma|(R\mathbf{1})^T e_1| + \gamma|b_1| \\ &< \frac{1}{3\cdot|\det(X)|} + \frac{1}{6\cdot|\det(X)|} = \frac{1}{2\cdot|\det(X)|}\,. \end{aligned} \tag{5}$$

We conclude the second claim (ii) as follows

$$\begin{aligned}&|\langle b, x_{d+1}\rangle - \langle b', x'_{d+1}\rangle| \\ &= |(X^{-1}\mathbf{1})^T x_{d+1} - (X'^{-1}\mathbf{1})^T x'_{d+1}| \\ &= |(X^{-1}\mathbf{1})^T x_{d+1} - (X'^{-1}\mathbf{1} - X^{-1}\mathbf{1} + X^{-1}\mathbf{1})^T x'_{d+1}| \\ &= |(X^{-1}\mathbf{1})^T x_{d+1} - (X^{-1}\mathbf{1})^T x'_{d+1} + (X^{-1}\mathbf{1} - X'^{-1}\mathbf{1})^T x'_{d+1}| \\ &= |(X^{-1}\mathbf{1})^T x_{d+1} - (X^{-1}\mathbf{1})^T x_{d+1} - \gamma\lambda_{d+1}(X^{-1}\mathbf{1})^T e_1 + (R\mathbf{1})^T x'_{d+1}| \\ &= |(R\mathbf{1})^T x_{d+1} + \gamma\lambda_{d+1}(R\mathbf{1})^T e_1 - \gamma\lambda_{d+1}(X^{-1}\mathbf{1})^T e_1| \\ &\leq |(R\mathbf{1})^T x_{d+1}| + \gamma|\lambda_{d+1}||(R\mathbf{1})^T e_1 - (X^{-1}\mathbf{1})^T e_1| \\ &< \frac{1}{3\cdot|\det(X)|} + \frac{1}{2\cdot|\det(X)|} < \frac{1}{|\det(X)|}\,, \end{aligned}$$

where the triangle inequality is followed by using the fact that $|\lambda_{d+1}| \leq 1$ and applying Equations (3) and (5).

Final Reductions. Finally, we set $m = n/2$ and $\varepsilon = 1/n$. Then, any algorithm that solves MaxHalfspace on R and B in time $O(m^{d-c}) = O((n/2)^{d-c})$ time or ε-MaxHalfspace in $O(\varepsilon^{-(d-c)})$ time can also be used to solve AffineDegeneracy in time $O(n^{d-c})$. ◀

Optimal-Cost Construction of Shallow Cuttings for 3-D Dominance Ranges in the I/O-Model

Yakov Nekrich

Indian Institute of Science, Bangalore, India

Abstract

Shallow cuttings are a fundamental tool in computational geometry and spatial databases for solving offline and online range searching problems. For a set P of N points in 3-D, at SODA'14, Afshani and Tsakalidis designed an optimal $O(N \log_2 N)$ time algorithm that constructs shallow cuttings for 3-D dominance ranges in internal memory. Even though shallow cuttings are used in the I/O-model to design space and query efficient range searching data structures, an efficient construction of them is not known till now. In this paper, we design an optimal-cost algorithm to construct shallow cuttings for 3-D dominance ranges. The number of I/Os performed by the algorithm is $O\left(\frac{N}{B} \log_{M/B}\left(\frac{N}{B}\right)\right)$, where B is the block size and M is the memory size.

As two applications of the optimal-cost construction algorithm, we design fast algorithms for offline 3-D dominance reporting and offline 3-D approximate dominance counting. We believe that our algorithm will find further applications in offline 3-D range searching problems and in improving construction cost of data structures for 3-D range searching problems.

1 Introduction

Shallow cuttings are one of the most fundamental tools used for designing range searching data structures in computational geometry [1, 2, 3, 4, 13] and spatial databases [16, 17, 6]. The main contribution of this paper is the first known optimal-cost construction of shallow cuttings for *3-D dominance ranges* in the *I/O-model*. As a consequence, we obtain efficient algorithms for the *offline 3-D dominance reporting* problem and the *offline 3-D approximate counting* problem.

Shallow cuttings for 3-D dominance ranges. Consider two 3-D points p and q. A point p *dominates* another point q if and only if p has a higher coordinate value than q in each dimension. Let P be a set of N points in 3-D. A *k-level shallow cutting* of P [1] (See Figure 1(a)) is a collection $\mathcal{C}$ of *cells* of the form $(-\infty, x] \times (-\infty, y] \times (-\infty, z]$ satisfying the following three properties:

1. The number of cells is $O(n/k)$, i.e., $|\mathcal{C}| = O(n/k)$.
2. Each cell in $\mathcal{C}$ contains at most $10k$ points from P.
3. Any 3-D point that dominates at most k points of P lies inside at least one cell in $\mathcal{C}$.

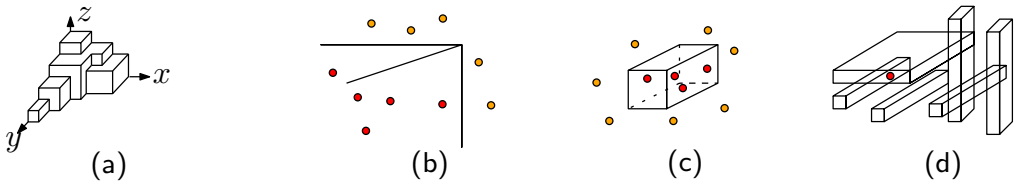

Figure 1 (a) A schematic representation of a k-level 3-D shallow cutting, (b) 3-D dominance reporting and approximate counting query, (c) 3-D orthogonal range reporting query, (d) 3-D rectangle stabbing query.

I/O-model of computation. We will construct shallow cuttings for 3-D dominance ranges in the I/O-model of computation [21]. In the era of big-data, it is natural that the input will not fit completely in the internal memory, and hence, resides in the hard-disk (or the external memory). In this model, the internal memory has M words, and the hard-disk has been formatted into *blocks* of B words. An I/O operation exchanges a block of data between the disk and the memory. The space of a data structure is the number of blocks occupied in the external memory, and the running time of an algorithm is the number of I/Os performed. The CPU calculation is free. A natural assumption is that $M = \Omega(B)$.

3-D orthogonal range searching. Orthogonal range searching and related problems are foundational problems on which the fields of computational geometry and spatial databases grew. Naturally, they have been well studied in the I/O-model of computation. Consider the following problems for which the state-of-the-art data structures in the I/O-model extensively rely on the clever use of shallow cuttings for 3-D dominance ranges:

1. In the *3-D orthogonal range reporting* problem (Figure 1(c)), the input is a set P of N points in 3-D. Preprocess P into a space-efficient data structure, so that given an axis-aligned query box $q = [x_1, x_2] \times [y_1, y_2] \times [z_1, z_2]$, the goal is to quickly report $P \cap q$ (the points of P lying inside q). AT FOCS'09, Afshani, Arge, and Larsen [2] presented a data structure for this problem with space $O\left(\frac{N}{B}\left(\frac{\log N}{\log\log_B N}\right)^3\right)$ and query I/Os $O(\log_B N + k/B)$, where k is the number of points reported.
2. The building block for the above problem is the *3-D dominance reporting* problem (Figure 1(b)), where the query is a 3-D dominance range $q = (-\infty, x] \times (-\infty, y] \times (-\infty, z]$. At ESA'08, Afshani [14] presented a data structure for this problem with space $O(N/B)$ and query I/Os $O(\log_B N + k/B)$. This is optimal in terms of space and query I/Os.
3. At SoCG'09, Afshani, Hamilton, and Zeh presented a general approach to design data structures to answer the *relative* $(1+\varepsilon)$*-approximate counting* query for a general class of problems including the 3-D dominance setting. Here the goal is to output the estimate of $|P \cap q|$. An optimal solution in terms of space and query I/Os was obtained.
4. *Rectangle stabbing reporting* (Figure 1(d)) is the "reverse" of orthogonal range reporting where the input is a set of axis-aligned 3-D boxes and the query is a 3-D point. Arguably, rectangle stabbing reporting is as important as orthogonal range reporting and is well studied in the literature. The current state-of-the-art results in internal memory models of computation for rectangle stabbing reporting by Rahul [15] at SODA'15 and Chan,

Nekrich, Rahul, and Tsakalidis [9] at ICALP'18 rely on shallow cuttings for 3-D dominance ranges. It is unlikely that a linear-space data structure in the I/O-model can be constructed without using shallow cuttings.

Lack of fast construction of data structures. An important criteria in the design of the data structures is to optimize the I/Os required to construct the data structure. A severe limitation of *all* the above solutions is the lack of such fast construction algorithms. In fact, quoting from one of the above papers (Afshani, Hamilton, and Zeh [4]),

"All data structures presented in this paper are static, and no efficient construction methods for these structures are known in the I/O or cache-oblivious model. The main obstacle is the lack of an I/O-efficient or cache-oblivious construction procedure for shallow cuttings."

We believe that our work on optimal-cost construction of shallow cuttings for 3-D dominance ranges will trigger further work to design fast construction of data structures for the above mentioned problems.

Lack of optimal solutions for offline 3-D orthogonal range searching. In the *offline* orthogonal range searching problem, we are given a set Q of queries upfront along with the point set P. Many 2-D offline problems in computational geometry (including range searching type problems) have been optimally solved in the I/O-model. See the survey paper by Vitter (Theorem 8.1 in [21] provides a comprehensive list of more than ten problems in 2-D which are solved I/O-optimally).

However, to the best of our knowledge, offline 3-D orthogonal range searching problems have not received the same attention in spite of their fundamental nature. Again, the lack of optimal-cost shallow cuttings in 3-D is the major bottleneck.

1.1 Our results

The main result in this paper is an optimal-cost construction of the k-level shallow cutting for 3-D dominance ranges in the I/O-model.

▶ **Theorem 1.** *The k-level shallow cutting for 3-D dominance ranges on N points can be constructed in $O\left(\frac{N}{B}\log_{M/B}\left(\frac{N}{B}\right)\right)$ I/Os. The construction cost is optimal in the I/O-model.*

To demonstrate the impact of our new construction, we use shallow cuttings for 3-D dominance ranges to obtain efficient algorithms for two fundamental problems: *offline 3-D dominance approximate counting* and *offline 3-D dominance reporting*.

▶ **Theorem 2** (Application-1)**.** *Let P be a set of N points in 3-D and Q be a set of 3-D dominance ranges. In the offline 3-D dominance approximate counting problem, for any $q \in Q$, the goal is to return a value in the range $[(1-\varepsilon)|P \cap q|, |P \cap q|]$, where $\varepsilon \in (0,1)$ is a fixed value. There is a deterministic algorithm to solve the problem in $O_\varepsilon\left(\frac{|P|}{B}\left(\log_{M/B}\frac{|P|}{B}\right)^{O(1)} + \frac{|Q|}{B}\log_{M/B}\frac{|P|}{B}\right)$ I/Os. The notation $O_\varepsilon(\cdot)$ hides the dependency on ε.*

The key feature in the above theorem is that the construction cost bound has the term M/B in the base of the logarithm which is desirable in the I/O-model (instead of *base*-2 obtained from straightforward adaptation of internal memory algorithms or *base-B* obtained from straightforward adaption of external memory data structures for online problems). In

terms of techniques, even though the final output is a relative approximation, the crucial ingredients in the algorithm are an additive error counting structure that is combined with a non-trivial *van-Emde-Boas-style recursion.*

▶ **Theorem 3** (Application-2). *Let P be a set of N points in 3-D and Q be a set of 3-D dominance ranges. In the offline 3-D dominance reporting problem, for any $q \in Q$, the goal is to report $P \cap q$. The problem can be solved in $O\left(\frac{|P|+|Q|}{B} \log_{M/B} \frac{|P|}{B} + \frac{K}{B}\right)$ I/Os, where K is the output size.*

The final algorithm is a combination of several ideas: filtering search (to charge the I/Os performed for a query to its output-size), optimal k-level shallow cuttings (which were not known before), roughly $O(\log \log N)$ levels of shallow cuttings, and a cleverly chosen base-case. The non-trivial part of the analysis is bounding the number of I/Os to perform the so-called offline-find-any procedures (defined later).

To prove the above theorems, we make use of data structures with specific requirements. For example, in Theorem 4 data structures with fast construction I/Os are considered and in Theorem 5 a data structure with large additive error is considered. Although there exist data structures with desired bounds to handle some of these queries [11, 12, 18, 19], we are not aware of any prior work that obtains these results using a common framework, which might be useful for other problems.

▶ **Theorem 4** (Reporting, counting, and selection). *Let P be a set of N points in 3-D and γ be a fixed constant in $(0, 1)$. Then there exists a data structure that can be constructed in $O(sort(N)) = O\left(\frac{N}{B} \log_{M/B}\left(\frac{N}{B}\right)\right)$ I/Os and then used to answer a*

- *3-D dominance reporting query in $O((N/B)^\gamma + t/B)$ I/Os, where t is the number of points reported. Given a 3-D dominance query range q, the goal is to report the points in $P \cap q$.*
- *3-D dominance counting query in $O((N/B)^\gamma)$ I/Os. Given a 3-D dominance query range q, the goal is to report $|P \cap q|$.*
- *3-D dominance x, y, z-selection query in $O((N/B)^\gamma)$ I/Os. In an x-selection query, given a query point $q = (q_x, q_y, q_z)$ and an integer $k' \in [1, N]$, the goal is to return a point $q_1 = (q'_x, q_y, q_z)$ that dominates k' points in P. Analogously, in a y-selection query (resp., z-selection query), the goal is to return a point $q_2 = (q_x, q'_y, q_z)$ (resp., $q_3 = (q_x, q_y, q'_z)$) that dominates k' points in P.*

▶ **Theorem 5** (Offline additive error counting). *Let P be a set of N points in 3-D and Q be a set of 3-D dominance ranges. In the offline additive error counting problem, for each query $q \in Q$, the goal is to return a value n_q such that $|P \cap q| - n_q \leq \varepsilon N^{2/3} B^{1/3}$. The data structure can be constructed using $O_\varepsilon(sort(N))$ I/Os and the queries are answered by using $O_\varepsilon\left(sort(N) + sort(|Q|)\right)$ I/Os.*

Our solution for additive error query can be extended to handle smaller values of error (such as $\varepsilon\sqrt{NB}$). However, for our purpose an additive error of $\varepsilon N^{2/3} B^{1/3}$ suffices.

The remaining paper is structured as follows. In Section 2, we discuss some preliminaries. In Section 3, we give an overview of two previous constructions of shallow cuttings for 3-D dominance ranges in internal memory. Then, in Section 4 we present our optimal-cost construction in the I/O-model. This is followed by two applications of our construction, offline 3-D dominance approximate counting (in Section 5) and offline 3-D dominance reporting (in the full version). In the full version, we also present the details of our supporting structures (Theorem 4 and Theorem 5) and potential directions for future work.

2 Preliminaries

Definitions. The *conflict list* of a cell $C \in \mathcal{C}$ is defined as the points of P that are inside C. The *apex point* of a cell or a 3-D dominance range $(-\infty, x] \times (-\infty, y] \times (-\infty, z]$ is defined as (x, y, z). The *depth* of a point $p = (x_p, y_p, z_p)$ w.r.t. a pointset P is the number of points of P lying in the cell $(-\infty, x_p] \times (-\infty, y_p] \times (-\infty, z_p]$.

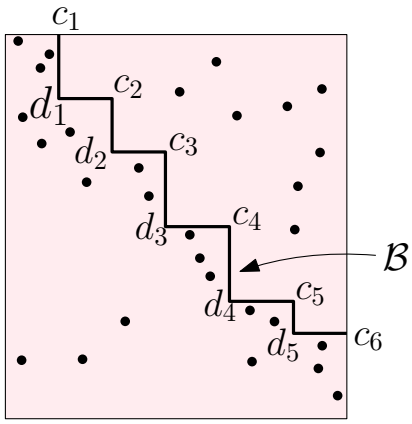

Figure 2 An example of a k-level 2-D shallow cutting. Here $k = 3$, so each inner corner d_i dominates three points and each outer corner c_i dominates six points.

Shallow cuttings for 2-D dominance ranges. As a warm-up, we first introduce shallow cuttings for *2-D dominance ranges*. Let P be a set of N points in 2-D. The collection $\mathcal{C}$ of cells in the k-level shallow cutting of P will be of form $(-\infty, x] \times (-\infty, y]$. Consider the union of the cells in $\mathcal{C}$. We will focus on constructing the *outer boundary* of the union that is shown in Figure 2. The outer boundary $\mathcal{B}$ is a 1-dimensional, monotone, and orthogonal curve. Specifically, $\mathcal{B}$ starts from $y = +\infty$ and consists of alternating vertical and horizontal segments. Let the sequence of endpoints of $\mathcal{B}$ be $c_1, d_1, c_2, d_2, \ldots, d_{t-1}$ and c_t. The c_i's are the *outer corners* and the d_i's are the *inner corners*. The number of points of P dominated by any outer corner (resp., inner corner) will be at most $2k$ (resp., equal to k). The k-level shallow cutting for 2-D dominance ranges can be constructed in $O(sort(N))$ I/Os. (Note that the $2k$ bound is tighter than the $10k$ bound we use for 3-D shallow cuttings.)

Offline-find-any procedure. The input to the *offline-find-any* problem is a collection of cells $\mathcal{C}$ in the k-level shallow cutting of P, for any $1 \leq k \leq n$, and a set Q of 3-D query points. In the offline-find-any procedure, for each $q \in Q$, the goal is to find *any* cell in $\mathcal{C}$ that contains q or report that none of them contain q. The distribution-sweeping approach in the survey paper of Vitter [21] can be used to solve this problem optimally.

▶ **Lemma 6.** *Given a set $\mathcal{C}$ of cells in 3-D and a set Q of query points in 3-D, the offline-find-any procedure requires $O\left(\left(\frac{|\mathcal{C}|+|Q|}{B}\right) \log_{M/B} \frac{|\mathcal{C}|}{B}\right)$ I/Os.*

3 Overview of previous construction algorithms

In this section we give an overview of a couple of previous constructions whose ideas will be required in our final solution.

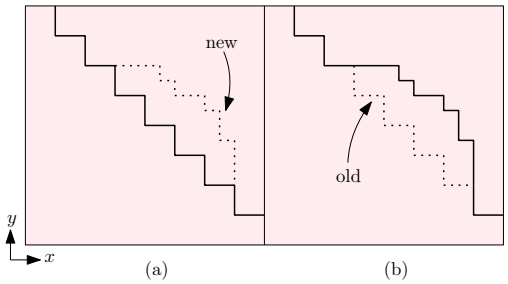

Figure 3 (a) Outer boundary (in bold) before the patching procedure. The dotted boundary is the new curve created during the patching procedure. (b) Outer boundary (in bold) after the patching procedure. The dotted curve was part of the outer boundary before patching. Each outer corner created during the patching procedure corresponds to the apex point of a 3-D cell in the k-level cutting of P.

3.1 Afshani and Tsakalidis's construction (AT-construction)

The problem becomes challenging in 3-D. At SODA'14, Afshani and Tsakalidis [5] obtained an optimal internal memory algorithm that constructs a k-level shallow cutting in $O(N \log_2 N)$ time. Their algorithm constructs the outer boundary $\mathcal{B}$ of the union of the cells in $\mathcal{C}$. In 3-D the outer boundary is a 2-dimensional, monotone, and orthogonal surface (see Figure 1(a)). The algorithm combines the sweep-plane approach with a method of maintaining a 2-D k-level shallow cutting under deletions. Let $z_1, \ldots, z_N$ be the sorted sequence of P in decreasing order of their z-coordinate values. Starting from $z = z_1$, a plane parallel to xy-plane is moved in the $-z$ direction. The *invariant* in the algorithm is to maintain a 2-D shallow cutting for the xy-projections of points of P below the sweep-plane, by ensuring that the depth of each (inner or outer) corner in the 2-D shallow cutting lies in the range $[k, 10k]$. When the sweep-plane reaches z_i, then z_i is deleted and if the invariant is violated, then the 2-D shallow cutting of xy-projections of $z_{i+1}, \ldots, z_n$ is updated via a procedure called *patching*. See Figure 3. The precise details of the patching procedure are not necessary for our final algorithm.

The running time of their algorithm can be summarized by the following equation:

$$T_1(N) = \underbrace{T_{sort}(N)}_{\text{sorting}} + \underbrace{\Theta(N) \cdot T_{pred}(N/k)}_{\text{bottleneck 1}} + \underbrace{O(N/k) \cdot T_{aux}(N)}_{\text{bottleneck 2}} \tag{1}$$

There are two bottlenecks in adapting their algorithm in the I/O-model. At any point in the sweep-plane, let $\mathcal{L}$ be the ordering of the corners in the 2-D shallow cutting based on their x-coordinate values. Each time a point $z_i \in P$ is deleted, a predecessor search is performed on $\mathcal{L}$. Also, the patching procedure leads to insertion and deletion of corners into $\mathcal{L}$. The predecessor search is performed to identify all the corners in $\mathcal{L}$ dominating z_i and then to update the conflict lists of those corners (at no extra asymptotic cost). This is the first bottleneck, since it is not possible to perform $\Theta(N)$ updates and $\Theta(N)$ predecessor queries to the list $\mathcal{L}$ in $sort(N)$ I/Os. (In fact, in [8] it was established that the easier problem of batched predecessor queries requires $T_{pred}(N) = \Omega(\log_B N)$ I/Os per query when the preprocessing cost is bounded by a polynomial in N.) It is not clear how to reduce the number of predecessor queries to $o(N)$, and the lower-bound discards the standard strategy in the I/O-model of performing predecessor search queries in batches.

The *second bottleneck* is the lack of I/O-efficient data structures for performing the patching procedure. The patching procedure involves constructing data structures for 3-D dominance x-selection and dominance y-selection queries on P, and querying them $O(N/k)$

times. For our purpose, the data structures have to be constructed in $O(sort(N))$ I/Os. In the full version, we present such data structures with query I/Os $T_{aux}(N) = O((N/B)^{\gamma})$ for some $\gamma \in (0,1)$ (Theorem 4). Therefore, the patching will require $O\left(\frac{N}{k}\left(\frac{N}{B}\right)^{\gamma}\right)$ I/Os, which is expensive.

3.2 Nekrich and Rahul's construction (NR-construction)

At SODA'23, Nekrich and Rahul [13] designed a data structure for 4-D dominance reporting query by constructing several shallow cuttings for 3-D dominance ranges. However, for their application, the conflict lists of the cells were not needed, and only the cells needed to be constructed. They modified the AT-construction to design an algorithm whose running time is proportional to the number of cells constructed (specifically $O(N \log_2 N)$ cells were constructed on different subsets of P in $O(N \log_2^5 N)$ time).

For a cell C in the shallow cutting with apex point (x, y, z), let $exp(C)$ be the largest z-coordinate such that $(x, y, exp(C))$ dominates less than k points of P. Then $exp(C)$ is defined as the *expiry* of C. For a cell C, its expiry $exp(C)$ can be computed via a 3-D dominance z-selection query on P. Similar to AT-construction approach, starting from $z = +\infty$, the algorithm sweeps a plane parallel to the xy-plane in the $-z$ direction and the same invariant is maintained. The key difference is in the *event points* visited by the sweep-plane algorithm. In the NR-construction, the event points will be the $exp(C)$ values of all cells C in the shallow cutting, which are stored in a simple priority-queue $\mathcal{Q}$.

At each time step, we find the event with the largest z-coordinate $z_{\max}$ in $\mathcal{Q}$ and set the z-coordinate of the sweep-plane to $z_{\max}$. When the cell C corresponding to z_{max} expires, (inner and outer) corners corresponding to C have to be removed from the 2-D shallow cutting at z_{max}. Therefore, the patching procedure is performed. After finishing the patching procedure, (a) the events corresponding to the new inner corners in the 2-D shallow cutting are inserted into $\mathcal{Q}$ and the events corresponding to the deleted corners in the 2-D shallow cutting are removed from $\mathcal{Q}$, (b) for each newly created outer corner (x, y) in the patching procedure, a new cell with apex point (x, y, z_{max}) gets *created*. We define $cre(C) = z_{max}$ for each cell C created. The algorithm finishes when the z-coordinate of the sweep-plane reaches $z = -\infty$. We omit the details of the NR-construction algorithm that are not needed to obtain our result. The following lemma summarizes the properties of the NR-construction that are relevant for our algorithm.

▶ **Lemma 7.** *Nekrich and Rahul's construction [13] of k-level shallow cuttings for 3-D dominance ranges can be summarized as follows:*

1. *It involves construction of a priority queue and 3-D dominance x, y, z-selection data structures.*[1]
2. *The number of updates and queries on the priority-queue is $O(N/k)$ and the number of 3-D dominance x, y, z-selection queries is $O(N/k)$.*
3. *In each selection query, if the query point is $q = (q_x, q_y, q_z)$, then the sweep-plane is at q_z and (q_x, q_y) is one of the corners in the 2-D shallow cutting of P at q_z after patching. The query integer $k' \leq 10k$ will be such that for an x-selection query, the reported point (q'_x, q_y, q_z) will have $q'_x > q_x$. However, for the y-selection and the z-selection queries, the reported points (q_x, q'_y, q_z) and (q_x, q_y, q'_z), respectively, will have $q'_y < q_y$ and $q'_z < q_z$.*

[1] Nekrich and Rahul [13] originally used *3-D dominance range counting* data structures as well, where the goal is to report $|P \cap q|$ for a 3-D dominance range q. However, both queries are almost equivalent: we can answer a 3-D dominance range selection query using $O(\log N)$ range counting queries (binary search). Conversely, we can also answer a 3-D dominance range counting query via $O(\log N)$ dominance z-selection queries.

The running time of the NR-construction can be summarized as follows:

$$T_2(N) = \underbrace{T_{\mathcal{Q}}\left(\frac{N}{k}\right)}_{\text{queue}} + \underbrace{O\left(\frac{N}{k}\right) \cdot T_{sel}(N)}_{\text{bottleneck}} \tag{2}$$

Similar to the second bottleneck in the AT-construction, the bottleneck in the NR-construction is the I/Os required to perform the dominance selection queries (with $O(sort(N))$ construction I/Os for the data structures, we have $O\left(\frac{N}{k}\right) \cdot T_{sel}(N) = O\left(\frac{N}{k}\left(\frac{N}{B}\right)^{\gamma}\right)$ I/Os which is expensive).

3.3 Other constructions

At ICALP'14, Afshani, Chan, and Tsakalidis [3] proposed an AT-construction variant (by sweeping upwards) for constructing shallow cuttings for 3-D dominance ranges in $O(N \log_2 \log_2 N)$ time in the word-RAM model. At STOC'96, Vengroff and Vitter [20] employed a structure that is similar to 3-D shallow cuttings to answer 3-D orthogonal range reporting queries. Unfortunately, the number of I/Os required to construct their data structure was not considered in their work.

Construction of shallow cuttings for halfspaces in 3-D has been another active area of research. However, typically the techniques and tools used for these problems (such as vertical decomposition, ε-cuttings, planar graph separators) have been different from the ones used for 3-D dominance ranges. For example, at SoCG'15, Chan and Tsakalidis [10] presented an optimal deterministic internal memory algorithm for the construction of shallow cuttings for halfspaces in 3-D. Their hierarchical construction relies on the fact that the cells of the shallow cutting do not intersect (to be precise, they are interior-disjoint). While this is true in the case of shallow cuttings for 3-D halfspaces, this property is not satisfied in our problem: cells of a k-level shallow cutting for 3-D dominance ranges are intersecting boxes. Also, in their hierarchy the levels go down by a constant factor which is not ideal for an I/O-efficient algorithm, whereas in our construction levels will go down at a faster rate.

4 Our algorithm for constructing k-level shallow cuttings

We are now ready to prove Theorem 1. Our algorithm follows the general approach used in [5, 13] and combines it with several other ideas. First, we construct a *hierarchy* of shallow cuttings such that the conflict list size of cells decreases exponentially. Second, somewhat counterintuitively, we use data structures with high query cost and fast pre-processing for 3-D dominance selection queries. The final algorithm is a combination of six pieces.

4.1 1st piece: Hierarchy of shallow cuttings

The main idea is to construct a hierarchy of shallow cuttings. We want to construct a k-level shallow cutting of P where $k \geq M/c$ and c is a sufficiently large constant. Let $t_i = (N/B)^{\delta^i}$ and $k_i = \max(Bt_i, k)$. We select the constant $\delta \in (0, 1)$ in such way that $k_i \leq k_{i-1}/10$ (for any i satisfying $k_i \geq M/c$). The algorithm works in stages (starting from stage 0). In the i-th stage, we construct the k_i-level shallow cutting. For the starting case of 0-th stage, since $k_0 = N$, the k_0-level shallow cutting consists of one cell containing all points of P. The algorithm terminates when $k_i = k$.

▶ **Lemma 8.** *The number of shallow cuttings constructed is* $r = O(\log_{M/B}(N/B))$.

Proof. Since $k_i = Bt_i \geq M/c$, we have $t_i \geq M/Bc$. Therefore, $t_{i+1} = t_i^{\delta} = t_i \cdot \frac{1}{t_i^{1-\delta}} \leq \frac{t_i}{(M/cB)^{1-\delta}}$. Unfolding the recursion, we obtain $t_{i+1} \leq \frac{t_0}{\left(\frac{M}{cB}\right)^{(i+1)(1-\delta)}}$. Setting $i \leftarrow \frac{c'}{1-\delta}\log_{M/cB}(N/B) - 1$, for $c' \geq 2$, we observe that $t_{i+1} \leq t_0/(N/B)^{c'} < 1$. This implies that $r = O(\frac{1}{1-\delta}\log_{M/B}(N/B)) = O(\log_{M/B}(N/B)$. ◀

4.2 2nd piece: Existence of parent cells

We will start with some definitions. For all $1 \leq i \leq r$, we will say that the k_{i-1}-level shallow cutting is the *parent* shallow cutting of the k_i-level shallow cutting. When the sweep-plane reaches z, then a cell C is *active* at z if $cre(C) \leq z \leq exp(C)$.

In the construction of the k_i-level shallow cutting, consider an outer corner (x_p, y_p) on the 2-D shallow cutting which got created when the sweep-plane is at position z. Then the *parent cell* of point $p = (x_p, y_p, z)$ is the cell C in the parent shallow cutting which satisfies the following two properties: (a) the apex point of C dominates p, and (b) the apex point of C has the smallest y-coordinate among all cells that are active at z.

▶ **Lemma 9.** *In the construction of the k_i-level shallow cutting (for $i \geq 1$), consider an outer corner (x_p, y_p) on the 2-D shallow cutting which got created when the sweep-plane is at position z. Then a parent cell always exists for the point (x_p, y_p, z).*

Proof. The depth of the point (x_p, y_p, z) will be less than or equal to $10k_i$ (an invariant maintained by the AT-construction), which is at most k_{i-1}. In the k_{i-1}-level shallow cutting construction, consider the 2-D shallow cutting when the sweep-plane reached z. This 2-D shallow cutting will have at least one outer corner, say p', which dominates (x_p, y_p) (by third property of k_{i-1}-level shallow cuttings). Let C be the 3-D cell in the k_{i-1}-level shallow cutting corresponding to the outer corner p'. Since C is active when the sweep-plane reached position z, it implies that the apex point of C dominates (x_p, y_p, z). This establishes property (a) of a parent cell, and hence, a parent cell exists. ◀

4.3 3rd piece: Query-expensive structures on small-sized inputs

A data structure built on N' points is query-expensive if the the number of I/Os required to answer a query is of the form $O((N'/B)^{\gamma})$ or $O((N'/B)^{\gamma} + t/B)$. Our next idea is to construct such query-expensive data structures, but only on small-sized inputs. Specifically, for the k_i-level shallow cutting, we will ensure that the a 3-D dominance x, y, z-selection query requires only $O(k_i/B)$ I/Os, and since the number of such selection queries performed is bounded by $O(N/k_i)$ (point 2 in Lemma 7), overall the selection queries will require only $O(N/B)$ I/Os. Similarly, we will ensure that generating the conflict list of a cell requires only $O(k_i/B)$ I/Os, and since there are $O(N/k_i)$ cells in the k_i-level cutting, generating all the conflict lists will require only $O(N/B)$ I/Os. The existence of parent cells and the following lemma will let us achieve the goal of utilizing query-expensive data structures I/O-efficiently.

▶ **Lemma 10.** *In the construction of the k_i-level shallow cutting (for $i \geq 1$), consider the sweep-plane at any time z. If patching is performed at time z, then let $p = (x_p, y_p)$ be a new outer corner created with parent cell C. Then the 3-D dominance x, y, z-selection queries with query point $p = (x_p, y_p, z)$ will output a point that lies inside C.*

Proof. This is trivial to see for a y-selection query since p already lies inside C and hence, the point reported by the query will also lie inside C (see Lemma 7). Similarly, it holds for a z-selection query as well. The non-trivial case is the x-selection query.

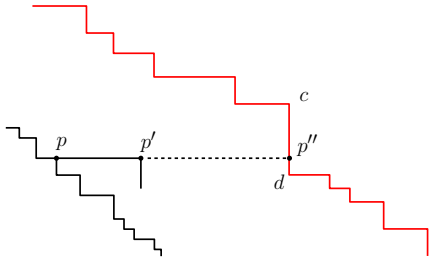

Figure 4 An example of x-selection query in Lemma 10. The point p is an outer corner of a 2-D shallow cutting of the k_i-level. The corner c is the outer corner of the parent staircase corresponding to the parent cell C of p, since c has the smallest y-coordinate among all apex points of the parent staircase dominating p.

Let p'' denote the point where the horizontal ray from p hits the 2-D shallow cutting of the parent at time z. See Figure 4. Let d be the inner corner immediately below p'' and c be the outer corner immediately above p''. Since the depth of d is at least k_{i-1}, the depth of p'' will also be at least k_{i-1}. Consider the 3-D dominance x-selection query with query point p and parameter $k' \leq 10k_i \leq k_{i-1}$. This implies that the output, p', will have an x-coordinate less than or equal to p''. Now the cell corresponding to the outer corner c is the parent cell of p and contains p' as well. ◀

▶ **Lemma 11.** *Assume that the k_{i-1}-level shallow cutting of P has been constructed in the $(i-1)$-th stage. Ignoring the I/Os required to find the parent cells, in the i-th stage, the k_i-level shallow cutting can be constructed in $O\left(\frac{N}{k_i}\log_B\frac{N}{k_i} + \frac{N}{B}\log_{M/B}\frac{k_{i-1}}{B}\right)$ I/Os.*

Proof. For each cell in the k_{i-1}-level shallow cutting, based on its conflict list we construct data structures supporting 3-D dominance reporting and 3-D dominance x, y, z-selection queries (Theorem 4) that requires $O((N/k_{i-1}) \cdot \frac{k_{i-1}}{B}\log_{M/B}(\frac{k_{i-1}}{B})) = O\left(\frac{N}{B}\log_{M/B}\frac{k_{i-1}}{B}\right)$ I/Os. By point 2 in Lemma 7, $O(N/k_i)$ x, y, z-selection queries will be performed. For each selection query, if the cost of finding the parent cell of the query point is ignored, then by Lemma 10 the answer to the query can be obtained by querying the x, y, z-selection data structure built at the parent cell. The query I/Os of each selection query will then be $O((k_{i-1}/B)^\gamma)$. Therefore, the number of I/Os performed to answer the selection queries is $O\left(\frac{N}{k_i}\left(\frac{k_{i-1}}{B}\right)^\gamma\right) = O\left(\frac{N}{Bt_i}\cdot t_{i-1}^\gamma\right) = O\left(\frac{N}{Bt_i}\cdot t_{i-1}^\delta\right) = O\left(\frac{N}{B}\right)$, by choosing $\gamma < \delta$.

By point 1 in Lemma 7, the number of operations on the priority-queue are $O(N/k_i)$ and using a vanilla B-tree as a priority-queue $O\left(\frac{N}{k_i}\log_B\frac{N}{k_i}\right)$ I/Os are performed.

Finally, for each cell C in the k_i-level cutting, its conflict list is generated by querying its parent cell's 3-D dominance reporting data structure. The number of I/Os performed is $O\left(\left(\frac{k_{i-1}}{B}\right)^\gamma + \frac{k_i}{B}\right) = O(k_i/B)$. Since the number of cells in the k_i-level cutting is $O(N/k_i)$, the total number of I/Os required to generate the conflict lists is $O(N/B)$. ◀

4.4 4th piece: Finding parent cells efficiently

By point 2 in Lemma 7, $O(N/k_i)$ x, y, z-selection queries are performed in the construction of a k_i-level shallow cutting. To perform each selection query, we first need an efficient routine to find the parent cell. Once the parent cell is found, then the selection query is performed on the data structure corresponding to the parent cell.

We will use partially persistent B-trees [7] to store the cells in the k_{i-1}-level shallow cutting. Versions of the partially persistent data structure are parameterized by z-coordinates: a cell is inserted (resp. deleted) at time t if the corresponding outer corner is added to the 2-D shallow cutting (resp. removed from the 2-D shallow cutting) when the z-coordinate of the sweep-plane is equal to t. This data structure supports successor queries with respect to y- coordinates of its apex points: for any pair (z_q, y_q) we can find the cell with the smallest y-coordinate among all cells of the parent shallow cutting that are active at time z_q and whose y-coordinate is not smaller than y_q.

▶ **Lemma 12.** *In the construction of k_i-level shallow cutting, the number of I/Os performed to compute the parent cells is $\left(\frac{N}{k_i}\log_B \frac{N}{k_{i-1}}\right)$.*

Proof. The number of cells in the k_{i-1}-level shallow cutting is $O(N/k_{i-1})$ and using persistent B-trees, a successor query and an update query can be supported in $O(\log_B(N/k_{i-1}))$ I/Os. By point 2 in Lemma 7, the total number of x, y, z-selection queries will be $O(N/k_i)$, and hence, the number of I/Os performed to compute the parent cells is $\left(\frac{N}{k_i}\log_B \frac{N}{k_{i-1}}\right)$. ◀

4.5 5th piece: Obtaining logarithmic bounds with the base M/B

To obtain $O(sort(N))$ I/Os bound, we need the base in the logarithm to be M/B. To circumvent the fact that finding parent cells and operations on the priority queue require $O(\log_B(N/k))$ query I/Os, we exploit the fact that k is large.

▶ **Lemma 13.** *For $k = \Omega(M)$, we have $O\left(\frac{N}{k}\log_B \frac{N}{k}\right) = O\left(\frac{N}{B}\log_{M/B} \frac{N}{B}\right)$.*

Proof. First, we will establish that $B\log(M/B) \le cM\log B$, where c is a sufficiently large constant. When $M \le B^c$, we have $cM\log B = M\log B^c \ge M\log M \ge B\log(M/B)$. When $M > B^c$, we have $cM\log B \ge cB\cdot M^{1-1/c}\log B \ge cB\cdot M^{1-1/c} \ge cB\log M \ge cB\log(M/B)$. Using this fact, we have

$$\frac{N}{k}\cdot\frac{\log(N/k)}{\log B} \le \frac{N}{M}\cdot\frac{\log(N/B)}{\log B} \le O\left(\frac{N}{B}\frac{\log(N/B)}{\log(M/B)}\right). \quad ◀$$

In summary, the running time of our algorithm is

$$T_3(N) = O\left(T_{\mathcal{Q}}\left(\frac{N}{k}\right) + \sum_{i=1}^{r}\frac{N}{k_i}\cdot T_{sel}(k_{i-1}) + \frac{N}{k}\cdot\log_B\frac{N}{k}\right) \tag{3}$$

▶ **Lemma 14.** *For $k = \Omega(M)$, the k-level shallow cutting for 3-D dominance ranges on N points can be constructed in $O\left(\frac{N}{B}\log_{M/B}\left(\frac{N}{B}\right)\right)$ I/Os.*

Proof. By combining Lemma 11 and Lemma 12, the number of I/Os required to construct a k_i-level shallow cutting is $O\left(\frac{N}{k_i}\log_B\frac{N}{k_i} + \frac{N}{B}\log_{M/B}\frac{k_{i-1}}{B}\right)$. Therefore,

$$\sum_{i=1}^{r} O\left(\frac{N}{k_i}\log_B\frac{N}{k_i} + \frac{N}{B}\log_{M/B}\frac{k_{i-1}}{B}\right) = O\left(\frac{N}{k}\log_B\frac{N}{k} + \frac{N}{B}\log_{M/B}\frac{N}{B}\right)$$

By Lemma 13, this can be bounded by $O\left(\frac{N}{B}\log_{M/B}\frac{N}{B}\right)$. ◀

4.6 Final piece: Handling Small Values of k

We will need a different procedure to handle $k = O(M)$. We will perform a two-level cutting. First, we will construct an (M/c)-level shallow cutting of P using Lemma 14. For each cell, say C, in the (M/c)-level, load its *entire* conflict list into the internal memory. This can be done I/O-efficiently since the size of the conflict list is $O(M)$. Next run an internal memory algorithm to compute the k-level shallow cutting of the conflict list of C. The final output is the union of the shallow cuttings obtained from each cell in the (M/c)-level.

▶ **Lemma 15.** *Suppose that we are given an (M/c)-level shallow cutting of P for some constant $c > 1$. Then for $k < M/c$, the k-level shallow cutting can be constructed in $O(N/B)$ I/Os.*

Proof. We will establish that the three properties of a k-level shallow cutting of P are satisfied by the algorithm. The number of cells constructed in the final cutting is $O(N/M) \cdot O(M/k) = O(N/k)$ (first property). It is easy to verify that the number of points of P lying inside each cell in the final cutting is $O(k)$ (second property). Consider a point q that dominates less than or equal to k points in P. By the third property of M/c-level shallow cutting of P, there exists a cell C that contains q. The number of points in the conflict list of C dominated by q will still be less than or equal to k. Therefore, in the k-level shallow cutting of the conflict list of C, there will exist some cell that contains q (third property).

Loading the conflict lists of all the cells in the (M/c)-level shallow cutting requires $O(N/M) \cdot O(M/B) = O(N/B)$ I/Os. For each cell in the (M/c)-level shallow cutting, writing the k-level shallow cutting of its conflict-list into external memory requires $O(M/B)$ I/Os. Thus, over all the cells in the (M/c)-level shallow cutting, it will require $O(N/M) \cdot O(M/B) = O(N/B)$ I/Os. ◀

Combining Lemma 14 and Lemma 15 completes the proof of Theorem 1.

5 Application-1: Offline 3-D dominance approximate counting

Recall that P is a set of N points in 3-D and Q is a set of query 3-D dominance ranges. Consider a parameter ε with a fixed value in $(0, 1)$. In the offline 3-D dominance approximate counting problem, the goal is to report a value in the range $[(1 - \varepsilon)|P \cap q|, |P \cap q|]$, for all $q \in Q$. We will prove Theorem 2 in this section.

5.1 Data structure and query algorithm

The overall data structure is recursive and we start at the root with pointset P. Construct a $(N^{2/3}B^{1/3})$-level cutting $\mathcal{C}$ based on P (Theorem 1). Also, construct an additive error counting structure based on P (Theorem 5). Finally, for each cell $C \in \mathcal{C}$, recurse on P_C, where P_C is the conflict list of C. The recursion stops when the size of pointset becomes less than or equal to M/c, where c is a sufficiently large constant.

The query algorithm will start from the root of the data structure. A point in Q is *deep* if no cell in $\mathcal{C}$ contains it; otherwise, it is *shallow*. Using the offline-find-any procedure on $\mathcal{C}$ and Q, we will classify each point in Q as shallow or deep. The result for the deep query points are obtained by querying the additive error counting structure. If a point $q \in Q$ is shallow, then it is *assigned* to one of the cells containing it. The shallow points are handled recursively. Specifically, for each cell $C \in \mathcal{C}$, *recurse* on Q_c, where $Q_c \subseteq Q$ is the set of shallow query points assigned to C.

To handle the base case, where $|P| \leq M/c$, first the points in P are loaded into the memory. Then the query objects are streamed into the main memory one block at a time, and the results for these queries are obtained without any additional I/Os and written to the external memory.

5.2 Analysis

We will first bound the number of I/Os performed by the algorithm.

▶ **Lemma 16.** *The number of I/Os required to construct the data structure is* $O\left(\frac{|P|}{B}\left(\log_{M/B}\frac{|P|}{B}\right)^{O(1)}\right)$.

Proof. The $(N^{2/3}B^{1/3})$-level cutting (Theorem 1) and the additive error counting structure (Theorem 5) can be constructed in $O(sort(|P|)$ I/Os. Therefore, the total number of I/Os required to construct the data structure is:

$$T(N) = \begin{cases} c_1\left(\frac{N}{B}\right)^{1/3} \cdot T(N^{2/3}B^{1/3}) + \frac{c_2 N}{B}\log_{M/B}\frac{N}{B}, \text{if } N \geq M/c \\ O(N/B), \text{ otherwise} \end{cases}$$

where $c_1(N/B)^{1/3}$ is the number of cells in the cutting and c_2 is the constant inside $O(sort(N))$. We will establish that $T(N) \leq \frac{c_3 N}{B}\left(\log_{M/B}\frac{N}{B}\right)^{c_4}$, where $c_3 = 2c_2$ and $c_1\left(\frac{2}{3}\right)^{c_4} = \frac{1}{2}$. As such,

$$\begin{aligned} T(N) &\leq c_1\left(\frac{N}{B}\right)^{1/3} \cdot c_3\frac{N^{2/3}B^{1/3}}{B}\left(\log_{M/B}\frac{N^{2/3}B^{1/3}}{B}\right)^{c_4} + \frac{c_2 N}{B}\log_{M/B}\frac{N}{B} \\ &\leq c_1 c_3\frac{N}{B}\cdot\left(\frac{2}{3}\right)^{c_4}\left(\log_{M/B}\frac{N}{B}\right)^{c_4} + \frac{c_2 N}{B}\log_{M/B}\frac{N}{B} \\ &\leq \frac{c_2 N}{B}\left(\log_{M/B}\frac{N}{B}\right)^{c_4} + \frac{c_2 N}{B}\left(\log_{M/B}\frac{N}{B}\right)^{c_4} = \frac{c_3 N}{B}\left(\log_{M/B}\frac{N}{B}\right)^{c_4} \end{aligned}$$

◀

▶ **Lemma 17.** *The number of I/Os performed by the query algorithm is* $O_\varepsilon\left(\frac{|P|}{B}\left(\log_{M/B}\frac{|P|}{B}\right)^{O(1)} + \frac{|Q|}{B}\log_{M/B}\frac{N}{B}\right)$.

Proof. By Theorem 5 and Lemma 6, the number of I/Os performed by the query algorithm at the root is $O_\varepsilon\left(sort(N) + sort(|Q|) + \left(\frac{|\mathcal{C}|+|Q|}{B}\right)\log_{M/B}\frac{|\mathcal{C}|}{B}\right)$, which can be bounded by $O_\varepsilon\left(sort(N) + \frac{|Q|}{B}\log_{M/B}\frac{N}{B}\right)$. The $O_\varepsilon(sort(N))$ I/Os can be charged to the construction of the data structure, and hence, by the proof of Lemma 16, it will be bounded by $O_\varepsilon\left(\frac{|P|}{B}\left(\log_{M/B}\frac{|P|}{B}\right)^{O(1)}\right)$ in the overall query algorithm.

Therefore, we will focus on the $O_\varepsilon\left(\frac{|Q|}{B}\log_{M/B}\frac{N}{B}\right)$ term. As such, the amortized number of I/Os performed for a *single* query point is $O_\varepsilon\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$. Including recursion, the number of I/Os performed to answer a single query is:

$$q(N) \leq q(N^{2/3}B^{1/3}) + O_\varepsilon\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right) = O_\varepsilon\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right),$$

which holds because we end up with a geometrically decreasing series. ◀

▶ **Lemma 18.** *For each $q \in Q$, the algorithm returns a $(1-\varepsilon)$-approximation of $|P \cap q|$.*

Proof. For any deep query point q at the root, the value n_q reported by the additive error counting structure will be such that $n_q \geq |P \cap q| - \varepsilon N^{2/3}B^{1/3} \geq (1-\varepsilon)|P \cap q|$, since $|P \cap q| \geq N^{2/3}B^{1/3}$ for a deep point (third property of shallow cuttings). The same argument applies at each node in the data structure (w.r.t. deep queries at that node). ◀

A Persistent Version of Latschev's Theorem

Steve Oudot

Lukas Waas
University of Oxford, UK

Abstract

Latschev's theorem provides sufficient conditions on a metric space M and $\delta > 0$ for the homotopy type of M to agree with that of the Vietoris-Rips complex $\mathcal{R}^\delta(\mathbb{M})$ of any nearby space $\mathbb{M}$ in the Gromov-Hausdorff distance. We prove a persistent version of this theorem, providing sufficient conditions on a pair $(M, f\colon M \to \mathbb{R}^N)$ and $\delta > 0$ for the persistent homotopy type of the sublevel set filtration of (M, f) to be interleaved with that of the function-Rips complex $\mathcal{R}^\delta(\mathbb{M}^\bullet)$ of any nearby pair $(\mathbb{M}, \mathbb{f})$. In particular, our result answers a longstanding question on the related topic of estimating sublevel set persistent homology from finite point samples.

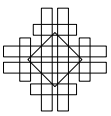
1 Introduction



This work connects three lines of research in TDA and metric topology. The first – and main – one aims at generalizing Latschev's result about the homotopy type of Vietoris-Rips complexes built on Gromov-Hausdorff approximations of compact Riemannian manifolds.

▶ **Theorem** (Latschev [25]). *Let M be a closed Riemannian manifold. Then there exists $\delta_0 > 0$ such that, for every $0 < \delta \leq \delta_0$, there exists an $\varepsilon > 0$ such that, for any metric space $\mathbb{M}$ with Gromov-Hausdorff distance to M less than ε, M is homotopy equivalent to the geometric realization $|\mathcal{R}^\delta(\mathbb{M})|$ of the Vietoris-Rips complex $\mathcal{R}^\delta(\mathbb{M})$ of parameter δ.*

To our knowledge, this result has been extended in the following directions:

- Replacing Riemannian manifolds with spaces of curvature bounded above [23];
- Quantifying the upper bounds on ε and δ [27, 29];
- Letting δ go past its upper bound on specific spaces, for instance the circle [1] or ellipses [3];
- Considering variants of the Vietoris-Rips complex, such as the selective Rips complex [26].

Here, we extend Latschev's result in another direction: To spaces equipped with filtration functions (Theorem 1 below). In this setting, the role of the homotopy type of M is taken by the so-called *persistent homotopy type* of the sublevel set filtration of a function $f\colon M \to \mathbb{R}^N$, denoted $M^\bullet$ (Notation 19). The role of the Vietoris-Rips complex of $\mathbb{M}$ is now taken by the filtered simplicial complex $\mathcal{R}^\delta(\mathbb{M}^\bullet)$, called the *function-Rips* complex. It is obtained by filtering the ordinary Rips complex of fixed parameter δ, $\mathcal{R}^\delta(\mathbb{M})$, through the Rips-complexes (at scale δ) of the sublevel sets of a function $\mathbb{f}\colon \mathbb{M} \to \mathbb{R}^N$ (Example 12). Finally, the role of correspondences (for the Gromov-Hausdorff distance) is taken by so-called *filtered correspondences* (Definition 32), and the role of homotopy equivalences is taken by a notion of *interleavings in the persistent homotopy category* (Definition 28, see also [24]). In the following, M denotes a compact metric space with curvature bounded above by some $\kappa \in \mathbb{R}$ (Recollection 5) and $f\colon M \to \mathbb{R}^N$ a componentwise 1-Lipschitz map. Finally, ρ_M^κ denotes the minimum of the convexity radius ϱ_M of M (see Recollection 4) and of either $\frac{\pi}{4\sqrt{\kappa}}$ if $\kappa > 0$ or ∞ if $\kappa \leq 0$.

▶ **Theorem 1** (Persistent Latschev's theorem). *Let $0 < \delta \leq \rho_M^\kappa$ and $\varepsilon \leq \min\{\rho_M^\kappa - \delta, \frac{1}{7}\delta\}$. Then, for any filtered ε-correspondence $(M, f) \approx_\varepsilon (\mathbb{M}, \mathbb{f})$, there is a $\frac{7}{4}\delta$-interleaving $M^\bullet \simeq_{\frac{7}{4}\delta} \mathcal{R}^\delta(\mathbb{M}^\bullet)$ in the persistent homotopy category.*

Note that, in contrast to the setup of Latschev's theorem, we cannot hope to get a homotopy equivalence between filtered spaces here. This is because the individual sublevel sets of f may be highly pathological even though M itself satisfies strict regularity conditions. Note also that we cannot expect interleavings at the level of topological spaces: any such interleaving would induce homeomorphisms at infinity, which generally do not exist.

In the special case $N = 0$ (i.e., $\mathbb{R}^N$ is a singleton), the homotopy theoretic interleaving $M^\bullet \simeq_{\frac{7}{4}\delta} \mathcal{R}^\delta(\mathbb{M}^\bullet)$ is just an isomorphism in the homotopy category, i.e., a zig-zag of weak homotopy equivalences. So, by an application of Whitehead's theorem, Theorem 1 recovers the quantitative version of Latschev's theorem given in [29], with the same bounds on δ and ε. As Theorem 1 is phrased at the persistent homotopy level, it also induces an interleaving at the persistent homology level. This connects our result to another line of research, the aim of which is to estimate the persistent homology of functions from finite point samples. In [14], the authors proposed an estimator for the persistent homology of $L^\bullet$, for a Lipschitz map $g\colon L \to \mathbb{R}$, from a finite sampling $\mathbb{L} \subset L$ of its domain L. The proof technique leveraged in this line of work made use of the interleaving between Vietoris-Rips and Čech complexes, and ultimately led to an estimator given by the image of morphisms of persistence modules $\mathrm{im}(H_*\mathcal{R}^\delta(\mathbb{L}^\bullet) \to H_*\mathcal{R}^{2\delta}(\mathbb{L}^\bullet))$, where $\mathbb{L}$ is filtered by $g|_{\mathbb{L}}$. This estimator was then specialized to the case where g is a density estimator in the context of unsupervised learning, yielding the clustering algorithm ToMATo [15]. It was later extended to more general noise models [10] and, more recently, to $\mathbb{R}^N$-valued maps:

▶ **Theorem** ([4]). *Let (L, g) be such that L is a compact metric space with $\varrho_L > 0$ and g is 1-Lipschitz. Let $\delta < \frac{1}{2}\varrho_L$ and $\varepsilon \leq \frac{1}{2}\delta$. Then, for any subset $\mathbb{L} \subset L$ that is ε-dense in L, there is a 2δ-interleaving $H_*(L^\bullet) \simeq_{2\delta} \mathrm{im}(H_*\mathcal{R}^\delta(\mathbb{L}^\bullet) \to H_*\mathcal{R}^{2\delta}(\mathbb{L}^\bullet))$ of persistence modules.*

Theorem 1 complements this result by showing that, under a more restrictive regularity condition on M (namely: that M has curvature bounded above), a single filtered Rips complex is enough to estimate the persistent homology of f, via a different proof approach that does not proceed through the interleaving between Vietoris-Rips and Čech complexes. The question of whether this is possible had been open since the beginning of this line of work, and it has important implications, including algorithmic ones. For instance, computing

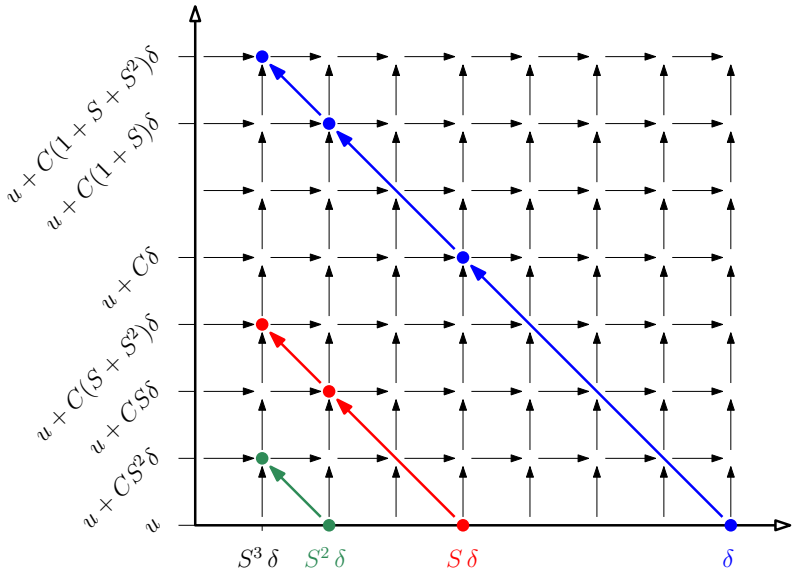

Figure 1 Shrinking transformation arrows (colored) and the object's structure morphisms (black).

a free presentation of $\mathrm{im}(H_*\mathcal{R}^\delta(\mathbb{M}^\bullet) \to H_*\mathcal{R}^{2\delta}(\mathbb{M}^\bullet))$ involves computing the free cover of a certain pullback for which efficient specialized algorithms exist only when $N = 1$ or 2 (see [4]); otherwise, one must resort to Schreyer's algorithm [33] with doubly exponential complexity in N. By contrast, free presentations of $H_*\mathcal{R}^\delta(\mathbb{M}^\bullet)$ can be computed efficiently for any $N \geq 1$ via specialized algorithms for the computation of Gröbner bases [18].

Similarly to the proof of the classical Latschev theorem, the proof of our persistent version (Theorem 1) is a two-step process. Firstly, one needs a persistent version of Hausmann's theorem allowing us to relate $M^\bullet$ to $\mathcal{R}^\delta(M^\bullet)$.

▶ **Theorem 2** (Persistent Hausmann's Theorem). *Let $0 < \delta \leq \rho_M^\kappa$. Then there is a δ-interleaving $M^\bullet \simeq_{\frac{3}{4}\delta} \mathcal{R}^\delta(M^\bullet)$ in the persistent homotopy category.*

This result, proven in the full version [31], is a rather straightforward consequence of a powerful new technique called metric thickening, which provides a more geometrical model for the Vietoris-Rips complex [2, 19]. The crucial and technically more difficult part of proving Theorem 1 is to relate $\mathcal{R}^\delta(M^\bullet)$ and $\mathcal{R}^\delta(\mathbb{M}^\bullet)$. Here, we prove the following result:

▶ **Theorem 3** (Approximation of function-Rips persistent homotopy type). *Let $0 < \delta \leq \rho_M^\kappa$ and $\varepsilon \leq \min\{\rho_M^\kappa - \delta, \frac{1}{7}\delta\}$. Then, for any filtered ε-correspondence $(\mathbb{M}, \mathbb{f}) \approx_\varepsilon (M, f)$, there is a δ-interleaving $\mathcal{R}^\delta(\mathbb{M}^\bullet) \simeq_\delta \mathcal{R}^\delta(M^\bullet)$ in the persistent homotopy category.*

To derive this result, we first prove a bivariate interleaving $\mathcal{R}^\bullet(M^\bullet) \simeq_\varepsilon \mathcal{R}^\bullet(\mathbb{M}^\bullet)$ from the filtered correspondence $(\mathbb{M}, \mathbb{f}) \approx_\varepsilon (M, f)$ in Section 3 (Proposition 34). Then, to leverage this interleaving, in Section 4, we introduce and study the general notion of a *shrinking transformation*: a transformation of the form $F^{\bullet_1,\bullet_2} \to F^{S\bullet_1,\bullet_2+C\bullet_1}$, with $C \geq 0$ and $0 \leq S < 1$, allowing one to move backwards in one parameter at the cost of increasing the other in a bivariate persistent object $F^{\bullet,\bullet}$, as illustrated in Figure 1. Shrinking transformations can be used to turn interleavings in two variables $F^{\bullet,\bullet} \simeq_\varepsilon G^{\bullet,\bullet}$ into interleavings of the form $F^{\delta,\bullet} \simeq_{C\delta+(1+C)\varepsilon} G^{\delta,\bullet}$ (Theorem 44). Then, in Section 5 we work out conditions on M that guarantee the existence of such a shrinking transformation on $\mathcal{R}^\bullet(M^\bullet)$ (Theorem 51). One incarnation of these conditions is verified in the quantitative version of Latschev's theorem [29]

and produces a shrinking transformation with $C = S = \frac{3}{4}$. From these conditions, combined with Proposition 34 and Theorem 44, we get Theorem 3. Together with Theorem 2, this gives the $\frac{7}{4}\delta$-interleaving $M^\bullet \simeq_{\frac{7}{4}\delta} \mathcal{R}^\delta(\mathbb{M}^\bullet)$ of Theorem 1.
We note that most of our techniques, particularly Theorems 44 and 51, are quite general and seem widely applicable. Indeed, in the full version of this article [31], we will use them to prove local stability theorems for the persistent homotopy types of function-Rips complexes.

2 Background

2.1 Spaces of curvature bounded above

▶ **Recollection 4** (Geodesics and convexity)**.** Let M be a metric space with metric d. By a (constant speed) *geodesic*, we mean a map $\gamma\colon [0,1] \to M$ such that $d(\gamma(s),\gamma(t)) = |s-t|\, d(\gamma(0),\gamma(1))$ for all $s \le t \in [0,1]$. We say that a subset $A \subset M$ is *convex*, if every pair of points $x, y \in A$ is connected by a unique constant speed geodesic γ from x to y in M, and furthermore every such geodesic is contained in A. We denote

$$\varrho_M(x) := \sup\{r > 0 \mid B_s(x) \text{ is convex, for all } s < r\}$$

the convexity radius at $x \in M$. The *convexity radius of* M is defined as $\varrho_M := \inf_{x\in M} \varrho_M(x)$.

▶ **Recollection 5** (Curvature bounded above)**.** Given $\kappa \in \mathbb{R}$, we call M_κ the following space:
1. for $\kappa > 0$, the sphere of radius $\frac{1}{\sqrt{\kappa}}$ in $\mathbb{R}^3$, equipped with the geodesic distance;
2. for $\kappa = 0$, the euclidean plane $\mathbb{R}^2$;
3. for $\kappa < 0$, the rescaling of the hyperbolic plane $\mathbb{H}$ by $\frac{1}{\sqrt{-\kappa}}$.

We denote by ϖ_κ the diameter of M_κ ($\varpi_\kappa = \frac{\pi}{\sqrt{\kappa}}$ if $\kappa > 0$ and $\varpi_\kappa = \infty$ if $\kappa \le 0$). We say that M *is a* CAT(κ) *space* if any two points with distance at most ϖ_κ are connected by a geodesic, and furthermore, every geodesic triangle of perimeter smaller than $2\varpi_\kappa$ is *no thicker than a comparison triangle in* M_κ (see Figure 2 and [31, 9] for a rigorous definition). A metric space M is called *of curvature bounded above by* κ - or a CBA(κ) space for short - if every point $x \in M$ admits a neighborhood that is a CAT(κ) space. For example, every Riemannian manifold with sectional curvature bounded above by κ is a CBA(κ) space.

▶ **Notation 6.** Let M be a compact CBA(κ) space. We denote $\rho_M^\kappa := \min\{\varrho_M, \frac{\varpi_\kappa}{4}\} > 0$.

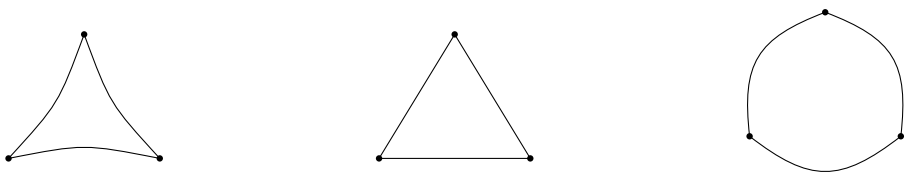

Figure 2 Illustration of equilateral triangles in curvatures $\kappa < 0$, $\kappa = 0$, and $\kappa > 0$, respectively.

2.2 Models for persistent homotopy types

We will use three models for *persistent homotopy types* in the following, arising from spaces, simplicial complexes, and simplicial sets, the last of which we discuss in Section 2.4.

▶ **Notation 7.** We denote by **sCplx** the category of simplicial complexes and simplicial maps, and by **Top** the category of topological spaces and continuous maps. We denote by $|K|$ the topological realization of a simplicial complex K. Often, we will just treat a complex as a space, and leave the realization implicit. The standard n-simplex, given by the set of non-empty subsets of $\{0,\dots,n\}$, will be denoted Δ^n_c.

▶ **Definition 8.** In the following, $\mathbb{P}$ will always denote a partially ordered set. When we treat $\mathbb{P}$ as a category, we mean the category whose objects are given by the elements of $\mathbb{P}$, and where there is a unique morphism $x \to y$ whenever $x \leq y$.
Let $\mathbf{C}$ be a category. A $\mathbb{P}$-*persistent object* in $\mathbf{C}$ is a functor $F\colon \mathbb{P} \to \mathbf{C}$. A morphism of $\mathbb{P}$-persistent objects is a natural transformation between such functors. We denote by $\mathbf{C}^{\mathbb{P}}$ the category of $\mathbb{P}$-persistent objects in $\mathbf{C}$ and their morphisms.

▶ **Notation 9.** We will usually denote persistent objects $F\colon \mathbb{P} \to \mathbf{C}$ in the form $F^\bullet$, to indicate their functoriality in $\mathbb{P}$. When the objects in a category $\mathbf{C}$ have a specific name, such as simplicial complexes, topological spaces or metric spaces, we will often refer to $\mathbb{P}$-persistent objects in $\mathbf{C}$ by adding the prefix persistent to that name.

▶ **Notation 10.** $N \geq 0$ will always be a non-negative integer and $\mathbb{R}^N$ will be considered as a partially ordered set via componentwise comparison. By a *space function pair* (often just pair), we will mean a topological space X together with a function $f\colon X \to \mathbb{R}^N$. When we speak of a *metric pair*, this will mean that we equip X with a metric, inducing its topology.

▶ **Example 11.** Given a pair (X, f), the sublevel sets $X^u := f^{-1}\{v \in \mathbb{R}^N \mid v \leq u\}$, together with functoriality given by inclusions, gives rise to a persistent space $u \mapsto X^u$, which we denote by $X^\bullet$. We abuse notation here insofar as the construction evidently depends on f. As all structure maps are given by inclusions $X^\bullet$ is often also referred to as a *filtered space*.

▶ **Example 12** (function-Rips complex)**.** Given a metric space $\mathbb{M}$ and $\delta \geq 0$, the open Vietoris-Rips complex of $\mathbb{M}$ (only Rips complex henceforth), denoted $\mathcal{R}^\delta(\mathbb{M})$, is the simplicial complex whose set of simplices is given by

$$\{\{x_0,\dots,x_n\} \mid x_i \in \mathbb{M}, d(x_i,x_j) < \delta, \text{ for all } 0 \leq i,j \leq n\}.$$

Varying the parameter $\delta \geq 0$, one obtains a persistent simplicial complex $\mathcal{R}^\bullet(\mathbb{M})\colon \mathbb{R}_{\geq 0} \to \mathbf{sCplx}$, with functoriality on relations given by inclusions. Suppose now that $\mathbb{M}$ is additionally equipped with a (not-necessarily continuous) function $\mathbb{f}\colon \mathbb{M} \to \mathbb{R}^N$. Then, for every $u \in \mathbb{R}^N$, one can consider the Vietoris-Rips complex of $\mathbb{M}^u := \{x \in \mathbb{M} \mid \mathbb{f}(x) \leq u\}$. Varying u with δ fixed gives rise to a persistent simplicial complex $\mathcal{R}^\delta(\mathbb{M}^\bullet)\colon \mathbb{R}^N \to \mathbf{sCplx}$, $u \mapsto \mathcal{R}^\delta(\mathbb{M}^u)$, called the *function-Rips complex*. Varying both u and δ gives rise to the bivariate variant $\mathcal{R}^\bullet(\mathbb{M}^\bullet)\colon \mathbb{R}_{\geq 0} \times \mathbb{R}^N \to \mathbf{sCplx}$, $(u,\delta) \mapsto \mathcal{R}^\delta(\mathbb{M}^u)$, called the *bivariate function-Rips complex*.

2.3 Persistent homotopy theory

Conceptually speaking, a $\mathbb{P}$-persistent homotopy type should be a $\mathbb{P}$-indexed functor valued in the *homotopy theory* or ∞-*category* of spaces, not just the ordinary 1-category of spaces (see also [21, 8]). As we do not expect familiarity with ∞-categorical language, we will instead work with the more elementary notion of relative categories, which we refer to as homotopy theories here.[1]

[1] This is justified insofar as relative categories provide a model for $(\infty,1)$-categories [28, 6, 7].

▶ **Definition 13.** By a *homotopy theory* we will mean a relative category; that is, a pair consisting of a category $\mathbf{C}$ and a wide subcategory $W \subset \mathbf{C}$. The morphisms in W are called *weak equivalences*. A morphism in $\mathbf{C}$ that is in W will often be denoted by the symbol $\xrightarrow{\simeq}$.

▶ **Example 14.** Recall that a weak homotopy equivalence between topological spaces is a continuous map that induces isomorphisms on the sets of path components and on all homotopy groups. The category **Top** of topological spaces equipped with the subcategory of weak homotopy equivalences forms a homotopy theory which we denote by $\mathcal{S}\mathbf{paces}$.[2]

▶ **Notation 15.** Given a homotopy theory $\mathcal{C} = (\mathbf{C}, W)$ and another category $\mathbb{I}$, we denote by $\mathcal{C}^{\mathbb{I}}$ the homotopy theory $(\mathbf{C}^{\mathbb{I}}, W^{\mathbb{I}})$, where $W^{\mathbb{I}}$ is the wide subcategory of $\mathbf{C}^{\mathbb{I}}$ consisting of those natural transformations $\varphi\colon F \Rightarrow G$ such that for every object $i \in \mathbb{I}$, the morphism $\varphi_i\colon F(i) \to G(i)$ is in W. [3] To indicate that we study functors (persistent objects) $F\colon \mathbb{I} \to \mathbf{C}$ in the context of the whole homotopy theory $\mathcal{C}$ we will often use the notation $F\colon \mathbb{I} \to \mathcal{C}$.

▶ **Example 16.** When $\mathcal{C} = \mathcal{S}\mathbf{paces}$ is the homotopy theory of spaces, then $\mathcal{S}\mathbf{paces}^{\mathbb{P}}$ will be referred to as the $\mathbb{P}$*-persistent homotopy theory of spaces*.

▶ **Notation 17.** Given a homotopy theory $\mathcal{C} = (\mathbf{C}, W)$, one can associate to it its homotopy category $\mathrm{ho}(\mathcal{C})$, defined as the localization $\mathbf{C}[W^{-1}]$ of $\mathbf{C}$ at the weak equivalences W.

▶ **Recollection 18.** Together with the canonical localization functor, $\mathbf{C} \to \mathbf{C}[W^{-1}] = \mathrm{ho}(\mathcal{C})$, $\mathrm{ho}(\mathcal{C})$ is characterized by the universal property that any functor $\mathbf{C} \to \mathbf{D}$ that sends weak equivalences to isomorphisms factors uniquely through $\mathrm{ho}(\mathcal{C})$. Explicitly, objects of $\mathrm{ho}(\mathcal{C})$ are the same as those of $\mathbf{C}$, and morphisms are given by equivalence classes of zig-zags of morphisms in $\mathbf{C}$, where backward-pointing arrows are weak equivalences. In this sense, $\mathrm{ho}(\mathcal{C})$ is the 1-category obtained by formally inverting the weak equivalences.

▶ **Notation 19.** We abuse notation insofar as we use the same symbols for objects and morphism in $\mathbf{C}$ and their images in $\mathrm{ho}(\mathcal{C})$. In the context of the persistent homotopy theory $\mathcal{S}\mathbf{paces}^{\mathbb{P}}$, a persistent space or persistent simplicial complex $X^\bullet$ will often be referred to as a *persistent homotopy type*. Note that while, set theoretically speaking, the persistent homotopy type $X^\bullet$ is the same as its underlying persistent space, in the context of the homotopy category $\mathrm{ho}(\mathcal{S}\mathbf{paces}^{\mathbb{U}})$, two persistent homotopy types are isomorphic when they are connected by a zig-zag of weak equivalences.

2.4 Persistent simplicial sets

At least half of the persistent homotopy types we are studying in this article arise from purely combinatorial data provided in the form of persistent simplicial complexes. It is thus convenient to have a model for the persistent homotopy theory of spaces that is more combinatorial in nature. This can be achieved by working with simplicial sets[4]. The reader not familiar with the theory of simplicial sets can treat them as a black-box that extends the category of simplicial complexes in a convenient way (see [20, 21] for an introduction).

---

[2] It follows as a consequence of Whitehead's theorem that this homotopy theory is equivalent to the one given by CW-complexes and homotopy equivalences.

[3] Note that this will generally only produce the ∞-categorical functor category when $\mathcal{C}$ is sufficiently well-behaved, for example when it extends to a model category, as is the case for our examples ([28]).

[4] From a categorical perspective, simplicial sets are a much preferable combinatorial model than simplicial complexes. Note, for example, that simplicial sets come with a natural weak equivalence $\mathrm{sd}_b X \xrightarrow{\simeq} X$ between the barycentric subdivision $\mathrm{sd}_b X$ of X and X, which we use in Section 5.

▶ **Recollection 20.** Recall that, conceptually speaking, a simplicial set is like a simplicial complex, where the simplices are ordered, and one allows for faces of simplices to collapse to lower dimensions. Categorically, this idea can be formalized as follows: Denote by Δ the category of finite linear posets $[n] = \{0 \leq \cdots \leq n\}$, for $n \geq 0$, with order-preserving maps. The category of simplicial sets $\mathbf{sSet}$ is the category of functors from Δ^{op} into $\mathbf{Set}$, i.e., $\mathbf{Set}^{\Delta^{\mathrm{op}}}$. Given a simplicial set $X \in \mathbf{sSet}$ and $n \geq 0$, the set $X([n])$ is denoted X_n, and called the set of n-simplices of X. A simplex $\sigma \in X_n$ that is not in the image of a structure map $X_k \to X_n$, for some $k < n$, is called non-degenerate.

▶ **Example 21.** As a simplicial set, the function-Rips complex at $u \in \mathbb{R}^N$ and $\delta \geq 0$ can be modeled by a simplicial set with n-simplices

$$\mathcal{R}^{u,\delta}(M,f)_n = \{(x_0,\ldots,x_n) \mid x_i \in M; d(x_i,x_j) < \delta; f(x_i) \leq u \text{ for all } i,j \in [n]\},$$

and functoriality on Δ^{op} given by precomposition.

▶ **Notation 22.** Given $n \in \mathbb{N}$, the image of $[n]$ under the Yoneda embedding $\Delta \hookrightarrow \mathbf{Set}^{\Delta^{\mathrm{op}}}$, $[k] \mapsto \Delta([k],[n])$, is denoted by Δ^n and referred to as the n-simplex. The functor $[n] \mapsto \Delta^n$ defines a fully faithful embedding $\Delta \hookrightarrow \mathbf{sSet}$, by which we treat Δ as a subcategory of $\mathbf{sSet}$.

▶ **Recollection 23.** Simplicial sets admit a topological realization functor. Observe that Δ embeds into $\mathbf{sCplx}$ by sending $[n]$ to the standard simplex Δ^n_c. The composition $\Delta \to \mathbf{sCplx} \xrightarrow{|-|} \mathbf{Top}$ defines a topological realization functor on $\Delta \subset \mathbf{sSet}$, which extends canonically to a colimit-preserving functor $|-|\colon \mathbf{sSet} \to \mathbf{Top}$, so that the realization of a simplicial set X, $|X|$, is glued from realizations of its simplices.

The most important reason why simplicial sets are so useful is that they can be used to define a homotopy theory equivalent to that of topological spaces.

▶ **Recollection 24.** A simplicial map $\varphi\colon X \to Y$ in $\mathbf{sSet}$ is called a weak homotopy equivalence if its topological realization $|\varphi|\colon |X| \to |Y|$ is a homotopy equivalence. Denote the wide subcategory of weak homotopy equivalences by W_{Kan}, and the resulting relative category $(\mathbf{sSet}, W_{\mathrm{Kan}})$ by $\mathbf{sSet}_{\mathrm{Kan}}$. It is a fundamental fact of homotopy theory, that the topological realization functor $|-|\colon \mathbf{sSet} \to \mathbf{Top}$ then defines a so-called *equivalence of homotopy theories (∞-categories)* $\mathbf{sSet}_{\mathrm{Kan}} \to \mathcal{S}\mathbf{paces}$ (see [32]). Conceptually speaking, this means that any homotopy theoretic construction or argument concerning $\mathcal{S}\mathbf{paces}$ can equivalently be performed in $\mathbf{sSet}_{\mathrm{Kan}}$. For our purposes, however, it suffices to observe that the functor $|-|\colon \mathbf{sSet}^{\mathbb{P}} \to \mathbf{Top}^{\mathbb{P}}$ descends to an equivalence of categories $|-|\colon \mathrm{ho}\big((\mathbf{sSet}, W_{\mathrm{Kan}})^{\mathbb{P}}\big) \to \mathrm{ho}(\mathcal{S}\mathbf{paces}^{\mathbb{P}})$, compatible with any reparametrization of the indexing poset $\mathbb{P}$.

▶ **Recollection 25.** In the same way as homotopies induce identifications of maps in the homotopy category $\mathrm{ho}(\mathcal{S}\mathbf{paces})$, morphisms of persistent simplicial sets of the form $X^\bullet \times \Delta^1 \to Y^\bullet$ (where $X^\bullet \times \Delta^1$ denotes the indexwise product) – so-called *elementary homotopies* – induce identifications of persistent simplicial maps in $\mathrm{ho}(\mathbf{sSet}^{\mathbb{P}}_{\mathrm{Kan}})$.

▶ **Recollection 26.** We frequently want to treat simplicial complexes as simplicial sets. There is a canonical fully faithful embedding $N_s\colon \mathbf{sCplx} \hookrightarrow \mathbf{sSet}$, mapping a simplicial complex, K, to the simplicial set given by $N_s(K)_n = \mathbf{sCplx}(\Delta^n_c, K)$, functorial in the obvious way in n and K (see [16, § 1.4]). For example, the simplicial set obtained by applying N_s to a function-Rips complex is precisely the one described in Example 21. We will usually omit N_s from the notation. Observe that from a homotopy-theoretic perspective, this is justified by the fact that, given $K \in \mathbf{sCplx}$, there is a canonical homotopy equivalence $|N_s(K)| \xrightarrow{\simeq} |K|$ (see [30, 5]) even though the equality $|K| \cong |N_s(K)|$ does not hold on the homeomorphism level. Hence, for our purposes, we can freely identify the two realizations.

2.5 Interleavings in the homotopy category

One of the core advantages of persistent settings is that they allow for approximate notions of equivalence, so called interleavings (see [17] for a more general setting). In the following, $\mathcal{C}$ will denote some homotopy theory. To define interleavings, we need the following notation.

▶ **Notation 27.** Henceforth, $\mathbb{U} \subset \mathbb{R}^N$, $\mathbb{U}' \subset \mathbb{R}^{N'}$ will always denote upsets of $\mathbb{R}^N$, i.e., subsets fulfilling $x \in \mathbb{U}, x \leq y \implies y \in \mathbb{U}$.
Suppose we are given a map of posets $S\colon \mathbb{U}' \to \mathbb{U}$ and a persistent object $F\colon \mathbb{U} \to \mathcal{C}$. We write $F^{S(\bullet)}$ to denote the persistent object obtained by precomposing F with S. In the special case where S is an inclusion of posets, we use the notation $F^\bullet|_{\mathbb{U}'}$ to denote the restriction of F to $\mathbb{U}'$. Suppose we are given another such map $S'\colon \mathbb{U}' \to \mathbb{U}$ such that $S(x) \leq S'(x)$, for all $x \in \mathbb{U}'$. In this case, we will use the notation $s\colon F^{S(\bullet)} \to F^{S'(\bullet)}$ to denote the natural transformation induced by the relations $S(x) \leq S'(x)$. Given $\varepsilon \geq 0$ write $(-) + \varepsilon\colon \mathbb{U} \to \mathbb{U}$ for the map of posets given by $x \mapsto x + \varepsilon(1, \dots, 1)$.

▶ **Definition 28.** An *ε-interleaving in the homotopy category* between $F^\bullet, G^\bullet\colon \mathbb{U} \to \mathcal{C}$ consists of morphisms $\varphi\colon F^\bullet \to G^{\bullet+\varepsilon}$ and $\psi\colon G^\bullet \to F^{\bullet+\varepsilon}$ in $\mathrm{ho}(\mathcal{C}^{\mathbb{U}})$ such that the diagrams

$$\begin{array}{ccc} F^\bullet & \xrightarrow{\quad s \quad} & F^{\bullet+2\varepsilon} \\ & {\scriptstyle\varphi}\searrow \quad \nearrow{\scriptstyle\psi^{+\varepsilon}} & \\ & G^{\bullet+\varepsilon} & \end{array} \qquad \begin{array}{ccc} G^\bullet & \xrightarrow{\quad s \quad} & G^{\bullet+2\varepsilon} \\ & {\scriptstyle\psi}\searrow \quad \nearrow{\scriptstyle\varphi^{+\varepsilon}} & \\ & F^{\bullet+\varepsilon} & \end{array} \tag{1}$$

in $\mathrm{ho}(\mathcal{C}^{\mathbb{U}})$ commute. We will denote such interleavings in the form $\varphi\colon F \simeq_\varepsilon G\colon \psi$.

▶ Remark 29. Two interleavings $\varphi\colon F^\bullet \simeq_\varepsilon G^\bullet\colon \psi$ and $\varphi'\colon G^\bullet \simeq_{\varepsilon'} J^\bullet\colon \psi'$ compose to an interleaving $(\varphi')^{+\varepsilon} \circ \varphi\colon F^\bullet \simeq_{\varepsilon+\varepsilon'} J^\bullet\colon \psi^{+\varepsilon'} \circ \psi'$ (see, for example, [17]). It follows that $d_{IH}(F^\bullet, G^\bullet) := \inf\{\varepsilon \geq 0 \mid F^\bullet \simeq_\varepsilon G^\bullet\}$, defines an extended pseudo distance on $\mathcal{C}^{\mathbb{U}}$ called the *interleaving distance in the homotopy category* (see [24]). Observe, also, that any interleaving $\varphi\colon F^\bullet \simeq_\varepsilon G^\bullet\colon \psi$ gives rise to an interleaving $s \circ \varphi\colon F^\bullet \simeq_{\varepsilon''} G^\bullet\colon s \circ \psi$, for any $\varepsilon'' \geq \varepsilon$.

▶ **Example 30.** When $\mathbb{U} = \mathbb{R}^0 = \{0\}$, we can identify $\mathcal{C}^{\mathbb{U}} = \mathcal{C}$, and $(-) + \varepsilon\colon \mathbb{U} \to \mathbb{U}$ is the identity. Then, an ε-interleaving in $\mathrm{ho}(\mathcal{C})$ is the same as an isomorphism in $\mathrm{ho}(\mathcal{C})$.

3 Stability of the bivariate function-Rips persistent homotopy type

To study the stability properties of the assignment $(\mathbb{M}, \mathbb{f}) \mapsto \mathcal{R}^\delta(\mathbb{M}^\bullet)$, it is useful to consider the latter as a bivariate construction by also varying δ.

▶ **Notation 31.** Given a persistent object of the form $F\colon \mathbb{R}_{\geq 0} \times \mathbb{U} \to \mathbf{C}$, we will use the notation $F^{\bullet,\bullet}$ to indicate the fact that it is a functor in two variables.

▶ **Definition 32** (See also [11])**.** Let $(\mathbb{M}_0, \mathbb{f}_0)$ and $(\mathbb{M}_1, \mathbb{f}_1)$ be metric pairs over $\mathbb{R}^N$, and let $\varepsilon \geq 0$. A *filtered ε-correspondence* between $(\mathbb{M}_0, \mathbb{f}_0)$ and $(\mathbb{M}_1, \mathbb{f}_1)$ is a subset $\mathfrak{C} \subset \mathbb{M}_0 \times \mathbb{M}_1$ such that $\pi_{\mathbb{M}_0}(\mathfrak{C}) = \mathbb{M}_0$ and $\pi_{\mathbb{M}_1}(\mathfrak{C}) = \mathbb{M}_1$, and such that, for all $(x, y), (x', y') \in \mathfrak{C}$, it holds that

$$|d_{\mathbb{M}_0}(x, x') - d_{\mathbb{M}_1}(y, y')| \leq \varepsilon \text{ and } |\mathbb{f}_0(x) - \mathbb{f}_1(y)|_\infty \leq \varepsilon.$$

We will denote filtered ε-correspondences in the form $\mathfrak{C}\colon (\mathbb{M}_0, \mathbb{f}_0) \approx_\varepsilon (\mathbb{M}_1, \mathbb{f}_1)$.

▶ Remark 33. Filtered correspondences give rise to a distance on metric pairs $(\mathbb{M}_0, \mathbb{f}_0)$ and $(\mathbb{M}_1, \mathbb{f}_1)$, defined as the infimum of the values ε such that there exists a filtered ε-correspondence $(\mathbb{M}_0, \mathbb{f}_0) \approx_\varepsilon (\mathbb{M}_1, \mathbb{f}_1)$. When $N = 0$, this distance is exactly twice the ordinary Gromov-Hausdorff distance.

The additional flexibility of varying the Rips parameter δ allows for a proof of the following stability result, homological variants of which can be found in several places ([12, 8]).

▶ **Proposition 34.** *A filtered ε-correspondence $\mathfrak{C}\colon (\mathbb{M}_0, \mathbb{f}_0) \approx_\varepsilon (\mathbb{M}_1, \mathbb{f}_1)$ gives rise to an interleaving $\mathcal{R}^\bullet(\mathbb{M}_0^\bullet) \simeq_\varepsilon \mathcal{R}^\bullet(\mathbb{M}_1^\bullet)$ in $\mathrm{ho}(\mathcal{S}\mathbf{paces}^{\mathbb{R}_{\geq 0}\times\mathbb{R}^N})$.*

We use Recollections 24 and 26 and construct the interleaving using the simplicial set model for the bivariate Rips complex. We will leverage a universal property of the Rips simplicial set here, which we state for the case of filtered simplicial sets $X^{\bullet,\bullet} \in \mathbf{sSet}^{\mathbb{R}_{\geq 0}\times\mathbb{R}^N}$, i.e., where all structure morphisms are inclusions (see Proposition 36 below.) It allows one to construct morphisms $X^{\bullet,\bullet} \to \mathcal{R}^\bullet(\mathbb{M}^\bullet)$ by defining a map with target $\mathbb{M}$ on the vertices of $X^{\bullet,\bullet}$ (see [13] which uses the simplicial complex analog). We write $X^\infty = \bigcup_{(\delta,u)\in\mathbb{R}_{\geq 0}\times\mathbb{R}^N} X^{\delta,u}$.

▶ **Construction 35.** Let $X\colon \mathbb{R}_{\geq 0}\times\mathbb{R}^N \to \mathbf{sSet}$ be a filtered simplicial set and $(\mathbb{M}, \mathbb{f})$ be a metric pair over $\mathbb{R}^N$. We denote by $S(X, (\mathbb{M}, \mathbb{f})) \subset \mathbf{Set}(X_0^\infty, \mathbb{M})$ the set of such maps $\varphi\colon X_0^\infty \to \mathbb{M}$ that fulfill the condition that, for all $(\delta, u) \in \mathbb{R}_{\geq 0}\times\mathbb{R}^N$, it holds that:
1. for all $x \in X_0^{\delta,u}$, we have $\mathbb{f}(\varphi(x)) \leq u$;
2. for all 1-simplices $\sigma \in X_1^{\delta,u}$, with vertices x_0 and x_1, we have $d(\varphi(x_0), \varphi(x_1)) < \delta$.

Associating to a morphism $X^{\bullet,\bullet} \to \mathcal{R}^\bullet(\mathbb{M}^\bullet)$ the induced simplicial map $X^\infty \to \mathcal{R}^\infty(\mathbb{M}, \mathbb{f}) = \mathcal{R}^\infty(\mathbb{M})$ and evaluating on vertices to obtain a map $X_0^\infty \to \mathcal{R}^\infty(\mathbb{M})_0 = \mathbb{M}$, defines a map

$$\eta\colon \mathbf{sSet}^{\mathbb{R}_{\geq 0}\times\mathbb{R}^N}(X^{\bullet,\bullet}, \mathcal{R}^\bullet(\mathbb{M}^\bullet)) \to S(X, (\mathbb{M}, \mathbb{f})).$$

▶ **Proposition 36** (See full version [31])**.** *η, as in Construction 35, defines a natural bijection.*

▶ Remark 37. Conceptually speaking, the injectivity part of Proposition 36 means that a morphism $X^{\bullet,\bullet} \to \mathcal{R}^\bullet(\mathbb{M}^\bullet)$ is uniquely determined by its values on vertices (the values can be identified with elements of $\mathbb{M}$). The surjectivity and well-definedness state that a map $X_0^\infty \to \mathbb{M}$ extends if and only if the criteria of Construction 35 are verified.

▶ Remark 38. We will often need to use a modified version of Proposition 36, where instead of $\mathcal{R}^\bullet(\mathbb{M}^\bullet)$, we consider a reparametrized version in which $\mathcal{R}^\bullet(\mathbb{M}^\bullet)\colon \mathbb{R}_{\geq 0}\times\mathbb{R}^N \to \mathbf{sSet}$ is replaced by a composition $\mathbb{R}_{\geq 0}\times\mathbb{R}^N \xrightarrow{(\delta',u')} \mathbb{R}_{\geq 0}\times\mathbb{R}^N \xrightarrow{\mathcal{R}^\bullet(\mathbb{M}^\bullet)} \mathbf{sSet}$ for poset maps δ', u'. Then, the analogous statement holds, replacing in Construction 35 u with $u'(\delta, u)$ and δ with $\delta'(\delta, u)$ in the defining inequalities for $S(X^{\bullet,\bullet}, (\mathbb{M}, \mathbb{f}))$. Furthermore, we will often encounter the modified case where we work with filtered simplicial sets $X^{\bullet,\bullet}$ over $\mathbb{I}\times\mathbb{R}^N$, with $\mathbb{I} = [0, \rho]$ or $\mathbb{I} = \{\rho\}$, and we restrict $\mathcal{R}^\bullet(\mathbb{M}^\bullet)$ to $\mathbb{I}\times\mathbb{R}^N$. In this case, again the essentially same statement holds, with the only change being the replacement of X^∞ by $X^{\rho,\infty} = \bigcup_{u\in\mathbb{R}^N} X^{\rho,u}$ and the defining condition for $S(X^{\bullet,\bullet}, (\mathbb{M}, \mathbb{f}))$ needing to be verified only for pairs $(\delta, u) \in \mathbb{I}\times\mathbb{R}^N$.

Next, let us construct the simplicial maps that define the interleaving of Proposition 34:

▶ **Construction 39.** Given a filtered ε-correspondence $\mathfrak{C}$, we define maps

$$\varphi\colon \mathcal{R}^\bullet(\mathbb{M}_0^\bullet) \to \mathcal{R}^{\bullet+\varepsilon}(\mathbb{M}_1^{\bullet+\varepsilon}) \quad \text{and} \quad \psi\colon \mathcal{R}^\bullet(\mathbb{M}_1^\bullet) \to \mathcal{R}^{\bullet+\varepsilon}(\mathbb{M}_0^{\bullet+\varepsilon})$$

by applying Proposition 36 as follows. Observe that for $X^{\bullet,\bullet} = \mathcal{R}^\bullet(\mathbb{M}_0^\bullet)$, we have $X_0^\infty = \mathbb{M}_0$. Then φ is defined under Proposition 36 by choosing for each $x \in \mathbb{M}_0$ an element $y \in \mathbb{M}_1$ with $(x, y) \in \mathfrak{C}$ and defining $\varphi(x) := y$. The map ψ is defined analogously.

Proof of Proposition 34. The conditions on $\mathfrak{C}$ ensure exactly that the (shifted) requirements of Proposition 36 and Remark 38 are fulfilled. It remains to see that φ and ψ define an ε-interleaving in the homotopy category. We show that $\psi^{+\varepsilon} \circ \varphi \simeq s$, the other equality

being shown analogously. To this end, we need to construct a homotopy $H\colon \mathcal{R}^{\bullet}(\mathbb{M}_0^{\bullet}) \times \Delta^1 \to \mathcal{R}^{\bullet+2\varepsilon}(\mathbb{M}_0^{\bullet+2\varepsilon})$ between $\psi^{+\varepsilon} \circ \varphi$ and s. We again use Proposition 36. In this case, it implies that the persistent simplicial maps $\psi^{+\varepsilon} \circ \varphi$ and s are elementarily homotopic, if for every pair $x, y \in \mathbb{M}_0$ it holds that $d(\psi^{+\varepsilon}(\varphi(x)), s(y)) \leq d(x,y) + 2\varepsilon$. Indeed, the inequality

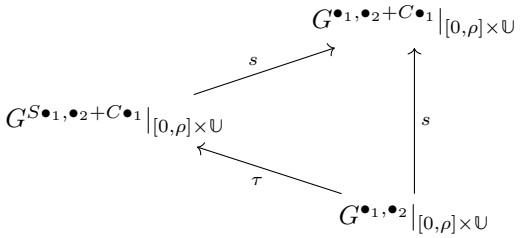
$$d(\psi^{+\varepsilon}(\varphi(x)), s(y)) = d(\psi^{+\varepsilon}(\varphi(x)), y) \leq d(\varphi(x), \varphi(y)) + \varepsilon \leq d(x,y) + 2\varepsilon,$$

holds by definition of φ and ψ in terms of $\mathfrak{C}$. ◀

4 The shrinking trick

For the remainder of this section, we will fix some homotopy theory $\mathcal{C}$. By an interleaving, we will always mean interleaving in the homotopy category.

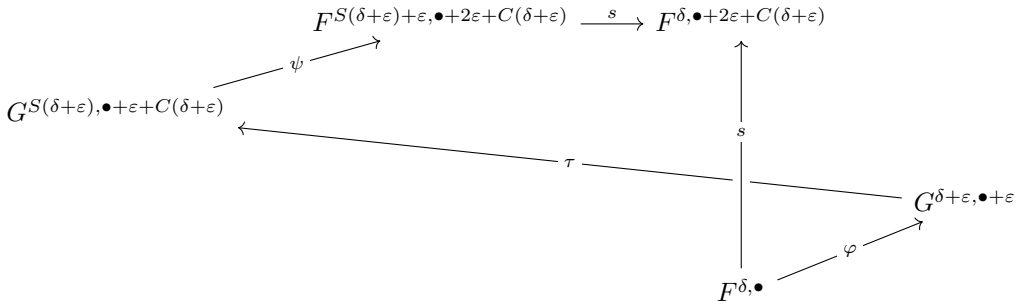
▶ **Notation 40.** When fixing either parameter of a persistent object $F^{\bullet,\bullet}\colon \mathbb{R}_{\geq 0} \times \mathbb{U} \to \mathcal{C}$, we will use the notation $F^{\delta,\bullet}$ or $F^{\bullet,u}$, to denote the resulting persistent objects on $\mathbb{U}$, or $\mathbb{R}_{\geq 0}$ respectively. At times, we will also use the notation $\bullet_1$ and $\bullet_2$ to indicate the first and second variable, respectively. For example $F^{\bullet_1,\bullet_2+\bullet_1}$ indicates the persistence module given by precomposing F with the endofunctor $(\delta, u) \mapsto (\delta, u+\delta)$ of $\mathbb{R}_{\geq 0} \times \mathbb{U}$.



Suppose we are given $\delta \geq 0$, as well as two persistent objects $F^{\bullet,\bullet}, G^{\bullet,\bullet}\colon \mathbb{R}_{\geq 0} \times \mathbb{U} \to \mathcal{C}$, together with an ε-interleaving $\varphi\colon F^{\bullet,\bullet} \simeq_\varepsilon G^{\bullet,\bullet}\colon \psi$. We want to deduce an interleaving $F^{\delta,\bullet} \simeq_{\varepsilon'} G^{\delta,\bullet}$, for some ε' depending on ε and δ. The issue at hand is, of course, that the interleaving morphisms φ and ψ only procure morphisms $F^{\delta,\bullet} \to G^{\delta+\varepsilon,\bullet+\varepsilon}$ and $G^{\delta,\bullet} \to F^{\delta+\varepsilon,\bullet+\varepsilon}$. To amend this, we introduce an additional structure on G, which we call a shrinking transformation. This transformation allows us to decrease the δ-part of the persistence parameter of G, at the cost of increasing the u-part.

▶ **Notation 41.** We fix constants $0 < S < 1, C \geq 0$ and $\rho > 0$ in $\mathbb{R}$.

▶ **Definition 42.** A *shrinking transformation* for $G\colon \mathbb{R}_{\geq 0} \times \mathbb{U} \to \mathcal{C}$ is a morphism



$$\tau\colon G^{\bullet_1,\bullet_2}|_{[0,\rho]\times\mathbb{U}} \to G^{S\bullet_1,\bullet_2+C\bullet_1}|_{[0,\rho]\times\mathbb{U}}$$

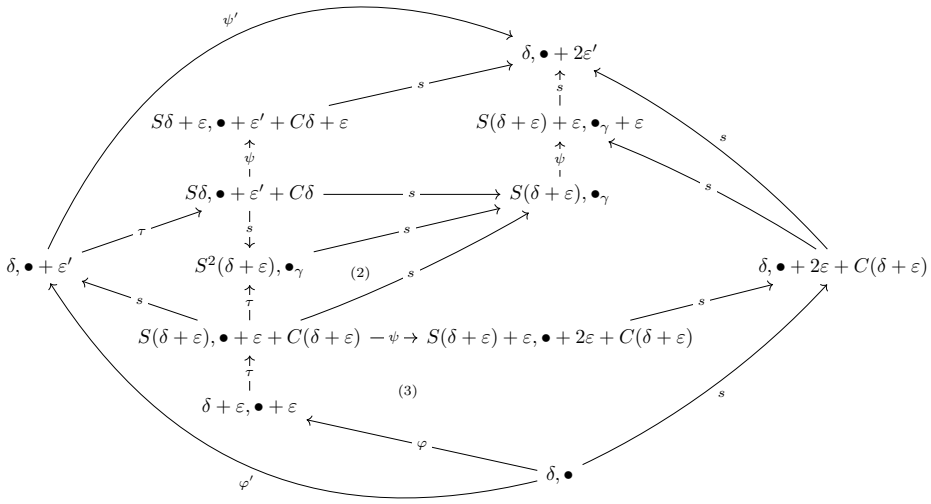
in $\mathrm{ho}(\mathcal{C}^{[0,\rho]\times\mathbb{U}})$ such that the following diagram in $\mathrm{ho}(\mathcal{C}^{[0,\rho]\times\mathbb{U}})$ commutes:

(2)

▶ **Definition 43.** Let $\delta \in [0,\rho]$ and $0 \leq \varepsilon$ be such that $\varepsilon \leq \min\{\rho - \delta, \frac{1-S}{1+S}\delta\}$. As we assumed $\varepsilon + \delta \leq \rho$, the morphism τ from Definition 42 restricts to a well-defined morphism $\tau\colon G^{\delta+\varepsilon,\bullet+\varepsilon} \to G^{S(\delta+\varepsilon),\bullet+\varepsilon+C(\delta+\varepsilon)}$, called by the same name by abuse of notation. We say that an ε-interleaving $\varphi\colon F^{\bullet,\bullet} \simeq_\varepsilon G^{\bullet,\bullet}\colon \psi$ is δ-*compatible* with τ if the following diagram in $\mathrm{ho}(\mathcal{C}^{\mathbb{U}})$ commutes:

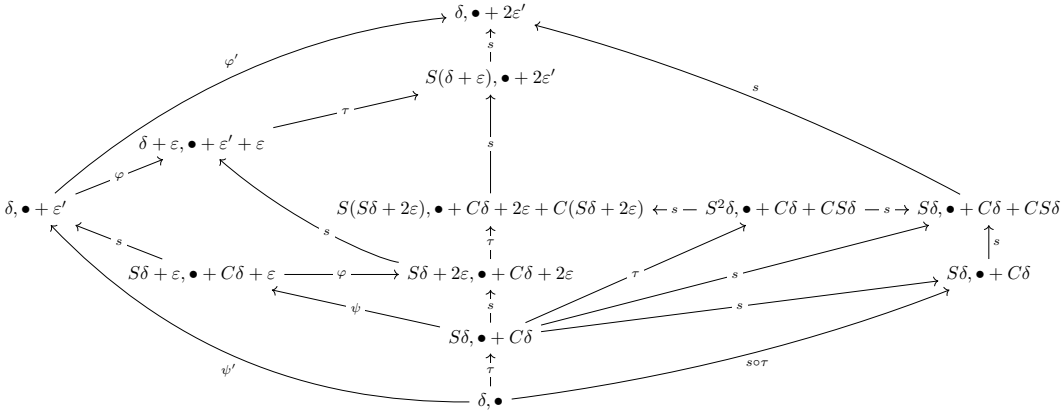
(3)

▶ **Theorem 44.** *Let $G\colon \mathbb{R}_{\geq 0} \times \mathbb{U} \to \mathcal{C}$ be a persistent object in $\mathcal{C}$, equipped with a shrinking transformation τ on G. Let $\varepsilon, \delta \geq 0$ be such that $\varepsilon \leq \min\{\rho - \delta, \frac{1-S}{1+S}\delta\}$.*
Furthermore, let $F\colon \mathbb{R}_{\geq 0} \times \mathbb{U} \to \mathcal{C}$ be another persistent object, together with an ε-interleaving $\varphi\colon F \simeq_\varepsilon G\colon \psi$ that is δ-compatible with τ. Then there is an interleaving



$$\varphi'\colon F^{\delta,\bullet} \simeq_{(1+C)\varepsilon+C\delta} G^{\delta,\bullet}\colon \psi',$$

explicitly given by the compositions



$$\varphi'\colon F^{\delta,\bullet} \xrightarrow{\varphi} G^{\delta+\varepsilon,\,\bullet+\varepsilon} \xrightarrow{\tau} G^{S(\delta+\varepsilon),\,\bullet+(1+C)\varepsilon+C\delta} \xrightarrow{s} G^{\delta,\,\bullet+(1+C)\varepsilon+C\delta},$$

$$\psi'\colon G^{\delta,\bullet} \xrightarrow{\tau} G^{S\delta,\,\bullet+C\delta} \xrightarrow{\psi} F^{S\delta+\varepsilon,\,\bullet+C\delta+\varepsilon} \xrightarrow{s} F^{\delta,\,\bullet+(1+C)\varepsilon+C\delta}.$$

Proof. The fact that all morphisms s and τ in the definition of φ' and ψ' are well-defined follows from the inequalities $\delta + \varepsilon \leq \rho$ and $S(\delta + \varepsilon) \leq S\delta + \varepsilon \leq S(\delta + \varepsilon) + \varepsilon \leq \delta$, which hold by the assumption on ε and δ. We now need to verify the defining commutativity conditions of an interleaving. To simplify notation, we define $\varepsilon' := (1 + C)\varepsilon + C\delta$ and $\bullet_\gamma := \bullet_2 + \varepsilon + C(\delta + \varepsilon) + CS(\delta + \varepsilon)$. To simplify notation even further, we will omit F and G from the notation and only spell out the superscript. Whether F or G is meant will be uniquely determined by the specified morphisms. Now, consider the first composition $\psi' \circ \varphi'$. To verify that $\psi' \circ \varphi' = s$ it suffices to verify the commutativity of the following diagram.

Observe that for every s arrow to be well-defined, we require the inequality $S(\delta+\varepsilon)+\varepsilon \leq \delta$, which we have already seen above. Observe that the canonical shift morphisms s commute with essentially every other morphism in sight (in the appropriate contextual sense). The commutativities of the cells in the diagram follow either from the universal commutativity of s or from Diagrams (2) and (3). This proves the first interleaving equality.
The second interleaving equality follows by chasing the following diagram.

Note that none of the cells require the δ-compatibility condition. Instead, one only uses the naturality properties of s, one of the two interleaving equalities, and the defining property of the shrinking transformation. ◀

5 Shrinking transformations for the bivariate function-Rips complex

We now want to apply Theorem 44 together with Proposition 34 to prove Theorem 3.

▶ **Notation 45.** For the remainder of this section, let M be a CBA(κ) space, for some $\kappa \in \mathbb{R}$, equipped with a 1-Lipschitz function $f\colon M \to \mathbb{R}^N$ (with respect to the $|-|_\infty$-norm on $\mathbb{R}^N$), and let S, C and ρ be as in Notation 41.

To establish the existence of a shrinking morphism, we use a classical technique in simplicial homotopy theory: Leveraging subdivisions to construct maps in the homotopy category.

▶ **Notation 46.** For the remainder of this section, we fix what we call a *subdivision functor*, by which we mean a pair consisting of a functor $\mathrm{sd}\colon \mathbf{sSet}_{\mathrm{Kan}} \to \mathbf{sSet}_{\mathrm{Kan}}$ that preserves inclusions and colimits, together with a natural weak equivalence $\lambda\colon \mathrm{sd} \xRightarrow{\simeq} 1_{\mathbf{sSet}}$.

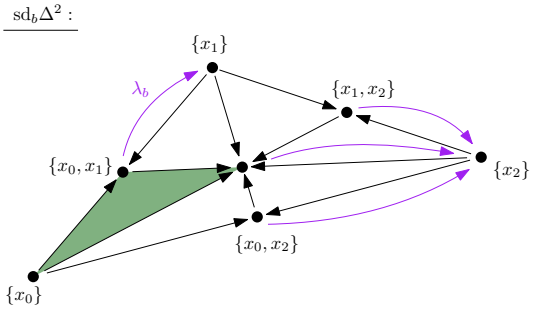


Figure 3 Illustration of the last vertex map λ_b on $\mathrm{sd}_b\Delta^2$. The purple arrows indicate where the vertices are mapped by λ_b. All but the green simplex are collapsed to lower-dimensional simplices.

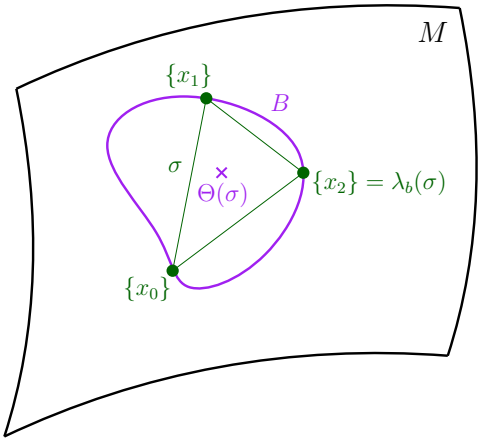

Figure 4 Illustration of the pseudo-barycenter map Θ.

▶ **Example 47.** For the purpose of this article, the only relevant example is the *barycentric subdivision functor* $\mathrm{sd}_b\colon \mathbf{sSet} \to \mathbf{sSet}$ together with the last vertex map $\lambda_b\colon \mathrm{sd}_b X \xrightarrow{\simeq} X$ (see [22]). Let us recall the special case $X = \mathcal{R}^\delta(M)$, which is the only one we will need. When $X = \mathcal{R}^\delta(M)$, each vertex of $\mathrm{sd}_b\mathcal{R}^\delta(M)$ corresponds to a sequence $(x_0, \dots, x_n)$ of elements of M that are less than δ apart from one another, and such that $x_i \neq x_{i+1}$ for all $i \in [n-1]$. Then. $\lambda_b\colon \mathrm{sd}_b\mathcal{R}^\delta(M) \xrightarrow{\simeq} \mathcal{R}^\delta(M)$ is given on vertices by mapping $(x_0, \dots, x_n) \in \mathrm{sd}_b(\mathcal{R}^\delta(M))_0$ to $x_n \in M = \mathcal{R}^\delta(M)_0$.

Shrinking transformations will then be obtained from the following types of maps:

▶ **Definition 48.** By a *pseudo-barycenter map*, we mean a map $\Theta\colon \mathrm{sd}\mathcal{R}^\rho(M)_0 \to M$ such that for all $0 < \delta \leq \rho$:

(a) For every $x \in \mathrm{sd}\mathcal{R}^\delta(M)_0$, we have $d(\lambda(x), \Theta(x)) \leq C\delta$;

(b) For $x, y \in \mathrm{sd}\mathcal{R}^\delta(M)_0$, if there is a 1-simplex from x to y in $\mathrm{sd}\mathcal{R}^\delta(M)$, then $d(\Theta(x), \Theta(y)) < S\delta$ and $d(\lambda(x), \Theta(y)) < S\delta$.

▶ **Example 49.** Let $\rho = \rho_M^\kappa$. Consider the map Θ that maps a vertex $\sigma = (x_0, \dots, x_n) \in \mathrm{sd}_b(\mathcal{R}^\rho(M))$ to the center of a minimal enclosing ball B of $\{x_0, \dots, x_n\} \subset M$- as illustrated in Figure 4. It follows from a geodesic version of Jung's theorem (see [23, Lemma 3.4], and also [34] for a related construction) that for any two finite sets $\{x_0, \dots, x_n\} \subset \{y_0, \dots, y_m\}$ of diameter $\delta < \rho_M^\kappa$, the associated centers $\Theta(x_0, \dots, x_n)$ and $\Theta(y_0, \dots, y_m)$ are well-defined and unique, and fulfill $d(\Theta(x_0, \dots, x_n), \Theta(y_0, \dots, y_m)) < \frac{3}{4}\delta$. As an immediate consequence, it follows that Θ defines a pseudo-barycenter map with constants $S = C = \frac{3}{4}$.

▶ **Construction 50.** We use Recollections 24 and 26 and construct the shrinking transformation in the homotopy category of persistent simplicial sets. Since sd preserves colimits, we have $\mathrm{sd}(\mathcal{R}^\bullet(M^\bullet))_0^{\infty,\rho} = \mathrm{sd}(\mathcal{R}^\rho(M))_0$. Now, under this identification, we can apply Proposition 36 and Remark 38 to uniquely extend Θ to a morphism $\tau'\colon \mathrm{sd}(\mathcal{R}^{\bullet_1}(M^{\bullet_2}))|_{[0,\rho]\times\mathbb{R}^N} \to \mathcal{R}^{S\bullet_1}(M^{\bullet_2 + C\bullet_1})|_{[0,\rho]\times\mathbb{R}^N}$ (see the proof of Theorem 51). Finally, in the persistent homotopy category $\mathrm{ho}(\mathbf{sSet}_{\mathrm{Kan}}^{[0,\rho]\times\mathbb{R}^N})$, we can invert the weak equivalence $\lambda\colon \mathrm{sd}\mathcal{R}^\bullet(M^\bullet) \simeq \mathcal{R}^\bullet(M^\bullet)$ and define τ_Θ as the composition:

$$\tau_\Theta\colon \mathcal{R}^{\bullet_1}(M^{\bullet_2})|_{[0,\rho]\times\mathbb{R}^N} \xrightarrow{\lambda^{-1}} \mathrm{sd}(\mathcal{R}^{\bullet_1}(M^{\bullet_2})|_{[0,\rho]\times\mathbb{R}^N}) \xrightarrow{\tau'} \mathcal{R}^{S\bullet_1}(M^{\bullet_2 + C\bullet_1})|_{[0,\rho]\times\mathbb{R}^N}.$$

Using this construction, we can state the main result of this section.

▶ **Theorem 51.** *The morphism* $\tau_\Theta\colon \mathcal{R}^{\bullet_1}(M^{\bullet_2})|_{[0,\rho]\times\mathbb{R}^N} \to \mathcal{R}^{S\bullet_1}(M^{\bullet_2+C\bullet_1})|_{[0,\rho]\times\mathbb{R}^N}$ *is a shrinking transformation and* δ*-compatible with every* ε*-interleaving* $\mathcal{R}^\bullet(\mathbb{M}^\bullet) \simeq_\varepsilon \mathcal{R}^\bullet(M^\bullet)$ *arising from a correspondence* $\mathfrak{C}\colon (\mathbb{M},\mathbb{f}) \approx_\varepsilon (M,f)$*, for* $\delta \le \rho$ *and* $\varepsilon \le \min\{\rho-\delta, \frac{1-S}{1+S}\delta\}$.

Proof. Throughout the proof, we are going to make use of the modified version of Proposition 36 in Remark 38. To simplify notation, we will write $\mathcal{R}^{\bullet,\bullet}$ for $\mathcal{R}^\bullet(M^\bullet)|_{[0,\rho]\times\mathbb{R}^N}$. We first show that τ', as defined in the previous construction, is indeed a well-defined morphism of persistent simplicial sets. Observe that compared to Proposition 36 the target persistent simplicial set has transformed under the parameter change $\bullet_1' = S\bullet_1$, $\bullet_2' = \bullet_2 + C\bullet_1$. The conditions that we need to verify for τ' to define a well-defined morphism (Remark 38) are explicitly given as follows. Let $\delta \in [0,\rho]$ and $u \in \mathbb{R}^N$. We need to verify the following:

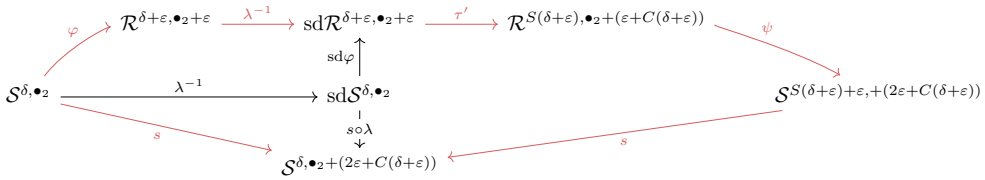
1. Let $\sigma \in \mathrm{sd}\mathcal{R}^\delta(M)_1$ be a 1-simplex with vertices $x, y \in \mathrm{sd}\mathcal{R}^\delta(M)_0$. Then the inequality $d(\Theta(x),\Theta(y)) < S\delta$ holds. This condition is assumed by Property b.
2. For $x \in \mathrm{sd}\mathcal{R}_0^{u,\delta}$, it holds that $f(\Theta(x)) \le u + C\delta$. This is a consequence of the inequalities

$$f(\lambda(x)) \le u \quad \text{and} \quad |f(\lambda(x)) - f(\Theta(x))|_\infty \le d(\lambda(x),\Theta(x)) \le C\delta.$$

The first of these holds as $\lambda(x) \in \mathcal{R}_0^{u,\delta}$. The second holds by Property a, which implies that $d(\lambda(x),\Theta(x)) \le C\delta$, together with the assumption that $f\colon M \to \mathbb{R}^N$ is 1-Lipschitz.

Next, let us verify the shrinking transformation condition. We need to show that the diagram

$$\begin{array}{ccccc} \mathcal{R}^{\bullet_1,\bullet_2} & \xrightarrow{\lambda^{-1}} & \mathrm{sd}\mathcal{R}^{\bullet_1,\bullet_2} & \xrightarrow{\tau'} & \mathcal{R}^{S\bullet_1,\bullet_2+C\bullet_1} \\ & \searrow^{s} & & & \downarrow{\scriptstyle s} \\ & & & & \mathcal{R}^{\bullet_1,\bullet_2+C\bullet_1} \end{array} \tag{4}$$



commutes. By precomposing with λ, this is equivalent to showing that the diagram

$$\begin{array}{ccc} \mathrm{sd}\mathcal{R}^{\bullet_1,\bullet_2} & \xrightarrow{\tau'} & \mathcal{R}^{S\bullet_1,\bullet_2+C\bullet_1} \\ {\scriptstyle\lambda}\downarrow & & \downarrow{\scriptstyle s} \\ \mathcal{R}^{\bullet_1,\bullet_2} & \xrightarrow[s]{} & \mathcal{R}^{\bullet_1,\bullet_2+C\bullet_1} \end{array} \tag{5}$$

commutes. In fact, it turns out that the two morphisms of persistent simplicial sets $s\circ\tau'$ and $s\circ\lambda$ are elementarily homotopic. To see this, consider the map

$$H\colon (\mathrm{sd}\mathcal{R}^{\bullet_1,\bullet_2}\times\Delta^1)_0 = (\mathrm{sd}\mathcal{R}^{\bullet_1,\bullet_2})_0 \times \{0,1\} \to M; \quad (x,i) \mapsto \begin{cases} \lambda(x), & i=0, \\ \Theta(x), & i=1, \end{cases}$$

and again apply Proposition 36 and Remark 38. As we already know that H_0 and H_1 fulfill the conditions of Proposition 36, it only remains to verify the condition on 1-simplices $\sigma \in (\mathrm{sd}\mathcal{R}^{\bullet_1,\bullet_2}\times\Delta^1)_1$ in Proposition 36 in the case where the vertices x and y are in $\mathrm{sd}\mathcal{R}^\delta(M)_0\times\{0\}$ and $\mathrm{sd}\mathcal{R}^\delta(M)_0\times\{1\}$ respectively. Observe that, by the definition of the simplicial product, we can identify σ with a simplex $\sigma' \in \mathrm{sd}\mathcal{R}^\delta(M)_1$, whose vertices we will also denote by x and y by abuse of notation. Then, the condition explicitly states that $d(\lambda(x),\Theta(y)) < \delta$ which follows from Property b in the definition of a pseudo-barycenter map. This shows that $s\circ\tau'$ and $s\circ\lambda$ are elementarily homotopic; thus, the shrinking transformation condition holds. It remains to show the compatibility with interleavings arising from a filtered correspondence. To this end, let $\mathfrak{C}$ be a filtered ε-correspondence between (M,f) and $(\mathbb{M},\mathbb{f})$, and let φ and ψ be the induced ε-interleaving maps. Furthermore, let $\varepsilon \le \min\frac{1-S}{1+S}\delta, \rho-\delta$. We write $\mathcal{S}^{\bullet_1,\bullet_2}$ for $\mathcal{R}^{\bullet_1}(\mathbb{M}^{\bullet_2})|_{[0,\rho]\times\mathbb{R}^N}$ and $\mathcal{S}^{\bullet_1}$ for $\mathcal{R}^{\bullet_1}(\mathbb{M})$. We now need to verify the commutativity of the outer diagram in

which we have marked in red. Observe that the left square commutes by the naturality of λ, and that the lower left triangle commutes by definition. It thus suffices to show that the remaining cell to the right commutes. To this end, we show that the two morphisms of persistent simplicial sets $s \circ \psi \circ \tau' \circ \mathrm{sd}\varphi$ and $s \circ \lambda$ are elementarily homotopic. To see this, we again use Proposition 36 and Remark 38, but this time applied to $\mathrm{sd}\mathcal{S}^{\delta,\bullet_2} \times \Delta^1$. Arguing exactly as above, we define a homotopy by extending the map

$$H' \colon (\mathrm{sd}\mathcal{S}^{\delta,\infty} \times \Delta^1)_0 = (\mathrm{sd}\mathcal{S}^{\delta})_0 \times \{0,1\} \to \mathbb{M}; \quad (x,i) \mapsto \begin{cases} \lambda(x), & i = 0. \\ (\psi \circ \tau' \circ \mathrm{sd}\varphi)(x), & i = 1; \end{cases}$$

By the same arguments as above, we can reduce to proving the following condition on 1-simplices $\sigma \in (\mathrm{sd}\mathcal{S}^{\delta,\bullet_2} \times \Delta^1)_1$ in Proposition 36 in the case where the vertices x and y are in $\mathrm{sd}(\mathcal{S}^{\delta,\bullet_2})_0 \times \{0\}$ and $\mathrm{sd}(\mathcal{S}^{\delta,\bullet_2})_0 \times \{1\}$, respectively: Given such a σ, it holds that

$$d(\lambda(x), (\psi \circ \tau' \circ \mathrm{sd}\varphi)(y)) < \delta.$$

To see this, we first apply the defining property of a correspondence to obtain

$$d(\lambda(x), (\psi \circ \tau' \circ \mathrm{sd}\varphi)(y)) \leq \varepsilon + d(\varphi(\lambda(x)), (\tau' \circ \mathrm{sd}\varphi)(y)) = \varepsilon + d(\varphi(\lambda(x)), \Theta((\mathrm{sd}\varphi)(y))).$$

By naturality of λ, we have $\varphi(\lambda(x)) = \lambda((\mathrm{sd}\varphi)(x))$. Hence, we only need to show that $d(\lambda(\mathrm{sd}\varphi(x)), \Theta((\mathrm{sd}\varphi)(y))) < \delta - \varepsilon$. By assumption, there exists a 1-simplex $\sigma' \in \mathrm{sd}\mathcal{S}_1^{\delta,\bullet_2}$ from x to y. Consequently, $\mathrm{sd}\varphi(\sigma') \in \mathrm{sd}\mathcal{R}_1^{\delta+\varepsilon,\bullet_2+\varepsilon}$ is a 1-simplex from $(\mathrm{sd}\varphi)(x)$ to $(\mathrm{sd}\varphi)(y)$ with $\delta + \varepsilon \leq \rho$. By Property b, we thus have

$$d(\lambda(\mathrm{sd}(\varphi)(x)), \Theta((\mathrm{sd}\varphi)(y))) < S(\delta + \varepsilon).$$

Finally, the assumption $\varepsilon \leq \frac{1-S}{1+S}\delta$ implies that $S(\delta+\varepsilon) \leq \delta - \varepsilon$, which concludes the proof. ◀

We can now finally combine the main results of this article to prove Theorem 3.

Proof of Theorem 3. By Proposition 34, the filtered correspondence $(\mathbb{M}, \mathbb{f}) \approx_\varepsilon (M, f)$ gives rise to an interleaving $\varphi \colon \mathcal{R}^\bullet(\mathbb{M}^\bullet) \simeq_\varepsilon \mathcal{R}^\bullet(M^\bullet) \colon \psi$ in the homotopy category. By Example 49, (M, f) admits a pseudo-barycenter map Θ with respect to $\rho = \rho_M^\kappa$ and $C = S = \frac{3}{4}$. Observe that $\frac{1-S}{1+S} = \frac{1}{7}$. By Theorem 51, Θ induces a shrinking transformation τ compatible with φ and ψ. Applying Theorem 44, we obtain an interleaving $\mathcal{R}^\delta(\mathbb{M}^\bullet) \simeq_{\frac{7}{4}\varepsilon + \frac{3}{4}\delta} \mathcal{R}^\delta(M^\bullet)$. Finally, since $\varepsilon \leq \frac{1}{7}\delta$ we have $\frac{7}{4}\varepsilon + \frac{3}{4}\delta \leq \delta$, and we obtain an interleaving $\mathcal{R}^\delta(\mathbb{M}^\bullet) \simeq_\delta \mathcal{R}^\delta(M^\bullet)$. ◀

Abstract

According to a classical result of Spencer, Szemerédi, and Trotter (1984), the maximum number of times the unit distance can occur among n points in the plane is $O(n^{4/3})$. This is far from Erdős's lower bound, $n^{1+O(1/\log\log n)}$, which is conjectured to be optimal. We prove a structural result for point sets with nearly $n^{4/3}$ unit distances and use it to reduce the problem to a conjecture on rigid frameworks. This conjecture, if true, would yield the first improvement on the bound of Spencer *et al.* A weaker version of this conjecture has been established by Raz and Solymosi.

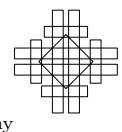
1 Introduction

1.1 Background

In 1946, Paul Erdős [6, 7] raised two different problems for the distribution of distances among n points in the plane or in any fixed metric space S:



Problem A. What is the maximum number of times the same distance can occur among n points in S?

Problem B. What is the minimum number of distinct distances determined by n points of S?

The problems generated a lot of research and led to over a thousand papers. This is partially because they turned out to be related to many deep questions in number theory, combinatorics, Fourier analysis, algebraic, incidence, and computational geometry [8, 10, 26, 27]. For many related problems, see the monographs [2, 13, 16].

© János Pach, Orit E. Raz, and József Solymosi;
licensed under Creative Commons License CC-BY 4.0

The two problems are obviously interconnected. If we obtain an upper bound $u(n)$ for the quantity in Problem A, it gives the lower bound $\binom{n}{2}/u(n)$ for the number of distinct distances in Problem B. In particular, Erdős conjectured that in the plane $u(n) = n^{1+O(1/\log\log n)}$, which is attained by a $\sqrt{n} \times \sqrt{n}$ piece of the square grid. A matching upper bound is known only in exceptional cases where the vectors determining the unit distances are from a restricted family [20, 19].

Unfortunately, despite many efforts, the best known upper bound for the number of times that (say) the *unit distance* can occur among n points in the plane is

$$u(n) = O(n^{4/3}). \tag{1}$$

This was first proved by Spencer, Szemerédi, and Trotter [23]. Since then, the problem has been tackled by Clarkson, Edelsbrunner, Guibas, Sharir, and Welzl [4], Székely [24], Pach and Tardos [17], using different approaches, all yielding precisely the same upper bound, $O(n^{4/3})$. None of these approaches offered much hope for possible improvement.

To partially explain why all previous methods yielded the same upper bound, we reformulate the unit distance problem as an incidence problem between points and unit circles in $\mathbb{R}^2$: Let P be a set of n points in $\mathbb{R}^2$, and let C be a set of n unit circles in $\mathbb{R}^2$. Consider the set of point-circle incidences

$$I(P, C) = \{(p, c) \in P \times C \mid p \in c\}.$$

Observe that

$$\max_{|P|=n, |C|=n} I(P, C) = \Theta(u(n)).$$

That is, the problem of upper bounding $u(n)$ is equivalent to the problem of upper bounding the number of incidences between n points and n unit circles in $\mathbb{R}^2$.

Bounding the number of incidences between points and curves in $\mathbb{R}^d$ is a well-studied problem in combinatorial geometry. Specifically, the instance of point-line incidences in $\mathbb{R}^2$ is the classical result of Szemerédi and Trotter from 1984:

▶ **Theorem 1** (Szemerédi–Trotter [25]). *Let P be a set of m points in $\mathbb{R}^2$, and let L be a set of n lines in $\mathbb{R}^2$. Then*

$$I(P, L) = O(m^{2/3}n^{2/3} + m + n).$$

Moreover, this bound is tight.

In the special case $m = n$, Theorem 1 yields $I(P, L) = O(n^{4/3})$, and this bound is best possible. If we want to obtain a better bound for the incidence problem between points and unit circles in the plane, one has to come up with a method that does not apply to point-line incidences; otherwise, we are doomed to fail. This is "the" reason why the unit distance problem appears to be so difficult. All known methods, with the exception of the one developed in [17], also apply to the point-line incidence problem, hence, they cannot yield any bound better than $O(n^{4/3})$. The approach in [17] can be used to bound the number of incidences between points and some other families of curves, for which the bound is tight; see [28, 21].

As for Erdős's other problem (Problem B), concerning the smallest number of distinct distances, the lower bound has been steadily improved over the years by Moser [15], Chung, Szemerédi, and Trotter [3], Solymosi and Cs. Tóth [22], and Katz and Tardos [12]. In May

2010, Elekes and Sharir reduced the question to an incidence problem in $\mathbb{R}^3$. A couple of months later, in November of the same year, Guth and Katz [11] achieved a major breakthrough by solving the incidence problem of Elekes and Sharir. They deduced that any set of n points in the plane determines at least $cn/\log n$ distinct distances, where $c > 0$ is a suitable constant. This is only a factor of $\sqrt{\log n}$ smaller than the conjectured minimum, which is attained again by the square grid construction.

1.2 Graph rigidity

Before formulating our results, we need to recall some basic notions from graph rigidity theory.

We review some standard definitions from rigidity theory. For more details, see, e.g., Asimow and Roth [1]. Let $G = (V, E)$ be a graph. A *realization* $\mathbf{p}$ of G in $\mathbb{R}^2$ is an embedding (not necessarily injective) of the vertex set $V = \{1, \ldots, |V|\}$ of G in $\mathbb{R}^2$. That is,

$$\mathbf{p} = (p_1, .., p_{|V|}) \in \mathbb{R}^2 \times ... \times \mathbb{R}^2 \cong \mathbb{R}^{2|V|}.$$

A pair $(G, \mathbf{p})$ of a graph G and a realization $\mathbf{p}$ is called a *framework*.

Define the *edge function* of G to be the map $f_G : \mathbb{R}^{2|V|} \to \mathbb{R}^{|E|}$ given by

$$(p_1, \ldots, p_{|V|}) \mapsto \left(||p_i - p_j||^2\right)_{\{i,j\} \in E},$$

where we fix an arbitrary order on the edges of G. Note that f_G is a polynomial map.

For a given graph G, let $\mathbf{p}$ and $\mathbf{q}$ be a pair of realizations of G in $\mathbb{R}^2$. We say that the corresponding frameworks, $(G, \mathbf{p})$ and $(G, \mathbf{q})$, are *equivalent* if $f_G(\mathbf{p}) = f_G(\mathbf{q})$, that is, if $\|p_i - p_j\| = \|q_i - q_j\|$ holds for every edge $\{i, j\} \in E$. We say that the frameworks $(G, \mathbf{p})$ and $(G, \mathbf{q})$ are *congruent* if $\|p_i - p_j\| = \|q_i - q_j\|$ for every size-2 subset $\{i, j\} \subset V$ (here $\{i, j\}$ is not necessarily an edge in G). Equivalently, $(G, \mathbf{p})$ and $(G, \mathbf{q})$ are congruent if there exists an isometry R of $\mathbb{R}^2$ such that $R(p_i) = q_i$, for every $i \in V$.

▶ **Definition 2** (Framework Rigidity). *We say that* $(G, \mathbf{p})$ *is a* rigid framework *if there exists a neighborhood* $U \subset (\mathbb{R}^2)^{|V|}$ *of* $\mathbf{p}$*, such that for every* $\mathbf{q} \in U$*, if* $(G, \mathbf{p})$ *and* $(G, \mathbf{q})$ *are equivalent, then they are necessarily also congruent. Equivalently, if there exists a neighborhood* U *of* $\mathbf{p}$ *such that*

$$f_G^{-1}(f_G(\mathbf{p})) \cap U = f_{K_{|V|}}^{-1}(f_{K_{|V|}}(\mathbf{p})) \cap U,$$

where $K_{|V|}$ *is the complete graph on* $|V|$ *vertices.*

Note that the notion of framework rigidity depends on both the graph G and the realization $\mathbf{p}$. That is, for a given graph G, and realizations $\mathbf{p}$ and $\mathbf{q}$, it might happen that $(G, \mathbf{p})$ is rigid and $(G, \mathbf{q})$ is not rigid.

A realization of G is called *generic* if the set of all coordinates of all of its points is algebraically independent over the rationals. It turns out that all *generic* realizations of G behave the same. That is, if G is fixed and $\mathbf{p}$ and $\mathbf{q}$ are some generic realizations of G, then $(G, \mathbf{p})$ is rigid if and only if $(G, \mathbf{q})$ is rigid. In this sense, rigidity is a property of the graph G, independent of the specific generic realization $\mathbf{p}$ one considers.

▶ **Definition 3** (Graph Rigidity). *We say that* $G = ([n], E)$ *is a* rigid graph *in* $\mathbb{R}^2$*, if* $(G, \mathbf{p})$ *is a rigid framework, for every generic realization* $\mathbf{p} \in (\mathbb{R}^2)^n$.

Most results in rigidity theory are concerned with the notion of generic rigidity, as in Definition 3. In the present note, we study realizations $\mathbf{p}$ arising from configurations of n points in the plane that maximize the number of unit distances. Such configurations are highly *non-generic*. Hence, for us *framework rigidity*, as in Definition 2, will be more relevant, and we will focus on this notion.

Specifically, given a framework $(G, \mathbf{p})$, we aim to find a rigid sub-framework within it. Note that this is an easy task if we restrict our attention to *generic* realizations. It is not hard to show that every sufficiently dense graph contains a *generically* rigid subgraph (see, e.g., [5] for technical details).

▶ **Lemma 4.** *Let $G = (V, E)$, let $\varepsilon > 0$ be fixed, and suppose that $|E| \geq n^{1+\varepsilon}$. Then there exists $G' \subset G$ with $|V(G')| \geq 3$ such that G' is generically rigid in $\mathbb{R}^2$.*

However, if our graph is given together with a realization, there is not much theory about this problem. The only useful result in this direction was obtained by Raz and Solymosi in [18].

▶ **Theorem 5** (Raz and Solymosi [18])**.** *Let $G = ([n], E)$, let $\alpha > 1/2$, and suppose that*

$$|E| = \Omega(n^{1+\alpha}). \tag{2}$$

Let $\mathbf{p} \in (\mathbb{R}^2)^n$ be a realization of G with the property that for every vertex $v \in [n]$, the neighbors of v are not embedded into a common line. Then there exists a subgraph $G' \subset G$, with $|V(G')| \geq 4$, such that $(G', \mathbf{p}|_{V(G')})$ is a rigid framework, provided n is large enough.

The smallest value of α for which the conclusion of Theorem 5 holds is not known. As was observed in [18], we need to assume at least $|E| = \Omega(n \log n)$; otherwise, the statement is false.

In [18], Theorem 5 was proved under the slightly stronger assumption that there are no *three* vertices of G that are mapped by $\mathbf{p} \in (\mathbb{R}^2)^n$ into collinear points. However, essentially the same proof also gives Theorem 5.

1.3 Main results

Our goal is to suggest a new approach to tackle the unit distance problem (Problem A) by reducing it to a rigidity problem.

For any point set P in the plane, let $u(P)$ denote the number of unit distance pairs determined by P, that is, the number of unordered pairs $\{p, q\} \subseteq P$ with $\|p - q\| = 1$. Given a graph $G = (V, E)$ and a realzation $\mathbf{p}$ of its vertex set into $\mathbb{R}^{2|V|}$ such that, $\mathbf{p}$ is injective, and the endpoints of every edge are mapped into two points whose distance is 1, we call $\mathbf{p}$ a *unit embedding* of G.

In the sequel, when we compare two functions, we will often use the notation $f(n) \lesssim g(n)$ instead of $f(n) = O(g(n))$. If we have $f(n) \lesssim g(n)$ and $g(n) \lesssim f(n)$, then we write $g(n) \approx h(n)$.

We tacitly assume that there exist n-element point sets P with $u(P)$ close to the currently best known upper bound $n^{4/3}$, and we study their structure. Our main technical result is the following.

▶ **Theorem 6** (Structure Theorem)**.** *Let $h(n)$ be a function tending to ∞, as $n \to \infty$. Let P be a set of n points in $\mathbb{R}^2$ satisfying $u(P) \geq \frac{n^{4/3}}{h(n)}$, and suppose that n is sufficiently large.*

Then there exist

1. *a subset $P' \subset P$ with $|P'| \approx n^{1/3} h(n)^4$;*
2. *bipartite graphs $G_i = (U_i \cup V_i, E_i)$ for every i $(1 \leq i \leq k)$, where $k \gtrsim n^{2/3}/h(n)^5$, such that $2 \leq |U_i|, |V_i| \lesssim h(n)^6$ and $|E_i| \gtrsim h(n)^7$;*

3. *unit embeddings* $\mathbf{p}^{(i)}$ *of* G_i *into* $(\mathbb{R}^2)^{|U_i|+|V_i|}$ *for every* i $(1 \leq i \leq k)$*, such that*
   - **(i)** *the sets* $\mathbf{p}^{(1)}(U_1), \ldots, \mathbf{p}^{(k)}(U_k)$ *are pairwise disjoint subsets of* P*,*
   - **(ii)** *the sets* $\mathbf{p}^{(1)}(V_1), \ldots, \mathbf{p}^{(k)}(V_k)$ *are subsets of* P'*.*

We conjecture that the statement of Theorem 5 remains true for any $\alpha \geq 1/6$. In other words, we state the following conjecture.

▶ **Conjecture 7** (Rigidity Conjecture)**.** *Let* $G = ([n], E)$ *be a graph with* $|E| \gtrsim n^{7/6}$*. Let* $\mathbf{p} \in (\mathbb{R}^2)^n$ *be a realization of* G *with the property that for every vertex* $v \in [n]$*, the neighbors of* v *are not embedded into a common line. Then there exists a subgraph* $G' \subset G$ *with* $|V(G')| \geq 4$ *such that* $(G', \mathbf{p}|_{V(G')})$ *is a rigid framework.*

Provided that Conjecture 7 is true, our approach would yield the first improvement of the classical upper bound, $O(n^{4/3})$, of Spencer, Szemerédi, and Trotter [23] on the number of unit distances for more than 40 years. Notably, we will deduce the following result.

▶ **Theorem 8.** *Conjecture 7 implies that the maximum number of unit distance pairs,* $u(n)$*, determined by* n *points in the plane satisfies*

$$u(n) = O\left(\frac{n^{4/3}}{\log^{1/12} n}\right).$$

The proofs of Theorems 8 and 6 are given in Sections 2 and 3, respectively.

2 Proof of Theorem 8

Let $P \subset \mathbb{R}^2$ with $|P| = n$, and assume for contradiction that $u(P) \geq \frac{n^{4/3}}{h(n)}$, for some function $h = h(n)$ that tends to zero as n tends to infinity. Let $P' \subset P$, k, $G_1 = (U_1 \cup V_1, E_1), \ldots, G_k = (U_k \cup V_k, E_k)$ and $\mathbf{p}^{(1)}, \ldots, \mathbf{p}^{(k)}$ be as given by Theorem 6.

Note that, since the realizations $\mathbf{p}^{(i)}$ are unit embeddings, the assumption in Conjecture 7, that the neighbors of a vertex v are not embedded to a common line, applies automatically. Thus, assuming that Conjecture 7 is true, it follows that, for every $i = 1, \ldots, k$, there exists a subgraph $G_i' = (U_i' \cup V_i', E_i') \subset G_i$ such that G_i' has at least 4 vertices and the unit framework $(G_i', \mathbf{p}^{(i)}|_{U_i' \cup V_i'})$ is rigid. Since G_i' is bipartite, this implies, in particular, that $|U_i|, |V_i| \geq 2$.

Recall that, by Theorem 6 item 2, we have that for each i, $2 \leq |U_i|, |V_i| \leq h^6$. Thus also $2 \leq |U_i'|, |V_i'| \leq h^6$. By the pigeonhole principle, there exists some bipartite graph $H = (U \cup V, E)$, with $2 \leq |U|, |V| \leq h^6$, such that for at least

$$k/2^{h^{12}},$$

indices i, we have that G_i' is isomorphic to H. Note that a rigid framework in the plane, on m vertices, has at most 9^m distinct non-congruent embeddings that induce the same edge lengths (see Milnor [14, Theorem 2]). Applying the pigeonhole principle once again, we conclude that there are at least

$$k/(2^{h^{12}} 9^{2h^6})$$

indices i, for which the frameworks $(G_i', \mathbf{p}^{(i)}|_{U_i' \cup V_i'})$ are pairwise congruent. Let I denote the subset of such indices. So $|I| \geq k/(2^{h^{12}} 9^{2h^6})$.

Let $v_1, v_2 \in V$. Then there exists a number $a > 0$ such that, for every $i \in I$, the embedding $\mathbf{p}^{(i)}$ maps v_1, v_2 to a pair of points in P' that are at distance a from each other.

We claim that for every $p, q \in P'$, there are at most two indices $i \in I$ such that v_1 is embedded by $\mathbf{p}^{(i)}$ to p and v_2 is embedded by $\mathbf{p}^{(i)}$ to q. Indeed, note that by fixing the embedding of v_1, v_2, we have that $\mathbf{p}^{(i)}$ must be one of at most two possible realizations of H (which can be obtained from each other by a reflection through the line pq). Thus, the embedding of U_i' is determined up to two possibilities. Since the sets $\mathbf{p}^{(i)}(U_i)$ are pairwise disjoint, it follows that i must be one of at most two possible indices in I. Similarly, there are at most two indices $i \in I$ such that $\mathbf{p}^{(i)}$ embeds v_1 to q and v_2 to p.

We conclude that the number of pairs in P' determining distance a is at least

$$k/(4 \cdot 2^{h^{12}} \cdot 9^{2h^6}).$$

Since the same distance can be repeated at most $\lesssim |P'|^{4/3}$ times in $|P'|$, we have

$$k/(4 \cdot 2^{h^{12}} \cdot 9^{2h^6}) \lesssim |P'|^{4/3} \approx (n^{1/3}h^4)^{4/3}.$$

Using the lower bound on k, we obtain that

$$\frac{n^{2/3}}{h^5 2^{h^{12}+2h^6+1}} \lesssim n^{4/9}h^{16/3}$$

or

$$n^{2/9} \lesssim 2^{h^{12}+2\log(9)h^6+1+(31/3)\log h}.$$

This yields a contradiction if $h(n) \approx \log^{1/12} n$, completing the proof of the theorem. ◀

3 Proof of Theorem 6

For the proof, we need the following result of Guth [9].

▶ **Theorem 9** (Guth [9, Theorem 0.3]). *Let Γ be a set of k-dimensional varieties in $\mathbb{R}^d$, each defined by at most b polynomial equations of degree at most δ. Then, for any $D \geq 1$, there is a nonzero polynomial f of degree at most D such that each connected component of $\mathbb{R}^d \setminus \{f = 0\}$ intersects $\lesssim D^{k-d}|\Gamma|$ varieties $\gamma \in \Gamma$, where the constant of proportionality depends on d, δ, and b.*

Let $P \subset \mathbb{R}^2$ with $|P| = n$, where n is sufficiently large. Assume that

$$u(P) \geq \frac{n^{4/3}}{h(n)},$$

for some function $h = h(n)$, which tends to ∞ as $n \to \infty$.

Let C denote the set of unit circles centred at the points of P. By our assumption on P, we have that the number of incidences between P and C is

$$|I(P, C)| \geq \frac{n^{4/3}}{h}$$

First partitioning

Set

$$r = \frac{n^{1/3}}{h^2}.$$

By Theorem 9, there exists $f \in \mathbb{R}[x,y]$, with $\deg(f) \leq r$, whose zero set partitions the plane into $\lesssim r^2$ cells such that each cell contains at most $\lesssim n/r^2$ points of P and meets at most $\lesssim n/r$ unit circles of C.

The number of incidences that occur on the zero set of f is at most

$$|I_0(P,C)| \leq nr + n + r^2 < \frac{1}{2}|I(P,C)|,$$

if $n \geq n_0$ is sufficiently large.

Thus, in what follows, we assume without loss of generality that $P \subset \mathbb{R}^2 \setminus Z(f)$ and that no circle in C is contained in $Z(f)$.

Let Ω denote the set of open connected components of $\mathbb{R}^2 \setminus Z(f)$. For $\omega \in \Omega$, let P_ω denote the set of points in P contained in ω, and let C_ω denote the set of circles in C that intersect ω. By our choice of f, we have

$$|\Omega| \lesssim \frac{n^{2/3}}{h^4},$$

and, for every $\omega \in \Omega$,

$$|P_\omega| \lesssim n/r^2 = n^{1/3}h^4$$

and

$$|C_\omega| \lesssim n/r = n^{2/3}h^2.$$

Recall our assumption that all incidences in $I(P,C)$ occur within the cells. Then, by the pigeonhole principle, there exists a cell $\omega_0 \in \Omega$ such that

$$|I(P_{\omega_0}, C_{\omega_0})| \gtrsim \frac{n^{4/3}}{h} / \frac{n^{2/3}}{h^4} = n^{2/3}h^3.$$

Let Q denote the set of centers of the unit circles in C_{ω_0}. Let D denote the set of unit circles centred at the points of P_{ω_0}. We have

$$\begin{aligned} |Q| &\lesssim n^{2/3}h^2, \\ |D| &\lesssim n^{1/3}h^4, \quad \text{and} \\ |I(Q,D)| &\gtrsim n^{2/3}h^3. \end{aligned}$$

Second partitioning

Set

$$t \approx \frac{n^{1/3}}{h^2}.$$

Let $g \in \mathbb{R}[x,y]$ be a bivariate polynomial of degree at most t such that $\mathbb{R}^2 \setminus Z(g)$ partitions $\mathbb{R}^2$ into at most $\lesssim t^2$ connected components, each of which contains at most $\lesssim |Q|/t^2 \lesssim h^6$ points of Q, and meets at most $\lesssim |D|/t \lesssim h^6$ unit circles in D.

Note that the number of incidences in $I(Q,D)$ that occur on the zero set of g is bounded by

$$|I_0(Q,D)| \leq t|D| + |Q| + t^2 < \frac{1}{2}|I(Q,D)|,$$

for $n \geq n_0$ sufficiently large. Thus, without loss of generality, we may assume that all incidences in $I(Q,D)$ occur within the cells.

Let Π denote the open connected components of $\mathbb{R}^2 \setminus Z(g)$. For $\pi \in \Pi$, let Q_π denote the set of points of Q contained in π, and let D_π denote the set of circles in D that meet π. By our choice of g, we get

$$|\Pi| \lesssim \frac{n^{2/3}}{h^4}$$

and, for every $\pi \in \Pi$, we have

$$|Q_\pi| \lesssim h^6 \quad \textit{and}$$
$$|D_\pi| \lesssim h^6,$$

as was already noted above.

Note that cells π with at most $\leq ch^7$ incidences, for some constant $c > 0$, contribute a total of at most

$$\lesssim \frac{n^{2/3}}{h^4} \cdot ch^7 = cn^{2/3}h^3 < \frac{1}{2}I(Q, D)$$

incidences, provided that $c > 0$ is chosen sufficiently small.

Let $\Pi' \subset \Pi$ be the subset of cells π for which $|I(Q_\pi, D_\pi)| \geq ch^7$. Observe that

$$|\Pi'| \gtrsim \frac{n^{2/3}}{h^5}. \tag{3}$$

Indeed, by the Szemerédi–Trotter bound, in each cell $\pi \in \Pi$, we have $|I(Q_\pi, D_\pi)| \lesssim (|Q_\pi||D_\pi|)^{2/3} \approx h^8$. Thus, we have

$$|\Pi'| \cdot h^8 \gtrsim \frac{1}{2}|I(Q, D)| \gtrsim n^{2/3}h^3,$$

which implies (3).

Finally, let $P' := P_{\omega_0}$, or, equivalently, the centers of the circles in D. Note that $P' \subset P$. For every $\pi \in \Pi'$, let G_π denote the incidence graph between the points in Q_π and the unit circles in D_π. Observe that G_π is a bipartite graph with parts Q_π, D_π, each of cardinality at most $\lesssim h^6$, and that the number of edges in G_π is $|E(G_\pi)| \gtrsim h^7$. Moreover, identifying the circles in D_π with their centers, we get that (Q_π, D_π) is a *unit embedding* of G_π, by construction. Observing also that the sets $Q_\pi \subset P$ are pairwise disjoint (by the properties of the partition induced by the partitioning polynomial g), and in view of (3), the proof of Theorem 6 is complete. ◀

Abstract

We consider the Voronoi diagram of lines in $\mathbb{R}^3$ under the Euclidean metric, and give a full classification of its structure in the base case of four lines in general position. We first show that the number of vertices in the Voronoi diagram of four lines in general position is always even, between 0 and 8, and all such numbers can be realized. We identify a key structure for the diagram formation, called a *twist*, which is a pair of consecutive intersections among trisector branches; only two types of twists are possible, so-called *full* and *partial* twists. A full twist is a purely local structure, which can be inserted or removed without affecting the rest of the diagram. Assuming no full twists, the nearest and the farthest Voronoi diagrams of four lines, each have 15 distinct topologies, which are in one-to-one correspondence; the two-dimensional faces are all unbounded, and the total number of vertices is at most six. The unbounded features of the farthest diagram, encoded in a two-dimensional spherical map, are also in one-to-one correspondence. The identified topologies are all realizable. Any Voronoi diagram of four lines in general position in $\mathbb{R}^3$ can be obtained from one of these topologies by inserting full twists; each twist induces a bounded face of exactly two vertices in both the nearest and farthest diagrams. We obtain the classification by an exhaustive search algorithm using some new structural and combinatorial observations of line Voronoi diagrams.

1 Introduction

Voronoi diagrams are fundamental space partitioning structures in Computational Geometry. Given a set S of n objects in some space, called sites, the *nearest* (respectively, *farthest*) Voronoi diagram of S decomposes the underlying space into regions that have the same nearest (resp., farthest) site. In this paper, we consider Voronoi diagrams of lines in $\mathbb{R}^3$ under the Euclidean metric, focusing on the elementary, yet fundamental base case of four lines.

The Euclidean Voronoi diagram of point sites in $\mathbb{R}^d$ is a classical geometric partitioning structure that is generally well-understood. It has complexity $O(n^{\lceil \frac{d}{2} \rceil})$ and can be computed in $O(n \log n + n^{\lceil \frac{d}{2} \rceil})$ time [7, 10, 16]; these bounds are tight. The results also hold for certain polyhedral norms such as the L_∞ or L_1 norms [6, 15]. For the Euclidean farthest Voronoi diagram of point sites, exact worst-case bounds in the range of $\Theta(n^{\lceil \frac{d}{2} \rceil})$ have also been reported by Seidel [20].

For sites more general than points, however, Voronoi diagrams in $\mathbb{R}^d$, $d \geq 3$, have not yet been well-understood. These diagrams get complicated because their bisecting surfaces are curved, triggering complicated algebraic descriptions of their features such as their trisector curves. The combinatorial complexity of the classical Voronoi diagram of n lines (or line segments) in $\mathbb{R}^3$ is a well-known outstanding open problem [19]. There is a gap of an order of magnitude between the $\Omega(n^2)$ lower bound [2] and the only known $O(n^{3+\varepsilon})$ upper bound by Sharir [21]. This gap extends to the Voronoi diagram of lines in $\mathbb{R}^d$, $d > 3$, where the known upper bound is $O(n^{d+\varepsilon})$ [21]. For $d \geq 4$, an $\Omega(n^{\lceil 2d/3 \rceil})$ lower bound has recently been reported by Glisse [13]. The upper bounds are derived from general complexity results on envelopes of algebraic functions in $\mathbb{R}^{d+1}$, under the general framework [10] for studying Voronoi diagrams in $\mathbb{R}^d$ through the *arrangement* of distance functions of the given sites in $\mathbb{R}^{d+1}$. Sharper complexity bounds have been established in certain special cases such as lines with c constant orientations [18] and parallel half-lines [3], and for norms induced by convex polyhedra of constant complexity [4, 8, 17].

The Voronoi diagram of only three lines in $\mathbb{R}^3$ was addressed by the authors of [12] who proved the fundamental properties of its structure. The trisector of three pairwise skew lines was shown to consist of four unbounded curves, which are roots of a nonsingular quartic, or a nonsingular cubic and a nonintersecting line. This is the first, most basic building block necessary in computing any Voronoi diagram of lines or polyhedra in $\mathbb{R}^3$, but it contains no Voronoi vertices. In this paper, we address the next basic building block, which is the Voronoi diagram of four lines in $\mathbb{R}^3$, where a minimal number of Voronoi vertices appears.

The unbounded features of the Euclidean order-k, $1 \leq k \leq n-1$, Voronoi diagrams of lines and line segments in $\mathbb{R}^d, d \geq 3$, were studied in [5]. They are encoded in a map on a *sphere of directions*, called the Gaussian map, which has complexity $O(\min\{k, n-k\}n^{d-1})$; for the farthest Voronoi diagram the Gaussian map has complexity $\Theta(n^{d-1})$.

The Voronoi diagram of lines in $\mathbb{R}^3$ can be computed in $O(n^{3+\epsilon})$ time [1] as part of a more general technique to compute the lower envelope of algebraic functions in $\mathbb{R}^4$. Using the envelope package of CGAL, a numerically robust algorithm for computing the Voronoi diagram of lines in $\mathbb{R}^3$ has been reported in [14]. Algorithms for computing approximations of the Voronoi diagram also exist, see e.g., [9, 11].

Contribution. In this paper, we prove structural properties of the Voronoi diagram of four lines in $\mathbb{R}^3$, building upon the previous work [12] on three lines. The case of four lines is fundamental, and is required for understanding any Voronoi diagram of lines or polyhedra in $\mathbb{R}^3$. We first show that the number of vertices in the Voronoi diagram of four lines in general position is always even, between 0 and 8, and all such numbers can be realized. We then identify basic structures in the arrangement of trisectors, called *twists*, which are critical for the formation of the diagram and the resulting number of its Voronoi vertices. A twist is a pair of consecutive trisector intersections along some trisector components (called branches, see Definition 10). We show that there are only two types of twists: *full twists* that involve four different trisector branches, and *partial twists* that involve six trisector branches, two of which are incident to both vertices of the twist (see Definition 11). A full twist has a *local* structure, in the sense that adding or removing one does not affect the rest of the diagram. It results in a bounded face with exactly two vertices in both the nearest and the farthest diagrams. Since full twists only have a local effect, we first assume that no full twists exist in the trisector arrangement and fully classify the Voronoi diagrams of four lines in this case. We prove the following theorems.

▶ **Theorem 1.** *The Voronoi diagram of four lines in general position in $\mathbb{R}^3$ (both the nearest and farthest diagram) has 15 distinct topologies, assuming there are no full twists among the trisectors. The distinct topologies of the nearest and the farthest diagrams are in one-to-one correspondence. Further, they are in one-to-one correspondence with the unbounded features of the farthest diagram. To obtain more than two Voronoi vertices, twists are required. The two-dimensional faces in both diagrams are unbounded and the total number of vertices is at most 6, see Table 1. In the nearest Voronoi diagram, all vertices are connected in a single component of the 1-skeleton.*

Table 1 Distinct topologies for each possible number of Voronoi vertices, assuming no full twists.

Number of vertices	0	2	4	6	8
Number of topologies	1	3	5	6	0

Additional structural properties are listed in Observation 21.

▶ **Theorem 2.** *The nearest (resp. farthest) Voronoi diagram of four lines in general position in $\mathbb{R}^3$ can be obtained from one of the 15 topologies of Theorem 1 by inserting the diagram's full twists. Inserting a full twist to a topology creates one new bounded face with two vertices in both the nearest and farthest diagram; it also splits an existing face in two faces. The total number of vertices, including full-twists, is at most 8.*

To obtain this classification, we devise an exhaustive search algorithm that enumerates possible *configurations* of projected trisector pairs. By ignoring the geometry and focusing on the structure, we encode a bisector and the two trisectors it contains as a *configuration* of eight curves in the plane, where each trisector has four branches. We identify necessary conditions under which a configuration is valid, and use them to create filters that eliminate impossible cases. We also create filters for six-tuples of configurations, where each tuple corresponds to the six bisectors of four lines. After an exhaustive search, which eliminates impossible cases by the derived necessary conditions, we are left with only 15 distinct configuration six-tuples. Each tuple corresponds to a distinct topology. The enumeration process is shown to be complete. All the remaining 15 tuples and their corresponding topologies are realizable as we demonstrate by concrete examples. Based on these results, we also provide an algebraically simple method to identify the structure of the Voronoi diagram.

In addition, we establish some simple new combinatorial results on the nearest and farthest Voronoi diagrams of n lines, expressing their features as a function of the number of Voronoi vertices (see Theorem 9). We use these results for $n = 4$ to obtain the aforementioned filters. For the farthest Voronoi diagram of n lines, we show that the region of each line has exactly $n-1$ three-dimensional cells, extending a result of [5] on the total number of cells.

The exhaustive search has been implemented as a program, available on Zenodo [22], that performs the actual search.

2 Preliminaries

Let $L = \{\ell_1, \ldots, \ell_n\}$ be a set of n lines in general position in $\mathbb{R}^3$. By general position, we mean the following: (1) lines are pairwise skew, and no three lines are parallel to a common plane; (2) no sphere can be tangent to four lines with coplanar tangency points; (3) no sphere is tangent to five lines; (4) no four lines have direction vectors whose representations on the sphere of directions are cocircular.

We denote by $d(x, y)$ the Euclidean distance between two points $x, y \in \mathbb{R}^3$. The distance $d(x, \ell)$ from a point $x \in \mathbb{R}^3$ to a line $\ell \in L$ is defined as $d(x, \ell) = \min\{d(x, y) \mid y \in \ell\}$. The i-sector of i lines in $\mathbb{R}^3$, $i \in \{2, 3\}$, is the locus of points equidistant from the i lines. For $i = 2$, a bisector $B(\cdot, \cdot)$ is a hyperbolic paraboloid; for $i = 3$, a trisector $T(\cdot, \cdot, \cdot)$ is a quartic consisting of four unbounded branches [12, 18]. Two trisectors are said to be *related* if they involve exactly four lines, i.e., they are of the form $T(\ell_i, \ell_j, \ell_k), T(\ell_i, \ell_j, \ell_l)$, with $k \neq l$.

The *nearest Voronoi diagram* of L, denoted $\mathrm{NVD}(L)$, subdivides $\mathbb{R}^3$ into maximal regions, each consisting of points closer to one line than to any other line. More generally, for $1 \leq k \leq n-1$, the *order-k Voronoi diagram*, denoted $\mathrm{VD}_k(L)$, subdivides $\mathbb{R}^3$ into maximal regions that have the same k nearest lines. The case $k = n-1$ gives the *farthest Voronoi diagram*, denoted $\mathrm{FVD}(L)$. Each diagram is a 3D cell complex, whose *features* are vertices, edges, faces (2D), and cells (3D). Unless otherwise stated, we call 2D faces simply *faces* and 3D cells simply *cells*.

The general position assumption implies the following properties. By assumption (1), the topology of trisectors is unique, [12] Theorem 1. By (2), related trisectors intersect transversely (see Lemma 3). By (3), vertices of the nearest and farthest Voronoi diagrams have degree 4. By (4), the asymptotes of related trisectors do not coincide (see Lemma 4).

▶ **Lemma 3.** *If two related trisectors (associated with four lines) intersect tangentially, then there exists a sphere tangent to the four lines such that the four contact points are coplanar.*

For a cell complex M, let B be a ball large enough to intersect any i-dimensional feature of M, where $0 \leq i \leq 3$, in one connected component. Let Γ be the boundary of B. The intersection $M \cap \Gamma$ encodes the unbounded features of M into a two-dimensional map on Γ, denoted $\Gamma(M)$. In particular, the unbounded edges, unbounded 2D faces, and unbounded 3D cells of M correspond exactly to the vertices, edges and faces, respectively, of $\Gamma(M)$.

Next, we give a summary of known elementary properties for the Voronoi diagram of four lines. Four lines induce four trisectors and six bisectors. When two trisectors intersect, the other two trisectors necessarily pass through the same intersection points. These intersections are Voronoi vertices in the order-k Voronoi diagram, $k \in \{1, 2, 3\}$. Voronoi vertices lie on all six bisectors. A trisector consists of four unbounded curves, called branches. Trisector branches are partitioned by the Voronoi vertices into arcs, which are order-k Voronoi edges for some k. Each trisector lies in three bisectors, and each bisector contains exactly two trisectors. A bisector is partitioned by the two trisectors it contains into faces, where each face belongs to an order-k Voronoi diagram, for some k. The nearest and farthest Voronoi diagrams of four lines share no edges or faces, by definition. Instead, both diagrams share their edges with the order-2 Voronoi diagram.

2.1 Algebraic framework and geometric reinterpretation

We recall the parametrization of lines from [12]. WLOG, let the coordinate system satisfy the following: ℓ_1 is defined by point $(0, 0, 1)$ and vector $(1, a, 0)$, ℓ_2 is defined by point $(0, 0, -1)$ and vector $(1, -a, 0)$, for some $a \in \mathbb{R}$. For $i \geq 3$, line ℓ_i is defined by point $(b_i, c_i, 0)$ and vector $(d_i, e_i, 1)$, with $b_i, c_i, d_i, e_i \in \mathbb{R}$. Then, the bisector $B(\ell_1, \ell_2)$ has the following formulation:

$$B(\ell_1, \ell_2) = \{(x, y, z) \mid (x, y) \in \mathbb{R}^2, z = \frac{-a}{1 + a^2} \cdot xy\}.$$

There is a natural homeomorphism $\Pi : B(\ell_1, \ell_2) \to \mathbb{R}^2$, given by $\Pi(x, y, z) = (x, y)$, that projects the bisector onto the Euclidean plane. We call $\Pi(B(\ell_1, \ell_2))$ the *projected bisector*. For any trisector $T = T(\ell_1, \ell_2, \ell_i)$ on $B(\ell_1, \ell_2)$, we call $\Pi(T)$ the *projected trisector*. The

following lemma summarizes key properties of the Voronoi diagram of three lines from [12], including Propositions 14 and 17 of [12]. We restate them in the following lemma in terms of projected trisectors on projected bisectors, as needed for analyzing four lines in Sections 4 and 5. Refer to Figure 1.

▶ **Lemma 4** ([12]). *A projected trisector T consists of four unbounded branches. It has two vertical and two horizontal asymptotes. There is a unique branch that admits exactly one asymptote, called the* middle branch*. The middle branch partitions a projected bisector into two regions: one containing a single branch and the other containing two branches; denote the single branch as the* U branch*. Furthermore, the following hold:*

1. *the middle branch of T is the same on all three bisectors that T lies on;*
2. *the three branches of T, other than the middle branch, each becomes a U branch on exactly one of the three bisectors that T lies on;*
3. *the four branches of T partition the bisector into five faces, two of which belong to the* NVD *and three belong to the* FVD *of the three lines;*
4. *if the asymptote of the middle branch is vertical, then all branches are y-monotone; otherwise, all branches are x-monotone.*

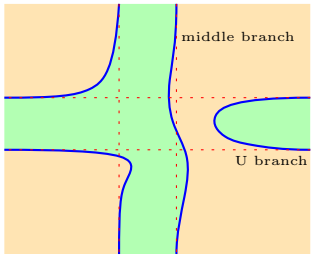

Figure 1 A projected trisector on a projected bisector. Branches are shown in blue and the asymptotes are shown in red. The NVD faces are shown in green and the FVD faces in orange.

3 Some combinatorial results on Voronoi diagrams of lines in $\mathbb{R}^3$

We first analyze the asymptotes of a projected trisector, building upon the results of [12]. The following lemma uses the parametrization notation of Section 2.1.

▶ **Lemma 5.** *The vertical and horizontal asymptotes of a projected trisector $\Pi(T(\ell_1, \ell_2, \ell_i))$, on the projected bisector $\Pi(B(\ell_1, \ell_2))$, are roots of quadratic polynomials whose coefficients depend only on the parameters a, d_i, e_i that define the direction of the line ℓ_i. Consequently, the asymptotes of the projected trisector are invariant under translation of the line ℓ_i.*

The number of vertices in the Voronoi diagram of four lines is known to be at most 8 [18]. We extend this observation and show that the number of vertices is always even.

▶ **Lemma 6.** *The number of vertices in a Voronoi diagram of four lines in general position is always even, between 0 and 8, and all numbers can be attained.*

The farthest Voronoi diagram of a set L of n lines in general position is known to have n^2-n distinct 3D cells, which are all unbounded, and do not form tunnels [5]. The following lemma follows from [5] and extends this result to the cells of individual lines.

▶ **Lemma 7.** *In the farthest Voronoi diagram of n lines in general position, $n \geq 2$, the Voronoi region of each line consists of exactly $n-1$ unbounded 3D cells.*

In NVD(L), where L is a set of n lines in general position, 3D Voronoi regions are connected, and each region is topologically an infinite cylinder with two unbounded ends, assuming $n \geq 3$. Thus, we can derive the following results for NVD(L). The farthest counterpart follows from [5] Theorem 5.12.

▶ **Lemma 8.** *The map* $\Gamma(\text{NVD}(L))$ *has* $4n-4$ *vertices,* $6n-6$ *edges, and* $2n$ *faces. The map* $\Gamma(\text{FVD}(L))$ *has* $2n^2-2n-4$ *vertices,* $3n^2-3n-6$ *edges, and* n^2-n *faces. The numbers indicate the unbounded Voronoi edges, faces, and cells, respectively, in each diagram.*

Note that the *Gaussian map* on the sphere of directions from [5] can be regarded as the limit of the unbounded features map on Γ, as Γ goes to infinity. Combining Lemma 8 and some counting arguments, we derive the following result, which we use for $n = 4$ in Section 5.

▶ **Theorem 9.** *Let* V_N *(resp.* V_F*) denote the number of vertices of* NVD(L) *(resp.* FVD(L)*).*
- NVD(L) *has* $2V_N+2n-2$ *edges,* V_N+3n-3 *faces, and* n *cells.*
- FVD(L) *has* $2V_F+n^2-n-2$ *edges,* V_F+2n^2-2n-3 *faces, and* n^2-n *cells.*

4 Twists

From this section onward, we focus on a set L of four lines in general position. The four lines give rise to four trisectors that form the trisector system of L, and six bisectors.

▶ **Definition 10.** *A pair of trisector intersections* (v_1, v_2) *is called a* twist*, if there exist two trisectors* T_1, T_2*, that both have a single branch passing through* v_1, v_2 *consecutively (i.e., no other vertices exist between* v_1 *and* v_2 *on either* T_1 *or* T_2*); see Figure 2.*

▶ **Definition 11.** *A twist* (v_1, v_2) *is called a* full twist*, if there are exactly four trisector branches passing through* v_1 *and* v_2 *consecutively (with no other vertices between* v_1, v_2 *on any branch); see Figure 2 right. A twist is called a* partial twist*, if there are exactly two trisectors with a single branch passing through both* v_1 *and* v_2*, and two trisectors with exactly two branches each, one passing through* v_1 *and the other through* v_2*; see Figure 2 left.*

Figure 2 Left: a partial twist. Right: a full twist. Different colors denote different trisectors.

The proof of the following lemma is deferred to the next section.

▶ **Lemma 12.** *A twist is either a full twist or a partial twist.*

4.1 Full twists

We show that the Voronoi diagram (both nearest and farthest) exhibits a unique local structure around any full twist; see Figure 3 for an illustration.

▶ **Lemma 13.** *Among the four bounded trisector arcs incident to a full twist, exactly two lie in* NVD(L) *and the other two lie in* FVD(L)*, defining one bounded face in each diagram called a full-twist face. The arcs* alternate *between the nearest and the farthest diagrams, alternate in the sense that the two full-twist faces intersect each other.*

Proof sketch. Assume to the contrary that at least 3 bounded arcs incident to the full twist vertices belong to NVD(L) (resp. FVD(L)); then each pair of these arcs bounds a distinct face of NVD(L) (resp. FVD(L)). But three such faces incident to both vertices of the full twist create a bounded 3D cell in the NVD(L) (resp. FVD(L)), which is a contradiction. Hence, there are two bounded arcs in NVD(L) and two in FVD(L) incident to the full twist. Assume now that the arcs are not alternating. WLOG, let the red and green arcs in Figure 3 left be in the NVD, and consider the face F_1 (resp. F_2) bounded by the red and blue (resp. green and brown) arcs in Figure 3 middle. Both faces must belong to $\mathrm{VD}_2(L)$, as each is bounded by one edge in NVD(L) and one edge in FVD(L). However, they intersect in a curve that is not an edge of the diagram, see Figure 3 middle, deriving a contradiction. ◀

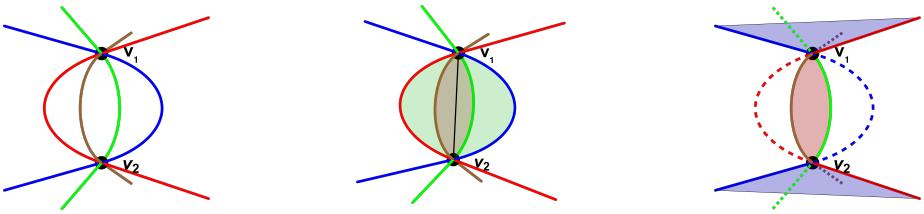

Figure 3 Left: a 3D view of a full twist. Middle: illustration for the proof of Lemma 13. Faces F_1 and F_2 are highlighted, intersecting at the black segment which is not an edge of the diagram. Right: the unique structure of the NVD(L) around the full twist.

The converse of the above lemma is also true, which will be shown in Lemma 16. Next, we describe a local modification on a Voronoi diagram associated with a full twist.

Local modification. Refer to Figure 4. Start with an NVD face incident to two edges from different trisectors (e.g., the blue face on $B(\ell_1, \ell_2)$ incident to the red and blue edges). Move the interior of the edges closer until they intersect twice (at vertices v_1, v_2). Consequently, each of the two original edges is split into three pieces, and the middle arcs no longer belong to the NVD. The original NVD face is split into two faces. Two new bounded edges from the other two trisectors appear in the diagram (the green and brown edges in Figure 4), which form a full-twist face in the NVD. The cells of ℓ_3 and ℓ_4 touch each other along the full-twist face. The local modification applies to the FVD in the same way.

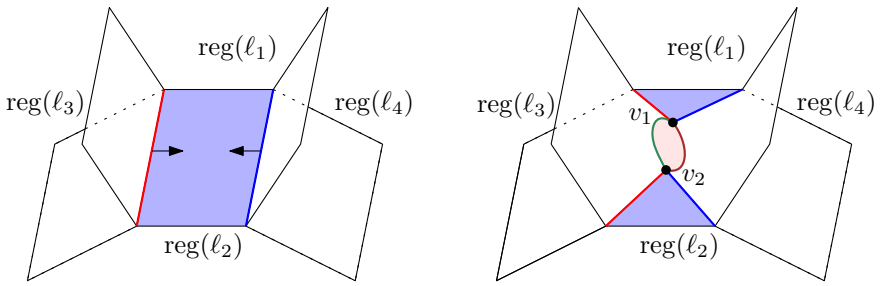

Figure 4 Left: local NVD/FVD structure; right: the modified diagram after adding a full twist.

We say that the diagram in Figure 4 right is obtained from the diagram in Figure 4 left by "adding a full twist". The local operation can be reversed by "removing a full twist". Since the effect of a full twist is purely local, we first focus on the global structure by restricting attention to Voronoi diagrams whose trisector arrangements have no full twists.

4.2 Partial twists and further properties

We illustrate the local structure of the Voronoi diagrams around twists, and prove that any twist in the trisector arrangement must be either full or partial.

▶ **Lemma 14.** *Let (v_1, v_2) be a twist and let (e_1, e_2) be the two trisector arcs incident to both v_1, v_2, as shown in Figure 5. Assume that a third trisector has two distinct branches, one of which passes through v_1 and the other through v_2. Then, one of e_1, e_2 belongs to* NVD(L) *and the other belongs to* FVD(L)*; the face bounded by e_1, e_2 belongs to $VD_2(L)$.*

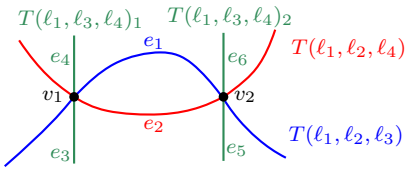

Figure 5 A local section of a trisector system, illustrating the setup of Lemma 14.

Proof. Refer to Figure 5. We distinguish two branches of trisector $T(\ell_1, \ell_3, \ell_4)$ as $T(\ell_1, \ell_3, \ell_4)_1$ and $T(\ell_1, \ell_3, \ell_4)_2$. Note that one of the edges e_3, e_4 in $T(\ell_1, \ell_3, \ell_4)_1$ is an NVD edge and the other is an FVD edge. Analogously for the edges e_5, e_6 in $T(\ell_1, \ell_3, \ell_4)_2$. Hence, WLOG, we assume that e_4, e_6 are edges of NVD(L).

Assume for the sake of contradiction that e_1, e_2 are both in NVD(L). Then, the face on $B(\ell_1, \ell_2)$ bounded by e_1 and e_2 is also in NVD(L). Further, there is a face of NVD(L) on $B(\ell_1, \ell_3)$ incident to e_1, e_4, e_6, and a face of NVD(L) on $B(\ell_1, \ell_4)$ incident to e_2, e_4, e_6. Hence, there are two faces f_1 and f_2 in NVD$(\{\ell_1, \ell_3, \ell_4\})$, on $B(\ell_1, \ell_3)$ and $B(\ell_1, \ell_4)$, respectively, that are incident to both branches $T(\ell_1, \ell_3, \ell_4)_1$ and $T(\ell_1, \ell_3, \ell_4)_2$. By [12], the Voronoi region of a line in the NVD of three lines is invariant, which is shown schematically in Figure 6-middle. To satisfy the aforementioned properties, faces f_1 and f_2 must be the top and bottom faces in Figure 6-middle, and the two branches $T(\ell_1, \ell_3, \ell_4)_1$ and $T(\ell_1, \ell_3, \ell_4)_2$ must be the green branches in the same figure. Adding line ℓ_2 to NVD$(\{\ell_1, \ell_3, \ell_4\})$ creates vertices v_1, v_2 on the green branches, with incident edges e_1, e_2 on the top and bottom faces, and a face bounded by e_1, e_2 in NVD(L), see Figure 6-right. This new face splits the 3D cell of ℓ_1 into two components, which is a contradiction as the 3D cells of NVD(L) are topological infinite cylinders.

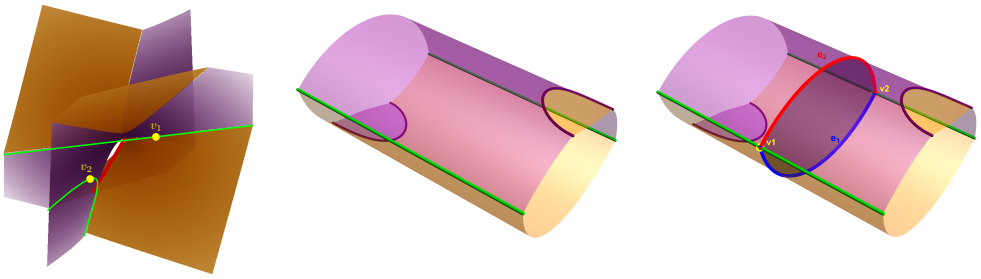

Figure 6 The region of ℓ_1 in NVD(ℓ_1, ℓ_3, ℓ_4), with the two green trisector branches highlighted. Left: a real instance. Middle: a schematic representation. The purple faces belong to $B(\ell_1, \ell_4)$ and the yellow faces belong to $B(\ell_1, \ell_3)$. Right: the result of inserting ℓ_2.

Next, assume that e_1, e_2 are both in FVD(L). Analogously, we can show that there are two faces in FVD($\{\ell_1, \ell_3, \ell_4\}$), on $B(\ell_1, \ell_3)$ and $B(\ell_1, \ell_4)$, respectively, that are incident to both trisector branches $T(\ell_1, \ell_3, \ell_4)_1$ and $T(\ell_1, \ell_3, \ell_4)_2$. However, such a pair of trisector branches does not exist, by Lemma 4 (items 2 and 3). Thus, one of e_1, e_2 is an NVD and the other is an FVD edge. Consequently, the face bounded by e_1 and e_2 lies in $\mathrm{VD}_2(L)$. ◀

▶ **Corollary 15.** *For any partial twist, the face bounded by the two trisector arcs incident to both vertices of the partial twist belongs to the order-2 Voronoi diagram $VD_2(L)$.*

We can now use Lemma 14 to prove Lemma 12.

Proof sketch of Lemma 12. Let (v_1, v_2) be a twist and assume that it is not partial nor full. If three trisector branches pass through v_1, v_2 consecutively, then the fourth trisector T_4, either (a) has two branches through v_1 and v_2, or (b) has a single branch through v_1 and v_2 but v_1, v_2 are not consecutive along this branch as otherwise (v_1, v_2) would create a full twist. In case (a) (Figure 7 left), by the pigeonhole principle, at least two of the three bounded edges incident to the twist both lie in NVD(L) or both lie in FVD(L). This contradicts Lemma 14. In case (b), consider a bisector containing T_4 together with any other trisector. Since trisector branches are unbounded and do not self-intersect, the number of vertices on T_4 between v_1 and v_2 must be even. The case with two such vertices is shown in Figure 7 right. We derive a contradiction by exploring faces on different bisectors. Additional cases might arise, e.g., two trisectors pass through v_1, v_2 consecutively and the other two have single branches passing through v_1, v_2 not consecutively. These are all ruled out by arguments analogous to case (b). ◀

Case (b) of the above proof shows that "nested full twists", as shown in Figure 7 right, are impossible. Consequently, full twists are either isolated or sequential.

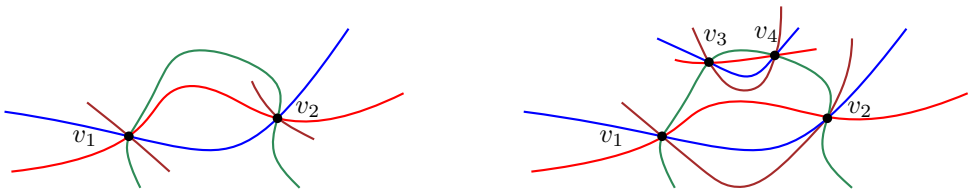

Figure 7 Left: a trisector system corresponding to (a) in the proof of Lemma 12. Right: two "nested full twists", corresponding to (b) in the proof of Lemma 12. Both are impossible.

▶ **Lemma 16.** *In* NVD(L) *(resp.* FVD(L)*), if there is a bounded face with exactly two edges and two vertices, then these vertices belong to a full twist.*

Proof sketch. If the two bounded edges both lie in NVD(L) (resp. FVD(L)), then each of the remaining two trisectors (other than those of the two edges) must have exactly one branch passing through the two vertices, by Lemma 14. If both remaining branches pass through the two vertices consecutively, then these vertices form a full twist. Otherwise, for at least one of the branches, there is an even number of vertices between the two vertices of the twist, which contradicts Lemma 12. ◀

Lemma 16 provides a concrete criterion to detect full twists by inspecting two projected trisectors (on a single bisector). It is used to classify Voronoi diagrams without full twists.

5 Identifying the Voronoi topologies by exhaustive search

In this section, we present an exhaustive search algorithm to classify the Voronoi diagram of four lines, assuming no full twists. To this end, we use the notion of a *configuration* as an abstraction for a projected bisector and the two relevant trisectors it contains.

We call a planar curve with four non-intersecting components *trisector-like*, if it satisfies the properties of the projected trisector of Lemma 4, in terms of the asymptotes and the middle trisector branch. Each trisector-like curve partitions the plane into faces, which we label as NVD or FVD according to Lemma 4, item 3. If a trisector-like curve is indeed the projected trisector of a set of three lines L, its faces are projections of $\mathrm{NVD}(L)$ and $\mathrm{FVD}(L)$.

We define a *configuration* on the plane as the overlay of two trisector-like curves. A configuration partitions the plane into faces, which we label as NVD, FVD, or VD_2. The faces labeled as NVD (resp. FVD) are the common intersections of the respectively labeled faces of the two trisector-like curves; any other face is labeled VD_2. A configuration is called *realizable* if there exist four lines L that define a bisector and two related trisectors whose projection has the same structure as the configuration. If a configuration is realizable, then the projected faces of $\mathrm{NVD}(L)$ (resp. $\mathrm{FVD}(L)$ and $\mathrm{VD}_2(L)$) on that bisector correspond exactly to the configuration faces labeled as NVD (resp. FVD and VD_2). For example, the configuration in Figure 8 right is realizable by the projected bisector and trisectors on the left.

Figure 8 Left: a real projected bisector with two projected trisectors on it. Right: a configuration. Green faces are NVD faces, orange faces are FVD faces, and white faces are VD_2 faces.

5.1 Properties of configurations

We give necessary conditions that restrict how trisectors and their asymptotes interact. These conditions rule out many unrealizable configurations. By Lemma 8, the map $\Gamma(\mathrm{NVD}(L))$ has 12 vertices that indicate the unbounded Voronoi edges.

▶ **Lemma 17.** *Given four lines L in general position, one of the following holds:*
1. *one trisector induces 6 vertices in $\Gamma(\mathrm{NVD}(L))$ and each other trisector induces 2;*
2. *one trisector induces 0 vertices in $\Gamma(\mathrm{NVD}(L))$ and each other trisector induces 4.*

Proof sketch. On a projected bisector, if there is an unbounded face in the positive x-direction, then there is also an unbounded face in the negative x-direction. These faces have two unbounded edges in each direction, which induce 4 vertices in $\Gamma(\mathrm{NVD}(L))$. If there are no such unbounded faces, then there are 0 vertices. The same holds for the y-directions. Hence, on one bisector, the two related trisectors together contribute 0, 4, or 8 vertices to $\Gamma(\mathrm{NVD}(L))$. The lemma follows by considering all six bisectors combined. ◀

A bisector is called an (i, j)-bisector if the two trisectors it contains induce i and j vertices in $\Gamma(\mathrm{NVD}(L))$. As a corollary of Lemma 17, we obtain the following classification of bisectors.

▶ **Corollary 18.** *Given four lines L in general position, one of the following holds:*
1. *there are three $(2,2)$-bisectors and three $(2,6)$-bisectors (with respect to $\Gamma(\mathrm{NVD}(L))$);*
2. *there are three $(0,4)$-bisectors and three $(4,4)$-bisectors (with respect to $\Gamma(\mathrm{NVD}(L))$).*

▶ **Lemma 19.** *Consider a bisector with two projected trisectors T_i, T_j. Let x_i^-, x_i^+ $(x_i^- < x_i^+)$ (resp. y_i^-, y_i^+) be the two vertical (resp. horizontal) asymptotes of T_i; analogously for T_j. It is impossible that simultaneously $x_i^- < x_j^- < x_j^+ < x_i^+$ and $y_j^- < y_i^- < y_i^+ < y_j^+$.*

Proof sketch. By Lemma 5, we express the asymptotes of the projected trisector $T(\ell_1, \ell_2, \ell_i)$ in the parameters a, d_i, e_i. Similarly for $T(\ell_1, \ell_2, \ell_j)$. We translate the given relation to a system of inequalities in the parameters and show that the system is infeasible. ◀

Figure 9 Left: a $(0,8)$-bisector, impossible by Corollary 18. Right: impossible by Lemma 19.

We apply Corollary 18 and Lemma 19 to filter out unrealizable configurations such as those illustrated in Figure 9. We say that two related trisectors (on a bisector) are *parallel* (denoted "$\cdot \parallel \cdot$"), if they are both x-monotone or both y-monotone; otherwise, they are not parallel ("$\cdot \nparallel \cdot$"). Parallelism of trisectors is transitive. The following is used as a filter in Section 5.2.

▶ **Lemma 20.** *For any three pairwise related trisectors T_i, T_j, T_k, if $T_i \parallel T_j$ and $T_j \parallel T_k$, then $T_i \parallel T_k$; if $T_i \nparallel T_j$ and $T_j \nparallel T_k$, then $T_i \parallel T_k$; see Figure 10.*

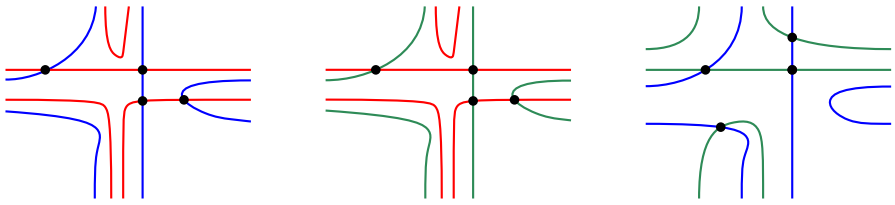

Figure 10 Three bisectors and trisectors; $T(\ell_1, \ell_2, \ell_3)$ is red, $T(\ell_1, \ell_2, \ell_4)$ is blue, $T(\ell_1, \ell_3, \ell_4)$ is green. They are not realizable by Lemma 20.

Next, we consider 6-*tuples of configurations*, where each configuration corresponds to one bisector associated with four lines. A configuration tuple is realizable if and only if there exists a set of four lines that realizes every configuration in the tuple. In a realizable 6-tuple, each trisector-like curve (12 in total) represents a trisector $T(\ell_i, \ell_j, \ell_k)$ whose representation must be consistent with all the elementary properties listed in Section 2 and Lemma 4 (by viewing a configuration as a bisector and a trisector-like curve as a trisector). Note that there are exactly three trisector-like curves that represent $T(\ell_1, \ell_2, \ell_3)$, and they lie on the configurations of $B(\ell_1, \ell_2)$, $B(\ell_1, \ell_3)$, and $B(\ell_2, \ell_3)$.

5.2 A search algorithm, proving Theorems 1 and 2

To classify the topology of the Voronoi diagram of four lines without full twists, we use the following exhaustive search algorithm.

Phase 1: Generate configurations. We generate all configurations with at most 8 vertices, excluding those that lead to full twists. Phase 1 works in two steps. In Step 1, we generate simple configurations that have no twists. By Lemma 4, such a configuration is uniquely determined by the asymptotes and the choice of the middle branches. We construct the simple configurations by enumerating all asymptote arrangements and all choices of middle branches of the two trisector-like curves. We label the faces of each configuration as described above. In Step 2, we add twists to simple configurations, as many as possible, provided that the number of resulting vertices is at most 8. To add a twist, we select two configuration edges that bound an existing face, fix their endpoints, and intersect their interior twice more. To avoid creating full twists, we only consider edge pairs incident to a face with label VD_2 (see Figure 11 (a)-(b)). This is sufficient because intersecting any other pair of edges produces a full twist, as shown in the proof of Theorem 1.

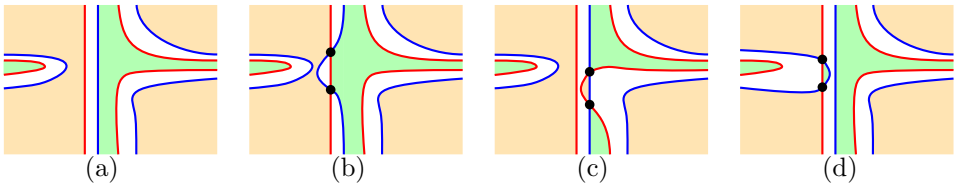

Figure 11 (a) A simple configuration. Faces labeled NVD (resp. FVD) are shown in green (resp. orange). (b) Add a twist by intersecting two edges bounding a VD_2 face (in white). (c), (d) Add a twist by intersecting two edges bounding an NVD or FVD face; both lead to a full twist.

Phase 2: Filter out configurations. We filter out any configurations of Phase 1 that are not realizable by applying filters derived from Corollary 18 and Lemma 19.

Phase 3: Filter out unrealizable configuration tuples. We generate all possible configuration 6-tuples from the configurations that remain at the end of Phase 2. We filter out unrealizable tuples by applying filters derived from the elementary properties of Section 2, Corollary 18, Lemma 20, , and Theorem 9, and obtain the set $\mathcal{P}$ of configuration tuples that survive these filters. Since the search space is large, we implement the filters in a program [22], which outputs 15 remaining configuration tuples at the end of Phase 3.

Each surviving configuration tuple in $\mathcal{P}$ can be realized by a set of four lines. It corresponds to a unique Voronoi diagram topology, as shown in the proof of Theorem 1. Then, straightforward inspection of the tuples and their topologies reveals the following properties.

▶ **Observation 21.** *Assuming no full twists, the following hold for* $\mathrm{NVD}(L)$ *and* $\mathrm{FVD}(L)$.

1. *Topologies with 0 or 2 vertices have no partial twists in their trisector system.*
2. *Topologies with 4 or more vertices have at least one partial twist.*
3. *No topology has 8 vertices; hence 8 Voronoi vertices require the presence of full twists.*
4. *The 2D faces of both* $\mathrm{NVD}(L)$ *and* $\mathrm{FVD}(L)$ *are all unbounded.*
5. *Each distinct* FVD *topology has a distinct map of unbounded features* $\Gamma(\mathrm{FVD}(L))$.
6. *There are only two distinct maps* $\Gamma(\mathrm{NVD}(L))$, *each corresponding to a case of Lemma 17.*

7. *A partial twist involves at least two middle trisector branches, each incident to exactly one vertex of the partial twist.*
8. *The 1-skeleton of* NVD(L) *has a single connected component that contains all vertices. This does not hold for* FVD(L).
9. *The edges of* FVD(L) *are unbounded except those incident to both vertices of a partial twist.*

Proof sketch of Theorem 1. We first argue that Phase 1 generates all possible configurations that do not induce full twists. Step 1 generates all simple configurations without twists. In Step 2, consider two arbitrary edges e_1, e_2 in a simple configuration. If e_1 and e_2 are incident to a common face labeled NVD (resp. FVD), then intersecting them twice creates a bounded face with two vertices labeled FVD (resp. NVD), see Figure 11 (c) and (d). By Lemma 16 such a face yields a full twist.

Assume now that e_1 and e_2 are not incident to a common configuration face. To intersect them, there must be at least one intermediate edge e_3 such that we first intersect e_1 and e_3 twice, after which e_1 and e_2 may become adjacent so that they can intersect. But the double intersections between e_1 and e_3 are no longer consecutive along e_1, so there is only one twist possible, namely the twist between e_1 and e_2 after they become adjacent. By a generalization of Lemma 16, the twist between e_1 and e_2 is a full twist. The case of more than one intermediate edge between e_1 and e_2 can be handled analogously. Hence, Step 2 correctly considers edges that are only incident to faces labeled VD_2, and these are enough to generate all relevant configurations.

Phases 2 and 3 use filters derived from necessary conditions of the diagrams that have already been proved. Thus, the output set $\mathcal{P}$ of Phase 3 contains every configuration tuple that may be realizable. Examples verify that the configuration tuples in $\mathcal{P}$ are realizable.

Each configuration tuple fixes the vertices, edges, and faces of all six configurations. The features with label NVD glue together uniquely, since the 2-skeleton of the Voronoi diagram of lines is connected. Analogously for the features with label FVD. Thus, there are at most 15 possible topologies for each of NVD(L) and FVD(L), which are in one-to-one correspondence with the configuration 6-tuples, and thus they are in one-to-one correspondence to each other. The correspondence naturally extends to $\mathrm{VD}_2(L)$. The remaining assertions of the theorem follow from inspecting the 15 configuration tuples. This completes the proof. ◀

As already mentioned, all configuration tuples that survive Phase 3 are realizable. This is crucial for the proof of Theorem 2, and further implies that the necessary conditions of the filters are also sufficient.

Proof sketch of Theorem 2. Consider four lines and their four trisectors. If there are no full twists in the trisector system, then the Voronoi diagram falls into one of the 15 topologies of Theorem 1. Assume that there are some full twists; by Lemma 12 they cannot be nested. Any full twist can be removed locally by the reverse local modification described in Section 4.1. Furthermore, if a configuration tuple satisfies the filters of the exhaustive search algorithm, then the configuration tuple derived after the removal of a full twist also does. Hence, the resulting configuration tuple, after removing all full twists, is one of the 15 configuration tuples in $\mathcal{P}$, all of which are realizable. This completes the proof. ◀

6 Examples and concluding remarks

Example 1: Voronoi diagram of four lines with 0 vertices. Assuming that there are 0 vertices, there are only two configurations (type (a) and type (b)) that satisfy Corollary 18 and Lemma 19; see Figure 12. Only one 6-tuple of configurations satisfies Corollary 18: three configurations of type (a) and three of type (b).

type (a) type (b)

Figure 12 Two configurations with 0 vertices. Faces with label NVD, FVD, and VD_2 are in green, orange, and white, respectively. Type (a) gives a $(2,6)$-bisector and type (b) gives a $(2,2)$-bisector.

An NVD example is shown in Figure 13 left. Of the four Voronoi regions, one is an unbounded triangular prism with three side faces (the region of the orange line in Figure 13 left); the other three have identical structure, which is schematically illustrated in Figure 13 right. The farthest Voronoi diagram is depicted schematically in Figure 15 left.

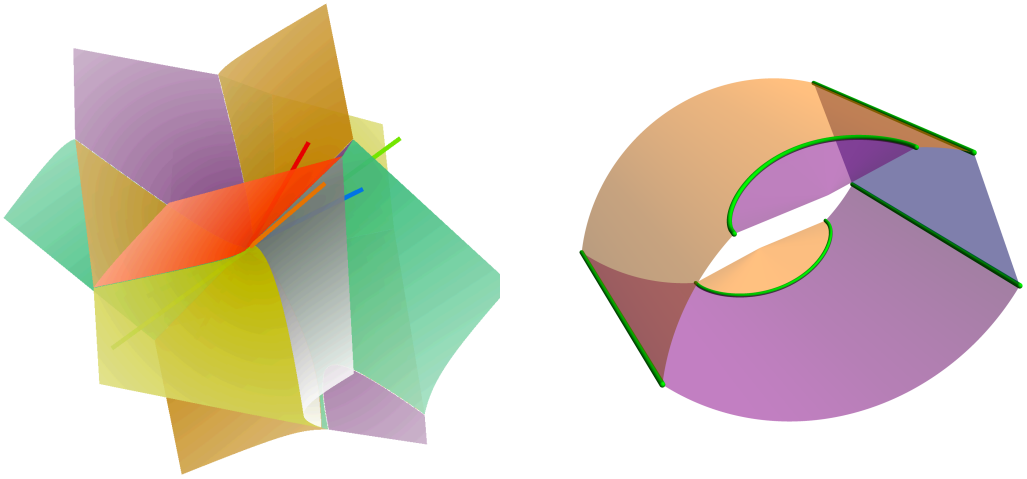

Figure 13 Left: NVD(L) with 0 vertices, faces in the same color are from the same bisector. Right: schematic illustration of a Voronoi region of NVD(L). Compare this with a region in the Voronoi diagram of three lines shown in Figure 6 middle.

Example 2: Voronoi diagram of four lines with 6 vertices. We show an example where the 6-tuple of configurations is symmetric: it consists of three configurations of type (c) and three of type (d), shown in Figure 14. The FVD is shown schematically in Figure 15 right.

Our classification results yield an algebraically simple method to compute the structure of the Voronoi diagram of four lines. We start by computing the Gaussian map of FVD(L) [5], which is simple algebraically. We then extract $\Gamma(\text{FVD}(L))$ by a minor adjustment (concerning the so-called vertices of anomaly of [5]). From $\Gamma(\text{FVD}(L))$, we can directly identify the matching base topologies of NVD(L) and FVD(L). Next, we decide if full twists exist by comparing the number of vertices in the base topology with the number of projected trisector intersections. The latter equals the number of real roots of a degree 8 univariate polynomial, which we compute via Sturm's theorem. If equal, there are no full twists, and the base topology provides the answer; otherwise, we need to locate the full twists. To this end, we derive the real configurations of each bisector (by applying the separation of four branches of

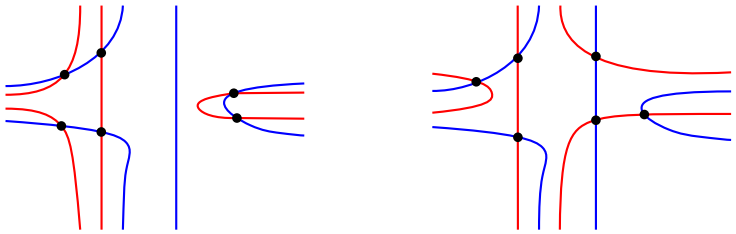

Figure 14 Two configuration types involved in Example 2.

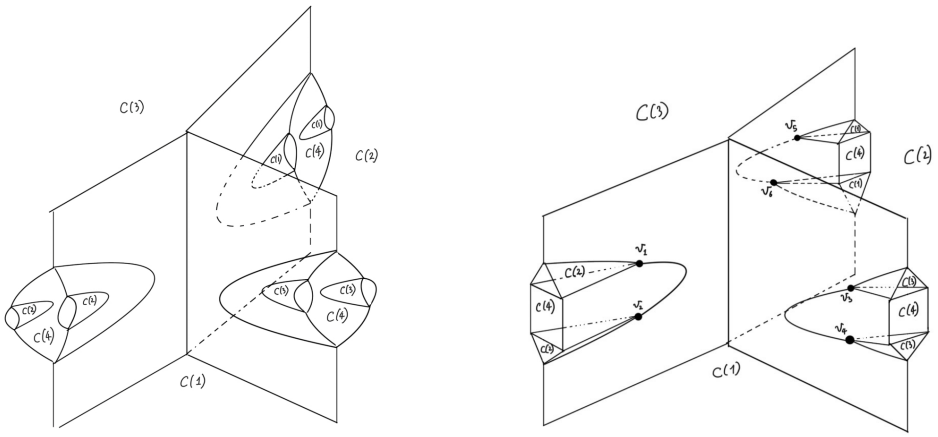

Figure 15 Left: schematic of the FVD(L) with 0 vertices. Right: schematic of the FVD(L) with 6 vertices of Example 2. Each label $C(i)$ denotes a cell in the farthest region of ℓ_i.

a trisector given in [12] to obtain (1) the corresponding simple configurations as in Phase 1, and (2) the number of intersections between all pairs of trisector branches). We compare with the configurations of the base topology, revealing the vertices of full twists, and add them to the base topology via the local modification. All operations can be done in low algebraic degrees, the most expensive being the location of full twists (whose degree is in the range of 8).

In conclusion, we have obtained a complete characterization of Voronoi diagrams of four lines in general position in $\mathbb{R}^3$. This offers a concrete foundation for future research on the Voronoi diagrams of n lines.

Abstract

The Optimal Morse Matching (OMM) problem asks for a discrete gradient vector field on a simplicial complex that minimizes the number of critical simplices. It is NP-hard and has been studied extensively in heuristic, approximation, and parameterized complexity settings. Parameterized by treewidth k, OMM has long been known to be solvable on triangulations of 3-manifolds in $2^{O(k^2)}n^{O(1)}$ time and in FPT time for triangulations of arbitrary manifolds, but the exact dependence on k has remained an open question. We resolve this by giving a new $2^{O(k \log k)}n$-time algorithm for any finite regular CW complex, and show that no $2^{o(k \log k)}n^{O(1)}$-time algorithm exists unless the Exponential Time Hypothesis (ETH) fails.

1 Introduction

Classical Morse theory [37] and its discrete counterpart [21, 22] provide a framework for simplifying spaces while preserving their essential topological features (see Figure 1). They do so by relating scalar functions to gradient flows in the smooth setting and discrete Morse functions to discrete gradient vector fields (Morse matchings) in the combinatorial setting. Much of the computational work on discrete Morse theory has focused on the matching perspective [32, 34, 40, 27, 1, 23], with the pioneering work on treewidth in computational topology [12] being no exception. At first sight, this close relationship suggests that the two formulations are interchangeable. In reality, they form diverging roads in the algorithmic landscape; let us follow the one less traveled by.

Morse theory has applications in topological data analysis and computational topology [27, 2, 33, 38, 23, 16], robotics and configuration spaces [20, 24], molecular modeling [14], and mesh and image processing [35, 18]. A recurring primitive in these works is to construct a discrete gradient vector field, also known as a Morse matching, with few critical simplices, yielding strong homotopy-preserving simplifications. Intuitively, such a field is a discrete

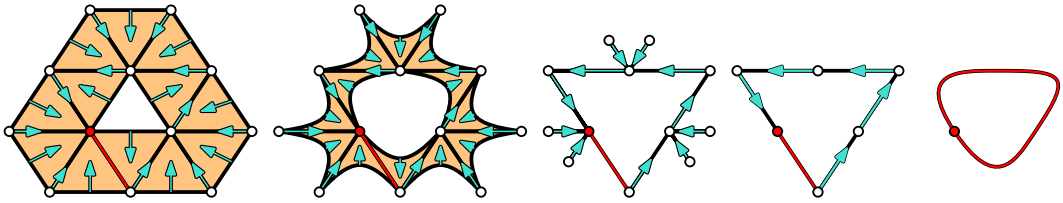

Figure 1 Discrete Morse theory can simplify a space while preserving its homotopy type.

vector field without "swirls": there are no loops in the flow lines, so one can contract the space along them without changing the homotopy type. Combinatorially, such a field corresponds to a matching in the Hasse diagram of the complex such that reversing the matched edges does not create any directed cycles. This motivates the Optimal Morse Matching (OMM) problem, also known as Min-/Max-Morse Matching, depending on whether the objective is to minimize the number of critical simplices or maximize the number of matched pairs:

▶ **Problem 1** (Optimal Morse Matching (OMM)).

Input: A finite simplicial complex K and a weight function $\omega : K \to \mathbb{R}_{\geq 0}$.
Task: Find a discrete gradient vector field W on K.
Optimize: Minimize the total weight of critical (i.e., unmatched) simplices.

From a computational complexity perspective, OMM and closely related variants are highly intractable: they are NP-hard [32], admit strong classical inapproximability bounds [3], and are linked to other hard topological decision problems such as Collapsibility [42, 36], Erasibility of 2-complexes [12, 3], and Shellability [25]. Algorithmic work includes approximation algorithms for Max-Morse Matching [40] and a variety of heuristic and workflow-based methods for practical simplification [2, 34, 27, 23, 1]. On the parameterized side, using the optimum number of critical simplices as parameter, Erasability and Min-Morse Matching are W[P]-hard and admit no FPT approximation schemes [12, 4].

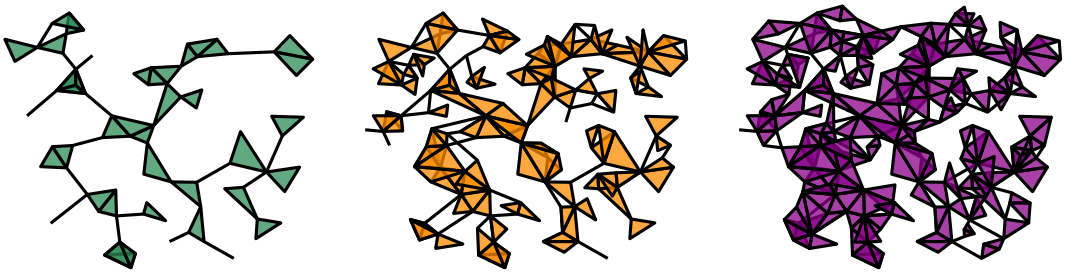

Figure 2 Three spaces from left to right, all of relatively low (but increasing) treewidth.

To circumvent these complexity barriers we turn to treewidth, which intuitively measures how close a combinatorial object is to being a tree; see Figure 2. An early systematic use of treewidth in discrete Morse theory is the fixed-parameter algorithm of [12] for OMM, which runs in time $2^{O(t^2)}n^{O(1)}$ when parameterized by the treewidth t of an associated spine graph for 2-complexes, and by the treewidth of either the spine graph or the dual graph for triangulated 3-manifolds. This was complemented by a Courcelle-style metatheorem for MSO-definable properties on triangulations [11], which yields fixed-parameter tractability for OMM on triangulated manifolds of fixed dimension when parameterized by the treewidth of

the dual graph. Since then, treewidth has become central in computational topology, leading to FPT algorithms for a range of NP-hard topological problems and invariants [10, 13, 6], ETH-tight lower bounds for several of these problems [8, 5, 7, 43], and detailed studies of the width of triangulated 3-manifolds [30, 28, 29].

▶ Remark 2. Across the literature, "treewidth k" is measured on different associated graphs (dual graphs, spine graphs, Hasse diagrams), chosen to suit the problem at hand. For fixed dimension, [11] shows that the treewidth of the Hasse diagram of a triangulation is bounded by a constant factor times the treewidth of its dual graph, and [12] shows that in dimension 3 the spine treewidth is likewise linearly bounded in terms of the dual treewidth. Thus, for fixed dimension these parameters coincide up to constant factors hidden in the $O(\cdot)$-notation. In this paper we simply write "treewidth k" and, in practice, work with the Hasse diagram.

1.1 Contributions

Algorithmic. We give an explicit dynamic program (DP) for a digraph formulation of Optimal Morse Matching parameterized by treewidth k, which in particular solves OMM on all finite regular CW complexes of treewidth k. It runs in time $2^{O(k \log k)}n$, thereby extending and improving both the earlier explicit treewidth-based algorithms for 2-complexes and triangulated 3-manifolds with running time $2^{O(k^2)}n^{O(1)}$ [12] and the implicit MSO-based algorithm for triangulated manifolds in [11]. The simple invariant and state space allowed us to implement the algorithm and verify it on small instances by exhaustive search.

Optimality. Under ETH, our running time is optimal: using a known treewidth-based lower bound for Directed Feedback Vertex Set (DFVS), we show that there is no $2^{o(k \log k)}n^{O(1)}$-time algorithm for Optimal Morse Matching parameterized by treewidth k, even on 2-dimensional complexes of top coface degree at most 4. This follows from a new polynomial-time reduction from DFVS to Erasability, to which we apply the recent Width Preserving Strategy (WiPS) framework of [43] to ensure that treewidth is preserved. Combined with the standard equivalence between Erasability and OMM on 2-dimensional complexes, this yields the ETH-tight $2^{\Theta(k \log k)}$ dependence.

Conceptual. Our order-based formulation (Feedback Morse Order) shows that working indirectly with vertex orders rather than directly with matchings captures exactly what a treewidth DP for OMM needs to remember. This ordering viewpoint transfers to Alternating Cycle-Free/Uniquely Restricted Matchings (AC-FM/URM) on bipartite graphs, but the connection breaks on general graphs. Here, AC-FM and URM still only admit $2^{\Theta(k^2)}n^{O(1)}$-time algorithms and lack tight-ETH lower bounds. We therefore point to AC-FM and URM as natural candidates for genuinely $2^{\Theta(k^2)}$-time problems in treewidth and as targets for either $2^{O(k \log k)}n$-time algorithms or matching $2^{o(k^2)}n^{O(1)}$ lower bounds.

▶ Remark 3. Some proofs of correctness, running-time analyses, and additional details are deferred to the full version [39].

2 Preliminaries

We use standard terminology from parameterized complexity [19, 17] and discrete Morse theory [21, 22, 41]. We write n for the input size; for OMM, n is the number of cells of the complex, which equals the number of vertices of its Hasse diagram.

2.1 Parameterized complexity theory

Treewidth and nice tree decompositions. When we speak of the treewidth of a digraph or a complex, we mean the treewidth of the natural underlying undirected graph in the first case, and of the Hasse diagram in the second. Informally, treewidth measures how close a graph is to being a tree (see also Figure 2): we cover the graph by overlapping bags of vertices arranged in a tree so that each edge lies entirely inside some bag and the bags containing any fixed vertex form a connected subtree; the width is one less than the size of the largest bag, and the treewidth k is the minimum width over all such decompositions; this k will be our parameter throughout the paper. Such decompositions let us localize global constraints: a dynamic program only needs to maintain partial solutions on a bag of size $k+1$ and combine them along the tree, so we can brute-force over states per bag rather than over the whole graph and obtain running times of the form $f(k)\,n^{O(1)}$. We use rooted nice tree decompositions; unless stated otherwise, we fix an arbitrary root bag and process the decomposition bottom–up. Formal definitions are given in the full version [39, App. A.1]. In this paper we work with the standard nice node types (leaf, introduce-vertex, forget-vertex, and join), and we also use auxiliary *introduce-edge* bags: unary nodes whose bag is identical to that of their child and that are annotated with a single edge uv in the bag, marking the point where that edge is processed in the dynamic program or reduction. This is a standard refinement that preserves width.

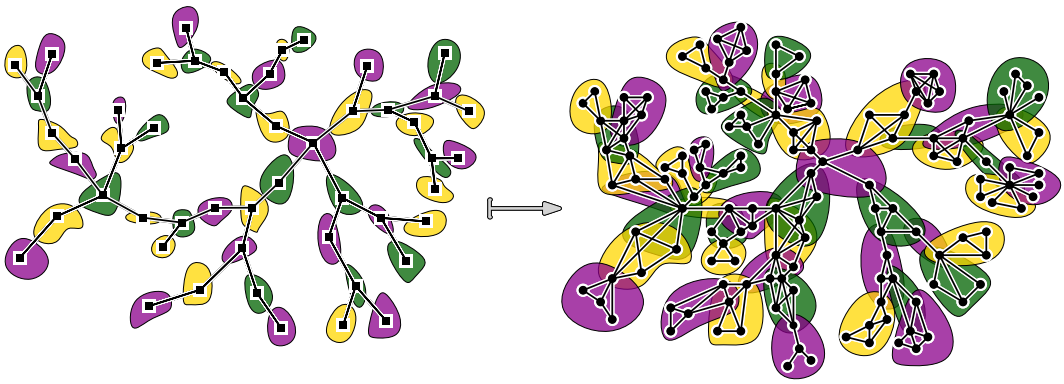

Figure 3 A graph G (right) and a tree decomposition T (left). Each node of T carries a bag $X_t \subseteq V(G)$, drawn as a blob containing vertices of G. Adjacent bags overlap so that every vertex and every edge of G is covered.

FPT and ETH. A parameterized problem with parameter k is *fixed-parameter tractable* (FPT) if it can be solved in time $f(k)\,n^{O(1)}$ for some computable function f; such running times are considered efficient when k is small compared to n, since the combinatorial explosion is confined to $f(k)$ while the dependence on the input size remains polynomial. For conditional lower bounds we assume the *Exponential Time Hypothesis* (ETH) [31], which states that 3-SAT on n variables cannot be solved in time $2^{o(n)}$; ETH is a strengthening of P $\neq$ NP that has withstood decades of algorithmic progress and underpins many tight running-time lower bounds. Our hardness source is Directed Feedback Vertex Set parameterized by the treewidth k of the underlying undirected graph of the input digraph D, where a *feedback vertex set* in a digraph $D = (V, E)$ is a set $J \subseteq V$ such that $D \setminus J$ is acyclic.

▶ **Problem 4** (Directed Feedback Vertex Set (DFVS)).

Input: A directed graph $D = (V, E)$ and an integer s.
Question: Does D contain a feedback vertex set of size at most s?

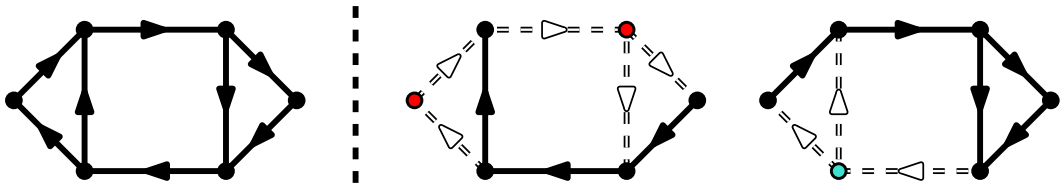

Figure 4 An instance of DFVS, a valid solution of size 2 and an optimal solution of size 1.

▶ **Theorem 5** (Bonamy et al. [9]). *Unless ETH fails,* DFVS *parameterized by the treewidth k of the underlying undirected graph of the input digraph cannot be solved in $2^{o(k \log k)} n^{O(1)}$-time.*

2.2 Discrete Morse theory

Complexes and Hasse diagrams. We use the standard notions of finite regular CW complexes and discrete Morse theory in the sense of Forman [21], and keep the topological preliminaries brief. Face relations are given by closure containment, so the face poset and its directed Hasse diagram encode the incidence data we use. We write $\overrightarrow{H}(X)$ for the directed Hasse diagram of a complex X; it has one vertex per cell and an arc $\sigma \to \tau$ whenever σ is an immediate face of τ (a cover relation in the face poset), and hence $\dim(\tau) = \dim(\sigma) + 1$. Let $H(X)$ be the underlying undirected graph; we measure treewidth on $H(X)$, denoted k. Simplicial complexes are the special case where cells are simplices (points, lines, triangles, tetrahedra, etc.); we use them in figures and in our reduction.

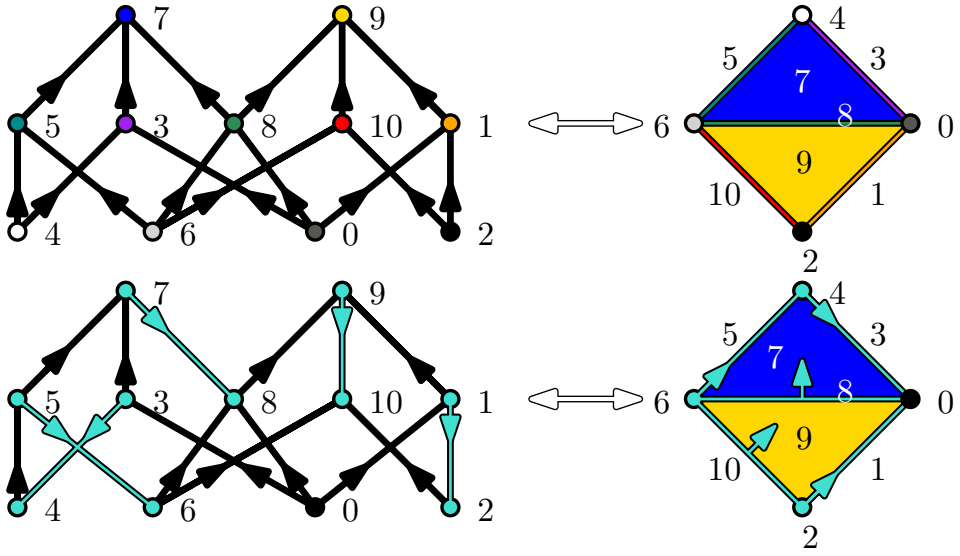

Figure 5 A discrete Morse function (top) on the Hasse diagram of a simplicial complex (left) and its geometric realization (right). Below, the induced discrete gradient vector field (Morse matching) is shown both on the Hasse diagram (left) and geometrically as a gradient vector field (right).

Discrete Morse theory on complexes. Forman's discrete Morse theory can be phrased entirely in terms of matchings on the Hasse diagram $\overrightarrow{H}(X)$ of a finite regular CW complex X. A *discrete vector field* is a matching W on $\overrightarrow{H}(X)$, i.e. a set of pairs (σ, τ) with $\sigma \to \tau$ an arc of $\overrightarrow{H}(X)$ such that each cell appears in at most one pair. From W we obtain a new

digraph $\overrightarrow{H}(X)_W$ by reversing exactly the matched arcs and leaving all others unchanged; if $\overrightarrow{H}(X)_W$ is acyclic, then W is a *discrete gradient vector field*. Forman's correspondence states that (i) every discrete Morse function on X induces such a gradient vector field, and (ii) conversely, every discrete gradient vector field arises from some discrete Morse function; in both directions, the unmatched cells in W are precisely the critical cells of the corresponding Morse function. Collapsing X along the gradient flow yields a smaller Morse complex (see Figure 1) that is homotopy equivalent to X and can make downstream topological computations much cheaper. The Optimal Morse Matching problem (Problem 1) asks for a discrete gradient vector field minimizing the total weight of these unmatched cells.

Erasibility in 2D. For our lower bound we use the notion of *erasibility* of 2-dimensional simplicial complexes K. A 1-simplex (edge) e is *free* if it is contained in exactly one 2-simplex τ, and removing e together with τ is an *elementary collapse*. A 2-simplex is *erasible* if it can be removed through a sequence of elementary collapses, and K is *erasible* if every 2-simplex can be eliminated in this way, that is, if K collapses to a 1-dimensional complex.

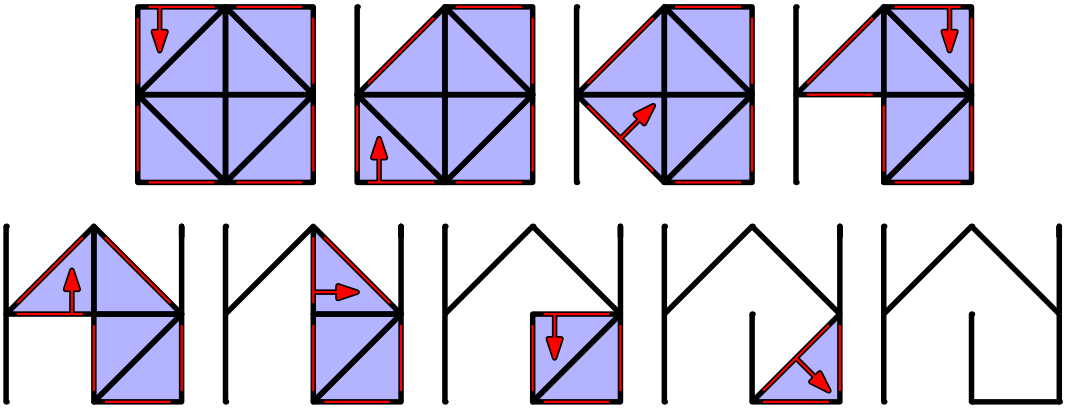

Figure 6 A triangulation of a square that is erasible with $S = \emptyset$: free edges are marked in red and elementary collapses by arrows. In contrast, a triangulation of a sphere has no free edges, so any erasibility requires $|S| > 0$.

▶ **Problem 6** (Erasibility).

Input: A 2-dimensional simplicial complex K and an integer $B \geq 0$.
Question: Is there a set S of 2-simplices in K such that $|S| \leq B$ and $K \setminus S$ is erasible?

▶ **Theorem 7** (Folklore; cf. [21, 32, 3]). *For finite 2-dimensional simplicial complexes,* Erasibility *and* Optimal Morse Matching *are computationally equivalent.*

3 Algorithm

We give a fixed-parameter algorithm for Feedback Morse Matching, a digraph generalization of Optimal Morse Matching, on digraphs whose underlying undirected graph has treewidth k. The algorithm rests on three ingredients: (i) we work in the general setting of arbitrary digraphs rather than Hasse diagrams only; (ii) we adopt the Morse-function viewpoint and encode solutions as vertex orders (Feedback Morse Orders) instead of matchings; and (iii) this yields a very simple dynamic program whose state at each bag

consists only of an order on the bag and a subset of its vertices. This order–mask formulation avoids the more involved connectivity machinery of previous approaches and leads to a running time of $2^{O(k \log k)}n$.

3.1 Of feedback Morse matchings and feedback Morse orders

Generalizing OMM to digraphs. For our algorithmic purposes it is convenient to generalize the matching viewpoint from Hasse diagrams to arbitrary digraphs, and to allow both positive and negative weights. Given a digraph $D = (V, E)$ and a matching $M \subseteq E$, let D_M be the digraph obtained by reversing every edge of M and leaving all other edges unchanged; we call M a *feedback Morse matching* if D_M is acyclic. In the resulting Feedback Morse Matching (FMM) problem (Problem 8), the input is a digraph D and a weight function $\omega : V(D) \to \mathbb{R}$, and the task is to find a feedback Morse matching minimizing the total weight of unmatched vertices. When D is the Hasse diagram $\overrightarrow{H}(K)$ of a simplicial complex K and $V(D)$ is identified with the simplices of K, discrete gradient vector fields on K are exactly feedback Morse matchings on D. Thus OMM is the special case of FMM where D comes from a complex and ω is nonnegative; in the classical unweighted case $\omega \equiv 1$, the objective is simply the number of critical simplices [32, 3]. Mixed-sign weights in this framework allow one to favour or penalize particular cells (useful for extending a Morse Matching), while the purely negative-weight variant (e.g. $\omega \equiv -1$) on general digraphs corresponds to finding a smallest feedback Morse matching, that is, a minimum-size matching whose reversals destroy all directed cycles in D.

▶ **Problem 8** (Feedback Morse Matching (FMM)).

Input: A finite directed graph $D = (V, E)$ and a weight function $\omega : V(D) \to \mathbb{R}$.
Question: Find a feedback Morse matching $M \subseteq E(D)$ that minimizes the total weight of unmatched vertices.

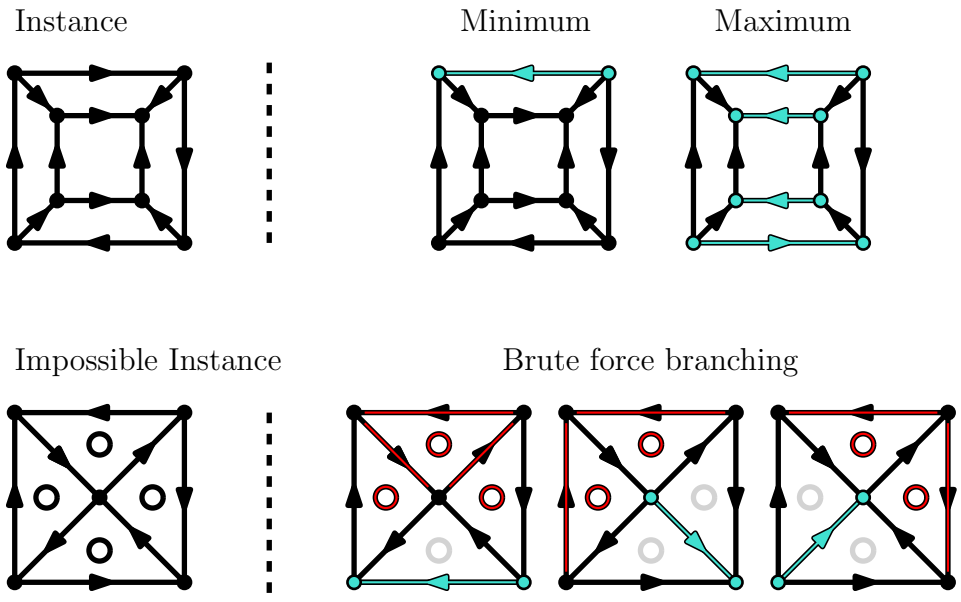

Figure 7 Feedback Morse matchings on digraphs. Top: an instance that admits feedback Morse matchings; two optimal solutions to FMM are shown. Bottom: an instance with no feedback Morse matching.

▶ **Theorem 9.** *Let $D = (V, E)$ be a digraph whose underlying undirected graph has treewidth k, and let $n := |V(D)|$. Given vertex weights $\omega : V \to \mathbb{R}$,* Feedback Morse Matching *on (D, ω) can be solved in time $2^{O(k \log k)} n$.*

Shifting from matchings to orders. As committed procrastinators, we now do our best to avoid thinking about matchings. Instead, we turn to vertex orders. Let $\pi = (v_1, \ldots, v_n)$ be a total order of V. An edge $(u, v) \in E$ is *backward* with respect to π if v appears before u in π, and let $M(\pi) := \{(u, v) \in E : (u, v)$ is backward w.r.t. $\pi\}$ be the set of backward edges. Once π is fixed, the set of edges to reverse is determined: we always take $M(\pi)$ and reverse exactly these edges. We call π a *feedback Morse order* if $M(\pi)$ is a matching (no two edges in $M(\pi)$ share a vertex).

▶ **Problem 10** (Feedback Morse Order (FMO))**.**

Input: A digraph $D = (V, E)$ and a weight function $\omega : V \to \mathbb{R}$.

Question: Find a feedback Morse order π that minimizes the total weight of vertices that are unmatched in $M(\pi)$.

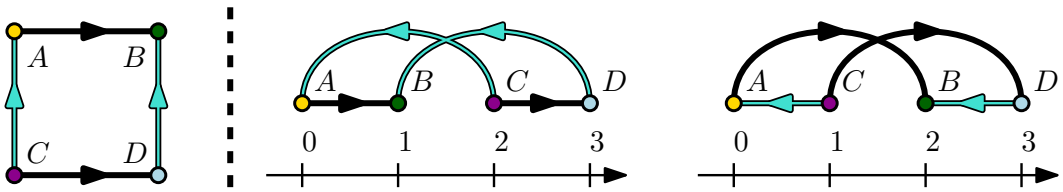

Figure 8 Two feedback Morse orders of the same digraph, drawn as permutations of the vertices. In both orders, the same set of backward edges (highlighted) forms a feedback Morse matching M, showing that one matching may admit many compatible orders; other orders can yield different backward-edge sets (and different matchings), or even no matching at all. For example, $D \prec C \prec B \prec A$ induces the other optimal matching $\{A \to B, C \to D\}$, $C \prec D \prec B \prec A$ induces only $\{A \to B\}$, and $A \prec D \prec C \prec B$ has backward edges $C \to A$ and $D \to C$, which is not a matching.

▶ **Lemma 11** (Matchings vs. orders)**.** *Let $D = (V, E)$ be a digraph. If π is a feedback Morse order, then $M(\pi)$ is a feedback Morse matching on D. Conversely, if M is a feedback Morse matching on D, then there exists a feedback Morse order π with $M(\pi) = M$.*

Proof. For any order π, reversing all backward edges makes every edge point forward along π, so reversing all backward edges yields an acyclic digraph; if $M(\pi)$ is a matching, it is a feedback Morse matching. Conversely, if M is a feedback Morse matching, then D_M is acyclic, and any topological order π of D_M satisfies $M(\pi) = M$. ◀

A Forman correspondence. By Lemma 11, FMO and FMM are equivalent optimization problems: every optimal feedback Morse order induces an optimal feedback Morse matching and vice versa, so in what follows we work entirely with the order-based formulation.

3.2 R-FMO: The boundary subproblem on bags

Orders and masks on bags. We run our dynamic program over a rooted nice tree decomposition of the underlying undirected graph of D, refined with introduce-edge bags as in Section 2. For a bag t let X_t be its vertex set, T_t the subtree rooted at t, W_t the vertices

appearing in bags of T_t, and G_t the subgraph on W_t whose edges are exactly those whose introduce-edge bags lie in T_t. Intuitively, G_t is the part of the graph already processed when we are at t, and X_t is its boundary. A global feedback Morse order π on D restricts at t to a total order g on X_t and a set $U \subseteq X_t$ of boundary vertices already matched inside G_t; we view U as a mask on X_t, marking which boundary vertices are already matched. This leads to the following boundary subproblem.

▶ **Problem 12** (Restricted Feedback Morse Order (R-FMO)).

Input: A digraph $G = (W, E')$ with vertex weights $\omega : W \to \mathbb{R}$, a boundary set $X \subseteq W$, a total order g of X, and a subset $U \subseteq X$.

Question: Among all feedback Morse orders π on G with $\pi|_X = g$ and $V(M(\pi)) \cap X = U$, minimize $\sum_{v \in W \setminus X : v \notin V(M(\pi))} \omega(v)$; if no such π exists, the optimum is defined as $+\infty$.

The global optimum of FMO (and hence of FMM) is the value of an R-FMO instance at the root bag, whose boundary is empty; in particular, every state in our dynamic program will consist of an order on the bag together with a mask of matched boundary vertices.

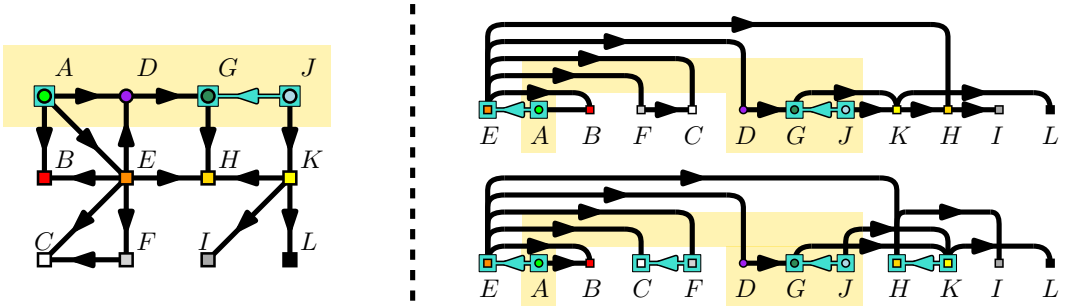

Figure 9 An instance of a Restricted Feedback Morse Order (R-FMO) subproblem (left), together with two feasible solutions (right): two different feedback Morse orders on the same instance (top and bottom) inducing different sets of matched and unmatched vertices.

3.3 Dynamic program on a tree decomposition

We now describe the dynamic program at a high level. Full recurrences and a formal DP invariant are presented in [39, App. A]. For each bag t and each state (g, U) on X_t as above, we maintain a table entry $c[t, g, U]$, defined as the optimum of the R-FMO instance (G_t, X_t, g, U), that is, the minimum total weight of unmatched vertices in $W_t \setminus X_t$ over all feedback Morse orders on G_t compatible with (g, U); if no such order exists, we set $c[t, g, U] = +\infty$. Figure 10 illustrates how such states are propagated along a tree decomposition and how locally invalid states are discarded. We process the nice tree decomposition bottom–up. At each bag type we update the table using only local information.

Leaf. The processed subgraph is empty, so there is a single state with empty order and empty matched set, and cost 0.

Introduce-vertex. A new vertex v enters the bag (and the graph) with no incident edges yet. It cannot already be matched, so $v \in U$ is forbidden. Otherwise we extend the order g by inserting v at its chosen position; the cost does not change.

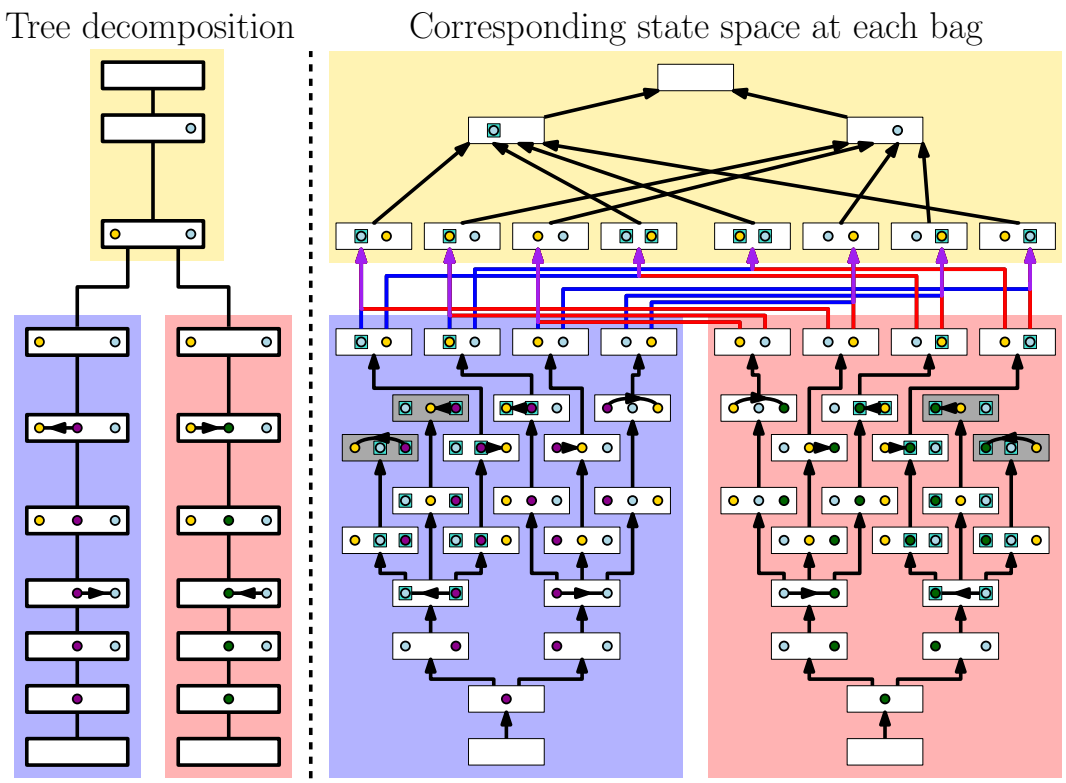

Figure 10 Dynamic program on the example from Figure 8. Bags of the tree decomposition are shown on the left; representative states (bag orders and matched subsets) on the right. States violating local adjacency, matching, or acyclicity constraints are discarded (grey).

Introduce-edge. A new edge (u, v) is introduced between vertices already in the bag. The order g determines whether it is forward or backward: (i) if (u, v) is forward in g, it can never be backward in any extension and thus can never enter the matching; (ii) if (u, v) is backward in g, it *must* be in the matching, and this is the unique place where it is introduced along the path. In the backward case we insist that u and v are currently unmatched in the child and become matched in the parent. Any state where this would create a double match in G_t is discarded.

Forget-vertex. A vertex v leaves the bag. At this moment all edges incident to v have already been introduced below, so v's matching status is final. We branch on whether v is matched in the child: if v is unmatched, we add $\omega(v)$ to the cost; if v is matched, v never contributes again. We then take the minimum over all child states in which v appears at some position in the child order and the projected order on the remaining bag is g.

Join. Two subtrees with the same bag X_t are merged. The processed subgraph G_t is the union of G_s and $G_{s'}$, and the bag order g is the same in all three bags. The order g already decides which bag-internal edges are backward, and hence which bag vertices are forced to be matched via those edges; call this set $M_I(g)$. Every feasible state $(g, U_\bullet)$ must satisfy $M_I(g) \subseteq U_\bullet$ for the parent and both children (if g induces conflicting backward edges, all such states are infeasible and $c[t, g, \cdot] = +\infty$). Outside $M_I(g)$, a bag vertex can be matched strictly below t in *at most one* of the two subtrees (there are no edges between the forgotten parts of

the two subgraphs). Thus for a parent state (g, U_t) we look over all pairs of child matched sets $(U_s, U_{s'})$ such that $M_I(g) \subseteq U_s, U_{s'}, U_t$ and $U_t \setminus M_I(g) = (U_s \setminus M_I(g)) \dot\cup (U_{s'} \setminus M_I(g))$. We then set $c[t, g, U_t]$ to the minimum of $c[s, g, U_s] + c[s', g, U_{s'}]$ over all such pairs.

A formal DP invariant and soundness/completeness proofs can be found in [39, App. A]. At the root bag r, the bag is empty, so there is a single state $(\emptyset, \emptyset)$; its value $c[r, \emptyset, \emptyset]$ is exactly the optimum of FMO on D, and hence of FMM and OMM.

3.4 Running time

We sketch the running-time bound; the full accounting is given in [39, App. A.11]. Let k be the treewidth of the underlying undirected graph of D and set $n := |V(D)|$. In a nice tree decomposition of width k, each bag has size at most $k{+}1$. A DP state is a pair (g, U) where g is a total order on the current bag and U is a subset of its vertices. Hence the number of states per bag is at most $(k{+}1)! \cdot 2^{k+1} \le (k{+}1)^{k+1} \cdot 2^{k+1} = 2^{(k+1)\log_2(k+1)+(k+1)} = 2^{O(k \log k)}$. For each fixed state, leaf/introduce-vertex/introduce-edge transitions take $k^{O(1)}$ time, and a forget transition branches over $k{+}2$ insertion positions. At a join bag, the order g is shared by both children, and combining solutions amounts to splitting the bag-mask information between the two subtrees, yielding at most 2^{k+1} admissible child pairs per state. Thus the work per bag is $2^{O(k \log k)}$, and since the decomposition has $O(n)$ bags, the total running time is $2^{O(k \log k)}\, n$.

4 ETH-optimality

How expensive is treewidth for OMM? Our $2^{O(k \log k)}n$-time algorithm shows what is achievable, and in this section we prove that this is indeed the true price under the Exponential Time Hypothesis (ETH). Starting from the ETH-based lower bound for Directed Feedback Vertex Set (DFVS) parameterized by treewidth, we give a new polynomial-time reduction from DFVS to Erasibility on 2-dimensional complexes of bounded coface degree. We then realize this reduction bag-by-bag using the Width Preserving Strategy (WiPS), which performs structural induction along a tree decomposition and keeps treewidth within a constant factor. As a consequence, any $2^{o(k \log k)}n^{O(1)}$-time algorithm for OMM (even in this restricted setting) would yield such an algorithm for DFVS, contradicting ETH and pinning down the dependence on k as $2^{\Theta(k \log k)}$.

▶ **Theorem 13.** *Assuming ETH,* Erasibility *parameterized by treewidth k admits no $2^{o(k \log k)}n^{O(1)}$-time algorithm, even when the input is restricted to 2-dimensional simplicial complexes of top coface degree at most* 4.

4.1 Gadgets and obstructions

Vertex gadgets: fuses and locks. Let D be a DFVS instance. For each vertex $v \in V(D)$ we build a local gadget $Y^v = \mathcal{F}(v) \cup \mathcal{L}(v)$, illustrated in Figure 11. The fuse $\mathcal{F}(v)$ is a 2-dimensional simplicial complex homeomorphic to a hollow cylinder $S^1 \times I$ with two boundary circles: one is a free boundary circle (marked in red) from which we can start collapsing the complex, "unravelling" the fuse by elementary collapses along the cylinder; the other boundary circle is non-free and is glued to the lock $\mathcal{L}(v)$. The lock $\mathcal{L}(v)$ is a 2-dimensional simplicial complex homeomorphic to a compact orientable surface of genus $\deg^+(v)$ with a single boundary component, which is attached to this non-free boundary circle of the fuse. For each outgoing arc $v \to w$ in D, we select a distinct simple closed curve on $\mathcal{L}(v)$ and glue it to a cross-section circle of the fuse $\mathcal{F}(w)$, so that each such curve acts like

a finger pinching the fuse: it prevents $\mathcal{F}(w)$ from collapsing past that cross-section as long as the lock $\mathcal{L}(v)$ is present. In the interior of $\mathcal{L}(v)$ we mark a single triangle deton(v) (the detonator); deleting this triangle makes the entire lock collapsible, eliminates all its pinches, and simultaneously releases every constraint that $\mathcal{L}(v)$ imposes on neighbouring fuses. We triangulate $\mathcal{L}(v)$ so that it becomes collapsible in either of two situations: after deleting deton(v), or after its attached fuse $\mathcal{F}(v)$ has been completely collapsed. In particular, as long as deton(v) is present and $\mathcal{F}(v)$ is intact, the lock cannot be collapsed while it still pinches some neighbouring fuse.

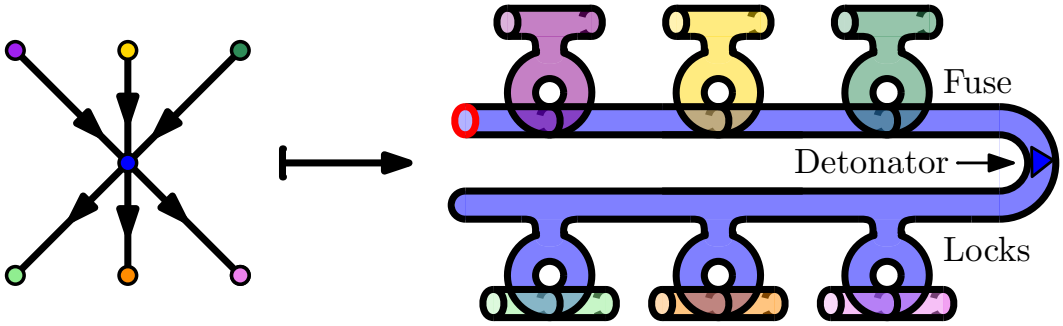

Figure 11 Schematic vertex gadget for a vertex v: the fuse $\mathcal{F}(v)$ and the lock region $\mathcal{L}(v)$.

Ouroboroi as obstructions. Fix a directed cycle $C = (v_1, \ldots, v_\ell)$ in D. For each arc (v_i, v_{i+1}) (indices modulo ℓ) we use one outgoing handle of $\mathcal{L}(v_i)$ and glue it so that it pinches the fuse $\mathcal{F}(v_{i+1})$ as described above. Taking exactly these pieces along the cycle yields a closed ring of vertex gadgets in which each lock pinches the next fuse; because of the visual similarity to a snake eating its own tail, we call such a ring an *ℓ-ouroboros*, see Figure 12. Along an ouroboros, each fuse can be collapsed from its free boundary until it reaches the first pinch, but it cannot be collapsed past that point while the corresponding lock is present. By construction, every edge in this ring belongs to at least two triangles (coming from the fuse, the lock, or their intersection), so inside this subcomplex there are no free edges and hence no elementary collapses. In particular, an ouroboros persists under any sequence of elementary collapses until at least one of its locks is destroyed, and we will use these rings as obstructions witnessing the presence of directed cycles in D.

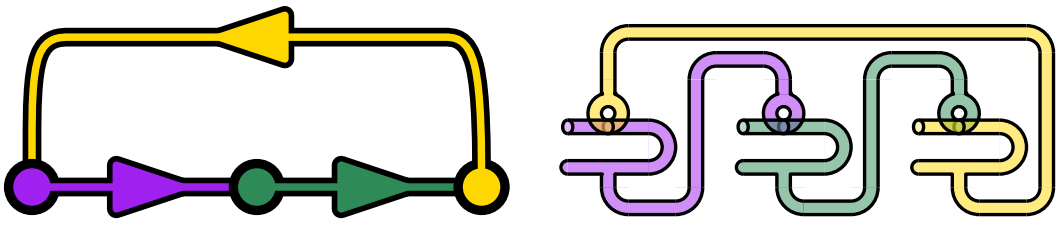

Figure 12 A directed 3-cycle in D and the corresponding 3-ouroboros: three vertex gadgets arranged in a ring, each lock pinching the next fuse. No edge on this ring is free, so it remains non-erasible until some detonator is deleted.

4.2 Correctness of the reduction

Let Y be the complex constructed from a DFVS instance D, and for each vertex v let $\mathrm{deton}(v)$ be its detonator triangle in the gadget Y^v. We show that this construction yields a parameter-preserving polynomial-time reduction from DFVS to Erasibility: for every integer s, D has a feedback vertex set of size at most s if and only if Y becomes erasible after deleting at most s triangles.

Forward direction. Let $S \subseteq V(D)$ be a feedback vertex set of size at most s, and let $T := \{\mathrm{deton}(v) \mid v \in S\}$. Deleting $\mathrm{deton}(v)$ makes the entire lock $\mathcal{L}(v)$ collapsible and removes all its pinches on neighbouring fuses, so in $Y \setminus T$ we can collapse every lock $\mathcal{L}(v)$ with $v \in S$. Since $D \setminus S$ is acyclic, we can order its vertices topologically and, in that order, collapse each remaining gadget Y^v: once all incoming locks to $\mathcal{F}(v)$ have been removed, the fuse $\mathcal{F}(v)$ collapses completely, and by the gadget design the remaining lock $\mathcal{L}(v)$ then collapses as well. At the end only gadgets for vertices in S remain, but their locks have already been removed and their fuses are just cylinders with a free boundary, so they also collapse. Thus $Y \setminus T$ is erasible after deleting $|T| = |S| \leq s$ triangles.

Backward direction. Conversely, let T be a set of at most s triangles such that $Y \setminus T$ is erasible, and define $S' := \{\, v \in V(D) \mid Y^v \cap T \neq \emptyset \,\}$. Clearly $|S'| \leq |T| \leq s$. Suppose for contradiction that $D \setminus S'$ still contains a directed cycle $C = (v_1, \ldots, v_\ell)$. By construction, the gadgets $Y^{v_1}, \ldots, Y^{v_\ell}$ contain an ℓ-ouroboros subcomplex Z. Since no gadget on C intersects T, Z is disjoint from T, and every edge of Z still lies in at least two triangles in $Y \setminus T$. Hence no edge of Z is ever free, so no sequence of elementary collapses can remove Z, and $Y \setminus T$ is not erasible – a contradiction. Thus $D \setminus S'$ is acyclic, and S' is a feedback vertex set of size at most s.

4.3 Preserving width via WiPS

Width blow-up. Hardness reductions for problems parameterized by treewidth must control the width of the target instance: a naïve "glue all gadgets at once" construction can easily turn a bounded-treewidth graph into a complex whose Hasse diagram has very large treewidth. In our setting, globally attaching all vertex gadgets Y^v would allow long fuses and many handles to interact and form large grid-like regions in the Hasse diagram, even when D itself has small treewidth; see [5] for a concrete construction or Figure 13 for intuition.

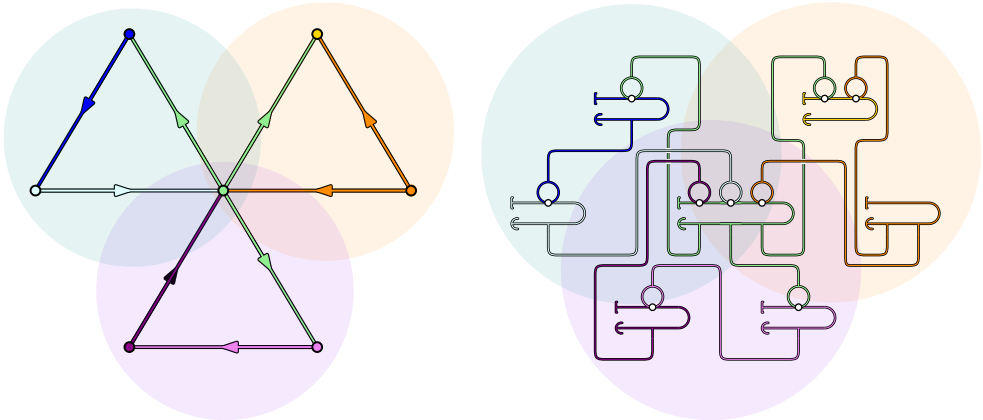

Figure 13 Naïve global gluing of all gadgets. The digraph (top) has small treewidth, but the assembled space (bottom) may develop large intertwined regions in the Hasse diagram, with no a priori width bound.

WiPS. To avoid this blow-up, we assemble the same gadgets *incrementally* along a nice tree decomposition of D, following the Width Preserving Strategy (WiPS) [43]. For each bag X_t we maintain a partial complex Y_t together with a small interface of boundary circles associated with the vertices in X_t, and when moving from a child bag to its parent we only apply constant-size local updates touching this interface: at an introduce-vertex bag we attach a fresh gadget $\mathcal{F}(v) \cup \mathcal{L}(v)$; at an introduce-edge bag we add a single pinching handle between $\mathcal{L}(u)$ and $\mathcal{F}(v)$; at a forget-vertex bag we cap off the remaining boundary components of v; and at a join bag we merge the two partial gadgets for each v along a constant-size interface (on the lock side via a pair-of-pants, on the fuse side by attaching both child cylinders to a common boundary circle and extending it by a short cylinder). Intuitively, each bag only "sees" a bounded portion of the complex, and only a bounded number of new simplices is introduced per bag; see Figure 14.

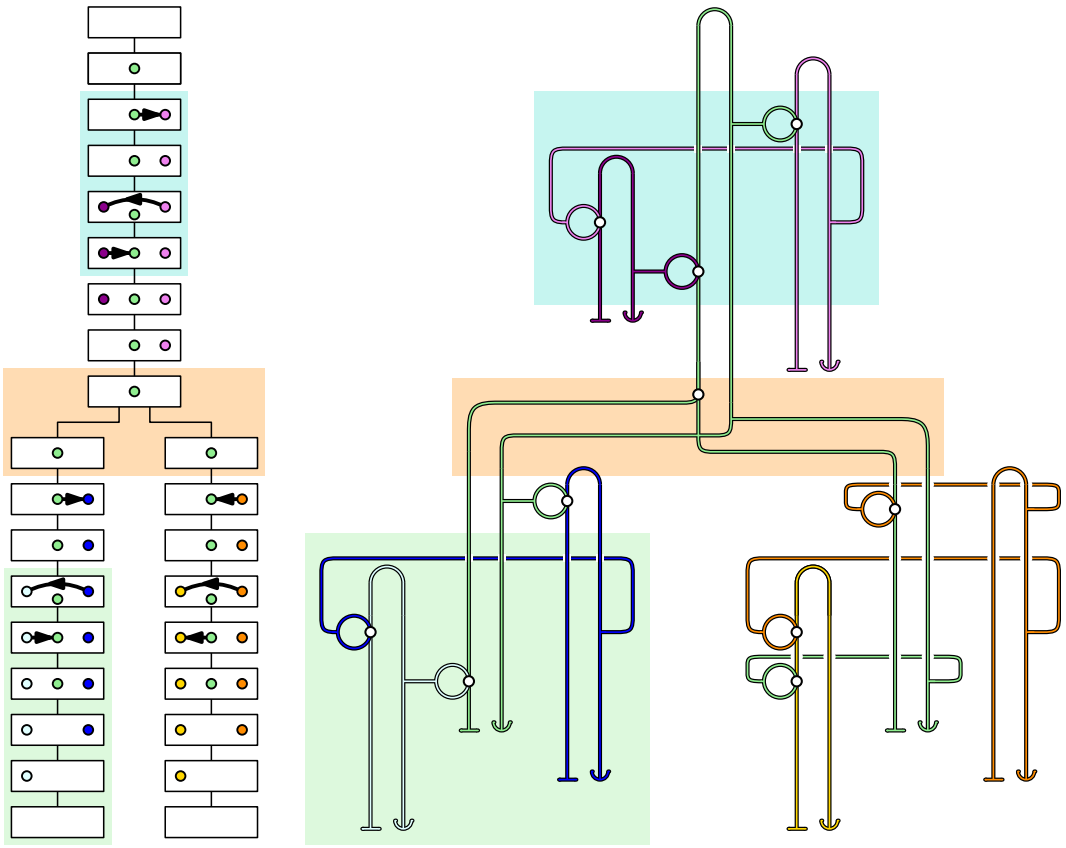

Figure 14 WiPS-style construction. Left: a nice tree decomposition of the digraph in Figure 13 Right: the space is grown bag-by-bag, each bag exposing only a small interface and adding only constant-size pieces. This ensures that the Hasse diagram maintains treewidth $O(k)$.

Summary. Instantiating WiPS with our gadgets, we obtain that if D has treewidth k, then the complex Y produced by the above construction has a Hasse diagram of treewidth at most $ck + c_0$ for fixed constants c, c_0 independent of D, and $|Y|$ remains polynomial in $|D|$. A detailed WiPS induction invariant and the exact bag-by-bag construction are in [39, App. B]. Here we only use this width bound together with the gadget behavior described above. Together with the correctness of the DFVS-to-Erasibility reduction proved above, this yields Theorem 13.

5 Discussion

Table 1 summarises our treewidth-parameterized bounds. For FMM/FMO on digraphs, OMM on Hasse diagrams, and 2D Erasability with coface degree at most 4 we obtain algorithms running in time $2^{O(k \log k)}n$, and our width-preserving reduction from DFVS shows that no $2^{o(k \log k)}n^{O(1)}$ algorithm exists under ETH. Thus these problems have optimal $2^{\Theta(k \log k)}n^{O(1)}$ dependence on treewidth. The rows with unknown ETH bounds in Table 1 show that the same dynamic programme extends to OMM on triangulated manifolds and to negative-weight FMM/FMO, and it remains open whether ETH lower bounds also carry over or whether the extra structure allows faster algorithms. Our algorithm also applies to AC-FM on bipartite graphs. In the single-level bipartite incidence-graph setting used in the matching-based formulation of discrete Morse theory (e.g. spine graphs), AC-FM, URM [26], and the corresponding discrete Morse matching problem are equivalent; see [12]. Hence we obtain a $2^{O(k \log k)}n^{O(1)}$-time algorithm for bipartite AC-FM/URM. Our ETH lower bound already holds for bipartite incidence graphs of maximum degree at most 4, in particular for those arising from 2-complexes, so the $2^{\Theta(k \log k)}n^{O(1)}$ dependence is ETH-tight in the bipartite setting. By contrast, on general graphs the recent treewidth-based dynamic programme of [15] runs in $2^{O(k^2)}n^{O(1)}$ time. Whether the $2^{O(k \log k)}$ dependence can also be achieved for general graphs remains open.

Table 1 Upper and lower running-time bounds in the treewidth parameter k for the problems considered in this paper, suppressing polynomial factors in n. The first block contains the problems we study explicitly, ordered from more general to more restricted settings. The bottom block records bounds for AC-FM/URM; the bounded-degree row indicates that the ETH lower bound already holds for bipartite incidence graphs arising from 2D Erasability.

Problem	Setting	Algorithm	ETH
FMM/FMO	General digraphs, any weights	$2^{O(k \log k)}$	$2^{o(k \log k)}$
FMM/FMO	General digraphs, negative weights	$2^{O(k \log k)}$	–
OMM	DAGs/Hasse diagrams	$2^{O(k \log k)}$	$2^{o(k \log k)}$
OMM	Triangulated d-manifolds	$2^{O(k \log k)}$	–
2D Erasability	Coface degree ≤ 4, unweighted	$2^{O(k \log k)}$	$2^{o(k \log k)}$
Conjectured $\rightarrow$	Coface degree ≤ 3, embeddable in $\mathbb{R}^3$	$2^{O(k \log k)}$	$2^{o(k \log k)}$
AC-FM/URM	General graphs, algorithm from [15]	$2^{O(k^2)}$	$2^{o(k \log k)}$
AC-FM/URM	Bipartite graphs	$2^{O(k \log k)}$	$2^{o(k \log k)}$
AC-FM/URM	Bipartite graphs, maximum degree ≤ 4	$2^{O(k \log k)}$	$2^{o(k \log k)}$

Representation matters. Forman's correspondence identifies discrete Morse matchings with Morse functions or orders on the underlying Hasse diagram, but these viewpoints behave very differently for treewidth-based algorithms. Most prior work, including Hasse-based formulations of OMM and the parameterized algorithm of [12], stays in the matching language: discrete gradients are matchings and gradient paths are alternating paths. In that setting one either appeals to meta-theorems such as Courcelle's theorem, with non-elementary state spaces, or designs ad-hoc state summaries based on alternating-path patterns on each bag of a tree decomposition. Figure 15 shows that such summaries are delicate: alternating reachability is not transitive, and merging states solely on the basis of their alternating pattern

can silently discard globally optimal extensions. In particular, our example suggests that the union–find based invariant used in [12], which implicitly treats alternating connectivity as an equivalence relation, is too coarse as stated; one really needs to know which vertices are alternating-reachable from which, not just which "components" they lie in. The recent AC-FM/URM dynamic program of [15] can be seen as a systematic matching-based repair: on each bag it stores an "alternating matrix" recording, for every pair of vertices, whether they are connected by an alternating path with respect to the current matching, that is, the full relation $R_M \subseteq B \times B$ of alternating reachability. This avoids over-pruning and, on bipartite incidence graphs (such as spines or Hasse diagrams), yields a faithful matching-based implementation of discrete Morse matchings, but at the price of a $2^{\Theta(k^2)}$ state space for bags of size $O(k)$, as reflected in Table 1. Beyond the bipartite/Hasse case the relationship between AC-FM and FMM breaks down, and we do not currently see how to compress alternating information on general graphs to obtain a $2^{O(k \log k)}$ dependence without a substantially different representation.

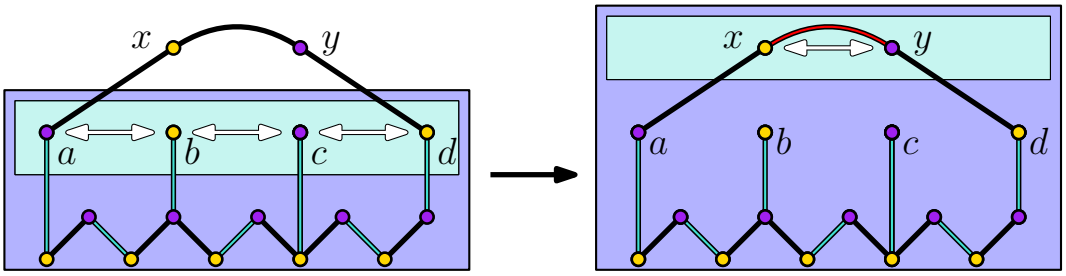

Figure 15 Summaries based only on alternating-path patterns can over-prune. **Left:** the DP merges states whenever the alternating-path pattern on the current bag is the same; in particular, states that differ only in how they treat a and d are identified. **Right:** after introducing x, y, the matching $\{ax, yd\}$ is a valid extension and can be arranged to be uniquely optimal, but no surviving state represents it, because all states that kept a and d separate were merged earlier.

Conclusion. We give an order-based dynamic program for Optimal Morse Matching on bounded-treewidth complexes with running time $2^{O(k \log k)}n$ and, via WiPS-style width-preserving reductions, ETH-tight lower bounds that persist even under strong restrictions on the input. For discrete Morse theory, our results suggest that for treewidth, taking the path of functions and orderings has made all the difference. Looking ahead, the road keeps going:

- **Three gaps suggested by Table 1.** First, prove the conjectured ETH-tight lower bound for 2D Erasability on complexes of coface degree ≤ 3 embeddable in $\mathbb{R}^3$. Second, for triangulated manifolds can we obtain a $2^{O(k)}n^{O(1)}$-time algorithm for OMM? Third, for AC-FM/URM we have an ETH-tight $2^{\Theta(k \log k)}n^{O(1)}$ running time on bipartite graphs, while on general graphs the best known DP runs in $2^{O(k^2)}n^{O(1)}$ time [15]. Can we show under ETH that a quadratic dependence on treewidth in the exponent is unavoidable in the general-graph case?
- **A locality constraint for** OMM**.** With solution-size parameterizations remaining W[P]-hard [12, 4], it is natural to look for complementary structural parameters. One concrete direction is to enforce *local* simplification by bounding (or minimizing) the length of the longest gradient path, equivalently the longest alternating path in the Hasse diagram after reversing matched edges. What is the complexity of OMM under such a locality constraint, and how does it interact with bounded treewidth?

- **WiPS beyond this paper.** Our ETH lower bound relies on the Width Preserving Strategy (WiPS) [43], which enables reductions to be carried out bag-by-bag while keeping treewidth under control. Can WiPS be developed into a general toolbox for proving tight treewidth lower bounds (and perhaps transferring XNLP-hardness) for other problems studied via treewidth in topology and geometry, for example quantum invariants and decision problems on triangulations [10, 13, 6]?

Expansion of Trivariate Polynomials Using Proximity

Orit E. Raz
Department of Mathematics, Ben-Gurion University of the Negev, Be'er Sheva, Israel

Abstract

We extend the proximity technique of Solymosi and Zahl [9] to the setting of trivariate polynomials. In particular, we prove the following result: Let $f(x,y,z) = (x-y)^2+(\varphi(x)-z)^2$, where $\varphi(x) \in \mathbb{R}[x]$ has degree at least 3. Then, for every finite $A, B, C \subset \mathbb{R}$ each of size n, one has $|f(A,B,C)| = \Omega(n^{5/3-\varepsilon})$, for every $\varepsilon > 0$, where the constant of proportionality depends on ε and on $\deg(\varphi)$. This improves the previous exponent 3/2, due to Raz, Sharir, and De Zeeuw [7]. To the best of our knowledge, prior to this work no trivariate polynomial was known to have expansion exceeding $\Omega(n^{3/2})$.

1 Introduction

In many cases in combinatorial geometry, counting questions involving distances, slopes, collinearity, etc., can be reformulated as analogous counting questions involving grid points lying on certain algebraic varieties. A unified study of such problems began with a question of Elekes [1] about expansion of bivariate real polynomials $f(x,y)$. Specifically, he asked: For a bivariate polynomial $f \in \mathbb{R}[x,y]$ and given finite sets $A, B \subset \mathbb{R}$, how small can be the image set

$$f(A,B) = \{f(a,b) \mid a \in A, b \in B\}.$$

Elekes conjectured that the image of f on an $n \times n$ Cartesian product must be of cardinality superlinear in n, unless f has a very concrete *special form*. This was confirmed in 2000 by Elekes and Rónyai [2], who proved the following dichotomy: Either f is one of the forms

$$\begin{aligned} &f(x,y) = h(p(x)+q(y)) \quad \text{or} \\ &f(x,y) = h(p(x)q(y)), \end{aligned} \tag{1}$$

for some univariate real polynomials p, q, h, or, otherwise, for every finite $A, B \subset \mathbb{R}$, each of size n, we have

$$|f(A,B)| = \omega(n). \tag{2}$$

In [8], Raz, Sharir and Solymosi introduced a new proof of the Elekes–Rónyai theorem, which also yields improved bounds on the expansion of f. Roughly speaking, for a given $f \in \mathbb{R}[x,y]$ and two finite sets $A, B \subset \mathbb{R}$, they bounded the number of quadruples $((a,b),(a',b')) \in (A \times B)^2$ satisfying $f(a,b) = f(a',b')$ by reducing it to a point-curve incidence problem in the plane. Concretely, incidences between the point set $A \times A$ and the family of curves $\{\gamma_{b,b'} \mid (b,b') \in B \times B\}$, where $\gamma_{b,b'}$ is given by the equation

$$f(x,b) = f(y,b').$$

If these curves are distinct, known incidence bounds can be applied to obtain the desired estimate. However, it may happen that many of the curves coincide, in which case the

incidence bound breaks down. Raz, Sharir, and Solymosi showed that this "failure" occurs if and only if f has a special form, namely one of the forms described in (1). In the non-special case, their analysis yields the lower bound $\Omega(n^{4/3})$

Solymosi and Zahl [9] recently improved the expansion bound for f in the non-special case, establishing the lower bound $\Omega(n^{3/2})$. Their argument builds on the framework of [8], but applies the incidence bound to carefully selected subsets of points and curves. In particular, they restrict to points $(a, a') \in A \times A$ with a and a' sufficiently close, and, similarly, to curves $\gamma_{b,b'}$ with parameters $(b, b') \in B \times B$ with b and b' sufficiently close. This refinement, referred to as the *proximity method*, overcomes a loss incurred in the earlier argument from an application of the Cauchy–Schwarz inequality.

A 3-variate analogue of the Elekes–Rónyai theorem was studied in Raz, Sharir, and De Zeeuw [7]. The case of $k \geq 4$ variables is studied by Raz and Shem Tov in [4].

▶ **Theorem 1** ([7, 4]). *Let $k \geq 3$ and assume that $f \in \mathbb{R}[x_1, \ldots, x_k]$ depends non-trivially on each of its varaiables. Then one of the following holds:*

(i) *For every finite $A_1, \ldots, A_k \subset \mathbb{R}$, with $|A_i| = n$, for $i = 1, \ldots, k$, one has*

$$|f(A_1, \ldots, A_k)| = \Omega(n^{3/2}),$$

where the constant of proportionality depends only on $\deg(f)$ and on k.

(ii) *f is of one of the special forms*

$$f(x_1, \ldots, x_k) = h(p_1(x_1) + \cdots + p_k(x_k)) \tag{3}$$
$$f(x_1, \ldots, x_k) = h(p_1(x_1) \cdot \ldots \cdot p_k(x_k))$$

for some univariate real polynomials $p_1, \ldots, p_k, h$.

Similar to the bivariate case, the analysis for $k = 3$ also reduces to a point-curve incidence problem in the plane. Specifically, for a trivariate polynomial $f \in \mathbb{R}[x, y, z]$ and finite sets $A, B, C \subset \mathbb{R}$, define $D := f(A, B, C)$ and consider incidences between the point set $A \times D$ and the family of curves $\{\gamma_{b,c} \mid (b, c) \in B \times C\}$, where $\gamma_{b,c}$ is given by the equation

$$w = f(x, b, c).$$

In some respects, the trivariate case is simpler than the bivariate one. Here, the structure of f is more directly reflected in properties of the variety $w = f(x, y, z)$, whereas in the bivariate case one must analyze the more intricate variety $f(x, y) = f(z, w)$. Moreover, in the trivariate setting the argument avoids an application of the Cauchy–Schwarz inequality, therefore eliminating the loss in the estimate that arises in the bivariate case.

As mentioned above, the proximity method of Solymosi and Zahl [9] improves the bivariate bound precisely by overcoming this loss from the Cauchy–Schwarz step. For this reason, it is not immediately clear how their method could extend to the trivariate case.

In this paper, we show how proximity can in fact be used to obtain a stronger expansion bound for trivariate polynomials. In particular, we establish an improved bound for a concrete family of trivariate polynomials. Namely, we prove the following main result.

▶ **Theorem 2.** *Let*

$$f(x, y, z) = (x - y)^2 + (\varphi(x) - z)^2,$$

where $\varphi(x)$ is a univariate real polynomial of degree at least 3. Then, for every $\varepsilon > 0$ and any finite sets $A, B, C \subset \mathbb{R}$, each of size n, we have

$$|f(A, B, C)| = \Omega(n^{5/3-\varepsilon}),$$

where the constant of proportionality depends on $\deg \varphi$ and on ε.

This improves upon the previous bound of $\Omega(n^{3/2})$, which follows from Theorem 1. To the best of our knowledge, prior to this work no trivariate polynomial was known to have expansion exceeding $\Omega(n^{3/2})$.

We remark that our approach is more general and extends to other trivariate polynomials. A natural direction for future research is to determine the precise subfamily of polynomials $\mathcal{F} \subset \mathbb{R}[x,y,z]$ for which the method yields the improved lower bound $\Omega(n^{5/3-\varepsilon})$.

2 Preliminaries

2.1 Point-curve incidences in the plane

For a finite set of points $\mathcal{P} \subset \mathbb{R}^2$ and a finite set of planar curves $\mathcal{C}$, we let $I(\mathcal{P},\mathcal{C})$ denote the set of point-curve incidences; that is

$$I(\mathcal{P},\mathcal{C}) = \{(p,\gamma) \in \mathcal{P} \times \mathcal{C} \mid p \in \gamma\}.$$

The classical Szemerédi–Trotter theorem [10] asserts that, for the special case where $\mathcal{C}$ is a set of lines, and putting $m := |\mathcal{P}|$ and $n := |\mathcal{C}|$, one has

$$|I(\mathcal{P},\mathcal{C})| = O\left(m^{2/3}n^{2/3} + m + n\right).$$

Since the Szemerédi–Trotter paper, numerous alternative proofs and related problems have been studied. For our result, we require an extension of Szemerédi–Trotter to point-curve incidence problems, established by Sharir and Zahl [6], in which the curves are algebraic and form an s-dimensional family. We now recall the relevant definitions from their work.

A bivariate polynomial $h \in \mathbb{R}[x,y]$ of degree at most D is a linear combination of the form $h(x,y) = \sum_{0\le i+j\le D} c_{ij}x^iy^j$. Note that the number of monomials x^iy^j such that $0 \le i+j \le D$ is $\binom{D+2}{2}$. In this sense, every point $\vec{c} \in \mathbb{R}^{\binom{D+2}{2}}$ (other than the all-zero vector) can be associated with a curve in $\mathbb{R}^2$, given by the zeroset of the bivariate polynomial whose coefficients are the entries of $\vec{c}$. If $\lambda \neq 0$, then f and λf have the same zero-set. Thus, the set of algebraic curves that can be defined by a polynomial of degree at most D in $\mathbb{R}^2$ can be identified with the points in the projective space $\mathbf{P}\mathbb{R}^{\binom{D+2}{2}}$.

Define an *s-dimensional family of plane curves of degree at most D* to be an algebraic variety $F \subset \mathbf{P}R^{\binom{D+2}{2}}$ such that $\dim(F) = s$. We will call the degree of the variety F the *complexity of the family*.

They then proved the following incidence bound:

▶ **Theorem 3** (Sharir–Zahl [6]). *Let Γ be a set of n algebraic plane curves that belong to an s-dimensional family of curves of degree at most D of constant complexity at most K, no two of which share a common irreducible component. Let P be a set of m points in the plane. Then for any $\varepsilon > 0$, the number of incidences $|I(P,\Gamma)|$ between the points of P and the curves of Γ satisfies*

$$|I(P,\Gamma)| = O_\varepsilon\left(m^{\frac{2s}{5s-4}}n^{\frac{5s-6}{5s-4}+\varepsilon}\right) + O\left(m^{2/3}n^{2/3} + m + n\right),$$

where the constant of proportionality depends on s, K, D, and in the first term also on ε.

2.2 Symmetry of curves

Given a set $S \subset \mathbb{R}^2$ and a transformation $T : \mathbb{R}^2 \to \mathbb{R}^2$, we say that T *fixes* S if $T(S) = S$. We say that a transformation T is a *symmetry* of a plane algebraic curve C if T is an isometry of $\mathbb{R}^2$ and fixes C. Recall that an isometry of $\mathbb{R}^2$ is either a rotation, a translation, or a glide reflection (a reflection combined with a translation).

The following lemma is proved by Pach and De Zeeuw [3, Lemma 2.5].

▶ **Lemma 4** (Pach and De Zeeuw [3, Lemma 2.5])**.** *An irreducible plane algebraic curve of degree d has at most $4d$ symmetries, unless it is a line or a circle.*

2.3 Complete bipartite graphs

We introduce some notation and recall some properties in the spirit of Raz–Solymosi [5, Section 3]. For completeness we give all the details here. Let $\mathbf{p} = (p_1, \ldots, p_k), \mathbf{p}' = (p'_1, \ldots, p'_k) \in \mathbb{R}^2 \times \cdots \times \mathbb{R}^2 \cong \mathbb{R}^{2k}$ be two k-tuples of points in $\mathbb{R}^2$. Define

$$\Sigma_{\mathbf{p},\mathbf{p}'} = \{(q, q') \in \mathbb{R}^2 \times \mathbb{R}^2 \mid \|p_i - q\| = \|p'_i - q'\| \text{ for each } i = 1, \ldots, k\} \subset \mathbb{R}^2 \times \mathbb{R}^2.$$

Let $\sigma_{\mathbf{p},\mathbf{p}'}$ (respectively, $\sigma'_{\mathbf{p},\mathbf{p}'}$) denote the projection of $\Sigma_{\mathbf{p},\mathbf{p}'}$ to the first (respectively, last) copy of $\mathbb{R}^2$ in $\mathbb{R}^2 \times \mathbb{R}^2$.

▶ **Lemma 5.** *Let $\mathbf{p} = (p_1, p_2, p_3), \mathbf{p}' = (p'_1, p'_2, p'_3) \in (\mathbb{R}^2)^3$, and assume that p_1, p_2, p_3 are pairwise distinct. Then either*
(i) $\mathbf{p}$ and $\mathbf{p}'$ are congruent, or
(ii) $\Sigma_{\mathbf{p},\mathbf{p}'}$ is at most one-dimensional, and each of $\sigma_{\mathbf{p},\mathbf{p}'}$ and $\sigma'_{\mathbf{p},\mathbf{p}'}$ is contained in an algebraic curve of degree at most two.

Proof. By definition, for $(q, q') \in \Sigma_{\mathbf{p},\mathbf{p}'}$ we have

$$\|p_i - q\|^2 = \|p'_i - q'\|^2, \quad i = 1, 2, 3$$

or

$$\|p_i\|^2 - 2p_i \cdot q + \|q\|^2 = \|p'_i\|^2 - 2p'_i \cdot q' + \|q'\|^2, \quad i = 1, 2, 3.$$

Subtracting the 3rd equation from each of the first two equations, we get the system

$$\begin{aligned} \|p_1\|^2 - \|p_3\|^2 - 2(p_1 - p_3) \cdot q &= \|p'_1\|^2 - \|p'_3\|^2 - 2(p'_1 - p'_3) \cdot q' \\ \|p_2\|^2 - \|p_3\|^2 - 2(p_2 - p_3) \cdot q &= \|p'_2\|^2 - \|p'_3\|^2 - 2(p'_2 - p'_3) \cdot q' \\ \|p_3\|^2 - 2p_3 \cdot q + \|q\|^2 &= \|p'_3\|^2 - 2p'_3 \cdot q' + \|q'\|^2. \end{aligned} \tag{4}$$

The system can be rewritten as

$$\begin{aligned} \tfrac{1}{2}u - Aq &= \tfrac{1}{2}v - Bq', \\ \|p_3\|^2 - 2p_3 \cdot q + \|q\|^2 &= \|p'_3\|^2 - 2p'_3 \cdot q' + \|q'\|^2, \end{aligned}$$

where A (resp., B) is a 2×2 matrix whose ith row equals $p_i - p_3$ (resp., $p'_i - p'_3$), for $i = 1, 2$, and

$$u = \begin{pmatrix} \|p_1\|^2 - \|p_3\|^2 \\ \|p_2\|^2 - \|p_3\|^2 \end{pmatrix}, \quad v = \begin{pmatrix} \|p'_1\|^2 - \|p'_3\|^2 \\ \|p'_2\|^2 - \|p'_3\|^2 \end{pmatrix}$$

are vectors in $\mathbb{R}^2$.

Assume first that p'_1, p'_2, p'_3 are not collinear. So the matrix B is invertible and we have

$$q' = B^{-1}Aq + w,$$

for $w = \frac{1}{2}B^{-1}(v - u) \in \mathbb{R}^2$. Let $T(q) := B^{-1}Aq + w$. So $(q, q') \in \Sigma_{\mathbf{p},\mathbf{p}'}$ if and only if $q' = T(q)$. Plugging this in the 3rd equation in (4) we get

$$\|p_3\|^2 - 2p_3 \cdot q + \|q\|^2 = \|p'_3\|^2 - 2p'_3 \cdot T(q) + \|T(q)\|^2, \tag{5}$$

which defines $\sigma_{\mathbf{p},\mathbf{p}'}$. Note that this gives a conic section unless (5) is trivial, i.e., the zero equation. Note that for this to happen the quadratic part has to be zero. That is,

$$\langle q, q\rangle = \langle B^{-1}Aq, B^{-1}Aq\rangle$$

or

$$\langle q, \left(I - (B^{-1}A)^{tr}B^{-1}A\right) q\rangle = 0$$

This defines a trivial quadratic equation if and only if

$$I - (B^{-1}A)^{tr}B^{-1}A = 0$$

or

$$(B^{-1}A)^{tr} = (B^{-1}A)^{-1},$$

which means that T is an isometry of $\mathbb{R}^2$. This implies that $\mathbf{p}$ and $\mathbf{p}'$ are congruent. We conclude that $\sigma_{\mathbf{p},\mathbf{p}'}$ is either conic section given by (5) or $\mathbf{p}$ and $\mathbf{p}'$ are congruent, which completes the proof for the case that p'_1, p'_2, p'_3 are non-collinear.

By symmetry, same analysis applies also when p_1, p_2, p_3 are non-collinear. So we need to prove the lemma for the case that each of the triples p_1, p_2, p_3 and p'_1, p'_2, p'_3 is collinear. In this case we may assume without loss of generality that $p_3 = p'_3 = (0, 0)$, and $p_1 = (a, 0)$, $p'_1 = (a', 0)$, $p_2 = (b, 0)$, and $p'_2 = (b', 0)$. Note that our assumption that p_1, p_2, p_3 are pairwise distinct implies $b \neq a \neq 0$. Writing $q = (x, y)$ and $q' = (x', y')$, the system of equations defining $\Sigma_{\mathbf{p},\mathbf{p}'}$ in this case becomes

$$\begin{aligned}(x-a)^2 + y^2 &= (x'-a')^2 + (y')^2\\ (x-b)^2 + y^2 &= (x'-b')^2 + (y')^2\\ x^2 + y^2 &= (x')^2 + (y')^2\end{aligned}$$

or

$$\begin{aligned}-2ax + a^2 &= -2a'x' + (a')^2\\ -2bx + b^2 &= -2b'x' + (b')^2\\ x^2 + y^2 &= (x')^2 + (y')^2.\end{aligned}$$

Recalling our assumption that p_1, p_2, p_3 are distinct, we have $b \neq a \neq 0$. Thus the first two equations give

$$\begin{aligned}x &= (a'/a)x' - (a')^2/(2a) + a/2\\ x &= (b'/b)x' - (b')^2/(2b) + b/2.\end{aligned}$$

So we either get unique values for x, x' or otherwise $a'/a = b'/b$. In the former case both $\sigma_{\mathbf{p},\mathbf{p}'}$ and $\sigma'_{\mathbf{p},\mathbf{p}'}$ are lines parallel to the y-axis, and so in particular (ii) holds. In the latter case, write $a'/a = b'/b = t$. Assume first that $t \neq 0$. Then

$$\begin{aligned}x &= tx' + (a/2)(1-t^2)\\ x &= tx' + (b/2)(1-t^2),\end{aligned}$$

and so either $t = \pm 1$, in which case $\mathbf{p}$ and $\mathbf{p}'$ are congruent, or $a = b$ which is a contradiction to our assumption that p_1, p_2, p_3 are distinct. So we may assume that $t = 0$, which means

that $a' = b' = 0$. Assume $(q, q') \in \Sigma_{\mathbf{p},\mathbf{p}'}$ and write $q = (x, y)$ and $q' = (x', y')$. Let $r := (x')^2 + (y')^2$. So $q = (x, y)$ must satisfy the system

$$\begin{aligned}(x-a)^2 + y^2 &= r\\ (x-b)^2 + y^2 &= r\\ x^2 + y^2 &= r.\end{aligned}$$

However, recalling that $b \neq a \neq 0$, this system has no solutions. So $\Sigma_{\mathbf{p},\mathbf{p}'}$ is empty in this case. This completes the proof of the lemma. ◀

3 Proof of Theorem 2

Let f be as in the statement and let $A, B, C \subset \mathbb{R}$ be finite sets, each of size n. Set

$$D := f(A, B, C).$$

Our goal is to lower bound $|D|$.

Let

$$t = n^{3/2}/(s|D|^{1/2}),$$

where $s > 0$ is a sufficiently large constant, to be determined later. Consider the partition of each A, B, C into t consecutive segments, each containing at most $\lceil n/t \rceil$ elements. Let $\{A_i\}_{i=1}^t$, $\{B_i\}_{i=1}^t$, $\{C_i\}_{i=1}^t$ stand for the corresponding partitions. We write $a \sim a'$ if $a \neq a'$ and there exists some index $i \in [t]$ such that $a, a' \in A_i$. We write similarly $b \sim b'$ and $c \sim c'$ according to the partitions of B and C respectively. Define

$$Q := \{((a,b,c),(a',b',c')) \in (A \times B \times C)^2 \mid f(a,b,c) = f(a',b',c'),\ \ a \sim a',\ b \sim b',\ c \sim c'\}$$

We prove a lower bound on $|Q|$.

▶ **Proposition 6.** *We have*

$$|Q| = \Omega(sn^3), \tag{6}$$

where the constant of proportionality depends only on $\deg(\varphi)$.

Proof. For each $d \in D$ let

$$G_d := \{(a,b,c) \in A \times B \times C \mid f(a,b,c) = d\}.$$

This defines a partition $A \times B \times C = \bigcup_{d \in D} G_d$, and thus in particular

$$\sum_{d \in D} |G_d| = n^3.$$

Let

$$D' := \{d \in D \mid |G_d| \geq n^3/(10|D|)\}.$$

Note that

$$\begin{aligned} n^3 &= \sum_{d \in D} |G_d| \\ &= \sum_{d \in D'} |G_d| + \sum_{d \in D \setminus D'} |G_d| \\ &\leq \sum_{d \in D'} |G_d| + n^3/(10|D|) \cdot |D| \end{aligned}$$

and so

$$\sum_{d\in D'} |G_d| \geq (9/10)n^3. \tag{7}$$

Next, fix $d \in D'$. Note that for each $(i,j,k) \in [t]^3$, the set $A_i \times B_j \times C_k$ is contained in an axis-parallel box in $\mathbb{R}^3$. Moreover, the boundaries of those boxes lie in the union of $3t$ planes. Let $T_d \subset [t]^3$ denote the subset of 3-tuples of indices of boxes that intersect the surface $f(x,y,z) = d$. Note that $|T_d| = O(t^2)$, with constant of proportionality that depends only on $\deg(\varphi)$. Let $T'_d \subset T_d$ be those 3-tuples of indices for which $|G_d \cap (A_i \times B_j \times C_k)| \geq s$.

We have

$$\begin{aligned}
|G_d| &= \sum_{(i,j,k)\in T_d} |G_d \cap (A_i \times B_j \times C_k)| \\
&= \sum_{(i,j,k)\in T'_d} |G_d \cap (A_i \times B_j \times C_k)| + \sum_{(i,j,k)\in T_d \setminus T'_d} |G_d \cap (A_i \times B_j \times C_k)| \\
&\leq \sum_{(i,j,k)\in T'_d} |G_d \cap (A_i \times B_j \times C_k)| + s \cdot O(t^2) \\
&\leq \sum_{(i,j,k)\in T'_d} |G_d \cap (A_i \times B_j \times C_k)| + O(n^3/(s|D|)) \\
&\leq \sum_{(i,j,k)\in T'_d} |G_d \cap (A_i \times B_j \times C_k)| + |G_d|/2,
\end{aligned}$$

where the inequality on the fourth line is by our choice of t, and the inequality on the last line is because $d \in D'$ and assuming $s > 0$ is taken sufficiently large. Thus

$$\sum_{(i,j,k)\in T'_d} |G_d \cap (A_i \times B_j \times C_k)| \geq |G_d|/2. \tag{8}$$

Using $\binom{m}{2} \geq cm$ for $m \geq 2c+1$, we conclude that, for every $d \in D'$, one has

$$\begin{aligned}
\sum_{(i,j,k)\in T'_d} \left| \binom{G_d \cap (A_i \times B_j \times C_k)}{2} \right| &\geq \frac{s-1}{2} \sum_{(i,j,k)\in T'_d} |G_d \cap (A_i \times B_j \times C_k)| \\
&\geq \frac{s-1}{4}|G_d| \\
&\geq \frac{s}{5}|G_d|,
\end{aligned}$$

where the last inequality assumes $s \geq 5$. Thus we get

$$\begin{aligned}
|Q| &= \sum_{d\in D} \sum_{(i,j,k)\in[t]^3} \left| \binom{G_d \cap (A_i \times B_j \times C_k)}{2} \right| \\
&\geq \sum_{d\in D'} \sum_{(i,j,k)\in T'_d} \left| \binom{G_d \cap (A_i \times B_j \times C_k)}{2} \right| \\
&\geq \frac{s}{5} \sum_{d\in D'} |G_d| \\
&\geq (9/50)sn^3,
\end{aligned}$$

where the last inequality uses (7). This completes the proof of Proposition 6. ◀

Next we prove an upper bound on $|Q|$.

▶ **Proposition 7.** *For every $\varepsilon > 0$, we have*

$$|Q| \leq O_\varepsilon\left((s^2 n|D|)^{9/8+\varepsilon}\right) + 4\deg(\varphi)n^3.$$

Proof. We reduce the problem of upper bounding Q to a point-curve incidence problem in the plane. For this, we associate with each $((b,c),(b',c')) \in (B\times C)^2$ the planar curve (with coordinates (x,x')), denoted by $\gamma_{b,c,b',c'}$, given by the equation

$$f(x,b,c) = f(x',b',c').$$

Note that distinct choices of $((b,c),(b',c'))$ might give rise to the same curve, or to distinct curves that share an irreducible component. Let

$$\Gamma := \{\gamma \subset \gamma_{b,c,b',c'} \text{ is irreducible} \mid ((b,c),(b',c')) \in (B\times C)^2,\ b\sim b',\ c\sim c'\}.$$

Consider the set of parameters associated with the curves, that is, the set

$$\hat{\Gamma} := \{((b,c),(b',c')) \in (B\times C)^2 \mid\ b\sim b',\ c\sim c'\}.$$

Let $\Gamma_0 \subset \Gamma$ be the set of isolated points in Γ. We first observe that

$$|\{((a_0,b,c),(a_0',b',c')) \in Q \mid (a_0,a_0') \text{ isolated point of } \gamma_{b,c,b',c'} \text{ for } ((b,c),(b',c')) \in \hat{\Gamma}\}| = O(|\hat{\Gamma}|). \quad (9)$$

Indeed, for every $((b,c),(b',c')) \in \hat{\Gamma}$, the curve $\gamma_{b,c,b',c'}$ has $O(1)$ isolated points, each giving rise to exactly one element of Q. Thus (9) follows.

We are now interested in one-dimensional components in Γ. For each $\gamma \in \Gamma$ we define

$$m(\gamma) = \{((b,c),(b',c')) \in \hat{\Gamma} \mid \gamma \subset \gamma_{b,c,b',c'}\}$$

We show that there exists a finite subset $\Gamma_1 \subset \Gamma\setminus\Gamma_0$ such that for every $\gamma \in \Gamma\setminus(\Gamma_1\cup\Gamma_0)$ we have $|m(\gamma)| \leq 4$. Indeed, let $\gamma \in \Gamma\setminus\Gamma_0$ and suppose that $|m(\gamma)| \geq 5$. So there are three pairs $p_i := (b_i,c_i)$, $p_i' := (b_i',c_i')$, with $(p_i,p_i') \in m(\gamma)$ for $i = 1,2,3$, such that without loss of generality p_1,p_2,p_3 are distinct.

Let $\mathbf{p} = (p_1,p_2,p_3)$ and $\mathbf{p'} = (p_1',p_2',p_3')$ and recall the definition of $\Sigma_{\mathbf{p},\mathbf{p'}}$ from Section 2.3. By definition of $m(\gamma)$, this means that for every $(x,x') \in \gamma$ one has

$$((x,\varphi(x)),(x',\varphi(x'))) \in \Sigma_{\mathbf{p},\mathbf{p'}}.$$

By Lemma 5, either $\mathbf{p},\mathbf{p'}$ are congruent, or $\sigma_{\mathbf{p},\mathbf{p'}}$ is a conic section. In the latter case this implies that $\{(t,\varphi(t)) \mid t\in\mathbb{R}\}$ is a conic section, which is a contradiction because $\deg(\varphi) \geq 3$ and this curve is irreducible. Thus necessarily $\mathbf{p}$ and $\mathbf{p'}$ are congruent. Thus, there exists an isometry of $\mathbb{R}^2$, R, such that

$$(x',\varphi(x')) = R(x,\varphi(x)),\ \text{for every } (x,x') \in \gamma.$$

Since γ is infinite, this implies that R maps $(t,\varphi(t))$ to itself. By Lemma 4, we have that R is one of at most $4\deg(\varphi)$ possible isometries, which in turn determines the corresponding curve γ up to at most $4\deg(\varphi)$ possibilities. We conclude that

$$|\Gamma_1| \leq 4\deg(\varphi)$$

and

$$\text{for every } \gamma \in \Gamma\setminus(\Gamma_1\cup\Gamma_0) \text{ we have } |m(\gamma)| \leq 4. \quad (10)$$

Next, let

$$\hat{\Gamma}_1 := \{((b,c),(b',c')) \in \hat{\Gamma} \mid \text{there exists } \gamma \in \Gamma_1 \setminus \Gamma_0 \text{ such that } \gamma \subset \gamma_{b,c,b',c'}\}.$$

We claim that

$$|\{((a,b,c),(a',b',c')) \in Q \mid ((b,c),(b',c')) \in \hat{\Gamma}_1\}| \leq 4\deg(\varphi)n^3. \tag{11}$$

Indeed, by what has just been argued, there exists an isometry R of $\mathbb{R}^2$, one of at most $4\deg(\varphi)$ possibilities, such that $(b',c') = R(b,c)$ and $(a',\varphi(a')) = R(a,\varphi(a))$. In other words, (a',b',c') is determined by (a,b,c), up to at most $4\deg(\varphi)$ possibilities. Thus (11) follows.

Finally, let

$$P = \{(a,a') \in A \times A \mid a \sim a'\},$$

and apply Theorem 3 to bound to $|I(P, \Gamma \setminus \Gamma_1)|$. Note that

$$|P| = \Theta\left(\binom{n/t}{2}t\right) = \Theta(n^2/t) = \Theta(sn^{1/2}|D|^{1/2})$$

and

$$\begin{aligned}|\Gamma \setminus (\Gamma_0 + \Gamma_1)| \leq \deg(f)|\hat{\Gamma}| &= \Theta\left(\binom{n/t}{2}\binom{n/t}{2}t^2\right)\\ &= \Theta(n^4/t^2)\\ &= \Theta(s^2 n|D|).\end{aligned}$$

We get

$$\begin{aligned}|Q| &\leq 4|I(P,\Gamma \setminus (\Gamma_0 \cup \Gamma_1))| + 4\deg(\varphi)n^3 + O(|\hat{\Gamma}|),\\ &= O_\varepsilon\left((sn^{1/2}|D|^{1/2})^{9/4+2\varepsilon}\right) + 4\deg(\varphi)n^3.\end{aligned}$$

This proves Proposition 7. ◀

Finally, combining the inequalities from Proposition 6 and Proposition 7, we conclude that

$$sn^3 \leq |Q| = O_\varepsilon\left((n|D|)^{9/8+\varepsilon}\right) + 4\deg(\varphi)n^3.$$

Choosing $s > 8\deg(\varphi)$ and rearranging, we get

$$|D| = \Omega_\varepsilon(n^{5/3-\varepsilon'}).$$

This completes the proof of Theorem 2. □

Robustness of Persistent Topological Features and Minimum Homological Cuts

University of Amsterdam, The Netherlands

Abstract

Persistent homology is a popular method for computing topological features of (metric) data. Standard approaches based on the Čech or Rips filtration are stable under small perturbations of the data, but highly sensitive to outliers. This lack of robustness has been frequently addressed in the literature. In this paper, we take a novel perspective by asking the following question: When can we guarantee that an observed persistent feature (a bar) is inherent to the underlying data in the presence of a limited number of unknown, arbitrary outliers. We formalize this question by introducing the notion of *adversarial robustness*, and study the problem of deciding whether a given bar in the barcode of a filtered simplicial complex is adversarially robust. We show that this problem is essentially equivalent to a homological variant of the minimum cut problem in simplicial complexes, which we believe to be of independent interest. As our main technical contribution, we provide the first computational complexity results for this problem, consisting of an efficient algorithm in 0-dimensional homology, NP-hardness for the general problem, and an efficient algorithm for codimension-1 in n-dimensional complexes embedded in $\mathbb{R}^n$. We also analyze its natural linear programming relaxation, whose dual defines a homological analog of the max-flow problem in graphs. We show that a max-flow/min-cut theorem does not hold in our setting, implying that the LP relaxation is not tight in general. Finally, in the special case of the Rips filtration, we provide a global heuristic based on the Hausdorff distance that guarantees adversarial robustness of sufficiently long bars. This connects adversarial robustness to standard stability theorems in persistent homology.

1 Introduction

Persistent homology is a central method in topological data analysis. It is used to extract topological features from (metric) data across a range of spatial scales. At a high level, it works as follows. First, we represent our data by a nested sequence of simplicial complexes, called a filtration. An important example is the (Vietoris-)Rips filtration, which arises from pairwise distances between points in a metric space. The evolution of the homology groups of the complexes in this filtration (i.e., its *persistent* homology) can be captured by a *barcode*, which consists of a (multi)set of intervals (or *bars*) whose endpoints represent the

© Pepijn Roos Hoefgeest and Lucas Slot;
licensed under Creative Commons License CC-BY 4.0

appearance (*birth*) and disappearance (*death*) of a homology class at a particular step in the filtration. Barcodes serve as a topological signature of the underlying data set. We refer to [19, 21, 26, 32] for surveys on persistent homology and its many applications.

Stability and robustness. An important property of barcodes is their *stability* under small perturbations: For example, the *Bottleneck distance* between the barcodes of Rips filtrations may be bounded in terms of the *(Gromov-)Hausdorff distance* between their underlying metric spaces [16]. On the other hand, barcodes are (in)famously sensitive to *outliers*. Indeed, even a single outlier may cause arbitrarily large changes in the barcode, which makes persistent homology unreliable in the presence of noise. This issue has been frequently addressed in the literature; we highlight three approaches. First, one may consider alternative metric interpretations of the data which take density into account, and whose resulting barcodes are (hopefully) more robust. For instance, a filtration based on the *distance-to-measure* function [14] achieves stability with respect to the *Wasserstein distance*, which tolerates small amounts of outliers [8]. See [24, 27] for similar approaches using kernel functions. A downside is that these filtrations are difficult to interpret geometrically, often depend on some choice of secondary parameters, and are computationally expensive, making them less suited for topological inference than the Rips filtration. A second approach is to (cleverly) subsample the data to determine so-called *landmarks*, and then construct a filtration based on these landmarks. An example is the *(lazy) witness filtration* [29]. Empirically, it appears that the landmarks may be chosen in a way that reduces the sensitivity to outliers (in the original data); see [30]. However, this effect is hard to quantify theoretically. Third, one may consider filtrations indexed by multiple parameters, modeling for example both scale and density. The persistent homology of such bifiltrations can be provably robust to certain types of noise [4]. However, multiparameter persistence modules are significantly more difficult to represent than their one-parameter counterparts. In particular, they generally do not have a barcode, which is a serious theoretical and practical drawback; see [7].

A new notion of robustness. In this paper, we take a different perspective. Rather than modify existing filtrations to increase their tolerance to noise, we ask the following question.

▶ **Question 1.** *When can we guarantee that an observed persistent feature (a bar) arising from a filtration is inherent to the underlying data in the presence of (adversarial) noise?*

To address this question, we introduce a new notion of outlier-robustness of persistent topological features (bars) arising from a filtration of a simplicial complex, which we call *adversarial robustness*. Before giving a formal definition, it is illustrative to first consider the Rips filtration on a (finite) set of metric data. Intuitively speaking, we say that a persistent feature of the Rips filtration is k-adversarially robust if it "continues to exist" after removing any k points from the data set. In this way, k-adversarial robustness certifies that a feature is *inherent* to an underlying data set even after adding (at most k) unknown, arbitrary outliers. Alternatively, the largest k for which a feature is k-adversarially robust can be thought of as a *measure of robustness* of that feature (possibly after dividing by the total number of data points). With respect to the earlier work outlined above, a key advantage of our approach is that we make no structural assumptions on the outliers.

In what follows, we give a formal definition of adversarial robustness. The key ingredient is the induced matching between barcodes [2], which allows us to relate the persistent features of a filtered simplicial complex to those of its filtered subcomplexes. Then, we study the computational problem of deciding whether a given bar is adversarially robust. To this end,

we first show that adversarial robustness of a bar can be determined by solving a homological variant of the minimum cut problem in a single (unfiltered) simplicial complex. Thus, it suffices to study the complexity of that problem, which we believe to be of independent interest. We give efficient algorithms for zero-dimensional homology and complexes embedded in $\mathbb{R}^n$. On the other hand, we show that the general problem is NP-hard. We also analyze its natural linear programming relaxation, whose dual defines a homological analog of the max-flow problem in graphs. We conclude by giving an efficiently computable heuristic for adversarial robustness in Rips filtrations, which is connected to Hausdorff stability.

1.1 Adversarially robust persistent features

Let K be a (finite) simplicial complex, and let $\mathcal{K} = (K_i)_{0\leq i\leq m}$ be a filtration of K, i.e., a sequence of simplicial complexes $\emptyset = K_0 \subseteq K_1 \subseteq \ldots \subseteq K_m = K$. Throughout, we assume that $\mathcal{K}$ is a *simplex-wise* filtration, i.e., for any $i < m$, the complex K_{i+1} is obtained by adding (at most) a single simplex to K_i. Any filtration can be made simplex-wise by breaking ties (arbitrarily, but so that face relations are preserved) whenever multiple simplices are added at once, which is also what is done in practice. For $p \geq 0$, we denote the p-dimensional persistent homology of $\mathcal{K}$ by $\mathrm{PH}_p(\mathcal{K})$, and we write $\mathcal{B}(\mathrm{PH}_p(\mathcal{K}))$ for its barcode. For $A \subseteq K$, we write $K - A$ for the largest subcomplex of K contained in $K \setminus A$. That is, $K - A$ is obtained from K by removing all simplices that have a face in A. Similarly, we write $\mathcal{K} - A$ for the filtration of $K - A$ given by $(K_i - A)_{0\leq i\leq m}$. There is a natural way to relate the barcodes associated with $\mathcal{K}$ and $\mathcal{K} - A$. Namely, the inclusion $K - A \hookrightarrow K$ induces a map $\mathrm{PH}_p(\mathcal{K} - A) \to \mathrm{PH}_p(\mathcal{K})$. In turn, this map induces a (partial) matching between the respective barcodes, which we denote $\mathcal{X}_{\mathcal{K}-A\hookrightarrow\mathcal{K}}$. This is a special case of the so-called *induced matching*, which plays a crucial role in a proof of the algebraic stability theorem [2]. Generally, the induced matching is *not* functorial, but in the context of simplex-wise filtrations it allows us to unambiguously relate bars in the barcodes of $\mathrm{PH}_p(\mathcal{K})$ and $\mathrm{PH}_p(\mathcal{K} - A)$; see Section 3 for more details. This allows us to give the central definition of this paper. For $s \in \mathbb{N}$, let $K^{(s)} \subseteq K$ denote the set of s-simplices in K.

▶ **Definition 2** (Adversarial robustness). *Let $\mathcal{K}$ be a simplex-wise filtration of a simplicial complex K. Let $p \geq 0$, and let $s \leq p$. A bar $B \in \mathcal{B}(\mathrm{PH}_p(\mathcal{K}))$ is* k-adversarially robust (in degree s) *if, for each subset $A \subseteq K^{(s)}$ of size at most k, we have $B \in \mathrm{Im}(\mathcal{X}_{\mathcal{K}-A\hookrightarrow\mathcal{K}})$.*

Definition 2 guarantees that a bar is "present" in any (filtered) subcomplex of K missing at most k s-simplices. If $\mathcal{K}$ is a Rips filtration, the 0-simplices (vertices) of K correspond to metric data points. Thus, k-adversarial robustness (in degree 0) of a bar means that it is present in the Rips filtration of any subset of the original data obtained by removing at most k points, matching our earlier intuitive description.

1.2 (Minimum) homological cuts

Adversarial robustness of bars is closely related to a novel homological variant of the min-cut problem in simplicial complexes, which we introduce in this work. For $C \subseteq K^{(s)}$, we write $\iota^*_{K-C\hookrightarrow K} : H_p(K - C) \to H_p(K)$ for the map induced by the inclusion $K - C \hookrightarrow K$.

▶ **Definition 3** (homological cuts). *Let K be a simplicial complex. Let $p \geq 0$, and $s \leq p$. We say that $C \subseteq K^{(s)}$ is a* homological s-cut *for $\gamma \in H_p(K)$ if $\gamma \notin \mathrm{Im}(\iota^*_{K-C\hookrightarrow K})$. We refer to the special cases $s = 0, s = 1$ as homological* vertex *and* edge *cuts, respectively; see Figure 1.*

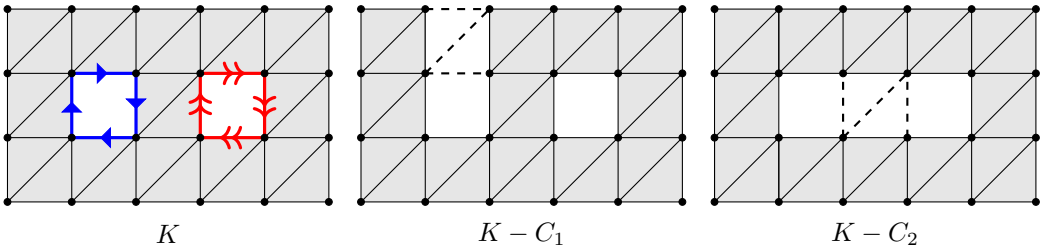

Figure 1 A simplicial complex K with cycles $c_{\text{left}}, c_{\text{right}} \in C_1(K;\mathbb{R})$ drawn in blue single arrows and red double arrows, respectively (all coefficients equal to 1). The classes $[c_{\text{left}}]$ and $[c_{\text{right}}]$ generate $H_1(K;\mathbb{R}) \cong \mathbb{R}^2$. On the right: two subcomplexes obtained by removing subsets $C_1, C_2 \subseteq K^{(1)}$ (dashed) from K, respectively. Note that C_1 is an edge cut for $[c_{\text{left}}]$ and $[c_{\text{left}} + c_{\text{right}}]$, but not for $[c_{\text{right}}]$. On the other hand, C_2 is a 1-cut for both $[c_{\text{left}}]$ and $[c_{\text{right}}]$, but not for $[c_{\text{left}} + c_{\text{right}}]$.

To connect homological cuts to adversarial robustness, we use the fact that, for a simplex-wise filtration $\mathcal{K}$, each bar $B \in \mathcal{B}(\mathrm{PH}_p(\mathcal{K}))$ corresponds to a pair (σ_B, τ_B) of simplices, whose insertions at steps $i = b$ and $i = d$, respectively, represent the birth and death of any cycle representing B. These are called *persistence pairs*. We call the complex $K_B := K_{d-1}$ the *predeath complex* of B. Now, the following proposition shows that adversarial robustness of B is characterized by homological cuts of $[\tau_B]$ in K_B. We give its proof in Section 3.2.

▶ **Proposition 4.** *Let $p \geq 0$, and let $B \in \mathcal{B}(\mathrm{PH}_p(\mathcal{K}))$ be a bar in the barcode of a simplex-wise filtration $\mathcal{K}$ of a simplicial complex K. Let K_B, τ_B be its pre-death complex and death simplex. Then, B is k-adversarially robust (in degree s) if, and only if,*

$$[\partial\tau_B] \in \mathrm{Im}(\iota^*_{K_B - A \hookrightarrow K_B}) \text{ for all } A \subseteq K^{(s)} \text{ with } |A| \leq k.$$

Thus, B is k-adversarially robust iff all homological s-cuts of $[\tau_B]$ in K_B have size at least k.

The above proposition motivates our study of the following problem.

▶ **Problem 5.** *The* minimum homological s-cut problem *asks to compute*

$$\mathrm{mhc}(K, \gamma, s) := \min_{C \subseteq K^{(s)}} \{|C| : C \text{ is a homological } s\text{-cut for } \gamma\}. \tag{MHC}$$

We call a set C attaining the minimum above a minimum homological s-cut *for γ (in K).*

Apart from its connection to adversarial robustness, we believe that the minimum homological cut problem is of intrinsic interest. It is related to, *but distinct from*, two types of well-studied problems in computational topology. On the one hand, there are problems related to finding a smallest (or otherwise "optimal") representing cycle of a homology class in a simplicial complex [3, 5, 12]; this is often referred to as *homology localization*. By contrast, the problem we consider can be thought of as *co*homology localization. The computational complexity of homology localization varies based on the choice of coefficient field, the dimension of the homology group, and additional assumptions on the underlying complex. For example, while the general problem is hard [15], a linear programming relaxation yields an efficient algorithm for finding minimum weight homologous cycles over integer coefficients for complexes whose boundary matrix is totally unimodular [17]. On the other hand, there are ordinary min-cut (and max-flow) problems in graphs with topological structure, e.g., graphs that can be embedded in a surface of low genus. There, (co)homological properties of cuts (or flows) can be used to achieve algorithmic speedups with respect to the general case [10, 11, 22].

Linear programming relaxations. As we explain in the full version of this paper [28], homological edge cuts of a class $\gamma \in H_1(K;\mathbb{R})$ are naturally related to (ordinary) cuts in graphs. Namely, we show that a minimum homological edge cut can be found by optimizing the number $\|\varphi\|_0$ of non-zero coefficients of a vector φ (indexed by the edges of K) under a set of linear constraints involving the boundary matrix of K. The relaxation of this problem obtained by optimizing the 1-norm $\|\varphi\|_1$ instead is a linear program. Its dual may be interpreted as a homological analog of the max-flow problem in graphs. Contrary to the graph setting, we show that there is no max-flow min-cut theorem in our case: homological max-flows are not necessarily integral, meaning the LP relaxation is not tight.

1.3 Main contributions

Complexity of the minimum homological cut problem. We prove positive and negative results on the computational complexity of the minimum homological cut problem (MHC) introduced above, in terms of the number of simplices $|K|$ in the complex K. By Proposition 4, these results have immediate implications on the complexity of determining adversarial robustness of bars. Our first contribution is an efficient algorithm for the case where $\gamma \in H_0(K)$ is a 0-dimensional homology class, i.e., $p = 0$.

▶ **Theorem 6.** *Let K be a simplicial complex , and let $\gamma \in H_0(K)$. We can compute a minimum homological vertex cut for γ in time $O(|K^{(0)}| + |K^{(1)}|)$.*

Theorem 6 follows from the fact that a minimum homological cut of a class in H_0 is always equal to the vertex set of a connected component of K, as we show in Section 4.1.

Next, we show that finding a minimum homological cut is NP-hard, already when $p = 1$.

▶ **Theorem 7.** *For $p = 1$ and $s = 1$, the minimum homological s-cut problem is NP-hard. This is true in particular when homology is taken with coefficients in $\mathbb{R}$ or $\mathbb{Z}/2\mathbb{Z}$.*

We give the proof of Theorem 7 in Section 4.2. It relies on a reduction from Exact Cover by 3-Sets (X3C). In [23, pp. 246], X3C is used to show hardness of the problem of finding minimum weight solutions to linear equations. It was also used in [25] to show hardness of finding the *sparsest* approximate solution to a set of linear equations. As mentioned, we show in the full version of this paper [28] that (MHC) can be solved by finding the sparsest solution to a particular set of linear equations. In light of these observations, X3C is a natural candidate for showing hardness of (MHC). In our proof, we construct for any X3C-instance an equivalent instance of (MHC). Our construction relies on "gluing together" punctured discs, each representing a 3-set of the X3C-instance, to obtain a topological space which is then triangulated carefully to ensure minimum homological cuts correspond to exact covers. This approach resembles earlier work on NP-hardness in homology localization [1, 15, 20]. A distinction is that these mostly rely on reductions from SAT-problems; to the best of our knowledge, a reduction from X3C was not considered before in this context. We remark that our construction can be extended to cover the case $s = 0$. Via Proposition 4, our result also implies that testing k-adversarial robustness of bars (in degree 0 and 1) is hard in general.

Finally, we give an efficient algorithm for the following special case, which covers, e.g., subcomplexes of the Delauney triangulation of a finite metric data set in $\mathbb{R}^n$.

▶ **Theorem 8.** *Suppose that K is an n-dimensional simplicial complex embedded in $\mathbb{R}^n$, and let $\gamma \in H_{n-1}(K)$. We can compute a minimum homological $(n-1)$-cut for γ in polynomial time in the number of simplices of K.*

Our proof of Theorem 8 in Section 4.3 relies on Alexander duality, which can be used to construct the so-called *extended dual graph* of K. In [18], this graph was used to find optimal generators for certain homology classes: these correspond to minimum cuts in the graph. For us, the situation is precisely the opposite: as we will show, minimum homological cuts in K correspond to shortest paths in the extended dual graph (allowing for efficient computation). The use of the extended dual graph in homology localization dates back to [31]; see also [9].

The Rips filtration. Complementing our hardness result, we give an efficiently computable *heuristic* based on the Hausdorff distance to test adversarial robustness of bars arising from the Rips filtration of a metric data set X. Namely, we show that any bar in the barcode of the Rips filtration of length at least

$$\mathcal{H}_{X,k} := \max_{A \subseteq X,\ |A| \leq k} d_H(X \setminus A, X)$$

is automatically k-adversarially robust (in degree 0)[1]; see Section 5 for a precise statement. Moreover, we show that the parameter $\mathcal{H}_{X,k}$ can be computed in time $O(|X|^2 \log |X|)$. This result links adversarial robustness to classical stability results in persistent homology. It shows that our definition is at least as expressive as a naive definition based only on the length of bars and the Hausdorff stability of the Rips filtration. That is, sufficiently long bars are outlier-robust according to our definition (as one would expect). But importantly, our definition is also capable of recognizing relatively short bars as robust; see Figure 2.

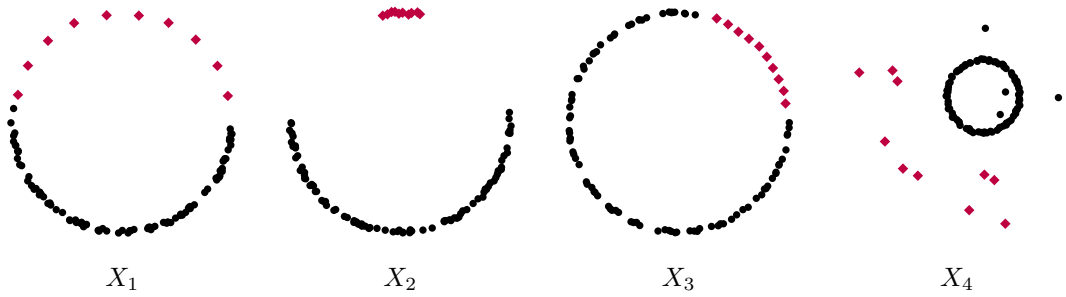

Figure 2 Four data sets in $\mathbb{R}^2$, each of size 100, whose Rips filtrations each induce a 1-dimensional persistent feature. For X_1 and X_2, these features are not k-adversarially robust for $k = 10$, evidenced by the subsets $A_1 \subseteq X_1$ and $A_2 \subseteq X_2$ marked in red. The points in A_2 are quite dense, and so standard subsampling techniques will likely not remove them. On the other hand, the feature is 10-robust in X_3, as its length exceeds $\mathcal{H}_{X_3,10}$, which equals $d_H(X_3 \setminus A_3, X_3)$ for the subset $A_3 \subseteq X_3$ marked in red (cf. Theorem 20). In X_4, the feature induced by the densely sampled circle is 10-robust, even though its bar has length strictly less than $\mathcal{H}_{X_4,10}$ (evidenced by the set A_4 marked in red).

2 Preliminaries

2.1 Simplicial complexes

An (abstract) simplicial complex (on a set Y) is a collection K of non-empty subsets $\sigma \subseteq Y$, called *simplices*, such that if $\tau \in K$ and $\sigma \subseteq \tau$, then $\sigma \in K$. In that case, σ is called a *face* of τ, and τ is called a *coface* of σ. For $A \subseteq K$, we denote by $K - A$ the largest subcomplex

[1] The Rips filtration is not simplex-wise, therefore, as mentioned, we must break ties to obtain a simplex wise filtration to apply Definition 2. This result does not depend on the choice of tiebreaker.

of K which does not contain any simplices in A (which is obtained by removing all simplices from K which have a face in A). For $s \in \mathbb{N}$, we write $K^{(s)}$ for the set of s-simplices of K, being the simplices $\sigma \in K$ with $|\sigma| = s + 1$. We write $V(K) := K^{(0)}$ for the vertices of K, and $E(K) := K^{(1)}$ for its edges. If there is a p such that $K^{(p)} \neq \emptyset$ and $K^{(q)} = \emptyset$ for all $q > p$, then we say that K is p-dimensional, and we call K a p-complex. If K is a p-complex and each simplex of K is contained in a p-simplex, then K is called a *pure* p-complex.

Embedded complexes. A *geometric* p-simplex σ in $\mathbb{R}^n$ is the convex hull of $p+1$ affinely independent vectors $v_0, \ldots, v_p \in \mathbb{R}^n$. The elements of $V(\sigma) := \{v_0, \ldots, v_p\}$ are called the vertices of σ. If τ is the convex hull of a subset of the vertices of σ, then τ is called a *face* of σ. A *geometric* simplicial complex K in $\mathbb{R}^n$ is a collection of geometric simplices in $\mathbb{R}^n$ with the properties that 1) the face of every simplex is in K; 2) for every pair of simplices $\sigma, \tau \in K$ with non-empty intersection, $\sigma \cap \tau$ is in K. We denote the *geometric realization* of K by $\|K\| := \bigcup_{\sigma \in K} \sigma \subseteq \mathbb{R}^n$, i.e. the subset of $\mathbb{R}^n$ consisting of the union of simplices that make up K. If K is a geometric simplicial complex, then $A(K) := \{V(\sigma) \,|\, \sigma \in K\}$ is an abstract simplicial complex. We say that an abstract simplicial complex L is *embedded in* $\mathbb{R}^n$ if $L \cong A(K)$ for some geometric simplicial complex K in $\mathbb{R}^n$, and we define the geometric realization of the embedded simplicial complex L to be $\|L\| := \|K\|$.

Simplicial homology. For a field $\mathbb{F}$, and $p \in \mathbb{N}$, we denote by $C_p(K; \mathbb{F})$ the simplicial p-chains on K. We write $\partial_p : C_p(K; \mathbb{F}) \to C_{p-1}(K; \mathbb{F})$ for the boundary operator. We have subspaces of cycles $Z_p(K; \mathbb{F}) = \mathrm{Ker}(\partial_p)$ and boundaries $B_p(K; \mathbb{F}) = \mathrm{Im}(\partial_{p+1})$, and the simplicial homology of K is defined as $H_p(K; \mathbb{F}) = Z_p(K; \mathbb{F})/B_p(K; \mathbb{F})$. Throughout, if we omit $\mathbb{F}$ from the notation, we mean homology over any field. For two complexes $K \subseteq K'$, we denote the inclusion $K \hookrightarrow K'$ by $\iota_{K \hookrightarrow K'}$. Then, we write $\iota^*_{K \hookrightarrow K'} : H_p(K) \to H_p(K')$, $[c] \mapsto [\iota_{K \hookrightarrow K'}(c)]$ for the induced maps in homology (suppressing p in the notation).

2.2 Persistent homology

A persistence module is a functor $M : (\mathbb{R}, \leq) \to \mathbf{vect}_{\mathbb{F}}$, where $\mathbf{vect}_{\mathbb{F}}$ denotes the category of finitely generated vector spaces. A morphism between persistence modules M and N is a natural transformation of functors $f : M \to N$. There exists a multiset of intervals $\mathcal{B}(M)$, called the barcode of M, that completely captures M up to isomorphism. We write $\mathbb{I}_I$ for the interval module over I, i.e, the persistence module which is equal to $\mathbb{F}$ on I, connected by identity morphisms, and 0 elsewhere. Then there is an isomorphism $M \cong \bigoplus_{I \in \mathcal{B}(M)} \mathbb{I}_I$ [6].

A filtration $\mathcal{K} = (K_i)_{0 \leq i \leq m}$ of simplicial complexes naturally defines a persistence module $\mathrm{PH}_p(\mathcal{K})$, called the persistent homology of $\mathcal{K}$, which is given at $t \in \mathbb{R}$ by $\mathrm{PH}_p(\mathcal{K})_t = \mathrm{H}_p(K_{\lfloor t \rfloor})$, and whose structure maps are maps induced by inclusions. If $\mathcal{K}$ is a simplex-wise filtration, there is at most one birth or death of a bar at each step of the filtration. Hence, any bar $B = [i, j) \in \mathcal{B}(\mathrm{PH}_p(\mathcal{K}))$ then uniquely corresponds to a pair of simplices (σ_B, τ_B), inserted at steps i and j respectively. This is called a *persistence pairing*, and we sometimes refer to the bar as $B = [\sigma_B, \tau_B)$. We denote by $K_B := K_{d-1} = K_d \setminus \{\tau_B\}$ the *predeath complex* of B. For a filtration $\mathcal{K}$ and a non-decreasing function $f : \mathbb{N} \to \mathbb{R}$, we get a persistence module $\mathrm{PH}_p(\mathcal{K}, f)$ given at time $t \in R$ by $\mathrm{H}_p(K_{\sup\{i : f(i) \leq t\}})$. We think of f as a reparametrization of the filtration. Note that if f is the identity, $\mathrm{PH}_p(\mathcal{K}, f) = \mathrm{PH}_p(\mathcal{K})$. For each bar B in the barcode of $\mathrm{PH}_p(\mathcal{K}, f)$ there is a bar $[i, j)$ in the barcode of $\mathrm{PH}_p(\mathcal{K})$ such that $B = [f(i), f(j))$.

3 Induced matchings, adversarial robustness and homological cuts

3.1 Induced matchings

While the barcode of a persistence module M is unique, the isomorphism $M \cong \bigoplus_{I \in \mathcal{B}(M)} \mathbb{I}_I$ is not. For a morphism $f : M \to N$, this makes it difficult to relate the barcodes $\mathcal{B}(M)$ and $\mathcal{B}(N)$ to one another in a way that reflects the algebraic structure of f. In [2], a procedure is described that associates a partial matching $\mathcal{X}_f : \mathcal{B}(M) \nleftrightarrow \mathcal{B}(N)$ with f, in a way that only depends on the barcodes of M, N, and $\mathrm{Im}(f)$, the image persistence module of f. Denote by $\langle \cdot, d \rangle_M \subseteq \mathcal{B}(M)$ the bars in the barcode of the form $[b, d)$ (for simplicity, we assume all intervals in the barcodes of M and N are half-open). If f is injective, it can be shown that $|\langle \cdot, d \rangle_M| \leq |\langle \cdot, d \rangle_N|$. Moreover, if we order the bars in both $\langle \cdot, d \rangle_M$ and $\langle \cdot, d \rangle_N$ by their length, there is an order preserving injection $\mathcal{X}_f^d : \langle \cdot, d \rangle_M \hookrightarrow \langle \cdot, d \rangle_N$, with the property that if $\mathcal{X}_f^d([b, d)) = [b', d)$, then $b' \leq b$. Note that if M and N come from simplex-wise filtrations, the sets $\langle \cdot, d \rangle_M$ and $\langle \cdot, d \rangle_N$ consist of at most one element. The induced matching $\mathcal{X}_f$ is then defined as the union of the matchings $\mathcal{X}_f^d$. If f is surjective, there is a similar way to match bars with the same birth in an order preserving way. For arbitrary $f : M \to N$, there is a factorization $f : M \twoheadrightarrow \mathrm{Im}(f) \hookrightarrow N$ of f into a composition of a surjective and an injective map. The induced matching $\mathcal{X}_f$ is then defined as the composition of the induced matchings of $M \twoheadrightarrow \mathrm{Im}(f)$ and $\mathrm{Im}(f) \hookrightarrow N$. The induced matching is *not* functorial in f.

A persistence module M is called ε-trivial if for each $t \in \mathbb{R}$, the internal morphism $\phi^M_{t \to t+\varepsilon} : M_t \to M_{t+\varepsilon}$ is the zero morphism. The following theorem is the main result of [2].

▶ **Theorem 9** (Induced matching theorem [2]). *Let $f : M \to N$ be a morphism with ε-trivial kernel. Then each bar $[b, d) \in \mathcal{B}(M)$ with $d - b > \varepsilon$ is matched to a bar in $\mathcal{B}(N)$ by $\mathcal{X}_f$. If $\mathrm{coker}(f)$ is ε-trivial, $\mathcal{X}_f$ matches each bar $[b, d) \in \mathcal{B}(N)$ with $d - b > \varepsilon$ to a bar in $\mathcal{B}(M)$.*

We will need this result for our proof of Theorem 20 in Section 5.

3.2 Adversarial robustness and minimum homological cuts

In this section, we show that k-adversarial robustness of a bar can be determined by solving a minimum homological vertex cut problem. That is, we prove Proposition 4.

Proof of Proposition 4. Let $B = [b, d)$ be a bar in the barcode of $\mathrm{PH}_p(\mathcal{K})$, thus with birth simplex σ_B inserted at step b, and death simplex τ_B inserted at time d. Let $K_B = K_{d-1}$ be its predeath complex. Let $A \subseteq K^{(s)}$, and write $\mathcal{X}_{\mathcal{K}-A \hookrightarrow \mathcal{K}}$ for the matching induced by the inclusion $\mathcal{K} - A \hookrightarrow \mathcal{K}$. We show that $B \in \mathrm{Im}(\mathcal{X}_{\mathcal{K}-A \hookrightarrow \mathcal{K}})$ if and only $[\partial \tau_B] \in \mathrm{Im}(\iota^*_{K_B - A \hookrightarrow K_B})$.

Note that any representative cycle for B is homologous to a scalar multiple of $\partial \tau_B$ in $C_p(K_B)$, as $[\partial \tau_B]$ generates the kernel of $H_p(K_B) \to H_p(K_B \cup \{\tau_B\})$. If $B \in \mathrm{Im}(\mathcal{X}_{\mathcal{K}-A \hookrightarrow \mathcal{K}})$, there is thus a bar $B' = [b', d)$ in the barcode of the image module $\mathrm{Im}(\mathrm{PH}_p(\mathcal{K}-A) \to \mathrm{PH}_p(\mathcal{K}))$. Then, any representative cycle $\xi \in C_p(K_{b'} - A) \subseteq C_p(K_{b'})$ for $[b', d)$, when considered as a homology class $[\xi] \in H_p(K_B)$ through the inclusions $K_{b'} - A \hookrightarrow K_{b'} \hookrightarrow K_B$, is in the kernel of $H_p(K_B) \to H_p(K_B \cup \{\tau_B\})$, and is hence homologous to a scalar multiple of $[\partial \tau_B]$.

Conversely, suppose that $[\partial \tau_B]$ is in the image of $H_p(K_B - A) \to H_p(K_B)$, and let $\xi \in C_p(K_B - A)$ be a cycle such that $[\xi] = [\partial \tau_B] \in H_p(K_B)$. Let $\xi_1, \ldots, \xi_k$ denote representative cycles for summands of $\mathrm{Im}(\mathrm{PH}_p(\mathcal{K} - A) \to \mathrm{PH}_p(\mathcal{K}))$ so that the $[\xi_i]$ are linearly independent in $H_p(K_B)$, and $[\xi] = \lambda_1[\xi_1] + \ldots + \lambda_k[\xi_k]$. Since $[\xi]$ is a non-zero element in the kernel of the map

$$\mathrm{Im}\Big(H_p(K_B - A) \to H_p(K_B)\Big) \to \mathrm{Im}\Big(H_p((K_B \cup \{\tau_B\}) - A) \to H_p(K_B \cup \{\tau_B\})\Big),$$

we see that one of the generators ξ_j must be in this kernel, and thus generate a summand isomorphic to $\mathbb{I}_{[b', d)}$ for some $b \leq b' < d$. This shows that B is in the image of $\mathcal{X}_{\mathcal{K}-A \hookrightarrow \mathcal{K}}$. ◀

4 Complexity of the minimum homological cut problem

4.1 An efficient algorithm for zero-dimensional cuts

Let $\gamma \in H_0(K)$. We show that minimum homological vertex cuts for γ have a very particular structure, allowing us to compute them efficiently. Let $\Gamma_1, \dots, \Gamma_q \subseteq V(K)$ be the vertex sets of the connected components of K, and let $c_1 \in V(\Gamma_1), \dots, c_q \in V(\Gamma_q)$. Then, $H_0(K)$ is generated by the classes $[c_1], \dots, [c_q]$, meaning we can write $\gamma = \sum_{i=1}^{q} \lambda_i [c_i]$, with $\lambda_i \in \mathbb{F}$.

▶ **Proposition 10.** *Let $\gamma = \sum_{i=1}^{q} \lambda_i [c_i] \in H_0(K)$ as in the above. A subset $C \subseteq V(K)$ is a homological vertex cut for γ iff $C \supseteq V(\Gamma_\ell)$ for some $1 \leq \ell \leq q$ with $\lambda_\ell \neq 0$. In particular, a homological mincut for γ is of the form $C = V(\Gamma_\ell)$, where $\ell = \arg\min_i \{|V(\Gamma_i)| : \lambda_i \neq 0\}$.*

Proof. Write $V = V(K)$. For any $A \subseteq V$, and any $v \in V \setminus A$ we have $\iota^*_{K-A \hookrightarrow K}([v]) = [v]$. Furthermore, for any $v, w \in V$, we have $[v] = [w]$ (in $H_0(K)$) if and only if v and w lie in the same connected component of K. Since the classes $[v]$, $v \in V \setminus A$, generate $H_0(K - A)$, we thus have $\gamma \in \mathrm{Im}(\iota^*_{K-A \hookrightarrow K})$ if and only if $V \setminus A$ contains a vertex in each connected component Γ_i of K with $\lambda_i \neq 0$. Thus, $\gamma \notin \mathrm{Im}(\iota^*_{K-A \hookrightarrow K})$ (i.e., A is a homological cut) iff A contains all the vertices of at least one connected component Γ_ℓ of K with $\lambda_\ell \neq 0$. ◀

Proof of Theorem 6. To determine a minimum homological vertex cut of a 0-dimensional class in a simplicial complex K, it suffices by Proposition 10 to find its connected components. We can do so in time linear in $|V(K)| + |E(K)|$ using a depth-first search. ◀

4.2 NP-hardness of the general problem

In this section, we prove Theorem 7. That is, we show that the minimum homological cut problem is hard when $p = s = 1$. Our arguments apply for homology taken over any field, and even over $\mathbb{Z}$. We use a reduction from the following NP-hard problem.

▶ **Problem 11** (Exact cover by 3-sets (X3C)). *Given a set U, and a collection $\mathcal{S} \subseteq \mathcal{P}(U)$ of subsets of U, each of size exactly 3, determine whether $\mathcal{S}$ contains an* exact cover *of U, i.e., whether there is an $\mathcal{S}' \subseteq \mathcal{S}$ so that each element of U occurs in* exactly one *element of $\mathcal{S}'$.*

We proceed as follows: To a given instance $(U, \mathcal{S})$ of the X3C problem, we associate a topological space $X = X(U, \mathcal{S})$, together with a specific homology class $\gamma \in H_1(X)$ (Construction 12). Then, we construct a triangulation $K = K(U, \mathcal{S})$ of this space, which satisfies useful technical properties (Lemma 13). Finally, we show that if there exists a minimum cut for γ in K of a particular size, there exists a solution to the X3C instance, and vice versa.

▶ **Construction 12.** *Let $(U, \mathcal{S})$ be an instance of exact cover by 3-sets. For each $u \in U$, denote by $\mathcal{S}_u = \{S_{u,1}, \dots S_{u,m_u}\} \subseteq \mathcal{S}$ the elements of $\mathcal{S}$ containing u. Let F_u denote the surface obtained from a 2-dimensional disk by removing $|\mathcal{S}_u|$ open disks from its interior. Label the outer boundary of F_u by u, and the interior boundary components by the respective elements of $\mathcal{S}$ they correspond to. Choose an orientation for F_u, inducing an orientation on its boundary components. Choose generators for the homology groups of the boundary components such that $\partial[F_u] = [u] + [S_{u,1}] + \dots + [S_{u,m_u}]$; see Figure 3.*

We obtain $X = X(U, \mathcal{S})$ from $\bigsqcup_{u \in U} F_u$ by gluing together the surfaces in the following way: We identify all outer boundary components with each other along orientation preserving homeomorphisms, so that $[u] = [v]$ in $H_1(X)$ for each $u, v \in U$. We also identify all interior boundary components with each other that have the same label, again in an orientation preserving way. This means that if $S = \{u, v, w\}$, then after gluing $S = S_{u,i_u} = S_{v,i_v} = S_{w,i_w}$, and $[S_{u,i_u}] = [S_{v,i_v}] = [S_{w,i_w}]$ in $H_1(X)$. Finally, we set $\gamma = [u] \in H_1(X)$ for some $u \in U$.

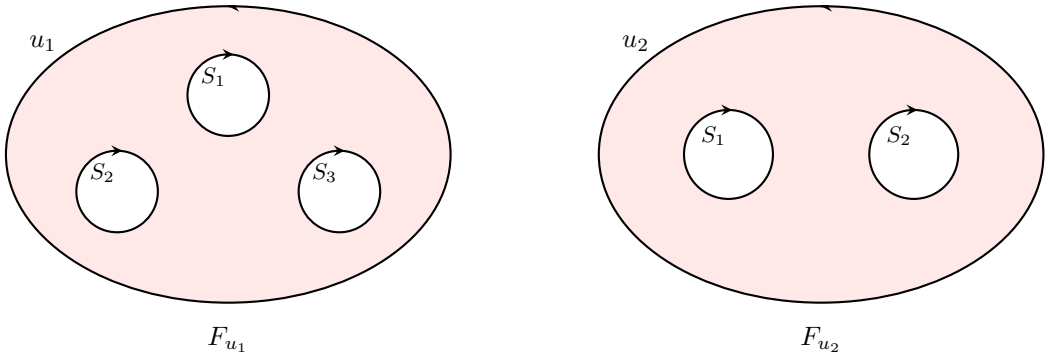

Figure 3 Surfaces F_{u_1} and F_{u_2} involved in the construction of $X(U,\mathcal{S})$ for $(U,\mathcal{S}) = (\{u_1,u_2,u_3,u_4\},\{S_1,S_2,S_3\})$ with $S_1 = \{u_1,u_2,u_3\}, S_2 = \{u_1,u_2,u_4\}, S_3 = \{u_1,u_3,u_4\}$. The surfaces are glued along boundary components with the same label, in an orientation preserving way.

▶ **Lemma 13.** *Let $(U,\mathcal{S})$ be an instance of X3C, and let $k = \max_{u\in U} |\{S \in \mathcal{S} \mid u \in S\}|$. Set $c = c(U,\mathcal{S}) := 5 \cdot \lceil \log_3(k) \rceil + 3$. There exists a triangulation $K = K(U,\mathcal{S})$ for the space $X(U,\mathcal{S})$ of Construction 12, obtained by constructing a triangulation L_u for each surface F_u and gluing them together, that has the following properties:*

1. *K is a pure 2-complex consisting of at most $O(|U| \cdot |S|)$ 2-simplices;*
2. *A minimum homology edge cut for $[u] \in H_1(L_u)$ consists of precisely $c+2$ edges;*
3. *A minimum homology edge cut for $[u]$ contains precisely one edge from u, and precisely one edge from any of the interior boundary components $S_{u,i}$. For any edge in u and any edge in any $S_{u,i}$, there is a minimum cut for $[u]$ containing both those edges.*

Proof. We give an explicit construction in the full version of this paper [28]. ◀

Using Lemma 13, we can sketch our reduction; a complete proof is given in the full version [28].

Proof sketch of Theorem 7. We show that there exists a solution to the X3C-instance $(U,\mathcal{S})$ if and only if there exists a cut for $\gamma \in H_1(K(U,\mathcal{S}))$ consisting of at most $c \cdot |U| + \frac{|U|}{3} + 1$ edges. If $\mathcal{S}^* \subseteq \mathcal{S}$ is a solution to $(U,\mathcal{S})$, for each $u \in U$, we pick a cut C_u for $[u] \in H_1(L_u)$ with the property that it contains one edge in the boundary labelled by u, and one in the boundary labeled by the set $S_u \in S^*$ for which $u \in S_u$. If we consistently choose the same edges in the intersections between surfaces, we can verify that $C = \bigcup_{u\in U} C_u$ is a cut for γ consisting of precisely $c \cdot |U| + \frac{|U|}{3} + 1$ edges. Conversely, suppose C is any cut for γ. Then it can be shown that for each $u \in U$, $C \cap L_u$ is a cut for $[u] \in H_1(L_u)$. By point 3 of Lemma 13, we then obtain a cover $\mathcal{C}_C$ for U. It can be checked that $|C| \geq c \cdot |U| + |\mathcal{C}_C| + 1$. It follows that if $|C| \leq c \cdot |U| + \frac{|U|}{3} + 1$, then $|\mathcal{C}_C| = \frac{|U|}{3}$, and so $\mathcal{C}_C$ is an exact cover. ◀

4.3 An efficient algorithm for embedded complexes

In this section, we prove Theorem 8. To construct an efficient algorithm, we rely on *Alexander duality*. Recall that, for an embedded complex $K \subseteq \mathbb{R}^n$, Alexander duality gives an isomorphism $H_{n-1}(K) \cong \tilde{H}^0(\mathbb{R}^n \setminus \|K\|)$ between $(n-1)$-dimensional homology and 0-dimensional (reduced) singular cohomology. For a subcomplex $L \subseteq K$, a class $\gamma \in H_{n-1}(K)$ lies in the image of $H_{n-1}(L) \to H_{n-1}(K)$ if and only if its Alexander dual lies in the image of the corresponding map $\tilde{H}^0(\mathbb{R}^n \setminus \|L\|) \to \tilde{H}^0(\mathbb{R}^n \setminus \|K\|)$. The latter map can be understood via an extension of the *dual graph* of K.

▶ **Definition 14** (Dual graph). *Let K be a simplicial complex. We denote by $\mathcal{G}_K$ the* dual graph *of K, which has a vertex for each n-simplex of K, and which has an edge between each pair of vertices whose corresponding simplices share an $(n-1)$-dimensional face.*

▶ **Definition 15** (Extended dual graph). *For an embedded simplicial complex K, the extended dual graph $\mathcal{G}_K^*$ of K has one vertex for each n-simplex of K and one vertex for each component of $\mathbb{R}^n \setminus \|K\|$. For each vertex v, we denote by $R_v \subseteq \mathbb{R}^n$ the interior of either the simplex or the connected component of $\mathbb{R}^n \setminus \|K\|$ to which v corresponds. For each $(n-1)$-simplex τ of K, $\mathcal{G}_K^*$ has an edge (v, w) between the vertices for which $\tau \subseteq \overline{R_v} \cap \overline{R_w}$ (possibly allowing loops and multi edges). We denote the set of vertices corresponding to connected components of $\mathbb{R}^n \setminus \|K\|$ by $V_{\mathbb{R}^n \setminus K}$, and the vertex corresponding to the unbounded component by v_∞.*

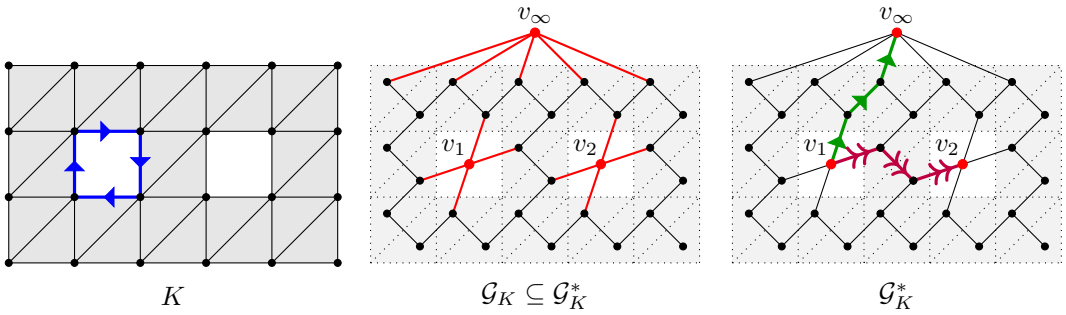

Figure 4 Left: The embedded simplicial complex K of Figure 1 with a class $\gamma \in H_1(K)$ (blue, single arrows). Center: The (extended) dual graph of K. The vertices $V_{\mathbb{R}^n \setminus K} = \{v_1, v_2, v_\infty\}$ and edges added to obtain $\mathcal{G}_K^*$ from $\mathcal{G}_K$ are in red. Only some of the edges incident to v_∞ are drawn. Right: A shortest path $v_1 \to v_\infty$ (green, single arrows) and a shortest path $v_1 \to v_2$ (purple, double arrows) in $\mathcal{G}_K^*$. These correspond to the (minimum) 1-cuts for γ depicted in Figure 1, see Proposition 18. The paths are directed for visual clarity only.

The outline for the rest of this section is as follows. First, we show that one can associate a subgraph $\mathcal{G}_C$ of $\mathcal{G}_K^*$ to any $C \subseteq K^{(n-1)}$ so that $H_{n-1}(K-C) \cong \tilde{H}^0(\mathcal{G}_C)$ (and this association is functorial). In case $C = \emptyset$, $\mathcal{G}_C = \mathcal{G}_K$ and this comes down to Alexander duality, and we see that any $\gamma \in H_{n-1}(K)$ can be written as a sum of homology classes corresponding to vertices in $V_{\mathbb{R}^n \setminus K}$. We then show that whether C is a homology cut for γ depends on the existence of paths in $\mathcal{G}_C$ between specific vertices in $V_{\mathbb{R}^n \setminus K}$. This allows us to reduce (MHC) to a (number of) shortest path problems in $\mathcal{G}_K^*$. See Figure 4 for an illustration.

▶ **Lemma 16.** *Let $K \subseteq \mathbb{R}^n$ be an embedded simplicial complex, and let $C \subseteq K^{(n-1)}$. Denote by $\mathcal{G}_C \subseteq \mathcal{G}_K^*$ the smallest subgraph of $\mathcal{G}_K^*$ containing both $V_{\mathbb{R}^n \setminus K}$ and the dual edges corresponding to the simplices in C. Then there is an isomorphism $H_{n-1}(K-C) \cong \tilde{H}^0(\mathcal{G}_C)$. Moreover, if $C \subseteq C'$, then the following diagram commutes:*

$$\begin{array}{ccc} H_{n-1}(K-C') & \xrightarrow{\cong} & \tilde{H}^0(\mathcal{G}_{C'}) \\ \downarrow & & \downarrow \\ H_{n-1}(K-C) & \xrightarrow{\cong} & \tilde{H}^0(\mathcal{G}_C) \end{array}$$

Proof. See the full version of this paper [28]. ◀

Recall that $H^0(\mathbb{R}^n \setminus \|K\|)$ consists of functions $f : \mathbb{R}^n \setminus \|K\| \to \mathbb{R}$ that are constant on each connected component of $\mathbb{R}^n \setminus \|K\|$. We represent $\tilde{H}^0(\mathbb{R}^n \setminus \|K\|)$ by locally constant functions that are 0 on the unbounded connected component. Similarly, we think of $\tilde{H}^0(\mathcal{G}_C)$

as functions that are constant on the components of $\mathcal{G}_C$, and 0 on the component containing v_∞. Moreover, if $C \subseteq C'$, the map $\tilde{H}^0(\mathcal{G}_{C'}) \to \tilde{H}^0(\mathcal{G}_C)$ is given by a restriction of functions. The following proposition allows us to relate cuts for specific elements of $H_{n-1}(K)$ to paths in the extended dual graph $\mathcal{G}_K^*$ of K.

▶ **Proposition 17.** *Let $v \in V_{\mathbb{R}^n \setminus K} \setminus \{v_\infty\}$. Consider the map $\mathbf{1}_v \in \tilde{H}^0(\mathcal{G}_\emptyset) \cong \tilde{H}^0(\mathbb{R}^n \setminus \|K\|)$. A set $C \subseteq K^{(n-1)}$ is a homological cut for the Alexander dual $\mathrm{AD}(\mathbf{1}_v) \in H_{n-1}(K)$ iff the set of edges in $\mathcal{G}_K^*$ dual to the simplices of C contains a path from v to another vertex in $V_{\mathbb{R}^n \setminus K}$. (Here, $\mathrm{AD}(\mathbf{1}_v)$ is meant to denote the Alexander dual of $\mathbf{1}_{R_v} \in \tilde{H}^0(\mathbb{R}^n \setminus \|K\|)$.)*

Proof. By Lemma 16, $\mathrm{AD}(\mathbf{1}_v)$ is in the image of $H_{n-1}(K-C) \to H_{n-1}(K)$ if and only if $\mathbf{1}_v$ is in the image of $\tilde{H}^0(\mathcal{G}_C) \to \tilde{H}^0(\mathcal{G}_\emptyset)$. This is the case if and only if the function $\mathbf{1}_v$ extends to a function $\varphi \in \tilde{H}^0(\mathcal{G}_C)$, which is possible if and only if v is in a different component from any other vertex of $V_{\mathbb{R}^n \setminus K}$ inside $\mathcal{G}_C$. That means that C is a homology cut for $\mathrm{AD}(\mathbf{1}_v)$ if and only if there is a path in $\mathcal{G}_C$ from v to some other vertex of $V_{\mathbb{R}^n \setminus K}$, proving our claim. ◀

We need the following generalization of the above proposition, that allows us to relate cuts for arbitrary elements of $H_1(K)$ to paths in $\mathcal{G}_K^*$; see Figure 4 for an example.

▶ **Proposition 18.** *Let $\gamma = \sum_{v \in V_{\mathbb{R}^n \setminus K}} \mathrm{AD}(\alpha_v \mathbf{1}_v)$ with $\alpha_{v_\infty} = 0$ be any element of $H_{n-1}(K)$. Then C is a homology cut for γ if and only if the set of edges dual to the simplices of C contains a path between a pair of vertices $v, w \in V_{\mathbb{R}^n \setminus K}$ for which $\alpha_v \neq \alpha_w$.*

Proof. The proof is similar to that of Proposition 17, with the following adjustment: The function $\psi = \sum_{v \in V_{\mathbb{R}^n \setminus K}} \alpha_v \mathbf{1}_v \in \tilde{H}^0(\mathcal{G}_\emptyset)$ extends to a function $\varphi \in \tilde{H}^0(\mathcal{G}_C)$ iff no pair of vertices $v, w \in V_{\mathbb{R}^n \setminus K}$ for which $\psi(v) = \alpha_v \neq \alpha_w = \psi(w)$ is in the same component of $\mathcal{G}_C$. ◀

Proof of Theorem 8. To compute a minimum homological cut for a class $\gamma \in H_{n-1}(K)$ of an n-complex K embedded in $\mathbb{R}^n$, we proceed in three steps:

1. **Constructing the extended dual graph.** First, we construct $\mathcal{G}_K^*$. For this we use the Void Boundary Reconstruction algorithm [18, Section 4], which outputs sets of oriented simplices $(\vec{\xi}_1, \ldots, \vec{\xi}_k)$ that constitute the boundaries of the components of $\mathbb{R}^n \setminus \|K\|$ (cf. Figure 4) in time bounded by $O(|K|^2)$. We assume wlog that $\vec{\xi}_k$ constitutes the boundary of the unbounded component of $\mathbb{R}^n \setminus \|K\|$. The sum of oriented simplices in any of the $\vec{\xi}_i$ with $i < k$ bounding a component $R_i \subseteq \mathbb{R}^n \setminus \|K\|$, which we denote by $[\vec{\xi}_i]$, represents the Alexander dual to the function $f_i \in \tilde{H}^0(\mathbb{R}^n \setminus \|K\|)$ that is constant 1 on R_i, and 0 everywhere else. From the $(\vec{\xi}_1, \ldots, \vec{\xi}_k)$ we can construct $\mathcal{G}_K^*$ in time linear in $k + |K|$. Each $\vec{\xi}_i$ corresponds to a vertex $v_i = v_{R_i} \in V_{\mathbb{R}^n \setminus K} \subseteq V(\mathcal{G}_K^*)$.
2. **Expressing γ in an appropriate basis.** We write γ as $\gamma = \sum_{i=1}^k \alpha_i [\vec{\xi}_i]$ with $\alpha_i \in \mathbb{F}$, $\alpha_k = 0$. This comes down to a change of basis, which can be done in matrix-multiplication time. The representation of γ is precisely the representation as assumed in Proposition 18, as $[\vec{\xi}_i]$ is the Alexander dual of $\mathbf{1}_{v_i}$.
3. **Determining shortest paths.** Using breadth-first search, we can find the minimum distance between any two vertices $v_i, v_j \in V_{\mathbb{R}^n \setminus K}$ inside $\mathcal{G}_K^*$ for which $\alpha_i \neq \alpha_j$ in time bounded by $O(k \cdot |\mathcal{G}_K^*|)$. Let P denote a path in $\mathcal{G}_K^*$ achieving this minimum. The set of $(n-1)$-simplices C_P dual to the edges constituting P form a cut for γ by Proposition 18. Since the edges dual to any cut C for γ must contain a path between vertices of $V_{\mathbb{R}^n \setminus K}$ with differing coefficients, the cut C_P is a minimum cut by minimality of P. ◀

5 Adversarial robustness for the Rips filtration

Let $X = (X, d)$ be a (finite) metric space. For a subset $\sigma \subseteq X$, write $\mathbf{r}(\sigma)$ for its diameter, i.e., the largest pairwise distance between points in σ. The Rips filtration of X is typically defined as the $\mathbb{R}$-indexed family of simplicial complexes $\mathcal{R}(X) := (\{\sigma \subseteq X : \mathbf{r}(\sigma) \leq r\})_{r\in\mathbb{R}}$. If we choose a total order $\preceq$ on the points in X, we can transform $\mathcal{R}(X)$ into a discrete, simplex-wise filtration. Namely, we insert simplices one-by-one according to their diameter, breaking ties first by simplex dimension, and then by the lexicographic order on subsets of X induced by $\preceq$. We denote the resulting *simplex-wise Rips filtration* by $\mathcal{R}^{\preceq}(X)$. The *length* of a bar $B = [\sigma_B, \tau_B)$ in the barcode of $\mathrm{PH}_p(\mathcal{R}^{\preceq}(X))$ is $\ell(B) := \mathbf{r}(\tau_B) - \mathbf{r}(\sigma_B)$.

We consider the following heuristic to determine adversarial robustness of bars in the barcode of $\mathrm{PH}_p(\mathcal{R}^{\preceq}(X))$ based on their length. We denote the Hausdorff distance between $A, B \subseteq X$ by $d_H(A, B) := \max\{\sup_{a\in A} d(a, B), \sup_{b\in B} d(b, A)\}$.

▶ **Definition 19** (Hausdorff heuristic). *Let X be a finite metric space. For $k \in \mathbb{N}$, we define*

$$\mathcal{H}_{X,k} := \max_{A\subseteq X,\, |A|\leq k} d_H(X \setminus A, X). \tag{1}$$

The Hausdorff heuristic has the following two key properties.

▶ **Theorem 20.** *Let $p \geq 0$, and let B be a bar in the barcode of $\mathrm{PH}_p(\mathcal{R}^{\preceq}(X))$. If B has length $\ell(B) \geq \mathcal{H}_{X,k}$, then B is k-adversarially robust in degree 0.*

▶ **Proposition 21.** *The parameter $\mathcal{H}_{X,k}$ can be computed in time $O(|X|^2 \log |X|)$.*

Proof sketch of Theorem 20. Consider the $\mathbb{R}$-indexed Rips filtration $\mathcal{R}(X)$. Let $A \subseteq X$, and set $\delta = d_H(X \setminus A, X)$. For any $r \in \mathbb{R}$, there is a map $\mathrm{H}_p(\mathcal{R}_r(X)) \to \mathrm{H}_p(\mathcal{R}_{r+\delta}(X - A))$ making the following diagram commute:

$$\begin{array}{ccc} H_p(\mathcal{R}_r(X \setminus A)) & \longrightarrow & H_p(\mathcal{R}_{r+\delta}(X \setminus A)) \\ \downarrow & \nearrow & \downarrow \\ H_p(\mathcal{R}_r(X)) & \longrightarrow & H_p(\mathcal{R}_{r+\delta}(X)) \end{array}$$

This can be shown similarly to how stability of Rips persistence is proved, e.g., as in [13]. It follows that the cokernel of $\mathrm{H}_p(\mathcal{R}(X \setminus A)) \to \mathrm{H}_p(\mathcal{R}(X))$ is δ-trivial, which would allow us to apply the induced matching theorem (Theorem 9).

To transport this idea to the simplex-wise Rips filtration $\mathcal{R}^{\preceq}(X)$, we make use of an "ε-smoothening". That is, an $\mathbb{R}$-indexed simplex-wise filtration $\mathcal{R}^{\varepsilon}(X)$, which inserts simplices in the same order as $\mathcal{R}^{\preceq}(X)$, and which is ε-interleaved with $\mathcal{R}(X)$, i.e.,

$$\mathcal{R}^{\varepsilon}_r(X) \subseteq \mathcal{R}_r(X) \subseteq \mathcal{R}^{\varepsilon}_{r+\varepsilon}(X) \quad \forall r \in \mathbb{R}.$$

Such a filtration exists for any $\varepsilon > 0$ small enough. Importantly, the persistence pairings and induced matchings of $\mathcal{R}^{\preceq}(X)$ and $\mathcal{R}^{\varepsilon}(X)$ agree. By the previous, the cokernel of $\mathrm{H}_p(\mathcal{R}^{\varepsilon}(X\setminus A)) \to \mathrm{H}_p(\mathcal{R}^{\varepsilon}(X))$ is $\delta{+}2\varepsilon$-trivial. By Theorem 9, every bar of length greater than $\delta{+}2\varepsilon$ in the barcode of $\mathcal{R}^{\varepsilon}(X)$ is in the image of the matching induced by $\mathcal{R}^{\varepsilon}(X\setminus A) \hookrightarrow \mathcal{R}^{\varepsilon}(X)$. Making ε arbitrarily small, the theorem follows. For details, see the full version [28]. ◀

Proof of Proposition 21. To compute $\mathcal{H}_{X,k}$ efficiently, we use the following structural lemma on the sets A that attain the maximum in (1); for its proof, see the full version [28].

▶ **Lemma 22.** *For $i \in \mathbb{N}$ and $x \in X$, let $\nu_i(x)$ denote the ith nearest neighbor of x. The set $A \subseteq X$ attaining the maximum in (1) is of the form $\{x\} \cup \{\nu_i(x) : i = 1, \ldots, k\}$, with $x \in X$. In particular, we have $\mathcal{H}_{X,k} = \max_{x \in X} d(x, \nu_k(x))$.*

For each $x \in X$, we can compute $\nu_k(x)$ by sorting the points in X by their distance to x, which can be done in $O(|X| \log |X|)$. This immediately proves Proposition 21. ◀

Integer Points in Dilates of Polytopes

Abstract

In this paper we study how the number of integer points in a polytope grows as we dilate the polytope. We prove new and essentially tight bounds on this quantity by specifically studying dilates of the Hadamard polytope.

The motivation for studying this question comes from the question of understanding the maximal number of monomials in a factor of a multivariate polynomial of s monomials. A recent result by Bhargava, Saraf and Volkovich [4] showed that if f is an n-variate polynomial, where each variable has degree d, and f has s monomials, then any factor of f has at most $s^{O(d^2 \log n)}$ monomials. The key technical ingredient of their proof was to show that any polytope with s vertices, where each vertex lies in $\{0, .., d\}^n$ can have at most $s^{O(d^2 \log n)}$ integer points. The precise dependence on d of the number of integer points was left open. We show that this bound, and in particular the dependence on d is essentially tight by studying dilates of the Hadamard polytope and proving new lower bounds on its number of integer points.

1 Introduction

Integer polytopes play a starring role in several areas of mathematics, and have recently found very interesting applications in theoretical computer science. In particular, the problem of counting integer points in polytopes lies at the intersection of combinatorics and convex geometry, with applications in algebraic geometry [7, 8], number theory [3, 6], optimization [2, 1], cryptography [10], and algebraic complexity theory [4], just to name a few. Perhaps the most celebrated result on this topic is the *Ehrhart polynomial*: given an integer polytope $P \subseteq \mathbb{R}^n$, the number of integer points in its *dilate*, $|dP \cap \mathbb{Z}^n|$, is a polynomial in d [9]. When P is an n-dimensional polytope, the leading term of its Ehrhart polynomial is $\mathrm{vol}(P)d^n$, which is a good approximation to the number of integer points for large values of d. However, the coefficients of the Ehrhart polynomial are notoriously difficult to compute (see, for example, [11] for examples of polytopes with *negative* Ehrhart coefficients), so we have little information about integer points when the dilation factor d is much smaller than the dimension n.

Motivation from algebraic complexity theory

Our interest in estimating $|dP \cap \mathbb{Z}^n|$ when d is smaller than n comes from the problem of *sparse polynomial factorization* in complexity theory. A multivariate polynomial $f \in \mathbb{F}[X_1, \ldots, X_n]$ where each variable X_i appears with degree $\leq d$ is *sparse* if it only has poly(n)

monomials. Polynomial factorization is a fundamental question in computational algebra, and sparse polynomial factorization is a special case that has been studied for several decades now [4, 5, 13]. The first randomized algorithm for sparse polynomial factorization exhibited a dependence on the sparsity of the factors of the polynomial [13], which raised the natural question: do factors of sparse polynomials have to be sparse?

We know that this is not true in general: if g is a factor of some polynomial f, there is no polynomial upper bound for the number of monomials of g in terms of the number of monomials of f. In characteristic 0, we have the counterexample $f = \prod_{i=1}^{n}(X_i^d - Y_i^d)$ and $g = \prod_{i=1}^{n}(X_i^{d-1} + X_i^{d-2}Y_i + \cdots + Y_i^{d-1})$. Here, f has 2^n monomials, but g is a factor of f with d^n monomials. In characteristic p, this gap can be more stark. Consider $f = \sum_{i=1}^{n} X_i^p$ and $g = (\sum_{i=1}^{n} X_i)^{\lfloor p/2 \rfloor}$, so f has n monomials, but g is a factor of f with at least $n^{p/2}$ monomials. In general, we do not have know better than the trivial upper bound of d^n for the number of monomials in a factor of a sparse polynomial. However, note that in the setting where we assume that the individual degree d is an absolute constant and n can be arbitrarily large, these two counterexamples no longer exhibit significant sparsity gaps.

The current best-known bound for sparse factorization in this setting is due to [4], who show that if f has s monomials and g is a factor of f, then g has at most $s^{O(d^2 \log n)}$ monomials. The key technique of their proof is to reduce the problem of counting monomials in f and g into one of counting integer points in their Newton polytopes. In this paper we further study the problem of counting integer points in polytopes, since a better upper bound there would directly imply a better bound for the factoring problem. Unfortunately, our results indicate that there is no better upper bound for polytopes, so any attempt to improve the bound for sparsity will require a new approach.

Connections to studying dilates of polytopes

The key technique to proving the upper bound of $s^{O(d^2 \log n)}$ in [4] is to study integer points in polytopes. In particular if $f = g \times h$, then one can show that the Newton polytope of f is the Minkowski sum of the Newton polytopes of g and h. The high-level idea in the proof is to show the following: If g has too many monomials, then the Newton polytope of g must necessarily have many vertices. This can then be used to show that the Newton polytope of f must also have many vertices, hence f must have many monomials. Their main technical contribution is to show that any polytope with s vertices, where each vertex lies in $[-d, +d]^n$, can have at most $s^{O(d^2 \log n)}$ integer points. The precise dependence on d of the number of integer points was left open.

The main goal of our paper is to understand if this bound for integer points in polytopes is tight. Saptharishi observed that the $\log n$ in the exponent of the bound is necessary (see [4] for a proof of this) by counting integer points in *Hadamard polytopes*, a class of simplices with vertices in $\{-1, 1\}^n$. Specifically, he shows that the number of integer points in the Hadamard polytope is at least $n^{\Omega(\log n)}$. In this paper, we show that the dependence of d^2 in the exponent is also essentially tight by studying dilates of the Hadamard polytope.

An astute reader may recognize the Hadamard polytope as the extremal solution to Hadamard's maximal determinant problem: the parallelepiped spanned by its vertices maximizes volume among all parallelepipeds with vertices in $\{-1, 1\}^n$. We expect that the Hadamard polytope should also maximize the number of integer points – a discrete analog of volume – among all simplices with vertices in $\{-1, 1\}^n$. This is the heuristic that motivates us to study the Hadamard polytope as the "worst-case simplex" for our problem.

In the case when $s = \text{poly}(n)$ (as with factors of sparse polynomials), we can reduce our problem about counting integer points in polytopes in $[-d, d]^n$ to counting integer points in dilates of polytopes as follows. First, by Carathéodory's theorem, each vertex of P is a

convex combination of at most $n+1$ points of $\{-d,d\}^n$. Replacing the vertices of P with these points, we obtain a polytope P_d containing P that still has poly(n) vertices, but they now lie in $\{-d,d\}^n$. So, $P_0 = \frac{1}{d}P_d$ is an integer polytope with vertices in $\{-1,1\}^n$ and $|dP_0 \cap \mathbb{Z}^n| \geq |P \cap \mathbb{Z}^n|$.

Our contribution in this paper is to provide lower bounds for the number of integer points in the Hadamard polytope. Our first main result is an elegant algebraic characterization of the integer points in the Hadamard polytope by constructing an explicit bijection with affine subspaces of $\mathbb{F}_2^{\log n}$. This underpins part of our second main result: a lower bound for the number of integer points in small dilates. To lower bound the points in larger dilates, we use the probabilistic method. These bounds show that both the dependences on d^2 and on $\log n$ in the bound $|dP \cap \mathbb{Z}^n| \leq |V(P)|^{O(d^2 \log n)}$ are necessary.

2 Main results

Let $n = 2^m$ for some $m \in \mathbb{N}$. The $n \times n$ *Hadamard matrix* H has its rows and columns indexed by elements of the vector space $\mathbb{F}_2^m$:

$$H(a,b) = (-1)^{\langle a,b\rangle},$$

where $\langle a,b\rangle$ is the standard dot product on $\mathbb{F}_2^m$.

▶ **Definition 1.** *The* Hadamard polytope $P_{\text{Had}} \subset \mathbb{R}^n$ *is the convex hull of the column vectors of* H*.*

The columns of H are linearly independent so they form the vertices of P_{Had}; the *Hadamard polytope* is an $(n-1)$–simplex with vertices in $\{-1,1\}^n$. The lower bound $|P_{\text{Had}} \cap \mathbb{Z}^n| \geq n^{\Omega(\log n)}$ was first observed by Ramprasad Saptharishi and appears in the paper [4]. Our contribution is a matching upper bound on $|P_{\text{Had}} \cap \mathbb{Z}^n|$ through a complete characterization of all integer points in the Hadamard polytope using the vector space structure of F_2^m. This characterization will also be useful when we study integer points in dilates of P_{Had}.

First, some notation: let $\{h_a : a \in \mathbb{F}_2^m\}$ be the set of column vectors of the Hadamard matrix H, i.e. the vertices of the Hadamard polytope P_{Had}. We can also identify the coordinates of $\mathbb{R}^n$ with vectors in $\mathbb{F}_2^m$, with the convention that the first coordinate in $\mathbb{R}^n$ corresponds to the zero vector in $\mathbb{F}_2^m$. For every $a \in \mathbb{F}_2^m$ and $v \in \mathbb{R}^n$, let $v(a)$ denote the ath coordinate of v in the standard basis, and

$$\text{supp}(v) = \{a \in \mathbb{F}_2^m : v(a) \neq 0\}$$

We also know that every point $v \in P_{\text{Had}}$ can be expressed as a convex combination $v = \sum_{a \in \mathbb{F}_2^m} t_a h_a$. Since the vectors $\{h_a : a \in \mathbb{F}_2^m\}$ are linearly independent, this expression is unique, and we can define

$$T(v) = \{a \in \mathbb{F}_2^m : t_a \neq 0\}.$$

This can also be thought of as the support of v in the basis $\{h_a : a \in \mathbb{F}_2^m\}$.

Statements of main results

▶ **Theorem 2.** *For every* $v \in P_{\text{Had}} \cap \mathbb{Z}^n$, supp$(v)$ *is a subspace of* $\mathbb{F}_2^m$*. Further,* $T(v) = \text{supp}(v)^\perp + b$ *for some* $b \in \mathbb{F}_2^m$*, and*

$$v = \frac{1}{|T(v)|} \sum_{c \in T(v)} h_c$$

is actually a uniform linear combination of vertices.

Notice that this theorem is a combinatorial correspondence between affine subspaces of $\mathbb{F}_2^m$ and integer points in P_{Had}. That is, every affine subspace $S \subseteq \mathbb{F}_2^m$, let v_S be the uniform convex combination of the vertices of P_{Had} corresponding to the points of S. In other words, v_S is the barycenter of the corresponding face of P_{Had}. Then, the map $S \to v_S$ is a bijection between affine subspaces of $\mathbb{F}_2^m$ and integer points in P_{Had}.

▶ **Corollary 3.** *The number of integer points in P_{Had} is $|P_{\text{Had}} \cap \mathbb{Z}^n| = n^{\Theta(\log n)}$.*

▶ **Theorem 4.** *For any $d < n \log n$ and fixed $0 < \varepsilon < 1/2$, the number of integer points in the dilate dP_{Had} is lower bounded by*

$$|dP_{\text{Had}} \cap \mathbb{Z}^n| \geq \begin{cases} n^{\Omega(d \log n)}, & d \leq \frac{\log n}{4}; \\ n^{\Omega(\log^2 n)}, & \frac{\log n}{4} \leq d \leq \log^{1.5} n \\ n^{2\varepsilon d^2 / \log n}, & \log^{1.5} n \leq d \leq (n \log n)^{1/2-\varepsilon}; \\ \left(d^{2\varepsilon}/4\right)^n, & (n \log n)^{1/2+\varepsilon} \leq d < n \log n. \end{cases}$$

Proofs of main results

Proof of Theorem 2. First, we need to show that $\text{supp}(v)$ is a subspace of $\mathbb{F}_2^m$. We will actually show something stronger: if $v(a) \neq 0$ and $v(b) \neq 0$, then $v(a+b) = v(a)v(b)$. Note that since v is an integer point in $P_{\text{Had}} \subset [-1,1]^n$, its coordinates actually lie in $\{-1,0,1\}^n$. So, the three cases we need to consider for our proof are: $v(a) = v(b) = 1$; $v(a) = v(b) = -1$; and $v(a) = 1$, $v(b) = -1$. We will write out the details for the case when $v(a) = v(b) = 1$, and the other cases will follow a similar computation.

Since v is a convex combination of the vertices of P_{Had}, we can write it as $v = \sum_{c \in \mathbb{F}_2^m} t_c h_c$, for some nonnegative real numbers $(t_c)_{c \in \mathbb{F}_2^m}$ that satisfy $\sum_{c \in \mathbb{F}_2^m} t_c = 1$. From the definition of the Hadamard matrix H, we get the following identities for the coordinates $a, b \in \mathbb{F}_2^m$,

$$v(a) = \sum_{c \in \mathbb{F}_2^m} t_c h_c(a) = \sum_{c \in \mathbb{F}_2^m} (-1)^{\langle c,a \rangle} t_c = \sum_{c \perp a} t_c - \sum_{c \not\perp a} t_c,$$
$$v(b) = \sum_{c \in \mathbb{F}_2^m} t_c h_c(b) = \sum_{c \in \mathbb{F}_2^m} (-1)^{\langle c,b \rangle} t_c = \sum_{c \perp b} t_c - \sum_{c \not\perp b} t_c.$$

Define

$$s_{ab} = \sum_{c \perp a, c \perp b} t_c; \quad s_a = \sum_{c \perp a, c \not\perp b} t_c; \quad s_b = \sum_{c \not\perp a, c \perp b} t_c; \quad s_0 = \sum_{c \not\perp a, c \not\perp b} t_c.$$

This allows us to rewrite our identity for $v(a)$ as

$$v(a) = s_{ab} + s_a - s_b - s_0.$$

A similar identity for $v(b)$ and the identity $\sum_{c \in \mathbb{F}_2^m} t_c = 1$ gives us the system of linear equations

$$s_{ab} + s_a - s_b - s_0 = v(a) = 1$$
$$s_{ab} - s_a + s_b - s_0 = v(b) = 1$$
$$s_{ab} + s_a + s_b + s_0 = 1$$

The general solution to this system has the form

$$\begin{aligned} s_{ab} - s_0 &= 1 \\ s_a + s_b &= 0 \\ s_b + s_0 &= 0. \end{aligned}$$

Since each of s_{ab}, s_a, s_b, and s_0 must be nonnegative, this yields a unique solution $s_{ab} = 1, s_a = s_b = s_0 = 0$. So,

$$\begin{aligned} v(a+b) &= \sum_{c \in \mathbb{F}_2^m} (-1)^{\langle a+b, c\rangle} t_c \\ &= \sum_{c \perp a, c \perp b} t_c - \sum_{c \perp a, c \not\perp b} t_c - \sum_{c \not\perp a, c \perp b} t_c + \sum_{c \not\perp a, c \not\perp b} t_c \\ &= s_{ab} - s_a - s_b + s_0 \\ &= 1 = v(a)v(b). \end{aligned}$$

The argument for the other cases follows similarly: we set up a system of equations in the variables s_{ab}, s_b, s_a, s_0 that has a unique solution subject to nonnegativity. Computing the value of $v(a+b)$ for this unique solution shows that $v(a+b) = v(a)v(b)$. This shows not only that $\mathrm{supp}(v)$ is a basis, but also that the entries of v are determined by their values on a basis of $\mathrm{supp}(v)$.

Now, let $b_1, \ldots, b_k \in \mathbb{F}_2^m$ be a basis for $\mathrm{supp}(v)$, and choose $\varepsilon_i \in \{0,1\}$ so that $v(b_i) = (-1)^{\varepsilon_i}$ for each $i = 1, \ldots, k$. Consider the linear map $\mathbb{F}_2^m \to \mathrm{supp}(v)$ that sends $c \in \mathbb{F}_2^m$ to $\langle b_1, c\rangle b_1 + \cdots + \langle b_k, c\rangle b_k \in \mathrm{supp}(v)$. The kernel of this map is exactly $\mathrm{supp}(v)^\perp$, so its range must be all of $\mathrm{supp}(v)$. In particular, there is some $b \in \mathbb{F}_2^m$ whose image under this map is $\varepsilon_1 b_1 + \cdots + \varepsilon_k b_k$. So, $v(b_i) = (-1)^{\langle b_i, b\rangle}$ for each $i = 1, \ldots, k$. For any $a \in \mathrm{supp}(v)$, we know that $a = \sum_{i \in I} b_i$ for some $I \subseteq [k]$, so

$$v(a) = \prod_{i \in I} v(b_i) = (-1)^{\sum_{i \in I} \langle b_i, b\rangle} = (-1)^{\langle a, b\rangle}.$$

We claim that $T(v) = \mathrm{supp}(v)^\perp + b$ for this vector b.

Define the vector $v' \in \mathbb{F}_2^m$ by

$$v' = \frac{1}{|\mathrm{supp}(v)^\perp|} \sum_{c \in \mathrm{supp}(v)^\perp + b} h_c.$$

We will show that $v' = v$ by showing that $v'(a) = v(a)$ for every coordinate $a \in \mathbb{F}_2^m$.

First, for each $a \in \mathrm{supp}(v)$ and $c \in \mathrm{supp}(v)^\perp + b$, we have that $\langle a, c\rangle = \langle a, b\rangle$. So,

$$\begin{aligned} v'(a) &= \frac{1}{|\mathrm{supp}(v)^\perp|} \sum_{c \in \mathrm{supp}(v)^\perp + b} h_c(a) \\ &= \frac{1}{|\mathrm{supp}(v)^\perp|} \sum_{c \in \mathrm{supp}(v)^\perp + b} (-1)^{\langle a, c\rangle} \\ &= (-1)^{\langle a, b\rangle} \\ &= v(a). \end{aligned}$$

Next, for each $a \notin \mathrm{supp}(v)$, the $\mathbb{F}_2$-linear map from $\mathrm{supp}(v)^\perp \to \{0,1\}$ that sends $c \in \mathrm{supp}(v)^\perp$ to $\langle a, c\rangle$ is not identically zero. So, the size of the preimage of 0 under this map is

equal to the size of the preimage of 1. This property still holds when we consider the translate $\mathrm{supp}(v)^\perp + b$: the dot product $\langle a, c\rangle$ is 0 for exactly half the vectors $c \in \mathrm{supp}(v)^\perp + b$, and is 1 for the other half. Thus, the average of $h_c(a)$ over all $c \in \mathrm{supp}(v)^\perp + b$ is zero, so

$$v'(a) = \frac{1}{|\mathrm{supp}(v)^\perp|} \sum_{c \in \mathrm{supp}(v)^\perp + b} (-1)^{\langle a,c\rangle} = 0 = v(a),$$

since $a \notin \mathrm{supp}(v)$. This shows that v does indeed have the form we claimed, with $T(v) = \mathrm{supp}(v)^\perp + b$ and

$$v = \frac{1}{|T(v)|} \sum_{c \in T(v)} h_c \qquad \blacktriangleleft$$

Proof of Corollary 3. Note again that the lower bound $|P_{\mathrm{Had}} \cap \mathbb{Z}^n| = n^{\Omega(\log n)}$ was already known by Saptharishi's contribution to [4]; we will provide a matching upper bound of $n^{O(\log n)}$. By Theorem 2, integer points of $P_{\mathrm{Had}} \cap \mathbb{Z}^n$ are in one-to-one correspondence with affine subspaces of $\mathbb{F}_2^m$. Any k-dimensional subspace $V \subseteq \mathbb{F}_2^m$ has exactly 2^{m-k} corresponding affine subspaces, and there are exactly $\begin{bmatrix} m \\ k \end{bmatrix}_2$ (the Gaussian binomial coefficient) subspaces of dimension k. So, using the upper bound $\begin{bmatrix} m \\ k \end{bmatrix}_2 \le 2^{4m^2}$ (see, for example, [12] for a proof of this bound),

$$|P_{\mathrm{Had}} \cap \mathbb{Z}^n| = \sum_{k=0}^{m} 2^{m-k} \begin{bmatrix} m \\ k \end{bmatrix}_2 \le (m+1)2^{m+4m^2} = n^{O(\log n)},$$

which completes the proof. $\blacktriangleleft$

Now we are ready to prove our main theorem: lower bounding the growth of integer points in the dilates dP_{Had}.

Proof of Theorem 4.

▶ **Case 1.** $d \le (\log n)/4$.

Let us introduce some more notation for our counting argument. We will show that there are $n^{\Omega(d \log n)}$ distinct sets of d integer points in P_{Had} whose sums are all distinct in dP_{Had}. For $v \in P_{\mathrm{Had}} \cap \mathbb{Z}^n$, define the *exponent* of v as $\exp(v) = \dim(\mathrm{supp}(v)^\perp)$, so $|T(v)| = 2^{\exp(v)}$, and

$$v = \frac{1}{2^{\exp(v)}} \sum_{a \in T(v)} h_a.$$

Let $t_a(v)$ be $2^{-\exp(v)}$ if $a \in T(v)$, and 0 otherwise; that is, $t_a(v)$ is the coefficient of the vertex h_a in the convex combination for v. Look at all sets $\{v_1, \ldots, v_d\}$ such that

- **(i)** $T(v_i)$ is a subspace, i.e. $T(v_i) = \mathrm{supp}(v_i)^\perp$;
- **(ii)** $\frac{\log n}{2} - d < \exp(v_i) < \frac{\log n}{2} + d$;
- **(iii)** $\exp(v_i) \ne \exp(v_j)$ if $i \ne j$.

Since $d \le \frac{\log n}{4}$, for n large enough, the number of subspaces of $\mathbb{F}_2^{\log n}$ with dimension k for some $k \in \left(\frac{\log n}{2} - d, \frac{\log n}{2} + d\right)$ is $\begin{bmatrix} \log n \\ k \end{bmatrix}_2 \ge 2^{k(\log n - k)} = n^{\Omega(\log n)}$. So, the number of choices for the set of subspaces $\{T(v_1), \ldots, T(v_d)\}$ with distinct exponents in $\left(\frac{\log n}{2} - d, \frac{\log n}{2} + d\right)$ is $n^{\Omega(d \log n)}$. We will now show that each set $\{v_1, \ldots, v_d\}$ satisfying these properties produces a distinct point in $dP_{\mathrm{Had}} \cap \mathbb{Z}^n$, proving the lower bound $|dP_{\mathrm{Had}} \cap \mathbb{Z}^n| \ge n^{\Omega(d \log n)}$.

Now, suppose $\{v_1, \ldots, v_d\}$ and $\{u_1, \ldots, u_d\}$ are two distinct sets satisfying the above conditions. And suppose for contradiction that $\sum_i v_i = \sum_i u_i$. Expanding this in terms of the vertices of P_{Had}, we get

$$\sum_{i=1}^{d} \sum_{a \in \mathbb{F}_2^m} t_a(v_i) h_a = \sum_{i=1}^{d} \sum_{a \in \mathbb{F}_2^m} t_a(u_i) h_a$$

Since the vertices of P_{Had} are linearly independent, we must have the following stronger identity for all $a \in \mathbb{F}_2^m$:

$$\sum_{i=1}^{d} t_a(v_i) = \sum_{i=1}^{d} t_a(u_i).$$

For each fixed a, since $t_a(v_i)$ is either zero or $2^{-\exp(v_i)}$ and the exponents are all distinct, we can think of each sum as the unique binary representation of some dyadic rational number.

When $a = 0$, we get $t_0(v_i) = 2^{-\exp(v_i)}$ and $t_0(u_i) = 2^{-\exp(u_i)}$ since $T(v_i)$ and $T(u_i)$ are linear subspaces containing 0, for every $i = 1, \ldots, d$. This gives us the identity

$$\sum_{i=1}^{d} 2^{-\exp(v_i)} = \sum_{i=1}^{d} 2^{-\exp(u_i)}.$$

So, the sets $\{\exp(v_i) : i \leq d\}$ and $\{\exp(u_i) : i \leq d\}$ must be equal since the above sums represent the same binary number. This means that the only way for the sums $\sum_{i=1}^{d} v_i$ and $\sum_{i=1}^{d} u_i$ to be equal at the 0th coordinate is if their exponents are all the same. Now we will find another coordinate where they differ.

Assume without loss of generality that $\exp(v_i) = \exp(u_i)$ for all $i = 1, \ldots, d$, and $\exp(v_1) < \cdots < \exp(v_d)$. There must be some k such that $T(v_k) \neq T(u_k)$. Choose $a \in T(v_k) \setminus T(u_k)$ (which is possible since they are different subspaces of the same dimension), and now look at the identity

$$\sum_{i=1}^{d} t_a(v_i) = \sum_{i=1}^{d} t_a(u_i).$$

Again, each sum is the unique binary representation of some dyadic rational number, but $t_a(v_k) \neq 0$ while $t_a(u_k) = 0$, so they cannot represent the same number, which is the desired contradiction.

▶ **Case 2.** $(\log n)/4 \leq d \leq \log^{1.5} n$.

We simply reuse the bound from case 1 (note that the lower bound is monotone in d and hence we can just use the bound in the setting $d = \frac{\log n}{4}$),

$$|dP_{\text{Had}} \cap \mathbb{Z}^n| \geq \left| \frac{\log n}{4} P_{\text{Had}} \cap \mathbb{Z}^n \right| \geq n^{\Omega(\log^2 n)}.$$

▶ **Case 3.** $d \geq \log^{1.5} n$.

For this final case we will use the probabilistic method. Take the projection $\mathbb{R}^n \to \mathbb{R}^{n-1}$ that deletes the first coordinate of every vector, and let P_0 be the image of P_{Had} under this map. Recall that $P_{\text{Had}} \subseteq \mathbb{R}^n$ is an $(n-1)$-simplex whose vertices all have first coordinate equal to 1, since the first coordinate corresponds to the zero vector in $\mathbb{F}_2^m$. So, this projection is a bijection on P_{Had}. In particular, integer points of dP_0 are in one-to-one correspondence with integer points of dP_{Had}, so $|dP_{\text{Had}} \cap \mathbb{Z}^n| = |dP_0 \cap \mathbb{Z}^{n-1}|$.

The new polytope P_0 is now a full-dimensional simplex in $[-1,1]^{n-1}$. Since the vertices of the original Hadamard polytope $P_{\text{Had}} \subseteq \mathbb{R}^n$ were orthogonal, for each vertex $v \in V(P_0) \subseteq \mathbb{R}^{n-1}$, the face of P_0 that does not contain v is defined by the hyperplane $\{x \in \mathbb{R}^{n-1} : \langle x, v\rangle = -1\}$. In particular, we can write the simplex P_0 as an intersection of half-spaces:

$$P_0 = \bigcap_{v \in V(P_0)} \{x \in \mathbb{R}^{n-1} : \langle x, v\rangle \geq -1\},$$

and

$$dP_0 = \bigcap_{v \in V(P_0)} \{x \in \mathbb{R}^{n-1} : \langle x, v\rangle \geq -d\}.$$

Fix some set of c coordinates $S \subset [n]$ and some $D \in [d]$ (with c and D to be determined later) and look at the discrete hypercube $H_S[D]$ supported on those coordinates,

$$H_S[D] = ([-D, D] \setminus \{0\})^S \times \{0\}^{[n]\setminus S}.$$

We will use the probabilistic method to show that P_0 contains at least $1/2$ the points of $H_S[D]$ for every choice of S. Note that the hypercubes $H_S[D]$ are disjoint by construction, so

$$|dP_0 \cap \mathbb{Z}^n| \geq \sum_{S \subseteq [n], |S|=c} |dP_0 \cap H_S[D]|.$$

Fix a vertex $v \in V(P_0)$, and a hypercube $H_S[D]$. Let X be a uniform random variable taking values in $H_S[D]$. Since v is a ± 1-valued vector, $\mathbb{E}|\langle X, v\rangle| = 0$. Hoeffding's inequality implies that

$$\mathbb{P}(|\langle X, v\rangle| > d) \leq 2e^{-d^2/2cD}.$$

By the union bound,

$$\mathbb{P}(X \notin dP_0) \leq \sum_{v \in V(P_0)} \mathbb{P}(|\langle X, v\rangle| > d) \leq 2ne^{-d^2/2cD}.$$

Assuming that $2cD \leq \frac{d^2}{2\log n}$, the above probability is at most $1/2$, so at least $1/2$ the points of $H_S[D]$ must be contained in dP_0. Now, summing over the disjoint sets $H_S[D]$ for all $\binom{n}{c}$ choices of S,

$$|dP_{\text{Had}} \cap \mathbb{Z}^n| = |dP_0 \cap \mathbb{Z}^{n-1}| \geq \sum_{S \subseteq [n], |S|=c} |H_S[D] \cap dP_0| \geq \frac{1}{2}\binom{n}{c}(2D)^c.$$

We divide our analysis into two subcases.

▶ **Case 3a.** *$d \leq (n \log n)^{\frac{1}{2}-\varepsilon}$, which implies that $\frac{d^2}{\log n} \leq n^{1-2\varepsilon}$*

In this case, set $D = 1$ and $c = \frac{d^2}{4\log n}$, so

$$\begin{aligned}
|dP_{\text{Had}} \cap \mathbb{Z}^n| &\geq \frac{1}{2}\binom{n}{c}(2D)^c && \text{Approximating the binomial coefficient} \\
&\geq \left(\frac{n}{c}\right)^c && \\
&\geq \left(\frac{n}{n^{1-2\varepsilon}}\right)^{d^2/\log n} && \text{Since } c \leq \tfrac{d^2}{\log n} \leq n^{1-2\varepsilon} \\
&\geq n^{2\varepsilon d^2/\log n} &&
\end{aligned}$$

▶ **Case 3b.** $d \geq (n \log n)^{\frac{1}{2}+\varepsilon}$.

For our probabilistic argument to work, we need $2cD \leq \frac{d^2}{2 \log n}$, which rearranges to $D \leq \frac{d^2}{4c \log n}$. Set $D = d^{2\varepsilon}/4$ and $c = n$. Now,

$$\begin{aligned} \frac{d^2}{4c \log n} &= \frac{d^2}{4n \log n} && \text{Subsituting } n \log n \leq d^{2/(1+2\varepsilon)} \\ &\geq \frac{d^2}{4d^{2/(1+2\varepsilon)}} && \\ &= \frac{d^{4\varepsilon/(1+2\varepsilon)}}{4} && \text{Since } \varepsilon \leq 1/2 \\ &\geq \frac{d^{2\varepsilon}}{4} = D && \end{aligned}$$

as desired. Now,

$$|dP_{\text{Had}} \cap \mathbb{Z}^n| \geq \frac{1}{2}\binom{n}{c}(2D)^c \geq \left(d^{2\varepsilon}/4\right)^n. \qquad \blacktriangleleft$$

Abstract

Recently, motivated by the rapid increase of the data size in various applications, Monemizadeh [APPROX'23] and Driemel, Monemizadeh, Oh, Staals, and Woodruff [SoCG'25] studied geometric problems in the setting where the only access to the input point set is via querying a range-search oracle. Algorithms in this setting are evaluated on two criteria: (i) the number of queries to the oracle and (ii) the error of the output. In this paper, we continue this line of research and investigate one of the most fundamental geometric problems in the oracle setting, i.e., the convex hull problem.

Let P be an unknown set of points in $[0,1]^d$ equipped with a range-emptiness oracle. Via querying the oracle, the algorithm is supposed to output a convex polygon $C \subseteq [0,1]^d$ as an estimation of the convex hull $\mathcal{CH}(P)$ of P. The error of the output is defined as the volume of the symmetric difference $C \oplus \mathcal{CH}(P) = (C \setminus \mathcal{CH}(P)) \cup (\mathcal{CH}(P) \setminus C)$. We prove tight and near-tight tradeoffs between the number of queries and the error of the output for different variants of the problem, depending on the type of the range-emptiness queries and whether the queries are non-adaptive or adaptive.

- **Orthogonal emptiness queries in d-dimensional space:**
  We show that the minimum error a deterministic algorithm can achieve with q queries is $\Theta(q^{-1/d})$ if the queries are non-adaptive, and $\Theta(q^{-1/(d-1)})$ if the queries are adaptive. In particular, in 2D, the bounds are $\Theta(1/\sqrt{q})$ and $\Theta(1/q)$ for non-adaptive and adaptive queries, respectively.
- **Halfplane emptiness queries in 2D:**
  We show that the minimum error a deterministic algorithm can achieve with q queries is $\Theta(1/\sqrt{q})$ if the queries are non-adaptive, and $\widetilde{\Theta}(1/q^2)$ if the queries are adaptive. Here $\widetilde{\Theta}(\cdot)$ hides logarithmic factors.

1 Introduction

Classic algorithms are designed to compute solutions to a problem instance by processing the *entire* input dataset. These algorithms can suffer two potential drawbacks. The first drawback concerns *efficiency*. As all of the input data has to be received and examined, the time complexity of such algorithms (even the most efficient ones) is at least linear in the input size. However, due to the rapidly growing size of the datasets involved in real-world applications nowadays, linear running time is already not satisfactory in many scenarios. The second drawback regards *data privacy*. For security reasons, sometimes the users would like to keep their data private and therefore cannot directly provide the exact dataset to the algorithm. Instead, they can only provide partial and implicit information of the dataset and ask the algorithm to give useful results based on the information provided. In this situation, the classic algorithms no longer work due to lack of full information of the dataset.

Motivated by removing these drawbacks, researchers have studied algorithms in the *oracle model*. In this model, the algorithm does not have direct access to the input dataset. Instead, a provided oracle built on the dataset can answer certain queries about the dataset. The algorithm is required to compute a good solution by performing queries to the oracle. Algorithms in this setting are usually evaluated on two criteria: (i) the number of queries to the oracle and (ii) the error of the output.

For geometric problems, various types of oracles have been considered in the literature [14, 16, 15, 17, 22]. When the input dataset is a set P of points in a Euclidean space $\mathbb{R}^d$, a natural type is the *range-search* oracle. A query to a range-search oracle is a *range* Q in the space $\mathbb{R}^d$ of a specific shape, and the oracle will return certain information about the points in $P \cap Q$. For example, a *range-counting* oracle returns $|P \cap Q|$ [1, 12], a *range-emptiness* oracle returns whether $P \cap Q = \emptyset$ or not [19, 26], a *range-reporting* oracle returns the set $P \cap Q$ itself [6, 23], etc. Range-search oracles have the following advantages. First, range search can usually be implemented very efficiently. As a fundamental topic in Computational Geometry, range search has been extensively studied over decades and many efficient data structures have been proposed for various range queries [4, 5, 9, 12, 13, 21]. Furthermore, most types of range search (except range reporting) do not reveal the exact data points inside the query range Q, and therefore data privacy is well guaranteed. Recently, Monemizadeh [22] and the authors of [17] studied multiple geometric problems with range-search oracles, following earlier work of Czumaj and Sohler [16] and the authors of [15]. Problems considered include facility location [22], clustering [16], Euclidean minimum spanning tree [15, 17], earth mover distance [17], etc. They show that for all these problems, one can obtain nontrivial approximation solutions via a small number of range-search queries.

In this paper, we continue this line of research and investigate one of the most fundamental geometric problems, the *convex hull* problem [7, 8, 10, 11, 24, 27], in the range-search oracle model. In the convex hull problem, the goal is to compute the *convex hull* of a set P of points in $\mathbb{R}^d$, denoted by $\mathcal{CH}(P)$, which by definition is the smallest convex body in $\mathbb{R}^d$ containing P. We study the problem with the simplest type of range-search oracles, i.e., *range-emptiness* oracles. We are interested in finding a convex body C^* as an approximation of $\mathcal{CH}(P)$ via a small number of range-emptiness queries. To this end, we need a measure for the error of the approximation. The most natural measure one can use is the relative error $\|C^* \oplus \mathcal{CH}(P)\| \,/\, \|\mathcal{CH}(P)\|$, where $\|\cdot\|$ denotes the volume and $C^* \oplus \mathcal{CH}(P) = (C^* \backslash \mathcal{CH}(P)) \cup (\mathcal{CH}(P) \backslash C^*)$ is the symmetric difference between C^* and $\mathcal{CH}(P)$. Unfortunately, one can easily see that it is impossible to approximate the convex hull with any bounded relative error no matter how many range-emptiness queries the algorithm performs[1]. Therefore, we shall instead consider the additive error $\|C^* \oplus \mathcal{CH}(P)\|$. Clearly, the additive error depends on the extent measure of P. So we need an extra normalization assumption: we require all points in P to lie in the unit hypercube $[0,1]^d$. Below we formulate the problem to be studied.

Approximate Convex Hull in $\mathbb{R}^d$ via range queries

Input: A (black-box) range-emptiness oracle $\mathcal{O}$ on a set P of points in $[0,1]^d$
Output: A convex body C^* that approximates $\mathcal{CH}(P)$

[1] Even in $\mathbb{R}^1$, there is no way to check whether P only contains one point, in which case $\|\mathcal{CH}(P)\| = 0$, or P contains at least two points, in which case $\|\mathcal{CH}(P)\| > 0$, via range-emptiness queries.

Regarding the above problem, a natural question concerns the tradeoff between the number of queries and the (additive) error of the output: if the algorithm is allowed to perform q queries to the oracle $\mathcal{O}$, what is the minimum error it can achieve (in the worst case)? The answer to this question depends on the following two features of the queries.

- **Shape of the query ranges.** Range queries with different shapes might behave very differently. The most commonly used queries are orthogonal queries [12], where the query ranges are axis-parallel rectangles/boxes. Besides these, well-studied range queries include halfplane/halfspace queries [2, 18], simplex queries [20], semi-algebraic queries [5, 26], etc.
- **Adaptivity of the queries.** In the non-adaptive query model, the algorithm must make all its queries at once, and then make its estimation based on the batched answer. In the adaptive query model, the algorithm is allowed to make queries at any time and the oracle will provide the answer immediately. In particular, the next query can be made after seeing the answers of the previous queries.

As the main contribution of this paper, we prove tight and near-tight tradeoffs between the number of queries and the error of the output for Approximate Convex Hull with orthogonal emptiness queries in $\mathbb{R}^d$ for any fixed d and halfplane emptiness queries in $\mathbb{R}^2$, in both non-adaptive and adaptive query models.

- **Orthogonal queries.** We show the minimum error a deterministic algorithm can achieve for Approximate Convex Hull in $\mathbb{R}^d$ with q orthogonal emptiness queries is $\Theta(q^{-1/d})$ if the queries are non-adaptive and is $\Theta(q^{-1/(d-1)})$ if the queries are adaptive. In particular, in 2D, the bounds are $\Theta(1/\sqrt{q})$ and $\Theta(1/q)$ for non-adaptive and adaptive queries, respectively.
- **Halfplane queries.** We show the minimum error a deterministic algorithm can achieve for Approximate Convex Hull in $\mathbb{R}^2$ with q halfplane emptiness queries is $\Theta(1/\sqrt{q})$ if the queries are non-adaptive and is $\widetilde{\Theta}(1/q^2)$ if the queries are adaptive[2].

Table 1 summarizes the tradeoffs we prove in this paper. All of our algorithms are deterministic and have offline time complexity (outside the oracle) polynomial in q. Our lower bounds similarly hold for deterministic algorithms.

Table 1 Minimum error one can achieve for Approximate Convex Hull with q queries.

Query shape	Space	Query type	Upper bound	Lower bound	Source
Orthogonal	$\mathbb{R}^d$	Non-adaptive	$O(q^{-1/d})$	$\Omega(q^{-1/d})$	Theorems 2 and 8
		Adaptive	$O(q^{-1/(d-1)})$	$\Omega(q^{-1/(d-1)})$	Theorems 12 and 13
Halfplane	$\mathbb{R}^2$	Non-adaptive	$O(1/\sqrt{q})$	$\Omega(1/\sqrt{q})$	Theorems 17 and 22
		Adaptive	$\widetilde{O}(1/q^2)$	$\Omega(1/q^2)$	Theorems 28 and 29

Related work. Both convex hulls and range search have been extensively studied in the literature. See [3, 25] for surveys of these topics. Problems related to convex hulls have also been considered in oracle models prior to this paper. For example, the celebrated work of Chazelle, Liu, and Magen [14] considered the problem of approximating the volume of the convex hull in 2D and 3D via a sampling oracle, which can uniformly sample an input point.

[2] The notation $\widetilde{\Theta}(\cdot)$ hides factors logarithmic in q.

Czumaj and Sohler [16] studied the problem of testing convex position via range queries. Here the goal is to check whether one can remove an ε-fraction of the points from the input point set to make it in convex position. The oracle used in [16] is slightly stronger than range-emptiness oracles – it can report one point in the query range.

2 Preliminaries

Basic notations. For a number $n \in \mathbb{N}$, we write $[n] = \{1, \ldots, n\}$. For a convex body C in $\mathbb{R}^d$, we denote by $\|C\|$ its volume. The notation $|\cdot|$ is used with different meanings depending on the context. For a segment σ, we use $|\sigma|$ to denote the length of σ. For an angle α, $|\alpha| \in [0, 2\pi)$ is the magnitude of α. Furthermore, for a vector $\vec{v}$, $|\vec{v}|$ denotes its magnitude.

Vectors and halfspaces. For a halfspace $H \subset \mathbb{R}^d$, denote by ∂H its bounding hyperplane. (More generally, ∂C denotes the boundary of any convex body C.) The *normal vector* of a halfspace H is a unit vector $\vec{v} \in \mathbb{S}^{d-1}$ perpendicular to ∂H so that for any $q \in \partial H$, $H = \{p \in \mathbb{R}^d : \langle p, \vec{v}\rangle \leq \langle q, \vec{v}\rangle\}$.

3 Approximating convex hulls via orthogonal queries

In this section, we present our results for Approximate Convex Hull in $\mathbb{R}^d$ via orthogonal emptiness queries. For non-adaptive queries (Section 3.1), the algorithm is very simple, while the lower bound proof is nontrivial and interesting. For adaptive queries (Section 3.2), the algorithm is more technical and the lower bound proof is simpler.

3.1 Non-adaptive orthogonal queries

We first present our algorithmic result with non-adaptive orthogonal emptiness queries. Let $P \subseteq [0,1]^d$ be an unknown set of points and $\mathcal{O}$ be the orthogonal emptiness oracle on P. For an axis-parallel box $\square$ in $\mathbb{R}^d$, let Query($\square$) denote the output of $\mathcal{O}$ when queried with $\square$, which is yes if $P \cap \square = \emptyset$ and is no if $P \cap \square \neq \emptyset$.

Algorithm 1 NonAdaptiveOrthogonal(q).

1: $r \leftarrow \lfloor q^{1/d} \rfloor$
2: $\Gamma \leftarrow$ Partition($[0,1]^d, r$)
3: $A_\square \leftarrow$ Query($\square$) for all $\square \in \Gamma$
4: $\Gamma_1 = \{\square \in \Gamma : A_\square = \text{no}\}$
5: $C^* \leftarrow \mathcal{CH}(\bigcup_{\square \in \Gamma_1} \square)$
6: **return** C^*

Our algorithm for approximating $\mathcal{CH}(P)$ is very simple (presented in Algorithm 1) and is similar to the algorithm of Czumaj and Sohler [16] for testing convex position. Let $r = \lfloor q^{1/d} \rfloor$. In line 2, the sub-routine Partition($[0,1]^d, r$) partitions $[0,1]^d$ evenly into r^d *cells* each of which is a hypercube of side-length $\frac{1}{r}$; let Γ be the set of the r^d cells. Then we query $\mathcal{O}$ with the boxes in Γ, and let $A_\square =$ Query($\square$) for $\square \in \Gamma$. Define Γ_1 as the set of cells $\square \in \Gamma$ with $A_\square =$ no (which are just the cells containing at least one point in P). Finally, the algorithm simply returns $C^* = \mathcal{CH}(\bigcup_{\square \in \Gamma_1} \square)$. Clearly, the number of queries to $\mathcal{O}$ is at most q, and they are non-adaptive as the algorithm performs them at the same time.

To bound the error of our algorithm, we need the following lemma about the volume of the Minkowski sum of a convex body and a ball; we include a proof in the full version. For two convex bodies X and Y in $\mathbb{R}^d$, denote by $X + Y = \{x + y : x \in X \text{ and } y \in Y\}$ their Minkowski sum.

▶ **Lemma 1.** *For constant d, let $C \subseteq [0,1]^d$ be a convex body and B_δ be the ball with radius $\delta \in [0,1]$ centered at the origin of $\mathbb{R}^d$. Then $\|(C + B_\delta)\backslash C\| = O(\delta)$ for all $\delta \in [0,1]$.*

By construction, we have $\mathcal{CH}(P) \subseteq C^*$. On the other hand, we observe that $C^* \subseteq \mathcal{CH}(P) + B$, where B is the ball in $\mathbb{R}^d$ centered at the origin with radius $\frac{d}{r}$. As C^* is a polytope, it suffices to show that every vertex of C^* lies in $\mathcal{CH}(P) + B$. A vertex z of C^* is a corner of some $\square \in \Gamma_1$. Since $A_\square = \mathsf{no}$, there exists a point $p \in P \cap \square$. The distance between z and p is at most $\frac{d}{r}$, as the side-length of $\square$ is $\frac{1}{r}$. Thus, $z \in p + B$ and $z \in \mathcal{CH}(P) + B$. It follows that $\|C^*\backslash\mathcal{CH}(P)\| \leq \|(\mathcal{CH}(P) + B)\backslash\mathcal{CH}(P)\|$. By Lemma 1, $\|(\mathcal{CH}(P) + B)\backslash\mathcal{CH}(P)\| = O(\frac{1}{r})$. So we have $\|C^*\backslash\mathcal{CH}(P)\| = O(\frac{1}{r}) = O(q^{-1/d})$.

▶ **Theorem 2.** *There exists an algorithm for* Approximate Convex Hull *in $\mathbb{R}^d$ that performs q non-adaptive orthogonal emptiness queries and has error $O(q^{-1/d})$.*

Interestingly, the above algorithm, while being very simple, is already the best one can hope. Specifically, we show that any deterministic algorithm for Approximate Convex hull with q non-adaptive orthogonal emptiness queries has error $\Omega(q^{-1/d})$.

Consider such an algorithm $\mathbf{A}$. Since the q queries $\mathbf{A}$ performs are non-adaptive, these queries are independent of the point set P (as well as the range-emptiness oracle). Let $\square_1, \ldots, \square_q$ be these queries, each of which is a box in $\mathbb{R}^d$. Without loss of generality, we may assume $\square_1, \ldots, \square_q \subseteq [0,1]^d$. Set $n = \lceil q^{1/d} \rceil + 1$ and $\delta = q^{-1/d}/c$ where c is a sufficiently large constant (which only depends on d). Define a sequence $H_0, H_1, \ldots, H_n$ of parallel hyperplanes in $\mathbb{R}^d$ where the equation of H_i is $x_1 + \cdots + x_d = 1 + \delta i$. For $i \in [n]$, we say a box $\square$ is *i-good* if $H_i \cap \square \neq \emptyset$ and $H_{i-1} \cap \square = \emptyset$. See figure 1.

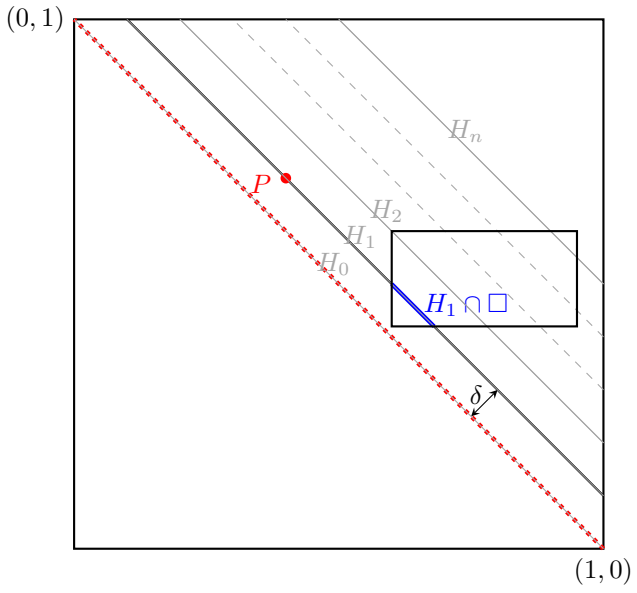

Figure 1 The lower bound construction in $d = 2$ dimensions for non-adaptive orthogonal queries with underlying points P (red) along the main diagonal H_0. The depicted query $\square$ is 1-good since its lower left corner lies between H_0 and H_1. The length of $H_1 \cap \square$ (blue) is $O(\delta^{d-1})$, so $\Omega(1/\delta^{d-1})$ 1-good queries are needed to cover H_1 in order to determine whether P contains a point on H_1. In total, $\Omega(n\delta^{d-1})$ i-good queries are needed to cover all $H_1, \cdots, H_n$.

▶ **Lemma 3.** *There exists $i \in [n]$ such that at most $\frac{q}{n}$ boxes in $\{\square_1, \ldots, \square_q\}$ are i-good.*

Proof. Observe that for different $i, j \in [n]$, no box in $\mathbb{R}^d$ can be both i-good and j-good. To see this, suppose $i < j$ without loss of generality. Let $\square$ be a j-good box. Then $H_j \cap \square \neq \emptyset$ and $H_{j-1} \cap \square = \emptyset$. So H_j and $\square$ are on the same side of H_{j-1}. If $i = j - 1$, then $H_i \cap \square = \emptyset$ and thus $\square$ is not i-good. Otherwise, $i \leq j - 2$. In this case, H_i and $\square$ are on the opposite sides of H_{j-1}, which implies $H_i \cap \square = \emptyset$ and $\square$ is not i-good. Therefore, any box in $\mathbb{R}^d$ can be i-good for at most one $i \in [n]$. Let t_i be the number of i-good boxes in $\{\square_1, \ldots, \square_q\}$. It follows that $\sum_{i=1}^{n} t_i \leq q$ and hence there exists $i \in [n]$ satisfying $t_i \leq q/n$. ◀

Let $i \in [n]$ such that at most $\frac{q}{n}$ boxes in $\{\square_1, \ldots, \square_q\}$ are i-good. Without loss of generality, assume $\square_1, \ldots, \square_t$ are i-good and $\square_{t+1}, \ldots, \square_q$ are not i-good, where $t \leq \frac{q}{n}$. Each $H_i \cap \square_j$ is a $(d-1)$-dimensional convex polytope, and let $\|H_i \cap \square_j\|'$ denote its $(d-1)$-dimensional volume.

▶ **Lemma 4.** *For all $j \in [t]$, $\|H_i \cap \square_j\|' = O(\delta^{d-1})$.*

Proof. Suppose $\square_j = [x_1^-, x_1^+] \times \cdots \times [x_d^-, x_d^+]$ and $\square_j' = [x_1^-, +\infty) \times \cdots \times [x_d^-, \infty)$. Since $\square_j$ is i-good, we have $H_i \cap \square_j \neq \emptyset$ and $H_{i-1} \cap \square_j = \emptyset$, which implies $1 + \delta i - \delta \leq x_1^- + \cdots + x_d^- \leq 1 + \delta i$. So the distance from the point $(x_1^-, \ldots, x_d^-) \in \mathbb{R}$ to H_i is $O(\delta)$. This implies $\|H_i \cap \square_j'\|' = O(\delta^{d-1})$, and thus $\|H_i \cap \square_j\|' = O(\delta^{d-1})$. ◀

▶ **Lemma 5.** $H_i \cap [0,1]^d \nsubseteq \bigcup_{j=1}^{t} \square_j$.

Proof. Equivalently, we prove that $H_i \cap [0,1]^d \nsubseteq \bigcup_{j=1}^{t} (H_i \cap \square_j)$. As $H_i \cap [0,1]^d$ and $H_i \cap \square_1, \ldots, H_i \cap \square_t$ are all $(d-1)$-dimensional convex polytopes, it suffices to show that $\|H_i \cap [0,1]^d\|' > \sum_{j=1}^{t} \|H_i \cap \square_j\|'$. Since $1 + \delta i = 1 + O(\frac{1}{c})$ and c is sufficiently large, $\|H_i \cap [0,1]^d\|'$ is lower bounded by a constant depending only on d. By Lemma 4, $\sum_{j=1}^{t} \|H_i \cap \square_j\|' = O(\delta^{d-1} t) = O(\frac{1}{c})$. Therefore, we have $\|H_i \cap [0,1]^d\|' > \sum_{j=1}^{t} \|H_i \cap \square_j\|'$, for sufficiently large c. ◀

Next, we construct two sets Z and Z' of points in $\mathbb{R}^d$. We include in Z the vertices of the polytope $H_{i-1} \cap [0,1]^d$. Furthermore, for each $j \in [q]$ such that $H_{i-1} \cap \square_j \neq \emptyset$, we include in Z a point $p_j \in H_{i-1} \cap \square_j$. Note that all points in Z lie on $H_{i-1} \cap [0,1]^d$ and we have $\mathcal{CH}(Z) = H_{i-1} \cap [0,1]^d$, so $\|\mathcal{CH}(Z)\| = 0$. To further construct Z', we pick a point $p \in (H_i \cap [0,1]^d) \backslash (\bigcup_{j=1}^{t} \square_j)$, which exists by Lemma 5. Then we define $Z' = Z \cup \{p\}$.

▶ **Lemma 6.** *For all $j \in [q]$, $Z \cap \square_j = \emptyset$ iff $Z' \cap \square_j = \emptyset$.*

Proof. If $p \notin \square_j$, then $Z \cap \square_j = Z' \cap \square_j$ and we are done. So assume $p \in \square_j$. Then $j \notin [t]$ by the choice of p. Thus, $\square_j$ is not i-good and we have either $H_i \cap \square_j = \emptyset$ or $H_{i-1} \cap \square_j \neq \emptyset$. But $H_i \cap \square_j \neq \emptyset$ since $p \in H_i \cap \square_j$. So we must have $H_{i-1} \cap \square_j \neq \emptyset$. By construction, we include in Z the point $p_j \in H_{i-1} \cap \square_j$, which implies $Z \cap \square_j \neq \emptyset$ and $Z' \cap \square_j \neq \emptyset$. ◀

The above lemma shows that the algorithm $\mathbf{A}$ cannot distinguish Z and Z', that is, it returns the same convex body when running on $P = Z$ and $P = Z'$.

▶ **Lemma 7.** $\|\mathcal{CH}(Z') \backslash \mathcal{CH}(Z)\| = \Omega(\delta)$.

Let C^* be the output of $\mathbf{A}$ when run on $P = Z$ or $P = Z'$. We have $\|\mathcal{CH}(Z') \backslash \mathcal{CH}(Z)\| \leq \|C^* \oplus \mathcal{CH}(Z)\| + \|C^* \oplus \mathcal{CH}(Z')\|$. Therefore, the above lemma implies either $\|C^* \oplus \mathcal{CH}(Z)\| = \Omega(\delta)$ or $\|C^* \oplus \mathcal{CH}(Z')\| = \Omega(\delta)$. As $\delta = \Theta(q^{-1/d})$, the error of $\mathbf{A}$ is $\Omega(q^{-1/d})$.

▶ **Theorem 8.** *Any deterministic algorithm for* Approximate Convex Hull *in $\mathbb{R}^d$ that performs q non-adaptive orthogonal emptiness queries has error $\Omega(q^{-1/d})$.*

3.2 Adaptive orthogonal queries

We now consider adaptive orthogonal emptiness queries, and show how to approximate $\mathcal{CH}(P)$ with error $O(q^{-1/(d-1)})$ via $O(q)$ queries. We shall define 2^d supersets of $\mathcal{CH}(P)$, one-to-one corresponding to the vectors in $\{-1,1\}^d$. Our algorithm independently approximates these supersets and then merges them together. For each $\vec{v} = (v_1, \ldots, v_d) \in \{-1,1\}^d$, let O_v be the orthant $\{(x_1, \ldots, x_d) : x_i v_i \geq 0 \text{ for all } i \in [d]\}$. We define $\mathcal{CH}_{\vec{v}}(P) = (\mathcal{CH}(P) + O_{-\vec{v}}) \cap [0,1]^d$. The following observation relates $\mathcal{CH}(P)$ with the supersets $\mathcal{CH}_{\vec{v}}(P)$ (proof in full version).

▶ **Lemma 9.** $\mathcal{CH}(P) = \bigcap_{\vec{v} \in \{-1,1\}^d} \mathcal{CH}_{\vec{v}}(P)$.

Algorithm 2 presents how to approximate $\mathcal{CH}_{\vec{v}}(P)$ for each $\vec{v} \in \{-1,1\}^d$. It essentially "sandwiches" the hull between two convex boundaries, refining the estimate at each iteration. Figure 2 illustrates one such refinement step. The subroutine SUBDIVIDE(R) evenly partitions the hypercube R into 2^d smaller hypercubes (each of which has side-length half of the side-length of R) and returns the set of these 2^d hypercubes. For a hypercube R and a vector $\vec{v} \in \{-1,1\}^d$, we define $\mathsf{cor}(R, \vec{v}) = \arg\max_{p \in R} \langle p, \vec{v} \rangle$ as the corner of R in the direction $\vec{v}$. The algorithm starts with a set $\mathcal{R}$ of hypercubes which initially consists of only $[0,1]^d$, and runs in $\lceil \frac{\log q}{d-1} \rceil$ rounds. In each round, we perform emptiness queries for the hypercubes in $\mathcal{R}$, and let $\mathcal{R}' \subseteq \mathcal{R}$ consist of the nonempty ones. Then define $U = \mathcal{CH}_{\vec{v}}(\{\mathsf{cor}(R, \vec{v}) : R \in \mathcal{R}'\})$ and $L' = \mathcal{CH}_{\vec{v}}(\{\mathsf{cor}(R, -\vec{v}) : R \in \mathcal{R}'\})$. Let $L = L' \setminus \partial L'$ be the interior of L'. This is simply to ensure that $\partial \mathcal{CH}_{\vec{v}}(P)$ is contained in $U \setminus L$. We then take all hypercubes in $\mathcal{R}$ that intersect $U \setminus L$, partition them using the subroutine SUBDIVIDE, and let the new $\mathcal{R}$ be the set of the resulting smaller hypercubes. (Technically, we only need to consider the nonempty queries in $\mathcal{R}'$, but this is equivalent in the worst case, and this way nicely ensures that our queries continue to cover all of $\partial CH_{\vec{v}}(P)$). Finally, we return the convex body U in the last iteration as an approximation of $\mathcal{CH}_{\vec{v}}(P)$.

Algorithm 2 ADAPTIVEORTHOGONAL($q, \vec{v}$).

```
1: R ← {[0,1]^d}
2: for i = 1 to ⌈log q / (d−1)⌉ do
3:     R' ← {R ∈ R : QUERY(R) = no}
4:     U ← CH_v({cor(R, v) : R ∈ R'})

9: return U
```

At a high level, the algorithm maintains an upper and lower bound (the sets U and L respectively) on the unknown convex body $\mathcal{CH}_{\vec{v}}(P)$. At each iteration of the loop, we reduce the error volume $\|(U \setminus \mathcal{CH}_{\vec{v}}(P)) \cap [0,1]^d\|$ by half. Let $t = \lceil \frac{\log q}{d-1} \rceil$ be the number of iterations. For $i \in [t]$, denote by $\mathcal{R}_i$ the set $\mathcal{R}$ at the end of the i-th iteration of the loop, and likewise for L_i, U_i, $\mathcal{R}'_i$, $\mathcal{R}''_i$. Without loss of generality, we assume that $\vec{v} = (1, \ldots, 1)$. The following two lemmas are used to bound the error and number of queries; their proofs are included in the full version.

▶ **Lemma 10.** *For all $i \in [t]$, $L_i \subset \mathcal{CH}_{\vec{v}}(P) \subseteq U_i$ and $\partial \mathcal{CH}_{\vec{v}}(P) \subseteq \bigcup_{R \in \mathcal{R}_i} R$.*

▶ **Lemma 11.** *The number of queries at the i-th iteration is at most $4^d d! \cdot (2^i + 1)^{d-1}$.*

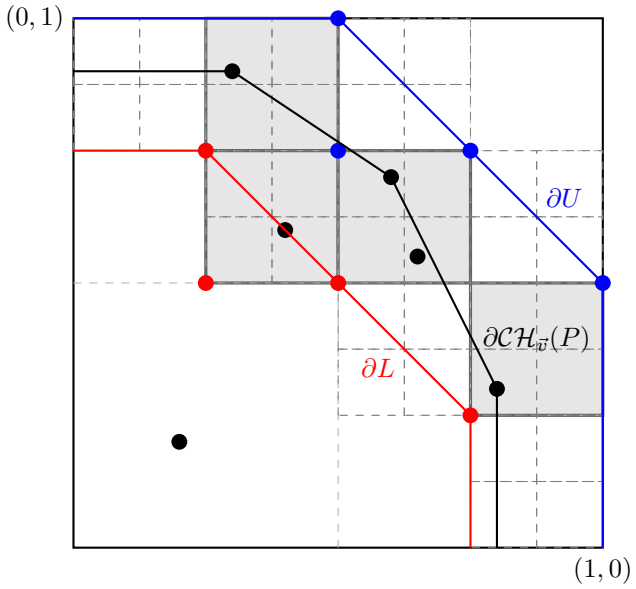

Figure 2 One iteration of Algorithm 2 for $d = 2, \vec{v} = (1, 1)$. The four queries in $\mathcal{R}'$ are filled in gray. The upper right corners of these queries are used to compute the set U with boundary shown in blue, while the lower left corners produce L in red. The boundary of $\mathcal{CH}_{\vec{v}}(P)$ lies in $U \setminus L$. The smallest dashed queries form the set $\mathcal{R}$ for the next iteration; their union covers $U \setminus L$.

As d is a constant, Lemma 11 implies the number of queries in the i-th iteration is $O((2^i+1)^{d-1})$. So the total number of queries is bounded by $\sum_{i=1}^{t}(2^i+1)^{d-1} = O(q)$. Since each query box in the i-th iteration has volume 2^{-id}, we have

$$\left\| \bigcup_{R \in \mathcal{R}_t} R \right\| \leq 2^{-td}|\mathcal{R}_t| = O(2^{-d \log q/(d-1)} q) = O(q^{-1/(d-1)}).$$

By Lemma 10, this further implies $\|(U_t \backslash \mathcal{CH}_{\vec{v}}(P)) \cap [0,1]^d\| = O(q^{-1/(d-1)})$, simply because $(U_t \backslash \mathcal{CH}_{\vec{v}}(P)) \cap [0,1]^d \subseteq (U_t \backslash L_t) \cap [0,1]^d \subseteq \bigcup_{R \in \mathcal{R}_t} R$.

We run Algorithm 2 for all $\vec{v} \in \{-1, 1\}^d$ and let $U_{\vec{v}}$ be the output for $\vec{v}$. Finally, we return $C^* = (\bigcap_{\vec{v} \in \{-1,1\}^d} U_{\vec{v}}) \cap [0,1]^d$ as the approximation of $\mathcal{CH}(P)$. The total number of queries is still $O(q)$. To bound the error $\|C^* \oplus \mathcal{CH}(P)\|$, we first observe $\mathcal{CH}(P) \subseteq C^*$. Indeed, since $\mathcal{CH}_{\vec{v}}(P) \subseteq U_{\vec{v}}$ for all $\vec{v} \in \{-1, 1\}^d$, we have $\mathcal{CH}(P) \subseteq \bigcap_{\vec{v} \in \{-1,1\}^d} U_{\vec{v}}$ by Lemma 9, which implies $\mathcal{CH}(P) \subseteq C^*$ because $P \subseteq [0,1]^d$. Again, by Lemma 9, we have

$$\|C^* \backslash \mathcal{CH}(P)\| \leq \sum_{\vec{v} \in \{-1,1\}^d} \|(U_{\vec{v}} \backslash \mathcal{CH}_{\vec{v}}(P)) \cap [0,1]^d\| = O(q^{-1/(d-1)}).$$

Therefore, the error of our algorithm is $O(q^{-1/(d-1)})$.

▶ **Theorem 12.** *There exists an algorithm for* Approximate Convex Hull *in* $\mathbb{R}^d$ *that performs* $O(q)$ *adaptive orthogonal emptiness queries and has error* $O(q^{-1/(d-1)})$.

We complement this result by showing that any deterministic algorithm with q adaptive orthogonal queries has error $\Omega(q^{-1/(d-1)})$. The argument is similar to and simpler than that of Theorem 8, so we include the precise details in the full version. The key difference is that Lemma 3 no longer holds for adaptive queries, but we can still apply the same argument for a single pair of hyperplanes and only lose a factor $n = q^{1/d}$ in the resulting error bound.

▶ **Theorem 13.** *Any deterministic algorithm for* Approximate Convex Hull *in* $\mathbb{R}^d$ *that performs* q *adaptive orthogonal emptiness queries has error* $\Omega(q^{-1/(d-1)})$.

4 Approximating convex hulls via halfplane queries

In this section, we present our results for Approximate Convex Hull in $\mathbb{R}^2$ via halfplane emptiness queries. Instead of working on halfplane emptiness queries directly, it is more convenient to consider *extreme halfplane queries*, which we formalize below. For two parallel lines ℓ and ℓ', let $\mathsf{dist}(\ell, \ell')$ denote the distance between them.

▶ **Definition 14** (extreme halfplane oracle)**.** *An* ***extreme halfplane oracle*** *on P takes a unit vector $\vec{v} \in \mathbb{S}^1$ as input and returns a halfplane H with normal vector $\vec{v}$ such that $P \subseteq H$. We say the oracle is* ***δ-accurate*** *for a number $\delta \geq 0$ if for every $\vec{v} \in \mathbb{S}^1$, the halfplane H returned by the oracle for query $\vec{v}$ satisfies the condition $\mathsf{dist}(\partial H, \partial H^*) \leq \delta$, where H^* is the minimal halfplane with normal vector $\vec{v}$ satisfying $P \subseteq H^*$.*

It is easy to see that a 0-accurate extreme halfplane oracle is stronger than a halfplane emptiness oracle. On the other hand, one can simulate an extreme halfplane query with accuracy δ via $O(1/\delta)$ evenly spaced non-adaptive halfplane emptiness queries. The query number can be reduced to $O(\log(1/\delta))$ via binary search in the adaptive model. The proofs of the following two lemmas are included in the full version.

▶ **Lemma 15.** *Given access to a halfplane emptiness oracle $\mathcal{O}$ on an unknown set P of points in the plane, one can build a δ-accurate extreme halfplane oracle on P which performs $O(\frac{1}{\delta})$ non-adaptive queries to $\mathcal{O}$ or performs $O(\log \frac{1}{\delta})$ adaptive queries to $\mathcal{O}$.*

We will also need the following lemma to argue that the error introduced by querying a δ-accurate extreme halfplane oracle, as opposed to a perfectly accurate one, is only $O(\delta)$.

▶ **Lemma 16.** *Let $H_1, \ldots, H_r$ be halfplanes, $C = \bigcap_{i=1}^r H_i$, and $\delta \in [0,1]$. Suppose $C \subseteq [0,1]^2$. For each $i \in [r]$, let H_i' be a halfplane parallel to H_i such that $C \subseteq H_i$ and $\mathsf{dist}(\partial H_i', \partial H_i) \leq \delta$. Define $C' = \bigcap_{i=1}^r H_i'$. Then $\|(C' \cap [0,1]^2) \oplus C\| = O(\delta)$.*

In what follows, we discuss the results for non-adaptive halfplane queries and adaptive halfplane queries individually. Same as before, for non-adaptive queries (Section 4.1), the algorithm is simple and the lower bound proof is nontrivial, while for adaptive queries (Section 4.2), the algorithm is more technical and the lower bound proof is simpler.

4.1 Non-adaptive halfplane queries

We first present our algorithmic result with non-adaptive halfplane emptiness queries. Let $P \subseteq [0,1]^2$ be a (unknown) set of points. We shall show how to approximate $\mathcal{CH}(P)$ with error $O(\frac{1}{q} + \delta)$ via q non-adaptive queries to a δ-accurate extreme halfplane oracle $\mathcal{E}$ on P. Setting $\delta = \frac{1}{q}$ and applying Lemma 15 yields an algorithm with error $O(1/q)$ that makes q^2 non-adaptive halfplane emptiness queries. Equivalently, q queries achieve error $O(1\sqrt{q})$.

Algorithm 3 NonAdaptiveHalfplane(q).

1: $V \leftarrow \{(\sin \frac{2i\pi}{q}, \cos \frac{2i\pi}{q}) : i \in [q]\}$
2: $H_{\vec{v}} \leftarrow \textsc{Query}(\vec{v})$ for all $\vec{v} \in V$
3: $C^* \leftarrow \bigcap_{\vec{v} \in V} H_{\vec{v}}$
4: **return** $C^* \cap [0,1]^2$

For a unit vector $\vec{v} \in \mathbb{S}^1$, let $\textsc{Query}(\vec{v})$ denote the output of $\mathcal{E}$ when queried with $\vec{v}$. Our algorithm for approximating $\mathcal{CH}(P)$ is very simple, and is presented in Algorithm 3. Let $V = \{(\sin \frac{2i\pi}{q}, \cos \frac{2i\pi}{q}) : i \in [q]\}$ be q unit vectors uniformly picked on $\mathbb{S}^1$. We query $\mathcal{E}$

with the vectors in V, and let $H_{\vec{v}} = \textsc{Query}(\vec{v})$ for all $\vec{v} \in V$. After that, we simply return $C^* \cap [0,1]^2$ where $C^* = \bigcap_{\vec{v} \in V} H_{\vec{v}}$. Clearly, the number of queries to $\mathcal{E}$ is q, and they are non-adaptive as the algorithm performs them at the same time. We bound the error to $O(1/\sqrt{q})$ in the full version.

▶ **Theorem 17.** *There exists an algorithm for* Approximate Convex Hull *in* $\mathbb{R}^2$ *that performs* q *non-adaptive halfplane emptiness queries and has error* $O(1/\sqrt{q})$.

Next, we show that any deterministic algorithm that performs q non-adaptive halfplane queries must have error $\Omega(1/\sqrt{q})$. Consider an algorithm $\mathbf{A}$. As the q queries performed by $\mathbf{A}$ are non-adaptive, they are independent of the point set P. Let $H_1, \ldots, H_q$ be these queries, each of which is a halfplane in $\mathbb{R}^2$. For $x, y \in (0,1)$, denote by $\ell_{x,y}$ the line that goes through the points $(x,0)$ and $(0,y)$. Also, for $X, Y \subseteq (0,1)$, define $\mathcal{L}_{X,Y} = \{\ell_{x,y} : x \in X \text{ and } y \in Y\}$. Fix a parameter $\delta = \frac{1}{10\sqrt{q}}$, and let $A = \{i\delta : i \in \mathbb{Z}\} \cap [\frac{1}{3}, \frac{2}{3}]$.

▶ **Lemma 18.** *There exists* $a, b \in A$ *such that* $\partial H_i \notin \mathcal{L}_{[a,a+\delta),[b,b+\delta)}$ *for all* $i \in [q]$.

Proof. Observe that for different $a, a' \in A$, the intervals $[a, a+\delta)$ and $[a', a'+\delta)$ are disjoint. Therefore, $\mathcal{L}_{[a,a+\delta),[b,b+\delta)}$ and $\mathcal{L}_{[a',a'+\delta),[b',b'+\delta)}$ are disjoint, for $(a,b), (a',b') \in A \times A$ with $(a,b) \neq (a',b')$. It follows that for each $i \in [q]$, there exists at most one pair $(a,b) \in A \times A$ such that $\partial H_i \in \mathcal{L}_{[a,a+\delta),[b,b+\delta)}$; we charge i to (a,b) if this is the case. By construction, $|A| \geq 3\sqrt{q}$ and thus $|A \times A| \geq 9q > q$. As such, there exists a pair $(a,b) \in A \times A$ such that no number in $[q]$ is charged to (a,b). We then have $\partial H_i \notin \mathcal{L}_{[a,a+\delta),[b,b+\delta)}$ for all $i \in [q]$. ◀

Let $a, b \in A$ be as in the above lemma, and $p^* = (\frac{a}{2} + \frac{\delta}{10}, \frac{b}{2} + \frac{\delta}{10})$. We define two sets $Z = \{(a,0), (0,b)\}$ and $Z' = \{(a,0), (0,b), p^*\}$; see figure 3.

▶ **Lemma 19.** *The point* p^* *is below the lines* $\ell_{a+\delta,b}$ *and* $\ell_{a,b+\delta}$.

Proof. Without loss of generality, we only need to show p^* is below $\ell_{a+\delta,b}$. The equation of $\ell_{a+\delta,b}$ is $bx + (a+\delta)y - b(a+\delta) = 0$. Since $a, b \in A$, we have $a, b \in [\frac{1}{3}, \frac{2}{3}]$. So we have

$$b\left(\frac{a}{2} + \frac{\delta}{10}\right) + (a+\delta)\left(\frac{b}{2} + \frac{\delta}{10}\right) - b(a+\delta) = \left(\frac{a+b+\delta}{10} - \frac{b}{2}\right)\delta < 0,$$

which implies that that p^* is below $\ell_{a+\delta,b}$. ◀

▶ **Corollary 20.** *For all* $i \in [q]$, $Z \cap H_i = \emptyset$ *iff* $Z' \cap H_i = \emptyset$.

Proof. If $p^* \notin H_i$, then $Z \cap H_i = Z' \cap H_i$ and we are done. So suppose $p^* \in H_i$. We claim that either $(a,0) \in H_i$ or $(0,b) \in H_i$. It suffices to show that at least one of $(a,0)$ and $(0,b)$ lies on the same side of ∂H_i as p^*. Assume both $(a,0)$ and $(0,b)$ are on the opposite side of ∂H_i from p^*. Then p^* and the segment $\ell_{a,b} \cap [0,1]^2$ must lie on the opposite side of ∂H_i. But by our construction, p^* is sufficiently close to $\ell_{a,b} \cap [0,1]^2$, which forces $\partial H_i = \ell_{x,y}$ for some $x \in [a,1]$ and $y \in [b,1]$. By Lemma 18, we cannot have $x \in [a, a+\delta)$ and $y \in [b, b+\delta)$ at the same time. So either $x \geq a+\delta$ or $y \geq b+\delta$. Without loss of generality, assume $x \geq a+\delta$. By Lemma 19, p^* is below $\ell_{a+\delta,b}$. Since $x \geq a+\delta$ and $y \geq b$, p^* is below ∂H_i as well. But both $(a,0)$ and $(0,b)$ are also below ∂H_i, contradicting our assumption. As such, we have either $(a,0) \in H_i$ or $(0,b) \in H_i$. It follows that $Z \cap H_i \neq \emptyset$ and $Z' \cap H_i \neq \emptyset$. ◀

The rest of the proof is almost the same as that of Theorem 8. The above lemma shows that the algorithm $\mathbf{A}$ cannot distinguish Z and Z', that is, it returns the same convex polygon when running on $P = Z$ and $P = Z'$. We only need to observe the following simple fact.

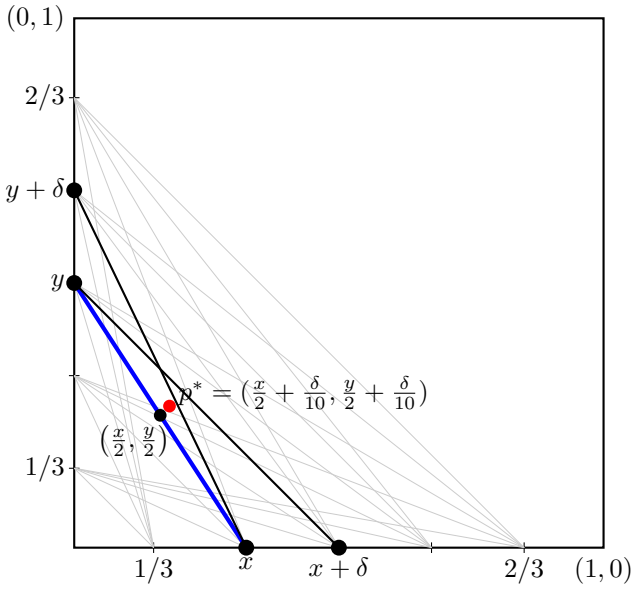

Figure 3 Lower bound construction for non-adaptive halfplane queries. The point p^* (red) is offset from the midpoint $(x/2, y/2)$ of $l_{x,y}$ to lie sufficiently far above $l_{x,y}$ (blue) but below both $l_{x+\delta,y}$ and $l_{x,y+\delta}$. Only a segment with both x-intercept in the interval $[x, x+\delta]$ and y-intercept in the interval $[y, y+\delta]$ can separate both $(x, 0), (0, y)$ from p^*. Doing so for all $\Theta(1/\delta^2) > q$ paired choices of x, y (gray lines) necessitates as many queries. Range [1/3, 2/3] enlarged for clarity.

▶ **Lemma 21.** $\|\mathcal{CH}(Z')\backslash\mathcal{CH}(Z)\| = \Omega(\delta)$.

Let C^* be the output of $\mathbf{A}$ when running on $P = Z$ or $P = Z'$. We have $\|\mathcal{CH}(Z')\backslash\mathcal{CH}(Z)\| \leq \|C^* \oplus \mathcal{CH}(Z)\| + \|C^* \oplus \mathcal{CH}(Z')\|$. Thus, the above lemma implies either $\|C^* \oplus \mathcal{CH}(Z)\| = \Omega(\delta)$ or $\|C^* \oplus \mathcal{CH}(Z')\| = \Omega(\delta)$. As $\delta = \Theta(1/\sqrt{q})$, the error of $\mathbf{A}$ is $\Omega(1/\sqrt{q})$.

▶ **Theorem 22.** *Any deterministic algorithm for* Approximate Convex Hull *in* $\mathbb{R}^2$ *that performs* q *non-adaptive halfplane emptiness queries incurs error* $\Omega(1/\sqrt{q})$.

4.2 Adaptive halfplane queries

We first present our algorithm with adaptive halfplane emptiness queries. Let $P \subseteq [0,1]^2$ be a (unknown) set of points. We shall show how to approximate $\mathcal{CH}(P)$ with error $O(\frac{1}{q^2} + q^2\delta)$ via $O(q \log q)$ adaptive queries to a δ-accurate extreme halfplane oracle $\mathcal{E}$ on P. Combining this with Lemma 15 will give us the desired result.

Same as before, for a unit vector $\vec{v} \in \mathbb{S}^1$, let Query$(\vec{v})$ denote the output of $\mathcal{E}$ when queried with $\vec{v}$. Our algorithm for approximating $\mathcal{CH}(P)$ is presented in Algorithm 4. We begin with a set V of unit vectors which is initially $\{(1,0),(0,1),(-1,0),(0,-1)\}$. We query $\mathcal{E}$ with the vectors in V and let $H_{\vec{v}} = \text{Query}(\vec{v})$. Then we iteratively add more vectors to V and query $\mathcal{E}$ with these vectors (the repeat-until loop in the algorithm). In each round, we first compute $C^* = \bigcap_{\vec{v}\in V} H_{\vec{v}}$ for the current V (line 4). Then line 5 sorts the vectors in the current V in clockwise order; let $\vec{v}_1, \ldots, \vec{v}_n$ be the sorted sequence. Let $\vec{v}_0 = \vec{v}_n$ and $\sigma_i = C^* \cap \partial H_{\vec{v}_i}$, which is the edge of C^* corresponding to the halfplane $H_{\vec{v}_i}$. We consider each pair $(\vec{v}_{i-1}, \vec{v}_i)$ of adjacent vectors satisfying $\mathsf{ang}(\vec{v}_{i-1}, \vec{v}_i) \cdot |\sigma_i| > \frac{1}{q^2}$, where $\mathsf{ang}(\vec{v}_{i-1}, \vec{v}_i)$ denotes the magnitude of the angle from $\vec{v}_{i-1}$ to $\vec{v}_i$. For each such pair $(\vec{v}_{i-1}, \vec{v}_i)$, we add a

new unit vector $\vec{v}$ to V, which is the bisector of $\vec{v}_{i-1}$ and $\vec{v}_i$, and query $\mathcal{E}$ with $\vec{v}$ to obtain the halfplane $H_{\vec{v}} = \textsc{Query}(\vec{v})$. After this, we proceed to the next round. The procedure terminates when no more vectors are added to V in a round. At the end, the algorithm returns the convex polygon $C^* \cap [0,1]^2$ as its output.

Algorithm 4 AdaptiveHalfplane(q).

$V \leftarrow \{(1,0),(0,1),(-1,0),(0,-1)\}$
$H_{\vec{v}} \leftarrow \textsc{Query}(\vec{v})$ for all $\vec{v} \in V$
repeat
  $C^* \leftarrow \bigcap_{\vec{v}\in V} H_{\vec{v}}$
  $(\vec{v}_1,\ldots,\vec{v}_n) \leftarrow \textsc{Sort}(V)$
  $\vec{v}_0 \leftarrow \vec{v}_n$
  $\sigma_i \leftarrow C^* \cap \partial H_{\vec{v}_i}$ for $i \in [n]_0$
  $I \leftarrow \{i \in [n] : \mathsf{ang}(\vec{v}_{i-1},\vec{v}_i) \cdot |\sigma_i| > \frac{1}{q^2}\}$
  for every $i \in I$ **do**
    $\vec{v} \leftarrow (\vec{v}_{i-1}+\vec{v}_i)/\|\vec{v}_{i-1}+\vec{v}_i\|_2$
    $V \leftarrow V \cup \{\vec{v}\}$
    $H_{\vec{v}} \leftarrow \textsc{Query}(\vec{v})$
until $I = \emptyset$
return $C^* \cap [0,1]^2$

Bounding the number of queries. Clearly, the number of queries we made in Algorithm 4 is just equal to the number of vectors in V at the end of the algorithm. Suppose the repeat-until loop in Algorithm 4 has t iterations. For $i \in [t]$, let V_i be the set V at the beginning of the i-th iteration and $C_i^* = \bigcap_{\vec{v}\in V_i} H_{\vec{v}}$ which is just the convex polygon C^* in the i-th iteration. Note that V_t is just the set V at the end of the algorithm, as the algorithm does not add new vectors to V in the last iteration. For convenience, we write $V_0 = \emptyset$. Denote by $\mathcal{A}(V_i)$ the set of angles between adjacent vectors in V_i. We first bound $|V_i \backslash V_{i-1}|$ for $i \in [t]$. The proofs for this subsection are included in the full version.

▶ **Lemma 23.** *$|V_i \backslash V_{i-1}| = O(q)$ for all $i \in [t]$.*

The above lemma directly implies $|V_t| = O(qt)$. Thus, it suffices to bound t. To this end, we establish the following properties for the angles in each $\mathcal{A}(V_i)$.

▶ **Lemma 24.** *For all $i \in [t]$ and $\alpha \in \mathcal{A}(V_i)$, we have $|\alpha| \geq \frac{1}{12q^2}$.*

▶ **Lemma 25.** *Let $i \in [t]$. We have $|\alpha| = \frac{\pi}{2^i}$ for all $\alpha \in \mathcal{A}(V_i) \backslash \mathcal{A}(V_{i+1})$.*

Lemma 24 and Lemma 25 together imply that $t = O(\log q)$. Indeed, $\mathcal{A}(V_i) \neq \mathcal{A}(V_{i+1})$ for all $i \in [t-1]$, for otherwise the algorithm terminates after the i-th iteration. Thus there exists $\alpha \in \mathcal{A}(V_{t-1}) \backslash \mathcal{A}(V_t)$. We have $\frac{\pi}{2^{t-1}} = |\alpha| \geq \frac{1}{q^2}$ by Lemma 24 and Lemma 25, which implies $t = O(\log q)$. It follows that $|V_t| = O(qt) = O(q \log q)$.

Bounding the error. Next, we show that the output $C^* \cap [0,1]^2$ of Algorithm 4 satisfies $\|(C^* \cap [0,1]^2) \oplus \mathcal{CH}(P)\| = O(\frac{1}{q^2} + \delta)$. Let $V = \{\vec{v}_1,\ldots,\vec{v}_n\}$ be the set of vectors at the end of Algorithm 4, where $\vec{v}_1,\ldots,\vec{v}_n$ are sorted in clockwise order. Set $\vec{v}_0 = \vec{v}_n$. As in the algorithm, for each $i \in [n]_0$, let $H_{\vec{v}_i} = \textsc{Query}(\vec{v}_i)$ and $\sigma_i = C^* \cap \partial H_{\vec{v}_i}$. Then $C^* = \bigcap_{i=1}^n H_{\vec{v}_i}$. We have $|\mathsf{ang}(\vec{v}_{i-1},\vec{v}_i)| \cdot (|\sigma_{i-1}| + |\sigma_i|) > \frac{1}{q^2}$ for all $i \in [n]_0$, for otherwise the repeat-until loop

in Algorithm 4 cannot terminate. Define $L_{\vec{v}_i}$ as the minimal halfplane with normal vector $\vec{v}_i$ that contains P and $C = \bigcap_{i=1}^{n} L_{\vec{v}_i}$. We have $C \subseteq C^*$, since $L_{\vec{v}_i} \subseteq H_{\vec{v}_i}$ for all $i \in [n]$. Also, we have $C \subseteq [0,1]^2$, since V consists of the four vectors $(1,0),(0,1),(-1,0),(0,-1)$, which guarantees that C is contained in the axis-parallel bounding box of P and thus contained in $[0,1]^2$. Now $\mathcal{CH}(P) \subseteq C \subseteq C^* \cap [0,1]^2$. By Lemma 16, $\|(C^* \cap [0,1]^2) \backslash C\| = O(\delta)$. So it suffices to show $\|C \backslash \mathcal{CH}(P)\| = O(\frac{1}{q^2} + \delta)$. Define $\mu_i = C \cap \partial L_{\vec{v}_i}$ for $i \in [n]$ and $\mu_0 = \mu_n$.

▶ **Lemma 26.** *$|\mu_i| \leq |\sigma_i| + O(q^2\delta)$ for all $i \in [n]$.*

Proof. Let a and a' be the endpoints of μ_i, where a (resp., a') is on the counterclockwise (resp., clockwise) side of μ_i with respect to C. We first consider the general case $\sigma_i \neq \emptyset$ and then discuss the special case $\sigma_i = \emptyset$. If $\sigma_i \neq \emptyset$, let b and b' be the endpoints of σ_i, where b (resp., b') is on the counterclockwise (resp., clockwise) side of σ_i with respect to C^*. As $\sigma_i \subseteq \partial H_{\vec{v}_i}$ and $\mu_i \subseteq \partial L_{\vec{v}_i}$, the 4-gon $aa'b'b$ is a trapezoid with parallel edges μ_i and σ_i. Therefore, we have the equation

$$|\mu_i| = |\sigma_i| + \frac{h}{\tan \angle baa'} + \frac{h}{\tan \angle b'a'a}.$$

where h is the height of this trapezoid. We have $h \leq \delta$ since $\mathsf{dist}(\partial H_{\vec{v}_i}, \partial L_{\vec{v}_i}) \leq \delta$. Furthermore, we observe that $|\angle baa'| \geq \mathsf{ang}(\vec{v}_{i-1}, \vec{v}_i)$ and $|\angle b'a'a| \geq \mathsf{ang}(\vec{v}_i, \vec{v}_{i+1})$. Indeed, $\angle baa' = \pi - \angle b'ba$. Since $a \in C^*$, the angle $\angle b'ba$ is smaller than or equal to the angle of C^* at the vertex b, where the latter is just $\pi - \mathsf{ang}(\vec{v}_{i-1}, \vec{v}_i)$. Thus,

$$|\angle baa'| = \pi - |\angle b'ba| \geq \pi - (\pi - \mathsf{ang}(\vec{v}_{i-1}, \vec{v}_i)) = \mathsf{ang}(\vec{v}_{i-1}, \vec{v}_i).$$

For the same reason, $|\angle b'a'a| \geq \mathsf{ang}(\vec{v}_i, \vec{v}_{i+1})$. By Lemma 24, it follows that $|\angle baa'| \geq \frac{1}{12q^2}$ and $|\angle b'a'a| \geq \frac{1}{12q^2}$. As such, $|\mu_i| = |\sigma_i| + O(q^2\delta)$.

If $\sigma_i = \emptyset$, then C^* is contained in the interior of $H_{\vec{v}_i}$. In this case, C^* has a unique vertex that is closest to $\partial H_{\vec{v}_i}$. Let both b and b' be this vertex. The same argument applies. ◀

The definition of each $L_{\vec{v}_i}$ guarantees that there exists a point $p_i \in P$ satisfying $p_i \in \partial L_{\vec{v}_i}$. As $p_i \in P \subseteq C$, we have $p_i \in \mu_i$. Let $P' = \{p_1, \ldots, p_n\}$. We have $P' \subseteq P$ and thus $\|C \backslash \mathcal{CH}(P')\| \geq \|C \backslash \mathcal{CH}(P)\|$. We shall show $\|C \backslash \mathcal{CH}(P')\| = O(\frac{1}{q^2} + \delta)$, which bounds $\|C \backslash \mathcal{CH}(P)\|$ as well. For each $i \in [n]$, let a_i be the intersection point of μ_{i-1} and μ_i, and τ_i be the segment with endpoints p_{i-1} and p_i. Note that $\|C \backslash \mathcal{CH}(P')\| = \sum_{i=1}^{n} \|\triangle p_{i-1}p_ia_i\|$.

▶ **Lemma 27.** *$\|\triangle p_{i-1}p_ia_i\| = O(|\tau_i| \cdot (\frac{1}{q^2} + q^2\delta))$ for all $i \in [n]$.*

Proof. By construction, the distance between p_{i-1} and p_i is just $|\tau_i|$. So we only need to show that the height h of $\triangle p_{i-1}p_ia_i$ with respect to the edge $p_{i-1}p_i$ is bounded by $O(\frac{1}{q^2} + q^2\delta)$. Let $\theta = \angle a_ip_ip_{i-1}$. As the distance between a_i and p_i is at most $|\mu_i|$, we have

$$h \leq |\mu_i| \cdot \sin|\theta| \leq |\mu_i| \cdot \theta \leq \mathsf{ang}(\vec{v}_{i-1}, \vec{v}_i) \cdot |\mu_i|.$$

By Lemma 26, this implies $h = \mathsf{ang}(\vec{v}_{i-1}, \vec{v}_i) \cdot |\sigma_i| + O(q^2\delta)$. Since $\mathsf{ang}(\vec{v}_{i-1}, \vec{v}_i) \cdot |\sigma_i| \leq \frac{1}{q^2}$, we have $h = O(\frac{1}{q^2} + q^2\delta)$ and thus $\|\triangle p_{i-1}p_ia_i\| = O(|\tau_i| \cdot (\frac{1}{q^2} + q^2\delta))$. ◀

The above lemma directly implies

$$\|C \backslash \mathcal{CH}(P')\| = \sum_{i=1}^{n} \|\triangle p_{i-1}p_ia_i\| = O((\sum_{i=1}^{n} |\tau_i|) \cdot (\frac{1}{q^2} + q^2\delta)).$$

As $\tau_1, \ldots, \tau_n$ are just the edge of the convex polygon $\mathcal{CH}(P')$, we have $\sum_{i=1}^{n} |\tau_i| = O(1)$ and thus $\|C \backslash \mathcal{CH}(P')\| = O(\frac{1}{q^2} + q^2\delta)$. As Lemma 16 implies $\|(C^* \cap [0,1]^2) \backslash C\| = O(\delta)$, we have $\|(C^* \cap [0,1]^2) \oplus \mathcal{CH}(P)\| \leq \|(C^* \cap [0,1]^2) \backslash \mathcal{CH}(P')\| = O(\frac{1}{q^2} + q^2\delta)$. Setting $\delta = \frac{1}{q^4}$, we see that one can approximate $\mathcal{CH}(P)$ with error $O(\frac{1}{q^2})$ via $O(q \log q)$ queries to a $\frac{1}{q^4}$-accurate extreme halfplane oracle for P.

Lemma 15 shows that a query to a $\frac{1}{q^4}$-accurate extreme halfplane oracle can be simulated with $O(\log q)$ adaptive halfplane emptiness queries. Therefore, one can approximate $\mathcal{CH}(P)$ with error $O(\frac{1}{q^2})$ via $O(q \log^2 q)$ adaptive halfplane emptiness queries. Equivalently, if we are allowed to use q queries, then the error achieved can be bounded by $O(\frac{\log^2 q}{q^2})$, i.e., $\widetilde{O}(\frac{1}{q^2})$.

▶ **Theorem 28.** *There exists an algorithm for* Approximate Convex Hull *in* $\mathbb{R}^2$ *that performs* q *adaptive halfplane emptiness queries and has error* $\widetilde{O}(1/q^2)$.

We remark that replacing the threshold $\frac{1}{q^2}$ in Algorithm 4 with an even smaller number cannot result in an improvement for Theorem 28: while it can decrease the error of the output, it also increases the number of queries substantially. In fact, the bound $\widetilde{O}(1/q^2)$ is already tight up to logarithmic factors. The details are included in the full version.

▶ **Theorem 29.** *Any deterministic algorithm for* Approximate Convex Hull *in* $\mathbb{R}^2$ *that performs* q *adaptive halfplane emptiness queries has error* $\Omega(1/q^2)$.

Better Sampling Bounds for Restricted Delaunay Triangulations and a Star-Shaped Property for Restricted Voronoi Cells

Jonathan Richard Shewchuk
University of California, Berkeley, CA, USA

Abstract

The restricted Delaunay triangulation of a closed surface Σ and a finite point set $V \subset \Sigma$ is a subcomplex of the Delaunay tetrahedralization of V whose triangles approximate Σ. It is well known that if V is a sufficiently dense sample of a smooth Σ, then the union of the restricted Delaunay triangles is homeomorphic to Σ. We show that an ϵ-sample with $\epsilon \leq 0.3245$ suffices. By comparison, Dey proves it for a 0.18-sample; our improved sampling bound reduces the number of sample points required by a factor of 3.25. More importantly, we improve a related sampling bound of Cheng et al. for Delaunay surface meshing, reducing the number of sample points required by a factor of 21. The first step of our homeomorphism proof is particularly interesting: we show that for a 0.44-sample, the restricted Voronoi cell of each site $v \in V$ is homeomorphic to a disk, and the orthogonal projection of the cell onto $T_v\Sigma$ (the plane tangent to Σ at v) is star-shaped.

1 Introduction

The *restricted Delaunay triangulation* (RDT) is a well-established way of generating good-quality triangulations on curved surfaces [23]. Researchers have developed a theory of surface sampling to determine how we should sample points on a surface to guarantee that an RDT (or a related triangulation) is a topologically correct and geometrically accurate approximation of the surface [1, 2, 3, 6, 10, 12, 13, 14, 15, 17, 16, 18, 20, 23, 24, 26, 31, 34, 35]. RDTs and this surface sampling theory have equipped geometers to rigorously prove the correctness of algorithms for surface reconstruction [20] and surface mesh generation [18].

Think of the RDT as a function that takes in two inputs: a smooth, closed (compact with no boundary) surface $\Sigma \subset \mathbb{R}^3$ and a finite set $V \subset \Sigma$ of points, called *sites* (or *vertices* of the RDT). The set V is a *sample* or a *point cloud*. The output is a simplicial complex $\mathcal{T}$ whose vertices are V. The RDT $\mathcal{T}$ is a subcomplex of the three-dimensional Delaunay triangulation $\operatorname{Del} V$, but in typical usage $\mathcal{T}$ contains no tetrahedra; only triangles, edges, and the vertices V.

If V is sufficiently dense, $\mathcal{T}$ is a (topological) *triangulation* of Σ, which means that the *underlying space* of $\mathcal{T}$, written $|\mathcal{T}| = \bigcup_{\tau \in \mathcal{T}} \tau$, is homeomorphic to Σ. This paper proves that a modest sampling requirement suffices to guarantee that homeomorphism.

What does it mean for V to be "sufficiently dense"? Intuitively, there should be no large unsampled bare spots on Σ. Ideally, sampling requirements are adaptive, as a denser spacing of sites is needed in regions where Σ has higher curvature or closely-spaced "parts" like fingers on a hand, but simple regions need few sites. Many provably good algorithms for surface reconstruction assume that V is a so-called ϵ-sample of Σ (defined in Section 2), an adaptive sample in which a smaller ϵ implies more sites, closer together.

One main result of this paper is that if V is a 0.3245-sample of Σ, the underlying space of the RDT is homeomorphic to Σ. Dey [20] proved the same for a 0.18-sample. The new result reduces the number of sample points required by a factor of 3.25 (the square of 0.3245/0.18). Some well-known surface reconstruction algorithms such as the Crust [1] and Cocone [3] algorithms rely on identifying a superset of the RDT's triangles then paring them down. Any substantial relaxation of their sampling requirements is good news for a broad swath of existing algorithms, and it helps to explain why they work well in practice.

As a point of comparison, Bjerkevik [5] shows that no proof will ever guarantee homeomorphism for 0.72-samples, as there exist 0.72-samples with multiple, topologically different, correct reconstructions. (This limitation holds also for smooth, closed curves in the plane.)

We define another adaptive sampling condition better suited to mesh generation, enabling stronger sampling bounds: we prove homeomorphism for what we call a 0.4132-*Voronoi sample*. Cheng et al. [18] proved the same for a 0.09-Voronoi sample; our result reduces the number of sample points required by a factor of 21. Our bound implies better sampling bounds for existing surface meshing algorithms; it is this paper's most important result.

Also of interest are the new techniques introduced here to obtain these bounds. In particular, for a 0.44-sample or a 0.78-Voronoi sample, the restricted Voronoi cell of each site $v \in V$ (defined in Section 2) is homeomorphic to a disk. Moreover, let $T_v\Sigma$ denote the plane tangent to Σ at v; the orthogonal projection of v's cell onto $T_v\Sigma$ is *star-shaped*: a union of (infinitely many) line segments terminating at v. It seems a bit surprising that restricted Voronoi cells are better behaved with respect to coarse samples than restricted Voronoi vertices or edges, because the proofs by Dey [20] and Cheng et al. [18] use the soundness of the restricted Voronoi edges to establish the soundness of the restricted Voronoi cells. This paper reverses that sequence and, in my opinion, gets at the heart of the reasons why a restricted Voronoi cell is nicely shaped. Remarkably, the results about the Voronoi cells generalize to manifolds of higher dimension embedded in higher-dimensional spaces with no degradation in the bounds [32], although the homeomorphism result does not and cannot generalize to higher dimensions [16, 11, 9].

Not everyone gets excited by improved constants, but I advocate for the importance of tighter sampling theory for computational geometry – just as numerical analysts have devoted much effort to improving constants associated with quadrature rules, interpolation theory, and more. Strong bounds show that RDTs are useful, not merely theoretical.

2 Restricted Delaunay triangulations and ϵ-samples

The RDT is defined by dualizing a *restricted Voronoi diagram*, which will be our main object of study. Let $|pq|$ denote the Euclidean distance from p to q; equivalently, the length of the line segment pq. Given a closed surface $\Sigma \subset \mathbb{R}^3$ and a sample $V \subset \Sigma$, the *restricted Voronoi cell* of a site $v \in V$ is $\mathrm{Vor}|_\Sigma v = \{p \in \Sigma : |pv| \leq |pw| \text{ for all } w \in V\}$. Equivalently, $\mathrm{Vor}|_\Sigma v = \Sigma \cap \mathrm{Vor}\, v$, where $\mathrm{Vor}\, v$ is v's standard Voronoi cell in $\mathbb{R}^3$. The name "restricted Voronoi cell" means that $\mathrm{Vor}|_\Sigma v$ is the restriction of $\mathrm{Vor}\, v$ to the surface Σ. See Figure 1.

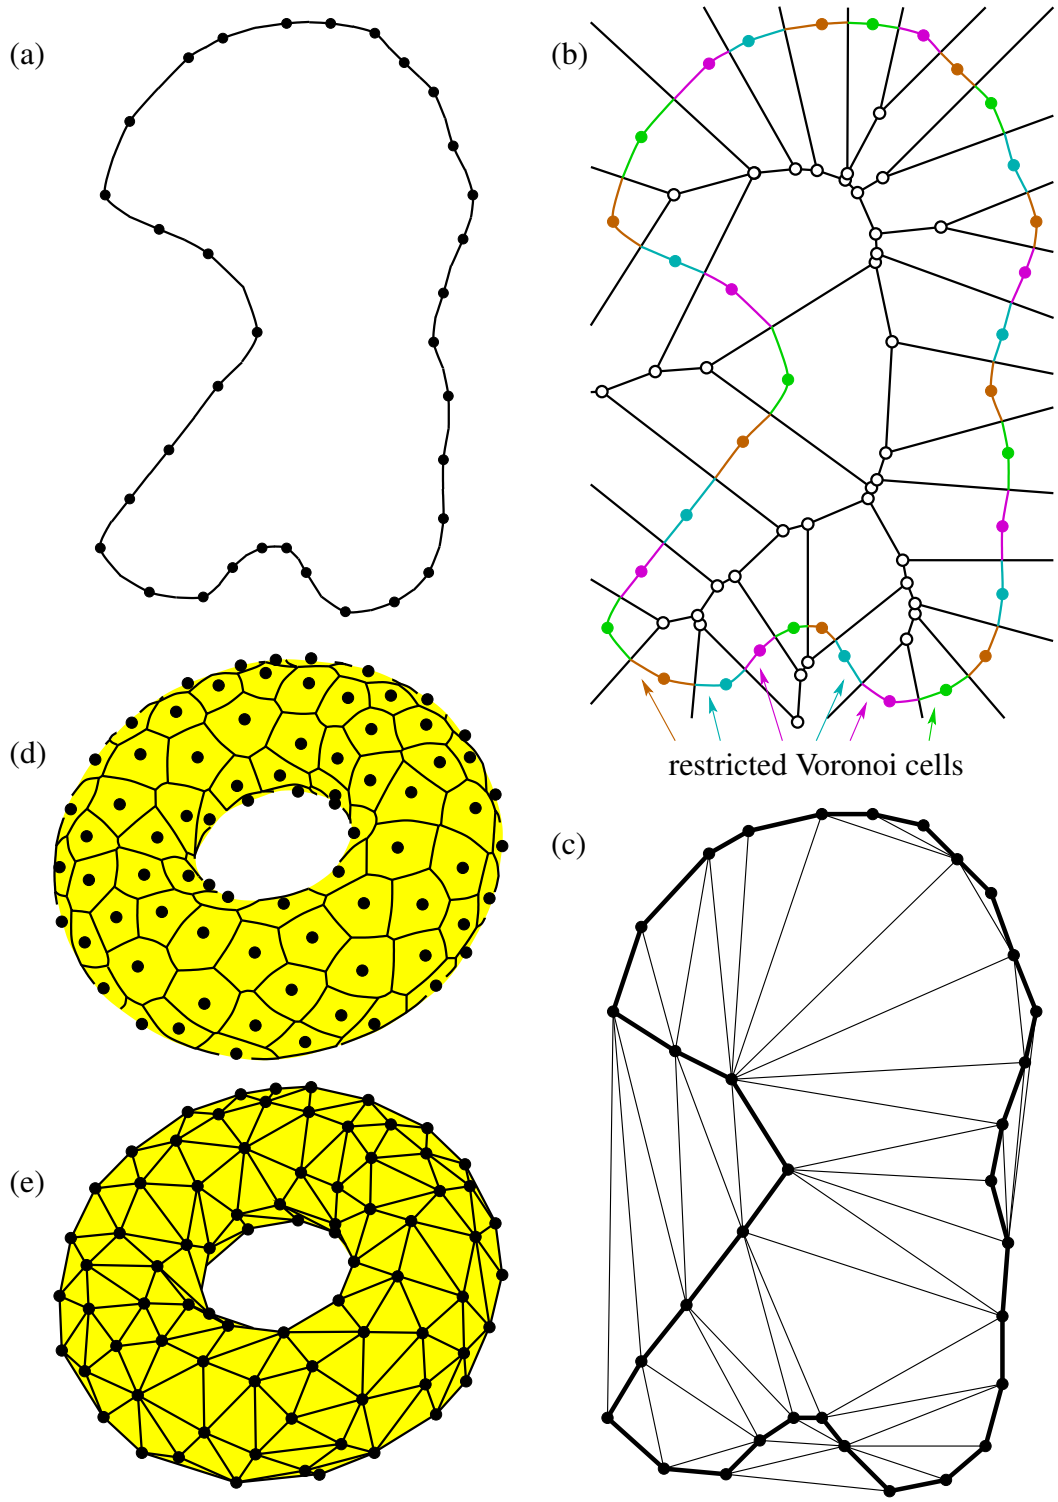

Figure 1 (a) A two-dimensional view of restricted Delaunay triangulations. The input is a smooth, closed curve Σ and a sample $V \subset \Sigma$. (b) The restricted Voronoi diagram is the restriction of the (classic) Voronoi diagram to Σ. (c) The restricted Delaunay triangulation (bold) is the dual of the restricted Voronoi diagram and a subcomplex of the (classic) Delaunay triangulation. (d) A restricted Voronoi diagram in three dimensions. (e) Its dual restricted Delaunay triangulation.

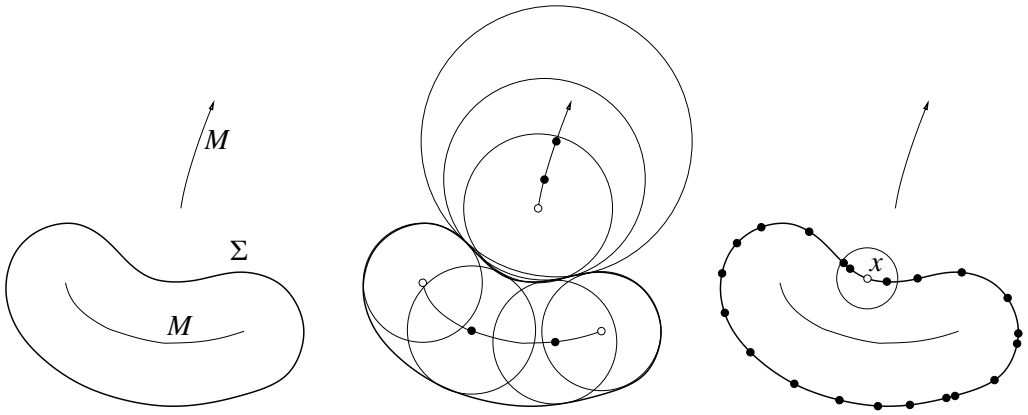

Figure 2 Left: A curve Σ and its medial axis M. Center: Some of the medial balls that define M. Balls with black centers touch two points on Σ. The white points are in the closure of the black centers. Right: A 0.5-sample of Σ (black points). The ball with center x and radius $0.5\,\mathrm{lfs}(x)$ contains a site.

A *restricted Voronoi face* is any nonempty intersection of one or more restricted Voronoi cells – i.e., $\Sigma \cap F$ for some face F in $\mathrm{Vor}\,V$. In particular, a *restricted Voronoi vertex* is the nonempty intersection of Σ with an edge in $\mathrm{Vor}\,V$; and a *restricted Voronoi edge* is the nonempty intersection of Σ with a polygonal 2-face in $\mathrm{Vor}\,V$. Typically these entities are a single point and a (curvy) path on Σ, respectively, but if V is not dense enough, they may take on more pathological forms – e.g., a restricted Voronoi "edge" could be a cycle, a pair of disjoint paths, or even a 2-dimensional blob. This paper aims to determine sampling conditions that eliminate such pathologies. The *restricted Voronoi diagram* $\mathrm{Vor}|_\Sigma V$ is the cell complex containing all the restricted Voronoi faces (including the restricted Voronoi cells).

The *Delaunay subdivision* $\mathrm{Del}\,V$ is the polyhedral complex dual to the Voronoi diagram, and the *restricted Delaunay subdivision* $\mathrm{Del}|_\Sigma V$ is the subcomplex of $\mathrm{Del}\,V$ dual to the restricted Voronoi diagram. That is, for each Voronoi face $F \in \mathrm{Vor}\,V$, let $W \subseteq V$ be the set of sites whose Voronoi cells include F and let F^* be the convex hull of W; we say that F^* is the face *dual* to F. Then $\mathrm{Del}\,V = \{F^* : F \in \mathrm{Vor}\,V\}$. The restricted Delaunay subdivision contains the dual faces whose primal faces intersect Σ; that is, $\mathrm{Del}|_\Sigma V = \{F^* \in \mathrm{Del}\,V : F \cap \Sigma \neq \emptyset\}$. The restricted Voronoi face $f = F \cap \Sigma$ has the same dual face as F, $f^* = F^*$. It is customary to subdivide the polyhedra in $\mathrm{Del}\,V$ into tetrahedra (in which case the duality is no longer strict); accordingly, we can subdivide the polygons in $\mathrm{Del}|_\Sigma V$ into triangles and call it a *restricted Delaunay triangulation*. This paper's results apply whether we do or don't.

A crucial observation in the theory of surface sampling is that the sampling density necessary for accurate approximation is proportional to a field called the *local feature size*. The *medial axis* M of Σ, illustrated in Figure 2, is the closure of the set of all points in $\mathbb{R}^3$ for which the closest point on Σ is not unique. A *medial ball* is a ball whose center lies on M and whose boundary intersects Σ (tangentially), but the interior of the ball does not. For any point $x \in \Sigma$, there are one or two medial balls that have x on their boundaries, called *medial balls at* x. One is inside Σ. If there are two, the other is outside. If not, there is an open halfspace tangent to Σ at x, disjoint from Σ, that we call a degenerate "medial ball."

The *local feature size* function is $\mathrm{lfs} : \Sigma \to \mathbb{R}$, $x \mapsto d(x, M)$ where $d(x, M) = \min_{m \in M} |xm|$. We require that Σ is smooth in the sense that $\inf_{x \in \Sigma} \mathrm{lfs}(x) > 0$. ($C^{1,1}$-continuity suffices.)

A finite point set $V \subset \Sigma$ is an *ϵ-sample of* Σ if for every point $x \in \Sigma$, there is a site $v \in V$ such that $|xv| \leq \epsilon\,\mathrm{lfs}(x)$. That is, the ball with center x and radius $\epsilon\,\mathrm{lfs}(x)$ contains at least one site. A finite $V \subset \Sigma$ is an *ϵ-Voronoi sample of* Σ if $V \neq \emptyset$ and for every site

$v \in V$ and every point $x \in \mathrm{Vor}|_\Sigma v$, $|xv| \leq \epsilon\,\mathrm{lfs}(v)$. That is, $\mathrm{Vor}|_\Sigma v$ is a subset of the ball with center v and radius $\epsilon\,\mathrm{lfs}(v)$. (Note that this condition implies the *ϵ-small condition* of Cheng et al. [18], though the converse is not true.) Only ϵ-samples are a well-known concept, but ϵ-Voronoi samples are nice because $\mathrm{lfs}(v)$ tends to give better sampling bounds than $\mathrm{lfs}(x)$.

Like the classical proofs [1, 18, 20], this paper's homeomorphism proofs rely on the Topological Ball Theorem of Edelsbrunner and Shah [23]. Given a sample $V \subset \Sigma$ of a closed surface $\Sigma \subset \mathbb{R}^3$, this theorem states that $|\mathrm{Del}|_\Sigma V|$ is homeomorphic to Σ if Σ and V satisfy two properties. The *closed ball property* is that for each Voronoi face $F \in \mathrm{Vor}\,V$, $f = F \cap \Sigma$ is either empty or a topological closed $(k-1)$-ball where k is the dimension of F. That is,

A. for a Voronoi 3-cell F, f is a topological closed disk;
B. for a Voronoi 2-face F, f is a topological closed interval or $\emptyset$;
C. for a Voronoi edge F, f contains at most one point; and
D. for a Voronoi vertex F, $f = \emptyset$.

If A–D hold, the *generic intersection property* is that for each $F \in \mathrm{Vor}\,V$, $\mathrm{int}\ f \subset \mathrm{int}\ F$ and $\mathrm{bd}\ f \subset \mathrm{bd}\ F$. In this definition, "interior" and "boundary" are interpreted by the rules of $(k-1)$-manifolds (for f) and k-manifolds (for F). (They are *not* the interior and boundary with respect to $\mathbb{R}^3$.) For a smooth Σ, the generic intersection property holds if properties A–D hold and there is no face $F \in \mathrm{Vor}\,V$ and no point $x \in F \cap \Sigma$ such that $F \subset T_x\Sigma$. That is,

E. there is no point where Σ intersects a 2-face of $\mathrm{Vor}\,V$ tangentially; and
F. there is no point where Σ intersects an edge of $\mathrm{Vor}\,V$ tangentially.

This paper is organized around proving that these conditions hold for a sufficiently dense sample V: properties A and E in Section 4, properties C and F in Section 5, and property B in Section 6. Property D ensures that $\mathrm{Del}|_\Sigma V$ contains no polyhedra – only faces of dimension two or less. Property D cannot be enforced by dense sampling, but it can be enforced by an infinitesimal perturbation of Σ so that Σ intersects no Voronoi vertex. This perturbation is easy to simulate symbolically in software simply by treating each Voronoi vertex on Σ as if it were strictly inside Σ (when deciding which faces of $\mathrm{Del}\,V$ are in $\mathrm{Del}|_\Sigma V$).

Unlike in Dey [20] or Cheng et al. [18], our proof of property A does not rely on property B or C. Property A holds for a 0.4401-sample or a 0.7861-Voronoi sample, whereas we prove property B only for a 0.3245-sample or a 0.4132-Voronoi sample. Property B (restricted Voronoi edges) is the bottleneck that determines our sampling requirements.

Some algorithms for triangulating surfaces guarantee topological correctness without RDTs, by other methods [4, 8, 19, 27, 29]. One alternative is to consider Voronoi diagrams with other distance metrics. Dyer, Zhang, and Möller [21, 22] and others [28, 7] use intrinsic distances within Σ, also known as geodesic distances when Σ is smooth, to define *intrinsic Voronoi diagrams* that dualize to *intrinsic Delaunay triangulations* (IDTs). Advantages are that the Voronoi cells are trivially star-shaped, and the sampling requirements needed to guarantee a homeomorphic triangulation are mild [22]. But intrinsic distances on smooth surfaces are painful to compute [30]. Restricted Delaunay triangulations will probably remain popular as an easy alternative. So let us see how far we can push them.

3 A relationship between surface points and nearby tangent planes

For a smooth, closed surface Σ and a point $x \in \Sigma$, let $T_x\Sigma \subset \mathbb{R}^3$ denote the plane tangent to Σ at x. ($T_x\Sigma$ passes through x; not necessarily through the origin.) Lemma 1, below, establishes a relationship between $T_x\Sigma$ and v for two nearby points $v, x \in \Sigma$. This relationship prepares us to prove in Section 4 that under suitable sampling conditions, a restricted Voronoi cell is a topological disk with a star-shaped projection on its site's tangent plane. Lemma 1 is surprisingly strong; the constant ξ (as it is applied in Theorem 6) will likely be hard to beat.

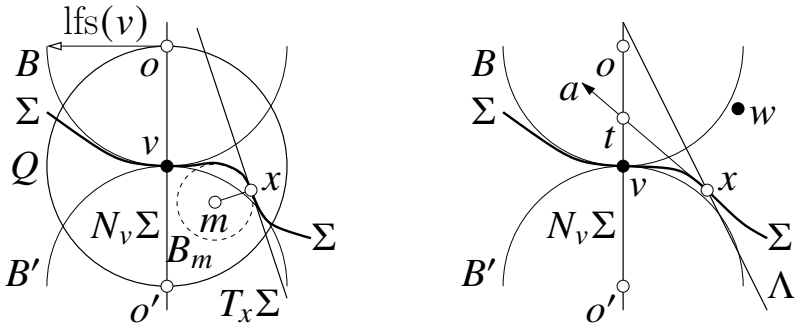

Figure 3 Left: for two nearby points $v, x \in \Sigma$, suppose that the tangent plane $T_x\Sigma$ does not intersect oo', as shown. This leads to a contradiction; hence $T_x\Sigma$ must intersect oo'. The medial ball B_m is tangent to Σ at x. The center m of B_m cannot lie in the open ball Q. The points v, x, o, and o' lie on the plane of the page, but m and w generally do not; imagine m floating above the page. The dashed circle shows the page's cross section of B_m, but B_m is larger. The surface Σ cannot intersect the open balls B, B', and B_m, so B and B_m are disjoint. Right: the plane Λ bisects vw. The ray $a \in T_x\Sigma$ intersects the relative interior of oo' and is strictly on the same side of Λ as v.

Let B and B' be the two open balls of radius $\operatorname{lfs}(v)$ tangent to Σ at v, and let o and o' be their centers. As B and B' are subsets of the open medial balls at v, they are disjoint from Σ.

▶ **Lemma 1.** *Consider two points $v, x \in \Sigma$ such that $|vx| < \xi \operatorname{lfs}(v)$, where $\xi = \sqrt{(\sqrt{5}-1)/2} \doteq 0.786151$. Then o and o' lie on strictly opposite sides of $T_x\Sigma$.*

Proof. Suppose for the sake of contradiction that o and o' do not lie on strictly opposite sides of $T_x\Sigma$, as illustrated in Figure 3, left. Then $T_x\Sigma \neq T_v\Sigma$ and $x \neq v$. Moreover, either $oo' \subset T_x\Sigma$ or $T_x\Sigma$ does not intersect the relative interior of oo'.

Let B_m be the open medial ball tangent to Σ at x that is on the same side of $T_x\Sigma$ as v (either side if $v \in T_x\Sigma$), as illustrated. If B_m is an open halfspace then $T_x\Sigma = \text{boundary } B_m$, $v \in T_x\Sigma$ (as $v \notin B_m$), $T_v\Sigma = T_x\Sigma$ (as $\Sigma \cap B_m = \emptyset$), and the lemma follows. So assume B_m is bounded. Its center m lies on Σ's medial axis. The line segment xm is perpendicular to $T_x\Sigma$.

Observe that v is in the relative interior of oo'. If $oo' \subset T_x\Sigma$, then $\angle vxm = \angle oxm = \angle o'xm = 90°$. Otherwise, $T_x\Sigma$ does not intersect the relative interior of oo', so $\angle vxm < 90°$, $\angle oxm \leq 90°$, and $\angle o'xm \leq 90°$ (the last two because o and o' cannot be on the side of $T_x\Sigma$ opposite from v). By Pythagoras' Theorem, $|ox|^2 + |mx|^2 \geq |om|^2$ and $|vx|^2 + |mx|^2 \geq |vm|^2$. As m lies on the medial axis, $|vm| \geq \operatorname{lfs}(v)$ (by the definition of lfs), so $|vx|^2 + |mx|^2 \geq \operatorname{lfs}(v)^2$.

The surface Σ intersects none of the open balls B, B', or B_m, but it passes between B and B' at v. As Σ is closed and cuts space into two pieces, one containing B and one containing B', the ball B_m must lie in one of those two pieces. Choose the labels B and B' so that B_m lies in the same piece as B', as illustrated; then B_m must be disjoint from B. The radii of B and B_m are $\operatorname{lfs}(v)$ and $|mx|$ respectively, so $|om| \geq \operatorname{lfs}(v) + |mx|$. Combining this with the inequality $|ox|^2 + |mx|^2 \geq |om|^2$ gives $|ox|^2 \geq \operatorname{lfs}(v)^2 + 2\operatorname{lfs}(v)\,|mx|$. Combining this with the inequality $|mx|^2 \geq \operatorname{lfs}(v)^2 - |vx|^2$ gives $|ox|^2 \geq \operatorname{lfs}(v)^2 + 2\operatorname{lfs}(v)\sqrt{\operatorname{lfs}(v)^2 - |vx|^2}$.

Let $N_v\Sigma$ be the line through o', v, and o (the vertical axis in Figure 3). Create a coordinate system with $v = (0,0,0)$ and $x = (x_h, x_v, 0)$ such that x_v is the coordinate in the direction parallel to $N_v\Sigma$ and x_h is the distance from $N_v\Sigma$ to x (the horizontal axis in Figure 3). Then $|ox|^2 + |o'x|^2 = x_h^2 + (x_v - \operatorname{lfs}(v))^2 + x_h^2 + (x_v + \operatorname{lfs}(v))^2 = 2x_h^2 + 2x_v^2 + 2\operatorname{lfs}(v)^2 = 2\,|vx|^2 + 2\operatorname{lfs}(v)^2$. Rewrite this as $|vx|^2 = (|ox|^2 + |o'x|^2 - 2\operatorname{lfs}(v)^2)/2$. As $x \notin B'$, $|o'x|^2 \geq \operatorname{lfs}(v)^2$. Combining these with the inequality $|ox|^2 \geq \operatorname{lfs}(v)^2 + 2\operatorname{lfs}(v)\sqrt{\operatorname{lfs}(v)^2 - |vx|^2}$ gives $|vx|^2 \geq \operatorname{lfs}(v)\sqrt{\operatorname{lfs}(v)^2 - |vx|^2}$.

As $|vx| < \xi \operatorname{lfs}(v)$, we have $\xi^2 > |vx|^2/\operatorname{lfs}(v)^2 \geq \sqrt{1 - |vx|^2/\operatorname{lfs}(v)^2} > \sqrt{1-\xi^2}$, which is equivalent to $\xi^4 + \xi^2 - 1 > 0$, hence $\xi > \sqrt{(\sqrt{5}-1)/2}$. The result follows by contradiction. ◀

4 Restricted Voronoi cells are topological disks

This section investigates sampling conditions that guarantee that (1) every restricted Voronoi cell has the topology of a closed disk (closed ball property A), (2) the projection of each restricted Voronoi cell onto its site's tangent plane is star-shaped, and (3) no 2-face in $\operatorname{Vor} V$ intersects Σ tangentially (generic intersection property E). Theorem 6 shows that a 0.78-Voronoi sample suffices, and Corollary 9 shows that a 0.44-sample suffices.

Consider a site $v \in V$, its Voronoi cell $\operatorname{Vor} v$, and its restricted Voronoi cell $\operatorname{Vor}|_\Sigma v = \Sigma \cap \operatorname{Vor} v$. Let φ be the map that orthogonally projects $\mathbb{R}^3$ onto $T_v\Sigma$. Note that $\varphi(v) = v$.

Define a *radial path* to be a topological closed interval $\gamma \subset \operatorname{Vor}|_\Sigma v$ such that

1. one endpoint of γ is the site v,
2. the other endpoint – call it z – lies on the boundary of $\operatorname{Vor} v$,
3. every point on $\gamma \setminus \{z\}$ lies in the interior of $\operatorname{Vor} v$, and
4. $\varphi|_\gamma$ is a homeomorphism from γ to a line segment on $T_v\Sigma$ with endpoints v and $\varphi(z)$, where $\varphi|_\gamma$ denotes the restriction of φ to the domain γ.

We will see that under suitable sampling conditions, every point in $\operatorname{Vor}|_\Sigma v$ lies on exactly one radial path, except v itself (Lemma 4). It follows that we can decompose $\operatorname{Vor}|_\Sigma v$ into radial paths such that no two share a point besides v (Lemma 5). That is, if we remove v from each radial path, then we have a partition of $\operatorname{Vor}|_\Sigma v \setminus \{v\}$ into paths. Therefore, $\varphi(\operatorname{Vor}|_\Sigma v)$ is star-shaped. Although $\operatorname{Vor}|_\Sigma v$ itself is not star-shaped, its decomposition into radial paths is a curvy variant of "star-shaped." As the lengths of the projected radial paths vary continuously with their polar angles, $\operatorname{Vor}|_\Sigma v$ is homeomorphic to a closed disk (Theorem 6).

Let $N_v\Sigma$ be the line normal to Σ at v (orthogonal to $T_v\Sigma$). Let B and B' be the two open balls of radius $\operatorname{lfs}(v)$ tangent to Σ at v, and let o and o' be their centers. Then $o, o' \in N_v\Sigma$.

The following lemma implies that if you are standing on the boundary of $\operatorname{Vor}|_\Sigma v$ and you walk toward v on a radial path, you immediately enter the interior of $\operatorname{Vor} v$. (The proof of Lemma 4 develops this idea further.) It also implies generic intersection property E.

▶ **Lemma 2.** *Consider two distinct sites $v, w \in V$ and a point $x \in \operatorname{Vor}|_\Sigma v \cap \operatorname{Vor}|_\Sigma w$. Suppose that $|vx| < \xi \operatorname{lfs}(v)$ where $\xi = \sqrt{(\sqrt{5}-1)/2} \doteq 0.786151$. Let Λ be the plane that orthogonally bisects the line segment vw (thus $x \in \Lambda$). By Lemma 1, $T_x\Sigma$ intersects the relative interior of the line segment oo' at a lone point t. Let a be the open ray $\vec{xt}$, and observe that $a \subset T_x\Sigma$.*

Then v and a are strictly on the same side of Λ.

Proof. See Figure 3, right. Neither B nor B' intersects Σ, hence neither ball contains w, hence $|vo| \le |wo|$ and $|vo'| \le |wo'|$. Therefore, each of o and o' lies either on Λ or on the same side of Λ as v, as illustrated. (More broadly, $oo' \subset \operatorname{Vor} v$.) As $v \in oo'$ and $v \notin \Lambda$, Λ does not intersect the relative interior of oo'. By contrast, a does intersect the relative interior of oo' (at t). Recall that a's origin x lies on Λ. Therefore, the open ray a is strictly on the same side of Λ as the relative interior of oo', which contains v. ◀

Lemma 4, below, shows that under suitable sampling conditions, every point in $\operatorname{Vor}|_\Sigma v \setminus \{v\}$ lies on one and only one radial path. It depends on the simple observation of Lemma 3.

▶ **Lemma 3.** *Let $v, x \in \Sigma$ be two points such that $|vx| < \xi \operatorname{lfs}(v)$. There exists an open neighborhood $N \subset \Sigma$ of x such that $\varphi|_N$ is a homeomorphism from N to its image $\varphi(N) \subset T_v\Sigma$.*

Proof. As $|vx| < \xi \operatorname{lfs}(v)$, by Lemma 1 (or Lemma 13), $T_x\Sigma$ is not perpendicular to $T_v\Sigma$. It follows from the smoothness of Σ that if N is sufficiently small, $\varphi|_N$ is injective. As $\varphi|_N$ is injective and both $\varphi|_N$ and its inverse are continuous, $\varphi|_N$ is a homeomorphism. ◀

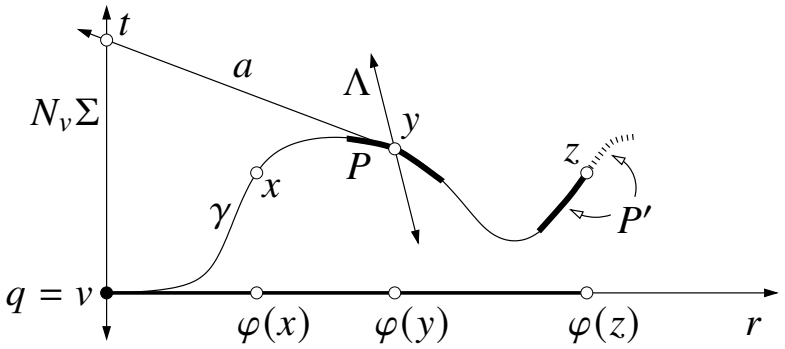

Figure 4 A radial path γ with endpoints v and z. (The path P' extends past γ on Σ.)

▶ **Lemma 4.** *Consider a site $v \in V$, its restricted Voronoi cell $C = \mathrm{Vor}|_\Sigma v$, and a point $x \in C \setminus \{v\}$. Let $r \in T_v\Sigma$ be the closed ray with origin v that passes through $\varphi(x)$. Suppose that for every point $y \in C$, $|vy| < \xi\,\mathrm{lfs}(v)$, where $\xi = \sqrt{(\sqrt{5}-1)/2} \doteq 0.786151$.*

Then there is a unique radial path $\gamma \subset C$ such that $x \in \gamma$. Furthermore, γ is the only radial path such that $\varphi(\gamma) \subseteq r$.

Proof. For every point $y \in C \setminus \{v\}$ (including x), $\varphi(y) \neq v$, as if $\varphi(y) = v$ we have a contradiction: $|vy| < \xi\,\mathrm{lfs}(v)$ and $y \neq v$ imply that y is in B or B' and thus not in C.

Define the point set $\varphi|_C^{-1}(r) = \{y \in C : \varphi(y) \in r\}$ (the intersection of C with the closed halfplane with boundary $N_v\Sigma$, passing through x). Clearly, $x \in \varphi|_C^{-1}(r)$. Let γ be the connected component of $\varphi|_C^{-1}(r)$ that contains x. We will show that γ is a radial path.

As $\gamma \subset C$, for every point $y \in \gamma$, $|vy| < \xi\,\mathrm{lfs}(v)$ and by Lemma 3 there exists an open neighborhood $N \subset \Sigma$ of y such that $\varphi|_N$ is a homeomorphism, so $\varphi|_{N\cap\gamma}$ is a homeomorphism from $N \cap \gamma$ to its image $\varphi(N \cap \gamma)$. In other words, $\varphi|_\gamma$ is a local homeomorphism from γ to its image $\varphi(\gamma)$. As γ is connected and $\varphi(\gamma)$ is embedded in the ray r, $\varphi|_\gamma$ is a (global) homeomorphism. (Intuitively, the map φ cannot cause the path to double back on itself, so $\varphi|_\gamma$ is an injection.) Therefore, γ is a topological interval or a lone point.

As C is compact and r is closed, $\varphi|_C^{-1}(r)$ is compact and γ is compact. Let q and z be the endpoints of γ, chosen so that $|v\varphi(q)| \leq |v\varphi(z)|$; see Figure 4. As $\varphi|_\gamma$ is a homeomorphism, $\varphi(q)$ and $\varphi(z)$ are the endpoints of $\varphi(\gamma)$. As $\varphi(\gamma)$ contains $\varphi(x)$ and $\varphi(x) \neq v$, $\varphi(z) \neq v$ and $z \neq v$. We will show that $q = v$ (which implies that $\varphi(C)$ is star-shaped) and that z is on the boundary of $\mathrm{Vor}\,v$, thereby establishing the first two criteria for γ to be a radial path.

But first, we show that $\gamma \setminus \{z\}$ is in the interior of $\mathrm{Vor}\,v$, the third criterion for γ to be a radial path. Suppose for the sake of contradiction that a point $y \in \gamma \setminus \{z\}$ lies on the boundary of $\mathrm{Vor}\,v$. Then y also lies in the restricted Voronoi cell $\mathrm{Vor}|_\Sigma w$ of another site $w \in V \setminus \{v\}$, and $y \in \Lambda$ where Λ is the plane that orthogonally bisects vw. Clearly, $y \neq v$. By Lemma 1, $T_y\Sigma$ intersects $N_v\Sigma$ at a lone point t. Let a be the open ray $\vec{yt}$. Observe that $a \subset T_y\Sigma$; moreover, a is tangent to γ at y, as illustrated in Figure 4.

By Lemma 2, v and a are strictly on the same side of Λ. Hence if you walk along γ from y to z – opposite to the direction of a – you enter w's side of Λ at the instant you leave y, as illustrated. This contradicts the fact that $\gamma \in \mathrm{Vor}|_\Sigma v$. So $\gamma \setminus \{z\}$ is in the interior of $\mathrm{Vor}\,v$.

Let us return to the first two criteria for γ to be a radial path. Consider a point $y \in \gamma \setminus \{v\}$. By Lemma 3, there exists an open neighborhood $N \subset \Sigma$ of y such that $\varphi|_N$ is a homeomorphism. Define $\varphi|_N^{-1}(r) = \{p \in N : \varphi(p) \in r\}$ and let P be the connected component of $\varphi|_N^{-1}(r)$ that contains y, illustrated in Figure 4. As $\varphi(y)$ is in the interiors of r and $\varphi(N)$, $\varphi(y)$ is in the interior of $r \cap \varphi(N)$. As $\varphi|_N$ is a homeomorphism, y is in the relative interior of $\varphi|_N^{-1}(r)$, so P is a path (topological interval) on Σ with y in its relative interior.

First, consider the case where y is in the interior of $\operatorname{Vor} v$ (but $y \neq v$). Then we can shrink the open neighborhood N of y so that $N \subset \operatorname{Vor} v$ and thus $N \subset C$, and thereby have $\varphi|_N^{-1}(r) \subseteq \varphi|_C^{-1}(r)$. As γ is the connected component of $\varphi|_C^{-1}(r)$ that contains y, $P \subseteq \gamma$. Hence y is not an endpoint of γ. We have seen that $\gamma \setminus \{z\}$ is in the interior of $\operatorname{Vor} v$; it follows that only v and z can be endpoints of γ. That is, the endpoint q is either v or z. Moreover, as $z \neq v$ is an endpoint of γ, z is on the boundary of $\operatorname{Vor} v$ (establishing the second criterion).

Second, consider the case where $y = z$. In this case, the path P looks like P' in Figure 4. We use this case to show that $q \neq z$. Suppose for the sake of contradiction that $q = z$; then $\gamma = \{z\}$. It follows that as you walk along P from z, you exit the restricted Voronoi cell C in both directions along P. Let a be the open ray $\vec{zt}$ where $\{t\} = T_z\Sigma \cap N_v\Sigma$ (hence $a \subset T_z\Sigma$); a is tangent to P at z. As P exits C, there exists a site $w \in V \setminus \{v\}$ and a plane Λ that orthogonally bisects vw such that $z \in \Lambda$ and a enters w's side of Λ at z. But this contradicts the fact that, by Lemma 2, v and a are strictly on the same side of Λ. Thus $q \neq z$, so $q = v$.

Therefore, the endpoints of γ are v and z, z is on the boundary of $\operatorname{Vor} v$, $\gamma \setminus \{z\}$ is in its interior, and $\varphi|_\gamma$ is a homeomorphism from γ to $v\varphi(z)$. By definition, γ is a radial path.

To see that γ is the *only* radial path containing x, observe that every radial path containing x is a subset of $\varphi|_C^{-1}(r)$, and moreover is a subset of γ (because a radial path is connected). No strict subset of γ can be a radial path, because every connected strict subset of γ is missing either v or a point on the boundary of $\operatorname{Vor} v$.

The reasoning of this proof holds equally well if we replace x with any other point $x' \in \varphi|_C^{-1}(r) \setminus \{v\}$, so every connected component of $\varphi|_C^{-1}(r)$ contains v. Therefore, $\varphi|_C^{-1}(r)$ is connected. Hence $\gamma = \varphi|_C^{-1}(r)$ and no radial path besides γ has its projection on r. ◀

It follows that we can decompose $\operatorname{Vor}|_\Sigma v$ into radial paths. Hence $\varphi(\operatorname{Vor}|_\Sigma v)$ is star-shaped. It also follows that the orthogonal projection φ, restricted to $\operatorname{Vor}|_\Sigma v$, is a homeomorphism.

▶ **Lemma 5.** *Let $v \in V$ be a site and let $C = \operatorname{Vor}|_\Sigma v$ be its restricted Voronoi cell. Suppose that for every point $y \in C$, $|vy| < \xi \operatorname{lfs}(v)$, where $\xi = \sqrt{(\sqrt{5}-1)/2} \doteq 0.786151$.*

Let Γ be the set of all radial paths for all points in $C \setminus \{v\}$.

Then $\bigcup_{\gamma\in\Gamma} \gamma = C$; hence $\varphi(C)$ is star-shaped. Moreover, no two paths in Γ share a common point besides v, and there is a one-to-one correspondence between paths in Γ and points where Σ intersects the boundary of $\operatorname{Vor} v$.

Moreover, $\varphi|_C$ is a homeomorphism from C to its image $\varphi(C)$ on $T_v\Sigma$.

Proof. By Lemma 4, for each point $x \in C \setminus \{v\}$, there is a unique radial path $\gamma \subset C$ such that $x \in \gamma$. Every radial path contains v. Hence $\bigcup_{\gamma\in\Gamma} \gamma = C$. As each $x \in C \setminus \{v\}$ lies on only one radial path, no two paths in Γ share a common point besides v. By definition, each radial path contains exactly one point on the boundary of $\operatorname{Vor} v$. Hence there is a one-to-one correspondence between radial paths and points where Σ intersects the boundary of $\operatorname{Vor} v$.

Let us see that $\varphi|_C$ is an injection. Consider two points $x, y \in C$ such that $\varphi(x) = \varphi(y)$; we will see that $x = y$. For every radial path $\gamma \in \Gamma$, $\varphi|_\gamma$ is a homeomorphism by the definition of radial path, so if x and y lie on the same radial path, then $x = y$. If x and y lie on distinct radial paths, then $x = y = v$, because by Lemma 4, for any two distinct radial paths $\gamma_1, \gamma_2 \in \Gamma$, $\varphi(\gamma_1)$ and $\varphi(\gamma_2)$ lie on two distinct rays with origin v.

As C is compact and $\varphi|_C$ is injective and continuous, $\varphi|_C$ is a homeomorphism [33]. ◀

Lemma 5 shows that $\operatorname{Vor}|_\Sigma v$ is homeomorphic to its image $I_v = \varphi(\operatorname{Vor}|_\Sigma v)$ on $T_v\Sigma$, but what is the shape of I_v? We obtain a homeomorphism from I_v to a closed unit disk on $T_v\Sigma$ by simply scaling each line segment $\varphi(\gamma)$ to have unit length. Thus we arrive at this section's main theorem, Theorem 6, which states that $\operatorname{Vor}|_\Sigma v$ is a topological closed disk. The proof is deferred to the full-length paper [32], but here is a sketch of the ideas.

Let $E = \{\varphi(\gamma) : \gamma \in \Gamma\}$ be the set of the orthogonal projections of the radial paths onto $T_v\Sigma$. Then we can write $I_v = \bigcup_{e\in E} e$, a decomposition of I_v into line segments with endpoint v, no two leaving v in the same direction (but every direction on $T_v\Sigma$ is represented).

For every point $x \in I_v \setminus \{v\}$, let $l(x)$ be the length of the unique line segment in E that contains x. Thus l is a function over the domain $I_v \setminus \{v\}$, but $l(v)$ is not defined. One can show that l is continuous [32]. This is a consequence of two facts: I_v is a compact point set and every point on a line segment $e \in E$ except one endpoint is in the interior of I_v.

Let $\chi : I_v \to T_v\Sigma$ map each line segment in E to a line segment with unit length (while preserving its direction) – specifically, $\chi(x) = v + \frac{1}{l(x)}(x - v)$ for $x \neq v$ and $\chi(v) = v$. Then χ is continuous as l is continuous and positive. As χ is a bijective, continuous map with a continuous inverse, χ is a homeomorphism from I_v to a closed unit disk.

▶ **Theorem 6.** *Let $v \in V$ be a site and let $C = \mathrm{Vor}|_\Sigma v$ be its restricted Voronoi cell. Suppose that for every point $y \in \mathrm{Vor}|_\Sigma v$, $|vy| < \xi \operatorname{lfs}(v)$, where $\xi = \sqrt{(\sqrt{5}-1)/2} \doteq 0.786151$.*

Then $\chi \circ \varphi|_C$ is a homeomorphism from $\mathrm{Vor}|_\Sigma v$ to a closed unit disk on $T_v\Sigma$.

If we impose the condition of Theorem 6 on *all* the restricted Voronoi cells, every connected component of Σ has at least six sites on it. Lemma 7 follows easily from Lemmas 4 and 13, but there isn't quite enough space here for the proof; see the full-length paper [32].

▶ **Lemma 7.** *Let V be an ϵ-Voronoi sample of Σ for some $\epsilon < \xi = \sqrt{(\sqrt{5}-1)/2} \doteq 0.786151$. Every connected component of Σ has at least six sites and six restricted Voronoi cells on it.*

To apply Theorem 6 to ϵ-samples, observe that 0.44-samples are 0.786-Voronoi samples.

▶ **Lemma 8** (Feature Translation Lemma [3, 20])**.** *Let $\Sigma \subset \mathbb{R}^3$ be a smooth, closed surface and let $p, q \in \Sigma$ be points such that $|pq| \leq \epsilon \operatorname{lfs}(p)$ for some $\epsilon < 1$. Then*

$$\operatorname{lfs}(p) \leq \frac{1}{1-\epsilon}\operatorname{lfs}(q) \quad \text{and} \quad |pq| \leq \frac{\epsilon}{1-\epsilon}\operatorname{lfs}(q).$$

▶ **Corollary 9.** *Let V be an ϵ-sample of Σ for $\epsilon < \frac{\xi}{\xi+1} \doteq 0.440137$.*

Then every restricted Voronoi cell in $\mathrm{Vor}|_\Sigma V$ is homeomorphic to a closed disk (closed disk property A), Σ does not intersect any 2-face of $\mathrm{Vor}\, V$ tangentially (generic intersection property E), every connected component of Σ has at least six sites and six restricted Voronoi cells on it, and no restricted Voronoi cell intersects the interior of another.

Proof. Consider any site $v \in V$ and any point $x \in \mathrm{Vor}|_\Sigma v$. As V is an ϵ-sample, $|vx| \leq \epsilon \operatorname{lfs}(x)$. By the Feature Translation Lemma (Lemma 8), $|vx| \leq \frac{\epsilon}{1-\epsilon} \operatorname{lfs}(v) < \xi \operatorname{lfs}(v)$.

The first three claims follow from Theorem 6 and Lemmas 2 and 7, respectively. The final claim follows from Lemma 5 because every point in the interior of $\mathrm{Vor}|_\Sigma v$ is in the interior of $\mathrm{Vor}\, v$ (by the definition of radial path) and cannot be shared with another cell. ◀

5 Restricted Voronoi vertices are lone points

A restricted Voronoi vertex is a nonempty intersection of Σ with an edge in $\mathrm{Vor}\, V$. However, without suitable sampling conditions, such an intersection might contain many points, even infinitely many. This section describes sampling conditions that guarantee closed ball property C: an intersection of three distinct restricted Voronoi cells contains at most one point, thereby justifying the name "vertex." Generic intersection property F comes as a byproduct. Lemma 10 shows that a 0.49-Voronoi sample suffices, and Corollary 11 shows

that a 0.33-sample suffices (which follows from Lemmas 10 and 8). Both proofs are postponed to the full-length paper [32], as restricted Voronoi vertices are not the bottleneck limiting our homeomorphism theorems' sample bounds. (Restricted Voronoi edges are the bottleneck; see Section 6.) Note that Cheng et al. [18] prove Lemma 10 for a 0.15-Voronoi sample.

▶ **Lemma 10.** *Consider three distinct sites $v, v', v'' \in V$ and the triangle $\tau = \triangle vv'v''$, where v is the vertex at τ's largest plane angle. Let $f = \mathrm{Vor}|_\Sigma v \cap \mathrm{Vor}|_\Sigma v' \cap \mathrm{Vor}|_\Sigma v''$, the restricted Voronoi face dual to τ. Let $\ell_\tau \subset \mathbb{R}^3$ be the line containing all points equidistant to the sites v, v', and v'' (thus $f \subset \ell_\tau$). Suppose that for every point $y \in f$, $|vy| < \kappa\,\mathrm{lfs}(v)$, where κ is the positive real root of $\kappa^4 = 4(1-\kappa^2)(1-\sqrt{3}\kappa)^2$, with approximate value $\kappa \doteq 0.495683$.*

Then f contains at most one point (i.e., a restricted Voronoi vertex). Moreover, if f contains a point, Σ is not tangent to ℓ_τ at that point.

▶ **Corollary 11.** *Let V be an ϵ-sample of Σ for $\epsilon < \frac{\kappa}{\kappa+1} \doteq 0.331409$. Consider three distinct sites $v, v', v'' \in V$ and let $f = \mathrm{Vor}|_\Sigma v \cap \mathrm{Vor}|_\Sigma v' \cap \mathrm{Vor}|_\Sigma v''$. Let $\ell_\tau \subset \mathbb{R}^3$ be the line containing all points equidistant to the sites v, v', and v''.*

Then f contains at most one point, and Σ is not tangent to ℓ_τ at that point.

6 Restricted Voronoi edges are topological intervals

Theorem 6 and Corollary 9 give conditions under which restricted Voronoi cells are topological closed disks. Lemma 10 and Corollary 11 give conditions under which the intersection of three distinct restricted Voronoi cells is at most one point. What about an intersection of two distinct restricted Voronoi cells? That could be empty, a restricted Voronoi vertex, or a *restricted Voronoi edge*, the last being a nonempty intersection of Σ with a 2-face of $\mathrm{Vor}\,V$. Under suitable sampling conditions, Lemma 17, below, guarantees closed ball property B: each restricted Voronoi edge is a topological interval.

The next six lemmas derive conditions in which an intersection $\mathrm{Vor}|_\Sigma v \cap \mathrm{Vor}|_\Sigma w$ is one interval or one isolated point. Lemma 15 applies to 0.32-samples, whereas Lemma 16 applies to 0.41-Voronoi samples, and Lemma 17 concludes both. Lemma 12 has no sampling requirements, only topological requirements; see the full-length paper for a proof [32].

▶ **Lemma 12.** *Let $\mathrm{Vor}|_\Sigma V$ be a restricted Voronoi diagram. Suppose that every restricted Voronoi cell is a topological closed disk and every intersection of three distinct restricted Voronoi cells is either empty or a lone point (henceforth called a restricted Voronoi vertex). Suppose also that no restricted Voronoi cell intersects the interior of another.*

Then for every pair of distinct sites $v, w \in V$, $\mathrm{Vor}|_\Sigma v \cap \mathrm{Vor}|_\Sigma w$ is one of these three: empty; a topological circle containing no restricted Voronoi vertex; or a union of disjoint topological closed intervals and isolated points, where each isolated point is a restricted Voronoi vertex and each interval contains exactly two restricted Voronoi vertices which are its endpoints.

Moreover, if each connected component of Σ has at least three sites in V lying on it, then the possibility that $\mathrm{Vor}|_\Sigma v \cap \mathrm{Vor}|_\Sigma w$ is a topological circle is eliminated, every restricted Voronoi cell has at least two restricted Voronoi vertices on its boundary, and every connected component of Σ has at least two restricted Voronoi vertices on it.

A closed Σ cuts space into two pieces, a bounded *inside* piece and an unbounded *outside* piece. For a point $x \in \Sigma$, let n_x denote the outside-facing vector normal to Σ at x (and normal to $T_x\Sigma$). Let $\angle(n_p, n_q) \in [0°, 180°]$ denote the angle separating two vectors.

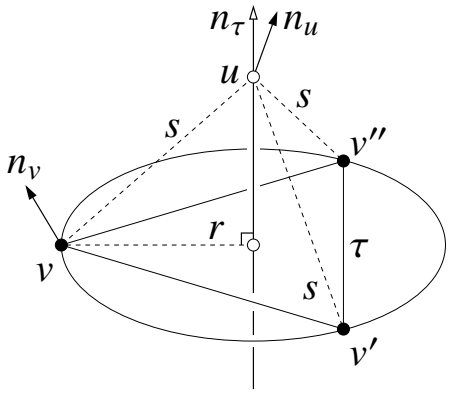

Figure 5 The sites v, v', and v'' and the restricted Voronoi vertex u lie on Σ (not shown).

▶ **Lemma 13** (Normal Variation Lemma [25]). *Consider two points $p, q \in \Sigma$ and let $\delta = |pq|/\mathrm{lfs}(p)$. If $\delta < \sqrt{4\sqrt{5}-8} \doteq 0.971736$, then $\angle(n_p, n_q) \leq \eta(\delta)$ where*

$$\eta(\delta) = \arccos\left(1 - \frac{\delta^2}{2\sqrt{1-\delta^2}}\right) \approx \delta + \frac{7}{24}\delta^3 + O(\delta^5) \text{ radians.}$$

▶ **Lemma 14** (Triangle Normal Lemma [25]). *Let τ be a triangle whose vertices lie on Σ. Let r be the radius of τ's circumscribing circle. Let v be a vertex of τ and let ϕ be τ's plane angle at v. Let n_τ be a vector normal to τ. Let $\mathrm{aff}\,\tau$ denote the affine hull of τ. Then*

$$\sin\angle(n_\tau, n_v) = \sin\angle(\mathrm{aff}\,\tau, T_v\Sigma) \leq \frac{r}{\mathrm{lfs}(v)} \max\left\{\cot\frac{\phi}{2}, 1\right\}.$$

▶ **Lemma 15.** *Let u be a restricted Voronoi vertex and let $\tau = \triangle vv'v''$ be its dual restricted Delaunay triangle. (If u's dual face is a polygon, you may choose any three of its vertices.) Let n_τ be a vector normal to τ, directed so that $\angle(n_v, n_\tau) \leq 90°$ (as illustrated in Figure 5). Let $s = |vu| = |v'u| = |v''u|$ and suppose that $s \leq 0.3245\,\mathrm{lfs}(u)$.*

Then $\angle(n_u, n_\tau) < 90°$ and $\angle(n_v, n_\tau) < 90°$. Equivalently, $n_u \cdot n_\tau$ and $n_v \cdot n_\tau$ are positive.

Proof. Let $w \in \{v, v', v''\}$ be the vertex at τ's largest plane angle. As $|vu| = |wu| = s \leq 0.3245\,\mathrm{lfs}(u)$, by the Normal Variation Lemma (Lemma 13), $\angle(n_v, n_u) \leq \eta(0.3245) < 19.21°$ and $\angle(n_w, n_u) \leq \eta(0.3245) < 19.21°$.

Let r be τ's circumradius. As Figure 5 illustrates, $r \leq s$, because u lies on the line perpendicular to τ through τ's circumcenter and r is the distance from v to that line. By the Feature Translation Lemma (Lemma 8), $\mathrm{lfs}(u) \leq \mathrm{lfs}(v)/(1 - 0.3245)$ and $\mathrm{lfs}(u) \leq \mathrm{lfs}(w)/(1 - 0.3245)$. Hence $r \leq s \leq 0.3245\,\mathrm{lfs}(u) \leq \frac{0.3245}{0.6755}\,\mathrm{lfs}(v)$ and $r \leq \frac{0.3245}{0.6755}\,\mathrm{lfs}(w)$.

If τ's plane angle at v is 53.932° or greater, then by the Triangle Normal Lemma (Lemma 14), $\sin\angle(n_v, n_\tau) \leq r \cot 26.966°/\mathrm{lfs}(v) < (0.3245/0.6755)\cdot 1.9655 < 0.9442$. Therefore, $\angle(n_v, n_\tau) < 70.77°$ and $\angle(n_u, n_\tau) \leq \angle(n_v, n_u) + \angle(n_v, n_\tau) < 19.21° + 70.77° = 89.98°$.

Otherwise, τ's plane angle at v is less than 53.932°, so τ's largest plane angle (at w) is greater than $(180° - 53.932°)/2 = 63.034°$. By the Triangle Normal Lemma, $\sin\angle(n_w, n_\tau) \leq r \cot 31.517°/\mathrm{lfs}(w) < (0.3245/0.6755) \cdot 1.6308 < 0.78342$. Therefore, either $\angle(n_w, n_\tau) < 51.575°$ or $\angle(n_w, n_\tau) > 128.425°$. The latter case is not possible, because $\angle(n_w, n_\tau) \leq \angle(n_w, n_u) + \angle(n_u, n_v) + \angle(n_v, n_\tau) < 19.21° + 19.21° + 90° = 128.42°$. In the former case, $\angle(n_u, n_\tau) \leq \angle(n_w, n_u) + \angle(n_w, n_\tau) < 19.21° + 51.575° = 70.785°$ and $\angle(n_v, n_\tau) \leq \angle(n_v, n_u) + \angle(n_w, n_u) + \angle(n_w, n_\tau) < 19.21° + 19.21° + 51.575° = 89.995°$. ◀

▶ **Lemma 16.** *Let u be a restricted Voronoi vertex and let $\tau = \triangle vv'v''$ be its dual restricted Delaunay triangle. (If u's dual face is a polygon, you may choose any three of its vertices.) Let $w \in \{v, v', v''\}$ be the vertex at τ's largest plane angle. Let n_τ be a vector normal to τ, directed so that $\angle(n_v, n_\tau) \leq 90°$. Let $s = |vu| = |v'u| = |v''u| = |wu|$ and suppose that $s \leq 0.4132\,\mathrm{lfs}(v)$ and $s \leq 0.4132\,\mathrm{lfs}(w)$.*

Then $\angle(n_u, n_\tau) < 90°$ and $\angle(n_v, n_\tau) < 90°$. Equivalently, $n_u \cdot n_\tau$ and $n_v \cdot n_\tau$ are positive.

The proof of Lemma 16 is much like that of Lemma 15; see the full-length paper [32].

The final lemma shows that a nonempty intersection of two restricted Voronoi cells is either a lone restricted Voronoi vertex (a "degenerate" case where four or more restricted Voronoi cells share a restricted Voronoi vertex, whereas the common case is three cells sharing a vertex) or a lone topological interval justifying the name "restricted Voronoi edge."

▶ **Lemma 17.** *Let $\mathrm{Vor}|_\Sigma V$ be a restricted Voronoi diagram that satisfies all the conditions of Lemma 12, including the condition that at least three sites in V lie on each connected component of Σ. Suppose that closed ball property D and generic intersection properties E and F hold: no vertex of $\mathrm{Vor}\, V$ lies on Σ, and no edge and no 2-face of $\mathrm{Vor}\, V$ intersects Σ tangentially. Suppose also that for every restricted Voronoi vertex $u \in \mathrm{Vor}|_\Sigma V$, either*

- *$|vu| \leq 0.3245\,\mathrm{lfs}(u)$ for every site v such that $u \in \mathrm{Vor}|_\Sigma v$, or*
- *$|vu| \leq 0.4132\,\mathrm{lfs}(v)$ for every site v such that $u \in \mathrm{Vor}|_\Sigma v$.*

Let $v, w \in V$ be two distinct sites, let $F = \mathrm{Vor}\, v \cap \mathrm{Vor}\, w$, and let $f = \mathrm{Vor}|_\Sigma v \cap \mathrm{Vor}|_\Sigma w = F \cap \Sigma$.

Then one of these three claims holds: f is empty; f is a lone point (a restricted Voronoi vertex) and F is an edge; or f is homeomorphic to a closed interval and F is a 2-face.

Proof. Suppose f is nonempty. By Lemma 12, f is a union of disjoint topological intervals and isolated points. As f is nonempty and no vertex of $\mathrm{Vor}\, V$ lies on Σ (closed ball property D), F is not a vertex of $\mathrm{Vor}\, V$. Hence F is either an edge or a 2-face of $\mathrm{Vor}\, V$. If F is a Voronoi edge, then F is the intersection of three or more Voronoi cells and thus f is the intersection of three or more restricted Voronoi cells; so by assumption (the conditions of Lemma 12), f is a lone restricted Voronoi vertex and the result holds.

Only the case where F is a 2-face of $\mathrm{Vor}\, V$ remains. As closed ball property D and generic intersection properties E and F hold, $\Sigma \cap F$ cannot contain any isolated points; so f is a union of disjoint topological intervals. By Lemma 12, each interval contains exactly two restricted Voronoi vertices, its endpoints. Both of them lie on the boundary of F.

Let n_v be an outside-facing vector normal to Σ at v. We will see shortly that F is not perpendicular to n_v. Assign a direction to each edge of F such that the angle between n_v and each directed edge is at most 90°, as illustrated in Figure 6. As F is a convex polygon, we thus partition its edges into two chains, each monotone in the direction n_v. (An edge perpendicular to n_v – there are at most two – can be assigned to either chain.)

Let u be a restricted Voronoi vertex on an edge e of F. Let τ be u's dual restricted Delaunay triangle (or polygon) with vertices v and w. Let n_τ be a vector that points in the same direction as e, and observe that n_τ is normal to τ and $\angle(n_v, n_\tau) \leq 90°$. By Lemma 15 or Lemma 16, $\angle(n_u, n_\tau) < 90°$ and $\angle(n_v, n_\tau) < 90°$. The latter implies that F is not perpendicular to n_v (as promised). The former implies that as one walks along one of the directed monotone chains, one might encounter a restricted Voronoi vertex where the chain passes from inside Σ to outside Σ, but not from outside to inside. Therefore, there can be only one restricted Voronoi vertex on each chain, and only two restricted Voronoi vertices on F. It follows that $\mathrm{Vor}|_\Sigma v \cap \mathrm{Vor}|_\Sigma w$ is just a single topological interval. ◀

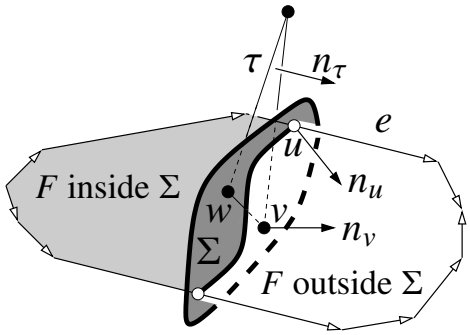

Figure 6 A Voronoi 2-face F, with its edges partitioned into two chains monotone in n_v.

7 The restricted Delaunay triangulation is homeomorphic to Σ

We conclude with homeomorphism theorems for 0.3245-samples and 0.4132-Voronoi samples.

▶ **Theorem 18.** *Let V be a finite ϵ-sample of Σ for some $\epsilon \leq 0.3245$. Suppose that no vertex of the three-dimensional Voronoi diagram $\mathrm{Vor}\, V$ lies on Σ. Then the underlying space of the restricted Delaunay triangulation, $|\mathrm{Del}|_\Sigma V|$, is homeomorphic to Σ.*

Proof. Corollary 9 guarantees closed ball property A and generic intersection property E. Corollary 11 guarantees closed ball property C and generic intersection property F. Closed ball property D holds by assumption. By Corollary 9, every connected component of Σ has at least six sites on it and no restricted Voronoi cell intersects the interior of another; all the preconditions of Lemmas 12 and 17 are satisfied. Lemma 17 guarantees closed ball property B. As Σ and V satisfy the preconditions A–F of the Topological Ball Theorem [23], $|\mathrm{Del}|_\Sigma V|$ is homeomorphic to Σ. ◀

▶ **Theorem 19.** *Let V be a finite ϵ-Voronoi sample of Σ for some $\epsilon \leq 0.4132$. Suppose that no vertex of the three-dimensional Voronoi diagram $\mathrm{Vor}\, V$ lies on Σ. Then the underlying space of the restricted Delaunay triangulation, $|\mathrm{Del}|_\Sigma V|$, is homeomorphic to Σ.*

Proof. Identical to the proof of Theorem 18, except that Corollary 9 is replaced by Theorem 6 and Lemmas 2, 7, and 5; and Corollary 11 is replaced by Lemma 10. ◀

The Hierarchy of Manifolds in a Stratification of the Set of Equivalent Linear Neural Networks

Jonathan Richard Shewchuk

Sagnik Bhattacharya
University of California, Berkeley, CA, USA

Abstract

A linear neural network computes a linear transformation of its input vector. Given a fully-connected linear network, the set of all weight vectors for which the network computes the same linear transformation is an algebraic variety in weight space, called a *fiber* under the *matrix multiplication map*. Sometimes this variety is a manifold, but usually not. The *rank stratification* of a fiber is a natural partition of the fiber into manifolds of various dimensions called *strata*. We characterize how these strata are connected to each other. They satisfy the *frontier condition*: if a stratum intersects the closure of another stratum, then the former stratum is a subset of the closure of the latter stratum. This subset relationship can be expressed as a partial order with a single minimal element. Our main result describes the relationship between this partial order and the ranks of certain matrices in the network. Each stratum represents a different pattern of information flow through the network, expressed as a *barcode*. Connections among the strata are best understood through simple transformations of the barcodes called *barcode moves*.

1 Introduction

In its simplest form, a *linear neural network* is a sequence of matrices whose product is a matrix.[1] The network takes an *input vector* x and produces an *output vector* $y = W_L W_{L-1} \cdots W_2 W_1 x$. We number the matrices in the order they are applied. The matrix W_1 linearly transforms x, producing a vector that W_2 linearly transforms, and so on. The composition of those transformations is also a linear transformation, represented by

$$W = \mu(W_L, W_{L-1}, \ldots, W_2, W_1) = W_L W_{L-1} \cdots W_2 W_1,$$

where μ is called the *matrix multiplication map*. Each matrix W_j is interpreted as a layer of edges (connections) in the network, edge layer number j, and each component of W_j is interpreted as the *weight* of an edge. For brevity, we omit added terms, which do not appreciably affect our results (but we address them in the full-length manuscript [20]).

[1] To a practitioner, a linear neural network is a neural network in which all the activation functions are the identity function. In this paper's neural networks, every layer of edges is fully-connected.

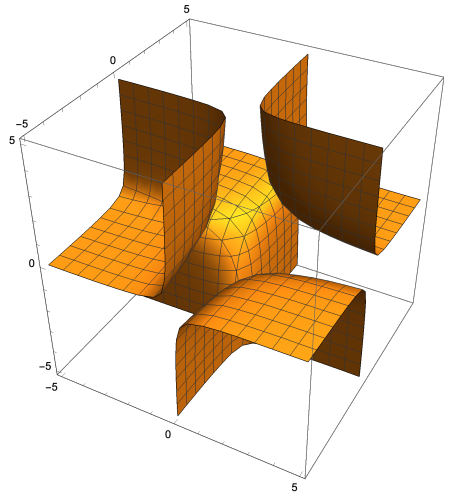

Figure 1 The fiber $\mu^{-1}([1])$ for the network $W_3W_2W_1 = [\theta_3][\theta_2][\theta_1] = [1] = W$.

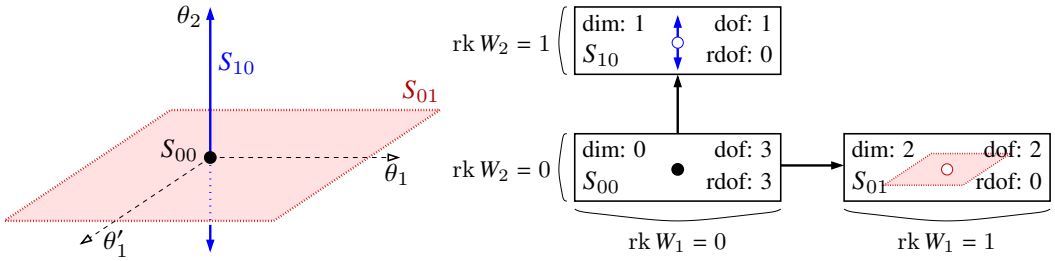

Figure 2 At left is the fiber $\mu^{-1}([0 \quad 0])$ for the network $W_2W_1 = [\theta_2][\theta_1 \quad \theta_1'] = [0 \quad 0] = W$, partitioned into three strata: S_{00} is the origin; S_{10} (blue) is the θ_2-axis with the origin removed; and S_{01} (pink) is the plane spanned by the θ_1- and θ_1'-axes with the origin removed. At right, the strata are arranged in a *stratum dag*, organized as a table indexed by the ranks of W_1 and W_2. Each dag vertex specifies the dimension of the stratum (dim), the number of degrees of freedom of motion on the fiber (dof = dim + rdof), and the number of rank-increasing degrees of freedom (rdof), which stay on the fiber but move off the stratum and onto a higher-dimensional stratum. A directed path from one stratum to another implies that the former is a subset of the closure of the latter.

We wish to study $\mu^{-1}(W)$, the set of all factorizations of a matrix W into a product of matrices of specified sizes. Said differently, we study the set of all choices of linear neural network weights such that the network computes the linear transformation W. This set is infinite (unless $L = 1$) and it is a *real algebraic variety* – the set of all real-valued solutions of a system of polynomial equations (specifically, multilinear equations). Trager, Kohn, and Bruna [23], whose paper inspired ours, call $\mu^{-1}(W)$ the *fiber* of W under the map μ. Understanding the fiber has applications in understanding gradient descent algorithms for training neural networks – but it is also a beautiful mathematical problem in its own right.

Sometimes the fiber is a manifold – see Figure 1 for an example – but usually not. Always it can be partitioned into smooth manifolds of various dimensions, called *strata*. The set of strata is called a *stratification* of the fiber. Figure 2 graphs the solutions of $[\theta_2][\theta_1 \quad \theta_1'] = [0 \quad 0]$ (an instantiation of $W_2W_1 = W$). The set of solutions can be partitioned into three strata: S_{00} is the origin, S_{10} is the θ_2-axis with the origin removed, and S_{01} is the θ_1-θ_1' plane with the origin removed. The two subscripts of S_{**} are the ranks of W_2 and W_1, respectively. The stratum S_{00} lies in the closures of both S_{10} and S_{01}; S_{00} serves to connect S_{10} to S_{01}.

Figure 2 illustrates what we call a *rank stratification* of the fiber $\mu^{-1}(W)$, which has one stratum for each *rank list* defined in Section 2; it is the most natural way to stratify a fiber of the matrix multiplication map. In the full-length manuscript [20], we show that the strata in a rank stratification are analytic manifolds (hence of class C^∞), derive their dimensions, and derive the tangent and normal spaces at each point of each stratum.

This paper characterizes how the strata are connected to each other. The strata satisfy the *frontier condition*: if a stratum intersects the closure of another stratum, then the former stratum is a subset of the closure of the latter stratum. This subset relationship induces a partial order with a single minimal element, a stratum that is included in the closure of every other stratum (in Figure 2, S_{00}). Our main result describes the relationship between this partial order and the ranks of certain matrices in the network. What makes it interesting is that each stratum represents a different pattern of information flow through the network.

In 1957, Hassler Whitney [24, 25, 26] proved that every real algebraic variety can be partitioned into a finite set of analytic manifolds. Łojasiewicz [16] generalized the result to semi-algebraic and semi-analytic sets. Mather [18] showed that Whitney's stratifications satisfy the frontier condition (but there exist stratifications that do not, hence we prove that rank stratifications do). Thom [22] introduced the terms *stratum* and *stratification*.

Linear neural networks compute only linear transformations; they are far less powerful than networks with nonlinear activation functions such as rectified linear units (ReLUs, also called ramp functions) and sigmoid functions (also called logistic functions). Yet linear networks have become a popular object of study [1, 2, 4, 5, 11, 12, 13, 14, 17, 19, 23, 27]. Why? We cannot fully understand the training of ReLU-based networks – or probably any neural networks – if we do not understand linear networks. Researchers have studied linear neural networks to understand phenomena observed in ReLU networks such as implicit regularization in optimizing the training algorithm's cost function [10, 2, 5], implicit acceleration of training by gradient descent [1], and the success of residual networks [11]. Close to our hearts, Trager, Kohn, and Bruna [23] show that the fiber $\mu^{-1}(W)$ is crucial for understanding the critical points of the cost functions minimized by neural network training algorithms. We aspire to build a related theory for ReLU networks, and we hope insights in this paper will help.

2 Notation

Let L be the number of matrices – that is, the number of layers of edges (connections) in the network. Alternating with the edge layers are $L+1$ layers of units, numbered from 0 to L, in which layer j has d_j real-valued *units* that represent a vector in $\mathbb{R}^{d_j}$. Unit layer 0 is the *input layer*, unit layer L is the *output layer*, and between them are $L-1$ *hidden layers*. The layers of edges are numbered from 1 to L, and the edge weights in edge layer j are represented by a real-valued $d_j \times d_{j-1}$ matrix W_j.

We collect all the network's weights in a *weight vector* $\theta = (W_L, W_{L-1}, \ldots, W_1) \in \mathbb{R}^{d_\theta}$, where $d_\theta = d_L d_{L-1} + d_{L-1} d_{L-2} + \ldots + d_1 d_0$ is the number of real-valued weights in the network (i.e., the number of connections). Recall the matrix multiplication map $\mu(W_L, W_{L-1}, \ldots, W_2, W_1)$; we can abbreviate it to $\mu(\theta) = W_L W_{L-1} \cdots W_2 W_1$. Given a fixed weight vector θ, the linear neural network takes an *input vector* $x \in \mathbb{R}^{d_0}$ and returns an *output vector* $y = W_L W_{L-1} \cdots W_2 W_1 x$, with $y \in \mathbb{R}^{d_L}$. Hence, the network implicitly applies a linear transformation specified by the $d_L \times d_0$ matrix $W = \mu(\theta)$, yielding $y = Wx$.

The map μ is not bijective (unless $L = 1$), so it has a preimage set, not an inverse. Given $W \in \mathbb{R}^{d_L \times d_0}$, let

$$\mu^{-1}(W) = \{\theta : \mu(\theta) = W\}$$

be the set of all factorizations of W for some fixed $d_L, d_{L-1}, \ldots, d_0$. Call $\mu^{-1}(W)$ the *fiber* of W under μ; it is a real algebraic variety in the weight space $\mathbb{R}^{d_\theta}$. With respect to $\mathbb{R}^{d_\theta}$, $\mu^{-1}(W)$ is a closed point set. Note that $\mu^{-1}(W)$ is empty if and only if $\operatorname{rk} W > \min_{j=1}^{L-1} d_j$.

Given a weight vector $\theta = (W_L, W_{L-1}, \ldots, W_1)$, its *subsequence matrices* are all the matrices of the form $W_{k \blacktriangleleft i} = W_k W_{k-1} \cdots W_{i+1}$. The notation $W_{k \blacktriangleleft i}$ indicates that this matrix transforms a vector at unit layer i to produce a vector at unit layer k. Note that $W = W_{L \blacktriangleleft 0}$ and $W_j = W_{j \blacktriangleleft j-1}$. We use the convention that $W_{k \blacktriangleleft k} = I_{d_k \times d_k}$, the $d_k \times d_k$ identity matrix. Assume that every $W_{k \blacktriangleleft i}$ in this paper is a function of θ. We call each W_j a *factor matrix*.

The *rank list* $\underline{r}$ for a weight vector $\theta \in \mathbb{R}^{d_\theta}$ is a sequence that lists the rank of every subsequence matrix $W_{k \blacktriangleleft i}$ such that $L \geq k \geq i \geq 0$. The list includes the unit layer sizes $\operatorname{rk} W_{k \blacktriangleleft k} = d_k$. For example, for a network with $L = 3$ layers of edges, the rank list of θ is

$$\underline{r} = \langle d_3, d_2, d_1, d_0, \operatorname{rk} W_3, \operatorname{rk} W_2, \operatorname{rk} W_1, \operatorname{rk} W_3 W_2, \operatorname{rk} W_2 W_1, \operatorname{rk} W \rangle.$$

We will use rank lists to partition a fiber into strata. Sometimes we do not want to specify a particular θ, but rather we wish to specify some target ranks. In that case, we let $r_{k \blacktriangleleft i}$ denote the target value of $\operatorname{rk} W_{k \blacktriangleleft i}$ and we write $\underline{r} = \langle r_{k \blacktriangleleft i} \rangle_{L \geq k \geq i \geq 0}$. For example, if we set $r_{3 \blacktriangleleft 1} = 2$, we select weight vectors for which $\operatorname{rk} W_3 W_2 = 2$. If $L = 2$ and we set $\underline{r} = \langle 9, 8, 7, 2, 3, 1 \rangle$, we select weight vectors for which W_2 is a 9×8 matrix of rank 2, W_1 is an 8×7 matrix of rank 3, and $W = W_2 W_1$ has rank 1.

Let $S_{\underline{r}}^W$ denote the set of points in W's fiber having rank list $\underline{r}$. That is,

$$S_{\underline{r}}^W = \{\theta \in \mu^{-1}(W) : \text{the rank list of } \theta \text{ is } \underline{r}\}.$$

If it is nonempty, we call $S_{\underline{r}}^W$ a *stratum* in the rank stratification of W's fiber. When W is clear from context, we just write $S_{\underline{r}}$. Each $S_{\underline{r}}$ is an analytic manifold [20] (but not necessarily closed nor connected nor bounded). The *rank stratification* of $\mu^{-1}(W)$ is

$$\mathbb{S} = \{S_{\underline{r}} : \underline{r} \text{ is the rank list of some weight vector in } \mu^{-1}(W)\}.$$

The members of $\mathbb{S}$ are disjoint and $\mu^{-1}(W) = \bigcup_{S \in \mathbb{S}} S$ – that is, $\mathbb{S}$ is a partition of $\mu^{-1}(W)$.

A rank list $\underline{r}$ is *valid* if there exists some weight vector $\theta \in \mathbb{R}^{d_\theta}$ that has rank list $\underline{r}$. We show in the full-length manuscript [20] that if $W \in \mathbb{R}^{d_L \times d_0}$ and $\underline{r}$ is a valid rank list with $r_{L \blacktriangleleft 0} = \operatorname{rk} W$, then there exists some $\theta \in \mu^{-1}(W)$ that has rank list $\underline{r}$, so $S_{\underline{r}}$ is nonempty.

Given two rank lists $\underline{r}$ and $\underline{z}$, we write $\underline{r} \leq \underline{z}$ to mean that $r_{k \blacktriangleleft i} \leq z_{k \blacktriangleleft i}$ for all $L \geq k \geq i \geq 0$. We write $\underline{r} < \underline{z}$ to mean that $\underline{r} \leq \underline{z}$ and $\underline{r} \neq \underline{z}$ (at least one of the inequalities holds strictly).

Given a set $S \subseteq \mathbb{R}^{d_\theta}$, let $\bar{S}$ denote the closure of S (with respect to the weight space $\mathbb{R}^{d_\theta}$).

3 Main result: The hierarchy of strata

▶ **Theorem 1.** *Let $\underline{r}$ and $\underline{z}$ be two valid rank lists for the same linear neural network (i.e., $r_{j \blacktriangleleft j} = z_{j \blacktriangleleft j} = d_j$ for all $j \in [0, L]$). Let $\mu^{-1}(W)$ be the fiber of a matrix $W \in \mathbb{R}^{d_L \times d_0}$ whose rank satisfies $\operatorname{rk} W = r_{L \blacktriangleleft 0} = z_{L \blacktriangleleft 0}$. Let $S_{\underline{r}}$ and $S_{\underline{z}}$ be the strata with rank lists $\underline{r}$ and $\underline{z}$ in the rank stratification $\mathbb{S}$ of $\mu^{-1}(W)$, and recall that validity implies that $S_{\underline{r}} \neq \emptyset$ and $S_{\underline{z}} \neq \emptyset$. Then the following statements are equivalent (imply each other).*

A. $S_{\underline{r}} \subseteq \bar{S}_{\underline{z}}$.
B. $S_{\underline{r}} \cap \bar{S}_{\underline{z}} \neq \emptyset$.
C. $\underline{r} \leq \underline{z}$.
D. *There exists a sequence of rank-one abstract barcode moves that proceed from $\underline{r}$ to $\underline{z}$, with all the intermediate rank lists being valid.*

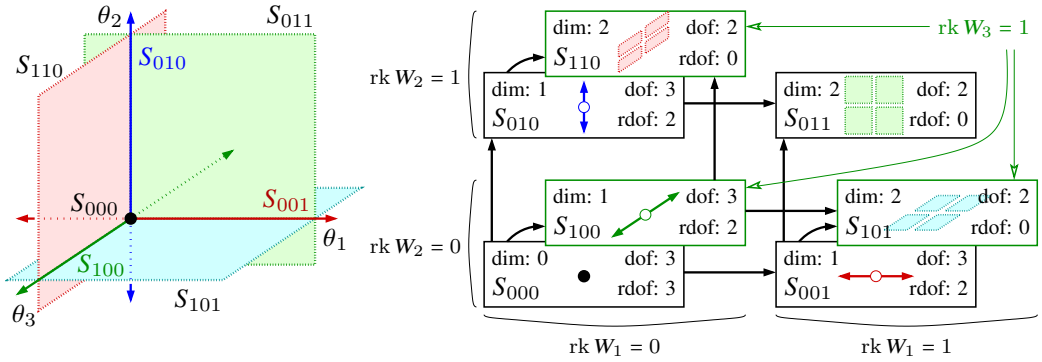

Figure 3 At left is the variety of solutions to $W_3W_2W_1 = [\theta_3][\theta_2][\theta_1] = [0] = W$, partitioned into seven strata: S_{000} is the origin; S_{001}, S_{010}, and S_{100} are the three coordinate axes with the origin removed; and S_{011}, S_{101}, and S_{110} are the three coordinate planes with the coordinate axes removed. At right is the stratum dag, organized as a table indexed by the ranks of W_3, W_2, and W_1.

We have not yet defined the terminology in statement D. A *stratum dag* is a directed acyclic graph (dag) with one vertex for each stratum in $\mathbb{S}$ and one directed edge for each rank-one abstract barcode move; see Figure 2, right. For now, just know that these moves are the central new concept in this paper, which organize the strata in $\mathbb{S}$ in a natural hierarchy. Read statement D as "there is a directed path in the stratum dag from $S_{\underline{r}}$ to $S_{\underline{z}}$." The stratum dag encodes the partial order of the strata induced by $\leq$, but it is not necessarily the simplest dag that does so (sometimes called a *Hasse diagram* or *transitive reduction*), for reasons we explain in the full-length manuscript [20].

Figures 3 and 4 depict two more examples of stratum dags. Notable in Figure 3 is that we arrange the stratum dag in a three-dimensional table, indexed by $\operatorname{rk} W_3$, $\operatorname{rk} W_2$, and $\operatorname{rk} W_1$. Ordinarily, three-matrix fibers ($L = 3$) require five indices to index the strata, as $\operatorname{rk} W_3W_2$ and $\operatorname{rk} W_2W_1$ can vary as well; but in this example every matrix is 1×1, so those two ranks are uniquely determined by the first three. Notable in Figure 4 is that the fiber has dimension as high as 35 at some points, and it is embedded in a 54-dimensional weight space. Unfortunately, we cannot visualize the fiber, but its strata are curved, like in Figure 1. In both dags, there is a unique minimal stratum – S_{000} and S_{11}, respectively – that is a subset of the closure of every other stratum. In all rank stratifications, the minimal stratum is the one in which every subsequence matrix's rank is $\operatorname{rk} W$, except the layer sizes $\operatorname{rk} W_{j \blacktriangleleft j} = d_j$. (In the full-length manuscript [20], we give an algorithm for computing stratum dags.)

Most important in Theorem 1 is the equivalence of statements A and C: $S_{\underline{r}} \subseteq \bar{S}_{\underline{z}}$ if and only if $\underline{r} \leq \underline{z}$. The rank lists tell you which strata's closures include (or intersect) which strata.

The fact that B implies A means that rank stratifications satisfy the frontier condition defined in the Introduction: for every pair of strata $S, T \in \mathbb{S}$, either $S \cap \bar{T} = \emptyset$ or $S \subseteq \bar{T}$. (The two possibilities are mutually exclusive, because $S \neq \emptyset$.) That is, the inclusion of points of S in $\bar{T}$ is all or nothing, which helps us to understand how strata are connected to each other. For example, if $S \subseteq \bar{T}$ and $S \neq T$, then $\dim S < \dim T$ and from any point on S there is an infinitesimal perturbation that takes us onto T.

As the fiber is a closed point set, Theorem 1 implies that $\bar{S}_{\underline{z}} = \bigcup_{\underline{r} \leq \underline{z}} S_{\underline{r}}$. In Figure 3, $\bar{S}_{011} = S_{011} \cup S_{010} \cup S_{001} \cup S_{000}$, whereas $S_{100} \cap \bar{S}_{011} = \emptyset$ and $S_{011} \cap \bar{S}_{100} = \emptyset$.

Our proof of Theorem 1 shows the four implications A $\rightarrow$ B $\rightarrow$ C $\rightarrow$ D $\rightarrow$ A. Clearly A implies B, as we assume $S_{\underline{r}} \neq \emptyset$. To see that B implies C, observe that an infinitesimal perturbation of a weight vector $\theta \in S_{\underline{r}}$ may increase the ranks of some subsequence matrices

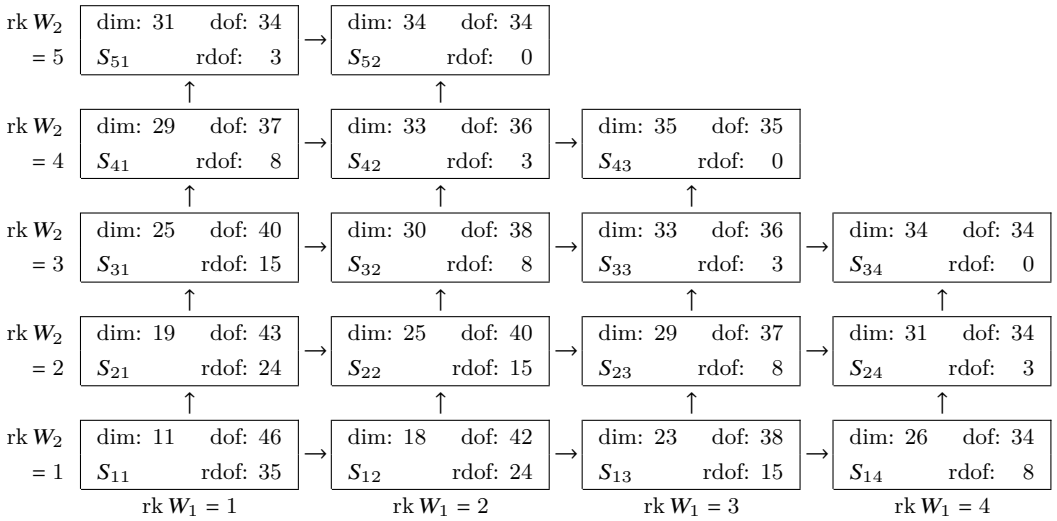

Figure 4 Stratum dag representing the stratification of $\mu^{-1}(W)$ for $W = W_2W_1$, $W_2 \in \mathbb{R}^{5\times 6}$, $W_1 \in \mathbb{R}^{6\times 4}$, and $\operatorname{rk} W = 1$. For every pair of strata S_{ts} and $S_{t's'}$ with $t \le t'$ and $s \le s'$, $S_{ts} \subseteq \bar{S}_{t's'}$.

but it cannot decrease any of their ranks, so a stratum $S_{\underline{z}}$ can have θ in its closure only if $\underline{r} \le \underline{z}$. Showing that D implies A is not difficult (an abstract move implies arbitrarily small geometric moves). The fact that C implies D was by far the hardest of the four implications to prove; for many months we did not know if C implies any of the other statements.

While statements A and B are statements about geometry, statements C and D are purely combinatorial. Our proof that C implies D is also purely combinatorial. Space is limited, so we give only part of that proof, including an algorithm that finds a suitable sequence of barcode moves (thereby showing one exists). The rest of this paper relates the geometry to the combinatorics, introduces barcode moves, and constructs the sequence of moves.

4 Prebases, fundamental subspaces, and barcodes

In this section, we show how to decompose each unit layer's space $\mathbb{R}^{d_j}$ into a *prebasis* of subspaces of $\mathbb{R}^{d_j}$; then decompose each edge layer's space $\mathbb{R}^{d_j\times d_{j-1}}$ into a prebasis of subspaces of $\mathbb{R}^{d_j\times d_{j-1}}$; then decompose the weight space $\mathbb{R}^{d_\theta}$ into a prebasis of subspaces of $\mathbb{R}^{d_\theta}$, which will illuminate the connections among strata. We assume the reader is familiar with the standard idea from linear algebra of a *basis* for $\mathbb{R}^d$, comprising d linearly independent *basis vectors*. A prebasis is like a basis, but it is made up of subspaces rather than vectors.

Given two subspaces $P, Q \subseteq \mathbb{R}^d$, their vector sum is $P + Q = \{p + q : p \in P \text{ and } q \in Q\}$. If P and Q are linearly independent – that is, if $P \cap Q = \{\mathbf{0}\}$ – then $P + Q$ is called a *direct sum*, sometimes written[2] $P \oplus Q$. Likewise, given a set of subspaces $\mathcal{P} = \{P_1, P_2, \ldots, P_m\}$, the direct sum notation $P_1 \oplus P_2 \oplus \ldots \oplus P_m$ implies that the subspaces in $\mathcal{P}$ are linearly independent – meaning that for every $i \in [1, m]$, $P_i \cap \sum_{j\neq i} P_j = \{\mathbf{0}\}$.

If $\mathbb{R}^d = P_1 \oplus P_2 \oplus \ldots \oplus P_m$, then $\mathcal{P} = \{P_1, P_2, \ldots, P_m\}$ is known as a *direct sum decomposition* of $\mathbb{R}^d$. For brevity, we call $\mathcal{P}$ a *prebasis* for $\mathbb{R}^d$, and we say that $\mathcal{P}$ *spans* $\mathbb{R}^d$. We call each P_i a *prebasis subspace* – a multidimensional analogue of a basis vector. The linear independence

[2] The notation $P \oplus Q$ is unconventional, because as an operator it produces $P + Q$, but it also implies a constraint on the subspaces P and Q: that $P \cap Q = \{\mathbf{0}\}$. If $P \cap Q \neq \{\mathbf{0}\}$, then $P \oplus Q$ is undefined.

of the prebasis subspaces implies that for every vector $v \in \mathbb{R}^d$, there is one and only one way to express v as a sum of vectors $v = \sum_{i=1}^{m} v_i$ such that $v_i \in P_i$. It also implies that $d = \sum_{i=1}^{m} \dim P_i$. If desired, it is conceptually easy to convert a prebasis into a traditional vector basis: just choose a basis for each P_i, then pool the d vectors together to form a basis for $\mathbb{R}^d$ – hence the name "prebasis." Why don't we do that here? Because details like the choice of basis for each prebasis subspace and the length of each basis vector are irrelevant and would make our presentation more complicated.

The following theorem identifies "fundamental" subspaces in a linear neural network's hidden layers analogous to the four fundamental subspaces [21] of a matrix M: the rowspace (denoted $\operatorname{row} M$), the nullspace ($\operatorname{null} M$), the columnspace ($\operatorname{col} M$), and the left nullspace ($\operatorname{null} M^\top$). The theorem originates in the study of persistent homology [8, 7] (for entirely different reasons) where it is used to analyze persistence modules [28, 29, 9, 3, 15], which are essentially linear neural networks – but usually over the field $\mathbb{Z}/2\mathbb{Z}$, in contrast to our real-valued weights. Given a matrix M and a subspace $P \subseteq \mathbb{R}^d$, define $MP = \{Mv : v \in P\}$.

▶ **Theorem 2** (Fundamental Theorem of Linear Neural Networks). *Let $\theta = (W_L, W_{L-1}, \ldots, W_1)$ be a weight vector representing a linear neural network with L layers of edges and unit layer sizes $d_L, d_{L-1}, \ldots, d_0$. For all indices k and i satisfying $L \geq k \geq i \geq 0$, let*

$$\omega_{ki} = \operatorname{rk} W_{k \blacktriangleleft i} - \operatorname{rk} W_{k \blacktriangleleft i-1} - \operatorname{rk} W_{k+1 \blacktriangleleft i} + \operatorname{rk} W_{k+1 \blacktriangleleft i-1}, \tag{1}$$

using the conventions that $\operatorname{rk} W_{j \blacktriangleleft j} = d_j$, $\operatorname{rk} W_{L+1 \blacktriangleleft i} = 0$, and $\operatorname{rk} W_{k \blacktriangleleft -1} = 0$.

Then there exist subspaces $a_{kji} \subseteq \mathbb{R}^{d_j}$ and $b_{kji} \subseteq \mathbb{R}^{d_j}$ of dimension ω_{ki} for all indices satisfying $L \geq k \geq j \geq i \geq 0$, such that for all $j \in [0, L]$,

- *$\mathcal{A}_j = \{a_{kji} \neq \{\mathbf{0}\} : k \in [j, L], i \in [0, j]\}$ is a direct sum decomposition of $\mathbb{R}^{d_j}$ and*
- *$\mathcal{B}_j = \{b_{kji} \neq \{\mathbf{0}\} : k \in [j, L], i \in [0, j]\}$ is also a direct sum decomposition of $\mathbb{R}^{d_j}$;*

and the subspaces satisfy the flow relationships

$$W_j a_{k,j-1,i} = \begin{cases} a_{kji}, & k \geq j, \\ \{\mathbf{0}\}, & k = j-1, \end{cases} \qquad \forall j \in [1, L], k \in [j-1, L], i \in [0, j-1], \qquad \text{and}$$

$$W_j^\top b_{kji} = \begin{cases} b_{k,j-1,i}, & j > i, \\ \{\mathbf{0}\}, & j = i, \end{cases} \qquad \forall j \in [1, L], k \in [j, L], i \in [0, j].$$

This decomposition into subspaces a_{kji} (or b_{kji}) is not necessarily unique, but the dimensions $\dim a_{kji} = \dim b_{kji} = \omega_{ki}$ are the same for all such decompositions. Moreover,

$$d_j = \sum_{t=j}^{L} \sum_{s=0}^{j} \omega_{ts}, \quad \forall j \in [0, L], \qquad \text{and} \qquad \operatorname{rk} W_{k \blacktriangleleft i} = \sum_{t=k}^{L} \sum_{s=0}^{i} \omega_{ts}, \quad L \geq k \geq i \geq 0. \tag{2}$$

The prebases $\mathcal{A}_j$ describe information flow through the network. As illustrated in Figure 5 (top), we interpret a_{kii} as an ω_{ki}-dimensional subspace that appears at unit layer i (its *birth layer*), being linearly independent of (but not necessarily orthogonal to) $\operatorname{col} W_i$, then flows through the weight layers $W_{i+1}, W_{i+2}, \ldots, W_k$ being linearly transformed into a sequence of subspaces $a_{k,i+1,i}, a_{k,i+2,i}, \ldots$, all of dimension ω_{ki}, reaches layer k (its *death layer*) in the form a_{kki}, still having ω_{ki} dimensions, and proceeds no farther – because either $a_{kki} \subseteq \operatorname{null} W_{k+1}$ or layer k is the output layer. These subspaces carry information from the input layer only if $i = 0$ and reach the output layer only if $k = L$; otherwise, they represent unused potential.

Symmetrically, the prebases $\mathcal{B}_j$ govern the transpose network $W^\top = W_1^\top W_2^\top \cdots W_{L-1}^\top W_L^\top$. We interpret b_{kki} as an ω_{ki}-dimensional subspace that appears at layer k, being linearly independent of $\operatorname{row} W_{k+1}$, then flows through the weight layers $W_k^\top, W_{k-1}^\top, \ldots, W_{i+1}^\top$ being linearly transformed into a sequence of ω_{ki}-dimensional subspaces $b_{k,k-1,i}, b_{k,k-2,i}, \ldots$, and stops at layer i in the form b_{kii} – either because $b_{kii} \subseteq \operatorname{null} W_i^\top$ or because $i = 0$.

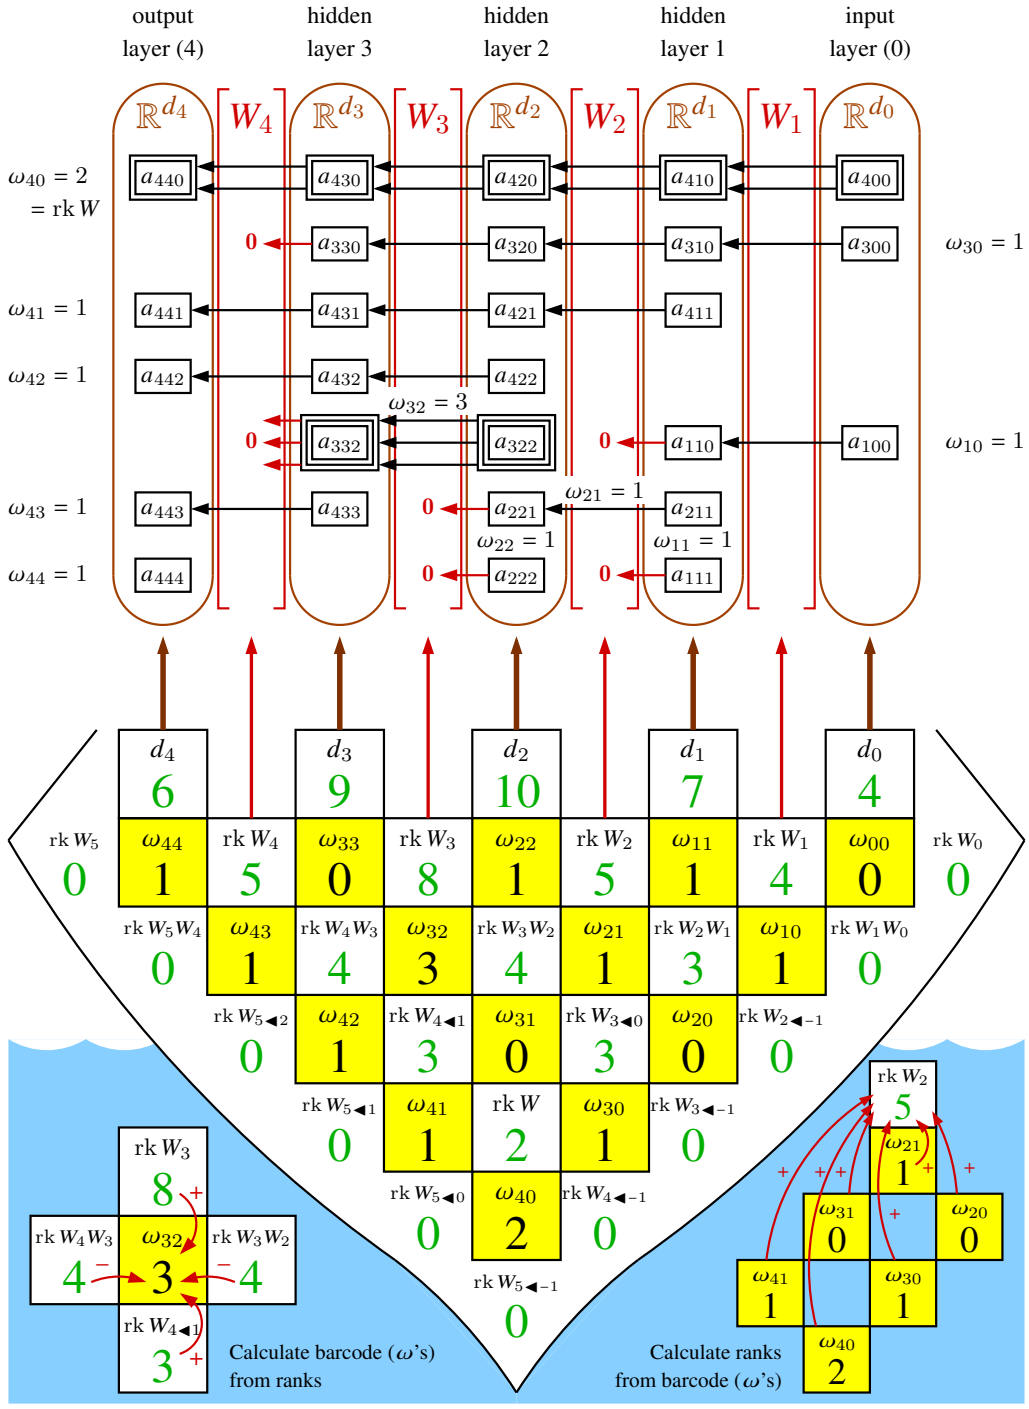

Figure 5 The top half is an annotated barcode that illustrates the flow of the prebasis subspaces a_{kji} through the network. Double boxes represent subspaces of dimension 2 and triple boxes represent subspaces of dimension 3. The bottom half relates the interval counts, the layer sizes, and the subsequence matrix ranks. The number of units d_j in unit layer j is the sum of the counts ω_{ts} of the intervals that touch layer j (i.e., the dimensions of the subspaces a_{tjs}). Each subsequence matrix rank $\operatorname{rk} W_{k\blacktriangleleft i}$ is the sum of the counts of the intervals that touch both layers k and i.

We call each ω_{ki} an *interval count*. An *interval* is a set of consecutive integers $[i,k] = \{i, i+1, \ldots, k-1, k\}$ that signifies consecutive unit layers, with i being the birth layer and k being the death layer for the information that the interval represents. The *barcode* for θ – an idea originating in persistent homology [9] – is a multiset of intervals that contains ω_{ki} copies of $[i,k]$ for all $0 \le i \le k \le L$. The top half of Figure 5 depicts a barcode annotated with prebasis subspaces. Barcodes show visually how information flows in linear networks.

The identities (1) and (2) express a bijection between rank lists and barcodes. The bottom half of Figure 5 depicts those identities visually.

We will see in Section 6 that we can understand the hierarchy of strata in terms of simple transformations of the barcode. (We can also understand it in terms of transformations of the rank list, but those transformations are not as simple.)

Now, we construct prebases for the factor matrix spaces $\mathbb{R}^{d_j \times d_{j-1}}$ and the weight space $\mathbb{R}^{d_\theta}$. Like the a_{kji}'s and b_{kji}'s, these prebases are defined at a specific weight vector θ. For indices satisfying $L \ge l \ge j \ge i \ge 0$ and $L \ge k \ge j-1 \ge h \ge 0$, define the prebasis subspace

$$o_{lkjih} = a_{lji} \otimes b_{k,j-1,h} = \{M \subseteq \mathbb{R}^{d_j \times d_{j-1}} : \operatorname{col} M \subseteq a_{lji} \text{ and } \operatorname{row} M \subseteq b_{k,j-1,h}\}.$$

Then $\dim o_{lkjih} = \dim a_{lji} \cdot \dim b_{k,j-1,h} = \omega_{li}\,\omega_{kh}$. For each $j \in [1, L]$, define the prebasis

$$O_j = \{o_{lkjih} \ne \{0\} : l \in [j, L], k \in [j-1, L], i \in [0, j], h \in [0, j-1]\}.$$

O_j is a prebasis for the weight layer $\mathbb{R}^{d_j \times d_{j-1}}$, as it pairs every subspace in the prebasis $\mathcal{A}_j$ (spanning $\mathbb{R}^{d_j}$) with every subspace in the prebasis $\mathcal{B}_{j-1}$ (spanning $\mathbb{R}^{d_{j-1}}$).

Now we construct a prebasis Θ_{O} for the weight space $\mathbb{R}^{d_\theta}$ that we call the *one-matrix prebasis*. The subspaces in Θ_{O} are called the *one-matrix subspaces* and have the form

$$\phi_{lkjih} = \{(0, \ldots, 0, M, 0, \ldots, 0) : M \in o_{lkjih}\}$$

with M in position j from the right (the position of W_j in θ). The one-matrix prebasis is

$$\Theta_{\mathrm{O}} = \{\phi_{lkjih} \ne \{\mathbf{0}\} : L \ge l \ge j \ge i \ge 0 \text{ and } L \ge k \ge j-1 \ge h \ge 0\}.$$

5 Moves on (and off) the fiber and the stratum

Imagine you are standing at a point θ on a fiber $\mu^{-1}(W)$. A *move* (θ, θ') is a step you take from θ to another point θ', which may or may not be on the fiber. Let $\Delta\theta = \theta' - \theta$ be the *displacement* of the move. We write

$$\theta' = (W'_L, W'_{L-1}, \ldots, W'_1) \in \mathbb{R}^{d_\theta} \quad \text{and} \quad \Delta\theta = (\Delta W_L, \Delta W_{L-1}, \ldots, \Delta W_1) \in \mathbb{R}^{d_\theta}.$$

We use analogous notation for the product $W' = \mu(\theta')$, its displacement $\Delta W = W' - W$, the modified subsequence matrices $W'_{t \blacktriangleleft s} = W'_t W'_{t-1} \cdots W'_{s+1}$, and their displacements $\Delta W_{t \blacktriangleleft s} = W'_{t \blacktriangleleft s} - W_{t \blacktriangleleft s}$. All prebasis subspaces below are defined at θ. (They are different at θ'!)

Moves on the fiber replace a linear neural network with another that computes the same function. Here, we are interested in *basic one-matrix moves*, for which $\Delta\theta \in \phi_{lkjih}$ for some $\phi_{lkjih} \in \Theta_{\mathrm{O}}$. ("Basic" means "from the prebasis," not "simple.") Equivalently, a basic move replaces W_j with $W'_j = W_j + \Delta W_j$, where $\Delta W_j \in o_{lkjih}$ and $o_{lkjih} \in O_j$. Once we understand basic moves, other moves can be understood as sequences of basic moves. We are particularly interested in basic moves that change the rank list and move from one stratum to another.

For each subspace $o_{lkjih} \in O_j$, we ask: does a move with displacement $\Delta W_j \in o_{lkjih}$ change W? Which subsequence matrices change? Which subsequence matrices change rank? Which subsequence matrices undergo a change in rowspace or columnspace? The three lemmas below answer these questions, and Figure 6 summarizes the answers. (Figure 6 assumes the displacement ΔW_j is nonzero; the lemmas do not.) These answers explain why we chose subspaces of the form $o_{lkjih} = a_{lji} \otimes b_{k,j-1,h}$.

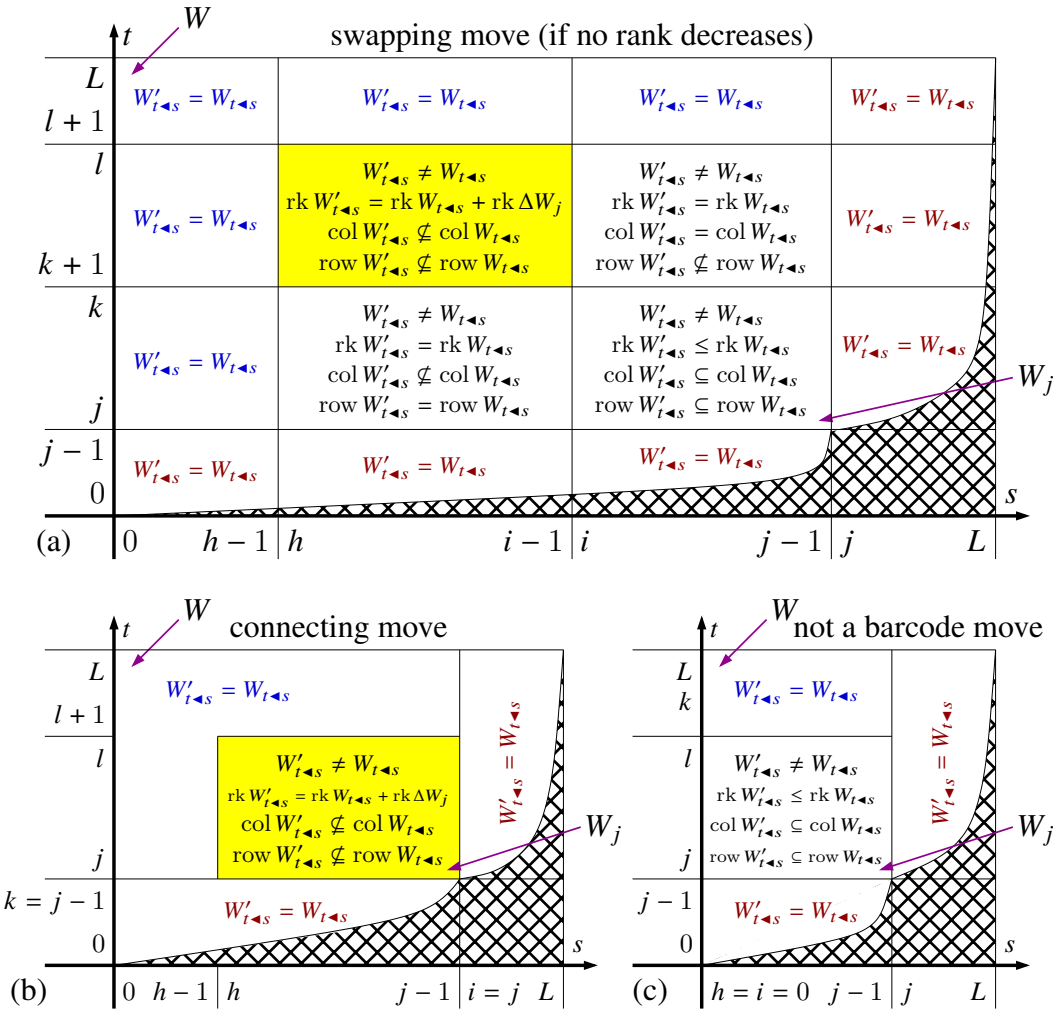

Figure 6 The influence of a basic move in which a factor matrix W_j undergoes a nonzero displacement $\Delta W_j \in o_{lkjih}$. The effects on the subsequence matrix $W_{t \blacktriangleleft s}$ are listed for every t and s with $L \geq t \geq s \geq 0$. These tables are triangular, though it's not obvious at first: the hatched regions represent unused zones where $t < s$. A yellow rectangle indicates which subsequence matrices increase in rank, constituting a barcode move if no rank decreases. The black font indicates where $W'_{t \blacktriangleleft s} \neq W_{t \blacktriangleleft s}$. The red font indicates where $W'_{t \blacktriangleleft s} = W_{t \blacktriangleleft s}$ because the matrix W_j is not a factor in $W_{t \blacktriangleleft s}$. The blue font indicates where $W'_{t \blacktriangleleft s} = W_{t \blacktriangleleft s}$ by properties of the flow relationships. (a) Table for the case where $L > l > k \geq j > i > h > 0$. An example of a swapping move. (b) The third row disappears if $k + 1 = j$, and the third column disappears if $i = j$. When $k + 1 = j = i$, the move is a connecting move. (c) The second row disappears if $k \geq l$, and the second column disappears if $i \leq h$. If either inequality holds, no subsequence matrix rank increases; the move is not a barcode move. The first column disappears if $h = 0$. (The first row disappears if $l = L$, though we don't depict that case here. If $h = 0$ and $l = L$, then $W' \neq W$ and we move off the fiber.)

▶ **Lemma 3.** *Given $L \geq t \geq s \geq 0$, $W'_{t \blacktriangleleft s} = W_{t \blacktriangleleft s}$ if and only if $\Delta W_j = 0$ or $j \notin [s+1, t]$ or $t > l$ or $s < h$. Moreover, if none of those four conditions holds, then $\operatorname{rk} \Delta W_{t \blacktriangleleft s} = \operatorname{rk} \Delta W_j$.*

▶ **Lemma 4.** *Given $L \geq t \geq s \geq 0$, $\operatorname{col} \Delta W_{t \blacktriangleleft s} \subseteq \operatorname{col} W_{t \blacktriangleleft s}$ (equivalently, $\operatorname{col} W'_{t \blacktriangleleft s} \subseteq \operatorname{col} W_{t \blacktriangleleft s}$) if and only if $\Delta W_j = 0$ or $j \notin [s+1, t]$ or $t > l$ or $s < h$ or $s \geq i$. Moreover, if none of those five conditions holds, then $\operatorname{col} \Delta W_{t \blacktriangleleft s} \cap \operatorname{col} W_{t \blacktriangleleft s} = \{\mathbf{0}\}$.*

Symmetrically, $\operatorname{row} \Delta W_{t \blacktriangleleft s} \subseteq \operatorname{row} W_{t \blacktriangleleft s}$ (equivalently, $\operatorname{row} W'_{t \blacktriangleleft s} \subseteq \operatorname{row} W_{t \blacktriangleleft s}$) if and only if $\Delta W_j = 0$ or $j \notin [s+1, t]$ or $t > l$ or $s < h$ or $t \leq k$. Moreover, if none of those five conditions holds, then $\operatorname{row} \Delta W_{t \blacktriangleleft s} \cap \operatorname{row} W_{t \blacktriangleleft s} = \{\mathbf{0}\}$.

▶ **Lemma 5.** *Given $L \geq t \geq s \geq 0$, if $t \in [j, k]$ and $s \in [i, j-1]$, then $\operatorname{rk} W'_{t \blacktriangleleft s} \leq \operatorname{rk} W_{t \blacktriangleleft s}$ and if $\|\Delta W_j\|$ is sufficiently small (in any matrix norm), $\operatorname{rk} W'_{t \blacktriangleleft s} = \operatorname{rk} W_{t \blacktriangleleft s}$.*

If $\Delta W_j \neq 0$ and $t \in [k+1, l]$ and $s \in [h, i-1]$, then $\operatorname{rk} W'_{t \blacktriangleleft s} = \operatorname{rk} W_{t \blacktriangleleft s} + \operatorname{rk} \Delta W_j$.

In all other cases, $\operatorname{rk} W'_{t \blacktriangleleft s} = \operatorname{rk} W_{t \blacktriangleleft s}$.

As $W = W_{L \blacktriangleleft 0}$, Lemma 3 tells us that a basic move moves off the fiber $\mu^{-1}(W)$ if and only if $\Delta\theta$ is a nonzero displacement from a subspace ϕ_{lkjih} with $l = L$ and $h = 0$. This motivates us to define a set of one-matrix subspaces that signify basic moves that stay on the fiber.

$$\Theta_{\mathrm{O}}^{\mathrm{fiber}} = \{\phi_{lkjih} \in \Theta_{\mathrm{O}} : L > l \text{ or } h > 0\}.$$

A *discrete move* is a move that changes the ranks of one or more subsequence matrices. If a discrete move stays on the fiber, it moves from one stratum to a different stratum. Lemma 5 tells us two ways a basic move can be discrete. Every subsequence matrix $W_{t \blacktriangleleft s}$ with $t \in [k+1, l]$ and $s \in [h, i-1]$ increases in rank, and their ranks all increase by the same amount: the rank of ΔW_j. A subsequence matrix $W_{t \blacktriangleleft s}$ with $t \in [j, k]$ and $s \in [i, j-1]$ *might* decrease in rank, but not if $\|\Delta W_j\|$ is sufficiently small.

A *small move* is a move that does not decrease the rank of any subsequence matrix. (Rather than fuss over "is $\|\Delta W_j\|$ small enough?", we define "small move" to meet our needs.) If a small, discrete move stays on the fiber, it moves to a stratum of higher dimension.

By Lemma 5, a small, basic move with displacement $\Delta\theta \in \phi_{lkjih}$ is discrete if and only if $\Delta\theta \neq \mathbf{0}$, $l > k$, and $i > h$ (so $[k+1, l] \neq \emptyset$ and $[h, i-1] \neq \emptyset$). We define a set of one-matrix subspaces that signify basic moves that increase the rank of some subsequence matrix.

$$\Theta_{\mathrm{O}}^{\mathrm{barc}} = \{\phi_{lkjih} \in \Theta_{\mathrm{O}} : l > k \text{ and } i > h\} = \{\phi_{lkjih} \neq \{\mathbf{0}\} : L \geq l \geq k+1 \geq j \geq i > h \geq 0\}.$$

6 Barcode moves: Walking the hierarchy of strata

To understand how the strata are connected to each other in the rank stratification of a fiber, it suffices to study small moves with displacements from subspaces in $\Theta_{\mathrm{O}}^{\mathrm{fiber}} \cap \Theta_{\mathrm{O}}^{\mathrm{barc}}$. Given a subspace $\phi_{lkjih} \in \Theta_{\mathrm{O}}^{\mathrm{fiber}} \cap \Theta_{\mathrm{O}}^{\mathrm{barc}}$, let $\theta + \phi_{lkjih}$ denote the *affine subspace* produced by translating ϕ_{lkjih} to pass through θ. By Lemma 3, $\theta + \phi_{lkjih} \subseteq \mu^{-1}(W)$, but by Lemma 5, no point in $\theta + \phi_{lkjih}$ except θ lies on the stratum S that contains θ. Whereas given a subspace $\phi_{lkjih} \in \Theta_{\mathrm{O}}^{\mathrm{fiber}} \setminus \Theta_{\mathrm{O}}^{\mathrm{barc}}$, $\theta + \phi_{lkjih} \subseteq \bar{S}$. These facts give us some hints about the connections among the strata and the shape of the stratification (albeit without addressing its curvature).

Interestingly, although a small, basic move may change the ranks of many subsequence matrices, at most four interval counts change. Recall the identity (1): $\omega_{ts} = \operatorname{rk} W_{t \blacktriangleleft s} - \operatorname{rk} W_{t \blacktriangleleft s-1} - \operatorname{rk} W_{t+1 \blacktriangleleft s} + \operatorname{rk} W_{t+1 \blacktriangleleft s-1}$. If all four ranks increase by $\operatorname{rk} \Delta W_j$, or exactly two ranks with opposite signs do, then ω_{ts} does not change.

For a small displacement $\Delta\theta \in \phi_{lkjih} \in \Theta_{\mathrm{O}}^{\mathrm{barc}}$, it is straightforward to check that ω_{kh} and ω_{li} decrease by $\operatorname{rk}\Delta W_j$, ω_{lh} and ω_{ki} increase by $\operatorname{rk}\Delta W_j$, and no other interval count changes. The barcode encodes the changes made by small, basic, discrete moves more elegantly than the rank list does. (The rank list is a *summed-area table* [6] of the interval counts.)

A *barcode move* is a small, basic, discrete move. There are two types of barcode moves: connecting moves and swapping moves. Every subspace $\phi_{lkjih} \in \Theta_{\mathrm{O}}$ has indices satisfying $k+1 \geq j \geq i$. A *connecting move* is a small move with a nonzero displacement $\Delta\theta \in \phi_{lkjih} \in \Theta_{\mathrm{O}}^{\mathrm{barc}}$ in the case where $k+1 = j = i$. In a connecting move, ω_{ki} does not exist (as $k < i$) and only three interval counts change. Figure 7 illustrates two examples of connecting moves and offers an interpretation in terms of a changing barcode: a connecting move deletes $\operatorname{rk}\Delta W_j$ copies of the interval $[h,k]$ and $\operatorname{rk}\Delta W_j$ copies of the interval $[i,l]$, and replaces them with $\operatorname{rk}\Delta W_j$ copies of the interval $[h,l]$. We think of this as connecting the intervals $[h,k]$ and $[i,l]$ together with an added link $[j-1,j] = [k,i]$ to create an interval $[h,l]$; hence the name "connecting move." (There is much intuition that can be gleaned from a careful study of the figure that is hard to explain in words.) The *rank* of a connecting move is $\operatorname{rk}\Delta W_j$.

A *swapping move* is a small move with a nonzero displacement $\Delta\theta \in \phi_{lkjih} \in \Theta_{\mathrm{O}}^{\mathrm{barc}}$ in the case where $k \geq i$. A swapping move changes four interval counts. Figure 8 illustrates two examples. A swapping move splices $\operatorname{rk}\Delta W_j$ copies of the interval $[h,k]$ with $\operatorname{rk}\Delta W_j$ copies of the interval $[i,l]$, replacing them with $\operatorname{rk}\Delta W_j$ copies of the interval $[h,l]$ (which is longer than both of the replaced intervals) and $\operatorname{rk}\Delta W_j$ copies of the interval $[i,k]$ (which is shorter than both). In effect, the interval endpoints are swapped. (Again, careful study of the figure is rewarding.) The *rank* of a swapping move is $\operatorname{rk}\Delta W_j$.

Each barcode move has an effect on the rank list (and the barcode) that depends solely on the indices h, i, k, and l and the rank of ΔW_j. This motivates the idea of an *abstract move* that maps one rank list to another rank list, and one barcode to another barcode, divorced entirely from any geometry. A *rank-c abstract barcode move* takes a valid rank list $\underline{r}$ and an index tuple (l,k,i,h) satisfying $L \geq l \geq k+1 \geq i > h \geq 0$, and yields the modified rank list $\underline{z}$ produced by setting $z_{t\blacktriangleleft s} = r_{t\blacktriangleleft s} + c$ for $t \in [k+1,l], s \in [h,i-1]$; for the other ranks, $z_{t\blacktriangleleft s} = r_{t\blacktriangleleft s}$. Equivalently, it takes the barcode for $\underline{r}$, decreases ω_{li} and ω_{kh} by c, and increases ω_{lh} and ω_{ki} by c – except that if $k+1 = i$, then ω_{ki} does not exist and only three interval counts change (an abstract connecting move). An abstract barcode move produces a valid rank list if and only if $\omega_{li} \geq c$ and $\omega_{kh} \geq c$ prior to the move.

We think the most interesting aspect of this paper is that the hierarchy of strata is captured by these simple discrete operations on barcodes – barcodes that indicate the flow of information through the neural network. Barcode moves create farther-reaching flows and may offer network training algorithms more opportunities to succeed.

7 Revealing the hierarchy of strata

We return to the hard part of Theorem 1, the claim that statement C implies statement D: if $\underline{r} \leq \underline{z}$, there exists a sequence of rank-one abstract barcode moves that takes us from $\underline{r}$ to $\underline{z}$. This claim is a bridge to showing that $S_{\underline{r}} \subseteq \bar{S}_{\underline{z}}$ if and only if $\underline{r} \leq \underline{z}$.

Given rank lists $\underline{r}$ and $\underline{z}$ with $\underline{r} < \underline{z}$, finding a sequence of abstract moves that takes us from $\underline{r}$ to $\underline{z}$ is a puzzle that took us three months to solve. The full proof does not fit here, but we include the constructive part of the proof: the algorithm FindLastMove in Figure 9 finds a rank list $\underline{u}$ such that $\underline{r} \leq \underline{u} < \underline{z}$ and a single rank-one abstract barcode move takes us from $\underline{u}$ to $\underline{z}$. Building on this step, a simple recursive algorithm, FindDAGPath in Figure 9, finds a sequence of abstract barcode moves that take us from $\underline{r}$ to $\underline{z}$ (computing the sequence in reverse order, from $\underline{z}$ to $\underline{r}$). The proof of correctness of FindDAGPath, and thus the proof that C implies D, follows by induction.

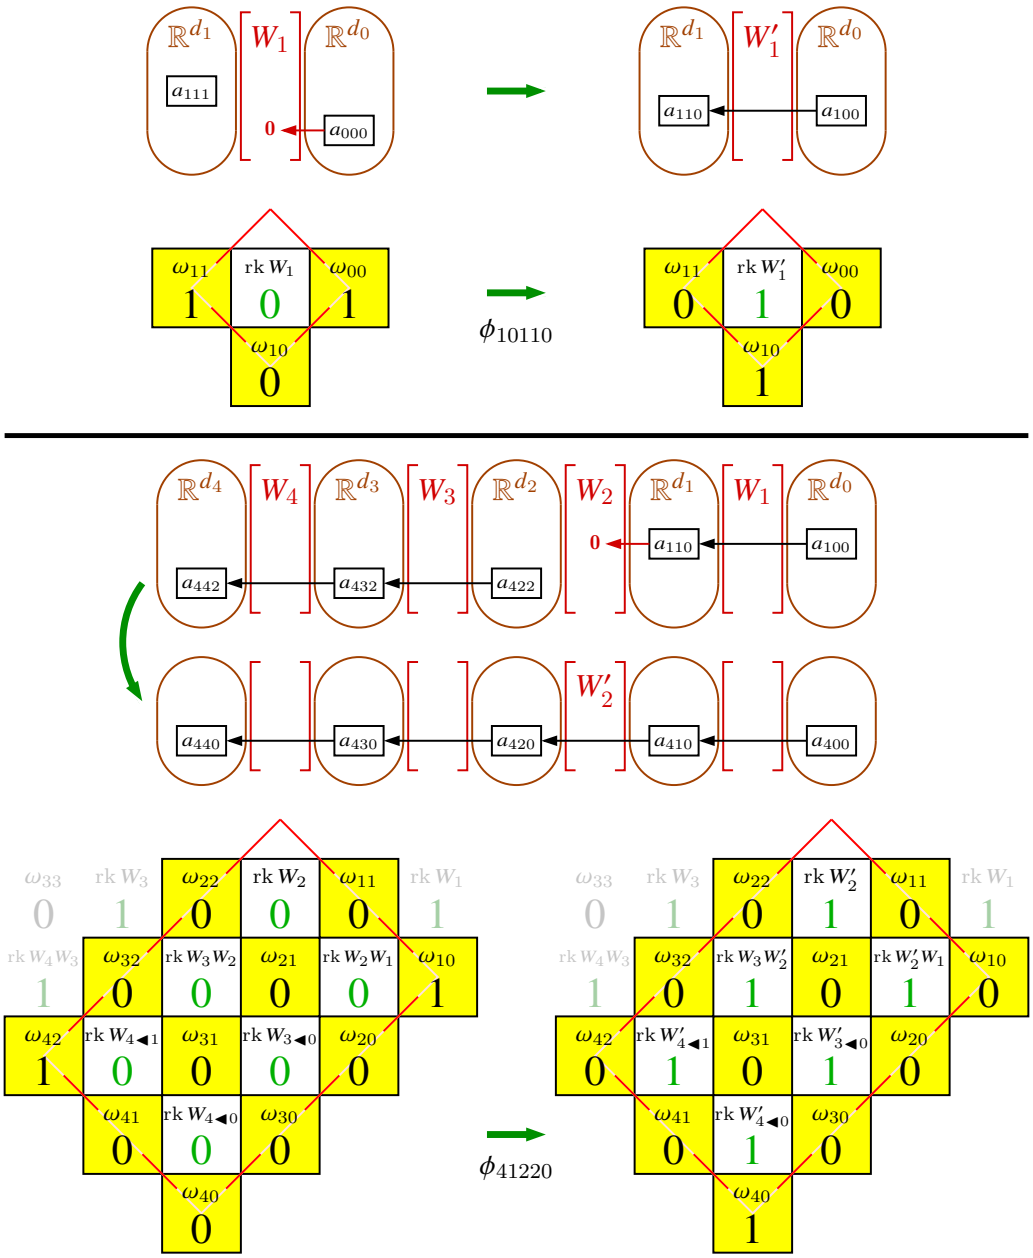

Figure 7 Two examples of connecting moves. The top example is the simplest example possible: W_1 has been perturbed to increase its rank from zero to one. In the bottom example, W_2 has been perturbed. In both examples, the perturbation of W_j replaces two intervals $[h, j-1]$ and $[j, l]$ with a single interval $[h, l]$. Three interval counts change, at three of the four corners of the red rectangle: ω_{lj} and $\omega_{j-1,h}$ decrease by one, and ω_{lh} increases by one. The ranks of the subsequence matrices $W_{t\blacktriangleleft s}$ increase by one for all $t \in [j, l]$ and $s \in [h, j-1]$ (the ranks inside the red rectangle, including $\operatorname{rk} W_j$). Outside the red rectangle, all interval counts and matrix ranks are unchanged.

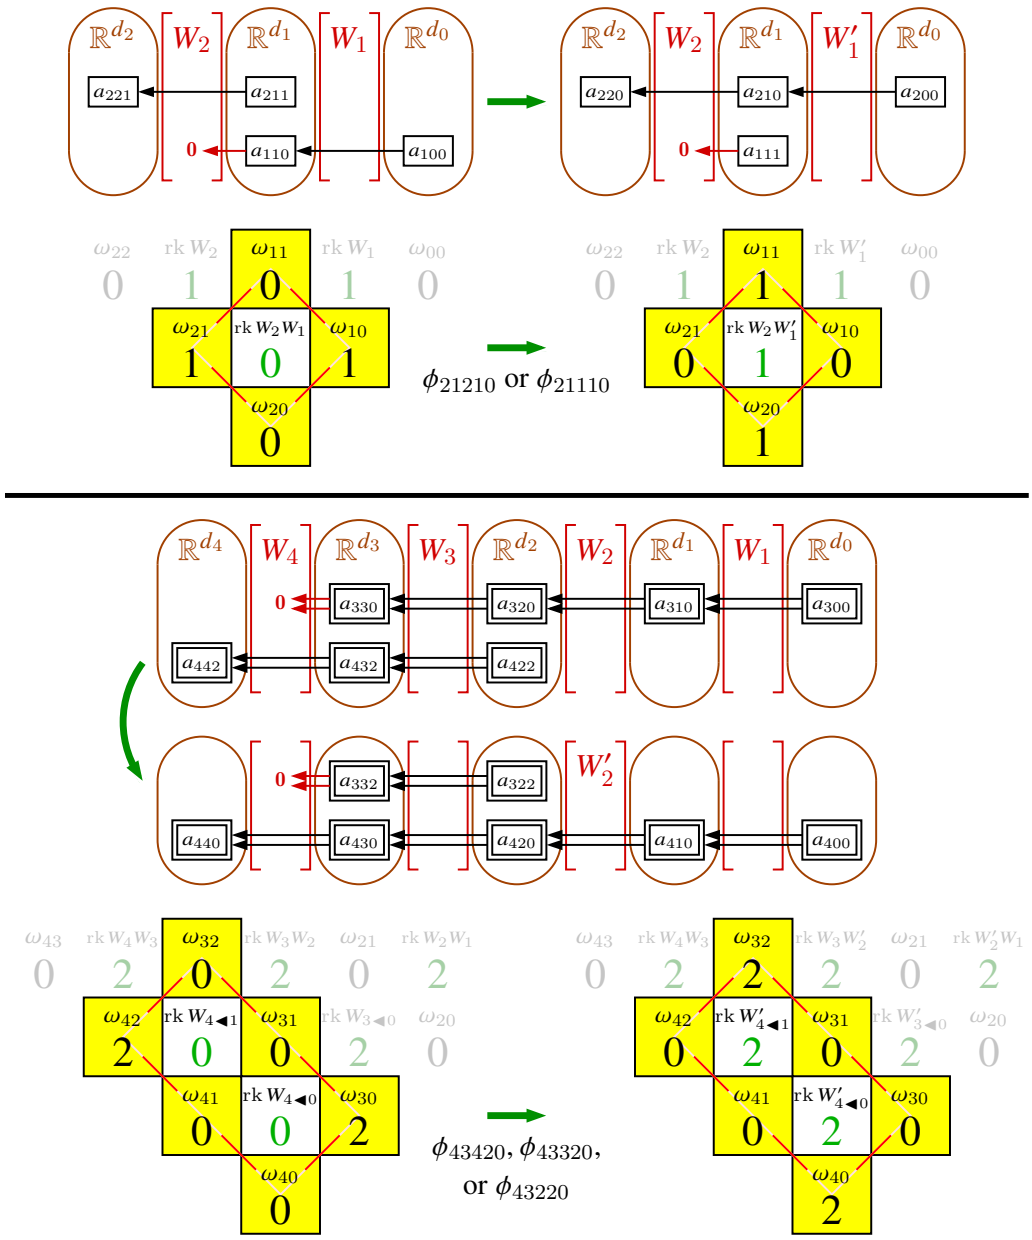

Figure 8 Two examples of swapping moves. In the top example – the simplest example possible – either W_1 or W_2 may be perturbed to cause the move. In the bottom example, any of W_2, W_3, or W_4 may be perturbed. The intervals $[h,k]$ and $[i,l]$ are replaced by an interval $[h,l]$, longer than both original intervals, and an interval $[i,k]$, shorter than both. Four interval counts change, at the four corners of the red rectangle: ω_{kh} and ω_{li} decrease, and ω_{lh} and ω_{ki} increase. The ranks of the subsequence matrices $W_{t\blacktriangleleft s}$ increase for all $t \in [k+1,l]$ and $s \in [h,i-1]$ (the ranks inside the red rectangle). Outside the red rectangle, all interval counts and matrix ranks are unchanged.

FindLastMove($\underline{r}, \underline{z}$)
// Given valid rank lists $\underline{r}$ and $\underline{z}$ such that $\underline{r} < \underline{z}$, returns a valid rank list $\underline{u}$ such that
// $\underline{r} \le \underline{u} < \underline{z}$ and a rank-one abstract barcode move takes us from $\underline{u}$ to $\underline{z}$.
for all t and s satisfying $L \ge t \ge s \ge 0$
    // From $\underline{r}$ and $\underline{z}$, compute all the interval counts with (1).
    $\omega^r_{ts} \leftarrow r_{t\blacktriangleleft s} - r_{t\blacktriangleleft s-1} - r_{t+1\blacktriangleleft s} + r_{t+1\blacktriangleleft s-1}$ // by convention, $r_{L+1\blacktriangleleft s} = r_{t\blacktriangleleft -1} = 0$
    $\omega^z_{ts} \leftarrow z_{t\blacktriangleleft s} - z_{t\blacktriangleleft s-1} - z_{t+1\blacktriangleleft s} + z_{t+1\blacktriangleleft s-1}$
    $\Delta\omega_{ts} \leftarrow \omega^z_{ts} - \omega^r_{ts}$
    $\Delta r_{t\blacktriangleleft s} \leftarrow z_{t\blacktriangleleft s} - r_{t\blacktriangleleft s}$ // every $\Delta r_{t\blacktriangleleft s}$ is nonnegative, as $\underline{r} < \underline{z}$
    // Initialize $\underline{u}$ to be the same as $\underline{z}$.
    $u_{t\blacktriangleleft s} \leftarrow z_{t\blacktriangleleft s}$
$[h, l] \leftarrow$ the longest interval (i.e., maximize $l - h$) such that $\Delta r_{l\blacktriangleleft h} > 0$
$i' \leftarrow$ the smallest index in $[h+1, l]$ such that $i' = l$ or $\Delta\omega_{l-1,i'} > 0$ or $\Delta r_{l\blacktriangleleft i'} = 0$
if $i' = l$ **or** $\Delta\omega_{l-1,i'} > 0$
    $i \leftarrow i'$; $k \leftarrow l - 1$
else // $\Delta r_{l\blacktriangleleft i'} = 0$
    $k \leftarrow$ the greatest index in $[i'-1, l-2]$ such that $k = i' - 1$ or $\Delta\omega_{ki} > 0$ for some $i \in [h+1, i']$
    $i \leftarrow$ the smallest index in $[h+1, i']$ such that $i = k+1$ or $\Delta\omega_{ki} > 0$
// Update $\underline{u}$ to perform a reverse rank-1 barcode move with index tuple (l, k, i, h).
for $t \leftarrow k+1$ **to** l
    for $s \leftarrow h$ **to** $i - 1$
        $u_{t\blacktriangleleft s} \leftarrow z_{t\blacktriangleleft s} - 1$
return $\underline{u}$

FindDAGPath($\underline{r}, \underline{z}$)
// Given rank lists $\underline{r}$ and $\underline{z}$ such that $\underline{r} \le \underline{z}$, finds and writes rank lists proceeding
// from $\underline{r}$ to $\underline{z}$ by a sequence of rank-one abstract barcode moves.
if $\underline{r} \ne \underline{z}$
    $\underline{u} \leftarrow$ FindLastMove($\underline{r}, \underline{z}$)
    FindDAGPath($\underline{r}, \underline{u}$)
Write $\underline{z}$

Figure 9 Algorithm to find a sequence of rank-1 abstract barcode moves that proceed from a rank list $\underline{r}$ to a rank list $\underline{z}$, assuming that $\underline{r} \le \underline{z}$. FindDAGPath operates recursively, repeatedly invoking FindLastMove to identify the last move in the sequence.

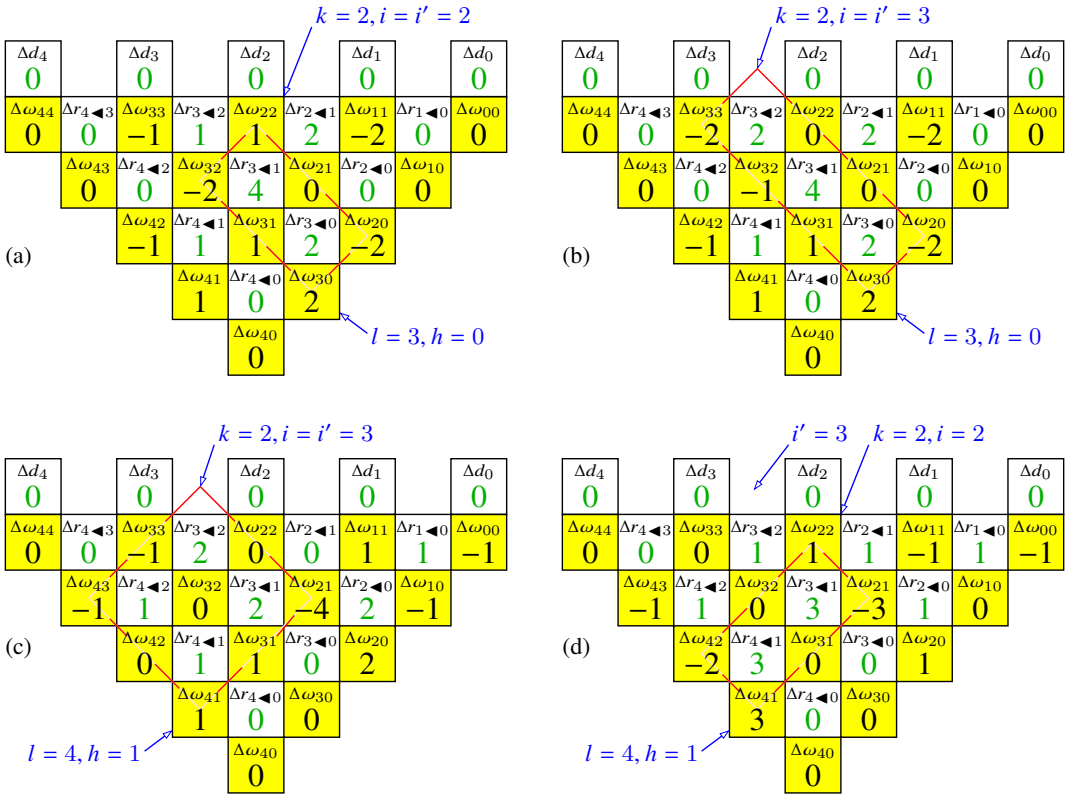

Figure 10 Four examples of reverse barcode moves found by the algorithm FindLastMove (shown prior to performing the reverse move). In each example, the algorithm finds a red rectangle such that its bottom corner lies at a bottommost positive $\Delta\omega_{lh}$, its top corner lies at a positive $\Delta\omega_{ki}$ or between two Δd's, and every Δr inside the rectangle is positive. In (b) and (c) the algorithm finds a reverse connecting move ($k = i - 1$), whereas in (a) and (d) it finds a reverse swapping move ($k \geq i$). In (a) and (b), Line 10 of FindLastMove determines the top corner of the rectangle (hence $k = l - 1$), whereas in (c) and (d), Lines 12 and 13 do (hence $k \leq l - 2$).

FindLastMove and our proofs use differences between the rank lists $\underline{r}$ and $\underline{z}$. Let the interval counts associated with $\underline{r}$ be ω^r_{ts} and the interval counts associated with $\underline{z}$ be ω^z_{ts}. Let

$$\Delta r_{t \blacktriangleleft s} = z_{t \blacktriangleleft s} - r_{t \blacktriangleleft s} \quad \text{and} \quad \Delta\omega_{ts} = \omega^z_{ts} - \omega^r_{ts} \quad \text{for all } t \text{ and } s \text{ satisfying } L \geq t \geq s \geq 0.$$

As we assume that $\underline{r} \leq \underline{z}$, no $\Delta r_{t \blacktriangleleft s}$ is negative. (No such constraint applies to $\Delta\omega_{ts}$.)

Figure 10 depicts examples of reverse moves found by FindLastMove, and thereby sheds light on Lines 7–13, the core of the algorithm. In each example, a red rectangle shows which reverse move the algorithm finds – specifically, the index tuple (l, k, i, h) of the move. Line 7 selects l and h so that the bottom corner of the red rectangle, $\Delta\omega_{lh}$, is a bottommost positive $\Delta\omega$. (Equivalently, the bottommost rank inside the rectangle, $\Delta r_{l \blacktriangleleft h}$, is a bottommost positive Δr.) Lines 8–13 search for values of k and i such that every Δr inside the rectangle is positive and the rectangle's top corner is either at a positive $\Delta\omega_{ki}$ or between two Δd's ($k = i - 1$) – these constraints guarantee that a reverse move yields a valid rank list. The hard part of our proof is showing that there always exists a rectangle satisfying these constraints.

Lines 8–9 check whether such a rectangle exists with $k = l - 1$. If so, Line 10 sets i to indicate the smallest such rectangle; see Figures 10(a) and (b) for examples. If not, the obstacle is some $\Delta r_{l \blacktriangleleft i'}$ equal to zero. In that case, Lines 12–13 find values of k and i that

satisfy the constraints; see Figures 10(c) and (d) for examples. Showing that Lines 12–13 always succeed is the part of the proof we must omit here. (It takes about two pages.)

We conclude with the hard part of Theorem 1.

▶ **Lemma 6.** *Let $\underline{r}$ and $\underline{z}$ be two valid rank lists for the same linear neural network (i.e., $r_{j\blacktriangleleft j} = z_{j\blacktriangleleft j} = d_j$ for all $j \in [0, L]$) such that $\underline{r} \leq \underline{z}$. Then there exists a sequence of valid rank lists that starts with $\underline{r}$ and ends with $\underline{z}$ such that each rank list after $\underline{r}$ can be obtained from the previous rank list in the sequence by a single rank-1 abstract barcode move. Moreover, the algorithm* FindDAGPath *in Figure 9 finds such a sequence.*

8 Final thoughts

Small moves are our tool for understanding stratum connections. But we speculate that longer moves on the fiber might be useful in practice to replace a neural network with an equivalent network more amenable to training by gradient descent algorithms, because barcode moves create farther-reaching flows, and longer moves make those flows stronger. A related idea is to modify gradient descent so it tends to move away from "bad" strata.

Given a smooth function $\ell(W)$, Trager, Kohn, and Bruna [23] call θ a *spurious critical point* if θ is a critical point of $\ell(\mu(\theta))$ but $\mu(\theta)$ is not a critical point of ℓ (where the domain of ℓ is restricted to matrices of rank $\min_{j=0}^{L} d_j$ or less). They show that there is no spurious critical point on $\mu^{-1}(W)$ if $\operatorname{rk} W = \min_{j=0}^{L} d_j$; also that there is no spurious critical point on any stratum $S_{\underline{r}}$ that satisfies, for some $j \in [1, L]$, both $r_{L\blacktriangleleft j} = d_L$ and $r_{j-1\blacktriangleleft 0} = d_0$.

We anticipate that geometric interpretations of cost functions in neural networks have the potential to become a thriving area, especially if we can incorporate ReLU activations.

Estimation of Conformal Metrics

Jérôme Taupin
Université Paris-Saclay, France
INRIA Saclay, Palaiseau, France

Abstract

We study deformations of the geodesic distances on a domain of $\mathbb{R}^N$ induced by a function called conformal factor. We show that under a positive reach assumption on the domain (not necessarily a submanifold) and mild assumptions on the conformal factor, geodesics for the conformal metric have good regularity properties in the form of a lower bounded reach. This regularity allows for efficient estimation of the conformal metric from a random point cloud with a relative error proportional to the Hausdorff distance between the point cloud and the original domain. We then establish convergence rates of order $n^{-1/d}$ that are close to sharp when the intrinsic dimension d of the domain is large, for an estimator that can be computed in $\mathcal{O}(n^2)$ time. Finally, this paper includes a useful equivalence result between ball graphs and nearest-neighbors graphs when assuming Ahlfors regularity of the sampling measure, allowing to transpose results from one setting to another.

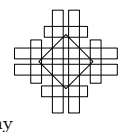
1 Introduction

This paper studies metrics over subsets of the Euclidean space $(\mathbb{R}^N, \|\cdot\|)$ obtained by conformal deformation of the shortest-path metric via a positive function. We are particularly interested in the regularity of such metrics and in their estimation via i.i.d. sampling of points.

▶ **Definition 1.1.** *Let $M \subset \mathbb{R}^N$ be a closed path-connected* domain *and $f : M \to \mathbb{R}_+^*$ be a* conformal factor. *For all $x, y \in M$ the* conformal distance *between x and y over M via f is defined as*

$$D_{M,f}(x,y) \overset{def}{=} \inf_{\gamma \in \Gamma_M(x,y)} \int_I f(\gamma(t)) \|\dot{\gamma}(t)\| \mathrm{d}t \tag{1}$$

where $\Gamma_M(x,y)$ is the set of all Lipschitz paths $\gamma : I \to M$ where $I = [a,b]$ is a nontrivial segment, $\gamma(a) = x$ and $\gamma(b) = y$. The quantity minimized over all paths γ is denoted



$$|\gamma|_f \overset{def}{=} \int_I f(\gamma(t)) \|\dot{\gamma}(t)\| \mathrm{d}t$$

and referred to as the conformal length of the curve γ via f. In the case where $f = 1$, we write $D_M(x,y) = D_{M,1}(x,y)$ and $|\gamma| = \int_I \|\dot{\gamma}\|$, respectively the distance between x and y induced by the ambient metric over M and the Euclidean length of a curve γ.

In the following, to ensure regularity of the conformal metric, the domain M is assumed to have positive reach τ_M, which we recall is defined as the supremum of all $r > 0$ such that any point in the offset $M^r = \{x \in \mathbb{R}^N : d(x,M) < r\}$ has a unique projection onto M – where $d(x,M) = \inf_{y \in M} \|x - y\|$ denotes the distance from point x to subset M – see [10]. Moreover, the conformal factor f is assumed to be κ-Lipschitz and lower bounded by $f_{\min} > 0$. These are the sole assumptions used in this paper regarding M and f.

Notice that f is defined over M in Definition 1.1 as paths are constrained to the domain. Since any Lipschitz function defined over a subset of $\mathbb{R}^N$ can be extended to the whole space preserving its Lipschitz property and lower bound (see [16, Theorem 1] for instance), one may assume without loss of generality that f is defined over the entire space $\mathbb{R}^N$, which is useful to estimate the conformal metric efficiently. The connectedness and positive reach of M ensure that for any endpoints $x, y \in M$, there exists a Lipschitz path from x to y in M, so that $\Gamma_M(x, y)$ is always nonempty and $D_{M,f}(x, y)$ is always finite. This can be deduced from Lemma 2.1 below. Most of the time, a path γ is chosen to be parameterized with constant velocity, i.e., $\|\dot{\gamma}\|$ is constant over I, with I being either $[0, 1]$ or $[0, |\gamma|]$. The latter is referred to as an *arc-length* parameterization, where $\|\dot{\gamma}\| = 1$ almost everywhere.

The *induced metric* $D_M = D_{M,1}$ is the metric induced by the ambient space $\mathbb{R}^N$ onto M. If M is a $\mathcal{C}^1$ submanifold of $\mathbb{R}^N$ and f is $\mathcal{C}^1$, $D_{M,f}$ is a Riemannian metric with tensor $f(x)^2 \cdot g_x$ at point $x \in M$ where g_x is the tensor of the induced metric D_M at x. The term "conformal" used in this paper is borrowed from the Riemannian literature. Finally, if μ is a measure over a submanifold M with density ρ with regard to (w.r.t.) the volume form of M and f is a negative power of the density ρ, $D_{M,f}$ has already been studied and is sometimes referred to as the *Fermat distance* [13]. This particular case is one of the main motivations for this article as the Fermat distance has been used for various practical applications, see for instance [12] and the references therein. Particular examples of the conformal factor f are discussed in Section 5.

Conformal metrics are included in the more general class of length-spaces, for which it is known that the infimum in Definition 1.1 is in fact a minimum [7, Theorem 2.5.23]. That is, for all $x, y \in M$ there exists a path $\gamma \in \Gamma_M(x, y)$ such that $D_{M,f}(x, y) = |\gamma|_f$, called a *minimizing geodesic* – and shortened to geodesic in this paper for brevity. Denote $\Gamma^\star_{M,f}(x, y)$ the set of such geodesics between two endpoints x and y along with $\Gamma^\star_{M,f} = \bigcup_{x \neq y \in M} \Gamma^\star_{M,f}(x, y)$ the set of all geodesics w.r.t. the conformal metric. We discuss in Section 2 the regularity of geodesics w.r.t. $D_{M,f}$ and show in Proposition 2.4 that under the aforementioned assumptions on M and f, geodesics have positive reach that is lower bounded by an explicit constant depending on the reach of the domain and on the conformal factor. In particular, any geodesic may be parameterized as a $\mathcal{C}^{1,1}$ curve with an explicit upper bound on the Lipschitz constant of its first derivative.

We then show in Section 3 that the conformal metric can be approached using polygonal paths on a weighted graph built from a point cloud $X \subset M$, provided that the graph only contains edges of length at most some threshold r and that X is close to M in Hausdorff distance. The small edges condition ensures that paths on the graph cannot venture too far outside the domain. This kind of construction is the same as the one used for the Isomap algorithm [5], although we allow more generality by adapting the weights to the conformal factor f. When $f = 1$ and M is a geodesically convex $\mathcal{C}^2$ submanifold, [5] provides a relative error bound of order $\frac{r^2}{\tau^2} + \frac{\rho}{r}$ where τ is the minimum radius of curvature of M and ρ denotes the Hausdorff distance between M and X. The term depending on ρ can be made quadratic as shown in [2], where an assumption called geodesic smoothness that is slightly weaker than that of a positive reach allows to obtain a bound of order $Ar + \frac{\rho^2}{r^2}$ where A depends on the assumption. This assumption however lacks precision when comparing distances at a local scale which results in the first term being of order r instead of r^2. By using a positive reach assumption instead, the upper bound can be further improved to $\frac{r^2}{\tau^2} + \frac{\rho^2}{r^2}$ according to [3] where τ is the reach of the domain, although the setup also implicitly assumes that the domain M is a smooth manifold isometric to a convex domain. Going back to our setup, we adapt these prior works to fit any conformal change. Under some condition on the

weight function used, that in particular always holds for the induced metric, we establish in Theorem 3.5 the same upper bound on the approximation error as in [3], that is $\frac{r^2}{\tau^2} + \frac{\rho^2}{r^2}$ where τ is the explicit lower bound on the reach of any geodesic provided by Proposition 2.4. This result emphasizes the fact that the only assumption on the domain needed for this level of precision is that of a positive reach. The approximation error can thus be made proportional to the Hausdorff distance between the point cloud and the domain by choosing appropriately $r \asymp \sqrt{\tau\ \rho}$. When the conformal factor f is unknown, replacing it with an estimate g does not alter the results provided that g is close enough to f, as shown in Lemma 3.6.

Assuming that $X = X_n$ is the outcome of $n \geq 1$ i.i.d. samples from a d-standard measure μ over M, we study in Section 4 the estimator of $D_{M,f}$ built on X_n following the construction of Section 3. This estimator is shown in Theorem 4.2 to converge to $D_{M,f}$ at a rate of $n^{-1/d}$ provided that f is known or can be estimated with same rate. This rate follows from Theorem 3.5 and the fact that X_n is known to converge to M in Hausdorff distance at a rate of $n^{-1/d}$. In particular, this allows for efficient estimation of the induced metric with the sole assumption that M has positive reach. This convergence is shown using ball graphs. However, practical estimation is made easier by using nearest-neighbors graphs instead, in part because it does not require to know the intrinsic dimension d to obtain an optimal convergence speed. For this reason, we show in Theorem 4.5 that it is possible to retrieve the same convergence speed when replacing the ball graph in the estimator with a k-nearest-neighbors graph with $k \asymp \sqrt{n}$. To do so, we establish an equivalence with high probability between nearest-neighbors graphs and ball graphs when their respective parameters are properly scaled and the underlying measure is d-Ahlfors, see Proposition 4.4. Finally, the nearest-neighbors estimator of the conformal distance between two fixed points may be computed in $\mathcal{O}(n^2)$ if the time complexity of evaluating f is considered constant. Under the stronger assumption that M is a $\mathcal{C}^k$ submanifold of dimension d with $k \geq 2$, the minimax optimal convergence rate for the induced metric is known to be of order $n^{-k/d}$ [1]. When only assuming positive reach and no differential structure on M, the discussion of the optimal minimax rate proves to be harder as we are not able to match the upper bound of $n^{-1/d}$ and obtain a lower bound of order $n^{-1/(d-1/2)}$ instead, see Theorem 4.6. We discuss with more details the comparison between our setup and the $\mathcal{C}^k$ case in Section 4.4.

Technical proofs are deferred to the appendix which is available in the full version [17].

2 Regularity of the geodesics for the conformal metric

Recall that the term "geodesic" refers in this paper to a curve that achieves a global minimum of the conformal length. In this section we study the regularity of the geodesics w.r.t. $D_{M,f}$. We show that geodesics are $\mathcal{C}^{1,1}$ curve with reach bounded from below by a constant depending only on τ_M, κ and $f_{\min}$. This regularity property is crucial to obtain a good approximation of the geodesics by polygonal paths. The reach of a set can be characterized through the local distortion of the induced metric compared to the Euclidean metric.

▶ **Lemma 2.1** ([6, Theorem 1]). *The reach of M may be expressed as*

$$\tau_M = \sup\left\{ r > 0 \ : \ \forall x, y \in M,\ \|x-y\| < 2r \Rightarrow D_M(x,y) \leq 2r \arcsin\left(\frac{\|x-y\|}{2r}\right)\right\} .$$

Given a path $\gamma \in \Gamma_M$ parameterized over an interval I and without self-intersection, denote τ_γ the reach of the curve $\gamma(I) \subset \mathbb{R}^N$ along with $D_\gamma = D_{\gamma(I)}$ the induced metric over the curve for short. $D_\gamma(x,y)$ is nothing more than the length of the curve $\gamma(I)$ between two intermediate point x and y. In particular if x and y are the endpoints of γ then $D_\gamma(x,y) = |\gamma|$.

One consequence of Lemma 2.1 is that the length of a geodesic between two points at most $2\tau_M$ apart is upper bounded by the length of an arc of radius τ_M between both points. That is, if $x, y \in M$ and $\|x - y\| < 2\tau_M$ then

$$D_M(x, y) \leq 2\tau_M \arcsin\left(\frac{\|x - y\|}{2\tau_M}\right) . \tag{2}$$

Moreover, if γ is a geodesic, it then induces a geodesic between any of the points it goes through, which implies that D_γ is exactly the restriction of D_M to the curve γ. Then, another consequence of the characterization of Lemma 2.1 is that the reach of M is the minimal reach of any geodesic, that is

$$\tau_M = \inf_{\gamma \in \Gamma^\star_M} \tau_\gamma .$$

We now introduce a notion of reach associated with the conformal deformation of M by f using the same point of view of the metric and its geodesics.

▶ **Definition 2.2.** *The* conformal reach *of M via f is defined as the minimal reach of any geodesic w.r.t. the conformal metric, that is*

$$\tau_{M,f} \overset{def}{=} \inf_{\gamma \in \Gamma^\star_{M,f}} \tau_\gamma .$$

In the case of the induced metric this notion coincides with the usual notion of reach, that is $\tau_{M,1} = \tau_M$. The characterization given by Lemma 2.1 also holds for the conformal reach.

▶ **Proposition 2.3.** *The conformal reach of M via f may be expressed as*

$$\tau_{M,f} = \sup \left\{ \begin{array}{c} r > 0 \ : \ \forall x, y \in M, \forall \gamma \in \Gamma^\star_{M,f}(x, y), \\ \|x - y\| < 2r \Rightarrow |\gamma| \leq 2r \arcsin\left(\dfrac{\|x - y\|}{2r}\right) \end{array} \right\} . \tag{3}$$

Beware that Equation (3) involves geodesic w.r.t. the conformal metric $D_{M,f}$, but compares their Euclidean length – not conformal – to the one of an arc of radius r. The proof is straightforward and included in the full version [17]. Using Proposition 2.3, we are able to lower bound the reach of any geodesic w.r.t. $D_{M,f}$.

▶ **Proposition 2.4.** *Assume that M has positive reach $\tau_M > 0$ and that f is κ-Lipschitz and lower bounded by $f_{\min} > 0$. Then any conformal geodesic γ w.r.t. $D_{M,f}$ has positive reach $\tau_\gamma > 0$. Precisely, the conformal reach of M via f is lower bounded as follows.*

$$\tau_{M,f} \geq \mathcal{T}_{M,f} \quad \textit{where} \quad \mathcal{T}_{M,f} \overset{def}{=} \min\left(\frac{\tau_M}{2} \ , \ \frac{f_{\min}}{8\kappa}\right) .$$

The reasoning behind Proposition 2.4 is the following. If the reach of a geodesic γ w.r.t. $D_{M,f}$ is small compared to τ_M, then according to Proposition 2.3 there exists a path in M significantly shorter than γ Euclidean-wise. If τ_γ is also small compared to $f_{\min}/\kappa$, then this path is shown to also have a shorter conformal length than γ due to the properties of f, which implies a contradiction with the geodesic nature of γ. This reasoning is detailed in [17, Appendix B.2]. Now, consider an arc-length parameterized geodesic $\gamma : I \to M$ w.r.t. $D_{M,f}$, i.e., such that $\|\dot\gamma\| = 1$ almost everywhere over I. Being a geodesic, γ has no self-intersection. Then, stating that γ has positive reach is equivalent to stating that γ is a $\mathcal{C}^{1,1}$ curve, i.e., that $\dot\gamma$ is Lipschitz w.r.t. the angular distance. Precisely, for all $t, s \in I$,

$$\angle(\dot\gamma(t), \dot\gamma(s)) \leq \frac{|t - s|}{\tau_\gamma} . \tag{4}$$

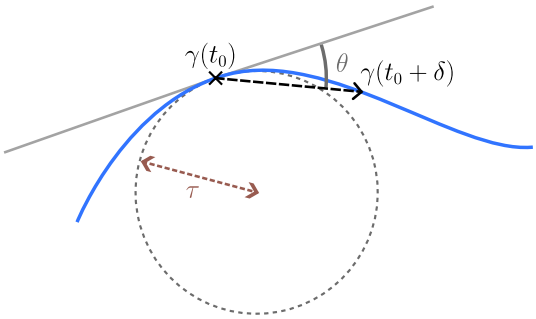

Figure 1 Bounding the angular velocity of a path with positive reach.

See [10, Remark 4.20] and [15, Theorem 4] for references. Equation (4) allows to obtain a finer control on the approximation error of the polygonal paths on the graph by upper bounding efficiently the difference between small successive steps $\gamma(t) - \gamma(t-\delta)$ and $\gamma(t+\delta) - \gamma(t)$ of a geodesic path.

▶ **Lemma 2.5.** *Let $\gamma : [0, |\gamma|] \to \mathbb{R}^N$ be an arc-length parameterized curve without self-intersection and with positive reach τ_γ. Then for all $t_0 \in [0, |\gamma|]$ and $\delta \in (0, \frac{\pi}{2}\tau_\gamma]$ such that $[t_0 - \delta, t_0 + \delta] \subset [0, |\gamma|]$, the angle between the velocity vector of γ at t_0 and the direction from $\gamma(t_0)$ to $\gamma(t_0 + \delta)$ is upper bounded as follows:*

$$\angle\big(\gamma(t_0+\delta) - \gamma(t_0), \dot\gamma(t_0)\big) \leq \frac{\delta}{2\tau_\gamma} \ . \tag{5}$$

Moreover, denoting $v^- = \gamma(t_0) - \gamma(t_0 - \delta)$ and $v^+ = \gamma(t_0 + \delta) - \gamma(t_0)$, the difference between small steps of the path on both side from t_0 is upper bounded as follows:

$$\left\| \frac{v^+}{\|v^+\|} - \frac{v^-}{\|v^-\|} \right\| \leq \frac{1}{\tau_\gamma} \min\left(\|v^+\|, \|v^-\|\right) \ . \tag{6}$$

Lemma 2.5 is key to obtain an approximation error of the conformal metric proportional to the Hausdorff distance between the domain and a point cloud. A proof is provided in [17, Appendix A.1] and Equation (5) is illustrated by Figure 1.

3 Polygonal approximation of the conformal metric

Consider a point cloud $X \subset M$ of points sampled from the domain. If the point cloud approximates well the domain, it is possible to estimate the conformal distance over M through weighted polygonal paths built over X within a small margin of error. Assuming that f is known, the edges of the polygonal path are weighted using f to approximate the conformal distance between their endpoints. The degree of approximation of M by X is measured using the Hausdorff distance

$$d_{\mathrm{H}}(M, X) \stackrel{\text{def}}{=} \max\left(\sup_{x\in M} d(x, X) \ , \ \sup_{x\in X} d(x, M)\right)$$

which simplifies to $d_{\mathrm{H}}(M, X) = \sup_{x\in M} d(x, X)$ assuming that $X \subset M$. By definition, any point in M is at distance at most $d_{\mathrm{H}}(M, X)$ from a point in X.

The idea behind the polygonal approximation is the following. Consider a geodesic $\gamma \in \Gamma^\star_{M,f}(x, y)$ between two points $x, y \in M$. If $d_{\mathrm{H}}(M, X)$ is small, there exists a polygonal path over X that follows closely the trajectory of γ. Assuming that the edges of this path

are equipped with appropriate weights to simulate the conformal distance between their endpoints, the total weight of the polygonal path should be close to the conformal length $|\gamma|_f$. Moreover, since γ is a geodesic, polygonal paths should not be able to have a weight much smaller than $|\gamma|_f$. This is ensured by using only short edges, which allows the weights to approximate well the conformal length by preventing shortcuts outside the domain. In the end, the shortest weighted path on the graph is expected to retrieve $|\gamma|_f = D_{M,f}(x, y)$.

3.1 Weighted graphs

Let us now describe formally this construction. The polygonal approximation of $D_{M,f}$ is defined as the metric of an appropriate weighted graph on a point cloud X.

▶ **Definition 3.1.** *Let $X \subset \mathbb{R}^N$ be a finite point cloud.*

- *For all $r > 0$, the* r-ball graph *over X is denoted $G_r(X)$ and is the graph of vertex set X and with an edge between points x and y if and only if $\|x - y\| \leq r$.*
- *For all integer $k \geq 1$, the* k-nearest-neighbors graph *(or k-NN graph) over X is denoted $\mathcal{G}_k(X)$ and is the graph of vertex set X with an edge between two points x and y if and only if x (or y) is among the k nearest points of X to y (or x) excluding self.*

In both cases, the parameter r or k is referred to as the threshold *of the graph.*

Ball graphs are more convenient to study whereas NN graphs are more practical, see Section 4.2. We define the polygonal metric in both contexts. The graph used is equipped with a weight function to approximate the conformal length of its edges.

▶ **Definition 3.2.** *Given a function $f : \mathbb{R}^N \to \mathbb{R}_+^*$, consider the weight functions*

$$w_{f,q}(x, y) \overset{def}{=} \frac{\|x - y\|}{2(q-1)} \left(f(x) + 2 \sum_{k=2}^{q-1} f\left(\frac{q-k}{q-1} x + \frac{k-1}{q-1} y \right) + f(y) \right)$$

defined for any $q \geq 2$ and $x, y \in \mathbb{R}^N$, along with

$$w_{f,\infty}(x, y) \overset{def}{=} \|x - y\| \int_0^1 f\big((1-t)x + ty\big) \mathrm{d}t \ .$$

The parameter $q \in \{2, \ldots, \infty\}$ is referred to as the resolution *of the weights.*

The weight function $w_{f,q}$ is meant to approximate the conformal distance between the endpoints of an edge. Proposition 3.3 below shows that it is indeed the case when the endpoints are close, which is the reason why graphs with small edges are used. Recall that we have assumed without loss of generality that f is defined over the whole space, allowing its evaluation outside M when $q \neq 2$. As q grows, the weight $w_{f,q}$ becomes more accurate and converges to the weight with infinite resolution $w_{f,\infty}$, the latter being exactly the conformal length of the straight path. However, the computational cost is linear with q and there is no closed-form formula for $w_{f,\infty}$ in general. On the other hand,

$$w_{f,2}(x, y) = \|x - y\| \frac{f(x) + f(y)}{2}$$

is the simplest choice for the weights and may be more suitable if evaluating f is possible only at points in X. Note that the weight $w_{f,q}$ is the optimal approximation of $w_{f,\infty}$ using only q samples of the Lipschitz function f. Under stronger assumptions on f such as $\mathcal{C}^k$ regularity, other definitions would be better suited.

▶ **Proposition 3.3.** *For all $x, y \in M$ such that $\|x-y\| \leq \tau_{M,f}$,*

$$\left|1 - \frac{w_{f,q}(x,y)}{D_{M,f}(x,y)}\right| \leq \frac{\kappa}{4f_{\min}} \frac{\|x-y\|}{q-1} + \frac{\|x-y\|^2}{16\mathcal{T}_{M,f}^2} \,. \tag{7}$$

and we denote $\delta_q(\|x-y\|)$ this upper bound. The first term in Equation (7) is to be interpreted as 0 if $q = \infty$ and represents the offset between $w_{f,q}$ and $w_{f,\infty}$, whereas the second term represents the offset between $w_{f,\infty}$ and $D_{M,f}$.

Proposition 3.3 shows that the conformal metric $D_{M,f}$ may be approximated locally by the weights $w_{f,q}$. Note that for fixed resolution q in the r-ball graph, the distortion between the weights and the conformal distances is linear in r. However, by choosing q to be inversely proportional to r, the distortion becomes quadratic in r. The proof for Proposition 3.3 is provided in [17, Appendix B.3]. We now introduce the polygonal approximation of the conformal metric as the metric of the weighted graph built on X.

▶ **Definition 3.4.** *Consider a point cloud $X \subset \mathbb{R}^N$, function $f : \mathbb{R}^N \to \mathbb{R}_+^*$ and parameters $r > 0$ or $k \geq 1$ and $q \in \{2, \dots, \infty\}$. The polygonal metric associated with these parameters is defined between two points $x, y \in \mathbb{R}^N$ as*

$$\widehat{D}_{X,f}(x,y) \overset{def}{=} \min_{(x_0,\dots,x_K)} \sum_{k=0}^{K-1} w_{f,q}(x_k, x_{k+1}) \tag{8}$$

where the minimum is taken over the set of paths $(x_0, \dots, x_K)$ such that $x_0 = x$ and $x_k = y$ in the graph G that is chosen either as the r-ball graph $G_r(X \cup \{x,y\})$ or the k-NN graph $\mathcal{G}_k(X \cup \{x,y\})$.

The choice of a ball graph or a NN graph along with the threshold r or k and the resolution q of the weights are left implicit when writing $\widehat{D}_{X,f}$ to avoid heavy notations. Note that when the endpoints x and y do not belong to the point cloud, the distance $\widehat{D}_{X,f}(x,y)$ is computed by adding them to the graph. As a result, $\widehat{D}_{X,f}$ induces a distance over X but not over M. Indeed, when considering endpoints outside X, $\widehat{D}_{X,f}$ may not satisfy the triangular inequality due to the set of possible paths depending on the endpoints.

3.2 Metric approximation

To evaluate how efficient is the approximation of a metric, the error between the true distances and their estimation may be measured using either of the multiplicative loss functions

$$\ell_{\infty,M}(D', D) \overset{\text{def}}{=} \sup_{x \neq y \in M} \left|\frac{D'(x,y) - D(x,y)}{D'(x,y) \vee D(x,y)}\right| \quad \text{and} \quad l_{\infty,M}(D'|D) \overset{\text{def}}{=} \sup_{x \neq y \in M} \left|1 - \frac{D'(x,y)}{D(x,y)}\right| .$$

In the case where D' takes infinite values – which happens for instance when D' is the metric of a non-connected graph – we let $\ell_{\infty,M}(D', D) = 1$ and $l_{\infty,M}(D'|D) = +\infty$. The inequality

$$\ell_{\infty,M}(D', D) \leq l_{\infty,M}(D'|D) \leq \frac{\ell_{\infty,M}(D', D)}{1 - \ell_{\infty,M}(D', D)} \tag{9}$$

holds in general, so that both losses are equivalent. The loss $\ell_{\infty,M}$ is however easier to manipulate in some situations as it is symmetric and upper bounded by 1. Thanks to the regularity of geodesics stated by Proposition 2.4 and the local approximation of the conformal metric by the weights $w_{f,q}$ stated by Proposition 3.3, we are able to show that the conformal metric $D_{M,f}$ is approximated by the polygonal metric from Definition 3.4 using the r-ball graph.

▶ **Theorem 3.5.** *Let $X \subset M$ be a point cloud, $r > 0$ and $q \in \{2, \dots, \infty\}$ two parameters. Assume that $4d_H(M, X) \leq r \leq \mathcal{T}_{M,f}$. Then the approximation $\widehat{D}_{X,f}$ defined in Definition 3.4 using the r-ball graph with resolution q satisfies*

$$l_{\infty,M}\big(\widehat{D}_{X,f} | D_{M,f}\big) \leq \frac{1}{32\mathcal{T}_{M,f}} \frac{r}{q-1} + \frac{r^2}{8\mathcal{T}_{M,f}^2} + 56\frac{d_H(M,X)^2}{r^2} \ . \tag{10}$$

The first term in Equation (10) *is to be interpreted as* 0 *if* $q = \infty$.

Let us describe the reasoning behind Theorem 3.5. Given $x \neq y \in X$, paths in $G_r(X)$ cannot create significant shortcuts outside M as $r \leq \tau_{M,f}$. This is illustrated by Proposition 3.3 from which it can be deduced that

$$\widehat{D}_{X,f}(x,y) \geq \big(1 - \delta_q(r)\big) D_{M,f}(x,y) \tag{11}$$

and, assuming that $\|x - y\| \leq r$,

$$\widehat{D}_{X,f}(x,y) \leq \big(1 + \delta_q(r)\big) D_{M,f}(x,y) \ . \tag{12}$$

As for when $\|x - y\| > r$, consider a geodesic $\gamma \in \Gamma^\star_{M,f}(x,y)$. Decompose γ into sections of length at most $r - 2d_{\mathrm{H}}(M,X)$ and for each intermediate point select a point in X at distance at most $d_{\mathrm{H}}(M,X)$. This process draws a polygonal path in $G_r(X \cup \{x,y\})$ as it uses edges of length at most r. Summing the approximation error from Proposition 3.3 between each edge of this path and the corresponding section of γ eventually yields the upper bound

$$\widehat{D}_{X,f}(x,y) \leq \left(1 + \delta_q(r) + c_1 \frac{d_{\mathrm{H}}(M,X)}{\mathcal{T}_{M,f}} + c_2 \frac{d_{\mathrm{H}}(M,X)^2}{r^2}\right) D_{M,f}(x,y) \tag{13}$$

when $\|x - y\| > r$ and where c_1 and c_2 are universal constants. The positive reach of γ and Lemma 2.5 play a crucial role in obtaining terms of order $d_{\mathrm{H}}(M,X)/\mathcal{T}_{M,f}$ and $d_{\mathrm{H}}(M,X)^2/r^2$ instead of $d_{\mathrm{H}}(M,X)/r$. Together, Equations (11)–(13) eventually imply Equation (10). The details of this reasoning are provided in [17, Appendix B.4]. The upper bound in Equation (10) is made proportional to $d_{\mathrm{H}}(M,X)$ by setting

$$r \asymp \sqrt{\mathcal{T}_{M,f}\ d_{\mathrm{H}}(M,X)} \quad \text{and} \quad q \asymp \sqrt{\frac{\mathcal{T}_{M,f}}{d_{\mathrm{H}}(M,X)}} \ .$$

In the case of the induced metric with $f = 1$, the first term in the right-hand side of Equation (10) disappears, and the error is of order $r^2/\tau_M^2 + d_{\mathrm{H}}(M,X)^2/r^2$ similarly to the one obtained in [3]. In the general conformal case, we keep this magnitude of error by setting the resolution q to be at least of order $1/r$. If it is not possible to evaluate f outside the point cloud X, setting $q = 2$ instead yields an error of order $r/\mathcal{T}_{M,f} + d_{\mathrm{H}}(M,X)^2/r^2$ which is slightly worse. A similar upper bound was achieved in [2] for the induced metric and the term linear in r was due to the geodesically smooth assumption used in the paper being slightly weaker than a positive reach assumption. In particular, the latter allows for an efficient local estimation in the form of Equation (12). The main takeaway of Theorem 3.5 is that the crucial assumption to achieve an approximation error proportional to $d_{\mathrm{H}}(M,X)$ is the positive reach. In particular, the domain need not be $\mathcal{C}^2$, or even a submanifold.

3.3 Unknown conformal factor

In general, f may not be known and needs to be estimated from the data. The polygonal metric $\widehat{D}_{X,g}$ from Definition 3.4 can be defined for any function $g : \mathbb{R}^N \to \mathbb{R}_+^*$ without the need of Lipschitz and lower bound assumptions. Then, the approximation error between $\widehat{D}_{X,g}$ and $D_{M,f}$ is upper bounded by the sum of the error w.r.t. the conformal factor and the error w.r.t. the domain.

▶ **Lemma 3.6.** *Let $f : \mathbb{R}^N \to \mathbb{R}_+$ a function lower bounded by $f_{\min}$, $X \subset M$ a point cloud and $g : \mathbb{R}^N \to \mathbb{R}_+^*$ such that $\|g - f\|_\infty \leq \frac{1}{2} f_{\min}$. Then*

$$\ell_{\infty,M}\big(\widehat{D}_{X,g}, D_{M,f}\big) \leq \frac{2}{f_{\min}}\|g - f\|_\infty + 2\ell_{\infty,M}\big(\widehat{D}_{X,f}, D_{M,f}\big) \ . \tag{14}$$

This result holds regardless of the type of graph, threshold and resolution as long as they are shared between $\widehat{D}_{X,f}$ and $\widehat{D}_{X,g}$.

The proof of Lemma 3.6 consists in straightforward computations and is deferred to [17, Appendix B.5]. As a consequence, in the context of estimation of the domain M by a point cloud X_n as in Section 4 and of the conformal factor f by a function $f_n : \mathbb{R}^N \to \mathbb{R}_+$, the rate of convergence of $\widehat{D}_{X_n,f_n}$ towards $D_{M,f}$ is the slowest rate of convergence among that of $\widehat{D}_{X_n,f}$ towards $D_{M,f}$ and that of f_n towards f. Recall that f_n is not required to satisfy the Lipschitz and lower bounded assumptions for the polygonal metric $\widehat{D}_{X_n,f_n}$ to be defined and for Lemma 3.6 to hold. It may also be defined only over X_n if the resolution is set to $q = 2$.

4 Estimation from random samples

In this section we transpose Theorem 3.5 to a probabilistic setup where the point cloud X is replaced with a random point cloud X_n consisting of n i.i.d. samples from a probability measure μ with support M. The following assumptions on μ are needed to ensure that X_n covers M efficiently as n grows, allowing to deduce explicit convergence rates for the estimator $\widehat{D}_{X_n,f}$ from Theorem 3.5.

▶ **Definition 4.1.** *Consider a probability measure μ with support $M \subset \mathbb{R}^N$ and $d \geq 2$.*

- *The measure μ is d-standard with lower constant $c_\mu > 0$ if for all $x \in M$ and $r > 0$,*

$$\mu\big(B(x,r)\big) \geq c_\mu r^d \wedge 1$$

  where $B(x,r)$ denotes the open ball centered at x with radius r.

- *The measure μ is d-Ahlfors with lower and upper constants $c_\mu > 0$ and $C_\mu > 0$ if for all $x \in M$ and $r > 0$,*

$$c_\mu r^d \wedge 1 \leq \mu\big(B(x,r)\big) \leq C_\mu r^d \ .$$

If μ is d-standard with lower constant c_μ, we also denote $L_\mu = c_\mu^{-1/d}$ which is related to the size of the support. The definition ensures that $\mu\big(\mathrm{B}(x, L_\mu)\big) = 1$ for all $x \in M$, hence $L_\mu \geq \mathrm{diam}(M)$. Moreover, d acts as the intrinsic dimension of the support M of μ. For instance, any measure with a density ρ w.r.t. the volume measure of a submanifold of $\mathbb{R}^N$ of dimension d is d-Ahlfors if ρ is bounded above and below. The d-standard assumption ensures that the random point cloud X_n converges to M in Hausdorff distance. Ahlfors regularity is a stronger assumption and is needed to show the equivalence between ball graphs and NN graphs in Proposition 4.4.

4.1 Convergence of the ball graph estimator

We first discuss the case of a ball graph estimator. It is known that if μ is d-standard, then $d_{\mathrm{H}}(M, X_n)$ is of order $L_\mu(\log(n)/n)^{1/d}$ at most, see [17, Appendix A.2]. This convergence combined with Theorem 3.5 allows to derive convergence rates for the estimation of $D_{M,f}$.

▶ **Theorem 4.2.** *Assume that X_n is the result of n i.i.d. samples from a d-standard probability measure μ with support M. Consider the estimator $\widehat{D}_{X_n,f}$ from Definition 3.4 using the r-ball graph with resolution q where r and q are specified below. Then there exists a constant n_0 depending on L_μ, $\mathcal{T}_{M,f}$ and d such that for all $n \geq n_0$ the following holds.*

- *If $r = 8\sqrt{L_\mu \mathcal{T}_{M,f}} \left(\frac{\log(n)}{n}\right)^{\frac{1}{2d}}$ and $q \geq 1 + 4\frac{\mathcal{T}_{M,f}}{r}$, then*

$$\mathbb{E}\left[\ell_{\infty,M}\big(\widehat{D}_{X_n,f}, D_{M,f}\big)\right] \leq 16\frac{L_\mu}{\mathcal{T}_{M,f}}\left(\frac{\log(n)}{n}\right)^{\frac{1}{d}} . \tag{15}$$

- *If $r = 8L_\mu^{2/3}\mathcal{T}_{M,f}^{1/3}\left(\frac{\log(n)}{n}\right)^{\frac{2}{3d}}$ and $q = 2$, then*

$$\mathbb{E}\left[\ell_{\infty,M}\big(\widehat{D}_{X_n,f}, D_{M,f}\big)\right] \leq 8\left(\frac{L_\mu}{\mathcal{T}_{M,f}}\right)^{\frac{2}{3}}\left(\frac{\log(n)}{n}\right)^{\frac{2}{3d}} . \tag{16}$$

The first case in Theorem 4.2 includes $q = \infty$. There is no use setting q to be greater than the indicated threshold of order $\mathcal{T}_{M,f}/r$, as the term in the upper bound depending on q becomes negligible past this threshold. Note that the optimal choice for r and q requires the knowledge of L_μ, $\mathcal{T}_{M,f}$ and most importantly d. Theorem 4.2 is stated with these choices of parameters to highlight the optimal theoretical dependency in these constants. For practical purposes, the knowledge of L_μ and $\mathcal{T}_{M,f}$ is not actually needed as, in general, any choice of $r \asymp (\log(n)/n)^{1/2d}$ and $q \gtrsim 1/r$ yields a convergence rate of $(\log(n)/n)^{1/d}$. Likewise, any choice of $r \asymp (\log(n)/n)^{2/3d}$ and $q = 2$ yields a convergence rate of $(\log(n)/n)^{2/3d}$. It is not possible however to get rid of the dependency in d for the range parameter r without altering the convergence rate. To circumvent this issue, one may use the NN graph instead, for which the optimal choice of the parameter is shown in Section 4.2 to be $k = \sqrt{n}$ which does not depend on d. Theorem 4.2 is derived directly from Theorem 3.5 and the convergence of X_n to M in Hausdorff distance. The precise computations are deferred to [17, Appendix C.1]. In the case of the induced metric, the weight function $w_{f,q}$ becomes the Euclidean distance regardless of the resolution and $\mathcal{T}_{M,f}$ is replaced with τ_M.

▶ **Corollary 4.3.** *Under the same assumptions as in Theorem 4.2 and when $f = 1$, there exists a constant n_0 depending on L_μ, τ_M and d such that for all $n \geq n_0$, setting $r = 8\sqrt{L_\mu \tau_M}(\log(n)/n)^{1/2d}$, the estimator $\widehat{D}_{X_n,1}$ satisfies*

$$\mathbb{E}\left[\ell_{\infty,M}\big(\widehat{D}_{X_n,1}, D_M\big)\right] \leq 16\frac{L_\mu}{\tau_M}\left(\frac{\log(n)}{n}\right)^{\frac{1}{d}} .$$

Recall that in the case of a submanifold of class $\mathcal{C}^k$ with $k \geq 2$ and dimension d, the optimal convergence rate for the estimation of the induced metric is $n^{-k/d}$ [1]. Corollary 4.3 extends the upper bound to any set of positive reach with the convergence rate $n^{-1/d}$.

4.2 Convergence of the nearest-neighbors graph estimator

We now treat the case of a NN graph estimator, by observing that for adequate choice of r and k, the r-ball graph and k-NN graph are similar. Indeed, assuming that μ is d-Ahlfors regular, a ball of radius r is expected to contain between $c_\mu n r^d$ and $C_\mu n r^d$ points from X_n.

▶ **Proposition 4.4.** *Let μ be a d-Ahlfors measure as defined in Definition 4.1 and X_n a point cloud sampled i.i.d. from μ. Let $k \geq 1$, $\varepsilon \in (0,1)$ and define*

$$r_- = \left((1-\varepsilon)\frac{k}{C_\mu(n-1)}\right)^{\frac{1}{d}} \quad \text{and} \quad r_+ = \left(\frac{1}{1-\varepsilon}\frac{k}{c_\mu(n-1)}\right)^{\frac{1}{d}} .$$

Then with probability at least $1 - 2ne^{-\varepsilon^2 k/2}$*, the* k*-NN graph* $\mathcal{G}_k(X_n)$ *is enclosed between two ball graphs* $G_{r_-}(X_n)$ *and* $G_{r_+}(X_n)$*, that is*

$$\mathbb{P}\left(G_{r_-}(X_n) \subset \mathcal{G}_k(X_n) \subset G_{r_+}(X_n)\right) \geq 1 - 2n\exp\left(-\frac{\varepsilon^2}{2}k\right)$$

where the inclusion $\subset$ *refers to the inclusion of edge sets.*

Proposition 4.4 shows that if r and k are chosen such that $k \asymp nr^d$, the k-NN graph and the r-ball graph are very similar with high probability. This result stems from a common intuition and a detailed proof is provided in [17, Appendix A.3] for completeness. Theorem 4.2 is then extended to k-NN graphs by choosing $k \asymp \sqrt{n\log(n)}$, which does not depend on d.

▶ **Theorem 4.5.** *Assume that* X_n *is the result of* n *i.i.d. samples from a* d*-Ahlfors probability measure* μ *with support* M*. Consider the estimator* $\widehat{D}_{X_n,f}$ *from Definition 3.4 using the* k*-NN graph with parameters* $k = \lceil\sqrt{n\log(n)}\,\rceil$ *and* $q = \lceil n^{1/4}\rceil$*. Then there exists a constant* n_0 *depending on* L_μ*,* $\mathcal{T}_{M,f}$ *and* d *such that for all* $n \geq n_0$ *the following holds.*

$$\mathbb{E}\left[\ell_{\infty,X_n}\left(\widehat{D}_{X_n,f}, D_{M,f}\right)\right] \leq C\left(\frac{\log(n)}{n}\right)^{\frac{1}{d}}$$

where C *is a constant depending on* L_μ *and* $\mathcal{T}_{M,f}$*.*

Notice that in Theorem 4.5 the loss is over X_n instead of M like in Theorem 4.2. The same result could be stated over M, although the proof would be more tedious and is therefore omitted here. Recall that no knowledge on either d, c_μ, C_μ, τ_M, κ or $f_{\min}$ is necessary to compute the estimator, so that it can be used in practice. Setting the resolution q to be $(n/\log(n))^{1/2d}$ would be sufficient to achieve the same upper bound, however this choice requires the knowledge of d. On the other hand, when setting the resolution to $q = 2$ the optimal choice of k can be shown similarly to be $k = n^{1/3}\log(n)^{2/3}$ and to yield a convergence rate of order $(\log(n)/n)^{2/3d}$. Theorem 4.5 is a direct consequence of Theorem 4.2 and Proposition 4.4 and the precise computations are provided in [17, Appendix C.2]. Regarding the case of the induced metric, the same statement as in Corollary 4.3 holds for NN graphs. Namely, the estimator $\widehat{D}_{X_n,1}$ defined over the k-NN graph with $k = \lceil\sqrt{n\log(n)}\,\rceil$ converges to D_M at rate $(\log(n)/n)^{1/d}$.

Let us now discuss the algorithmic complexity of the k-NN estimator with resolution q. In general, building the k-NN graph over a point cloud X of size n is done in $\mathcal{O}(n^2N)$ time when the ambient dimension N is large. Now, consider two points $x, y \in \mathbb{R}^N$ and assume that f can be evaluated at any point with cost c_f. Computing the edges of the graph $\mathcal{G}_k(X \cup \{x,y\})$ takes $\mathcal{O}(nkqc_f)$ time as the amount of edges in the graph is $\mathcal{O}(nk)$ and the weight of each edge uses q evaluations of f. Finally, computing the infimum that defines $D_{X,f}(x,y)$ in Definition 3.4 using Dijkstra's algorithm takes $\mathcal{O}(n\log(n) + nk)$ time. Overall, if $k = \lceil\sqrt{n\log(n)}\,\rceil$ and $q = \lceil n^{1/4}\rceil$, the time complexity is $\mathcal{O}(n^2N + n^{7/4}\log(n)^{1/2}c_f)$.

4.3 Minimax lower bound

We now study the worst case performance of any estimator of the induced metric D_M.

▶ **Theorem 4.6.** *Denote* $\mathfrak{D}_n$ *the set of all estimators* $\widehat{D}$ *of the induced metric based on* n *samples, that given any point cloud* X *of* n *points in* $\mathbb{R}^N$ *provides a function* $\widehat{D}_X : \mathbb{R}^N \times \mathbb{R}^N \to \mathbb{R}_+$*. Let* $2 \leq d \leq N$*,* $L, \tau > 0$ *and* $\mathcal{M}(d, L, \tau)$ *be the set of all* d*-standard measures* μ *with* $L_\mu \leq L$ *and support* $M_\mu \subset \mathbb{R}^N$ *that has positive reach lower bounded by* τ*. Then there exists two constants* $C > 0$ *and* n_0 *depending on* d*,* L *and* τ *such that for all* $n \geq n_0$*,*

$$\inf_{\widehat{D}\in\mathfrak{D}_n} \sup_{\mu\in\mathcal{M}(d,L,\tau)} \mathbb{E}_{X\sim\mu^{\otimes n}}\left[\ell_{\infty,M_\mu}\left(\widehat{D}_X, D_{M_\mu}\right)\right] \geq C\left(\frac{1}{n}\right)^{\frac{1}{d-1/2}} . \tag{17}$$

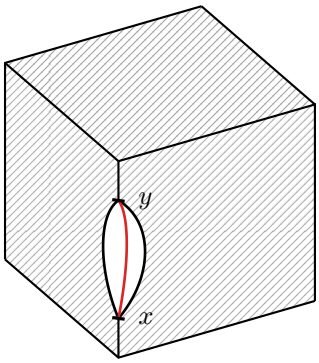

Figure 2 Carving an edge of the cube in $\mathbb{R}^3$.

Notice that Theorem 4.6 only addresses the case of the induced metric. This is not a loss of generality and in fact highlights the fact that the conformal change does not make the problem any harder, as we have established in Section 2 that geodesics have the same regularity as in the case of the induced metric. Given any other function f satisfying the assumptions for a conformal metric, the same lower bound may be obtained with a similar reasoning as what follows, albeit with more technicalities. The rate $n^{-1/(d-1/2)}$ is faster than the rate $n^{1/d}$ obtained in Theorems 4.2 and 4.5, although the difference becomes negligible when d is large. The nature of the minimax convergence rate remains therefore open. Under stronger assumptions on the domain, this question is already solved – see [1] – which we discuss in Section 4.4.

Theorem 4.6 is based on Le Cam's method [19], for which a statement adapted to our setup is given in [17, Lemma C.1]. The method consists in finding two measures μ_1 and μ_2 in $\mathcal{M}(d, L, \tau)$ that are at most $1/n$ apart in total variation distance and such that the relative difference between D_{M_1} and D_{M_2} is of order at least $n^{-1/(d-1/2)}$.

Consider μ_1 the uniform probability on the cube $M_1 = [-\alpha L, \alpha L]^d \times \{0\}^{N-d} \subset \mathbb{R}^N$ where $\alpha > 0$. Let $0 < \varepsilon \leq \alpha L \wedge \tau$ and consider M_2 the result of removing from M_1 its intersection with a ball of radius τ centered at $(0, t, t, \dots, t)$ for some $t > \alpha L$ such that the ball intersects the edge from $(-\alpha L, \alpha L, \alpha L, \dots, \alpha L)$ to $(\alpha L, \alpha L, \alpha L, \dots, \alpha L)$ at two points x and y that are 2ε apart, as pictured in Figure 2. Denote μ_2 the uniform probability over M_2, which has reach exactly τ due to the carved area. By choosing α small enough, which depends only on d, μ_1 and μ_2 are d-standard with lower constant L^{-d}. Then μ_1 and μ_2 both belong to $\mathcal{M}(d, L, \tau)$. The volume of the carved area is of order $\varepsilon(\varepsilon^2)^{d-1}$ as it spans a length 2ε between x and y and a length of order ε^2 for every other dimension of the cube. This implies that the total variation distance between μ_1 and μ_2 is of order ε^{2d-1}. Moreover, The distance from x to y goes from 2ε in M_1 to $2\tau \arcsin(\varepsilon/\tau)$ in M_2, following the red arc of radius τ in Figure 2. This implies that the relative difference between both distances is of order ε^2. Choosing $\varepsilon \asymp n^{-1/2d-1}$ so that the total variation distance is at most $1/n$ eventually yields the desired bound. This reasoning is detailed in [17, Appendix C.3] and the reason why it fails to achieve a bound of order $n^{-1/d}$ is discussed more in depth in the full version [17].

4.4 Case of a smooth manifold

Recall that the minimax convergence rate for the induced metric of a $\mathcal{C}^k$ manifold of dimension d is $n^{-k/d}$ [1]. The methods that achieve such rates are however not computationally feasible in practice as they rely on manifold reconstruction via non-discrete sets. For instance, the

optimal convergence rate in the $\mathcal{C}^2$ case was achieved by [3] using the tangential Delaunay complex. Precisely, these methods build a $n^{-k/d}$-approximation of the manifold w.r.t. the Hausdorff distance, then state that the induced metric over this reconstruction is an estimation of the original metric with an error proportional to the Hausdorff distance.

In order to get a concrete estimator, one may use such manifold reconstruction, then sample a fine $n^{-k/d}$-net over it which approximates the original domain with the same Hausdorff error. Our work then implies that the polygonal metric over this net would be an estimation of the original metric with minimax optimal error of order $n^{-k/d}$. Such construction would however be very costly as the point cloud size would grow from n to n^k.

5 Practical examples of conformal factors

We discuss two examples of conformal factors associated with a measure from the literature.

5.1 Density as a conformal factor

If μ is a measure with density ρ w.r.t. the volume measure over a submanifold M, the conformal change via $f = \rho^{-\beta}$ for some parameter $\beta > 0$ is sometimes referred to as the *Fermat distance* due to the parallel with the Fermat principle in optics – that may however be observed with any conformal change. This metric has been applied to various topological data analysis and learning problems, e.g., in [11, 12], as it tends to accentuate features and disparities in the data. Moreover, the metric can be estimated in a simple fashion by using the same overall reasoning as ours but using weights of the form $w(x, y) = \|x - y\|^\alpha$ where $\alpha > 1$ is a parameter depending on β and d [13, 14]. However, this kind of estimation does not feature any known convergence rate. Using our estimator instead provides an alternative method with quantitative guarantees, granted that an estimator of the density is available. To this extent, density estimation is a well-studied problem with many propositions in the literature. For instance, [4] provides a kernel density estimator ρ_n that converges in L^p norm towards ρ at a rate of $n^{-1/d+1}$ under our assumptions and provided that M is a $\mathcal{C}^1$ submanifold and that ρ is also $\mathcal{C}^1$. Under these assumptions, setting $f_n = \rho_n^{-\beta}$ yields a convergence rate of $n^{-1/d}$ according to Lemma 3.6, at the cost of a more complex computation than the usual discrete Fermat distance studied in [13].

5.2 Distance-to-measure as a conformal factor

In general, given a parameter $m \in (0, 1)$, the *distance-to-measure* $d_{\mu,m} : \mathbb{R}^N \to \mathbb{R}_+$ introduced in [8] is defined for any measure μ over $\mathbb{R}^N$. It is 1-Lipschitz and lower bounded by a positive value as long as μ has no atom, hence satisfies the assumption for our work. A slightly different setup where paths are allowed to leave the domain under a specific constraint is studied in [18], where it is argued that this metric should behave similarly to the conformal metric associated with the density but with more stability w.r.t. the measure. The distance-to-measure is shown [9] to be estimated from n i.i.d. samples of the underlying measure with convergence rate $n^{-1/2}$, which is faster than $n^{-1/d}$ hence does not impact the convergence speed of the estimator of the conformal metric according to Lemma 3.6.

6 Conclusion

In this work, we have shown that under a reach assumption on the domain and Lipschitz lower bounded assumptions on the conformal change, the conformal metric has the same regularity as the induced metric in the sense of geodesics having positive reach. We have

also shown that positive reach is a sufficient assumption to ensure metric estimation from a polygonal metric with error proportional to the Hausdorff distance between the point cloud and the original domain. This leads to a convergence rate of order $n^{-1/d}$ for the estimation of the conformal metric using n i.i.d. samples from a d-standard measure, which in particular applies to the induced metric of any set with positive reach.

Simplicial Approximation to CW Complexes with Spherical Delaunay Triangulations

Raphaël Tinarrage
Institute of Science and Technology Austria, Klosterneuburg, Austria

Abstract

Simplicial approximation provides a framework for constructing simplicial complexes that are homotopy equivalent to a given manifold, provided a CW structure is explicitly known. However, its conventional implementation quickly becomes intractable on a computer: barycentric subdivision produces poorly shaped simplices, and the star condition introduces many vertices. To address these limitations, this article develops a subdivision scheme based on spherical Delaunay triangulations, which attains better refinement properties than barycentric subdivisions. Moreover, the star condition is reframed as two independent problems, one geometric and the other combinatorial, respectively tackled in the language of locally equiconnected spaces and the list homomorphism problem, allowing an exponential reduction in the number of vertices. Via a prototype implementation, we obtain simplicial complexes homotopy equivalent to Grassmannians and Stiefel manifolds up to dimension 5.

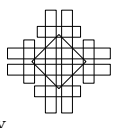
1 Introduction



1.1 Topology software

In computational topology, a popular way to represent a topological space is via a simplicial complex. Once a space is triangulated, it can be explored algorithmically, and a range of homotopy invariants can be evaluated [36, 37, 38, 69, 39, 64, 65, 66, 112, 90]. More generally, triangulations open the door to many further developments: they allow us to test conjectures and discover new properties [16, 15], they serve as a benchmark for comparing software [14, 9, 108] and they lay the foundation for new data analysis techniques [103, 106, 59, 111].

Over the past two decades, software for computations on simplicial complexes has advanced substantially. Existing libraries span a wide range of goals, from algebra to geometry and data analysis. They have underpinned numerous concrete advances: proofs and counterexamples in 3-manifold topology with `Regina` and `SnapPy` [35, 48]; large-scale enumerations that tested conjectures with `BISTELLAR` and `Twister` [18, 13]; new homotopy and cohomology computations in `Kenzo` and `HAP` [50, 56]; and persistent homology pipelines that surfaced new properties of datasets with `GUDHI`, `Ripser`, and `TTK` [91, 11, 110], among many others.

On the other hand, computational topology lacks *explicit* examples of triangulated manifolds, as noted in [16, 66, 9, 108]. By explicit, we mean stored on a computer as a list of simplices, or obtainable in reasonable time by an implemented algorithm. This is especially striking in dimension 4 and above, as summarized in Table 1, which collects known

triangulations of certain classical manifolds. Apart from the real and complex projective spaces, most triangulations are "accidental", i.e., arising from special homeomorphisms with known spaces. The aim of this article is to develop an algorithm for triangulating new spaces.

Table 1 Known explicit triangulations of a selection of manifolds.

Space	Known cases	References / Known identifications
Real projective space $\mathbb{R}P^n$	$n \geq 1$	[83, 8, 4]
Complex projective space $\mathbb{C}P^n$	$n \geq 1$	[84, 102, 6, 7, 101, 49]
Special orthogonal group $\mathrm{SO}(n)$	$n \leq 4$	$\mathrm{SO}(3) \cong \mathbb{R}P^3$, $\mathrm{SO}(4) \cong S^3 \times \mathrm{SO}(3)$
Special unitary group $\mathrm{SU}(n)$	$n \leq 2$	$\mathrm{SU}(2) \cong S^3$
Unitary group $\mathrm{U}(n)$	$n = 1$	$\mathrm{U}(1) \cong S^1$
Real Stiefel manifold $\mathcal{V}(d, n)$	$d = 1$ or $n \leq 4$	$\mathcal{V}(1, n) \cong S^{n-1}$, $\mathcal{V}(d-1, d) \cong \mathrm{SO}(d)$
Real Grassmannian $\mathcal{G}(d, n)$	$d = 1$ or $d = n - 1$	$\mathcal{G}(1, n) \cong \mathcal{G}(n-1, n) \cong \mathbb{R}P^{n-1}$

1.2 Related work

Traditionally, explicit triangulations of manifolds are obtained by two main approaches. The first is combinatorial and relies on specific descriptions of the manifolds under consideration. For example, small triangulations of $\mathbb{R}P^n$ have recently been constructed by exploiting its realization from a symmetric polytope [4]. Topological properties can also guide the enumeration of combinatorial manifolds, as in the work of Lutz [87, 107]. However, combinatorial complexity grows rapidly with the dimension. Thus, in dimensions 3 and 4, more structured constructions are preferred, based on layered triangulations [76, 75, 77], Dehn fillings [52], Heegaard diagrams [57, 74, 58], and Kirby diagrams [33, 34]. The present work follows this perspective by exploiting the *CW structure* of the spaces involved, which is well understood.

Sampling-based methods offer a different viewpoint. A large body of work studies how to reconstruct an embedded manifold $\mathcal{M} \subset \mathbb{R}^n$ from a finite sample $X \subset \mathbb{R}^n$. The goal is usually not to recover a triangulation of $\mathcal{M}$ itself, but rather a simplicial complex with the same homotopy type. A standard construction is the Čech complex. Recovery is guaranteed when the sampling density is sufficiently fine relative to an appropriate condition number, typically the reach of $\mathcal{M}$ [94]. Quantitative refinements use less restrictive geometric quantities, such as the μ-reach [40, 78], weak feature size [41], local feature size [42], convexity defects [5], and convexity radius [61]. In higher dimensions, however, the Čech complex may be prohibitively expensive to compute, and one may instead use the Vietoris–Rips complex, which depends only on pairwise distances. Following the foundational results of Hausmann and Latschev [73, 85], quantitative guarantees have been established in terms of the reach [88, 89], the μ-reach [78], and convexity defects [5]. Other approaches rely on Delaunay complexes [23, 24, 22, 1], witness complexes [104, 70, 25, 26], and metric thickenings [2, 3].

These methods nevertheless remain computationally demanding. Vietoris–Rips complexes are the cheapest to compute, but their guarantees are weaker and they typically require many vertices. Čech complexes present the same difficulty, as they may contain a large number of simplices, potentially of high dimension. In contrast, more refined constructions such as Delaunay complexes require substantial computation time and scale poorly with dimension.

Grassmannians $\mathcal{G}(d, n)$ are a notable example, regarded as difficult to triangulate. Theoretical results indicate that the minimal number of facets increases exponentially with n [68]. Knudson considered triangulating $\mathcal{G}(2, 4)$ by embedding it into $\mathbb{R}^{16}$ and constructing a Vietoris–Rips complex [79]. In practice, the approach amounted to increasing the scale until

obtaining a complex with the expected homology. This proved too costly in memory, and a witness complex was used instead. Although a complex with the correct homology was found, this construction does not satisfy the hypotheses of the available theorems.

1.3 Contributions

In Algorithm 2 we present an implementation of *simplicial approximation to CW complexes*, a framework well established in theory yet overlooked in practice. Given a CW structure on a topological space, the algorithm outputs a *homotopy equivalent* simplicial complex. Although not homeomorphic, such a complex still suffices for many of the applications mentioned above. Crucially, our complexes are equipped with a *point location* routine, making them practical surrogates for the manifold in data-driven applications.

Turning the textbook construction into a practical implementation requires several adjustments; in particular, we aim to keep the resulting complexes as small as possible. To this end, in Section 2, we adopt Delaunay refinement instead of barycentric subdivision; in Section 3, we build a simplicial mapping cone that avoids subdividing the complex; and in Section 4, we substitute the star condition for a more efficient constraint satisfaction problem.

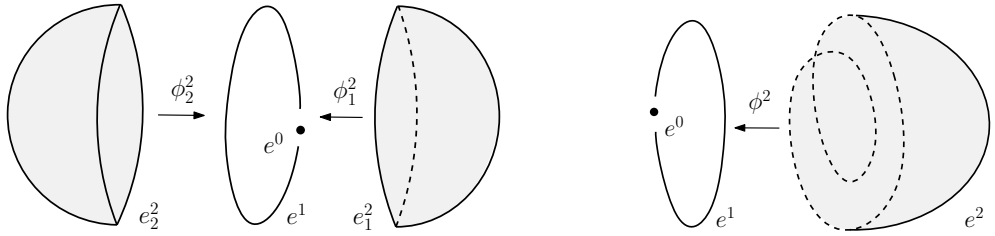
We implemented two versions of the algorithm, using either global or local refinement. Only the first is currently proven to terminate, but the second often produces smaller complexes. In both cases, when the algorithm terminates, the output is correct (see Theorem 13).

The software is provided as supplementary material.[1] The repository includes complexes homotopy equivalent to $\mathcal{G}(2,4)$ and $\mathcal{V}(2,4)$ (of dimensions 4 and 5), which were not available prior to this work. We intend to address higher-dimensional examples in future work by increasing computational resources; the current results were obtained on a personal laptop.

The algorithm is sketched in the next section. In Sections 2–4 we develop the theoretical results required for its implementation. Proofs appear in the full version of the article.

1.4 Overview and discussion of the construction

CW complexes. The theoretical background can be found in Hatcher's book [72, Section 2.C]. A *CW complex* of dimension n is a topological space X endowed with a decomposition $X = X^n \supset X^{n-1} \supset \cdots \supset X^0$ where X^0 is finite and each X^d is equal to a disjoint union



$$X^d = X^{d-1} \coprod_{1 \le i \le m(d)} e_i^d,$$

where each e_i^d, called a *d-cell*, is homeomorphic to an open ball of dimension d, and $m(d)$ is their number. It is required that the homeomorphism extends to the closed ball B^d, yielding a map $\Phi_i^d \colon B^d \to \bar{e}_i^d \subset X^d$, called the *characteristic map*. Its restriction to the boundary of B^d – i.e., the sphere S^{d-1} – is called the *gluing map* and is denoted $\phi_i^d \colon S^{d-1} \to X^{d-1}$. In other words, X^d is homeomorphic to the gluing of d-balls along their boundary on X^{d-1}:

$$X^d \cong X^{d-1} \cup_{\phi_1^d} B^d \cup_{\phi_2^d} B^d \cup \cdots \cup_{\phi_{m(d)}^d} B^d.$$

Figure 1a shows a CW structure on S^2, made of one 0- and 1-cell and two 2-cells. Figure 1b depicts the usual structure on $\mathbb{R}P^2$: one cell per dimension and a gluing map $\phi^2 \colon S^1 \to S^1$ of degree 2. Similarly, all the manifolds in Table 1 admit a well-known CW structure. We refer the interested reader to [92, Section 6] for the classical structure on Grassmannians, [72, Section 3.D] for Stiefel manifolds and orthogonal groups, and [113] for unitary groups.

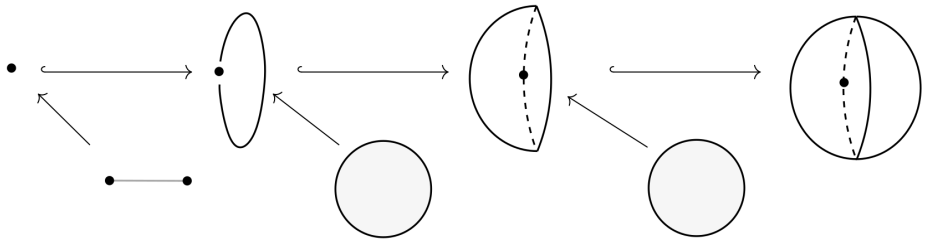
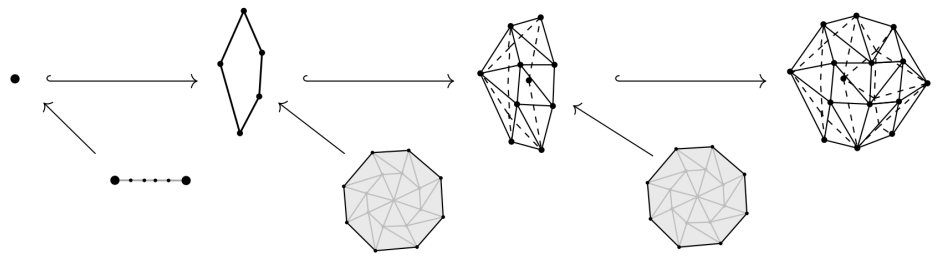
(a) S^2. **(b)** $\mathbb{R}P^2$.

Figure 1 Examples of CW structures on the sphere S^2 (four cells in total) and the projective plane $\mathbb{R}P^2$ (one cell per dimension). If only one d-cell is attached, we omit the subscript in e_i^d.



Sketch of the approach. One can "convert" a CW complex into a simplicial complex by gluing *simplicial balls* instead of cells; the idea is sketched in Figure 2. The construction proceeds inductively on the dimension. Suppose we have already built a simplicial complex L^d homotopy equivalent to the d-skeleton X^d; we denote by $|L^d|$ its geometric realization. For each $(d+1)$-cell e_i^{d+1}, we perform the following steps:

- We apply *simplicial approximation* (see below) to the gluing map $\phi_i^{d+1}\colon S^d \to |L^d|$. This yields a triangulation K_i^d of S^d and a simplicial map $g_i^{d+1}\colon K_i^d \to L^d$ homotopic to ϕ_i^{d+1}.
- From K_i^d, we construct a simplicial ball $B(K_i^d)$ with boundary K_i^d and glue it to L^d along this boundary via g_i^{d+1}. This amounts to the simplicial mapping cone of g_i^{d+1}.



After all $(d+1)$-cells have been attached, the resulting complex L^{d+1} is homotopy equivalent to the skeleton X^{d+1}, and the procedure can be iterated in the next dimension.

(b) Geometric visualization of the diagram above.

(c) Simplicial approximation of the diagram.

Figure 2 Schematic view of the simplicial approximation procedure for CW complexes.

Computational obstacles. Conventionally, the simplicial approximation of $\phi_i^{d+1}\colon S^d \to |L^d|$ is obtained as follows: one starts from any triangulation K of S^d and repeatedly applies barycentric subdivision until the triangulation is fine enough. More precisely, one stops when the map satisfies the *star condition*: each closed star of a vertex $v \in K$ is mapped by ϕ_i^{d+1} into the open star of some vertex $w \in L^d$. The simplicial approximation theorem ensures that this procedure terminates [72, Theorem 2C.1]. The assignment of vertices $v \mapsto w$ defines a simplicial map g_i^{d+1} homotopic to ϕ_i^{d+1} (through a homotopy that is linear on each simplex).

In practice, this approach quickly becomes intractable for two reasons. First, barycentric subdivision introduces a large number of vertices: a d-simplex is converted into a complex with $2^{d+1}-1$ vertices. In Section 2, we propose to use instead the *Delaunay complexes* and their refinements. We show in Theorem 4 that Delaunay refinement enjoys better approximation properties than barycentric subdivision: the simplices shrink more rapidly.

Secondly, the star condition itself is too coarse: each facet of L^d requires $d+1$ vertices of K that are mapped into it. This contributes further to the exponential growth in the number of vertices. In Section 4, we avoid the star condition altogether by decomposing the problem into two parts: a geometric step (constructing a homotopy equivalence) and a combinatorial step (constructing a simplicial map). Proposition 12 ensures that this procedure is correct.

Last, the standard construction of a simplicial mapping cone, going back to Cohen [47], relies on the barycentric subdivision of K, which again leads to large complexes. In Section 3, we consider a lighter triangulation, based on *staircase triangulation* of products. Proposition 7 shows that this object is homotopy equivalent to the standard mapping cone.

2 Successive refinements of spherical Delaunay triangulations

Our construction begins with a refinement scheme for spherical Delaunay complexes, which generates arbitrarily fine triangulations and is well suited to concrete implementation.

2.1 Spherical Delaunay triangulations

Definition

Let $X \subset \mathbb{R}^d$ be finite. A subset of $d+1$ points has the *empty circle property* if its circumscribing (open) ball is empty of points of X. These subsets form the facets of an abstract simplicial complex $\mathrm{Del}(X)$, called the *Delaunay complex*. Under the genericity assumption that no subset of $d+2$ points lies on the same sphere, $\mathrm{Del}(X)$ is naturally embedded in $\mathbb{R}^d$ [20].

These definitions adapt to the spherical case: given a subset X of the unit sphere $S^d \subset \mathbb{R}^{d+1}$, the empty circle property is understood with respect to the geodesic distance on S^d; the resulting complex is called the *spherical Delaunay complex* and is still denoted $\mathrm{Del}(X)$. If no subset of $d+2$ points lies on the same geodesic sphere, then it is naturally embedded in $\mathbb{R}^{d+1}$. We shall implicitly make this assumption throughout the article.

It is well-known that the spherical Delaunay complex coincides with the boundary of the convex hull of its vertices, thus reducing the computation of $\mathrm{Del}(X)$ to $\mathrm{conv}(X)$ [31]. In our implementation, we used `Qhull`, a popular software package for computing convex hulls [10].

Point location

A natural map $|\mathrm{Del}(X)| \to S^d$ is given by the scaling $x \mapsto x/\|x\|$, which is a homeomorphism provided that the origin is included in the interior of the convex hull of X. A set X satisfying this assumption will be referred to as *admissible*, and $\mathrm{Del}(X)$ as an *admissible triangulation*.

We call the inverse homeomorphism $r\colon S^d \to |\mathrm{Del}(X)|$ the *radial projection*. Computationally speaking, the radial projection of $x \in S^d$ is found by identifying a facet $\sigma \in \mathrm{Del}(X)$ to which $r(x)$ belongs, then computing a simple line/hyperplane intersection.

We perform point location via a conventional *Jump-and-Walk* strategy [93]: it consists of choosing a first candidate $\sigma \in \mathrm{Del}(X)$, hopefully close to $r(x)$, then walking through its neighbor facets until reaching one that contains $r(x)$. Unlike popular software packages such as `STRIPACK` or `CGAL` [109, 98], our implementation does not make use of spherical geometric predicates. Instead, we project $\mathrm{Del}(X)$ into the tangent space of S^d at x via the stereographic projection $p\colon S^d \setminus \{-x\} \to T_xS^d$ and work in the induced Euclidean triangulation (the simplices are replaced with the convex hull of their vertices). This approach lets us reuse Euclidean routines already present in our code. In this step, we exclude from $\mathrm{Del}(X)$ all simplices incident to $-x$, since their images under p are not defined.

A caveat is that stereographic projection distorts geodesics: in general, the image geodesic simplex $p(|\sigma|)$ need not coincide with the linear simplex $\mathrm{conv}(\{p(v_0), \ldots, p(v_d)\})$ on the image of its vertices. Consequently, a point might map to the "wrong" linear simplex. The next lemma shows that this cannot happen at the pole x, which justifies our procedure.

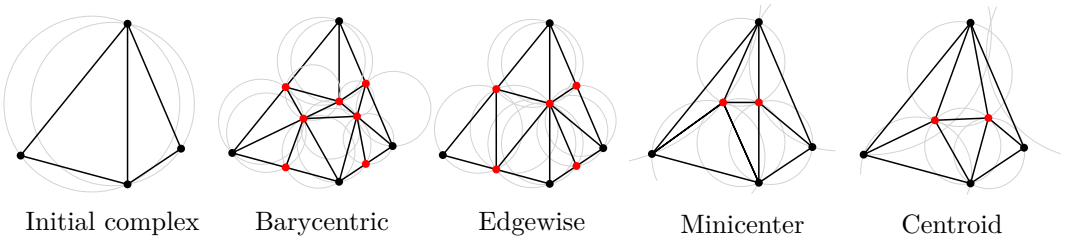
▶ **Lemma 1.** *Let $\sigma = [v_0, \ldots, v_d] \in \mathrm{Del}(X)$ and $x \in S^d$ such that $r(x) \in |\sigma|$. Then $p(x) \in \mathrm{conv}(\{p(v_0), \ldots, p(v_d)\})$, where p is the stereographic projection at x.*

2.2 Global Delaunay refinements

Given a spherical Delaunay triangulation $\mathrm{Del}(X_0)$ with vertex set $X_0 \subset S^d$, one obtains a finer triangulation by choosing additional points $Y_0 \subset S^d$ and building the Delaunay complex on $X_1 = X_0 \cup Y_0$. The new points are called *Steiner points*, and this procedure is known as a *Delaunay refinement*. This construction can be iterated, yielding a sequence of Steiner points Y_0, Y_1, Y_2, ... and complexes $\mathrm{Del}(X_0)$, $\mathrm{Del}(X_1)$, $\mathrm{Del}(X_2)$, ...

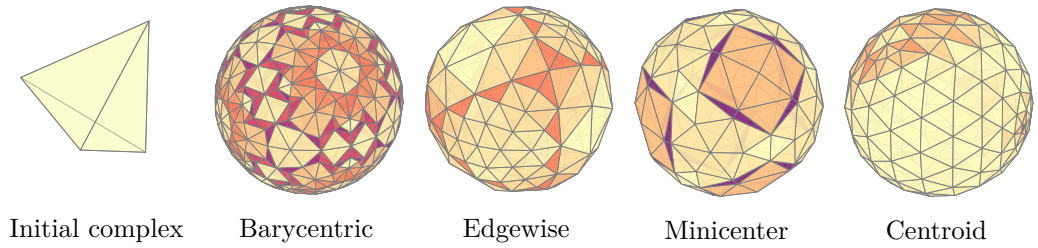
In computational geometry, Delaunay refinement lies at the core of popular algorithms for generating and refining Euclidean meshes; see [43] for a modern presentation. For instance, Chew's and Ruppert's algorithms [44, 45, 99] take a set of input constraints (e.g., boundary segments that must appear as edges) and iteratively improve the mesh by eliminating poor-quality triangles. The refinement step consists of marking a bad triangle and inserting its circumcenter as a new vertex, after which the Delaunay triangulation is recomputed.

Our objective here is different: we seek triangulations whose simplices can be made arbitrarily small, enabling the simplicial approximation of maps described in Section 1.4. To this end, we introduce several families of Delaunay-based refinements, visualized in Figure 3.



Barycentric refinement: Inspired by barycentric subdivision, we let the Steiner points Y_i be the barycenters of all simplices of $\mathrm{Del}(X_i)$, except its vertices.

Edgewise refinement: We may instead insert the midpoints of all edges of $\mathrm{Del}(X_i)$, in analogy with the popular Coxeter-Freudenthal-Kuhn subdivisions of simplices, also called edgewise subdivisions [17, 54, 67, 97, 82, 80, 46, 27, 32, 19, 28, 29].



Minicenter refinement: Closer in spirit to conventional Delaunay refinement, we also consider inserting the minicenters of the facets (centers of minimal enclosing balls). We favor minicenters over circumcenters because, unlike circumcenters, they always lie inside the simplex that defines them, which better reflects the local nature of classical subdivision.

Centroid refinement: Finally, we may insert the barycenters of only the *facets* of $\mathrm{Del}(X_i)$ (the maximal simplices), standing as a cheaper alternative to barycentric refinement.

In all cases, the *spherical* Steiner points are considered (i.e., spherical barycenters or minicenters). This is equivalent to computing their Euclidean counterpart in the ambient space $\mathbb{R}^{d+1}$ and projecting them onto the sphere; see, for instance, Fiedler's book [63, Section 5.4].

(a) Local picture: A Delaunay complex on a set of four points in $\mathbb{R}^2$ and the four refinements proposed.

(b) Global picture: Spherical Delaunay complexes after three or four refinements of an initial triangulation of S^2 (the boundary of the standard simplex). The colors indicate the simplex ratio inradius/circumradius.

Figure 3 We employ Delaunay refinement as a subdivision scheme for triangulations of S^d.

Note that, strictly speaking, $\mathrm{Del}(X_{i+1})$ is not a subdivision of $\mathrm{Del}(X_i)$: when realized on the sphere, a simplex of $\mathrm{Del}(X_{i+1})$ need not be contained in a single simplex of $\mathrm{Del}(X_i)$. This can be seen in Figure 3a, where only the edgewise and minicenter refinements are subdivisions. As a consequence, it is not immediate that simplices become smaller under refinement. In particular, adding a point to a Delaunay triangulation can increase the maximal edge length, as illustrated in Figure 4 (shown in the plane for clarity). Instead, we show that the *maximal (spherical) circumradius* of $\mathrm{Del}(X_i)$, denoted $\rho_{\mathrm{circ}}(\mathrm{Del}(X_i))$, decreases monotonically to zero. Since the maximal diameter of the simplices of $\mathrm{Del}(X_i)$ is at most twice its maximal circumradius, it follows that the maximal diameter also tends to zero.

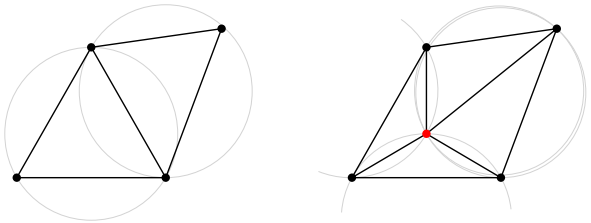


Figure 4 Adding a point to a Delaunay complex may increase the maximal edge length.

A convenient quantity to study a Delaunay complex on a subset $X \subset S^d$ is its *covering radius* (also known as sampling radius) [21, 20]. On the sphere, it is defined by

$$\rho_{\mathrm{cov}}(X) = \sup_{y \in S^d} \inf_{x \in X} \mathrm{d}(x, y),$$

where $\mathrm{d}(x, y)$ is the geodesic (great-circle) distance on the sphere. We note that the set X is admissible as long as $\rho_{\mathrm{cov}}(X) < \pi/2$ (i.e., X is not contained in a closed hemisphere).

The maximal circumradius and covering radius are related by the following standard result.

▶ **Lemma 2.** *For every admissible finite subset $X \subset S^d$, it holds that $\rho_{\mathrm{circ}}(\mathrm{Del}(X)) = \rho_{\mathrm{cov}}(X)$.*

We take advantage of this shift to the covering radius to prove the following lemma.

▶ **Lemma 3.** *Consider a finite subset $X \subset S^d$ and let Y denote the Steiner points associated with* $\mathrm{Del}(X)$*. Assume that $\rho_{\mathrm{cov}}(X) \leq \pi/3$. Then*

$$\rho_{\mathrm{cov}}(X \cup Y) \leq \alpha \rho_{\mathrm{cov}}(X),$$

where $\alpha = \alpha' / \cos(\rho_{\mathrm{cov}}(X))$, and α' depends on the chosen refinement, as given in the table

Refinement	Edgewise	Minicenter	Centroid
α'	$1/\sqrt{2}$	$1/\sqrt{2}$	$d/(d+1)$

The quantity $\cos(\rho_{\mathrm{cov}}(X))$ reflects the spherical distortion of lengths; it goes to 1 as the covering radius goes to zero. A similar lemma can be obtained in the Euclidean case, without this factor. We point out that we have not been able to obtain a satisfactory bound for barycentric refinement; for lack of a better estimate, we use the bound for edgewise refinement.

By iterating this lemma, we obtain our main result on Delaunay refinement.

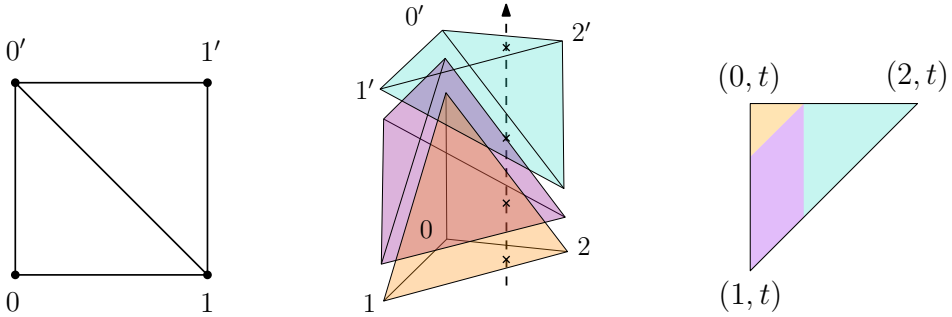
▶ **Theorem 4.** *Assume the initial sample $X_0 \subset S^d$ is sufficiently dense so that $\alpha < 1$, where $\alpha = \alpha(X_0)$ is defined in Lemma 3. Then the n^{th} iteration of Delaunay refinement satisfies*

$$\rho_{\mathrm{cov}}(X_n) \leq \alpha^n \rho_{\mathrm{cov}}(X_0).$$

In particular, the maximal diameter of simplices of $\mathrm{Del}(X_n)$ *goes to zero.*

▶ Remark 5. This result highlights a notable distinction between Delaunay refinement and standard subdivision. While barycentric refinement reduces diameters asymptotically by $1/\sqrt{2}$ (at most), the best bound for barycentric subdivision is $d/(d+1)$. Likewise, centroid refinement reduces them by $d/(d+1)$, even though it introduces only one vertex per facet.

3 Simplicial mapping cones with staircase triangulations



In this section, we assume that a simplicial approximation $g\colon K \to L$ of $f\colon S^d \to |L|$ is given. We build a simplicial mapping cone $C_{\mathrm{simp}}(g)$ and show it is homotopy equivalent to the usual mapping cone $C(f)$. The construction proceeds by building a simplicial ball $B(K)$ through staircase triangulation, which we first recall. Although this construction already appears in the literature, notably in [105, Exercise E, p. 151] and [12, Proposition 2], we include a detailed account here in order to collect the properties that will be used in the sequel.

3.1 Triangulation of the ball

Staircase triangulation of the prism

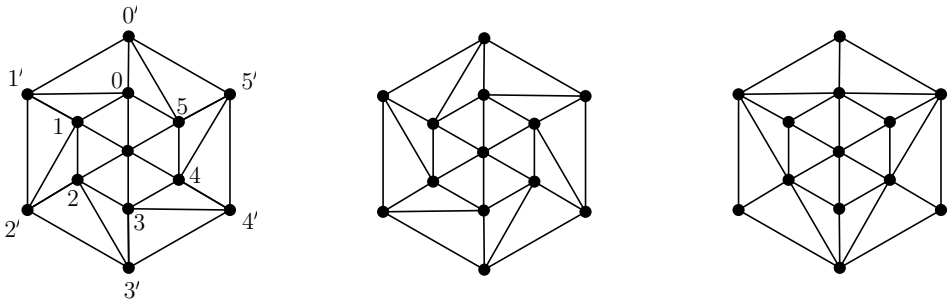
To triangulate the Cartesian product of a d-simplex σ with an interval $I = [0, 1]$, the *staircase triangulation* consists of first ordering the vertices $\{v_0, \ldots, v_d\}$ of σ, taking a copy $\{v'_0, \ldots, v'_d\}$, and inserting the simplices $\sigma_k = [v_k, \ldots, v_d, v'_0, \ldots, v'_k]$ for all $k \in \{0, \ldots, d\}$ [86]. We shall refer to the product $|\sigma| \times I$ as a *prism*, and its face $[v_k, \ldots, v_d]$ (resp. $[v'_0, \ldots, v'_k]$) as the *inner face* (resp. the *outer face*). Geometrically, they correspond to $|\sigma| \times \{0\}$ and $|\sigma| \times \{1\} \subset |\sigma| \times I$.

The relation $\sigma_k < \sigma_{k+1}$ defines an order on the prism's $d+1$ facets. In particular, the following observation will be useful later: *vertical* straight lines in the prism – i.e., of the form $t \mapsto (x, t)$ for a certain $x \in |\sigma|$ – cross each facet consecutively. Indeed, for $k \in \{1, \ldots, d-1\}$, the only neighboring facets of σ_k are σ_{k-1} and σ_{k+1}; see Figures 5a and 5b. On the other hand, *horizontal* sections of the prism – i.e., sets $|\sigma| \times \{t\}$ for $t \in [0, 1]$ – inherit subdivisions in polyhedral cells; see Figure 5c. These are closely related to *mixed subdivisions* [86, 100].

(a) The square $|\Delta^1| \times I$ is triangulated with two triangles. **(b)** The prism $|\Delta^2| \times I$ is triangulated with three tetrahedra. **(c)** Horizontal sections inherit a subdivision into polygonal cells.

Figure 5 A triangulation of the prism $|\sigma| \times I$ is obtained by ordering the vertices $\{v_0, \dots, v_d\}$ of σ, taking a copy $\{v'_0, \dots, v'_d\}$, and inserting the simplices $\sigma_k = [v_k, \dots, v_d, v'_0, \dots, v'_k]$ for $0 \le k \le d$.

Filling the sphere



Let K be an admissible triangulation of the sphere $S^d \subset \mathbb{R}^{d+1}$ (a convex hull of unit vectors that contains the origin). We obtain a triangulation of the unit ball B^{d+1} in three steps.

- The polyhedron $|K|$ is embedded in $\mathbb{R}^{d+1}$ and called the *outer layer*. We prime its vertex labels ($0'$, $1'$, *etc.*). Besides, a copy of $|K|$ is taken and scaled by a factor $\rho_{\text{inner}} \in (0, 1)$; it is seen as a triangulation of the sphere of radius ρ_{inner}, referred to as the *inner layer*.
- Each simplex of the outer layer is connected to the corresponding inner-layer simplex via staircase triangulation, forming a prism. Together, these prisms yield a triangulation of the spherical shell of radii $(\rho_{\text{inner}}, 1)$, which we call the *outer shell*.
- Last, the origin is added to the triangulation as a new vertex, over which the inner layer is coned, forming the *inner ball*.

The resulting geometric simplicial complex, denoted $B(K)$, is a triangulation of the unit ball.

In our implementation, we chose $\rho_{\text{inner}} = 1/2$. Besides, because the construction uses staircase triangulations, it depends on a choice of ordering of the vertices in each facet of K. These orderings must be compatible across neighboring facets. Equivalently, the construction requires an "orientation" on K, by which we mean an orientation of its edges such that no facet contains a directed cycle. Different choices may lead to different $B(K)$; see Figure 6.

Each facet $\sigma \in K$ generates a *sector*, defined as the subcomplex $\text{Sect}(\sigma) \subset B(K)$ containing the origin, its cone with σ seen in the inner layer, and the prism built on it. Most of the constructions to follow will be carried out sector by sector.

(a) $0 \to 1 \to 2 \to 3 \to 4 \to 5 \to 0$. **(b)** $5 \to 4 \to 3 \to 2 \to 1 \to 0 \to 5$. **(c)** $0 \to 1 \leftarrow 2 \to 3 \leftarrow 4 \to 5 \leftarrow 0$.

Figure 6 The simplicial ball $B(K)$ built from K depends on an orientation of the edges of K.

Radial normalization

A number of natural homeomorphisms $|B(K)| \to B^{d+1}$ exist. For instance, one could lift the vertices of $B(K)$ to the upper $(d+1)$-hemisphere of $\mathbb{R}^{d+2} \supset \mathbb{R}^{d+1} \times \{0\}$ via orthographic or stereographic projection, build geodesic simplices, and take them back to $B^{d+1} \subset \mathbb{R}^{d+1}$. However, we found that the idea of *radial normalization* was more appropriate for our problem.

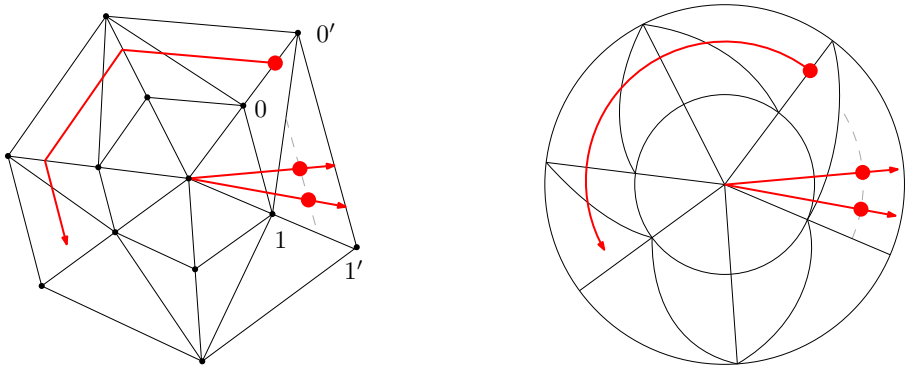
As for any convex domain, the *gauge function* of $|B(K)|$ is defined for all $x \in \mathbb{R}^{d+1}$ as

$$J(x) = \inf\{t > 0 \mid t^{-1}x \in |B(K)|\}.$$

It is a convex, positively homogeneous function. The reciprocal of the gauge is known as the *radial function*, used in the study of star-shaped sets [71]. It can be written as

$$J(x)^{-1} = \sup\{t > 0 \mid tx \in |B(K)|\}.$$

If x is a unit vector, then $J(x)^{-1}$ is the length of the part of $[0, x]$ contained in $|B(K)|$. In particular, the minimum of $J(x)^{-1}$ over the unit sphere is equal to the polyhedron's inradius.



Our preferred homeomorphism $\nu\colon |B(K)| \to B^{d+1}$ is the *radial normalization*, defined as

$$\nu(x) = J\left(\frac{x}{\|x\|}\right)x,$$

with inverse $\nu^{-1}(x) = J(x/\|x\|)^{-1}x$. Although not explicitly written, ν depends on $|B(K)|$. One of its main advantages is its simple geometric behavior, illustrated in Figure 7.

▶ **Lemma 6.** *Under inverse radial normalization* $\nu^{-1}\colon B^{d+1} \to |B(K)|$,

- *rays through the origin are mapped to rays through the origin;*
- *circular arcs – i.e., intersections of linear planes with spheres centered at the origin – are mapped to paths which are linear in each sector* $|\mathrm{Sect}(\sigma)| \subset |B(K)|$ *and parallel to* $|\sigma|$.

(a) The polyhedron $B(K)$ seen in $\mathbb{R}^{d+1}$. **(b)** Its image, the Euclidean ball $B^{d+1} \subset \mathbb{R}^{d+1}$.

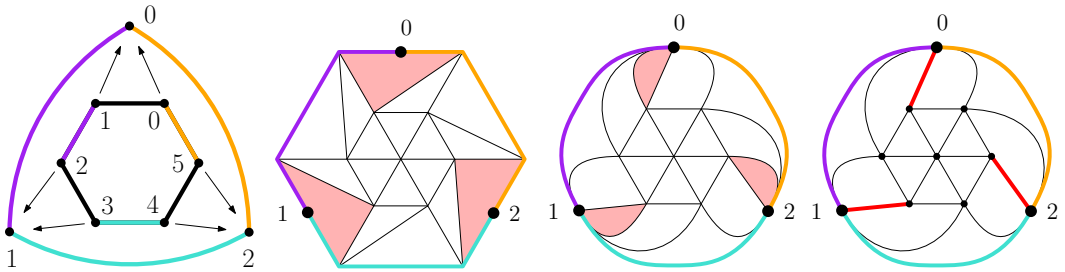


Figure 7 Radial normalization yields a homeomorphism $\nu\colon |B(K)| \to B^{d+1}$.

3.2 Homotopy equivalence between the mapping cones

We still consider a simplicial approximation $g\colon K \to L$ to $f\colon S^d \to |L|$. In the previous section we built a simplicial ball and a homeomorphism $B^{d+1} \to |B(K)|$. We now face three distinct gluings, represented in Figure 8, which we will show are homotopy equivalent:

$$|L| \cup_f B^{d+1} \longrightarrow |L| \cup_{|g|} B^{d+1} \longrightarrow |L \cup_g B(K)|.$$

The first two are the (standard) mapping cones of f and $|g|$, also denoted $C(f)$ and $C(|g|)$. The latter is the *simplicial mapping cone* of g, also denoted $C_{\text{simp}}(g)$. We define it as the quotient of $B(K) \sqcup L$ by the relation $v \sim g(v)$ for all vertices v in the outer layer $K \subset B(K)$.

(a) $g\colon K \to L$. **(b)** $|L| \cup_f B^{d+1}$. **(c)** $|L| \cup_{|g|} |B(K)|$. **(d)** $L \cup_g B(K)$.

Figure 8 The mapping cones involved in our problem. Here, $f\colon |K| \to |L|$ is the identity between two triangulations of S^1 on 6 and 3 vertices, and g is the simplicial map $0, 1 \mapsto 0$; $2, 3 \mapsto 1$; $4, 5 \mapsto 2$.

First, it is a standard fact that mapping cones built from homotopic maps are homotopy equivalent [72, Proposition 0.18]. More precisely, since our domains are balls, an explicit homotopy equivalence $|L| \cup_f B^{d+1} \to |L| \cup_{|g|} B^{d+1}$ is given by

$$x \longmapsto \begin{cases} x & \text{if } \ x \in |L|, \\ x/\rho_{\text{hom}} & \text{if } \ x \in B^{d+1} \ \text{ and } \ \|x\| < \rho_{\text{hom}}, \\ H\big(x/\|x\|,\ (\|x\| - \rho_{\text{hom}})/(1-\rho_{\text{hom}})\big) & \text{if } \ x \in B^{d+1} \ \text{ and } \ \|x\| \geq \rho_{\text{hom}}. \end{cases} \tag{1}$$

where H is a homotopy between $|g|$ and f, and $\rho_{\text{hom}} \in (0,1)$ is a parameter, chosen as 0.9 in our implementation. Visually, the homotopy is performed by scaling the ball B^{d+1} by a factor $1/\rho_{\text{hom}}$ and by using the outer shell $\{x \mid \|x\| \geq \rho_{\text{hom}}\}$ to interpolate between $|g|$ and f.

Second, to compare the remaining two gluings, we can simply use the quotient map

$$q\colon |L| \cup_{|g|} |B(K)| \to |L \cup_g B(K)|.$$

It has the effect of collapsing simplices on which g is not injective; compare Figures 8c and 8d.

▶ **Proposition 7.** *The quotient map q is a homotopy equivalence.*

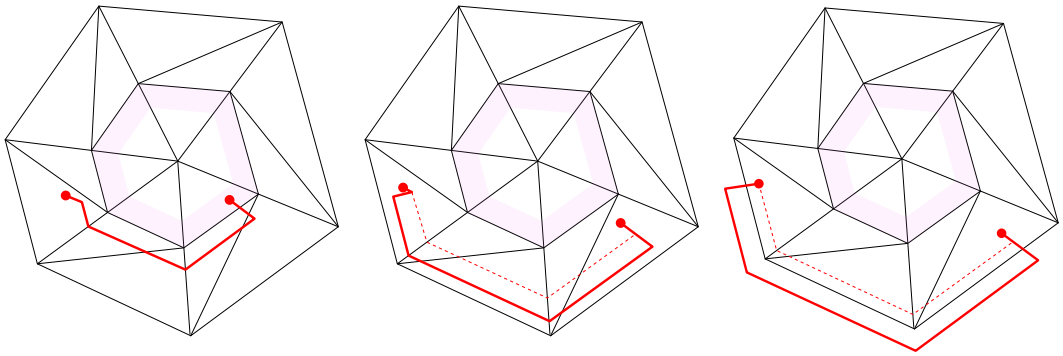
We close this section with a result that will help us navigate the mapping cone.

▶ **Lemma 8.** *Let $x \in |B(K)|$. Under the projection $p\colon |B(K)| \to |L \cup_g B(K)|$, the image of the partial ray $\{tx \mid 0 \leq t \leq 1/\|x\|\}$ only depends on the image of x.*

4 Simplicial approximation as a list homomorphism problem

The final ingredient in our construction is a more efficient simplicial approximation. We consider a continuous map $f\colon S^d \to |L|$ and a triangulation K of S^d. For each vertex v of K, the point $f(v)$ lies in the geometric realization of a unique simplex of L, called its *carrier* and denoted $\text{carr}(f(v))$. We seek a simplicial map $g\colon K \to L$ such that $g(v) \in \text{carr}(f(v))$ for all vertices. The existence of such a map is a purely combinatorial question that we address as a constraint satisfaction problem. A further issue is the existence of a homotopy H between f and $|g|$; we formulate the problem in the framework of locally equiconnected spaces.

4.1 Constructing the homotopy



A practical framework for explicitly constructing a homotopy is provided by the theory of *locally equiconnected spaces* (LEC) introduced by Dugundji in 1965 [51]. Namely, Y is LEC if there exists a neighborhood $U \subset Y \times Y$ of the diagonal and a continuous map $\Pi\colon U \times I \to Y$ such that $\Pi(x, y, 0) = x$, $\Pi(x, y, 1) = y$ and $\Pi(x, x, t) = x$ for all $(x, y, t) \in U \times I$. The map Π is called an *equiconnecting map*, and the pair (U, Π) is called *LEC-data*.

In this section, we aim to build LEC-data for simplicial mapping cones $Y = C_{\text{simp}}(g)$ on simplicial maps $g\colon K \to L$. Dyer and Eilenberg [53] have shown how to build LEC-data of *standard* mapping cones $C(|g|)$, provided that both $|K|$ and $|L|$ are LEC. Their construction, however, does not descend to the quotient $C_{\text{simp}}(g)$. We present here a closely related construction, adapted to simplicial mapping cones, in the particular case where K is a sphere.

In general, it is too much to expect an equiconnecting map on Y: we are able to build one only when $g\colon K \to L$ is *2-distance injective*, i.e., injective when restricted to the closed star of each vertex. In the language of graphs, this is equivalent to saying that g is a 2-distance coloring of the 1-skeleton of K [81, 30]. Without this hypothesis, we instead construct a *local motion planner* [60], i.e., a continuous map $\Pi\colon U \times I \to Y$, where $U \subset Y \times Y$ is a neighborhood of the diagonal, satisfying $\Pi(x, y, 0) = x$ and $\Pi(x, y, 1) = y$ for all $(x, y) \in U$. In contrast with equiconnecting maps, the path $t \mapsto \Pi(x, x, t)$ need not be constant.

▶ **Theorem 9.** *If $g\colon K \to L$ is 2-distance injective and $|L|$ is endowed with LEC-data, then $|C_{\text{simp}}(g)|$ also admits LEC-data (U, Π). When g is not 2-distance injective, the same result holds for local motion planners instead of equiconnecting maps.*

As illustrated in Figure 9, we construct a planner on $C_{\text{simp}}(g)$ by first defining it on $B(K)$, through a combination of "elementary paths" (rays, straight paths, circular arcs). We prove that they descend along the projection map $|B(K)| \to |C_{\text{simp}}(g)|$, yielding a well-defined local planner that can subsequently be spliced with the original planner on $|L|$.

(a) Points are connected through a combination of elementary paths.

(b) For distant points, the paths are pushed to the boundary.

(c) Close to the boundary, paths are interpolated with those on $|L|$.

Figure 9 We build a local motion planner on $C_{\text{simp}}(g) = L \cup_g B(K)$ by first defining it on $B(K)$.

▶ Note 10. Equiconnecting maps or planners allow us to test the homotopy between maps. Indeed, two maps $a, b\colon X \to Y$ are homotopic whenever $(a(x), b(x)) \in U$ for all $x \in X$; a homotopy is given by $H(x, t) = \Pi(a(x), b(x), t)$. We say that the maps are *U-close*. During the proof of Theorem 9, we describe U explicitly. In particular, for points x, y in the ball $|B(K)|$ and their images in the mapping cone via $|B(K)| \to |C_{\text{simp}}(g)|$, the corresponding pair lies in U when x and y are sufficiently close to the origin or when they are not antipodal.

4.2 Simplicial approximation routine

Planner condition

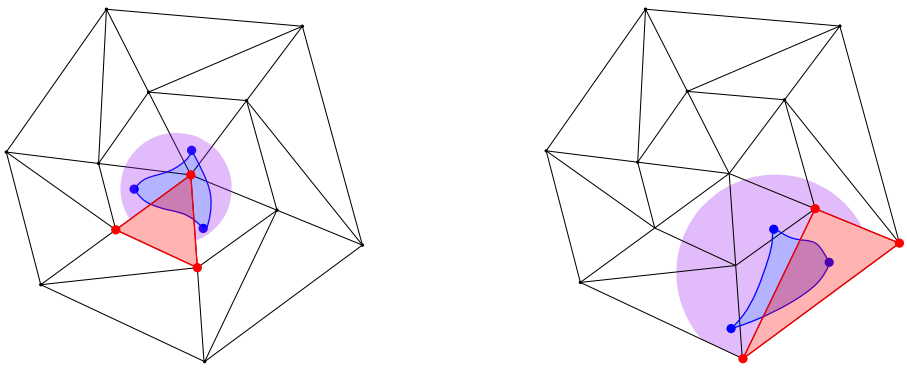
We return to the problem of simplicial approximation for $f\colon S^d \to |L|$ where L is a mapping cone $L = L_0 \cup_{g_0} B(K_0)$ now endowed with a local motion planner (U, Π). Given a triangulation K of S^d, we ask whether it is fine enough so that the planner can be applied on each facet.

More precisely, for each facet $\sigma = [v_0, \dots, v_d] \in K$ we look for a simplicial assignment

$$v_i \mapsto g(v_i) \in \operatorname{carr}(f(v_i))$$

such that, on $|\sigma|$, the continuous map f and the linear map $|g|$ are U-close, i.e., $(f(x), |g|(x)) \in U$ for all $x \in |\sigma|$. Let us assume for simplicity that $f(|\sigma|)$ is contained in the last cell $B(K_0)$ of $L = L_0 \cup_{g_0} B(K_0)$; the general case is treated recursively along the filtration.

As explained in Note 10, a pair $(x, y) \in B(K_0) \times B(K_0)$ belongs to U provided the points are sufficiently close to the origin or are not antipodal ($x/\|x\| \neq -y/\|y\|$). To guarantee this condition uniformly on $f(|\sigma|)$, we estimate its size using the edge lengths of $|\sigma|$ and a Lipschitz bound λ for f. This Lipschitz constant is computed explicitly for each f.



▶ **Lemma 11.** *Let $\sigma = [v_0, \dots, v_d]$ be a geometric simplex in $\mathbb{R}^n$ and $f\colon |\sigma| \to \mathbb{R}^m$ a λ-Lipschitz continuous map. For $I \subset \{0, \dots, d\}$ nonempty, define the barycenter and length*

$$c_I = \frac{1}{|I|} \sum_{i \in I} f(v_i) \quad \text{and} \quad r_I = \max_{0 \le k \le d} \frac{1}{|I|} \sum_{i \in I} \|v_k - v_i\|.$$

Then $f(|\sigma|)$ is included in the closed ball $B(c_I, \lambda r_I)$.

In our implementation we use the case $I = \{0, \dots, d\}$ only, corresponding to the barycenter of all vertices $f(v_i)$, although the estimate can be sharpened by considering other subsets I.

If σ is small enough, Lemma 11 and the description of U ensure that the required assignment g exists: σ is mapped to inner vertices if $f(|\sigma|)$ is close to the origin, or $g(\sigma)$ avoids the origin if $f(|\sigma|)$ is close to the boundary; see Figure 10. We refer to this requirement on σ as the *planner condition*. If the condition fails on some facet, we subdivide K until it is satisfied. The termination of this procedure is established in Proposition 12.

(a) Image $f(|\sigma|)$ close to the origin. **(b)** Image $f(|\sigma|)$ away from the origin.

Figure 10 For every facet $\sigma \in K$, the *planner condition* checks whether the image $f(|\sigma|)$ (in blue) is U-close to a simplex τ of L (in red). Lemma 11 allows us to enclose $f(|\sigma|)$ in a ball (in purple).

List homomorphism problem

Once the planner condition is satisfied on K, we obtain, for each facet $\sigma \in K$, a collection of admissible simplices $\tau_1, \tau_2, \ldots$ of L. From these, we derive for each vertex $v \in V(K)$ a set $\mathcal{L}(v) \subset V(L)$ of admissible images, thus defining a map to the power set

$$\mathcal{L}\colon V(K) \to \mathcal{P}(V(L))$$

Given these lists of candidates, the remaining task is to find a simplicial map g with $g(v) \in \mathcal{L}(v)$ for every vertex. The motion planner ensures that such a map is homotopic to f.

In this form, the problem is essentially an instance of the *list homomorphism problem*, denoted `LHom`. Conventionally, it is formulated for graphs rather than simplicial complexes, and one typically forbids collapsing an edge to a vertex. It is known that `LHom` can be solved in polynomial time when L is a bi-arc graph and is NP-complete otherwise [62, 55].

In practice, we treat our instance as a constraint satisfaction problem and solve it using the `CP-SAT` solver from the `OR-Tools` suite [95, 96]. If the resulting problem is unsatisfiable, we refine the triangulation K and repeat the procedure, as formalized in Algorithm 1.

Delaunay simplifications

Once a simplicial map $g\colon K \to L$ has been found, we apply a postprocessing step that we call *Delaunay simplification*. Since the simplicial sphere K arises as a Delaunay complex $K = \mathrm{Del}(X)$ on a finite set $X \subset S^d$, we seek a subset $X' \subset X$ such that the induced vertex map $g'\colon \mathrm{Del}(X') \to L$ is still simplicial and homotopic to f.

Concretely, we inspect the vertices of X one by one, remove a candidate vertex, recompute the Delaunay complex, and then check whether the new facets still satisfy the planner condition and whether the induced map remains simplicial. This procedure is efficient, since deleting a point $v \in X$ only affects the open star of v in $\mathrm{Del}(X)$. Besides, to promote larger simplices, we preferentially remove vertices that belong to facets with the smallest inradius.

Local Delaunay refinements

A drawback of our method is that it refines the entire complex, even when the obstruction is localized on a few facets. To address this, we introduce a *local refinement* strategy. If the solver reports that the instance is infeasible, we instead consider a weaker problem that we call `LHomDrop`: determine a minimal set of facets $\sigma_0, \ldots, \sigma_k$ of K whose removal makes the instance feasible. We then perform a local refinement by inserting Steiner points (see Section 2.2) only on the facets blamed by the solver. In practice, we impose a time limit and use the best solution found by the solver so far (30 seconds in our implementation).

To accelerate the procedure, we apply `LHom` iteratively on the i-skeleta and use the solution in dimension i as a hint for dimension $i+1$. If the instance is infeasible in dimension i, we call `LHomDrop` to identify which i-simplices are to blame, and refine their maximal cofaces.

In the same spirit, when enforcing the planner condition we may refine only those facets on which the condition fails. We write down our procedure, both for global and local refinements, in Algorithm 1 below. We are currently able to prove termination only for the variant with global refinement. However, in all our experiments the local refinement strategy also terminated and produced significantly smaller triangulations.

▶ **Proposition 12.** *With global refinement, Algorithm 1 terminates and produces a simplicial map homotopic to the input continuous map. With local refinement, if it terminates, then the output is also homotopic to the given map.*

Algorithm 1 Simplicial approximation with global or local refinement and simplification.

Input: map $f\colon S^d \to |L|$, triangulation K of S^d, planner (U, Π) on L, scalar $\lambda > 0$
Output: refinement of K and simplicial map $g\colon K \to L$ homotopic to f

repeat
  compute admissible lists $\mathcal{L}(v) \subset V(L)$ via the planner condition;
  solve `LHom` with a SAT solver to obtain g;
  if *no solution* **then**
    apply Delaunay refinement on K (global, or only facets blamed by `LHomDrop`);
until *a solution g is found*;
apply Delaunay simplification to (K, g);
return (K, g);

4.3 Full algorithm

We now assemble the ingredients of Sections 2–4 into the full procedure, summarized in Algorithm 2. The input is a finite CW complex X together with explicit attaching maps for its cells and Lipschitz constants. The output is a finite simplicial complex L together with a homotopy equivalence $X \to |L|$ encoded as a point location routine on $|L|$.

Algorithm 2 Simplicial approximation to CW complexes with global or local refinement.

Input: CW complex X of dimension n with cells e_i^d, attaching maps ϕ_i^d, scalars λ_i
Output: simplicial complex L endowed with a homotopy equivalence $X \to |L|$

$L \leftarrow$ discrete simplicial complex on the 0-cells of X;
for $d = 1, \dots, n$ **do**
  foreach *d-cell e_i^d with attaching map $\phi_i^d\colon S^{d-1} \to X^{d-1}$* **do**
    compose ϕ_i^d with $X^{d-1} \to |L|$ to obtain $f_i^d\colon S^{d-1} \to |L|$;
    use Algorithm 1 to obtain $g_i^d\colon K_i \to L$ homotopic to f_i^d (with global or local refinement, and parameter λ_i);
    construct a simplicial ball $B(K_i)$ and glue it to L along K_i via g_i^d, i.e., let $L \leftarrow L \cup_{g_i^d} B(K_i)$;
    endow $|L \cup_{g_i^d} B(K_i)|$ with an equiconnecting map or a local motion planner;
return L;

▶ **Theorem 13.** *With global refinement, Algorithm 2 terminates and produces a simplicial complex homotopy equivalent to the given CW complex. With local refinement, if it terminates, then the output is also homotopy equivalent to the input CW complex.*

Abstract

We propose a novel geometric-topological descriptor called a mixup barcode. Intuitively, it characterizes the shape of a point cloud as well as its spatial relationship with another point cloud embedded in the same ambient space. More technically, it enriches a standard persistence barcode with information on the image persistent homology. In three dimensions it captures natural spatial relationships like overlap and surrounding; in higher dimensions more intricate spatial relationships are captured. We provide a theoretical setup and a simple algorithm for mixup barcodes.

As a proof of concept, we explore data arising in a geometric-topological problem from machine learning. Specifically, we take first steps towards verifying a hypothesis stating that geometric-topological relationships within intermediate point cloud representations in an artificial neural network can hinder its training. More broadly, our experiments suggest that mixup barcodes are useful for characterizing spatial relationships and spatial interactions (i.e. the evolution of spatial relationships) that are hard to directly visualize or capture using standard methods.

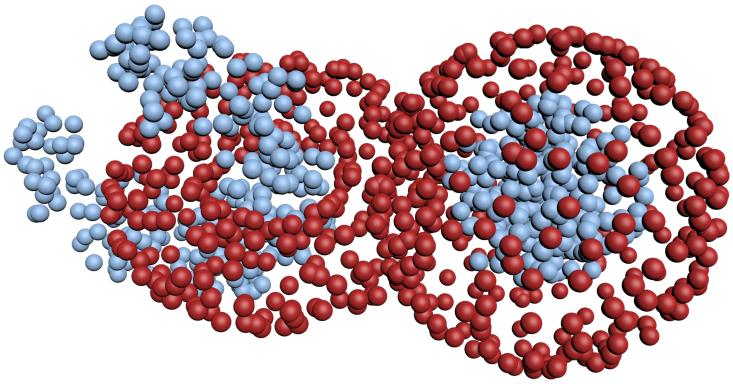

Figure 1 TDA allows us to characterize the shapes of the two, red and blue, point clouds. We also ask: what are the spatial relationships between these point clouds? Intuitively, a portion of the blue point cloud is surrounded by the spherical part of the red one; similarly, another portion of the blue point cloud loops around the toroidal subset of the red points. These are natural questions and we currently lack the tools (and in some cases the language) to discuss them. High-dimensional generalizations play an important role in the machine learning problem we consider.

1 Introduction

Computational geometry delivers a variety of tools for characterizing the shape of a point cloud. One can compute the convex hull, the Delaunay triangulation and its variants, and related filtrations such as alpha filtrations. Analogs for high dimensional point clouds such as Rips and Čech filtrations are becoming better understood [20] and more computable [4, 14].

The shape of data. In recent years, it has become popular to summarize the geometric-topological structure of a point cloud using persistent homology. It involves computing a persistence diagram, or barcode, serving as a geometric-topological descriptor of a dataset.

Beyond the shape of data. There are important problems which require characterizing the **spatial relationships** among datasets. We provide a new tool, called a **mixup barcode**, which captures both the shape of data and its spatial relationships with another dataset embedded in the same ambient space. See Figure 1 for an example. We will also consider spatial interactions, by which we mean the evolution of spatial relationships over time.

In overview, mixup barcodes capture how the inclusion of another point cloud affects the persistent homology of an existing point cloud. Specifically, we ask how the lifetime of each topological feature shortens in the presence of new data. This way we quantify the spatial relationships between the two point clouds. While this task fits the general framework of multi-parameter persistent homology, we take a more pragmatic and computable approach. We frame this intuition in terms of persistent homology as well its variant, image persistent homology, which was recently shown to be efficiently computable [7]. We carefully combine these two pieces of information.

A proof of concept application. Our method is motivated by a problem arising in machine learning. We will refer to this problem as *the disentanglement problem*. In [29], it was hypothesized that training can be hindered by geometric-topological interactions within the intermediate representations (point clouds) produced by such models. Intuitively, a

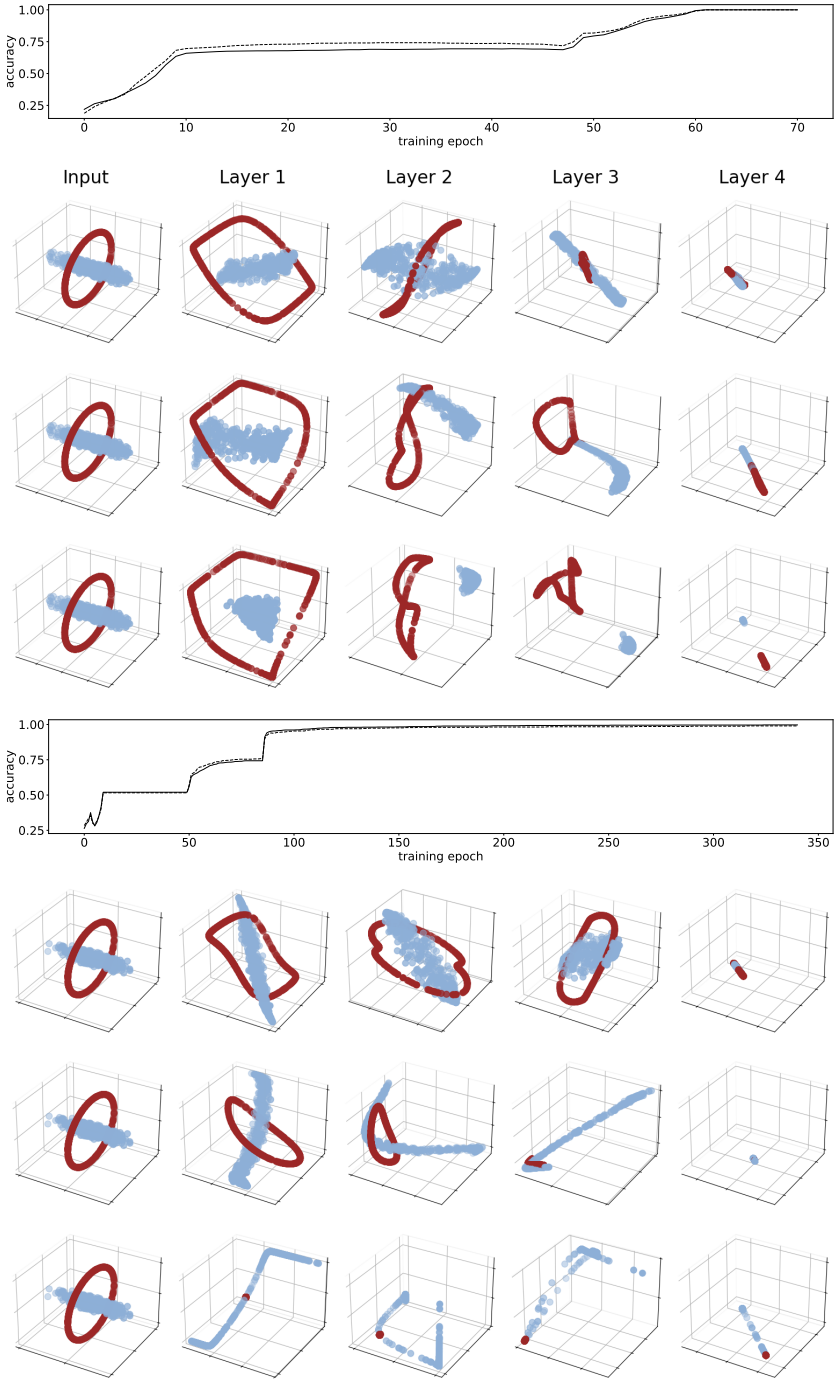

Figure 2 Two training runs of the same MLP classifier. For each run, three selected training epochs are shown as rows. Each row shows the outputs of consecutive layers from left to right. Intuitively, at the end of the training, the blue and red points output by the *last* layer should be separated. In both cases (almost) perfect test accuracy is achieved. However, in the second run the model failed to *disentangle* the red and blue points, and a small portion of the blue points became *confused* with the red points. In particular, this behavior lowers the generalization power of the model (since certain new inputs are bound to be misclassified). We propose tools for detecting such situations.

model may fail to **disentangle** the representations corresponding to data with different labels – see Figure 2 for a concrete example. First steps towards testing this hypothesis were recently made using persistent homology [27, 39]. We argue that our method offers additional, useful information, and present experiments supporting this claim. We elaborate on the experimental setup in Section 7.

Contributions. The contributions of this paper include:

1. Mathematical foundations for a new topological descriptor called a *mixup barcode* characterizing spatial relationships between point clouds.
2. Summary statistics quantifying the robustness of these relationships.
3. Experiments showing the computability and usefulness of mixup barcodes in the above-mentioned machine-learning problem.
4. A simple practical algorithm for computing mixup barcodes.
5. This is one of the first applications of image persistence [13] and the first application we are aware of for high-dimensional data.

Connections and potential impacts. We expect this work to expand the standard paradigm of topological data analysis, namely from summarizing and learning from the shape of a point cloud, to summarizing and learning from the spatial relationships among point clouds. This goal is aligned with the emerging direction of Chromatic Topological Data Analysis outlined in [16]. Our work was developed independently, but both directions build on the same theoretical and algorithmic foundation [13]. The main novelty of our approach comes from providing a single, compound descriptor that merges two simpler barcodes. These barcodes are typically considered in isolation – which loses important information that our method retains (at a negligible computational cost). We will contrast these approaches further in Section 8.

Once the theoretical and computational aspects are fully developed, the proposed tool will likely open new applications of geometric-topological methods.

2 Related work

We briefly review related work in computational geometry and topology, as well as their relevant applications in machine learning.

Image persistence. Regarding computational methods for image persistence, an algorithm was proposed by Cohen-Steiner and collaborators [13]. An implementation is available in the first version of Morozov's Dionysus library, but not in the current version. Recently, Bauer and Schmahl proposed a version [7] of the Ripser library for image persistence of Vietoris–Rips complexes, which informs our implementation. One of the first practical applications of image persistence was done recently in the context of image segmentation [33].

Cultrera di Montesano and collaborators [17] have proposed an approach for analyzing the mingling of a small number of 3-dimensional point clouds using image (as well as kernel and cokernel) persistence. One crucial development is the chromatic alpha complex which allows for the efficient computation of these variants of persistence for data embedded in low dimensions. Their motivation is similar to ours, although both projects were started and developed independently. Our focus is on a single descriptor combining standard persistence with image persistence, while theirs is on different types of persistent homology and connections between them. Natarajan et al., study the Morse theory of chromatic Delaunay complexes [28] and provide an implementation.

Induced matching. Our results are also related to work on induced matchings originating in [6]. In particular, similar ideas were independently explored by Gonzalez-Diaz and coauthors [22, 23, 35].

Persistent homology in machine learning. Techniques and tools from topological data analysis have recently found a number of fruitful applications to machine learning and in particular deep neural networks [44]. Persistent homology has been used in developing topological network layers [21, 24, 26]. Another approach incorporates topological information about the data into the loss function of a neural network [11, 12, 25, 37]. Topological methods were also used to analyze other aspects of artificial neural networks [9, 30, 32, 38, 40, 42]. In [3] a variant of persistent homology was developed to compare neural networks.

Disentanglement in deep neural networks. In machine learning, disentanglement is a broad concept. We are interested in how embeddings corresponding to different classes are separated during the training of a classifier. A motivation for this work goes back to an influential 2014 blog post [29] by Olah on "Neural Networks, Manifolds, and Topology" – ten years later we have appropriate computational tools to address this challenge.

Perhaps the fist explicit mention of (manifold) disentanglement in the context of deep learning is in the work of Brahma, Wu and Yiyuan [8]. The work of Zhou and collaborators provides a topological view on disentanglement in the context of machine learning as well as a thorough overview [43]. We refer the reader interested in the machine learning details there, and focus on geometric-topological aspects of the problem. Our experiments are inspired by the work by Naitzat and collaborators [27] and the follow-up by Wheeler, Bouza and Bubenik [39]. We alleviate some of the shortcomings of these approaches that stem from the limitations of persistent homology applied to a single point cloud. Reani and Bobrowski proposed a data-analysis method [31] based on matching geometrically close cycles.

3 Mixup barcodes

In this technical section we propose the mathematical setup for mixup barcodes. We delay detailed interpretation to the next section. We will work with filtrations of simplicial complexes, chain complexes, persistence modules and their decompositions.

Overview. In the simple case, we study point clouds A and B, via the inclusion $A \hookrightarrow A \cup B$. We ask how the persistence of each topological feature arising from A is shortened by the inclusion of points in B. The constructed *mixup barcode* splits each bar in the standard persistence barcode of A into two sub-bars. The first sub-bar quantifies this new, shortened lifetime, and is computed using a variant of persistent homology called image persistence. The second sub-bar is called a mixup sub-bar, and quantifies the shortening of the lifetime.

We follow up with technical definitions, but a reader interested in an intuitive explanation could jump to Section 5 and especially Figure 3.

Technical definitions. We will work with two filtrations L and K – which will be connected by an inclusion that we describe in a moment. Specifically, let K denote a filtered finite simplicial complex $K_1 \hookrightarrow K_2 \hookrightarrow \cdots \hookrightarrow K_n$ with inclusion maps $K_i \hookrightarrow K_j$ for $1 \leq i \leq j \leq n$, and similarly for L.

We assume that both filtrations are simplex-wise, i.e. for each i, L_{i+1} differs from L_i by at most one simplex and similarly for K. We further assume that each σ added in L_i, is not already present in K, namely $\sigma \notin K_{i-1}$, where $K_0 = \emptyset$. The index of a simplex is the i at

which it appears in the filtration, which is uniquely defined under the above assumptions. Further, we will sometimes assume that we have a real-valued order-preserving function f assigning a **filtration value** to each simplex.

The above assumptions may be met in the context of Vietoris–Rips filtrations, which will be our practical setup. In particular, while several simplices will typically appear at the same filtration value, it is easy to use an ordering of the simplices to obtain a finer simplex-wise filtration. We remark that everything in this section also generalizes to finite cell complexes.

The studied inclusion map. For each $k \geq 0$ we consider the inclusion map $\iota : L \hookrightarrow K$ between our filtrations L and K. This gives rise to a variety of algebraic structures and induced maps between them. Of primary interest are the persistence modules $H_k(L)$ and $H_k(K)$ and an induced map between them $H_k(\iota) : H_k(L) \to H_k(K)$. This information is summarized in the following commutative diagram of vector spaces and linear maps.

$$\begin{array}{ccccccccc} H_k(L_1) & \longrightarrow & H_k(L_2) & \longrightarrow & \dots & \longrightarrow & H_k(L_i) & \longrightarrow & \dots & \longrightarrow & H_k(L_n) \\ {\scriptstyle H_k(\iota_1)}\downarrow & & {\scriptstyle H_k(\iota_2)}\downarrow & & & & {\scriptstyle H_k(\iota_i)}\downarrow & & & & {\scriptstyle H_k(\iota_n)}\downarrow \\ H_k(K_1) & \longrightarrow & H_k(K_2) & \longrightarrow & \dots & \longrightarrow & H_k(K_i) & \longrightarrow & \dots & \longrightarrow & H_k(K_n) \end{array} \tag{1}$$

The image of the map of persistence modules in (1) is the following persistence module:

$$\mathrm{im}(H_k(\iota)) = \mathrm{im}(H_k(\iota_1)) \to \mathrm{im}(H_k(\iota_2)) \to \cdots \to \mathrm{im}(H_k(\iota_i)) \to \cdots \to \mathrm{im}(H_k(\iota_n))$$

We are interested in the barcodes of the persistence module $H_k(L)$ (i.e. the persistent homology of L) and the persistence module $\mathrm{im}(H_k(\iota))$ (i.e. the image persistent homology of the inclusion). Specifically, we will combine the information contained in these barcodes in a meaningful way, to form a single richer descriptor.

To do so, we notice that under our assumptions for each index $i \in \{1, 2 \dots, n\}$ there is at most one interval in the barcode with minimum value i. We call such i the **birth index** of the corresponding interval in the barcode. This allows us to match these barcodes by the birth *indices*; for brevity we refer to the following more general result.

▶ **Theorem 1** (Matching [6, Theorem 4.2, Proposition 5.7])**.** *There is a canonical surjective matching from the barcode of $H_k(L)$ to the barcode of $\mathrm{im}(H_k(\iota))$ which matches intervals with the same birth index.*

With this, we reorganize the information in this canonical matching of barcodes as follows.

▶ **Definition 2** (Mixup barcode)**.** *The **mixup barcode** in degree k of the inclusion $L \hookrightarrow K$ is the collection of triples of indices consisting of a triple (b, d', d) for each pair of matched intervals $[b, d)$ and $[b, d')$ in the barcodes of $H_k(L)$ and $\mathrm{im}(H_k(\iota))$; and a triple (b, b, d) for each unmatched interval $[b, d)$ in the barcode of $H_k(L)$.*

The above definition is in terms of the filtration indices. In practice, we often replace them with the filtration values of the corresponding simplex. Typically the distinction will be clear from context, but sometimes we will explicitly talk about **index mixup barcodes**.

Viewing the mixup barcode as a refinement of the persistence barcode of L, we visualize it in a similar way. Specifically, we plot the image sub-bar in a light color, and its complement, the mixup sub-bar, in a darker color. We consider a separate mixup barcode for each degree; see Figure 3 for an example.

Mixup barcodes for point clouds. We consider two finite point clouds, $A, B \subset \mathbb{R}^d$, or more generally, a finite metric space X with $A \subset X$ and $B = X \setminus A$, and construct Vietoris–Rips filtrations of A and $A \cup B$, with a common sequence of radii, $r_1 \leq r_2 \leq \cdots \leq r_n$. The simplicial filtrations L and K are given by $L_i = \mathrm{VR}(A; r_i)$ and $K_i = \mathrm{VR}(A \cup B; r_i)$. By the mixup barcode of $A \hookrightarrow A \cup B$, we mean the mixup barcode induced by $L \hookrightarrow K$ as defined above. Unlike a persistence barcode, a mixup barcode is sensitive to the *ordering* of the simplices, since it may affect the matching.

4 Related concepts and statistics

With the main technical definition in place, we explain the rationale behind it, and mention some properties. We start with defining an analog of a **persistence pair** [18] that can be expressed either in terms of the indices or filtration values.

▶ **Definition 3** (Mixup triple). *Each triple (b, d', d) in the mixup barcode of $L \hookrightarrow K$ is called an **mixup triple**.*

We reiterate what information is stored in each mixup triple.

▶ **Definition 4** (Persistence bar and image and mixup sub-bars). *For each mixup triple (b, d', d), we have a **persistence bar** $[b, d)$, which splits into what we call:*
- i *an **image sub-bar** $[b,\ d')$, and*
- ii *a **mixup sub-bar** $[d',\ d)$,*

noting that degenerate sub-bars of the form $[x, x)$ are allowed.

▶ **Observation 5.** *The mixup barcode of $L \hookrightarrow K$ contains the persistence bars of L and its image sub-bars correspond to the image persistence barcode. However, the mixup sub-bars will generally* not *coincide with any bars of kernel persistence barcode. We provide an explicit example in the full version of the paper.*

▶ **Definition 6** (Premature death). *Given an index mixup triple (b, d', d) we interpret the index d' as the index of premature death of the unique homology class γ born at L_b. Specifically, we mean the first index at which γ becomes trivial or merges with an older homology class in $H_k(L)$.*

▶ **Observation 7.** *We stress that a premature death arises from the image persistent homology vector spaces of our inclusion, namely $\frac{Z_k(L_i)}{B_k(K_j) \cap Z_k(L_i)}$. (Contrast this with the standard persistence: $\frac{Z_k(L_i)}{B_k(L_j) \cap Z_k(L_i)}$.) This premature death is therefore caused by the extra boundaries coming from K – but not by merging with another homology class present in $H_k(K)$ but absent from $H_k(L)$.*

4.1 Statistics

It is often useful to extract a single number from a persistence barcode. For example, the total persistence – the sum of the lengths of all bars – is used to quantify the topological complexity of a point cloud. In a similar vein, we define simple ways of extracting a number to quantify the strength of interactions between filtrations L and K.

▶ **Definition 8** (Mixup). *The mixup of a mixup triple (b, d', d) is the value $d - d'$.*

In other words, it is the length of the sub-bar (d', d) which quantifies the prematurity of the death of a single homology class.

▶ **Definition 9** (Total mixup). *The **total mixup** of $L \hookrightarrow K$ is the sum of the mixups for the bars in the mixup barcode.*

In our visualization, it is simply the sum of the lengths of the dark bars. We refer to this sum as total-mixup(A, B). Equivalently, it is the difference between the total persistence of A and the total image persistence of $A \hookrightarrow A \cup B$.

Scale invariant statistics. The next two definitions allow us to make scale-invariant measurements. Firstly, this allows us to compare data embedded in different dimensions. Secondly, the geometric scale of topological features is irrelevant for our application.

▶ **Definition 10** (Mixup percentage). *The **mixup percentage** of mixup triple $t = (b, d', d)$ is*

$$mixup_{\%}(t) = \frac{mixup(t)}{pers(t)} = \frac{d - d'}{d - b}. \tag{2}$$

▶ **Definition 11** (Total mixup percentage). *The **total mixup percentage** (**mean mixup percentage**) of a mixup barcode is the sum (mean) of the mixup percentages for all its bars.*

Note that the latter variant is between 0 and 1, but is *not* the ratio of the total mixup and the total persistence. The mean mixup percentage has the added benefit of allowing for the comparison between datasets of differing total persistence, which will be crucial in our application.

5 Geometric interpretation

In this section we provide intuitive interpretations of the information captured by mixup barcodes in various degrees. It turns out that they often capture natural spatial relationships.

Holes. We recall that for a shape embedded in three dimensional space, homology groups in **degree** 0, 1, 2 are often interpreted as various types of holes: the gaps between distinct parts of the object (or dually the connected components); tunnels (or handles); voids enclosed by the object. Note that in general voids correspond to H_{n-1} for objects in $\mathbb{R}^n$. Persistent homology captures the births and deaths of such features along the filtration.

Spatial relationships for point clouds. Going back to the case of a pair of point clouds A and B in $\mathbb{R}^3$, the shortening of the lifetime of a homological feature conveys how points from B fill the holes of different types.

Specifically, in degree 0, mixup quantifies to what extent the connected components in A *merge quicker* via points in B – which has natural interpretations as A and B **overlapping** or A being **separated** by B. In degree 1, it quantifies how much quicker points in B fill up a loop or tunnel formed by A – for example when a portion of A encircles a portion of B (like in a Hopf link). In degree 2, it quantifies how points in B contribute to filling up a void inside A – which we interpret as a portion of A **surrounding** a portion of B. Figure 3 illustrates these spatial relationships and the corresponding mixup barcode.

For the machine learning example illustrated in Figure 2, mixup in degree 1 is most relevant as it captures the red points initially *encircling* the blue points, and then either *tightening* around them, or *separating* from them. For the second case, mixup in degree 0 is also useful.

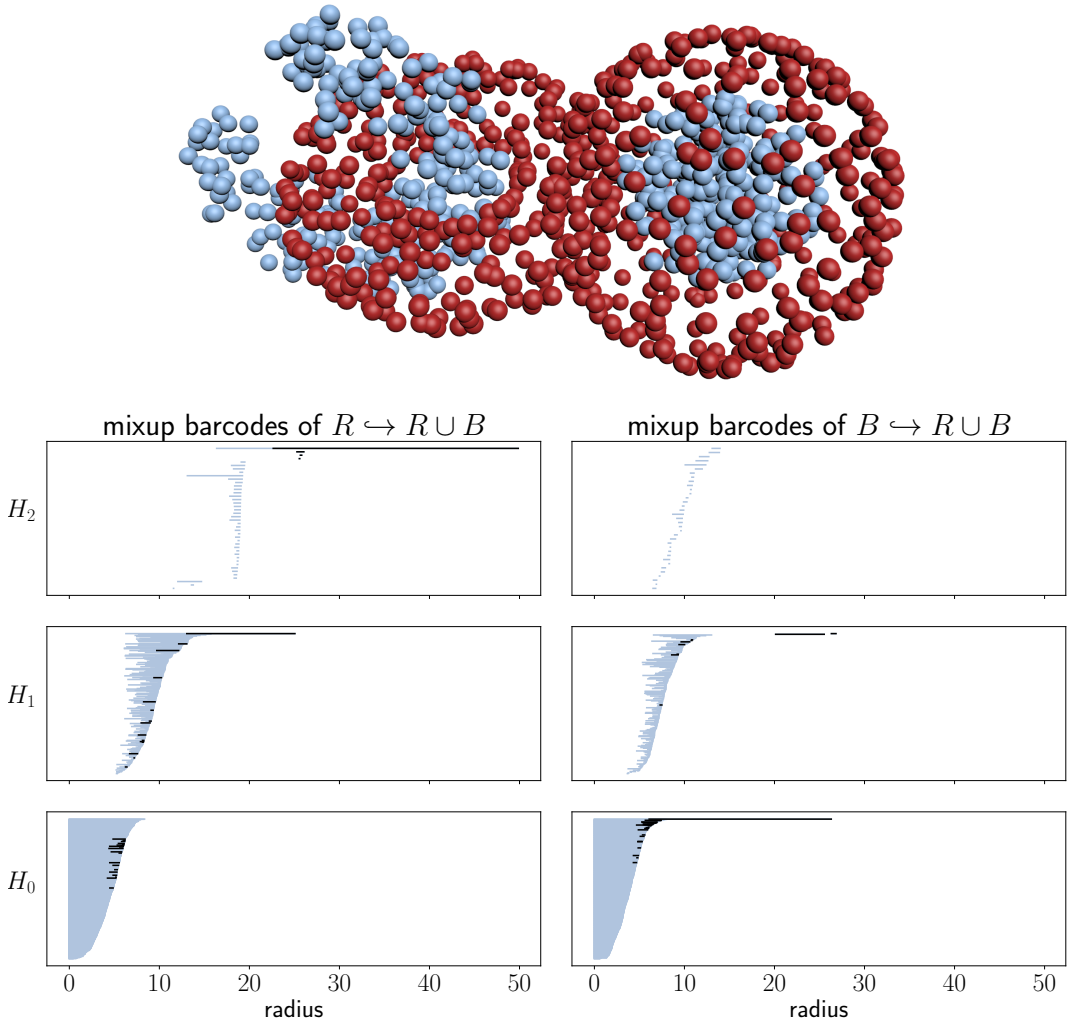

Figure 3 Top: Two point clouds: R red (dark) and B blue (light). **Bottom:** Mixup barcodes of R and B included in their union, in degrees $2, 1, 0$. Recall that each persistence bar is split into an image sub-bar and a mixup sub-bar (marked in thick black). **Bottom left:** In H_2, we see a prominent persistence bar with a long mixup bar. It detects the red **void** partially filled by blue points, interpreted as the red object **surrounding** a part of the blue object. Similarly in H_1 the prominent mixup bar detects the red handle (tunnel) that **encircles** the blue points. No significant mixup occurs in H_0, although the many shorter mixup bars detect the **overlap** between the two shapes. **Bottom right:** In H_1 the mixup barcode detects the handle **encircled** by the red object, with the late birth indicating that a large part is missing. The prominent bar for H_0 detects that the two blue connected components connect quicker via the red points. We interpret this as **separation** of the two blue parts by the red object. As expected, there is no prominent persistence in H_2.

In summary, for point clouds in $\mathbb{R}^n$, the mixup barcode captures: **overlap** or **separation** in degree 0 and **surrounding** in degree $n-1$. In remaining degrees it captures how holes in degree k present in L are filled by boundaries in K, which corresponds to more subtle and harder to name interactions.

6 Algorithm

In this section we describe a simple algorithm for the decomposition of a persistence barcode into a mixup barcode and prove its correctness under the assumptions in Section 3. We start by recalling the algorithms for standard and image persistent homology, which will be part of our construction.

Standard reduction algorithm. Persistent homology can be computed using a version of Gaussian elimination on the boundary matrix representing the filtration [18]. We call such an algorithm REDUCE.

The ordering of columns and rows corresponds to the order in which the elements (typically simplices) appear in the filtration. By adding the columns (only from left to right) modulo 2, the algorithm removes conflicts between columns, by which we mean columns having the same pivot. The index persistence pairs are formed by the indices of nonzero columns and their pivots in the final (reduced) matrix. This information does not depend on the choice of column additions [19].

Image persistent homology computations. Image persistent homology can be computed using a variant of the above algorithm, as described in [13, pp. 5-6]. Perhaps surprisingly, this algorithm reorders the *rows* of the boundary matrix, so that the elements from L come first (ordered by the filtration index), followed by the elements from $K \setminus L$ (also ordered by the filtration index). The image index persistence pairs are of the form (σ, τ'), where the τ' is the index of a nonempty column whose pivot σ corresponds to a simplex in L [13, Observations (ii),(iii)]. This yields a modified Elder rule: The youngest class from $K \setminus L$ is destroyed whenever available; otherwise, the youngest class from L is destroyed, as usual [18]. A cohomological version is obtained by working on anti-transposed matrices [5].

Mixup barcodes algorithm. Algorithm 1 outlines the algorithm that decomposes the bars in the standard persistence diagram into the mixup barcode. The key new idea is to coordinate the two matrix reductions, but preparing two filtrations with consistent indexing. These reductions yield the standard and image persistent homology. The latter computation involves the reordering of the rows, as mentioned above. This coordinated reduction allows us to merge the two pieces of information. In contrast, computing the standard and image persistence on two unrelated filtrations loses the correspondence between these two pieces of information. Additionally, we reiterate that mixup bars generally do not coincide with kernel persistence, necessitating the use of our algorithm.

Computational complexity and implementation. Due to the use of Gaussian elimination, the algorithm runs in $O(n^3)$ worst-case time, where n is the number of simplices. As with standard persistence [5], the running time is significantly better in practice.

Algorithm 1 Algorithm for Mixup Barcode in degree k.

Require: Simplex-wise filtrations L and K as in Section 3; f assigning the filtration value to each simplex; degree k

BK = matrix with columns containing the boundaries of the k- and $(k+1)$-simplices of K with rows and columns ordered by the filtration index
reorder the rows of BK such that the simplices from L have smaller indices than the simplices of $K \setminus L$ while retaining the relative order of simplices in L and also in $K \setminus L$
form matrix BL by zeroing out the entries in BK involving the simplices of $K \setminus L$
REDUCE matrices BL and BK.
for each index σ of a k-simplex in L such that $BL[\sigma] = 0$ **do**
    $birth = f(\sigma)$; $death = death' = \infty$
    if $\exists\ \tau$ such that $\text{pivot}(BL[\tau]) = \sigma$ **then** $death = f(\tau)$
    if $\exists\ \tau'$ such that $\text{pivot}(BK[\tau']) = \sigma$ **then** $death' = f(\tau')$
    record mixup triple $(birth, death', death)$
return all the recorded mixup triples

▶ **Theorem 12** (Mixup Decomposition Theorem)**.** *The algorithm in Algorithm 1 returns a correct mixup barcode of $L \hookrightarrow K$.*

Proof is in the Appendix of the full version of the paper.

7 Experiments

We apply our method to analyzing high-dimensional point clouds. They come from a geometric problem arising in machine learning. The goal is to gain insights about the training of an artificial neural network [2], the **multilayer perceptron** (MLP). It is the simplest *deep learning* method, often used for classification. We remark that models based solely on MLPs can achieve state of the art performance on challenging tasks [34].

Model parameters. We use a 5-layer MLP, with embedding dimensions $512, 256, 128, 10$ and L, where L depends on the number of considered labels (in our case 3 or 10). The model has $565,248 + 10L$ trainable parameters (weights).

7.1 Datasets

We use two well known datasets with different levels of complexity. Note that while performing classification on these datasets is considered solved – understanding how machine learning models achieve their good performance is an open problem.

MNIST. This is a standard dataset, containing 60,000 grayscale images of size 28×28 depicting handwritten decimal digits. It is a heavily preprocessed version of real-world images, so that the Euclidean distance between two images closely corresponds to their perceptual dissimilarity. For this reason, representing the images as a (labeled) point cloud in $\mathbb{R}^{784}$ yields a faithful representation of the data. It comes split into 50,000 training images, and 10,000 test images. We normalize the values to be between 0 and 1. The model achieves 99% test accuracy when trained and tested on the images with labels 0,1 and 2, which we then use for our experiments. These are images of handwritten zeros, ones and twos. It is known to be an easy problem so we expect to see low mixup at the end of training. We are however curious about the higher-dimensional embeddings coming from the intermediate layers.

CIFAR10. Another standard dataset, containing 50,000 color photos of size 32×32 depicting various objects, animals etc. We treat this data as a (labeled) point cloud in $\mathbb{R}^{3072}$, but the Euclidean distance fails to capture the perceptual similarity. We expect to see more significant entanglement between different classes. This dataset is quite challenging for a basic MLP which achieves only 76% test accuracy when trained and tested the images with labels 0, 1 and 2. These are images of airplanes, cars and birds. We expect it to fail to disentangle the data, especially differentiating between airplanes and birds may be hard due to similar backgrounds.

7.2 Experiments

We use the new method to analyze geometric data arising from a machine learning model. The goal is to quantify geometric-topological difficulties during training – as theoretically outlined by Olah [29]. The results highlight the usefulness of the new methodology – especially in comparison to existing applications of persistent homology [27,39] that focused on quantifying the shape of a single point cloud.

In geometric terms, such a model learns a sequence of linear transformations each followed by a projection onto the positive orthant of $\mathbb{R}^m$, where m may be different at each step. This is done in an iterative training process, whose goal is to finally embed each input point with label number q near the q-th standard basis vector.

Goals. We consider the intermediate representation of the data produced by the i initial layers of the model, namely $M_k = \ell_k \circ \ell_{k-1} \circ ... \circ \ell_1$. Given a single input vector v, we consider $(M_k(v))_k$, namely the sequence of embeddings of v produced by each M_k. Extending this to the entire input point cloud, we get a sequence of point clouds – which additionally change as training progresses. Figure 2 illustrates this for a simplified three-dimensional case.

> We analyze how the representation of input data disentangles passing through the layers – and track this process during training. We aim to verify the conjecture that complicated spatial interactions can hinder training.

We return to the training depicted in Figure 2. In one of the two cases, the model failed to fully disentangle the two point clouds, even though both training and test accuracy reach almost 100%. Such a model is problematic. In this particular case, consider new examples corresponding to the blue region around which the red loop was constricted. These examples are likely to be misclassified, and can for example be exploited in an adversarial attack. More generally, this example shows that geometric-topological information about the embeddings can reveal information about the quality of the training, even when the accuracy (and by analogy the value of the loss function) suggest no such problems.

This situation is of course idealized: the intermediate embedding dimensions can be arbitrarily high, which simplifies the disentanglement problem. Still, complicated entanglement is hypothesized [29, 43] to correlate with training difficulties such as over-fitting and lack of generalization. Indeed, even if disentanglement is theoretically possible, it does not mean that the simplistic training process (oblivious to the global geometric-topological relationships) can realize it. Case in point: in our example, the problem was solvable in this dimension, but one of the training runs failed.

Datasets. To train the model, we will be using two datasets MNIST (easier, 99% accuracy) and CIFAR10 (harder, 76% accuracy). See Section 7.1 for more details. After training, we consider the embeddings produced from the test data. We treat the datasets fa finite labeled point cloud in $X \subset \mathbb{R}^d$. By X_q we mean **class** q of dataset X, namely the subset of points with label number q.

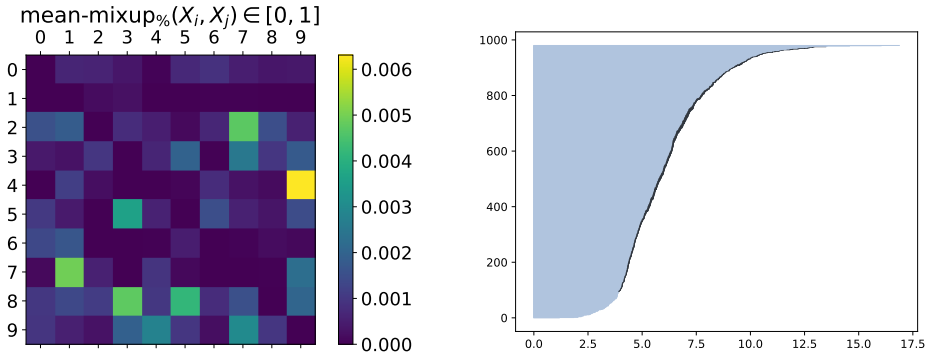

Figure 4 Left: The mean mixup percentage (in degree 0) between all pairs of MNIST classes. Most values are low, as expected due to the simplicity of this data. **Right**: The mixup barcode between the images of fours and nines, which have the greatest mixup. Many bars with small – but positive – mixup suggest that the two point clouds overlap along a broad but shallow interface.

Computations and subsampling. Due to space restrictions we elaborate on these aspects in the full version of the paper.

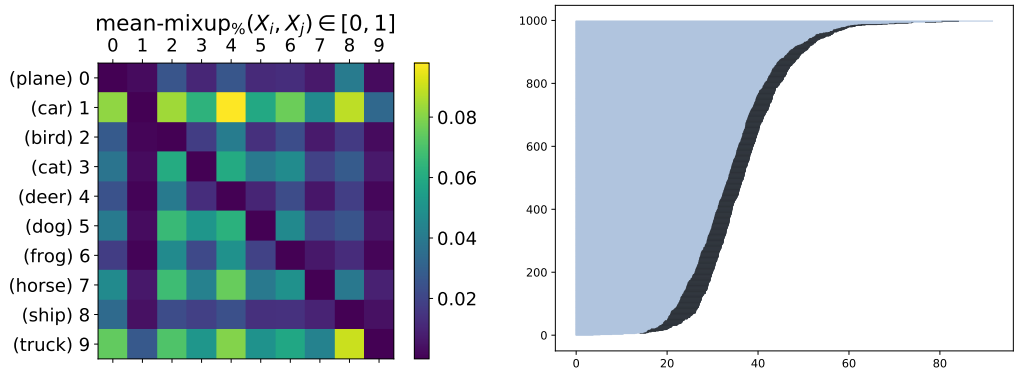

Figure 5 Left: The mean mixup percentage (in degree 0) between all pairs of CIFAR10 classes. Note that the values are generally an order of magnitude higher than for the other dataset, with the highest value of 0.09 between classes 1 (car) and 4 (deer). **Right:** The mixup barcode between classes 1 and 4, suggesting a significantly more robust overlap than we saw in the other dataset.

7.3 Warmup: mixup barcodes on raw inputs

While our primary focus is to analyze the model (and not the input data), we focus on the raw MNIST data for a moment. We do this because previous studies considered the disentanglement of different classes of this dataset [39] through the lens of persistent homology.

However, strong performance of (non-kernel) linear classifiers on MNIST [15, 41] suggests that pairs of point clouds belonging to different classes are easy to separate using an affine hyperplane. This suggests that they are unlikely to be strongly entangled.

As a sanity check, we verified that despite complicated topology, the mixup (which we use as a proxy for entanglement) is typically low. Specifically, we compute the mean percentage mixup in degree 0 for all pairs of classes of examples, namely for $A = X_i$ and $B = X_j$ for all $0 \leq i, j < 10$. The results for MNIST and CIFAR10 are in Figures 4 and 5.

As expected, CIFAR10 exhibits greater mixup, often by an order of magnitude. It is easy to see that persistence barcodes do not distinguish between the two cases. (The only difference comes from different dimensions of the two datasets.)

We emphasize that in general persistent homology of the data may be complicated, even if subsets of point clouds do not exhibit complex spatial relationships. Using persistence directly may overestimate the amount of entanglement. The extra information present in the mixup barcodes is therefore crucial for robust characterization of such phenomena.

7.4 Characterizing the disentanglement across layers

Our goal is to track disentanglement across layers during training. Specifically, we will analyze a labeled point cloud $X_{kqt} \subset \mathbb{R}^n$ for each layer k ($1 \leq k \leq 5$), training epoch t, and label q ($1 \leq q \leq 3$). The information about disentanglement will be characterized using the following concept.

▶ **Definition 13** (Mixup profile). *At each layer k and training epoch t, the mixup profile is computed as: $P_{kt} = \max_j\{\textit{total-mixup}_{\%}(X_{kjt}, \bigcup_{r\neq j} X_{krt})\}$, in homological degrees 0 and 1.*

The **mixup profile**, P_{kt}, measures complexity and strength of interactions between data representations with different labels, serving as a proxy for entanglement. It is visualized as a surface plot, with k (layer) and t (time) on the horizontal axes and P_{kt} (strength of spatial relationship) as the height.

Outcomes. See Figures 6 and 7 for a direct visualization of the mixup profiles for the MNIST and CIFAR datasets.

The main observation is that the mixup profiles are significantly different for the intermediate representations of the two datasets, suggesting that the interactions captured by the mixup barcodes indeed correlate with training difficulties.

Outcomes summary. The mixup profiles successfully distinguish between the training on the CIFAR and MNIST datasets. In particular, the mixup quickly drops for the easier dataset (MNIST), and not for the harder dataset (CIFAR). Overall, the statistics derived from the mixup barcodes do correlate with difficulties during training. They therefore support the conjecture stated in [29]. We stress that while MNIST and CIFAR10 are simple datasets, we analyze the training process on these datasets – which is poorly understood, even for these datasets. We discuss this further momentarily.

8 Discussion

We presented a novel geometric-topological descriptor called a mixup barcode, and its summary statistics. Unlike persistence barcodes, mixup barcodes can be used to characterize not only the shape of a dataset but also its spatial relationships with other datasets. While developed independently, it complements recent development of **Chromatic TDA**, an emerging branch of computational geometry and topology [16]. One advantage of our approach is that a single barcode is produced, which is often simpler to explain and analyze, especially compared to the six barcodes in [16]. Additionally, the mixup barcode retains the

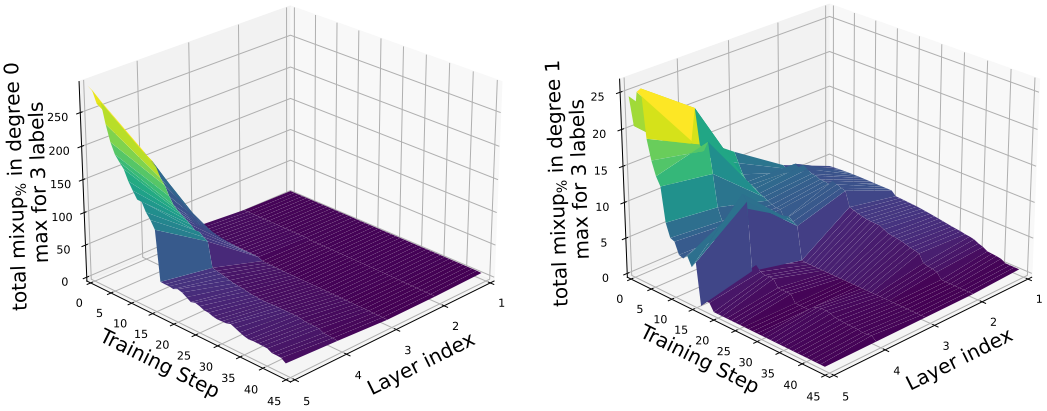

Figure 6 Mixup profiles characterizing the training on the MNIST dataset, in degree 0 (**left**) and degree 1 (**right**). We recall that the height corresponds to the mixup – the complexity of geometric-topological relationships – between intermediate embeddings of data with different labels at a given training step and layer of the model. The point closest to the viewer corresponds to the last layer at the end of training. Here, the mixup initially *grows* with consecutive layers (which makes sense since the input data is simple, but the matrix in each layer is initially random). On the other hand, mixup drops throughout with successive training iterations. This reflects that the network successfully *disentangles* all the embeddings.

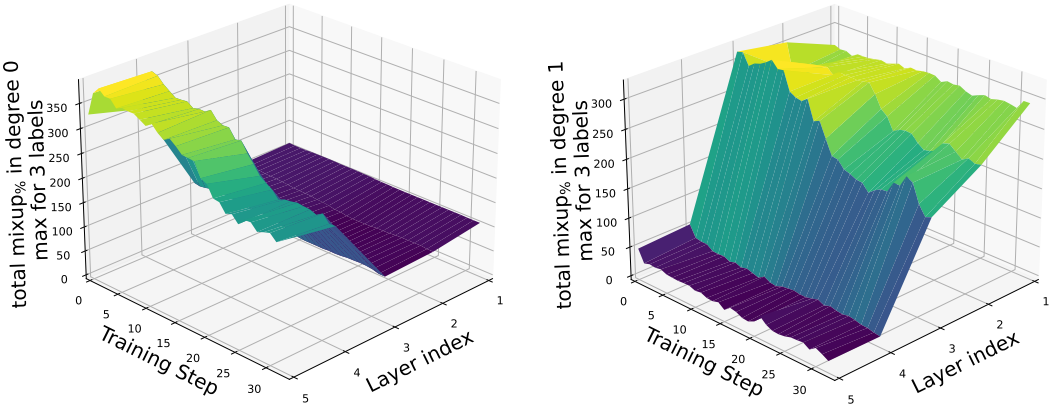

Figure 7 Mixup profiles characterizing the training on the more challenging CIFAR dataset. While the total mixup percentage generally drops during training, it remains generally much higher for CIFAR compared to MNIST. This is consistent with the worse performance of this model on the CIFAR dataset. In particular, for the last layer, mixup in degree 0 initially drops but stabilizes at a relatively high value (which is consistent with the partially successful training); in degree 1 it remains constant (and much higher than for MNIST) – this hints at more complicated spatial relationships between inputs with different classes that were hard to disentangle. Overall, the graphs suggest that the information captured in the mixup barcodes does indeed correlate with training difficulties and the model's failure to disentangle the embeddings.

crucial matching (between the two relevant barcodes), which is otherwise lost. Note that this information cannot in general be reconstructed using individual barcodes, expressed in terms of filtration values. Indeed, the proposed algorithm, working at the level of *index* persistence of two *consistently indexed* filtrations, is necessary.

We also reiterate that kernel persistence bars capture different information than our mixup sub-bars. For our application, it was crucial to use the total mixup percentage, which relies on the matching between persistence and image bars.

Our experiments mark the first application of Chromatic TDA ideas to analyzing high-dimensional data – as well as the first practical application of image persistence to such data. We believe image persistence (and related variants) are powerful tools, but currently underdeveloped and underutilized. We expect that other pairs (or perhaps larger subsets) of barcodes can be combined in a similar way.

On the applied side, this new tool sheds light on the complicated geometry and topology of the training process of machine learning models. The experiments suggest that the theoretical considerations proposed in [29] (in terms of smooth manifolds, point-set topology and knot theory) can now be verified computationally (on finite point clouds). The main outcome is that mixup barcodes capture spatial interactions that were conjectured to hinder training [29].

We expect that this new tool could help detect problems – such as overfitting – already during training, and regularize (or otherwise better control) the training to avoid such problems altogether.

However, further progress, including more detailed experiments, is limited by underdeveloped computational tools and theory. In particular a vectorization, for example generalizing persistence landscapes [10] or images [1], would allow us to feed the mixup barcodes into a statistical or machine learning pipeline. Relatively slow computation [7] of image persistence is another bottleneck. For now we are limited to simple descriptive statistics on small data.

Still, we do believe that our preliminary experiments hint at the usefulness of mixup barcodes, in particular in the context of high-dimensional data.

An Optimal Algorithm for Computing Many Faces in Line Arrangements

Haitao Wang
Kahlert School of Computing, University of Utah, Salt Lake City, UT, USA

Abstract

Given a set of m points and a set of n lines in the plane, we consider the classical problem of computing the faces of the arrangement of the lines that contain at least one point. We present an algorithm of $O(m^{2/3}n^{2/3} + (n+m)\log n)$ time for the problem. We also prove that this matches the lower bound under the algebraic decision tree model and thus our algorithm is optimal. In particular, when $m = n$, the runtime is $O(n^{4/3})$, which matches the worst case combinatorial complexity $\Omega(n^{4/3})$ of all output faces. This is the first optimal algorithm since the problem was first studied more than three decades ago [Edelsbrunner, Guibas, and Sharir, SoCG 1988].

1 Introduction

Let P be a set of m points and L a set of n lines in the plane. We consider the problem of computing the faces of the arrangement of the lines of L that contain at least one point of P; these faces are called *non-empty faces*. Note that each non-empty face only needs to be output once if it contains multiple points of P. Let $\mathcal{A}(L)$ denote the arrangement of L.

Previous work. This is one of the most fundamental problems in computational geometry and has been studied extensively. A straightforward algorithm can implicitly determine the non-empty faces of $\mathcal{A}(L)$ in $O(m\log n + n^2)$ time, by first constructing $\mathcal{A}(L)$, building a point location data structure for $\mathcal{A}(L)$ [15, 21, 25], and then finding the non-empty faces using the point location queries for points of P. The following upper bounds have been proved on the combinatorial complexity of all non-empty faces of $\mathcal{A}(L)$: $O(m^{2/3}n^{2/3}+n)$ [10], $O(n\sqrt{m})$ [17], and $O(n+m\sqrt{n})$ [17]. A lower bound of $\Omega(m^{2/3}n^{2/3}+n)$ [17] is also known, which matches the $O(m^{2/3}n^{2/3}+n)$ upper bound in [10]. Note that the minimum of the above upper bounds is at most $O(m\log n + n^2)$ regardless of the values of m and n. Hence, using the above straightforward approach, $O(m\log n + n^2)$ time is also sufficient to output all non-empty faces explicitly. To have a more efficient algorithm, Edelsbrunner, Guibas, and Sharir [14] first studied the problem and gave a randomized algorithm of $O(m^{2/3-\delta}n^{2/3+2\delta}\log n + n\log n\log m)$ expected time, for any $\delta > 0$. Subsequently, an improved deterministic algorithm of $O(m^{2/3}n^{2/3}\log^{5/3} n\log^{1.11}(m/\sqrt{n}) + (m+n)\log n)$ time was proposed by Agarwal [1]. Also, Agarwal, Matoušek, and Schwarzkopf [2] presented a randomized algorithm of $O(m^{2/3}n^{2/3}\log(n/\sqrt{m}) + (m+n)\log n)$ expected time. No progress had been made for a while until Wang [26] revisited the problem in SODA 2022 and derived a new deterministic algorithm of $O(m^{2/3}n^{2/3}\log^{2/3}(n/\sqrt{m}) + (m+n)\log n)$ time.

On the other hand, $\Omega(m^{2/3}n^{2/3} + n\log n + m)$ is a lower bound for solving the problem due to the above $\Omega(m^{2/3}n^{2/3} + n)$ lower bound [17] on the combinatorial complexity of all non-empty faces and also because computing a single face in line arrangements requires $\Omega(n\log n)$ time in the algebraic decision tree model (indeed, a special case of the problem is to compute the lower envelope of all lines, which has an $\Omega(n\log n)$ time lower bound). In particular, in the *symmetric case* where $m = n$, $\Omega(n^{4/3})$ is a lower bound since the worst case combinatorial complexity of all non-empty faces is $\Omega(n^{4/3})$ [17].

Our result. We propose a new (deterministic) algorithm of $O(m^{2/3}n^{2/3} + (m+n)\log n)$ time for the problem, which is $O(n^{4/3})$ when $m = n$ and matches the above $\Omega(n^{4/3})$ lower bound. For the *asymmetric case* where $m \neq n$, using Ben-Or's techniques [5], we prove that $\Omega(m\log n)$ is also a lower bound under the algebraic decision tree model. Combining with the above $\Omega(m^{2/3}n^{2/3} + n\log n + m)$ lower bound, we thus obtain the $\Omega(m^{2/3}n^{2/3} + (m+n)\log n)$ lower bound for solving the problem. As such, our algorithm for the asymmetric case is also optimal. Although our solution only improves the previously best result of Wang [26] by a factor of $\log^{2/3}(n/\sqrt{m})$, the result is important for providing the first optimal solution to a fundamental and classical problem in computational geometry.

Our algorithm takes a different approach than the previous work. For example, the most recent work of Wang [26] first solves the problem in $O(n\log n + m\sqrt{n\log n})$ time in the dual setting. Then, the algorithm is plugged into the framework of Agarwal [1] as a subroutine. More specifically, the framework first utilizes a cutting of L to divide the problem into a collection of subproblems and then solves these subproblems using Wang's new algorithm.

We dispense with the framework of Agarwal [1], and propose a new algorithm for the problem in the primal setting, which is different from that of Wang [26] in the dual setting. One key subproblem is to merge convex hulls, for which our techniques rely on a crucial observation that certain pairs of convex hull boundaries can intersect at most $O(1)$ times. Using a hierarchical cutting of L [8] and combining our new algorithm with Wang's, we obtain a recursive algorithm that runs in $n^{4/3} \cdot 2^{O(\log^* n)}$ time for the symmetric case $m = n$.

To further reduce the $2^{O(\log^* n)}$ factor, we resort to the recent techniques from Chan and Zheng [7]: the Γ-*algorithm framework* for bounding algebraic decision tree complexities. More specifically, after $O(1)$ recursive steps in our recursive algorithm, we reduce the problem to $O((n/b)^{4/3})$ subproblems of size $O(b)$ each (i.e., in each subproblem, we need to compute the non-empty faces of an arrangement of b lines for b points), with $b = O(\log\log n)$. As b is very small, solving the problem efficiently under the algebraic decision tree model (i.e., only count the number of comparisons) can lead to an efficient algorithm under the conventional computational model (e.g., the real RAM model). With Chan and Zheng's techniques, we developed an algorithm that solves each subproblem in $O(b^{4/3})$ decision tree complexity (i.e., the algorithm uses $O(b^{4/3})$ comparisons). Since b is small, we are able to build a decision tree for the algorithm in $O(n)$ time. With the decision tree, each subproblem can then be solved in $O(b^{4/3})$ time in the conventional computation model. Consequently, the original problem is solved in $O(n^{4/3})$ time. In addition, using this algorithm as a subroutine, the asymmetric case of the problem where $m \neq n$ can be solved in $O(m^{2/3}n^{2/3} + (m+n)\log n)$ time.

Note that our algorithm is not a direct application of Chan and Zheng's techniques. Nor it is a simple adaption of their algorithm for Hopcroft's problem. Indeed, in order to fit the Γ-algorithm framework, we need to design new procedures for a number of subproblems (notably, our techniques involve shaving log factors to merge convex hulls), which may be interesting in their own right. This is also the case for solving other problems when Chan and Zheng's techniques are applied. For instance, Chan, Cheng, and Zheng [6] recently used the technique to tackle the higher-order Voronoi diagram problem and presented an optimal

algorithm by improving the previous best algorithm by a factor of $2^{O(\log^* n)}$. To this end, they had to develop new techniques and made a great effort. On the other hand, there are other problems whose current best solutions have $2^{O(\log^* n)}$ factors, but it is not clear whether the Γ-algorithm techniques [6, 7] can be used to further reduce these factors. For instance, the biclique partition problem for a set of n points in the plane can be solved in $n^{4/3} \cdot 2^{O(\log^* n)}$ time [20, 27]. It has been open whether an $O(n^{4/3})$ time algorithm is possible.

Related work. Other related problems have also been studied in the literature, e.g., the segment case where L consists of n line segments. Although faces in an arrangement of lines are convex, they may not even be simply connected in an arrangement of segments. Therefore, the segment case becomes more challenging. It has been proved that the combinatorial complexity of all non-empty faces of the segment arrangement is bounded by $O(m^{2/3}n^{2/3} + n\alpha(n) + n \log m)$ [4] and $O(n\sqrt{m}\alpha(n))$ [13], where $\alpha(n)$ is the inverse Ackermann function; a lower bound $\Omega(m^{2/3}n^{2/3} + n\alpha(n))$ [14] was also known. To compute all non-empty faces, Edelsbrunner, Guibas, and Sharir [14] first gave a randomized algorithm of $O(m^{2/3-\delta}n^{2/3+2\delta} \log n + n\alpha(n) \log^2 n \log m)$ expected time for any $\delta > 0$. Agarwal [1] presented an improved deterministic algorithm of $O(m^{2/3}n^{2/3} \log n \log^{2.11}(n/\sqrt{m}) + n \log^3 n + m \log n)$ time. Also, Agarwal, Matoušek, and Schwarzkopf [2] derived a randomized algorithm of $O(n^{2/3}m^{2/3} \log^2 n + (n\alpha(n) + n \log m + m) \log n)$ expected time. Wang [26] proposed an $O(n^{2/3}m^{2/3} \log n + \tau(n\alpha^2(n) + n \log m + m) \log n)$ time deterministic time, where $\tau = \min\{\log m, \log(n/\sqrt{m})\}$. An intriguing question is whether our new techniques for the line case can somehow be utilized to tackle the segment case. One obstacle, for example, is that the problem for the segment case in the dual setting is not "cleanly" defined and thus we do not have a corresponding algorithm in the dual setting.

In part because of the difficulty, a special case has been studied extensively, in which we wish to compute a single face in an arrangement of segments. The problem can be solved in $O(n\alpha(n) \log n)$ expected time using a randomized algorithm [9], or in $O(n\alpha^2(n) \log n)$ time using a deterministic algorithm [3]. These algorithms provide improvements over the previous deterministic methods, which required $O(n \log^2 n)$ time [23] and $O(n\alpha(n) \log^2 n)$ time [14] respectively. An open problem in this field has been whether it is possible to have an $O(n\alpha(n) \log n)$ time deterministic algorithm. It is worth noting that computing the upper envelope of all segments can be accomplished more efficiently in $O(n \log n)$ time [19].

The online query problems have also been studied, i.e., preprocess a set of lines or segments so that the face containing a query point can be quickly computed; see, e.g., [12, 18, 26].

Outline. After introducing notation in Section 2, we present an algorithm in Section 3 that solves the problem in the primal plane. Then, in Section 4, we describe the second algorithm (which is mainly from [26]) that tackles the problem in the dual plane. We combine the two algorithms in Section 5 to obtain our final algorithm. Due to the space limit, many details and proofs are omitted but can be found in the full paper.

2 Preliminaries

We follow the same notation as in Section 1, e.g., L, P, n, m, $\mathcal{A}(L)$. Our goal is to compute all nonempty cells of $\mathcal{A}(L)$. For ease of discussion, we assume that no point of P lies on a line of L. Note that this implies that each point of P is in the interior of a face of $\mathcal{A}(L)$. We also make a general position assumption that no line of L is vertical. These assumptions can be relaxed without difficulty by the standard perturbation techniques [16, 28].

For any point p, denote by $F_p(L)$ the face of the arrangement $\mathcal{A}(L)$ that contains p. For a region R in the plane, we often use $P(R)$ to denote the subset of P in R, i.e., $P(R) = P \cap R$.

Cuttings. A tool that will be frequently used in our algorithm is cuttings [8, 22]. For a region R in the plane, we use L_R to denote the subset of lines of L that intersect the interior of R (we also say that these lines *cross* R and L_R is the *conflict list* of R).

A *cutting* for L is a collection Ξ of closed cells (each of which is a possibly unbounded triangle) with disjoint interiors, which together cover the entire plane [8, 22]. The *size* of Ξ is defined to be the number of cells in Ξ. For a parameter r with $1 \leq r \leq n$, a cutting Ξ for L is a $(1/r)$-*cutting* if $|L_\sigma| \leq n/r$ holds for every cell $\sigma \in \Xi$.

We say that a cutting Ξ' *c-refines* another cutting Ξ if each cell of Ξ' is wholly contained within a single cell of Ξ, and if every cell in Ξ encompasses at most c cells from Ξ'.

A hierarchical $(1/r)$-*cutting*, characterized by constants c and ρ, consists of a series of cuttings $\Xi_0, \Xi_1, \ldots, \Xi_k$ with the following property. Ξ_0 has a single cell that is the entire plane. For each $1 \leq i \leq k$, Ξ_i is a $(1/\rho^i)$-cutting of size $O(\rho^{2i})$ that c-refines Ξ_{i-1}. To make Ξ_k a $(1/r)$-cutting, we select $k = \Theta(\log r)$ to ensure $\rho^{k-1} < r \leq \rho^k$. Consequently, the size of Ξ_k is $O(r^2)$. As already shown in [8], it can be easily verified that the total number of cells of all cuttings Ξ_i, $0 \leq i \leq k$, is also $O(r^2)$, and the total size of the conflict lists L_σ for all cells σ of Ξ_i, $0 \leq i \leq k$, is bounded by $O(nr)$. If a cell σ within Ξ_{i-1} contains a cell σ' in Ξ_i, we call σ the *parent* of σ' and σ' a *child* of σ. In the following, we often use Ξ to denote the set of all cells of all cuttings Ξ_i, $0 \leq i \leq k$.

For any $1 \leq r \leq n$, a hierarchical $(1/r)$-cutting of size $O(r^2)$ for L (together with the conflict lists L_σ for all cells σ of Ξ_i for all $i = 0, 1, \ldots, k$) can be computed in $O(nr)$ time [8].

3 The first algorithm in the primal plane

We present our first algorithm for the problem, which works in the primal plane.

For any subset $L' \subseteq L$, let $\mathcal{U}(L')$ denote the upper envelope of the lines of L'.

Consider a point $p \in P$. Our algorithm needs to output the face $F_p(L)$ of $\mathcal{A}(L)$ that contains p. Let $L_+(p)$ (resp., $L_-(p)$) denote the subset of lines of L that are below (resp., above) p. It is not difficult to see that the face $F_p(L)$ is the common intersection of the region above the upper envelope $\mathcal{U}(L_+(p))$ and the region below the lower envelope of $L_-(p)$; see Fig. 1. Our algorithm will compute binary search trees of height $O(\log n)$ that represent $\mathcal{U}(L_+(p))$ and the lower envelope of $L_-(p)$, respectively. Using the two trees, $F_p(L)$ can be computed in $O(\log n)$ time by computing the two intersections between $\mathcal{U}(L_+(p))$ and $\mathcal{U}(L_-(p))$, and $F_p(L)$ can then be output in additional $O(|F_p(L)|)$ time. In what follows, we focus on computing $\mathcal{U}(L_+(p))$ since the lower envelope of $L_-(p)$ can be treated likewise. In the following discussion, depending on the context, an upper envelope (or lower envelope) may refer to a binary search tree that represents it. For example, the phrase "computing $\mathcal{U}(L_+(p))$" means "computing a binary search tree that represents $\mathcal{U}(L_+(p))$".

We start with computing a hierarchical $(1/r)$-cutting $\Xi_0, \Xi_1, \ldots, \Xi_k$ for the lines of L in $O(nr)$ time [8], for a parameter $r \in [1, n]$ to be determined later. Let Ξ denote the set of all cells $\sigma \in \Xi_i$, $0 \leq i \leq k$. The algorithm also produces the conflict lists L_σ for all cells $\sigma \in \Xi$. For each cell $\sigma \in \Xi_i$, $1 \leq i \leq k$, we define $\widehat{L}_\sigma$ as the subset of lines of $L_{\sigma'}$ that are completely below σ, where σ' is the parent of σ (and thus σ' is a cell of Ξ_{i-1}). As $L_{\sigma'}$ is already available and σ' has $O(1)$ children, computing $\widehat{L}_\sigma$ for all children σ of σ' can be done in $O(|L_{\sigma'}|)$ time by brute force. As such, computing $\widehat{L}_\sigma$ for all cells $\sigma \in \Xi$ takes $O(nr)$ time.

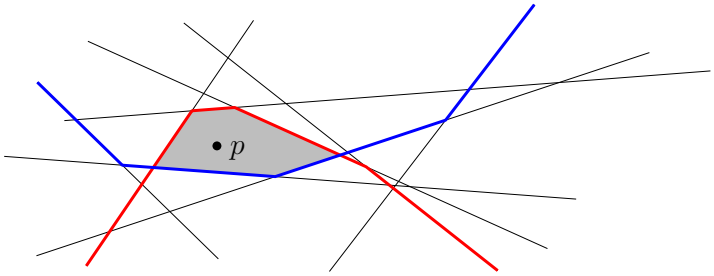

Figure 1 $F_p(L)$: the grey cell; $\mathcal{U}(L_+(p))$: blue segments; lower envelope of $L_-(p)$: red segments.

We wish to maintain a binary search tree to represent the upper envelope $\mathcal{U}(\widehat{L}_\sigma)$ of $\widehat{L}_\sigma$. To compute it in linear time, we need to have lines of $\widehat{L}_\sigma$ in sorted order by their slopes. If we sort each $\widehat{L}_\sigma$ individually, the total sorting time for all cells $\sigma \in \Xi$ is $O(nr \log n)$. To reduce the $\log n$ factor, we adopt the following strategy. We presort all lines of L in $O(n \log n)$ time. Then, we have the following lemma (see the full paper for the proof).

▶ **Lemma 1.** *Suppose we have a sorted list of the lines of L by their slopes. Then, $\widehat{L}_\sigma$ for all cells $\sigma \in \Xi$ can be sorted in $O(nr)$ time.*

After each $\widehat{L}_\sigma$ is sorted, we compute its upper envelope $\mathcal{U}(\widehat{L}_\sigma)$, which takes $O(|\widehat{L}_\sigma|)$ time. As such, computing $\mathcal{U}(\widehat{L}_\sigma)$ for all cells $\sigma \in \Xi$ can be done in $O(nr)$ time.

Next, we compute $P(\sigma)$, which is defined to be $P \cap \sigma$, for all cells $\sigma \in \Xi$. This can be done in $O(m \log r)$ time by point locations in a top-down manner in the hierarchical cutting. Specifically, for each point $p \in P$, starting from Ξ_0, which comprises a single cell that is the entire plane, suppose the cell σ of Ξ_i containing p is known; then since σ has $O(1)$ cells, locating the cell of Ξ_{i+1} containing p can be done in $O(1)$ time. As such, performing point locations for p takes $O(\log r)$ time. Note that $\sum_{\sigma \in \Xi} |P_\sigma| = O(m \log r)$ as every point of P is stored in a single cell of Ξ_i for each $0 \le i \le k$.

For each cell $\sigma \in \Xi_i$, $0 \le i \le k+1$, define $L_+(\sigma)$ as the subset of the lines of L completely below σ. We have the following lemma (see the full paper for the proof).

▶ **Lemma 2.** *For each cell $\sigma \in \Xi$, suppose σ' is the parent of σ. Then, $L_+(\sigma) = L_+(\sigma') \cup \widehat{L}_\sigma$ and thus $\mathcal{U}(L_+(\sigma))$ is the upper envelope of $\mathcal{U}(L_+(\sigma'))$ and $\mathcal{U}(\widehat{L}_\sigma)$.*

We wish to compute the upper envelope $\mathcal{U}(L_+(\sigma))$ for every cell σ in the last cutting Ξ_k. For this, we show below $\mathcal{U}(L_+(\sigma))$ for all cells $\sigma \in \Xi$ can be computed in $O(r^2 \log n)$ time.

We work on the hierarchical cutting in a top-down manner. Suppose $\mathcal{U}(L_+(\sigma'))$ for a cell σ' has been computed (which is true initially when σ' is the only cell of Ξ, in which case $L_+(\sigma') = \emptyset$ and thus $\mathcal{U}(L_+(\sigma')) = \emptyset$). Then, for each child σ of σ', we compute $\mathcal{U}(L_+(\sigma))$ as follows. By Lemma 2, $\mathcal{U}(L_+(\sigma))$ is the upper envelope of $\mathcal{U}(L_+(\sigma'))$ and $\mathcal{U}(\widehat{L}_\sigma)$. The following Lemma 3 (see the full paper for the proof) provides an algorithm that computes $\mathcal{U}(L_+(\sigma))$ based on $\mathcal{U}(L_+(\sigma'))$ and $\mathcal{U}(\widehat{L}_\sigma)$. The technical crux of the result is a crucial observation that the dual of $\mathcal{U}(L_+(\sigma'))$, which is the lower hull of the dual points of the lines of $L_+(\sigma')$, has only $O(1)$ intersections with the dual of $\mathcal{U}(\widehat{L}_\sigma)$, which is the lower hull of the dual points of the lines of $\widehat{L}_\sigma$. Note that the algorithm does not report $\mathcal{U}(L_+(\sigma))$ explicitly but rather returns a binary search tree representing $\mathcal{U}(L_+(\sigma))$, which is obtained by splitting and merging binary search trees of $\mathcal{U}(L_+(\sigma'))$ and $\mathcal{U}(\widehat{L}_\sigma)$.

▶ **Lemma 3.** *$\mathcal{U}(L_+(\sigma))$ can be obtained from $\mathcal{U}(L_+(\sigma'))$ and $\mathcal{U}(\widehat{L}_\sigma)$ in $O(\log n)$ time.*

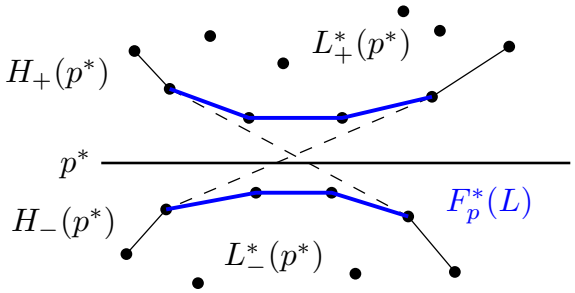

Figure 2 Illustrating the notation in the dual plane: $F_p^*(L)$, which is dual to $F_p(L)$, is composed of the blue edges between the two inner common tangents (the dashed segments).

By virtue of Lemma 3, we can compute $\mathcal{U}(L_+(\sigma))$ for all cells $\sigma \in \Xi$ in $O(|\Xi| \cdot \log n)$ time, which is $O(r^2 \log n)$ as Ξ has $O(r^2)$ cells.

Consider a cell $\sigma \in \Xi_k$. For any point $p \in P(\sigma)$, let $L_\sigma^+(p)$ denote the subset of lines of L_σ below p. It is easy to see that $L_+(p) = L_+(\sigma) \cup L_\sigma^+(p)$. Hence, $\mathcal{U}(L_+(p))$ is the lower envelope of $\mathcal{U}(L_+(\sigma))$ and $\mathcal{U}(L_\sigma^+(p))$. The above already computes $\mathcal{U}(L_+(\sigma))$. Suppose $\mathcal{U}(L_\sigma^+(p))$ is also available. Then, we compute $\mathcal{U}(L_+(p))$ by merging $\mathcal{U}(L_+(\sigma))$ and $\mathcal{U}(L_\sigma^+(p))$ in $O(\log n)$ time by the algorithm of Lemma 3. Indeed, since all lines of $L_\sigma^+(p)$ cross σ while all lines of $L_+(\sigma)$ are completely below σ, the same algorithm as Lemma 4 is also applicable here. Consequently, once the upper envelopes $\mathcal{U}(L_\sigma^+(p))$ for all points $p \in P$ are computed, $\mathcal{U}(L_+(p))$ for all $p \in P$ can be computed in additional $O(m \log n)$ time.

It remains to compute $\mathcal{U}(L_\sigma^+(p))$. To this end, we recursively apply the above algorithm on L_σ and $P(\sigma)$. A subtle issue is that while $|L_\sigma| \leq n/r$, we do not have a good upper bound for $P(\sigma)$. To address this issue, we do the following. If $|P(\sigma)| > m/r^2$, then we arbitrarily partition $P(\sigma)$ into groups of at most m/r^2 points each. Since Ξ_k has $O(r^2)$ cells, the number of groups for all cells $\sigma \in \Xi_k$ is still bounded by $O(r^2)$. Now for each cell $\sigma \in \Xi_k$, for each group P' of $P(\sigma)$, we apply the above algorithm recursively on P' and L_σ. Thus, we obtain the following recurrence for the runtime of the entire algorithm (excluding the time for presorting L), for any $1 \leq r \leq n$:

$$T(m, n) = O(nr + m \log n + r^2 \log n) + O(r^2) \cdot T(m/r^2, n/r). \tag{1}$$

We will use the recurrence later in our combined algorithm in Section 5.

4 The second algorithm in the dual plane

We discuss another algorithm, which deals with the problem in the dual plane. It mostly follows Wang's algorithm in [26] with a slight change to make the algorithm recursive.

Let P^* be the set of lines dual to the points of P and L^* the set of points dual to the lines of L. Consider a point $p \in P$. Recall that $F_p(L)$ is the face of $\mathcal{A}(L)$ that contains p. Without loss of generality, we assume that the dual line p^* of p is horizontal. In the dual plane, p^* divides the points of L^* into two subsets and the portions of the convex hulls of the two subsets between their inner common tangents are dual to $F_p(L)$ [1, 12]; see Fig 2. Specifically, define $L_+^*(p^*)$ (resp., $L_-^*(p^*)$) to be the subset of points of L^* above (resp., below) p^*. Let $H_+(p^*)$ be the lower hull of the convex hull of $L_+^*(p^*)$ and $H_-(p^*)$ the upper hull of $L_-^*(p^*)$; see Fig 2. Hence, the boundary of $F_p(L)$ is dual to the portions of $H_+(p^*)$ and $H_-(p^*)$ between their inner common tangents; let $F_p^*(L)$ denote the dual of $F_p(L)$.

The algorithm will compute binary search trees of height $O(\log n)$ to represent $H_+(p^*)$ and $H_-(p^*)$, respectively. Using the trees, their inner common tangents can be computed in $O(\log m)$ time [18] and then $F_p^*(L)$ can be reported in additional $O(|F_p^*(L)|)$ time. We only discuss how to compute $H_+(p^*)$ (i.e., compute the tree for it).

The algorithm uses a hierarchical $(1/r)$-cutting $\Xi_0, \Xi_1, \ldots, \Xi_k$ for the lines of P^*. The following recurrence for the runtime of the whole algorithm can be obtained (excluding a presorting step), for any $1 \leq r \leq m$:

$$T(m,n) = O(mr \log n + n \log r) + O(r^2) \cdot T(m/r, n/r^2). \tag{2}$$

See the full paper for the algorithm details. Recurrence (2) will be used in our combined algorithm in Section 5. We highlight some details below that are needed in Section 5.

▶ Remark. For each dual line $p^* \in P^*$ (assume it is horizontal), the algorithm for Recurrence (2) computes a set of convex hulls $\mathcal{H}_+(p^*)$ such that (1) they are completely above p^*; (2) they are pairwise disjoint and each of them is a convex hull of a subset of points of L^*; (3) $H_+(p^*)$ is the lower hull of them; (4) $\sum_{p^* \in P^*} |\mathcal{H}_+(p^*)| = O(n^{4/3})$. Again, for each convex hull of $\mathcal{H}_+(p^*)$, we have a binary search tree that represents it. As a final step, called *the convex hull merge procedure*, the algorithm computes the lower hull (which is $H_+(p^*)$) of the vertices of all convex hulls of $\mathcal{H}_+(p^*)$, for all $p^* \in P^*$. The term $O(mr \log n)$ in (2) is due to this convex hull merge procedure. If this procedure could be performed in $O(mr)$ time (which is one of our goals in Section 5), then the term in (2) would become $O(mr)$.

5 Combining the two algorithms

In this section, we combine the two algorithms presented in the last two sections to obtain a final algorithm to compute all non-empty faces of $\mathcal{A}(L)$ for the points of P.

We first discuss the symmetric case where $m = n$. If we apply (2) and then (1) using the same r, we can obtain: $T(n,n) = O(nr \log n + r^4 \log(n/r^2)) + O(r^4) \cdot T(n/r^3, n/r^3)$. Setting $r = n^{1/3}/\log n$ leads to the following

$$T(n,n) = O(n^{4/3}) + O((n/\log^3 n)^{4/3}) \cdot T(\log^3 n, \log^3 n). \tag{3}$$

The recurrence solves to $T(n,n) = n^{4/3} \cdot 2^{O(\log^* n)}$. In the following, we improve the algorithm to $O(n^{4/3})$ time using the Γ-algorithm framework of Chan and Zheng [7].

5.1 Improvement

We apply the recurrence (3) one more time to obtain the following with $b = (\log \log n)^3$:

$$T(n,n) = O(n^{4/3}) + O((n/b)^{4/3}) \cdot T(b,b). \tag{4}$$

As b is very small, we show that after $O(n)$ time preprocessing, we can solve each subproblem $T(b,b)$ of (4) in $O(b^{4/3})$ time. Consequently, we obtain $T(n,n) = O(n^{4/3})$.

More precisely, we will demonstrate that following a preprocessing step requiring $O(2^{\text{poly}(b)})$ time, where $\text{poly}(\cdot)$ represents a polynomial function, each subproblem $T(b,b)$ can be solved by performing only $O(b^{4/3})$ comparisons. Alternatively, we can solve $T(b,b)$ using an algebraic decision tree with a height of $O(b^{4/3})$. Given that $b = (\log \log n)^3$, the term $2^{\text{poly}(b)}$ remains bounded by $O(n)$. To adapt this approach to the conventional computational model (such as the standard real RAM model), we explicitly construct the decision tree for the aforementioned algorithm. This construction, which can also be viewed as part of the

preprocessing for solving $T(b, b)$, can be accomplished in $O(2^{\text{poly}(b)})$ time. Consequently, with just $O(n)$ time spent on preprocessing, we can efficiently solve each subproblem $T(b, b)$ in $O(b^{4/3})$ time. In the subsequent discussion, for notational convenience, we will use n instead of b. Our objective is to establish the following lemma.

▶ **Lemma 4.** *After $O(2^{poly(n)})$ time preprocessing, $T(n, n)$ can be solved using $O(n^{4/3})$ comparisons.*

We first apply recurrence (2) by setting $m = n$ and $r = n^{1/3}$, and obtain

$$T(n, n) = O(n^{4/3} \log n) + O(n^{2/3}) \cdot T(n^{2/3}, n^{1/3}). \tag{5}$$

As remarked at the end of Section 4, the $O(n^{4/3} \log n)$ term is due to the convex hull merge procedure for computing $H_+(p^*)$ by merging the convex hulls of $\mathcal{H}_+(p^*)$, for all $p^* \in P^*$. If the procedure could be done using $O(n^{4/3})$ comparisons, then the term would become $O(n^{4/3})$. Note that $\sum_{p^* \in P^*} |\mathcal{H}_+(p^*)| = O(n^{4/3})$. As such, to solve $T(n, n)$ by $O(n^{4/3})$ comparisons, there are two challenges: (1) perform the merge procedure on the $O(n^{4/3})$ convex hulls using $O(n^{4/3})$ comparisons; (2) solve each subproblem $T(n^{2/3}, n^{1/3})$ using $O(n^{2/3})$ "amortized" comparisons, so that all $O(n^{2/3})$ such subproblems in (5) together cost $O(n^{4/3})$ comparisons.

Γ-algorithm framework. To address these challenges, we resort to the Γ-*algorithm framework* for bounding decision tree complexities, as recently introduced by Chan and Zheng [7]. We provide a brief overview here, with more detailed information available in [7, Section 4.1].

In essence, this framework constitutes an algorithm that exclusively counts the number of comparisons, termed Γ-*comparisons* in [7], to determine if a point belongs to a semialgebraic set of degree $O(1)$ within a constant-dimensional space. Solving our problem of finding the non-empty faces is equivalent to locating the cell C^* that contains a point p^* defined by the input (i.e., the lines of L and the points of P in our problem) within an arrangement $\mathcal{A}^*$ comprising the boundaries of $O(n)$ semialgebraic sets in an $O(n)$-dimensional space (because our input size is $O(n)$). Constructing this arrangement can be achieved in $O(2^{\text{poly}(n)})$ time without inspecting the input values, thereby obviating the need for any comparisons. Notably, the number of cells in $\mathcal{A}^*$ is bounded by $n^{O(n)}$.

As the Γ-algorithm progresses, it maintains a set Π consisting of cells from $\mathcal{A}^*$. Initially, Π comprises all cells of $\mathcal{A}^*$. During the algorithm's execution, Π can only shrink, yet it always contains the sought-after cell C^*. Upon completion of the algorithm, C^* is located.

We define a potential function Φ as $\log |\Pi|$. Given that $\mathcal{A}^*$ contains $n^{O(n)}$ cells, initially Φ is $O(n \log n)$. For any operation or subroutine of the algorithm, let $\Delta\Phi$ denote the change in Φ. Since Φ monotonically decreases throughout the algorithm, we always have $\Delta\Phi \leq 0$. The sum of $-\Delta\Phi$ over the entire algorithm is $O(n \log n)$. Consequently, this allows us to accommodate costly operations or subroutines, as long as they result in a decrease in Φ.

Two algorithmic tools are introduced in [7] under the framework: the *basic search lemma* [7, Lemma 4.1] and the *search lemma* [7, Lemma A.1]. Roughly speaking, these lemmas operate as follows: when presented with a set of r predicates, where each predicate assesses whether $\gamma(x)$ holds true for the input vector x, it is guaranteed that at least one of these predicates is true for all inputs within the active cells. In such cases, the basic search lemma can identify a predicate that holds true by conducting $O(1 - r \cdot \Delta\Phi)$ comparisons. The search lemma is for scenarios involving a binary tree (or a more general directed acyclic graph of $O(1)$ degree) with nodes v, each associated with a predicate γ_v, and where for each internal node v, γ_v implies γ_u for a child u of v across all inputs in the active cells. This lemma can compute a leaf node v for which γ_v holds true with $O(1 - \Delta\Phi)$ comparisons.

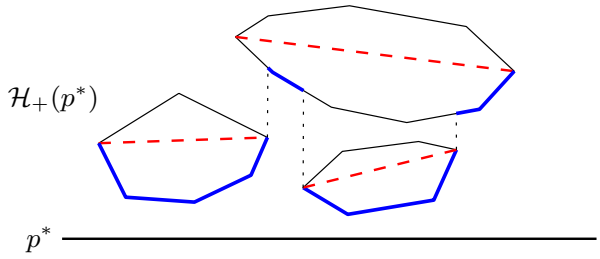

Figure 3 Illustrating the lower envelope $\mathcal{L}(\mathcal{H}_+(p^*))$ (the thick blue edges) of the convex hulls of $\mathcal{H}_+(p^*)$. The dashed segments inside convex hulls are their representative segments.

As discussed in [7], intuitively the basic search lemma provides a mild form of nondeterminism, allowing us to "guess" which one of r choices is correct, with only $O(1)$ amortized cost instead of $O(r)$. This situation naturally occurs in the context of point location, where we seek to determine which one of the r cells contains a given point. Another noteworthy application of both lemmas, as also discussed in [7], is the task of finding the predecessor of a query number within a sorted list of input numbers. As will be seen later, some subproblems in our algorithm also involves point locations as well as finding predecessors within sorted lists, making both the basic search lemma and the search lemma highly applicable.

In the following two subsections, we will address the aforementioned challenges individually. Let P represent a set of n points and L a set of n lines, for the problem in Recurrence (5).

5.2 The convex hull merge procedure

We follow the notation in the remark of Section 4. Define $K_{p^*} = |\mathcal{H}_+(p^*)|$. Hence, $\sum_{p^* \in P^*} K_{p^*} = O(n^{4/3})$. Our task is to compute (a binary search tree that represents) the lower hull (which is $H_+(p^*)$) of the vertices of all convex hulls of $\mathcal{H}_+(p^*)$, for all $p^* \in P^*$. Wang [26] gave an algorithm that can constructs $H_+(p^*)$ in $O(K_{p^*} \log n)$ time, resulting in a total of $O(n^{4/3} \log n)$ time for all $p^* \in P^*$. We will convert the algorithm to a more efficient Γ-algorithm that uses only $O(n^{4/3})$ comparisons. Below, we first review Wang's algorithm.

Constructing $H_+(p^*)$: A conventional algorithm from Wang [26]. Since $H_+(p^*)$ is the lower hull of all convex hulls of $\mathcal{H}_+(p^*)$, it is only necessary to focus on the lower hull of each convex hull of $\mathcal{H}_+(p^*)$. For each convex hull of $\mathcal{H}_+(p^*)$, since we have its binary search tree, we can obtain a binary search tree only representing its lower hull in $O(\log n)$ time. This is achieved by initially identifying the leftmost and rightmost vertices of the convex hulls and subsequently executing split/merge operations on these trees. The total time for doing this for all convex hulls of $\mathcal{H}_+(p^*)$ is $O(K_{p^*} \log n)$.

Next we compute the portions of each lower hull $H \in \mathcal{H}_+(p^*)$ that are vertically visible from the line p^*. A point $q \in H$ is *vertically visible* from p^* if the vertical segment connecting q to p^* does not intersect any other lower hull of $\mathcal{H}_+(p^*)$. Remarkably, these visible portions collectively form the lower envelope of $\mathcal{H}_+(p^*)$, denoted by $\mathcal{L}(\mathcal{H}_+(p^*))$; see Fig. 3.

For each convex hull H within $\mathcal{H}_+(p^*)$, we define its *representative segment* as the line segment connecting the leftmost and rightmost endpoints of H (see Fig. 3). Define S to be the set of the representative segments of all convex hulls of $\mathcal{H}_+(p^*)$. Because the convex hulls are pairwise disjoint, so are the segments of S. Observe that the lower envelope $\mathcal{L}(S)$ of S corresponds to $\mathcal{L}(\mathcal{H}_+(p^*))$ in the following manner. For each maximal segment $\overline{ab}$ of $\mathcal{L}(S)$, suppose it lies on the representative segment of a convex hull H of $\mathcal{H}_+(p^*)$. Then the vertical projection of $\overline{ab}$ onto the lower hull of H constitutes a maximal portion of the

lower hull of H on $\mathcal{L}(\mathcal{H}_+(p^*))$. This specific portion can be obtained in $O(\log n)$ time by splitting the binary search tree representing the lower hull of H at the x-coordinates of a and b, respectively. Consequently, once $\mathcal{L}(S)$ is available, $\mathcal{L}(\mathcal{H}_+(p^*))$, where each maximal portion is represented by a binary search tree, can be obtained in additional $O(|\mathcal{L}(S)| \log n)$ time. Since segments of S are disjoint, we have $|\mathcal{L}(S)| \leq 2K_{p^*} - 1$ and constructing $\mathcal{L}(S)$ can be accomplished in $O(K_{p^*} \log K_{p^*})$ time by a straightforward plane sweeping algorithm. Note that $K_{p^*} \leq n$ since vertices of each convex hull of $\mathcal{H}_+(p^*)$ are all from L^* (whose size is n). As such, $\mathcal{L}(\mathcal{H}_+(p^*))$ can be computed in $O(K_{p^*} \log n)$ time.

With $\mathcal{L}(\mathcal{H}_+(p^*))$, we proceed to compute the lower hull $H_+(p^*)$. As previously discussed, $\mathcal{L}(\mathcal{H}_+(p^*))$ comprises at most $2K_{p^*} - 1$ pieces, ordered from left to right. Each piece is a portion of a lower hull of $\mathcal{H}_+(p^*)$ and is represented by a binary search tree.

To begin, we merge the first two pieces by computing their lower common tangent, a task achievable in $O(\log n)$ time [24], since these two pieces are separated by a vertical line. After that we obtain a binary search tree that represents the lower hull of the first two pieces of $\mathcal{L}(\mathcal{H}_+(p^*))$. We proceed to merge this lower hull with the third piece of $\mathcal{L}(\mathcal{H}_+(p^*))$ in a similar manner. This process continues until all pieces of $\mathcal{L}(\mathcal{H}_+(p^*))$ have been merged, culminating in a binary search tree representing $H_+(p^*)$. The runtime is $O(K_{p^*} \log n)$, as each merge operation consumes $O(\log n)$ time, and $\mathcal{L}(\mathcal{H}_+(p^*))$ has at most $2K_{p^*} - 1$ pieces.

As such, the lower hull $H_+(p^*)$ can be computed in $O(K_{p^*} \log n)$ time. Applying the algorithm to all dual lines p^* of P^* will compute the lower hulls $H_+(p^*)$ for all $p^* \in P^*$. It should be noted that after the algorithm is applied to one line $p^* \in P^*$, binary search trees of convex hulls of $\mathcal{H}_+(p^*)$ may have been destroyed due to the split and merge operations during the algorithm. The destroyed convex hulls may be used later for other lines of P^*. To address the issue, we can use persistent binary search trees with path-copying [11, 25] to represent convex hulls so that standard operations on the trees (e.g., merge, split) can be performed in $O(\log n)$ time each and after each operation the original trees are still kept.

Constructing $H_+(p^*)$: a new and faster Γ-algorithm. We now convert the above algorithm to a faster Γ-algorithm. In the above algorithm, the procedures that take $O(K_{p^*} \log n)$ time are the following: (1) Computing the trees representing the lower hulls of $\mathcal{H}_+(p^*)$; (2) computing the lower envelope $\mathcal{L}(S)$ of S; (3) computing the lower envelope $\mathcal{L}(\mathcal{H}_+(p^*))$ of $\mathcal{H}_+(p^*)$ by using $\mathcal{L}(S)$; (4) computing $H_+(p^*)$ by merging the pieces of $\mathcal{L}(\mathcal{H}_+(p^*))$. Each of these procedures leads to an overall $O(n^{4/3} \log n)$ time for all $p^* \in P^*$ since $\sum_{p^* \in P^*} |\mathcal{H}_+(p^*)| = O(n^{4/3})$.

For each of these procedures, we will design a corresponding "Γ-procedure" that uses only $O(n^{4/3})$ comparisons for all $p^* \in P^*$ (thus the amortized cost for each p^* is $O(K_{p^*})$). In particular, the fourth procedure poses the most challenge and its solution is also the most interesting. See the full paper for our Γ-algorithms for the first three procedures.

5.2.1 The fourth procedure

The fourth procedure is to compute $H_+(p^*)$. The idea is to merge pieces of $\mathcal{L}(\mathcal{H}_+(p^*))$ one by one from left to right, and each merge is done by first computing the lower common tangent. Note that each piece is a portion of the lower hull of a convex hull of $\mathcal{H}_+(p^*)$ and is represented by a binary search tree. Specifically, suppose we have the lower hull H_i for the first i pieces, i.e., we have a binary search tree T_i for H_i. The next step is to merge H_i with the $(i+1)$-th piece H by first computing the lower common tangent of H_i and H. Let T_H be the binary search tree for H. With the lower common tangent, we perform split and merge operations on T_i and T_H for H to obtain a new tree T_{i+1} for the lower hull of the first $i+1$ pieces. Finding the lower common tangent can be done in $O(\log n)$ time [24] and constructing the tree T_{i+1} also takes $O(\log n)$ time.

In the following, we focus on describing a Γ-procedure that can compute the lower common tangent of H_i and H using $O(1 - n^{1/4} \cdot \Delta\Phi)$ comparisons. After the lower common tangent is computed, constructing T_{i+1} does not need any comparisons because split and merge operations on T_i and T_H do not involve any comparisons.

5.2.1.1 Notation and algorithm overview

For notational convenience, let $H_1 = H_i$, $H_2 = H$, $T_1 = T_i$, and $T_2 = T_H$.

We will use the basic search lemma of the Γ-algorithm framework of Chan and Zheng [7] discussed above. We will also rely on the technique from Overmars and van Leeuwen [24] for computing common tangents of two convex hulls.

Let the line segment $\overline{t_1t_2}$ be the lower common tangent between H_1 and H_2, with $t_1 \in H_1$ and $t_2 \in H_2$. We call t_1 and t_2 the *tangent points*. For ease of exposition, we assume that $\overline{t_1t_2}$ is not collinear with any edge of $H_1 \cup H_2$. Thus, the tangent points t_1 and t_2 are unique.

For each $i = 1, 2$, since we are searching a vertex t_i from H_i, from now on, we view H_i as a sequence of vertices ordered from left to right. We use a *chain* to refer to a contiguous subsequence of H_i. For two vertices u and v of H_i with u left of v, we use $H_i[u, v]$ to denote the chain of H_i from u to v including both u and v, while $H_i(u, v)$ is defined to be $H_i[u, v] \setminus \{u, v\}$. Similarly, $H_i[u, v)$ refers to the chain of H_i from u to v including u but excluding v; $H_i(u, v]$ is defined likewise. In addition, for any vertex u of H_i, we use $u - 1$ (resp., $u + 1$) to refer to the left (resp., right) neighboring vertex of u in H_i; for convenience, if u is the leftmost (resp., rightmost) vertex of H_i, then $u - 1$ (resp., $u + 1$) refers to u. For example, $H_i(u, v) = H_i[u + 1, v - 1]$. The following lemma is based on the technique of Overmars and van Leeuwen [24], which will be used in our algorithm.

▶ **Lemma 5** (Overmars and van Leeuwen [24]). *Given two points $p_1 \in H_1$ and $p_2 \in H_2$, p_1 (resp., p_2) partitions H_1 (resp., H_2) into two chains (we assume that neither chain contains p_i, $i = 1, 2$). Then, among the four chains of H_1 and H_2, we can determine at least one chain that does not contain a tangent point based on the following six points: p_1 (resp., p_2) and its two neighboring vertices of H_1 (resp., H_2); such a chain is called* OvL-prunable[1].

Lemma 5 provides a pruning criterion for the binary search algorithm of [24] that can compute $\overline{t_1t_2}$ in $O(\log n)$ time. We will use the lemma in a different way. For any subchain of an OvL-prunable chain determined by the lemma, we also say that the subchain is *OvL-prunable* (a subchain is a contiguous subsequence of vertices of the chain).

For each $i = 1, 2$, we maintain two vertices u_i and v_i of H_i such that $t_i \in H_i(u_i, v_i)$. After $O(1)$ iterations, either $H_i(u_1, v_1)$ or $H_i(u_2, v_2)$ contains a single point. The single point is t_1 in the former case and t_2 in the latter one. In either case, one tangent point is determined. After that, the other tangent point can be computed by a similar (and simpler) procedure. For the simplicity of discussion, we assume t_i is not an endpoint of H_i, for each $i = 1, 2$.

5.2.1.2 Computing a tangent point

Initially, for each $i = 1, 2$, we set u_i and v_i to be the two endpoints of H_i, respectively. This guarantees that the algorithm invariant holds, i.e., $t_i \in H_i(u_i, v_i)$. We consider a general step of the algorithm. To apply the basic search lemma, we define a predicate $\gamma(u_1, v_1, u_2, v_2)$ with respect to u_1, v_1, u_2, v_2, as follows.

▶ **Definition 6.** *Define $\gamma(u_1, v_1, u_2, v_2)$ to be true if neither $H_1(u_1, v_1)$ nor $H_2(u_2, v_2)$ is OvL-prunable when Lemma 5 is applied to (p_1, p_2) for any $p_1 \in \{u_1, v_1\}$ and $p_2 \in \{u_2, v_2\}$.*

[1] OvL is the last name initials of Overmars and van Leeuwen.

By Lemma 5, whether γ is true can be determined by $O(1)$ points of L^*, i.e., at most six points are needed for each pair (p_1, p_2) with $p_1 \in \{u_1, v_1\}$ and $p_2 \in \{u_2, v_2\}$, and thus the predicate is of $O(1)$ degree (where the variables are the coordinates of the $O(1)$ points).

Each iteration of the algorithm proceeds as follows. For each $i = 1, 2$, partition $H_i[u_i, v_i]$ into r chains of roughly equal lengths: $H_i[u_{ij}, v_{ij}]$, $1 \leq j \leq r$, for a parameter r to be determined later. Define $C_i = \{H_i[u_{ij} - 1, v_{ij} + 1] \mid 1 \leq j \leq r\}$. As such, the length of each chain of C_i is roughly equal to the length of $H_i[u_i, v_i]$ divided by r. Define $\mathcal{C} = C_1 \times C_2$, i.e., $\mathcal{C}$ consists of $O(r^2)$ pairs of chains such that in each pair, the first chain is from C_1 and the second one is from C_2. We have the following observation (see the full paper for the proof).

▶ **Observation 7.** *$\mathcal{C}$ must contain a pair of chains $H_1[u_{1j_1}, v_{1j_1}]$ and $H_2[u_{2j_2}, v_{2j_2}]$ such that the predicate $\gamma(u_{1j_1}, v_{1j_1}, u_{2j_2}, v_{2j_2})$ holds true.*

In light of the above observation, we apply the basic search lemma on the $O(r^2)$ cells of $\mathcal{C}$ to find a pair of chains $H_1[u_{1j_1}, v_{1j_1}]$ and $H_2[u_{2j_2}, v_{2j_2}]$ such that the predicate $\gamma(u_{1j_1}, v_{1j_1}, u_{2j_2}, v_{2j_2})$ is true. By the basic search lemma, this can be accomplished using $O(1 - r^2 \cdot \Delta\Phi)$ comparisons. The subsequent lemma (see the full paper for the proof), which proves a key property, ensures our ability to recursively employ the algorithm.

▶ **Lemma 8.** *If $\gamma(u_{1j_1}, v_{1j_1}, u_{2j_2}, v_{2j_2})$ is true, then either $t_1 \in H_1[u_{1j_1}, v_{1j_1}]$ or $t_2 \in H_2[u_{2j_2}, v_{2j_2}]$, and which case happens can be determined using $O(1)$ comparisons.*

By Lemma 8, without loss of generality, we assume $t_1 \in H_1[u_{1j_1}, v_{1j_1}]$ (and thus $t_1 \in H_1(u_{1j_1} - 1, v_{1j_1} + 1)$). This finishes the current iteration. We proceed on the next iteration with the two chains $H_1[u_{1j_1} - 1, v_{1j_1} + 1]$ and $H_2[u_2, v_2]$, i.e., update $u_1 = u_{1j_1} - 1$ and $v_1 = v_{1j_1} + 1$ (and thus $t_1 \in H_1(u_1, v_1)$). As $t_2 \in H_2(u_2, v_2)$, the algorithm invariant holds.

In this way, each iteration on $H_1[u_1, v_1]$ and $H_2[u_2, v_2]$ shrinks one of them to a subchain of size roughly $1/r$ of its original size. Since $|H_1| + |H_2| \leq n$, after $O(\log_r n)$ iterations, a tangent point can be found. The total number of comparisons is thus $O(\log_r n - r^2 \cdot \Delta\Phi)$.

The above finds one tangent point. The other one can be found by a similar but simpler algorithm, which uses $O(\log_r n - r \cdot \Delta\Phi)$ comparisons. See the full paper for details.

In summary, with $O(\log_r n - r^2 \cdot \Delta\Phi)$ comparisons, the lower tangent $\overline{t_1 t_2}$ can be computed. Setting $r = n^{1/8}$ leads to an upper bound of $O(1 - n^{1/4} \cdot \Delta\Phi)$ on the number of comparisons.

In this way, the total number of comparisons for constructing the lower hull $H_+(p^*)$ by merging the pieces of $\mathcal{L}(\mathcal{H}_+(p^*))$ is $O(K_{p^*} - n^{1/4} \cdot \Delta\Phi)$ since $\mathcal{L}(\mathcal{H}_+(p^*))$ has at most $2K_{p^*} - 1$ pieces. As $\sum_{p^* \in P^*} K_{p^*} = O(n^{4/3})$ and the sum of $-\Delta\Phi$ in the entire algorithm is $O(n \log n)$, the total number of comparisons for computing $H_+(p^*)$ for all $p^* \in P^*$ is $O(n^{4/3})$.

5.3 Solving the subproblems $T(n^{2/3}, n^{1/3})$

We can solve all $O(n^{2/3})$ subproblems $T(n^{2/3}, n^{1/3})$ in Recurrence (5) using a total of $O(n^{4/3})$ comparisons. See the full paper for details.

5.4 Putting it all together, the asymmetric case, and the lower bound

This proves Lemma 4, and thus $T(n, n)$ in Recurrence (5) can be bounded by $O(n^{4/3})$ after $O(2^{\text{poly}(n)})$ time preprocessing, as discussed before. Equivalently, $T(b, b)$ in Recurrence (4) is $O(b^{4/3})$ after $O(2^{\text{poly}(b)})$ time preprocessing. Notice that the preprocessing work is done only once and for all subproblems $T(b, b)$ in (4). Since $b = (\log \log n)^3$, we have $2^{\text{poly}(b)} = O(n)$. As such, $T(n, n)$ in (4) solves to $O(n^{4/3})$ and we thus obtain the following theorem.

▶ **Theorem 9.** *Given a set of n points and a set of n lines in the plane, we can report all faces of the line arrangement that contain at least one point in $O(n^{4/3})$ time.*

The asymmetric case is handled in the following corollary; see the full paper for the proof.

▶ **Corollary 10.** *Given a set of m points and a set of n lines in $\mathbb{R}^2$, we can report all faces of the line arrangement that contain at least one point in $O(m^{2/3}n^{2/3} + (n+m)\log n)$ time.*

Theorem 11 finally proves the lower bound below, with the help of Ben-Or's technique [5]. This justifies the optimality of Corollary 10. See the full paper for the proof.

▶ **Theorem 11.** *Computing all non-empty faces of the line arrangement requires $\Omega(m^{2/3}n^{2/3} + (n+m)\log n)$ time under the algebraic decision tree model.*

Abstract

The *sliding cubes model* serves as a well-established theoretical framework for formalizing and analyzing reconfiguration algorithms in modular robotic systems built from face-connected cubic modules. We extend the parallel sliding cubes model from two to three dimensions, presenting new algorithms, surprising complexity results, and a generalization of the best known bounds from two to three dimensions. A companion video visualizes and explains our results.

1 Introduction

Programmable matter systems are composed of large numbers of simple modules that are capable of autonomously reconfiguring their collective shape. These systems have attracted significant attention for applications in robotics, manufacturing, and distributed computing. In practice, identifying reconfiguration sequences that transform one connected configuration into another while preserving connectivity and avoiding collisions is a highly nontrivial algorithmic problem. We consider the Sliding Cubes model introduced by Fitch, Butler,

and Rus [5], where identical modules move via discrete moves in a three-dimensional lattice. Modules can perform two types of *move*, a *slide* or a *convex transition*, as shown in Figure 1. A slide translates the module by one unit along the surface of two adjacent modules, while a convex transition displaces it along the surface of only one module along two axes.

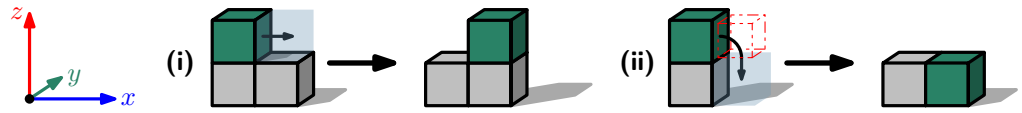

Figure 1 Two types of legal move, (i) slide and (ii) convex transition.

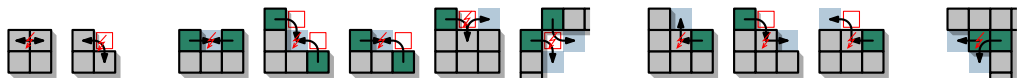
Our work considers the coordinated *parallel* motion of unit cubes in the three-dimensional integer grid, following and extending the notation of [2]. Parallel moves are performed in discrete *transformations* with unit-time duration; as in the two-dimensional model [2], both types of move take unit time to complete and occur at a fixed, constant speed. Transformations must preserve a connected *backbone* which requires moving modules to be *free*: moving modules do not provide connectivity. A set of modules M is free in a configuration C if the removal of any subset of M from C leaves a connected configuration. In addition, transformations must not induce *collisions*, in which the volume of two modules overlap. For instance, modules thus cannot trade places during a transformation or perform a convex transition through the same cell. We refer to [2] and Figure 2 for details.



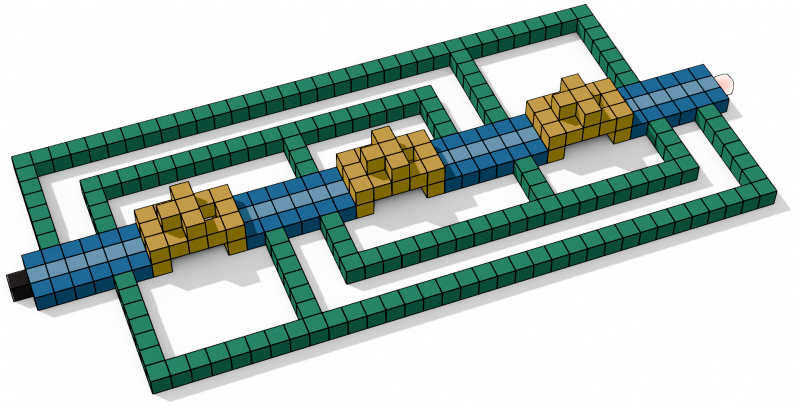


Figure 2 Examples of collisions. Figure from [2], used with the authors' permission.

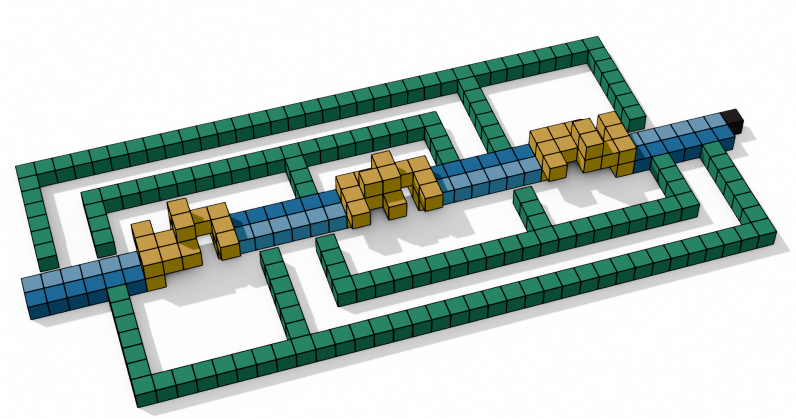
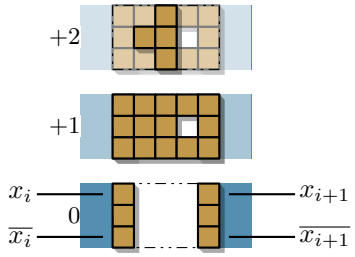
2 Algorithm and complexity

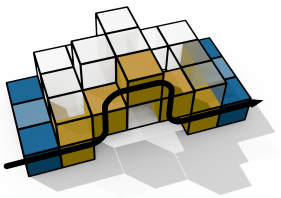


In this media exposition, we illustrate and interactively visualize three main results. All technical details of the complexity results as well as the algorithm that are presented in the accompanying video to this abstract are given in the full version [1].

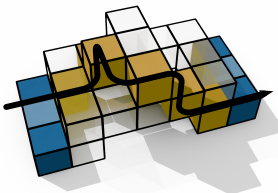
1. Deciding the minimum makespan for Parallel Sliding Cubes is para-NP-hard when parameterized by the makespan and symmetric difference size: There is no polynomial time algorithm even for the case in which both values are constant (unless P = NP).
2. The makespan minimization problem in both Parallel and Sequential Sliding Cubes is log-APX-hard and cannot be approximated by a factor better than $\Theta(\log n)$.
3. Schedules for universal reconfiguration of makespan $\mathcal{O}(A + h)$ can be computed in polynomial time, where A is the area of the projection of the configuration onto the base of its bounding box and h is the height of the bounding box. In the worst case this input-sensitive bound becomes $\mathcal{O}(n)$ which is worst-case optimal.



Parameterized complexity. To prove para-NP-hardness, the full paper reduces from the NP-hard problem 3Sat, which asks whether a given Boolean formula φ is satisfiable [3]. The reduction constructs two configurations, illustrated in Figure 3, using *gadgets* that encode the variables (blue) and clauses (green) of φ. These gadgets are connected by *connectors* (yellow), and the two configurations differ by a single module (black/transparent) at one end. Solving the instance in a single transformation requires a continuous path of modules to move between the two endpoints without disconnecting the structure, forcing the transformation to encode an assignment satisfying φ.



(a)



(b)

(c)

(d)

(e)

Figure 3 The construction for $\varphi = (x_1 \vee x_3 \vee x_4) \wedge (x_1 \vee x_2 \vee x_3) \wedge (\overline{x_1} \vee \overline{x_2} \vee \overline{x_4}) \wedge (\overline{x_2} \vee \overline{x_3} \vee \overline{x_4})$ is shown in (a). In (b), a solution is illustrated (moving modules deleted). Variable gadgets are placed in ascending order left to right. In (c)–(e) we show the connector gadget and possible paths.

Inapproximability. The full paper shows log-APX-hardness by reduction from Set Cover [4]. An instance of this problem defines k sets $S = \{s_1, \ldots, s_k\}$ over $[n] = \{1, \ldots, n\}$ such that $\bigcup_{i=1}^{k} s_i = [n]$ and asks for a minimum cardinality subset $S^\star \subseteq S$ with $\bigcup_{s_i \in S^\star} s_i = [n]$. The construction has a bounding box of size $\mathcal{O}(n^4 k^7)$ for an instance with n elements and k sets; a schematic example is shown in Figure 4.

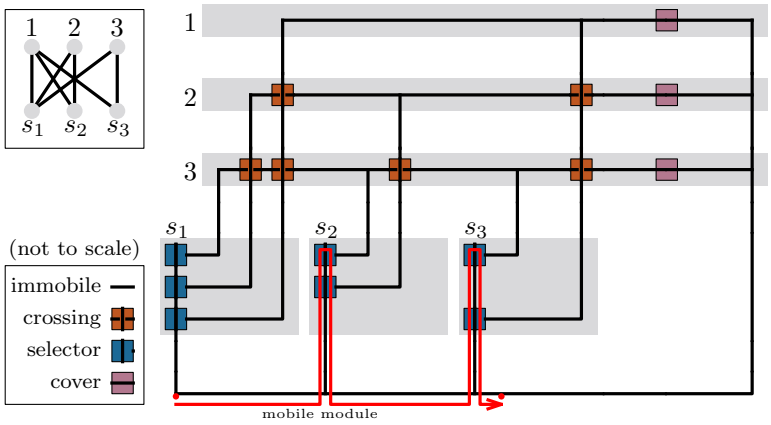


Figure 4 A diagram showing our construction for the Set Cover instance with $n = 3$ over the sets $s_1 = \{1, 2, 3\}$, $s_2 = \{2, 3\}$, and $s_3 = \{1, 3\}$. Indicated is a schedule representing $S^\star = \{s_2, s_3\}$.

A worst-case optimal algorithm. At a high level, the algorithm generalizes the methods given in [2] for two dimensions to three dimensions. The approach proceeds in three phases: (1) Gather, (2) Compress, and (3) Compact Reconfiguration. The goal of (1) Gather is to form a *snake*, which is informally a connected sequence of $5 \times 5 \times 5$ metamodules. Intuitively, the snake can move freely through the configuration without disrupting the connectivity of the remaining modules. As it moves, it collects non-cut modules, growing in size until it is sufficiently large to initiate the second phase. At a high level, in (2) Compress the snake collects the remaining modules of the configuration, creating a *compact* configuration. A configuration C is compact if for every module $\mathsf{u} \in C$, the cuboid defined by the position of u and the origin is entirely contained in the configuration:

$$\forall \mathsf{u} \in C: \quad \forall a \in [0, x(\mathsf{u})] : \forall b \in [0, y(\mathsf{u})] : \forall c \in [0, z(\mathsf{u})] : \quad (a, b, c) \in C.$$

The (3) Compact Reconfiguration phase deals with arbitrary reconfiguration of these.

3 Contributed media

To assist with developing an intuitive understanding of key pieces from the algorithm and hardness gadgets, we created visualizations of them. An interactive form of these will be hosted online using the WebVis[1] tool created by the UML Modular Robotics group and presented in [6]. We implemented new features for the tool to facilitate the creation of manual animations of reconfiguration sequences. We have compiled these implementations into an accompanying video for a presentation during CG week, similar to [7] which appeared at CG week 2024.

Abstract

We analyze and visualize collaboration within the Computational Geometry community by modeling co-authorship relations as a graph, where nodes correspond to individual researchers and edges represent shared publications. By aggregating and time-slicing conference data, we construct a dynamic representation of the community that supports both interactive visualization and structured search.

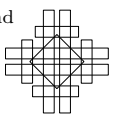
1 Introduction



The project is motivated by an empirical observation: over the past years a member of our group repeatedly encountered co-authors of another member at different conferences where the other member was not in attendance. This prompted some speculation on our part: What is the average coauthor distance within the community? What would a co-authorship graph of the community look like? Who are the centers of this graph? What is its diameter?

We set out to study and visualize collaborative structures within the computational geometry community. In particular, we investigate the formation and persistence of cliques and larger clusters, as well as the role of individual researchers as bridges or central actors. To this end, we compute a range of graph-theoretic properties, including diameter, radius, center, and connectivity measures across different temporal snapshots, and make available through a visualization.

The idea of quantifying scholarly proximity through graph distance is well established, most prominently through the `Erdős number` [6]. The Erdős number of a researcher is defined as the length of the shortest co-authorship path to Paul Erdős, where direct co-authors have Erdős number 1, their co-authors have Erdős number 2, and so on. This concept illustrates how collaboration graphs can be used to measure relational distance and has inspired a variety of tools and datasets, such as `csauthors.net` [2], which provide searchable views of co-authorship networks in computer science, as well as the `Mathematics Genealogy`

Project [3], and the Academic Family Tree [4]. Building on these ideas, our project focuses on the computational geometry community and extends beyond static distance measures by emphasizing temporal evolution, structural metrics, and interactive exploration.

2 A web application

A variety of interactive applications exist for exploring communities and networked data, many of which are proprietary or require paid access, like PURE. In contrast, our application is tailored specifically to the CG community and is based entirely on publicly available data. This allows for open exploration of the community and its underlying structures. Moreover, another key feature of our application is the ability to explore how the community evolves over time, revealing how relationships and activity patterns develop. A snapshot of the application can be seen in Figure 1.

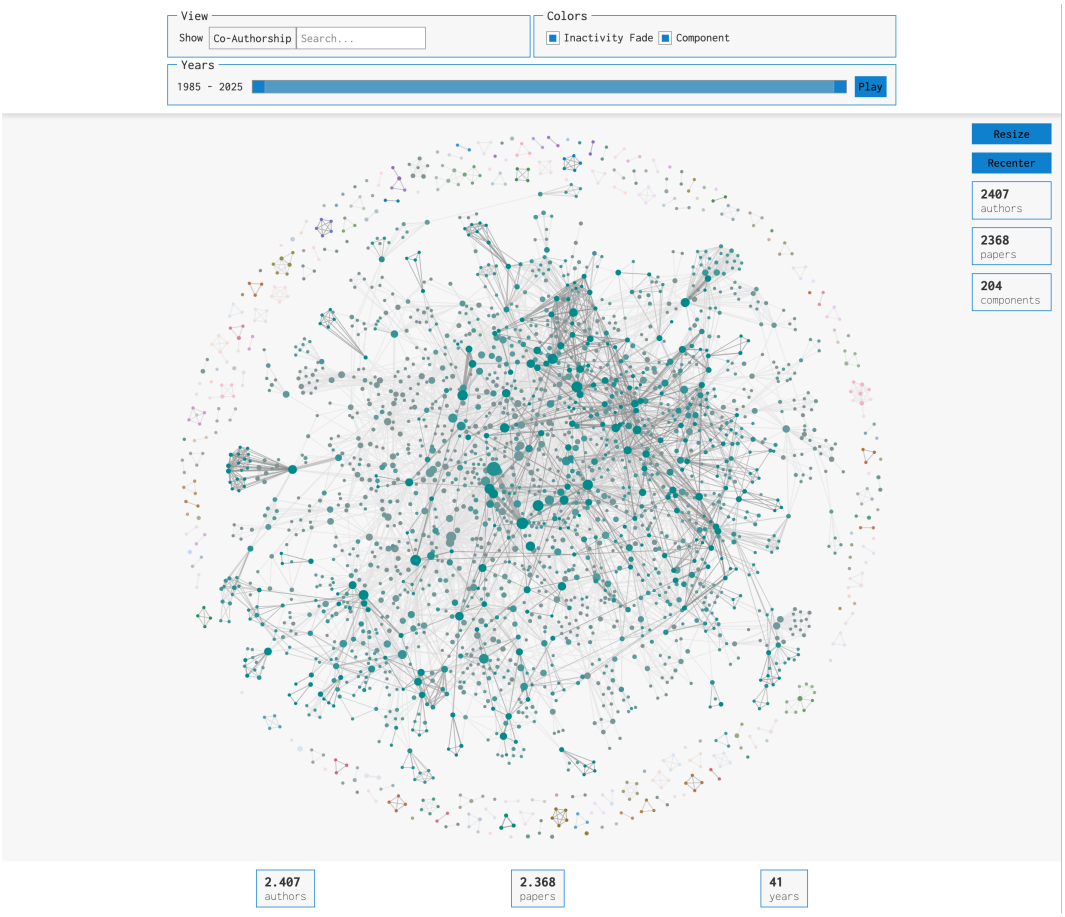

Figure 1 The web application is currently accessible via: https://cgcg.peterkramer.eu.

DBLP. Our main data source is the dblp computer science bibliography [5]. It offers bibliographic datasets covering leading journals and conference proceedings in computer science, which is updated regularly and provided as open data in the public domain. It was founded in 1993 by the University of Trier and is now operated by Schloss Dagstuhl.

Processing and visualizing the data. Upon launch, the web application retrieves the relevant data directly from `dblp` and stores it in a local `SQLite` database [7, 9] in the user's browser. Individual datapoints and their relationships are analyzed using `graphology` [8] and visualized using the `force-graph` [1] library for force-directed graph drawing.

Filtering the data. To support an interactive exploration of the CG community graph, the application offers a set of complementary filters that allow users to progressively shape and refine the view. A basic search function allows users to find specific individuals and highlight their immediate neighborhood. Temporal dynamics are conveyed through visual weighting: nodes and edges representing more recent activity are displayed with higher intensity, while older entries are shown with reduced visual prominence. In addition, node and edge sizes encode the total number of publications, and the number of joint publications.

Properties of the graph. To summarize the full story, the aggregated collaboration graph for 1985–2025 contains 2,407 researchers who collectively authored 2,368 papers, forming 204 connected components, including 82 singletons. The largest clique contains 14 researchers, whereas the average clique size is only 3.39, indicating that tightly interconnected groups remain relatively small. A similar pattern emerges when examining the connected components. Although the largest component is substantial, comprising 1,960 researchers and 2,105 papers, and having a diameter of 12 and a radius of 6, the graph is otherwise highly fragmented: the mean component size is merely 11.7 nodes, increasing to 19.05 when singleton components are excluded. This suggests that, beyond the dominant core, collaboration is dispersed across many small components. Consistently, the average number of authors per paper is relatively modest, at 2.76 overall and rising to 3.13 when single-author papers are excluded, reflecting the prevalence of small collaborative teams.

Privacy. Since all data is publicly available via `dblp`, we consider an "opt-out" policy appropriate. Authors can request removal of their bibliography from `dblp`, and our visualization, being dynamically linked, will reflect such changes. However, we do realize that someone may wish to remain listed in `dblp` but not appear in our visualization; in that case, they can contact any of the authors to have their data excluded. We also note that `dblp` treats different publication names, for example after a name change, as separate entities. We have not merged these to avoid potential privacy concerns; such merging may be requested.

3 Future work

In its current version (March 27, 2026), our web application only includes the SoCG data from `dblp`. However, it can be straightforwardly extended to include additional conferences and journals indexed by `dblp`. For example, we can readily incorporate CCCG and JoCG, for which a dataset is already available. Since EuroCG has no official proceedings, it is generally not indexed, apart from a few isolated exceptions. To capture the computational geometry community as comprehensively as possible, future work will focus on compiling a dedicated EuroCG dataset; however, this will necessarily be a gradual process, largely because not all books of abstracts are readily accessible.

In addition, we will provide ongoing support of basic features, such as allowing individuals to be anonymized if they prefer not to appear in our application, or merging multiple `dblp` identifiers corresponding to the same person, along with similar adjustments. Moreover, we will add a variety of interesting statistics over time to enrich the content. For example, whether parts of the CG community graph exhibits small-world characteristics.

Initially, we had wished to add an “affiliation” filter to visualize collaborations by institution. However, the architecture of the `dblp` database makes loading this data dynamically infeasible. We therefore leave this as a future goal.

For the CG community. This application is not intended to rank or compare individuals. Its purpose is simply to foster open and collaborative exploration and deepen our understanding of the CG community. We envision this project as a shared endeavor, “owned” and developed by our community. Therefore, we warmly invite you to explore the data, share insights, and contribute ideas or new features that will help guide its future. To actively join the project, simply reach out to any of our current members. We would love to have you on board.

Abstract

Floodlight illumination problems are *art-gallery* variants, where a target domain needs to be illuminated by guards, each associated with a field of view. The *rotating rays Voronoi diagram* is a Voronoi diagram with rays as sites under the *angular distance*. There is a natural connection of this Voronoi structure with the problem of finding the minimum aperture such that a given set of uniform aperture floodlights illuminates a target domain. In this work we present an interactive visualization software for such problems, supporting different angular distances, namely, *oriented* and *unoriented* versions, and for different domains, namely, the plane and simple polygons.

1 Introduction

Given a ray r and a point $x \in \mathbb{R}^2$, the *oriented angular distance* $d_\angle(x, r)$ is the counterclockwise angle needed to rotate r around its apex until it passes through x. The *unoriented angular distance* is equal to $\min(d_\angle(x, r), 2\pi - d_\angle(x, r))$. We call α-*floodlight* the cone around r formed by the points with angular distance at most α; see Figure 1. Given a domain $\mathcal{D}$ and a set $\mathcal{S}$ of n rays, we consider the following two closely related problems.

- The **α^*-floodlight illumination** of $\mathcal{D}$ by $\mathcal{S}$: Each ray $r \in \mathcal{S}$ induces an α-floodlight and the goal is to find the minimum α, denoted by α^*, that illuminates/covers $\mathcal{D}$.
- The construction of the **rotating rays Voronoi diagram** of $\mathcal{S}$ restricted to $\mathcal{D}$, denoted by $\mathrm{RVD}(\mathcal{S})$: The diagram is a partition of $\mathcal{D}$ into regions, where each region consists of all points in $\mathcal{D}$ that are nearest to a particular ray under the angular distance function.

Figure 1 Oriented (left) and unoriented (right) angular distances and the respective α-floodlights.

The α^*-floodlight illumination reduces to the construction of the rotating rays Voronoi diagram, since the angle α^* is realized on a feature of $\mathrm{RVD}(\mathcal{S})$ [1]. Hence, after constructing the diagram, α^* can be found in time linear in $|\mathrm{RVD}(\mathcal{S})|$ by a traversal. Each problem has two variants, the *unoriented* and the *oriented*, depending on the distance considered.

For optimization problems where these concepts can be applied see [4, 5, 7, 12, 15, 21]. For an overview of Voronoi diagrams and illumination problems, see [6, 16] and [17, 18, 22].

Contribution. To motivate and facilitate further research on the aforementioned problems, we provide an interactive visualization software (`https://github.com/VD-collective/rvd-explorer`) that supports both angular distance functions in different domains, namely the plane and polygons. Next, we describe our software and then give an overview of results.

2 Software description

Our software RVD explorer allows users to explore rotating rays Voronoi diagrams and the α^*-floodlight illumination problem; see a screenshot of the software in Figure 2.

Users can specify a Number of sites, place their apices and directions, and select a Diagram type between RVD_RAYS_ORIENTED and RVD_RAYS_UNORIENTED. Every site, and its corresponding Voronoi region, is associated with a distinct color for clearer visualization. Show diagram skeleton highlights (in black) the graph structure of the diagram. Show point of maximum angle highlights (with a white disk) a point inside the selected frame which realizes α^*, i.e., the last point of the frame to be illuminated if all apertures started growing from 0 to α^*. The Max aperture can be bounded from above and the user can change the Current aperture (%) and also Rotate rays using the respective sliders. There are many additional features useful for studying the diagrams; the full list is shown when pressing the Help button.

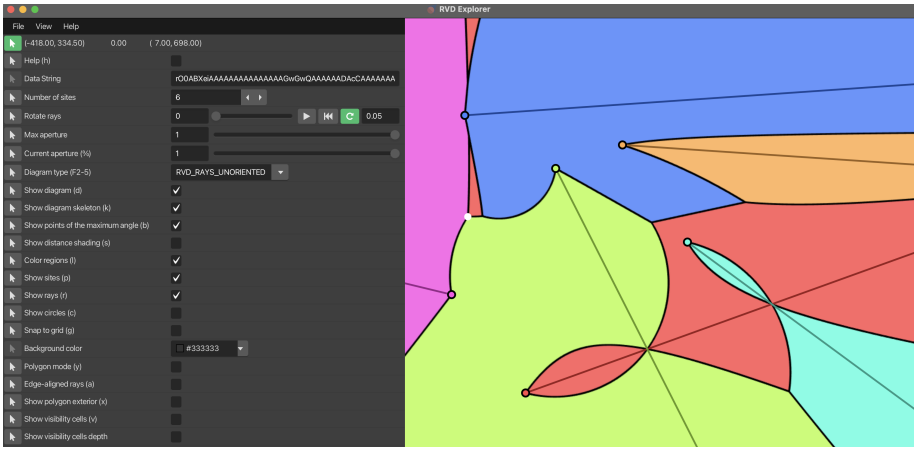

Figure 2 Image of the software showing an unoriented rotating rays Voronoi diagram in $\mathbb{R}^2$.

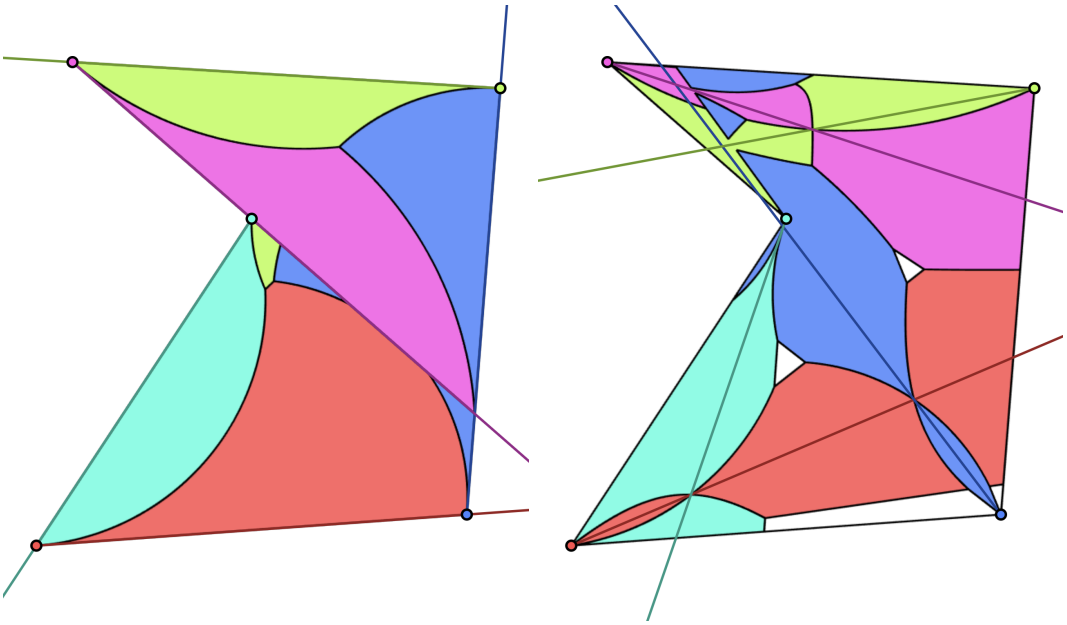

Figure 3 Diagrams of a 5-sided polygon: (left) edge-aligned, (right) $\pi/12$ bounded max aperture.

Domains. Both the entire plane and polygonal domains are supported. The domain can be chosen by toggling Polygonal domain. In the plane, rays can be placed anywhere in $\mathbb{R}^2$ and distances are evaluated over the entire $\mathbb{R}^2$; see, e.g., Figures 2 and 4. In polygonal domains, a polygon $\mathcal{P}$ is given with one ray per vertex, and distances are only evaluated inside $\mathcal{P}$. When Edge-aligned rays is enabled, each edge $\overline{v_i, v_{i+1}}$ of $\mathcal{P}$ induces a ray r_i with apex v_i passing through v_{i+1}, as in the *Brocard illumination problem* [3, 14]; see, e.g., Figures 3 and 5.

Implementation details. The application is implemented in the JavaFX graphics framework. Diagrams are rendered by pixel-based rasterization of the viewport. For each pixel, angular distances to all rays are evaluated and colored by the nearest site. Thus, for a $W \times H$ viewport, each frame renders in $O(nWH)$ time. All computations run on the CPU. To maintain a fluid interactivity, pixel rows are processed in parallel and expensive operations are avoided, e.g., angles are compared without computing their values. Diagram edges are detected by comparing neighboring pixel assignments and selectively supersampled for anti-aliasing. The user interface is built on a custom lightweight library for interactive parameter control.

3 The plane

Let the domain be $\mathbb{R}^2$. We consider both the oriented and unoriented variants; see Figure 4.

Oriented RVD($\mathcal{S}$). A comprehensive study of the oriented RVD($\mathcal{S}$) was given in [1]. A key property is that the distance function is discontinuous, at 2π, and that the bisectors consist of circular arcs and rays. The worst-case combinatorial complexity of RVD($\mathcal{S}$) is shown to be $\Omega(n^2)$ and the same is true for the complexity of a single Voronoi region. An $O(n^{2+\epsilon})$ complexity upper bound, for any $\epsilon > 0$, is obtained via 3-dimensional envelopes [20]; the same approach yields a construction algorithm running in $O(n^{2+\epsilon})$ time.

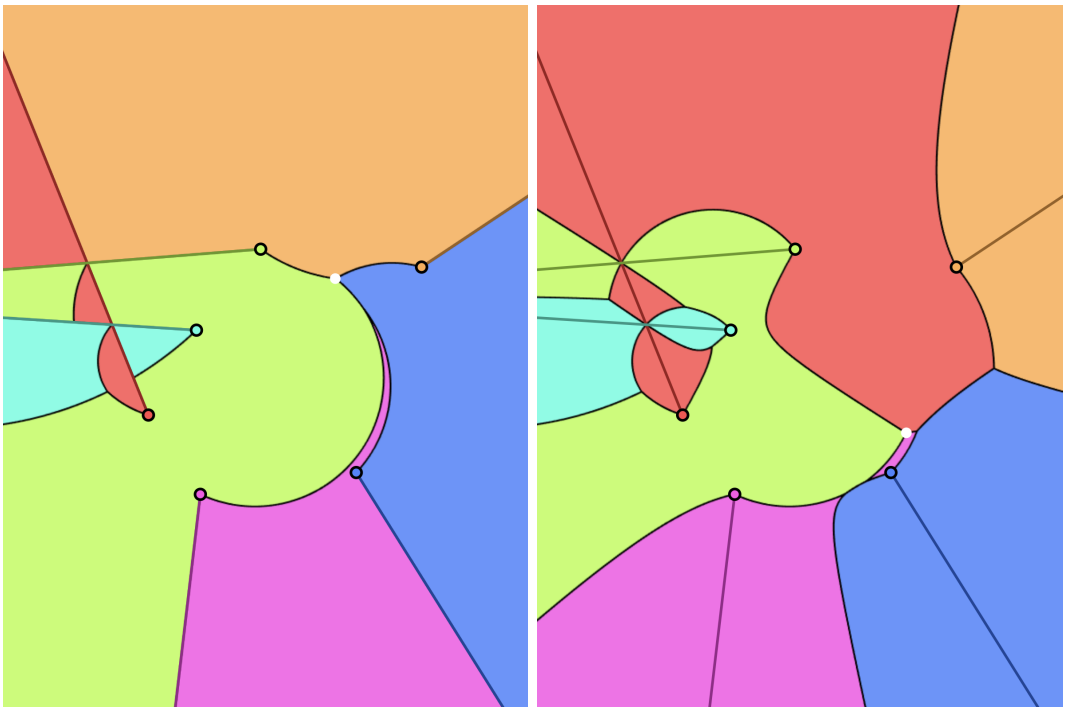

Figure 4 Voronoi diagrams of 5 rays in $\mathbb{R}^2$ in the oriented (left) and unoriented (right) variants.

Unoriented RVD($\mathcal{S}$). The unoriented RVD($\mathcal{S}$) was first proposed in [9], accompanied by an $\Omega(n^2)$ worst-case complexity bound. Its bisectors were investigated in [11]; they consist of circular and hyperbolic arcs. Notably, several results of the oriented case [1] carry over: for example, with minor adaptations of the 3-dimensional envelope methods, we can obtain an $O(n^{2+\epsilon})$ complexity upper bound and an $O(n^{2+\epsilon})$-time algorithm.

α^*-floodlight illumination. The angle α^* takes values in $[2\pi/n, 2\pi]$ in the oriented variant [1], and in the unoriented, it takes values in $[\pi/n, \pi]$. It can be obtained by a traversal after constructing RVD($\mathcal{S}$), so it requires $O(n^{2+\epsilon})$ total time [1]. It is unknown whether α^* can be computed faster directly, without RVD($\mathcal{S}$). Still, computing α^* admits an $\Omega(n \log n)$ lower bound: the simple case where all rays share the same apex is equivalent to the Max-Gap problem on a circle, which has an $\Omega(n \log n)$ lower bound in the real RAM model [13, 19].

4 Polygonal domains

We consider simple polygons as domains, with edge-aligned rays induced by the polygon boundary, i.e., related to Brocard illumination [3, 14]. For such inputs, the two variants, oriented and unoriented, coincide, as by definition only counterclockwise rotation is meaningful.

Convex polygons. The Voronoi diagram RVD($\mathcal{S}$) constrained to a convex polygon $\mathcal{P}$ was studied extensively in [1]. It is a tree, has $\Theta(n)$ combinatorial complexity, and can be constructed in optimal deterministic $\Theta(n)$ time using an elaborate divide-and-conquer scheme. This result is accompanied by a simple $O(n \log n)$-time algorithm; a similar algorithm to directly compute α^* is given in [3]. The angle α^* takes values in $(0, \pi/2 - \pi/n]$ [1].

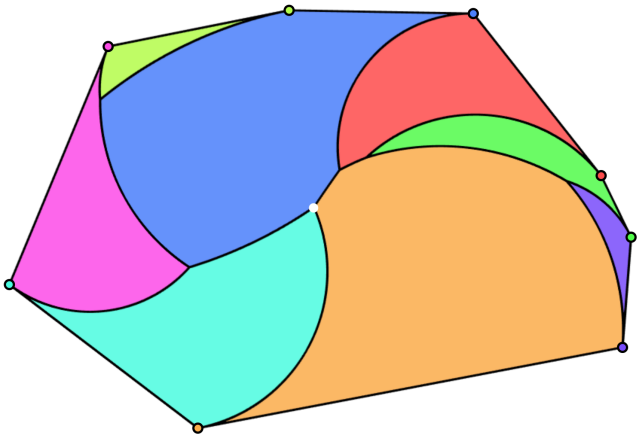

Figure 5 Voronoi diagram of a convex polygon with 8 vertices, inducing 8 edge-aligned rays.

Simple polygons. For simple polygons few results are known. The challenge comes from the presence of reflex vertices which obstruct the visibility of the rays. To construct RVD($\mathcal{S}$), an $O(n^{4+\epsilon}r)$-time algorithm was described in [14], where r is the number of reflex vertices: $\mathcal{P}$ is decomposed in $O(n^2r)$ visibility cells in $O(n^3)$ time [8, 10] and the $O(n^{2+\epsilon})$-time algorithm [1] is applied in each cell. The above implies an $O(n^{4+\epsilon}r)$ combinatorial complexity bound. A worst-case $\Omega(n^2)$ lower bound can be realized by star-shaped polygons, as the one in Figure 6.

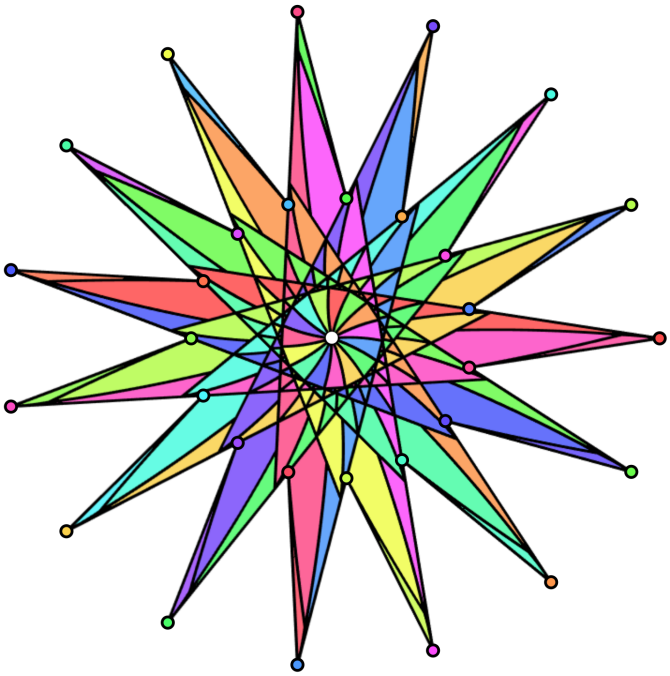

Figure 6 Diagram of a polygon with $\Theta(n^2)$ complexity, induced by the $\Theta(n^2)$ ray intersections.

Regarding the angle α^*, an $O(n^3 \log^2 n)$-time algorithm to compute it directly was given in [3]. The angle takes values in $(0, 2\pi - \pi/6)$ and instances arbitrarily close to the upper bound can be realized by windmill-shaped polygons as shown in Figure 7. It is a regular triangle with three outward wings attached on the corners.

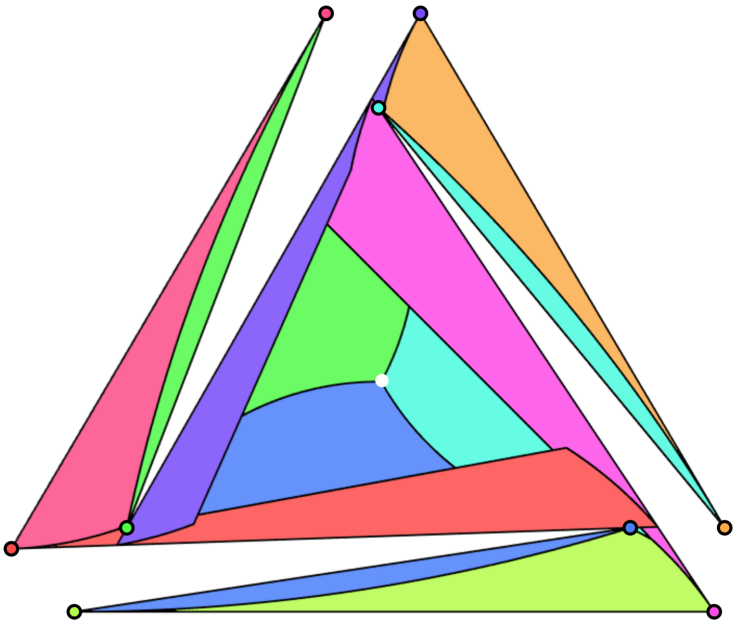

Figure 7 Voronoi diagram of a polygon with α^* close to $2\pi - \pi/6$, realized in the central triangle.

Abstract

Neighborhood graphs and clustering algorithms are fundamental structures in both computational geometry and data analysis. Visualizing them can help build insight into their behavior and properties. The Ipe extensible drawing editor, developed by Otfried Cheong, is a widely used software system for generating figures. One particular aspect of Ipe is the ability to add Ipelets, which extend its functionality. Here we showcase a set of Ipelets designed to help visualize neighborhood graphs and clustering algorithms. These include: ε-neighbor graphs, furthest-neighbor graphs, Gabriel graphs, k-nearest neighbor graphs, k^{th}-nearest neighbor graphs, k-mutual neighbor graphs, k^{th}-mutual neighbor graphs, asymmetric k-nearest neighbor graphs, asymmetric k^{th}-nearest neighbor graphs, relative-neighbor graphs, sphere-of-influence graphs, Urquhart graphs, Yao graphs, and clustering algorithms including complete-linkage, DBSCAN, HDBSCAN, k-means, k-means++, k-medoids, mean shift, and single-linkage. Our Ipelets are all programmed in Lua and are freely available.

1 Introduction

We present a set of **Ipelets** for visualizing clustering and neighborhood graph algorithms on point sets in $\mathbb{R}^2$. These Ipelets include: ε-neighbor graphs, furthest-neighbor graphs, Gabriel graphs, k-nearest neighbor graphs, k^{th}-nearest neighbor graphs, k-mutual neighbor graphs, k^{th}-mutual neighbor graphs, asymmetric k-nearest neighbor graphs, asymmetric k^{th}-nearest neighbor graphs, relative-neighbor graphs, sphere-of-influence graphs, Urquhart graphs, Yao graphs, and clustering algorithms including complete-linkage, DBSCAN, HDBSCAN,

k-means, k-means++, k-medoids, mean shift, and single-linkage. Some of these are also implemented in CGAL [9]. All our Ipelets are programmed in Lua and are freely available on GitHub. To install any Ipelet, download the file from the GitHub repository, and place it in the `ipelets` sub-folder of your Ipe folder. This work builds on previous ipelets to add functionality in various contexts [4, 8, 12, 14]. Our contribution is in line with that of several other researchers who have worked on neighborhoods of point sets, such as Voronoi diagrams and Delaunay triangulations [4, 14], and β-skeletons [11]. Ipelets can be invoked from the "Ipelets" menu, see Figure 1 for usage instructions.

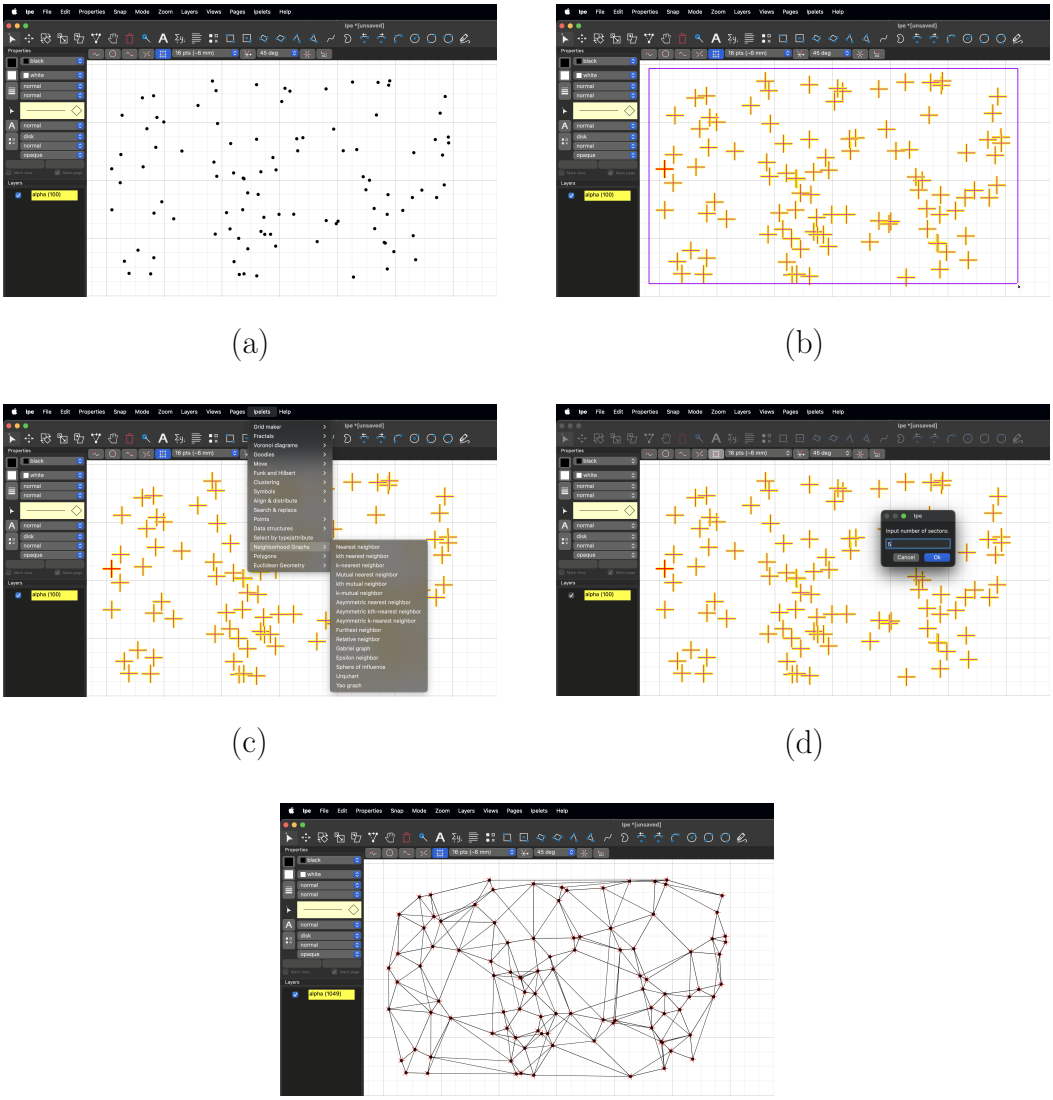

Figure 1 (a) Place a point set in Ipe, (b) select the points, (c) choose a graph from the "Ipelets" menu, (d) enter a parameter value if prompted, (e) the resulting graph is drawn automatically.

2 Neighborhood graphs

In this section, we describe the neighborhood graphs our Ipelets compute on point sets. We loosely separate them by type and briefly describe our contributions.

2.1 Nearest-neighbor variants

Nearest neighborhood graphs are fundamental tools in data analysis on a point set P. A point $p \in P$ is connected to $q \in P$ when one is the nearest neighbor of the other. The *k-nearest neighbor graph* connects p to q when q is among the k nearest neighbors of p; the *k^{th}-nearest neighbor graph* connects p to q when q is the k^{th} nearest neighbor of p; *mutual nearest neighbor graphs* connect p to q when each is the other's nearest neighbor; the *k-mutual neighbor graph* connects p to q when each is among the other's k nearest neighbors; the *k^{th}-mutual neighbor graph* connects p to q when each is exactly the other's k^{th} nearest neighbor; *asymmetric nearest neighbor graphs* connect p to q when exactly one is the other's nearest neighbor; *asymmetric k-nearest neighbor graphs* connect p to q when exactly one has the other among their k nearest neighbors; *asymmetric k^{th}-nearest neighbor graphs* connect p to q when exactly one has the other as their k^{th} nearest neighbor; and *furthest neighbor graphs* connect p to q when q is p's furthest neighbor. See illustration in Figure 2.

2.2 Proximity graphs

A proximity graph is a graph in which points are connected when a region-based condition is satisfied, often in the context of network analysis. The *Gabriel graph* connects two points p and q when the disk defined by the diameter of p and q contains no other points [10]. A *relative neighborhood graph* connects two points p and q exactly when no point is closer to both p and q than they are to each other, or equivalently, no point is in the lune of p and q (intersection of the ball at p with q on its boundary and the ball at q with p on its boundary) [15]. A *sphere of influence graph* assigns to each point a disk with radius given as the distance to its nearest neighbor and connects points when their disks overlap [16]. An *ε-graph* connects pairs of points if they lie within ε of each other. A *Urquhart graph* is the Delaunay triangulation with the longest edge of each triangle removed [17]. A *Yao graph* divides the plane into sectors by angle around points, and points are connected to their closest neighbor per sector [18]. See visuals in Figure 3.

3 Clustering

In this section, we describe the clustering algorithms we implemented for point sets. As before, we loosely separate them by type and briefly describe our contributions.

3.1 Centroid-based

Centroid-based clustering partitions a point set in space into clusters using a centroid-based method. The *k-Means* clustering partitions points into k clusters, assigning points to its nearest centroid and recomputing the centroids iteratively until it is stable. The *k-Means++* variant is similar, except it chooses initial centroids that are likely to be far apart to improve convergence. Unlike *k-means*, *k-Medoids* clustering uses preexisting points in the data as the centroids of the cluster [13]. Each iteration, a point replaces the medoid if it decreases the total intra-cluster distance. Illustrations of the methods can be seen in Figure 4.

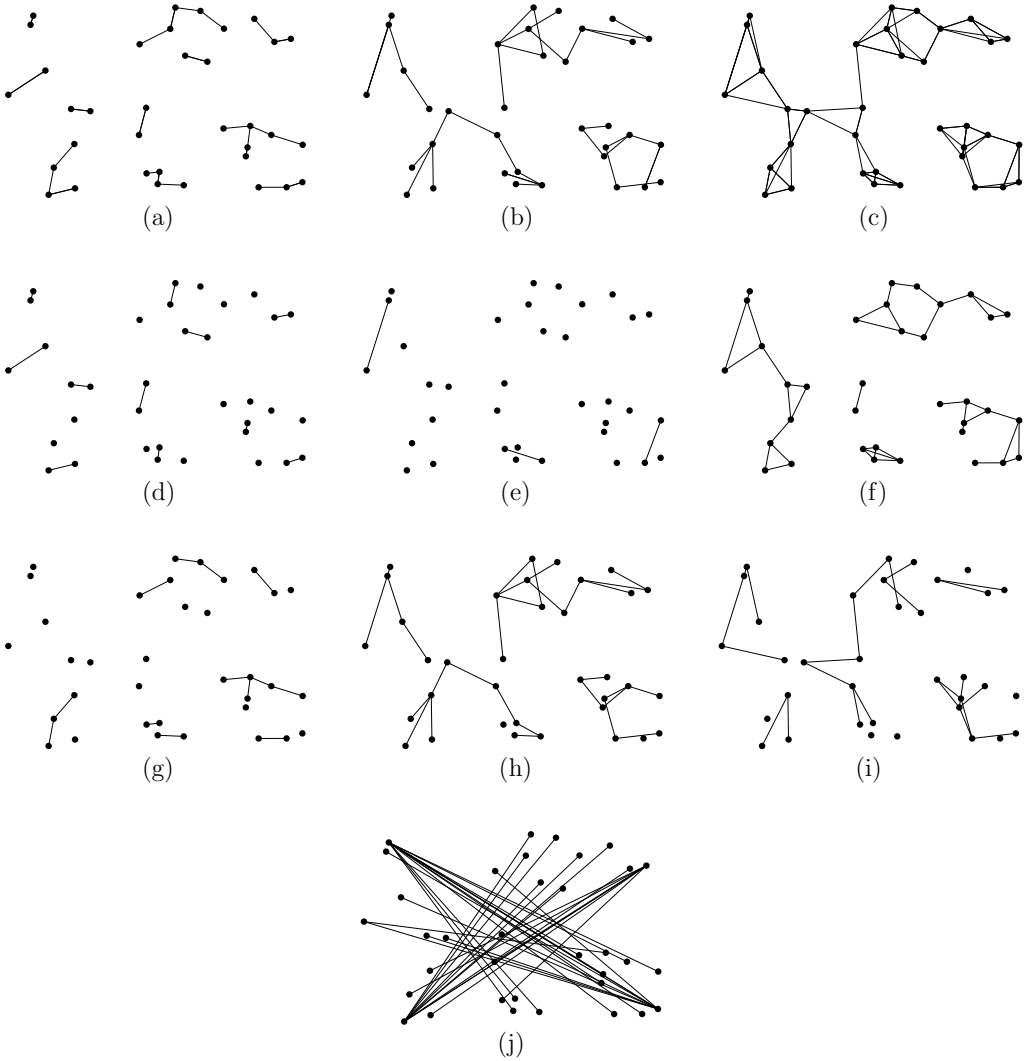

Figure 2 (a) Nearest, (b) k^{th}-nearest, (c) k-nearest, (d) mutual nearest, (e) k^{th}-mutual, (f) k-mutual, (g) asymmetric nearest, (h) asymmetric k^{th}-nearest, (i) asymmetric k-nearest, and (j) furthest neighbor graphs. In each $k = 3$.

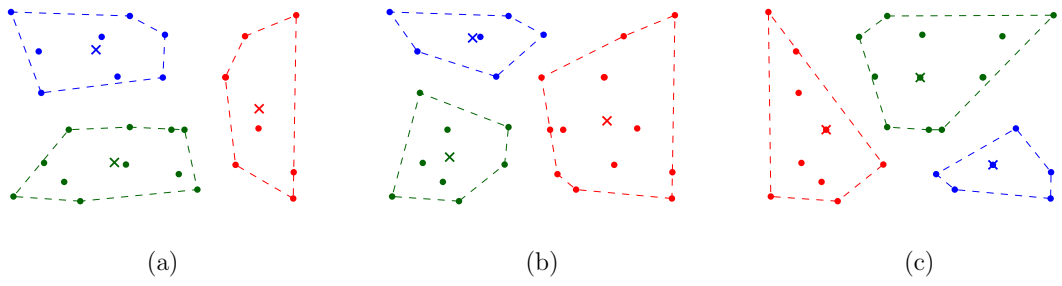

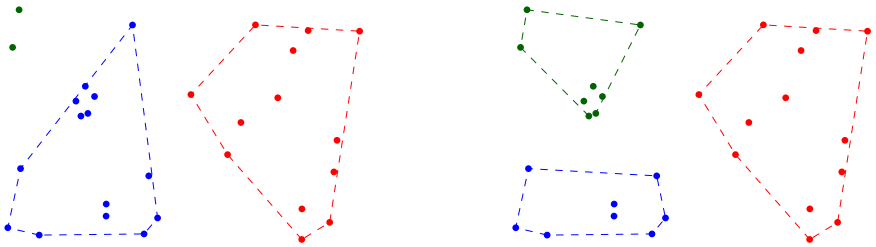

Figure 4 (a) k-Means, (b) k-Means++, and (c) k-Medoids.

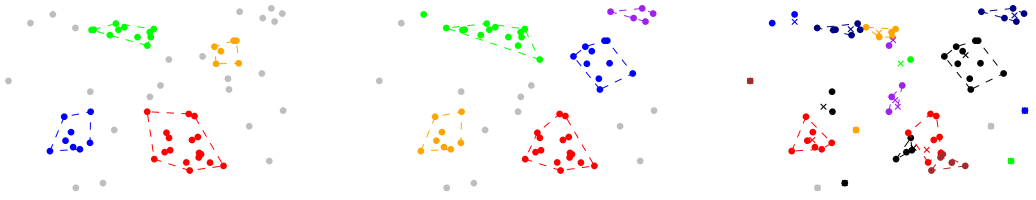
3.2 Hierarchical

Hierarchical clustering methods work by treating each point as a cluster and iteratively merging clusters until only a specified number remain. *Single-linkage clustering* defines the cluster distance between clusters as the minimum pairwise distance between their points, while *complete-linkage clustering* uses the maximum [7]. See Figure 5.



(a) (b)

Figure 5 (a) Single Linkage Clustering, (b) Complete Linkage Clustering.

3.3 Density-based

Density-based clustering partitions a point set into clusters based on how densely points are packed. *DBSCAN* groups points that are within a specified distance, ε, of each other and have a minimum number of neighboring points (MinPts). Points meeting these criteria form clusters (distinguished by colors), while points that don't are labeled as noise [6]. *HDBSCAN*, on the other hand, applies a hierarchical approach to density-based clustering [3]. It builds a mutual reachability graph and a minimum spanning tree to identify clusters at varying densities. Instead of relying on a fixed distance threshold like *DBSCAN*, *HDBSCAN* evaluates the stability of clusters across different scales. It then uses the Excess of Mass method to select stable clusters. *Mean shift* computes where each point would converge if moved towards the mean of its neighbors within the given bandwidth radius. Points whose trajectories converge on the same location form a cluster [5]. See Figure 6.

Figure 6 (a) HDBSCAN, (b) DBSCAN, and (c) Mean shift.

4 Conclusion

In this paper, we presented a collection of Ipelets for visualizing neighborhood graphs and clustering algorithms on point sets in $\mathbb{R}^2$. These tools are designed to assist in the understanding of these structures and their properties, and we hope they will be useful to researchers, educators, and artists alike. All Ipelets are freely available on GitHub.

Abstract

Higher-order Voronoi diagrams and Delaunay mosaics in polygonal metrics have only recently been studied, yet no tools exist for visualizing them. We introduce a tool that fills this gap, providing dynamic interactive software for visualizing higher-order Voronoi diagrams and Delaunay mosaics along with clustering and tools for exploring overlap and outer regions in the Hilbert polygonal metric. We prove that k^{th} order Voronoi cells are not always star-shaped and establish complexity bounds for our algorithm, which generates all order Voronoi diagrams at once. Our software unifies and extends previous tools for visualizing the Hilbert, Funk, and Thompson geometries.

1 Introduction

The Hilbert metric has attracted recent interest due to its applications in clustering [17], non-linear embeddings [18], convex approximation [1, 2], and real analysis [14]. As such, there has been work on extending results from computational geometry to the Hilbert metric, such as Voronoi diagrams (including farthest-point Voronoi) [9, 12, 15], minimum enclosing balls [6], and Delaunay triangulations [11]. To aid in these endeavors, software to help visualize the Hilbert metric has been progressively developed. This began with a Hilbert ball

visualizer [16], then some Voronoi demo software [9], which evolved into software for the Funk and Thomson polygonal geometry [5]. We build on this foundation by providing the first software with interactive support for dynamically visualizing higher-order Voronoi diagrams and Delaunay mosaics in the Hilbert metric, exploring overlap and outer regions (defined in Section 3), and step-by-step clustering on arbitrary convex polygonal domains. The software is implemented in JavaScript, it runs interactively in the browser, and it includes a tutorial video and brute force Voronoi mode for verification. It also maintains the features from all previous software.

2 Higher order structures

The study of k^{th} order abstract Voronoi diagrams started with "On the complexity of higher order abstract Voronoi diagrams" where cells were determined by the k closest sites [7]. The Hilbert metric does not immediately fall into the category of k^{th} order abstract Voronoi diagrams, but can be made to fit it by extending bisectors to infinity without the extensions crossing. As such, there exist frameworks for efficient k^{th} order Voronoi diagrams [7, 8]. Our visualization generates all orders at once using an edge labeling technique similar to those used in Euclidean geometry [10]. For completeness, we begin this section by proving two supporting lemmas that show our algorithm works. Then we present the algorithm. Throughout, we assume that we have been given some convex polygonal region Ω with m sides and a set of n sites S. Both proofs use a classical technique using properties of balls [13].

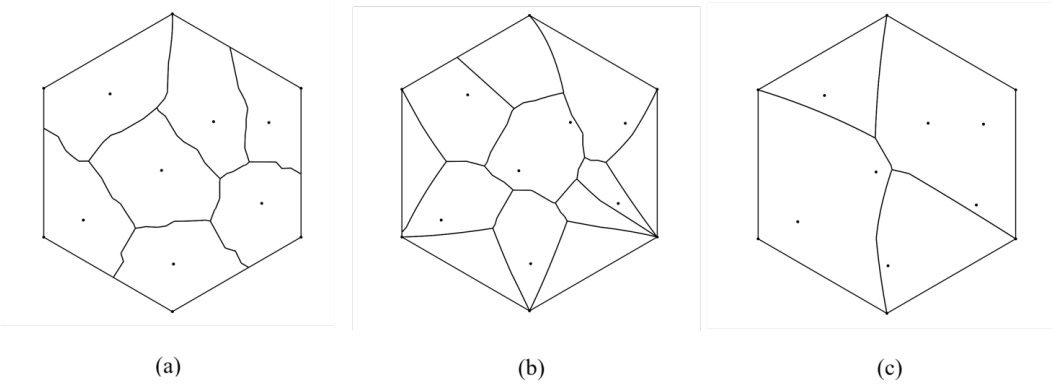

Figure 1 (a) First order Hilbert Voronoi (b) second order (c) final ($(n-1)^{th}$) order.

▶ **Lemma 1.** *The circumcenter of any three sites serves as a Voronoi vertex in both the k^{th} and $(k+1)^{th}$ order Hilbert Voronoi diagrams for some $0 < k < n-1$.*

Proof. Consider the circumcenter of three sites s_1, s_2, s_3 lying on the boundary of ball B, with $k-1$ sites of S in the ball. Perturbing B towards one of the sites will change which of s_1, s_2, s_3 is the k^{th} closest site to the center of B. Perturbing and growing the ball along one of the bisectors to include two sites will change which site is the $(k+1)^{st}$ closest. ◀

▶ **Lemma 2.** *Every bisector path between circumcenters belongs to exactly one k^{th} order cell.*

Proof. Consider the bisector between two sites $s_1, s_2 \in S$ lying on a k^{th}-order cell. A ball moving along the bisector and passing through both sites contains exactly $k-1$ other sites before reaching a circumcenter with a third site. Perturbing the ball off the bisector causes it to include either s_1 or s_2, shifting the center into the k^{th} order cell of one or the other. ◀

Our algorithm proceeds in three phases: Preprocessing computes all pairwise bisectors and all three site circumcenters parametrized along their respective bisectors. Looping over the bisectors lets us determine the diagram containment of the first bisector portion by checking the distance to each site. Traversing the bisector and updating diagram containment at each circumcenter yields a labeling of each bisector portion by the degree-order Hilbert Voronoi diagram it is part of, allowing us to display it quickly based on user input.

In the following we implicitly use three facts from [11,12]; first, we can order the boundary of Ω to calculate Hilbert distances in time $O(\log m)$, second we can order the boundary of Ω to calculate circumcenters in time $O(\log^3 m)$, and third, bisectors have complexity $O(m)$.

▶ **Corollary 3.** *Our algorithm takes time* $O(n^2 m \log m + n^3 \log^3 m + n^3 \log n \log m)$ *with space* $O(m \log m + n^3 + n^2 m)$.

Proof. Preprocessing takes $O(n^2 m \log m)$ time to compute all bisectors and $O(n^3 \log^3 m)$ time for computing all circumcenters (which we bucket by bisector). Sorting the circumcenters along the bisectors in the buckets takes $O(n^3 \log n)$.

We determine the containment of the first bisector component in $O(n \log n \log m)$ time per bisector. Then, we traverse the bisector, determining the containment of each vertex and each bisector segment in $O(n)$ time, since there are $O(n)$ circumcenters along each bisector. Since we do this for all n^2 bisectors, this takes $O(n^2(n \log n \log m + n))$. Our final runtime is $O(n^2 m \log m + n^3 \log^3 m + n^3 \log n \log m)$.

The storage consists of $O(m \log m)$ to order the boundary, $O(n^3)$ for circumcenters ordered along bisectors, and $O(n^2 m)$ for the bisectors, giving us $O(m \log m + n^3 + n^2 m)$ storage. ◀

▶ **Observation 4.** *In the Hilbert metric,* k^{th} *order Voronoi cells are not always star-shaped, a star-shaped region has an interior point from which all others are visible via a segment.*

Proof. This can be seen with the following Ω: a square with coordinates from (100, 100) to (300, 300) and sites at (160, 284.9), (140, 170), (130, 165), (180, 285). The second-order Voronoi generates a non-star-shaped region. This configuration is in general position. ◀

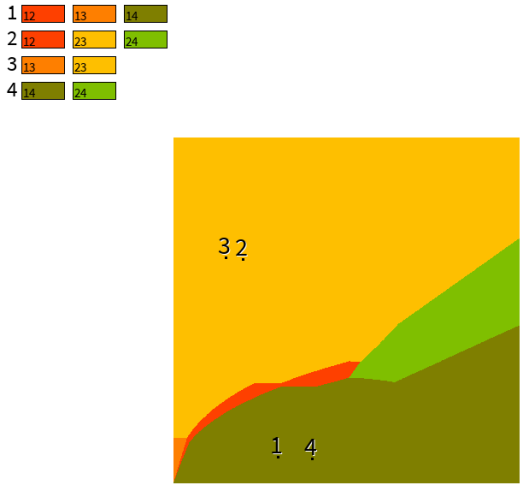

Figure 2 The red region, the Voronoi cell closest to 1 and 2, is not a star-shaped region.

We leverage our results on k^{th}-order cells to compute the Delaunay mosaic by computing a modified Fréchet mean (a point that minimizes the sum of distances) of the sites of each cell, and connecting them if their cells are adjacent.

3 Overlap and Outer Region

One notable property of the Hilbert metric is that three sites do not always have a circumcenter [9]. First we recall what it means to be a ball at infinity through two sites [11]. Then we define the overlap and outer regions which characterize circumcenter existence.

▶ **Definition 5** (Infinite Ball). *Given two sites $s_1, s_2 \in S$, consider balls passing through them with centers along the bisector parametrized by $t \in [0, 1]$. This yields two limit balls on the boundary of Ω: $B_0(p : q)$ at $t = 0$ and $B_1(p : q)$ at $t = 1$. (See Figure 3.)*

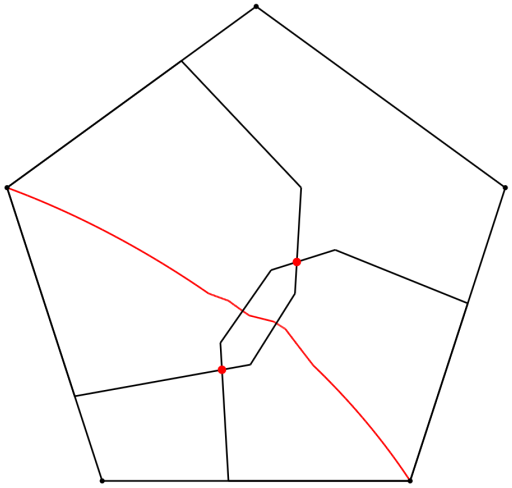

Figure 3 Two infinite balls along bisector through two sites (in red) generated by our software.

▶ **Definition 6** (Overlap Region). *Given two sites $s_1, s_2 \in S$, their overlap region, denoted $Z(p, q)$, is $B_0(p : q) \cap B_1(p : q)$.*

▶ **Definition 7** (Outer Region). *Given two sites $s_1, s_2 \in S$, their outer region, denoted $W(p, q)$, is $\operatorname{int}\Omega - (B_0(p : q) \cup B_1(p : q))$.*

The *overlap* is the region between two sites s_1, s_2 where there is no circumcenter between s_1, s_2, and p [11]. The *outer region* is the region that is not between the two sites where there is no circumcenter. In our software, we give users the option to display these regions dynamically. Users can generate these regions for any two sites, then move a third site between them to observe the behavior of the bisectors of the three sites.

4 Clustering

In 2019, Nielsen and Sun introduced clustering in the Hilbert simplex [17]. We expand on this by allowing users to interactively visualize clustering on arbitrary Hilbert polygonal geometries. We provide k-means and single linkage clustering (see Figure 4).

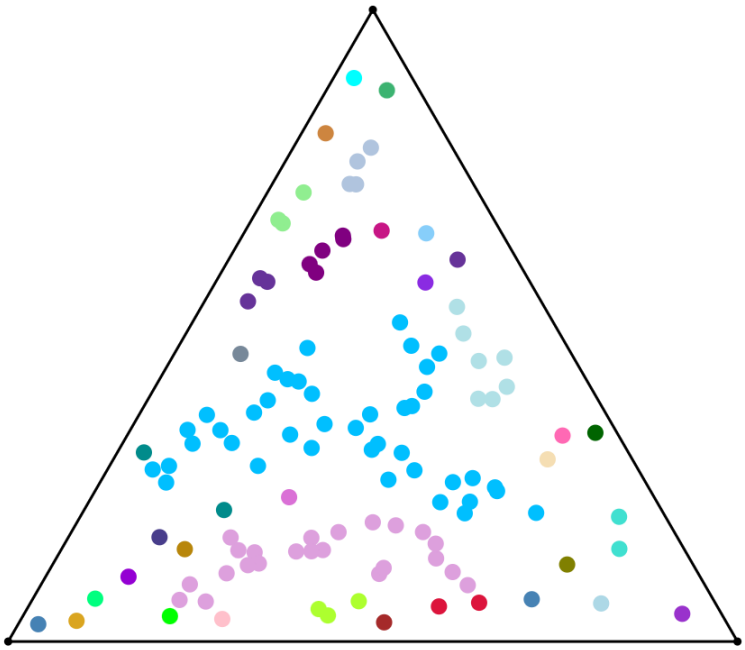

Figure 4 120 points in 38 clusters using single link clustering.

5 Conclusion

We have introduced the first software for visualizing higher-order Voronoi diagrams, Delaunay mosaics, clustering, overlap and outer regions in arbitrary convex Hilbert polygonal geometries.

Lori Ziegelmeier
Department of Mathematics, Statistics, and Computer Science, Macalester College, St. Paul, MN, USA

Abstract

Procedural content generation often employs grid-based methods to create virtual environments. We present a pipeline that utilizes Voronoi diagrams and Lloyd's Relaxation to construct an irregular mesh for terrain generation. We implement a customizable "Land Anchor" system combined with Perlin noise to determine landmass shapes, distinct from standard radial distribution methods. Furthermore, we simulate hydrology using priority-flood routing on the Voronoi edges and assign biomes via a Gaussian-smoothed Whittaker classification. The full pipeline is exposed through an interactive application that enables real-time parameter tuning and terrain export, and resulting geometric data is extruded in Blender to produce a 3D terrain model.

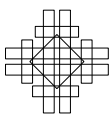
1 Introduction



Procedural Content Generation (PCG) creates virtual environments algorithmically [15, 10]. While grid-based approaches are computationally efficient, they often produce rectilinear artifacts. Polygonal map generation based on Voronoi diagrams offers an alternative for constructing irregular meshes; our work is inspired by the framework detailed in [13].

Existing polygonal implementations to generate terrains, such as [13], commonly employ a radial island mask biasing land generation toward the map center and utilize simplified hydrology models. In this work, we extend this polygonal approach to support flexible landmass design as well as 3D visualization. Our approach introduces three primary modifications:

1. **Geometry Generation:** Instead of a radial mask, we implement a customizable "Land Anchor" system combined with Perlin noise, allowing for the generation of non-convex landmasses and archipelagos.

© Batsambuu Batbold and Lori Ziegelmeier;
licensed under Creative Commons License CC-BY 4.0

2. **Hydrology Simulation:** We use a priority-flood algorithm to simulate flow accumulation for river generation along the Voronoi edges.
3. **3D Visualization:** We extend the 2D graph data into a 3D pipeline, converting the mesh into heightmaps for rendering in Blender.

We discuss each step of our approach in the following sections.

2 Geometric Foundation

2.1 Voronoi Diagrams and Duality

To create an irregular mesh, we partition the plane using a *Voronoi diagram* [8]. Given a set of points S as sites, the Voronoi region V_p corresponding to a site $p \in S$ contains all points in the plane closer to p than to any other site in S.

We construct this mesh via its dual graph, the *Delaunay triangulation*. We utilize the `delaunator` library [12] to efficiently compute the triangulation. The circumcenters of the resulting Delaunay triangles serve as the vertices of the Voronoi polygons, while the edges between them define the adjacency relationships between cells.

2.2 Lloyd's Relaxation

Voronoi sites are generated uniformly at random, though naive sampling produces uneven distributions with high variance in cell area and edge length. To regularize the mesh, we apply *Lloyd's Relaxation* [11], which iteratively converges to a Centroidal Voronoi Tessellation [9]. This redistributes sites more evenly, producing cells that are relatively uniform in area while retaining irregular boundaries; see Figure 1.

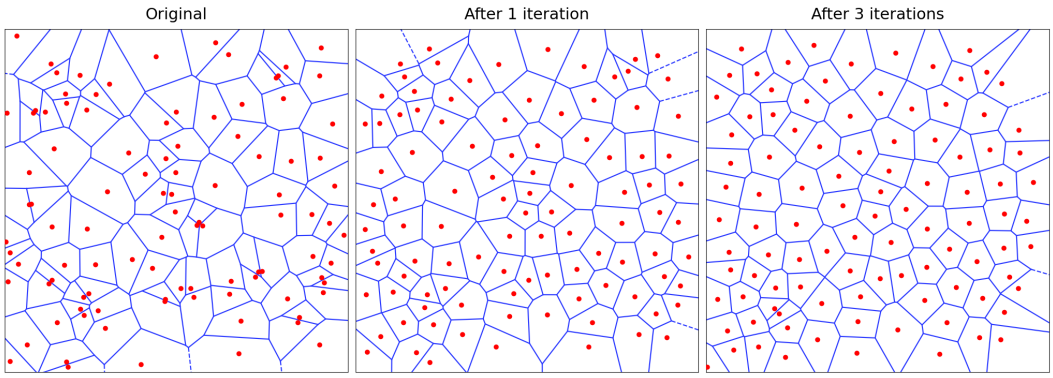


Figure 1 (Left) Voronoi mesh generated from random points. (Right) Uniform mesh resulting from 3 iterations of Lloyd's Relaxation.

3 Procedural Shaping

3.1 Elevation: Noise and Anchors

To generate elevation in our terrain, we use *Perlin noise* [14] implemented in [5], which provides spatially coherent values unlike uncorrelated sampling. We introduce a *Land Anchor* system to control terrain shape. Rather than a single radial mask for island formation, our method generalizes to N arbitrary anchor points. The final elevation E of a cell with Voronoi

site at (x, y) is defined as $E_{final} = \text{Perlin}(x, y) - (d_{min}/R)^2$ where d_{min} is the Euclidean distance to the nearest land anchor, and R is the map radius. This approach concentrates high elevation values around specific focal points while preserving the irregular, jagged nature of the noise along the coastlines; see Figure 2. Subsequently, a piecewise power curve is applied to the elevation data to compress low-lying areas into flat beaches and exponentially scale higher values into steep mountain peaks.

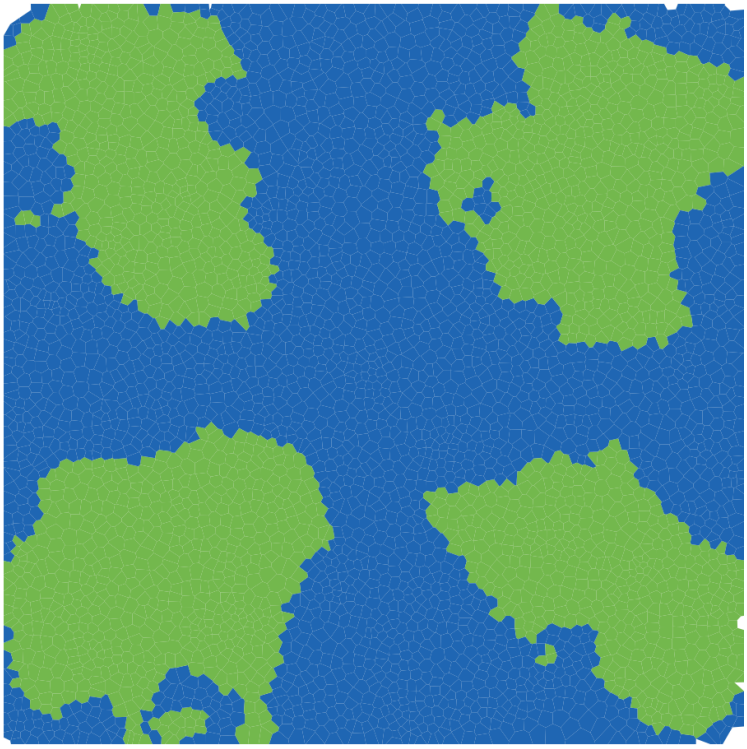

Figure 2 Non-radial archipelago layout generated using a four-land anchor configuration.

3.2 Biomes and Gaussian Smoothing

To texture the terrain, we simulate moisture using a secondary Perlin noise map modified by proximity to water. Cells are classified into biomes (e.g., Desert, Forest, Snow) using a *Whittaker Biome Diagram* [17], which maps $(Elevation, Moisture)$ pairs to terrain types.

Discrete biome classification can result in abrupt transitions between distinct zones; see Figure 3 (left). To mitigate this, we implement a smoothing pipeline:

1. Generate a 256×256 lookup table representing the Whittaker classification.
2. Apply SciPy's [16] *Gaussian Blur* ($\sigma = 8$) to the table to generate boundary gradients.
3. Assign cell colors using bilinear interpolation on this blurred table.

This results in gradient transition zones, such as a grassland buffer separating a forest from a beach; see Figure 3 (right).

3.3 Hydrology: Priority-Flood Routing

We simulate hydrology by utilizing the graph structure of the mesh, defining river channels along Voronoi edges. A *priority-flood algorithm* [1] is implemented to model flow dynamics:

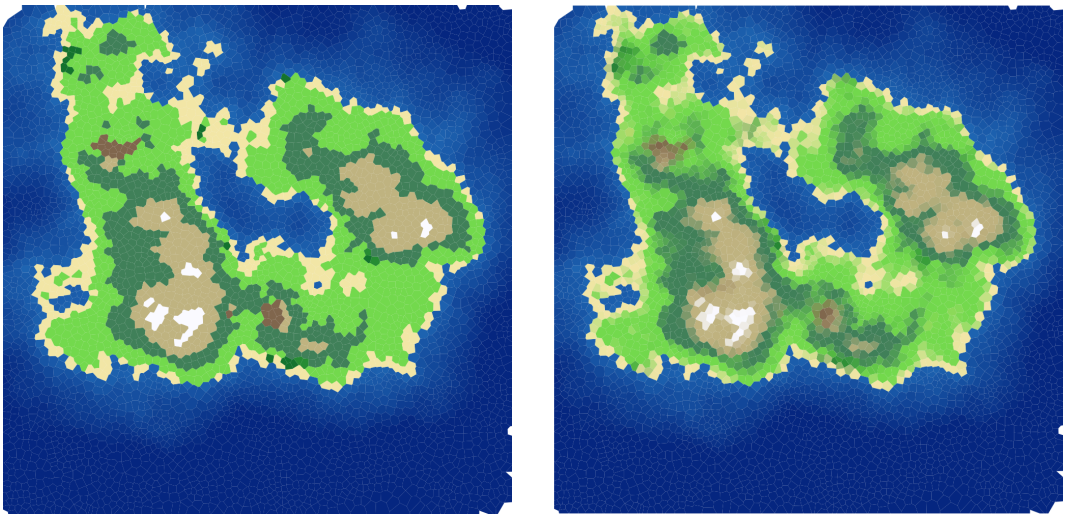

Figure 3 Biome distribution using rigid classification (left) and Gaussian-smoothed gradients between distinct zones (right).

1. **Flow Routing:** We construct a directed graph where each vertex connects to its lowest neighbor, creating a continuous path to the ocean.
2. **Flow Accumulation:** We traverse the graph from local maxima to the coast, aggregating flow values at each step.

The resulting accumulation values determine the width of the river segments, generating a river network structure; see Figure 4.

4 3D Visualization and Results

To visualize the generated terrain in three dimensions, we export the graph data using the Python Imaging Library [7]. We generate three primary texture maps:

- **Heightmap:** A 16-bit grayscale PNG representing the elevation data.
- **Colormap:** An RGB image representing the Gaussian-smoothed biome colors.
- **River Mask:** A binary mask isolating river pixels for shader application.

These textures are imported into Blender [6] to construct the 3D mesh. We apply a displacement modifier to a high-resolution plane to deform the geometry according to the heightmap. A custom shader utilizes the river mask to assign distinct material properties (specularity and roughness) to water surfaces. Figure 5 displays an example final output.

5 Conclusion

We present a pipeline for procedural terrain generation (see project webpage [2], interactive application [3] with example in Figure 6, and github repo [4]) that constructs a Voronoi mesh regularized via Lloyd's relaxation. Land shape was determined through a Land Anchor system with Perlin noise, and hydrology was simulated using a graph-based priority-flood algorithm. The mesh was exported to Blender for 3D rendering. The system produced plausible terrain, though the current Python implementation exhibited performance limitations at high polygon counts ($N > 50{,}000$). Future work includes computational optimization and atmospheric extensions (e.g., wind and temperature modeling) to support richer biome variation.

Abstract

A common sensing problem is to use a set of stationary tracking locations to monitor a collection of moving devices. Given n objects that need to be tracked, each following its own trajectory, and m stationary traffic control stations, each with a sensing region that can be changed over time; how should we adjust the individual sensor ranges in order to optimize energy consumption? We illustrate how to combine geometric insights with mathematical optimization to find optimal solutions for the min max variant of the problem, which aims at minimizing peak power consumption. Instances with 500 moving objects and 25 stations can be solved in the order of seconds for scenarios that take minutes to play out in the real world, demonstrating real-time capability of our methods.

1 Introduction

Keeping track of a collection of moving objects is a fundamental problem with a long history in Computational Geometry. In air traffic control, stationary centers monitor planes with powerful tracking devices to coordinate overall motion. With the growing ubiquity of drones, air traffic control needs further development [4, 16], such as the use of less powerful tracking stations: How should we adjust sensing radii over time to minimize power consumption?

We illustrate exact and heuristic methods for the min max variant of the Kinetic Disk Cover problem (KDC): Given a set of m stationary sensors at positions $\mathcal{Y} \subset \mathbb{R}^2$, as well as a set $\mathcal{P}$ of n moving objects, each moving along a linear trajectory $p_i(t)$ over the time interval $t \in [0, 1]$. How should we adjust the sensor range $r_i(t)$ to each center $y_i \in \mathcal{Y}$ at each time t, such that all objects are always within range of some sensor, and the maximum sum of areas $\max_{t\in[0,1]} \sum_{i=1}^{m} \pi r_i(t)^2$ of all disks is minimized?

Figure 1 A solution for an instance of the Kinetic Disk Covering Problem for $n = 10$ and $m = 5$. Stations are shown as green triangles, points move along the line segments.

Related work. The stationary Disk Cover problem (DC) [1] and its generalization, the non-uniform minimum-cost multi-cover (MCMC) problem [12, 13] are known to be NP-hard. Recently, there has been some work on optimally multi-covering fixed points with disks of varying sizes [11]. Other work examines multi-covering points with the minimum number of unit disks, with centers at arbitrary locations [10]. Research on fundamental concepts for kinetic data structures [2] enabled algorithms for k-center and k-means problem for both kinetic stations and objects [3].

2 Algorithmic approach

We solve the kinetic problem with a primal–dual, iterative strategy. By combining exact stationary solutions with good heuristics for obtaining overall kinetic solutions, we generate a sequence of tighter and tighter upper and lower bounds and therefore provably near-optimal or even optimal solutions.

Our approach starts from a feasible, stationary solution at time $t = 0$. We can extend any solution to the DC problem at time t to a solution for the KDC problem over time by maintaining the same assignment of objects to stations and altering the supporting point of each station as needed to ensure coverage. This produces a feasible solution for all $t \in [0, 1]$, yielding an upper bound for the optimal objective value. The upper bound can be further improved by considering the times at which it is advantageous to switch objects between covering stations, so-called *handover points*. In the full version of our paper [14], we establish the following; this can be generalized to three or more stations.

▶ **Lemma 1.** *In $\mathcal{O}(m^2n^3)$ time, all $\mathcal{O}(m^2n^3)$ possible handovers of objects between two stations (when extending a stationary solution to $t \in [0, 1]$) can be computed.*

On the other hand, we can consider the time t' at which the peak total area is attained; an optimal solution for the static DC problem at t', which can be computed with the help of an Integer Programming (IP) solver, provides a lower bound for the kinetic problem.

$$\begin{aligned} \text{minimize} \quad & \pi \cdot \sum_{d_i \in C} r_i^2 x_i \\ \text{subject to} \quad & \sum_{\substack{d_i \in C \\ p_j \in d_i}} x_i \geq 1, \qquad \forall p_j \in \mathcal{P} \\ & x_i \in \{0, 1\}, \quad \forall d_i \in C \end{aligned}$$

In this formulation, C is the set of all possible disks that can be formed by a station and an object, r_i is the radius of the disk d_i, and x_i indicates whether d_i is selected. A solution for the stationary problem can again be extended to an overall solution for the kinetic problem. Combining it with the previous kinetic solution by extracting the lower envelope of both solutions yields an improved feasible solution, and thus a better upper bound, see Figure 2.

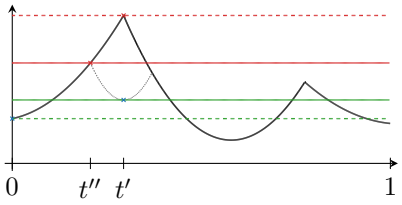

Figure 2 Improvement of the static solution at time t'. Green and red lines denote lower and upper bounds on the optimal solution.

3 Evaluation

We carried out extensive experiments for solving a wide range of benchmark instances; see our full paper [14, 15] for a detailed description.

We considered the following benchmark sets.

`fix_n` Fix number of objects to $n = 500$. For $m \in \{5, 10, \ldots, 50\}$ we generate 10 instances.

`fix_m` Fix number of sensors to $m = 25$. For $n \in \{50, 100, \ldots, 500\}$ we generate 10 instances.

`pub` Instances from well-known publicly available benchmarks used in [8], such as point sets from the CG:SHOP challenges [5, 6] and [7, 18, 19]. We scaled point sets to a fixed size and sampled $m = 25$ centers and point pairs (for trajectories) at random.

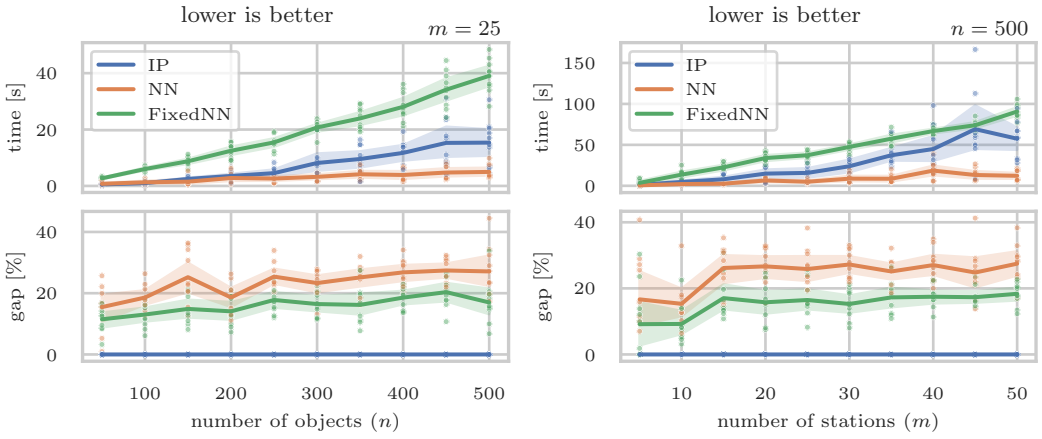

Figure 3 Performance of `IP`, `NN` and `FixedNN` on instances from the `fix_m` and `fix_n` datasets. While `IP` is significantly slower than `NN`, it produces optimal solutions for all instances. `FixedNN` is slightly better in terms of solution quality than `NN` but significantly slower.

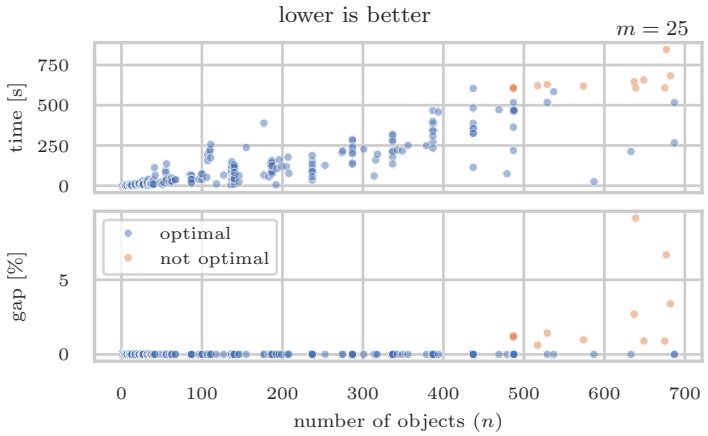
Influence of m and n. We evaluate the influence of the number of objects n and the number of stations m on the performance of the algorithm. We execute the algorithm from Section 2 with both an IP solver and a nearest neighbor heuristic to solve the DC problem

in each iteration. We denote the IP-based algorithm as `IP` and the nearest neighbor based algorithm as `NN`. Additionally, we implemented another heuristic that divides the time $[0, 1]$ into $k = 10$ evenly spaced intervals and computes the nearest neighbor solution at each border. The algorithm `FixedNN` then extends all solutions and reports the lower envelope. Figure 3 shows the performance of the different algorithms. Overall, `IP` is able to solve all instances to optimality in a matter of seconds, demonstrating real-time capability for scenarios that take minutes to play out in the real world.

Instances from Literature. We further assess the algorithm's performance on the `pub` instance set, as shown in Figure 4 and illustrated by Figure 5. The presence of degeneracies (such as equidistant points and collinearities), originating from real-world data, led to various numerical challenges in our implementation. To address these issues, we developed an alternative version of `IP` utilizing exact number types for computations; see the full paper [14, 15] for details. Our results show that 290 out of 302 instances with up to 700 objects could be solved to provable optimality within 600 s of computation time.



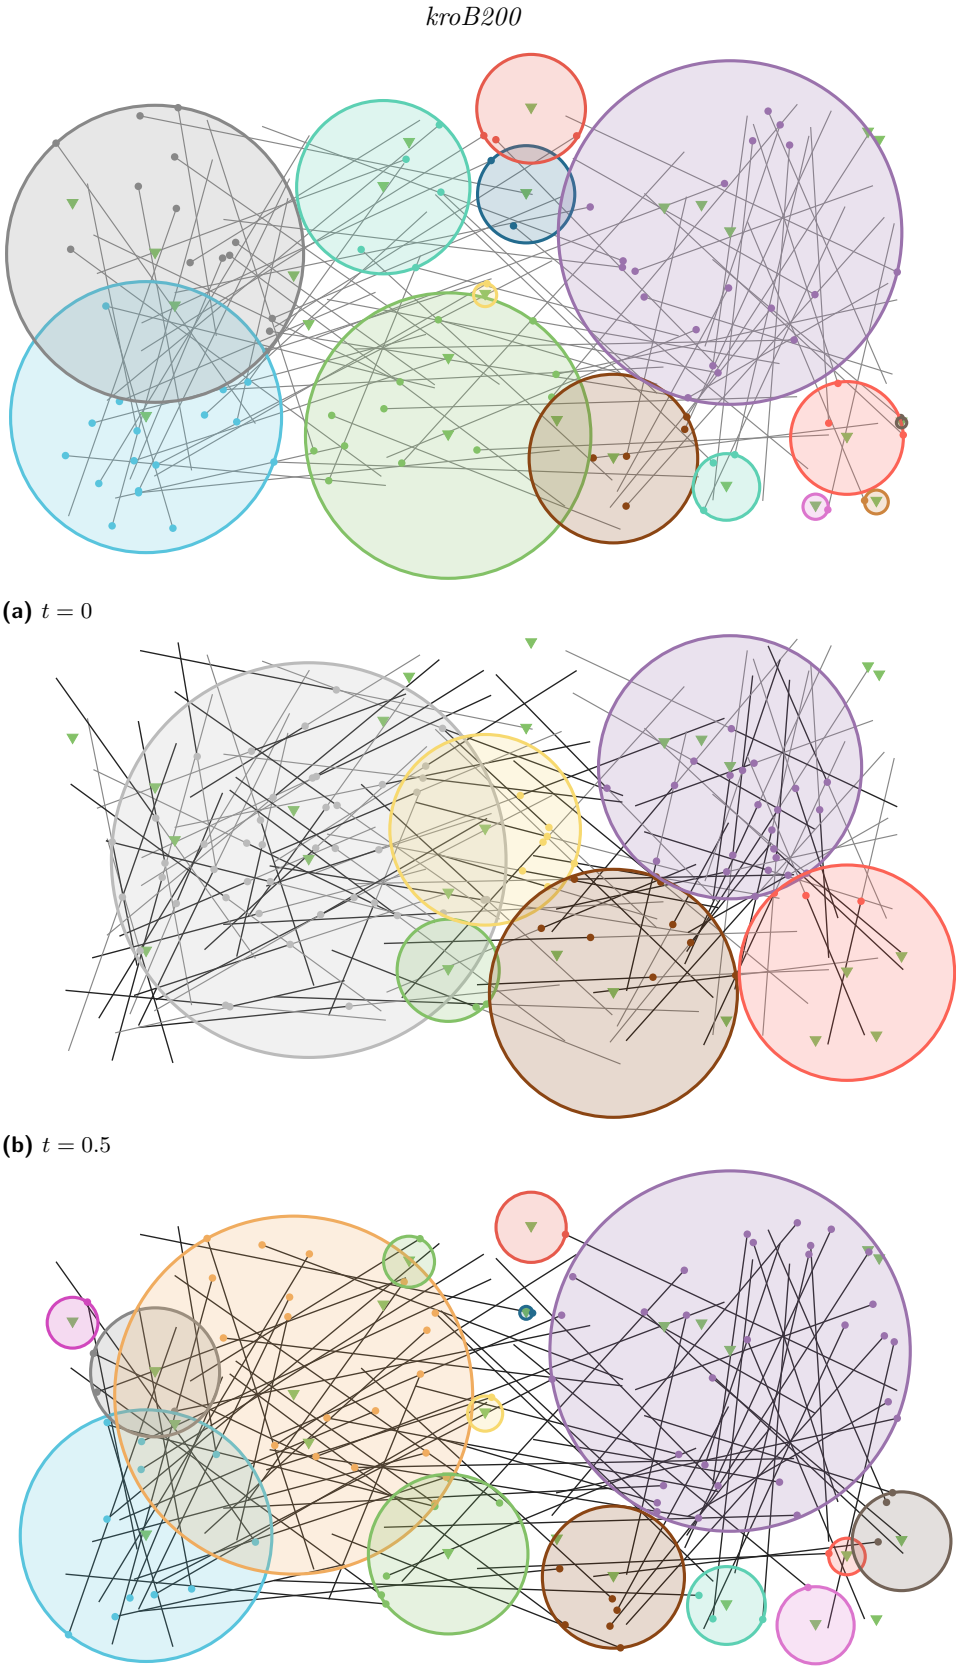


Figure 4 Performance of the exact version of `IP` on the `pub` dataset. Despite the variety and degeneracies, almost all instances can be solved to provable optimality.

4 The video

We start by introducing and motivating the KDC problem before describing the primal-dual approach, illustrating the computation of upper and lower bounds as well as the overall iterative method. We proceed by showing some of the involved technical components and evaluations, concluding with a benchmark instance with 87 objects and 25 stations derived from a point set of the well-known TSPLIB benchmark library, as shown in Figure 5.

Overall video production was based on an integrated tool chain: Visual elements were produced with the free, open-source software Manim [20] for creating mathematical animations, which also supports conversion from scripted text to synchronized voiceover and animation. Voiceover was generated with the help of Microsoft Azure Speech [17].

Abstract

We motivate and demonstrate simulation and evaluation of large-scale, fine-grained hydrodynamic flows, triggered by heavy-rain events. We show significant progress for simulating time-dependent, high-resolution runoff in large-scale heavy-rain scenarios, based on different geometry-based algorithmic speedup techniques. This enables us to address a second challenge: How can we deal with the instability of precipitation events, which are notoriously difficult to predict with good accuracy?

1 Introduction

Throughout human history, natural disasters have been a significant threat [17]. Both frequency and extent of heavy-rain events have increased in recent time, as observed by [10] in 2020 for Germany, Thus, the development of efficient and stable tools for hydrodynamic modeling has been an active field for decades, both in research and in product development [12]. The use of high-resolution elevation models is important for capturing terrain details that can have a major impact on the runoff behavior of surface water [11]; however, the high-resolution simulation is computationally highly intensive, making it difficult to employ it for larger areas, especially in early warning systems [8, 13]. Accordingly, many existing tools offer different compromises between modeling details, preprocessing time, and computation time. Scalable approaches for these important tasks are based on combining a number of algorithmic tools, including methods from computational geometry. While previous success stories (most notably by Arge et al. [1–7, 14]) have made significant progress on stationary flood levels in largely flat terrain, the problem of flooding with time-dependent water flow in sloped terrain remains computationally demanding even with modern tools and commercial software.

© Sándor P. Fekete, Phillip Keldenich, Michael Perk, and Tobias Wallner;
licensed under Creative Commons License CC-BY 4.0

Beyond all these efforts for scalable simulation methods, a second, potentially even bigger challenge looms: How can we deal with the unreliable nature of one of the most crucial inputs for any such model – the precipitation data, in time and space? Acquiring this time-dependent input with an accuracy similar to that of a finely resolved, static terrain is highly challenging, and even more difficult when it comes to forecasting such precipitation. As a consequence, computational methods from meteorology, computational physics or modern AI will likely continue to struggle to obtain reliable, fine-grained input, due to the instability of critical weather phenomena. This also implies that real-time intervention, as well as preemptive measures, will continue to suffer from a lack of reliable forecasting of the ensuing runoff.

2 Study Area and Hydraulic Modeling

While our methodological work is applicable to any region with sufficiently detailed terrain data, the main focus area of our work is a 370 km^2 polygonal domain centered on Goslar, Germany, and lies entirely within the federal state of Lower Saxony (Niedersachsen). Elevations increase from ca. 100 m above sea level (a.s.l.) in the Oker valley north of Goslar to almost 800 m a.s.l. in the southern sector according to Copernicus EU-DEM v1.1 [9].

Testing, improving and benchmarking of our simulations was performed with the commercial solver TUFLOW HPC version 2025.1.0, which is a 1D/2D hydraulic modeling software that solves the depth-averaged Navier-Stokes equations, also known as the shallow water equations, to simulate the flow of water over a terrain. TUFLOW uses an explicit finite volume solution with a square grid, whose cells might vary in size. Further details on the numerical scheme can be found in the TUFLOW manual [16] and in our full paper [15].

3 Enhancing Simulations

In general, there are two main challenges when simulating large areas with high resolution. Firstly, the memory footprint of the simulation becomes prohibitively large, making it infeasible to run the simulation on current hardware. Secondly, the runtime of the simulation also eventually grows beyond a reasonable time frame. This is often countered by using coarser resolution models, which can lead to a loss of accuracy in crucial areas.

Our work [15] is based on two algorithmic improvements. Firstly, we have developed a subdivision algorithm that partitions the terrain into smaller regions that can be simulated independently, thus reducing the memory footprint of the simulation; see Figure 1. Secondly, we use a quadtree refinement approach that (given areas and desired resolution as inputs) automatically refines the mesh in critical regions. A key contribution of our work is the analysis of *what* regions require refinement and *how much* refinement is necessary to maintain accuracy while minimizing computational cost; see Figure 2. Both approaches can be combined to enable large-scale simulations on modern hardware.

4 Outcomes

There are two main outcomes of our work: (I) progress for simulating time-dependent, high-resolution runoff in large-scale heavy-rain scenarios, based on the two algorithmic approaches described in Section 3. In combination with state-of-the-art commercial software and powerful computing devices, these approaches can achieve simulation times that are significantly shorter than the duration of the simulated events for modestly sized regions (on the order of tens of square kilometers) at meter-scale resolution. The exact times depend on

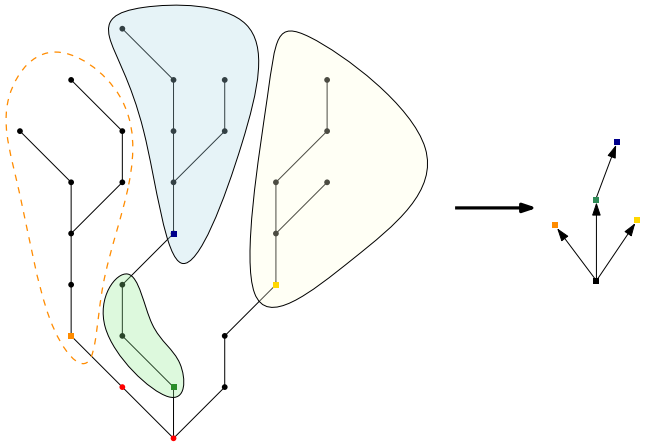

Figure 1 (Left) Subdividing a large hydrodynamic flow graph into smaller, dependency-aware polygonal regions bounded by an inflow threshold, enabling memory-efficient and parallelizable simulation. (Right) Dependency graph of the flow components after subdivision. Each node represents a component and edges indicate dependencies between them.

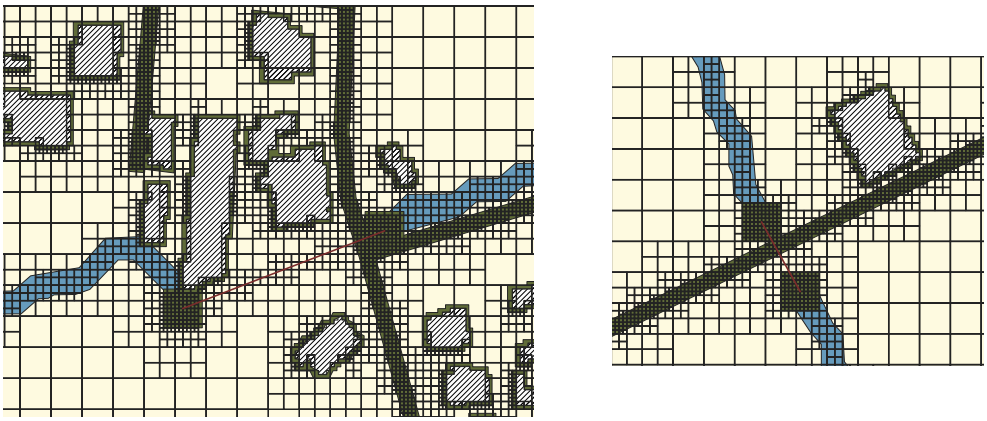

Figure 2 Quadtree-refined meshes. Base resolution is 8 m, with refinements down to 1 m around streets, culverts, buildings (green) and 2 m around streams (blue). Culverts are marked in red.

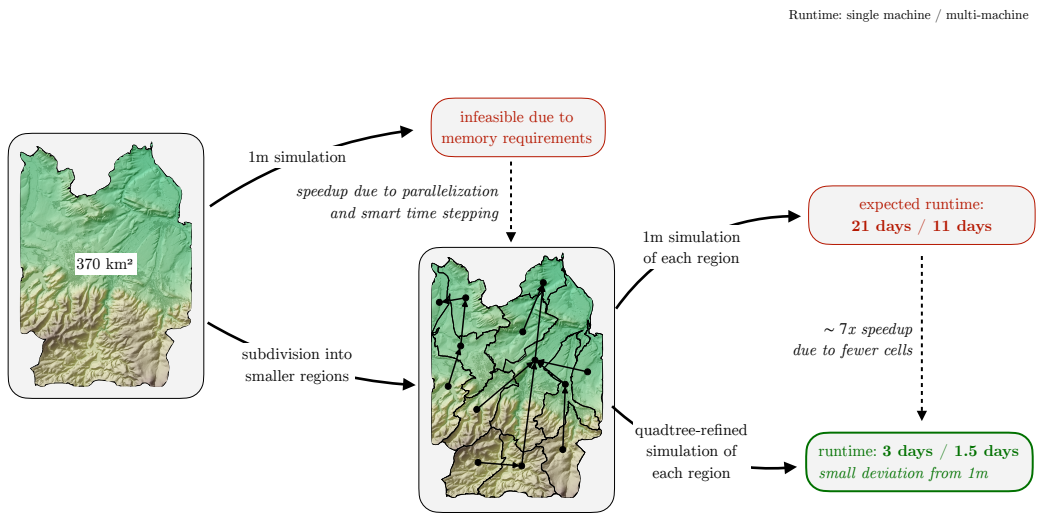

Figure 3 Overview of the interplay between our techniques for simulating large areas with high resolution and their trade-offs in terms of runtimes.

many factors, such as the amount of precipitation, condition numbers, terrain characteristics and the presence of 1D model elements such as culverts, which are also modeled. For very large domains (such as our area of interest of 370 km^2 in the mountainous Harz region) at 1 m resolution, the limitations of available GPU memory prohibits running a simulation on the entire region at once. Our subdivision technique makes such a simulation feasible, requiring roughly three weeks to simulate a five-hour heavy-rain event on a single machine and eleven days when parallelization is used to the full extent possible with the given dependency graph. Combining this with our grid refinement technique reduces the required time to three days on a single machine and to around 36 hours when parallelized, see Figure 3.

This progress enables us to demonstrate how the second challenge can be addressed: (II) We use our new computational capabilities to conduct a large-scale, multifaceted sensitivity analysis, providing insights into different scenarios for possible time-dependent runoff and flooding when varying the input precipitation for our study area. This makes it possible to identify both regions of stability (for which the outcomes are largely unchanged under input variations) as well as critically unstable locations (for which the outcome may change significantly under input variations). In particular the latter is of crucial value for effective disaster mitigation: Knowing where relatively small changes can make a significant difference in the outcome is highly valuable when deciding where to invest limited resources with the greatest impact. We demonstrate the viability of this approach by identifying such a critical location for our study area, see Figure 4.

5 The Video

After introducing the global challenges and previous work from Computational Geometry (culminating in SCALGO), the video describes the challenges and approaches to dealing with *time-dependet, dynamic* scenarios, such as in our study region in the Harz mountains. After visualizing the two main outcomes from above, we highlight how these improvements make it possible to identify critical locations, where small changes can have a large effect.

Abstract

This paper introduces interactive software tools for studying 2-face path unfoldings of the tesseract (4D hypercube). We present: (1) an algorithm to verify whether a given 24-omino is a valid path unfolding of the tesseract, (2) a web-based visualization tool for exploring and animating unfolding sequences with smooth 3D interpolation, and (3) a design interface integrated with SVG Painter, with a similar design to Demaine's SVG Painter [3], to create custom unfoldings. We demonstrate these tools by designing a geometric font of 36 path unfoldings resembling Latin letters and digits, illustrating the rich diversity and accessibility of tesseract geometry.

1 Introduction

Unfolding polyhedra is a classical problem in discrete and computational geometry [4]. In the traditional *edge unfolding* problem, we cut a subset of edges of a given polyhedron and unfold its surface so that the faces remain connected and lie flat in the plane without overlap. A natural extension to higher dimensions is *ridge unfolding*: cut the $(d-2)$-dimensional faces (ridges) of a d-dimensional polytope and lay down the $(d-1)$-dimensional faces (facets) flat in the plane. Turney [8] showed that there are exactly 261 polycube unfoldings of the tesseract (4D hypercube), and Diaz and O'Rourke [5] investigated the 2D polyomino unfoldings derived from these 3D unfoldings.

Recently, Akitaya and Kandarpa [1] introduced *2-face unfoldings*, which unfolds the 2-skeleton of a polytope directly to 2D. The *2-skeleton* consists of all 2-dimensional faces glued together at their shared edges. A 2-face unfolding cuts some of these shared edges so that the 2-skeleton unfolds to a connected, nonoverlapping 2D polyomino. For the tesseract, all 24 square faces appear exactly once, yielding a 24-omino.

In this paper, we focus on *path unfoldings* where the dual graph forms a Hamiltonian path through the 24 square faces. These have the maximum possible diameter in the dual graph. The tesseract has eight 3D cube faces, including four pairs of opposite cubes that

© Soham Samanta, Hugo A. Akitaya, Erik Demaine, and Martin Demaine;
licensed under Creative Commons License CC-BY 4.0

share no square face. We call one such opposite pair the *top* and *bottom* cubes. The twelve remaining square faces form the *side faces* connecting top and bottom. In prior work [2, 7], a subset of the authors studied *alternating* path unfoldings – those that visit top and bottom cubes alternately (six times each) with a side face visit in between – and enumerated all 35,520 such unfoldings.

However, working with tesseract unfoldings presents significant challenges: understanding the 4D geometry requires substantial mental effort, verifying whether a proposed polyomino can fold into the tesseract is non-trivial, and designing specific unfolding shapes requires iterative trial and error. These difficulties motivated the development of computational tools to make tesseract unfoldings more accessible to researchers.

Contribution. This paper introduces software tools to facilitate research on tesseract path unfoldings: (1) A **verification algorithm** that checks whether a given 24-omino is a valid path unfolding using recursive backtracking; (2) A **web-based visualization tool** that renders unfoldings and animates folding sequences with smooth 3D interpolation; (3) An integrated **design workflow** combining SVG Painter with our verification tool for rapid prototyping.

2 Software

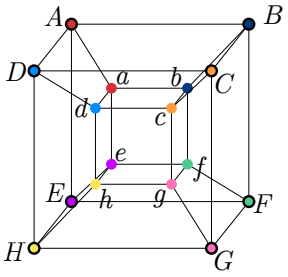

Figure 1 Naming convention for vertices. Top cube: $ABCDabcd$; bottom cube: $EFGHefgh$; side faces connect them.

Tesseract Structure. We label the top cube as $ABCDabcd$ and the bottom cube as $EFGHefgh$. The twelve side faces connect the top and bottom cubes. This labeling convention is used throughout our visualization tool, as in Figure 1.

Path Unfolding Checker. We developed a verification algorithm that determines whether a given 24-omino can be folded into the 2-skeleton of the tesseract via a Hamiltonian path. The algorithm uses recursive backtracking to simultaneously: traverse a potential Hamiltonian path in the dual graph of the input polyomino, walk through the face-adjacency graph of the tesseract, and verify that adjacencies in the polyomino correspond to valid face adjacencies in the tesseract.

The algorithm maintains a partial mapping from polyomino squares to tesseract faces. At each step, it selects an unmapped square adjacent to the current path endpoint, tries assigning it to each tesseract face that could validly extend the path, and recursively attempts to complete the mapping or backtracks if no valid completion exists.

Complexity. The search space is bounded by the number of tesseract faces (24) times the branching factor at each step, which is at most the degree in the face-adjacency graph of the tesseract (at most 4 neighbors per square face). In the worst case (an invalid input requiring full exploration), the algorithm explores $O(4^{24})$ partial assignments, though in practice aggressive pruning via adjacency constraints reduces this dramatically. On all inputs tested, including invalid 24-ominoes, verification completes in well under one second in a browser environment.

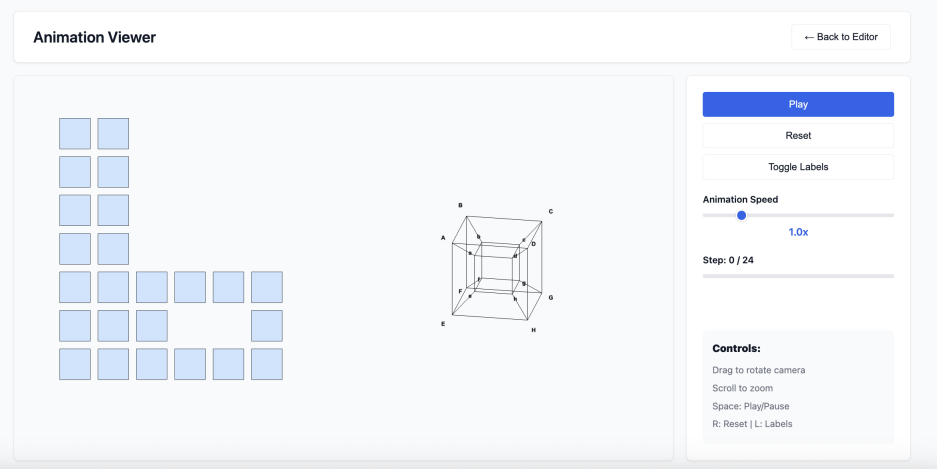

Figure 2 Web-based visualization tool interface showing the 24-omino with face labels and animation controls.

Visualization Tool. Our web-based visualization tool provides an interactive interface for exploring tesseract path unfoldings. Built using HTML5 Canvas and Three.js, the tool features: face labeling, color schemes highlighting cube structure, dual path visualization, export options, interactive zoom/pan controls, and 3D folding animation.

Animation Mathematics. The visualization animates how the flat 24-omino folds into the tesseract's 2-skeleton using smooth interpolation between the 2D unfolding (source) and 3D tesseract projection (destination).

Smoothstep Interpolation. For visually pleasing animations with smooth acceleration and deceleration, we use Perlin's smoothstep function [6]. Given linear time parameter $t \in [0, 1]$, we compute smoothed parameter $s(t) = 6t^5 - 15t^4 + 10t^3$. This quintic polynomial satisfies $s(0) = 0$, $s(1) = 1$, with $s'(0) = s'(1) = 0$ and $s''(0) = s''(1) = 0$, creating smooth ease-in/ease-out.

Position and Vertex Interpolation. For each face i, we compute source position $\mathbf{p}_{\text{src}}$ (center in flat unfolding) and destination position $\mathbf{p}_{\text{dst}}$ (center in tesseract projection). The animated center position is $\mathbf{p}(t) = \mathbf{p}_{\text{src}} + (\mathbf{p}_{\text{dst}} - \mathbf{p}_{\text{src}}) \cdot s(t)$. Each vertex j similarly interpolates: $\mathbf{v}_j(t) = \mathbf{v}_{\text{src},j} + (\mathbf{v}_{\text{dst},j} - \mathbf{v}_{\text{src},j}) \cdot s(t)$, morphing the square from flat to its 3D orientation.

Rotation and Projection. The tesseract projection is interactively rotatable via mouse drag. We apply rotation matrices: first y-axis rotation by θ_y, then x-axis rotation by θ_x:

$$R_y(\theta_y) = \begin{pmatrix} \cos\theta_y & 0 & \sin\theta_y \\ 0 & 1 & 0 \\ -\sin\theta_y & 0 & \cos\theta_y \end{pmatrix}, \quad R_x(\theta_x) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\theta_x & -\sin\theta_x \\ 0 & \sin\theta_x & \cos\theta_x \end{pmatrix} \tag{1}$$

We use orthographic projection (discarding z after transformations) to preserve parallel lines and geometric relationships, avoiding perspective distortion.

The animation sequence proceeds face-by-face: each face turns white, interpolates from flat position to tesseract over $t \in [0, 1]$, then joins the tesseract structure. Animation speed is user-controllable, and the tesseract can be rotated during animation.

Design Workflow. To create custom path unfoldings, we developed an integrated workflow: (1) Sketch 24-omino in SVG Painter in our format. (2) Verify using our checker algorithm; (3) Iterate if invalid; (4) Visualize and animate the valid unfolding.

We created our FONT using this method, which can be seen below.

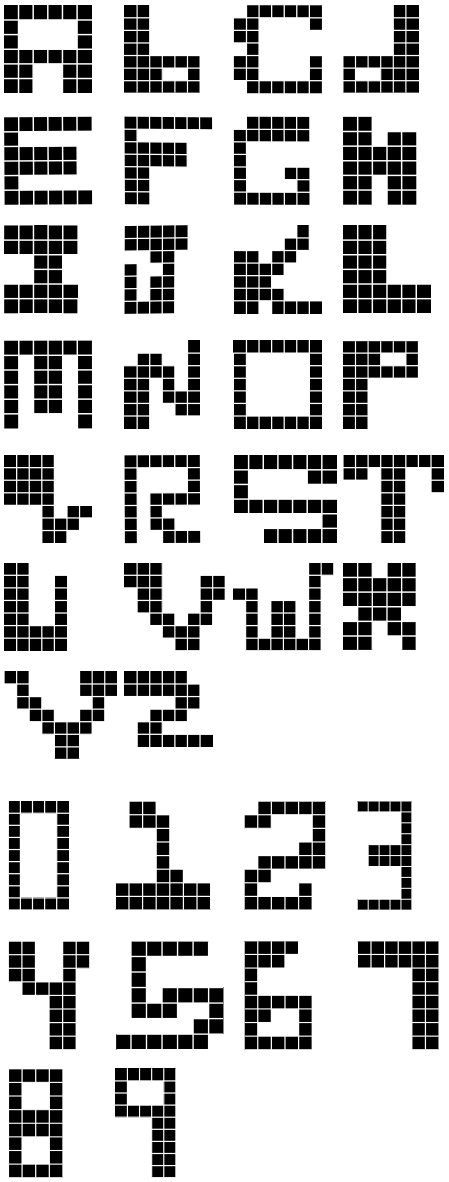

Figure 3 Tesseract font. Each letter/digit is represented by a path 2-face unfolding of the tesseract.

ETH Flippers Approach to Parallel Reconfiguration of Triangulations: SAT Formulation and Heuristics

Lorenzo Battini
ETH Zürich, Switzerland

Marko Milenković
ETH Zürich, Switzerland

Abstract

We describe the algorithms used by the ETH Flippers team in the CG:SHOP 2026 Challenge. Each instance consists of a set of triangulations on a common point set, and the objective is to find a central triangulation that minimizes the total parallel flip distance to the input set. Our strategy combines an exact solver for small and medium-sized instances with a suite of heuristics for larger instances. For the exact approach, we formulate the problem as a SAT instance with XOR clauses to model edge transitions across multiple rounds, further optimized by lower bounds derived from exact pairwise distances. For larger instances, we use a greedy local search and edge-coloring techniques to identify maximal sets of independent flips. Our approach ranked second overall and first in the junior category, computing provably optimal solutions for 186 out of 250 instances.

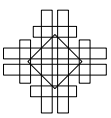
Acknowledgements We would like to thank the Challenge organizers and other competitors for their time, feedback, and for making this whole event possible. This work was conducted as part of the Practical Work course at ETH Zürich under the supervision of Michael Hoffmann, whose guidance was invaluable. We sincerely thank Bernd Gärtner for providing travel support to attend the conference. We also acknowledge the ETH High Performance Computing group for providing the computational resources of the Euler cluster.

1 Introduction



Triangulations of point sets, in this context, maximal straight-line crossing-free graphs with endpoints in the point set, have many applications, for instance, in computer graphics and in reconstruction problems in geodesy.

A common problem is transforming a triangulation into another on the same point set using edge flips, replacing an internal edge whose incident triangles form a convex quadrilateral with its other diagonal. Hurtado, Noy, and Urrutia [4] introduced parallel edge flips, which consist of flipping at the same time a set of edges such that none of the pairs of edges in the set shares a triangle.

The "CG:SHOP Challenge" (Computational Geometry: Solving Hard Optimization Problems) is a computational challenge competition about a hard geometric optimization problem. This year's challenge problem was proposed by Aichholzer, Dorfer, and Kramer. The goal is to find a central triangulation C and, for each of the given m triangulations

© Lorenzo Battini and Marko Milenković;

$T_1, T_2, \ldots, T_m$ on the same pointset P, a sequence of parallel flips transforming T_i into C, such that the sum of the lengths of these sequences is minimized. The solution methods are evaluated on a benchmark of 250 instances. We refer to [1] for further challenge details.

We present an exact solution method based on formulating the problem as a SAT problem with XOR clauses, which is used to solve the small and medium instances, as well as various heuristics that we used for the larger instances.

Our team, ETH flippers, ranked second overall and first in the junior category. We computed a provably optimal solution for 186 instances. Three further instances were solved, but a technical bug during our local validation caused us to stop at sub-optimal values. The largest instances we optimally solved featured twenty 320-point triangulations, while the highest total parallel flip distance among our optimally solved instances is 92. Notably, for this latter instance (`random_instance_440_160_20`), our solution was uniquely the best among all participating teams (see Figure 1).

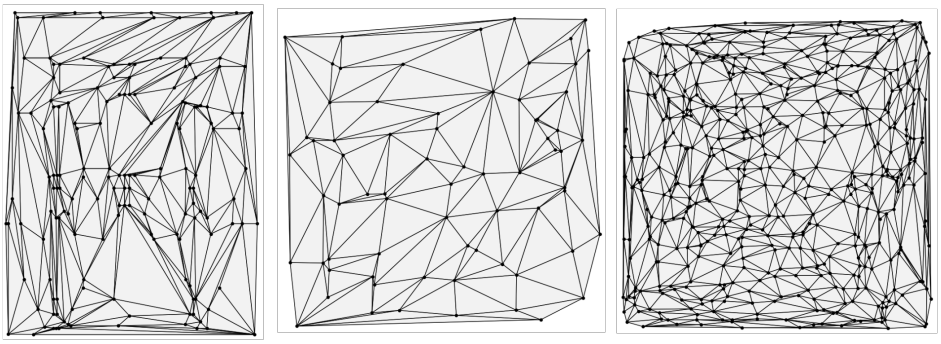

Figure 1 Our best centers to instances `random_instance_440_160_20`, `woc-70-random-9a7d18d3`, `rirs-500-50-23d00ec5`.

2 2-SAT formulation

Given a set of m triangulations, $\mathcal{T} = \{T_1, T_2, \ldots, T_m\}$, we formulate a 2-SAT instance to search for a triangulation C such that the distance from each $T_i \in \mathcal{T}$ to C is at most one.

For every convex quadrilateral q formed by a pair of facial triangles that share an edge in any T_i, we fix an arbitrary reference diagonal. Let the variable x_q denote whether C uses its reference diagonal and let the constant $b_q^{(i)}$ denote its state in T_i. To prevent invalid simultaneous flips, we add the clause $\neg(b_q^{(i)} \oplus x_q) \vee \neg(b_{q'}^{(i)} \oplus x_{q'})$ for all pairs of intersecting quadrilaterals q, q' in each T_i. This determines the existence of a central triangulation C in $\mathcal{O}(mn)$ time.

3 SAT formulation with XOR clauses

XOR clauses. The most natural approach to modelling parallel flips is a round-by-round progression. We need to keep the state of each edge across intermediate parallel flips.

We model the state transition of an edge e over k parallel flips using XOR operations. Let $e^0, e^k \in \{0, 1\}$ denote the presence of e in the initial and final triangulations, respectively. Let $\{q_1, \ldots, q_g\}$ be the set of all potential convex empty quadrilaterals that share e as a diagonal. We let $f_i^j \in \{0, 1\}$ indicate whether a flip is performed on q_i during step j.

Because the final state of edge e after k parallel flips is simply its initial state XORed with all intermediate flips across its potential quadrilaterals $q_{1\dots g}$, we add the constraint

$$e^0 \oplus e^k \oplus \bigoplus_{j=1}^{k} \bigoplus_{i=1}^{g} f_i^j = 0$$

We decided to use the CryptoMiniSat5 [8] solver, since it supports inputs with XOR clauses.

Formulation

We extend the previous formulation to search for a center C whose distance to each $T_i \in \mathcal{T}$ is upper bounded by a given target $d[i]$.

Geometric Preconditions for Flips. Let $\mathcal{Q}$ be the set of all convex empty quadrilaterals defined on the pointset, which we identified via spatial hashing [9]. Let the variable e_{uv}^t denote the presence of edge (u, v) at step t. For a flip $f_q^t \in \{0, 1\}$ to be geometrically valid at step t, the four boundary edges ∂q of its corresponding quadrilateral $q \in \mathcal{Q}$ must exist in the prior step. We enforce this constraint with implication $f_q^t \implies \bigwedge_{(u,v)\in\partial q} e_{uv}^{t-1}$.

Target Equivalence with Center C. We introduce global boolean variables c_{uv} representing the edges of the center C. We enforce consistency at the final step k via the equivalence $e_{uv}^k \iff c_{uv}$. This link forces the final state of every flip sequence to be identical to the global center, effectively merging the independent SAT sub-problems to a shared solution.

Edge Transition Constraints. We must ensure that the triangulation changes only through valid flip operations. An edge (u, v) changes its status (present or absent) between parallel flips $t-1$ and t if and only if a flip is performed on a quadrilateral where (u, v) serves as the diagonal.

Let $\mathcal{Q}_{uv}$ be the set of all convex empty quadrilaterals for which (u, v) is a diagonal. The relationship between the edge's state at consecutive parallel flips and the flip variables is enforced via an XOR constraint: $e_{uv}^{t-1} \oplus e_{uv}^t \oplus \bigoplus_{q\in\mathcal{Q}_{uv}} f_q^t = 0$.

For edges on the convex hull, the set $\mathcal{Q}_{uv}$ is empty, effectively enforcing that these edges remain constant throughout the transformation.

Constraints on Simultaneous Flips. We must enforce strict independence between simultaneous operations. Specifically, for any subset of four vertices $\{v_1, v_2, v_3, v_4\}$, there can be at most one active flip operation at time t involving three of these vertices. This prevents structural conflicts where multiple flips compete for the same triangle.

We iterate through all quadruplets of vertices and identify the set of potential flip variables $\mathcal{F}_{v_{1..4}}^t$ of size r associated with them. We then enforce an *At-Most-One* (AMO) constraint on this set $\sum_{f\in\mathcal{F}_{v_{1..4}}^t} f \leq 1$. There are multiple ways to model this constraint using a linear number of clauses [7]. The ladder encoding that we implemented uses $2r-1$ variables and $3r-2$ clauses, compared to r variables and $\binom{r}{2}$ clauses. Due to the $\mathcal{O}(n^4)$ possible number of convex empty quadrilaterals, clauses generation becomes a computational bottleneck.

Initial State and Boundary Conditions. We initialize the SAT model for each input triangulation by fixing e_{uv}^0 to true if the edge (u, v) exists in it and false otherwise. Furthermore, since parallel flips only affect internal diagonals of convex quadrilaterals, the convex hull edges $\mathcal{H}$ remain invariant. We hard-code e_{uv}^t to true for all $(u, v) \in \mathcal{H}$ across all steps $t \in \{1, \dots, k\}$, effectively pruning the search space by preventing flips of boundary edges.

Pruning clauses. To significantly prune the search space, we precompute the minimum flip distance required to introduce each edge into triangulation T_i using an iterative breadth-first reachability search. We then omit all SAT variables and clauses associated with an edge for any time step prior to this theoretical minimum.

4 Exact solving

Lower bound. To establish a lower bound, we first compute exact pairwise parallel flip distances $D_{i,j}$ using our SAT formulation. Any valid central triangulation at distances d_k to inputs T_k must satisfy the triangle inequality $d_i + d_j \geq D_{i,j}$ for all pairs i, j. To test if a target total distance S is feasible, we find all integer assignments $(d_1, \ldots, d_m)$ summing to S that satisfy these pairwise constraints via recursive backtracking. For instances with $m = 20$ triangulations, we use some further pruning techniques. We compute the minimum parallel flip distance $s_{dist}(i)$ for the last i triangulations, for $i \geq i_{start}$, where we used $i_{start} = 11$ for most instances since it was experimentally found to be sufficiently fast to compute. Then we use those suffix distances by pruning a branch whenever $S - \sum_{k=1}^{i} d_k < s_{dist}(i)$. Moreover, after the first 10 and 15 distances have been assigned recursively, we prune the branch if the prefix is not satisfiable.

Choosing the distribution of distances. The upper bound search is existential. Consequently, prioritizing candidates that are more likely to be satisfiable can significantly accelerate the search.

Let $d = (d_1, \ldots, d_n)$ represent a potential assignment vector. We define the scoring function $\mathcal{S}(d)$ as the sum of absolute differences between all pairs of elements: $\mathcal{S}(d) = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} |d_i - d_j|$. The candidate distributions are processed in ascending order of $\mathcal{S}(d)$.

Empirical analysis reveals that this heuristic is remarkably effective for randomly generated instances. In the majority of cases, the satisfiable distribution corresponds to the candidate with the minimal $\mathcal{S}(d)$ score. Even in cases where the global minimum is not the solution, the valid assignment is consistently found among the top-ranked candidates.

▶ **Conjecture 1.** *For a randomly generated triangulation instance under the standard uniform distribution model, ordering of candidate distance vectors by increasing $\mathcal{S}(x)$ minimizes the expected number of queries required to find a satisfiable assignment.*

5 Heuristics

Transforming a triangulation into another. To transform a triangulation T into another T', we flip edges such that the number of intersecting edges decreases. We now describe how, at each step, we choose a subset of independent edges to flip among the ones that reduce the number of intersections.

Firstly, we choose edges that, if flipped, introduce an edge that is present in T'. To do so, we start by creating a graph containing those edges, where the nodes correspond to faces incident to them. Then we compute an edge coloring of this graph using the Misra and Gries algorithm [5] from the Boost Graph Library [6]. Finally, we flip the edges corresponding to the color class of maximum cardinality, and all the isolated edges. Since the boundary edges cannot be flipped, and the bounded faces are triangles, the maximum degree Δ is at most 3. Since the Misra and Gries algorithm uses at most $\Delta + 1 \leq 4$ colors, at least one fourth of the edges in the graph are flipped.

Secondly, we greedily pick the edges that are independent from all the edges that have already been picked, in order of non-increasing reduction of the number of intersections.

This transforms a triangulation into the other in a finite number of steps, since it can be seen as an adaptation to parallel flips of the algorithm described by Hanke, Ottmann, and Schuierer [3]. Given the flip sequence $\mathcal{F} = \{F_1, F_2, ..., F_{|\mathcal{F}|-1}\}$ that we obtain with the described heuristic, let $\{\tau_0 = T, \tau_1, ..., \tau_{|\mathcal{F}|-1} = T'\}$ be the corresponding sequence of triangulations, where τ_{k+1} is the triangulation we obtain after the parallel flip F_k. The reversed flip sequence $\mathcal{F}'$ transforms T' into T and it can be obtained by reversing the order of the parallel flips, and replacing each individual flip $e \to e'$ with $e' \to e$.

We can obtain other heuristic flip sequences $\mathcal{F}_k$, with $k \in [0, |\mathcal{F}| - 1]$, by concatenating the heuristic flip sequence that turns T into τ_k with the reversed flip sequence that turns T' into τ_k.

Since these sequences are heuristic, their length might differ, and so we try multiple values of k and choose the shortest flip sequence.

We empirically observed that trying all intermediate k values typically reduces each triangulation's distance by 1. Therefore, to maintain computational efficiency on large instances, we only do this when the total distance is within $currentBest + m$. Here, $currentBest$ is the smallest objective value among all the centers that were computed before.

Choosing centers. Apart from input triangulations, we also generate candidate centers by greedily flipping edges in input triangulations to minimize total intersections with the entire point set until a local optimum is reached.

We then record all the intermediate triangulations at the end of each parallel flip, which is used to transform an input triangulation into one of those centers. To avoid trying all centers, we sort them in increasing order of total number of intersections with all the input triangulations and only compute the heuristic parallel flip distance for a fraction of them.

6 Combined Strategies

Fixed center. A promising combined strategy involves using the heuristic to select a candidate center triangulation, denoted as T_{heur}, and using the exact SAT solver to compute the minimal parallel flip distances from all input triangulations to T_{heur}, one by one.

Although this approach remains heuristic, it was effective on the *rirs* instances, but it also indirectly helped significantly with large non-*rirs* instances. Finding a slightly better solution allows the exact solver to handle cases that were previously out of reach.

Solving a subproblem. A natural extension to computing pairwise distances is to compute exact distances for larger subsets. This yielded negligible improvements to the lower bound, likely due to the triangle inequality holding strong even for pairwise constraints.

Similar reasoning proved highly effective for the *woc* (especially *tsplib*) instances, observing that the distances to the optimal center were not uniformly distributed. By identifying and excluding outlier triangulations, we could exactly solve for the center of the remaining subset. This produced a robust heuristic center for the fixed center heuristic.

Abstract

We present our approach for the CG:SHOP 2026 challenge. In this international challenge, the goal was to find a median triangulation for a set of triangulations in the parallel flip reconfiguration graph of all triangulations of an underlying point set. Our simulated-annealing-based approach makes use of two ingredients: a heuristic edge selection for approximating the parallel flip distance of two given triangulations, and a heuristic procedure to generate good initial triangulations.

1 Introduction

In this paper, we study changing triangulations of a planar point set using *parallel flips*. Given a set of planar triangulations of some point set, we search for a central triangulation and a sequence of parallel flip operations from each input triangulation to the central triangulation, so as to minimize the sum of the number of parallel flip operations in each sequence.

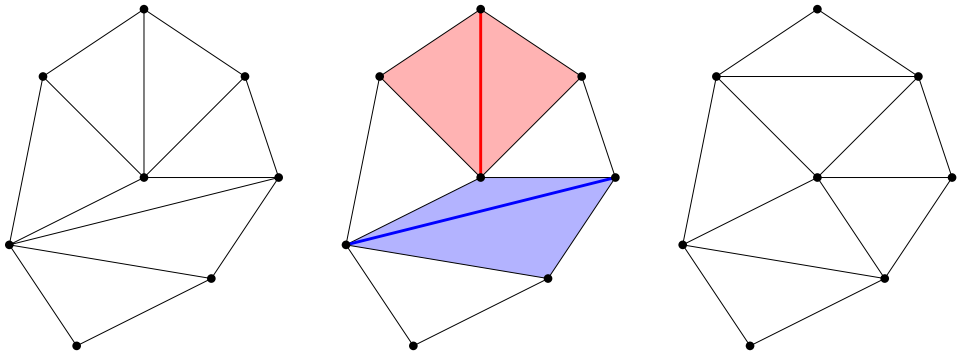

Figure 1 Two edges with their corresponding quadrilateral. They do not share a triangle and can be flipped in parallel, transforming the left triangulation into the right triangulation.

This problem represents the core of the 2026 Computational Geometry Challenge [1] (CG:SHOP), which ranked teams based on their solutions to a provided set of instances. Our team, `jflip2`, was invited to publish its methods after finishing in 4th place with an approach based on heuristic methods inspired by observations for the classical flip distance [5].

For a point set $\mathcal{S} \subset \mathbb{R}^2$, a triangulation $\mathcal{D}$ is a maximal set of non-crossing straight-line edges incident to points in $\mathcal{S}$. In a triangulation, every interior edge e not on the boundary of $\text{conv}(\mathcal{S})$ is adjacent to exactly two triangles. If two such triangles form a convex quadrilateral Q, then we call e *flippable*, and replacing e with the other diagonal $\text{flip}(e)$ results in a valid triangulation $\mathcal{D}' = \mathcal{D} \setminus \{e\} \cup \{\text{flip}(e)\}$. Replacing e with $\text{flip}(e)$ is called a *unit flip*.

A set of edges E in a triangulation $\mathcal{D}$ is called a *parallel flip operation* if each edge $e \in E$ is flippable and no two edges in E are part of the same triangle [4]. Since no two edges in a parallel flip share a triangle, we again obtain that $\mathcal{D}' = \mathcal{D} \setminus E \cup \{\text{flip}(e) \mid e \in E\}$ is a valid triangulation. Parallel flips induce a graph PG, whose vertices are the set $\mathfrak{D}$ of all triangulations, in which two triangulations are adjacent if one can be transformed into the other by exactly one parallel flip. Note that the edges of this graph are undirected, since parallel flips are reversible, i.e., $\text{flip}(\text{flip}(e)) = e$, and, classically, this graph is connected [7]. A sequence of parallel flip operations transforming $\mathcal{D}$ to $\mathcal{D}'$ is a path in PG from $\mathcal{D}$ to $\mathcal{D}'$. The length $\mathrm{d}_{\text{pf}}(\mathcal{D}, \mathcal{D}')$ of a shortest path from $\mathcal{D}$ to $\mathcal{D}'$ in PG is called the *parallel flip distance*.

Given these definitions, we formulate the challenge posed in the CG:SHOP contest.

▶ **Problem 1** (Median Point for Parallel Flip Distance). *Given a set $\mathcal{S}$ of points and a set $\mathfrak{T} = \{\mathcal{T}_1, \ldots, \mathcal{T}_m\}$ of triangulations (terminals), find a triangulation (center) $\mathcal{C}$ and paths $\{P_i\}$ in PG from each $\mathcal{T}_i$ to $\mathcal{C}$, minimizing*

$$\text{cost}(\mathcal{C}, \mathfrak{T}) = \sum_{\mathcal{T}_i \in \mathfrak{T}} |P_i|$$

Ideally, we want $|P_i|$ to be $\mathrm{d}_{\text{pf}}(\mathcal{C}, \mathcal{T}_i)$. This raises the intermediate problem of computing the parallel flip distance of two triangulations. Computing the unit flip distance, where the goal is minimizing the number of unit flips, is NP-hard [8, 10]. The complexity of computing the parallel flip distance remains open. For the unit flip distance, exact methods [9] based on shortest paths and integer linear programs have been employed. To us, these approaches appeared ill-suited for large instances (although the winning team `Shadoks` [3] ultimately employed an optimal SAT solver with great success). Instead, we employ a greedy approach inspired by [5] for the sub-task of approximating $\mathrm{d}_{\text{pf}}(\cdot)$.

Based on this heuristic distance computation, we solve Problem 1 via a simulated-annealing-based approach. Our method is separated into three stages:

1. Compute an initial candidate center $\mathcal{C}$.
2. Improve $\mathcal{C}$ via simulated annealing, with parallel flip distance heuristics as a guide.
3. Use more expensive distance heuristics to improve $\text{cost}(\mathcal{C}, \mathfrak{T})$.

We describe our parallel flip distance heuristics in Section 2 and our simulated-annealing-based center search in Section 3. Finally, we present experimental results in Section 4.

2 Parallel Flip Distance Heuristics

We start with an observation on parallel flips. Given a triangulation $\mathcal{D}$, we define the *conflict graph* $G_{\mathcal{D}}$ as the graph whose vertices correspond to all flippable edges in $\mathcal{D}$, and in which two vertices are adjacent if the corresponding edges are part of the same triangle and hence cannot be part of the same parallel flip. Thus, parallel flips correspond to independent sets in $G_{\mathcal{D}}$. Based on this, the idea of our flip heuristics $H_u(\mathcal{D}_s, \mathcal{D}_t)$ can be summarized as follows:

1. Start with $\mathcal{D}_0 = \mathcal{D}_s$.
2. Compute a utility value $u(e)$ for each flippable edge $e \in \mathcal{D}_i$, such that flipping an edge with high utility is expected to produce a triangulation closer to the given target $\mathcal{D}_t$.
3. Find a maximum-weight independent set (MWIS) heuristically.
4. Apply the corresponding parallel flip operation to obtain a new triangulation $\mathcal{D}_{i+1}$.
5. Repeat Steps 2–4 with $\mathcal{D}_{i+1}$ until the target triangulation is reached.

Typically, the resulting flip distance estimate is asymmetric, i.e., $H_u(\mathcal{D}, \mathcal{D}') \neq H_u(\mathcal{D}', \mathcal{D})$.

Flip Utilities. Hanke et al. [5] observed that the number of proper crossings between edges of two triangulations is an upper bound on the (unit) flip distance. Consequently, they introduced a heuristic that aims to aggressively decrease the number of such crossings. This definition extends nicely to the parallel flip distance, and serves as the basis for our utility function: Let e be an edge connecting two vertices of $\mathcal{S}$, and let $\mathcal{D}_t$ denote the target triangulation. Define $\text{cr}_{\mathcal{D}_t}(e)$ as the number of proper crossings between e and the edges of $\mathcal{D}_t$. For a flippable edge e in $\mathcal{D}$, let $u_H(e, \mathcal{D}, \mathcal{D}_t) = \text{cr}_{\mathcal{D}_t}(e) - \text{cr}_{\mathcal{D}_t}(\text{flip}(e))$, while for non-flippable edges, let $u_H(e, \mathcal{D}, \mathcal{D}_t) = -\infty$. Note that if $\mathcal{D} \neq \mathcal{D}_t$, at least one edge has positive utility [5]. This heuristic is heavily geared towards the unit flip distance: it does not take into account that flipping an edge e blocks all other edges of its two triangles from being added to the current parallel flip. Consequently, we define a natural extension to this heuristic: Let

$$u_{2L}(e, \mathcal{D}, \mathcal{D}_t) = u_H(e, \mathcal{D}, \mathcal{D}_t) - \sum_{z \in \delta(e)} u_H(z, \mathcal{D}, \mathcal{D}_t),$$

where $\delta(e)$ denotes the (flippable) neighbors of e in the conflict graph $G_{\mathcal{D}}$. Our edge selection for the construction of a parallel flip is sequential, so during the selection process, some neighbors of an edge e may already be blocked by previously selected edges. Thus, we can dynamically exclude them from the penalty sum in $u_{2L}(e, \mathcal{D}, \mathcal{D}_t)$. The values cr, u_H, and u_{2L} naturally extend to multiple target triangulations by summing over all terminals.

MWIS Heuristics. Our main MWIS heuristic scans all flippable edges in decreasing order of utility $u(e, \mathcal{D}, \mathcal{D}_t)$ and adds an edge e if the solution remains an independent set and $u(e, \mathcal{D}, \mathcal{D}_t) > 0$. For more accuracy, at the expense of runtime, we refine the initial greedy solution via a local search that swaps selected edges with some of their non-selected neighbors, as long as it increases the total utility. This process ends when no beneficial swaps remain.

Randomization. We introduce randomization into the greedy edge selection algorithm and rerun the randomized parallel flip sequence computation multiple times to increase the overall accuracy. Concretely, given a parameter k (usually $k \leq 50$), we maintain a buffer of the k unblocked edges with the highest utility. At each selection step, one edge from the buffer is selected uniformly at random and added to the parallel flip before updating the buffer.

Engineering. The main runtime cost of the heuristic $H_u(\mathcal{D}_s, \mathcal{D}_t)$ is the initial computation of $\mathrm{cr}_{\mathcal{D}_t}(e)$ for edges $e \in \mathcal{D}_s$ with respect to the target $\mathcal{D}_t$. Here, a brute-force approach combined with an R-tree outperformed a Bentley-Ottmann sweep [2], which requires exact arithmetic for rational crossing points. For small instances ($|\mathcal{S}| \leq 1000$), we speed up computations of the form $H_u(\mathcal{C}, \mathcal{T})$, with current center $\mathcal{C}$ and terminal $\mathcal{T}$, by precomputing a table that contains the number of crossings $\mathrm{cr}_{\mathcal{T}}(e)$ for every possible edge $e \in \binom{\mathcal{S}}{2}$. As the size of this table is quadratic in $|\mathcal{S}|$, we do not compute it for larger instances.

3 Center Search via Simulated Annealing

To optimize the chosen center, we employ simulated annealing [6] with a fixed time horizon t_{total}. Simulated annealing is a local search technique that iteratively explores the solution space by moving to randomly generated neighboring solutions. Improving moves are always accepted, while worsening moves are accepted with a probability $P_{\text{accept}}(\Delta, t)$ that depends on the objective change Δ and the normalized progress $t = t_{\text{current}}/t_{\text{total}}$. This probability is controlled by a temperature parameter that evolves according to a cooling schedule.

Cooling Schedule. We use an exponential cooling schedule that quickly reduces the temperature such that, in the final quarter of the runtime, the algorithm effectively behaves as a greedy local search. Concretely, we set $T_{\text{quarter}} = -\frac{1}{\ln 0.02}$, and $T(t) = T_0 \cdot \left(\frac{T_{\text{quarter}}}{T_0}\right)^{t/0.75}$, ensuring $T(0.75) = T_{\text{quarter}}$. To dampen the impact of large cost increases, we use a sublinear transformation of Δ and accept moves with probability $P_{\text{accept}}(\Delta, t) = \exp\left(-\frac{\Delta^{2/3}}{T(t)}\right)$. With $T_0 = 30$, this yields strong exploration early on and greedy behavior in the final quarter.

Initial Centers. We use four different strategies to generate the initial center:

1. Delaunay: A simple choice for the initial center is the Delaunay triangulation.
2. Path: For each terminal pair $\mathcal{T}, \mathcal{T}' \in \mathfrak{T}$, compute a short heuristic flip path, evaluate all triangulations along the paths and select the best one as the initial center.
3. Intersection: For each edge $e \in \binom{\mathcal{S}}{2}$, count the total number $\mathrm{cr}_{\mathfrak{T}}(e)$ of crossings with all terminals. Construct the center greedily by adding edges in increasing order of $\mathrm{cr}_{\mathfrak{T}}(e)$.
4. Frequency: Each edge e in $\binom{\mathcal{S}}{2}$ is assigned a frequency based on how many terminals contain e. The initial triangulation then results from greedily selecting edges in decreasing order of frequency, using edges with frequency 0 if necessary.

Neighbor Generation. For small instances, where evaluating the flip heuristic is fast, we generate neighbors randomly: We pick a random number k, then we pick k flippable edges uniformly at random and apply the flips in random order, skipping blocked edges.

For larger instances, increased running time of the distance heuristic results in fewer candidates $\mathcal{C}$ being evaluated, so in later stages, we use an informed neighbor generation: We select a random subset $\mathfrak{T}' \subset \mathfrak{T}$, compute $u_H(e, \mathcal{C}, \mathfrak{T}')$ for all flippable edges and select a random greedy flip with a (small) k-buffer. The transition from uninformed to informed

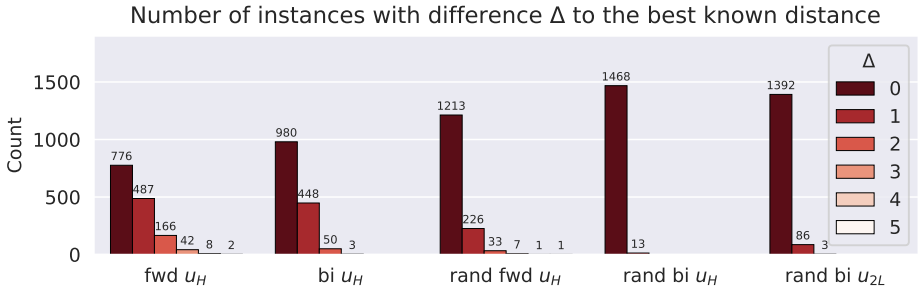

Figure 2 Comparison of deterministic and randomized heuristics: only-forward u_H, bidirectional u_H, only-forward randomized u_H, bidirectional randomized u_H, and bidirectional randomized u_{2L}.

neighbor generation is again controlled by a schedule that gradually increases the probability of selecting an informed neighbor. In the mostly greedy last quarter of the search, we substantially increase the buffer size k for informed flips, reintroducing randomness.

Heuristic Selection. We evaluated the simulated annealing algorithm with many heuristic combinations. The one we found to be the most promising was the following: First, during the exploration phase, we use u_H or u_{2L} to compute only the asymmetric deterministic variants of the heuristics, focusing on computational speed. Then, in the final (greedy) phase of the algorithm, we transition to the full ensemble of heuristics, including all introduced randomization schemes, and their opposites $H_u^{\text{opp}}(\mathcal{D}, \mathcal{D}')$., i.e., $H_u^{\text{opp}}(\mathcal{D}, \mathcal{D}') = H_u(\mathcal{D}', \mathcal{D})$.

4 Experiments

The competition data set consists of 250 instances, grouped into 100 `random`, 101 `woc`, and 49 `rirs` instances. The `random` and `woc` instances are small (15–320 points and 2–20 terminals), whereas the `rirs` instances are substantially larger (500–12 500 points and 20–200 terminals). All experiments were conducted on nodes of the HPC cluster Marvin (University of Bonn), each equipped with 1024 GB RAM and two Intel Xeon Sapphire Rapids 2.10 GHz CPUs.

Parallel Flip Distance Heuristics. To evaluate the quality of the heuristics, we generated up to ten distinct terminal pairs for each instance (1481 samples in total) and computed the parallel flip distance using u_H and u_{2L}, combining greedy and local search to compute the MWIS. The computed flip distances range from 1 to 37 and increase with the instance size.

We observed that the distance values of the heuristics using different utility functions differ in only 6% of instances. Hence, in Figure 2, we focus on u_H. As expected, applying the heuristic in a single direction (H_{u_H}) performs worst, with some outliers deviating by up to five flips from the best known values. Taking the minimum of both directions ($\min(H_{u_H}, H_{u_H}^{\text{opp}})$) increases the number of best values found by 25% and eliminates most of the extreme outliers.

Notably, even the unidirectional randomized variant outperforms the bidirectional deterministic one, yielding a further performance gain of 25%, although some outliers with large deviations from the best value remain. Minimizing over both directions yields the best solutions for most instances; using u_{2L} instead of u_H performs better in only thirteen cases.

Center Search with Simulated Annealing. We select one representative instance from each data set. Figure 3 shows the progression of the objective value during the center search for different configurations. All configurations use u_H for exploration and the full heuristic

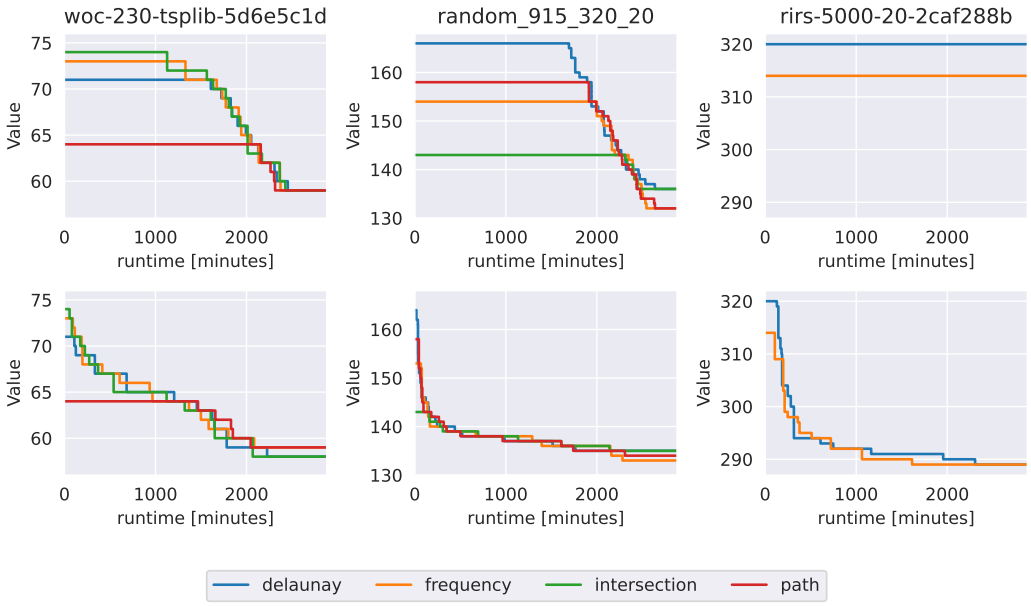

Figure 3 Objective value progression for different configurations during simulated annealing with varying initial centers. Top: uninformed neighbors; bottom: uninformed and informed neighbors.

ensemble in the final quarter. The main difference is in the neighbor selection: the upper row uses only random neighbors, while the bottom row incorporates informed neighbors. As expected, purely random neighbors do not improve the current best value during the exploration phase, but then improve the solution during the final (greedy) search. In contrast, the informed search shows gradual improvements, albeit with a higher risk of getting trapped in local optima. For small instances, the random configuration achieves slightly better final results, but unlike the informed search, it fails to find improvements on the `rirs` instance.

Figure 4 shows that the final objective value changes little with longer runtime for either neighbor selection and can even get worse due to randomization. Further experiments indicate that two to three days is a sweet spot, and that reruns should be favored over extended optimization time. Overall, our example instances are representative: on `random`, uninformed usually wins; on `rirs`, informed always wins; and on `woc`, both outcomes were observed.

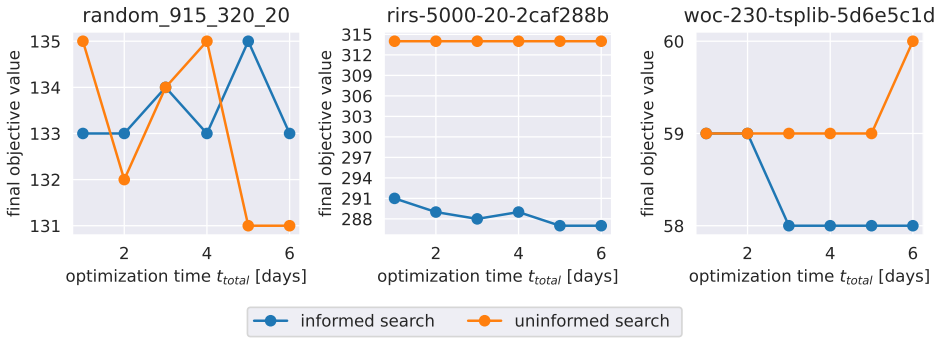

Figure 4 Final objective value after running for t_{total} days starting at the frequency center.

1 Introduction

The CG:SHOP Challenge is an annual competition in geometric optimization. In 2026, the challenge focuses on a reconfiguration problem between planar triangulations. Our team, called *Shadoks*, won first place with the best solution (among the 28 participating teams) to 249 instances out of 250 instances and provably optimal solutions to 189 instances.

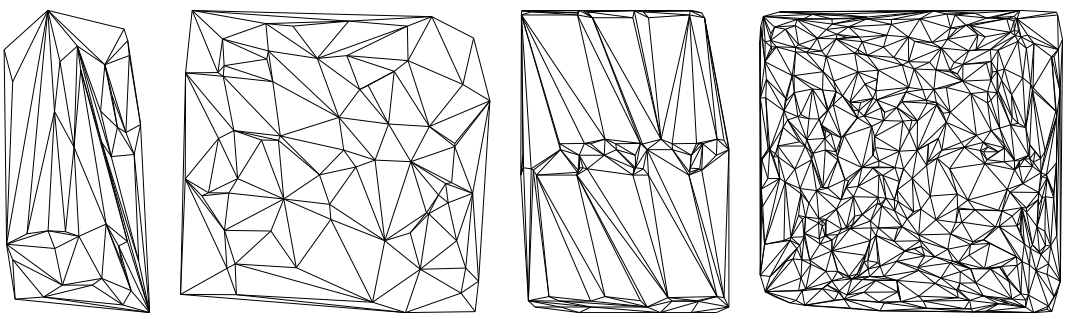

Figure 1 Our best centers to instances `random_78_40_10`, `woc-70-random-9a7d18d3`, `woc-90-tsplib`, and `rirs-500-50-23d00ec5`, respectively.

In this paper, we outline the exact methods that we employed. The heuristic solvers are only presented in the full version due to space limitations. We start with some definitions that allow us to describe the problem. Throughout, we consider triangulations of a common point set $S \subset \mathbb{R}^2$.

Given a triangulation T, a *unit flip* is the operation that removes an edge $e \in T$ and adds an edge e'. The unit flip of the edge $e = uv$ considers the empty convex quadrilateral u, u_2, v, v_2 and replaces its diagonal uv it by the other diagonal u_2v_2 (Figure 2).

Similarly, a *parallel flip* removes a set of edges $E \subset T$ and adds a set of edges E', in a way that $T' = T \setminus E \cup E'$ is a triangulation, with the condition that no two edges of E are in the same triangle in T. A *path* of *length* ℓ is a sequence of triangulations $T_0, \ldots, T_\ell$ such that for all i, the triangulation T_{i+1} is obtained from T_i by performing a parallel flip.

An *instance* is a set $S \subset \mathbb{R}^2$ of n points and a set $\mathcal{T} = \mathbf{T}_1, \ldots, \mathbf{T}_{|\mathcal{T}|}$ of triangulations of S, called *input triangulations*. A *solution* is a set of paths $P_1, \ldots, P_{|\mathcal{T}|}$ such that P_i starts at $\mathbf{T}_i$ for all i and all paths end in a common triangulation called *center*. The goal is to find a solution that minimizes the *objective value* defined as the sum of the lengths of its paths.

During the competition, the organizers provided a total of 250 instances, with n ranging from 15 to 12,500 points and $|\mathcal{T}|$ ranging from 2 to 200 triangulations. The 250 instances are divided into three classes: 100 `random` instances, 101 `woc` instances, and 49 `rirs` instances. The former two instances have up to 320 points and 2 to 20 input triangulations (hence, we call them `small` instances), while the latter have 500 to 12500 points and 20 to 200 input triangulations. The centers of some of our best solutions are presented in Figure 1. Additional details about the challenge can be found in the organizers' survey paper [2].

Our best solvers heavily rely on the SAT solver `CaDiCal` [5] and the MaxSAT solver `EvalMaxSAT` [3]. Nevertheless, we also developed heuristics that do not rely on any external solver, which are important to find initial solutions to large instances, which are then improved by roughly 10% using SAT and MaxSAT solvers., which are presented in the full version.

Other team strategies include SAT solvers for small instances [4], heuristics [9], and local search and simulated annealing [7] to improve solutions.

2 Exact Algorithms

2.1 Path SAT Formulation

Next, we describe a SAT formulation for the following decision problem. The input is a set S of n points, an integer ℓ and two triangulations T_0, T_ℓ. The output is whether there exists a path $T_0, \ldots, T_\ell$ of length ℓ.

We define two types of variables. For $i = 0, \ldots, \ell$ and for $u \neq v \in S$, we define an *edge variable* $e(u, v, i)$. The variable $e(u, v, i)$ represents that the edge uv is in the triangulation T_i. There are $O(n^2\ell)$ edge variables. It would be possible to define a SAT formulation using only such variables. However, a SAT formulation that performed much better in our experiments uses a second type of variable.

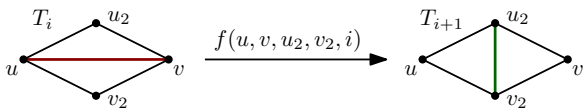

Figure 2 Illustration of a flip and the associated variable $f(u, v, u_2, v_2, i)$.

We say that a convex quadrilateral is *empty* if it contains no point of S except for its vertices. For $i = 0, \ldots, \ell$-1 and for an empty convex quadrilateral u, u_2, v, v_2, we introduce *flip variables* $f(u, v, u_2, v_2, i)$, which is true if and only if uv is in triangulation T_i and u_2v_2 is in triangulation T_{i+1}, as shown in Figure 2. Notice that if the points are uniformly distributed, then the number of empty convex quadrilaterals is $\Theta(n^2)$ [8], which means that for uniformly distributed points, the number of flip variables is also $O(n^2\ell)$. However, the number of flip variables is $\Theta(n^4\ell)$ if the points are in convex position (which is not the case for the challenge instances). Next, we describe the different types of clauses.

Start and target. For every edge variable $e(u, v, 0)$, we have the clause $e(u, v, 0)$ if $uv \in T_0$ and $\neg e(u, v, 0)$ if $uv \notin T_0$. For every edge variable $e(u, v, \ell)$, we have the clause $e(u, v, \ell)$ if $uv \in T_\ell$ and $\neg e(u, v, \ell)$ if $uv \notin T_\ell$.

Flips need edges. For every flip variable $f(u, v, u_2, v_2, i)$, we have the 5 binary CNF clauses translating the implication

$$f(u, v, u_2, v_2, i) \implies e(u, v, i) \wedge e(u, v_2, i) \wedge e(u, u_2, i) \wedge e(v, v_2, i) \wedge e(v, u_2, i).$$

Flips keep edges. Similarly, or every flip variable $f(u, v, u_2, v_2, i)$, we have the 5 binary CNF clauses translating the implication

$$f(u, v, u_2, v_2, i) \implies e(u_2, v_2, i{+}1) \wedge e(u, v_2, i{+}1) \wedge e(u, u_2, i{+}1) \wedge e(v, v_2, i{+}1) \wedge e(v, u_2, i{+}1).$$

Flips flip edges. For every flip variable $f(u, v, u_2, v_2, i)$, we have the binary clauses translating

$$f(u, v, u_2, v_2, i) \implies \neg e(u, v, i + 1).$$

Edge changes require flips. The last type of clause is the only one that has more than 2 variables in CNF form. It states that if the edge variable changes from triangulation i to $i + 1$, then there must be a flip. The $\bigvee$ below considers all values of the subscript that define existing flip variables. We have two such clauses for each edge variable:

$$e(u, v, i) \wedge \neg e(u, v, i + 1) \implies \bigvee_{u_2, v_2} f(u, v, u_2, v_2, i) \text{ and}$$

$$\neg e(u_2, v_2, i) \wedge e(u_2, v_2, i + 1) \implies \bigvee_{u, v} f(u, v, u_2, v_2, i).$$

Eliminating variables and clauses. The number of variables and clauses grows very fast, even though the number of clauses is linear in the number of variables. Next, we show how to eliminate many variables from the model. All eliminated variables are defined as *false* and the clauses that become tautologies are eliminated. If a CNF clause becomes empty, then the problem is unsatisfiable.

The following theorem is easy to prove and implies that $\Omega(\log n)$ parallel flips are sometimes necessary to reconfigure two triangulations of n points, even when the points are in convex position. We say that two segments *cross* if they intersect at a point that is not an endpoint of either segment.

▶ **Theorem 1.** *Consider two triangulations T, T' of S such that a parallel flip transforms T into T' and a segment s with endpoints in S. Let χ, χ' respectively denote the number of edges of T, T' crossed by s. We then have $\chi' \geq \lfloor \chi/2 \rfloor$.*

Consequently, we only define the variable $e(u, v, i)$ when uv crosses strictly less than 2^i edges of T_0 and strictly less than $2^{\ell-i}$ target edges. We only define flip variables when a certain set of edge variables is defined: $f(u, v, u_2, v_2, i)$ is only defined when $uv, uv_2, uu_2, vv_2, vu_2$, are all defined at i and $u_2v_2, uv_2, uu_2, vv_2, vu_2$, are all defined at $i + 1$.

2.2 Solution SAT Formulation

Next, we describe a SAT formulation for the following decision problem. Recall that an instance is a set S of n points and a list $\mathcal{T}$ of input triangulations $\mathbf{T}_1, \ldots, \mathbf{T}_{|\mathcal{T}|}$. The input of the decision problem is an instance and $|\mathcal{T}|$ integers $\ell_1, \ldots, \ell_{|\mathcal{T}|}$. The output is whether there exists a solution $P_1, \ldots, P_{|\mathcal{T}|}$ such that path P_i has length ℓ_i for all i.

We model the $|\mathcal{T}|$ paths $P_1, \ldots, P_{|\mathcal{T}|}$ independently as before, starting path P_i at the input triangulation $\mathbf{T}_i$. The final triangulation of each path is unknown, but the same edge variables are used for the final triangulation of every path, since a valid solution requires that all paths end in the same triangulation. It is easy to see that the SAT formulation is satisfiable if and only if there exists a solution with the given lengths.

2.3 Lower Bound

In order to obtain an exact solution to an instance $\mathcal{I}$, we start by computing a lower bound to its objective value. We say that the *distance* between two triangulations T, T' is the length of the shortest path from T to T'. We create a complete directed graph $G(\mathcal{I})$ with edge lengths as follows. The vertices are the triangulations $\mathcal{T}$ and the length of each edge is the distance between the corresponding triangulations. A *cycle packing* of G is a collection of vertex-disjoint directed cycles, i.e. a subset of edges such that each vertex has at most one outgoing and at most one incoming edge in the subset. The graph is directed to allow for cycles with only 2 edges. The *length of a cycle* is the sum of the lengths of its edges, and the *length of a cycle packing* is the sum of the lengths of its cycles. The maximum length cycle packing can be solved in polynomial time using a reduction to maximum weight bipartite matching [6]. The following theorem is easy to show.

▶ **Theorem 2.** *Given an instance $\mathcal{I}$, the objective value of a solution is at least the length of any cycle packing of $G(\mathcal{I})$ divided by 2.*

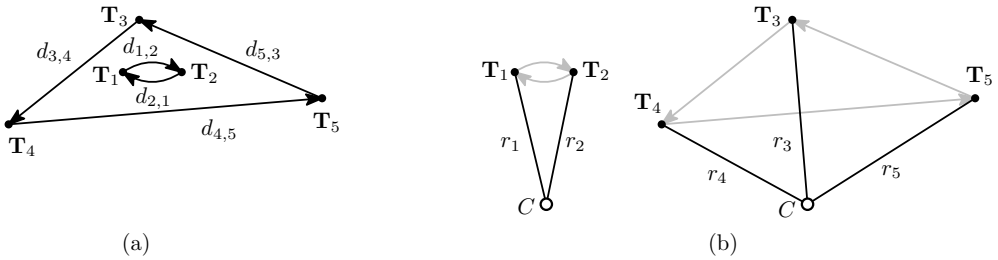

Figure 3 (a) A cycle packing. (b) Illustration of the proof. In this example,$d_{1,2} \leq r_1 + r_2$, $d_{2,1} \leq r_2 + r_1$, $d_{3,4} \leq r_3 + r_4$, $d_{4,5} \leq r_4 + r_5$, and $d_{5,3} \leq r_5 + r_3$ by triangle inequality.

2.4 The Exact Solver

First, we use the exact path formulation from Section 2.1 to calculate the distance between all $\binom{\mathcal{T}}{2}$ pairs of input triangulations using a SAT solver (in our case, `CaDiCal` [5]). It is easy to formulate the problem of finding a maximum length cycle packing as a weighted MaxSAT problem, which provides a lower bound b to the objective value (see Section 2.3). We solve this problem using a weighted MaxSAT solver (in our case `EvalMaxSAT` [3]). We then use backtracking to list all integer solutions to $\ell_0, \ldots, \ell_{|\mathcal{T}|} = b$ that satisfy $\ell_i + \ell_j \geq \text{distance}(T_i, T_j)$. We use the SAT formulation from Section 2.2 to test the existence of a solution with the given lengths $\ell_0, \ldots, \ell_{|\mathcal{T}|}$, again using the `CaDiCal` SAT solver. If a solution is found, then it is optimal. Otherwise, we increment b and repeat. Notice that b is always a lower bound to the objective value. Hence, if a solution obtained by a heuristic attains this lower bound, then it is optimal.

2.5 Happy Edges Conjecture

The happy edges conjecture [1] is a general conjecture that is *false* for some reconfiguration problems and *true* for others.

▶ **Conjecture 3.** *For any pair of configurations T, T', there exists a shortest path between T, T' where the edges that are common to both T and T' appear in all intermediate configurations.*

The conjecture is *false* for triangulations under unit flips and arbitrary points [10] but *true* when the points are in convex position [11]. Our experiments lead us to believe that the conjecture is *true* for parallel flips, as we could not find a counterexample.

When computing a path of length ℓ from T_0 to T_ℓ using SAT, for every edge uv that appears in both T_0 and T_ℓ, we add clauses $e(u, v, i)$ that force the variable to be true for all i. More importantly, we then eliminate every edge variables corresponding to edges that cross uv. The same idea can be applied to the SAT formulation that finds a solution, but then only the edges that appear in all input triangulations are forced to be true for all i, and again the edges that cross them are eliminated.

Furthermore, when computing a path, for every edge $uv \in T_\ell$, we eliminate flip variables that remove uv, i.e. $f(u, v, u_2, v_2, i)$ for all u_2, v_2, i. Similarly, for every edge $u_2v_2 \in T_0$, we eliminate flip variables that insert u_2v_2, that is $f(u, v, u_2, v_2, i)$ for all u, v, i.

3 Results

In this section, we present the computational results that we obtained with our implementation of the aforementioned algorithm. In Section 3.1, we present the results on computing short paths between two given triangulations. In Section 3.2, we present our exact solver, with and without the happy edges conjecture.

The solvers were coded in C++ and compiled with GCC and run a single thread. During the competition, they were executed on several Linux computers, either using GNU Parallel [12] for local executions or Slurm [13] for cluster executions. It was very useful to have access to machines with 128GB or more RAM to solve large SAT formulations with `CaDiCal` [5], which has been able to solve SAT instances with more than 50 million variables and 500 million clauses. The time measurements on this paper use an AMD Ryzen 9 9900X CPU and ASUS TUF B650M motherboard with 128GB of RAM running Fedora Core 43.

Table 1 Length and computation time (in milliseconds) for a path from the Delaunay triangulation to the first input triangulation of the `rirs-`n`--20` instance for different values of the number of points n. The Heuristic column shows the smallest length obtained by applying four heuristics (greedy (forward/backward) and squeaky-wheel (forward/backward)) described in the full version of the paper and the total time to run the four heuristics. The SAT columns correspond to SAT formulation with or without the happy edges conjecture, unless it takes too long.

	Heuristic		SAT happy		SAT exact	
n	length	total time	length	time	length	time
500	**12**	70.9	**12**	1512	**12**	10191

3.1 Path Calculation

Computing short paths between two given triangulations is a key component to obtain good solutions. Typically, these paths are computed with an input triangulation as one extreme, and a triangulation that makes a reasonably good center as the other extreme. Table 1 shows the best length of the path obtained with our heuristics (described in the full version of the paper) with the associated running times compared to our SAT formulation with and without the happy edges conjecture. The paths are computed from the Delaunay triangulation that makes a reasonably good (but not very good) center to the first input triangulation of several instances. The SAT paths are obtained by first running a heuristic in both directions, and then iteratively decreasing the path length with our SAT solution.

3.2 Exact Solutions

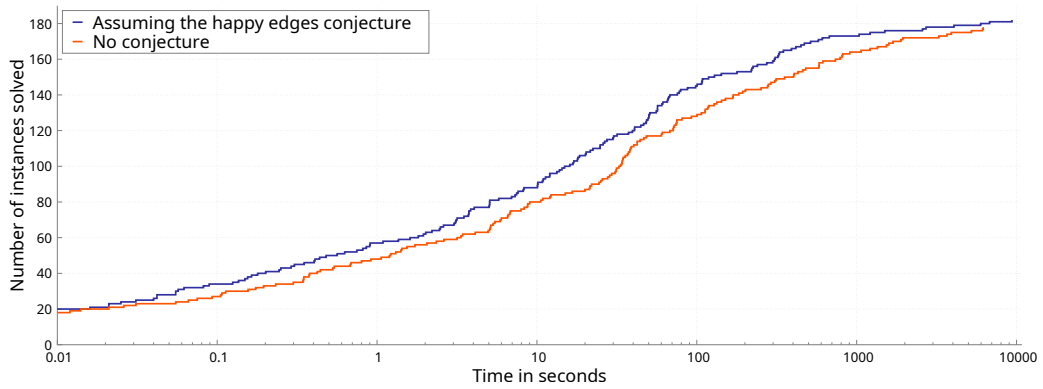

Figure 4 Number of exact solutions found as a function of the running time over 3 hours of execution with and without assuming the happy edges conjecture.

We end the paper with the performance of our exact solver. Figure 4 plots the number of exact solutions found as a function of runtime, with and without the happy edges conjecture. Since the solution values are identical in both cases, the happy edge conjecture holds.

Abstract

In the CG:SHOP 2026 Challenge, the goal is to compute a central triangulation for a given set of triangulations on the same point set while minimizing the sum of parallel flip distances. To address the problem, our team (CG#Hunters) constructs an initial solution by iteratively applying parallel flips to reduce the total number of crossings between the triangulations until none remain. To optimize these solutions, we shorten the paths by using a score-based greedy edge selection and refine the central triangulation via a large scale neighborhood search. Additionally, a representative-set-based approach is utilized to efficiently handle large instances. With these combined approaches, we achieved third place by successfully computing central triangulations with sufficiently short parallel flip paths for all 250 instances.

1 Introduction

An edge flip of a triangulation T is an operation that removes a shared edge e between two adjacent triangles forming a convex quadrilateral, and replaces it with the opposite diagonal of the quadrilateral. Given two triangulations T_1, T_2 on the same point set P, there exists a flip path from T_1 to T_2, which is a sequence of flips applied to T_1 to make T_2. There has been a fair amount of work on computing flip paths between two triangulations [2, 3, 5, 6], and it is known to be NP-complete to compute a shortest one [7].

Taking a step further, the CG:SHOP 2026 Challenge considers a *parallel flip* operation, which is a set of multiple edge flips that can be performed simultaneously because they do not share any triangles. We call a sequence of parallel flips a *parallel flip path*. In the problem, we are given a set of triangulations on the same point set and the goal is to compute a central triangulation on the same point set while minimizing the sum of the lengths of parallel flip paths from each triangulation. The problem is formally defined as follows.

▶ **Problem 1.** *Given a problem instance $I = (P, \mathcal{T})$, where P is a set of points in $\mathbb{R}^2$ and $\mathcal{T}$ is a set of triangulations of P, find a central triangulation C of P and a parallel flip path $\pi(T, C)$ from each $T \in \mathcal{T}$ to C while minimizing $\sum_{T\in\mathcal{T}} |\pi(T, C)|$.*

There were 250 instances of three types (*random-*, *woc-*, and *rirs-*) given. For more details on the instances, see the survey paper [1].

Preliminaries. We say that an edge e in a triangulation is *flippable* if it is shared by two triangles forming a convex quadrilateral. Two flippable edges of the same triangulation are *independent* if they do not share any triangle. Hence, a set of independent flippable edges can be chosen as a single parallel flip operation.

Our main approach relies on *the number of crossings* among a set of triangulations. We say that two edges are *crossing* if they intersect at a point in the interior of an edge. For an edge e and a triangulation T, we use $\mathrm{cr}(e, T)$ to denote the number of edges crossing e in T. Note that $\mathrm{cr}(e, T) = 0$ if $e \in T$. We slightly abuse the notation by letting $\mathrm{cr}(T, T') = \sum_{e\in T} \mathrm{cr}(e, T')$ denote the number of crossings between two triangulations T and T', and $\mathrm{cr}(\mathcal{T}) = \frac{1}{2} \cdot \sum_{T,T'\in\mathcal{T},T\neq T'} \mathrm{cr}(T, T')$ denote the total number of crossings among a set of triangulations $\mathcal{T}$.

2 Initial algorithm

First, we introduce our initial algorithm for computing an initial solution for each instance. Given an instance $I = (P, \mathcal{T})$, our algorithm runs while maintaining a (multi)-set of triangulations $\widehat{\mathcal{T}}$, starting with $\widehat{\mathcal{T}} = \mathcal{T}$. At each step, it selects one triangulation in $\mathcal{T}$ and applies a parallel flip to reduce the total number of intersections among the triangulations $\mathrm{cr}(\widehat{\mathcal{T}})$. The algorithm terminates when $\mathrm{cr}(\widehat{\mathcal{T}})$ becomes zero, which implies that the triangulations in $\widehat{\mathcal{T}}$ are the same. Then the algorithm returns the triangulation as the central triangulation C.

In doing so, we first use the following observation from [3].

▶ **Lemma 2** (Lemma 2 and 3 of [3]). *Let T, T' be two different triangulations on the same points. There exists an edge flip from T that reduces* $\mathrm{cr}(T, T')$.

Lemma 2 implies that we can always find a parallel flip from a triangulation $T \in \widehat{\mathcal{T}}$ that reduces the total number of intersections when $|\widehat{\mathcal{T}}| = 2$. To use this observation for an instance with $|\mathcal{T}| > 2$, we claim the following stronger argument.

▶ **Conjecture 3.** *Let $\widehat{\mathcal{T}}$ be a set of triangulations on the same point set. Then there exists a triangulation $T \in \widehat{\mathcal{T}}$ and an edge flip in T that reduces* $\mathrm{cr}(\widehat{\mathcal{T}})$, *unless* $\mathrm{cr}(\widehat{\mathcal{T}}) = 0$.

We presume that Conjecture 3 holds to design our algorithm, and so far during the contest, we have not encountered any counterexample. Using Conjecture 3, a single step of our algorithm works as follows. For each flippable edge e in each triangulation $T \in \widehat{\mathcal{T}}$, let e' be the edge obtained by flipping e in T. Then we define a *score* for e as the change in $\mathrm{cr}(\widehat{\mathcal{T}})$ after flipping e, that is, $\sum_{T' \in \widehat{\mathcal{T}} \setminus \{T\}} (\mathrm{cr}(e, T') - \mathrm{cr}(e', T'))$ and compute it. Observe that there is at least one positive-scored edge if Conjecture 3 holds.

After computing the scores of the edges, we compute a possible parallel flip to reduce $\mathrm{cr}(\widehat{\mathcal{T}})$ for each $T \in \widehat{\mathcal{T}}$. Within T, the edges to flip are chosen in a greedy manner. First, our algorithm sorts the positive-scored edges in T in descending order of their scores. Then, it scans through the sorted edges and picks an edge if it is independent of the already picked edges. After scanning, the algorithm chooses a triangulation with a possible parallel flip that reduces $\mathrm{cr}(\widehat{\mathcal{T}})$ the most and applies the parallel flip. Then the algorithm proceeds to the next step. See Figure 1.

By tracking the parallel flips applied to the triangulations during the algorithm, we can also obtain a parallel flip path $\pi(T, C)$ for each $T \in \mathcal{T}$. We mainly used this algorithm for obtaining initial solutions. However, this approach requires high computational cost. To address this, we also used a representative-set-based approach, which is described in Section 4.

3 Optimization

In this section, we address our two optimization approaches to improve our solutions: recomputing the paths and finding a new central triangulation.

3.1 Parallel flip path between two triangulations

In order to optimize the objective value $\sum_{T \in \mathcal{T}} |\pi(T, C)|$ for all triangulations in the given instance $I(P, \mathcal{T})$, one effective way is to compute shorter parallel flip paths. Our first optimization technique is specifically designed to compute a shorter parallel flip path from a given triangulation T to the central triangulation C without changing C itself.

To do so, we develop a core algorithm for computing a parallel flip path between two different triangulations T_1 and T_2 on the same point set. At each step, for each flippable edge in T_1 that is not present in T_2, a certain *score* of the edge with respect to T_2 is computed. These candidate edges are sorted in decreasing order of their scores. From this sorted list, a set of independent positive-scored edges is selected in a greedy manner. Finally, the edges in the set are flipped simultaneously, and the set of edges is recorded as an element for the sequence of the parallel flip path $\pi(T_i, T_j)$. The procedure above is repeated until $T_1 = T_2$.

During the competition, we used three different score measures to evaluate the geometric benefit of flipping an edge. For a flippable edge e in T_1 but not in T_2, let e' be the new edge obtained by flipping e. The measures for an edge e are defined as follows:

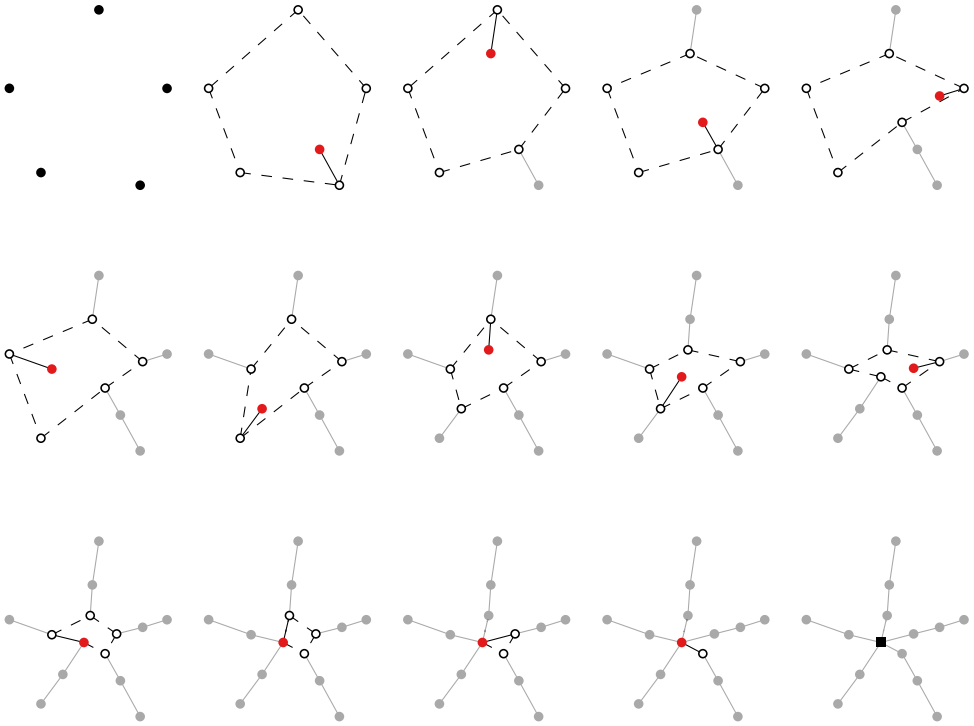

Figure 1 A visualization of the initial algorithm. Given an instance with five triangulations (black disks), the algorithm proceeds with maintaining $\widehat{\mathcal{T}}$ (empty disks). For each step, it picks one triangulation among $\widehat{\mathcal{T}}$ and applies a parallel flip (red disk) to the triangulation to reduce $\mathrm{cr}(\widehat{\mathcal{T}})$. The algorithm stops when triangulations in $\widehat{\mathcal{T}}$ are the same, and the triangulation (black box) is reported as a central triangulation.

1. $\mathrm{cr}(e, T_2)$: The absolute crossing number. This measure focuses on edges that have a high number of intersections with the target triangulation.
2. $\mathrm{cr}(e, T_2) - \mathrm{cr}(e', T_2)$: The absolute reduction in crossings. This evaluates the direct decrease in the number of intersections, favoring flips that consistently guide the current triangulation toward the target.
3. $(\mathrm{cr}(e, T_2) - \mathrm{cr}(e', T_2))/\mathrm{cr}(e, T_2)$: The relative reduction rate. This approach normalizes the reduction by the initial crossing count, favoring flips that resolve a larger proportion of their existing intersections.

Note that without proper cycle prevention, the algorithm may repeatedly select two edges alternatively, entering an infinite loop. See Figure 2. We were able to prevent it by prohibiting the edges flipped in the immediate previous step from being flipped again.

To derive the minimum parallel flip path $\pi(T_1, T_2)$, the aforementioned algorithm is extended by exploring diverse path generation strategies. For any given pair of triangulations, multiple candidate paths are generated using the following variations:

- **Forward/Reverse search:** Paths are computed not only from T_1 to T_2 but also from T_2 to T_1, with the latter being subsequently reversed.
- **Two-way search:** Paths are explored simultaneously from both triangulations. At each step, a parallel flip is greedily executed on the side yielding the higher score gain, allowing the two sequences to meet efficiently in the middle.
- **Local refinement:** After the candidate paths are generated, intermediate sub-paths between local states are iteratively extracted and recomputed using the strategies above.

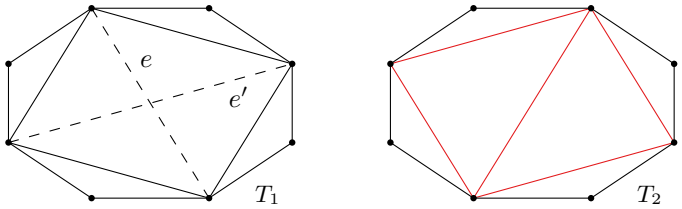

Figure 2 Two different triangulations T_1, T_2 for given a point set. Two dashed lines e and e' having $\mathrm{cr}(e, T_2) = 3$ and $\mathrm{cr}(e', T_2) = 3$ can be selected alternately in T_1 and fall into an infinite loop. Flipping e' right after flipping e is prevented allowing to flip other edges with crossing number 3.

3.2 Large scale neighborhood search

We optimize our solutions by finding a new central triangulation using large scale neighborhood search. Consider an instance $I = (P, \mathcal{T})$ and assume that we have already computed an initial solution consisting of a central triangulation C of I and parallel flip paths $\pi(T, C)$ for each $T \in \mathcal{T}$. Then for each $T \in \mathcal{T}$, a triangulation M_T along $\pi(T, C)$ is selected at random. Now, the initial algorithm is applied to compute a central triangulation C' for I', which is a new hypothetic instance $I' = (P, \mathcal{T}')$ where $\mathcal{T}' = \{M_T \mid T \in \mathcal{T}\}$ and to compute parallel flip paths $\pi'(M_T, C')$ for every $T \in \mathcal{T}$. A new solution for I is obtained by setting C' as a new central triangulation of I. The path from T to C' is then updated by concatenating $\pi(T, M_T)$−a sub-path in $\pi(T, C)$−with the new parallel flip path $\pi'(M_T, C')$.

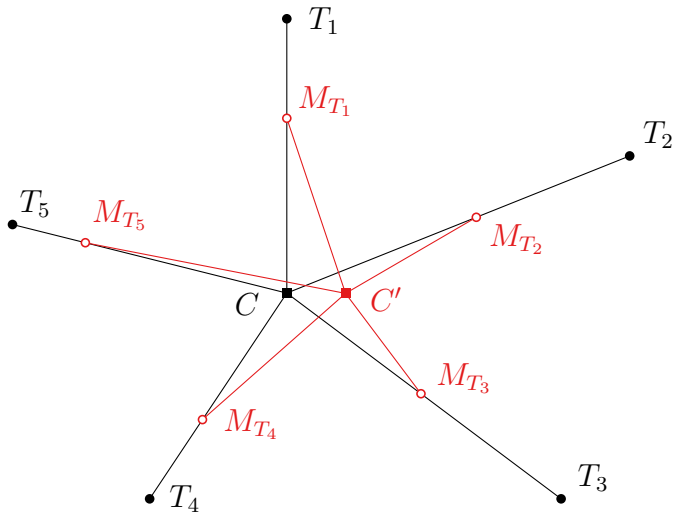

Figure 3 A visualization of the algorithm in Section 3.2.

4 Representative-set-based approach

Additionally, to reduce the computational cost of the finding central triangulation C, we utilize a *weighted representative-set-based approach*. This method is motivated by the concept of 1-*median coresets* [4], leveraging the fact that the parallel flip distance satisfies the triangle inequality. By discretizing the metric space, we construct a compact surrogate set $\mathcal{T}_{\mathrm{rep}}$ that preserves the properties of the objective function while significantly reducing the number of triangulations to be processed.

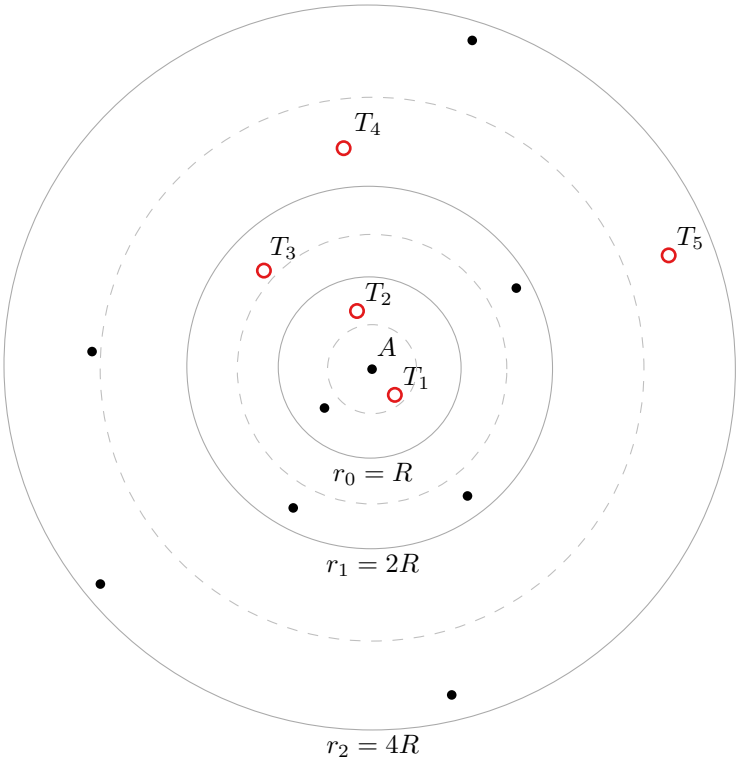

Figure 4 A visualization of the representative-set-based approach. There are $|\mathcal{T}| = 14$ triangulations. Here $A \in \mathcal{T}$, $\varepsilon = 0.5$, $\mathcal{T}_{\text{rep}}$ is $\{T_1, T_2, T_3, T_4, T_5\}$ with $w(T_1) = 2$, $w(T_2) = 2$, $w(T_3) = 4$, $w(T_4) = 1$, and $w(T_5) = 5$.

The construction of $\mathcal{T}_{\text{rep}}$ is executed through a *two-stage distance-based partitioning* process. First, if a central triangulation C from an initial solution is available, we set the *anchor triangulation* A as C; otherwise, we choose A as a random triangulation $T \in \mathcal{T}$. For each triangulation $T_i \in \mathcal{T}$, we compute $\pi(T_i, A)$ and the distance $\delta_i := |\pi(T_i, A)|$. We establish exponentially growing intervals that double in size based on the baseline scale $R := \sum_i \delta_i / |\mathcal{T}|$, and then partition $\mathcal{T}$ by grouping each triangulation T_i according to which interval its distance δ_i falls into. Next, we refine these partitions by sorting the triangulations by δ_i within each interval and further subdividing them into $1/\varepsilon$ subsets according to the granularity parameter $\varepsilon \in (0, 1)$. Finally, from each refined subset, we select a random triangulation and add it to $\mathcal{T}_{\text{rep}}$. We assign its weight $w(T)$ equal to the size of that subset, ensuring the total sum of weights equals the original size $|\mathcal{T}|$. See Figure 4.

The effectiveness and accuracy of this approach are summarized in Table 1. As shown, the proposed method substantially reduces the number of triangulations $|\mathcal{T}|$ – especially for large instances – while yielding objective values closely approximating the solutions derived from the whole triangulation set.

5 Results and discussions

In the following, we present a few observations about our approaches.

- When comparing the total parallel flip distance of *rirs-* instance and the three instances between top teams, we were in second place. See Table 2.

Table 1 Performance of the representative-set-based approach ($\varepsilon = 0.1$). Reduction denotes $|\mathcal{T}|$ decrease; objective ratio compares the results using $\mathcal{T}_{\text{rep}}$ to full $\mathcal{T}$.

Category	Number of instances	Avg. $\lvert\mathcal{T}\rvert$ reduction	Obj. value ratio
Small ($\lvert\mathcal{T}\rvert \leq 10$)	176	15.12%	1.082
Large ($\lvert\mathcal{T}\rvert > 10$)	74	78.35%	1.103
Total average	**-**	**33.84%**	**1.088**

- To understand above results, we compared the initial algorithm and various optimizations. For *rirs-* instances, the initial algorithm produced sufficiently short paths. For other instances, however, the path optimizations in Section 3.1 significantly reduced the distances in most cases. See Figure 5.
- For some *rirs-* instances, the large scale neighborhood search in Section 3.2 repeatedly generated the same central triangulation (i.e. $C = C'$ in Figure 3), regardless of the randomly selected M_T's. Nevertheless, the parallel flip paths were consistently shorter.

Table 2 The difference between four best teams' parallel flip distances and best among them. For example, our total parallel flip distance in *rirs-* instances is 3491 greater than the best 32897, meaning that 49 instances are on average 71.24 longer than the best. The number of instances of each type (*random-, woc-, rirs-*) are (100, 101, 49).

instances	best sum	Shadoks	ETH Flippers	ours	jflip2
random-	3221	1(0.01)	66(0.66)	132(1.32)	85(0.85)
woc-	3434	0(0.0)	37(0.37)	90(0.89)	82(0.81)
rirs-	32897	0(0.0)	4774(97.43)	3491(71.24)	3840(78.37)
Total	39553	1	4877	3713	4007

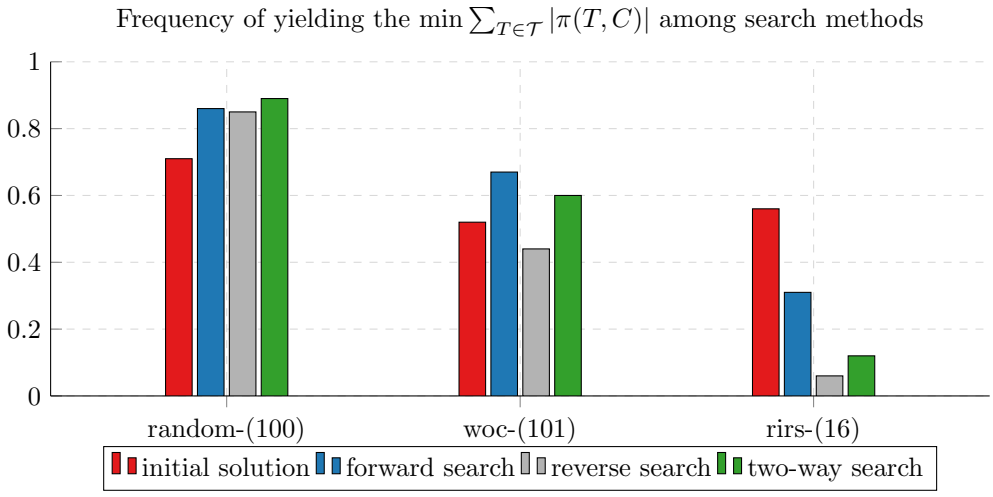

Figure 5 To evaluate the initial algorithm against various path optimizations, we measured the frequency of achieving the min $\sum_{T\in\mathcal{T}} |\pi(T,C)|$ among them from our initial solutions. We tested *rirs-* instances with $|\mathcal{T}| = 20$ and all *random-* and *woc-* instances.
