LIPIcs – Leibniz International Proceedings in Informatics

LIPIcs is a series of high-quality conference proceedings across all fields in informatics. LIPIcs volumes are published according to the principle of Open Access, i.e., they are available online and free of charge.

APPROX

Improved Approximation Algorithm for Maximum Balanced Biclique
Pasin Manurangsi 1:1–1:9

Stochastic Caching via Subset Entropy
Ravi Kumar, Roie Levin, Joseph (Seffi) Naor, and Debmalya Panigrahi 2:1–2:24

Socially Fair Clustering: Parameterized Approximation and Local Search
Aditya Anand, Yury Makarychev, and Liren Shan 3:1–3:22

Near-Optimal Streaming Approximation for Max-DICUT in Sublinear Space Using Two Passes
Santhoshini Velusamy 4:1–4:23

Incremental Dominating Set
Ilan Doron Arad, Jonathan Gal, and Joseph (Seffi) Naor 5:1–5:21

Bichromatic Geometric Spanners
Theodore Fung and Csaba D. Tóth 6:1–6:16

Improved Approximation Algorithms for Bounded-Length Path Augmentation
Felix Hommelsheim 7:1–7:22

Capacitated Partition Vertex Cover and Partition Edge Cover
Rajni Dabas, Samir Khuller, and Emilie Rivkin 8:1–8:24

A Bad Example for Jain's Iterative Rounding Theorem for the Cover Small Cuts Problem
Miles Simmons, Ishan Bansal, and Joe Cheriyan 9:1–9:15

Hardness of the Binary Covering Radius Problem in Large ℓ_p Norms
Huck Bennett and Peter Ly 10:1–10:21

Improved Algorithms and Lower Bounds for Parametrized Metrical Service Systems
Junhao Gan, Xiao Sun, and Seeun William Umboh 11:1–11:18

Uncrossed Multiflows and Applications to Disjoint Paths
Chandra Chekuri, Guyslain Naves, Joseph Poremba, and F. Bruce Shepherd 12:1–12:23

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2026).
Editors: Mohit Singh and Tom Gur
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Approximating (Weighted) Chromatic Correlation Clustering via Cluster LP
Fateme Abbasi, Hyung-Chan An, Jarosław Byrka, Changyeol Lee, and Yongho Shin 13:1–13:20

Hitting Axis-Parallel Segments with Weighted Points
Rajiv Raman, Siddhartha Sarkar, and Jatin Yadav 14:1–14:22

Length-Constrained Network Design in Planar Digraphs
Chandra Chekuri and Rhea Jain 15:1–15:24

Directed Low Diameter Decomposition for Structured Digraphs
Shinwoo An and Arnold Filtser 16:1–16:24

Bi-Lipschitz Extensions and Outlier Embeddings into Trees
Shuchi Chawla, Arnold Filtser, Kristin Sheridan, and Yonatan Trachtenberg 17:1–17:24

Tight Approximation Results for Matroid Optimization with a Linear Constraint
Ilan Doron-Arad, Hadas Shachnai, and Gilad Shmerler 18:1–18:19

Strong Inapproximability for a Promise Rank Problem
Venkatesan Guruswami, Xuandi Ren, and Shaoxuan Tang 19:1–19:22

On the Approximability of Parameterized Minimum Monotone Satisfying Assignment
Venkatesan Guruswami, Bingkai Lin, Xuandi Ren, and Xin Zheng 20:1–20:14

Cycle Cancellation for Submodular Fractional Allocations and Applications
Chandra Chekuri, Pooja Kulkarni, Ruta Mehta, and Jan Vondràk 21:1–21:20

A Configuration-LP Framework for Connected k-Median Clustering
Kushagra Chatterjee, Rojin Rezvan, and Ali Vakilian 22:1–22:20

Approximation Algorithms for Matroidal Prerequisite Systems
Robert P. Streit and Vijay K. Garg 23:1–23:24

The Code Distortion Problem
Huck Bennett, Matthew Fox, and Bryant Morrell 24:1–24:22

Online Matching with Size-Based and Convex Delays
Junhao Gan, Xiao Sun, and Seeun William Umboh 25:1–25:23

Online TCP Acknowledgment Under General Delays
Sujoy Bhore, Michał Pawłowski, and Seeun William Umboh 26:1–26:24

Approximation Algorithms for Discounted Graph Search with Norm Objectives
Svenja M. Griesbach, Felix Hommelsheim, and Max Klimm 27:1–27:20

Threshold Rounding and Bounded-Degree Boolean MAX 2-CSP
Suprovat Ghoshal, Neng Huang, Euiwoong Lee, Konstantin Makarychev, and Yury Makarychev 28:1–28:21

Incremental Consistent k-Center Clustering
Mara Grilnberger and Antonis Skarlatos 29:1–29:19

Optimal Stable Coresets for Geometric Median via Uniform Sampling
Amir Carmel, Robert Krauthgamer, and Nir Petruschka 30:1–30:14

RANDOM

Unbounded-Width CSPs Are Untestable in a Sublinear Number of Queries
Yumou Fei 31:1–31:9

Tight Simulation of a Distribution Using Conditional Samples
Tomer Adar 32:1–32:20

When Local and Non-Local Meet: Quadratic Improvement for Edge Estimation with Independent Set Queries
Tomer Adar, Yahel Hotam, and Amit Levi 33:1–33:21

Two-Sided Lossless Expanders in the Unbalanced Setting
Eshan Chattopadhyay, Mohit Gurumukhani, Noam Ringach, and Yunya Zhao 34:1–34:19

Towards Tight Bounds for Testing k-Colorability
Nick Kushnir and Asaf Shapira 35:1–35:13

Distributed Gaussian Mean Testing Under Communication Constraints: Messages, Samples, and Coins
Clément L. Canonne and Nimitt 36:1–36:20

Hard-To-Sample Distributions from Robust Extractors
Farzan Byramji, Daniel M. Kane, Jackson Morris, and Anthony Ostuni 37:1–37:22

Almost All Graphs Are Vertex-Minor Universal
Ruben Ascoli, Bryce Frederickson, Sarah Frederickson, Caleb McFarland, and Logan Post 38:1–38:20

Improved Error Reduction for Weighted PRGs
Ben Chen, Gil Cohen, Dean Doron, Yuval Khaskelberg, and Amnon Ta-Shma 39:1–39:23

Output-Sparse Matrix Multiplication Using Compressed Sensing
Huck Bennett, Karthik Gajulapalli, Alexander Golovnev, and Evelyn Warton 40:1–40:20

From Decision to Random Certificates: Exponential Separation for Edge Estimation with Independent Set Queries
Debarshi Chanda, Buddha Dev Das, Arijit Ghosh, and Gopinath Mishra 41:1–41:23

Glauber Dynamics for Random Field Ising Models on Bounded Degree Graphs
Yi Han 42:1–42:18

Markov Chains with Rewinding
Amir Azarmehr, Soheil Behnezhad, Alma Ghafari, and Madhu Sudan 43:1–43:24

One-Way Functions and Polynomial-Time Dimension
Satyadev Nandakumar, Subin Pulari, Akhil S, and Suronjona Sarma 44:1–44:23

Recovering Planted Colorings in Sublinear Time
Weronika Wrzos-Kaminska 45:1–45:23

One-Sided-Error Parameterized Reductions for the Minimum Distance and Shortest Vector Problems
Shuichi Hirahara and Kazuki Ogitsuka 46:1–46:22

Sequential Sweeps and High Dimensional Expansion
Vedat Levi Alev and Ori Parzanchevski 47:1–47:24

An Elementary Proof of the First LP Bound on the Rate of Binary Codes
Nati Linial and Elyassaf Loyfer 48:1–48:10

Ultra-Sparse Expanders and the Free Method
Gil Cohen and Gal Maor 49:1–49:20

Entropy Equivalence Testing
Clément L. Canonne, Yash Pote, Jonathan Scarlett, and Joy Qiping Yang 50:1–50:23

On Computing Total Variation Distance Between Mixtures of Product Distributions
Weiming Feng, Yucheng Fu, Minji Yang, and Anqi Zhang 51:1–51:21

Testing k-Submodularity
Themistoklis Haris and Diptaksho Palit 52:1–52:21

Symmetric Distributions from Shallow Circuits
Daniel M. Kane, Anthony Ostuni, and Kewen Wu 53:1–53:15

Load Balancing Under Adaptive Bin Deletions
Haim Kaplan, Shay Sapir, and Uri Stemmer 54:1–54:25

Arboricity Matters in Triangle Counting with Random Edges
Arijit Bishnu, Debarshi Chanda, and Gopinath Mishra 55:1–55:25

An Improved Construction of Variety-Evasive Subspace Families
Robert Andrews and Abhibhav Garg 56:1–56:12

Testing Unate Distributions
Daeho Lee, Shivam Nadimpalli, Mingda Qiao, and Ronitt Rubinfeld 57:1–57:24

Homomorphism Testing with Resilience to Online Manipulations
Esty Kelman, Uri Meir, Debanuj Nayak, and Sofya Raskhodnikova 58:1–58:24

On the LSH Distortion of Ulam and Cayley Similarities
Flavio Chierichetti, Mirko Giacchini, Ravi Kumar, and Erasmo Tani 59:1–59:21

Fine-Grained Complexity via Quantum Natural Proofs
Yanlin Chen, Yilei Chen, Rajendra Kumar, Subhasree Patro, and Florian Speelman 60:1–60:23

Locality of Curve-Decoding and Improved Proximity Gaps
Rohan Goyal, Venkatesan Guruswami, Yihang Sun, and Mary Wootters 61:1–61:23

Learning and Testing Convex Functions
Renato Ferreira Pinto Jr., Cassandra Marcussen, Elchanan Mossel, and Shivam Nadimpalli 62:1–62:24

Mixing and Cutoff for the Systematic Scan Dynamics of the Mean-Field Ferromagnetic Potts Model
Antonio Blanca and Md Tahmidur Rafid 63:1–63:22

Lifting Polynomial Complexity Measures Using Error-Correcting Codes
Ivan Hu and Dieter van Melkebeek 64:1–64:10

Property Testing of Computational Networks
Artur Czumaj and Christian Sohler 65:1–65:23

On the Advantage of Adaptivity for Sampling with Cell Probes
Farzan Byramji, Daniel M. Kane, Jackson Morris, and Anthony Ostuni 66:1–66:9

Fast List Recovery of Univariate Multiplicity Codes
Rohan Goyal, Prahladh Harsha, Mrinal Kumar, and Ashutosh Shankar 67:1–67:18

Algorithmic Phase Transition for Large Independent Sets in Dense Hypergraphs
Abhishek Dhawan, Nhi U. Dinh, Eren C. Kızıldağ, Neeladri Maitra, and Bayram A. Şahin 68:1–68:13

QMA Lower Bounds for Batch Verification via Approximate Degree
Mark Bun, Mandar Juvekar, and Samuel King 69:1–69:22

Good Locally Testable Codes with Small Alphabet and Small Query Size
Uriya A. First and Stav Lazarovici 70:1–70:23

Parallel Sampling from the Ising p-Spin Model
Nima Anari, Aniket Das, and Alireza Haqi 71:1–71:23

Quantum Algorithms for Path and Cycle Containment Problems
Arjan Cornelissen, Amin Shiraz Gilani, and Subhasree Patro 72:1–72:23

Testing the Independent Set Property in Hypergraphs
Elena Grigorescu, Shreya Nasa, and Cameron Seth 73:1–73:15

Toward a KKL Theorem for Any HDX
Max Hopkins 74:1–74:14

Improved Local Computation of Edge Orientation
Reut Levi and Bar Rushkin 75:1–75:15

High Probability Streaming Lower Bounds for F_2 Estimation
William Swartworth, David P. Woodruff, and Samson Zhou 76:1–76:23

Approximate Cauchy-Schwarz Inequality and Improved Bounds for Sherali-Adams Refutation of Semirandom CSPs
Pravesh K. Kothari and Andrew D. Lin 77:1–77:20

Local Algorithms and the Failure of Log-Depth Quantum Advantage on Sparse Random CSPs
Antares Chen, Neng Huang, and Kunal Marwaha 78:1–78:26

Preface

This volume contains the papers presented at the 29th International Conference on Approximation Algorithms for Combinatorial Optimization Problems (APPROX 2026) and the 30th International Conference on Randomization and Computation (RANDOM 2026). APPROX focuses on algorithmic and complexity issues surrounding the development of efficient approximate solutions to computationally-difficult problems, and the 2026 edition was the 29th in the series. RANDOM is concerned with applications of randomness to computational and combinatorial problems, and the 2026 edition was the 30th in the series. The two conferences were held in parallel at Boston University, Boston, MA, USA during August 19–21, 2026. This year, the plenary speaker for APPROX was Chandra Chekuri from University of Illinois, Urbaba-Champaign, and the plenary speaker for RANDOM was Madhu Sudan from Harvard University.

Topics of interest for APPROX include approximation algorithms, hardness of approximation, small space, sub-linear time and streaming algorithms, online algorithms, approaches that go beyond worst case analysis, distributed and parallel approximation, embeddings and metric-space methods, mathematical-programming methods, spectral methods, combinatorial optimization, algorithmic game theory, mechanism design and economics, computational geometry problems, approximate learning. Those at RANDOM include the design and analysis of randomized algorithms, randomized complexity theory, pseudorandomness and derandomization, random combinatorial structures, random walks/Markov chains, expander graphs and randomness extractors, probabilistic proof systems, random projections and embeddings, error-correcting codes, average-case analysis, smoothed analysis, property testing, sublinear-time and local algorithms, computational learning theory, and the role of (pseudo)randomness in other areas of computer science such as cryptography, data privacy, and quantum information.

Prior to 2003, APPROX took place in Aalborg (1998), Berkeley (1999), Saarbrücken (2000), Berkeley (2001), and Rome (2002), while RANDOM took place in Bologna (1997), Barcelona (1998), Berkeley (1999), Geneva (2000), Berkeley (2001), and Harvard (2002). Since 2003, APPROX and RANDOM have been co-located, taking place in Princeton (2003), Cambridge (2004), Berkeley (2005), Barcelona (2006), Princeton (2007), Boston (2008), Berkeley (2009), Barcelona (2010), Princeton (2011), Boston (2012), Berkeley (2013), Barcelona (2014), Princeton (2015), Paris (2016), Berkeley (2017), Princeton (2018), Boston (2019), Atlanta (2023), London (2024) and Berkeley (2025). In 2020, 2021, and 2022, the conferences were held online.

The volume contains 30 contributed papers selected by the APPROX Program Committee out of 75 submissions, and 48 contributed papers selected by the RANDOM Program Committee out of 125 submissions. We would like to thank all the authors who submitted papers, the members of the program committees, and the external reviewers. We are grateful for the guidance of the steering committees: Jarosław Byrka, Alina Ene, Samir Khuller, Amit Kumar, Monaldo Mastrolili, Nicole Megow, Laura Sanità, Chaitanya Swamy, László Végh, Virginia Vassilevska Williams, and David P. Williamson for APPROX, and Oded Goldreich, Raghu Meka, Cris Moore, Anup Rao, Omer Reingold, Dana Ron, Noga Ron-Zewi, Ronitt Rubinfeld, Amit Sahai, Ronen Shaltiel, Alistair Sinclair, and Paul Spirakis for RANDOM.

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2026).
Editors: Mohit Singh and Tom Gur

Leibniz International Proceedings in Informatics
Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

We would also like to thank the local organizing committee at Boston University Alina Ene, Sofya Raskhodnikova, Adam Smith and the Dagstuhl Publishing Team for their dedicated handling of the proceedings.

It was our pleasure to serve as chairs of the Approx/Random 2026 Program Committees, and to edit this volume of the proceedings.

Mohit Singh and Tom Gur

Improved Approximation Algorithm for Maximum Balanced Biclique

Pasin Manurangsi
Google Research, Bangkok, Thailand

Abstract

We study the Maximum Balanced Biclique (MBB) problem: Given a bipartite graph G with n vertices on each side, find a balanced biclique in G with maximum size. We give a polynomial-time $\left(\frac{n}{\widetilde{\Omega}\left((\log n)^3\right)}\right)$-approximation algorithm for the problem, which improves upon an $\left(\frac{n}{\Omega\left((\log n)^2\right)}\right)$-approximation by Chalermsook et al. [8] and answers their open question. Furthermore, our approximation ratio matches that of the maximum clique problem by Feige [11] up to an $O(\log \log n)$ factor.

1 Introduction

The *Maximum Clique* problem – where we are given an undirected graph and the goal is to find a maximum clique – is one of the most well studied problems in all of combinatorial optimization. One of the original 21 NP-hard problems shown by Karp [20], Maximum Clique also played a central role in the foundation for connections between the PCP Theorem and hardness of approximation [12, 2, 3, 5, 18, 21, 9, 23, 29]. Specifically, it is NP-hard to approximate Maximum Clique to within a factor of $n^{1-\epsilon}$ for any constant $\epsilon > 0$ [18, 29]. Under a stronger assumption that NP $\not\subseteq$ BPTIME$\left(2^{(\log n)^{O(1)}}\right)$, Khot and Ponnuswami [23] ruled out any polynomial-time algorithm with approximation ratio $n/2^{(\log n)^{3/4+\gamma}}$ for any constant $\gamma > 0$. This remains the best known hardness of approximation for Maximum Clique to date. Meanwhile, many approximation algorithms for Maximum Clique have been devised (e.g. [7, 1, 11]). In particular, Feige's algorithm [11] achieves the best known approximation ratio of $O\left(n \cdot \frac{(\log \log n)^2}{(\log n)^3}\right)$ in polynomial time.

In this work, we study a bipartite variant of the Maximum Clique problem, called the *Maximum Balanced Biclique (MBB)* problem. Recall that a k-biclique, denoted by $K_{k,k}$, is the complete bipartite subgraph where each side contains k vertices. In MBB, we are given a bipartite graph $G = (U, V, E)$ where $|U| = |V| = n$, and the goal is to find a maximum k-biclique in G.

The exact version of MBB was stated[1] to be NP-hard in Garey and Johnson's seminal book [16, page 196]. However, despite a considerable amount of effort over the years (e.g. [10, 13, 22, 26, 6, 27]), it is *not* even known to be NP-hard to approximate to within

[1] Originally, the book did not provide a proof, but such a proof was later published e.g. in [19].

licensed under Creative Commons License CC-BY 4.0

a factor of $1+\epsilon$ for any constant $\epsilon > 0$. Nevertheless, hardness of approximation results are known under other assumptions [10, 13, 22, 26, 6, 27]. Specifically, it is known to be NP-hard (under randomized reductions) to approximate to within a factor of $n^{1-\epsilon}$ for any $\epsilon > 0$, assuming strengthenings of the Unique Games Conjecture [6, 27].

Despite the apparent challenges in proving hardness of approximation results for MBB, not much is known in terms of approximation algorithms either. It is straightforward to see that an "enumeration style" algorithm yields $\left(\frac{n}{\tilde{\Omega}(\log n)}\right)$-approximation for MBB in polynomial time. Only recently did Chalermsook et al. [8] manage to improve upon this approximation guarantee, obtaining an $\left(\frac{n}{\tilde{\Omega}((\log n)^2)}\right)$-approximation. As an open question, they asked whether it is possible to improve this guarantee to match the $\left(\frac{n}{\tilde{\Omega}((\log n)^3)}\right)$-approximation by [11] for the Maximum Clique problem.

1.1 Our Contribution

Our main result is an algorithm that achieves such an approximation guarantee:

▶ **Theorem 1** (Main Theorem). *There is a randomized polynomial-time $O\left(n \cdot \left(\frac{\log\log n}{\log n}\right)^3\right)$-approximation for Maximum Balanced Biclique.*

Our approximation ratio matches the aforementioned algorithm of Feige for the Maximum Clique [11] problem up to an $O(\log\log n)$ factor.

Proof Overview

To explain the proof techniques, let us use k to denote the size of the optimal balanced biclique in G, and let $t = n/k$. We first review the algorithmic guarantee of [8]: If $t \leq (\log n)^{O(1)}$, then they show how to use graph removal technique from [11] on *matchings* in order to find $\tilde{\Omega}((\log n)^2)$-biclique, as formalized below.

▶ **Theorem 2** ([8]). *Given a graph G that contains a k-biclique, there is a polynomial-time algorithm that finds a $\Theta\left(\left(\frac{\log n}{\log t}\right)^2\right)$-biclique in G where $t = n/k$.*

It is not hard to see that the above theorem immediately yields $O(n/(\log n)^2)$-approximation. For our purpose, observe further that, if $t \geq \tilde{\Omega}(\log n)$, then the above already yields $\left(\frac{n}{\tilde{\Omega}((\log n)^3)}\right)$-approximation. Thus, we can focus on the case $t \leq \tilde{O}(\log n)$, i.e. when the optimum k is at least $\frac{n}{\tilde{O}(\log n)}$.

For the case of Maximum Clique, this case can be solved via semi-definite program (SDP) rounding [1, 17] or via subgraph removal [7]. In particular, for $t \leq O\left(\frac{\log n}{\log\log n}\right)$, these algorithms can find a clique of size $n^{1/O(t)}$. Unfortunately, Chalermsook et al.'s [8] technique of reducing MBB to Maximum Clique has a square blow up on the parameter t. This means that one can only apply these Maximum Clique algorithms in a black-box manner[2] when $t \leq \tilde{O}(\sqrt{\log n})$, which is not sufficient for our purpose.

Instead, our main result is to show that, in the regime $t \leq O\left(\frac{\log n}{\log\log n}\right)$, a more direct SDP relaxation and rounding can yield a balanced biclique of size $n^{1/O(t)}$, as stated below. As mentioned earlier, combining this with Chalermsook et al.'s result (Theorem 2) immediately yields the final approximation guarantee.

[2] See [28] for a more detailed description on how to interpret [8] as a reduction from MBB to Maximum Clique.

▶ **Theorem 3** (Main SDP Rounding). *There exists a constant $D > 1$ such that the following holds. If $\{u_i\}, e$ is a feasible solution to the SDP relaxation in Figure 2 with $k \geq n \cdot \frac{D \cdot \log\log n}{\log n}$, there is an efficient rounding algorithm for finding a balanced biclique of at least size $n^{\frac{1}{D \cdot t}}$ with high probability, where $t = n/k$.*

Integrality Gap for A Natural Relaxation

To illustrate a challenge faced when using SDP relaxation for MBB, let us first state the following "natural" extension of Lovasz's ϑ function [25], which is used[3] for Maximum Clique [1, 17]. Here, we associate a vector $u_i \in \mathbb{R}^d$ with each $i \in U \cup V$, and let $e \in \mathbb{R}^d$ be an arbitrary unit vector.

$$
\begin{aligned}
\text{Maximize} \quad & k \\
\text{Subject to} \quad & \|e\|^2 = 1 \\
& \|u_i\|^2 = \langle u_i, e \rangle && \forall i \in U \cup V \\
& \sum_{i \in U} \langle u_i, e \rangle = \sum_{j \in V} \langle u_j, e \rangle = k && (1) \\
& \langle u_i, u_j \rangle = 0 && \forall (i,j) \in (U \times V) \setminus E \\
& \langle u_i, u_j \rangle \geq 0 && \forall (i,j) \in U \times V
\end{aligned}
$$

Figure 1 SDP Relaxation for MBB (First Attempt).

If G contains $K_{k,k}$, there is a feasible solution (setting vectors in the biclique to e and all others to 0) of value k. We remark that the only difference compared to the Maximum Clique formulation here is the constraint (1), which aims to ensure that the number of vertices picked in U is the same as that in V (so that the biclique is balanced).

Unfortunately, this SDP relaxation is completely unhelpful. We can always find a solution with $k = n/2$: Let f be any unit vector orthogonal to e, and let $u_i = \frac{e+f}{2}$ for all $i \in U$ and $u_j = \frac{e-f}{2}$ for all $j \in V$. This ensures that $\langle u_i, u_j \rangle = 0$ for all $(i,j) \in U \times V$. In other words, the integrality gap is unbounded.

Our SDP Relaxation

Given the integrality gap, we thus use a stronger SDP relaxation for MBB. We again associate a vector $u_i \in \mathbb{R}^d$ with each $i \in U \cup V$, and let $e \in \mathbb{R}^d$ be a unit vector. The SDP relaxation is stated below. Note that we formulate it as a feasibility problem rather than an optimization problem.

We note that the only additional constraints are (5) and (6), which are "fractional degree" constraints aiming to ensure that if i is picked, then k of its neighbor must be picked. Again, if G contains $K_{k,k}$, there is a feasible solution (setting vectors in the biclique to e and all others to 0).

[3] Note that the formulation below looks different from one defined in [25] but the latter can be written in this form [24].

$$
\begin{aligned}
&\|e\|^2 = 1 && && \\
&\|u_i\|^2 = \langle u_i, e\rangle && \forall i \in U \cup V && \\
&\sum_{i\in U}\langle u_i, e\rangle = \sum_{j\in V}\langle u_j, e\rangle = k && && (2)\\
&\langle u_i, u_j\rangle = 0 && \forall (i,j) \in (U \times V) \setminus E && (3)\\
&\langle u_i, u_j\rangle \geq 0 && \forall (i,j) \in U \times V && (4)\\
&\sum_{j\in V}\langle u_i, u_j\rangle = k\langle u_i, e\rangle && \forall i \in U && (5)\\
&\sum_{i\in U}\langle u_i, u_j\rangle = k\langle u_j, e\rangle && \forall j \in V && (6)
\end{aligned}
$$

Figure 2 SDP Relaxation for MBB.

Our main technical contribution (Theorem 3) is to show that a feasible solution to this SDP can be rounded to a large biclique. It turns out that the rounding procedure is essentially the same as that of [17] in the clique case: After some preprocessing, pick a random Gaussian g and keep a vertex i if its dot product with g is at least a certain threshold. (The full procedure is presented in Figure 3.)

The main difference however is in the analysis. In [17], one simply computes the expected number of vertices that survive the rounding and the expected survived number of non-edge pairs. If the former is much larger than the latter, then (with not too small probability) we can find a large clique by deleting one end of every non-edge pair. This analysis does not work for us: Even if the expected number of survived vertices is large, it is possible that the rounding either keep all vertices in U and no vertex in V, or vice versa. Indeed, this is the situation that occurs with the above integrality gap instance of the SDP in Figure 1.

To overcome this issue, we instead lower bound the expected number of survived *edges*. We do this by showing that, due to the extra constraints (5) and (6), many edges $(i,j) \in E$ are "good" in the sense that $\langle u_i, u_j\rangle$ is not too small. This implies that they are positively correlated in the rounding procedure, which allows us to lower bound the expected number of survived edges. This conclude our proof overview for the rounding procedure, which is formalized in Section 3 after some preliminaries.

2 Preliminaries

Throughout this work, we use log to denote the natural logarithm.

2.1 Gaussian Tail Bounds

Our rounding scheme relies on probability bounds for (multivariate) normal distributions, which we will state here for convenience. We note that these bounds are standard and are also used in approximation algorithms for Maximum Clique (e.g. [17]). First, let us start with the following lemma:

▶ **Lemma 4** ([15]). *Let $\phi(x) = \frac{1}{\sqrt{2\pi}} \cdot \exp(-x^2/2)$ be the PDF of the standard Gaussian distribution $\mathcal{N}(0,1)$. If $Z \sim \mathcal{N}(0,1)$ and $\tau \geq 2$, then $\frac{\phi(\tau)}{2\tau} \leq \Pr[Z \geq \tau] \leq \frac{\phi(\tau)}{\tau}$.*

For two standard Gaussian variables X, Y with correlation $\rho = \mathbb{E}[XY]$, we use the following bivariate tail bounds for $\Pr[X \geq \tau, Y \geq \tau]$ for $\tau \geq 2$:

- **Positive Correlation ($\rho \geq 0$):** Since X, Y are positively correlated, the joint probability is lower-bounded by the product of their marginals:

$$\Pr[X \geq \tau, Y \geq \tau] \geq \Pr[X \geq \tau] \Pr[Y \geq \tau] \geq \frac{\phi(\tau)^2}{4\tau^2}, \tag{7}$$

  where the last inequality is due to Lemma 4.
- **Negative Correlation ($\rho < 0$):** Notice that $\frac{X+Y}{\sqrt{2+2\rho}} \sim \mathcal{N}(0,1)$. Thus,

$$\Pr[X \geq \tau, Y \geq \tau] \leq \Pr[X + Y \geq 2\tau] < \frac{1}{\sqrt{2}\tau} \cdot \phi\left(\frac{\sqrt{2} \cdot \tau}{\sqrt{1+\rho}}\right) \leq \frac{\sqrt{\pi}}{\tau} \cdot \phi(\tau)^2 \cdot \exp\left(\rho \cdot \tau^2\right) \tag{8}$$

  where the first inequality is due to Lemma 4 and $\rho < 0$, and the second inequality follows from $\rho < 0$.

2.2 Biclique Extraction Lemma

Before we describe the rounding, let us also state a self-contained combinatorial step of extracting a balanced biclique from a sufficiently dense surviving subgraph.

▶ **Lemma 5** (Greedy Extraction). *Let $H = (U_H, V_H, E_H)$ be a bipartite graph with at most n vertices on each side. Let F be the total number of edges (i.e. $F = |E_H|$) and Q be the total number of non-edges in H (i.e. $Q = |U_H| \cdot |V_H| - |E_H|$). If there exists an integer $r \geq 1$ such that $F - 2rQ \geq 2nr$, then there is a polynomial-time algorithm that finds a $K_{r,r}$ in H.*

Proof. Let $d_F(i)$ and $d_Q(i)$ be the degrees of a vertex i in the edges and non-edges of H, respectively. We apply the following two-stage procedure:

1. **Density Cleaning:** While there exists any vertex i such that $d_F(i) \leq 2r \cdot d_Q(i)$, delete i from H.

   To analyze this procedure, we track $W = F - 2rQ$. Upon deleting i, the change in W is $-d_F(i) + 2r \cdot d_Q(i) \geq 0$. Thus, the final cleaned graph $H' = (U_{H'}, V_{H'}, E_{H'})$ satisfies $W' \geq 2nr$.

   Since $W' \leq |E_{H'}| \leq |U_{H'}| \cdot |V_{H'}|$ and we assume that each side of H is of size at most n, we can conclude that $|U_{H'}|, |V_{H'}|$ are both at least $2r$.
2. **Biclique Construction:** We arbitrarily select exactly r vertices from $U_{H'}$ to form U_{cliq}. For each selected $u \in U_{cliq}$, we delete its non-neighbors from $V_{H'}$; from how H' is constructed, there are at most $\frac{|V_{H'}|}{2r}$ such non-neighbors. Thus, the total number of vertices deleted from $V_{H'}$ is at most $r\left(\frac{|V_{H'}|}{2r}\right) = \frac{|V_{H'}|}{2}$. Consequently, the number of vertices surviving in $V_{H'}$ is at least $\frac{|V_{H'}|}{2}$. Because we established $|V_{H'}| \geq 2r$, at least $\frac{2r}{2} = r$ vertices remain. We arbitrarily select r of these surviving vertices to form V_{cliq}. The set $U_{cliq} \cup V_{cliq}$ is the desired balanced biclique. ◀

We remark that, for the regime $\Theta(1) \leq r \leq n^{1-\Omega(1)}$, known techniques [14, 4] can be used in the "Biclique Construction" step to improve the bound from r to $\Omega(r \log n)$. However, this does not affect the overall approximation ratio of our algorithm and, thus, we opt for the argument above for simplicity.

3 The Rounding Algorithm and Proof of Theorem 3

The full SDP rounding procedure is presented in Figure 3.

1. **SDP:** Let $\{u_i\}, e$ be vectors satisfying Figure 2. Let $t = n/k$, and $c_i = \langle u_i, e\rangle$ for all $i \in U \cup V$.
2. **Heavy Sets:** Let $A = \{i \in U \mid c_i \geq \frac{1}{8t}\}$ and $B = \{j \in V \mid c_j \geq \frac{1}{8t}\}$.
3. **Shifting:** Let $\alpha = 1 - 1/\sqrt{2}$, and let $u'_i = u_i - \alpha c_i e$ for all $i \in A \cup B$.
4. **Gaussian Thresholding:** Sample $g \sim \mathcal{N}(0, I_d)$. Keep vertices $i \in A \cup B$ iff $X_i := \langle g, \frac{u'_i}{\|u'_i\|}\rangle \geq \tau$, where $\tau = \sqrt{0.1 \log n}$. Let the surviving induced subgraph be H.
5. **Biclique Extraction:** Run the procedure from Lemma 5 on H, and output the result.

Figure 3 SDP Rounding Algorithm for MBB.

Proof of Theorem 3. We will next analyze the guarantee of the rounding algorithm. To do so, let $D = 1000$ and assume that $t \leq \frac{\log n}{D \cdot \log\log n}$.

For any subsets $S \subseteq U$ and $T \subseteq V$, let $M(S,T) := \sum_{(i,j)\in S\times T}\langle u_i, u_j\rangle$. We have

$$\begin{aligned}
M(A,B) &= M(U,V) - M(U\setminus A, V) - M(U, V\setminus B) + M(U\setminus A, V\setminus B)\\
&\overset{(4)}{\geq} M(U,V) - M(U\setminus A, V) - M(U, V\setminus B)\\
&= \sum_{i\in U}\left(\sum_{j\in V}\langle u_i,u_j\rangle\right) - \sum_{i\in U\setminus A}\left(\sum_{j\in V}\langle u_i,u_j\rangle\right) - \sum_{j\in V\setminus B}\left(\sum_{i\in U}\langle u_i,u_j\rangle\right)\\
&\overset{(5),(6)}{=} \sum_{i\in U} k\cdot c_i - \sum_{i\in U\setminus A} k\cdot c_i - \sum_{j\in V\setminus B} k\cdot c_j\\
&\overset{(2)}{=} k^2 - \sum_{i\in U\setminus A} k\cdot c_i - \sum_{j\in V\setminus B} k\cdot c_j\\
&\overset{(\star)}{\geq} k^2 - n\cdot k\cdot\frac{1}{8t} - n\cdot k\cdot\frac{1}{8t} \qquad = \frac{3}{4}k^2,
\end{aligned} \tag{9}$$

where $(\star)$ follows from our definition of A, B.

Let $E^+ = \{(i,j) \in A\times B \mid \langle u_i, u_j\rangle > \frac{1}{2}c_i c_j\}$.

Note that $\sum_{(i,j)\in A\times B} c_i c_j \leq (\sum_U c_i)(\sum_V c_j) \overset{(2)}{=} k^2$. Hence,

$$\sum_{(i,j)\in A\times B}\left(\langle u_i,u_j\rangle - \frac{1}{2}c_i c_j\right) \geq M(A,B) - \frac{k^2}{2} \overset{(9)}{\geq} \frac{k^2}{4}$$

Any pair $(i,j) \notin E^+$ contributes a non-positive value to this sum. This, together with the fact that $\langle u_i, u_j\rangle \leq 1$ for all $i, j \in U \cup V$, implies that $|E^+| \geq \frac{k^2}{4}$. Note also that, by (3), all pairs $(i,j) \in E^+$ must be an edge.

Next, consider any $i, j \in U \cup V$. We have $\langle u'_i, u'_j\rangle = \langle u_i, u_j\rangle - \frac{1}{2}c_i c_j$. Note that this also implies $\|u'_i\|_2^2 = c_i(1 - \frac{1}{2}c_i) \leq c_i$. We next analyze the expected number of edges and non-edges in H. To do this, let F denote the number of surviving edges in H, Q denote the number of non-edges in H, and let

$$r = \frac{1}{64\sqrt{\pi}\cdot\tau\cdot t^2}\cdot\exp\left(\frac{\tau^2}{16t}\right).$$

Note that, for sufficiently large n, we have

$$r \geq \frac{1}{O((\log n)^3)} \cdot n^{\frac{1}{160t}} \geq n^{\frac{1}{D \cdot t}}. \tag{10}$$

- **Lower Bounding $\mathbb{E}[F]$:** For $(i,j) \in E^+$, since $\langle u_i, u_j \rangle \geq \frac{1}{2} c_i c_j$, we have $\langle u'_i, u'_j \rangle \geq 0$. Thus, $\mathbb{E}[X_i X_j] \geq 0$. Applying (7), the probability that (i,j) is kept in H is at least $\frac{\phi(\tau)^2}{4\tau^2}$. Hence,

$$\mathbb{E}[F] \geq |E^+| \cdot \frac{\phi(\tau)^2}{4\tau^2} \geq \frac{k^2}{4} \cdot \frac{\phi(\tau)^2}{4\tau^2}. \tag{11}$$

  Since $k = n/t$ and due to our bound on t, for any sufficiently large n, we have

$$\mathbb{E}[F] \geq \frac{n^2}{O((\log n)^3)} \cdot \exp(-0.1 \log n) \geq n^{1.8} \geq n \cdot \exp\left(\frac{\tau^2}{16t}\right) \geq 8nr. \tag{12}$$

- **Upper Bounding $\mathbb{E}[Q]$:** Consider any $(i,j) \in (A \times B) \setminus E$. By (3), $\langle u_i, u_j \rangle = 0$, which implies $\langle u'_i, u'_j \rangle = -\frac{1}{2} c_i c_j$. Normalizing bounds the correlation:

$$\mathbb{E}[X_i X_j] = \left\langle \frac{u'_i}{\|u'_i\|}, \frac{u'_j}{\|u'_j\|} \right\rangle \leq \frac{-\frac{1}{2} c_i c_j}{\sqrt{c_i c_j}} = -\frac{1}{2}\sqrt{c_i c_j} \leq -\frac{1}{16t},$$

  where the last inequality follows from definition of A, B. Applying (8), we have

$$\mathbb{E}[Q] \leq n^2 \cdot \frac{\sqrt{\pi}}{\tau} \cdot \phi(\tau)^2 \cdot \exp\left(-\frac{\tau^2}{16t}\right) \overset{(11)}{=} \frac{1}{4r} \cdot \mathbb{E}[F]. \tag{13}$$

Thus, we have

$$\mathbb{E}[F - 2rQ] \overset{(13)}{\geq} \mathbb{E}[F]/2 \overset{(12)}{\geq} 4nr.$$

Since $F - 2rQ$ has value at most n^2, we have $F - 2rQ \geq 2nr$ with probability at least $1/n^2$. When this occurs, Lemma 5 guarantees an r-biclique which satisfies the desired size bound due to (10). To achieve high probability, we simply repeat the rounding process n^3 times. This concludes our proof. ◀

4 Putting Things Together: Proof of Theorem 1

Finally, we prove our main theorem (Theorem 1) by combining our SDP rounding (in the large optimum case) with the algorithm of Chalermsook et al. from Theorem 2 (in the small optimum case).

Proof of Theorem 1. We solve the SDP from Figure 2 for $k = \left\lceil n \cdot \frac{10 \cdot D \cdot \log\log n}{\log n} \right\rceil$. If the SDP is feasible, then we simply run the rounding algorithm from Theorem 3. This ensures that we find a biclique of size at least $(\log n)^{10}$, which yields $n/(\log n)^{10} \leq O\left(n \cdot \left(\frac{\log\log n}{\log n}\right)^3\right)$-approximation.

If the SDP is infeasible, then the maximum balanced biclique has size at most $O\left(n \cdot \frac{\log\log n}{\log n}\right)$. We run Chalermsook et al.'s algorithm (Theorem 2). If the maximum balanced biclique has size at least $n/\log^3 n$, we have $t \leq \log^3 n$ and thus the algorithm produces $\Theta\left(\left(\frac{\log n}{\log\log n}\right)^2\right)$-biclique, which yields $O\left(n \cdot \left(\frac{\log\log n}{\log n}\right)^3\right)$-approximation. On the other hand, if the maximum balanced biclique has size at most $n/\log^3 n$, we automatically get $n/\log^3 n \leq O\left(n \cdot \left(\frac{\log\log n}{\log n}\right)^3\right)$-approximation. ◀

5 Conclusion and Open Questions

In this work, we give a polynomial-time $\left(\frac{n}{\widetilde{\Omega}((\log n)^3)}\right)$-approximation algorithm for the Maximum Balanced Biclique problem. Our algorithm is via SDP rounding in the case where the optimum is large, combined with the known result of Chalermsook et al. [8] in the case where the optimum is small. Apart from trying to improve the approximation ratio further, it remains an interesting question whether the former case can be handled directly via combinatorial algorithms. We remark that, in the Maximum Clique case, subgraph removal techniques–which are completely combinatorial–suffice for this case [7].

Another intriguing question is whether one can achieve a similar approximation for the Maximum *Edge* Biclique (MEB) problem. In MEB, we are looking for a (not necessarily balanced) biclique in G that contains the maximum number of edges. A trivial algorithm yields n-approximation, and a simple "enumeration style" algorithm can improve this to $\frac{n}{\widetilde{\Omega}(\log n)}$. However, we are not aware of any further improvement to this. In particular, it is unclear how to apply SDP rounding when the optimum is large.

Abstract

A classic approach to beyond worst-case algorithm design is to impose stochastic assumptions on the input. However, a limiting feature of such stochastic analyses is that, by the min-max principle, performance on worst-case distributions mirrors that of randomized algorithms on worst-case inputs. In other words, the same shortcoming of worst-case analysis – its inability to distinguish between "easy" and "hard" instances – reappears as an inability to distinguish between "easy" and "hard" distributions. This raises a natural question: *Can we characterize "easy" input distributions with useful beyond worst-case bounds?*

A canonical example is the *stochastic caching* problem (Aho, Denning, and Ullman, 1971). When the page requests are drawn i.i.d. from the uniform distribution, the best achievable competitive ratio is $O(\log k)$, matching the performance of the best randomized algorithm on worst-case instances (Fiat, Karp, Luby, McGeoch, Sleator, and Young, 1991). However, when the input distribution has less entropy, intuition suggests that we should be able to do better by exploiting the information provided by the distribution. In this paper, we formalize this intuition by defining a new information-theoretic parameter of probability distributions called *subset entropy*. We then use this parameter to give a fine-grained characterization of the competitive ratio of stochastic caching, including a new analysis for the well-known LRU algorithm on stochastic inputs.

While our technical results are for the caching problem, we believe the broader principle – parameterizing algorithmic performance by an entropy measure of the input – is of independent interest and might apply to other online and stochastic optimization problems. Indeed, for many other fundamental problems such as (comparison-based) sorting, online matching, online load balancing, etc., the hardest stochastic instances involve high-entropy distributions. We hope our work is a step toward a broader theory of fine-grained algorithmic performance for this class of problems.

1 Introduction

Stochastic optimization is a well-known and extensively-studied framework for beyond worst-case analysis of algorithmic problems. The basic premise is to make an assumption about the input being drawn from a probability distribution, rather than being generated adversarially, thereby enabling algorithms that exploit structural properties of the distribution. However, a common shortfall of this strategy is that algorithmic performance on the worst-case input distribution often mirrors that of the best randomized algorithm for worst-case inputs. This equivalence, a consequence of the min-max principle (Yao [35]), is often useful for proving randomized lower bounds for algorithms but, conversely, also lower bounds the performance of the best stochastic algorithms. This is rather limiting because it brings back the main deficiency of worst-case analysis – its inability to separate "easy" from "hard" instances – as being unable to differentiate between "easy" and "hard" distributions. This raises the natural question: *can we obtain a finer-grained characterization of input distributions that yields beyond worst-case bounds for "easy" distributions?*

The Caching Problem. A case in point is the classical online *caching* (or paging) problem. In this problem, a sequence of page requests arrives online from a universe of n pages. The goal is to serve each request using a cache that can only hold k ($\ll n$) pages at a time while minimizing the total number of page swaps. Caching is used in almost every extant computer system. It is also a focal point for modern developments in online algorithms such as the online primal-dual method, projections, and mirror descent [13, 12, 11]. The problem is considered well-understood in online adversarial models: in their seminal work, Sleator and Tarjan [33] showed that the *least-recently used* (LRU) policy is k-competitive, and that any deterministic online algorithm is at least k-competitive. When randomization is allowed, Fiat et al. [17] showed an elegant and improved $O(\log k)$-competitive algorithm. Unfortunately, this bound is asymptotically tight for randomized algorithms even when page requests are sampled i.i.d. from a known distribution, since no algorithm can do better on the uniform distribution over $n = k + 1$ pages [17].

Yet, our understanding of the caching problem is wanting even in the simplest "beyond worst-case" setting, where each request is drawn independently from a fixed distribution. As noted, the uniform distribution *is* the worst-case distribution – but this is also the least compelling case for caching. If requests are uniform, there is no reason for a caching algorithm to prefer one page over another, and any caching algorithm is as good as any other. In contrast, if page requests are skewed toward a set of fewer than k pages, smart caching can be effective, as one can hope to identify the frequently requested pages and prioritize evicting others.

This leads to our main questions: *Which distributions admit better-than-worst-case competitive ratios? And which online caching algorithms attain tighter bounds for distributions that are caching-friendly?*

1.1 Our Results

We study the *stochastic caching* problem, where we assume the input sequence of requests is drawn independently from a fixed distribution. The *competitive ratio* of a stochastic caching algorithm is the ratio of the expected cost of the algorithm and the expected cost of an optimal offline solution, where both expectations are taken over the input distribution (and the algorithm, if randomized).

Our first contribution is a new measure called *subset entropy* to quantify the competitive ratio of a stochastic caching instance. A reasonable first guess for such a measure would be the *entropy* of the input distribution; indeed, this would align in the case of the uniform distribution over $n = k + 1$ pages, where the entropy is $\Theta(\log k)$. However, if the distribution places $1-\varepsilon$ mass on one page, and $\varepsilon/(n-1)$ on each of the remaining pages, then the entropy is near zero, but this is essentially the same stochastic caching instance as before, but with a cache of size $k-1$, and with the $n-1$ pages of low probability in the original instance.

This motivates our definition of subset entropy for a distribution $\mathcal{D}$: it is the maximum, taken over all subsets in the support of a distribution $\mathcal{D}$, of the entropy of $\mathcal{D}$ conditioned to the subset. In the case of stochastic caching, we only need to consider subsets of size at most k in the support; we call this *k-subset entropy* and denote it $\mathscr{H}(\mathcal{D}, k)$, or $\mathscr{H}$ for short when $\mathcal{D}$ and k are clear from context. In Section 3, we show how to achieve competitive ratio $O(\mathscr{H})$ for every input distribution $\mathcal{D}$.[1]

▶ **Theorem 1** (Informal). *There is a caching algorithm that for a given distribution $\mathcal{D}$ and a sequence of page requests drawn i.i.d. from $\mathcal{D}$, achieves a competitive ratio of $O(\mathscr{H})$.*

Note that $\mathscr{H}$ is at most the worst case bound $O(\log k)$, but it is also much sharper for many distributions. In fact, we show in Section 2 that the only distributions for which $\mathscr{H} = \Theta(\log k)$ are those that are nearly uniform, namely those for which some subset of $\Omega(\text{poly}(k))$ pages have probabilities within a constant factor of each other. To our knowledge, the notion of subset entropy is novel and would be interesting to explore in other contexts as well. For example, does it encapsulate interesting information-theoretic properties of a distribution? We show one property in Section 2: informally, we show that it captures the cardinality of the largest (approximately) uniform distribution embedded in the overall distribution. A different question: is $\mathscr{H}$ (exactly) computable efficiently? We answer this in the affirmative in Appendix E, given explicit access to the distribution. We hope this new parameter will be studied from other angles in the future.

The algorithm we use to establish Theorem 1 is natural: since $\mathcal{D}$ is known, we keep the top k-1 pages by probability in cache permanently and use the last cache slot to serve all other requests;[2] we call this algorithm Top-k. Indeed, in an important work from 1971, Aho, Delling, and Ullman [2] showed that this is the *optimal* online caching strategy in the i.i.d. setting.[3] Though the algorithm is unsurprising, the analysis is new. We show that Top-k is $O(\mathscr{H})$-competitive against the *offline* optimum. This quantifies the precise role of randomness in the input sequence on the competitive ratio, namely the difference between knowing the input *distribution* versus the actual *realization* of the input sequence.

The previous Top-k algorithm requires knowing the input distribution (we call this the *known* i.i.d. setting). Now, we consider the *unknown* i.i.d. setting where the caching algorithm no longer has access to the input distribution. Intuitively, we would still like to keep the top k pages by probability in the cache. Ordering pages by decreasing probability is equivalent to ordering them by increasing expected length of the interval between consecutive requests. Since we do not have access to the expected interval lengths, we use as a surrogate the length

[1] There do exist distributions for which $\mathscr{H}$ is large and yet the distribution admits smaller competitive ratio. E.g., the uniform distribution with $n = 10k$ pages has $\mathscr{H} = O(\log k)$ but any algorithm is constant-competitive. To our knowledge this is true of most parameterized results, since it is rare to identify a parameter that guarantees *both* upper and lower bounds.

[2] For ease of analysis, we define the Top-k algorithm slightly differently from the optimal online strategy; see Section 3.

[3] In the stochastic setting, an optimal online solution is well-defined. It can be obtained from a Markov decision process via a dynamic program which, in general, can have an exponential-sized state space.

of the interval since the last request for every page – i.e., keep in cache the k most recently requested pages. This is none other than the well-known LRU algorithm, and our second result shows that it is $O(\mathscr{H}^3)$-competitive even in the unknown i.i.d. setting.

▶ **Theorem 2.** *When given a sequence of page requests drawn i.i.d. from an unknown distribution $\mathcal{D}$, the* LRU *caching algorithm achieves a competitive ratio of $O(\mathscr{H}^3)$.*

As intuition would predict, LRU approximately learns which pages in cache are most likely to be requested furthest in future and evicts these first. How well it does so depends on how predictable is this information, which in turn is captured by the subset entropy of $\mathcal{D}$. Since $\mathscr{H} = O(\log k)$, this also shows that LRU is $O(\log^3 k)$-competitive for unknown i.i.d. inputs. To our knowledge, this is the first analysis of LRU in a stochastic setting that yields an $o(k)$-competitive factor.

A more precise (although also not as lightweight) alternative to LRU is the *least-frequently used* (LFU) algorithm that always evicts the page with the least number of requests so far. Our third result shows that LFU is $O(\mathscr{H})$-competitive for i.i.d. inputs. This implies that up to constant factors, the known and unknown i.i.d. settings have the same competitive ratio.

▶ **Theorem 3.** *When given a sequence of page requests drawn i.i.d. from an unknown distribution $\mathcal{D}$, the LFU caching algorithm achieves a competitive ratio of $O(\mathscr{H})$.*

This theorem is not surprising in an asymptotic sense, since LFU eventually converges to the Top-k algorithm. But a priori, the rate of convergence could be arbitrarily slow depending on the difference between the probability values of pages requests. We show that the additive loss of the LFU algorithm vis-à-vis the Top-k algorithm is $O(k\mathscr{H})$, and is therefore absorbed in the multiplicative factor in Theorem 3.[4] In other words, LFU matches the performance of Top-k *even when it has not finished learning the input distribution.* We view this as an interesting insight into learning-augmented algorithms: it demonstrates the difference between statistically learning a distribution and learning it well enough to devise an effective algorithmic strategy.

1.2 Techniques and Overview

We start in Section 2 with our characterization of k-subset entropy in terms of the largest (up to size k) approximately uniform distribution embedded in $\mathcal{D}$. Indeed, by definition, any conditional distribution in $\mathcal{D}$ gives a lower bound on subset entropy. To show the converse, we use a factor-revealing LP to bound the maximum value of subset entropy when every approximately uniform distribution is size-constrained.

In Section 3, we show that the Top-k algorithm has a competitive ratio of $O(\mathscr{H})$, thereby establishing Theorem 1. The k pages with the largest values of p_i are permanently in the cache in the Top-k algorithm; we call them the *head* of the distribution and call the remaining pages the *tail*. The expected cost of the Top-k algorithm is immediate: it is the total probability in the tail, denoted $p(\mathbb{T})$. But how do we lower bound the expected cost of an offline optimal solution? The usual technique is to use dual fitting, i.e., write primal and dual LPs and then construct a feasible dual solution of sufficiently large value. Here, since the instance itself is random, so are the coefficients of the primal and dual LPs, and what we really have is a *distribution* over LPs. How do we argue about the expected value of the optimal solution of such a distribution? (Contrast this to randomized dual fitting [15] where the LPs are fixed but the primal and dual solutions are random.)

[4] k is required for all algorithms as an initialization cost from an empty cache.

We start by writing the "expected" primal-dual LPs whose coefficients are the expected values of the (random) coefficients over the distributions of the primal and dual LPs. For this LP, we construct a feasible dual solution of value $p(\mathbb{T})$ that satisfies these "expected constraints". Interestingly, this dual solution to the "expected" LP turns out to be quite different from those used in standard primal-dual analysis of caching algorithms (e.g., in [5]). However, we want the dual solution to be feasible for the actual realized constraints, not the expected constraints. Constraints for which the realized dual coefficients are "close" to their expected values (in a specific sense that we define later) are already approximately satisfied by the expected dual. The main challenge is to handle the "tail constraints", namely those that realize very differently from their expected form. These realizations can happen in many different ways and tracking their feasibility precisely is onerous. Instead, we carefully zero out dual variables to make sure that the tail constraints are also satisfied. This creates a distribution over dual solutions, since the set of tail constraints, and therefore, zeroed out variables, depends on the particular realization. Nevertheless, crucially, for each realized dual instance, the corresponding dual is *always* feasible. The key is to show that since each constraint is a tail constraint with small probability, we do not lose too much in the objective by zeroing out dual variables. In fact, we precisely lose a factor of $O(\mathscr{H})$. Hence this process gives a randomly defined dual solution that is deterministically feasible for the corresponding random instance, and the expected value of the dual objective over these random solutions is $\Omega\left(p(\mathbb{T})/\mathscr{H}\right)$.

In Section 4, we study the LRU algorithm and establish Theorem 2. Recall that LRU is an empirical implementation of the Top-k algorithm which evicts pages based on the *expected* length time between subsequent requests. Thus it is tempting to imagine that the ideal scenario for LRU is when the empirical length of a request interval exactly matches its expected value for every page. Unfortunately, this intuition is misleading. Consider a uniform input distribution $\mathcal{D}$ over $n = k + 1$ pages. If an instantiation creates a round-robin request sequence, then the empirical length of a request interval is exactly $k + 1$, i.e., its expected value. However, LRU is k-competitive for this input sequence! Therefore, we need to use the symmetry-breaking properties of a random sequence in our analysis. Suppose a page i is requested at time t. If page i is not in the cache at time t, then by the properties of LRU, page i is not among the last k distinct pages requested before time t. What is the probability of this event? By reversing time, this is the same as the probability that page i is not going to be among the next k distinct pages to be requested after time t. Now, define a random variable for every page denoting the time till the first request of the page. Although these times are dependent, to first approximation, we can imagine that each page i is running an independent Poisson process with rate p_i, i.e., we can approximate the length of the request intervals by exponential variables. Then, we use the properties of Poisson processes to bound the probability that at least k other processes fired before process i, eventually proving Theorem 2.

In Section 5, we study the LFU algorithm and prove Theorem 3. We note that LFU might suffer more cache misses than Top-k because of inversions in the ranked order of pages by empirical frequency counts vis-à-vis their true probabilities. We bound the effect of these inversions in two parts. First, we show that inversions due to pairs that have probabilities within (say) a factor of 2 only incur an expected cost $O(p(\mathbb{T}))$. It is crucial that these inversions do not cost us in the additive term because such inversions might persist for an arbitrarily long time (e.g., if two pages differ in probability by ε). It remains to bound the cost due to inversions where one page is twice as likely as the other. We show that after $O(\mathscr{H})$ requests for a page, its count will forever be higher (with good probability) than the count of any page with less than half its probability. This incurs an additive loss of $O(k\mathscr{H})$ on the pages in the head, which is ultimately absorbed in the multiplicative factor.

The Bigger Picture. Having discussed our technical results for stochastic caching, we now return to the broader perspective: obtaining finer-grained analyses for stochastic optimization problems. We argue that identifying a distributional quantity, such as entropy, and analyzing algorithms with respect to this quantity, offers a promising direction for beyond worst-case analysis in stochastic settings. Indeed, for many fundamental problems – such as comparison-based sorting, online matching, online load balancing, and related tasks – the hardest stochastic instances correspond to high-entropy (often uniform) distributions. Intuitively, this is consistent with the view that distributions with higher entropy are less informative than those with lower entropy. We view our work as a first step toward a theory, based in entropy and its variants, that provides a refined analysis of algorithmic performance across stochastic versions of this rich class of problems.

1.3 Related Work

In a classic paper, Belady [8] introduced the optimal "furthest in the future" rule for evicting pages from a cache in the offline setting. Soon after, stochastic versions of the online caching problem were considered and adaptations of Belady's rule to online distributional settings were proposed and analyzed [2, 18]. Over the next few decades, a rich array of input models were introduced for online caching; some highlights include the work of Lund et al. [26] and Pabbaraju and Vakilian [29], who obtained approximations against the best online strategy even in partial information settings, the Markov paging model of Karlin et al. [23], where the input sequence is a Markov chain, and the access graph setting of Borodin et al. [10] (see also [9, Ch. 5]), where the request sequence is generated by a simple walk on an "access graph" defined on the pages. Somewhat related to our work is that of Pandurangan and Upfal [31], who studied the relationship between the performance of the best online caching algorithm and the entropy of a request sequence generated by a stochastic process. In particular, they showed that entropy is not sufficient to capture the performance of online caching algorithms.

We note that many further variants of online caching have been proposed, e.g., when pages have non-uniform weights [4, 21, 37], non-uniform sizes [3, 5, 22], as well as non-standard caching models such as elastic caches [19], caching with time windows [20], and caching with dynamic weights [16], interleaved caching [25], and caching with machine learning predictions [27, 6]. In contrast to the i.i.d. setting that we study in this paper, many models try to capture *locality of reference*, i.e., the phenomenon that pages requested recently tend to be re-requested [24, 36, 7, 30]. The validity of locality of reference varies by application domain, e.g., is more applicable for centralized settings like operating systems on computing devices compared to distributed and resource-shared settings like data centers where the requests come from a large number of independent processes. Nevertheless, we view the extensive literature on stochastic paging – including our work – and that on models capturing locality of reference as complementary, since they capture different aspects of a fundamental problem. Indeed, this complementarity can sometimes be leveraged to obtain richer models that try to incorporate both phenomenon, such as Markov paging [23].

In our work, the input model is the classic i.i.d. setting, but we are interested in characterizing input distributions that are amenable to caching and obtaining better-than-worst-case bounds for such inputs. In this sense, it aligns with the recent focus on "beyond worst-case" algorithm design, and in particular, with the emerging field of learning-augmented algorithms, e.g., [1]. The main difference is that while the typical goal in the latter context is to use additional information about the input and automatically adapt the performance bounds to the *quality* of this information, our goal is to adapt performance bounds to the quality of the input distribution itself without using additional information about the input. We point the reader to an excellent survey of "beyond worst-case" caching models in [32, Ch. 24] for a detailed discussion of related models.

2 Problem Definition and Background

2.1 The Stochastic Caching Problem

There is a universe of n pages indexed $[n] = \{1, \ldots, n\}$, a cache of size $k \le n$, a request sequence of length T indexed by $[T]$, and a distribution $\mathcal{D}$ on $[n]$. At each time $t \in [T]$, the algorithm gets a page request $r_t \in [n]$, where r_t is drawn independently from $\mathcal{D}$. The algorithm maintains at most k pages in the cache at all times with the constraint that page r_t must be in the cache at time t. Swapping in/out a page in the cache incurs unit cost; the goal is to minimize the total cost, i.e., the number of page swaps. We call this the *stochastic caching* problem.

The distribution $\mathcal{D}$ is defined by probabilities $p_1, \ldots, p_n$, where $p_i > 0$ is the probability that page $i \in [n]$ is requested at any given time. Clearly, $\sum_i p_i = 1$. We also denote $p(S) = \sum_{i \in S} p_i$ for a subset $S \subseteq [n]$. Wlog, we index pages in decreasing order of probabilities, i.e., $p_1 \ge p_2 \ge \cdots \ge p_n$, breaking ties arbitrarily. The top k pages are called the *head* of the distribution $\mathcal{D}$ and denoted $\mathbb{H} := [k]$; the remaining pages $\mathbb{T} := [n] \setminus [k]$ comprise the *tail* of the distribution. The total probability mass in the tail is denoted $p(\mathbb{T}) := \sum_{i=k+1}^{n} p_i = 1 - p(\mathbb{H})$. In this paper, we consider two cases: when $\mathcal{D}$ is *known* and when $\mathcal{D}$ is *unknown* to the algorithm.

2.2 Subset Entropy

For a distribution $\mathcal{D}$ with support U and for a subset $S \subseteq U$, let $\mathcal{D}_S$ denote the distribution $\mathcal{D}$ conditioned on S, i.e., $\mathcal{D}_S(u) = \frac{\mathcal{D}(u)}{\sum_{u \in S} \mathcal{D}(u)}$ for $u \in S$. Let $\mathrm{H}(\cdot)$ denote the *Shannon entropy* function: $\mathrm{H}(\mathcal{D}_S) := -\sum_{u \in S} \mathcal{D}_S(u) \cdot \log \mathcal{D}_S(u)$. (All logarithms throughout the paper are base 2 unless otherwise stated.)

We define *k-subset entropy* of a distribution $\mathcal{D}$ as follows:

▶ **Definition 4** (k-Subset Entropy)**.** For a discrete distribution $\mathcal{D} : U \to [0, 1]$ and any positive integer $k \le |U|$, the *k-subset entropy* of $\mathcal{D}$ is defined as the following:

$$\mathscr{H}(\mathcal{D}, k) = \max_{S \subseteq U : |S| \le k} \mathrm{H}(\mathcal{D}_S). \tag{2.1}$$

While k-subset entropy suffices in the context of caching, an interesting information-theoretic counterpart is the unrestricted version that maximizes entropy of conditional distributions over *all* subsets of U. We call this *subset entropy*, and it is the special case of k-subset entropy when $k = n$.

Next, we prove an important fact about k-subset entropy, which we rely on in the rest of the paper.

▶ **Lemma 5** (k-Subset Entropy Lemma)**.** *Suppose we have a distribution $\mathcal{D} : U \to [0, 1]$. Let $S_\ell = \{u \in U : 1/2^{\ell+1} < \mathcal{D}(u) \le 1/2^{\ell}\}$ for any $\ell \ge 1$ and let $n_{\max} := \max_\ell |S_\ell|$. Then,*

$$\mathscr{H}(\mathcal{D}, k) = \Theta(\log(\min\{k, n_{\max}\})).$$

One direction is immediate: clearly $\mathscr{H}(\mathcal{D}, k) \ge \log(\min(k, n_{\max}))$ since the set S in the definition (2.1) could be chosen as (a subset of size $\le k$ of) the S_ℓ for which $n_{\max} = |S_\ell|$, and by the definition of Shannon entropy, $H(D_{S_\ell}) = \Theta(\log |S_\ell|)$. Surprisingly, the converse holds: if $\mathscr{H}(\mathcal{D}, k) = h$, then there is a set $S \subseteq U, |S| \ge 2^{\Theta(h)}$, over which the conditional distribution $\mathcal{D}_S$ is uniform up to constants. Intuitively, this means that the k-subset entropy of a distribution is dictated by the largest (up to k) approximately uniform distribution

embedded in it. The proof (Appendix A) is via dual fitting of a factor revealing LP: we show that even if we ignore the original distribution $\mathcal{D}$ and choose the probabilities of the pages in the maximizing set S completely freely, if we are constrained to choosing at most $n_{\max}$ pages within a factor 2 of each other, we cannot give S a conditional entropy greater than $O(\log n_{\max})$.

In Appendix E, we also show that the maximizing set in the Definition (2.1) is always a subinterval of U, when arranged in sorted order of probabilities. This gives an efficient algorithm for computing k-subset entropy *exactly*. Nevertheless, the approximate characterization above is convenient to work with in our applications.

We use henceforth the shorthand $\mathscr{H}$ to denote the k-subset entropy $\mathscr{H}(\mathcal{D}, k)$, since it is implicit that the distribution $\mathcal{D}$ is the input distribution and the parameter k is the cache size.

3 Stochastic Caching for a Known Distribution

We begin with the known distribution setting. Recall our simple algorithm Top-k: keep the pages of the head $\mathbb{H}$ in cache; when a page from the tail $\mathbb{T}$ is requested, swap out an arbitrary page in cache for the requested page, then immediately swap the same page back. The main result of this section, which establishes Theorem 1, is the following:

▶ **Theorem 6.** *The competitive ratio of the algorithm* Top-k *for the stochastic caching problem for input distribution $\mathcal{D}$ is $O(\mathscr{H})$.*

To establish Theorem 6, we first bound the expected cost of the Top-k algorithm.

▶ **Lemma 7.** *The expected cost of the* Top-k *algorithm for each request is $2p(\mathbb{T})$.*

Proof. For each request, the probability that the requested page is not in the cache is exactly $p(\mathbb{T})$, in which case the algorithm performs two evictions. ◀

The harder challenge is to lower bound the expected cost of an offline optimal solution. To this end, we fit a dual to the LP relaxation of the knapsack-cover (or KC) integer programming formulation for caching (see, e.g., [5])[5]. As noted in the introduction, while focusing on LP duality is a reasonable instinct, the main challenge is that the LP is defined via a distribution over coefficients, i.e., both the primal and dual LPs are random. We have to produce a feasible dual solution for *every* realization of the random instance, and then bound the expected objective value across the realizations.

Fortunately, since we are in an i.i.d. setting, the distribution over dual constraints that apply at any given time t is time-invariant, i.e., is independent of t. We view this distribution over dual constraints in two parts – the set of constraints that apply within a high probability interval, and the remaining constraints that are in the tail of the distribution. For the former, we set dual variables corresponding to the "expected" constraints and these are approximately feasible. For the latter, there are a large number of possibilities and it is onerous to track feasibility across all these realizations. Instead, we carefully zero out a subset of dual variables to ensure feasibility for the constraints in the tail of the distribution. Of course, the set of dual constraints that fall in the tail region is random, and therefore the set of zeroed out variables is also random. Nevertheless, we show that since a constraint

[5] Note that our choice of the KC inequality strengthened formulation is for convenience; it is not strictly necessary because the standard LP formulation is already integral.

is in the tail with low probability (by standard concentration inequalities), this last step of zeroing out variables to ensure feasibility has limited impact on the expected value of the dual objective.

▶ **Lemma 8.** *The expected cost of an offline optimal solution is* $\Omega\left(\frac{p(\mathbb{T})}{\mathscr{H}}\right)$.

Proof Sketch. Let $x(i,r)$ be the indicator variable for the event that page i is evicted in the time interval $I(i,r) := [t(i,r)+1, t(i,r+1)-1]$, where $t(i,r)$ is the time of the rth request to page i. Let $\rho(i,t)$ be the number of requests to page i up to and including time t. Consider the formulation:

$\min \sum_{i=1}^{n} \sum_{r=1}^{\rho(i,T)} x(i,r)$	subject to
$\sum_{i \in S \setminus \{r_t\}} x(i, \rho(i,t)) \geq \lvert S \rvert - k$	$\forall t \in [T]$ $\forall S \subseteq [n]$
$x(i,r) \geq 0$	$\forall i \in [n]$ $\forall r \in [\rho(i,T)]$

$\max \sum_{t=1}^{T} \sum_{S \subseteq [n]} (\lvert S \rvert - k) \cdot y_S^t$	subject to
$\sum_{t \in I(i,r)} \sum_{S: i \in S} y_S^t \leq 1$	$\forall i \in [n]$ $\forall r \in [\rho(i,T)]$
$y_S^t \geq 0$	$\forall t \in [T]$ $\forall S \subseteq [n]$

This formulation is standard, but our dual fitting is not (see [5] for the usual way the online dual is fit using multiplicative weights). We start by finding a stationary solution to the *expected* dual, i.e., find a vector y that is the same for each $t \in [T]$, such that the expected dual constraint is satisfied.

Intuitively, we should expect every time t to lie in an interval of length $1/p_i$ between subsequent requests to page i, and hence these expected constraints would ask that there be less than 1 total y mass on page subsets containing i on these intervals, i.e., that there be less than p_i mass on these subsets per time step t. Define

$$y_S^t = \begin{cases} p_i - p_{i+1} & \text{if } S = [i] \text{ and } i \in \mathbb{T} \setminus \{n\}, \\ p_n & \text{if } S = [n], \\ 0 & \text{otherwise.} \end{cases}$$

Then, by design, for all $i \in \mathbb{T}$ we have $\sum_{S: i \in S} y_S^t = \sum_{j=i}^{n-1} (p_j - p_{j+1}) + p_n = p_i$, as desired. For the remaining $i \in \mathbb{H}$, we have $\sum_{S: i \in S} y_S^t = \sum_{j=k+1}^{n-1} (p_j - p_{j+1}) + p_n = p_{k+1} \leq p_i$, Furthermore, the dual objective (per time step) is $\sum_S (\lvert S \rvert - k) \cdot y_S^t = n \cdot p_n + \sum_{j=1}^{n} j \cdot (p_j - p_{j+1}) = \sum_{i \in \mathbb{T}} p_i$.

However, this is too good to be true! If this were a legal dual solution, weak duality would imply that Top-k in fact achieves competitive ratio $O(1)$, which we know is impossible, as demonstrated by the uniform distribution case. Indeed, for the dual to witness a true lower bound on the primal program, it must be feasible with probability 1, and our stationary solution, as described, might violate dual constraints corresponding to intervals that happen to be longer than their expectation.

To construct our actual dual, we start with the stationary y described above. We then show how to carefully drop some coordinates to account for the random fluctuation in interval lengths. Since the dual is a packing problem, we can always make a solution feasible this way. The crux is to do this while approximately preserving the objective value. In Appendix B, we give the details of our modified dual construction and show that we only lose an $O(\mathscr{H})$ factor in the objective. ◀

4 The LRU Algorithm

In this section, we analyze the popular *least recently used* (LRU) algorithm for stochastic caching. Note that LRU does not use distributional information, and hence can be used in the unknown distribution setting. Our main result is:

▶ **Theorem 9.** *The* LRU *algorithm has a competitive ratio* $O(\mathscr{H}^3)$ *for the stochastic caching problem.*

We now provide the main ideas needed for proving this and defer the technical claims to Appendix C. We saw in Section 3 that the expected cost of an offline optimal solution is $\Omega\left(\frac{p(\mathbb{T})}{\mathscr{H}}\right)$. Hence, it suffices to bound the expected cost of LRU as $O(\mathscr{H}^2 \cdot p(\mathbb{T}))$. Note that LRU has a cache miss when the requested page is not among the last k distinct pages requested. Thus, for any page i, the probability that i incurs a cache miss (at any point of time) is the same as that of page i not being among the first k distinct pages requested in a sequence of pages drawn from $\mathcal{D}$. We denote this probability q_i for page i. With this notation, the expected cost of the LRU algorithm for any request is $\sum_{i\in[n]} p_i q_i$. Our goal from here on is to show

$$\sum_{i\in[n]} p_i q_i \le O(\mathscr{H}^2 \cdot p(\mathbb{T})). \tag{4.2}$$

Before we begin, note that when $p(\mathbb{T}) > 1/2$, any algorithm, even one that incurs a cache miss at every time step, has cost $O(p(\mathbb{T}))$. Thus, we can assume without loss of generality that:

▶ **Assumption 10.** *The tail has total probability* $p(\mathbb{T}) \le 1/2$.

Note that the contribution of the tail to the LHS of (4.2) is easy to handle, since the q_i's are probabilities.

▶ **Observation 11** (Bounding $\mathbb{T}$)**.** *The contribution of* $\mathbb{T}$ *is bounded as* $\sum_{i\in\mathbb{T}} p_i q_i \le p(\mathbb{T})$.

This leaves us with the task of bounding the contribution of the head $\mathbb{H}$ to the LHS of (4.2).

4.1 Probability Levels

We first group the pages in the head $\mathbb{H}$ into doubling intervals by probability values p_i. In particular, for $\ell \ge 0$, we use L_ℓ to denote the set of all pages i with $p_i \in [1/2^{\ell+1}, 1/2^\ell)$; we say that the pages in p_ℓ are at level ℓ and denote $|L_\ell| = n_\ell$. Furthermore, we say that ℓ is a *dominant level* if $\sum_{i\in L_\ell} p_i > 1/2$; else, ℓ is a *non-dominant level*. Note that there is either no dominant level or a single unique dominant level.

Let X_ℓ be the random variable denoting the number of pages in L_ℓ that do not appear among the first k distinct pages in any particular sequence of page requests. Let M_ℓ be the multiset of page requests up to and including the first time all the pages in L_ℓ are requested. We denote $Y_\ell = |M_\ell|$ and Z_ℓ to be the number of page requests from M_ℓ to pages in $\mathbb{T}$.

We need certain structural properties of these random variables.

▶ **Lemma 12.** *The following three properties hold for* X_ℓ, Y_ℓ, *and* Z_ℓ*:*

(i) *For any level* ℓ *with* $n_\ell > 0$,

$$\sum_{i\in L_\ell} p_i q_i \le \frac{1}{2^\ell} \cdot \sum_{i\in L_\ell} q_i = \frac{1}{2^\ell} \cdot \mathbb{E}[X_\ell]. \tag{4.3}$$

(ii) *Let ℓ be a level with $n_\ell > 0$, and let H_{n_ℓ} denote the n_ℓth Harmonic number. Then,*

$$\mathbb{E}[Y_\ell] \le 2^{\ell+1} \cdot H_{n_\ell}. \tag{4.4}$$

(iii) *Suppose ℓ is a non-dominant level. Then, we have*

$$\Pr[Z_\ell \ge t] \le \begin{cases} 2 \cdot p(\mathbb{T}) \cdot 2^{\ell+1} \cdot \mathscr{H} & \text{for } t = 1, \quad (4.5) \\ \left(2e^2 \cdot p(\mathbb{T}) \cdot 2^{\ell+1} \cdot \mathscr{H}\right)^t & \text{for } t \ge 2. \quad (4.6) \end{cases}$$

Next, using these properties, we bound the total contribution of any single level L_ℓ to $\sum_i p_i q_i$ (i.e., to the LHS in (4.2)):

▷ Claim 13. For any level ℓ, we have $\sum_{i \in L_\ell} p_i q_i \le 4\mathscr{H} \cdot p(\mathbb{T})$.

Proof. By (4.3), $\sum_{i \in L_\ell} p_i q_i \le \frac{\mathbb{E}[X_\ell]}{2^\ell} \le \frac{\mathbb{E}[Z_\ell]}{2^\ell}$ since $X_\ell \le Z_\ell$ for any level ℓ.

So, it suffices to bound $\mathbb{E}[Z_\ell]$. Recall that M_ℓ denotes the sequence of requests until all pages in L_ℓ are requested. Color every request in M_ℓ red, blue, or green depending on whether it is for a page in $\mathbb{T}$, for a page in $\mathbb{H}$ but not in L_ℓ, and for a page in L_ℓ, respectively. Variable Z_ℓ counts the number of red requests in M_ℓ.

Let N denote the number of green requests in M_ℓ and let Γ_i, for $i \ge 1$, be the number of red requests between the $(i-1)$st and ith green request. Note that the random variables Γ_i are independent and identically distributed; let Γ denote the common distribution. Furthermore, N is independent of the sequence $\Gamma_1, \Gamma_2, \ldots$. Therefore, by Wald's identity we have

$$\mathbb{E}[Z_\ell] = \sum_i \mathbb{E}[\Gamma_i] = \mathbb{E}[\Gamma] \cdot \mathbb{E}[N]. \tag{4.7}$$

We bound the two terms in the RHS of (4.7) separately. For $\mathbb{E}[N]$, we use standard coupon collector bounds since the probabilities of pages in level ℓ are uniform up to a factor of 2: $\mathbb{E}[N] \le 2n_\ell H_{n_\ell} \le 2n_\ell \cdot \mathscr{H}$.

To bound $\mathbb{E}[\Gamma]$, note that Γ denotes the number of red requests before the first green request. Denote $p(\ell) := \sum_{i \in L_\ell} p_i$ as the probability of a green request and recall that $p(\mathbb{T})$ is the probability of a red request. Then, $\mathbb{E}[\Gamma] = \left(\frac{p(\ell)}{p(\ell)+p(\mathbb{T})}\right)^{-1} - 1 = \frac{p(\mathbb{T})}{p(\ell)} \le \frac{p(\mathbb{T})}{n_\ell \cdot 2^{-(\ell+1)}}$.

Therefore, by (4.7), $\mathbb{E}[Z_\ell] = \mathbb{E}[\Gamma] \cdot \mathbb{E}[N] < \frac{p(\mathbb{T})}{n_\ell \cdot 2^{-(\ell+1)}} \cdot 2n_\ell \cdot \mathscr{H} = 4\mathscr{H} \cdot p(\mathbb{T}) \cdot 2^\ell$, thus yielding the claim. ◀

The above bound is sufficiently tight for levels ℓ where the probabilities p_i are comparable to (or smaller than) the value of the tail probability $p(\mathbb{T})$. However, in higher levels with larger probabilities, the above bound is quite loose and we need a stronger guarantee.

Let r_1 be the largest index i such that $p_i \ge 4e^2 \cdot \mathscr{H} \cdot p(\mathbb{T})$ and let ℓ_1 be the level that contains page p_{r_1}. Roughly speaking, our tighter bound for levels $\ell < \ell_1$ geometrically shrinks as we go to levels with larger probabilities; this will later allow us to add these bounds across levels in a lossless manner.

▷ Claim 14. For any non-dominant level $\ell < \ell_1$, we have $\sum_{i \in L_\ell} p_i q_i \le \frac{80\mathscr{H}^2 \cdot p(\mathbb{T})}{2^{\ell_1 - \ell}}$.

Proof Sketch. Since $X_\ell \le Z_\ell$, we get from Lemma 12*(i)* that

$$\sum_{i \in L_\ell} p_i q_i \le \frac{1}{2^\ell} \cdot \mathbb{E}[X_\ell] \le \Pr[X_\ell = 1 \mid Z_\ell = 1] \cdot \Pr[Z_\ell \ge 1] + \sum_{t \ge 2} \Pr[Z_\ell \ge t], \tag{4.8}$$

where we split between $X_\ell = 1$ and $X_\ell \ge 2$, and replaced X_ℓ with Z_ℓ. We bound $\sum_{t \ge 2} \Pr[Z_\ell \ge t]$ and $\Pr[Z_\ell \ge 1]$ using Lemma 12 *(iii)*. The interesting part is to bound $\Pr[X_\ell = 1 \mid Z_\ell = 1]$.

Note that since $Z_\ell = 1$, there is only one request from $\mathbb{T}$ before all pages in level ℓ are requested. Therefore, a necessary event for $X_\ell = 1 \wedge Z_\ell = 1$ is that the last page requested in $\mathbb{H}$ must be from level ℓ; in particular, page r_1 (in level $\ell_1 > \ell$) is requested before some page in L_ℓ. Let $\mathcal{E}$ denote this event; we bound

$$\Pr[X_\ell = 1 \mid Z_\ell = 1] \le \Pr[\mathcal{E} \mid Z_\ell = 1] = \sum_{t \ge 1} \Pr[\mathcal{E} \mid Z_\ell = 1, Y_\ell = t] \cdot \Pr[Y_\ell = t]. \tag{4.9}$$

Consider any fixed number of requests, say t. The conditional probability of any page in the head $\mathbb{H}$ increases when we decrease the number of requests for pages in the tail $\mathbb{T}$ among these t requests. Therefore,

$$\Pr[\mathcal{E} \mid Z_\ell = 1, Y_\ell = t] \le \Pr[\mathcal{E} \mid Z_\ell = 0, Y_\ell = t] = \frac{1/2^{\ell_1}}{1 - p(\mathbb{T})} \cdot t \le \frac{t}{2^{\ell_1 - 1}}, \text{ since } p(\mathbb{T}) < 1/2.$$

Here, we used that given $Z_\ell = 0$, the probability that any request is for page r_1 is $\frac{1/2^{\ell_1}}{1-p(\mathbb{T})}$. The claim can now be established by putting together the bounds we have obtained in (4.8). ◁

4.2 Splitting the Head

We have established bounds on the contribution of individual levels to $\sum_i p_i q_i$. We are now ready to put these together to bound the total contribution of the head $\mathbb{H}$. To do this, we subdivide the head $\mathbb{H} = [k]$ into three intervals $\mathbb{H}_1 := [1, r_1]$, $\mathbb{H}_2 = [r_1 + 1, r_2]$, and $\mathbb{H}_3 := [r_2 + 1, k]$ as follows: we define r_1 to be the largest index i such that $p_i \ge 4e^2 \mathscr{H} \cdot p(\mathbb{T})$ (this is the same definition of r_1 that we used to define the level ℓ_1), and r_2 to be the largest index i such that $p_i \ge p(\mathbb{T})/2^{\mathscr{H}}$. We will separately bound the contribution of each of these intervals to $\sum_{i=1}^{k} p_i q_i$.

▶ **Lemma 15** (Bounding $\mathbb{H}_1$). *The contribution of $\mathbb{H}_1$ is bounded as $\sum_{i \in \mathbb{H}_1} p_i q_i \le 88 \mathscr{H}^2 \cdot p(\mathbb{T})$.*

Proof Sketch. This follows by using Claim 13 for a dominant level, if it exists, and level ℓ_1, the last level in $\mathbb{H}_1$, and using Claim 14 for the remaining levels. ◀

▶ **Lemma 16** (Bounding $\mathbb{H}_2$). *The contribution of $\mathbb{H}_2$ is bounded as $\sum_{i \in \mathbb{H}_2} p_i q_i \le 12 \mathscr{H}^2 \cdot p(\mathbb{T})$.*

Proof. By construction, the number of levels in $\mathbb{H}_2$ is at most $\log(4e^2 \mathscr{H} \cdot 2^{\mathscr{H}}) \le 6\mathscr{H}$. The claim now follows from Claim 13. ◀

▶ **Lemma 17** (Bounding $\mathbb{H}_3$). *The contribution of $\mathbb{H}_3$ is bounded as $\sum_{i \in \mathbb{H}_3} p_i q_i \le 4p(\mathbb{T})$.*

Proof Sketch. To bound the contribution of $\mathbb{H}_3$, we note that $q_i \le 1$ for all pages i and $\sum_{i \in L_\ell} p_i$ for any level ℓ is at most $n_\ell \cdot \frac{1}{2^\ell} \le 2^{\mathscr{H}} \cdot \frac{1}{2^\ell}$ by Lemma 5. The lemma now follows by adding over all levels in $\mathbb{H}_3$ and using $p_i \le p(\mathbb{T})/2^{\mathscr{H}}$ for any page $i \in \mathbb{H}_3$. ◀

We conclude with the proof of the main theorem.

Proof of Theorem 9. By adding up the bounds from Observation 11 and Lemmas 15–17, we get

$$\sum_{i \in [n]} p_i q_i \le (100\mathscr{H}^2 + 5) \cdot p(\mathbb{T}) = O(\mathscr{H}^2 p(\mathbb{T})).$$

By Lemma 8, this implies that LRU is $O(\mathscr{H}^3)$-competitive for stochastic caching. ◀

5 The LFU Algorithm

In this section, we analyze the Least Frequently Used (LFU) algorithm for stochastic caching. Recall that in LFU, we maintain a count for every page of the number of times that page was requested, and we keep in cache the k pages with the highest count. When a page outside of cache is requested, we evict the lowest count page in order to serve the request, then revert back to the k pages with highest count if necessary. Clearly, in the limit, the empirical count distribution will converge to the true distribution, and LFU will eventually behave identically to Top-k. However, the "burn-in" period until convergence could be arbitrarily long as a function of n; e.g., if $p_k - p_{k+1} = \epsilon$, then to even distinguish these two pages with probability δ requires $\Omega(\log(1/\delta)/\epsilon^2)$ samples (e.g., [14]).

Despite this, we show that LFU achieves an additive loss of $O(\mathscr{H} \cdot k)$ in addition to the $O(p(\mathbb{T}))$ cost paid by Top-k. Since k is incurred as an initialization cost for any algorithm, we show:

▶ **Theorem 18.** *The* LFU *algorithm has a competitive ratio $O(\mathscr{H})$ for the stochastic caching problem.*

The general proof idea is to show that every page in $\mathbb{H}$ (i.e., top k) might be requested while it is outside of cache many times, but that after $O(\mathscr{H})$ such cache misses, its count will forever be higher (from that point on, with good probability) than the count of any page with less than half its probability. If this is the case, we can charge any cache miss due to a request to $\mathbb{T}$ to $T \cdot p(\mathbb{T})$. Each of the k pages in $\mathbb{H}$ will only miss $O(\mathscr{H})$ times before the only pages displacing it from cache are ones with very similar probability, and hence distinguishing between these does not matter; the total contribution from these pages in $\mathbb{H}$ is $O(k\mathscr{H} + T \cdot p(\mathbb{T}))$. Below, we formalize this argument.

Proof. Define a parameter $\gamma = 16 \log(\min(k, n_{\max})) = O(\mathscr{H})$. For every $i \in \mathbb{H}$ and $j \in [n]$ such that $p_j \le p_i/2$, define $\mathcal{E}_{ij}$ to be the bad event that if the first time t that the empirical count of i is at least γ, there is at least one time $t' \ge t$ such that the empirical count of j exceeds the count of i. We show that $\mathcal{E}_{ij}$ is extremely unlikely for well separated p_i and p_j.

▷ Claim 19. For all $i \in \mathbb{H}$, $j \in [n]$ such that $p_j \le p_i/2^h$ for some $h \ge 1$, we have $\Pr[\mathcal{E}_{ij}] \le 2^{-h\gamma/8}$.

The proof uses standard facts and we leave it to Appendix D. The last claim only gets easier if instead of considering a single page j with $p_j \le p_i/2^h$, we consider a group of pages whose cumulative probability is at most $p_i/2^h$, and ask what are the odds that any of these pages pass i in count. (Since, even as we grouped these pages, their total count would still not exceed that of i with the same probability as before.)

▶ **Corollary 20.** *For all $i \in \mathbb{H}$ and any subset $S \subseteq [n]$ such that $\sum_{j \in S} p_j \le p_i/2^h$ for some $h \ge 1$, we have $\Pr[\bigcup_{j \in S} \mathcal{E}_{ij}] \le 2^{-h\gamma/8}$.*

For every $i \in \mathbb{H}$, let R_i be the number of requests to page i until the count of i never goes below that of any page j with $p_j \le p_i/2$. Using Claim 19 and Corollary 20, we can show that the expected number of requests until we achieve this count separation can be upper bounded.

▷ Claim 21. For every $i \in \mathbb{H} \setminus D$ for some set D such that $\sum_{i \in D} p_i = 2p(\mathbb{T})$, we have $\mathbb{E}[R_i] \le 2\gamma$.

Note that if we had set $\gamma = \Theta(\log n)$, we could guarantee by a union bound over all pairs of pages i and j that every page $i \in \mathbb{H}$ sees at most γ requests before no page j with $p_j \le p_i/2$ ever has count higher than i (with high probability). However, we can get away with smaller γ using a more careful analysis, which we again defer to Appendix D. We now show how to conclude the proof.

Let S_t be the subset of pages i in $\mathbb{H}$ that are both outside of cache at time t and that have been requested at least R_i times by time t. In other words, these are the pages $i \in \mathbb{H}$ outside of cache at time t such that no page j with $p_j \le p_i/2$ will have a count exceeding that of page i after time t. Define an arbitrary perfect matching M between the pages of S_t and a subset of the pages from $\mathbb{T}$ in cache at time t. If page $i \in S_t$ is matched to page $M(i)$, then $p_{M(i)} \ge p_i/2$, since the count of $M(i)$ must be higher than that of i, and $i \in S_t$.

Let C^t be the k pages with highest counts at time t. Then we can write the total cost of the LFU algorithm as

$$\begin{aligned}
\sum_t \sum_{i=1}^{n} p_i \Pr\left[i \notin C^t\right] &\le \sum_t \sum_{i \notin S_t} p_i \Pr\left[i \notin C^t\right] + \sum_t \sum_{i \in S_t} p_i \Pr\left[i \notin C^t\right] + \sum_t p(\mathbb{T}) \\
&\le 2T \cdot p(\mathbb{T}) + \sum_{i \in \mathbb{H}} \mathbb{E}[R_i] + \sum_t \sum_{i \in S_t} p_i \Pr\left[i \notin C^t\right] + T \cdot p(\mathbb{T}) && (5.10) \\
&\le 2\gamma \cdot k + 2 \cdot \sum_t \sum_{i \in S_t} p_{M(i)} + 3T \cdot p(\mathbb{T}) && (5.11) \\
&\le 2\gamma \cdot k + 5T \cdot p(\mathbb{T}). && (5.12)
\end{aligned}$$

Step (5.10) follows because the expected number of misses for each page $i \in \mathbb{H}$ until it belongs to S_t is $\mathbb{E}[R_i]$, step (5.11) follows by Claim 21 and since $p_i \le 2p_{M(i)}$, and step (5.12) follows since the matched pages in cache form a subset of $\mathbb{T}$, and hence their total probability is less than $p(\mathbb{T})$. ◀

6 Closing Remarks

In this work, we study the stochastic caching problem as a way to move beyond worst-case competitive ratio analysis for online algorithms. We give new evidence for the effectiveness of the popular LRU and LFU caching policies, by showing that for many distributions, they incur approximation factors significantly better than classical bounds predict. En route, we identify subset entropy as an important parameter of the distribution governing the achievable competitive ratio of stochastic caching; this information-theoretic quantity might be of independent interest.

There are several avenues for future work. The first obvious direction is to either improve the competitive ratio of LRU from $O(\mathscr{H}^3)$ to $O(\mathscr{H})$, or show that this is not possible. In Appendix F, we show that there are distributions for which the cost of LRU is $\Omega(\mathscr{H} \cdot p(\mathbb{T}))$, meaning that our techniques can at best prove an $O(\mathscr{H}^2)$ bound.

Another direction is to generalize the result to more complex stochastic models, e.g., the Markov paging model [23] (this would entail developing an analogous quantity to subset entropy). Going beyond caching, we often prove lower bounds for randomized online algorithms by exhibiting pathological input distributions. Parameterizing what makes these distributions difficult and, more generally, understanding and quantifying the performance of an online algorithm through a fine-grained measure such as subset entropy are promising directions of future research.

A Missing Proofs from Section 2

Proof of Lemma 5. Note that for every ℓ, the distribution $\mathcal{D}_{S_\ell}$ is uniform up to a factor of 2 (i.e., the maximum probability is at most twice the minimum probability). As noted, the Shannon entropy of such a distribution is $\Theta(\log n_\ell)$, where n_ℓ is the size of its support. We choose S as follows: if $n_{\max} \le k$, then $S = \arg\max_\ell |S_\ell|$ and hence $|S| = n_{\max}$; else, S is any k-sized subset of $\arg\max_\ell |S_\ell|$ and hence $|S| = k$. Then, we get

$$\mathscr{H}(\mathcal{D}, k) \ge \mathrm{H}(\mathcal{D}_S) = \Omega(\log |S|) = \Omega(\log(\min\{k, n_{\max}\})).$$

We now show the other direction, by proving that for any distribution $\mathcal{D}'$ with $\max_\ell |\{u \in U : 1/2^{\ell+1} < \mathcal{D}'(u) \le 1/2^\ell)\}| \le N$, we have that $H(\mathcal{D}') \le O(\log N))$. Note that $N \le \min\{2n_{\max}, k\}$ for $\mathcal{D}_S$, where $S \subseteq [n]$ is any subset of cardinality at most k, since pages in S whose probabilities in $\mathcal{D}_S$ differ by at most a factor of two can come from at most two adjacent levels of the original distribution $\mathcal{D}$.

Letting $S'_\ell := \{u : 1/2^{\ell+1} < \mathcal{D}'(u) \le 1/2^\ell\}$, we have,

$$\mathrm{H}(\mathcal{D}') = -\sum_u \mathcal{D}'(u) \cdot \log \mathcal{D}'(u) = -\sum_\ell \sum_{u \in S'_\ell} \mathcal{D}'(u) \cdot \log \mathcal{D}'(u).$$

Now, for any $u \in S'_\ell$, we have $\mathcal{D}'(u) \le 1/2^\ell$ and $-\log \mathcal{D}'(u) = \log 1/\mathcal{D}'(u) < \log 2^{\ell+1} = \ell + 1$.

Therefore, $\mathrm{H}(\mathcal{D}') \le \sum_\ell n_\ell \cdot \frac{\ell+1}{2^\ell}$. where $n_\ell := |S'_\ell|$.

To bound the RHS of this inequality, we use a factor-revealing LP. We note that $\mathrm{H}(\mathcal{D}')$ is at most the optimal primal objective in the following LP:

$$\text{maximize } \sum_{\ell \geq 1} n_\ell \cdot \frac{\ell+1}{2^\ell} \text{ subject to } \sum_{\ell} \frac{n_\ell}{2^\ell} \leq 1 \text{ and } \{n_\ell \leq N\}_{\forall \ell}.$$

The dual LP is

$$\text{minimize } \alpha + N \sum_{\ell} \beta_\ell, \text{ subject to } \left\{ \frac{\alpha}{2^\ell} + \beta_\ell \geq \frac{\ell+1}{2^\ell} \right\}_{\forall \ell}.$$

Now, a feasible dual solution is given by:

$$\alpha = \log N \qquad \beta_\ell = \begin{cases} \frac{\ell+1}{2^\ell} & \text{if } \ell > \log N - 1 \\ 0 & \text{if } \ell \leq \log N - 1. \end{cases}$$

The dual objective for this solution is $O(\log N) = O(\log(\min\{k, n_{\max}\}))$. Therefore, $\mathscr{H}(\mathcal{D}, k) = \mathrm{H}(\mathcal{D}_S) \leq O(\log(\min\{k, n_{\max}\})) = O(\log(\min\{k, \max_\ell |S_\ell|\}))$. ◀

B Missing Proofs from Section 3

We first define our true dual vector y. For any time t, let $G(t) \subseteq [n]$ be the set of pages $i \notin [k]$, for which the interval $I(i, \rho(i,t))$ has $|I(i, \rho(i,t))| \leq 3/p_i$. Let $\sigma^t_1, \ldots, \sigma^t_{m^t}$ be the pages of $G(t)$ in decreasing order of p_i. Then define $S^t_j = [k] \cup \{\sigma^t_1, \ldots, \sigma^t_j\}$, and

$$y^t_S = \begin{cases} p_{\sigma^t_j} - p_{\sigma^t_{j+1}} & \text{if } S = S^t_j \text{ and } j < m^t. \\ p_{\sigma^t_{m^t}} & \text{if } S = S^t_j \text{ and } j = m^t. \\ 0 & \text{otherwise.} \end{cases}$$

In words, we define dual variables only for prefixes of the pages in decreasing order of probability (after removing pages whose intervals exceed their expected length by a constant), and include the k pages in $\mathbb{H}$ in all these prefixes.

We argue that this dual is approximately feasible with constant probability, and that its objective value is sufficiently large. We start with the first claim. Let $n_{\max} := \max_\ell |S_\ell|$ in Lemma 5 and let $\eta := \min\{n_{\max}, k\}$. Recall that by Lemma 5, we have that $\mathscr{H} = \Theta(\log \eta)$.

▶ **Lemma 22.** *Fix a time step t. With probability at least $3/4$, for all $i \in [n]$, the solution y satisfies the dual constraints associated with $(i, \rho(i,t))$ up to a factor of $3\ln(2\eta)$.*

Proof. Since t is fixed, for convenience we define $I(i) := I(i, \rho(i,t))$.

For pages $i \in [n] \setminus ([k] \cup G(t))$, for all $t' \in I(i)$ and S such that $i \in S$, note that $y^{t'}_S = 0$. So, the corresponding dual constraint is satisfied vacuously.

Next, consider constraints associated with pages $i \in G(t)$. For all $t' \in I(i)$, if $j^*(t')$ is the index of i in $\sigma^{t'}_1, \ldots, \sigma^{t'}_{m^{t'}}$, then by design

$$\sum_{S: i \in S} y^{t'}_S = \sum_{j=j^*(t)}^{m^{t'}-1} \left(p_{\sigma^{t'}_j} - p_{\sigma^{t'}_{j+1}} \right) + p_{\sigma^{t'}_{m^{t'}}} = p_{\sigma^{t'}_{j^*(t')}} = p_i,$$

which means

$$\sum_{t' \in I(i)} \sum_{S: i \in S} y^{t'}_S = p_i \cdot |I(i)| \leq p_i \cdot \frac{3}{p_i} = 3.$$

It remains to handle constraints associated with $i \in [k]$. This time, for all $t' \in I(i)$, we have

$$\sum_{S: i \in S} y^{t'}_S = \sum_{j=1}^{m^{t'}-1} \left(p_{\sigma^{t'}_j} - p_{\sigma^{t'}_{j+1}} \right) + p_{\sigma^{t'}_{m^{t'}}} = p_{\sigma^{t'}_1} \leq p_k,$$

and hence

$$\Pr\left[\sum_{t'\in I(i)}\sum_{S:\,i\in S} y_S^{t'} \geq 3\ln(2\eta)\right] \leq \Pr\left[|I(i)|\cdot p_k \geq 3\ln(2\eta)\right] \leq \Pr\left[|I(i)| \geq E[|I(i)|]\cdot 3\ln(2\eta)\cdot\frac{p_i}{p_k}\right].$$

Since $|I(i,j)|$ is a geometric random variable with parameter p_i, we get that

$$\Pr\left[\sum_{t'\in I(i)}\sum_{S:\,i\in S} y_S^{t'} \geq 3\ln(2\eta)\right] \leq (1-p_i)^{E[|I(i)|]\cdot 3\ln(2\eta)\cdot\frac{p_i}{p_k}} \leq e^{-3\ln(2\eta)\cdot\frac{p_i}{p_k}} \leq (2\eta)^{-3\cdot\frac{p_i}{p_k}}.$$

Let L_ℓ be the pages i in $[k]$ such that $p_k\cdot 2^{\ell+1} > p_i \geq p_k\cdot 2^\ell$. Note that $|L_\ell| \leq 2n_{\max}$ since it contains pages from at most two sets $S_{\ell'}, S_{\ell'+1}$ for some ℓ'. Moreover, $|L_\ell| \leq k$. Hence, $|L_\ell| \leq 2\eta$.

Now, let $\mathcal{E}$ be the event that there exists an $i \in [k]$ for which $\sum_{t'\in I(i)}\sum_{S:\,i\in S} y_S^{t'} \geq 3\ln(2\eta)$, i.e., the dual constraint for page i is violated beyond a factor of $3\ln(2\eta)$. By a union bound,

$$\Pr[\mathcal{E}] \leq \sum_{\ell\geq 0}\sum_{\substack{i\in[k]:\\ i\in L_\ell}} (2\eta)^{-3\cdot\frac{p_i}{p_k}} \leq \sum_{\ell\geq 0}\sum_{\substack{i\in[k]:\\ i\in L_\ell}} (2\eta)^{-3\cdot 2^\ell} \leq \sum_{\ell\geq 0} 2\eta\cdot(2\eta)^{-3\cdot 2^\ell} \leq (2\eta)^{-2} \leq \frac{1}{4}. \qquad \blacktriangleleft$$

▶ **Lemma 23.** *The expected objective of the dual y at time t is at least $2p(\mathbb{T})/3$.*

Proof. By construction, the dual objective at time t is

$$\sum_S (|S|-k)\cdot y_S^t = m^t\cdot p_{\sigma^t_{m^t}} + \sum_{j=1}^{m^t-1} j\cdot(p_{\sigma^t_j} - p_{\sigma^t_{j+1}}) = \sum_{i\in G(t)} p_i.$$

By a Markov bound, every page $i \in [n]\setminus[k]$ appears in $G(t)$ with probability at least $2/3$, hence the claim. $\blacktriangleleft$

Using these, we can conclude the proof of Lemma 8, which in turn implies Theorem 6 by weak duality.

Proof of Lemma 8. From Lemma 22 and Lemma 23, there exists a dual solution y such that:

(a) At every time t, with probability $\geq 3/4$, solution y simultaneously satisfies all constraints (i,j) such that $t \in I(i,j)$ up to a multiplicative factor of $3\ln(2\eta)$.

(b) The expected dual objective value of this solution y is $2p(\mathbb{T})/3$.

Define a modified dual solution $\widehat{y}$ as follows. For every time t, if there exists a dual constraint (i,j) such that $t \in I(i,j)$ that is violated by a multiplicative factor greater than $3\ln(2\eta)$ (call this event $\mathcal{E}(t)$), then set $\widehat{y}_S^t = 0$ for all $S \subseteq [n]$. Otherwise, set $\widehat{y}_S^t = y_S^t/(3\ln(2\eta))$.

The new dual is always feasible. Furthermore, when $y_S^t > 0$, we have $\widehat{y}_S^t = y_S^t/(3\ln(2\eta))$ with probability at least $3/4$. Hence, by the linearity of expectation, the dual objective of $\widehat{y}$ is

$$\begin{aligned}\sum_S (|S|-k)\cdot\mathbb{E}\big[\widehat{y}_S^t\big] &\geq \frac{1}{3\ln(2\eta)}\sum_S (|S|-k)\cdot\left(\mathbb{E}\big[y_S^t\big] - \mathbb{E}\big[y_S^t \,\big|\, \mathcal{E}(t)\big]\cdot\Pr[\mathcal{E}(t)]\right)\\ &\geq \frac{2p(\mathbb{T})/3 - p(\mathbb{T})/4}{3\ln(2\eta)} \qquad \text{(B.13)}\\ &\geq \frac{5p(\mathbb{T})/12}{3\ln(2\cdot\min\{k,n_{\max}\})},\end{aligned}$$

where in (B.13) we used $\sum_S (|S|-k)\cdot y_S^t \leq p(\mathbb{T})$ with probability 1, together with Lemmas 22 and 23.

The characterization of $\mathscr{H} = \Theta(\log\min\{k, n_{\max}\})$ from Lemma 5 concludes the proof. $\blacktriangleleft$

C Missing Proofs from Section 4

C.1 Proof of Lemma 12

Proof of Lemma 12. We prove the three parts separately.

(i) It follows from the fact that $0 \le X_\ell \le n_\ell$, and the fact that $\mathbb{E}[X_\ell] = \sum_{i \in L_\ell} q_i$.

(ii) This fact follows from standard coupon collector bounds, since each request is for a page in L_ℓ with probability $\ge 1/2^{\ell+1}$ and there are n_ℓ distinct pages in L_ℓ.

(iii) Since ℓ is a non-dominant level, even after conditioning on the page requests being from level ℓ, the probability that any request is for a page in $\mathbb{T}$ is at most $2p(\mathbb{T})$. We use this fact in the rest of this proof.

For $t = 1$, we have

$$\begin{aligned}\Pr[Z_\ell \ge 1] \le \mathbb{E}[Z_\ell] &= \sum_{L \ge 1} \mathbb{E}[Z_\ell \mid Y_\ell = L] \cdot \Pr[Y_\ell = L] \le 2p(\mathbb{T}) \sum_{L \ge 1} L \cdot \Pr[Y_\ell = L] \\ &= 2p(\mathbb{T}) \cdot \mathbb{E}[L] \le p(\mathbb{T}) \cdot 2^{\ell+1} \cdot \mathscr{H}.\end{aligned}$$

For $t \ge 2$, let $\mu := \mathbb{E}[Y_\ell] \le 2^{\ell+1} \cdot \mathscr{H}$. Now, the value of Y_ℓ can be partitioned into intervals $(e(\gamma-1)\mu, e\gamma\mu]$ for integers $\gamma \ge 1$. Using this partitioning, we get

$$\begin{aligned}\Pr[Z_\ell \ge t] &= \sum_{\gamma \ge 1} \Pr[Z_\ell \ge t \mid e(\gamma-1)\mu < Y_\ell \le e\gamma\mu] \cdot \Pr[e(\gamma-1)\mu < Y_\ell \le e\gamma\mu] \\ &= \sum_{\gamma \ge 1} \Pr[Z_\ell \ge t \mid Y_\ell \le e\gamma\mu] \cdot \Pr[Y_\ell > e(\gamma-1)\mu].\end{aligned}$$

Using the Binomial distribution, we get $\Pr[Z_\ell \ge t \mid Y_\ell \le e\gamma\mu] \le \binom{e\gamma\mu}{t}(2p(\mathbb{T}))^t \le \left(\frac{e^2\gamma\mu}{t}\right)^t (2p(\mathbb{T}))^t$, where the last step used Stirling's approximation.

We now bound the second term, $\Pr[Y_\ell > e(\gamma-1)\mu]$. Observe that for $Y_\ell > e(\gamma-1)\mu$ to hold, each of the first $\gamma - 1$ blocks of $e\mu$ requests must fail to request all the pages from level ℓ. By Markov's inequality, since $\mu = \mathbb{E}[Y_\ell]$, each block of $e\mu$ requests fails to request all pages from level ℓ with probability at most $1/e$, and since these failure events are independent, $\Pr[Y_\ell > e(\gamma-1)\mu] \le e^{-(\gamma-1)}$. Therefore, for $\gamma \ge 1$, we have $\Pr[Y_\ell > e(\gamma-1)\mu] \le e^{-(\gamma-1)}$. Putting these together, we get

$$\begin{aligned}\Pr[Z_\ell \ge t] &\le \sum_{\gamma \ge 1} \left(\frac{e^2\gamma\mu}{t}\right)^t (2p(\mathbb{T}))^t \cdot e^{-(\gamma-1)} \\ &\le \left(\frac{e^2\mu}{t}\right)^t \cdot (2p(\mathbb{T}))^t \cdot \sum_{\gamma=1}^{\infty} \frac{\gamma^t}{e^{\gamma-1}} \le \left(\frac{e^2\mu}{t}\right)^t \cdot (2p(\mathbb{T}))^t \cdot \left(\sum_{\gamma=1}^{2t\ln(t)-1} \frac{\gamma^t}{e^{\gamma-1}} + \sum_{\gamma=2t\ln t}^{\infty} \frac{\gamma^t}{e^{\gamma-1}}\right) \\ &\le \left(\frac{e^2\mu}{t}\right)^t \cdot (2p(\mathbb{T}))^t \cdot \left((2t\ln(t)-1) \cdot \frac{t^t}{e^{t-1}} + 1\right) \qquad \text{(C.14)} \\ &\le \left(2e^2\mu\right)^t \cdot p(\mathbb{T})^t. \qquad \text{(since } t \ge 2\text{)}\end{aligned}$$

Step (C.14) follows since the expression $\gamma^t/e^{\gamma-1}$ is maximized at $\gamma = t$, so the first partial sum can be bounded by its length times the maximum t^t/e^{t-1}. The suffix sum converges to less than one. ◀

C.2 Proof of Claim 14

Proof of Claim 14. Recall that by (4.3), we have that for any level ℓ, $\sum_{i \in L_\ell} p_i q_i \le \frac{1}{2^\ell} \cdot \mathbb{E}[X_\ell]$, where X_ℓ denotes the number of pages in L_ℓ that do not appear among the first k distinct pages. We proceed to bound $\mathbb{E}[X_\ell]$. By definition, $X_\ell \le Z_\ell$. Therefore, we can write

$$\begin{aligned}\mathbb{E}[X_\ell] &= \sum_{t\geq 1} t\cdot \Pr[X_\ell = t] = \Pr[X_\ell = 1] + \sum_{t\geq 2} t\cdot \Pr[X_\ell = t] = \Pr[X_\ell = 1] + \sum_{t\geq 2}\Pr[X_\ell \geq t]\\ &\leq \Pr[X_\ell = 1 \mid Z_\ell = 1]\cdot \Pr[Z_\ell = 1] + \sum_{t\geq 2}\Pr[Z_\ell \geq t]\\ &\leq \Pr[X_\ell = 1 \mid Z_\ell = 1]\cdot \Pr[Z_\ell \geq 1] + \sum_{t\geq 2}\Pr[Z_\ell \geq t]. \end{aligned} \tag{C.15}$$

We can bound factors of (C.15) of the form $\Pr[Z_\ell \geq t]$ using (4.6). We get

$$\sum_{t\geq 2}\Pr[Z_\ell \geq t] \leq \sum_{t\geq 2}\left(2e^2\cdot p(\mathbb{T})\cdot 2^{\ell+1}\cdot \mathscr{H}\right)^t \leq 2\left(2e^2\cdot p(\mathbb{T})\cdot 2^{\ell+1}\cdot \mathscr{H}\right)^2,$$

where in the last step, we used

$$2e^2\cdot p(\mathbb{T})\cdot 2^{\ell+1}\cdot \mathscr{H} \leq 2e^2\cdot p(\mathbb{T})\cdot 2^{\ell_1}\cdot \mathscr{H} \leq \frac{2e^2\cdot p(\mathbb{T})\cdot \mathscr{H}}{4e^2\mathscr{H}\cdot p(\mathbb{T})} = 1/2.$$

Thus, $\sum_{t\geq 2}\Pr[Z_\ell \geq t] \leq 2\left(2e^2\cdot p(\mathbb{T})\cdot 2^{\ell+1}\cdot \mathscr{H}\right)^2 \leq \frac{\mathscr{H}\cdot p(\mathbb{T})}{2^{\ell_1-2\ell-6}}$, since $p(\mathbb{T}) \leq 1/(4e^2\mathscr{H}\cdot 2^{\ell_1})$.

It remains to bound the first part of (C.15). From (4.5), we have that $\Pr[Z_\ell \geq 1] \leq 2p(\mathbb{T})\cdot 2^{\ell+1}\cdot \mathscr{H}$. We are left to bound $\Pr[X_\ell = 1 \mid Z_\ell = 1]$. Since there is only one request from $\mathbb{T}$ before all pages in level ℓ are requested, a necessary event for X_ℓ to be 1 is that the last page requested in $\mathbb{H}$ must be from level ℓ. In particular, consider page r_1 which is in level ℓ_1 and therefore not in level $\ell < \ell_1$. Let $\mathcal{E}$ denote the event that page r_1 is requested before all pages in level ℓ are requested. Then,

$$\Pr[X_\ell = 1 \mid Z_\ell = 1] \leq \Pr[\mathcal{E} \mid Z_\ell = 1] = \sum_{t\geq 1}\Pr[\mathcal{E} \mid Z_\ell = 1, Y_\ell = t]\cdot \Pr[Y_\ell = t]. \tag{C.16}$$

Consider any fixed number of requests, say t. The conditional probability of any page in the head $\mathbb{H}$ increases when we decrease the number of requests for pages in the tail $\mathbb{T}$ among these t requests. Therefore, $\Pr[\mathcal{E} \mid Z_\ell = 1, Y_\ell = t] \leq \Pr[\mathcal{E} \mid Z_\ell = 0, Y_\ell = t]$.

Now, let $I_t(\mathcal{E})$ denote the number of requests for page r_1 among the first t requests. Given that $Z_\ell = 0$, the probability that any request is for page r_1 is $2^{-\ell_1}/(1-p(\mathbb{T}))$. Therefore,

$$\Pr[\mathcal{E} \mid Z_\ell = 1, Y_\ell = t] \leq \mathbb{E}[I_t(\mathcal{E}) \mid Z_\ell = 0] = \frac{1/2^{\ell_1}}{1-p(\mathbb{T})}\cdot t \leq \frac{t}{2^{\ell_1-1}},$$

since $p(\mathbb{T}) < 1/2$. Substituting in (C.16), we get

$$\begin{aligned}\Pr[X_\ell = 1 \mid Z_\ell = 1] &= \sum_{t\geq 1}\Pr[\mathcal{E} \mid Z_\ell = 1, Y_\ell = t]\cdot \Pr[Y_\ell = t] \leq \sum_{t\geq 1}\frac{t}{2^{\ell_1-1}}\cdot \Pr[Y_\ell = t]\\ &\leq \frac{\mathbb{E}[Y_\ell]}{2^{\ell_1-1}} \leq \frac{\mathscr{H}\cdot 2^{\ell+1}}{2^{\ell_1-1}} = \frac{4\mathscr{H}}{2^{\ell_1-\ell}},\end{aligned}$$

where we again used (4.4) in the last inequality. Therefore,

$$\Pr[X_\ell = 1 \mid Z_\ell = 1]\cdot \Pr[Z_\ell \geq 1] \leq \frac{4\mathscr{H}}{2^{\ell_1-\ell}}\cdot 2p(\mathbb{T})\cdot 2^{\ell+1}\cdot \mathscr{H} = \frac{\mathscr{H}^2\cdot p(\mathbb{T})}{2^{\ell_1-2\ell-4}}.$$

This bounds the first expression in (C.15).

Substituting our bounds for both expressions in (C.15), we get

$$\mathbb{E}[X_\ell] \leq \frac{\mathscr{H}^2\cdot p(\mathbb{T})}{2^{\ell_1-2\ell-4}} + \frac{\mathscr{H}\cdot p(\mathbb{T})}{2^{\ell_1-2\ell-6}} \leq \frac{80\mathscr{H}^2\cdot p(\mathbb{T})}{2^{\ell_1-2\ell}}.$$

Therefore,

$$\sum_{i\in L_\ell} p_i q_i \leq \frac{1}{2^\ell}\cdot \mathbb{E}[X_\ell] \leq \frac{1}{2^\ell}\cdot \frac{80\mathscr{H}^2\cdot p(\mathbb{T})}{2^{\ell_1-2\ell}} = \frac{80\mathscr{H}^2\cdot p(\mathbb{T})}{2^{\ell_1-\ell}}. \qquad \triangleleft$$

C.3 Proof of Lemma 15

Proof of Lemma 15. We use Claim 13 to bound both a dominant level, if it exists, and the last level in $\mathbb{H}_1$, i.e., ℓ_1. For both these levels $\ell = \ell^*$ and $\ell = \ell_1$, we get $\sum_{i \in L_\ell} p_i q_i \le 4\mathscr{H} \cdot p(\mathbb{T})$, by Claim 13.

For non-dominant levels $\ell < \ell_1$, we use Claim 14. Thus, $\sum_{\ell<\ell_1} \sum_{i \in L_\ell} p_i q_i \le \sum_{\ell_1 - \ell \ge 1} \frac{80\mathscr{H}^2 \cdot p(\mathbb{T})}{2^{\ell_1 - \ell}} \le 80\mathscr{H}^2 \cdot p(\mathbb{T})$. Summing the bounds, we get $\sum_{i \in \mathbb{H}_1} p_i q_i \le 4\mathscr{H} \cdot p(\mathbb{T}) + 80\mathscr{H}^2 \cdot p(\mathbb{T}) \le 88\mathscr{H}^2 \cdot p(\mathbb{T})$. ◀

C.4 Proof of Lemma 17

Proof of Lemma 17. Let ℓ_3 be the first level ℓ that contains pages from $\mathbb{H}_3$, i.e., all pages in $\mathbb{H}_3$ are in levels ℓ_3 and above. Then, $\sum_{i \in \mathbb{H}_3} p_i q_i \le \sum_{\ell \ge \ell_3} \frac{1}{2^\ell} \sum_{i \in L_\ell} q_i \le \sum_{\ell \ge \ell_3} \frac{1}{2^\ell} \cdot n_\ell$, since $q_i \le 1$ by virtue of being a probability.

By Lemma 5, for any level ℓ, the number pages n_ℓ is at most $2^{\mathscr{H}}$. Therefore,

$$\sum_{i \in \mathbb{H}_3} p_i q_i \le \sum_{\ell \ge \ell_3} \frac{1}{2^\ell} \cdot n_\ell \le 2^{\mathscr{H}} \cdot \sum_{\ell \ge \ell_3} \frac{1}{2^\ell} \le 2^{\mathscr{H}} \cdot \frac{1}{2^{\ell_3 - 1}}.$$

Note that $p_i \le p(\mathbb{T})/2^{\mathscr{H}}$ for any page $i \in \mathbb{H}_3$. If page i is in level ℓ, then $p_i \ge 1/2^{\ell+1}$. Combining the two, we get $\frac{1}{2^{\ell+1}} \le p_i \le \frac{p(\mathbb{T})}{2^{\mathscr{H}}}$, and, in particular, $\frac{1}{2^{\ell_3 - 1}} \le \frac{4p(\mathbb{T})}{2^{\mathscr{H}}}$. Putting these together, we get $\sum_{i \in \mathbb{H}_3} p_i q_i \le 2^{\mathscr{H}} \cdot \frac{1}{2^{\ell_3 - 1}} \le 4p(\mathbb{T})$. ◀

D Missing Proofs from Section 5

D.1 Proof of Claim 19

Proof of Claim 19. Fix $i \in \mathbb{H}$ and j such that $p_j \le p_i/2$. Consider the following random walk on the line that starts at 0, moves +1 with probability $p_i/(p_i + p_j) \ge 1 - 1/(2^h + 1)$, and moves −1 with probability $p_j/(p_i + p_j) \le 1/(2^h + 1)$. After γ time steps, the position is at least $\gamma/2$ with probability at least $1 - 2^{-h\gamma/4}$. Indeed, observe that the probability the walk is at position $< \gamma/2$ after γ time steps is the probability that γ i.i.d. Bernoullis $X_1, \ldots, X_\gamma$ with probability $q = 1/(2^h + 1)$ sum to $\gamma/4$. The sum $X = \sum_i X_i$ has mean $\mu = q\gamma$ and if we set $\delta = \gamma/(4\mu) - 1$, by a Chernoff bound,

$$\Pr\left[\sum_i X_i \ge \frac{\gamma}{4}\right] = \Pr\left[\sum_i X_i \ge (1+\delta)\mu\right] \le \frac{e^{(1+\delta)\mu}}{(1+\delta)^{(1+\delta)\mu}} \le e^{\gamma/4}(4q)^{-\gamma/4} \le 2^{-h\gamma/4}.$$

A random walk with bias $1 - 1/(2^h + 1)$ at position z returns to 0 with probability exactly 2^{-hz} (see, e.g., [34, page 6]).

Now, it is easy to see that the event $\mathcal{E}_{ij}$ has the same probability as that of this random walk returning to 0 after γ time steps. Therefore, if $\mathcal{E}_{ij}$ holds either (1) the random walk was at position $\le \gamma/4$ after γ steps, or (2) starting at position $\gamma/4$, the walk returned to 0 after a finite amount of time. By a union bound, $\Pr[\mathcal{E}_{ij}] \le 2^{-h\gamma/8}$. ◁

D.2 Proof of Claim 21

Proof of Claim 21. Recall that $\gamma = 16\mathscr{H} = 16 \log \min(k, n_{\max})$. We do a case analysis.

Case 1. Suppose that $k \le n_{\max}$, so $\gamma = 16 \log k$. Recalling that the pages of $\mathbb{T}$ are ordered by decreasing probability, define $G_\ell := \{i \in \mathbb{T} \mid i \ge 2k+1,\ i = \ell \mod k\}$. Define $q := 2 \cdot \sum_{i \in G'_0} p_i$, and let $I = \{i \in \mathbb{H} \mid p_i \ge q\}$.

Note that the total probability mass of $\mathbb{H} \setminus I$ is at most $k \cdot q = O(p(\mathbb{T}))$. Also, for all $i \in I$ and all ℓ, we have $p_i \ge 2 \sum_{j \in G_\ell} p_j$. By Corollary 20, after γ requests to i, the probability any page in G_ℓ ever has count exceeding that of i is $2^{-\gamma} = 1/\mathrm{poly}(k)$. By the same argument, the probability any page in $\{k+1, \dots, 2k\}$ exceeds the count of i after γ requests to i is also $1/\mathrm{poly}(k)$. By a union bound, no page in the tail exceeds the count of i after γ requests to i with probability $1 - \mathrm{poly}(k)$, and hence the expected number of requests to i before this condition holds is at most 2γ.

Case 2. Suppose now that $n_{\max} \le k$, so $\gamma = 16 \log n_{\max}$. Then let $L_\ell = \{j \in \mathbb{T} \mid p_i \in [p_k 2^\ell, p_k 2^{\ell-1})\}$. By definition $|L_\ell| \le n_{\max}$. For every $i \in \mathbb{H}$ and every $\ell \ge 1$, by Corollary 20 after γ requests to i, a page j in L_ℓ will have count exceeding i with probability no more than $2^{-h\gamma/8} = (n_{\max})^{-2\ell}$. By a union bound, no page in L_ℓ has count exceeding i with probability $(n_{\max}^{-\ell}) \le 2^{-\ell-1}$, and hence by another union bound, no page in $\mathbb{T}$ with probability more than $p_i/2$ will have count exceeding i with probability at least $1/2$. Once again, this means the expected number of requests to i before this condition holds is 2γ. ◁

E Computing Subset Entropy

We recall the definition of k-subset entropy (2.1). We show the following lemma, which immediately implies an efficient algorithm for computing $\mathscr{H}(\mathcal{D}, k)$ (we call this the interval property of $\mathscr{H}(\mathcal{D}, k)$):

▶ **Lemma 24** (Interval Property of $\mathscr{H}(\mathcal{D}, k)$)**.** *Consider a discrete distribution $\mathcal{D} : [n] \to [0,1]$ such that $\mathcal{D}(i) \ge \mathcal{D}(j)$ for any $i \ge j$. Let $k \le n$ be any positive integer. Then, there is always a subset $S \subseteq [n], |S| \le k$ that maximizes $\mathrm{H}(\mathcal{D}_S)$ among subsets of $[n]$ of cardinality at most k which is of the form $S = \{r, r+1, \dots, t\}$.*

Next, we prove this lemma. An important parameter in our proof will be the weighted geometric mean defined as $\tau = \prod_{i \in S} p_i^{q_i}$.

▷ Claim 25. The weighted geometric mean $\tau = \prod_{i \in S} p_i^{q_i}$ satisfies the following condition:

$$\frac{\partial \mathrm{H}(S)}{\partial p_j} \begin{cases} < 0 & \text{if } p_j > \tau \\ = 0 & \text{if } p_j = \tau \\ > 0 & \text{if } p_j < \tau. \end{cases}$$

Proof. Let us use the notation $p_i := \mathcal{D}(i)$, i.e., $p_1 \ge p_2 \ge \cdots \ge p_n$. We have:

$$\mathrm{H}(S) = -\frac{\sum_{i \in S} p_i \log \frac{p_i}{\sum_{i \in S} p_i}}{\sum_{i \in S} p_i} = -\frac{\sum_{i \in S} p_i \log p_i}{\sum_{i \in S} p_i} + \log\left(\sum_{i \in S} p_i\right).$$

Note that the entropy of the conditional distribution on S given by $\mathrm{H}(\mathcal{D}_S)$ is a function of the values $p_i, i \in S$. We consider the partial derivative of this function with respect to any specific $p_j, j \in S$:

$$\begin{aligned} \frac{\partial \mathrm{H}(S)}{\partial p_j} &= -\frac{\left(\sum_{i \in S} p_i\right)(1 + \log p_j) - \sum_{i \in S} p_i \log p_i}{\left(\sum_{i \in S} p_i\right)^2} + \frac{1}{\sum_{i \in S} p_i} \\ &= -\frac{\log p_j}{\sum_{i \in S} p_i} + \frac{\sum_{i \in S} p_i \log p_i}{\left(\sum_{i \in S} p_i\right)^2} = \frac{\frac{\sum_{i \in S} p_i \cdot \log p_i}{\sum_{i \in S} p_i} - \log p_j}{\sum_{i \in S} p_i} = \frac{\sum_{i \in S} q_i \log p_i - \log p_j}{\sum_{i \in S} p_i}, \end{aligned}$$

where $q_i := \frac{p_i}{\sum_{i \in S} p_i}$. Recall that $\tau = \prod_{i \in S} p_i^{q_i}$, i.e., $\log \tau = \sum_{i \in S} q_i \log p_i$. The claim follows. ◁

Next, we state some simple properties of the weighted geometric mean τ.

▷ Claim 26. The weighted geometric mean τ over a set S does not change if τ is added to S.

Proof. Recall that $\tau = \prod_{i \in S} p_i^{q_i}$ where $q_i = p_i/p$, where $p = \sum_{i \in S} p_i$. Let q'_i be the weighted geometric mean if we include τ, i.e.,

$$q'_i = \begin{cases} p_i/p+\tau & \text{if } i \in S \\ \tau/p+\tau & \text{if } p_i = \tau. \end{cases}$$

The new weighted geometric mean τ' is given by

$$\tau' = \left(\prod_{i \in S} p_i^{q'_i}\right) \cdot \tau^{\tau/p+\tau} = \left(\prod_{i \in S} p_i^{p_i/p+\tau}\right) \cdot \tau^{\tau/p+\tau} = \left(\prod_{i \in S} p_i^{p_i/p}\right)^{p/p+\tau} \cdot \tau^{\tau/p+\tau} = \tau^{p/p+\tau} \cdot \tau^{\tau/p+\tau} = \tau. \quad \triangleleft$$

▷ Claim 27. Consider two sets $S_1 = S \cup \{p_{\max}\}, S_2 = S \cup \{p_{\min}\}$ such that for any $i \in S$, we have $p_{\min} \le p_i \le p_{\max}$. Let τ_1, τ_2 be the weighted geometric means of S_1, S_2 respectively. Then, $\tau_1 \ge \tau_2$.

Proof. Let $p = \sum_{i \in S} p_i$. We have

$$\frac{\tau_1}{\tau_2} = \frac{\prod_{i \in S} p_i^{p_i/p+p_{\max}}}{\prod_{i \in S} p_i^{p_i/p+p_{\min}}} \cdot \frac{p_{\max}^{p_{\max}/p+p_{\max}}}{p_{\min}^{p_{\min}/p+p_{\min}}} \ge \prod_{i \in S} p_i^{\frac{p_i(p_{\min}-p_{\max})}{(p+p_{\max})(p+p_{\min})}} \cdot p_{\max}^{\frac{p(p_{\max}-p_{\min})}{(p+p_{\max})(p+p_{\min})}}$$

$$= \prod_{i \in S} \left(\frac{p_{\max}}{p_i}\right)^{\frac{p_i(p_{\max}-p_{\min})}{(p+p_{\max})(p+p_{\min})}} \ge 1. \quad \triangleleft$$

Now, we are ready to prove Lemma 24.

Proof of Lemma 24. Let $S_{\max}$ denote a subset that maximizes $\mathrm{H}(\mathcal{D}_S)$. Let $p_{\min}, p_{\max}$ respectively denote the minimum and maximum values in $S_{\max}$. Assume for contradiction that there is some $q \notin S_{\max}$ such that $p_{\max} < q < p_{\min}$. We will show that $\max\left(\mathrm{H}(S_{\max} \cup \{q\} \setminus \{p_{\max}\}), \mathrm{H}(S_{\max} \cup \{q\} \setminus \{p_{\min}\})\right) \ge \mathrm{H}(S_{\max})$. Clearly, this would establish the lemma.

We consider two continuous processes. The first is to decrease the value $p_{\max}$. As we do so, it might not remaining the maximum value in set $S_{\max}$ but we still denote the dynamic value by $p_{\max}$. Note that the value of the weighted geometric mean of $S_{\max}$, denoted τ, also changes; the termination condition we define below is with respect to the current value of the geometric mean and not its original value. This process ends when either of the following two events happens:

- either, $p_{\max}$ decreases to the current value of the weighted geometric mean τ.
- or, $p_{\max}$ decreases all the way to q while always staying above the (dynamic) weighted geometric mean τ. Then, by Claim 25, the value of $\mathrm{H}(S_{\max})$ is non-decreasing throughout this entire process. Therefore, we have replaced $p_{\max}$ by q and not decreased $\mathrm{H}(S_{\max})$, which is a contradiction.

Next, we consider the second process. This is similar to the first process, except that we now increase $p_{\min}$ instead of decreasing $p_{\max}$. As earlier, as we increase the value of $p_{\min}$, it might not remaining the minimum value in set $S_{\max}$ but we still denote the dynamic value by $p_{\min}$. Also, as in the previous process, the value of the weighted geometric mean τ changes during this process, and the termination condition we define below is with respect to the current value of the geometric mean and not its original value. This process ends when either of the following two events happens:

- either, $p_{\min}$ increases to the current value of the weighted geometric mean τ.
- or, $p_{\min}$ increases all the way to q while always staying below the (dynamic) weighted geometric mean τ. Then, by Claim 25, the value of $\mathrm{H}(S_{\max})$ is non-decreasing throughout this entire process. Therefore, we have replaced $p_{\min}$ by q and not decreased $\mathrm{H}(S_{\max})$, which is a contradiction.

We are left with the case that in both processes, the first event happened. Let τ_1, τ_2 be the final values of τ in these two processes respectively. For the first event to happen in the first process, we must have $q < \tau_1$; similarly, for the first event to happen in the second process, we must have $q > \tau_2$. Thus

$$\tau_2 < q < \tau_1. \tag{E.17}$$

By *Claim* 26, the value of τ_1 is the weighted geometric mean of the set $S_{\max} \setminus \{p_{\max}\}$; similarly, the value of τ_2 is the weighted geometric mean of the set $S_{\max} \setminus \{p_{\min}\}$. Therefore, by Claim 27, $\tau_1 < \tau_2$. This contradicts (E.17). ◀

F Lower Bound on LRU

▶ **Theorem 28.** *There are distributions $\mathcal{D}$ such that the cost of LRU is $\Omega(p(\mathbb{T})) \cdot \mathscr{H}$.*

Proof. Let $\mathcal{D}$ be a distribution that has one page with probability $\varepsilon = 4/(k \log k)$, and k pages with probability $(1-\varepsilon)/k$. By a Markov bound, the ε probability page appears by time $2/\varepsilon = k \log k/2$ with probability at least $1/2$. Furthermore, by lower bounds on the coupon collector time (see, e.g., [28, pages 60-63]) the last page of the top k appears before time $9/10 \cdot k \log k$ with probability less than $1/4$. Hence, with probability at least $1/4$, the algorithm pays $(1-\varepsilon)/k = \Omega(p(\mathbb{T}) \cdot \mathscr{H})$. ◀

This does not rule out that LRU is $\mathscr{H}$-competitive, since this bound is witnessed by a distribution for which $p(\mathbb{T}) \approx \mathsf{opt}$, but it means a different proof technique than ours is required.

Socially Fair Clustering: Parameterized Approximation and Local Search

Abstract

We study the Socially Fair Clustering problem introduced by Abbasi, Bhaskara, and Venkatasubramanian [2] and by Ghadiri, Samadi, and Vempala [14], along with its extension, the (p, q)-Socially Fair Clustering problem. This problem generalizes k-median and k-means to settings where data points are partitioned into ℓ groups, and the goal is to find a fair clustering that is simultaneously good for all groups. We present several algorithms for this problem.

1. For ℓ_p-Socially Fair Clustering, we give the first constant-factor FPT-approximation parameterized by the number of groups ℓ, resolving the open question raised by Ghadiri, Singh, and Vempala [15]. Our main ingredient is a new algorithm for closing additional centers in parameterized time inspired by local search.
2. We then turn to the more general (p, q)-Socially Fair Clustering problem. The known algorithm for this problem, proposed by Chlamtáč, Makarychev, and Vakilian [13], achieves a very good approximation but is complex, slow and difficult to implement. We analyze the performance of a simple local search algorithm and show that it provides an $O(q)$-approximation in the worst case.
3. Finally, we design approximation algorithms for the facility location variant of the problem, where the number of facilities (centers) is not fixed in advance, and opening each facility incurs an opening cost. Unlike in previous work, we do not assume these opening costs are the same for all groups.

1 Introduction

1.1 Overview

Today, computers are widely used to analyze and classify data, generate recommendations, and make decisions that affect many aspects of people's lives. Traditionally, algorithms have focused on optimizing the overall quality of a solution. As a result, their decisions may be unfair to specific individuals or groups. Given the significance of these decisions, addressing fairness in algorithmic decision-making has become essential.

The k-median and k-means objectives are widely used in clustering and typically yield solutions that perform well for most data points. However, some points may be much farther from their assigned centers than others, and therefore incur disproportionately high costs. This is especially problematic when data points represent people, and those bearing the highest costs disproportionately belong to minority groups. Consider, for example, a facility location problem modeled using k-median: we wish to open k facilities (e.g., hospitals or grocery stores) in a city to serve all residents effectively. The goal is to minimize the sum of distances from each person (data point) to their nearest facility (center): $\sum_{u \in X} d(u, C)$. If a minority group resides in an isolated neighborhood, it is possible that none of the facilities will be placed nearby, leaving that group underserved.

To address this issue, [2] and [14] independently introduced the *Socially Fair Clustering* problem. This problem was also previously studied by [6] in the context of clustering under uncertainty. In the fair clustering setting, the n data points belong to ℓ groups $G_1, \ldots, G_\ell \subseteq X$, representing minority or otherwise protected populations (the groups may overlap and do not have to cover X). The goal is to find a clustering that performs well for all groups simultaneously. It is convenient to assign weights to data points: for group i, let $w_i(u)$ denote the weight of point u, where $w_i(u) > 0$ if $u \in G_i$ and $w_i(u) = 0$ otherwise; one natural choice is $w_i(u) = 1/|G_i|$ for $u \in G_i$.

The ℓ_p-Socially Fair Clustering problem, referred to as ℓ_p-Clustering for brevity, asks for a set of k centers C from a set of potential centers $F \subseteq X$ that minimizes

$$\max_{i \in \{1,\ldots,\ell\}} \left(\sum_{u \in X} w_i(u) d(u, C)^p \right)^{1/p}, \tag{1}$$

ensuring that the solution performs well across all groups. In other words, we compute the p-norm of distances $\left(\sum_{u \in X} w_i(u) d(u, C)^p\right)^{1/p}$ for each group G_i, and the objective aggregates these by taking a maximum (many papers define the objective as the p-th power of ours; the two formulations are essentially equivalent: an α-approximation for our objective corresponds to an α^p-approximation for the alternative, and vice versa).

A more general variant of the problem, known as (p, q)-Socially Fair Clustering with $1 \leq p \leq q \leq \infty$, employs a different aggregation function.[1] In this formulation, we construct a vector whose i-th coordinate represents the p-norm of the distances for group i, and then take the ℓ_q norm of this vector:

$$\left(\sum_{i=1}^{\ell} \left(\sum_{u \in X} w_i(u) d(u, C)^p \right)^{q/p} \right)^{1/q}. \tag{2}$$

We refer to this problem simply as (p, q)-Clustering. When $q = \infty$, the objective in (2) reduces to that in (1); thus, ℓ_p-Clustering and (p, ∞)-Clustering are equivalent. Moreover, the $(p, \max\{p, \log \ell\})$-objective approximates the ℓ_p-objective within a constant factor. This follows from the more general fact that the ℓ_q and ℓ_r norms of a d-dimensional vector

[1] We assume that $q \geq p$, since otherwise the objective would favor *unfair* clusterings. For example, let $p = 2q$ and $\ell = 2$. Suppose there are two candidate solutions: in the first, each group has p-norm distance 1, while in the second, the p-norms of the distances for the two groups are $2^{1/p}$ and 0 (where the p-norm distance of group i is given by $\left(\sum_{u \in X} w_i(u) d(u, C)^p\right)^{1/p}$). The corresponding aggregated objectives are $(1^{1/2} + 1^{1/2})^{1/q} = 2^{1/q}$ and $(2^{1/2} + 0^{1/2})^{1/q} = 2^{1/(2q)}$. Thus, we would prefer the second solution, even though it is clearly less fair.

are within a factor of $d^{|\frac{1}{q}-\frac{1}{r}|}$ of each other, which can be shown by a simple computation. Hence in all our results for (p,q)-Clustering, we obtain results for ℓ_p-Clustering by setting $q = \max\{p, \log \ell\}$.

1.2 Known results

The problem has been extensively studied since its introduction. We begin by summarizing previously published approximation algorithms. [6] gave an $O(\log n + \log \ell)$-approximation for ℓ_1-Clustering. [2] and [14] provided $O(\ell^{1/p})$-approximation algorithms for ℓ_p-Clustering with $p \in \{1, 2\}$. Additionally, [2] presented a bicriteria approximation algorithm that achieves a constant-factor approximation by opening $O(k)$ centers.

The approximation factor was later improved by [22], who obtained an $O\left(\frac{\log \ell}{\log\log \ell}\right)^{1/p}$-approximation. This approximation factor is optimal under the assumption that $NP \not\subseteq \bigcap_{\delta>0} DTIME(2^{n^\delta})$, as was shown by [10]. Finally, [13] studied the (p,q)-Clustering problem and gave an $O\left(\frac{q}{\ln(1+q/p)}\right)^{1/p}$-approximation for it. This approximation factor matches that for ℓ_p-clustering when $q = \log \ell$.

Another line of research has focused on designing fixed-parameter tractable (FPT) algorithms for ℓ_p-Clustering. In a significant result, [16] settled the approximability of ℓ_p-Fair Clustering for FPT algorithms parameterized by k by designing a $3+\varepsilon$-approximation algorithm and proving a matching lower bound of $3-\varepsilon$. They also established lower bounds of $1 + 2/e - \varepsilon$ and $\sqrt{1+8/e} - \varepsilon$ for the approximability of ℓ_1 and ℓ_2-Clustering when parameterized by both k and ℓ.

[15] observed that in practice, ℓ is typically a small constant, while k may be very large. They presented a polynomial-time algorithm achieving a $5 + 2\sqrt{6}$ bicriteria approximation by opening at most $k + \ell$ centers. Building on the bicriteria result mentioned above, they also designed algorithms with running times $n^{O_p(\ell^2)}$ and $k^\ell \mathrm{poly}(n)$, achieving approximation factors of $5 + 2\sqrt{6} + \varepsilon$ and $15 + 6\sqrt{6} + \varepsilon$, respectively. The latter is an FPT algorithm parameterized by both k and ℓ. They then raised the question of whether there exists a FPT algorithm achieving a constant-factor approximation parameterized solely by ℓ. This question remained open until our current work.

We also note that the problem admits a $(1+\varepsilon)$-approximation when parameterized by k for certain special classes of metric spaces, as shown by [1]. In many real-world applications, the number of centers – typically referred to as facilities in this context – is not fixed in advance. Instead, opening each facility incurs a cost. As is standard, we refer to this setting as the Facility Location problem. [2] presented a 4-approximation algorithm for the Facility Location variant of ℓ_1-Clustering, assuming homogeneous costs across groups (i.e., the cost of opening a facility is shared equally among all groups).

1.3 Other related work

The theme of fair clustering has received a lot of attention in recent years. Some other notions of fairness that have been adopted include balancedness [11], no over-representation [4], fair hierarchical clustering [3], individual fairness [20], pairwise fairness [9, 8]. Many of these incorporate constraints on clusters rather than enforcing fairness through a new objective, as is the case for Socially Fair Clustering.

1.4 Our results

1.4.1 FPT Algorithm parameterized by ℓ

In this paper, we address several important open problems in the field. First, we resolve the open question posed by [15] by presenting a constant-factor approximation FPT algorithm for ℓ_p-Clustering, parameterized by the number of groups ℓ.

▶ **Theorem 1.** *For every $\varepsilon > 0$, there exists a $(17 + 6\sqrt{6} + \varepsilon)$-approximation algorithm for ℓ_p-Clustering that runs in time $f(\ell, p, \frac{1}{\varepsilon}) \cdot n^{O(1)}$.*

We prove this result by designing a new algorithm that reduces the number of centers in fixed-parameter time.

▶ **Theorem 2.** *There exists an algorithm that, given an instance of ℓ_p-Clustering, a c-approximate solution C with $k + t$ centers, and a parameter $\varepsilon > 0$, returns a $(3c + 2 + \varepsilon)$-approximate solution with k centers. The algorithm runs in time $f(\ell, p, t, \frac{1}{\varepsilon}) \cdot n^{O(1)}$.*

Combining Theorem 2 with the following result of [15], we immediately obtain Theorem 1, thereby answering their open question.

▶ **Theorem 3** ([15])**.** *There is a bicriteria polynomial-time algorithm for ℓ_p-Clustering that finds a $(5 + 2\sqrt{6})$-approximate solution with $k + \ell$ centers.*

Additionally, in the full version of this paper, we strengthen Theorem 3 in the important case of ℓ_1-Clustering by presenting a local-search algorithm that finds a $(3+\varepsilon)$-approximation with $k + f(\ell, \frac{1}{\varepsilon})$ centers. This yields a variant of the algorithm from Theorem 1 with a $(11 + \varepsilon)$-approximation for ℓ_1-Clustering.

1.4.2 Local Search Algorithm for (p, q)-Clustering

The second theme of our paper is the design of a more efficient and implementable algorithm for (p, q)-Clustering. The algorithm in [13] solves an exponential-size convex relaxation using the round-or-cut framework, which is impractical and difficult to implement. In contrast, local search algorithms are well known for their efficiency and ease of implementation. Previously, [7] showed how to obtain a $(5 + \varepsilon)$-approximation for k-median using a single-swap local search algorithm, and a $(3 + \varepsilon)$-approximation using a multiple-swap variant. This result was generalized by [17], who gave an $O(p)$-approximation for the single-group case of ℓ_p-Clustering and showed that this analysis is tight – there are instances where the algorithm returns only an $\Omega(p)$-approximate solution.

We analyze the performance of the single-swap local search algorithm on instances of (p, q)-Clustering with an arbitrary number of groups ℓ, and show that it yields an $O(q)$-approximation. The aforementioned lower bound in [17] implies that our analysis is tight. While our approximation guarantee is worse than those of [22] and [13], it comes close in a particularly important case: ℓ_1-Clustering. For that problem, we obtain an $O(\log \ell)$-approximation by setting $q = \log \ell$, which matches the best known approximation factor of $O(\log \ell / \log \log \ell)$ up to a $\log \log \ell$ factor. Our algorithm is simpler, more implementable, and much faster than the algorithm of [13].[2]

▶ **Theorem 4.** *There is a single-swap local search algorithm for the (p, q)-Clustering problem that gives an $O(q)$-approximation, performs at most $O(kq \log n)$ iterations and runs in time $O_{p,q}(n^2 \ell k^2 \log n)$.*

[2] The running time in [13] is polynomial, but it is not stated explicitly.

1.4.3 (p, q)-Socially Fair Facility Location

Finally, we study the (p, q)-Socially Fair Facility Location problem, an important and practically motivated variant of (p, q)-Clustering. Building on the result of [2] for ℓ_1, we present a $(4 + \varepsilon)$-approximation algorithm for (p, q)-Socially Fair Facility Location with homogeneous costs. We then consider a more general setting with heterogeneous costs, where different groups incur different facility opening costs. In this case, we obtain an $O(q/\log q)$-approximation; in particular, for $p = 1, q = \infty$, this yields an $O(\log \ell/\log\log \ell)$-approximation[3], which almost matches the approximation hardness of $\Omega(\log^{1-\varepsilon} \ell)$ for this problem; see the full version for details.

▶ **Theorem 5.** *For Socially Fair Facility Location with group-homogeneous facility cost, there exists a polynomial-time algorithm that achieves a $(4 + \varepsilon)$-approximation for any $\varepsilon > 0$.*

▶ **Theorem 6.** *For Socially Fair Facility Location with group-heterogeneous facility cost, there exists a polynomial-time algorithm that achieves an $O(q/\log q)$-approximation.*

Organization

Section 3 gives an overview of the proofs of our results. In Section 4, we present our fixed-parameter tractable (FPT) algorithm for ℓ_p-Clustering. In Section 5, we analyze a simple single-swap local search algorithm for (p, q)-Clustering. In Section 6, we describe our algorithm for (p, q)-Socially Fair Facility Location. In the full version of the paper, we give a $(3 + \varepsilon)$-bicriteria local-search algorithm that opens $k + f(\ell)$ centers for ℓ_1-Clustering.

2 Preliminaries

This paper focuses on the ℓ_p and (p, q)-Fair Clustering Problems, referred to below simply as ℓ_p- and (p, q)-Clustering. In these problems, we are given a metric space (X, d), where the points represent data points or clients, and a set of potential center or facility locations $F \subseteq X$. Let n be the number of data points or clients. For each point $u \in X$, we are also given a vector of weights $w(u) \in \mathbb{R}^{\ell}_{\geq 0}$, where the i-th coordinate $w_i(u)$ denotes the weight for group i. We denote the number of groups by ℓ. The goal is to select a subset of k centers $C \subseteq F$ that minimizes objective (1) for ℓ_p-Clustering and (2) for (p, q)-Clustering.

To analyze these objectives, we define the ℓ_p-cost of the clustering (raised to the power p) with respect to a weight function $w_i : X \to \mathbb{R}_{\geq 0}$ and centers C as

$$\mathrm{cost}(w_i, C) = \sum_{u \in X} w_i(u) d(u, C)^p,$$

where $d(u, C) = \min_{c \in C} d(u, c)$. We then define the cost vector induced by weights w and centers C as the ℓ-dimensional vector whose i-th coordinate is $\mathrm{cost}(w_i, C)^{1/p}$. Then the ℓ_p-objective in (1) is the ℓ_∞-norm of the cost vector, while the (p, q)-objective in (2) is its ℓ_q-norm.

We will need the following claim.

▷ Claim 7 (see e.g. Lemma A.1 in [21]). For all non-negative real numbers a and b, and for every $p \geq 1$ and $\varepsilon > 0$, we have

$$(a + b)^p \leq (1 + \varepsilon)^{p-1} a^p + (1 + 1/\varepsilon)^{p-1} b^p,$$

[3] We recall that the $(1, \log \ell)$ objective approximates the $(1, \infty)$ objective up to a constant factor

3 Proof Overview

In this section, we offer a technical overview of the proofs of our main results. We focus primarily on the fixed-parameter tractable (FPT) approximation algorithm for ℓ_p-Clustering parameterized by the number of groups ℓ (Section 4), and then briefly describe the ideas underlying the remaining results.

3.1 FPT approximation for ℓ_p-Clustering (Section 4)

Our goal is to design a constant-factor approximation algorithm for ℓ_p-Clustering that runs in time $f(\ell) \cdot n^{O(1)}$, parameterized only by the number of groups ℓ. As a starting point, we run the algorithm of [15] (see Theorem 3) to get a $(5 + 2\sqrt{6})$-approximate solution with at most $k + \ell$ centers in polynomial time. In the special case of ℓ_1-Clustering, we can alternatively use the local-search-based bicriteria approximation algorithm (see the full version of the paper), which yields a better approximation. Let C denote the resulting set of $k + t$ centers, where $t = \ell$, and let c be the corresponding approximation factor.

Given such a bicriteria solution, the main challenge is to close t centers and reassign the clients assigned to them to other centers, while controlling the cost increase for all groups. We proceed in two steps. First, we show that *existentially* it is possible to close t centers C_1 and reassign every client assigned to a center c in C_1 to the center closest to c in $C \setminus C_1$ so that the cost of the resulting solution is within a constant factor of the cost of C (see Lemma 9 for the exact guarantee). The key idea is that the new connection cost for a client u can be bounded in terms of both the cost of connecting u to its originally assigned center in C_1 and the cost of connecting u to the center serving u in the optimal solution C^*. This observation is important because it allows us to reassign the clients assigned to the t closed centers to at most t centers (that are not closed), and this property is crucial for our algorithm.

However, we cannot use the procedure from Lemma 9 directly, as it requires knowledge of C^*. Thus, to obtain an FPT algorithm, we need to identify the set C_1 without access to the optimal solution. This is achieved using the technique of color coding introduced by [5]. Let $C_2 \subseteq C \setminus C_1$ be the set formed by selecting, for each $c \in C_1$, a closest center to c in $C \setminus C_1$. Note that $|C_2| \leq |C_1| = t$ (each center $c_1 \in C_1$ contributes at most one selected center; and different centers in C_1 may potentially have the same closest center in $C \setminus C_1$). We color all centers in C randomly using two colors, red and blue. Each center is colored red or blue independently with probability $1/2$. Note that with probability at least 2^{-2t}, all centers in C_1 are colored red and all centers in C_2 are colored blue. By running the algorithm $O(2^{2t} \log n)$ times, we obtain a coloring with this property with high probability. We denote the sets of red and blue centers by R and B, respectively.

Now, we introduce the notion of a Z-profile of a center c. Loosely speaking, the Z-profile is a vector in $\mathbb{R}^\ell$ that captures, for each of the ℓ groups, the reassignment cost incurred by closing center c and reassigning all clients assigned to c to the center closest to c in Z. Crucially, the C_2-profiles of all centers in C_1 fully determine the reassignment cost: the reassignment cost vector is simply the sum of the C_2-profiles of all centers in C_1. Importantly, if we were to find another set of centers in R with the same profiles, the reassignment cost would be the same. However, there are two challenges in finding such a set. First, as defined, the number of possible profiles is unbounded. Second, since we do not know the set C_2, we cannot compute the C_2-profiles of centers in R.

To resolve the first issue, we discretize the set of all possible profiles so that their number is bounded by a function of ℓ, t, p, and $1/\varepsilon$. We then "guess" the number of centers in C_1 with each possible profile. Next, we observe that the C_2-profiles and B-profiles of centers in

C_1 are equal, and thus we can use B as a proxy for C_2. We select centers in R according to our guess of the profile counts and obtain a set D_1 of t centers to close. Given the discussion above, it is not hard to see that by closing the centers in D_1 and reassigning clients to their closest centers in B, we obtain a constant-factor approximation.

3.2 Local search for (p, q)-Clustering (Section 5)

Building on the local search algorithms from [7] and [17] for k-median, k-means, and (k, p)-clustering, we design and analyze a local search algorithm for the more general (p, q)-Clustering problem. The general approach is similar to that of [7] and [17], but the analysis is more complex, as it requires fine-grained control over the distribution of swaps (see below).

The algorithm starts with an arbitrary set C of k centers and repeatedly finds and performs a swap $c \to c'$ that replaces one of the centers $c \in C$ with a center c' outside of C. The swaps are chosen to minimize the (p, q)-Clustering objective, and the algorithm terminates when no swap decreases the current potential Φ by more than $\Phi/(8k)$. To prove that the algorithm achieves an $O(q)$-approximation, we show that if the cost of the current solution exceeds the optimal cost by $\Omega(q)$ times, then there must exist an improving swap. To this end, we present a distribution over special swaps that replace centers in C with centers in an unknown optimal solution C^* (The algorithm may choose a swap from the distribution or any other swap improving the objective; we use the distribution only for the analysis). While this approach resembles that of [7] and [17], we require significantly more control over the distribution of swaps to handle the more complex objective. In particular, we use careful linear approximations for the change in the non-linear objective that allow us to show that there is indeed such a distribution over improving swaps.

To obtain these linear approximations, roughly speaking, we can obtain upper and lower bounds on the derivative of the cost function in the desired range. One can then use the mean-value theorem to find a linear approximation of the change in the objective using these bounds. The actual proof is slightly different, and uses convexity arguments along with the mean value theorem. Carefully combining this with the standard linear-objective analysis for k-Median, we show that the algorithm is an $O(q)$ approximation.

3.3 Socially Fair Facility Location (Section 6)

Finally, we study (p, q)-Socially Fair Facility Location. We consider two variants of the problem: facility location with homogeneous opening costs and facility location with heterogeneous opening costs. For the homogeneous case, we use a rounding algorithm inspired by the standard facility location algorithm of [23]. For the heterogeneous case, we replace the greedy step that selects and opens the cheapest facility within a certain ball B_u with a randomized rounding step that opens a facility in B_u with probability proportional to the target probability given by the convex relaxation. We then use Rosenthal's inequality to bound the expected ℓ_q-norm of the solution. We also give a hardness result showing that our algorithm is near-optimal for ℓ_1-Socially Fair Facility Location (the case when $p = 1$, $q = \infty$).

4 FPT algorithm for ℓ_p-socially fair clustering

As discussed in the introduction, we provide an FPT algorithm for ℓ_p-Clustering, parameterized by the number of groups ℓ. The algorithm first finds an approximate solution with $k + t$ centers using Theorem 3. This solution provides only a *bicriteria* approximation. To obtain a *true* approximation, the algorithm closes t centers – using Theorem 2.

We now proceed with the proof of Theorem 2. Given the instance of ℓ_p-Clustering on point set X and metric d, a set of centers C and an assignment $\alpha : X \to C$, we define the cost with respect to the weight function w_i and assignment α as follows:

$$\text{cost}_i(\alpha) = \text{cost}(w_i, \alpha) := \sum_{u \in X} w_i(u) d(u, \alpha(u))^p.$$

Note that the ℓ_p-objective function for the assignment α is then $\max_{i \in [\ell]} \text{cost}_i(\alpha)^{1/p}$. Throughout this section, we fix an optimal set of centers C^* and a corresponding optimal assignment β^*. Let us define OPT to be the optimal assignment ℓ_p-objective, so that $\text{OPT} = \max_i \text{cost}_i(\beta^*)^{1/p}$.

First, we show that given any set C of $k + t$ centers which is a c-approximate solution, indeed there exists a subset of t centers that can be closed such that the resulting subset of k-centers is a $(3c + 2)$-approximate solution. However, besides this, we show a stronger property that our algorithm requires: every client assigned to some center of C (in an optimal assignment of clients to C) that is closed in this process can now be reassigned to one of at most t open centers in C. The next key lemma proves this result. Before we state the lemma, the following definition will be useful.

▶ **Definition 8.** *Given a set of open centers C, an assignment $\alpha : X \to C$ of points to centers in C, and two disjoint subsets $C_1, C_2 \subseteq C$, we define a new assignment α' obtained from α by reassigning clients as follows. For each client $u \in X$, if $\alpha(u) \in C_1$, we find the closest center c_2 in C_2 to $c_1 \equiv \alpha(u)$ and let $\alpha'(u) = c_2$. If $\alpha(u) \notin C_1$, we set $\alpha'(u) = \alpha(u)$ (do not change the assignment).*

We then define $\text{cost}(\alpha, C_1, C_2)$ *to be the vector* $(v_1, v_2, \ldots, v_\ell)$ *with* $v_i = \text{cost}_i(\alpha') - \text{cost}_i(\alpha)$ *for each* $i \in [\ell]$.

Simply put, $\text{cost}_i(\alpha, C_1, C_2)$ measures the increase in cost for group (coordinate) i by re-assigning each point assigned to a center $c_1 \in C_1$ to the center in C_2 closest to c_1. We use the shorthand $\text{cost}(\beta, c_1, C_2)$ to denote $\text{cost}(\beta, \{c_1\}, C_2)$. If β is an optimal assignment, then $\text{cost}(\beta, c_1, C_2)$ is coordinatewise non-negative, since any reassignment can only increase the cost. We also have:

$$\text{cost}(\beta, C_1, C_2) = \sum_{c_1 \in C_1} \text{cost}(\beta, c_1, C_2) \tag{3}$$

We formalize this nearest-neighbor redirection operation in the following lemma, showing that one can close a set C_1 of t centers and reassign all affected clients to a set C_2 of at most t receiving centers while keeping the reassignment cost controlled. The redirection operator in the definition captures exactly what happens when we close centers $C_1 \subseteq C$: for each closed center $c_1 \in C_1$, we send all of its clients to the closest open center $c_2 \in C \setminus C_1$. Let C_2 be the set of such receiving centers.

▶ **Lemma 9.** *Given a c-approximate solution C with $k + t$ centers and a corresponding optimal assignment β of clients to centers in C, there exist disjoint sets $C_1, C_2 \subseteq C$ with $|C_2| \leq |C_1| = t$ such that*

- $\| \text{cost}(\beta, C_1, C_2) \|_\infty \leq ((3c + 2)^p - c^p)\text{OPT}^p$
- $C_2 = \{c_2 : c_2$ *is the closest point from* $C \setminus C_1$ *to* c_1 *for some* $c_1 \in C_1\}$.

Proof. Let $C^* = \{c_1^*, c_2^*, \ldots, c_k^*\}$ be an optimal set of centers, and let β^* be an optimal assignment of clients to the centers in C^*. For each c_i^*, mark $\gamma(c_i^*) \in C$, the closest center to c_i^* in C. Then there are at most k marked centers in C and at least t unmarked ones. Choose any subset of t unmarked centers in C to be the set C_1. For each center of C_1, we take the closest center in $C \setminus C_1$ to obtain the set C_2. Note that this means $|C_2| \leq |C_1|$.

We now show that this choice of C_1, C_2 satisfies the statement of the lemma. Let $c_1 \in C_1$ and let c_2 be the closest center to c_1 in $C \setminus C_1$ (which must be in C_2). Then, for every point $u \in X$ with $\beta(u) = c_1$, we reassign u to c_2.

We wish to bound the reassignment cost of u to c_2. Let $c^* = \beta^*(u)$ be u's assigned center in C^*. By the triangle inequality,

$$\begin{aligned}
d(u, c_2) &\le d(u, c_1) + d(c_1, c_2) \\
&\le d(u, c_1) + d\big(c_1, \gamma(c^*)\big) \text{ (c_2 is the closest center to c_1 in $C \setminus C_1$)} \\
&\le d(u, c_1) + d(c_1, c^*) + d\big(c^*, \gamma(c^*)\big) \\
&\le d(u, c_1) + 2d(c_1, c^*) \text{ (by definition of } \gamma(c^*)) \\
&\le d(u, c_1) + 2\big(d(u, c_1) + d(u, c^*)\big) \text{ (again by triangle inequality)} \\
&\le 3d(u, c_1) + 2d(u, c^*)
\end{aligned}$$

It follows from Claim 7 that for every $\delta > 0$, we get the inequality

$$d(u, c_2)^p \le 3^p d(u, c_1)^p (1+\delta)^{p-1} + 2^p d(u, c^*)^p \left(1 + \frac{1}{\delta}\right)^{p-1}$$

We can now use this to bound the change in cost. By definition, it follows that the contribution of client u to $\mathrm{cost}_i(\beta, C_1, C_2)$ is $w_i(u)\big(d(u, c_2)^p - d(u, c_1)^p\big)$. Now repeating the analysis for each point u, and recalling that $c_1 = \beta(u), c^* = \beta^*(u)$, we obtain

$$\begin{aligned}
\mathrm{cost}_i(\beta, C_1, C_2) \le \sum_{u \in X} w_i(u) \Big(& 3^p (1+\delta)^{p-1} \, d\big(u, \beta(u)\big)^p \\
& + 2^p \Big(1 + \frac{1}{\delta}\Big)^{p-1} d\big(u, \beta^*(u)\big)^p - d(u, \beta(u))^p \Big) \\
\le & \Big((3c)^p (1+\delta)^{p-1} + 2^p \Big(1 + \frac{1}{\delta}\Big)^{p-1} - c^p \Big) \ \mathrm{OPT}^p \quad \text{for each } i \in [\ell],
\end{aligned}$$

where we use the fact that $\sum_{u \in X} w_i(u) d\big(u, \beta^*(u)\big)^p \le \mathrm{OPT}^p$ and $\sum_{u \in X} w_i(u) d\big(u, \beta(u)\big)^p \le c^p \, \mathrm{OPT}^p$, since C is a c-approximate solution.

Now we set $\delta = \frac{2}{3c}$. It then follows that

$$\mathrm{cost}_i(\beta, C_1, C_2) \le \big((3c+2)^p - c^p\big) \, \mathrm{OPT}^p \, . \qquad \blacktriangleleft$$

Next, we describe how to find such sets in FPT time. We will use the color coding technique of [5]. We remark that while our algorithm is stated as a randomized algorithm for simplicity, it can be easily derandomized using standard techniques (see, for example, [12, Lemma 1]).

▶ **Lemma 10.** *Given a c-approximate solution C with $k + t$ centers and a corresponding optimal assignment β of clients to centers in C, one can find disjoint sets D_1, D_2 with $|D_2| \le |D_1| = t$ satisfying $\|\mathrm{cost}(\beta, D_1, D_2)\|_\infty \le \big((3c+2)^p - c^p + \varepsilon^p\big) \, \mathrm{OPT}^p$ in time $f(\ell, t, p, \frac{1}{\varepsilon}) n^{O(1)}$.*

Proof. Let $C_1, C_2 \subseteq C$ be the (unknown) subsets of C guaranteed by Lemma 9. We use color coding. Randomly and independently color each center in C red or blue, each with probability $1/2$. Call a coloring *good* if every center of C_1 is colored red and every center of C_2 is colored blue. Then a random coloring is good with probability at least 2^{-2t}. By independently sampling $O(2^{2t} \log n)$ random colorings, we can ensure that we enumerate a good coloring with high probability. Henceforth, assume that we are given a good coloring (we will try all the $O(2^{2t} \log n)$ colorings). Let $R \subseteq C$ be the red-colored centers, and $B \subseteq C$ be the blue-colored centers in this good coloring.

For a set $Z \subseteq C$, we say that the Z-profile of $c \in C$ is $(i_1, i_2, \ldots, i_\ell)$ if the m-th coordinate of $\text{cost}(\beta, c, Z)$ is in the interval $\left[\frac{(i_m-1)\varepsilon^p}{t}\,\text{OPT}^p, \frac{i_m\varepsilon^p}{t}\,\text{OPT}^p\right]$ for each $m \in [\ell]$. Here $i_1, i_2 \ldots i_\ell$ are positive integers. Let $\mathcal{P}$ be the set of profiles with all $i_j \le t(\frac{3c+2}{\varepsilon})^p$. Then $|\mathcal{P}| \le (t(\frac{3c+2}{\varepsilon})^p)^\ell$. Note that the C_2-profile of every $c_1 \in C_1$ lies in $\mathcal{P}$. This is the case because, for every coordinate $i \in [\ell]$, (1) $\text{cost}_i(\beta, c_1, C_2) \ge 0$, since β is an optimal assignment, and (2) $\text{cost}_i(\beta, c_1, C_2) \le \text{cost}_i(\beta, C_1, C_2) \le \|\text{cost}(\beta, C_1, C_2)\|_\infty \le (3c+2)^p\,\text{OPT}^p$ by (3) and Lemma 9.

For each profile $P \in \mathcal{P}$, guess the number of centers in C_1 with C_2-profile P. Let n_P denote this number for each P. Then $\sum_{P\in\mathcal{P}} n_P = |C_1| = t$. The number of guesses we need to make is at most $|\mathcal{P}|^t \le \left(t(\frac{3c+2}{\varepsilon})^p\right)^{\ell t}$.

Consider $c_1 \in C_1$ and let c_2 be the closest point to c_1 in $C \setminus C_1$. Note that $c_2 \in C_2$ (per item 2 in Lemma 9) and c_2 is also the closest point to c_1 in B, since $c_2 \in C_2 \subseteq B \subseteq C \setminus C_1$. Therefore, the C_2- and B-profiles of c_1 are the same. In particular, there are n_P centers with B-profile P in C_1. Since all centers in C_1 are red (recall that we assumed that the coloring is good), there are at least n_P red centers with B-profile P.

Now for each $P \in \mathcal{P}$, we choose exactly n_P red centers whose B-profile is P to form the set D_1[4]. Once we choose D_1, we let D_2 be the set of all centers $d_2 \in B$ such that d_2 is the closest center in B to some $d_1 \in D_1$. This concludes the construction of the sets D_1 and D_2.

▶ **Lemma 11.** $\|\text{cost}(\beta, D_1, D_2)\|_\infty \le ((3c+2)^p - c^p + \varepsilon^p)\,\text{OPT}^p$.

Proof. There is a one-to-one map $f : C_1 \to D_1$ such that the C_2-profile of c_1 and the B-profile of $d_1 = f(c_1)$ are the same for every $c_1 \in C_1$.

It follows that for every $d_1 \in D_1$ and every coordinate $i \in [\ell]$,

$$\text{cost}_i(\beta, d_1, D_2) = \text{cost}_i(\beta, d_1, B) \le \text{cost}_i(\beta, f^{-1}(d_1), C_2) + \frac{\varepsilon^p}{t}\,\text{OPT}^p\,.$$

The term $\frac{\varepsilon^p}{t}\,\text{OPT}^p$ is exactly the length of an interval in the definition of profiles. Summing this upper bound on $\text{cost}(\beta, d_1, B)$ over all $d_1 \in D_1$ and using (3), we get

$$\begin{aligned}
\text{cost}_i(\beta, D_1, D_2) &= \sum_{d_1\in D_1} \text{cost}_i(\beta, d_1, D_2) \\
&\le \sum_{d_1\in D_1} \left(\text{cost}_i(\beta, f^{-1}(d_1), C_2) + \frac{\varepsilon^p}{t}\,\text{OPT}^p\right) \\
&\le \text{cost}_i(\beta, C_1, C_2) + \varepsilon^p\,\text{OPT}^p \le \left((3c+2)^p - c^p + \varepsilon^p\right)\text{OPT}^p.
\end{aligned}$$

◀

◀

Proof of Theorem 2. Let β be an optimal assignment for the center set C. Invoke Lemma 10 to obtain the sets D_1, D_2. After obtaining the sets D_1, D_2, we close the centers D_1. Since $|D_1| = t$, it follows that we obtain a solution with at most k centers.

We have $\|\text{cost}(\beta)\|_\infty \le c^p\,\text{OPT}^p$, and by Lemma 10, the additional cost incurred is at most $\|\text{cost}(\beta, D_1, D_2)\|_\infty \le ((3c+2)^p - c^p + \varepsilon^p)\,\text{OPT}^p$. Thus the ℓ_p-objective of the resulting solution with k centers is at most $\left((3c+2)^p - c^p + \varepsilon^p + c^p\right)^{1/p}\text{OPT} \le (3c+2+\varepsilon)\,\text{OPT}$ where in the final step we use the inequality $(a+b)^{1/p} \le a^{1/p} + b^{1/p}$, which holds for every $p \ge 1, a, b \ge 0$. ◀

[4] While we do not know OPT, we can guess OPT^p up to a factor of $(1+\varepsilon)$, but we omit this detail in the proof for the sake of simplicity

By Theorem 3 of [15], we can find a $c = 5 + 2\sqrt{6}$-approximate solution with $k + \ell$ centers in polynomial time. By Lemma 10, we can close ℓ centers in this bicriteria approximation solution to get a solution with k centers in time $\left(\ell(\frac{3c+2}{\varepsilon})^p\right)^{\ell^2} n^{O(1)}$. This proves Theorem 1.

5 Local search algorithm for (p, q)-clustering

5.1 Local search with scalar costs

Following [7] and [17], we first revisit the local search algorithm for (k, p)-clustering. We will later apply the results of this section to analyze the performance of the local search algorithm for (p, q)-Clustering.

Let (X, d) be a metric space, and let $w(u)$ be non-negative vertex weights. We consider one step of the local search algorithm. Let $C = \{c_1, \dots, c_k\}$ be the current set of k centers, and $C^* = \{c_1^*, \dots, c_k^*\}$ be a target set. Later, C^* will be an optimal solution for the (p, q)-objective, but for now, we make no assumptions about it.

We define the cost of C as

$$\operatorname{cost}(w) = \operatorname{cost}(w, C) = \sum_{u \in X} w(u) d(u, C)^p,$$

and the cost of C^* as

$$\operatorname{cost}^*(w) = \operatorname{cost}(w, C^*) = \sum_{u \in X} w(u) d(u, C^*)^p.$$

Consider a swap operation $c_a \to c_b^*$ that replaces c_a with c_b^*. We denote the resulting set of centers by

$$C_{ab} = (C \setminus \{c_a\}) \cup \{c_b^*\},$$

and its cost by $\operatorname{cost}_{ab}(w) = \operatorname{cost}(w, C_{ab}) = \sum_{u \in X} w(u) d(u, C_{ab})^p$.

Consider a probability distribution $\mathcal{D}$ on the set of swaps $c_a \to c_b^*$ (equivalently, on $[k] \times [k]$). The expected cost after a random swap drawn from $\mathcal{D}$ is $\mathbb{E}_{(a,b)\sim\mathcal{D}}[\operatorname{cost}_{ab}(w)]$.

We derive the following guarantees for local search. Conceptually, the proof closely follows the analyses in [7] and [17]. However, the bounds we require are more intricate, as we need finer control over the distribution of swaps. We prove this lemma in Section 5.4.

▶ **Lemma 12.** *Let (X, d) be a metric space, and let C and C^* be two sets of centers. There exists a probability distribution $\mathcal{D}$ over swaps such that the following holds. For every $p \geq 1$, weights w, parameters $M \geq m > 0$, and coefficients $\xi_{ab} \in [m, M]$, we have:*

1. *For $\alpha = \frac{10Mp}{m}$, the following inequality holds.*

$$\mathbb{E}_{\mathcal{D}}[\xi_{ab} \cdot (\operatorname{cost}_{ab}(w) - \operatorname{cost}(w))] \leq \frac{m}{2k}(\alpha^p \operatorname{cost}^*(w) - \operatorname{cost}(w)) \tag{4}$$

2. *We also have:*

$$\mathbb{E}_{\mathcal{D}}[\xi_{ab} \cdot (\operatorname{cost}_{ab}(w) - \operatorname{cost}(w))] \leq \frac{(1 + 2^{2p})M}{k}(\operatorname{cost}^*(w) + \operatorname{cost}(w)) \tag{5}$$

3. *Finally, for every swap $c_a \to c_b^*$ in the support of $\mathcal{D}$ and every $\delta_0 \in (0, 1/4)$, we have*

$$\operatorname{cost}_{ab}(w) \leq (1 + \theta_0) \operatorname{cost}^*(w) + (1 + \delta_0) \operatorname{cost}(w), \tag{6}$$

where $\theta_0 = 2^p (5p/(4\delta_0))^{p-1}$.

At a high level, the necessity for such guarantees is as follows. In k-median, the objective is linear, and the effects of the change in cost due to a single swap can be directly accounted for. However, in (p,q)-Clustering, the objective involves two layers of non-linearity (the inner and outer norms). To deal with this non-linearity, we can write the change in the objective for each swap $c_a \to c_b^*$ as a linear change with multipliers ξ_{ab} using the mean value theorem and convexity. Here the multipliers ξ_{ab} are bounded in the range $[m, M]$ for some appropriate choice of m and M. The above lemma then assumes this boundedness of ξ_{ab} and derives guarantees on the change in $\text{cost}(w)$, which in turn bounds the change in the objective.

5.2 Single swap analysis w.r.t. the (p,q)-objective

Now we consider the local search algorithm for (p,q)-Clustering – the goal is to minimize the following objective function:

$$\left(\sum_{i=1}^{\ell}\left(\sum_{u\in X} w_i(u)d(u,C)^p\right)^{q/p}\right)^{1/q} = \left(\sum_{i=1}^{\ell}\text{cost}(w_i,C)^{q/p}\right)^{1/q}$$

From now on, let C^* be an optimal solution for the (p,q)-Clustering problem. We assume that swap $c_a \to c_b^*$ is sampled from distribution $\mathcal{D}$ constructed in Lemma 12. Define $r = q/p$ and $\varphi(t) = t^r$, and

$$z_i = \text{cost}(w_i), \qquad z_i' = \text{cost}_{ab}(w_i), \qquad z_i^* = \text{cost}^*(w_i)$$
$$\Phi = \sum_{i=1}^{\ell}\varphi(z_i), \qquad \Phi_{ab} = \sum_{i=1}^{\ell}\varphi(z_i'), \qquad \Phi^* = \sum_{i=1}^{\ell}\varphi(z_i^*)$$

Note that $(\Phi^*)^{1/q}$ is the cost of the optimal solution, $\Phi^{1/q}$ is the cost of the current solution, and $\Phi_{ab}^{1/q}$ is the cost of the solution after a swap $c_a \to c_b^*$. Also, let

$$\Delta_i = \mathbb{E}\left[\varphi(z_i') - \varphi(z_i)\right].$$

Fix a coordinate i. Now we get an upper bound for $\varphi(z_i')$ by approximating φ with a piecewise linear function. Let $\hat{z}_i$ be the maximum of z_i' over all swaps in the support of $\mathcal{D}$ (we will obtain an upper bound on $\hat{z}_i$ later using Lemma 12, item 3). Let $M = \frac{\varphi(\hat{z}_i)-\varphi(z_i)}{\hat{z}_i - z_i}$ and $m = \varphi(z_i)/z_i = z_i^{r-1}$. Note that $M \le \varphi'(\hat{z}_i)$ when $\hat{z}_i > z_i$, by the Mean Value Theorem and monotonicity of φ'. Since φ is convex, we have (see Figure 1)

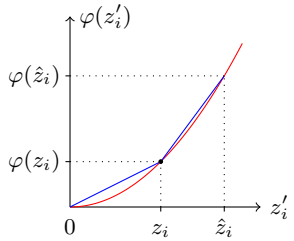

Figure 1 We approximate $\varphi(z_i')$ on the interval $[0, \hat{z}_i]$ using a piecewise linear function consisting of two segments: the first with slope m, and the second with slope M.

$$\varphi(z_i') \le \begin{cases} \varphi(z_i) + m\cdot(z_i' - z_i), & \text{if } z_i' < z_i \\ \varphi(z_i) + M\cdot(z_i' - z_i), & \text{if } z_i' \ge z_i \end{cases}$$

Define coefficients ξ_{ab} as follows

$$\xi_{ab} = \begin{cases} m, & \text{if } z_i' < z_i \\ M, & \text{otherwise} \end{cases}$$

Then $\varphi(z_i') \le \varphi(z_i) + \xi_{ab} \cdot (z_i' - z_i)$, and we have $\Delta_i \equiv \mathbb{E}\left[\varphi(z_i') - \varphi(z_i)\right] \le \mathbb{E}\left[\xi_{ab} \cdot (z_i' - z_i)\right]$.

We are now in a position to use Lemma 12, from which we derive the following key inequality, whose proof is deferred to Section 5.5.

$$\Delta_i \le \frac{1}{4k}\left(\beta^q \varphi(z_i^*) - \varphi(z_i)\right) \tag{7}$$

with $\beta = O(q)$. Adding up the inequality over all coordinates $i \in [\ell]$, we get

$$\mathbb{E}\left[\Phi_{ab} - \Phi\right] = \sum_{i=1}^{\ell} \Delta_i \le \frac{1}{4k}\left(\beta^q \Phi^* - \Phi\right).$$

In particular, this means that there is always a swap $c_a \to c_b^*$, for which

$$\Phi_{ab} - \Phi \le \frac{1}{4k}\left(\beta^q \Phi^* - \Phi\right).$$

5.3 Putting everything together

Consider the local search algorithm that at each iteration finds a swap $c_a \to c'$ with $c_a \in C$ and $c' \in F \setminus C$ that produces the greatest decrease in the potential function Φ, where C is the current set of open centers and F is the candidate facility set. The algorithm terminates when no swap decreases the current potential Φ by more than $\frac{\Phi}{8k}$.

5.3.1 Bounding the number of iterations

Suppose that $\Phi > 2\beta^q \Phi^*$. Then, for the improving swap $c_a \to c_b^*$ identified above, we have

$$\Phi_{ab} - \Phi \le -\frac{\Phi}{8k}$$

and

$$\Phi_{ab} - \Phi^* \le (\Phi - \Phi^*) - \frac{\Phi}{8k} \le \left(1 - \frac{1}{8k}\right)(\Phi - \Phi^*).$$

Thus when the algorithm stops, we must have $\Phi \le 2\beta^q \Phi^*$. Until the algorithm stops, in every iteration, the above inequality holds. It follows that after at most $8k \log_e(\Phi/\Phi^*)$ iterations, the algorithm will find a clustering of cost at most $2^{1/q} \cdot \beta \cdot (\Phi^*)^{1/q}$.

As is standard, by truncating distances and rounding weights, we may assume that all distances and weights are integers bounded polynomially in n. Therefore, the cost of any clustering is polynomial in n; hence, $\log_e(\Phi/\Phi^*)$ is bounded by $O(q \log n)$. We conclude that the algorithm returns a solution of cost at most $O(q)$ OPT in at most $O(qk \log n)$ iterations.

5.3.2 Running time per iteration

In each iteration, we maintain the current set of centers C. For each point u, we maintain its closest and second-closest centers $s_1(u)$ and $s_2(u)$ in C. At the beginning of every iteration, these quantities can be computed in time $O(nk)$. We can compute the change in cost due

to a swap $a \to b$ for each point u using $s_1(u), s_2(u)$ and the distances $d(u,a), d(u,b)$. Then we add these costs for each group in time $O_{p,q}(n\ell)$ and re-compute the potential. Thus, for every swap $a \to b$, we spend time $O_{p,q}(n\ell)$ and there are $O(nk)$ swaps, giving a per-iteration running time of $O(n^2k\ell)$. Since there are $O(kq \log n)$ iterations, the running time is at most $O_{p,q}(n^2\ell k^2 \log n)$. This concludes the proof of Theorem 4.

5.4 Proof of Lemma 12

In this Section, we prove Lemma 12.

Proof.

Defining the distribution of swaps. For each center $c_b^* \in C^*$, let $\gamma(c_b^*)$ denote the nearest center in C (see Figure 2). We partition the centers in C based on the number of preimages under γ:

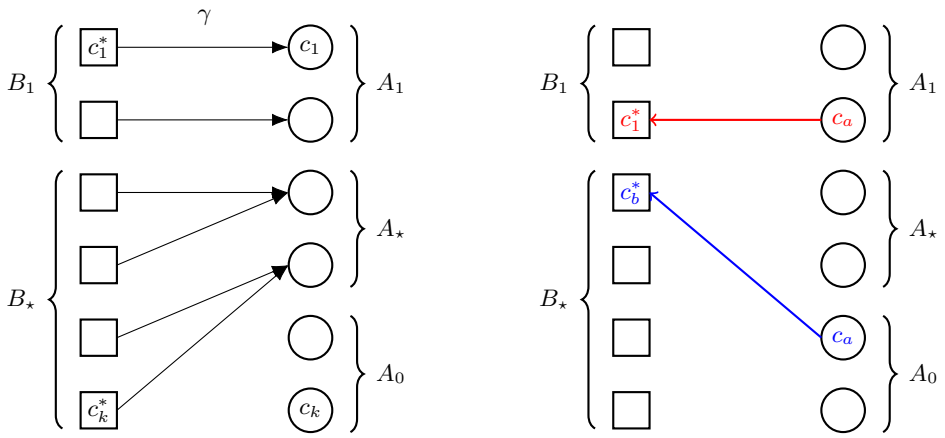

Figure 2 The left figure shows the map γ that maps every optimal center c_i^* to the closest current center c_j. This map defines the partition of the optimal centers into sets B_1 and $B_\star$ and the current centers into sets A_0, A_1, and $A_\star$. The right figure illustrates two possible types of swaps $c_a \to c_b$.

- A_1: centers with exactly one preimage,
- A_0: centers with no preimages,
- $A_\star$: centers with two or more preimages.

Define $B_1 = \gamma^{-1}(A_1)$ and $B_\star = \gamma^{-1}(A_\star)$. We observe:

- γ is a one-to-one map between B_1 and A_1,
- γ maps $B_\star$ onto $A_\star$, with every $c \in A_\star$ having at least two preimages.

Denote $s = |A_1|$. From the observations above, we get $|B_1| = |A_1| = s$ and $|A_\star| \le |B_\star|/2 = (k-s)/2$. Thus, $|A_0| = k - |A_1| - |A_\star| \ge (k-s)/2$. Now we are ready to define a probability distribution $\mathcal{D}$ over swaps.

1. With probability $\frac{s}{k}$, select $c_b^* \in B_1$ uniformly at random and set $c_a = \gamma(c_b^*) \in A_1$,
2. With probability $\frac{k-s}{k}$, select c_a uniformly from A_0 and c_b^* uniformly from $B_\star$.

This yields a random swap $c_a \to c_b^*$. Note that b is uniformly distributed in $[k]$ and therefore the probability that $b = b_0$ is $1/k$ for every fixed $b_0 \in [k]$. In general, a is not uniformly distributed; however, for every fixed $a_0 \in [k]$, the probability that $a = a_0$ is at most $\max(\frac{s}{k} \cdot \frac{1}{|A_1|}, \frac{k-s}{k} \cdot \frac{1}{|A_0|}) \le \max(1/k, 2/k) = 2/k$:

$$\Pr\{a = a_0\} \le 2/k \qquad \text{and} \qquad \Pr\{b = b_0\} = 1/k \tag{8}$$

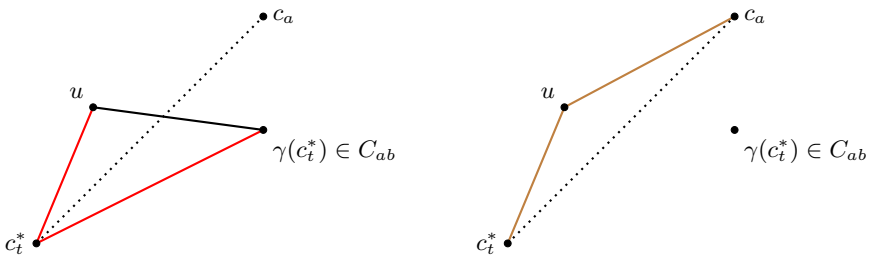

Figure 3 We assign point u to $\gamma(c_t^*)$, which is guaranteed to be in C_{ab}. The distance from u to $\gamma(c_t^*)$ is upper bounded by $d(u, c_t^*) + d(c_t^*, \gamma(c_t^*))$. Further, $d(c_t^*, \gamma(c_t^*)) \le d(c_t^*, c_a)$, since $\gamma(c_t^*)$ is the closest current center to c_t^*. In turn, $d(c_t^*, c_a)$ is upper bounded by $d(c_t^*, u) + d(u, c_a)$.

We will need below that for all $t \neq b$,

$$\gamma(c_t^*) \neq c_a. \tag{9}$$

Indeed, in item 1, $\gamma^{-1}(c_a) = \{c_b^*\}$; in item 2, $\gamma^{-1}(c_a) = \varnothing$. In either case, $c_t^* \notin \gamma^{-1}(c_a)$.

Upper bounding connection cost

Let $x_u = d(u, C)$ denote the distance from u to the closest center in the current solution C, $x'_u = d(u, C_{ab})$ the updated distance after the swap, and $x_u^* = d(u, C^*)$ the distance to the closest center in C^*. Let V_a be the Voronoi cell of c_a in C, and V_b^* the Voronoi cell of c_b^* in C^*. For $u \in V_b^*$,

$$x_u'^p - x_u^p \le x_u^{*p} - x_u^p.$$

For $u \in V_a \setminus V_b^*$, assume $u \in V_t^*$ for some $t \neq b$. By (9), $\gamma(c_t^*) \neq c_a$; thus, $\gamma(c_t^*) \in C_{ab}$ and

$$\begin{aligned} x'_u &= d(u, C_{ab}) \le d(u, \gamma(c_t^*)) \le d(u, c_t^*) + d(c_t^*, \gamma(c_t^*)) \le d(u, c_t^*) + d(c_t^*, c_a) \\ &\le d(u, c_t^*) + \big(d(c_t^*, u) + d(u, c_a)\big) = 2x_u^* + x_u. \end{aligned}$$

Here, we used that $d(c_t^*, \gamma(c_t^*)) \le d(c_t^*, c_a)$, since $\gamma(c_t^*)$ is the nearest center in C to c_t^*.

Applying Claim 7 with $\delta = (1+\varepsilon)^{p-1} - 1$ and $\theta = 2^p(1 + 1/\varepsilon)^{p-1}$, we get

$$x_u'^p \le (x_u + 2x_u^*)^p \le (1+\delta)x_u^p + \theta x_u^{*p}.$$

Thus,

$$x_u'^p - x_u^p \le \delta x_u^p + \theta x_u^{*p}.$$

Finally, if $u \notin V_a \cup V_b^*$, then $x'_u \le x_u$. We have,

$$\begin{aligned} \mathrm{cost}_{ab}(w) - \mathrm{cost}(w) &\le \sum_{u \in V_b^*} w_u \left(x_u'^p - x_u^p\right) + \sum_{u \in V_a \setminus V_b^*} w_u \left(x_u'^p - x_u^p\right) && (10) \\ &\le \sum_{u \in V_b^*} w_u \left(x_u^{*p} - x_u^p\right) + \sum_{u \in V_a} w_u \left(\delta x_u^p + \theta x_u^{*p}\right). && (11) \end{aligned}$$

We now derive an upper bound for $\xi_{ab} \cdot (\mathrm{cost}_{ab}(w) - \mathrm{cost}(w))$. Since $0 < m \le \xi_{ab} \le M$, we can replace ξ_{ab} with M in positive terms and with m in negative terms. We have:

$$\xi_{ab} \cdot (\mathrm{cost}_{ab}(w) - \mathrm{cost}(w)) \le \sum_{u \in V_b^*} w_u \left(M x_u^{*p} - m x_u^p\right) + M \sum_{u \in V_a} w_u \left(\delta x_u^p + \theta x_u^{*p}\right)$$

Now we assume that the swap $c_a \to c_b^*$ is sampled from the distribution $\mathcal{D}$ defined above. We get

$$\begin{aligned}&\mathbb{E}\left[\xi_{ab} \cdot (\mathrm{cost}_{ab}(w) - \mathrm{cost}(w))\right]\\ &\quad\le \sum_{u\in X} \Pr\{u \in V_b^*\} \cdot w_u \left(M x_u^{*p} - m x_u^p\right) + M \sum_{u\in X} \Pr\{u \in V_a\} \cdot w_u \left(\delta x_u^p + \theta x_u^{*p}\right)\end{aligned}$$

From 8, we get $\Pr\{u \in V_b^*\} = \frac{1}{k}$ and $\Pr\{u \in V_a\} \le \frac{2}{k}$ and thus

$$k\mathbb{E}\left[\xi_{ab} \cdot (\mathrm{cost}_{ab}(w) - \mathrm{cost}(w))\right] \le (1+2\theta)M\,\mathrm{cost}^*(w) - (m - 2\delta M)\,\mathrm{cost}(w). \tag{12}$$

We will use (12) to derive (4), (5), and (6). We will use different values of parameters ε, δ, and θ in these derivations. We will need the following lemma.

▶ **Lemma 13.** *For every $p \ge 1$ and every value of $\delta_0 \in (0, 1/4)$, there exists $\varepsilon > 0$ such that $\delta = (1+\varepsilon)^{p-1} - 1 \le \delta_0$ and $\theta \le 2^p \left(\frac{5p}{4\delta_0}\right)^{p-1}$.*

Proof. If $p = 1$, we let $\varepsilon = 1$, resulting in $\delta = 0$ and $\theta = 2$, and we are done. If $p > 1$, we choose ε so that $\delta = \delta_0$. Applying the Mean Value Theorem, we get

$$\varepsilon = (1+\delta_0)^{1/(p-1)} - 1 \ge \delta_0 \cdot \min_{t\in(0,\delta_0)} \frac{(1+t)^{1/(p-1)-1}}{p-1} \ge \frac{4}{5} \cdot \frac{\delta_0}{p-1},$$

where we used that $1 + t \le 1 + \delta_0 \le 5/4$ and $1/(p-1) - 1 \ge -1$. Therefore,

$$\theta = 2^p(1+1/\varepsilon)^{p-1} \le 2^p \left(\frac{5(p-1)+4\delta_0}{4\delta_0}\right)^{p-1} \le 2^p \left(\frac{5p}{4\delta_0}\right)^{p-1}. \qquad \blacktriangleleft$$

First, we establish the upper bound (4). We choose parameters according to Lemma 13 with $\delta_0 = m/(4M)$. Then $\theta \le 2^p(5pM/m)^{p-1}$. Since $0.5 \cdot 2^p(5Mp/m)^{p-1} \ge 2^{p-1} \ge 1$, we have

$$(1+2\theta)M \le 2.5 \cdot 2^p \left(\frac{5Mp}{m}\right)^{p-1} \cdot \frac{M}{m} \cdot m \le \frac{1}{2}\left(\frac{10Mp}{m}\right)^p m.$$

We conclude that

$$\mathbb{E}\left[\xi_{ab} \cdot (\mathrm{cost}_{ab}(w) - \mathrm{cost}(w))\right] \le \frac{m}{2k}\left(\left(\frac{10Mp}{m}\right)^p \mathrm{cost}^*(w) - \mathrm{cost}(w)\right).$$

Now we prove (5). We set $\varepsilon = 1$; then $\theta = 2^{2p-1}$ and $\delta = 2^{p-1} - 1$. From (12), we get

$$\begin{aligned}&k\mathbb{E}\left[\xi_{ab} \cdot (\mathrm{cost}_{ab}(w) - \mathrm{cost}(w))\right]\\ &\le (1+2\theta)M\,\mathrm{cost}^*(w) + 2\delta M\,\mathrm{cost}(w) \le (1+2^{2p})M(\mathrm{cost}(w) + \mathrm{cost}^*(w))\end{aligned}$$

Finally, for every swap $c_a \to c_b^*$ in the support of $\mathcal{D}$, we get the following upper bound from (11),

$$\begin{aligned}\mathrm{cost}_{ab}(w) - \mathrm{cost}(w) &\le \sum_{u\in V_b^*} w_u \left(x_u^{*p} - x_u^p\right) + \sum_{u\in V_a} w_u \left(\delta x_u^p + \theta x_u^{*p}\right)\\ &\le \sum_{u\in X} w_u x_u^{*p} + \sum_{u\in X} w_u \left(\delta x_u^p + \theta x_u^{*p}\right) \le (1+\theta)\,\mathrm{cost}^*(w) + \delta\,\mathrm{cost}(w).\end{aligned}$$

Choosing ε according to Lemma 13, we get the desired bound. $\blacktriangleleft$

5.5 Proof of Inequality 7

Applying Lemma 12, we get for $\alpha = 10Mp/m$,

$$\Delta_i \le \frac{m}{2k}\left(\alpha^p z_i^* - z_i\right) \tag{13}$$

$$\Delta_i \le \frac{(1+2^{2p})M}{k}(z_i + z_i^*). \tag{14}$$

From Lemma 12, item 3, with $\delta_0 = 1/(5r)$ and

$$\theta_0 = 2^p \left(\frac{25pr}{4}\right)^{p-1},$$

we get

$$\widehat{z}_i \le (1+\theta_0)z_i^* + (1+\delta_0)z_i \le \left(1+\frac{1}{5r}\right) z_i + (1+\theta_0)z_i^*. \tag{15}$$

Fix a threshold $T = \max\left(\frac{5r(1+\theta_0)}{4},\ 2(10eq)^p\right) = O(q)^p$. Consider two cases.

Current cost z_i is small: $z_i \le Tz_i^*$

From (15) and $1+\theta_0 \le \frac{4}{5r}T$,

$$\hat{z}_i \le \frac{6}{5}Tz_i^* + \frac{4}{5}Tz_i^* = 2Tz_i^*.$$

Accordingly, when $\hat{z}_i > z_i$, $M \le \varphi'(\hat{z}_i) = r\hat{z}_i^{r-1} \le r(2Tz_i^*)^{r-1}$. Also, $m \le M$. By (14)

$$\begin{aligned}\Delta_i &\le \frac{(4^p+1)M}{k}(z_i^* + z_i) = \frac{(4^p+1)}{k}\left(M\cdot(z_i^* + z_i + \frac{m}{M}z_i) - m\cdot z_i\right)\\ &\le \frac{(4^p+1)}{k}((2T+1)Mz_i^* - mz_i) \le \frac{1}{2k}\left(4^{p+2}\cdot r\cdot(2T)^r\varphi(z_i^*) - \varphi(z_i)\right).\end{aligned}$$

Letting $\beta = (2\cdot 4^{p+2}\cdot r\cdot(2T)^r)^{1/q} = O(q)$, we get

$$\Delta_i \le \frac{1}{4k}\left(\beta^q\varphi(z_i^*) - \varphi(z_i)\right).$$

Current cost z_i is large: $z_i \ge Tz_i^*$

We show that $2\alpha^p \le T$. From (15) and $1+\theta_0 \le \frac{4}{5r}T$, we have

$$\hat{z}_i \le \left(1 + \frac{1}{5r} + \frac{1+\theta_0}{T}\right) z_i \le \left(1+\frac{1}{r}\right) z_i.$$

Hence, when $\hat{z}_i > z_i$, $M \le \varphi'(\hat{z}_i) = r\hat{z}_i^{r-1} \le erz_i^{r-1}$ and $\alpha \le 10p\cdot(M/m) \le 10p\cdot(er) = 10eq$. Using that $z_i \ge Tz_i^* \ge 2(10eq)^p z_i^* \ge 2\alpha^p z_i^*$ and $\varphi(z_i) = mz_i$, we get from (13),

$$\Delta_i \le \frac{m}{2k}(\alpha^p z_i^* - z_i) \le -\frac{m}{2k}\cdot\frac{z_i}{2} = -\frac{1}{4k}\varphi(z_i).$$

6 Socially fair facility location

In this section, we consider two variants of the Socially Fair Facility Location problem and provide approximation algorithms for them.

We are given a set of n points X and a metric d on it, forming a metric space (X, d), as well as a set of possible facility locations F. There are ℓ groups on X represented by a weight function $w : X \to \mathbb{R}^{\ell}_{\geq 0}$ where $w_i(u) \geq 0$ denotes the weight of client u in group i. Each facility $c \in F$ is associated with a facility opening cost $f(c)$. We consider the following two settings with different types of facility opening costs: (1) group-homogeneous facility cost; (2) group-heterogeneous facility cost.

Group-homogeneous facility costs

Each facility $c \in F$ has a scalar opening cost $f(c) \geq 0$, paid equally across groups. The objective is to choose $C \subseteq F$ minimizing

$$\mathrm{FL}_{\mathrm{hom}}(w, f, C) := \left(\sum_{i=1}^{\ell} \mathrm{cost}(w_i, C)^{q/p} \right)^{1/q} + \sum_{c \in C} f(c),$$

where $\mathrm{cost}(w_i, C) = \sum_{u \in X} w_i(u)\, d(u, C)^p$.

[2] studied this objective with $p = 1$ and $q = \infty$ and gave a 4-approximation algorithm for it.

Group-heterogeneous facility costs

Each facility $c \in F$ has a vector opening cost $f(c) \in \mathbb{R}^{\ell}_{\geq 0}$, where group i pays $f_i(c)$ to open c.[5]

In this case, the objective is[6]

$$\mathrm{FL}_{\mathrm{het}}(w, f, C) := \left(\sum_{i=1}^{\ell} \left(\mathrm{cost}(w_i, C)^{1/p} + \sum_{c \in C} f_i(c) \right)^q \right)^{1/q}.$$

We get the following results for homogeneous and heterogeneous facility costs.

▶ **Theorem 5.** *For Socially Fair Facility Location with group-homogeneous facility cost, there exists a polynomial-time algorithm that achieves a $(4 + \varepsilon)$-approximation for any $\varepsilon > 0$.*

▶ **Theorem 6.** *For Socially Fair Facility Location with group-heterogeneous facility cost, there exists a polynomial-time algorithm that achieves an $O(q/\log q)$-approximation.*

We now provide the approximation algorithm for the group-heterogeneous setting.

---

[5] We interpret $f_i(c)$ as a group-specific *fixed* charge for opening facility c (e.g., taxes/subsidies or administrative overhead). Thus, group i pays $f_i(c)$ whenever c is opened, regardless of whether any group-i client is assigned to c; this keeps opening costs dependent only on the opened set C, as in standard fixed-charge facility location.

[6] If the heterogeneous opening costs are *group-uniform*, i.e., $f_i(c) = f(c)$ for all $i \in [\ell]$ and $c \in F$, then the objective becomes $\left(\sum_{i=1}^{\ell} \left(\mathrm{cost}(C, w_i)^{1/p} + \sum_{c \in C} f(c) \right)^q \right)^{1/q}$. We refer to this as the *group-uniform cost* variant. This objective is generally *different* from the group-homogeneous facility costs above. The two coincide when $q = \infty$, but they differ for finite q. By using our heterogeneous convex relaxation with $f_i(c) = f(c)$ and applying the rounding scheme used for the homogeneous costs, we obtain an $(8 + \varepsilon)$-approximation for this group-uniform cost variant.

Proof of Theorem 6. We use a relaxation of the problem and then use a randomized rounding procedure to get an integer solution. We consider the following relaxation

$$
\begin{aligned}
\min \quad & H \\
\text{s.t.} \quad & \sum_{i=1}^{\ell} z_i \le H^q \\
& z_i \ge \left(\sum_u w_i(u) \sum_{c \in F} d(u,c)^p \cdot x_{u,c} \right)^{\frac{q}{p}} && \forall i \in [\ell] && (16) \\
& z_i \ge \left(\sum_{c \in F} y_c \cdot f_i(c) \right)^q && \forall i \in [\ell] && (17) \\
& z_i \ge \sum_{c \in F} y_c \cdot f_i(c)^q && \forall i \in [\ell] && (18) \\
& \sum_{c \in F} x_{u,c} \ge 1 && \forall u \in X && (19) \\
& x_{u,c} \le y_c && \forall u \in X,\ \forall c \in F \\
& 0 \le y_c \le 1 && \forall c \in F \\
& 0 \le x_{u,c} \le 1 && \forall u \in X,\ \forall c \in F
\end{aligned}
$$

We can binary search on H. For any fixed value of H, the relaxation above is convex.

We then apply the following randomized rounding algorithm inspired by [19, 24]. Let (x^*, y^*, z^*, H^*) denote the fractional solution to the convex program above. The key difference is that, instead of opening the cheapest facility in B_u, we open exactly one facility c_u in B_u selected randomly with probability proportional to y^*_c. For each point $u \in X$, let $A_u = \sum_{c \in F} d(u,c)^p x^*_{u,c}$ denote the connection cost of point u given by the fractional solution. Then, we sort all points in X by their connection costs in increasing order. We iteratively perform the following steps until all points are assigned to open facilities. We first pick the unassigned point u with the smallest connection cost A_u as an anchor point. Let $B_u = \{c \in F : d(u,c)^p \le 2A_u\}$ be all facilities in a ball with radius $(2A_u)^{1/p}$ centered at u. It can be shown that the balls corresponding to distinct anchor points are disjoint. Then, we sample exactly one facility c_u in B_u with probability proportional to y^*_c. Assign all unassigned points v with distance $d(v,u) \le (2A_u)^{1/p} + (2A_v)^{1/p}$ to this new facility c_u. Let $\widehat{C}$ be the set of centers sampled by the rounding algorithm.

We now analyze the cost of this integer solution given by the rounding algorithm. Let $\hat{y}_c \in \{0,1\}$ be the indicator variable to denote whether facility c is selected in $\widehat{C}$. We first analyze the facility opening cost of this solution. By a simple averaging argument, for each iteration with anchor node u, we have $\sum_{c \in B_u} y^*_c \ge 1/2$. Since we open exactly one facility c_u in B_u with probability proportional to y^*_c, we have, for each facility $c \in B_u$,

$$\mathbb{E}[\hat{y}_c] = \frac{y^*_c}{\sum_{c \in B_u} y^*_c} \le 2y^*_c.$$

Consider any fixed group i. For each iteration with anchor point u, we define a random variable $Y_u = \sum_{c \in B_u} \hat{y}_c f_i(c)$ which represents the contribution to the facility cost of group i from that iteration. Since the choices made in distinct, disjoint anchor balls are independent, the collection $\{Y_u\}$ forms a set of independent non-negative random variables. By the

Rosenthal inequality (see [18]), we have

$$\mathbb{E}\left[\left(\sum_u Y_u\right)^q\right]^{1/q} \leq O\left(\frac{q}{\log q}\right)\max\left\{\left(\sum_u \mathbb{E}[Y_u^q]\right)^{1/q}, \sum_u \mathbb{E}[Y_u]\right\}.$$

Note that in each iteration, exactly one facility c_u in B_u is opened, which means exactly one random variable $\hat{y}_{c_u} = 1$ and all other $\hat{y}_c = 0$ in B_u. Thus, we have

$$\mathbb{E}[Y_u^q] = \mathbb{E}\left[\left(\sum_{c\in B_u} \hat{y}_c \cdot f_i(c)\right)^q\right] = \mathbb{E}\left[\sum_{c\in B_u} \hat{y}_c \cdot f_i(c)^q\right] \leq 2\sum_{c\in B_u} y_c^* \cdot f_i(c)^q.$$

Hence, we have $\sum_u \mathbb{E}[Y_u^q] \leq 2\sum_{c\in\bigcup_u B_u} y_c^* \cdot f_i(c)^q \leq 2z_i^*$. We also have

$$\sum_u \mathbb{E}[Y_u] = \sum_{c\in\bigcup_u B_u} f_i(c)\mathbb{E}[\hat{y}_c] \leq 2\sum_{c\in\bigcup_u B_u} f_i(c)y_c^* \leq 2(z_i^*)^{1/q} \leq O\left(\frac{q}{\log q}\right)H^*.$$

Therefore, we have

$$\mathbb{E}\left[\left(\sum_{c\in\bigcup_u B_u} \hat{y}_c f_i(c)\right)^q\right] \leq O\left(\left(\frac{2q}{\log q}\right)^q\right) z_i^*.$$

By taking the sum over all groups and applying Markov's inequality, with probability at least $1/2$, we have

$$\sum_{i=1}^{\ell}\left(\sum_{c\in\bigcup_u B_u} \hat{y}_c f_i(c)\right)^q \leq O\left(\left(\frac{2q}{\log q}\right)^q\right)\sum_{i=1}^{\ell} z_i^* \leq O\left(\left(\frac{2q}{\log q}\right)^q\right)(H^*)^q$$

We then analyze the connection cost of this integer solution. If v is assigned when u is the anchor, then $A_u \leq A_v$ and $d(v, c_u) \leq d(v, u) + d(u, c_u) \leq 3(2A_v)^{1/p}$. Hence, the connection cost for each group i given by $\widehat{C}$ is at most

$$\mathrm{cost}(w_i, \widehat{C})^{1/p} = \left(\sum_{u\in X} w_i(u)\cdot d(u,\widehat{C})^p\right)^{1/p} \leq \left(3^p\cdot 2\sum_{u\in X} w_i(u)\cdot A_u\right)^{1/p} \leq 6(z_i^*)^{1/q}.$$

By combining with the facility opening cost, the facility location cost is at most

$$\left(\sum_{i=1}^{\ell}\left(\mathrm{cost}(w_i,\widehat{C})^{1/p} + \sum_{c\in\widehat{C}} f_i(c)\right)^q\right)^{1/q}$$
$$\leq \left(\sum_{i=1}^{\ell} 2^q\,\mathrm{cost}(w_i,\widehat{C})^{q/p} + 2^q\left(\sum_{c\in\widehat{C}} f_i(c)\right)^q\right)^{1/q} \leq O\left(\frac{q}{\log q}\right)\cdot H^*.$$

Therefore, by computing a $(1+\varepsilon)$-approximate solution to the convex relaxation, this randomized rounding provides the desired approximation with probability at least $1/2$. ◀

Near-Optimal Streaming Approximation for Max-DICUT in Sublinear Space Using Two Passes

Santhoshini Velusamy
David R. Cheriton School of Computer Science, University of Waterloo, Canada

Abstract

The Max-DICUT problem has emerged as a canonical problem for understanding the approximability of constraint satisfaction problems in the streaming model. A seminal result of Kapralov and Krachun [STOC 2019] shows that it is impossible to beat 1/2-approximation for Max-DICUT in sublinear space in the single-pass streaming setting, even on bounded-degree graphs. In a recent work, Saxena, Singer, Sudan, and Velusamy [SODA 2025] prove that the above lower bound is tight by giving a single-pass algorithm for bounded-degree graphs that achieves $(1/2 - \epsilon)$-approximation in sublinear space, for every constant $\epsilon > 0$. For arbitrary graphs of unbounded degree, they give an $O(1/\epsilon)$-pass $O(\log n)$ space algorithm. Their work left open the question of obtaining 1/2-approximation for arbitrary graphs in the single-pass setting in sublinear space. We make progress towards this question and give a two-pass algorithm that achieves $(1/2 - \epsilon)$-approximation in sublinear space, for every constant $\epsilon > 0$.

1 Introduction

The maximum directed cut problem (Max-DICUT) is the analogue of the maximum cut (Max-CUT) problem for directed graphs. In particular, given a directed graph $G(V, E)$, the Max-DICUT problem asks to find an ordered bipartition (a "left" set L and a "right" set R) of the vertex set V that maximizes the number of edges that go from L to R. In contrast, in Max-CUT, we measure all the edges that cross L and R. Both Max-CUT and Max-DICUT are NP Hard and so, we study algorithms that approximately solve these problems. An α-approximation algorithm is one that outputs a solution that has a value which is at least α fraction of the optimum. Besides being fundamental problems in their own right, Max-CUT and Max-DICUT also belong to a large class of combinatorial optimization problems called the constraint satisfaction problems (CSPs) which capture several fundamental optimization problems in computer science. CSPs are well studied in theoretical computer science, owing in

part to their structure which allows for finite characterizations of the infinite set of problems they contain, in several computational settings. Their study has led to the discovery of several important algorithmic and complexity-theoretic tools including SDP approximations, the PCP theorem, and Unique Games.

In many computational settings, Max-CUT has successfully served as a canonical problem in the study of CSPs. For example, in the polynomial time setting, Goemans and Williamson [14] gave the first SDP-based approximation algorithm for Max-CUT. And on the lower bound side, conditioned on the Unique Games conjecture, Khot, Kindler, Mossell, and O'Donnell [20] constructed tight integrality gap instances showing that the Goemans-Williamson SDP for Max-CUT is optimal. In a breakthrough follow-up work, Raghavendra [22] generalized both these works to all CSPs and gives an optimal SDP-based characterization for the approximability of every CSP in polynomial time. However, in the streaming setting, Max-CUT does not capture all CSPs.

In the single-pass streaming model of computation, the constraints of a CSP instance (or edges of a graph in the case of Max-CUT, Max-DICUT) arrive in a stream. The streaming algorithm is allowed one pass over this stream and is required to compute an approximation to the optimum *value* of the instance, using limited space. The amount of space available to the algorithm is typically parameterized by n, the number of variables in the instance (or vertices of the input graph in the case of Max-CUT, Max-DICUT). For every CSP, there exists a trivial sampling-based algorithm [1, 28] that can achieve $(1-\epsilon)$-approximation using $\tilde{O}(n)$ space. Therefore, the interesting regime is when the algorithm is allowed only $o(n)$ space. Surprisingly, Max-CUT has no non-trivial approximation in this regime! In particular, 1/2-approximation is trivial (just output 1/2 for every input graph) since any graph has a bipartition with at least half the edges crossing the bipartition. A series of works [17, 18, 19], culminating with the breakthrough result of Kapralov and Krachun [19] show that for any constant $\epsilon > 0$, any single-pass streaming algorithm that achieves $(1/2+\epsilon)$-approximation for Max-CUT requires $\Omega(n)$ space. A follow-up work due to Chou, Golovnev, Sudan, Velingker, and Velusamy [7] proves optimal inapproximability results for multiple CSPs in $o(n)$ space, generalizing techniques from the Max-CUT lower bound [19].

On the algorithmic side, the first non-trivial approximation algorithm was discovered by Guruswami, Velingker, and Velusamy [16] for Max-DICUT. While Max-DICUT has a trivial 1/4-approximation, they gave a single-pass algorithm that achieves $(2/5-\epsilon)$-approximation using only $O(\log n)$ space, for every constant $\epsilon > 0$. Chou, Golovnev, and Velusamy [10] later achieved $(4/9-\epsilon)$-approximation in $O(\log n)$ space. They also prove that the 4/9 factor is optimal in $o(\sqrt{n})$ space, generalizing the techniques from the $\Omega(\sqrt{n})$ space lower bound of Max-CUT due to Kapralov, Khanna, and Sudan [17]. They further generalized their results to prove a $O(\log n)$ vs $\Omega(\sqrt{n})$ space dichotomy theorem for every Max-2CSP. This served as the basis for their subsequent works with Sudan [8, 9] which prove a $O(\log^3 n)$ vs $\Omega(\sqrt{n})$ space dichotomy characterization for every CSP.[1] Saxena, Singer, Sudan, and Velusamy [24] show that the $\Omega(\sqrt{n})$ lower bound in [10] is tight and give a 0.485-approximation algorithm for Max-DICUT in $\tilde{O}(\sqrt{n})$ space. In a later work [25], the same authors also show that it is possible to achieve $(1/2-\epsilon)$-approximation for *bounded-degree* (i.e., maximum degree bounded by a constant) graphs in $O(n^{1-\Omega(1)})$ space, for every $\epsilon > 0$. A trivial reduction from Max-CUT shows that the factor 1/2 is also optimal for Max-DICUT in $o(n)$ space.

[1] Their dichotomy characterization is for *dynamic* streaming algorithms which allow deletions and can process arbitrarily long streams.

In the multi-pass setting, a streaming algorithm is allowed to do multiple passes over the same stream of constraints. Assadi and Nagargoje [3] show that any p-pass algorithm for Max-CUT achieving $(1-\epsilon)$-approximation requires at least $\Omega(n^{1-O(\epsilon p)})$ space. A recent breakthrough result of Fei, Minzer, and Wang [11] shows that for any $\epsilon > 0$, any p-pass algorithm for Max-CUT (also Max-DICUT) achieving $(1/2+\epsilon)$-approximation requires at least $\Omega(n^{1/3}/p)$ space. In contrast, for *dense* instances of average degree at least n^{δ}, a two-pass streaming algorithm due to Bhaskara, Daruki, and Venkatasubramanian [5], achieves $(1-\epsilon)$-approximation for Max-CUT (also Max-DICUT) using $\tilde{O}(n^{1-\delta})$ space. An algorithm due to Saxena, Singer, Sudan, and Velusamy achieves $(1/2-\epsilon)$-approximation on arbitrary graphs in $O(1/\epsilon)$ passes using $O(\log n)$ space [25]. In a prior work [23], the same authors give a two-pass algorithm that achieves 0.485-approximation using $O(\log n)$ space. A recent result due to Fei, Minzer, and Wang [12] gives a dichotomy characterization in the multi-pass setting based on the basic LP relaxation for every CSP. In particular, they show that the techniques from [27, 25] can be combined with the distributed algorithms of Yoshida [29] to obtain a streaming algorithm that solves the LP relaxation for every CSP in $O(1/\epsilon^2)$ passes and $O(\log n)$ space. And to beat the approximation achieved by the basic LP, any p-pass streaming algorithm requires at least $\Omega(n^{1/3}/p)$ space.

The connection between streaming algorithms and LP relaxations was also identified in a concurrent work by Singer, Tulsiani, and Velusamy [26]. They conjecture that for every CSP, there must be a single-pass $o(n)$ space streaming algorithm that solves its LP relaxation, and any algorithm beating this factor must require at least $\Omega(n)$ space. For Max-DICUT, its basic LP achieves 1/2-approximation and so their conjecture states that there is a single-pass algorithm that achieves 1/2-approximation in $o(n)$ space. In this work, we make progress towards this conjecture and prove it in the two-pass setting.

▶ **Theorem 1.1** (Main result). *For every $\epsilon > 0$, there is a two-pass streaming algorithm that achieves $(1/2-\epsilon)$-approximation for* Max-DICUT *on any n-vertex graph using space $O(n^{1-\Omega_\epsilon(1)})$.*

2 Technical overview

In this section, we present a technical overview of the proof of our main result.

There are three main ingredients to our proof: 1) a single-pass $(1/2-\epsilon)$-approximation algorithm of Saxena, Singer, Sudan, and Velusamy [25] for bounded-degree graphs that uses $O(n^{1-\Omega(1)})$ space, 2) Trevisan's reduction [27] from unbounded-degree to bounded-degree graphs that approximately preserves the Max-DICUT value, and 3) Bhaskara, Daruki, and Venkatasubramanian's [5] two-pass algorithm that achieves $(1-\epsilon)$-approximation on graphs of average degree at least n^{δ} using $\tilde{O}(n^{1-\delta})$ space. The following theorems formally state their results.

▶ **Theorem 2.1** ([25]). *For every $d \in \mathbb{N}$ and $\epsilon > 0$, there is a single-pass streaming algorithm that achieves $(1/2-\epsilon)$-approximation for* Max-DICUT *on any n-vertex graph of maximum degree at most d using space $O(n^{1-\Omega(1)})$.*

▶ **Theorem 2.2** ([27]). *For any directed graph $G(V,E)$ on n vertices and m edges, and $0 < \epsilon \leq 1$, there exists a (random) directed graph $\overline{G}(\overline{V},\overline{E})$ on $2m$ vertices and $O(m/\epsilon^2)$ edges such that with probability at least $5/6$, $\textsf{Max-DICUT}(G)-\epsilon' \leq \textsf{Max-DICUT}(\overline{G}) \leq \textsf{Max-DICUT}(G)+\epsilon$, and the maximum degree of a vertex in $\overline{G}$ is at most $O(1/\epsilon^2)$.*

▶ **Theorem 2.3** ([5]). *For every $\epsilon, \delta \in (0, 1]$, there is a two-pass streaming algorithm that achieves $(1-\epsilon)$-approximation for* Max-DICUT *on any n-vertex graph of average degree at least n^{δ}, using space $\tilde{O}(n^{1-\delta})$.*

At a high level, our idea is to reduce the input graph which could potentially have an unbounded maximum degree to a bounded-degree graph using Trevisan's reduction [27], and then execute the [25] algorithm for bounded-degree graphs. However, there are challenges to this naive approach. Firstly, Trevisan's reduction is not a small-space reduction and requires the knowledge of the degree of every vertex in the graph. This would be too expensive to store in the streaming setting. Secondly, the reduction produces a graph with $2m$ vertices, which could be $\Theta(n^2)$ in the worst case, hence the [25] algorithm could require $\Omega(n)$ space. We deal with the second challenge by running the [25] algorithm only when the input graph is sufficiently sparse, i.e., has at most $n^{1+\delta}$ edges, for some suitably chosen δ so that the space usage is still at most $O(n^{1-\Omega(1)})$. And when the input instance is dense, we run the [5] algorithm. Thus, the space usage is always at most $O(n^{1-\Omega(1)})$. To deal with the first challenge, we implement the [25] algorithm in a non black-box manner. We do not produce the entire bounded-degree graph from the Trevisan reduction and instead only sample parts of this graph that are required for the [25] algorithm. Below, we give a high-level overview of both these algorithms and our implementation of them.

Trevisan reduction. The reduction is quite simple. Say $G(V, E)$ is an unweighted directed graph on n vertices and m edges, with possible multi-edges but no self-loops. Given G, Trevisan first creates a weighted graph $G'(V', E')$: for every vertex $v \in V$, he adds $\deg(v)$ many "copies" of it, labeled $(v, 0), \ldots, (v, \deg(v) - 1)$, to V'. For every edge $u \to v \in E$, and $i \in [\deg(u)], j \in [\deg(v)]$,[2] he adds an edge $(u, i) \to (v, j)$ of weight $\frac{1}{\deg(u)\deg(v)}$ to E'. It is not hard to see that the Max-DICUT values of G and G' are equal.[3] He then samples a random graph $\tilde{G}$ based on G' in the following way. The vertex set of $\tilde{G}$ is V' and he samples the edge set as follows: he sets a parameter $d = O(1/\epsilon^2)$ and samples dm edges independently (with repetition) from G', where in each sample, an edge in E' is sampled with probability proportional to its weight. He finally deletes a minimal set of edges from $\tilde{G}$ so that the degree of every vertex is at most $O(d)$. He argues that with high probability, at most an ϵ fraction of the edges are deleted, and that the Max-DICUT value is preserved up to an additive ϵ factor.

SSSV algorithm. Saxena, Singer, Sudan, and Velusamy make a key observation that on bounded-degree graphs, in order to simulate a distributed algorithm for Max-DICUT, it suffices to estimate certain neighborhood distributions of the input graph (see Section 3.1 for more details). They show that such distributions can be estimated from the induced subgraph of a randomly sampled subset of the vertex set. Finally, based on a previous distributed algorithm of Censor-Hillel, Levy, and Shachnai [6], they give a distributed algorithm that achieves $(1/2 - \epsilon)$-approximation for Max-DICUT, and efficiently simulate it in sublinear space in the single-pass setting using the above techniques.

[2] For a natural number $n \in \mathbb{N}$, we define $[n] = \{0, \ldots, n-1\}$. Note that this is slightly different from the standard definition.

[3] For every $u \in V$ and $i, i' \in [\deg(u)]$, the copies (u, i) and (u, i') have identical neighborhood structure. Hence, for any fixed assignment of the remaining vertices, the DICUT value is locally maximized by placing all copies of u on the same side of the cut.

Putting them together (a three-pass algorithm). Since the [25] algorithm only requires the induced subgraph of a randomly sampled subset of the vertex set, we do not need to do the Trevisan reduction on the entire input graph. Instead, we directly sample a random subset of vertices from the bounded-degree graph, i.e., from $V' = \{(v, i) : v \in V; i \in [\deg(v)]\}$, and perform a *partial* Trevisan reduction on their *parent* vertices. To sample from V', we first map every edge $e \in E$, based on its position in the stream, to two unique vertices in V', i.e., no two edges map to the same vertex. In particular, an edge $u \to v$ is mapped to (u, i) and (v, j) iff it is the i-th edge (resp. j-th edge) incident on u (resp. v) in the stream. Thus, as the edges arrive in the stream, we can sample from V'.[4] Once the vertices are sampled, we have to sample the induced subgraph on these vertices. The original Trevisan reduction performs a *global* sampling of the edges, where every edge is sampled with probability proportional to its weight. In order to perform such a sampling, one would have to compute the weights on all the edges, which is infeasible in the streaming setting. We therefore modify the reduction to a *local* sampling procedure, where for every edge $u \to v \in E$, we create $d = O(1/\epsilon^2)$ "copies" of it in E' and for every copy of the edge, we independently sample a uniform random copy of u and a uniform random copy of v in V' as its endpoints.[5]We also delete *all* the edges incident on high-degree vertices and not just the minimal set of edges, as it is not clear how to compute the minimal set without generating the entire graph. We argue in Section 4 that this procedure still preserves the Max-DICUT value up to an additive ϵ factor with high probability. Now that we have this local procedure, we generate the induced subgraph on the sampled vertices as follows. After we sample the vertices in the first pass, we store the degrees of their parent vertices in the second pass. In the third pass, we again scan through the edges in the stream and if $u \to v$ is such that both u and v have at least one of their copies sampled, then we sample d independent copies of the edge as outlined above (we can do this since we know the degrees of u and v), and we store those edges that are in the induced subgraph. If neither u nor v have any copies in the sampled set of vertices, then we do nothing. If only one of them, say u, has sampled copies, then we sample only the endpoints corresponding to u's copies for the d copies of the edge. We do this to keep track of the degrees of all the sampled vertices, and in the end, delete all the edges incident on the high-degree vertices. The formal description of the procedure and the proof of correctness are described in Section 5.

Modifications to obtain a two-pass algorithm. In Section 6, we modify the above algorithm and get a two-pass algorithm by getting rid of the second pass which computes and stores the degrees of the parent vertices *exactly*. In particular, we show that our modified Trevisan reduction in Section 4 works even when we have only *approximate* estimates for the degrees of high-degree vertices. In the first pass, along with sampling vertices like in the above algorithm, we estimate the degrees of high-degree vertices using standard sampling methods. In particular, for every vertex, we sample each edge incident to it independently with probability $p = n^{-O_\epsilon(1)}$ and rescale the total number of sampled edges by $1/p$ to estimate its degree. This procedure would estimate the degrees accurately (up to a multiplicative error) for vertices of sufficiently-large polynomial degree, say n^c. We can ensure that the

[4] There is a subtlety here. We do not have enough space to remember the ordering of the edges incident on every vertex in the input graph, which is crucial in the above mapping. Instead, we label the sampled copies of a vertex based on the order in which they are sampled by our algorithm, and argue that this relabeling does not affect the correctness of the algorithm (see Section 5 for more details).

[5] A slightly different reduction, also amenable to streaming, was recently proposed by Fei, Minzer, and Wang in [12].

space is still sublinear because we run the Trevisan procedure only on graphs with bounded average degree. We then use these estimates to run edge sampling as in the third pass of the above algorithm. However, the copies of the edges incident on low-degree vertices will not be sampled correctly in this step. To fix this, for every vertex that is sampled in the first pass, we store the first n^c edges incident on its *parent* vertex in the second pass.[6] Thus, we can identify parent vertices of degree less than n^c, and also compute their degrees *exactly*. In post-processing, we delete the edges incident to the copies of such vertices, and resample them according to their correct distributions (since we now have the exact degrees of the low-degree parent vertices).

BDV algorithm for Max-CUT. Finally, we give a high-level description of the two-pass algorithm for dense instances of Max-CUT in [5]. While their paper explicitly states the result only for Max-CUT, their algorithm immediately extends to Max-DICUT as well. Their main idea is to use certain non-uniform sampling methods to construct a "core-set" of *sublinear* size for the input graph, which preserves the Max-CUT value up to an additive error ϵ. A core-set of linear size can be obtained for any graph by uniformly sampling $\tilde{O}(n/\epsilon^2)$ edges [1, 28]. And for very dense graphs of average degree at least $\Omega(n)$, constant-size core-sets can be constructed [15, 2, 21]. In the polynomial density regime (i.e., average degree n^δ for $\delta < 1$), previous works [13, 4] show that if both the maximum and the minimum degrees are $\Theta(n^\delta)$, then a core-set of size $\tilde{O}(n^{1-\delta})$ exists. Bhaskara, Daruki, and Venkatasubramanian [5] extend this result to general graphs in this regime, and give a two-pass streaming algorithm to construct a core-set of size $\tilde{O}(n^{1-\delta})$.

3 Preliminaries

In this paper, any reference to a directed graph G means unweighted graphs with multi-edges but no self-loops. For a directed graph $G(V, E)$, a dicut is an ordered bipartition of the vertex set V. An edge $u \to v$ is said to belong to a dicut $L \sqcup R$ if $u \in L$ and $v \in R$. The value of the dicut, denoted by $\mathsf{DICUT}(G, L \sqcup R)$ is the fraction of edges in G that belong to the dicut $L \sqcup R$. We define $\mathsf{Max\text{-}DICUT}(G)$ to be $\max_{L \sqcup R} \mathsf{DICUT}(G, L \sqcup R)$. For any function $\rho : V \to [0, 1]$, we define the expected dicut value of G under the rounding ρ, denoted by $\mathsf{DICUT}(G, \rho)$, to be $\mathbb{E}[\mathsf{DICUT}(G, L \sqcup R)]$, where every vertex in V belongs to L independently with probability $\rho(v)$.

For any function $f : A \to B$ that maps a domain A to a co-domain B, and $C \subseteq A$, we denote the restriction of the function to the domain C by $f|_C : C \to B$.

Distribution Notation

Let $\Delta(S)$ denote the set of all probability distributions over a finite set S. A distribution $\mu \in \Delta(S)$ assigns to each element $x \in S$ a probability $\mu(x) \geq 0$ such that $\sum_{x \in S} \mu(x) = 1$.

Total Variation Distance

The *total variation distance* between two distributions $\mu, \nu \in \Delta(S)$ is defined as

$$d_{\mathrm{TV}}(\mu, \nu) = \frac{1}{2} \sum_{x \in S} |\mu(x) - \nu(x)|.$$

[6] We need to be a bit careful when defining the degree thresholds and the sampling probabilities, but they can be set in a way to keep the space sublinear.

Equivalently,

$$d_{\mathrm{TV}}(\mu,\nu) = \max_{A\subseteq S} |\mu(A) - \nu(A)|,$$

where $\mu(A) = \sum_{x\in A}\mu(x)$. The total variation distance satisfies $d_{\mathrm{TV}}(\mu,\nu) \in [0,1]$, with $d_{\mathrm{TV}}(\mu,\nu) = 0$ if and only if $\mu = \nu$, and $d_{\mathrm{TV}}(\mu,\nu) = 1$ if and only if the supports of μ and ν are disjoint.

We now list some standard concentration bounds that will be used in the rest of the paper.

▶ **Theorem 3.1** (Chebyshev's inequality). *Let X be a random variable with variance σ^2. For any $a > 0$, we have*

$$\Pr[|X - \mathbb{E}[X]| > a] \leq \frac{\sigma^2}{a^2}.$$

▶ **Theorem 3.2** (Chernoff bound). *Let $X_1, \ldots, X_n$ be independent random variables taking values in $\{0,1\}$. Consider the sum of these random variables, $S_n = X_1 + \cdots + X_n$. Let $\mu = \mathbb{E}[S_n]$. Then for $R \geq 2e\mu$,*

$$\Pr[S_n \geq R] \leq 2^{-R}.$$

▶ **Theorem 3.3** (Hoeffding's inequality). *Let $X_1, \ldots, X_n$ be independent bounded random variables such that $a_i \leq X_i \leq b_i$. Consider the sum of these random variables, $S_n = X_1 + \cdots + X_n$. Then Hoeffding's theorem states that for all $t > 0$,*

$$\Pr[|S_n - \mathbb{E}[S_n]| \geq t] \leq 2\exp\left(-\frac{2t^2}{\sum_{i=1}^n (b_i - a_i)^2}\right).$$

3.1 Neighborhood distributions and the simulation of local algorithms

A key contribution of Saxena, Singer, Sudan, and Velusamy in [25] is the identification of a connection between streaming and local algorithms, where they show that it is possible to estimate local neighborhood distributions of graphs in the streaming setting and use these distributions to simulate constant-round distributed algorithms. We recall some of the notations introduced in their paper and reprove their main theorem that shows that sampling vertices uniformly at random and estimating local neighborhood distributions from the induced subgraph suffices to estimate the value of a local algorithm that is executed on the original graph.

First, we formally define the LOCAL model for distributed algorithms for the Max-DICUT problem and state the result of [6, 25].

▶ **Definition 3.4** (The LOCAL model for distributed algorithms for Max-DICUT). *Let $G(V,E)$ be a directed graph on n vertices and m edges. G describes the topology of a communication network, where each node can communicate with both its incoming and outgoing neighbors. Communication happens in synchronous rounds, where in every round, every node does some internal computations and sends an arbitrarily long message to each of its neighbors. At the end, each node v computes a fractional assignment $\rho(v) \in [0,1]$ and the approximation ratio achieved by the algorithm is defined to be $\mathsf{DICUT}(G,\rho)/\mathsf{Max\text{-}DICUT}(G)$. In randomized algorithms, the nodes also have access to an arbitrarily long private random bit string that is sampled prior to any communication between the nodes.*

▶ **Theorem 3.5** ([6, 25]). *For every $\epsilon > 0$, there exists a distributed algorithm for* Max-DICUT *in the LOCAL model that achieves $(1/2-\epsilon)$-approximation with probability at least $9/10$, and requires at most $1/\epsilon$ rounds of communication. It is a randomized algorithm where every node uses only an $O(\log(1/\epsilon))$-bit private random string, and the random strings can be sampled from a pairwise independent hash family.*

Saxena, Singer, Sudan, and Velusamy [25] observed that for each vertex v, $\rho(v)$ depends only on the structure of a ball of radius $1/\epsilon$ centered at that node, and the private random strings of all the nodes in this ball. They called this the "neighborhood type" of a vertex. They observed that in order to compute $\mathsf{DICUT}(G,\rho) = (\sum_{u\to v\in E}\rho(u)(1-\rho(v)))/m$ with a small additive error and a constant success probability, it suffices to sample a random constant-sized subset $S \subset E$ and output $\sum_{u\to v\in S}\rho(u)(1-\rho(v))/|S|$. This motivated them to define the notion of a neighborhood type of an edge that captures the neighborhood types of both its endpoints. Thus, estimating the distribution of the edge-neighborhood types would suffice to estimate $(\sum_{u\to v\in E}\rho(u)(1-\rho(v)))/m$, which in turn gives a $(1/2-\epsilon)$-approximation to $\mathsf{Max\text{-}DICUT}(G)$. For graphs whose maximum degree is bounded by a constant, the set of all possible edge-neighborhood types is constant sized, and hence, they could estimate their distribution efficiently in the streaming setting. In what follows, we will set up some notations to define the neighborhood types and reprove a key theorem from [25].

Let $G(V,E)$ be a directed graph and $u, v \in V$. We say that v is of distance at most ℓ from u if there exists a *path* from u to v which is a sequence of vertices $u = w_0, w_1, \ldots, w_{\ell-1}, w_\ell = v \in V$ such that for each $i \in [\ell]$, $w_{i-1} \to w_i \in E$ or $w_i \to w_{i-1} \in E$. Let $\mathbf{Typ}_c^{\ell,D}$ denote the set of all isomorphism classes of doubly rooted labeled graphs where every vertex is of degree at most D, has a c-bit label, and is of distance at most ℓ from (at least) one of the roots. Consider a directed graph $G(V,E)$ whose maximum degree is at most D. Let $\mathcal{H}_n$ be the pairwise independent hash family that is used to sample the private random strings for every node in the distributed algorithm of [6, 25]. Let $h : V \to \{0,1\}^c$ be any hash function in $\mathcal{H}_n$. For an edge $e \in E$, consider the following doubly rooted labeled graph $\mathcal{G}_e$: $\mathcal{G}_e$ is rooted at the endpoints of e and consists of all the vertices in G which are of distance at most ℓ from (at least) one of the roots, and their corresponding induced subgraph. In addition, each vertex v in G_e is labeled $h(v)$. The radius-ℓ neighborhood type of e with respect to G and the hash function h, $\mathsf{nbhdtype}^{\ell}_{G,h}(e)$, is defined to be the representative of the isomorphism class in $\mathbf{Typ}_c^{\ell,D}$ that contains $\mathcal{G}_e$. The neighborhood edge-type distribution of G with respect to the hash function h is defined as follows.

▶ **Definition 3.6** (Edge-type distribution). *Let $h : V \to \{0,1\}^c$, $\ell, D \in \mathbb{N}$ and $G = (V,E)$ be a directed graph of maximum degree D. The* radius-ℓ neighborhood type distribution *of G with respect to h, denoted $\mathsf{EdgeNbhdTypeDist}^{\ell}_{G;h}$, is the distribution over $\mathbf{Typ}_c^{\ell,D}$ given by sampling a random $e \sim \mathsf{Unif}(E)$ and outputting $\mathsf{nbhdtype}^{\ell}_{G,h}(e)$.*

▶ **Corollary 3.7** ([6, 25]). *For every $\epsilon'' > 0$, there exist $\ell, c, n_0 \in \mathbb{N}$ and a function $\mathtt{Local} : \mathbf{Typ}_c^{\ell,D} \to [0,1]$ such that for every $n \geq n_0$, there exists a hash family $\mathcal{H}_n$ such that the following holds. Let $G = (V,E)$ be a directed graph on n vertices and of maximum degree D. Let $h \sim \mathsf{Unif}(\mathcal{H}_n)$. Then with probability at least $9/10$,*

$$\frac{\mathsf{Max\text{-}DICUT}(G)}{2} - \epsilon'' \leq \mathbb{E}_{T\sim\mathsf{EdgeNbhdTypeDist}^{\ell}_{G;h}}[\mathtt{Local}(T)] \leq \mathsf{Max\text{-}DICUT}(G).$$

The following corollary implies that it suffices to compute a distribution that is close in total variation distance to $\mathsf{EdgeNbhdTypeDist}^{\ell}_{G;h}$.

▶ **Corollary 3.8.** *If $\mathcal{D} \in \Delta(\mathbf{Typ}_c^{\ell,D})$ is such that $\mathsf{tvd}(\mathcal{D}, \mathsf{EdgeNbhdTypeDist}^{\ell}_{G;h}) \leq \epsilon''$, then*

$$\frac{\mathsf{Max\text{-}DICUT}(G)}{2} - 2\epsilon'' \leq \mathbb{E}_{T\sim\mathcal{D}}[\mathtt{Local}(T)] \leq \mathsf{Max\text{-}DICUT}(G) + \epsilon''.$$

The following theorem (combined with Corollary 3.8) shows that for bounded-degree graphs, in order to achieve a $(1/2-\epsilon)$-approximation to Max-DICUT, it suffices to sample a sublinear number of random vertices and compute a "rescaled" edge-type neighborhood distribution of the induced subgraph.

▶ **Theorem 3.9** (Simplified non-streaming version of Algorithm 2 in [25]). *For every $\epsilon'' > 0, \alpha \in [0,1), D, c, \ell \in \mathbb{N}$, there exist $\beta_0 \in (0,1)$ and $n_0 \in \mathbb{N}$ such that for all $n \geq n_0$ and $n^{-\beta_0} \leq p \leq 1$, the following hold: Let $G(V,E)$ be a directed graph on n vertices and m edges such that the maximum degree is at most D and at most α fraction of the vertices are isolated. Let $h \in V \to \{0,1\}^c$. Let $V' \subset V$ be a random subset where every vertex in V is sampled independently with probability p. Let $G' \subseteq G$ be the induced subgraph of G on the vertices in V'. For every $T \in \mathbf{Typ}_c^{\ell,D}$, let a_T denote the number of edges e in G' such that all the vertices in G which are at a distance of at most ℓ from at least one of the endpoints of e, are contained in V', and $\mathsf{nbhdtype}^{\ell}_{G',h|_{V'}}(e) = T$. Consider the distribution $\mathcal{D} \in \Delta(\mathbf{Typ}_c^{\ell,D})$, defined to be*

$$\mathcal{D}(T) = \frac{a_T \cdot p^{-|T|}}{\sum_{T' \in \mathbf{Typ}_c^{\ell,D}} a_{T'} \cdot p^{-|T'|}},$$

where $T \in \mathbf{Typ}_c^{\ell,D}$ and $|T|$ denotes the number of vertices in T. Then, with probability at least $9/10$, $\mathsf{tvd}(\mathcal{D}, \mathsf{EdgeNbhdTypeDist}^{\ell}_{G;h}) \leq \epsilon''$.

A formal proof of this theorem appears in the full version.

4 Reduction from unbounded-degree graphs to bounded-degree graphs

In this section, we give a generalized version of the Trevisan reduction [27] that is tailored to be implementable in the two-pass streaming setting in Section 6.

Algorithm 1 Algorithm for reducing unbounded-degree graphs to bounded-degree graphs.

Parameters: $n, m \in \mathbb{N}$, $\epsilon' > 0$, $\zeta > 0$
Input:
A directed graph $G(V,E)$ on n vertices and m edges
An n-length array $\mathsf{approx\text{-}deg}$ (indexed by V) such that when $\deg(v) < n^{\zeta}$, we have $\mathsf{approx\text{-}deg}(v) = \deg(v)$ and when $\deg(v) \geq n^{\zeta}$, we have $(1-\epsilon'/100)\deg(v) \leq \mathsf{approx\text{-}deg}[v] \leq (1+\epsilon'/100)\deg(v)$

Initialize directed graphs $\tilde{G}(\tilde{V},\tilde{E}), \overline{G}(\overline{V},\overline{E})$, where $\tilde{V} = \overline{V} = \{(v,i) : v \in V, i \in [\deg(v)]\}$ and $\tilde{E} = \emptyset, \overline{E} = \emptyset$
Set a parameter $d = 80/(\epsilon')^2$
for every edge $u \to v \in E$ **do**
    Initialize $\mathsf{i} = 1$
    for $\mathsf{i} \leq d$ **do**
        Sample $i_1 \sim \mathsf{Unif}([\mathsf{approx\text{-}deg}(u)])$
        Sample $i_2 \sim \mathsf{Unif}([\mathsf{approx\text{-}deg}(v)])$
        if $i_1 < \deg(u)$ and $i_2 < \deg(v)$ **then**
            Add $(u,i_1) \to (v,i_2)$ to $\tilde{E}$
        Increment i by 1
Copy all the edges in $\tilde{E}$ to $\overline{E}$
for every $v \in \overline{V}$ such that $\deg(v) > 11d$ **do**
    Delete all the edges incident on v in $\overline{E}$
Output $\overline{G}(\overline{V},\overline{E})$

▶ **Theorem 4.1.** *Let $n \geq 2, m \geq 10 \in \mathbb{N}$. For any directed graph $G(V,E)$ on n vertices and m edges, and $0 < \epsilon' \leq 1$, $\zeta > 0$, with probability at least $5/6$, Algorithm 1 outputs a directed graph $\overline{G}(\overline{V},\overline{E})$ on $2m$ vertices and $\Theta(m/(\epsilon')^2)$ edges such that $\mathsf{Max\text{-}DICUT}(G) - \epsilon' \leq \mathsf{Max\text{-}DICUT}(\overline{G}) \leq \mathsf{Max\text{-}DICUT}(G) + \epsilon'$, and the maximum degree of a vertex in $\overline{G}$ is at most $O(1/(\epsilon')^2)$.*

Proof. Recall the construction of $\tilde{G}$ in Algorithm 1. We will first argue that the number of edges in $\tilde{E}$ is at least $md(1-\epsilon'/8)$, with high probability. Observe that for any edge $u \to v \in E$, when we sample its i-th copy in $\tilde{G}$, the probability that either i_1 or i_2 fail to satisfy the condition in Algorithm 1 is at most $\epsilon'/50$. Therefore, applying Chernoff bound (Theorem 3.2), we conclude that with probability at least $1-\exp(-10m)$, $|\tilde{E}| \geq md(1-\epsilon'/8)$.

Max-DICUT value of $\tilde{G}$. Fix any ordered bipartition $L \sqcup R$ of $\tilde{V}$. For an edge $e \in E$, let $X_{e,\mathsf{i}}$ be the indicator random variable for the event that in the i-th iteration corresponding to edge e, the condition in Algorithm 1 is satisfied and the corresponding edge in $\tilde{E}$ belongs to the dicut $L \sqcup R$. Then, the DICUT value of $\tilde{G}$ under $L \sqcup R$ is given by

$$\mathsf{DICUT}(\tilde{G}, L \sqcup R) = \frac{\sum_{e\in E, 1\leq \mathsf{i}\leq d} X_{e,\mathsf{i}}}{|\tilde{E}|}\,.$$

Let us define a function $\rho_{L\sqcup R} : V \to [0,1]$ such that for $v \in V$, $\rho_{L\sqcup R}(v) = (|L \cap \{(v,i) : i \in [\deg(v)]\}|)/\deg(v)$, i.e., $\rho_{L\sqcup R}(v)$ is the fraction of copies of v in L. Then,

$$\mathsf{DICUT}(G, \rho_{L\sqcup R}) - \epsilon'/33 \leq \frac{\sum_{e\in E, 1\leq \mathsf{i}\leq d} \mathbb{E}[X_{e,\mathsf{i}}]}{dm} \leq \mathsf{DICUT}(G, \rho_{L\sqcup R}) + \epsilon'/33\,.$$

This is because for every $u \to v \in E, 1 \leq \mathsf{i} \leq d$,

$$\rho_{L\sqcup R}(u)(1-\rho_{L\sqcup R}(v)) - \epsilon'/33 \leq X_{u\to v,\mathsf{i}} \leq \rho_{L\sqcup R}(u)(1-\rho_{L\sqcup R}(v)) + \epsilon'/33\,, \tag{4.1}$$

and

$$\mathsf{DICUT}(G,\rho) = \frac{\sum_{u\to v} \rho(u)(1-\rho(v))}{m}\,.$$

To see why Equation (4.1) is true, observe that for $i_1 \sim \mathsf{Unif}([\mathsf{approx\text{-}deg}[u]])$, we have

$$\rho_{L\sqcup R}(u) - \epsilon'/99 \leq \Pr[i_1 < \deg(u) \text{ and } (u,i_1) \in L] \leq \rho_{L\sqcup R}(u) + \epsilon'/99\,,$$

since for every $u \in V$, $\mathsf{approx\text{-}deg}[u]$ satisfies

$$(1-\epsilon'/100)\deg(u) \leq \mathsf{approx\text{-}deg}[u] \leq (1+\epsilon'/100)\deg(u)\,,$$

Since all the edges were sampled independently and $d = 80/(\epsilon')^2$, we can apply Hoeffding's bound (Theorem 3.3) to conclude that with probability at least $1-\exp(-4m)$,

$$\left|\frac{\sum_{e\in E, 1\leq \mathsf{i}\leq d} X_{e,\mathsf{i}}}{dm} - \mathsf{DICUT}(G,\rho_{L\sqcup R})\right| \leq \epsilon'/4\,.$$

Conditioned on $|\tilde{E}| \geq md(1-\epsilon'/8)$, we have

$$\left|\mathsf{DICUT}(\tilde{G}, L\sqcup R) - \mathsf{DICUT}(G,\rho_{L\sqcup R})\right| \leq \epsilon'/2\,.$$

Since $\mathsf{Max\text{-}DICUT}(G) = \max_{\rho:V\to\{0,1\}} \mathsf{DICUT}(G,\rho) = \sup_{\rho:V\to[0,1]} \mathsf{DICUT}(G,\rho)$, taking the union bound over the 2^{2m} possible partitions of $\tilde{V}$,[7] we conclude that with probability at least $1-\exp(-2m)$,

$$|\mathsf{Max\text{-}DICUT}(\tilde{G}) - \mathsf{Max\text{-}DICUT}(G)| \le \epsilon'/2\,.$$

The total number of edges incident on high-degree vertices in $\tilde{G}$. For a vertex $\tilde{v} \in \tilde{V}$, let $Y_{\tilde{v}} = \mathbb{1}[\deg(\tilde{v}) > 11d]\deg(\tilde{v})$. Then $Y = \sum_{\tilde{v}\in\tilde{V}} Y_{\tilde{v}}$ denotes the total sum of the degrees of vertices whose degree is larger than $11d$. It suffices to show that for any $\tilde{v}$, $\mathbb{E}[Y_{\tilde{v}}] < 1$. This is because applying Markov's inequality, we would get that $Y < 8m/7 < \epsilon'|\tilde{E}|/8$ with probability at least $7/8$, conditioned on $|\tilde{E}| \ge md(1-\epsilon'/8)$. Since $\mathsf{Max\text{-}DICUT}(\tilde{G}) \ge |\tilde{E}|/4$, the graph $\overline{G}$ obtained by deleting all the edges incident on vertices of degree larger than $11d$ in $\tilde{G}$ would satisfy $|\mathsf{Max\text{-}DICUT}(\overline{G}) - \mathsf{Max\text{-}DICUT}(\tilde{G})| \le \epsilon'/2$. We also get that $|\overline{E}| \ge md(1-\epsilon')/4$.

It remains to show that $\mathbb{E}[Y_{\tilde{v}}] < 1$. We will argue that for $d' > 11d$, $\Pr[\deg(\tilde{v}) \ge d'] \le 2^{-d'}$ (thus, $\mathbb{E}[Y_{\tilde{v}}] \le \sum_{d'>11d} \frac{d'}{2^{-d'}} < 1$). Consider any vertex $\tilde{v} = (v,i) \in V$. Consider any edge $e \in E$ that is incident on v. For $1 \le j \le d$, let $Z_{e,j}$ be the indicator random variable for the event that in the j-th iteration corresponding to e, the condition in Algorithm 1 is satisfied and the edge that is sampled is incident on $\tilde{v}$. We have

$$\deg(\tilde{v}) = \sum_{e\in E: e \text{ is incident on } v} \sum_{1\le j\le d} Z_{e,j}\,.$$

Observe that $\mathbb{E}[Z_{e,j}] \le \frac{1}{\deg(v)(1-\epsilon'/100)}$ Thus, by linearity of expectation, $\mathbb{E}[\deg(\tilde{v})] \le \frac{d\deg(v)}{\deg(v)(1-\epsilon'/100)} \le 2d$ and since the edges were sampled independently, we can apply Chernoff bound (Theorem 3.2) to conclude that $\Pr[\deg(\tilde{v}) \ge d'] \le 2^{-d'}$. ◀

5 Three-pass streaming algorithm for graphs of bounded average degree

In this section, for every constant $\epsilon > 0$, we give a three-pass streaming algorithm that achieves $(1/2-\epsilon)$-approximation on any n-vertex graph with average degree *at most* n^{δ}, using space $O(n^{1-\delta})$, for some $\delta \in (0,1)$.

Algorithm 2 Three-pass streaming algorithm for Max-DICUT on graphs of bounded average degree.

Parameters: $n \in \mathbb{N}$, $\epsilon \in (0, 1/2)$
Input: A stream $\boldsymbol{\sigma}$ of edges of directed graph $G(V,E)$ on n vertices and at most $n^{1+\delta}$ edges, where $\delta = \epsilon^{25/\epsilon}$

First pass:

Maintain a counter for the number of edges m
Set a parameter $\beta \triangleq \epsilon^{20/\epsilon}$
Initialize $V', E' = \emptyset$
Initialize an n-length array count (indexed by V) to be 0^n
for every edge $u \to v$ in the stream **do**

[7] In particular, consider the Max-DICUT partition $\rho^* : V \to \{0,1\}$ of G and the partition $L \sqcup R$ of $\tilde{V}$ where $(v,i) \in L$ iff $\rho^*(v) = 1$. By definition, $\rho_{L\sqcup R} = \rho^*$.

Sample $z_1, z_2 \sim \mathsf{Bern}(n^{-\beta})$ independently[a]

[a] We denote by $\mathsf{Bern}(p)$ the Bernoulli distribution where we draw 1 with probability p and 0 with probability $1-p$.

if $z_1 = 1$ **then**
  Add $(u, \mathsf{count}[u])$ to V' and increment $\mathsf{count}[u]$ by 1
if $z_2 = 1$ **then**
  Add $(v, \mathsf{count}[v])$ to V' and increment $\mathsf{count}[v]$ by 1
if $|V'| > n^{1-3\beta/4}$ **then**
  Terminate the execution

Second pass:

if $m \le n^{1-\epsilon^{1/\epsilon}}$ **then**
  Store all the edges and compute the Max-DICUT value.
else
  for every $v \in V$ such that $\mathsf{count}[v] > 0$ **do**
    Compute $\deg(v)$ in the stream
    $\forall i \in [\mathsf{count}[v]]$, initialize $d(v,i) = 0$

Third pass:

Set a parameter $d = 320/\epsilon^2$
for every edge $u \to v$ in the stream **do**
  Initialize $\mathsf{i} = 1$
  for $\mathsf{i} \le d$ **do**
    if $\mathsf{count}[u] > 0$ **then**
      Sample $i_1 \sim \mathsf{Unif}([\deg(u)])$
      if $i_1 < \mathsf{count}[u]$ **then**
        Increment $d(u, i_1)$ by 1
    if $\mathsf{count}[v] > 0$ **then**
      Sample $i_2 \sim \mathsf{Unif}([\deg(v)])$
      if $i_2 < \mathsf{count}[v]$ **then**
        Increment $d(v, i_2)$ by 1
    if $\mathsf{count}[u] > 0, \mathsf{count}[v] > 0$ and $i_1 < \mathsf{count}[u], i_2 < \mathsf{count}[v]$ **then**
      Add $(u, i_1) \to (v, i_2)$ to E'
      if $|E'| > n^{1-\epsilon^{25/\epsilon}}$ **then**
        Terminate the execution
    Increment i by 1

Post processing steps of Algorithm 2

1. For every $(u,i) \in V'$ such that $d(u,i) > 11d = 3520/\epsilon^2$, delete every edge incident on (u,i) in E' and decrement $d(\cdot)$ each of its endpoints by 1. Finally, set $d(u,i) = 0$. Let $\mathcal{G}(V', E')$ be the directed graph on vertex set V' and edge set E'.
2. Let $\ell, c \in \mathbb{N}$ be set according to Corollary 3.7 for parameter $\epsilon'' = \epsilon/8$. Let $D = 11d$. Let $\mathcal{H}_{2m}$ be the hash family in Corollary 3.7 corresponding to directed graphs on $2m$ vertices. Sample $h \sim \mathsf{Unif}(\mathcal{H}_{2m})$.
3. For $T \in \mathbf{Typ}_c^{\ell,D}$, let a_T denote the number of edges $e \in E'$ such that every vertex $(v,i) \in V'$ which is at a distance of at most $\ell - 1$ from at least one of the endpoints of e satisfies the property that $\deg_{\mathcal{G}}(v,i) = d(v,i)$, and $\mathsf{nbhdtype}^{\ell}_{\mathcal{G},h|_{V'}}(e) = T$.

4. Consider the distribution $\mathcal{D} \in \Delta(\mathbf{Typ}_c^{\ell,D})$, defined to be

$$\mathcal{D}(T) = \frac{a_T \cdot n^{\beta|T|}}{\sum_{T' \in \mathbf{Typ}_c^{\ell,D}} a_{T'} \cdot n^{\beta|T'|}},$$

where $T \in \mathbf{Typ}_c^{\ell,D}$ and $|T|$ denotes the number of vertices in T.
5. Let $\texttt{Local} : \mathbf{Typ}_c^{\ell,D} \to [0,1]$ be the function in Corollary 3.7. Output $\mathbb{E}_{T\sim\mathcal{D}}[\texttt{Local}(T)]$.

▶ **Theorem 5.1.** *For every $\epsilon \in (0,1/2)$, there exists $\mathsf{n}_0 \in \mathbb{N}$ such that for all $n \geq \mathsf{n}_0$ and every directed graph G on n vertices and $m \leq n^{1+\epsilon^{25/\epsilon}}$ edges, Algorithm 2 outputs a value v satisfying*

$$\frac{\mathsf{Max\text{-}DICUT}(G)}{2} - \epsilon \leq v \leq \mathsf{Max\text{-}DICUT}(G) + \epsilon,$$

with probability at least $2/3$, using space $n^{1-\epsilon^{O(1/\epsilon)}}$.

Proof. We first analyze the space usage of Algorithm 2 and then argue its correctness.

Space usage of Algorithm 2. It follows from Algorithm 2 that $|V'|, |E'| \leq n^{1-\epsilon^{O(1/\epsilon)}}$. In Algorithm 2, we can maintain count as an associative array with keys in V, thus storing only the non-zero entries in count, which is at most $|V'|$. We initialized count as an n-length array to keep the presentation simple.

Correctness of Algorithm 2. Consider the bounded-degree graph $\overline{G}$ that we constructed in Theorem 4.1 such that

$$\mathsf{Max\text{-}DICUT}(G) - \epsilon/2 \leq \mathsf{Max\text{-}DICUT}(\overline{G}) \leq \mathsf{Max\text{-}DICUT}(G) + \epsilon/2.$$

We will show that with probability at least $2/3$,

$$\mathsf{tvd}(\mathcal{D}, \mathsf{EdgeNbhdTypeDist}^{\ell}_{\overline{G};h}) \leq \epsilon/8.$$

Therefore, combining Theorem 4.1 and Corollaries 3.7 and 3.8, the correctness of Algorithm 2 immediately follows. Let us first recall the construction of $\overline{G}$ in Algorithm 1 for the parameter $\epsilon' = \epsilon/2$, and when $\mathsf{est\text{-}deg}[v] = \deg(v)$ for every $v \in V$. For every vertex $v \in V$, we add $\deg(v)$ many copies of it to $\overline{V}$, i.e., $\overline{V} = \{(v,i) : v \in V, i \in [\deg(v)]\}$. We fix a parameter $d = 10/(\epsilon')^2 = 40/\epsilon^2$. For every edge $u \to v \in E$, we sample a copy (u,i) of u and a copy (v,j) of v uniformly at random from $\overline{V}$, and add the edge $(u,i) \to (v,j)$ to $\overline{E}$. We repeat this process d times independently for every edge, and finally, for every vertex of degree larger than $11d$ in $\overline{V}$, we delete all the edges incident to it. We prove that with probability at least $5/6$,

$$\mathsf{Max\text{-}DICUT}(G) - \epsilon/2 \leq \mathsf{Max\text{-}DICUT}(\overline{G}) \leq \mathsf{Max\text{-}DICUT}(G) + \epsilon/2.$$

For now, let us ignore the termination conditions in Algorithm 2. We will later argue that these events occur with very low probability and hence, do not affect the success probability of the algorithm by much. We claim the following.

▷ Claim 5.2. At the end of the third pass (before post processing), the following hold:
1. V' has the same distribution as sampling every vertex from $\overline{V}$ independently with probability $n^{-\beta}$, and applying a relabeling on the vertices, and

2. for $u \to v \in E$, if both u and v have copies in V', then the copies of $u \to v$ in $\tilde{G}$ are sampled identically in Algorithms 1 and 2. If only one of u or v has a copy in V', then the endpoints corresponding to the copies of that vertex in the copies of $u \to v$ in $\tilde{G}$ are sampled identically in Algorithms 1 and 2.

Proof. Consider the map $f : \overline{V} \to E$ defined as follows: for $(v, i) \in \overline{V}$, $f(v, i) = e$, where e is the $(i + 1)$-th edge incident on v in the stream $\boldsymbol{\sigma}$. Observe that for every edge $u \to v$, there are exactly two vertices in $\overline{V}$ that map to it, namely (u, i) and (v, j) where i, j are such that e is the $(i + 1)$-th edge (resp. $(j + 1)$-th edge) incident on u (resp. v) in the stream $\boldsymbol{\sigma}$. Therefore, sampling every vertex in $\overline{V}$ independently with probability $n^{-\beta}$ is the same as sampling each vertex in $f^{-1}(e)$, for every edge e, independently with probability $n^{-\beta}$. This is exactly what we do in Algorithm 2 in Algorithm 2. However, since we cannot maintain information about the streaming order of all the edges incident on every vertex in V, we relabel the copies of v in $\overline{V}$ based on the order in which they are sampled by our algorithm. In particular, for a vertex $v \in V$, the first copy that is sampled is labeled $(v, 0)$, the second copy that is sampled is labeled $(v, 1)$, and so on. This proves Item 1 of Claim 5.2. To see Item 2 of Claim 5.2, recall how the edges were sampled for $\tilde{G}$ in Algorithm 1. For our purposes, it suffices to consider the sampling of the copies of only those edges in E that are incident on a vertex $v \in V$ which has a copy in V', i.e., $V' \cap \{(v, i) : i \in [\deg(v)]\} \neq \emptyset$. Algorithm 2 check for this condition and if they are satisfied, the sampling is identical to Algorithm 1 of Algorithm 1. For an edge $u \to v$, its copy is added to E' in Algorithm 2 iff the sampled copies of both its endpoints are in V'. Observe that for $(v, i) \in V'$, all the edges incident on v in E satisfy either the condition in Algorithm 2 or Algorithm 2. ◁

Given the above claim, we consider $\tilde{G}$ where for $u \to v \in E$, if both u and v have copies in V', then the copies of $u \to v$ are sampled according to Algorithm 2 (prior to the post-processing steps). If only one of u or v has a copy in V', then the endpoints corresponding to the copies of that vertex in the copies of $u \to v$ are sampled according to Algorithm 2 and the other endpoints are sampled independently, according to Algorithm 1. The remaining edges are also sampled according to Algorithm 1. Finally, like in Algorithm 1, we define $\overline{G}$ as $\tilde{G}$ with edges incident on vertices of degree larger than $11d$ deleted.[8] Observe that for $\overline{G}$ as defined above, $\mathcal{G}(V', E')$ is the induced subgraph of $\overline{G}$ on V' and furthermore, at the end of the post-processing steps of Algorithm 2, for $(v, i) \in V'$, $d(v, i)$ is degree of (v, i) in $\overline{G}$. This is true because for any vertex $(v, i) \in V'$, its degree in $\tilde{G}$ depends only on the randomness in Algorithm 2.

We are now ready to show that with probability at least 3/4,

$$\mathsf{Max\text{-}DICUT}(G) - \epsilon/2 \leq \mathsf{Max\text{-}DICUT}(\overline{G}) \leq \mathsf{Max\text{-}DICUT}(G) + \epsilon/2\,,$$

and

$$\mathsf{tvd}(\mathcal{D}, \mathsf{EdgeNbhdTypeDist}^{\ell}_{\overline{G};h}) \leq \epsilon/8\,.$$

We apply Theorems 3.9 and 4.1. In particular, for Theorem 4.1, we set the parameter $\epsilon' = \epsilon/2$. We get that with probability at least 5/6,

- $\mathsf{Max\text{-}DICUT}(G) - \epsilon/2 \leq \mathsf{Max\text{-}DICUT}(\overline{G}) \leq \mathsf{Max\text{-}DICUT}(G) + \epsilon/2$,
- the maximum degree of any vertex in $\overline{G}$ is at most $110/(\epsilon')^2 = 3520/\epsilon^2$, and
- $\overline{G}$ has at least $240m/\epsilon^2$ edges.

[8] A key observation here is that sampling $\overline{G}$ first and then sampling V' is equivalent to sampling V' and then sampling $\overline{G}$.

Since $\overline{G}$ has exactly $2m$ vertices, it follows that at most 0.94 fraction of them are isolated. Now conditioned on this $\overline{G}$, we set the parameters of Theorem 3.9. We set $\epsilon'' = \epsilon/8, D = 3520/\epsilon^2$, and c, ℓ, h according to Algorithm 2, and $\alpha = 0.94$. Now set β_0 and n_0 according to the proof of Theorem 3.9. It follows from Claim 5.2 that V' is obtained by sampling every vertex in $\overline{V}$ independently with probability $n^{-\beta}$, and $\mathcal{G}(V', E')$ is the induced subgraph of $\overline{G}$ on V'. Say $2m \geq n_0$. To apply Theorem 3.9, observe that sampling $\overline{G}$ first and then sampling V' is the same as sampling V' first and then sampling $\overline{G}$, and relabeling of the copies of the vertices does not the change the distribution. Thus, it remains to show the following.

1. The sampling probability $n^{-\beta}$ is at least $(2m)^{-\beta_0}$, and
2. a_T defined in the third post-processing step of Algorithm 2 is the same as the a_T defined in Theorem 3.9.

If $m \leq n^{1-\epsilon^{1/\epsilon}}$, then Algorithm 2 would simply store all the edges and compute the Max-DICUT value. So without loss of generality, we can assume that $m > n^{1-\epsilon^{1/\epsilon}}$, and in this case, $n^{-\beta} \geq (2m)^{-\beta_0}$. In Claim 5.2, we also show that for every $(v, i) \in V'$, $d(v, i)$ is the degree of (v, i) in $\overline{G}$. Hence, for any edge $e \in E'$, its radius-ℓ neighborhood in $\overline{G}$ is contained entirely within $\mathcal{G}$ iff for every vertex $(v, i) \in V'$ which is at a distance of at most $\ell - 1$ from at least one of the endpoints of e satisfies $\deg_{\mathcal{G}}(v, i) = d(v, i)$. It follows that the a_T defined in the post-processing steps of Algorithm 2 is the same as the one in Theorem 3.9. Thus, conditioned on $\overline{G}$ satisfying the properties that we stated above and $2m \geq n_0$, with probability at least 9/10,

$$\mathsf{tvd}(\mathcal{D}, \mathsf{EdgeNbhdTypeDist}^{\ell}_{\overline{G};h}) \leq \epsilon/8\,.$$

Set $\mathsf{n}_0 = \max\left\{n_0^{(1-\epsilon^{1/\epsilon})^{-1}}, (\frac{1}{\epsilon^2})^{\frac{1}{\epsilon}\frac{25}{\epsilon}}\right\}$. Thus, whenever $n \geq \mathsf{n}_0$, we have $m \geq n_0$.

We finally argue that the termination conditions in Algorithm 2 happen with very low probability. Since $m \leq n^{1+\epsilon^{25/\epsilon}}$ and $|\overline{V}| = 2m$, we have $\mathbb{E}[V'] \leq n^{1-7\beta/8}$. By applying Chernoff bound, we conclude that with very high probability, $|V'| \leq n^{1-3\beta/4}$. For an edge $e \in \overline{E}$, let Z_e be the indicator random variable for the event that $e \in E'$. Let $Z = \sum_{e \in \overline{E}} Z_e$. We have $\mathbb{E}[Z_e] = n^{-2\beta} = n^{-2\epsilon^{20/\epsilon}}$ and $\mathsf{Var}[Z] \leq (3520/\epsilon^2)\mathbb{E}[Z]$, since the maximum degree of any vertex in $\overline{G}$ is at most $3520/\epsilon^2$. Since $|\overline{E}| \leq 320m/\epsilon^2$, $\mathbb{E}[Z] \leq n^{1-\epsilon^{22/\epsilon}}$. By applying Chebyshev's inequality, we conclude that with high probability, $|E'| \leq n^{1-\epsilon^{25/\epsilon}}$. This concludes the proof of correctness of Algorithm 2. ◀

6 Two-pass streaming algorithm for Max-DICUT

In this section, we modify[9] Algorithm 2 to give a two-pass streaming algorithm that achieves $(1/2 - \epsilon)$-approximation on any n-vertex graph with average degree *at most* n^{δ}, using space $O(n^{1-\delta})$, for some $\delta \in (0, 1)$. Combining our algorithm with the two-pass algorithm of Bhaskara, Daruki, and Venkatasubramanian [5] (see Theorem 2.3) that achieves for every $\epsilon, \delta \in (0, 1)$, $(1 - \epsilon)$-approximation for graphs of average degree *at least* n^{δ} using space $\tilde{O}(n^{1-\delta})$, we obtain our algorithm that works on arbitrary graphs (see Algorithm 4).

Algorithm 3 Two-pass streaming algorithm for Max-DICUT on graphs of bounded average degree.

Parameters: $n \in \mathbb{N}$, $\epsilon \in (0, 1/2)$

Input: A stream $\boldsymbol{\sigma}$ of edges of directed graph $G(V, E)$ on n vertices and at most $n^{1+\delta}$ edges, where $\delta = \epsilon^{25/\epsilon}$

[9] The specific modifications are highlighted in the code.

First pass:

Maintain a counter for the number of edges m
Set a parameter $\beta \triangleq \epsilon^{20/\epsilon}$
Initialize $V', E' = \emptyset$
Initialize an n-length array count (indexed by V) to be 0^n
Initialize an n-length array est-deg (indexed by V) to be 0^n
for every edge $u \to v$ in the stream **do**
    Sample $z_1, z_2 \sim \mathsf{Bern}(n^{-\beta})$ independently
    if $z_1 = 1$ **then**
        Add $(u, \mathsf{count}[u])$ to V' and increment $\mathsf{count}[u]$ by 1
    if $z_2 = 1$ **then**
        Add $(v, \mathsf{count}[v])$ to V' and increment $\mathsf{count}[v]$ by 1
    if $|V'| > n^{1-3\beta/4}$ **then**
        Terminate the execution
    Sample $y_1, y_2 \sim \mathsf{Bern}(n^{-\beta/4})$ independently
    if $y_1 = 1$ **then**
        Increment $\mathsf{est\text{-}deg}[u]$ by $n^{\beta/4}$
    if $y_2 = 1$ **then**
        Increment $\mathsf{est\text{-}deg}[v]$ by $n^{\beta/4}$
    if # non-zero entries in est-deg $> n^{1-\beta/8}$ **then**
        Terminate the execution

for every $v \in V$ such that $\mathsf{count}[v] > 0$ **do**
    $\forall i \in [\mathsf{count}[v]]$, initialize $d(v, i) = 0$
Initialize an n-length array store-deg (indexed by v) to be 0^n
Initialize $\hat{E} = \emptyset$

Second pass:

if $m \le n^{1-\epsilon^{1/\epsilon}}$ **then**
    Store all the edges and compute the Max-DICUT value.
else
    Set a parameter $d = 320/\epsilon^2$
    for every edge $u \to v$ in the stream **do**
        if $\mathsf{count}[u] > 0$ and $\mathsf{store\text{-}deg}[u] < n^{2\beta/3}$ **then**
            Add $u \to v$ to $\hat{E}$
            Increment $\mathsf{store\text{-}deg}[u]$
        if $\mathsf{count}[v] > 0$ and $\mathsf{store\text{-}deg}[v] < n^{2\beta/3}$ **then**
            Add edge $u \to v$ to $\hat{E}$ if it was not previously added in Algorithm 3
            Increment $\mathsf{store\text{-}deg}[v]$
        Initialize $\mathsf{i} = 1$
        for $\mathsf{i} \le d$ **do**
            if $\mathsf{count}[u] > 0$ and $\mathsf{est\text{-}deg}(u) > 0$ **then**
                Sample $i_1 \sim \mathsf{Unif}([\mathsf{est\text{-}deg}(u)])$
                if $i_1 < \mathsf{count}[u]$ **then**
                    Increment $d(u, i_1)$ by 1
            if $\mathsf{count}[v] > 0$ and $\mathsf{est\text{-}deg}(v) > 0$ **then**

Sample $i_2 \sim \mathsf{Unif}([\mathsf{est\text{-}deg}(v)])$
if $i_2 < \mathsf{count}[v]$ **then**
Increment $d(v, i_2)$ by 1
if $(\mathsf{count}[u] > 0, \mathsf{est\text{-}deg}(u) > 0, i_1 < \mathsf{count}[u])$ or $(\mathsf{count}[v] > 0, \mathsf{est\text{-}deg}(v) > 0, i_2 < \mathsf{count}[v])$ **then**
Add $(u, i_1) \to (v, i_2)$ to E'
if $|E'| > n^{1-\epsilon^{25/\epsilon}}$ **then**
Terminate the execution
Increment i by 1

Post-processing I: Resampling edges incident to low-degree vertices:
Initialize $E'' = E'$
for every $u \in V$ such that $\mathsf{count}[u] > 0$ and $\mathsf{store\text{-}deg}[u] < n^{2\beta/3}$ **do**
Initialize $i = 0$
for $i \in [\mathsf{est\text{-}deg}[u]]$ **do**
for every edge $(u, i) \to (v, j) \in E''$ or $(v, j) \to (u, i) \in E''$ **do**
Delete the edge; decrement $d(u, i)$ (resp. $d(v, j)$) if $(u, i) \in V'$ (resp. $(v, j) \in V'$)
for every $u \to v \in \hat{E}$ **do**
Initialize j = 1
for j $\leq d$ **do**
if $\mathsf{count}[u] > 0$ and $\mathsf{store\text{-}deg}(u) < n^{2\beta/3}$ **then**
Sample $j_1 \sim \mathsf{Unif}([\mathsf{store\text{-}deg}(u)])$
if $j_1 < \mathsf{count}[u]$ **then**
Increment $d(u, j_1)$ by 1
if $\mathsf{count}[v] > 0$ **then**
if $\mathsf{store\text{-}deg}(v) < n^{2\beta/3}$ **then**
Sample $j_2 \sim \mathsf{Unif}([\mathsf{store\text{-}deg}(v)])$
else
Sample $j_2 \sim \mathsf{Unif}([\mathsf{est\text{-}deg}(v)])$
if $j_2 < \mathsf{count}[v]$ **then**
Increment $d(v, j_2)$ by 1
if $j_1 < \mathsf{count}[u]$ **then**
Add $(u, j_1) \to (v, j_2)$ to E''
else if $\mathsf{count}[v] > 0$ and $\mathsf{store\text{-}deg}(v) < n^{2\beta/3}$ **then**
Sample $j_2 \sim \mathsf{Unif}([\mathsf{store\text{-}deg}(v)])$
if $j_2 < \mathsf{count}[v]$ **then**
Increment $d(v, j_2)$ by 1
if $\mathsf{count}[u] > 0$ **then**
Sample $j_1 \sim \mathsf{Unif}([\mathsf{est\text{-}deg}(u)])$
if $j_1 < \mathsf{count}[u]$ **then**
Increment $d(u, j_1)$ by 1
if $j_2 < \mathsf{count}[v]$ **then**
Add $(u, j_1) \to (v, j_2)$ to E''
Increment j by 1
Delete every edge in E'' that is incident on a vertex not in V'

Post-processing II (analogous to the post processing steps in Algorithm 2)

1. For every $(u,i) \in V'$ such that $d(u,i) > 11d = 3520/\epsilon^2$, delete every edge incident on (u,i) in E'' and decrement $d(\cdot)$ each of its endpoints by 1. Finally, set $d(u,i) = 0$. Let $\mathcal{G}(V', E'')$ be the directed graph on vertex set V' and edge set E''.
2. Let $\ell, c \in \mathbb{N}$ be set according to Corollary 3.7 for parameter $\epsilon'' = \epsilon/8$. Let $D = 11d$. Let $\mathcal{H}_{2m}$ be the hash family in Corollary 3.7 corresponding to directed graphs on $2m$ vertices. Sample $h \sim \mathsf{Unif}(\mathcal{H}_{2m})$.
3. For $T \in \mathbf{Typ}_c^{\ell,D}$, let a_T denote the number of edges $e \in E''$ such that every vertex $(v,i) \in V'$ which is at a distance of at most $\ell - 1$ from at least one of the endpoints of e satisfies the property that $\deg_{\mathcal{G}}(v,i) = d(v,i)$, and $\mathsf{nbhdtype}^{\ell}_{\mathcal{G},h|_{V'}}(e) = T$.
4. Consider the distribution $\mathcal{D} \in \Delta(\mathbf{Typ}_c^{\ell,D})$, defined as

$$\mathcal{D}(T) = \frac{a_T \cdot n^{\beta|T|}}{\sum_{T' \in \mathbf{Typ}_c^{\ell,D}} a_{T'} \cdot n^{\beta|T'|}},$$

   where $T \in \mathbf{Typ}_c^{\ell,D}$, and $|T|$ denotes the number of vertices in T.
5. Let $\mathtt{Local} : \mathbf{Typ}_c^{\ell,D} \to [0,1]$ be the function in Corollary 3.7. Output $\mathbb{E}_{T\sim\mathcal{D}}[\mathtt{Local}(T)]$.

▶ **Theorem 6.1.** *For every $\epsilon \in (0,1/2)$, there exists $\mathsf{n}_0 \in \mathbb{N}$ such that for all $n \geq \mathsf{n}_0$ and every directed graph G on n vertices and $m \leq n^{1+\epsilon^{25/\epsilon}}$ edges, Algorithm 3 outputs a value v satisfying*

$$\frac{\mathsf{Max\text{-}DICUT}(G)}{2} - \epsilon \leq v \leq \mathsf{Max\text{-}DICUT}(G) + \epsilon,$$

with probability at least $2/3$, using space $n^{1-\epsilon^{O(1/\epsilon)}}$.

Proof. At a high level, the main change from Algorithm 2 is that for vertices randomly sampled from $\overline{V}$ in the first-pass, we don't use an additional pass like in Algorithm 2 to exactly compute the degrees of all their parent vertices. Instead, in the first pass, we approximately estimate the degrees of all high-degree vertices (of degree at least $n^{2\beta/3}$) with high probability. As shown in Theorem 4.1, for high-degree vertices, an approximate estimate of their degrees suffices for the reduction to work. In the second pass, we handle the low degree vertices and store all the edges incident to parent vertices of degree less than $n^{2\beta/3}$ and resample their copies in $\overline{G}$ in the post-processing steps from Algorithm 3 to Algorithm 3. In addition, for technical reasons, E' now stores *all* edges incident on vertices in V', not just the induced edges (see Algorithm 3). This helps us maintain accurate degrees of the sampled vertices when we delete the edges sampled in the second pass that were incident to copies of low degree vertices and resample them later in post-processing I. We now formally analyze the space usage and argue the correctness of Algorithm 3.

Space usage of Algorithm 3. Compared to Algorithm 2, Algorithm 3 also stores est-deg, store-deg, and $\hat{E}$. It follows from the termination condition in Algorithm 3 that est-deg has at most $n^{1-\beta/8}$ non-zero entries, and the value stored in each entry is at most $\mathrm{poly}(n)$. Thus, the space required to store est-deg is at most $n^{1-\epsilon^{O(1/\epsilon)}}$. The termination condition in Algorithm 3 ensures that $|V'| \leq n^{1-3\beta/4}$. The number of non-zero entries in store-deg is at most $|V'|$. Finally, whenever an edge is added to $\hat{E}$, both its endpoints have copies in V' and at least one of them currently has fewer than $n^{2\beta/3}$ edges incident on it in $\hat{E}$. Therefore, the number of edges stored in $\hat{E}$ is at most $|V'|n^{2\beta/3} \leq n^{1-\beta/12}$.

Correctness of Algorithm 3. For now, let us ignore the termination conditions in Algorithm 3. We will later argue that these events occur with very low probability, and hence, do not alter the success probability of Algorithm 3 by much. We first prove the following claim.

▷ Claim 6.2. Let n be sufficiently large. With probability at least $1 - \exp(n^{-\Omega(\epsilon^{O(1/\epsilon)})})$, for every $v \in V$ such that $\deg(v) \geq n^{2\beta/3}$, we have

$$(1 - \epsilon/100)\deg(v) \leq \textsf{est-deg}[v] \leq (1 + \epsilon/100)\deg(v)\,.$$

Proof. Fix any vertex $v \in V$ whose degree is at least $n^{2\beta/3}$. For $i \in [\deg(v)]$, let $Y_i \sim \textsf{Bern}(n^{-\beta/4})$ independently. Then, $\textsf{est-deg}[v] = \sum_{i\in[\deg(v)]} Y_i \cdot n^{\beta/4}$. Therefore, $\mathbb{E}[\textsf{est-deg}[v]] = \deg(v)$. By applying Hoeffding's inequality (Theorem 3.3), we conclude that with probability at least $1 - \exp(n^{-\Omega(\epsilon^{O(1/\epsilon)})})$,

$$(1 - \epsilon/100)\deg(v) \leq \textsf{est-deg}[v] \leq (1 + \epsilon/100)\deg(v)\,.$$

The claim follows from taking a union bound over at most n vertices. ◁

Now let us condition on est-deg that satisfies the above property. We define an n-length array approx-deg as follows. For every vertex $v \in V$, if $\deg(v) < n^{2\beta/3}$, then $\textsf{approx-deg}[v] := \deg(v)$, else $\textsf{approx-deg}[v] := \textsf{est-deg}[v]$. Consider the bounded-degree graph $\overline{G}(\overline{V}, \overline{E})$[10] that is output by Algorithm 1, corresponding to the input graph $G(V, E)$, parameters $\epsilon' = \epsilon/2$ and $\zeta = 2\beta/3$, and approx-deg. It follows from Theorem 4.1 that with probability at least 5/6,

- $\textsf{Max-DICUT}(G) - \epsilon/2 \leq \textsf{Max-DICUT}(\overline{G}) \leq \textsf{Max-DICUT}(G) + \epsilon/2$,
- the maximum degree of any vertex in $\overline{G}$ is at most $110/(\epsilon')^2 = 3520/\epsilon^2$, and
- $\overline{G}$ has exactly $2m$ vertices and at least $240m/\epsilon^2$ edges.

We will prove the following claim (analogous to Claim 5.2 in Theorem 5.1).

▷ Claim 6.3. At the end of post-processing I, the following hold:

1. V' has the same distribution as sampling every vertex from $\overline{V}$ independently with probability $n^{-\beta}$, and applying a relabeling on the vertices, and
2. for $u \to v \in E$, if both u and v have copies in V', then the copies of $u \to v$ in $\tilde{G}$ are sampled identically in Algorithms 1 and 3. If only one of u or v has a copy in V', then the endpoints corresponding to the copies of that vertex in the copies of $u \to v$ in $\tilde{G}$ are sampled identically in Algorithms 1 and 3.

Proof. The proof of Item 1 of Claim 6.3 is analogous to the proof of Item 1 of Claim 5.2. To prove Item 2, we first consider the edges incident to high-degree vertices which have copies in V'. Since approx-deg and est-deg are the same for vertices of degree at least $n^{2\beta/3}$, the sampling in Algorithm 3 of Algorithm 3 is the same as the sampling in Algorithm 1 of Algorithm 1 for edges whose both endpoints are of degree at least $n^{2\beta/3}$ in G. Similar, if only one of the endpoints of $u \to v$ has a copy in V' and if the parent vertex of that copy is of degree at least $n^{2\beta/3}$, then the the endpoints corresponding to the copies of that vertex in the copies of $u \to v$ in $\tilde{G}$ are sampled identically in Algorithms 1 and 3. Now consider the edges incident to low-degree vertices which have copies in V'. While these edges are **not** sampled with the correct probabilities in Algorithm 3, this is fixed in the post processing steps

[10] We implicitly assume that Algorithm 1 uses the same randomness as in Algorithm 3 to sample copies of the edges incident on the parent vertices of vertices in V'. To sample the remaining edges, it uses independent random bits.

from Algorithm 3 to Algorithm 3. For every $(u,i) \in V'$, observe that $\textsf{store-deg}[u] < n^{2\beta/3}$ if and only if $\deg(u) < n^{2\beta/3}$. In addition, when $\deg(u) < n^{2\beta/3}$, $\textsf{store-deg}[u] = \deg[u]$. In post-processing I, for every low-degree vertex that has a copy in V', we delete all edges in E'' that are incident on *any* of its copies, including those not contained in V'. All edges incident to low-degree vertices (which have a copy in V') are stored in $\hat{E}$. Since $\textsf{store-deg}[u] = \deg[u]$ for these vertices, we resample the copies of the edges incident on them identical to the sampling in Algorithm 1. ◁

Given the above claim, we consider $\tilde{G}$ where for $u \to v \in E$, if both u and v have copies in V', then the copies of $u \to v$ are sampled according to Algorithm 3 (prior to post-processing II). If only one of u or v has a copy in V', then the endpoints corresponding to the copies of that vertex in the copies of $u \to v$ are sampled according to Algorithm 3 and the other endpoints are sampled independently, according to Algorithm 1. The remaining edges are also sampled according to Algorithm 1. Finally, like in Algorithm 1, we define $\overline{G}$ as $\tilde{G}$ with edges incident on vertices of degree larger than $11d$ deleted. Observe that for $\overline{G}$ as defined above, $\mathcal{G}(V', E'')$ is the induced subgraph of $\overline{G}$ on V'. Furthermore, at the end of post-processing II of Algorithm 3, for $(v,i) \in V'$, $d(v,i)$ is degree of (v,i) in $\overline{G}$. Now, the rest of the proof of correctness follows similarly as in the proof of Theorem 5.1.

Finally, we argue that the termination conditions in Algorithm 3 happen with very low probability. Observe that V' is sampled exactly in the same way as in Algorithm 2. Therefore, the same proof goes through. To analyze the number of non-zero entries in $\textsf{est-deg}$, for $i \in [\log n]$, consider any vertex $v \in V$ whose degree is larger than 2^i and at most 2^{i+1}. Let Z^i_v be the indicator variable for the event that $\textsf{est-deg}[v] \neq 0$ and let $Z^i = \sum_{v:2^i < \deg(v) \leq 2^{i+1}} Z^i_v$. Observe that $\mathbb{E}[Z^i_v] \leq 2^{i+1} n^{-\beta/4}$ and by the linearity of expectation,

$$\mathbb{E}[Z^i] \leq \frac{2m}{2^i} \cdot 2^{i+1} n^{-\beta/4} = 4mn^{-\beta/4} \leq n^{1-\beta/6}\,.$$

Since the events are independent, applying Chernoff bound (Theorem 3.2), we conclude that with probability at least $1 - \exp(n^{-\Omega(\epsilon^{O(1/\epsilon)})})$, $Z^i \leq (\log n) n^{1-\beta/6}$. Taking a union bound over all $i \in [\log n]$, we get that with high probability, $\sum_{i \in [\log n]} Z^i \leq (\log n)^2 n^{1-\beta/6} < n^{1-\beta/8}$. We now analyze the termination condition on E' in Algorithm 3. Let E'_ℓ denote the set of edges in E' which are incident to vertices in V' whose parent vertices have degree less than $n^{2\beta/3}$. Let E'_h denote the set of edges in E' which are incident to vertices in V' whose parent vertices have degree at least $n^{2\beta/3}$. Observe that $E' = E'_\ell \cup E'_h$. We previously argued (in Section 5) that with high probability, $|V'| \leq n^{1-3\beta/4}$. Therefore, with high probability, $|E'_\ell| \leq n^{1-\beta/12}$. It follows from Claim 6.2 that with high probability, for every $v \in V$ such that $\deg(v) \geq n^{2\beta/3}$, we have

$$(1 - \epsilon/100)\deg(v) \leq \textsf{est-deg}[v] \leq (1 + \epsilon/100)\deg(v)\,.$$

Therefore, conditioned on this event, $\mathbb{E}[|E'_h|] \leq dn^{1+\delta}(2n^{-\beta}(1-\epsilon/100)^{-1}) \leq n^{1-3\beta/4}$, for sufficiently large n. Applying Markov's inequality, we conclude that with high probability, $|E'_h| \leq n^{1-2\beta/3}$. Thus, the termination condition on E' in Algorithm 3 occurs with very low probability, and this concludes the proof of correctness of Algorithm 3. ◀

Below, we describe our algorithm for Max-DICUT on arbitrary graphs.

Algorithm 4 Two-pass streaming algorithm for Max-DICUT.

Parameters: $n \in \mathbb{N}$, $\epsilon > 0$
Input: A stream $\boldsymbol{\sigma}$ of edges of a directed graph $G(V, E)$ on n vertices

First pass:
Maintain a counter for the number of edges m and execute the first passes of Algorithm 3 and the algorithm in [5], in parallel

Second pass:
if $m \leq n^{1+\epsilon^{4/\epsilon}}$ **then**
    Continue executing the second pass of Algorithm 3 and abandon the execution of [5]
else
    Abandon the execution of Algorithm 3 and execute the second pass of [5]

Finally, we conclude with a proof of our main theorem.

Proof of Theorem 1.1. The proof of correctness and the space usage of Algorithm 4 immediately follows from Theorem 6.1 and Theorem 2.3. ◀

Abstract

Dominating Set is a fundamental problem in graph theory: given a graph, find a minimum-weight subset of vertices such that every vertex is either selected or adjacent to a selected vertex. In online settings where vertices arrive sequentially, comparing algorithms against an offline optimum with full knowledge of the input leads to extremely strong lower bounds, where even a simple star graph shows that any online algorithm must have competitive ratio $\Omega(\Delta)$, with Δ the largest degree of any vertex in the graph, matching the trivial strategy of selecting all vertices.

We study the *incremental* dominating set problem, where the optimal algorithm is constrained to the same choices available to online algorithms. This introduces a benchmark that enables a meaningful comparison between algorithms.

We present the first results for vertex-weighted graphs and randomized algorithms in this model. For incremental dominating set, we give an $O(\Delta)$-competitive deterministic algorithm and an $O(\log^2 \Delta)$-competitive randomized algorithm. We extend these results to the Connected Dominating Set problem using a linear-programming formulation that captures connectivity through local constraints. When the neighborhood of each arriving vertex is known *in advance*, deterministic algorithms achieve similar polylogarithmic competitive ratios as their randomized counterparts. Finally, we establish matching lower bounds, showing that our results are optimal up to constant factors.

1 Introduction

Dominating Set is a fundamental and extensively studied problem in graph theory and algorithm design, e.g. [15, 18, 24]. Given a graph $G = (V, E)$ with vertex weights $w : V \to \mathbb{R}^+$, we say that vertex u dominates vertex v if either $u = v$ or $(u, v) \in E$. A subset of vertices $D \subseteq V$ is then called a dominating set if every vertex in V is dominated by at least one vertex in D. Variants include the Connected Dominating Set problem [10, 11, 27], which requires the dominating set to be connected, and the Total Dominating Set problem [2, 7], where every vertex must be dominated by a distinct neighbor. These, and related problems, have found applications in network routing [26], facility location [16, 22], efficient transmission [20], and more [23].

We consider online versions of these problems. In the online setting, domination requests arrive sequentially, requiring the algorithm to make irrevocable decisions, while maintaining feasibility at each step without knowledge of future requests [3, 8, 17].

Online domination has primarily been studied under two models: the known-graph and unknown-graph settings. In the known-graph model, the entire graph is known upfront, and requests for dominating specific vertices arrive sequentially. This model is a special case of the online set cover problem, for which the known competitive bounds are polylogarithmic in the number of sets and elements [1]. Several works have extended these bounds to variants of the known-graph model in the context of domination problems [21].

In the unknown-graph model, the vertices are revealed one by one along with the edges connecting them to previously seen vertices. Each revealed vertex must be immediately dominated. The version most commonly studied in this model is the late accept variant [3], in which a vertex can be added to the dominating set at any time after it arrives, but cannot be removed once it is added.

Most research in this setting analyzes online algorithms by comparing them to a powerful offline algorithm. Consider the star graph in Figure 1; it demonstrates that every online algorithm must have competitive ratio $\Theta(\Delta)$, where Δ is the maximum degree of a vertex, matching the trivial strategy that always adds all vertices to the dominating set. Thus, there has been very little research in this direction [3, 9].

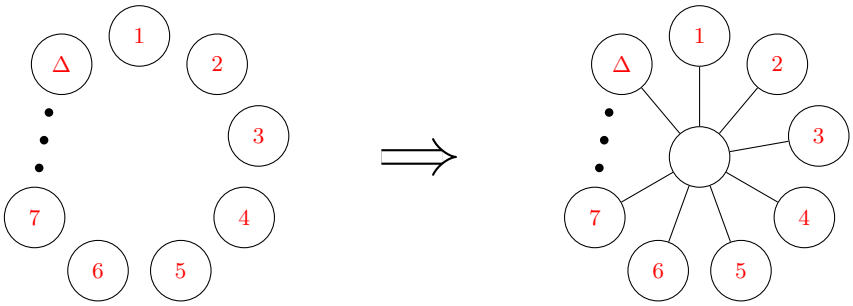

Figure 1 A star graph where the center vertex is revealed last. An online algorithm, unable to choose the center vertex before it is requested must select all leafs, while an offline algorithm needs only to select the center vertex, yielding a competitive ratio of $\Omega(\Delta)$. However, against the optimal **incremental** solution, which is also unable to choose the center vertex, the competitive ratio is 1.

To provide a more meaningful benchmark, we propose comparing online algorithms with their incremental counterparts. In the incremental dominating set (DS) problem, we are given a graph $G = (V, E)$ and an ordering $v_1, v_2, \ldots, v_n$ of the vertices. The goal is to choose a subset $S \subseteq V$ such that for every $t \in [n]$, the set $S \cap \{v_1, \ldots, v_t\}$ is a dominating set for the subgraph induced by $\{v_1, \ldots, v_t\}$. Since both the algorithm and the optimal incremental solution face the same arrival constraints, this benchmark is more informative. In the example in Figure 1, the competitive ratio is reduced to 1 from $\Omega(\Delta)$.

This problem naturally models constraints that online algorithms face in the unknown-graph setting. Boyar et al. [3] were the first to consider deterministic online algorithms for the incremental model on unweighted graphs in the unknown-graph setting. They showed that any deterministic online algorithm has a competitive ratio of $\Theta(\Delta)$. This result implies that, for unweighted graphs, no deterministic online algorithm can substantially outperform the naïve approach of simply selecting all vertices. However, the question of obtaining improved competitive bounds for other settings, such as weighted graphs, where achieving an $O(\Delta)$ competitive algorithm is non-trivial, or randomized algorithms, has remained open.

Table 1 Results for incremental DS and incremental CDS. Entries marked with - follow from results in other rows. All results apply to weighted graphs unless specified otherwise. Δ refers to the maximum degree of the graph induced by requested vertices, while Δ_G refers to the maximum degree of the revealed graph.

	Incremental DS	**Incremental CDS**	**Lower Bound**
Deterministic	$O(\Delta)$	$O(\Delta)$	$\Omega(\Delta)$ [3]
Randomized (Polynomial Time)	$O(\log^2 \Delta)$	$O(\log^2 \Delta)$	$\Omega(\log^2 \Delta)$
Randomized (General)			$\Omega(\log \Delta)$
Known Neighborhood Unweighted	$O(\log^2 \Delta_G)$	$O(\log^2 \Delta_G)$	$\Omega(\log^2 \Delta)$
Known Neighborhood (Polynomial Time)	$O(\log n \log \Delta)$	–	$\Omega(\log^2 \Delta)$
Known Neighborhood (Deterministic)			$\Omega(\log^2 \Delta / \log\log \Delta)$
Random Order Arrival	–	–	$\Omega(\log \Delta)$
Offline (Known Input)	$O(\log \Delta)$	$O(\log \Delta)$	$\Omega(\log \Delta)$

1.1 Our Contribution & Results

We address several open questions in online domination problems: obtaining competitive ratios for weighted graphs, randomized algorithms, and settings with additional structural information.

We start by formulating both incremental Dominating Set (DS) and incremental Connected Dominating Set (CDS) as covering problems. For incremental CDS we manage to encode both domination and connectivity requirements using a small number of linear constraints. This is the first use of such formulation in the online setting.

In the deterministic weighted setting, we show that incremental DS and incremental CDS admit an $O(\Delta)$-competitive algorithm, matching the unweighted lower bound [3]. For randomized algorithms, we achieve $O(\log^2 \Delta)$ competitive ratio and prove this is optimal up to a constant factor for polynomial-time algorithms. For computationally unbounded algorithms we prove an $\Omega(\log \Delta)$ lower bound.

We also study the **known neighborhood** model, where requesting a vertex reveals its full neighborhood. Surprisingly, knowing just the neighborhood of requested vertices in advance yields substantially stronger *deterministic* bounds: $O(\log^2 \Delta_G)$-competitive in the unweighted case for both incremental DS and incremental CDS where Δ_G is the maximum degree of the revealed graph (containing vertices which are not requested), and $O(\log n \log \Delta)$-competitive for weighted incremental DS. These competitive ratios hold at every step of the algorithm, and in particular the final solution remains competitive even if some revealed vertices were never requested. These bounds are asymptotically tight.

We also study offline and random-order models. In the offline setting, we establish tight $\Theta(\log \Delta)$ polynomial time approximation bounds unless NP $\subseteq$ BPP. In the random-order setting, we prove an $\Omega(\log \Delta)$ lower bound, showing that random arrival order does not substantially improve the competitive ratio.

A summary of our upper and lower bounds across different models appears in Table 1. We now discuss our results in detail.

1.1.1 Online Incremental

We begin with the online setting of incremental DS and CDS. Boyar et al. [3] have shown a $\Theta(\Delta)$ deterministic lower bound for incremental DS and incremental CDS, which matches the competitive bound of the trivial algorithm that selects all vertices in unweighted graphs. In contrast, we design a deterministic algorithm with a non-trivial competitive ratio for weighted graphs.

▶ **Theorem 1.** *There is a* $(\Delta + 1)$*-competitive deterministic algorithm for* incremental DS *and* incremental CDS*.*

In the randomized setting, the competitive ratio improves exponentially.

▶ **Theorem 2.** *There is an* $O(\log^2 \Delta)$*-competitive randomized algorithm for* incremental DS *and* incremental CDS*.*

We note that this result gives the first sublinear-competitive algorithm for weighted online CDS. In contrast, in the known-graph model (or in any model in which we only need to dominate a subset of the vertices) the problem reduces to non-metric TSP, for which obtaining an $f(n)$-approximation is hard for every polynomial-time computable function [11]. Thus, the incremental model allows substantially better guarantees.

We also study the **known neighborhood** model, where requesting a vertex v_i reveals its full neighborhood $N[v_i]$. Importantly, this extra information does not change the original setting, as the neighbors of v_i become visible to the algorithm, but cannot be added to the dominating set until they are requested. Surprisingly, this additional information enables deterministic algorithms to achieve polylogarithmic competitive ratios matching their randomized counterparts.

▶ **Theorem 3.** *When the neighborhood of requested vertices is known, and the graph is unweighted, then there is an* $O(\log^2 \Delta_G)$*-competitive deterministic algorithm for both* incremental DS *and* incremental CDS*.*

Here Δ_G denotes the maximum degree of the fully revealed graph, which may contain vertices that are never requested. The competitive ratio holds at every step of the algorithm, and remains valid even if the adversary stops requesting vertices before all revealed vertices have been requested. In the case where all revealed vertices are eventually requested we have $\Delta = \Delta_G$ and the algorithm is $O(\log^2 \Delta)$-competitive.

In the weighted case we still get polylogarithmic results for incremental DS.

▶ **Theorem 4.** *When the neighborhood of requested vertices is known, there is an* $O(\log n \log \Delta)$*-competitive deterministic algorithm for* incremental DS*.*

Here n denotes the number of revealed vertices and Δ the maximum degree of $G[V_n]$, the subgraph induced by requested vertices. As in the unweighted case, the competitive ratio holds at every step of the algorithm.

We establish matching lower bounds for our randomized algorithms.

▶ **Theorem 5.** *There is no polynomial-time online algorithm for* incremental DS *or* incremental CDS *with competitive ratio* $o(\log^2 \Delta)$ *unless* NP $\subseteq$ BPP*, even when the neighborhood of requested vertices is known.*

For deterministic algorithms, we obtain a stronger lower bound.

▶ **Theorem 6.** *There is no deterministic online algorithm for* incremental DS *or* incremental CDS *with competitive ratio* $o(\log^2 \Delta / \log\log \Delta)$*, even when the neighborhood of requested vertices is known.*

Finally, in the random-order setting where vertices arrive according to a uniformly random permutation, we establish a logarithmic lower bound.

▶ **Theorem 7.** *There is no online random-order algorithm for* incremental DS *or* incremental CDS *with competitive ratio* $o(\log \Delta)$*.*

The random-order model is a restriction of the fully adversarial model, the above lower bound immediately implies the following.

▶ **Corollary 8.** *There is no online algorithm for* incremental DS *or* incremental CDS *with competitive ratio* $o(\log \Delta)$*. This lower bound also holds when the neighborhood of requested vertices is known.*

1.1.2 The Offline Setting

We study the offline variants of incremental DS and CDS, where the entire graph and the vertex request order are known in advance. We show that these problems remain NP-complete and hard to approximate, and establish tight approximation bounds up to constant factors.

▶ **Theorem 9.** Incremental DS *and* incremental CDS *are* NP-complete*. Furthermore, unless* NP $\subseteq$ BPP *there is no polynomial-time* $o(\log \Delta)$ *approximation algorithm for either problem.*

Complementing this lower bound, we give a matching polynomial-time $O(\log \Delta)$-approximation algorithm for both problems.

▶ **Theorem 10.** *There is a polynomial-time* $O(\log \Delta)$*-approximation algorithm for* incremental DS *and* incremental CDS*.*

1.2 Our Techniques

We start in Section 3 by formulating both incremental DS and incremental CDS as covering problems. The formulation of incremental DS is standard, but for incremental CDS we introduce a more involved formulation that maintains connectivity throughout. For each newly requested vertex, we create different constraints depending on whether it connects to zero, one, or more than one existing connected component. This formulation captures both domination and connectivity requirements, while ensuring that both the maximum constraint size and maximum frequency are linear in Δ, enabling the application of standard techniques for online covering problems. This formulation is the foundation for most of our results.

As an immediate result from the linear formulation we prove the $O(\log^2 \Delta)$-competitive ratio for online randomized algorithms, and an $O(\log \Delta)$ approximation ratio for the offline setting, where both the graph and request order are known in advance. Another result of this formulation is a greedy deterministic $O(\Delta)$-competitive algorithm for the weighted variant of both settings.

In Section 4, we use the extra information provided by knowing the neighborhood of requested vertices to exponentially improve the competitive ratio for deterministic algorithms. When the graph is unweighted, we maintain both a fractional and an integral solution, coupled through a potential function that is exponential in the fractional coverage of elements not yet covered integrally. The exponential growth ensures that at most $O(|\mathrm{OPT}|)$ elements can be covered fractionally without being covered integrally. We combine this bound with an algorithm that guarantees that whenever a new uncovered vertex is requested, we add a

logarithmic number of vertices to the dominating set. Together, these techniques provide the desired competitive ratio. We note that our potential function approach is inspired by Alon et al. [1], yet our solution gives improved competitive bounds and handles a wider range of settings.

We note that Δ_G can increase over time, to handle this we use a guess-and-square technique that achieves the desired $O(\log^2 \Delta_G)$ competitive ratio, improving upon the $O(\log^3 \Delta_G)$ bound obtained by the standard guess-and-double approach (see Section 4.1.2 for more details). This technique is used several times throughout the paper for algorithms where the maximum degree of the graph is not known in advance.

To get a similar competitive ratio for incremental CDS, we partition constraints into two sets: the first one contains the constraints handled by the incremental DS algorithm and the second one contains at most $O(|\mathrm{OPT}|)$ other constraints. The small size of the second set ensures that satisfying these constraints preserves the competitive ratio.

For the weighted case, we augment the potential function with a term that bounds the difference between the cost of the integral and fractional solutions while simultaneously bounding the increase of the potential throughout the runtime, yielding a logarithmic competitive ratio for incremental DS.

To obtain matching lower bounds on our competitive ratios, we provide reductions from dominating set and online set cover. A key insight in both reductions is the use of auxiliary vertices that are revealed first and must be selected. Then, we reveal vertices which are covered by these auxiliary vertices, revealing information about the instance to the incremental algorithm (either the sets or the graph depending on the reduction), thus enabling us to construct the reductions. These reductions preserve both the instance size and the optimal solution size, allowing us to transfer known lower bounds to our setting.

For the random-order lower bound, we replicate vertices so that a random permutation induces the adversarial set cover sequence with high probability, transferring random-order set cover lower bounds to the random order setting.

2 Preliminaries

We introduce the notation used throughout the paper, formally defining the problems we study, and presenting their covering formulations.

Let $G = (V, E, w)$ denote an undirected graph with vertex set V, edge set E, and weight function $w : V \to \mathbb{R}^+$. Let $w(S) = \sum_{s \in S} w(s)$ denote the total weight of all elements in $S \subseteq V$. The set of all connected components of G is denoted by $C(G)$.

Without loss of generality, we assume that $V = \{v_1, \ldots, v_n\}$, and that vertices are requested in this order, i.e., vertex v_1 is requested first, then v_2, and so on. Denote $V_i = \{v_1, \ldots, v_i\}$ when the order is understood from context.

For a vertex v, we denote by $N(v)$ the set of neighbors of v and $N[v] = N(v) \cup \{v\}$. We define the natural extensions to sets $N[U] = \bigcup_{u \in U} N[u]$.

For any $H \subseteq V$, let $G[H]$ be the induced subgraph of G on H.

We now define the competitive ratio used to benchmark our algorithms throughout the paper.

▶ **Definition 11** (Competitive Ratio). *The* competitive ratio *of an online algorithm $\mathcal{A}$ is*

$$\sup \frac{w(\mathcal{A})}{w(\mathrm{OPT})},$$

where OPT *denotes the cost of the optimal algorithm, and the supremum is taken over all graphs, weight functions, and request sequences.*

In this paper, OPT always refers to an optimal **incremental** algorithm.

2.1 Problem Definitions

We begin by defining the dominating set and connected dominating set problems.

▶ **Definition 12** (Dominating Set). *For a graph G, a* dominating set *is a subset $S \subseteq V$ such that $\bigcup_{v \in S} N[v] = V$. The objective is to minimize $w(S)$.*

In addition to covering all vertices, we may impose the requirement that the dominating set be connected within each connected component of the graph.

▶ **Definition 13** (Connected Dominating Set). *A* connected dominating set (CDS) *is a* dominating set *of G such that for every connected component C of G, the set $S \cap C$ is connected.*

To model the decisions an online algorithm must make incrementally, we define the incremental dominating set problem and its connected variant. Recall that V_i denotes the set containing the first i vertices requested by the online process.

▶ **Definition 14** (Incremental Dominating Set). *For a graph G, an* incremental dominating set *is a subset $S \subseteq V$ such that for all $i \in [n]$, $S \cap V_i$ is a* dominating set *of $G[V_i]$.*

▶ **Definition 15** (Incremental Connected Dominating Set). *For a graph G, an* incremental connected dominating set *is a subset $S \subseteq V$ such that for all $i \in [n]$, $S \cap V_i$ is a* connected dominating set *of $G[V_i]$.*

In the online setting, the vertices of a graph are requested one by one. In this paper, we consider two information models: at step i, the algorithm either knows the induced subgraph $G[V_i]$, which corresponds to the standard vertex arrival model, or the neighborhood subgraph $G[N[V_i]]$. Throughout the paper, the competitive ratio is measured against OPT, the optimal incremental dominating set.

▶ **Definition 16** (Known Neighborhood Model). *In the* known neighborhood model*, at step i when vertex v_i is requested, the algorithm observes the induced subgraph $G[N[V_i]]$ rather than just $G[V_i]$. Vertices in $N[V_i] \setminus V_i$ are visible but cannot be selected for the dominating set until requested.*

We work in the late-accept model [3, 4], where vertices can be added to the solution at any time but cannot be removed once chosen. We now define the online variants of the incremental Dominating Set and incremental Connected Dominating Set problems.

▶ **Definition 17** (Online Incremental Dominating Set). *In the* online incremental dominating set *problem, the algorithm must maintain a dominating set of $G[V_i]$ at each step i.*

▶ **Definition 18** (Online Incremental Connected Dominating Set). *In the* online incremental connected dominating set *problem, the algorithm must maintain a connected dominating set of $G[V_i]$ at each step i.*

Since any superset of a CDS is also a CDS, the late accept setting does not violate the incrementality requirements of previous steps. Adding vertices to the solution at later steps preserves the CDS property for all previous graphs.

2.2 Covering Problems

In this paper, we use linear programs with covering constraints

▶ **Definition 19** (Covering Problem). *A* covering problem *is a linear program of the form:*

$$\begin{aligned} \min \quad & \sum_{i\in[n]} w(i)\cdot x_i \\ & s.t. \\ a^j \cdot \vec{x} &\geq 1, && \forall j \in [m] \\ x_i &\geq 0 && \forall i \in [n] \end{aligned} \tag{1}$$

where $a^j \in \{0,1\}^n$ *for all* $j \in [m]$.

3 Covering LPs for Incremental DS and Incremental CDS

We now formulate linear programming (LP) relaxations for incremental DS and incremental CDS, expressing both as covering problems with each constraint involving at most $O(\Delta)$ variables and each variable participating in $O(\Delta)$ constraints. Formulating both problems as covering LPs has two main advantages. First, it allows us to leverage techniques already known in the literature for online covering problems. Second, it provides a unified framework for designing algorithms for both problems simultaneously, an approach we exploit in later sections.

We formalize these observations in the following theorem,

▶ **Theorem 20.** *Both* incremental DS *and* incremental CDS *have* LP *relaxations that are covering problems. The size of each constraint is bounded, and so is the number of variables in each constraint. More precisely:*

1. *For* incremental DS*, each constraint involves at most* $\Delta + 1$ *variables.*
2. *For* incremental CDS*, each constraint involves at most* Δ *variables.*
3. *In both relaxations, each variable appears in at most* $\Delta + 1$ *covering constraints, and a single non-negativity constraint.*

3.1 Incremental DS as a Covering Problem

We begin by formulating the LP relaxation for incremental DS. For each vertex v_i, we introduce a variable $x_i \in [0,1]$.

Proof of Theorem 20(1). When v_i is requested, either v_i or one of its (previously requested) neighbors needs to be in the dominating set, so

$$\sum_{j:v_j\in N[v_i]\cap V_i} x_j \geq 1.$$

Due to the monotone nature of the solution, it suffices to ensure that each newly requested vertex is covered when it appears. This gives us the following relaxation

$$\begin{aligned} \min \quad & \sum_{i\in[n]} x_i \cdot w(v_i) \\ & \text{s.t.} \\ \sum_{j:v_j\in N[v_i]\cap V_i} & x_j \geq 1, && \forall i \in [n] \\ x_i &\geq 0, && \forall i \in [n] \end{aligned} \tag{2}$$

This relaxation is a covering problem. Each constraint involves at most $\Delta + 1$ variables since it includes v_i and its neighbors in V_i. Moreover, each variable x_j appears only in the non-negativity constraint and constraints for vertices v_i such that $v_j \in N[v_i]$. Since $|N[v_i]| \leq \Delta + 1$, each variable x_j appears in at most $\Delta + 1$ covering constraints. ◀

3.2 Incremental CDS as a Covering Problem

Here we prove Theorem 20(2) by identifying a small set of integral constraints that ensures the chosen subset is both a dominating set and is connected. We provide the intuition for the LP formulation here, and defer the details to the full version of the paper.

To express connectivity using local constraints, we classify each new vertex by how it interacts with existing components: it may start a new one, attach to one, or join several together. The cases require different types of constraints to maintain both domination and connectivity. To the best of our knowledge, this is the first time that connectivity is captured using only local constraints.

Proof of Theorem 20(2). We start by classifying the vertices into three types:

1. Opener – A vertex that, upon arrival, is not connected to any other vertex. Formally, $N[v_i] \cap V_i = \{v_i\}$. For example, the first vertex v_1 is always an opener.
2. Attacher – A vertex that, upon arrival, is connected to only one component. Formally, there exists $C \in C(G[V_{i-1}])$ such that for all $C' \neq C$, $N[v_i] \cap V_i \cap C' = \emptyset$.
3. Joiner – A vertex that connects at least two components upon arrival. Formally, there exist $C_1, C_2 \in C(G[V_{i-1}])$ such that $N[v_i] \cap V_i \cap C_1 \neq \emptyset$ and $N[v_i] \cap V_i \cap C_2 \neq \emptyset$.

We now add the appropriate constraints for each type to enforce both domination and connectivity.

Case 1: Opener. An Opener creates a new component and must be chosen to dominate itself. The only way to satisfy the dominating set requirement is to include it in the dominating set, thus $x_i \geq 1$.

Case 2: Attacher. An Attacher connects to one existing component C. The domination and connectivity constraints are satisfied as follows:

- If v_i is added to the CDS, at least one of its neighbors in C must also be in the CDS to maintain connectivity.
- If v_i is **not** added to the CDS, at least one of its neighbors must be added to satisfy the domination requirement.

Both scenarios are enforced by the constraint:

$$\sum_{v_j \in N(v_i) \cap V_i} x_j \geq 1.$$

This constraint is sufficient because the neighbors of v_i are already adjacent to the CDS, so adding any neighbor maintains both domination and connectivity constraints.

Case 3: Joiner. The joiner connects multiple components $C_1, \ldots, C_k$. After adding the joiner the dominating set of any pair of components must have a path between them, but such a path must go through the joiner. As a result the joiner must be added to the dominating set. To maintain connectivity:

- v_i must be included in the CDS, $x_i \geq 1$.
- For each component C_h, at least one neighbor of v_i within C_h must be included:

$$\sum_{v_j \in N(v_i) \cap V_i \cap C_h} x_j \geq 1.$$

This requirement is sufficient since any other vertex is already adjacent to the CDS, so adding a neighbor keeps the joiner connected to the dominating set in C_h.

The maximum size of a constraint is Δ for attachers. Moreover, each constraint corresponds to a vertex v_i and involves only its neighbors. Any variable x_j appears in one non-negativity constraint, at most one constraint for each neighbor v_i, and at most one constraint for v_j itself. Since each vertex has at most Δ neighbors, each variable appears in at most $\Delta + 2$ constraints overall. ◀

3.3 Algorithmic Implications

We start by showing the strength of Theorem 20 by combining it with several known theorems about covering problems to obtain immediate results.

The first of such results is for the offline problem, where from Srinivasan [25] we have the following theorem.

▶ **Theorem 21** (Srinivasan [25]). *For any covering problem with sparsity d (i.e., each variable appears in at most d constraints), there is an $O(\log d)$-approximation algorithm.*

Combining Theorems 20 and 21 yields the approximation ratio for the offline setting of both incremental DS and incremental CDS.

▶ **Theorem 10.** *There is a polynomial-time $O(\log \Delta)$-approximation algorithm for* incremental DS *and* incremental CDS*.*

Proof. By Theorem 20, both incremental DS and incremental CDS can be formulated as covering integer programs where each variable appears in at most $\Delta + 1$ constraints, meaning that the column sparsity is $d = \Delta + 1$. Applying Theorem 21 yields an $O(\log(\Delta + 1)) = O(\log \Delta)$-approximation algorithm for both problems. ◀

For the online setting, we apply the following theorem from Gupta and Nagarajan [13].

▶ **Theorem 22** (Gupta and Nagarajan [13]). *There exists an $O(\log k \cdot \log d)$-competitive randomized online algorithm for covering problems, where k is the maximum number of variables in any constraint and d is the sparsity (maximum number of constraints any variable appears in).*

Again, combining Theorems 20 and 22 immediately yields the randomized competitive ratio.

▶ **Theorem 2.** *There is an $O(\log^2 \Delta)$-competitive randomized algorithm for* incremental DS *and* incremental CDS*.*

Proof. By Theorem 20, the LP relaxations of both problems are online covering problems with row sparsity $k \leq \Delta + 1$ and column sparsity $d \leq \Delta + 1$. Applying Theorem 22 gives an $O(\log^2 \Delta)$-competitive randomized online algorithm. ◀

Greedy Deterministic Online Algorithm

We present a deterministic greedy algorithm for the weighted variants of incremental DS and incremental CDS. Upon the arrival of each covering constraint, the algorithm selects the minimum-weight vertex satisfying the constraint, adding it to the dominating set if it has not been selected previously. The analysis is based on the covering formulation of Theorem 20. Since each variable participates in at most $\Delta + 1$ covering constraints, the greedy algorithm is $(\Delta + 1)$-competitive. The complete proof is straightforward and is deferred to the full version of the paper.

▶ **Theorem 1.** *There is a $(\Delta + 1)$-competitive deterministic algorithm for* incremental DS *and* incremental CDS*.*

4 Know Thy Neighbor

In this section we present improved deterministic algorithms for the case where the neighborhood of each requested vertex v_i ($N[V_i]$) is revealed when v_i needs to be dominated. The setting remains incremental and vertices which have not been requested (yet were revealed earlier) cannot be used to cover requested vertices. In other words, when a vertex is requested, we learn about its neighbors, but only the requested vertex itself needs to be dominated.

Knowing the neighborhood of each requested vertex complies with the arrival model studied in previous sections, except that additional information is provided at runtime. This extra information allows us to design deterministic algorithms with polylogarithmic competitive ratios, a substantial improvement over the $\Omega(\Delta)$ lower bound from the setting where only requested vertices are known (without full neighborhood information).

Since revealed vertices need not all be requested, we distinguish between Δ_G, the maximum degree of the full revealed graph, and Δ, the maximum degree of $G[V_n]$, the subgraph induced by requested vertices.

In Section 4.1, we present an $O(\log^2 \Delta_G)$-competitive deterministic algorithm for the unweighted case, for both incremental DS and incremental CDS. Then, in Section 4.2, we show that in the weighted case there exists an $O(\log n \log \Delta)$-competitive deterministic algorithm for incremental DS. We leave improving the upper bound for weighted incremental CDS as an open problem.

This model differs from that of [14], where a vertex must be covered only when its last neighbor is revealed, and late acceptance is disallowed.

4.1 Unweighted Case

We first present a deterministic algorithm for incremental DS. Our approach is based on maintaining both a fractional solution and an integral dominating set D, coupled through a potential function. The potential function penalizes vertices that are covered fractionally but not integrally, ensuring that vertices with high fractional coverage are added to the integral solution.

The algorithm maintains a parameter m, initialized to an upper bound on the maximum degree of the revealed graph Δ_G, and updated dynamically to remain an upper bound as new vertices arrive (see Section 4.1.2). We also maintain a fractional solution x (possibly infeasible), initialized with $x_i = \frac{1}{4m}$ for each vertex v_i.

To track how well each vertex is covered fractionally, we define the potential cover c_v for each known vertex v. This measure has two components: the fractional coverage from revealed neighbors, and a correction term that accounts for potential neighbors that have not yet been revealed. Specifically, when a new neighbor of v is revealed, it contributes $\frac{1}{4m}$ to the fractional coverage, while simultaneously decreasing the correction term by the same amount, ensuring c_v remains unchanged. Formally, for each revealed vertex v we define:

$$c_v = \sum_{u_j \in N[v] \cap V_i} x_j + \frac{m - |N[v] \cap V_i|}{4m}.$$

Let D be the dominating set maintained by the algorithm at the current step, and denote the set of uncovered elements as $U_i = N[V_i] \setminus N[D]$. Define the potential at step i as $\Phi_i = \sum_{v \in U_i} m^{3c_v}$. The exponential term ensures that vertices with high fractional coverage cannot remain uncovered integrally.

At each step, we first initialize any newly revealed neighbors of v_i with fractional value $\frac{1}{4m}$. If v_i is uncovered, we snapshot the current potential as Φ_s, then increase the weights of vertices in $N[v_i] \cap V_i$ until v_i is covered fractionally. We then add the smallest subset of $N[v_i] \cap V_i$ to D such that the potential is restored to at most Φ_s; by Lemma 23 this subset has size $O(\log m)$. Finally, if v_i remains uncovered after this process, we add v_i itself to D. A pseudocode of the algorithm is described in Algorithm 1.

Algorithm 1 Unweighted Known Neighborhood Deterministic.

```
   // Notation as defined in the preceding text.
1  Initialize D ← ∅ (initial dominating set).
2  for vertex v_i ∈ V do
3      For each newly revealed vertex v_j, set x_j ← 1/(4m), and increment Φ_i by
       m^{3c_{v_j}} ≤ m^{3/4}. if v_i ∈ U_i then
4          Set Φ_s ← Φ_i.
5          while c_{v_i} < 1 do
6              For each v_j ∈ N[v_i] ∩ V_i, multiply x_j by two.
7          Add the smallest subset of vertices to D for which Φ_i ≤ Φ_s. // By Lemma 23,
           the size of such a subset is O(log m).
8      if v_i is not covered then
9          Add v_i to D.
```

To begin the analysis, we show that after each weight increase the algorithm can avoid an increase in the potential function by adding only a small subset of vertices to the dominating set in Line 7.

▶ **Lemma 23.** *If v_i is uncovered at step i, then there exists a subset of $N[v_i] \cap V_i$ of size at most $6 \log m$ such that adding the vertices in the subset to D ensures that the potential does not increase, i.e.,*

$$\Phi_i \leq \Phi_s,$$

where Φ_s is the potential prior to the weight increases in Line 6.

The proof is deferred to the full version of the paper. We next move from considering how much is added per update to bounding how often such updates happen.

▶ **Lemma 24.** *The total number of times the* **if** *statement in Line 3 in Algorithm 1 is triggered is at most $O(|\mathrm{OPT}| \log m)$.*

Proof. Every coordinate x_j is initialized to $1/(4m)$ and the algorithm only multiplies coordinates by 2 (Line 6). Moreover, Line 5 ensures that the algorithm never increases the value of any coordinate beyond 2. Thus, for every index j the number of times x_j can be doubled is at most $\log(8m) = O(\log m)$.

Since v_i must be dominated by a vertex in OPT, each time the **if** statement is triggered at least one coordinate corresponding to a vertex of OPT is doubled.

Combining these results, the total number of times that the **if** statement can be triggered is upper bounded by $O(|\mathrm{OPT}| \cdot \log m)$. ◀

Having bounded the number of update steps, we now show that the increase in the potential function itself remains bounded throughout the execution. Since each vertex added in the final while loop decreases the potential by a large amount, bounding the total potential increase immediately implies a bound on the number of vertices added in that phase.

▶ **Lemma 25.** *At step i, $\Phi_i \leq i \cdot \Delta_G \cdot m$.*

Proof. The potential can change in three places: when a vertex is requested, when weights are increased in Line 6, and when new vertices are revealed.

First, consider the moment when a vertex $v_i \in N[u]$ is requested. Its initial contribution of $1/(4m)$ is added to the first summand of c_u, but at the same time $|N[u] \cap V_i|$ increases by one, which decreases the correction term $(m - |N[u] \cap V_i|)/4m$ by exactly $1/(4m)$. The two changes cancel, and c_u does not change.

Second, by Lemma 23, after each weight increase in Line 6 the vertices added to D in Line 7 ensure that the potential does not increase, so weight increases cause no net increase in the potential.

Therefore the only source of increase is when new vertices are revealed. For each new vertex u, the increase in the potential is at most $m^{3c_u} \leq m$, since $c_u \leq \frac{1}{4}$ at reveal. After i steps, the number of revealed vertices is bound by $i \cdot \Delta_G$, the total increase is bounded by $i \cdot \Delta_G \cdot m$. ◀

We now use the bounded increase in Φ to bound the number of vertices added in the final loop of the algorithm. Intuitively, since each additional vertex in that phase reduces the potential by a large amount, a global bound on the total potential increase immediately limits how many such insertions can occur.

▶ **Lemma 26.** *Denote the number of total requested vertices throughout the algorithm as r. The number of vertices added by Lines 8-9 is bounded by $\frac{r \cdot \Delta_G}{m^2}$, and if $m \geq \Delta_G$ then the bound is $2 \cdot |\mathrm{OPT}|$.*

Proof. When we insert v_i to D in Line 9, we remove at least $m^{3c_u} \geq m^3$ from the potential. By lemma 25 the number of added vertices is at most

$$\frac{r \cdot \Delta_G \cdot m}{m^3} = \frac{r \cdot \Delta_G}{m^2}$$

If $m \geq \Delta_G$ then $|\mathrm{OPT}| \geq r/(\Delta_G + 1) \geq r/(2\Delta_G)$, giving us the upper bound. ◀

We are now ready to combine the previous bounds to obtain the overall competitive ratio.

▶ **Lemma 27.** *If $m \geq \Delta_G$, the competitive ratio of algorithm 1 is $O(\log^2 m)$.*

Proof. By Lemma 24 we enter the **if** in Line 3 at most $O(|\mathrm{OPT}| \cdot \log m)$ times, and by Lemma 23 each time we add $4 \log m$ vertices to D. By Lemma 26 we then add at most $2|\mathrm{OPT}|$ vertices in Lines 8-9. Hence

$$|D| \;\leq\; O(|\mathrm{OPT}| \cdot \log m) \cdot 4 \log m + 2|\mathrm{OPT}| \;=\; O(|\mathrm{OPT}| \cdot \log^2 m),$$

proving the claimed competitive ratio. ◀

We note that Algorithm 1 extends naturally to the case where constraints are of the form $N(v_i) \cap D$ (as with attacher constraints), where the requested vertex itself is excluded. If $N(v_i) = \emptyset$ then v_i is an isolated vertex and no constraint is enforced. Otherwise, all we need to do is replace all instances of $N[v_i]$ with $N(v_i)$. The potential function argument is unchanged, and the same $O(\log^2 \Delta_G)$-competitive bound holds.

4.1.1 Connected Dominating Set

In this part we extend the result of Section 4.1 to incremental CDS. The algorithm is similar to Algorithm 1, but with a special case for joiners (recall that a joiner is a vertex that joins two connected components, see Section 3.2 for the formal definition). When a joiner is requested, for each constraint created by it, we immediately add an arbitrary vertex from the constraint to the dominating set. We prove that the number of vertices added this way is bounded by $O(|\mathrm{OPT}|)$.

▶ **Lemma 28.** *The number of constraints added by joiners is bounded by* $2 \cdot |\mathrm{OPT}|$.

Proof. We actually prove a stronger statement, namely that the total number of constraints created by openers and joiners is at most $2 \cdot |\mathrm{OPT}|$. Let $\mathcal{O}$ be the number of openers and let $\mathcal{J}$ be the number of joiners. By the transformation in Section 3.2, every opener and joiner must belong to the dominating set, so $|\mathrm{OPT}| \geq \mathcal{O} + \mathcal{J}$.

We use a charging argument. When an opener is requested, it becomes the representative of its component. When a joiner is requested, each connected component it merges creates one constraint, which we charge to that component's representative. The joiner then becomes the representative of the merged component.

Each vertex can be charged at most twice: once when requested (as an opener or joiner), and at most once later as a representative. Therefore, the total number of constraints is at most $2(\mathcal{O} + \mathcal{J}) \leq 2 \cdot |\mathrm{OPT}|$. ◀

4.1.2 Guess and Increase

To extend our algorithm to the case where the maximum degree Δ_G is not known in advance, we use a guess-and-update technique inspired by the standard "guess-and-double" framework. A straightforward adaptation, starting with an underestimate of Δ_G and doubling it whenever the maximum degree exceeds the current guess, leads to a competitive ratio of

$$\sum_{j=1}^{\log \Delta_G} O(\log^2(\Delta_G/2^j)) \cdot \mathrm{OPT} = O(\log^3 \Delta_G) \cdot \mathrm{OPT},$$

which is asymptotically worse than the optimal bound. To handle this discrepancy, instead of doubling the current estimate of Δ_G, we square it upon discovering that the maximum degree violates the current guess.

We are now ready to prove the main theorem of the section.

▶ **Theorem 3.** *When the neighborhood of requested vertices is known, and the graph is unweighted, then there is an* $O(\log^2 \Delta_G)$*-competitive deterministic algorithm for both* incremental DS *and* incremental CDS*.*

Proof. Denote by OPT_i the cost of the optimal solution for the first i vertices, and let Δ_i be the maximum degree of the revealed graph at this step. Since each new vertex introduces additional constraints, it follows that $\mathrm{OPT}_i \leq \mathrm{OPT}$ for all i.

We maintain an adaptive upper bound Δ' on the current maximum degree, initialized to a constant. As vertices arrive, whenever $\Delta_i > \Delta'$, we update $\Delta' \leftarrow (\Delta')^2$, restart the algorithm with the new bound, and include in the global solution all vertices selected during the new run while retaining vertices selected during previous solutions.

By Lemma 27, each phase with bound Δ' has cost $O(\log^2 \Delta') \cdot \mathrm{OPT}$. Since Δ' grows quadratically, after k such increases the total cost is bounded by

$$O\left(\sum_{j=0}^{k} \log^2\left(\Delta_G^{1/2^{k-j}}\right)\right) \cdot \mathrm{OPT} \leq O\left(\sum_{j=0}^{\infty} \log^2\left(\Delta_G^{2^{-j}}\right)\right) \cdot \mathrm{OPT} = O(\log^2 \Delta_G) \cdot \mathrm{OPT}.$$

Therefore, the adaptive algorithm preserves the $O(\log^2 \Delta_G)$ competitive ratio even when Δ_G is unknown in advance.

To extend the result to incremental CDS, we use the CDS formulation from Section 3.2. We use Algorithm 1 to handle the attacher constraints (as defined in Section 3.2, these are the constraints corresponding to vertices that attach to an existing component) and achieve an $O(\log^2 \Delta_G)$-competitive dominating set for these constraints. Since the optimal solution for the attacher constraints is at most $|\mathrm{OPT}|$, the number of vertices selected by Algorithm 1 is bounded by $O(\log^2 \Delta_G) \cdot |\mathrm{OPT}|$. By Lemma 28, there are at most $2|\mathrm{OPT}|$ constraints created by openers and joiners, and adding one vertex per such constraint contributes at most $2|\mathrm{OPT}|$ additional vertices. Combining both contributions results in a valid incremental CDS of size $O(\log^2 \Delta_G) \cdot |\mathrm{OPT}|$, finishing the proof. ◀

4.2 Weighted Case

In this part, we show an $O(\log m \log \Delta)$ deterministic algorithm for incremental DS that uses an upper bound on the value of the optimal solution α, and a parameter m which represents an upper bound on the number of **requested** vertices n. In this section Δ represents the degree of $G[V_n]$, the subgraph induced by requested vertices, disregarding vertices which are revealed but not requested. We apply doubling to handle the case where α is not known, and we later show how to increase m dynamically, using a technique similar to doubling, to obtain the desired competitive ratio of $O(\log n \log \Delta)$. If the number of requested vertices n is known in advance we can set $m = n$ instead.

Our algorithm maintains both a fractional and an integral solution. We use the fractional solution to guide which vertices to add to the integral dominating set D, while a potential function ensures the two solutions remain balanced. To obtain the fractional solution, we apply the following result from Buchbinder et al. [5]:

▶ **Theorem 29.** *There is a deterministic $O(\log d)$-competitive fractional algorithm for covering problems with constraint size up to d.*

Since each covering constraint involves at most $\Delta + 1$ variables, Theorem 29 guarantees an online monotone fractional solution which is $O(\log \Delta)$ competitive.

Denote the dominating set as D. Let the set of vertices adjacent to requested vertices that are not yet dominated at step i be $U_i = N[V_i] \setminus N[D]$. Denote $c_{v_i} = \sum_{u_j \in N[v_i] \cap V_i} x_j$ as the fractional coverage of v_i, and define the potential at step i as

$$\Phi_i = \sum_{v \in U_i} m^{2c_v} + \exp\left(\frac{1}{2\alpha}\left(\sum_{v \in D} w(v) - 3 \log m \sum_{v_j \in V_i} w(v_j) x_j\right)\right).$$

The first sum ensures that every vertex is covered when it is requested, and the second term ensures that the integral and fractional solutions do not differ by too much.

At each step a vertex v_i is requested to be dominated. We update the potential function for the newly revealed neighbors of v_i, and then add the covering constraint $\sum_{j \in N[v_i] \cap V_i} x_j \geq 1$ to the LP. We increase the weights of vertices in $N[v_i] \cap V_i$ in the fractional solution until this constraint is satisfied. Then, we add a subset of vertices to D that ensures that the

potential does not increase. Vertices v_j with $w(v_j) > \alpha$ are kept at $x_j = 0$ in the fractional solution, ensuring that heavy vertices are never selected. The algorithm is described formally in Algorithm 2.

Algorithm 2 Known Neighborhood Deterministic.

```
   // Notation as defined in the preceding text.
1  Initialize D ← ∅ (initial dominating set).
2  Initialize x ← 0⃗, Φ_0 ← e^0 = 1.
3  for vertex v_i ∈ V do
4      For each newly revealed vertex u, increment Φ_i by m^{2c_u} = 1.
5      Add covering constraint for v_i and compute the online fractional solution x̃ from
        Theorem 29.
6      for j = 1, ..., i do
7          Set x_j ← x̃_j. // Update fractional solution
8          If Φ_i increased by the change in last line, add v_j to D
```

The analysis follows the same potential-function framework as in the unweighted case, where vertices are added to the integral solution in a way that ensures the potential function decreases. Combining this approach with the $O(\log \Delta)$-competitive fractional algorithm yields an $O(\log m \log \Delta)$ competitive ratio. The detailed analysis is deferred to the full version of the paper, and establishes the following result.

▶ **Theorem 4.** *When the neighborhood of requested vertices is known, there is an* $O(\log n \log \Delta)$*-competitive deterministic algorithm for* incremental DS.

5 Lower Bounds

5.1 Lower Bounds via Online Set Cover

We present a reduction from the online set cover problem to the online incremental Dominating Set problem. The reduction preserves the instance size up to polynomial factors and maintains the optimal solution size up to a constant additive term. This allows us to transfer known hardness results for online set cover and prove Theorems 5 and 6.

Given an instance of online set cover with universe $U = \{e_1, e_2, \ldots, e_n\}$ and collection $\mathcal{S} = \{S_1, S_2, \ldots, S_m\}$ with $S_i \subseteq U$, construct the incremental dominating set instance as follows. The vertex set is

$$V = \{r, t, t'\} \cup \mathcal{S} \cup U,$$

where r is a root adjacent to all set nodes, and t is a terminal adjacent to all element nodes, with a neighbor t'. The edge set is

$$E = (\{r\} \times \mathcal{S}) \cup \{(S_i, e_j) \mid e_j \in S_i\} \cup (U \times \{t\}) \cup \{(r, t), (t, t')\}.$$

That is, every set S_i is adjacent to r, a set S_i and element e_j are adjacent iff $e_j \in S_i$, every element of U is adjacent to t, and t is adjacent to both r and t'.

In the online adversarial setting, vertex r is requested first, followed by the vertices in $\mathcal{S}$. When an element is requested in the online set cover instance, the corresponding vertex is requested in the incremental DS instance. Once the set cover instance is finished, the terminal t is requested, followed by t', and then vertices in U which were not yet requested. A visualization of the reduction appears in Figure 2. We prove the following lemma,

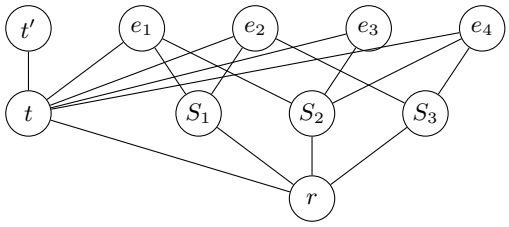

Figure 2 The resulting reduction from a set cover instance with 4 elements $E = \{e_1, e_2, e_3, e_4\}$ and 3 sets $S_1 = \{e_1, e_2\}$, $S_2 = \{e_1, e_3, e_4\}$ and $S_3 = \{e_2, e_4\}$. The vertices r and S_1, S_2, S_3 are requested first, and then when an element e_i is requested in the online set cover instance its corresponding vertex is requested in the reduction. After the online set cover instance is finished, t and t' are requested, followed by the rest of the vertices in E.

▶ **Lemma 30.** *There is an optimal solution for the reduced incremental instance that contains only elements belonging to* $\{r, t\} \cup \mathcal{S}$.

Proof. Let $\mathcal{I}$ be a solution to the reduced incremental instance. Vertex $r \in \mathcal{I}$, as r is the first requested vertex. Let $\mathcal{S}' = \mathcal{S} \cap \mathcal{I}$ and $U' = U \cap \mathcal{I}$. For each $u \in U'$ we choose some set $s_u \in \mathcal{S}$ that contains it. Define $\mathcal{S}_{U'} = \{s_u | u \in U'\}$, and let $\mathcal{I}' = \{r, t\} \cup \mathcal{S}' \cup \mathcal{S}_{U'}$.

The solution $\mathcal{I}'$ dominates all requested vertices: each $u \in U'$ is adjacent to $s_u \in \mathcal{I}'$, every set vertex is dominated by r, and r dominates itself. Since t' has only one neighbor t, any solution must contain t or t', so replacing whichever appears in $\mathcal{I}$ with t does not increase the solution size. Finally, $|\mathcal{S}_{U'}| \leq |U'|$ gives $|\mathcal{I}'| \leq |\mathcal{I}|$. ◀

We now proceed to proving that the reduction satisfies several properties.

▶ **Lemma 31.** *Our reduction satisfies the following properties:*

1. *The number of vertices in the resulting incremental instance is* $n + m + 3$.
2. *The optimal solution size in the incremental instance differs from the optimal set cover size by 2.*
3. *The reduction is online, meaning that each request in the online set cover instance is translated into a corresponding vertex in the online incremental DS instance.*
4. *There is an optimal solution that is connected.*

Proof. Property 1 is true by the way the reduction is defined.

The set cover solution selects a subset $\mathcal{S}' \subseteq \mathcal{S}$ to cover all the requested elements. The set $\{r, t\} \cup \mathcal{S}'$ is a valid solution to the reduction, since all vertices corresponding to sets in $\mathcal{S}$ are dominated by r, each requested element in U must be covered by an element in $\mathcal{S}'$, and all other elements in U are dominated by t. Thus a set-cover solution of size k yields an incremental solution of size $k+2$. By Lemma 30, let $\mathcal{I} \subseteq \{r, t\} \cup \mathcal{S}$ be the optimal solution to the reduced incremental instance, then $\mathcal{I} \backslash \{r, t\}$ is a feasible cover for the set cover instance of size $|\mathcal{I}| - 2$. Combining both directions proves the claim.

By Lemma 30, an optimal solution lies in $\{r, t\} \cup \mathcal{S}$. Since r and $\mathcal{S}$ are revealed before any element is requested, each subsequent element request corresponds exactly to the arrival of its matching vertex, and once t is requested it dominates all remaining elements of U without further additions, proving Property 3.

By Lemma 30, there exists an optimal solution containing only r, t, and elements from $\mathcal{S}$, where each vertex in $\mathcal{S}$ is adjacent to r. Since r is requested first and all other vertices in the optimal solution are connected to r, the partial solution remains connected at every step, thus proving Property 4. ◀

By combining these properties with known hardness results for online set cover [1, 19] the following results are established. The analysis is straightforward and is provided to the full version of the paper.

▶ **Theorem 5.** *There is no polynomial-time online algorithm for* incremental DS *or* incremental CDS *with competitive ratio* $o(\log^2 \Delta)$ *unless* NP $\subseteq$ BPP*, even when the neighborhood of requested vertices is known.*

▶ **Theorem 6.** *There is no deterministic online algorithm for* incremental DS *or* incremental CDS *with competitive ratio* $o(\log^2 \Delta / \log\log \Delta)$*, even when the neighborhood of requested vertices is known.*

5.2 Random Order Lower Bound

We present here a lower bound of $\Omega(\log n)$ on random order incremental DS. This proves Theorem 7. As a result, we can conclude that no algorithm has an $o(\log n)$ competitive ratio in the adversarial case, proving Theorem 8. We start with the result of Gupta et al. [12].

▶ **Theorem 32** (Theorem 5.1 in [12])**.** *There is an instance of set cover with n elements and $\Theta(n)$ sets, where any online algorithm for random order set cover is $\Omega(\log n)$-competitive.*

Let (S, E) be the set cover instance used in Theorem 32, where S is the collection of subsets and E is the ground set of elements. We construct an incremental Dominating Set instance as follows:

The vertex set includes all elements in E. For each subset $s_i \in S$, we create a clique $S_i = s_i^1, \ldots, s_i^{n^3}$. Each vertex in S_i is connected to all elements $e \in s_i$. Additionally, the clique $R = r^1, \ldots, r^{n^5}$ is added, where each $r^j \in R$ is connected to all vertices in every S_i.

Let η be the event that a vertex in R is requested first, and also for each S_i a vertex $s \in S_i$ is requested before all the vertices in E. We show that event η occurs with probability at least $1/2$.

▶ **Lemma 33.** *For sufficiently large n, $\mathbb{P}[\eta] \geq \frac{1}{2}$.*

The main idea is that $|R| = n^5$ is large relative to the $\Theta(n^4)$ remaining vertices, and each S_i's clique of size n^3 is large relative to the $\Theta(n)$ vertices of E that depend on it, so both events hold with high probability for sufficiently large n. The detailed calculation is provided in the full version of the paper. We now prove the lower bound.

▶ **Theorem 7.** *There is no online random-order algorithm for* incremental DS *or* incremental CDS *with competitive ratio* $o(\log \Delta)$.

Proof. Assume the event η occurs. Then some vertex in R is selected first, and for every $s_i \in S$, a vertex $s_i^j \in S_i$, which is already dominated by r, is requested before any $e \in E$.

When vertices in E are requested, each $e \in E$ is adjacent only to vertices s_i^j such that $e \in s_i$. To maintain the domination invariant, the algorithm must select such an s_i^j upon e's arrival. Selecting e itself would dominate only e, while selecting a neighboring s_i^j may also dominate future elements in E, so we may assume the algorithm avoids selecting e directly.

This simulates the random order set cover problem of Theorem 32, where the algorithm must cover elements of E using sets s_i. Given η, any algorithm incurs competitive ratio $\Omega(\log n)$. By Lemma 33 η occurs with constant probability, so the expected competitive ratio is $\Omega(\log n)$. The reduction produces a graph of size polynomial in n with maximum degree $\Delta = \Theta(n^5)$, so this establishes a lower bound of $\Omega(\log \Delta)$ for random-order incremental Dominating Set. ◀

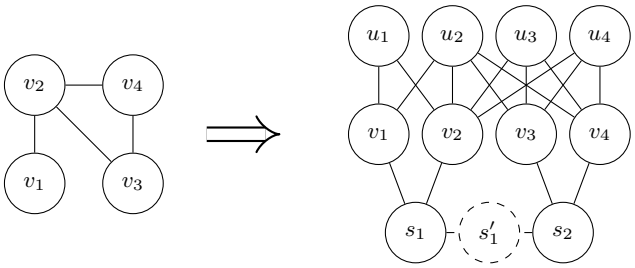

Figure 3 An example of the reduction presented in Section 5.3. The original graph is on the left, and the reduced instance on the right. Vertices in the reduced instance are requested from the bottom row to the top. The vertex s'_1 (dashed) is added for incremental CDS.

5.3 Hardness of Approximation

We construct a reduction from the offline Dominating Set (DS) problem to the incremental Dominating Set and incremental Connected Dominating Set (CDS) problems. The reduction preserves the number of vertices and maintains the maximum degree up to a constant factor. This construction is used to prove Theorem 9.

Let $G = (V, E)$ be an input graph with $V = \{v_1, \ldots, v_n\}$, maximum degree Δ, and minimum dominating set of size OPT. We define a new graph $G' = (V', E')$ by adding $S = \{s_1, \ldots, s_{n/\Delta}\}$ (wlog we assume that Δ divides n) and $U = \{u_1, \ldots, u_n\}$ to V. The full vertex set is $V' = V \cup S \cup U$, consisting of $n(2 + 1/\Delta)$ vertices.

We define the following edge sets in the new graph:

$$E_s = \{(s_i, v_{\Delta \cdot i+j}) \mid i \in [n/\Delta],\ j \in [\Delta]\},$$
$$E_u = \{(v_i, u_j) \mid (v_i, v_j) \in E\} \cup \{(v_i, u_i) \mid i \in [n]\}.$$

The final edge set is $E' = E_s \cup E_u$.

Intuitively, the set U is a duplicate of V as the edges are mirrored from V to U, and each vertex $v_i \in V$ is also connected to its counterpart $u_i \in U$. The vertices are requested in the following order: first the vertices in S, then those in V, and finally those in U.

The degree of vertex s_i is Δ, of v_i is bounded by $2\Delta + 1$ and of u_i is at most $\Delta + 1$. Thus, the maximum degree is $O(\Delta)$. In Figure 3 an example of the reduction is given.

We now prove that the size of any solution is almost preserved between the two models

▶ **Lemma 34.** *If D is a dominating set of G, then $D' = S \cup D$ is an incremental dominating set of G' with $|D'| \leq 3|D|$.*

Proof. If D is a dominating set of G, then the set $D' = S \cup D$ is an incremental dominating set in G'. Each vertex s_i is added to the solution immediately upon arrival. By construction, every vertex $v_i \in V$ is adjacent to at least one such s_j, ensuring that V is dominated once it arrives. For each vertex $u_i \in U$, if $v_i \in D$, then u_i is directly adjacent to $v_i \in D'$. Otherwise, since D is a dominating set in G, there exists a neighbor $v_j \in D$ of v_i, and in this case u_i is adjacent to $v_j \in D'$ via the edge $(v_j, u_i) \in E_u$.

The size of D' is

$$|D| + \frac{n}{\Delta} \leq |D| + 2\frac{n}{\Delta + 1} \leq 3|D|.$$

The first inequality holds because $\Delta > 0$, and the second follows from the standard lower bound on the size of any dominating set in a graph with maximum degree Δ. ◀

For the converse direction:

▶ **Lemma 35.** *If I is an incremental dominating set of G', then the set $D = \{v_i \mid v_i \in I \text{ or } u_i \in I\}$ is a dominating set of G and satisfies $|D| = O(|I|)$.*

Proof. Fix any $v_i \in V$.

- If $v_i \in D$, then v_i is trivially dominated.
- If $v_i \notin D$, but v_i is adjacent in G to some $v_j \in I$, then v_i is dominated via $v_j \in D$.
- Else, $u_i \in V'$ must be dominated in G', and since $u_i \notin I$, there must exist a vertex $v_j \in I$ such that $(v_j, u_i) \in E_u$. By construction of E_u, this implies $(v_i, v_j) \in E$, and $v_j \in D$.

In all cases, v_i is adjacent to some $v_j \in D$, so D is a dominating set of G.

To bound the size of D, note that $S \subseteq I$, and each $v_i \in D$ corresponds to at most two vertices in I. Therefore,

$$2|D| \geq |I| - |S| = |I| - \frac{n}{\Delta} \geq |I| - 2\frac{n}{\Delta + 1}.$$

Using $|D| \geq \frac{n}{\Delta+1}$, we get $4|D| \geq 2|D| + 2\frac{n}{\Delta+1} \geq |I|$. ◀

To extend the reduction to incremental CDS, we introduce an additional set of vertices $S' = \{s'_1, \ldots, s'_{n/\Delta-1}\}$ and add the edges (s_i, s'_i) and (s_i, s'_{i+1}) for all $i \in [n/\Delta - 1]$. These vertices are requested after S and must be selected to maintain connectivity. As a result, any valid incremental CDS solution must include the entire set S' to maintain connectivity. Moreover, the reduction preserves the asymptotic relationship between the size of the original dominating set and the size of the corresponding incremental CDS solution.

The reduction preserves the maximum degree up to a constant factor, and by Lemmas 34 and 35 the sizes of optimal solutions in G and G' are linearly related, a polynomial-time $o(\log \Delta)$-approximation algorithm for incremental DS would yield the same for classical Dominating Set, contradicting known hardness results [6]. This establishes the following.

▶ **Theorem 9.** Incremental DS *and* incremental CDS *are* NP-complete. *Furthermore, unless* NP $\subseteq$ BPP *there is no polynomial-time $o(\log \Delta)$ approximation algorithm for either problem.*

Abstract

For an edge-weighted graph $G = (V, E)$ and a stretch parameter $t \geq 1$, a t-spanner is a subgraph $H \subseteq G$ such that the shortest path distances in G and H satisfy $\delta_H(u, v) \leq t\,\delta_G(u, v)$ for all $u, v \in V$. In metric spanners, V is a finite metric space, and G is the complete graph with edge weights corresponding to the distances between the endpoints. When G is the complete graph on n points in the plane, $O(n)$-size t-spanners are possible for any $t > 1$: For every $\varepsilon > 0$, there is an $(1+\varepsilon)$-spanner with $O(n/\varepsilon)$ edges (the stretch can be arbitrarily close to 1).

When $G = K(R, B)$ is the complete bipartite graph on n bichromatic points in the plane, in general, no spanner construction can achieve stretch $t < 3$ with $o(n^2)$ edges. Bose et al. (SICOMP 2009) constructed a $(3+\varepsilon)$-spanner with $O(n \log n)$ edges for any constant $\varepsilon > 0$. Our main result is a new construction for a $(3+\varepsilon)$-spanner with $O(\sqrt{1/\varepsilon} \cdot n)$ edges. Eliminating the $O(\log n)$ factor resolves a problem left open for more than 17 years, and raises a new research problem about optimizing the dependence on ε. We also study spanners for $G = K(R, B)$ on n bichromatic points on the real line: In this case, we show that the MST of $K(R, B)$ is a 7-spanner, and we construct a 3-spanner with at most $2n - 3$ edges.

1 Introduction

A t-spanner for an edge-weighted graph $G = (S, E)$ is a subgraph $H = (S, E')$ that contains, for every edge $ab \in E$, an ab-path of weight at most $t \cdot w(ab)$. Let S be a set of n bichromatic points in Euclidean plane, with coloring $c : S \to \{\text{red}, \text{blue}\}$. Let R and B, resp., denote the set of red and blue points in S, and let $K(R, B)$ denote the complete bipartite graph on the partite sets R and B. The weight of an edge ab is the Euclidean length $|ab|$ of the line segment ab.

For a set S of n (uncolored) points in the plane and any $\varepsilon > 0$, there exists a $(1+\varepsilon)$-spanner with $O(n/\varepsilon)$ edges [18, 23]. Bose et al. [15] noted that for a complete bipartite graph $K(R, B)$, in general, one cannot find a t-spanner with $o(n^2)$ edges and stretch $t < 3$. Specifically, for every $\varepsilon > 0$, one can arrange $\lceil n/2 \rceil$ red and $\lfloor n/2 \rfloor$ blue points in two clusters of diameter $\frac{\varepsilon}{3}$ at unit distance apart: If a subgraph $H \subseteq K(R, B)$ misses any bichromatic

edge ab, then every ab-path in H has length at least $(3-\varepsilon)|ab|$. On the positive side, Bose et al. [15] constructed, for every bichromatic set $S = R \cup B \subset \mathbb{R}^2$ and constant $\varepsilon > 0$, an $(5+\varepsilon)$-spanner with $O(n)$ edges and a $(3+\varepsilon)$-spanner with $O(n \log n)$ edges. They did not analyze the dependency on the stretch parameter ε. The main problem left open in their work is whether a bichromatic $(3+\varepsilon)$-spanner with $O(n)$ edges always exists. Our main result settles this problem in the affirmative.

▶ **Theorem 1.** *For every $\varepsilon > 0$ and every set of n bichromatic points in the plane, there exists a $(3+\varepsilon)$-spanner with $O(\sqrt{1/\varepsilon} \cdot n)$ edges, which can be constructed in $O(\sqrt{1/\varepsilon} \cdot n \log n)$ time.*

While we settle the problem posed by Bose et al. [15], our result raises a new problem to determine the optimal tradeoff between $\varepsilon > 0$ and the size of a bichromatic $(3+\varepsilon)$-spanner in the plane. Theorem 1 generalizes to Euclidean d-space for constant dimension $d \geq 2$, and yields a $(3+\varepsilon)$-spanner with $O(n/\varepsilon^{(d-1)/2})$ edges. Moreover, in the related version of the paper, Theorem 1 has been generalized to every set of n multichromatic points in the plane. We describe the spanner construction and analyze it in detail in the plane, and then briefly sketch the generalization to higher dimensions.

We also study spanners for $K(R, B)$ in the real line. The lower bound construction by Bose et al. [15] can be realized already in the line: It shows that, in general, a spanner construction cannot achieve stretch $t < 3$ with $o(n^2)$ edges. We construct a 3-spanner with at most $2n - 3$ edges (Proposition 9). We also show that the bichromatic Euclidean MST (i.e., the MST of the complete bipartite graph $K(R, B)$ with Euclidean edge weights) is a 7-spanners; and the stretch bound 7 is the best possible (Proposition 10). For comparison, recall that for n (uncolored) points on the line, the Euclidean MST is an x-monotone path, which is a 1-spanner. However, for n (uncolored) points in the plane, the Euclidean MST has unbounded stretch.

Comparison to Previous Work and Technical Highlights. As mentioned above, Bose et al. [15] constructed a $(3+\varepsilon)$-spanner with $O(n \log n)$ edges for a bichromatic set $S = R \cup B$ of n points and constant $\varepsilon > 0$. Their spanner construction uses a hierarchical space partition, but a crucial step of their approach has a $\Omega(n \log n)$ barrier. Our approach is significantly different and perhaps conceptually simpler. We briefly review the spanner construction in [15] and point out key differences from our construction.

For a bichromatic set $S = R \cup B$ of n points in the plane, Bose et al. [15] use the classical *well-separated pair decomposition* (WSPD, for short) by Callahan and Kosaraju [17]. A WSPD with separation parameter $\varrho > 0$ is a collection of unordered pairs $\mathcal{P} = \big\{\{S_i, T_i\} : i = 1, \ldots, m\big\}$ such that every point pair $\{s, t\} \in \binom{S}{2}$ appears there is an i such that $|\{s, t\} \cap S_i| = 1$ and $|\{s, t\} \cap T_i| = 1$; and $\operatorname{dist}(R_i, B_i) \geq \varrho \cdot \max\{\operatorname{diam}(R_i), \operatorname{diam}(B_i)\}$ for all i. A WSPD of size $m = O(n)$ can be construed using split trees [17, 26] or compressed quadtrees [20]. For an uncolored set of n points in $\mathbb{R}^d$, WSPDs with separation parameter $\varrho = \Theta(1/\varepsilon)$ were previously used for constructing $(1+\varepsilon)$-spanners of size $O(n/\varepsilon^d)$ [17, 19, 21]; and this bound is the best possible. Given a WSPD, each set S_i (resp., T_i) could be either monochromatic or bichromatic. Bose et al. [15] choose an arbitrary *representative* from each monochromatic set S_i and T_i; and two representatives of different colors from bichromatic sets. Their spanner consists of specific edges chosen for each pair $\{S_i, T_i\}$ of the WSPD. If S_i and T_i are bichromatic, they add a single edge between a pair of representative from S_i and T_i, respectively. However, if a set S_i is monochromatic, they need a path from all points of S_i to its representative: They achieve this by connecting all points in S_i to the

representative of a closest cluster $S_j = \mathrm{cl}(S_i)$ that contains a point of the other color (hence every point in S_i will have a 2-hop path to the representative of S_i). They prove that this graph is $(5+\varepsilon)$-spanner of size $O(n)$. They further show that *if* the WSPD has the additional property that $\min\{|S_i|, |T_i|\} = 1$ for all i, then their construction yields a $(3+\varepsilon)$-spanner. However, a WSPD with the additional property that size $m = O(n \log n)$, which is the best possible [17, 26], and dominates the size of their $(3+\varepsilon)$-spanner.

Our spanner design is crucially different in handling well-separated pairs with monochromatic clusters. If both S_i and T_i are bichromatic, we also add just two edges between representative. If S_i is monochromatic, we connect all points in S_i to the representative of T_i of the opposite color (and similarly, if T_i is monchromatic, we connect all points in T_i to a representative of S_i). Overall, for each well-separated pair (S_i, T_i), a star, a bistar, or just a pair of edges between S_i and T_i (see Cases 1–3 in Section 2.2). In particular, we do not use a detour via any closest cluster $S_j = \mathrm{cl}(S_i)$. This approach would already give a bichromatic $(3+\varepsilon)$-spanner of size $O(n)$ for any constant $\varepsilon > 0$.

Instead of a quadtree-based WSPD, however, we use a custom-made space partition scheme with rectangular cells of aspect ratio $\Theta(\sqrt{1/\varepsilon})$ to improve the dependence on $\varepsilon > 0$. In a standard quadtree-based WSPD with separation parameter $\varrho = \Theta(1/\varepsilon)$, the number of pairs is $m = O(\varrho^2 n) = O(n/\varepsilon^2)$ [20, Theorem 4.1.3]. Even though the separation parameter must be $\varrho = \Theta(1/\varepsilon)$ for a $(1+\varepsilon)$-spanner on uncolored point sets, our stretch analysis for a $(3+\varepsilon)$-spanner also works with a smaller separation parameter $\varrho = \Theta(\sqrt{1/\varepsilon})$. This would reduce the size of our spanner to $O(n/\varepsilon)$.

Furthermore, we have noticed that our inductive stretch analysis goes through even if we replace the square cells of a quadtree with rectangular cells with a larger aspect ratio provided that any two edges between the well-separated cells make an angle $O(\sqrt{\varepsilon})$. This relaxes the separation condition to $\mathrm{dist}(S_i, T_i) \geq \Theta(\sqrt{1/\varepsilon}) \cdot \max\{\mathrm{width}(S_i), \mathrm{width}(T_i)\}$, and further reduces the size of our $(3+\varepsilon)$-spanner to $O(n/\sqrt{\varepsilon})$. We present this construction (without standard quadtrees and WSPDs) in Section 2. Our system of tilings with exponentially increasing scales and $\Theta(\sqrt{\varepsilon})$ directions is presented in Section 2.1, and our spanner is constructed based on pairs of well-separated tiles in Section 2.2. The stretch and sparsity analyses are presented in Section 2.3 and Section 2.4, respectively. We analyze the running time of our spanner construction in Section 2.5, and briefly outline generalizations to dimensions $d \geq 3$ in Section 2.6.

Previous work on bichromatic points. Bose et al. [16] studied a related problem: Given a finite set S in the plane, partition S into two nonempty color classes, $S = R \cup B$, so as to minimize the spanning ratio of the resulting complete bipartite graph $G = K(R, B)$, where the weight of every edge equals its Euclidean length. This problem is fundamentally different: In our problem, the color classes and $K(R, B)$ are fixed, and we need to find a small spanner in $K(R, B)$.

Bereg et al. [8] recently considered Euclidean spanners for the graph $G(R, B)$ of all red-blue and blue-blue edges (excluding red-red edges) on a set $S = R \cup B$ of n bichromatic points in $\mathbb{R}^d$. They constructed a 1.998-spanner of size at most $13n$ for $G(R, B)$ in the plane, and showed that the stretch of any spanner for $G(R, B)$ with $O(n)$ edges is at least $1 + \eta$ for some absolute constant $\eta > 0$. They also constructed a 1-spanner of size at most $2n$ for points in the real line.

Bichromatic variants for network optimization problems on n points in the plane, restricted to $K(R, B)$, have been studied extensively. In general, these problems are known to be more challenging than their original uncolored versions: For example, the Euclidean MST is always

a noncrossing straight-line graph; however, the bichromatic Euclidean MST may have crossing edges [3, 12]. Researchers studied bichromatic MSTs [11], bichromatic noncrossing MSTs [4, 14], bichromatic bottleneck MSTs [2], and bicromatic bottlenck noncrossing matchings [13]. Bichromatic TSP [22, 27], Euclidean TSP [6] and bichromatic Voronoi diagrams [5, 25] were also studied. Many of these problems are already nontrivial for bichromatic points on a line [1, 7].

2 Bichromatic $(3+\varepsilon)$-Spanners in the Plane

2.1 Tilings in the Plane

We begin by establishing some preliminary definitions. For a given $\varepsilon \in (0,1)$, let $\delta = \sqrt{\varepsilon/3} = \Theta(\sqrt{\varepsilon})$. We construct a tiling of the plane with rectangular tiles of aspect ratio $1/\delta$.

▶ **Definition 2.** *For every $i, j \in \mathbb{Z}$, we define the* tile

$$T(i,j) = [i-1, i] \times [(j-1)\delta, j\delta].$$

The set of all tiles forms a tiling $T = \{T(i,j) : i, j \in \mathbb{Z}\}$.

In our spanner construction, we use several affine copies of the tiling T, each copy is obtained by transforming all tiles in T by the same affine transformation (rotation, scaling, and translation). Recall that every tile $T(i,j) \in T$ is an axis-aligned rectangle of width 1. Let $T' = \{T(i,j) + (0, \frac{\delta}{2}) : i, j \in \mathbb{Z}\}$ denote the tiling obtained by T by translation, with vector $(0, \frac{\delta}{2})$. For every angle $\theta \in [0, 2\pi)$ and every $\lambda > 0$, let $T_{\theta,\lambda}$ (resp., $T'_{\theta,\lambda}$) be the tiling obtained from T (resp., T') by a counterclockwise rotation through θ about the origin, followed by a dilation with factor λ.

However, we restrict ourselves to a discrete family of tilings: We use only $O(\sqrt{1/\varepsilon})$ angles θ, and a discrete set of exponentially increasing scaling factors, that we define now. Let $\varphi = \arctan(\delta/22)$ and $k = \lceil \pi/\varphi \rceil$. Note that $\varphi \in \Theta(\sqrt{\varepsilon})$ and $k \in \Theta(\sqrt{1/\varepsilon})$. Our discrete set of k angles is $\Phi = \{2r\pi/k : r = 0, 1, \ldots, k-1\}$. Let $\gamma = 3^{1/11}$, and note that $3^{1/11} < 10/9$. Our discrete set of scaling factors is $\Lambda = \{\gamma^p : p \in \mathbb{Z}\}$. The family of all tilings with rotation angle in Φ and scaling factor in Λ is

$$\mathcal{T} = \bigcup_{\theta \in \Phi} \bigcup_{\lambda \in \Lambda} (T_{\theta,\lambda} \cup T'_{\theta,\lambda}).$$

The following lemma provides an important property of the family of tilings $\mathcal{T}$, which also plays a crucial role in the stretch analysis of our construction.

▶ **Lemma 3.** *For every pair of distinct points $a, b \in \mathbb{R}^2$, there exist $\theta^* \in \Phi$, $\lambda^* \in \Lambda$ and $i^*, j^* \in \mathbb{Z}$ such that at least one of the following holds:*

1. *tiles $T_{\theta^*,\lambda^*}(i^*, j^*)$ and $T_{\theta^*,\lambda^*}(i^*+10, j^*)$ each contain one of a and b,*
2. *tiles $T'_{\theta^*,\lambda^*}(i^*, j^*)$ and $T'_{\theta^*,\lambda^*}(i^*+10, j^*)$ each contain one of a and b.*

Proof. Let ψ be the counterclockwise angle between the positive x-axis and vector $\vec{ab}$. We choose $\theta^* \in \Phi$ such that θ^* is the closest angle to ψ; i.e., θ^* is the solution to the minimization problem

$$\theta^* = \arg\min_{\theta \in \Phi} |\theta - \psi|.$$

We may assume (by suitable rotation and reflections, if necessary) that $\theta^* = 0$, $\varphi \geq 0$, and $x(a) < x(b)$, where $x(a)$ and $x(b)$, resp., denote the x-coordinate of a and b. Next, we show that there exists a scale $\lambda^* \in \Lambda$ that satisfies

$$9\lambda^* \leq x(b) - x(a) < 10\lambda^*. \tag{1}$$

Let $\lambda^* = \gamma^{p^*}$, where

$$p^* = \left\lfloor \frac{\ln \frac{x(b)-x(a)}{9}}{\ln \gamma} \right\rfloor.$$

This gives $\gamma^{p^*} \leq \frac{x(b)-x(a)}{9} \leq \gamma^{p^*+1}$; and combined with $\gamma = 3^{1/11} < 10/9$, it implies Equation (1).

Since T_{θ^*,λ^*} is a tiling of $\mathbb{R}^2$, there exist $i^*, j^* \in \mathbb{Z}$ such that $a \in T_{\theta^*,\lambda^*}(i^*, j^*)$. Now Equation (1) implies that $x(a) + 9\lambda^* \leq x(b) \leq x(a) + 10\lambda^*$, and so $b \in T_{\theta^*,\lambda^*}(i^* + 10, j^{**})$ for some $j^{**} \in \mathbb{Z}$. Let $y(a)$ and $y(b)$, resp., denote the y-coordinate of a and b. If $y(a) = y(b)$, then we must have $j^* = j^{**}$. Suppose $y(a) \neq y(b)$, we may assume w.l.o.g. that $y(a) < y(b)$ and $\lambda^* = 1$. Under these assumptions, we have $T_{\theta^*,\lambda^*}(i^*, j^*) = T(i^*, j^*)$, which is an axis-aligned rectangle of width 1 and height δ. By our choice of φ, we can bound $y(b)$ from above, and conclude that

$$y(b) - y(a) = (x(b) - x(a)) \tan(\psi) \leq 11 \tan(\varphi) = \frac{\delta}{2}. \tag{2}$$

A horizontal median of the tile $T_{\theta^*,\lambda^*}(i^*, j^*)$ subdivides $T_{\theta^*,\lambda^*}(i^*, j^*)$ into two congruent rectangles, that we call the *upper* and *lower half* of $T_{\theta^*,\lambda^*}(i^*, j^*)$. Then one of the following two cases occurs

- **Case 1:** a is in the lower half of $T_{\theta^*,\lambda^*}(i^*, j^*)$. In this case, we have $0 \leq y(a) \leq \delta/2$, and Equation (2) gives $0 \leq y(b) \leq \delta/2$. Thus $a \in T_{\theta^*,\lambda^*}(i^*, j^*)$ and $b \in T_{\theta^*,\lambda^*}(i^* + 10, j^*)$.
- **Case 2:** a is in the upper half of $T_{\theta^*,\lambda^*}(i^*, j^*)$. In this case, we have $\delta/2 \leq y(a) \leq \delta$, and Equation (2) gives $\delta/2 \leq y(b) \leq \frac{3}{2}\delta$. Consequently, $a \in T'_{\theta^*,\lambda^*}(i^*, j^*)$ and $b \in T'_{\theta^*,\lambda^*}(i^* + 10, j^*)$.

This concludes the proof of Lemma 3. ◀

2.2 Spanner Construction

We are given a set $S = R \cup B$ of n bichromatic points in the plane and a parameter $\varepsilon > 0$. Let $\mathcal{T}$ be the family of tilings defined in Section 2.1. For every nonempty tile $T_{\theta,\lambda}(i, j)$, we denote by $N_{\theta,\lambda}(i, j)$ its *neighborhood* obtained by taking the union of $T_{\theta,\lambda}(i, j)$ and its eight surrounding tiles at the same scale. We say that $N_{\theta,\lambda}(i, j)$ is *bichromatic* if it contains at least one point of each color. Similarly, $N_{\theta,\lambda}(i, j)$ is *monochromatic* if all points in $N_{\theta,\lambda}(i, j)$ have the same color. It is important to note that $N_{\theta,\lambda}(i, j)$ can be bichromatic even if all points in $T_{\theta,\lambda}(i, j)$ are of the same color. For our construction, we begin by initializing a graph $G = (S, E)$ to be the empty graph.

For a set $Q \subseteq S$, we say that point q is *leftmost* in $Q \cap N_{\theta,\lambda}(i, j)$ if, after a clockwise rotation of $Q \cap N_{\theta,\lambda}(i, j)$ through θ, its x-coordinate is minimal. Likewise, the point q is *rightmost* in $Q \cap N_{\theta,\lambda}(i, j)$ if, after the same rotation, its x-coordinate is maximal. Note that several leftmost (resp., rightmost) points may exist (which have the same x-coordinate after suitable rotation). We choose a rightmost red point r^* in $N_{\theta,\lambda}(i, j)$ and a leftmost blue point b^* in $N_{\theta,\lambda}(i + 10, j)$. Similarly, we choose a rightmost blue point b^{**} in $N_{\theta,\lambda}(i, j)$ and a leftmost red point r^{**} in $N_{\theta,\lambda}(i + 10, j)$.

Consider every $\theta \in \Phi$, $\lambda \in \Lambda$, and $i, j \in \mathbb{Z}$ such that both $T_{\theta,\lambda}(i,j)$ and $T_{\theta,\lambda}(i+10,j)$ are nonempty (the translated tiles are handled similarly if both $T'_{\theta,\lambda}(i,j)$ and $T'_{\theta,\lambda}(i+10,j)$ are nonempty). We distinguish between four cases based on whether the neighborhoods $N_{\theta,\lambda}(i,j)$ and $N_{\theta,\lambda}(i+10,j)$ are monochromatic or bichromatic:

- **Case 0:** Both $N_{\theta,\lambda}(i,j)$ and $N_{\theta,\lambda}(i+10,j)$ are monochromatic, and all points in $N_{\theta,\lambda}(i,j) \cup N_{\theta,\lambda}(i+10,j)$ have the same color. In this case, we do not add any edges G.
- **Case 1:** Both $N_{\theta,\lambda}(i,j)$ and $N_{\theta,\lambda}(i+10,j)$ are monochromatic, but they contain different colors. Assume w.l.o.g. that $N_{\theta,\lambda}(i,j) \cap S \subset R$ and $N_{\theta,\lambda}(i+10,j) \cap S \subset B$ (the other case is symmetric); see Figure 1. In this case, we add edges to G between r^* and every point in $T_{\theta,\lambda}(i+10,j) \cap B$, between b^* and every point in $T_{\theta,\lambda}(i,j) \cap R$, as well as the edge r^*b^*. In particular, the edges added to G form a *bistar* centered at r^* and b^*.

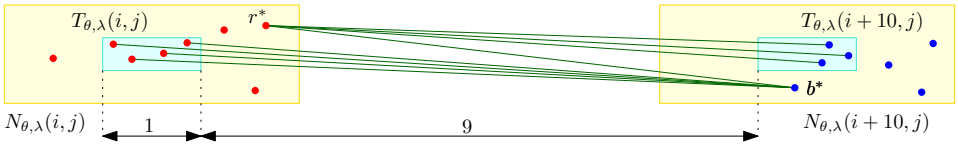

Figure 1 Case 1: Both $N_{\theta,\lambda}(i,j)$ and $N_{\theta,\lambda}(i+10,j)$ are monochromatic.

- **Case 2:** Exactly one of $N_{\theta,\lambda}(i,j)$ and $N_{\theta,\lambda}(i+10,j)$ is monochromatic. Assume w.l.o.g. that $N_{\theta,\lambda}(i,j)$ is monochromatic and $N_{\theta,\lambda}(i+10,j)$ is bichromatic; see Figure 2 (the other case is symmetric). If $N_{\theta,\lambda}(i,j) \cap S \subset R$, we add an edge to G between b^* and every point in $T_{\theta,\lambda}(i,j) \cap R$. Otherwise, (when $N_{\theta,\lambda}(i,j) \cap S \subset B$), we add an edge to G between r^{**} and every point in $T_{\theta,\lambda}(i,j) \cap B$. In this case, the edges added to G form a *star*.

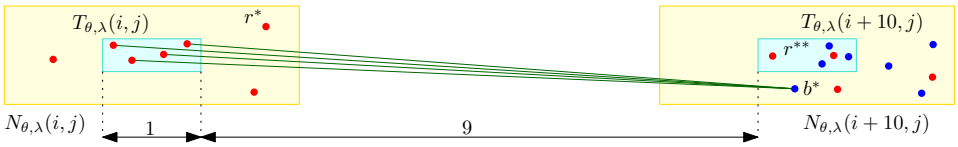

Figure 2 Case 2: $N_{\theta,\lambda}(i,j)$ is monochromatic and $N_{\theta,\lambda}(i+10,j)$ is bichromatic.

- **Case 3:** Both $N_{\theta,\lambda}(i,j)$ and $N_{\theta,\lambda}(i+10,j)$ are bichromatic; see Figure 3. In this case, we add two edges to G: the edges r^*b^* and $r^{**}b^{**}$.

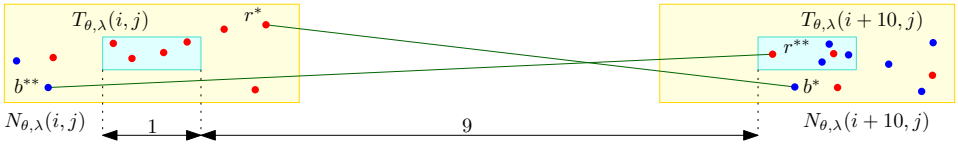

Figure 3 Case 3: Both $N_{\theta,\lambda}(i,j)$ and $N_{\theta,\lambda}(i+10,j)$ are bichromatic.

This completes the construction of the bipartite graph $G = (R \cup B, E)$. We show that G is a $(3+\varepsilon)$-spanner of $K(R,B)$ in Section 2.3, and that it contains $O(n/\sqrt{\varepsilon})$ edges in Section 2.4. We describe how to compute G in $O(\sqrt{1/\varepsilon} \cdot n \log n)$ time in Section 2.5.

2.3 Stretch Analysis

In this section, we prove that graph G is a $(3+\varepsilon)$-spanner of $K(R,B)$. We begin with a preliminary observation. The Euclidean length of an edge is given by the Pythagorean theorem for its x- and y-extents. However, if the y-extent is much smaller than the x-extent,

we can bound the Euclidean length from above by a polynomial as follows: For all $x \geq 1$ and $y > 0$, we have

$$\sqrt{x^2 + y^2} \leq x + y^2/2. \tag{3}$$

We can now prove the main result of this subsection.

▶ **Lemma 4.** *For every finite bichromatic set $S = R \cup B$ in the plane, the graph $G \subseteq K(R, B)$ constructed in Section 2.2 is $(3 + \varepsilon)$-spanner for $K(R, B)$.*

Proof. We proceed by induction on the length of the bichromatic edges in $K(R, B)$. Specifically, let $D = \{|rb| : (r, b) \in R \times B\}$ be the set of distances between red-blue pairs in S; and let $0 = d_0 < d_1 < \ldots < d_m$ be elements of $\{0\} \cup D$ in increasing order.

We prove, by induction on $\ell = 0, 1, \ldots, m$, that for all $(r, b) \in R \times B$ with $|rb| \leq d_\ell$, the graph G contains an rb-path of length at most $(3 + \varepsilon)|rb|$. In the base case, where $\ell = 0$ and $d_\ell = 0$, the claim vacuously holds, as there is no red-blue pair (r, b) with $|rb| = 0$.

In the induction step, let $d_\ell \in D$ and assume that for all $(r', b') \in R \times B$, if $|r'b'| < d_\ell$, then G contains an $r'b'$-path of length at most $(3+\varepsilon)|r'b'|$. Let $(r, b) \in R \times B$ with $|rb| = d_\ell$. By Lemma 3, there exist $\theta \in \Phi$, $\lambda \in \Lambda$ and $i, j \in \mathbb{Z}$ such that $T_{\theta,\lambda}(i, j)$ and $T_{\theta,\lambda}(i + 10, j)$ each contain one of r and b; or $T'_{\theta,\lambda}(i, j)$ and $T'_{\theta,\lambda}(i + 10, j)$ each contain one of r and b. To simplify our argument, we may assume w.l.o.g. that $\theta = 0$ and $\lambda = 1$, $r \in T_{\theta,\lambda}(i, j)$ and $b \in T_{\theta,\lambda}(i + 10, j)$. Under these assumptions, $N_{\theta,\lambda}(i, j) = N(i, j)$, which is an axis-aligned rectangle of width 3 and height 3δ. We distinguish between three cases:

- **Case 1:** Both $N(i, j)$ and $N(i + 10, j)$ are monochromatic; see Figure 1. By construction (Case 1), G contains the rb-path $P = (r, b^*, r^*, b)$. Since the pair r^* is the rightmost red point in $N(i, j)$ and b^* is the leftmost blue point in $N(i + 10, j)$, then we have $x(r) \leq x(r^*) < x(b^*) \leq x(b)$, where $x(r)$, $x(r^*)$, $x(b^*)$ and $x(b)$, resp., denote the x-coordinate of r, r^*, b^* and b. Then, the length of b^*r^* can be bounded above by $|b^*r^*| \leq \sqrt{(x(b^*) - x(r^*))^2 + (3\delta)^2} \leq \sqrt{(x(b) - x(r))^2 + (3\delta)^2}$. Using Equation (3) and $9 \leq |rb|$, it follows that

$$\begin{aligned} |b^*r^*| &\leq \sqrt{(x(b) - x(r))^2 + (3\delta)^2} \\ &\leq x(b) - x(r) + 9\delta^2/2 \\ &= x(b) - x(r) + 3\varepsilon/2 \\ &\leq (1 + \varepsilon/3)|rb|. \end{aligned}$$

  By a similar process, we obtain $|rb^*| \leq (1 + \varepsilon/3)|rb|$ and $|r^*b| \leq (1 + \varepsilon/3)|rb|$. Thus, the length of the rb-path P is at most $(3 + \varepsilon)|rb|$ since $|P| = |rb^*| + |b^*r^*| + |r^*b| \leq 3(1+\varepsilon/3)|rb| = (3+\varepsilon)|rb|$. (Note that we did not use the induction hypothesis in Case 1.)
- **Case 2:** One of $N(i, j)$ and $N(i + 10, j)$ is monochromatic and the other is bichromatic. Assume w.l.o.g. that $N(i, j)$ is monochromatic and $N(i+10, j)$ is bichromatic; see Figure 4 (the other case is symmetric). Let $\tilde{r} \in R \cap N(i + 10, j)$. Since $b^*, \tilde{r} \in N(i + 10, j)$, we have $|b^*\tilde{r}| \leq \operatorname{diam}(N(i + 10, j)) = 3 \operatorname{diam}(T(i, j))$. Furthermore, since $b \in T(i + 10, j)$, then the edge $\tilde{r}b$ lies in an axis-aligned rectangle spanned by $T(i + 10, j)$ and an adjacent tile, which implies $|\tilde{r}b| \leq 2 \operatorname{diam}(T(i, j))$. Note that $\operatorname{diam}(T(i, j)) = \sqrt{1 + \delta^2}$ by the Pythagorean Theorem. Equation (3) yields $\operatorname{diam}(T(i, j)) = \sqrt{1 + \delta^2} \leq 1 + \varepsilon/6$. Since $9 \leq |rb|$, it now follows that $|b^*\tilde{r}| \leq 3 \operatorname{diam}(T(i, j)) \leq 3(1 + \varepsilon/6) < 9 \leq |rb|$. Similarly, we have $|\tilde{r}b| < |rb|$.

  By the induction hypothesis, G contains some paths

$$P_1 = (b^*, \ldots, \tilde{r}) \quad \text{and} \quad P_2 = (\tilde{r}, \ldots, b),$$

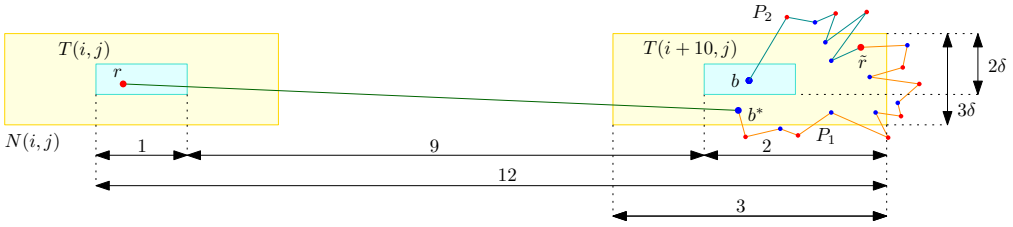

Figure 4 An rb-path when $N(i,j)$ is monochromatic and $N(i+10,j)$ is bichromatic.

resp., of length at most $(3+\varepsilon)|b^*\tilde{r}|$ and $(3+\varepsilon)|\tilde{r}b|$. Then, the concatenation of $rb^* \oplus P_1 \oplus P_2$ is an rb-path in G and its length can be bounded above as follows

$$\begin{aligned}
|rb^*| + |P_1| + |P_2| &\leq \sqrt{11^2 + (2\delta)^2} + (3+\varepsilon)|b^*\tilde{r}| + (3+\varepsilon)|\tilde{r}b| \\
&\leq 11 + 2\delta^2 + 3(3+\varepsilon)\operatorname{diam}(T(i,j)) + 2(3+\varepsilon)\operatorname{diam}(T(i,j)) \\
&= 11 + 2\varepsilon/3 + 5(3+\varepsilon)(1+\varepsilon/6) \\
&= 11 + 2\varepsilon/3 + 5(3 + 3\varepsilon/2 + \varepsilon^2/6).
\end{aligned}$$

Recall that $0 < \varepsilon < 1$, hence $\varepsilon^2 < \varepsilon$. It follows that

$$\begin{aligned}
|rb^*| + |P_1| + |P_2| &\leq 11 + 2\varepsilon/3 + 5(3 + 5\varepsilon/3) \\
&= 26 + 9\varepsilon \\
&< 9(3+\varepsilon) \\
&\leq (3+\varepsilon)|rb|.
\end{aligned}$$

So, the concatenation of $rb^* \oplus P_1 \oplus P_2$ is an rb-path in G of length at most $(3+\varepsilon)|rb|$.

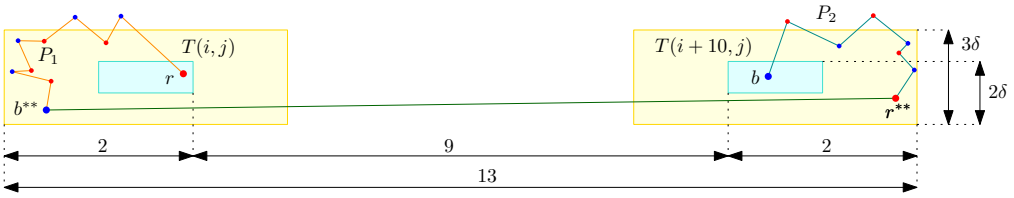

Figure 5 An rb-path when both $N(i,j)$ and $N(i+10,j)$ are bichromatic.

Case 3: Both $N(i,j)$ and $N(i+10,j)$ are bichromatic; see Figure 5. Similarly to Case 2, we have $|rb^{**}| \leq \operatorname{diam} N(i,j) < |rb|$ and $|r^{**}b| \leq \operatorname{diam} N(i+10,j) < |rb|$. By the induction hypothesis, G contains some paths

$$P_1 = (r, \ldots, b^{**}) \quad \text{and} \quad P_2 = (r^{**}, \ldots, b),$$

resp., of length at most $(3+\varepsilon)|rb^{**}|$ and $(3+\varepsilon)|r^{**}b|$. Then, the concatenation $P = P_1 \oplus b^{**}r^{**} \oplus P_2$ is an rb-path of G, and observe that by a similar process as in Case 2, its length be bounded above as follows

$$\begin{aligned}
|P| &= |P_1| + |b^{**}r^{**}| + |P_2| \\
&\leq (3+\varepsilon)|rb^{**}| + \operatorname{diam}(N(i,j) \cup N(i+10,j)) + (3+\varepsilon)|r^{**}b| \\
&\leq 2(3+\varepsilon)\operatorname{diam}(T(i,j)) + \sqrt{13^2 + (3\delta)^2} + 2(3+\varepsilon)\operatorname{diam}(T(i+10,j)) \\
&\leq 4(3+\varepsilon)(1+\varepsilon/6) + 13 + 3\varepsilon/2 \\
&\leq 4(3+5\varepsilon/3) + 13 + 3\varepsilon \\
&= 25 + 49\varepsilon/6 \\
&< 9(3+\varepsilon) \\
&\leq (3+\varepsilon)|rb|.
\end{aligned}$$

So, the concatenation $P_1 \oplus b^{**}r^{**} \oplus P_2$ is an rb-path in G of length at most $(3+\varepsilon)|rb|$. Overall, the bipartite graph G is a $(3+\varepsilon)$-spanner of $K(R,B)$. ◀

2.4 Sparsity Analysis

Fix an angle $\theta \in \Phi$. We distinguish between two types of edges in G. An edge is of *Type 1* if it was added when the construction processed a pair of tiles $T_{\theta,\lambda}(i,j), T_{\theta,\lambda}(i+10,j)$ where one of the tiles had monochromatic neighborhood; otherwise it is of *Type 2*. In particular, edges of Type 1 correspond to Cases 1-2 of the construction, and Type 2 to Case 3.

Overview. We count edges of each type separately in Lemmas 6 and 8 below. Edges of Type 1 are the main concern, since our spanner may contain many edges of Type 1 for each pair $T_{\theta,\lambda}(i,j), T_{\theta,\lambda}(i+10,j)$. However, even if the neighborhood of one of the tiles is monochromatic, their union $N_{\theta,\lambda}(i,j) \cup N_{\theta,\lambda}(i+10,j)$ contains both colors. We show (Lemma 5) that if we go up 26 scales higher, then every point in $T_{\theta,\lambda}(i,j) \cup T_{\theta,\lambda}(i+10,j)$ is contained in a bichromatic neighborhood: It follows that each point $s \in S$ is incident to an edge of Type 1 in $O(1)$ scales; hence there are $O(n)$ edges of Type 1 (for each $\theta \in \Phi$).

For every pair $T_{\theta,\lambda}(i,j), T_{\theta,\lambda}(i+10,j)$ with bichromatic neighborhoods, we add only two edges of Type 2, so it is enough to analyze the number of such pairs. We rely on the classic result that a quadtree-based WSPD has $m = O(n)$ well-separated pairs [20, Theorem 4.1.4]. The proof of this result hinges on properties of quadtrees and compressed quadtrees: The compressed quadtree for n points is known to have $O(n)$ nodes, but chains of single-child nodes in the uncompressed quadtree must be handled carefully. We adapt this approach to our pairs of tiles (Lemma 7).

It is easy to arrange the tiles $T_{\theta,\lambda}$, $\lambda \in \Lambda$, into groups in which the scales differ by integer factors – so we can obtain a laminar system, which supports a quadtree. However, for tiles in a standard quadtree, the translated tiles $T'_{\theta,\lambda}$ would not be laminar. For this reason, we use a variation of quadtrees: nonatrees [10], in which each tile is subdivided into nine congruent subtiles. Using nonatrees, the tiles in $T_{\theta,\lambda}$ and $T'_{\theta,\lambda}$, over all $\lambda \in \Lambda$, can be grouped into laminar systems.

Edges of Type 1. We introduce a charging scheme: We charge each edge st of Type 1 to one of its vertices as follows. Assume st was added to G when processing the pair tiles $T_{\theta,\lambda}(i,j)$ and $T_{\theta,\lambda}(i+10,j)$. If $N_{\theta,\lambda}(i,j)$ is monochromatic, we charge st to s, otherwise (when $N_{\theta,\lambda}(i+10,j)$ is monochromatic), we charge st to t.

▶ **Lemma 5.** *Let $s \in S$. Assume that s lies in tiles $T_{\theta,\lambda}(i,j)$ and $T_{\theta,\lambda'}(i',j')$ with monochromatic neighborhoods, where $\lambda = \gamma^p, \lambda' = \gamma^{p'}$ with $p < p'$, and our construction added an edge st of Type 1 when processing the pair of tiles $T_{\theta,\lambda}(i,j)$ and $T_{\theta,\lambda}(i+10,j)$. Then we have $p' < p + 26$.*

Proof. Assume w.l.o.g. that $\theta = 0$ and s is red (i.e., $s \in R$). Since we added an edge st for some $t \in N_{\theta,\lambda}(i+10,j)$, then t is blue. Note that

$$|x(s) - x(t)| \le |(i-1)\gamma^p - (i+12)\gamma^p| = 13\gamma^p < 3^{26/11}\,\gamma^p = \gamma^{p+26},$$
$$|y(s) - y(t)| \le \delta\gamma^p.$$

Recall that $s \in T_{\theta,\lambda'}(i,' j')$. For any $q \in \mathbb{R}^2$ such that $|x(s) - x(q)| \le \gamma^{p'}$ and $|y(s) - y(q)| \le \delta \cdot \gamma^{p'}$, we have $q \in N_{\theta,\lambda'}(i,' j')$. Hence $p' \ge p + 26$ implies $t \in N_{\theta,p'}(i,' j')$, and so the neighborhood $N_{\theta,d'}(i,' j')$ is bichromatic, and st cannot be charged to s. We conclude that $p' < p + 26$, as claimed. ◀

▶ **Lemma 6.** *For every bichromatic set $S = R \cup B$ of n points in the plane, and for every $\theta \in \Phi$, the graph G has $O(n)$ edges of Type 1.*

Proof. Each vertex $s \in S$ receives charges from at most 26 scales by Lemma 5. Consequently, there are $O(|S|) = O(n)$ edges of Type 1. ◀

Edges of Type 2. For the purpose of analyzing the edges of Type 2, we arrange the nonempty tiles $T_{\theta,\lambda}(i,j)$ into eleven nonatrees as follows. For $\sigma = 0, 1, \ldots, 10$, let

$$\Lambda_\sigma = \{\gamma^\sigma \cdot 3^p : p \in \mathbb{Z}\} = \left\{3^{\sigma/11} \cdot 3^p : p \in \mathbb{Z}\right\}.$$

Then the set of tiles $\{T_{\theta,\lambda}(i,j) : \lambda \in \Lambda_\sigma\}$ is a laminar set system (i.e., any two tiles are either interior-disjoint or one contains the other). Importantly, the translated tiles $\{T'_{\theta,\lambda}(i,j) : \lambda \in \Lambda_\sigma\}$ also form a laminar system [10] (this is why we use nonatrees, instead of quadtrees). Let $\mathcal{Q}_\sigma$ denote the set of tiles $T_{\theta,\lambda}(i,j)$ such that $\lambda \in \Lambda_\sigma$ and $T_{\theta,\lambda}(i,j) \cap S \neq \emptyset$ (the case of the tiles $T'_{\theta,\lambda}(i,j)$ is analoguous). Containment among the tiles in $\mathcal{Q}_\sigma$ defines a hierarchy (i.e., poset or tree); and we refer to $\mathcal{Q}_\sigma$ as a *nonatree*. We can now define a parent-child relationship between the tiles in $\mathcal{T}_\sigma$: For $T_{\theta,\lambda}(i,j), T_{\theta,\lambda'}(i',j') \in \mathcal{T}_\sigma$, we say that $T_{\theta,\lambda}(i,j)$ is a *child* of $T_{\theta,\lambda'}(i',j')$ if $T_{\theta,\lambda}(i,j) \subset T_{\theta,\lambda'}(i',j')$ and $\lambda' = 3\lambda$. It is clear from the definition that every tile has at most nine children. Let $\mathcal{R}_\sigma$ be the set of tiles $T \in \mathcal{Q}_\sigma$ that have two or more children. Containment among the tiles in $\mathcal{R}_\sigma$ gives a partition tree on S for every $\sigma \in \{0, \ldots, 10\}$, consequently

$$|\mathcal{R}_\sigma| \le n. \tag{4}$$

Note that every tile $T \in \mathcal{Q}_\sigma$ is contained in some tile $\widehat{T} \in \mathcal{R}_\sigma$; possibly $\widehat{T} = T$. For every $T \in \mathcal{Q}_\sigma$, let $\overline{p}(T)$ be the smallest tile in $\mathcal{R}_\sigma$ that contains T (i.e., $\overline{p}(T)$ is the closest ancestor of T in $\mathcal{R}_\sigma$).

We can now introduce a charging scheme: Consider the edges r^*b^* and $r^{**}b^{**}$ of Type 2 that were added to G when we processed the pair of tiles $\{T_1, T_2\} = \{T_{\theta,\lambda}(i,j), T_{\theta,\lambda}(i+10,j)\}$ with bichromatic neighborhoods. Let λ_1 and λ_2 be the scales of $\overline{p}(T_1)$ and $\overline{p}(T_2)$, respectively. If $\lambda_1 \le \lambda_2$, then we *charge* both edges to $\overline{p}(T_1)$; otherwise (if $\lambda_1 > \lambda_2$), we charge them to $\overline{p}(T_2)$.

▶ **Lemma 7.** *In the charging scheme above, every tile $T \in \bigcup_{\sigma=0}^{10} \mathcal{R}_\sigma$ receives $O(1)$ charges.*

Proof. Let $\sigma \in \{0, \ldots, 10\}$ and $T \in \mathcal{R}_\sigma$. We claim that T has received at most 148 units of charges. Suppose, for contradiction, that T receives 149 or more charges. Assume w.l.o.g. that $T = T_{\theta,\lambda}(i, j)$ with $\theta = \lambda = \sigma = 0$. In particular, T is an axis-aligned rectangle of $\text{width}(T) = 1$.

Let $\mathcal{P}_1$ be the collection of pairs of tiles (T_1, T_2) such that two bichromatic edges corresponding to (T_1, T_2) are charged to T and $\overline{p}(T_1) = T$. By assumption, we have $|\mathcal{P}_1| \geq \lceil 149/2 \rceil = 75$. In each pair $(T_1, T_2) \in \mathcal{P}_1$, the tile T_1 is either *left* (i.e., $T_1 = T(i, j)$ and $T_2 = T(i + 10, j)$) or *right* (i.e., $T_1 = T(i + 10, j)$ and $T_2 = T(i, j)$). We may assume w.l.o.g. that in at least half of these pairs, T_1 is left. Let $\mathcal{P}_2 \subseteq \mathcal{P}_1$ be the set of these pairs; note that $|\mathcal{P}_2| \geq \lceil |\mathcal{P}_1|/2 \rceil = 38$.

For each pair $(T_1, T_2) \in \mathcal{P}_2$, either $T_1 = T$ of the nonatree $\mathcal{Q}_\sigma$ contains a descending chain $\text{chain}(T_1)$ from T to T_1 where all intermediate tiles have only one child (i.e., they are in $\mathcal{Q}_\sigma \setminus \mathcal{R}_\sigma$). There is at most one pair $(T_1, T_2) \in \mathcal{P}_2$ such that $T_1 = T$; so T_1 is a strict descendant of T in at least 37 pairs in $\mathcal{P}_2$. If $T_1 \neq T$, then $\text{chain}(T_1)$ includes exactly one child of T. Since T has at most nine children in $\mathcal{Q}_\sigma$, there are at least $\lceil 37/9 \rceil = 5$ pairs in $\mathcal{P}_2$ where $\text{chain}(T_1)$ includes the same child of T; let T_{child} denote this child of T and let $\mathcal{P}_3$ be the set of these pairs; see Figure 6.

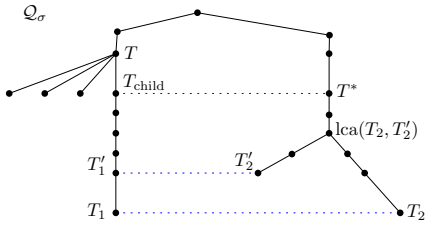

Figure 6 A schematic layout of the nodes in the nonatree $\mathcal{Q}_\sigma$.

Note for all pairs $(T_1, T_2) \in \mathcal{P}_3$, the tiles T_1 are at different scales (since they are in the same single-child chain). Let (T_1, T_2) and (T_1', T_2') be the pairs in $\mathcal{P}_3$ at the lowest and the second lowest scales, respectively. Since $|\mathcal{P}_3| \geq 5$ and $\text{width}(T) = 1$, then $\text{width}(T_1) \leq 3^{-5}$ and $\text{width}(T_1') \leq 3^{-4}$. Since $T_1 \subseteq T_1'$, then $\text{dist}(T_1', T_2) \leq \text{dist}(T_1, T_2) = 9\,\text{width}(T_1) \leq 3\,\text{width}(T_1')$. It follows that

$$\begin{aligned}
\text{dist}(T_2, T_2') &\geq \text{dist}(T_1', T_2') - \text{dist}(T_1', T_2) - \text{width}(T_2) \\
&\geq \text{dist}(T_1', T_2') - \text{dist}(T_1, T_2) - \text{width}(T_2) \\
&\geq \left(9 - 3 - \frac{1}{3}\right) \text{width}(T_1') > 5\,\text{width}(T_1') > 0,
\end{aligned}$$

and, in particular, the tiles T_2 and T_2' are disjoint. Furthermore, $T_1 \subset T_1' \subseteq T_{\text{child}}$ implies

$$\begin{aligned}
\text{dist}(T_{\text{child}}, T_2) &\leq \text{dist}(T_1, T_2) = 9\,\text{width}(T_1) \leq \frac{9}{3^5} < \frac{1}{9}, \\
\text{dist}(T_{\text{child}}, T_2') &\leq \text{dist}(T_1', T_2') = 9\,\text{width}(T_1') \leq \frac{9}{3^4} < \frac{1}{3}.
\end{aligned}$$

As $\text{width}(T_{\text{child}}) = \frac{1}{3}$, both T_2 and T_2' are contained in some tile $T^* \in \mathcal{Q}_\sigma$ at the same scale as T_{child}. But $\text{chain}(T_1)$ is a single-child chain of tiles, so $T_2, T_2' \not\subseteq T_{\text{child}}$, and $T^* \neq T_{\text{child}}$ (although, T^* could be a sibling of T_{child}). Note that the least common ancestor $\text{lca}(T_2, T_2')$ of T_2 and T_2' in the nonatree $\mathcal{Q}_\sigma$ satisfies $\text{lca}(T_2, T_2') \subseteq T^*$. In particular, $\text{lca}(T_2, T_2')$ is at a scale below T; and $\text{lca}(T_2, T_2')$ has at least two children, which implies $\text{lca}(T_2, T_2') \in \mathcal{R}_\sigma$.

Consequently, both $\overline{p}(T_2)$ and $\overline{p}(T_2')$ are at a scale below $T = \overline{p}(T_1) = \overline{p}(T_1')$; and so our charging scheme could not have charged (T_1, T_2) and (T_1', T_2') to T: A contradiction. We conclude that at most 148 edges were charged to the tile T. ◀

▶ **Lemma 8.** *For every bichromatic set $S = R \cup B$ of n points in the plane, and for every $\theta \in \Phi$, the graph G has $O(n)$ edges of Type 2.*

Proof. This readily follows from the combination of Equation (4) and Lemma 7. ◀

2.5 Running Time Analysis

For every set S of n bichromatic points in the plane and every $\varepsilon > 0$, our spanner construction (Section 2.2) can be implemented in $O(\sqrt{1/\varepsilon} \cdot n \log n)$ time. The construction is done independently for each $\theta \in \Phi$, where $|\Phi| = O(\sqrt{1/\varepsilon})$, so it is enough to show that the construction takes $O(n \log n)$ time for each $\theta \in \Phi$. Assume w.l.o.g. that $\theta = 0$. Instead of infinite tilings, we can use nonatrees (the generalization of quadtrees, where each cell is split into 9 congruent cells) after an affine transformation $f(x, y) = (x, y/\delta)$, which maps an $1 \times \delta$ rectangle into a unit square. Let $S_0 := f(S)$. Let B_0 be an axis-aligned bounding box of S_0 where $\text{width}(B_0) = 2\,\text{height}(B_0)$, and scale B_0 centrally up by factors of $3^{\sigma/11}$ for $\sigma = 0, \ldots, 10$. Each scaled copy of B_0 can be expressed as an intersection of two axis-aligned squares $B_0 = B \cap B'$, where $\text{width}(B) = \text{width}(B') = \text{width}(B_0)$; note that $B' = B + (0, \frac{1}{2}\,\text{height}(B))$.

Starting from each of these 22 squares (B and B' with $\sigma = 0, \ldots, 10$), as root cells, we can build compressed nonatrees $\mathcal{R}_\sigma$ and $\mathcal{R}_\sigma'$ for S_0 in $O(n \log n)$ time; analogously to the construction of a quadtrees [10, 9, 20]. The compressed nonatree for n points has $O(n)$ cells, but the (uncompressed) nonatree can have arbitrarily many cells (as it may have descending chains of arbitrarily length). By Lemmas 5 and 7, our construction only uses (uncompressed) nonatree nodes that have an ascending chain of length at most 5 to a nodes of the compressed nonatree $\mathcal{R}_\sigma$: We augment $\mathcal{R}_\sigma$ with up to 5 single-child descendants per node to obtain a tree $\mathcal{R}_\sigma^*$ with $O(n)$ nodes. In a bottom-up traversal of $\mathcal{R}_\sigma^*$, we can find the leftmost and rightmost red (blue) points in each cell in $O(n)$ time. For each cell $T(i, j)$, we can find their eight adjacent cells in $N(i, j)$ in $O(\log n)$ time, and classify $N(i, j)$ as either monochromatic or bichromatic. In another bottom-up traversal, we find all pairs of tiles $T(i, j)$ and $T(i + 10, j)$ and find the edges of G, according to Cases 1–3 in Section 2.2, in $O(n)$ time.

2.6 Generalization to Higher Dimensions

It is straightforward to generalize our construction to Euclidean d-space: In $\mathbb{R}^2$, we used basic tiles of size $1 \times \sqrt{\varepsilon/3}$, and rotated the tilings with a set $\Phi \subset [0, \pi]$ of $\Theta(\sqrt{1/\varepsilon})$ angles at distance $\arctan(\sqrt{\varepsilon/3}/22) = O(\sqrt{\varepsilon})$ apart. In d-space, for $d \geq 3$, we use basic tiles of size $1 \times \sqrt{\varepsilon/(d+1)} \times \ldots \times \sqrt{\varepsilon/(d+1)}$, and we use a set Φ of rotations constructed as follows: We choose a set $U_d \subset \mathbb{S}^{d-1}$ of unit vectors such that the $O(\sqrt{\varepsilon})$-neighborhoods of the vectors in $\mathbb{S}^{d-1}$ (where each neighborhood is a spherical cap) cover U_d. A standard packing argument shows that $O(1/\varepsilon^{(d-1)/2})$ directions suffice. Then for each $\vec{u} \in U_d$, we rotate the basic tiling such such that the positive x_1-axis is parallel to $\vec{u}$. With this setup, Lemma 3, generalizes. The construction, as well as the stretch and sparsity analyses readily extend to $\mathbb{R}^d$. The number of edges is $O(|U_d| \cdot n) = O(n/\varepsilon^{(d-1)/2})$.

3 Bichromatic Spanners on the Line

In this section, we study spanners for n bichromatic points on the real line $\mathbb{R}$. The lower bound construction in [15] shows, that for every $\varepsilon > 0$, there is a bichromatic point set such that a $(3-\varepsilon)$-spanner must contain all edges of the complete bipartite graph $K(A, B)$; this construction consists of two monochromatic clusters of diameter $\frac{\varepsilon}{3}$ at unit distance apart, and can be realized already in 1-dimension. We show that there is 3-spanner with at most $2n-3$ edges (Proposition 9; furthermore, the minimum spanning tree of $K(R, B)$ (denoted minBST(S)) is a 7-spanner, and stretch bound 7 is the best possible (Proposition 10).

We start by introducing some notation. Let $S = R \cup B$ be a set of n bichromatic points on a line. Assume that $S = \{s_1, \ldots, s_n\}$, where the points are labeled in linear order along the line. Partition S into maximal subsets of consecutive points of the same color $S = \bigcup_{i=1}^{k} S_i$; we call these subsets *blocks*. Clearly, the blocks span disjoint intervals along the line, which are also ordered linearly. For any nonempty subset $S' \subseteq S$, denote by $\ell(S')$ and $r(S')$ the leftmost and rightmost point in S', respectively.

▶ **Proposition 9.** *For a set $S = B \cup R$ of n bichromatic points on a line, there is a 3-spanner with at most $2n-3$ edges that can be constructed in $O(n \log n)$ time.*

Proof. We construct a subgraph H of $K(A, B)$ as follows. Consider the partition of S into blocks, $S = \bigcup_{i=1}^{k} S_i$. For every $i = 1, \ldots, k$, and for every point $s \in S_i$, add edges $sr(S_{i-1})$ and $s\ell(S_{i+1})$ to H (if these edges exist). In particular, we add only one edge for every $s \in S_1 \cup S_k$, and two edges for all other vertices. Note also that the $k-1$ edges of the form $r(S_i)\ell(S_{i+1})$ are counted twice. Since $|S_1| \geq 1$, $|S_k| \geq 1$, and $k \geq 2$, then the total number of edges in H is $2n - (|S_1| + |S_k|) - (k-1) \leq 2n - 2 - 1 = 2n - 3$.

Next we show that H is a 3-spanner. Let $a, b \in S$ be two points of opposite colors, and assume w.l.o.g. that $a \in S_i$, $b \in S_j$ for some $1 \leq i < j \leq k$. Then H contains the path

$$P = (a, \ell(S_{i+1}), r(S_i), r(S_{i+1}), \ldots, r(S_{j-1}), b).$$

The first three edges of the path P intersect in the interval, $r(S_i), \ell(S_{i+1})$. All subsequent edges are pairwise interior disjoint (from each other and from the first three edges). This implies that every point on the line is contained in at most 3 edges of P, which immediately implies that $|P| \leq 3\,|ab|$, as required. ◀

Bichromatic Minimum Spanning Tree. Bandyapadhyay et al. [7] showed that if n bichromatic points are already sorted along the line, then minBST(S) can be computed in $O(n)$ time. (Biniaz et al. [11] showed how to compute minBST(S) in $O(n \log n)$ in the plane.)

We start with a characterization of minBST(S), based on the observations in [7]. Consider a block S_i, $1 \leq i \leq k$, defined above. For every point $s \in S_i$, the closest point of the opposite color is either $r(S_{i-1})$ or $\ell(S_{i+1})$. We define a partition $S_i = S_i^- \cup S_i^+$, where S_i^- (resp., S_i^+) is the set of points in S_i for which the closest point of the opposite color is in S_{i-1} (resp., S_{i+1}). Note that $S_1^- = \emptyset$ and $S_k^+ = \emptyset$, but S_i^- or S_i^+ may be empty for any $1 < i < k$.

Recall, that if $G = (V, E, w)$ is an edge-weighted connected graph with positive edge weights, then for every nontrivial cut $V = V_1 \cup V_2$, the MST of G contains a minimum-weight edge between V_1 and V_2. We apply this observation for nontrivial cuts $S = \{s_1, \ldots, s_j\} \cup \{s_{j+1}, \ldots, s_n\}$ for $i = 1, \ldots, n-1$ in the complete bipartite graph $K(R, B)$. Specifically, if s_j and s_{j+1} are in different blocks, then the shortest bichromatic edge across the cut is $s_j s_{j+1}$; in this case $s_j = r(S_i)$ and $\ell(S_{i+1})$ for some $1 \leq i \leq k$. Now assume that both s_j and s_{j+1} are in the same block S_i. If $s_j, s_{j+1} \in S_i^-$ (resp., $s_j, s_{j+1} \in S_i^+$), then $r(S_{i-1})s_j$

(resp., $\ell(S_{j+1})s_{i+1}$) is the shortest bichromatic edge across the cut. Finally, if $s_i \in S_j^-$ and $s_{i+1} \in S_j^+$, then the shortest bichromatic edge across the cut is the shorter of two candidates: $r(S_{i-1})s_j$ or $\ell(S_{j+1})s_{i+1}$. Note that we considered $n-1$ nontrivial cuts, and obtained $n-1$ distinct edges: Let H be the graph formed by these edges. Since H has $n-1$ edges and it is a subgraph of $\mathrm{minBST}(S)$, then $H = \mathrm{minBST}(S)$.

We give a tight bound on the stretch of the bichromatic MST on a line.

▶ **Proposition 10.** *For a set $S = B \cup R$ of n bichromatic points on a line, $\mathrm{minBST}(S)$ is a 7-spanner; and for every $\varepsilon > 0$, there is a bichromatic point set $S \subset \mathbb{R}$ such that the stretch of $\mathrm{minBST}(S)$ is at least $7 - \varepsilon$.*

Proof. It is enough to show that for any pair of points a, b in consecutive blocks, $\mathrm{minBST}(S)$ contains a path of length at most $7\,|ab|$. Indeed, if $a \in S_i$ and $b \in S_j$, where $i < j$, then we can first consider the path $P = (a, \ell(S_{i+1}), \ldots, \ell(S_{j-1}), b)$ in $K(R, B)$. Note that $|P| = |ab|$, and every edge of P is between points in consecutive blocks. By replacing every edge $e \subseteq P$ by a path in minBST of length at most $7\,|e|$, we obtain an ab-path in minBST of length at most $\sum_{e \subseteq P} 7\,|e| = 7\,|P| = 7\,|ab|$.

We may assume w.l.o.g. that $a \in S_i$ and $b \in S_{i+1}$. We claim that $\mathrm{minBST}(S)$ contains a path P_1 from a to $\ell(S_{i+1})$ of length $|P_1| \le 3\,|ab|$; and symmetrically a path P_2 from $r(S_i)$ to b of length $|P_2| \le 3\,|ab|$. Then the concatenation $P_1 \oplus \ell(S_{i+1})r(S_i) \oplus P_2$ is an ab-path in $\mathrm{minBST}(S)$, and its length is at most $|P_1| + |\ell(S_{i+1})r(S_i)| + |P_2| \le (3+1+3)|ab| = 7\,|ab|$, as required. It remains the prove the claim. We distinguish between two cases:

- **Case 1: $a \in S_i^+$ or $a = r(S_i^-)$ and $r(S_i^-)\ell(S_{i+1}) \in \mathrm{minBST}(S)$.** In this case, P_1 is a single edge path, and $|P_1| = |a\,\ell(S_{i+1})| \le |ab|$.
- **Case 2: $a \in S_i^-$ and if $a = r(S_i^-)$, then $r(S_i^-)\ell(S_{i+1}) \notin \mathrm{minBST}(S)$.** The latter condition implies that $r(S_{i-1})\ell(S_i^+) \in \mathrm{minBST}(S)$ because $r(S_{i-1})\ell(S_i^+)$ is shorter than $r(S_i^-)\ell(S_{i+1})$. In particular, we have $|r(S_{i-1})\ell(S_i^+)| \le |r(S_i^-)\ell(S_{i+1})| \le |ab|$. In this case, let $P_1 = (a, r(S_{i-1}), \ell(S_i^+), r(S_{i+1}))$. Now each of the three edges of P_1 has length at most $|ab|$, and so $|P_1| \le 3\,|ab|$, as required.

This confirms the claim in both cases; and completes the proof of the upper bound.

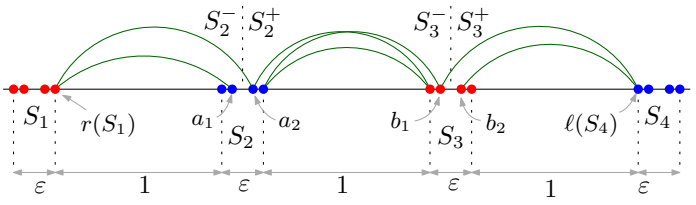

Figure 7 Lower bound construction.

For a lower bound consider a bichromatic point set with 4 blocks, $S = \bigcup_{i=1}^4 S_i$, each of 4 points, such that each block spans an interval of length $\varepsilon > 0$ for a sufficiently small $\varepsilon > 0$, and the distance between any two consecutive blocks is 1; see Figure 7. Let a_1, a_2 be the two interior points in S_2 such that $a_1 \in S_2^-$, $a_2 \in S_2^+$, and $|r(S_1)a_2| < |a_1\ell(S_3)|$. Symmetrically, let b_1, b_2 be the two interior points in S_3 such that $b_1 \in S_3^-$, $b_2 \in S_3^+$, and $|b_1\ell(S_4)| < |r(S_2)b_2|$. Then a_1 has degree 1 in $\mathrm{minBST}(S)$, and its only neighbor is $r(S_1)$. Similarly, the only neighbor of b_2 is $\ell(S_4)$. The set $S_2^+ \cup S_3^-$ induces a bistar centered at $r(S_2)$ and $\ell(S_3)$: A bistar on 4 vertices forms a spanning path on $S_2^+ \cup S_3^-$ between a_2 and b_1. Overall, the a_1b_2-path in $\mathrm{minBST}(S)$ is

$$P = (a_1, r(S_1), a_2, \ell(S_3), r(S_2), b_1, \ell(S_4), b_2).$$

We have $|a_1b_2| \le 1 + 2\varepsilon$, but every edge of P has length at least 1. Consequently the stretch of $\mathrm{minBST}(S)$ is at least $|P|/|a_1b_2| \ge 7/(1+2\varepsilon)$, which tends to 7 as $\varepsilon \to 0$. ◀

4 Conclusions

We conclude with a few open problems. What is the tight dependence on $\varepsilon > 0$ for the size of a $(3+\varepsilon)$-spanner for n bichromatic points in the plane? We have proved an upper bounds of $O(\sqrt{1/\varepsilon} \cdot n)$ in the plane, and $2n-3$ (i.e., no dependence on ε) on the line.

The *lightness* of a spanner H for an edge-weighted graph G is the ratio $w(H)/w(\mathrm{MST}(G))$ of the weight of the spanner to the weight of a minimum spanning tree of G. On bichromatic points on the line, we have shown (Proposition 10) that there is a 7-spanner of lightness 1. It remains an open to obtain upper bounds for stretch $3 \leq t < 7$ on the line, and for any $t > 3$ in the plane.

Our results give existential bounds on the size of a bichromatic spanners. The corresponding *optimization problems* remain open: For a given bichromatic point set $S = R \cup B$ and stretch $t \geq 1$, find a t-spanner of $K(R, S)$ of minimum size or minimum weight (note that for a given instance, stretch $1 \leq t < 3$ can be feasible). We conjecture that these problems are NP-hard already in Euclidean plane. Finding good approximations is left for future research. For monochromatic spanners in the plane, these optimization problems are known to be NP-hard, and bicriteria approximation algorithms were obtained only recently [24]. However, for bichromatic points, the optimization problem is already open for n red-blue points on the line with stretch $1 < t < 7$.

Improved Approximation Algorithms for Bounded-Length Path Augmentation

Felix Hommelsheim[1]
University of Cologne, Germany

Abstract

The Forest Augmentation Problem (FAP) asks for a minimum set of additional edges (links) that makes a given forest 2-edge-connected while spanning all vertices. A key special case is the Path Augmentation Problem (PAP), where the input forest consists of vertex-disjoint paths. Grandoni, Jabal Ameli, and Traub [STOC'22] recently broke the long-standing 2-approximation barrier for FAP, achieving a 1.9973-approximation. A crucial component of this result was their 1.9913-approximation for PAP; the first better-than-2 approximation for PAP.

In this work, we present a 1.9412-approximation for bounded-length PAP, in which each path of the input forest has constant length $p_{\max}$. The running-time of our algorithm is $O(n^{p_{\max}})$. One of our key innovations is a $(\frac{11}{6} + \varepsilon)$-approximation preserving reduction to so-called structured instances, which simplifies the problem and enables our improved approximation. Additionally, we introduce a new relaxation inspired by 2-edge covers and analyze it via a corresponding packing problem, where the relationship between the two problems is similar to the relationship between 2-edge covers and 2-matchings. Using a factor-revealing LP, we bound the cost of our solution to the packing problem w.r.t. the relaxation and derive a strong initial solution. We then transform this solution into a feasible PAP solution, combining techniques from FAP and related connectivity augmentation problems, along with new insights.

1 Introduction

Designing reliable networks that can withstand failures is a fundamental challenge in real-world applications. The field of *survivable network design* (SND) aims to construct cost-efficient networks that maintain connectivity even when some edges fail. Many natural SND problems are NP-hard (even APX-hard), justifying the study of approximation algorithms. A landmark result in this area is Jain's 2-approximation algorithm [31], which applies to a broad class of connectivity problems. However, breaking the 2-approximation barrier remains a major open question, even for many special cases of SND.

In this paper, we focus on the Path Augmentation Problem (PAP), which is a special case of the Forest Augmentation Problem (FAP), a fundamental network augmentation problem. In the Forest Augmentation Problem we are given an undirected graph $G = (V, F \cup L)$, where F is a forest and $L \subseteq \binom{V}{2}$ is a set of additional edges (links) and the goal is to find a minimum-cardinality subset $S \subseteq L$ such that $(V, F \cup S)$ is 2-edge-connected[2]. The assumption that F is a forest is no restriction, as one can obtain an equivalent instance by contracting each 2-edge-connected component of F into a single vertex. The Path Augmentation Problem (PAP) is a special case of FAP where the given forest is composed of vertex-disjoint paths. We formally denote an instance of PAP by $G = (V, E(\mathcal{P}) \cup L)$, where $\mathcal{P}$ is the set of vertex-disjoint paths and $E(\mathcal{P})$ denotes its corresponding edge set. The goal is to find a minimum-cardinality subset $S \subseteq L$ such that $(V, E(\mathcal{P}) \cup S)$ is 2-edge-connected. Both problems are APX-hard [16, 18], ruling out the possibility of a Polynomial-Time Approximation Scheme (PTAS), unless P = NP. Until recently, no polynomial-time algorithm achieving a better-than-2 approximation was known for either problem.

Grandoni, Jabal Ameli, and Traub [25] were the first to break this barrier for PAP and FAP. In more detail, they obtained a 1.9913-approximation for PAP[3]. Combining this result with another result of [25] led to a 1.9973-approximation for FAP.

1.1 Our Contribution

In this paper, we consider *bounded-length PAP*, the special case of PAP in which each path in $\mathcal{P}$ contains at most $p_{\max}$ edges. This problem generalizes several well-established problems in connectivity augmentation, such as the unweighted 2-edge connected spanning subgraph problem (2ECSS), in which each path has length 0, or the Matching Augmentation Problem (MAP), in which each path has length 1; see Section 1.2 for more details. Our main result is a substantial improvement for bounded-length PAP.

▶ **Theorem 1.** *There is a* 1.9412*-approximation algorithm for PAP with running-time* $n^{O(p_{\max})}$.

To achieve this improvement, we introduce a new $(\frac{11}{6} + \varepsilon)$-approximation preserving reduction to structured instances, which is key to our approach. Additionally, we introduce a new relaxation of PAP, called 2-Edge Cover with Path Constraints (2ECPC), in which we have to compute a minimum-cardinality set of links $X \subseteq L$ such that $(V, E(\mathcal{P}) \cup X)$ is a 2-edge cover with the additional property that each path $P \in \mathcal{P}$ has two outgoing links. Instead of directly obtaining an approximate solution for 2ECPC, we consider a novel packing problem, called the Track Packing Problem (TPP). TPP is in some sense the corresponding packing problem to the covering problem 2ECPC, where the relationship between the two problems is inspired by the relationship between 2-edge covers and 2-matchings (precise definitions follow). We compute up to $|\mathcal{P}| + 2$ many solutions to TPP and analyze their cost using a factor-revealing linear program (LP). The resulting approximate solution serves as a suitable starting point for our framework. Later, this solution is turned into a feasible solution, highly relying on the fact that the input instance is structured. Our techniques also combine insights from [25] with methods used in other augmentation problems, together with new ideas tailored for structured instances of bounded-length PAP. We believe that

[2] A graph is k-edge-connected (kEC) if it remains connected after the removal of an arbitrary subset of $k - 1$ edges.

[3] In [25] a different result is shown with a bi-criteria approximation ratio. However, the result stated here for PAP is given implicitly in [25].

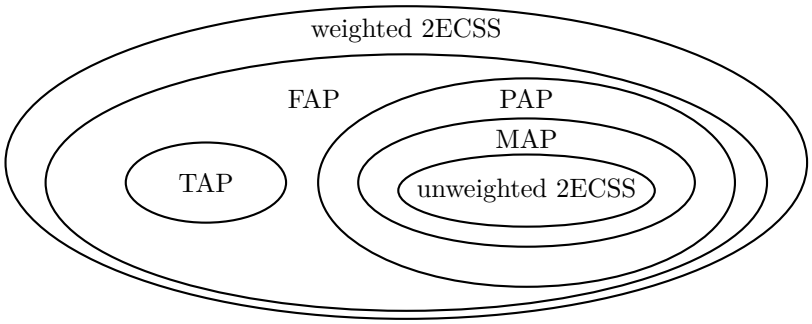

Figure 1 Hierarchical relation between weighted/unweighted 2ECSS, FAP, TAP, PAP, and MAP.

both the reduction to structured instances and the new relaxation 2ECPC as well as the corresponding packing problem TPP may be of independent interest for other connectivity augmentation problems.

1.2 Previous and Related Work

FAP generalizes several well-known network design problems, many of which have seen improvements beyond the 2-approximation barrier, see Figure 1. One important special case is the Tree Augmentation Problem (TAP), where F is a tree. Over the past decades, a sequence of results [1, 9, 10, 11, 14, 17, 19, 20, 26, 32, 36, 37, 38, 39] has led to a 1.393-approximation by Cecchetto, Traub, and Zenklusen [6]. The weighted version of TAP has also been extensively studied, culminating in a $1.5 + \varepsilon$ approximation by Traub and Zenklusen [42], which even holds for the more general connectivity augmentation problem. In the connectivity augmentation problem we are given a k-edge-connected graph G and additional links L and the task is to compute a set of links $X \subseteq L$ of minimum size such that $G \cup X$ is $(k+1)$-edge-connected. Before, the barrier of 2 for connectivity augmentation was breached by Byrka, Grandoni, and Jabal Ameli [5].

Another relevant special case of FAP and PAP is the unweighted 2-edge-connected spanning subgraph problem (unweighted 2ECSS), where $F = \emptyset$. Several works [12, 22, 30, 33, 35, 41] have led to better-than-2 approximations. Bosch-Calvo, Garg, Grandoni, Hommelsheim, Jabal Ameli, and Lindermayr [3] obtained a $\frac{5}{4}$-approximation, which was recently improved slightly by Hommelsheim, Lindermayr, and Liu [29].

The Matching Augmentation Problem (MAP) is the special case of PAP in which F is a matching, i.e., each path consists of a single edge. Cheriyan, Dippel, Grandoni, Khan, and Narayan introduced this problem and gave a $\frac{7}{4}$-approximation [7]. Cheriyan, Cummings, Dippel, and Zhu [8] improved this to $\frac{5}{3}$ and Garg, Hommelsheim, and Megow improved this further to $\frac{13}{8}$ [23]. An LP-based approximation algorithm for MAP with worse guarantee, yet simpler analysis has been developed by Bamas, Drygala, and Svensson [2].

Beyond edge connectivity, many of these problems have natural vertex connectivity counterparts, where the objective is to compute a 2-vertex connected spanning subgraph, ensuring connectivity despite a single vertex failure. For the vertex-connected version of unweighted 2ECSS, several algorithms obtain better-than-2 approximations [13, 24, 27, 33]. The current best-known result is a $\frac{4}{3}$-approximation by Bosch-Calvo, Grandoni, and Jabal Ameli [4].

1.3 Notation

We assume that all instances of optimization problems studied in this paper admit a feasible solution, which can be tested in polynomial time. Throughout this paper, we consider an instance of PAP given by $G = (V, E(\mathcal{P}) \cup L)$, where $\mathcal{P}$ is a collection of disjoint paths, $E(\mathcal{P})$ denotes their edge set, and $L \subseteq \binom{V}{2}$ is a set of additional links. We define $E = E(\mathcal{P}) \cup L$ as the set of edges of G and set $p_{\max} := \max_{P \in \mathcal{P}} |E(P)|$ to be the maximum length of a path in $\mathcal{P}$. For $\mathcal{P}' \subseteq \mathcal{P}$ we write $V^{\text{end}}(\mathcal{P}')$ to denote the set of endpoints (endvertices) of all paths in $\mathcal{P}'$, i.e., vertices that have degree at most 1 w.r.t. $E(\mathcal{P}')$. We define $V^{\text{end}} := V^{\text{end}}(\mathcal{P})$. Every vertex of $V(G)$ that is not an endvertex has degree 2 w.r.t. $E(\mathcal{P})$; such vertices are called interior vertices (of some path $P \in \mathcal{P}$). We further define the following subsets of links: $L^{\text{end}} \subseteq L$ is the set of links uv such that $u, v \in V^{\text{end}}$. We use $L^{\text{end,in}} \subseteq L^{\text{end}}$ to denote the set of links of L^{end} whose endpoints belong to the same path, while $L^{\text{end,out}} = L^{\text{end}} \setminus L^{\text{end,in}}$ contains links of L^{end} that connect different paths. For a subgraph H of G we write $L(H)$ to denote the set of links contained in H. For $P \in \mathcal{P}$ and $u, v \in V(P)$, let P^{uv} be the path from u to v on P. We denote by $\text{OPT}(G)$ some optimal solution of G and by $\text{opt}(G)$ the cost of an optimal solution, i.e., the number of links in $\text{OPT}(G)$. If G is clear from context, we simply write OPT and opt, respectively.

Further, we mainly use standard graph notation. Given a set of vertices $U \subseteq V$, we let $G|U$ denote the multi-graph obtained from G by contracting U to a single vertex. For a subgraph H of G we simply write $G|H$ instead of $G|V(H)$. More generally, given a set $\mathcal{T} = \{T_1, \dots, T_k\}$ of vertex-disjoint sets $T_1, \dots, T_k \subseteq V(G)$, $G|\{T_1, \dots, T_k\}$ (or $G|\mathcal{T}$ in short) denotes the graph obtained by contracting each T_i into a single vertex. A set $X \subseteq V$ is a separator if $G \setminus X$ is disconnected. For $V' \subseteq V(G)$ we define $N_G(V')$ as the neighborhood of V' in G and $\delta(V')$ refers to the edge set with exactly one endpoint in V'. A bridge in G is an edge whose removal from G increases the number of connected components. A subgraph H is a 2-edge cover of G if $|\delta_H(v)| \geq 2$ for each $v \in V(G)$.

2 Overview of Our Approach

In this section, we provide an overview of our algorithmic approach to prove Theorem 1. At a high level, we follow the approach recently introduced for FAP and PAP [25], unweighted 2ECSS [3, 22, 29] and MAP [7, 8, 23]. Our approach has four main steps.

1. Reduction to Structured Instances. The first step is a reduction to structured instances. Specifically, we show that for any $\alpha \geq \frac{11}{6}$ and any small constant $\varepsilon > 0$, if an α-approximation exists for structured instances of bounded-length PAP, then an $(\alpha + \varepsilon)$-approximation exists for arbitrary bounded-length instances of PAP. These structured instances possess key properties that enable and simplify our subsequent algorithmic steps. This step has not been utilized in the previous work on FAP and PAP, except for a reduction to PAP without isolated vertices in [25]. We remark that this is the only place where we require the length of the paths in the instance of PAP to be bounded.

2. Computing a Low-Cost Starting Solution. The second step includes one of our key innovations. Here, we compute a *low-cost* starting solution $S \subseteq L$ such that the graph $H = (V, E(\mathcal{P}) \cup S)$ is not necessarily feasible but has important structural properties. In later steps, we will turn this starting solution into a feasible solution. To guide this process, we introduce a credit scheme that assigns to any spanning subgraph H' of G credits to vertices, edges, blocks, and components of H'. The total sum of credits of H' is denoted

by credits(H'), and we define cost(H') = $|H' \cap L|$ + credits(H'), i.e., the number of links in H' plus the total sum of credits assigned to H'. This scheme helps to maintain a cost measure that accounts not only for the number of selected links but also for structural penalties. Roughly speaking, the number of credits assigned to a solution reflects its distance to a feasible solution. To compute the starting solution, we introduce a novel relaxation of PAP, which we use as a lower bound on opt and which is related to 2-edge covers. Instead of computing a solution to the relaxation directly, we consider a closely related packing problem, where the relationship between the packing problem and the relaxation of PAP is similar to the relationship between 2-matchings and 2-edge covers[4]. Although it turns out that the packing problem and the relaxation are still NP-hard (see full version [28]), we can compute a solution S to the packing problem such that $H_0 = (V, E(\mathcal{P}) \cup S)$ satisfies cost(H_0) $\leq 1.9412 \cdot$ opt. In fact, we compute up to $|\mathcal{P}| + 2$ many solutions H and output the one minimizing cost(H). We analyze the cost of this solution using a factor-revealing LP. This (most likely infeasible) solution is used as a starting solution.

In the remainder, we step-by-step turn H_0 into solutions $H_1, H_2, \ldots$ that are "closer to being feasible", while always keeping the invariant that the new solution H_{i+1} satisfies cost(H_{i+1}) $\leq$ cost(H_i). Since the credits are non-negative and the starting solution satisfies cost(H_0) $\leq 1.9412 \cdot$ opt, eventually we will have a feasible solution using at most $1.9412 \cdot$ opt many links.

There are two reasons why a solution H is not yet feasible: 1) there is a bridge in H, and 2) there are several connected components in H. The next two steps deal with these reasons for infeasibility.

3. Bridge-Covering. The third step, called bridge-covering, ensures that the intermediate solution H' is bridgeless. Our goal is to add (and sometimes remove) links to (from) H such that the resulting graph H' is bridgeless, while keeping the invariant cost(H') $\leq$ cost(H). At this stage, we heavily exploit the fact that G is structured, which allows us to prove the existence of cheap augmenting link sets needed to decrease the number of bridges.

4. Gluing. In the fourth and final step, called gluing, we transform H into a feasible solution, i.e., a 2-edge-connected spanning subgraph. At this point, H consists of multiple 2-edge-connected components that must be merged into a single 2-edge-connected component. We achieve this by iteratively adding well-chosen cycles in the *component graph*, ensuring that each step maintains feasibility and preserves the approximation guarantee. The component graph $G^{\text{comp}}(H)$ arises from G by contracting each component of H to a single vertex. To prove the existence of such cycles we again heavily exploit that G is structured.

The remainder of this section provides a more detailed overview of these four steps, along with lemmas formalizing each transformation. The subsequent sections are dedicated to the individual steps, leading to the proof of Theorem 1, which follows from the four main lemmas established before.

3 Reduction to Structured Instances

Unlike previous algorithms for FAP and PAP [25], we introduce a reduction to structured instances, which plays a crucial role in our approach. Informally, a structured instance is one that avoids certain degenerate configurations that would complicate the design of good

[4] For a graph $G = (V, E)$ a 2-matching $M \subseteq E$ satisfies $\delta_M(v) \leq 2$ for all $v \in V$. A classical result states that one can compute a minimum 2-edge cover by computing a maximum 2-matching and greedily adding edges to each vertex $v \in V$ with $\delta_M(v) < 2$; see [40] for more details.

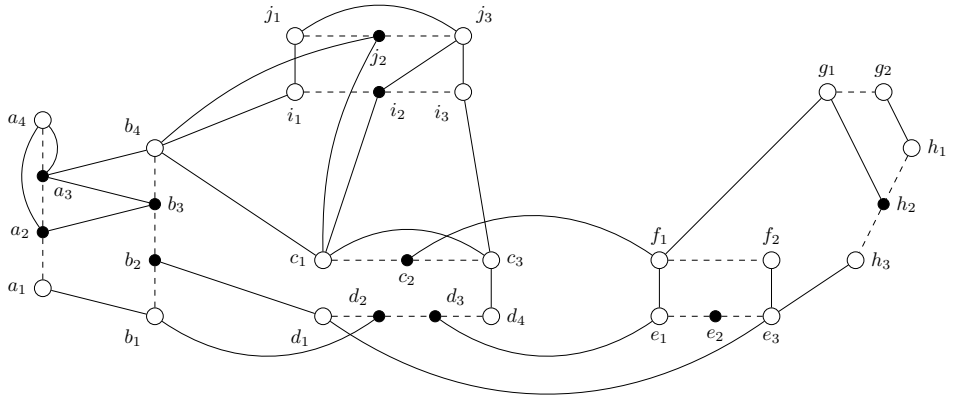

Figure 2 Non-structured PAP instance. Dashed edges are in $E(\mathcal{P})$, solid edges in L. Interior vertices of paths from $\mathcal{P}$ are filled, endvertices of paths from $\mathcal{P}$ are empty. The cycle $a_2a_3a_4a_2$ is a 1-contractible subgraph, the path $P = b_1b_2b_3b_4 \in \mathcal{P}$ is a path-separator, the path $c_1c_2c_3d_4d_3d_2d_1$ is a P^2-separator, the cycle $e_1e_2e_3f_2f_1e_1$ is a C^2-separator, and the path $j_1j_2j_3$ is a degenerate path.

approximation algorithms in our approach. We formally define structured instances and establish that solving bounded-length PAP on structured instances suffices to achieve a good approximation algorithm for general bounded-length PAP. We prove that for all $\alpha \geq \frac{11}{6}$ and any small constant $\varepsilon > 0$, if there exists a polynomial-time α-approximation for bounded-length PAP on structured instances, then there is a polynomial-time $(\alpha+\varepsilon)$-approximation for arbitrary instances of bounded-length PAP. This guarantees that improvements on structured instances directly translate into improvements for the general case.

To define structured instances, we introduce several graph properties, see Figure 2. First, structured instances do not contain contractible subgraphs. Roughly speaking, a subgraph is (strongly) α-contractible if at least a $\frac{1}{\alpha}$ fraction of its links must appear in any feasible solution, allowing us to safely contract it without a loss in the approximation guarantee. We ensure that such subgraphs can be identified and handled efficiently. Formally, we define α-contractible subgraphs as follows.

▶ **Definition 2** (α-contractible subgraph). *Let $\alpha \geq 1$ and $t \geq 1$ be fixed constants. Given a 2-edge-connected graph G, a collection $\mathcal{H}$ of vertex-disjoint 2-edge-connected subgraphs $H_1, H_2, \ldots, H_k$ of G, such that $G|\mathcal{H}$ is also an instance of* PAP*, is called* weakly (α, t, k)-contractible *if $1 \leq |L(H_i)| \leq t$ for every $i \in [k]$ and there exists some optimal solution that contains at least $\frac{1}{\alpha}|\bigcup_{i\in[k]} L(H_i)|$ links from $\bigcup_{i\in[k]} L(G[V(H_i)])$. Furthermore, $\mathcal{H}$ is* strongly (α, t, k)*-contractible if additionally every 2EC spanning subgraph of G contains at least $\frac{1}{\alpha}|\bigcup_{i\in[k]} L(H_i)|$ links from $\bigcup_{i\in[k]} L(G[V(H_i)])$.*

Every strongly (α, t, k)-contractible subgraph is also a weakly (α, t, k)-contractible subgraph. We say that $\mathcal{H}$ is an (α, t, k)-contractible subgraph if it is a weakly or strongly (α, t, k)-contractible subgraph. If α, t, k are clear from the context, we simply refer to α-contractible subgraphs or even contractible subgraphs. A typical example of a strongly contractible subgraph occurs if an endvertex v of some path $P \in \mathcal{P}$ is only adjacent to vertices on P: If u is the neighbor of v on P furthest away from v, then $(V(P^{uv}), P^{uv} \cup \{uv\})$ is strongly $(1, 1, 1)$-contractible, since $(V(P^{uv}), P^{uv} \cup \{uv\})$ is 2-edge-connected and every feasible solution must contain a link connecting v and $V(P^{uv})$. This is summarized in Property (P2) of Definition 4; see also Figure 2.

Second, structured instances avoid certain small separators. Specifically, we prevent the existence of path-separators, P^2-separators, and C^2-separators, which are roughly defined as follows (leaving out some technicalities, see full version [28]). A path-separator is a path $P \in \mathcal{P}$ that is a separator, i.e., $G \setminus V(P)$ is not connected. A P^2-separator is a separator that consists of two paths $P, P' \in \mathcal{P}$ such that there is a link in $L^{\text{end,out}}$ connecting one endvertex of P and one of P'. Note that $E(P) \cup E(P') \cup \{e\}$ is a simple path on $V(P) \cup V(P')$. Similarly, a C^2-separator is a separator that consists of two paths $P, P' \in \mathcal{P}$ such that there are two links in $e, e' \in L^{\text{end,out}}$ such that $E(P) \cup E(P') \cup \{e, e'\}$ is a cycle. Note that a C^2-separator is also a P^2-separator, but the additional edge required for C^2-separators allows us to obtain stronger results due to technical reasons omitted here. If an instance contains such a separator, we decompose it into smaller subinstances, solve each recursively, and merge their solutions while maintaining the desired approximation guarantee. Formal definitions are given in the full version [28]. We remark that we only require the length of the paths in the instance of PAP to be bounded for the reduction to avoid path-separators and P^2-separators.

A final obstacle to obtain structured instances is the presence of too many degenerate paths, which are paths $P \in \mathcal{P}$ with limited connectivity to the rest of the graph. When the fraction of degenerate paths exceeds the threshold $\varepsilon|\mathcal{P}|$, we identify certain well-connected subgraphs that we can contract and then solve the resulting subinstances recursively.

▶ **Definition 3** (Degenerate Path). *Let $P, P' \in \mathcal{P}$ be two distinct paths with endpoints u', v' and u, v, respectively, such that $u'u \in L$, $v'v \in L$ and $u'v' \in L$. We say that P' is a degenerate path if $N(u'), N(v') \subseteq V(P') \cup V(P)$.*

Using these definitions, we define structured instances.

▶ **Definition 4** ((α, ε)-structured Instance). *We call an instance $G = (V, \mathcal{P} \cup L)$ of bounded-length PAP (α, ε)-structured if the following properties are satisfied:*

(P0) $\text{opt}(G) > \frac{3}{\varepsilon}$.
(P1) *G does not contain strongly $(\alpha, t, 1)$-contractible subgraphs with $t \leq 10$ many links.*
(P2) *Every endpoint of a path $P \in \mathcal{P}$ has a link to some other path $P' \in \mathcal{P}$, $P' \neq P$.*
(P3) *G does not contain path-separators.*
(P4) *G does not contain P^2-separators.*
(P5) *G does not contain C^2-separators.*
(P6) *G contains at most $\varepsilon \cdot |\mathcal{P}|$ many degenerate paths.*
(P7) *Every vertex $v \in V$ is on some path $P \in \mathcal{P}$ that contains at least 2 vertices.*

If α and ε are clear from the context, we simply say G is structured. In the subsequent subsections we outline how these properties are useful to obtain good approximation algorithms. Our main lemma in this section is the following.

▶ **Lemma 5.** *For all $\alpha \geq \frac{11}{6}$ and constant $\varepsilon \in \left(0, \frac{1}{12}\right]$, if there exists a polynomial-time α-approximation algorithm for bounded-length* PAP *on (α, ε)-structured instances, then there exists a polynomial-time $(\alpha + \varepsilon)$-approximation algorithm for bounded-length* PAP *on arbitrary instances.*

We give a rough overview on how we obtain Lemma 5. Assume that G is not structured. In this overview, we focus only on three obstacles that prevent G from being structured: 1) G contains a contractible subgraph, 2) G contains a forbidden separator, or 3) G contains more than $\varepsilon|\mathcal{P}|$ many degenerate paths. If G contains one of these subgraphs, we can decompose G into at most 2 smaller subinstances, solve each recursively, and merge their solutions while maintaining the approximation guarantee. We outline our approach for each of these three cases.

Property (P1) is not met. We can safely contract each component of an α-contractible subgraph $\mathcal{H}$ into a single vertex and work with $G|\mathcal{H}$, as long as we only aim for an α-approximation. Indeed, any α-approximate solution for $G|\mathcal{H}$ can be turned into an α-approximate solution for G by adding the links of $\mathcal{H}$. In general, it is not straightforward to argue that a 2EC subgraph is weakly α-contractible. However, under certain conditions we can argue that this is indeed the case. We will show that we can find strongly $(\alpha, t, 1)$-contractible subgraphs in polynomial time if t is constant, i.e., if there is only one component and there are only a constant number of links in the contractible subgraph. Hence, after our preprocessing, we can assume that G does not contain any strongly $(\alpha, t, 1)$-contractible subgraphs for some constant t (here $t = 10$ suffices).

Property (P3), (P4), or (P5) is not met. Assume that G contains a forbidden separator X, resulting in $G \setminus X$ to decompose into two disjoint vertex sets V_1 and V_2 and there are no edges between V_1 and V_2. Here, we construct two sub-instances $G_1 = (G \setminus V_2)|X$ and $G_2 = (G \setminus V_1)|X$ arising from G by removing either V_1 or V_2 and contracting X into a single vertex. We recursively solve these sub-instances approximately and combine both solutions while preserving the desired approximation guarantee. By introducing a proper notion of *size* of an instance, one can ensure that the sum of the sizes of the two sub-instances is smaller than the size of the original instance and hence this step runs in polynomial time.

Property (P6) is not met. One of the main innovations in our reduction to structured graphs compared to previous work deals with degenerate paths. For degenerate paths, we can not do the same strategy as for separators and instead do the following: Let $\mathcal{P}' = \{P'_1, \dots, P'_\ell\}$ be a set of degenerate paths. We define two collections $\mathcal{K}$ and $\mathcal{C}$ of ℓ vertex-disjoint 2-edge-connected subgraphs, each subsuming $V(\mathcal{P}')$. We show that either $\mathcal{C}$ is weakly $(\alpha, 2, \ell)$-contractible or $\mathcal{K}$ is weakly $(\alpha, 1, \ell)$-contractible for any $\alpha \geq \frac{11}{6}$. Hence, either an α-approximate solution for $G|\mathcal{K}$ or an α-approximate solution for $G|\mathcal{C}$ can be turned into an α-approximate solution for G by adding the edges contained in $\mathcal{K}$ or $\mathcal{C}$, respectively.

Unfortunately, in general this recursive procedure leads to an exponential running time if $|\mathcal{P}'|$ is small: We need to recursively solve the two sub-instances $G|\mathcal{K}$ and $G|\mathcal{C}$ that both may have roughly the same size as the original instance. Since we might need to apply this reduction again in later steps in our reduction to structured graphs, this procedure can result in an exponential running time. However, we circumvent this by only applying the above procedure if some constant fraction ε of the paths in $\mathcal{P}$ is degenerate, and hence each sub-instance is significantly smaller than the original one, which overall results in a polynomial running time.

In light of Lemma 5, it remains to give a 1.9412-approximation for bounded-length PAP on $(\frac{11}{6}, \varepsilon)$-structured instances. Hence, for the remaining steps, we assume the instance $G = (V, E(\mathcal{P}) \cup L)$ is a $(\frac{11}{6}, \varepsilon)$-structured instance of bounded-length PAP. In fact, for the remainder of this paper we only require the instance to be a $(\frac{11}{6}, \varepsilon)$-structured instance of PAP; the requirement of bounded-length was only needed for the reduction to structured graphs.

4 Credit Scheme, Relaxation, and Starting Solution

Throughout our algorithm, we maintain a temporary solution $S \subseteq L$, which is not necessarily a feasible solution. To track progress and guide modifications, we assign certain credits to parts of the current graph $H = (V, E(\mathcal{P}) \cup S)$. These credits are used to ensure that

every transformation preserves an approximation bound while gradually converting H into a feasible solution. We first define key structural components and introduce a cost function that incorporates both the number of selected links and assigned credits.

We use the following notation of blocks from related works on unweighted 2ECSS [22, 3, 29] and MAP [7, 8, 23]. A block is a maximal 2-edge-connected subgraph containing at least 2 vertices. A block B is called *simple* if there is some $P \in \mathcal{P}$ such that $V(B) \subseteq V(P)$, it is called *small* if there are two distinct paths $P_1, P_2 \in \mathcal{P}$ such that $V(B) = V(P_1) \cup V(P_2)$, and *large* if there are three distinct paths $P_1, P_2, P_3 \in \mathcal{P}$ such that $V(P_1) \cup V(P_2) \cup V(P_3) \subseteq V(B)$. A connected component that is 2EC is called a 2EC *component*. We call 2EC components small if they contain exactly 2 links and large if they contain at least 3 links.

Let H be a spanning subgraph of G, and let C be a connected component of H. A component is called *complex* if it contains bridges. For any such C, we define the graphs G_C and H_C as follows: G_C is the graph obtained from G by contracting every connected component of H except for C, as well as every block of C. H_C is the corresponding contraction of H. The structure of H_C consists of a tree T_C along with singleton vertices. A vertex in G_C or H_C that corresponds to a block in H is called a *block vertex*. If a block vertex corresponds to a simple block, it is called a *simple block vertex*. We identify the edges/links in G and the corresponding edges/links in G_C and H_C, resp.

A component C is called *trivial* if it consists of a single path $P \in \mathcal{P}$ (i.e., $V(C) = V(P)$). Otherwise, it is called *non-trivial*. A vertex $v \in V$ is called *lonely* if it does not belong to any 2-edge-connected component or block of H. For two paths $P, P' \in P$ with endpoints u, v and u', v', resp., we say that $uu' \in L$ is an *expensive link* if $N_G(v) \subseteq (V(P) \cup V(P')) \setminus \{v'\}$. If additionally $uu' \in L(H)$ is a bridge in H and v is a lonely leaf in H, then v is called an *expensive leaf vertex*.

For a given $H = (V, E(\mathcal{P}) \cup S)$, we assign credits as follows.

- **(A)** Every lonely vertex v that is a leaf of some complex component C receives 1 credit.
  - **(i)** It receives an additional $\frac{1}{4}$ credit if v is an expensive leaf vertex.
  - **(ii)** It receives an additional $\frac{1}{4}$ credit if there is a path in H_C from v to a simple block vertex of C without passing through a non-simple block vertex.
- **(B)** Every bridge $\ell \in S$ (i.e., a link that is not part of any 2-edge-connected component of H) receives $\frac{3}{4}$ credits.
- **(C)** Every complex component receives 1 credit.
- **(D)** Every non-simple 2-edge-connected block receives 1 credit.
- **(E)** Every 2-edge-connected component receives:
  - 2 credits if it is large or contains a degenerate path.
  - $\frac{3}{2}$ credits if it is small (i.e., has exactly 2 links) and does not contain a degenerate path.

For any spanning subgraph $H = (V, E(\mathcal{P}) \cup S)$, we define the total credit as credits(H), which is the sum of all assigned credits under these rules. We define cost$(H) :=$ credits$(H) + |S|$.

As an example, consider the right solution in Figure 3. There are three connected components: (1) The 2EC component containing v_1, which receives a credit of 2 (Rule (E)). (2) The complex component containing v_7. This component receives a credit of 1 (Rule (C)), the bridge u_7u_8 receives a credit of $\frac{3}{4}$ (Rule (B)), and the lonely leaf vertices u_7, u_8 receive a credit of 1 each (Rule (A)). (3) The complex component containing v_6. This component receives a credit of 1 (Rule (C)), the bridges $u_6w_3, w_3w_4, w_4u_5, v_5u_9, v_9w_{11}, w_{11}v_{10}$ receive a credit of $\frac{3}{4}$ (Rule (B)) each, and the lonely leaf vertices v_6, u_{10} receive a credit of 1 each (Rule (A)) (potentially plus $\frac{1}{4}$ if Rule (A) (i) applies).

To prove the approximation guarantee, we show that we maintain the following invariants.

▶ **Invariant 6.** $\text{cost}(H) \leq 1.9412 \cdot \text{opt}(G)$.

▶ **Invariant 7.** *Every lonely vertex of H has degree at most 2 in H. Every simple 2EC block B is part of some complex component C and has degree exactly 2 in H_C. Furthermore, for any complex component C, no two simple block vertices of C are adjacent to each other in H_C.*

▶ **Invariant 8.** *For every non-simple 2EC block B of H there are two distinct paths $P, P' \in \mathcal{P}$ such that $V(P) \cup V(P') \subseteq V(B)$.*

Our goal is to design a polynomial-time algorithm that computes a solution $S \subseteq L$ such that $H = (V, E(\mathcal{P}) \cup S)$ satisfies all invariants above. This is formalized in the following lemma.

▶ **Lemma 9.** *Given a structured graph, in polynomial time we can compute a set of links $S \subseteq L$ such that $H = (V, E(\mathcal{P}) \cup S)$ satisfies the Invariants 6-8.*

Next, we outline how to compute such a solution. The approaches in [3, 22, 7, 8, 23] for special cases of PAP, such as unweighted 2ECSS and MAP, use a relaxation of the problem, for which an optimum solution can be computed in polynomial time and a solution serves as a good starting solution. In particular, these prior works used a minimum 2-edge cover as a relaxation. For *structured instances* of these special cases of PAP, optimum 2-edge covers are usually not too far away from an optimum solution of the original problem (i.e., unweighted 2ECSS or MAP), and hence they serve as a good lower bound. However, for PAP, a 2-edge cover can be far away from an optimum solution. For example, if the 2-edge cover of an instance of PAP only contains edges of $E(\mathcal{P})$ and $L^{\text{end,in}}$, then this edge set only 2-edge-connects the paths individually, but it does not help to establish overall 2-edge-connectivity. This motivates us to define a more suitable relaxation for PAP, called 2-Edge Cover with Path Constraints (2ECPC).

4.1 A relaxation of PAP: The 2-Edge Cover with Path Constraints

The input consists of a structured instance of PAP where each path $P_i \in \mathcal{P}$ has exactly three vertices: two endpoints $u_i, v_i \in V^{\text{end}}(P_i)$ and an interior vertex w_i. The goal is to compute a minimum-cardinality link set $X \subseteq L$ such that $E(\mathcal{P}) \cup X$ is a 2-edge cover with the additional constraint that each path P_i is incident to at least two outgoing links in X. More formally, X has to satisfy the following:

- Every vertex $u \in V^{\text{end}}(P_i)$ is incident to at least one link in X, i.e., $|\delta_X(u)| \geq 1$.
- Each path $P_i \in P$ has at least two outgoing edges in X, i.e., $|\delta_X(P_i)| \geq 2$.

One can easily obtain an instance of 2ECPC from an instance of PAP by doing the following for each path: If the path contains at least 4 vertices, we contract all internal vertices to a single vertex, and if the path contains 2 vertices, we add a dummy vertex as an interior vertex. Recall that for structured instances, every vertex is part of some path $P \in \mathcal{P}$ containing at least 2 vertices (Property (P7)). There is a one-to-one correspondence between links in the graph of the instance of PAP and links in the graph of the instance of 2ECPC. One can verify that any feasible solution to the PAP instance is also feasible for its corresponding 2ECPC instance; hence 2ECPC is indeed a relaxation for PAP. Instead of computing an (approximate) solution to 2ECPC, we consider a packing problem, which we call the Track Packing Problem (TPP).

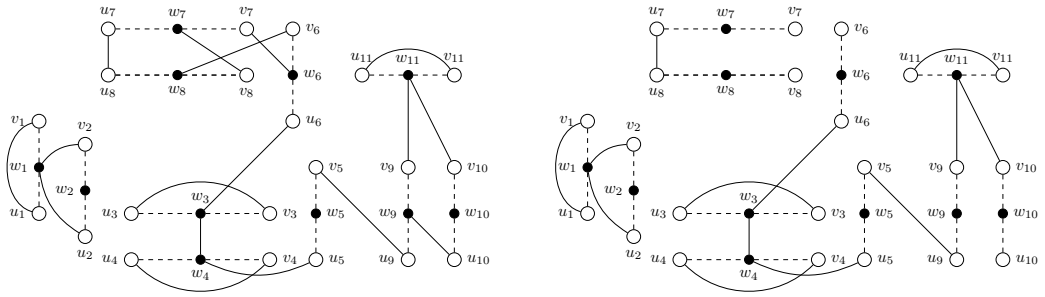

Figure 3 Dashed edges are in $E(\mathcal{P})$, solid edges are links of L. Filled vertices are interior vertices of paths from $\mathcal{P}$, empty vertices are endvertices of paths in $\mathcal{P}$. Left: Feasible solution Y for 2ECPC, since $E(\mathcal{P}) \cup Y$ is a 2-edge cover with $\delta_Y(P) \geq 2$ for each $P \in \mathcal{P}$. Right: Solution $X = \{T_1, T_2, T_3, T_4, T_5\}$ for the corresponding TPP instance with two tracks containing 1 link ($T_1 = \{u_7u_8\}$ and $T_2 = \{v_5u_9\}$), two tracks containing 3 links ($T_3 = \{u_2w_1, u_1v_1, w_1v_2\}$ and $T_4 = \{v_9w_{11}, u_{11}v_{11}, w_{11}v_{10}\}$) and one track containing 5 links ($T_5 = \{u_5w_4, u_4v_4, w_4w_3, u_3v_3, w_3u_6\}$). Note that $|Y| = 17 = 2|\mathcal{P}| - 5 = 2|\mathcal{P}| - |X|$.

We denote by OPT and OPT_C the optimum solutions for the PAP and the 2ECPC instance, respectively, and define opt and opt_C to be their objective values. It is easy to verify that any feasible solution to the PAP instance is also feasible for its corresponding 2ECPC instance, and hence 2ECPC is indeed a relaxation for PAP. We summarize this as follows.

▶ **Proposition 10.** *Let G be a structured instance of* PAP. *Then* $\text{opt} \geq \text{opt}_C$.

It is easy to see that $|\mathcal{P}| \leq \text{opt}_C \leq 2|\mathcal{P}|$: Observe that since the input graph G is structured, each endpoint u of some path $P \in \mathcal{P}$ is incident to a link $e \in \delta(P)$. Therefore, by picking such an edge for each endpoint u, there is a straightforward solution containing at most $2|\mathcal{P}|$ many links. Furthermore, note that any feasible solution must pick at least $|\mathcal{P}|$ many links. Therefore, we obtain the inequalities above.

Similar to other connectivity augmentation problems, we assume that the instance of 2ECPC is *shadow-complete*. In our setting this means the following: Let $P_i, P_j \in P$ such that $P_i \neq P_j$. If there is a link u_iu_j from an endpoint u_i of P_i to some other endpoint u_j of P_j, then we also add the *weaker* links u_iw_j, w_iu_j and w_iw_j, where w_i, w_j are the interior vertices of the paths P_i and P_j, respectively. Furthermore, if there is a link u_iw_j from an endpoint u_i of P_i to the interior vertex w_j of P_j, then we also add the *weaker* link w_iw_j, where w_i is the interior vertex of P_i. These weaker links are then also called the *shadows* of their original links. An instance that contains all such shadows is called shadow-complete.

It is not hard to see that for any feasible instance of 2ECPC, a feasible solution to the shadow-complete instance can be turned into a feasible solution to the original instance of the same cost.

▶ **Lemma 11.** *For any feasible instance of* 2ECPC *arising from a structured graph, a feasible solution Y to the shadow-complete instance can be turned into a feasible solution Y' to the original instance such that $|Y'| \leq |Y|$.*

Hence, from now on we assume that our instance of 2ECPC is shadow-complete.

4.2 The Track Packing Problem

TPP is inspired by the relationship between 2-matchings and 2-edge covers, where the covering constraints are expressed as a packing problem. Formally, we construct an instance of TPP from a shadow-complete instance of 2ECPC (see full version [28] for formal definitions). For some link set $A \subseteq L$ let $V^{\text{end}}(A) \coloneqq V^{\text{end}}(\mathcal{P}) \cap V(A)$ be the set of vertices that are endpoints of some path and are incident to some link in A. A *track* $T \subseteq L$ with $T = Q(T) \cup I(T)$ is a subset of links such that the following conditions hold.

- $Q(T)$ is a simple path in G of length at least one, where the start vertex u and the endvertex v of $Q(T)$ are endpoints of some paths $P, P' \in \mathcal{P}$ (not necessarily $P \neq P'$) such that $u \neq v$,
- any interior vertex of $Q(T)$, i.e., a vertex from $V(Q(T)) \setminus \{u, v\}$, is the interior vertex of some path $P \in \mathcal{P}$,
- $I(T) \subseteq L$ contains exactly the following set of links: for each interior vertex $w_i \in V(Q(T)) \setminus \{u, v\}$, which is an interior vertex of some path $P_i \in \mathcal{P}$, there is a link $u_i v_i \in I(T)$, where $u_i, v_i \in V^{\text{end}}(P_i)$ are the endvertices of P_i, and
- if $|T| = 1$, i.e., if $|Q(T)| = 1$ and $|I(T)| = 0$, then the start vertex u of $Q(T)$ and the endvertex v of $Q(T)$ belong to distinct paths.

For any track T, we refer to $Q(T)$ and $I(T)$ as above. Observe that the number of links in a track is odd, since $|Q(T)| = |I(T)| + 1$. Note that a track of length 1 is simply a link in $L^{\text{end,out}}$, i.e., a link between two endvertices of two distinct paths.

The instance of TPP is now defined as follows. The input is a (shadow-complete) instance of 2ECPC of some structured graph G. Let $\mathcal{T}$ be the set of all tracks in G. The task is to select a maximum number of disjoint tracks from $\mathcal{T}$, where two tracks T, T' are disjoint if $V(T) \cap V(T') = \emptyset$.

In the following we establish a relationship between solutions of 2ECPC and its corresponding TPP instance. This connection is similar to the connection between 2-matchings and 2-edge covers. In particular, an optimum solution to one of the problems can be turned into an optimum solution to the other problem in polynomial time. We note that the additional condition required in Lemma 12 and Lemma 13 is always satisfied for structured graphs. The relationship between 2ECPC and TPP is highlighted in Figure 3.

▶ **Lemma 12.** *Given a solution X for a shadow-complete instance of* TPP*, in which each endvertex of a path is connected to a vertex of a different path, we can compute in polynomial time a solution Y to the corresponding* 2ECPC *instance of value $2|\mathcal{P}| - |X|$.*

▶ **Lemma 13.** *Consider a shadow-complete instance I of* 2ECPC*, in which each endvertex of a path is connected to a vertex of a different path. Given an inclusion-wise minimal solution Y to I such that $|Y| \leq 2|\mathcal{P}|$, we can compute in polynomial time a solution X to the corresponding* TPP *instance of value at least $2|\mathcal{P}| - |Y|$.*

We also note that TPP is NP-hard by a reduction from the NP-hard P_2-Packing problem [34]. In the P_2-Packing problem we are given a graph G and the task is to select a maximum number of vertex-disjoint P_2's, i.e., paths that contain exactly 2 edges.

▶ **Proposition 14.** *The Track Packing Problem is* NP*-hard, even on shadow-complete instances, in which each endvertex of a path is connected to a vertex of a different path.*

Note that due to the above relationship between 2ECPC and TPP established in Lemma 12 and Lemma 13, Proposition 14 also implies NP-hardness for 2ECPC.

▶ **Proposition 15.** *The 2-Edge Cover with Path Constraints is* NP*-hard.*

Despite this hardness, in the remaining part we show how to compute a solution to TPP which serves as a good starting solution for our algorithmic framework.

4.3 Computing a good starting solution

Our goal is to compute a solution to TPP. By its close relationship to 2ECPC, we can bound the cost of this solution in terms of opt_C, the optimum solution value for the instance of 2ECPC, and since 2ECPC is a relaxation of PAP, we can in turn bound its cost in terms of opt. We do not compute an approximate solution to TPP relative to its optimum solution value; instead we do the following: For a solution X to TPP we compute $H_X = (V, E(\mathcal{P}) \cup (X \cap L))$, and we want to find a solution X to TPP such that $\text{cost}(H_X) = |X \cap L| + \text{credits}(H_X) \leq 1.9412 \cdot \text{opt}$.

To find such a solution, we view TPP as a Set-Packing problem. Therein, we are given a set of elements U and a set of subsets $\mathcal{S} \subseteq 2^U$ of U and the task is to compute a set $X \subseteq \mathcal{S}$ of maximum cardinality such that for any two sets $S, S' \in X$ we have $S \cap S' = \emptyset$. Set-Packing is APX-hard and the state-of-the-art polynomial-time approximation algorithms for it achieve an approximation factor of $\frac{3}{1+k+\varepsilon}$ for any constant $\varepsilon > 0$, where $k \coloneqq \max_{S \in \mathcal{S}} |S|$ is the maximum size of a set in $\mathcal{S}$ [15, 21]. TPP can be reduced to Set-Packing by viewing each $v \in V^{\text{end}}(\mathcal{P})$ as an element and each track as a set, which exactly contains those vertices $v \in V^{\text{end}}(\mathcal{P})$ to which the track is incident to.

Using such set-packing algorithms, we define three different algorithms that compute sets of disjoint tracks, where the maximum size of a track we consider contains at most 4 vertices of $V^{\text{end}}(\mathcal{P})$. In total, we compute up to $|\mathcal{P}| + 2$ different solutions and output the solution X minimizing $\text{cost}(H_X)$. It can be easily shown that H_X satisfies Invariant 7 and Invariant 8. To show that H_X satisfies Invariant 6, that is, $\text{cost}(H_X) \leq 1.9412 \cdot \text{opt}$, we bound the cost of H_X in terms of variables that depend on the three algorithms and certain parameters of an optimum solution. Here, we heavily exploit the connection between optimum solutions of TPP and 2ECPC from above. We then derive a factor-revealing LP, which proves $\text{cost}(H_X) \leq \rho \cdot \text{opt}$ if the polyhedron is empty for a specific value of ρ. Indeed, for $\rho = 1.9412$ this is the case, implying Invariant 6. This then proves Lemma 9.

Throughout this section we fix an optimum solution OPT_P for the instance of TPP and assume that $\text{OPT}_P = \bigcup_{i=1}^{n} O_i$, where O_i is the set of tracks T in the optimum solution such that $|Q(T)| = i$. We define $\omega_i = |O_i|$. Hence, $|\text{OPT}_P| = \sum_{i=1}^{n} \omega_i$. We additionally let ω_0 be the number of vertices of $V^{\text{end}}(\mathcal{P})$ that are not incident to any track in OPT_P. Since each endvertex of $V^{\text{end}}(\mathcal{P})$ can be incident to at most one track and each track T with $|Q(T)| = i$ is incident to $2i$ distinct endvertices of $V^{\text{end}}(\mathcal{P})$, we have that $\omega_0 + \sum_{i=1}^{n} 2i \cdot \omega_i = 2|\mathcal{P}|$. Finally, let $\omega_1^e \leq \omega_1$ be the number of tracks T contained in OPT_P such that $|Q(T)| = 1$ and T corresponds to an expensive link.

Algorithm A

In Algorithm A we first only consider tracks of size 1, which are just links from $L^{\text{end,out}}$. In the first step we compute a maximum number of disjoint tracks of size 1, i.e., we compute a maximum matching $A_1 \subseteq L^{\text{end,out}}$, which can be done in polynomial time.

For the second step, let R_A be the set of endvertices of $V^{\text{end}}(\mathcal{P})$ that are not incident to some link of A_1. Let I_{R_A} be the resulting set-packing instance where we have one element for each vertex in R_A and consider only those tracks T that are only incident to vertices

from R_A and additionally satisfy $|Q(T)| = 2$ (i.e., $Q(T)$ contains exactly 2 links). We then compute a solution A_2 to I_{R_A} using the $\frac{3}{5+\varepsilon}$-approximation algorithm from [21] and output the solution $S_A = A_1 \cup A_2$.

Algorithm B

Algorithm B is similar to Algorithm A, but we compute a different matching in the first step. We aim at "guessing" the value ω_1^e, i.e., how many tracks of size 1 are contained in the optimum solution OPT_P that correspond to an expensive link. There are at most $|\mathcal{P}|$ many guesses, hence we can simply try all possible values.

Given a guess of ω_1^e, we compute a subset $B_1 \subseteq L^{\mathrm{end,out}}$ of maximum size, such that B_1 contains at most ω_1^e many expensive links. This can be done by guessing the size k of the maximum matching with at most ω_1^e many expensive links and giving each expensive link in $L^{\mathrm{end,out}}$ a cost of 1 and any other link of $L^{\mathrm{end,out}}$ a cost of 0 and computing a minimum-cost matching of size exactly k. The maximum k for which the cost of the solution is at most ω_1^e is then the desired solution. This gives us the edge set B_1, which corresponds to a maximum set of disjoint tracks of length 1 with at most ω_1^e many expensive links. Note that a minimum-cost matching of size exactly k in a weighted graph with n vertices (and non-negative weights) can be found by reducing it to a minimum-cost perfect matching problem by adding $n - 2k$ dummy vertices and connecting each dummy vertex to every original vertex with an edge of cost 0.

The second step in Algorithm B is identical to the second step of Algorithm A: Let R_B be the set of endvertices of $V^{\mathrm{end}}(\mathcal{P})$ that are not incident to some link of B_1. Let I_{R_B} be the resulting set-packing instance where we have one element for each vertex in R_B and consider only those tracks T that are only incident to vertices from R_B and additionally satisfy $|Q(T)| = 2$ (i.e., $Q(T)$ contains exactly 2 links). We then compute a solution B_2 to I_{R_B} using the $\frac{3}{5+\varepsilon}$-approximation algorithm from [21] and output the solution $S_B = B_1 \cup B_2$.

Algorithm C

In the third algorithm, we directly consider the corresponding set-packing problem in which we only consider tracks T with $|Q(T)| \leq 2$ (i.e., tracks T such that $|Q(T)| = 1$ or $|Q(T)| = 2$). We then compute a solution S_C to this set-packing instance using the $\frac{3}{5+\varepsilon}$-approximation algorithm from [21] and output S_C. We set $S_C = C_1 \cup C_2$, where C_i is the set of tracks T such that $|Q(T)| = i$.

Final Algorithm

The final solution is then computed as follows. For a solution $H = (V, E(\mathcal{P}) \cup S)$ we defined $\mathrm{cost}(H) \coloneqq \mathrm{credits}(H) + |S|$. For each guess $i \in \{0, 1, \ldots, |\mathcal{P}|\}$ of ω_1^e in Algorithm B we have a solution $H^i_{\mathrm{AlgB}} = (V, E(\mathcal{P}) \cup S^i_B)$ and for Algorithm A and C we have one solution $H_{\mathrm{AlgA}} = (V, E(\mathcal{P}) \cup S_A)$ and $H_{\mathrm{AlgC}} = (V, E(\mathcal{P}) \cup S_C)$, respectively. For each of the $|\mathcal{P}| + 3$ many solutions, we then compute their respective cost as defined above and output the solution with lowest cost. We let $H = (V, E(\mathcal{P}) \cup S)$ be this final solution.

We note that in fact one of the solutions computed in Algorithm B will be identical to the solution computed in Algorithm A. This is true if the guess of ω_1^e is 0 and hence in Algorithm B, we simply compute a maximum matching of $L^{\mathrm{end,out}}$. However, for notational purposes it will be more convenient to also consider Algorithm A with its solution S_A.

4.4 Bounding the cost of the solution

We now bound $\text{cost}(H)$. We bound the number of links in the optimum solution as follows.

▶ **Lemma 16.** *We have* $\text{opt}_C \geq 2|\mathcal{P}| - \sum_{i\geq 1} \omega_i$.

Proof. By Lemmas 12 and 13 we have that $\text{opt}_C = 2|\mathcal{P}| - \text{opt}_P$. By definition, we have that $\text{opt}_P = \sum_{i\geq 1} \omega_i$ and therefore obtain the result. ◀

Let S_B be the solution from Algorithm B which corresponds to the correct guess of ω_1^e. From now on, we only need this solution from Algorithm B and do not consider the solutions for the other guesses of ω_1^e. Let $S_A = A_1 \cup A_2$, where A_i is the set of tracks T from S_A such that $|Q(T)| = i$ and define $\alpha_i = |A_i|$ for $i = 1, 2$. Similarly, we define $S_B = B_1 \cup B_2$ and $S_C = C_1 \cup C_2$ and set $\beta_i = |B_i|$ and $\gamma_i = |C_i|$ for $i = 1, 2$. Furthermore, let $\alpha_0, \beta_0, \gamma_0$ be the number of vertices from $V^{\text{end}}(\mathcal{P})$ that are not incident to some track of S_A, S_B or S_C, respectively. Note that such vertices correspond to leaves in S_A and S_B, respectively. Additionally, let $\alpha_0^e \leq \alpha_0$, $\beta_0^e \leq \beta_0$, and $\gamma_0^e \leq \gamma_0$ be the number of such leaves as above that are expensive w.r.t. S_A, S_B and S_C, respectively. Finally, for $j = 0, 1, 2$ let α_1^j be the number of tracks $T = uv$ of size 1 in S_A such that exactly j vertices of $\{u, v\}$ intersect some track of size 1 in OPT_P. Similarly, for $j = 0, 1, 2$ we define β_1^j. Note that $\alpha_1 = \alpha_1^0 + \alpha_1^1 + \alpha_1^2$ and $\beta_1 = \beta_1^0 + \beta_1^1 + \beta_1^2$. First, we prove the following bound on the cost of a solution by giving it certain credits.

▶ **Lemma 17.** *Let S be a solution computed by Algorithm A, B, or C. If each track of length 1 receives a credit of $\frac{3}{4}$, each track of length 3 a credit of 2, each lonely leaf vertex a credit of $\frac{3}{2}$ if it is not expensive and $\frac{7}{4}$ if it is expensive, and each degenerate path an additional credit of $\frac{1}{2}$, then we can redistribute the credits such that the credit rules (A)-(E) are satisfied. Furthermore, Invariants 7 and 8 are satisfied.*

Next, we show that also Invariant 6 is satisfied. To do so, we establish the following lemmas.

▶ **Lemma 18.** *If we assign to H_{AlgA}, H_{AlgB} and H_{AlgC} credits according to Lemma 17, then we have* $\text{cost}(H_{\text{AlgA}}) \leq 3|\mathcal{P}| - \frac{5}{4}\alpha_1 - \alpha_2 + \frac{1}{4}\alpha_0^e + \frac{1}{2}\varepsilon'|\mathcal{P}|$, $\text{cost}(H_{\text{AlgB}}) \leq 3|\mathcal{P}| - \frac{5}{4}\beta_1 - \beta_2 + \frac{1}{4}\beta_0^e + \frac{1}{2}\varepsilon'|\mathcal{P}|$ *and* $\text{cost}(H_{\text{AlgC}}) \leq 3|\mathcal{P}| - \frac{5}{4}\gamma_1 - \gamma_2 + \frac{1}{4}\gamma_0^e + \frac{1}{2}\varepsilon'|\mathcal{P}|$, *where $\varepsilon'|\mathcal{P}|$ is the number of degenerate paths in G.*

Next, we obtain some further constraints on the variables we defined earlier.

▶ **Lemma 19.** *The following inequalities are valid:*

1. $\alpha_1 \geq \omega_1, \beta_1, \gamma_1$,
2. $\alpha_1 \geq \omega_1 + \alpha_1^0$,
3. $\alpha_1 \geq \omega_1 + \beta_1^0$,
4. $\beta_1 \geq \omega_1$,
5. $\alpha_1 \geq \alpha_0^e$,
6. $\beta_1 \geq \beta_0^e$,
7. $\gamma_1 \geq \gamma_0^e$,
8. $\omega_0 \geq \beta_0^e$,
9. $\alpha_1 = \alpha_1^0 + \alpha_1^1 + \alpha_1^2$,
10. $\beta_1 = \beta_1^0 + \beta_1^1 + \beta_1^2$,
11. $\alpha_2 \geq \frac{3}{5+\varepsilon} \cdot (\omega_2 - 2\alpha_1^0 - \alpha_1^1)$,
12. $\beta_2 \geq \frac{3}{5+\varepsilon} \cdot (\omega_2 - 2\beta_1^0 - \beta_1^1)$, *and*
13. $\gamma_1 + \gamma_2 \geq \frac{3}{5+\varepsilon} \cdot (\omega_1 + \omega_2)$.

Recall that $H = (V, E(\mathcal{P}) \cup S)$, where S is the best solution output by Algorithms A, B, and C w.r.t. their cost. Note that the following lemma proves that H satisfies Invariant 6.

▶ **Lemma 20.** *For $\varepsilon \leq 0.001$ we have* $\text{cost}(H) \leq 1.9412 \cdot \text{opt}(G)$.

Proof. Let $\varepsilon'|\mathcal{P}|$ be the number of degenerate paths. Note that $\text{opt}(G) \geq |\mathcal{P}|$, and therefore $\varepsilon'|\mathcal{P}| \leq \varepsilon' \text{opt}(G)$. We prove the statement by giving a factor-revealing LP, which proves $\text{cost}(H) \leq \rho \cdot \text{opt}(G)$ if the polyhedron is empty for a specific value of ρ. The parameter ρ will then give the desired approximation ratio. The factor-revealing LP is as follows. We use the same variables as before, but for simplicity we divide all constraints by $|\mathcal{P}|$. For ease of exposition, we do not replace each variable with a new variable, which is simply the old variable divided by $|\mathcal{P}|$. Instead, we simply use the same variable names.

We use the constraints we obtained by the preceding discussion and lemmas. That is, we use the constraints obtained from Lemma 16, Lemma 17, Lemma 18, Lemma 19, and constraints that we naturally obtained from the definitions of the variables. Additionally, we simplify the constraints on the optimum solution value as follows. From Lemma 16 we get $\text{opt}_C \geq 2|\mathcal{P}| - \sum_{i\geq 1} \omega_i$. Furthermore, by definition, we have $\omega_0 + \sum_{i=1}^{n} 2i \cdot \omega_i = 2$ (recall that we divide all numbers by $|\mathcal{P}|$). Since in all the constraints we used there is no other bound on γ_3, both inequalities can be simplified to $\text{opt}_C \geq 2 - \omega_1 - \omega_2 - \omega_3$ and $\omega_0 + 2\omega_1 + 4\omega_2 + 6\omega_3 \leq 2$. We then get the following polyhedron.

$$
\begin{aligned}
\text{opt}_C &\geq 2 - \omega_1 - \omega_2 - \omega_3 \\
\text{cost}(H) &\geq \rho \cdot \text{opt}_C \\
\text{cost}(H) &\leq 3 - \frac{5}{4}\alpha_1 - \alpha_2 + \frac{1}{4}\alpha_0^e + \frac{1}{2}\varepsilon' \\
\text{cost}(H) &\leq 3 - \frac{5}{4}\beta_1 - \beta_2 + \frac{1}{4}\beta_0^e + \frac{1}{2}\varepsilon' \\
\text{cost}(H) &\leq 3 - \frac{5}{4}\gamma_1 - \gamma_2 + \frac{1}{4}\gamma_0^e + \frac{1}{2}\varepsilon' \\
2 &\geq \omega_0 + 2\omega_1 + 4\omega_2 + 6\omega_3 \\
\alpha_1 &\geq \omega_1, \beta_1, \gamma_1 \\
\alpha_1 &\geq \omega_1 + \alpha_1^0 \\
\alpha_1 &\geq \omega_1 + \beta_1^0 \\
\beta_1 &\geq \omega_1 \\
\alpha_1 &\geq \alpha_0^e \\
\beta_1 &\geq \beta_0^e \\
\gamma_1 &\geq \gamma_0^e \\
\omega_0 &\geq \beta_0^e \\
\alpha_1 &= \alpha_1^0 + \alpha_1^1 + \alpha_1^2 \\
\beta_1 &= \beta_1^0 + \beta_1^1 + \beta_1^2 \\
\alpha_2 &\geq \frac{3}{5+\varepsilon} \cdot (\omega_2 - 2\alpha_1^0 - \alpha_1^1) \\
\beta_2 &\geq \frac{3}{5+\varepsilon} \cdot (\omega_2 - 2\beta_1^0 - \beta_1^1) \\
\gamma_1 + \gamma_2 &\geq \frac{3}{5+\varepsilon} \cdot (\omega_1 + \omega_2) \\
\omega_0, \omega_1, \omega_2, \omega_3 &\geq 0 \\
\alpha_0^e, \alpha_1, \alpha_1^0, \alpha_1^1, \alpha_1^2, \alpha_2 &\geq 0 \\
\beta_0^e, \beta_1, \beta_1^0, \beta_1^1, \beta_1^2, \beta_2 &\geq 0 \\
\gamma_0^e, \gamma_1, \gamma_1^0, \gamma_1^1, \gamma_1^2, \gamma_2 &\geq 0 \ .
\end{aligned}
$$

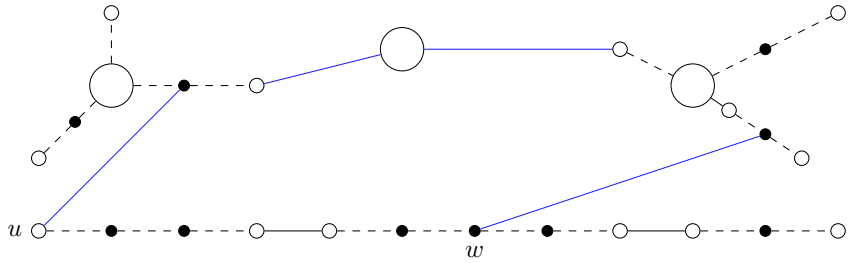

Figure 4 Example for the bridge-covering process: a pseudo-ear covering the witness path from u to w. H consists of the dashed edges (in $E(\mathcal{P})$) and solid black edges (links of H). Filled vertices are interior vertices of paths from $\mathcal{P}$, empty vertices are endvertices of paths in $\mathcal{P}$. The big circles represent 2EC blocks or components. The blue edges form a pseudo-ear Q^{uw} from u to w. All bridges, vertices and blocks on the path from u to w in H will be in a 2EC block in $H \cup Q^{uw}$.

By plugging this into a standard solver and setting $\rho \geq 1.9412$, $\varepsilon \leq 0.001$ and $\varepsilon' \leq 0.0001$, we obtain that the polyhedron is empty and hence we obtain the result. ◀

5 Bridge-Covering

After computing a good starting solution, our next goal is to ensure that the current partial solution $H = (V, E(\mathcal{P}) \cup S)$ is bridgeless. This process, called *bridge-covering*, eliminates all bridges in H while preserving Invariants 6-8. In particular, we show the following lemma.

▶ **Lemma 21.** *Let G be some structured instance of* PAP *and $H = (V, E(\mathcal{P}) \cup S)$ be a solution satisfying the Invariants 6-8. In polynomial time we can compute a solution $H' = (V, E(\mathcal{P}) \cup S')$ that satisfies Invariants 6-8 and contains no bridges.*

Throughout this section we assume that H contains some complex component C (a component that contains bridges), as otherwise the lemma holds trivially. We prove Lemma 21 by showing that we can iteratively turn H into a solution H' such that H' also satisfies the Invariants 6-8 and additionally H' contains fewer bridges than H (except for one case that we need for technical reasons). Applying this procedure exhaustively proves Lemma 21.

Intuitively, as long as our current solution H contains complex components, i.e., it contains bridges, our goal is to add certain links to H in order to "cover" the bridges and, at the same time, maintain the Invariants 6-8. To do so, it will be convenient to add so-called pseudo-ears to H, defined as follows. Similar definitions have been used in [8] and [23].

▶ **Definition 22** (Pseudo-ear and Witness Path)**.** *Let C be a complex component of H and $u, v \in V(C)$ be distinct vertices in G_C. A* pseudo-ear *Q^{uv} from u to v is a simple path in G_C that starts in u and ends in v and does not visit any vertex of C except u and v. The unique path W^{uv} from u to v in H_C is called the* witness path *of Q^{uv}. Note that the edges of W^{uv} are bridges of C.*

An example for a pseudo-ear is given in Figure 4. We first show that a pseudo-ear Q^{uv} can be found in polynomial time, if one exists. Furthermore, pseudo-ears are useful in the following sense. If, for some pseudo-ear Q^{uv}, its witness path W^{uv} contains "enough" credit, e.g., if W^{uv} contains 2 block-nodes, 2 lonely vertices, or a lonely vertex or block node and 2 bridges from $H \cap L$, then we can add Q^{uv} to H to obtain the graph H'. Afterward, H' is a graph that contains fewer bridges than H, the number of connected components in H' is at most the number of connected components in H, and H' satisfies all invariants.

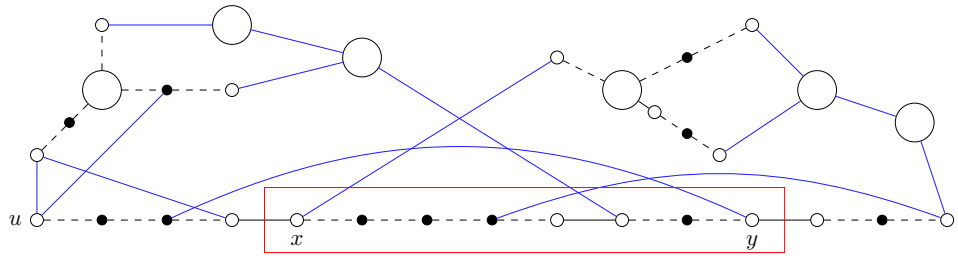

Figure 5 No witness path of a pseudo-ear starting in u contains 2 bridges of $H \cap L$. Note that the two paths P_1 and P_2 containing x and y (vertices in red box), respectively, form a separator in G (in fact, a P^2-separator).

Using pseudo-ears, we then show that in polynomial time we can find link sets $R \subseteq L \setminus S$ and $F \subseteq S$, such that $(H \cup R) \setminus F$ has fewer bridges than H and also satisfies all invariants. This then proves Lemma 21. It is crucial for this step that G is structured: We usually argue that G must have a desired pseudo-ear, as otherwise the absence of it implies that G is not structured, a contradiction.

We give an intuition for how we use structured graphs to prove Lemma 21 (see also Figure 5): If from a lonely leaf vertex u (or a leaf block node) there exists a pseudo-ear such that its witness path contains at least one other leaf vertex, one block node, or 2 bridges in L, then we can add this pseudo-ear to H, and we reduced the number of bridges while satisfying all invariants, as desired. Otherwise, if there exists no such pseudo-ear, then this complex component C must look locally like a path. Furthermore, the absence of this pseudo-ear implies that in C there must be two paths $P_1, P_2 \in \mathcal{P}$ such that $V(P_1) \cup V(P_2)$ is a separator in G. However, since C locally looks like a path, there is a link e in C connecting one endvertex of P_1 with one endvertex of P_2 in C. But then P_1 and P_2 together with e form a P^2-separator, which is a contradiction to G being structured (Property (P4)). Thus, there must be a desired pseudo-ear, which we can find in polynomial time, and hence we make progress. This is the whole intuition for proving Lemma 21. However, there are many corner cases that we have to deal with, which makes the proof a bit lengthy.

6 Gluing Algorithm

After the bridge-covering step, the graph $H = (V, P \cup S)$ consists of multiple 2-edge-connected components that remain disconnected from each other. The final step of our algorithm, called *gluing*, ensures that these components are merged into a single 2-edge-connected graph while maintaining the approximation guarantee. We show the following.

▶ **Lemma 23.** *Let G be some structured instance of* PAP *and $H = (V, E(\mathcal{P}) \cup S)$ be a solution satisfying the Invariants 6-8 that contains no bridges. In polynomial time we can compute a solution $H' = (V, E(\mathcal{P}) \cup S')$ satisfying the Invariants 6-8 such that H' is a 2-edge-connected spanning subgraph.*

Throughout this section we are given a solution S such that $H = (V, E(\mathcal{P}) \cup S)$ consists of several 2-edge-connected components, and each component contains at least the vertex set of two distinct paths $P, P' \in \mathcal{P}$. According to the credit scheme (Part (E)), each component has a credit of 2 if it is large, or it is small and contains a degenerate path. Otherwise, if it is small and not degenerate, it has a credit of $\frac{3}{2}$. Recall that a 2EC component is small if it contains exactly 2 links.

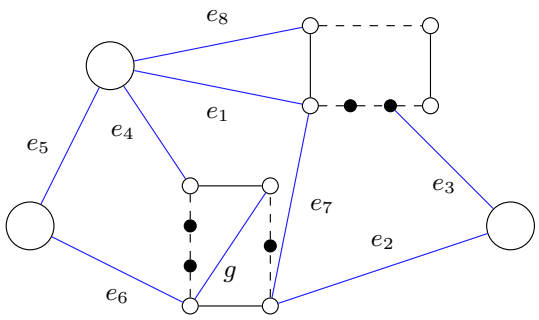

Figure 6 Example for the gluing algorithm and a good cycle. The bridgeless 2-edge-cover consists of large components (big circles) and small components (short cycles). H consists of the dashed edges (in $E(\mathcal{P})$) and solid black edges (links of H). Blue edges are edges in $E(G) \setminus E(H)$. The cycle $e_4e_5e_6$ is a good cycle in the component graph as it contains 2 large components. The cycle $e_4e_1e_7$ is also a good cycle as it shortcuts a small component using the Hamiltonian path through g.

Our approach here is to find *good* cycles in the component graph $G^{\text{comp}}(H)$, that is, the graph arising from G by contracting each 2-edge-connected component of H to a single vertex. Adding cycles from the component graph to H reduces the number of components and does not introduce any bridges. By iteratively adding such cycles, we eventually end up with a single 2-edge-connected component, and we are done.

Good cycles are cycles that either contain 2 components with credit 2 each, or a small component that can be *shortcut*. A small component C can be shortcut w.r.t. a cycle K of $G^{\text{comp}}(H)$ if we can replace $E(C)$ by a Hamiltonian path $Q \subseteq G[V(C)]$ such that $|Q \cap L| < |E(C) \cap L|$ and the vertices of C that are incident to K are the endvertices of Q. If a good cycle contains a shortcut, we then update H to $H' = (H \setminus E(C)) \cup K \cup Q$ and refer to this operation as *augmenting* H with K. Two examples of good cycles can be found in Figure 6. We then show that 1) augmenting H with a good cycle results in a graph with fewer components that is bridgeless and satisfies all invariants, 2) we can find good cycles in polynomial time if one exists, and 3) the component graph of a structured graph always admits a good cycle. This then proves Lemma 23. To prove 3), we use that G is structured: We show that every small component that does not contain a degenerate path is incident to 2 edges in G that can be used to construct a shortcut. Furthermore, since G is structured and contains no C^2-separator, these 2 edges are contained in some cycle in the component graph $G^{\text{comp}}(H)$, which we can find in polynomial time.

7 Proof of Theorem 1

Theorem 1 now easily follows from Lemmas 5-23.

Proof of Theorem 1. For structured graphs G, we first use Lemma 9 to compute a solution S such that $H = (V, E(\mathcal{P}) \cup S)$ satisfies Invariants 6-8. Lemma 21 now guarantees that we can transform H into a solution H' that is bridgeless and satisfies Invariants 6-8. Finally, Lemma 23 ensures that we can obtain in polynomial time a 2-edge-connected spanning subgraph $H'' = (V, E(\mathcal{P}) \cup S'')$ satisfying Invariants 6-8. In particular, H'' is a feasible solution and satisfies $\text{cost}(H'') = |S''| + \text{credits}(H'') \leq 1.9412 \cdot \text{opt}$. Since $\text{credits}(H'') \geq 0$, we have $|S''| \leq 1.9412 \cdot \text{opt}$, implying that our algorithm is a polynomial-time 1.9412-approximation for structured graphs. Finally, Lemma 5 then guarantees that this leads to a $(1.9412 + \varepsilon)$-approximation for arbitrary instances of bounded-length PAP. However,

we mention here that the guarantee of 1.9412 from Lemma 9 has some slack, and hence we can choose ε small enough (still constant) so that we have a 1.9412-approximation for bounded-length PAP. ◀

8 Conclusion and Future Work

In this paper we designed a 1.9412-approximation for the Path Augmentation problem, where the length of each path is bounded. We established several key ingredients: (1) a $(\frac{11}{6}+\varepsilon)$-approximation preserving reduction to structured instances of bounded-length PAP; (2) a new relaxation of the problem together with a related packing problem, which we used to obtain a good starting solution using a factor-revealing LP; (3) leveraging concepts of other connectivity augmentation problems to turn the starting solution into a feasible solution.

There might be room for improvement, in particular in bounding the cost of the starting solution. Obtaining a better bound on the cost of the starting solution, while still maintaining the credit invariants, directly gives an improved approximation ratio for bounded-length PAP. However, to improve the approximation ratio below $\frac{11}{6}$ requires new insights.

We emphasize that the requirement of bounded-length instances of PAP is only needed for the reduction to structured graphs; the remaining parts of the algorithm also work for unbounded-length PAP as long as the input is structured. Hence, it would be nice to see if this assumption can be dropped without any loss in the approximation guarantee.

Abstract

We study generalizations of the classical Vertex Cover and Edge Cover problems that incorporate group-wise coverage.

Our first focus is the Capacitated Partition Vertex Cover (C-PVC) problem in hypergraphs. In C-PVC, we are given a hypergraph with capacities on its vertices and a partition of the hyperedge set into ω distinct groups. The objective is to select a minimum size subset of vertices that satisfies two main conditions: (1) in each group, the total number of covered hyperedges meets a specified threshold, and (2) the number of hyperedges assigned to any vertex respects its capacity constraint. A covered hyperedge is required to be assigned to a selected vertex that belongs to the hyperedge. This formulation generalizes classical Vertex Cover, Partial Vertex Cover, and Partition Vertex Cover.

We investigate two primary variants: soft capacitated (multiple copies of a vertex are allowed) and hard capacitated (each vertex can be chosen at most once). Let f denote the rank of the hypergraph (i.e., the maximum number of vertices contained in any single hyperedge). Our main contributions are: (i) an $(f+1)$-approximation algorithm for the weighted soft-capacitated C-PVC problem, which runs in polynomial time for constant ω, and (ii) an $(f+\epsilon)$-approximation algorithm for the unweighted hard-capacitated C-PVC problem, which runs in $n^{O(\omega/\epsilon)}$ time.

We also study a natural generalization of the edge cover problem, the *Weighted Partition Edge Cover* (W-PEC) problem, where each edge has an associated weight, and the vertex set is partitioned into groups. For each group, the goal is to cover at least a specified number of vertices using incident edges, while minimizing the total weight of the selected edges. We present the first exact polynomial-time algorithm for the weighted case, improving runtime from $O(\omega n^3)$ to $O(mn + n^2 \log n)$ and simplifying the algorithmic structure over prior unweighted approaches (that rely on the tropical matching problem).

1 Introduction

The classical *Vertex Cover* (VC) problem in graphs is defined as follows: given a graph $G = (V, E)$ with weights on the vertices, find a minimum size subset of vertices S so that every edge of the graph is covered, in other words, at least one of its end points is in S. This

extremely simple problem has a rich history. It was one of the earliest problems shown to be NP-complete by Karp [30] and was shown to have a polynomial time solution when the graph is bipartite. On the hardness side, [31] assumes the Unique Games Conjecture and shows that Vertex Cover is hard to approximate within a factor $(2-\epsilon)$ for every $\epsilon > 0$. Gavril [22] showed that a simple algorithm that takes all the vertices of any maximal matching is a 2-approximation (because the cardinality of any maximal matching is a lower bound on the optimal solution size). Subsequently, this simple algorithm was extended to weighted[1] graphs as well, but this required significantly deeper understanding of the role played by linear programming (LP) relaxations [24] and finally a simple combinatorial algorithm was developed based on LP duality [6]. This problem also paved the way for improvements and the well known local ratio technique [7] that found numerous applications. In addition, approximation algorithms easily follow from the work of Nemhauser and Trotter who showed that an optimal LP solution has a very simple structure [35]. In the Fixed Parameter Tractability arena, again Vertex Cover has played a crucial role in the understanding of kernelization and efficient algorithms.

Several extensions of VC have been studied. One major direction introduces capacities on vertices, leading to the *Capacitated Vertex Cover* (CVC) problem. Here, each selected vertex may cover only a limited number of incident edges. In this problem, a key distinction arises between *soft capacities* (where multiple copies of a vertex can be purchased) and *hard capacities* (where each vertex is chosen at most once). For soft capacities, Guha et al.[23] first introduced the problem and provided a 2-approximation using a primal-dual algorithm; another 2-approximation using dependent randomized rounding was later given by Gandhi et al. [20]. Notably, these results often hold for the weighted setting where vertices have costs. The hard capacity variant (VC-HC) presents significantly more challenges. Chuzhoy and Naor [12] initiated its study, giving a 3-approximation for the unweighted version on simple graphs. Crucially, they also showed that the weighted version of VC-HC is at least as hard as Set Cover, which is NP-hard to approximate within a factor of $(1-\epsilon)\ln n$ for every $\epsilon > 0$ [16]. Focusing on the unweighted VC-HC, Gandhi et al. [21] improved the approximation to a tight 2. When generalizing these problems to hypergraphs, approximation guarantees typically depend on the maximum size of a hyperedge. Let f denote the rank of the hypergraph, defined as the maximum number of vertices contained in any single hyperedge. A hypergraph whose rank is bounded by f is commonly referred to as an f-hypergraph. For f-hypergraphs, Saha and Khuller [36] provided the first $O(f)$-approximation (specifically $\min\{6f, 65\}$). Cheung, Goemans, and Wong [11] then improved the bounds to $2f$ using a deterministic two-stage LP rounding approach. The gap was finally closed to a tight f-approximation for unweighted VC-HC on f-hypergraphs, achieved independently by Kao [28] and Wong [37], using iterative rounding techniques.

A separate parallel line of work relaxes the requirement to cover all edges. *Partial Vertex Cover* asks to cover at least a specified number of edges [10, 5, 21]. A further generalization is *Partition Vertex Cover* (PVC), where the edge set is partitioned into ω groups, the solution must cover a specified minimum number of edges from each group. PVC was introduced by Bera et al. [9], who obtained an $O(\log \omega)$-approximation via a strengthened LP with exponentially many constraints. They also proved that the problem is at least as hard as Set Cover when ω is unbounded. For f-hypergraphs, Hong and Kao [25] obtained a $(f+1)\log \omega$ approximation for the uncapacitated PVC problem. This is particularly relevant as the techniques in Bera et al. for graphs do not extend naturally to hypergraphs.

[1] Every vertex has a weight and the aim is to find a minimum weighted subset of vertices.

For constant ω, and unweighted graphs, Bandyapadhyay et al. [3] gave a $(2+\epsilon)$-approximation in time $n^{O(\omega/\epsilon)}$, later improved to the weighted case with running time $n^{O(\omega)}$ independently by Liu and Li [32] and Dabas et al. [13].

Combining both dimensions - vertex capacities and partition-based coverage - yields richer and significantly more challenging models. While Partial VC with capacities has been investigated[2], these methods fail when coverage requirements are partitioned across multiple groups. In this paper, we close this gap by introducing the *Capacitated Partition Vertex Cover* (C-PVC) problem, which unifies the capacitated and partition variants of the Vertex Cover problem. We study the problem in the general setting of hypergraphs.

Beyond theoretical generalization, C-PVC provides a framework for fair resource allocation in systems where demands can be served by multiple potential providers. For example, companies like Amazon solve a massive "Capacitated Coverage" problem to assign specific fulfillment centers to zip codes for same-day delivery. In 2016, Bloomberg published an investigation showing that Amazon's Prime Free Same-Day Delivery excluded predominantly Black neighborhoods (like Roxbury in Boston and the Bronx in New York) while covering the white neighborhoods surrounding them [26]. Similar fairness concerns arise in urban mobility, where car-sharing fleets are often concentrated in high-income and advantaged zones, failing to improve accessibility in underserved communities [15]. The direct applicability of the C-PVC framework stems from the fact that these resource allocation challenges are naturally modeled as Hypergraph Vertex Cover problems rather than simple graph problems. C-PVC formulation addresses equity by enforcing a coverage threshold ρ_g for each group ensuring that every demographic/geographic sector receives a minimum standard of service.

▶ **Definition 1** (Capacitated Partition Vertex Cover (C-PVC)). *We are given a hypergraph $H=(V,E)$, where $f=\max_{e\in E}|e|$ is the rank of the hypergraph. We are also given, a vertex weight function $w: V\to\mathbb{R}_{\geq 0}$, a vertex capacity function $k: V\to\mathbb{Z}^+$, a partition of the hyperedge set $E=E_1\cup E_2\cup\cdots\cup E_\omega$, and a coverage requirement (threshold) $\rho_g\in\mathbb{Z}^+$ for each group E_g.*

We denote the capacity of a vertex v by k_v and its weight by w_v. A feasible solution consists of a set of integer copy counts $\{x_v\}_{v\in V}$ (where $x_v\in\mathbb{Z}_{\geq 0}$) and an assignment $\varphi: E'\to V$ for a subset of covered edges $E'\subseteq E$, satisfying:

1. ***Valid Assignment:*** *For every edge $e\in E'$, the assigned vertex must be in the edge, i.e., $\varphi(e)\in e$.*
2. ***Capacity Constraint:*** *The number of edges assigned to any vertex v is at most its total capacity:*

$$|\{e\in E' \mid \varphi(e)=v\}|\leq x_v\cdot k_v \quad \forall v\in V$$

3. ***Partition Constraint:*** *For each group $g\in[\omega]$, the number of covered edges from that group meets its threshold:*

$$|E'\cap E_g|\geq \rho_g$$

The objective is to find a feasible solution that minimizes $\sum_{v\in V} x_v\cdot w_v$. We refer to this as the soft-capacitated variant. The hard-capacitated variant adds the constraint that $x_v\in\{0,1\}$ for all $v\in V$.

[2] For hard capacities, Kao et al [29] give an f-approximation using iterative rounding. For soft capacities, Bar-Yehuda et al [8] give an f-approximation using the local ratio method and Mestre [34] gives a 2-approximation using a primal-dual algorithm.

In this work, we present two algorithms for the C-PVC problem. We obtain an $(f+1)$-approximation for the soft-capacitated weighted case.(Theorem 2) and an $(f+\epsilon)$-approximation for the hard-capacitated unweighted case (Theorem 3). Both algorithms run in polynomial time with respect to n and m but exhibit exponential dependence on ω, which yields an efficient polynomial-time solution when the number of groups ω is constant. This dependence on ω is consistent with previous work on partition-constrained problems. While the exact problem is known to be $W[1]$-hard parameterized by the number of groups ω (which rules out exact FPT algorithms), the existence of an FPT approximation algorithm parameterized by ω remains an intriguing open question.

For the weighted variant of the hard-capacitated case, Chuzhoy and Naor [12] showed a hardness of $\Omega(\log n)$ of any poly-time approximation. Briefly, we can give the same upper bound for Hard C-PVC. Let H be a hypergraph of rank f. For each group $g \in [\omega]$, add one vertex v_g with capacity $|E_g| - \rho_g$ (the allowed number of uncovered edges of that group) and $w_{v_g} = 0$. For each hyperedge $e \in E_g$, add v_g to e. Now, we can solve a full-coverage instance of weighted vertex cover with hard capacities on hypergraph H' with rank $f+1$ using Chuzhoy and Naor's approximation algorithm for hypergraph vertex cover. This[3] will give an approximation with factor $O(\log(n+\omega)) = O(\log(n))$ for constant ω. For this reason, we only consider the unweighted variant of Hard C-PVC.

▶ **Theorem 2.** *There exists a $(f+1)$-factor approximation algorithm for the* Soft Capacitated Weighted Partition Vertex Cover *problem that runs in polynomial time for constant ω.*

▶ **Theorem 3.** *For any fixed $\epsilon > 0$, there exists an $(f+\epsilon)$-factor approximation algorithm for the* Hard Capacitated Unweighted Partition Vertex Cover *problem that runs in time $n^{O(\omega/\epsilon)}$.*

While the vertex cover problem focuses on selecting a subset of vertices to cover all edges, a natural dual problem is the *edge cover* problem. In this variant, the goal is to select a subset of edges such that every vertex is incident to at least one selected edge. Although structurally similar to vertex cover, the edge cover problem has very different algorithmic properties—it can be solved in polynomial time via reductions to maximum matching—and it arises in applications such as network design and resource allocation.

In this paper, we study a natural generalization of the edge cover problem called the *Partition Edge Cover* (Partition-EC) problem which is defined as follows.

▶ **Definition 4** (Weighted Partition-EC)**.** *We are given a graph $G = (V, E)$ with a weight function $p : E \to \mathbb{R}_{\geq 0}$, a partition of the vertex set $V = V_1 \cup \cdots \cup V_\omega$, and a parameter ρ_g for each group. We want to find a minimum-weight subset of edges such that at least ρ_g vertices from group V_g are covered.*

Bandyapadhyay et al. [4] studied this problem in the unweighted setting and gave an exact polynomial-time algorithm with a runtime of $O(\omega n^3)$. Their approach first reduces the problem to *Budgeted Matching*, which is then reduced to *Tropical Matching*, allowing the use of known algorithms for the latter to obtain an optimal solution.

In this work, we present a simpler algorithm with improved running time (Theorem 5). Our algorithm avoids the use of tropical matching and runs in time $O(mn + n^2 \log n)$. Moreover, our approach naturally extends to the more general *weighted* setting, where edges have arbitrary non-negative weights.

[3] This does not generalize to soft capacities, since we could pick unlimited copies of these additional zero weight vertices.

▶ **Theorem 5.** *The Weighted Partition Edge Cover problem can be solved exactly in* $O(mn + n^2 \log n)$ *time.*

Related Work. The closely related k-center problem has also been well studied in the partition framework. The first algorithm was proposed by Bandyapadhyay et al. [4], providing a polynomial time 2-approximation while allowing $k+\omega$ centers. A subsequent result by Anegg et al. [1] eliminated the violation in cardinality of centers and obtained a 4-approximation in time $O(n^\omega)$, which was later improved to a 3-approximation in time $O(n^{\omega^2})$ by Jia et al. [27]. The same framework for facility location and k-median objectives has also been studied; see, for example, Dabas et al. [14], Bajpai et. al. [2], and the references therein.

Organization of the paper. The remainder of the paper is organized as follows. We highlight the technical challenges and key ideas used to achieve our results in Section 1.1. Sections 2 and 3 present the $(f+1)$-approximation and $(f+\epsilon)$-approximation algorithms for soft and hard capacitated PVC, respectively. In Section 4, we describe the algorithm for W-PEC. Proofs marked by (†) are deferred to the Appendix.

1.1 Technical Challenges and Key Ideas

Covering problems are extensively studied, but partial versions of these questions (that require coverage of a given number of elements) make the problems much harder and significant new ideas and techniques were required to obtain approximation algorithms for Facility Location, k-median, k-center, Vertex Cover, etc. Despite the seemingly "small" generalization from $\omega = 1$ to $\omega > 1$, the problems again become much harder. For example, for the k-center problem with outliers, there is a simple greedy algorithm with a factor 3 and a simple LP rounding algorithm with a factor 2. As mentioned in the related work, the problem for $\omega > 1$ is considerably more involved; the best approximation factor of 3 requires a very high run time of $O(n^{\omega^2})$.

The same situation also arises for Vertex Cover, where for $\omega = 1$ there is basically no fundamental difference between full coverage and partial coverage and a matching bound of 2 can be obtained. But for $\omega > 1$ there is still no combinatorial algorithm that gives a $O(1)$ bound.

Soft C-PVC. For the soft-capacitated variant, the main challenge is managing fractional values in the LP relaxation while respecting the lower bound threshold for each group. Our algorithm first transforms an optimal fractional solution so that edge coverage is handled either by an already rounded high vertex or by a unique low vertex. We then formulate a configuration LP to handle low vertices. A configuration for a low vertex records, for each group g, how many edges of E_g are served by one copy of that vertex (therefore has one block of variables for each low vertex) and ω coverage constraints. The key insight here is that this configuration LP has at most ω fractional vertex blocks. We round one copy for each fractional block and retain its fractional configuration mixture - a max-flow computation determines the actual edge assignments. In the weighted case, we control the additive cost of the at most ω rounded blocks by guessing the ω most expensive relevant vertices. Our approach also eliminates the enumerative step for the unweighted case, thereby removing the running time's dependence on ϵ present in Bandyapadhyay et al. [3]. While this $(f+1)$ ratio is higher than the graph-specific $(2+\epsilon)$ ratio in prior work, the removal of $1/\epsilon$ from the exponent of the runtime is a significant algorithmic simplification and efficiency gain, particularly for the weighted case.

Hard C-PVC. Our algorithm uses an iterative rounding algorithm to fix vertices and assignments with large fractional values in each iteration. A final enumeration handles the remaining small solution space. This structure matches the known tight techniques for hard-capacitated hypergraph VC [37] but the core technical difficulty stems from integrating the ω partition constraints into the iterative rounding framework. The algorithm in Wong [37] crucially rely on a *counting argument* applied to the final LP's extreme point solution. This argument bounds the cost of rounding the remaining "small" fractional vertices by bounding their total number. However, introducing ω new partition constraints fundamentally alters the structure of this extreme point, as these ω constraints can also be tight. This breaks the standard counting argument. Our key technical contribution is a modified iterative algorithm that demonstrates that the number of remaining fractional variables is bounded by a function of ω. We then manage this remaining set via a final enumeration step, yielding an $(f + \epsilon)$-approximation algorithm whose runtime depends exponentially on ω.

Weighted Partition-EC. Prior work by Bandyapadhyay et al. [4] for the unweighted setting relied on a reduction to *Tropical Matching*. A major challenge is that it is not clear whether the tropical matching-based approach can be extended to handle weighted instances, and the existing method requires heavy algorithmic machinery. We circumvent this by identifying a simpler structure that allows us to avoid tropical matching entirely. By reducing the problem to a simpler matching formulation, we are able to handle arbitrary weights and significantly improve the runtime to $O(mn + n^2 \log n)$.

2 Soft-Capacitated Weighted Partition Vertex Cover

We first present an integer program for the SC-PVC problem. Note that we add an upper bound of m on the multiplicity x_v, since any vertex v has $k_v \geq 1$ and $|\delta(v)| \leq m$.

$$\begin{aligned}
\text{minimize} \quad & \sum_{v \in V} w_v x_v && && \text{(IP-SC)}\\
\text{subject to} \quad & \sum_{v \in e} y_{e,v} \leq 1 && \forall e \in E\\
& \sum_{e \in E_g} \left(\sum_{v \in e} y_{e,v} \right) \geq \rho_g && \forall g \in \{1, \ldots, \omega\}\\
& \sum_{e \in \delta(v)} y_{e,v} \leq k_v x_v && \forall v \in V\\
& 0 \leq y_{e,v} \leq x_v && \forall v \in e \in E\\
& x_v \in \{0, 1, \ldots, m\} && \forall v \in V\\
& y_{e,v} \in \{0, 1\} && \forall v \in e \in E
\end{aligned}$$

We will say that an integral solution is *feasible* if we have an integral multiplicity x_v for each vertex and an assignment function $\varphi : E \to V \cup \{\perp\}$ such that $|\{e \in E_g : \varphi(e) \neq \perp\}| \geq \rho_g$ for all $g \in [\omega]$ and $|\{e \in \delta(v) : \varphi(e) = v\}| \leq k_v x_v$.

We only need x to be integral in a feasible solution $\langle x, y \rangle$ in order to find a fully integral solution. The following lemma is utilized in several prior works on capacitated vertex cover and involves a simple reduction to a network flow problem.

▶ **Lemma 6** (†). *Let $\langle x, y \rangle$ be a feasible solution to the linear relaxation of IP-SC such that x is integral. In polynomial time, we can compute an integral solution $\hat{y}$ such that $\langle x, \hat{y} \rangle$ is feasible.*

2.1 The Residual LP

We now partition the vertex set and generate a modified instance of the problem.

- Let $M \subseteq V$ with $|M| = \omega$. For each $v \in M$, let m_v be a fixed integer multiplicity.
- Define $R = \{v \in V \setminus M : w_v \leq \min_{v \in M} w_v\}$.
- Define $Z = V \setminus (M \cup R)$.

We now give a modified linear program for each choice of M and guessed multiplicty for nodes in M. Denote its value by $\mathrm{OPT}_{\mathrm{res}}(M)$.

Our guessing step separates the expensive part of the solution from the residual rounding problem. If the optimal solution uses at most ω vertices, we can enumerate to find the exact solution. We may therefore assume that the optimal solution uses more than ω distinct vertices. In this case, we guess the set M of ω highest weight vertices and their multiplicities. Under the correct guess, every remaining optimal vertex is no more expensive than the least expensive guessed vertex, so we may safely exclude all more expensive unguessed vertices. Later, the guessed vertices also provide the budget for a set of rounded fractional vertices.

$$\begin{aligned}
\text{minimize} \quad & \sum_{v \in R} w_v x_v && && \text{(LP-RES}_{\mathrm{M}}\text{)} \\
\text{subject to} \quad & \sum_{v \in e} y_{e,v} \leq 1 && \forall e \in E \\
& \sum_{e \in E_g} \left(\sum_{v \in e} y_{e,v} \right) \geq \rho_g && \forall g \in \{1, \ldots, \omega\} \\
& \sum_{e \in \delta(v)} y_{e,v} \leq k_v x_v && \forall v \in V \\
& 0 \leq y_{e,v} \leq x_v && \forall v \in e \in E \\
& 0 \leq x_v \leq m && \forall v \in R \\
& x_v = m_v && \forall v \in M \\
& x_v = 0 && \forall v \in Z
\end{aligned}$$

For ease of notation, we will use $c_e := \sum_{v \in e} y_{e,v}$ to refer to the coverage of an edge.

▶ **Observation 7.** *Let* OPT^I *be the value of the optimal integral solution to IP-SC. There exists a set* $M \subseteq V$ *with selected multiplicites* $\{m_v\}_{v \in M}$ *such that the resulting* LP-RES$_{\mathrm{M}}$ *has integral solution of value* $\mathrm{OPT}^I_{\mathrm{res}}(M)$ *with*

$$\mathrm{OPT}^I_{\mathrm{res}}(M) + \sum_{v \in M} w_v m_v = \mathrm{OPT}^I .$$

The proof of the following lemma is somewhat technical and deferred to Subsection 2.3.

▶ **Lemma 8.** *For any feasible solution* $\langle x, y \rangle$ *to* LP-RES$_{\mathrm{M}}$*, we can construct a feasible solution* $\langle \hat{x}, \hat{y} \rangle$ *such that* $\hat{x}$ *is integral and has the following properties:*

1. *for vertices in* M*,*
$$\sum_{v \in M} w_v \hat{x}_v \leq f \sum_{v \in M} w_v x_v;$$
2. *for the vertices involved in* LP-RES$_{\mathrm{M}}$*,*
$$\sum_{v \in R} w_v \hat{x}_v \leq (f+1)\,\mathrm{OPT}_{\mathrm{res}}(M) + \sum_{v \in F} w_v,$$
where $F \subseteq R$ *with* $|F| \leq \omega$*.*

In order to complete the proof of Theorem 2, we need to show how the correct choice of $M \subseteq V$ eliminates the term $\sum_{v \in F} w_v$. Recall that for all $v \in F \subseteq R$ and all $v_j \in M$, $w_v \leq w_{v_j}$. By combining this with Observation 7, we get

$$\begin{aligned}
\sum_{v \in V} w_v \hat{x}_v &= \sum_{v \in M} w_v \hat{x}_v + \sum_{v \in R} w_v \hat{x}_v \\
&\leq f \sum_{v \in M} w_v m_v + (f+1)\,\mathrm{OPT}_{\mathrm{res}}(M) + \sum_{v \in F} w_v \\
&\leq f \sum_{v \in M} w_v m_v + (f+1)\left(\mathrm{OPT}^I - \sum_{v \in M} w_v m_v\right) + \sum_{v \in F} w_v \\
&= (f+1)\,\mathrm{OPT}^I + f \sum_{v \in M} w_v m_v - (f+1) \sum_{v \in M} w_v m_v + \sum_{v \in F} w_v \\
&= (f+1)\,\mathrm{OPT}^I - \sum_{v \in M} w_v m_v + \sum_{v \in F} w_v \\
&\leq (f+1)\,\mathrm{OPT}^I .
\end{aligned}$$

Thus our rounded solution, which is feasible with respect to both group and capacity constraints, exceeds the integral optimal solution by a factor of no more than $f+1$. There are $n^{O(\omega)}$ possible sets M, and each set has m^ω different sets of multiplicities. After checking all possibilities, we output the lowest-cost feasible solution; since this is the correct guess, its cost is bounded by Theorem 2.

Before we prove Lemma 8, we first describe a rounding scheme starting from the solution to LP-RES$_{\mathrm{M}}$.

2.2 The Rounding Scheme

We give a partition of V:

- $H := M \cup \left\{v \in R : x_v \geq \frac{1}{f+1}\right\}$
- $L := \left\{v \in R : 0 < x_v < \frac{1}{f+1}\right\}$

Any vertices with $x_v = 0$ are disregarded, and we set $\hat{x}_v = 0$. Now, we round the edge variables. If any edge is such that all vertices have $\hat{x}_v = 0$, that edge cannot be covered. For simplicity, we will remove such edges from consideration going forward (these will remain uncovered). For each $v \in L$, create an empty set L_v. Some edges may include vertices that are already rounded to 0. For clarity, let $L' = L \cup \{v \in V : \hat{x}_v = 0\}$.

The next step preserves the total coverage c_e of every edge. It only moves this coverage between endpoints such that the coverage of each edge is partitioned between vertices in H or given to one unique vertex in L.

1. $e \cap L' = \emptyset$: all coverage is handled by vertices in H. Set $\hat{y}_{e,v} = y_{e,v}$ for all $v \in e$.
2. $e \cap H = \emptyset$: all coverage is handled by vertices in L. Let $v_\ell = \arg\max_{v \in e \cap L} y_{e,v}$. Set $\hat{y}_{e,v_\ell} = c_e$ and $\hat{y}_{e,v} = 0 \;\forall\; v \in e \setminus v_\ell$. Add e to L_{v_ℓ}.
3. $e \cap H, e \cap L \neq \emptyset$: coverage is distributed between vertices in L and vertices in H.
   a. If $y_{e,v_\ell} \geq \frac{c_e}{f+1}$, let $v_\ell = \arg\max_{v \in e \cap L} y_{e,v}$. Set $\hat{y}_{e,v_\ell} = c_e$ and $\hat{y}_{e,v} = 0$ for all other $v \in e$. Add e to L_{v_ℓ}.
   b. Otherwise, let $c_e^\ell = \sum_{v \in e \cap L} y_{e,v}$ and $c_e^h = \sum_{v \in e \cap H} y_{e,v}$. Then, $\hat{y}_{e,v} = y_{e,v} + \frac{y_{e,v}}{c_e^h} c_e^\ell$ for $v \in e \cap H$ and $\hat{y}_{e,v} = 0$ for $v \in e \cap L$.

Note that, in case (3), if an endpoint in L is above the threshold $\frac{c_e}{f+1}$, it can absorb the entire edge with an $(f+1)$-fold increase; otherwise, the coverage provided by all endpoints in L is proportionately transfered to the endpoints in H. Therefore, the threshold is carefully chosen to work for both cases. Also observe that the sets L_v are disjoint, meaning that each edge has no more than one $v \in L$ that is responsible for its coverage. For now, we only round $v \in H$: $\hat{x}_v = \left\lceil \frac{f+1}{2} x_v \right\rceil$.

▶ **Lemma 9** (†). *For all $v \in H$,*

$$\sum_{e \in \delta(v)} \hat{y}_{e,v} \leq \frac{f+1}{2} k_v x_v \leq k_v \hat{x}_v.$$

Moreover, if $v \in H \cap R$, $\hat{x}_v \leq (f+1)x_v$, and if $v \in M$, $\hat{x}_v \leq f \cdot x_v$.

We are now covering some subset of edges in each group. For $g \in [\omega]$,

$$h_g := \sum_{v \in H} \sum_{e \in \delta(v) \cap E_g} \hat{y}_{e,v}.$$

In Lemma 9, we showed that the rounded multiplicities $\tilde{x}_v$ for $v \in H$ can cover all rounded fractional edges that they are responsible for. Now, we have to open some vertices in L to cover the remaining $\rho_g - h_g$ edges of each group.

2.3 The Configuration LP

Our final task is to round the vertices in L. For these vertices, we will only consider whether or not we will open one copy of each vertex. For $v \in L$ and $g \in [\omega]$, let $N_{v,g} = E_g \cap L_v$ be the set of edges of group g that v is responsible for, and let $\eta_{v,g} = |N_{v,g}|$.

Since each L_v is disjoint, some vertex v covering some edge $e \in L_v$ has no bearing on whether another vertex v' can cover some edge $e' \in L_{v'}$, even if v and v' are adjacent. Therefore, we consider the following question: if we were to open one copy of v, how many different ways could v cover up to k_v edges in L_v? With this framing, we simplify the remaining problem by rendering edges of the same group in each L_v indistinguishable.

A feasible configuration for a vertex $v \in L$ is a vector $A = (A_1, \ldots, A_\omega) \in \mathbb{Z}^\omega_{\geq 0}$ with $A_g \leq \eta_{v,g}$ for all $g \in [\omega]$ and $\sum_{g=1}^{\omega} A_g \leq k_v$. The coordinate A_g records how many owned edges of group g are served by one copy. The bounds $A_g \leq \eta_{v,g}$ and $\sum_g A_g \leq k_v$ enforce edge availability and capacity, respectively. Let $\mathcal{A}_v$ be the set of all feasible configurations for $v \in L$. We now solve this configuration LP:

$$\text{minimize} \quad \sum_{v \in L} w_v \sum_{A \in \mathcal{A}_v \setminus \mathbf{0}} \lambda_{v,A} \qquad \text{(LP-CONFIG)}$$

$$\text{subject to} \quad \sum_{A \in \mathcal{A}_v} \lambda_{v,A} = 1 \qquad \forall v \in L \qquad (1)$$

$$\sum_{v \in L} \sum_{A \in \mathcal{A}_v} A_g \lambda_{v,A} \geq \rho_g - h_g \qquad \forall g \in \{1, \ldots, \omega\} \qquad (2)$$

$$\lambda_{v,A} \geq 0 \qquad \forall v \in L, A \in \mathcal{A}_v$$

We consider the zero configuration $\mathbf{0}$ to mean that the vertex is not chosen, so each $\lambda_{v,\mathbf{0}}$ does not contribute to the cost.

We first need to connect the solution of LP-CONFIG to the solution of LP-RES$_{\text{M}}$ restricted to the vertices in L. In order to do this, we will construct a feasible solution to LP-CONFIG using the solution $\langle x, y \rangle$ restricted to vertices in L and edges in $\bigcup_{v \in L} L_v$ and the rounding scheme described in Subsection 2.2.

▶ **Lemma 10.** *LP-CONFIG has a feasible solution of cost no more than* $(f+1)\sum_{v\in L} w_v x_v$.

Proof. We start by considering the edges in the sets L_v for each $v \in L$. If an edge was rounded using case (2), we have

$$\hat{y}_{e,v} = c_e \leq f \cdot y_{e,v} \leq (f+1)x_v.$$

If it was rounded using case (3a), v must be such that $y_{e,v} \geq \frac{c_e}{f+1}$, so

$$\hat{y}_{e,v} = c_e \leq (f+1)y_{e,v} \leq (f+1)x_v.$$

We also observe that, because L contains only vertices with $x_v < \frac{1}{f+1}$, we must have $(f+1)x_v < 1$. Finally, by summing over edges in L_v, we have

$$\sum_{e\in L_v} c_e \leq (f+1)\sum_{e\in L_v} y_{e,v} \leq (f+1)k_v x_v$$

from the feasibility of the LP solution. This implies that

$$\sum_{e\in L_v} \frac{c_e}{(f+1)x_v} \leq k_v.$$

Consider the following set of vectors:

$$\mathcal{P}(d,k) = \left\{z \in \mathbb{R}^d : 0 \leq \|z\|_\infty \leq 1, \|z\|_1 \leq k\right\}.$$

This defines a concave set with integral extremal points. Assume that we ordered the edges of L_v. Then, the vector

$$z_v = \left(\frac{c_{e_1}}{(f+1)x_v}, \frac{c_{e_2}}{(f+1)x_v}, \dots\right)$$

is contained within $\mathcal{P}(|L_v|, k_v)$. Let $\mathcal{S}_v = \{S \subseteq L_v : |S| \leq k_v\}$. We can now use the set of indicators $\mathbf{1}_S$ of $S \in \mathcal{S}_v$ as a basis for z_v. Write $z_v = \sum_{S\in\mathcal{S}_v} \zeta_{v,S}\mathbf{1}_S$ for $\sum_{S\in\mathcal{S}_v} \zeta_{v,S} = 1$.

Next, we want to move from the vectors $\mathbf{1}_S$ to feasible edge configurations. Define the projection $\pi_v : \mathbb{R}^{|L_v|} \to \mathbb{R}^\omega$ such that column g is $\mathbf{1}_{N_{v,g}}$. Each $\pi_v\mathbf{1}_S$ is a feasible edge configuration. For each $A \in \mathcal{A}_v \setminus \mathbf{0}$, let $S_A = \{S \in \mathcal{S}_v : \pi_v S = A\}$. Define $\lambda_{v,A} = (f+1)x_v \sum_{S\in S_A} \zeta_{v,S}$ and $\lambda_{v,\mathbf{0}} = 1 - \sum_{A\neq\mathbf{0}} \lambda_{v,A}$. Therefore, λ satisfies the constraints (1).

Now, we look at the constraints (2). For one edge, $\sum_{S\ni e} \zeta_{v,S} = \frac{c_e}{(f+1)x_v}$. We know that the edges are sufficiently covered in the rounded solution, so

$$\begin{aligned}
\sum_{v\in L}\sum_{A\in\mathcal{A}_v} A_g\lambda_{v,A} &= \sum_{v\in L}\sum_{A\in\mathcal{A}_v} A_g \sum_{S\in S_A} \zeta_{v,S}(f+1)x_v \\
&= \sum_{v\in L}(f+1)x_v \sum_{S\in\mathcal{S}} \mathbf{1}_{N_{v,g}} \cdot \mathbf{1}_S \zeta_{v,S} \\
&= \sum_{v\in L}\sum_{S\in\mathcal{S}_v}\sum_{e\in S\cap N_{v,g}} (f+1)x_v\zeta_{v,S} \\
&= \sum_{v\in L}(f+1)x_v \sum_{e\in N_{v,g}}\sum_{S\ni e} \zeta_{v,S} \\
&= \sum_{v\in L}(f+1)x_v \sum_{e\in N_{v,g}} \frac{c_e}{(f+1)x_v} \\
&= \sum_{v\in L}\sum_{e\in N_{v,g}} c_e \geq \rho_g - h_g
\end{aligned}$$

Now that the projection defines a feasible solution to LP-CONFIG, we need to show that the objective function value is bounded:

$$\begin{aligned}\sum_{v\in L} w_v \sum_{A\in\mathcal{A}_v\setminus\mathbf{0}} \lambda_{v,A} &= \sum_{v\in L} w_v \sum_{A\in\mathcal{A}_v\setminus\mathbf{0}} (f+1)x_v \sum_{S\in S_A} \zeta_{v,S} \\ &= \sum_{v\in L} w_v(f+1)x_v \sum_{S\in\mathcal{S}\setminus\mathbf{0}} \zeta_{v,S} \\ &\le (f+1)\sum_{v\in L} w_v x_v.\end{aligned}$$

◀

Let $F \subseteq L$ be the set of vertices with fractional $\lambda_{v,A}$. While we also want to open this set of vertices, bounding the cost is made difficult by the lack of an integral configuration.

▶ **Lemma 11.** *Any optimal basic feasible solution λ to LP-CONFIG has $|F| \le \omega$.*

Proof. We start by turning constraints (2) into equalities. Our new LP is

$$\begin{aligned}\text{minimize} \quad & \sum_{v\in L} w_v \sum_{A\in\mathcal{A}_v\setminus\{0\}} \lambda_{v,A} && \\ \text{subject to} \quad & \sum_{A\in\mathcal{A}_v} \lambda_{v,A} = 1 && \forall v \in L \\ & \sum_{v\in L}\sum_{A\in\mathcal{A}} A_g\lambda_{v,A} = \rho_g - h_g + s_g && \forall g \in \{1,\dots,\omega\} \\ & \lambda_{v,A} \ge 0 && \forall v \in L, A \in \mathcal{A}_v \\ & s_g \ge 0 && \forall g \in \{1,\dots,\omega\}\end{aligned}$$

A solution to this LP has up to $|L|+\omega$ non-tight variables, meaning that up to $|L|+\omega$ of the variables $\lambda_{v,A}$ and s_g are positive. Constraints (1) ensures that at least one $\lambda_{v,A}$ per $v \in L$ is positive, and at least $|L|-\omega$ of those constraints has only one positive $\lambda_{v,A}$, so up to ω of these constraints can have fractional $\lambda_{v,A}$. ◀

We now have the machinery to prove Lemma 8. Recall the statement:

▶ **Lemma 8.** *For any feasible solution $\langle x, y\rangle$ to* LP-RES$_{\text{M}}$*, we can construct a feasible solution $\langle \hat{x}, \hat{y}\rangle$ such that $\hat{x}$ is integral and has the following properties:*

1. *for vertices in M,*

$$\sum_{v\in M} w_v\hat{x}_v \le f\sum_{v\in M} w_v x_v;$$

2. *for the vertices involved in* LP-RES$_{\text{M}}$*,*

$$\sum_{v\in R} w_v\hat{x}_v \le (f+1)\,\text{OPT}_{\text{res}}(M) + \sum_{v\in F} w_v,$$

where $F \subseteq R$ with $|F| \le \omega$.

Proof. For each $v \in L$, if $\lambda_{v,\mathbf{0}} = 1$, set $\hat{x}_v = 0$ and $\hat{y}_{e,v} = 0$ for all $e \in L_v$. Otherwise, set $\hat{x}_v = 1$. If $v \notin F$, there is one integral edge configuration. Select a set $N(A)$ consisting of A_g edges from each $N_{v,g}$, and set $\hat{y}_{e,v} = \mathbf{1}_{e\in N(A)}$. If $v \in F$, let $\mathcal{F}_v = \{A \in \mathcal{A}_v : \lambda_{v,A}\} > 0$. For each configuration $A \in \mathcal{F}_v$, define a set of edges $N(A)$. Then, set $\hat{y}_{e,v} = \sum_{A\in\mathcal{F}_v} \lambda_{v,A}\mathbf{1}_{e\in N(A)}$.

Since the solution λ is feasible for LP-CONFIG,

$$\sum_{v\in L}\sum_{e\in N_{v,g}}\hat{y}_{e,v} = \sum_{v\in L\setminus F}\sum_{e\in N_{v,g}}\mathbf{1}_{e\in N(A)} + \sum_{v\in F}\sum_{A\in\mathcal{F}_v}\sum_{e\in N_{v,g}}\lambda_{v,A}\mathbf{1}_{e\in N(A)}$$
$$= \sum_{v\in L}A_g + \sum_{v\in F}\sum_{A\in\mathcal{F}_v}\sum_{e\in N_{v,g}}\lambda_{v,A}A_g \geq \rho_g - h_g,$$

since the L_v are disjoint and no edge can be double-counted. Moreover, if $v \in L \setminus F$,

$$\sum_{e\in\delta(v)}\hat{y}_{e,v} = \sum_{g=1}^{\omega}A_g \leq k_v = k_v\hat{x}_v.$$

If $v \in F$,

$$\sum_{e\in\delta(v)}\hat{y}_{e,v} = \sum_{e\in\delta(v)}\sum_{A\in\mathcal{F}_v}\lambda_{v,A}\mathbf{1}_{e\in N(A)} = \sum_{e\in\delta(v)}\sum_{A\in\mathcal{F}_v}\lambda_{v,A}A_g \leq k_v = k_v\hat{x}_v.$$

From Lemma 9, the vertices in H respect the capacity constraints. Thus, we can conclude that $\langle\tilde{x},\tilde{y}\rangle$ over all $v \in L \cup H$ satisfies both the group and capacity constraints. We now bound the cost of the rounded vertices. We use Lemma 9. For part (1), we can sum over the bound on $\hat{x}_v$ for all vertices in M. For part (2),

$$\sum_{v\in R\cap H}w_v\hat{x}_v \leq (f+1)\sum_{v\in R\cap H}w_vx_v.$$

From Lemma 10,

$$\sum_{v\in L}w_v\hat{x}_v \leq (f+1)\sum_{v\in L}w_vx_v + \sum_{v\in F}w_v.$$

By combining these statements, we have

$$\sum_{v\in R}w_v\hat{x}_v \leq (f+1)\sum_{v\in R}w_vx_v + \sum_{v\in F}w_v = (f+1)\,\mathrm{OPT}_{\mathrm{res}}(M) + \sum_{v\in F}w_v,$$

which concludes the proof of Lemma 8. ◀

2.4 The Full Algorithm

We end this section with an overview of the algorithm and a discussion of the runtime.

1. Enumerate through every set of vertices of size at most ω and every integral multiplicity from 1 to m. If any set is feasible, take the cheapest feasible set. Otherwise, continue to the main algorithm. There are $(|V|+|E|)^{O(\omega)}$ such sets.
2. For every set $M \subseteq V$ with $|M| \leq \omega$ and every integral multiplicity from 1 to m, solve LP-RES$_{\mathrm{M}}$. There are $(|V|+|E|)^{O(\omega)}$ such sets.
   a. Round the solution using Lemma 9.
   b. Solve LP-CONFIG for the vertices in L. The LP has up to $|V|(|E|+1)^{\omega}$ variables and $|V|+\omega$ constraints.
   c. Round the fractional vertices using Lemmas 10 and 11.
   d. Continue with the lowest-cost feasible solution, which corresponds to the correct guess of M.
3. Find an integral edge assignment using Lemma 6. The network has $O(|V|+|E|+\omega)$ nodes and $O(|V|+|E|+\omega)$ arcs.

Each step requires time that is polynomial in the $|V|+|E|$, and we repeat each step a number of times that is polynomial in $|V|+|E|$. Since ω is assumed to be constant, the overall algorithm is polynomial in $|V|+|E|$. Note that this runtime is independent of the hyperedge size f. This completes the proof of Theorem 2.

3 Hard Capacitated Unweighted Partition Vertex Cover

In this section, we study the Hard Capacitated Unweighted Partition Vertex Cover problem in hypergraphs using iterative rounding. Before detailing the iterative steps, we define the LP relaxation using fractional vertex variables x and assignment variables y. These variables are constrained to satisfy the partition thresholds and vertex capacities while ensuring that no edge assignment exceeds the fractional status of its endpoints. This formulation minimizes the total fractional vertex count, establishing a baseline solution that informs the subsequent rounding iterations. The integer program closely resembles IP-SC, so we will not restate it. The formal relaxation is presented below:

$$\text{minimize} \quad \sum_{v \in V} x_v$$

subject to:

$$\sum_{v \in e} y_{e,v} \leq 1 \qquad \forall e \in E$$

$$\sum_{e \in E_g} \left(\sum_{v \in e} y_{e,v} \right) \geq \rho_g \qquad \forall g \in \{1, \ldots, \omega\}$$

$$y_{e,v} \leq x_v \qquad \forall v \in e \in E$$

$$\sum_{e \in \delta(v)} y_{e,v} \leq k_v x_v \qquad \forall v \in V$$

$$0 \leq x_v \leq 1 \qquad \forall v \in V$$

$$y_{e,v} \geq 0 \qquad \forall v \in e \in E$$

It is sufficient to find an integral solution for x; an integral assignment y can then be found efficiently via a max-flow computation. Our algorithm therefore focuses on finding an integral x with a bounded cost.

3.1 Algorithm

Our algorithm is based on an iterative rounding framework. The core idea is to repeatedly solve an LP relaxation, fix a subset of variables to integral values based on the solution, and then re-solve a smaller, updated LP on the remaining problem. This process is guided by a dynamic LP formulation that adapts to the decisions made in each step (see LP-IP).

We maintain several sets for the iterative rounding algorithm. Let D be the set of vertices whose final integral counts have been determined, and let T_v^g denote the set of edges of group g that have been definitively assigned to vertex v. We define $T = \bigcup_{v \in V} \bigcup_{g=1}^{\omega} T_v^g$ as the set of all covered edges. Based on the fractional solution from the previous step, we partition the remaining undecided vertices into two groups: $U = \{v \in V \setminus D \mid x_v^* \geq 1/f\}$, which contains vertices with high fractional values, and $W = \{v \in V \setminus D \mid 0 < x_v^* < 1/f\}$, which contains those with low fractional values. U is further divided into $U_> = \{v \in V \setminus D \mid x_v^* > 1/f\}$ and $U_= = \{v \in V \setminus D \mid x_v^* = 1/f\}$. Let $Z = \{v \in V \setminus D \mid x_v^* = 0\}$. Initially the sets T and D are empty.

$$\text{minimize} \quad \sum_{v \in V \setminus D} x_v \tag{LP-IP}$$

subject to:

$$\sum_{v \in e \setminus D} y_{e,v} \leq 1 - \sum_{v' \in e \cap D} \bar{y}_{e,v'} \qquad \forall e \in E \setminus T$$

$$\sum_{e \in E_g \setminus T} \sum_{v \in e \setminus D} y_{e,v} \geq \rho_g - \sum_{v \in V} |T_v^g| - \sum_{e \in E_g \setminus T} \left(\sum_{v' \in e \cap D} \bar{y}_{e,v'} \right) \qquad g \in \{1, \ldots, \omega\}$$

$$y_{e,v} \leq x_v \qquad \forall e \in E \setminus T, v \in e \setminus D$$

$$\sum_{e \in \delta(v) \setminus T} y_{e,v} \leq \left(k_v - \sum_{g \in \omega} |T_v^g| \right) x_v \qquad \forall v \in U_>$$

$$\sum_{e \in \delta(v) \setminus T} y_{e,v} \leq k_v x_v \qquad \forall v \in W$$

$$1/f \leq x_v \leq 1 \qquad \forall v \in U_>$$

$$0 \leq x_v \leq 1/f \qquad \forall v \in W$$

$$y_{e,v} \geq 0 \qquad \forall e \in E \setminus T, v \in e \setminus D$$

Note that there is no capacity constraint included for vertices in $U_=$ within LP-IP. This is because any vertex u entering $U_=$ is immediately processed by the algorithm (its value is fixed to $\bar{x}_u = 1$ and it is moved to the decided set D). Thus, it is no longer an active variable in the updated LP over $V \setminus D$, and omitting it does not cause the feasible region to grow. The complete iterative rounding framework is detailed in Algorithm 1. It formalizes the process of identifying which variables to fix, updating the problem state, and iterating until a fully integral solution is found.

Note that when a tight edge is found and permanently assigned (Lines 8-11), we intentionally do not fix x_u to 1. The variable x_u remains active and fractional in the updated LP so its residual capacity can be utilized for other incident edges, and to prevent a premature increase in the LP objective. Since $u \in U$, Lemma 6 guarantees its fractional value remains at least $1/f$, ensuring it will be safely rounded to 1 at the end of the algorithm.

3.2 Analysis

▶ **Lemma 12.** *Suppose a vertex u satisfies $x_u^* \geq 1/f$ at some iteration. Then $x_u^* \geq 1/f$ in all subsequent iterations as long as $u \notin D$. Consequently, the final integral value $\bar{x}_u$ will be at least 1.*

Proof. When $x_u^* \geq 1/f$, the vertex u is placed in the set U. We consider two cases based on its value.

- If $x_u^* = 1/f$, then $u \in U_=$. In the same iteration, the algorithm adds u to the set of decided vertices D and fixes its final integral value as $\bar{x}_u = 1$.
- If $x_u^* > 1/f$, then $u \in U_>$. For all subsequent iterations where u remains an undecided variable, the updated LP-IR includes the explicit constraint $x_u \geq 1/f$. This ensures its fractional value cannot drop below $1/f$.

Algorithm 1 Iterative Rounding Algorithm

Solve the initial LP Relaxation to get an extreme point solution $\langle x^*, y^* \rangle$.
$T_v^g \leftarrow \emptyset$ for all $v \in V$ (which implicitly sets $T = \emptyset$), $g \in \{1, \ldots, \omega\}$ and $D \leftarrow \emptyset$.
Initialize $U, U_>, U_=, W, Z$ based on $\langle x^*, y^* \rangle$.
repeat
  for $v \in Z$ **do** ▷ Handle zero-valued vertices
    Set $\bar{x}_v \leftarrow 0$.
    $D \leftarrow D \cup \{v\}$.
  end for
  if $y^*_{e,u} = x^*_u$ for some $u \in U$ and $e \in \delta(u) \setminus T$ **then** ▷ Assign tight edges
    Set $\bar{y}_{e,u} \leftarrow 1$, and $\bar{y}_{e,v} \leftarrow 0$ for $v \in e \setminus \{u\}$.
    $T_u^g \leftarrow T_u^g \cup \{e\}$ **for** $e \in E_g$.
  end if
  for $u \in U_=$ **do** ▷ Handle boundary-valued vertices
    Set $\bar{x}_u \leftarrow 1$.
    Set $\bar{y}_{e,u} \leftarrow y^*_{e,u}$ **for** $e \in \delta(u) \setminus T$. ▷ Fix edge assignments
    $D \leftarrow D \cup \{u\}$.
  end for
  Solve the updated LP-IR for a new solution $\langle x^*, y^* \rangle$.
  Update $U, U_>, U_=, W, Z$ based on the new $\langle x^*, y^* \rangle$.
until $U_= = \emptyset$ and $Z = \emptyset$ and no tight edges are found
for $v \notin D$ **do** ▷ Final rounding step
  Set $\bar{x}_v \leftarrow \lceil x^*_v \rceil$.
end for
return integral solution $\bar{x}$.

Eventually, either u enters $U_=$ (and is rounded to $\bar{x}_u = 1$) or the algorithm terminates with $u \notin D$. In the latter case, it is rounded up in the final step, yielding $\bar{x}_u = \lceil x^*_u \rceil \geq \lceil 1/f \rceil = 1$. In all possible outcomes, if u ever enters U, its final value $\bar{x}_u$ is at least 1. ◀

▶ **Lemma 13.** *The solution $\bar{x}$ returned by the algorithm is a feasible integral solution to the problem.*

Proof. The final solution $\bar{x}$ is integral by construction. Variables are set to integer values (0 or 1) during the loop, and the final step applies the ceiling function.

Next, the initial LP ensures that the group coverage ρ_g is satisfied fractionally. As the algorithm fixes variables and assigns edges to T, it reduces the coverage requirement for subsequent LPs. The final LP solution $\langle x^*, y^* \rangle$ satisfies the remaining coverage fractionally. The final rounding step, $\bar{x}_v = \lceil x^*_v \rceil$, only increases the available capacity, which means at least as many edges can be covered as in the fractional solution. Thus, the integral solution meets or exceeds the fractional coverage and satisfies all group coverage requirements.

Finally, we consider capacity constraints for each group of vertices:

- **For vertices in $U_>$:** The capacity used by any "tight" edges is explicitly subtracted and budgeted for in later steps. When the remaining vertices are rounded up, the new integer capacity is always greater than or equal to the fractional capacity required by the LP solution ($k_u \lceil x^*_u \rceil \geq k_u x^*_u$), ensuring the constraint holds.
- **For vertices in $U_=$:** When a vertex is rounded from $1/f$ to 1, the LP guarantees that its fractional edge assignments required a capacity of at most $(k_u - \sum_{g \in [\omega]} |T_u^g|)/f$. This is well within the newly allocated integer capacity of $(k_u - \sum_{g \in [\omega]} |T_u^g|)$, so the assignment is valid.
- **For vertices in W:** At the end of the algorithm, these vertices are rounded up from a value less than $1/f$ to 1. The LP solution's required capacity was less than the final integer capacity ($k_w x^*_w < k_w \cdot 1$), so the final assignment is feasible. ◀

▶ **Lemma 14.** *Let $\langle x^*, y^* \rangle$ be the extreme point solution upon which the algorithm terminates. $|W| \leq |U_1| + \omega$ where $U_1 = \{u \in U : x^*_u = 1\}$.*

Proof. The proof is by a counting argument on the variables and constraints of the final LP-IR. As an extreme point solution, it is uniquely defined by a system of linear equations formed by setting a subset of the LP's inequality constraints to be tight. A fundamental property of such solutions is that the number of variables must equal the number of linearly independent tight constraints.

At termination, the set of undecided vertices is $V \setminus D = U_> \cup W$. The algorithm's termination conditions ensure that for any $u \in U_>$, we have $x^*_u > 1/f$ and $y^*_{e,u} < x^*_u$. For any $w \in W$, we have $0 < x^*_w < 1/f$.

The variables in the final LP are the $\{x_v\}$ for undecided vertices and the associated $\{y_{e,v}\}$ assignment variables. The total number of variables is

$$|U_>| + |W| + \sum_{e \in E \setminus T} |e \setminus D| = |U_>| + |W| + \sum_{e \in E \setminus T} |e \cap U_>| + \sum_{e \in E \setminus T} |e \cap W|.$$

Next, we establish an upper bound on the number of linearly independent constraints that can be tight. For the **partition constraints**, **capacity constraints for $U_>$:**, and **upper bounds $x_u \leq 1$:** at most ω, $|U_>|$, and $|U_1|$ constraints can be tight.

The **constraints involving W vertices** include the capacity constraint for each $w \in W$ ($\sum y_{e,w} \leq k_w x_w$), the coupling constraints ($y_{e,w} \leq x_w$), and the non-negativity constraints ($y_{e,w} \geq 0$). The maximum number of constraints from this group is limited for two reasons. First, for any specific edge e, the constraints $y_{e,w} \geq 0$ and $y_{e,w} \leq x_w$ cannot both be tight simultaneously. This is because $x^*_w > 0$. Thus, for each edge, at most one of these two boundary constraints can be part of the basis. Second, the entire collection of constraints for vertex w is linearly dependent. For a given vertex w, if the constraints corresponding to $y_{e,w}$ are chosen to be all tight, the tightness of the capacity constraint is a direct consequence and is therefore redundant; it cannot add a new linearly independent equation to the basis. Due to these two properties, the maximum number of independent tight constraints associated with any single vertex w is $|\delta(w) \setminus T|$. Summing over all vertices in W establishes the total contribution of at most

$$\sum_{w \in W} |\delta(w) \setminus T| = \sum_{e \notin T} |e \cap W|$$

constraints to the basis.

Finally, in order to handle the **constraints involving $U_>$ vertices**, we do a per-edge analysis. For each edge $e \in E \setminus T$, we analyze the relationship between its edge coverage constraint and its non-negativity constraints for $U_>$ endpoints. Let C_e be the edge coverage constraint

$$\sum_{v \in e \setminus D} y_{e,v} \leq 1 - \sum_{v' \in e \cap D} \bar{y}_{e,v'},$$

and let $\{N_{e,u}\}$ be the set of non-negativity constraints: $y_{e,u} \geq 0$ for all $u \in e \cap U_>$.

▷ Claim. For any edge e with at least one endpoint in $U_>$, it is impossible for C_e and all constraints in $\{N_{e,u}\}$ to be tight simultaneously.

Proof. Assume for contradiction that for an edge e where $|e \cap U_>| \geq 1$, constraint C_e and all constraints $N_{e,u}$ are tight. The tightness of all $N_{e,u}$ implies $y_{e,u} = 0$ for all $u \in e \cap U_>$.

Thus, the edge's total coverage comes only from W vertices:

$$\sum_{v \in e \setminus D} y_{e,v} = \sum_{w \in e \cap W} y_{e,w}.$$

Since $y_{e,w} < 1/f$ for any $w \in W$, we have a strict upper bound:

$$\sum_{v \in e \setminus D} y_{e,v} < |e \cap W|/f.$$

The tightness of C_e means

$$\sum_{v \in e \setminus D} y_{e,v} = 1 - \sum_{v' \in e \cap D} \bar{y}_{e,v'}.$$

This right-hand side has a lower bound of $|e \setminus D|/f$. Combining these gives

$$|e \setminus D|/f \leq \sum_{v \in e \setminus D} y_{e,v} < |e \cap W|/f.$$

This implies

$$|e \cap U_>| + |e \cap W| < |e \cap W|,$$

which simplifies to $|e \cap U_>| < 0$, a contradiction. ◁

This claim implies that for each edge e, the set of $1 + |e \cap U_>|$ constraints (consisting of C_e and $\{N_{e,u}\}$) are linearly dependent when all are tight. Therefore, at most $|e \cap U_>|$ of them can be chosen for a linearly independent basis. The total number of tight constraints from this group, summed over all edges, is at most $\sum_{e \in E \setminus T} |e \cap U_>|$.

By equating the number of variables to the upper bound on the number of tight, linearly independent constraints, we have:

$$|U_>| + |W| + \sum_{e \in E \setminus T} |e \cap U_>| + \sum_{e \in E \setminus T} |e \cap W| \leq \omega + |U_>| + |U_1| + \sum_{e \in E \setminus T} |e \cap W| + \sum_{e \in E \setminus T} |e \cap U_>|.$$

Canceling the common terms from both sides yields the desired result. ◀

We can now return to the proof of Theorem 3.

▶ **Theorem 3.** *For any fixed $\epsilon > 0$, there exists an $(f+\epsilon)$-factor approximation algorithm for the* Hard Capacitated Unweighted Partition Vertex Cover *problem that runs in time $n^{O(\omega/\epsilon)}$.*

Proof. The feasibility of the integral solution $\bar{x}$ produced by the algorithm is guaranteed by Lemma 13. We now bound its cost.

Let OPT_{LP} be the optimal value of the initial LP relaxation. First, observe that the optimal value of the LP relaxation does not decrease between iterations. When rounding decisions are made in the main loop, the problem is modified by either fixing variables or enforcing stricter inequalities (e.g., $x_v \geq 1/f$ instead of $x_v \geq 0$). Because we shrink the feasible region of a minimization problem, the objective value cannot improve. The cost added to our integral solution during the main loop can be bounded by charging it to the fractional value removed from the LP. Specifically, when $x^*_u \geq 1/f$ is rounded to 1, the cost ratio is at most $1/(1/f) = f$.

Let S_L be the set of vertices finalized during the iterative loop and $S_F = U_> \cup W$ be the set of vertices rounded at the end. An accounting argument based on the above observation shows that the cost from vertices rounded during the loop, $|S_L|$, plus f times the cost of the final LP, $f \cdot \mathrm{OPT}_F$, is at most $f \cdot \mathrm{OPT}_{LP}$.

The cost from the final rounding step is $\mathrm{Cost}(S_F) = \sum_{v \in U_> \cup W} \lceil x^*_v \rceil = |U_>| + |W|$. By Lemma 14, this is bounded by $|U_>| + |U_1| + \omega$. For any $u \in U_>$, we have $1 < f \cdot x^*_u$. This is sufficient to show that, for $f \geq 2$,

$$|U_>| + |U_1| \leq f \cdot \sum_{u \in U_>} x^*_u \leq f \cdot \mathrm{OPT}_F \,.$$

Therefore, the cost of the final step is bounded as

$$\mathrm{Cost}(S_F) = |U_>| + |W| \leq f \cdot \mathrm{OPT}_F + \omega$$

Combining the costs from both phases gives the total cost

$$\mathrm{Cost}(\bar{x}) = |S_L| + \mathrm{Cost}(S_F) \leq |S_L| + f \cdot \mathrm{OPT}_F + \omega$$

Since $|S_L| + f \cdot \mathrm{OPT}_F \leq f \cdot \mathrm{OPT}_{LP}$, we have a solution with a total cost bounded by $f \cdot \mathrm{OPT}_{LP} + \omega$.

We enumerate all possible solutions of size $\kappa = 1, 2, \ldots, \lceil \omega/\epsilon \rceil$. This step takes $n^{O(\omega/\epsilon)}$ time. If a feasible solution is found, the first one encountered must be an optimal solution, since we are checking solution sizes in increasing order, and we are done.

Otherwise, if this process is completed without finding a feasible solution, we know that the optimal integral solution, OPT, has a cost greater than ω/ϵ. In this case, we run our iterative rounding algorithm. By the analysis above, it returns a feasible solution with a cost bounded by

$$\mathrm{Cost}(\bar{x}) \leq f \cdot \mathrm{OPT}_{LP} + \omega$$

Since $\mathrm{OPT}_{LP} \leq \mathrm{OPT}$ and we have established that $\mathrm{OPT} > \omega/\epsilon$, we can bound the cost of our solution as

$$\mathrm{Cost}(\bar{x}) < f \cdot \mathrm{OPT} + \epsilon \cdot \mathrm{OPT} = (f + \epsilon) \cdot \mathrm{OPT} \,.$$

This provides an $(f + \epsilon)$-approximation for the problem. ◀

4 Weighted Partition Edge Cover

We consider the following generalization from [3]:

▶ **Definition 15** (Weighted Budgeted Matching). *We are given a graph $G = (V, E)$ with a weight function $p : E \to \mathbb{R}_{\geq 0}$, a partition of the vertex set $V = V_1 \cup \cdots \cup V_\omega$, and a parameter ρ_g for each group. We want to find a minimum-weight matching such that at least ρ_g vertices from group V_g are matched.*

First, we note that the reduction between Partition-EC and Budgeted Matching in Lemma 5 [3] holds in the weighted case.

▶ **Lemma 16** ([3]). *If Weighted Budgeted Matching can be solved in time $T(n, m)$, then Partition-EC can be solved in time $T(2n, m + n) + O(m + n)$. Here n and m refer to the number of nodes and edges respectively.*

In order to be matched or covered at minimum cost, a vertex will pay for its least expensive adjacent edge, so we can modify the reduction by giving the edge between each vertex and its auxillary vertex this minimum adjacent weight. Moreover, we eliminate the dependence on ω.

Now, we give a simple reduction to the standard problem of finding a maximum weight matching in a graph. This allows us to generalize the problem to weighted graphs, improve the running time, and avoid the reduction to tropical matching completely. Our algorithm also admits the use of standard libraries for weighted matching.

1. Let M be large with $M > \sum_e p_e$.
2. Let H be a copy of G with the following vertex sets added. For each group g add a set V_g' of $|V_g| - \rho_g$ nodes. Add edges between all nodes in V_g' and V_g for each g. The weight of an edge e in H is $2M - p_e$ when $e \in E$, and the weight of an edge (x, y) where $x \in V_g', y \in V_g$ is M. See Figure 1 for an example
3. Find a maximum weight matching $\mathcal{M}_H$ in H using the algorithm by Gabow [17, 18] The matched edges induced by the nodes of G should be a minimum weight matching satisfying the group requirements. If the weight of the maximum weight matching is at most $(n-1)M$ then no solution exists.

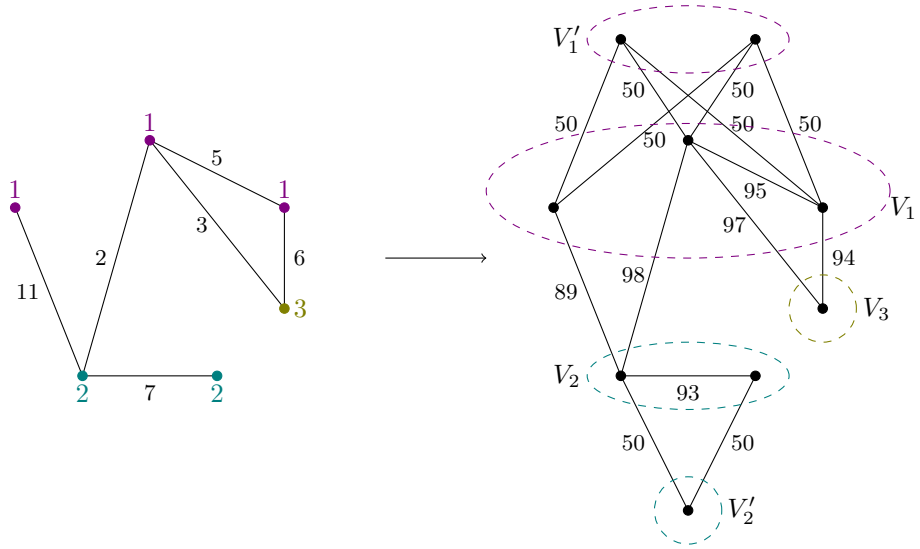

Figure 1 The reduction from Weighted Budgeted Matching to Maximum Matching for an instance with $\rho_1 = \rho_2 = \rho_3 = 1$. Here we let $M = 50$.

▶ **Lemma 17.** *If maximum-weight matching can be solved in time $T(n, m)$, then Weighted Budgeted Matching can be solved in time $T\left(2n, m + n^2\right)$.*

Proof. For each group g we add $\left|V_g'\right| \leq |V_g|$ vertices for a total of at most n additional vertices. We then add a complete bipartite graph with $\left|V_g'\right| \cdot |V_g|$ edges for each color, which totals at most n^2 additional edges. ◀

▶ **Lemma 18** (†). *In $\mathcal{M}_H$, at least ρ_g vertices from each group V_g are matched by edges from G.*

▶ **Lemma 19** (†). *The matching $\mathcal{M} = \mathcal{M}_H \cap E(G)$ with original edge weights has total weight equal to the optimum of the Weighted Budgeted Matching problem.*

To speed up the algorithm, we do a reduction to the problem of finding a max weight subgraph with upper bounds on degrees (f-factor). We contract the set V'_g into a single node V'_g with edges to all vertices in V_g of weight M and give a degree constraint of $|V_g| - \rho_g$ to V'_g. All nodes of V will have a degree constraint of 1. This new graph has only $n + \omega$ vertices, and at most n extra edges, preserving the sparsity of the graph. We now use the algorithm by Gabow [18] (see also [19]) which gives $O(nm + n^2 \log n)$ running time.

Lemmas 16, 17, 18 and 19 together imply Theorem 5.

5 Conclusion

While our algorithm achieves an $(f + \epsilon)$-approximation for the hard-capacitated problem, the algorithm for the weighted soft-capacitated (SC-PVC) variant has an approximation factor of $f+1$. Bridging this gap by designing an f-approximation algorithm for the weighted SC-PVC problem remains an intriguing open question. A natural question is about the dependence on ω in the run-time. Is it possible to derive an f approximation in time $O(f(\omega)n^c)$ so that the dependence on ω in the run-time is not $O(n^\omega)$? We already know that the problem is Set Cover hard for unbounded ω. The same runtime issue arises in the k-center problem as mentioned earlier (in related work).

Another interesting direction for future research is to develop an efficient combinatorial algorithm for the Partition Vertex Cover problem, even in the uncapacitated case. While such primal-dual methods exist for the related Partial Vertex Cover problem [34], developing one for the partition generalization is an open question.

For the distinct but related problem of maximizing edge coverage given a budget on the cardinality of the chosen vertex cover, Marx [33] shows how to obtain an FPT approximation scheme for unweighted simple graphs for $\omega = 1$. It will be interesting to obtain similar results for arbitrary ω.

A Remaining Proofs from Section 2

▶ **Lemma 6** (†). *Let $\langle x, y\rangle$ be a feasible solution to the linear relaxation of IP-SC such that x is integral. In polynomial time, we can compute an integral solution $\hat{y}$ such that $\langle x, \hat{y}\rangle$ is feasible.*

Proof. We present the construction for completeness. Consider the input instance and a solution $\langle x, y\rangle$ with x integral. We construct a network flow instance F. The nodes of F are $s \cup E \cup (V \cup \{U_1, \ldots, U_\omega\}) \cup t$. The source and sink are s and t, respectively. The nodes $U_1, \ldots, U_\omega$ correspond to the uncovered sets for each group. We define the arcs and capacities:

- (s, e) for each $e \in E$ with capacity 1;
- (e, v) for each $v \in e$ with capacity 1;
- (e, U_g) where $e \in E_g$ with capacity 1;
- (v, t) for each $v \in V$ with capacity $k_v x_v$;
- (U_g, t) for each $g = 1, \ldots, \omega$ with capacity $|E_g| - \rho_g$.

We know that $\langle x, y\rangle$ is feasible, so there must be a flow of $|E|$ in F from s to t. The capacity on each arc is integral, so there exists and integral flow of value $|E|$ from s to t. Define $\hat{y}_{e,v} = 1$ (meaning that $\varphi(e) = v$) if the flow (e, v) is 1 and $\hat{y}_{e,v} = 0$ otherwise. If an edge goes unassigned, meaning that the flow from e to U_g is 1, $\varphi(e) = \perp$. Then, $\langle x, \hat{y}\rangle$ is a feasible integral solution. ◀

▶ **Lemma 9** (†). *For all $v \in H$,*

$$\sum_{e \in \delta(v)} \hat{y}_{e,v} \leq \frac{f+1}{2} k_v x_v \leq k_v \hat{x}_v.$$

Moreover, if $v \in H \cap R$, $\hat{x}_v \leq (f+1)x_v$, and if $v \in M$, $\hat{x}_v \leq f \cdot x_v$.

Proof. We only consider vertices affected by rounding cases (1) and (3b). For (1), the value of the edge variable is unchanged. In the case of (3b), we know that for all $v \in e \cap L$, $y_{e,v} < \frac{c_e}{f+1}$. We consider the worst possible case for rounding here. An endpoint in H handles $1 + \frac{c_e^\ell}{c_e^h}$ times more edge coverage, which increases as the mass c_e^ℓ increases. This added responsibility is therefore maximized when the edge contains $f - 1$ endpoints in L and a single endpoint in $v_h \in H$. Hence it suffices to analyze this worst case. Then,

$$\hat{y}_{e,v_h} = c_e = y_{e,v_h} + \sum_{v \in e \cap L} y_{e,v} < y_{e,v_h} + (f-1)\frac{c_e}{f+1}.$$

We can then conclude that

$$\hat{y}_{e,v_h} = c_e < \frac{f+1}{2} y_{e,v_h}.$$

Taking the sum over edges incident to v gives us the first inequality.

Now, we bound $\hat{x}_v$. For $v \in H \cap R$, we consider two cases. If $\frac{1}{f+1} \leq x_v \leq \frac{2}{f+1}$, then

$$\hat{x}_v = \left\lceil \frac{f+1}{2} x_v \right\rceil = 1 \leq (f+1)x_v.$$

Otherwise, we have $x_v > \frac{2}{f+1}$. In that case,

$$\hat{x}_v = \left\lceil \frac{f+1}{2} x_v \right\rceil < \frac{f+1}{2} x_v + 1 < (f+1)x_v.$$

For $v \in M$, $x_v \in \mathbb{N}$. Therefore,

$$\hat{x}_v = \left\lceil \frac{f+1}{2} x_v \right\rceil \leq \lceil f \cdot x_v \rceil = f \cdot x_v.$$

where the first inequality follows simply because $\frac{f+1}{2} \leq f$ for $f \geq 2$ and last equality follows because both f and x_v are integers. ◀

B Remaining Proofs from Section 4

▶ **Lemma 18** (†). *In $\mathcal{M}_H$, at least ρ_g vertices from each group V_g are matched by edges from G.*

Proof. Let $\mathcal{M}^* \subseteq G$ be an optimal solution to the budgeted matching problem. We now construct a matching $\mathcal{M}^*_H$ in H by including all edges from $\mathcal{M}^*$, and for each vertex in V_g not matched in $\mathcal{M}^*$, adding an auxiliary edge to a unique free node in V'_g.

Let k^*_g be the number of vertices in V_g matched by $\mathcal{M}^*$. Since $k^*_g \geq \rho_g$, we have, $|V_g| - k^*_g \leq |V_g| - \rho_g = |V'_g|$, so there are enough auxiliary vertices in V'_g to complete the matching without conflict. Thus, $\mathcal{M}^*_H$ is a feasible matching in H that matches all the vertices in V_g for every g. This also ensures that the cost of the maximum matching in H is strictly greater than $(n-1)M$ since each matched node in V contributes M to the weight of the matching, and even after subtracting the weight of a few edges we have a solution of weight between nM and $(n-1)M$. Any matching that does not match all nodes of G (that also belong to H) cannot have weight larger than $(n-1)M$.

Now consider the maximum weight matching $\mathcal{M}_H$ in H. Suppose, for contradiction, that $\mathcal{M}_H$ matches fewer than ρ_g vertices from some group V_g via edges from G. The number of vertices matched by auxiliary edges is at most $|V'_g| = |V_g| - \rho_g$. Therefore, at least one vertex $u \in V_g$ must be unmatched by $\mathcal{M}_H$. Therefore, for large M, $\mathcal{M}^*_H$ is better than $\mathcal{M}_H$, which is a contradiction. ◀

▶ **Lemma 19** (†). *The matching $\mathcal{M} = \mathcal{M}_H \cap E(G)$ with original edge weights has total weight equal to the optimum of the Weighted Budgeted Matching problem.*

Proof. We assume $n = |V|$ is even. This is perfectly fine because the reduction from Partition Edge Cover in Lemma 15 yields a Budgeted Matching instance with exactly $2n$ vertices, ensuring it is always an even-size instance. Let $\mathcal{M}^* \subseteq G$ be an optimal solution to the budgeted matching problem with total weight OPT. As in proof of Lemma 18, we can extend $\mathcal{M}^*$ to a matching $\mathcal{M}^*_H$ in H by adding auxiliary edges of weight M to unmatched vertices in V. Since all $n = |V|$ vertices in V are matched in $\mathcal{M}^*_H$, and exactly $n - 2|\mathcal{M}^*|$ auxiliary edges are used, the total weight of $\mathcal{M}^*_H$ is:

$$\sum_{e \in \mathcal{M}^*_H} p^H_e = \sum_{e \in \mathcal{M}^*} (2M - p_e) + (n - 2|\mathcal{M}^*|)M = nM - \text{OPT}.$$

Let $\mathcal{M}_H$ be a maximum weight matching in H, and let $\mathcal{M} = \mathcal{M}_H \cap E(G)$. Note that $\mathcal{M}_H$ also matches all n vertices in V. Therefore,

$$\sum_{e \in \mathcal{M}_H} p^H_e = \sum_{e \in \mathcal{M}} (2M - p_e) + (n - 2|\mathcal{M}|)M = nM - \sum_{e \in \mathcal{M}} p_e.$$

Since $\mathcal{M}_H$ maximizes the weight,

$$\sum_{e \in \mathcal{M}_H} p^H_e \geq \sum_{e \in \mathcal{M}^*_H} p^H_e \Rightarrow \sum_{e \in \mathcal{M}} p_e \leq \text{OPT}.$$

By Lemma 18, $\mathcal{M}$ is a feasible solution to the budgeted matching problem, so equality must hold and $\mathcal{M}$ is optimal. ◀

A Bad Example for Jain's Iterative Rounding Theorem for the Cover Small Cuts Problem

Abstract

The Cover Small Cuts problem is a key problem in Network Design. In the Cover Small Cuts problem, we are given a capacitated (undirected) graph $G = (V, E, u)$ and a threshold value λ, as well as a set of links L with end-nodes in V and a non-negative cost for each link $\ell \in L$; the goal is to find a minimum-cost set of links such that each non-trivial cut of capacity less than λ is covered by a link.

Jain's iterative rounding theorem is a well-known result in the area of approximation algorithms and, more broadly, in combinatorial optimization. The theorem asserts that LP relaxations of several problems in network design and combinatorial optimization have the following key property: for every basic feasible solution x there exists a variable x_e that has value at least a constant (e.g., $x_e \geq \frac{1}{2}$).

We construct an example showing that this property fails to hold for the standard LP relaxation of the Cover Small Cuts problem. This indicates that the polyhedron of feasible solutions to the LP (for Cover Small Cuts) differs in an essential way from the polyhedrons associated with several problems in combinatorial optimization. Moreover, our example shows that a direct application of Jain's iterative rounding algorithm does not give an $O(1)$ approximation algorithm for Cover Small Cuts.

We mention that Bansal et al. [6] showed that the WGMV primal-dual algorithm, due to Williamson et al. [19], applied to the same standard LP relaxation achieves approximation ratio 16 for the Cover Small Cuts problem. That is, the WGMV primal-dual algorithm, applied to the same LP relaxation, finds an integer solution of cost ≤ 16 times the optimal value of the LP.

1 Introduction

The Cover Small Cuts problem has emerged as a key problem in Network Design since the publication of the first major result in ICALP 2023, see [5, 6]. In the Cover Small Cuts problem, we are given a capacitated (undirected) graph $G = (V, E, u)$ and a threshold value λ, as well as a set of links L with end-nodes in V and a non-negative cost c_ℓ for each link $\ell \in L$; the goal is to find a minimum-cost set of links such that each non-trivial cut of

capacity less than λ is covered by a link. In more detail, a subset $F \subseteq L$ of links is said to *cover* a node-set S if there exists a link $\ell \in F$ with exactly one end-node in S, and the objective is to find a minimum-cost $F \subseteq L$ that covers each nonempty $S \subsetneq V$ such that $u(\delta_E(S)) < \lambda$. Bansal et al. [6] formulated this problem, and they showed that the WGMV primal-dual algorithm, due to Williamson et al. [19], achieves approximation ratio 16 for this problem. Later, Bansal [2, 3] and Nutov [15] proved that the same algorithm achieves approximation ratio 6. Simmons et al. [18, 17] improved the approximation ratio to 5. Recently, Nutov [16] constructed an example of the Cover Small Cuts problem such that the WGMV primal-dual algorithm finds a solution of cost $(5-\epsilon)\text{OPT}$, where OPT denotes the cost of an optimal (integral) solution and $\epsilon > 0$ is an arbitrarily small number. This shows that the 5-approximation analysis of [18, 17] is tight We mention that the same problem is called by other names in the recent literature, e.g., AugSmallCuts [6], Small Cut Augmentation [3], Small Cuts Cover [15], etc.

We may use abbreviations for some standard terms, e.g., we may use Cover Small Cuts as an abbreviation for "the Cover Small Cuts problem".

Given a graph $G = (V, E)$ whose edges have both costs and capacities, a fundamental task in network design is to find a spanning subgraph of minimum cost that satisfies some specified edge-connectivity requirements. *Capacitated network design* refers to the more general (and more challenging) setting where edges have non-uniform capacities. This topic has attracted intense research efforts over the last few years; see below for discussion and citations. In the context of algorithmic research and combinatorial optimization, the Cap-k-ECSS problem sits in the core of capacitated network design. In this problem, we are given an (undirected) graph $G = (V, E)$, where each edge has a non-negative cost and a positive integer capacity, and the algorithmic goal is to find a minimum-cost spanning subgraph such that every non-trivial cut has capacity k or more. Let $n = |V|$ and let u_{min} (respectively, u_{max}) denote the minimum (respectively, maximum) capacity of an edge; assume that $u_{max} \leq k$. One of the earliest approximation algorithms for Cap-k-ECSS is due to Goemans et al. [10], and it achieves an approximation ratio of $\min\{2k, |E|\}$. Over the last three decades, there have been several advances, and the best approximation ratio known is $\min(O(\log n), O(\log(k/u_{min})), k, 2u_{max})$, due to, respectively, Chakrabarty et al. [8], Bansal et al. [4], and Boyd et al. [7]. Let us mention that there are no known hardness results that rule out the possibility of better asymptotic approximation ratios. Most of the advances of this decade on Cap-k-ECSS are based on $O(1)$ approximation algorithms for Cover Small Cuts.

For the benefit of readers who are not familiar with the papers cited above, let us sketch a simple reduction from Cap-k-ECSS to Cover Small Cuts that incurs a multiplicative factor of $\lceil \frac{k}{u_{min}} \rceil$ in the approximation ratio, see [6, section 5] for further details, and see section 1.3 below for our notation. The algorithm is as follows: Initialize the "solution" edge-set F to be the empty set; during the execution of the algorithm, $G_F = (V, F)$ is our current "solution graph." While the minimum capacity of a cut $\delta_F(S)$, $\emptyset \neq S \subsetneq V$, in (V, F) is less than k, run an α-approximation algorithm for Cover Small Cuts with input $G_F = (V, F)$ and with link-set $L := E - F$, to augment all cuts $\delta_F(S)$, $\emptyset \neq S \subsetneq V$, with $u(\delta_F(S)) < k$ and obtain a valid augmentation $F' \subseteq L$. Update F by adding F', that is, $F := F \cup F'$. On exiting the while loop, output the edge-set F. Bansal et al. [6, Theorem 1.3] show that the cost of F is $\leq \alpha \cdot \lceil \frac{k}{u_{min}} \rceil \cdot \text{OPT}$, where OPT denotes the optimal cost for the Cap-k-ECSS instance.

1.1 Jain's iterative rounding method and the f-connectivity problem

Jain's iterative rounding method [12] and its extensions such as iterative relaxation [14] form a key theoretical tool for proving approximation guarantees, as well as characterizing optimal solutions of well-known (poly-time solvable) problems in combinatorial optimization.

Several connectivity augmentation problems can be formulated in a general framework called f-connectivity. In this problem, we are given an undirected graph $G = (V, E)$ on n nodes with nonnegative costs $c \in \mathbb{Q}^E_{\geq 0}$ on the edges and a requirement function $f : 2^V \to \mathbb{Z}_{\geq 0}$ on subsets of nodes. The algorithmic goal is to find an edge-set $J \subseteq E$ with minimum cost $c(J) := \sum_{e \in J} c_e$ such that for all cuts $\delta(S)$, $S \subseteq V$, we have $|\delta(S) \cap J| \geq f(S)$. A function f is called *weakly supermodular* if $f(V) = 0$, and for all $A, B \subseteq V$, either $f(A) + f(B) \leq f(A - B) + f(B - A)$, or $f(A) + f(B) \leq f(A \cap B) + f(A \cup B)$. The following is an LP relaxation for the f-connectivity problem.

$$\begin{aligned} \text{min} \quad & \sum_{e \in E} c_e x_e && && \text{(LP: f-connectivity)} \\ \text{subject to:} \quad & \sum_{e \in E \cap \delta(S)} x_e \geq f(S) && \forall\, S \subset V \\ & 0 \leq x_e \leq 1 && \forall\, e \in E. \end{aligned}$$

Assuming that the function f is weakly supermodular, integral, and has a positive value for some $S \subset V$, Jain [12] presented a 2-approximation algorithm for the f-connectivity problem, based on the following key result.

▶ **Theorem 1** (Jain [12, Theorem 3.1]). *Assume that the function f is weakly supermodular, integral, non-negative and non-zero. Then, in any basic feasible solution x to the LP relaxation, for at least one edge, e, x_e is at least $1/2$.*

The Jain property

For the sake of notational convenience, let us define a particular LP relaxation of a combinatorial problem to have the *Jain property* if there exists a constant c_0 such that every basic feasible solution x of the LP relaxation has an entry x_e such that $x_e \geq 1/c_0$ (i.e., the infinity norm of x is lower-bounded by a constant).

1.2 Our main result: A bad extreme point for the LP relaxation of Cover Small Cuts

We construct an example showing that the Jain property fails to hold for the standard LP relaxation of the Cover Small Cuts problem, and we mention that the WGMV primal-dual algorithm applied to the *same* LP relaxation finds an integer solution of cost $\leq 6 \cdot \text{LP}_{\text{opt}}$. This indicates that the polyhedron of feasible solutions to the LP relaxation (for Cover Small Cuts) differs in an essential way from the polyhedrons associated with several problems in combinatorial optimization. Moreover, our example shows that a direct application of Jain's iterative rounding algorithm does not give an $O(1)$ approximation algorithm for Cover Small Cuts.

Consider an instance $G = (V, E, u)$, λ of the Cover Small Cuts problem. Let $\mathcal{C} = \{\emptyset \neq S \subsetneq V : u(\delta_E(S)) < \lambda\}$. Then we have the following covering LP relaxation of the problem.

$$\begin{aligned} \text{LP}_{\text{opt}} := \min \quad & \sum_{f \in L} c_f x_f && \text{(LP: Cover Small Cuts)} \\ \text{subject to:} \quad & \sum_{f \in L \cap \delta(S)} x_f \geq 1 && \forall\ S \in \mathcal{C} \\ & 0 \leq x_f && \forall\ f \in L. \end{aligned}$$

▶ Remark 2. Let $f_{\text{CSC}} : 2^V \to \{0, 1\}$ be the requirement function for Cover Small Cuts; thus, for $S \subseteq V$, $f_{\text{CSC}}(S) = 1$ iff $S \in \mathcal{C}$. Although f_{CSC} is *not* weakly supermodular, f_{CSC} is a pliable function that satisfies property (γ), see [6] for definitions, and the $O(1)$ approximation analysis of [6] relies on this.

▶ **Theorem 3.** *Let $k \geq 4$ be an even integer. There is an instance of the* Cover Small Cuts *problem $G = (V, E), L, u$ such that the LP relaxation* (LP: Cover Small Cuts) *has a basic feasible solution x^* such that every positive variable of x^* has value $1/k$.*

Discussion and contrast with previous results

Jain's iterative rounding theorem [12] (see Theorem 1 above) asserts that for the LP relaxation of f-connectivity, whenever f is weakly supermodular, every basic feasible solution x has at least one variable $x_e \geq \frac{1}{2}$. This Jain property is the lever behind Jain's 2-approximation algorithm and has been applied widely in network design; see [14] for a comprehensive treatment. A natural question is whether the Jain property extends beyond the weakly supermodular setting, in particular, to LP relaxations of problems with *node-connectivity* requirements. The short answer is no, and the previous literature shows that there are (at least) two distinct reasons.

The first, and fundamental, reason comes from the area of hardness of approximation. Kortsarz, Krauthgamer, and Lee [13] proved that the node-connectivity Survivable Network Design Problem (NC-SNDP) admits no polynomial-time $O(1)$-approximation algorithm unless NP $\subseteq$ DTIME($n^{O(\log \log n)}$). Since the natural LP relaxation of NC-SNDP can be solved in polynomial time via a separation oracle based on max-flow computations, this hardness result implies – by a direct contrapositive argument – that the Jain property cannot hold for that LP: if every basic feasible solution x had some variable $x_e \geq 1/c_0$ for a fixed positive constant c_0, then iterating Jain's rounding scheme would yield a polynomial-time $O(1)$-approximation algorithm, contradicting the hardness result of [13].

The second reason is constructive: one can show directly that the standard LP relaxations for certain node-connectivity problems do not have the Jain property; nevertheless, it is possible that the underlying problem may admit a good approximation algorithm via a different LP relaxation or method. Fleischer, Jain, and Williamson [9] studied iterative rounding for minimum-cost node-connectivity problems and showed that it gives a 2-approximation for the *element connectivity* problem – a relaxation of node connectivity in which two "source-sink" paths are permitted to share so-called terminal nodes (but are required to be disjoint on the edges and the Steiner nodes). Their analysis establishes that the Jain property holds for the standard LP relaxation of element connectivity. Crucially, however, their result does not extend to the node-connectivity setting: the requirement function for node connectivity is not weakly supermodular, and the LP does not inherit the Jain property. For the mincost k-node-connected spanning subgraph problem (mincost k-NCSS), which is the core problem of node-connectivity network design, Aazami, Cheriyan, and Laekhanukit [1] gave an

explicit family of bad examples for the standard iterative rounding method. Specifically, they constructed instances for which the setpair LP relaxation has a basic feasible solution x satisfying $\max_e x_e \leq O(1)/\sqrt{k}$, thereby showing that the standard iterative rounding method cannot achieve an approximation ratio better than $\Omega(\sqrt{k})$ for mincost k-NCSS.

Our main result, Theorem 3, differs from the previous results in two essential ways.

(a) Edge-connectivity versus node-connectivity. The results of [13, 9, 1] all concern problems with *node-connectivity* requirements: the requirement function counts internally node-disjoint paths (or a relaxation thereof). Our bad example, by contrast, applies to the Cover Small Cuts problem, which has *edge-connectivity* requirements; recall that the goal is to find a minimum-cost set of links such that every cut of edge-capacity less than λ is covered by at least one link. The standard LP relaxation of Cover Small Cuts (see (LP: Cover Small Cuts)) is a covering LP of the same type as the LP for f-connectivity, yet our construction shows that the Jain property does *not* hold for it. To the best of our knowledge, there is no prior bad example for the Jain property for any problem defined by uniform edge-connectivity requirements.

(b) Hardness versus polyhedral structure. A key distinction between our result and the hardness-based argument of [13] is that Cover Small Cuts *does* admit a polynomial-time $O(1)$-approximation algorithm [6, 3, 15], achieved via the primal-dual method of Williamson et al. [19], rather than iterative rounding. Thus the failure of the Jain property for Cover Small Cuts cannot be attributed to hardness of approximation. This separates Cover Small Cuts from NC-SNDP: for NC-SNDP, the Jain property fails (in part) because the problem is hard to approximate; for Cover Small Cuts, the problem allows an $O(1)$ approximation algorithm, but the known iterative rounding methods via the natural covering LP cannot achieve an $O(1)$ approximation ratio. In the context of network design on undirected graphs with uniform edge-connectivity requirements, our construction indicates that the "limits" of the iterative rounding method are "tighter" than what is indicated by the previous literature.

1.3 Basic notation and definitions

For a positive integer k, we use $[k]$ to denote the set $\{1, 2, \ldots, k\}$. A pair of subsets A, B of V (the ground-set) is said to *cross* if each of the four sets $A \cap B, V - (A \cup B), A - B, B - A$ is nonempty.

For a graph $G = (V, E)$ and $S \subseteq V$, the cut $\delta_E(S)$ refers to the set of edges that have exactly one end-node in S; $\delta_E(S)$ is called a non-trivial cut if $\emptyset \neq S \subsetneq V$.

For each of the minimization problems (in network design or flexible graph connectivity), we use OPT to denote the optimal value (i.e., the minimum cost of an integer solution), and $\mathrm{LP}_{\mathrm{opt}}$ to denote the optimal value of an LP relaxation. The context will resolve potential ambiguities.

2 The Capacitated Graph

Let $k \geq 4$ be an even integer. The capacitated graph $G = (V, E), u$ has $n = 2 + \binom{k}{2}$ nodes, and $m = (n-1) + (k-1) = \binom{k}{2} + k$ edges. The edge capacities are chosen from the set $\{1, 2, 3\}$ and λ (the threshold value for small cuts) is chosen to be 5.

We denote the nodes of G by $v_1, v_2, \ldots, v_n$, as well as by the indices $1, 2, \ldots, n$. For notational convenience, let $s = v_1$ and let $t = v_n$.

The family of small cuts consists of two sub-families. One sub-family corresponds to the node-sets $N_1 = \{v_1\}, N_2 = \{v_1, v_2\}, \ldots, N_{n-1} = \{v_1, v_2, \ldots, v_{n-1}\}$. In other words, for each of the sets $N_i = \{v_1, v_2, \ldots, v_i\}, i = 1, \ldots, n-1$, $\delta_E(N_i)$ is a small cut. We call the sets N_i $(i = 1, \ldots, n-1)$ the *nested sets*. The other sub-family corresponds to the $(k-1)$ node-sets $Q_1 = \{v_2, v_3, \ldots, v_{1+\frac{k}{2}}\}, Q_2 = \{v_{2+\frac{k}{2}}, v_{3+\frac{k}{2}}, \ldots, v_{1+2\cdot\frac{k}{2}}\}, \ldots, Q_{(k-1)} = \{v_{2+(k-2)\cdot\frac{k}{2}}, v_{3+(k-2)\cdot\frac{k}{2}}, \ldots, v_{1+(k-1)\cdot\frac{k}{2}}\}$. Note that these sets form a partition of $V(G)-\{s,t\}$ into $(k-1)$ sets, each of cardinality $k/2$. In other words, for each of the $(k-1)$ "intervals" Q_j $(j = 1, \ldots, k-1)$ formed by picking the node with index $2 + (j-1)\cdot\frac{k}{2}$ and the next $(\frac{k}{2}-1)$ consecutively indexed nodes, $\delta_E(Q_j)$ is a small cut. We call the sets Q_j $(j = 1, \ldots, k-1)$ the *Q-sets*; moreover, by the *first node* of Q_j we mean the node of lowest index in Q_j (i.e., node $2 + (j-1)\cdot\frac{k}{2}$), and by the *last node* of Q_j we mean the node of highest index in Q_j (i.e., node $1 + (j)\cdot\frac{k}{2}$). For notational convenience, let $Q_0 = \{s\} = \{v_1\}$ and let $Q_k = \{t\} = \{v_n\}$; moreover, let $s = v_1$ be the *last node* of Q_0 and let $t = v_n$ be the *first node* of Q_k. (Consequently, in the proofs below, s may only serve as the last node of a Q-set, and t may only serve as a first node. Thus, if we examine the case that a specified node v is a first node, it is guaranteed that $v \neq s$ (i.e., the Q-set containing v is not Q_0); similarly, if we examine the case that a specified node v is a last node, it is guaranteed that $v \neq t$ (i.e., the Q-set containing v is not Q_k)).

For a nested set N_i $(i = 1, \ldots, n-1)$ and a Q-set Q_j $(j = 1, \ldots, k-1)$, observe that $s = v_1 \in N_i - Q_j$ and $t = v_n \notin N_i \cup Q_j$; moreover, if $N_i \cap Q_j$ is nonempty, then either Q_j crosses N_i (i.e., both $Q_j - N_i$ and $Q_j \cap N_i$ are nonempty) or $Q_j \subsetneq N_i$.

There are two types of edges in G. There are $n-1$ edges that form the s,t-path $v_1, v_2, \ldots, v_n$; we use E_1 to denote the edge set of this path. The first edge and the last edge of this path have capacity 2, thus, $u_{v_1v_2} = 2 = u_{v_{n-1}v_n}$. Consider any other edge v_iv_{i+1} $(i = 2, \ldots, n-2)$ of this path. If both v_i and v_{i+1} are in the same Q-set then v_iv_{i+1} has capacity 3, otherwise, v_iv_{i+1} has capacity one. Moreover, there are $(k-1)$ other edges (that are not in the s,t-path), and each of these edges has capacity one; we use E_2 to denote this set of $(k-1)$ edges. The nodes incident to the j-th edge of E_2 $(j = 1, \ldots, k-1)$ have indices $1 + (j-1)\cdot\frac{k}{2}$ and $2 + j\cdot\frac{k}{2}$. Thus, E_2 has an edge between $s = v_1$ and the first node of Q_2, an edge between the last node of Q_{k-2} and $t = v_n$, and, for each $j = 1, \ldots, k-3$, E_2 has an edge between the last node of Q_j and the first node of Q_{j+2}.

The following figure illustrates the construction of the capacitated graph for $k = 4$; the graph has $\binom{k}{2} + 2 = 8$ nodes and $\binom{k}{2} + k = 10$ edges.

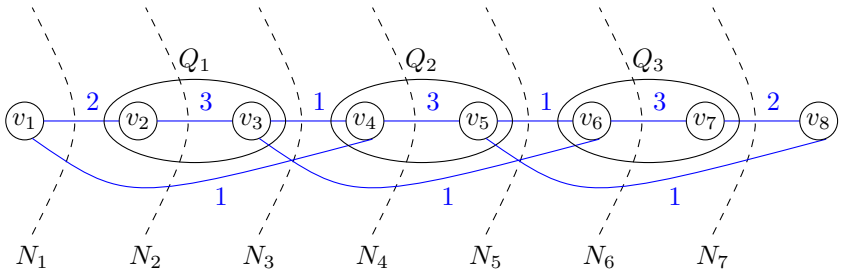

Figure 1 The capacitated graph for $k = 4$. The small cuts are given by the nested sets $N_1, \ldots, N_7$ (indicated by dashed lines) and the sets Q_1, Q_2, Q_3 (indicated by ovals).

We defer the proofs of the next two results to section 5; our proofs are straightforward and use case analysis.

▶ **Proposition 4.** *Each of the nested cuts $\delta(N_i), i = 1, \ldots, n-1$ and each of the Q-cuts $\delta(Q_j), j = 1, \ldots, k-1$ has capacity less than $\lambda = 5$.*

▶ **Proposition 5.** *Every non-trivial cut $\delta(S)$, $\emptyset \subsetneq S \subsetneq V$, of G that is neither a nested cut nor a Q-cut has capacity $\geq \lambda = 5$.*

3 The Links Graph

Let (V, L) denote the graph of the links; thus L is the set of links, and we denote the links by the symbol ℓ, e.g., ℓ_i, ℓ', etc. The number of links is $m = n + k - 2 = \binom{k}{2} + k$. The links are partitioned into k internally node disjoint s,t-paths that we denote by $P_1, \ldots, P_{k-1}, P_k$. The s,t-path P_k has one link $st = v_1 v_n$. Each of the s,t-paths $P_1, \ldots, P_{k-1}$ has $k/2$ internal nodes and has $1 + \frac{k}{2}$ links. Moreover, the sequence of node indices of each of these s,t-paths is an increasing sequence; that is, the node sequence has the form $v_1, v_{i_2}, v_{i_3}, \ldots, v_{i_{(\frac{k}{2}+1)}}, v_n$, where $1 < i_2 < i_3 < \cdots < i_{(\frac{k}{2}+1)} < n$. Each of the nodes $v_2, \ldots, v_{n-1}$ is in one of the s,t-paths $P_1, \ldots, P_{k-1}$; thus, each of these nodes is incident to two links.

Recall that we have $(k-1)$ Q-sets, each with $k/2$ nodes, and $(k-1)$ s,t-paths $P_1, \ldots, P_{k-1}$ each with $k/2$ internal nodes. Each of the s,t-paths P_i $(i = 1, \ldots, k-1)$ is constructed such that it is incident to precisely one node of $k/2$ (of the $(k-1)$) Q-sets, and it is disjoint from the other $(k - 1 - \frac{k}{2})$ Q-sets. The s,t-path P_i $(i = 1, \ldots, k-1)$ is incident to the Q-set with index i and the next $(k/2) - 1$ consecutively indexed Q-sets (with "wrap around"); thus, for $i = 1, \ldots, k-1$ and $j = 1, \ldots, k-1$, the s,t-path P_i and the set Q_j have a node in common iff

$$j \geq i \quad \textbf{and} \quad j \leq \min(i + \frac{k}{2} - 1,\ k-1), \quad \textbf{or}$$
$$j < i \quad \textbf{and} \quad 1 \leq j \leq i - \frac{k}{2}.$$

If an s,t-path P_i and a set Q_j have a node in common, then any one node of Q_j could be assigned to P_i; in other words, our construction does not specify the internal nodes of P_i, it only specifies the Q-sets that intersect P_i.

Let A^{PQ} denote the $(k-1) \times (k-1)$ zero-one matrix that has a row for each s,t-path P_i $(i = 1, \ldots, k-1)$ and a column for each set Q_j $(i = 1, \ldots, k-1)$ such that the entry $A^{PQ}_{i,j}$ is one iff P_i and Q_j have a node in common. Then, by construction, A^{PQ} is a circulant matrix with entries of zero or one such that each row has $k/2$ consecutive ones (with "wrap around") and the remaining $(k - 1 - \frac{k}{2})$ entries of the row are zero. Observe that the number of ones in each row, $k/2$, and the size of the matrix, $k-1$, are relatively prime (i.e., $\gcd(\frac{k}{2}, k-1) = 1$). For an illustration, see the example at the end of section 4.

▶ **Lemma 6.** *The matrix A^{PQ} has rank $(k-1)$. Moreover, $\det(A^{PQ}) = k/2$.*

One can prove this lemma directly, by applying row operations (and applying the matrix determinant lemma [1] to a square matrix with diagonal entries 2 and all other entries one). Alternatively, the lemma follows directly from a result of Hariprasad [11, Theorem 2.1].

Figure 2 illustrates the construction of the links graph for $k = 4$. The graph has $\binom{k}{2} + 2 = 8$ nodes and $\binom{k}{2} + k = 10$ links. The links partition into $k = 4$ (internally node disjoint) s,t-paths $P_1, \ldots, P_4$; the links of $P_1, \ldots, P_4$ are indicated by distinct colours.

[1] https://en.wikipedia.org/wiki/Matrix_determinant_lemma

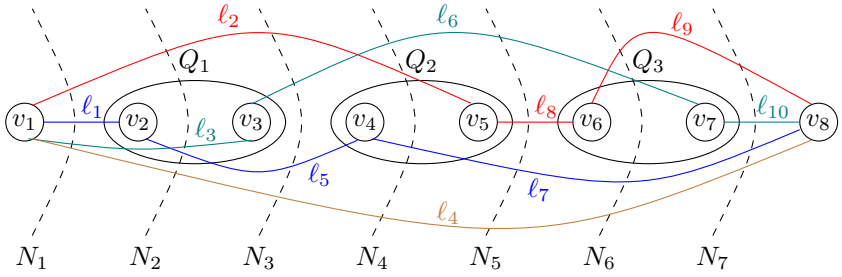

Figure 2 The links graph for $k = 4$. The links partition into s, t-paths $P_1, \ldots, P_4$, and the links of each of these s, t-paths is indicated by a distinct colour. Thus, the links of P_1 are ℓ_1, ℓ_5, ℓ_7, the links of P_2 are ℓ_2, ℓ_8, ℓ_9, the links of P_3 are $\ell_3, \ell_6, \ell_{10}$, and P_4 has the link ℓ_4. The small cuts are given by the nested sets $N_1, \ldots, N_7$ (indicated by dashed lines) and the sets Q_1, Q_2, Q_3 (indicated by ovals).

We construct a basic feasible solution x^* by assigning the value $1/k$ to each link, thus, $x^*_\ell = 1/k, \forall \ell \in L$. Informally speaking, we are assigning a value $1/k$ to each of the s, t-paths $P_1, \ldots, P_k$. It is easy to verify that each of the small cuts, namely, $\delta(N_i)$ $(i = 1, \ldots, n-1)$ and $\delta(Q_j)$ $(j = 1, \ldots, k-1)$, is "tightly covered" by x^*. First, consider a cut $\delta(N_i)$ $(i = 1, \ldots, n-1)$, and observe that each of the s, t-paths $P_1, \ldots, P_k$ has exactly one of its links in $\delta(N_i)$, hence, $x^*(\delta(N_i)) = (k)\frac{1}{k} = 1$. Next, consider a cut $\delta(Q_j)$ $(j = 1, \ldots, k-1)$, and observe that $k/2$ of the s, t-paths $P_1, \ldots, P_k$ have exactly one internal node in Q_j, hence, each of these s, t-paths has exactly two links in $\delta(Q_j)$, therefore, $x^*(\delta(Q_j)) = 2(\frac{k}{2})(\frac{1}{k}) = 1$. Note that the tight constraints at x^* are the covering constraints for the small cuts, and none of the lower bound constraints is tight (since $0 < 1/k < 1$).

The basis matrix A of x^* has one row for each small cut and one column for each link; the entry of A corresponding to a small cut $\delta(S)$ and a link ℓ is one if $\ell \in \delta(S)$, otherwise, the entry is zero. Thus, A is an $m \times m$ matrix with entries of zero or one; recall that $m = n + k - 2 = \binom{k}{2} + k$. In the next section, we show that matrix A has full rank, and that will prove our claim that x^* is a basic feasible solution of the LP relaxation of Cover Small Cuts.

4 The rank of the incidence matrix of small cuts and links

Let A denote the zero-one incidence matrix of the small cuts and the links; A is an $m \times m$ matrix, where $m = n + k - 2 = \binom{k}{2} + k$. The matrix A has rows corresponding to the cuts of the Q-sets followed by rows corresponding to the cuts of the nested sets; the columns of A correspond to the links. In this section, the main goal is to show that $\det(A)$ is non-zero; equivalently, A has full rank. We start by fixing a convenient indexing for the rows and columns of A. The rows $1, \ldots, (k-1)$ of A correspond to the cuts of $Q_1, \ldots, Q_{(k-1)}$, and the rows $k, (k+1), \ldots, m$ of A correspond to the cuts of $N_1, \ldots, N_{(n-1)}$. The links $\ell \in L$ are indexed as follows: The link of the s, t-path P_i $(i = 1, \ldots, k)$ incident to node $s = v_1$ is denoted ℓ_i; thus, each of $\ell_1, \ldots, \ell_k$ is in $\delta(s)$, and there is a bijection between these links and the s, t-path $P_1, \ldots, P_k$. Note that each of the remaining links is incident to one of the nodes $v_2, \ldots, v_{n-1}$, and, for each $i = 2, \ldots, (n-1)$, the unique link that is incident to node v_i and is in the cut $\delta(N_i)$ is assigned the index $(k + i - 1)$. The columns $1, \ldots, m$ of A correspond to the links $\ell_1, \ldots, \ell_m$.

Let us view the matrix A as a 2×2 block matrix $\begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}$ where A_{11} is the $(k-1) \times (k-1)$ sub-matrix of A whose rows correspond to the cuts of $Q_1, \ldots, Q_{(k-1)}$ and whose columns correspond to the links $\ell_1, \ldots, \ell_{(k-1)}$, and A_{22} is the $(m-k+1) \times (m-k+1)$ sub-matrix of A whose rows correspond to the cuts of $N_1, \ldots, N_{(n-1)}$ and whose columns correspond to the links $\ell_k, \ell_{(k+1)}, \ldots, \ell_m$.

▷ Claim 7. The sub-matrix A_{22} is lower-triangular and all entries on the diagonal are one; thus, $\det(A_{22}) = 1$.

Proof. The link ℓ_k (with end nodes s and t) is in each of the cuts $\delta(N_i)$, $i = 1, \ldots, (n-1)$. For each of the links $\ell_{(k+i-1)}$ where $i = 2, \ldots, (n-1)$, note that the link is in the cut $\delta(N_i)$ and it is in none of the cuts $\delta(N_1), \ldots, \delta(N_{(i-1)})$. ◁

Our plan is to apply row operations to the first $(k-1)$ rows of A in order to transform the submatrix $\begin{pmatrix} A_{11} & A_{12} \end{pmatrix}$ to a submatrix of the form $\begin{pmatrix} (A^{PQ})^\top & \mathbf{0}_{(k-1)\times(m-k+1)} \end{pmatrix}$, where $(A^{PQ})^\top$ denotes the transpose of the matrix A^{PQ} and $\mathbf{0}_{(k-1)\times(m-k+1)}$ denotes a $(k-1) \times (m-k+1)$ matrix of zeros. Therefore, using row operations, we will rewrite the matrix A as the 2×2 block matrix $\begin{pmatrix} (A^{PQ})^\top & \mathbf{0}_{(k-1)\times(m-k+1)} \\ A_{21} & A_{22} \end{pmatrix}$; then, by applying Lemma 6 as well as a result on the determinant of 2×2 block matrices, we see that the determinant of the re-written matrix A is $\det(A^{PQ}) \det(A_{22}) = \det(A^{PQ}) \neq 0$.

See the example at the end of this section for an illustration.

Let us introduce some notation to describe and analyse our row operations. For any set of links L' let $\chi^{L'}$ denote the zero-one row incidence vector of L'; thus, for any link ℓ, $\chi^{L'}_\ell = 1$ iff $\ell \in L'$. Note that rows $1, \ldots, (k-1)$ of A correspond to $\chi^{\delta(Q_1)}, \ldots, \chi^{\delta(Q_{(k-1)})}$. For any link ℓ, let $\phi(\ell)$ denote the index i of the s,t-path P_i that contains ℓ. For each of the links ℓ_i, $i = 1, \ldots, (k-1)$, note that $\phi(\ell_i) = i$, since we have a bijection between these links and the s,t-paths $P_1, \ldots, P_{(k-1)}$. For any set of links L', let $\Phi(L')$ denote the set of indices of the s,t-paths $P_1, \ldots, P_{(k-1)}$ that contain at least one of the links of L'; thus, $\Phi(L') \subseteq \{1, \ldots, k\}$, and index i is in $\Phi(L')$ iff the s,t-path P_i contains one of the links of L'. For example, if L' is a subset of $\{\ell_1, \ldots, \ell_{(k-1)}\}$, then $\Phi(L') = \{i \ : \ \ell_i \in L'\}$.

Consider any row j, $j = 1, \ldots, (k-1)$ of the matrix A; this row-vector is the same as $\chi^{\delta(Q_j)}$. Let g denote the largest index i such that the nested set N_i is disjoint from Q_j, and let h denote the smallest index i such that the nested set N_i contains Q_j. (By our construction, the $k/2$ nodes of Q_j are in the interval $[(g+1), (g+2), \ldots, h]$.)

▷ Claim 8. $\left(\chi^{\delta(Q_j)} - \chi^{\delta(N_h)} + \chi^{\delta(N_g)}\right) = 2\chi^{L'}$, where L' is the set of $k/2$ links in $\delta(Q_j) \cap \delta(N_g)$.

Proof. By construction, every link has its two end nodes in two different Q-sets. Hence, every link $\ell \in \delta(Q_j)$ that has its lower-index node in Q_j is in $\delta(N_h)$; similarly, every link $\ell \in \delta(Q_j)$ that has its higher-index node in Q_j is in $\delta(N_g)$. Moreover, $\delta(N_g) - \delta(Q_j) = \delta(N_h) - \delta(Q_j)$ is the set of links that have their lower-index node in N_g and their higher-index node in $V - N_h$. The equation in the claim follows from these statements. ◁

In the above claim, note that L' is contained in the cut of a Q-set, hence, the link $\ell_k = st$ cannot be in L'.

Our plan is to (separately) apply the row operations described in the above claim to each of the rows $j = 1, \ldots, (k-1)$ of A. The next lemma explains how to apply row operations to $\chi^{L'}$, where L' is any set of $k/2$ links contained in some nested cut $\delta(N_i)$ and $\ell_k \notin L'$, to transform $\chi^{L'}$ to the vector $\chi^{\widehat{L}}$, where $\widehat{L} = \{\ell_i \ : \ i \in \Phi(L')\}$. Informally speaking, we can

apply row operations to "map" any row vector $\chi^{L'}$, where $L' \subset \delta(N_i) - \{\ell_k\}$ and $|L'| = k/2$, to the row incidence vector (padded with zeros on the right) of the $k/2$ s,t-paths among $P_1, \ldots, P_{(k-1)}$ that contain (at least) one of the links of L'. Thus, by applying the above claim and the next lemma, we "map" each row of the submatrix $\begin{pmatrix} A_{11} & A_{12} \end{pmatrix}$ to a distinct row of the submatrix $\begin{pmatrix} (A^{PQ})^\top & \mathbf{0}_{(k-1)\times(m-k+1)} \end{pmatrix}$.

▶ **Lemma 9.** *Let $i = 1, \ldots, n-1$, and let $L' \subset \delta(N_i) - \{\ell_k\}$ be any set of $k/2$ links. By applying row operations, one can transform the vector $\chi^{L'}$ to the vector $\chi^{\widehat{L}}$, where $\widehat{L} = \{\ell_i \,:\, i \in \Phi(L')\}$.*

Proof. By induction on the index of the nested set whose cut contains L'.

Let h be the smallest index such that the nested cut $\delta(N_h)$ contains L'. If $h = 1$, then we have $\widehat{L} = L'$ and the lemma is proved.

Now, suppose $h \geq 2$; thus, L' contains a link ℓ_j with $j > k$. Observe that L' contains the link $\ell_{(h+k-1)}$ which is incident to node v_h and is in the cut $\delta(N_h)$; informally speaking, the presence of $\ell_{(h+k-1)}$ in L' certifies that L' is contained in $\delta(N_h)$ and L' is not a subset of $\delta(N_j)$ for any $j < h$. Let $\overline{L}$ denote the set of links $\delta(N_h) - L'$; $\overline{L}$ is a "complementary set" of $k/2$ links w.r.t. $\delta(N_h)$ and L'. For every link $\ell_j \in \overline{L}$, observe that $j < (h+k-1)$ (since $\ell_j \in \delta(N_h)$ and $\ell_{(h+k-1)} \notin \overline{L}$).

Let g be the smallest index such that the nested cut $\delta(N_g)$ contains $\overline{L}$. Again, observe that $\overline{L}$ contains the link $\ell_{(g+k-1)}$ which is incident to node v_g and is in the cut $\delta(N_g)$. Clearly, $g < h$ and $\delta(N_g) \neq \delta(N_h)$, since $\ell_{(h+k-1)} \in \delta(N_h)$ and $\ell_{(h+k-1)} \notin \delta(N_g)$.

▷ Claim 10. There exists a set of $k/2$ links of $\delta(N_g) - \{\ell_k\}$, call it L'', such that
(i) $\chi^{L''} = \chi^{L'} - \chi^{\delta(N_h)} + \chi^{\delta(N_g)}$, and
(ii) $\Phi(L'') = \Phi(L')$.

Proof. Observe that $\overline{L} = \delta(N_h) - L'$, and that $\overline{L}$ is contained in $\delta(N_g)$; also, note that ℓ_k is in $\overline{L}$. Let $L'' = \delta(N_g) - \overline{L}$; observe that L'' is a set of $k/2$ links and $\ell_k \notin L''$. Hence, we have $\chi^{\delta(N_g)} - \chi^{\delta(N_h)} = \chi^{L''} - \chi^{L'}$. This proves part (i) of the claim.

Moreover, note that each of the nested cuts contains exactly one link from each of the s,t-paths $P_1, \ldots, P_k$; that is, for each $i = 1, \ldots, n-1$, $\Phi(\delta(N_i)) = \{1, \ldots, k\}$. Hence, $\Phi(L') = \Phi(\delta(N_h) - \overline{L}) = \{1, \ldots, k\} - \Phi(\overline{L}) = \Phi(\delta(N_g) - \overline{L}) = \Phi(L'')$. This proves part (ii) of the claim. ◁

In the induction step (of the proof of the lemma), we apply the above claim to replace the set L' by the set L''; note that L'' has the properties of L' (listed in the lemma statement) and $\Phi(L'') = \Phi(L')$. Moreover, L'' is contained in the cut of a nested set of smaller index than the index of any nested set whose cut contains L'.

Thus, the lemma follows by induction. ◀

Our main result of this section follows from the above discussion.

▶ **Theorem 3.** *Let $k \geq 4$ be an even integer. There is an instance of the* Cover Small Cuts *problem $G = (V, E), L, u$ such that the LP relaxation* (LP: Cover Small Cuts) *has a basic feasible solution x^* such that every positive variable of x^* has value $1/k$.*

4.1 Example with $k = 4$

In this subsection, we fix $k = 4$, and we illustrate our row operations, in particular, the row operations of Claims 8,10, on the links graph shown in Figure 2. The links partition into s,t-paths $P_1, \ldots, P_4$, and the links of P_1 are ℓ_1, ℓ_5, ℓ_7, the links of P_2 are ℓ_2, ℓ_8, ℓ_9, the links of P_3 are $\ell_3, \ell_6, \ell_{10}$, and P_4 has the link ℓ_4.

The incidence matrix A^{PQ} of the s,t-paths P_1, P_2, P_3 and the Q-sets is given below.

$$\begin{array}{ccc} Q_1 & Q_2 & Q_3 \\ \left(\begin{array}{ccc} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{array}\right) & & \begin{array}{c} P_1 \\ P_2 \\ P_3 \end{array} \end{array}$$

The incidence matrix A of the small cuts and the links is given below. Note that the submatrix A_{22} (of the nested cuts and the links $\ell_4, \ldots, \ell_{10}$) is lower-triangular with diagonal entries of one.

$$\begin{array}{ccc|cccccccc} \ell_1 & \ell_2 & \ell_3 & \ell_4 & \ell_5 & \ell_6 & \ell_7 & \ell_8 & \ell_9 & \ell_{10} & \\ \hline 1 & 0 & 1 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & Q_1 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 0 & Q_2 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 & Q_3 \\ \hline 1 & 1 & 1 & \textcircled{1} & 0 & 0 & 0 & 0 & 0 & 0 & N_1 \\ 0 & 1 & 1 & 1 & \textcircled{1} & 0 & 0 & 0 & 0 & 0 & N_2 \\ 0 & 1 & 0 & 1 & 1 & \textcircled{1} & 0 & 0 & 0 & 0 & N_3 \\ 0 & 1 & 0 & 1 & 0 & 1 & \textcircled{1} & 0 & 0 & 0 & N_4 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & \textcircled{1} & 0 & 0 & N_5 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & \textcircled{1} & 0 & N_6 \\ 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 1 & \textcircled{1} & N_7 \end{array}$$

We describe the row operations for $\delta(Q_1), \delta(Q_2), \delta(Q_3)$, i.e., rows 1,2,3 of A; in particular, we describe the row operations of Claims 8,10.

Q_1: $\chi^{\delta(Q_1)} = \chi^{\{\ell_1,\ell_3,\ell_5,\ell_6\}}$. In Claim 8, for $j = 1$, we have $h = 3, g = 1$. $\left(\chi^{\delta(Q_1)} - \chi^{\delta(N_3)} + \chi^{\delta(N_1)}\right) = 2\chi^{\{\ell_1,\ell_3\}}$.
Note that $\Phi(\delta(Q_1)) = \{1, 3\}$.

Q_2: $\chi^{\delta(Q_2)} = \chi^{\{\ell_2,\ell_5,\ell_7,\ell_8\}}$. In Claim 8, for $j = 2$, we have $h = 5, g = 3$. $\left(\chi^{\delta(Q_2)} - \chi^{\delta(N_5)} + \chi^{\delta(N_3)}\right) = 2\chi^{\{\ell_2,\ell_5\}}$.
Next, Claim 10 is applied with $L' = \{\ell_2, \ell_5\}$, and we have $h = 2, g = 1$. $\chi^{\{\ell_2,\ell_5\}} - \chi^{\delta(N_2)} + \chi^{\delta(N_1)} = \chi^{\{\ell_1,\ell_2\}}$.
Note that $\Phi(\delta(Q_2)) = \{1, 2\}$.

Q_3: $\chi^{\delta(Q_3)} = \chi^{\{\ell_6,\ell_8,\ell_9,\ell_{10}\}}$. In Claim 8, for $j = 3$, we have $h = 7, g = 5$. $\left(\chi^{\delta(Q_3)} - \chi^{\delta(N_7)} + \chi^{\delta(N_5)}\right) = 2\chi^{\{\ell_6,\ell_8\}}$.
Next, Claim 10 is applied with $L' = \{\ell_6, \ell_8\}$, and we have $h = 5, g = 4$. $\chi^{\{\ell_6,\ell_8\}} - \chi^{\delta(N_5)} + \chi^{\delta(N_4)} = \chi^{\{\ell_2,\ell_6\}}$.
Next, Claim 10 is applied with $L' = \{\ell_2, \ell_6\}$, and we have $h = 3, g = 2$. $\chi^{\{\ell_2,\ell_6\}} - \chi^{\delta(N_3)} + \chi^{\delta(N_2)} = \chi^{\{\ell_2,\ell_3\}}$.
Note that $\Phi(\delta(Q_3)) = \{2, 3\}$.

5 The Capacitated Graph: Deferred Proofs

In this section, we present the proofs of Propositions 4 and 5, deferred from section 2.

▶ **Proposition 4.** *Each of the nested cuts $\delta(N_i), i = 1, \ldots, n-1$ and each of the Q-cuts $\delta(Q_j), j = 1, \ldots, k-1$ has capacity less than $\lambda = 5$.*

Proof. We examine a few cases.

Nested cut $\delta(N_i)$ such that N_i does not cross any Q-set: Then, either $2 \leq i \leq n-2$ and there is a largest index $j = 1, \ldots, k-2$ such that Q_j is contained in N_i, or else $i \in \{1,\ (n-1)\}$.

If $i = 1$, then $\delta(N_i)$ has two edges, namely, (i) the E_1-edge v_1v_2 of capacity 2, and (ii) the E_2-edge (of capacity one) between $s = v_1$ and the first node of Q_2; clearly, $\delta(N_1)$ has capacity $3 < \lambda = 5$. Similarly, if $i = (n-1)$, then $\delta(N_i)$ has two edges and has capacity $3 < \lambda = 5$.

Otherwise, $\delta(N_i)$ has three edges, namely, (i) the E_1-edge v_iv_{i+1} of capacity one, (ii) the E_2-edge (of capacity one) between the last node of Q_{j-1} and the first node of Q_{j+1}, and (iii) the E_2-edge (of capacity one) between the last node of Q_j and the first node of Q_{j+2}, Thus, the cut $\delta(N_i)$ has capacity $3 < \lambda = 5$.

Nested cut $\delta(N_i)$ such that N_i crosses a Q-set: Suppose that N_i crosses Q_j, where $j = 1, \ldots, k-1$. Clearly, the first node of Q_j is in N_i and the last node of Q_j is not in N_i. Note that $\delta(N_i)$ has two edges, namely, the E_1-edge v_iv_{i+1} of capacity 3, and the E_2-edge (of capacity one) between the last node of Q_{j-1} and the first node of Q_{j+1}. Thus, the cut $\delta(N_i)$ has capacity $4 < \lambda = 5$.

Q-cut $\delta(Q_j)$: First, suppose that $j = 2, \ldots, (k-2)$. Observe that $\delta(Q_j)$ consists of the following four unit-capacity edges. There are two edges of E_1 in the cut, namely, the edge between the last node of Q_{j-1} and the first node of Q_j, and the edge between the last node of Q_j and the first node of Q_{j+1}. Moreover, there are two edges of E_2 in the cut; namely, the edge between the last node of Q_{j-2} and the first node of Q_j, and the edge between the last node of Q_j and the first node of Q_{j+2}.

The cuts $\delta(Q_1)$ and $\delta(Q_{k-1})$ have capacity four since each of these cuts has only one edge of E_2 (since no E_2-edge is incident to the first node of Q_1 or to the last node of Q_{k-1}), and has two edges of E_1, one edge of capacity 2 (i.e., $sv_2 \in \delta(Q_1)$ and $v_{n-1}t \in \delta(Q_{k-1})$) and the other edge of capacity one. ◀

▶ **Proposition 5.** *Every non-trivial cut $\delta(S)$, $\emptyset \subsetneq S \subsetneq V$, of G that is neither a nested cut nor a Q-cut has capacity $\geq \lambda = 5$.*

Proof. We denote the nodes $v_1, \ldots, v_n$ by their indices $1, \ldots, n$ for this proof. (Notational remark: In this proof, the symbols ℓ_1, ℓ_2, etc., refer to the indices $1, \ldots, n$ rather than to links in L; in fact, links are not relevant in this section.) W.l.o.g., assume that S is a set of nodes such that $1 \in S$ (thus, S contains v_1), $S \neq N_i, i = 1, \ldots, n-1$, and $S \neq (V - Q_j), j = 1, \ldots, k-1$. Let $\ell_1 = 1$ and let r_1 denote the smallest index such that $r_1 \in S$ and $(r_1 + 1) \notin S$; note that r_1 is well defined, since $S \neq V$; possibly, $r_1 = \ell_1$. Thus, $[\ell_1, \ldots, r_1]$ is a maximal interval contained in S. Clearly, $S \neq [\ell_1, \ldots, r_1]$, otherwise, we would have $S = N_{r_1}$ (contradicting our assumption that S is not a nested set). Thus, $r_1 \leq (n-2)$. Let ℓ_2 be the smallest index $> r_1$ that is in S; thus, $\ell_2 = \min_i\{i \in S, i \in [(r_1+1), \ldots, n]\}$. Moreover, let r_2 be the smallest index $\geq \ell_2$ such that either $r_2 = n$ or else $(r_2 + 1) \notin S$; thus, $r_2 = n$ if $[\ell_2, \ldots, n] \subset S$, and $r_2 = \min\{i \in S, i+1 \notin S, i \in [\ell_2, \ldots, n]\}$ if $[\ell_2, \ldots, n] \not\subset S$. Then, $[\ell_2, \ldots, r_2]$ is another maximal interval contained in S. Clearly, both the E_1-edges $v_{r_1}v_{(r_1+1)}$ and $v_{(\ell_2-1)}v_{\ell_2}$ are in $\delta(S)$.

For any node i $(i = 1, \ldots, n)$, we use $q(i)$ to denote the index of the (unique) Q-set that contains i; thus, $q(i) = \lceil (i-1)/\frac{k}{2} \rceil$.

We examine a few cases and show that $\delta(S)$ has capacity $\geq \lambda = 5$ in each case.

- Node r_1 is not the last node of its Q-set, $Q_{q(r_1)}$, and node ℓ_2 is not the first node of its Q-set, $Q_{q(\ell_2)}$:
  Note that $r_1 \neq s = 1$ and $\ell_2 \neq t = n$.

Then the E_1-edge $v_{r_1}v_{(r_1+1)}$ has capacity 3, and the E_1-edge $v_{(\ell_2-1)}v_{\ell_2}$ has capacity 3, hence, $\delta(S)$ has capacity $\geq 6 > \lambda = 5$.

- Node r_1 is not the last node of its Q-set, $Q_{q(r_1)}$, and node ℓ_2 is the first node of its Q-set, $Q_{q(\ell_2)}$:
  Note that $r_1 \neq s = 1$, and, possibly, $\ell_2 = t = n$.
  Thus, $r_1 \geq 2$. Then the E_1-edge $v_{r_1}v_{(r_1+1)}$ has capacity 3.
  Suppose $\ell_2 = t = n$. Then the E_1-edge $v_{(\ell_2-1)}v_{\ell_2}$ has capacity two. Thus, $\delta(S)$ has capacity $\geq 5 = \lambda = 5$.
  Now, suppose $\ell_2 \neq t = n$. Then the E_1-edge $v_{(\ell_2-1)}v_{\ell_2}$ has capacity one. Note that $q(r_1) \geq 1$ and $2 \leq q(\ell_2) \leq (k-1)$. We have two subcases, depending on $q(\ell_2) - q(r_1)$.
  $q(\ell_2) = q(r_1) + 1$: Then we have two further subcases.
  - **(i)** First, suppose that $r_2 = n$; thus, $[\ell_2, \ldots, n]$ is a maximal interval contained in S. Then the last node of $Q_{q(r_1)}$ is not in S and the first node of $Q_{(q(r_1)+2)}$ is in S. Then the E_2-edge between the last node of $Q_{q(r_1)}$ and the first node $Q_{(q(r_1)+2)}$ is in $\delta(S)$. Thus, the cut $\delta(S)$ has capacity $\geq 5 = \lambda = 5$.
  - **(ii)** Now, suppose that $r_2 < n$. Then the E_1-edge $v_{r_2}v_{(r_2+1)}$ is in $\delta(S)$, and it has capacity one or more. Thus, the cut $\delta(S)$ has capacity $\geq 5 = \lambda = 5$.

  $q(\ell_2) \geq q(r_1) + 2$: Then the last node of $Q_{(q(r_1)-1)}$ is in S and the first node of $Q_{(q(r_1)+1)}$ is not in S. Then the E_2-edge between the last node of $Q_{(q(r_1)-1)}$ and the first node $Q_{(q(r_1)+1)}$ is in $\delta(S)$. Thus, the cut $\delta(S)$ has capacity $\geq 5 = \lambda = 5$.
- Node r_1 is the last node of its Q-set, $Q_{q(r_1)}$, and node ℓ_2 is not the first node of its Q-set, $Q_{q(\ell_2)}$:
  Possibly, $r_1 = s = 1$, and recall that $r_1 \leq (n-2)$. Note that $\ell_2 \neq t = n$.
  First, suppose $r_1 = 1$. Then the E_1-edge $v_{r_1}v_{(r_1+1)}$ has capacity two, and the E_1-edge $v_{(\ell_2-1)}v_{\ell_2}$ has capacity 3. Hence, $\delta(S)$ has capacity $\geq 5 = \lambda = 5$.
  Now, suppose $r_1 \geq 2$. Then, $1 \leq q(r_1) \leq (k-2)$. Then the E_1-edge $v_{r_1}v_{(r_1+1)}$ has capacity one, and the E_1-edge $v_{(\ell_2-1)}v_{\ell_2}$ has capacity 3. Clearly, $\delta(S)$ has both these edges, as well as the E_2-edge between the last node of $Q_{q(r_1)-1}$ and the node (r_1+1) (first node of $Q_{q(r_1)+1}$). Hence, $\delta(S)$ has capacity $\geq 5 = \lambda = 5$.
- Node r_1 is the last node of its Q-set, $Q_{q(r_1)}$, and node ℓ_2 is the first node of its Q-set, $Q_{q(\ell_2)}$: Possibly, $r_1 = s = 1$, and recall that $r_1 \leq (n-2)$. Possibly, $\ell_2 = t = n$.
  Note that $q(r_1) \geq 0$ and $2 \leq q(\ell_2) \leq (k)$.
  The E_1-edge $v_{(\ell_2-1)}v_{\ell_2}$ has capacity one or two.
  If $r_1 = s$, then the E_1-edge $v_{r_1}v_{(r_1+1)}$ has capacity two, otherwise, this edge has capacity one.
  If $r_1 \neq s$, then $q(r_1) \geq 1$; moreover, $(r_1+1) \notin S$ and (r_1+1) is the first node of its Q-set, $Q_{q(r_1+1)}$; hence, the E_2-edge between the last node of $Q_{(q(r_1)-1)}$ and (r_1+1) is in $\delta(S)$.
  At this point in the analysis, it is clear that $\delta(S)$ has capacity at least 3.
  We have two subcases, depending on $q(\ell_2) - q(r_1)$.
  $q(\ell_2) \geq q(r_1) + 3$: Then the interval $[(r_1+1), \ldots, (\ell_2-1)]$ (which is a subset of $V - S$) contains two or more Q-sets. We will show that the second and the last-but-one of the Q-sets each contribute an E_2-edge to $\delta(S)$.
  Since r_1 is the last node of its Q-set, $r_1 \in S$, and the first node of $Q_{(q(r_1)+2)}$ is not in S, the E_2-edge between these two nodes is in $\delta(S)$.
  Similarly, since ℓ_2 is the first node of its Q-set, $\ell_2 \in S$, and the last node of $Q_{(q(\ell_2)-2)}$ is not in S, the E_2-edge between these two nodes is in $\delta(S)$.
  Thus, $\delta(S)$ has capacity $\geq 5 = \lambda = 5$.

$q(\ell_2) \leq q(r_1) + 2$: In this case, $q(\ell_2) = q(r_1) + 2$, since the first node of $Q_{(q(r_1)+1)}$, which is $(r_1 + 1)$, is not in S, and ℓ_2 (which is the first node of its Q-set) is in S.
Observe that $r_2 \neq n$; that is, $r_2 \leq (n-1)$ and the node (r_2+1) is not in S. Otherwise, we would have $S = V - Q_{(q(r_1)+1)}$, contradicting our assumption that S is not the complement of a Q-set.
First, suppose $r_2 = (n-1)$. Then $\delta(S)$ has the edge $v_{(n-1)}v_n$ of capacity two. Hence, overall, $\delta(S)$ has capacity $\geq 5 = \lambda = 5$.
Now, suppose $r_2 \leq (n-2)$. If the E_1-edge $v_{r_2}v_{(r_2+1)}$ has capacity 3, then, overall, $\delta(S)$ has capacity $\geq 6 = \lambda = 5$. Otherwise, the E_1-edge $v_{r_2}v_{(r_2+1)}$ has capacity one. Observe that the node r_2 is the last node of its Q-set; moreover, the node (r_2+1) is the first node of its Q-set and $q(r_2+1) \leq (k-1)$. If the interval $[(r_2+1), (r_2+2), \ldots, n]$ has one or more nodes of S, then $\delta(S)$ has one more E_1-edge (besides $v_{r_2}v_{(r_2+1)}$) of capacity one or more, hence, overall, $\delta(S)$ has capacity $\geq 5 = \lambda = 5$. Finally, suppose that the interval $[(r_2+1), (r_2+2), \ldots, n]$ has no nodes of S. Then, the node r_2 is in S and the first node of $Q_{(q(r_2)+2)}$ is not in S, hence, the E_2 edge between these two nodes is in $\delta(S)$. Thus, overall, $\delta(S)$ has capacity $\geq 5 = \lambda = 5$. ◀

Hardness of the Binary Covering Radius Problem in Large ℓ_p Norms

Huck Bennett
University of Colorado Boulder, CO, USA

Peter Ly
University of Colorado Boulder, CO, USA

Abstract

We study the hardness of the γ-approximate decisional Covering Radius Problem on lattices in the ℓ_p norm (γ-GapCRP$_p$). Specifically, we prove that there is an explicit function $\gamma(p)$, with $\gamma(p) > 1$ for $p > p_0 \approx 35.31$ and $\lim_{p\to\infty} \gamma(p) = 9/8$, such that for any constant $\varepsilon > 0$, $(\gamma(p) - \varepsilon)$-GapCRP$_p$ is NP-hard. This shows the first hardness of GapCRP$_p$ for explicit $p < \infty$. Work of Haviv and Regev (CCC, 2006 and CJTCS, 2012) previously showed Π_2-hardness of approximation for GapCRP$_p$ for all sufficiently large (but non-explicit) finite p and for $p = \infty$.

In fact, our hardness results hold for a variant of GapCRP called the *Binary Covering Radius Problem* (BinGapCRP). The Binary Covering Radius Problem trivially reduces to both GapCRP and the decisional Linear Discrepancy Problem (LinDisc) in any norm in an approximation-preserving way. We also show Π_2-hardness of $(9/8 - \varepsilon)$-BinGapCRP in the ℓ_∞ norm for any constant $\varepsilon > 0$.

Our work extends and heavily uses the work of Manurangsi (IPL, 2021), which showed Π_2-hardness of $(9/8 - \varepsilon)$-LinDisc in the ℓ_∞ norm.

1 Introduction

The *covering radius* $\mu(\mathcal{L})$ of a lattice $\mathcal{L}$ is the maximum distance of a point in the span of $\mathcal{L}$ to a vector in $\mathcal{L}$. It is one of the most fundamental lattice quantities. Accordingly, the (decisional) Covering Radius Problem ((Gap)CRP) is among the most fundamental lattice problems. Indeed, it is connected to the main applications of lattices in computer science. Approximate GapCRP is one of the worst-case problems from which there is a reduction to the average-case problems used in lattice-based cryptography [32], and it is related to fast algorithms for integer programming (see, e.g., [8]).

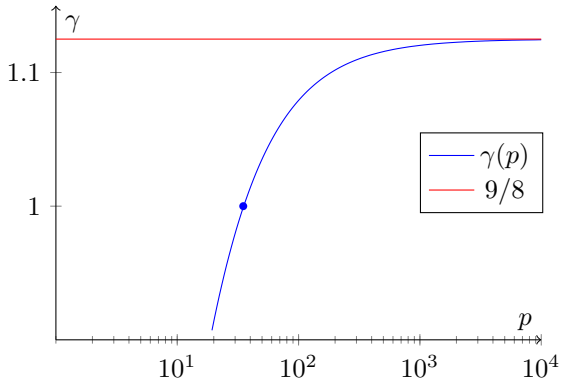

Figure 1 A linear-log plot of the approximation factor $\gamma = \gamma(p)$ for which we show NP-hardness of $(\gamma - \varepsilon)$-BinGapCRP in the ℓ_p norm (in blue; see Theorem 1). The function $\gamma(p)$, specified in Equation (1), is greater than 1 for all $p > p_0 = 35.310188...$ and satisfies $\lim_{p\to\infty} \gamma(p) = 9/8$. (The blue dot is at the point $(p, \gamma) = (p_0, 1)$, where p_0 is the unique value of p such that $\gamma(p) = 1$. The horizontal asymptote of 9/8 is shown in red.) This factor of 9/8 also appears in our Π_2-hardness result for BinGapCRP$_\infty$ (Theorem 2) and in the work of Manurangsi [29] on LinDisc, which is the foundation of our work..

Yet, the hardness of GapCRP is perhaps the least well understood among major lattice problems. In particular, it is not even known that *exact* GapCRP in the ℓ_2 norm is NP-hard, even though it is plausibly NP-hard to approximate within any constant $\gamma \geq 1$ and Π_2-hard to approximate to within a small constant $\gamma > 1$. This stands in contrast to, e.g., the decisional Shortest Vector Problem (γ-GapSVP), which a long line of elegant work [2, 31, 25, 24, 36, 21, 33] showed to be NP-hard in any ℓ_p norm for any constant $\gamma \geq 1$.[1]

Seminal work of Haviv and Regev [20] was the first – and prior to this work, only – to study the hardness of GapCRP. (Other work has studied the complexity of GapCRP more generally, including limitations on its hardness [15, 28]. See Section 1.2.) Let γ-GapCRP$_p$ be γ-approximate GapCRP in the ℓ_p norm. Haviv and Regev [20] showed that for any constant $\varepsilon > 0$, $(3/2 - \varepsilon)$-GapCRP$_\infty$ is Π_2-hard, and that for all sufficiently large p there exists $\gamma = \gamma(p) > 1$ such that γ-GapCRP$_p$ is Π_2-hard. However, the cutoff for "sufficiently large" in their work is non-explicit and presumably quite high, and so in some sense not much more is known about the hardness of GapCRP$_p$ for any explicit, finite p than for $p = 2$.

1.1 Our Results

In this work, we address the problem above by showing NP-hardness of $(\gamma - \varepsilon)$-GapCRP$_p$ for all p greater than an *explicit* value $p_0 \approx 35.31$ with an explicit approximation factor $\gamma = \gamma(p) > 1$. This is the first new hardness result for GapCRP since [20], which was first published 20 years ago.

In fact, we show hardness for a new promise variant of γ-GapCRP$_p$ called γ-BinGapCRP$_p$ where in the YES case every vector in the fundamental parallelepiped $\mathcal{P}(\mathbf{B}) := \mathbf{B} \cdot [0,1]^n$ of the input basis $\mathbf{B} \in \mathbb{R}^{m\times n}$ is close in ℓ_p distance to a lattice vector $\mathbf{Bx}$ with a *binary* coefficient vector $\boldsymbol{x} \in \{0,1\}^n$. That is, in the YES case, for every $\boldsymbol{w} \in [0,1]^n$ there exists $\boldsymbol{x} \in \{0,1\}^n$ such that $\|\mathbf{B}(\boldsymbol{w} - \boldsymbol{x})\|_p$ is small. This implies that the covering radius $\mu_p(\mathcal{L}(\mathbf{B}))$

[1] Formally, this NP-hardness is only known under *randomized reductions*, although several works – some of which are very recent [16, 22, 17, 38]! – have derandomized the reductions in some cases.

is small. (See Equation (4) and the surrounding text for a formal definition of the covering radius and a discussion of why this is true.) In the NO case, there exists a vector in $\mathcal{P}(\mathbf{B})$ that is far from *every* lattice vector $\mathbf{B}\boldsymbol{x}$ for $\boldsymbol{x} \in \mathbb{Z}^n$, as with standard γ-GapCRP$_p$.

BinGapCRP is reminiscent of the "binary coefficient vector" variant of the Closest Vector Problem often used in hardness reductions (see, e.g., [13, Definition 7] and [3, Definition 3.1]), and may be of independent interest. It has the YES instances of the Linear Discrepancy Problem (LinDisc) and the NO instances of GapCRP. It therefore trivially reduces to both problems in any norm in an approximation-preserving way (see Section 2.2 for definitions of these problems). In particular, our result not only implies new hardness for GapCRP$_p$ with $p < \infty$, but also for LinDisc in the ℓ_p norm for $p < \infty$ (LinDisc in finite ℓ_p norms does not seem to have been studied before).

Our main result is the following theorem. See also Figure 1.

▶ **Theorem 1** (NP-hardness of approximation for BinGapCRP$_p$)**.** *Let*

$$\gamma(p) := \left(\frac{9^p + 159 \cdot 3^p}{8^{p+2} + 96 \cdot 6^p}\right)^{1/p}, \tag{1}$$

and let $p_0 = 35.310188\ldots$ *be the unique value of* $p \geq 1$ *such that* $\gamma(p) = 1$*. Then for all* $p > p_0$ *and any constant* $\varepsilon > 0$*,* $(\gamma(p)-\varepsilon)$-BinGapCRP$_p$ *is* NP*-hard. Therefore,* $(\gamma(p)-\varepsilon)$-GapCRP$_p$ *and* $(\gamma(p)-\varepsilon)$-LinDisc$_p$ *for such* p *and* ε *are also* NP*-hard.*

We note that the expression $\gamma(p)$ in Equation (1) satisfies $\lim_{p\to\infty} \gamma(p) = 9/8$. Our second result shows how to achieve Π_2-hardness (rather than just NP-hardness) of $(9/8-\varepsilon)$-BinGapCRP in the ℓ_∞ norm.

▶ **Theorem 2** (Π_2-hardness of approximation for BinGapCRP$_\infty$)**.** *For any constant* $\varepsilon > 0$*,* $(9/8-\varepsilon)$-BinGapCRP$_\infty$ *is* Π_2*-hard.*

Theorem 2 is a strengthening of the main result in [29] – it shows hardness not just of $(9/8-\varepsilon)$-LinDisc$_\infty$ but of $(9/8-\varepsilon)$-BinGapCRP$_\infty$, where LinDisc$_\infty$ is the Linear Discrepancy Problem in the ℓ_∞ norm. Theorem 2 also gives an alternative proof of Π_2-hardness of approximation for γ-GapCRP$_\infty$, albeit with a smaller approximation factor than the one achieved by [20].

1.2 Related Work

Early work of McLoughlin [30] showed that the Covering Radius Problem on error-correcting codes is Π_2-hard by a reduction from a Π_2-hard variant of the 3-Dimensional Matching Problem, which is in turn shown to be Π_2-hard by a reduction from Π_2-3-SAT.[2] Twenty years later, work of Guruswami, Micciancio, and Regev [15] studied the complexity of the Covering Radius Problem both on codes and lattices. It showed a number of results, including that the Covering Radius Problem on codes is NP-hard to approximate to within any constant and Π_2-hard to approximate to within some constant. (It did not show hardness results for GapCRP on lattices.)

The work [15] also showed that 2-GapCRP$_p$ for any p is in AM via an elegant protocol. The fact that 2-GapCRP$_p$ is in AM provides evidence that γ-GapCRP$_p$ for $\gamma \geq 2$ is unlikely to be Π_2-hard, since if it were the polynomial hierarchy would collapse. However, being in AM says nothing about the potential NP-hardness of these problems. In particular it could very well be the case that γ-GapCRP is NP-hard for every constant $\gamma \geq 1$ as is the case for the Covering Radius Problem on codes.

[2] Here and throughout this section we refer to linear error-correcting codes simply as "codes."

The factor of $\gamma = 2$ in the [15] AM protocol follows generically for GapCRP in any norm from the triangle inequality, but it is not always tight. Follow-up work by Haviv, Lyubashevsky, and Regev [19] studied the distribution of the (normalized) ℓ_p distance of a random point in a fundamental domain of a lattice to the lattice. This distribution is closely related to the [15] AM protocol, and [19] showed that γ-GapCRP$_2$ for $\gamma > \sqrt{3} \approx 1.732$ is in AM under a certain conjecture about this distribution in the ℓ_2 norm. Their conjecture was subsequently proved by Magazinov [28].

Understanding the worst-case hardness of γ-GapCRP is also motivated by its relevance to cryptography. Indeed, [32] showed that γ-GapCRP with sufficiently large polynomial $\gamma = \gamma(n)$ can be taken as the starting worst-case problem for a worst-case to average-case reduction to the problems used as the foundation of lattice-based cryptography.

The Haviv-Regev hardness reduction

The work of Haviv and Regev [20] is the only prior work that studied the worst-case hardness of GapCRP on lattices. As noted above, they showed that for every constant $\varepsilon > 0$, $(3/2-\varepsilon)$-GapCRP$_\infty$ is Π_2-hard and that for all sufficiently large p there exists $\gamma = \gamma(p)$ such that γ-GapCRP$_p$ is Π_2-hard to approximate. However, the cutoff for "sufficiently large" and the approximation factors $\gamma(p)$ for $p < \infty$ are non-explicit.

The reduction in [20] is from the Group Coloring Problem on graphs with respect to the group $\mathbb{Z}_3$, a problem that is Π_2-hard.[3] The problem is defined as follows. The input is a directed graph $G = (V, E)$. The goal is to decide whether for every assignment $\phi : E \to \mathbb{Z}_3$ of labels to edges, there exists a coloring $c : V \to \mathbb{Z}_3$ of vertices such that for every edge $e = (u, v) \in E$, $c(u) - c(v) \neq \phi(e)$. The reduction to GapCRP is as follows. Let $A = A(G) \in \mathbb{Z}^{m \times n}$ for $m := |E|$, $n := |V|$ be the incidence matrix of G. That is, A is the matrix with two non-zero entries per row defined as

$$A_{i,j} := \begin{cases} -1 & \text{if edge } e_i = (v_j, u) \text{ for some } u \in V, \\ 1 & \text{if edge } e_i = (u, v_j) \text{ for some } u \in V, \\ 0 & \text{otherwise.} \end{cases}$$

The reduction then outputs (a basis of) the lattice $\mathcal{L} := A \cdot \mathbb{Z}^n + 3\mathbb{Z}^m$. One may also view A as the generator matrix of a ternary code $\mathcal{C} \subseteq \mathbb{F}_3^m$, and $\mathcal{L}$ as the Construction-A lattice $\mathcal{C} + 3\mathbb{Z}^m$.

To show NP-hardness of γ-GapCRP$_p$ in some ℓ_p norm (for large γ), one might try to reduce from variants of the 3-Coloring Problem, which is the NP analog of the Π_2-complete $\mathbb{Z}_3$-Group Coloring Problem. Indeed, strong hardness of approximation results are known for Almost-3-Coloring – the optimization variant of 3-Coloring in which the goal is to minimize the number of monochromatic edges – assuming variants of the Unique Games Conjecture [9]. However, it is unclear how to get this approach to work.

Combinatorial and linear discrepancy

The (combinatorial) *discrepancy* of a set system $S_1, \ldots, S_m \subseteq \{x_1, \ldots, x_n\}$ is defined as $\min_{x_1,\ldots,x_n \in \{-1,1\}} \max_{i \in [m]} |\sum_{j \in S_i} x_j|$, and the goal of the *combinatorial discrepancy problem* is, given the set system as input, to find $x_1, \ldots, x_n \in \{-1, 1\}$ that achieve this minimum.

[3] Their reduction actually works with $\mathbb{Z}_q$ for any $q \geq 3$, but they achieve the best hardness of approximation with $q = 3$.

Equivalently, if $\mathbf{A} \in \{0,1\}^{m \times n}$ is the incidence matrix of the input set system, the goal is to find $\boldsymbol{x} \in \{-1,1\}^n$ that minimizes $\|\mathbf{A}\boldsymbol{x}\|_\infty$. Combinatorial discrepancy and other variants of discrepancy are used widely in computer science and math (see, e.g., [7]).

Linear discrepancy was originally defined and related to other notions of discrepancy in work of Lovász, Spencer, and Vestergombi [27], and it appears as a key ingredient in certain approximation algorithms (see, e.g., [11, 37, 23]). Formally, we define the linear discrepancy $\operatorname{lindisc}(\mathbf{B})$ of a matrix $\mathbf{B}$ in the ℓ_p norm as

$$\operatorname{lindisc}_p(\mathbf{B}) := \max_{\boldsymbol{w} \in [0,1]^n} \min_{\boldsymbol{x} \in \{0,1\}^n} \|\mathbf{B}(\boldsymbol{w} - \boldsymbol{x})\|_p \ . \tag{2}$$

This definition is syntactically very similar to the definition of the covering radius in the ℓ_p norm, μ_p. The difference is that in the definition of μ_p, the minimum is taken over $\boldsymbol{x} \in \mathbb{Z}^n$ rather than $\boldsymbol{x} \in \{0,1\}^n$. See Sections 2.1 and 2.2.

Combinatorial discrepancy is captured, up to translation and scaling, by fixing $\boldsymbol{w} := \frac{1}{2} \cdot \mathbf{1}$ in Equation (2) instead of taking the max over all $\boldsymbol{w} \in [0,1]^n$ there. Linear discrepancy was first investigated from a complexity perspective by Li and Nikolov [26], who provided both algorithms and hardness results. In particular, they showed that the exact Linear Discrepancy Problem in the ℓ_∞ norm, LinDisc_∞, is NP-hard and that it is contained in Π_2. Their hardness result was subsequently improved by Manurangsi [29], who showed that γ-LinDisc_∞ is Π_2-hard for $\gamma := 9/8 - \varepsilon$ for any constant $\varepsilon > 0$. Our work makes extensive use of [29].

"Standard" linear discrepancy corresponds to $\operatorname{lindisc}_\infty$, and, to the best of our knowledge, our work is the first to extend the definition to finite ℓ_p norms. This extension is useful for our work. Moreover, we note that although linear discrepancy does not seem to have been studied in finite ℓ_p norms before, both combinatorial discrepancy and hereditary discrepancy have (see, e.g., [34]).

Lattice hardness results in large ℓ_p norms

We recall that our main hardness result in Theorem 1 only holds for GapCRP_p with $p > p_0 \approx 35.31$, whereas likely the most interesting case is $p = 2$. We note that it has been the case several times that progress on showing hardness of lattice problems in large ℓ_p norms has precipitated progress for the Euclidean case of $p = 2$. In particular, Khot [25] showed randomized NP-hardness of approximation for the Shortest Vector Problem (SVP) in large ℓ_p norms, and then shortly thereafter showed such hardness in all ℓ_p norms with $p > 1$ in [24]. More recently, Hair and Sahai [16] showed *deterministic* NP-hardness of approximation for SVP in ℓ_p norms for $p > 2$, and then showed hardness of approximation for SVP in the Euclidean norm [17].

More generally, quite a few works on the hardness of lattice problems have shown their strongest results in large ℓ_p norms (see, e.g., [1, 4, 5]).

1.3 Technical Overview

At a high level, our hardness reduction for BinGapCRP_p follows the hardness reduction for LinDisc_∞ in [29]. The reduction in [29] reduces from NAE-E3-SAT,[4] the constraint

[4] In fact, [29] reduces from the NAE-3-SAT problem (rather than the NAE-E3-SAT problem), in which constraints may have two literals (rather than always having three). The reduction simply doubles an arbitrary literal in any constraint with two literals, which leads to the "incidence" matrix $\mathbf{B}$ defined below potentially containing entries from $\{-2, 2\}$ as well as $\{-1, 0, 1\}$. In this work, we reduce from NAE-E3-SAT.

satisfaction problem in which each constraint is a function of three literals (Boolean variables v_j or their negations $\neg v_j$), and a constraint is satisfied by an assignment to its variables if and only if the assignment neither satisfies none of its literals nor all of its literals.

Specifically, on input a NAE-E3-SAT formula $\phi(v_1, \ldots, v_n)$ with n Boolean variables and with m constraints, the NP-hardness reduction in [29] first computes the constraint-variable incidence matrix $\mathbf{B} = \mathbf{B}(\phi) \in \mathbb{Z}^{m \times n}$ with entries

$$B_{i,j} := \begin{cases} 1 & \text{if constraint } i \text{ contains } v_j \ , \\ -1 & \text{if constraint } i \text{ contains } \neg v_j \ , \\ 0 & \text{otherwise .} \end{cases}$$

It then outputs a $\mathrm{LinDisc}_\infty$ instance with matrix

$$\mathbf{A} := \begin{pmatrix} \frac{1}{3}\mathbf{B} & \frac{1}{3}\mathbf{B} & \frac{1}{3}\mathbf{B} \\ & \mathbf{G} \otimes \mathbf{I}_n & \end{pmatrix} \in \mathbb{Q}^{(m+3n)\times 3n} \ , \tag{3}$$

where $\mathbf{G}$ is the 3×3 gadget matrix

$$\mathbf{G} := \begin{pmatrix} 1 & 1 & -1 \\ 1 & -1 & 1 \\ -1 & 1 & 1 \end{pmatrix} \ ,$$

$\otimes$ is the Kronecker product and $\mathbf{I}_n$ is the $n \times n$ identity matrix.

Both the completeness and soundness analysis of the reduction in [29] crucially use properties of $\mathbf{G}$. For example, [29, Lemma 3] argues that $\mathbf{G}$ has low discrepancy by upper bounding the distance between $\mathbf{G}\boldsymbol{u}$ and $\mathbf{G} \cdot \{0,1\}^3$ for each $\boldsymbol{u} \in [0,1]^3$ via a case analysis on the ℓ_1 norm of $\boldsymbol{u}$. The soundness analysis shows that, if there exists a close vector in the set $\mathbf{A} \cdot \{0,1\}^{3n}$ to $\mathbf{A} \cdot (\frac{1}{2}\mathbf{1})$, then ϕ must be satisfiable. [29] also shows Π_2-hardness of $(9/8 - \varepsilon)$-$\mathrm{LinDisc}_\infty$ by outputting and analyzing a matrix $\mathbf{A}' = \mathbf{A}'(\phi)$ defined in terms of ϕ that is related to the matrix $\mathbf{A}$ defined in Equation (3) but more complicated. We use this same matrix $\mathbf{A}'$ (defined in Equation (27)) to prove Theorem 2.

At a technical level, our NP-hardness result adapts the machinery in [29] from ℓ_∞ to general ℓ_p norms, and shows that, if the NAE-E3-SAT formula ϕ is unsatisfiable, then not only is $\mathrm{lindisc}(\mathbf{A})$ large, in fact $\mu(\mathcal{L}(\mathbf{A}))$ is large. That is, we show that if ϕ is unsatisfiable then there exists $\boldsymbol{w} \in [0,1]^{3n}$ (in fact, $\boldsymbol{w} := \frac{1}{2} \cdot \mathbf{1}$) such that $\|\mathbf{A}(\boldsymbol{w} - \boldsymbol{x})\|_p$ is large not only for all $\boldsymbol{x} \in \{0,1\}^{3n}$ but for all $\boldsymbol{x} \in \mathbb{Z}^{3n}$. Doing these things requires making a number of modifications to the hardness reduction and analysis used by [29], such as:

1. Using *hardness of approximation* for NAE-E3-SAT with soundness $15/16 + \varepsilon$ and perfect completeness; see Theorem 10.
2. Taking the Kronecker product of G with the "ℓ_p norm degree" diagonal matrix

   $$\mathbf{D}_p := \mathbf{D}_p(\phi) = \mathrm{diag}(\deg(v_1)^{1/p}, \ldots, \deg(v_n)^{1/p}) \in \mathbb{R}^{n \times n}$$

   in the definition of $\mathbf{A}$ instead of just taking the Kronecker product with I_n. Here $\deg(v_i)$ counts the number of occurrences of the variable v_i and its negation $\neg v_i$ in the formula ϕ.
3. Extending the analysis from [29] for the gadget matrix $\mathbf{G}$. For example, we prove an ℓ_p analog of the fact that $\mathrm{lindisc}(\mathbf{G})_\infty$ is small (and in fact, that something stronger is true) in Lemma 11, and we observe that $\mathbf{G} \cdot \mathbf{0} = \mathbf{0}$ and $\mathbf{G} \cdot \mathbf{1} = \mathbf{1}$ are the only closest vectors in $\mathcal{L}(\mathbf{G}) = \mathbf{G} \cdot \mathbb{Z}^3$ to $\mathbf{G} \cdot (\frac{1}{2}\mathbf{1})$ (and not just the only closest vectors in $\mathbf{G} \cdot \{0,1\}^3$ to $\mathbf{G} \cdot (\frac{1}{2}\mathbf{1})$) in Lemma 12.

For Item 1, we note that the soundness-to-completeness ratio of 15/16 in Theorem 10 is *not* tight. In fact, recent work of Brakensiek, Huang, Potechin, and Zwick [6] shows tight upper and lower bounds for NAE-E3-SAT with a lower (i.e., better) soundness-to-completeness ratio of roughly $0.9089 < 15/16 = 0.9375$. However, Theorem 10 shows hardness of (δ, ε)-NAE-E3-SAT *with perfect completeness* (i.e., with $\varepsilon = 1$), whereas the result of [6] does not. This is important since our main hardness reduction for BinGapCRP_p requires reducing from (δ, ε)-NAE-E3-SAT with nearly perfect completeness. The hardness result in Theorem 10 appeared in work of Guruswami [14], which observed that it follows by combining a reduction due to Petrank [35] and a hardness result due to Håstad [18]. (We include a proof of this result in the full version.)

The reason for using $\mathbf{D}_p$ as in Item 2 is as follows. In our analysis, we analyze the quantity $\|\mathbf{A}\boldsymbol{y}\|_p^p$ for coefficient vectors $\boldsymbol{y} \in \mathbb{Z}^{3n}$ expressed as a sum indexed by the m constraints in ϕ (see Lemma 13). We wish to penalize vectors $\boldsymbol{y}$ that do not correspond to valid assignments to ϕ by having $\|\mathbf{A}\boldsymbol{y}\|_p^p$ be larger for such $\boldsymbol{y}$. Using the matrix $\mathbf{D}_p$ allows us to do this. Specifically, it allows us to balance the contributions of the top part $\begin{pmatrix}\frac{1}{3}\mathbf{B} & \frac{1}{3}\mathbf{B} & \frac{1}{3}\mathbf{B}\end{pmatrix} \cdot \boldsymbol{y}$ and the bottom part $(\mathbf{G} \otimes \mathbf{D}_p) \cdot \boldsymbol{y}$ of $\mathbf{A}\boldsymbol{y}$ to each term in this sum. The top part's contribution to a summand will be large if $\boldsymbol{y}$ corresponds to a valid but unsatisfying assignment to ϕ, and the bottom part's contribution to a summand will be large if $\boldsymbol{y}$ corresponds to an invalid assignment to ϕ.

1.4 Open Questions

We again emphasize the central open question that we consider in this work: For which values of $\gamma = \gamma(p)$ is γ-GapCRP in the ℓ_p norm NP-hard, and for which is it Π_2-hard? In particular, we reiterate that the problem of showing NP-hardness of exact GapCRP in the ℓ_2 norm (the most important special case) remains open. We again note that the AM protocol of [15] for approximate GapCRP (conditionally) rules out Π_2-hardness for γ-GapCRP_p for $\gamma \geq 2$, but says nothing about NP-hardness of γ-GapCRP_p. Manurangsi [29] notes that no such analogous AM protocol is known for LinDisc, and asks if one exists.

2 Preliminaries

We will use boldface, lowercase letters to denote vectors. We will sometimes abuse notation when defining column vectors in terms of other column vectors by writing things like $\boldsymbol{x} := (\boldsymbol{y}, \boldsymbol{z})$ to mean $\boldsymbol{x} := (\boldsymbol{y}^T, \boldsymbol{z}^T)^T$. We will use $\mathbf{0}$ and $\mathbf{1}$ to denote the all-0s and all-1s vectors, respectively.

We define the predicate $\text{sgndiff}(\boldsymbol{x}, \boldsymbol{y})$ on vectors $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^n$ to be true if and only if the Hadamard (entry-wise) product $\boldsymbol{x} \odot \boldsymbol{y} \in \mathbb{R}^n$ has at least one non-positive coordinate and at least one non-negative coordinate. We will use the simple fact that if $\text{sgndiff}(\boldsymbol{x}, \boldsymbol{y})$ holds and if $\max_i |x_i y_i| \leq r$ for some $r \geq 0$, then $|\langle \boldsymbol{x}, \boldsymbol{y} \rangle| = |\sum_{i=1}^n x_i y_i| \leq r(n-1)$.

2.1 Covering Radius and Linear Discrepancy

We call a matrix $\mathbf{B} = (\boldsymbol{b}_1, \ldots, \boldsymbol{b}_n) \in \mathbb{R}^{m \times n}$ with full column rank a *basis*. In particular, $m \geq n$ for a basis. The lattice $\mathcal{L}(\mathbf{B})$ generated by $\mathbf{B}$ is defined as

$$\mathcal{L}(\mathbf{B}) := \left\{ \sum_{i=1}^n a_i \boldsymbol{b}_i : a_1, \ldots, a_n \in \mathbb{Z} \right\} .$$

For $p \geq 1$, the ℓ_p *covering radius* of a lattice $\mathcal{L} \subset \mathbb{R}^m$ is defined as

$$\mu_p(\mathcal{L}) := \max_{\boldsymbol{t} \in \mathrm{span}(\mathcal{L})} \mathrm{dist}_p(\boldsymbol{t}, \mathcal{L}) \ ,$$

where for a discrete set S, we define $\mathrm{dist}_p(\boldsymbol{t}, S) := \min_{\boldsymbol{y} \in S} \|\boldsymbol{t} - \boldsymbol{y}\|_p$. The *span* $\mathrm{span}(\mathcal{L})$ of a lattice $\mathcal{L}$ is the linear span of the vectors in the lattice (or equivalently, the linear span $\mathrm{span}(\boldsymbol{b}_1, \ldots, \boldsymbol{b}_n)$ of the vectors in a basis $\mathbf{B} := (\boldsymbol{b}_1, \ldots, \boldsymbol{b}_n)$ of $\mathcal{L}$). Because $\mathrm{dist}_p(\boldsymbol{t} + \boldsymbol{y}, \mathcal{L}) = \mathrm{dist}_p(\boldsymbol{t}, \mathcal{L})$ for any $\boldsymbol{t} \in \mathbb{R}^m$ and $\boldsymbol{y} \in \mathcal{L}$, we have that if $\mathcal{L} = \mathcal{L}(\mathbf{B})$ for a basis $\mathbf{B} \in \mathbb{R}^{m \times n}$,

$$\mu_p(\mathcal{L}) = \max_{\boldsymbol{w} \in \mathbb{R}^n} \min_{\boldsymbol{x} \in \mathbb{Z}^n} \|\mathbf{B}(\boldsymbol{w} - \boldsymbol{x})\|_p = \max_{\boldsymbol{w} \in [0,1]^n} \min_{\boldsymbol{x} \in \mathbb{Z}^n} \|\mathbf{B}(\boldsymbol{w} - \boldsymbol{x})\|_p \ . \tag{4}$$

That is, because the distance of a vector $\mathbf{B}\boldsymbol{w}$ to $\mathcal{L}(\mathbf{B})$ is invariant under shifts by lattice vectors (i.e., vectors $\mathbf{B}\boldsymbol{x}$ for $\boldsymbol{x} \in \mathbb{Z}^n$), it suffices to consider the maximum distance of vectors $\mathbf{B}\boldsymbol{w}$ in the fundamental parallelepiped $\mathcal{P}(\mathbf{B}) := \mathbf{B} \cdot [0,1]^n$ to the lattice.

We will also work with *linear discrepancy*, a quantity closely related to the covering radius that was first defined in [27]. For $p \geq 1$, the linear discrepancy $\mathrm{lindisc}(\mathbf{B})$ of a matrix $\mathbf{B}$ is defined as[5]

$$\mathrm{lindisc}_p(\mathbf{B}) := \max_{\boldsymbol{w} \in [0,1]^n} \min_{\boldsymbol{x} \in \{0,1\}^n} \|\mathbf{B}(\boldsymbol{w} - \boldsymbol{x})\|_p \ . \tag{5}$$

Covering radius versus linear discrepancy

We note that the equivalent formulation of $\mu_p(\mathcal{L})$ on the right-hand side of Equation (4) and the definition of $\mathrm{lindisc}(\mathbf{B})$ are syntactically very similar. The only difference is that the minimum in Equation (4) is taken over $\boldsymbol{x} \in \mathbb{Z}^n$ (which corresponds to the entire lattice $\mathcal{L}(\mathbf{B}) = \{\mathbf{B}\boldsymbol{x} : \boldsymbol{x} \in \mathbb{Z}^n\}$) whereas in Equation (5) the minimum is only taken over $\boldsymbol{x} \in \{0,1\}^n$ (which corresponds to *binary* linear combinations $\mathbf{B}\boldsymbol{x}$ of basis vectors).

Despite the similarity of the definitions of μ_p and $\mathrm{lindisc}_p$, we emphasize that they capture different quantities. In particular, the closest vector in the lattice $\mathcal{L}(\mathbf{B}) := \mathbf{B} \cdot \mathbb{Z}^n$ to a vector $\mathbf{B} \cdot \boldsymbol{w}$ for $\boldsymbol{w} \in [0,1]^n$ need not be a vector in $\mathbf{B} \cdot \{0,1\}^n$. We give a simple example of this for the lattice $\mathbb{Z}^2$ when the input basis $\mathbf{B}$ consists of rather long vectors.

▶ **Example 3.** Consider the basis

$$\mathbf{B} := \begin{pmatrix} 3 & 4 \\ 1 & 1 \end{pmatrix} \ ,$$

and note that $\mathcal{L}(\mathbf{B}) = \mathbb{Z}^2$ since $\det(\mathbf{B}) = -1$ (i.e., $\mathbf{B}$ is unimodular). Let $\boldsymbol{w} := (1, 1/2)^T$, and note that $\mathbf{B}\boldsymbol{w} = (5, 3/2)^T$. Then

$$\mathrm{dist}_p(\mathbf{B}\boldsymbol{w}, \mathcal{L}(\mathbf{B})) = \mathrm{dist}_p(\mathbf{B}\boldsymbol{w}, \mathbb{Z}^2) = \|\mathbf{B}((3, -1)^T - \boldsymbol{w})\|_p = 1/2 \ ,$$

but one can check that $\|\mathbf{B}(\boldsymbol{x} - \boldsymbol{w})\|_p > 1/2$ for all $\boldsymbol{x} \in \{0,1\}^2$.

2.2 Covering Radius and Linear Discrepancy as Computational Problems

We next define the approximate decisional Covering Radius Problem in the ℓ_p norm, γ-GapCRP, and the closely related approximate Linear Discrepancy Problem in the ℓ_p norm, γ-$\mathrm{LinDisc}_p$.

[5] The definition of $\mathrm{lindisc}(\mathbf{B})$ does not require $\mathbf{B}$ to be a basis. I.e., $\mathbf{B}$ is allowed to have linearly dependent columns.

▶ **Definition 4.** *Let $p \in [1, \infty]$ and let $\gamma = \gamma(n) \geq 1$. The* γ-approximate decisional Covering Radius Problem in the ℓ_p norm *(γ-GapCRP$_p$), is the problem where, on input a basis $\mathbf{B} \in \mathbb{Q}^{m \times n}$ and a value $r > 0$, the goal is to distinguish between the following two cases.*

- *(YES instance.)* $\mu_p(\mathcal{L}(\mathbf{B})) \leq r$.
- *(NO instance.)* $\mu_p(\mathcal{L}(\mathbf{B})) > \gamma r$.

▶ **Definition 5.** *Let $p \in [1, \infty]$ and let $\gamma = \gamma(n) \geq 1$. The* γ-approximate decisional Linear Disrepancy Problem in the ℓ_p norm *(γ-LinDisc$_p$) is the problem where, on input a basis $\mathbf{B} \in \mathbb{Q}^{m \times n}$ and a value $r > 0$, the goal is to distinguish between the following two cases.*

- *(YES instance.)* $\text{lindisc}_p(\mathbf{B}) \leq r$.
- *(NO instance.)* $\text{lindisc}_p(\mathbf{B}) > \gamma r$.

Finally, we define the binary decisional Covering Radius Problem BinGapCRP, which has the YES instances of LinDisc and the NO instances of GapCRP.

▶ **Definition 6.** *Let $p \in [1, \infty]$ and let $\gamma = \gamma(n) \geq 1$. The* γ-approximate decisional Binary Covering Radius Problem in the ℓ_p norm *(γ-BinGapCRP$_p$) is the problem where, on input a basis $\mathbf{B} \in \mathbb{Q}^{m \times n}$ and a value $r > 0$, the goal is to distinguish between the following two cases.*

- *(YES instance.)* $\text{lindisc}_p(\mathbf{B}) \leq r$.
- *(NO instance.)* $\mu_p(\mathcal{L}(\mathbf{B})) > \gamma r$.

We note that $\mu_p(\mathcal{L}(\mathbf{B})) \leq \text{lindisc}_p(\mathbf{B})$ for any $p \in [1, \infty]$ and any basis $\mathbf{B}$. Therefore, for any $p \in [1, \infty]$ and $\gamma \geq 1$, YES (respectively, NO) instances of γ-BinGapCRP$_p$ are YES (respectively, NO) instances of both γ-GapCRP$_p$ and γ-LinDisc$_p$. We therefore immediately have the following observation.

▶ **Proposition 7.** *For any $\gamma \geq 1$ and $p \in [1, \infty]$, the identity mapping $(\mathbf{B}, r) \mapsto (\mathbf{B}, r)$ is a (polynomial-time) reduction from* γ-BinGapCRP$_p$ *to* γ-GapCRP$_p$ *and to* γ-LinDisc$_p$.

2.3 Constraint Satisfaction Problems

A (Boolean) *constraint satisfaction problem* (CSP) is defined by a set of Boolean variables $X = \{x_1, \ldots, x_n\}$, and a set of functions called *constraints* $\mathcal{C} = \{C_1, \ldots, C_m\}$ with $C_i \colon \{0,1\}^{|C_i|} \to \{0,1\}$. An *assignment* of the variables is a map from $X \to \{0,1\}$. A constraint C_i is *satisfied* by an assignment if the output of the constraint on the assignment of the variables is 1. Let ϕ be a CSP and let ψ be an assignment of the variables in ϕ. We define $\text{val}_\psi(\phi)$ to be the fraction of constraints in ϕ satisfied by an assignment ψ, and define the *value* of ϕ to be $\text{val}(\phi) := \max_\psi \text{val}_\psi(\phi)$. We then define the computational problem (δ, ε)-CSP as follows.

▶ **Definition 8** (Constraint Satisfaction Problems (CSP))**.** *For $\delta, \varepsilon \in \mathbb{R}$ be such that $0 < \delta \leq \varepsilon \leq 1$, (δ, ε)-CSP is the decision problem defined as follows. On input a collection of constraints $\mathcal{C} = \{C_1, \ldots, C_m\}$, the goal is to decide between the follows two cases.*

- *(YES instance.)* $\text{val}(\phi) \geq \varepsilon$.
- *(NO instance.)* $\text{val}(\phi) < \delta$.

We now introduce NAE-Ek-SAT, a k-ary CSP that will be important for our hardness reductions.

▶ **Definition 9** ((δ, ε)-NAE-Ek-SAT problem)**.** *A* NAE-Ek-SAT *formula ϕ consists of n Boolean variables $X = \{x_1, \ldots, x_n\}$ and m constraints $C_1, \ldots, C_m$, where each constraint C_i is a function of exactly k distinct literals (Boolean variables x_j or their negations $\neg x_j$). A constraint C_i is satisfied by an assignment if and only if not all k of its literals evaluate either to 1 or to 0.*

Let $\delta, \varepsilon \in \mathbb{R}$ be such that $0 < \delta \leq \varepsilon \leq 1$. The goal of the (δ, ε)-NAE-Ek-SAT problem is, given a NAE-Ek-SAT *formula as input, to decide between the following two cases.*

- *(YES instance.)* $\mathrm{val}(\phi) \geq \varepsilon$.
- *(NO instance.)* $\mathrm{val}(\phi) < \delta$.

We represent NAE-Ek-SAT constraints C as sets of k literals, and we use the notation $\mathrm{vars}(C)$ to denote the set of indices of variables involved in a NAE-E3-SAT constraint C. For example, if $k = 3$ and $C := \{v_1, \neg v_3, \neg v_4\}$ then $\mathrm{vars}(C) = \{1, 3, 4\}$. We define $\mathrm{sgn}(\ell) \in \{-1, 1\}$ and $\mathrm{var}(\ell)$ to be the sign and the index of the variable underlying a literal ℓ, respectively. For example, $\mathrm{sgn}(\neg v_4) = -1$ and $\mathrm{var}(\neg v_4) = 4$.

We next give a result showing NP-hardness of $(15/16+\varepsilon, 1)$-NAE-E3-SAT for any constant $\varepsilon > 0$ in Theorem 10. This hardness result appeared in work of Guruswami [14], which observed that it follows by combining a reduction due to Petrank [35] and a hardness result due to Håstad [18].

▶ **Theorem 10.** *For any constant $\varepsilon \in (0, 1/16)$, $(15/16 + \varepsilon, 1)$-NAE-E3-SAT is NP-hard.*

See our full version for a proof of Theorem 10.

3 Reduction from NAE-E3-SAT to BinaryGapCRP

3.1 The Reduction

We start by giving our reduction from (δ, ε)-NAE-E3-SAT to γ-BinGapCRP$_p$ for certain values of $\delta, \varepsilon, \gamma, p$. In what follows, we will analyze the reduction and for which parameter values it is valid. We emphasize again that the reduction is similar to the NP-hardness reduction in [29] for $\mathrm{LinDisc}_\infty$.

Let ϕ be the input (δ, ε)-NAE-E3-SAT formula, and assume that ϕ has n variables $v_1, \ldots, v_n$ and m constraints $C_1, \ldots, C_m$. We define the incidence matrix $\mathbf{B} \in \mathbb{R}^{m \times n}$ of ϕ as

$$B_{i,j} := B_{i,j}(\phi) = \begin{cases} 1 & \text{if constraint } C_i \text{ contains literal } v_j \ , \\ -1 & \text{if constraint } C_i \text{ contains literal } \neg v_j \ , \\ 0 & \text{otherwise .} \end{cases} \tag{6}$$

We will also use the following gadget matrix, defined in [29], which we analyze in Section 3.2.

$$\mathbf{G} := \begin{pmatrix} 1 & 1 & -1 \\ 1 & -1 & 1 \\ -1 & 1 & 1 \end{pmatrix} . \tag{7}$$

Let $\deg_\phi(v_j)$ denote the number of constraints C_i in ϕ containing either v_j or $\neg v_j$. When the formula ϕ is clear from context, we simply write $\deg(v_j)$. For $p \in [1, \infty]$, define the $n \times n$ diagonal matrix

$$\mathbf{D}_p := \mathbf{D}_p(\phi) = \mathrm{diag}(\deg(v_1)^{1/p}, \ldots, \deg(v_n)^{1/p}) = \begin{pmatrix} \deg(v_1)^{1/p} & & \\ & \ddots & \\ & & \deg(v_n)^{1/p} \end{pmatrix} .$$

Finally, we output the γ-BinGapCRP$_p$ instance consisting of the matrix

$$\mathbf{A} := \mathbf{A}_p(\phi) = \begin{pmatrix} \frac{1}{3}\mathbf{B} & \frac{1}{3}\mathbf{B} & \frac{1}{3}\mathbf{B} \\ & \mathbf{G} \otimes \mathbf{D}_p & \end{pmatrix} \in \mathbb{R}^{(m+3n) \times 3n} \ , \tag{8}$$

and distance threshold

$$r := (\varepsilon m \cdot (4/3)^p + (1 - \varepsilon)m \cdot 2^p + 3m(2 + (4/3)^p))^{1/p} > 0 \ . \tag{9}$$

3.2 Analysis of the matrix G

We begin by presenting some technical lemmas about $\mathbf{G}$ that will be useful in our hardness reductions. We start with Lemma 11, which adapts [29, Lemma 3] from the ℓ_∞ norm to ℓ_p norms.

▶ **Lemma 11.** *For any $\boldsymbol{u} \in [0,1]^3$ and $b \in \{-1,1\}$, there exists $\boldsymbol{z} \in \{0,1\}^3$ such that*

1. *(Low discrepancy w.r.t. $\mathbf{G}$.) $\|\mathbf{G}(\boldsymbol{u}-\boldsymbol{z})\|_p^p \leq 2 + (4/3)^p$, where $\mathbf{G}$ is as defined in Equation (7).*
2. *(Sign agreement.) $b \cdot (\mathbf{1}^T(\boldsymbol{u}-\boldsymbol{z})) \geq 0$.*
3. *(Low discrepancy w.r.t. $\mathbf{1}^T$.) $|\mathbf{1}^T(\boldsymbol{u}-\boldsymbol{z})| \leq 2$.*

Proof. The second and third properties are identical to the corresponding properties in [29, Lemma 3] (which are proved there), and so we only prove the first property. We follow the structure of the proof of [29, Lemma 3, Item 1] to prove the first property.

We assume without loss of generality that $0 \leq u_1 \leq u_2 \leq u_3 \leq 1$ throughout the proof. This assumption is justified by the easy-to-check fact that for all 3×3 permutation matrices $\mathbf{P}$ and $\boldsymbol{x} \in \mathbb{R}^3$, $\|\mathbf{G}\boldsymbol{x}\|_\infty = \|\mathbf{G}\mathbf{P}\boldsymbol{x}\|_\infty$.

We now proceed to the proof of Item 1. We will consider three cases, and in each case we will bound each coordinate of $\mathbf{G}(\boldsymbol{u}-\boldsymbol{z})$ individually.

Case 1: $\mathbf{1}^T\boldsymbol{u} \geq 2$. In this case we set $\boldsymbol{z} := (0,1,1)^T$, and have

$$\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}) = \begin{pmatrix} u_1+u_2-u_3 \\ u_1-u_2+u_3 \\ -u_1+u_2+u_3-2 \end{pmatrix}.$$

We have following bounds:

- $-1 \leq -u_3 \leq (\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}))_1 = (\mathbf{G}\boldsymbol{u})_1 \leq u_1 \leq 1$.
- $-1 \leq -u_2 \leq (\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}))_2 = (\mathbf{G}\boldsymbol{u}))_2 \leq u_3 \leq 1$.
- $-4/3 \leq u_3 - 2 \leq (\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}))_3 = (\mathbf{G}\boldsymbol{u})_3 - 2 \leq -u_1 \leq 0$.

Case 2: $\mathbf{1}^T\boldsymbol{u} < 2$ and $(\mathbf{G}\boldsymbol{u})_3 \leq 4/3$.[6] In this case we set $\boldsymbol{z} := \mathbf{0}$, and have

$$\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}) = \begin{pmatrix} u_1+u_2-u_3 \\ u_1-u_2+u_3 \\ -u_1+u_2+u_3 \end{pmatrix}.$$

We have the following bounds:

- $-1 \leq -u_3 \leq (\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}))_1 = (\mathbf{G}\boldsymbol{u})_1 \leq u_1 \leq 1$.
- $-1 \leq -u_2 \leq (\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}))_2 = (\mathbf{G}\boldsymbol{u})_2 \leq u_3 \leq 1$.
- $0 \leq u_3 \leq (\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}))_3 = (\mathbf{G}\boldsymbol{u})_3 \leq 4/3$.

Case 3: $\mathbf{1}^T\boldsymbol{u} < 2$ and $(\mathbf{G}\boldsymbol{u})_3 > 4/3$. In this case we set $\boldsymbol{z} := (0,0,1)^T$, and have

$$\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}) = \begin{pmatrix} u_1+u_2-u_3+1 \\ u_1-u_2+u_3-1 \\ -u_1+u_2+u_3-1 \end{pmatrix}.$$

We have the following bounds:

[6] In fact, the assumption that $\mathbf{1}^T\boldsymbol{u} < 2$ is not even necessary here.

- $0 \le -u_3 + 1 \le (\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}))_1 = (\mathbf{G}\boldsymbol{u})_1 + 1 \le u_1 + 1 = \frac{1}{2}(\mathbf{1}^T\boldsymbol{u} - (\mathbf{G}\boldsymbol{u})_3) + 1 < 1/3 + 1 = 4/3.$
- $-1 \le u_1 - 1 \le (\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}))_2 = (\mathbf{G}\boldsymbol{u})_2 - 1 \le u_3 - 1 \le 0.$
- $-1 \le u_3 - 1 \le (\mathbf{G}(\boldsymbol{u}-\boldsymbol{z}))_3 = (\mathbf{G}\boldsymbol{u})_3 - 1 \le \mathbf{1}^T\boldsymbol{u} - 1 < 1.$

In each case, we have $\|\mathbf{G}(\boldsymbol{u}-\boldsymbol{z})\|_p^p \le 2 + (4/3)^p$, as needed. ◀

Lemma 12 is the other part of the extension of [29, Lemma 3], and facilitates a reduction to BinGapCRP, rather than just LinDisc. We both adapt [29, Lemma 3] to ℓ_p norms for $p < \infty$ and show that $\mathbf{G}(1/2 \cdot \mathbf{1}) = (1/2) \cdot \mathbf{1}$ is far from all vectors in $\mathcal{L}(\mathbf{G}) \setminus \{\mathbf{0}, \mathbf{1}\} = \mathbf{G} \cdot (\mathbb{Z}^3 \setminus \{\mathbf{0}, \mathbf{1}\})$ rather than just vectors in $\mathbf{G} \cdot (\{0,1\}^3 \setminus \{\mathbf{0}, \mathbf{1}\})$.

▶ **Lemma 12.** *Let $\boldsymbol{z} \in \mathbb{Z}^3$ and $p \in [1, \infty]$. Then we have the following:*

1. *For $\boldsymbol{z} \in \{\mathbf{0}, \mathbf{1}\}$, $\mathbf{G}(1/2 \cdot \mathbf{1} - \boldsymbol{z}) \in \{-1/2, 1/2\}^3$. Therefore, $\|\mathbf{G}(1/2 \cdot \mathbf{1} - \boldsymbol{z})\|_p^p = 3/2^p$ if $p < \infty$ and $\|\mathbf{G}(1/2 \cdot \mathbf{1} - \boldsymbol{z})\|_\infty = 1/2$.*
2. *For $\boldsymbol{z} \in \mathbb{Z}^3 \setminus \{\mathbf{0}, \mathbf{1}\}$, $\|\mathbf{G}(1/2 \cdot \mathbf{1} - \boldsymbol{z})\|_p^p \ge (2 + 3^p)/2^p$ if $p < \infty$ and $\|\mathbf{G}(1/2 \cdot \mathbf{1} - \boldsymbol{z})\|_\infty \ge 3/2$.*

Proof. We note that $\mathbf{G}((1/2) \cdot \mathbf{1} - \boldsymbol{z}) = (1/2) \cdot \mathbf{1} - \mathbf{G}\boldsymbol{z}$ so that[7]

$$\{(\mathbf{G}(1/2 \cdot \mathbf{1} - \boldsymbol{z}) : \boldsymbol{z} \in \mathbb{Z}^3\} = \{\mathbf{G}\boldsymbol{z} : \boldsymbol{z} \in \mathbb{Z}^3\} + (1/2) \cdot \mathbf{1} \subseteq (\mathbb{Z} + 1/2)^3 \ .$$

That is, for any $\boldsymbol{z} \in \mathbb{Z}^3$, each coordinate of $G((1/2 \cdot \mathbf{1} - \boldsymbol{z})$ is contained in $\mathbb{Z} + 1/2$. Fix such a coefficient vector $\boldsymbol{z} \in \mathbb{Z}^3$. Then for $p < \infty$, $\|\mathbf{G}((1/2) \cdot \mathbf{1} - \boldsymbol{z})\|_p^p = 3/2^p$ if $\mathbf{G}\boldsymbol{z} \in \{0,1\}^3$ and $\|\mathbf{G}((1/2) \cdot \mathbf{1} - \boldsymbol{z})\|_p^p \ge (2 + 3^p)/2^p$ otherwise. Similarly, $\|\mathbf{G}((1/2) \cdot \mathbf{1} - \boldsymbol{z})\|_\infty = 1/2$ if $\mathbf{G}\boldsymbol{z} \in \{0,1\}^3$ and $\|\mathbf{G}((1/2) \cdot \mathbf{1} - \boldsymbol{z})\|_\infty \ge 3/2$ otherwise. The lemma then follows by noting that $\mathcal{L}(\mathbf{G}) \cap \{0,1\}^3 = \{\mathbf{0}, \mathbf{1}\}$. ◀

3.3 Completeness Analysis

We start with an expression for the value of $\|\mathbf{A}(\boldsymbol{w} - \boldsymbol{x})\|_p^p$ for the matrix $\mathbf{A} = \mathbf{A}(\phi)$ defined in Equation (8) in terms of a NAE-E3-SAT formula ϕ and vectors $\boldsymbol{w}, \boldsymbol{x}$.

▶ **Lemma 13.** *Let $p \ge 1$, and for $i \in [3]$, let $\boldsymbol{y}^i \in \mathbb{R}^n$, let ϕ be an* NAE-E3-SAT *formula with constraints $C_1, \ldots, C_m$, and let $\mathbf{A} := \mathbf{A}_p(\phi)$ as defined in Equation (8). Let $\boldsymbol{y} := (\boldsymbol{y}^1, \boldsymbol{y}^2, \boldsymbol{y}^3) \in \mathbb{R}^{3n}$, let $\boldsymbol{y}^{sum} := \boldsymbol{y}^1 + \boldsymbol{y}^2 + \boldsymbol{y}^3 \in \mathbb{R}^n$, and for $j \in [n]$, let $\boldsymbol{y}_j := (y_j^1, y_j^2, y_j^3) \in \mathbb{R}^3$. Then*

$$\|\mathbf{A}\boldsymbol{y}\|_p^p = (1/3^p) \cdot \|\mathbf{B}\boldsymbol{y}^{sum}\|_p^p + \sum_{j=1}^{n} \deg(v_j) \cdot \left\|\mathbf{G}\boldsymbol{y}_j\right\|_p^p \ . \tag{10}$$

Let $\boldsymbol{x}^1, \boldsymbol{x}^2, \boldsymbol{x}^3 \in \mathbb{R}^n$, let $\boldsymbol{x} := (\boldsymbol{x}^1, \boldsymbol{x}^2, \boldsymbol{x}^3) \in \mathbb{R}^{3n}$, and let $\boldsymbol{x}^{sum} := \boldsymbol{x}^1 + \boldsymbol{x}^2 + \boldsymbol{x}^3 \in \mathbb{R}^n$. Furthermore, for $j \in [n]$, let $\boldsymbol{x}_j := (x_j^1, x_j^2, x_j^3)^T \in \mathbb{R}^3$, and let $\boldsymbol{b}_i$ denote the ith row of $\mathbf{B}$. Then in particular,

$$\left\|\mathbf{A}\left(\frac{1}{2} \cdot \mathbf{1} - \boldsymbol{x}\right)\right\|_p^p = \sum_{i=1}^{m} \left(\left|\frac{1}{3}\boldsymbol{b}_i\left(\frac{3}{2} \cdot \mathbf{1} - \boldsymbol{x}^{sum}\right)\right|^p + \sum_{j \in \mathrm{vars}(C_i)} \left\|\mathbf{G}\left(\frac{1}{2} \cdot \mathbf{1} - \boldsymbol{x}_j\right)\right\|_p^p \right) \ . \tag{11}$$

[7] This is equivalent to the fact that $\mathbf{G}$ has $\mathbf{1}$ as an eigenvector with corresponding eigenvalue 1.

Proof. For Equation (10),

$$\begin{aligned}\|\mathbf{A}(\boldsymbol{y})\|_p^p &= \left\|(1/3)\cdot(\mathbf{B}\boldsymbol{y}^1+\mathbf{B}\boldsymbol{y}^2+\mathbf{B}\boldsymbol{y}^3)\right\|_p^p + \|(\mathbf{G}\otimes\mathbf{D}_p)\cdot\boldsymbol{y}\|_p^p \\ &= \|(1/3)\cdot\mathbf{B}\boldsymbol{y}^{\text{sum}}\|_p^p + \sum_{j=1}^n \deg(v_j)\cdot\left\|\mathbf{G}\boldsymbol{y}_j\right\|_p^p .\end{aligned}$$

For Equation (11), we set $\boldsymbol{y} := \frac{1}{2}\cdot\mathbf{1}-\boldsymbol{x}$ and continue by re-grouping some terms.

$$\begin{aligned}\left\|\mathbf{A}\left(\frac{1}{2}\cdot\mathbf{1}-\boldsymbol{x}\right)\right\|_p^p &= \frac{1}{3^p}\cdot\left\|\mathbf{B}\left(\frac{3}{2}\cdot\mathbf{1}-\boldsymbol{x}^{\text{sum}}\right)\right\|_p^p + \sum_{j=1}^n \deg(v_j)\cdot\left\|\mathbf{G}\left(\frac{1}{2}\cdot\mathbf{1}-\boldsymbol{x}_j\right)\right\|_p^p \\ &= \frac{1}{3^p}\cdot\sum_{i=1}^m\left|\boldsymbol{b}_i\left(\frac{3}{2}\cdot\mathbf{1}-\boldsymbol{x}^{\text{sum}}\right)\right|^p + \sum_{j=1}^n \deg(v_j)\cdot\left\|\mathbf{G}\left(\frac{1}{2}\cdot\mathbf{1}-\boldsymbol{x}_j\right)\right\|_p^p \\ &= \sum_{i=1}^m\left(\left|\frac{1}{3}\boldsymbol{b}_i\left(\frac{3}{2}\cdot\mathbf{1}-\boldsymbol{x}^{\text{sum}}\right)\right|^p + \sum_{j\in\text{vars}(C_i)}\left\|\mathbf{G}\left(\frac{1}{2}\cdot\mathbf{1}-\boldsymbol{x}_j\right)\right\|_p^p\right).\end{aligned}$$

The first equality follows by setting $\boldsymbol{w} := 1/2\cdot\mathbf{1}$ in Equation (10). The third equality follows by noting for any expression $K(j)$ depending on j,

$$\sum_{j=1}^n \deg(v_j)K(j) = \sum_{j=1}^n \sum_{\text{vars}(C_i):x_j\in\text{vars}(C_i)} K(j) = \sum_{i=1}^m \sum_{j:x_j\in\text{vars}(C_i)} K(j) . \tag{12}$$

Indeed, one can view the two double sums as counting constraint-variable incidences in two different ways. ◀

We now state lemmas that will be used in the proof of Theorem 17. We begin with a lemma for completeness in which we upper bound $\text{lindisc}_p(\mathbf{A})$.

▶ **Lemma 14.** *Let $p\in[1,\infty)$, let $\varepsilon\in[0,1]$, let ϕ be an* NAE-E3-SAT *instance with m constraints and $\text{val}(\phi)\geq\varepsilon$, and let $\mathbf{A}:=\mathbf{A}_p(\phi)$ be defined as in Equation* (8)*. Then*

$$\text{lindisc}_p(\mathbf{A})^p \leq (\varepsilon\cdot(4/3)^p + (1-\varepsilon)\cdot 2^p + 3(2+(4/3)^p))\cdot m . \tag{13}$$

Proof. Let ψ be an assignment to the variables of ϕ such that $\text{val}_\psi(\phi)\geq\varepsilon$. Let $\boldsymbol{w}^1,\boldsymbol{w}^2,\boldsymbol{w}^3\in[0,1]^n$, and let $\boldsymbol{w} := (\boldsymbol{w}^1,\boldsymbol{w}^2,\boldsymbol{w}^3)$. We define $\boldsymbol{x} := (\boldsymbol{x}^1,\boldsymbol{x}^2,\boldsymbol{x}^3)$ for $\boldsymbol{x}^1,\boldsymbol{x}^2,\boldsymbol{x}^3\in\{0,1\}^n$ as follows. For each $j\in[n]$, the vector $\boldsymbol{x}_j := (x_j^1,x_j^2,x_j^3)^T$ is the vector $\boldsymbol{z}$ guaranteed by Lemma 11 applied to the vector $\boldsymbol{u} := \boldsymbol{w}_j = (w_j^1,w_j^2,w_j^3)^T$ and sign $b := 1-2\psi(v_j)$.

We begin by upper bounding $\|\mathbf{A}(\boldsymbol{w}-\boldsymbol{x})\|_p^p$, which we do by upper bounding the terms on the right-hand side of Equation (10) individually with $\boldsymbol{y} := \boldsymbol{w}-\boldsymbol{x}\in\mathbb{R}^{3n}$. From Lemma 11, Item 1 and the fact that ϕ has total degree $\sum_{j=1}^n\deg(v_j)=3m$, we have

$$\sum_{j=1}^n \deg(v_j)\cdot\|\mathbf{G}(\boldsymbol{w}_j-\boldsymbol{x}_j)\|_p^p \leq \sum_{j=1}^n \deg(v_j)\cdot(2+(4/3)^p) = 3m(2+(4/3)^p). \tag{14}$$

To upper bound $\left\|\frac{1}{3}\mathbf{B}(\boldsymbol{w}^{\text{sum}}-\boldsymbol{x}^{\text{sum}})\right\|_p^p$, we upper bound the magnitude of each coordinate i of $\mathbf{B}(\boldsymbol{w}^{\text{sum}}-\boldsymbol{x}^{\text{sum}})\in\mathbb{R}^m$. Suppose that constraint $C_i=\{\ell_{i,1},\ell_{i,2},\ell_{i,3}\}$ for some literals $\ell_{i,1},\ell_{i,2},\ell_{i,3}$. Then

$$(\mathbf{B}(\boldsymbol{w}^{\text{sum}}-\boldsymbol{x}^{\text{sum}}))_i = \sum_{j=1}^3 \text{sgn}(\ell_{i,j})\cdot(w^{\text{sum}}_{\text{var}(\ell_{i,j})} - x^{\text{sum}}_{\text{var}(\ell_{i,j})}) . \tag{15}$$

By Lemma 11, Item 3, we have that $|\mathbf{1}^T(\boldsymbol{w}_j - \boldsymbol{x}_j)| = |w_j^{\text{sum}} - x_j^{\text{sum}}| \leq 2$ for all $j \in [n]$. So, the expression in Equation (15) always has magnitude at most 6 by triangle inequality and has magnitude at most 4 as long as the signs of its summands are not all the same (i.e., as long as $\text{sgndiff}(\boldsymbol{b}_i, \boldsymbol{w}^{\text{sum}} - \boldsymbol{x}^{\text{sum}})$ holds, where $\boldsymbol{b}_i$ is the ith row of $\mathbf{B}$). We show that this is the case if ψ satisfies constraint C_i. Assume without loss of generality that $w^{\text{sum}}_{\text{var}(\ell_{i,j})} \neq x^{\text{sum}}_{\text{var}(\ell_{i,j})}$ for $j \in [3]$ (since otherwise the expression clearly has magnitude at most 4). By Lemma 11, Item 2 and our choice of the sign $1 - 2\psi(v_j)$ when applying Lemma 11 to $\boldsymbol{w}_j$, we have that for all $j \in [n]$, $(1 - 2\psi(v_j)) \cdot (w_j^{\text{sum}} - x_j^{\text{sum}}) \geq 0$, which implies that $(1 - 2\psi(v_j)) = \text{sgn}(w_j^{\text{sum}} - x_j^{\text{sum}})$. So, for $j \in [3]$,

$$\text{sgn}(\ell_{i,j}) \cdot \text{sgn}(w^{\text{sum}}_{\text{var}(\ell_{i,j})} - x^{\text{sum}}_{\text{var}(\ell_{i,j})}) = \text{sgn}(\ell_{i,j}) \cdot (1 - 2\psi(v_j)) = \begin{cases} -1 & \text{if } \psi \text{ satisfies literal } \ell_{i,j} \ , \\ 1 & \text{otherwise} \ . \end{cases} \tag{16}$$

By definition, a NAE-E3-SAT constraint C_i is satisfied if and only if at least one of its literals is satisfied and at least one is not satisfied. So, if ψ satisfies C_i, $\text{sgn}(\ell_{i,j}) \cdot \text{sgn}(w^{\text{sum}}_{\text{var}(\ell_{i,j})} - x^{\text{sum}}_{\text{var}(\ell_{i,j})})$ is equal to 1 for some $j \in [3]$ and is equal to -1 for some $j \in [3]$. It follows that the expression in Equation (15) has magnitude at most 4. Because $\text{val}(\phi) \geq \varepsilon$ by assumption,

$$\|(1/3) \cdot \mathbf{B}(\boldsymbol{w}^{\text{sum}} - \boldsymbol{x}^{\text{sum}})\|_p^p \leq \frac{1}{3^p} \cdot (\varepsilon m \cdot 4^p + (1 - \varepsilon) m \cdot 6^p) = (\varepsilon \cdot (4/3)^p + (1 - \varepsilon) \cdot 2^p) \cdot m \ . \tag{17}$$

Combining the upper bounds of Equations (14) and (17) to the terms in Equation (10) (with $\boldsymbol{y} := \boldsymbol{w} - \boldsymbol{x}$) implies Equation (13), as needed. ◀

3.4 Soundness Analysis

We now give two lemmas for analyzing the soundness of our reduction. The first lemma establishes that vectors of the form $\mathbf{A}\boldsymbol{x}$ where $\boldsymbol{x} \in \{0,1\}^{3n}$ are closest vectors in $\mathcal{L}(\mathbf{A})$ to $\mathbf{A} \cdot (1/2 \cdot \mathbf{1})$.

▶ **Lemma 15.** *Let $p \in [1, \infty]$, let ϕ be an* NAE-E3-SAT *instance, and let $\mathbf{A} := \mathbf{A}(\phi)$ be as defined in Equation* (8)*. Then for every $\boldsymbol{y} \in \mathbb{Z}^{3n}$, there exists $\boldsymbol{x} := (\boldsymbol{x}', \boldsymbol{x}', \boldsymbol{x}') \in \{0,1\}^{3n}$ with $\boldsymbol{x}' \in \{0,1\}^n$ such that $\|\mathbf{A}(1/2 \cdot \mathbf{1} - \boldsymbol{x})\|_p \leq \|\mathbf{A}(1/2 \cdot \mathbf{1} - \boldsymbol{y})\|_p$.*

Proof. Let $\boldsymbol{y}^1, \boldsymbol{y}^2, \boldsymbol{y}^3 \in \mathbb{Z}^n$ be such that $\boldsymbol{y} = (\boldsymbol{y}^1, \boldsymbol{y}^2, \boldsymbol{y}^3) \in \mathbb{Z}^{3n}$, let $\boldsymbol{y}^{\text{sum}} := \boldsymbol{y}^1 + \boldsymbol{y}^2 + \boldsymbol{y}^3 \in \mathbb{Z}^n$, and for each $j \in [n]$, let $\boldsymbol{y}_j := (y_j^1, y_j^2, y_j^3)$. For each $j \in [n]$, define

$$x'_j := \begin{cases} 0 & \text{if } y_j^{\text{sum}} \leq 1 \ , \\ 1 & \text{if } y_j^{\text{sum}} \geq 2 \ . \end{cases} \tag{18}$$

Furthermore, define $\boldsymbol{x}' := (x'_1, \ldots, x'_n)^T \in \{0,1\}^n$, $\boldsymbol{x} := (\boldsymbol{x}', \boldsymbol{x}', \boldsymbol{x}') \in \{0,1\}^{3n}$, and for each $j \in [n]$, $\boldsymbol{x}_j := (x'_j, x'_j, x'_j) \in \{0,1\}^3$.

We continue the proof by upper and lower bounding the ith terms in the sum in Equation (11) for $\|\mathbf{A}(1/2 \cdot \mathbf{1} - \boldsymbol{x})\|_p^p$ and for $\|\mathbf{A}(1/2 \cdot \mathbf{1} - \boldsymbol{y})\|_p^p$, respectively. Specifically, we show that the value of the ith term in the former sum is at most the value of the ith term in the latter sum for every $i \in [m]$. By the definition of $\boldsymbol{x}$ in terms of $\boldsymbol{y}$, these ith terms are the same if $\boldsymbol{y}_j \in \{\mathbf{0}, \mathbf{1}\}$ for all $j \in \text{vars}(C_i)$, where C_i is the ith constraint of ϕ. So, we assume without loss of generality that this is not the case, i.e., that for every $i \in [m]$ there exists $j \in \text{var}(C_i)$ such that $\boldsymbol{y}_j \in \mathbb{Z}^3 \setminus \{\mathbf{0}, \mathbf{1}\}$.

We begin by upper bounding the terms in $\|\mathbf{A}(1/2\cdot\mathbf{1}-\boldsymbol{x})\|_p^p$. Fix some $i \in [m]$ corresponding to a term of Equation (11). Because $\boldsymbol{x}_j \in \{\mathbf{0},\mathbf{1}\}$ for all $j \in [n]$ by definition, by Lemma 12, we have the equality

$$\sum_{j\in\mathrm{vars}(C_i)} \|\mathbf{G}(1/2\cdot\mathbf{1}-\boldsymbol{x}_j)\|_p^p = \sum_{j\in\mathrm{vars}(C_i)} 3/2^p = 3\cdot(3/2^p) = 9/2^p \ . \tag{19}$$

Let $\boldsymbol{b}_i$ be the ith row of the matrix $\mathbf{B}$ in Equation (6), as in Equation (11). Again using the fact that each $\boldsymbol{x}_j \in \{\mathbf{0},\mathbf{1}\}$, we have

$$|\langle \boldsymbol{b}_i, (1/2)\cdot\mathbf{1}-\boldsymbol{x}'\rangle| = \Big|\sum_{j\in\mathrm{vars}(C_i)} B_{i,j}\cdot(1/2-x'_j)\Big| = \begin{cases} 1/2 & \text{if } \mathrm{sgndiff}(\boldsymbol{b}_i, 1/2\cdot\mathbf{1}-\boldsymbol{x}') \ , \\ 3/2 & \text{otherwise} \ . \end{cases} \tag{20}$$

Combining Equations (19) and (20), we have

$$|\langle \boldsymbol{b}_i, (1/2)\cdot\mathbf{1}-\boldsymbol{x}'\rangle|^p + \sum_{j\in C_i} \|\mathbf{G}(1/2\cdot\mathbf{1}-\boldsymbol{x}_j)'\|_p^p = \begin{cases} 10/2^p & \text{if } \mathrm{sgndiff}(\boldsymbol{b}_i, 1/2\cdot\mathbf{1}-\boldsymbol{x}') \ , \\ (9+3^p)/2^p & \text{otherwise} \ . \end{cases} \tag{21}$$

We now lower bound $\|\mathbf{A}(1/2\cdot\mathbf{1}-\boldsymbol{y})\|_p^p$. We have that

$$\sum_{j\in\mathrm{vars}(C_i)} \|\mathbf{G}(1/2\cdot\mathbf{1}-\boldsymbol{y}_j)\|_p^p \geq (3/2)^p + 8/2^p \ . \tag{22}$$

Indeed, by Lemma 12, the terms for which $\boldsymbol{y}_j \in \{\mathbf{0},\mathbf{1}\}$ are equal to $3/2^p$ and the terms in the sum for which $\boldsymbol{y}_j \notin \{\mathbf{0},\mathbf{1}\}$ must have value at least $(3/2)^p + 2/2^p$. And, since we are only considering constraints C_i for which there exists j such that $\boldsymbol{y}_j \notin \{\mathbf{0},\mathbf{1}\}$, at least one term must have value at least $(3/2)^p + 2/2^p$.

We continue by giving a lower bound for $|(1/3)\cdot\boldsymbol{b}_i(3/2\cdot\mathbf{1}-\boldsymbol{y}^{\mathrm{sum}})|$. Here, we observe that $(1/2)-(y_j^{\mathrm{sum}}/3) \in \{1/6,3/6,5/6\}+\mathbb{Z}$. This implies that

$$\begin{aligned} \langle \boldsymbol{b}_i, (1/2)\cdot\mathbf{1}-\boldsymbol{y}^{\mathrm{sum}}/3\rangle &= \Big|\sum_{j\in\mathrm{vars}(C_i)} B_{i,j}\cdot(1/2-y_j^{\mathrm{sum}}/3)\Big| \\ &\geq \begin{cases} 1/6 & \text{if } \mathrm{sgndiff}(\boldsymbol{b}_i, 1/2\cdot\mathbf{1}-\boldsymbol{y}^{\mathrm{sum}}/3) \\ 1/2 & \text{otherwise} \end{cases} , \end{aligned} \tag{23}$$

where the inequality follows by noting that because all three summands in the middle expression are elements of $\{1/6,3/6,5/6\}+\mathbb{Z}$. If all signs of the summands are the same, one obtains the lower bound $3/6 = 1/2$, whereas if the signs of the summands differ, one only has the lower bound of $1/6$.

By combining Equations (22) and (23), we have the lower bound

$$\begin{aligned} |\langle \boldsymbol{b}_i, (1/2)\cdot\mathbf{1}-\boldsymbol{y}^{\mathrm{sum}}/3\rangle|^p + &\sum_{j\in\mathrm{vars}(C_i)} \|\mathbf{G}(1/2\cdot\mathbf{1}-\boldsymbol{y}_j)\|_p^p \\ &\geq \begin{cases} 1/6^p + (3/2)^p + 8/2^p & \text{if } \mathrm{sgndiff}(\boldsymbol{b}_i, 1/2\cdot\mathbf{1}-\boldsymbol{y}^{\mathrm{sum}}/3) \\ (9+3^p)/2^p & \text{otherwise} \end{cases} . \end{aligned} \tag{24}$$

Finally, by definition of $\boldsymbol{x}'$ (Equation (18)), we have that for all $j \in [n]$, $\mathrm{sgn}(x'_j - 1/2) = \mathrm{sgn}(y_j^{\mathrm{sum}}/3 - 1/2)$. Then, it follows that for all $i \in [m]$ that $\mathrm{sgndiff}(\boldsymbol{b}_i, 1/2 \cdot \mathbf{1} - \boldsymbol{x}')$ if and only if $\mathrm{sgndiff}(\boldsymbol{b}_i, 1/2 \cdot \mathbf{1} - \boldsymbol{y}^{\mathrm{sum}}/3)$. By noting that for all $p \geq 1$, $2/2^p \leq 1/6^p + (3/2)^p$, we combine Equations (21) and (24) to obtain that for all $i \in [m]$,

$$\begin{aligned} &|\langle \boldsymbol{b}_i, (1/2) \cdot \mathbf{1} - \boldsymbol{x}' \rangle|^p + \sum_{j \in \mathrm{vars}(C_i)} \|\mathbf{G}(1/2 \cdot \mathbf{1} - \boldsymbol{x}_j)\|_p^p \\ &\leq |\langle \boldsymbol{b}_i, (1/2) \cdot \mathbf{1} - \boldsymbol{y}^{\mathrm{sum}}/3 \rangle|^p + \sum_{j \in \mathrm{vars}(C_i)} \|\mathbf{G}(1/2 \cdot \mathbf{1} - \boldsymbol{y}_j)\|_p^p \ , \end{aligned}$$

where we note that the left- and right-hand sides of the inequality are equal to the ith term in the sum in Equation (11). The result follows. ◀

The following lemma shows soundness for our reduction. Specifically, it shows how to construct an assignment satisfying a large fraction of constraints in an NAE-E3-SAT formula ϕ from a close vector $\mathbf{A}\boldsymbol{x}$ for $\boldsymbol{x} \in \{0,1\}^{3n}$ to $\mathbf{A}(1/2 \cdot \mathbf{1}_{3n})$, where $\mathbf{A} = \mathbf{A}_p(\phi)$.

▶ **Lemma 16.** *Let $p \in [1, \infty)$, let ϕ be an* NAE-E3-SAT *instance with n variables and m constraints, let $\mathbf{A} := \mathbf{A}_p(\phi)$ be as defined in Equation* (8)*, and let $\delta \in [0,1]$. Suppose that there exists some vector $\boldsymbol{x} := (\boldsymbol{x}^1, \boldsymbol{x}^2, \boldsymbol{x}^3) \in \mathbb{Z}^{3n}$ such that*

$$\|\mathbf{A}((1/2) \cdot \mathbf{1} - \boldsymbol{x})\|_p^p \leq \delta m \cdot (10/2^p) + (1 - \delta)m \cdot (9/2^p + (3/2)^p) \ . \tag{25}$$

Then $\mathrm{val}(\phi) \geq \delta$.

Proof. Suppose that there exists $\boldsymbol{x} \in \mathbb{Z}^{3n}$ satisfying Equation (25). Then by Lemma 15, we may assume without loss of generality that $\boldsymbol{x} = (\boldsymbol{x}', \boldsymbol{x}', \boldsymbol{x}')$ for $\boldsymbol{x}' \in \{0,1\}^n$ and let $\boldsymbol{x}_j := (x'_j, x'_j, x'_j)$ for each $j \in [n]$. Therefore, for each $i \in [m]$, both Equations (19) and (20) hold for $\boldsymbol{x}$.

First, we obtain the bound

$$\begin{aligned} \frac{1}{3^p} \cdot \|\mathbf{B}((3/2) \cdot \mathbf{1} - \boldsymbol{x}^{\mathrm{sum}})\|_p^p &= \|\mathbf{A}((1/2) \cdot \mathbf{1} - \boldsymbol{x})\|_p^p - \sum_{j=1}^{n} \deg(v_j) \cdot \|\mathbf{G}((1/2) \cdot \mathbf{1} - \boldsymbol{x}_j)\|_p^p \\ &= \|\mathbf{A}((1/2) \cdot \mathbf{1} - \boldsymbol{x})\|_p^p - m \cdot (9/2^p) \\ &\leq \delta m \cdot (1/2^p) + (1 - \delta)m \cdot (3/2)^p \ , \end{aligned}$$

where the first equality uses Equation (10) with $\boldsymbol{y} := (1/2) \cdot \mathbf{1} - \boldsymbol{x}$, the second equality uses Equation (19), and the inequality is by assumption (Equation (25)).

It then follows from Equation (20) that at least an δ fraction of indices $i \in [m]$ satisfy $\mathrm{sgndiff}(\boldsymbol{b}_i, 1/2 \cdot \mathbf{1} - \boldsymbol{x}')$. Define an assignment ψ to the variables $v_1, \ldots, v_n$ of ϕ by $\psi(v_j) = x'_j$. We claim that if $\mathrm{sgndiff}(\boldsymbol{b}_i, 1/2 \cdot \mathbf{1} - \boldsymbol{x}')$ then ψ satisfies constraint C_i, which combined with the fact that at least an δ fraction of indices $i \in [m]$ satisfy $\mathrm{sgndiff}(\boldsymbol{b}_i, 1/2 \cdot \mathbf{1} - \boldsymbol{x}')$, would imply the lemma.

It remains to prove the claim. Observe that if constraint $C_i = \{\ell_{i,1}, \ell_{i,2}, \ell_{i,3}\}$ for literals $\ell_{i,1}, \ell_{i,2}, \ell_{i,3}$ then, as in Equation (15),

$$(\mathbf{B}(1/2 \cdot \mathbf{1} - \boldsymbol{x}'))_i = \sum_{j=1}^{3} \mathrm{sgn}(\ell_{i,j}) \cdot (1/2 - x_{\mathrm{var}(\ell_{i,j})}) \ .$$

Furthermore, as in Equation (16), for $j \in [3]$,

$$\mathrm{sgn}(\ell_{i,j}) \cdot \mathrm{sgn}(1/2 - x_{\mathrm{var}(\ell_{i,j})}) = \begin{cases} -1 & \text{if } \psi \text{ satisfies literal } \ell_{i,j} \ , \\ 1 & \text{otherwise} \ . \end{cases}$$

The predicate $\mathrm{sgndiff}(\boldsymbol{b}_i, 1/2 \cdot \mathbf{1} - \boldsymbol{x}')$ holds exactly when $\mathrm{sgn}(\ell_{i,j}) \cdot (1/2 - x_{\mathrm{var}(\ell_{i,j})}) = 1$ for some $j \in [3]$ and $\mathrm{sgn}(\ell_{i,j}) \cdot (1/2 - x_{\mathrm{var}(\ell_{i,j})}) = -1$ for some $j \in [3]$, meaning that ψ satisfies at least one literal in C_i and does not satisfy at least one literal in C_i. This in turn implies that ψ satisfies C_i, as needed. ◀

3.5 The Main Theorem

We now state and prove the main technical theorem of the paper.

▶ **Theorem 17.** *Let $\delta, \varepsilon \in \mathbb{R}$ be such that $0 < \delta \leq \varepsilon \leq 1$ and let $p \in [1, \infty)$. There is a polynomial-time mapping reduction from (δ, ε)-NAE-E3-SAT to γ-BinGapCRP$_p$ for*

$$\gamma = \gamma(\delta, \varepsilon, p) := \left(\frac{\delta \cdot 10/2^p + (1-\delta) \cdot ((3/2)^p + 9/2^p)}{\varepsilon \cdot (4/3)^p + (1-\varepsilon)2^p + 3(2 + (4/3)^p)} \right)^{1/p} . \tag{26}$$

Proof. Let ϕ be the input instance of (δ, ε)-NAE-E3-SAT. Assume that ϕ has m constraints. The reduction outputs the BinGapCRP$_p$ instance consisting of the matrix $\mathbf{A} = \mathbf{A}_p(\phi)$ defined in Equation (8) and the distance threshold $r := (\varepsilon m \cdot (4/3)^p + (1-\varepsilon) m \cdot 2^p + 3m(2 + (4/3)^p))^{1/p}$ defined in Equation (9).

It is clear that the reduction runs in polynomial time, and it remains to show correctness. We start with completeness. If ϕ is a YES instance of (δ, ε)-NAE-E3-SAT, then $\mathrm{lindisc}_p(\mathbf{A}) \leq r$ by Lemma 14 and so the output is a YES instance of BinGapCRP$_p$.

For soundness, we show the contrapositive. Suppose that

$$\mu_p(\mathcal{L}(\mathbf{A})) \leq \gamma r = (\delta m \cdot 10/2^p + (1-\delta) m \cdot ((3/2)^p + 9/2^p))^{1/p} .$$

Then there exists $\boldsymbol{y} \in \mathbb{Z}^{3n}$ such that $\|\mathbf{A}((1/2 \cdot \mathbf{1}) - \boldsymbol{y})\|_p \leq \gamma r$, and so $\mathrm{val}(\phi) \geq \delta$ by Lemma 16. The result follows. ◀

We conclude by obtaining Theorem 1, which asserts that γ-BinGapCRP$_p$ is NP-hard for any constant $1 \leq \gamma < \gamma(p)$, as a corollary of Theorem 17.

Proof of Theorem 1. Let $\gamma(p) := \gamma(15/16, 1, p)$, where $\gamma(\cdot, \cdot, \cdot)$ is as defined in Equation (26). Then

$$\begin{aligned} \gamma(p) &= \left(\frac{(15/16) \cdot 10/2^p + (1/16) \cdot ((3/2)^p + 9/2^p)}{(4/3)^p + 3(2 + (4/3)^p)} \right)^{1/p} \\ &= \left(\frac{9^p + 159 \cdot 3^p}{8^{p+2} + 96 \cdot 6^p} \right)^{1/p} , \end{aligned}$$

By Theorem 10, $(15/16 + \varepsilon', 1)$-NAE-E3-SAT is NP-hard for every constant $\varepsilon' > 0$. So, by Theorem 17, $\gamma(15/16 + \varepsilon', 1, p)$-BinGapCRP is NP-hard for every such ε'. The theorem follows by noting that for every constant $\varepsilon > 0$ there exists a constant $\varepsilon' > 0$ such that $\gamma(15/16 + \varepsilon', 1, p) \geq \gamma(p) - \varepsilon$. ◀

4 Π_2-hardness of approximating BinaryGapCRP in the ℓ_∞ norm

In this section, we show that the Π_2-hardness of approximation result for LinDisc$_\infty$ given in Manurangsi [29] can be extended to BinGapCRP$_\infty$. We first give the definition of $\forall\exists$-NAE-E3-SAT, the Π_2-hard problem that we reduce to approximate BinGapCRP. The problem $\forall\exists$-NAE-3-SAT (in which constraints may have either two or three literals) was originally shown to be Π_2-hard in [12], and (a very special case of) $\forall\exists$-NAE-E3-SAT was shown to be Π_2-hard in [10, Theorem 4.7].

▶ **Definition 18** (∀∃-NAE-E3-SAT). *The* ∀∃-NAE-E3-SAT *problem is the decision problem where, on input a* NAE-E3-SAT *formula $\phi(V_A, V_E)$ defined over the disjoint union $V_A \sqcup V_E$ of variable sets V_A and V_E, the goal is to distinguish between the following two cases.*

- *(YES instance.) For every assignment $\psi_A : V_A \to \{0,1\}$, there exists an assignment $\psi_E : V_E \to \{0,1\}$ such that (ψ_A, ψ_E) satisfies ϕ.*
- *(NO instance.) There exists an assignment $\psi_A : V_A \to \{0,1\}$ such that for all assignments $\psi_E : V_E \to \{0,1\}$), (ψ_A, ψ_E) does not satisfy ϕ.*

Let $\phi(V_A, V_E)$ be a NAE-E3-SAT formula with $n' = |V_A|$ and $n - n' = |V_E|$. We define the matrix $\mathbf{A}' = \mathbf{A}'(\phi) \in \mathbb{R}^{(m+3n+2n')\times(3n+n')}$ (originally defined in [29]) as

$$\mathbf{A}' := \left(\begin{array}{cccccc|c} \multicolumn{6}{c|}{\mathbf{A}_\infty(\phi)} & \mathbf{0}_{n'\times n'} \\ \hline \frac{2}{3}\mathbf{I}_{n'} & \mathbf{0}_{n'\times(n-n')} & \frac{2}{3}\mathbf{I}_{n'} & \mathbf{0}_{n'\times(n-n')} & \frac{2}{3}\mathbf{I}_{n'} & \mathbf{0}_{n'\times(n-n')} & -2\mathbf{I}_{n'} \\ \hline \multicolumn{6}{c|}{\mathbf{0}_{n'\times 3n}} & \frac{8}{3}\mathbf{I}_{n'} \end{array}\right), \tag{27}$$

where $\mathbf{A}_\infty(\phi)$ is as defined in Equation (8) and where we have used the notation $\mathbf{0}_{m\times n}$ to denote an $m \times n$ matrix of 0s.

We next give a simple expression for $\|\mathbf{A}'(\boldsymbol{y}')\|_\infty$ for a vector $\boldsymbol{y}'$ in terms of the blocks of $\mathbf{A}'$.

▶ **Lemma 19** ([29, Equation 4]). *Let $\phi(V_A, V_E)$ be an* ∀∃-NAE-E3-SAT *instance with n' universal variables (variables in V_A) and $n - n'$ existential variables (variables in V_E), and for each $i \in [3]$, let $\boldsymbol{y}^i \in \mathbb{R}^n$, and let $\boldsymbol{y}^* \in \mathbb{R}^{n'}$. Furthermore, let $\boldsymbol{y}' := (\boldsymbol{y}^1, \boldsymbol{y}^2, \boldsymbol{y}^3, \boldsymbol{y}^*) = (\boldsymbol{y}, \boldsymbol{y}^*) \in \mathbb{R}^{3n+n'}$. Finally, let $\boldsymbol{y}^{sum} = \boldsymbol{y}^1 + \boldsymbol{y}^2 + \boldsymbol{y}^3$. Then $\mathbf{A}' = \mathbf{A}'(\phi)$ satisfies*

$$\|\mathbf{A}'\boldsymbol{y}'\|_\infty = \max\{\|\mathbf{A}\boldsymbol{y}\|_\infty, \max_{i\in[n']}|(2/3)\cdot y_i^{sum} - 2y_i^*|, (8/3)\cdot\max_{i\in[n']}|y_i^*|\} \tag{28}$$

Proof. The claim follows by inspection of the blocks of $\mathbf{A}'\boldsymbol{y}'$. ◀

We next state the completeness and soundness results from the reduction in [29] for showing Π_2-hardness of $\mathrm{lindisc}_\infty(A)$.

▶ **Lemma 20** (Completeness for Π_2-hardness reduction, [29]). *Let ϕ be an* ∀∃-NAE-E3-SAT *instance, and $\mathbf{A}' := \mathbf{A}'(\phi)$ as defined in Equation* (27)*. Suppose that ϕ is a YES instance. Then $\mathrm{lindisc}_\infty(\mathbf{A}') \le 4/3$.*

Proof. The claim follows from the completeness argument in [29, Proof of Lemma 5]. ◀

▶ **Lemma 21** (Soundness for Π_2-hardness reduction, [29]). *Let $\phi(V_A, V_E)$ be an instance of* ∀∃-NAE-E3-SAT *with $n' := |V_A|$ universally quantified variables and $n := |V_A| + |V_E|$ variables, and let $\mathbf{A}' = \mathbf{A}'(\phi)$ be as defined in Equation* (27)*. Suppose that for every $\boldsymbol{w}' := (\boldsymbol{w}, \boldsymbol{w}^*)$ for $\boldsymbol{w} := 1/2 \cdot \mathbf{1} \in \mathbb{R}^{3n}$ and $\boldsymbol{w}^* \in \{1/3, 2/3\}^n$ there exists a vector $\boldsymbol{x}' \in \{0,1\}^{3n+n'}$ such that $\|\mathbf{A}'(\boldsymbol{w}' - \boldsymbol{x}')\|_\infty < 3/2$. Then ϕ is a YES instance of* ∀∃-NAE-E3-SAT*.*

Proof. The claim follows from the soundness argument in [29, Proof of Lemma 5]. ◀

We now state a lemma that guarantees that if a vector $\boldsymbol{w}'$ of the form in Lemma 21 and $\boldsymbol{x}' \in \mathbb{Z}^{3n+n'}$ satisfy $\|\mathbf{A}'(\boldsymbol{w}' - \boldsymbol{x}')\|_\infty < 3/2$, then it must be the case that $\boldsymbol{x}' \in \{0,1\}^{3n+n'}$.

▶ **Lemma 22.** *Let $\phi(V_A, V_E)$ be an* ∀∃-NAE-E3-SAT *instance with $n' := |V_A|$ universally quantified variables and $n := |V_A| + |V_E|$ variables, and let $\mathbf{A}' = \mathbf{A}'(\phi)$ be as defined in Equation* (27)*. Furthermore, let $\boldsymbol{w} := 1/2 \cdot \mathbf{1} \in \mathbb{R}^{3n}$, let $\boldsymbol{w}^* \in \{1/3, 2/3\}^{n'}$, let $\boldsymbol{x} \in \mathbb{Z}^{3n}$, and let $\boldsymbol{x}^* \in \mathbb{Z}^{n'}$. Let $\boldsymbol{w}' := (\boldsymbol{w}, \boldsymbol{w}^*) \in \mathbb{R}^{3n+n'}$ and let $\boldsymbol{x}' := (\boldsymbol{x}, \boldsymbol{x}^*) \in \mathbb{Z}^{3n+n'}$. Assume that $\|\mathbf{A}'(\boldsymbol{w}' - \boldsymbol{x}')\|_\infty < 3/2$. Then $\boldsymbol{x}' \in \{0,1\}^{3n+n'}$.*

Proof. We have that

$$\max_{j\in[n]}\|\mathbf{G}(\boldsymbol{w}_j-\boldsymbol{x}_j)\|_\infty \le \|\mathbf{A}(\boldsymbol{w}-\boldsymbol{x})\|_\infty \le \|\mathbf{A}'(\boldsymbol{w}'-\boldsymbol{x}')\|_\infty < 3/2\ , \tag{29}$$

where the first inequality follows from the definition of $\mathbf{A}$ (Equation (8)), the second inequality follows from Lemma 19, and the third inequality is an assumption. Let $\boldsymbol{x}^1,\boldsymbol{x}^2,\boldsymbol{x}^3\in\mathbb{Z}^n$ be such that $\boldsymbol{x}:=(\boldsymbol{x}^2,\boldsymbol{x}^2,\boldsymbol{x}^3)$, and for $j\in[n]$, let $\boldsymbol{x}_j:=(x_j^1,x_j^2,x_j^3)\in\mathbb{Z}^3$. By Equation (29) we then have that for all $j\in[n]$, $\|\mathbf{G}(1/2\cdot\mathbf{1}-\boldsymbol{x}_j)\|_\infty<3/2$. Therefore, by Lemma 12 we have have that for all $j\in[n]$, $\boldsymbol{x}_j\in\{\mathbf{0},\mathbf{1}\}$. In particular, $\boldsymbol{x}\in\{0,1\}^{3n}$.

Again, by setting $\boldsymbol{y}':=\boldsymbol{w}'-\boldsymbol{x}'$ in Lemma 19, we have that $(8/3)\cdot\max_{i\in[n']}|w_i^*-x_i^*|<3/2$, or equivalently, that for all $i\in[n']$, $|w_i^*-x_i^*|<9/16<2/3$. It follows that if $w_i^*=1/3$ then $x_i^*=0$, and if $w_i^*=2/3$ then $x_i^*=1$. In particular, $\boldsymbol{x}^*\in\{0,1\}^{n'}$, as needed. ◀

Finally, we obtain the following theorem that adapts [29, Lemma 5] to the BinGapCRP$_\infty$ problem.

▶ **Theorem 23.** *For any constant $\varepsilon>0$, there is a polynomial-time mapping reduction from* ∀∃-NAE-E3-SAT *to* $(9/8-\varepsilon)$-BinGapCRP$_\infty$.

Proof. Let ϕ be an instance of the ∀∃-NAE-E3-SAT problem. The reduction outputs the BinGapCRP instance with matrix $\mathbf{A}':=\mathbf{A}'(\phi)$, as defined in Equation (27), and distance threshold $r:=4/3$. The reduction is efficient by inspection. If ϕ is a YES instance, then $\mathrm{lindisc}_\infty(\mathbf{A}')\le 4/3$ by Lemma 20.

On the other hand, if $\mu_\infty(\mathcal{L}(\mathbf{A}'))<3/2$, then by definition of the covering radius and Lemma 22 we have that for all $\boldsymbol{w}':=(\boldsymbol{w},\boldsymbol{w}^*)\in\mathbb{R}^{3n+n'}$ with $\boldsymbol{w}:=1/2\cdot\mathbf{1}^{3n}$ and $\boldsymbol{w}^*\in\{1/3,2/3\}^{n'}$, there exists $\boldsymbol{x}'\in\{0,1\}^{3n+n'}$ such that $\|\mathbf{A}'(\boldsymbol{w}'-\boldsymbol{x}')\|_\infty<3/2$. Therefore, ϕ is a YES instance by Lemma 21. The result follows. ◀

The proof of Theorem 2 now follows easily.

Proof of Theorem 2. The result follows from the Π_2-hardness of ∀∃-NAE-E3-SAT (shown in [10, Theorem 4.7]) and the reduction in Theorem 23. ◀

Abstract

We consider the parametrized setting of the classical metrical service system (MSS) problem first studied by Bubeck and Rabani (APPROX/RANDOM 2020). In this setting, the adversary is restricted to a set of m distinct request types, known to the algorithm in advance. The goal is to obtain competitive ratio bounds in terms of m. In this work, we make significant progress in understanding the landscape of parametrized MSS and resolve several open problems from Bubeck and Rabani.

Our first main result is a tight bound for parametrized MSS on weighted stars. Previously, Bubeck and Rabani gave a randomized lower bound of $\Omega(m)$ and deterministic upper bound of $O(2^m)$. We show that, surprisingly, a deterministic $O(m)$-competitive algorithm exists, matching the randomized lower bound. Our key insight is an interval covering formulation of MSS on weighted stars which enables an application of the primal-dual method.

Our second main contribution is an improved lower bound construction for parametrized MSS on hierarchically separated trees (HSTs). Bubeck and Rabani's construction gave a $\omega(1)$ lower bound when $m \geq 6$. Our improved lower bounds are tight for 2-level HSTs and also rule out $O(1)$-competitive algorithms on HSTs when the parameter $m \geq 4$. We also complement these results by giving a deterministic $O(1)$-competitive algorithm on general metrics when $m = 2$ while showing that it is impossible when $m \geq 3$.

1 Introduction

The *metrical task system* (MTS) problem introduced by Borodin et al. [2] is a general framework that models a wide range of online computing problems, e.g., paging [15] and k-server [13]. In this problem, one server moves between different points (also called states) in an n-point metric space to process a sequence of requests that arrive one by one; each request incurs different costs when the server is at different states. The total cost is the sum of the transition cost of moving between different states and the cost of serving the requests. An important special case is the *metrical service system* (MSS) problem [9] where every request has cost either 0 or infinity everywhere in the whole metric space. Note that paging and k-server are both MSS problems.

Since its introduction almost four decades ago, MTS has been intensively studied on both general metrics and some special classes of metrics. On general metrics, in a series of recent breakthrough results, Bubeck et al. [4] showed that the randomized competitive ratio is $O(\log^2 n)$ and Bubeck et al. [3] gave a matching *existential lower bound*[1], refuting the previous widely-believed conjecture of the existence of a logarithmic upper bound. Bubeck et al. [3] also showed a *universal lower bound*[2] of $\Omega(\log n)$, which is also tight in the sense that an $O(\log n)$ upper bound can be achieved on some special metrics, e.g. uniform metrics [2] and weighted stars [4]. While MSS is a special case of MTS, the best competitive ratio that can be achieved by both deterministic and randomized algorithms for MSS in all cases is asymptotically the same as that of MTS only up to a constant factor.

While many online problems are metrical task systems, the best bounds on their competitive ratios are much lower than those implied by the general worst-case MTS bounds. For instance, while the k-server problem in an N-point uniform metric space can be reduced to an MSS instance with $n = \binom{N}{k}$ states, the randomized competitive ratio is known to be $O(\log k)$, which is much lower than the lower bound of $\Omega(\log \binom{N}{k})$ implied by the universal lower bound for MSS with $\binom{N}{k}$ states. The reason for this discrepancy is because while there are $2^n - 1$ possible requests in a general n-state MSS, there are only N possible requests for a k-server.

The above example motivates studying the competitive ratio of MTS in terms of a parameter of the set of possible requests, instead of the number of states n. Burley and Irani [8] proposed examining request sequences drawn from a given set. For uniform metrics, they provided a deterministic algorithm with competitive ratio $O(\log n)$ times the (unknown) best possible competitive ratio. Another example that shows the power of restricting the set of possible requests is the power management problem [11] in which there are only two possible requests and the competitive ratio is $O(1)$ [1]. For MSS, one parameter that has been studied is the *width* (e.g. [10, 14, 7]), which is the maximum size of every requested set. Width is well-motivated as MSS can also be viewed as online set chasing, in the sense that the server needs to move to a state in the feasible set where the cost of the current request is 0 rather than ∞, and we only need to consider transition cost while the service cost is zero if the server stays in the feasible set at every step.

Parametrized MTS. The parametrized MTS proposed by Bubeck and Rabani [5] studies the number of possible requests as the parameter. In particular, the adversary can only generate requests from a fixed set of m requests known to the algorithm in advance. On

[1] The existential lower bound means that there exist n-point metrics on which the lower bound holds.
[2] The universal lower bound means that it holds for every n-point metric space.

uniform metrics, they showed that the deterministic competitive ratio is $\Theta(m \log(en/m))$, which is significantly better than the general bound of $\Theta(n)$. Interestingly, the randomized competitive ratio on uniform metrics is still $\Theta(\log n)$ even when $m = 2$. On the other hand, for two-level hierarchically separated tree (HST) metrics, the deterministic competitive ratio is $\Theta(n)$ and the randomized competitive ratio is $\Theta(\log n)$, even when m is constant. In summary, restricting m only improves the deterministic competitive ratio for uniform metrics, and does not help for two-level HSTs.

Parametrized MSS. The more interesting case is parametrized MSS, where parametrization leads to substantial improvements of the competitive ratio from the general case. For MSS, restricting possible requests within a fixed set of size m improves both deterministic and randomized competitive ratios: for uniform metrics, the deterministic and randomized competitive ratios are both $\Theta(m)$ and thus significantly better when $n \gg m$. Another interesting aspect of this result is that deterministic algorithms are essentially as powerful as randomized algorithms, which refutes the folklore that the randomized competitive ratio is polylogarithmic in the deterministic competitive ratio for most problems that can be interpreted as metrical task systems. As for the case of two-level HSTs, there are still gaps between the currently known upper and lower bounds: the deterministic competitive ratio is between $\Omega(\binom{m}{\lfloor m/2 \rfloor}) = \Omega(2^m/\sqrt{m})$ and $O(m2^m)$ and the randomized competitive ratio is at least $\Omega(2^{\lfloor m/2 \rfloor})$.

Bubeck and Rabani [5] proposed the following open problems in the study of parametrized MSS, which involve not only the exact tight bound of the competitive ratio in certain scenarios, but also understanding how restricting the number of possible requests m can help improve the competitive ratio, e.g., can we devise an online algorithm whose competitive ratio is purely in terms of m rather than metric space size n, and can we do this for some special classes of metrics like HSTs or even general metrics?

▶ **Question 1.** *What is the deterministic competitive ratio on weighted star metrics?*

▶ Remark 1.1. It is easy to design an $O(2^m)$-competitive deterministic algorithm and an $O(m)$-competitive randomized algorithm by reducing the problem to MSS on a weighted star where there are only $2^m - 1$ different states and applying the state-of-the-art result for MTS on weighted stars. For the special case of uniform metrics, the deterministic and randomized competitive ratios are both known to be $\Theta(m)$ so it is natural to ask if the deterministic algorithm can be generalized to weighted stars.

▶ **Question 2.** *What is the tight bound of the worst-case competitive ratio on all HSTs of two and higher levels?*

▶ **Question 3.** *For what constant values of m can we get constant-competitive algorithms for general metrics or some special classes of metrics like HSTs?*

1.1 Our Contributions

In this paper, we make substantial progress towards understanding the competitiveness of parametrized MSS.

Weighted stars. Our first main result answers Question 1 affirmatively.

▶ **Theorem 1.2.** *There is a $2m$-competitive deterministic algorithm for parameterized MSS on weighted stars.*

The result brings more insight into the foundation of this problem and the power of randomization as well, because it matches the lower bound of $\Omega(m)$ for randomized algorithms since the uniform metric is a special class of the weighted star. Theorem 1.2 shows that deterministic algorithms are essentially as powerful as randomized algorithms in achieving the best possible competitive ratio of $O(m)$ on weighted stars, the same as the case for the parametrized metrical service system problem on uniform metrics.

2-level HSTs. Next, we address Question 2 by settling the randomized competitive ratio on 2-level HSTs. Let $c_{k,m}$ denote the best possible randomized competitive ratio of the MSS problem that can be achieved on all k-level HSTs with m request types:

▶ **Theorem 1.3.** $c_{2,m} = \Theta(\binom{m}{\lceil m/2 \rceil}) = \Theta(2^m/\sqrt{m})$.

This theorem contains two separate claims: $c_{2,m} = O(\binom{m}{\lceil m/2 \rceil})$ (Theorem 4.17) and $c_{2,m} = \Omega(\binom{m}{\lceil m/2 \rceil})$ (Theorem 4.7). The lower bound is existential, in the sense that there exists a 2-level HST and m request types on it such that no randomized algorithm can achieve a better worst-case competitive ratio on all possible request sequences. Theorem 1.3 improves upon previous upper and lower bounds. Previously, the lower bound of $\Omega(\binom{m}{\lceil m/2 \rceil})$ is only known to hold for deterministic algorithms, and we prove that it also holds for randomized algorithms using a new hard instance.

Higher level HSTs. Finally, we turn to Question 3. Previously, Bubeck and Rabani [5] obtained lower bounds on $c_{k,m}$ for $k \geq 3$ by iterating their lower bound construction for $k = 2$. As a consequence, their lower bound rules out $O(1)$-competitive algorithms for $m \geq 6$. By iterating our construction in the proof of Theorem 4.7 to higher level HSTs, we also obtain improved lower bounds on $c_{k,m}$ for $k \geq 3$. The formal theorem statement (Theorem 4.8) is somewhat technical so we defer it to Section 4.1.4 and instead state the following corollary.

▶ **Corollary 1.4.** *For $m \geq 4$, there is no algorithm that achieves constant competitive ratio on HSTs.*

Combined with Observation 1.6, we conclude that the only open case for Question 3 on HSTs is $m = 3$.

General metrics. We resolve Question 3 on general metrics by the following two complement results.

We first show that a constant competitive ratio cannot be achieved on general metrics when m is at least 3 by the following existential lower bound of $\Omega(\log n)$:

▶ **Theorem 1.5.** *For $m \geq 3$, there exist $3n$-point metrics on which every randomized algorithm has competitive ratio of $\Omega(\log n)$.*

We refer the reader to the full version to see the proofs of Theorem 1.5 as well as the following Observation 1.6.

On the other hand, a constant competitive ratio can be achieved on general metrics when $m = 2$.

▶ **Observation 1.6.** *When $m = 2$, there is a 6-competitive deterministic algorithm on general metrics.*

This result follows from the observation that when $m = 2$, we can assume that the input sequence is strictly alternating between two request types, because MSS can be regarded as chasing feasible sets and hence repeating the same request does not incur additional cost. Therefore, the only uncertainty of the input is its total length, and the optimal cost can be expressed as a non-decreasing function of the input length. This observation allows us to apply the Guess-and-Double Method to design a constant-competitive algorithm for general metrics when $m = 2$.

Therefore, the open problems for Question 3 now lie on some special classes of metrics, including HSTs that we study in this paper.

1.2 Our Techniques

Weighted stars. In MSS, we can think of a request as the set of states that the server must move to. Bubeck and Rabani [5] use an algorithm that works in phases similar to the classical marking algorithm to provide a $O(m)$-deterministic algorithm for parametrized MSS on uniform metrics: in each phase, it moves to an arbitrary state in the intersection of the requests in the phase; if the intersection is empty, the algorithm starts a new phase and moves to an arbitrary requested state. It is clear that any solution needs to move at least once during each phase, and they show that the algorithm moves at most m times during each phase to prove the upper bound. This method is heavily based on the fact that the metric space is uniform and hence we can simply compare the number of times the algorithm's server moves with that of the optimal server. It is unclear whether their method can be adapted to solve the problem on weighted stars.

We use a significantly different approach based on an interval covering formulation of the problem and apply the primal-dual method. Each interval corresponds to a consecutive subsequence of requests, and the cost to buy this interval is the minimum possible cost of moving to a state that can satisfy all request types in this subsequence. Our analysis exploits the fact that there are only m different request types to show that the algorithmic cost is at most m times the feasible dual solution that we maintain and thus obtain the desired competitive ratio. Our formulation is similar to that in [6] but we exploit the property of MSS requests that allows us to only consider the unique state with minimum cost to satisfy every subsequence, while for MTS we have to consider various costs of serving the same subsequence of requests in n different states, thus leading to the appearance of n in the competitive ratio instead of purely in terms of m. We hope that similar methods under the linear programming and primal-dual framework can be adapted to solve the more general parametrized MTS problem.

Lower bounds on HSTs. We use the same high-level approach used by Bubeck and Rabani [5] in which a construction for the uniform metric[3] is lifted to HSTs of higher levels. The main conceptual difference is in our construction for the uniform metric. In Bubeck and Rabani's construction, there are $2^{m/2}$ points, each labeled by a node of the Boolean hypercube $\{0,1\}^{m/2}$ (we assume m is even here for simplicity). Each of the m requests correspond to a an axis-aligned halfspace of the Boolean hypercube. Thus, if we construct a sequence of $m/2$ requests by picking a random halfspace for each dimension with equal probability, then for each request, the algorithm has to move with probability $1/2$. On the other hand, the adversary can move to the point in the intersection of the halfspaces. This construction can be lifted to HSTs of higher levels by partitioning the set of all possible labels of the lower level case into pairs of antipodes and treating them as complementary requests.

[3] A 1-level HST is equivalent to a uniform metric.

Our key idea is to use a construction for the uniform metric that has more points. In particular, we use $\binom{m}{m/2}$ points, each corresponding to an $\frac{m}{2}$-sized subset of $[m]$. As a result, when we apply the above lifting process, for every fixed level k of the HST, there are more subtrees in our construction when m is sufficiently large. We need to be more careful in our analysis as it is no longer true that each request causes the algorithm to move with constant probability. Instead, we prove that its average is still lower bounded by a positive constant.

2 Preliminaries

Given a metric space $\mathcal{M} = (X, d)$ where X is the set of points and $d : X \times X \to \mathbb{R}_{\geq 0}$ is the distance function, a parametrized metrical service system instance consists of an initial location $s_0 \in X$ of the server and a sequence of requests $\{\rho_t\}_{t\geq 1}$, where each ρ_t is from a fixed collection $\{K_1, \ldots, K_m\}$ of m non-empty subsets of X. Upon the arrival of a request $\rho_t = K_i$ for some $1 \leq i \leq m$ at every step $t \geq 1$, one must move the server to some state $s_t \in K_i$ to maintain a feasible solution if its previous state s_{t-1} does not satisfy this, and the decision must be made without knowing future requests after ρ_t. As a result, MSS can be regarded as the online set chasing problem, illustrating that we always need to move the server to a state in the current requested set, and the parametrized setting restricts that there are only m different request types. The cost of a solution $\{s_t\}_{t\geq 1}$is defined to be

$$\sum_{t\geq 1} d(s_{t-1}, s_t),$$

where $d(s_{t-1}, s_t)$ denotes the transition cost to move from s_{t-1} to s_t upon the arrival of ρ_t. This can be interpreted as the total length of the trajectory of the server.

A randomized algorithm $\mathcal{A}$ has competitive ratio c if there exists some constant β that is independent of the input sequence (it might depend on the metric space $\mathcal{M}$) such that for every input sequence $\boldsymbol{\rho}$:

$$\mathbb{E}[\text{cost}_{\mathcal{A}}(\boldsymbol{\rho})] \leq c \cdot \text{cost}^*(\boldsymbol{\rho}) + \beta,$$

where $\mathbb{E}[\text{cost}_{\mathcal{A}}(\boldsymbol{\rho})]$ is the expected cost of $\mathcal{A}$ on input $\boldsymbol{\rho}$ and $\text{cost}^*(\boldsymbol{\rho})$ is the minimum cost among all feasible solutions of $\boldsymbol{\rho}$. If $\beta = 0$, then we say that c is a strict competitive ratio of $\mathcal{A}$. When we talk about the competitive ratio of a problem class (e.g. parametrized MSS with m requests on a class of metrics), we are referring to the best possible competitive ratio that can be achieved by some algorithm $\mathcal{A}$ on all possible inputs from this problem class.

3 Weighted Stars

On every weighted star metric, there is one root node to which every leaf node (state) is connected with a single edge of non-negative weight. Let d_s denote the weight of the edge between state s and the root, then the distance between two different states s_1 and s_2 is $d(s_1, s_2) = d_{s_1} + d_{s_2}$, where d_{s_1} can be charged as the cost of leaving state s_1 and d_{s_2} can be charged as that of entering state s_2 if the server moves from s_1 to s_2.

A common practice on weighted stars is that instead of charging the cost of both leaving s_1 and entering s_2, we only need to consider the cost of entering the new state at every step, i.e. we can regard the cost of moving from s_1 to a different state s_2 as only d_{s_2}, for both the algorithmic cost and the optimal solution. Over the entire process, the number of times that the server leaves any state is the same as the number of times that the server enters the same state, except for the initial and the last state. Now we formally show that this setting will only lose the competitive ratio of the original problem setting by a factor of at most 2.

▶ **Lemma 3.1.** *Every strictly c-competitive algorithm for the problem setting under the new transition costs has strict competitive ratio at most $2c$ in the original setting.*

Proof. Suppose that the initial state of the server is s_0, the algorithm moves to states $s_1, \ldots, s_n$ by the chronological order during its execution, and some fixed solution moves to states $s'_1, \ldots, s'_m$ one by one. By the fact that the algorithm achieves strict competitive ratio c under the new setting, it holds that $\sum_{j=1}^{n} d_{s_j} \leq c \sum_{j=1}^{m} d_{s'_j}$. Then we have $d_{s_0} + 2\sum_{j=1}^{n-1} d_{s_j} + d_{s_n} \leq d_{s_0} + 2\sum_{j=1}^{n} d_{s_j} \leq d_{s_0} + 2c\sum_{j=1}^{m} d_{s'_j} \leq 2c(d_{s_0} + 2\sum_{j=1}^{m-1} d_{s'_j} + d_{s'_m})$, which suggests that the same algorithm achieves strict competitive ratio $2c$ in the original setting by the arbitrariness of the solution that we are comparing the algorithmic cost with. ◀

State labels. In this setting, we do not need to consider the initial state. Moreover, each state can be labeled with a subset of $[m] = \{1, 2, \ldots, m\}$, which implies the set of request types that are feasible at this position. To formalize, given the label $S \subseteq [m]$ of some state s and $\{K_1, \ldots, K_m\}$ of the parametrized MSS setting of m possible request types as subsets of the metric space, $S = \{i \mid s \in K_i\}$. We may use the notations of a state s and its label S interchangeably, as well as a set of natural numbers and the set of request types K_i's whose indices are in this set.

Assumptions. It suffices to consider $2^m - 1$ states that correspond to $2^m - 1$ different non-empty subsets of $[m]$, since if there are at least two states with exactly the same label, then any reasonable algorithm should only visit the one whose edge to the node has the minimum weight. For every non-empty $S \subseteq [m] = \{1, 2, \ldots, m\}$, we use d_S to denote the minimum edge weight between the root and any node whose label is exactly equal to S. If no such node exists, just set $d_S = \infty$.

We now make another assumption, which is without loss of generality, yet important for the validity of the algorithm that we are going to propose.

▶ **Assumption 3.2.** *$d_S \leq d_{S'}$ for every $S \subseteq S'$.*

Otherwise, if there exist two different non-empty subsets S and S' of $[m]$ such that $S \subseteq S'$ yet $d_S > d_{S'}$, then every visit to state S can be replaced by a visit to state S', maintaining the feasibility because $S' \supseteq S$ while only reducing the cost. In this case, we can set d_S to $d_{S'}$ instead, which does not increase the optimal cost since we are only reducing edge lengths, while the algorithmic solution can replace each visit to S with one visit to S' in the original setting, which means that every algorithm can be transformed into one whose cost in the original setting is no more than that under this assumption.

We make one final assumption. Against any deterministic algorithm, one can assume that the adversary always forces the algorithm to move to a different state at every step as long as there is some K_i such that the current state of the algorithm is not in K_i, and the input ends when the current state is in the intersection of all K_i's for $1 \leq i \leq m$, if such a scenario exists. A straightforward consequence of this assumption on our problem setting is that any two consecutive requests from the input sequence are of different types, but we will eventually use a stronger argument that also exploits the algorithmic decisions seen by the adversary in the deterministic model to bound the desired competitive ratio.

Integer programming formulation. Under the input sequence $\{\rho_t\}_{t \geq 1}$, we use $S_{i,j}$ to denote the set of request types that appear in the subsequence $\rho_i, \ldots, \rho_j$, i.e. $S_{i,j} = \{\ell \mid K_\ell = \rho_t \text{ for some } i \leq t \leq j\}$, which also corresponds to a unique node of the weighted star in our

notation. Then we can write down an integer programming formulation of the problem whose minimum objective function value is a lower bound of the optimal solution of the original problem. We use T to express the number of steps of the whole input sequence.

$$\begin{aligned} \text{minimize} \quad & \sum_{1\le i\le j\le T} d_{S_{i,j}} x_{i,j} \\ \text{subject to} \quad & \sum_{i\le t\le j} x_{i,j} \ge 1, \quad \forall 1 \le t \le T \\ & x_{i,j} \in \{0,1\}, \quad \forall 1 \le i \le j \le T \end{aligned} \tag{1}$$

▶ **Lemma 3.3.** *The minimum value of (1) is no more than the optimal value of the parametrized MSS problem on the weighted star in our setting.*

Proof. Given any solution of the parametrized MSS problem on the weighted star, for every state that the server stays at from step i to j, we can just assume that it stays at state $S_{i,j}$ due to Assumption 3.2, otherwise the cost can only be higher. We set $x_{i,j} = 1$ for every such state that the server visits, then this is a feasible solution of (1), and its value is the same as the given solution of the parametrized MSS on the weighted star instance. ◀

The next step is to write down the dual program of the linear relaxation of (1), whose maximum value is no more than the minimum value of its primal linear program and thus the minimum value of the original program (1) as well:

$$\begin{aligned} \text{maximize} \quad & \sum_{1\le t\le T} y_t \\ \text{subject to} \quad & \sum_{t:i\le t\le j} y_t \le d_{S_{i,j}}, \forall 1 \le i \le j \le T \\ & y_t \ge 0, \quad \forall 1 \le t \le T \end{aligned} \tag{2}$$

Primal-dual algorithm. We are now ready to state our primal-dual algorithm. From a high level, our algorithm maintains a feasible dual solution and at every step t: increases the dual variable y_t until some dual constraint becomes tight, and then decides which state to move to depending on the tight dual constraint.

Now we come to its formal description. Upon the arrival of request ρ_t, increase the value of the dual variable y_t from the initial value 0 until some dual constraint is tight, i.e.

$$\sum_{\ell=i}^{t} y_\ell = d_{S_{i,t}}$$

for some $i \le \ell \le t$; or equivalently, we can write the value as

$$y_t = \min_{1\le i\le t} \left\{ d_{S_{i,t}} - \sum_{\ell=i}^{t-1} y_\ell \right\}, \tag{3}$$

where the value of $\sum_{\ell=i}^{t-1} y_\ell$ is defined to be zero for $i = t$.

If the tight dual constraint is $\sum_{\ell=i}^{t} y_\ell = d_{S_{i,t}}$, then the algorithm moves the server to the state labeled with $S_{i,t}$ (the one with the minimum edge weight to the root based on our previous assumption), to process request ρ_t. Ties are broken in an arbitrary way.

Algorithm analysis. We first prove that the algorithm indeed maintains a feasible dual solution.

▶ **Lemma 3.4.** *The algorithm maintains a feasible dual solution.*

Proof. At every step t, a new dual variable y_t whose initial value is zero appears with a set of new dual constraints, and we need to show that these constraints are not violated when $y_t = 0$, so that it is feasible to increase the value of y_t from zero until some dual constraint becomes tight.

It suffices to prove that $\sum_{\ell=i}^{t-1} y_\ell \le d_{S_{i,t}}$ for every $i \le t$, given the values y_1 to y_{t-1} well-defined from previous steps. The case that $i = t$ is trivial, since $d_{S_{i,t}}$ is non-negative based on the problem definition. For every $1 \le i \le t-1$, it holds that $\sum_{\ell=i}^{t-1} y_\ell \le d_{S_{i,t-1}}$ given that we maintain a feasible solution for dual variables and constraints that have appeared until step $t-1$, and the result follows by Assumption 3.2 and the fact that $S_{i,t-1} \subseteq S_{i,t}$. ◀

Now we are ready to use values of y_t's that the algorithm computes under its execution to provide an upper bound of its cost.

▶ **Lemma 3.5.** *The cost of the algorithm is at most* $m \sum_{\ell=1}^{T} y_\ell$.

Proof. When the algorithm moves to state $S_{i,t}$ at step t, $S_{i,t}$ is the set of request types in some subsequence $\rho_i, \ldots, \rho_t$ and the values of dual variables assigned by the algorithm so far satisfy that $\sum_{\ell=i}^{t} y_\ell = d_{S_{i,t}}$, since the algorithm chooses state $S_{i,t}$ to move to according to the tight dual constraint at every step. As a result, the cost of moving to state $S_{i,t}$ at every step t can be charged to some y_ℓ's. Now we show that every y_ℓ is only charged to at no more than m different steps t and their corresponding states $S_{i,t}$'s, which means that we need to show there are at most m pairs of (i,t)'s such that $i \le \ell \le t$ and the algorithm moves to state $S_{i,t}$ at step t.

Suppose there are two different steps $t_1 < t_2$ such that the algorithm moves to state S_{i_1,t_1} at step t_1 and state S_{i_2,t_2} at step t_2, and $i_1 \le \ell \le t_1$ and $i_2 \le \ell \le t_2$. The subsequence $\rho_{t_1+1}, \ldots, \rho_{t_2}$ contains at least one request that is not in set S_{i_1,t_1} – namely, ρ_{t_1+1} – as otherwise the algorithm has no incentive to move to a different state. As a result, since $S_{t_1+1,t_2} \subseteq S_{\ell,t_2}$ and $S_{\ell,t_1} \subseteq S_{i_1,t_1}$, we get $S_{\ell,t_2} \setminus S_{\ell,t_1} \supseteq S_{t_1+1,t_2} \setminus S_{i_1,t_1} \neq \varnothing$, and hence $|S_{\ell,t_2}| \ge |S_{\ell,t_1}| + 1$ because $S_{\ell,t_1} \subseteq S_{\ell,t_2}$. Now if we have in total k such different steps $\ell \le t_1 < \ldots < t_k$, then it holds that $|S_{\ell,t_k}| \ge k$, which directly implies that $k \le m$. ◀

Lemmas 3.1 and 3.5 and the fact that the maximum value of the linear dual program (2) is no more than the minimum value of the original program (1) imply Theorem 1.2.

4 Randomized Competitive Ratio on HSTs

In this section, we consider hierarchically separated trees (HSTs), a highly symmetric rooted tree structure where the edge weights between a node and all its children are equal. The path between one internal node to all leaves in the subtree rooted at this node has the same number of edges, meaning that the level of a node as the number of edges from it to any of its descendant leaf is well-defined (the level of every leaf node is 0). Moreover, the edge weight between an internal node and all its children is a function of the node level. Since we regard all leaf nodes as the points in the metric space induced by a rooted tree, the distance between two points is a function of the level of their lowest common ancestor. We say that an HST is a k-level HST if its root is at level k.

The bulk of this section is devoted to proving our lower bounds in Section 4.1. We finish with the tight upper bound for 2-level HSTs in Section 4.2.

4.1 Iterative Lower Bounds

The key ingredient for our improved lower bounds is a new construction for uniform metrics (i.e. 1-level HSTs). Thus, we begin in Section 4.1.1 by giving the construction and analysis for uniform metrics. Then, we show how to lift our ideas to construct higher level HSTs in Section 4.1.2. In Section 4.1.3, we prove our improved lower bound $c_{2,m} = \Omega(\binom{m}{\lceil m/2 \rceil})$ on 2-level HSTs. Finally, we prove our lower bounds for higher level HSTs.

Iterative sequence. We first introduce the following iterative sequence which will be used to express the constructions of hard instances and the lower bounds:

$$A_{1,m} = \binom{m}{\lceil m/2 \rceil}, \qquad A_{k,m} = \binom{A_{k-1,m}}{\lceil A_{k-1,m}/2 \rceil} \quad \text{for } k \geq 2. \tag{4}$$

▶ **Proposition 4.1.** *For every fixed $m \geq 4$, we have $A_{1,m} > m$ and so the sequence $\{A_{k,m}\}_{k \geq 1}$ is unbounded.*

Labels and requests. In this section, the requests are defined by assigning a label $S \subseteq [m]$ to each leaf node. The request type K_i (as a feasible set) is then defined to be the leaf nodes whose labels contain i, i.e. request type K_i is served by moving to a node v whose label S contains i. We may use number i to refer to request type K_i when the context is clear, especially when we use the corresponding subset of $[m]$ to refer to a set of request types.

Randomized lower bounds. To prove a lower bound of α on the competitive ratio of randomized online algorithms, we use Yao's minimax principle [17], and give a distribution over input instances such that every deterministic algorithm has expected competitive ratio at least α.

In the following, we will only describe and analyze a randomized input sequence whose length is a function of k and m. This process can be repeated to generate arbitrarily many rounds and hence the request sequence can be arbitrarily long and have arbitrarily large cost.

4.1.1 Warm-up: Uniform Metrics

We begin with a warm-up on a 1-level HST (uniform metric) which we will lift to higher level HSTs.

Lower bound instance. The key property of our 1-level HST is that for every request sequence that is a permutation of $[m]$, there is a leaf that can serve the first $\lceil \frac{m}{2} \rceil$ requests and another leaf that can serve the remaining requests, and thus there is always a solution that moves at most twice. Define the 1-level HST structure $\mathcal{T}_{1,m}$ as follows: it has $\binom{m}{\lceil m/2 \rceil} = A_{1,m}$ leaves, each labeled with a $\lceil \frac{m}{2} \rceil$-size subset of $[m]$ and the distance between every two leaves is 1. The adversarial request sequence is a uniform random permutation of $[m]$.

Before we start our analysis, we prove the following proposition which will be useful in bounding the expected cost of the algorithm.

▶ **Proposition 4.2.** *There exists a universal constant $\kappa > 0$ such that for every $M \geq 2$, we have*

$$\sum_{t=1}^{\lfloor M/2 \rfloor} \frac{\lfloor M/2 \rfloor - t + 1}{M - t + 1} \geq \kappa \cdot M.$$

Proof. We have

$$\begin{aligned}\sum_{t=1}^{\lfloor M/2\rfloor}\frac{\lfloor M/2\rfloor-t+1}{M-t+1} &= \sum_{t=1}^{\lfloor M/2\rfloor}\frac{(M-t+1)-\lceil M/2\rceil}{M-t+1}\\ &= \lfloor M/2\rfloor - \lfloor M/2\rfloor\sum_{i=\lceil M/2\rceil+1}^{M}\frac{1}{i}\\ &= \lfloor M/2\rfloor - \lceil M/2\rceil(H_M - H_{\lceil M/2\rceil})\\ &= \lfloor M/2\rfloor - \lceil M/2\rceil(\ln 2 + o(1)) = \frac{1-\ln 2}{2}M(1+o(1)),\end{aligned}$$

where H_i is the ith harmonic number. ◀

▶ **Theorem 4.3.** *The expected competitive ratio of every deterministic algorithm against the uniform random permutation of m request types on $\mathcal{T}_{1,m}$ is $\Omega(m)$.*

Proof. First, we show that there is a solution with cost at most 2. The whole sequence $\rho_1,\ldots,\rho_m$ has each of the possible request types $K_1,\ldots,K_m$ exactly once. The solution processes requests $\rho_1,\ldots,\rho_{\lceil m/2\rceil}$ at the state labeled by the set of all indices of request types in $\rho_1,\ldots,\rho_{\lceil m/2\rceil}$, i.e. at $S=\{i \mid K_i \text{ is in subsequence } \rho_1,\ldots,\rho_{\lceil m/2\rceil}\}$, and then moves to the state labeled by the set of all indices of request types in the subsequence $\rho_{\lfloor m/2\rfloor+1},\ldots,\rho_m$. The total cost of this solution is at most 2, no matter which initial state the server is in.

We now lower bound the expected cost of every deterministic algorithm. Fix a deterministic algorithm. For each step t, let R_t be the set of request types that have not appeared prior to this step and S_{t-1} denote the label of the state of the algorithm right before the arrival of ρ_t. It holds that $|R_t| = m-t+1$ and $|S_{t-1}| = \lceil m/2\rceil$, and hence $|R_t \setminus S_{t-1}| \geq \lfloor m/2\rfloor - t + 1$. Let Y_t denote the event that the algorithm has to move at step t (i.e. because $\rho_t \notin S_{t-1}$). Since ρ_t is chosen u.a.r. from R_t, we have $\mathbb{E}[Y_t] \geq (\lfloor m/2\rfloor - t + 1)/(m-t+1)$ for every $1 \leq t \leq \lfloor m/2\rfloor$. For $\lfloor m/2\rfloor + 1 \leq t \leq m$, we use the trivial bound $\mathbb{E}[Y_t] \geq 0$. Thus, the total expected cost of the deterministic algorithm is

$$\sum_{t=1}^{m}\mathbb{E}[Y_t] \geq \sum_{t=1}^{\lfloor m/2\rfloor}\frac{\lfloor m/2\rfloor-t+1}{m-t+1} = \Omega(m),$$

by Proposition 4.2. ◀

4.1.2 Lifting to Higher Levels

For every k and m, we construct an HST $\mathcal{T}_{k,m}$ to lower bound $c_{k,m}$.

Key property of $\mathcal{T}_{k,m}$. The key property of $\mathcal{T}_{1,m}$ and the distribution of request sequences is that for every request sequence in the support of the distribution, there is a leaf that can serve the first half of the requests, and another leaf that can serve the second half. Thus, there is a solution that only moves twice. We generalize this to $\mathcal{T}_{k,m}$ as follows. The distribution of request sequences and $\mathcal{T}_{k,m}$ have the property that for every sequence in the support of the distribution, there are two "safe" $(k-1)$-level subtrees such that there is a low-cost solution that can serve the first half of the request sequence in one of them and the second half in the other. In other words, the low-cost solution only moves twice between $(k-1)$-level subtrees.

Higher-level labels. In our construction of $\mathcal{T}_{k,m}$, we will assign labels to all nodes except the root. The labels for leaves come from the set $\mathcal{P}_0 := \binom{[m]}{\lceil m/2 \rceil}$[4]. The labels for ℓ-level nodes are collections of those for $(\ell-1)$-level nodes as follows: Let $\mathcal{P}_\ell$ be the set of ℓ-level labels, then $\mathcal{P}_\ell := \binom{\mathcal{P}_{\ell-1}}{\lceil |\mathcal{P}_{\ell-1}|/2 \rceil}$ for every $1 \le \ell \le k-1$. It is easy to see that $|\mathcal{P}_\ell| = A_{\ell+1,m}$. We also define the label of a subtree to be the label of its root node.

Construction of $\mathcal{T}_{k,m}$. For $k \ge 2$, the HST $\mathcal{T}_{k,m}$ is constructed iteratively in a top-down fashion as follows. For every label $P \in \mathcal{P}_{k-1}$, the root of the HST has a child labeled P. For every level $k-1 \ge \ell \ge 1$, every level-ℓ node v has $|P(v)|$ children where $P(v)$ is its label, each given a unique label $p \in P(v)$.[5] We remark that there is exactly one level-$(k-1)$ node per label in $\mathcal{P}_{k-1}$ but for $\ell < k-1$, there are several level-ℓ nodes from different $(\ell+1)$-level subtrees that share the same label. For every $1 \le \ell \le k$, the distance between every two leaves whose lowest common ancestor is on level ℓ is $C_{\ell-1}$[6] ($C_0 = 1$), where C_ℓ's depend on k and m and will be defined later in Section 4.1.4.

▶ **Observation 4.4.** *In $\mathcal{T}_{k,m}$, every ℓ-level node has exactly $\lceil A_{\ell,m}/2 \rceil$ level-$(\ell-1)$ children with distinct labels, for every $1 \le \ell \le k-1$.*

4.1.3 Lower Bound Sequence for $\mathcal{T}_{2,m}$

We now prove our lower bound of $c_{2,m}$. Recall that C_1 is the distance between two leaves in different 1-level subtrees, and $\mathcal{P}_0$ is the set of all $\lceil m/2 \rceil$-size subsets of $[m]$. For each label $S \in \mathcal{P}_0$, define $\boldsymbol{\rho}(S)$ to be an arbitrary permutation of S.

Now we describe the adversarial randomized input sequence. The adversary first samples a uniformly random permutation $\{S_t\}_{t=1}^{|\mathcal{P}_0|}$ of $\mathcal{P}_0$ and then proceeds in $|\mathcal{P}_0| = A_{1,m}$ phases as follows: in phase t, it repeats the sequence $\boldsymbol{\rho}(S_t)$ for C_1 times. Thus, the entire input is a concatenation of all those phases:

$$\underbrace{\boldsymbol{\rho}(S_1), \ldots, \boldsymbol{\rho}(S_1)}_{C_1 \text{ times}}, \underbrace{\boldsymbol{\rho}(S_2), \ldots, \boldsymbol{\rho}(S_2)}_{C_1 \text{ times}}, \ldots, \underbrace{\boldsymbol{\rho}(S_{|\mathcal{P}_0|}), \ldots, \boldsymbol{\rho}(S_{|\mathcal{P}_0|})}_{C_1 \text{ times}}.$$

For every $1 \le t \le A_{1,m}$, we use T^1_{t-1} to denote the label of the 1-level subtree in which the state of the algorithm is located right before the beginning of the phase t.

▶ **Lemma 4.5.** *For every C_1, every deterministic algorithm has expected cost of at least $\Omega(A_{1,m}C_1)$.*

Proof. We first show that: the cost incurred during the whole phase t is at least C_1 if T^1_{t-1} does not contain S_t. If $S_t \notin T^1_{t-1}$, either the algorithm moves to another 1-level subtree that contains S_t as a leaf node, or the algorithm needs to move at least once during every loop of $\boldsymbol{\rho}(S_t)$ since there is no state in T^1_{t-1} that can satisfy all request types in S_t. In either way, the cost is at least C_1.

Now we consider the probability of the event that T^1_{t-1} does not contain S_t. Similar to the proof of Theorem 4.3, at every phase $1 \le t \le \lfloor A_{1,m}/2 \rfloor$, the probability that T^1_{t-1} does not contain a node labeled S_t is at least $(\lfloor A_{1,m}/2 \rfloor - t + 1)/(A_{1,m} - t + 1)$ because T^1_{t-1} contains exactly $\lceil A_{1,m}/2 \rceil$ different leaf labels. So, Proposition 4.2 implies that the total expected cost incurred during the first $\lfloor A_{1,m}/2 \rfloor$ phases is $\Omega(A_{1,m}C_1)$. ◀

---

[4] The notation $\binom{S}{k}$ means the collection of all k-size subsets of S.
[5] Recall that $P(v)$, a label of a level-ℓ node, is a collection of level-$(\ell-1)$ labels.
[6] We always assume that $C_\ell/C_{\ell-1}$ is an integer for every $\ell \ge 1$.

▶ **Lemma 4.6.** *For every C_1, the optimal offline cost is at most $2C_1 + A_{1,m}$ no matter where the initial state is.*

Proof. Consider the following solution. It moves to the subtree labeled $\{S_1, \ldots, S_{\lceil A_{1,m}/2 \rceil}\}$ and for phases $1 \le t \le \lfloor A_{1,m}/2 \rfloor$, it serves the repetitions of the subsequence $\boldsymbol{\rho}(S_t)$ at the node labeled S_t in the subtree. Then, it moves to the subtree labeled $\{S_{\lfloor A_{1,m}/2 \rfloor + 1}, \ldots, S_{A_{1,m}}\}$ and for $\lfloor A_{1,m}/2 \rfloor < t \le A_{1,m}$, serves the repetitions of the subsequence $\boldsymbol{\rho}(S_t)$ at the node labeled S_t in the subtree. It incurs a cost of at most $2C_1$ for movement between different 1-level subtrees and at most $A_{1,m}$ for movement within each of the two 1-level subtrees. Thus, the total cost is at most $2C_1 + A_{1,m}$. ◀

Since the two lemmata that we have just proven hold for every value C_1, we can set it to be some value such that $C_1 = \omega(A_{1,m})$ with both values regarded as functions of m, and the desired lower bound immediately follows.

▶ **Theorem 4.7.** *Every randomized algorithm has a worst case competitive ratio $\Omega(A_{1,m})$ on some instances of 2-level HSTs.*

4.1.4 General Iterative Lower Bounds on Higher Levels

We now prove the lower bound on $c_{k,m}$ for $k \ge 3$ expressed with the iterative sequence $\{A_{k,m}\}_{k \ge 1}$ defined in Equation (4) at the beginning of Section 4.1.

▶ **Theorem 4.8.** *$c_{k,m} = \Omega(A_{k-1,m})$ for every $k \ge 3$.*

Corollary 1.4 now follows from Theorem 4.8 and Proposition 4.1.

Sequences of labels. We have provided the construction of $\mathcal{T}_{k,m}$ for every k, and now we need to describe the adversary's strategy to generate a randomized input sequence on which no deterministic algorithm achieves competitive ratio better than $c_{k,m}$. Recall that every sequence in the support of the randomized input on $\mathcal{T}_{2,m}$ is a concatenation of sequences $\boldsymbol{\rho}(S)$ for labels $S \in \mathcal{P}_0$. Now we want to generalize this concept, the sequence of a label, to every level-ℓ label (i.e. every element of $\mathcal{P}_l$).

We define inductively on ℓ with $\ell = 0$ as the base case. For every $\ell \ge 1$ and every label $T^\ell \in \mathcal{P}_\ell$, the sequence $\boldsymbol{\rho}(T^\ell)$ is constructed in $|T^\ell|$ phases as follows. Let $T_1^{\ell-1}, \ldots, T_{|T^\ell|}^{\ell-1}$ be an arbitrary permutation of T^ℓ. During each phase $1 \le t \le |T^\ell|$, the sequence $\boldsymbol{\rho}(T^{\ell-1})$ is repeated consecutively for $\frac{C_\ell}{C_{\ell-1}}$ (we can choose values of C_ℓ's to make this amount always an integer at the end) times, and the entire sequence $\boldsymbol{\rho}(T^\ell)$ is a concatenation of those phases:

$$\underbrace{\boldsymbol{\rho}(T_1^{\ell-1}), \ldots, \boldsymbol{\rho}(T_1^{\ell-1})}_{\frac{C_\ell}{C_{\ell-1}} \text{ times}}, \underbrace{\boldsymbol{\rho}(T_2^{\ell-1}), \ldots, \boldsymbol{\rho}(T_2^{\ell-1})}_{\frac{C_\ell}{C_{\ell-1}} \text{ times}}, \ldots, \underbrace{\boldsymbol{\rho}(T_{|T^\ell|}^{\ell-1}), \ldots, \boldsymbol{\rho}(T_{|T^\ell|}^{\ell-1})}_{\frac{C_\ell}{C_{\ell-1}} \text{ times}}.$$

▶ **Lemma 4.9.** *Let $1 \le \ell \le k-2$ and $P \in \mathcal{P}_\ell$. Consider a solution for $\boldsymbol{\rho}(P)$ whose initial state is not in an ℓ-level subtree with label P. Then, the solution incurs a cost of at least C_ℓ on $\boldsymbol{\rho}(P)$.*

Proof. We prove by induction on ℓ. The base case is when $\ell = 1$. Fix some $P \in \mathcal{P}_1$. The sequence $\boldsymbol{\rho}(P)$ consists of C_1 consecutive repetitions of the sequence $\boldsymbol{\rho}(p)$ for every child $p \in P$. If the initial state is in a 1-level subtree labeled $T^1 \ne P$, then there exists some $p \in P$ such that $p \notin T^1$ and thus there is no leaf in the subtree labeled p. As a result, the algorithm either visits a different 1-level subtree, or incurs cost 1 during every repetition of $\boldsymbol{\rho}(p)$, thus costing at least C_1.

Suppose the claim holds for every sequence $\boldsymbol{\rho}(p)$ such that $p \in \mathcal{P}_\ell$ $(1 \le \ell \le k-3)$. Now consider a sequence $\boldsymbol{\rho}(P)$ for some $P \in \mathcal{P}_{\ell+1}$. For every $p \in P$, it contains $\frac{C_{\ell+1}}{C_\ell}$ consecutive repetitions of $\boldsymbol{\rho}(p)$. If the initial state is in an $(\ell+1)$-level subtree labeled $T^{\ell+1} \neq P$, then there exists $p \in P \setminus T^{\ell+1}$ because $|T^{\ell+1}| = |P|$. If the algorithm moves to a different $(\ell+1)$-level subtree, it incurs a cost of $C_{\ell+1}$. Now suppose the algorithm does not move to a different $(\ell+1)$-level subtree. Since $p \notin T_{\ell+1}$, the current subtree does not have an ℓ-level subtree labeled p. Thus at the start of each of the $C_{\ell+1}/C_\ell$ repetitions of $\boldsymbol{\rho}(p)$, by the inductive hypothesis, it incurs a cost of at least C_ℓ. The total cost is thus at least $C_{\ell+1}$. ◀

We now define another iterative sequence $\{B_\ell\}_{1 \le \ell \le k-1}$ and show that it can be used to express the upper bound of the optimal solution of the request sequences:

$$B_1 = \left\lceil \frac{A_{1,m}}{2} \right\rceil, \qquad B_\ell = \left\lceil \frac{A_{\ell,m}}{2} \right\rceil \left[(B_{\ell-1} + C_{\ell-2}) \cdot \frac{C_\ell}{C_{\ell-1}} + C_{\ell-1} \right] \quad \text{for } 2 \le \ell \le k-1.$$

▶ **Lemma 4.10.** *For every label T^ℓ in $\mathcal{P}_\ell$ and subtree labeled T^ℓ in $\mathcal{T}_{k,m}$, there exists a trajectory contained within the subtree that incurs cost of no more than B_ℓ to serve the sequence $\boldsymbol{\rho}(T^\ell)$, for every $1 \le \ell \le k-1$.*

Proof. We prove by induction on ℓ. Consider the base case $\ell = 1$. Fix some $T^1 \in \mathcal{P}_1$. Order the elements $S_1, \ldots, S_{\lceil A_{1,m}/2 \rceil}$ of T in the same order as the phases in $\boldsymbol{\rho}(T^1)$. Consider the trajectory that first moves to the leaf node labeled S_1 in the 1-level subtree labeled T^1 and then moves to leaves $S_2, \ldots, S_{\lceil A_{1,m}/2 \rceil}$ one by one with cost 1 each time since they are all in the same 1-level subtree. The total cost is at most $\left\lceil \frac{A_{1,m}}{2} \right\rceil = B_1$.

Now we consider $\boldsymbol{\rho}(T^\ell)$ for $2 \le \ell \le k-1$, given that the property for $\ell-1$ has been proven. Suppose that $\boldsymbol{\rho}(T^\ell)$ is the concatenation of $\boldsymbol{\rho}(T_1^{\ell-1}), \ldots, \boldsymbol{\rho}(T^{\ell-1}_{\lceil A_{\ell,m}/2 \rceil})$ by the chronological order where each $\boldsymbol{\rho}(T_j^{\ell-1})$ is repeated for $\frac{C_\ell}{C_{\ell-1}}$ times before proceeding to the next one. Consider the trajectory that for each phase $1 \le j \le \lceil A_{\ell,m}/2 \rceil$, consists of $\frac{C_\ell}{C_{\ell-1}}$ copies of the trajectory obtained by applying the inductive hypothesis to $\boldsymbol{\rho}(T_j^{\ell-1})$. In each phase j, for each copy of $\boldsymbol{\rho}(T_j^{\ell-1})$, the trajectory incurs a cost of at most $C_{\ell-2}$ to move to its initial state within the subtree with label $T_j^{\ell-1}$ and then a cost of $B_{\ell-1}$ to serve $\boldsymbol{\rho}(T_j^{\ell-1})$ within the same subtree. Thus, for each phase j, the trajectory's cost is at most $\frac{C_\ell}{C_{\ell-1}}(B_{\ell-1} + C_{\ell-2})$ plus at most $C_{\ell-1}$ to move to an $(\ell-1)$-level subtree labeled $T_j^{\ell-1}$ at the start of the phase. As there are $\lceil A_{\ell,m}/2 \rceil$ phases, the total cost of the trajectory is bounded by B_ℓ, as desired. ◀

Adversary's strategy and analysis. We are finally ready to describe the adversary's strategy on $\mathcal{T}_{k,m}$. It first samples a uniformly random permutation $\{T_t^{k-2}\}_{t=1}^{A_{k-1,m}}$ of $\mathcal{P}_{k-2}$ (note that $|\mathcal{P}_{k-2}| = A_{k-1,m}$), and then proceeds in $A_{k-1,m}$ phases: in each phase t, $\boldsymbol{\rho}(T_t^{k-2})$ is repeated consecutively for $\frac{C_{k-1}}{C_{k-2}}$ times, and the whole input is the concatenation of all $A_{k-1,m}$ phases.

▶ **Lemma 4.11.** *The optimal cost is no more than $2(C_{k-1} + B_{k-1})$ regardless of the initial state.*

Proof. The whole sequence can be regarded as the concatenation of the sequences $\boldsymbol{\rho}(T^{k-1})$'s of two $(k-1)$-level subtrees:

$$\{T_1^{k-2}, \ldots, T^{k-2}_{\lceil A_{k-1,m}/2 \rceil}\} \text{ and } \{T^{k-2}_{\lfloor A_{k-1,m}/2 \rfloor + 1}, \ldots, T^{k-2}_{A_{k-1,m}}\}.$$

The repetitions of $\boldsymbol{\rho}(T^{k-2}_{\lfloor A_{k-1,m}/2 \rfloor + 1})$ appear in both of the $(k-1)$-level subtrees' sequence when m is odd, but it does not affect our conclusion since we are proving an upper bound. As a result, the optimal solution just pays the cost at most B_{k-1} in each T^{k-1} (Lemma 4.10) plus the cost at most $2C_{k-1}$ to visit two $(k-1)$-level subtrees. ◀

▶ **Lemma 4.12.** *The expected cost of every deterministic algorithm to serve this randomized input on $\mathcal{T}_{k,m}$ is $\Omega(A_{k-1,m}C_{k-1})$.*

Proof. The proof is similar those of Theorem 4.3 and Lemma 4.5. Fix a deterministic algorithm. During every phase $1 \le t \le \lfloor A_{k-1,m}/2 \rfloor$ when some $\boldsymbol{\rho}(T_t^{k-2})$ is repeated for $\frac{C_{k-1}}{C_{k-2}}$ times, the probability that $\boldsymbol{\rho}(T_t^{k-2})$ is not in the current $(k-1)$-level subtree containing the algorithm's server has probability is at least $\frac{\lfloor A_{k-1,m}/2 \rfloor - t+1}{A_{k-1,m}-t+1}$. When this happens, the algorithm only has two choices: either move to a new $(k-1)$-level subtree with cost C_{k-1}, or incur cost of at least C_{k-2} during each repetition of $\boldsymbol{\rho}(T_t^{k-2})$ according to Lemma 4.9 since the initial state cannot be in a $(k-2)$-level subtree with label T_t^{k-2}. ◀

It remains to show that there exist possible values of C_ℓ's and B_ℓ's for $1 \le \ell \le k-1$ such that $C_{k-1} = \omega(B_{k-1})$ as m tends to infinity[7]. This would show that the randomized competitive ratio on $\mathcal{T}_{k,m}$ is at least $\Omega(\frac{A_{k-1,m}C_{k-1}}{C_{k-1}+B_{k-1}}) = \Omega(A_{k-1,m})$ as a function of m.

Let $C_1 = \omega(\prod_{j=1}^{k-1} A_{j,m})$ and $C_\ell = \omega((\prod_{j=\ell}^{k-1} A_{j,m})C_{\ell-1})$ for $2 \le \ell \le k-1$. We now prove that such a sequence satisfies the desired property.

▶ **Lemma 4.13.** $C_{k-1} = \omega(B_{k-1})$.

Proof. We prove that $C_\ell = \omega((\prod_{j=\ell+1}^{k-1} A_{j,m})B_\ell)$ as m tends to infinity for every $1 \le \ell \le k-1$ inductively, where $\prod_{j=k}^{k-1} A_{j,m}$ is defined to be 1.

Clearly the result holds for $\ell = 1$ because $B_1 = \Theta(A_{1,m})$. With the inductive hypothesis that $C_\ell = \omega((\prod_{j=\ell+1}^{k-1} A_{j,m})B_\ell)$ for some $1 \le \ell \le k-2$, then in order to prove that $C_{\ell+1} = \omega((\prod_{j=\ell+2}^{k-1} A_{j,m})B_{\ell+1})$, according to the definition that $B_{\ell+1} = \left\lceil \frac{A_{\ell+1,m}}{2} \right\rceil [(B_\ell + C_{\ell-1}) \cdot \frac{C_{\ell+1}}{C_\ell} + C_\ell]$, it suffices to show that the following two statements both hold:

$$C_{\ell+1} = \omega(A_{\ell+1,m} \cdot (\prod_{j=\ell+2}^{k-1} A_{j,m})C_\ell) = \omega(\prod_{j=\ell+1}^{k-1} A_{j,m}C_\ell), \tag{5}$$

which is exactly our definition of $C_{\ell+1}$, and

$$C_\ell = \omega((\prod_{j=\ell+1}^{k-1} A_{j,m})(B_\ell + C_{\ell-1})), \tag{6}$$

while (6) can be further reduced to that the following two formulae $C_\ell = \omega((\prod_{j=\ell+1}^{k-1} A_{j,m})B_\ell)$ and $C_\ell = \omega((\prod_{j=\ell+1}^{k-1} A_{j,m})C_{\ell-1})$ both hold, where the first one holds due to the inductive hypothesis and the second holds due to the definition of C_ℓ. ◀

This completes the proof of Theorem 4.8.

▶ Remark 4.14. Our iterative sequence of lower bounds on k-level HSTs marks an improvement from the one provided in Section 4.2 of [5] in the sense that: given every fixed $k \ge 2$, the lower bound provided by our sequence is asymptotically tighter than theirs when the parameter m tends to infinity. To formalize, consider their iterative sequence $\{\hat{c}_{k,m}\}_{k \ge 1}$ defined as the following: $\hat{c}_{1,m} = \lfloor m/2 \rfloor$ and $\hat{c}_{k,m} = 2^{\hat{c}_{k-1,m}-1}$. We can use inductive arguments on k to show that, $A_{k,m} = \omega(\hat{c}_{k,m})$ for every $k \ge 2$: it is clear that the statement

[7] Here both C_{k-1} and B_{k-1} are functions of m. When we consider both m and k as constants, the lower bound can be achieved by setting the ratio $C_\ell/C_{\ell-1}$ sufficiently large for every $1 \le \ell \le k-1$ and the proof idea is similar.

holds for $k = 2$, since $A_{2,m} = \binom{m}{\lceil m/2 \rceil} = \Theta(2^m/\sqrt{m})$ and $\hat{c}_{2,m} = \Theta(2^{m/2})$; suppose that $\lim_{m\to\infty} A_{k-1,m}/\hat{c}_{k-1,m} = \infty$, then we show that $\lim_{m\to\infty} \log(A_{k,m}/\hat{c}_{k,m}) = \infty$ and hence $\lim_{m\to\infty} A_{k,m}/\hat{c}_{k,m} = \infty$. To see this, $\log(A_{k,m}/\hat{c}_{k,m}) = \log A_{k,m} - \log \hat{c}_{k,m} = A_{k-1,m} - \log(A_{k-1,m})/2 - \hat{c}_{k-1,m} + O(1)$. Due to the inductive hypothesis, $\hat{c}_{k-1,m} = o(A_{k-1,m})$. Therefore, $A_{k-1,m} - \log(A_{k-1,m})/2 - \hat{c}_{k-1,m} \sim A_{k-1,m}$ and $\lim_{m\to\infty} \log(A_{k,m}/\hat{c}_{k,m}) = \infty$.

4.2 Tight Upper Bound for 2-Level HSTs

The idea to show a general upper bound for 2-level HSTs is as follows: even if there is no restriction on the size of the whole tree itself, some leaves and subtrees are redundant in the sense that any reasonable solution should not move to them, or does not need to move to them while maintaining feasibility and not increasing the cost. As a result, we can trim off those redundant nodes and hence reduce the graph size, just as how we show that we only need to consider $2^m - 1$ states for the weighted star case. This idea has also been applied by Bubeck and Rabani to give iterative upper bounds for 2 and higher levels of HSTs (see Section 4.2 Deeper Trees in [5]), and we present a refined argument on 2-level HSTs that closes the gap between upper and lower bounds. We show that the number of leaves remained after such preprocessing is bounded in terms of m and apply the optimal MTS algorithm for HSTs from [4].

Since the initial state can be arbitrarily given, in this part we only consider those leaves different from the initial state, to evaluate whether some states can be totally replaced by others and every algorithm can still maintain a feasible solution with equal or less cost. This is without loss of generality up to a constant factor, since there is only one initial state and thus it is sufficient to give an upper bound of the amount of states that are not the initial state.

In this part, we express leaf nodes lexicographically by a tuple (S, T) where S is the label of the leaf node itself and T is the label of the 1-level subtree that it is in. The label of every node is defined in the same way as the previous subsection[8] . A preliminary observation is that, if two leaf nodes share exactly the same tuple, then they are isomorphic and it suffices to only keep one in the tree. The feasibility of removing redundant nodes is that, when m possible requests and their corresponding feasible sets in the whole metric are fixed, running an algorithm over a subset of states produces a feasible solution for the whole metric as well, therefore what we need to show is that the optimal cost does not increase while we trim off some states.

▶ **Proposition 4.15.** *If there are two leaves (S_1, T) and (S_2, T) in the same 1-level subtree such that $S_1 \subseteq S_2$, then any move to (S_1, T) can be replaced with one to (S_2, T) without increasing the cost.*

Proof. Any request that is feasible at (S_1, T) is also feasible at (S_2, T) since $S_1 \subseteq S_2$. Moreover, for any state different from (S_1, T) and (S_2, T), it has the same distance from those two nodes that are within the same 1-level subtree T according to the 2-level HST structure. ◀

As a result, we can assume that every 1-level subtree is an antichain over subsets of $[m]$, which contains at most $\binom{m}{\lceil m/2 \rceil} = A_{1,m}$ elements according to Sperner's theorem [16]. The next thing is to consider the maximum amount of such 1-level subtrees, which is equivalent to the amount of antichains over subsets of $[m]$. This amount is called Dedekind number $D(m)$ and its following asymptotic approximation property has been proven in [12]:

[8] Recall that the label of a leaf node is the set of request types that this state can satisfy, and the label of a 1-level subtree is the set of labels of leaf nodes contained in it.

▶ **Lemma 4.16** ([12]). $\log D(m) = O(A_{1,m})$.

▶ **Theorem 4.17.** $c_{2,m} = O(A_{1,m})$.

Proof. It suffices to consider at most $O(D(m)A_{1,m})$ leaf nodes (including the initial state and at most $A_{1,m}$ other leaves in the same 1-level subtree as they cannot be pruned by the above process) and apply the optimal online MTS algorithm on an HST that has competitive ratio $O(\log n)$, where n is the number of points in the metric. According to the asymptotic property of $D(m)$ as shown in Lemma 4.16, $\log(D(m)A_{1,m}) = O(A_{1,m} + \log A_{1,m}) = O(A_{1,m})$. ◀

5 Open Problems

Following the initial study of parametrized metrical task systems (MTS) and metrical service systems (MSS) by Bubeck and Rabani [5], our research answers several open problems posed by Bubeck and Rabani. We provide a deterministic $O(m)$-competitive algorithm on weighted stars, tighten the gap between the upper and lower bounds of randomized competitive ratios on HSTs of different levels, and show that it is possible to design a strictly constant-competitive algorithm on general metrics when $m = 2$. However, multiple problems remain open: as Question 3 has been resolved on general metrics by showing the contrast between $m = 2$ and $m = 3$ cases, the focus is now on special classes of metrics, e.g., is it possible to obtain a finite competitive ratio for chasing 3 sets on HSTs or line metrics? Another interesting open problem is whether the $O(\binom{m}{\lceil m/2 \rceil})$ upper bound of randomized algorithms on 2-level HSTs can also be achieved by a deterministic algorithm. The progress on this problem will not only close the gap between the upper and lower bounds known for deterministic algorithms for this particular class of metrics, but also deepen our fundamental understanding of the parametrized MSS problem, as it concerns whether deterministic algorithms are essentially as powerful as randomized algorithms on 2-level HSTs and other classes of metrics. Moreover, the technique that we use in Section 3 is a linear programming primal-dual method that exploits the properties of parametrized MSS with m request types, and we wonder whether this framework can be generalized to prove the results of the more general parametrized MTS on uniform metrics (the tight deterministic bound of $\Theta(m \log(en/m))$ was proven by Bubeck and Rabani) or weighted stars (no result yet).

Abstract

A multiflow in a planar graph is *uncrossed* if the curves identified by its support paths do not cross in the plane. Recently, uncrossed flows have played a role in approximation algorithms for maximum disjoint paths in "fully-planar" instances, where the combined supply-plus-demand graph is planar. They are also used in algorithms to find low-congestion unsplittable flows for both fully-planar and single-source instances. For these two instance classes, any fractional multiflow can be converted into one that is uncrossed, which these algorithms then exploit to obtain their results.

We investigate the utility of uncrossed flow more generally and ask three key questions. First, are there other interesting planar multiflow instances that admit uncrossed flows (beyond fully-planar and single-source)? We answer affirmatively, demonstrating a new family of "pairwise-planar" instances whose fractional flows can be uncrossed. This family subsumes fully-planar but includes substantially more, such as (2-connected) fully-compliant series-parallel instances and some instances that have large clique demand graphs. Second, can we always round a fractional uncrossed flow to a "good" integral flow? We again answer positively. For maximization problems, we show any fractional uncrossed flow can be rounded to an integral flow with a constant fraction of its value. For congestion problems (where we must fully route all given demands), we give a rounding procedure that yields an integral multiflow with edge congestion 2. Consequently, we obtain constant-factor approximation algorithms for maximum disjoint paths and minimum congestion integer multiflow for pairwise-planar instances, and show such instances have a constant integral flow-multicut gap. Finally we ask, given an arbitrary planar instance, can we determine if there exists a congestion-1 uncrossed fractional flow (congestion setting) or find the maximum value uncrossed fractional flow (maximization setting)? For congestion, we show this problem is NP-hard, but finding uncrossed edge-disjoint paths is polytime solvable if the demands span a bounded number of faces. For maximization, we present a strong (almost-polynomial) inapproximability result.

Figure 1 A fully-planar multiflow instance with two different multiflows routing its demands. Dashed edges represent demands, and coloured paths are support paths of the flow. The support paths on the left cross, while the multiflow on the right is uncrossed.

1 Introduction

In *multicommodity flow*, we are given an edge-capacitated *supply graph* (G, u) and a set of source-sink pairs called *demands* or *commodities*. The demands are represented by a *demand graph* H on the same node set as G. Unless otherwise specified, graphs are *undirected*. We seek to route flow for the demands simultaneously, while respecting the capacities of the supply graph. There are two flavours of the multiflow problem. In the *maximization* setting, the objective is to find a flow x that respects the capacities and maximizes the total sum of demands being routed. A feasible flow for (G, H, u) needs to respect the capacities, but has freedom in the quantities of each demand that it routes. In the *congestion* setting, we are given target amounts $d(s, t)$ for each $(s, t) \in E(H)$. To be feasible for (G, H, u, d), a flow must (in addition to respecting capacities) fully route this amount for each demand. The objective is to determine whether d can be satisfied in the capacities u, or to find the minimum scaling factor $\alpha \geq 1$ such that d can be satisfied in capacities αu.

Both fractional and integer versions of these problems are fundamental in combinatorial optimization (cf. [28]). Due to applications, the literature often emphasizes problems where the supply graph is planar [20]. The integer problems are hard even for planar supply graphs with 3 demand edges [33]. There exist, however, good approximation algorithms in so-called *fully-planar* instances where the joint supply-demand graph $G + H$ is planar[2]. Often approximation algorithms follow a "relax-and-round" approach: relax the integer problem to its fractional version, find a fractional solution with "nice properties", and then round the nice fractional solution to an integral solution.

A recurring "nice property" for planar multiflow is that the support paths (i.e. paths routing non-zero flow) do not cross in the plane. A multiflow satisfying this property is *uncrossed* (see Figure 1). It is known how to construct uncrossed multiflows for single-source (H is a star) and fully-planar instances, the latter using an algorithm of Matsumoto et al. [21]. This was recently leveraged to give constant-factor approximation algorithms for *maximum edge-disjoint paths* (MEDP) [15] and *maximum node-disjoint paths* (MNDP) [25, 24] for fully-planar instances. Very recently uncrossed flows were used to round fractional flows to *unsplittable* flows, routing the same demand quantities with small additive error, in both single-source [31] and fully-planar contexts [12]. In an unsplittable flow, each demand is routed on a single path.

[2] In this paper, if we say a multiflow instance is *planar* we only mean that the supply graph G is planar. If we mean $G + H$ is planar, we will say fully-planar.

In the above results, the uncrossed property of the fractional solution plays a key role, but the arguments are still specialized to the structure of (G, H). For example, for the fully-planar context, the uncrossed flow can be shown to be *laminar*: if one considers the family of cycles obtained by joining demand edges of H to their support paths in G, the result is a nested family of cycles in the plane. However, this same property does not hold for all instances that admit uncrossed flows. For instance, if G is a cycle and H consists of mutually crossing demands, then no paths within G cross, but the path-plus-demand cycles are not nested. Our aim is to expand on a theory of uncrossed flows - when can we find them, and do they always admit good rounding algorithms, even outside the laminar/single-source cases? We have three motivating questions.

▶ **Question 1.** *Do there exist other (interesting) families of (G, H) satisfying the following property: for all capacities u and demand values d, if (G, H, u, d) has a feasible (fractional) multiflow x, then (G, H, u, d) has a feasible multiflow y that is uncrossed?*

We say (G, H) is an *uncrossable layout* if it satisfies the conditions of Question 1. For instance, if (G, H) is fully-planar or H is single-source, then (G, H) is an uncrossable layout.

▶ **Question 2.** *Suppose we are given a feasible fractional multiflow x that is uncrossed (not assuming that the multiflow x is laminar). Can we round x to a "good" integer multiflow y? Specifically:*

1. *(Congestion Setting) Given feasible uncrossed fractional multiflow x for (G, H, u, d), can we compute an integer multiflow y feasible for $(G, H, \alpha u, d)$, for some constant α?*
2. *(Maximization Setting) Given feasible uncrossed fractional multiflow x for (G, H, u), can we compute an integer multiflow y feasible for (G, H, u) whose value is $1/\beta$ times that of x, for some constant β?*

The answer to Question 1 and both parts of Question 2 is: yes! First, we define a new class of (G, H) and prove it gives uncrossable layouts.

▶ **Theorem 1.** *Let G be a planar graph with a fixed embedding. Let H be such that for any pair of demands $h_1, h_2 \in E(H)$, h_1 and h_2 can be embedded inside (possibly different) faces of G so they do not cross each other. Then (G, H) is an uncrossable layout.*

We say any (G, H) satisfying this property is *pairwise-planar* (see Figure 6 in Section 3 for a depiction). The pairwise-planar class includes fully-planar as a subset, but includes substantially more. For instance, it contains layouts where $G + H$ is highly non-planar (and thus, do not admit laminar flows). It also includes the 2-connected *fully-compliant*[3] family introduced in [7], which were not previously known to give uncrossed layouts to our knowledge. Pairwise-planar also differs from previous uncrossable layouts in an important structural sense. Namely, fully-planar and single-source (G, H) are *cut-sufficient* (essentially, they have a Max-Flow Min-Cut theorem in the congestion setting), while some pairwise-planar (G, H) are not.

As for Question 2, we prove the following results. We begin with the maximization setting.

▶ **Theorem 2.** *Let (G, H, u) be a planar maximization instance where u is integral. Let f be a feasible fractional flow that is uncrossed. There exists a feasible integral flow f' achieving an $\Omega(1)$ fraction of the value of f. The integral flow can be computed in polynomial time.*

[3] (G, H) is fully-compliant if G is series-parallel and $G + h$ is series-parallel for every $h \in E(H)$.

We prove this result by establishing an "approximate integer decomposition property", exploiting colouring results on a restricted class of string graphs (path intersection graphs). This integer decomposition also implies $\Omega(1)$ rounding holds for the *weighted* maximization version, where each $(s,t) \in E(H)$ has an associated weight $w(s,t)$, and a flow achieves $w(s,t)$ value for each unit of (s,t)-flow that it routes. Additionally, this result extends to *node-capacitated* multiflows (i.e. u is a capacity function on nodes rather than edges).

For the congestion setting, we give a factor 2 rounding for converting a fractional uncrossed multiflow into an integral multiflow. Moreover, for an extra additive penalty we can round to an unsplittable flow.

▶ **Theorem 3.** *Let (G, H, u, d) be a planar congestion instance where u, d are integral. Let f be a feasible fractional multiflow that is strongly uncrossed*[4]*. Then there exists both:*

1. *an integral multiflow f' that is feasible for (G, H, u', d) where $u'(e) \leq 2u(e)$ for each $e \in E(G)$, and*
2. *an unsplittable multiflow f'' that is feasible for (G, H, u'', d) where $u''(e) < 2u(e) + d_{\max}$ for every $e \in E(G)$, where $d_{\max} = \max_{h \in E(H)} d(h)$.*

The integral and unsplittable multiflows can be computed in polynomial time.

Using Theorems 1, 2, and 3, we obtain constant-factor approximation algorithms for integer multiflow problems with pairwise-planar inputs.

▶ **Corollary 4.** *There exist polynomial time constant-factor approximation algorithms for maximum edge-disjoint paths and maximum node-disjoint paths (and more generally, maximum integer multiflow), as well as minimum congestion integer multiflow, for inputs where (G, H) is pairwise-planar.*

Another interesting corollary concerns the *integral flow-multicut gap*, which is the ratio of the minimum capacity of a multicut (a set $F \subseteq E(G)$ whose removal destroys all paths connecting demands of H) to the maximum value of an *integral* multiflow. Using their flow rounding algorithms, [17] [15] show the gap is constant for fully-planar (G, H), but the gap can be as large as $\Theta(|E(H)|)$ even for planar supply graphs [14]. Combining our results with a theorem of [30], we obtain a constant gap for pairwise-planar instances.

▶ **Corollary 5.** *For any maximization instance (G, H, u) where (G, H) is pairwise-planar, the minimum capacity of a multicut is at most $O(1)$ times the maximum value of an integral multiflow.*

The third key question requires slightly more motivation. If (G, H) is not an uncrossable layout, it only means the structure of (G, H) alone is insufficient to guarantee uncrossed solutions. However for specific capacities u and demands d we may still be able to find an uncrossed flow and round it. Thus it would be nice to have algorithms to determine whether (in the congestion setting) we can find a feasible fractional flow that is uncrossed, or (in the maximization setting) find the largest feasible flow that is uncrossed.

▶ **Question 3.** *Suppose we are given an* arbitrary *planar multiflow instance. Can we solve the fractional multiflow problem if we constrain the feasible space to only allow uncrossed solutions? Specifically:*

[4] We defer the more technical definition of strongly uncrossed to Section 2.4. Importantly, the uncrossable layouts mentioned in this paper, including pairwise-planar, admit strongly uncrossed flows.

1. *(Congestion Setting) Given* (G, H, u, d)*, can we determine whether there exists a feasible fractional multiflow that is uncrossed?*
2. *(Maximization Setting) Given* (G, H, u)*, can we compute a feasible fractional uncrossed multiflow whose value is (approximately) maximum amongst feasible uncrossed solutions (*maximum uncrossed multiflow*)?*

These questions concern *fractional* multiflows and may feel like linear optimization problems. However the requirement of uncrossed flow paths makes these computationally much more challenging. Interestingly, the positive result of Theorem 2 can be combined with results of [8, 9] to establish strong almost-polynomial inapproximability for maximum uncrossed fractional multiflow (for both edge and node capacities).

▶ **Theorem 6.** *For planar* G*, maximum uncrossed fractional multiflow is not approximable to within a factor of* $2^{\Omega(\log^{1-\epsilon} n)}$ *for any* $\epsilon > 0$ *assuming that* $NP \not\subseteq DTIME(n^{polylog\ n})$*. Moreover, there is no* $n^{O\left(\frac{1}{(\log\log n)^2}\right)}$*-approximation polynomial-time algorithm assuming that for some constant* $\delta > 0$*,* $NP \not\subseteq DTIME(2^{n^\delta})$*. These results hold even when* G *is maximum degree* 3 *(or even* G *is a wall graph) and the capacities are unit.*

For the congestion setting, we prove the problem posed by Question 3 is NP-complete.

▶ **Theorem 7.** *It is NP-complete to determine whether planar congestion instance* (G, H, u, d) *has a feasible fractional uncrossed multiflow, even with unit-valued capacities and demands.*

We remark that since this problem is not a linear program anymore, it is not even obvious that the problem is in NP, however we establish this as well. On the positive side, we show that finding uncrossed edge-disjoint paths can be (polytime) reduced to a node-disjoint paths instance. Hence we may find uncrossed solutions if $E(H)$ is incident with a bounded number of faces using a result of Schrijver [27].

▶ **Theorem 8.** *For instances where* G *is planar, the edges of* H *are incident with a bounded number of faces, and the capacities and demands are unit-valued, there is a polynomial time algorithm to find a feasible integral uncrossed multiflow for* (G, H, u, d) *or declare none exists.*

1.1 Organization of the Paper

Section 2 lays the groundwork for the theory of uncrossed flows, including detailed definitions. Section 3 discusses pairwise-planar instances, proves they admit uncrossed flows, and shows a constant integral flow-multicut gap. Section 4 covers our maximization results, both rounding (Theorem 2) and inapproximability (Theorem 6). The rounding result for congestion (Theorem 3) appears in Section 5. This manuscript includes the important aspects of each proof, though occasionally some details are deferred to the full version. The NP-completeness result (Theorem 7) and the integral uncrossed flow algorithm for a bounded number of H-incident faces (Theorem 8) are deferred to the full version.

1.2 Related Work

Uncrossed flows have played a role in previous routing algorithms in planar graphs, such as Schrijver's Homotopy Method [26] for node-disjoint paths. Most relevant are recent algorithms for maximum disjoint paths in fully-planar instances ($G + H$ planar). In [17, 15], constant-factor approximation algorithms are given for maximum edge-disjoint paths, then extended to the node-disjoint setting in [25, 24]. These algorithms glue uncrossed flow paths to their respective demand edges to obtain an uncrossed (laminar) family of cycles in a

planar graph. Our rounding algorithms are agnostic in the sense that they just operate on uncrossed flow paths, not assuming that demands lie within a face or that demands of a common face are non-crossing (indeed for our pairwise-planar instances, it is even possible for demands within a face to form a clique).

Uncrossed flows for fully-planar instances are typically constructed by a primal algorithm [21] that computes an uncrossed flow from scratch. We build on a different approach, taking a feasible flow (with many crossings) and iteratively decreasing total crossing (used for example in [18] to find cycles in higher-genus surfaces that cross at most once). We discuss obstacles faced in extending this to pairwise-planar in Section 3.

In [15] the initial flow is first rounded to a half-integral flow (using linear programming theory such as total unimodularity), then this half-integral flow is rounded to an integral flow using a 4-colouring of the (planar) intersection graph of the cycles. Extending to the node-disjoint setting, [25] uses a different argument, iteratively constructing a high-value solution by showing one can always find an "efficient" cycle that only intersects the other cycles on a small set of its nodes. Our rounding technique for Theorem 2 instead uses an approach based on establishing an "approximate integer decomposition property" [3, 5]. A key ingredient comes from looking at a subset of *string graphs*, which are the intersection graphs from curves in the plane. Specifically, we are interested in those that arise from curves that do not cross, studied for example in [11], and for which an important colouring result was proven by Fox and Pach [13][5].

The fully-planar maximum disjoint paths algorithms were extended [25, 18] to uncrossable families of cycles in higher-genus surfaces, yielding approximation algorithms for maximum disjoint paths when $G + H$ is embedded in a surface of genus g; the approximation ratio is polynomial in the genus g. By contrast our work extends uncrossing techniques to a broader family of multiflow instances (pairwise-planar) while remaining *in the plane*. Some pairwise-planar instances have $G + H$ of arbitrarily high genus (e.g. H contains a large clique), but we show nevertheless that they admit uncrossed flows in the plane in order to achieve constant-factor approximations. Results in [25] use the context of uncrossed cycle families, as defined by Goemans and Williamson [16], which is a combinatorial rather than topological definition of crossing.

The works of [17], [15] use their rounding algorithms to establish that the integral flow-multicut gap of fully-planar instances is constant. The integral flow-multicut gap can be as large as $\Theta(|E(H)|)$ for general planar G [14], so further restrictions on (G, H) are needed to establish constant bounds. Other classes known to give constant integral flow-multicut gaps include: when G is a tree [14], when $G + H$ is series-parallel [10] (note that these are less general than fully-compliant), when G has fixed cyclomatic number [1], when $G + H$ has fixed genus [18], and when G has fixed tree-width [4]. A common ingredient in these results is a bound on the *fractional* flow-multicut gap for $K_{r,r}$-minor-free G by [30, 19].

Other works using uncrossed flow come from the study of unsplittable flow in the congestion model (where specified demand quantities must be fully routed). For directed single-source planar instances (H is a star) [31], it is shown how to convert a feasible fractional uncrossed flow into an unsplittable flow that exceeds capacities by a small amount and has no increase in cost. For (undirected) fully-planar instances, [12] shows how to convert a laminar flow into an unsplittable flow y with small capacity violation (no cost guarantee).

[5] This manuscript is unpublished, but the result is mentioned in [32] and their writeup was shared with us [23].

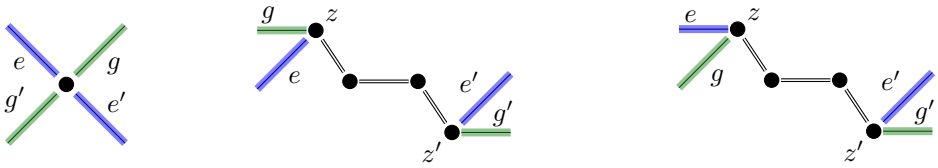

Figure 2 (Left) Two edge-disjoint paths that cross at a common node. (Center) Two paths that cross at a common subpath. (Right) Two paths that share a common subpath, but are uncrossed. Uncoloured edges are shared between the two paths.

2 Uncrossed Multiflows

2.1 Multiflow Preliminaries

All graphs are undirected in this paper. Consider a supply graph $G = (V, E(G))$ and demand graph $H = (V, E(H))$. Endpoints of edges in H are *terminals*, and the edges themselves are *demands* or *commodities*. Together, (G, H) define a *layout*[6]. For nodes $s, t \in V$, let $\mathcal{P}_{st}$ denote the set of st-paths. By *path* we always mean simple path. A *multiflow* is a function $x : \mathcal{P} \to \mathbb{R}_{\geq 0}$, where $\mathcal{P} = \bigcup_{(s,t)\in E(H)} \mathcal{P}_{st}$. Multiflows are fractional unless explicitly stated as integral. A multiflow can also be viewed as a collection of single-commodity flows $(x^{st} : (s, t) \in E(H))$. For $e \in E(G)$, we let $x(e) = \sum_{P\in\mathcal{P}:e\in P} x(P)$ (the amount of flow on e). For $(s, t) \in E(H)$ we let $|x^{st}| = \sum_{P\in\mathcal{P}_{st}} x(P)$ (the amount of demand (s, t) that is routed).

A *maximization instance* has the form (G, H, u), where $u : E(G) \to \mathbb{R}_{\geq 0}$ are *capacities*. A multiflow x is *feasible* for the instance if for every $e \in E(G)$, $x(e) \leq u(e)$. The objective is to maximize the value of a feasible multiflow, where the value of a multiflow x is $|x| = \sum_{P\in\mathcal{P}} x(P) = \sum_{(s,t)\in E(H)} |x^{st}|$. If $u = \vec{1}$ and we restrict to integral x, this problem is the *maximum edge-disjoint paths* problem (MEDP). A *weighted* maximization instance also comes equipped with per-unit profits $w : E(H) \to \mathbb{R}_{\geq 0}$, in which case the value of x is instead defined $|x|_w = \sum_{(s,t)\in E(H)} w(s, t)|x^{st}|$.

A *congestion instance* has the form (G, H, u, d), where $u : E(G) \to \mathbb{R}_{\geq 0}$ are capacities and $d : E(H) \to \mathbb{R}_{\geq 0}$ are *demand values*. A multiflow x is *feasible* for the instance if for every $e \in E(G)$ we have $x(e) \leq u(e)$ and for every $(s, t) \in E(H)$ we have $|x^{st}| = d(s, t)$. As a decision problem, the goal is to determine whether (G, H, u, d) has a feasible multiflow. As an optimization problem, the objective is to find the minimum $\alpha \geq 1$ such that $(G, H, \alpha u, d)$ has a feasible multiflow.

In either setting, we say an instance is *planar* if G is planar. We emphasize that $G + H$ is not necessarily planar. We always assume a fixed embedding of planar graph G.

2.2 Uncrossed Paths and Multiflows

First, we define what it means for paths to cross. Edge-disjoint paths can cross at a common node, but in general we need to consider common subpaths (see Figure 2).

▶ **Definition 9** (Crossing). *Let Z be a maximal shared subpath of paths P and Q that does not include any of their endpoints. Say the ends of Z are z and z'. The edges of $(P \cup Q) \setminus Z$ incident with z or z' have a clockwise ordering about Z in the plane. The paths* cross *at*

[6] Sometimes in the literature, (G, H) is called a *multiflow topology*. We avoid this term to avoid confusion with the topology of the plane.

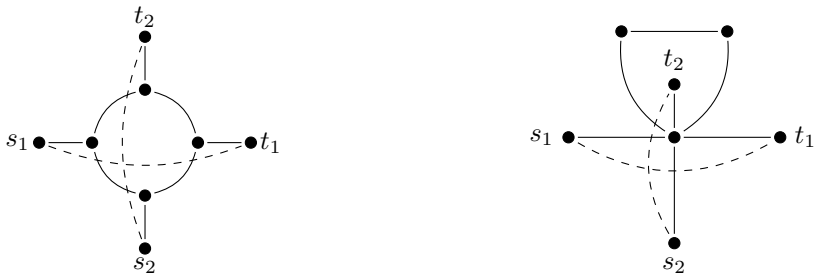

Figure 3 Problematic instances for uncrossability. Capacities and demand values are unit. (Left) A congestion instance with a feasible multiflow but no uncrossed multiflow. (Right) The *Keyhole Instance*, a congestion instance with a feasible uncrossed trail-multiflow but no uncrossed path-multiflow.

Z if the edges of P and Q alternate clockwise about Z. That is, if $P = P_1, e, Z, e', P_2$ and $Q = Q_1, g, Z, g', Q_2$, the edges occur e, g, e', g' or e, g', e', g clockwise about Z. Two paths are uncrossed *if they do not cross at any such subpath*[7].

The *support paths* of a multiflow x are the paths with $x(P) > 0$. The following is the natural extension of "uncrossed" to the multiflow setting (though we discuss a stronger condition in Section 2.4).

▶ **Definition 10** (Uncrossed Multiflow). *A multiflow is* uncrossed *if its support paths are pairwise uncrossed.*

We are interested in when a feasible multiflow x can be converted into an uncrossed one that routes the same demands. Our discussion here focuses on the congestion setting, but still applies to the maximization setting (since we can define target demand values d equal to whatever quantities x routes). As shown in Figure 3, even if (G, H, u, d) is feasible, it may not have an uncrossed feasible multiflow[8]. However several classes do admit uncrossed solutions. We say (G, H) is an *uncrossable layout* if for all u, d, if (G, H, u, d) has a feasible multiflow, then (G, H, u, d) has a feasible uncrossed multiflow. Matsumoto et al. [21] give an algorithm that, given a feasible fully-planar ($G + H$ planar) instance, produces a feasible uncrossed flow. Thus fully-planar layouts are uncrossable. It is also well-known that single-source layouts (H is a star) are uncrossable. Another uncrossable layout is given when G is a cycle with parallel edges and H is arbitrary, which we call *ring* layouts. In Section 3 we introduce *pairwise-planar* layouts and prove they are uncrossable.

2.3 Another View on Crossing: Parallelizations

There are more intuitive ways to think about uncrossed paths that we frequently use.

[7] We emphasize that paths can only cross at maximal common subpaths that do *not* contain their endpoints. Both paths must have edges before and after the common subpath in order to cross. For example, if P contains an endpoint of Q and Z is the maximal common subpath containing that endpoint, then P and Q do not cross at Z.

[8] In fact, it is not always possible to find an uncrossed flow with bounded congestion. One may modify the canonical grid instance [14] so it has a half-integral routing of demands, but any uncrossed multiflow incurs polynomial congestion.

Figure 4 (Left) An uncrossed parallelization of the uncrossed paths from Figure 2. (Right) Disk-expansion of the node z after uncrossed parallelization.

Widened Graph. Suppose we "widen" G, making its nodes into small disks and its edges into small channels. A family of pairwise uncrossed paths can have its paths drawn as curves simultaneously, each curve following the node disks and edge channels corresponding to its path, so that the curves are disjoint.

Parallelizations. To avoid dealing with the formal topology of widened graphs, we use an equivalent notion based on "separating" the paths at each edge. Consider a family of paths $\mathcal{P}$ and for each $e \in E(G)$ let $\mathcal{P}_e = \{P \in \mathcal{P} : e \in E(P)\}$. Let G' be obtained by replacing each e with $|\mathcal{P}_e|$ parallel copies of itself. Intuitively, the parallel edges represent the curves within the channel of e.

Now, for each $e \in E(G)$ we decide on some one-to-one mapping ϕ_e from $\mathcal{P}_e$ to the parallel class of e in G'. For each $P \in \mathcal{P}$, we obtain a path P_ϕ in G' whose edges are $\{\phi_e(P) : e \in P\}$. This induces a family of edge-disjoint paths $\mathcal{P}_\phi$ in G'. We call $\mathcal{P}_\phi$ a *parallelization* of $\mathcal{P}$. If we (arbitrarily) orient each $e \in E(G)$, it gives a linear ordering $\leq_e$ of $\mathcal{P}_e$. Different choices for $(\phi_e : e \in E(G))$ yield different parallelizations. The family $\mathcal{P}$ is pairwise uncrossed if and only if there is some parallelization that is pairwise uncrossed at every node of G' (rather than needing to consider longer shared subpaths). Using parallelizations helps us simplify subsequent definitions by assuming paths are edge-disjoint. Given a collection of paths, one can compute in polynomial time an uncrossed parallelization or find a crossing pair of paths.

Disk-Expansion. After parallelization, we sometimes go a step closer to the widened graph idea by "expanding" a node v. We draw a small disk with v at its centre (small enough that its boundary intersects only $\delta(v)$, and hits each edge once). Where an edge copy intersects the boundary, we place a new node. We terminate the edges at these new nodes. For an uncrossed parallelization, it is then possible to (simultaneously) draw edges in the open interior of the disk between nodes that correspond to consecutive edges of the same path, such that the drawing is planar. An example is shown in Figure 4.

2.4 Strongly Uncrossed Multiflows

Consider an uncrossed multiflow. For any $(s,t) \in E(H)$, its support paths have a clockwise ordering about s (and t) given by the parallelization. We call the regions of the plane bounded between two consecutive paths *sectors* for this commodity (defined more formally in Section 5).

The proof of Theorem 3 uses that sectors of different commodities are non-crossing as sets - that is, we want that if $A, B \subseteq \mathbb{R}^2$ are sectors of different commodities, then either $A \cap B = \emptyset$ or one contains the other. One might think this non-crossing property follows

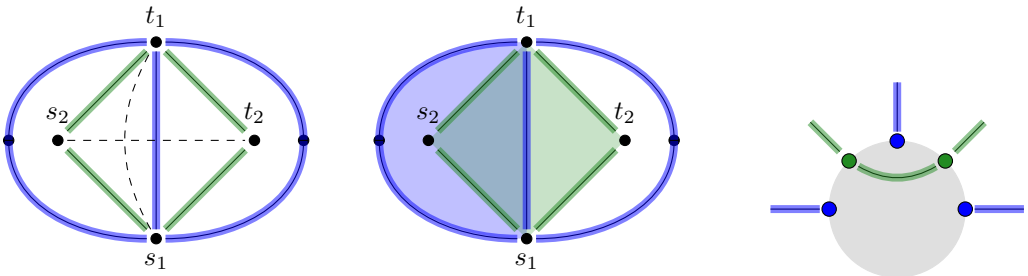

Figure 5 (Left) An uncrossed multiflow. The blue paths are for (s_1, t_1) and the green paths are for (s_2, t_2). No pair of support paths cross. (Center) A sector from the s_1t_1-flow (blue shaded region) that crosses a sector from the s_2t_2-flow (green shaded region). (Right) The disk-expansion of s_1. The green path separates the blue nodes in the disk. There is a quasicrossing at s_1.

from Definition 10, however Figure 5 shows a counterexample[9]. In the figure, no pair of flow paths cross, but the green s_2t_2-paths "slip between" the blue s_1t_1-paths to move between two distinct sectors. We define *strongly uncrossed* multiflows by imposing stricter restrictions on the support paths of different commodities at their terminals. Many layout classes admit strongly uncrossed flows, including fully-planar, single-source, and rings, as well as pairwise-planar.

▶ **Definition 11** (Quasicrossing, Strongly Uncrossed). *Let f be a multiflow with a fixed parallelization (so we assume edge-disjoint support paths). Consider a node z and the clockwise ordering of edges $e_1, \ldots, e_k$ about z. For a commodity h, a* type-1 (h, z)-interval *is $[i, j]$ (where $i < j$) such that e_i, e_j are consecutive edges of a single support path for h that transits through z. A* type-2 (h, z)-interval *is $[i, j]$ such that e_i, e_j both terminate (different) support paths for h at z. Note that two paths cross at z if and only if their corresponding type-1 intervals cross*[10]*. We say a* quasicrossing *occurs at z if there exists an (h, z)-interval I and an (h', z)-interval I' that cross where $h \neq h'$ and at least one of the intervals is type-2. If there are no crossings and no quasicrossings at any node, we say f is* strongly uncrossed.

2.5 Walk-Multiflows

It is standard for flows to only route on (simple) paths, since a flow walk could just be short-circuited into a flow path. Disturbingly, this operation is not benign in the uncrossed flow setting. The *Keyhole Instance* of Figure 3 is an example that requires the use of a non-simple flow trail to obtain an uncrossed solution. Since we would like to understand which instances have uncrossed solutions, we must consider *trail-multiflows* and *walk-multiflows* in addition to the usual *path-multiflows*. A *trail* can repeat nodes but not edges, while a *walk* can repeat both. Ultimately we can show our rounding results (Theorem 2, Theorem 3) and hardness results (Theorem 6, Theorem 7) presented earlier hold for all three models. The necessary modifications are minor and we defer the details to the full version.

[9] The desired non-crossing sector property does hold for uncrossed flows in *leaf instances*, where terminals all have degree 1. Moving terminals to leaves is a standard pre-processing operation, but is not safe for uncrossed flows - it may turn an uncrossable layout into one that is not. For example, ring instances admit uncrossed flows but Figure 3 (left) does not, even though it is obtained by adding leaves to a ring.

[10] Two intervals $[i, j], [i', j']$ cross if $i < i' < j < j'$ or $i' < i < j' < j$.

3 Uncrossed Flows in Pairwise-Planar Instances

Here we introduce a new class of multiflow layouts and prove they are uncrossable. We assume a fixed embedding of G. We say $(s,t) \in E(H)$ *fits* face F of G if both s,t lie in F (i.e. the demand could be drawn within the face). A layout (G,H) is *facial* if each (s,t) fits at least one face of G (but demands fitting a common face may still cross each other).

▶ **Definition 12.** *We say (G,H) is* pairwise-planar *if (G,H) is facial, and moreover for any pair $h_1, h_2 \in E(H)$, h_1 and h_2 can be embedded inside (possibly different) faces of G so they do not cross each other.*

Unlike fully-planar, we do not require simultaneous uncrossed embedding of all demands. This matters because a demand edge may fit multiple faces (a *multi-faced* demand). Figure 6 shows an example. However we emphasize that the embedding of G is fixed and does not change as we embed different pairs of $E(H)$.

Clearly pairwise-planar generalizes fully-planar, but how substantial is this generalization? We briefly argue it is a much richer class. First, it is easy to construct examples where H contains arbitrarily large cliques, meaning H and $G+H$ have arbitrarily large genus (though G remains planar). It also generalizes rings (G is a cycle with parallel edges, H is arbitrary). This is worth remarking because fully-planar does not capture ring layouts. More broadly, pairwise-planar captures what are known as *fully-compliant* layouts (under mild connectivity assumptions). Introduced in [7], in such layouts G is series-parallel and every $h \in E(H)$ satisfies that $G+h$ is series-parallel. In the full version, we argue the following.

▶ **Proposition 13.** *If (G,H) is fully-compliant and G is 2-connected, then (G,H) is pairwise-planar for any planar embedding of G.*

Pairwise-planar extends further than fully-planar and fully-compliant in another fundamental way through a property known as *cut-sufficiency*. For a multiflow instance (G,H,u,d), we say the *cut condition* holds if for every $S \subseteq V$, $u(\delta_G(S)) \geq d(\delta_H(S))$, where $\delta(S)$ denotes the edges with one end in S and one end in $V \setminus S$. The cut condition is necessary, but not in general sufficient, for the existence of a feasible (fractional) multiflow. A layout (G,H) is called cut-sufficient if, for all capacities and demands (u,d), the cut condition is sufficient for the existence of a feasible multiflow. The Max-Flow Min-Cut Theorem can be equivalently stated as: single-source (G,H) are cut-sufficient. Understanding the relationship between the cut condition and feasibility is a fundamental question in network flows, and cut-sufficient instances tend to admit stronger integrality properties and approximation algorithms. A result of Seymour [29] shows that fully-planar (G,H) are cut-sufficient, and Chekuri et al. [7] show that fully-compliant instances are cut-sufficient. However, pairwise-planar layouts need not be cut-sufficient. The quintessential examples of series-parallel layouts that are not cut-sufficient are the *odd spindles*[11] [6, 2], but these are pairwise-planar.

3.1 Uncrossing Procedure

In this section we show why feasible pairwise-planar instances have uncrossed flows. We focus on congestion instances (G,H,u,d) (where a feasible flow must satisfy all demands), since given a feasible flow x for a maximization instance (G,H,u), one can define demand

[11] In a *spindle*, $G = K_{2,p}$ where $p \geq 3$ and H consists of a simple p-cycle between the nodes in the larger side of the partition and an edge between the two nodes in the other side. A spindle is *odd* if p is odd. In some sense, the odd spindles characterize non-cut-sufficiency for series-parallel layouts, see [2].

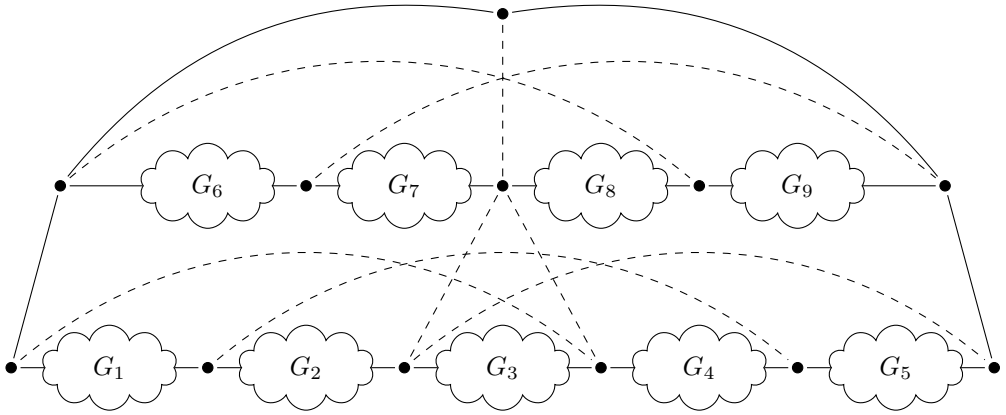

Figure 6 A pairwise-planar layout. Each G_i is a connected planar graph. The demand edges cannot be simultaneously embedded so that $G + H$ is planar ($G + H$ contains a $K_{3,3}$-minor and a K_5-minor). However, taking advantage of multi-faced demands, any *single pair* of demands can be embedded without crossing. One could make the layout more complicated by putting demands inside the G_i's following similar patterns.

values $d(s,t) = |x^{st}|$ and apply the congestion result. We present an inductive proof that a feasible uncrossed flow exists. It is straightforward to convert this into an algorithm, with one catch for polynomial time implementation that we explain at the end.

For fully-planar instances, [15, 12] use an algorithm by Matsumoto et al. [21] that builds an uncrossed flow from scratch starting from the zero flow. Our procedure has more in common with [18] (which concerns finding cycles in higher-genus surfaces that cross at most once) in that we begin with a (potentially highly crossing) feasible flow x and "uncross" it bit-by-bit. The following is an important lemma.

▶ **Lemma 14.** *Let (G, H, u, d) be a planar congestion instance that is feasible. There exists a feasible flow f^* such that every pair of support paths crosses at most once, and any pair of support paths that share a terminal do not cross.*

We say a flow satisfying this property is *almost-uncrossed*. Proving this lemma formally is somewhat tedious, but such arguments have appeared in the literature before - the essence of the argument is in Lemma 1 of [22] and a similar method is used in [18]. Loosely, the argument goes as follows. Begin with a feasible flow x. One can show that if a pair of support paths cross twice (or cross once but share a terminal), then one can re-route flow on their edges to decrease the "amount of crossing" between the two paths ("uncrossing" the two paths) and argue that this re-routing does not increase crossing with other support paths. Thus the total amount of crossing decreases, and we iterate until x is uncrossed. For completeness we give a careful proof of this lemma (and precisely define "amount of crossing") in the full version.

Lemma 14 immediately implies single-source layouts are uncrossable. With a small trick it also proves fully-planar layouts are uncrossable: augment the instance by adding leaves. That is, for each $h = (s,t) \in E(H)$, add nodes s_h, t_h into the interior of the face where h is embedded, add supply edges $(s_h, s), (t_h, t)$, move the endpoints of the demand h to (s_h, t_h), and extend the flow paths appropriately to route this instance. At first, adding leaves may actually increase the amount of crossing. However, since the demands do not cross, it can be shown that every pair of support paths that cross must cross at least twice. Then Lemma 14 allows one to conclude there exists a feasible uncrossed flow in the augmented instance. The leaves can then be contracted away without introducing any new crossing.

Extending this trick to pairwise-planar instances is not immediate. After adding leaves, it may not be the case that support paths that cross must cross at least twice. We cannot "commit" a demand to a particular face up front. Consider if a demand h fits into two different faces F_1 and F_2, but there are demands h_1 and h_2 that fit those respective faces and cross h in those faces. If we add leaves into F_1, then we can "uncross" support paths for h and h_2, however we cannot uncross support paths between h and h_1, and vice versa.

We take the following approach. Begin with a feasible flow z that we want to uncross. We temporarily "commit" each demand to one of the faces it fits (if multi-faced, choose arbitrarily). We accept for now that flow paths of demands committed to the same face may cross, but compute a flow x so that demands committed to different faces do not cross. In fact we aim for a more strict condition on x: we show how to find x so that, if we define x^F as the multiflow corresponding to demands committed to face F, the x^F's are "uncoupled" from each other. Here, "uncoupled" is a structural property (defined precisely below) which guarantees that if we can uncross each x^F separately, regardless of how we do so, we can still safely glue the resulting flows back together without introducing crossing. Then we can just focus on uncrossing each x^F inductively/recursively. We now make this "committing" process and "uncoupled" property precise.

▶ **Definition 15** (Facial Decomposition). *Let (G, H, u, d) be a facial multiflow instance. Let $\mathcal{F}$ be the set of faces of G. A* facial decomposition *is a collection $(H_F : F \in \mathcal{F})$ of subgraphs of H indexed by F such that:*

- *$(E(H_F) : F \in \mathcal{F})$ forms a partition of $E(H)$, and*
- *for every face $F \in \mathcal{F}$, every demand $h \in E(H_F)$ fits F (but cannot necessarily all be embedded simultaneously in F without crossing).*

For a facial decomposition $(H_F : F \in \mathcal{F})$ and a feasible flow x, we let x^F be the portion of x used to route H_F. Note that if $h \in E(H)$ is multi-faced, the facial decomposition still only puts h into one of the H_F's. Now we define the "uncoupled" condition and show that we can find a flow satisfying this property. We let $\mathrm{supp}(x^F)$ denote the set of support paths of x^F, and let $G[\mathrm{supp}(x^F)]$ denote the graph induced by the edges in those paths.

▶ **Definition 16** (Nested Supports Property). *Let (G, H, u, d) be a facial multiflow instance, and let $(H_F : F \in \mathcal{F})$ be a facial decomposition. For a flow x and a face F, we define the* stellated support graph *$G[x, F]$ as follows: begin with the support graph $G[\mathrm{supp}(x^F)]$, add a node v_F into the interior of F, and then for each demand $(s, t) \in E(H_F)$ add edges (s, v_F) and (t, v_F), embedded (without crossing) in the face F. We say x satisfies the* nested supports property *if for every pair of distinct faces $F_1, F_2 \in \mathcal{F}$, the graph $G[x, F_1]$ is entirely contained within a single face of the graph $G[x, F_2]$, and vice versa.*

▶ **Lemma 17.** *Let (G, H, u, d) be a facial multiflow instance that is feasible. Let $(H_F : F \in \mathcal{F})$ be a facial decomposition. There exists a feasible flow x satisfying the nested supports property.*

The proof of this lemma is slightly tricky to make rigorous, so we include only a sketch here and defer details to the full version.

Proof Sketch of Lemma 17. We augment the instance by adding leaves into the faces: for every face F and demand $h = (s, t) \in E(H_F)$, add nodes s_h, t_h into the face F and supply edges $(s_h, s), (t_h, t)$ of capacity equal to $d(h)$, and move the demand h from (s, t) to (s_h, t_h). We keep the same facial decomposition. We now invoke Lemma 14 to obtain a feasible flow x that is almost-uncrossed for this new instance. It is not hard to show that for support

paths P_1, P_2 associated with distinct faces, if we consider the embedded cycles $C(P_1), C(P_2)$ obtained by joining the endpoints of the paths with their respective demand edges, that these cycles do not cross (though cycles associated with paths of the same face may cross).

Now, for each face F, we let G_F be the union of $G[\text{supp}(x^F)]$ and all supply edges incident with the face F itself (regardless of whether they are in the support). It is possible to argue that for distinct faces F, F', G_F must be contained in a single face of $G_{F'}$, and vice versa. Once this property is established, we argue the nested supports property holds for flow x. ◀

Given such a flow, we show that we can focus on uncrossing each face's flow independently.

▶ **Lemma 18.** *Let (G, H, u, d) be a facial multiflow instance. Let $(H_F : F \in \mathcal{F})$ be a facial decomposition, and let x be a feasible flow satisfying the nested supports property. For every $F \in \mathcal{F}$, let u_F be the capacity vector defined by $u_F(e) = x^F(e)$ and let d_F be the demand vector d restricted to H_F. If for every $F \in \mathcal{F}$, the instance (G, H_F, u_F, d_F) has a feasible uncrossed solution y^F, then $y = \sum_{F \in \mathcal{F}} y^F$ is a feasible uncrossed solution for (G, H, u, d).*

Proof. The feasibility of y is clear from the construction of the subproblems. Also observe that, by construction, y still satisfies the nested supports property (since $G[y, F]$ is a subgraph of $G[x, F]$ for each face F of G).

We prove that y is uncrossed assuming each y^F is uncrossed. It remains to check for distinct faces F_1, F_2 and $P_1 \in \text{supp}(y^{F_1}), P_2 \in \text{supp}(y^{F_2})$, that P_1 and P_2 do not cross.

Consider two distinct faces F_1, F_2. Let $P_1 \in \text{supp}(y^{F_1}), P_2 \in \text{supp}(y^{F_2})$. Let $h_1 = (s_1, t_1), h_2 = (s_2, t_2)$ be the demands routed by P_1, P_2 respectively. Suppose P_1 and P_2 cross, for the sake of contradiction. Consider the (simple) cycle C in $G[y, F]$ obtained as $C = P_1 \bullet (s_1, v_{F_1}) \bullet (v_{F_1}, t_1)$, where $\bullet$ denotes concatenation. Since P_1 and P_2 cross, P_2 has some segment in the open exterior of C and some segment in the open interior of C. However, since C is a simple cycle, these two segments of P_2 must lie in distinct faces of $G[y, F]$, contradicting that y satisfies the nested supports property. ◀

Using Lemma 18, we are able to reduce to finding a feasible uncrossed flow for each instance (G, H_F, u_F, d_F) in isolation. No matter how we do this, we can safely combine the flows using the lemma. Importantly, to tackle the instance (G, H_F, u_F, d_F), we are allowed to re-commit multi-faced demands that were originally committed to F to other faces.

▶ **Theorem 19.** *Let (G, H) be pairwise-planar and let (G, H, u, d) be a congestion instance. If the instance is feasible, there exists a feasible uncrossed flow.*

Proof. We prove the result by induction on $|E(H)|$. If $|E(H)| = 1$ then the instance is single-source and the result follows, so suppose $|E(H)| \geq 2$. Let $\mathcal{H} = (H_F : F \in \mathcal{F})$ be an arbitrary facial decomposition.

We first consider the case that at least two faces F have that H_F is non-empty. We obtain a feasible flow x for (G, H, u, d) that satisfies the nested supports property for $\mathcal{H}$ by way of Lemma 17. For each face F, let u_F, d_F be defined as in the statement of Lemma 18. Each instance (G, H_F, u_F, d_F) is feasible via the flow x^F. Additionally, since there are at least two faces F such that H_F is non-empty, we have $|E(H_F)| < |E(H)|$ for every face F. Hence by induction, there is a feasible uncrossed flow y^F for each instance (G, H_F, u_F, d_F). Then by Lemma 18, the sum of these flows is a feasible uncrossed flow for (G, H, u, d).

Now, we consider the case where H_F is empty for all faces F except one, call it F^*. That is, $E(H) = E(H_{F^*})$, and in particular every demand fits F^*. If none of the demands cross within F^*, then the layout is fully-planar and we are done. Otherwise, there exist $h, h' \in E(H)$ that cross when drawn in the face F^*. However, since (G, H) is pairwise-planar,

there exists another face $F' \neq F^*$ such that at least one of these two demands, without loss of generality say h', also fits F'. Now we define a facial decomposition $\widehat{\mathcal{H}} = (\widehat{H}_F : F \in \mathcal{F})$ as follows. We define $E(\widehat{H}_{F^*}) = E(H) \setminus \{h'\}$, $E(\widehat{H}_{F'}) = \{h'\}$, and $E(\widehat{H}_F) = \emptyset$ for all other faces F. That is, we now view h' as being associated with F' rather than F^*.

We obtain a feasible flow x for the instance (G, H, u, d) satisfying the nested supports property for this new facial decomposition $\widehat{\mathcal{H}}$ by way of Lemma 17. We define capacities u_F, d_F for each face F as in the statement of Lemma 18 using the new decomposition $\widehat{\mathcal{H}}$. Each instance $(G, \widehat{H}_F, u_F, d_F)$ is feasible. Additionally, each satisfies that $|E(\widehat{H}_F)| < |E(H)|$, and thus $(G, \widehat{H}_F, u_F, d_F)$ has a feasible uncrossed flow y^F by induction. Then the sum of these flows is a feasible uncrossed flow for (G, H, u, d) by Lemma 18. ◀

With a little extra effort, we can modify Lemma 18 and Theorem 19 to show that pairwise-planar instances admit strongly uncrossed flows.

It is straightforward to convert this inductive argument into a polynomial time algorithm, provided we have a polynomial time algorithm to compute a feasible almost-uncrossed flow, as in Lemma 14. However, this is somewhat tricky. To prove Lemma 14, we re-route flow on twice-crossing paths to reduce the total amount of crossing, but the amount of progress depends on the flow values of the crossing paths and could be very small. We defer the details to the full version, but one can efficiently compute an almost-uncrossed flow that is *approximately* feasible - for any $\epsilon > 0$, in polynomial time we can find an almost-uncrossed flow that is feasible for $(G, H, (1+\epsilon)u, d)$. The details are similar to the uncrossing algorithm in [18]. Essentially, by judiciously rounding each path's flow value, we ensure the values are common multiples of a small but sufficiently large fraction to ensure each uncrossing step makes significant progress. We summarize the final result below.

▶ **Theorem 20.** *Let (G, H) be pairwise-planar and let (G, H, u, d) be a congestion instance. Let $\epsilon > 0$ be any constant. If the instance is feasible, then there exists a strongly uncrossed flow f' that is feasible for $(G, H, (1+\epsilon)u, d)$. The flow can be computed in polynomial time.*

Note that $f'/(1+\epsilon)$ is feasible for $(G, H, u, d/(1+\epsilon))$, so this approximate guarantee is useful for maximization as well as congestion. Combining this theorem with our rounding results Theorem 2 and Theorem 3, we obtain Corollary 4.

3.2 Integral Flow-Multicut Gap

In this subsection we prove Corollary 5. Here we are concerned with maximization instances (G, H, u). A *multicut* is a set of supply edges $R \subseteq E(G)$ such that $G - R$ does not contain an st-path for any $(s, t) \in E(H)$. The minimum capacity of a multicut is at least the maximum value of a (fractional) multiflow. The ratio of these quantities is the *(fractional) flow-multicut gap*[12]. The *integral flow-multicut gap* is the ratio of the minimum capacity of a multicut to the maximum value of an integral multiflow.

An immediate corollary of Theorems 19 and 2 is that for pairwise-planar (G, H), the integral flow-multicut gap is bounded by $O(1)$ times the (fractional) flow-multicut gap. We combine this with the following result by Tardos and Vazirani [30] to conclude Corollary 5.

▶ **Theorem 21** (Tardos and Vazirani [30])**.** *For any maximization instance (G, H, u) where G is planar, the (fractional) flow-multicut gap is bounded by $O(1)$.*

[12] This is different from the similarly named *flow-cut gap* (cf. [7]), which is defined for congestion instances and relates the minimum congestion value to sparsity of cuts (not necessarily multicuts).

4 Maximization Setting: Rounding and Hardness

In this section, we prove Theorem 2 and Theorem 6, which cover our rounding and inapproximability results for maximum uncrossed multiflow.

4.1 Uncrossed String Graphs and Approximate Integer Decomposition

First we prove Theorem 2. Our approach is to establish a so-called approximate integer decomposition property [3, 5] for uncrossed multiflows. The outline of the strategy is as follows. Suppose we are given an uncrossed multiflow f, which achieves a value of β. Imagine scaling f by a positive integer k such that kf is integral. Of course, kf may not be feasible. However suppose we are able to show that kf can be decomposed as the sum of a small number b of feasible integral flows. That is $kf = \sum_{i=1}^{b} f^i$ where each f^i is integral and feasible. At least one of the f^i flows achieves a $1/b$ fraction of the value of kf, and hence a k/b fraction of the value of f.

How can we achieve such a decomposition? Suppose (for simplicity) that kf sends 1 unit of flow along paths $\mathcal{P} = \{P_1, \ldots, P_\ell\}$. Furthermore suppose that each edge of G has unit capacity and hence each appears on at most k paths. Our goal then is to partition the paths into classes such that every edge appears at most once in each class; the classes then define the flows f^i. Equivalently, we seek to partition the paths so that paths in the same class do not share an edge. Phrased this way, we can recognize this as a graph colouring problem on the edge-intersection graph of $\mathcal{P}$.

The edge-intersection graph U of $(G, \mathcal{P})$ has node set $\mathcal{P}$, and an edge between distinct $P_1, P_2 \in \mathcal{P}$ if there exists $e \in E(P_1) \cap E(P_2)$. The *load* of $e \in E(G)$ is the number of paths in which e occurs, and the *load* of $(G, \mathcal{P})$ is the maximum load of an edge $e \in E(G)$. Graphs U constructed in this way are a special type of the well-studied family of *string graphs*, which are the intersection graphs of curves in the plane.

▶ **Definition 22** (Uncrossed String Graph, Realization)**.** *An* uncrossed string graph U *is the edge-intersection graph of a family of uncrossed paths* $\mathcal{P}$ *in a planar graph* G*. We say* $(G, \mathcal{P})$ *is a* realization *of* U*.*

Uncrossed string graphs have been studied before for their own sake [11, 32]. Given that U has a load k realization, we want that its chromatic number $\chi(U)$ is some small function of k, ideally $O(k)$. This question is strongly related to the concept of a χ-*bounded* graph family. A family of graphs $\mathcal{G}$ is χ-bounded if there exists a function f such that for all $U \in \mathcal{G}$, $\chi(U) \leq f(\omega(U))$, where $\omega(U)$ is the clique number of U. It is worth noting that general string graphs are not χ-bounded, and it is not obvious that uncrossed string graphs should be. An $O(k)$ bound was conjectured originally in [11], and proven by Fox and Pach [13].

▶ **Theorem 23** (Fox and Pach)**.** *Let* U *be an uncrossed string graph with realization* $(G, \mathcal{P})$ *such that each edge* $e \in E(G)$ *has load at most* k*. Then* $\chi(U) \leq 6ek + 1$*.*

The result of Fox and Pach has not been published, however the proof is elegant and short. It establishes via a probabilistic proof (similar to a standard proof giving a bound on the crossing number of a graph) that U has at most $3ek|\mathcal{P}|$ edges. Hence a greedy colouring procedure that removes the minimum degree vertex (which has degree at most $6ek$) and colours the rest of the graph inductively obtains a $6ek + 1$ colouring. We were not initially aware of Fox and Pach's result and independently proved a weaker bound that $\chi(U) \leq O(k^2 \log |\mathcal{P}|)$. For the sake of completeness we present this proof in the full version.

We now use the colouring result to establish an approximate integer decomposition property and prove a generalization of Theorem 2 with weighted profits on $E(H)$.

▶ **Theorem 24.** *There exists a universal constant $\gamma \geq 1$ such that the following holds. Let (G, H, u) be a planar maximization instance where u is integral, equipped with per-unit profits $w(h) \geq 0$ for $h \in E(H)$. Let f be a feasible uncrossed multiflow. There exists a feasible integral multiflow f^* that is uncrossed and achieves value $|f^*|_w \geq \frac{1}{\gamma}|f|_w$. This solution can be computed in polynomial time.*

Proof. We first present the case where the capacities are unit-valued $u = \vec{1}$. We show how to handle general capacities in the full version - while not hard, it requires some care to handle polynomial time aspects.

Let $\beta = |f|_w$. Let $\mathcal{P}$ be the family of support paths for f. Since $u = \vec{1}$, we have that $f(P) < 1$ for each $P \in \mathcal{P}$. Now, let k be a positive integer such that kf is integral. Since kf is integral, for each P we have that $f(P) = \alpha_P/k$ where $\alpha_P \leq k$ is a positive integer. By treating each P as α_P distinct paths, we may assume that each path routes exactly $\frac{1}{k}$ units of flow. Then, since $\sum_{P:e\in P} f(P) \leq 1$ by feasibility, at most k paths use each edge of G.

Let U be the edge-intersection graph of $(G, \mathcal{P})$, which has load at most k. By Theorem 23, U is b-colourable where $b = O(k)$. Now for each colour class i, we let f_i denote the flow obtained by sending one unit of flow on each path in that colour class, and zero flow on all other paths. Then f_i is integral and satisfies that $\sum_{P:e\in P} f_i(P) \leq 1$ for each $e \in E(G)$, and $kf = \sum_{i=1}^{b} f_i$ since each path's flow was blown up by a factor of k. Since the value of kf is $k\beta$, at least one of the f_i flows has a value of $k\beta/b$. Since $b = O(k)$, then this flow has value $\Omega(1)$ times that of f, as desired.

However, this proof is existential thus far, and does not immediately give a polynomial time algorithm because k could be very large. To fix this, we first have a pre-processing step where we convert f into a feasible flow $\hat{f}$ that uses a subset of f's support paths (so that it remains uncrossed) such that each value $\hat{f}(P)$ is a multiple of $\frac{1}{\text{poly}(n)}$, and so that $|\hat{f}|_w$ is a large fraction of $|f|_w$. We then run the above procedure on $\hat{f}$ instead of f, giving a polynomial time algorithm. We prove the following.

▶ **Lemma 25.** *Let $\epsilon \in (0, 1)$ be any constant. There exists a positive constant N_ϵ such that the following holds. Let $(G, H, u = \vec{1})$ be a unit-capacity planar maximization instance on $n \geq N_\epsilon$ nodes, equipped with per-unit profits $w(h) \geq 0$ for $h \in E(H)$. Let f be a feasible multiflow such that $|f|_w \geq w_{\max} = \max_{h\in E(H)} w(h)$. There exists a multiflow $\hat{f}$ satisfying:*

1. *$\hat{f}$ is feasible,*
2. *the support paths of $\hat{f}$ are a subset of the support paths of f,*
3. *$|\hat{f}|_w \geq (1-\epsilon)|f|_w$, and*
4. *for every path P, $\hat{f}(P)$ is a multiple of $\frac{1}{\log^2 n}$.*

There is a polynomial time algorithm that computes such an $\hat{f}$.

We prove this in the full version using a randomized rounding and re-scaling argument (which can be de-randomized to give a deterministic algorithm). The two conditions that $|f|_w \geq w_{\max}$ and $n \geq N_\epsilon$ are only minor technicalities, as we argue in that version. ◀

It is straightforward to generalize this to the node-capacitated setting - the colouring and integer decomposition property proceed in exactly the same way.

4.2 Inapproximability of Maximum Uncrossed Fractional Multiflow

Next we prove Theorem 6 on the inapproximability of maximum uncrossed (fractional) multiflow. We make use of a strong inapproximability result given by Chuzhoy, Kim, and Nimavat for maximum edge-disjoint paths (MEDP) and maximum node-disjoint paths (MNDP) in planar graphs; i.e. maximum integer multiflow for unit capacities. One minor technicality is that in their formulation, a feasible solution is only allowed to route one unit of flow for each demand. We call these problems *capped MEDP* and *capped MNDP* respectively.

▶ **Theorem 26** (Theorems 1.1 and 1.2, [9]). *For every constant $\epsilon > 0$, there is no $2^{\Omega(\log^{1-\epsilon} n)}$-approximation polynomial-time algorithm for capped MEDP or capped MNDP, assuming that $NP \not\subseteq DTIME(n^{polylog\ n})$. Moreover, there is no $n^{O\left(\frac{1}{(\log\log n)^2}\right)}$-approximation polynomial-time algorithm for capped MEDP or capped MNDP, assuming that for some constant $\delta > 0$, $NP \not\subseteq DTIME(2^{n^\delta})$. These results hold even when the input graph is a maximum degree 3 planar graph, or even if G is a wall graph.*

We now prove Theorem 6 which relies on this result. We focus on the edge-capacitated version (the node-capacitated version is similar).

Proof of Theorem 6. We give a polytime reduction from capped MEDP in wall graphs to maximum uncrossed multiflow in wall graphs, that preserves the approximation ratio up to a constant factor. For an instance (G, H) of the capped MEDP problem where G is a wall graph (which is planar and has maximum degree 3), define the following quantities.

- Let $D_E(G, H)$ denote the maximum number of demands in H which can be routed on edge-disjoint paths in G (i.e. the optimal value for capped MEDP).
- Let $U_E(G, H)$ denote the maximum value of a (fractional) uncrossed multiflow for $(G, H, u = \vec{1})$.

Observe that any capped MEDP solution for (G, H) is a feasible (integral) uncrossed multiflow for $(G, H, u = \vec{1})$. To see this, consider a collection of edge-disjoint paths that form a capped MEDP solution. Recall from Section 2.2 that two edge-disjoint paths cross only if they cross at a node (rather than a longer common subpath). Since G has maximum degree 3, a node crossing is not possible. Thus we have $D_E(G, H) \leq U_E(G, H)$.

Suppose we have a β-approximation algorithm for maximum uncrossed (fractional) multiflow in wall graphs. We obtain an approximation algorithm for capped MEDP as follows. We run our β-approximation algorithm for maximum uncrossed multiflow on $(G, H, u = \vec{1})$ to obtain flow f whose value is at least $U_E(G, H)/\beta$. We apply the polytime algorithm from Theorem 24 to compute a feasible uncrossed integral multiflow f' whose value is $1/\gamma$ that of f. It may still not be a valid capped MEDP solution, since it may route more than one flow path for the same commodity. However, since G has maximum degree 3, it routes on at most 3 paths for each commodity, so by selecting exactly one path for each commodity we obtain a capped MEDP solution whose value is at least $\frac{1}{3}$ that of f'. Thus this algorithm outputs a capped MEDP solution whose value is at least $\frac{U_E(G,H)}{3\gamma\beta} \geq \frac{D_E(G,H)}{3\gamma\beta}$, and is thus a $3\gamma\beta$-approximation algorithm. ◀

5 Congestion Setting: Rounding

In this section, we focus on planar congestion instances (G, H, u, d) where the demands must be fully routed. We show Theorem 3, which states that we can convert (fractional) strongly uncrossed multiflows into integral flows that violate the capacities by a factor of at most 2, and if we accept an additional additive error of less than $d_{\max} = \max_{h \in E(H)} d(h)$ the flow can be made unsplittable. Section 5.1 presents the relevant properties of strongly uncrossed flows, and Section 5.2 gives the proof of Theorem 3.

Figure 7 (Left) The disk expansion of a node z. Paths of the same colour are for the same commodity. The blue and red paths terminate at z, while the green path transits through z. There is no crossing or quasicrossing at z. (Right) We add a node into the disk for each commodity terminating there (blue, red) and connect the new node to the endpoints of that commodity's support paths. Since there is no crossing or quasicrossing at z, this operation can be done without causing edge crossings.

5.1 Clockwise Orderings and Sectors

Let f be a strongly uncrossed multiflow for planar congestion instance (G, H, u, d). Let $\mathcal{P}$ be the set of support paths, and let $\mathcal{P}^h$ be the support paths routing demand $h \in E(H)$. Fix a strongly uncrossed parallelization ϕ. We parallelize the edges and perform disk-expansion at each node (see Section 2.2) so the paths become node-disjoint. Then, for each commodity $h = (s, t) \in E(H)$, we add a node and edges into the disk corresponding to s to join the endpoints of the paths for h, and similarly for the disk of t. This can be done in a planar fashion for all demands simultaneously since the flow is strongly uncrossed (see Section 2.4 and Figure 7). We denote the new graph G_ϕ. For $P \in \mathcal{P}$, we let $\widehat{P}$ be its corresponding path in G_ϕ. For $P, Q \in \mathcal{P}^h$, $\widehat{P}$ and $\widehat{Q}$ are internally node-disjoint paths that share their endpoints. For $P, Q \in \mathcal{P}$ routing different demands, $\widehat{P}$ and $\widehat{Q}$ are (completely) node-disjoint.

Consider a commodity $h = (s, t) \in E(H)$. We use the notation $G_\phi[h]$ to mean the subgraph of G_ϕ induced by the paths $\widehat{\mathcal{P}}^h = \left\{\widehat{P} : P \in \mathcal{P}^h\right\}$. In G_ϕ, the paths of $\widehat{\mathcal{P}}^h$ have a clockwise cyclic ordering about s, say $\widehat{P}_1, \ldots, \widehat{P}_k$. Informally, a *sector* is the region between consecutive paths in the clockwise ordering. We make this more precise as follows.

Consider two paths $\widehat{P}_i$ and $\widehat{P}_j$ in G_ϕ. Orient $\widehat{P}_i$ from s to t, and orient $\widehat{P}_j$ from t to s. The directed curve $\widehat{P}_i \bullet \widehat{P}_j$, obtained by concatenating these oriented curves, is a simple closed (Jordan) curve, and partitions the plane into two regions. We define $\mathrm{CW}^\circ(\widehat{P}_i, \widehat{P}_j)$ to be the set of points q in $\mathbb{R}^2 \setminus (\widehat{P}_i \cup \widehat{P}_j)$ such that q is "to the right" of $\widehat{P}_i \bullet \widehat{P}_j$; that is, if we draw a directed curve from q to $\widehat{P}_i \bullet \widehat{P}_j$ (avoiding $\widehat{P}_i \bullet \widehat{P}_j$ except at the extremity), it hits $\widehat{P}_i \bullet \widehat{P}_j$ from the right. We let $\mathrm{CW}(\widehat{P}_i, \widehat{P}_j)$ denote the closed region $\mathrm{CW}^\circ(\widehat{P}_i, \widehat{P}_j) \cup \widehat{P}_i \cup \widehat{P}_j$. We analogously define $\mathrm{ACW}^\circ(\widehat{P}_i, \widehat{P}_j)$ and $\mathrm{ACW}(\widehat{P}_i, \widehat{P}_j)$ by taking the opposite orientation. Any curve that does not cross and is internally disjoint from $\widehat{P}_i$ and $\widehat{P}_j$ either stays entirely within $\mathrm{CW}(\widehat{P}_i, \widehat{P}_j)$ or stays entirely within $\mathrm{ACW}(\widehat{P}_i, \widehat{P}_j)$.

Now, for our clockwise-ordered family of paths $\widehat{P}_1, \ldots, \widehat{P}_k$, we refer to $\mathrm{CW}^\circ(\widehat{P}_i, \widehat{P}_{i+1})$ for $i = 1, \ldots, k$ (addition modulo k) as the *open sectors* of f^h, and define the *closed sectors* similarly using $\mathrm{CW}(\widehat{P}_i, \widehat{P}_{i+1})$. The open sectors partition $\mathbb{R}^2 \setminus (\widehat{P}_1 \cup \cdots \cup \widehat{P}_k)$. One sector contains the infinite face of $G_\phi[h]$; we call this the *outer sector* of h, and the others the *inner sectors* of h. The *outer paths* of h are the two paths $P, Q \in \mathcal{P}^h$ whose corresponding paths $\widehat{P}, \widehat{Q} \in \widehat{\mathcal{P}}^h$ define the outer sector of h.

Now consider an edge e of the original graph G that appears in $\mathcal{P}^h$. If e lies in any outer path of $\mathcal{P}^h$, it is an *outer edge* of h, otherwise it is an *inner edge* of h. For our congestion result, we exploit the following key properties.

▶ **Lemma 27.** *Let f be a strongly uncrossed multiflow, with a fixed strongly uncrossed parallelization ϕ. For distinct $h, h' \in E(H)$, the sets of inner edges of h and h' are disjoint.*

Proof. To prove the result, we show that if an edge e is shared between the two single-commodity flows in G, then it is an outer edge for one of the commodities.

▷ Claim 28. $G_\phi[h']$ is entirely contained within a single sector of h, and $G_\phi[h]$ is entirely contained within a single sector of h'.

Proof. By symmetry, it suffices to prove the first part. Recall that in G_ϕ, two paths for distinct commodities are completely disjoint, so each individual $\widehat{P} \in \widehat{\mathcal{P}}^{h'}$ lies in at most one sector of h. However, all paths of $\widehat{\mathcal{P}}^{h'}$ share common terminals in G_ϕ, so it must be the same sector for all of $\widehat{\mathcal{P}}^{h'}$. ◁

▷ Claim 29. Either $G_\phi[h']$ is contained in the outer sector of h, or $G_\phi[h]$ is contained in the outer sector of h'.

Proof. By the previous claim and by symmetry, it suffices to show that if $G_\phi[h']$ is contained within an inner sector of h, then $G_\phi[h]$ is contained within the outer sector of h'. Suppose $G_\phi[h']$ is in the inner sector of h defined by paths $\widehat{P}_i$ and $\widehat{P}_{i+1}$. Since $\mathrm{CW}(\widehat{P}_i, \widehat{P}_{i+1})$ is an inner sector, it is bounded, which means $G_\phi[h']$ is contained in the interior of the curve $\widehat{P}_i \bullet \widehat{P}_{i+1}$ rather than the exterior. This implies that $\widehat{P}_i$ and $\widehat{P}_{i+1}$ are contained within the infinite face of $G_\phi[h']$, and so therefore are in the outer sector of h'. Since the entirety of $G_\phi[h]$ is within the same sector of h', it is within the outer sector of h'. ◁

Now, without loss of generality, suppose that $G_\phi[h]$ is contained within the outer sector of h'. Then $G_\phi[h]$ and $G_\phi[h']$ both contain one of the copies of the shared edge e. The copy belonging to h is contained in the infinite face of $G_\phi[h']$, and (by how G_ϕ is constructed) so too is the copy belonging to h'. So then e is an outer edge of h', not an inner edge. ◀

Now, associating the circular ordering $P_1, \ldots, P_k$ to $\mathcal{P}^h$ corresponding to the clockwise ordering $\widehat{P}_1, \ldots, \widehat{P}_k$ of $\widehat{\mathcal{P}}^h$, we prove the second key property.

▶ **Lemma 30.** *Suppose that in G, $P_i, P_j \in \mathcal{P}^h$ share an edge e. One of the following holds:*

- *every path between P_i and P_j in the circular ordering also uses e, or*
- *every path between P_j and P_i in the circular ordering also uses e.*

Proof. In G_ϕ, consider subdividing the copies of e belonging to $\widehat{P}_i$ and $\widehat{P}_j$ by adding one node into each edge. Then add an edge e' between the two new nodes, adding e' such that it only crosses copies of e. The new edge either separates $\mathrm{CW}(\widehat{P}_i, \widehat{P}_j)$ or it separates $\mathrm{ACW}(\widehat{P}_i, \widehat{P}_j)$, where by separates we mean that any path of $\widehat{\mathcal{P}}^h$ that is within the sector must cross e'. The paths between $\widehat{P}_i$ and $\widehat{P}_j$ in the clockwise ordering all lie in $\mathrm{CW}(\widehat{P}_i, \widehat{P}_j)$, and the paths between $\widehat{P}_j$ and $\widehat{P}_i$ in the clockwise ordering all lie in $\mathrm{ACW}(\widehat{P}_i, \widehat{P}_j)$. If a path $\widehat{P}_r$ crosses e', then it means that it uses a copy of e, and hence its corresponding path P_r in G also uses e. The result follows. ◀

5.2 Main Congestion Argument

We are now ready to prove Theorem 3.

Proof of Theorem 3. First, we show how to prove Item 2 (unsplittable flow), since Item 1 ultimately follows from it. Let f be a feasible strongly uncrossed flow with a fixed strongly uncrossed parallelization ϕ. Recall that we let $f(e) = \sum_{P: e \in P} f(P)$ and let f^h be the single-commodity flow for $h \in E(H)$.

Consider a commodity h. Let $P_1, \ldots, P_k$ be the paths of $\mathcal{P}^h$, ordered according to the cyclic clockwise ordering of their corresponding paths $\widehat{P}_1, \ldots, \widehat{P}_k \in \widehat{\mathcal{P}}^h$ in G_ϕ. Re-index so that P_1 and P_k are the outer paths. Let i^* be the smallest index i such that $\sum_{j \le i} f^h(P_j) \ge \frac{d(h)}{2}$. We define $Q^h = P_{i^*}$, and call it the *central path* for h.

▷ Claim 31. If $e \in Q^h$ and e is an outer edge for h (i.e. it lies in P_1 or P_k), then $f^h(e) \ge \frac{d(h)}{2}$.

Proof. Since e is an outer edge, it is in either P_1 or P_k, in addition to $Q^h = P_{i^*}$. From Lemma 30 we have that $e \in P_r$ either for all $1 \le r \le i^*$ or for all $i^* \le r \le k$. In the former case, $f^h(e) \ge \sum_{1 \le r \le i^*} f^h(P_r) \ge \frac{d(h)}{2}$. For the latter case, $f^h(e) \ge \sum_{i^* \le r \le k} f^h(P_r) = d(h) - \sum_{1 \le r < i^*} f^h(P_r) > d(h) - \frac{d(h)}{2} = \frac{d(h)}{2}$, where the last inequality follows since $\sum_{1 \le r < i^*} f^h(P_r) < \frac{d(h)}{2}$ by definition of i^*. ◁

To obtain an unsplittable flow f', for each $h \in E(H)$ we route $d(h)$ units of flow along the path Q^h. For the congestion bound, consider an arbitrary edge $e \in E(G)$. We will bound the amount of flow through e. Let $H_e = \{h \in E(H) : e \in Q^h\}$, so $f'(e) = \sum_{h \in H_e} d(h)$. Define $O_e = \{h \in H_e : e \text{ is an outer edge of } h\}$ and also $I_e = \{h \in H_e : e \text{ is an inner edge of } h\}$. These sets partition H_e, so $f'(e) = \sum_{h \in O_e} d(h) + \sum_{h \in I_e} d(h)$. We know that $|I_e| \le 1$ from Lemma 27. Additionally, by Claim 31, for each $h \in O_e$ we have that $f^h(e) \ge \frac{d(h)}{2}$. We now split into two cases.

Case 1: $\sum_{h \in O_e} \frac{d(h)}{2} < u(e)$. Then,

$$f'(e) < 2u(e) + \sum_{h \in I_e} d(h) \le 2u(e) + d_{\max}.$$

Case 2: $\sum_{h \in O_e} \frac{d(h)}{2} \ge u(e)$. Then $\sum_{h \in O_e} f^h(e) \ge \sum_{h \in O_e} \frac{d(h)}{2} \ge u(e)$, so the commodities of O_e saturate e in f. It follows that $I_e = \emptyset$. Hence,

$$f'(e) = \sum_{h \in O_e} d(h) \le \sum_{h \in O_e} 2f^h(e) \le 2f(e) \le 2u(e) < 2u(e) + d_{\max}.$$

This concludes the proof of Item 2. The above is easily turned into a polynomial time algorithm. We show how to prove Item 1 from Item 2 in the full version. ◀

Abstract

Correlation Clustering is a fundamental clustering problem that is generalized to Chromatic Correlation Clustering to incorporate categorical data. Both problems have been intensively studied, and recently, substantial improvements were obtained in the approximation algorithms for Correlation Clustering. At the heart of this success lies a new linear program (LP) formulation called the *cluster LP*; a natural question was whether this LP can be extended to Chromatic Correlation Clustering to enable similar success.

We answer this question in the affirmative by presenting a $(2+\varepsilon)$-approximation algorithm for the problem using a *chromatic* cluster LP. We then consider Weighted Chromatic Correlation Clustering, in which edges have fractional weights satisfying the probability constraints, to show that our algorithm extends to this weighted version to yield the same approximation guarantee.

1 Introduction

Given a complete graph where each edge is labeled by either "+" or "−", Correlation Clustering (CC) asks to find a vertex clustering that minimizes the total number of *disagreed edges*, where we say an edge is disagreed if it is a "−" edge within a cluster or a "+" edge across clusters. This problem is a fundamental combinatorial optimization problem that has been extensively studied in various forms across fields [28, 23, 15, 7, 12, 24, 6]. The readers are also referred to Wahid and Hassini [26] for a dedicated survey on this problem.

This problem is well-known to be NP/APX-hard [24, 6, 12, 10], and recently, it is further shown that the problem cannot be approximated within a constant smaller than 24/23 unless P = BPP [9]. There has also been a long line of work [6, 10, 2, 11, 14, 13, 9] on improving the approximation ratio for this problem that recently culminated in 1.485 due to Cao, Cohen-Addad, Lee, Li, Newman, and Vogl [9]. A key component of their positive result is in approximately solving an exponential-sized LP, called the *cluster LP*, in polynomial time and rounding this nearly optimal solution to an integral solution.

Chromatic Correlation Clustering (CCC) is a generalization of CC motivated by clustering data with categorical interactions [8, 5, 3]. In this generalization, "+" edges are labeled with colors. The objective is to find a clustering of vertices and a coloring of the clusters that minimize the total number of disagreements, where "+" edges within a cluster are deemed disagreed if their colors differ from that of the cluster. This chromatic version has been intensively studied in the literature [8, 4, 18, 27, 20], but previous approaches to this generalization were nevertheless limited to color-blind algorithms [18], reduction to the monochromatic version [4, 18, 27], and rounding algorithms using the standard LP relaxation [4]. The recent work by Lee, Fan, and Lee [20] achieving an approximation ratio of 2.15 for CCC is also based on reducing to monochromatic CC using an optimal solution to the standard LP relaxation for CCC.

In light of success of the cluster LP in CC, it is interesting to see if a chromatic version of the cluster LP helps improve the approximation algorithm for CCC. In this paper, we affirmatively answer this question: we show that a natural adaptation of the cluster LP, called the *chromatic cluster LP*, can be solved nearly optimally in polynomial time, and any feasible solution to the chromatic cluster LP can be rounded into an integral solution of cost within a factor of 2. These together yield a $(2+\varepsilon)$-approximation algorithm for CCC, improving upon 2.15 due to Lee et al. [20]. Furthermore, we identify how we can generalize this approach to the weighted case of CCC.

In addition to CCC, Weighted (Monochromatic) Correlation Clustering [6, 17, 2, 25, 11, 21] is another well-studied generalization of CC. In this problem, rather than "integrally" declaring an edge as "+" or "−", each edge is now assigned a fractional "+" weight and "−" weight. These two weights must be nonnegative and sum to 1. This condition is thereby called the *probability constraint*. The objective of the problem is to find a clustering of vertices that minimizes the total *weight* of disagreements. It is worth noting that there exists an approximation-preserving reduction to unweighted CC due to Chawla, Makarychev, Schramm, and Yaroslavtsev [11]. This reduction is based on replacing each vertex in the original weighted instance by a sufficiently large clique of "+" edges while the numbers of "+" and "−" edges between two cliques are proportional to the weights between the corresponding vertices.

In this paper, we study the weighted generalization of CCC, called Weighted Chromatic Correlation Clustering (WCCC), which is naturally defined as follows: each edge is assigned "+" weights, one for each color, and a (colorless) "−" weight. These weights

must respect the probability constraint. The goal is to find a clustering that minimizes the total weighted disagreements. We demonstrate that our approach for CCC smoothly extends to this weighted generalization, yielding an approximation algorithm with the same factor of $(2+\varepsilon)$. The aforementioned approximation-preserving reduction for the monochromatic version [11] unfortunately does not easily extend to this chromatic version because it is unclear how one could assign colors to the edges within each clique originated from a vertex in the original instance.

Recently, Fan, Lee, and Lee [16] presented a 1.64-approximation algorithm for unweighted CCC. They also approximately solve the same chromatic cluster LP in polynomial time using a slightly different approach from ours, and then round this solution with both a cluster-based algorithm and a pivot-based algorithm, yielding the 1.64-approximation algorithm. One notable difference in solving the chromatic cluster LP lies in the construction of *admissible edges* (see Section 5.2): they adapted Cao et al.'s construction [9] into a color-sensitive version with parallel admissible edges introduced, while we show that the original construction is sufficient. Furthermore, we extend our results to the weighted setting, demonstrating the applicability of this approach to other settings. We note that our results for CCC presented in this paper were obtained independently, whereas our results for WCCC were obtained after the arXiv announcement [19] of the unweighted results of Fan et al [16].

2 Problem definitions

We begin with defining Chromatic Correlation Clustering (CCC). An instance of CCC consists of a set L of colors and a complete graph (V, E) where each edge is specified as either a $+$ edge or a $-$ edge, and each $+$ edge e is associated with a color $c_e \in L$. Let E^ℓ be the set of edges colored ℓ; let $E^+ := \bigcup_{\ell \in L} E^\ell$ and $E^- := E \setminus E^+$ denote the sets of $+$ and $-$ edges, respectively. Given an instance $(V, E, L, \{c_e\}_{e \in E^+})$ of the problem, a (feasible) solution consists of a partition $\mathcal{C}$ of V and a coloring function $\chi : \mathcal{C} \to L$ that assigns a color to each part. Given a solution $(\mathcal{C}, \chi)$, an edge $e = uv$ is called a *disagreement* if and only if one of the following conditions holds:

- e is a $-$ edge and both u and v belong to the same cluster $C \in \mathcal{C}$;
- e is a $+$ edge and u and v belong to different clusters $C \neq C' \in \mathcal{C}$; and
- e is a $+$ edge and both u and v belong to the same cluster $C \in \mathcal{C}$, but $\chi(C) \neq c_e$.

We also refer to a disagreement simply as a *disagreed* edge. If an edge is not a disagreement, we call it an *agreement* or an *agreed* edge. The goal of the problem is to find a solution that minimizes the total number of disagreements, which is also referred to as the cost of the solution.

We now turn our attention to Weighted Chromatic Correlation Clustering (WCCC). An instance of WCCC consists of a complete graph where each edge e is associated with $|L \cup \{-\}|$ *weights*, denoted by $\{w^\ell(e)\}_{\ell \in L \cup \{-\}}$. The weights of each edge satisfy the *probability constraint*, i.e., $w^\ell(e) \geq 0$ for every $\ell \in L \cup \{-\}$ and $\sum_{\ell \in L \cup \{-\}} w^\ell(e) = 1$. A (feasible) solution to a WCCC instance (V, E, L, w) also consists of a partition $\mathcal{C}$ of V and a coloring function $\chi : \mathcal{C} \to L$. To define the total cost of a solution $(\mathcal{C}, \chi)$, we define the cost incurred by an edge $e = uv$ in the solution, denoted by $\mathsf{cost}_{(\mathcal{C},\chi)}(e)$, as follows:

- $\mathsf{cost}_{(\mathcal{C},\chi)}(e) := \sum_{\ell \in L} w^\ell(e) = 1 - w^-(e)$ if u and v belong to different clusters in $\mathcal{C}$;
- $\mathsf{cost}_{(\mathcal{C},\chi)}(e) := \sum_{\ell \in L \cup \{-\} \setminus \{\chi(C)\}} w^\ell(e) = 1 - w^{\chi(C)}(e)$ if both u and v belong to a cluster $C \in \mathcal{C}$.

The cost of a solution $(\mathcal{C}, \chi)$ is then defined to be the sum of costs incurred by all edges, i.e., $\sum_{e \in E} \mathsf{cost}_{(\mathcal{C},\chi)}(e)$. We may omit the subscript $(\mathcal{C}, \chi)$ when it is clear from context. The objective of the problem is to find a solution of the minimum cost.

We further define the notation that will be used. Let $n := |V|$ denote the number of vertices. For the unweighted CCC problem, let $E^{-\ell} := E \setminus E^{\ell}$ for every $\ell \in L$. Given $F \subseteq E$, $u \in V$, and $S \subseteq V$, let $F(u,S) := \{uv \in F \mid v \in S\}$; for example, given $u \in V$ and $S \subseteq V$, $E^{+}(u,S)$ denotes the set of $+$ edges whose one endpoint is u and the other endpoint is in S.

On the other hand, for WCCC, given $U \subseteq L \cup \{-\}$ and $S,T \subseteq V$, let $w^{U}(S,T) := \sum_{\ell \in U} \sum_{uv:u \in S, v \in T} w^{\ell}(uv)$. For notational simplicity, let $w^{U}(u,T)$ and $w^{U}(u,v)$, respectively, denote $w^{U}(\{u\},T)$ and $w^{U}(\{u\},\{v\})$. For any edge $e = uv$, $w^{U}(u,v)$ can be written as $w^{U}(e)$. Note that $w^{U}(u,u) = 0$ by definition. For $\ell \in L$, let $w^{-\ell}(S,T) := w^{L \cup \{-\} \setminus \{\ell\}}(S,T)$. Similarly, let $w^{+}(S,T) := w^{L}(S,T)$.

3 A constant-factor approximation algorithm for WCCC

This section is devoted to a constant-factor approximation algorithm for WCCC. The algorithm is a reduction to CCC inspired by Bansal, Blum, and Chawla [6]. Recall that constant-factor approximation algorithms [4, 18, 27, 20] are known for CCC.

Given an instance $I_{\mathsf{ori}} = (V, E, L, w_{\mathsf{ori}})$ of WCCC, we construct a new instance $I_{\mathsf{new}} = (V, E^{+} \cup E^{-}, L, c)$ for CCC as follows:

$$E^{-} := \{e \in E \mid \arg\max_{\ell \in L \cup \{-\}} \{w^{\ell}_{\mathsf{ori}}(e)\} = -\} \text{ and}$$
$$c_e := \arg\max_{\ell \in L} \{w^{\ell}_{\mathsf{ori}}(e)\} \text{ for } e \in E^{+} := E \setminus E^{-},$$

where ties are broken arbitrarily. We then run a ρ-approximation algorithm for CCC on I_{new}, and return the output of this algorithm.

Let $\mathsf{cost}_{\mathsf{ori}}(\cdot)$ and $\mathsf{cost}_{\mathsf{new}}(\cdot)$ denote the total cost of a solution with respect to I_{ori} and I_{new}, respectively. Let $\mathrm{OPT}_{\mathsf{ori}}$ and $\mathrm{OPT}_{\mathsf{new}}$ denote optimal solutions to I_{ori} and I_{new}, respectively, and let SOL denote the final output of the algorithm. Note that $\mathsf{cost}_{\mathsf{new}}(\mathrm{SOL}) \le \rho\, \mathsf{cost}_{\mathsf{new}}(\mathrm{OPT}_{\mathsf{new}})$ by the execution.

▶ **Lemma 1.** $\mathsf{cost}_{\mathsf{ori}}(\mathrm{SOL}) \le \mathsf{cost}_{\mathsf{new}}(\mathrm{SOL}) + \mathsf{cost}_{\mathsf{ori}}(\mathrm{OPT}_{\mathsf{ori}})$.

Proof. Fix any edge $e \in E$. If e is disagreed by SOL in I_{new}, it incurs a unit cost in I_{new}. Since the cost incurred by any edge in I_{ori} is trivially bounded by 1, the total cost incurred by the edges disagreed by SOL is at most $\mathsf{cost}_{\mathsf{new}}(\mathrm{SOL})$.

On the other hand, if e is agreed by SOL in I_{new}, we cannot use the above argument because it incurs no cost in I_{new}. Observe however that this edge incurs $1 - w^{\ell}_{\mathsf{ori}}(e)$ in SOL in I_{ori}, where $\ell = \arg\max_{\ell' \in L \cup \{-\}} \{w^{\ell'}_{\mathsf{ori}}(e)\}$ by the construction of I_{new}. Note that, in I_{ori}, any solution must incur $1 - w^{\ell}_{\mathsf{ori}}(e)$ from e due to the choice of ℓ. Hence, the total cost incurred by the edges agreed by SOL is bounded from above by $\mathsf{cost}_{\mathsf{ori}}(\mathrm{OPT}_{\mathsf{ori}})$. ◀

▶ **Lemma 2.** *For any solution* $\mathcal{S}$, $\mathsf{cost}_{\mathsf{new}}(\mathcal{S}) \le 2\, \mathsf{cost}_{\mathsf{ori}}(\mathcal{S})$.

Proof. Fix any edge $e \in E$ disagreed by $\mathcal{S}$ in I_{new}. Let $\ell := -$ if $e \in E^{-}$ and $\ell := c_e$ if $e \in E^{+}$. Observe that $w^{\ell'}_{\mathsf{ori}}(e) \le \frac{1}{2}$ for any $\ell' \in L \cup \{-\} \setminus \{\ell\}$ due to the construction of I_{new}. Hence, the cost incurred by e in $\mathcal{S}$ in I_{ori} is then at least $\min_{\ell' \in L \cup \{-\} \setminus \{\ell\}} \{1 - w^{\ell'}_{\mathsf{ori}}(e)\} \ge \frac{1}{2}$. ◀

▶ **Theorem 3.** *This algorithm is a* $(2\rho+1)$*-approximation algorithm for WCCC.*

Proof. We can derive that

$$\begin{aligned}
\mathsf{cost}_{\mathsf{ori}}(\mathrm{SOL}) &\le \mathsf{cost}_{\mathsf{new}}(\mathrm{SOL}) + \mathsf{cost}_{\mathsf{ori}}(\mathrm{OPT}_{\mathsf{ori}}) \\
&\le \rho\, \mathsf{cost}_{\mathsf{new}}(\mathrm{OPT}_{\mathsf{new}}) + \mathsf{cost}_{\mathsf{ori}}(\mathrm{OPT}_{\mathsf{ori}}) \\
&\le \rho\, \mathsf{cost}_{\mathsf{new}}(\mathrm{OPT}_{\mathsf{ori}}) + \mathsf{cost}_{\mathsf{ori}}(\mathrm{OPT}_{\mathsf{ori}}) \\
&\le (2\rho+1)\, \mathsf{cost}_{\mathsf{ori}}(\mathrm{OPT}_{\mathsf{ori}}),
\end{aligned}$$

where the first inequality is due to Lemma 1, and the last is due to Lemma 2. ◀

4 Chromatic cluster LPs

In this section, we define the chromatic cluster LPs for CCC and WCCC, respectively, and present a rounding algorithm whose expected cost is at most twice the cost of the given LP solution.

Chromatic cluster LPs. Define the *chromatic cluster LP* for CCC as follows:

$$\begin{aligned} \min\ & \textstyle\sum_{S\subseteq V,\ell\in L}\left(\frac{|\delta^+(S)|}{2}+|E^{-\ell}[S]|\right)z_S^\ell \\ \text{s.t.}\ & \textstyle\sum_{S\ni v,\ell\in L} z_S^\ell = 1, && \forall v\in V, \\ & z_S^\ell \geq 0, && \forall S\subseteq V\,\forall \ell\in L, \end{aligned}$$

where $z_S^\ell = 1$ indicates whether S is a cluster of color ℓ, $\delta^+(S) := \{(u,v)\in E^+ \mid u\in S, v\notin S\}$, and $E^{-\ell}[S] := \binom{S}{2}\cap E^{-\ell}$. Let $t_v^\ell := 1-\sum_{S\ni v} z_S^\ell$ indicate whether v is *not* colored ℓ and $x_{uv}^\ell := 1-\sum_{S\supseteq uv} z_S^\ell$ denote whether u and v are *not* together in a same cluster colored ℓ. Observe that

$$\textstyle\sum_{S\ni u,S\not\ni v} z_S^\ell = \sum_{S\ni u} z_S^\ell - \sum_{S\supseteq uv} z_S^\ell = x_{uv}^\ell - t_u^\ell, \qquad \forall \ell\in L\,\forall uv\in E \tag{1}$$

$$\textstyle\sum_{\ell\in L} t_v^\ell = |L| - \sum_{\ell\in L, S\ni v} z_S^\ell = |L|-1, \qquad \forall v\in V. \tag{2}$$

Using these equalities, we can rephrase the objective function as $\mathrm{obj}(x) := \sum_{uv\in E^+} x_{uv}^{c_{uv}} + \sum_{uv\in E^-}\sum_{\ell\in L}(1-x_{uv}^\ell)$. We defer its derivation to Appendix A.

The chromatic cluster LP for WCCC has the same sets of variables and constraints, while the objective function is replaced with

$$\textstyle\sum_{S\subseteq V,\ell\in L}\left(\frac{w^+(S,V\setminus S)}{2}+w^{-\ell}(S,S)\right)z_S^\ell.$$

Through a similar derivation to the unweighted version, the objective function can be rephrased as $\mathrm{obj}(x) := \sum_{uv\in E,\ell\in L}\left(w^\ell(uv)x_{uv}^\ell + w^-(uv)(1-x_{uv}^\ell)\right)$. The derivation can also be found in Appendix A.

Cluster-based algorithm. The algorithm is the same for CCC and WCCC. Given a solution z feasible to the chromatic cluster LP, consider the following algorithm. Let V' be the currently unclustered vertices (initially, $V' := V$). Until V' becomes empty, we randomly sample a cluster $S\subseteq V$ colored ℓ with probability $\frac{z_S^\ell}{\sum_{\ell'\in L, S'\subseteq V} z_{S'}^{\ell'}}$. We then cluster $V'\cap S$ colored ℓ and update $V' := V'\setminus S$ accordingly. This ends the description of the cluster-based algorithm.

We begin by analyzing the algorithm for CCC. Recall that $x_{uv}^\ell = 1-\sum_{S\supseteq uv} z_S^\ell$ for every $\ell\in L$ and $uv\in E$. For notational simplicity, let $x_{uv} := 1-\sum_{\ell\in L, S\supseteq uv} z_S^\ell$ indicate whether u and v are *not* clustered together (regardless of its color). Note that we have $1-x_{uv} = \sum_{\ell\in L}(1-x_{uv}^\ell)$, implying that, for any $\ell\in L$, $x_{uv}\leq x_{uv}^\ell$. The following lemma is useful in showing the approximation ratios, whose proof is deferred to Appendix A.

▶ **Lemma 4.** *For every $uv\in E$ and color $\ell\in L$, the probability that uv is in a same cluster colored ℓ is $\frac{1-x_{uv}^\ell}{1+x_{uv}}$, and the probability that uv is separated is $\frac{2x_{uv}}{1+x_{uv}}$.*

▶ **Theorem 5.** *Given a feasible solution z to the chromatic cluster LP for CCC, the cluster-based algorithm outputs an integral solution $(\mathcal{C},\chi)$ whose expected cost is at most twice the objective value of z. The algorithm terminates in time $\mathsf{poly}(n,|\mathsf{supp}(z)|)$ with high probability, where $\mathsf{supp}(z)$ denotes the support set of z.*

Proof. From Lemma 4, we can derive that the probability that $uv \in E$ is not in a cluster colored ℓ is at most $1 - \frac{1-x^\ell_{uv}}{1+x_{uv}} \leq \frac{2x^\ell_{uv}}{1+x_{uv}}$. Hence, the expected cost of $(\mathcal{C}, \chi)$ for CCC is bounded by

$$\begin{aligned}
&\textstyle\sum_{uv\in E^+} \Pr[uv \text{ is not in a same cluster } C \text{ of color } \chi(C) = c_{uv}] \\
&\qquad + \textstyle\sum_{uv\in E^-} \Pr[uv \text{ is not separated}] \\
&\leq \textstyle\sum_{uv\in E^+} \frac{2x^{c_{uv}}_{uv}}{1+x_{uv}} + \sum_{uv\in E^-} \frac{1-x_{uv}}{1+x_{uv}} \\
&\leq 2\textstyle\sum_{uv\in E^+} x^{c_{uv}}_{uv} + \sum_{uv\in E^-} (1 - x_{uv}) \\
&\leq 2\textstyle\sum_{uv\in E^+} x^{c_{uv}}_{uv} + \sum_{uv\in E^-} \sum_{\ell\in L}(1 - x^\ell_{uv}) \leq 2\,\mathrm{obj}(x).
\end{aligned}$$

To show that the algorithm terminates in time $\mathsf{poly}(n, |\mathsf{supp}(z)|)$, observe that, for any vertex $v \in V$, the probability of v being clustered in each iteration is $\frac{\sum_{S\ni v,\ell\in L} z^\ell_S}{\sum_{\ell\in L, S\subseteq V} z^\ell_S} \geq \frac{1}{|\mathsf{supp}(z)|}$. Hence, using the union bound, we can show the algorithm terminates in $\Theta(|\mathsf{supp}(z)| \log n)$ iterations with high probability. ◀

For WCCC, note that Lemma 4 is still satisfied because the algorithm is equivalent. We thus have the weighted version for Theorem 5 as below.

▶ **Theorem 6.** *Given a feasible solution z to the chromatic cluster LP for WCCC, the cluster-based algorithm outputs an integral solution $(\mathcal{C}, \chi)$ whose expected cost is at most twice of the objective value of z. The algorithm terminates in time $\mathsf{poly}(n, |\mathsf{supp}(z)|)$ with high probability.*

Proof. For WCCC, observe that the objective value can be written as

$$\begin{aligned}
\mathrm{obj}(x) &= \textstyle\sum_{e\in E,\ell\in L} \left(w^\ell(e)x^\ell_e + w^-(e)(1 - x^\ell_e)\right) \\
&= \textstyle\sum_{e\in E} \left[\sum_{\ell\in L} w^\ell(e)x^\ell_e + w^-(e)(1 - x_e)\right].
\end{aligned}$$

It thus suffices to show that the expected cost incurred by each $e \in E$ is bounded by twice $\sum_{\ell\in L} w^\ell(e)x^\ell_e + w^-(e)(1 - x_e)$. Observe that

$$\begin{aligned}
\mathbb{E}[\mathsf{cost}(e)] &= \textstyle\sum_{\ell\in L} \left[w^\ell(e)\Pr[e \text{ separated}] + (1 - w^\ell(e))\Pr[e \subseteq C \wedge \chi(C) = \ell]\right] \\
&\leq \textstyle\sum_{\ell\in L} \left[w^\ell(e)\,2x_e + (1 - w^\ell(e))\,(1 - x^\ell_e)\right] \\
&= \textstyle\sum_{\ell\in L} \left[w^\ell(e)(x_e + x^\ell_e) + (1 - x^\ell_e) - w^\ell(e)(1 - x_e)\right] \\
&= \textstyle\sum_{\ell\in L} w^\ell(e)(x_e + x^\ell_e) + w^-(e)(1 - x_e) \\
&\leq 2\textstyle\sum_{\ell\in L} w^\ell(e)x^\ell_e + w^-(e)(1 - x_e),
\end{aligned}$$

where the first inequality follows from Lemma 4, the last equality from the fact that $w^-(e) = 1 - \sum_{\ell\in L} w^\ell(e)$ and $1 - x_e = \sum_{\ell\in L}(1 - x^\ell_e)$, and the last inequality from the fact that $x_e \leq x^\ell_e$ for any $\ell \in L$.

The same argument used in the proof of Theorem 5 for termination completes the proof. ◀

5 Preclustering

Due to Theorems 5 and 6, to obtain a $(2 + \varepsilon)$-approximation algorithm, it suffices to argue that a nearly optimal solution to the chromatic cluster LPs can be found in polynomial time. To this end, we adapt the notion of a *preclustered instance* [13, 9] to the chromatic versions as follows.

▶ **Definition 7** (Preclustered instance). *Given an instance, a* preclustered instance *is defined by a triple* $(\mathcal{K}, \chi_{\mathsf{pre}}, E_{\mathsf{adm}})$ *such that*

- $\mathcal{K}$ *is a partition of* V*;*
- $\chi_{\mathsf{pre}} : \mathcal{K}_{>1} \to L$ *is a color assignment for every non-singleton part in* $\mathcal{K}$*, where we denote by* $\mathcal{K}_{>1} := \{K \in \mathcal{K} \mid |K| > 1\}$ *the set of non-singleton parts of* $\mathcal{K}$*; and*
- $E_{\mathsf{adm}} \subseteq \{uv \in \binom{V}{2} \mid \nexists K \in \mathcal{K} \text{ such that } uv \subseteq K\}$ *is a set of edges across* $\mathcal{K}$*.*

We call $\mathcal{K}$ *and* E_{adm} *a* preclustering *and* admissible *edges, respectively. Each part in* $\mathcal{K}$ *is called a* precluster*. Any pair* uv *of two vertices* u *and* v *in a same precluster is called an* atomic *edge. Any pair that is neither atomic nor admissible is called a* non-admissible *edge.*

▶ **Definition 8** (Respecting solution). *Given a preclustered instance* $(\mathcal{K}, \chi_{\mathsf{pre}}, E_{\mathsf{adm}})$ *and a feasible solution* $(\mathcal{C}, \chi)$*, we say the solution* respects *the preclustered instance when*

- $\mathcal{K}$ *subdivides* $\mathcal{C}$*, i.e., for every precluster* $K \in \mathcal{K}$*, there exists a cluster* $C \in \mathcal{C}$ *such that* $K \subseteq C$*;*
- *for every non-singleton precluster* $K \in \mathcal{K}_{>1}$ *and the cluster* $C \in \mathcal{C}$ *containing* K*,* $\chi_{\mathsf{pre}}(K) = \chi(C)$*; and*
- *for every non-admissible edge* uv*, the two vertices* u *and* v *are not in a same cluster in the solution.*

In this section, we prove the following theorem.

▶ **Theorem 9.** *For any sufficiently small constant* $\varepsilon > 0$*, there exists an algorithm that, in time* $n^{\mathsf{poly}(\varepsilon^{-1})}$*, outputs a preclustered instance* $(\mathcal{K}, \chi_{\mathsf{pre}}, E_{\mathsf{adm}})$ *such that there exists a solution respecting the preclustered instance whose cost is at most* $(1+\varepsilon)\,\mathrm{opt}$*, and* $|E_{\mathsf{adm}}| \le O(\varepsilon^{-2})\,\mathrm{opt}$*, where* opt *denotes the cost of an optimal solution in the instance input to the algorithm.*

5.1 Constructing $\mathcal{K}$ and χ_{pre}

In this subsection, we present an algorithm for constructing a preclustering $\mathcal{K}$ and a color assignment $\chi_{\mathsf{pre}} : \mathcal{K}_{>1} \to L$. The algorithm is an adaptation of Cao et al.'s construction [9] to the chromatic versions. In particular, one subtlety in our algorithm is that we do not assume a self-loop for each vertex which is no loss of generality in the monochromatic version.

Algorithm description. We first describe the algorithm for CCC, and then state the changes needed for WCCC. We use parameters $\alpha, \beta \in (0,1)$ such that $\eta := \frac{\alpha+\beta}{1-\beta} \in (0, \frac{1}{13})$. Note that $\alpha = \beta = 0.02$ is one feasible choice.[2]

At the very start, we obtain a solution $(\mathcal{C}_{\mathsf{init}}, \chi_{\mathsf{init}})$ by running any constant-factor approximation algorithm for CCC on the given instance. We then iterate over every vertex $u \in V$ in an arbitrary order, and mark u if either

$$|E^{-\ell}(u, C)| \ge \alpha(|C| - 1) \text{ or } |E^{+}(u, V \setminus C)| \ge \alpha(|C| - 1) \text{ (or both)}, \tag{3}$$

where we denote by $C \in \mathcal{C}_{\mathsf{init}}$ the cluster containing u and by $\ell := \chi_{\mathsf{init}}(C)$ its color. After marking all such vertices, we now iterate over every cluster $C \in \mathcal{C}_{\mathsf{init}}$, and if the number of marked vertices in C is at least $\beta(|C| - 1)$, we mark all the vertices in C. We obtain $\mathcal{K}$ by making all marked vertices singleton clusters from $\mathcal{C}_{\mathsf{init}}$. The color assignment χ_{pre} is constructed by inheriting χ_{init}, i.e., for any non-singleton $K \in \mathcal{K}_{>1}$, we have $\chi_{\mathsf{pre}}(K) = \chi_{\mathsf{init}}(C)$, where $C \supseteq K$ is the cluster in $\mathcal{C}_{\mathsf{init}}$ containing K.

[2] The choice of α and β affects the constant hidden in the exponent of the running time $n^{\mathsf{poly}(\varepsilon^{-1})}$ for constructing a nearly optimal solution to the chromatic cluster LPs: this constant decreases as $\alpha\beta$ increases.

For WCCC, we only need to change the condition (3) of $u \in V$ being marked in the first iteration to

$w^{-\ell}(u, C) \geq \alpha(|C| - 1)$ or $w^{+}(u, V \setminus C) \geq \alpha(|C| - 1)$ (or both).

Recall that we present a constant-factor approximation algorithm for WCCC in Section 3.

Sketch of analysis. Let us now sketch the analysis of this algorithm. We focus on CCC while we mention the changes needed for WCCC at the end. The full analysis for CCC is given in Appendix B.1; while the proof for WCCC can be found in the full version.

We aim at proving the first two conditions of Definition 8 are satisfied by any optimal solution with the constructed $\mathcal{K}$ and χ_{pre}. Fix an arbitrary optimal solution $(\mathcal{C}^\star, \chi^\star)$. The next two lemmas are useful in the proof of the main lemmas of this subsection.

▶ **Lemma 10.** *For any non-singleton precluster $K \in \mathcal{K}_{>1}$ with $\ell := \chi_{\mathsf{pre}}(K)$ and $u \in K$, we have $|E^{-\ell}(u, K)| < \eta(|K| - 1)$ and $|E^{+}(u, V \setminus K)| < \eta(|K| - 1)$.*

▶ **Lemma 11.** *For any non-singleton precluster $K \in \mathcal{K}_{>1}$, if a cluster $C_1^\star \in \mathcal{C}^\star$ colored $\chi_{\mathsf{pre}}(K)$ intersects K (i.e., $\chi^\star(C_1^\star) = \chi_{\mathsf{pre}}(K)$ and $K \cap C_1^\star \neq \emptyset$), we have $|C_1^\star \setminus K| < 2\eta|K|$.*

Intuitively speaking, the former lemma follows from the execution of the algorithm in a fairly straightforward manner. The latter can be derived because, otherwise, splitting $C_1^\star$ into $C_1^\star \setminus K$ and $C_1^\star \cap K$ in $\mathcal{C}^\star$ incurs less cost due to the second condition of Lemma 10.

The following is the main technical lemma for the first condition of Definition 8. We provide a proof sketch of this lemma while the full proof can be found in Appendix B.1.

▶ **Lemma 12.** *$\mathcal{K}$ subdivides $\mathcal{C}^\star$, i.e., for any $K \in \mathcal{K}$, there is $C^\star \in \mathcal{C}^\star$ such that $K \subseteq C^\star$.*

Proof sketch. Suppose toward contradiction that $\mathcal{C}^\star$ is not subdivided by $\mathcal{K}$. Then, there exists a non-singleton precluster $K \in \mathcal{K}_{>1}$ such that $K \setminus C^\star$ is nonempty for every cluster $C^\star \in \mathcal{C}^\star$. We choose an arbitrary such precluster $K \in \mathcal{K}_{>1}$, and let $\ell := \chi_{\mathsf{pre}}(K)$ be the color of K in the preclustering. Let ξ be a constant between $\frac{1+5\eta}{2}$ and $1 - 4\eta$. Note that we can always choose such ξ because $\frac{1+5\eta}{2} < 1 - 4\eta$ for $\eta \in (0, \frac{1}{13})$. Observe that $\frac{1}{2} < \xi < 1$.

We break the proof into two cases depending on the existence of a cluster $C^\star \in \mathcal{C}^\star$ that "dominantly" intersects K, i.e., $|K \cap C^\star| \geq \xi|K|$. In each case, we respectively construct a new solution whose cost is strictly less than $(\mathcal{C}^\star, \chi^\star)$, leading to contradiction that $(\mathcal{C}^\star, \chi^\star)$ is optimal.

Case 1. No dominant intersections. Suppose that, for all $C^\star \in \mathcal{C}^\star$, $|K \cap C^\star| < \xi|K|$. In this case, we consider a new solution $(\mathcal{C}, \chi)$ by removing $K \cap C^\star$ from each $C^\star \in \mathcal{C}^\star$ and inserting K colored $\ell := \chi_{\mathsf{pre}}(K)$.

The "gain" of $(\mathcal{C}, \chi)$ over $(\mathcal{C}^\star, \chi^\star)$ is at least the total number of ℓ-colored edges within K but crossing $\mathcal{C}^\star$. For each $u \in K$, at least $(1 - \xi)|K|$ edges are crossing $\mathcal{C}^\star$ inside K due to the condition of this case, while at most $\eta|K|$ edges can be colored other than ℓ due to Lemma 10, implying that the gain is at least $\frac{1-\xi-\eta}{2}|K|^2$.

On the other hand, the "loss" of $(\mathcal{C}, \chi)$ over $(\mathcal{C}^\star, \chi^\star)$ is due to either the appropriately colored $+$ edges crossing K but within a cluster in $\mathcal{C}^\star$ or the $-$ edges within K but crossing $\mathcal{C}^\star$. By Lemma 10, we can bound this loss from above by $\frac{3\eta}{2}|K|^2 < \frac{1-\xi-\eta}{2}|K|^2$, where the inequality is due to the choice of ξ.

Case 2. A dominant intersection exists. Suppose now there exists a cluster $C_1^\star \in \mathcal{C}^\star$ such that $|K \cap C_1^\star| \geq \xi|K|$. Note that we always have at most one such cluster since $\xi > \frac{1}{2}$. Let $K_1 := K \cap C_1^\star$.

Assume for now that $\chi^\star(C_1^\star) = \chi_{\mathsf{pre}}(K)$. We construct a solution $(\mathcal{C}, \chi)$ by transferring one arbitrary vertex $u \in K \setminus C_1^\star$ to $C_1^\star$. We can then see that the gain of $(\mathcal{C}, \chi)$ over $(\mathcal{C}^\star, \chi^\star)$ is due to the ℓ-colored edges between u and $C_1^\star$, whereas the loss is due to the appropriately colored + edges incident with u within the cluster containing u in $\mathcal{C}^\star$ and edges other than ℓ-colored ones between u and $C_1^\star$. Using the dominance condition of this case and Lemma 10, we can show that the gain is at least $(\xi - \eta)|K|$.

To bound the loss from above, we prove that the number of the first type of edges is at most $(1 - \xi + \eta)|K|$ using the fact that $|K \setminus C_1^\star| \le (1 - \xi)|K|$ due to the case condition, and Lemma 10. On the other hand, the second type of edges can be partitioned into ones within K and ones incident with $C_1^\star \setminus K$; the former is bounded by $\eta|K|$ due to Lemma 10 while the latter is bounded by $2\eta|K|$ due to Lemma 11. Hence, the loss cannot exceed $(1 - \xi + 4\eta)|K| < (\xi - \eta)|K|$ by the choice of ξ.

Finally, for the case where $\chi^\star(C_1^\star) \neq \chi_{\mathsf{pre}}(K)$, we construct a solution $(\mathcal{C}, \chi)$ from $(\mathcal{C}^\star, \chi^\star)$ by splitting $C_1^\star$ into $K_1 := K \cap C_1^\star$ colored $\ell = \chi_{\mathsf{pre}}(K)$ and $C_1^\star \setminus K_1$ colored $\ell' := \chi^\star(C_1^\star)$. We observe that the gain of $(\mathcal{C}, \chi)$ against $(\mathcal{C}^\star, \chi^\star)$ is at least the number of the ℓ-colored edges within K_1 while the loss is at most the number of the ℓ'-colored edges within K_1 and between K_1 and $C_1^\star \setminus K_1$. Through a similar argument using Lemma 10, we can show that the gain is at least $\frac{1}{2}|K_1|(\xi|K| - 1 - \eta(|K| - 1))$ while the loss is at most $\frac{3}{2}\eta|K_1|(|K| - 1)$. The net gain is therefore at least $\frac{1}{2}|K_1| \cdot (\xi|K| - 1 - 4\eta(|K| - 1)) > 0$, where the inequality can be derived from the fact that K is non-singleton and the choice of ξ and η. ◀

The second condition of Definition 8 is also satisfied through a similar argument. The proof can be found in Appendix B.1.

▶ **Lemma 13.** *For every cluster $C^\star \in \mathcal{C}^\star$ and any non-singleton precluster $K \in \mathcal{K}$ contained in $C^\star$, we have $\chi_{\mathsf{pre}}(K) = \chi^\star(C^\star)$.*

For WCCC, we generalize the above analysis for CCC by substituting the number of edges satisfying a condition with the total sum of edge weights satisfying the same condition. In particular, instead of Lemma 10 for CCC, we have the following lemma for WCCC:

▶ **Lemma 14.** *For any non-singleton precluster $K \in \mathcal{K}_{>1}$ with $\ell := \chi_{\mathsf{pre}}(K)$ and $u \in K$, we have $w^{-\ell}(u, K) < \eta(|K| - 1)$ and $w^{+}(u, V \setminus K) < \eta(|K| - 1)$.*

Likewise, we have the counterparts of Lemmas 11, 12, and 13 for WCCC. The complete analysis can be found in the full version.

5.2 Constructing E_{adm}

We now present the construction of admissible edges E_{adm}. Interestingly, it turns out that a color-oblivious construction as in Cao et al. [9] suffices for the chromatic versions. Here we present its construction in the notation of WCCC.

For the unweighted version, it is noteworthy that the original construction [9] for the unweighted monochromatic version already incorporates weights. Hence, there exists a straightforward interpretation for CCC where we define $w^+(S, S') := |\{uv \in E^+ : u \in S, v \in S'\}|$ and $w^-(S, S') := |\{uv \in E^- : u \in S, v \in S'\}|$ for $S, S' \subseteq V$.

Given $\mathcal{K}$ from the previous section, the construction of E_{adm} is as follows. For $K \in \mathcal{K}$, let $d(K) := \frac{w^+(K, V \setminus K)}{|K|} + \frac{|K|}{2}$, $N_1(K) := \{K' \in \mathcal{K} \mid \varepsilon \cdot d(K') < d(K) < \frac{1}{\varepsilon} \cdot d(K')\}$, and $N_2(K) := \{K' \in \mathcal{K} \setminus \{K\} \mid K, K' \in N_1(K) \cap N_1(K')\}$. For distinct $K, K' \in \mathcal{K}$ and $\mathcal{K}' \subseteq \mathcal{K}$ such that $K, K' \in \mathcal{K}'$, we further define

$$W(K,K',\mathcal{K}') := \sum_{K''\in\mathcal{K}'\setminus\{K,K'\}} \left[|K''| \cdot \frac{w^+(K,K'')}{|K|\cdot|K''|} \cdot \frac{w^+(K',K'')}{|K'|\cdot|K''|}\right] + \frac{w^+(K,K')}{|K|} + \frac{w^+(K',K)}{|K'|}$$

Moreover, for two distinct preclusters $K, K' \in \mathcal{K}$, we denote by $K \sim K'$ if $K' \in N_2(K)$ and $W(K, K', N_1(K) \cap N_1(K')) > \varepsilon(d(K) + d(K'))$. We can then define $E_{\mathsf{adm}} := \{uv \in E \mid \exists K, K' \in \mathcal{K}$ such that $K \sim K', u \in K, v \in K'\}$.

This choice of E_{adm}, together with $\mathcal{K}$ and χ_{pre} from the previous section, satisfies the conditions of Theorem 9; the complete proof is given in the full version.

6 Solving the chromatic cluster LP

In this section, we present an algorithm for solving the chromatic cluster LP nearly optimally, using the preclustered instance $(\mathcal{K}, \chi_{\mathsf{pre}}, E_{\mathsf{adm}})$ satisfying Theorem 9. Our technique is obtained by introducing one more dimension of color to Cao et al.'s approach [9]. Recall that they first formulate the *bounded sub-cluster LP* making use of a constant-level Sherali-Adams hierarchy, present a procedure that samples one cluster using Raghavendra and Tan's rounding scheme [22], and lastly argue that the Monte Carlo method with sufficiently many samples from the procedure produces a nearly optimal solution with high probability.

In what follows, we describe the algorithm for solving the chromatic cluster LPs, adapted from Cao et al.'s approach to the chromatic versions. We remark that there are no differences in the algorithm and analysis between CCC and WCCC except the objective function of the bounded sub-cluster LP. The entire analysis is given in the full version.

Bounded sub-cluster LP. We first present the bounded sub-cluster LP for the chromatic versions. Given $\varepsilon > 0$ sufficiently small, we define $\varepsilon_1 := \varepsilon^3$, $\varepsilon_{\mathrm{rt}} := \varepsilon_1^2 = \varepsilon^6$, and $r := \Theta(\varepsilon_{\mathrm{rt}}^{-2}) = \Theta(\varepsilon^{-12})$. We assume that r is an integer where a large enough constant is hidden in its Θ-notation. For $u \in V$, let $K_u \in \mathcal{K}$ be the precluster containing u. For $u \in V$, let $N_{\mathsf{adm}}(u) := \{v \in V \mid uv \in E_{\mathsf{adm}}\}$; for $K \in \mathcal{K}$, let $N_{\mathsf{adm}}(K) := \{v \in V \mid \exists u \in K, uv \in E_{\mathsf{adm}}\}$. Then, the bounded sub-cluster LP is defined as follows:

$$\begin{aligned}
&\min \operatorname{obj}(x)\\
&\text{s.t. } y_S^\ell = \textstyle\sum_{s=1}^n y_S^{\ell,s}, && \forall \ell \in L\ \forall S \subseteq V : |S| \le r,\\
&\quad t_v^\ell = 1 - y_v^\ell, && \forall \ell \in L\ \forall v \in V,\\
&\quad x_{uv}^\ell = 1 - y_{uv}^\ell, && \forall \ell \in L\ \forall uv \in \tbinom{V}{2},\\
&\quad \textstyle\sum_{\ell\in L} y_v^\ell = 1, && \forall v \in V,\\
&\quad \textstyle\sum_{v\in V} y_{Sv}^{\ell,s} = s\, y_S^{\ell,s}, && \forall \ell \in L\ \forall s \in [n]\ \forall S \subseteq V : |S| \le r-1,\\
&\quad x_{uv}^{\chi_{\mathsf{pre}}(K)} = 0, && \forall uv \subseteq K \in \mathcal{K}_{>1},\\
&\quad x_{uv}^\ell = 1, && \forall uv \subseteq K \in \mathcal{K}_{>1}\ \forall \ell \ne \chi_{\mathsf{pre}}(K),\\
&\quad y_{uv}^{\ell,s} = y_u^{\ell,s}, && \forall \ell \in L\ \forall s \in [n]\ \forall u \in V\ \forall v \in K_u,\\
&\quad x_{uv}^\ell = 1, && \forall \text{non-admissible } uv\ \forall \ell \in L,\\
&\quad y_v^{\ell,s} = 0, && \\
&\qquad \forall \ell \in L\ \forall v \in V\ \forall s \in [|K_v| - 1] \cup [|K_v| + 1, |K_v| + \varepsilon_1 |N_{\mathsf{adm}}(v)|],
\end{aligned}$$

$$
\begin{aligned}
& y_S^{\chi_{\mathsf{pre}}(K),|K|} = y_v^{\chi_{\mathsf{pre}}(K),|K|}, && \forall v \in K \in \mathcal{K}_{>1}\ \forall S \subseteq K : |S| \le r, \\
& y_S^{\chi_{\mathsf{pre}}(K),|K|} = 0, && \forall K \in \mathcal{K}_{>1}\ \forall S \not\subseteq K : |S| \le r, S \cap K \neq \emptyset, \\
& \textstyle\sum_{T' \subseteq T} (-1)^{|T'|} y_{S \cup T'}^{\ell,s} \in [0, y_S^{\ell,s}], && \\
& \qquad \forall \ell \in L\ \forall s \in [n]\ \forall S, T \subseteq V : S \cap T = \emptyset, |S \cup T| \le r, && \\
& y_S^{\ell,s} \ge 0, && \forall \ell \in L\ \forall s \in [n]\ \forall S \subseteq V : |S| \le r,
\end{aligned}
$$

where $y_S^{\ell,s} = 1$ indicates whether S is a subset of a cluster of size s colored ℓ. The only distinction between CCC and WCCC is in the objective function, $\mathrm{obj}(x)$. Since the size of the bounded sub-cluster LP is indeed bounded by $n^{\mathsf{poly}(\varepsilon^{-1})}$, we can solve this LP in time $n^{\mathsf{poly}(\varepsilon^{-1})}$.

Sampling one colored cluster. We now present the procedure for sampling one cluster from the bounded sub-cluster LP. Let y be an optimal solution to the bounded sub-cluster LP. The procedure randomly samples a color $\ell \in L$ with probability $y_\emptyset^\ell / y_\emptyset$ where $y_\emptyset := \sum_{\ell' \in L} y_\emptyset^{\ell'}$, a cardinality $s \in [n]$ with probability $y_\emptyset^{\ell,s} / y_\emptyset^\ell$, and a pivot $u \in V$ with probability $y_u^{\ell,s} / (s \cdot y_\emptyset^{\ell,s})$. With these sampled ℓ, s, and u, define y' as $y'_S := y_{Su}^{\ell,s} / y_u^{\ell,s}$ for every $S \subseteq V$ of size $|S| \le r-1$. The procedure then runs Raghavendra and Tan's rounding scheme [22] upon y' to sample a cluster $C \subseteq V$, and return C colored $\chi(C) := \ell$.

Monte Carlo method. Finally, we describe the Monte Carlo method for constructing a nearly optimal solution. Let $\Delta := \Theta\left(\frac{n^4 \log n}{\varepsilon_1^2 |E_{\mathsf{adm}}|}\right)$ with a sufficiently large hidden constant. (Here, we assume $E_{\mathsf{adm}} \neq \emptyset$; otherwise, $(\mathcal{K}, \chi_{\mathsf{pre}})$ given by Theorem 9, with arbitrary colors assigned to singleton preclusters, is already a $(1+\varepsilon)$-approximate integral solution.) In particular, we assume that $\Delta y_\emptyset$ is an integer and $\Delta \ge \frac{1}{\varepsilon - \varepsilon_1} = \frac{1}{\varepsilon - \varepsilon^3}$. The method independently samples colored clusters from the above procedure for $\Delta y_\emptyset$ times. Let $C_1, \ldots, C_{\Delta y_\emptyset}$ be the sampled colored clusters. Let $\ell_1, \ldots, \ell_{\Delta y_\emptyset}$ denote their corresponding colors. For each vertex $v \in V$, let $R_v := \{t \in \{1, 2, \ldots, \Delta y_\emptyset\} \mid v \in C_t\}$, and let $\tilde{R}_v$ be the set of the $\lceil (1-\varepsilon)\Delta \rceil$ smallest indices in R_v. For every $t \in \{1, 2, \ldots, \Delta y_\emptyset\}$, we define $\tilde{C}_t := \{v \in V \mid t \in \tilde{R}_v\} \subseteq C_t$. The final output is $\tilde{z}_S^\ell := \frac{|\{t | \tilde{C}_t = S \wedge \ell_t = \ell\}|}{\lceil (1-\varepsilon)\Delta \rceil}$ for every $\ell \in L$ and $S \subseteq V$.

A Deferred analysis from Section 4

We can rephrase the objective function for CCC as follows:

$$
\begin{aligned}
&\textstyle\sum_{S\subseteq V,\ell\in L}\left(\frac{|\delta^+(S)|}{2}+|E^{-\ell}[S]|\right)z_S^\ell\\
&=\textstyle\sum_{uv\in E^+}\left[\frac{1}{2}\sum_{\ell\in L}\left(\sum_{S\ni u,S\not\ni v}z_S^\ell+\sum_{S\not\ni u,S\ni v}z_S^\ell\right)+\sum_{S\supseteq uv,\ell\neq c_{uv}}z_S^\ell\right]\\
&\quad+\textstyle\sum_{uv\in E^-}\sum_{\ell\in L}\sum_{S\supseteq uv}z_S^\ell\\
&=\textstyle\sum_{uv\in E^+}\left[\sum_{\ell\in L}x_{uv}^\ell-\sum_{\ell\in L}\frac{t_u^\ell+t_v^\ell}{2}+\sum_{\ell\neq c_{uv}}\sum_{S\supseteq uv}z_S^\ell\right]\\
&\quad+\textstyle\sum_{uv\in E^-}\sum_{\ell\in L}\sum_{S\supseteq uv}z_S^\ell\\
&=\textstyle\sum_{uv\in E^+}\left[\sum_{\ell\in L}x_{uv}^\ell-(|L|-1)+\sum_{\ell\neq c_{uv}}(1-x_{uv}^\ell)\right]\\
&\quad+\textstyle\sum_{uv\in E^-}\sum_{\ell\in L}\sum_{S\supseteq uv}z_S^\ell\\
&=\textstyle\sum_{uv\in E^+}x_{uv}^{c_{uv}}+\sum_{uv\in E^-}\sum_{\ell\in L}(1-x_{uv}^\ell)=:\mathrm{obj}(x),
\end{aligned}
$$

where the second equality comes from (1) and the third from (2).

Using a similar derivation, we can also rephrase the objective function for WCCC as follows:

$$
\begin{aligned}
&\sum_{S\subseteq V,\ell\in L}\left(\frac{w^+(S,V\setminus S)}{2}+w^{-\ell}(S,S)\right)z_S^\ell\\
&=\sum_{uv\in E}\left[\frac{w^+(u,v)}{2}\sum_{\ell\in L}\left(\sum_{S\ni u,S\not\ni v}z_S^\ell+\sum_{S\not\ni u,S\ni v}z_S^\ell\right)+\sum_{S\supseteq uv}\sum_{\ell\in L}w^{-\ell}(u,v)\cdot z_S^\ell\right]\\
&=\sum_{uv\in E}\left[w^+(u,v)\cdot\left(\sum_{\ell\in L}x_{uv}^\ell-\sum_{\ell\in L}\frac{t_u^\ell+t_v^\ell}{2}\right)+\sum_{S\supseteq uv}\sum_{\ell\in L}w^{-\ell}(u,v)\cdot z_S^\ell\right]\\
&=\sum_{uv\in E}\left[w^+(u,v)\cdot\left(\sum_{\ell\in L}x_{uv}^\ell-(|L|-1)\right)+\sum_{\ell\in L}w^{-\ell}(u,v)\cdot(1-x_{uv}^\ell)\right]\\
&=\sum_{uv\in E}\left[\sum_{\ell\in L}(w^+(u,v)-w^{-\ell}(u,v))\cdot x_{uv}^\ell-w^+(u,v)(|L|-1)+\sum_{\ell\in L}w^{-\ell}(u,v)\right]\\
&=\sum_{uv\in E}\left[\sum_{\ell\in L}(w^\ell(u,v)-w^-(u,v))\cdot x_{uv}^\ell+w^-(u,v)|L|\right]
\end{aligned}
$$

$$= \sum_{uv \in E} \sum_{\ell \in L} \left(w^{\ell}(u,v) x^{\ell}_{uv} + w^{-}(u,v)(1 - x^{\ell}_{uv}) \right)$$
$$=: \mathrm{obj}(x),$$

where the second equality comes from (1), the third from (2), and the fifth from the definition of w^{+} and $w^{-\ell}$.

Proof of Lemma 4. Consider the set S such that $S \cap \{u, v\} \neq \emptyset$ for the first time. We have

$$\begin{aligned} \textstyle\sum_{\ell' \in L, S : S \cap uv \neq \emptyset} z^{\ell'}_S &= \textstyle\sum_{\ell' \in L, S \ni u} z^{\ell'}_S + \sum_{\ell' \in L, S \ni v} z^{\ell'}_S - \sum_{\ell' \in L, S \supseteq uv} z^{\ell'}_S \\ &= 1 + x_{uv}. \end{aligned}$$

For the first statement, recall that $\sum_{S \supseteq uv} z^{\ell}_S = 1 - x^{\ell}_{uv}$. The second statement immediately follows from the fact that $\sum_{\ell' \in L, S \supseteq uv} z^{\ell'}_S = 1 - x_{uv}$. ◀

B Deferred analysis from Section 5

B.1 Constructing $\mathcal{K}$ and χ_{pre} for CCC

Recall that we use parameters $\alpha, \beta \in (0,1)$ such that $\eta := \frac{\alpha+\beta}{1-\beta} \in (0, \frac{1}{13})$.

▶ **Lemma 15** (Restatement of Lemma 10). *For any non-singleton precluster $K \in \mathcal{K}_{>1}$ with $\ell := \chi_{\mathsf{pre}}(K)$ and $u \in K$, we have*

$$|E^{-\ell}(u, K)| < \eta(|K| - 1) \text{ and } |E^{+}(u, V \setminus K)| < \eta(|K| - 1).$$

Proof. Let $C \in \mathcal{C}_{\mathsf{init}}$ be the cluster containing $K \subseteq C$. Since K is non-singleton, the vertices in K remain unmarked during the execution of the algorithm, implying that

$$|C \setminus K| < \beta(|C| - 1). \tag{4}$$

Since $|C \setminus K| = (|C| - 1) - (|K| - 1)$, rearranging the terms yields

$$|C| - 1 < \frac{1}{1-\beta}(|K| - 1). \tag{5}$$

Let $\ell := \chi_{\mathsf{pre}}(K) = \chi_{\mathsf{init}}(C)$. We can also observe that

$$|E^{-\ell}(u, C)| < \alpha(|C| - 1) \text{ and } |E^{+}(u, V \setminus C)| < \alpha(|C| - 1) \tag{6}$$

since $u \in K$ is unmarked. We therefore have

$$|E^{-\ell}(u, K)| \leq |E^{-\ell}(u, C)| < \alpha(|C| - 1) < \frac{\alpha}{1-\beta}(|K| - 1) < \eta(|K| - 1),$$

where the first inequality follows from the fact that $E^{-\ell}(u, K) \subseteq E^{-\ell}(u, C)$ and the second-to-last inequality is due to Inequality (5). Furthermore, we have

$$\begin{aligned} |E^{+}(u, V \setminus K)| &= |E^{+}(u, C \setminus K)| + |E^{+}(u, V \setminus C)| \leq |C \setminus K| + |E^{+}(u, V \setminus C)| \\ &< \beta(|C| - 1) + \alpha(|C| - 1) < \frac{\alpha + \beta}{1 - \beta}(|K| - 1) = \eta\,(|K| - 1), \end{aligned}$$

where the second inequality is derived from Inequalities (4) and (6) and the last from Inequality (5). ◀

In what follows, we may instead use the following slightly weaker inequalities in most cases:

$$|E^{-\ell}(u, K)| < \eta|K| \text{ and } |E^{+}(u, V \setminus K)| < \eta|K|.$$

Now, fix any optimal solution $(\mathcal{C}^\star, \chi^\star)$ to the given instance I.

▶ **Lemma 16** (Restatement of Lemma 11 for CCC). *For any non-singleton precluster $K \in \mathcal{K}_{>1}$, if a cluster $C_1^\star \in \mathcal{C}^\star$ colored $\chi_{\mathsf{pre}}(K)$ intersects K (i.e., $\chi^\star(C_1^\star) = \chi_{\mathsf{pre}}(K)$ and $K \cap C_1^\star \neq \emptyset$), we have $|C_1^\star \setminus K| < 2\eta|K|$.*

Proof. Let $\ell := \chi_{\mathsf{pre}}(K) = \chi^\star(C_1^\star)$ and $K_1 := K \cap C_1^\star$. We define a solution $(\mathcal{C}, \chi)$ constructed from $(\mathcal{C}^\star, \chi^\star)$ by splitting $C_1^\star$ into K_1 and $C_1^\star \setminus K_1$. That is,

$$\mathcal{C} := \mathcal{C}^\star \setminus \{C_1^\star\} \cup \{K_1, C_1^\star \setminus K_1\} \text{ and } \chi(C) := \begin{cases} \ell, & \text{if } C \in \{K_1, C_1^\star \setminus K_1\}, \\ \chi^\star(C), & \text{if } C \in \mathcal{C} \cap \mathcal{C}^\star. \end{cases}$$

Suppose toward contradiction that $|C_1^\star \setminus K| \geq 2\eta|K|$. We show that the number of disagreements in $(\mathcal{C}, \chi)$ is less than that of $(\mathcal{C}^\star, \chi^\star)$. To this end, we classify all edges as follows, and determine whether each edge is a disagreement or not in $(\mathcal{C}, \chi)$ and in $(\mathcal{C}^\star, \chi^\star)$:

1. Each $-$ edge across K_1 and $C_1^\star \setminus K_1$ is an agreement in $(\mathcal{C}, \chi)$, but a disagreement in $(\mathcal{C}^\star, \chi^\star)$.
2. Each $-$ edge across K_1 and $V \setminus C_1^\star$ is an agreement in both solutions.
3. Each $+$ edge colored ℓ across K_1 and $C_1^\star \setminus K_1$ is a disagreement in $(\mathcal{C}, \chi)$, but an agreement in $(\mathcal{C}^\star, \chi^\star)$.
4. Each $+$ edge colored differently from ℓ across K_1 and $C_1^\star \setminus K_1$ is a disagreement in both solutions.
5. Each $+$ edge across K_1 and $V \setminus C_1^\star$ is a disagreement in both solutions.
6. Each edge within K_1 has the same status in both solutions.
7. The remaining edges outside $C_1^\star$ also have the same statuses in both solutions, respectively.

We first lower bound the "gain" in cost of the constructed solution $(\mathcal{C}, \chi)$ – the number of edges that are agreed in $(\mathcal{C}, \chi)$, but not in $(\mathcal{C}^\star, \chi^\star)$. Observe that the type 1 edges contribute to this gain. For any $u \in K_1$, note that

$$\begin{aligned} |E^{-}(u, C_1^\star \setminus K_1)| &= |E(u, C_1^\star \setminus K_1)| - |E^{+}(u, C_1^\star \setminus K_1)| \\ &= |E(u, C_1^\star \setminus K_1)| - |E^{+}(u, C_1^\star \setminus K)| \\ &\geq |E(u, C_1^\star \setminus K_1)| - |E^{+}(u, V \setminus K)| \\ &= |C_1^\star \setminus K_1| - |E^{+}(u, V \setminus K)| \\ &> |C_1^\star \setminus K_1| - \eta|K|, \end{aligned}$$

where the last equality comes from $u \notin C_1^\star \setminus K_1$, and the last inequality from Lemma 15 (recall that K is non-singleton). We can thus derive that the gain of $(\mathcal{C}, \chi)$, the total number of type 1 edges, is strictly greater than $|K_1| \cdot (|C_1^\star \setminus K_1| - \eta|K|) = |K_1| \cdot (|C_1^\star \setminus K| - \eta|K|)$.

We now upper bound the "loss" in cost of $(\mathcal{C}, \chi)$ – the number of edges that are agreed in $(\mathcal{C}^\star, \chi^\star)$, but not in $(\mathcal{C}, \chi)$. Note that the edges of type 3 contribute to this loss. For any $u \in K_1$, we have

$$|E^{\ell}(u, C_1^\star \setminus K_1)| = |E^{\ell}(u, C_1^\star \setminus K)| \leq |E^{+}(u, V \setminus K)| < \eta|K|$$

where the last inequality is again due to Lemma 15, yielding that the loss of $(\mathcal{C}, \chi)$ is strictly less than $|K_1| \cdot \eta|K|$.

We can thus conclude that the "net gain" in cost of the constructed solution $(\mathcal{C}, \chi)$ against $(\mathcal{C}^\star, \chi^\star)$ is strictly greater than

$$|K_1| \cdot (|C_1^\star \setminus K| - \eta|K|) - |K_1| \cdot \eta|K| = |K_1| \cdot (|C_1^\star \setminus K| - 2\eta|K|) \geq 0,$$

where the inequality is due to the assumption that $|C_1^\star \setminus K| \geq 2\eta|K|$, contradicting the optimality of $(\mathcal{C}^\star, \chi^\star)$. ◀

▶ **Lemma 17** (Restatement of Lemma 12). *$\mathcal{K}$ subdivides $\mathcal{C}^\star$, i.e., for any $K \in \mathcal{K}$, there is $C^\star \in \mathcal{C}^\star$ such that $K \subseteq C^\star$.*

Proof. Suppose toward contradiction that $\mathcal{C}^\star$ is not subdivided by $\mathcal{K}$. Then, there exists a non-singleton precluster $K \in \mathcal{K}_{>1}$ such that $K \setminus C^\star$ is nonempty for every cluster $C^\star \in \mathcal{C}^\star$. We choose an arbitrary such precluster $K \in \mathcal{K}_{>1}$, and let $\ell := \chi_{\mathsf{pre}}(K)$ be the color of K in the preclustering. Let ξ be a constant between $\frac{1+5\eta}{2}$ and $1 - 4\eta$. Note that we can always choose such ξ because $\frac{1+5\eta}{2} < 1 - 4\eta$ for $\eta \in (0, \frac{1}{13})$. Observe that $\frac{1}{2} < \xi < 1$.

We break the analysis into two cases depending on the existence of a cluster $C^\star \in \mathcal{C}^\star$ that "dominantly" intersects K, i.e., $|K \cap C^\star| \geq \xi|K|$. The overall structure of the proof for each case is similar to the proof of Lemma 16: we respectively construct a solution whose cost is strictly less than $(\mathcal{C}^\star, \chi^\star)$, leading to contradiction that $(\mathcal{C}^\star, \chi^\star)$ is optimal.

Case 1. No dominant intersections. Suppose that, for all $C^\star \in \mathcal{C}^\star$, $|K \cap C^\star| < \xi|K|$. Consider a new solution $(\mathcal{C}', \chi')$ constructed by inserting K colored $\ell = \chi_{\mathsf{pre}}(K)$. More precisely, we have

$$\mathcal{C}' := \{K\} \cup \{C^\star \setminus K \mid C^\star \in \mathcal{C}^\star \text{ with } |C^\star \setminus K| > 0\} \text{ and}$$
$$\chi'(C) := \begin{cases} \ell, & \text{if } C = K; \\ \chi^\star(C^\star), & \text{if } C = C^\star \setminus K. \end{cases}$$

We classify each edge and determine whether it is a disagreement or not in both solutions.

1. Each $-$ edge across K and $V \setminus K$ is agreed in $(\mathcal{C}', \chi')$, and possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
2. Each $+$ edge across K and $V \setminus K$ is disagreed in $(\mathcal{C}', \chi')$, but possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
3. Each $-$ edge within K is disagreed in $(\mathcal{C}', \chi')$, but possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
4. Each $+$ edge e of color $c_e = \ell$ within $K \cap C^\star$ for some $C^\star \in \mathcal{C}^\star$ is agreed in $(\mathcal{C}', \chi')$, and possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
5. Each $+$ edge e of color $c_e \neq \ell$ within $K \cap C^\star$ for some $C^\star \in \mathcal{C}^\star$ is disagreed in $(\mathcal{C}', \chi')$, but possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
6. Each $+$ edge e of color $c_e = \ell$ that is within K but across clusters in $\mathcal{C}^\star$ is agreed in $(\mathcal{C}', \chi')$, but disagreed in $(\mathcal{C}^\star, \chi^\star)$.
7. Each $+$ edge e of color $c_e \neq \ell$ that is within K but across clusters in $\mathcal{C}^\star$ is disagreed in both solutions.
8. The remaining edges outside K have the same statuses in both solutions, respectively.

Observe that the gain in cost of $(\mathcal{C}', \chi')$ against $(\mathcal{C}^\star, \chi^\star)$ is lower-bounded by the number of type 6 edges while the loss in cost of $(\mathcal{C}', \chi')$ is upper-bounded by the number of edges of types 2, 3, and 5.

To give a lower bound on the number of type 6 edges, we consider any $u \in K$ and let $C_u^\star \in \mathcal{C}^\star$ be the cluster containing u in $\mathcal{C}^\star$. We then have

$$\begin{aligned} |E^\ell(u, K \setminus C_u^\star)| &= |E(u, K \setminus C_u^\star)| - |E^{-\ell}(u, K \setminus C_u^\star)| \\ &\geq |E(u, K \setminus C_u^\star)| - |E^{-\ell}(u, K)| \\ &= |K \setminus C_u^\star| - |E^{-\ell}(u, K)| > |K \setminus C_u^\star| - \eta|K| \\ &\geq (1 - \xi)|K| - \eta|K| = (1 - \xi - \eta)|K|, \end{aligned}$$

where the second equality comes from $u \notin K \setminus C_u^\star$, the second inequality from Lemma 15, and the last inequality from the condition of this case. Hence, the number of type 6 edges is bounded from below by

$$\frac{1}{2}\sum_{u\in K}|E^{\ell}(u, K\setminus C_u^\star)| > \frac{1-\xi-\eta}{2}|K|^2.$$

This is also a lower bound for the gain in cost of $(\mathcal{C}', \chi')$ against $(\mathcal{C}^\star, \chi^\star)$.

We now consider the edges of types 2, 3 and 5. Due to the second inequality of Lemma 15, we can upper bound the number of type 2 edges by $|K|\cdot\eta|K| = \eta|K|^2$. On the other hand, the total number of type 3 and type 5 edges is bounded from above by

$$\frac{1}{2}\sum_{u\in K}|E^{-\ell}(u, K)| < \frac{\eta}{2}|K|^2$$

due to the first inequality of Lemma 15. Hence, the loss in cost of $(\mathcal{C}', \chi')$ against $(\mathcal{C}^\star, \chi^\star)$ is strictly less than $\frac{3\eta}{2}|K|^2$. Since $\xi \le 1-4\eta$, we have

$$\frac{1-\xi-\eta}{2}|K|^2 - \frac{3\eta}{2}|K|^2 \ge 0,$$

implying that $(\mathcal{C}', \chi')$ has fewer disagreements than $(\mathcal{C}^\star, \chi^\star)$. This contradicts the optimality of $(\mathcal{C}^\star, \chi^\star)$.

Case 2. A dominant intersection exists. Suppose now there exists a cluster $C_1^\star \in \mathcal{C}^\star$ such that $|K\cap C_1^\star| \ge \xi|K|$. Note that we always have at most one such cluster since $\xi > \frac{1}{2}$. Let $K_1 := K \cap C_1^\star$.

We first claim that $\chi^\star(C_1^\star) \ne \chi_{\mathsf{pre}}(K)$. Otherwise, if $\chi^\star(C_1^\star) = \chi_{\mathsf{pre}}(K)$, we construct a solution $(\mathcal{C}'', \chi'')$ by transferring one arbitrary vertex $w \in K \setminus C_1^\star$ to $C_1^\star$. In other words,

$$\mathcal{C}'' := \{C_1^\star \cup \{w\}\} \cup \{C^\star \setminus \{w\} \mid C^\star \in \mathcal{C}^\star \setminus \{C_1^\star\}\} \text{ and}$$
$$\chi''(C) = \begin{cases} \chi^\star(C_1^\star), & \text{if } C = C_1^\star \cup \{w\}, \\ \chi^\star(C^\star), & \text{if } C = C^\star \setminus \{w\}. \end{cases}$$

Since $K \setminus C_1^\star$ is nonempty, we can always choose $w \in K \setminus C_1^\star$ in the above construction. Recall also that $\ell = \chi_{\mathsf{pre}}(K) = \chi^\star(C_1^\star)$. Consider the following classification of edges:

1. Each edge in $E^{\ell}(w, C_1^\star)$ is agreed in $(\mathcal{C}'', \chi'')$, but disagreed in $(\mathcal{C}^\star, \chi^\star)$.
2. Each edge in $E^{-\ell}(w, C_1^\star)$ is disagreed in $(\mathcal{C}'', \chi'')$, but possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
3. Each edge in $E^{+}(w, V\setminus C_1^\star)$ is disagreed in $(\mathcal{C}'', \chi'')$, but possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
4. Each edge in $E^{-}(w, V\setminus C_1^\star)$ is agreed in $(\mathcal{C}'', \chi'')$, and possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
5. All the edges that are not incident with w have the same statuses in both solutions, respectively.

Hence, the gain in cost of $(\mathcal{C}'', \chi'')$ against $(\mathcal{C}^\star, \chi^\star)$ is bounded from below by $|E^{\ell}(w, C_1^\star)|$, whilst the loss in cost of $(\mathcal{C}'', \chi'')$ is bounded from above by $|E^{-\ell}(w, C_1^\star)| + |E^{+}(w, V\setminus C_1^\star)|$. For the type 1 edges, we have

$$\begin{aligned} |E^{\ell}(w, C_1^\star)| &\ge |E^{\ell}(w, K_1)| = |E(w, K_1)| - |E^{-\ell}(w, K_1)| \\ &= |K_1| - |E^{-\ell}(w, K_1)| \ge |K_1| - |E^{-\ell}(w, K)| \\ &> |K_1| - \eta|K| \ge \xi|K| - \eta|K| = (\xi-\eta)|K|, \end{aligned}$$

where the second equality comes from $w \notin K_1$, and the second-to-last inequality from Lemma 15. For type 2 edges,

$$\begin{aligned}|E^{-\ell}(w, C_1^\star)| &= |E^{-\ell}(w, K_1)| + |E^{-\ell}(w, C_1^\star \setminus K_1)| \\ &\le |E^{-\ell}(w, K)| + |C_1^\star \setminus K_1| \\ &= |E^{-\ell}(w, K)| + |C_1^\star \setminus K| \\ &< \eta|K| + 2\eta|K| = 3\eta|K|,\end{aligned}$$

where the last inequality comes from Lemma 15 and Lemma 16. Lastly, for type 3 edges,

$$\begin{aligned}|E^{+}(w, V \setminus C_1^\star)| &= |E^{+}(w, K \setminus C_1^\star)| + |E^{+}(w, (V \setminus K) \setminus C_1^\star)| \\ &< |K \setminus C_1^\star| + |E^{+}(w, V \setminus K)| \\ &\le (1-\xi)|K| + |E^{+}(w, V \setminus K)| \\ &< (1-\xi)|K| + \eta|K| = (1-\xi+\eta)|K|,\end{aligned}$$

where the second inequality comes from that $|K \cap C_1^\star| \ge \xi|K|$, and the last inequality is due to Lemma 15. Hence, the net gain in cost of $(\mathcal{C}'', \chi'')$ against $(\mathcal{C}^\star, \chi^\star)$ is strictly greater than

$$(\xi - \eta)|K| - (1 - \xi + 4\eta)|K| \ge 0,$$

where the inequality follows from the choice of $\xi > \frac{1+5\eta}{2}$, contradicting the optimality of $(\mathcal{C}^\star, \chi^\star)$. This completes the proof of our claim that $\chi^\star(C_1^\star) \neq \chi_{\mathsf{pre}}(K)$.

We now construct another solution $(\mathcal{C}, \chi)$ from $(\mathcal{C}^\star, \chi^\star)$ by splitting $C_1^\star$ into K_1 colored $\ell = \chi_{\mathsf{pre}}(K)$ and $C_1^\star \setminus K_1$ colored $\chi^\star(C_1^\star)$, i.e.,

$$\mathcal{C} := \mathcal{C}^\star \setminus \{C_1^\star\} \cup \{K_1, C_1^\star \setminus K_1\} \quad \text{and} \quad \chi(C) := \begin{cases} \ell, & \text{if } C = K_1, \\ \chi^\star(C_1^\star), & \text{if } C = C_1^\star \setminus K_1, \\ \chi^\star(C), & \text{if } C \in \mathcal{C} \cap \mathcal{C}^\star. \end{cases}.$$

Consider the following breakdown of the edges:

1. Each $-$ edge across K_1 and $V \setminus K_1$ is agreed in $(\mathcal{C}, \chi)$, and possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
2. Each $+$ edge across K_1 and $C_1^\star \setminus K_1$ is disagreed in $(\mathcal{C}, \chi)$, but possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
3. Each $+$ edge across K_1 and $V \setminus C_1^\star$ is disagreed in both solutions.
4. Each $-$ edge within K_1 is disagreed in both solutions.
5. Each $+$ edge e of color $c_e = \ell$ within K_1 is agreed in $(\mathcal{C}, \chi)$, but disagreed in $(\mathcal{C}^\star, \chi^\star)$.
6. Each $+$ edge e of color $c_e \neq \ell$ within K_1 is disagreed in $(\mathcal{C}, \chi)$, but possibly agreed in $(\mathcal{C}^\star, \chi^\star)$.
7. All the remaining edges outside K_1 have the same statuses in both solutions, respectively.

We can thus see that the gain in cost of $(\mathcal{C}, \chi)$ against $(\mathcal{C}^\star, \chi^\star)$ is at least the number of type 5 edges, while the loss is at most the total number of type 2 and type 6 edges.

To lower-bound the number of type 5 edges, we first fix an $u \in K_1$ and consider the type 5 edges incident to u. We then have

$$\begin{aligned}|E^{\ell}(u, K_1)| &= |E(u, K_1)| - |E^{-\ell}(u, K_1)| = |K_1| - 1 - |E^{-\ell}(u, K_1)| \\ &\ge |K_1| - 1 - |E^{-\ell}(u, K)| > |K_1| - 1 - \eta(|K| - 1) \\ &\ge \xi|K| - 1 - \eta(|K| - 1),\end{aligned}$$

where the second inequality comes from Lemma 15, and the last inequality comes from the condition of K_1. Hence, the number of type 5 edges is at least

$$\frac{1}{2}\sum_{u\in K_1}|E^{\ell}(u,K_1)| > \frac{1}{2}|K_1|\cdot(\xi|K|-1-\eta(|K|-1)).$$

We now upper-bound the number of edges of types 2 and 6. For any $u \in K_1$, we have

$$|E^{+}(u,C_1^{\star}\setminus K_1)| = |E^{+}(u,C_1^{\star}\setminus K)| \le |E^{+}(u,V\setminus K)| < \eta(|K|-1),$$

where the last inequality is due to Lemma 15, implying that the number of type 2 edges is strictly less than $|K_1|\cdot\eta(|K|-1)$. On the other hand, we also have that, for every $u \in K_1$,

$$|E^{+}\cap E^{-\ell}(u,K_1)| \le |E^{-\ell}(u,K)| < \eta(|K|-1)$$

where the last inequality comes from Lemma 15, yielding that the number of type 6 edges is strictly upper-bounded by $\frac{1}{2}|K_1|\cdot\eta(|K|-1)$.

We can thus derive that the net gain in cost of $(\mathcal{C},\chi)$ against $(\mathcal{C}^{\star},\chi^{\star})$ is greater than

$$\frac{1}{2}|K_1|\cdot(\xi|K|-1-\eta(|K|-1)) - \frac{1}{2}|K_1|\cdot 3\eta(|K|-1)$$
$$= \frac{1}{2}|K_1|\cdot(\xi|K|-1-4\eta(|K|-1)).$$

Observe that $\xi > \frac{1+5\eta}{2} > \frac{1}{2} > \frac{4}{13} > 4\eta$ by the choice of ξ and η. We can thus see

$$\xi|K|-1-4\eta(|K|-1) = (\xi-4\eta)|K|-1+4\eta \ge 2\xi-4\eta-1 > \eta,$$

where the first inequality comes from the fact that K is non-singleton and $\xi > 4\eta$, and the last inequality from the fact that $\xi > \frac{1+5\eta}{2}$. This again contradicts the optimality of $(\mathcal{C}^{\star},\chi^{\star})$, completing the entire proof of this case. ◀

The above lemma shows that each precluster $K \in \mathcal{K}$ is fully contained in some cluster $C^{\star} \in \mathcal{C}^{\star}$. We can also show that every non-singleton precluster must be colored the same as the cluster in $\mathcal{C}^{\star}$ containing it.

▶ **Lemma 18** (Restatement of Lemma 13 for CCC)**.** *For every cluster $C^{\star} \in \mathcal{C}^{\star}$ and any non-singleton precluster $K \in \mathcal{K}$ contained in $C^{\star}$, we have $\chi_{\mathsf{pre}}(K) = \chi^{\star}(C^{\star})$.*

Proof. Suppose toward contradiction that there exists a non-singleton K and $C_1^{\star}$ such that $K \subseteq C_1^{\star}$ but $\chi_{\mathsf{pre}}(K) \neq \chi^{\star}(C_1^{\star})$. We show that a solution $(\mathcal{C},\chi)$ obtained by splitting $C_1^{\star}$ into K of color $\chi_{\mathsf{pre}}(K)$ and $C_1^{\star}\setminus K$ of color $\chi^{\star}(C_1^{\star})$ has fewer disagreements than $(\mathcal{C}^{\star},\chi^{\star})$. The proof indeed follows from exactly the same argument as in the latter half of Case 2 in the proof of Lemma 17. ◀

▶ **Lemma 19.** *$(\mathcal{K},\chi_{\mathsf{pre}})$ is a constant-approximate solution.*

Proof. We show that the number of disagreements in $(\mathcal{K},\chi_{\mathsf{pre}})$ is within a constant factor of that in $(\mathcal{C}_{\mathsf{init}},\chi_{\mathsf{init}})$; since $(\mathcal{C}_{\mathsf{init}},\chi_{\mathsf{init}})$ is a constant-approximate solution, this completes the proof. To this end, we charge the edges newly disagreed in $(\mathcal{K},\chi_{\mathsf{pre}})$ due to the algorithm to the edges already disagreed in $(\mathcal{C}_{\mathsf{init}},\chi_{\mathsf{init}})$.

Consider any non-singleton cluster $C \in \mathcal{C}_{\mathsf{init}}$ of color $\ell := \chi_{\mathsf{init}}(C)$. Observe that, if a vertex $u \in C$ becomes a singleton precluster in $\mathcal{K}$, the set of newly disagreed edges is precisely $E^{\ell}(u,C)$. Let

$$B_1 := \{u \in C \mid |E^{-\ell}(u,C)| \ge \alpha(|C|-1)\} \text{ and}$$
$$B_2 := \{u \in C \mid |E^{+}(u,V\setminus C)| \ge \alpha(|C|-1)\}.$$

Note that $B_1 \cup B_2$ is the set of marked vertices in C right after iterating over V. We break the analysis into two cases depending on the size of $B_1 \cup B_2$.

Case 1. $|B_1 \cup B_2| < \beta(|C| - 1)$. In this case, the vertices in $C \setminus (B_1 \cup B_2)$ remain unmarked, and hence, it suffices to consider the vertices in $B_1 \cup B_2$. For any $u \in B_1$, observe that

$$\begin{aligned}|E^{\ell}(u, C)| &= |E(u, C)| - |E^{-\ell}(u, C)| = |C| - 1 - |E^{-\ell}(u, C)| \\ &\leq (1 - \alpha)(|C| - 1) \leq \frac{1 - \alpha}{\alpha}|E^{-\ell}(u, C)| < \frac{1}{\alpha}|E^{-\ell}(u, C)|,\end{aligned}$$

where the first and second inequalities are due to the definition of B_1; on the other hand, for $u \in B_2$, we have

$$|E^{\ell}(u, C)| \leq |C| - 1 \leq \frac{1}{\alpha}|E^{+}(u, V \setminus C)|,$$

where the last inequality is due to the definition of B_2. Hence, for any $u \in B_1 \cup B_2$, it is sufficient to cover $|E^{\ell}(u, C)|$ by charging $\frac{1}{\alpha}$ to each edge in $E^{-\ell}(u, C) \cup E^{+}(u, V \setminus C)$. Hence the total charged amount for the cluster C is at most

$$\frac{1}{\alpha}\left(2\,|\{uv \in E^{-\ell} \mid uv \subseteq C\}| + |\{uv \in E^{+} \mid |uv \cap C| = 1\}|\right).$$

Case 2. $|B_1 \cup B_2| \geq \beta(|C| - 1)$. Recall that, in this case, the algorithm marks all vertices in C. The total number of newly disagreed edges is at most $\binom{|C|}{2}$. Note that, by the definition of B_1,

$$|\{uv \in E^{-\ell} \mid uv \subseteq C\}| \geq \frac{1}{2}\sum_{u \in B_1}|E^{-\ell}(u, C)| \geq \frac{1}{2}\,|B_1| \cdot \alpha(|C| - 1),$$

and, by the definition of B_2,

$$|\{uv \in E^{+} \mid |uv \cap C| = 1\}| \geq \sum_{u \in B_2}|E^{+}(u, V \setminus C)| \geq |B_2| \cdot \alpha(|C| - 1).$$

We can thus derive that

$$\begin{aligned}&2\,|\{uv \in E^{-\ell} \mid uv \subseteq C\}| + |\{uv \in E^{+} \mid |uv \cap C| = 1\}| \\ &\geq \alpha(|B_1| + |B_2|)(|C| - 1) \\ &\geq \alpha\beta(|C| - 1)^2,\end{aligned}$$

where the last inequality is due to the condition that $|B_1| + |B_2| \geq |B_1 \cup B_2| \geq \beta(|C| - 1)$. This yields

$$\begin{aligned}\binom{|C|}{2} &= \frac{|C|(|C| - 1)}{2} \leq (|C| - 1)^2 \\ &\leq \frac{1}{\alpha\beta}\left(2\,|\{uv \in E^{-\ell} \mid uv \subseteq C\}| + |\{uv \in E^{+} \mid |uv \cap C| = 1\}|\right),\end{aligned}$$

where the first inequality is because C is non-singleton. It therefore suffices to cover the new disagreements due to C by charging $\frac{2}{\alpha\beta}$ to each edge in $\{uv \in E^{-\ell} \mid uv \subseteq C\}$ and $\frac{1}{\alpha\beta}$ to each edge in $\{uv \in E^{+} \mid |uv \cap C| = 1\}$, respectively.

Due to the above charging argument, we can see that every disagreement in $(\mathcal{C}_{\mathsf{init}}, \chi_{\mathsf{init}})$ is charged at most $\frac{2}{\alpha\beta}$ while sufficiently covering the cost incurred by the new disagreements in $(\mathcal{K}, \chi_{\mathsf{pre}})$. ◀

Hitting Axis-Parallel Segments with Weighted Points

Abstract

We study a geometric hitting-set problem in which the input consists of a set P of weighted points and a family $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ of axis-parallel segments in the plane. The goal is to select a minimum-weight subset of P that hits every segment in $\mathcal{S}$. Even restricted geometric hitting-set problems are known to be computationally hard, and for axis-parallel segments the standard decomposition into horizontal and vertical sub-instances yields only a simple factor-2 approximation.

We present an LP-rounding algorithm that breaks the factor-2 barrier. For the weighted problem, we obtain a randomized $(1 + 2/e)$-approximation by combining systematic rounding on horizontal lines with an exact repair step on residual vertical sub-instances. In the unweighted case, a sharper analysis gives a $(1 + 1/(e - 1))$-approximation. Finally, we consider the case where one of the sub-instances consists of lines instead of line segments, a problem considered by Fekete et al. (Geometric Hitting Set for Segments of Few Orientations, Theor. Comp. Sys., 62 (2) 2018),. In this case, we improve their result to obtain an approximation factor of $1 + 1/e$ and show that the problem is APX-hard. We also present algorithms for the generalization to d orientations, as well as PTASes for bounded-complexity subclasses of the unweighted Hitting Set problem.

1 Introduction

A *set system* $(P, \mathcal{S})$ consists of a set P of elements and a collection $\mathcal{S}$ of subsets of P. Given a set system, $(P, \mathcal{S})$, a set $P' \subseteq P$ is a *hitting set* if each set in $\mathcal{S}$ contains an element of P'. In the *unweighted* Hitting Set Problem, the goal is to find a hitting set of minimum cardinality, and in the *weighted* Hitting Set Problem, we are additionally given a weight function $w : P \to \mathbb{R}$ and the goal is to select a minimum weight hitting set P', i.e., a hitting set such that $\sum_{p \in P'} w(p)$ is minimized. The set systems considered in this paper are finite. We assume that $|P| = n$ and $|\mathcal{S}| = m$.

Without restrictions, the Hitting Set Problem is equivalent to the Set Cover Problem on the *dual set system*, where points in P and sets in $\mathcal{S}$ swap roles. For these general systems, $O(\log m)$-approximation algorithms exist with nearly matching lower bounds. However, we can often bypass these limits by exploiting the structure of restricted instances. focuses on *geometric set systems*, where elements and sets are defined by objects in the plane. While Hitting Set and Set Cover remain NP-hard in these settings, they frequently admit better approximation ratios than general systems. Despite this, a unified set of techniques and a complete characterization of these systems remain elusive.

There are two broad frameworks that yield improved approximation algorithms for Hitting Set and Set Cover. The first is via ϵ-nets and LP-rounding ([20, 8, 16, 36, 10]) that yield algorithms with approximation factors depending on the *combinatorial complexity* (such as *VC-dimension*, or *shallow-cell complexity*) of the instance. However, these techniques at best yield $O(1)$-approximation algorithms with large hidden constants even for simple objects such disks or squares.

A second framework is *local search*, that yields PTASes when the geometric set system is *non-piercing*, but works only in the unweighted setting [28, 13, 32]. Informally, a set $\mathcal{S}$ of objects in the plane is non-piercing if the boundary of each object in $\mathcal{S}$ is a simple Jordan curve, and for any $A, B \in \mathcal{S}$, $A \setminus B$ and $B \setminus A$ are both connected sets (see [32] for a precise definition). On the other hand, Chan and Grant [10] (see also Har-Peled and Quanrud [19]) showed even with nearly congruent *almost-squares*, the Set Cover and Hitting Set problems become APX-hard. Recently, Banik et al. [6] showed that the local search technique yields a PTAS for the Set Cover problem even when the geometric shapes are not non-piercing, i.e., they *pierce*, but in a bounded manner. However, no such result is known for the Hitting Set Problem.

Our goal is to develop improved approximation algorithms for structured, weighted geometric set systems. Specifically, we address the Hitting Set problem for axis-parallel line segments (formally defined below).

Weighted Geometric Hitting Set for Axis-Parallel Segments

Input: A finite set P of points in the plane with a non-negative weight function $w\colon P \to \mathbb{R}_{\geq 0}$, and a family $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ of axis-parallel segments (where $\mathcal{H}$ are horizontal and $\mathcal{V}$ are vertical).

Goal: Find a subset $Q \subseteq P$ that minimizes the total weight $\sum_{p \in Q} w(p)$ such that Q hits every segment in $\mathcal{S}$ (i.e., $Q \cap s \neq \emptyset$ for all $s \in \mathcal{S}$).

Axis-parallel segments generalize several tractable special cases. When all segments in $\mathcal{S}$ are parallel to a single axis, the problem becomes one-dimensional; alternatively, if segments only intersect those of orthogonal orientations, the problem maps to bipartite graphs. In both scenarios, the Hitting Set, Set Cover, and also the Independent Set problems are solvable in polynomial time because their natural LP-relaxations are integral, owing to totally unimodular constraint matrices [34]. Crucially, this total unimodularity breaks down in our setting, where segments possess both orientations and parallel segments overlap.

For Hitting Set, Set Cover, and Independent Set, a trivial 2-approximation follows from independently solving the one-dimensional sub-instances for each axis and combining the results. Remarkably, while this remains the best-known approximation factor for Set Cover and Independent Set, our primary contribution is breaking this factor-2 barrier for the weighted Hitting Set problem.

1.1 Our Contributions

Our main contribution is a suite of improved approximation algorithms for the Hitting Set problem on axis-parallel line segments and points in the plane, summarized in Table 1. For line segments in two orientations, we achieve a $(1 + 2/e) \approx 1.74$-approximation in the

weighted setting and a $(1 + 1/(e - 1)) \approx 1.58$-approximation in the unweighted setting. When one orientation consists of infinite lines instead of segments, we improve this to a $(1 + 1/e) \approx 1.36$-approximation. We further generalize our results to segments parallel to one of d directions. These results are obtained via a randomized rounding procedure on the natural linear program, but can be derandomized using the standard method of conditional expectations (See [33]). We also present a PTAS for specific restricted instances.

Table 1 The table above summarizes our results. Note that the previously best-known 2-approximation is considered a folklore result.

Problem	Approx. Factor	Complexity	Previous bounds
Wt. axis-parallel	$1 + 2/e$ (Th. 1)		2
Unwt. axis-parallel	$1 + 1/(e - 1)$ (Th. 2)		2, APX-hard [17]
d-dir wt.	$\ln d + \ln \ln d + O(1)$ (Th. 3)		d
Hor-seg, vert lines	$1 + 1/e$ (Thm. 5)	APX-hard (Thm. 6)	5/3 [17]
k-restricted unwt.	PTAS (Thm. 8)		NP-hard
Lines in 3-directions		APX-hard (Thm. 7)	4/3 [15], NP-hard [17]

▶ **Theorem 1** (Weighted). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal and vertical line segments in the plane and let P be a set of points with a weight function $w : P \to \mathbb{R}_{\geq 0}$ such that each segment in $\mathcal{S}$ contains at least one point of P. Then, there is a randomized $(1 + 2/e)$-approximation algorithm for the weighted Hitting Set problem defined by $\mathcal{S}$ and P.*

For the unweighted setting, we obtain a better approximation factor.

▶ **Theorem 2** (Unweighted). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal and vertical line segments in the plane and let P be a set of points such that each segment in $\mathcal{S}$ contains at least one point of P. Then, there is a randomized $(1 + 1/(e - 1))$-approximation algorithm for the Hitting Set problem defined by $\mathcal{S}$ and P.*

We can generalize the result for axis-parallel segments in the setting where each segment is parallel to one of d directions. Fekete et al. [17] studied the setting where each object to be hit is not a single segment, but is the union of h segments (each coming from one of d orientations). The authors provide an $(h \cdot d)$-approximation for this setting. Applying the result below, it is possible to obtain an improved $h \cdot (\log d + \log \log d + O(1))$-approximation.

▶ **Theorem 3** (d-Directions). *Let $\mathcal{S}$ be a set of segments, each parallel to one of d directions in the plane for some $d \geq 2$, and let P be a set of points with a weight function $w : P \to \mathbb{R}_{\geq 0}$ such that each segment in $\mathcal{S}$ contains at least one point of P. Then, there is a randomized algorithm that is a $(\ln d + \ln \ln d + O(1))$-approximation relative to the natural LP.*

We show that the natural LP-relaxation of the unweighted problem has an integrality gap of at least 5/4.

▶ **Theorem 4** (Integrality gap). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal and vertical line segments in the plane and let P be a set of points such that each segment in $\mathcal{S}$ contains at least one point of P. The natural LP-relaxation of the problem has an integrality gap of at least 5/4.*

We also consider the setting when the segments in one of the orientations is replaced by lines, a variant considered by Fekete et al. [17], who gave a (5/3)-approximation for the unweighted case. We obtain a $1 + 1/e \approx 1.36$-approximation.

▶ **Theorem 5** (Lines and Segments). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal line segments and vertical lines in the plane and let P be a set of points with a weight function $w : P \to \mathbb{R}_{\geq 0}$ such that each object in $\mathcal{S}$ contains at least one point of P. Then, there is a randomized $(1 + 1/e)$-approximation algorithm for the weighted Hitting Set problem defined by $\mathcal{S}$ and P.*

This setting with lines in one direction was shown to be NP-hard by Fekete et al. [17] if the point set consists of all points in the plane. However, if the set P is finite, we show that in fact, the problem is APX-hard.

▶ **Theorem 6** (APX-Hardness). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal line segments and vertical lines in the plane and P be a finite set of points in the plane such that each object in $\mathcal{S}$ contains at least one point of P. The Hitting Set problem with $\mathcal{S}$ and P is APX-hard.*

If instead of line segments, we have lines in two dimensions, the Hitting Set problem with a set P of points is polynomial time solvable via a reduction to Edge Cover in bipartite graphs. Fekete [17] showed that if the set P consists of all points in the plane, then the problem is NP-hard. We sharpen their result to show that if we are additionally given a finite set P of points, then the problem becomes APX-hard.

▶ **Theorem 7** (3-Line-APX-hardness). *Let $\mathcal{S} = \mathcal{X} \cup \mathcal{Y} \cup \mathcal{Z}$ be three sets of lines such that lines in the plane in each set $\mathcal{X}, \mathcal{Y}$ and $\mathcal{Z}$ are parallel. Let P be a set of points such that each line contains at least one point. The Hitting Set problem defined by $\mathcal{S}$ and P is APX-hard.*

Finally, we consider a restricted setting where each segment intersects segments of the opposite orientation that lie on at most k distinct parallel lines. We call this the k-restricted setting. In this setting, we show that the problem admits a PTAS.

▶ **Theorem 8** (k-restricted). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal and vertical line segments in the plane such that each segment intersects segments of the opposite orientation lying on at most k parallel lines. Let P be a set of points such that each segment in $\mathcal{S}$ contains at least one point of P. Then, there is a PTAS for the Hitting Set problem with $\mathcal{S}$ and P.*

ϵ-nets. Geometric Hitting Set and Set Cover approximations heavily depend on shape complexity. The ϵ-net framework[1] (see [26] for results on ϵ-nets) connects ϵ-net sizes to LP integrality gaps, where bounded VC-dimension yields $O(\log \mathrm{OPT})$-approximations [8, 16, 20]. Many geometric set systems have bounded VC-dimension, thus yielding an $O(\log \mathrm{OPT})$-approximation algorithms. Since the ϵ-net is obtained by uniform random sampling, the approximation algorithms extend to the weighted setting as well. While ϵ-nets of size $O(1/\epsilon)$ are known for some objects such as *pseudodisks*[2] and halfspaces [25, 31], translating to $O(1)$-approximation for Hitting Set, these smaller nets do not yield improved approximation algorithms for the weighted problem. If a geometric set system has linear *shallow-cell complexity*, then the *quasi-uniform sampling* technique [36, 12] yield improved approximation algorithms for the weighted problems. However, point-segment systems lack linear shallow-cell complexity.

[1] For a set system $(P, \mathcal{S})$, a set $P' \subseteq P$ is an ϵ-net if it is a hitting set for all sets $S \in \mathcal{S}$ such that $|S| \geq \epsilon |P|$.

[2] A set $\mathcal{S}$ of objects in the plane, each of whose boundary is a simple Jordan curve is a set of pseudodisks if for any $A, B \in \mathcal{S}$, the boundaries of A and B intersect in either 2 or 0 points.

Piercing and non-piercing. For the weighted setting, there is a QPTAS for the Set Cover problem [27] with non-piercing regions in the plane, but no such result is known for the Hitting Set problem. For the unweighted problem, local search provides PTASes for Hitting Set of pseudodisks, as shown by Mustafa and Ray [28]. The technique also extends to non-piercing regions [7, 32], and also yields PTASes for the Set Cover, Independent Set and Dominating Set problems. Recently, Banik et al. [6] showed that local search also yields PTASes for the Set Cover and Independent Set problems when the objects have a *bounded amount of piercing* [6]. Allowing objects to pierce in an unbounded manner however, renders the Hitting Set and Set Cover problems APX-hard, even for nearly congruent shapes like almost-square rectangles [10] and nearly equilateral triangles [19].

Segments. *Axis-Parallel Covering:* Fekete et al. [17] proved that the Hitting Set problem for axis-parallel segments is APX-hard. For the restricted case where one direction consists of lines, they established NP-hardness and provided a (5/3)-approximation. For Set Cover, Kowalska and Pilipczuk [22] showed APX-hardness for horizontal and vertical segments (even with δ-extensions) and W[1]-hardness for the exact weighted problem. They also developed several FPT algorithms and parameterized approximation schemes parameterized by the solution size k.

Independent Set: For the Independent Set (IS) problem, Marx [24] showed the axis-parallel case is in FPT, whereas arbitrary orientations are W[1]-hard. Parameterized approximation schemes also exist for the axis-parallel setting [14]. Furthermore, Caoduro et al. [9] established a $2-\epsilon$ lower bound on the ratio between clique cover and independence numbers for segment intersection graphs. Consequently, the natural LP-relaxation for IS on axis-parallel segments has an integrality gap of 2, contrasting with our Hitting Set results.

Arbitrary Orientations: For segments with arbitrary orientations, ϵ-nets have a known size of $O(1/\epsilon \log(1/\epsilon))$ because the VC-dimension is 2. However, Alon [2] and Balogh et al. [5] established an ϵ-net lower bound of $\Omega(1/\epsilon \log^{1/3}(1/\epsilon))$, limiting the best possible ϵ-net-based approximation to $O(\log^{1/3-o(1)} \mathrm{OPT})$. Finally, for the IS problem on arbitrary segments, there is a weighted QPTAS [1] and an unweighted $O(n^{\epsilon})$-approximation [18].

Rectangles. Axis-parallel segments can also be seen as a special case of axis-parallel rectangles. For the Hitting Set problem with axis-parallel rectangles, Aronov, Ezra and Sharir [3] obtained an $O(\log \log \mathrm{OPT})$-approximation by showing that this set system admits an ϵ-net of size $O(1/\epsilon \log \log 1/\epsilon)$, and this is the best approximation factor known. Pach and Tardos [29] showed that in fact, this bound is tight, and therefore, the natural LP-relaxation for the Hitting Set problem has an integrality gap of $\Omega(\log \log \mathrm{OPT})$.

Organization

Section 2 presents the main algorithm and analysis. Section 3 gives an explicit integrality-gap example. The extension to d-orientations is in Section 4. Section 5 records a separator-based PTAS for bounded-complexity subclasses. Section 6 and Section 7 give the hardness results, and we conclude in Section 8.

2 LP-rounding Algorithm

Let P be a set of n points in the plane with nonnegative weight function $w\colon P \to \mathbb{R}_{\geq 0}$. Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of m axis-parallel segments, where $\mathcal{H}$ is the set of horizontal segments and $\mathcal{V}$ is the set of vertical segments. For a segment s, let $P \cap s$ denote the candidate points

lying on s. We always assume $P \cap s \neq \emptyset$ for every $s \in \mathcal{S}$. When we refer to a horizontal or vertical line, we mean a line that contains at least one point of P. The natural LP relaxation for the Hitting Set Problem is

$$\begin{aligned} \min \quad & \sum_{p \in P} w(p)\, x_p \\ \text{s.t.} \quad & \sum_{p \in P \cap s} x_p \geq 1 \qquad \forall s \in \mathcal{S}, \\ & 0 \leq x_p \leq 1 \qquad \forall p \in P. \end{aligned}$$

Fix an optimal LP solution x, and let

$$\mathrm{LP} := \sum_{p \in P} w(p)\, x_p.$$

Since this is a relaxation of the hitting-set problem, $\mathrm{LP} \leq \mathrm{OPT}$.

We use one elementary fact repeatedly: if all candidate points and all segments lie on a single line, then the induced stabbing problem is an interval stabbing instance, whose constraint matrix has the consecutive-ones property and is therefore totally unimodular [34]. Consequently, the one-dimensional problem can be solved exactly in polynomial time.

Algorithm. The algorithm has two phases. In the first phase, we use randomized rounding to obtain a hitting set for the horizontal segments. In doing so, we ensure that each point p is in the hitting set produced with probability x_p, its LP-value. This solution partitions the vertical segments into *blocks*. Each block B is a one-dimensional problem, and the LP solution restricted to B is feasible for the intervals contained in B. Therefore, we can obtain a solution of value at most $\sum_{p \in B} w(p) x_p$. While the algorithm remains the same for the weighted and unweighted problems, the analysis for the unweighted problem can be somewhat sharpened.

We now describe Phase I, where we obtain a hitting set for the horizontal segments. Fix a horizontal line h and let $p_1, \ldots, p_k$ be the points on h from left to right. We define the cumulative sums a_i, $i = 0, \ldots, k$ as follows:

$$a_0 := 0, \qquad a_i := \sum_{j=1}^{i} x_{p_j} \quad (i = 1, \ldots, k),$$

For each i let $I_i := [a_{i-1}, a_i)$. Choose a random shift U_h uniformly from $[0, 1]$. We select point p_i in Phase I if and only if I_i contains an integer of the shifted lattice $U_h + \mathbb{Z}$. We perform this rounding independently for every horizontal line.

We claim that each point p is selected in Phase I with probability x_p, and that the points selected in Phase I constitute a hitting set for the horizontal segments.

▶ **Lemma 9.** *For each point $p \in P$, the probability that p is selected in Phase I is exactly x_p.*

Proof. If $p = p_i$, then the interval I_i has length $x_{p_i} \leq 1$. As the shift U_h varies uniformly over $[0, 1)$, the set of shifts for which I_i contains a point of $U_h + \mathbb{Z}$ has measure exactly $|I_i| = x_{p_i}$. Hence $\mathbb{P}[p_i \text{ is selected in Phase I}] = x_{p_i}$. ◀

▶ **Lemma 10.** *Every horizontal segment is hit by Phase I with probability* 1.

Proof. Let $s \in \mathcal{H}$ be a horizontal segment on line h, and suppose it contains the consecutive points $p_i, p_{i+1}, \ldots, p_j$. The union of the corresponding intervals is $[a_{i-1}, a_j)$, whose length is

$$a_j - a_{i-1} = \sum_{t=i}^{j} x_{p_t} \geq 1$$

by the LP constraint for s. Any interval of length at least 1 contains a point of $U_h + \mathbb{Z}$ for every shift $U_h \in [0, 1)$. Therefore at least one point of $s \cap P$ is selected. ◀

In Phase II, we solve the residual problem obtained on removing the points selected in Phase I and the segments in $\mathcal{S}$ hit by these points. This residual problem consists of a disjoint collection of vertical segments, each of which is called a *block*. Each block consists of a maximal consecutive run of unselected points on a vertical line and the segments that lie entirely in the block. Each block can be solved optimally either via dynamic programming, or by solving a natural LP-relaxation for the block. We now analyze the cost of the solution returned by the algorithm. First, we observe that the expected cost of the points selected in Phase I is exactly equal to the LP cost.

▶ **Lemma 11.** $\mathbb{E}[\text{cost}(\textit{Phase I})] = \text{LP}$

Proof. $\mathbb{E}[\text{cost(Phase I)}] = \sum_{p \in P} w(p)\mathbb{P}[p \text{ selected in Phase I}] = \sum_{p \in P} w(p)x_p = \text{LP}$, where the second-last equality follows from Lemma 9. ◀

We analyze Phase II separately for the weighted case, the unweighted case, and the case where vertical segments are replaced by lines.

2.1 Weighted Hitting Set

Consider a block B in Phase II. Let $x(B)$ denote the sum of the LP values of all the points contained in the block. If $x(B) < 1$, then observe that no segment is completely contained in B. We can therefore, safely ignore such blocks and only deal with blocks with $x(B) \geq 1$. Let the weight of a block B be $w(B) = \sum_{i \in B} w(i)x_i$. For a point $p \in P$, let A_p be the event that p is unselected in Phase I and the block containing p has total LP mass at least 1. Observe that an LP-relaxation for the Hitting Set problem restricted to a block B has an optimal solution at most $w(B)$ if its mass $x(B)$ is at least 1. Therefore,

$$\mathbb{E}[\text{cost(Phase 2)}] \leq \sum_{p \in P} w(p)x_p\,\mathbb{P}[A_p].$$

We now obtain an upper bound on $\mathbb{P}[A_p]$. Fix a vertical line ℓ with ordered points $1, 2, \ldots, m$ from bottom to top, and fix a point $p \in \{1, \ldots, m\}$. Define random variables D_p and U_p as follows.

- D_p is the total LP mass of the maximal consecutive run of unselected points ending at p. If p itself is selected in Phase I, then $D_p = 0$.
- U_p is the total LP mass of the maximal consecutive run of unselected points immediately above p.

If p is unselected, then $D_p + U_p$ is exactly the total LP mass of the block containing p. Therefore, $\mathbb{P}[A_p] \leq \mathbb{P}[D_p + U_p \geq 1]$. We now show that the probability that D_p or U_p has mass at least t decreases exponentially.

▶ **Lemma 12.** *For every $t \geq 0$, $\mathbb{P}[D_p \geq t] \leq e^{-t}$ and $\mathbb{P}[U_p \geq t] \leq e^{-t}$. Moreover, D_p and U_p are independent.*

Proof. We prove the claim for D_p; the proof for U_p is identical. Since the claim is trivially true for $t = 0$, we consider $t > 0$. If no suffix of points ending at p has total LP mass at least t, then $\mathbb{P}[D_p \geq t] = 0$. Otherwise, let $j \leq p$ be the largest index such that $\sum_{i=j}^{p} x_i \geq t$. If $D_p \geq t$, then all points $j, j+1, \ldots, p$ must be unselected in Phase I. Since Phase I decisions on a vertical line are independent, $\mathbb{P}[D_p \geq t] \leq \prod_{i=j}^{p}(1 - x_i) \leq \exp\Big(-\sum_{i=j}^{p} x_i\Big) \leq e^{-t}$.

Finally, D_p depends only on the decisions for points at or below p, while U_p depends only on the decisions strictly above p. These sets of decisions are independent, so D_p and U_p are independent. ◀

We require the following technical lemma on stochastic dominance (See [35], Theorem 1.A.3, or the full version of our paper [33] for a proof).

▶ **Lemma 13.** *Let X_1, X_2, Y_1, Y_2 be random variables such that X_1 is independent of X_2 and Y_1 is independent of Y_2. If $X_1 \preceq_{\text{st}} Y_1$ and $X_2 \preceq_{\text{st}} Y_2$, then $X_1 + X_2 \preceq_{\text{st}} Y_1 + Y_2$.*

Let $E_1, E_2 \sim \text{Exp}(1)$ be independent exponential random variables. The tail bound above implies $D_p \preceq_{\text{st}} E_1$ and $U_p \preceq_{\text{st}} E_2$. By Lemma 13, we have $D_p + U_p \preceq_{\text{st}} E_1 + E_2$. Therefore, $\mathbb{P}[D_p + U_p \geq 1] \leq \mathbb{P}[E_1 + E_2 \geq 1]$.. Since $E_1 + E_2$ has the $\Gamma(2, 1)$ distribution, $\mathbb{P}[E_1 + E_2 \geq 1] = e^{-1}(1 + 1) = 2/e$. Hence $\mathbb{P}[A_p] \leq 2/e$ for every point p, and therefore

$$\mathbb{E}[\text{cost(Phase 2)}] \leq \frac{2}{e} \sum_{p \in P} w(p) x_p = \frac{2}{e}\text{LP}.$$

▶ **Theorem 1** (Weighted). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal and vertical line segments in the plane and let P be a set of points with a weight function $w : P \to \mathbb{R}_{\geq 0}$ such that each segment in $\mathcal{S}$ contains at least one point of P. Then, there is a randomized $(1 + 2/e)$-approximation algorithm for the weighted Hitting Set problem defined by $\mathcal{S}$ and P.*

Proof. Combining the bound on Phase I from Lemma 11, and the bound on A_p above, we obtain

$$\mathbb{E}[\text{cost(output)}] \leq \text{LP} + \frac{2}{e}\text{LP} = \left(1 + \frac{2}{e}\right)\text{LP} \leq \left(1 + \frac{2}{e}\right)\text{OPT}.$$ ◀

2.2 Unweighted Hitting Set

Fix a vertical line ℓ containing at least one vertical segment in $\mathcal{V}$. Let the points on this line be $q_1, \ldots, q_m$ ordered bottom to top. Let t denote the highest point such that the sum of the LP values of the points above t is at least 1. That is, $t = \max\Big\{j \in \{1, \ldots, m\} : \sum_{i=j}^{m} x_i \geq 1\Big\}$. Since the line contains at least one segment, the LP value on ℓ is ≥ 1. Therefore, we can assume that t is defined. In the unweighted setting, we can improve the analysis by observing that the value of an optimal solution for a block B is at most $\lfloor \sum_{p \in B} x_p \rfloor$.

For ease of analysis, we introduce a sentinel point 0 immediately below point 1, and declare it always selected. For every $i \in \{0, 1, \ldots, m\}$, let $B(i)$ denote the maximal block of consecutive unselected points immediately above i, and define $Y_i := \lfloor x(B(i)) \rfloor$, where $x(B(i)) := \sum_{p \in B(i)} x_p$. Every block on the line is either $B(0)$ or a block $B(i)$ following a selected point $i \geq 1$. Thus the Phase II cost on this line is at most $Y_0 + \sum_{i=1}^{m} \mathbf{1}[i \text{ selected}]\, Y_i$, where $\mathbf{1}[i \text{ selected}]$ is the indicator random variable that is 1 if i is selected, and 0 otherwise. Moreover, if $i \geq t$, then $\sum_{j=i+1}^{m} x_j < 1$, so $Y_i = 0$. Therefore only $Y_0, Y_1, \ldots, Y_{t-1}$ matter.

▶ **Lemma 14.** *For every $i \in \{0, 1, \ldots, t-1\}$, $\mathbb{E}[Y_i \mid i \text{ is selected}] \leq \frac{1}{e-1}$, where for $i = 0$ the conditioning is vacuous.*

Proof. Fix $i \in \{0, 1, \ldots, t-1\}$. For every integer $k \geq 1$,

$$\mathbb{P}\big[x(B(i)) \geq k \mid i \text{ is selected}\big] \leq e^{-k}.$$

Indeed, if the above probability is non-zero, let $r > i$ be the smallest index such that $\sum_{j=i+1}^{r} x_j \geq k$. Then all points $i+1, \ldots, r$ must not be selected in Phase I. Since the rounding decisions on a vertical line are independent and the event that i is selected depends only on point i, conditioning on the selection of i does not affect the points above it. Thus

$$\mathbb{P}\big[x(B(i)) \geq k \mid i \text{ is selected}\big] \leq \prod_{j=i+1}^{r} (1 - x_j) \leq \exp\left(-\sum_{j=i+1}^{r} x_j\right) \leq e^{-k}.$$

Using the tail-sum formula[3],

$$\begin{aligned}\mathbb{E}[Y_i \mid i \text{ is selected}] = \sum_{k \geq 1} \mathbb{P}\big[Y_i \geq k \mid i \text{ is selected}\big] &\leq \sum_{k \geq 1} \mathbb{P}\big[x(B(i)) \geq k \mid i \text{ is selected}\big] \\ &\leq \sum_{k \geq 1} e^{-k} = \frac{1}{e-1}.\end{aligned}$$

◀

▶ **Lemma 15.** *For every vertical line,* $\mathbb{E}[\text{cost}(\textit{Phase II on this line})] \leq \frac{1}{e-1} \sum_{i=1}^{m} x_i$.

Proof. Using the block decomposition above,

$$\mathbb{E}[\text{cost(Phase II on this line)}] \leq \mathbb{E}[Y_0] + \sum_{i=1}^{t-1} \mathbb{P}[i \text{ selected}]\, \mathbb{E}[Y_i \mid i \text{ selected}].$$

By Lemma 14, every conditional expectation is at most $1/(e-1)$, and point i is selected with probability x_i. Hence,

$$\mathbb{E}[\text{cost(Phase II on this line)}] \leq \frac{1}{e-1} + \sum_{i=1}^{t-1} \frac{x_i}{e-1} = \frac{1 + \sum_{i=1}^{t-1} x_i}{e-1}.$$

By the definition of t, we have $\sum_{i=t}^{m} x_i \geq 1$, so $1 + \sum_{i=1}^{t-1} x_i \leq \sum_{i=1}^{m} x_i$. Substituting this inequality completes the proof. ◀

▶ **Theorem 2** (Unweighted). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal and vertical line segments in the plane and let P be a set of points such that each segment in $\mathcal{S}$ contains at least one point of P. Then, there is a randomized $(1 + 1/(e-1))$-approximation algorithm for the Hitting Set problem defined by $\mathcal{S}$ and P.*

Proof. Phase I still has expected cost exactly $\text{LP} = \sum_{p \in P} x_p$. Summing the previous line bound over all vertical lines gives $\mathbb{E}[\text{cost(Phase 2)}] \leq 1/(e-1)\text{LP}$. Therefore

$$\mathbb{E}[\text{cost(output)}] \leq \text{LP} + \frac{1}{e-1}\text{LP} = \left(1 + \frac{1}{e-1}\right)\text{LP} \leq \left(1 + \frac{1}{e-1}\right)\text{OPT}.$$

◀

The analysis above is asymptotically tight as we show below.

[3] If X is a non-negative integer-valued random variable ($X \in \{0, 1, 2, \ldots\}$), the expected value is: $\mathbb{E}[X] = \sum_{n=1}^{\infty} \mathbb{P}(X \geq n)$

2.3 Tightness of the Unweighted Analysis

We record a family of instances showing that the analysis in Section 2.2 is asymptotically tight. Let k tend to infinity, and set $n := k^2$. The point set is the $n \times n$ grid $P = [n] \times [n]$. The input contains every horizontal and vertical segment consisting of exactly k consecutive grid points.

First, $\mathrm{OPT} = n^2/k = k^3$. Indeed, the k disjoint length-k horizontal segments in each row show that every feasible solution has size at least $nk = k^3$. Conversely, the set

$$Q^\star := \{(i,j) \in [n] \times [n] : j - i \equiv 0 \pmod{k}\}$$

has exactly k points in every row and every column, with consecutive chosen points spaced exactly k apart. Hence every length-k horizontal or vertical segment contains one point of $Q^\star$, so $|Q^\star| = k^3 = n^2/k$.

The same disjoint-segment lower bound also applies to the LP, and the uniform assignment $x_p = 1/k$ for every grid point is feasible. Hence this assignment is an optimal LP solution. We now run the algorithm with this symmetric optimum. On each row, Phase I chooses exactly one residue class modulo k, independently and uniformly from row to row. Thus Phase I selects exactly k points on each row, and

$$\text{cost(Phase I)} = k^3 = \mathrm{OPT}.$$

It remains to compute the expected repair cost on the columns. Fix a column. A row is already selected in this column with probability $p := 1/k$, independently across rows. Let $q := 1 - p$ and let Z be the Phase II repair cost on this column. If a maximal run of unselected points has length L, then the residual vertical segments inside this run are exactly the length-k intervals contained in the run, and the optimum one-dimensional repair cost is $\lfloor L/k \rfloor$: the lower bound comes from the disjoint length-k intervals in the run, and selecting every kth point attains it.

For $a \geq 1$, let N_a be the number of unselected runs in the column whose length is at least ak. Then $Z = \sum_{a=1}^{k} N_a$. A run of length at least ak starts in the first row with probability q^{ak}; it starts at any later row with probability pq^{ak}, requiring the previous row to be selected and the next ak rows to be unselected. Therefore, with $\alpha := q^k = (1 - 1/k)^k$,

$$\mathbb{E}[Z] = \sum_{a=1}^{k} \left(q^{ak} + (n - ak)pq^{ak}\right) = \sum_{a=1}^{k} (k - a + 1)\alpha^a \geq k\frac{\alpha(1-\alpha^k)}{1-\alpha} - \frac{\alpha}{(1-\alpha)^2},$$

using $\sum_{a=1}^{k}(a-1)\alpha^a \leq \sum_{a=1}^{\infty} a \cdot \alpha^a = \alpha/(1-\alpha)^2$. Now, there are k^2 columns each contributing $\mathbb{E}[Z]$ to the expected cost of Phase II and $\mathrm{OPT} = k^3$. Hence, the ratio of the expected cost of Phase II and OPT satisfies:

$$\frac{\alpha(1-\alpha^k)}{1-\alpha} - \frac{1}{k}\frac{\alpha}{(1-\alpha)^2} \leq \frac{\mathbb{E}[\text{cost(Phase II)}]}{\mathrm{OPT}} \leq \frac{1}{e-1}, \tag{1}$$

where the second inequality follows from our analysis of the unweighted case in Section 2.2. Now, as $k \to \infty$, we have $\alpha = (1 - 1/k)^k \to e^{-1}$, thus the left hand side of (1) tends to $e^{-1}/(1 - e^{-1}) = 1/(e - 1)$. Thus, the approximation factor $(1 + 1/(e - 1))$ obtained in the unweighted analysis is asymptotically tight for the algorithm.

2.4 Horizontal Segments and Vertical Lines

In this section, we show that the approximation factor can be improved when in one of the directions, we have lines instead of line segments.

▶ **Theorem 5** (Lines and Segments). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal line segments and vertical lines in the plane and let P be a set of points with a weight function $w : P \to \mathbb{R}_{\geq 0}$ such that each object in $\mathcal{S}$ contains at least one point of P. Then, there is a randomized $(1 + 1/e)$-approximation algorithm for the weighted Hitting Set problem defined by $\mathcal{S}$ and P.*

Proof. Each vertical line ℓ that is not hit by the Phase I points contributes $\min_{p\in\ell} w(p) \leq \sum_{p\in\ell} w(p)x_p$ to the Phase II cost, and each vertical line that is hit by the Phase I points contributes 0. Thus,

$$\mathbb{E}[\text{cost(Phase II)}] \leq \sum_{\ell\in\mathcal{V}} \mathbb{P}[\ell \text{ is not hit by Phase I}] \sum_{p\in\ell} w(p)x_p.$$

Now, since $\sum_{p\in\ell} x_p \geq 1$, we have that $\mathbb{P}[\ell \text{ is not hit by Phase I}] \leq \frac{1}{e}$, and hence the total expected cost of Phase II is upper bounded by $\frac{\text{LP}}{e}$. Thus, from Lemma 11, we get that the total expected cost is at most $(1 + 1/e)\text{LP}$. ◀

3 An Explicit Integrality-Gap Construction

In this section, we present an instance on which the integrality gap of the standard LP for the unweighted problem is 1.25.

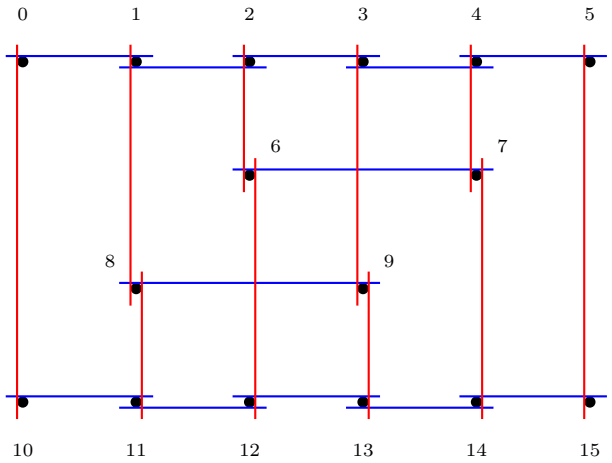

Figure 1 An integrality-gap instance for unweighted axis-parallel segment hitting. Segments are drawn with slight offsets for readability. The blue segments denote the horizontal segments $\mathcal{H}$, and the red segments denote the vertical segments $\mathcal{V}$.

Let $P = \{0, 1, \ldots, 15\}$ be the candidate points shown in Figure 1. Segments in the instance are formed by pairs of points that are on the same horizontal or vertical level, and have no other point on the segment connecting them. Thus, along the top chain we include every segment corresponding to consecutive pairs of points from $\{0, 1, 2, 3, 4, 5\}$, along the bottom chain every segment corresponding to consecutive pairs of points from $\{10, 11, 12, 13, 14, 15\}$, and so on.

▶ **Theorem 16.** *The instance of Figure 1 has integrality gap exactly 5/4 for the natural LP relaxation.*

Proof. Our hitting set instance is precisely an instance of vertex cover where the vertices are the points and for each segment, there is an edge between the vertices corresponding to the two points on the segment. Let G denote this graph. Set $x_p := 1/2$ for every point $p \in P$. Every segment in the construction contains at least two marked points, so this assignment is feasible. Hence the LP value is at most $\sum_{p\in P} x_p = 16 \cdot \frac{1}{2} = 8$.

In fact this bound is tight. The eight pairwise vertex-disjoint segments $\{0,1\}$, $\{2,3\}$, $\{4,5\}$, $\{6,7\}$, $\{8,9\}$, $\{10,11\}$, $\{12,13\}$, $\{14,15\}$ already force $\sum_{p\in P} x_p \geq 8$, so LP $= 8$. It remains to compute the optimum integral value. Since this is a vertex-cover instance,

$$\mathrm{OPT} = |V(G)| - \alpha(G) = 16 - \alpha(G),$$

where $\alpha(G)$ is the maximum independent-set size. The set $\{0,2,4,8,12,14\}$ is independent, so $\alpha(G) \geq 6$. For the reverse inequality, consider the 6-cycle $C = \{2,3,9,13,12,6\}$ and the two 5-cycles $L = \{0,1,8,11,10\}$ and $R = \{4,5,15,14,7\}$. Every independent set contains at most 3 vertices from C and at most 2 vertices from each of L and R. If an independent set I has $|I \cap C| \leq 2$, then immediately $|I| \leq 2+2+2 = 6$.

Suppose instead that $|I \cap C| = 3$. Then $I \cap C$ must be one of the two alternating triples $\{2,9,12\}$ or $\{3,6,13\}$. If I contains $\{2,9,12\}$, then the edges $(1,2)$, $(8,9)$, and $(11,12)$ exclude $1,8,11$ from the left 5-cycle. Only 0 and 10 remain available in L, and they are adjacent, so $|I \cap L| \leq 1$. Since $|I \cap R| \leq 2$, we get $|I| \leq 3+1+2 = 6$. The case of the other alternating triple ($\{3,6,13\}$) is symmetric.

Therefore $\alpha(G) = 6$, and hence OPT $= 16 - 6 = 10$. The integrality gap is

$$\frac{\mathrm{OPT}}{\mathrm{LP}} = \frac{10}{8} = \frac{5}{4}.$$

◀

4 Generalization to d orientations (weighted case)

Suppose segments are allowed to have d distinct orientations $\theta_1, \theta_2, \ldots, \theta_d$, and let $S^{(r)}$ denote the set of segments of orientation θ_r. The LP relaxation is unchanged:

$$\min \sum_{p\in P} w(p)x_p \qquad \text{s.t.} \sum_{p\in P\cap s} x_p \geq 1 \ \forall s \in \bigcup_{r=1}^{d} S^{(r)}, \quad 0 \leq x_p \leq 1.$$

Let x be an optimal LP solution with value LP.

Algorithm with a parameter k. Fix $k \in \{1,2,\ldots,d\}$ and call $\theta_1,\ldots,\theta_k$ the primary orientations. For every line of each primary orientation, independently run the same random-start systematic rounding used above, after rotating coordinates along that line. The output of the primary step is the union of all points selected by these k rounds. Therefore its expected cost is at most

$$\sum_{p\in P} w(p)\mathbb{P}[p \text{ is selected in at least one primary round}] \leq \sum_{p\in P} w(p) \sum_{t=1}^{k} x_p = k \cdot \mathrm{LP}.$$

All segments in the primary orientations are hit with probability one.

For every remaining orientation $r > k$, we then repair the residual one-dimensional instances on lines of orientation θ_r. These repairs may be performed independently for all remaining orientations and then unioned with the primary solution. This can only overcount the final cost, so it is enough to bound the sum of the repair costs orientation by orientation.

▶ **Lemma 17.** *Fix a remaining orientation θ_r and a point p on a line of orientation θ_r. Let A_p be the event that p survives the primary step and lies in a surviving block of LP mass at least 1 along that line. Then $\mathbb{P}[A_p] \leq (k+1)e^{-k}$.*

Proof. Fix a line ℓ of orientation θ_r and order its points along ℓ. In one primary orientation, a point i survives with probability $1 - x_i$; hence after all k primary rounds it survives with probability $(1 - x_i)^k$. Moreover, for any primary orientation θ_t and any two distinct points on ℓ, the two θ_t-lines through these points are distinct; otherwise a θ_t-line would meet ℓ in two points, forcing it to be ℓ, contrary to $\theta_t \neq \theta_r$. Thus the collections of primary-line shifts determining the survival of distinct points on ℓ are disjoint and independent, so the survival events of distinct points on ℓ are independent.

Now repeat the weighted-case block analysis from the proof of Lemma 12 with "survives the primary step" in place of "is unselected in Phase I". Let D_p be the LP mass of the maximal surviving run ending at p, and let U_p be the LP mass of the maximal surviving run immediately after p. If A_p occurs, then $D_p + U_p \geq 1$.

For any $t \geq 0$, the same suffix argument as in the proof of Lemma 12 gives

$$\mathbb{P}[D_p \geq t] \leq \prod_{i \in J}(1 - x_i)^k \leq \exp\left(-k \sum_{i \in J} x_i\right) \leq e^{-kt},$$

where J is a minimal consecutive suffix ending at p with LP mass at least t; if no such suffix exists, the probability is 0. Similarly, $\mathbb{P}[U_p \geq t] \leq e^{-kt}$, and D_p, U_p are independent. Thus D_p and U_p are stochastically dominated by independent exponential random variables E_1, E_2 of rate k. Therefore,

$$\mathbb{P}[A_p] \leq \mathbb{P}[D_p + U_p \geq 1] \leq \mathbb{P}[E_1 + E_2 \geq 1] = (k + 1)e^{-k},$$

where the second inequality follows from Lemma 13. ◀

Thus, we get that for each remaining orientation $r > k$,

$$\mathbb{E}[\text{repair cost for orientation } \theta_r] \leq \sum_{p \in P} x_p w(p) \mathbb{P}[A_p] \leq (k + 1)e^{-k}\text{LP}.$$

Summing over the $d - k$ remaining orientations and adding the primary cost yields

$$\mathbb{E}[\text{total cost}] \leq \left(k + (d - k)(k + 1)e^{-k}\right)\text{LP}. \tag{2}$$

▶ **Theorem 3** (d-Directions). *Let $\mathcal{S}$ be a set of segments, each parallel to one of d directions in the plane for some $d \geq 2$, and let P be a set of points with a weight function $w : P \to \mathbb{R}_{\geq 0}$ such that each segment in $\mathcal{S}$ contains at least one point of P. Then, there is a randomized algorithm that is a $(\ln d + \ln \ln d + O(1))$-approximation relative to the natural LP.*

Proof. Take $k = \min(d, \lceil \ln d + \ln \ln d \rceil)$. For large enough d, k equals $\lceil \ln d + \ln \ln d \rceil$, and thus $(d - k)(k + 1)e^{-k} = O(1)$, yielding the claimed approximation ratio when substituted in (2). ◀

We can further generalize this result to the case when each object to be hit is a union of up to h segments, each of which has one of d orientations.

▶ **Corollary 18.** *There exists a randomized algorithm that, given an instance of the weighted Hitting Set problem where each object is a union of at most h segments of d distinct orientations, computes a solution with an expected approximation factor of $h \cdot (\ln d + \ln \ln d + O(1))$ relative to the natural LP.*

Proof. Let x be a feasible solution to the natural LP. Since each object O is a union of at most h segments, the LP constraint $\sum_{p\in O} x_p \geq 1$ implies there is some segment $s \subseteq O$ such that $\sum_{p\in s} x_p \geq 1/h$. Choose one such segment for each object, and define $y_p := \min\{1, hx_p\}$. Then $0 \leq y_p \leq 1$, $\sum_p w(p)y_p \leq h \cdot \mathrm{LP}$, and for every chosen segment s we have $\sum_{p\in s} y_p \geq 1$: if some $p \in s$ has $hx_p \geq 1$ this is immediate, and otherwise $\sum_{p\in s} y_p = h\sum_{p\in s} x_p \geq 1$. Thus y is feasible for the chosen segment instance, and hitting these chosen segments hits every original object. Running the algorithm for d orientations on y yields the claimed expected approximation factor. ◀

5 Local Search PTASes for k-restricted instances

In this section, we show that if we restrict the input so that each segment intersects segments of the opposite orientation lying on at most k-distinct lines, then we obtain a PTAS for the unweighted Hitting Set problem. The results of Raman and Ray [32] only work if the objects are non-piercing. While Banik et al. [6] works for the case where each object has a bounded amount of piercing, their results only work for the Set Cover and Independent Set problems. The restriction on the number of such intersections is essential, as otherwise, as Section 6 shows, the problem is APX-hard.

▶ **Definition 19.** *A family $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ of axis-parallel segments is* k-restricted *if every segment in $\mathcal{H}$ intersects segments of $\mathcal{V}$ lying on at most k parallel lines, and every segment in $\mathcal{V}$ intersects segments of $\mathcal{H}$ lying on at most k parallel lines.*

Observe that in a k-restricted instance, a segment can intersect an unbounded number of segments of the opposite orientation. The only restriction is that these segments lie on at most k distinct parallel lines.

The local-search algorithm is standard. Fix an integer parameter t. Starting from any feasible hitting set, repeatedly replace at most t objects of the current solution by a strictly smaller feasible set, as long as such an improving swap exists. For fixed t, this process terminates in polynomial time. The key issue is to prove that a t-locally optimal solution is globally near-optimal when $t = t(\varepsilon)$ is chosen large enough [32, 4, 13, 28].

The analysis relies on showing the existence of a suitable *exchange graph* $G = (L \cup O, E)$ on a locally optimal solution L and an optimal solution O. This exchange graph has two properties: the *local property* that for any $L' \subseteq L$, $(L' \setminus L) \cup N_G(L')$ is also a hitting set for $\mathcal{S}$, where $N_G(L')$ are the neighbors of L' in the exchange graph G, and the *separator property* that G comes from a hereditary family $\mathcal{G}$ of graphs with sub-linear size separators. That is, there is an absolute constant $\epsilon > 0$ such that any graph $H \in \mathcal{G}$ has a separator of size $O(|V(H)|^{1-\epsilon})$[4].

Given two disjoint hitting sets R and B for a set $\mathcal{S}$ of axis-parallel segments, we show the existence of a suitable exchange graph. A PTAS then follows by standard arguments.

▶ **Lemma 20.** *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of k-restricted horizontal and vertical segments and let R and B be two disjoint hitting sets for the segments $\mathcal{S}$. Then, there is a local-exchange graph $G = (R \cup B, E)$ that satisfies the local exchange and the separator properties.*

[4] A balanced separator, or just a separator for a graph $G = (V, E)$ is a subset $S \subseteq V$ of vertices whose removal partitions the graph such that no resulting connected component contains more than $\alpha|V|$ vertices, where $\alpha < 1$ is a fixed constant, typically $1/2$ or $2/3$. A graph admits a sub-linear separator if there exists an absolute constant $\epsilon > 0$ such that $|S| = O(|V|^{1-\epsilon})$.

Proof. The graph $G = (R \cup B, E)$ is constructed as follows. Starting with the empty graph on $R \cup B$, for each segment $s \in \mathcal{S}$, let R_s and B_s denote respectively, the points of R in s and the points of B in s. Suppose no point in R_s is adjacent to a point in B_s, we choose an arbitrary pair of points, one in R_s and the other in B_s that are consecutive along s and add the edge $\{r, b\}$ to G as a straight-line segment along s. We claim that G is the desired local-exchange graph. We say that the points r and s are *responsible* for hitting s.

Let $R' \subseteq R$. We claim that $T = (R \setminus R') \cup N_G(R')$ is a hitting set. Indeed, for a segment s, if the vertex r responsible for hitting s is not selected in R', then s is still hit by a point in the set T. If not, since the vertex $b \in B$ responsible for hitting s is adjacent to r, it implies that s is hit by b. Therefore, G satisfies the local-exchange property.

Consider the natural embedding of G in the plane, where the edges are drawn as straight-line segments between the points. By construction, each edge in G is only intersected by edges of the opposite orientation. Since any edge lies along a segment, and the instance is k-restricted, it implies that each edge of G is crossed by at most k other edges. That is G is a *k-planar graph*[5]. k-planar graphs form a hereditary family as removing vertices leaves the induced graph k-planar.

Since k-planar graphs have $O(\sqrt{k}n)$ edges [30], where $n = |R| + |B|$ and any two segments intersect in at most one point we obtain a plane graph H with $O(k^{3/2}n)$ vertices, by splitting each pair of crossing edges by adding a new *splitting vertex* at their intersection point. We assign a weight of 1 to each vertex of G and a weight of 0 to each splitting vertex. By the Planar Separator Theorem [23], there is a balanced separator S of H of size $O(\sqrt{|V(H)|}$ such that both sides of the partition has weight at most 2/3 the total weight of the vertices in H. To obtain a separator in G, for each vertex in S, if a splitting vertex s lies in S, we add the four end-points corresponding to the pair of crossing edges defined by s. The resulting set S' is a balanced separator in G, and has size $O(|S|)$. Therefore, we obtain a sub-linear sized separator in G. ◀

▶ **Theorem 8** (k-restricted). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal and vertical line segments in the plane such that each segment intersects segments of the opposite orientation lying on at most k parallel lines. Let P be a set of points such that each segment in $\mathcal{S}$ contains at least one point of P. Then, there is a PTAS for the Hitting Set problem with $\mathcal{S}$ and P.*

Proof sketch. Let L be a t-locally optimal Hitting Set and let O be an optimal Hitting Set. We can assume that $L \cap O = \emptyset$, as otherwise, we can remove the points in $L \cap O$ and the segments hit by them, and consider the residual instance. This can only improve the approximation factor. By Lemma 20, there is an exchange graph satisfying the local-exchange property. Now, a PTAS follows directly via the techniques in [28]. ◀

6 APX-hardness

The proof of the following theorem is based on the proof of APX-hardness of Minimum Hitting Set for orthogonal segments by Fekete et al. [17]. Fekete et al. show NP-hardness for the *piercing problem*, i.e., when we are allowed to choose any point in $\mathbb{R}^2$ to hit the segments. On the other hand, we show that if P is restricted to a discrete set, the problem becomes APX-hard.

[5] A graph is k-planar if it has an embedding in the plane such that each edge is crossed by at most k other edges

▶ **Theorem 6** (APX-Hardness). *Let $\mathcal{S} = \mathcal{H} \cup \mathcal{V}$ be a set of horizontal line segments and vertical lines in the plane and P be a finite set of points in the plane such that each object in $\mathcal{S}$ contains at least one point of P. The Hitting Set problem with $\mathcal{S}$ and P is APX-hard.*

Proof. We give an approximation-preserving reduction from Max-2SAT(3), the maximum satisfiability problem for CNF formulae with two literals per clause, in which each variable appears in at most three clauses. This problem is APX-hard [21].

Let Φ be an instance of Max-2SAT(3) with variables $x_1, \ldots, x_n$ and clauses $C_1, \ldots, C_m$. We may assume that every variable appears in at least one clause; isolated variables can be deleted. Since each clause contains two literals, the total number of literal occurrences is $2m$; therefore, $n \leq 2m$.

Let OPT denote the maximum number of clauses of Φ that can be satisfied. Also, since a uniformly random truth assignment satisfies each 2-literal-clause with probability at least $1/2$, we have $\text{OPT} \geq \frac{m}{2}$.

We construct an instance of Minimum Hitting Set as follows. For each variable x_i, let $d_i \in \{1, 2, 3\}$ be the number of occurrences of x_i in Φ. We construct a variable gadget G_i consisting of $2d_i + 4$ geometric objects: $2d_i + 2$ horizontal segments and two vertical lines. For each variable x_i, there is vertical line L_i at the left end and there is a vertical line R_i at the right end. These objects are arranged so that their intersection graph is an even cycle of length $2d_i + 4$, and no point intersects three objects of the variable gadget. Equivalently, the only points that hit two objects of G_i are the consecutive intersections along this cycle. Refer to Figure 2.

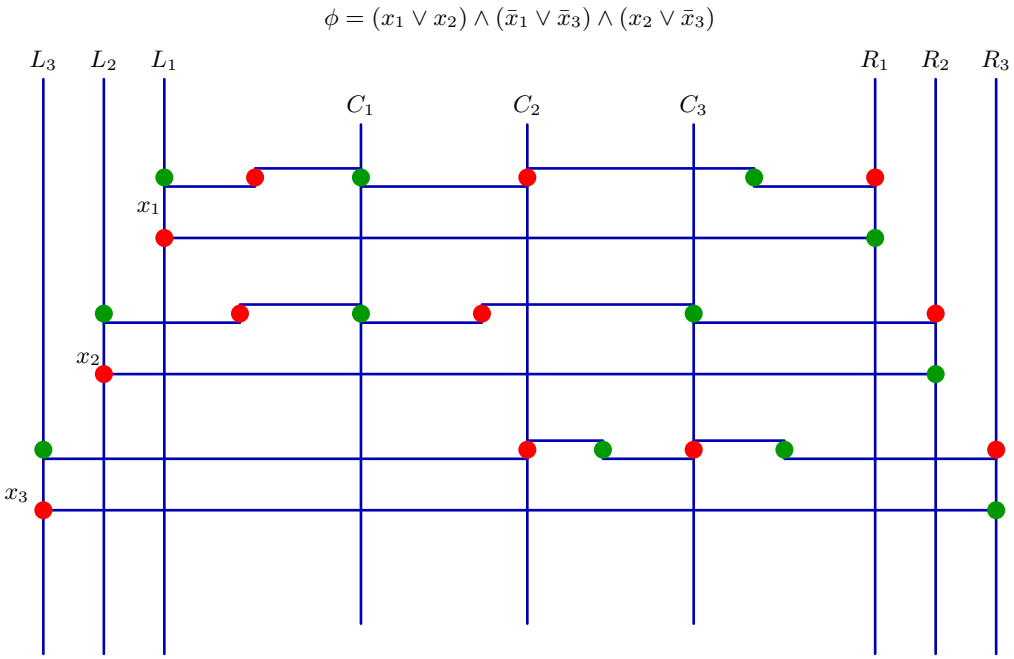

Figure 2 A hitting-set instance corresponding to $\phi = (x_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{x}_3) \wedge (x_2 \vee \bar{x}_3)$.

Color the consecutive intersection points of this cycle alternately red and green. Since G_i has $2d_i + 4$ objects and every point hits at most two objects of G_i, any hitting set for G_i has size at least $b_i := d_i + 2$.

Moreover, in a hitting set of size exactly b_i, every selected point must lie at an intersection of two consecutive objects of G_i. Therefore, it corresponds to a perfect matching of the cycle. Thus there are exactly two canonical optimum hitting sets for G_i: the set of all red points and the set of all green points. We interpret the green solution as setting $x_i = \text{true}$ and the red solution as setting $x_i = \text{false}$.

For each clause C_j, introduce a vertical line ℓ_j. If the literal x_i occurs in C_j, we make ℓ_j pass through the green point of G_i reserved for this occurrence. If the literal $\overline{x_i}$ occurs in C_j, we make ℓ_j pass through the corresponding red point of G_i. The lines and input points are placed such that these are the only points at which a clause line passes through. Thus, each clause line passes through exactly two input points. Let $B := \sum_{i=1}^{n} b_i$. Since $\sum_i d_i = 2m$, we get $B = 6m$.

We first relate satisfying assignments to hitting sets. Given an optimal truth assignment satisfying OPT clauses, choose in each variable gadget the canonical red or green hitting set corresponding to the truth value of the variable. This uses exactly B points. Every satisfied clause line is hit at the corresponding literal point. Each unsatisfied clause line can be hit by one additional point placed anywhere on that line. Therefore, if k denotes the optimum solution size of the constructed hitting-set instance, then $k \leq B + (m - \text{OPT})$. In particular, $k \leq B + m \leq 7m$.

Conversely, let H be any hitting set for the constructed instance. We normalize H without increasing its cardinality. Consider a variable gadget G_i. Since G_i has $2b_i$ objects and no point hits more than two objects of G_i, the points of H used to hit objects of G_i have cardinality at least b_i.

If the selected points of H for the variable gadget G_i are consistent, that is, all are red or all are green, then we replace the points of H used inside G_i by the corresponding canonical optimum set of b_i red or green points. This does not increase the number of points.

If the selected literal points are inconsistent, then H uses literal points of both colors. Since the two canonical solutions are the only size-b_i hitting sets for G_i, the portion of H used for G_i has size at least $b_i + 1$. We replace it by one canonical optimum set of size b_i, choosing the majority color among the selected literal points. Since $d_i \leq 3$, at most one clause line that was previously hit through a minority-colored literal point becomes unhit. We use the one saved point to hit that clause line separately. Again, the total number of points does not increase.

Applying this operation independently to all variable gadgets, we obtain a hitting set of the form $H_v \cup H_c$, with $|H_v| = B$ and $|H_v| + |H_c| \leq |H|$.

The set H_v is canonical in every variable gadget, and hence defines a truth assignment. The set H_c consists of additional points placed on clause lines. Every clause not satisfied by the assignment induced by H_v must be hit by a point of H_c. Therefore, if alg is the number of clauses satisfied by the induced assignment, then

$$\text{alg} \geq m - |H_c|.$$

Now suppose there is a polynomial-time $(1+\varepsilon)$-approximation algorithm for the hitting-set problem on horizontal segments and vertical lines. Applied to the constructed instance, it returns a hitting set H with $|H| \leq (1+\varepsilon)k$, and after the normalization above, $|H_c| \leq |H| - B \leq (1+\varepsilon)k - B$. Hence,

$$\text{alg} \geq m - |H_c| \quad \geq m - (1+\varepsilon)k + B = (m + B - k) - \varepsilon k.$$

Since $k \leq B + (m - \text{OPT})$, we have $m + B - k \geq \text{OPT}$, Thus, $\text{alg} \geq \text{OPT} - \varepsilon k$. Using $k \leq 7m$ and $\text{OPT} \geq m/2$, we obtain

$$\varepsilon k \leq 7\varepsilon m \leq 14\text{OPT}.$$

Therefore,

$$\text{alg} \geq (1 - 14\varepsilon)\,\text{OPT}.$$

Consequently, a PTAS for minimum hitting set with horizontal segments and vertical lines would imply a PTAS for Max-2SAT(3), contradicting its APX-hardness. Hence the hitting-set problem for horizontal segments and vertical lines is APX-hard. ◀

7 Discrete 3-Slope Line Cover is APX-hard

Discrete 3-Slope-Line-Cover (3SLC) refers to the problem of computing a minimum-cardinality hitting set for a set $\mathcal{S}$ of lines having three distinct slopes with a subset of a given set P of points. In this section, we prove that this problem is APX-hard [17].

▶ **Definition 21.** *(L-reduction) [11] A pair of functions f and g, both computable in polynomial time, is an L-reduction from an optimization problem $\mathcal{P}$ to an optimization problem $\mathcal{P}'$ if there are positive constants α and β such that for each instance x of $\mathcal{P}$, the following hold:*

- *(L1) The function f maps instances of $\mathcal{P}$ to instances of $\mathcal{P}'$ such that $OPT(f(x)) \leq \alpha \cdot OPT(x)$.*
- *(L2) The function g maps feasible solutions y of $f(x)$ to feasible solutions $g(y)$ of x such that $|c_x(g(y)) - OPT(x)| \leq \beta.|c_{f(x)}(y) - OPT(f(x))|$, where c_x and $c_{f(x)}$ are the cost functions of the instances x and $f(x)$ respectively.*

▶ **Theorem 7** (3-Line-APX-hardness). *Let $\mathcal{S} = \mathcal{X} \cup \mathcal{Y} \cup \mathcal{Z}$ be three sets of lines such that lines in the plane in each set $\mathcal{X}, \mathcal{Y}$ and $\mathcal{Z}$ are parallel. Let P be a set of points such that each line contains at least one point. The Hitting Set problem defined by $\mathcal{S}$ and P is APX-hard.*

Proof. We give an L-reduction from Special-3SC, which is APX-hard [11]. Recall that an instance of Special-3SC is obtained from a cubic graph $G = (V, E)$. For every vertex $v_t \in V$, there are four elements w_t, x_t, y_t, z_t, and for every edge $e_i \in E$, there is an element a_i. If the three edges incident to v_t are e_i, e_j, e_k, with $i < j < k$, then the instance contains the five sets $\{w_t, a_i\}, \{w_t, x_t\}, \{x_t, y_t, a_j\}, \{y_t, z_t\}, \{z_t, a_k\}$. Moreover, every element a_i belongs to exactly two sets.

We first construct an equivalent finite discrete 3SLC instance in the dual plane. Let L_1, L_2, L_3 be three vertical lines, from left to right. We place the elements w_t, y_t on L_1, the elements x_t, z_t on L_2, and the elements a_i on L_3. The placement is chosen so that, for each v_t with incident edges e_i, e_j, e_k, $i < j < k$, there are five non-vertical candidate lines whose intersections with the constructed point set are exactly

$$\{w_t, a_i\}, \quad \{w_t, x_t\}, \quad \{x_t, y_t, a_j\}, \quad \{y_t, z_t\}, \quad \{z_t, a_k\}.$$

We briefly justify that such a placement can be found in polynomial time. Put the edge points $a_1, \ldots, a_n$ on L_3 in this order. For each vertex v_t, reserve two small open intervals $I_t^1 \subset L_1$ and $I_t^2 \subset L_2$, with these intervals pairwise disjoint over different vertices, such that every line joining a point of I_t^1 to an edge point a_r meets L_2 inside I_t^2. Such intervals are obtained, for example, by taking disjoint thin vertical cross-sections of triangles with common base on L_3.

Now choose $y_t \in I_t^1$ and let x_t be the intersection of $\overline{y_t a_j}$ with L_2. Choose $w_t \in I_t^1$ and $z_t \in I_t^2$. At each step, the forbidden choices are only those causing one of the five intended candidate lines to pass through an unintended point. There are finitely many such forbidden positions. Hence we can choose rational points avoiding all of them. See Figure 3.

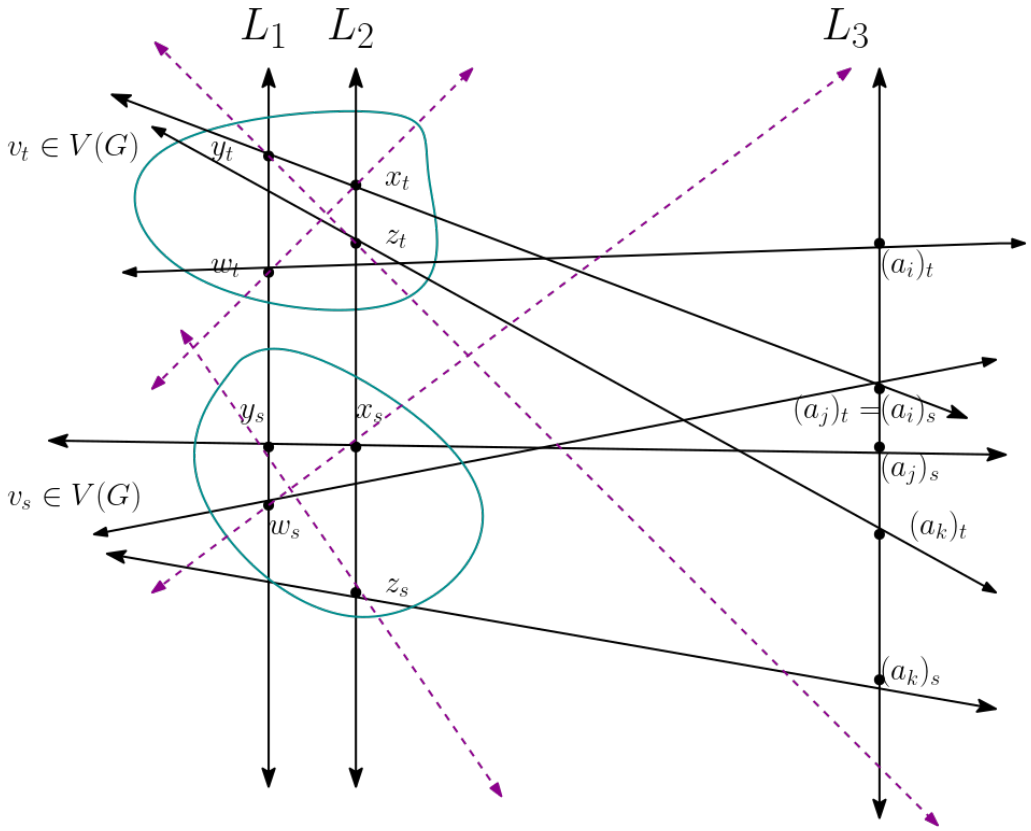

Figure 3 Two vertex gadgets for $v_s, v_t \in V$ in the dual construction, where $(v_s, v_t) \in E$. For each vertex v_t incident to edges e_i, e_j, e_k, $i < j < k$, the points w_t, y_t lie on L_1 and x_t, z_t lie on L_2. The three solid lines encode the sets $\{w_t, a_i\}$, $\{x_t, y_t, a_j\}$, and $\{z_t, a_k\}$; the dashed magenta lines encode the non-edge sets $\{w_t, x_t\}$ and $\{y_t, z_t\}$.

It follows that the constructed dual finite line-cover instance has exactly the same set system as the Special-3SC instance: selecting a candidate line is equivalent to selecting the corresponding set, and a subfamily covers all points if and only if the corresponding sets cover the universe. Therefore

$$\mathrm{OPT}_{\mathrm{dual}} = \mathrm{OPT}_{\mathrm{SC}},$$

where $\mathrm{OPT}_{\mathrm{dual}}$ denotes the optimal solution value for the dual line-cover instance and $\mathrm{OPT}_{\mathrm{SC}}$ denotes the optimal solution value for the Special-3SC instance.

It remains to pass from this dual finite line-cover instance to Discrete 3-Slope-Line-Cover. We use the standard point-line duality

$$p = (p_x, p_y) \longleftrightarrow p^* : b = p_x a - p_y,$$

and

$$\ell : y = ax - b \longleftrightarrow \ell^* = (a, b),$$

which preserves incidences. The three vertical lines L_1, L_2, L_3 in the dual plane become three slopes in the primal plane. The dual points become the input lines S, and the dual candidate lines become the finite candidate point set P. Hence we obtain an instance of Discrete

3-Slope Line Cover. Since incidence and cardinality are preserved, feasible covers in the dual line-cover instance are in one-to-one correspondence with feasible hitting sets in the resulting Discrete 3-Slope-Line-Cover instance.

Thus, for the reduction f,

$$\mathrm{OPT}_{\mathrm{3SLC}}(f(I)) = \mathrm{OPT}_{\mathrm{SC}}(I),$$

so condition (L1) of an L-reduction holds with $\alpha = 1$. Given any feasible solution to $f(I)$, mapping each selected point back by duality gives the corresponding selected set of the Special-3SC instance, with the same cardinality. Therefore

$$|c_{\mathrm{SC}}(g(Y)) - \mathrm{OPT}_{\mathrm{SC}}(I)| = |c_{\mathrm{3SLC}}(Y) - \mathrm{OPT}_{\mathrm{3SLC}}(f(I))|\,,$$

so condition (L2) holds with $\beta = 1$. The construction is polynomial-time computable. Hence Discrete 3-Slope-Line-Cover is APX-hard. ◀

8 Conclusion

We gave a short LP-rounding framework for hitting axis-parallel segments with weighted points. The algorithm improves the immediate factor-2 bound by rounding one orientation exactly and repairing the residual subproblem on the other orientation using exact one-dimensional optimization. This yields a deterministic $(1+2/e)$-approximation for the weighted problem and a deterministic $(1 + 1/(e-1))$-approximation in the unweighted case. For bounded-complexity subclasses, local search yields a PTAS for the Hitting Set problem, and we also extend our results for segments in d orientations.

Two natural directions remain open. First, it would be interesting to determine whether the analysis can be strengthened further, or whether these bounds are close to the true integrality behavior of the natural LP. For the Set Cover and Independent Set problems, the best known approximation is the straightforward factor-2 bound. The integrality gap of the natural LP-formulation for Independent Set was shown to be 2 [9]. Hence, breaking the factor-2 for the independent set problem cannot go via rounding the natural LP and new ideas are required. Finally, the approach suggests exploring whether similar one-orientation-first rounding schemes can be extended to richer families such as thin rectangles.

Abstract

We study *length-constrained* generalizations of Directed Steiner Tree (DST) and Directed Steiner Forest (DSF) in planar digraphs. In both problems, the input is a directed graph with edge costs. DST asks for a min-cost subgraph connecting a root to a given set of terminals, and DSF asks for a min-cost subgraph connecting each of a given set of source-sink terminal pairs. In the length-constrained setting, each edge has both a cost and a length, and the input includes a length bound h; the goal is to find a min-cost subgraph connecting each terminal pair via a path of length at most h. Our work is motivated by a recent line of results showing that several network design problems that are traditionally hard in directed graphs admit polylogarithmic approximation ratios in planar digraphs. We give polylogarithmic bicriteria approximation algorithms for length-constrained analogues of DST and DSF in planar digraphs. Our approximation ratios match the best known for DST and DSF in planar digraphs, with an $O(\log k)$ violation of the length constraint, where k denotes the number of terminals (or terminal pairs). As corollaries, we obtain polylogarithmic approximations for *buy-at-bulk* DST and DSF in planar digraphs.

1 Introduction

Directed Steiner Tree (DST) and *Directed Steiner Forest* (DSF) are fundamental problems in network design with a wide array of applications. For both problems, the input consists of a directed graph $G = (V, E)$ with edge costs $c : E \to \mathbb{R}_+$. In Directed Steiner Tree, given a root $s \in V$ and terminals $S \subseteq V \setminus \{s\}$, the goal is to find a min-cost subgraph containing an s-t path for each $t \in S$. Directed Steiner Forest generalizes DST to the *multicommodity* setting: given a set of demand pairs $D = \{(s_i, t_i)\}_{i \in [k]}$, the goal is to find a min-cost subgraph containing an s_i-t_i path for each $i \in [k]$.

DST and DSF are NP-hard, and in fact have strong lower bounds on their approximability. DST generalizes several hard problems in combinatorial optimization, such as Set Cover and Group Steiner Tree. It is hard to approximate to an $\Omega(\log^2 k / \log \log k)$-factor under plausible complexity assumptions [33], and to a slightly weaker $\Omega(\log^{2-\epsilon} k)$-factor unless

NP is contained in randomized quasi-poly time [37]; here, k denotes $|S|$. The best known approximation ratios are $O(\log^2 k/\log\log k)$ in *quasi-polynomial* time [33, 31, 10] and $O(k^\epsilon)$ for any fixed $\epsilon > 0$ in polynomial time [60]. Whether DST admits a polylogarithmic approximation in polynomial time is a major open question. We remark that the natural LP relaxation for DST has polynomial-factor integrality gap [61, 51]; this is one reason that developing improved approximations for DST has proven challenging. DSF is hard to approximate to a factor $\Omega(2^{\log^{1-\epsilon}(n)})$ for any $\epsilon > 0$ and thus does not admit a polylogarithmic approximation [24]. The best known approximation ratios are $O(k^{\frac{1}{2}+\epsilon})$ [12] and $O(n^{2/3+\epsilon})$ [7]. An exciting recent line of work has shown that many problems that are hard to approximate in general directed graphs are tractable when the input graph is *planar* [45, 29, 17, 14]. In planar digraphs, DST admits an $O(\log k)$-approximation [29], a natural LP relaxation has integrality gap $O(\log^2 k)$ [17], and DSF admits an $O(\log^6 k)$-approximation [14].

In this paper, we consider a generalization of DST and DSF to the *length-constrained* setting. As the name suggests, these impose an additional constraint on the length of paths used to connect terminal pairs. Formally, in *Length-Constrained Directed Steiner Tree* (LC-DST) and *Length-Constrained Directed Steiner Forest* (LC-DSF), we are given an additional *length* function on the edges $\ell : E \to \mathbb{R}_+$ and a length constraint h; the goal is to find a min-cost subgraph in which terminal pairs are connected via a path of length at most h. There are several practical reasons why connectivity alone may not suffice: short paths are desirable for faster transportation and communication, improved tolerance to failure, and more. Furthermore, length-constrained network design is closely related to several other important problems in combinatorial optimization. For instance, *buy-at-bulk* network design (closely related to cost-distance and other problems) is a well-studied and practical model which places a penalty on the path lengths in the objective function instead of imposing strict bounds on path lengths. Progress in length-constrained network design has led to the resolution of several open problems in buy-at-bulk network design [13, 16]. As a result of its practical and theoretical importance, length-constrained network design has been very well studied; see Section 1.3 for details.

In undirected graphs, adding length constraints to problems adds significant complexity to a problem. As an example, consider the minimum spanning tree problem; this is easily solvable in polynomial time. However, the length-constrained minimum spanning tree problem is essentially equivalent in approximability to DST (see [39] for a formal reduction). A common way to handle this difficulty is by relaxing the length constraint, allowing for some slack in both the length and the cost (see Definition 1). In directed graphs, on the other hand, length constraints do not add inherent complexity. A simple reduction shows that LC-DST is equivalent to DST, as shown in Figure 1,[1] and one can define a similar reduction from LC-DSF to DSF. However, these reductions do not preserve planarity. Given the fruitful progress on network design problems in planar digraphs, it is natural to ask if LC-DST and LC-DSF admit polylogarithmic approximations in planar digraphs. We answer these questions affirmatively.

1.1 Our Results

We obtain polylogarithmic *bicriteria* approximation algorithms for LC-DST and LC-DSF in planar digraphs.

[1] For polynomial edge lengths one can replace each edge e with a path of length $\ell(e)$. For larger edge lengths, one can obtain a similar reduction losing a $(1+\epsilon)$ factor in length slack.

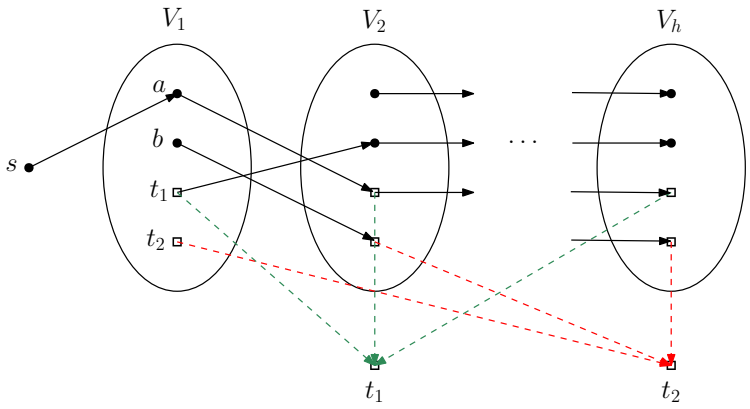

Figure 1 This example assumes all edge lengths are 1. Suppose the input graph is a path s, a, t_1, b, t_2 with terminals t_1, t_2. We create h copies of the vertex set $V_1, \ldots, V_h$, and for every $(u, v) \in E$ and all $i < h$, we add an edge from the copy of u in V_i to that of v in V_{i+1}. The terminals in the resulting DST instance are given at the bottom of the figure.

▶ **Definition 1.** *An (α, β)-bicriteria approximation for a length constrained network design problem with length constraint h is a solution $F \subseteq E$ in which all demand pairs are connected via a path of length at most $\beta \cdot h$, and $c(F) \leq \alpha \cdot \mathrm{OPT}$, where* OPT *is the cost of an optimal solution. We refer to α as the* approximation ratio *and β as the* length slack*.*

The approximation factors for all of our results match the best known ratios for DST and DSF in planar digraphs without length constraints; all algorithms incur an $O(\log k)$ factor in the length slack. We remark that this $O(\log k)$ length slack factor is essentially the best known for many problems in length-constrained network design when one seeks a polylogarithmic approximation ratio, including length-constrained MST in undirected graphs. There are known algorithms for length-constrained MST with polynomial approximation ratio that do not lose any length slack. Reducing the length slack to $O(1)$ while ensuring polylogarithmic approximation ratio is an enticing research direction with some partial progress discussed further in Section 1.3. We highlight one such recent work: in undirected planar graphs, [39] obtains an $O(\log^{1+\epsilon}(n))$-approximation with $(1+\epsilon)$ length slack. However, it is unknown if this approach would extend to the directed setting, and there appear to be several challenges.

We first consider length-constrained Directed Steiner Tree. An approximation algorithm is *LP-competitive* if the cost of the given solution is at most α times the value of an optimum *fractional* solution to a natural LP relaxation. We describe an LP relaxation to LC-DST in Section 3. We obtain two algorithms: the first (Theorem 2) is with respect to the optimum integral solution, and the second (Theorem 3) is LP-competitive.

▶ **Theorem 2.** *There is a bicriteria $(O(\log k), O(\log k))$-approximation for LC-DST in planar digraphs.*

▶ **Theorem 3.** *There is a bicriteria $(O(\log^2 k), O(\log k))$ LP-competitive approximation for LC-DST in planar digraphs.*

Next, we consider length-constrained Directed Steiner Forest. Note that Theorem 4 provides an approximation algorithm with respect to the optimum integral solution; obtaining an LP-competitive approximation remains open. We note that an LP-competitive approximation for planar DSF is not known even without length constraints.

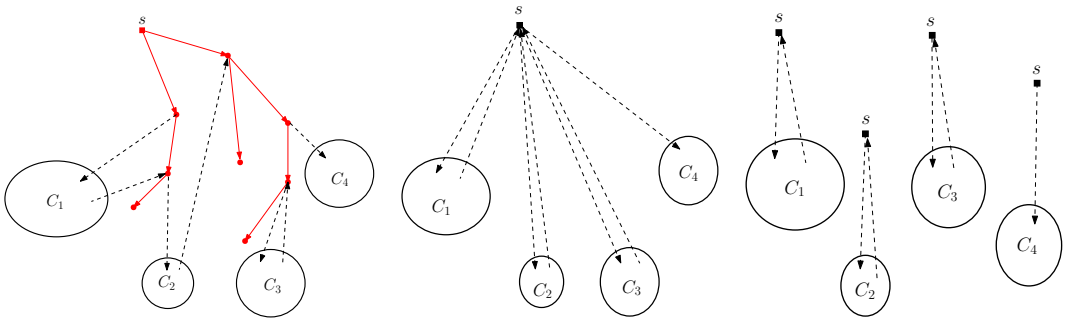
▶ **Theorem 4.** *There is a bicriteria $(O(\log^6 k), O(\log k))$-approximation for Length-Constrained Directed Steiner Forest in planar digraphs.*

1.1.1 Extensions

We mention two further extensions of our work. Details and formal theorem statements are omitted as they are technically involved and require new machinery, see [41] for details.

Buy-at-bulk network design. As mentioned earlier, there are known connections between buy-at-bulk and length-constrained network design problems. Prior work in *undirected* graphs [13, 16] demonstrated an LP-based reduction from a buy-at-bulk problem to its corresponding length-constrained problem. The resulting approximation ratio for the buy-at-bulk problem depends on both the approximation and length slack of the algorithm for the length-constrained problem. These arguments extend to directed graphs; thus, one can obtain a polylogarithmic approximation for buy-at-bulk DST in planar digraphs as a corollary of Theorem 3. In the multicommodity setting, more effort is needed, since Theorem 4 does not yield an LP-competitive solution. Nevertheless, one can obtain a polylogarithmic approximation for buy-at-bulk DSF in planar digraphs by arguing that there exists a low-density *junction tree*. Similar arguments have been used in [11, 4, 13].

Group, Covering, and Polymatroid Steiner Tree. Chekuri et al. [17] developed polylogarithmic approximation algorithms for several rooted generalizations of Directed Steiner Tree in planar digraphs. This includes the *Directed Polymatroid Steiner Tree* problem, where a polymatroid is defined on the vertex set, and a feasible tree is required to span a base of the polymatroid. A polymatroid is an integer-valued, normalized, monotone, submodular function. This generalizes several important network design problems, including Group and Covering Steiner Tree. At a high level, the algorithm of [17] explicitly constructs the recursion tree of the divide-and-conquer algorithm of [29]. One can view this recursion tree as a "tree embedding" suitable for solving rooted problems, allowing one to reduce to solving the problem on a tree. One can similarly construct a "tree embedding" that respects length constraints, based on the divide-and-conquer algorithm of Theorem 2. Thus, one can obtain polylogarithmic approximations for length-constrained rooted variants of directed polymatroid, covering, and group problems.



1.2 Technical Overview

The proofs of Theorem 2 and Theorem 3 on LC-DST adapt established ideas to the length-constrained setting. The main novel contribution of this work is Theorem 4 on LC-DSF, as the previous approach for DSF in planar digraphs fails to extend. We outline the ideas for all three algorithms here.

Approximation for DST in planar digraphs. We start by giving an overview of the divide-and-conquer $O(\log k)$-approximation given by Friggstad and Mousavi [29]. The algorithm uses Thorup's shortest path separator theorem applied to directed graphs:

▶ **Lemma 5** ([29, 58]). *Let G be a planar directed graph with non-negative edge costs $c(e)$, non-negative vertex weights $w(v)$, and a root $s \in V$ such that every vertex in V is reachable from s. There exists a polynomial time algorithm to find three shortest dipaths P_1, P_2, P_3 starting at s such that every weakly connected component of $G \setminus (P_1 \cup P_2 \cup P_3)$ has at most half the vertex weight of G.*

The high-level idea in [29] is simple; see Figure 2. Suppose we can guess the optimum solution value OPT for a given DST instance. Then, we can remove all vertices farther than OPT from s and use Lemma 5 to find three paths, each of cost at most OPT, whose

(a) Step 1. **(b)** Step 2. **(c)** Step 3.

Figure 2 High-level overview of the divide-and-conquer algorithm. In Step 1, we compute the planar separator (shown in red). Step 2 demonstrates contracting the separator into the root, and Step 3 demonstrates the resulting independent sub-instances.

removal results in connected components each containing at most half the terminals. We shrink the paths into s and recurse on the resulting sub-instances. The recursion depth is $O(\log k)$, which bounds the total cost to $O(\log k) \cdot \mathrm{OPT}$. Implementing the guess of OPT in each recursive call is challenging; naively guessing requires quasipolynomial time. [29] obtain a polynomial time algorithm by a refined argument where the guess for OPT is folded into the recursion itself.

Handling Length-Constraints and Bounding Integrality Gap. The main challenge in using the approach of [29] in *length-constrained* Directed Steiner Tree lies in defining the shortest path tree on which to apply the planar separator result. Ideally, one would like for the tree to capture length-constrained distances, where the h-length-constrained distance from u to v is the min-cost over all u-v paths of length at most h. Unfortunately, length-constrained distances do not form a metric, so one cannot use a standard shortest path tree. To circumvent this issue, we use the well-known "mixture-metric", which balances length constraints and costs. This suffices to obtain Theorem 2. We remark that recent work of [39] on length-constrained MST in *undirected planar graphs* also uses the mixture-metric to apply the separator lemma. To prove Theorem 3, we use an idea introduced in [17], which uses the LP optimum value as the estimate for OPT instead of guessing. The algorithm of [17] extends to the length-constrained setting with the mixture-metric in a similar fashion.

Directed Steiner Forest via Junction Trees. To tackle the multicommodity setting, we build on the *junction tree* based algorithm of [14] for planar DSF. At a high level, junction trees allow one to reduce a multicommodity problem to its single-source counterpart. This technique has been used in a variety of network design problems; it was first explicitly described in the context of non-uniform buy-at-bulk network design [36, 11], though it was implicitly used earlier for Directed Steiner Forest in [10]. The idea is to repeatedly find well-structured *low-density partial solutions*, where a partial solution is feasible for a subset of terminal pairs, and the density is the ratio of cost to the number of terminal pairs connected. Using a standard iterative approach for covering problems, one can reduce a multicommodity problem to its corresponding min-density partial solution problem, losing an $O(\log k)$ factor in the approximation ratio. We aim to find partial solutions that contain a "junction" vertex $v \in V$ through which many pairs connect. This allows us to view the problem as a single-source problem with source v. The approximation for DSF in planar

digraphs of [14] consists of two steps: (1) proving the existence of a low-density junction tree, and (2) efficiently finding an approximate min-density junction tree. The second step uses a bucketing-and-scaling technique introduced by [11], which relies on the existence of an LP-competitive single-source algorithm. With Theorem 3, this extends with little difficulty to the length-constrained setting. Our main technical contribution is the first step: showing existence of a low-density junction tree, as length constraints pose several new challenges, and the proof of [14] does not cleanly extend. We defer further discussion to Section 4.

1.3 Related Work

Directed Steiner Tree. Zelikovsky [60] was the first to address the approximability of DST. He obtained an $O(k^\epsilon)$-approximation for any fixed $\epsilon > 0$ via two ideas. He developed a recursive greedy algorithm and analyzed its performance as a function of recursion depth. He then showed that one can reduce the problem on a general directed graph to a problem on a depth d DAG (via the transitive closure of the original graph) at the loss of an approximation factor that depends on d. Charikar et al. [10] refined the algorithm and analysis in [60] and combined it with the depth reduction. They showed that one can obtain an $O(d^2 k^{1/d} \log k)$ approximation in $O(n^{O(d)})$-time; this led to an $O(\log^3 k)$-approximation in quasi-polynomial time. Subsequently, Grandoni et al. [33] improved the approximation to $O(\log^2 k / \log\log k)$ in quasi-polynomial time via a more sophisticated LP-based approach. A different approach that also yields the same bound was given by Ghuge and Nagarajan [31], and this is based on a refinement of the recursive greedy algorithm for walks in graphs [18]. The approach of [31] extends to several related problems, including directed single-source buy-at-bulk.

Zosin and Khuller [61] showed that the natural cut-based LP relaxation for DST has an integrality gap of $\Omega(\sqrt{k})$. However, their example only showed a gap of $\Omega(\log n)$ as a function of the number of nodes n. There was some hope that the integrality gap is polylogarithmic in n; however, [51] recently showed that the gap is $\Omega(n^\delta)$ for some $\delta > 0$ by modifying the construction in [61]. Interestingly, these lower bound examples are DAGs with $O(1)$-layers, for which the recursive-greedy algorithm yields an $O(\log k)$-approximation in polynomial-time. Rothvoss [57] showed that $O(\ell)$-levels of the Lasserre SDP hierarchy when applied to the standard cut-based LP reduces the integrality gap to $O(\ell \log k)$ on DAGs with ℓ layers. This was later refined to show that $O(\ell)$-levels of the Sherali-Adams hierarchy suffices [27]. However, both these approaches also require quasi-polynomial time to obtain a polylogarithmic approximation. Recent work by Laekhanukit [50] shows a flow-based LP relaxation that has polylogarithmic integrality gap under some strong assumptions on the structure of an optimal fractional solution.

Directed Steiner Forest. The first nontrivial approximation for Directed Steiner Forest was an $\tilde{O}(k^{2/3})$-approximation given by Charikar et al. [10]. This follows a similar iterative density-based procedure as the *junction tree* approach; however, they restrict to trees of a much simpler structure. This approximation ratio was subsequently improved to $O(k^{\frac{1}{2}+\epsilon})$ by Chekuri et al. [12]; they showed that given an instance (G, D) of DSF, there exists a junction tree of density at most $O(k^{1/2})$ times the optimum. They then provided an algorithm to find a low-density junction tree via height reduction and Group Steiner Tree rounding. DSF has improved approximation ratios when k is large. Feldman, Kortsarz, and Nutov [25] obtained an $O(n^\epsilon \cdot \min(n^{4/5}, m^{2/3}))$-approximation using a junction-based approach. This analysis was refined by Berman et al. [7] using ideas developed for finding directed spanners, giving an improved approximation ratio of $O(n^{2/3+\epsilon})$. For DSF with *uniform* edge costs, Chlamtáč et al. obtained an $O(n^{3/5+\epsilon})$-approximation [19], which was subsequently improved to $O(n^{4/7+\epsilon})$ by Abboud and Bodwin [1].

Length-Constrained Network Design. Length-constrained network design has been primarily studied in undirected graphs. It was first introduced by Balakrishnan and Altinkemer [5], and has since been studied in both approximation and fast exact algorithms. The length-constrained s-t shortest path problem is solvable exactly in polynomial time when edge lengths are polynomially bounded, via the textbook Bellman-Ford dynamic programming algorithm. However, it is NP-hard for arbitrary lengths [42].[2] Moreover, length-constrained MST is NP-hard even in the special case of hop constraints.[3] From an approximation algorithms standpoint, until recently, the majority of the work on length-constrained network design had been limited to single-source settings, such as s-t shortest path [43, 59, 38, 32, 53, 8], MST [21, 2, 55, 3, 47, 56, 54, 40], Steiner Tree [49, 44], and k-Steiner Tree [36, 46]. While s-t shortest path admits an FPTAS [38], other length-constrained problems have strong hardness results under *strict* length constraints. Length-constrained MST is as hard as Directed Steiner Tree, and the length-constrained variant of Steiner forest has no $o(2^{\log^{1-\epsilon}(n)})$-approximation [23]. These problems are more tractable when length constraints are relaxed. A simple merging algorithm [54] yields an $(O(\log n), O(\log n))$-bicriteria approximation for length-constrained MST and Steiner Tree. Recent progress by Hershkowitz and Huang allows one to reduce the length slack to $O(\log n/\log\log n)$ while increasing the approximation ratio by a polylogarithmic factor [40]. The multicommodity setting has been more challenging. For length-constrained Steiner Forest, polylogarithmic bicriteria approximations were implicitly known via buy-at-bulk [11, 48]. There has also been a line of work on hop-constrained *tree embeddings*, which have led to bicriteria approximations for hop-constrained Steiner Forest and various related problems [35, 26]. Chekuri and Jain [13], building on hop-constrained oblivious routing tools of Ghaffari, Haeupler, and Zuzic [30], obtained LP-competitive algorithms for multicommodity problems in buy-at-bulk and length-constrained settings. In directed graphs, a recent work obtains polynomial factor approximations for Directed Buy-at-Bulk and related spanner problems [34]; these approximation ratios essentially match the best known factors for DSF in general digraphs.

Planar and Minor-Free Graphs. Improved approximation ratios have been obtained for several problems in special classes of graphs, such as planar and minor-free graphs. We first discuss undirected graphs. In planar graphs, Steiner Tree admits a PTAS [9]; this was later extended to a PTAS for Steiner Forest in graphs of bounded genus [6]. Recently, [20] obtained a QPTAS for Steiner Tree in minor-free graphs. Furthermore, although the node-weighted variant of Steiner Tree captures Set Cover in general graphs, there exists a constant factor approximation in planar graphs, and more generally, in any proper minor-closed graph family [22]. In directed graphs, several recent results have built on tools given by Thorup [58] to obtain approximation algorithms in planar digraphs. Kawarabayashi and Sidiropoulos [45] gave a polylogarithmic upper bound on the multicommodity flow-cut gap in planar digraphs; this was derandomized and extended to the node-weighted setting by [15]. As discussed earlier, Friggstad and Mousavi [29] obtained an $O(\log k)$-approximation for DST in planar digraphs. This was extended by Chekuri et al. [17] to an LP-competitive $O(\log^2 k)$-approximation. Chekuri et al. [17] also obtained polylogarithmic approximations for several rooted variants of DST in planar digraphs, such as group, covering, polymatroid, and multirooted versions. Chekuri and Jain [14] then obtained an $O(\log^6 k)$-approximation for DSF in planar digraphs. In minor-free input graphs that are *quasi-bipartite*, Friggstad and Mousavi [28] obtained a constant-factor approximation for DST.[4]

[2] The length-constrained shortest path problem is often referred to as *Restricted Shortest Path*.
[3] Hop constraints refer to the unit-edge-length setting of length-constrained network design.
[4] The input is quasi-bipartite if there are no edges between any two non-terminal nodes.

2 Preliminaries

2.1 Notation

Let $G = (V, E)$ be a directed graph with edge costs $c : E \to \mathbb{R}_+$. For $E' \subseteq E$, we denote $c(E') = \sum_{e \in E'} c(e)$. We assume all edge costs $c(e) \geq 1$ and are polynomially bounded in n. This can be done with a $(1 + o(1))$ factor loss in approximation, by guessing the cost of the optimal solution OPT, contracting edges with cost much smaller than OPT, and scaling appropriately.

For $S \subseteq V$, we use $E[S]$ to denote the set of edges of E with both endpoints in S, $G[S]$ to denote the subgraph $(S, E[S])$ *induced by* S in G, and $\delta^+(S) = \{(u, v) \in E : u \in S, v \notin S\}$ to denote the *out-cut* of S. The *height* of an out-tree T rooted at s is the maximum over all $v \in V(T)$ of the number of edges on the unique s-v path. The *size* of the tree is the number of vertices in the tree. To *contract* an edge (u, v) is to merge its endpoints into a single vertex w_{uv}, replacing all edges incident to u or v with edges incident to w_{uv} and removing resulting self-loops. For a subgraph $G' \subseteq G$, we use G/G' to denote the graph obtained by contracting every edge of G' and $G - G'$ to denote the graph obtained by deleting every edge in G'. A graph H obtained from G via edge contractions and edge or vertex deletions is called a *minor* of G. It is easy to see that if G is planar, then any minor of G is planar as well. A weakly connected component of G is a maximal connected component of the underlying undirected graph obtained from G by ignoring the edge orientations. We call this undirected graph the *undirected version* of G.

The length $\ell(p)$ of a path p is the sum of the lengths of its edges. More generally, we write $\ell(F) := \sum_{e \in F} \ell(e)$ for any $F \subseteq E$. For any subset of edges $F \subseteq E$ and any pair of vertices $u, v \in V$, we let $\ell_F(u, v)$ denote the length of the shortest-length u-v path in F. We generalize this notation to sets: for $A, B \subseteq V$, $\ell_F(A, B)$ is the length of the shortest-length path in F from A to B. We drop F when it is clear from context. For a tree T and vertices $u, v \in V(T)$, we write $P_T(u, v)$ to denote the unique u-v path in T.

2.2 Mixture Metric

We write $d^{(h)}(s, t)$ to denote the cost of the shortest h-length constrained s-t path. Computing $d^{(h)}(s, t)$ is NP-hard [42]; however, it can be approximated to a $(1 + \epsilon)$-factor [38]. Unlike traditional graph distances, $d^{(h)}$ does not form a metric. We instead consider the *mixture metric*; this is a standard notion to facilitate working with length constraints, and was highlighted in recent work in length-constrained network design by [35].

Given a length constraint h and a cost bound γ, we define the mixture metric as follows: for each $e \in E$, the *mixture cost* function is $c'(e) = c(e) + \frac{\gamma}{h}\ell(e)$. For all $s, t \in V$, let $d'(s, t)$ be the cost of the shortest s-t path with respect to c'. It is not difficult to see that d' forms a metric. Claim 6 demonstrates how d' approximates $d^{(h)}$; the proof is simple and deferred to a full version.

▷ Claim 6. Let d' be the mixture metric with length constraint h and cost bound γ.

1. $d'(s, t) \leq d^{(h)}(s, t) + \gamma$;
2. $d^{(h')}(s, t) \leq d'(s, t)$, where $h' = \frac{d'(s,t)}{\gamma} \cdot h$.

2.3 Planar Separator

The key property of planarity used in our algorithms is the fact that planar graphs have good shortest path separators, as shown in Lemma 5. We state a more general lemma on *undirected graphs*. This lemma, essentially proved by Lipton and Tarjan [52], but given

explicitly by Thorup [58], states that every spanning tree on any planar graph contains three paths whose removal results in connected components each containing at most half the number of vertices. The formal statement is as follows.

▶ **Lemma 7** ([52, 58]). *Let G be an undirected connected graph with non-negative edge costs $c(e)$, non-negative vertex weights $w(u)$, and a spanning tree T rooted at $v \in V$. There exists a polynomial time algorithm to find three vertices $u_1, u_2, u_3 \in V$ such that each component of $G \setminus (P_T(v,u_1) \cup P_T(v,u_2) \cup P_T(v,u_3))$ has at most half the vertex weight of G.*

Note that one can recover the directed variant (Lemma 5) by considering the spanning tree T to be a shortest path tree rooted at v.

3 Length-Constrained Directed Steiner Tree

In this section, we consider length-constrained Directed Steiner Tree. We provide an $O(\log k)$-approximation in Section 3.1, and an LP-based $O(\log^2 k)$-approximation in Section 3.2.

First, we define a subroutine PruneAndSeparate (Algorithm 1) which will be used in both the integral and LP-based algorithms. This subroutine takes as input a graph $G = (V, E)$ with edge costs $c(e)$, a root $s \in V$, terminals $S \subseteq V$, and a guess γ for the cost of the optimal solution. PruneAndSeparate(G, s, S, γ) removes all vertices further than γ away from s, and uses Lemma 5 on the resulting graph with vertex weights set to 1 on the terminals and 0 elsewhere. This yields a *planar separator* $P := P_1 \cup P_2 \cup P_3$ in which each resulting component of $G \setminus P$ has at most half the terminals. The subroutine contracts P into s; each component of $G \setminus P$ corresponds to a new subinstance induced by the terminals in that component along with s. PruneAndSeparate(G, s, S, γ) returns P along with the subinstances for each component.

Algorithm 1 PruneAndSeparate(G, s, S, γ).

Delete all vertices $v \in V$ with $d_G(s, v) > \gamma$
Let $P := P_1 \cup P_2 \cup P_3$ be given by Lemma 5 with weights $w(v) = \mathbb{1}_{v \in S}$ for $v \in V(G)$
Let G_P be obtained from G by contracting P into s
Let $C_1, \ldots, C_\tau$ be components of $G \setminus P$, and let $G_i \leftarrow G_P[C_i \cup \{s\}]$
return $(P, (G_1, C_1), \ldots, (G_\tau, C_\tau))$

3.1 Approximation with respect to Integral Optimum

We follow the divide-and-conquer algorithm given by Friggstad and Mousavi [29], adapted to handle length constraints. Recall the high level approach: the algorithm branches on two cases and returns the cheaper solution. In the first branch, it recurses with a halved guess for OPT; this handles the case where OPT $\leq \gamma/2$. In the second branch, it computes a planar separator P under the *mixture cost* c', and recursively solves each resulting component independently. Using the mixture cost for the separator is the main adaptation for length constraints, which ensures that the separator paths have bounded cost *and* bounded length. For clarity, we write the algorithm as though $d^{(h)}(s,t)$ can be computed exactly; replacing this with a $(1+\epsilon)$-approximation does not affect the approximation guarantees.

Algorithm 2 h-DST(I, γ): an instance $I = (G, s, S, h)$ and a "guess" γ for OPT.

if $\exists t \in S$ such that $d^{(h)}(s,t) > \gamma$ **then**
  return Infeasible (∞)
if $|S| = 1$ **then**
  return min-cost h-length-constrained s-t path in G, where t is the terminal in S
// **Recursive Step 1:**
$F^1 \leftarrow$ h-DST$(I, \gamma/2)$
// **Recursive Step 2:**
Define mixture cost $c'(e) = c(e) + \frac{\gamma}{h}\ell(e)$
$(P, (G_1, C_1), \ldots, (G_\tau, C_\tau)) \leftarrow$ PruneAndSeparate$(G = (V, E, c'), s, S, 2\gamma)$
$F^2 \leftarrow P$
for $i \in [\tau]$ **do**
  $F_i \leftarrow$ h-DST$(I_i := (G_i, s, S \cap C_i, h), \gamma)$
  $F^2 \leftarrow F^2 \cup F_i$
return $\arg\min_{F \in \{F^1, F^2\}} c(F)$

First, we argue that the algorithm runs in polynomial time. This follows directly from [29]; the proof is deferred to a full version.

▶ **Lemma 8.** *Algorithm 2 runs in polynomial time.*

Next, we prove feasibility and bound the cost of the given solution. The proof of Lemma 11 is deferred to a full version. We start with a simple property about the planar separator.

▷ Claim 9. The planar separator P computed by h-DST(I, γ) for any feasible instance satisfies the following: (i) $c(P) \le 6\gamma$, (ii) $\ell(P) \le 6h$.

Proof. Let $P = P_1 \cup P_2 \cup P_3$ be the planar separator computed by h-DST(I, γ). Recall that each P_i, for $i \in [3]$, is a shortest path from s with respect to c'. Since all vertices $u \in V$ with $d_{G,c'}(s,u) > 2\gamma$ are removed, each path P_i must have $c'(P_i) = c(P_i) + \frac{\gamma}{h}\ell(P_i) \le 2\gamma$. Since both terms are non-negative, $c(P_i) \le 2\gamma$, so $c(P) \le 6\gamma$. Similarly, $\frac{\gamma}{h}\ell(P_i) \le 2\gamma$, so $\ell(P_i) \le 2h$ and thus $\ell(P) \le 6h$. ◁

▶ **Lemma 10.** *Let F be the solution returned by* h-DST(I, γ) *for a feasible instance (I, γ). Then, F contains an s-t path of length at most $O(\log |S|) \cdot h$ for each terminal $t \in S$.*

Proof. We prove by induction on $\gamma + |S|$ that if the instance (I, γ) is feasible, then $F :=$ h-DST(I, γ) contains a path from s to t of length at most $6h(\log |S| + 1)$, for each $t \in S$. The base case is clear; if there is one terminal, then F is an s-t path of length h.

We consider the two recursive cases separately. For the first recursive case, if $(I, \gamma/2)$ is infeasible, then $c(F^1)$ is infinite and $F \neq F^1$. Else, by induction, F^1 contains an s-t path of length at most $6h(\log |S| + 1)$ for each $t \in S$.

Next, we consider the second recursive case. Fix $t \in S$. Observe that since (I, γ) is feasible, $d^{(h)}(s,t) \le \gamma$, so there exists an s-t path q of length at most h and cost at most γ. In particular, $c'(q) = c(q) + \frac{\gamma}{h}\ell(q) \le 2\gamma$, so t is not deleted in the pruning step. Therefore, t is either in the planar separator P or in some component C_i of $G \setminus P$. If $t \in P$, then P contains an s-t path of length at most $\ell(P) \le 6h$, by Claim 9. If $t \in C_i$, then since the recursive sub-instance contracts P into s, C_i contains a path from $\{s\} \cup P$ to t of length at most $6h(\log |S \cap C_i| + 1)$, by induction. Therefore, F^2 contains an s-t path of length at most

$$\ell(P) + 6h(\log |S \cap C_i| + 1) \le 6h + 6h(\log(|S|/2) + 1) = 6h + 6h \log |S| = 6h(\log |S| + 1).$$

This concludes the inductive argument and the proof of the lemma. ◀

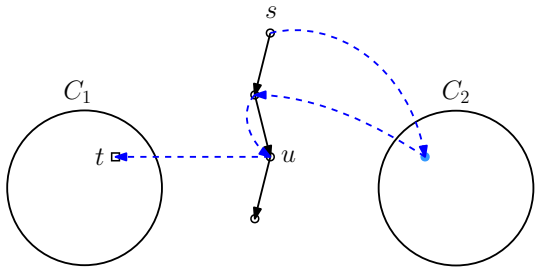


Figure 3 Consider the s-t path p shown in blue dashed lines; here the separator P is black and bolded. The portion of the path from u to t corresponds to p'.

▶ **Lemma 11.** *The cost of the solution returned by* h-DST(I, γ) *for a feasible instance* (I, γ) *is at most* $O(\log |S|) \cdot \text{OPT}$.

Theorem 2 follows from Lemma 8, Lemma 10, and Lemma 11 by applying Algorithm 2 to the given input instance I, with γ chosen to be any upper bound on OPT; e.g. $c(E)$.

3.2 LP-Based Approximation

The goal of this section is to obtain a polylogarithmic upper bound on the integrality gap of a natural LP relaxation for LC-DST in planar digraphs, defined as follows. For each terminal $t \in S$, let $\mathcal{P}_t^h$ denote the set of all s-t paths in G of length at most h. The variables x_e indicate whether an edge e is in the final solution, and variables f_p indicate how much s-t flow is sent on path p.

$$\begin{aligned} \min \quad & \sum_{e \in E} c(e) x_e \\ s.t. \quad & \sum_{p \in \mathcal{P}_t^h} f_p \geq 1 && \forall t \in S \\ & \sum_{p \in \mathcal{P}_t^h, e \in p} f_p \leq x_e && \forall e \in E, t \in S \\ & x_e, f_p \geq 0 && \forall e \in E, p \in \cup_{t \in S} \mathcal{P}_t^h \end{aligned} \tag{LC-DST-LP}$$

The LP contains an exponential number of variables but can be solved approximately (up to a $(1+\epsilon)$ factor) via separation oracle on the dual.

We provide an LP-based algorithm following a similar framework as above; here, we use the LP solution as the "guess" for OPT. This is the same approach used by [17] to obtain an LP-based approximation for DST in planar graphs. The algorithm h-frac-DST$(I, (x, f))$ is as follows, where $I = (G, s, S, h)$ is a problem instance and (x, f) is a feasible LP solution to the relaxation for LC-DST-LP.

- **Base Case.** If $S = \{t\}$, we return the min-cost h-length constrained s-t path.
- **Prune and Separate.** We set $\gamma = 2 \log |S| \sum_{e \in E} c(e) x_e$ to be the "guess" for OPT. As in Algorithm 2, we define the mixture edge cost function as $c'(e) = c(e) + \frac{\gamma}{h} \ell(e)$. Let $(P, (G_1, C_1), \ldots, (G_\tau, C_\tau))$ denote the output of PruneAndSeparate$(G = (V, E, c'), s, S, 2\gamma)$.
- **Recursive Step.** For each component $i \in [\tau]$, we define the recursive sub-instance $I_i = (G_i, s, S \cap C_i, h)$. In order to construct a feasible LP solution for I_i, we first scale up the solution; let $(\bar{x}, \bar{f}) = \left(1 + \frac{1}{\log |S|}\right)(x, f)$. We set $x_e^i = \bar{x}_e$ for all $e \in G_i$.

For the path variables, fix a terminal $t \in S \cap C_i$. For each path $p \in \mathcal{P}_t^h$ (in the graph G *before* contracting P into s), let p' denote the corresponding contracted path with resulting cycles deleted. Note that $\ell(p') \leq h$ since contraction cannot increase path length, so p' is a valid s-t path in the new sub-instance. We define $\mathcal{Q}(p')$ as the set of all paths in $\mathcal{P}_t^h$ that map to p' after contraction and cycle removal; see Figure 3. We set $f_{p'}^i = \sum_{p \in \mathcal{Q}(p')} \bar{f}_p$ for all such p' fully contained in G_i. We recursively compute $F_i = \text{h-frac-DST}(I_i, (x^i, f^i))$.

- Return $P \cup (\cup_i F_i)$

It is clear that this algorithm runs in polynomial time. We show that each recursive call is valid by showing that the constructed LP solutions are feasible for the subinstances.

▶ **Lemma 12.** *For each $i \in [\tau]$, (x^i, f^i) is a feasible LP solution on instance I_i.*

Proof. Fix $i \in [\tau]$. We show that (x^i, f^i) satisfies all LP constraints. Fix $t \in S \cap C_i$. To distinguish between the set of h-length-constrained s-t paths in the new instance I_i versus in the original input instance I, we write $\mathcal{P}_t^i$ versus $\mathcal{P}_t$; the length-constraint h is dropped from this notation for visual clarity.

We start by showing that $\sum_{p \in \mathcal{P}_t, c'(p) \leq 2\gamma} \bar{f}_p \geq 1$; that is, scaling up by a $1 + 1/\log|S|$ factor compensates for vertices deleted during the pruning step. Consider a path $p \in \mathcal{P}_t$ with $c'(p) > 2\gamma$. Since $p \in \mathcal{P}_t$, $\ell(p) \leq h$. Thus, $c(p) = c'(p) - \frac{\gamma}{h}\ell(p) > 2\gamma - \gamma = \gamma$. Observe that since (x, f) satisfies the LP constraints,

$$\sum_e c(e)x_e \geq \sum_e c(e) \sum_{p \in \mathcal{P}_t : e \in p} f_p = \sum_{p \in \mathcal{P}_t} f_p c(p) > \gamma \sum_{p \in \mathcal{P}_t : c(p) > \gamma} f_p.$$

In particular, $\sum_{p \in \mathcal{P}_t : c(p) > \gamma} f_p < \frac{1}{\gamma} \sum_e c(e)x_e = 1/(2\log|S|)$. Furthermore, since (x, f) is feasible for I, $\sum_{p \in \mathcal{P}_t} f_p \geq 1$. Therefore,

$$\sum_{p \in \mathcal{P}_t, c'(p) \leq 2\gamma} \bar{f}_p \geq (1 + \frac{1}{\log|S|}) \sum_{p \in \mathcal{P}_t : c(p) \leq \gamma} f_p \geq \left(1 + \frac{1}{\log|S|}\right)\left(1 - \frac{1}{2\log|S|}\right) \geq 1.$$

Next, we show that $\sum_{p \in \mathcal{P}_t^i} f_p^i = \sum_{p \in \mathcal{P}_t, c'(p) \leq 2\gamma} \bar{f}_p$. Let $p \in \mathcal{P}_t$, and let p' denote the corresponding contracted path. Since $c'(p) \leq 2\gamma$, no vertices of p are deleted during the pruning step. We want to show that p' is contained in G_i. Let v be the *last* vertex on p that is not in C_i; note that p must end in C_i since p is an s-t path and $t \in C_i$. Since the components $C_1, \ldots, C_\tau$ are weakly connected in $G \setminus P$, there must be no edges between them. Thus, $v \in P \cup \{s\}$. Therefore, when P is contracted into s, the path $p[s, v]$ corresponds to a walk starting and ending at the contracted supernode s. This implies that $p' = p[v, t]$, which in the contracted graph, is contained in G_i. Therefore, $p \in \mathcal{Q}(p')$ for some $p' \in \mathcal{P}_t^i$, so $\sum_{p \in \mathcal{P}_t, c'(p) \leq 2\gamma} \bar{f}_p \leq \sum_{p' \in \mathcal{P}_t^i} \sum_{p \in \mathcal{Q}(p')} \bar{f}_p = \sum_{p' \in \mathcal{P}_t^i} f_{p'}^i$, as desired. Thus, $\sum_{p \in \mathcal{P}_t^i} f_p^i \geq 1$, so the first set of LP constraints is satisfied.

Proving that the second set of LP constraints are satisfied is more straightforward. We want to show that for all edges $e \in E(G[C_i \cup \{s\}])$, $\sum_{p \in \mathcal{P}_t^i, e \in p} f_p^i \leq x_e^i$.

$$\sum_{p' \in \mathcal{P}_t^i, e \in p'} f_{p'}^i = \sum_{p' \in \mathcal{P}_t^i, e \in p'} \sum_{p \in \mathcal{Q}(p')} \bar{f}_p \leq \sum_{p \in \mathcal{P}_t, e \in p} \bar{f}_p,$$

since the sets $\mathcal{Q}(p')$ are disjoint. To conclude, since (x, f) is a feasible LP solution,

$$\sum_{p \in \mathcal{P}_t, e \in p} \bar{f}_p = (1 + \frac{1}{\log|S|}) \sum_{p \in \mathcal{P}_t, e \in p} f_p \leq (1 + \frac{1}{\log|S|}) x_e = x_e^i. \qquad \blacktriangleleft$$

The "prune and separate" portion of h-frac-DST is the same as in h-DST (Algorithm 2). Therefore, Claim 9 holds for h-frac-DST. It is not difficult to see that the resulting solution $F = \text{h-frac-DST}(I, (x, f))$ contains an s-t path of length at most $O(\log |S|) \cdot h$ for each terminal $t \in S$, using reasoning analogous to that of Lemma 10. We bound the approximation ratio in the following lemma, which concludes the proof of Theorem 3.

▶ **Lemma 13.** *If (x, f) is a feasible LP solution to the LC-DST instance I, then the cost of the solution returned by* h-frac-DST$(I, (x, f))$ *is at most $O(\log^2 k) \sum_e c(e)x_e$.*

Proof. Let F be the solution returned by h-frac-DST$(I, (x, f))$. We let $X = \sum_e c(e)x_e$. We prove by induction on the number of terminals that $c(F) \leq 12(\log |S| + 1)^2 X$.

In the base case, it is easy to see that the cost of the min-cost h-length-bounded s-t path is at most X. For the recursive step, for each $i \in [\tau]$, let X_i denote the value of the LP solution (x^i, f^i), and let F_i denote the output of h-frac-DST$(I_i, (x^i, f^i))$. By Claim 9, $c(P) \leq 6\gamma = 12X \log |S|$. By induction,

$$c(F) = c(P) + \sum_{i \in [\tau]} c(F_i) \leq 12X \log |S| + \sum_{i \in [\tau]} 12X_i (\log |S \cap C_i| + 1)^2.$$

Since the number of terminals is halved at each recursive step, $\log |S \cap C_i| \leq \log(|S|/2) \leq \log |S| - 1$. Furthermore, since $C_1, \ldots, C_\tau$ are disjoint, $\sum_{i \in [\tau]} X_i \leq (1 + \frac{1}{\log |S|})X$. Thus

$$\begin{aligned} c(F) &\leq 12 \log |S| X + \sum_{i \in [\tau]} 12 (\log |S|)^2 X_i \leq 12 \log |S| X + 12 (\log |S|)^2 (1 + \frac{1}{\log |S|}) X \\ &= 12X(\log^2 |S| + 2 \log |S|) \leq 12X(\log |S| + 1)^2. \end{aligned}$$

This concludes the inductive argument; thus, $c(F) \leq O(\log^2 k) \sum_{e \in E} c(e)x_e$. ◀

4 Length-Constrained Directed Steiner Forest

In this section, we consider length-constrained Directed Steiner Forest in planar digraphs (called length-constrained planar DSF). We are given as input a directed graph $G = (V, E)$ with non-negative edge costs $c(e)$, lengths $\ell(e)$, length constraint h, and demand pairs $D = \{(s_i, t_i)\}_{i \in [k]}$. The goal is to find a min-cost subgraph $H \subseteq G$ such that for each $(s_i, t_i) \in D$, H contains an s_i-t_i path of length at most h. We employ the *junction tree* approach, discussed in Section 1. We formally define an h-length-constrained junction tree.

▶ **Definition 14.** *Given an instance (G, D, h) of LC-DSF, an* h-length-constrained junction tree *that covers terminal pairs $D_H \subseteq D$ is a subgraph $H \subseteq G$ with a root $v \in V(H)$ such that for each $(s_i, t_i) \in D_H$, H contains an s_i-v path and a v-t_i path, each of length at most h. The* density *of H is $c(H)/|D_H|$.*

We first show, in Section 4.1, that given any instance to planar LC-DSF, there exists a low-density length-constrained junction tree. In Section 4.2, we describe the approximation algorithm to find such a junction tree, and conclude the proof of Theorem 4.

4.1 Existence of a good junction tree

We prove the following theorem.

▶ **Theorem 15.** *Given an instance (G, D, h) of length-constrained planar DSF, there exists a $(3h)$-length-constrained junction tree of density at most $O(\log^2 k) \cdot \text{OPT}/k$.*

For planar-DSF *without* length-constraints, [14] showed that every instance of planar-DSF contains a low density junction tree. We outline the approach of [14], as we follow a similar framework. The proof proceeds by considering an optimum solution $E^* \subseteq E$ and finding several junction trees in E^* that are essentially disjoint and cover a large fraction of terminal pairs. The construction of these junction trees follows three steps. The first is a "layering" of a directed graph, where each layer has a tree-like structure, and all paths in the original graph are contained in at most two consecutive layers. This layering scheme was given by Thorup [58] and also used by Kawarabayashi and Sidiropoulos [45] to obtain improved upper bounds on the multicommodity flow-cut gap in directed planar graphs. The second step is a recursive approach based on the planar separator theorem (Lemma 7). The third step is to show that in one level of recursion, if many s_i-t_i paths pass through the separator, then there exist vertices on the separator that behave as roots of low-density junction trees.

The proof of Theorem 15 follows the same three-step strategy. First, we reduce to the case where the optimal solution is an *h-length-constrained* 3*-layered digraph* (Lemma 17).

▶ **Definition 16.** *An h-length-constrained* 3*-layered spanning tree T of a digraph G is a spanning tree of the* undirected version *of G, such that any root-to-leaf path in T is the concatenation of at most* 3 *dipaths in G, each of length at most h. An h-length-constrained* 3*-layered digraph is one that has an h-length-constrained* 3*-layered spanning tree. The root of the digraph is the root of the spanning tree.*

The argument uses a similar decomposition as in [14], but requires additional care to handle lengths. Second, we apply the planar separator and corresponding divide-and-conquer argument to reduce to a so-called "one-path" setting (Lemma 20). This step is essentially identical to the corresponding argument in [14]. The third step is a new contribution: handling the one-path setting under length constraints. The argument of [14] no longer applies, and we give a new argument (Lemma 23).

4.1.1 Reduction to length-constrained layered digraphs

First, we reduce to the case where the optimal solution is an h-length-constrained 3-layered digraph, by proving the following lemma.

▶ **Lemma 17.** *Let (G, D, h) be an instance of length-constrained planar DSF and let $G^* = (V^*, E^*)$ be an optimal solution. Then, there exists a subgraph $H \subseteq G^*$ and a subset of terminals $D_H \subseteq D$ such that the following holds.*

1. *H is an h-length-constrained* 3*-layered digraph with root v;*
2. *For each $(s_i, t_i) \in D_H$, there exists an s_i-t_i path in $H \setminus \{v\}$ of length at most h;*
3. *H is a minor of G^*, and $H \setminus \{v\}$ is a subgraph of G^*.*
4. $\frac{c(E(H))}{|D_H|} \leq 3 \cdot \frac{c(E^*)}{|D|}$.

To prove Lemma 17, we will decompose G^* into a series of 3-layered digraphs and show that at least one satisfies the necessary properties. We assume G^* is weakly connected; else, this decomposition can be applied separately on each weakly connected component. Let v_0 be an arbitrary node in V^*. Let L_0 be the set of all nodes in V^* that are reachable from v_0 (in G^*) with a path of length at most h. We then define alternating layers until all vertices have been covered by a layer.

$$L_j = \begin{cases} \{u \in V^* \setminus \cup_{j'<j} L_{j'} : \ell(u, L_{j-1}) \leq h\} & j \text{ is odd} \\ \{u \in V^* \setminus \cup_{j'<j} L_{j'} : \ell(L_{j-1}, u) \leq h\} & j \text{ is even} \end{cases}$$

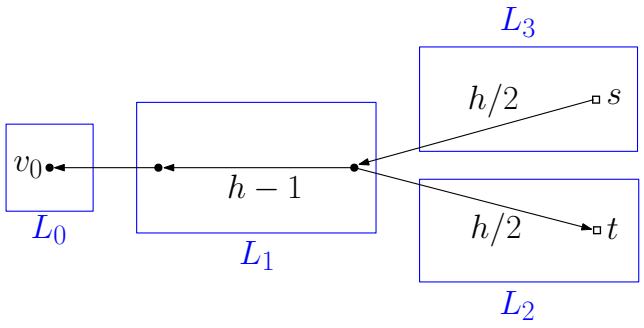

Figure 4 Example of graph in which s-t path spans 3 layers, L_1, L_2, L_3.

Let q denote the total number of layers. For each layer $j \leq q-2$, we define G_j to be the graph obtained from G^* by contracting $\cup_{j'<j} L_{j'}$ into a new node v_j, and deleting $\cup_{j''>j+2} L_{j''}$.

▷ Claim 18. For each demand pair $(s_i, t_i) \in D$, there exists $j \in \{0, \ldots, q-2\}$ such that $G_j \setminus \{v_j\}$ contains an s_i-t_i path of length at most h.

Proof. Let P_i be an s_i-t_i path of length at most h in G^*; such a path must exist as G^* is a feasible solution to the given LC-DSF instance. Let j be the minimum index such that $P_i \cap L_j \neq \emptyset$. We assume j is odd; the case where j is even is similar. Let u be in $P_i \cap L_j$. Then, since $\ell(u, t_i) \leq h$, t_i must be contained in $\cup_{j' \leq j+1} L_{j'}$. Since all of P_i can reach t_i with a path of length at most h, $P_i \subseteq \cup_{j' \leq j+2} L_{j'}$. Therefore, since L_j is the first layer that intersects with P_i, $P_i \subseteq L_j \cup L_{j+1} \cup L_{j+2} \subseteq G_j \setminus \{v_j\}$.[5] ◁

▶ Remark 19. When considering planar-DSF *without* length constraints, [14] shows that all s_i-t_i paths are contained in at most 2 layers. With length constraints, however, 3 layers are needed; see Figure 4 for an example of a graph in which the s-t path spans 3 layers.

Proof of Lemma 17. For each $j \in \{0, \ldots, q-2\}$, let D_j denote the set of terminal pairs for which $G_j \setminus v_j$ contains an s_i-t_i path of length at most h. We show that the first three properties required by Lemma 17 hold for all (G_j, D_j). The first and third properties follow by construction: each G_j is an h-length-constrained 3-layered digraph with root v_j, and G_j is constructed from G^* via contraction (to form the root) and deletion. The second property follows by definition of D_j.

To conclude, we show that there exists some (G_j, D_j) that satisfies the fourth property. By Claim 18, $\cup_j D_j = D$. Furthermore, it is not difficult to see that $\sum_{j<q-1} c(G_j) \leq 3c(E^*)$, since each edge of E^* is either contained in one layer L_j, or goes between two layers L_j and L_{j+1} – in either case, it exists only in G_j, G_{j-1}, and G_{j-2}. By an averaging argument, there must be some $j \in [q-2]$ such that

$$\frac{c(G_j)}{|D_j|} \leq \frac{\sum_j c(G_j)}{\sum_j |D_j|} \leq \frac{3c(E^*)}{|D|}.$$ ◀

[5] We point out a minor technicality – this claim is not true when $j = 0$. However, one can circumvent this issue by creating a new dummy vertex as the root of G_0 and adding a 0-length edge to v_0.

4.1.2 Divide-and-conquer via planar separator

Next, we use the fact that planar digraphs have good separators to reduce to the so-called "one-path" case. We prove the following lemma.

▶ **Lemma 20.** *Let $G^* = (V^*, E^*)$ be a planar h-length-constrained 3-layered digraph with root v, and let $D \subseteq V^* \times V^*$ be a set of demand pairs such that for each $(s_i, t_i) \in D$, $G^* \setminus \{v\}$ has an s_i-t_i path of length at most h. Then, there exists a subgraph $H \subseteq G^* \setminus \{v\}$, an h-length path $P \subseteq H$, and subset of terminals $D_H \subseteq D$ satisfying the following.*

1. *For each $(s_i, t_i) \in D_H$, there exists an h-length s_i-t_i path in H that intersects P;*
2. $\frac{c(E(H))}{|D_H|} \leq O(\log |D|) \frac{c(E^*)}{|D|}$.

The proof follows the same argument as that of [14]; we rewrite it here for completeness and borrow the terminology. Fix an instance (G, D) of planar-DSF and a feasible solution E^* satisfying the conditions outlined in the statement of Lemma 20 above. Let $T^* \subseteq E^*$ be an h-length-constrained 3-layered spanning tree of G^*. We will follow a recursive process to partition D into subsets on which we build junction trees.

- Set vertex weights as $w(s_i) = w(t_i) = 1$ for all $(s_i, t_i) \in D$, and 0 otherwise.
- Consider the undirected version of E^* and apply Lemma 7 on the undirected version of spanning tree T^* with vertex weights w. From this, we obtain u_1, u_2, u_3.
- Since T^* is an h-length-constrained 3-layered tree, each (undirected) path $P_{T^*}(v, u_i)$ consists of at most 3 dipaths, each of length at most h. Remove the root v and let Q_i^j for $i, j \leq 3$ denote the 3 dipaths of $P_{T^*}(v, u_i) \setminus \{v\}$. Let $S_0 = \cup_{i,j \leq 3} Q_i^j$ denote this collection of at most 9 dipaths, we call this the *separator*.
- Define $D_0 \subseteq D$ to be the set of all terminal pairs (s_i, t_i) such that E^* contains an h-length s_i-t_i path that intersects one of the dipaths in S_0. Equivalently, $(s_i, t_i) \in D_0$ iff there exists an h-length s_i-t_i path $P_i \subseteq E^*$ such that $V(P_i) \cap V(S_0) \neq \emptyset$. We say these terminal pairs are *separated*.
- Let $\mathcal{C}_1$ be the set of weakly connected components of $G \setminus (\cup_{i \in [3]} P_{T^*}(v, u_i))$; we drop "weakly connected" and simply refer to these as "components" in the remainder of this section. Note that each $C \in \mathcal{C}_1$ has at most half the total number of terminals.

We then follow a recursive process, similar to PruneAndSeparate described in Section 3. For each $C \in \mathcal{C}_1$, we contract S_0 into v and recurse on the sub-instance consisting of $G^*[C \cup \{v\}]$ with terminal set $\{(s_i, t_i) \in D : s_i, t_i \in C\} \setminus D_0$. It is easy to verify that $G^*[C \cup \{v\}]$ is an h-length-constrained 3-layered digraph with root v. Furthermore, each (s_i, t_i) pair in the new terminal set has an h-length-bounded path that does not intersect v; else, (s_i, t_i) would have been included in D_0. Therefore, we can apply the same process as above, and repeat this recursive process until each component has at most one terminal. Since the number of terminals halves at each step, the recursion depth is at most $\lceil \log 2k \rceil = \lceil \log k \rceil + 1$.

We use the following notation. For an instance defined on component C at recursive depth j, we let S_j^C, D_j^C denote the separator and corresponding separated terminal pairs. We let $\mathcal{C}_j$ denote the set of all components at recursive depth j (in particular, $\mathcal{C}_0 = \{G^*\}$), and denote by $S_j := \cup_{C \in \mathcal{C}_j} S_j^C$ and $D_j := \cup_{C \in \mathcal{C}_j} D_j^C$. The following claim is simple; the proof is deferred to a full version.

▷ Claim 21. $D \subseteq \cup_{j=0}^{\lceil \log k \rceil + 1} D_j$.

▶ **Corollary 22.** *There exists a level of recursion $j^* \in \{0, \ldots, \lceil \log k \rceil + 1\}$ such that $|D_{j^*}| \geq \frac{k}{\lceil \log k \rceil + 2}$.*

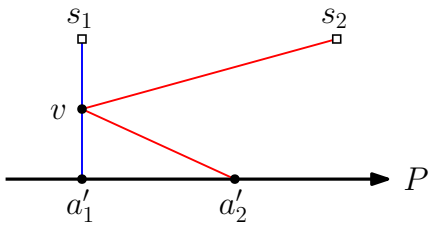

Figure 5 Suppose $\ell(s_1, v) = 1, \ell(v, a'_1) = h - 1, \ell(s_2, v) = h - 1, \ell(v, a'_2) = 1$. The argument in [14] would re-route s_2 to P via the path from v to a'_1; however, this would increase the length of the path from s_2 to P to $2h - 2$. In general, merging arbitrarily many terminals would make these paths to P arbitrarily long.

Proof of Lemma 20. Let j^* be the recursion level given by Corollary 22 such that $|D_{j^*}| \geq \frac{k}{\lceil \log k \rceil + 2}$. Since components of $\mathcal{C}_{j^*}$ are disjoint, $\sum_{C \in \mathcal{C}_{j^*}} c(E(C)) \leq c(E^*)$ and $\{D^C_{j^*}\}_{C \in \mathcal{C}_{j^*}}$ form a partition of D_{j^*}. Using an averaging argument, there exists a component C such that $c(E(C))/|D^C_{j^*}| \leq c(E^*)/|D_{j^*}|$. Furthermore, since $S^C_{j^*}$ consists of at most 9 dipaths, there exists at least one dipath Q^* such that at least $\frac{1}{9}$ terminal pairs of $D^C_{j^*}$ intersect Q^*; we denote this set of terminals by D^*.

We claim C, Q^*, D^* satisfy the required properties of the lemma statement. The first follows by construction; for all terminal pairs $(s_i, t_i) \in D^*$, there exists an h-length s_i-t_i path in C that intersects Q^*. For the second, $\frac{c(E(C))}{|D^*|} \leq 9 \cdot \frac{c(E(C))}{|D^C_{j^*}|} \leq 9 \cdot \frac{c(E^*)}{|D_{j^*}|} \leq O(\log k) \frac{c(E^*)}{|D|}$. ◀

4.1.3 One Path Case

To conclude, we show that in the "one-path" setting, there always exists a low-density junction tree. This subsection contains the core technical contribution over [14], since previously used techniques for handling the one-path setting do not extend to length-constraints.

▶ **Lemma 23.** *Let $G^* = (V^*, E^*)$ be a planar subgraph that contains an h-length path $P \subseteq G^*$, and let $D \subseteq V^* \times V^*$ be a set of demand pairs such that for each $(s_i, t_i) \in D$, there exists an h-length s_i-t_i path in G^* that intersects P. Then, G^* contains a $3h$-length-constrained junction tree of density $O(\log k)c(E^*)/k$, where $k = |D|$.*

Let $v_1, \ldots, v_{|P|}$ denote the vertices of P. For each terminal pair $(s_i, t_i) \in D$, the lemma assumption guarantees an h-length s_i-t_i path in G^* that intersects P. Let a'_i denote the first vertex of P on this path, and let b'_i denote the last vertex of P on this path; note that $a'_i \leq_P b'_i$. Let P_{s_i} be the subpath from s_i to a'_i, and let P_{t_i} be the subpath from b'_i to t_i; both have length at most h. We can assume without loss of generality that $E^* = P \cup (\cup_{i \in [k]}(P_{s_i} \cup P_{t_i}))$, since this satisfies the lemma assumptions. The main challenge with length constraints in the one-path setting is in handling edges of $E^* \setminus P$. In particular, the argument in [14] relies on the fact that for any $i, i' \in [k]$, if $P_{s_i} \cap P_{s_{i'}} \neq \emptyset$, then $a'_i = a'_{i'}$. This no longer holds, as demonstrated by Figure 5.

We adopt a different perspective. For each $(s_i, t_i) \in D$, let a_i denote the first node in P that s_i can reach within a path of length *at most* $2h$, and let b_i denote the last node in P that can reach t_i within length at most $2h$. We use the following simple claim.

▷ Claim 24. For all $i \in [k]$, $a_i \leq_P a'_i \leq_P b'_i \leq_P b_i$.

Proof. By definition, $a'_i \leq_P b'_i$. For the other two inequalities, $a_i \leq_P a'_i$, since a_i is the *first* node on P that s_i can reach within length $2h$, and P_{s_i} is an s-P path of length h. Similarly, $b'_i \leq_P b_i$, since b_i is the *last* node on P that can reach t_i within length $2h$, and P_{t_i} is a path from P to t_i of length h. ◁

Let μ be the midpoint of the path P (i.e., $\mu = v_{\lfloor |P|/2 \rfloor}$). We partition D into three sets:

$$\begin{cases} L = \{(s_i, t_i) : a_i \leq_P b_i <_P \mu\} \\ R = \{(s_i, t_i) : b_i \geq_P a_i >_P \mu\} \\ M = \{(s_i, t_i) : a_i \leq_P \mu \leq_P b_i\} \end{cases}$$

▷ Claim 25. E^* contains a $3h$-length-constrained junction tree with root μ on terminals M.

Proof. It suffices to show that for each $(s_i, t_i) \in M$, there exist $3h$-length paths in E^* from s_i to μ and from μ to t_i. By definition, $\ell(s_i, a_i) \leq 2h$. Furthermore, since $a_i \leq_P \mu$ and P is an h-length path, $\ell(a_i, \mu) \leq h$. Therefore, $\ell(s_i, \mu) \leq 3h$. The argument for t_i is similar. ◁

We follow a recursive process. First, we construct the junction tree H_μ with root μ given by Claim 25. We conflate indices with vertices, and let $(\mu - 1)$ and $(\mu + 1)$ denote the vertices directly before and after μ on P. At a high level, the idea is then to recurse on the sub-paths $P[0, \mu - 1]$, $P[\mu + 1, v_{|P|}]$, with corresponding paths in $E \setminus P$ to connect terminals. Formally, let $E_L = P[0, \mu - 1] \cup \big(\cup_{(s_i,t_i) \in L}(P_{s_i} \cup P_{t_i})\big)$, and $E_R = P[\mu + 1, v_{|P|}] \cup \big(\cup_{(s_i,t_i) \in R}(P_{s_i} \cup P_{t_i})\big)$. We recurse on the edge-induced subgraph $G_L := G[E_L]$ with terminal set L, and $G_R := G[E_R]$ with terminal set R. The following claim follows directly from Claim 24, and proves that these are valid recursive calls.

▷ Claim 26. For each $(s_i, t_i) \in D$, recall that a'_i, b'_i denote the endpoints on P of P_{s_i}, P_{t_i} respectively. If $(s_i, t_i) \in L$, then $a'_i, b'_i \in P[0, \mu - 1]$, and if $(s_i, t_i) \in R$, then $a'_i, b'_i \in P[\mu + 1, v_{|P|}]$.

We continue this recursive process until P consists of one vertex v, in which case all remaining terminal pairs can be routed through v. This process terminates after $O(\log |P|) = O(\log k)$ recursive steps, since $|P|$ is halved at each step. The following key lemma bounds the total cost of the junction trees constructed. Let $E_s = E(\cup_{i \in [k]} P_{s_i})$ and $E_t = E(\cup_{i \in [k]} P_{t_i})$.

▷ Claim 27. $E_s \cap E_L$ is disjoint from $E_s \cap E_R$. Similarly, $E_t \cap E_L$ is disjoint from $E_t \cap E_R$.

Proof. We prove the claim for E_s; the argument for E_t is similar. Suppose for the sake of contradiction there exists an edge $e = (u, v)$ in $E_s \cap E_L \cap E_R$. Since $e \in E_L \cap E_s$, there must be a terminal s_i such that $e \in P_{s_i}$ and $a_i \leq_P b_i <_P \mu$. By Claim 24, $a'_i <_P \mu$. Similarly, since $e \in E_R$, there exists s_j such that $e \in P_{s_j}$ and $a_j >_P \mu$. Consider the path $P' = P_{s_j}[s_j, u] \circ P_{s_i}[u, a'_i]$. Since P_{s_j} and P_{s_i} are both h-length paths, P' has length at most $2h$. Thus, s_j can reach a'_i with a path of length $\leq 2h$, and $a'_i <_P a_j$, a contradiction. ◁

Proof of Lemma 23. The recursive process described yields a series of junction trees denoted H_v for some vertices $v \in P$ that, in total, cover all terminal pairs. By Claim 25, each H_v is a $3h$-length-constrained junction tree. To bound the cost, it is helpful to think of E_s, E_t and $E(P)$ as disjoint sets; this can be achieved by making at most 3 copies of each edge in E^*. Then, by Claim 27, E_L is disjoint from E_R. Therefore, each edge is in at most one junction tree per recursive level, so it is in at most $O(\log k)$ total junction trees. Therefore, the total cost of all junction trees is at most $3 \cdot O(\log k) c(E^*) = O(\log k) c(E^*)$. By an averaging argument, there must be one junction tree of density at most $O(\log k) c(E^*)/k$. ◀

To conclude, the proof of Theorem 15 follows from Lemma 17, Lemma 20, and Lemma 23.

4.2 Finding an Approximate Low-Density Junction Tree

The main lemma we prove in this section is the following.

▶ **Lemma 28.** *Suppose there exists a bicriteria (α, β)-approximation for LC-DST in planar graphs with respect to the optimal solution to LC-DST-LP. Then, given a planar-LC-DSF instance (G, D, h), there exists an efficient algorithm to obtain a βh-length-constrained junction tree of G of density at most $O(\alpha \cdot \log k)$ times the optimal.*

The algorithm is as follows. First, we guess the root of the junction tree; we can run this algorithm for each candidate root $v \in V$ and return the junction tree with minimum density. Next, we solve the following LP relaxation for the min-density junction tree rooted at v. We follow a similar structure to that of LC-DST-LP, with additional variables y_i for each $i \in [k]$ to indicate whether or not the pair (s_i, t_i) is covered in the solution. For each $(s_i, t_i) \in D$, we let $\mathcal{P}^h_{s_i}$ denote the set of all h-length-constrained paths from s_i to v, and $\mathcal{P}^h_{t_i}$ denote the set of all h-length-constrained paths from v to t_i. Following LC-DST-LP, we have variables x_e for each $e \in E$ indicating whether an edge e is in junction tree, and variables f_p indicating which paths are used to connect s_i to v and v to t_i. The resulting density of the junction tree would be $(\sum_{e \in E} c(e)x_e)/(\sum_{i \in [k]} y_i)$; we normalize $\sum_{i \in [k]} y_i = 1$.

$$
\begin{aligned}
\min \quad & \sum_{e \in E} c(e) x_e & & \\
s.t. \quad & \sum_{p \in \mathcal{P}^h_{s_i}} f_p \geq y_i & & \forall i \in [k] \\
& \sum_{p \in \mathcal{P}^h_{t_i}} f_p \geq y_i & & \forall i \in [k] \\
& \sum_{p \in \mathcal{P}^h_{s_i}, e \in p} f_p \leq x_e & & \forall e \in E, i \in [k] \\
& \sum_{p \in \mathcal{P}^h_{t_i}, e \in p} f_p \leq x_e & & \forall e \in E, i \in [k] \\
& \sum_{i \in [k]} y_i = 1 & & \\
& x_e, f_p, y_i \geq 0 & & \forall e \in E, p \in \cup_{i \in [k]} \left(\mathcal{P}^h_{s_i} \cup \mathcal{P}^h_{t_i} \right), i \in [k]
\end{aligned}
\tag{LC-Den-LP}
$$

Let x^*, f^*, y^* be an optimal solution to LC-Den-LP. Partition the set of terminal pairs into groups $D_0, \ldots, D_{\log k}$, where $(s_i, t_i) \in D_j$ if $y^*_i \in (\frac{1}{2^{j+1}}, \frac{1}{2^j}]$. We will abuse notation and sometimes write $i \in D_j$ for ease.

▷ Claim 29. There exists $\theta \in \{0, \ldots, \log k\}$ such that $\sum_{i \in D_\theta} y^*_i \geq 1/(2(\log k + 1))$.

Proof. If $(s_i, t_i) \in D \setminus (\cup_{j=0}^{\log k} D_j)$, then $y^*_i \leq \frac{1}{2^{\log k + 1}} = \frac{1}{2k}$. Thus, $\sum_{i \notin \cup_{j=0}^{\log k} D_j} y^*_i \leq \sum_{i \notin \cup_{j=0}^{\log k} D_j} \frac{1}{2k} \leq \frac{1}{2}$. Recall that $\sum_{i \in [k]} y^*_i = 1$. Therefore, $\sum_{i \in \cup_{j=0}^{\log k} D_j} y^*_i \geq \frac{1}{2}$. Since there are $\log k + 1$ disjoint groups, there must be at least one group D_θ with $\sum_{i \in D_\theta} y^*_i$ at least $1/(2(\log k + 1))$. ◁

Let θ be given by Claim 29. We use the (α, β)-approximation algorithm for LC-DST twice: first, we consider the instance on G with root v and terminal set $D^t_\theta = \{t_i : (s_i, t_i) \in D_\theta\}$, and obtain a solution T_t. Second, we let G^R be obtained from G by reversing the direction of all edges. We consider the LC-DST instance on G^R with root v and terminal set

$D^s_\theta = \{s_i : (s_i, t_i) \in D_\theta\}$ and obtain a solution T'_s in G^R. Note that T'_s contains an h-length-constrained v-s_i path in G^R for all $s_i \in D^s_\theta$. Thus, if we reverse all edges of T'_s, the resulting graph T_s is a subgraph of G containing an h-length-constrained s_i-v path for all $s_i \in D^s_\theta$. Therefore, $T = T_t \cup T_s$ is a (βh)-length-constrained junction tree on terminal pairs D_θ.

▷ Claim 30. Let $\lambda = 2^{\theta+1}$. Then $(\lambda x^*, \lambda f^*)$ is a feasible solution to LC-DST-LP on both of the following instances:

- G with terminal set D^t_θ,
- G^R with terminal set D^s_θ.

In both cases, f^* is restricted to relevant paths for terminals in D^t_θ, D^s_θ.

Proof. We prove the claim for G^R with terminal set D^s_θ, as the argument for (G, D^t_θ) is analogous. Recall that $\mathcal{P}^h_{s_i}$ is the set of all h-length-constrained s_i-v paths in G. Thus, each path in $\mathcal{P}^h_{s_i}$ is an h-length constrained v-s_i path in G^R. Since (x^*, f^*, y^*) is a feasible solution to LC-Den-LP, $\sum_{p\in\mathcal{P}^h_{s_i}} f^*_p \geq y^*_i$. Furthermore, since $i \in D_\theta$, $y^*_i > \frac{1}{2^{\theta+1}}$. Thus, $\sum_{p\in\mathcal{P}^h_{s_i}} \lambda f^*_p \geq \lambda y^*_i > 1$.

The fact that $(\lambda x^*, \lambda f^*)$ satisfies the second constraint of LC-DST-LP follows immediately from the fact that (x^*, f^*) satisfies the third constraint of LC-DST-LP, since both x^* and f^* are scaled by the same value. ◁

▷ Claim 31. The density of T is at most $O(\alpha \log k) \sum_{e\in E} c(e)x^*_e$.

Proof. The algorithms used to construct T_s and T_t are (α, β)-approximations with respect to the LP. This, along with Claim 30, implies that the costs of T_t and T_s are each upper bounded by $\alpha\lambda \sum_{e\in E} c(e)x^*_e$, where $\lambda = 2^{\theta+1}$.

To bound $|D_\theta|$, observe that $\sum_{i\in D_\theta} y^*_i \leq \sum_{i\in D_\theta} 1/2^\theta = |D_\theta|/2^\theta$. Furthermore, recall that θ was defined by Claim 29 such that $\sum_{i\in D_\theta} y^*_i \geq 1/(2(\log k + 1))$. Therefore, $|D_\theta| \geq 2^\theta \sum_{i\in D_\theta} y^*_i \geq \frac{2^\theta}{2(\log k+1)}$. The density of T is at most

$$\frac{c(T_t) + c(T_s)}{|D_\theta|} \leq \frac{2\log k + 2}{2^\theta} \left(2\alpha\lambda \sum_{e\in E} c(e)x^*_e\right) = 8\alpha(\log k + 1) \sum_{e\in E} c(e)x^*_e. \quad \triangleleft$$

Lemma 28 follows from Claim 31 and the fact that T is a (βh)-length-constrained junction tree. Combining Lemma 28 with the bicriteria LP-competitive approximation for LC-DST in planar digraphs (Theorem 3) then yields Theorem 32.

▶ **Theorem 32.** *Given an instance (G, D, h) of LC-DSF in planar digraphs, there exists an efficient algorithm to obtain an $O(\log k)$-length-constrained junction tree of G of density at most $O(\log^3 k)$ times the optimal.*

This, along with Theorem 15, yields an efficient algorithm to find an $O(\log k)$-length-constrained junction tree of density at most $O(\log^5 k)\mathrm{OPT}/k$. By the standard covering argument, this yields a bicriteria $(O(\log^6 k), O(\log k))$-approximation for LC-DSF in planar digraphs, concluding the proof of Theorem 4.

Directed Low Diameter Decomposition for Structured Digraphs

Shinwoo An
Bar-Ilan University, Ramat Gan, Israel

Arnold Filtser
Bar-Ilan University, Ramat Gan, Israel

Abstract

Low diameter decompositions, or LDDs for short, are a fundamental primitive in the design of efficient graph algorithms. Roughly speaking, an LDD is a distribution over partitions of the vertices into bounded-diameter clusters such that nearby vertices are likely to be clustered together. Recently, there has been growing interest in lifting the notion of LDDs into *directed graphs*. In particular, there are two natural directed analogues. The first is a directed LDD, where after removing a random subset of edges, every strongly connected component has a small diameter. The second is a quasipartition, which imposes the stronger requirement that whenever one vertex can still reach another after the edge removal, the two vertices must be close in the original directed metric. Every quasipartition yields an LDD, but the converse does not necessarily hold.

In this work, we initiate the systematic study of LDDs in structured directed graphs. As our first main result, we show that any directed graph with pathwidth pw admits an $(O(\mathsf{pw}), \Delta)$-LDD. This improves upon the previous best-known $(2^{O(\mathsf{pw}^2)}, \Delta)$-LDD construction, which was implicitly derived from the quasipartition result of Salmasi, Sidiropoulos, and Sridhar [SODA'19].

As our second result, we show that the integrality gap of the Directed Non-Bipartite Sparsest-Cut LP relaxation on an n-vertex graph with treewidth tw is $O(\mathsf{tw} \log n)$. This improves upon the $O(\mathsf{tw} \log^2 n)$ bound of Mémoli, Sidiropoulos, and Sridhar [ICALP'16, Algorithmica'18]. We obtain this result through the refined analysis of the quasipartition construction of Mémoli et al. for bounded treewidth graphs.

1 Introduction

Decomposing graphs into well-structured pieces is a central paradigm in the design of graph algorithms. In particular, low diameter decompositions (LDDs), which are a distribution over partitions of the vertices into bounded-diameter clusters such that nearby vertices are likely to be clustered together, have played a central role in undirected graphs. They serve as key primitive underlying a wide range of problems, a partial list of examples include: metric embedding [6, 18, 34, 41, 21], multi-commodity flow [32, 38], Steiner point removal [17], near-linear SDD solvers [10], Lipschitz extension [36], spanners [24, 28], and more. undirected graphs, low diameter decompositions have been extensively studied not only in general graphs, but also in structured graph classes [32, 19, 1, 3, 20, 23, 15], where additional structure often leads to improved guarantees.

Recently, there has been a growing interest in extending low diameter decompositions to *directed graphs* [8, 9, 12, 39], despite the inherent technical challenges compared to the undirected setting. A notable application of this line of work is a recent near-linear time algorithm for the negative-weight single-source shortest path (SSSP) problem [9]. A *strongly connected component* of a directed graph G, an SCC in short, is a maximal subgraph H of G such that for every pair u, v of vertices in H, both u is reachable from v and v is reachable from u. For vertices u, v of G, let $d_G(u, v)$ denote the length of a shortest directed path from u to v in G, with $d_G(u, v) = \infty$ if no such path exists. For a subgraph $H \subseteq G$, the strong diameter of H is $\max_{u,v \in V(H)} d_H(u, v)$, whereas the weak diameter of H is $\max_{u,v \in V(H)} d_G(u, v)$. Here, $V(H)$ denotes the vertex set of H.

▶ **Definition 1** (Directed Low-Diameter Decomposition, [8, 9]). *Given an edge-weighted directed graph $G = (V, E, w)$ and a parameter $\Delta > 0$, a (β, Δ)-LDD is a distribution over subsets $S \subset E$ of edges, called a cutset, such that*

1. *every strongly connected component in $G \setminus S$ has a weak diameter of at most Δ, and*
2. *for every edge $e \in E$, $\Pr[e \in S] \leq \beta \cdot \frac{w(e)}{\Delta}$.*

We call β the loss parameter.

On the other hand, a parallel line of work has focused on *quasipartitions* for directed graphs [40, 31, 43], motivated by their connection to the integrality gap of the directed sparsest cut problem and the directed multicut problem [13].

▶ **Definition 2** ((Random) Quasipartition [40]). *Given an edge-weighted directed graph $G = (V, E, w)$ and a parameter $\Delta > 0$, a (β, Δ)-quasipartition is a distribution over a cutset $S \subseteq E$ such that*

- *for every u-v path in $G \setminus S$, $d_G(u, v) \leq \Delta$, and*
- *for every edge $e \in E$, $\Pr[e \in S] \leq \beta \cdot \frac{w(e)}{\Delta}$.*

We call β the loss parameter.

Notably, quasipartitions impose strictly stronger constraints than LDDs, and thus any (β, Δ)-quasipartition immediately yields a (β, Δ)-LDD, but not vice versa. Intuitively, in the quasipartition construction, one has to enforce that the distance between endpoints of every valid path is at most Δ. In contrast, the LDD construction only restricts the distance between endpoints of the paths within a *strongly connected component*. One specific example is directed acyclic graphs (DAGs), which are directed graphs avoiding directed cycles. It is easy to observe that every DAG itself is a $(0, \Delta)$-LDD for every parameter $\Delta > 0$ since its SCCs are isolated singletons. On the other hand, constructing a quasipartition with a small loss parameter on a DAG remains highly non-trivial, as a DAG still might contain arbitrarily long paths that must be cut. This separation is also reflected in a polynomial gap over the achievable loss parameters. While every directed graph on n vertices admits an $(O(\log n \cdot \log \log n), \Delta)$-LDD [12], there exists an n-vertex directed graph that does not admit any $(o(n^{1/7} \log^{4/7} n), \Delta)$-quasipartition [40].

Quasipartitions and LDDs are not merely theoretical concepts. Rather, they play a crucial role in driving distance-preserving graph sparsification scheme. Here, the goal is to obtain a simplified representation of the given graph while approximately preserving its distances. A number of such structures for directed graphs have been studied: including spanners [7], distance preservers [11], hopsets [33], and more. From the aforementioned lower

bound for the quasipartition, [40] showed that one cannot efficiently embed a directed graph into *quasiultrametric space*, which is equivalent to the shortest path metric in directed trees. In contrast, by changing the viewpoint to LDDs, Assadi, Hoppenworth, and Wein [5] showed that one can (stochastically) embed any directed graph into two DAGs with distortion $O(\log^3 n)$. The distortion bound has been improved to $O(\log n \cdot \log\log n)$ by Filtser [22].

In structured directed graph classes, the distinction between the two decompositions remains poorly explored. First, all known LDD results for structured directed graphs have an indirect nature: Instead of being tailored directly to LDDs, they are either obtained via quasipartition constructions (bounded pathwidth and bounded treewidth [40, 43]) or simply bypassed by applying general graph bounds [12] (planar graphs [31]). In addition, there are no techniques that are specifically tailored to constructing LDDs in this setting.

Second, among the prior works that are indirectly derived from the quasipartition constructions, the resulting bounds fail to yield a clear improvement over the general graph bounds. Specifically, the loss parameter either suffers from a polynomial dependence on treewidth [40] or even worse, an exponential dependency on pathwidth [43]. Consequently, these results surpass the general bounds of [12] only when the parameters are strictly sublogarithmic in the graph size.

To overcome these barriers, a natural starting point is to focus on pathwidth [42]- one of the most standard and well-studied graph parameters which intuitively measures the degree to which a given graph resembles a path. Indeed, based on their structural advantage, bounded pathwidth graphs admit a wide range of efficient algorithms for fundamental graph problems [2, 25, 26, 30, 35]. From the perspective of LDDs, such graphs also enjoy improved guarantees on the loss parameter compared to general graphs in the undirected setting [3]. Hence, it is natural to ask whether the same phenomenon holds in the directed setting.

Motivated by these insights and the gap between the undirected and directed settings, we initiate the study of LDDs in structured directed graphs, especially bounded pathwidth graphs, moving beyond those obtained indirectly via quasipartition approaches. Our main result is that every directed graph of pathwidth pw admits an $(O(\mathsf{pw}), \Delta)$-LDD. This significantly improves the previous best-known result of $(2^{O(\mathsf{pw}^2)}, \Delta)$-LDD [40] in this setting.

▶ **Theorem 3.** *Let G be an edge-weighted directed graph and $\mathsf{pw}(G) = k$. Then, for any $\Delta > 0$, there is a $(O(k), \Delta)$-LDD of G.*

Classical constructions of (undirected/directed) LDDs rely on the ball carving technique [6], where we recursively compute clusters by removing regions defined by distance thresholds around a center. In graphs of bounded pathwidth, prior work for undirected graphs [3] bypasses the general bound of [6] via a path-carving approach: repeatedly choosing a shortest path as a backbone and removing a distance-threshold neighborhood around it, exploiting the path-like structure of the graph. Provided that one can efficiently remove this neighborhood [3, 29], this approach yields an improved loss bound compared to [6].

On the other hand, in general directed graphs, one natural difficulty is that, once we carve a nearby region around a center as a cluster, we cannot guarantee the diameter of the cluster. To overcome this difficulty, all prior works that directly compute LDDs [8, 9, 12, 39] recursively apply the ball carving approach for each carved cluster. It seems difficult to eliminate the $\log n$ dependency on the loss parameter under this approach.

Our main technical contribution is a novel carving procedure with respect to a shortest path, which we call *scissors carving*, that avoids this difficulty. In essence, our approach carefully decomposes a shortest path into shorter subpaths, and applies the ball carving to each segment in a "local" sense. The key insight is that, we can efficiently carve away a path

Table 1 Previous and new results on graph partition in directed graphs.

whose length is sufficiently short[1]. In addition, we ensure that any carved cluster from such short paths has a small diameter. We believe that our technique provides a first step toward developing LDD techniques tailored to structured directed graphs, and that the technique itself is of independent interest.

As a secondary contribution, we revisit quasipartitions in directed graphs of bounded treewidth [40], and improve the $O(\mathsf{tw}\log^2 n)$ bound on the integrality gap of the directed non-bipartite sparsest cut [40] by a factor of $O(\log n)$, through a better analysis. Previous and new results about the integrality gap are summarized in Table 2. See Section 5 for the problem definitions and details of prior works on it.

2 Preliminaries

Throughout this paper, all missing proofs can be found in the full version. For a positive integer n, we denote by $[n]$ the set of all positive integers at most n.

Graph notations. Let $G = (V, E, w)$ be an edge-weighted directed graph, with n vertices. We often use $V(G)$ and $E(G)$ to denote the vertex set and the edge set in G, respectively. For a set A of vertices in G, we use $G \setminus A$ to denote the graph obtained from G by removing all vertices in A and their adjacent edges. We use $G[A]$ to denote a *induced subgraph* of G with respect to A. That is, $G[A] = G \setminus (V \setminus A)$. Similarly, for a set B of edges in G, we use $G \setminus B$ to denote the graph obtained from G by removing all edges in B. Two vertices u, v in

G are *strongly connected* if there exist both a u-v path and a v-u path in G. A graph G is *strongly connected* if there is a u-v path for every $u, v \in V$. A *strongly connected component* of G, an SCC in short, is a maximal strongly connected subgraph of G. For a path P in G, the *length* of P is defined as the total edge weight in P. We use $d_G(u, v)$ to denote the *distance* between u and v in G. The *diameter* of G is defined as the maximum value of $d_G(u, v)$ among every pair $(u, v) \in V \times V$.

Treewidth and Pathwidth. A *tree-decomposition* (resp. *path-decomposition*) of an *undirected* graph G is a pair $(T, \{B_t\}_{t \in V(T)})$ consisting of a tree (resp. path) T and a family of sets $\{B_t\}_{t \in V(T)}$ of vertices in G such that

1. $V(G) = \bigcup_{t \in V(T)} B_t$,
2. for every edge $uv \in E(G)$, there exists a node $t \in V(T)$ such that $\{u, v\} \subseteq B_t$, and
3. for every vertex $v \in V(G)$, the set $\{t \in V(T) : v \in B_t\}$ induces a connected subtree (resp. subpath) of T.

The *width* of a tree-decomposition (resp. path-decomposition) $(T, \{B_t\}_{t \in V(T)})$ is defined as $\max_{t \in V(T)} |B_t| - 1$. The *treewidth* $\mathsf{tw}(G)$ (resp. *pathwidth* $\mathsf{pw}(G)$) of a graph G is the minimum width among all tree decompositions (resp. path decompositions) of G.

For a *directed* graph $G = (V, E)$, we consider the undirected graph $\bar{G}$ obtained by ignoring the edge directions and removing any parallel edges. Formally speaking, $\bar{G}$ has a vertex set $V(\bar{G}) = V$ and an edge set $E(\bar{G}) = \{\{u, v\} \mid (u, v) \in E \text{ or } (v, u) \in E\}$. We say that G has treewidth (resp. pathwidth) k if its underlying undirected graph $\bar{G}$ has treewidth (resp. pathwidth) k.

3 Technical Overview

Low diameter decomposition (LDD) for undirected graphs. Let G be an undirected graph. A (β, Δ)-LDD of G is a distribution over vertex partitions such that in every partition, each cluster has a diameter of at most Δ, and for every vertex pair u, v, the probability that u, v belong to different clusters is at most $\beta \cdot \frac{d_G(u,v)}{\Delta}$. We call β the *loss parameter*. Every n-vertex graph admits an $(O(\log n), \Delta)$-LDD for any $\Delta > 0$, which is tight [6].

Ball carving is a classical technique for computing an LDD. For a vertex $u \in V$ and parameter $R > 0$, a *ball* $B_G(u, R)$ is defined as the set of vertices $v \in V$ such that $d_G(u, v) \leq R$. We call R the *radius* of $B_G(u, R)$. The algorithm of Bartal [6] repeatedly takes a vertex w from the remaining graph, samples a radius R from an exponential distribution with the

parameter $\Theta(\log n/\Delta)$, and removes the ball $B_G(w, R)$ from the graph as a single cluster. Using the memoryless property of the exponential distribution, Bartal [6] showed that the algorithm yields an $(O(\log n), \Delta)$-LDD.

Low diameter decomposition for bounded pathwidth graphs. Abraham et al. [3] showed that if G has pathwidth pw, it admits an $(O(\log \mathsf{pw}), \Delta)$-LDD. While this is a special case of a more general framework for minor-free graphs, we sketch their approach for the bounded pathwidth graphs. The following lemma was implicitly proved by several works (e.g., [3, 29]).

▶ **Lemma 5.** *Let G be an undirected graph and P be a shortest path in G. For any $\Delta > 0$, there is a set $N \subset P$ of vertices, called a net, such that*
1. *(Covering) $P \subset \bigcup_{v \in N} B_G(v, \Delta)$, and*
2. *(Sparsity) for every $u \in G$, $|B_G(u, 2\Delta) \cap N| = O(1)$.*

Their algorithm works in several rounds. In each round, for each connected component in the current graph, we pick a shortest path P connecting a vertex in the first bag and a vertex in the last bag (in a path decomposition), and compute a net N of that path using Lemma 5. Next, for each $v \in N$, we sample a radius R_v from a *truncated exponential distribution* with a parameter λ over the range $[\frac{\Delta}{4}, \frac{\Delta}{2}]$ so that each cluster has a diameter at most Δ. That is, the exponential distribution with the parameter λ conditioned on the event that the output belongs to $[\frac{\Delta}{4}, \frac{\Delta}{2}]$. We will define λ later. Finally, we carve $B_G(v, R_v)$ from the current graph as a single cluster.

Crucially, due to the covering property of Lemma 5, all vertices of P are carved away after the carving step. Moreover, since P is a path connecting a vertex in the first bag and a vertex in the last bag, P intersects every bag of the path decomposition. Therefore, the pathwidth of the graph decreases by at least one. Thus, the algorithm terminates after pw rounds. Due to the sparsity property of Lemma 5, we can show that for every pair $u, v \in V$, at most $\nu = O(\mathsf{pw})$ balls, called threateners, affect the probability that u, v belong to different clusters.

Roughly speaking, the truncated exponential distribution behaves similarly to the exponential distribution, i.e., retaining a memoryless property, up to a small error. These errors from the sampled radii of different threateners are accumulated. In order to keep the total error negligible, the parameter should be at least logarithmic in the number of threateners. In light of this, Abraham et al. [3] set the parameter $\lambda = \Theta(\frac{\log \nu}{\Delta}) = \Theta(\frac{\log \mathsf{pw}}{\Delta})$, yielding an $(O(\log \mathsf{pw}), \Delta)$-LDD of G. This path-carving framework is the key ingredient that we will adapt to the directed setting later.

Low diameter decomposition for general directed graphs. A directed analogue of the low diameter decomposition (Definition 1) was very recently introduced by Bernstein, Gutenberg, and Wulff-Nilsen [8] (though not stated explicitly), who showed that every n-vertex directed graph G admits an $(O(\log^2 n), \Delta)$-LDD for every parameter $\Delta > 0$. Later, Bernstein, Nanongkai, and Wulff-Nilsen [9] explicitly defined the notion of a low diameter decomposition and presented a simpler algorithm yielding an $(O(\log^2 n), \Delta)$-LDD. This bound has been improved to $O(\log n \cdot \log \log n)$ by Bringmann et al. [12].

The algorithm of Bernstein et al. [9] follows the ball carving framework: it samples a radius and carves either an in-ball or an out-ball[2] around a chosen vertex. A key difficulty in the directed setting is that, unlike the undirected case, one cannot guarantee the weak

[2] We defer the definitions of an in-ball and an out-ball to Section 3.2

diameter bound of an SCC contained in a single ball. To resolve this, the algorithm of [9] recursively applies the same carving procedure to every SCC until all SCCs have a small weak diameter. By carefully selecting centers, Bernstein et al. [9] managed to bound the recursion depth by $O(\log n)$. This yields an $O(\log^2 n)$ bound on the loss parameter.

3.1 Low diameter decomposition for special classes of directed graphs

The aforementioned issue remains even for special classes of directed graphs, such as those with bounded pathwidth, bounded treewidth, or planar graphs. We briefly review some prior works that circumvented this issue. We remark that while all prior work primarily addressed random quasipartitions for those graph classes, their quasipartition results directly translate to low diameter decompositions with the same loss parameter[3]. Consequently, we present the prior work from the viewpoint of low diameter decompositions.

Separator-based approach. Mémoli, Sidiropoulos, and Sridhar [40] showed that every n-vertex directed graph with treewidth tw admits an $(O(\mathsf{tw}\log n), \Delta)$-LDD for every parameter $\Delta > 0$. Their approach is based on a balanced separator. We call $U \subset V(G)$ a *balanced separator* if the number of vertices in each connected component of $G \setminus U$ is at most $\frac{2}{3}|V(G)|$. It is well known that every graph G with treewidth tw admits a *balanced separator* $U \subset V(G)$ of size at most $\mathsf{tw}+1$.

The algorithm of [40] computes a balanced separator U, samples a radius, and constructs both in-balls and out-balls around each vertex of U. Next, it adds the boundary edges of these balls to the cutset S. Then, it recursively proceeds on each SCC of $G \setminus U$. Critically, any SCC of $G \setminus S$ is either disjoint from U or has a weak diameter of at most Δ. The loss parameter at a single recursion level is $O(\mathsf{tw})$ since the algorithm computes a cutset through $2|U| = O(\mathsf{tw})$ balls. In addition, the recursion depth is $O(\log n)$. Overall, the algorithm of [40] yields an $(O(\mathsf{tw}\log n), \Delta)$-LDD.

Kawarabayashi and Sidiropoulos [31] showed that every n-vertex planar directed graph admits an $(O(\log^2 n), \Delta)$-LDD. Instead of a (balanced) vertex separator, they utilized the shortest path separator of [44], which consists of a constant number of shortest paths. Again, the $O(\log n)$ factor arises from the fact that the recursion depth is $O(\log n)$. We remark that it seems difficult to avoid the $O(\log n)$ factor in any separator-based approach since the recursion depth is $O(\log n)$ and the edge-cut probability incurred in each round must be handled independently.

LDD of constant loss parameter for bounded pathwidth directed graphs. Salmasi, Sidiropoulos, and Sridhar [43] showed that every n-vertex directed graph G with pathwidth pw admits a $(2^{O(\mathsf{pw}^2)}, \Delta)$-LDD for every parameter $\Delta > 0$. This is the only known LDD result for structured directed graphs where the loss parameter is independent of n.

We briefly sketch their approach at a high level. We start by setting the current graph to $H = G$. In each round, [43] computes a u-v shortest path P that connects the first and last bags of the path decomposition. Instead of carving the balls around the net vertices along P, the algorithm computes a random shift $z \in [0, \Delta]$ and adds all edges crossing distances of $i\Delta + z$ from u for every integer i, to the cutset. Notably, after this, they remove the edge set of P from H (recall that in the ball carving framework, the cutset is removed) and recurse. Finally, the algorithm repeats the entire procedure in the reversed direction. The recursion depth is $O(\mathsf{pw}^2)$.

[3] From Definitions 1 and 2, it is easy to check that every (β, Δ)-quasipartition is a (β, Δ)-LDD.

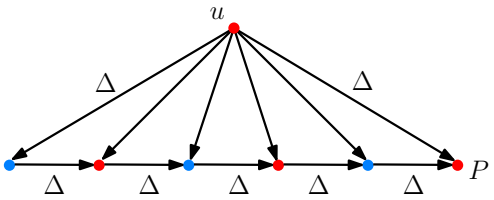

Figure 1 Counter-example of Lemma 5 for directed graphs. Consider a directed graph G consisting of a shortest path P of n edges of weight Δ, an apex vertex u, and an edge (u, p) of weight Δ for every vertex $p \in P$. Then, for any subset $N \subseteq P$ that satisfies the covering property, i.e., $P \subset \bigcup_{v \in N} B_G^+(v, \Delta)$, notice that each ball covers at most $O(1)$ vertices of P. Therefore, $|N| = \Theta(n)$. The blue points indicate the points in N. Since $d_G(u, v) = \Delta$ for every $v \in P$, $N \subseteq B_G^+(u, 2\Delta)$.

Salmasi, Sidiropoulos, and Sridhar [43] managed to eliminate the dependency on n by carving away the boundary edges of concentric layers with a random shift. On the other hand, they remove the edge set of P instead of the cutset edges. This causes a more involved analysis of bounding the weak diameter, and yields a $(2^{O(\mathsf{pw}^2)}, \Delta)$-LDD. We also remark that their analysis crucially utilizes the structure of the bounded pathwidth graphs, making it seemingly difficult to lift their result to bounded treewidth graphs or planar graphs.

3.2 Our solution: Scissors Carving

Our algorithm departs from the previous approaches. We develop a new carving procedure, which we call *scissors carving*. This is our main technical contribution that enables us to achieve an $(O(\mathsf{pw}), \Delta)$-LDD. Let $G = (V, E, w)$ be an edge-weighted directed graph. For a vertex $u \in V$ and a parameter $R > 0$, we define the *out-ball* $B_G^+(u, R)$ and the *in-ball* $B_G^-(u, R)$ as

$$B_G^+(u, R) := \{x \in V \mid d_G(u, x) \leq R\}, \text{ and } B_G^-(u, R) := \{x \in V \mid d_G(x, u) \leq R\},$$

respectively. We call R the *radius*.

At a high level, suppose we are given a target x-y path P that we want to carve away. We compute an out-ball around x and an in-ball around y with radii proportional to $d_G(x, y)$, and then remove their boundary edges. Then, we recurse on each SCC intersecting P.

The key insight is that this approach always makes progress for each recursive SCC: either the length of the portion of P contained in each SCC, called the *forward distance*, is reduced, or the pathwidth of the SCC is decreased. Once the length of the current path becomes sufficiently small, we apply the same procedure in the reverse direction, i.e., computing an in-ball around x and an out-ball around y, to reduce the *backward distance* $d_G(y, x)$. The separation between the forward-reduction stage and the backward-reduction stage is essential, as reducing the backward distance using two balls is only possible once the forward distance is sufficiently small.

We demonstrate the two advantages of the scissors carving framework as follows. First, we recursively compute two balls of geometrically decreasing radii. Even though we may compute many balls across the recursion, most of them have radii much larger than Δ. This allows us to bound the edge cut probability by $\Pr[e \in S] \leq O(1) \cdot \frac{w(e)}{\Delta}$.

Second, after both the forward-reduction stage and the backward-reduction stage, we ensure that both the forward distance and the backward distance of each remaining SCC H are sufficiently small. Using this structural advantage, we show that any SCC of H fully contained in a single ball of radius Δ around $u \in H$ has a weak diameter of at most $O(\Delta)$.

This overcomes the limitation that, in general directed graphs, an SCC contained in a single ball of radius Δ can have an arbitrarily large diameter. This allows us to ensure the desired diameter bound.

Based on the scissors carving procedure, we compute an $(O(\mathsf{pw}), \Delta)$-LDD following the framework of [3]. Specifically, we start by setting the current graph to $H = G$. At each stage, we take a shortest path P in H that we want to carve away. In particular, we choose P such that $\mathsf{pw}(H \setminus P) < \mathsf{pw}(H)$. Then, we apply scissors carving to P and update the cutset S. This ensures that every SCC of $H \setminus S$ either has a bounded weak diameter or a reduced pathwidth (See Lemma 6). Furthermore, we shall guarantee that every SCC disjoint from P has a reduced pathwidth. Then, we recurse on every SCC of $H \setminus S$ whose weak diameter is greater than Δ. By taking the union S of the cutsets computed from all recursive calls, we ensure that every SCC of $G \setminus S$ has a weak diameter of at most Δ. The recursion depth is at most $\mathsf{pw}(G)$. Due to the union bound of probability, the probability bound of Lemma 6 yields $\Pr[e \in S] \leq O(\mathsf{pw}(G)) \cdot \frac{w(e)}{\Delta}$.

▶ **Lemma 6** (informal).[4] *Let H be a strongly connected subgraph of G. There is a randomized algorithm that computes a cutset $S \subset E(H)$ such that for every strongly connected component C of $H \setminus S$, either $\mathsf{pw}(C) < \mathsf{pw}(H)$ or the weak diameter of C is $O(\Delta)$. Moreover, for every $e \in E(H)$, $\Pr[e \in S] \leq O(1) \cdot \frac{w(e)}{\Delta}$.*

In the rest of this section, we explain the core idea of the scissors carving technique and give a proof sketch of Lemma 13, especially for the first statement. We begin by defining some notation used in this paper. For a vertex set $C \subseteq V$, we denote the set of edges whose source endpoint is in C and target endpoint is outside C by $\delta^+(C)$. Similarly, we denote the set of edges whose source endpoint is outside C and target endpoint is inside C by $\delta^-(C)$.

Let H be a subgraph of G and P be a shortest path in G whose two endpoints are contained in H. For a strongly connected *subgraph* C of H, let u and v be the first and the last vertices of $P \cap C$ (along the order of P), respectively. We define the *surviving subpath* of P with respect to C, denoted as $P[C]$, as the u-v subpath of P. Note that $P[C]$ may not be fully contained in C. We define the *forward distance* and the *backward distance* of C (with respect to P) as $d_G(u, v)$ and $d_G(v, u)$, respectively, and denote them by $f_P(C)$ and $b_P(C)$, respectively. Note that we analyze these distances with respect to the shortest paths in G, rather than the current subgraph C. This is sufficient for our purpose since our goal is to bound the *weak diameter* of each SCC.

We use the following lemma. See Figure 2 for an illustration.

▶ **Lemma 7.** *Let $B_1 = B^*_G(v, R)$ and $B_2 = B^{*'}_G(v, R)$ with $*, *' \in \{+, -\}$, and let C be a strongly connected subgraph of G. Then,*

- *every SCC of $C \setminus (\delta^*(B_1) \cup \delta^{*'}(B_2))$ is either fully contained in $B_1 \cap B_2$ or disjoint from $B_1 \cap B_2$, and*
- *every SCC of $C \setminus (\delta^*(B_1) \cup \delta^{*'}(B_2))$ is either fully contained in B_1, or fully contained in $B_2 \setminus B_1$, or disjoint from $B_1 \cup B_2$.*

Next, we explain the scissors carving procedure. We are given a strongly connected subgraph H of G and a shortest path P as input, such that the two endpoints of P are contained in H, and $\mathsf{pw}(H \setminus P) < \mathsf{pw}(H)$. The algorithm consists of three stages, and the first two stages operate recursively. As we will see below, these stages aim to reduce the forward distance, reduce the backward distance, and bound the weak diameter of each SCC, respectively.

[4] Here, we give an informal statement in order to hide several technical terms behind it. See Lemma 13 for details.

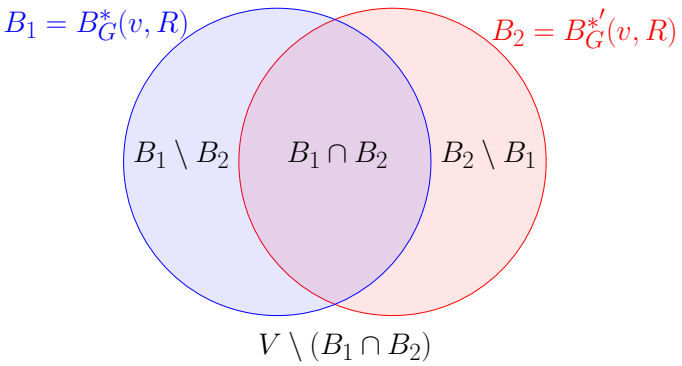

Figure 2 Due to the definition of $\delta^*(\cdot)$, every SCC of $H \setminus \delta^*(B_1)$ is either contained in B_1 or disjoint from B_1. The same holds symmetrically for B_2. Therefore, every SCC of $H \setminus (\delta^*(B_1) \cup \delta^{*'}(B_2))$ is fully contained in one of the regions of the Venn diagram. This proves both items of Lemma 7 for the special case of $C = G$. See Section 4 for the general case.

First stage: reducing forward distance. In the first stage we are given a strongly connected subgraph C of H as input. Let $P[C] = \langle u, \ldots, v \rangle$ and $\tau = f_P(C)$. We sample the radius R uniformly at random from $[\frac{1}{2}\tau, \frac{2}{3}\tau]$, and compute two balls $B_1 = B^+_G(u, R)$, $B_2 = B^-_G(v, R)$ and add their boundary edges $\delta^+(B_1) \cup \delta^-(B_2)$ into the cutset S. We then recursively apply this approach to each SCC of $C \setminus S$ contained in $B_1 \cup B_2$. We halt the first stage when $f_P(C) \leq \Delta$, and proceed to the second stage. This completes the first stage.

We show that the above procedure ensures that each resulting SCC for the recursive calls has a reduced forward distance, while the remaining SCCs have a reduced pathwidth. Hence, it suffices to proceed with the SCCs of the former type, i.e., those with a reduced forward distance. To see this, since we take R from the range $[\frac{1}{2}\tau, \frac{2}{3}\tau]$ and $P[C]$ is a shortest path in G, for every $w \in P[C]$, either $d_G(u, w) \leq R$ or $d_G(w, v) \leq R$. Hence, $P \subseteq B_1 \cup B_2$. In addition, due to Lemma 7, every SCC of $C \setminus S$ is either fully contained in B_1, or fully contained in $B_2 \setminus B_1$, or disjoint from $B_1 \cup B_2$. Let C' be an SCC of $C \setminus S$ and $P[C'] = \langle x, \ldots, y \rangle$. Since $P[C']$ is a subpath of P and $C' \subseteq C$, $P[C']$ is a subpath of $P[C]$. If C' is contained in B_1,

$$d_G(x, y) \leq d_G(u, y) \overset{B_1}{\leq} R \leq \frac{2}{3}\tau.$$

Otherwise, if C' is contained in $B_2 \setminus B_1$, we have that

$$d_G(x, y) \leq d_G(x, v) \overset{B_2}{\leq} R \leq \frac{2}{3}\tau.$$

Finally, if C' is disjoint from $B_1 \cup B_2$, $P \subseteq B_1 \cup B_2$ implies that C' is a subset of $C \setminus P$. Then, we have that $\mathsf{pw}(C') \leq \mathsf{pw}(C \setminus P) \leq \mathsf{pw}(H \setminus P) < \mathsf{pw}(H)$. Hence, we conclude that every SCC of $G \setminus S$ either has a reduced forward distance or a reduced pathwidth, as desired.

Second stage: reducing backward distance. In the second stage, we are given a strongly connected subgraph C of H as input with the additional property that $f_P(C) \leq \Delta$. Let $P[C] = \langle u, \ldots, v \rangle$ and $b_P(C) = \tau'$. Importantly, throughout this stage, we ensure that the condition on $f_P(C)$ always holds. Our algorithm is almost identical to that of the first stage, except that we compute two balls in the reversed direction and sample the radius R from a narrower interval. The reason we choose a narrower interval is to reduce the backward distance by a constant fraction.

More precisely, we sample R uniformly at random from $[\frac{1}{2}\tau', \frac{13}{24}\tau']$, compute two balls $B_1 = B_G^-(u, R), B_2 = B_G^+(v, R)$ and add $\delta^-(B_1) \cup \delta^+(B_2)$ to the cutset S. We recursively apply this approach to each SCC of $C \setminus S$ contained in $B_1 \cup B_2$. We halt the second stage when $b_P(C) \leq 8\Delta$. Here, 8 is also a carefully chosen constant in order to bound the backward distance.

We show that a symmetrical property holds for this stage: Every SCC contained in $B_1 \cup B_2$ has a reduced backward distance, and every SCC disjoint from $B_1 \cup B_2$ has a reduced pathwidth. Let C' be an SCC of $C \setminus S$ and $P[C'] = \langle x, \ldots, y \rangle$. First, we bound $b_P(C')$ in the case where $C' \subseteq B_1 \cup B_2$. From Lemma 7, without loss of generality, let us assume $C' \subseteq B_1$. The other case where $C' \subseteq B_2 \setminus B_1$ is analogous. From the argument of the first stage, $P[C']$ is a subpath of $P[C]$ and $d_G(u, v) = f_P(C) \leq \Delta$. In addition, due to the triangle inequality, we have that:

$$d_G(y, x) \overset{\triangle}{\leq} d_G(y, u) + d_G(u, x) \leq d_G(y, u) + d_G(u, v) \overset{B_1}{\leq} R + d_G(u, v) \leq R + \Delta \leq \frac{13}{24}\tau' + \Delta.$$

Since the halting condition is $\tau' \leq 8\Delta$, we have that $\frac{13}{24}\tau' + \Delta \leq \frac{2}{3}\tau'$ throughout the second stage. Hence, the backward distance is reduced by $2/3$.

Next, we bound the pathwidth of C' in the case where C' is disjoint from $B_1 \cup B_2$. The difference is that $P[C]$ may not be fully contained in $B_1 \cup B_2$. For simplicity, let us assume that u and v are the leftmost and rightmost vertices of P in the path decomposition, respectively. That is, for two bags X_u and X_v containing u and v respectively, every bag X that intersects P, lies between X_u and X_v in the path decomposition[5]. We consider a shortest v-u path P' of length τ' in G. Since $R \geq \frac{1}{2}\tau'$, it is easy to check that $P' \subseteq B_1 \cup B_2$. Moreover, since P' intersects every bag X between X_u and X_v, P' intersects every bag X that intersects P. Since C' is disjoint from $B_1 \cup B_2$, it is disjoint from P' as well. Hence, for each bag X intersecting $P \cap C'$, we have that:

$$|C' \cap X| < |C' \cap X| + |P' \cap X| = |(C' \cup P') \cap X| \leq |C \cap X|.$$

This establishes that $\mathsf{pw}(C') < \mathsf{pw}(C)$, as desired. See Figure 3(b) for an illustration.

Third stage: reducing the weak diameter. Finally, the third stage serves as the base case. We are given a strongly connected subgraph C of H as input, where the two previous stages guarantee that $f_P(C) \leq \Delta$ and $b_P(C) \leq 8\Delta$. One might ask whether $f_P(C), b_P(C) = O(\Delta)$ directly implies that the weak diameter of C is $O(\Delta)$. This is not true in general. What we can guarantee is only the (bi-)distance between two endpoints of $P[C]$, which does not necessarily bound the distance between every pair of vertices in C.

Let $P[C] = \langle u, \ldots, v \rangle$. We compute two balls $B_G^+(u, R_1)$ and $B_G^-(u, R_2)$ around the same vertex u, where we sample R_1, R_2 uniformly at random from $[\Delta, 2\Delta]$ and $[9\Delta, 10\Delta]$, respectively. Then, we add $\delta^+(B_1) \cup \delta^-(B_2)$ into the cutset S. Every SCC contained in $B_1 \cap B_2$ has a small weak diameter, since for every pair of vertices in $B_1 \cap B_2$, we can draw a detour of length $O(\Delta)$ through u. In addition, it is straightforward to verify that $P[C] \subset B_1 \cap B_2$. Subsequently, every SCC disjoint from $B_1 \cap B_2$ has a reduced pathwidth. Due to Lemma 7 we conclude that every SCC of $G \setminus S$ after the third stage either has a weak diameter of at most Δ or a reduced pathwidth. This completes the proof sketch of Lemma 6.

[5] Indeed, we can guarantee this assumption by carefully taking certain subpaths in each recursion step. See Section 4 for details.

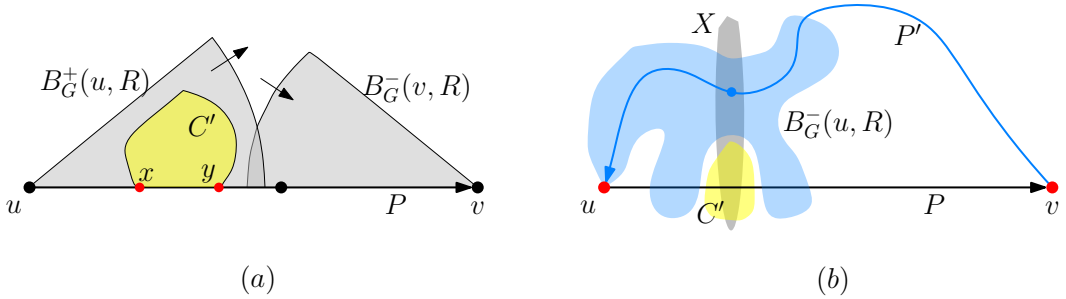

Figure 3 (a) Illustration of the first stage. The gray region denotes two balls $B_G^+(u,R)$ and $B_G^-(v,R)$ where R is sampled from $[\frac{1}{2}\tau, \frac{2}{3}\tau]$ with $\tau = d_G(u,v)$. For an SCC C' (yellow region) contained in $B_1 = B_G^+(u,R)$ and $x, y \in P \cap C'$, we have that $d_G(x,y) \leq d_G(u,y) \leq \frac{2}{3}\tau$, since P is a shortest path in G. (b) Illustration of the second stage. The blue region denotes $B_G^-(u,R)$, and P' represents the shortest v-u path in G. In addition, the yellow region denotes an SCC C' which is disjoint from $B_G^-(u,R)$. Let us assume that u and v are the leftmost and rightmost vertices of P with respect to the path decomposition. Then, for every bag X that intersects $P \cap C'$, X also intersects P' (blue vertex). Since C' is disjoint from P', we can derive $\mathsf{pw}(C') < \mathsf{pw}(C)$.

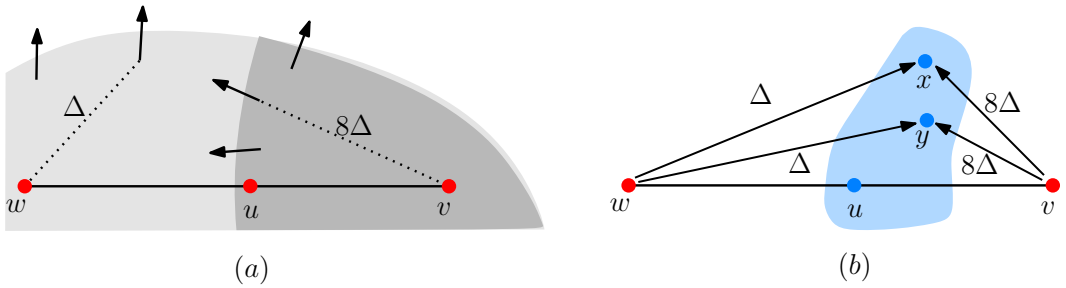

Figure 4 (a) Illustration of the graph partition from the first two stages. In the first stage, an out-ball $B_G^+(w,\Delta)$ (light gray region) containing u, v is computed. In the second stage, an out-ball $B_G^+(v,8\Delta)$ (dark gray region) containing u is computed. (b) At the start of the third stage, an SCC (blue region) might have a large diameter, as no upper bounds for $d_G(x,u)$ and $d_G(y,u)$ are assumed. In the third stage, we reduce the weak diameter of an SCC intersecting P by computing two balls of radii $O(\Delta)$ around u.

▶ Remark. One may expect a logarithmic loss parameter of $O(\log(\mathsf{ppw}(G)))$ as in [3]. However, our scissors carving framework differs from previous ball carving in the following sense. In previous work, once the interior of a ball was carved away, the resulting cluster became "safe", meaning that it was no longer affected by further ball carving steps. This allowed [3] to sample the radius from a (truncated) exponential distribution and utilize its (almost) memoryless property, ensuring them to bound the loss parameter by the logarithmic number of threateners.

In contrast, in our scissors carving, once we compute two balls that cover a shortest path, the interiors of these balls are conveyed to the next round. That is, each edge can be threatened multiple times regardless of whether it is inside a ball or not. Thus, the cut probability becomes linear in the number of threateners. We also remark that the same phenomenon is observed in the directed treewidth case [40].

4 Directed LDDs for Bounded-Pathwidth Directed Graphs

▶ **Theorem 3.** *Let G be an edge-weighted directed graph and $\mathsf{pw}(G) = k$. Then, for any $\Delta > 0$, there is a $(O(k), \Delta)$-LDD of G.*

In this section, we prove Theorem 3. While we state our result in terms of pathwidth, we find it more convenient to use the notion of *path partition-width* (see Definition 8 below). This is a directed analogue of the (undirected) tree partition-width [16] for the directed graphs with small pathwidth.

▶ **Definition 8** (Path Partition)**.** *A* path partition *of a directed graph $G = (V, E)$ is a path $\mathcal{P}$ whose vertices are bijectively associated with the sets of a partition $\mathcal{X} = \{X_1, X_2, \ldots, X_m\}$ of V, called* bags*, such that for every $(u, v) \in E$, there exist $X_i, X_{i+1} \in \mathcal{X}$ for some $1 \leq i \leq m-1$ such that $\{u, v\} \subset X_i \cup X_{i+1}$. The* width *of $\mathcal{X}$ is $\max_{i \in [m]}\{|X_i|\}$. The path partition-width $\mathsf{ppw}(G)$ of G is the minimum width among all path partitions of G.*

To begin with, we apply an edge-preserving isometric embedding from a directed graph with bounded pathwidth into another directed graph with bounded path partition-width. Note that our embedding is not new. Filtser et al. [23] defined a similar embedding from (undirected) bounded treewidth graphs into graphs of bounded tree partition-width[6] graphs. Although not stated explicitly, their embedding is also an edge-preserving isometric embedding.

▶ **Definition 9.** (Edge-preserving isometric embedding)[23] *Let $G = (V, E, w)$, $H = (U, E_H, w_H)$ be directed graphs. We say that a map $\phi : V \to U$ is an* edge preserving isometric embedding *if the following conditions hold:*

- *(isometry) $d_G(u, v) = d_H(\phi(u), \phi(v))$ for every $u, v \in V$,*
- *(edge preservation) there is an injective mapping $\bar{\phi} : E \to E_H$ such that for every $e \in E$, $w(e) = w_H(\bar{\phi}(e))$ and $\bar{\phi}(e)$ belongs to a shortest $\phi(u)$-$\phi(v)$ path in H.*

While the ultimate goal is to design an LDD for directed graphs of bounded pathwidth, our construction algorithm is formally defined on graphs of bounded path partition-width. We remark that a similar approach was used by Filtser et al. [23] to compute an LDD for (undirected) graphs of bounded treewidth. There is an edge-preserving isometric embedding from graphs with bounded pathwidth into graphs with bounded path partition-width. In addition, an LDD of the embedded graph can be transferred back to the original graph without any additional loss.

▶ **Lemma 10.** *Let $G = (V, E, w)$ be a directed graph. Then, there is an edge-preserving isometric embedding from G into a directed graph $H = (U, E_H, w_H)$ such that $\mathsf{ppw}(H) \leq \mathsf{pw}(G) + 1$.*

▶ **Lemma 11.** *Let ϕ be an edge-preserving isometric embedding from G into H, and $\mathcal{D}$ be a (β, Δ)-LDD of H. Then there is a (β, Δ)-LDD of G.*

Based on Lemmas 10 and 11, it suffices to show the existence of $(O(k), \Delta)$-LDD for the directed graphs with path partition-width at most k. Throughout this section, we let G be a directed graph, and let $(\mathcal{P}, \mathcal{X} = \{X_1, X_2, \ldots, X_m\})$ be the path partition of G with width $\mathsf{ppw}(G)$. If it is clear from the context, we slightly abuse the notation and simply

[6] Tree partition can be viewed as a natural generalization of path partition, in the same way that tree decomposition generalizes path decomposition.

denote the path partition $(\mathcal{P}, \mathcal{X})$ by $\mathcal{P}$. Furthermore, we may assume that G is strongly connected as otherwise, we can independently execute our algorithm on each SCC of G. For a subgraph H of G, we define the *induced path partition* of H with respect to $\mathcal{P}$ as $(\mathcal{P}, \{X_i \cap V(H) \mid X_i \in \mathcal{X}\})$, and denote it by $\mathcal{P}[H]$. We denote the width of $\mathcal{P}[H]$ by $w(\mathcal{P}[H])$. Note that for every subgraph H of G, $\mathsf{w}(\mathcal{P}[H]) \leq \mathsf{w}(\mathcal{P}[G]) = \mathsf{ppw}(G)$ trivially holds.

The remainder of this section is devoted to proving the following lemma.

▶ **Lemma 12.** *For any $\Delta > 0$, there is an $(O(\mathsf{ppw}(G)), \Delta)$-LDD of G.*

Next, we present a randomized recursive algorithm Directed-LDD, which receives as input a directed graph $G = (V, E, w)$, a path partition $\mathcal{P}$ of G, a strongly connected subgraph H of G, and a parameter $\Delta > 0$. In addition, Directed-LDD computes a (randomized) cutset of H whose distribution induces a $(O(\mathsf{w}(\mathcal{P}[H])), \Delta)$-LDD of H. See Algorithm 1 for the pseudocode. The algorithm immediately terminates if $\mathsf{w}(\mathcal{P}[H]) = 0$, which implies that H is an empty subgraph. For the other case where $\mathsf{w}(\mathcal{P}[H]) > 0$, Algorithm 1 calls Scissors-Carving algorithm[7], whose function is summarized in the following lemma. We defer the detailed description of Scissors-Carving to Sections 4.1.

▶ **Lemma 13.** *There is an algorithm Scissors-Carving$(G, \mathcal{P}, H, \bar{P}, \Delta)$ which computes a (random) cutset S of $E(H)$ such that:*

1. *For every strongly connected component C of $H \setminus S$, either $\mathsf{w}(\mathcal{P}[C]) < \mathsf{w}(\mathcal{P}[H])$ or the weak diameter of C is at most 12Δ, and*
2. *for every edge e in $E(H)$, $\Pr[e \in S] \leq O(1) \cdot \frac{w(e)}{\Delta}$.*

Then, for each strongly connected component C of $H \setminus S$ such that the weak diameter of C is greater than Δ, the algorithm executes a recursive call Directed-LDD $(G, \mathcal{P}, C, \Delta)$ to compute a random cutset S_C of C. Finally, Directed-LDD returns the union of S and all cutsets S_C returned by the recursive calls. This completes the description of Directed-LDD.

Algorithm 1 Directed-LDD$(G, \mathcal{P}, H, \Delta)$.

```
if w(P[H]) = 0 then
    return ∅
S ← Scissors-Carving(G, P, H, P̄, Δ)
C ← Collection of SCCs of H \ S whose weak diameter is greater than 12Δ
for all C ∈ C do
    S_C ← Directed-LDD(G, P, C, Δ)
    S ← S ∪ S_C
return S
```

Let $S = \text{Directed-LDD}(G, \mathcal{P}, H, \Delta)$.

▶ **Lemma 14.** *The weak diameter of each SCC of $H \setminus S$ is at most 12Δ.*

▶ **Lemma 15.** *For every edge e in H, $\Pr[e \in S] \leq O(\mathsf{w}(\mathcal{P}[H])) \cdot \frac{w(e)}{\Delta}$.*

Finally, Lemma 12 follows from applying Lemmas 14 and 15 by taking $H \leftarrow G$ and $\Delta \leftarrow \frac{\Delta}{12}$.

[7] The algorithm receives $\bar{P}$ as an additional input parameter, where $\bar{P}$ is a sequence of vertices in G satisfying certain conditions. We provide the details of $\bar{P}$ in Section 4.1.

4.1 Reducing path partition-width

In this section, we explain our key subroutine Scissors-Carving. To this end, we define some additional notation that will be used in this section. Recall that $\mathcal{P} = (\mathcal{P}, \mathcal{X})$ consists of m bags $X_1, X_2, \dots X_m$. Let H be a strongly connected subgraph of G. We say an index $i \in [m]$ is a *critical* index of H if $|V(H) \cap X_i| = \mathsf{w}(\mathcal{P}[H])$. Equivalently, we refer to X_i as a *critical bag* of H. Let $\mathcal{C}(H) = \{j_1, j_2, \dots, j_\ell\}$ be the set of critical indices of H such that $1 \le j_1 < j_2 < \dots < j_\ell \le m$.

We say a shortest u-v path P in G is a *critical path* with respect to H if $u \in X_{j_1} \cap H$ and $v \in X_{j_\ell} \cap H$. From the definition of a path partition, P intersects every bag X_t with $j_1 \le t \le j_\ell$. Hence, P intersects every critical bag of H.

▶ **Observation 16.** *For any critical path P with respect to H, $\mathsf{w}(\mathcal{P}[H \setminus P]) < \mathsf{w}(\mathcal{P}[H])$.*

Due to technical reasons, throughout the algorithm, we maintain a certain subsequence of the critical path P, called a *critical sequence*, which is defined as follows. For each critical index j of H, let $v_j \in X_j \cap H$ be the vertex that appears earliest in P along the direction from u to v. We may assume $v = v_{j_\ell}$ as otherwise, we can take the u-v_{j_ℓ} subpath of P. Then, $v_{j_1}, v_{j_2}, \dots, v_{j_\ell}$ are naturally ordered along the path P. We call $\langle v_{j_1}, v_{j_2}, \dots v_{j_\ell} \rangle$ a *critical sequence* of H with respect to P, and denote it by $\bar{P}[H]$. Note that this critical sequence $\bar{P}[H]$ is uniquely defined for a fixed H and P. See Figure 5(a) for an illustration. Since $\bar{P}[H]$ intersects every critical bag of H, we observe the following.

▶ **Observation 17.** *For a critical sequence $\bar{P}[H]$ of H, $\mathsf{w}(\mathcal{P}[H \setminus \bar{P}[H]]) < \mathsf{w}(\mathcal{P}[H])$.*

For a critical sequence $\bar{P} = \langle u, \dots, v \rangle$ of H with respect to P, and a strongly connected subgraph C of H, let x and y be the first and the last vertices of $\bar{P} \cap C$, respectively. We define the *surviving subsequence* of $\bar{P}$ with respect to C, denoted by $\bar{P}[C]$, as the consecutive subsequence of $\bar{P}[H]$ that starts at x and ends at y. Note that while $\bar{P}[C]$ may not be fully contained in C, the two endpoints x, y are contained in C. See Figure 5(b) for an illustration.

We define the *forward disatnce* and the *backward distnace* of C (with respect to P) as $d_G(x, y)$ and $d_G(y, x)$, respectively, and denote them by $f_{\bar{P}}(C)$ and $b_{\bar{P}}(C)$, respectively. Note that we analyze these distances with respect to the shortest paths in the original graph G, rather than the subgraph C. This is sufficient for our purpose since our goal is to bound the *weak diameter* of each SCC. We show that $\bar{P}[C]$ plays the role of a "critical" sequence for C. That is, the removal of $\bar{P}[C]$ from C reduces its path partition-width. Based on the following lemma, in the remainder of this section, we slightly abuse the notation and refer to $\bar{P}[C]$ as a *critical sequence* of C.

▶ **Lemma 18.** *Let C be a strongly connected subgraph of H and let $\bar{P}$ be a critical sequence of H with respect to a critical path P. Then, $\mathsf{w}(\mathcal{P}[C \setminus \bar{P}[C]]) < \mathsf{w}(\mathcal{P}[H])$.*

▶ **Observation 19.** *Let $\bar{P}$ be a critical sequence of H with respect to a critical path P. Then, for every strongly connected subgraph C of H, $\bar{P}[C]$ is a subsequence of a shortest path in G.*

Algorithm. We describe our algorithm Scissors-Carving $(G, \mathcal{P}, H, \bar{P}, \Delta)$. See Algorithm 2 for the pseudocode. It receives as input a directed graph G, a path partition $\mathcal{P}$ of G, a strongly connected subgraph H of G, a critical sequence $\bar{P}$ of H with respect to P, and a parameter $\Delta > 0$. Moreover, it outputs a random cutset S of $E(H)$ such that for every SCC C of $H \setminus S$, either $\mathsf{w}(\mathcal{P}[C]) < \mathsf{w}(\mathcal{P}[H])$ or the weak diameter of C is at most 12Δ.

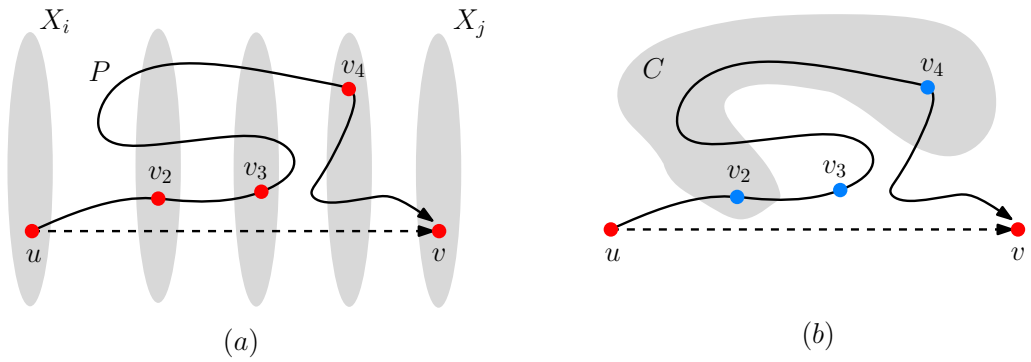

Figure 5 Illustration of the critical path and critical sequence of H. (a) The gray shaded region denotes the critical bags of H. A critical path P connects a vertex u in the first critical bag and a vertex v in the last critical bag. A critical sequence $\bar{P}$ of H with respect to P is $\langle u, v_2, v_3, v_4, v\rangle$. (b) For a subgraph C of H, the surviving subsequence $\bar{P}[C] = \langle v_2, v_3, v_4\rangle$ is depicted as blue points.

The algorithm is a recursive procedure with respect to H and $\bar{P}$. Depending on the forward distance $f_{\bar{P}}(H)$ and the backward distance $b_{\bar{P}}(H)$ of H, the procedure proceeds in one of three stages. The first stage is executed when $f_{\bar{P}}(H) = \tau > \Delta$. At this stage, we sample a random radius R uniformly at random from $[\frac{1}{2}\tau, \frac{2}{3}\tau]$. Then, we compute two balls, an out-ball $B_1 = B^+_G(u, R)$ and an in-ball $B_2 = B^-_G(v, R)$, compute a set S_1 of boundary edges of B_1 and B_2 that intersect H, i.e., $S_1 = H \cap (\delta^+(B_1) \cup \delta^-(B_2))$. Next, we recursively apply the algorithm to each SCC C of $H \setminus S_1$ which is fully contained in $B_1 \cup B_2$. In addition, we pass the surviving subsequence $\bar{P}[C]$ as the critical sequence to the next recursive call.

The second stage is executed when $f_{\bar{P}}(H) \leq \Delta$ and $b_{\bar{P}}(H) = \tau' > 8\Delta$. At this stage, we sample a random radius R uniformly at random from $[\frac{1}{2}\tau', \frac{13}{24}\tau']$. Then, we compute two balls, an in-ball $B_1 = B^-_G(u, R)$ and an out-ball $B_2 = B^+_G(v, R)$, compute a set S_1 of boundary edges of B_1 and B_2 that intersect H, i.e., $S_1 = H \cap (\delta^-(B_1) \cup \delta^+(B_2))$. Next, we recursively apply the algorithm to each SCC of $H \setminus S_1$ which is fully contained in $B_1 \cup B_2$. In addition, we pass the surviving subsequence $\bar{P}[C]$ to the next recursive call.

The third stage is executed when $f_{\bar{P}}(H) \leq \Delta$ and $b_{\bar{P}}(H) \leq 8\Delta$. We sample two random radii R_1, R_2 uniformly at random from $[\Delta, 2\Delta]$ and $[9\Delta, 10\Delta]$, respectively. Then, we compute two balls, an out-ball $B_1 = B^+_G(u, R_1)$ and an in-ball $B_2 = B^-_G(v, R_2)$, return $H \cap (\delta^+(B_1) \cup \delta^-(B_2))$.

Finally, we provide a crucial technical remark: As an extreme case, our algorithm immediately returns the empty set whenever $\bar{P}[C]$ is empty (lines 1-2). Intuitively, due to Lemma 18, $\bar{P}[C] = \emptyset$ implies $\mathsf{w}(\mathcal{P}[C]) < \mathsf{w}(\mathcal{P}[H])$, which satisfies our structural goal.

Algorithm 2 Scissors-Carving $(G, \mathcal{P}, H, \bar{P} = \langle u, \dots, v \rangle, \Delta)$.

if $\bar{P} = \emptyset$ **then**
  return $\emptyset$
$\tau, \tau', S_1, S_2 \leftarrow d_G(u,v), d_G(v,u), \emptyset, \emptyset$
/* **Stage 1. Reducing forward distance** */
if $\tau > \Delta$ **then**
  Sample R uniformly at random in the range $[\frac{1}{2}\tau, \frac{2}{3}\tau]$
  $B_1 \leftarrow B_G^+(u, R)$
  $B_2 \leftarrow B_G^-(v, R)$
  $S_1 \leftarrow H \cap (\delta^+(B_1) \cup \delta^-(B_2))$
  $\mathcal{C} \leftarrow$ SCCs of $H \setminus S_1$ that are fully contained in $B_1 \cup B_2$
  for $C \in \mathcal{C}$ **do**
    $S_2 \leftarrow S_2 \cup$ Scissors-Carving $(G, \mathcal{P}, C, \bar{P}[C], \Delta)$
  return $S_1 \cup S_2$
/* **Stage 2. Reducing backward distance** */
if $\tau \le \Delta$ and $\tau' > 8\Delta$ **then**
  Sample R uniformly at random in the range $[\frac{1}{2}\tau', \frac{13}{24}\tau']$
  $B_1 \leftarrow B_G^-(u, R)$
  $B_2 \leftarrow B_G^+(v, R)$
  $S_1 \leftarrow H \cap (\delta^-(B_1) \cup \delta^+(B_2))$
  $\mathcal{C} \leftarrow$ SCCs of $H \setminus S_1$ that are fully contained in $B_1 \cup B_2$
  for $C \in \mathcal{C}$ **do**
    $S_2 \leftarrow S_2 \cup$ Scissors-Carving $(G, \mathcal{P}, C, \bar{P}[C], \Delta)$
  return $S_1 \cup S_2$
/* **Stage 3. Bounding weak diameter** */
else
  Sample R_1 uniformly at random from $[\Delta, 2\Delta]$, and R_2 uniformly at random from $[9\Delta, 10\Delta]$
  $B_1 \leftarrow B_G^+(u, R_1)$
  $B_2 \leftarrow B_G^-(u, R_2)$
  return $H \cap (\delta^+(B_1) \cup \delta^-(B_2))$

5 Directed Sparsest Cut Problem for Bounded-Treewidth Digraphs

Directed non-bipartite sparsest cut problem. Let G be an edge-weighted directed graph with *capacities* $c(e)$ for all edges $e \in E(G)$. Let T be a set of terminal pairs $T = \{(s_1, t_1), (s_2, t_2), \dots, (s_\ell, t_\ell)\}$ of vertices. For each $i \in [\ell]$, let $\mathsf{dem}(i)$ be a non-negative real number, called the *demand*, for the terminal pair (s_i, t_i). A *cut* S of G is a subset $S \subseteq E(G)$ of edges. For a cut S, let $c(S) := \sum_{e \in S} c(e)$ be the *capacity* of S. Let $I_S \subseteq [\ell]$ be the set of integers i such that every s_i-t_i path (not necessarily a shortest path) contains at least one edge of S. We define the *demand* of S by $\mathsf{dem}(S) := \sum_{i \in I_S} \mathsf{dem}(i)$. The *sparsity* of S is defined by $c(S)/\mathsf{dem}(S)$. The goal of the directed non-bipartite sparsest cut problem is to find a cut S that minimizes the sparsity.

The integrality gap of the LP relaxation for this problem is called the directed multi-commodity flow cut-gap. For non-uniform demands, Hajiaghayi and Räcke showed an $O(\sqrt{n})$ upper bound for the flow-cut gap [27]. This has been improved to $\tilde{O}(n^{11/23})$ by Agarwal, Alon, and Charikar [4]. On the other hand, the current best-known lower bound is due to Chuzhoy and Khanna [14], who showed a $\tilde{\Omega}(n^{1/7})$ lower bound for the flow-cut gap.

Mémoli, Sidiropoulos, and Sridhar [40] showed that every n-vertex directed graph with treewidth tw admits an $(O(\mathsf{tw}\log n), \Delta)$-quasipartition for every parameter $\Delta > 0$. They used their quasipartition construction to show that the flow-cut gap is $O(\mathsf{tw}\log^2 n)$ for such graphs. We now present the main result of this section.

▶ **Theorem 4.** *Let G be an n-vertex directed graph of treewidth tw. The integrality gap (also called the flow-cut gap) of the Directed Non-Bipartite Sparsest-Cut LP relaxation on G is $O(\mathsf{tw}\log n)$.*

This improves upon the $\log n$ factor of the previously best-known bound from [40]. At a high level, we follow the procedure of [40], but provide a better analysis of their approach.

We briefly explain the approach of [40], which proved that the integrality gap is $O(\mathsf{tw}\log^2 n)$. First, they showed that for every $\Delta > 0$, G admits a (β, Δ)-quasipartition with $\beta = O(\mathsf{tw}\log n)$. Using this quasipartition, they proved that the quasimetric space with respect to the shortest path metric of G can be embedded into a convex combination of 0-1 quasimetric spaces (see Definition 21 and Lemma 22) with a distortion of $O(\beta\log n) = O(\mathsf{tw}\log^2 n)$. Finally, by using the known relationship between the convex combination of 0-1 quasimetric spaces and the integrality gap for the directed non-bipartite sparsest cut problem [13], they showed that the integrality gap is $O(\mathsf{tw}\log^2 n)$.

▶ **Definition 20.** *A quasimetric space $M = (X, d)$ is a function d over $X \times X$ that satisfies all but the symmetry axiom for a metric space. In other words, d satisfies the following properties:*

- *$d(u, u) = 0$ for all $u \in X$.*
- *(Triangle inequality) $d(u, v) \leq d(u, w) + d(w, v)$ for all $u, v, w \in X$.*

▶ **Definition 21.** *A quasimetric space $M = (X, d)$ is a 0-1 quasimetric space if every metric distance $d(u, v)$ is either 0 or 1.*

▶ **Lemma 22** (Lemma 16 of [40])**.** *Suppose a directed graph G admits a (β, Δ)-quasipartition for every $\Delta > 0$. Then there is an embedding of G into a convex combination of 0-1 quasimetric spaces with a distortion of $O(\beta\log n)$.*

5.1 Deep dive into the approach of [40]

In this section, we carefully review the previous approach of [40] step-by-step, and then describe our improvement. First, we analyze the $(O(\mathsf{tw}\log n), \Delta))$-quasipartition construction of [40].

The construction is achieved by a recursive approach. Given a tree decomposition $(T, \{B_t\}_{t\in T})$, we choose a central bag B_t, meaning that each subgraph of G induced by the maximal subtree of $T \setminus \{t\}$ contains at most $\frac{2}{3}|V(G)|$ vertices. We then sample a radius R uniformly at random from $[\frac{1}{2}\Delta, \Delta]$. For each vertex $v \in B_t$, we compute two balls, an out-ball $B_1 := B_G^+(v, R)$ and an in-ball $B_2 := B_G^-(v, R)$, add $\delta^+(B_1) \cup \delta^-(B_2)$ to the cutset S, and recursively apply this procedure to each subgraph induced by the connected components of $T \setminus \{t\}$. Note that any x-y path intersecting v such that $d_G(x, y) > 2\Delta$ must intersect $\delta^+(B_1) \cup \delta^-(B_2)$ because, due to the triangle inequality, we have that:

$$\max(d_G(x, v), d_G(v, y)) \geq \frac{1}{2}(d_G(x, v) + d_G(v, y)) \geq \frac{1}{2}d_G(x, y) > \Delta.$$

This implies that for every path (not necessarily a shortest path) connecting two vertices from different trees of $T \setminus \{t\}$, either it intersects S, or it satisfies $d_G(x, y) \leq 2\Delta$. This justifies the recursion: after the recursion terminates, we can conclude that for every x-y path in $G \setminus S$, we have $d_G(x, y) \leq 2\Delta$.

We briefly analyze the probability that a single edge belongs to the cutset, i.e., $\Pr[e \in S]$. Since B_t plays the role of a separator, each edge e is affected by at most one instance at each level of the recursion. Moreover, since B_t is a central bag, the recursion depth is $O(\log n)$. At a single level, e is affected by at most $2|B_t| = 2(\mathsf{tw}+1)$ balls. Hence, due to the union bound on the probability,

$$\Pr[e \in S] \leq O(\log n) \cdot O(\mathsf{tw}) \cdot \frac{w(e)}{\Delta} = O(\mathsf{tw} \log n) \cdot \frac{w(e)}{\Delta}.$$

Next, we analyze the second part which gives an embedding of a quasimetric space into a convex combination of 0-1 quasimetric spaces (Lemma 22). For simplicity, suppose every edge weight of G is a positive integer and $\max_{u,v}\{d_G(u,v)\} = 2^k$ for some integer $k = O(\log n)$. Then, for each scale $i \in \{0,1,\ldots,k\}$, we compute a $(\beta, 2^i)$-quasipartition $\mathcal{D}_i$ of G using the above procedure. Importantly, each quasipartition $\mathcal{D}_i$ is a distribution over a cutset $S_i \subset E(G)$. Using these, we compute a random quasipartition of G according to the following procedure. Let $c = 2^{k+1} - 1$. First, we select one $\mathcal{D}_i$ among $\{\mathcal{D}_0, \mathcal{D}_1, \ldots, \mathcal{D}_k\}$ with probability $\frac{2^i}{c}$. Then, we pick a random cutset S from the chosen $\mathcal{D}_i$. This yields a distribution $\mathcal{D}$ over the cutsets.

Next, for each cutset S of $\mathcal{D}$, we define a 0-1 quasimetric space $(V(G), d_S)$ where $d_S(x,y) = 0$ if there is an x-y path in $G \setminus S$ and $d_S(x,y) = 1$ otherwise. This yields a distribution over 0-1 quasimetric spaces which can be expressed as a convex combination of 0-1 quasimetric spaces. Let $(V(G), d^*)$ be the resulting quasimetric space. Then, we have

$$d^*(u,v) = \Pr_{S\sim\mathcal{D}}[\text{there is no } u\text{-}v \text{ path in } G \setminus S] \tag{1}$$

$$= \sum_{i=0}^{k} \frac{2^i}{c} \Pr_{S_i\sim\mathcal{D}_i}[\text{there is no } u\text{-}v \text{ path in } G \setminus S_i] \tag{2}$$

$$\leq \sum_{i=0}^{k} \frac{2^i}{c} \beta \cdot \frac{d_G(u,v)}{2^i} \tag{3}$$

$$= \frac{(k+1)\cdot\beta}{c} d_G(u,v). \tag{4}$$

For the other direction, [40] showed that $d^*(u,v) \geq \frac{1}{c} \cdot d_G(u,v)$, yielding a distortion of $(k+1)\beta = O(\beta \log n)$.

5.2 Removing the extra $O(\log n)$ factor from Lemma 22

In this section, we provide a better analysis that improves the distortion by a factor of $O(\log n)$. We focus on the $O(\log n)$ additional factor arising from Lemma 22. This factor comes from combining the distortion contributions across $O(\log n)$ scales, where each scale contributes independently.

Our idea is to avoid this factor by considering all scales simultaneously. To formalize this idea, we revisit the construction in Section 5.1. For a fixed edge $e = (x,y)$ and a scale i, we compute a set $V(e) \subset V(G)$ of size $O(\mathsf{tw} \log n)$ as follows. For each recursive instance that contains e, we add the vertices in the central bag to $V(e)$. Since e is contained in $O(\log n)$ instances (from the construction in Section 5.1), we have $|V(e)| = O(\mathsf{tw} \log n)$. Note that $V(e)$ is independent of the scale i.

Now, we reinterpret the construction in Section 5.1 as follows. For every scale i, we sample a radius R_i uniformly at random from $[2^{i-1}, 2^i]$, and we add e to the cutset S_i if e is contained in one of the boundaries of the (in- and out-) balls of radius $R_i \in [2^{i-1}, 2^i]$ centered at some vertex in $V(e)$. This defines the quasipartition $\mathcal{D}_i$ over the cutsets. We prove the following useful lemma.

▶ **Lemma 23.** *Let $e = (x, y)$ be an edge and z be a vertex in $V(e)$. Then, there are at most $O(1)$ scales $i \in [k]$ satisfying the following conditions:*
(a) $\Pr[e \in \delta^+(B^+_G(z, R_i))] > 0$, *and*
(b) $2^i > w(e)$.

Proof. Let i be an index satisfying conditions $(a), (b)$. Note that e is contained in $\delta^+(B^+_G(z, R_i))$ if and only if $d_G(z, x) \leq R_i$ and $d_G(z, y) > R_i$. Subsequently, from condition (a), we have that:

$$\Pr_{R_i}[(d_G(z, x) \leq R_i) \cap (d_G(z, y) > R_i))] > 0.$$

Since R_i is sampled uniformly at random from $[2^{i-1}, 2^i]$, we have that:

$$d_G(z, x) < 2^i, \text{ and } d_G(z, y) \geq 2^{i-1}.$$

By the triangle inequality and condition (b), we obtain:

$$2^{i-1} \leq d_G(z, y) \leq d_G(z, x) + d_G(x, y) \leq d_G(z, x) + w(e) < 2^i + 2^i = 2^{i+1}.$$

Let j be the fixed integer such that $d_G(z, y) \in [2^j, 2^{j+1}]$. Then, $i \in \{j-1, j, j+1, j+2\}$. We conclude that there are at most 4 scales i satisfying both conditions $(a), (b)$. This completes the proof. ◀

Using exactly the same argument, we can show the following lemma.

▶ **Lemma 24.** *Let $e = (x, y)$ be an edge and z be a vertex in $V(e)$. Then, there are at most $O(1)$ scales $i \in [k]$ satisfying the following conditions:*
(a) $\Pr[e \in \delta^-(B^-_G(z, R_i))] > 0$, *and*
(b) $2^i > w(e)$.

For an edge e and a vertex $z \in V(e)$, let $I(z, e)$ be the set of indices i such that $\Pr[e \in \delta^+(B^+_G(z, R_i)) \cup \delta^-(B^-_G(z, R_i))] > 0$ and $2^i > w(e)$. Due to Lemmas 23 and 24, we have that:

$$|I(z, e)| = O(1). \tag{5}$$

Let $i \in I(z, e)$. Since R_i is chosen uniformly at random from $[2^{i-1}, 2^i]$, we have that:

$$\Pr_{R_i}[(d_G(z, x) \leq R_i) \cap (d_G(z, y) > R_i))] \leq O(1) \cdot \frac{w(e)}{2^i}. \tag{6}$$

Next, we analyze the probability $q := \Pr_{S \sim \mathcal{D}}[\text{there is no } u\text{-}v \text{ path in } G \backslash S]$. Our argument closely follows that of [40]. Let $\mathcal{P} = \{p_1, p_2, \ldots, p_\ell\}$ be the set of all u-v paths in G. For every $m \in [\ell]$, let X_m be the event that p_m contains at least one edge in S. Then, $q = \Pr[X_1 \wedge X_2 \wedge \ldots \wedge X_\ell] \leq \Pr[X_m]$ for all $m \in [\ell]$. Now let us consider a fixed *shortest path* $p_m = \langle u = v_1, v_2, \ldots, v_t = v \rangle \in \mathcal{P}$. For every $j \in [t-1]$, let Y_j be the event that $(v_j, v_{j+1}) \in S$. Then, $\Pr[X_m] = \Pr[Y_1 \vee Y_2 \vee \ldots \vee Y_{t-1}] \leq \sum_j \Pr[Y_j]$ due to the union bound of probability. In addition, let $e_j = (v_j, v_{j+1})$. Then,

$$\Pr[Y_j] = \Pr[e_j \in S] = \sum_{i=0}^{k} \frac{2^i}{c} \cdot \Pr[e_j \in S_i] \tag{7}$$

$$\leq \sum_{i=0}^{k} \frac{2^i}{c} \cdot \sum_{z \in V(e_j)} \Pr_{R_i}[(d_G(z, v_j) \leq R_i) \cap (d_G(z, v_{j+1}) > R_i))] \tag{8}$$

$$= \sum_{z \in V(e_j)} \sum_{i=0}^{k} \frac{2^i}{c} \cdot \Pr_{R_i}[(d_G(z, v_j) \leq R_i) \cap (d_G(z, v_{j+1}) > R_i))]. \tag{9}$$

We analyze the inner summation over i as follows. We split the sum over k scales at $i = \lfloor \log w(e_j) \rfloor$. Since $I(z, e_j) \subseteq \{i : 2^i > w(e_j)\}$, we can bound each part separately. Let $P_{i,z} := \Pr_{R_i}[(d_G(z, v_j) \le R_i) \cap (d_G(z, v_{j+1}) > R_i))]$. Then,

$$\begin{aligned}
&\sum_{i=0}^{k} \frac{2^i}{c} \cdot \Pr_{R_i}[(d_G(z, v_j) \le R_i) \cap (d_G(z, v_{j+1}) > R_i))] = \sum_{i=0}^{k} \frac{2^i}{c} \cdot P_{i,z} \\
&= \sum_{i=0}^{\lfloor \log w(e_j) \rfloor} \frac{2^i}{c} \cdot P_{i,z} + \sum_{i=\lfloor \log w(e_j) \rfloor + 1}^{k} \frac{2^i}{c} \cdot P_{i,z} \\
&\le \sum_{i=0}^{\lfloor \log w(e_j) \rfloor} \frac{2^i}{c} + \sum_{i \in I(z,e_j)} \frac{2^i}{c} \cdot P_{i,z} \\
&\overset{(6)}{\le} \frac{2 \cdot w(e_j)}{c} + \sum_{i \in I(z,e_j)} \frac{2^i}{c} \cdot (O(1) \cdot \frac{w(e_j)}{2^i}) \overset{(5)}{=} O(1) \cdot \frac{w(e_j)}{c}.
\end{aligned}$$

Returning to Equation (9), we obtain:

$$\begin{aligned}
\Pr[Y_j] &\le \sum_{z \in V(e_j)} \sum_{i=0}^{k} \frac{2^i}{c} \cdot \Pr_{R_i}[(d_G(z, v_j) \le R_i) \cap (d_G(z, v_{j+1}) > R_i))]. \\
&\le \sum_{z \in V(e_j)} O(1) \cdot \frac{w(e_j)}{c} = O(|V(e_j)|) \cdot \frac{w(e_j)}{c} = O(\mathsf{tw} \log n) \cdot \frac{w(e_j)}{c}.
\end{aligned}$$

Here, the last equality follows from the fact that $|V(e)| = O(\mathsf{tw} \log n)$ for every edge e. Since p_m is a shortest u-v path in G, we have that:

$$q \le \Pr[X_m] \le \sum_j \Pr[Y_j] \le O(\mathsf{tw} \log n) \cdot \sum_j \frac{w(e_j)}{c} = O(\mathsf{tw} \log n) \cdot \frac{d_G(u, v)}{c}. \tag{10}$$

Putting everything together, we show that the probability bound from Eq.(1) to Eq.(4) can be improved as follows:

$$d^*(u, v) = \Pr_{S \sim \mathcal{D}}[\text{there is no } u\text{-}v \text{ path in } G \setminus S] \overset{(10)}{\le} O(\mathsf{tw} \log n) \cdot \frac{d_G(u, v)}{c}.$$

This confirms the improved distortion guarantee for the algorithm of [40].

▶ **Lemma 25.** *Given a directed graph G having treewidth* tw*, there is an embedding of G into the convex combination of 0-1 quasimetric space with distortion $O(\mathsf{tw} \log n)$.*

▶ **Theorem 4.** *Let G be an n-vertex directed graph of treewidth* tw*. The integrality gap (also called the flow-cut gap) of the Directed Non-Bipartite Sparsest-Cut LP relaxation on G is $O(\mathsf{tw} \log n)$.*

Abstract

We develop low distortion embeddings with outliers from arbitrary metrics into hierarchically separated trees (HSTs). In particular, we develop an efficient algorithm that for any $\epsilon > 0$, given an input metric (X, d), and a probabilistic embedding of all but k points from X into HSTs with distortion c, samples from a probabilistic embedding of all but $O(\frac{k}{\epsilon} \log k)$ points into HSTs that achieves distortion at most $(32 + \epsilon)c$.

Our results are based on two key technical components. First, we extend an algorithm of Munagala et al. [53] for minimizing the distortion of embeddings without outliers into HSTs to the setting with outliers. We combine this with new results on bi-Lipschitz extensions into trees and ℓ_1 space. In particular, we show that any probabilistic embedding into HSTs can be extended to k additional points with only a factor $O(\log k)$ of additional distortion. This bi-Lipschitz extension result utilizes a new probabilistic partitioning scheme that we call *onion partitioning*.

1 Introduction

Low-distortion embeddings into trees are a fundamental algorithmic tool for reducing optimization problems on general graph metrics to the special case of tree metrics, where they are often easier to solve. The distortion of an embedding, defined as the maximum

© Shuchi Chawla, Arnold Filtser, Kristin Sheridan, and Yonatan Trachtenberg;

multiplicative change in pairwise distances, directly determines the loss in performance incurred by such a reduction. A series of works [7, 12, 13, 37] showed that *probabilistic* embeddings can embed any n-point metric into hierarchically separated trees (HSTs) with expected distortion $O(\log n)$. While uniform distortion bounds are helpful in understanding the general effectiveness of using metric embeddings to solve a problem, from a practical perspective, we may ask how well a particular given metric (X, d) can embed into trees. Indeed, for some metrics the optimal distortion is $\Omega(\log n)$ but for others it may be much smaller, e.g. $O(1)$, providing better algorithmic results.

In this paper we investigate instance-optimal distortion for probabilistic embeddings into trees by exploring the role of outliers. For a finite metric (X, d), a (k, c)-outlier embedding is a map defined on "most of" X – that is on all but k vertices, which we designate as outliers – into another metric space Y such that the distortion over the non-outliers is bounded by c. Intuitively, we can view the outliers as noisy or adversarial data that may hurt the quality of the instance-optimal embedding from X into Y. The goal of the outlier embedding is to identify and remove these outliers upfront so as to obtain a much better embedding over the remaining points. Algorithmically, given a target distortion c, we want to find the smallest k such that the removal of k outliers enables embedding the rest of the metric with distortion at most c. In this paper, we develop probabilistic outlier embeddings into trees, providing a tradeoff between outlier set size and distortion. Our main result is as follows.

▶ **Theorem 1** (HSTs admit outlier embeddings). *Let (X, d) be any metric that admits a (k, c) probabilistic outlier embedding into HSTs. Then for any constant $\epsilon > 0$, there exists an algorithm that efficiently samples from a probabilistic embedding into HSTs of some $S \subseteq X$ with $|X \setminus S| \leq O(\frac{1}{\epsilon} k \log k)$ and expected distortion at most $(32 + \epsilon)c$.*

Technical contribution: improved bi-Lipschitz extensions

A key technical component in our construction is a bi-Lipschitz extension for embeddings of arbitrary finite metrics into trees. Given a finite metric (X, d) and a low distortion embedding α from a subset $S \subset X$ into a host space Y, a bi-Lipschitz extension extends the domain of α to the entire set X, while only modestly increasing the distortion of the embedding. We show that if the distortion of the original embedding α is c_α, it is possible to obtain a bi-Lipschitz extension with distortion at most $O(c_\alpha \log k)$ where $k = |X \setminus S|$. Formally, we achieve the following bounds, where the expansion factor L_{exp} is the multiplicative increase in pairwise distances beyond the expansion of the original embedding α, and the contraction factor L_{contr} is the multiplicative decrease beyond the contraction in α.

▶ **Theorem 2** (HSTs have probabilistic bi-Lipschitz extensions). *Let $\mathcal{H}$ be the class of all HSTs. For any subset $S \subseteq X$ with $k := |X \setminus S|$ and a probabilistic embedding $\mathcal{D}_S : S \hookrightarrow \mathcal{H}$, there exists a probabilistic bi-Lipschitz extension of $\mathcal{D}_S$, $\mathcal{D} : X \hookrightarrow \mathcal{H}$, with expansion factor $L_{exp} = O(\log k)$ and contraction factor $L_{contr} = 4$.*

Further, we can efficiently sample from the distribution $\mathcal{D}$ if we can efficiently sample from $\mathcal{D}_S$.

A connection between outlier embeddings and Lipschitz extensions was first established by Chawla and Sheridan [26] in the context of deterministic embeddings into normed metrics. They showed that deterministic embeddings into ℓ_2 admit a Lipschitz extension with expansion factor $O(\log k)$ (but potentially unbounded contraction), and this suffices to obtain a bicriteria approximation for outlier embeddings into ℓ_2. We extend this approach to embeddings into HSTs by combining it with an LP-rounding approximation algorithm of Munagala et al. [53] for instance-optimal probabilistic embedding into HSTs.

Probabilistic extension and bounded contraction

Extending the approach of [26] to HSTs poses two new technical challenges. First, while Chawla and Sheridan [26]'s construction can tolerate arbitrary contraction in the Lipschitz extension, in order to employ Munagala et al.'s LP relaxation for HST embeddings, we necessarily need to control contraction as well. The second challenge is applying the notion of Lipschitz extension to probabilistic embeddings. This is important because probabilistic tree embeddings can obtain exponentially smaller distortion than deterministic tree embeddings. Consider, in particular, a distribution $\mathcal{D}$ over embeddings from some subset S of a given metric (X, d) into a host space Y. Simply drawing an embedding α from $\mathcal{D}$ and extending it to X may result in distortion $\propto \mathbb{E}_{\alpha\sim\mathcal{D}}[\max_{u,v\in X}(d_\alpha(u,v)/d(u,v))]$. This can be much larger than the desired distortion $\max_{u,v\in X}(\mathbb{E}_\alpha[d_\alpha(u,v)]/d(u,v))$.

We resolve both challenges by constructing a bi-Lipschitz extension through a sequence of "merge" operations, each of which combines two embeddings over domains that intersect in a single point. By carefully aligning and stitching each such pair of embeddings, we ensure strong bounds on both contraction and expansion.

Improved expansion via "onion-like" partitions

Chawla and Sheridan's Lipschitz extension for ℓ_2 employs a probabilistic partitioning procedure over the outliers $X \setminus S$ similar to that of Calinescu, Karloff, and Rabani [22], and attaches an embedding of each component of the partition to its closest point in S (that we call the *anchor point*). This approach combined with the merge operation described above yields a *bi-Lipschitz* extension for HSTs with expansion factor $O(\log^2 k)$. We develop a new technique to obtain a quadratic improvement over this factor, leading to Theorem 2. Our key observation is that the largest distortion is suffered by pairs that are separated into different components by the CKR partitioning procedure – one logarithmic factor arises from the probability of separation, and the second arises from the distortion between the points and their respective anchor points.

To improve upon this distortion, we construct a probabilistic partitioning where each component has an "onion-shell" shape – all points are roughly equidistant from the anchor point. We then employ an embedding of each component that preserves distances to the anchor point within a constant factor (while potentially inflating other distances by a logarithmic factor). This allows us to bound the distortion between any pair of points by $O(\log k)$ times the distortion of the embedding over S.

Our improved partitioning approach also applies to ℓ_1, providing a bi-Lipschitz extension with expansion factor $O(\log k)$. [26] previously obtained a bi-Lipschitz extension for ℓ_1 with expansion factor $O(\frac{1}{c_S}\log^2 k + \log k)$, where c_S is the distortion of the embedding of S into ℓ_1; this can be a logarithmic factor worse than the bound we achieve when c_S is $O(1)$.

▶ **Theorem 3** (ℓ_1 has bi-Lipschitz extensions, informal)**.** *Deterministic ℓ_1 embeddings have deterministic bi-Lipschitz extensions with expansion factor $O(\log k)$ and contraction factor $O(1)$.*

Related work

Embedding into HSTs has been studied primarily with the objective of minimizing expected distortion. See e.g. [7, 12, 13, 24, 37, 14, 46]. In our work, we will use as a subroutine the algorithm of Fakcharoenphol et al. [37], which for any n point metric samples from an $O(\log n)$ distortion probabilistic embedding into HSTs. *Instance-optimal* distortion has been studied for target spaces such as constant dimensional Euclidean space [10, 51, 30, 31, 58],

the line [9, 51, 38, 57], trees [11, 27], and ultrametrics [6, 53]. The goal in such embeddings is to minimize the distortion needed for the given *specific* (X, d), which in some cases may be smaller than the best bound achievable for all metrics of that size.

The notion of outlier embeddings was initially defined by Sidiropolous et al. [59] when they studied deterministic embeddings into ultrametrics, trees, and constant-dimensional ℓ_2 space. They consider approximating *deterministic, isometric* outlier embeddings (where the distortion c is 1) and bicriteria approximations with additive distortion. The structural properties used for isometric approximations don't apply to non-isometric embeddings, and techniques for bounding additive distortion tend to be quite different from those for multiplicative distortion, the focus of this work. Chubarian and Sidiropolous [29] continued the work on outlier embeddings and studied non-isometric outlier embeddings of unweighted graph metrics into the line. Later, Chawla and Sheridan [26] studied deterministic outlier embeddings into ℓ_2 space with unbounded dimension.

Several related notions of distortion were previously studied. One notion is *embeddings with slack*, in which the goal is to minimize the number of pairs that are distorted by more than some target factor [1, 23, 47]. An even stronger notion is that of *scaling distortion*, where for every $\varepsilon > 0$, at most ε fraction of the pairs suffer from distortion $\geq f(\varepsilon)$ (for some function f), see [45, 3, 4, 16]. Another notion is *terminal distortion*, where instead of an outlier set, there is a subset of terminals $K \subseteq X$, and the goal is only to preserve distance pairs involving a terminal $K \times X$ [32, 49, 56, 28]. A stronger notion is *prioritized distortion* [33, 34, 39] where there is a priority ordering over the vertices, and the distortion guarantee is w.r.t. the priorities. Another notion is that of local embeddings [2, 8, 25] where the goal is to minimize the distortion from each point to its k nearest neighbors.

Outlier embeddings are also closely related to metric Ramsey theory [21, 17, 19, 18, 52, 55, 20, 5, 15, 41, 42]. Given inputs n and c, metric Ramsey theory asks: What is the largest m such that *all* metrics of size n have a submetric of size m that embeds into some target space with distortion at most c? In this paper we are primarily focused on *instance-optimal* solutions rather than universal bounds that apply to all metrics, and we seek to approximate the size of the outlier set rather than the size of the non-outlier set.

Many other types of embedding compositions or extensions have been considered. One particular example is the notion of a Lipschitz extension [44, 48, 54], which seeks to leave non-outliers unaltered from the original embedding and ensure the expansion (but not necessarily the contraction) of every pair of nodes is bounded. Given an embedding on $S \subseteq X$, Calinescu, Karloff, and Rabani [22] develop a partitioning algorithm for $X \setminus S$ that implicitly defines Lipschitz extensions with a contraction factor at most $O(\log |S|)$ for all metric spaces. Chawla and Sheridan [26] define essentially the same partitioning algorithm, except that in their algorithm, [22] pick a uniformly random permutation over the set S, but [26] take a random permutation over the set of $X \setminus S$'s closest neighbors in S. The resulting Lipschitz extension factor is $O(\log |X \setminus S|)$. We will permute over the same set as [26], but we follow the cleaner analysis of [22]. Another related notion is that of 0-extension [22, 36, 35, 40] where one seeks a stochastic contraction $f : X \to K$ from the metric point set to a subset K of terminals while minimizing $\max_{x,y \in X} \mathbb{E}\left[\frac{d_X(f(x),f(y))}{d_X(x,y)}\right]$.

2 Definitions and results

Embeddings and distortion

A metric space is a set of points X with distances $d_X(\cdot, \cdot)$ between them that obey the triangle inequality. That is, for all $x, y, z \in X$, $d_X(x, z) \leq d_X(x, y) + d_X(y, z)$. We assume without loss of generality (via scaling) that in the metrics we consider, the minimum

distance between distinct pairs of points is at least 1. For subsets $S, T \subseteq X$, denote $d(S,T) := \min_{s\in S, t\in T}\{d(s,t)\}$ If $\alpha : X \to Y$ is a map from (X, d_X) to (Y, d_Y), we write $d_\alpha(x,y) := d_Y(\alpha(x), \alpha(y))$ to denote the distance between the images of two points $x, y \in X$ under this map.

$\mathcal{D}$ is a probabilistic embedding of (X, d_X) into $\mathcal{Y}$ if for each function α in the support of $\mathcal{D}$, $\alpha : X \to Y(\alpha)$ for some $(Y(\alpha), d_{Y(\alpha)}) \in \mathcal{Y}$. This embedding has expected *expansion* $c_{exp} \geq 1$, *contraction* $c_{contr} \geq 1$, and expected *distortion* $c_{contr} \cdot c_{exp}$ if for all $x, y \in X$ we have:

$$d_\alpha(x,y) \geq \frac{1}{c_{contr}} \cdot d(x,y) \qquad \forall \alpha \in \text{support}(\mathcal{D})$$
$$\mathop{\mathbb{E}}_{\alpha\sim\mathcal{D}}[d_\alpha(x,y)] \leq c_{exp} \cdot d(x,y).$$

Observe that *every* embedding in the support of $\mathcal{D}$ has contraction at most c_{contr}, but pairwise expansion (and thus distortion) is bounded in expectation over the randomness in $\mathcal{D}$. If the support of $\mathcal{D}$ contains a single embedding, it is a *deterministic* embedding. Further, an embedding is *expanding* or *non-contracting* if it has contraction 1.

We use the notation $\alpha : X \xhookrightarrow{c_{exp}, c_{contr}} Y$ to denote a deterministic or probabilistic embedding with expansion c_{exp} and contraction c_{contr} from (X, d_X) into (Y, d_Y). If c_{contr} is not specified, the embedding is expanding.

Bi-Lipschitz extensions

▶ **Definition 4** (Bi-Lipschitz extension). *Let (X, d) be a metric, $S \subseteq X$, and $\alpha_S : S \xhookrightarrow{c_S, c'_S} Y$ for some parameters c'_S, c_S. Then an embedding $\alpha : X \to Y$ is a (strong)* bi-Lipschitz extension *of α_S with extension factors L_{exp}, L_{contr} if* [1]

$$\text{for all } u \in S, \qquad \alpha(u) = \alpha_S(u), \tag{1}$$
$$\text{for all } u, v \in X \qquad d_\alpha(u,v) \geq \frac{1}{c'_S \cdot L_{contr}} d(u,v) \tag{2}$$
$$\text{and, for all } u, v \in X, \qquad d_\alpha(u,v) \leq L_{exp} \cdot c_S \cdot d(u,v). \tag{3}$$

If Y is a normed vector space, for Constraint 1 we require only that the restriction of α to the subspace spanned by S matches the embedding α_S. [2]

Further, α is a weak bi-Lipschitz extension *with extension factors L_{exp}, L_{contr} if Constraint 1 is replaced with the following weaker constraint:*

$$\text{for all } u, v \in S, \qquad d_\alpha(u,v) = d_{\alpha_S}(u,v).$$

In this paper, we discuss bi-Lipschitz extensions in the probabilistic setting. In particular, we model a probabilistic bi-Lipschitz extension on the weak version of a deterministic bi-Lipschitz extension, requiring that the *joint distribution* of distances between pairs of nodes in s is the same under the extended embedding.

[1] Note that L_{exp}, L_{contr} could be factors that depend on X and S.

[2] Notably, to get non-trivial extensions we must allow α to "extend" the dimension of α_S in some cases. To see this, consider an isometric (distortion 1) embedding of one or two points of a length n cycle into the real line. Any bi-Lipschitz extension that also embeds into the real line must have $L_{ext} \cdot L_{contr} = \Omega(n)$, as $\Omega(n)$ distortion is required to embed the cycle into a line.

▶ **Definition 5** (Probabilistic bi-Lipschitz extension). *Let (X, d) be a metric, $S \subseteq X$, and $\mathcal{D}_S \xrightarrow{c_S, c'_S} \mathcal{Y}$ for some parameters c_S, c'_S. Then a probabilistic embedding $\mathcal{D} : X \to \mathcal{Y}$ is a* probabilistic bi-Lipschitz extension *of α_S with extension factors L_{exp}, L_{contr} if*

$$(d_\alpha(x,y))_{x,y \in S \times S} \text{ has the same joint distribution for } \alpha \sim \mathcal{D} \text{ and } \alpha \sim \mathcal{D}_S \tag{4}$$

$$\text{for all } x, y \in X, \text{ and for all } \alpha \in \operatorname{support}(\mathcal{D}), \qquad d_\alpha(x,y) \geq \frac{1}{L_{contr} \cdot c'_S} \cdot d(x,y) \tag{5}$$

$$\text{and, for all } x, y \in X, \qquad \mathop{\mathbb{E}}_{\alpha \sim \mathcal{D}}[d_\alpha(x,y)] \leq L_{exp} \cdot c_S \cdot d(x,y). \tag{6}$$

Outlier embeddings

If $\mathcal{D}$ is a probabilistic embedding from (X, d_X) into $\mathcal{Y}$ and $K \subseteq X$, define $\mathcal{D}_{X \setminus K}$ to be the distribution identical to $\mathcal{D}$ but with all functions α in the support restricted to the set $X \setminus K$ (i.e. we can sample from $\mathcal{D}_{X \setminus K}$ by sampling from $\mathcal{D}$ and restricting the domain of the function drawn).

▶ **Definition 6.** *A probabilistic embedding $\mathcal{D}$ of (X, d_X) into $\mathcal{Y}$ is a* probabilistic (k, c)-outlier embedding *if there exists $K \subseteq X$ such that $|K| \leq k$ and $\mathcal{D}_{X \setminus K}$ is a probabilistic embedding of $(X \setminus K, d_X)$ into $\mathcal{Y}$ with distortion c.*

Note that in Definition 6, the subset K is chosen *deterministically* (not sampled). The distances from K to other nodes (and each other) are ignored. The randomness is only on the embedding for the remaining nodes in $X \setminus K$.

Hierarchically Separated Trees (HSTs), ultrametrics, and ℓ_p

▶ **Definition 7.** *A metric (X, d) is a* β-hierarchically separated tree (β-HST) *if there is a map from X to the leaves of a tree such that the following hold:*

- *Each node u in the tree is associated with ("labeled" with) some value η_u, and $\eta_v = \beta \cdot \eta_u$ whenever u is a child of v and u is not a leaf.*[3] *Further, for all leaves v, $\eta_v = 0$, and for nodes v that are parents of leaves, $\eta(v) = 1$.*
- *For two leaves $x, y \in X$ with least common ancestor z, $d(x, y) = \eta_z$.*

For simplicity, we will primarily focus on 2-HSTs, and in referring to HSTs, we mean 2-HSTs unless otherwise noted. We use $\mathcal{H}$ to denote the set of all 2-HSTs. Note that focusing on β-HSTs for a different constant β at worst changes results by a constant factor.

▶ **Definition 8.** *An* ultrametric *is a metric (X, d) that fulfills a strong triangle inequality guarantee: for all $x, y, z \in X$, $d(x, y) \leq \max\{ d(x, z), d(z, y) \}$.*

HSTs form a subset of the set of *ultrametrics*. Further, any ultrametric embeds into an HST with distortion at most 2 [17]. We will use $\mathcal{U}$ to denote the set of all ultrametrics.

▶ **Definition 9** (ℓ_p space). *ℓ_p in dimension δ, denoted ℓ_p^δ, is $(\mathbb{R}^\delta, d_{\ell_p})$ where for $x, y \in \mathbb{R}^\delta$, d_{ℓ_p} is defined as*

$$d_{\ell_p}(x,y) := \left(\sum_{i=1}^{\delta} |x_i - y_i|^p \right)^{1/p}.$$

We let ℓ_p space refer to the set of all spaces ℓ_p^δ for $\delta \in [1, \infty)$.

[3] In this paper, we will use the term β-HSTs to refer to what other sources sometimes call exact β-HSTs. These sources typically define non-exact β-HSTs as only requiring $\eta_v \geq \beta \cdot \eta_u$.

Main results

Our primary results are for probabilistic bi-Lipschitz extensions of embeddings into HSTs and deterministic bi-Lipschitz extensions of embeddings into ℓ_1 space.

▶ **Theorem 2** (HSTs have probabilistic bi-Lipschitz extensions). *Let $\mathcal{H}$ be the class of all HSTs. For any subset $S \subseteq X$ with $k := |X \setminus S|$ and a probabilistic embedding $\mathcal{D}_S : S \hookrightarrow \mathcal{H}$, there exists a probabilistic bi-Lipschitz extension of $\mathcal{D}_S$, $\mathcal{D} : X \hookrightarrow \mathcal{H}$, with expansion factor $L_{exp} = O(\log k)$ and contraction factor $L_{contr} = 4$.*

Further, we can efficiently sample from the distribution $\mathcal{D}$ if we can efficiently sample from $\mathcal{D}_S$.

We can also argue for the existence of deterministic extensions for ℓ_1 embeddings, though we do not know how to find such deterministic embeddings efficiently.

▶ **Theorem 3** (ℓ_1 has bi-Lipschitz extensions). *For any subset $S \subseteq X$ with an embedding $\alpha_S : S \xhookrightarrow{c_S, c'_S} \ell_1$, there exists*

1. *a deterministic* weak *bi-Lipschitz extension of α_S, $\alpha : X \hookrightarrow \ell_1$ with extension factors $L_{exp} = O(\log k)$ and $L_{contr} = 1$, where $k := |X \setminus S|$ and*
2. *a deterministic strong bi-Lipschitz extension with $L_{exp} = O(\log k)$ and $L_{contr} = 7$.*

Our bi-Lipschitz extensions into ℓ_1 are asymptotically optimal. Some metrics on n points (namely expander graph metrics) require $\Omega(\log n)$ distortion for embedding into ℓ_1 [50]. We can always "extend" a distortion 1 embedding on one or two points to an embedding on an expander graph metric, obtaining an embedding of distortion at most $L_{exp} \cdot L_{contr}$. Thus, we must have $L_{exp} \cdot L_{contr} = \Omega(\log k)$. Likewise, some metrics require $\Omega(\log n)$ distortion to embed probabilistically into HSTs [12], so our HST results are also asymptotically optimal.

Our results for probabilistic bi-Lipschitz extensions into HSTs allow us to obtain a bicriteria approximation for probabilistic outlier embeddings into HSTs, which we discussed in the introduction.

▶ **Theorem 1** (HSTs admit outlier embeddings). *Let (X, d) be any metric that admits a (k, c) probabilistic outlier embedding into HSTs. Then for any constant $\epsilon > 0$, there exists an algorithm that efficiently samples from a probabilistic embedding into HSTs of some $S \subseteq X$ with $|X \setminus S| \leq O(\frac{1}{\epsilon} k \log k)$ and expected distortion at most $(32 + \epsilon)c$.*

In Section 6, we expand our results to the weighted outlier setting, and we use a modification of the LP from Munagala et al. [53] to prove Theorem 1. Our LP-based techniques also allow us to obtain the following result for the weighted variant of the problem.[4]

▶ **Corollary 10.** *Given a metric (X, d), node weights w, and target distortion c, let w^* be the optimal outlier set cost for probabilistically embedding (X, d) into HSTs with c distortion and let k be the size of such an optimal outlier set. Then for any constant $\epsilon > 0$, there exists an algorithm that efficiently samples from a probabilistic embedding into HSTs of some $S \subseteq X$ with $w(X \setminus S) \leq O(\frac{1}{\epsilon} w^* \log k)$ and expected distortion at most $(32 + \epsilon)c$.*

[4] In the weighted outlier set problem we are given weights w_i on all nodes i in the metric space. The cost of a subset K of the metric space is $w(K) := \sum_{i \in K} w_i$, and the goal is to find an outlier embedding with some target distortion such that the cost of the outlier set is minimized.

3 Components of a bi-Lipschitz extension

The bi-Lipschitz extensions we discuss in this paper have three primary components. In particular, given a probabilistic embedding $\mathcal{D}_S : S \to \mathcal{Y}$ for $S \subseteq X$, we develop bi-Lipschitz extensions for $\mathcal{D}_S$ when the relevant spaces have certain properties. Namely, the space X should admit what we refer to as "onion partitions" and the space $\mathcal{Y}$ should admit "bounded-diameter embeddings" and "perfect merge functions." We show in Section 4 that onion partitions always exist, so our bi-Lipschitz extensions depend on the existence of bounded-diameter embeddings and perfect merge functions for the space into which we are embedding.

At a high level, we will use the onion partitions to find clusters of the set $K = X \setminus S$ and assign an "anchor point" in S to each such cluster. Then we find a bounded-diameter embedding on each cluster with its anchor point, and we "merge" each of these embeddings with the original embedding on S using a perfect merge function.

3.1 Onion partitions

We begin by defining what we call onion partitions. Given a metric (X, d) and a subset $S \subseteq X$ with $K = X \setminus S$, an onion partition of K is a partition $\mathcal{K} = \{ K_i \}$ of K such that each K_i has an assigned "anchor point" from S. For any point $x \in K_i$, we refer to its cluster's assigned point in S as the anchor point of x. The partition should satisfy three properties: (1) for any $x, y \in K$, the probability that x and y are separated in the partition is proportional to $d(x, y)/d(\{ x, y \}, S)$; (2) for each $x \in K$, the distance between x and its anchor point is (deterministically) similar to $d(x, S)$; and (3) for any cluster $K_i \in \mathcal{K}$, the distance between $x \in K_i$ and its assigned anchor point is (deterministically) not too much smaller than the diameter of the cluster K_i itself.

▶ **Definition 11** (Onion partitions). *Let (X, d) be a metric and let $S \subseteq X$ with $K := X \setminus S$. Then an* onion partition *of K is a joint distribution over $(\mathcal{K} = \{ K_i \}_{i \in \mathbb{N}}, r : \mathcal{K} \to S)$ such that $\mathcal{K}$ is a partition of K.*

For any $(\mathcal{K}, r)$ in the support of the distribution and $K_i \in \mathcal{K}$, we call $r(K_i)$ the anchor point *of K_i. We extend the domain of r to points in K: for $x \in K$, $r(x)$ denotes the anchor point assigned to the component containing x in the random partition $(\mathcal{K}, r)$. Likewise, let Δ_{K_i} denote the diameter of a component K_i, and Δ_x denote the (random) diameter of the component containing x in the random partition $(\mathcal{K}, r)$. Additionally, for any fixed $(\mathcal{K}, r)$ we let K_i^+ denote the set $K_i \cup \{ r(K_i) \}$ for each $K_i \in \mathcal{K}$.*

An onion partition has separation parameter $\rho > 0$, closeness $b > 1$, *and* band thickness $\gamma > 1$ *if it meets the following three criteria:*

1. ***Low separation probability.*** *For any $x, y \in K$, the probability that x and y are in different components of the partition is upper bounded by $\rho \cdot \frac{d(x,y)}{d(\{ x,y \},S)}$*
2. ***An anchor point is a "close" point in S.*** *For any $x \in K$ and any $(\mathcal{K}, r)$ in the support of the distribution, $d(x, r(x)) \leq b \cdot d(x, S)$ with probability 1.*
3. ***Cluster points are arranged in a thin band around their anchor point.*** *For any $x \in K$ and any $(\mathcal{K}, r)$ in the support of the distribution, $d(x, r(x)) \geq \Delta_x / \gamma$ with probability 1.*

Figure 1 gives a visual depiction of the third property of onion partitions, and in Section 4, we show the following theorem about their existence.

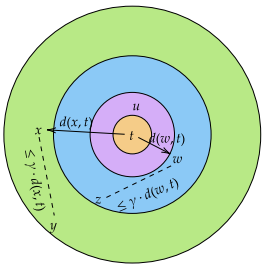

Figure 1 This figure depicts the third property of onion partitions. In particular, for any point $t \in S$, we think of the clusters with anchor point t as rings around t (like the rings of an onion). For any $x, y \in K$, if x and y are in the same cluster with anchor point $r(x) = r(y) = t$, then the third criterion of onion partitions states that they must be a distance at most $\gamma \cdot d(x,t)$ apart.

▶ **Theorem 12** (Onion partitions). *For any metric (X,d) and any $S \subseteq X$, there exists an onion partition on $K = X \setminus S$ with separation parameter $O(\log k)$, closeness 2, and band thickness 6, where $k = |K|$.*

3.2 Bounded-diameter embeddings

The second component of our extension method involves what we call bounded-diameter embeddings. In particular, we consider expanding embeddings that are parameterized not only by their worst expected expansion for any pair of nodes, but also by their expected expansion of the *diameter* of the original metric. That is, a bounded-diameter embedding can place a smaller upper bound on the expected expansion for pairs of nodes that are relatively far apart in the original metric than it does for other pairs of nodes. We define this formally in Definition 13.

▶ **Definition 13** (Bounded diameter embedding). *A probabilistic embedding $\mathcal{D} : X \to \mathcal{Y}$ is an expanding* bounded-diameter embedding *with expansion c and* diameter expansion *c_Δ if the following conditions hold:*

$$d_\alpha(x,y) \geq d(x,y) \qquad \forall x,y \in X, \forall \alpha \in \text{support}(\mathcal{D})$$
$$\mathop{\mathbb{E}}_{\alpha \sim \mathcal{D}}[d_\alpha(x,y)] \leq c \cdot d(x,y) \qquad \forall x,y \in X$$
$$\mathop{\mathbb{E}}_{\alpha \sim \mathcal{D}}[d_\alpha(x,y)] \leq c_\Delta \cdot \max_{x',y' \in X} \{ d(x',y') \} \qquad \forall x,y \in X$$

Further, we say $\mathcal{Y}$ admits bounded-diameter embeddings with expansion c_k and diameter expansion *c_Δ if for all metrics (X,d) of size k, there is a bounded-diameter embedding of X into $\mathcal{Y}$ with the given parameters.*

Notably, if all metrics of size k can embed into $\mathcal{Y}$ with expected expansion at most c_k, then $\mathcal{Y}$ admits bounded-diameter embeddings with expansion and diameter expansion equal to c_k. However, in the settings we consider here (namely HSTs and ℓ_1 space), we will consider bounded-diameter embeddings where c_Δ is tighter than c_k. In this paper, we will use FRT embeddings [37] as our bounded diameter embeddings.

▶ **Theorem 14** ([37]). *For any metric (X,d) with $|X| = n$, there exists a probabilistic expanding bounded diameter embedding (an FRT embedding) of X into HSTs with expansion $O(\log k)$ and diameter expansion 2.*

In fact, for HST embeddings, we can assume without loss of generality an even stronger property than that required by Definition 13: For any embedding α in the support of an HST embedding on X, the diameter of the image of α is at most twice the diameter of X. To see this, let Δ be the diameter of X and consider an HST embedding with diameter larger than $2^{\lceil \log \Delta \rceil}$. The nodes of the HST at level $2^{\lceil \log \Delta \rceil}$ or higher can all be merged into a single node without incurring any new contraction between any pair of points, as their new distance under this contraction is the minimum of their old distance and $2^{\lceil \log \Delta \rceil}$.

Further, trees embed isometrically into ℓ_1, so we immediately get the following corollary.

▶ **Corollary 15.** *For any metric (X, d) with $|X| = n$, there exists a probabilistic expanding bounded diameter embedding (an FRT embedding) of X into ℓ_1 with expansion $O(\log k)$ and diameter expansion 2.*

3.3 Perfect merge functions

In the final step of our extension method, we "merge" the embedding α_S on $S \subseteq X$ with bounded-diameter embeddings on the clusters of our onion partition. In particular, a *merge function* is a function whose input is two embeddings whose domains overlap at a single point and whose output is a new embedding on the union of their domains. For our purposes, we want to ensure some of the necessary distance properties are maintained. In particular, for any pair of nodes that appeared in the domain of the same input embedding, the distance under the new embedding should be the same as under the original one. Additionally, we want to ensure that no pair of nodes is allowed to be "too close" in the new embedding. This extra requirement will allow us to bound contraction in our final bi-Lipschitz extension.

▶ **Definition 16** (Perfect merge). *A procedure `Merge` is a* perfect merge function *for embedding X into $\mathcal{Y}$ with* contraction factor *η if for any $Z_1, Z_2 \subseteq X$ with $Z_1 \cap Z_2 = \{v\}$ and any deterministic embeddings $\alpha_1 : Z_1 \to Y_1$, $\alpha_2 : Z_2 \to Y_2$ for $Y_1, Y_2 \in \mathcal{Y}$, it produces an embedding $\alpha : Z_1 \cup Z_2 \to Y$ for some $Y \in \mathcal{Y}$ such that:*

1. *For all $x, y \in Z_1$, $d_\alpha(x, y) = d_{\alpha_1}(x, y)$.*
2. *For all $x, y \in Z_2$, $d_\alpha(x, y) = d_{\alpha_2}(x, y)$.*
3. *For $x \in Z_1$ and $y \in Z_2$, we have $d_\alpha(x, y) \geq \frac{d_{\alpha_1}(x,v) + d_{\alpha_2}(v,y)}{\eta}$.*

We say $\mathcal{Y}$ admits perfect merge functions if there is a perfect merge function for any metric X.

In Section 5, we prove the following existence results about perfect merge functions for HSTs and ℓ_1.

▶ **Lemma 17.** *HSTs admit a perfect merge function with contraction factor 2.*

▶ **Lemma 18.** *ℓ_1 admits a perfect merge function with contraction factor 1.*

Putting the components together

With our three components defined, we now put them together to construct bi-Lipschitz extensions for amenable target spaces $\mathcal{Y}$. In particular, given a metric (X, d) with subset $S \subseteq X$ and $\mathcal{D}_S : S \to \mathcal{Y}$, our extension proceeds in the following manner:

1. Sample an embedding on α_S from $\mathcal{D}_S$.
2. Sample an onion partition $(\mathcal{K}, r)$ of $K = X \setminus S$.
3. For each $K_i \in \mathcal{K}$, sample an embedding α_i from a bounded diameter embedding of $K_i^+ = K_i \cup \{ r(K_i) \}$.
4. Use a perfect merge function to sequentially merge each α_i with α_S.

Algorithm 1 formalizes this sampling process, and Theorem 19 states that the embedding sampled by Algorithm 1 samples from a bi-Lipschitz extension of the input embedding $\mathcal{D}_S$. We highlight in red the places where Algorithm 1 uses each of the three components we have discussed so far.

Algorithm 1 Bi-Lipschitz extension: Algorithm for finding a probabilistic bi-Lipschitz extension when the requirements of Theorem 19 are met.

Input: Metric space (X, d), subset $S \subseteq X$, embedding $\mathcal{D}_S : S \to \mathcal{Y}$; the spaces X and $\mathcal{Y}$ should meet the conditions of Theorem 19, and `PerfectMerge` will be the designated perfect merge function

Output: A randomly sampled embedding $\alpha : X \to \mathcal{Y}$.

Sample a partition $(\mathcal{K} = \{ K_i \}_{i \in \mathbb{N}}, r)$ from an onion partition of $K = X \setminus S$
Let K_i^+ be $K_i \cup \{ r(K_i) \}$ for all $K_i \in \mathcal{K}$
Sample $\alpha \sim \mathcal{D}_S$
for each non-empty K_i **do**
    Let $\mathcal{D}_i$ be an expanding bounded-diameter embedding of K_i^+ into $\mathcal{Y}$
    Sample $\alpha_i \sim \mathcal{D}_i$
    $\alpha \leftarrow$ `PerfectMerge`(α, α_i)
Return α

▶ **Theorem 19.** *Let (X, d) be a metric with $S \subseteq X$ and let $\mathcal{D}_S : S \to \mathcal{Y}$ be a probabilistic embedding with contraction at most c'_S and expansion at most c_S.*
Then, if:

1. *X admits an onion partition with separation parameter ρ, closeness 2,[5] and band thickness γ,*
2. *$\mathcal{Y}$ admits expanding bounded-diameter embeddings on sets of size k with expansion c_k and diameter expansion c_Δ, and*
3. *$\mathcal{Y}$ admits a perfect merge function with contraction factor η,*

$\mathcal{D}_S$ has a bi-Lipschitz extension to all of X with extension factors $L_{exp} = O(\gamma \cdot \rho \cdot (c_\Delta / c_S + 1) + c_k / c_S)$ and $L_{contr} = \eta^2$. Further, Algorithm 1 samples from such an extension.

Before proving this theorem, we observe that due to the first two properties of a perfect merge function, it is sufficient to bound the first extension Algorithm 1 produces that includes both x and y in the domain.

▶ **Observation 20.** *Let $x, y \in X$. Consider the first iteration of Algorithm 1 in which both x and y are in the domain of α, and let $\hat{d}$ be $d_\alpha(x, y)$ at that time step. Then at every subsequent iteration of the algorithm, $d_\alpha(x, y) = \hat{d}$.*

We are now ready to bound the contraction and expansion of the embedding procedure, which we do in Lemmas 21 and 22. We defer the full proofs of these lemmas to the full version of this paper and just give a brief overview of the ideas here.

▶ **Lemma 21** (Contraction bound). *Let $X, S, \mathcal{D}_S$ be as in Theorem 19 and let $\alpha : X \to \mathcal{Y}$ be the embedding returned by Algorithm 1. Then for all $x, y \in X$, $d_\alpha(x, y) \geq d(x, y)/\eta^2$.*

[5] This could be defined for more general closeness parameters, but it greatly complicates the algebra, so we set $b = 2$ in our analysis.

To intuitively understand the contraction bound, note that when some node $v \in K_i$ is added to the domain of α, there is no contraction between v and other nodes in K_i^+, as $\mathcal{D}_i$ is non-contracting and we use a perfect merge function to combine this with α. Further, for any node u already in the domain of α when v was added, property 3 of perfect merge functions ensures $d_\alpha(u,v) \geq (d_\alpha(u,r(v)) + d_\alpha(v,r(v)))/\eta$. Applying the triangle inequality and appropriate contraction bounds on α prior to this point gives us the result.

We are now ready to bound the expected expansion for each pair of nodes. This argument follows a similar line of reasoning to that for bi-Lipschitz extensions for ℓ_1 in [26], but because we are using onion partitions rather than CKR partitions, we are able to better bound the distortion in the "bad case" of the embedding.

More specifically, the bad case for the embedding is when a pair of nodes $x, y \in K$ is separated by the partition and they are much closer to each other than they are to S (so routing their path through S potentially causes a large distortion). In this situation, we bound the distance between x and y in terms of $d(x,S)$ and $d(y,S)$, and we use the fact that the probability of separation is bounded by $\rho \cdot \frac{d(x,y)}{d(\{x,y\},S)}$ to obtain our final bound. Crucially, the bound we obtain for the distance between $x \in K_i$ and $y \in K_j$ depends on walking from x to $r(x)$ (the anchor point of x) through the embedding on K_i^+, then from $r(x)$ to $r(y)$ (the anchor point of y) through the embedding on S, and then from $r(y)$ to y through the embedding on K_j^+ (see Figure 2). In the simplest sense, we could apply a bound of c_S for the expansion of the distance between $r(x)$ and $r(y)$ and a bound of c_k (the distortion bound for embedding subsets of size k) for the distances between x and s and between y and t. Because we must pay ρ as part of the separation probability in the partition, our overall expected distortion goes up to $O(\rho \cdot (c_S + c_k))$.[6]

However, because of the onion partitions we use here, $d(x,s)$ is forced to be within a factor of γ of the diameter Δ_x of the cluster x is in. Further, because we use diameter-bounded embeddings on the set K_i^+, we know that the maximum distance between any pair of nodes in that embedding is at most $c_\Delta \cdot \Delta_x$. Thus, the distance between x and $r(x)$ in this embedding is within a constant factor of their true distance, allowing us to reduce our expansion factor in this bad case to $O(\rho \cdot \gamma \cdot (c_S + c_\Delta))$. We potentially still incur a cost of c_k if x and y are in the same component, so our overall cost is $O((c_S + c_\Delta) \cdot \rho \cdot \gamma + c_k)$, which gives us a potential savings if c_S and c_Δ are much smaller than c_k and γ is a constant. Our analysis follows a similar reasoning to that of Calinescu, Karloff, and Rabani [22] for the 0-extension problem, though we deal with an additional merge step and resulting effect on the embedding. See the full version of the paper for a full proof.

▶ **Lemma 22** (Expansion bound). *Let $X, S, \mathcal{D}_S$ be as in Theorem 19, and let $\mathcal{D}$ be the distribution over embeddings from which Algorithm 1 draws when given inputs $X, S, \mathcal{D}_S$. Then for all $x, y \in X$*

$$\mathop{\mathbb{E}}_{\alpha \sim \mathcal{D}}[d_\alpha(x,y)] \leq O(c_k + \gamma \cdot \rho \cdot (c_S + c_\Delta)) \cdot d(x,y),$$

where c_k is the bound on the expansion of the bounded-diameter embeddings for each part of the partition used by the algorithm, c_S is the expansion of $\mathcal{D}_S$, c_Δ is the diameter expansion of the bounded-diameter embeddings used by the algorithm, and $k = |X \setminus S|$.

[6] In fact, this bound applies even if we do not have a bounded diameter embedding (i.e. we just have an embedding with expected expansion c_k on sets of size k) and even if the partitions we use do not meet the third criterion of onion partitions (requiring that the distance between a cluster node and S be similar to the diameter of the cluster).

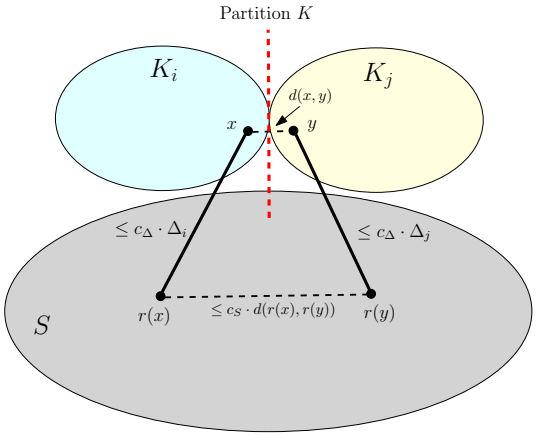

Figure 2 The "bad case" routing scenario for expansion bounds. Nodes $x \in K_i$ and $y \in K_j$ are physically close but separated by the onion terminal partition $\mathcal{K}$. The expected distance between x and y in the merged embedding is bounded by routing the path through their respective anchor points $r(x)$ and $r(y)$ within the base embedding S.

Noting that Algorithm 1 always outputs an embedding in which the distances on pairs of points in S are the same as under the sampled embedding α_S, Theorem 2 (finding bi-Lipschitz extensions for HSTs) is immediate from Theorems 12, 14, and 19 and Lemma 17. Theorem 3 (finding bi-Lipschitz extensions for ℓ_1) takes a little more work, and we prove it in Section 5.

4 Onion partitions

In this section we prove Theorem 12.

▶ **Theorem 12** (Onion partitions). *For any metric (X, d) and any $S \subseteq X$, there exists an onion partition on $K = X \setminus S$ with separation parameter $O(\log k)$, closeness 2, and band thickness 6, where $k = |K|$.*

We begin with a discussion of the partition algorithm given by Calinescu, Karloff, and Rabani in their work on the 0-extension problem [22], which we refer to as CKR partitions. Our onion partitions will consist of CKR partitions intersected with a randomized bucketing scheme for $K = X \setminus S$. The CKR partitions ensure that nodes are separated with a probability proportional to their distance, and the randomized bucketing allows us to control the diameter of each cluster relative to the designated anchor point without increasing the probability of separation between x and y by too much.

Given a metric (X, d) and a subset $S \subseteq X$, [22] finds a partition $\{K_1, K_2, \ldots, K_{|S|}\}$ of $K := X \setminus S$ such that the "anchor point" of K_s is $s \in S$, the probability of $x, y \in K$ being separated is $O(\log k \cdot \frac{d(x,y)}{d(\{x,y\},S)})$, and $x \in K_s$ for $s \in S$ implies $d(x, s) \leq 2d(x, S)$. Algorithm 2 presents a variation of the CKR algorithm in which we use a subset $T \subseteq S$ as the set of anchor points, rather than the entire set S.

The CKR partitioning algorithm works by selecting a random permutation on some set of terminals and then "assigning" points in $X \setminus S$ to terminals in $T \subseteq S$ such that (1) a node in $X \setminus S$ is always assigned to a terminal that is fairly close to it, and (2) the probability that a pair of nodes $x, y \in X$ are placed in separate part of the partition is proportional to $d(x, y)/d(\{x, y\}, T)$. We state these two properties as Observation 23 and Lemma 24. Note that if we let the anchor point of a cluster K_t for $t \in T$ be t itself, then these two facts imply that CKR partitions meet criteria (1) and (2) of onion partitions, so we're left with fulfilling criterion (3).

Algorithm 2 CKR partitioning.

Input: Metric space (X, d), subset $S \subseteq X$, a set of terminals $T \subseteq S$
Output: A partition $\{ K_t \}_{t \in T}$ of $X \setminus S$

1: Sample a permutation π uniformly at random over T
2: Sample $\mu \in [1, 2)$ uniformly at random.
3: **for** Each node $x \in X \setminus S$ **do**
4: Let $t \in T$ be the first terminal under the ordering π such that $d(x, t) \leq \mu \cdot d(x, T)$
5: Add x to K_t
6: Return $\{ K_t \}_{t \in T}$, where the anchor point of K_t is set to t

▶ **Observation 23** (Deterministic Proximity of CKR Rounding, implicit in [22]). *For any $x \in X \setminus S$, if Algorithm 2 assigns x to K_t for some $t \in T$, then*

$$d(x, t) \leq \mu \cdot d(x, T) \leq 2 \cdot d(x, T),$$

where the last inequality holds because $\mu \in [1, 2)$.

▶ **Lemma 24** (CKR Separation, Lemma 2.2 in [22]). *Fix $x, y \in X$ and let $\delta := d(x, y)$. If $0 < \delta \leq \frac{1}{4} \min\{d(x, T), d(y, T)\}$, then:*

$$\Pr[x, y \text{ are separated}] \leq 4\mathcal{H}_{|T|} \left(\frac{\delta}{d(x, T)} + \frac{\delta}{d(y, T)} \right),$$

where $\mathcal{H}_m = 1 + \frac{1}{2} + \cdots + \frac{1}{m}$ denotes the m-th harmonic number.

For our partitions, we will pick T to be the set of "nearest neighbors" of nodes in K. That is, $T := \{ t \in \arg\min_{s \in S} \{ d(s, x) \} \mid x \in K \}$. We assume that for each $x \in K$, we add only one of the nearest neighbors of x to T so that $|T| \leq k$. Moreover, by the choice of T, we also have $d(x, T) = d(x, S)$ for all $x \in K$.

Randomized bucketing

Now we show how to refine the CKR partition technique so that the diameter of each partition is bounded by a constant factor times the distance from that partition to the terminal set T. In particular, we will use a technique called *randomized scale partitioning*. For any point $x \in K$, let $A_x = d(x, T)$ denote its distance to the nearest terminal. We choose a shift parameter $u \in [0, 1)$ uniformly at random and define $\beta = 2^u$. We then (randomly) bucket K into disjoint scales B_i by distance from T:

$$B_i := \{x \in K \mid \beta \cdot 2^i \leq A_x < \beta \cdot 2^{i+1}\}.$$

Given a metric (X, d) with diameter Δ, subset $S \subseteq X$, and terminal set $T \subseteq S$, we will randomly partition $K = X \setminus S$ into sets $\{ K_t \}_{t \in T}$ and buckets $\{ B_i \}_{i \in [\lceil \log \Delta \rceil]}$,[7] where the K_t are chosen by finding a CKR partition on K with terminal set T and the B_i are chosen by randomized scale partition. Then we define a new partition $\{ K_{t,i} \}_{t \in T, i \in [\lceil \log \Delta \rceil]}$, where $K_{t,i} := (K_t \cap B_i)$ and let the anchor point of this set be t – that is, $r(K_{t,i}) = t$.

[7] Here, $[n]$ denotes $\{ 0, 1, 2, \ldots, n \}$.

The primary properties of this partitioning that we will use are (1) for any node $x \in K_{t,i}$, the distance from x to another node in $K_{t,i}$ is not too much larger than the distance from x to T, and (2) the probability that a pair of nodes x and y are separated in this partition is not too much larger than the probability that x and y are separated under the CKR embedding. We express these as Observation 25 and Lemma 26, respectively.

▶ **Observation 25** (Partition diameter bound). *For any part $K_{t,i}$ of our scale partition and any node $x \in K_{t,i}$, if $\Delta_{t,i}$ is the diameter of $K_{t,i}$, then $d(x,t) \geq \Delta_{t,i}/6$*

Proof. For any pair $x, y \in K_{t,i}$, we have $d(x,y) \leq d(x,t) + d(t,y) \leq 2d(x,T) + 2d(y,T) \leq 6d(x,T)$. The first inequality is by the deterministic properties of CKR partitions, and the second is because x and y being in the same bucket implies $d(y,T)$ is no more than twice $d(x,T)$. Thus, $\Delta_{t,i} \leq 6 \cdot d(x,T) \leq 6 \cdot d(x,t)$. ◀

▶ **Lemma 26** (Scale Partition Separation). *For any pair of points $x, y \in K = X \setminus S$, let $\delta := d(x,y)$, and assume without loss of generality that $A_x \leq A_y$. The probability that x and y assigned to distinct buckets B_i and B_j is bounded by $O\left(\frac{\delta}{A_x}\right)$.*

Thus, by the union bound and Lemma 24, the probability that x and y are in different parts of the partition $\{ K_{t,i} \}$ is at most $O(\log |T| \cdot \frac{\delta}{A_x})$.

Proof. Let x be in bucket i and y be in bucket j. The scale boundaries are determined by $\beta 2^i = 2^{i+u}$, which is equivalent to placing a grid of integers shifted by a uniformly random $u \in [0,1)$ on a logarithmic scale. The probability that an integer boundary falls strictly between $\log_2 A_x$ and $\log_2 A_y$ is bounded by the length of the interval between their logarithmic distances. By the metric triangle inequality, $A_y \leq A_x + \delta$. Therefore:

$$\begin{aligned}
\Pr[i \neq j] &\leq \log_2(A_y) - \log_2(A_x) \\
&= \log_2\left(\frac{A_y}{A_x}\right) \\
&\leq \log_2\left(\frac{A_x + \delta}{A_x}\right) = \log_2\left(1 + \frac{\delta}{A_x}\right) \\
&\leq \frac{\delta}{A_x \ln 2} \;=\; O\left(\frac{\delta}{A_x}\right)
\end{aligned}$$

where the final inequality follows from the standard logarithmic bound $\ln(1+z) \leq z$ for all $z \geq 0$. ◀

Thus, the partitions we have constructed inherit property (2) of onion partitions with closeness 2 from the CKR bounds on anchor point distances and our choice of T (as the nearest neighbors of nodes in K), and they inherit property (3) of onion partitions with band thickness 6 from bounds on the diameter of randomized bucketing (and the fact that taking a subset of a cluster never increases its diameter). They also achieve property (1) with parameter $O(\log k)$ by Lemmas 24 and 26, our choice of T, and a union bound. Thus, we get Theorem 12.

5 Merge functions for HSTs and ℓ_1

In this section, we give explicit perfect merge functions for ℓ_1 and HSTs, and we prove Theorem 3.

Algorithm 3 `MergeL1`(α_1, α_2) Algorithm for merging two ℓ_1 embeddings.

Input: Embeddings $\alpha_1 : Z_1 \to \ell_1$, $\alpha_2 : Z_2 \to \ell_1$, where $|Z_1 \cap Z_2| = 1$.
Output: An embedding of $Z_1 \cup Z_2$ into ℓ_1

1: Let $u = Z_1 \cap Z_2$
2: For all $x \in Z_1$, let $\alpha(x) \leftarrow \alpha_1(x) \circ \alpha_2(u)$, where $\circ$ is concatenation
3: For all $x \in Z_2$, let $\alpha(x) \leftarrow \alpha_1(u) \circ \alpha_2(x)$
4: Return α

5.1 Merge for ℓ_1

We begin by presenting a perfect merge function for ℓ_1 embeddings. This is captured in Algorithm 3, which essentially just extends each input embedding to the entire set $Z_1 \cup Z_2$ by mapping everything not already in the domain to the same point as $u \in Z_1 \cap Z_2$ and concatenating the resulting embeddings together. This is easily seen to meet the requirements of a perfect merge function with contraction bound 1 and thus we get Lemma 18 which states that ℓ_1 has perfect merge functions. We now move on to proving Theorem 3.

▶ **Theorem 3** (ℓ_1 has bi-Lipschitz extensions). *For any subset $S \subseteq X$ with an embedding $\alpha_S : S \xhookrightarrow{c_S, c'_S} \ell_1$, there exists*

1. *a deterministic* weak *bi-Lipschitz extension of α_S, $\alpha : X \hookrightarrow \ell_1$ with extension factors $L_{exp} = O(\log k)$ and $L_{contr} = 1$, where $k := |X \setminus S|$ and*
2. *a deterministic strong bi-Lipschitz extension with $L_{exp} = O(\log k)$ and $L_{contr} = 7$.*

Proof. Part (1) of the proof is almost immediate from Theorems 12, 14, and 19, the fact that ℓ_1 has a perfect merge function with contraction factor 1, and the fact that Algorithm 1 outputs an embedding in which pairs of nodes in S have the same distance as under α_S. The problem is that Theorem 19 implies the existence of a *probabilistic* extension of the original embedding. However, for any finite support probabilistic embedding $\mathcal{D}$ of X into ℓ_1, there exists a deterministic embedding $\alpha : X \to \ell_1$ with $d_\alpha(x, y) = \mathbb{E}_{\alpha' \sim \mathcal{D}}[d_{\alpha'}(x, y)]$. (Note that the dimension of α may be much larger than those of the embeddings in the support of $\mathcal{D}$, and it is not clear how to efficiently find α when $\mathcal{D}$ has a large support.) See e.g. [26] for more. Proving the second part of this theorem requires a bit more of a sophisticated de-randomization method, and we defer it to the full version of the paper. ◀

5.2 Merge for HSTs

We now present a perfect merge function for HSTs to prove Lemma 17, which states that HSTs have perfect merge functions with contraction factor 2.

Algorithm 4 takes in two β-HSTs for a fixed ratio β and returns another β-HST. This algorithm works by "combining" the ancestors of the common point u at each level of the two HSTs. That is, the new HST consists of u and all its ancestors, and each ancestor of u has as its child subtrees the child subtrees of the ancestor of u at its same level in each HST. Figure 3 gives a visual depiction of this algorithm. We defer the correctness proof for Lemma 17 to the full version of the paper and briefly outline the idea here.

For any $x, y \in Z_1$ or $x, y \in Z_2$, the least common ancestor of x and y must be at the same level in the new tree as it was in the original embedding of Z_1 or Z_2, so their distance is unchanged from the original embedding. To bound the distance between $x \in Z_1, y \in Z_2$, consider the least common ancestor of x and y in the HST produced at the algorithm. The first ancestor of y that has descendants from Z_1 is the least common ancestor of y and u.

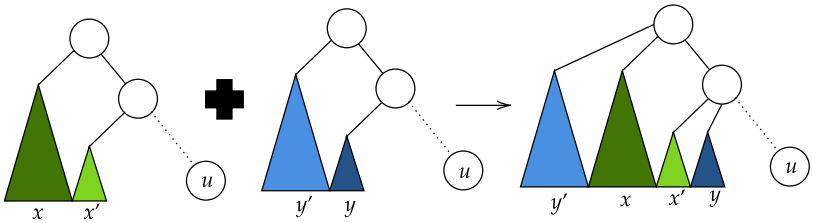

Figure 3 This figure depicts what happens in the algorithm `MergeHST`. In particular, u is the node common to both HSTs on the left side of the figure. The triangles represent subtrees, and the letters below the triangles indicate the presence of the corresponding node as a leaf of that subtree. Note that after merging trees, the least common ancestor of x and y is that of x and u from the first tree, as this was higher than that of y and u. This is the foundational idea behind why $d_\alpha(x,y) \geq \max\{ d_{\alpha_1}(u,x), d_{\alpha_2}(u,y) \}$ holds when α is the output embedding for `MergeHST` on inputs α_1 and α_2.

Thus, the least common ancestor of x and y cannot be lower than the least common ancestor of y and u, so the distance between x and y is at least that between y and u under the original embedding on Z_2. Likewise, the distance between x and y is at least the distance between x and u under the original embedding on Z_1, so we get contraction at most 2.

Algorithm 4 `MergeHST`(α_1, α_2) Algorithm for merging two β-HSTs.

Input: Embeddings $\alpha_1 : Z_1 \to T_1$, $\alpha_2 : Z_2 \to T_2$ for β-HSTs T_1, T_2, where $|Z_1 \cap Z_2| = 1$. We assume without loss of generality that the height of T_1 is at least as large as the height of T_2.
Output: An embedding of $Z_1 \cup Z_2$ into a single β-HST

Let $u = Z_1 \cap Z_2$
Create a new HST T that is initially a copy of T_1
$\alpha(x) \leftarrow \alpha_1(x)$ for all $x \in Z_1$
for $i = 0$ to the height of T_1 **do**
    for the subtree of each child of $\alpha_2(u)$'s ancestor at height i in T_2 **do**
        if the subtree does not contain $\alpha_2(u)$ **then** ▷ i.e. if the subtree is not yet merged into T_1
            Copy the subtree and make it a child of $\alpha_1(u)$'s ancestor at level i in T
            for any $x \in Z_2 \setminus \{ u \}$ such that $\alpha_2(x)$ is in the subtree at this step **do**
                Set $\alpha(x)$ to be the copy of $\alpha_2(x)$ created in T at this step
Return α

6 Outlier embeddings for HSTs

Now, given the existence of bi-Lipschitz extensions for HSTs, we turn to approximating outlier embeddings into HSTs. In [26], this type of approximation is obtained for ℓ_2 by introducing new "outlier variables" into a semidefinite program for a minimum distortion ℓ_2 embedding and rounding. We will employ a similar technique here using the linear program and associated rounding algorithm of [53] to approximate the optimal distortion for probabilistic HST embeddings.

Let Δ be the diameter of (X,d) and let $M = \{ 2^0, 2, 2^2, \ldots, 2^{\lceil \log \Delta \rceil} \}$. Let ζ be the constant factor from Theorem 2 and let $B_i(r) := \{ j \in X : d(i,j) \leq r \}$. We define (HST LP), which is parameterized by inputs $((X,d),k,c)$. The changes from [53] are highlighted in red.

Table 1 We imagine assigning a "representative" at each node of the HST such that the representative of a leaf node is the leaf node itself, and the representative of any other node is the same as one of its children's representatives. This table describes the intuitive meaning of each variable in the LP (which is largely the same as in [53]).

variable	intuitive meaning
δ_i	indicator for whether i is an outlier
$z^r_{ijj'}$	the probability that i is the representative of j and j' at level r
$\gamma^r_{jj'}$	the probability that j and j' are separated at level r
x^r_{ij}	the probability that i is the representative of j at level r

Table 1 gives an intuitive description of the variables in the LP. Note that in our LP c is a parameter, but in [53] it is the variable they are minimizing. The biggest change from [53] is that we have introduced new variables δ_i for each $i \in X$ that we use as an indicator for whether i is an outlier in the embedding.

$$\min \sum_{i=1}^{n} \delta_i \tag{HST LP}$$

$$\forall j, j' \sum_{r \in M} r \cdot \gamma^r_{jj'} \leq (4 + \zeta \cdot (\delta_j + \delta_{j'}) \cdot \log k) \cdot c \cdot d(j, j') \tag{7}$$

$$\forall i, r, (j, j' \in B_i(r)) \quad \min(x^r_{i,j}, x^r_{ij'}) \geq z^r_{ijj'} \tag{8}$$

$$\forall j, j', i, r \sum_{i: j, j' \in B_i(r)} z^r_{ijj'} \geq 1 - \gamma^r_{jj'} \tag{9}$$

$$\forall j, r \sum_{i: j \in B_i(r)} x^r_{ij} = 1 \tag{10}$$

$$\forall j, j', (r < d(j, j')) \quad \gamma^r_{jj'} = 1 \tag{11}$$

$$\forall j, j', r \quad \gamma^r_{jj'} \leq 1 \tag{12}$$

$$\forall i, j, j', r \quad \gamma^r_{jj'} x^r_{ij}, z^r_{ijj'}, \delta_i \geq 0; \delta_i \leq 1 \tag{13}$$

Given an optimal solution to this linear program, we need to define an outlier embedding with low distortion and few outliers. To do so, we will first use the rounding algorithm of [53] to find an embedding on the entire metric, and then we take as outliers all vertices i such that $\delta_i \geq \delta^*$ for some threshold δ^*. In the full version of the paper we formally prove that this rounding algorithm works and gives us Theorem 1 as a result. In a similar manner to ℓ_2 outlier embeddings in [26], we use the existence of nested embeddings to bound the optimal LP solution and thus obtain our final result.

Further, if we modify (HST LP) by changing the objective function to $\sum_i w_i \cdot \delta_i$ for some set of weights w_i, we can use the same technique to obtain a bicriteria approximation for the weighted variant of the outlier embedding problem, where the cost of making i an outlier is w_i. This result is expressed as Corollary 10, and we prove it in the full version of the paper.

7 Applications

In the Minimum Cost Communication Tree (MCCT) problem, we are given a finite metric $\mathcal{X} = (X, d)$ and weights r_{ij} for all pairs of nodes i, j and we are asked for a non-contracting embedding α of X into a tree with vertex set X such that $\sum_{i,j \in X} r_{ij} \cdot d_\alpha(i, j)$ is minimized. This problem is motivated by evolutionary biology, in which a scientist may attempt to

reconstruct a tree of relationships between multiple organisms, and she comes to the problem with some known minimum distances between them, derived through a method such as DNA sequence analysis. In such a setting, the r_{ij} are an additional tunable parameter that can allow the scientist to indicate pairs she considers "more likely" to be related, by giving them a bigger r_{ij} value. As noted by Wu et al. [60], this problem can be approximated in expectation to within a factor of $O(\log n)$ by simply embedding randomly into an HST and converting it to a tree with vertex set X. Directly applying the algorithm of Munagala et al. [53] with the observations of Wu et al. [60], we have a randomized algorithm that gets an $O(c(\mathcal{X}))$-approximation for the MCCT problem, where $c(\mathcal{X})$ is the minimum distortion needed to probabilistically embed $\mathcal{X}$ into HSTs.

It is quite natural to consider an outlier version of the MCCT problem. In the evolutionary biology setting, we could consider the case that we are given some noisy data points, or points that don't really belong in the set being analyzed. One approach to this type of outlier problem may be to look for a k outlier tree embedding of minimum distortion, but the set of outliers that minimizes the embedding distortion does not necessarily also minimize the MCCT solution cost. We may expect that the outlier MCCT problem is easier to solve on tree metrics than on general metrics, so we could instead try the following approach: embed the input metric into a tree, and *then* try to find the best outliers for the resulting tree metric. In fact, if no outliers are allowed, MCCT is trivial on tree metrics. Further, in Subsection 7.1 we give a bicriteria approximation to the k-outlier MCCT problem when the input is a tree metric. In particular, if the optimal cost of a k outlier solution for a given instance of a tree metric is OPT_k, then we give an algorithm that finds a solution with at most $3k$ outliers and at most $24OPT_k$ cost. Let $c_k(\mathcal{X})$ be the minimum distortion required for probabilistically embedding all but at most k points in $\mathcal{X}$ into HSTs. We can use the outlier embedding algorithm from this paper to embed any input metric into a tree with outliers and then apply the approximation algorithm for outlier MCCT on trees, obtaining a solution with at most $O(\frac{k}{\epsilon}\log k)$ outliers and expected cost $O((1+\epsilon)\cdot c_k(\mathcal{X})\cdot OPT_k)$. By contrast, directly using the embedding algorithm of [53] with the tree approximation algorithm from this section instead gives a solution with at most $3k$ outliers and $O((1+\epsilon)\cdot c_0(\mathcal{X})\cdot OPT_k)$ expected cost, so we are unable to save on the cost of the optimal solution if there is a large subset that embeds well into HSTs but the entire metric does not. We explain this further in the full version of the paper.

7.1 MCCT with outliers

Let (T,d) be a tree metric, and let k be an integer. Then we define variables x_{ij} for each pair of nodes ij and variables δ_i for each variable i. We can use them to make the following linear program.

$$\min \sum_{i,j\in T} x_{ij}\cdot r_{ij}\cdot d(i,j) \quad s.t. \qquad \text{(MCCT Outlier LP)}$$

$$\forall i,j\in T: \quad \delta_i+\delta_j+x_{ij}\geq 1$$

$$\sum_{i\in T}\delta_i \leq k$$

$$\forall i,j\in T: \quad \delta_i, x_{ij}\in[0,1]$$

▷ Claim 27. Let (T,d) be a tree metric such that there exists a subset $K\subseteq T$, $|K|\leq k$, and $\sum_{i,j\in T\setminus K} r_{ij}\cdot d(i,j)\leq D$.

Then the following procedure finds a subset $K' \subseteq T$ with $|K'| \leq 3k$ and an embedding α of $T \setminus K'$ into a tree with the same vertex set and $\sum_{i,j \in T \setminus K'} d_\alpha(i,j) \leq 24D$.

1. Solve MCCT Outlier LP and let x_{ij}, δ_j be the resulting values
2. Let $K' = \{ i : \delta_i \geq 1/3 \}$
3. Embed $T \setminus K'$ into a tree T' with distortion at most 8, using the algorithm of Gupta [43]

Proof. First, MCCT Outlier LP has a solution of value at most D. In particular, let K be as in the claim statement and consider setting $\delta_i = \begin{cases} 1 & i \in K \\ 0 & else \end{cases}$ and $x_{ij} = \begin{cases} 1 & \delta_i = \delta_j = 0 \\ 0 & else \end{cases}$. As there are only k outliers, the second constraint is clearly satisfied, and we have defined x_{ij} such that the other constraints are also satisfied. Further, x_{ij} is 0 if either i or j is an outlier in K, so the objective function value is just $\sum_{i,j \in T \setminus K} r_{ij} d(i,j)$, which by the claim statement is bounded by D.

Let K' be as in the claim. As the δ_i sum to at most k, we know $|K'| \leq 3k$. Consider any x_{ij} with $i, j \notin K'$ We have $x_{ij} \geq 1 - \delta_i - \delta_j \geq 1/3$ by how we chose K'. The cost associated with a given pair ij of non-outliers in our solution is $r_{ij} d(i,j)$, but that same pair contributed at least $r_{ij} d(i,j)/3$ to the optimal objective function value, so our final cost is at most 3 times the objective, which is at most $3D$. At this point, we have an isometric (distortion 1) embedding of the metric induced by $T \setminus K'$ into the original metric T itself. Thus, we can view K' as a set of Steiner points in our original metric.

Finally we consider the loss incurred applying the algorithm of Gupta [43]. This creates a tree embedding that removes Steiner points and incurs distortion at most 8, so the cost of this embedding on $T \setminus K'$ is at most $24D$, as desired. This step is what prevents us from applying this algorithm directly to general metrics. ◁

8 Open questions

There are still many open questions we can ask about topics in this space, such as:

- Is it NP-hard to find the optimal outlier set size when probabilistically embedding a given metric into HSTs with a small fixed distortion? This question is known to be hard for deterministic embeddings into some spaces [59, 26].
- Even if finding the optimal outlier set size for probabilistically embedding into HSTs is NP-hard, can the approximation factors in this paper be improved?
- Which other metric spaces admit perfect merge functions (and thus bi-Lipschitz extensions), and can we approximate optimal outlier embeddings in such spaces?

Abstract

We study the following class of *matroid optimization problems with a linear constraint* ($\mathcal{P}$-MOL). Given a matroid $\mathcal{M} = (E, \mathcal{I})$, two nonnegative weight functions $v, w : E \to \mathbb{R}_{\geq 0}$, and a threshold $L \in \mathbb{R}_{\geq 0}$, find $\mathsf{opt}\, v(S)$ where S is either an independent set or a base of $\mathcal{M}$ satisfying a budget-type constraint: $w(S) \leq L$ or $w(S) \geq L$, and $\mathsf{opt} \in \{\min, \max\}$. $\mathcal{P}$-MOL provides a unified representation for a broad family of NP-hard optimization problems, including BUDGETED MATROID INDEPENDENT SET, CONSTRAINED MINIMUM-BASIS, and KNAPSACK-COVER variants with a matroid constraint. Also, it naturally extends to multiple matroid constraints. In particular, we consider the MATROID INTERSECTION COVER (MIC) problem, where feasibility is defined by the common independent sets of two matroids and one seeks minimum $v(S)$ subject to $w(S) \geq L$.

Our main result is a unified *efficient polynomial-time approximation scheme* (EPTAS) for all nontrivial $\mathcal{P}$-MOL variants, obtained by generalizing a technique of Hassin and Levin (SIAM J. Comput., 2004) for solving the CONSTRAINED MINIMUM SPANNING TREE problem. Specifically, for any fixed $\varepsilon > 0$, we present an algorithm running in time $|E|^{O(1)} \cdot (1/\varepsilon^2)^{O(1/\varepsilon)}$ that outputs a feasible solution S whose value is at most $(1+\varepsilon)\mathsf{OPT}$ for minimization variants and at least $(1-\varepsilon)\mathsf{OPT}$ for maximization variants. This resolves the complexity status of all members of $\mathcal{P}$-MOL, as none of these problems admits a *fully* polynomial-time approximation scheme (Doron-Arad, Kulik and Shachnai, ICALP'24). Finally, we separate the $\mathcal{P}$-MOL family from its extension to matroid intersection. We show that an EPTAS is unlikely to exist for the matroid intersection variant of $\mathcal{P}$-MOL under a covering constraint, whereas an EPTAS is known to exist under a budget constraint. This highlights a qualitative difference between these two types of linear constraints that does not arise in the single-matroid setting.

1 Introduction

Matroids offer a unifying abstraction for "independence" in combinatorial structures: they capture linear independence in vector spaces, forests in graphs, and many other systems constrained by an exchange principle. A *matroid* is a set system $(E, \mathcal{I})$, where E is a finite set and $\mathcal{I} \subseteq 2^E$ are the *independent sets (IS)* such that (i) $\emptyset \in \mathcal{I}$, (ii) for all $A \in \mathcal{I}$ and $B \subseteq A$ it holds that $B \in \mathcal{I}$, and (iii) for all $A, B \in \mathcal{I}$ where $|A| > |B|$, there is $e \in A \setminus B$ such that $B \cup \{e\} \in \mathcal{I}$.[1] A broad range of classical problems can be cast as *matroid*

[1] Properties (ii) and (iii) are known, respectively, as *hereditary property*, and *exchange property*.

optimization: one seeks a minimum-cost or maximum-value independent set or basis of a matroid. Canonical examples include minimum spanning trees, maximum-weight forests, and a variety of assignment and scheduling problems.

In many applications, however, matroid feasibility alone is insufficient. Solutions must also satisfy an additional *budget-type* constraint, such as an upper bound on total length or cost, or a lower bound on total coverage. Adding even a single linear constraint of this form typically turns an otherwise polynomial-time matroid optimization problem into an NP-hard one, and has motivated a long line of work on approximation algorithms.

1.1 The $\mathcal{P}$-MOL Class and Our Framework

We start by defining the class of problems studied in this paper. Let $\mathcal{M} = (E, \mathcal{I})$ be a matroid, and let $v, w : E \to \mathbb{R}_{\geq 0}$ be two nonnegative functions. The value v_e contributes to the main objective, and w_e contributes to a budget constraint. For the matroid $\mathcal{M} = (E, \mathcal{I})$ we define $\mathsf{IS}(\mathcal{M}) := \mathcal{I}$ and $\mathsf{bases}(\mathcal{M}) := \{ S \in \mathcal{I} : |S| = \mathsf{rank}(\mathcal{M}) \}$, where $\mathsf{rank}(\mathcal{M}) := \max\{ |T| : T \in \mathcal{I} \}$ is the rank of $\mathcal{M}$, i.e., the maximum cardinality of an independent set.

We are interested in three design choices:

- **Objective direction.** We may want to minimize or maximize $v(S)$.[2]
- **Matroid family.** We may optimize over independent sets or bases of $\mathcal{M}$.
- **Budget direction.** The budget constraint may take the form $w(S) \leq L$ or $w(S) \geq L$.

We encode these choices by three parameters

$$\mathsf{opt} \in \{\min, \max\}, \qquad \mathcal{F} \in \{\mathsf{IS}, \mathsf{bases}\}, \qquad \triangleright \in \{\leq, \geq\}.$$

Given a threshold $L \geq 0$, we consider the optimization problem

$$\mathsf{opt}\ v(S) \qquad \text{s.t.} \qquad S \in \mathcal{F}, \quad w(S)\ \triangleright\ L. \tag{1}$$

We refer to (1) as a $\mathcal{P}$-MOL (Matroid Optimization with a Linear constraint) problem, with the descriptor $\mathcal{P} = (\mathsf{opt}, \mathcal{F}, \triangleright)$. An instance of a $\mathcal{P}$-MOL problem is specified by a tuple $\mathcal{A}_{\mathcal{P}} = (E, \mathcal{I}, v, w, L)$.

For a fixed descriptor $\mathcal{P}$, we denote the optimal value of (1) by $\mathsf{OPT}_{\mathcal{P}}$, or simply OPT when the context is clear:

$$\mathsf{OPT}_{\mathcal{P}}\ :=\ \mathsf{opt}\big\{\, v(S) : S \in \mathcal{F}(\mathcal{M}),\ w(S) \triangleright L \,\big\},$$

This formulation captures, in a uniform way, several extensively studied problems. For example:

- $(\max, \mathsf{IS}, \leq)$ gives the BUDGETED MATROID INDEPENDENT SET problem, generalizing 0/1-KNAPSACK.
- $(\min, \mathsf{bases}, \leq)$ gives CONSTRAINED MINIMUM-BASIS problems, including CONSTRAINED MINIMUM SPANNING TREE when $\mathcal{M}$ is a graphic matroid.
- $(\min, \mathsf{IS}, \geq)$ corresponds to KNAPSACK-COVER WITH A MATROID.

Among the eight possible choices of $(\mathsf{opt}, \mathcal{F}, \triangleright)$, only $(\min, \mathsf{IS}, \leq)$ is trivial (its optimum is $S = \emptyset$); we focus on the remaining seven nontrivial variants.

The $\mathcal{P}$-MOL viewpoint also naturally extends beyond a single matroid. If one lets $\mathcal{F}$ denote the intersection of two matroids, then (1) becomes matroid-intersection optimization with a linear constraint. A notable example is the MATROID INTERSECTION COVER (MIC)

[2] For any vector $p = (p_e)_{e \in E}$ and any $S \subseteq E$ we use the shorthand $p(S) := \sum_{e \in S} p_e$.

problem: given matroids $\mathcal{M}_1 = (E, \mathcal{I}_1)$ and $\mathcal{M}_2 = (E, \mathcal{I}_2)$ and weights $v, w : E \to \mathbb{R}_{\geq 0}$, find a set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ with $w(S) \geq L$ minimizing $v(S)$. In our terminology, MIC aligns with a $(\min, \mathsf{intersection}, \geq)$-MOL formulation, with feasibility governed by $\mathcal{I} = \mathcal{I}_1 \cap \mathcal{I}_2$.

1.2 Our Contribution

We present (in Section 2) a unified approximation framework for $\mathcal{P}$-MOL problems by generalizing a technique of Hassin and Levin [20]. This allows to obtain an EPTAS for all non-trivial variants of $\mathcal{P}$. Specifically, for every fixed $\varepsilon > 0$ there exists an algorithm which, given an instance $\mathcal{A}_\mathcal{P}$, outputs a feasible solution S satisfying

$$\mathsf{opt} = \min \implies v(S) \leq (1+\varepsilon)\,\mathsf{OPT}_\mathcal{P}, \qquad \mathsf{opt} = \max \implies v(S) \geq (1-\varepsilon)\,\mathsf{OPT}_\mathcal{P}.$$

The running time is $h(1/\varepsilon) \cdot \mathrm{poly}(|\mathcal{A}_\mathcal{P}|)$ for an arbitrary function h. This resolves the complexity status of all members of $\mathcal{P}$-MOL, as none of these problems admits a *fully* polynomial-time approximation scheme (FPTAS) [15]. Table 1 presents the best known results for the $\mathcal{P}$-MOL class. Results obtained in this paper are marked in boldface.

We also consider the natural extension of $\mathcal{P}$-MOL variants to matroid intersection. For BUDGETED MATROID INTERSECTION, an EPTAS was presented in [12]. In contrast to our positive result for the $\mathcal{P}$-MOL class, where matroid optimization is over a *single* matroid constraint, we show that a unified EPTAS is unlikely to exist for *all* $\mathcal{P}$-MOL variants, already when the single matroid constraint is replaced by a *matroid intersection* constraint. Specifically, we prove (in Section 3) that MIC does not admit an EPTAS unless W[1] = FPT.

1.3 Techniques

A Unified EPTAS for $\mathcal{P}$-MOL

For BUDGETED MATROID INDEPENDENT SET, as well as for its extension to BUDGETED MATROID INTERSECTION, recent works [13, 12] give EPTASs based on the *representative-set* methodology. Roughly, it computes a small candidate pool that is guaranteed to contain the high-value elements of some near-optimal solution, and then recovers the near-optimum by exhaustive enumeration over this pool. However, this approach inherently (i) loses the profit of $O(1)$ elements, and (ii) may drop $O(1)$ elements to restore feasibility. Thus, a solution output by the representative set approach may be a non-basis for the given matroid. It may also be infeasible w.r.t. a covering constraint. Therefore, the EPTASs of [13, 12] cannot be extended to EPTASs for the *entire* $\mathcal{P}$-MOL class, which must handle both $\mathsf{IS}(\mathcal{M})$ and $\mathsf{bases}(\mathcal{M})$, and all four choices of $(\mathsf{opt}, \triangleright)$.

Instead, we generalize (in Section 2) a technique of Hassin and Levin [20] to obtain a unified EPTAS for all members of $\mathcal{P}$-MOL under a general matroid constraint. The following is a high-level overview of the algorithmic framework.

Given a constant-factor guarantee $\hat{V}$ for OPT, we bucket elements according to their values v_e. Elements with $v_e \leq \varepsilon\hat{V}$ are classified as *small*, while the remaining elements are partitioned into $O(1/\varepsilon^2)$ narrow buckets. We note that any optimal solution contains only $O(1/\varepsilon)$ *large* elements. This allows us to enumerate *configuration vectors* $\vec{k}$ that specify the number of selected elements from each bucket.

For a fixed configuration $\vec{k}$, we enforce these counts by intersecting the matroid with a partition matroid, yielding a matroid-intersection family $\mathcal{F}_{\vec{k}}$. We then use a Lagrangian relaxation of the linear constraint $w(S) \triangleright L$ and compute $\lambda^\star_{\vec{k}}$, an optimal value of the multiplier λ.

The main technical challenge is to convert the Lagrangian optimum into a feasible solution. At $\lambda^\star_{\vec{k}}$, the family $\mathcal{O}_{\vec{k}}$ of Lagrangian-optimal sets is *well connected*: any two of its members can be transformed into one another via a sequence of exchanges, each replacing at most one element per bucket. We compute sets $S^-, S^+ \in \mathcal{O}_{\vec{k}}$ that respectively minimize and maximize the signed violation of $w(S) \triangleright L$, and hence lie on opposite sides of feasibility. Traversing the one-per-bucket exchange path from S^- to S^+, we select the first feasible set $S^\star$.

Because elements within each bucket have nearly identical v-values, each exchange affects the objective value by at most the total *bucket spread* – that is, the difference between the maximum and minimum v-value within a bucket. Consequently, the first feasible set $S^\star$ yields an objective value within an additive $O(\varepsilon \mathsf{OPT})$ of the Lagrangian bound. Taking the best such $S^\star$ over all configurations yields an EPTAS.

We note that some variants in our descriptor-based formulation are related by standard reductions. Nevertheless, we keep the unified formulation for completeness and to make the scope of the algorithm explicit, since such reductions may not always preserve the approximation guarantees in a straightforward way. In particular, budget-type and covering-type constraints require careful treatment: the existence of an EPTAS for the budget setting under a matroid intersection constraint [12] does not, by itself, imply an analogous result for the covering setting. Our hardness result in Theorem 13 highlights this distinction. Therefore, we present the argument directly for the descriptor class $\mathcal{P} = (\mathsf{opt}, \mathcal{F}, \triangleright)$.

Hardness of MIC

We establish a parameterized lower bound for MATROID INTERSECTION COVER (MIC). Via a reduction from k-Clique, we show that MIC admits no EPTAS unless $W[1] = \text{FPT}$ (Theorem 13). The novelty of our result lies in the fact that this reduction rules out an *EPTAS*, whereas a similar construction of [15] is used only to exclude an *FPTAS*. Our result complements recent applications of related reductions to 3-MATROID INTERSECTION [16]. Together, our findings demonstrate that for matroid intersection, different linear constraints (cover versus budget) lead to markedly different algorithmic behavior, in contrast to the case of a single matroid.

Table 1 Our positive results for $\mathcal{P}$-MOL problems and the matching negative results of [15].

Problem Type	Opt	$\mathcal{F}$	$\triangleright$	Positive Result	Negative Result
Budgeted Matroid Independent Set	max	IS	$\leq$	EPTAS [13]	No FPTAS
Knapsack-Cover with a Matroid	min	IS	$\geq$	**EPTAS**	No FPTAS
Budgeted Matroid Basis	max	Bases	$\leq$	**EPTAS**	No FPTAS
Constrained Minimum Basis	min	Bases	$\leq$	**EPTAS** [3]	No FPTAS
Lower-Bounded Max Basis	max	Bases	$\geq$	**EPTAS**	No FPTAS
Lower-Bounded Min Basis	min	Bases	$\geq$	**EPTAS**	No FPTAS
Lower-Bounded Indep. Set	max	IS	$\geq$	**EPTAS**	No FPTAS

[3] Previously, an EPTAS was known for the special case of Constrained Minimum Basis in a *graphic* matroid [20].

1.4 Related Work

Knapsack and approximation schemes

The 0/1-Knapsack problem is a canonical benchmark for approximation schemes. Early work already established a fully polynomial-time approximation scheme [24], and dynamic-programming–based FPTASs and their implications have since been extensively studied [8]. More recent progress has focused on fine-grained analyses and improved time–approximation tradeoffs [4, 9].

Matroid and matching constraints with a single budget

Adding a matroid or matching feasibility constraint to 0/1-Knapsack gives rise to the well-studied problems of Budgeted Matching and Budgeted Matroid Intersection. A PTAS for both variants was obtained by Berger et al. [1]. Subsequent work strengthened these results to EPTAS guarantees: for Budgeted Matroid Independent Set [13], and for Budgeted Matching and Budgeted Matroid Intersection via representative sets [12].

While an FPTAS is ruled out for general instances of Budgeted Matroid Independent Set [15], FPTASs are known for several special cases, including Cardinality-Constrained Knapsack [5], Multiple-Choice Knapsack [22], and laminar matroids [14, 27]. Additional variants of the problem have also been studied, for example in [11, 10, 17].

$\mathcal{P}$-MOL problems have also been studied in the covering setting (as opposed to a budget constraint), in conjunction with a matroid feasibility constraint. For Lower-Bounded Minimum Independent Set, the best known result prior to this work was a PTAS, due to [6]. For constrained minimum spanning tree, a PTAS was given in [26], followed by an EPTAS in [20]. Furthermore, a multi-criteria FPTAS is known for this problem [21].

Multiple budgets

When multiple budget constraints are present, PTASs are known for variants with either matroid intersection or matching constraints, using techniques such as dependent randomized rounding [7] and structural properties of matroid polytopes [19]. On the other hand, even seemingly simple extensions face strong complexity barriers: for example, the Multidimensional Knapsack problem with just two budget constraints already rules out an EPTAS under standard complexity assumptions [23].

2 An EPTAS for the $\mathcal{P}$-MOL Class

Let $\mathcal{A}_{\mathcal{P}} = (E, \mathcal{I}, v, w, L)$ be an instance of $\mathcal{P}$-MOL with descriptor $\mathcal{P} = (\mathsf{opt}, \mathcal{F}, \triangleright)$ and fix $\varepsilon > 0$. Recall that $\mathcal{F}$ denotes the underlying combinatorial family: either all independent sets or all bases of $\mathcal{M}$. Our EPTAS combines a value-bucketing scheme with a Lagrangian relaxation applied to the intersection of $\mathcal{M}$ with a partition matroid (defined below). We begin by describing the bucketing and configuration step. Let $n := |E|$ denote the ground-set size.

2.1 Value Bucketing and Configuration Vectors

We first obtain a constant-factor estimate of OPT.

▶ **Lemma 1.** *Given an instance $\mathcal{A}_{\mathcal{P}}$, one can guess in $|E|^{O(1)}$ time a value $\hat{V}$ such that*

$$\frac{OPT}{2} \le \hat{V} \le OPT \quad \text{if } \mathsf{opt} = \max, \qquad \text{and} \qquad OPT \le \hat{V} \le 2OPT \quad \text{if } \mathsf{opt} = \min.$$

Proof. We obtain $\hat{V}$ by iterating over all powers of 2 in the domain $[0, v(E)]$. In one of these iterations we necessarily hit a value within a factor 2 of OPT, and we output this guess as $\hat{V}$. For simplicity of presentation, in the remainder we assume that we are given such a value $\hat{V}$ satisfying the stated 2-approximation guarantees.

The number of guesses is $O(\log v(E))$. Since $\mathsf{OPT} \le v(E) \le n\, v_{\max}$,

$$\log v(E) \le \log(n v_{\max}) = O(\log n + \log v_{\max}).$$

Let b be the bit-length of $v_{\max}$. If $b = \mathrm{poly}(n)$ we are done; otherwise b is exponential in n and we can solve the instance exactly by enumerating all 2^n subsets of E, which is still polynomial in $|E|$. ◀

We assume w.l.o.g. that $v_e \le 2\hat{V}$ for all $e \in E$ (any e with $v_e > 2\hat{V}$ cannot belong to an optimal solution, since all values are nonnegative and $\mathsf{OPT} \le 2\hat{V}$ by Lemma 1). We partition the ground set E into bins according to the values v_e. We first define the bin of *small* elements:

$$B_0 := \{e \in E : v_e \le \varepsilon \hat{V}\}.$$

All other elements are considered *large* and are further categorized into $T = \left\lceil \frac{2-\varepsilon}{\varepsilon^2} \right\rceil$ bins:

$$B_i := \left\{e \in E : (\varepsilon + (i-1)\varepsilon^2)\hat{V} < v_e \le (\varepsilon + i\varepsilon^2)\hat{V}\right\}, \qquad i = 1, \dots, T.$$

▶ **Lemma 2.** *In any optimal solution S^{opt}, at most $2/\varepsilon$ elements belong to $\bigcup_{i=1}^{T} B_i$.*

Proof. Suppose, for the sake of contradiction, that S^{opt} contains more than $2/\varepsilon$ elements from $B_1 \cup \cdots \cup B_T$. By the definition of these bins, every such element has value strictly larger than $\varepsilon\hat{V}$, and hence

$$v\big(S^{\mathsf{opt}}\big) \ge v\big(S^{\mathsf{opt}} \cap (B_1 \cup \cdots \cup B_T)\big) \;>\; \frac{2}{\varepsilon} \cdot \varepsilon\hat{V} \;=\; 2\hat{V}.$$

Hence $v(S^{\mathsf{opt}}) > 2\hat{V}$. If $\mathsf{opt} = \max$, then by Lemma 1 we have $\mathsf{OPT} \le 2\hat{V}$, contradicting $v(S^{\mathsf{opt}}) = \mathsf{OPT} > 2\hat{V}$. If $\mathsf{opt} = \min$, then Lemma 1 gives $\mathsf{OPT} \le \hat{V}$ and hence $\mathsf{OPT} \le 2\hat{V}$, again contradicting $v(S^{\mathsf{opt}}) = \mathsf{OPT} > 2\hat{V}$. Thus S^{opt} contains at most $2/\varepsilon$ elements from $\bigcup_{i=1}^{T} B_i$. ◀

We therefore restrict our attention to solutions with at most $2/\varepsilon$ large elements. We encode such solutions via a *configuration vector* $\vec{k} = (k_0, k_1, \dots, k_T)$, where k_i denotes the number of elements that should be chosen from bin B_i. We only consider vectors satisfying

$$\sum_{i=1}^{T} k_i \le \left\lceil \frac{2}{\varepsilon} \right\rceil, \qquad \sum_{i=0}^{T} k_i \le |E|. \tag{2}$$

For such a vector $\vec{k}$, a set $S \subseteq E$ *respects the configuration* $\vec{k}$ if $|S \cap B_i| \;=\; k_i$ for all $i = 0, \dots, T$.

▶ **Lemma 3.** *The number of distinct configuration vectors satisfying* (2) *is at most* $O\left(|E| \cdot \left(\frac{1}{\varepsilon^2}\right)^{2/\varepsilon}\right)$.

Proof. Let $m := \lceil 2/\varepsilon \rceil$. By (2), the number of valid tuples $(k_1, \ldots, k_T)$ corresponds to the number of non-negative integer solutions to the inequality $\sum_{i=1}^{T} k_i \leq m$. By introducing a slack variable $k^\star \geq 0$ such that $k^\star + \sum_{i=1}^{T} k_i = m$, this count is equivalent to the number of weak compositions of m into $T+1$ parts. Applying the stars and bars formula, we obtain exactly

$$\binom{(T+1)+m-1}{m} = \binom{T+m}{m}$$

configurations. For each fixed tuple, k_0 is bounded by $|E|$. For a fixed ε (and thus fixed m), the number of configurations is

$$|E| \cdot \binom{T+m}{m} \;\leq\; |E| \cdot (T+m)^m \;=\; O(|E| \cdot T^m) \;=\; O\left(|E| \cdot \left(\frac{1}{\varepsilon^2}\right)^{2/\varepsilon}\right). \qquad \blacktriangleleft$$

Let $\vec{k}^{\mathsf{opt}}$ denote the configuration vector of an optimal solution S^{opt}. By Lemma 2, $\vec{k}^{\mathsf{opt}}$ satisfies (2), hence it is among the vectors considered by our algorithm.

2.2 Partition Matroid and Restricted Family

Fix a configuration vector $\vec{k} = (k_0, \ldots, k_T)$ satisfying (2), and let $K := \sum_{i=0}^{T} k_i$. We can enforce the cardinality of $\mathcal{M}$ by considering its truncation to rank K, denoted $\mathcal{M}_{\leq K}$, whose independent sets are $\mathcal{I}_{\leq K} = \mathsf{IS}(\mathcal{M}_{\leq K}) = \{S \in \mathcal{I} : |S| \leq K\}$.

Next, we encode the bin-wise upper bounds prescribed by $\vec{k}$ via a partition matroid. Let $B_0, \ldots, B_T$ be the bins (a partition of E). Define the partition matroid $\mathcal{M}^P_{\vec{k}}$ on E by

$$S \in \mathcal{I}^P_{\vec{k}} = \mathsf{IS}(\mathcal{M}^P_{\vec{k}}) \quad \Longleftrightarrow \quad |S \cap B_i| \leq k_i \;\text{ for all } i = 0, \ldots, T.$$

We restrict the $\mathcal{P}$-MOL problem to sets that satisfy both matroid constraints and have exactly K elements:

$$\mathcal{F}_{\vec{k}} \;:=\; \{\, S \subseteq E :\; S \in \mathcal{I}_{\leq K} \cap \mathcal{I}^P_{\vec{k}} \text{ and } |S| = K \,\}.$$

If $K > \mathsf{rank}(\mathcal{M})$, then $\mathcal{F}_{\vec{k}} = \emptyset$ (since no independent set can have size K); in the algorithm we simply skip such configurations.

Equivalently, $\mathcal{F}_{\vec{k}}$ is the family of common bases of $\mathcal{M}_{\leq K}$ and $\mathcal{M}^P_{\vec{k}}$ (since in each matroid, a set is a base iff it is independent and has size equal to the matroid rank, here K). If the original feasible family is $\mathcal{F} = \mathsf{IS}(\mathcal{M})$, then the above definition applies for any $K \leq \mathsf{rank}(\mathcal{M})$. If instead $\mathcal{F} = \mathsf{bases}(\mathcal{M})$, then we must have $K = \mathsf{rank}(\mathcal{M})$; otherwise no set of size K can be a base of $\mathcal{M}$. Accordingly, in the bases variant we only consider configuration vectors with $K = \mathsf{rank}(\mathcal{M})$ (and for other K we take $\mathcal{F}_{\vec{k}} = \emptyset$).

Finally, note that membership in $\mathcal{F}_{\vec{k}}$ forces the bin constraints of $\mathcal{M}^P_{\vec{k}}$ to be tight. Indeed, for any $S \in \mathcal{F}_{\vec{k}}$, we have

$$|S \cap B_i| \leq k_i \;\; \forall i \in \{0, \ldots, T\} \quad \text{and} \quad \sum_{i=0}^{T} |S \cap B_i| = |S| = K = \sum_{i=0}^{T} k_i,$$

implying that $|S \cap B_i| = k_i$ for all i. In particular, every $S \in \mathcal{F}_{\vec{k}}$ is a base of the partition matroid $\mathcal{M}^P_{\vec{k}}$ and also a base of the truncated matroid $\mathcal{M}_{\leq K}$ since $|S| = K$.

For $\mathsf{opt} = \max$, let $\mathsf{OPT}_{\vec{k}}$ denote the maximum of $v(S)$ over all $S \in \mathcal{F}_{\vec{k}}$ satisfying $w(S) \triangleright L$; for $\mathsf{opt} = \min$ we define $\mathsf{OPT}_{\vec{k}}$ analogously as a minimum. If $\vec{k} = \vec{k}^{\mathsf{opt}}$ is the configuration of an optimal solution, then clearly $\mathsf{OPT}_{\vec{k}^{\mathsf{opt}}} = \mathsf{OPT}$.

2.3 Lagrangian Relaxation

Returning to our problem, we must satisfy both the matroid-intersection constraint and the linear constraint: $w(S) \triangleright L$. Since the linear constraint is typically the harder one to handle directly, we apply *Lagrangian relaxation* to incorporate it into the objective via a penalty term.

To express the different orientations in a unified form, we define two sign parameters:

$$s_{\mathsf{opt}} = \begin{cases} +1 & \text{if } \mathsf{opt} = \max, \\ -1 & \text{if } \mathsf{opt} = \min, \end{cases} \qquad s_{\triangleright} = \begin{cases} +1 & \text{if } \triangleright = \geq, \\ -1 & \text{if } \triangleright = \leq . \end{cases}$$

For $\lambda \geq 0$ and $S \subseteq E$, we define the Lagrangian objective

$$\phi_\lambda(S) \;:=\; v(S) + s_{\mathsf{opt}} s_{\triangleright} \lambda\big(w(S) - L\big).$$

The corresponding Lagrangian relaxation value for some fixed configuration vector $\vec{k}$ is

$$V_{\vec{k}}(\lambda) \;:=\; \mathsf{opt}_{S \in \mathcal{F}_{\vec{k}}}\, \phi_\lambda(S). \tag{3}$$

Finally, we define the optimal value of the Lagrangian relaxation by

$$\mathrm{LR}_{\vec{k}} := \begin{cases} \min\limits_{\lambda \geq 0} V_{\vec{k}}(\lambda) & \text{if } \mathsf{opt} = \max, \\ \max\limits_{\lambda \geq 0} V_{\vec{k}}(\lambda) & \text{if } \mathsf{opt} = \min . \end{cases}$$

▶ **Lemma 4.** *For every configuration vector $\vec{k}$, the function $V_{\vec{k}} : \mathbb{R}_{\geq 0} \to \mathbb{R}$ is piecewise linear. Moreover, if $\mathsf{opt} = \max$, then $V_{\vec{k}}$ is convex, and if $\mathsf{opt} = \min$, then $V_{\vec{k}}$ is concave.*

Proof. Fix $\vec{k}$ and consider any $S \in \mathcal{F}_{\vec{k}}$. The function $\phi_\lambda(S)$ is affine in λ. Therefore, $V_{\vec{k}}(\lambda)$ is the pointwise optimum of finitely many affine functions (one for each $S \in \mathcal{F}_{\vec{k}}$), and hence $V_{\vec{k}}$ is piecewise linear.

Moreover, if $\mathsf{opt} = \max$ then $V_{\vec{k}}$ is the pointwise maximum of affine functions and hence convex; if $\mathsf{opt} = \min$ then $V_{\vec{k}}$ is the pointwise minimum of affine functions and hence concave. ◀

▶ **Lemma 5.** *For every configuration vector $\vec{k}$, if $\mathsf{opt} = \max$, then $\mathrm{LR}_{\vec{k}} \geq \mathit{OPT}_{\vec{k}}$, and if $\mathsf{opt} = \min$, then $\mathrm{LR}_{\vec{k}} \leq \mathit{OPT}_{\vec{k}}$.*

Proof. Let S be any feasible solution with configuration $\vec{k}$, i.e., $S \in \mathcal{F}_{\vec{k}}$ and $w(S) \triangleright L$. Then $s_{\triangleright}\big(w(S) - L\big) \geq 0$. For any $\lambda \geq 0$,

$$s_{\mathsf{opt}}\, \phi_\lambda(S) = s_{\mathsf{opt}}\, v(S) + s_{\triangleright}\, \lambda\big(w(S) - L\big) \;\geq\; s_{\mathsf{opt}}\, v(S).$$

Optimizing over all such S yields $s_{\mathsf{opt}} V_{\vec{k}}(\lambda) \geq s_{\mathsf{opt}} \mathsf{OPT}_{\vec{k}}$. If $\mathsf{opt} = \max$ (so $s_{\mathsf{opt}} = +1$), this implies $V_{\vec{k}}(\lambda) \geq \mathsf{OPT}_{\vec{k}}$ for all λ, hence $\mathrm{LR}_{\vec{k}} = \min_{\lambda \geq 0} V_{\vec{k}}(\lambda) \geq \mathsf{OPT}_{\vec{k}}$. The minimization case is analogous. ◀

We now argue that the Lagrangian relaxation (3) can be solved efficiently.

▶ **Lemma 6.** *For every configuration vector $\vec{k}$ and any $\lambda \geq 0$, the value $V_{\vec{k}}(\lambda)$ and a set $S_{\vec{k},\lambda} \in \mathcal{F}_{\vec{k}}$ attaining this value can be computed in polynomial time. Moreover, a multiplier $\lambda^\star_{\vec{k}}$ satisfying $V_{\vec{k}}(\lambda^\star_{\vec{k}}) = \mathrm{LR}_{\vec{k}}$ can be computed in polynomial time.*

Proof. Fix a configuration vector $\vec{k}$ and $\lambda \geq 0$, and define the modified weight function v^λ as follows

$$v_e^\lambda := v_e + s_{\mathsf{opt}} s_\triangleright \lambda w_e \quad \text{for all } e \in E.$$

Then, for any $S \subseteq E$, we can write

$$\phi_\lambda(S) = v(S) + s_{\mathsf{opt}} s_\triangleright \lambda\big(w(S) - L\big) = \sum_{e \in S} v_e^\lambda \; - \; s_{\mathsf{opt}} s_\triangleright \lambda L.$$

Hence, for fixed λ, optimizing ϕ_λ over $S \in \mathcal{F}_{\vec{k}}$ is equivalent (up to an additive constant independent of S) to solving the following optimization problem

$$\mathsf{opt}_{S \in \mathcal{F}_{\vec{k}}} \sum_{e \in S} v_e^\lambda.$$

For both $\mathcal{F} \in \{\mathsf{IS}, \mathsf{bases}\}$, the restriction to $\mathcal{F}_{\vec{k}}$ imposes a fixed cardinality constraint $|S| = K$ (where $K = \sum_i k_i$, and in the bases case necessarily $K = \mathsf{rank}(\mathcal{M})$, otherwise $\mathcal{F}_{\vec{k}} = \emptyset$). Consequently, the problem of optimizing a linear objective over $\mathcal{F}_{\vec{k}}$ is a cardinality-constrained weighted matroid intersection instance between $\mathcal{M}$ (or $\mathcal{M}_{\leq K}$) and the partition matroid $\mathcal{M}_{\vec{k}}^P$. This problem is solvable in polynomial time by the algorithm of Brezovec et al. [2]. Therefore, for any fixed $\vec{k}$ and $\lambda \geq 0$, we can compute $V_{\vec{k}}(\lambda)$ in polynomial time.

It remains to find a multiplier $\lambda_{\vec{k}}^\star \geq 0$ such that $V_{\vec{k}}(\lambda_{\vec{k}}^\star) = \mathrm{LR}_{\vec{k}}$. Since the objective weights v_e^λ depend linearly on λ, we can apply Megiddo's parametric-search framework [25] to compute such an optimal multiplier $\lambda_{\vec{k}}^\star$ in polynomial time. ◀

Let $\lambda_{\vec{k}}^\star$ be such an optimal multiplier, and define the family of Lagrangian–optimal solutions

$$\mathcal{O}_{\vec{k}} := \{\, S \in \mathcal{F}_{\vec{k}} : \phi_{\lambda_{\vec{k}}^\star}(S) = \mathrm{LR}_{\vec{k}} \,\}.$$

For every $S \in \mathcal{O}_{\vec{k}}$ we have $\phi_{\lambda_{\vec{k}}^\star}(S) = \mathrm{LR}_{\vec{k}}$, which can be rewritten as

$$v(S) = \mathrm{LR}_{\vec{k}} - s_{\mathsf{opt}} s_\triangleright \, \lambda_{\vec{k}}^\star\big(w(S) - L\big). \tag{4}$$

We next consider the degenerate edge case in which $\lambda_{\vec{k}}^\star = 0$. In this case, the Lagrangian objective reduces to the original objective over $\mathcal{F}_{\vec{k}}$. Let

$$S_{\vec{k}}^0 \in \operatorname*{arg\,opt}_{S \in \mathcal{F}_{\vec{k}}} v(S)$$

be an unconstrained optimum chosen to maximize $s_\triangleright(w(S) - L)$ among all unconstrained optima. If $S_{\vec{k}}^0$ is feasible, we add it directly to the candidate pool. If no unconstrained optimum is feasible, this configuration contributes no candidate in the case $\lambda_{\vec{k}}^\star = 0$. Henceforth, we assume that $\lambda_{\vec{k}}^\star > 0$.

2.4 Spread and Adjacency

We introduce a bound on the change in $v(\cdot)$ under a one-per-bin exchange, and then prove an adjacency property of $\mathcal{O}_{\vec{k}}$ showing that any two solutions in $\mathcal{O}_{\vec{k}}$ are connected by a sequence of such exchanges. For each bin B_i define its *spread*

$$\Delta_i \; := \; \max_{e \in B_i} v_e \; - \; \min_{e \in B_i} v_e,$$

with the convention that $\Delta_i = 0$ if $B_i = \emptyset$. For a configuration vector $\vec{k}$, define the total spread

$$\Sigma_\Delta(\vec{k}) := \sum_{i:\, k_i > 0} \Delta_i.$$

▶ **Lemma 7.** *Fix a configuration vector $\vec{k}$ satisfying (2).*

1. *If $S, S' \in \mathcal{F}_{\vec{k}}$ differ by exchanging at most one element per bin, then $|v(S) - v(S')| \le \Sigma_\Delta(\vec{k})$.*
2. *It holds that $\Sigma_\Delta(\vec{k}) \le 8\varepsilon\, \mathit{OPT}$.*

Proof. *Part* (1). Fix a bin B_i with $k_i > 0$. By assumption, passing from S to S' removes at most one element from B_i and therefore (to maintain $|S' \cap B_i| = |S \cap B_i|$, since $S, S' \in \mathcal{F}_{\vec{k}}$) it also adds at most one element to B_i. Hence the contribution of bin B_i to the value can change by at most Δ_i, i.e., $|v(S \cap B_i) - v(S' \cap B_i)| \le \Delta_i$. Summing over all bins with $k_i > 0$ yields

$$|v(S) - v(S')| \le \sum_{i:\, k_i > 0} |v(S \cap B_i) - v(S' \cap B_i)| \le \sum_{i:\, k_i > 0} \Delta_i = \Sigma_\Delta(\vec{k}).$$

Part (2). By the bucketing construction, $\Delta_0 \le \varepsilon \hat{V}$ and $\Delta_i \le \varepsilon^2 \hat{V}$ for all $i \ge 1$. Moreover, (2) implies that the number of indices $i \ge 1$ with $k_i > 0$ is at most $\lceil 2/\varepsilon \rceil$. Therefore,

$$\Sigma_\Delta(\vec{k}) = \Delta_0 \cdot \mathbf{1}[k_0 > 0] + \sum_{i \ge 1:\, k_i > 0} \Delta_i \le \varepsilon \hat{V} + \left\lceil \frac{2}{\varepsilon} \right\rceil \cdot \varepsilon^2 \hat{V} \le \varepsilon \hat{V} + 3\varepsilon \hat{V} \le 4\varepsilon \hat{V}.$$

Finally, by Lemma 1, we have $\hat{V} \le \mathsf{OPT}$ when $\mathsf{opt} = \max$, and $\hat{V} \le 2\mathsf{OPT}$ when $\mathsf{opt} = \min$; thus, in both cases $\Sigma_\Delta(\vec{k}) \le 8\varepsilon\, \mathsf{OPT}$. ◀

We next establish the adjacency property of $\mathcal{O}_{\vec{k}}$, namely that any two sets in $\mathcal{O}_{\vec{k}}$ can be connected by a sequence of exchanges that swaps at most one element per bin. Our proof uses the following theorem of Brezovec et al. [3].

▶ **Lemma 8** (Theorem 4 from [3]). *Let $\mathcal{M}_1 = (E, \mathcal{I}_1)$ be a matroid and let $\mathcal{M}_2 = (E, \mathcal{I}_2)$ be a partition matroid on the same ground set E, given by a partition $E = B_0 \cup \cdots \cup B_T$ and capacities $(k_0, \ldots, k_T)$. Let $c : E \to \mathbb{R}$ be a weight function, and let S be a common base of $\mathcal{M}_1$ and $\mathcal{M}_2$.*

Define the directed bipartite exchange graph *$B_S = (U \cup V, A)$ by $U := S, V := E \setminus S$, (i.e., one vertex for each element), and for each $e \in U$ and $f \in V$ define arcs as follows:*

- *if $S - e + f \in \mathcal{I}_1$, add an arc (e, f) with cost $c(f) - c(e)$;*
- *if $S - e + f \in \mathcal{I}_2$, add an arc (f, e) with cost 0.*

Let D_S be the directed graph obtained from B_S by compressing, for each $i \in \{0, \ldots, T\}$, all vertices in $V \cap B_i$ into a single vertex v_i, and then deleting parallel arcs while keeping, for each ordered pair of vertices, only the arc of minimum length.

For the graph D_S the following hold:

- *There are no negative cycles in D_S if and only if S is optimal for the weighted matroid intersection instance.*
- *If D_S contains a directed cycle C of negative total length, then there exists a common base T of $\mathcal{M}_1$ and $\mathcal{M}_2$ that is obtained from S by exchanging elements along C and satisfies $c(T) < c(S)$.*

Using this lemma, we obtain the following exchange-path guarantee.

▶ **Lemma 9.** *For any $S, S' \in \mathcal{O}_{\vec{k}}$, we can find in polynomial time a sequence of solutions $S = S_0, S_1, \ldots, S_\ell = S'$ such that:*

1. *$S_j \in \mathcal{O}_{\vec{k}}$ for all $j = 0, \ldots, \ell$;*
2. *For each $j = 0, \ldots, \ell - 1$ and for each bin B_i,*

$$|(S_j \setminus S_{j+1}) \cap B_i| = |(S_{j+1} \setminus S_j) \cap B_i| \leq 1.$$

Proof. Fix a configuration vector $\vec{k}$, and let $v^* = v^{\lambda^*_{\vec{k}}}$. W.l.o.g., assume that $\mathcal{O}_{\vec{k}}$ consists of *minimum*-cost bases with respect to v^* (otherwise, replace v^* by $-v^*$).

We prove the statement by induction on $x := |S' \setminus S|$. The case $x = 0$ is trivial. Assume that $x \geq 1$ and the lemma holds for every pair $T, T' \in \mathcal{O}_{\vec{k}}$ satisfying $|T' \setminus T| < x$. We prove the claim for the given pair S, S' with $|S' \setminus S| = x$.

Fix $\delta > 0$ and define $v' : E \to \mathbb{R} \cup \{+\infty\}$ by

$$v'(e) = \begin{cases} v^*(e) + \delta, & e \in S \setminus S', \\ v^*(e) - \delta, & e \in S' \setminus S, \\ v^*(e), & e \in S \cap S', \\ +\infty, & e \notin S \cup S'. \end{cases}$$

Then $v'(S) = v^*(S) + x\delta$ and $v'(S') = v^*(S') - x\delta$, and hence $v'(S') = v^*(S') - x\delta < v^*(S) + x\delta = v'(S)$, where we used $v^*(S) = v^*(S')$ since $S, S' \in \mathcal{O}_{\vec{k}}$. To avoid choosing an explicit infinitesimal δ, we implement this perturbation lexicographically. Let U be an integer upper bound on $\sum_{e \in S} |v^*(e)|$ over all $S \in \mathcal{F}_{\vec{k}}$ (e.g., $U := K \cdot \max_{e \in E} |v^*(e)|$), and set $M := 2U + 1$. Define an auxiliary weight function $\tilde{v} : E \to \mathbb{R}$ by

$$\tilde{v}(e) = \begin{cases} M \cdot v^*(e) + 1, & e \in S \setminus S', \\ M \cdot v^*(e) - 1, & e \in S' \setminus S, \\ M \cdot v^*(e), & e \in S \cap S', \\ M \cdot v^*(e) + M^2 + K, & e \notin S \cup S'. \end{cases}$$

We claim that $\tilde{v}(S') < \tilde{v}(S)$. Indeed, since $S, S' \in \mathcal{O}_{\vec{k}}$ we have $v^*(S) = v^*(S')$. Moreover, letting $x := |S' \setminus S| = |S \setminus S'|$, the definition of $\tilde{v}$ implies

$$\tilde{v}(S) = \sum_{e \in S} \tilde{v}(e) = M \sum_{e \in S} v^*(e) + |S \setminus S'| = M\, v^*(S) + x,$$

and similarly

$$\tilde{v}(S') = \sum_{e \in S'} \tilde{v}(e) = M \sum_{e \in S'} v^*(e) - |S' \setminus S| = M\, v^*(S') - x.$$

Therefore,

$$\tilde{v}(S) - \tilde{v}(S') = M\big(v^*(S) - v^*(S')\big) + 2x = 2x > 0,$$

and hence $\tilde{v}(S') < \tilde{v}(S)$.

Since the weights $v^*(e)$ may be rational, we first scale them to integers. Let D be a common denominator of $\{v^*(e) : e \in E\}$, and define $\bar{v}^*(e) := D \cdot v^*(e)$ for all $e \in E$. Then $\bar{v}^*(e) \in \mathbb{Z}$ for all e, and for any two common bases T_1, T_2 we have $\bar{v}^*(T_1) - \bar{v}^*(T_2) \in \mathbb{Z}$.

We redefine $\tilde{v}$ using $\bar{v}^*$ as follows. Let $U := K \cdot \max_{e \in E} |\bar{v}^*(e)|$ and set $M := 2U + 1$. Define $\tilde{v} : E \to \mathbb{Z}$ by $\tilde{v}(e) = M \cdot \bar{v}^*(e) + 1$ for $e \in S \setminus S'$, $\tilde{v}(e) = M \cdot \bar{v}^*(e) - 1$ for $e \in S' \setminus S$, $\tilde{v}(e) = M \cdot \bar{v}^*(e)$ for $e \in S \cap S'$, and $\tilde{v}(e) = M \cdot \bar{v}^*(e) + M^2 + 2MU + 2K$ for $e \notin S \cup S'$.

Our redefinition preserves the computation for S and S'. In particular, using $\bar{v}^*(S) = \bar{v}^*(S')$ we have $\tilde{v}(S) = M \cdot \bar{v}^*(S) + x$ and $\tilde{v}(S') = M \cdot \bar{v}^*(S') - x$, so $\tilde{v}(S') < \tilde{v}(S)$.

▷ Claim 10. Any $\tilde{v}$-minimum common base is (i) a v^*-minimum common base (and hence belongs to $\mathcal{O}_{\vec{k}}$), and (ii) consists solely of elements from $S \cup S'$.

Proof. We first show that minimizing $\tilde{v}$ enforces minimization of v^* (lexicographically). Fix any common base $T \in \mathcal{F}_{\vec{k}}$. Write $\tilde{v}(T) = M \cdot \bar{v}^*(T) + \tau(T)$, where $\tau(T)$ is the additive tie-breaking term induced by the ± 1 offsets (and 0 offsets) in the definition of $\tilde{v}$. Since $|T| = K$, we have the uniform bound $|\tau(T)| \le K$ whenever $T \subseteq S \cup S'$. Moreover, if T contains some element $e \notin S \cup S'$, then

$$\tilde{v}(T) \ge M \cdot \bar{v}^*(T) - K + (M^2 + 2MU + 2K) \ge -MU - K + (M^2 + 2MU + 2K) = M^2 + MU + K.$$

On the other hand, for every common base $T \subseteq S \cup S'$ we have

$$\tilde{v}(T) = M \cdot \bar{v}^*(T) + \tau(T) \le MU + K.$$

Therefore any $\tilde{v}$-minimum common base must be contained in $S \cup S'$.

Now let $T_1, T_2 \subseteq S \cup S'$ be any two common bases. Then

$$\tilde{v}(T_1) - \tilde{v}(T_2) = M\big(\bar{v}^*(T_1) - \bar{v}^*(T_2)\big) + \big(\tau(T_1) - \tau(T_2)\big),$$

and $|\tau(T_1) - \tau(T_2)| \le 2K$. Choose U so that $U \ge K \cdot \max_{e \in E} |\bar{v}^*(e)|$, and set $M := 2U + 1$ as above. Then $M > 2K$. Moreover, since $\bar{v}^*(T_1), \bar{v}^*(T_2) \in \mathbb{Z}$, if $\bar{v}^*(T_1) > \bar{v}^*(T_2)$ then $\bar{v}^*(T_1) - \bar{v}^*(T_2) \ge 1$, and hence

$$\tilde{v}(T_1) - \tilde{v}(T_2) = M\big(\bar{v}^*(T_1) - \bar{v}^*(T_2)\big) + \big(\tau(T_1) - \tau(T_2)\big) \ge M - 2K > 0.$$

Therefore $\tilde{v}(T_1) > \tilde{v}(T_2)$. Consequently, among all common bases contained in $S \cup S'$, every $\tilde{v}$-minimum base is also v^*-minimum. Moreover, as shown above, if a common base T contains an element outside $S \cup S'$, then $\tilde{v}(T) \ge M^2 + MU + K$, whereas every common base $T \subseteq S \cup S'$ satisfies $\tilde{v}(T) \le MU + K$. Hence no $\tilde{v}$-minimum common base uses elements outside $S \cup S'$. Therefore, any $\tilde{v}$-minimum common base belongs to $\mathcal{O}_{\vec{k}}$ and is contained in $S \cup S'$. ◁

Apply Lemma 8 to the pair $(\mathcal{M}_{\le K}, \mathcal{M}^P_{\vec{k}})$, the weight function $\tilde{v}$, and the current base S. Since $\tilde{v}(S') < \tilde{v}(S)$, the base S is not $\tilde{v}$-optimal, so the compressed graph D_S contains a negative cycle. Let C be a negative directed cycle in D_S with the minimum number of arcs. Lemma 8 yields a common base S'' obtained from S by exchanging along C such that $\tilde{v}(S'') < \tilde{v}(S)$. By the choice of $\tilde{v}(e)$ for $e \notin S \cup S'$, we have $S'' \subseteq S \cup S'$.

Since D_S is bipartite, any directed cycle C alternates between vertices $e \in S$ and contracted bin vertices v_i. We chose C with the minimum number of arcs, hence C cannot visit the same v_i twice; otherwise C would split into two directed cycles, and at least one of them would still have negative total length but fewer arcs, contradicting minimality. Thus, C visits each bin at most once, so the corresponding exchange inserts at most one element from each bin B_i, i.e. $|(S'' \setminus S) \cap B_i| \le 1$. Finally, S and S'' are both bases of the partition matroid $\mathcal{M}^P_{\vec{k}}$, so in each bin B_i an insertion must be matched by a deletion from the same bin in order to keep $|S \cap B_i| = k_i$. Hence, the numbers of inserted and deleted elements match in every bin:

$$|(S \setminus S'') \cap B_i| = |(S'' \setminus S) \cap B_i| \le 1 \qquad \forall i \in \{0, \dots, T\}.$$

Since $S \in \mathcal{O}_{\vec{k}}$ is v^*-minimum, we have $v^*(T) \ge v^*(S)$ for every common base T. In particular, for every common base $T \subseteq S \cup S'$ we have $\bar{v}^*(T) \ge \bar{v}^*(S)$. Now $S'' \subseteq S \cup S'$ and $\tilde{v}(S'') < \tilde{v}(S)$. If $\bar{v}^*(S'') > \bar{v}^*(S)$ then $\tilde{v}(S'') - \tilde{v}(S) \ge M - 2K > 0$, a contradiction. Hence $\bar{v}^*(S'') = \bar{v}^*(S)$, i.e., $v^*(S'') = v^*(S)$, and therefore $S'' \in \mathcal{O}_{\vec{k}}$.

Finally, since the inserted elements come from $E \setminus S$ and, by the definition of $\tilde{v}$, must lie in $S' \setminus S$, we add at least one element of $S' \setminus S$; thus $|S' \setminus S''| < |S' \setminus S| = x$.

The induction hypothesis applies to the pair (S'', S'). Hence there exists a sequence $S'' = S_0, S_1, \ldots, S_m = S'$ with $S_j \in \mathcal{O}_{\vec{k}}$ for all j and such that each transition $S_j \to S_{j+1}$ exchanges at most one element per bin. Appending the initial step $S \to S''$ to this sequence yields the desired path from S to S'.

The above inductive argument yields an explicit polynomial-time procedure to construct the sequence. Given $S, S' \in \mathcal{O}_{\vec{k}}$, form the perturbed weight function $\tilde{v}$ as in the proof. Since $\tilde{v}(S') < \tilde{v}(S)$, the base S is not $\tilde{v}$-optimal, so by Lemma 8 the compressed exchange graph D_S contains a negative directed cycle, which can be found in polynomial time (e.g. by Bellman–Ford; extracting a *simple* negative cycle ensures no bin-vertex v_i is repeated). Exchanging along this cycle produces $S'' \in \mathcal{O}_{\vec{k}}$ that differs from S by at most one element per bin and satisfies $|S' \setminus S''| < |S' \setminus S|$. Repeating for at most $|S' \setminus S| \leq K$ iterations constructs $S = S_0, S_1, \ldots, S_\ell = S'$. ◀

2.5 Deriving an EPTAS

We now show that for every feasible configuration vector $\vec{k}$, there is a Lagrangian–optimal solution that is both feasible for the original linear constraint and nearly optimal in value.

▶ **Lemma 11.** *Fix a configuration vector $\vec{k}$ with $\mathcal{F}_{\vec{k}} \neq \emptyset$, and let $\lambda^\star_{\vec{k}}$, $\mathrm{LR}_{\vec{k}}$, and $\mathcal{O}_{\vec{k}}$ be as defined above. Then, there exists a set $S^\star \in \mathcal{O}_{\vec{k}}$ such that $w(S^\star) \triangleright L$ and the following holds:*

- *if $\mathsf{opt} = \min$, then $v(S^\star) \leq \mathrm{LR}_{\vec{k}} + \Sigma_\Delta(\vec{k})$,*
- *if $\mathsf{opt} = \max$, then $v(S^\star) \geq \mathrm{LR}_{\vec{k}} - \Sigma_\Delta(\vec{k})$.*

Proof. Recall that $\mathcal{O}_{\vec{k}} = \arg \mathsf{opt}_{S \in \mathcal{F}_{\vec{k}}} \phi_{\lambda^\star_{\vec{k}}}(S)$. Choose $S^-, S^+ \in \mathcal{O}_{\vec{k}}$ such that $s_\triangleright(w(S^-) - L)$ is minimized over $\mathcal{O}_{\vec{k}}$ and $s_\triangleright(w(S^+) - L)$ is maximized over $\mathcal{O}_{\vec{k}}$ (These can be computed in polynomial time by lexicographic optimization over $\mathcal{F}_{\vec{k}}$: first optimize $\phi_{\lambda^\star_{\vec{k}}}$, and among ties minimize/maximize $s_\triangleright w(S)$, implemented via weighted matroid intersection).

We claim that $s_\triangleright(w(S^-) - L) \leq 0 \leq s_\triangleright(w(S^+) - L)$. Otherwise, if $s_\triangleright(w(S) - L) > 0$ for all $S \in \mathcal{O}_{\vec{k}}$ (or < 0 for all such S), then perturbing $\lambda^\star_{\vec{k}}$ slightly in the appropriate direction would improve $V_{\vec{k}}(\lambda)$, contradicting the optimality of $\lambda^\star_{\vec{k}}$ in the definition of $\mathrm{LR}_{\vec{k}}$.

For simplicity, we present the remainder of the proof for the minimization case; the maximization case is analogous. Using Eq. (4) with $\mathsf{opt} = \min$ (so $s_{\mathsf{opt}} = -1$), we have $v(S) - \mathrm{LR}_{\vec{k}} = s_\triangleright \lambda^\star_{\vec{k}}\big(w(S) - L\big)$. Since $\lambda^\star_{\vec{k}} \geq 0$, it follows that $s_\triangleright\big(w(S^-) - L\big) \leq 0$ implies $v(S^-) \leq \mathrm{LR}_{\vec{k}}$, and $s_\triangleright\big(w(S^+) - L\big) \geq 0$ implies $v(S^+) \geq \mathrm{LR}_{\vec{k}}$.

By Lemma 9, there is a sequence $S^- = S_0, S_1, \ldots, S_\ell = S^+$ inside $\mathcal{O}_{\vec{k}}$ such that each step exchanges at most one element per bin. Since $v(S_0) \leq \mathrm{LR}_{\vec{k}}$ and $v(S_\ell) \geq \mathrm{LR}_{\vec{k}}$, there exists an index j such that $v(S_j) \leq \mathrm{LR}_{\vec{k}} \leq v(S_{j+1})$.

Combining this inequality with Lemma 7 yields

$$v(S_{j+1}) \leq v(S_j) + \Sigma_\Delta(\vec{k}) \leq \mathrm{LR}_{\vec{k}} + \Sigma_\Delta(\vec{k}).$$

Moreover, since $v(S_{j+1}) \geq \mathrm{LR}_{\vec{k}}$ and $v(S_{j+1}) - \mathrm{LR}_{\vec{k}} = s_\triangleright \lambda^\star_{\vec{k}}\big(w(S_{j+1}) - L\big)$ with $\lambda^\star_{\vec{k}} \geq 0$, it follows that $s_\triangleright\big(w(S_{j+1}) - L\big) \geq 0$, i.e., $w(S_{j+1}) \triangleright L$. Thus $S^\star := S_{j+1}$ is feasible and satisfies the desired bound, which completes the proof.

All objects used above can be computed in polynomial time. First, $\lambda^\star_{\vec{k}}$ is computed as in Lemma 6, and S^-, S^+ are obtained by two lexicographic weighted-matroid-intersection calls over $\mathcal{F}_{\vec{k}}$ (optimize $\phi_{\lambda^\star_{\vec{k}}}$, and among ties minimize/maximize $s_\triangleright w(S)$). Next, Lemma 9 yields an explicit sequence $S^- = S_0, \ldots, S_\ell = S^+$ inside $\mathcal{O}_{\vec{k}}$ with one-per-bin exchanges; scanning this sequence finds an index j with $v(S_j) \leq \mathrm{LR}_{\vec{k}} \leq v(S_{j+1})$, and we output $S^\star := S_{j+1}$. ◀

Algorithm 1 EPTAS for $\mathcal{P}$-MOL .

Input: An instance $\mathcal{A}_{\mathcal{P}} = (E, \mathcal{I}, v, w, L)$, a descriptor $\mathcal{P} = (\mathsf{opt}, \mathcal{F}, \triangleright)$ and $\varepsilon > 0$.
Output: A feasible set S which is $(1 \pm \varepsilon)$-approximation of OPT.

Compute a feasible set $\hat{S}$ and set $\hat{V} := v(\hat{S})$, as guaranteed by Lemma 1.
Define the buckets $B_0, \ldots, B_T \subseteq E$.
$\mathcal{K} \leftarrow \left\{\vec{k} = (k_0, \ldots, k_T) \in \mathbb{Z}_{\geq 0}^{T+1} : \sum_{i=1}^{T} k_i \leq \lceil 2/\varepsilon \rceil,\ \sum_{i=0}^{T} k_i \leq n\right\}$.
$S^{\text{best}} \leftarrow \hat{S}$
for $\vec{k} \in \mathcal{K}$ **do**
    Construct the partition matroid $\mathcal{M}_{\vec{k}}^{P}$ from $\vec{k}$ and define $\mathcal{F}_{\vec{k}} \subseteq 2^E$.
    Compute $\lambda_{\vec{k}}^{\star}$ and $\mathrm{LR}_{\vec{k}}$ (Lemma 6), and compute two sets $S_{\vec{k}}^{-}, S_{\vec{k}}^{+} \in \mathcal{O}_{\vec{k}}$ as in Lemma 11 (with $s_{\triangleright}(w(S_{\vec{k}}^{-}) - L) \leq 0 \leq s_{\triangleright}(w(S_{\vec{k}}^{+}) - L)$).
    Using Lemmas 7, 9 and 11, compute $S_{\vec{k}}^{\star} \in \mathcal{F}_{\vec{k}}$ with $w(S_{\vec{k}}^{\star}) \triangleright L$ and $s_{\mathsf{opt}}\big(\mathrm{LR}_{\vec{k}} - v(S_{\vec{k}}^{\star})\big) \leq \Sigma_{\Delta}(\vec{k})$.
    if $\mathsf{opt} = \min$ and $v(S_{\vec{k}}^{\star}) < v(S^{\text{best}})$ **then**
        $S^{\text{best}} \leftarrow S_{\vec{k}}^{\star}$
    if $\mathsf{opt} = \max$ and $v(S_{\vec{k}}^{\star}) > v(S^{\text{best}})$ **then**
        $S^{\text{best}} \leftarrow S_{\vec{k}}^{\star}$
return S^{best}

Our main result is the following.

▶ **Theorem 12.** *For every fixed $\varepsilon > 0$, there exists an EPTAS for the $\mathcal{P}$-MOL problem. Given an instance $\mathcal{A}_{\mathcal{P}}$, the algorithm runs in time $|E|^{O(1)} \cdot (1/\varepsilon^2)^{O(1/\varepsilon)}$ and outputs a feasible solution S satisfying*

$$\mathit{opt} = \min \implies v(S) \leq (1+\varepsilon)\,\mathit{OPT}, \qquad \mathit{opt} = \max \implies v(S) \geq (1-\varepsilon)\,\mathit{OPT}.$$

Proof. We first describe our EPTAS for the $\mathcal{P}$-MOL class (see Algorithm 1). Using a constant-factor estimate $\hat{V}$ of OPT, we first bucket the elements by their v-values so that elements within the same bucket have nearly equal value. We then enumerate all feasible configuration vectors $\vec{k}$; each such $\vec{k}$ defines a partition matroid $\mathcal{M}_{\vec{k}}^{P}$ and a restricted family $\mathcal{F}_{\vec{k}}$. For every configuration, we solve the Lagrangian relaxation of the linear constraint over $\mathcal{F}_{\vec{k}}$ to obtain $\lambda_{\vec{k}}^{\star}$, $\mathrm{LR}_{\vec{k}}$ and the set $\mathcal{O}_{\vec{k}}$ of Lagrangian-optimal solutions. Finally, using the adjacency property of $\mathcal{O}_{\vec{k}}$ together with a bound on the per-bucket value spread, we find a set $S_{\vec{k}}^{\star} \in \mathcal{F}_{\vec{k}}$ that satisfies the original linear constraint and is within $\Sigma_{\Delta}(\vec{k})$ of the Lagrangian bound. The algorithm returns the best such solution over all configurations.

We now proceed to prove the approximation guarantee of Algorithm 1. Let S^{opt} be an optimal solution and $\vec{k}^{\mathsf{opt}}$ its configuration vector. Lemma 2 establishes that $\vec{k}^{\mathsf{opt}}$ satisfies Eq. (2), so the algorithm considers this vector. In that iteration, we get $\mathsf{OPT}_{\vec{k}^{\mathsf{opt}}} = \mathsf{OPT}$. It holds that

$$\mathsf{opt} = \min \ \Rightarrow\ v(S_{\vec{k}^{\mathsf{opt}}}^{\star}) \leq \mathrm{LR}_{\vec{k}^{\mathsf{opt}}} + \Sigma_{\Delta}(\vec{k}^{\mathsf{opt}}) \leq \mathsf{OPT} + \Sigma_{\Delta}(\vec{k}^{\mathsf{opt}}) \leq \mathsf{OPT} + 8\varepsilon\mathsf{OPT} = (1+8\varepsilon)\mathsf{OPT},$$

$$\mathsf{opt} = \max \ \Rightarrow\ v(S_{\vec{k}^{\mathsf{opt}}}^{\star}) \geq \mathrm{LR}_{\vec{k}^{\mathsf{opt}}} - \Sigma_{\Delta}(\vec{k}^{\mathsf{opt}}) \geq \mathsf{OPT} - \Sigma_{\Delta}(\vec{k}^{\mathsf{opt}}) \geq \mathsf{OPT} - 8\varepsilon\mathsf{OPT} = (1-8\varepsilon)\mathsf{OPT},$$

where the first inequality in each row is by Lemma 11, the second is due to Lemma 5 and the last holds by Lemma 7. Therefore, running the algorithm with parameter $\varepsilon/8$ internally, we obtain the claimed $(1 \pm \varepsilon)$ guarantees. The feasibility of $S_{\vec{k}^{\mathsf{opt}}}^{\star}$ is immediate due to Lemma 11.

The running time is dominated by the enumeration of configuration vectors (Lemma 3) and, for each $\vec{k}$, a polynomial number of calls to (cardinality-constrained) weighted matroid intersection and local exchange operations. This yields a total running time of $|E|^{O(1)} \cdot (1/\varepsilon^2)^{O(1/\varepsilon)}$, as required. ◀

3 Hardness Proof for MIC

▶ **Theorem 13.** *The* Matroid Intersection Cover *problem admits no* EPTAS*, unless* $W[1] = \text{FPT}$.

Proof. We show a reduction from the k-clique problem. Given a graph $G = (V, E)$ and $k \in \mathbb{N}$ we need to decide if there is a clique of size k in G. Let $n = |V|$, and denote by $C(G)$ the set of all cliques in G. We define below a MIC instance, where we assume, without loss of generality, that $0 < k \leq n$ and $n \geq 1$; otherwise, the problem becomes trivial.

Let $V = \{v_1, \ldots, v_n\}$, and for each vertex $v_i \in V$ define a copy u_i, forming the set $U = \{u_1, \ldots, u_n\}$, where $U \cap V = \emptyset$. We refer to u_i and v_i as the two *copies* of the same vertex. Define a function $f : V \cup U \to [n]$ satisfying the following properties:

1. The restriction of f to V is a bijection onto $[n]$.
2. For every $i \in [n]$, it holds that $f(u_i) = f(v_i)$.

For a set $T \subseteq V \cup U$, we write $f(T) := \{f(x) \mid x \in T\}$ for the image of T under f. We also write $\sigma_f(T) := \sum_{x \in T} f(x)$ for the sum of the labels of the elements in T. Using the function f, we define a matroid $M_1 = (V \cup U, \mathcal{F}_1)$, where the independent sets are given by $\mathcal{F}_1 = \mathcal{I}_1 \cup \mathcal{I}_2 \cup \mathcal{I}_3 \cup \mathcal{I}_4$, with the four families defined as follows:

$$\begin{aligned}
\mathcal{I}_1 &= \{T \subseteq V \cup U \;\big|\; |T| < n\} \\
\mathcal{I}_2 &= \{T \subseteq V \cup U \;\big|\; |T| = n, f(T) \neq f(V)\} \\
\mathcal{I}_3 &= \{T \subseteq V \cup U \;\big|\; |T| = n, |T \cap V| \neq k\}. \\
\mathcal{I}_4 &= \{T \subseteq V \cup U \;\big|\; |T| = n, |T \cap V| = k, f(T) = f(V), T \cap V \in C(G)\}.
\end{aligned} \tag{5}$$

▷ Claim 14. M_1 is a matroid.

Proof. We verify the three matroid axioms. First, $\emptyset \in \mathcal{I}_1$ since $0 < n$, and therefore $\emptyset \in \mathcal{F}_1$. Second, for the hereditary property, let $A \in \mathcal{F}_1$ and let $B \subseteq A$. Since $|B| < |A| \leq n$, we have $|B| < n$, hence $B \in \mathcal{I}_1 \subseteq \mathcal{F}_1$. Third, for the exchange property, let $A, B \in \mathcal{F}_1$ such that $|A| > |B|$. We distinguish cases based on the size of B.

- $|B| < n - 1$. Then, for all $e \in A \setminus B$ it holds that $|B + e| < (n - 1) + 1 = n$, and hence $B + e \in \mathcal{I}_1 \subseteq \mathcal{F}_1$. Such an element $e \in A \setminus B$ exists because $|A| > |B|$.
- $|B| = n - 1$ and $|A| = n$. We further distinguish two subcases.
  1. $B \subseteq A$. Then, $A \setminus B = \{e\}$ for some e, and thus $B + e = A \in \mathcal{F}_1$.
  2. $B \not\subseteq A$. Since $|B| = n - 1$ and $|A| = n$, we have $|B \cap A| \leq |B| - 1 = n - 2$. Hence, $|A \setminus B| = |A| - |A \cap B| \geq n - (n - 2) = 2$, so there exist $x, y \in A \setminus B$, such that $x \neq y$. We now consider two cases according to their images under f.
     - **a.** $f(x) \neq f(y)$. Therefore, there is $q \in \{x, y\}$ such that $f(B + q) \neq f(V)$. We conclude that $B + q \in \mathcal{I}_2 \subseteq \mathcal{F}_1$, as required.
     - **b.** $f(x) = f(y)$. By the definition of f, there exists $i \in [n]$ such that $\{x, y\} = \{v_i, u_i\}$ (or vice versa). Hence, adding x or y to B changes the number of selected vertices from V, i.e., $|(B + x) \cap V| \neq |(B + y) \cap V|$. Thus, it follows that for at least one $q \in \{x, y\}$, $|(B + q) \cap V| \neq k$, implying $B + q \in \mathcal{I}_3 \subseteq \mathcal{F}_1$. ◁

We now define a second matroid, $M_2 = (U \cup V, \mathcal{F}_2)$, by

$$\mathcal{F}_2 = \{T \subseteq V \cup U \mid |T \cap \{u_i, v_i\}| \leq 1 \; \forall i \in [n]\}. \tag{6}$$

Note that M_2 is a partition matroid, in which any independent set contains at most one copy of each vertex. We define a weight function $w : (U \cup V) \to \mathbb{R}_{\geq 0}$ by

$$w(x) = \begin{cases} 1 + \frac{f(x)}{2n^2}, & x \in V, \\ \frac{f(x)}{2n^2} & x \in U. \end{cases}$$

and a valuation function $v : (U \cup V) \to \mathbb{R}_{\geq 0}$, given by

$$v(x) = \begin{cases} 1, & x \in V, \\ 0 & x \in U. \end{cases}$$

Finally, we set the threshold $L = k + \frac{\sigma_f(V)}{2n^2}$ and define the MIC instance $\mathcal{A} = (V \cup U, \mathcal{I}, v, w, L)$, where $\mathcal{I} = \mathcal{F}_1 \cap \mathcal{F}_2$.

▷ Claim 15. G contains a clique of size k if and only if $\mathcal{A}$ admits a feasible solution of value k.

Proof. Let Q_V be a clique of size k in G. Define $Q_U = \{u_i \mid i \in [n], v_i \notin Q_V\}$ and $K = Q_V \cup Q_U$. By construction, K contains exactly one copy of each vertex, either v_i or u_i. Therefore, $K \cap V = Q_V \in C(G)$, $|K \cap V| = |Q_V| = k$, and $f(K) = f(V)$, since $f(u_i) = f(v_i)$ for every $i \in [n]$ (and K contains exactly one copy from each vertex, either from U or from V).

Thus, by (5) we have that $K \in \mathcal{I}_4$ implying that $K \in \mathcal{F}_1$. Moreover, since K includes exactly one element from each pair $\{u_i, v_i\}$, it also satisfies the partition constraint and hence $K \in \mathcal{F}_2$. We therefore have $K \in \mathcal{F}_1 \cap \mathcal{F}_2$. In addition, the weight of K satisfies

$$w(K) = w(Q_V) + w(Q_U) = k + \frac{\sigma_f(Q_V)}{2n^2} + \frac{\sigma_f(Q_U)}{2n^2} = k + \frac{\sigma_f(V)}{2n^2} = L,$$

where we use that $|Q_V| = k$, $f(u_i) = f(v_i)$ for all $i \in [n]$, and K contains exactly one copy of each vertex. Hence, K is a feasible solution for $\mathcal{A}$ with value $v(K) = |K \cap V| = |Q_V| = k$.

For the other direction, let Q be a solution for $\mathcal{A}$ with a value k. By the definition of the valuation function v, it follows that $|Q \cap V| = k$. In addition, the total weight of Q is bounded by

$$w(Q) = k + \frac{\sigma_f(Q)}{2n^2} \leq k + \frac{\sigma_f(V)}{2n^2} = L. \tag{7}$$

The first equality follows from $|Q \cap V| = k$, and the inequality holds because $Q \in \mathcal{F}_2$, so Q contains at most one of $\{v_i, u_i\}$ for each $i \in [n]$, so f contributes at most once per vertex of V. Since Q is feasible for $\mathcal{A}$, it must also satisfy $w(Q) \geq L$, and therefore $w(Q) = L$. Combined with (7), this implies $\sigma_f(Q) = \sigma_f(V)$.

Now, notice that if $|Q| < n$, then $\sigma_f(Q) < \sigma_f(V)$, since M_2 ensures that each vertex contributes at most once. Thus we must have $|Q| = n$. We have now established that

$$|Q \cap V| = k, \qquad |Q| = n, \qquad \sigma_f(Q) = \sigma_f(V).$$

Since $Q \in \mathcal{F}_2$, it contains at most one element from each pair $\{u_i, v_i\}$, and therefore the labels in $f(Q)$ are distinct. As $|Q| = n$ and $\sigma_f(Q) = \sigma_f(V) = 1 + \cdots + n$, it follows that $f(Q) = f(V)$. Since Q is feasible, it belongs to one of the families defining $\mathcal{F}_1$; the only possible family is $\mathcal{I}_4$. By (5), we conclude that $Q \cap V \in C(G)$. Hence, $Q \cap V$ is a clique of size k in G. ◁

To complete the proof, assume toward a contradiction that there exists an EPTAS for MIC. Using this scheme, we can decide whether G contains a clique of size k in FPT time. Consider the instance $\mathcal{A}$ constructed above, and run the EPTAS with $\varepsilon = \frac{1}{2k}$. Observe that any feasible solution for $\mathcal{A}$ must include at least k vertices from V. The weight constraint encoded by w and L enforces this requirement, as each vertex from V contributes 1 to the value function v.

By Claim 15, G has a clique of size k if and only if $\mathcal{A}$ admits a feasible solution of value exactly k. If such a solution for $\mathcal{A}$ exists, then the EPTAS would yield a solution whose value is at most $(1+\varepsilon)k = k + \frac{1}{2} < k+1$. Since the valuation function v is integral, the only integer value below $k+1$ is k, and therefore the scheme must return a solution of value exactly k. Thus, the EPTAS correctly determines whether $\mathcal{A}$ has a solution of value k and, by Claim 15, whether G contains a clique of size k.

The running time of the EPTAS is $g(\frac{1}{\varepsilon}) \cdot m^{O(1)}$ for some computable function g, where m is the encoding size of the k-clique instance. Since $\varepsilon = \Theta(\frac{1}{k})$, our reduction decides the k-clique problem in time $g(k) \cdot m^{O(1)}$. As the k-clique problem is known to be W[1]-Hard [18], it implies that there is no EPTAS for MIC unless $W[1] = \text{FPT}$. ◀

4 Discussion

In this paper, we present tight approximation results for a broad class of matroid optimization problems with a linear constraint, along with a hardness result for MIC. Our unified EPTAS for all $\mathcal{P}$-MOL problems resolves the complexity status of this class, and the hardness of MIC suggests that such a unified EPTAS is unlikely to extend to *all* $\mathcal{P}$-MOL variants once the single matroid constraint is replaced by a *matroid intersection* constraint.

A natural direction for future work is to characterize the approximability landscape of $\mathcal{P}$-MOL variants under matroid intersection constraints. In particular, the existence of a PTAS for MIC remains open.

Finally, it would be interesting to identify settings in which stronger guarantees are attainable. For instance, for graphic matroids and for linear matroids given by an explicit representation, we obtain an EPTAS, while the existence of an FPTAS in these cases remains open.

Abstract

Given a linear subspace of $n \times n$ matrices over $\mathbb{F}_{2^r}$ that is promised to contain a matrix of rank 1, we prove that it is hard to find a matrix of rank $n^{o(1/\log\log n)}$, assuming NP doesn't have sub-exponential algorithms. In addition to being a basic problem, the hardness of this problem, even for the exact version, drove recent PCP-free inapproximability results for minimum distance and shortest vector problems concerning codes and lattices.

The proof combines the concept of superposition soundness introduced by Khot and Saket with moment matrices. To produce a rank-gap of 1 vs. k, the reduction runs in time $n^{O(\log k)}$. We also give another moment-matrix-based construction which runs in time $n^{O(k)}$ but works for any finite field $\mathbb{F}_q$.

1 Introduction

Given a linear subspace $\mathcal{L} \subseteq \mathbb{F}^{N\times N}$ that is promised to contain a matrix of rank one, we study the problem of finding a nonzero matrix in $\mathcal{L}$ of minimum rank.

This problem is closely related to the problem of finding the *minimum rank distance* of a rank-metric code [5, 9, 17]. In fact, there is a simple and classical embedding of Hamming-metric codes into this setting. Given a linear code $C \subseteq \mathbb{F}^N$, consider the diagonal matrix code

$$\mathrm{Diag}(C) := \{\mathrm{diag}(c) : c \in C\} \subseteq \mathbb{F}^{N\times N}.$$

© Venkatesan Guruswami, Xuandi Ren, and Shaoxuan Tang;
licensed under Creative Commons License CC-BY 4.0

For every $c \in C$,

$$\mathrm{rank}(\mathrm{diag}(c)) = \|c\|_0,$$

and hence the minimum rank distance of $\mathrm{Diag}(C)$ is exactly the minimum Hamming distance of C. Consequently, hardness results for the Minimum Distance Problem (MDP) [7, 4, 1, 15, 3] directly translate to hardness for approximating the minimum rank in a matrix subspace.

However, this diagonal reduction also explains what it does *not* prove. The YES case inherited from MDP only promises a nonzero matrix of rank $d(C)$, the minimum distance of the code, which is generally not 1. In fact, it is trivial to check if the minimum distance of a code is 1. It is therefore natural to ask whether the problem remains hard under the stronger promise that the subspace contains a nonzero matrix of smallest possible rank, namely rank 1.

A second motivation comes from recent PCP-free inapproximability results for sparse vector problems, including the Minimum Distance Problem and the Shortest Vector Problem [3]. These reductions start from systems of quadratic equations and view each quadratic constraint as a linear constraint on a matrix: if $X = xx^\top$, then a quadratic form in x becomes a linear form in the entries of X. Hence honest solutions to the original quadratic system correspond to rank-one matrices. The main soundness issue is to rule out spurious higher-rank matrices.

In [3], this issue is handled via a non-overlap lemma. Specifically, if C is a linear code of distance $d(C)$ over $\mathbb{F}$, then honest rank-one matrices in the tensor code $C \otimes C$ attain the minimum Hamming weight $d(C)^2$. On the other hand, every matrix in $C \otimes C$ of rank at least 2 has Hamming weight at least $\alpha \cdot d(C)^2$, for some $\alpha > 1$ depending on $\mathbb{F}$. Thus the Hamming-weight gap driving the MDP hardness is, at its core, a structural gap between rank-one matrices and matrices of rank at least two. This suggests stripping away the Hamming-weight objective and asking for the rank gap directly.

In this work, we show strong hardness of distinguishing

$$\exists\, 0 \neq A \in \mathcal{L} \text{ with } \mathrm{rank}(A) = 1 \qquad \text{from} \qquad \forall\, 0 \neq A \in \mathcal{L},\ \mathrm{rank}(A) > k$$

over any fixed finite field of characteristic 2. Specifically, we give a deterministic reduction from 3SAT producing a rank gap of 1 versus k, with matrix dimension $n^{O(\log k)}$. The resulting inapproximability consequences are summarized in the following main theorem.

▶ **Theorem 1.1.** *Let*

$$\mathrm{minrank}(\mathcal{L}) := \min\{\mathrm{rank}(A) : 0 \neq A \in \mathcal{L}\}.$$

For every fixed integer $r \geq 1$, no polynomial-time algorithm can, given a linear subspace $\mathcal{L} \subseteq \mathbb{F}_{2^r}^{N \times N}$, distinguish between

- *(YES)* $\mathrm{minrank}(\mathcal{L}) = 1$,
- *(NO)* $\mathrm{minrank}(\mathcal{L}) > \gamma$,

in the following regimes:

(a) *assuming* $\mathsf{NP} \neq \mathsf{P}$, *when $\gamma > 1$ is any constant;*

(b) *assuming* $\mathsf{NP} \not\subseteq \mathsf{DTIME}(2^{\log^{O(1)} n})$, *when* $\gamma = 2^{(\log N)^{1-\epsilon}}$ *for any fixed* $0 < \epsilon < 1$;

(c) *assuming* $\mathsf{NP} \not\subseteq \bigcap_{\delta > 0} \mathsf{DTIME}(2^{n^\delta})$, *when* $\gamma = N^{c/\log\log N}$ *for some fixed constant* $c > 0$.

We present the reduction in Section 3. The proof combines the superposition-soundness framework of Khot and Saket [12] with linearized moment matrices. A satisfying assignment to the starting quadratic system gives a rank-one moment matrix. Conversely, a low-rank

feasible matrix can be decomposed into a bounded number of symmetric rank-one pieces; these pieces behave like several assignments satisfying the quadratic system in superposition. The soundness analysis of Khot–Saket soundness rules out such superpositions, while the moment-matrix equal-union constraints ensure that the remaining zero-sum case cannot hide a nonzero low-rank matrix.

We also include a simpler direct moment-matrix reduction in Section 4. This construction avoids the superposition-soundness and works over every finite field $\mathbb{F}_q$, at the cost of producing matrices of dimension $n^{O(k)}$. The corresponding inapproximability statement is the following.

▶ **Theorem 1.2.** *Let*

$$\operatorname{minrank}(\mathcal{L}) := \min\{\operatorname{rank}(A) : 0 \neq A \in \mathcal{L}\}.$$

For every fixed finite field $\mathbb{F}_q$, no polynomial-time algorithm can, given a linear subspace $\mathcal{L} \subseteq \mathbb{F}_q^{N\times N}$, distinguish between

- *(YES)* $\operatorname{minrank}(\mathcal{L}) = 1$,
- *(NO)* $\operatorname{minrank}(\mathcal{L}) > \gamma$,

in the following regimes:

(a) *assuming* NP $\neq$ P, *when $\gamma > 1$ is any constant;*

(b) *assuming* NP $\not\subseteq$ DTIME$(2^{\log^{O(1)} n})$, *when $\gamma = (\log N)^{1-\epsilon}$ for any fixed $0 < \epsilon < 1$;*

(c) *assuming* NP $\not\subseteq \bigcap_{\delta>0}$ DTIME(2^{n^δ}), *when $\gamma = c \log N / \log\log N$ for some fixed constant $c > 0$.*

Proof overview

The key ingredient in both reductions is the pseudo-moment matrix. Fix a moment level d. We introduce a pseudo-moment coordinate y_R for every Boolean monomial $x^R := \prod_{i\in R} x_i$ of degree at most $2d$. Note that the vector (y_R) is not assumed to come from an actual Boolean assignment, for which reason it is called pseudo-moment vector. The associated degree-d pseudo-moment matrix[1] is defined by

$$H_d(y)_{S,T} = y_{S\cup T}. \qquad (|S|, |T| \leq d)$$

In the matrix formulation, we impose the equal-union constraints

$$A_{S,T} = A_{S',T'} \qquad \text{whenever} \qquad S \cup T = S' \cup T'.$$

This way, the matrix is not an arbitrary linearization of the products $x^S x^T$. All factorizations of the same Boolean monomial $x^{S\cup T}$ are forced to share a single pseudo-moment coordinate.

This hidden redundancy is what makes rank a useful test. If a pseudo-moment y_R is nonzero, it is not isolated in one entry of the matrix: it appears in every entry whose row and column labels union to R. Therefore a feasible low-rank matrix is constrained not only by the original equations, but also by the truncated Boolean monomial algebra encoded by these equal-union identities.

[1] This is the standard moment-matrix object from the Sum-of-Squares literature: for a pseudoexpectation $\widetilde{\mathbb{E}}$ over the Boolean cube, the moment matrix has entries $\widetilde{\mathbb{E}}[x^S x^T] = \widetilde{\mathbb{E}}[x^{S\cup T}]$. The Lasserre/SoS hierarchy additionally imposes normalization and positive-semidefiniteness of moment matrix. See, e.g., [13, 16, 14, 2].

We first record the simple but powerful observation related to the rank of pseudo-moment matrices that is used in both reductions, and then give an overview of the two reductions separately.

▶ **Lemma 1.3** (Informal structural lemma, used in Lemma 3.10 and Lemma 4.3)**.** *Let A be a matrix satisfying the above equal-union constraints, and let y be the pseudo-moment vector it represents. Suppose R is a minimum-size set with $y_R \neq 0$. Then,*

$$\operatorname{rank}(A) \geq \binom{|R|}{\lfloor |R|/2 \rfloor}.$$

The proof idea is to look at the submatrix with rows indexed by the $\lfloor |R|/2 \rfloor$-subsets $F \subseteq R$ and columns indexed by the $\lceil |R|/2 \rceil$-subsets $G \subseteq R$. Its (F, G) entry is $y_{F \cup G}$. By the minimality of R, this entry is zero unless $F \cup G = R$. Hence the submatrix is a permutation matrix, giving the rank lower bound.

The two reductions use this observation in different ways. In the $n^{O(\log k)}$ superposition reduction, the observation turns the zero-sum case from Khot–Saket soundness into the conclusion that the whole low-rank matrix is zero. In the $n^{O(k)}$ direct pseudo-moment reduction, the same observation forces the existence of a nonzero flat level from which one can round to an honest Boolean solution.

The $n^{O(\log k)}$ superposition reduction over $\mathbb{F}_{2^r}$

We first prove the rank gap over $\mathbb{F}_2$ and then extend it to $\mathbb{F}_{2^r}$ in a black-box way. We adapt the Khot–Saket superposition reduction [12] to produce a constant-free quadratic system $\mathcal{Q}$. After introducing a homogenizing variable x_0, and introducing variables y_S for non-constant monomials x^S of degree at most $d = \Theta(\log k)$, we obtain a quadratic system with the following property. In the YES case, an honest satisfying assignment gives a solution to $\mathcal{Q}$. In the NO case, if t assignments satisfy $\mathcal{Q}$ in superposition, meaning that the sum of their evaluations on every equation of $\mathcal{Q}$ is zero, then their coordinate-wise sum is the zero assignment.

After that, for each quadratic equation

$$\sum_{S,T} c_{S,T} y_S y_T + \sum_R b_R y_R = 0$$

in $\mathcal{Q}$, we linearize it as

$$\sum_{S,T} c_{S,T} A_{S,T} + \sum_R b_R A_{R,R} = 0,$$

and we also impose all equal-union constraints.

For completeness, an honest satisfying assignment gives a feasible rank-one moment matrix.

For soundness, suppose in the NO case that a nonzero feasible matrix A has rank at most k. A decomposition lemma[2] shows

$$A = \sum_{i=1}^{t} u^{(i)} u^{(i)\top}, \qquad t \leq \left\lfloor \frac{3k}{2} \right\rfloor.$$

[2] This decomposition is not obvious: we require a sum of *symmetric* rank-1 terms, which is more restrictive than a general rank decomposition.

Substituting this decomposition into the linearized constraints shows that the assignments $u^{(i)}$ satisfy $\mathcal{Q}$ in superposition[3]. By the soundness guarantee, the sum of these assignments is zero. Consequently, every diagonal entry of A vanishes:

$$A_{S,S} = \sum_i (u_S^{(i)})^2 = \sum_i u_S^{(i)} = 0.$$

The equal-union constraints then imply $A_{S,T} = A_{S\cup T, S\cup T} = 0$ whenever $|S \cup T| \le d$.

We still need to rule out nonzero entries whose union has size larger than d. Suppose such an entry exists, and choose $A_{S,T} \neq 0$ with $|S \cup T|$ minimum. Put $R = S \cup T$. By the structural lemma,

$$\operatorname{rank}(A) \ge \binom{|R|}{\lfloor |R|/2 \rfloor} \ge \binom{d+1}{\lfloor (d+1)/2 \rfloor} > k,$$

contradicting the rank assumption.

Finally, to work over $\mathbb{F}_{2^r}$, we interpret the same $\mathbb{F}_2$-linear equations over the extension field; a nonzero rank-at-most-k matrix over $\mathbb{F}_{2^r}$ would descend, via an $\mathbb{F}_2$-linear functional, to a nonzero matrix over $\mathbb{F}_2$ of rank at most rk. So we just run the base-field reduction with gap rank parameter rk.

The $n^{O(k)}$ direct reduction. This construction starts from QuadEq over an arbitrary finite field $\mathbb{F}_q$. We set $d = k$ and build the pseudo-moment matrix whose rows and columns are indexed by all monomials of degree at most d, including the empty monomial. We impose the same equal-union constraints, and for each equation of the QuadEq instance

$$f_\ell(x) = \sum_{U \subseteq [n],\ |U| \le 2} c_{\ell,U} x^U$$

we impose the following pseudo-moment versions of the identities $x^W f_\ell(x) = 0$:

$$\sum_{\substack{U \subseteq [n] \\ |U| \le 2}} c_{\ell,U} y_{U \cup W} = 0 \qquad \forall W,\ |W| \le 2d - 2\ .$$

These are the pseudo-moment versions of the identities $x^W f_\ell(x) = 0$. The completeness is immediate: a Boolean solution gives a rank-one moment matrix solution, and it is nonzero because the empty-coordinate entry is 1.

For soundness, suppose the source instance is unsatisfiable but there is a nonzero feasible pseudo-moment matrix $H_d(y)$ of rank at most d. Let $r_e = \operatorname{rank} H_e(y)$; this sequence is nondecreasing in e. The structural lemma shows that the first nonzero level already has a reasonably large rank that the sequence r_e cannot keep increasing strictly up to level d. Hence there must be a nonzero flat level

$$r_e = r_{e+1} > 0$$

for some $e < d$.

[3] The constant-free assumption is needed here. If a quadratic equation has a nonzero constant term, substituting a decomposition $A = \sum_{i=1}^t u^{(i)} u^{(i)\top}$ counts that constant with a parity depending on the number of summands, so a linearized feasible matrix yields the desired superposition condition only when t is odd. Huang [11], building on the Khot–Saket superposition framework, uses precisely this oddness phenomenon: he proves that superposition satisfaction by an odd number of assignments is equivalent to odd-covering.

At such a flat level, multiplying a column label by x_i creates no new column direction. Thus multiplication by x_i defines a linear operator T_i on the column space C_e of $H_e(y)$. These operators satisfy the Boolean rules

$$T_i^2 = T_i, \qquad T_iT_j = T_jT_i,$$

and the localizing constraints translate into the operator identities $f_\ell(T) = 0$ on C_e for every source equation f_ℓ. Since the T_i are commuting projections over $\mathbb{F}_q$, they have a common eigenvector with eigenvalues $a_i \in \{0,1\}$. The tuple $a = (a_1, \ldots, a_n)$ is therefore a Boolean point, and the identities $f_\ell(T) = 0$ imply $f_\ell(a) = 0$ for all ℓ, contradicting unsatisfiability.

2 Preliminaries

We now formally define the concepts related to monomial-indexing and pseudo-moments used in Section 3 and Section 4, which we already sketched in the introduction.

Let $[n] := \{1, 2, \ldots, n\}$ for any positive integer n. For a subset S, we write $x^S := \prod_{i \in S} x_i$, and we set $x^\emptyset := 1$. All products of monomials and polynomials are taken in the Boolean squarefree monomial algebra. Equivalently, over the relevant field we identify polynomials modulo the relations $x_i^2 = x_i$, so that $x^S x^T = x^{S \cup T}$.

Write

$$\mathcal{U}_{n,d} := \{S \subseteq \{0, 1, \ldots, n\} : 1 \le |S| \le d\};$$
$$\mathcal{V}_{n,d} := \{S \subseteq \{1, \ldots, n\} : 0 \le |S| \le d\}.$$

Here $\mathcal{U}_{n,d}$ is used for the homogenized $n^{O(\log k)}$ construction: it allows the coordinate 0 but excludes the empty monomial. The set $\mathcal{V}_{n,d}$ is used for the direct $n^{O(k)}$ construction: it uses only the original variables and includes the empty monomial.

When $\mathcal{W}_d$ is either $\mathcal{U}_{n,d}$ or $\mathcal{V}_{n,d}$, define a *monomial assignment of degree d* to be a map

$$\sigma : \{x^S : S \in \mathcal{W}_d\} \to \mathbb{F}.$$

Equivalently, any monomial assignment of degree d can be written as a *degree-d pseudo-moment assignment*, or *pseudo-moment vector*,

$$y = (y_R)_{R \in \mathcal{W}_d}.$$

When a degree-$2d$ pseudo-moment vector is given, its associated *pseudo-moment matrix* is defined as

$$H_d(y) := \left(y_{S \cup T}\right)_{S,T \in \mathcal{W}_d}.$$

If a is an actual Boolean point in $\{0,1\}^{n+1}$ (or $\{0,1\}^n$, respectively), the "honest" moment assignment generated by a is $y_R = a^R$. The corresponding moment vector is

$$v_d(a) := (a^S)_{S \in \mathcal{W}_d},$$

and in this case

$$H_d(y) = v_d(a) v_d(a)^\top.$$

In particular, $H_d(y)$ has rank one whenever $v_d(a) \neq 0$.

On the other hand, any matrix $A \in \mathbb{F}^{\mathcal{W}_d \times \mathcal{W}_d}$ satisfying

$$A_{S,T} = A_{S',T'} \qquad \text{whenever } S \cup T = S' \cup T',$$

is a pseudo-moment matrix $H_d(y)$ for some unique pseudo-moment vector $y \in \mathbb{F}^{\mathcal{W}_{2d}}$. We therefore sometimes state the linear constraints on the pseudo-moment matrix in terms of the associated pseudo-moment vector y.

3 An $n^{O(\log k)}$ Construction over $\mathbb{F}_{2^r}$

In this section, we prove the following theorem.

▶ **Theorem 3.1.** *For every fixed integer $r \geq 1$ and every integer $k \geq 1$, there is a deterministic $n^{O(\log k)}$-time reduction which maps a* 3SAT *instance on n variables to a linear subspace*

$$\mathcal{L} \subseteq \mathbb{F}_{2^r}^{N \times N}, \qquad N = n^{O(\log k)},$$

such that:

- *(YES) if the input formula is satisfiable, then $\mathcal{L}$ contains a nonzero matrix of rank 1;*
- *(NO) if the input formula is unsatisfiable, then $\mathcal{L}$ contains no nonzero matrix of rank at most k.*

To prove Theorem 3.1, we first prove the result over $\mathbb{F}_2$, then transfer it to any $\mathbb{F}_{2^r}$ by a rank-descent argument. Our reduction has four steps:

1. First, we reduce 3SAT to a degree-d polynomial equation system $\mathcal{B}$ over $\mathbb{F}_2$ on the variables $x_0, x_1, \ldots, x_n$. The homogenizing variable x_0 replaces the constant 1 and makes every equation in $\mathcal{B}$ have zero constant term.
2. Next, we replace each nonconstant monomial x^S, $S \in \mathcal{U}_{n,d}$, by a new variable y_S, and we add the moment constraints $y_S y_T = y_{S \cup T}$. This produces a quadratic equation system $\mathcal{Q}$ with zero constant term. Furthermore, we obtain Khot–Saket superposition soundness: in the NO case, if t assignments $\tau^{(1)}, \ldots, \tau^{(t)}$ satisfy every equation of $\mathcal{Q}$ in superposition (see Definition 3.5), then the sum of the t assignments

$$\tau := \sum_{i=1}^{t} \tau^{(i)}$$

must vanish on every y-coordinate.
3. We then linearize the quadratic system $\mathcal{Q}$ by introducing matrix variables $A_{S,T}$ for the products $y_S y_T$. By adding equal-union constraints to enforce the Boolean monomial identity $x^S x^T = x^{S \cup T}$, and by the rank observation in Lemma 1.3, we get the rank gap over $\mathbb{F}_2$.
4. Finally, we extend the hardness from $\mathbb{F}_2$ to $\mathbb{F}_{2^r}$ by interpreting the same homogeneous linear constraints over the extension field. The rank-descent lemma Lemma 3.12 converts any nonzero matrix of rank at most k over $\mathbb{F}_{2^r}$ into a nonzero matrix over $\mathbb{F}_2$ of rank at most rk. Running the $\mathbb{F}_2$ construction with rank parameter rk gives the claimed gap over $\mathbb{F}_{2^r}$.

The four steps are carried out in Sections 3.1–3.4, respectively. For orientation, the first three variable-changing steps are summarized in Figure 1; the corresponding variables and their roles are listed in Table 1.

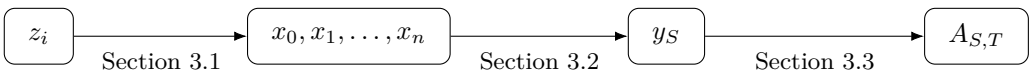

Figure 1 Roadmap of the reduction steps in this section.

Table 1 Variables defined in this section and their roles.

Variables	Meaning	Used in
z_i	original 3SAT variables	starting NP-hardness source
$x_0, x_1, \ldots, x_n$	homogenized Boolean variables	degree-d polynomial system $\mathcal{B}$ with no constant term; x_0 replaces 1
y_S	variable for monomial x^S	quadratic system $\mathcal{Q}$ with Khot–Saket superposition soundness
$A_{S,T}$	matrix variable linearizing $y_S y_T$	linear matrix subspace $\mathcal{L}_d(\mathcal{Q})$ for the rank-gap reduction

3.1 Reducing from 3Sat to constant-free polynomial equations

In this subsection, before presenting our main reduction in Theorem 3.4, we first introduce the following duality fact used in [12]: any assignment to all nonconstant monomials of degree at most d can be represented as the sum of evaluations at actual points of $\mathbb{F}_2^{n+1}$.

▶ **Lemma 3.2** (Monomial assignments as sums of points, [12]). *Let $\mathbb{F}_2[x]_{\le d}$ denote the $\mathbb{F}_2$-vector space of multilinear polynomials in variables $x_0, \ldots, x_n$ of degree at most d. For every monomial assignment*

$$\sigma : \{x^S : S \in \mathcal{U}_{n,d}\} \to \mathbb{F}_2,$$

define $\sigma(1) = 1$ and extend σ by linearity to all polynomials in $\mathbb{F}_2[x]_{\le d}$. Then, there is a subset $\beta \subseteq \mathbb{F}_2^{n+1}$ such that

$$\sigma(q) = \sum_{a \in \beta} q(a)$$

holds for every $q \in \mathbb{F}_2[x]_{\le d}$.

Since $\sigma(1) = 1$, any set β representing σ must have odd cardinality. Among all sets representing σ in this sense, fix one with minimum cardinality and denote it by β_σ. Due to the page limit, we defer the proofs of Lemma 3.2 and the following point-isolator lemma, Lemma 3.3, to the full version of this paper.

▶ **Lemma 3.3** (Point isolator). *Let $\rho \ge 0$ be an integer, $T \subseteq \mathbb{F}_2^{n+1}$ with $|T| < 2^\rho$, and let $a \in T$. Then there exists a multilinear polynomial q of degree at most ρ such that*

$$q(a) = 1 \qquad \text{and} \qquad q(b) = 0 \quad \text{for all } b \in T \setminus \{a\}.$$

We now give the reduction from 3SAT to a system of degree-d constant-free polynomial equations. This is a constant-free analogue of the Khot–Saket construction. We homogenize the usual Boolean constraints by introducing a variable x_0, which plays the role of the constant 1 in honest assignments, and by adding the equations $x_i(x_i + x_0) = 0$. If $x_0 = 1$, the clause polynomials encode the original 3SAT instance. If $x_0 = 0$, these equations force every variable to vanish as well.

▶ **Theorem 3.4** (Constant-free low-weight soundness). *For every integer $d \ge 4$, there is a deterministic $n^{O(d)}$-time reduction from a 3SAT instance on n variables to a system $\mathcal{B}$ of constant-free degree-d polynomial equations in $n+1$ variables over $\mathbb{F}_2$ such that:*

- *(YES) if the input formula is satisfiable, then $\mathcal{B}$ has a satisfying assignment $a \in \mathbb{F}_2^{n+1}$ with $a_0 = 1$;*
- *(NO) if the input formula is unsatisfiable and σ is a monomial assignment of degree d satisfying all equations in $\mathcal{B}$, then either $\beta_\sigma = \{\mathbf{0}\}$ or $|\beta_\sigma| \geq 2^{d-3}$.*

Proof. Let the input formula be φ with variables $z_1, \ldots, z_n$ and clauses $C_1, \ldots, C_m$. We introduce variables $x_0, x_1, \ldots, x_n$. For a literal ℓ, define its false-literal form by

$$h_\ell(x) = \begin{cases} x_0 + x_i & \text{if } \ell = z_i, \\ x_i & \text{if } \ell = \neg z_i. \end{cases}$$

When $x_0 = 1$, this is 1 if and only if the literal ℓ is false. For a clause $C_j = \ell_{j,1} \vee \ell_{j,2} \vee \ell_{j,3}$, define the clause polynomial

$$p_j(x) := h_{\ell_{j,1}}(x) h_{\ell_{j,2}}(x) h_{\ell_{j,3}}(x).$$

For every original variable, define the Booleanity polynomial

$$b_i(x) := x_i(x_i + x_0).$$

Every p_j and b_i has no constant term, and their degrees are at most 3 and 2, respectively.

The system $\mathcal{B}$ consists of the following equations:

(1) $x^S p_j(x) = 0$ for every $j \in [m]$ and every monomial x^S, including $S = \emptyset$, of degree at most $d - 3$;

(2) $x^S b_i(x) = 0$ for every $i \in [n]$ and every monomial x^S, including $S = \emptyset$, of degree at most $d - 2$.

All equations have degree at most d and no constant term.

In the YES case, take a satisfying Boolean assignment $(a_1, \ldots, a_n)$ to φ and set $a_0 = 1$. Then each $b_i(a)$ vanishes. In every clause at least one literal is true, so at least one of the three corresponding false-literal forms is zero, and hence every $p_j(a)$ vanishes. All monomial multiples in $\mathcal{B}$ therefore vanish at a as well.

Now assume φ is unsatisfiable, and let σ be a monomial assignment satisfying all equations in $\mathcal{B}$. Suppose, for contradiction, that $\beta_\sigma \neq \{\mathbf{0}\}$ and $|\beta_\sigma| < 2^{d-3}$. By the parity observation above, β_σ is nonempty; since it is not $\{\mathbf{0}\}$, it contains a nonzero point. Choose such a point $a \in \beta_\sigma$. We use the following point-isolating lemma to distinguish a from the remaining points in β_σ.

By Lemma 3.3, there exists a polynomial q of degree at most $d - 3$ such that

$$q(a) = 1 \qquad \text{and} \qquad q(b) = 0 \quad \text{for all } b \in \beta_\sigma \setminus \{a\}.$$

First we show that $a_0 = 1$. For every $i \in [n]$, the polynomial $q(x)b_i(x)$ is an $\mathbb{F}_2$-linear combination of equations in $\mathcal{B}$, so

$$0 = \sigma\big(q(x)b_i(x)\big) = \sum_{b \in \beta_\sigma} q(b)b_i(b) = a_i(a_i + a_0). \tag{1}$$

If $a_0 = 0$, then (1) forces $a_i = 0$ for every $i \in [n]$, contradicting the choice of the nonzero point a. Hence $a_0 = 1$.

With $a_0 = 1$, (1) says that the point a obeys the intended Booleanity constraints on the original coordinates, and the values $h_\ell(a)$ are the usual false-literal indicators of the Boolean assignment $(a_1, \ldots, a_n)$. Since φ is unsatisfiable, this assignment falsifies some clause, say C_j, and therefore $p_j(a) = 1$. Again $q(x)p_j(x)$ is an $\mathbb{F}_2$-linear combination of equations in $\mathcal{B}$, and hence

$$0 = \sigma\big(q(x)p_j(x)\big) = \sum_{b\in\beta_\sigma} q(b)p_j(b) = q(a)p_j(a) = 1,$$

a contradiction. Thus either $\beta_\sigma = \{\mathbf{0}\}$ or $|\beta_\sigma| \geq 2^{d-3}$. ◀

3.2 Obtaining Khot–Saket superposition soundness

We now define superposition satisfaction, a notion ruled out by the soundness analysis of Khot–Saket. We are particularly interested in this notion because assignments in superposition satisfaction naturally correspond to the factors in the symmetric rank-one decomposition given by Lemma 3.8.

▶ **Definition 3.5** (Superposition satisfaction and aggregate assignment)**.** *Let*

$$g(y) = \sum_{U,V} c_{U,V}\, y_U y_V + \sum_W d_W y_W$$

be a polynomial of degree at most 2 *and without constant term over* $\mathbb{F}_2$*. We say that assignments* $\tau^{(1)}, \ldots, \tau^{(t)}$ satisfy $g(y) = 0$ in superposition *if*

$$\sum_{i=1}^{t} g\big(\tau^{(i)}\big) = 0.$$

Their aggregate assignment *is the coordinate-wise sum*

$$\tau := \sum_{i=1}^{t} \tau^{(i)}.$$

For $\beta \subseteq \mathbb{F}_2^{n+1}$ and a polynomial f, write

$$\chi_\beta(f) := (-1)^{\sum_{a\in\beta} f(a)}.$$

The following correlation estimate is from [12, Lemma 3.3], which further builds on [6, Theorem 20].

▶ **Lemma 3.6** (Khot–Saket correlation bound; [12, Lemma 3.3])**.** *Let* $d \geq 8$ *be a positive multiple of* 4*. Let* σ *be a degree-*d *monomial assignment, and let* β_σ *be a minimum-cardinality set representing* σ *as in Lemma 3.2. Suppose* $|\beta_\sigma| \geq 2^{d-3}$*, and let* $\gamma, \alpha \subseteq \mathbb{F}_2^{n+1}$ *be arbitrary. Let* g *be a uniformly random multilinear polynomial of degree at most* $3d/4$*, and let* h *be a uniformly random multilinear polynomial of degree at most* $d/4$ *with zero constant term. Then*

$$\left|\mathop{\mathbb{E}}_{g,h}\big[\chi_{\beta_\sigma}(gh)\chi_\gamma(g)\chi_\alpha(h)\big]\right| \leq 2^{-2^{d/4-2}+1}.$$

▶ **Theorem 3.7** (Constant-free exact-superposition soundness, adapted from [12])**.** *There is a constant* $c > 0$ *such that the following holds. Let* $t \geq 1$*, and let* d *be a positive multiple of* 4 *with* $d \geq \max\{8, c\log(t+1)\}$*. From a* 3Sat *instance on* n *variables, one can construct in time* $n^{O(d)}$*, a system* $\mathcal{Q}$ *of quadratic equations with zero constant term, in variables*

$$\{y_S : S \in \mathcal{U}_{n,d}\}$$

with the following properties:

- *(YES) if the* 3Sat *instance is satisfiable, then $\mathcal{Q}$ has a satisfying assignment y with $y_{\{0\}} = 1$;*
- *(NO) if the* 3Sat *instance is unsatisfiable and $\tau^{(1)}, \dots, \tau^{(t)}$ satisfy all equations of $\mathcal{Q}$ in superposition, then their aggregate assignment $\tau := \sum_{i=1}^{t} \tau^{(i)}$ vanishes on every coordinate y_S, $S \in \mathcal{U}_{n,d}$.*

Moreover, $\mathcal{Q}$ is obtained by replacing each nonconstant monomial x^S in the system $\mathcal{B}$ from Theorem 3.4 with the variable y_S, and by adjoining the constraints

$$y_S y_T = y_{S \cup T} \qquad \text{for all } S, T \in \mathcal{U}_{n,d} \text{ with } |S \cup T| \le d.$$

Proof. Apply Theorem 3.4 to obtain the constant-free system $\mathcal{B}$ in the variables $x_0, x_1, \dots, x_n$. For every $S \in \mathcal{U}_{n,d}$ introduce a variable y_S, intended to represent the monomial x^S. Since every equation of $\mathcal{B}$ has zero constant term, no variable corresponding to $x^{\emptyset}$ is needed. The system $\mathcal{Q}$ contains:

- **(i)** for every equation $\sum_S c_S x^S = 0$ in $\mathcal{B}$, the linear equation $\sum_S c_S y_S = 0$ obtained by replacing each monomial x^S with y_S;
- **(ii)** every multiplicativity constraint $y_S y_T = y_{S \cup T}$ with $S, T \in \mathcal{U}_{n,d}$ and $|S \cup T| \le d$.

The YES case follows directly from Theorem 3.4. If a is the satisfying assignment there, with $a_0 = 1$, then setting $y_S := a^S$ satisfies all linearized equations from $\mathcal{B}$ and all multiplicativity constraints. In particular $y_{\{0\}} = 1$.

For the NO case, let $\tau^{(1)}, \dots, \tau^{(t)}$ be assignments to the variables y_S satisfying all equations of $\mathcal{Q}$ in superposition. Write

$$\tau_S^{(i)} := \tau^{(i)}(y_S), \qquad \tau_S := \sum_{i=1}^{t} \tau_S^{(i)} \qquad (S \in \mathcal{U}_{n,d}).$$

Thus $\tau = (\tau_S)_{S \in \mathcal{U}_{n,d}}$ is the aggregate y-assignment. Define the associated degree-d monomial assignments σ and $\sigma^{(i)}$ by

$$\sigma(x^S) := \tau_S, \qquad \sigma^{(i)}(x^S) := \tau_S^{(i)} \qquad (S \in \mathcal{U}_{n,d}),$$

extending them to polynomials by the constant-preserving convention from Lemma 3.2. Thus τ lives on the y-coordinates, while σ is the corresponding assignment to the x-monomials.

The main idea here is that, since the equations inherited from $\mathcal{B}$ are linear and homogeneous, superposition satisfaction forces the aggregate assignment $\tau = \sum_i \tau^{(i)}$ to satisfy these equations. Viewing the y-coordinates of τ as a monomial assignment σ, Theorem 3.4 then gives a dichotomy: either $\beta_\sigma = \{\mathbf{0}\}$, or β_σ is large. The latter possibility is ruled out by converting the superposition satisfaction of product equations $y_S y_T = y_{S \cup T}$ into a low-degree correlation identity, and applying the Khot–Saket correlation bound (Lemma 3.6).

The equations inherited from $\mathcal{B}$ become linear after the monomial-to-variable replacement in (i), and they have no constant term. Therefore superposition satisfaction implies that τ satisfies every such linearized equation. Equivalently, σ satisfies every equation of $\mathcal{B}$. By Theorem 3.4, either $\beta_\sigma = \{\mathbf{0}\}$ or $|\beta_\sigma| \ge 2^{d-3}$. If $\beta_\sigma = \{\mathbf{0}\}$, then for every $S \in \mathcal{U}_{n,d}$,

$$\tau_S = \sigma(x^S) = x^S(\mathbf{0}) = 0,$$

which is exactly the claimed vanishing of every coordinate y_S.

It remains to rule out the case $|\beta_\sigma| \ge 2^{d-3}$. For each i, let $\beta_i := \beta_{\sigma^{(i)}}$. The multiplicativity constraint $y_S y_T = y_{S \cup T}$, satisfied in superposition, gives

$$\sigma(x^{S \cup T}) = \tau_{S \cup T} = \sum_{i=1}^{t} \tau_S^{(i)} \tau_T^{(i)} = \sum_{i=1}^{t} \sigma^{(i)}(x^S) \sigma^{(i)}(x^T) \tag{2}$$

whenever $S, T \in \mathcal{U}_{n,d}$ and $|S \cup T| \leq d$. Using the same constant-preserving extension, (2) implies, by checking monomial pairs and extending $\mathbb{F}_2$-bilinearly, that

$$\sigma(gh) = \sum_{i=1}^{t} \sigma^{(i)}(g)\sigma^{(i)}(h) \tag{3}$$

for every polynomial g of degree at most $3d/4$ and every polynomial h of degree at most $d/4$ with zero constant term. Indeed, since h has zero constant term, it suffices to check $h = x^T$ and $g = 1$ or $g = x^S$. The case $g = x^S$ is exactly (2); the case $g = 1$ is the coordinate identity $\tau_T = \sum_i \tau_T^{(i)}$. The degree bounds ensure $|S \cup T| \leq d$ in the first case.

To analyze (3) using Fourier analysis, we need to switch from $\mathbb{F}_2$ to the real values in $\{-1, 1\}$. For bits $u, v \in \mathbb{F}_2$, if $a = (-1)^u$ and $b = (-1)^v$, then

$$(-1)^{uv} = a \wedge b := \frac{1 + a + b - ab}{2}.$$

Taking signs in (3) and using Lemma 3.2, we obtain, for every such pair g, h,

$$\chi_{\beta_\sigma}(gh) \prod_{i=1}^{t} (\chi_{\beta_i}(g) \wedge \chi_{\beta_i}(h)) = 1. \tag{4}$$

Now choose g and h uniformly at random from the two polynomial spaces above. The expectation of the left-hand side of (4) is 1. On the other hand, expanding each factor

$$a \wedge b = \frac{1 + a + b - ab}{2}$$

expresses the same expectation as a sum of at most 4^t terms, each with coefficient of absolute value at most 2^{-t} and each of the form

$$\mathop{\mathbb{E}}_{g,h}\left[\chi_{\beta_\sigma}(gh)\chi_\gamma(g)\chi_\alpha(h)\right]$$

for some subsets $\gamma, \alpha \subseteq \mathbb{F}_2^{n+1}$. By Lemma 3.6 above, the absolute value of the whole expectation is at most

$$2^t \cdot 2^{-2^{d/4-2}+1}.$$

Choosing the absolute constant c sufficiently large makes this quantity strictly smaller than 1 for every $t \geq 1$, contradicting (4). Hence the case $|\beta_\sigma| \geq 2^{d-3}$ cannot occur, and the aggregate assignment must vanish on every coordinate y_S. ◀

3.3 Linearizing the superposition instance

Fix a degree parameter d, and let $\mathcal{Q}$ be the quadratic system from Theorem 3.7. Its variables are $\{y_S : S \in \mathcal{U}_{n,d}\}$. We define a linear subspace of matrices with rows and columns indexed by $\mathcal{U}_{n,d}$ by imposing two kinds of linear constraints.

(1) *Equal-union constraints:*

$$A_{S,T} = A_{S',T'} \qquad \text{whenever } S \cup T = S' \cup T'. \tag{5}$$

(2) *Equation constraints:* for every equation of $\mathcal{Q}$ in the form

$$\sum_{S,T \in \mathcal{U}_{n,d}} c_{S,T} y_S y_T + \sum_{R \in \mathcal{U}_{n,d}} b_R y_R = 0, \tag{6}$$

where $c_{S,T}, b_R \in \mathbb{F}_2$, impose

$$\sum_{S,T \in \mathcal{U}_{n,d}} c_{S,T} A_{S,T} + \sum_{R \in \mathcal{U}_{n,d}} b_R A_{R,R} = 0. \tag{7}$$

Let $\mathcal{L}_d(\mathcal{Q})$ be the set of matrices satisfying (5) and (7). This is a linear subspace of $\mathbb{F}_2^{N\times N}$, where

$$N = |\mathcal{U}_{n,d}| = \sum_{j=1}^{d} \binom{n+1}{j}.$$

Furthermore, $\mathcal{L}_d(\mathcal{Q})$ only contains symmetric matrices due to the constraints $A_{S,T} = A_{T,S}$ in (5).

▶ **Lemma 3.8** (Decomposition into symmetric rank-one matrices, [12]). *Let $A \in \mathbb{F}_2^{N\times N}$ be symmetric of rank k. Then there is an integer t with $0 \le t \le \lfloor 3k/2 \rfloor$ and vectors $u^{(1)}, \dots, u^{(t)} \in \mathbb{F}_2^N$ such that*

$$A = \sum_{i=1}^{t} u^{(i)} u^{(i)\top}.$$

A proof of Lemma 3.8 can be found in the full version of this paper.

▶ **Lemma 3.9** (Low rank gives superposition assignments). *Let $k \ge 1$. Let $A \in \mathcal{L}_d(\mathcal{Q})$ have rank at most k, and let $t \ge \lfloor 3k/2 \rfloor$. Then there exist $u^{(1)}, \dots, u^{(t)} \in \mathbb{F}_2^N$ such that*

$$A = \sum_{i=1}^{t} u^{(i)} u^{(i)\top},$$

and the assignments $y_S \mapsto u_S^{(i)}$ satisfy every equation of $\mathcal{Q}$ in superposition.

Proof. Since $A \in \mathcal{L}_d(\mathcal{Q})$ satisfies the equal-union constraints, it is symmetric. By Lemma 3.8, A is a sum of at most $\lfloor 3k/2 \rfloor \le t$ symmetric rank-one matrices. Padding with zero vectors if necessary, write

$$A = \sum_{i=1}^{t} u^{(i)} u^{(i)\top}.$$

Fix an equation of $\mathcal{Q}$ written as in (6). Since A satisfies the corresponding equation constraint (7), we have

$$0 = \sum_{S,T\in\mathcal{U}_{n,d}} c_{S,T} A_{S,T} + \sum_{R\in\mathcal{U}_{n,d}} b_R A_{R,R}.$$

Substituting the rank-one decomposition and using $(u_R^{(i)})^2 = u_R^{(i)}$ over $\mathbb{F}_2$ gives

$$\begin{aligned} 0 &= \sum_{i=1}^{t} \left(\sum_{S,T\in\mathcal{U}_{n,d}} c_{S,T} u_S^{(i)} u_T^{(i)} + \sum_{R\in\mathcal{U}_{n,d}} b_R (u_R^{(i)})^2 \right) \\ &= \sum_{i=1}^{t} \left(\sum_{S,T\in\mathcal{U}_{n,d}} c_{S,T} u_S^{(i)} u_T^{(i)} + \sum_{R\in\mathcal{U}_{n,d}} b_R u_R^{(i)} \right). \end{aligned}$$

The last expression is the superposition sum of this equation evaluated on the assignments $y_S \mapsto u_S^{(i)}$. Hence the assignments satisfy every equation of $\mathcal{Q}$ in superposition. ◀

▶ **Lemma 3.10** (Zero aggregate assignment forces vanishing). *Let $A \in \mathcal{L}_d(\mathcal{Q})$, $A \neq 0$, admit a decomposition*

$$A = \sum_{i=1}^{t} u^{(i)} u^{(i)\top}$$

such that its aggregate assignment is zero:

$$\sum_{i=1}^{t} u_U^{(i)} = 0 \qquad \text{for every } U \in \mathcal{U}_{n,d}.$$

Then

$$\operatorname{rank}(A) \geq \binom{d+1}{\lfloor (d+1)/2 \rfloor}.$$

Proof. The zero-aggregation condition gives

$$A_{U,U} = \sum_{i=1}^{t} (u_U^{(i)})^2 = \sum_{i=1}^{t} u_U^{(i)} = 0, \qquad \forall U \in \mathcal{U}_{n,d}.$$

If $U, V \in \mathcal{U}_{n,d}$ and $|U \cup V| \leq d$, then $U \cup V \in \mathcal{U}_{n,d}$, and the equal-union constraints give

$$A_{U,V} = A_{U \cup V, U \cup V} = 0. \tag{8}$$

Suppose $A \neq 0$, and choose U, V with $A_{U,V} = 1$ minimizing $s := |U \cup V|$. By (8), we have $d < s \leq 2d$. Put $R := U \cup V$. For every pair $U', V' \in \mathcal{U}_{n,d}$ with $U' \cup V' = R$, the equal-union constraints give $A_{U',V'} = A_{U,V} = 1$.

Let

$$\mathcal{F} := \{F \subseteq R : |F| = \lfloor s/2 \rfloor\}, \qquad \mathcal{G} := \{G \subseteq R : |G| = \lceil s/2 \rceil\}.$$

Because $d < s \leq 2d$, every set in $\mathcal{F} \cup \mathcal{G}$ lies in $\mathcal{U}_{n,d}$. In the submatrix $A|_{\mathcal{F},\mathcal{G}}$, the entry indexed by (F, G) is 1 exactly when $G = R \setminus F$: in that case $F \cup G = R$, while all other pairs have union a proper subset of R and hence have entry 0 by the minimality of s. Thus $A|_{\mathcal{F},\mathcal{G}}$ is a permutation matrix, so

$$\operatorname{rank}(A) \geq \binom{s}{\lfloor s/2 \rfloor} \geq \binom{d+1}{\lfloor (d+1)/2 \rfloor}. \qquad \blacktriangleleft$$

▶ **Theorem 3.11** (Rank gap over $\mathbb{F}_2$). *For every integer $k \geq 1$, there is a deterministic $n^{O(\log k)}$-time reduction from a* 3SAT *instance on n variables to a linear subspace*

$$\mathcal{L} \subseteq \mathbb{F}_2^{N \times N}, \qquad N = n^{O(\log k)},$$

such that satisfiable instances yield a nonzero rank-1 matrix in $\mathcal{L}$, and unsatisfiable instances yield no nonzero matrix in $\mathcal{L}$ of rank at most k.

Proof. Set

$$t := \left\lfloor \frac{3k}{2} \right\rfloor,$$

and choose d to be a positive multiple of 4 such that

$$d \geq \max\{8, c \log(t+1)\} \qquad \text{and} \qquad \binom{d+1}{\lfloor (d+1)/2 \rfloor} > k,$$

where c is the constant from Theorem 3.7. Then $d = O(\log k)$.

Apply Theorem 3.7 with this d and output $\mathcal{L} := \mathcal{L}_d(\mathcal{Q})$. The construction time is $n^{O(d)} = n^{O(\log k)}$, and

$$N = |\mathcal{U}_{n,d}| = \sum_{j=1}^{d} \binom{n+1}{j} = n^{O(d)} = n^{O(\log k)}.$$

In the YES case, take a satisfying Boolean assignment to the original formula, set $a_0 = 1$, and define $y_S := a^S$ for every $S \in \mathcal{U}_{n,2d}$. Then $H_d(y) = v_d(a)v_d(a)^\top$ is nonzero of rank 1. Since every equation of $\mathcal{Q}$ vanishes at $(a^S)_{S\in\mathcal{U}_{n,d}}$, the matrix $H_d(y)$ satisfies both the equal-union constraints and the equation constraints. Hence $H_d(y) \in \mathcal{L}$.

In the NO case, suppose $A \in \mathcal{L}$ is nonzero and $\mathrm{rank}(A) \le k$. By Lemma 3.9, there are exactly t assignments whose rank-one sum is A and which satisfy all equations of $\mathcal{Q}$ in superposition. By Theorem 3.7, their aggregate assignment is zero. Then Lemma 3.10 and the choice of d imply that $\mathrm{rank}(A) > k$. ◀

3.4 Extending the hardness from $\mathbb{F}_2$ to $\mathbb{F}_{2^r}$

The following descent lemma is the black-box field-extension step. It loses a factor of r in the rank parameter, which is why the base-field gap below is run with parameter rk. Due to the page limit, we defer its proof to the full version of this paper.

▶ **Lemma 3.12** (Rank descent). *Let $\mathbb{K} = \mathbb{F}_{2^r}$, and let $\mathcal{L} \subseteq \mathbb{F}_2^{N\times N}$ be a linear subspace. If $A \in \mathcal{L} \otimes_{\mathbb{F}_2} \mathbb{K}$ is nonzero and $\mathrm{rank}_{\mathbb{K}}(A) \le k$, then there exists a nonzero $B \in \mathcal{L}$ with*

$$\mathrm{rank}_{\mathbb{F}_2}(B) \le rk.$$

Proof of Theorem 3.1. Let $\mathbb{K} = \mathbb{F}_{2^r}$ and set $k_0 := rk$. Apply Theorem 3.11 with rank parameter k_0 to obtain $\mathcal{M} \subseteq \mathbb{F}_2^{N\times N}$, and output

$$\mathcal{L} := \mathcal{M} \otimes_{\mathbb{F}_2} \mathbb{K} \subseteq \mathbb{K}^{N\times N},$$

equivalently the same homogeneous linear equations interpreted over $\mathbb{K}$.

Completeness is preserved under field extension: a nonzero rank-1 matrix in $\mathcal{M}$ remains a nonzero rank-1 matrix in $\mathcal{L}$. For soundness, suppose that the input formula is unsatisfiable and that $A \in \mathcal{L}$ is nonzero with $\mathrm{rank}_{\mathbb{K}}(A) \le k$. By Lemma 3.12, there is a nonzero $B \in \mathcal{M}$ with $\mathrm{rank}_{\mathbb{F}_2}(B) \le rk = k_0$, contradicting the soundness of $\mathcal{M}$.

The running time and dimension are

$$n^{O(\log k_0)} = n^{O(\log(rk))}, \qquad N = n^{O(\log k_0)} = n^{O(\log(rk))}.$$

For fixed extension degree r, this is $n^{O(\log k)}$ time and $N = n^{O(\log k)}$. ◀

The inapproximability statement Theorem 1.1 is a canonical corollary of Theorem 3.1.

▶ Remark 3.13 (Toward arbitrary finite fields). It is natural to ask whether the $n^{O(\log k)}$ rank-gap reduction of this section can be obtained over an arbitrary fixed finite field $\mathbb{F}_q$. The main technical step to achieve this is replacing the binary low-degree long code used in the Dinur–Guruswami and Khot–Saket frameworks [6, 12] with a suitable q-ary analogue. In particular, carrying out the superposition-soundness argument over $\mathbb{F}_q$ requires extending the relevant low-error Reed–Muller testing and, crucially, generalizing the correlation bound of Lemma 3.6 to arbitrary finite fields.

4 An $n^{O(k)}$ Construction over any $\mathbb{F}_q$

In this section, we start with the canonical NP-hardness of Boolean QuadEq, and prove Theorem 4.2 by a direct moment-matrix construction.

▶ **Lemma 4.1** (Boolean QuadEq hardness, [8, 10]). *Let $\mathbb{F}_q$ be any finite field. Given squarefree quadratic polynomials $f_1, \dots, f_m$ over $\mathbb{F}_q$ in variables $x_1, \dots, x_n$, it is NP-hard to decide whether there exists $a \in \{0,1\}^n \subseteq \mathbb{F}_q^n$ such that $f_1(a) = \cdots = f_m(a) = 0$. Equivalently, each input polynomial may be written as*

$$f_\ell(x) = \sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} x^U, \qquad c_{\ell,U} \in \mathbb{F}_q,$$

where the coordinate indexed by $\emptyset$ is the constant term.

▶ **Theorem 4.2.** *Fix a finite field $\mathbb{F}_q$. For every integer $k \geq 1$, there is a deterministic $n^{O(k)}$-time reduction from a Boolean QuadEq instance with n variables over $\mathbb{F}_q$ to a linear subspace*

$$\mathcal{L} \subseteq \mathbb{F}_q^{N \times N}, \qquad N = n^{O(k)},$$

such that:

- *(YES) if the Boolean QuadEq instance is satisfiable, then $\mathcal{L}$ contains a nonzero matrix of rank 1;*
- *(NO) if the Boolean QuadEq instance is unsatisfiable, then $\mathcal{L}$ contains no nonzero matrix of rank at most k.*

Throughout this section all vector spaces, matrices, and polynomials are over a fixed finite field $\mathbb{F}_q$. We use the Boolean monomial and pseudo-moment conventions from Section 2; in particular, $\mathcal{V}_{n,d}$ includes the empty set.

4.1 The pseudo-moment subspace

Fix an integer $d \geq 1$. Following the notation of Section 2, a degree-$2d$ pseudo-moment vector is $y = (y_S)_{S \in \mathcal{V}_{n,2d}}$, and its associated pseudo-moment matrix is $H_d(y)$.

We define a linear subspace of matrices with rows and columns indexed by $\mathcal{V}_{n,d}$ by imposing two kinds of linear constraints.

(1) *Equal-union constraints:*

$$A_{S,T} = A_{S',T'} \qquad \text{whenever } S \cup T = S' \cup T'. \tag{9}$$

After imposing these constraints, for every $R \in \mathcal{V}_{n,2d}$ we write y_R for the common value $A_{S,T}$ over all pairs $S, T \in \mathcal{V}_{n,d}$ with $S \cup T = R$. For convenience, we describe the next set of constraints in terms of y.

(2) *Localizing constraints:* For each QuadEq equation

$$f_\ell(x) = \sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} x^U, \qquad c_{\ell,U} \in \mathbb{F}_q,$$

we impose the linear constraints

$$\sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U}\, y_{U \cup W} = 0 \qquad \text{for every } \ell \in [m] \text{ and every } W \in \mathcal{V}_{n,2d-2}. \tag{10}$$

These are the moment analogues of the equations $x^W f_\ell(x) = 0$: after multiplying f_ℓ by any squarefree monomial of degree at most $2d-2$, the corresponding linear combination of pseudo-moments must vanish.

Let $\mathcal{L}_d(f_1, \ldots, f_m)$ denote the set of matrices satisfying the constraints above. This is a linear subspace of $\mathbb{F}_q^{N \times N}$, where

$$N = |\mathcal{V}_{n,d}| = \sum_{j=0}^{d} \binom{n}{j} = n^{O(d)}.$$

For completeness, if $a = (a_1, \ldots, a_n) \in \{0,1\}^n$ satisfies all equations $f_\ell(a) = 0$, set $y_S := a^S$ for every $S \in \mathcal{V}_{n,2d}$. Then $H_d(y) = v_d(a)v_d(a)^\top$ has rank 1 and is nonzero because the coordinate indexed by $\emptyset$ is 1. Moreover, for every $W \in \mathcal{V}_{n,2d-2}$,

$$\sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} y_{U \cup W} = a^W f_\ell(a) = 0,$$

so $H_d(y) \in \mathcal{L}_d(f_1, \ldots, f_m)$.

We now begin the soundness proof. It suffices to show that every nonzero matrix in $\mathcal{L}_d(f_1, \ldots, f_m)$ with rank at most d yields an actual Boolean solution of the source instance. Let y be the unique pseudo-moment vector associated with such a matrix A, so $A = H_d(y)$ and y satisfies (10). For a genuine Boolean point a, multiplying the label of a monomial column by x_i multiplies that column by the scalar a_i; equivalently, the column space is invariant under multiplication by each variable. We will find two consecutive levels where low rank forces a similar form of invariance.

For $0 \le e \le d$, let

$$H_e(y) := \big(y_{S \cup T}\big)_{S,T \in \mathcal{V}_{n,e}}, \qquad r_e := \operatorname{rank} H_e(y),$$

and let C_e denote the column space of $H_e(y)$.

The soundness argument has four steps.

(1) Low rank forces a nonzero *flat level*, meaning a level e with $r_e = r_{e+1} > 0$.

(2) At such a flat level, multiplying a basis column by any variable x_i creates no new column direction. This defines a linear map $T_i : C_e \to C_e$, interpreted as multiplication by x_i.

(3) Because the relevant column relations are certified one level up (a.k.a inside C_{e+1}), these maps satisfy the Boolean multiplication rules $T_i^2 = T_i$ and $T_iT_j = T_jT_i$, and the localizing equations become the operator identities $f_\ell(T) = 0$.

(4) The commuting projections T_i have a common eigenvector. Their eigenvalues form a Boolean point $a \in \{0,1\}^n \subseteq \mathbb{F}_q^n$, and the identities $f_\ell(T) = 0$ force $f_\ell(a) = 0$.

4.2 Finding a nonzero flat level

Note that the ranks $r_0, r_1, \ldots, r_d$ are non-decreasing, and the final rank is at most d. Monotonicity alone would still allow the ranks to be zero for many initial levels and then grow by one at each remaining level. The key point is that a nonzero pseudo-moment cannot start growing this slowly. If S is a minimum-size set with $y_S \neq 0$, then the same permutation-submatrix idea as in Lemma 3.10 already forces, at level $s = \lceil |S|/2 \rceil$, the lower bound $r_s \ge s + 1$ (indeed $r_s \ge 2^{\Omega(s)}$ except for the smallest cases). If every subsequent positive step were strict, then

$$r_d \ge r_s + (d - s) \ge (s + 1) + (d - s) = d + 1,$$

contradicting $r_d \le d$. Thus some nonzero plateau $r_e = r_{e+1}$ must occur.

▶ **Lemma 4.3.** *Let $d \geq 1$. Suppose $H_d(y)$ is nonzero and* $\operatorname{rank} H_d(y) \leq d$. *Then there exists $e \in \{0, 1, \ldots, d-1\}$ such that*

$$r_e = r_{e+1} > 0.$$

Proof. Choose a set $S \in \mathcal{V}_{n,2d}$ of minimum size such that $y_S \neq 0$, and put

$$\lambda := y_S, \qquad h := |S|, \qquad s := \lceil h/2 \rceil .$$

Since $h \leq 2d$, we have $s \leq d$. The first step is the following rank lower bound forced by the first nonzero moment:

$$r_s \geq s + 1. \tag{11}$$

If $h = 0$, then $s = 0$ and $y_\emptyset = \lambda \neq 0$, so $r_s = r_0 = 1 = s + 1$. If $h = 1$, say $S = \{i\}$, then the minimality of S gives $y_\emptyset = 0$ and $y_S = \lambda$. The submatrix of $H_1(y)$ with rows and columns indexed by $\emptyset, S$ is

$$\begin{pmatrix} y_\emptyset & y_S \\ y_S & y_S \end{pmatrix} = \begin{pmatrix} 0 & \lambda \\ \lambda & \lambda \end{pmatrix},$$

which has rank $2 = s + 1$.

It remains to consider $h \geq 2$. Use the subsets $A \subseteq S$ of size $\lfloor h/2 \rfloor$ as row labels and the subsets $B \subseteq S$ of size $\lceil h/2 \rceil = s$ as column labels. The resulting submatrix of $H_s(y)$ has entries $y_{A \cup B}$. By the minimality of S, this entry is λ exactly when $A \cup B = S$, and is 0 otherwise. For each row A, there is a unique such column, namely $B = S \setminus A$. Thus this submatrix is λ times a permutation matrix of size

$$\binom{h}{\lfloor h/2 \rfloor}.$$

Therefore

$$r_s \geq \binom{h}{\lfloor h/2 \rfloor} \geq h \geq \lceil h/2 \rceil + 1 = s + 1,$$

where the middle inequality uses $h \geq 2$. This proves (11) in all cases.

The matrices $H_0(y), H_1(y), \ldots, H_d(y)$ are nested principal submatrices, so the ranks $r_0, r_1, \ldots, r_d$ are nondecreasing. Suppose, for contradiction, that no $e \in \{0, 1, \ldots, d-1\}$ satisfies $r_e = r_{e+1} > 0$. Since $r_s > 0$ and the ranks are nondecreasing, the ranks strictly increase at every such step. Thus

$$r_d \geq r_s + (d - s) \geq (s + 1) + (d - s) = d + 1,$$

contradicting $r_d = \operatorname{rank} H_d(y) \leq d$. Therefore a nonzero flat level exists. ◀

4.3 Multiplication operators and localizing identities

For $0 \leq e \leq d$ and a set $A \subseteq [n]$ with $|A| \leq 2d - e$, define the truncated column

$$\mathbf{c}_e(A) := \big(y_{R \cup A}\big)_{R \in \mathcal{V}_{n,e}} \in \mathbb{F}_q^{\mathcal{V}_{n,e}}.$$

If $A \in \mathcal{V}_{n,e}$, then $\mathbf{c}_e(A)$ is exactly the column of $H_e(y)$ indexed by A. If $|A| = t > e$, it is not literally a column of $H_e(y)$, but it is still the degree-e truncation of the column indexed by A, in a larger moment matrix $H_t(y)$.

We now explain how the flat level is used. At a flat level $r_e = r_{e+1}$, any basis of the column space C_e remains a basis after lifting the columns to level $e+1$. Hence multiplying the column label by x_i gives a well-defined operator $T_i : C_e \to C_e$. Furthermore, this extra-level lift certifies that

$$T_i \mathbf{c}_e(A) = \mathbf{c}_e(A \cup \{i\})$$

for every $A \in \mathcal{V}_{n,e+1}$. This allows us to multiply the column label by a second variable consistently, yielding $T_i^2 = T_i$, $T_iT_j = T_jT_i$, and ultimately translating the localizing constraints into the operator identities $f_\ell(T) = 0$.

▶ **Lemma 4.4.** *Assume $r_e = r_{e+1}$ and $e \le d-1$. Let $\mathcal{I} \subseteq \mathcal{V}_{n,e}$ be such that the vectors $\{\mathbf{c}_e(B) : B \in \mathcal{I}\}$ form a basis for C_e. Then, for every $i \in [n]$, there is a linear map $T_i : C_e \to C_e$ satisfying*

$$T_i \mathbf{c}_e(B) = \mathbf{c}_e(B \cup \{i\}) \qquad \text{for every } B \in \mathcal{I}.$$

Moreover, for every $A \in \mathcal{V}_{n,e+1}$ and every $i \in [n]$, the vector $\mathbf{c}_e(A)$ lies in C_e and

$$T_i \mathbf{c}_e(A) = \mathbf{c}_e(A \cup \{i\}). \tag{12}$$

Proof. First observe that the longer vectors $\{\mathbf{c}_{e+1}(B) : B \in \mathcal{I}\}$ are linearly independent: any linear relation among them restricts, on the rows indexed by $\mathcal{V}_{n,e}$, to the same linear relation among the basis vectors $\{\mathbf{c}_e(B) : B \in \mathcal{I}\}$. Since $r_e = r_{e+1}$, these longer vectors form a basis for the column space of $H_{e+1}(y)$.

For every $i \in [n]$ and every $B \in \mathcal{I}$, the vector $\mathbf{c}_{e+1}(B \cup \{i\})$ is a column of $H_{e+1}(y)$, and hence has a unique expansion in the basis $\{\mathbf{c}_{e+1}(P) : P \in \mathcal{I}\}$. Restricting that expansion to rows of degree at most e shows that $\mathbf{c}_e(B \cup \{i\}) \in C_e$. We may therefore define T_i on the basis by

$$T_i \mathbf{c}_e(B) := \mathbf{c}_e(B \cup \{i\}) \qquad (B \in \mathcal{I}),$$

and extend linearly to all of C_e.

Now fix $A \in \mathcal{V}_{n,e+1}$. We would like to argue that $T_i \mathbf{c}_e(A) = \mathbf{c}_e(A \cup \{i\})$. Since $\mathbf{c}_{e+1}(A)$ is a column of $H_{e+1}(y)$, there are unique coefficients $\lambda_{A,B} \in \mathbb{F}_q$ such that

$$\mathbf{c}_{e+1}(A) = \sum_{B \in \mathcal{I}} \lambda_{A,B} \mathbf{c}_{e+1}(B).$$

Restricting to rows in $\mathcal{V}_{n,e}$ gives

$$\mathbf{c}_e(A) = \sum_{B \in \mathcal{I}} \lambda_{A,B} \mathbf{c}_e(B),$$

so $\mathbf{c}_e(A) \in C_e$. By linearity and the definition of T_i on the basis,

$$T_i \mathbf{c}_e(A) = \sum_{B \in \mathcal{I}} \lambda_{A,B} T_i \mathbf{c}_e(B) = \sum_{B \in \mathcal{I}} \lambda_{A,B} \mathbf{c}_e(B \cup \{i\}).$$

It remains to identify the last expression with $\mathbf{c}_e(A \cup \{i\})$. Fix a row label $R \in \mathcal{V}_{n,e}$. Since $R \cup \{i\} \in \mathcal{V}_{n,e+1}$, evaluating the expansion of $\mathbf{c}_{e+1}(\cdot)$ at the row $R \cup \{i\}$ gives

$$\begin{aligned}
\sum_{B \in \mathcal{I}} \lambda_{A,B} \big(\mathbf{c}_e(B \cup \{i\})\big)_R &= \sum_{B \in \mathcal{I}} \lambda_{A,B} y_{R \cup B \cup \{i\}} \\
&= \sum_{B \in \mathcal{I}} \lambda_{A,B} \big(\mathbf{c}_{e+1}(B)\big)_{R \cup \{i\}} \\
&= \big(\mathbf{c}_{e+1}(A)\big)_{R \cup \{i\}} \\
&= y_{R \cup A \cup \{i\}} = \big(\mathbf{c}_e(A \cup \{i\})\big)_R.
\end{aligned}$$

This holds for every row $R \in \mathcal{V}_{n,e}$, so $T_i \mathbf{c}_e(A) = \mathbf{c}_e(A \cup \{i\})$. The vector on the right is well-defined because $|A \cup \{i\}| \le e + 2 \le 2d - e$, using $e \le d - 1$. ◀

▶ **Lemma 4.5.** *Assume $r_e = r_{e+1} > 0$ and $e \le d-1$. Let C_e be the column space of $H_e(y)$. If y satisfies the equations* (10)*, then there are linear maps*

$$T_1, \dots, T_n : C_e \to C_e$$

with the following properties:

(i) *$T_i^2 = T_i$ for every i;*

(ii) *$T_i T_j = T_j T_i$ for every i, j;*

(iii) *for every $\ell \in [m]$,*

$$\sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} T_U = 0 \qquad \text{as a linear map on } C_e,$$

where $T_U := \prod_{i \in U} T_i$ and $T_\emptyset$ is the identity map.

Proof. Choose $\mathcal{I} \subseteq \mathcal{V}_{n,e}$ such that $\{\mathbf{c}_e(B) : B \in \mathcal{I}\}$ is a basis for C_e, and define the maps T_i as in Lemma 4.4. By Lemma 4.4, for every $A \in \mathcal{V}_{n,e+1}$ and every i,

$$T_i \mathbf{c}_e(A) = \mathbf{c}_e(A \cup \{i\}). \tag{13}$$

We first prove the Boolean multiplication rules. Fix $B \in \mathcal{I}$ and $i, j \in [n]$. Taking $A = B$ in (13) gives $T_i \mathbf{c}_e(B) = \mathbf{c}_e(B \cup \{i\})$. Since $B \cup \{i\} \in \mathcal{V}_{n,e+1}$, applying (13) with $A = B \cup \{i\}$ and variable j gives

$$T_j T_i \mathbf{c}_e(B) = T_j \mathbf{c}_e(B \cup \{i\}) = \mathbf{c}_e(B \cup \{i, j\}). \tag{14}$$

Taking $j = i$ in (14) gives $T_i^2 \mathbf{c}_e(B) = T_i \mathbf{c}_e(B)$, because $B \cup \{i, i\} = B \cup \{i\}$. Since this holds on the basis vectors $\{\mathbf{c}_e(B) : B \in \mathcal{I}\}$, we get $T_i^2 = T_i$. Swapping i and j in (14) gives

$$T_i T_j \mathbf{c}_e(B) = \mathbf{c}_e(B \cup \{j, i\}) = \mathbf{c}_e(B \cup \{i, j\}) = T_j T_i \mathbf{c}_e(B),$$

again on every basis vector. Hence $T_i T_j = T_j T_i$.

It remains to translate the original equations into operator identities. Because the T_i commute, $T_U := \prod_{i \in U} T_i$ is well-defined. From (13) when $|U| \le 1$, and from (14) when $|U| = 2$, we have

$$T_U \mathbf{c}_e(B) = \mathbf{c}_e(B \cup U) \qquad \text{for every } B \in \mathcal{I} \text{ and every } U \in \mathcal{V}_{n,2}.$$

Therefore, for every row label $R \in \mathcal{V}_{n,e}$,

$$\left(\sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} T_U \mathbf{c}_e(B) \right)_R = \sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} y_{R \cup B \cup U}.$$

Here $R \cup B$ has size at most $2e$. Since $e \le d-1$, we have $2e \le 2d-2$, so the localizing equations (10) apply with $W = R \cup B$. Hence the last sum is 0. Thus $\sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} T_U$ kills every basis vector of C_e, and therefore it is the zero map on C_e. ◀

4.4 Decoding a satisfying assignment from commuting projections

The next lemma records the common-eigenvector property for commuting projections. We omit the proof here.

▶ **Lemma 4.6.** *Let C be a nonzero finite-dimensional vector space over $\mathbb{F}_q$, and let $T_1, \dots, T_n$ be commuting linear maps on C with $T_i^2 = T_i$ for every i. Then there are $v \in C \setminus \{0\}$ and scalars $a_i \in \{0,1\} \subseteq \mathbb{F}_q$, $i \in [n]$, such that*

$$T_i v = a_i v \qquad \text{for every } i = 1, \dots, n.$$

▶ **Lemma 4.7.** *Let C be a nonzero finite-dimensional vector space over $\mathbb{F}_q$, and let $T_1, \dots, T_n$ be commuting linear maps on C. Suppose that, for every $\ell \in [m]$,*

$$\sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} T_U = 0 \qquad \text{as a linear map on } C,$$

where $T_U := \prod_{i \in U} T_i$ and $T_\emptyset$ is the identity map. If there are $v \in C \setminus \{0\}$ and scalars $a_1, \dots, a_n \in \{0,1\} \subseteq \mathbb{F}_q$ such that $T_i v = a_i v$ for every i, then $a = (a_1, \dots, a_n)$ satisfies $f_1(a) = \cdots = f_m(a) = 0$.

Proof. Since the operators commute, for every $U \in \mathcal{V}_{n,2}$ we have

$$T_U v = a^U v.$$

Therefore, for every ℓ,

$$0 = \Big(\sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} T_U \Big) v = \Big(\sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} a^U \Big) v = f_\ell(a) v.$$

Since $v \neq 0$, the scalar $f_\ell(a)$ must be zero. Hence the Boolean point $a = (a_1, \dots, a_n)$ satisfies all equations. ◀

We are now ready to prove Theorem 4.2.

Proof of Theorem 4.2. Given the Boolean QuadEq instance $f_1, \dots, f_m$, set $d := k$ and output

$$\mathcal{L} := \mathcal{L}_d(f_1, \dots, f_m).$$

The matrix size is

$$N = |\mathcal{V}_{n,d}| = \sum_{j=0}^{k} \binom{n}{j} = n^{O(k)},$$

and the number of equal-union and localizing constraints is also $(n+m)n^{O(k)}$, so the construction has the claimed running time.

If the Boolean QuadEq instance has a solution, the completeness argument above shows that $\mathcal{L}$ contains a nonzero rank-1 matrix. If the Boolean QuadEq instance has no solution and $A \in \mathcal{L}$ is nonzero with $\operatorname{rank}(A) \le k$, then the unique pseudo-moment vector y associated with A satisfies $A = H_k(y)$ and (10). By Lemma 4.3, choose a flat level e with $r_e = r_{e+1} > 0$. By Lemma 4.5, the column space C_e carries commuting projections $T_1, \dots, T_n$, and for every $\ell \in [m]$,

$$\sum_{U \in \mathcal{V}_{n,2}} c_{\ell,U} T_U = 0.$$

By Lemma 4.6, there are a nonzero vector $v \in C_e$ and scalars $a_1, \dots, a_n \in \{0,1\} \subseteq \mathbb{F}_q$ such that $T_i v = a_i v$ for every i. By Lemma 4.7, a is a Boolean solution, a contradiction. Hence no such nonzero matrix exists. ◀

The inapproximability statement Theorem 1.2 is a standard corollary of Theorem 4.2.

Abstract

The parameterized Minimum Monotone Satisfying Assignment (k-MMSA) problem asks whether a monotone Boolean circuit admits a satisfying assignment of Hamming weight at most k. The MMSA hierarchy is defined by allowing a bounded number of alternations between AND and OR gates in the circuit. While the polynomial-time approximability of the MMSA hierarchy has been studied extensively, much less is known in the parameterized setting. In particular, k-MMSA$_2$ is the well-known k-SetCover problem, whose parameterized inapproximability lies in the $\mathsf{polylog}(n)$ regime. In contrast, k-MMSA$_4$ captures k-MinLabel, for which known lower bounds give $\mathsf{poly}(n)$ inapproximability. Sandwiched by k-MMSA$_2$ and k-MMSA$_4$, the inapproximability of k-MMSA$_3$ remained comparatively unexplored.

In this paper, we give an FPT-time $O(2^k \log n)$-approximation algorithm for k-MMSA$_3$, suggesting that in the fixed-parameter regime, the third level of MMSA remains surprisingly close to the second level. Complementing this algorithm, we also give an FPT-time gap-preserving reduction from k-MMSA$_3$ to k-MMSA$_2$. Thus, stronger inapproximability for k-MMSA$_3$ would imply new hardness for k-MMSA$_2$, potentially offering a route around the current barriers for the latter problem.

Revisiting Marx's reduction from k-MMSA$_t$ to gap k-MMSA$_{t+2}$, we also show that k-MMSA$_4$ admits no $n^{o(1)}$-factor FPT approximation unless W[2]=FPT, and no $n^{O(1/k)}$-factor approximation running in $n^{o(k)}$ time under ETH. These results separate the parameterized approximability behavior of the third and fourth levels and clarify where stronger inapproximability enters the k-MMSA hierarchy.

1 Introduction

Given a Boolean circuit C consisting of only $\wedge$ and $\vee$ gates on n input bits, the Minimum Monotone Satisfying Assignment (MMSA) problem asks to find a satisfying assignment of C with minimum Hamming weight.

MMSA was first introduced by Alekhnovich, Buss, Moran and Pitassi [1]. In a later work, Dinur and Safra [9] defined a hierarchy of MMSA problems by restricting the number of alternations of the monotone circuit[1]. Specifically, MMSA_t refers to the problem where the alternation starts with an $\wedge$, and has at most t levels. This hierarchy turns out to be equivalent to an AND/OR scheduling hierarchy suggested by Goldwasser and Motwani [15].

Looking into this hierarchy, MMSA_1 can be solved easily by simply outputting the width of the $\wedge$ gate. MMSA_2 is equivalent to the classical Set Cover problem, by identifying each set with a variable and each element to cover with an inner disjunction. Thus, MMSA_2 inherits the $O(\log n)$-approximation [16, 21, 7] and $(1-o(1))\ln n$ NP-inapproximability [8] of Set Cover. In [9], Dinur and Safra showed a $2^{\log^{1-o(1)} n}$ inapproximability for MMSA_3 via a reduction from PCP, and placed the Label-Cover problem[2] between MMSA_3 and MMSA_4. Recently, Chlamtáč, Makarychev, and Vakilian [6] revisited the polynomial-time approximability of this hierarchy. They gave an $\widetilde{O}(N^{1/3})$-approximation for MMSA_3 and MMSA_4, and more generally an $\widetilde{O}(N^{1-\delta_t})$-approximation for MMSA_t, where N is the total number of gates and variables, and $\delta_t = \frac{1}{3}\cdot 2^{3-\lceil t/2\rceil}$.

In a separate line of work, Umans [23] studied the *semantic* variant of Minimum Monotone Satisfying Assignment problem. In his formulation, the input is a circuit that is promised to accept a monotone set of strings. In contrast, [1, 9] studies the syntactic variant where the circuit itself is required to be monotone. Umans showed the NP-hardness of an $n^{1/5-\varepsilon}$-approximation for the semantic problem.

In the parameterized world, there is even more connection between MMSA and other important problems. Parameterized by the target Hamming weight k, the unbounded-alternation circuit version of k-MMSA is $\mathsf{W[P]}$-complete, whereas the corresponding formula version is $\mathsf{W[SAT]}$-complete; imposing constant-depth and weft-t restrictions on weighted circuit satisfiability yields the usual $\mathsf{W}[t]$-hierarchy [13, 11]. As for the bounded-depth variants, k-MMSA_2 is equivalent to k-Setcover, the canonical $\mathsf{W}[2]$-complete problem [10, 13, 11]. Inapproximability for k-Setcover was known under different complexity assumptions: there are no $n^{o(k)}$ time (respectively, $n^{k-\varepsilon}$ time) $(\frac{\log n}{\log\log n})^{1/k}$-approximation under ETH (respectively, SETH) [19]; no FPT time $(\log n)^{o(1)}$-approximation under $\mathsf{W}[1]\neq\mathsf{FPT}$ [17, 19][3]; and no FPT time constant approximation under $\mathsf{W}[2]\neq\mathsf{FPT}$ [20].

Despite these substantial results, the parameterized inaprproximability of k-Setcover is not yet fully understood. Several central questions remain open and have been raised repeatedly in the literature [12, 17, 19, 18, 20]. Can the FPT-time inapproximability factor be strengthened to match the $O(\log n)$-approximation by the greedy algorithm? Can the total-FPT-inapproximability[4] be based on the minimal assumption $\mathsf{W}[2]\neq\mathsf{FPT}$? Under

[1] Strictly speaking, [9] studied monotone *formulae* rather than general *circuits*. For fixed depth t, the two are interconvertible with polynomial blow-up. The distinction matters only in the unbounded-depth setting, e.g., in our later discussion on $\mathsf{W[P]}/\mathsf{W[SAT]}$-completeness of unbounded-alternation k-MMSA.

[2] This is the minimization Label-Cover problem in the Arora–Lund sense [3], rather than the Projection-game formulation, where the value is the maximum fraction of satisfied constraints.

[3] The factor in the statement of [17] is $(\log n)^{1/\mathsf{poly}(k)}$, but by a simple padding trick, we can actually get any FPT-time $(\log n)^{o(1)}$-factor inapproximability. See Lemma 2.8 for a formal discussion.

[4] By total-FPT-inapproximability, we mean ruling out FPT-time $f(k)$-approximation algorithms for every computable function f.

ETH, or even Gap-ETH, can one go beyond the current $(\log n)^{1/k}$-scale barrier for $n^{o(k)}$-time inapproximability? These questions motivate the study of k-MMSA$_3$, the closest natural extension of k-MMSA$_2$ in the k-MMSA hierarchy. In particular, we ask whether the additional expressive power of k-MMSA$_3$ enables reductions that bypass the known barriers for k-SetCover, and whether the techniques developed for k-MMSA$_3$ can in turn shed light on k-SetCover itself.

We remark that Dinur and Safra's approach [9] for non-parameterized MMSA$_3$ relies on building one Boolean variable $L[x, a]$ for each (variable, value) pair in the PCP construction. In the yes case, selecting exactly one value per PCP variable yields a satisfying assignment of weight n, where n is the number of variables. However, this approach does not extend to the parameterized setting: to keep the solution weight bounded by k, one would need to start from a *parameterized* CSP with only k variables, but for such CSPs, even just greedily satisfying the constraints adjacent to the maximum degree variable gives a $k^{O(1)}$ factor approximation[5], which precludes deriving any inapproximability factor that grows with n.

With an extra level of alternation, k-MMSA$_4$ possesses a stronger inapproximability. In his paper studying parameterized monotone and antimonotone circuit satisfiability, Marx [22] gave a gap-creating reduction from any k-MMSA$_t$ to k-MMSA$_{t+2}$, and thus ruled out any FPT-time $f(k)$-approximation for k-MMSA$_4$ under W[2] $\neq$ FPT. We remark that k-MMSA$_4$ also captures the k-MinLabel problem defined in [4]. It was known in [4] that, under Gap-ETH, any $f(k)$-approximation of k-MinLabel requires $n^{\Omega(k)}$ time. It was also implicit in [17, 18] that, k-MinLabel is hard to approximate within an $n^{o(1)}$-factor[6] in FPT time under W[1] $\neq$ FPT, or an $n^{1/\mathrm{poly}(k)}$-factor in $n^{o(k)}$ time under ETH, via reductions from k-MaxCover.

Our Contributions

In this paper, we give an FPT time $O(2^k \log n)$-approximation algorithm for k-MMSA$_3$ (Theorem 3.1), which shows, in contrast to the non-parameterized world, that approximating k-MMSA$_3$ is not significantly harder than approximating k-MMSA$_2$. On the hardness side, we give a reduction from (k, h)-gap k-MMSA$_3$ to $(2^k, h/k)$-gap k-MMSA$_2$ (Theorem 4.1). This connection has two implications. First, it helps explain why stronger inapproximability for k-MMSA$_3$ has not appeared separately from k-MMSA$_2$. Second, via this reduction, any sufficiently strong lower bound for k-MMSA$_3$ would yield new FPT inapproximability results for k-SetCover. In particular, a $(\log n)^{\Omega(1)}$-factor FPT inapproximability for k-MMSA$_3$ under W[1] $\neq$ FPT would imply the same for k-SetCover. Similarly, under W[2] $\neq$ FPT, an $\omega(2^k)$ FPT inapproximability for k-MMSA$_3$ would translate into a superconstant FPT inapproximability for k-SetCover, resolving long standing open problems.

We also revisit Marx's reduction [22] and show that it yields stronger consequences than previously recognized. By carefully picking the parameters, we show k-MMSA$_4$ is hard to approximate within an $n^{o(1)}$-factor[6] in FPT time under W[2] $\neq$ FPT, and hard to approximate within an $n^{O(1/k)}$-factor in $n^{o(k)}$ time under ETH, improving the previous $f(k)$-factor [22] and $n^{1/\mathrm{poly}(k)}$-factor [17, 18], respectively.

We summarize the (in)approximability results for parameterized MMSA hierarchy in Table 1.

[5] We may assume without loss of generality that the parameterized CSP has arity 2. Arity-q CSPs reduce to arity 2 by the standard label-coverization trick, with only an $O(q)$-factor loss in the gap.
[6] Requires padding, see Lemma 2.8.

2 Preliminaries

2.1 Perfect Hash Families

▶ **Definition 2.1** ((n, m, Σ, h)-perfect hash family [14]). *An (n, m, Σ, h)-perfect hash family is a family of m functions $\mathcal{F} = \{f_i : [n] \to \Sigma \mid i \in [m]\}$, such that for every subset $T \subseteq [n]$ where $|T| \leq h$, there is a function $f \in \mathcal{F}$ such that*

$$\forall x, y \in T \text{ with } x \neq y,\ f(x) \neq f(y).$$

In other words, $\mathcal{F}$ is an (n, m, Σ, h)-perfect hash family if for any h distinct elements in $[n]$, there is a function $f \in \mathcal{F}$ which maps them to h distinct values.

When $|\Sigma| \geq h^2$, an (n, m, Σ, h)-perfect hash family can be constructed efficiently and deterministically:

▶ **Lemma 2.2** ([2]). *An (n, m, Σ, h)-perfect hash family with $|\Sigma| = h^2, m = h^{O(1)} \log n$ can be constructed deterministically in time $h^{O(1)} \cdot n \log n$.*

2.2 Parameterized Problems

We begin with a definition of the parameterized version of the MMSA problem.

▶ **Definition 2.3** (k-MMSA$_t$). *For any $t, k \in \mathbb{N}^+$, k-MMSA$_t$ asks whether there is a satisfying assignment with Hamming weight at most k, for a monotone circuit C of the following form.*

$$C(x_1, \ldots, x_n) = \begin{cases} \bigwedge_{i_1=1}^{n} \bigvee_{i_2=1}^{n} \cdots \bigwedge_{i_t=1}^{n} x_{w_{i_1,\ldots,i_t}}, & t \text{ is odd}, \\ \bigwedge_{i_1=1}^{n} \bigvee_{i_2=1}^{n} \cdots \bigwedge_{i_{t-1}=1}^{n} \bigvee_{i_t=1}^{n} x_{w_{i_1,\ldots,i_t}}, & t \text{ is even}, \end{cases}$$

where for every $i_1, \ldots, i_t \in [n]$, $w_{i_1,\ldots,i_t}$ is an index in $[n]$[7].

[7] We generally allow the width of each gate to be polynomial in the number of input bits, but for simplicity, we can pad unused bits and thus use n for both of them.

We write $\mathrm{SAT}(C)$ *to denote the set of satisfying assignments of* C*, and write* $\mathrm{OPT}(C)$ *to denote the minimum weight of any satisfying assignment.*

For any $h > k$*, we write* (k, h)*-gap MMSA*$_t$ *for the task of distinguishing between* $\mathrm{OPT}(C) \le k$ *and* $\mathrm{OPT}(C) > h$*, or equivalently, finding a satisfying assignment of* C *with weight at most* h *given the promise that* $\mathrm{OPT}(C) \le k$*.*

For the special case of k-MMSA$_3$, it will be convenient to replace the ordered list of literals feeding into each bottom conjunction by the set of input indices appearing in that gate. Specifically, a k-MMSA$_3$ instance can be written as

$$C(x) = \bigwedge_{i=1}^{n} \bigvee_{j=1}^{n} \bigwedge_{t \in N_{i,j}} x_t,$$

where $N_{i,j} \subseteq [n]$ for every $i, j \in [n]$.

The following lemma shows that given a k-MMSA$_3$ instance, one can prune any bottom conjunction term with $|N_{i,j}| > k$ without hurting the gap.

▶ **Lemma 2.4.** *There is a polynomial-time deterministic algorithm which, given as input a* k*-MMSA*$_3$ *instance*

$$C(x) = \bigwedge_{i=1}^{n} \bigvee_{j=1}^{n} \bigwedge_{t \in N_{i,j}} x_t,$$

outputs a k*-MMSA*$_3$ *instance*

$$C'(x) = \bigwedge_{i=1}^{n} \bigvee_{j=1}^{n} \bigwedge_{t \in N'_{i,j}} x_t,$$

where for every $i \in [n]$ *and* $j \in S_i$*,* $|N_{i,j}| \le k$*. Furthermore,*

- *If* $\mathrm{OPT}(C) \le k$*, then* $\mathrm{OPT}(C') \le k$*.*
- $\mathrm{SAT}(C') \subseteq \mathrm{SAT}(C)$*. In particular, for every* $h > k$*, if* $\mathrm{OPT}(C) > h$*, then* $\mathrm{OPT}(C') > h$*.*

Proof. C' is obtained from C by simply removing every bottom conjunction with $|N_{i,j}| > k$. That is, let $S_i := \{j \in [n] \mid |N_{i,j}| \le k\}$, and let

$$C'(x) := \bigwedge_{i=1}^{n} \bigvee_{j \in S_i} \bigwedge_{t \in N_{i,j}} x_t.$$

To pad the size of the second layer to n, we simply duplicate its inputs.

Obviously, $C(x) \ge C'(x)$, hence $\mathrm{SAT}(C') \subseteq \mathrm{SAT}(C)$. On the other hand, suppose $\mathrm{OPT}(C) \le k$, and let x be a satisfying assignment to C with $\|x\|_0 \le k$. Since $|N_{i,j}| > k$ for every $i \in [n]$ and $j \notin S_i$, we have $\bigwedge_{t \in N_{i,j}} x_t = 0$, thus

$$\begin{aligned} C'(x) &= \bigwedge_{i=1}^{n} \left(\left(\bigvee_{j \in S_i} \bigwedge_{t \in N_{i,j}} x_t \right) \vee \left(\bigvee_{j \notin S_i} \bigwedge_{t \in N_{i,j}} x_t \right) \right) \\ &= \bigwedge_{i=1}^{n} \bigvee_{j=1}^{n} \bigwedge_{t \in N_{i,j}} x_t = C(x). \end{aligned}$$

Hence x is also a satisfying assignment to C', which implies that $\mathrm{OPT}(C') \le k$. ◀

We next introduce two closely related parameterized problems: k-MaxCover and k-MinLabel.

▶ **Definition 2.5** (k-MaxCover and k-MinLabel)**.** *k-MaxCover and k-MinLabel are both defined on a partitioned bipartite graph $G = (A, B, E)$ where $A = A_1 \dot\cup \ldots \dot\cup A_k, B = B_1 \dot\cup \ldots \dot\cup B_m$ and $m \le n$, with different optimizing objectives.*

We say a set $X \subseteq A$ (possibly contain multiple vertices from the same part) covers a right part B_j if there exists some $b \in B_j$, such that for every $i \in [k]$, there exists a vertex $a_i \in A_i \cap X$ which is connected to b.

The goal of k-MaxCover is to pick one vertex a_i from each left part A_i, to cover the maximum fraction of right parts B_j, while the goal of k-MinLabel is to pick minimum-sized subset $X \subseteq A$, to cover every right part B_j. We write the two values as $\mathsf{MaxCover}(G)$ *and* $\mathsf{MinLabel}(G)$*, respectively. Specifically,*

$$\mathsf{MaxCover}(G) = \frac{1}{m}\left(\max_{a_1\in A_1,\ldots,a_k\in A_k} \left|\left\{j \in [m] \;\middle|\; \exists b \in B_j \text{ such that } \forall i \in [k],\ (a_i, b) \in E\right\}\right|\right),$$

$$\mathsf{MinLabel}(G) = \min_{X\subseteq A, X \text{ covers every } B_j,\ j\in[m]} |X|.$$

There is a canonical reduction from $(1, \varepsilon)$-gap k-MaxCover to $(1, \varepsilon^{-1/k})$-gap k-MinLabel, as formalized in [4, 17]. We omit the proof here and refer the reader to [17, Proposition A.1].

▶ **Lemma 2.6** ([4, 17])**.** *Let $G = (A, B, E)$ be a k-MaxCover/k-MinLabel instance with $A = A_1 \dot\cup \cdots \dot\cup A_k$ and $B = B_1 \dot\cup \cdots \dot\cup B_m$.*

- *If* $\mathsf{MaxCover}(\Gamma) = 1$*, then* $\mathsf{MinLabel}(\Gamma) = k$.
- *If* $\mathsf{MaxCover}(\Gamma) \le \varepsilon$ *for some* $\varepsilon > 0$*, then* $\mathsf{MinLabel}(\Gamma) \ge (1/\varepsilon)^{1/k} \cdot k$.

We remark that k-MinLabel can be written as a restricted special case of MMSA_4. Therefore, the inapproxiambility of k-MinLabel applies to k-MMSA_4 as well. This observation is formalized in the following lemma.

▶ **Lemma 2.7.** *Let $G = (A, B, E)$ be a k-MinLabel instance with $A = A_1 \dot\cup \cdots \dot\cup A_k$ and $B = B_1 \dot\cup \cdots \dot\cup B_m$. There is a polynomial-time construction of a k-MMSA_4 circuit C_G such that*

$$\mathrm{OPT}(C_G) = \mathsf{MinLabel}(G).$$

Proof. For every left vertex $a \in A$, introduce one Boolean variable x_a. For a right vertex $b \in B$, write

$$N_G(b) = \{a \in A \mid (a, b) \in E\}.$$

Define the monotone circuit

$$C_G(x) = \bigwedge_{j\in[m]} \bigvee_{b\in B_j} \bigwedge_{i\in[k]} \bigvee_{a\in A_i\cap N_G(b)} x_a.$$

After padding dummy gates/variables to make the width of each gate equal to the number of variables, $C_G(x)$ becomes a k-MMSA_4 circuit and can be constructed in polynomial time. It's also easy to check the one-to-one correspondence between a subset $X \subseteq A$ covering every B_j in G and a satisfying assignment of C_G. ◀

We next present a canonical padding lemma which boosts any FPT-time inapproximability for k-MMSA with factor $f(n)^{1/g(k)}$ to $f(n)^{o(1)}$.

▶ **Lemma 2.8** (Boosting the inapproximability of k-MMSA$_t$ by padding). *Fix $t \in \mathbb{N}^+$. Let $f : \mathbb{N} \to \mathbb{R}^+$ be a computable, nondecreasing, unbounded, and padding-stable function in the following sense: for every constant $a \in \mathbb{N}$, there is a sufficiently large $n_0(a)$ such that*

$$f(n+a) \le f(n)^2 \qquad \forall n \ge n_0(a).$$

Let $g : \mathbb{N} \to \mathbb{R}^+$ be a computable, nondecreasing and unbounded function. Suppose for k-MMSA$_t$, no FPT algorithm can distinguish between

$$\mathrm{OPT}(C) \le k \qquad \text{and} \qquad \mathrm{OPT}(C) > k \cdot f(n)^{1/g(k)}.$$

Then, for every computable function $\alpha : \mathbb{N} \to \mathbb{R}^+$ with $\alpha(k) = o(1)$, no FPT algorithm can distinguish between

$$\mathrm{OPT}(C) \le k \qquad \text{and} \qquad \mathrm{OPT}(C) > k \cdot f(n)^{\alpha(k)}.$$

In other words, k-MMSA$_t$ doesn't admit an FPT-time $f(n)^{o(1)}$-approximation.

Proof. Fix $\alpha(k) = o(1)$ and choose K sufficiently large such that $\alpha(K) \le 1/(4g(k))$. Given an MMSA$_t$ circuit C on n variables, add $K - k$ fresh variables which are forced to be one in any satisfying assignment:

$$\widehat{C}(x, y) = C(x) \wedge y_1 \wedge \cdots \wedge y_{K-k}.$$

By representing each new variable as a dummy length-t unary path, the new instance $\widehat{C}$ is still a MMSA$_t$ instance with new parameter K. Furthermore, $\widehat{C}$ has $N = n + K - k$ many variables, satisfies

$$\mathrm{OPT}(\widehat{C}) = \mathrm{OPT}(C) + K - k,$$

and can be constructed in FPT time. Suppose for contradiction that there is an FPT-time algorithm which can distinguish between

$$\mathrm{OPT}(\widehat{C}) \le K \qquad \text{and} \qquad \mathrm{OPT}(\widehat{C}) > K \cdot f(N)^{\alpha(K)}.$$

Since for sufficiently large N depending only on K, padding-stability gives $f(N) = f(n + K - k) \le f(n)^2$, and f is unbounded, we have

$$K \cdot f(N)^{\alpha(K)} \le K \cdot f(n)^{2\alpha(K)} \le K \cdot f(n)^{1/(2g(k))} \le K - k + k \cdot f(n)^{1/g(k)}.$$

Thus, the same algorithm can also distinguish between

$$\mathrm{OPT}(C) \le k \qquad \text{and} \qquad \mathrm{OPT}(C) > k \cdot f(n)^{1/g(k)}$$

in FPT time, a contradiction. ◀

3 An FPT-time $O(2^k \log n)$-Approximation for k-MMSA$_3$

▶ **Theorem 3.1.** *There is a deterministic FPT-time $O(2^k \log n)$-approximation algorithm for k-MMSA$_3$ on n input bits.*

Proof. Write the input instance as

$$C(x) = \bigwedge_{i=1}^{n} \bigvee_{j=1}^{n} \bigwedge_{t \in N_{i,j}} x_t,$$

where $N_{i,j} \subseteq [n]$ for every $i, j \in [n]$. By Lemma 2.4, we can without loss of generality assume that $|N_{i,j}| \le k$.

The algorithm proceeds by repeatedly assigning some variables to 1, until the whole instance C is satisfied. Let

$$S = \{i \in [n] \mid x_i = 1\}$$

be the set of variables that are assigned to 1, the i-th clause

$$\left(\bigvee_{j=1}^{n} \bigwedge_{t \in N_{i,j}} x_t \right)$$

is covered if and only if there exists some term $j \in [n]$ such that $N_{i,j} \subseteq S$. Let

$$\mathrm{Cov}(S) = \{i \in [n] \mid \exists j \in [n] \text{ with } N_{i,j} \subseteq S\}.$$

The algorithm starts with $S_0 = \emptyset$. In the r-th iteration, it takes the set $N_{a,b}$ maximizing the number of newly covered indices

$$\left|\mathrm{Cov}(S_{r-1} \cup N_{a,b}) \setminus \mathrm{Cov}(S_{r-1})\right|,$$

and sets $S_r = S_{r-1} \cup N_{a,b}$. Given the fact that $|N_{i,j}| \leq k$ for every $i, j \in [n]$, it suffices to prove that the algorithm stops after $O(2^k \log n)$ iterations, and thus outputs a satisfying assignment of C with weight at most $O(k \cdot 2^k \log n)$.

Let $x \in \{0,1\}^n$ be a satisfying assignment of C and let $X = \mathrm{supp}(x)$. Fix the r-th iteration, let

$$U_r = [n] \setminus \mathrm{Cov}(S_r)$$

be the set of currently uncovered indices. For every $i \in U_r$, since x satisfies C, there exists some witness $j = j(i) \in [n]$ with $N_{i,j(i)} \subseteq X$. Every chosen witness is a subset of X, and X has at most 2^k distinct subsets. Therefore, by an averaging argument, some set $W \subseteq X$ appears as $N_{i,j(i)}$ for at least $|U_r|/2^k$ indices $i \in U_r$. The best enumerated set covers at least $|U_r|/2^k$ currently uncovered indices. Consequently,

$$|U_{r+1}| \leq \left(1 - \frac{1}{2^k}\right) |U_r|.$$

Iterating this inequality, for $T = \lceil 2^k \ln n \rceil$,

$$|U_T| \leq n \left(1 - \frac{1}{2^k}\right)^T \leq n \exp\left(-\frac{T}{2^k}\right) < 1.$$

Since $|U_T|$ is an integer, $U_T = \emptyset$. Thus, the algorithm returns a satisfying assignment for C with weight at most $kT = O(k2^k \log n)$.

The algorithm is deterministic and runs in FPT time: it performs $O(2^k \log n)$ iterations, and in each iteration it enumerates at most n^2 candidate sets and computes their gains in polynomial time. This proves the theorem. ◀

4 A Reduction from (k, h)-gap MMSA$_3$ to $(2^k, h/k)$-gap MMSA$_2$

▶ **Theorem 4.1.** *There is an FPT-time reduction, which takes as input a k-MMSA$_3$ instance*

$$F(z) = \bigwedge_{i \in [n]} \bigvee_{j \in [n]} \bigwedge_{t \in N_{i,j}} z_t,$$

on $z \in \{0,1\}^n$, outputs a 2^k-MMSA$_2$ instance G on $x \in \{0,1\}^{n^2}$, such that

- *(Completeness) If $\mathrm{OPT}(F) \leq k$, then $\mathrm{OPT}(G) \leq 2^k$.*
- *(Soundness) Fix any $h > k$, if $\mathrm{OPT}(F) > h$, then $\mathrm{OPT}(G) > h/k$.*

The reduction contracts each distinct bottom conjunction of F into one variable of the k-MMSA$_2$ instance G. Namely, for every distinct set $N_{i,j}$ we create a variable intended to mean that all original variables in $N_{i,j}$ are set to 1. Since there are at most n^2 bottom conjunctions, this gives at most n^2 variables.

For completeness, suppose F has a satisfying assignment z whose support Z has size at most k. Every bottom conjunction that is true under z corresponds to a set $N_{i,j} \subseteq Z$ of size $\leq k$, and there are at most 2^k many such sets. Setting the variables representing these true conjunctions to one gives a satisfying assignment of G of weight at most 2^k.

For soundness, suppose G has a satisfying assignment x of weight at most h/k. Decode x back to an assignment z for F by taking the union of all sets represented by the ones in x. Since every represented set has size at most k, the decoded assignment has weight at most h.

Proof of Theorem 4.1. Let

$$\mathcal{S} := \{N_{i,j} \mid i, j \in [n]\}.$$

By Lemma 2.4, we can without loss of generality assume that every set in $\mathcal{S}$ has size at most k. Since $|\mathcal{S}| \leq n^2$, fix an injective map $f : \mathcal{S} \to [n^2]$. For every $i, j \in [n]$, write

$$s_{i,j} := f(N_{i,j}).$$

For every $s \in \mathrm{Im}(f)$, let T_s denote the unique set in $\mathcal{S}$ such that $f(T_s) = s$.

Define the k-MMSA$_2$ instance

$$G(x) := \bigwedge_{i \in [n]} \bigvee_{j \in [n]} x_{s_{i,j}}.$$

The instance uses at most n^2 variables and has size $n^{O(1)}$. It can clearly be constructed in polynomial time, and hence in FPT time.

Completeness. Suppose there exists $z \in \{0,1\}^n$ such that $F(z) = 1$ and $\|z\|_0 \leq k$. Let

$$Z := \mathrm{supp}(z) = \{t \in [n] : z_t = 1\}.$$

Define $x \in \{0,1\}^{n^2}$ by

$$x_s := \begin{cases} 1, & \text{if } s \in \mathrm{Im}(f) \text{ and } T_s \subseteq Z, \\ 0, & \text{otherwise.} \end{cases}$$

We first show that $G(x) = 1$. Fix any $i \in [n]$. Since $F(z) = 1$, there exists some $j \in [n]$ such that

$$\bigwedge_{t \in N_{i,j}} z_t = 1,$$

equivalently, $N_{i,j} \subseteq Z$. As $T_{s_{i,j}} = N_{i,j}$, the definition of x gives $x_{s_{i,j}} = 1$. Therefore every outer clause of G is satisfied, and hence $G(x) = 1$.

It remains to bound the weight of x. If $x_s = 1$, then $s \in \mathrm{Im}(f)$ and $T_s \subseteq Z$. Because f is injective, distinct coordinates correspond to distinct subsets of Z. Hence

$$\|x\|_0 \leq 2^{|Z|} \leq 2^k.$$

Thus $\mathrm{OPT}(G) \leq 2^k$.

Soundness. Fix $h > k$, and suppose for contradiction that there exists $x \in \{0,1\}^{n^2}$ such that $G(x) = 1$ and $\|x\|_0 \leq h/k$. Let

$$\mathcal{A} := \{T_s \mid s \in \mathrm{Im}(f) \text{ and } x_s = 1\}$$

be the family of original bottom sets represented by the selected variables of G, and let

$$U := \bigcup_{T \in \mathcal{A}} T.$$

Define $z \in \{0,1\}^n$ to be the indicator vector of U.

Since every $T \in \mathcal{A}$ has size at most k, and since $|\mathcal{A}| \leq \|x\|_0$, we have

$$\|z\|_0 = |U| \leq \sum_{T \in \mathcal{A}} |T| \leq k \cdot |\mathcal{A}| \leq k\|x\|_0 \leq h.$$

We now show that $F(z) = 1$. Fix any $i \in [n]$. Since $G(x) = 1$, there exists some $j \in [n]$ such that $x_{s_{i,j}} = 1$. By construction, $T_{s_{i,j}} = N_{i,j}$, so $N_{i,j} \in \mathcal{A}$ and therefore $N_{i,j} \subseteq U = \mathrm{supp}(z)$. Hence

$$\bigwedge_{t \in N_{i,j}} z_t = 1.$$

This holds for every $i \in [n]$, so $F(z) = 1$, contradicting $\mathrm{OPT}(F) > h$. ◀

▶ **Corollary 4.2.** *For any computable function $t(n,k)$, if there is an FPT-time $t(n,k)$-approximation for k-MMSA$_2$, then there is an FPT-time $(t(n^2, 2^k) \cdot 2^k)$-approximation for k-MMSA$_3$. Equivalently, if there is no FPT-time $t(n,k)$-approximation for k-MMSA$_3$, then there is no FPT-time $\frac{t(\sqrt{n}, \log k)}{k}$-approximation for k-MMSA$_2$.*

In particular, a $(\log n)^{\Omega(1)}$-factor FPT inapproximability for k-MMSA$_3$ under W[1] $\neq$ FPT, or an $\omega(2^k)$-factor FPT inapproximability for k-MMSA$_3$ under W[2] $\neq$ FPT, could imply new FPT inapproximability results for k-MMSA$_2$ under the respective assumptions, improving [17, 19, 20].

5 A Reduction from k-MMSA$_t$ to Gap k-MMSA$_{t+2}$

In this section, we first summarize known inapproximability results for k-MMSA$_4$, then introduce [22]'s reduction from k-MMSA$_t$ to k-MMSA$_{t+2}$, and finally plug a better set of parameters into it to get improved inapproximability of k-MMSA$_4$ under W[2] $\neq$ FPT and ETH.

5.1 Inapproximability of k-MMSA$_4$ from Literature

The following inapproximability on k-MaxCover was from [17, 18]. We remark that [17] also provides the inapproximability under other assumptions such as SETH or the k-SUM Hypothesis. However, we choose to present only the most relevant assumptions here.

▶ **Lemma 5.1** (Inapproximability of k-MaxCover [17, 18])**.**

- *Assuming* W[1] $\neq$ FPT*, no FPT algorithm can approximate k-MaxCover within an $n^{1/\mathsf{poly}(k)}$ factor.*
- *Assuming* ETH*, no $n^{o(k)}$-time algorithm can approximate k-MaxCover within an $n^{1/\mathsf{poly}(k)}$ factor.*

Passing Lemma 5.1 through the reduction chain of Lemmas 2.6–2.8, we have:

▶ **Corollary 5.2** (Inapproximability of k-MMSA$_4$, implicit in [17, 18]).

- *Assuming* W[1] $\neq$ FPT*, no FPT algorithm can approximate k-MMSA$_4$ within an $n^{o(1)}$ factor.*
- *Assuming* ETH*, no $n^{o(k)}$-time algorithm can approximate k-MMSA$_4$ within an $n^{1/\mathsf{poly}(k)}$ factor.*

Marx [22] also showed a total-FPT-inapproximability for k-MMSA$_4$ under the weaker assumption W[2] $\neq$ FPT.

▶ **Lemma 5.3** ([22]). *Assuming* W[2] $\neq$ FPT*, for any computable function f, no FPT algorithm can approximate k-MMSA$_4$ within an $f(k)$ factor.*

5.2 Revisiting Marx's Reduction

▶ **Theorem 5.4** (Adapted from [22]). *Let $t \in \mathbb{N}^+$ and let $h \geq k$. Given a k-MMSA$_t$ instance C on n variables and an (n, m, Σ, h)-perfect hash family $\mathcal{F} = \{f_1, \ldots, f_m\}$ with $|\Sigma| \geq k$, there is a reduction that outputs a k-MMSA$_{t+2}$ instance C' on the same n variables such that:*

- *the size and running time are at most $\left(m \cdot \binom{|\Sigma|}{k} \cdot |C|\right)^{O(1)}$;*
- *if C has a satisfying assignment of weight at most k, then the same assignment satisfies C';*
- *if every satisfying assignment of C has weight at least $k+1$, then every satisfying assignment of C' has weight more than h.*

Proof. For every $i \in [m]$ and every $T \in \binom{\Sigma}{k}$, write

$$N_{i,T} := f_i^{-1}(T).$$

Define

$$C'(x) := \bigwedge_{i \in [m]} \bigvee_{T \in \binom{\Sigma}{k}} C\big(x \wedge \mathbf{1}_{N_{i,T}}\big).$$

This is a monotone circuit with two additional outer layers, hence an MMSA$_{s+2}$ instance, and its size is bounded by $\left(m \cdot \binom{|\Sigma|}{k} \cdot |C|\right)^{O(1)}$.

For completeness, let x be a satisfying assignment of C with support $X \subseteq [n]$ and $|X| \leq k$. For every $i \in [m]$, choose $T_i \in \binom{\Sigma}{k}$ such that

$$f_i(X) \subseteq T_i.$$

This is possible because $|f_i(X)| \leq |X| \leq k$ and $|\Sigma| \geq k$. Then $X \subseteq N_{i,T_i}$, so

$$x \wedge \mathbf{1}_{N_{i,T_i}} = x.$$

Therefore every outer conjunction of C' is satisfied, and hence $C'(x) = 1$.

For soundness, let x be any satisfying assignment of C' and let $X = \mathrm{supp}(x)$. Since $C'(x) = 1$, for every $i \in [m]$ there exists some $T_i \in \binom{\Sigma}{k}$ such that

$$C\big(x \wedge \mathbf{1}_{N_{i,T_i}}\big) = 1.$$

By the soundness assumption on C, the assignment $x \wedge \mathbf{1}_{N_{i,T_i}}$ must have weight at least $k+1$. Equivalently,

$$|X \cap N_{i,T_i}| \geq k+1 \qquad \text{for every } i \in [m].$$

Suppose toward contradiction that $|X| \leq h$. Since $\mathcal{F}$ is an (n, m, Σ, h)-perfect hash family, there exists some $i^\star \in [m]$ such that $f_{i^\star}$ is injective on X. For this $i^\star$, every $T \in \binom{\Sigma}{k}$ can contain images of at most k elements of X. Thus

$$|X \cap f_{i^\star}^{-1}(T)| \leq k \qquad \forall T \in \binom{\Sigma}{k},$$

contradicting

$$|X \cap N_{i^\star,T_{i^\star}}| \geq k+1.$$

Hence $|X| > h$. ◀

▶ Remark 5.5. We remark that the goal of Marx [22] was to rule out $f(k)$-factor FPT approximation algorithms for any computable function f. Thus, it was sufficient for him to choose h to be larger than the approximation factor $f(k)$. In his hardness proof, h was used as the parameter of an intermediate *FPT cost-approximation algorithm*, which in turn forced h to depend only on k. In contrast, our argument proceeds more directly, allowing us to choose h to be as large as $n^{O(1/k)}$.

We apply Theorem 5.4 using an (n, m, Σ, h)-perfect hash family from Lemma 2.2 with $h = n^{\Theta(1/k)}$, $|\Sigma| = h^2$ and $m = h^{O(1)} \log n$. Then

$$\binom{|\Sigma|}{k} \leq h^{2k},$$

so the reduction size and running time are bounded by

$$\left(m \cdot \binom{|\Sigma|}{k} \cdot |C|\right)^{O(1)} = \left(h^{O(1)} \log n \cdot h^{2k} \cdot |C|\right)^{O(1)} \leq n^{O(1)}.$$

It was known [5] that under ETH, k-MMSA$_2$ (a.k.a. k-SetCover) cannot be solved in $n^{o(k)}$ time. We thus have the following immediate corollary:

▶ **Corollary 5.6.** *Assuming* ETH*, no $n^{o(k)}$-time algorithm can approximate k-MMSA$_4$ within some $n^{O(1/k)}$ factor.*

Using the same set of parameters and invoking the padding lemma (Lemma 2.8), we also have the following W[2]-hardness:

▶ **Corollary 5.7.** *Assuming* W[2] $\neq$ FPT*, no FPT algorithm can approximate k-MMSA$_4$ within any $n^{o(1)}$ factor.*

Corollary 5.6 and Corollary 5.7 improve upon Corollary 5.2 and Lemma 5.3, respectively.

Abstract

We consider discrete allocation problems where m indivisible goods need to be allocated among n agents. When agents' valuation functions are additive, the well-known cycle canceling lemma [39, 47, 45] plays a key role in the design and analysis of rounding algorithms. In this paper, we prove an analogous lemma for the case of submodular valuations. Our algorithm removes cycles in the support graph of a fractional allocation while guaranteeing that each agent's value, measured using the multilinear extension, does not decrease.

We demonstrate applications of the cycle-canceling algorithm, along with other ideas, to obtain new algorithms and results for three well-studied allocation objectives: max-min (Santa Claus problem), Nash social welfare (NSW), and maximin-share (MMS). For the submodular NSW problem, we obtain a $\frac{1}{5}$-approximation; for the MMS problem, we obtain a $\frac{1}{2}(1-1/e)$-approximation through new simple algorithms. For various special cases where the goods are "small" valued or the number of agents is constant, we obtain tight/best-known approximation algorithms. All our results are in the value-oracle model.

1 Introduction

Allocation problems are fundamental to both theory and practice. They arise naturally in diverse applications from optimization to fair division, and have been an influential source of techniques in discrete (combinatorial) optimization. In this paper we give a new tool for addressing allocation problems with submodular valuations.

Consider the problem of allocating a set $\mathcal{M}$ of m *indivisible* items to a set $\mathcal{N}$ of n agents with diverse preferences. An allocation can be viewed as a partition of $\mathcal{M}$ into sets $S_1, S_2, \ldots, S_n$ with S_i being the set given to agent i. Each agent i has a valuation function $v_i : 2^{\mathcal{M}} \to \mathbb{R}_+$ where $v_i(S)$ is the value that they obtain for subset $S \subseteq \mathcal{M}$. We will assume v_is to be *monotone submodular*[2], capturing decreasing marginal returns, and normalized so that $v_i(\emptyset) = 0$. Throughout this work, we denote an instance of the allocation problem by $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$ and the set of all allocations as $\Pi_{|\mathcal{N}|}(\mathcal{M})$.

Allocation problems with submodular valuations are extensively studied within optimization [43, 20, 25] and fair division [42, 35, 48, 32, 29] communities under various objective functions. Also, see Section 1.1 for more detailed related works. A prominent example is to allocate items to maximize social welfare: find an allocation $S_1, \ldots, S_n$ to max $\sum_{i\in\mathcal{N}} v_i(S_i)$. While this is trivial for additive valuations (simply assign each good to the agent that values it the most), it is an interesting optimization problem for submodular valuations, and is NP-Hard. A simple greedy algorithm achieves an approximation ratio of 1/2 [44, 38] while a much more sophisticated approach achieves a tight approximation ratio of $(1 - 1/e)$ [49, 15]. The latter result was instrumental in developing the multilinear relaxation approach for submodular maximization problems. In this paper, we are concerned with more challenging objectives arising from fairness, efficiency, and other considerations, with the goal of designing unifying tools and techniques. Three such objectives are: (i) Max-min allocation (also referred to as the (Submodular) Santa Claus problem) [42], (ii) Nash Social Welfare (NSW) [36], and (iii) Maximin-share (MMS) [13]. These problems are well-known to be challenging even when agents' valuation functions are additive, i.e, $v_i(S) = \sum_{j\in S} v_i(\{j\})$ for all $i \in \mathcal{N}$. See Section 1.1 for more details about these problems.

Relax-and-round is a natural approach for most of these problems, where first a good *fractional allocation* is obtained and then rounded to an integral allocation while incurring some loss. The purpose of this paper is to develop a widely applicable technical tool that helps round a fractional allocation effectively under submodular valuations. We further highlight the utility of this tool by instantiating it on the above mentioned three objectives. Our tool is inspired by a corresponding result in the additive setting: A fractional allocation is an $m \cdot n$ dimensional vector $\mathbf{x}$ which we interpret as consisting of values $x_{i,j}$ for $i \in \mathcal{N}$ and $j \in \mathcal{M}$; $x_{i,j} \in [0, 1]$ is the fractional amount of item j that is assigned to agent i. We require that $\sum_i x_{i,j} = 1$ for each item j. We let $\mathbf{x}_i$ denote the m-dimensional vector consisting of the variables $x_{i,j}$, $j \in [m]$. Each fractional allocation $\mathbf{x}$ defines an allocation graph $G_{\mathbf{x}}$ which is a bipartite graph with agents on one side and items on the other side and an edge between i and j labeled with the number $x_{i,j}$ iff $x_{i,j} > 0$; in other words it is a representation of the support of $\mathbf{x}$. For a fractional allocation $\mathbf{x}$ the value of agent i in the additive setting, denoted by $v_i(\mathbf{x}_i)$ is naturally defined as $\sum_j v_i(\{j\})x_{i,j}$. Then the following rounding procedure is known.

▶ **Lemma 1** ([39, 47]). *Let* $\mathbf{x}$ *be a fractional allocation and* v_i *additive functions. Then there is another allocation* $\mathbf{y}$ *in the support of* $\mathbf{x}$ *such that (i) the allocation graph* $G_{\mathbf{y}}$ *has no cycles and (ii) for all agents* i, $v_i(\mathbf{y}_i) \geq v_i(\mathbf{x}_i)$. *Furthermore, the allocation* $\mathbf{y}$ *can be rounded to an integral allocation* $\mathcal{A} = (A_1, \ldots, A_n)$ *such that for all agents* i, $v_i(A_i) \geq V_i(\mathbf{y}_i) - \alpha_i$ *where* $\alpha_i = \max_{j:y_{i,j}>0} v_i(\{j\})$.

[2] A real-valued set function $f : 2^{\mathcal{M}} \to \mathbb{R}_+$ is submodular if $f(A + g) - f(A) \geq f(B + g) - f(B)$ for any $A \subseteq B$ and $g \in B \setminus A$; in other words the function exhibits diminishing marginal utility. Monotonicity means that $f(A) \leq f(B)$ for all $A \subseteq B$.

▶ **Corollary 2.** *Suppose* $\mathbf{x}$ *is a fractional allocation such that* $\max_{j:x_{i,j}>0} v_i(\{j\}) \leq \epsilon v_i(\mathbf{x}_i)$ *for each agent* i*. Then there is an integral allocation* $\mathbf{z}$ *such that* $v_i(\mathbf{z}_i) \geq (1-\epsilon)v_i(\mathbf{x}_i)$*.*

The corollary immediately allows one to find a good approximation in the so-called "small" items scenario. One can view the lemma and the corollary as interpolating between the fully fractional setting (which can be solved optimally via LP) and the discrete setting in which no single item is too important to an agent. The utility of the lemma can be understood by considering an alternative rounding strategy: randomly allocate each item independently to an agent based on fractional solution. The parameters obtained by such a rounding are much weaker – a logarithmic factor in the number of agents is typically lost since one has to rely on concentration inequalities followed by a union bound.

Here we generalize the preceding lemma to the submodular setting. In order to do this we need to work with a continuous extension of submodular functions. As mentioned above, for maximization problems the multilinear extension [14] has played a natural role.

▶ **Definition 3** (Multilinear Extension of f)**.**

$$F(x) \coloneqq \sum_{S \subseteq V} f(S) \prod_{j \in S} x_j \prod_{j \in V \setminus S} (1 - x_j) \tag{1}$$

It inherits some useful properties of submodularity and moreover, its value and partial derivatives can be evaluated for a given point $\mathbf{x}$ via random sampling.

Our first contribution is to formulate and prove the following theorem.

▶ **Theorem 4.** *Given an instance of the allocation problem* $(\mathcal{N}, \mathcal{M}, (v_i)_{i \in \mathcal{N}})$ *with monotone submodular valuations* v_i*, and a fractional allocation* $\mathbf{x}$ *of the goods to the agents, there is a fractional allocation* $\mathbf{x}'$ *such that (i) the allocation graph* $G_{\mathbf{x}'}$ *is acyclic, and (ii)* $V_i(\mathbf{x}') \geq V_i(\mathbf{x})$ *for all agents* $i \in \mathcal{N}$*; where* V_i *is the multilinear extension of* v_i*.*

We state the preceding theorem in a non-constructive way. A polynomial-time algorithm requires one to use approximations due to the sampling aspects of the multilinear extension. We defer formal details of this to a full version of the paper since they are somewhat standard. An efficient version of the lemma yields an allocation that loses a $(1 - o(1))$-factor in the value for each agent which we ignore in this version. See the end of Section 2 for more details.

Next we discuss application of this lemma to obtained improved algorithms and/or results for the three objectives mentioned above.

1.1 Applications

We demonstrate the utility of Theorem 4 on three problems that arise in fair allocation. The focus is not on obtaining improved approximation factors, but rather to illustrate how the cycle canceling procedure can be applied in conjunction with other ideas to design new relaxation-based algorithms. Table 1 gives a summary of our results.

All the three applications we discuss in this paper have seen a lot of work in the literature. While the table gives the current best-known guarantees, we discuss more details here.

[3] The results from [43] are for welfare maximization. However, the structure of instance used for the reduction directly implies the same bound for the problems mentioned here.

Table 1 Summary of Applications of Theorem 4. For the result marked with (*), while our result matches the existing result, we need ϵ to be a constant independent of n in this paper whereas the prior work required ϵ to be $\Omega(1/\log n)$. Results marked with (**) are information theoretic lower bounds whereas the other results are NP-hardness.

Fairness Notion	Problem Setting	Lower Bound	Prior Work	This Paper
Max-min	$v_i(j) \leq \epsilon\mathsf{OPT}\ \forall i,j$	–	–	$(1-1/e-\epsilon)$
Max-min	Constant n	$(1-1/e+\epsilon)$ [43] **	$(1-1/e-\epsilon)$ [20]	$(1-1/e-\epsilon)$*
NSW	General	$(1-1/e+\epsilon)$ [32]	$\approx 1/3.9$ [11]	1/5
NSW	Constant n	$(1-1/e+\epsilon)$ [32]	$(1-1/e-\epsilon)$ [32]	$(1-1/e-\epsilon)$*
MMS	General	$(1-1/e+\epsilon)$ [43][3]**	≈ 0.370 [48]	≈ 0.316
MMS	$v_i(j) \leq \epsilon\mathsf{MMS}_i\ \forall i,j$	–	≈ 0.370 [48]	$(1-1/e-\epsilon)$

1.1.1 Santa Claus (Max-min)

In Section 3.1, we investigate the max-min objective where given an instance of the fair allocation problem, $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$, the goal is to output an allocation $\mathcal{A} = \{A_1, \ldots, A_n\} \in \Pi_{|\mathcal{N}|}(\mathcal{M})$ that maximizes $\min_{i\in\mathcal{N}} v_i(A_i)$. It is alternatively referred to as the Santa Claus problem.

1.1.1.1 Related work

Max-min was first considered as a fair allocation problem by [42]. There has been substantial work since then. Despite this, the approximability is still not well understood even in the additive setting. [12] showed that one cannot approximate max-min to a factor better than 2 in the additive setting unless P = NP. On the positive side, [8] gave an $O(\frac{\log\log m}{\log\log\log m})$-approximation algorithm in the restricted assignment setting (i.e., for each agent $v_i(\{j\}) \in \{v_j, 0\}$). The current best approximation for this setting is $\frac{1}{4+\epsilon}$ [22]. In the general setting, [17] gave a $\tilde{\Omega}(\frac{1}{n^\epsilon})$ approximation algorithm in time $n^{O(1/\epsilon)}$; in particular this implies a $\Omega(\frac{1}{poly(\log n)})$-approximation in quasi-polynomial time. These results were extended to the submodular setting: [7] gave a $\Omega(\frac{1}{poly(\log n)})$-approximation algorithm with running time $n^{O(\log n/\log\log n)}$, and for any fixed $\epsilon > 0$; a $\tilde{\Omega}(\frac{1}{n^\epsilon})$-approximation algorithm with running time $n^{O(1/\epsilon)}$. For the restricted case with submodular valuations, [6] gave an $\Omega(\frac{1}{\log\log n})$-approximation algorithm. Here, restricted submodular Santa Claus is defined as follows: there is a common submodular valuation function v, each agent has a subset $X_i \subseteq \mathcal{M}$ and the value of agent i is $v_i(S) = v(S \cap X_i)$. Another result known for additive valuations was by [12] who showed that there is always an allocation which gives each agent a value of at least $(\mathsf{OPT} - \max_{i\in\mathcal{N}, j\in\mathcal{M}} v_i(j))$ where OPT is the optimal max-min value, and this is via the cycle-cancellation lemma.

1.1.1.2 Our Contributions

In this work, we study the *submodular* Santa Claus problem. We show an additive approximation guarantee that is analogous to the result in [12] for additive valuations. While additive and multiplicative approximation guarantees are incomparable in general, when the goods are small valued, additive approximation imply multiplicative approximations. We thereby achieve the first non-trivial multiplicative approximation for the small-goods case with submodular valuations. Furthermore, we give a $(1-1/e-\epsilon)$ approximation for the case when the instance has a fixed number of agents. This was previously known from [20], however, we achieve a more efficient algorithm (see Remark 15).

1.1.2 Nash social welfare (NSW)

In Section 3.2, we investigate Nash social welfare which is a popular fairness *and* efficiency notion. The objective is to find an allocation $\mathcal{A} = (A_1, \ldots, A_n)$ that maximizes the geometric mean of agent valuations i.e., $\mathcal{A} = \text{argmax}_{S \in \Pi_{|\mathcal{N}|}(\mathcal{M})} \left(\prod_{i \in [n]} v_i(S_i)\right)^{1/n}$.

1.1.2.1 Related work

The Nash social welfare (NSW) objective has been proved to offer a natural balance between utilitarian welfare (sum of utilities) and fairness (max–min welfare) [36, 16]. Even for additive valuations, maximizing NSW is APX-hard [37] and obtaining a constant factor approximation was challenging. The first constant factor for additive valuations was presented by Cole and Gkatzelis [24], using a market equilibrium approach. Alternative approaches were found afterwards, using either market equilibria or fractional relaxations, that provide constant factors for additive, budget-additive and piecewise-linear concave valuations [4, 5, 23, 10, 28]. For submodular valuations, [32] gave the first approximation independent of the number of goods using a "matching-rematching" along with greedy allocation approach. [30] extended the matching-rematching approach along with fractional allocations and proved a constant factor for "Rado valuations" (a subclass of submodular valuations related to matroids). This framework was thereafter extended to a 1/380-approximation for submodular valuations by [40], which was subsequently improved to a 1/4-approximation using matching-rematching and local search [29]. A recent line of work [27, 26, 11] studied the *weighted* NSW problem, maximizing the weighted geometric mean of valuations, and obtained constant-factor approximations for additive and submodular valuations even in this setting. For additive valuations, their guarantees match the best known bound for unweighted NSW ($e^{1/e}$) from [10]; for submodular valuations, the most recent approximation factor is $\sim \frac{1}{3.56}$ [11] via computer-aided analysis. These algorithms are based on a configuration-type relaxation and randomized rounding.

1.1.2.2 Our Contributions

Our primary result here is to present a simple algorithm that still achieves a small constant-factor approximation for submodular NSW. Our algorithm is based on the matching-relaxation-rematching framework like [32, 30, 40] and provides a 1/5-approximation guarantee. Additionally, we also give a $(1 - 1/e - \epsilon)$-approximation for the case when the instance has constantly many agents in a more efficient manner than was previously done by [32] (see Remark 21).

1.1.3 Maximin Share (MMS)

In Section 3.3, we look at the Maximin share objective. An agent's MMS value, denoted by MMS_i is the maximum value she can ensure for herself if she divides the goods into n parts and chooses the worst part for herself.

1.1.3.1 Related work

Maximin Share (MMS) was defined as a fairness notion by [13]. [46] proved that MMS-allocations i.e., allocations that give every agent their MMS value need not exist even with additive valuations. Therefore, a series of works that obtain α-MMS allocation, i.e., each agent receives a value of α-MMS have been studied for additive valuations [46, 3, 33, 34, 2, 1]

culminating in a $3/4 + O(1)$-approximation. The algorithms in these works are mostly combinatorial and rely on either matching-based or greedy-based techniques. For general valuations, [9, 35] initiated the study for approximate MMS allocations. [9] gave a $\sim 1/10$ approximation algorithm via round-robin allocation and [35] gave a 1/3-approximation via local search. Recently, [48] gave an algorithm that provides 10/27-approximation to MMS using a greedy algorithm. For a subclass of submodular valuations called SPLC, [19] gave a 1/2 approximation algorithm based on market-equilibrium solution followed by rounding. Several other works on MMS on other valuation functions or in constrained settings exist that we do not list here.

1.1.3.2 Our Contributions

Our main theorem naturally extends the equilibrium-rounding approach to submodular valuations to give a $\frac{1}{2}(1-1/e-o(1))$-approximation algorithm. Additionally, when the goods are small compared to the MMS value (at most ϵMMS), we obtain a novel $(1-1/e-\epsilon)$-MMS allocation using the same approach.

2 Cycle-Cancellation under Multilinear Extension

In this section we present the main technical contribution of this work – Theorem 4. This theorem states that given an instance $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$ of the allocation problem and any fractional allocation $\mathbf{x}$, we can convert it to an allocation with at most $|\mathcal{N}|-1$ fractional variables whose allocation graph forms a forest, while retaining the value received by any agent *under the multilinear relaxation*. It is well-known that when the function is submodular, the multilinear extension is convex in any $\mathbf{e}_i - \mathbf{e}_j$ direction [14]. We first generalize this to show that the multilinear extension is convex in any direction given by $t_i\mathbf{e}_i - t_j\mathbf{e}_j$, where $t_i, t_j \geq 0$. This allows us to argue how the function value changes when we move goods along a cycle allowing us to eventually cancel cycles in the allocation graph.

▶ **Theorem 4.** *Given an instance of the allocation problem $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$ with monotone submodular valuations v_i, and a fractional allocation $\mathbf{x}$ of the goods to the agents, there is a fractional allocation $\mathbf{x}'$ such that (i) the allocation graph $G_{\mathbf{x}'}$ is acyclic, and (ii) $V_i(\mathbf{x}') \geq V_i(\mathbf{x})$ for all agents $i \in \mathcal{N}$; where V_i is the multilinear extension of v_i.*

Before we prove the theorem, we see what happens to the value of the multilinear extension when for two goods i, j with $i \neq j$, we increase the allocation of good i by t_i and decrease the amount of good j by t_j. We remark that an equivalent lemma appears in an independent work on the knapsack problem with a submodular objective [41].

▶ **Lemma 5.** *Given a submodular function f with multilinear extension F, and allocations $\mathbf{x} = (x_1, \ldots, x_m)$ and $\bar{\mathbf{x}} = (x_1, \ldots, x_i + t_i, \ldots, x_j - t_j, \ldots, x_m)$, for any t_i, t_j such that either both $t_i \geq 0$ and $t_j \geq 0$, or both $t_i \leq 0$ and $t_j \leq 0$, we have,*

$$F(\bar{\mathbf{x}}) - F(\mathbf{x}) \geq t_i \frac{\partial F}{\partial x_i}\Big|_{\mathbf{x}} - t_j \frac{\partial F}{\partial x_j}\Big|_{\mathbf{x}}.$$

Proof. Let $\mathbf{x} = (x_1, \ldots, x_m)$, $\bar{\mathbf{x}} = (x_1, \ldots, x_i + t_i, \ldots, x_j - t_j, \ldots, x_m)$ and $P_{\mathbf{x}}(R) = \prod_{g\in R} x_g \prod_{g\in[m]\setminus R}(1 - x_g)$. Note that $\mathbf{x}$ and $\bar{\mathbf{x}}$ differ in probabilities only on the goods i and j. Therefore, when we expand the multilinear extension, the only places the terms differ are on the probabilities of selecting (or not selecting) i or j. We explicitly separate these terms. Towards this, we denote "$R : i, j$" to indicate all sets that include the elements i and j,

"$R : \tilde{i}, \tilde{j}$" are all sets that do not include the elements i and j. "$R : \tilde{i}, j$" and "$R : i, \tilde{j}$" are defined analogously. Further, we define $P_{\downarrow i,j}(R) = \prod_{g \in R \setminus \{i,j\}} x_g \prod_{g \in [m] \setminus R \setminus \{i,j\}} (1 - x_g)$ i.e., the probability of picking a set R according to a distribution $\mathbf{x}$ except that we ignore the probabilities corresponding to i and j. With this notation, we can write the difference of multilinear extensions as:

$$\begin{aligned}
F(\bar{\mathbf{x}}) - F(\mathbf{x}) &= \sum_R (P_{\bar{\mathbf{x}}}(R) - P_{\mathbf{x}}(R)) f(R) \\
&= \sum_{R:\tilde{i},\tilde{j}} P_{\downarrow i,j}(R)(t_j(1-x_i) - t_i(1-x_j) - t_i t_j) f(R) \\
&\quad + \sum_{R:i,\tilde{j}} P_{\downarrow i,j}(R)(t_i t_j + t_i(1-x_j) + x_i t_j) f(R) \\
&\quad + \sum_{R:\tilde{i},j} P_{\downarrow i,j}(R)(t_i t_j - (1-x_i)t_j - t_i x_j) f(R) \\
&\quad + \sum_{R:i,j} P_{\downarrow i,j}(R)(t_i x_j - x_i t_j - t_i t_j) f(R).
\end{aligned}$$

We rewrite the above equations by combining the terms in $t_i t_j$, t_i and t_j together and we get the following equation

$$\begin{aligned}
F(\bar{\mathbf{x}}) - F(\mathbf{x}) =& t_i t_j \sum_{R:\tilde{i},\tilde{j}} P_{\downarrow i,j}(R)(-f(R) + f(R+i) + f(R+j) - f(R+i+j)) \\
&+ t_i \sum_{R:\tilde{i},\tilde{j}} P_{\downarrow i,j}(R)(-(1-x_j)f(R) + (1-x_j)f(R+i) - x_j f(R+j) + x_j f(R+i+j)) \\
&+ t_j \sum_{R:\tilde{i},\tilde{j}} P_{\downarrow i,j}(R)((1-x_i)f(R) - x_i f(R+i) - x_j f(R+j) - x_i f(R+i+j))
\end{aligned}$$

Let $f(R+i) + f(R+j) - f(R) - f(R+i+j) = \alpha_R$. Note that the coefficient of t_i is $\frac{\partial F}{\partial x_i}\Big|_{\mathbf{x}}$ and that of t_j is $-\frac{\partial F}{\partial x_j}\Big|_{\mathbf{x}}$. Substituting these values, we get

$$F(\bar{\mathbf{x}}) - F(\mathbf{x}) = t_i t_j \sum_{R:\tilde{i},\tilde{j}} P_{\downarrow i,j}(R)\alpha_R + t_i \frac{\partial F}{\partial x_i}\Big|_{\mathbf{x}} - t_j \frac{\partial F}{\partial x_j}\Big|_{\mathbf{x}} \geq t_i \frac{\partial F}{\partial x_i}\Big|_{\mathbf{x}} - t_j \frac{\partial F}{\partial x_j}\Big|_{\mathbf{x}}$$

where the second inequality follows since $\alpha_R \geq 0$ for submodular valuation functions and we assumed t_i, t_j to be non-negative. ◀

▶ Remark 6. We note that it is well-known that when f is a submodular function, its multilinear extension F is convex along the direction $e_i - e_j$ for any $i, j \in [m]$. The above lemma proves a stronger version of this result i.e., the multilinear extension is convex along any $t_i e_i - t_j e_j$ for any $i, j \in [m]$ and $t_i, t_j \geq 0$.

We can now prove Theorem 4. Recall that the instance of allocation problem is denoted by $(\mathcal{N}, \mathcal{M}, (v_i)_{i \in \mathcal{N}})$ and we assume that each v_i is submodular. We denote the multilinear extension of v_i by V_i. Note that while we write $V_i(\mathbf{x})$, the value of V_i only depends on the part of $\mathbf{x}$ corresponding to agent i's allocation $\mathbf{x}_i$. Additionally, we use $V'_{i,j}$ to denote the partial derivative of V_i at $\mathbf{x}_i$ with respect to good j.

Proof of Theorem 4. The main idea is that if there is a cycle with fractional values x_{ij}, we can move values along the cycle consistently so that no agent loses in value, and some variable becomes an integer. For any given allocation $\mathbf{x}$, consider a cycle $a_0 - g_0 - a_1 - g_1 -$

$\cdots - a_{\ell-1} - g_{\ell-1} - a_0$ where a_i are the agents and g_i are the goods. To reallocate along the cycle, we need to maintain two constraints: (1) the total fractional allocation of each good remains constant, (2) no agent's value (under the multilinear extension) decreases. To maintain the first constraint, we will change the allocation of good i by δ_i on one edge and $-\delta_i$ on the other adjacent edge. Therefore, a reallocation strategy looks as follows:

$$x'_{a_i g_i} = x_{a_i g_i} + \delta_i$$
$$x'_{a_{i+1} g_i} = x_{a_{i+1} g_i} - \delta_i$$

with index operations modulo ℓ. By Lemma 5, for agent a_i not to lose value, it is sufficient to satisfy:

$$\delta_i V'_{a_i,g_i} - \delta_{i-1} V'_{a_i,g_{i-1}} \geq 0 \tag{2}$$

where, the index operations are modulo ℓ. We get ℓ such inequalities corresponding to the ℓ agents on the cycle. We claim that there is always a non-trivial solution to these inequalities, for any choice of V'_{a_i,g_i}, $V'_{a_i,g_{i-1}}$.

First, if $V'_{a_i,g_i} = 0$ for some agent i, we can set $\delta_{i'} = 0$ for all $i' \neq i$, and choose $\delta_i < 0$ to ensure that the gain of every agent is non-negative. Similarly, if $V'_{a_i,g_{i-1}} = 0$, we can set $\delta_{i'} = 0$ for all $i' \neq i-1$ and choose $\delta_{i-1} > 0$ to ensure that the gain of all agents is non-negative.

Hence, we can assume that $V'_{a_i,g_i} > 0$ and $V'_{a_i,g_{i-1}} > 0$ for all agents on the cycle. In this case, for any value δ_0, we can iteratively find values of $\delta_1, \ldots, \delta_{\ell-1}$ of the same sign such that $\delta_i V'_{a_i,g_i} - \delta_{i-1} V'_{a_i,g_{i-1}} = 0$ for $1 \leq i \leq \ell - 1$. These conditions mandate that $\delta_i = \delta_{i-1} \frac{V'_{a_i,g_{i-1}}}{V'_{a_i,g_i}}$, so we obtain inductively

$$\delta_{\ell-1} = \delta_0 \frac{V'_{a_1,g_0}}{V'_{a_1,g_1}} \frac{V'_{a_2,g_1}}{V'_{a_2,g_2}} \cdots \frac{V'_{a_{\ell-1},g_{\ell-2}}}{V'_{a_{\ell-1},g_{\ell-1}}}.$$

The last remaining condition is that

$$\delta_0 V'_{a_0,g_0} - \delta_{\ell-1} V'_{a_0,g_{\ell-1}} \geq 0$$

which is equivalent to

$$\delta_0 V'_{a_0,g_0} - \delta_0 \frac{V'_{a_1,g_0}}{V'_{a_1,g_1}} \frac{V'_{a_2,g_1}}{V'_{a_2,g_2}} \cdots \frac{V'_{a_{\ell-1},g_{\ell-2}}}{V'_{a_{\ell-1},g_{\ell-1}}} V'_{a_0,g_{\ell-1}} \geq 0.$$

We still have a free choice of $\delta_0 \neq 0$, so we can choose its sign appropriately so that the last condition is satisfied. By construction, this satisfies condition (2) for all agents i.

Denote by $\mathbf{x}'$ the modified fractional solution where $x'_{a_i,g_i} = x_{a_i,g_i} + \delta_i$. By the discussion above, all the δ_i's are determined by δ_0. We want to choose the magnitude of δ_0 so that $\mathbf{x}'$ is feasible and at least one variable on the cycle becomes an integer. This can be accomplished by choosing the supremum or infimum of δ_0 (depending on the desired sign) such that $\mathbf{x}'$ defined by the changes described above is still feasible. We claim that such $\mathbf{x}'$ must have a new integer variable: If all the variables on the cycle are fractional, then there is a larger/smaller value of δ_0 that we can choose and $\mathbf{x}'$ is still feasible. An extreme choice of δ_0 still defines a feasible solution, because the assignment polytope is a closed set.

Finally, we argue that the value for any agent cannot decrease in this operation. After choosing δ_0 as above, the remaining δ_i for $i \in [\ell]$ are chosen as $\delta_i = \delta_{i-1} \frac{V'_{a_i,g_{i-1}}}{V'_{a_i,g_i}}$. Since the partial derivatives are all positive, all δ_is will have the same sign. Therefore, by Lemma 5, we have $V_{a_i}(\mathbf{x}') \geq V_{a_i}(\mathbf{x})$. Note that it is in this step that we use the convexity of the multilinear extension along the direction that we modify our fractional solution. ◀

Note that the proof does not work for non-monotone submodular functions. We could possibly define δ_i to satisfy (2) even for non-monotone submodular functions, but since two variables could be increasing or decreasing at the same time, the relevant multilinear function could be concave rather than convex along the direction of change.

Notes on computational aspects of the procedure: In the discussion above, we ignore the computational issues of computing or estimating the values of $V_i(\mathbf{x})$ and $\frac{\partial V_i}{\partial x_{ij}}$. These issues can be handled by techniques similar to prior work using the multilinear extension: The values of $V_i(\mathbf{x})$ and its partial derivatives are expectations over a certain product distribution and hence can be estimated by random sampling. The sampling error can be made smaller than $\frac{\alpha_i}{poly(m,n)}$ where $\alpha_i = \max_{j \in \mathcal{M}: x_{ij} > 0} v_i(\{j\})$. Since variables are changing by at most 1 in each step, the true change in $V_i(\mathbf{x})$ might be off by $\frac{\alpha_i}{poly(m,n)}$ compared to our estimates. The number of rounding steps is polynomial in m and n (at least one new variable becomes an integer in each step), and hence we can choose the sampling parameters so that the loss for each agent is less than $\frac{\alpha_i}{poly(m,n)}$ at the end. In many applications, this additive error is negligible compared to the loss of α_i which we shall incur in any case due to the rounding on the remaining forest. For completeness, we give our computational result:

▶ **Theorem 7.** *Given an instance of the allocation problem $(\mathcal{N}, \mathcal{M}, (v_i)_{i \in \mathcal{N}})$ with monotone submodular valuations v_i, and a fractional allocation $\mathbf{x}$ of the goods to the agents, in randomized polynomial time, we can compute with high probability another fractional allocation $\mathbf{y}$ such that the support of $\mathbf{y}$ is acyclic, and $V_i(\mathbf{y}) \geq V_i(\mathbf{x}) - \frac{\alpha_i}{poly(m,n)}$ for all agents $i \in [n]$ where V_i is the multilinear extension of v_i and $\alpha_i = \max_{j \in \mathcal{M}: x_{ij} > 0} v_i(\{j\})$.*

3 Applications

In this section we discuss applications of the cycle-cancellation. All applications we discuss use the same rounding based on cycle-cancellation which we call NonUniformPipageRounding and is outlined in Algorithm 1. Similar rounding has appeared in the context where valuations are additive or SPLC[4] (eg., [24, 19]).

Algorithm 1 NonUniformPipageRounding$((\mathcal{N}, \mathcal{M}, (v_i)_{i \in \mathcal{N}}), \mathbf{x})$.

1. Create $\mathbf{x}'$ from $\mathbf{x}$ using Theorem 4.
2. In the forest of $G_{\mathbf{x}'}$, root each tree at an arbitrary agent
3. Allocate each fractional good to its parent in the rooted tree

We can prove the following guarantee of this algorithm.

▶ **Lemma 8.** *Given an instance of the allocation problem, $(\mathcal{N}, \mathcal{M}, (v_i)_{i \in \mathcal{N}})$ and any fractional allocation $\mathbf{x}$, Algorithm 1 (NonUniformPipageRounding) finds an allocation $\mathcal{A} = (A_1, \ldots, A_{|\mathcal{N}|}) \in \Pi_{|\mathcal{N}|}(\mathcal{M})$ such that $v_i(A_i) \geq V_i(\mathbf{x}) - v_i(\ell_i)$ for all $i \in \mathcal{N}$, where $\ell_i = max_{j \in \mathcal{M}} v_i(\{j\})$.*

Proof. From Theorem 4, the agents lose no value in converting to $\mathbf{x}'$. Then, since the graph is acyclic, step 2 can be executed. Since each agent in the rounding can lost at most one good (the parent good), the agents lose a single good. By submodularity (in fact, subadditivity), the lemma follows. ◀

[4] SPLC is a class of functions that capture additive valuations and are a subset of submodular valuations.

▶ Remark 9. As mentioned at the end of previous section, we ignore the computational aspects of cycle-cancellation procedure. All our applications use the NonUniformPipageRounding where the rounding incurs loss of one good. The loss due to computational aspects of cycle-cancellation (result of Theorem 7) is negligible compared to this loss and therefore can be safely ignored. For keeping the notation clean, we do not add that loss here. Similar to the computational version of Theorem 4, we get the following computational version:

▶ **Lemma 10.** *Given an instance of the allocation problem, $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$ and any fractional allocation $\mathbf{x}$, Algorithm 1* (NonUniformPipageRounding)*, in randomized polynomial time finds with high probability an allocation $\mathcal{A} = (A_1, \ldots, A_{|\mathcal{N}|}) \in \Pi_{|\mathcal{N}|}(\mathcal{M})$ such that $v_i(A_i) \geq V_i(\mathbf{x}) - v_i(\ell_i) - \frac{\ell_i}{poly(|\mathcal{N}|,|\mathcal{M}|)}$ for all $i \in \mathcal{N}$, where $\ell_i = max_{j\in\mathcal{M}} v_i(\{j\})$.*

3.1 Approximating Submodular Max-min

The max-min problem also known as the Santa Claus problem is defined as: given an instance of the allocation problem, $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$, output an allocation $\mathcal{A} = (A_i, \ldots, A_{|\mathcal{N}|}) \in \Pi_{|\mathcal{N}|}(\mathcal{M})$ to maximize $\min_{i\in\mathcal{N}} v_i(A_i)$. This value is called the max-min value and we denote it as $\mathsf{OPT} = \max_{\mathcal{A}\in\Pi_{|\mathcal{N}|}(\mathcal{M})} \min_{i\in\mathcal{N}} v_i(A_i)$.

As discussed in Section 1.1.1, our primary aim is to provide an additive approximation for the Submodular Santa Claus problem. We show that this directly gives a multiplicative approximation for "small" goods. Additionally, we also show how to use cycle-cancellation to achieve a multiplicative approximation for the special case when the instance has a fixed number of agents. The key to these results is the NonUniformPipageRounding subroutine (Algorithm 1). To use the subroutine, we naturally need a fractional solution. To obtain this fractional solution for the max-min problem, we use the following result by [20, 18].

▶ **Theorem 11** ([20, 18])**.** *Let $f_1, \ldots, f_n$ be monotone non-negative submodular functions over a common ground set N, $B_1, B_2, \ldots, B_n \in \mathbb{R}_+$ and let $Q \in [0,1]^{|N|}$ be a solvable*[5] *polytope. For every fixed $\epsilon > 0$ there is a polynomial time randomized algorithm that either outputs a point $\mathbf{x} \in Q$ such that for all i,*

$$F_i(\mathbf{x}) \geq (1 - 1/e - \epsilon)B_i$$

or correctly decides that there is no point $\mathbf{x}$ in Q such that $F_i(\mathbf{x}) \geq B_i$ for all i.

▶ **Theorem 12.** *Consider an instance, $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$ of the Submodular Santa Claus problem with the optimal value OPT. Denote the maximum value of any good as $\mathrm{Max} = \max_{i\in\mathcal{N}, j\in\mathcal{N}} v_i(j)$. For any fixed $\epsilon > 0$, one can obtain in randomized polynomial time an allocation $\mathcal{A} = (A_1, \ldots, A_{|\mathcal{N}|})$ such that $v_i(A_i) \geq (1 - 1/e - \epsilon)\mathsf{OPT} - \mathrm{Max}$.*

Proof. First, we obtain a fractional allocation $\mathbf{x} = (\mathbf{x}_1, \ldots, \mathbf{x}_{|\mathcal{N}|})$ such that $V_i(\mathbf{x}_i) \geq (1 - 1/e - \epsilon)\mathsf{OPT}$. This can be done as follows. We guess the value of OPT via binary search. We then define Q as a partition matroid constructed as follows: for each good, create $|\mathcal{N}|$ copies, one corresponding to each agent. All copies of a given good belong to the same part, and there are $|\mathcal{M}|$ such parts, corresponding to each good. An independent set of this matroid can include at most one element from each part. This construction naturally defines an allocation: each selected copy corresponds to a specific agent, and that agent receives

[5] A polytope is called solvable if we can optimize linear functions over the polytope in polynomial time.

the associated good. The agents' valuation functions extend naturally while preserving submodularity: given an independent set of the matroid, the value F_i for agent i is computed by considering only the copies associated with that agent. This construction first appeared in [38]. Assuming that OPT is a valid estimate of a value that each agent can achieve, we use Theorem 11 to find an $\mathbf{x} \in Q$ that achieves $V_i(\mathbf{x}_i) \geq (1 - 1/e - \epsilon)OPT$ for each agent. To round this fractional solution, we apply the NonUniformPipageRounding to $\mathbf{x}$, and obtain an integral allocation $\mathcal{A} = (A_1, \ldots, A_{|\mathcal{N}|})$ such that $v_i(A_i) \geq V_i(\mathbf{x}_i) - v_i(\ell_i)$ where ℓ_i is the largest valued good for agent i. Therefore, we obtain $v_i(A_i) \geq (1 - 1/e - \epsilon)\mathsf{OPT} - \text{Max}$. ◀

As a corollary, we obtain the following result when $\text{Max} \leq \epsilon\mathsf{OPT}$.

▶ **Corollary 13.** *Consider an instance of Submodular Santa Claus with a promise that there is a feasible allocation $(S_1^*, S_2^*, \ldots, S_{\mathcal{N}}^*)$ of value OPT such that $v_i(j) \leq \epsilon\mathsf{OPT}$ for each $i \in \mathcal{N}$ and each $j \in S_i$. In this setting, for any fixed $\epsilon' > 0$, there is an efficient randomized algorithm that with high probability either outputs an allocation $(S_1, S_2, \ldots, S_{|\mathcal{N}|})$ such that $v_i(S_i) \geq (1 - 1/e - \epsilon - \epsilon')\mathsf{OPT}$ or correctly refutes the promise.*

3.1.1 Constant Number of Agents

Here we consider the setting with a fixed number of agents. In the additive setting there is a PTAS for this case. For the submodular setting the following result can be obtained.

▶ **Theorem 14.** *For any fixed $\epsilon > 0$ and any fixed number of agents $|\mathcal{N}| \geq 1$, there is a $(1 - 1/e - \epsilon)$-approximation for the Submodular Santa Claus problem.*

Proof Sketch. We sketch the ideas since the essence of this has already been captured in Theorem 12. Suppose we have guessed OPT. Since $|\mathcal{N}|$ is fixed we can guess all the "large" items for each agent i from some fixed optimum allocation $(S_1^*, \ldots, S_{|\mathcal{N}|}^*)$. More formally, for each agent i we guess a set $A_i \subset S_i^*$ such that for all $j \in S_i^* \setminus A_i$, $v_i(A_i + j) - v_i(A_i) \leq \epsilon\mathsf{OPT}$. It is easy to see that there exists such a set with $|A_i| \leq (1/\epsilon + 1)$. Thus there are $|\mathcal{M}|^{O(|\mathcal{N}|/\epsilon)}$ guesses that the algorithm needs to try and this is polynomial when $|\mathcal{N}|$ is fixed. Once these are guessed we can then find a fractional allocation and round as in the proof of Theorem 12. The one good loss for an agent i in this setting is at most $\epsilon v_i(A_i)$ due to the preprocessing. The running time is dominated by the guessing step which incurs an overhead of $|\mathcal{M}|^{O(|\mathcal{N}|/\epsilon)}$. ◀

▶ Remark 15. One can use a different rounding approach for the second step after the guessing the large items and solving the relaxation. This was the approach that was outlined in [20] and is based on randomly allocating the items according the fractional allocation; more precisely we allocate each item j independently to exactly one agent where the probablity of agent i receiving item j is precisely $x_{i,j}$. Since the fractional items are "small", one can then use concentration properties of submodular functions, to argue that each agent will have their value preserved to within a $(1 - \epsilon)$-factor of their fractional value with sufficiently high probability; one then uses union bound over all agents. However, randomized rounding incurs larger errors than our rounding method. To make randomized rounding work, we need to use the fact that the number of agents is small, and we need $\epsilon = \Omega(1/\log|\mathcal{N}|)$ for the union bound rather than a fixed constant as above.

3.2 Nash social welfare with submodular valuations

Nash Social Welfare (NSW) is another possible objective in allocation problems: Given a set $\mathcal{M}$ of m items, and a set $\mathcal{N}$ of n agents with valuations $(v_i : i \in \mathcal{N})$, find an allocation $\mathcal{A} = (A_1, \ldots, A_n)$ to maximize the Nash social welfare objective,

$$\left(\prod_{i \in \mathcal{N}} v_i(A_i)\right)^{1/n}.$$

In this section, we present a new $\frac{1}{5}$-approximation algorithm for this problem with monotone submodular valuations, using the rounding lemma.

As mentioned in Section 1.1.2, our algorithm follows the matching-rematching approach that has been used for maximizing NSW with submodular valuations [32, 40, 29]. [40] used this framework with a log-multilinear relaxation and randomized rounding, which gave the first constant factor for NSW with submodular valuation [40]; however, the factor was rather small ($\approx 1/380$). Later, the factor was significantly improved to $1/4$ [29], by replacing the log-multilinear relaxation by discrete local search. Here we return to the log-multilinear relaxation and show that it can be actually used to extract a good approximation factor as well. This is accomplished primarily by the new rounding lemma. In addition, we provide an alternative way to solve the log-multilinear relaxation (approximately) by continuous local search; this also helps in improving the approximation factor, but the effect of this improvement is relatively minor (essentially replacing $1/e$ by $1/2$).

3.2.1 A $\frac{1}{5}$-Approximation Algorithm

Let us describe our new algorithm. It consists of 3 phases: (1) initial matching, (2) relaxation, (3) rematching. The relaxation phase is the new contribution here: we solve the log-multilinear relaxation using continuous local search, and then round it using the non-uniform rounding lemma. A formal description of the algorithm follows.

Algorithm 2 1/5-approximation for NSW with submodular valuations.

Input : Instance $(\mathcal{N}, \mathcal{M}, (v_i)_{i \in \mathcal{N}})$
Output : An allocation of items with NSW at least $\frac{1}{5}$OPT

$\tau :=$ matching $\mathcal{N} \to \mathcal{M}$ maximizing $\sum_{i \in \mathcal{N}} \log v_i(\tau(i))$
$H := \tau[\mathcal{N}], \mathcal{M}' = \mathcal{M} \setminus H$
$\mathbf{x} :=$ ContinuousLocalSearch$(\mathcal{M}', \{v_i : i \in \mathcal{N}\})$
$(S_1, \ldots, S_n) :=$ NonUniformPipageRound$(\mathbf{x}, \{v_i : i \in \mathcal{N}\})$
$\sigma :=$ matching $\mathcal{N} \to \mathcal{M}$ maximizing $\sum_{i \in \mathcal{N}} \log v_i(S_i + \sigma(i))$
return $(S_i + \sigma(i) : i \in \mathcal{N})$

First, we have the following simple lemma about the initial matching.

▶ **Lemma 16.** *If $\tau : \mathcal{N} \to \mathcal{M}$ is the initial optimal matching, then for every agent $i \in \mathcal{N}$ and every remaining item $j \in \mathcal{M} \setminus \tau[N]$, $v_i(j) \le v_i(\tau(i))$.*

Proof. If $v_i(j) > v_i(\tau(i))$, then we could improve the matching by redefining $\tau(i) := j$; note that this item is not allocated to anybody else in the matching. ◀

Algorithm 3 ContinuousLocalSearch$(\mathcal{M}', (v_i : i \in \mathcal{N})$.

Let $P := \{\mathbf{x} \in \mathcal{R}_+^{\mathcal{M}' \times \mathcal{N}} : \forall j \in \mathcal{M}, \sum_{i \in \mathcal{N}} x_{ij} = 1\}$ (the assignment polytope)
Initialize $\mathbf{x}^{(0)} := \frac{1}{n}\mathbf{1} \in P$, and $t := 0$
Define the function $F(\mathbf{x}) = \sum_{i \in [n]} \log V_i(\mathbf{x}_i)$.
while $\exists \mathbf{y} \in P, (\mathbf{y} - \mathbf{x}) \cdot \nabla F(\mathbf{x}) > 0$ **do**
  $\mathbf{x}^{(t+1)} := \mathbf{x}^{(t)} + \epsilon(\mathbf{y} - \mathbf{x}^{(t)})$
  $t = t + 1$

Next, we analyze the continuous local search algorithm. Here we ignore numerical issues of convergence of the algorithm; we assume that the output is a local optimum, which can be implemented up to an arbitrarily small error. Note that here we do not state the computational versions of our results. To implement Algorithm 3 in polynomial time, we need to discretize the process like [21]. Let P denote the assignment polytope as in the description of ContinuousLocalSearch.

▶ **Lemma 17.** *Suppose that* $\mathbf{x} \in P$ *is the output of* ContinuousLocalSearch*, and* $\mathbf{x}^* \in P$ *is any other feasible solution. Then*

$$\sum_{i \in \mathcal{N}} \frac{V_i(\mathbf{x}_i^*)}{V_i(\mathbf{x}_i)} \leq 2|\mathcal{N}|.$$

Proof. If $\mathbf{x}$ is a local optimum, then we have

$$(\mathbf{x}^* - \mathbf{x}) \cdot \nabla F(\mathbf{x}) = \sum_{i \in \mathcal{N}} (\mathbf{x}_i^* - \mathbf{x}_i) \cdot \nabla(\log V_i(\mathbf{x}_i)) \leq 0.$$

Consider the points $\mathbf{x} \vee \mathbf{x}^*$ and $\mathbf{x} \wedge \mathbf{x}^*$ (the coordinate maximum and minimum). We can write $(\mathbf{x} \vee \mathbf{x}^*) + (\mathbf{x} \wedge \mathbf{x}^*) = \mathbf{x} + \mathbf{x}^*$, and hence

$$\sum_{i \in \mathcal{N}} ((\mathbf{x}_i \vee \mathbf{x}_i^*) - \mathbf{x}_i) \cdot \nabla(\log V_i(\mathbf{x}_i)) \leq \sum_{i \in \mathcal{N}} (\mathbf{x}_i - (\mathbf{x}_i \wedge \mathbf{x}_i^*)) \cdot \nabla(\log V_i(\mathbf{x}_i)).$$

By the chain rule, $\nabla(\log V_i(\mathbf{x}_i)) = \frac{\nabla V_i(\mathbf{x}_i)}{V_i(\mathbf{x}_i)}$. Also, by submodularity of V_i, we have $((\mathbf{x}_i \vee \mathbf{x}_i^*) - \mathbf{x}_i) \cdot \nabla V_i(\mathbf{x}_i) \geq V_i(\mathbf{x}_i \vee \mathbf{x}_i^*) - V_i(\mathbf{x}_i)$. Similarly, $(\mathbf{x}_i - (\mathbf{x}_i \wedge \mathbf{x}_i^*)) \cdot \nabla V_i(\mathbf{x}_i) \leq V_i(\mathbf{x}_i) - V_i(\mathbf{x}_i \wedge \mathbf{x}_i^*)$ From here and the inequality above,

$$\sum_{i \in \mathcal{N}} \frac{V_i(\mathbf{x}_i \vee \mathbf{x}_i^*) - V_i(\mathbf{x}_i)}{V_i(\mathbf{x}_i)} \leq \sum_{i \in \mathcal{N}} \frac{V_i(\mathbf{x}_i) - V_i(\mathbf{x}_i \wedge \mathbf{x}_i^*)}{V_i(\mathbf{x}_i)}.$$

This inequality is valid even for non-monotone submodular functions. Since here we are dealing with monotone submodular functions, we can drop $V_i(\mathbf{x}_i \wedge \mathbf{x}_i^*)$ and estimate $V_i(\mathbf{x}_i \vee \mathbf{x}_i^*) \geq V_i(\mathbf{x}_i^*)$, which gives

$$\frac{1}{n} \sum_{i \in \mathcal{N}} \frac{V_i(\mathbf{x}_i^*)}{V_i(\mathbf{x}_i)} \leq 2.$$ ◀

Next, we apply the non-uniform pipage rounding procedure. Given a fractional solution $\mathbf{x}$, it produces an allocation $(S_1, \ldots, S_n)$ of the items in $\mathcal{M}'$ such that

$$v_i(S_i) \geq V_i(\mathbf{x}_i) - v_i(\ell(i))$$

where

$$\ell(i) = \operatorname*{argmax}_{j \in \mathcal{M}'} v_i(j).$$

For the analysis of the last stage, we need the following "rematching lemma", which has appeared in various forms in this line of work. The variant we use here appears in [31].

▶ **Lemma 18.** *If $\tau : \mathcal{N} \to \mathcal{M}$ is an optimal initial matching, $H = \tau[\mathcal{N}]$, $\pi : \mathcal{N} \to H$ is any other matching on H, $(S_i : i \in \mathcal{N})$ is any partition of $\mathcal{M}' = \mathcal{M} \setminus H$, and $\ell(i) = \operatorname{argmax}_{j \in \mathcal{M}'} v_i(j)$, then there is a matching $\sigma : \mathcal{N} \to H$ such that*

$$\prod_{i \in \mathcal{N}} v_i(S_i + \sigma(i)) \geq \prod_{i \in \mathcal{N}} \max\{v_i(S_i), v_i(\ell(i)), v_i(\pi(i))\}.$$

Using the rematching lemma, we conclude the analysis as follows.

▶ **Theorem 19.** *If* OPT *is the* NSW *value of the optimal solution, then our algorithm finds a solution of value*

$$\left(\prod_{i \in \mathcal{N}} v_i(S_i + \sigma(i))\right)^{1/n} \geq \frac{1}{5}\mathsf{OPT}.$$

Proof. Let the optimal allocation be $(H_i \cup O_i : i \in \mathcal{N})$, where $H_i \subset H$ and $O_i \subset \mathcal{M}' = \mathcal{M} \setminus H$. Let $\pi : \mathcal{N} \to H$ be a matching such that $\pi(i) = \operatorname{argmax}_{j \in H_i} v_i(j)$ if $H_i \neq \emptyset$, and otherwise $\pi(i)$ an arbitrary item in H so that π is matching. By submodularity, we have

$$v_i(H_i \cup O_i) \leq v_i(O_i) + |H_i| v_i(\pi(i)) = V_i(\mathbf{x}_i^*) + |H_i| v_i(\pi(i))$$

where $\mathbf{x}_i^* = \mathbf{1}_{O_i}$.

From Lemma 18, we have that the value obtained by our algorithm is

$$\mathsf{ALG} = \left(\prod_{i \in \mathcal{N}} v_i(S_i + \sigma(i))\right)^{1/n} \geq \left(\prod_{i \in \mathcal{N}} W_i\right)^{1/n}$$

where $W_i = \max\{v_i(S_i), v_i(\ell(i)), v_i(\pi(i))\}$. From the pipage rounding procedure, we get $v_i(S_i) \geq V_i(\mathbf{x}_i) - v_i(\ell(i))$. Hence,

$$W_i \geq \max\{V_i(\mathbf{x}_i) - v_i(\ell(i)), v_i(\ell(i)), v_i(\pi(i)\} \geq \max\{\frac{1}{2}V_i(\mathbf{x}_i), v_i(\pi(i))\}.$$

Finally, we estimate by AM-GM

$$\begin{aligned} \frac{\mathsf{OPT}}{\mathsf{ALG}} &\leq \left(\prod_{i \in \mathcal{N}} \frac{v_i(H_i \cup O_i)}{W_i}\right)^{1/n} \leq \frac{1}{n}\sum_{i \in \mathcal{N}} \frac{v_i(H_i \cup O_i)}{W_i} \\ &\leq \frac{1}{n}\sum_{i \in \mathcal{N}} \frac{V_i(\mathbf{x}_i^*) + |H_i| v_i(\pi(i))}{W_i} \leq \frac{1}{n}\sum_{i \in \mathcal{N}} \left(\frac{V_i(\mathbf{x}_i^*)}{\frac{1}{2}V_i(\mathbf{x}_i)} + |H_i|\right). \end{aligned}$$

Using Lemma 17 and the fact that $\sum_{i \in \mathcal{N}} |H_i| \leq n$, we conclude that $\frac{\mathsf{OPT}}{\mathsf{ALG}} \leq 5$. ◀

3.2.2 Constant number of agents

We can prove the following theorem for NSW with a constant number of agents. This theorem also works for weighted NSW. We note that a similar result was known previously [32]. See Remark 21 for a comparison.

▶ **Theorem 20.** *Given an instance of the fair allocation problem, $(\mathcal{N}, \mathcal{M}, (v_i)_{i \in \mathcal{N}})$, we can compute in randomized polynomial time an allocation $A_i \in \Pi_n([m])$ such that the value of* NSW *of the allocation is $(1 - 1/e - \epsilon)$*OPT *where* OPT *is the value of the optimal Nash social welfare.*

Proof Sketch. The proof is similar to proof of constantly many agents for the max-min problem (see 14) and we only sketch the idea here. First, we predict the value agent i receives in an optimal allocation, say OPT_i. For a particular agent, we can guess this to a $(1+\epsilon)$ multiplicative approximation using a grid search in polynomial time. Therefore, for constantly many agents, we can guess the valuation profile for an optimal NSW solution in polynomial time. Now, consider the corresponding optimal allocation, $(S_1^*, \ldots, S_n^*)$. From each S_i^*, we guess a subset $A_i \subseteq S_i^*$ such that for each $g \in S_i^* \setminus A_i$, $v_i(g \mid A_i) \leq \epsilon\mathsf{OPT}_i$. It is clear that we can have an A_i such that $|A_i| \leq (1/\epsilon)$ otherwise, we have a value of more than OPT_i for agent i. Therefore, together for all n agents, this A_i can be guessed in $m^{O(n/\epsilon)}$ time. This is clearly polynomial when n and ϵ are constants. Now, we find a fractional solution for the NSW problem – for each agent, we define it's new valuation function to be $v_{i|A_i}$ which is the function that gives marginal values of sets on A_i. It is well-known and easy to see that this function is also submodular. For this function, we aim to allocate agent i value $\mathsf{OPT}_i - v_i(A_i)$. Again, following the Theorem 11 from previous section, if such an allocation exists, we can compute a fractional allocation $\mathbf{x}$ in time polynomial in m, n and ϵ' such that $v_i(\mathbf{x}_i) \geq (1-1/e-\epsilon')(\mathsf{OPT}_i - v_i(A_i))$. Further, we can also ensure that no agent is allocated a good of value more than $\epsilon \cdot \mathsf{OPT}$ by making the value of any such good for the agent zero (this also maintains submodularity). Then we run the non-uniform pipage rounding algorithm and obtain an allocation that allocates each agent a value of $(1-1/e-\epsilon'-\epsilon)\mathsf{OPT}_i$. Therefore, in time polynomial in m, n and $\epsilon'' = \epsilon' + \epsilon$, we can compute an allocation that maximizes NSW with constant number of agent up to a factor of $(1-1/e-\epsilon'')$ i.e., we have a PTAS for this problem with constantly many agents. Note that this algorithm also works with asymmetric agents. ◀

▶ Remark 21. A $(1-1/e-\epsilon)$-approximation for constant n was achieved previously [32]. That work relied on an integral version of Theorem 11 which in turn was based on the same ideas as in max-min allocation from [20]. Therefore, to obtain an approximation guarantee of $(1-1/e-\epsilon)$ for any fixed $\epsilon > 0$, [32] requires guessing from an optimal allocation all goods allocated to an agent i of value at least $\epsilon \cdot \mathsf{OPT}_i/\log n$. In the preceding theorem, for a fixed $\epsilon > 0$, we need to guess the "large" goods of value at least $\epsilon\mathsf{OPT}_i$. Therefore the size of the set to be guessed is reduced.

3.3 Approximating MMS for Submodular Valuations

MMS is another fairness objective frequently studied in allocation problems. It is a share-based guarantee, i.e., each agent demands a certain value a.k.a. share. An allocation is considered to be fair if all agents receive their share. In case of MMS, this value for a particular agent i depends only on the valuation function of the agent, v_i and the number of agents $|\mathcal{N}|$. It is defined as follows:

$$\mathsf{MMS}_i^{|\mathcal{N}|}(\mathcal{M}) := \max_{A \in \Pi_{|\mathcal{N}|}(\mathcal{M})} \min_{i \in [n]} v_i(A_i).$$

Essentially, the MMS value of an agent is the maximum value she can ensure for herself when she divides the goods into $|\mathcal{N}|$ parts and chooses the worst part for herself. When $\mathcal{M}$ and $\mathcal{N}$ are clear from the context, we denote $\mathsf{MMS}_i^{|\mathcal{N}|}(\mathcal{M})$ as simply MMS_i. As mentioned in Section 1.1.3, since MMS-allocations do not exist, we study α-MMS allocations for $\alpha(\leq 1)$ as large as possible. Here, we give an algorithm that achieves a value of $\approx 1/2(1-1/e) \approx 0.316$ based on a simple application of the NonUniformPipageRounding. Our approach is again to round a fractional allocation. While in the previous two sections we solved some fractional

program to find the fractional allocation, in this section, we give a direct solution using two known results. To state the results, we need to define another extension of submodular valuation functions called the concave extension. Given a submodular function, f the concave extension, f^+ of f is defined as follows.

▶ **Definition 22** (Concave extension of f)**.**

$$f^+(\mathbf{x}) = \max_{(\alpha_S)_{S\in 2^{\mathcal{M}}}} \{\sum_S f(S)\alpha_S : \sum_S \alpha_S = 1 \text{ and } \sum_{S\ni j} \alpha_S = x_j \quad \forall j \in \mathcal{M} \text{ and } \alpha_S \geq 0 \quad \forall S \in 2^{\mathcal{M}}\}.$$

Now, we state the aforementioned results. The first one, from [19] gives an upper bound on MMS in terms of the concave extension. The second one, from [14], is called the correlation gap and connects the value of the concave extension at any fractional point with value of the multilinear extension at the same point.

▶ **Lemma 23** ([19])**.** *Given an instance of the fair division problem, $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$ with submodular valuations, $\mathsf{MMS}_i \leq v_i^+(\frac{1}{|\mathcal{N}|}(\mathbf{1}^{|\mathcal{M}|}))$ for all $i \in \mathcal{N}$, where v_i^+ is the concave extension of the function v_i.*

▷ Claim 24 ([14]). For any monotone submodular function, f with concave extension f^+ and multilinear extension F,

$$F(\mathbf{x}) \geq \left(1 - \frac{1}{e}\right) f^+(\mathbf{x}).$$

Combining the above two results, we get,

▷ Claim 25. Given an instance of the fair division problem, $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$ with submodular valuations, $\mathsf{MMS}_i \leq \left(\frac{e}{e-1}\right) \cdot V_i(\frac{1}{|\mathcal{N}|}(\mathbf{1}^{|\mathcal{M}|}))$.

We can now use NonUniformPipageRounding to obtain:

▶ **Theorem 26.** *Given a fair division instance, $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$ with submodular valuations, if $\max_{i,j} v_i(\{j\}) \leq \epsilon \cdot \mathsf{MMS}_i$ for all $i \in \mathcal{N}, j \in \mathcal{M}$, we can compute an allocation in randomized polynomial time where each agent receives a value of $\left(1 - \frac{1}{e} - \epsilon\right) \mathsf{MMS}_i$.*

Proof. We run NonUniformPipageRounding on the allocation $\mathbf{x} = (\frac{1}{|\mathcal{N}|}\mathbf{1}^{|\mathcal{M}|})$. Therefore, we get an integral allocation, $\mathcal{A} = (A_1, \ldots, A_{|\mathcal{N}|})$ such that $v_i(A_i) \geq V_i(\frac{1}{|\mathcal{N}|}(\mathbf{1}^{|\mathcal{M}|})) - v_i(\ell_i)$ where $\ell_i \coloneqq \operatorname{argmax}_j v_i(\{j\})$. Since by assumption $v_i(\ell_i) \leq \epsilon\mathsf{MMS}_i$ by assumption, and from Claims 24 and 25, $V_i(\frac{1}{|\mathcal{N}|}(\mathbf{1}^{|\mathcal{M}|})) \geq \left(1 - \frac{1}{e}\right) \mathsf{MMS}_i$, the theorem follows. ◀

Algorithm 4 gives a ≈ 0.316-approximation for MMS with submodular valuations. To analyze this, we first understand the algorithm. Step (6) is performing our NonUniformPipageRounding. The while loop in lines (2) to (4) performs an operation that is called as "single good reduction". The following claim regarding this is well-known and used in almost all works on MMS.

▷ Claim 27. Given a fair division instance $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$, the MMS value of any agent is retained if we remove any single agent and any single good. That is,

$$\mathsf{MMS}_i^{|\mathcal{N}|}(\mathcal{M}) \leq \mathsf{MMS}_i^{|\mathcal{N}|-1}(\mathcal{M} \setminus \{g\}) \qquad \text{for all } g \in \mathcal{M}$$

We can now prove the following result for Algorithm 4.

Algorithm 4 $\frac{1}{2}(1-\frac{1}{e}-o(1))$-approximation for MMS with submodular valuations.

Input : Instance $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$
Output : An allocation where each agent receives at least $\frac{1}{2}(1-\frac{1}{e}-o(1))\mathsf{MMS}_i$.

1 Initialize $\mathcal{N}' \leftarrow \mathcal{N}$ and $\mathcal{M}' \leftarrow \mathcal{M}$
2 **while** *there exists* $i \in \mathcal{N}'$ *and* $g \in \mathcal{M}'$ *with* $v_i(g) \geq \frac{1}{2}V_i(\frac{1}{|\mathcal{N}'|}\mathbf{1}^{|\mathcal{M}'|})$ **do**
3 Allocate g to i
4 Update $\mathcal{N}' \leftarrow \mathcal{N}' \setminus i$ and $\mathcal{M}' \leftarrow \mathcal{M}' \setminus g$
5 Initialize $\mathbf{x} = \left(\frac{1}{|\mathcal{N}'|}(\mathbf{1}^{|\mathcal{N}'|\times|\mathcal{M}'|})\right)$
6 $(A_1, \ldots, A_{|\mathcal{N}'|}) \leftarrow$ NonUniformPipageRound($\mathbf{x}$)
7 **return** $(A_1, \ldots, A_{|\mathcal{N}|})$

▶ **Theorem 28.** *Given a fair division instance,* $(\mathcal{N}, \mathcal{M}, (v_i)_{i\in\mathcal{N}})$ *with submodular valuations, Algorithm 4 outputs an allocation where each agent receives a value of* $\frac{1}{2}\left(1-\frac{1}{e}-o(1)\right)\mathsf{MMS}_i$.

Proof. First, let us assume that we can compute $V_i(\mathbf{y})$ exactly for any $\mathbf{y} \in [0,1]^{|\mathcal{N}|\times|\mathcal{M}|}$. Note that as per Algorithm 4, an agent can receive an allocation either in the while loop of Steps 2-4 or in Step 6 via NonUniformPipageRounding. In every iteration of the while loop, we remove one agent and one good. Therefore, by Claim 27, the MMS value of any agent in the residual instance does not decrease. As a result, until the algorithm reaches Step 6, we always have $\mathsf{MMS}_i \leq (\frac{e}{e-1})V_i(\frac{1}{|\mathcal{N}'|}\mathbf{1}^{|\mathcal{M}'|})$. Therefore, any agent who gets a good in the while loop receives a good of value at least $\frac{1}{2}(1-\frac{1}{e})\mathsf{MMS}_i$. Now, in Step 6, by Lemma 8, we get an allocation of value at least $V_i(\frac{1}{|\mathcal{N}'|}\mathbf{1}^{|\mathcal{M}'|}) - v_i(\ell_i) \geq \frac{1}{2}V_i(\frac{1}{|\mathcal{N}'|}\mathbf{1}^{|\mathcal{M}'|}) \geq \frac{1}{2}(1-\frac{1}{e})\mathsf{MMS}_i$.

Now, we note that the values of $V_i(\frac{1}{|\mathcal{N}'|}\mathbf{1}^{|\mathcal{M}'|})$ are computed by sampling and in polynomial time, we can only compute them to a factor of $(1-\epsilon)$. Accounting for this, we get that in randomized polynomial time we can guarantee each agent a value of $(1-\frac{1}{e}-o(1))\mathsf{MMS}_i$. This proves the theorem. ◀

Abstract

We study the *connected k-median* clustering problem, a clustering problem that augments the classical k-median objective with connectivity constraints. We focus on the *overlapping* variant of the problem, where clusters are allowed to share vertices. In addition to a metric space (V, d), the input contains a connected graph G on the same vertex set V of size n. The goal is to select at most k centers C and assign vertices to them so as to minimize the k-median cost (i.e., $\sum_{v \in V} d(v, C)$), subject to the constraint that each cluster induces a connected subgraph of G. Since the metric space and the connectivity graph are independent, the problem is significantly more challenging than standard clustering. Eube et al. [29] showed that even the assignment version is $\Omega(\log n)$-hard to approximate and gave approximation algorithms with guarantees depending polynomially on k.

We develop a configuration-LP-based framework that combines covering LP techniques with a rooted minimum-density oracle. For the assignment version, we obtain an $O(\log^2 n)$-approximation. For the general version, we develop a bicriteria framework that opens $O(k \log n)$ centers while achieving an $O(\log^2 n)$-approximation in cost.

1 Introduction

Clustering is a central problem in algorithms and data analysis, with classical objectives such as k-center [35, 39] and k-median [15, 14, 19] extensively studied over the past decades. In the k-median problem, we are given a vertex set V of size n together with a metric $d : V \times V \to \mathbb{R}_{\geq 0}$ and an integer k, and the goal is to select k centers so as to minimize the sum of distances of each vertex to its assigned center. While the vanilla k-median problem admits constant-factor approximation algorithms [15, 14, 5, 23], many modern applications require incorporating additional structural constraints into the clustering process.

In this work, we study the *connected k-median* problem, an extension of the classical k-median problem that incorporates *connectivity constraints*. In addition to the metric space (V, d), the input includes an unweighted undirected graph $G = (V, E)$, referred to as the *connectivity graph*. The goal is to select k centers and assign vertices to them so as

to minimize the k-median objective, subject to the constraint that each cluster induces a connected subgraph in G. Importantly, the graph G is completely independent of the metric d, making the problem fundamentally different from classical clustering.

We focus on the *overlapping* variant of the connected k-median problem, where a vertex may belong to more than one cluster. This is natural in applications such as community detection [8, 30], where individuals can participate in multiple groups, and it also allows vertices such as articulation points to serve as connectors between several clusters. Theoretically, this distinction is crucial; Eube et al. [29] showed that the disjoint version is extremely hard to approximate, admitting an $\Omega(n^{1-\varepsilon})$ lower bound even for $k = 2$.

Connected clustering arises naturally in settings where both *attribute data* and *relational structure* are present. For instance, in applications such as community detection in social networks [8, 30] or spatial partitioning tasks like school redistricting [18], the input consists of data points equipped with features as well as an underlying graph capturing relationships such as social interactions or geographic adjacency. In such settings, it is desirable to form clusters that are not only metrically coherent but also respect the connectivity structure of the graph. For example, in school redistricting, geographical units must be grouped into contiguous regions, ensuring that each cluster forms a connected area, while still optimizing criteria such as proximity or compactness. This motivates the study of clustering models that integrate geometric objectives with graph-theoretic constraints.

From an algorithmic perspective, connectivity constraints significantly increase the difficulty of clustering problems. Even in the *assignment version* of connected k-median, where the set of centers is fixed, and the goal is only to assign vertices to centers, Eube et al. [29] showed that the problem is $\Omega(\log n)$-hard to approximate, and provided an $O(k \log n)$-approximation algorithm. For the general version, where centers must also be selected, they obtained an $O(k^2 \log n)$-approximation. These results demonstrate a substantial gap between k-median clustering and its connected variant.

Our contributions. Our main contribution is a configuration-LP framework for connected k-median clustering. Unlike the cut-based relaxation of Eube et al. [29], where connectivity is enforced indirectly through constraints, our LP uses variables indexed by connected sets rooted at centers, thereby encoding connectivity directly into the variables themselves. We combine this formulation with covering-LP techniques and rooted minimum-density oracles to obtain approximation guarantees for connected k-median. Our main results are summarized below.

- **Assignment version.** We obtain an $O(\log^2 n)$-approximation algorithm for general graphs, which improves Eube et al [29] assignment version result when $k = \omega(\log n)$.
- **General version (bicriteria approximation).** We develop a bicriteria framework that allows opening more than k centers. In particular, we compute a solution that opens at most $O(k \log n)$ centers while achieving an $O(\log^2 n)$-approximation in cost, yielding an $(O(\log n), O(\log^2 n))$ bicriteria approximation.

The bicriteria guarantee highlights a tradeoff between the number of opened centers and the approximation factor in cost. The algorithm of Eube et al. [29] gives a solution with k centers with approximation factor of $O(k^2 \log n)$ for the general version. In contrast, our bicriteria framework opens $O(k \log n)$ centers and achieves an $O(\log^2 n)$ cost approximation, eliminating the polynomial dependence on k in the objective guarantee.

1.1 Technical Overview

Our algorithms are based on a configuration-LP viewpoint. Instead of assigning vertices to centers directly, we introduce a variable for each pair (c, T), where c is a center and T is a connected vertex set containing c. Choosing such a configuration corresponds to opening a connected cluster rooted at c. This formulation captures the connectivity requirement directly: every integral solution selects connected sets, and the covering constraints ensure that every vertex is contained in at least one selected cluster. It is useful to contrast this formulation with the cut-based LP used by Eube et al. [29]. In the cut-LP, the variables x_v^c represent fractional assignments of vertices to centers, and connectivity is enforced indirectly through cut constraints: if v is assigned to c, then every v–c cut must contain enough mass assigned to c. This is a natural and compact relaxation, but it is still a *vertex-assignment* formulation; after rounding, one must still ensure that the assigned vertices form connected clusters. In contrast, the configuration LP works directly with connected sets. A variable $y_{T,c}$ corresponds to selecting an entire connected cluster T rooted at c, so connectivity is built into the variables themselves rather than enforced only through constraints.

This global representation is particularly useful for rounding. Once a configuration (c, T) is sampled, it already defines a connected set containing its center, and the union of sampled configurations with the same root remains connected. Thus, the randomized rounding step only needs to ensure coverage of vertices; connectivity is preserved automatically. Moreover, every configuration-LP solution induces a feasible solution to the cut-LP by setting $x_v^c = \sum_{\substack{T \in \mathcal{T}_c \\ v \in T}} y_{T,c}$, with the same objective value, so the configuration LP can be viewed as a more structured relaxation. The price of this stronger representation is that the LP contains exponentially many variables, so solving it exactly is not straightforwardly achievable in polynomial time. In fact, we can only solve this LP relaxation approximately, using column generation based on the rooted minimum-density connected-set oracle.

For the assignment version, where the center set C is fixed, the configuration LP is a pure covering LP. We solve it approximately using the multiplicative weight update framework of Plotkin, Shmoys and Tarods [43] for covering linear programs. The key step is the pricing problem: given weights α_v on the vertices that correspond to the covering constraints, we need to find a connected set $T \ni c$ minimizing the ratio between its cost and the total weight of vertices it covers. This is exactly a rooted minimum-density connected-set problem:

$$\min_{T | T \ni c} \frac{\sum_{v \in T} d(v, c)}{\sum_{v \in T} \alpha_v}.$$

Thus, a ρ-approximate oracle for rooted minimum-density connected sets yields a ρ-approximate pricing oracle for the configuration LP. Combining this with the Plotkin–Shmoys–Tardos framework gives a polynomial-support fractional solution whose cost is within a factor $O(\rho)$ of the optimum LP fractional value. We obtain such density oracles using connections to the *node-weighted Steiner tree* problem.

The rounding step is simple and uses the standard independent randomized rounding. Given a fractional solution $\hat{y}$, we sample each configuration (c, T) with probability proportional to $\hat{y}_{T,c} \log n$. For each center c, the final cluster is the union of all the sampled configurations rooted at c. This union remains connected because every sampled set contains the common root c. The logarithmic oversampling ensures, by a union bound over all vertices, that every vertex is covered with high probability. Linearity of expectation bounds the expected cost by an additional $O(\log n)$ factor. This yields an $O(\rho \log n)$-approximation for the assignment version. For general graphs, the rooted minimum-density problem admits an $O(\log n)$-approximation via known algorithms for the *budgeted node-weighted Steiner tree* problem.

This yields an $O(\log^2 n)$-approximation for the assignment version. For minor-closed graphs, the techniques of [25, 17] suggest that the rooted minimum-density problem may admit an $O(1)$-approximation, which would improve the assignment-version guarantee to $O(\log n)$.

For the general version, we provide a bicriteria approximation guarantee. We avoid the center-rounding step of Eube et al [29] and instead formulate a non-fixed-center configuration LP. This LP has variables for all roots $c \in V$ and all connected sets $T \in \mathcal{T}_c$, together with a fractional center-budget constraint $\sum_{c \in V} \sum_{T \in \mathcal{T}_c} y_{T,c} \leq k$. This LP is a mixed packing/covering program. Its pricing problem again reduces to a rooted minimum-density connected-set problem, except that the ratio includes both the connection cost of the configuration and the multiplier corresponding to the center-budget constraint. After computing a near-optimal fractional solution, we apply the same randomized rounding scheme. The covering constraints guarantee that all vertices are covered with high probability, while the budget constraint implies that the number of sampled configurations, and hence the number of opened centers, is at most $O(k \log n)$ with high probability. This gives an $(O(\log n), O(\rho \log n))$ bicriteria approximation, which becomes $(O(\log n), O(\log^2 n))$ for general graphs.

1.2 Related Work

Clustering problems such as k-center and k-median are among the most well-studied optimization problems in algorithm design. Both problems are known to be NP-hard. For the k-center problem, a tight 2-approximation algorithm is known [33, 35], and this factor is optimal unless P=NP [36]. For metric k-median, the current best polynomial-time approximation guarantee is $2 + \varepsilon$, for any fixed $\varepsilon > 0$, achieved by the recent algorithm of Cohen-Addad et al. [22]. In contrast, no polynomial-time algorithm can achieve an approximation ratio smaller than $1 + 2/e \approx 1.736$, unless P = NP [37].

Connected clustering. Clustering with connectivity constraints has been studied in several contexts. Ge et al. [31] introduced the connected k-center problem as a model for jointly clustering attribute data and relationship data: the metric captures similarity between attribute vectors, while the connectivity graph captures relational information. They gave an exact dynamic program when the connectivity graph is a tree, and also studied general graphs, although without a known approximation guarantee. For general graphs with disjoint clusters, Drexler et al. [26] obtained an $O(\log^2 k)$-approximation; they also gave constant-factor approximations for Euclidean metrics of constant dimension and metrics of constant doubling dimension, motivated by applications in geodesy and sea-level analysis. In contrast, when overlapping clusters are allowed, connected k-center admits a simple 2-approximation, highlighting an important distinction between the disjoint and overlapping models.

For the k-median objective, the connected variant has been studied more recently. Validi et al. [46] consider connected k-median in the context of districting, where geographical units must be grouped into contiguous regions while optimizing a proximity-based objective. They formulate the problem as an integer linear program, which can be solved optimally but requires exponential time in the worst case. Gupta et al. [34] study the inapproximability of clustering with connectivity constraints and show that even when $k = 2$ and the connectivity graph is star-like, the problem is $\Omega(\log n)$-hard to approximate. They also provide an $O(\log n)$-approximation algorithm for some restricted instances of the problem.

Clustering with additional constraints. Beyond connectivity, a large body of work has focused on incorporating additional constraints into clustering problems motivated by real-world applications. Capacitated clustering introduces upper bounds on cluster sizes [40], while

models with outliers allow for excluding a small fraction of points from the clustering [16]. More recently, fairness constraints have been extensively studied, requiring clusters to satisfy various fairness conditions [21, 9, 6, 10, 24, 38, 41, 45, 32, 1, 42, 28, 27, 20]. Fairness constraints have also been studied for other types of clustering problems, like correlation clustering [3, 2, 4] and consensus clustering [13, 11, 12]. These variants highlight the increasing importance of structured clustering models, where combinatorial constraints are integrated with geometric objectives.

2 Preliminaries and Problem Statement

In this section, we introduce the definitions and notation used throughout the paper. We also formally state the problem and present our main results.

Problem Statement. We are given a vertex set V, a metric $d : V \times V \to \mathbb{R}_{\geq 0}$, and a connected *connectivity graph* $G = (V, E)$, which is unrelated to d. We consider the problem in two settings.

- **Assignment Version:** A set of centers $C \subseteq V$ with $|C| \leq k$, for some integer k is given. A feasible *overlapping* clustering solution outputs connected sets $\mathcal{S} := (S_c)_{c \in C}$ such that (i) $c \in S_c$ for all $c \in C$, (ii) $G[S_c]$ is connected for all $c \in C$, and (iii) $\bigcup_{c \in C} S_c = V$.
- **General Version:** An integer k is given, and the goal is to choose a set of centers $C \subseteq V$ with $|C| \leq k$ together with connected sets $\mathcal{S} := (S_c)_{c \in C}$ satisfying the same conditions as above.

In both cases, the objective is to find a feasible solution $\mathcal{S}$ that minimizes

$$\text{cost}(\mathcal{S}) := \sum_{c \in C} \sum_{v \in S_c} d(v, c),$$

where a vertex assigned to multiple clusters contributes once per cluster. Here $G[S_c]$ denotes the subgraph of G induced by the vertex set S_c.

▶ Remark 1. Let $G_1, \ldots, G_\ell$ be the connected components of G. In the assignment version, if some component contains at least one vertex but no center, then the instance is infeasible. Otherwise, each component can be solved independently, and the solutions can be combined. Hence, without loss of generality, we assume throughout that G is connected and every vertex can reach some center.

▶ Remark 2 (Bounded aspect ratio). Throughout the paper we assume the metric d has polynomially bounded aspect ratio: if $D_{\max} := \max_{u,v \in V} d(u, v)$ and $\delta_{\min} := \min_{u \neq v \in V} d(u, v)$, we assume

$$\Delta := \frac{D_{\max}}{\delta_{\min}} = \text{poly}(n).$$

This is the standard bounded-spread condition used throughout the metric clustering and embedding literature. All stated polynomial running times in this paper are with respect to n, k, and $1/\varepsilon$ under this assumption.

Our Results. We now formally state our results. A feasible overlapping clustering solution for either version is referred to as a *connected k-median clustering* of the vertex set V. We say that a clustering $\mathcal{S}$ is an α-approximate connected k-median clustering if $\text{cost}(\mathcal{S}) \leq \alpha \cdot \text{cost}(\mathcal{S}^*)$, where $\mathcal{S}^*$ denotes an optimal connected k-median clustering.

For the assignment version, we obtain an improved approximation guarantee when $k = \omega(\log n)$. In particular, we show the following.

▶ **Theorem 3.** *Given a vertex set V, a metric $d : V \times V \to \mathbb{R}_{\geq 0}$, an undirected, unweighted connectivity graph $G = (V, E)$, and a set of centers $C \subseteq V$ with $|C| \leq k$, there exists a polynomial-time algorithm that computes an $O(\log^2 n)$-approximate connected k-median clustering.*

We now consider the general version of the problem, where the set of centers is not given and must be chosen as part of the solution. For the general version, we have obtained bicriteria approximation guarantees. For this, we need to define a bicriteria notion of approximation that allows the algorithm to open more than k centers. A clustering $\mathcal{S}$ is said to be a (β, α)-approximate connected k-median clustering if it uses at most βk centers and satisfies $\text{cost}(\mathcal{S}) \leq \alpha \cdot \text{cost}(\mathcal{S}^*)$, where $\mathcal{S}^*$ is an optimal solution that uses at most k centers.

We obtain the following bicriteria guarantees.

▶ **Theorem 4.** *Given a vertex set V, a metric $d : V \times V \to \mathbb{R}_{\geq 0}$, an undirected, unweighted connectivity graph $G = (V, E)$ and an integer k, there exists a polynomial-time algorithm that computes an $(O(\log n), O(\log^2 n))$-approximate connected k-median clustering.*

3 Assignment Version

In this section, we prove our results for the assignment version of the problem. In particular, we prove Theorem 3, which we restate below.

▶ **Theorem 3.** *Given a vertex set V, a metric $d : V \times V \to \mathbb{R}_{\geq 0}$, an undirected, unweighted connectivity graph $G = (V, E)$, and a set of centers $C \subseteq V$ with $|C| \leq k$, there exists a polynomial-time algorithm that computes an $O(\log^2 n)$-approximate connected k-median clustering.*

To prove Theorem 3, we employ a *configuration LP* formulation. Since this LP has exponentially many variables, we compute a near-optimal fractional solution using a *rooted minimum-density connected set oracle* in conjunction with the Plotkin–Shmoys–Tardos [43] multiplicative weight update framework for covering LPs. We then round this fractional solution to obtain the desired approximation guarantee. The details are presented in the subsequent sections.

3.1 Configuration LP

We follow a *configuration LP* route: formulate an exponential-size covering LP over all connected clusters, solve it approximately via column generation/packing-covering with a *minimum-density* oracle, and round it in one shot via randomized rounding. This yields an $O(\rho \log n)$ approximation given a ρ-approximation oracle for the rooted minimum-density connected set problem.

For each center $c \in C$, let $\mathcal{T}_c$ denote the family of all connected vertex sets $T \subseteq V$ such that $c \in T$ and $G[T]$ is connected. For $T \in \mathcal{T}_c$, define

$$\text{cost}_c(T) := \sum_{v \in T} d(v, c).$$

We introduce a variable $y_{T,c} \geq 0$ for each pair (c, T) to represent the extent to which we choose configuration (c, T). We define the primal and dual relaxation of the assignment problem as follows.

Primal (Configuration) LP

$$\min \quad \sum_{c\in C}\sum_{T\in\mathcal{T}_c} \mathrm{cost}_c(T)\, y_{T,c} \tag{1}$$

$$\text{s.t.} \quad \sum_{c\in C}\sum_{\substack{T\in\mathcal{T}_c\\ v\in T}} y_{T,c} \geq 1 \qquad \forall v \in V \setminus C, \tag{2}$$

$$y_{T,c} \geq 0 \qquad \forall c \in C,\ \forall T \in \mathcal{T}_c. \tag{3}$$

Dual LP

$$\max \quad \sum_{v\in V\setminus C} \alpha_v \tag{4}$$

$$\text{s.t.} \quad \sum_{v\in T\setminus\{c\}} \alpha_v \leq \mathrm{cost}_c(T) \qquad \forall c \in C,\ \forall T \in \mathcal{T}_c, \tag{5}$$

$$\alpha_v \geq 0 \qquad \forall v \in V \setminus C. \tag{6}$$

▶ **Lemma 5.** *The configuration LP* (1)–(3) *is a valid relaxation of the assignment version of connected k-median with overlapping clusters. In particular, its optimal value is at most* OPT*.*

Proof. We provide the proof in the appendix. ◀

3.2 The Oracle: Rooted Minimum-Density Connected Set

Since the configuration LP has exponentially many variables (one for each connected set $T \in \mathcal{T}_c$ and each center $c \in C$), it is not immediate how to solve it in polynomial time. We follow the standard oracle-based approach for large-scale packing/covering linear programs: rather than enumerating all configurations explicitly, we access them through an optimization subroutine that, for suitable dual weights, returns an approximately best column [43, 47]. In our setting, this subroutine is the *rooted minimum-density connected-set problem* defined below.

▶ **Definition 6.** *Given a graph $G = (V, E)$, a root $c \in V$, nonnegative node* profits *$\alpha : V \to \mathbb{R}_{\geq 0}$, and nonnegative node* costs *$w : V \to \mathbb{R}_{\geq 0}$, the rooted minimum-density problem asks for a connected set $T \ni c$ minimizing*

$$\mathrm{dens}(T) := \frac{\sum_{v\in T} w(v)}{\sum_{v\in T} \alpha_v},$$

with the convention $\mathrm{dens}(T) = +\infty$ *if* $\sum_{v\in T} \alpha_v = 0$.

In our application, the dual variables are defined only on $V \setminus C$, so we set $\alpha_c := 0$. Thus $\sum_{v\in T} \alpha_v = \sum_{v\in T\setminus\{c\}} \alpha_v$, which matches the left-hand side of the dual packing constraint (5). In particular, minimizing $\mathrm{dens}(T)$ identifies the most violated dual constraint, and hence the most promising column for the primal configuration LP.

▶ **Definition 7.** *A ρ-approximate density oracle returns a connected set $T \ni c$ such that* $\mathrm{dens}(T) \leq \rho \cdot \min_{T'\ni c} \mathrm{dens}(T')$.

▶ **Lemma 8.** *There is a polynomial-time $O(\log n)$-approximate density oracle.*

Proof. The proof uses a result by Bateni et al [7]. We provide the full proof in the appendix. ◀

3.3 Computing a ρ-Approximate Solution of the Assignment Version of the Configuration LP

We next explain how to approximately solve the configuration LP using the rooted minimum-density oracle from the previous subsection. We follow the standard oracle-based approach for large covering LPs: we view the configuration LP as a covering problem over an implicit column set and apply the framework of Plotkin–Shmoys–Tardos [43]; the key point is that the corresponding pricing subproblem is exactly a rooted minimum-density connected-set problem. Therefore, a ρ-approximate density oracle yields, in polynomial time, a $(1+\varepsilon)\rho$-approximate fractional solution to the configuration LP.

▶ **Theorem 9.** *Assume a ρ-approximate density oracle. Then for any $\varepsilon \in (0,1)$, one can compute in polynomial time a feasible fractional solution $\hat{y}$ to the Configuration LP (1)–(3) satisfying*

$$\sum_{c\in C}\sum_{T\in\mathcal{T}_c} \mathrm{cost}_c(T)\hat{y}_{T,c} \le (1+\varepsilon)\rho\cdot \mathrm{OPT}_{\mathrm{CLP}} \le (1+\varepsilon)\rho\cdot \mathrm{OPT},$$

with support size $\mathrm{poly}(n, \varepsilon^{-1}, \rho)$.

Proof. We cast the configuration LP as a pure covering LP and apply a standard fractional packing/covering approximation scheme (Plotkin–Shmoys–Tardos [43]), whose guarantee is that an approximately optimal *fractional* solution can be computed given oracle access to an approximate *pricing* subproblem.

We discard all columns (c,T) with $T \cap (V \setminus C) = \emptyset$. Such columns cover no covering constraint and therefore play no role in the covering LP. After this restriction, every remaining column satisfies $\mathrm{cost}_c(T) > 0$.

Step 1: Configuration LP as a covering LP. Let $U_0 := V \setminus C$ and $n_0 := |U_0|$. Index columns by pairs (c,T) with $c \in C$ and $T \in \mathcal{T}_c$. Define the incidence matrix $A \in \{0,1\}^{n_0 \times N}$ and cost vector $c \in \mathbb{R}^N_{>0}$ by

$$A_{v,j} := \mathbf{1}[v \in T], \qquad c_j := \mathrm{cost}_c(T) = \sum_{u\in T} d(u,c).$$

Since d is a metric with $d(u,c) > 0$ for all $u \neq c$, every column $j = (c,T)$ with $T \neq \{c\}$ satisfies $c_j > 0$, so there are no $0/0$ anomalies in the pricing step. The configuration LP (1)–(3) is then $\min\{c^\top y : Ay \ge \mathbf{1}, y \ge 0\}$, a non-negative covering LP with $m := n_0$ constraints and N columns.

Step 2: Pricing is (approximate) rooted minimum-density. In the Plotkin–Shmoys–Tardos framework for covering LPs, the algorithm maintains a non-negative weight vector $p \in \mathbb{R}^{U_0}_{\ge 0}$ on constraints and, in each iteration, needs a column whose *cost per covered weight* is minimum (equivalently, whose covered weight per unit cost is maximum). For a column $j = (c,T)$, the covered weight under p is $\langle p, A_{\cdot,j}\rangle = \sum_{v\in T\cap U_0} p_v$, so the ratio is

$$\frac{c_j}{\langle p, A_{\cdot,j}\rangle} = \frac{\sum_{u\in T} d(u,c)}{\sum_{v\in T\cap U_0} p_v}.$$

This is the rooted minimum-density objective (Definition 6) with root c, costs $w_c(u) := d(u,c)$, and profits $\alpha_v := p_v$ (with $\alpha_c := 0$ for centers). A ρ-approximate density oracle therefore provides a ρ-approximate pricing oracle for the covering LP: calling it for each $c \in C$ and returning the column of globally smallest density gives an ρ-approximate minimizer of the ratio over all columns.

Step 3: Width and the upper bound q on $\mathrm{OPT}_{\mathrm{CLP}}$. To apply Theorem 10, we need (i) an upper bound $q \geq \mathrm{OPT}_{\mathrm{CLP}}$ and (ii) the associated width

$$W \geq q \cdot \max_{v \in U_0, j=(c,T)} \frac{A_{v,j}}{c_j} = q \cdot \max_{j=(c,T):T \neq \{c\}} \frac{1}{\mathrm{cost}_c(T)}. \tag{7}$$

Upper bound q. Construct the following explicit feasible solution: for each $v \in U_0$, let P_v be a shortest G-path from the nearest center c_v to v, which exists by the assumption on connectivity of G, and set $y_{V(P_v),c_v} = 1$ (with remaining variables 0). This is feasible (every v is covered) and has cost

$$q \coloneqq \sum_{v \in U_0} \mathrm{cost}_{c_v}(V(P_v)) \leq \sum_{v \in U_0} \sum_{u \in V(P_v)} d(u, c_v) \leq n_0 \cdot n \cdot D_{\max},$$

where $D_{\max} \coloneqq \max_{u,v \in V} d(u,v)$. Since the "Width W" step below normalizesd so that $\delta_{min} = 1$, then $D_{\max}$ conincides with the aspect ratio Δ, which is $\mathrm{poly}(n)$ by Remark 2. Therefore, $q = \mathrm{poly}(n)$.

Width W. After normalizing d by its minimum positive value so that $\delta \coloneqq \min_{u \neq v} d(u,v) = 1$ (this leaves all approximation ratios unchanged and ensures $c_j \geq 1$ for all non-trivial columns), the width in (7) becomes

$$W = q \cdot \max_j \frac{1}{c_j} \leq q \cdot \frac{1}{\delta} = q = \mathrm{poly}(n).$$

Step 4: Apply Theorem 10. With $m = n_0$, the ρ-approximate pricing oracle from Step 2, the upper bound $q \geq \mathrm{OPT}_{\mathrm{CLP}}$ from Step 3, and the width $W \leq q$ from Step 3, Theorem 10 yields a feasible $\hat{y}$ with

$$c^\top \hat{y} \leq \rho(1 + \varepsilon + \varepsilon^2)\mathrm{OPT}_{\mathrm{CLP}} \leq (1+\varepsilon)\rho \cdot \mathrm{OPT}_{\mathrm{CLP}}$$

absorbing ε^2 into ε by replacing ε with $\varepsilon/2$, and support size

$$|\mathrm{supp}(\hat{y})| = \widetilde{O}\left(\frac{n_0 W \rho}{\varepsilon^3}\right) = \widetilde{O}\left(\frac{n_0 q \rho}{\varepsilon^3}\right) = \mathrm{poly}(n).$$

Since $\mathrm{OPT}_{\mathrm{CLP}} \leq \mathrm{OPT}$ (Lemma 5), the stated bound $c^\top \hat{y} \leq (1+\varepsilon)\rho \cdot \mathrm{OPT}$ follows.

Runtime. Each iteration of the Plotkin–Shmoys–Tardos framework calls the density oracle $k \coloneqq |C|$ times (once per center) and selects the column of globally smallest density. The total number of iterations is $\widetilde{O}(n_0 W \rho/\varepsilon^3) = \mathrm{poly}(n)$. After all iterations, the restricted LP on the generated columns is solved exactly in polynomial time. Each oracle call is polynomial by Lemma 8, so the entire algorithm runs in polynomial time. ◀

The following theorem is a standard oracle-based reformulation of the fractional covering framework of Plotkin–Shmoys–Tardos; we cite Sharma [44, Theorems 3 and 4] for a clean restatement with approximate pricing and support bounds. For completeness, we provide a self-contained proof of Theorem 10 in the appendix.

▶ **Theorem 10** (Plotkin–Shmoys–Tardos [43]; cf. Sharma [44, Theorems 3 and 4])**.** *Consider the covering linear program* $\min\{c^\top y : Ay \geq \mathbf{1},\ y \geq 0\}$, *where* $A \in \mathbb{R}^{m \times N}_{\geq 0}$ *and* $c \in \mathbb{R}^N_{>0}$. *Let* OPT *denote its optimal value, and let* $q \geq \mathrm{OPT}$ *be a given upper bound on the optimal objective. Assume that for every weight vector* $w \in \mathbb{R}^m_{\geq 0}$, *there is a polynomial-time* α*-approximate pricing oracle returning a column* $j \in [N]$ *with*

$$\frac{c_j}{\sum_i A_{ij} w_i} \leq \alpha \cdot \min_{j' \in [N]} \frac{c_{j'}}{\sum_i A_{ij'} w_i}.$$

Let $W \geq q \max_{i,j}(A_{ij}/c_j)$ be a width bound. Then for every $\varepsilon \in (0,1]$, there is a polynomial-time algorithm that computes a feasible $\hat{y}$ with $c^\top \hat{y} \leq \alpha(1+\varepsilon+\varepsilon^2)\mathrm{OPT}$. Moreover, $|\mathrm{supp}(\hat{y})| = \widetilde{O}(mW\alpha/\varepsilon^3)$.

▶ Remark 11. The approximation ratio $\alpha(1+\varepsilon+\varepsilon^2)$ in Theorem 10 depends only on the oracle quality α and the accuracy parameter ε; it is *independent* of the width W. The width W affects only the support size and iteration count, not the approximation guarantee. In our setting $W \leq q = \mathrm{poly}(n)$, so both quantities are polynomial.

3.4 Rounding the Configuration LP

▶ **Theorem 12.** *Let $\hat{y}$ be any feasible solution to (1)–(3) with polynomial support. There is a randomized polynomial-time algorithm that, with high probability, outputs a feasible integral overlap solution $(S_c)c \in C$ covering all of $V \setminus C$ and its cost is $O(\log n) \cdot \sum_{c\in C}\sum_{T\in\mathcal{T}_c} \mathrm{cost}_c(T)\hat{y}_{T,c}$.*

Proof. Fix $\lambda \geq 2$. Independently for each pair (c,T) *in the support of* $\hat{y}$ (which is of polynomial size), sample T with probability $p_{T,c} \coloneqq \min\{1,\ \lambda \ln(n) \cdot \hat{y}_{T,c}\}$. For each $c \in C$, let $\mathcal{F}_c$ be the (multi)set of the sampled configurations and define $S_c \coloneqq \{c\} \cup \bigcup_{T\in\mathcal{F}_c} T$. Adding $\{c\}$ ensures $c \in S_c$ even if $\mathcal{F}_c = \emptyset$; since $d(c,c) = 0$, this adds zero cost. Each sampled T is connected and contains c, so S_c is a union of connected sets sharing c, hence connected.

Coverage. Fix $v \in V \setminus C$. Feasibility of $\hat{y}$ gives $\sum_{c,T:v\in T} \hat{y}_{T,c} \geq 1$. If any $p_{T,c} = 1$ for a pair with $v \in T$, then v is certainly covered. Otherwise $p_{T,c} = \lambda \ln(n)\hat{y}_{T,c}$ for all covering pairs, and

$$\Pr[v \text{ uncovered}] = \prod_{c,T:\, v\in T} (1 - p_{T,c}) \leq \exp\Big(-\sum_{c,T:\, v\in T} p_{T,c}\Big) \leq \exp(-\lambda \ln n_0) = n_0^{-\lambda}.$$

Union bound over $v \in V \setminus C$ (there are n_0 such vertices):

$$\Pr[\text{any } v \text{ uncovered}] \leq n_0 \cdot n_0^{-\lambda} \leq n_0^{-(\lambda-1)} \leq 1/n_0 = 1/\Omega(n)$$

for $\lambda \geq 2$.

Cost. For each c, since the cost of a union is at most the sum of costs:

$$\sum_{v\in S_c} d(v,c) \ \leq \ \sum_{T\in\mathcal{F}_c}\sum_{v\in T} d(v,c) = \sum_T \mathbf{1}[T \text{ sampled}] \cdot \mathrm{cost}_c(T).$$

Taking expectation and summing over c:

$$\mathbb{E}[\mathrm{ALG}] \leq \sum_{c,T} \mathrm{cost}_c(T) \cdot p_{T,c} \leq \lambda \ln(n) \sum_{c,T} \mathrm{cost}_c(T)\hat{y}_{T,c} = O(\log n) \sum_{c,T} \mathrm{cost}_c(T)\hat{y}_{T,c}.$$

By Markov's inequality, a single run has cost at most twice its expectation with constant probability; therefore, by performing $O(\log n)$ independent runs and returning the minimum-cost feasible solution, we obtain an $O(\log n)$-approximation with high probability. ◀

3.5 Proof of Theorem 3

Now we are ready to complete the proof of Theorem 3.

Proof of Theorem 3. By combining Theorem 9 and Theorem 12, we obtain that if there exists a ρ-approximate density oracle, then there is a polynomial-time algorithm that computes an $O(\rho \log n)$-approximate connected k-median clustering. For general graphs, Lemma 8 provides an $O(\log n)$-approximate density oracle. Substituting $\rho = O(\log n)$, we obtain an $O(\log^2 n)$-approximation. ◀

4 General Version

In this section, we establish bicriteria approximation guarantees for the general version of the connected k-median clustering problem. In particular, we prove Theorem 4, which we restate below.

▶ **Theorem 4.** *Given a vertex set V, a metric $d : V \times V \to \mathbb{R}_{\geq 0}$, an undirected, unweighted connectivity graph $G = (V, E)$ and an integer k, there exists a polynomial-time algorithm that computes an $(O(\log n), O(\log^2 n))$-approximate connected k-median clustering.*

To prove Theorem 4, we follow an approach similar to that used for the assignment version. We first formulate a configuration LP for the general case and compute a near-optimal fractional solution in polynomial time. We then round this solution to obtain the desired bicriteria guarantee. We provide the details in the subsequent sections.

4.1 General Version of the Configuration LP

Primal (Configuration) LP

$$\min \quad \sum_{c \in V} \sum_{T \in \mathcal{T}_c} \mathrm{cost}_c(T)\, y_{T,c} \tag{8}$$

$$\text{s.t.} \quad \sum_{c \in V} \sum_{\substack{T \in \mathcal{T}_c \\ v \in T}} y_{T,c} \geq 1 \qquad \forall v \in V, \tag{9}$$

$$\sum_{c \in V} \sum_{T \in \mathcal{T}_c} y_{T,c} \leq k \tag{10}$$

$$y_{T,c} \geq 0 \qquad \forall c \in V,\ \forall T \in \mathcal{T}_c. \tag{11}$$

4.2 Computing a ρ-Approximate Solution of the Configuration LP for the General Variant

First, we interpret the center-budget constraint as $\sum_{c \in V} \sum_{T \in \mathcal{T}_c} y_{T,c} \leq k$, which bounds the total configuration mass. This serves as a fractional relaxation of the requirement that at most k centers are opened. In particular, the variables $y_{T,c}$ are now defined for all $c \in V$ and all $T \in \mathcal{T}_c$. Let $\mathrm{OPT}_{\mathrm{GCLP}}$ denote the optimal value of this general configuration LP.

▶ **Lemma 13.** *Assume a ρ-approximate rooted minimum-density oracle for arbitrary non-negative node costs and profits. Then, for every $\varepsilon \in (0, 1)$, one can compute in polynomial time a polynomial-support fractional solution $\hat{y}$ satisfying*

$$\sum_{c \in V} \sum_{\substack{T \in \mathcal{T}_c \\ v \in T}} \hat{y}_{T,c} \geq 1 \qquad \forall v \in V, \tag{12}$$

$$\sum_{c \in V} \sum_{T \in \mathcal{T}_c} \hat{y}_{T,c} \leq (1+\varepsilon)k, \tag{13}$$

$$\sum_{c \in V} \sum_{T \in \mathcal{T}_c} \mathrm{cost}_c(T)\hat{y}_{T,c} \leq (1+\varepsilon)\rho \cdot \mathrm{OPT}_{\mathrm{GCLP}}. \tag{14}$$

Moreover, $\hat{y}$ may be chosen with support size polynomial in the input size and $1/\varepsilon$.

Proof. Write the general configuration LP as a mixed packing/covering program with one packing constraint. The covering constraints are indexed by vertices $v \in V$, and the columns are indexed by pairs (c, T) with $c \in V$ and $T \in \mathcal{T}_c$. For such a column, define

$$A_{v,(c,T)} \coloneqq \mathbf{1}[v \in T], \qquad b_{(c,T)} \coloneqq 1, \qquad q_{(c,T)} \coloneqq \mathrm{cost}_c(T).$$

Thus the LP has the form

$$\min \sum_{c,T} q_{(c,T)} y_{T,c} \quad \text{s.t.} \quad Ay \geq \mathbf{1}, \qquad \sum_{c,T} b_{(c,T)} y_{T,c} \leq k, \qquad y \geq 0.$$

We apply the standard oracle-based framework for mixed packing and covering programs, as in Young [47] and Plotkin–Shmoys–Tardos [43]. It suffices to identify the pricing problem required by this framework.

For a guessed objective value τ, the feasibility version is

$$Ay \geq \mathbf{1}, \qquad \sum_{c,T} y_{T,c} \leq k, \qquad \sum_{c,T} \mathrm{cost}_c(T) y_{T,c} \leq \tau, \qquad y \geq 0.$$

In the mixed packing/covering framework, a pricing step is given nonnegative weights p_v on the covering constraints and nonnegative multipliers η, θ for the two packing constraints. It asks for a column minimizing the ratio

$$\frac{\eta \cdot b_{(c,T)} + \theta \cdot q_{(c,T)}}{\sum_{v \in V} p_v A_{v,(c,T)}} = \frac{\eta + \theta\, \mathrm{cost}_c(T)}{\sum_{v \in T} p_v}.$$

For a fixed root c, this is exactly a rooted minimum-density connected-set problem. Indeed, define node costs $w_c^{\eta,\theta}(u) := \theta\, d(u, c) + \eta \cdot \mathbf{1}[u = c]$, and node profits $\alpha_u \coloneqq p_u$. Since every $T \in \mathcal{T}_c$ contains c, we have

$$\sum_{u \in T} w_c^{\eta,\theta}(u) = \theta \sum_{u \in T} d(u, c) + \eta = \theta \mathrm{cost}_c(T) + \eta.$$

Therefore the pricing ratio is precisely $\frac{\sum_{u \in T} w_c^{\eta,\theta}(u)}{\sum_{v \in T} \alpha_v}$. Calling the rooted minimum-density oracle once for each possible root $c \in V$ and taking the best returned column gives a ρ-approximate pricing oracle for the mixed packing/covering instance.

By the standard guarantee for mixed packing and covering with a ρ-approximate pricing oracle, binary search over τ and the above pricing routine compute, in polynomial time, a solution satisfying (12), (13), and (14). The factor $(1 + \varepsilon)$ accounts for the usual accuracy loss in the mixed packing/covering feasibility procedure.

Finally, the algorithm generates only polynomially many columns. Solving the restricted mixed LP over the generated columns and taking a basic feasible solution yields a polynomial-support solution $\hat{y}$ with the same bounds. ◀

▶ **Corollary 14.** *For general connectivity graphs, one can compute in polynomial time a fractional solution $\hat{y}$ satisfying* (12)*,* (13)*, and*

$$\sum_{c \in V} \sum_{T \in \mathcal{T}_c} \mathrm{cost}_c(T) \hat{y}_{T,c} \leq O(\log n) \cdot \mathrm{OPT}_{\mathrm{GCLP}}.$$

Proof. By Lemma 8, the rooted minimum-density oracle has approximation ratio $\rho = O(\log n)$ on general graphs. Applying Lemma 13 with a constant ε gives the claim. ◀

4.3 Rounding the General Version of the Configuration LP

In this subsection, we round the fractional solution obtained from Lemma 13.

▶ **Lemma 15.** *Suppose we are given a polynomial-support feasible solution $\hat{y}$ to (8)–(11) of cost at most Γ. Then there is a randomized polynomial-time algorithm that outputs, with high probability, an overlapping connected clustering using at most $O(k \log n)$ centers of cost $O(\log n) \cdot \Gamma$.*

Proof. Fix a constant $\lambda \geq 2$. Independently for every pair (c, T) in the support of $\hat{y}$, sample the configuration T with probability $p_{T,c} := \min\{1, \lambda \ln n \cdot \hat{y}_{T,c}\}$. For each $c \in V$, let $\mathcal{F}_c$ be the collection of the sampled configurations rooted at c. We open center c if $\mathcal{F}_c \neq \emptyset$, and define its cluster as $S_c := \bigcup_{T \in \mathcal{F}_c} T$. Since every sampled set $T \in \mathcal{T}_c$ contains c and is connected, the union S_c is connected whenever $\mathcal{F}_c \neq \emptyset$.

We first prove coverage. Fix a vertex $v \in V$. By feasibility of $\hat{y}$, $\sum_{c \in V} \sum_{\substack{T \in \mathcal{T}_c \\ v \in T}} \hat{y}_{T,c} \geq 1$. If there exists a pair (c, T) with $v \in T$ and $p_{T,c} = 1$, then v is covered with probability one. Otherwise,

$$\begin{aligned}\Pr[v \text{ is uncovered}] = \prod_{c,T:v \in T} (1 - p_{T,c}) &\leq \exp\Big(- \sum_{c,T:v \in T} p_{T,c} \Big) \\ &= \exp\Big(- \lambda \ln n \sum_{c,T:v \in T} \hat{y}_{T,c} \Big) \leq n^{-\lambda}.\end{aligned}$$

Taking a union bound over all vertices, the probability that some vertex is uncovered is at most $n^{1-\lambda}$, which is at most $1/n$ for $\lambda \geq 2$.

Next, we bound the number of opened centers. Let N be the number of the sampled configurations. Since the number of opened centers is at most N, it suffices to bound N. We have

$$\mathbb{E}[N] = \sum_{c \in V} \sum_{T \in \mathcal{T}_c} p_{T,c} \leq \lambda \ln n \sum_{c \in V} \sum_{T \in \mathcal{T}_c} \hat{y}_{T,c} \leq \lambda(1 + \varepsilon) k \ln n,$$

where the last inequality follows from Constraint (13). By a Chernoff bound, $N = O(k \log n)$ with high probability. Therefore, the algorithm opens at most $O(k \log n)$ centers with high probability.

Finally, we bound the cost. Since the cost of a union is at most the sum of the costs of the sampled configurations,

$$\text{cost}(\{S_c\}) = \sum_{c:\mathcal{F}_c \neq \emptyset} \sum_{v \in S_c} d(v, c) \leq \sum_{c \in V} \sum_{T \in \mathcal{F}_c} \text{cost}_c(T).$$

Taking expectation,

$$\mathbb{E}[\text{cost}(\{S_c\})] \leq \sum_{c \in V} \sum_{T \in \mathcal{T}_c} p_{T,c} \, \text{cost}_c(T) \leq \lambda \ln n \sum_{c \in V} \sum_{T \in \mathcal{T}_c} \text{cost}_c(T) \hat{y}_{T,c} = O(\log n) \cdot \Gamma.$$

By Markov's inequality, a single run has cost at most twice its expectation with constant probability; therefore, by performing $O(\log n)$ independent runs and returning the minimum-cost feasible solution, we obtain an $O(\log n)$-approximation with high probability. This proves the claimed bicriteria guarantee. ◀

4.4 Proof of Theorem 4

Now, we are ready to complete the proof of Theorem 4.

Proof of Theorem 4. Let $\hat{y}$ be the fractional solution returned by Lemma 13 with a fixed constant $\varepsilon \in (0,1)$. Then $\hat{y}$ satisfies the covering constraints and $\sum_{c\in V}\sum_{T\in\mathcal{T}_c} \hat{y}_{T,c} \le (1+\varepsilon)k$, and its cost is at most $(1+\varepsilon)\rho \cdot \mathrm{OPT}_{\mathrm{GCLP}} \le (1+\varepsilon)\rho \cdot \mathrm{OPT}$, where the last inequality follows because the general configuration LP is a relaxation of the non-assignment overlapping connected k-median problem.

Now apply Lemma 15 to $\hat{y}$ with $\Gamma := (1+\varepsilon)\rho \cdot \mathrm{OPT}$. The rounding opens at most $O\big((1+\varepsilon)k\log n\big) = O(k\log n)$ centers with high probability, and its expected cost is at most $O(\log n)\cdot\Gamma = O(\rho\log n)\cdot\mathrm{OPT}$. Thus we obtain an $\big(O(\log n), O(\rho\log n)\big)$ bicriteria approximation.

For general graphs, Lemma 8 gives $\rho = O(\log n)$. Therefore the bicriteria guarantee becomes $\big(O(\log n), O(\log^2 n)\big)$. This proves Theorem 4. ◀

5 Conclusion and Open Problems

In this paper, we developed a configuration-LP framework for the connected k-median problem. Unlike previous cut-based relaxations, our formulation incorporates connectivity directly into the LP variables by working with connected configurations rooted at centers. We combined this viewpoint with covering-LP techniques and rooted minimum-density oracles to obtain approximation guarantees for both the assignment version and a bicriteria variant of the general version. In particular, we obtained an $O(\log^2 n)$-approximation for the assignment version on general graphs, together with an $(O(\log n), O(\log^2 n))$ bicriteria approximation for the general version.

More broadly, our results suggest that configuration LPs provide a natural framework for handling connectivity constraints in clustering problems. By separating the problem into a covering-LP layer and a graph-theoretic rooted density oracle, the framework makes it possible to incorporate stronger oracles for special graph families and related connectivity models. We believe this viewpoint may be useful beyond connected k-median, particularly for other constrained clustering objectives where connectivity plays a central role.

Several interesting open problems remain. The most natural question is whether one can obtain polylogarithmic approximation guarantees for the general version containing exactly k centers. More generally, it would be interesting to better understand the power and limitations of configuration-LP formulations for connectivity-constrained clustering problems. Another promising direction is to design stronger rooted minimum-density oracles for restricted graph families, such as minor-closed graphs. Since the rooted minimum-density problem already admits an $O(\log n)$-approximation in general graphs, improving this guarantee on structured graph families would immediately translate into stronger approximation guarantees within our framework.

A Proof of Lemma 5

Proof. Fix a feasible overlapping solution $(S_c)_{c\in C}$. By feasibility, for every $c \in C$, we have $c \in S_c$ and $G[S_c]$ is connected. Hence $S_c \in \mathcal{T}_c$ for every center c. Define a configuration-LP solution y by

$$y_{T,c} := \begin{cases} 1, & \text{if } T = S_c, \\ 0, & \text{otherwise.} \end{cases}$$

We verify feasibility. First, for every $v \in V \setminus C$, the overlapping solution satisfies $\bigcup_{c\in C} S_c = V$, so there exists at least one center c such that $v \in S_c$. Therefore, $\sum_{c\in C} \sum_{\substack{T\in\mathcal{T}_c \\ v\in T}} y_{T,c} \geq 1$, and thus the covering constraints (2) hold for all $v \in V \setminus C$. Second, by construction, all variables satisfy $y_{T,c} \geq 0$, so (3) also holds. Finally, the objective value of this LP solution is

$$\sum_{c\in C} \sum_{T\in\mathcal{T}_c} \mathrm{cost}_c(T)\, y_{T,c} = \sum_{c\in C} \mathrm{cost}_c(S_c) = \sum_{c\in C} \sum_{v\in S_c} d(v,c),$$

which is exactly the cost of the given integral solution.

Since every feasible solution to the assignment variant of connected k-median with overlapping clusters induces a feasible solution to the configuration LP with the same cost, the optimal value of the configuration LP is at most OPT, the optimal cost of connected k-median with overlapping clusters for the prescribed center set C. ◀

B Proof of Lemma 8

Proof. Write $w(T) := \sum_{v\in T} w(v)$ and $\alpha(T) := \sum_{v\in T} \alpha_v$. Let T^* be an optimal density solution with $\lambda^* := w(T^*)/\alpha(T^*)$.

We use the bicriteria guarantee of Bateni et al. [7, Theorem 3] for the *rooted budgeted node-weighted Steiner tree problem*. In this problem, we are given a graph $G = (V, E)$, a designated root $c \in V$, a non-negative node-cost function $w : V \to \mathbb{R}_{\geq 0}$, a non-negative node-profit function $\alpha : V \to \mathbb{R}_{\geq 0}$, and a budget $B \geq 0$. The goal is to find a connected tree $T \subseteq G$ containing c whose total node cost is at most B and whose total profit $\alpha(T) := \sum_{v\in T} \alpha(v)$ is as large as possible. Let

$$\alpha^*(B) := \max\{\alpha(T) : T \ni c \text{ is connected and } w(T) \leq B\} \text{ where } w(T) := \sum_{v\in T} w(v).$$

Then, for any budget B and any $\varepsilon > 0$, there is a polynomial-time algorithm that returns a connected tree $T_B \ni c$ such that $w(T_B) \leq (1+\varepsilon)B$ and $\alpha(T_B) \geq \frac{\varepsilon}{O(\log n)} \cdot \alpha^*(B)$. In other words, the algorithm may violate the budget by a factor of at most $1+\varepsilon$, while guaranteeing an $O(\log n/\varepsilon)$-approximation to the maximum achievable profit under budget B.

Set $W_{\max} := w(V)$ and try the $O(\log W_{\max})$ budgets $B \in \{1, 2, 4, \ldots, 2^{\lceil \log_2 W_{\max} \rceil}\}$. There exists $B^\star$ in this list with $w(T^*) \leq B^\star \leq 2w(T^*)$. Apply the guarantee of Bateni et al. [7] with $\varepsilon := 1$. Since $w(T^*) \leq B^\star$, we have $\alpha^*(B^\star) \geq \alpha(T^*)$. The algorithm returns $T_{B^\star} \ni c$ with $w(T_{B^\star}) \leq 2B^\star \leq 4w(T^*)$ and $\alpha(T_{B^\star}) \geq \alpha(T^*)/O(\log n)$. Therefore,

$$\operatorname{dens}(T_{B^\star}) = \frac{w(T_{B^\star})}{\alpha(T_{B^\star})} \leq \frac{4\,w(T^*)}{\alpha(T^*)/O(\log n)} = O(\log n) \cdot \lambda^*.$$

Returning $\arg\min_B \operatorname{dens}(T_B)$ over all tried budgets yields an $O(\log n)$-approximate density oracle in polynomial time. ◀

C Proof of Theorem 10

Proof. The covering LP $\min\{c^\top y : Ay \geq \mathbf{1},\ y \geq 0\}$ has (in our usage) exponentially many columns, so we cannot solve it directly; we only have oracle access to an approximately-best column for any given constraint weighting. The proof has three parts.

1. We first observe that the α-approximate *pricing* oracle we are given is indeed also an η-weak *index-finding* oracle ($\eta = 1/\alpha$) for a natural quantity $D_j(w)$, the "coverage per unit weight" of column j.
2. We then show that an index-finding oracle over columns is the same thing as a point-finding oracle over a certain simplex-like polytope P_r (all vectors of cost exactly r). This is the step that lets us invoke a known black-box algorithm for fractional covering, which expects a point-finding oracle, not a column oracle.
3. The black-box algorithm, for a *fixed* guess r of the optimal cost, either certifies cost r suffices (up to a small violation) or fails. We do not know OPT in advance, so we do a binary search over r; two monotonicity facts about this success/failure signal pin down $r \approx \mathrm{OPT}$ and let us convert the near-feasible solution found at the end into a genuinely feasible one, at a controlled extra cost.

In what follows, we elaborate on each of these steps.

Part 1: from pricing to index-finding. For a column j and weight vector $w \in \mathbb{R}^m_{\geq 0}$, let $D_j(w) := \frac{w^\top A_{\cdot j}}{c_j} = \frac{\sum_i A_{ij} w_i}{c_j}$. Think of $D_j(w)$ as how much weighted coverage column j buys you per unit of its cost. An oracle is an *η-weak index-finding oracle* if, given $w \geq 0$, it returns some j with $D_j(w) \geq \eta \max_\ell D_\ell(w)$, in other words a column that is within a factor $\eta \leq 1$ of the best possible coverage-per-cost.

The assumed pricing oracle minimizes the *reciprocal* quantity $c_j/(w^\top A_{\cdot j}) = 1/D_j(w)$ to within a factor α: If $\frac{c_j}{w^\top A_{\cdot j}} \leq \alpha \cdot \min_{j'} \frac{c_{j'}}{w^\top A_{\cdot j'}}$, then taking reciprocals (all quantities are positive since $c > 0$; the degenerate case $\max_\ell D_\ell(w) = 0$, i.e. when w is orthogonal to every column, makes the index-finding requirement vacuous and is set aside), then

$$D_j(w) \geq \frac{1}{\alpha} \max_\ell D_\ell(w).$$

So the pricing oracle *is* an η-weak index-finding oracle with $\eta := 1/\alpha$.

Part 2: from index-finding to point-finding on P_r. Fix a target cost $r \geq 0$ and consider the cost-r slice of the nonnegative orthant, $P_r := \{y \in \mathbb{R}^N_{\geq 0} : c^\top y = r\}$. We introduce this set because known fractional-covering algorithms are stated abstractly for a polytope P together with a *point-finding* oracle (return an approximately-best point of P for a given linear objective), and we want to feed our column oracle into one of them. The set P_r is exactly the right polytope: every $y \in P_r$ can be written as $y = \sum_{j=1}^N \frac{c_j y_j}{r} \cdot \frac{r}{c_j} e_j$, and the coefficients $c_j y_j / r$ are nonnegative and sum to 1 (since $\sum_j c_j y_j = c^\top y = r$), so y is a convex combination of the points $\{(r/c_j)e_j : j \in [N]\}$. In other words, P_r is the simplex whose vertices are, for each column j, spend the entire budget r on column j alone. Maximizing a linear function over a simplex is achieved at a vertex, so for any weight vector $w \geq 0$,

$$\max_{y \in P_r} w^\top A y = \max_{j \in [N]} w^\top A\Big(\frac{r}{c_j} e_j\Big) = r \cdot \max_j D_j(w).$$

This identity is the crux of this part: finding a good *point* of P_r for objective $w^\top A(\cdot)$ is literally the same problem as finding a good *column* for $D_j(w)$, just rescaled by r. So our η-weak index-finding oracle, applied to w, returns a column j with $D_j(w) \geq \eta \max_\ell D_\ell(w)$; setting $y := (r/c_j)e_j \in P_r$ gives

$$w^\top A y = r D_j(w) \geq \eta \cdot r \max_\ell D_\ell(w) = \eta \max_{y' \in P_r} w^\top A y',$$

In other words, y is an η-weak maximizer of $w^\top A y$ over P_r. We have therefore converted our column oracle into an η-weak point-finding oracle for P_r, for every r simultaneously (the construction above does not depend on r except through the final rescaling).

We also record the *width* of this setup, since the black-box algorithm's running time depends on it: by the same vertex computation,

$$\mathrm{width}(A, \mathbf{1}, P_r) := \max_{y \in P_r} \max_i (Ay)_i = \max_{i,j} A_{ij} \cdot \frac{r}{c_j} = r \max_{i,j} \frac{A_{ij}}{c_j}.$$

Using any known bound $q \geq \mathrm{OPT}$ and the given $W \geq q \max_{i,j} A_{ij}/c_j$, we get, for every $r \leq q$,

$$\mathrm{width}(A, \mathbf{1}, P_r) = r \max_{i,j} \frac{A_{ij}}{c_j} \leq q \max_{i,j} \frac{A_{ij}}{c_j} \leq W.$$

Part 3: black-box covering, then binary search on r. We now invoke, as a black box, the standard guarantee for fractional covering with an approximate point-finding oracle (Plotkin–Shmoys–Tardos; we use the clean restatement of Sharma [44], Theorems 3–4): given the η-weak point-finding oracle for P_r from Part 2 and the width bound W from Part 2, and setting $\mu := \frac{\eta}{1+\epsilon}$, the algorithm either correctly reports $\{y \in P_r : Ay \geq \mathbf{1}\}$ is empty or returns some $y \in P_r$ with $Ay \geq \mu\mathbf{1}$ (i.e. every covering constraint is satisfied up to a $(1-\mu)$ shortfall) using a number of oracle calls that yields support size $|\mathrm{supp}(y)| = \widetilde{O}(mW/(\eta\epsilon^3))$ when the oracle always returns a single vertex (which ours does, by construction in Part 2). Call this routine on input r and write $g(r) = 1$ if it succeeds (returns such a y) and $g(r) = 0$ if it reports infeasibility.

The routine above only tells us, for a *given* r, whether spending exactly r can nearly cover everything. We do not know OPT, so we search for the smallest r at which $g(r)$ flips from 0 to 1. The bisection argument has two parts:

(i) $r \geq \mathrm{OPT} \implies g(r) = 1$. Let y^* be an optimal solution of the original covering LP, so $c^\top y^* = \mathrm{OPT}$ and $Ay^* \geq \mathbf{1}$. Rescaling, $\frac{r}{\mathrm{OPT}} y^* \in P_r$ (it has cost exactly r) and $A\big(\frac{r}{\mathrm{OPT}} y^*\big) = \frac{r}{\mathrm{OPT}} Ay^* \geq \frac{r}{\mathrm{OPT}}\mathbf{1} \geq \mathbf{1}$ since $r \geq \mathrm{OPT}$. So $\{y \in P_r : Ay \geq \mathbf{1}\}$ is genuinely nonempty, and since it is nonempty (and in particular $Ay \geq \mathbf{1} \geq \mu\mathbf{1}$ trivially, as $\mu \leq 1$), the routine cannot correctly report infeasibility; hence $g(r) = 1$.

(ii) $r < \mu \cdot \mathrm{OPT} \implies g(r) = 0$. Suppose instead $g(r) = 1$, i.e. the routine returns $y \in P_r$ with $Ay \geq \mu\mathbf{1}$. Rescale: $\hat{y} := y/\mu$ satisfies $A\hat{y} = Ay/\mu \geq \mathbf{1}$, so $\hat{y}$ is feasible for the *original* covering LP, with cost $c^\top \hat{y} = (c^\top y)/\mu = r/\mu < \mathrm{OPT}$ (using $r < \mu \cdot \mathrm{OPT}$). This contradicts optimality of OPT. So $g(r) = 1$ is impossible, i.e. $g(r) = 0$.

Then, we initialize $\ell = 0$, $u = q$ (both satisfy $g(\ell) = 0, g(u) = 1$, using fact (ii) at $\ell = 0$ whenever $\mathrm{OPT} > 0$), and repeatedly query the midpoint $r = (\ell + u)/2$: if $g(r) = 0$ set $\ell := r$, otherwise set $u := r$ and record the returned vector. Stop once $u \leq (1+\delta)\ell$ for $\delta := \varepsilon^2/(1+\varepsilon)$; this takes $O(\log(q/(\delta \cdot (\text{smallest gap}))))$ iterations, polynomial in the input size.

Finally, at termination $g(\ell) = 0$ forces $\ell < \mathrm{OPT}$ (else fact (i) would give $g(\ell) = 1$), so $u \leq (1+\delta)\ell < (1+\delta)\,\mathrm{OPT}$. Let $y^{(u)} \in P_u$ be the vector recorded at the last successful call ($g(u) = 1$), so $Ay^{(u)} \geq \mu\mathbf{1}$ and $c^\top y^{(u)} = u$. Define $\hat{y} := \frac{1}{\mu} y^{(u)}$. Exactly as in fact (ii)'s rescaling, $A\hat{y} \geq \mathbf{1}$, so $\hat{y}$ is feasible for the original covering LP. Its cost is $c^\top \hat{y} = \frac{u}{\mu} \leq \frac{(1+\delta)}{\mu}\mathrm{OPT}$. Substituting $\mu = \eta/(1+\varepsilon)$ and $\delta = \varepsilon^2/(1+\varepsilon)$:

$$\frac{1+\delta}{\mu} \;=\; \Big(1 + \frac{\varepsilon^2}{1+\varepsilon}\Big) \cdot \frac{1+\varepsilon}{\eta} = \frac{1+\varepsilon+\varepsilon^2}{\eta} = \alpha(1+\varepsilon+\varepsilon^2),$$

using $\eta = 1/\alpha$ from Part 1. This gives the claimed cost bound $c^\top \hat{y} \leq \alpha(1+\varepsilon+\varepsilon^2)\mathrm{OPT}$. Rescaling by $1/\mu$ does not change the support, so

$$|\mathrm{support}(\hat{y})| = |\mathrm{support}(y^{(u)})| = \widetilde{O}\Big(\frac{mW}{\eta\varepsilon^3}\Big) = \widetilde{O}\Big(\frac{mW\alpha}{\varepsilon^3}\Big),$$

matching the statement of the theorem.

Runtime. Each bisection step invokes the black-box covering routine once, which in turn calls our point-finding oracle (equivalently, the original pricing oracle, once per iteration of that routine) $\mathrm{poly}(m, W, 1/\varepsilon)$ times; the number of bisection steps is $\mathrm{poly}(\log(q/\mathrm{OPT}), \log(1/\delta))$. All oracle calls and arithmetic operations are polynomial whenever q, W, and the input encoding lengths are polynomially bounded, giving the stated overall polynomial running time. ◀

Approximation Algorithms for Matroidal Prerequisite Systems

Robert P. Streit
Dept. of Electrical & Computer Engineering, The University of Texas at Austin, TX, USA

Vijay K. Garg
Dept. of Electrical & Computer Engineering, The University of Texas at Austin, TX, USA

Abstract

Optimal selections in a decision process are often constrained by prerequisites. However, such prerequisites can encode functional rather than literal dependencies, so a required dependency may be supplied by one or several interacting alternatives. We introduce *matroidal prerequisite systems (MPS)*, a combinatorial constraint structure where a poset specifies prerequisites while a matroid determines when those prerequisites have been satisfied by its span. This creates an order-sensitive notion of feasibility over words, where feasible words are associated with independent sets, while dependencies may be fulfilled through substitutable functionality.

Our main contribution is approximation algorithms for nonnegative additive maximization and monotone submodular maximization over the feasible words of an MPS. The guarantees are determined by two structural parameters: the maximum matroid rank Δ of a principal ideal in the poset and the maximum matroid connectivity $\lambda_{\max}$. These measure the distance an MPS is from encoding a matroid or a poset antimatroid, respectively, both of which are generalized by an MPS. For additive maximization, we obtain deterministic Δ- and $(1+\lambda_{\max})$-approximation algorithms. By extending these techniques, we obtain efficient deterministic $(2+\lambda_{\max})$-approximation and randomized $(\Delta^2 \cdot (1-1/e-\delta)^{-1})$-approximation algorithms for all $\delta > 0$ for submodular maximization. The algorithm design and analysis use the theory of polymatroid greedoids, via a cryptomorphism we prove between an MPS and a *strong polymatroid greedoid*. Finally, a reduction from densest k-subgraph shows it is not possible to efficiently compute a $\min\{\Delta, \lambda_{\max}\}^{o(1)}$-approximation to nonnegative additive maximization over the feasible words of an MPS under the Gap Exponential Time Hypothesis. Thus, an MPS provides a tractable, but provably nontrivial, framework for combinatorial optimization with interacting prerequisites, independence, and substitution.

1 Introduction

In a discrete decision process, some decisions are not meaningful, feasible, or useful until other functionality is already present. This is perhaps most obvious in task scheduling problems, where dependencies impose constraints on what can and cannot be completed. However, such dependencies are rarely literal. Some project task may require not an earlier task itself, but rather some interface or information that earlier tasks are meant to provide. These required

functionalities may be satisfied by alternative selections of one or many interacting decisions. Yet, existing prerequisite models (e.g. [38, 19, 41, 31, 20]) typically require prerequisites to be selected explicitly; i.e. if y is a prerequisite of z, then z can only be chosen after y. So, there is no awareness of the overlap or substitutable nature of the decision functionalities.

Matroids encode such a substitution structure. A *matroid* $\mathcal{M}$ is a nonempty set family, whose members are called *independent*, such that every subset of an independent set is independent and for all independent X and Y with $|Y| > |X|$ there exists $z \in Y \setminus X$ such that $X + z$ is independent. The *rank* $r_{\mathcal{M}}(X)$ of an arbitrary set X is the size of a maximal independent set it contains, while the *span* $\sigma_{\mathcal{M}}(X)$ is the union of X with the elements which do not increase its rank. Now, if feasible sequences of decisions $x_1 \dots x_\ell$ are always such that $\{x_1, \dots, x_\ell\}$ is independent, then the span $\sigma_{\mathcal{M}}(\{x_1, \dots, x_\ell\})$ can encode the functionalities covered by $x_1 \dots x_\ell$. So, two decisions $y, z \notin \sigma_{\mathcal{M}}(\{x_1, \dots, x_\ell\})$ which are not made redundant by these functionalities (in the sense they are spanned by $\{x_1 \dots x_\ell\}$) are $\{x_1, \dots, x_\ell\}$-*substitutable* if and only if $\sigma_{\mathcal{M}}(\{x_1, \dots, x_\ell, y\}) = \sigma_{\mathcal{M}}(\{x_1, \dots, x_\ell, z\})$. This is, given what is already covered by $x_1 \dots x_\ell$, any new functionality added by y or z leads to equivalent coverage. Matroids hold a central place in discrete optimization because their structure models many problems and gives algorithms for many settings (see [40, 10, 35, 5, 14, 45]).

In this work, we study the optimization problems that arise when prerequisite and matroidal substitution structure are forced to interact. Our reasons are both modeling based and algorithmic. Many applications lead to prerequisite structure defined via substitutable functionalities rather than irreplaceable objects, and we would like to capture this. We will also see the resulting constraint systems form a structured class weaker than matroids that still admits approximation algorithms for additive and submodular maximization. To that end, we propose the *matroidal prerequisite system (MPS)*, which is a simple language (words without repeating letters) over a finite alphabet Σ defined by an interaction between a matroid $(\Sigma, \mathcal{M})$ and poset $(\Sigma, \rightsquigarrow)$. The words $y_1 \dots y_\ell$ in the language, denoted by $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$, are such that their letters always form independent sets, and each y_i is such that all prerequisites $x \rightsquigarrow y_i$ are either spanned by the prefix $\{y_1, \dots, y_{i-1}\}$ in the matroid or x and y_i are $\{y_1, \dots, y_{i-1}\}$-substitutable. This, along with a compatibility condition stating that letters spanned by feasible words must be such that their prerequisites are also spanned, defines an MPS. The upshot is the poset and matroid retain their usual roles, but no longer act independently. Specifically, the poset specifies which decisions require earlier prerequisite coverage, and the matroid determines when that prerequisite coverage has been supplied via its span while continuing to enforce nonredundancy via independence. An MPS generalizes matroids, as $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is the permutations of independent sets if the ordering relation is empty, as well as *poset antimatroids* (the language of linear extensions of a poset) as $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is the linear extensions of $(\Sigma, \rightsquigarrow)$ if $\mathcal{M}$ is free (all sets are independent).

Our main contributions are approximation algorithms for maximization over the words of an MPS of nonnegative additive and monotone submodular functions. Our guarantees are given in terms of structural parameters measuring the distance of an MPS from being a matroid or poset antimatroid. First is the largest matroid rank of a principal ideal,

$$\Delta \triangleq \max_{z \in \Sigma} r_{\mathcal{M}}(\downarrow z), \quad \text{where } \downarrow z \triangleq \{y \in \Sigma \mid y \rightsquigarrow z\} \cup \{z\}. \tag{1}$$

If the MPS is a matroid (i.e. "$\rightsquigarrow$" is empty) then $\Delta = 1$, and as the prerequisites become more complex Δ will increase. The second parameter is defined by the largest value taken by the (Tutte) connectivity function λ (see [47, 48, 37]) of the matroid,

$$\lambda_{\max} \triangleq \max_{X \subseteq \Sigma} \lambda(X), \quad \text{where } \lambda(X) \triangleq r_{\mathcal{M}}(X) + r_{\mathcal{M}}(\Sigma \setminus X) - r_{\mathcal{M}}(\Sigma). \tag{2}$$

The connectivity $\lambda(X)$ computes how much the complement $\Sigma \setminus X$ can cover X in its span, in terms of rank. Equivalently, $\lambda(X)$ measures how much of X can be substituted with its complement. So, $\lambda_{\max}$ measures how complex the substitutes structure is. Note $\lambda_{\max} \geq 0$. For free matroids where every set is independent, we see $\lambda_{\max} = 0$. So, $\lambda_{\max} = 0$ when the MPS defines a poset antimatroid and increases as the substitutes structure becomes more complex. This leads to our first main result.

▶ **Main Result 1** (Theorems 12, 13, 14, and 15)**.** *Let $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be a matroidal prerequisite system. Assume we are given a matroid rank oracle.*

1. *There exists an efficient deterministic $\min\{\Delta, 1 + \lambda_{\max}\}$-approximation algorithm for nonnegative additive maximization over the feasible words of $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$,*
2. *There exists an efficient deterministic $(2 + \lambda_{\max})$-approximation and, for every $\delta > 0$, an efficient randomized $(\Delta^2 \cdot (1 - 1/e - \delta)^{-1})$-approximation algorithm for monotone submodular maximization over the feasible words of $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$.*

Observe, our methods achieve exact solutions for additive maximization whenever the MPS is a matroid or poset antimatroid. These are the two "easy" cases, and the approximation smoothly degrades as we drift towards a more complex MPS structure (as Δ and $\lambda_{\max}$ will increase). For submodular maximization we achieve essentially the best possible approximation [34] when the MPS is a matroid. For poset antimatroids, the problem becomes trivialized as the entirety of Σ can always be permuted into a linear extension, so outputting this permutation always leads to an exact solution even for monotone submodular objectives. But, our guarantee would give a 2-approximation. Whether it is possible to improve this to smoothly interpolate between this scenario and more complex MPS structures (like in the additive case) is something we leave to future work. Finally, we note that the expected $(\Delta^2 \cdot (1 - 1/e - \delta)^{-1})$-approximation guarantee comes from using the continuous greedy algorithm [5] as a black-box subroutine. We present our methods with this chosen subroutine because it is the most recognizable to the widest audience, but one could replace this with any of [45, 14, 4, 7] to obtain various improvements.

Our algorithmic techniques make use of *strong polymatroid greedoids* recently introduced in [44]. Specifically, a polymatroid greedoid is a greedoid whose feasibility structure can be encoded by a polymatroid rank function called a *representation*. Strong polymatroid greedoids are a subclass admitting certain closure operators and a canonical representation called *the greatest representation*. We prove a cryptomorphism in Theorem 9 showing a greedoid is a strong polymatroid greedoid if and only if it can be encoded as an MPS. This allows us to use the greatest representation in our algorithms after verifying this function can be evaluated efficiently using a matroid rank oracle. In particular, Section 5 presents algorithms based off of solving a relaxation over the base polytope of the greatest representation, while Section 6 uses the greatest representation to create modified greedy algorithms. The correctness will follow from Lemma 11, which discusses how to iteratively "fill-in" sets of letters contained in feasible words to converge to a full feasible word in a strong polymatroid greedoid.

To complement the algorithmic results, we also investigate the hardness of nonnegative additive maximization. We give an approximation-preserving reduction from Densest k-Subgraph. By [29], this shows our algorithmic guarantees are meaningful in that exponential improvements are not possible under the Gap Exponential Time Hypothesis (see [30, 9, 6]).

▶ **Main Result 2.** *Under the Gap Exponential Time Hypothesis, there is no $\min\{\Delta, \lambda_{\max}\}^{o(1)}$-approximation algorithm for additive maximization over a matroidal prerequisite system.*

Our reduction uses uniform matroids, so we note that this hardness applies even to an MPS defined with a uniform matroid. While Main Result 2 shows constant or logarithmic-approximation algorithms in these parameters are unlikely, the result doesn't comment on sublinear approximations in their entirety. We leave the resolution of this gap to future work.

Overview. We begin by surveying related work and making comparisons in Section 2. Then, in Section 3 we overview some background. Section 4 will introduce the MPS. Section 4.1 examines the greedoid theory of an MPS, and proves a cryptomorphism between the class of MPS and strong polymatroid greedoids from [44] in Theorem 9. Section 4.2 shows that the greatest representation of a MPS can be evaluated efficiently via a matroid rank query, while Section 4.3 proves that every sequence of letters such that the marginal return of each letter against its prefix in the greatest representation is greater than zero can be "filled" into a feasible word by repeated letter insertions.

In Section 5 we design approximation algorithms with guarantees varying in Δ. Section 5.1 gives a method for additive maximization which is based on solving a relaxation defined by the greatest representation and projecting the solution onto a feasible word using Lemma 11. This is Algorithm 1, which Theorem 12 shows is a Δ-approximation algorithm. Then, in Section 5.2 we obtain a method for monotone submodular maximization by applying the continuous greedy algorithm [5] to the *natural matroid* construction [16, 3] of the greatest representation, and using the solution to create an additive underestimation which is fed into Algorithm 3. The analysis in Theorem 13 shows this process leads to an expected approximation at most a Δ^2 factor worse than that of [5] for submodular maximization over matroids. In Section 6, we design approximation algorithms with guarantees varying in $\lambda_{\max}$. Section 6.1 begins by examining algorithms for additive objectives, and presents a modified greedy algorithm (Algorithm 3) using the greatest representation to adjust the perceived value of available letters in each round, and the closure operator of strong polymatroid greedoids to determine where to insert selected letters into a working solution. Theorem 14 shows the resulting solution is a $(1 + \lambda_{\max})$-approximation. Then, Section 6.2 extends the technique to achieve a $(2 + \lambda_{\max})$-approximation for submodular objective functions. Finally, we conclude by proving Main Result 2 in Section 7.

2 Related Work

Our MPS is in many ways a relaxation of matroids for designing approximation algorithms in more general settings. Other approaches have been made in this spirit. See for example p-systems [35], k-intersection [21, 27], k-extendible [32], and k-exchange [13] systems. All come with approximate guarantees decaying in the "distance" from a matroid, like the Δ parameter used in Main Result 1. But, a key difference is our feasibility model is order-sensitive. This is to say, where previous works maintain a subset-closed set family, our approach injects a notion of prerequisites using a poset that destroys such structure. This is why we interpret our MPS as a greedoid [25], as this theory accommodates order-sensitive feasibility.

On that note, there do exist works mixing prerequisite structure with other combinatorial constraint systems. A notable example is precedence constrained knapsack variants [41, 19, 20] and maximum closure [38, 31] problems. However, the prerequisite constraints of these problems require a "complete" closure, in the sense that an element can only be selected once *all* of its prerequisites are present. In contrast, we use a matroid to encode notion of substitution or redundancy. Along these lines, AND/OR scheduling problems [33] use Boolean formulae to allow for alternatives through disjunction. However, in [33] the formulae are explicit inputs, while our delegation to the matroid induces a stateful and implicit notion of substitutability which varies over the decision process.

Our work uses greedoids, a structure introduced by Korte and Lovász to generalize matroids by removing the definitional dependence on subset-closed set families [22, 25, 2]. For linear optimization, [23, 15] give a necessary and sufficient called *strong exchange* for

the correctness of the greedy algorithm in greedoids, which was later generalized to the idea of a *matroid embedding* in [17]. In Section 4 we will see that the greedy algorithm fails to solve additive maximization on an MPS, and so these results do not apply to our setting. Without strong exchange, there do exist certain characterizations on the types of objective functions which the greedy algorithm can correctly solve [25, 46, 12], but they are sensitive to the greedoid structure and quite restrictive. Polymatroid greedoids are introduced in [24], and recently studied in [44]. This class is defined by an interaction between a polymatroid and a greedoid which allows for the use of submodular analysis (which is typically not fully available in the greedoid setting, unlike matroids). The latter work [44] introduces *strong polymatroid greedoids*, which give special properties we use for the design and analysis of our algorithms after showing an MPS is cryptomorphically equivalent to such a greedoid.

3 Preliminaries

For any set X, let $X!$ give its permutations, and $\chi_X \in \{0,1\}^\Sigma$ be its characteristic vector. We often iterate over words written like $y_1 \dots y_{i-1}$, so we are implicitly writing $y_1 \dots y_0$ when $i = 1$. Let $y_1 \dots y_0 = \epsilon$, where ϵ is the empty word, and $\{y_1, \dots, y_0\} = \varnothing$. Finally, for $v \in \mathbb{R}^\Sigma$, the *support* $\operatorname{supp}(v) \triangleq \{y \in \Sigma \mid v(y) \neq 0\}$ is the set of labels for the nonzero coordinates in v.

Submodularity. An *additive function* is a set function defined by assigning each letter a weight via $w : \Sigma \to \mathbb{R}$ and mapping sets to the sum of the weights of letters they contain, like $X \mapsto \sum_{y \in X} w(y)$. A *submodular function* $f : 2^\Sigma \to \mathbb{R}$ is a set function satisfying the *law of diminishing returns* defined as $X \subseteq Y$ implies $(f/X)(z) \geq (f/Y)(z)$ for all $z \in \Sigma$. where $(f/X)(z) \triangleq f(X + z) - f(X)$ is the evaluation of the *contraction of f by X* at the letter z. We adopt the convention that $(f/X)(z) = 0$ whenever $z \in X$. Note, if $X = \{y_1, \dots, y_\ell\}$, then $f(X) = \sum_{i=1}^{\ell} (f/\{y_1, \dots, y_{i-1}\})(y_i)$. And so, submodular functions generalize additive functions. Nonnegative additive and monotone (i.e. $X \subseteq Y$ implies $f(X) \leq f(Y)$) submodular functions are the objective functions we consider. We will assume that f is *normalized*, i.e. $f(\varnothing) = 0$, to remove any translation effects from our approximation ratios. This is a common maneuver, see [35, 5, 14] for example.

A *polymatroid rank function* $\rho : 2^\Sigma \to \mathbb{Z}$ is a monotone, normalized, submodular function. Though integrality is not strictly required, the polymatroid rank functions used in this work will have integral codomains. A matroid rank function $r_\mathcal{M}$ is simply a *subcardinal* polymatroid rank function, i.e. $r_\mathcal{M}(X) \leq |X|$ always holds. In this way, polymatroids generalize matroids. They can also be viewed as a multiset generalization of matroids as well. These perspectives lead to a few different ways of constructing matroids from polymatroids, which we will see in Section 4.1 and Section 5.2. The *base polytope* of a polymatroid is the set of nonnegative vectors in $\mathbb{R}^\Sigma$ saturating the total rank and satisfying a collection of rank inequalities over all subsets like $\left\{v \in \mathbb{R}^\Sigma_+ \;\middle|\; \|v\|_1 = \rho(\Sigma) \text{ and } (\forall X \subseteq \Sigma)\ \sum_{y \in X} v(y) \leq \rho(X)\right\}$. Famously, when introducing polymatroids Edmonds gave a greedy algorithm for solving linear maximization [11]. For a solution over the base polytope, this is sorting the coordinates by weight and iteratively increasing each coordinate by its marginal return against its predecessors in the sorted order (see [11] for details). Finally, the *span* operator $\sigma_\rho : 2^\Sigma \to 2^\Sigma$ is defined as $\sigma_\rho(X) \triangleq \{y \in \Sigma \mid \rho(X + y) = \rho(X)\}$, i.e. those elements for which the marginal return follows $(\rho/X)(y) = 0$. The span is a closure operator, that is it is *monotone* (i.e. $X \subseteq Y$ implies $\sigma_\rho(X) \subseteq \sigma_\rho(Y)$), *idempotent* (i.e. $\sigma_\rho(\sigma_\rho(X)) = \sigma_\rho(X)$, and *extensive* (i.e. $X \subseteq \sigma_\rho(X)$). We note that the ρ-closed sets are closed under intersection, and that this is a necessary and sufficient description of any closure operator. And so, those sets $X \subseteq \Sigma$

such that $X = \sigma_\rho(X)$ are called ρ-*closed*. Notice, $\sigma_{r_\mathcal{M}} = \sigma_\mathcal{M}$ for a matroid $\mathcal{M}$. A defining feature is the *Steinitz-Maclane exchange property*, which is $y, z \notin \sigma_\mathcal{M}(X)$ and $y \in \sigma_\mathcal{M}(X + z)$ implies $z \in \sigma_\mathcal{M}(X + y)$. This is the reason why we may use matroid span operators to encode substitutability in constraint structures, as the Steinitz-Maclane exchange property ensures that z "capturing" y in the increased span $\sigma_\mathcal{M}(X + z)$ is symmetric. Finally, a *loop* $y \in \Sigma$ is an element such that $\rho(y) = 0$.

Lattices and Order. Let $\mathscr{P} = (\mathcal{X}, \sqsubset)$ be a poset with reflexive closure "$\sqsubseteq$". A set $I \subseteq \mathscr{P}$ is an (order) *ideal* if $\mathbf{z} \in I$ and $\mathbf{y} \sqsubset \mathbf{z}$ implies $\mathbf{y} \in I$. The ideal generated by an arbitrary set S is $\downarrow S \triangleq \{\mathbf{y} \in \mathcal{X} \mid (\exists \mathbf{z} \in S)\ \mathbf{y} \sqsubseteq \mathbf{z}\}$. A *principal ideal* $\downarrow \mathbf{y}$ is generated by a single poset element. For $\mathbf{x}, \mathbf{y} \in \mathscr{P}$ the *meet* $\mathbf{x} \sqcap \mathbf{y}$ is the binary infimum while the *join* $\mathbf{x} \sqcup \mathbf{y}$ is the binary supremum whenever unique such elements exist. A poset is a *lattice* when a meet and join is defined for every pair. The *covering relation*, which we denote by "$\prec$" for any poset, is such that $\mathbf{x} \prec \mathbf{y}$ if and only if $\mathbf{x} \sqsubset \mathbf{y}$ and there is no $\mathbf{z}$ with $\mathbf{x} \sqsubset \mathbf{z} \sqsubset \mathbf{y}$. One visualizes posets via *Hasse diagrams*, consisting of nodes corresponding to the elements of the ground set $\mathcal{X}$ and line segments such that there is a line directed upwards from $\mathbf{x}$ to $\mathbf{y}$ if and only if $\mathbf{x} \prec \mathbf{y}$. A poset $\mathscr{P}$ is *graded* whenever there exists a function $g : \mathscr{P} \to \mathbb{Z}_+$ such that $\mathbf{x} \prec \mathbf{y}$ implies $g(\mathbf{x}) = g(\mathbf{y}) - 1$. A grade taking value zero on bottom elements is the *height function*. Finally, a lattice is *semimodular* if and only if $\mathbf{x} \succ \mathbf{x} \sqcap \mathbf{y}$ implies $\mathbf{y} \prec \mathbf{x} \sqcup \mathbf{y}$. We note semimodular lattices are always graded.

Greedoids. Let Σ^* be all finite sequences over Σ. Each $\alpha \in \Sigma^*$ is a *word* $\alpha = y_1 \dots y_k$ composed of *letters* from Σ. A *language* $\Lambda \subseteq \Sigma^*$ is a set of words. We only examine *simple* languages which do not contain words with repeated letters. To model problems of interest using languages, one can let letters symbolize decisions which can be made over a process, while words give the *feasible* arrangements of decisions. The *support* $\widetilde{\alpha}$ is the set of letters forming α, and we refer to the length of a word via $|\alpha|$. Longest words in Λ are called *basic*. Finally, a *loop* $y \in \Sigma$ is a letter such that $y \notin \widetilde{\alpha}$ for all $\alpha \in \Lambda$, i.e. a loop does not appear in any word. A *greedoid* can be defined as a language generalization of a matroid.

▶ **Definition 1** (Greedoid). *A* greedoid Λ *over* Σ *is a nonempty simple language satisfying,*
1. (Hereditary) $\alpha\beta \in \Lambda$ *implies the prefix* α *is feasible, i.e.* $\alpha \in \Lambda$*,*
2. (Exchange) *For all* $\alpha, \beta \in \Lambda$*, if* $|\alpha| > |\beta|$ *then there exists* $x \in \widetilde{\alpha}$ *such that* $\beta x \in \Lambda$*.*

We give an example relevant to our MPS construction in Section 4, and point the reader towards [25, 2] for more examples. Non-emptiness and the hereditary axiom together imply $\epsilon \in \Lambda$, and exchange makes all basic words equal in length. A prominent class is *interval greedoids*, which possess a stronger variant of exchange: call a simple $\alpha' \in \Sigma^*$ a *subword* of $\alpha \in \Lambda$ if and only if $\widetilde{\alpha'} \subseteq \widetilde{\alpha}$ and the letters of α' occur in an order agreeing with α (i.e. x appears before y in α' implies x appears before y in α).

▶ **Definition 2** (Interval Property). *Let* Λ *be a greedoid.* Λ *has the* interval property *if for all* $\alpha, \beta \in \Lambda$ *with* $|\beta| > |\alpha|$*, there exists a subword* β' *of* β *of length* $|\beta'| \geq |\beta| - |\alpha|$ *with* $\alpha\beta' \in \Lambda$*.*

The contraction minor Λ/α, where $\alpha \in \Lambda$, is the language of simple words which can be concatenated onto α while maintaining feasibility in Λ, i.e. $\Lambda/\alpha \triangleq \{\beta \in \Sigma^* \mid \alpha\beta \in \Lambda\}$. Λ/α is a greedoid, and we call the single length words $y \in \Lambda/\alpha$ *continuations* since they are exactly $y \in \Sigma$ with $\alpha y \in \Lambda$. Define the equivalence relation $\alpha \sim \beta$ by $\Lambda/\alpha = \Lambda/\beta$. A *flat* is an equivalence class of $\Lambda/\sim$, and the class associated with α is $[\alpha]$. One can order the flats by a kind of reachability: let $[\alpha] \sqsubseteq [\beta]$ if and only if there exists $\gamma \in \Lambda/\alpha$ where $\alpha\gamma \in \Lambda$

and $\alpha\gamma \sim \beta$. For interval greedoids, the resulting poset $(\Lambda/\!\sim, \sqsubseteq)$ is a semimodular lattice. Finally, we define the *flat support* as the union of supports of words in a flat. This is given by $\kappa : \Lambda/\!\sim \to 2^\Sigma$ defined as $\kappa[\alpha] \triangleq \bigcup_{\beta\sim\alpha} \widetilde{\beta}$. For interval greedoids κ is invertible, so ordering the flat supports by containment gives a lattice isomorphic to $(\Lambda/\!\sim, \sqsubseteq)$.

A *polymatroid greedoid*, introduced in [24], is such that there exists a polymatroid rank function $\rho : 2^\Sigma \to \mathbb{Z}$ satisfying $\Lambda = \{x_1 \dots x_k \in \Sigma^* \mid (\forall i \in \{1, \dots, k\})\ \rho(\{x_1, \dots, x_i\}) = i\}$. Examples include matroids, poset antimatroids, and certain ordered geometries; see Ch. 7 of [25]. Following [44], in this context we call ρ a *representation* as it encodes how one builds feasible words in Λ. This is, for all $\alpha \in \Lambda$ and $y \notin \widetilde{\alpha}$, $\alpha y \in \Lambda$ if and only if $(\rho/\widetilde{\alpha})(y) = 1$. But more importantly, the representation defines a global submodular structure over the greedoid, which applies to both those sets corresponding to and those which do not correspond to supports of feasible words. This submodular structure is a crucial property given by matroid rank functions which is lost when generalizing from matroids to greedoids. The concept of representation is thus notable because it restores this feature. In [44], the authors define a subclass called *strong polymatroid greedoids* by those guaranteeing the function $\check{\rho}$, where $\check{\rho}(X)$ is the height of a minimal flat support containing X in the lattice $(\kappa(\Lambda/\!\sim), \subseteq)$, i.e. $\check{\rho}(X) \triangleq \min\{|\alpha| \mid X \subseteq \kappa[\alpha]\}$ is a polymatroid rank function representing the greedoid. When true, $\check{\rho}$ is called the *greatest representation* because it can be shown to be coordinatewise larger than all other representations. The authors give a combinatorial description of such greedoids: a greedoid is *optimistic* whenever for every basic word $y_1 \dots y_R$ and nonloop $z \in \Sigma$ there exists an index i making $y_1 \dots y_{i-1} z \in \Lambda$. We remark that all polymatroid greedoids are optimistic [44, 24]. Then, Λ is a strong polymatroid greedoid if and only if it is an optimistic interval greedoid whose flat supports are closed under intersection [44], i.e. $\kappa(F) \cap \kappa(F') = \kappa(F \sqcap F')$ for all $F, F' \in \Lambda/\!\sim$. This shows the existence of a closure operator $\mathrm{cl}(X) \triangleq \bigcap\{\kappa[\alpha] \mid X \subseteq \kappa[\alpha]\}$ which preserves the greedoid structure. Notice, cl also simplifies the definition of $\check{\rho}$ to make $\check{\rho}(X)$ the height of $\mathrm{cl}(X)$ in $(\kappa(\Lambda/\!\sim), \subseteq)$. By inspection then $\sigma_{\check{\rho}} = \mathrm{cl}$, and so the greatest representation gives us functional access to this closure system. For this reason, $\check{\rho}$ and cl are meaningful tools for algorithm design.

4 Matroidal Prerequisite Systems

Now we define a matroidal prerequisite system. This is an interaction between a poset and a matroid, with the poset encoding prerequisites and the matroid encoding a substitutability structure, combined with a compatibility condition (we use this naming to informally refer to Eq. 3) ensuring this interaction is well-behaved.

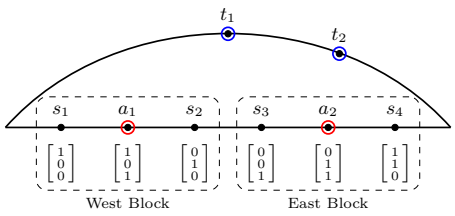
▶ **Definition 3** (Matroidal Prerequisite System (MPS)). *Fix a finite alphabet Σ, and let $(\Sigma, \mathcal{M})$ and $(\Sigma, \rightsquigarrow)$ be a (loopless) matroid and poset respectively. Define $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ as the set of simple words $x_1 \dots x_\ell \in \Sigma^*$ with $\{x_1, \dots, x_\ell\} \in \mathcal{M}$ and,*

$$y \rightsquigarrow x_i \implies y \in \sigma_{\mathcal{M}}(\{x_1, \dots, x_{i-1}\}) \text{ or } \sigma_{\mathcal{M}}(\{x_1, \dots, x_{i-1}, y\}) = \sigma_{\mathcal{M}}(\{x_1, \dots, x_{i-1}, x_i\}),$$

for all $i \in \{1, \dots, \ell\}$. Then, $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is a matroidal prerequisite system *if and only if,*

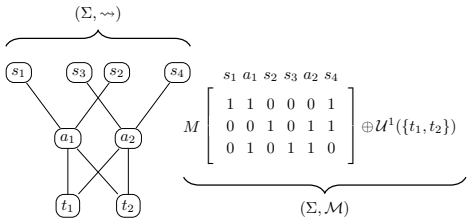
$$\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow) \text{ and } z \in \sigma_{\mathcal{M}}(\widetilde{\alpha}) \implies (\forall y \rightsquigarrow z)\ y \in \sigma_{\mathcal{M}}(\widetilde{\alpha}). \tag{3}$$

This is, $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is words with independent supports such that every prerequisite of a letter y in a feasible word is either spanned by prefix ending at y (exclusive) in the matroid or is substitutable with y against that prefix. Call the words of $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ *feasible*. Then, the compatibility condition in Eq. 3 states that whenever a letter is covered by the matroid span



of a feasible word, so must all of its prerequisites. This has good semantic meaning with the problems we are interested in modeling (i.e. a decision which has been made redundant is such that all of its prerequisite decisions are redundant as well), and is required to verify $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is an optimistic greedoid (which we need to use $\check{\rho}$, cl, and other concepts inducing correct behavior in our algorithms). We also implicitly assume the matroid is loopless so as to prevent complications or cumbersome notation caused by loops. This can be satisfied by simply removing letters with matroid rank zero from the groundset. Finally, as discussed in Section 1, this abstracts matroids and poset antimatroids by considering the MPS defined over an empty order and free matroid, respectively.

Before continuing, we list a few properties. Firstly, every basic word of $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is always supported on a basic set (largest independent set) in $\mathcal{M}$. This is because, for all $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$, any minimal (w.r.t. "$\rightsquigarrow$") letter $y \in \Sigma \setminus \sigma_{\mathcal{M}}(\widetilde{\alpha})$ is such that minimality guarantees all its prerequisites are covered by $\sigma_{\mathcal{M}}(\widetilde{\alpha})$. Moreover, $y \notin \sigma_{\mathcal{M}}(\widetilde{\alpha})$ also implies $\widetilde{\alpha} + y$ is independent, and so $\alpha y \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$. Such a y always exists whenever $\sigma_{\mathcal{M}}(\widetilde{\alpha}) \neq \Sigma$, which occurs exactly when $\widetilde{\alpha}$ is not a basic set of the matroid. Secondly, this implies every MPS defined by a loopless matroid is also loopless. Specifically, since $\sigma_{\mathcal{M}}(\widetilde{\alpha}) = \Sigma$ for every basic word α, for all $y \in \Sigma$ there exists an α-prefix $\alpha' z$ such that $y \in \sigma_{\mathcal{M}}(\widetilde{\alpha'} + z) \setminus \sigma_{\mathcal{M}}(\widetilde{\alpha'})$. Then, since y is $\widetilde{\alpha'}$-substitutable with all its prerequisites by the compatibility condition (Eq. 3), it follows that $\alpha' y \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$. In what comes, we show an MPS is optimistic, and so this looplessness will mean that given any basic word and letter $y \in \Sigma$ we can assert the existence of a prefix possessing y as a continuation.



As a technical example, let $\mathcal{U}_n^R$ be a *uniform matroid* of rank R. That is, every set of cardinality at most R is independent. $\mathcal{L}(\mathcal{U}_n^R, \rightsquigarrow)$ always satisfies the compatibility condition, regardless of the prerequisite order $(\Sigma, \rightsquigarrow)$. This is because the only independent sets with span not equal to themselves are basic. So, basic words in $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ are the only feasible words whose corresponding matroid span contains any letters not from their support. Therefore, for all $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ which are not basic we have $z \in \sigma_{\mathcal{M}}(\widetilde{\alpha})$ implies $z \in \widetilde{\alpha}$, and so all prerequisites $y \rightsquigarrow z$ are contained in $\sigma_{\mathcal{M}}(\widetilde{\alpha})$ by MPS feasbility, while if α is basic then it is supported on a basic set of $\mathcal{U}_n^R$ and $\sigma_{\mathcal{M}}(\widetilde{\alpha}) = \Sigma$ trivially makes the conclusion of Eq. 3 true. This makes $\mathcal{L}(\mathcal{U}_n^R, \rightsquigarrow)$ a matroidal prerequisite system. We can use this to model cardinality constrained optimization over a poset antimatroid. This is equivalent to adding a cardinality constraint on the previously studied maximum closure over a directed acyclic graph [38], and restricting to unit-weights for previously studied poset constrained knapsacks [19, 41, 20].

▶ **Example 4** (Cardinality Constrained Optimization on a Poset Antimatroid)**.** Let $(\Sigma, \rightsquigarrow)$ be a poset with $|\Sigma| = n$, $w : \Sigma \to \mathbb{R}$ a nonnegative weight function, and $k \leq n$ an integer. Our task is to find an ideal of size k of maximum cumulative weight, or equivalently finding a k-length prefix of a linear extension with maximum cumulative weight. Add an additional "sentinel letter" t by letting $\Sigma' = \Sigma + t$, and consider the matroid $(\Sigma', \mathcal{U}_{n+1}^{k+1})$. Extend the order to $(\Sigma', \rightsquigarrow')$ by letting $y \rightsquigarrow z \implies y \rightsquigarrow' z$ and $y \rightsquigarrow' t$ for all $y \in \Sigma$. This is, the derived order inherits the relations given by "$\rightsquigarrow$" while making every letter lesser than the sentinel. Finally, make the derived weight function $w' : \Sigma' \to \mathbb{R}$ by letting $w'(y) = w(y)$ for all $y \in \Sigma$, and $w'(t) = \max_{y \in \Sigma} w(y) + 1$. It can be seen that any word of maximum weight over the MPS $\mathcal{L}(\mathcal{U}_{n+1}^{k+1}, \rightsquigarrow')$ is a basic word ending in t. It follows that the first k letters of such a word will be an ideal of $(\Sigma, \rightsquigarrow)$ of size k maximizing $X \mapsto \sum_{y \in X} w(y)$.

As a less technical example, we discuss how our MPS can be used to enrich the constraint structure in sensor placement problems.

(a) A bridge with sensor placements. Modal signatures are underneath each sensor. Baseline sensors are outlined in red, sync hardware is outlined in blue, and the remaining sensors are for anomaly detection.

(b) A MPS following Example 5 is given by a poset like above and the direct sum of a linear matroid on GF(2) over the modal signatures with the rank 1 uniform matroid over $\{t_1, t_2\}$.

Figure 1 Following Example 5, modal signatures of the baseline sensor of each block must be spanned before an anomaly detection sensor is placed in that block. Furthermore, we must place sync hardware before any other sensor. This leads to the poset structure on the right. For budget reasons, we can only place one sync hardware. A linear matroid encodes the substitution structure of the signatures as well as a linear independence condition in the measurements, so the matroid is given by a direct sum like on the right. To save space, verifying the compatibility condition is deferred to the full version. Some examples of basic words are $t_1a_1s_1s_2$, $t_1a_2s_4s_1$, and $t_2a_1a_2s_1$.

▶ **Example 5** (Sensor Networks for Anomaly Detection)**.** Sensor placement to maximize mutual information [26] is a classic instance of monotone submodular maximization, with particularly natural matroid constraints encoding budget, network interference, etc. (see [39, 8] for example). One task is using sensors to detect anomalies; for example the presence of errant vibration frequencies indicates damage in a structure [1]. However, it is not possible to interpret anomalies without a frame of reference given by baseline measurements. This creates a prerequisite structure, where modes corresponding to a baseline must be spanned before anomaly detection can occur. Other operational prerequisites may coexist, like requiring synchronization hardware is placed before other hardware to ensure a correct boot procedure.

An instance of detecting anomalous frequencies on a bridge is shown in Figure 1. A modal signature is a binary vector encoding the capabilities of each sensor, and a linear matroid in combination with a poset encodes the requirement that baseline sensor modal signatures in each block must be spanned before anomaly detecting sensors in those blocks can be placed, along with the requirement that clock synchronization hardware is placed before any sensor. An interesting feasible word is $t_1a_2s_4s_1$. Even though the baseline sensor a_1 was never placed in the East block, we still place s_1 after $t_1a_2s_4$ since the modal signature of a_1 is in the span of $\{a_2, s_4\}$. This is because the functionality of a_1 is redundant in the presence of a_2 and s_4.

In Section 4.1, we examine the greedoid theory of an MPS. In particular, we show every MPS can be described as a strong polymatroid greedoid and vice versa. The utility of this is best seen in Section 4.3, where we use the greatest representation and closure operator of strong polymatroid greedoids to give procedures for "filling-in" and "projecting" partial optimization solutions on to the basic words of an MPS. This is Lemma 11, which will be the foundation of our algorithms in Sections 5 and 6. Finally, since we use the greatest representation in our algorithms, we verify that it can be computed efficiently when given a matroid rank oracle in Section 4.2. This is because, even though our algorithms are described in terms of strong polymatroid greedoid concepts, our previous examples show that the MPS is a widely applicable and interpretable constraint model. And so, while strong polymatroid greedoids give the mechanisms for our algorithms, an MPS grounds our motivations for designing them in the first place. Therefore, we must verify that given an MPS it is possible to efficiently compute strong polymatroid greedoid concepts under reasonable assumptions.

4.1 Greedoid Theoretic Aspects

We now develop the greedoid theory of an MPS. In particular, we will show that a greedoid is a strong polymatroid greedoid if and only if there exists a matroid and poset giving its feasible words as an MPS. We first verify an MPS is an optimistic interval greedoid.

▶ **Proposition 6.** *Let $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be a matroidal prerequisite system. Then, $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is an optimistic interval greedoid.*

Proof. From the definition $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is nonempty and hereditary. Let $\alpha, \beta \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ with $|\beta| > |\alpha|$. Select the first z_1 appearing in $\widetilde{\beta}$ with $z_1 \notin \sigma_{\mathcal{M}}(\widetilde{\alpha})$. We show αz_1 is feasible. Well, $z_1 \notin \sigma_{\mathcal{M}}(\widetilde{\alpha})$ implies $\widetilde{\alpha} + z_1$ is independent. And, if $\beta' z_1$ is the β-prefix ending at z_1, we see $\widetilde{\beta'} \subseteq \sigma_{\mathcal{M}}(\widetilde{\alpha})$ by construction, thus $\sigma_{\mathcal{M}}(\widetilde{\beta'}) \subseteq \sigma_{\mathcal{M}}(\widetilde{\alpha})$. So, for every $y \rightsquigarrow z_1$ such that $y \notin \sigma_{\mathcal{M}}(\widetilde{\alpha})$, it follows that $y \notin \sigma_{\mathcal{M}}(\widetilde{\beta'})$. Since $\beta' \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$, as we have already shown the hereditary property, it must be that y and z_1 are $\widetilde{\beta'}$-substitutable. Hence,

$$\sigma_{\mathcal{M}}(\widetilde{\alpha} + y) = \sigma_{\mathcal{M}}(\widetilde{\alpha} \cup \sigma_{\mathcal{M}}(\widetilde{\beta'} + y)) = \sigma_{\mathcal{M}}(\widetilde{\alpha} \cup \sigma_{\mathcal{M}}(\widetilde{\beta'} + z_1) = \sigma_{\mathcal{M}}(\widetilde{\alpha} + z_1),$$

by $\sigma_{\mathcal{M}}(\widetilde{\beta'}) \subseteq \sigma_{\mathcal{M}}(\widetilde{\alpha})$, and so y and z_1 are $\widetilde{\alpha}$-substitutable. Thus $\alpha z_1 \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$. If $|\beta| - |\alpha| > 1$, one can repeat this argument on the first letter z_2 in β with $z_2 \notin \sigma_{\mathcal{M}}(\widetilde{\alpha z_1})$ to show $\alpha z_1 z_2 \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ as well. Repeating in this way $|\beta| - |\alpha| - 2$ more times shows the existence of the $k = |\beta| - |\alpha|$ length β-subword $z_1 \dots z_k$ such that $\alpha z_1 \dots z_k \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$. And so, $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is an interval greedoid.

Now, let $x_1 \dots x_R \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be basic. Select $y \in \Sigma$ and let i be the smallest index with $y \in \sigma_{\mathcal{M}}(\{x_1, \dots, x_i\})$. By Steinitz-Maclane exchange property, x_i and y are $\{x_1, \dots, x_{i-1}\}$-substitutes. Well, for every $z \rightsquigarrow y$ with $z \notin \sigma_{\mathcal{M}}(\{x_1, \dots, x_{i-1}\})$, the compatibility condition and the observation that x_i and y are $\{x_1, \dots, x_{i-1}\}$-substitutes combine for,

$$y \in \sigma_{\mathcal{M}}(\{x_1, \dots, x_{i-1}, x_i\}) \implies z \in \sigma_{\mathcal{M}}(\{x_1, \dots, x_{i-1}, y\}).$$

So, $x_1 \dots x_{i-1} y \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$, and optimism follows. ◀

Now, we make observations about the interaction between the flat supports, matroid, and prerequisite order. Specifically, the next lemma first verifies flat supports are always $r_{\mathcal{M}}$-closed and ideals of $(\Sigma, \rightsquigarrow)$. This then shows the flat supports are closed under intersection.

▶ **Lemma 7.** *Let $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be a matroidal prerequisite system. The following are all true:*
1. *For all $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$, $\sigma_{\mathcal{M}}(\widetilde{\alpha}) = \kappa[\alpha]$,*
2. *Every flat support is an ideal in the prerequisite order $(\Sigma, \rightsquigarrow)$,*
3. *The flat supports are closed under intersection.*

To prove the first item, we need the following statement which follows from the semimodularity of the flats of interval greedoids. See [2] for proof.

▶ **Lemma 8** ([2])**.** *Let Λ be an interval greedoid, and select nonempty words $\alpha x \in \Lambda$ and $\alpha y \in \Lambda$. If $\alpha x \not\sim \alpha y$, then $\alpha x y \in \Lambda$ and $\alpha y x \in \Lambda$.*

Proof of Lemma 7. For what follows, recall Proposition 6 shows $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is an optimistic interval greedoid. Let $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ and select $y \in \sigma_{\mathcal{M}}(\widetilde{\alpha})$. Since supports of feasible words are independent, there exists no word in the contraction $\mathcal{L}(\mathcal{M}, \rightsquigarrow)/\alpha$ containing y in its support. So by optimism (since every feasible word can be extended into a basic word), there exists an α-prefix $\alpha' z$ with $y \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)/\alpha'$. Let $\alpha' z$ be a longest such prefix, so that $\alpha' y, \alpha' z \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ while neither $\alpha' y z$ or $\alpha' z y$ are feasible. By contrapositive of Lemma 8, it

follows that $\alpha' y \sim \alpha' z$. Because our construction makes $[\alpha' z] \sqsubseteq [\alpha]$, it follows that $[\alpha' y] \sqsubseteq [\alpha]$. So, there exists $\beta \in \Sigma^*$ making $\alpha' y \beta \in [\alpha]$, thus $y \in \kappa[\alpha]$. This shows $\sigma_{\mathcal{M}}(\widetilde{\alpha}) \subseteq \kappa[\alpha]$. Now, select $z' \notin \sigma_{\mathcal{M}}(\widetilde{\alpha})$. Then, there exists $\beta \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)/\alpha$ with $z' \in \widetilde{\beta}$: There must exist a minimal $y' \in {\downarrow} z' \setminus \sigma_{\mathcal{M}}(\widetilde{\alpha})$ w.r.t. "$\rightsquigarrow$", and this minimal y' must be a continuation of α since its prerequisites are covered by $\sigma_{\mathcal{M}}(\widetilde{\alpha})$. Therefore, if $\alpha z' \notin \mathcal{L}(\mathcal{M}, \rightsquigarrow)$, we can append y' onto α. If we continue this process, eventually z' will be substitutable with every prerequisite that hasn't been covered, at which point z' will be a continuation. This makes $z' \notin \kappa[\alpha]$. So, as we've shown $\sigma_{\mathcal{M}}[\alpha] \subseteq \kappa[\alpha]$ and $\Sigma \setminus \sigma_{\mathcal{M}}(\widetilde{\alpha}) \subseteq \Sigma \setminus \kappa[\alpha]$, it follows that $\sigma_{\mathcal{M}}(\widetilde{\alpha}) = \kappa[\alpha]$. This gives Lemma 7.1. Finally, we note that our compatibility condition in Eq. 3 makes $\sigma_{\mathcal{M}}(\widetilde{\alpha})$ equal to an ideal in $(\Sigma, \rightsquigarrow)$. Since we've shown $\kappa[\alpha] = \sigma_{\mathcal{M}}(\widetilde{\alpha})$, this gives Lemma 7.2.

This description of the flat supports is convenient for showing they are closed under intersection. In particular, since ideals of a poset are always closed under intersection, it follows that $\kappa(F) \cap \kappa(F')$ is an ideal on $(\Sigma, \rightsquigarrow)$ for all $F, F' \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)/\sim$. It is also true that $\kappa(F \sqcap F')$ and $\kappa(F) \cap \kappa(F')$ are closed in $\mathcal{M}$. Now, observe that the inclusion $\kappa(F \sqcap F') \subseteq \kappa(F) \cap \kappa(F')$ is always true by $(\Lambda/\sim, \sqsubseteq) \cong (\kappa(\Lambda/\sim), \subseteq)$, so for 2. to hold we need only verify the reverse inclusion. By way of contradiction, suppose there exists $z \in (\kappa(F) \cap \kappa(F')) \setminus \kappa(F \sqcap F')$. Without loss of generality, let z be a minimal letter in this difference w.r.t. "$\rightsquigarrow$". Because $\kappa(F \sqcap F')$ is an ideal, minimality implies $y \in \kappa(F \sqcap F')$ for all $y \rightsquigarrow z$. Therefore, for all $\mu \in F \sqcap F'$, every prerequisite of z is covered by the span $\sigma_{\mathcal{M}}(\widetilde{\mu})$ since $\sigma_{\mathcal{M}}(\widetilde{\mu}) = \kappa(F \sqcap F')$ by 1. This makes z a continuation of words in $F \sqcap F'$, hence $F \sqcap F' \prec [\mu z]$. But, $z \in \kappa(F) \cap \kappa(F')$ implies $[\mu z]$ is lesser than both F and F'. One (of many) ways to see why is because if we select a word $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)/\mu$ making $\mu\alpha \in F$, then by exchange there is an α-subword α' of length $|\alpha| - 1$ such that $\mu z \alpha'$ is feasible. This construction makes both $\widetilde{\mu z \alpha'} \subseteq \kappa(F)$, and the flats F and $[\mu z \alpha']$ the same height in $(\Lambda/\sim, \sqsubseteq)$. So, by $(\Lambda/\sim, \sqsubseteq) \cong (\kappa(\Lambda/\sim), \subseteq)$, this makes $\mu z \alpha' \in F$. A symmetric argument applies to show $[\mu z] \sqsubseteq F'$ as well. Therefore $[\mu z] \sqsubseteq F \sqcap F'$. Yet, this contradicts $F \sqcap F' \prec [\mu z]$, so $\kappa(F) \cap \kappa(F') = \kappa(F \sqcap F')$. So we've shown Lemma 7.3. ◀

Therefore, by Lemma 7.3 and Proposition 6, every MPS is a strong polymatroid greedoid by the description from [44]. For logical completeness, we give a construction encoding every strong polymatroid greedoid as an MPS. Because the forthcoming results only use the direction already proven, we defer this to the full version to satisfy space constraints.

▶ **Theorem 9.** *Let Λ be a greedoid on the alphabet Σ. There exists a matroid $(\Sigma, \mathcal{M})$ and compatible poset $(\Sigma, \rightsquigarrow)$ such that Λ equals the words of the matroidal prerequisite system $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ if and only if Λ is a strong polymatroid greedoid.*

4.2 Computing the Greatest Representation

Our algorithms use the greatest representation $\check{\rho}$. To ensure this is well-founded, we show $\check{\rho}$ can be evaluated via a single rank query on the underlying matroid. Specifically, the greatest representation of an MPS $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is the composition of the matroid rank and ideal operator on $(\Sigma, \rightsquigarrow)$. Note that ideals can be computed efficiently in $\mathsf{poly}(|\Sigma|)$-time by repeated ordered comparisons.

▶ **Proposition 10.** *Let $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be an MPS. Then, $\check{\rho} = r_{\mathcal{M}} \circ {\downarrow}$.*

Proof. Fix $X \subseteq \Sigma$. We verify $\check{\rho}(X) = r_{\mathcal{M}}({\downarrow} X)$. Perform the following procedure: Begin with a word $\alpha = \epsilon$. Then, in each step, select a smallest $z \in {\downarrow} X \setminus \widetilde{\alpha}$ satisfying $r_{\mathcal{M}}(\widetilde{\alpha} + z) > r_{\mathcal{M}}(\widetilde{\alpha})$. Terminate once no such z exists. See that $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ because, fixing z to a selection made in any round, minimality makes every $y \rightsquigarrow z$ spanned by the round's value of α. Moreover,

it is the case that $(r_{\mathcal{M}}/\widetilde{\alpha})(\downarrow X) = 0$ upon termination. So, with α being the value at the end of the final round, we have $\downarrow X \subseteq \sigma_{\mathcal{M}}(\widetilde{\alpha})$. Yet combining this with $\widetilde{\alpha} \subseteq \downarrow X$ makes $r_{\mathcal{M}}(\widetilde{\alpha}) \leq r_{\mathcal{M}}(\downarrow X) \leq r_{\mathcal{M}}(\widetilde{\alpha})$, so $r_{\mathcal{M}}(\downarrow X) = |\alpha|$ since $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ implies $\widetilde{\alpha} \in \mathcal{M}$. Now, take note that $\downarrow X \subseteq \sigma_{\mathcal{M}}(\widetilde{\alpha})$ also implies that no $\beta \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)/\alpha$ satisfies $\widetilde{\beta} \cap \downarrow X \neq \varnothing$, as the supports of feasible words must be independent. This makes $(\check{\rho}/\widetilde{\alpha})(y) \neq 1$ for all $y \in \downarrow X$ in particular. By optimism (see Proposition 6) it follows that there exists an α-prefix $\alpha^{(y)}z$ for each $y \in \downarrow X$ such that $\alpha^{(y)}y$ is feasible. So, $(\check{\rho}/\widetilde{\alpha}^{(y)})(y) = 1$. But by the law of diminishing returns and $(\check{\rho}/\widetilde{\alpha})(y) \neq 1$ it follows that $1 = (\check{\rho}/\widetilde{\alpha}^{(y)})(y) > (\check{\rho}/\widetilde{\alpha})(y)$ for all $y \in \downarrow X$. And so, as $\check{\rho}$ is integral, we have $(\check{\rho}/\widetilde{\alpha})(y) = 0$ for all $y \in \downarrow X$. This makes $\downarrow X \subseteq \mathrm{cl}(\widetilde{\alpha})$. Therefore $\check{\rho}(\widetilde{\alpha}) \leq \check{\rho}(\downarrow X) \leq \check{\rho}(\widetilde{\alpha})$, and so $\check{\rho}(\downarrow X) = \check{\rho}(\widetilde{\alpha})$. But, because flat supports are ideals by Lemma 7.2, we see $\downarrow X \subseteq \mathrm{cl}(X)$, and so $\check{\rho}(X) \leq \check{\rho}(\downarrow X) \leq \check{\rho}(X)$ by $\mathrm{cl} = \sigma_{\check{\rho}}$. Therefore, $\check{\rho}(X) = \check{\rho}(\widetilde{\alpha})$, and since $\check{\rho}$ is a representation we have $\check{\rho}(\widetilde{\alpha}) = |\alpha|$. Hence we've found $r_{\mathcal{M}}(\downarrow X) = |\alpha|$ and $\check{\rho}(X) = |\alpha|$. ◀

4.3 Projection and Fill-In

In Sections 5 we present algorithms based on projecting a relaxed solution back onto the words of an MPS, while in Section 6 our algorithms build words through repeated insertions eventually converging to a feasible word. Both ideas require a description of what sets of letters, which might not support a feasible word, can be "filled" into a feasible word. In the following, we show that words $x_1 \dots x_\ell$ such that $(\check{\rho}/\{x_1, \dots, x_{i-1}\})(x_i) > 0$ for all $i \in \{1, \dots, \ell\}$ satisfy this. We note this is a special property of strong polymatroid greedoids.

▶ **Lemma 11.** *Suppose Λ is a strong polymatroid greedoid. Then, for all simple $x_1 \dots x_k \in \Sigma^*$, if $(\check{\rho}/\{x_1, \dots, x_{i-1}\})(x_i) > 0$ for all $i \in \{1, \dots, k\}$, there exists a set of letters $\{y_{i,1}, \dots, y_{i,\ell_i}\}$ with $\ell_i = (\check{\rho}/\{x_1, \dots, x_{i-1}\})(x_i) - 1$ inducing the feasible word,*

$$y_{1,1} \dots y_{1,\ell_1} x_1 y_{2,1} \dots y_{2,\ell_2} x_2 \dots y_{k,1} \dots y_{k,\ell_k} x_k \in \Lambda.$$

Proof. By $(\check{\rho}/\{x_1, \dots, x_{i-1}\})(x_i) > 0$ for all $i \in \{1, \dots, k\}$, the existence of the strictly ascending chain $\varnothing \subsetneq \mathrm{cl}(\{x_1\}) \subsetneq \mathrm{cl}(\{x_1, x_2\}) \subsetneq \dots \subsetneq \mathrm{cl}(\{x_1, \dots, x_k\})$ of flat supports in $(\kappa(\Lambda/{\sim}), \subseteq)$ follows. Then, select letters $\{y_{i,1}, \dots, y_{i,\ell_i}\}$ for each x_i inducing a covering chain beginning at $\mathrm{cl}(\{x_1, \dots, x_{i-1}\})$ and ending at $\mathrm{cl}(\{x_1, \dots, x_i\})$ like,

$$\begin{aligned} \mathrm{cl}(\{x_1, \dots, x_{i-1}\}) \prec \mathrm{cl}(\{x_1, \dots, x_{i-1}, y_{i,1}\}) \prec \dots \prec \mathrm{cl}(\{x_1, \dots, x_{i-1}, y_{i,1}, \dots, y_{i,\ell_i}\}), \\ \prec \mathrm{cl}(\{x_1, \dots, x_{i-1}, y_{i,1}, \dots, y_{i,\ell_i}, x_i\}) = \mathrm{cl}(\{x_1, \dots, x_i\}). \end{aligned} \tag{4}$$

This is always possible because cl is a closure operator. In particular, since $\sigma_{\check{\rho}} = \mathrm{cl}$, having already selected $y_{i,1}, \dots, y_{i,j-1}$, one takes an arbitrary $y_{i,j}$ satisfying both of,

$$\begin{cases} (\check{\rho}/\{x_1, \dots, x_{i-1}, y_{i,1}, \dots, y_{i,j-1}\})(y_{i,j}) = 1, \\ \mathrm{cl}(\{x_1, \dots, x_{i-1}, y_{i,1}, \dots, y_{i,j-1}\} + y_{i,j}) \subseteq \mathrm{cl}(\{x_1, \dots, x_i\}), \end{cases} \tag{5}$$

whenever $(\check{\rho}/\{x_1, \dots, x_{i-1}, y_{i,1}, \dots, y_{i,j-1}\})(x_i) \neq 1$, and terminates otherwise. A letter $y_{i,j}$ satisfying the conditions in Eq. 5 must exist when $(\check{\rho}/\{x_1, \dots, x_{i-1}, y_{i,1}, \dots, y_{i,j-1}\})(x_i) \neq 1$, as there is a flat support below $\mathrm{cl}(\{x_1, \dots, x_i\})$ covering $\mathrm{cl}(\{x_1, \dots, x_{i-1}, y_{i,1}, \dots, y_{i,j-1}\})$ in $(\kappa(\Lambda/{\sim}), \subseteq)$, and any letter in the difference of this cover and $\mathrm{cl}(\{x_1, \dots, x_{i-1}, y_{i,1}, \dots, y_{i,j-1}\})$ will satisfy the conditions in Eq. 5. Now, recall that $\check{\rho}(X)$ is defined as the height of the least flat support containing X (recall flat supports are closed under intersection, so a least such flat is unique). So, $\check{\rho}$ grades the cl-image. Then, the covering chain structure from Eq. 4 and $\sigma_{\check{\rho}} = \mathrm{cl}$ makes,

$$(\overset{\vee}{\rho}/\{x_1,\ldots,x_{i-1},y_{i,1},\ldots,y_{i,j-1}\})(y_{i,j}) = 1, \quad \forall j \in \{1,\ldots,\ell_i\}. \tag{6}$$

This means, for example, that $y_{1,1}\ldots y_{1,\ell_1}x_1 \in \Lambda$ by the definition of representation in polymatroid greedoids. Then, since selecting like Eq. 4 makes $\mathrm{cl}(\{y_{1,1},\ldots,y_{1,\ell_1},x_1\}) = \mathrm{cl}(\{x_1\})$, applying the same argument using Eq. 6 for $i = 2$ shows $y_{1,1}\ldots y_{1,\ell_1}x_1y_{2,1}\ldots y_{2,\ell_2}x_2 \in \Lambda$. One repeats this procedure up to $i = k$ to get the result. ◀

5 Scaffolding Solutions via Polymatroid Relaxations

Observe, every polymatroid greedoid is such that the characteristic vectors of its basic words are base vectors of any of its polymatroid representations. To see why, note that Edmonds' algorithm [11] over the base polytope always returns an extreme point. Let $y_1\ldots y_R \in \mathcal{L}(\mathcal{M},\rightsquigarrow)$ be any basic word of an MPS with greatest representation $\overset{\vee}{\rho}$. Then, a weight function $w : \Sigma \to \mathbb{R}$ such that $w(y_i) = R - (i-1)$ for all $i \in \{1,\ldots,R\}$ and $w(z) = 0$ for $z \notin \{y_1,\ldots y_R\}$ will make Edmonds' algorithm examine coordinates in the order dictated by the basic word. Because $\overset{\vee}{\rho}$ is a representation, we see that $(\overset{\vee}{\rho}/\{y_1,\ldots,y_{i-1}\})(y_i) = 1$ for all i, and Lemma 11 certifies that this ends at y_R, as the existence of $z \in \Sigma$ with $(\overset{\vee}{\rho}/\{y_1,\ldots,y_R\})(z) > 0$ would imply $y_1\ldots y_R$ is not basic. Therefore, Edmonds' algorithm will increase each coordinate from $\{y_1,\ldots,y_R\}$ to exactly one and terminate on the characteristic vector of the support of the basic word.

In what follows we will examine nonnegative additive maximization and monotone submodular maximization algorithms based on using the greatest representation as a relaxation. Specifically, Section 5.1 will first describe a method for additive maximization in Algorithm 1 which is based on computing a relaxed solution via Edmonds' algorithm and projecting onto a basic word using Lemma 11. In Section 5.2 we approach submodular maximization using the continuous greedy algorithm [5] to compute a set of weights forming an additive underestimation of the objective, which we give to our Algorithm 1 to compute a solution on the MPS. The resulting guarantees will vary in largest matroid rank of a principal ideal Δ.

5.1 Additive Maximization

Let $w : \Sigma \to \mathbb{R}_+$ be a nonnegative weight function. Our task is to find a feasible word α of a MPS $\mathcal{L}(\mathcal{M},\rightsquigarrow)$ maximizing $\alpha \mapsto \sum_{y\in\tilde{\alpha}} w(y)$. Let $v^\star \in \mathbb{R}^\Sigma$ be base vector of $\overset{\vee}{\rho}$ computed by Edmonds' algorithm, and sort the nonzero coordinates $\{x_1,x_2,\ldots\} = \mathrm{supp}(v^*)$ so that $w(x_1) \geq w(x_2) \geq \ldots$. This is, we sort the support of $v^\star$ in order of the coordinate increases made by Edmonds' algorithm. Since $x_i \in \mathrm{supp}(v^\star)$, it follows that $(\overset{\vee}{\rho}/\{x_1,\ldots,x_{i-1}\})(x_i) > 0$ for all $i \in \{1,\ldots,|\mathrm{supp}(v^\star)|\}$. This satisfies the premise of Lemma 11, and so perform a fill-in procedure like in the proof of Lemma 11 to obtain a feasible word containing $\mathrm{supp}(v^\star)$.

This idea is shown in Algorithm 1. We first compute a "scaffold" $v^\star$ for the solution using Edmonds' greedy algorithm on $\overset{\vee}{\rho}$ in line 1, whose support we then sort in line 2. Then, we use the same arbitrary fill-in scheme presented in the proof of Lemma 11, in particular Eq. 5, to obtain a feasible word α such that $\mathrm{supp}(v^\star) \subseteq \widetilde{\alpha}$ in lines 4 through 8. Note that the while loop cannot terminate with $(\overset{\vee}{\rho}/\widetilde{\alpha})(x_i) = 0$: if a selected fill-in letter y with $(\overset{\vee}{\rho}/\widetilde{\alpha})(y) = 1$ made $x_i \in \mathrm{cl}(\widetilde{\alpha}+y)$, then we would have $(\overset{\vee}{\rho}/\widetilde{\alpha})(x_i) \leq 1$ which contradicts the loop condition.

Recall, in Section 1 we defined Δ as the maximum matroid rank of a principal ideal of $(\Sigma,\rightsquigarrow)$. By the law of diminishing returns, it follows that each coordinate of $v^\star$ is at most Δ. When comparing $v^\star$ and $\chi_{\tilde{\alpha}}$, it follows that any entry in $v^\star$ is at most a Δ-factor smaller in $\chi_{\tilde{\alpha}}$. This idea shows Algorithm 1 computes a Δ-approximation.

Algorithm 1 Scaffolded Greedy with Arbitrary Fill-In.

1 $v^\star \leftarrow$ solution from Edmonds' algorithm [11] on $\check{\rho}$ with weights w
2 select $x_1 \dots x_k \in \mathrm{supp}(v^\star)!$ with $w(x_1) \geq w(x_2) \geq \dots \geq w(x_k)$
3 $\alpha \leftarrow \epsilon$
4 **for** $i \in \{1, \dots, k\}$ **do**
5 **while** $(\check{\rho}/\widetilde{\alpha})(x_i) > 1$ **do**
6 select $y \in \Sigma$ with $\big(\check{\rho}/\widetilde{\alpha}\big)(y) = 1$ and $\widetilde{\alpha} + y \subseteq \mathrm{cl}(\{x_1, \dots, x_i\})$
7 $\alpha \leftarrow \alpha y$
8 $\alpha \leftarrow \alpha x_i$
9 **return** α

▶ **Theorem 12.** *Let $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be a matroidal prerequisite system, $w : \Sigma \to \mathbb{R}_+$ a nonnegative weight function, and* $\mathrm{OPT} = \max_{\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)} \sum_{y \in \widetilde{\alpha}} w(y)$. *Algorithm 1 outputs $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ with $\sum_{y \in \tilde{\alpha}} w(y) \geq \Delta^{-1} \cdot \mathrm{OPT}$.*

Proof. Firstly, one sees that the fill-in (lines 4-8) is done in the same way as the proof of Lemma 11, so it is clear from our discussion at the start of the section that the resulting α is feasible. Moreover, it is basic as $\check{\rho}(\mathrm{supp}(v^\star)) = \check{\rho}(\Sigma)$ and $\mathrm{cl}(\widetilde{\alpha}) = \mathrm{cl}(\mathrm{supp}(v^\star))$ makes $\check{\rho}(\widetilde{\alpha}) = \check{\rho}(\Sigma)$. For each $x_i \in \mathrm{supp}(v^\star)$, by definition of Edmonds' algorithm (see [11]) we have $v^\star(x_i) = (\check{\rho}/\{x_1, \dots, x_{i-1}\})(x_i)$. Therefore, for any choice of $y \in \mathrm{supp}(v^\star)$, we have $v^\star(y) \leq \check{\rho}(y)$ by the law of diminishing returns. Of course $\check{\rho}(y) \leq \Delta$, and so,

$$\chi_{\tilde{\alpha}}(y) \geq \frac{1}{\Delta} \cdot v^\star(y), \quad \forall y \in \mathrm{supp}(v^\star). \tag{7}$$

Then, let α_{OPT} be an optimal word. Recall by our discussion at the beginning of Section 5 that $\chi_{\widetilde{\alpha}_{\mathrm{OPT}}}$ is an extreme point of the base polytope, and so as Edmonds' algorithm is optimal over this constraint set we see $\mathrm{OPT} = w^\intercal \chi_{\tilde{\alpha}_{\mathrm{OPT}}} \leq w^\intercal v^\star$. Combining this with Eq. 7 shows the desired $w^\intercal \chi_{\tilde{\alpha}} \geq \Delta^{-1} \cdot w^\intercal v^\star \geq \Delta^{-1} \cdot \mathrm{OPT}$. ◀

5.2 Monotone Submodular Maximization

For what comes, we require the following: Every integral polymatroid can be associated with a matroid via the *natural matroid* construction [16]. Specifically, define the ground set as,

$$E_{\check{\rho}} \triangleq \bigcup_{y \in \Sigma} \{(y, 1), \dots, (y, \check{\rho}(y))\}.$$

This just introduces $\check{\rho}(y)$ copies of each letter $y \in \Sigma$. This is equivalently seen as a multiset, so let the multiplicity vector of $S \subseteq E_{\check{\rho}}$ be given by $\mu_S(y) \triangleq |S \cap (\{y\} \times \{1, \dots, \check{\rho}(y)\})|$. Then, a matroid $M(\check{\rho})$ is defined by letting S be independent if and only if $\mu_S^\intercal \chi_X \leq \check{\rho}(X)$ for all $X \subseteq \Sigma$. The resulting rank function is,

$$r_{M(\check{\rho})}(S) \triangleq \min_{X \subseteq \Sigma} \check{\rho}(X) + \sum_{y \in \Sigma \setminus X} \mu_S(y),$$

which we note can be evaluated efficiently by submodular minimization algorithms [28, 42, 18, 36] over $X \mapsto \check{\rho}(X) + \sum_{y \in \Sigma \setminus X} \mu_S(y)$. This is a standard construction; see [16, 3] or Ch. 44 of [43] for more discussion.

Algorithm 2 Scaffolding with Weights Computed from Continuous Greedy.

```
1  S ← continuous greedy with rounding on T ↦ Σ_{k=1}^{Δ} f(T(k)) over (E_ρ^∨, M(ρ^∨))
2  forall k ∈ {1, ..., Δ} do
3  |  select any y_1 y_2 ... ∈ S(k)!
4  |  forall i ∈ {1, ..., |S(k)|} do
5  |  |  w^(k)(y_i) ← (f/{y_1, ..., y_{i-1}})(y_i)
6  |  forall z ∉ S(k) do
7  |  |  w^(k)(z) ← 0
8  w̄ ← Δ^{-1} · Σ_{k=1}^{Δ} w^(k)
9  α ← scaffolded greedy on L(M, ⇝) with weights w̄        // Using Algorithm 1
10 return α
```

Now, let $f : 2^{\Sigma} \to \mathbb{R}$ be a monotone submodular function. Our next algorithm is based off of solving a monotone submodular maximization, using a derived objective function $g : 2^{E_\rho^\vee} \to \mathbb{R}$, over the natural matroid using the continuous greedy algorithm [5]. The corresponding solution then defines an additive function underestimating the objective f, which we feed into Algorithm 1 to obtain a word from the MPS. To define g, for $S \subseteq E_\rho^\vee$ let its kth slice $S(k)$ be $S(k) \triangleq \{y \in \Sigma \mid (y,k) \in S\}$. Notice, as Δ is the maximum rank of a principal ideal and $\rho^\vee = r_{\mathcal{M}} \circ \downarrow$, it follows there are at most Δ slices to evaluate for any $S \subseteq E_\rho^\vee$. Then, define $g : 2^{E_\rho^\vee} \to \mathbb{R} : S \mapsto \sum_{k=1}^{\Delta} f(S(k))$. Note g is monotone submodular since it is a sum of monotone submodular functions on disjoint restricted domains.

Algorithm 2 begins by obtaining an approximate solution S to maximizing g over the natural matroid $(E_\rho^\vee, M(\rho^\vee))$ in line 1. Then, in lines 3 through 7 we compute a set of weights for each slice of S. Specifically, an arbitrary permutation $y_1 y_2 \ldots$ is chosen from $S(k)!$ to make $w^{(k)}(y_i) = (f/\{y_1, \ldots, y_{i-1}\})(y_i)$ for all $i \in \{1, \ldots, |S(k)|\}$ and $w^{(k)}(z) = 0$ for $z \notin S(k)$. These weight functions are averaged together in line 8 to obtain the weight function $\overline{w}$. This is, in some sense, an additive estimate of f informed by a solution obtained from a proxy function. We then obtain a word of the MPS in line 9 by running Algorithm 1 with the weights defined by $\overline{w}$, and output that word. The resulting guarantee is that of continuous greedy with pipage rounding [5] degraded by a Δ^2-factor due to the maneuvers involved in translating its solution to a feasible word.

▶ **Theorem 13.** *Let $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be a matroidal prerequisite system, $f : 2^{\Sigma} \to \mathbb{R}$ a (normalized) monotone submodular function, and* $\mathrm{OPT} = \max_{\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)} f(\widetilde{\alpha})$. *Algorithm 2 outputs $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ with $\mathbb{E}[f(\widetilde{\alpha})] \geq \Delta^{-2}(1 - 1/e - \delta) \cdot \mathrm{OPT}$ in randomized* $\mathsf{poly}(|\Sigma|, 1/\delta)$*-time for $\delta > 0$.*

Proof. Let S be the independent set of $(E_\rho^\vee, M(\rho^\vee))$ approximately maximizing g, as computed in line 1. Then, $\overline{w}^\intercal \mu_S = \Delta^{-1} \cdot \sum_{k=1}^{\Delta} \sum_{y \in \Sigma} \mu_S(y) w^{(k)}(y)$. But, because lines 6-9 make $\sum_{y \in S(k)} w^{(k)}(y) = f(S(k))$, we find,

$$\frac{1}{\Delta} \cdot \sum_{k=1}^{\Delta} \sum_{y \in \Sigma} \mu_S(y) w^{(k)}(y) \geq \frac{1}{\Delta} \cdot \sum_{k=1}^{\Delta} \sum_{y \in S(k)} w^{(k)}(y) \geq \frac{1}{\Delta} \cdot \sum_{k=1}^{\Delta} f(S(k)) = \frac{g(S)}{\Delta},$$

hence $\overline{w}^\intercal \mu_S \geq \Delta^{-1} \cdot g(S)$.

Now, let $v^\star$ be the solution computed by Edmonds' algorithm over the base polytope of $\rho^\vee$ when given weights $\overline{w}$, and examine the final word α computed in line 9. Because no coordinate in $v^\star$ can exceed value Δ, $\sum_{y \in \widetilde{\alpha}} \overline{w}(y) \geq \Delta^{-1} \overline{w}^\intercal v^\star$ follows by the law of

Algorithm 3 Marginal Adjusted Greedy for Additive Maximization.

1 $\alpha \leftarrow \epsilon$
2 **while** $|\alpha| < r_{\mathcal{M}}(\Sigma)$ **do**
3 $\quad \ell \leftarrow |\alpha|$
4 $\quad x_1 \dots x_\ell \leftarrow \alpha$
5 $\quad K_0 \leftarrow \varnothing$
6 $\quad$ **for** $i \in \{1, \dots, \ell\}$ **do** $K_i \leftarrow \mathrm{cl}(\{x_1, \dots, x_i\})$
7 $\quad$ **for** $i \in \{0, \dots, \ell\}$ **do**
8 $\quad\quad$ **if** $i < \ell$ **then** $\Psi_i \leftarrow \{y \in \Sigma \mid K_i \subsetneq \mathrm{cl}(K_i + y) \subsetneq K_{i+1}\}$
9 $\quad\quad$ **else** $\Psi_i \leftarrow \{y \in \Sigma \mid K_i \subsetneq \mathrm{cl}(K_i + y) \subseteq \Sigma\}$
10 $\quad (y^\star, i^\star) \leftarrow \underset{y \in \Psi_i : 0 \le i \le \ell}{\arg\max} \frac{w(y)}{(\overset{\vee}{\rho}/K_i)(y)}$
11 $\quad \alpha \leftarrow x_1 \cdots x_{i^\star}\, y^\star\, x_{i^\star+1} \cdots x_\ell$
12 **return** α

diminishing returns. But, the natural matroid construction shows μ_S is in the base polytope, and so by optimality of $v^\star$ we see $\overline{w}^\intercal \mu_S \le \overline{w}^\intercal v^\star$. So, combining this with the insight of the last paragraph $\overline{w}^\intercal v^\star/\Delta \ge \overline{w}^\intercal \mu_S/\Delta \ge g(S)/\Delta^2$. Then, noting that $\sum_{y \in X} w^{(k)}(y) \le f(X)$ for all $k \in \{1, \dots, \Delta\}$ and $X \subseteq \Sigma$ by the law of diminishing returns, combining the last equation with $\sum_{y \in \widetilde{\alpha}} \overline{w}(y) \ge \Delta^{-1} \overline{w}^\intercal v^\star$ shows $f(\widetilde{\alpha}) \ge \sum_{y \in \widetilde{\alpha}} \overline{w}(y) \ge \Delta^{-2} g(S)$. To finish things up, let α_{OPT} be an optimal basic word, and $T_{\alpha_{\mathrm{OPT}}} = \{(y, 1) \mid y \in \widetilde{\alpha}_{\mathrm{OPT}}\}$. See that $g(T_{\alpha_{\mathrm{OPT}}}) = f(\widetilde{\alpha}_{\mathrm{OPT}}) + \sum_{k=2}^{\Delta} f(\varnothing) = f(\widetilde{\alpha}_{\mathrm{OPT}}) = \mathrm{OPT}$. So, combining this with the guarantees of [5] and $f(\widetilde{\alpha}) \ge \Delta^{-2} g(S)$ gives $\mathbb{E}[f(\widetilde{\alpha})] \ge \Delta^{-2} \mathbb{E}[g(S)] \ge \Delta^{-2}(1 - 1/e - \delta) \cdot \mathrm{OPT}$, which is the desired result. ◀

6 Marginal Adjusted Greedy Algorithms

The last algorithms were based upon "scaffolding" the solution with good letters from a relaxed solution, and using the fill-in procedure from Lemma 11 to project this solution to a characteristic vector corresponding to a basic word. However, the fill-in procedure was such that the letters were chosen only for feasibility, not with any heuristic guiding their value for a solution. In the next algorithms, we instead select letters using a greedy heuristic driven by the greatest representation. These algorithms will lead to approximation guarantees varying in the largest matroid connectivity $\lambda_{\max}$.

6.1 Additive Maximization

Algorithm 3 works by iteratively selecting letters to insert into a working solution (initially the empty word) in a way that both achieves good value and converges to a feasible word. In each round, the method first computes in line 6 the closed set K_i given by each prefix $x_1 \dots x_i$ of the current value of α, which we assume to be of length ℓ. We also make $K_0 = \varnothing$. Then, in line 8, for each $i \in \{0, 1, \dots, \ell\}$ we compute the set Ψ_i consisting of letters which strictly increase the closed set spanned by K_i to a closed set strictly less than K_{i+1}. The set Ψ_ℓ poses a boundary condition which is handled in line 9. We save such letters in the set Ψ_i because they can be inserted into α between x_i and x_{i+1} (or appended onto the beginning or end of α when i equals 0 or ℓ, respectively) while maintaining the invariant that the process will converge to a feasible word by way of Lemma 11. In particular, one can

view α as consisting of decisions we have already committed to (along with their relative ordering). Under this perspective, we use the closure structure and construction of the sets $\{\Psi_i\}_i$ to identify new decisions we can feasibly make while still preserving the structure of the decisions we have already committed to. This is shown in a technical way in Eq. 11 in the proof of Theorem 14. Finally, observe each letter is a member of at most one Ψ_i, because $y \in \Psi_i$ implies $y \in K_{i+1} \setminus K_i$ and the sequence $\{K_i\}_i$ forms a filtration.

Keeping this in mind, in line 10 we compute a marginal-adjusted weight for every letter $y \in \bigcup_{i=0}^{\ell} \Psi_i$. Specifically, when $y \in \Psi_i$, we divide $w(y)$ by the marginal return $(\check{\rho}/K_i)(y)$. This is because $(\check{\rho}/K_i)(y)$ is exactly the difference in grade between K_i and $\mathrm{cl}(K_i + y)$, and so a large marginal return corresponds to a large jump in the closed set structure. If we commit to selecting y, then we commit to selecting a sequence of letters making a saturated chain between K_i and $\mathrm{cl}(K_i + y)$. This is, the larger the size of this jump, the more we constrain the set of letters we can feasibly select in future rounds to insert into the solution. So, we divide the weight by $(\check{\rho}/K_i)(y)$ to penalize letters which induce large jumps in the closure structure. Then, in line 10, we select the letter $y^\star$ with the largest marginal adjusted weight, and save the index $i^\star$ with $y^\star \in \Psi_{i^\star}$. We then insert $y^\star$ into α between the letters $x_{i^\star}$ and $x_{i^\star+1}$ (or place onto the beginning or end of α when i equals 0 or ℓ respectively), and repeat until $|\alpha|$ equals the length of a basic word in $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$.

For the analysis, let α_{OPT} be an optimal word. We need to "charge" each letter in the optimal word to a decision made by the algorithm. So, first let $y_t^\star$ be the letter selected in round t and $K_t^\star$ be $K_{i^\star}$ from that round. Also, let $R = \check{\rho}(\Sigma)$. By optimism, for all letters $z \in \Sigma$, there exists $t \in \{1, \ldots, R\}$ such that $z \in \mathrm{cl}(K_t^\star + y_t^\star) \setminus K_t^\star$. Then, let L_t be the letters from $\widetilde{\alpha}_{\mathrm{OPT}}$ for which t is the last round this occurs. Formally, this is given by the recursion over $t \in \{1, \ldots, R\}$,

$$L_t \triangleq \left(\mathrm{cl}(K_t^\star + y_t^\star) \setminus K_t^\star\right) \setminus \left(\bigcup_{t'=t+1}^{R} L_t\right), \quad \text{with } L_R = \mathrm{cl}(K_R^\star + y_R^\star) \setminus K_R^\star. \tag{8}$$

And, by our prior observation we see $(L_t)_t$ is a partition of $\widetilde{\alpha}_{\mathrm{OPT}}$. This sets up the sum,

$$\sum_{y \in \widetilde{\alpha}_{\mathrm{OPT}}} w(y) = \sum_{t=1}^{R} \left(\sum_{y \in L_t} w(y)\right). \tag{9}$$

But, letting $\delta_t = (\check{\rho}/K_t^\star)(y_t^\star)$, the choice rule makes $w(y) \le \delta_t^{-1} w(y_t^\star)\delta_t \cdot \left(\check{\rho}/K_{i^\star}\right)(y)$ for all $y \in L_t$, while $L_t \subseteq \mathrm{cl}(K_t^\star + y_t^\star) \setminus K_t^\star$ makes $\left(\check{\rho}/K_t^\star\right)(y) \le \left(\check{\rho}/K_t^\star\right)(y_t^\star) = \delta_t$ for all $y \in L_t$. Therefore,

$$\sum_{t=1}^{R} \left(\sum_{y \in L_t} w(y)\right) \le \sum_{t=1}^{R} \left(|L_t| \cdot \frac{w(y_t^\star)}{\delta_t} \cdot \left(\check{\rho}/K_{i^\star}\right)(y)\right) \le \sum_{t=1}^{R} |L_t| \cdot w(y_t^\star). \tag{10}$$

So, noting that $\sum_{t=1}^{R} w(y_t^\star)$ is the value of the solution returned by Algorithm 3, we need only obtain a uniform bound on $|L_t|$ for an approximation guarantee. This is our approach. Recall from Section 1 that $\lambda_{\max}$ is the maximum value of the matroid connectivity function of the matroid defining the MPS (see Eq. 2). A careful analysis will show $|L_t| \le 1 + \lambda_{\max}$.

▶ **Theorem 14.** *Let $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be a matroidal prerequisite system, $w : \Sigma \to \mathbb{R}_+$ a nonnegative weight function, and* $\mathrm{OPT} = \max_{\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)} \sum_{y \in \widetilde{\alpha}} w(y)$. *Algorithm 3 outputs $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ with $\sum_{y \in \widetilde{\alpha}} w(y) \ge (1 + \lambda_{\max})^{-1} \cdot \mathrm{OPT}$.*

Proof. Firstly, see that α is feasible because lines 8 and 9 in Algorithm 3 ensure the following invariant: the evaluations of cl on each prefix of the working solution forms a strictly increasing chain in $(\kappa(\Lambda)/\!\sim)$. Since $\sigma^{\vee}_{\rho} = \mathrm{cl}$, it can be seen then that the working solution satisfies the premise of Lemma 11 at all times. Hence, once it achieves the length of a basic word, it must be feasible.

Now, before continuing, observe the letters of the solution α are not arranged in the order in which they were inserted. In light of this, let $\pi : \{1, \ldots, R\} \to \{1, \ldots, R\}$ map the index corresponding to the position of a letter in α to the round index it was added to the solution. Then, we may write $\alpha = y^{\star}_{\pi(1)} \ldots y^{\star}_{\pi(R)}$ while still identifying the round a letter was added. Furthermore, also define $X_i \triangleq \left\{y^{\star}_{\pi(1)}, \ldots, y^{\star}_{\pi(i)}\right\}$ as the first i letters in the algorithm's solution α. Take note that as $y^{\star}_{\pi(1)}, \ldots, y^{\star}_{\pi(0)} = \epsilon$ by convention, it follows that $X_0 = \varnothing$. Moreover, the insertion scheme of Algorithm 3 maintains,

$$\mathrm{cl}(X_i) = \mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right), \quad \forall i \in \{1, \ldots, R\}. \tag{11}$$

To see why, fix $i \in \{1, \ldots, R\}$ and select an index j minimizing $\pi(j)$ among $j < i$ making $\pi(j) > \pi(i)$; this is, $y^{\star}_{\pi(j)}$ is the first letter preceding $y^{\star}_{\pi(i)}$ in position in α which was selected for insertion in a later round than $y^{\star}_{\pi(i)}$ was selected. Note that if no such j exists, then Eq. 11 holds as $K^{\star}_{\pi(i)} = \mathrm{cl}(X_{i-1})$ would have to be true. Then, $y^{\star}_{\pi(j)}$ belongs to a set in the sequence $(\Psi_{i'})_{i'}$ computed in line 8, and because $y^{\star}_{\pi(j)}$ precedes $y^{\star}_{\pi(i)}$ in position in α and minimizes $\pi(j)$ amongst such letters, this set from $(\Psi_{i'})_{i'}$ must be a subset of,

$$\mathrm{cl}\left(\left\{y^{\star}_{\pi(k)} \mid \pi(k) \leq \pi(i) \text{ and } k \leq i\right\}\right) = \mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right). \tag{12}$$

So, $y_{\pi(j)} \in \mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right)$. Now, to induct, select an arbitrary index j' with $j' < i$ and $\pi(j') > \pi(j)$. This is, $y^{\star}_{\pi(j')}$ is any letter preceding $y^{\star}_{\pi(i)}$ in position in α which was selected for insertion in a later round than $y^{\star}_{\pi(i)}$ and $y^{\star}_{\pi(j)}$. By inductive hypothesis,

$$k < i \text{ and } \pi(i) < \pi(k) < \pi(j') \implies y^{\star}_{\pi(k)} \in \mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right).$$

Combining this with Eq. 12 shows $\mathrm{cl}\left(\left\{y^{\star}_{\pi(k)} \mid \pi(k) < \pi(j') \text{ and } k \leq i\right\}\right) = \mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right)$. The left hand side is the closure of the support of the prefix of the working solution ending at $y^{\star}_{\pi(i)}$ in round $\pi(j')$. Then, because $j' < i$, i.e. $y^{\star}_{\pi(j')}$ precedes $y^{\star}_{\pi(i)}$ in position in α, line 8 implies $y^{\star}_{\pi(j')} \in \mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right)$ as well. So, by the principle of induction we see $X_{i-1} \subseteq \mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right)$, which by $X_{i-1} + y^{\star}_{\pi(i)} = X_i$ and idempotency of closure operators implies $\mathrm{cl}(X_i) \subseteq \mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right)$. Of course, the reverse inclusion follows from,

$$\begin{aligned}
\mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right) &= \mathrm{cl}\left(\mathrm{cl}\left(\left\{y^{\star}_{\pi(k)} \mid k < i \text{ and } \pi(k) < \pi(i)\right\}\right) + y^{\star}_{\pi(i)}\right), \\
&= \mathrm{cl}\left(\left\{y^{\star}_{\pi(k)} \mid k < i \text{ and } \pi(k) < \pi(i)\right\} + y^{\star}_{\pi(i)}\right),
\end{aligned}$$

which is a subset of $\mathrm{cl}(X_i)$ by the monotonicity of closure operators. And so, Eq. 11 follows.

With that done, the approximation guarantee will follow by proving the following,

$$z \in L_{\pi(i)} \implies z \in \mathrm{cl}\left(X_i\right) \setminus \mathrm{cl}\left(X_{i-1}\right). \tag{13}$$

To see why, observe $L_{\pi(i)} \subseteq \mathrm{cl}\left(K^{\star}_{\pi(i)} + y^{\star}_{\pi(i)}\right) \setminus K^{\star}_{\pi(i)}$. So, by way of contradiction, suppose Eq. 13 does not hold. There exists $z \in L_{\pi(i)}$ with $z \notin \mathrm{cl}\left(X_i\right) \setminus \mathrm{cl}\left(X_{i-1}\right)$. As

$z \in \operatorname{cl}\left(K^\star_{\pi(i)} + y^\star_{\pi(i)}\right) \setminus K^\star_{\pi(i)}$ and $\operatorname{cl}\left(K^\star_{\pi(i)} + y^\star_{\pi(i)}\right) \subseteq \operatorname{cl}(X_i)$, since $K^\star_{\pi(i)} + y^\star_{\pi(i)}$ is the union of the cl-closure of a subset of X_{i-1} unioned with the ith letter in α, for Eq. 13 to not hold it must be that $z \in \operatorname{cl}(X_{i-1})$. This shows,

$$\left(\exists z \in L_{\pi(i)}\right)\ z \in \operatorname{cl}\left(X_{i-1}\right) \setminus K^\star_{\pi(i)}. \tag{14}$$

However, $\operatorname{cl}(X_{i-1}) = \operatorname{cl}\left(K^\star_{\pi(i-1)} + y^\star_{\pi(i-1)}\right)$ by Eq. 11, so by $z \in L_{\pi(i)}$ it must be that $\pi(i-1) < \pi(i)$. This means that $y^\star_{\pi(i-1)}$ was in the support of the working solution when $y^\star_\pi(i)$ was inserted. Since $y^\star_{\pi(i-1)}$ directly precedes $y^\star_\pi(i)$ in position in α, this implies $K^\star_{\pi(i)} = \operatorname{cl}\left(K^\star_{\pi(i-1)} + y^\star_{\pi(i-1)}\right)$. But $\operatorname{cl}(X_{i-1}) = \operatorname{cl}\left(K^\star_{\pi(i-1)} + y^\star_{\pi(i-1)}\right)$ implies $\operatorname{cl}\left(X_{i-1}\right) = K^\star_{\pi(i)}$, which contradicts Eq. 14. So, we find Eq. 13 holds true.

As a result, we observe $L_t \subseteq \widetilde{\alpha}_{\text{OPT}} \cap \left(\operatorname{cl}\left(X_i\right) \setminus \operatorname{cl}\left(X_{i-1}\right)\right)$. Now, we make use of the matroid structure to introduce $\lambda_{\max}$. Because $\widetilde{\alpha}_{\text{OPT}}$ is a basic set in $\mathcal{M}$ (see Section 4),

$$\left|\widetilde{\alpha}_{\text{OPT}} \cap \operatorname{cl}\left(X_{i-1}\right)\right| = r_{\mathcal{M}}(\Sigma) - r_{\mathcal{M}}(\widetilde{\alpha}_{\text{OPT}} \setminus \operatorname{cl}\left(X_{i-1}\right)). \tag{15}$$

Continuing on, note that because $\operatorname{cl}(X_i)$ is the smallest flat support containing $y^\star_1 \dots y^\star_i$, it follows that $\operatorname{cl}(X_i) = \kappa[y^\star_1 \dots y^\star_i]$. This logic also shows $\operatorname{cl}(X_{i-1}) = \kappa[y^\star_1 \dots y^\star_{i-1}]$. Then, $\operatorname{cl}(X_i) = \sigma_{\mathcal{M}}(\{y^\star_1, \dots, y^\star_i\})$ and $\operatorname{cl}(X_{i-1}) = \sigma_{\mathcal{M}}(\{y^\star_1, \dots, y^\star_{i-1}\})$ by Lemma 7.1. Because feasible words in the MPS are independent in $\mathcal{M}$, we have $r_{\mathcal{M}}(\operatorname{cl}(X_i)) = r_{\mathcal{M}}(\operatorname{cl}(X_{i-1})) + 1$. Since independence implies $|\widetilde{\alpha}_{\text{OPT}} \cap \operatorname{cl}(X_i)| \leq r_{\mathcal{M}}(\operatorname{cl}(X_i))$, we see $|\widetilde{\alpha}_{\text{OPT}} \cap \operatorname{cl}(X_i)| \leq r_{\mathcal{M}}(\operatorname{cl}(X_{i-1})) + 1$. This observation combines with Eq. 15 for,

$$\begin{aligned}
|L_t| &\leq |\widetilde{\alpha}_{\text{OPT}} \cap (\operatorname{cl}(X_i) \setminus \operatorname{cl}(X_{i-1}))\,|,\\
&= |\widetilde{\alpha}_{\text{OPT}} \cap \operatorname{cl}(X_i)| - |\widetilde{\alpha}_{\text{OPT}} \cap \operatorname{cl}(X_{i-1})|,\\
&\leq 1 + r_{\mathcal{M}}(\operatorname{cl}(X_{i-1})) + r_{\mathcal{M}}(\widetilde{\alpha}_{\text{OPT}} \setminus \operatorname{cl}(X_{i-1})) - r_{\mathcal{M}}(\Sigma),\\
&\leq 1 + \left(r_{\mathcal{M}}(\operatorname{cl}(X_{i-1})) + r_{\mathcal{M}}(\Sigma \setminus \operatorname{cl}(X_{i-1})) - r_{\mathcal{M}}(\Sigma)\right),
\end{aligned}$$

which is less than or equal to $1 + \lambda_{\max}$ by definition (see Eq. 2). And so, by Eq.s 9 and 10 it is true that $\text{OPT} \leq \sum_{t=1}^{R} |L_t| \cdot w(y^\star_t) \leq (1 + \lambda_{\max}) \cdot \sum_{t=1}^{R} w(y^\star_t)$, which shows α is a $(1 + \lambda_{\max})$-approximation of the optimal solution. ◀

6.2 Monotone Submodular Maximization

We can extend this method to submodular maximization by modifying the selection heuristic: the only change from Algorithm 3 is that we compute the adjusted weight of a letter y in line 10 using the marginal return $(f/\widetilde{\alpha})(y)$ under f against the current working solution instead of the weight $w(y)$. We reuse the previous analysis to obtain the following.

▶ **Theorem 15.** *Let $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be a matroidal prerequisite system, $f : 2^\Sigma \to \mathbb{R}$ a (normalized) monotone submodular function, and $\text{OPT} = \max_{\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)} f(\widetilde{\alpha})$. After modifying line 10 of Algorithm 3 to compute the marginal adjusted weight $(f/\widetilde{\alpha})(y)/(\overset{\vee}{\rho}/K_i)(y)$, the algorithm outputs α with $f(\widetilde{\alpha}) \geq (2 + \lambda_{\max})^{-1} \cdot \text{OPT}$.*

Proof. Our analysis reuses parts of that presented for Algorithm 3. Notably, α is feasible by way of Lemma 11. Continuing on, define L_t in the same way as Eq. 8. Notice that the argument bounding $|L_t|$ presented in the proof of Theorem 14 only uses properties of the MPS and not the additive objective function, so we have $|L_t| \leq 1 + \lambda_{\max}$. Also let $y^\star_t$ be the

letter selected in round t, α_{OPT} and $K_t^\star$ defined as before, as well as $\alpha^{(t)}$ be the value of the working solution α at the end of round t (with the convention $\alpha^{(0)} = \epsilon$). Now, our choice rule makes,

$$\left(f/\widetilde{\alpha}^{(t-1)}\right)(z) \leq \frac{\left(f/\widetilde{\alpha}^{(t-1)}\right)(y_t^\star)}{(\overset{\vee}{\rho}/K_t^\star)(z)}(\overset{\vee}{\rho}/K_t^\star)(y_t^\star) \leq \left(f/\widetilde{\alpha}^{(t-1)}\right)(y_t^\star), \quad \forall z \in L_t,$$

and so we find that for all $t \in \{1, \ldots, R\}$,

$$\sum_{z \in L_t} \left(f/\widetilde{\alpha}^{(t-1)}\right)(z) \leq |L_t| \cdot \left(f/\widetilde{\alpha}^{(t-1)}\right)(y_t^\star) \leq (1 + \lambda_{\max}) \cdot \left(f/\widetilde{\alpha}^{(t-1)}\right)(y_t^\star).$$

So, because $f(\widetilde{\alpha}) = \sum_{t=1}^{R} \left(f/\widetilde{\alpha}^{(t-1)}\right)(y_t^\star)$, summing over all rounds shows,

$$\sum_{t=1}^{R} \sum_{z \in L_t} \left(f/\widetilde{\alpha}^{(t-1)}\right)(z) \leq (1 + \lambda_{\max}) \cdot f(\widetilde{\alpha}). \tag{16}$$

We relate the left-hand side to OPT via $\mathrm{OPT} \leq f(\widetilde{\alpha} \cup \widetilde{\alpha}_{\mathrm{OPT}}) \leq f(\widetilde{\alpha}) + \sum_{z \in \widetilde{\alpha}_{\mathrm{OPT}} \setminus \widetilde{\alpha}} (f/\widetilde{\alpha})(z)$, as the first inequality follows by monotonicity, while the second follows by the law of diminishing returns. Well, by the law of diminishing returns we also have $z \in L_t$ implies $\left(f/\widetilde{\alpha}^{(t-1)}\right)(z) \geq (f/\widetilde{\alpha})(z)$ since $\widetilde{\alpha}^{(t-1)} \subseteq \widetilde{\alpha}$ always holds by our construction. This and Eq. 16 implies $\mathrm{OPT} \leq f(\widetilde{\alpha}) + \sum_{t=1}^{R} \sum_{z \in L_t} \left(f/\widetilde{\alpha}^{(t-1)}\right)(z) \leq (2 + \lambda_{\max}) \cdot f(\widetilde{\alpha})$. Rearranging terms gives the desired result. ◀

7 Hardness of Approximation of Additive Maximization

Finally, we show that a $\min\{\Delta, \lambda_{\max}\}^{o(1)}$-approximation for nonnegative additive maximization over an MPS is intractable. We reduce from *Densest k-Subgraph (Dk-S)*: Given an undirected graph (V, E) and integer k, select a vertex subset $S \subseteq V$ of size $|S| = k$ maximizing the induced edges. The Gap Exponential Time Hypothesis (Gap-ETH) conjectures the existence of a small $\delta > 0$ for which no subexponential time algorithm can distinguish between a satisfiable 3-SAT formula and one where at most a $(1 - \delta)$-fraction of clauses can be satisfied [30, 9, 6]. Under the Gap-ETH, there is no $|V|^{o(1)}$-approximation to Dk-S [29].

For a coming arithmetic exercise, define $B = |E| + 1$. We construct an MPS whose nonnegative additive maximization solutions encode Dk-S solutions in a way preserving their approximation quality. For each $u \in V$ make B "dummy" letters $d_{u,1}, \ldots, d_{u,B}$, include each vertex u, and include each edge $e = \{u, v\} \in E$. For the weights set,

$$w(y) = \begin{cases} 1, & \text{if } y \text{ is an edge letter,} \\ 0, & \text{otherwise,} \end{cases} \tag{17}$$

and let the matroid $\mathcal{M}$ be the uniform matroid of rank $R \triangleq k(B+1) + |E| + 1$. Finally, for the prerequisite order, each vertex u is greater than all its dummy letters $d_{u,1}, \ldots, d_{u,B}$ and each edge $e = \{u, v\} \in E$ is greater than u and v. Recall, we showed in Section 4 that uniform matroids always satisfy compatibility with $(\Sigma, \rightsquigarrow)$. So, $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$ is a MPS.

We describe how the solutions values of the MPS and Dk-S instances are related in the following two claims. This is then used to prove Lemma 18, which gives an approximation-preserving reduction from Dk-S to nonnegative additive maximization over an MPS.

▷ Claim 16. There is an efficient procedure to extract a k-subgraph with at least $\mathrm{VAL} - 1$ edges from every basic word of cumulative weight VAL.

Proof. Let $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$ be a basic word of value VAL, and let α' be the prefix excluding the last letter. We exclude the last letter because it can correspond to an edge which was added without both its incident vertices being present in the word. However, because the matroid is uniform, it is not possible for the prerequisites of any edge in $\widetilde{\alpha}'$ to be satisfied "virtually" without their membership in the support. Therefore, because the edges correspond to the only letters with nonzero weight, if we let the cumulative weight of the support of α' be VAL$'$ then the vertices in $\widetilde{\alpha}'$ must induce a subgraph with at least VAL$'$ edges.

Then, examine the set $X = \{v \in V \mid (\exists e \in \widetilde{\alpha}' \cap E)\ v \in e\}$. We claim $|X| \leq k$. By way of contradiction, suppose this is not true. Our prior observations make $X \subseteq \widetilde{\alpha}'$. Note then that for every letter in X, the B dummy prerequisite letters must also be present. So, if $|X| > k+1$ it follows that there are at least $k+1$ vertex letters and $B(k+1)$ dummy letters in $\widetilde{\alpha}'$. By recalling $B = |E|+1$, one observes $|\widetilde{\alpha}'| \geq (k+1)(B+1) = k(B+1) + |E| + 2 > R$. This means $\widetilde{\alpha}'$ is not independent, which contradicts the fact that it is the prefix of a basic word of $\mathcal{L}(\mathcal{M}, \rightsquigarrow)$. And so, because $|X| \leq k$, one can output a feasible Dk-S solution of value at least VAL$'$ by listing the vertices in X along with a choice of $k - |X|$ additional vertices. Since VAL$' \geq$ VAL $- 1$, this shows the claim. ◁

▷ Claim 17. For any Dk-S solution inducing VAL edges, there exists a basic word of cumulative weight at least VAL.

Proof. Let X be a Dk-S solution of value VAL. Take $S = \{(u,v) \in E \mid \{u,v\} \subseteq X\}$ as the edges in the induced subgraph; clearly $|S| =$ VAL. Now, examine a word α formed by taking any linear extension of the ideal generated by S in $(\Sigma, \rightsquigarrow)$. Observe, $|X| = k$ implies there can be at most k vertex letters in this ideal, and each vertex letter is above exactly B letters associated with its dummies. Thus $|\alpha| \leq k(B+1) + (\text{VAL}) \leq k(B+1) + |E|$, and so $\widetilde{\alpha}$ is independent. Furthermore, the prerequisite conditions are trivially satisfied by α since it is a linear extension of an ideal (i.e. for any $y \in \widetilde{\alpha}$, *every* $x \rightsquigarrow y$ is such that $x \in \widetilde{\alpha}$ in a position occurring before the appearance of y), so $\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)$. Since the support of α contains VAL edges, its cumulative weight is at least VAL. Therefore, any basic word formed by concatenating α with a suffix from $\mathcal{L}(\mathcal{M}, \rightsquigarrow)/[\alpha]$ gives the result. ◁

▶ **Lemma 18.** *Fix a Dk-S instance. Let Σ, $\mathcal{M}$, and $(\Sigma, \rightsquigarrow)$ as constructed, and $w : \Sigma \to \mathbb{R}$ be as defined in Eq. 17. Let $\text{OPT}_{Dk\text{-}S}$ be the number of edges in an optimal Dk-S solution, and $\text{OPT}_{MPS} = \max_{\alpha \in \mathcal{L}(\mathcal{M}, \rightsquigarrow)} \sum_{y \in \widetilde{\alpha}} w(y)$. If there exists an efficient δ^{-1}-approximation algorithm to nonnegative additive maximization over the MPS, then there exists an efficient algorithm giving a Dk-S solution inducing $\delta \cdot (\text{OPT}_{Dk\text{-}S} + O(1)) - 1$ edges.*

Proof. Let OPT_{MPS} be the weight of an optimal basic word. The first claim we proved shows $\text{OPT}_{\text{MPS}} \leq \text{OPT}_{\text{D}k\text{-S}} + 1$ while the second shows $\text{OPT}_{\text{D}k\text{-S}} \leq \text{OPT}_{\text{MPS}}$. So, $\text{OPT}_{\text{MPS}} = \text{OPT}_{\text{D}k\text{-S}} + O(1)$. Moreover, the first claim also shows an efficient procedure for extracting a Dk-S solution of value $\delta \cdot \text{OPT}_{\text{MPS}} - 1$ from any δ-approximation to the nonnegative additive maximization over the MPS. Altogether, $\delta \cdot \text{OPT}_{\text{MPS}} - 1 = \delta \cdot (\text{OPT}_{\text{D}k\text{-S}} + O(1)) - 1$. ◀

Proof of Main Result 2. Now, observe the principal ideal of any edge letter is a maximum sized such ideal with cardinality exactly $2 \cdot (B+1) + 1$. Since $R \geq 2 \cdot (B+1)$ for $k \geq 1$, this means for any choice of edge e we have $\Delta = r_{\mathcal{M}}(\downarrow e) = \Theta(|E|) = O(|V|^2)$. Therefore, by Lemma 18, any $\Delta^{o(1)}$-approximation algorithm for an MPS computes a $|V|^{o(1)}$-approximation to Dk-S. Moreover, one can observe that $\lambda_{\max} \leq r_{\mathcal{M}}(\Sigma)$ is always true. And so, $\lambda_{\max} \leq R = O(|E|) = O(|V|^2)$. Thus, Lemma 18 also implies any $\lambda_{\max}^{o(1)}$-approximation algorithm for an MPS is a $|V|^{o(1)}$-approximation to Dk-S. ◀

The Code Distortion Problem

Huck Bennett
University of Colorado Boulder, CO, USA

Matthew Fox
University of Colorado Boulder, CO, USA

Bryant Morrell
University of Colorado Boulder, CO, USA

Abstract

Two linear error-correcting codes $\mathcal{C}_1, \mathcal{C}_2 \subseteq \mathbb{F}_q^n$ are called *linearly equivalent* if there is a linear isometry mapping $\mathcal{C}_1$ to $\mathcal{C}_2$. In this work, we generalize the notion of linear equivalence and study the minimum distortion $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$ of a linear mapping between codes $\mathcal{C}_1, \mathcal{C}_2 \subseteq \mathbb{F}_q^n$, which *quantifies* how similar $\mathcal{C}_1$ and $\mathcal{C}_2$ are. We introduce and study the Code Distortion Problem (CDP), which asks to find a minimum distortion mapping between two input codes $\mathcal{C}_1$ and $\mathcal{C}_2$. CDP generalizes the Linear Code Equivalence Problem (LCE), which is essentially the special case of CDP where $\mathcal{D}(\mathcal{C}_1, C_2) = 1$ and which is well-studied because of its role in cryptography.

We prove that (decisional) CDP is NP-hard to approximate to within any constant factor, and that it is in Σ_2^{P}. We also give a single-exponential-time k^2-approximation algorithm for CDP, where k is the dimension of the input codes. Furthermore, we give a single-exponential-time $\left(\frac{2k+1}{3}\right)^2$-approximation algorithm for a natural special case of CDP, and we show that our analysis is tight in this case.

We use techniques from analogous work on the Lattice Distortion Problem (LDP) by Bennett, Dadush, and Stephens-Davidowitz (ESA, 2016). We also introduce or study a number of additional concepts that might be of independent interest. These include an adaptation of the celebrated reduction of Goldreich, Micciancio, Safra, and Seifert (IPL, 1999) from the Shortest Vector Problem (SVP) to the Closest Vector Problem (CVP) on lattices to the analogous problems on codes; successive minima bases for codes; and the matrix $0 \to 0$ "norm" on subspaces.

Acknowledgements We thank Alexander Golovnev and Noah Stephens-Davidowitz for useful conversations [20], and in particular for allowing us to include Theorem 22 about the coNP-hardness of approximating the matrix $0 \to 0$ norm on subspaces in this work. We also thank the anonymous APPROX reviewers for helpful comments, and in particular for identifying an incorrect inequality (which is now fixed).

1 Introduction

A *linear error-correcting code* (or simply, *code*) is a linear subspace $\mathcal{C} \subseteq \mathbb{F}_q^n$. Although best known for their use in robust communication, codes also appear prominently in algorithms, computational complexity, and cryptography. Notably, several of the cryptosystems appearing

© Huck Bennett, Matthew Fox, and Bryant Morrell;
licensed under Creative Commons License CC-BY 4.0

in late rounds or standardized by the National Institute of Standards and Technology's (NIST) post-quantum cryptography standardization process are based on the intractability of certain computational problems on codes [1, 12, 17].

One central problem on codes of cryptographic interest is the *Linear Code Equivalence Problem* (LCE), in which, given generator matrices of two codes $\mathcal{C}_1, \mathcal{C}_2 \subseteq \mathbb{F}_q^n$ as input, the goal is to decide whether $\mathcal{C}_1$ and $\mathcal{C}_2$ are *linearly equivalent*, i.e., whether one can convert $\mathcal{C}_1$ into $\mathcal{C}_2$ simply by permuting coordinates and scaling coordinates by non-zero values. In particular, the LESS cryptosystem [12, 5] crucially relies on the hardness of LCE. It is currently a second-round candidate in NIST's "Additional Digital Signature Schemes" standardization process [26]. Furthermore, a large body of work has studied LCE and its variants from an algorithmic and complexity-theoretic standpoint. See, e.g., [21, 28, 30, 4, 10, 6, 15, 9, 27, 7].

A linear isometry (i.e., distance-preserving map) on $\mathbb{F}_q^n$ corresponds to a matrix $M \in \mathbb{F}_q^{n\times n}$ such that for all $\boldsymbol{x} \in \mathbb{F}_q^n$, $\|M\boldsymbol{x}\|_0 = \|\boldsymbol{x}\|_0$, where $\|\cdot\|_0$ denotes the Hamming weight of a vector. It is not hard to check that a matrix M satisfying this property can be written as the product $M = DP$ of a non-singular diagonal matrix D (which corresponds to scaling) and a permutation matrix P (such matrices M are called *monomial matrices*). In other words, the two operations in the definition of LCE – permuting and scaling coordinates by non-zero values – exactly characterize the linear isometries on $\mathbb{F}_q^n$.

So, LCE asks whether there is a (perfectly) distance-preserving linear map between two input codes $\mathcal{C}_1, \mathcal{C}_2$. However, it is natural to ask a refined version of this question:

Is there a linear map T such that $T(\mathcal{C}_1) = \mathcal{C}_2$ and T *approximately* preserves distances?

We make this precise and quantitative by asking what the minimum *distortion* of such a map T from $\mathcal{C}_1$ to $\mathcal{C}_2$ is. We define the distortion of a map T with $T(\mathcal{C}_1) = \mathcal{C}_2$ as

$$\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) := \Big(\max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\Big) \Big/ \Big(\min_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\Big) \,, \tag{1}$$

and we define $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) := \min_T \mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2)$, where the minimum is taken over all linear maps T such that $T(\mathcal{C}_1) = \mathcal{C}_2$. Informally, $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2)$ is the ratio of the most T blows up distances and the most it shrinks distances. We note that $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2)$ is simply the distortion of the map T in the standard sense of metric embeddings, where the codes $\mathcal{C}_1$ and $\mathcal{C}_2$ are the ambient spaces and each is equipped with the Hamming metric. (See, e.g., the lecture notes of Matoušek [22] for background on metric embeddings.) Moreover, $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$ is the minimum distortion over all such linear maps T, and it therefore quantifies how similar $\mathcal{C}_1$ and $\mathcal{C}_2$ are. Intuitively, linearly equivalent codes are essentially the same, and codes $\mathcal{C}_1, \mathcal{C}_2$ with $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \gg 1$ are quite different. One can show that $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \geq 1$ (see Lemma 15), and that equality holds if and only if there exist linearly equivalent "unary scalings" of $\mathcal{C}_1$ and $\mathcal{C}_2$ (see Proposition 19).

Recall that a code $\mathcal{C} \subseteq \mathbb{F}_q^n$ of dimension k, called an $[n, k]_q$ code, is often represented by a generator matrix (basis) $G \in \mathbb{F}_q^{n\times k}$.[1] I.e., the code generated by G is $\mathcal{C}(G) := \{G\boldsymbol{x} : \boldsymbol{x} \in \mathbb{F}_q^k\}$. And, one can represent an arbitrary linear map between two $[n, k]_q$ codes in terms of generator matrices $G_1 := (\boldsymbol{g}_1^{(1)}, \ldots, \boldsymbol{g}_k^{(1)}) \in \mathbb{F}_q^{n\times k}$ and $G_2 := (\boldsymbol{g}_1^{(2)}, \ldots, \boldsymbol{g}_k^{(2)}) \in \mathbb{F}_q^{n\times k}$ of the respective codes by $\boldsymbol{g}_i^{(1)} \mapsto \boldsymbol{g}_i^{(2)}$.

[1] In this work we use *column* bases for codes, although row bases are often used in the literature.

For example, consider the generator matrices

$$G_1 := \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 1 \\ 0 & 1 \end{pmatrix} \in \mathbb{F}_2^{4\times 2}\ , \qquad G_2 := \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 1 \\ 0 & 1 \end{pmatrix} \in \mathbb{F}_2^{4\times 2}\ , \qquad G_2' := \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 1 \\ 1 & 1 \end{pmatrix} \in \mathbb{F}_2^{4\times 2}\ .$$

Notice that $\mathcal{C}_1 := \mathcal{C}(G_1)$ and $\mathcal{C}_2 := \mathcal{C}(G_2)$ are not linearly equivalent, but that $\mathcal{C}_2 = \mathcal{C}(G_2')$, i.e., G_2 and G_2' are different generator matrices of the same code. Letting T and T' be linear maps such that $T(G_1) = G_2$ and $T'(G_1) = G_2'$, it is straightforward to check that

$$\begin{aligned}\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) &= \Big(\max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\Big) \Big/ \Big(\min_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\Big) \\ &= \Big(\frac{\|(1,1,1,0)\|_0}{\|(1,0,0,0)\|_0}\Big) \Big/ \Big(\frac{\|(1,0,0,1)\|_0}{\|(1,1,1,1)\|_0}\Big) \\ &= \frac{3}{1} \cdot \Big(\frac{1}{2}\Big)^{-1} = 6\ ,\end{aligned}$$

and

$$\begin{aligned}\mathcal{D}_{T'}(\mathcal{C}_1, \mathcal{C}_2) &= \Big(\max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \frac{\|T'\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\Big) \Big/ \Big(\min_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \frac{\|T'\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\Big) \\ &= \Big(\frac{\|(1,0,0,1)\|_0}{\|(1,0,0,0)\|_0}\Big) \Big/ \Big(\frac{\|(1,1,1,0)\|_0}{\|(1,1,1,1)\|_0}\Big) \\ &= \frac{2}{1} \cdot \Big(\frac{3}{4}\Big)^{-1} = \frac{8}{3}\ .\end{aligned}$$

In other words, T' is a substantially lower distortion mapping between $\mathcal{C}_1$ and $\mathcal{C}_2$ than T is. Part of the reason for this is that G_2' is a better basis of $\mathcal{C}_2$ than G_2 is in a sense that we will make precise in the sequel.

In this work, we study code distortion from a computational standpoint. Let $\gamma \geq 1$ be an approximation factor. Specifically, we study the γ-approximate Code Distortion Problem (γ-CDP), which asks to compute a linear mapping T between two codes $\mathcal{C}_1$ and $\mathcal{C}_2$ such that $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) \leq \gamma \cdot \mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$. We also study its decision version, γ-GapCDP, in which the goal is to decide whether $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \leq D$ or $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) > \gamma D$ for a given input distortion threshold value $D \geq 1$. When emphasizing the finite field $\mathbb{F}_q$ that the input codes are over, we add a subscript q to the problems.

1.1 Our Results

We study CDP from both an algorithmic and complexity-theoretic perspective. We first prove hardness of approximation for GapCDP with (fixed) $D > 1$.

▶ **Theorem 1.** *For any constant $\gamma \geq 1$, any constant $D > 1$, and any prime power $q \leq \mathrm{poly}(n)$, γ-GapCDP$_q$ with distortion threshold D is* NP*-hard under deterministic Cook reductions.*

As we formalize in Proposition 19, GapCDP with distortion threshold $D = 1$ is equivalent to LCE up to scaling. From this it follows that GapCDP with $D = 1$ is in NP, but, because of a result of Petrank and Roth [28] showing that LCE is in coAM, it is not NP-hard unless the polynomial hierarchy collapses. In contrast, Theorem 1 asserts that if D is just slightly larger than 1 then GapCDP is NP-hard even to approximate to within any constant factor γ.

For example, taking $D = 1.01$ and $\gamma = 1000$, Theorem 1 shows that it is NP-hard to decide whether $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \leq 1.01$ or $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) > 1010$ when one of these is promised to hold. The result holds for codes $\mathcal{C}_1, \mathcal{C}_2 \subseteq \mathbb{F}_q^n$ for any field $\mathbb{F}_q$ with $q \leq \text{poly}(n)$.

We further show in Theorem 24 that GapCDP is in the complexity class Σ_2^{P}. Interestingly, it is not clear that GapCDP is contained in NP. This stands in contrast both to LCE and the Lattice Distortion Problem (LDP), the analogous problem to GapCDP on lattices, which [8] noted is in NP.[2] The main difference between LDP and GapCDP is that the $2 \to 2$ norm $\|T\|$ of a real-valued matrix T is efficient to compute (indeed, $\|T\|$ is simply the largest singular value of T), whereas the problem of computing the $0 \to 0$ "norm" of a linear operator T mapping one code to another is coNP-hard even to approximate to within any constant factor! See Corollary 23.[3]

We next give algorithms for CDP. In Lemma 27, we give and analyze a brute force, exact algorithm for CDP_q on $[n,k]_q$ codes, which runs in $O^*(q^{k(k+1)}) \approx q^{k^2}$ time – essentially the amount of time it takes to enumerate all generator matrices of a given $[n,k]_q$ code.[4] It is unclear how to get a faster exact algorithm, and so we turn to giving approximation algorithms. We first give a single-exponential-time, k^2-approximation algorithm for CDP on $[n,k]_q$ codes.

▶ **Theorem 2.** *For any prime power q, there is an algorithm for k^2-CDP on $[n,k]_q$ codes that runs in $O^*(q^k)$ time and $\text{poly}(n, \log q)$ space.*

We contrast the approximation factor of k^2 in Theorem 2 with the trivial bound bound of $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) \leq n^2$, which holds for any linear map T such that $T(\mathcal{C}_1) = \mathcal{C}_2$ for $[n,k]_q$ codes $\mathcal{C}_1, \mathcal{C}_2$; see Lemma 15. Since $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) \geq 1$ also always holds, this implies a trivial n^2-approximation algorithm for GapCDP. We do not know of a better bound (even a non-constructive one), although we show an upper bound of n when allowing for *non-linear* maps between the codes; see Lemma 17. However, even in this case it is not clear that *finding* such a map would be at all efficient, and we note that Theorem 2 holds for approximate *search* CDP.

For an $[n,k]_q$ code $\mathcal{C}$ and $i \in [k]$, we define the *ith successive minimum* $\lambda_i(\mathcal{C})$ of $\mathcal{C}$ to be the minimum value $r \in \{1, \ldots, n\}$ such that $\mathcal{C}$ contains i linearly independent vectors of Hamming weight at most r. In particular, $\lambda_1(\mathcal{C})$ is the minimum distance of $\mathcal{C}$. We get a strengthening of Theorem 2 when the input codes are binary and when all of the successive minima of both of the input codes are the same.

▶ **Theorem 3.** *There is an algorithm for $\left(\frac{2k+1}{3}\right)^2$-CDP on $[n,k]_2$ codes $\mathcal{C}_1, \mathcal{C}_2$ satisfying $\lambda_1(\mathcal{C}_1) = \cdots = \lambda_k(\mathcal{C}_1) = \lambda_1(\mathcal{C}_2) = \cdots = \lambda_k(\mathcal{C}_2)$ that runs in $O^*(2^k)$ time and $\text{poly}(n)$ space.*

In fact, the *algorithm* used to prove both Theorems 2 and 3 is the same, but all of the codes' successive minima being the same allows for a tighter analysis of its approximation factor. In fact, the analysis of Theorem 3 is tight. However, due to space constraints, we defer the proof to the full version of our paper. Additionally, we note that although we give Theorem 3 only for $\mathbb{F}_2$, one can show that it extends to $\mathbb{F}_q$ for arbitrary prime powers q with a more complicated proof; see [25].

---

[2] Recall that a *lattice* is the analog of a code over the integers or real numbers. Specifically, the lattice generated by a basis $B \in \mathbb{R}^{n \times k}$ with full column rank is $\mathcal{L}(B) := \{B\boldsymbol{z} : \boldsymbol{z} \in \mathbb{Z}^k\}$.

[3] The $0 \to 0$ norm of a linear operator acting on all of $\mathbb{F}_q^n$ (and not restricted restricted to a code/subspace) is also efficiently computable; see Proposition 20.

[4] In this paper, we use $O^*(\cdot)$ to suppress polynomial factors in n and $\log q$.

1.2 Overview of Techniques

At a high level, the proofs of Theorems 1 and 2 follow along similar lines to those used to show upper and lower bounds for the Lattice Distortion Problem (LDP) in [8]. However, they also require a number of additional concepts, which may be of independent interest. The proof of Theorem 3 goes along similar lines to the proof of Theorem 2, but it is substantially more nuanced.

Approximation algorithms

We prove a constructive upper bound using what we call *successive minima bases* for codes. We define a successive minima basis of an $[n,k]_q$ code $\mathcal{C}$ to be a generator matrix $G := (\boldsymbol{g}_1, \ldots, \boldsymbol{g}_k) \in \mathbb{F}_q^{n\times k}$ such that $\|\boldsymbol{g}_i\|_0 = \lambda_i(\mathcal{C})$, i.e., the columns of G are linearly independent and their Hamming weights achieve the successive minima of $\mathcal{C}$. Every code has a successive minima basis (essentially because any k linearly independent vectors in $\mathcal{C}$ form a basis of $\mathcal{C}$) and they can be computed in roughly q^k time; see Lemma 6. In contrast, not every lattice $\mathcal{L}$ has a successive minima basis.[5] Although successive minima are widely used in the study of lattices, to the best of our knowledge they have not previously been explicitly used for codes.

Our approximation algorithm for CDP that leads to Theorems 2 and 3 is simply to compute successive minima bases $G_1 := (\boldsymbol{g}_1^{(1)}, \ldots, \boldsymbol{g}_k^{(1)}) \in \mathbb{F}_q^{n\times k}$ and $G_2 := (\boldsymbol{g}_1^{(2)}, \ldots, \boldsymbol{g}_k^{(2)}) \in \mathbb{F}_q^{n\times k}$ of the respective input $[n,k]_q$ codes $\mathcal{C}_1$ and $\mathcal{C}_2$, and to take the mapping $T : \boldsymbol{g}_i^{(1)} \mapsto \boldsymbol{g}_i^{(2)}$ that they induce.

We show that such a mapping T is a k^2-approximation, proving Theorem 2, as follows. For $[n,k]_q$ codes $\mathcal{C}_1$ and $\mathcal{C}_2$, define $M(\mathcal{C}_1,\mathcal{C}_2) := \max_{i\in[k]} \lambda_i(\mathcal{C}_1)/\lambda_i(\mathcal{C}_2)$. (An analogous quantity for lattices appeared in [8].) We show that the mapping T defined above in terms of successive minima bases satisfies $\mathcal{D}_T(\mathcal{C}_1,\mathcal{C}_2) \le k^2 \cdot M(\mathcal{C}_1,\mathcal{C}_2)M(\mathcal{C}_2,\mathcal{C}_1)$. Furthermore, we show that *any* linear map T' such that $T'\mathcal{C}_1 = \mathcal{C}_2$ must satisfy $\mathcal{D}_{T'}(\mathcal{C}_1,\mathcal{C}_2) \ge M(\mathcal{C}_1,\mathcal{C}_2)M(\mathcal{C}_2,\mathcal{C}_1)$, and therefore $\mathcal{D}(\mathcal{C}_1,\mathcal{C}_2) \ge M(\mathcal{C}_1,\mathcal{C}_2)M(\mathcal{C}_2,\mathcal{C}_1)$. Combining these two bounds, we have that

$$M(\mathcal{C}_1,\mathcal{C}_2)M(\mathcal{C}_2,\mathcal{C}_1) \le \mathcal{D}(\mathcal{C}_1,\mathcal{C}_2) \le \mathcal{D}_T(\mathcal{C}_1,\mathcal{C}_2) \le k^2 \cdot M(\mathcal{C}_1,\mathcal{C}_2)M(\mathcal{C}_2,\mathcal{C}_1)\ ,$$

and therefore that T is k^2-approximately optimal, i.e., that $\mathcal{D}_T(\mathcal{C}_1,\mathcal{C}_2) \le k^2 \cdot \mathcal{D}(\mathcal{C}_1,\mathcal{C}_2)$.

Showing the refined result in Theorem 3 for codes over $\mathbb{F}_2$ all of whose successive minima are the same requires more work. We assume that G_1 and G_2 are successive minima bases of the input $[n,k]_2$ codes (so that each vector in G_1 and G_2 has Hamming weight $\lambda := \lambda_1(\mathcal{C}_1) = \cdots = \lambda_k(\mathcal{C}_1) = \lambda_1(\mathcal{C}_2) = \cdots = \lambda_k(\mathcal{C}_2)$), and we let T be a mapping such that $TG_1 = G_2$. We then analyze

$$\mathcal{D}_T(\mathcal{C}_1,\mathcal{C}_2) := \max_{\boldsymbol{a}\in\mathbb{F}_2^k}\left(\frac{\|G_2\boldsymbol{a}\|_0}{\|G_1\boldsymbol{a}\|_0}\right)\max_{\boldsymbol{b}\in\mathbb{F}_2^k}\left(\frac{\|G_1\boldsymbol{b}\|_0}{\|G_2\boldsymbol{b}\|_0}\right) = \max_{\boldsymbol{a},\boldsymbol{b}\in\mathbb{F}_2^k}\left(\frac{\|G_1\boldsymbol{b}\|_0}{\|G_1\boldsymbol{a}\|_0}\frac{\|G_2\boldsymbol{a}\|_0}{\|G_2\boldsymbol{b}\|_0}\right)$$

[5] As an explicit example, consider the lattice $\mathcal{L} = \mathcal{L}(B) \subset \mathbb{R}^5$ generated by the basis

$$B = (\boldsymbol{b}_1, \ldots, \boldsymbol{b}_5) := \begin{pmatrix} 1 & 0 & 0 & 0 & 1/2 \\ 0 & 1 & 0 & 0 & 1/2 \\ 0 & 0 & 1 & 0 & 1/2 \\ 0 & 0 & 0 & 1 & 1/2 \\ 0 & 0 & 0 & 0 & 1/2 \end{pmatrix}\ .$$

One can check that $\boldsymbol{e}_i \in \mathcal{L}$ for $i = 1, \ldots, 5$, and that every vector in $\mathcal{L}$ has norm at least 1. So, $\lambda_1(\mathcal{L}) = \cdots = \lambda_5(\mathcal{L}) = 1$. However, any basis of $\mathcal{L}$ must contain $\pm\boldsymbol{b}_5$, which has norm greater than 1.

We upper bound the quantity $\frac{\|G_2\boldsymbol{a}\|_0\|G_1\boldsymbol{b}\|_0}{\|G_1\boldsymbol{a}\|_0\|G_2\boldsymbol{b}\|_0}$ on the right-hand side for non-zero $\boldsymbol{a}, \boldsymbol{b} \in \mathbb{F}_q^k$ in cases. In each case, we make use of the fact that for non-zero $\boldsymbol{x}$, $\lambda \leq \|G_1\boldsymbol{x}\|_0 \leq \lambda\|\boldsymbol{x}\|_0$, where the upper bound follows from the triangle inequality. Similar bounds hold for G_2.

If $\|\boldsymbol{a}\|_0 + \|\boldsymbol{b}\|_0 \leq \left(\frac{2k+1}{3}\right)$, then by the AM-GM inequality $\|\boldsymbol{a}\|_0\|\boldsymbol{b}\|_0 \leq \left(\frac{2k+1}{3}\right)^2\lambda^2$. So,

$$\frac{\|G_2\boldsymbol{a}\|_0\|G_1\boldsymbol{b}\|_0}{\|G_1\boldsymbol{a}\|_0\|G_2\boldsymbol{b}\|_0} \leq \frac{\left(\frac{2k+1}{3}\right)^2\lambda^2}{\lambda^2} = \left(\frac{2k+1}{3}\right)^2 .$$

On the other hand, if $\|\boldsymbol{a}\|_0 + \|\boldsymbol{b}\|_0 > \left(\frac{2k+1}{3}\right)$ then the supports of $\boldsymbol{a}$ and $\boldsymbol{b}$ have large intersection, which leads to a similar upper bound on $\frac{\|G_2\boldsymbol{a}\|_0\|G_1\boldsymbol{b}\|_0}{\|G_1\boldsymbol{a}\|_0\|G_2\boldsymbol{b}\|_0}$.

Hardness of approximation

To show hardness of approximation for GapCDP, we roughly follow the approach used in [8] for showing hardness of approximation for LDP. We give a pair of reductions, the first of which reduces from the Minimum Distance Problem (GapMDP) to a promise variant of the Nearest Codeword Problem (GapNCP). This first reduction is an adaptation of the reduction from the Shortest Vector Problem (GapSVP) to the Closest Vector Problem (GapCVP) on lattices from [19], and it is likely of independent interest.[6]

The second reduction is from GapNCP to GapCDP. We recall that the input to GapNCP is a pair consisting of a generator matrix $G \in \mathbb{F}_q^{n\times k}$ of a code $\mathcal{C}$ and a target vector $\boldsymbol{t} \in \mathbb{F}_q^n$, and the goal is to decide whether the minimum distance between $\boldsymbol{t}$ and a codeword in $\mathcal{C}$ (i.e., $\min_{\boldsymbol{x}\in\mathcal{C}} \|\boldsymbol{t} - \boldsymbol{x}\|_0$) is at most some threshold. The idea behind our hardness reduction is to construct the following pair of generator matrices, corresponding to an instances of CDP:

$$G_1 := \begin{pmatrix} G & \mathbf{0} \\ 0 & \mathbf{1}_r \end{pmatrix} , \qquad G_2 := \begin{pmatrix} G & -\boldsymbol{t} \\ 0 & \mathbf{1}_r \end{pmatrix} . \tag{2}$$

Here $r \in \mathbb{Z}^+$. Let $\mathcal{C}_1 := \mathcal{C}(G_1)$ and $\mathcal{C}_2 := \mathcal{C}(G_2)$.

If $\min_{\boldsymbol{c}\in\mathcal{C}} \|\boldsymbol{c} - \boldsymbol{t}\|_0$ is small then $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$ is small. If on the other hand $\min_{\boldsymbol{c}\in\mathcal{C}} \|\boldsymbol{c} - \boldsymbol{t}\|_0$ is large, then we would *hope* is that $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$ is large. However, this does not clearly work directly, and we need to modify the reduction. (The attempted reduction sketched here in Equation (2) is the natural analog of the analogous hardness reduction in [8] for LDP; the modified reduction is slightly more involved.)

Because GapMDP is known to be NP-hard to approximate to within any constant [16, 13], this pair of reductions implies that CDP is also NP-hard to approximate to within any constant.

[6] We note that GapMDP and GapNCP are the coding problems analogous to the lattice problems GapSVP and GapCVP, respectively. Furthermore, we note that while [2] showed hardness of approximation for GapNCP, it did not show hardness of the variant that we use in the present work, which has an added promise in the NO case. Finally, we note that our reduction has the advantage of being directly from GapMDP, and of being dimension- and approximation-preserving.

The complexity of GapCDP and its relationship to the $0 \to 0$ norm

We note that the complexity of GapCDP seems closely related to the complexity of computing what we call the matrix $0 \to 0$ *norm restricted to a subspace*. The matrix $0 \to 0$ norm[7]

$$\|T\|_{0\to 0} := \max_{\boldsymbol{x}\in\mathbb{F}_q^n\setminus\{\mathbf{0}\}} \frac{\|M\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} .$$

of a matrix $T \in \mathbb{F}_q^{m\times n}$ is also efficiently computable; see Proposition 20. However, the matrix $0 \to 0$ norm restricted to a subspace $\mathcal{C} \subseteq \mathbb{F}_q^n$ (i.e., code $\mathcal{C}$), defined as,

$$\|T_{|\mathcal{C}}\|_{0\to 0} := \max_{\boldsymbol{x}\in\mathcal{C}\setminus\{\mathbf{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} .$$

is coNP-hard even to approximate; see Corollary 23. We note that for a linear map T with $T\mathcal{C}_1 = \mathcal{C}_2$ for codes $\mathcal{C}_1, \mathcal{C}_2$, $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) = \|T_{|\mathcal{C}_1}\|_{0\to 0} \cdot \|(T^{-1})_{|\mathcal{C}_2}\|_{0\to 0}$. The most obvious approach to showing that GapCDP is in NP would be to use a low-distortion map T between the input codes as a witness, and to have the verifier check that $\|T_{|\mathcal{C}_1}\|_{0\to 0} \cdot \|(T^{-1})_{|\mathcal{C}_2}\|_{0\to 0} \le D$. However, because computing the matrix $0 \to 0$ norm restricted to a subspace is coNP-hard, this approach does not work. (We note that this coNP-hardness does not obviously translate to GapCDP.) As a result, the best upper bound that we get on GapCDP is to show containment in Σ_2^{P}. (As we also note elsewhere, it is a tantalizing question whether one can improve our NP-hardness result for GapCDP to Σ_2^{P}-hardness, and therefore show that GapCDP is Σ_2^{P}-complete.)

1.3 An Approach for a Faster Approximation Algorithm

A natural direction for making our approximation algorithm in Theorem 2 more efficient would be to use reduced (but not necessarily optimal) bases in place of successive minima bases. Indeed, this is how [8] achieves a time-approximation tradeoff in its algorithm for LDP, which includes a polynomial-time approximation algorithm in one regime. (On the other hand, our approximation algorithm in Theorem 2 only runs in polynomial time for an extreme parameter regime – when $k = O(\log_q n)$.) And, a recent line of work has studied basis reduction algorithms for codes [14, 18], including analogs of basis reduction algorithms for lattices. However, it is not clear how to leverage bases reduced in any of the senses they consider to get an approximation algorithm running in a reasonable amount of time and with a reasonable approximation factor.

1.4 Open Questions

Our work leaves open several interesting questions. On the complexity side, our results showing that GapCDP is both NP-hard and in Σ_2^{P} begs the question of whether GapCDP is also Σ_2^{P}-hard, and thus Σ_2^{P}-complete. Moreover, as part of the inspiration for this work comes from the analogous Lattice Distortion Problem (LDP) [8], it is natural to ask whether (approximate) CDP reduces to LDP. We note that a fairly simple reduction from LCE to the

[7] In fact, $\|\cdot\|_{0\to 0}$ is not a matrix norm just as Hamming weight is not a vector norm (even over the real numbers). It does not satisfy the absolute homogeneity property $\|\alpha M\|_{0\to 0} = |\alpha| \, \|M\|_{0\to 0}$ for real-valued matrices M and scalars α, and the magnitude of a finite field element is not even defined. However, the $0 \to 0$ norm satisfies the other axioms of a matrix norm, including the triangle inequality ($\|A + B\|_{0\to 0} \le \|A\|_{0\to 0} + \|B\|_{0\to 0}$), and it is sub-multiplicative (i.e., $\|AB\|_{0\to 0} \le \|A\|_{0\to 0}\|B\|_{0\to 0}$). So, we abuse notation slightly and refer to $\|\cdot\|_{0\to 0}$ as a matrix norm.

Lattice Isomorphism Problem (LIP) – problems that essentially correspond to the distortion $D = 1$ cases of CDP and LDP, respectively – was given in [29, 9]. On the algorithmic side, it is natural to ask whether there is a better exact algorithm than the brute force, roughly q^{k^2}-time algorithm that we give, and whether there is a more efficient approximation algorithm for CDP than our roughly q^k. Finally, we ask given whether it is possible to build cryptography whose security guarantee rests on the hardness of approximate CDP. This seems particularly natural given the role of LCE both as security assumption for the LESS cryptosystem [12], and as a closely related problem to the McEliece cryptosystem [23, 1].[8]

2 Preliminaries

We define a *monomial matrix* M to be the product $M = DP$ of a non-singular diagonal matrix D and a permutation matrix P. We denote the set of $n \times n$ monomial matrices over a field $\mathbb{F}$ as $\mathcal{M}_n(\mathbb{F})$.

2.1 Codes

A *linear code* is a linear subspace $\mathcal{C} \subseteq \mathbb{F}^n$, where $\mathbb{F}$ is field. Generally, $\mathbb{F}$ is the finite field $\mathbb{F}_q$ for some prime power q, and when $q = 2$ (as is common in practice) the code is a *binary code*. A linear code $\mathcal{C}$ is often characterized as an $[n, k]$ or $[n, k, d]_q$ code, where q indicates the order of the field $\mathbb{F}_q$ that the code is taken over, k is the dimension of the code, and d is the minimum Hamming distance of $\mathcal{C}$, i.e.

$$d := \min_{\substack{\boldsymbol{x},\boldsymbol{y}\in\mathcal{C}\\ \boldsymbol{x}\neq\boldsymbol{y}}} \|\boldsymbol{x}-\boldsymbol{y}\|_0 = \min_{\boldsymbol{x}\in\mathcal{C}\setminus\{\boldsymbol{0}\}} \|\boldsymbol{x}\|_0.$$

We also call n the *block length* of the code.

An $[n, k]$ code $\mathcal{C} \subseteq \mathbb{F}^n$ is usually specified by a *generator matrix* $G \in \mathbb{F}^{n\times k}$ with linearly independent columns. The code is then the span of the columns of G, and any *codeword* $\boldsymbol{x} \in \mathcal{C}$ can be expressed as $G\boldsymbol{m}$ for some *message* $\boldsymbol{m} \in \mathbb{F}^k$. Likewise, each message $\boldsymbol{m} \in \mathbb{F}^k$ corresponds to a unique codeword $G\boldsymbol{m} \in \mathcal{C}$.

We will also find it useful to refer to the *support* of a vector $\boldsymbol{x} \in \mathbb{F}^k$. Denoted $\mathrm{supp}(\boldsymbol{x})$, the support of $\boldsymbol{x}$ is the set of indices i for which $\boldsymbol{x}_i \neq 0$. The Hamming weight can then be expressed as $|\mathrm{supp}(\boldsymbol{x})|$, the size of the support.

▶ **Definition 4** (Successive Minima for Codes)**.** *Let $n, k \in \mathbb{Z}^+, k \leq n$, let q be a prime power, and let $\mathcal{C}$ be an $[n, k]_q$ code. For $1 \leq i \leq k$, the* ith successive minimum *of $\mathcal{C}$, denoted $\lambda_i(\mathcal{C})$, is defined as the minimum value $r \in \mathbb{Z}^+$ such that $\mathcal{C}$ contains at least i linearly independent codewords with Hamming weight at most r.*

We note that $\lambda_1(\mathcal{C})$ is the minimum distance d of $\mathcal{C}$. We emphasize again that successive minima are well-studied for lattices, but do not seem to have been studied much for codes. We will make use of the following definition, which formalizes one notion of optimal bases for codes.

▶ **Definition 5** (Successive Minima Basis)**.** *Let $n, k \in \mathbb{Z}^+, k \leq n$, let q be a prime power, and let $\mathcal{C}$ be an $[n, k]_q$ code. A generator matrix $G = (\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$ of $\mathcal{C}$ is a* successive minima basis *of $\mathcal{C}$ if $\|\boldsymbol{v}_i\|_0 = \lambda_i(\mathcal{C})$ for all $1 \leq i \leq k$.*

[8] One can check that the public and private generator matrices in McEliece generate linearly equivalent codes. However, it is not clear that breaking McEliece reduces to solving LCE or vice-versa.

We next give an algorithm for computing successive minima bases, which in particular implies that such bases always exist.

▶ **Lemma 6.** *Let $n, k \in \mathbb{Z}^+, k \leq n$, let q be a prime power, and let $\mathcal{C}$ be an $[n,k]_q$ code. Then there exists a $O^*(q^k)$-time, polynomial space algorithm for computing a sucessive minima basis of $\mathcal{C}$. In particular, such a basis of $\mathcal{C}$ always exists.*

Proof. Let $\boldsymbol{v}_1 \in \mathcal{C}$ be a codeword that satisfies $\|\boldsymbol{v}_1\| = \lambda_1(\mathcal{C})$, and define $\boldsymbol{v}_i$ recursively for $1 < i \leq k$ so that

$$\boldsymbol{v}_i \in \operatorname*{arg\,min}_{\boldsymbol{x} \in (\mathcal{C} \setminus \operatorname{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_{i-1}))} \|\boldsymbol{x}\|_0 \ .$$

We prove inductively that $\|\boldsymbol{v}_i\|_0 = \lambda_i(\mathcal{C})$. This is clearly true in the base case of $i = 1$ since $\boldsymbol{v}_1$ is a shortest non-zero codeword by definition. For the inductive step with $i \geq 2$, assume that we can find $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_{i-1} \in \mathcal{C}$ satisfying $\|\boldsymbol{v}_j\|_0 = \lambda_j(\mathcal{C})$ for $1 \leq j \leq i-1$. Additionally, observe that for any $1 \leq i \leq k$, the span of the set $S_i = \{\boldsymbol{v} \in \mathcal{C} : \|\boldsymbol{v}\|_0 \leq \lambda_i(\mathcal{C})\}$ has dimension at least i as a result of there being at least i linearly independent codewords in S_i. On the other hand, the set $\{\boldsymbol{v}_1, \ldots, \boldsymbol{v}_{i-1}\} \subset S_i$ has dimension only $i-1$, so there must exist some $\boldsymbol{v}_i \in \mathcal{C}$ such that $\|\boldsymbol{v}_i\|_0 \leq \lambda_i(\mathcal{C})$ and $\boldsymbol{v}_i \notin \operatorname{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_{i-1})$.

We next show that $\|\boldsymbol{v}_i\|_0 \geq \lambda_i(\mathcal{C})$ (and therefore $\|\boldsymbol{v}_i\|_0 = \lambda_i(\mathcal{C})$) for $i \geq 2$. Suppose not. Then $\|\boldsymbol{v}_i\|_0 < \lambda_i(\mathcal{C})$. We have by definition that $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_i$ are linearly independent, and by the induction hypothesis, $\lambda_j(\mathcal{C}) = \|\boldsymbol{v}_j\|_0$ for all $1 \leq j \leq i-1$. By definition, $\|\boldsymbol{v}_1\|_0 \leq \cdots \leq \|\boldsymbol{v}_i\|_0$, and it follows that $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_i \in \mathcal{C}$ are linearly independent vectors all of Hamming weight strictly less than $\lambda_i(\mathcal{C})$, which is a contradiction.

The recursive process above yields k linearly independent codewords $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k$ with $\|\boldsymbol{v}_i\|_0 = \lambda_i(\mathcal{C})$ for all i. Since $\mathcal{C}$ is a k-dimensional subspace of $\mathbb{F}_q^n$, any k linearly independent vectors in $\mathcal{C}$ (and particularly our $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k$) must span $\mathcal{C}$ and thus form a basis for it.

Computing each $\boldsymbol{v}_i$ involves a search over the $O(q^k)$ codewords in $\mathcal{C}$ with polynomial time required to check the linear independence and Hamming weight of each, so it takes $O^*(q^k)$ time to compute. This enumeration can be done in polynomial space. Therefore, by repeating this k times, we find the entire successive minima basis in $O^*(q^k)$ time and polynomial space. ◀

2.2 Coding Problems

Given a code, it is natural to ask what its minimum distance is. The Minimum Distance Problem formalizes this, and we give here the approximation version of the problem.

▶ **Definition 7.** *For $\gamma = \gamma(k) \geq 1$ and a prime power q, the* decisional γ-approximate Minimum Distance Problem over $\mathbb{F}_q$ *(γ-GapMDP$_q$) is the decision problem defined as follows. An instance consists of (a generator matrix $G \in \mathbb{F}_q^{n \times k}$ of) a code $\mathcal{C}$ and an integer distance $0 \leq d \leq m$. It is a:*

- *YES instance if $\lambda_1(\mathcal{C}) \leq d$.*
- *NO instance if $\lambda_1(\mathcal{C}) > \gamma d$.*

We note that GapMDP is NP-hard to approximate to within any constant factor. This was first established by Cheng and Wan [13]. (Earlier work showed NP-hardness under randomized reductions [16], and subsequent work showed simplified deterministic reductions [3, 24].)

▶ **Theorem 8** ([13])**.** *For all constants $\gamma \geq 1$ and all prime powers q, γ-GapMDP$_q$ is* NP*-hard.*

We now define a variant of the Nearest Codeword Problem with a stronger promise in the NO case.

▶ **Definition 9.** *For $\gamma = \gamma(k) \geq 1$, $\alpha = \alpha(k) > 0$, and a prime power q, the* decisional γ-approximate Nearest Codeword Problem over $\mathbb{F}_q$ with distance promise α *(γ-GapNCP$_q^\alpha$) is the decision problem defined as follows. An instance consists of (a generator matrix $G \in \mathbb{F}_q^{n\times k}$ of) a code $\mathcal{C}$, a target vector $\boldsymbol{t} \in \mathbb{F}_q^n$, and a distance parameter $d \in \mathbb{Z}^+$. It is a:*

- *YES instance if* $\operatorname{dist}(\boldsymbol{t}, \mathcal{C}) \leq d$.
- *NO instance if* $\operatorname{dist}(\boldsymbol{t}, \mathcal{C}) > \gamma d$ *and* $d < \alpha\lambda_1(\mathcal{C})$.

We additionally define γ-GapNCP$_q$ to be γ-GapNCP$_q^\infty$. I.e., in γ-GapNCP$_q$ there is no promised upper bound on d in the NO case. We note that γ-GapNCP$_q^\alpha$ trivially reduces to γ-GapNCP$_q^{\alpha'}$ for $\alpha' \geq \alpha$, and in particular γ-GapNCP$_q^\alpha$ trivially reduces to "plain" γ-GapNCP$_q$ for any $\alpha > 0$.

2.3 Matrix Norms

While there are many ways to define matrix norms, the most useful for us is the matrix $p \to q$ norm, where $p, q \in [1, \infty]$. We note in passing that matrix $p \to q$ norms over the real numbers have been studied from a computational standpoint; see, e.g., [11].

We can extend the definition of the matrix $p \to q$ norm to arbitrary (finite) fields $\mathbb{F}$ and to include $p = 0$ and $q = 0$, with $\|\boldsymbol{x}\|_0$ being the Hamming weight as is standard. Note, however, that the matrix $0 \to 0$ "norm" is not in fact a matrix norm as it is not scale-invariant. However, it does satisfy the triangle inequality and it is sub-multiplicative. Ultimately, throughout this article, we abuse notation and nevertheless refer to it as a norm. Additionally, we employ a "restricted" version of the matrix $0 \to 0$ norm, where one only maximizes over those vectors $\boldsymbol{x} \in \mathcal{C}$ for some subspace $\mathcal{C} \subseteq \mathbb{F}^n$. More formally:

▶ **Definition 10.** *Let $n \in \mathbb{Z}^+$, let $\mathbb{F}$ be a field, let $T \in \mathrm{GL}_n(\mathbb{F})$ be a matrix, and let $\mathcal{C} \subseteq \mathbb{F}^n$ be a subspace. The* matrix $0 \to 0$ norm of T restricted to the subspace $\mathcal{C}$ *is the quantity*

$$\|T|_{\mathcal{C}}\|_{0\to 0} \coloneqq \max_{\boldsymbol{x}\in\mathcal{C}\setminus\{\boldsymbol{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}.$$

Note that the restricted matrix $0 \to 0$ norm is also sub-multiplicative.

2.4 Distortion

To compare pairs of general codes, we introduce a quantity that captures how similar they are. We formalize this with *distortion*, similar to the formulation for the Lattice Distortion Problem [8] and distortion on metric embeddings. We start by defining the distortion of a particular transformation between two codes.

▶ **Definition 11.** *Let $n, k \in \mathbb{Z}^+$, $k \leq n$, let q be a prime power, let $\mathcal{C}_1, \mathcal{C}_2$ be $[n, k]_q$ codes, and let T be a linear map such that $T(\mathcal{C}_1) = \mathcal{C}_2$. The* distortion $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2)$ of T *the minimum value D such that for all $\boldsymbol{x} \in \mathcal{C}_1$,*

$$D_1 \cdot \|\boldsymbol{x}\|_0 \leq \|T\boldsymbol{x}\|_0 \leq D_2 \cdot \|\boldsymbol{x}\|_0$$

for some values $D_1, D_2 > 0$ satisfying $D_2/D_1 \leq D$. Equivalently,

$$\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) := \Big(\max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\boldsymbol{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\Big) \Big/ \Big(\min_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\boldsymbol{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\Big)\ ,$$

which is the definition we gave in Section 1. Moreover, when $T \in \mathrm{GL}_n(\mathbb{F}_q)$ *and thus is invertible, this is equivalent to*

$$\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) = \|T|_{\mathcal{C}_1}\|_{0\to 0} \cdot \|T^{-1}|_{\mathcal{C}_2}\|_{0\to 0}. \tag{3}$$

Consequently, at least in the case when T is invertible, the distortion between two codes $\mathcal{C}_1$ and $\mathcal{C}_2$ is inextricably tied to computing two matrix $0 \to 0$ norms, where one is restricted to $\mathcal{C}_1$ and the other is restricted to $\mathcal{C}_2$. Interestingly, as we show in Lemma 18, the assumption that T is invertible can be made without loss of generality, so we may take Equation (3) as an equivalent definition of distortion. Furthermore, while we require the codes in Definition 11 to have the same block length n, the definition can be extended to codes with different block lengths by simply padding the shorter code with zeros (or, one could allow for non-square matrices T).

We can now define the distortion between two codes generically as the lowest possible distortion between them using any transformation.

▶ **Definition 12.** *Let* $n, k \in \mathbb{Z}^+$, $k \le n$ *and let* q *be a prime power. The* distortion $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$ *between* $[n,k]_q$ *codes* $\mathcal{C}_1$ *and* $\mathcal{C}_2$ *is defined as the minimum value* D *such that there exists* $T \in \mathrm{GL}_n(\mathbb{F}_q)$ *with* $T(\mathcal{C}_1) = \mathcal{C}_2$ *and* $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) = D$*. In other words,*

$$\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \coloneqq \min_{\substack{T \in \mathrm{GL}_n(\mathbb{F}_q),\\ T(\mathcal{C}_1)=\mathcal{C}_2}} \mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2)\ . \tag{4}$$

2.4.1 The Code Distortion Problem

Using this definition of code distortion, we now define both the search and decision versions of the (γ-approximate) Code Distortion Problem (CDP).

▶ **Definition 13.** *For* $\gamma = \gamma(n) \ge 1$ *and a prime power* q*, the* γ-approximate Code Distortion Problem over $\mathbb{F}_q$ *(γ-*CDP_q*) is the search problem defined as follows. An instance consists of (generator matrices* $G_1, G_2 \in \mathbb{F}_q^{m\times n}$ *of) codes* $\mathcal{C}_1, \mathcal{C}_2 \subseteq \mathbb{F}_q^n$*, and the goal is to output* D *such that* $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \le D \le \gamma \cdot \mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$*.*

▶ **Definition 14.** *For* $\gamma = \gamma(n) \ge 1$ *and a prime power* q*, the* decisional γ-approximate Code Distortion Problem over $\mathbb{F}_q$ *(γ-*GapCDP_q*) is the decision problem defined as follows. An instance consists of (generator matrices* $G_1, G_2 \in \mathbb{F}_q^{m\times n}$ *of) codes* $\mathcal{C}_1, \mathcal{C}_2 \subseteq \mathbb{F}_q^n$ *and* $D \ge 1$*. It is a:*

- *YES instance if* $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \le D$*.*
- *NO instance if* $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) > \gamma D$*.*

The exact versions of these problems, CDP_q and GapCDP_q, are then defined to be 1-CDP_q and 1-GapCDP_q, respectively. Furthermore, the Linear Code Equivalence Problem is essentially the special case of CDP with $D = 1$. We formalize this relationship in Proposition 19 in the next section.

2.5 Basic Facts about Distortion

We next present several basic facts about the distortion between codes. We start with the following bounds on $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$.

▶ **Lemma 15.** *Let* $\mathcal{C}_1$ *and* $\mathcal{C}_2$ *be* $[n,k]_q$ *codes. Then, for any linear map* T *such that* $T(\mathcal{C}_1) = \mathcal{C}_2$*,* $1 \le \mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) \le n^2$*. As a consequence,* $1 \le \mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \le n^2$

Proof. For the lower bound, simply note that by the sub-multiplicativity of the matrix $0 \to 0$ norm on subspaces, it holds for all $T \in \mathrm{GL}_n(\mathbb{F})$ such that $T(\mathcal{C}_1) = \mathcal{C}_2$ that

$$1 = \|(T^{-1}T)|_{\mathcal{C}_1}\|_{0\to 0} \leq \|T^{-1}|_{\mathcal{C}_2}\|_{0\to 0} \cdot \|T|_{\mathcal{C}_1}\|_{0\to 0} = \mathcal{D}_T(C_1, \mathcal{C}_2).$$

For the upper bound, note that for all $T \in \mathrm{GL}_n(\mathbb{F})$ such that $T(\mathcal{C}_1) = \mathcal{C}_2$, it holds that

$$\|T|_{\mathcal{C}_1}\|_{0\to 0} = \max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} \leq \max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \|T\boldsymbol{x}\|_0 \leq n \ ,$$

where the last inequality follows from the fact that $\mathcal{C}_2$ is an $[n,k]_q$ code and for all $x \in \mathcal{C}_1\setminus\{\mathbf{0}\}$, $T\boldsymbol{x} \in \mathcal{C}_2\setminus\{\mathbf{0}\}$. A similar argument establishes that $\|T^{-1}|_{\mathcal{C}_2}\|_{0\to 0} \leq n$, and consequently

$$\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) = \|T|_{\mathcal{C}_1}\|_{0\to 0} \cdot \|T^{-1}|_{\mathcal{C}_2}\|_{0\to 0} \leq n^2 \ ,$$

as desired. The fact that $1 \leq \mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \leq n^2$ then follows from the definition of $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$. ◀

It is an open question if the upper bound in Lemma 15 can be reduced below n^2. Indeed, we do not know an example of a code with distortion n^2, but we do know an example of a code with distortion n, which we detail in the following.

▶ **Lemma 16.** *For every $n \in \mathbb{Z}^+$, there exist $[n,2]_2$ codes $\mathcal{C}_1, \mathcal{C}_2$ such that $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) = n$.*

Proof. Let $\mathcal{C}_1, \mathcal{C}_2$ be the codes defined as follows:

$$\mathcal{C}_1 = \left\{\mathbf{0}_n, \begin{pmatrix}1\\ \mathbf{0}_{n-1}\end{pmatrix}, \begin{pmatrix}0\\ \mathbf{1}_{n-1}\end{pmatrix}, \mathbf{1}_n\right\}, \quad \mathcal{C}_2 = \left\{\mathbf{0}_n, \begin{pmatrix}1\\1\\0\\ \mathbf{0}_{n-3}\end{pmatrix}, \begin{pmatrix}0\\1\\1\\ \mathbf{0}_{n-3}\end{pmatrix}, \begin{pmatrix}1\\0\\1\\ \mathbf{0}_{n-3}\end{pmatrix}\right\}.$$

It is easy to check that $\mathcal{C}_1$ and $\mathcal{C}_2$ are linear codes. Each non-zero codeword in $\mathcal{C}_2$ has Hamming weight 2 (the constant weight of non-zero codewords in $\mathcal{C}_2$ is the only property of it that we are using) while the non-zero codewords in $\mathcal{C}_1$ have minimum weight 1 and maximum weight n. As such, the distortion for any transformation T from $\mathcal{C}_1$ to $\mathcal{C}_2$ is

$$\max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} \max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}} \frac{\|\boldsymbol{x}\|_0}{\|T\boldsymbol{x}\|_0} = \frac{2}{1} \cdot \frac{n}{2} = n \ .$$ ◀

Ultimately, while we are unable to prove a matching upper bound of n on $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$, we are nevertheless able to prove such a bound when including *non-linear transformations* T.

▶ **Lemma 17.** *Let $\mathcal{C}_1$ and $\mathcal{C}_2$ be $[n,k]_q$ codes. Then, $\min_T \mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) \leq n$, where the minimum is over all maps T (including non-linear maps) such that $T(\mathcal{C}_1) = \mathcal{C}_2$.*

Proof. List all non-zero codewords in $\mathcal{C}_1$ in monotonically increasing order of Hamming weight, and prepare a similar list for $\mathcal{C}_2$. Let T be the map that takes codeword i in the first list to codeword i in the second list. Let $N := q^k - 1$, and let $1 \leq a_1 \leq \cdots \leq a_N \leq n$ and $1 \leq b_1 \leq \cdots \leq b_N \leq n$ be the Hamming weights of the non-zero codewords in the respective lists. Then, the distortion of T is

$$\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) = \left(\max_{i\in[N]} \frac{a_i}{b_i}\right) \cdot \left(\max_{j\in[N]} \frac{b_j}{a_j}\right) \ .$$

Now put $i^* = \arg\max_{i\in[N]} a_i/b_i$, and let $M = a_{i^*}/b_{i^*}$. We assume without loss of generality that $M \geq 1$ (otherwise, repeat the argument with the two codes flipped). Then, for all $j > i^*$,

$b_j/a_j \le n/a_{i^*} \le nb_{i^*}/a_{i^*} = n/M$. And, for all $j \le i^*$, $b_j/a_j \le b_{i^*}/1 = a_{i^*}/M \le n/M$. Consequently, for all $j \in [N]$, $b_j/a_j \le n/M$. Therefore,

$$\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) = \left(\max_{i\in[N]} \frac{a_i}{b_i}\right) \cdot \left(\max_{j\in[N]} \frac{b_j}{a_j}\right) \le M \cdot \frac{n}{M} = n \ ,$$

as desired. ◀

We next show that if there exists a matrix T such that $T\mathcal{C}_1 = \mathcal{C}_2$, then then exists an efficiently computable, *invertible* matrix T' such that $T'\mathcal{C}_1 = \mathcal{C}_2$ and $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) = \mathcal{D}_{T'}(\mathcal{C}_1, \mathcal{C}_2)$.

▶ **Lemma 18.** *Let T be a (not necessarily invertible) matrix such that $T(\mathcal{C}_1) = \mathcal{C}_2$ for $[n,k]_q$ codes $\mathcal{C}_1$, $\mathcal{C}_2$ such that $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) \le D$. Then there exists an invertible matrix T' such that $T'(\mathcal{C}_1) = \mathcal{C}_2$ and $\mathcal{D}_{T'}(\mathcal{C}_1, \mathcal{C}_2)$.*

Proof. Now consider a generator matrix $G_1 \in \mathbb{F}_q^{n\times k}$ of $\mathcal{C}_1$ and the corresponding generator matrix of $\mathcal{C}_2$, $G_2 := T(G_1) \in \mathbb{F}_q^{n\times k}$. Now, let $H_1, H_2 \in \mathbb{F}_q^{n\times(n-k)}$ be such that $A := (G_1|H_1), B := (G_2|H_2) \in \mathbb{F}_q^{n\times n}$ are full-rank. (In particular, it suffices to take H_1 and H_2 to be (transposed) parity-check matrices for $\mathcal{C}_1$ and $\mathcal{C}_2$, respectively.) Finally, let $T' := BA^{-1}$. Note that T' is invertible, and that $T\boldsymbol{c} = T'\boldsymbol{c}$ for every $\boldsymbol{c} \in \mathcal{C}$. It follows that $T'(\mathcal{C}_1) = \mathcal{C}_2$ and $\mathcal{D}_{T'}(\mathcal{C}_1, \mathcal{C}_2) = \mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) = D$, as needed. ◀

We next show that two codes $\mathcal{C}_1$ and $\mathcal{C}_2$ being linearly equivalent is equivalent to $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) = 1$ up to "scaling."

▶ **Proposition 19.** *Let $\mathcal{C}_1, \mathcal{C}_2$ be $[n,k]_q$ codes for some $n, k \in \mathbb{Z}^+$ and prime power q. Then $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) = 1$ if and only if $\mathcal{C}_1 \otimes \mathbf{1}_{r_1}$ (padded with some number of zeros to reach block length $r_2 n$) is linearly equivalent to $\mathcal{C}_2 \otimes \mathbf{1}_{r_2}$ for some $r_1, r_2 \in \mathbb{Z}^+$, $r_1 \le r_2$.*

Proof. We start with the backward direction. Let $\mathcal{C}_1'$ be the result of padding $\mathcal{C}_1 \otimes \mathbf{1}_{r_1}$ with $r_2 n - r_1 n$ zeros and let $\mathcal{C}_2' = \mathcal{C}_2 \otimes \mathbf{1}_{r_2}$. Suppose we have $r_1, r_2 \in \mathbb{Z}^+$, $r_1 \le r_2$ such that $\mathcal{C}_1'$ is linearly equivalent to $\mathcal{C}_2'$. Then, there must exist a monomial matrix T such that $T(\mathcal{C}_1') = \mathcal{C}_2'$ and $\|T(\boldsymbol{x} \otimes \mathbf{1}_{r_1})\|_0 = \|\boldsymbol{x} \otimes \mathbf{1}_{r_1}\|_0$ for all $\boldsymbol{x} \in \mathcal{C}_1$. Additionally, we can define $S_1 = I_n \otimes \mathbf{1}_{r_1}$, which maps $\mathcal{C}_1$ to $\mathcal{C}_1'$ with uniform scaling $\|S_1\boldsymbol{x}\|_0 = r_1\|\boldsymbol{x}\|_0$ for any $\boldsymbol{x} \in \mathcal{C}_1$, and $S_2 = I_n \otimes \boldsymbol{e}_1^\top$,[9] which maps $\mathcal{C}_2'$ to $\mathcal{C}_2$ with uniform scaling of $\|S_2\boldsymbol{x}\|_0 = \frac{1}{r_2}\|\boldsymbol{x}\|_0$ for any $\boldsymbol{x} \in \mathcal{C}_2'$. We now compose these to define a transformation $T' = S_2 T S_1$ that maps $\mathcal{C}_1$ to $\mathcal{C}_2$ and note that for any $\boldsymbol{x} \in \mathcal{C}_1$,

$$\frac{\|T'\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} = \frac{\|S_2 T S_1 \boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} = \frac{1}{r_2} \cdot \frac{\|TS_1\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} = \frac{1}{r_2} \cdot \frac{\|S_1\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} = \frac{r_1}{r_2} \cdot \frac{\|\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} = \frac{r_1}{r_2}.$$

As this is true for all $\boldsymbol{x} \in \mathcal{C}_1$, we can see that $\|T'|_{\mathcal{C}_1}\|_{0\to 0} = \frac{r_1}{r_2}$ and $\|(T')^{-1}|_{\mathcal{C}_2}\|_{0\to 0} = \frac{r_2}{r_1}$. Thus, $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) = \mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) = 1$.

For the forward direction, we are now given that $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) = 1$, i.e., there exists some T such that $T(\mathcal{C}_1) = \mathcal{C}_2$ and $\|T\boldsymbol{x}\|_0 = c\|\boldsymbol{x}\|_0$ for all $\boldsymbol{x} \in \mathcal{C}_1$ and some $c \in \mathbb{Q}^+$ (we assume without loss of generality that $c \le 1$). Let $c = \frac{r_1}{r_2}$ for some $r_1, r_2 \in \mathbb{Z}^+$, and once again take $\mathcal{C}_1' = \mathcal{C}_1 \otimes \mathbf{1}_{r_1}$ (padded with $r_2 n - r_1 n$ zeros) and $\mathcal{C}_2' = \mathcal{C}_2 \otimes \mathbf{1}_{r_2}$. Finally, we redefine $S_1 = \left(I_n \otimes \begin{pmatrix}1 & \mathbf{0}_{r_1-1}\end{pmatrix}\right)$, $S_2 = I_n \otimes \mathbf{1}_{r_2}$. As before, note that $S_1(\mathcal{C}_1') = \mathcal{C}_1$, $S_2(\mathcal{C}_2) = \mathcal{C}_2'$, $\|S_1\boldsymbol{x}\|_0 = \frac{1}{r_1}\|\boldsymbol{x}\|_0$ for all $\boldsymbol{x} \in \mathcal{C}_1'$, and $\|S_2\boldsymbol{x}\|_0 = r_2\|\boldsymbol{x}\|_0$ for all $\boldsymbol{x} \in \mathcal{C}_2$. We define $T' = S_2 T S_1$ so that T' maps $\mathcal{C}_1'$ to $\mathcal{C}_2'$, and again compute that

$$\|T'\boldsymbol{x}\|_0 = \|S_2 T S_1 \boldsymbol{x}\|_0 = r_2\|TS_1\boldsymbol{x}\|_0 = cr_2\|S_1\boldsymbol{x}\|_0 = \frac{cr_2}{r_1}\|\boldsymbol{x}\|_0 = \|\boldsymbol{x}\|_0 \ .$$

This is true for all $\boldsymbol{x} \in \mathcal{C}_1'$, so $\mathcal{C}_1' = \mathcal{C}_1 \otimes \mathbf{1}_{r_1}$ is equivalent to $\mathcal{C}_2' = \mathcal{C}_2 \otimes \mathbf{1}_{r_2}$ as required to complete the proof. ◀

[9] Here $\boldsymbol{e}_1 \in \mathbb{F}_q^{r_2}$ is the first standard normal basis vector in r_2 dimensions.

2.6 Reductions

In this paper, we employ three different types of reductions. The first and most general notion is that of a *Turing reduction*. Formally, there is a Turing reduction from a decision problem A to a decision problem B if and only if there exists an algorithm for A, given oracle access to B. In other words, A Turing-reduces to B if, given a subroutine for B, one can decide A. The second type of reduction is a *Cook reduction*. Formally, a Cook reduction is a polynomial-time Turing reduction, i.e., A Cook-reduces to B if and only if A Turing-reduces to B and the overall algorithm runs in polynomial time. The third and final type of reduction is that of a *Karp reduction* (a.k.a., a *polynomial-time many-one reduction*). Formally, a Karp reduction is a deterministic and polynomial-time algorithm that maps YES and NO instances of A to YES and NO instances of B, respectively.

3 The Complexity of the Code Distortion Problem

We now study some basic facts about the complexity of both the exact and approximate versions of GapCDP. Given the relationship of GapCDP to the matrix $0 \to 0$ norm (Section 2.3), we start by discussing the complexity of computing both the unrestricted and restricted versions of the matrix $0 \to 0$ norm.

3.1 The Complexity of the Matrix $0 \to 0$ Norm

Interestingly, the (unrestricted) matrix $0 \to 0$ norm is easy to compute.

▶ **Proposition 20.** *Let $\mathbb{F}$ be a field, let $m, n \in \mathbb{Z}^+$, and let $T = (\boldsymbol{t}_1, \ldots, \boldsymbol{t}_n) \in \mathbb{F}^{m \times n}$. Then,*

$$\|T\|_{0\to 0} = \max_{i\in[n]} \|\boldsymbol{t}_i\|_0 \ .$$

Proof. By the triangle inequality, it holds for all $\boldsymbol{x} \in \mathbb{F}^n \setminus \{\boldsymbol{0}\}$ that

$$\begin{aligned}
\frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} &= \frac{\|\sum_{i\in\mathrm{supp}(\boldsymbol{x})} x_i \boldsymbol{t}_i\|_0}{|\mathrm{supp}(\boldsymbol{x})|} \\
&\leq \frac{\sum_{i\in\mathrm{supp}(\boldsymbol{x})} \|x_i \boldsymbol{t}_i\|_0}{|\mathrm{supp}(\boldsymbol{x})|} \\
&\leq \frac{|\mathrm{supp}(\boldsymbol{x})| \cdot \max_{i\in\mathrm{supp}(\boldsymbol{x})} \|\boldsymbol{t}_i\|_0}{|\mathrm{supp}(\boldsymbol{x})|} \\
&= \max_{i\in\mathrm{supp}(\boldsymbol{x})} \|\boldsymbol{t}_i\|_0 \ .
\end{aligned}$$

Furthermore, $\max_{i\in\mathrm{supp}(x)} \|\boldsymbol{t}_i\|_0 \leq \max_{i\in[n]} \|\boldsymbol{t}_i\|_0$, so $\|T\|_{0\to 0} \leq \max_{i\in[n]} \|\boldsymbol{t}_i\|_0$. On the other hand,

$$\|T\|_{0\to 0} \geq \max_{i\in[n]} \frac{\|T\boldsymbol{e}_i\|_0}{\|\boldsymbol{e}_i\|_0} = \max_{i\in[n]} \|\boldsymbol{t}_i\|_0 \ . \qquad \blacktriangleleft$$

We note that an immediate consequence of Proposition 20 is that there is a $\mathrm{poly}(m, n)$-time algorithm for computing $\|T\|_{0\to 0}$ for a matrix $T \in \mathbb{F}^{m\times n}$: simply compute the maximum Hamming weight of a column of T. That said, we show that matrix $0 \to 0$ norm *restricted to a subspace* is hard to compute, even approximately. We formalize this by defining a decisional version of the problem.

▶ **Definition 21.** *Let $\mathbb{F}$ be a field, let $m, n, k, q \in \mathbb{Z}^+$, and let $\gamma = \gamma(m,n) \geq 1$. The* decisional γ-approximate matrix $0 \to 0$ norm problem over a subspace of $\mathbb{F}_q$ *(γ-GapNorm$_q^{0\to 0}$) is the promise problem defined as follows. An instance consists of a basis $G \subseteq \mathbb{F}_q^{n\times k}$ of a subspace $\mathcal{C} \subseteq \mathbb{F}_q^n$, a matrix $T \in \mathbb{F}_q^{m\times n}$, and threshold $r \geq 0$. It is a:*

- *YES instance if $\|T|_{\mathcal{C}}\|_{0\to 0} \leq r$.*
- *NO instance if $\|T|_{\mathcal{C}}\|_{0\to 0} > \gamma r$.*

We will now give a reduction from γ'-GapMDP$_2$ to γ-GapNorm$_2^{0\to 0}$ for which it suffices to take $\gamma' = O(\gamma)$. This result is due to Golovnev and Stephens-Davidowitz [20].

▶ **Theorem 22** ([20])**.** *Let $\gamma \geq 1$ and let $\epsilon > 0$ be a constant. Then, for all $\gamma' > \left(\frac{1+\epsilon}{1-\epsilon}\right) \cdot \gamma$, there is a Karp reduction from γ'-GapMDP$_2$ to γ-GapNorm$_2^{0\to 0}$.*

Proof. Let $(G \in \mathbb{F}_2^{m\times n}, r')$ be an instance of γ'-GapMDP$_2$, where $m, n \in \mathbb{Z}^+$. Moreover, let T be a generator matrix of an $[m,n]_2$ code that is ε-balanced, i.e., all non-zero codewords in $\mathcal{C}(T)$ have Hamming weight in the interval $[(1-\varepsilon)\frac{m}{2}, (1+\varepsilon)\frac{m}{2}]$. By a result of Ta-Shma [31], such a T exists and, moreover, can be constructed in deterministic polynomial time.

Now, if (G, r') is a YES instance of γ'-MDP$_2$, then for all $\boldsymbol{x} \in \mathcal{C}\backslash\{\mathbf{0}\}$ with $\|\boldsymbol{x}\|_0 = \lambda_1(\mathcal{C})$,

$$\|T|_{\mathcal{C}}\|_{0\to 0} \geq \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} \geq \frac{\|T\boldsymbol{x}\|_0}{r'} \geq \frac{(1-\epsilon)m/2}{r'}.$$

Here, the first inequality uses the definition of the restricted matrix $0 \to 0$ norm, the second uses the fact that (G, r') is a YES instance, and the third uses the fact that T generates an ε-balanced code.

On the other hand, if (G, r') is a NO instance of γ'-MDP$_2$, then for all $\boldsymbol{x} \in \mathcal{C}\backslash\{\mathbf{0}\}$,

$$\frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} < \frac{(1+\epsilon)m/2}{\gamma' r'},$$

which implies

$$\|T|_{\mathcal{C}}\|_{0\to 0} = \max_{\boldsymbol{x}\in\mathcal{C}\backslash\{\mathbf{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} < \frac{(1+\epsilon)m/2}{\gamma' r'}.$$

Altogether, with $\gamma = \frac{1-\varepsilon}{1+\varepsilon}(\gamma' + \delta)$ and $r = \frac{(1+\epsilon)m/2}{(\gamma'+\delta)r'}$ for any $\delta > 0$, it holds that $\|T|_{\mathcal{C}}\|_{0\to 0} > \gamma r$ (a YES instance of co-γ-GapNorm$_2^{0\to 0}$) implies a YES instance of γ'-MDP$_2$, and $\|T|_{\mathcal{C}}\|_{0\to 0} \leq r$ (a NO instance of co-γ-GapNorm$_2^{0\to 0}$) implies a NO instance of γ'-MDP$_2$. ◀

Consequently, by Theorem 8, γ-GapNorm$_2^{0\to 0}$ is coNP-hard. In fact, it is coNP-complete.

▶ **Corollary 23.** *For all $\gamma \geq 1$, γ-GapNorm$_2^{0\to 0}$ is coNP-complete.*

Proof. Since γ-GapNorm$_2^{0\to 0}$ is coNP-hard, it suffices to prove that γ-GapNorm$_2^{0\to 0} \in$ coNP. But this is plain, since if (G, T, r) is a YES instance, then for all $\boldsymbol{x} \in \mathcal{C}\backslash\{\mathbf{0}\}$, $\|T\boldsymbol{x}\|_0/\|\boldsymbol{x}\|_0 \leq r$, and if (G, T, r) is a NO instance, then there exists $\boldsymbol{x} \in \mathcal{C}\backslash\{\mathbf{0}\}$ for which $\|T\boldsymbol{x}\|_0/\|\boldsymbol{x}\|_0 \geq \gamma r$. ◀

3.2 GapCDP is in Σ_2^{P}

We now show that the code distortion problem is in Σ_2^{P}, the second level of the polynomial hierarchy. Recall that a language $L \in \Sigma_2^{\mathsf{P}}$ if and only if there exists two polynomials p_1 and p_2 as well as a polynomial-time deterministic Turing machine M such that for all inputs $x \in \{0,1\}^*$, $x \in L$ if and only if $(\exists y \in \{0,1\}^{p_1(|x|)})(\forall z \in \{0,1\}^{p_2(|x|)}) : M(x,y,z) = 1$.

▶ **Theorem 24.** *For all $q \in \mathbb{Z}^+$, $\mathrm{GapCDP}_q \in \Sigma_2^{\mathsf{P}}$.*

Proof. Let (G_1, G_2, D) be an instance of GapCDP_q, where G_1 and G_2 generate the codes $\mathcal{C}_1$ and $\mathcal{C}_2$, respectively. By definition, (G_1, G_2, D) is a YES instance if and only if $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \leq D$. This holds if and only if there exists $T \in \mathrm{GL}_m(\mathbb{F}_q)$ with $T(\mathcal{C}_1) = \mathcal{C}_2$ such that for all $\boldsymbol{x}, \boldsymbol{y} \in \mathcal{C}_1 \backslash \{\mathbf{0}\}$,

$$\left(\frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\right) \cdot \left(\frac{\|T\boldsymbol{y}\|_0}{\|\boldsymbol{y}\|_0}\right)^{-1} \leq D.$$

For all such T, $\boldsymbol{x}$, and $\boldsymbol{y}$, the above inequality is checkable in deterministic polynomial time. Moreover, the size of all such T, $\boldsymbol{x}$, and $\boldsymbol{y}$ is a polynomial in the size of the input (G_1, G_2, D). Consequently, as the order of the $\exists$ and $\forall$ quantifiers in the above reformulation of GapCDP_q is consistent with the class Σ_2^{P}, it holds that $\mathrm{GapCDP}_q \in \Sigma_2^{\mathsf{P}}$, as desired. ◀

As mentioned in Section 1.4, we suspect GapCDP_q is also Σ_2^{P}-hard, thus making it Σ_2^{P}-complete. However, proving this remains an interesting open question.

3.3 GMSS for Codes

We will now give a reduction from γ-GapMDP to γ-GapNCP that is analogous to the seminal reduction from the Shortest Vector Problem to the Closest Vector Problem on lattices due to [19]. We will use this result in our proof of NP-hardness of approximate CDP.

▶ **Theorem 25** (GMSS for Codes)**.** *Let $m, n \in \mathbb{Z}^+$ with $n \leq m$, let $\gamma = \gamma(m, n) \geq 1$, and let q be a prime power. Then there is a $\mathrm{poly}(m, q)$-time Turing reduction from γ-GapMDP_q on $[m, n]_q$ codes to γ-$\mathrm{GapNCP}_q^{1/\gamma}$ (and hence also γ-GapNCP_q) on $[m, n-1]_q$ codes.*

Proof. Let $(G = (\boldsymbol{g}_1, \ldots, \boldsymbol{g}_n) \in \mathbb{F}_q^{m \times n}, d)$ be the input instance of γ-GapMDP_q. The reduction does the following. It constructs $(q-1)n$ many instances $(G_i, \boldsymbol{t}_{i,j} := -j \cdot \boldsymbol{g}_i, d)$ of GapNCP_q for $1 \leq i \leq n$ and $j \in \mathbb{F}_q^*$, where $G_i := (\boldsymbol{g}_1, \ldots, \boldsymbol{g}_{i-1}, \boldsymbol{g}_{i+1}, \ldots, \boldsymbol{g}_n)$ is "G with its ith column removed." It then calls its γ-$\mathrm{GapNCP}_q^{1/\gamma}$ oracle on each instance $(G_i, \boldsymbol{t}_{i,j}, d)$. The reduction outputs YES if the oracle responds with YES on some input, and otherwise it outputs NO.

It is clear that the reduction runs in the stated amount of time, and it remains to show its correctness. Suppose that the input is a YES instance. Then there exists $\boldsymbol{a} \in \mathbb{F}_q^n \backslash \{\mathbf{0}\}$ such that $\|G\boldsymbol{a}\|_0 \leq d$. Let a_i be a non-zero coordinate of $\boldsymbol{a}$, and let $\boldsymbol{a}' := (a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_n) \in \mathbb{F}_q^{n-1}$ be "$\boldsymbol{a}$ with its ith coordinate deleted." Then for $j = a_i$, we have that

$$\|G_i\boldsymbol{a}' - \boldsymbol{t}_{i,j}\|_0 = \|G_i\boldsymbol{a}' + j\boldsymbol{g}_i\|_0 = \Big\| \sum_{\ell \neq i} a_\ell \boldsymbol{g}_\ell + a_i \boldsymbol{g}_i \Big\|_0 = \|G\boldsymbol{a}\|_0 \leq d \ .$$

So, the γ-$\mathrm{GapNCP}_q^{1/\gamma}$ oracle outputs YES on input $(G_i, \boldsymbol{t}_{i,j}, d)$, as needed.

Now, suppose that the input is a NO instance. Let $\mathcal{C} := \mathcal{C}(G)$ and let $\mathcal{C}_i := \mathcal{C}(G_i)$. We note that for every $1 \leq i \leq n$ and $j \in \mathbb{F}_q^*$,

$$\mathcal{C}_i \subset \mathcal{C} \text{ and } \mathcal{C}_i - \boldsymbol{t}_{i,j} \subset \mathcal{C} \setminus \{\mathbf{0}\} \ .$$

It follows that $\lambda_1(\mathcal{C}_i) \geq \lambda_1(\mathcal{C})$ and that $\mathrm{dist}(\boldsymbol{t}_{i,j}, \mathcal{C}_i) \geq \lambda_1(\mathcal{C})$ for all $1 \leq i \leq n$ and $j \in \mathbb{F}_q^*$. Because the input is a NO instance, $\lambda_1(\mathcal{C}) > \gamma d$, and so we have that for every $1 \leq i \leq n$, $\lambda_1(\mathcal{C}_i) \geq \lambda_1(\mathcal{C}) > \gamma d$, and therefore $d < \lambda_1(\mathcal{C}_i)/\gamma$. Moreover, for every $1 \leq i \leq n$ and $j \in \mathbb{F}_q^*$, $\mathrm{dist}(\boldsymbol{t}_{i,j}, \mathcal{C}_i) \geq \lambda_1(\mathcal{C}) > \gamma d$. Therefore, each instance $(G_i, \boldsymbol{t}_{i,j}, d)$ is a NO instance of γ-$\mathrm{GapNCP}_q^{1/\gamma}$, as needed. ◀

3.4 NP-hardness of the Code Distortion Problem

We next give a reduction from γ'-GapNCP$_q^\alpha$ to γ-CDP$_q$ for which it suffices to take $\gamma' = O(\gamma)$.

▶ **Theorem 26.** *Let $\gamma \geq 1$, let q be a prime power, and let $D > 1$ be a constant. Then for any $\gamma' > \lceil \frac{D+1}{D-1} \rceil D \cdot \gamma$, there is a Karp reduction from γ'-GapNCP$_q^{1/\gamma'}$ to γ-CDP with distortion D.*

Proof. Let $(G \in \mathbb{F}_q^{n \times k}, \boldsymbol{t} \in \mathbb{F}_q^n, d \in \mathbb{Z}^+)$ be an instance of γ'-GapNCP$_q^{1/\gamma'}$. Define

$$G_1 := \begin{pmatrix} G & 0 & \mathbf{0} \\ 0 & G & \mathbf{0} \\ 0 & 0 & \mathbf{1}_r \end{pmatrix}, \qquad G_2 := \begin{pmatrix} G & 0 & -\boldsymbol{t} \\ 0 & G & \mathbf{0} \\ 0 & 0 & \mathbf{1}_r \end{pmatrix}$$

with $r := \lceil \frac{D+1}{D-1} \rceil \cdot d$. The reduction outputs the γ-CDP$_q$ instance (G_1, G_2, D).

It is clear that the reduction is efficient, and it remains to shows its correctness. Let $\mathcal{C} := \mathcal{C}(G)$, $\mathcal{C}_1 := \mathcal{C}(G_1)$, and $\mathcal{C}_2 := \mathcal{C}(G_2)$. Suppose that the input is a YES instance of γ'-GapNCP$_q^{1/\gamma'}$. Let $\boldsymbol{t}' \in \mathcal{C} - \boldsymbol{t}$ be such that $\|\boldsymbol{t}'\|_0 = \mathrm{dist}(\boldsymbol{t}, \mathcal{C})$, i.e., $\boldsymbol{t}'$ is a shortest codeword in the coset $\mathcal{C} - \boldsymbol{t}$. Define

$$G_2' := \begin{pmatrix} G & 0 & \boldsymbol{t}' \\ 0 & G & \mathbf{0} \\ 0 & 0 & \mathbf{1}_r \end{pmatrix}$$

Notice that $\mathcal{C}(G_2) = \mathcal{C}(G_2')$, and, because the input is a YES instance, that $\|\boldsymbol{t}'\|_0 \leq d$.[10] Let $G_1 = (\boldsymbol{g}_1, \ldots, \boldsymbol{g}_{2n+1})$, let $G_2' = (\boldsymbol{g}_1', \ldots, \boldsymbol{g}_{2n+1}')$, and let M be an invertible linear map such that $M : \boldsymbol{g}_i \mapsto \boldsymbol{g}_i'$ for every i. Such a full-rank map M exists because G_1 and G_2' are full-rank, and it is clear that M maps $\mathcal{C}_1$ to $\mathcal{C}_2$.

Let $\boldsymbol{x} \in \mathcal{C}_1$ be an arbitrary non-zero codeword. We can write $\boldsymbol{x} = (\boldsymbol{x}', \boldsymbol{x}'', a\mathbf{1}_r)$ for some $\boldsymbol{x}', \boldsymbol{x}'' \in \mathcal{C}$ and $a \in \mathbb{F}_q$. If $a = 0$, then $\|M\boldsymbol{x}\|_0 = \|\boldsymbol{x}\|_0$, and so $\|M\boldsymbol{x}\|_0 / \|\boldsymbol{x}\|_0 = 1$. On the other hand, assume that $a \neq 0$. Then $M\boldsymbol{x} = \boldsymbol{x} + (a\boldsymbol{t}', \mathbf{0})$, and so by triangle inequality and the fact that $\|\boldsymbol{t}'\|_0 \leq d$, $\|M\boldsymbol{x}\|_0 \leq \|\boldsymbol{x}\|_0 + d$. Therefore,

$$\frac{\|M\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} \leq \frac{\|\boldsymbol{x}\|_0 + d}{\|\boldsymbol{x}\|_0} \leq \frac{\|\boldsymbol{x}\|_0 + d}{\|a\mathbf{1}_r\|_0} = 1 + d/r \ . \tag{5}$$

Furthermore, $\boldsymbol{x} = M\boldsymbol{x} - (a\boldsymbol{t}', \mathbf{0})$, and so $\|\boldsymbol{x}\|_0 = \|M\boldsymbol{x} - (a\boldsymbol{t}', \mathbf{0})\|_0 \leq \|M\boldsymbol{x}\|_0 + \|\boldsymbol{t}'\|_0 \leq \|M\boldsymbol{x}\|_0 + d$. It follows that $\|M\boldsymbol{x}\|_0 \geq \|\boldsymbol{x}\|_0 - d$, and therefore,

$$\frac{\|M\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} \geq \frac{\|\boldsymbol{x}\|_0 - d}{\|\boldsymbol{x}\|_0} = 1 - \frac{d}{\|\boldsymbol{x}\|_0} \geq 1 - \frac{d}{\|a\mathbf{1}_r\|_0} = 1 - d/r \ . \tag{6}$$

Recalling that $r = \lceil \frac{D+1}{D-1} \rceil d \geq \frac{D+1}{D-1} d$, we get that $d/r \leq \frac{D-1}{D+1}$. By combining Equations (5)

[10] Actually computing $\boldsymbol{t}'$ amounts to solving γ'-GapNCP$_q^{1/\gamma'}$, which is a hard problem. However, here we are only using $\boldsymbol{t}'$ and G_2' for analysis, and we are not computing them.

and (6) we then have that

$$\begin{aligned}\mathcal{D}(\mathcal{C}_1,\mathcal{C}_2) &\leq \max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}}\left(\frac{\|M\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\right)\Big/\min_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}}\left(\frac{\|M\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\right)\\ &\leq (1+d/r)\,/\,(1-d/r)\\ &\leq \left(1+\frac{D-1}{D+1}\right)/\left(1-\frac{D-1}{D+1}\right)\\ &= \left(\frac{2D}{D+1}\right)/\left(\frac{2}{D+1}\right)\\ &= D,\end{aligned}$$

as needed.

Now, suppose that the input is a NO instance, and let M be an invertible linear map such that $M(\mathcal{C}_1)=\mathcal{C}_2$. Let $\boldsymbol{y}:=M\boldsymbol{g}_{2n+1}=M\cdot(\mathbf{0},\mathbf{1}_r)$, and note that $\boldsymbol{y}=(\boldsymbol{y}'-a\boldsymbol{t},\boldsymbol{y}'',a\mathbf{1}_r)$ for some $\boldsymbol{y}',\boldsymbol{y}''\in\mathcal{C}$ and $a\in\mathbb{F}_q$. If $a\neq 0$, then

$$\|\boldsymbol{y}\|_0=\|\boldsymbol{y}'-a\boldsymbol{t}\|_0+\|\boldsymbol{y}''\|_0+\|a\mathbf{1}_r\|_0\geq \operatorname{dist}(-a\boldsymbol{t},\mathcal{C})+r>\gamma' d+r\ ,$$

where we have used that $\operatorname{dist}(-a\boldsymbol{t},\mathcal{C})=\operatorname{dist}(\boldsymbol{t},\mathcal{C})$ for $a\neq 0$. On the other hand, if $a=0$, then

$$\|\boldsymbol{y}\|_0=\|\boldsymbol{y}'\|_0+\|\boldsymbol{y}''\|_0\geq\lambda_1(\mathcal{C})>\gamma' d\ ,$$

where the first inequality holds because at least one of $\boldsymbol{y}'$ and $\boldsymbol{y}''$ is a non-zero codeword in $\mathcal{C}$ (since $\boldsymbol{y}\neq\mathbf{0}$), and the second inequality holds because of the assumption that $d<\lambda_1(\mathcal{C})/\gamma'$, which follows from the definition of NO instances of γ'-GapNCP$_q^{1/\gamma'}$. In either case, we have that

$$\max_{\boldsymbol{x}\in\mathcal{C}_1\setminus\{\mathbf{0}\}}\frac{\|M\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}\geq\frac{\|M\boldsymbol{g}_{2n+1}\|_0}{\|\boldsymbol{g}_{2n+1}\|_0}=\frac{\|\boldsymbol{y}\|_0}{r}>\gamma' d/r\ . \tag{7}$$

Now, let $\boldsymbol{x}'\in\mathcal{C}$ be such that $\|\boldsymbol{x}'\|_0=\lambda_1(\mathcal{C})$, and define $\boldsymbol{x}_1:=(\boldsymbol{x}',\mathbf{0},\mathbf{0}),\boldsymbol{x}_2:=(\mathbf{0},\boldsymbol{x}',\mathbf{0})$. Note that $\boldsymbol{x}_1,\boldsymbol{x}_2\in\mathcal{C}_2$, and that $\boldsymbol{y}_1:=M^{-1}\boldsymbol{x}_1=(\boldsymbol{y}_1',\boldsymbol{y}_1'',a_1\mathbf{1}_r)$ and $\boldsymbol{y}_2:=M^{-1}\boldsymbol{x}_2=(\boldsymbol{y}_2',\boldsymbol{y}_2'',a_2\mathbf{1}_r)$ for some $\boldsymbol{y}_1',\boldsymbol{y}_1'',\boldsymbol{y}_2',\boldsymbol{y}_2''\in\mathcal{C}$ and $a_1,a_2\in\mathbb{F}_q$. Furthermore, because $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ are linearly independent and M is invertible, $\boldsymbol{y}_1$ and $\boldsymbol{y}_2$ must also be linearly independent. So, at least one of $\boldsymbol{y}_1',\boldsymbol{y}_1'',\boldsymbol{y}_2',\boldsymbol{y}_2''$ is non-zero, and therefore $\max\{\|M^{-1}\boldsymbol{x}_1\|_0,\|M^{-1}\boldsymbol{x}_2\|_0\}\geq\lambda_1(\mathcal{C})$. It follows that

$$\begin{aligned}\max_{\boldsymbol{x}\in\mathcal{C}_2\setminus\{\mathbf{0}\}}\frac{\|M^{-1}\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0}&\geq\max\left\{\frac{\|M^{-1}\boldsymbol{x}_1\|_0}{\|\boldsymbol{x}_1\|_0},\frac{\|M^{-1}\boldsymbol{x}_2\|_0}{\|\boldsymbol{x}_2\|_0}\right\}\\ &=\max\{\|M^{-1}\boldsymbol{x}_1\|_0,\|M^{-1}\boldsymbol{x}_2\|_0\}/\lambda_1(\mathcal{C})\geq 1\ .\end{aligned} \tag{8}$$

Combining Equations (7) and (8) then gives

$$\mathcal{D}(\mathcal{C}_1,\mathcal{C}_2)>\gamma' d/r=\frac{\gamma'}{\lceil\frac{D+1}{D-1}\rceil}>\frac{\lceil\frac{D+1}{D-1}\rceil\cdot\gamma D}{\lceil\frac{D+1}{D-1}\rceil}=\gamma D\ ,$$

as needed. ◀

From Theorems 25 and 26 and the fact that γ-GapMDP is NP-hard for any constant $\gamma\geq 1$, we conclude that the CDP is NP-hard to approximate to within any constant factor.

▶ **Theorem 1.** *For any constant $\gamma \geq 1$, any constant $D > 1$, and any prime power $q \leq \text{poly}(n)$, γ-GapCDP$_q$ with distortion threshold D is* NP*-hard under deterministic Cook reductions.*

Proof. Combine the NP-hardness result in Theorem 8 with the reductions in Theorems 25 and 26. ◀

We note that restriction on the field size q in Theorem 1 is due the running time of the reduction in Theorem 25.

4 Algorithms for Code Distortion

We now turn to giving algorithms for code distortion.

4.1 An Exact Algorithm

We first analyze the running time of a brute force exact algorithm for CDP, which is the best exact algorithm we know.

▶ **Lemma 27.** *Let $n, k \in \mathbb{Z}^+$, $k \leq n$, let q be a prime power, and let $\mathcal{C}_1, \mathcal{C}_2$ be $[n,k]_q$ codes. The distortion $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$ can be computed in $O^*(q^{k(k+1)})$ time.*

Proof. A linear transformation T with $T\mathcal{C}_1 = \mathcal{C}_2$ must map a generator matrix of $\mathcal{C}_1$ to a generator matrix of $\mathcal{C}_2$. So, it suffices to fix a generator matrix of $G_1 \in \mathbb{F}_q^{n\times k}$, enumerate generator matrices $G_2 \in \mathbb{F}_q^{n\times k}$ of $\mathcal{C}_2$, and compute $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2)$ for the induced map T such that $TG_1 = G_2$.

To enumerate generator matrices G_2 of $\mathcal{C}_2$, it suffices to compute $G_2 := G_2'U$ for a fixed generator matrix G_2' of $\mathcal{C}_2$ and each $U \in \text{GL}_k(\mathbb{F}_q)$. In order to enumerate elements of $\text{GL}_k(\mathbb{F}_q)$, it suffices to enumerate all matrices $U \in \mathbb{F}_q^{k\times k}$, and discard them if they are singular. This takes $O^*(q^{k^2})$ time.

To compute $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2)$ for a given map T, it suffices to compute $\|T\boldsymbol{x}\|_0/\|\boldsymbol{x}\|_0$ for all $\boldsymbol{x} \in \mathcal{C}_1 \setminus \{\mathbf{0}\}$ and $\|T^{-1}\boldsymbol{y}\|_0/\|\boldsymbol{y}\|_0$ for all $\boldsymbol{y} \in \mathcal{C}_2 \setminus \{\mathbf{0}\}$. This can be done in $O^*(q^k)$ time since $|\mathcal{C}_1| = |\mathcal{C}_2| = q^k$. So, overall the algorithm runs in $O^*(q^{k(k+1)})$, as needed. ◀

We then get the following corollary.

▶ **Corollary 28.** *Let $n, k \in \mathbb{Z}^+$, $k \leq n$, let q be a prime power, and let $\mathcal{C}_1, \mathcal{C}_2$ be $[n,k]_q$ codes. The distortion $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$ can be computed in* poly(n) *time if $k = O\left(\sqrt{\log_q n}\right)$.*

Notably, Lemma 27 runs in roughly q^{k^2} time, and at a minimum it would be desirable to find a single-exponential, roughly q^k-time algorithm. Although we do not give an exact such q^k-time algorithm, we do give a roughly q^k-time *approximation* algorithm for CDP$_q$.

4.2 A General Approximation Algorithm

Our approximation algorithm uses the following fact.

▶ **Lemma 29.** *Let $n, k \in \mathbb{Z}^+, k \leq n$, let q be a prime power, and let $\mathcal{C}_1, \mathcal{C}_2$ be $[n,k]_q$ codes with successive minima bases $G_1 = (\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k), G_2 = (\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k)$, respectively, and let T be a linear transformation such that $TG_1 = G_2$. Furthermore, let $\boldsymbol{x} = G_1\boldsymbol{a}$ for $\boldsymbol{a} \in \mathbb{F}_q^k$ be a non-zero codeword in $\mathcal{C}_1$. Suppose that $j \in [k]$ is the maximum index such that $a_j \neq 0$. Then*

$$\frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} \leq \frac{\sum_{i=1}^{j} \lambda_i(\mathcal{C}_2)}{\lambda_j(\mathcal{C}_1)} .$$

Proof. Since $TG_1 = G_2$, we know that $T\boldsymbol{v}_i = \boldsymbol{w}_i$ for $1 \leq i \leq k$ and that $T\boldsymbol{x} = \sum_{i=1}^{j} T(a_i\boldsymbol{v}_i) = \sum_{i=1}^{j} a_i\boldsymbol{w}_i$. Using the triangle inequality, we get the upper bound $\|T\boldsymbol{x}\|_0 \leq \sum_{i=1}^{j}\|a_i\boldsymbol{w}_i\|_0 \leq \sum_{i=1}^{j}\|\boldsymbol{w}_i\|_0 = \sum_{i=1}^{j}\lambda_i(\mathcal{C}_2)$.

On the other hand, the j vectors $\boldsymbol{x}$ and $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_{j-1}$ must be linearly independent because $a_j \neq 0$ and $\boldsymbol{v}_j \notin \operatorname{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_{j-1})$. By the definition of successive minima, we then have that $\|\boldsymbol{x}\|_0 \geq \lambda_j(\mathcal{C}_1)$. Combining this lower bound on $\|\boldsymbol{x}\|_0$ with the upper bound on $\|T\boldsymbol{x}\|_0$ above implies the claim. ◀

We define the following quantity relating the successive minima of $[n,k]_q$ codes $\mathcal{C}_1$ and $\mathcal{C}_2$:

$$M(\mathcal{C}_1, \mathcal{C}_2) \coloneqq \max_{i\in[k]} \frac{\lambda_i(\mathcal{C}_2)}{\lambda_i(\mathcal{C}_1)} \ . \tag{9}$$

We will use this quantity to give lower and upper bounds on the distortion $\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$.

▶ **Theorem 30.** *Let $n, k \in \mathbb{Z}^+, k \leq n$, let q be a prime power, and let $\mathcal{C}_1, \mathcal{C}_2$ be $[n,k]_q$ codes. Let $G_1 = (\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$ and $G_2 = (\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k)$ be successive minima bases of $\mathcal{C}_1$ and $\mathcal{C}_2$, respectively, and let T be a linear transformation such that $TG_1 = G_2$ Then*

$$M(\mathcal{C}_1, \mathcal{C}_2)M(\mathcal{C}_2, \mathcal{C}_1) \leq \mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \leq \mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) \leq k^2 \cdot M(\mathcal{C}_1, \mathcal{C}_2)M(\mathcal{C}_2, \mathcal{C}_1) \ .$$

Proof. We first prove the upper bound. For any $\boldsymbol{x} \in \mathcal{C}_1 \backslash \{\boldsymbol{0}\}$, we can write $\boldsymbol{x} = G\boldsymbol{a}$ for some $\boldsymbol{a} \in \mathbb{F}_q^k \setminus \{\boldsymbol{0}\}$. Let $j \in [k]$ be the maximum index such that $a_j \neq 0$. By Lemma 29, we then have that

$$\frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} \leq \frac{\sum_{i=1}^{j}\lambda_i(\mathcal{C}_2)}{\lambda_j(\mathcal{C}_1)} \leq \frac{\sum_{i=1}^{j}\lambda_j(\mathcal{C}_2)}{\lambda_j(\mathcal{C}_1)} \leq k \cdot \frac{\lambda_j(\mathcal{C}_2)}{\lambda_j(\mathcal{C}_1)} \leq k \cdot \max_{i\in[k]} \frac{\lambda_i(\mathcal{C}_2)}{\lambda_i(\mathcal{C}_1)} \ .$$

As this is true for all $x \in \mathcal{C}_1 \backslash \{\boldsymbol{0}\}$, it holds that

$$\max_{\boldsymbol{x}\in\mathcal{C}_1\backslash\{\boldsymbol{0}\}} \frac{\|T\boldsymbol{x}\|_0}{\|\boldsymbol{x}\|_0} \leq k \cdot \max_{i\in[k]} \frac{\lambda_i(\mathcal{C}_2)}{\lambda_i(\mathcal{C}_1)} = k \cdot M(\mathcal{C}_1, \mathcal{C}_2) \ .$$

A symmetric argument applied to T^{-1} yields

$$\max_{\boldsymbol{y}\in\mathcal{C}_2\backslash\{\boldsymbol{0}\}} \frac{\|T^{-1}\boldsymbol{y}\|_0}{\|\boldsymbol{y}\|_0} \leq k \cdot M(\mathcal{C}_2, \mathcal{C}_1) \ ,$$

and plugging both into the definition of distortion yields the upper bound

$$\mathcal{D}(\mathcal{C}_1, \mathcal{C}_2) \leq k^2 \cdot M(\mathcal{C}_1, \mathcal{C}_2)M(\mathcal{C}_2, \mathcal{C}_1) \ .$$

We next prove the lower bound using an analogous proof to one in [8]. Let U be an arbitrary full-rank linear map such that $U\mathcal{C}_1 = \mathcal{C}_2$. Then, because $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_i$ are linearly independent for every $i \in [k]$, $U\boldsymbol{v}_1, \ldots, U\boldsymbol{v}_i$ are also linearly independent. It therefore follows that

$$\lambda_i(\mathcal{C}_2) \leq \max_{j\in[i]}\|U\boldsymbol{v}_j\|_0 \leq \|U|_{\mathcal{C}_1}\|_{0\to 0} \cdot \max_{j\in[i]}\|\boldsymbol{v}_j\|_0 = \|U|_{\mathcal{C}_1}\|_{0\to 0}\lambda_i(\mathcal{C}_1) \ .$$

This yields the bound $\frac{\lambda_i(\mathcal{C}_2)}{\lambda_i(\mathcal{C}_1)} \leq \|U|_{\mathcal{C}_1}\|_{0\to 0}$ for all i, which implies $\max_{i\in[k]} \frac{\lambda_i(\mathcal{C}_2)}{\lambda_i(\mathcal{C}_1)} \leq \|U|_{\mathcal{C}_1}\|_{0\to 0}$. A symmetrical argument with $(U^{-1})|_{\mathcal{C}_2}$ mapping successive minima vectors of $\mathcal{C}_2$ to $\mathcal{C}_1$ yields $\max_{i\in[n]} \frac{\lambda_i(\mathcal{C}_1)}{\lambda_i(\mathcal{C}_2)} \leq \|U^{-1}|_{\mathcal{C}_2}\|_{0\to 0}$, and multiplying the bounds together shows that

$$\left(\max_{i\in[n]} \frac{\lambda_i(\mathcal{C}_2)}{\lambda_i(\mathcal{C}_1)}\right)\left(\max_{i\in[n]} \frac{\lambda_i(\mathcal{C}_1)}{\lambda_i(\mathcal{C}_2)}\right) \leq \|U|_{\mathcal{C}_1}\|_{0\to 0}\|U^{-1}|_{\mathcal{C}_2}\|_{0\to 0}.$$

Because U was chosen arbitrarily, we then have that $M(\mathcal{C}_1, \mathcal{C}_2)M(\mathcal{C}_2, \mathcal{C}_1) \leq \mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$. ◀

We now restate and prove Theorem 2, which gives our main approximation algorithm for CDP_q.

▶ **Theorem 2.** *For any prime power q, there is an algorithm for k^2-*CDP *on $[n,k]_q$ codes that runs in $O^*(q^k)$ time and $\mathrm{poly}(n, \log q)$ space.*

Proof. The algorithm works by computing successive minima bases G_1 and G_2 for $\mathcal{C}_1$ and $\mathcal{C}_2$, respectively, using Lemma 6, and then computing and outputting a linear transformation T such that $TG_1 = G_2$. By Lemma 6, computing G_1 and G_2 takes $O^*(q^k)$ time and polynomial space, and using these bases it is efficient to compute T. Furthermore, $\mathcal{D}_T(\mathcal{C}_1, \mathcal{C}_2) \leq k^2 \cdot \mathcal{D}(\mathcal{C}_1, \mathcal{C}_2)$ by Theorem 30. The theorem follows. ◀

Abstract

We study the online min-cost perfect matching with delay (MPMD) problem where m requests arrive in a metric space of n points. In MPMD, an algorithm can choose to match a request or to delay, and the objective is to minimise the sum of connection and delay costs. The connection cost of a match is the distance between the locations of two matched requests in the metric, and the increase of the delay cost is a function of the set of unmatched requests at every moment. In this paper, we study two different types of delay functions, size-based (MPMD-Size) and convex delays (MPMD-Convex).

The study of MPMD-Size was initiated by Deryckere and Umboh (APPROX/RANDOM 2023) where the instantaneous delay increment is a non-negative monotone function of the number of unmatched requests. We give an exponential improvement on the lower bounds for the deterministic and randomized competitive ratios. We also give improved upper bounds in terms of n, as opposed to Deryckere and Umboh's upper bounds that were functions of m, which can be much larger than n. Our results settle the deterministic competitive ratio (up to constants). At the heart of these results is a succinct encoding scheme of MPMD-Size on a given n-point metric as a metrical task system problem on a 2^{n-1}-point metric.

We also consider MPMD-Convex proposed by Liu et al. (ISAAC 2018) where the delay cost incurred by each request is a uniform convex delay function of the time difference between its arrival time and the moment that it is matched by the algorithm. They focused on delay functions f that are unbounded, non-decreasing, continuous, and satisfy $f(0) = f'(0) = 0$, and showed that the deterministic competitive ratio is $\Omega(n)$ for n-point uniform metrics. We show that, surprisingly, when f is a non-negative, monotone polynomial with $f'(0) > 0$, there is an $O(1)$-competitive deterministic algorithm for uniform metrics. Our result completes our understanding of MPMD-Convex on uniform metrics for a broad class of functions.

1 Introduction

In recent years, there has been much interest in revisiting classical online problems through the lens of online problems with delay (e.g. [3, 17, 13]). In such problems, instead of serving every request immediately, one can choose to delay the service of a request while accumulating a delay cost, and the total cost of a solution is the cost of serving all requests plus the accumulated delay costs. In such problems, the trade-off between service cost and delay cost is at the center of the decision making of an online algorithm: the algorithm can wait until many requests have arrived and then apply an offline algorithm to serve them cheaply as a batch, but this will incur a large delay cost.

In this paper, we study the Min-Cost Perfect Matching with Delay (MPMD) problem proposed by Emek et al. [16]. In MPMD, there is an underlying metric space of n points in which m requests arrive over time at different points. At every moment when there is an available request, the online algorithm can choose to either match it with another request and incur a *connection cost* equal to the distance between the locations of two requests, or to leave it unmatched and incur a *delay cost*.

MPMD has many intuitive interpretations and real-life applications. For example, suppose that one needs to design a mechanism for an online game platform which always needs to match two players to compete against each other. The mechanism wants to match two players who have similar levels to each other as this could reduce their dissatisfaction, which is a connection cost that the platform wants to minimize. The platform is allowed to choose not to match a player immediately but to wait for another player whose level is close enough to the first player to join the game and then to match them, so that the connection cost can be reduced. However, if one player has been waiting too long, they might lose patience and become more and more unsatisfied with this game platform, which will incur more delay cost instead. Therefore, the online algorithm needs to balance the trade-off between these two types of costs, which is at the center of studies in this area. This kind of problems are inherently online since we do not know what will come in the future, and once we have made a decision, it is irreversible.

Delay costs. While the connection cost of a match is the distance between the locations of the two requests that are matched, there are various delay models according to how the delay cost increases at every moment when there is at least one request pending. Some delay models apply a uniform delay function that the total delay of each request is a function of the time different between its arrival and being matched, e.g. linear [16], convex [20], and concave delays [5]. The most general framework is that the delay increment is a function of the set of requests that are pending at every moment and the algorithm is non-clairvoyant that it does not know future delay functions, e.g. set and size-based delays [14].

Competitive ratios: n vs m. Prior studies on these delay models have achieved results that express competitive ratios as functions of n or m. Note that m can be incomparably larger than n when the request sequence is sufficiently long, and such algorithms can perform badly even on a simple one-point metric when m tends to infinity (e.g. [4]). Thus, we aim at designing algorithms whose competitive ratios depend only on n.

1.1 Our Contributions

In this paper, we make contributions to the study of two generalizations of linear delay functions mentioned above that are much less understood than the others: size-based and convex delays.

Size-based delay (MPMD-Size). In the size-based delay setting, at every step the delay increment is a monotone function of the number of currently pending requests (See Section 3.1 for a formal definition). We prove bounds on the deterministic and randomized competitive ratios in terms of n. Previously, only upper bounds in terms of m are known.

▶ **Theorem 1.1.** *For every n-point metric, the deterministic competitive ratio of MPMD-Size is $\Theta(2^n)$.*

▶ **Theorem 1.2.** *For every n-point metric, the randomized competitive ratio (against an oblivious adversary) of MPMD-Size is $O(n^2)$ and $\Omega(n)$.*

We emphasize that the lower bounds in Theorems 1.1 and 1.2 are universal lower bounds: they apply to *every* metric space.

Table 1 Comparisons between the results from [14] and our new results for MPMD-Size. The lower bounds of [14] only apply to uniform metrics while ours apply to every metric.

Competitive Ratio	Results from [14]	Our Results
Deterministic	$O(2^m)$ and $\Omega(n)$	$\Theta(2^n)$
Randomized	$O(m^4)$ and $\Omega(\log n)$	$O(n^2)$ and $\Omega(n)$

Theorems 1.1 and 1.2 improve upon previous results on size-based delays by Deryckere and Umboh [14] in two ways. First, the previous upper bounds for both deterministic and randomized algorithms are expressed as functions of m, the number of requests, while our results are expressed as functions of n, the number of points in the given metric space, and thus is an improvement in the more interesting regime where $m \gg n$. Second, we also provide a reduction from MTS to MPMD-Size while theirs is only from MPMD-Size to MTS, which exponentially improves lower bounds for both deterministic and randomized algorithms on *every* n-point metric. In contrast, their lower bound only holds for uniform metrics. Our results settle the deterministic competitive ratio, up to a constant. See Table 1 for a detailed comparison between our results and those by Deryckere and Umboh.

Convex delay (MPMD-Convex). We also consider the convex delays on n-point uniform metrics, first studied by Liu et al. [20]. Convex delay is applicable to a lot of real-life scenarios as well, e.g., a gaming platform where players think it is acceptable to wait for a short period yet a longer delay can be more and more frustrating and even affect the player's willingness to join the platform again. In this problem, there is a non-decreasing delay function f associated with every request and the delay cost of request r incurred until t is $f(t - a(r))$, where $a(r)$ is its arrival time, and the total delay cost is the sum of every request's individual delay. The previous study by Liu et al. focused on the setting where f is non-decreasing, continuous, unbounded and satisfy $f(0) = f'(0) = 0$. They gave a deterministic lower bound of $\Omega(n)$ and a matching upper bound when f is also a monomial.

We consider polynomials f such that $f'(0) > 0$. Prior to our work, the only known result is that when f is linear, the deterministic competitive ratio is $O(1)$ [2]. Our second main result fills this gap and completes our understanding of the landscape of the competitive ratio of MPMD under uniform convex monotone polynomial delays on uniform metrics.

▶ **Theorem 1.3** (Informal; see Theorem 4.1)**.** *For any fixed convex monotone polynomial delay f such that $f'(0) > 0$, there is an $O(1)$-competitive deterministic algorithm for MPMD under delay f on all n-point uniform metrics.*

Surprisingly, for different delay functions, their local derivatives at $t = 0$ can totally change the competitiveness, even when they have the same superlinear asymptotic behavior when $t \to \infty$. For example, the deterministic competitive ratio is $\Omega(n)$ for $f(t) = t^2$, yet a minor perturbation to $f(t) = (t + \varepsilon)^2 - \varepsilon^2$ by any small $\varepsilon > 0$ completely changes it to $O(1)$. We will see in the proof that it is due to the approximability between $f(t)$ and the linear delay $g(t) = t$: as long as $f(0) = f'(0) = 0$, the ratio between f and g tends to 0 when t tends to 0 and so we cannot use g to approximate f within positive constant factors. The $O(1)$-competitive result applies to a broader class of functions beyond polynomials as well, even some exponential functions; see Remark 4.18 for further discussion.

1.2 Our Techniques

MPMD-Size. We employ a similar high-level approach as Deryckere and Umboh [14] of encoding MPMD-Size as a *metrical task system* (MTS) problem (defined in Section 2). Our key contribution is a significantly more efficient encoding.

The main idea is to define the MTS states so that matching requests in the MPMD-Size instance corresponds to a state transition in the MTS instance, and at each timestep, the instantaneous delay increment in the MPMD-Size instance can be realized by a cost vector in the MTS instance. Deryckere and Umboh used the obvious encoding in which there is an MTS state for each even-sized subset of the requests that have arrived so far, and the current MTS state is the set of requests that have been matched so far. While this makes it trivial to encode the instantaneous delay increment as an MTS cost vector – the cost of a state is exactly the instantaneous delay increment of the requests that have arrived but are not matched – the total number of MTS states is the number of all possible even-sized subsets of the requests, which is exponential in m. It also complicates matters when applying MTS algorithms as the MTS state space grows as new requests arrive.

Our key insight that enables a more succinct encoding of MPMD-Size as MTS is the following. It never hurts to match two pending requests if they are co-located and so the number of unmatched requests at each point is either 0 or 1. Thus, to determine the number of unmatched requests (which in turn determines the instantaneous delay increment), it suffices to keep track for each point, whether there is an unmatched request at that point. This, in turn, can be done by keeping track of the parity of the number of times a request on that point has been previously matched (see the discussion following Lemma 3.1). Therefore, we can simply express the current state of an MPMD-Size algorithm using an n-dimensional Boolean vector. Thus, the total number of MTS states is $O(2^n)$.

Finally, our reductions between MTS and MPMD-Size go in both directions. This lets us improve the lower bounds for both deterministic and randomized algorithms exponentially, and in particular, settle the deterministic competitive ratio (up to constants).

MPMD-Convex on uniform metrics. Different from the linear delay, a convex delay function has an unbounded increase rate when it has been pending unmatched for enough long time. As a result, a reasonable algorithm should avoid this case, otherwise even a short period of waiting may lead to huge delay increase. Therefore, we introduce the concept of T-impatient algorithms, where a request that has been pending for time T must be matched immediately once there is another available request anywhere in the metric space. In this way, we naturally divide the time axis into two parts according to whether there is a request that has been pending for longer than time T at the moment. If there is no request that has been pending for longer than time T, then the delay increase rate of every request is upper and lower bounded by two positive constants (to guarantee the positive lower bound, the property that

$f'(0) > 0$ is necessary) and we can use the linear delay to approximate it up to a constant factor. As for the other case, based on the T-impatient property of the algorithm, the only reason that a request has been pending that long is because there is neither another pending request nor the arrival of a new request to be matched with, which means that there must be a request continuously pending throughout this time period under the optimal solution as well, which provides a lower bound of the optimal cost. Luckily, for all monotone polynomials, such a lower bound is within a constant factor of the delay incurred under the algorithm.

Therefore, to design an algorithm for monotone polynomial delays such that $f'(0) > 0$ on uniform metrics, it can be reduced to designing a T-impatient algorithm whose competitive ratio is a constant for linear delay on uniform metrics. We show that the seminal algorithm for MPMD on tree metrics by Azar et al. [2] does not satisfy the T-impatient property while being implemented on uniform metrics, and thus propose a new algorithm and prove it has the desired property.

1.3 Related Works

Linear delay. When MPMD was first introduced by Emek et al. [16], the delay function they studied is the uniform linear delay. They proposed a randomized algorithm with competitive ratio $O(\log^2 n + \log \Delta)$, where n is the number of points in the metric space and Δ is its aspect ratio. Azar et al. [2] improved the upper bound of the randomized competitive ratio for linear delays to $O(\log n)$ by designing an algorithm based on the randomized tree embedding technique into weighted HSTs from [6]. The current best lower bound for the uniform linear delay function is $\Omega(\log n / \log \log n)$ of any randomized algorithm from [1], which shows a gap between known upper and lower bounds even for the most classical delay setting.

The above results that express competitive ratios in terms of n and Δ usually require the algorithm to know the metric space beforehand, and such competitive ratios are independent of the length of the request sequence. However, there are also results where the competitive ratio is expressed in terms of m, the number of requests in the input sequence, while the algorithm does not need to know the metric space prior to its execution: the first such result was proposed by Bienkowski et al. [9] and their deterministic algorithm is $O(m^{2.46})$-competitive. Bienkowski et al. [8] later improved the result to $O(m)$ by an adaptation of the deterministic primal-dual moat growing technique, and independently and concurrently, Azar and Fanani [4] devised a sublinear $O(m^{0.59})$-competitive deterministic algorithm. So far, the best result that expresses the competitive ratio as a function of m is an $O(\log^5 m)$-competitive deterministic algorithm by Dufay and Wattenhofer [15].

Concave delay. Azar et al. [5] considered the MPMD problem with uniform concave delays. They designed an $O(1)$-competitive deterministic algorithm for the single point and an $O(\log n)$-competitive randomized algorithm for general n-point metric spaces. Deryckere and Umboh [14] generalized the primal-dual framework from [8] and proposed an $O(m)$-competitive deterministic algorithm for uniform concave delays.

Convex delay. Liu et al. [20] considered the MPMD problem with uniform convex delays on n-point uniform metric spaces. They studied monomial functions $f(t) = t^\alpha$ such that $\alpha > 1$ (where t is the time difference between arrival and being matched for each request). They provided a deterministic $O(n)$-competitive algorithm and showed a matching deterministic lower bound of $\Omega(n)$ for all uniform non-decreasing unbounded continuous delay functions such that $f(0) = f'(0) = 0$. This result demonstrates a gap between the solutions for the cases with linear and convex delays, as the algorithm proposed by Azar et al. [2] achieves

constant competitive ratio on uniform metrics because uniform metrics can be seen as trees of height 1. They also provided a randomized $\Omega(\log n)$ lower bound for delay functions in the same class. There is no result for convex delays beyond uniform metrics yet.

Set and size-based delays. In all of the above studies, there is one uniform delay function $f(t)$ known to the algorithm in advance that applies to every request from the input, suggesting how its delay cost increases as time goes by, and the total delay cost is the sum of delay costs incurred by each request. Deryckere and Umboh [14] studied another model of delay function that is not accumulated request-wise but step-wise: at every time step t, the instantaneous delay cost is incurred as a function of the set of unmatched requests during this step. This set-delay model studies MPMD problem in the least restrictive way, as there is essentially no restriction on the structure of the delay functions and the setting is non-clairvoyant, i.e. the algorithm does not know future delays. Similar non-clairvoyant delay settings have been studied in other online problems with delays, e.g., TCP Acknowledgment Problem [7] and Subadditive Joint Replenishment Problem [19, 18]. Unfortunately, under the most general set-delay setting, every deterministic algorithm has competitive ratio of at least $\Omega(\Delta)$, where Δ is the aspect ratio of the metric space. Instead, Deryckere and Umboh further restricted to the case of size-based delays, which have natural applications in practical settings with service-level agreements such as cloud computing. They showed that there is an $O(2^m)$-competitive deterministic algorithm and an $O(m^4)$-competitive randomized algorithm by a reduction to the classical MTS problem introduced by Borodin et al. [10] and applying the best upper bounds for both deterministic and randomized algorithms by Borodin et al. and Bubeck et al. [12] respectively. They also provided lower bounds in terms of n, which is $\Omega(n)$ for deterministic algorithms and $\Omega(\log n)$ for randomized algorithms. These upper and lower bounds show significant gaps between m and n in the scenarios where a request sequence of unbounded length is generated on a given finite metric.

Paper organization. We start by introducing the formal definition of MTS in Section 2. In Section 3, we show the reductions between MPMD-Size and MTS on both directions and hence complete the proof of Theorems 1.1 and 1.2. We study MPMD-Convex on uniform metrics and prove Theorem 1.3 in Section 4. We conclude by some discussion on the results as well as open problems.

2 Preliminaries

In this section, we introduce the definition and properties of the Metrical Task System problem, which will be used in Section 3 to prove the main results of our paper on MPMD-Size. The formal definitions and notations of MPMD-Size and MPMD-Convex, two different delay models of MPMD that we study, are in Sections 3 and 4 respectively.

The metrical task system (MTS) problem, introduced by Borodin et al. [10], can be defined as a sequence of requests $\{\rho_t\}_{t\geq 1}$ on a given finite metric space (V, d) and an initial state $s_0 \in V$ of the server. Each request $\rho_t : V \to \mathbb{R}_{\geq 0}$ is a non-negative cost function on the state space V, illustrating the cost of the server to process request ρ_t in different points from V. Upon the arrival of request ρ_t at every step $t \geq 1$, the server can be moved to some state $s_t \in V$ to process ρ_t, and this incurs *service cost* of $\rho_t(s_t)$. Since MTS is an online problem, the state s_t at every step t must be output without knowing future requests. The total cost of a solution $\{s_t\}_{t\geq 1}$ that expresses the state s_t where the server processes request

ρ_t at every step $t \geq 1$ consists of service cost and *transition cost*, where the transition cost at every step t is the distance $d(s_{t-1}, s_t)$ of moving to s_t from its previous state s_{t-1}. As a result, the cost of a solution $\{s_t\}_{t\geq 1}$ is defined as:

$$\sum_{t\geq 1}[\rho_t(s_t) + d(s_{t-1}, s_t)].$$

For MTS problems, we say that an online algorithm $\mathcal{A}$ is *lazy* if: at every step t when it moves from s_{t-1} to a different state s_t to process ρ_t, it must hold that $\rho_t(s_{t-1}) > 0$. Intuitively speaking, a lazy algorithm $\mathcal{A}$ only makes a move when its current state incurs positive cost for the upcoming request while always staying still if the service cost of the new request in the current state is zero.

▶ **Lemma 2.1.** *Given any online algorithm $\mathcal{A}$ for MTS, there is an online mechanism that transforms $\mathcal{A}$ to a lazy algorithm without increasing the cost.*

From now on, we can assume that every MTS algorithm that we use is lazy.

Let MTS-Single denote the subclass of MTS problem where every request ρ_t incurs positive cost at exactly one point $v_t \in V$, i.e. $\rho_t(v_t) > 0$ and $\rho_t(v) = 0$ for every $v \in V \setminus \{v_t\}$. When a metric space is given, we use c_{m} to denote the minimum possible worst-case competitive ratio that can be achieved by an algorithm for MTS problem on it, and c_{ms} to denote that can be achieved for MTS-Single problem. The following result is folklore for both deterministic and randomized algorithms:

▶ **Lemma 2.2.** $c_{\mathrm{m}} \leq c_{\mathrm{ms}}$.

The proofs of Lemmas 2.1 and 2.2 can be found in the full version. They will be used in Section 3 to establish the reductions between MPMD-Size and MTS.

3 Reduction between MPMD-Size and MTS

In this section, we first formally define the MPMD problem with size-based delays (MPMD-Size), and then describe the reduction between it and MTS.

3.1 Definition and Property of MPMD-Size

The MPMD problem is defined on a metric space (V, d), where V is the set of points and $d : V \times V \to \mathbb{R}_{\geq 0}$ is the distance function. An online input consists of a sequence of requests that arrive over time. Every request r is defined by two characteristics: its arrival time $a(r)$ and location $\ell(r) \in V$. We view the problem in the discrete way that any request can only arrive at a time step $t \in \mathbb{N}_{>0}$, yet it is possible that multiple requests arrive at the same time step t. This model captures the original definition by Emek et al. [16] when we divide the continuous time axis into discrete steps where a step covers an interval of infinitesimal length.

Suppose Q_t is the set of requests that have arrived up to and including time step t. At every step, the instantaneous delay function $f_t : 2^{Q_t} \to \mathbb{R}_{\geq 0}$ specifies the increment of delay cost at this step for every possible $P_t \subseteq Q_t$, where P_t is the set of requests that are pending during time step t. At every step t, the algorithm first sees the newly-arriving requests (if any) and the instantaneous delay function f_t, then makes a decision on matching some requests. A match between two requests r_1 and r_2 incurs a connection cost of $d(\ell(r_1), \ell(r_2))$. This process results in an updated P_t, and the instantaneous delay $f_t(P_t)$ is then incurred

after the matching performed at step t. Observe that the definition is consistent with metrical task systems (defined in Section 2) in the sense that at every step, the algorithm first sees the new input, then decides which state to move to (possibly the same state), and incurs the cost of the resulting state. The goal is to minimize the sum of its connection cost and delay cost incurred among all steps.

In the MPMD-Size problem, the instantaneous delay function incurred at time step t can be expressed as $f_t(|P_t|)$, where $f_t : \mathbb{N}_{\geq 0} \to \mathbb{R}_{\geq 0}$ is a monotone function. We note that the well-studied linear delay cost is a special case of the size-based delay where $f_t(|P_t|) = |P_t|$ at every moment t.

We say that an online algorithm $\mathcal{A}$ is *smart* if no two requests are pending at the same point during any time step. One important property of sized-based delay functions is that we can without loss of generality assume that every algorithm or solution is smart, because of the following lemma whose proof can be found in the full version:

▶ **Lemma 3.1.** *For size-based delays, given any online algorithm $\mathcal{A}$, there is an online mechanism that transforms $\mathcal{A}$ to a smart algorithm without increasing the cost.*

Lemma 3.1 provides us with not only a nice property of the optimal solution, but also a mechanism of online transformations that allows us to always automatically match two requests at the same point immediately at any moment. As a result, we do not need to explicitly describe the a match of two requests at the same point in the metric anymore. Based on this, we can assume that at every point $v \in V$ there is either one or zero pending request at every time step t, and there are at most n requests pending in the whole metric space V. Moreover, at every given time step, we can refer to a match between two requests at two different points as a match between these two points without ambiguity. Throughout the paper, we may use expressions such as "the algorithm matches point v_1 with point v_2" and "point v has been matched for an odd number of times", where the former refers to a match between requests at these two points v_1 and v_2, and the latter refers to the total number of times where a request at v has been matched with some request at another point. As we have discussed in Section 1.2, this allows us to encode the state of an algorithm with a Boolean vector that has an entry over every point in V, which builds the foundation of our reductions.

3.2 Construction of MTS Metric Space

Before we formally describe the reduction between two problems, we first specify the corresponding metric space $(\mathcal{K}^V, D)$ on which the request sequence for both MTS and MTS-Single problems is based, given a metric space (V, d) for an MPMD-Size instance.

▶ **Definition 3.2.** *Given any finite set V, define $\mathcal{K}^V := \{\mathbf{u} \in \{0,1\}^V \mid \sum_{v \in V} \mathbf{u}(v) = 0 \mod 2\}$, where $\mathbf{u}(v)$ is the entry of $\mathbf{u}$ on a given $v \in V$ for every $\mathbf{u} \in \{0,1\}^V$.*

Observe that $|\mathcal{K}^V| = 2^{n-1}$.

Intuition for $(\mathcal{K}^V, D)$. To have an intuitive understanding of the structure of $(\mathcal{K}^V, D)$ defined on a metric (V, d) and its addition operation, we can give a Boolean variable to every point in V, and see every match between two points in V as an operation that flips the Boolean variable associated with these two points simultaneously. If the default setting is that the Boolean variable associated with every point in V is 0, then $\mathcal{K}^V$ is exactly the set of states that can be attained by applying the matching operations, where each state is a

Boolean vector that specifies the value of the Boolean variable associated with every point in V. With this intuition, if the cost of a match is exactly the distance of the two points involved in it, then the distance between two states in $\mathcal{K}^V$ should be the minimum cost to transform one state into another by applying matching operations.

As a result, we define the concept of the induced matching of every element in $\mathcal{K}^V$ (Definition 3.5) and use it to express the distance D on $\mathcal{K}^V$. We will see that this definition of distance indeed satisfies the min-cost transformation property between every two states (Lemma 3.18).

▶ **Definition 3.3** (Addition operation on $\{0,1\}^V$). *Let $\oplus$ denote the XOR Boolean operation over $\{0,1\}$, i.e. $a \oplus b = 0$ if $a = b$ and $a \oplus b = 1$ if $a \neq b$, for $a, b \in \{0,1\}$. For every $\mathbf{u}_1, \mathbf{u}_2 \in \{0,1\}^V$, $\mathbf{u}_1 \oplus \mathbf{u}_2 := (\mathbf{u}_1(v) \oplus \mathbf{u}_2(v))_{v \in V}$.*

We use $\mathbf{0}$ to denote $(0)_{v \in V}$ and $\mathbf{1}$ to denote $(1)_{v \in V}$. We first note that $\mathcal{K}^V$ is a closed subgroup of $\{0,1\}^V$ under this addition operation.

▷ Claim 3.4. For every $\mathbf{u}_1, \mathbf{u}_2 \in \mathcal{K}^V$, we have $\mathbf{u}_1 \oplus \mathbf{u}_2 \in \mathcal{K}^V$.

Proof. If $\sum_{v \in V} \mathbf{u}_1(v) = \sum_{v \in V} \mathbf{u}_2(v) = 0 \mod 2$, then $\sum_{v \in V} (\mathbf{u}_1 \oplus \mathbf{u}_2)(v) = \sum_{v \in V} (\mathbf{u}_1(v) \oplus \mathbf{u}_2(v)) = \sum_{v \in V} \mathbf{u}_1(v) + \sum_{v \in V} \mathbf{u}_2(v) = 0 \mod 2$. ◁

▶ **Definition 3.5** (Induced matching of an element in $\mathcal{K}^V$). *Given $\mathbf{u} \in \mathcal{K}^V$, let $T_{\mathbf{u}} = \{v \in V \mid \mathbf{u}(v) = 1\}$. Define the* induced matching *of $\mathbf{u}$ to be an arbitrary min-cost perfect matching of points in $T_{\mathbf{u}}$ in the metric space (V, d).*[1] *For every min-cost perfect matching M of $T_{\mathbf{u}}$, we associate the vector $\mathbf{u}$ with M.*

▶ **Definition 3.6** (Distance D on $\mathcal{K}^V$). *Given $\mathbf{u}_1, \mathbf{u}_2 \in \mathcal{K}^V$, define their distance $D(\mathbf{u}_1, \mathbf{u}_2)$ to be the weight of a min-cost perfect matching induced by $\mathbf{u}_1 \oplus \mathbf{u}_2$.*

See the full version for the proof of the following claim.

▷ Claim 3.7. $(\mathcal{K}^V, D)$ is a metric space.

3.3 From MPMD-Size to MTS

Given any instance of MPMD-Size on the metric space (V, d), we first describe the reduction from it to an instance of MTS on the corresponding $(\mathcal{K}^V, D)$, as well as how to translate an online algorithm for MTS to one for the original MPMD-Size.

We introduce some notations to express the state of an MPMD-Size instance under the execution of a given algorithm at step t, including: the total arrivals of requests at different points, and the effect of all matches made by the algorithm so far.

▶ **Definition 3.8.** *Given an algorithm for MPMD-Size on the metric space (V, d), for every step $t \geq 1$, let $R_t \in \{0,1\}^V$ be the Boolean vector such that $R_t(v) = 1$ if and only if the parity of the number of requests that have arrived at $v \in V$ until (including) step t is odd, $M_t \in \mathcal{K}^V$ be the Boolean vector such that $M_t(v) = 1$ if and only if v has been matched for an odd number of times until (including) step t. The initial setting ($t = 0$) is that $R_0 = M_0 = \mathbf{0}$.*

In MPMD-Size, at every step t, new requests arrive and the instantaneous delay function f_t is revealed at the same time, and an online algorithm needs to make decisions to match according to this information. At each step t, we need to handle two situations: when new

[1] A perfect matching exists since $|T_{\mathbf{u}}|$ is even, by the definition of $\mathcal{K}^V$.

requests have arrived at t and before the algorithm has made new decisions yet, and after the algorithm has made decisions at time t. The former determines the matchings that the algorithm can make, and the latter determines the instantaneous cost incurred at the end of step t. With notations introduced in Definition 3.8, it is easy to see that the former state can be expressed as $R_t \oplus M_{t-1}$ and the latter state can be expressed as $R_t \oplus M_t$. With the smart algorithm property and the mechanism shown in Lemma 3.1, it is not hard to see that we can assume that requests at the same point cancel out each other automatically for state $R_t \oplus M_{t-1}$ as well. We summarize the above discussion in the following observation that expresses the number of request at every point with a Boolean vector:

▶ **Observation 3.9.** *Upon the arrivals of new requests at time step t (before new matches are made by the algorithm at step t), the number of pending requests at every point v is equal to $M_{t-1}(v) \oplus R_t(v)$; once the algorithm has made decisions at step t, the number of pending requests at v is equal to $M_t(v) \oplus R_t(v)$ when the delay cost is incurred at step t.*

If $(M_{t-1} \oplus R_t)(v) = 0$, then there is no request pending at v after new arrivals at t, and of course there cannot be any request at v after new matches are performed at t as well, thus leading to the following observation:

▶ **Observation 3.10.** $(R_t \oplus M_{t-1})(v) \leq (R_t \oplus M_t)(v)$ *for every $v \in V$ and time step t.*

For every $\mathbf{u} \in \{0,1\}^V$, we use $|\mathbf{u}|$ to denote the number of 1's among all entries of $\mathbf{u}$, i.e. $|\mathbf{u}| = \sum_{v \in V} \mathbf{u}(v)$. During every step t when the delay cost is incurred, $R_t \oplus M_t$ is the Boolean vector that denotes the state of the input under the algorithm as per Observation 3.9. Based on these notations and the property of size-based delays, the delay cost incurred during step t can be expressed as $f_t(|R_t \oplus M_t|)$.

Construction of MTS instance. Now we are ready to define the MTS instance that we reduce MPMD-Size to. We set the server's initial position of the MTS instance to be $C_0 = \mathbf{0}$. Upon every time step $t \geq 1$, we assign a request vector $(\rho_t(\mathbf{u}))_{\mathbf{u} \in \mathcal{K}^V}$ to the MTS instance according to R_t, the Boolean vector that we have defined to denote the parity of the number of requests that have arrived at each point in V until (and including) t, and f_t, the instantaneous delay cost function of the MPMD-Size instance incurred at step t. More specifically, the cost to process ρ_t at $\mathbf{u}$ is $\rho_t(\mathbf{u}) = f_t(|R_t \oplus \mathbf{u}|)$ for every $\mathbf{u} \in \mathcal{K}^V$.

Let $\mathrm{OPT_m}$ denote the value of the optimal solution of the MTS instance and $\mathrm{OPT_{size}}$ denote that of the MPMD-Size instance.

▶ **Lemma 3.11.** $\mathrm{OPT_{size}} \geq \mathrm{OPT_m}$.

Proof. Given any solution $\mathrm{SOL_{size}}$ of MPMD-Size, we convert it to a solution $\mathrm{SOL_m}$ of MTS without increasing the cost. Upon every step t, let M_t be the sum of Boolean vectors of matches made by $\mathrm{SOL_{size}}$ so far, then M_t is an element of $\mathcal{K}^V$, and $\mathrm{SOL_m}$ moves from state M_{t-1} to M_t (this is feasible at step 1 since at the beginning $M_0 = \mathbf{0}$ and the initial configuration of the MTS instance is given as $C_0 = \mathbf{0}$ as well).

We now compare the cost of two solutions. At every step t, the number of pending requests in the MPMD-Size solution is $|R_t \oplus M_t|$. As a result, the delay cost incurred during step t is $f_t(|R_t \oplus M_t|)$, which is equal to $\rho_t(M_t)$, the cost to process the task ρ_t at M_t, based on our setting of $(\rho_t(\mathbf{u}))_{\mathbf{u} \in \mathcal{K}^V}$. By Lemma 3.18, the connection cost of $\mathrm{SOL_{size}}$ at step t is at least the distance $D(M_{t-1}, M_t)$, which equals the cost of MTS to move from M_{t-1} to M_t. ◀

Translating MTS algorithm to MPMD-Size. We now describe how to transform an algorithm $\mathcal{A}_{\text{m}}$ for the MTS instance to one $\mathcal{A}_{\text{size}}$ for the MPMD-Size instance in an online way. As we see from the proof of Lemma 3.11, there is naturally a one-to-one correspondence between the current MTS state and the current total matching Boolean vector M_t of MPMD-Size, which can be seen as the state of an MPMD-Size algorithm. Therefore, given an online algorithm $\mathcal{A}_{\text{m}}$ for MTS problem on $(\mathcal{K}^V, D)$ that processes request ρ_t at state C_t, intuitively, we want to transit MPMD-Size algorithm to state $M_t = C_t$ as well. However, such a transition is not always feasible, as there is no guarantee that there is an available request at every point that the algorithm needs to match to transit to C_t. If this happens, then we want to update M_{t-1} to M_t that is the closest possible to C_t among all feasible matchings that can be made: we check every pair of match in the min-cost perfect matching induced by $M_{t-1} \oplus C_t$, and match every feasible pair of requests. See the description of Algorithm 1 for more details.

Algorithm 1 The translation algorithm of an online algorithm $\mathcal{A}_{\text{m}}$ for MTS on $(\mathcal{K}^V, D)$ to $\mathcal{A}_{\text{size}}$ for MPMD-Size on (V, d).

Initialize: $M_0 = \mathbf{0}$ for MPMD-Size, and the initial configuration of MTS is $C_0 = \mathbf{0}$.

At every step t:

Given R_t, the arrivals of requests so far in the MPMD-Size instance and f_t the instantaneous size-based delay cost, task vector ρ_t of MTS is constructed such that $\rho_t(\mathbf{u}) = f_t(|R_t \oplus \mathbf{u}|)$ for every $\mathbf{u} \in \mathcal{K}^V$, and we are given $\mathcal{A}_{\text{m}}$'s state C_t at step t.

Upon arrivals of new requests at t, the Boolean vector of current available requests in V is $R_t \oplus M_{t-1}$ (Observation 3.9).

Calculate $M_{t-1} \oplus C_t$, the Boolean vector of the matching that $\mathcal{A}_{\text{size}}$ intends to make to transit to state M_t. For every edge (u, v) in the min-cost perfect matching induced by $M_{t-1} \oplus C_t$, if $(M_{t-1} \oplus R_t)(u) = (M_{t-1} \oplus R_t)(v) = 1$, then there is a pending request at both u and v after new arrivals at step t, and we match u and v in this case.

After all matches have been performed, the new vector M_t is updated accordingly.

▷ Claim 3.12. For every $v \in V$, if $M_t(v) \neq C_t(v)$, then $(M_{t-1} \oplus C_t)(v) = 1$.

Proof. We prove the contrapositive. If $(M_{t-1} \oplus C_t)(v) = 0$, then $\mathcal{A}_{\text{m}}$ does not make any match that involves v at step t, and so $M_t(v) = M_{t-1}(v) = C_t(v) = 0$. ◁

The following claim guarantees the local optimality of $\mathcal{A}_{\text{m}}$ as per the transition from M_{t-1} to M_t by matches at step t:

▷ Claim 3.13. The connection cost of $\mathcal{A}_{\text{m}}$ at step t is equal to $D(M_{t-1}, M_t)$.

Proof. Let J_1 be the set of edges matched by $\mathcal{A}_{\text{m}}$ at step t and J_2 be the set of edges in the min-cost perfect matching induced by $M_{t-1} \oplus C_t$, then $J_1 \subseteq J_2$ by the mechanism of $\mathcal{A}_{\text{m}}$. If J_1' is a another perfect matching on $T_{M_{t-1} \oplus M_t} = \{v \in V \mid (M_{t-1} \oplus M_t)(v) = 1\}$ such that the cost of J_1' is smaller than J_1, then $(J_2 \setminus J_1) \cup J_1'$ is a perfect matching on $T_{M_{t-1} \oplus C_t} = \{v \in V \mid (M_{t-1} \oplus C_t)(v) = 1\}$ whose cost is smaller than J_2, a contradiction to the assumption that J_2 is a min-cost perfect matching! ◁

We prove that the cost of $\mathcal{A}_{\text{size}}$ is no more than that of $\mathcal{A}_{\text{m}}$ by the following lemmas. First, we compare the instantaneous delay cost of $\mathcal{A}_{\text{size}}$ incurred at step t with the cost of processing task ρ_t by $\mathcal{A}_{\text{m}}$, and this is where the size-based property of the delay function f_t plays a vital role.

▶ **Lemma 3.14.** *The delay cost at step t by $\mathcal{A}_{\text{size}}$ is no more than the service cost to process request ρ_t by $\mathcal{A}_{\text{m}}$, given that f_t is a size-based delay.*

Proof. The delay cost of $\mathcal{A}_{\text{size}}$ at step t is $f_t(|R_t \oplus M_t|)$ and the service cost to process request ρ_t by $\mathcal{A}_{\text{m}}$ is $f_t(|R_t \oplus C_t|)$. By the monotonicity of the size-based delay function, it suffices to show that $|R_t \oplus M_t| \leq |R_t \oplus C_t|$. We do this by constructing an injective map $h_t : P'_t \setminus P_t \to P_t \setminus P'_t$, where

$$P'_t = \{v \in V \mid (R_t \oplus M_t)(v) = 1\}; \qquad P_t = \{v \in V \mid (R_t \oplus C_t)(v) = 1\}.$$

For every $v \in P'_t \setminus P_t$, it holds that $M_t(v) \neq C_t(v)$ according to the definition of P'_t and P_t. By Claim 3.12, it must be that $(M_{t-1} \oplus C_t)(v) = 1$. Let u be the request that is matched with u in the min-cost perfect matching induced by $M_{t-1} \oplus C_t$. We now prove that $u \in P_t \setminus P'_t$, and hence we can define $h_t(v) = u$.

By Observation 3.10, $(R_t \oplus M_{t-1})(v) = 1$ for every $v \in P'_t$. By the construction of $\mathcal{A}_{\text{size}}$, if $(R_t \oplus M_{t-1})(v) = 1$ and $M_t(v) \neq C_t(v)$ both hold, then it must be that $(R_t \oplus M_{t-1})(u) = 0$ making v unmatched at step t. In this case, it holds that $(R_t \oplus M_t)(u) \leq (R_t \oplus M_{t-1})(u) = 0$ according to Observation 3.10, which implies that $u \notin P'_t$ by definition. On the other hand, $(M_{t-1} \oplus C_t)(u) = 1$ yet u is unmatched at step t, which implies that $(R_t \oplus C_t)(u) = (R_t \oplus M_{t-1})(u) \oplus 1 = 1$, and so $u \in P_t$. As a result, $u \in P_t \setminus P'_t$ and h_t is well-defined on $P'_t \setminus P_t$.

We now prove that h_t is injective. For any $v_1 \neq v_2$ from $P'_t \setminus P_t$, $h_t(v_1)$ is matched with v_1 and $h_t(v_2)$ is matched with v_2 in the min-cost perfect matching induced by $M_{t-1} \oplus C_t$. As a result, $h_t(v_1) \neq h_t(v_2)$ by the matching property, and h is an injection. ◀

The next lemma compares the connection cost of $\mathcal{A}_{\text{size}}$ (which is $D(M_{t-1}, M_t)$ at every step t according to Claim 3.13) with the transition cost of $\mathcal{A}_{\text{m}}$.

▶ **Lemma 3.15.** *$\sum_{t=1}^{T} D(M_{t-1}, M_t) \leq \sum_{t=1}^{T} D(C_{t-1}, C_t)$, where T is the final step of both of the corresponding MTS and MPMD-Size instances.*

Proof. We define a potential function $\phi_t = D(M_t, C_t)$ for each step t. It is easy to see that $\phi_0 = 0$ and $\phi_t \geq 0$ for every t. We prove the telescopic inequalities

$$D(M_{t-1}, M_t) \leq D(C_{t-1}, C_t) - (\phi_t - \phi_{t-1})$$

for every step $t \geq 1$ to draw the conclusion.

First, by the triangle inequality on the metric space $(\mathcal{K}^V, D)$, it holds that

$$D(M_{t-1}, C_t) \leq D(M_{t-1}, C_{t-1}) + D(C_{t-1}, C_t) = D(C_{t-1}, C_t) + \phi_{t-1}.$$

We now show that $D(M_{t-1}, M_t) + \phi_t = D(M_{t-1}, M_t) + D(C_t, M_t) \leq D(M_{t-1}, C_t)$, then we get the desired inequality by summing up these two.

Define

$$T_1 = \{v \in V \mid (M_{t-1} \oplus M_t)(v) = 1\}; \qquad T_2 = \{v \in V \mid (M_t \oplus C_t)(v) = 1\}.$$

We first observe that $T_{M_{t-1} \oplus C_t} = \{v \in V \mid (M_{t-1} \oplus C_t)(v) = 1\} = T_1 \Delta T_2$, according to the definition of $\oplus$ operation of Boolean vectors. By Claim 3.12, for every $v \in T_2$, it must hold that $v \in T_{M_{t-1} \oplus C_t}$ and hence $v \notin T_1$, which implies that $T_1 \cap T_2 = \varnothing$. As a result, we can express $T_{M_{t-1} \oplus C_t} = T_1 \sqcup T_2$[2] . Moreover, for each pair (u, v) in the min-cost perfect

[2] $T_1 \sqcup T_2$ is the disjoint union of T_1 and T_2.

matching induced by $M_{t-1} \oplus C_t$, either u, v are both in T_1, or u, v are both in T_2, according to the mechanism of $\mathcal{A}_{\text{size}}$ to update M_t at every step. Therefore, we can divide all matches in the min-cost perfect matching induced by $M_{t-1} \oplus C_t$ into two parts: J_1 that forms a matching on T_1, and J_2 that forms a matching on T_2. Using $w(\cdot)$ to denote the weight of a matching, we have $w(J_1) + w(J_2) = D(M_{t-1}, C_t)$ since $J_1 \cup J_2$ forms the min-cost perfect matching induced by $M_{t-1} \oplus C_t$. Moreover, $D(M_{t-1}, M_t) \leq \omega(J_1)$ and $D(M_t, C_t) \leq \omega(J_2)$ by the definition of distance D. This proves the desired inequality. ◀

Combining Lemmas 3.14 and 3.15, we conclude that the total cost of $\mathcal{A}_{\text{size}}$ on the MPMD-Size instance on (V, d) is no more than the total cost of $\mathcal{A}_{\text{m}}$ on the MTS instance on $(\mathcal{K}^V, D)$, yielding the following theorem of the reduction.

▶ **Theorem 3.16.** *Let (V, d) be a metric, c_{m} be the competitive ratio of MTS on $(\mathcal{K}^V, D)$ and c_{size} be that of MPMD-Size on (V, d). Then, $c_{\text{size}} \leq c_{\text{m}}$.*

Applying the upper bound of $O(N)$ for deterministic algorithms from [10] and that of $O(\log^2 N)$ for randomized algorithms from [12] of MTS on every N-point metric gives the upper bounds in Theorems 1.1 and 1.2.

▶ **Corollary 3.17.** *There is an $O(2^n)$-competitive deterministic algorithm and an $O(n^2)$-competitive randomized algorithm for MPMD-Size on every n-point metric.*

3.4 From MTS-Single to MPMD-Size

In this part, we establish the reduction from any given instance of MTS-Single on $(\mathcal{K}^V, D)$ to one of MPMD-Size on (V, d), where V is a given metric space and $|V| = n$.

MPMD-Size delay function. We first state the structure of the size-based delay function f_t of the MPMD-Size instance for every step $t \geq 1$:

$$f_t(N) = \begin{cases} 0 & \text{if } N < n; \\ \varepsilon_t & \text{if } N \geq n. \end{cases}$$

Here ε_t denotes a positive amount in our construction that will depend on the request of the MTS-Single instance at step t. More specifically, at every step t there is exactly one point that is "hit" with a positive cost by the request in MTS-Single, and we use ε_t to denote the amount of this positive cost.

Requests of MPMD-Size instance. We assume that the initial setting of the MTS server is $C_0 = \mathbf{0}$, otherwise we set $R_t \oplus \mathbf{u}_t = C_0 \oplus \mathbf{1}$ and show that the property maintained in the proof of Lemma 3.19 is $M_t \oplus C_t = C_0$ for every step t instead (it is intuitively like "shifting" both R_t and $M_t \oplus C_t$ by C_0). At every step t when the new request ρ_t arrives in the MTS-Single instance on $(\mathcal{K}^V, D)$, suppose that $\rho_t(\mathbf{u}_t) = \varepsilon_t > 0$ and $\rho_t(\mathbf{u}) = 0$ for every $\mathbf{u} \in \mathcal{K}^V \setminus \{\mathbf{u}_t\}$, then we set $R_t = \mathbf{u}_t \oplus \mathbf{1}$ for the MPMD-Size instance. To have a more intuitive understanding of how new requests arrive in the metric space at step t, we use the difference between R_{t-1} and R_t, i.e. $R_{t-1} \oplus R_t$, to denote the new arrivals at step t, such that $(R_{t-1} \oplus R_t)(v) = 1$ if and only if a new request arrives at step t at point v, for every $v \in V$. Moreover, we can express this amount as $R_{t-1} \oplus R_t = R_{t-1} \oplus \mathbf{u}_t \oplus \mathbf{1}$, which can be computed from R_{t-1} that has been well-defined from previous steps, and $\mathbf{u}_t$ defined by the new request of MTS-Single instance at step t. As a result, the MPMD-Size instance that we reduce MTS-Single to is well-defined.

The following lemma provides a lower bound of a solution's connection cost at step t, given M_{t-1} and M_t, the two consecutive states of matches that have been made so far.

▶ **Lemma 3.18.** *The cost of matches made at step t is at least $D(M_{t-1}, M_t)$.*

Proof. Let $M(v)$ denote the number of times that the algorithm matches v with another point at step t, then $M(v)$ is either 0 or 1 based on the assumption that there is at most one available request at every $v \in V$ and so we naturally regard M as a Boolean vector. For every $v \in V$, it holds that $M_t(v) = M_{t-1}(v) \oplus M(v)$, according to the definition of M_t and M_{t-1} and the addition operation on Boolean vectors. As a result, M is a perfect matching of $T_{M_{t-1} \oplus M_t} = \{v \in V \mid (M_{t-1} \oplus M_t)(v) = 1\}$ (since we only consider matches between different points). The statement follows by Definition 3.6. ◀

Let $\mathrm{OPT}_{\mathrm{ms}}$ denote the value of the optimal solution of the MTS-Single instance and $\mathrm{OPT}_{\mathrm{size}}$ denote the that of the MPMD-Size instance.

▶ **Lemma 3.19.** $\mathrm{OPT}_{\mathrm{ms}} \geq \mathrm{OPT}_{\mathrm{size}}$.

See the full version of our paper for the proof of Lemma 3.19.

The next step is to convert an online algorithm $\mathcal{A}_{\mathrm{size}}$ for the MPMD-Size instance to one $\mathcal{A}_{\mathrm{ms}}$ for the MTS-Single instance without increasing the cost. At every step t after new matches have been made by $\mathcal{A}_{\mathrm{size}}$ and M_t is updated, $\mathcal{A}_{\mathrm{ms}}$ processes request ρ_t in state M_t.

▶ **Lemma 3.20.** *The cost of $\mathcal{A}_{\mathrm{ms}}$ is no more than that of $\mathcal{A}_{\mathrm{size}}$.*

Proof. It is easy to see the transition cost of $\mathcal{A}_{\mathrm{ms}}$ is no more than the connection cost of $\mathcal{A}_{\mathrm{size}}$. This is because the matching made by $\mathcal{A}_{\mathrm{size}}$ at t must be at least the value of a min-cost perfect matching induced by $M_t \oplus M_{t-1}$ according to Lemma 3.18, which is equal to $D(M_{t-1}, M_t)$, the cost of moving from the previous state M_{t-1} to a new state M_t at step t in the MTS-Single instance.

On the other hand, the delay cost incurred for MPMD-Size during step t is equal to $\varepsilon_t = \rho_t(\mathbf{u}_t)$ (recall that $\mathbf{u}_t$ is the only state in $\mathcal{K}^V$ where ρ_t incurs positive cost) if and only if $R_t \oplus M_t = \mathbf{1}$, which is equivalent to that $M_t = \mathbf{u}_t$ based on our setting of the MPMD-Size instance that $R_t \oplus \mathbf{u}_t = \mathbf{1}$. Thus, the service cost of $\mathcal{A}_{\mathrm{ms}}$ is equal to the delay cost of $\mathcal{A}_{\mathrm{size}}$. ◀

Now the reduction from MTS-Single to MPMD-Size has been established as the following:

▶ **Theorem 3.21.** *Let (V, d) be a metric, c_{ms} be the competitive ratio of MTS-Single on $(\mathcal{K}^V, D)$ and c_{size} be that of MPMD-Size on (V, d). Then, $c_{\mathrm{ms}} \leq c_{\mathrm{size}}$.*

Combined with Lemma 2.2, we can use c_{m}, the competitive ratio of the general MTS problem, to provide lower bounds for the MPMD-Size problem. Therefore, we obtain the following corollary when we apply the universal lower bound of $\Omega(N)$ for deterministic algorithms from [10] and that of $\Omega(\log N)$ for randomized algorithms from [11] of MTS on every N-point metric.

▶ **Corollary 3.22.** *No deterministic algorithm can achieve competitive ratio better than $\Omega(2^n)$ and no randomized algorithm can achieve competitive ratio better than $\Omega(n)$ for MPMD-Size on any n-point metric.*

This gives the lower bounds in Theorems 1.1 and 1.2.

4 MPMD-Convex on Uniform Metrics

In this section, we study another form of delay functions that does not fall in the category of size-based delays. We use the continuous time model to study the online matching with uniform delays, where the same monotone continuous delay function $f : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ (we further assume that $f(0) = 0$ without loss of generality) applies to every request r in the following way: suppose the arrival time of a request r is $a(r)$ and t is the time when it is matched by the algorithm, then the total delay cost incurred by request r is $f(t - a(r))$. In this section, we still use $\ell(r)$ to denote the location of request r in the metric space, and the connection cost of matching two requests r_1 and r_2 at locations $\ell(r_1)$ and $\ell(r_2)$ respectively is still $d(\ell(r_1), \ell(r_2))$. The total cost of a solution consists of its total connection cost of matching request into pairs, and the sum of delay cost incurred by every request.

We study monotone convex polynomial delay functions f such that $f'(0) > 0$ on n-point uniform metrics where the distance between any two different points is $2\delta > 0$. Equivalently, such a metric can be interpreted as a star metric where leaf nodes are points in the metric space, the distance between every leaf and the root is δ, and the distance between two leaves is the length of the shortest path between them, which is 2δ. The previous study by Liu et al. [20] gives a tight $\Theta(n)$ deterministic bound for a class of convex delay functions (including all monotone polynomials) such that $f(0) = f'(0) = 0$, and our study complements the landscape by the following result for functions that $f'(0) > 0$:

▶ **Theorem 4.1.** *For any fixed convex monotone polynomial delay f such that $f'(0) > 0$, there is a constant-competitive deterministic algorithm for MPMD under delay function f on all n-point uniform metrics with inter-point distance δ for constant δ.*

The contrast of this result compared with the $\Omega(n)$ deterministic lower bound of the case of continuous non-decreasing unbounded delays satisfying that $f(0) = f'(0) = 0$ demonstrates that even the local property of the delay function at time $t = 0$ significantly affects the solution and competitiveness of the online MPMD problem. Different from the linear delay case, here the distance 2δ between different points in the metric space also affects the competitive ratio: our algorithm is constant competitive under a fixed function f when δ is considered as a constant (the same as the study by Liu et al. [20]), while the competitive ratio can also be regarded as a function of δ, which provides another parameter that might be interesting to study for convex delays.

4.1 Simpler Polynomials

Without loss of generality, we study f in the form $f(t) = \frac{1}{k}t^k + t$ for $k \geq 2$. To see why we can make this assumption, suppose that we have another polynomial $h(t) = \sum_{i=1}^{k} a_i t^i$ that is monotone on $\mathbb{R}_{\geq 0}$, such that $a_k > 0, a_1 > 0$. [3] The following claim proves that h can be approximated by f within constant factors.

▷ Claim 4.2. There exist constants $A, B > 0$ such that $A \leq \frac{f(t)}{h(t)} \leq B$ for every $t \geq 0$.

Proof. Consider the rational function $\frac{f(t)}{h(t)}$. Since $h(0) = 0$ and h is monotone on $\mathbb{R}_{\geq 0}$, it holds that $h(t) > 0$ for every $t > 0$. As a result, $\frac{f(t)}{h(t)}$ is well-defined for every $t \in (0, +\infty)$.

Moreover, it holds that $\lim_{t\to 0^+} \frac{f(t)}{h(t)} = \frac{1}{a_1}$ according to L'Hôpital's rule and $\lim_{t\to+\infty} \frac{f(t)}{h(t)} = \frac{1}{ka_k}$, and both values are strictly bigger than zero based on our assumption that a_k and a_1 are both non-zero values and $h(t)$ is monotone on $\mathbb{R}_{\geq 0}$. Based on the definition of the

[3] We need $a_1 > 0$ to have $h'(0) > 0$.

limit, there exists $T > 0$ such that $0 < \frac{1}{2ka_k} < \frac{f(t)}{h(t)} < \frac{2}{ka_k}$ for every $t > T$. Because $\frac{f(t)}{h(t)}$ is a continuous positive function on the closed interval $[0, T]$ (define $\frac{f(0)}{h(0)} = \frac{1}{a_1}$), it has positive upper and lower bounds on $[0, T]$. Combined with the positive upper and lower bounds on $(T, +\infty)$, we conclude that $\frac{f(t)}{h(t)}$ has positive upper and lower bounds on $\mathbb{R}_{\geq 0}$. ◁

As a result, if there is a competitive algorithm for delay function f, then the same algorithm can be applied to delay function h and the lost factor of the competitive ratio is within a constant factor that only depends on A and B, independent of both n and δ.

If we apply this idea of comparing the costs of the same solution under different delay functions to comparing the convex delay function $f(t) = \frac{1}{k}t^k + t$ with the classical linear delay function $g(t) = t$ on the same request sequence, the only difference that can lead to different costs and different optimal solutions are delay functions f and g. In the following part, we focus on the linear delay function g, and prove that a competitive algorithm for g with certain properties also works well for f. Given an algorithm $\mathcal{A}$ and some delay function h, we use $\text{cost}_{\mathcal{A}}(h)$ to denote the cost of $\mathcal{A}$ when the delay function is set to h. As the total cost consists of connection cost and delay cost, we use $\text{cost}^d_{\mathcal{A}}(h)$ to denote its connection cost and $\text{cost}^t_{\mathcal{A}}(h)$ to denote its delay cost. Similarly for any solution SOL, we use $\text{SOL}(h)$ to denote its total cost under h, as well as $\text{SOL}^d(h)$ and $\text{SOL}^t(h)$ to denote its connection and delay costs respectively. These are the notations that we will use in computations in the next section.

4.2 T-Impatient Algorithms

For an online algorithm $\mathcal{A}$ and a request r, define $t_{\mathcal{A}}(r)$ to be the time that r is matched by $\mathcal{A}$.

▶ **Definition 4.3** (T-impatient algorithms). *An online algorithm $\mathcal{A}$ is* T-impatient *for a fixed value $T > 0$ if for every request r such that $t_{\mathcal{A}}(r) - a(r) > T$, r is the only pending request in the whole metric space at every moment throughout the whole time interval $[a(r) + T, t_{\mathcal{A}}(r))$, i.e. all previous requests have been matched and no new requests arrive during the interval.*

Intuitively, a T-impatient algorithm will only leave a request r unmatched for more than T time only if there is no other request it can match r to. Equivalently, if a request r has been pending for time T, then $\mathcal{A}$ is going to match r with another request immediately as long as there is such a request available. The T-impatient property guarantees a lower bound of the optimal solution during the period when there is a request pending for longer than T. On the other hand, when no request is pending for longer than T, the delay increment can be approximated by the linear delay up to a constant factor as long as $f'(0) > 0$. These two properties guarantee the competitiveness of a T-impatient algorithm under convex delays.

The next lemma is the key to guaranteeing that the cost of a T-impatient algorithm during the period when there is a request that has been pending beyond time T is within a constant factor of the cost incurred by the optimal solution during the same period.

▶ **Lemma 4.4.** *Given $f(t) = \frac{1}{k}t^k + t$ and a constant $T > 0$, $\frac{f(x)-f(T)}{f(x-T)} < 2^k(T^{k-1} + 1)$ for every $x > T$.*

We now formally state the reduction from convex delay $f(t) = \frac{1}{k}t^k + t$ to linear delay $g(t) = t$ under any T-impatient algorithm.

▶ **Lemma 4.5.** *On every n-point uniform metric, if a T-impatient algorithm $\mathcal{A}$ is γ-competitive ($\gamma \geq 1$) under delay function $g(t) = t$, then $\mathcal{A}$ is $2^{k+1}(T^{k-1} + 1)\gamma$-competitive under delay function $f(t) = \frac{1}{k}t^k + t$.*

The proofs of Lemmas 4.4 and 4.5 can be found in the full version.

With this reduction, now the goal is to find an T-impatient algorithm for some constant T independent of n that achieves competitive ratio γ under delay function $g(t) = t$, where γ is a constant independent of n as well.

▶ Remark 4.6. At this stage, it is natural to ask whether the previous algorithm that works well for the linear delay on a tree from [2] (as uniform metrics are a special class of trees with height 1 when we view the graph as a star) satisfies the T-impatient property. Unfortunately, this is not true and we do have to propose a new algorithm to be applied to convex delays. See the full version for a brief discussion on how their algorithm runs on a uniform star metric, and why it does not satisfy the T-impatient property for any constant T even when δ is a constant.

4.3 Constructing a T-Impatient Algorithm

In this section, we propose a T-impatient algorithm and prove that it is competitive under linear delay $g(t) = t$, and thus a competitive algorithm under $f(t) = \frac{1}{k}t^k + t$ according to Lemma 4.5.

High-level description. Recall that a uniform metric can be regarded as a star where each leaf corresponds to a point in the metric space, and the distance between each leaf and the root is δ. We assign a counter to every vertex of the star graph, i.e. all leaves and the root.

During the execution of our algorithm (Algorithm 2), each request can be in one of three states: LEAF, ROOT and READY. A request r is in LEAF if and only if it is contributing to the increase of the leaf counter $z_{\ell(r)}$ ($\ell(r)$ is the location of r), in ROOT if it is neither in LEAF nor in READY. If we want to view the dynamic of a request moving between states, then after a request r arrives, initially it is in LEAF until $z_{\ell(r)}$ is saturated (if $z_{\ell(r)}$ is already saturated at arrival time $a(r)$, we can still say that the time length when r is in LEAF is zero). Once $z_{\ell(r)}$ is saturated, r transits to ROOT, and will only transit from ROOT to READY if the condition of either Case 1 or Case 2 is satisfied. The state transition diagram LEAF $\to$ ROOT $\to$ READY is acyclic, which means that once a request r transits to the next state, there is no way back to the previous state. Based on the fact that the counter $z_{\ell(r)}$ is saturated is equivalent to that r is in ROOT or READY for a pending request r, the conditions to trigger a match between two requests at different points can also be expressed as: either both are in ROOT, or one is in READY.

Note that the priority rule guarantees that if one request is in READY, then it should be matched immediately as long as there is another pending request, which is vital in guaranteeing the T-impatient property.

▷ Claim 4.7. ALG is 4δ-impatient.

Proof. It suffices to show that a request r with arrival time $a(r)$ transits to state READY no later than $a(r) + 4\delta$. It takes time at most δ to transit from LEAF to ROOT and at most 3δ (the sum of Cases 1 and 2) to transit from ROOT to READY after the arrival of a request if it stays unmatched. ◁

Overview of analysis. Our analysis is similar to that in [2, 1] in the sense that we analyze counters associated with different points separately, where the time axis can be divided into phases for each counter according to when it is saturated, and we compare the algorithm with another given solution based on *alignment status* (to be defined later). The biggest difference is that their algorithms only match two requests on a uniform metric when both

Algorithm 2 A Deterministic Algorithm for MPMD on n-point uniform metrics with linear delay $g(t) = t$.

Initialize: For each leaf vertex v, $z_v \leftarrow 0$. For the root vertex u, $z_u \leftarrow 0$.

At every step t:

While there is a request r pending at $\ell(r)$:

1. if $z_{\ell(r)} < \delta$, then r contributes to the increase of the counter $z_{\ell(r)}$ with unit rate and r is in the state LEAF, otherwise if $z_{\ell(r)} = \delta$ then r is in ROOT until it transits to READY;
2. if $z_{\ell(r)} = \delta$ and r is the only pending request, then then r contributes to the increase of the root counter z_u;
3. if the single request r has contributed the total value δ to counter z_u, then r transits from ROOT to READY (Case 1);
4. if the total amount of time when r is in ROOT while not contributing to the increase of z_u accumulates to 2δ, then r transits from ROOT to READY (Case 2).

The conditions that trigger a match and counter resetting:

If there are two pending requests r_1 and r_2 such that $\ell(r_1) = \ell(r_2)$, match r_1 and r_2.

If there are two pending requests r_1 and r_2 such that $z_{\ell(r_1)} = z_{\ell(r_2)} = \delta$, match r_1 and r_2 and reset both $z_{\ell(r_1)}$ and $z_{\ell(r_2)}$ to 0.

If there are two pending requests r_1 and r_2 such that r_1 is in READY, match r_1 and r_2 and only reset $z_{\ell(r_1)}$ to 0.

Priority rule: If multiple matches can occur at the same time, then the request that transited to state ROOT at the earliest time (as long as it exists) is prioritized.

counters associated with these two requests are saturated, while our algorithm has another case that a request in READY is matched with another request immediately when it appears without waiting for another request's counter to also be saturated. This is the key property that makes Algorithm 2 satisfy the desired T-impatient property. To deal with this case for the cost analysis, we prove that the total cost incurred by matches of this case provides a lower bound of the optimal cost as well, hence proving that our new algorithm is also competitive.

Throughout the analysis, we use ALG to denote both the algorithm that we propose and its cost, and SOL to denote a fixed offline solution and its cost that we are comparing ALG with, and the costs are always incurred under delay function g. The superscripts d and t that represent connection and delay costs respectively work in the same way as before.

We first note that our algorithm is smart (defined in Section 3.1) as well, which will be used for the alignment status analysis that we are going to introduce.

▶ **Observation 4.8.** *There is at most one request pending at the same point in the metric space at every moment except when a match occurs.*

We can also assume that Observation 4.8 holds for every offline solution SOL, because linear delay is a special case of the size-based delay and Lemma 3.1 holds for this case as well. Our delay function is continuous, which means that the instantaneous delay increment at the discrete moments when a match occurs is negligible. As a result, if we want to compare the status of pending requests under ALG with another solution SOL, at every moment there are four cases at every point $v \in V$: there is one request pending at v under both ALG and SOL, there is no request pending at v under both ALG and SOL, there is one request pending at v under ALG but no request pending at v under SOL, there is one request pending at v under SOL but no request pending at v under ALG. We say that a point $v \in V$ is *aligned* if it is one of the first two cases among the four, otherwise v is *misaligned*.

▶ **Observation 4.9.** *The alignment status of a point $v \in V$ changes if and only if exactly one of* ALG *and* SOL *matches v with another point.*

We say that a request r *carries* v if ALG makes a match between r that is in READY and a request at $v \neq \ell(r)$. For such a request r, let $t_1(r)$ be the moment when it starts to be in ROOT and $t_2(r)$ be the moment when it starts to be in READY.

▷ Claim 4.10. Suppose that two different requests r and r' both have reached READY status under Algorithm 2, then $[t_1(r), t_2(r)) \cap [t_1(r'), t_2(r')) = \varnothing$.

Proof. Without loss of generality, assume that $t_1(r) \leq t_1(r')$. At the time $t_1(r')$ when r' reaches ROOT, if $t_2(r) > t_1(r')$, i.e., r is still unmatched in ROOT status, then r and r' should have been matched immediately at $t_1(r')$ if no other request matches either of them, a contradiction to that r, r' both have reached READY at some later time. ◁

▶ **Lemma 4.11.** *Suppose that a request r carries some point, then* SOL $|_{[t_1(r),t_2(r))} \geq \delta$.

Proof. We discuss different cases by how r transits from states ROOT to READY. By the design of ALG, now we cover cases 1 and 2 separately.

Case 1. Every moment when r is contributing to the increase of the root counter z_u, r is the only request that is pending, which means that the total number of arrivals of requests in the input sequence so far is an odd number. Therefore, under any solution SOL, there is at least one request pending and hence the delay is increasing with rate at least 1 at every moment when z_u is increasing. By the condition of Case 1 that r has contributed δ to the increase of z_u, the delay cost of SOL during this period must be at least δ as well.

Case 2. It is easy to see that ALG does not match any two requests at different points during $(t_1(r), t_2(r))$, since every such match must involve another request that has just reached state ROOT, while the priority rule would have matched r instead. If SOL makes a match between two requests at different points, then cost of at least 2δ is incurred.

Otherwise, by Observation 4.9, the alignment of every point stays unchanged throughout $(t_1(r), t_2(r))$. Let $\mathbf{t} = t_2(r) - t_1(r)$ denote the length of this interval, then $\mathbf{t} \geq 2\delta$ by the condition of Case 2 that r transits into READY. For all other points in the metric than $\ell(r)$ denoted by $v_1, \ldots, v_{n-1}$ respectively, let $x_1, \ldots, x_{n-1}$ denote the increased counter value of $v_1, \ldots, v_{n-1}$ during this period respectively, then $x_i \leq \delta$ for every $1 \leq i \leq n-1$, otherwise some counter z_{v_i} should have been saturated since no counter is reset in this period and r should have been matched according to the priority rule. Moreover, $x_1 + \ldots + x_{n-1} \geq 2\delta$, since the total time when there is at least one counter increasing among $v_1, \ldots, v_{n-1}$ has reached 2δ for r to transit into READY. By the definition of the alignment status, for every v_i, either it is aligned and therefore there is a request pending at it throughout the total time x_i when z_{v_i} is increasing, or it is misaligned and therefore there is a request pending at it throughout the total time $\mathbf{t} - x_i$ when z_{v_i} is not increasing. In either way, the delay cost incurred by a request pending at v_i is at least $\min\{x_i, \mathbf{t} - x_i\}$, which is equal to x_i by the fact that $x_i \leq \delta$ and $\mathbf{t} \geq 2\delta$. As a result, the total delay time incurred at all points in $v_1, \ldots, v_{n-1}$ is at least $x_1 + \ldots + x_{n-1} \geq 2\delta$.

Therefore, the cost incurred by SOL is at least δ during $[t_1(r), t_2(r))$ for both cases. ◀

The following corollary is a direct result of combining Claim 4.10 and Lemma 4.11.

▶ **Corollary 4.12.** *Let $R = \{r \mid r$ carries some point during the execution of* ALG$\}$*, then*

$$\text{SOL} \geq \sum_{r \in R} \delta |R|.$$

Now we start to analyze the cost of ALG under the linear delay $g(t) = t$ based on the increments of all leaf counters z_v's and z_u. For each leaf counter z_v, let y_v denote the total increments of the value of z_v throughout the execution of ALG without any reset. Similarly, let y_u denote the final value of the root counter z_u since the value of z_u is never reset to zero. We refer the reader to the full version of our paper for the proofs of the remaining lemmas in this section.

▶ **Lemma 4.13.** $\mathrm{ALG}^t \le 2\sum_{leaf\ v} y_v + y_u$.

▶ **Lemma 4.14.** $\mathrm{ALG}^d \le 2\sum_{leaf\ v} y_v$.

Now we need to relate the final value y_u of the root counter and y_v's of leaf counters to the cost of any SOL. Given a solution SOL, for every leaf v, let x_v denote the delay cost incurred by requests at v, x'_v denote the connection cost incurred by matching v with another point (i.e. $x'_v = k\delta$ if v is matched with another point for k times by SOL, and the total connection cost is just the sum among all leaf points). We introduce an additional term based on ALG rather than SOL, which is b_v, to denote the number of times that v is *carried* by another request under the execution of ALG.

▶ **Lemma 4.15.** $y_u \le \mathrm{SOL}^t$.

▶ **Lemma 4.16.** $y_v \le 2x_v + x'_v + \delta \cdot b_v$ *for every leaf* v.

▶ **Theorem 4.17.** *Algorithm 2 achieves competitive ratio* 13 *under delay function* $g(t) = t$ *and* $13 \cdot 2^{k+1}((4\delta)^{k-1} + 1)$ *under delay function* $f(t) = \frac{1}{k}t^k + t$ *for every* $k \ge 2$.

Proof. From Lemmas 4.13 and 4.14, the algorithmic cost $\mathrm{ALG} = \mathrm{ALG}^t + \mathrm{ALG}^d$ is at most $4\sum_{\mathrm{leaf}\ v} y_v + y_u$. By Lemmas 4.15 and 4.16, this is at most $\mathrm{SOL}^t + \sum_{\mathrm{leaf}\ v}(8x_v + 4x'_v + 4\delta \cdot b_v) = 9 \cdot \mathrm{SOL}^t + 4 \cdot \mathrm{SOL}^d + 4\delta \cdot \sum_{\mathrm{leaf}\ v} b_v$, where b_v is the number of times that v is carried by another request. By Corollary 4.12, $\delta \cdot \sum_{\mathrm{leaf}\ v} b_v \le \mathrm{SOL}$. All combined together, we have $\mathrm{ALG} \le 13 \cdot \mathrm{SOL}$, and this is the competitive ratio that ALG achieves under the linear delay function. According to Lemma 4.5, it achieves competitive ratio $13 \cdot 2^{k+1}((4\delta)^{k-1} + t)$ under the delay function $f(t) = \frac{1}{k}t^k + 1$ for $k > 1$. ◀

▶ Remark 4.18. In this section, we use functions of the form $f(t) = \frac{1}{k}t^k + t$ for every $k > 1$ as representatives as all monotone convex polynomials, and show that the competitive ratio can be preserved up to a constant factor independent of n and δ because of the approximation properties as Claim 4.2. In fact, the $O(1)$-competitive ratio can be achieved by the same algorithm for a broader class of non-negative, non-decreasing convex functions where $f'(0) > 0$, as long as they hold similar properties to Lemma 4.4 that $\frac{f(x)-f(T)}{f(x-T)}$ is upper bounded by a positive value depending on T when $x \to \infty$ for any $T > 0$. This covers every non-negative, non-decreasing and smooth convex function f that $f'(0) > 0$ whose leading term is $\Theta(x^\alpha)$ for any $\alpha > 1$, as well as $\Theta(e^x)$. However, exceptions do exist. For example, $f(x) = e^{x^2} - 1$ does not satisfy this property.

5 Discussions and Open Problems

In this paper, we improved both upper and lower bounds of MPMD-Size on every n-point metric space. We show that the problem is equivalent to MTS on another 2^{n-1}-point metric space, and the results are consistent with the state-of-the-art results of MTS. The deterministic competitive ratio is settled up to a constant as the $\Theta(N)$ bound of MTS holds for every N-point metric. However, there is still a gap between the upper and lower

bounds for randomized algorithms. This is because the randomized competitive ratio of MTS depends on metric structures: as the randomized competitive ratio of $O(\log N)$ can be achieved on some N-point metrics like uniform metrics [10] and weighted stars [12], there also exist N-point metrics where the lower bound of $\Omega(\log^2 N)$ holds [11]. As a result, to make further improvements, we need to study the structure of the metric space $(\mathcal{K}^V, D)$. Given a metric space (V, d), the definition of $(\mathcal{K}^V, D)$ is naturally from the Boolean status of every point in v, with some similarities to the earthmover distance, yet this structure has not been well studied, and may be of independent interest.

Our study of MPMD-Convex on uniform metrics covers the case $f'(0) > 0$ that has not been considered before, and very surprisingly, such local property at $t = 0$ totally changes the competitiveness compared with the case $f'(0) = 0$. As the majority of smooth convex delay functions have been covered on uniform metrics, the natural open problem is to design an algorithm for convex delays on more general metrics. There are still some open problems on uniform metrics as well: when we consider randomization, there is only a lower bound of $\Omega(\log n)$ for unbounded, non-decreasing and continuous functions that $f(0) = f'(0) = 0$, while it is open whether there is a randomized algorithm that can achieve competitive ratio of $O(\log n)$ in this case. As for the case $f'(0) > 0$, we note that although Algorithm 2 achieves constant competitive ratio when the distance between points is a fixed constant 2δ, the competitive ratio depends on δ and tends to infinity when δ is sufficiently large. This is different from the linear delay case where the scale of the metric does not affect the competitive ratio. As a result, it might be interesting to study whether it is possible to design an algorithm whose competitive ratio is also independent of δ.

Another natural research direction is to study the bipartite case of MPMD-Size and MPMD-Convex, where every request has either positive or negative polarity and only requests of opposite polarities can be matched. The online min-cost bipartite perfect matching with delay problem has been studied for linear [1] and concave delays [5], yet there is no result for convex or size-based delay. While the proofs and results by Deryckere and Umboh [14] can be easily adapted for the bipartite matching problem by treating every even-sized subset whose sum of polarities is zero as an MTS state, our method for MPMD-Size does not easily extend to the bipartite case as it is not sufficient to express the states with Boolean vectors because multiple requests of the same polarity can accumulate at the same location.

Abstract

In a seminal work, Dooly, Goldman, and Scott (STOC 1998; JACM 2001) introduced the classic *Online TCP Acknowledgment* problem. In this problem, a sequence of n packets arrives over time, and the objective is to minimize both the number of acknowledgments sent and the total delay experienced by the packets. They showed that a natural greedy algorithm, which acknowledges when the delay of pending packets equals the acknowledgment cost, is 2-competitive.

Online TCP Acknowledgment is the canonical online problem with delay, capturing the fundamental tradeoff between reducing service cost through batching and the delay incurred by pending requests. Prior work has largely focused on richer service-cost models, e.g., Joint Replenishment and Multi-Level Aggregation. However, other than the work of Albers and Bals (SODA 2003), which studies maximum delay and closely related objectives, not much is known about general delay costs beyond the sum of delay costs of requests.

In this work, we study Online TCP Acknowledgment under two generalized delay-cost models that we call *batch-aware* and *batch-oblivious*. In the batch-aware model, each batch incurs a delay cost that depends on the packet delays within that batch. For the max-over-batches objective, which generalizes Albers and Bals, we show that greedy remains 2-competitive for every monotone batch-delay function. For the sum-over-batches objective, the picture changes sharply: greedy is $\Omega(n)$-competitive, and the optimal deterministic competitive ratio is $\Theta(\log n)$. Our matching upper bound requires only the minimal assumption that the batch delay function is monotone.

In the batch-oblivious model, the delay cost is a function of the global packet-delay vector. We show that greedy is 2-competitive for continuous submodular delay costs, and more generally under a weaker zero-coordinate diminishing-marginals condition. This yields 2-competitive algorithms for ℓ_p norms, Top-k norms, and ordered norms. Using the submodular-norm approximation of Patton, Russo, and Singla, we also obtain an $O(\log n)$-competitive algorithm for arbitrary symmetric norms.

1 Introduction

The *Online TCP Acknowledgment* problem, introduced by Dooly, Goldman, and Scott in their seminal STOC 1998 paper [28], arose from critical challenges in computer networking. Specifically, it addresses the dynamic management of acknowledgment delays within the Transmission Control Protocol (TCP), a cornerstone of the Internet's architecture (see [4, 24, 25]). The TCP protocol requires the recipient of a stream of packets to acknowledge every packet. On the other hand, excessive delay can disrupt TCP's congestion control mechanisms. Consequently, limiting the latency between a packet's arrival and its acknowledgment is vital for maintaining network performance and protocol stability.

In the Online TCP Acknowledgment problem – the TCP problem henceforth – a sequence of packets arrive online over time. At each time, we can transmit an acknowledgment to acknowledge all currently pending packets at a cost of 1. Each packet accrues a delay cost until it is acknowledged. More formally, the TCP problem involves a sequence of packet arrival times $A = (a_1, \ldots, a_n)$, and the objective is to partition A into k contiguous subsequences $\sigma_1, \sigma_2, \ldots, \sigma_k$, for some k. The end of each subsequence corresponds to the time an acknowledgment is transmitted. Thus, each σ_i is a *batch* of packets that are acknowledged together by the acknowledgment sent at time t_i. The batches σ_i and the acknowledgment times t_i are required to satisfy the following constraints: each packet can only be acknowledged after its arrival, i.e. $t_i \geq a_j$ for every $j \in \sigma_i$; and every packet must be acknowledged, i.e. the final acknowledgment time $t_k \geq a_n$, the arrival time of the last packet. The tradeoff between the cost of acknowledgments and the cost of delaying acknowledgments is modeled with the objective function

$$k + \sum_{i=1}^{k} \text{delay}(\sigma_i, t_i). \tag{1}$$

The number of acknowledgments k is called the *acknowledgment cost* and $\sum_{i=1}^{k} \text{delay}(\sigma_i, t_i)$ the *delay cost*. We refer to $\text{delay}(\cdot, \cdot)$ as the *batch delay cost function*.

TCP with Additive Delay Cost. The most classic and well-studied setting is when the delay function $\text{delay}(\sigma_i, t_i) = \sum_{j \in \sigma_i} (t_i - a_j)$, i.e. the delay cost is simply the total waiting time between each packet's arrival time and its acknowledgment time. The competitiveness of this problem has been completely characterized. For deterministic algorithms, Dooly, Goldman, and Scott [28, 29] proved that the following natural (in hindsight) Greedy algorithm achieves a competitive ratio of 2: acknowledge whenever the delay cost has increased by the cost of an acknowledgment. This is also the optimal deterministic competitive ratio as TCP with additive delay generalizes the well-known Ski Rental problem for which a lower bound of 2 is known [40]. Subsequently, Seiden [48] established a lower bound of $e/(e-1) \approx 1.58$ on the competitive ratio of randomized algorithms; a matching upper bound was shown by Karlin, Kenyon, and Randall [39] shortly after. These algorithms also work for slightly more general delay costs: each request j incurs a delay cost c_j that is a non-decreasing function of its waiting time, and the overall delay cost is $\sum_{j=1}^{n} c_j$. We call this more general problem *TCP with additive delay*, since the delay cost is the sum of the delay costs of the requests.

Beyond TCP. TCP with additive delay is the simplest problem in the class of *online problems with delay*, which captures trade-offs between batching requests to reduce service costs and minimize delays. An online problem with delay involves a sequence of requests that arrive online and a *service cost function* g which is a function on the set of requests; the

goal is to partition the requests into (possibly non-contiguous) batches and a service time t_i for each batch σ_i so as to minimize the objective function $\sum_i g(\sigma_i) + \text{delay}(\sigma_i, t_i)$. The sum $\sum_i g(\sigma_i)$ is called the *service cost*.

Most prior work on online problems with delay has focused on objective functions with more general service costs, with the overall delay cost computed as the sum of the delay costs of requests. These objective functions capture various types of economies of scale arising in varied practical domains such as scheduling, supply chain management, and logistics. The ones most relevant to our work are: joint replenishment [21, 16, 23, 37, 45, 49, 9, 27], multi-level aggregation [19, 20, 14, 15, 42], network design with delay [11, 12, 51], set cover [7, 50, 33], set aggregation [22], online service with delay [8, 18, 41, 35, 36, 52, 53], and matching [31, 6, 5, 17, 32, 10, 26, 38, 43, 30, 34].

Beyond Additive Delay Cost. In many of the above practical domains, it is natural to consider non-additive delay costs, where the penalty incurred by delaying requests is not simply the sum of their waiting times or delay costs. For example, one may wish to control tail latency by ensuring that no request waits too long, or, more generally, by penalizing the largest few waiting times. In settings with service-level agreements, another natural objective is to limit the number of requests that experience positive delay or exceed a prescribed delay threshold. Such objectives capture global quality-of-service or incident-based costs that are not well represented by additive delays.

The main goal of our work is to initiate a systematic study of online problems with delay beyond additive delay costs, starting with the setting that has the simplest service cost function: online TCP Acknowledgment. We investigate the following broad questions.

▶ **Question 1.** *For what families of natural delay costs can we obtain a good competitive ratio for the online TCP acknowledgment problem?*

As Greedy is heavily used as a subroutine in many algorithms for online problems with delay to determine service times (e.g. in [12, 23]), a good understanding of the power of Greedy can help us extend those algorithms to work with non-additive delay costs.

▶ **Question 2.** *For what families of natural delay costs is Greedy a good algorithm for the online TCP Acknowledgment problem?*

To the best of our knowledge, the only previous works on online problems with delay that go beyond additive delay costs are those below.

General Batch Delay Cost. Dooly, Goldman, and Scott [28, 29] considered a far-reaching generalization of the objective in Equation (1) where the batch delay cost function $\text{delay}(\cdot, \cdot)$ is only assumed to be monotone non-decreasing: if σ is a subsequence of σ' and $t \leq t'$, then $\text{delay}(\sigma, t) \leq \text{delay}(\sigma', t)$ and $\text{delay}(\sigma, t) \leq \text{delay}(\sigma, t')$. Equivalently, the marginal delay cost at each timestep depends only on the set of currently pending requests. These general batch-delay cost functions can be used to model not only the goal of avoiding requests waiting too long but also the goal of avoiding too many pending requests at any time. The former can be modeled using ℓ_p-norms, while the latter can be modeled by taking $\text{delay}(\sigma_i, t_i)$ to be a function of $|\sigma_i|$.[1] Dooly, Goldman, and Scott showed that Greedy is 2-competitive when $\text{delay}(\sigma_i, t_i) = \max_{j \in \sigma_i}(t_i - a_i)$, i.e. the batch delay cost is the maximum waiting time of

[1] This type of delay cost function was also studied under the name "size-based delay" by Deryckere and Umboh [26] and Gan, Sun, and Umboh [34] for online matching with delay.

the batch. They also claimed that Greedy is 2-competitive for monotone, nondecreasing batch-delay costs. However, we show that Greedy is actually $\Omega(n)$-competitive, and thus new algorithms are required.

Penalizing Long Delays. Later, Albers and Bals [2, 3] explored a structurally different objective function of the form

$$k + \max_{i=1}^{k} \max_{j \in \sigma_i} (t_i - a_j)^p$$

for some integer $p \geq 1$. When $p = 1$, the delay cost is simply the maximum waiting time of any packet. They gave tight upper and lower bounds on the competitive ratio of deterministic online algorithms: when $p = 1$, it is $\pi^2/6 \approx 1.644$; when $p > 1$, it is an expression that approaches 1.5 as p tends to infinity. For randomized algorithms, they showed lower bounds of $3/(3 - 2/e) \approx 1.324$ and $2/(2 - 1/e) \approx 1.225$, when $p = 1$ and when $p > 1$, respectively. A comprehensive overview of this area until 2003 can be found in Chapter 7.2 of the survey by Albers [1].

1.1 Our Contributions

In this work, we make significant progress towards answering the above questions. We consider three broad classes of delay costs that generalize those considered in previous works: *max-monotone*, *sum-monotone*, and *batch-oblivious*.

Max-Monotone Delay Cost. We begin by considering a generalization of the delay cost considered by Albers and Bals [3]. In the *max-monotone delay* setting, the objective function is

$$k + \max_{i=1}^{k} \text{delay}(\sigma_i, t_i) \tag{Max-Monotone}$$

for some monotone non-decreasing $\text{delay}(\cdot, \cdot)$. We show that Greedy is 2-competitive without any further restrictions on $\text{delay}(\cdot, \cdot)$ using a similar analysis as Greedy under additive delay costs.

▶ **Theorem 1.1.** *Greedy is a deterministic* 2*-competitive algorithm for TCP Acknowledgment with max-monotone delay cost.*

Sum-Monotone Delay Cost. Our main technical contributions are for the *sum-monotone delay* setting, where the objective is

$$k + \sum_{i=1}^{k} \text{delay}(\sigma_i, t_i) \tag{Sum-Monotone}$$

for some monotone non-decreasing $\text{delay}(\cdot, \cdot)$.

Intuitively, given the success of Greedy for max-monotone delay, and the apparent simplicity of the problem – that at any point in time, we only need to decide between two actions (to acknowledge or not) – one expects that Greedy is also good for sum-monotone. Indeed, Dooly, Goldman, and Scott [29, Theorem 10] claimed that the same analysis of Greedy under additive delays can be extended to sum-monotone delays. Surprisingly, we show that Greedy is actually terrible.

▶ **Theorem 1.2** (Informal; see Theorem 4.1). *Greedy is $\Omega(n)$-competitive for TCP Acknowledgment with sum-monotone delay cost.*

A further surprise is that there is no deterministic constant-competitive algorithm for sum-monotone delays. We give a lower bound of $\Omega(\log n)$ on the deterministic competitive ratio for sum-monotone delays via the Parking Permit problem – a generalization of Ski Rental – and a matching upper bound.

▶ **Theorem 1.3.** *The deterministic competitive ratio for TCP Acknowledgment with sum-monotone delay cost is $\Theta(\log n)$.*

Note that we measure the waiting time of a packet $j \in \sigma_i$ as $t_i - a_j$. However, all of our results also apply if the waiting time is transformed by any monotone, nondecreasing (possibly nonlinear) function before aggregation. Since all delay cost functions we consider are monotone non-decreasing, such transformations can equivalently be absorbed into the definition of the batch delay cost function $\text{delay}(\cdot, \cdot)$.

Batch-Oblivious Delay Cost. In the *batch-oblivious delay* setting, the delay cost is given by applying a monotone non-decreasing function f to the *delay vector* d of waiting times of each packet. More precisely, the j-th coordinate of the vector d is the waiting time of the j-th packet. To summarize, the batch-oblivious objective is

$$k + f(d). \tag{Batch-Oblivious}$$

Unlike max-monotone and sum-monotone delays, batch-oblivious delays are "global" objectives. For example, we can measure the ℓ largest waiting times among all requests by taking f to be the Top-ℓ norm;[2] note that this objective is not captured by sum-monotone and max-monotone delays.

In this setting, we show that a natural extension of Greedy is 2-competitive not only for ℓ_p norms and Top-ℓ norms, but also for a broader class of functions that are *continuous submodular*. The proof is much subtler than for additive delay.

▶ **Theorem 1.4.** *Greedy is a deterministic 2-competitive algorithm for TCP Acknowledgment with batch-oblivious continuous submodular delay cost.*

Continuous submodularity (Definition 5.1) generalizes the notion of submodularity for discrete functions to functions on real vectors [13]. Patton, Russo, and Singla [47] observed that ℓ_p norms and several other symmetric norms are continuous submodular. They also showed that any symmetric norm can be approximated by a continuous submodular norm up to a logarithmic factor. Using the results of [47], we get the following result.

▶ **Corollary 1.5.** *There is a deterministic 2-competitive algorithm for TCP Acknowledgment, where the delay cost is: an ℓ_p norm, a Top-ℓ norm, or an ordered norm. When the delay cost is a symmetric norm $\|\cdot\|$, then there is a deterministic $O(\log \rho)$-competitive algorithm where $\rho = \|(1, 1, \ldots, 1)\| \,/\, \|(1, 0, \ldots, 0)\| \leq n$. In particular, there is a deterministic $O(\log n)$-competitive algorithm when the delay cost is a monotone symmetric norm.*

Our final result shows that if we venture too far from norms to concave functions, then the problem becomes significantly more difficult.[3]

▶ **Theorem 1.6.** *Every deterministic algorithm is $\Omega(\sqrt{n})$-competitive for TCP Acknowledgment with batch-oblivious concave delay cost.*

[2] The Top-ℓ norm of a vector is the sum of its ℓ-largest entries.
[3] Recall that norms are convex.

1.2 Our Techniques

We first develop intuition for our algorithms by recalling the Greedy algorithm and its analysis for the classic additive delay costs. Then, we describe the modifications required to prove that Greedy is 2-competitive for max-monotone and continuous submodular delay costs. Finally, we give an overview of our algorithmic framework for sum-monotone delays, where greedy strategies are no longer competitive, and outline the phase-based approach that overcomes this barrier, together with the accompanying logarithmic lower bound.

Recap: Additive Delay. The Greedy algorithm can be easily described as follows: send an acknowledgment when the total increase in its delay cost since the last acknowledgment equals 1 – the cost of an acknowledgment. For additive delays, this is equivalent to sending an acknowledgment when the total waiting time of unacknowledged requests since the last acknowledgment reaches 1. Let us now analyze the competitive ratio of Greedy for additive delays. Suppose Greedy makes k acknowledgments at times $t_1 < \ldots < t_k$, with batches $\sigma_1, \ldots, \sigma_k$. The analysis consists of two main components:

1. By design, Greedy's acknowledgment cost equals its delay cost, so its cost is exactly $2k$.
2. The optimal solution pays at least 1 during each of the k intervals $I_j = [t_{j-1}, t_j)$ for $j \in [k]$, where $t_0 = 0$. This is because with additive delays, if the optimal solution does not send an acknowledgment within the time interval I_j, then the packets in batch σ_i contribute $\text{delay}(\sigma_i, t)$ to its delay cost.

While the first component still holds for any monotone delay cost, the second component breaks for the delay costs that we consider.

Max-Monotone Delay. For max-monotone delays, we get that $\text{delay}(\sigma_j, t_j) = j$ and if the optimal solution does not send an acknowledgment during interval I_j, then the packets of σ_j were acknowledged together at some time $t_j^* \geq t_j$, and so by monotonicity of $\text{delay}(\cdot, \cdot)$, the delay cost of the optimal solution is at least j. Thus, if the optimal solution makes $k^* < k$ acknowledgments, its delay cost is at least $k - k^*$, and so its total cost is at least k.

Sum-Monotone Delay. For sum-monotone delay costs, greedy strategies are not competitive. We show that for any constant threshold, there exists an instance where a greedy algorithm incurs a cost that is $\Omega(n)$ times larger than that of the offline optimum. This fundamental limitation stems from the additive nature of the delay cost: greedy algorithms react too locally, failing to recognize when it would be better to wait and serve a larger group of packets with a single acknowledgment. For instance, if the delay function is concave and grows steadily up to the acknowledgment cost, and if the packets are spaced far enough apart, greedy will serve each packet individually – incurring an acknowledgment cost each time – while the optimal solution serves all at once at the last packet arrival, paying the delay cost only once and saving on acknowledgments.

To overcome this, we use our offline dynamic programming solution to guide online decisions. The key idea is to monitor the cost of the optimal solution on the packets seen so far. We partition the execution of the algorithm into consecutive *services*, each of which aggregates packets and ends with an acknowledgment. At the start of a service, we examine the sequence of packets observed so far and identify the longest suffix for which the offline optimum issues a single acknowledgment. The cost of optimally serving this suffix determines a *budget* for the service. The algorithm then continues to accumulate packets and issues an acknowledgment as soon as the total delay cost exceeds this budget. Thus, the service budget is derived directly from the structure of an optimal offline solution on the currently observed packets.

To avoid repeatedly issuing acknowledgments with small accumulated delay costs, each budget service is followed by three *buffer services* whose budgets are larger by a constant factor than that of the preceding budget service. These buffer services separate consecutive budget services and later allow us to analyze their costs independently. Throughout the execution, the algorithm continues to monitor newly observed suffixes. During a budget service, the arrival of any longer critical suffix triggers an update of the service budget, whereas during a buffer service, such an update occurs only if the offline cost of a suffix increases by a constant factor. This controlled budget growth ensures that the number of services grows only logarithmically, implying that the total cost incurred by the algorithm is within an $O(\log n)$ factor of the offline optimum.

Lower Bound for Sum-Monotone Delay. Observe that if the batch delay cost depends only on the maximum waiting time of the requests in the batch, then the offline problem essentially reduces to an interval covering problem, where we seek to cover the arrival times with intervals whose cost is a function of the interval length. Thus, it makes sense to consider the Parking Permit Problem [44], a generalization of the classic Ski Rental problem. In this problem, we are given different permit types and for each permit type k, its cost C_k and duration D_k. Purchasing permit k at time t covers the time up to $t + D_k$. Online, a sequence of requests over time, and for each requested time t, we need to ensure that it is covered by a purchased permit. A deterministic lower bound of $\Omega(\log n)$ is known for this problem [46].

Offline, it is straightforward to reduce Parking Permit to our problem, since both problems are interval covering problems in which the cost of an interval depends only on its length. However, it is unclear how to do the reduction online. Intuitively, we would like to use an algorithm for our problem to solve Parking Permit as follows: when a request arrives for Parking Permit at time t, we give the same request to the TCP Acknowledgment algorithm, see how long it waits before acknowledging the request, and buy a permit of the corresponding length. Unfortunately, at the time the request arrives, the TCP Acknowledgment algorithm does not need to commit to when it will acknowledge the request. Indeed, if the next request arrives immediately after, it may be acknowledged at a different time than if it arrives much later. We leave the possibility of an online reduction from Parking Permit to our problem as an open, tantalizing problem.

Fortunately, the deterministic adversarial sequence for Parking Permit ensures that the next requested time is later than all the permits the algorithm has purchased so far. Thus, when the Parking Permit request arrives at time t, we pass it to the TCP Acknowledgment algorithm and simulate it into the future to determine at what time t^* it would acknowledge the request, assuming no further requests, and purchase the corresponding permit that covers up to time t^*. Since the next Parking Permit request arrives after the permit expires, the next TCP Acknowledgment request also arrives after t^*. Since the TCP Acknowledgment algorithm is online and the actual request sequence up to time t^* matches the simulation, it also acknowledges at time t^*. Thus, the TCP Acknowledgment algorithm and the Parking Permit algorithm behave identically, yielding the desired lower bound.

Continuous Submodular Delay. The proof of Theorem 1.4 requires a more subtle analysis of Greedy. The second part of the greedy analysis for additive delays breaks down even when the continuous submodular delay cost is a concave function of the total waiting time. Intuitively, this is because the optimal solution can "front-load" its delay cost by acknowledging, e.g., the first few packets a long time after their arrival. This increases the delay cost, so later packets contribute only a small marginal amount to it. To address this, we consider a hypothetical

solution that produces the same acknowledgments as the optimal solution, but each packet's waiting time is capped at its waiting time in Greedy. Since f is monotone, capping the waiting times can only decrease the delay cost. Thus, the cost of the hypothetical solution is at most the cost of the optimal solution, so it suffices to prove a lower bound on the cost of the hypothetical solution. The capping prevents the hypothetical solution from front-loading its delay cost and enables us to argue that if it does not make an acknowledgment during interval I_j, then its delay cost increases by at least 1 during the interval.

2 Preliminaries

Problem Setup. We consider the *Online TCP Acknowledgment* problem. The input is a sequence of packet arrival times $A = (a_1, a_2, \ldots, a_n)$, where a_j is the time at which the j-th packet arrives, and we assume $a_1 \leq a_2 \leq \cdots \leq a_n$. An *online algorithm* must select acknowledgment times $t_1 < t_2 < \cdots < t_k$, such that every packet is acknowledged at or after arrival – that is, for each $1 \leq j \leq n$, there exists some $1 \leq i \leq k$ with $a_j \leq t_i$. Each acknowledgment t_i covers the batch $\sigma_i = \{\, j : t_{i-1} < a_j \leq t_i \,\}$, where we set $t_0 = 0$. These batches form a partition of the packet indices $\{1, \ldots, n\}$. Each packet $j \in \sigma_i$ experiences a *waiting time* (or *delay*) $d_j = t_i - a_j$, and we denote the full delay vector by $d = (d_1, \ldots, d_n)$. The goal is to minimize the total cost, which typically balances two competing objectives: reducing the number of acknowledgments and limiting the total incurred delay. The online nature of the problem is that, as time t increases, the algorithm is aware only of requests whose arrival time is at most t and can only make an acknowledgment at the current time t.

Batch-Aware TCP. The *Batch-Aware TCP* model defines the delay cost in terms of the individual acknowledgment batches. Let $\text{delay}(\sigma_i, t_i)$ denote the delay cost of acknowledging batch σ_i at time t_i. The total delay cost is then computed from the per-batch costs, thereby capturing richer dependencies between the acknowledgment structure and delay.

In this work, we focus on two important classes of batch-aware cost models. In the *sum-monotone delay* model, the total cost is given by $k + \sum_{i=1}^{k} \text{delay}(\sigma_i, t_i)$. Here, the function $\text{delay}(\cdot, \cdot)$ is required to be monotone non-decreasing: if one batch is a subsequence of another and the acknowledgment times are ordered accordingly, the delay cost cannot decrease. This model captures objectives in which the overall delay accumulates across batches and scales with the batch size or delay duration.

In the *max-monotone delay* model, the objective is $k + \max_{1 \leq i \leq k} \text{delay}(\sigma_i, t_i)$, where $\text{delay}(\cdot, \cdot)$ is any monotone non-decreasing function. Unlike the sum-based case, this model focuses on minimizing the worst per-batch delay contribution, which is natural in applications where fairness or tail performance is critical.

Batch-Oblivious TCP. In the *Batch-Oblivious TCP* model, the delay cost is defined globally over the entire delay vector d. Specifically, the delay cost is given by a function $f_n(d_1, \ldots, d_n)$, where $f_n : \mathbb{R}_+^n \to \mathbb{R}_+$ is assumed to be monotone and consistent under zero-padding. Since the number of packets n is not known in advance, we assume the algorithm learns the function f_i only when the ith packet arrives. These functions satisfy the consistency condition

$$f_{i+1}(d_1, \ldots, d_i, 0) = f_i(d_1, \ldots, d_i),$$

ensuring that appending a packet with zero delay does not affect the cost. A natural example of this model is total waiting time, where $f_n(d) = \sum_{j=1}^{n} d_j$. The overall objective in this setting is to minimize $k + f_n(d)$, where k denotes the number of acknowledgments. We refer to this setting as batch-oblivious because the delay cost treats all packet delays globally, regardless of which acknowledgment batch a packet belongs to.

3 Max-Monotone Delay Cost

We begin our investigation with the max-monotone delay model, where the total cost is given by the number of acknowledgments plus the maximum per-batch delay cost. We show that the natural greedy algorithm is 2-competitive.

▶ **Theorem 1.1.** *Greedy is a deterministic 2-competitive algorithm for TCP Acknowledgment with max-monotone delay cost.*

Proof. Recall that we assume the acknowledgment cost is normalized to 1. We analyze the natural greedy algorithm that sends an acknowledgment whenever the total cost increases by 1. Since we are in the max-monotone model, this is equivalent to acknowledging a batch of packets once its delay cost reaches the current batch index. For example, the algorithm sends the first acknowledgment when the currently pending packets accumulate delay cost 1, then the second when the pending batch reaches delay cost 2, and so on. In this way, each acknowledgment increases the total cost by exactly 1 from the delay, in addition to the unit cost of the acknowledgment.

Let t_j denote the time when the algorithm makes its j-th acknowledgment, and define the interval $T_j = (t_{j-1}, t_j]$, with $t_0 = 0$. Moreover, let σ_j be the batch of packets acknowledged at time t_j. By design, we have $\text{delay}(\sigma_j, t_j) = j$, since the algorithm waited until this batch's delay cost reached exactly j. Thus, the total cost of the algorithm is k from acknowledgments and $\max_{1 \le j \le k} \text{delay}(\sigma_j, t_j) = k$ from delay, totaling at most $2k$.

Denote by k^* the number of acknowledgments made by the optimal solution. We now argue that its total cost is at least k, which implies that the greedy algorithm is 2-competitive.

▷ Claim 3.1. If the optimal solution does not send an acknowledgment during interval T_j, then its delay cost is at least j.

Proof. Since no acknowledgment is made during T_j, all packets in σ_j must be acknowledged by the optimal solution in a later batch σ^*, sent at time $t^* \ge t_j$. Because $\text{delay}(\cdot, \cdot)$ is monotone non-decreasing in both batch size and acknowledgment time, it follows that $\text{delay}(\sigma^*, t^*) \ge \text{delay}(\sigma_j, t_j)$, which equals j, proving the claim. ◁

Suppose that the optimal solution makes k^* acknowledgments. If $k^* \ge k$, then we are done. Otherwise, Claim 3.1 implies that the delay cost of the optimal solution is at least $k - k^*$ (as the acknowledgments can be placed in the last k^* T_i intervals) and so the optimal solution has total cost at least k, as desired. ◀

4 Sum-Monotone Delay Cost

In this section, we focus on TCP acknowledgment under the sum-monotone delay-cost model. First, we prove that any deterministic greedy policy is $\Omega(n)$-competitive: there exists an input of size n that enforces the greedy algorithm to pay n-fold more than the offline optimum. We then turn to the offline problem and present a polynomial-time algorithm via dynamic programming, that computes an exact optimum schedule. By embedding this offline oracle into an online framework, we obtain a new algorithm with an $O(\log n)$ competitive ratio: at each decision point, it computes the offline optimum schedule for the set of all packets that have arrived so far and uses that schedule to guide its acknowledgments. Finally, we show that every deterministic algorithm is $\Omega(\log n)$-competitive.

4.1 Lower Bound for Greedy

We begin with a more precise statement of Theorem 1.2. Elsewhere in this paper, when we talk about the Greedy algorithm, we refer to the algorithm that sends an acknowledgment whenever $\text{delay}(\sigma, t) = 1$, where σ is the set of currently unacknowledged packets and t is the current time. Our lower bound holds for a family of greedy algorithms: for $\tau > 0$, algorithm Greedy_τ sends an acknowledgment when $\text{delay}(\sigma, t) = \tau$.

▶ **Theorem 4.1.** *For every $\tau > 0$, the algorithm Greedy_τ is $\Omega(n)$-competitive for TCP Acknowledgment with sum-monotone delay cost.*

Proof. Fix $\tau > 0$. Define the batch delay function $\text{delay}(\sigma, t) = \min\{\sum_{i\in\sigma} d_i, \tau\}$, where $d_i = a_i - t$. Consider the sequence of n packet with arrival times $a_i = i(\tau + \epsilon)$ for a small enough ϵ. Observe that Greedy_τ makes an acknowledgment exactly τ time steps after the arrival of each packet. Thus, Greedy_τ makes n acknowledgments and incurs a delay cost of $n\tau$ for a total cost $n(1 + \tau)$. On the other hand, the solution that waits to make a single acknowledgment at the arrival time of the last packet a_n has a total cost of at most $1 + \tau$. Thus, the competitive ratio of Greedy_τ is at least n. ◀

4.2 Offline Model

Solving the offline version of the TCP acknowledgment under the sum-monotone delay-cost model can be efficiently performed using dynamic programming. The general structure of the solution closely follows the approach used by Dooly et al. [29], though here we consider a general batch cost function $\text{delay}(\sigma, t)$, making our model a natural generalization of their framework.

Let σ be the given sequence of packets, and $\sigma|_i^j$ be its subsequence containing packets i through j. We define the subproblems for our dynamic programming solution as follows. Let $\text{DP}[i]$ denote the minimum total cost of acknowledging packets 1 through i, and set $\text{DP}[0] = 0$. Then, the optimal cost can be computed using the following recurrence relation:

$$\text{DP}[i] = \min_{1\le j\le i} \left\{\text{DP}[j-1] + \text{delay}\left(\sigma|_j^i, a_i\right) + 1\right\}.$$

Intuitively, at each step i, the algorithm evaluates all possible previous acknowledgment positions j and selects the one that minimizes the sum of the optimal cost up to $j - 1$, the delay cost $\text{delay}(\sigma|_j^i, a_i)$, and the acknowledgment cost 1.

The correctness of this approach follows directly from the optimal substructure property: an optimal partitioning of packets into acknowledged subsequences necessarily implies that each of these subsequences itself must be an optimal solution to the corresponding subproblems. The computational complexity of this method is $O(n^2)$, since evaluating each $\text{DP}[i]$ involves examining $O(n)$ previous acknowledgment points, and we have n such subproblems.

4.3 Online Model

Using the offline result from the previous subsection, we now prove the following lemma.

▶ **Lemma 4.2.** *There is a deterministic $O(\log n)$-competitive algorithm for TCP Acknowledgment with sum-monotone delay cost.*

The key idea is to use the cost of the optimal offline solution on the sequence of packets seen so far to guide when our algorithm issues acknowledgments. Suppose the j-th packet arrives and there are no pending packets; we then start a new *budget service s*. Let $\sigma|^j$ denote

the sequence of the first j packets observed so far.[4] We first identify the longest *critical suffix* of $\sigma|^j$, that is, a suffix $\sigma_s \subseteq \sigma|^j$ such that the optimal offline strategy for σ_s consists of issuing a single acknowledgment exactly at the arrival time of its last packet. Observe that at least one such suffix always exists, namely the one containing only packet j. Moreover, notice that for a critical suffix σ_s, the optimal cost of serving it equals $\text{delay}(\sigma_s, a_j) + 1$. To simplify notation, we define $\text{serve}(\sigma_s, a_j) = \text{delay}(\sigma_s, a_j) + 1$. Whenever an acknowledgment is issued at the arrival time of the last packet in the suffix, we omit the second argument and write $\text{serve}(\sigma_s)$.

Based on σ_s, we define a budget b_s for service s (its precise definition will be given later). The service s then aggregates arriving packets and issues an acknowledgment as soon as their total accumulated delay cost reaches b_s; we refer to this moment as the *critical time* of service s. If, during the aggregation phase of a budget service, a new packet arrives, we again compute the longest critical suffix $\sigma' \subseteq \sigma|^j$. If σ' strictly extends σ_s (that is, if it starts earlier than σ_s), we update the budget b_s accordingly to reflect the increased cost suggested by the offline optimum.

When a budget service s finally issues its acknowledgment, the algorithm schedules three consecutive *buffer services*, each with a budget equal to twice the budget of s. Each buffer service aggregates packets and acknowledges them as soon as their delay cost reaches its assigned budget, and this process is repeated three times.[5] During a buffer service, if a packet arrives that induces a critical suffix whose cost is at least twice the cost of σ_s, then the current service is immediately promoted to a new budget service, with its budget defined accordingly.

Assigning exponentially larger budgets to buffer services prevents the algorithm from issuing many low-cost acknowledgments in situations where the offline optimum would issue a single high-cost acknowledgment. By scaling service budgets exponentially in response to increasing costs of critical suffixes, the algorithm ensures that its total cost increases only logarithmically relative to the optimal offline cost, yielding an $O(\log n)$ competitive ratio.

In what follows, we use $\texttt{OPT}(\sigma_s)$ to denote the cost of the optimal offline solution for batch σ_s.

4.3.1 Algorithm Description

We begin by formalizing the notion of *critical batches*, which correspond to the critical suffixes discussed earlier and will play a central role in the design and analysis of our algorithm.

▶ **Definition 4.3** (Critical Batch). *We call batch* σ critical *if it satisfies* $\texttt{OPT}(\sigma) = \text{serve}(\sigma)$.

We are now ready to present Algorithm 1. This algorithm is structured around two event-driven functions: "UponArrival", which is triggered whenever a new packet arrives, and "UponCriticalTime", which is triggered when a precomputed critical time is reached. Together, these functions manage the scheduling of acknowledgments based on the observed input structure.

When a packet arrives, the `UponArrival` appends it to the already-seen packets sequence and finds the largest critical suffix. Then, depending on whether there is a service running and if so – of what type it is – we possibly update the budget of the service (and its type, as in line 11). Notice that line 13 sets the critical time t_c so that acknowledging all currently

[4] Here we slightly overload notation: earlier, $\sigma|^j$ denoted the j-th batch served by the algorithm.
[5] The purpose of these buffer services is to separate consecutive budget services and simplify the analysis.

Algorithm 1 Sum-Monotone TCP Algorithm.

Initialization: sequence of already seen packets $\sigma = []$, critical time $t_c = 0$, critical batch $\sigma_c = []$ and budget b

Function UponArrival(r):

1: put r at the end of σ
2: let σ' be the largest critical suffix
3: **if** there is no service running, i.e., σ_c is empty **then** ▷ start a buffer service
4: $\sigma_c = \sigma'$
5: **else if** there is a budget service running **then**
6: **if** $\sigma_c \subseteq \sigma'$ **then** ▷ check if the current critical suffix is a larger
7: $\sigma_c = \sigma'$ ▷ if so, update the critical batch
8: **else if** there is a buffer service running **then**
9: **if** $\text{serve}(\sigma') \geq 2 \cdot \text{serve}(\sigma_c)$ **then** ▷ check whether the critical suffix is large enough
10: $\sigma_c = \sigma'$ ▷ if so, update the critical batch
11: switch the current service to a budget service
12: $b = 2 \cdot \text{serve}(\sigma_c)$ ▷ update the critical batch
13: let t_c be such that $\text{serve}(\text{pending packets}, t_c) = b$ ▷ update the critical time

Function UponCriticalTime(): ▷ called when t_c is reached

1: make an acknowledgment
2: **if** the budget service ended **then**
3: start a new buffer service and double the budget $b \leftarrow 2b$
4: **else if** the first or second buffer service ended **then**
5: start a consecutive buffer service
6: **else if** the third buffer service ended **then**
7: $\sigma_c = []$, $b = 0$ ▷ reset the variables

pending packets at time t_c will incur a delay cost exactly equal to the budget b. If this cost never reaches b, we assume $t_c = \infty$, meaning the current service will conclude only at the end of the input sequence.

The `UponCriticalTime` function is called when t_c is reached. It performs an acknowledgment and issues a new service, or resets the state if all buffer services have completed.

4.3.2 Critical Batches and Relations Between Them

We begin by introducing some notation. Suppose that Algorithm 1 issues k acknowledgments for budget services over a sequence of n requests. We denote the corresponding critical batches by σ_c^i for $i \in \{1, 2, \ldots, k\}$. Each critical batch may be followed by up to three buffer services. We denote by $\sigma_{b,l}^i$, for $l \in \{1, 2, 3\}$, the sequences of packets acknowledged by these services. If a particular buffer service is not started, we define the corresponding batch to be the empty sequence.

▶ **Definition 4.4** (Critical Batch Intersection). *We say that the critical batch σ_c^j* intersects *σ_c^i, $i < j$, if*

(1) *$j = i + 1$ and the budget service corresponding to σ_c^j was started in line 11 of the `UponArrival` function in Algorithm 1, or*

(2) $\sigma^i_{b,2}$ *and* $\sigma^i_{b,3}$ *are both not empty, while* σ^j_c *and* $\sigma^i_{b,2}$ *share at least one packet, that is,* $\sigma^j_c \cap \sigma^i_{b,2} \neq \emptyset$.

When using set-theoretic notation, we implicitly identify a sequence with the set of packets it contains.

Understanding how critical batches intersect is key to analyzing the proposed algorithm. To make our reasoning simpler, we introduce a few new terms to describe this relation.

▶ **Definition 4.5** (Parent Batch). *Given a critical batch* σ^i_c*, we define the set* $\texttt{children}(\sigma^i_c)$ *to consist of all earlier critical batches that* σ^i_c *intersects and for which* σ^i_c *is the first subsequent critical batch to do so. For each batch* $\sigma^j_c \in \texttt{children}(\sigma^i_c)$*, we refer to* σ^i_c *as its* parent batch*. We use the terms* ancestor *and* descendant *to denote the transitive closure of this relation.*

▶ **Definition 4.6** (Final Critical Batch). *We call a batch with no parent a* final critical batch.

In what follows, we also use the following notation for the pivotal packet arrival times. We use t^i_s and t^i_c to denote the first and the last packet's arrival times in σ^i_c. Moreover, if σ^i_c is a parent batch, we let σ^i_e be its descendant that was acknowledged the earliest, and let t^i_e be the arrival of the first packet in σ^i_e.

▶ **Definition 4.7** (Coverage Interval). *Given a critical batch* σ^i_c*, we define its* coverage interval *as follows. If* σ^i_c *has no children, then its coverage interval is* $[t^i_s, t^i_b]$*; otherwise, it is* $[t^i_e, t^i_b]$*. We denote this interval by* I^i_c*. When convenient, we also use* I^i_c *to denote the set of packets arriving within this time interval.*

4.3.3 Analysis

Let us start by showing how final critical batches relate to the optimal cost of serving packets.

▶ **Lemma 4.8.** *Let* $\sigma^1_c, \ldots, \sigma^\ell_c$ *be a sequence of final critical batches obtained during a run of Algorithm 1 on a packet sequence* $\hat{\sigma}$*. We assume that they are listed in the order in which the corresponding budget services were issued, and that the list contains all such batches. Then, it holds that*

$$\texttt{OPT}\left(\hat{\sigma}\right) \geq \sum_{i=1}^{\ell} \texttt{OPT}\left(I^i_c\right).$$

Proof. Let $\hat{\sigma}_1, \ldots, \hat{\sigma}_p$ denote the partition of $\hat{\sigma}$ induced by the optimal solution, where each $\hat{\sigma}_i$ corresponds to a single acknowledgment. By definition, each $\hat{\sigma}_i$ forms a critical batch and therefore must be recognized by Algorithm 1.

Suppose that for some $j \in \{1, \ldots, p\}$, the batch $\hat{\sigma}_j$ overlaps with at least two coverage intervals corresponding to the final critical batches identified by the algorithm. Let σ^k_c, for some $k \in \{1, \ldots, \ell\}$, be the latest such critical batch, and let $\hat{j}$ denote the last packet in $\hat{\sigma}_j$. Finally, let $\sigma^{k,j}_c$ be the largest critical batch among σ^k_c and its descendants such that $\hat{j}$ belongs to one of the services associated with this batch.

If $\hat{j}$ is served by the budget service associated with $\sigma^{k,j}_c$, then at the moment $\hat{j}$ arrives, the `UponArrival` function would recognize $\hat{\sigma}_j$ in either line 4 or 7 and act upon it. Otherwise, if $\hat{j}$ is served by a buffer service, it would trigger the start of a new budget service in line 11. Indeed, since $\hat{\sigma}_j$ overlaps with all packets acknowledged by the budget service corresponding to $\sigma^{k,j}_c$, its service cost exceeds $2 \cdot \text{serve}(\sigma^{k,j}_c)$, as stated in line 12, and thus the condition in line 9 is satisfied.

Therefore, no batch served by the optimal solution can overlap with more than one coverage interval. Consequently, for each coverage interval I_c^i, we consider the set of all batches $\hat{\sigma}_j$ that overlap with it. This set covers at least as many packets as I_c^i, and hence its total cost is at least $\texttt{OPT}(I_c^i)$. Since each batch $\hat{\sigma}_j$ is counted at most once, the desired inequality follows. ◀

From there, we obtain two straightforward properties.

▶ **Corollary 4.9.** *The total cost of* OPT *on a given sequence of packets σ is at least equal to the sum of the optimal costs of serving coverage intervals of all the final critical batches recognized during the run of Algorithm 1 on σ.*

▶ **Corollary 4.10.** *For any critical batch with children, the optimal cost of serving its coverage interval is at least the sum of the children's critical interval optimal serving costs.*

Now, observe that also the following holds for any critical batch with children.

▶ **Lemma 4.11.** *Let σ_c^i be a critical batch such that* $\texttt{children}(\sigma_c^i) \neq \emptyset$*. Then, for any child batch σ_c^j, we have* $\text{serve}(\sigma_c^i) \geq 2 \cdot \text{serve}(\sigma_c^j)$.

Proof. Since σ_c^i is a parent of σ_c^j, Definition 4.5 implies that σ_c^i intersects σ_c^j. Therefore, one of the two conditions in Definition 4.4 – namely, 1 or 2 – must hold.

We first consider condition 1. In this case, we have $j = i + 1$, and the budget service corresponding to σ_c^j is initiated in line 11 of the `UponArrival` function by some critical suffix σ'. Consequently, the condition in line 9 holds, which implies that $\text{serve}(\sigma') \geq 2 \cdot \text{serve}(\sigma_c^i)$. Since $\sigma' \subseteq \sigma_c^j$ (as σ' may have been extended in line 6 to become σ_c^i), the claimed inequality follows.

We now turn to condition 2. In this case, both $\sigma_{b,2}^i$ and $\sigma_{b,3}^i$ are non-empty, and σ_c^j shares at least one packet with $\sigma_{b,2}^i$, that is, $\sigma_c^j \cap \sigma_{b,2}^i \neq \emptyset$. Since σ_c^j overlaps with $\sigma_{b,2}^i$, it must also cover $\sigma_{b,3}^i$, which immediately follows $\sigma_{b,2}^i$. As $\sigma_{b,3}^i \neq \emptyset$, its service cost satisfies $\text{serve}(\sigma_{b,3}^i) = 2 \cdot 2 \cdot \text{serve}(\sigma_c^i)$, by lines 3 of the `UponCriticalTime` function and 12 of the `UponArrival` function. Hence, $\text{serve}(\sigma_c^j) \geq \text{serve}(\sigma_{b,3}^i) = 4 \cdot \text{serve}(\sigma_c^i)$, and the desired inequality also holds in this case. ◀

▶ **Lemma 4.12.** *The budget service associated with the critical batch σ_c^i incurs a cost of $2 \cdot \text{serve}(\sigma_c^i)$, while each buffer service associated with σ_c^i incurs a cost of at most $4 \cdot \text{serve}(\sigma_c^i)$.*

Proof. By the definition of the algorithm. ◀

▶ **Lemma 4.13.** *Every final critical batch σ_c^i has at most $\log(\texttt{OPT}(I_c^i)) \leq \log n$ levels of descendant sets.*

Proof. By Lemma 4.11, each child batch has a cost at least twice that of the parent. Since the minimum cost is 1 (the acknowledgment cost), the first property follows. To observe the upper bound on this value, notice that one of the possible solutions is to acknowledge each packet individually, and thus $\texttt{OPT}(I_c^i) \leq n$. ◀

Combining the above lemmas gives us Lemma 4.2. Indeed, by Lemma 4.13 and a recursive application of Corollary 4.10, we have that the sum of optimal costs for all the critical batches processed by our algorithm (i.e., those for which a service was issued) is at most equal to $\log n \cdot \sum_{i=1}^{\ell} \texttt{OPT}(I_c^i)$. Thus, by Lemma 4.12, the algorithm paid at most $14 \log n \cdot \sum_{i=1}^{\ell} \texttt{OPT}(I_c^i)$ to serve all the packets. The lower bound on optimal cost from Corollary 4.9 completes the proof.

4.4 Lower Bounds for Arbitrary Algorithms

We show that the deterministic $O(\log n)$ competitive ratio of our algorithm (Algorithm 1) is tight. We start by defining the Parking Permit Problem [44]. It is known that for every deterministic algorithm $\mathcal{B}$ for Parking Permit, there is an adversarial request sequence A on which $\mathcal{B}$ is $\Omega(\log n)$-competitive (Lemma 4.14 [46]). Then, we show how to convert any deterministic algorithm $\mathcal{A}$ for TCP Acknowledgment into a deterministic algorithm $\mathcal{B}_{\mathcal{A}}$ for Parking Permit. Finally, we show that $\mathcal{A}$ is $\Omega(\log n)$-competitive on the adversarial sequence for $\mathcal{B}_{\mathcal{A}}$ (Lemma 4.17).

Parking Permit Problem [44]. An instance of the Parking Permit Problem. For each timestep $t \geq 1$, a request may arrive, and if so, needs to be covered by a permit. There are several different types of permits that can be purchased at any time throughout the time horizon. A permit of type $k \geq 0$ has cost C_k and duration D_k: when bought at time t, it covers the time interval $[t, t + D_k]$. The goal is to minimize the cost of the purchased permits.

Hard Parking Permit instances. A *hard Parking Permit instance* is one where $C_k = 2^k$ and $D_k = 4^k$ for each $k \geq 0$.

▶ **Lemma 4.14** ([46]). *Let $\mathcal{B}$ be a deterministic online algorithm for Parking Permit. Consider a hard Parking Permit instance where the sequence of request arrival times A is generated by the following adversary: for each $1 \leq j \leq n$ (in ascending order), request j arrives at the earliest timestep that is not yet covered by the permits bought by $\mathcal{B}$.*

When run on A, algorithm $\mathcal{B}$

- *buys a separate permit $[a_j, t_j]$ for each request j; moreover, $a_{j+1} = t_j + 1$ for each $j < n$;*
- *has competitive ratio $\Omega(\log n)$.*[6]

Hard TCP Acknowledgment instances. We now define the corresponding TCP Acknowledgment instances. Define the piecewise-linear concave function $f(x) = \min_{k \geq 0} C_k + x \cdot (C_k/D_k)$ where C_k and D_k are defined as above. A *hard TCP Acknowledgment instance* is one in which the total cost of a batch σ acknowledged at time t – i.e., sum of the acknowledgment cost[7] and the delay cost of the batch $\text{delay}(\sigma, t)$ – is given by $f(t - a(\sigma))$ where $a(\sigma)$ is the earliest arrival time among the packets in σ. That is, $\text{delay}(\sigma, t) = f(t - a(\sigma)) - 1$.

Converting TCP Acknowledgment algorithm to Parking Permit. Observe that a hard Parking Permit instance with arrival sequence A has a corresponding hard TCP Acknowledgment instance with the same arrival sequence. Our goal now is to show how to map decisions of a TCP Acknowledgment algorithm on the corresponding instance into decisions for the Parking Permit instance. We begin by presenting the two necessary ingredients.

First, we need to decide which permit to buy when a request arrives even though the TCP Acknowledgment algorithm is not required to commit on arrival of a request, when the request will be acknowledged. For a sequence A, let A_j denote the subsequence containing the first j elements. The following lemma, together with Proposition 4.16, lets us decide which permit to buy on arrival of a request.

[6] We remark that the Parking Permit Problem is typically defined as having a time horizon $[1, N]$ (on which n requests arrive) and Lemma 21 of [46] gives a lower bound of $\Omega(\log N)$. Since $N \geq n$, we get a lower bound of $\Omega(\log n)$.

[7] Recall that the acknowledgment cost is 1.

▶ **Lemma 4.15.** *Let $\mathcal{A}$ be a deterministic online algorithm for TCP Acknowledgment. Then, there exists a function* next *such that for every sequence of packet arrival times $A = (a_1, \ldots, a_n)$ and for every j, if $a_{j+1} > \text{next}(A_j)$, then packet j is acknowledged at time $\text{next}(A)$. The function* next *is called the* threshold function *of $\mathcal{A}$.*

Proof. Fix a sequence A and $1 \leq j \leq n$. Define $\text{next}(A_j) \geq a_j$ to be the time that $\mathcal{A}$ acknowledges the last packet of A_j when $\mathcal{A}$ is run on A_j. If $a_{j+1} > \text{next}(A_j)$, then up till time $\text{next}(A_j)$, the executions of $\mathcal{A}$ on A_j and of $\mathcal{A}$ on A see the same information. Since $\mathcal{A}$ is an online algorithm, the execution of $\mathcal{A}$ on A will also acknowledge at time $\text{next}(A_j)$. ◀

Second, we need to be able to map batches to permits. In general, the time between when a batch is acknowledged and the earliest arrival time of the batch can be arbitrary, while permits can only have lengths $D_k = 4^k$. The following lets us approximately map batches to permits.

▶ **Proposition 4.16.** *For every $x \geq 0$, there exists $k^* \geq 0$ such that $D_{k^*} \geq x$ and $C_{k^*} \leq 2f(x)$.*

Proof. Suppose $f(x) = C_k + x(C_k/D_k)$. If $x < D_k$, then $f(x) \geq C_k$ so choosing $k^* = k$ works. Next, we consider the case when $x > D_k$. Let $k^* > k$ be such that $D_{k^*-1} \leq x \leq D_{k^*}$. Observe that $C_k/D_k = (1/2)^k \leq (1/2)^{k^*-1} = C_{k^*-1}/D_{k^*-1}$. Together with the fact that $x \geq D_{k^*-1}$, we have

$$f(x) \geq x(C_k/D_k) \geq D_{k^*-1}(C_{k^*-1}/D_{k^*-1}) = C_{k^*-1} = C_{k^*}/2,$$

as desired. ◀

We now have the ingredients to convert any deterministic algorithm $\mathcal{A}$ for hard TCP Acknowledgment instances to a deterministic algorithm $\mathcal{B}_\mathcal{A}$ for hard Parking Permit instances. Let $\text{next}(\cdot)$ be the threshold function of $\mathcal{A}$. The algorithm $\mathcal{B}_\mathcal{A}$ works as follows. For each request arrival a_j that is not covered by permits bought so far:

(1) let A_j be the sequence of arrival times so far, including a_j;
(2) let k^* be such that $D_{k^*} \geq x$ and $f(D_{k^*}) \leq 2f(\text{next}(A_j) - a_j)$ as guaranteed by Proposition 4.16;
(3) buy permit $[a_j, a_j + D_{k^*}]$.

▶ **Lemma 4.17.** *Let $\mathcal{A}$ be a deterministic algorithm for hard TCP Acknowledgment instances and A^* be the adversarial sequence for $\mathcal{B}_\mathcal{A}$ given by Lemma 4.14. Then, $\mathcal{A}$ is $\Omega(\log n)$-competitive on A^*.*

Proof. Let $\texttt{OPT}_{\text{PP}}(A^*)$ and $\texttt{OPT}_{\text{TCP}}(A^*)$ be the cost of the optimal Parking Permit and TCP Acknowledgment solutions to A^*, respectively. Since Lemma 4.14 already shows that $\mathcal{B}_\mathcal{A}$ is $\Omega(\log n)$-competitive on A^*, it suffices to show the cost of $\mathcal{A}$ on A^* is at least $\Omega(1)$ times the cost of $\mathcal{B}_\mathcal{A}$ on A^*, and that $\texttt{OPT}_{\text{TCP}}(A^*) = O(1)\texttt{OPT}_{\text{PP}}(A^*)$.

By Lemma 4.14 and by definition of $\mathcal{B}_\mathcal{A}$, for every $j < n$, we have that $a_{j+1} > a_j + D_{k^*} \geq \text{next}(A_j)$. Thus, for each request j, Lemma 4.15 implies that $\mathcal{A}$ acknowledges j by itself at time $\text{next}(A_j)$ and the total cost of the batch is $f(\text{next}(A_j) - a_j))$; on the other hand, $\mathcal{B}_\mathcal{A}$ buys permit $[a_j, a_j + D_{k^*}]$ of cost $C_{k^*} \leq 2f(\text{next}(A_j) - a_j)$. Thus, the cost of $\mathcal{A}$ on A^* is at least $1/2$ the cost of $\mathcal{B}_\mathcal{A}$ on A^*.

Next, we show that $\texttt{OPT}_{\text{TCP}}(A^*) = O(1)\texttt{OPT}_{\text{PP}}(A^*)$. Let $P_i = [s_i, t_i]$ be the i-th permit bought by the optimal solution for the hard instance of Parking Permit with arrival sequence A. We construct a solution to the hard TCP Acknowledgment instance as follows: while there is an unacknowledged packet, let a_j be the earliest unacknowledged packet and send an acknowledgment at time t where t is the furthest end time among all permits covering a_j (at least one such permit exists since the permits have to cover A).

We now argue that we can charge the total cost of each batch to a unique permit. For each batch σ_i acknowledged at time t_i, let $P_{(i)}$ be the permit that covers $a(\sigma_i)$ and has end time t_i. Since $P_{(i)}$ is the permit with the furthest end time, we have that $P_{(i')} \neq P_{(i)}$ for $i' \neq i$. Let $C_{(i)}$ and $D_{(i)}$ be the cost and duration of $P_{(i)}$. Since $a(\sigma_i) \in P_{(i)}$, we get that the total cost of σ_i is $f(t_i - a(\sigma_i)) \leq f(D_{(i)}) = 2C_{(i)}$. Thus the cost of each batch σ_i is charged to at most twice the cost of permit $P_{(i)}$, and each permit is charged by at most one batch. Thus, we have shown that $\texttt{OPT}_{\text{TCP}}(A^*) = O(1)\texttt{OPT}_{\text{PP}}(A^*)$, completing the proof of the lemma. ◀

Thus, we conclude that every deterministic algorithm for TCP Acknowledgment with sum-monotone delay costs is $\Omega(\log n)$-competitive, as desired. This also completes the proof of Theorem 1.3.

5 Batch-Oblivious Delay Costs

We now turn to the batch-oblivious model, where the delay cost is defined globally over the vector of packet delays, without reference to how packets are grouped in acknowledgments. Formally, the objective is to minimize $k + f(d)$, where k is the number of acknowledgments, $f : \mathbb{R}_+^n \to \mathbb{R}_+$ is a monotone delay function, and $d = (d_1, \ldots, d_n)$ is the vector of waiting times, where d_i denotes how long packet i waits before being acknowledged. The function f is revealed incrementally as packets arrive. While this framework captures natural objectives such as total waiting time, it also includes more general functions, such as concave or submodular delay costs. As discussed earlier, greedy algorithms that succeed for additive delay fail in these settings, due to the ability of the optimal solution to concentrate delay on a few early packets and reduce marginal costs for the rest. A formal lower bound for concave delay functions is provided in Section 5.1. Here, we focus on broader classes of delay functions, including submodular functions and norms.

5.1 Concave Delay Cost

▶ **Theorem 1.6.** *Every deterministic algorithm is $\Omega(\sqrt{n})$-competitive for TCP Acknowledgment with batch-oblivious concave delay cost.*

Proof. Let $\ell \leq n/2$ and $\epsilon \in [0, 1]$ be parameters that will be set later. Define $x, y \in \mathbb{R}^n$ such that: each of the first ℓ coordinates of x is ϵ and each of the remaining coordinates is 1; each of the first ℓ coordinates of y is n/ℓ and each of the remaining is ϵ. Given a waiting time vector d, define $d_{\leq \ell} = \sum_{i \leq \ell} d_i$ and $d_{>\ell} = \sum_{i>\ell} d_i$. We now define the delay function

$$f(d) = \min\{d \cdot x, d \cdot y\} = \min\left\{\epsilon d_{\leq \ell} + d_{>\ell}, \frac{n}{\ell} d_{\leq \ell} + \epsilon d_{>\ell}\right\}.$$

Note that the function f is concave as it is the point-wise minimum of linear functions.

The adversary proceeds as follows. For the first ℓ packets, it releases packet i at time i. Let A_ℓ be the number of packets made by the algorithm just before time $\ell + 1$. If $A_\ell \geq \ell/2$ (case 1), it releases the remaining $n - \ell$ packets together at time $\ell + 1$; otherwise (case 2), it continues releasing each remaining packet i at time i.

We now show that in both cases, the adversary can construct a significantly cheaper solution. Consider case 1: the algorithm incurs a cost of at least $\ell/2$. Meanwhile, the adversary can use a single acknowledgment at time $\ell + 1$. Let d^* denote the resulting waiting time vector, where $d_i^* = \ell + 1 - i$ for $i \leq \ell$, and $d_i^* = 0$ for $i > \ell$. The delay cost of this solution is at most $f(d^*) \leq \epsilon \sum_{i=1}^{\ell} i = O(\ell^2 \epsilon)$, and the total cost is $1 + O(\ell^2 \epsilon)$. Therefore, the competitive ratio of the algorithm is $\Omega\big(\min\{\ell, 1/(\ell\epsilon)\}\big)$ in this case.

Next, we consider case 2. Let k denote the total number of acknowledgments made by the algorithm. Without loss of generality, we may assume that each acknowledgment occurs at the arrival time of some packet, as this can only reduce the total cost. Recall that in this case, packets arrive at unit times $1, 2, \ldots, n$. Thus, for any time interval starting at a packet arrival, the number of acknowledgments made during the interval plus the total waiting time incurred by the packets arriving within it must be at least the length of the interval. This is because the acknowledgment cost is 1, so each acknowledgment can "pay for" at most one unit of waiting time.

Now, consider the first ℓ packets. By assumption, the algorithm makes $A_\ell < \ell/2$ acknowledgments during this interval. From our previous observation, it follows that the total delay incurred by these packets is at least $\ell - A_\ell > \ell/2$. Thus, we obtain that $d \cdot y \geq (n/\ell) \cdot (\ell/2) = \Omega(n)$. On the other hand, consider only the remaining $n - \ell$ packets. Here, the number of acknowledgments and the overall waiting time sum up to $(k - A_\ell) + d_{>\ell}$. As noted above, this sum must be at least the length of the interval $(\ell, n]$, which is greater than $n/2$, since $\ell < n/2$. Hence, we have $k + d \cdot x \geq (k - A_\ell) + d_{>\ell} = \Omega(n)$. Thus, the total cost of the algorithm satisfies $k + \min\{d \cdot x, d \cdot y\} \geq \Omega(n)$.

On the other hand, consider the solution that acknowledges each of the first ℓ packets on arrival and makes one acknowledgment at the end at time n. Let d^* be its waiting time vector. Then, it holds that $f(d^*) \leq d^* \cdot y = \epsilon d_{>\ell} \leq O(n^2\epsilon)$ and so the solution has total cost $\ell + O(n^2\epsilon)$. Thus, the competitive ratio is $\Omega(\min\{n/\ell, 1/(n\epsilon)\})$ in this case.

Setting $\ell = \lceil \sqrt{n} \rceil$ and $\epsilon = 1/n^2$ gives the theorem. ◀

5.2 Submodular Delay Cost and Norms

We begin by defining continuous submodularity.

▶ **Definition 5.1** (Continuous submodular functions). *A function $f : \mathbb{R}^n_+ \to \mathbb{R}_+$ is* continuous submodular *if for every $x, y \in \mathbb{R}^n$, it satisfies $f(x \vee y) + f(x \wedge y) \leq f(x) + f(y)$, where $\vee$ denotes coordinate-wise maximum and $\wedge$ denotes coordinate-wise minimum.*

We remark that, unlike the case of discrete submodular functions, continuous submodularity is only equivalent to a weaker notion of diminishing marginals: for every $x, y \in \mathbb{R}^n_+$ such that $x \leq y$, $i \in [n]$ such that $x_i = y_i$ and $a \geq 0$, we have $f(x + ae_i) - f(x) \geq f(y + ae_i) - f(y)$, where e_i is the i-th standard basis vector. We refer the reader to [47, Remark 7 and Appendix A.1] for further discussion on this topic.

In fact, our analysis only uses an even weaker condition, where the diminishing-marginals property is required only when the coordinate being increased is zero in both vectors. We say that f satisfies *zero-coordinate diminishing marginals* if for every $x, y \in \mathbb{R}^n_+$ such that $x \leq y$, every $i \in [n]$ such that $x_i = y_i = 0$, and every $a \geq 0$, we have $f(x + ae_i) - f(x) \geq f(y + ae_i) - f(y)$. Clearly, continuous submodularity implies this condition.

For a vector $\Delta \in \mathbb{R}^n_+$, let $\mathrm{supp}(\Delta) = \{i \in [n] : \Delta_i > 0\}$. We will use the following simple observation.

▶ **Observation 5.2.** *Suppose that f satisfies zero-coordinate diminishing marginals. Let $u, v, \Delta \in \mathbb{R}^n_+$ be such that $u \leq v$ and $u_i = v_i = 0$ for every $i \in \mathrm{supp}(\Delta)$. Then*

$$f(u + \Delta) - f(u) \geq f(v + \Delta) - f(v).$$

Indeed, one can add the coordinates in $\mathrm{supp}(\Delta)$ one at a time. Before each coordinate is added, it is still zero in both the smaller and the larger vector, so zero-coordinate diminishing marginals apply. Summing these inequalities over all coordinates in $\mathrm{supp}(\Delta)$ gives the desired inequality.

▶ **Theorem 1.4.** *Greedy is a deterministic 2-competitive algorithm for TCP Acknowledgment with batch-oblivious continuous submodular delay cost.*

Proof. Recall that Greedy makes an acknowledgment whenever its delay cost increases by 1. We now analyze the competitive ratio of the algorithm. First, observe that by construction, the cost of the algorithm is at most twice the number of acknowledgments. Let k be the number of acknowledgments made by the algorithm. Fix an optimal solution. In the rest of the proof, we argue that its cost is at least k.

Let t_j be the time when the algorithm made its j-th acknowledgment, and define $T_j = (t_{j-1}, t_j]$ with $t_0 = 0$. For each packet i, let $d_i(j)$ and $d_i^*(j)$ be the amount of waiting time that packet i incurred up till t_j in the algorithm's solution and the optimal solution, respectively. If packet i arrived after t_j, we define $d_i(j)$ and $d_i^*(j)$ to be both 0.

At a high level, we adopt the proof framework of [29] for the standard TCP Acknowledgment setting and generalize it to our case: within each interval T_j, the optimal solution either issues an acknowledgment and pays a cost of 1 or its delay cost increases by at least 1. However, if the optimal solution allows earlier packets to wait a long time, it can effectively "front-load" its delay cost, which causes the marginal cost in later intervals to be too small. To address this, we introduce a capped version of the optimal delay vector, denoted $\bar{d}$, where each entry is defined as $\bar{d}_i(j) = \min\{d_i^*(j), d_i(j)\}$. In what follows, we use $d(j)$ and $\bar{d}(j)$ to denote the vectors $(d_1(j), \ldots, d_n(j))$ and $(\bar{d}_1(j), \ldots, \bar{d}_n(j))$, respectively. By monotonicity, the optimal solution's delay cost $f(d^*) \geq f(\bar{d})$ and so it suffices to show that if the optimal solution makes no acknowledgment in T_j, then the increase in the delay cost of the capped optimal delay vector in T_j is $f(\bar{d}(j)) - f(\bar{d}(j-1)) \geq 1$.

▷ Claim 5.3. For each interval T_j, if the optimal solution did not make an acknowledgment in T_j, then

$$f(\bar{d}(j)) - f(\bar{d}(j-1)) \geq f(d(j)) - f(d(j-1)) = 1.$$

Proof. The equality follows from the fact that $f(d(j)) - f(d(j-1))$ is the increase in the algorithm's delay cost during interval T_j, and the algorithm makes an acknowledgment exactly when its delay cost increases by 1 since the last acknowledgment.

It remains to prove the inequality. Let $\Delta^j = d(j) - d(j-1)$ be the increase in the algorithm's delay vector during interval T_j. Since the algorithm acknowledged all pending packets at time t_{j-1}, the only packets whose delay can increase during T_j are the packets that arrive during T_j. Hence, for every $i \in \mathrm{supp}(\Delta^j)$, we have $d_i(j-1) = 0$. Moreover, by the definition of the capped vector, $\bar{d}_i(j-1) = 0$. We also have $\bar{d}(j-1) \leq d(j-1)$. Therefore, applying Observation 5.2 with $u = \bar{d}(j-1)$, $v = d(j-1)$, and $\Delta = \Delta^j$, we get

$$f(\bar{d}(j-1) + \Delta^j) - f(\bar{d}(j-1)) \geq f(d(j-1) + \Delta^j) - f(d(j-1)).$$

Since $d(j-1) + \Delta^j = d(j)$, this gives

$$f(\bar{d}(j-1) + \Delta^j) - f(\bar{d}(j-1)) \geq f(d(j)) - f(d(j-1)). \tag{2}$$

It remains to compare $\bar{d}(j-1) + \Delta^j$ with $\bar{d}(j)$. We claim that $\bar{d}(j-1) + \Delta^j \leq \bar{d}(j)$ coordinatewise. Fix a packet i. If i arrived during T_j, then, since the optimal solution did not make an acknowledgment in T_j, the packet has the same waiting time up till t_j in both solutions. Thus, $d_i^*(j) = d_i(j)$, and hence $\bar{d}_i(j) = d_i(j) = \Delta_i^j$. Also, $\bar{d}_i(j-1) = 0$, so the desired inequality holds with equality.

If packet i arrived no later than t_{j-1}, then the algorithm does not incur additional waiting time for packet i during T_j, so $\Delta_i^j = 0$. Since waiting times in the optimal solution do not decrease while no acknowledgment is made, and since $d_i(j) = d_i(j-1)$, we have

$\bar{d}_i(j-1) \le \bar{d}_i(j)$. Thus, the desired inequality again holds. Finally, if packet i arrives after t_j, all relevant quantities are 0, and the inequality is trivial. Therefore, $\bar{d}(j-1) + \Delta^j \le \bar{d}(j)$, as desired.

Applying monotonicity of f to the above inequality, we have $f(\bar{d}(j)) \ge f(\bar{d}(j-1) + \Delta^j)$. Plugging this into Equation (2) gives

$$f(\bar{d}(j)) - f(\bar{d}(j-1)) \ge f(d(j)) - f(d(j-1)).$$

Together with the greedy rule $f(d(j)) - f(d(j-1)) = 1$, this proves the claim. ◁

Suppose the optimal solution makes k^* acknowledgments. If $k^* \ge k$, then we are done. Otherwise, there exist at least $k - k^*$ intervals in which the optimal solution did not make an acknowledgment. By monotonicity of f and Claim 5.3, the optimal solution's delay cost is

$$f(d^*) \ge f(\bar{d}) = \sum_{j=1}^{k} f(\bar{d}(j)) - f(\bar{d}(j-1)) \ge k - k^*.$$

Thus, the optimal solution's total cost is at least k. ◀

Patton, Russo, and Singla [47] observed that ℓ_p norms, Top-k norms and ordered norms are submodular. They also proved a result on the approximability of symmetric norms by submodular norms. Using these results give us the following corollary.

▶ **Corollary 1.5.** *There is a deterministic 2-competitive algorithm for TCP Acknowledgment, where the delay cost is: an ℓ_p norm, a Top-ℓ norm, or an ordered norm. When the delay cost is a symmetric norm $\|\cdot\|$, then there is a deterministic $O(\log \rho)$-competitive algorithm where $\rho = \|(1,1,\ldots,1)\| \,/\, \|(1,0,\ldots,0)\| \le n$. In particular, there is a deterministic $O(\log n)$-competitive algorithm when the delay cost is a monotone symmetric norm.*

▶ Remark 5.4. The zero-coordinate diminishing-marginals condition has a natural modeling interpretation in practical domains beyond TCP Acknowledgment. It says that the marginal cost of making a new coordinate positive is smaller when more other coordinates are already present. This is appropriate for incident-based or SLA-type[8] delay costs, where the first few delayed requests may create most of the operational or reputational cost, while additional newly delayed requests are partly absorbed into the same incident. For example, functions of the form $f(d) = g(\mathrm{supp}(d))$, where g is a monotone submodular function, satisfy zero-coordinate diminishing marginals: adding a new positive coordinate corresponds exactly to adding a new element to a larger set, whose marginal contribution is smaller by the submodularity of g. Such functions model global costs depending on the set of requests that experience any positive delay, rather than on the precise magnitude of each delay.

6 Conclusion

In this work, we revisit Online TCP Acknowledgment under broad and natural generalizations of delay costs. We show that the classical guarantees of Greedy extend well beyond additive delays: it remains 2-competitive for *max-monotone* objectives and for a rich class of *batch-oblivious* continuous submodular delay costs. At the same time, we identify a sharp boundary where this paradigm breaks, by proving that Greedy can be $\Omega(n)$-competitive for *sum-monotone* delays. For this harder regime, we develop a new phase-based online algorithm

[8] SLA = Service Level Agreement.

that achieves a tight $\Theta(\log n)$ competitive ratio. Together, our results give a more complete picture of TCP under non-additive delay objectives and lay conceptual groundwork for online problems with delay more broadly.

There are several intriguing open problems. First, what is the competitiveness of other problems such as Joint Replenishment, Multi-Level Aggregation, and Set Cover with Delay under the more general delay cost models considered in this work? Second, while we have a tight characterization of the deterministic competitive ratio for sum-monotone delays, it is unclear whether randomization can help. For the Parking Permit problem, Meyerson [44] showed that the randomized competitive ratio is $\Theta(\log \log n)$. A reduction from Parking Permit will imply the same lower bound. Finally, are there other interesting delay objectives? For example, fairness-oriented delay objectives, where the goal is to balance efficiency with equitable treatment of packets, a setting that remains largely unexplored in the TCP acknowledgment framework.

Abstract

We introduce a unified framework for classical search and routing problems, including pathwise search, expanding search, the minimum spanning tree problem, and the traveling salesperson problem. The framework is based on two parameters. The first is a discount factor $\alpha \in [0, 1]$: the first traversal of an edge incurs its full cost, whereas each subsequent traversal incurs only an α-fraction of this cost. For a path starting at a designated root vertex, the α-latency of a vertex is the discounted cost accumulated until the vertex is first visited. The second parameter is a norm parameter $p \geq 1$. The objective is to find a root-starting path that visits all vertices and minimizes the p-norm of the resulting vector of α-latencies.

The model interpolates between several well-studied objectives. For $p = 1$ and $\alpha = 1$, it recovers pathwise search; for $p = 1$ and $\alpha = 0$, it recovers expanding search. As p tends to infinity, the objective converges to a makespan-type criterion. At the endpoints $\alpha = 1$ and $\alpha = 0$, this limiting objective corresponds to TSP-type and MST-type behavior, respectively. For $p = 1$, we give polynomial-time constant-factor approximation algorithms for all $\alpha \in [0, 1]$, matching the best known guarantees for expanding search at $\alpha = 0$ and pathwise search at $\alpha = 1$. For general $p \geq 1$, we obtain a randomized constant-factor approximation algorithm and a derandomized pseudo-polynomial-time algorithm with the same guarantee.

1 Introduction

Pathwise search, expanding search, the traveling salesperson problem, and the minimum spanning tree problem are four fundamental models for exploring or connecting a network. At first glance, these problems optimize rather different objectives: pathwise and expanding

search minimize sums of discovery times, while the traveling salesperson problem and the minimum spanning tree problem minimize the time until all vertices are reached or connected. In this paper, we study a common framework that unifies these problems through two parameters. The first parameter determines how repeated traversals of edges are charged, and the second parameter determines how the individual vertex latencies are aggregated.

We are given an undirected graph $G = (V, E)$ with non-negative edge cost $c_e \in \mathbb{N}$, and a designated start vertex s. A solution is a traversal of the graph, i.e., a path starting in s that may visit edges more than once and eventually visits all vertices. For a vertex v, its latency is the time at which v is visited for the first time. Classical search problems ask for a traversal that minimizes the sum of these latencies.

The *pathwise search problem* asks for such a traversal when every traversal of an edge e requires c_e time units. Thus, the latency of a vertex is equal to the total cost of the prefix of the path until the vertex is first visited, and the goal is to minimize the sum of the latencies of all vertices. The problem, also known as the *traveling repairperson problem*, captures situations in which all traversals of an edge take the same amount of time. Hence, it has been used as a model for the movement of a repairperson in a road network or for disk heads on a hard drive. The problem is NP-hard even on weighted trees (Sitters [27]), so much research has focused on approximation algorithms. An algorithm is a ϱ-approximation algorithm if for any instance it runs in polynomial time and the cost of the solution output by the algorithm is at most $\varrho \cdot \textsc{Opt}$, where Opt denotes the cost of an optimum solution to the respective instance. The factor ϱ is called the approximation ratio or guarantee. The best currently known approximation algorithm for general graphs with unit weights for all vertices yields a 3.59-approximation (Chaudhuri et al. [15]).

The *expanding search problem* asks for a sequence of edges with the property that every prefix of edges is a connected subgraph and, without loss of generality, a tree containing s. The latency of a vertex is the total cost of the edges added until the vertex first appears in the sequence, and the goal is again to minimize the sum of the latencies of all vertices. It captures situations in which a tree network needs to be installed, and the cost of an edge is interpreted as the time needed to establish a connection between its end vertices. Hence, it has been used as a model for clearing paths in an area devastated by disasters or for mining. The problem is NP-hard (Averbakh and Pereira [9]) and the best currently known approximation algorithm for general graphs yields a 5.44-approximation (Griesbach et al. [22]).

We propose and study a general model of graph exploration that we term the *discounted graph search problem*. As in pathwise search, a solution is a traversal π starting in s that may visit edges more than once and eventually visits all vertices. The first parameter of the model is a discount factor $\alpha \in [0, 1]$. While the first traversal of an edge e in the sequence requires c_e time units, every further traversal of the same edge requires only $\alpha \cdot c_e$ time units. We call the cost of a path where repeated traversals are discounted in this way the *α-cost* of the path. Given a traversal π, the *α-latency* $C_{\alpha,v}(\pi)$ of a vertex v is defined as the α-cost of the smallest prefix of π that visits v.

The second parameter is a norm parameter $p \geq 1$, which determines how the individual α-latencies are aggregated. For a traversal π, its p-norm α-latency is

$$\|\mathbf{C}_\alpha(\pi)\|_p = \left(\sum_{v \in V} C_{\alpha,v}(\pi)^p \right)^{1/p}.$$

The goal is to compute a traversal π minimizing this quantity.

This two-parameter model contains several classical problems as special cases or limiting cases. For $p = 1$ and $\alpha = 1$, every traversal of an edge is charged its full cost, and the objective is the sum of the first-visit times of all vertices. Thus, we recover the pathwise search problem. For $p = 1$ and $\alpha = 0$, repeated traversals of already used edges are free. Therefore, only the cost of newly added edges contributes to the discovery time of vertices, and we recover the expanding search problem.

The parameter p interpolates between sum-of-latencies objectives and makespan-type objectives. As $p \to \infty$, the p-norm objective converges to the maximum α-latency of any vertex. For $\alpha = 1$, this limiting objective asks for a shortest traversal starting at s that visits all vertices, since the maximum latency is exactly the time when the last vertex is first reached. This is the path version of the traveling salesperson problem. For $\alpha = 0$, the maximum α-latency is the total cost of the distinct edges that have been introduced by the time all vertices are reached. Minimizing this quantity is therefore equivalent to finding a minimum-cost connected subgraph spanning all vertices, and hence to the minimum spanning tree problem. Intermediate values of $\alpha \in (0, 1)$ capture situations where the first traversal of an edge is more time-consuming than later traversals, for example, because of additional delays due to pathfinding or clearing a road, while further traversals still require a non-negligible amount of time. Intermediate values of p capture settings in which one wants to balance the average discovery time of vertices with the time until the last vertices are reached. The parameter p can also be interpreted from a fairness perspective. For $p = 1$, the objective minimizes the total latency and thus corresponds to a social-welfare objective, whereas larger values of p put increasing emphasis on vertices with large latency; in the limit $p \to \infty$, the objective becomes an egalitarian objective that minimizes the worst latency. The special case of $p = 2$ and $\alpha = 1$ has been studied as the *traveling firefighter problem* in the literature [16]. The authors motivate this particular choice of objective by firefighters looking for an order in which to tackle wildfires whose damage grows quadratically with the elapsed time.

1.1 Our Results

We first note that the discounted graph search problem is computationally hard already in the case $p = 1$. In particular, the hardness of pathwise and expanding search carries over to the endpoints $\alpha = 1$ and $\alpha = 0$, and we also show that the problem remains hard for every fixed intermediate value $\alpha \in (0, 1)$. The proof can be found in the full version of the paper.

▶ **Theorem 1.** *For $p = 1$ and every constant $\alpha \in [0, 1]$, there exists a constant $\varepsilon > 0$ such that there is no polynomial-time $(1 + \varepsilon)$-approximation algorithm for the discounted graph search problem with discount factor α, unless* P = NP.

We therefore focus on approximation algorithms. We first consider the case $p = 1$, where the objective is the total α-latency. For this case, we obtain a polynomial-time approximation algorithm with approximation ratio

$$\varrho_1(\alpha) \coloneqq \begin{cases} 2\mathrm{e} & \text{if } \alpha = 0, \\ 2\frac{\alpha}{(1+\alpha)W(\alpha/\mathrm{e})} & \text{otherwise,} \end{cases}$$

where $W : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ is the Lambert-W function, which assigns $x \geq 0$ the unique value $w \geq 0$ such that $w\mathrm{e}^w = x$. This gives the following result.

▶ **Theorem 2.** *For $p = 1$ there is a polynomial-time $\varrho_1(\alpha)$-approximation algorithm for the discounted graph search problem.*

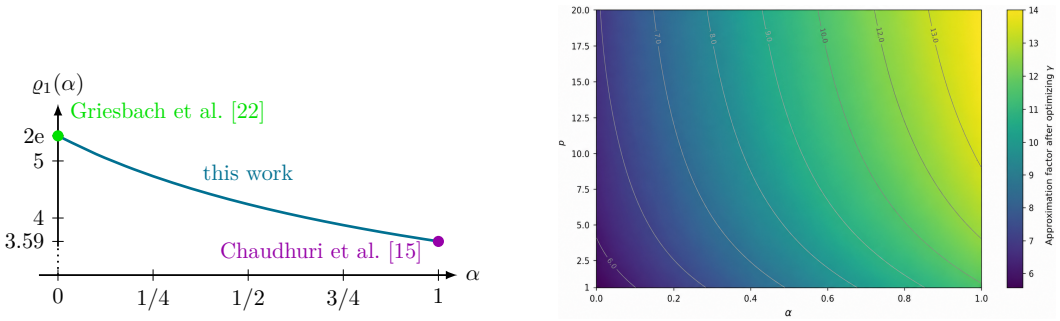

Figure 1 Approximation ratios $\varrho(\alpha)$ obtained in this work: (a) for $p = 1$ as a function of α; (b) as a function of $p > 1$ and α.

For $\alpha = 0$, the approximation factor is 2e, which matches the best currently known approximation guarantee for the expanding search problem (Griesbach et al. [22]). For $\alpha = 1$, the approximation factor is 3.59, which matches the best currently known approximation guarantee for the pathwise search problem in general graphs with unit vertex weights (Chaudhuri et al. [15]). For arbitrary values of $\alpha \in [0, 1]$, the approximation ratio interpolates smoothly between these two values; see Figure 1.

Like the algorithms of Chaudhuri et al. [15] and Griesbach et al. [22], our algorithm is based on a sequence of certain trees of exponentially growing cost. The trees that we consider are related to the concept of *good* trees used by Chaudhuri et al. [15] in their 3.59-approximation for the pathwise search problem. Roughly speaking, a tree is called *good* if it contains a certain number of vertices and its cost is bounded by the cost of an appropriate path visiting the same number of vertices. We extend this concept to general values of α. Specifically, we define good k-trees for α and show that such trees can be computed in polynomial time for the values of k required by our algorithm. For $\alpha = 1$, this recovers the trees used by Chaudhuri et al. [15]. For $\alpha = 0$, the good k-trees correspond to k-MSTs, and the resulting bound matches the best known approximation guarantee for expanding search.

We then turn to the more general case $p \geq 1$, where the objective is the p-norm of the vertices' α-latencies. For $p > 1$, the approach for the case $p = 1$ cannot be applied directly. The main difficulty is that the objective is no longer linear in the latencies, and hence the auxiliary-graph construction used for $p = 1$ no longer directly captures the contribution of each additional tree. Moreover, the good-tree machinery from the $p = 1$ case does not provide suitable trees for every value of k.

We therefore use a randomized construction that is closer in spirit to the geometric tree sequences used for $p = 1$, but relies only on 2-approximate k-MSTs. For every $k \in [n]$, we compute such a tree, choose a random geometric offset, and concatenate trees whose costs grow geometrically. Analyzing the p-th moments of the resulting vertex latencies gives the following guarantee.

▶ **Theorem 3.** *For every $p \geq 1$, there is a polynomial-time randomized algorithm for the discounted graph search problem with approximation factor*

$$\varrho_p(\alpha) = \min_{\gamma > 1} \left\{ \frac{2(1+\alpha)}{\gamma - 1} \left[\frac{\gamma^{2p} - \gamma^p}{p \ln \gamma} \right]^{1/p} \right\}.$$

The approximation factor from Theorem 3 is depicted in Figure 1. For fixed α, the optimized factor tends to $8(1 + \alpha)$ as $p \to \infty$. Over the range $\alpha \in [0, 1]$, the smallest value is attained at $\alpha = 0$ and $p = 1$, where the factor is 2e, while the largest value is approached for $\alpha = 1$ and $p \to \infty$, where the factor tends to 16.

For the traveling firefighter problem, corresponding to the cases $\alpha = 1$ and $p = 2$, this yields an approximation factor of ≈ 11.28. This is worse by a factor of 2 than the approximation factor of ≈ 5.65 claimed by Farhadi et al. [16]. However, as we discuss in Section 1.2, we do not believe that this discrepancy can be resolved straightforwardly.

Finally, we derandomize the p-norm algorithm using an auxiliary graph, as in the case $p = 1$. The difference is that for $p > 1$ the state must also record the accumulated cost of the trees traversed so far, since this quantity determines the nonlinear contribution to the p-norm objective. This yields a two-dimensional, time-expanded auxiliary graph and the following deterministic guarantee.

▶ **Theorem 4.** *For every $p \geq 1$, there is a deterministic pseudo-polynomial-time algorithm for the discounted graph search problem with approximation factor $\varrho_p(\alpha)$ defined in Theorem 3. Moreover, if the tree costs are integral and polynomially bounded, then the algorithm runs in polynomial time.*

1.2 Related Work

The pathwise search problem is also known as the *traveling repairperson problem*. This problem was shown to be NP-hard on general graphs by Sahni and Gonzalez [26], and to be NP-hard even on weighted trees by Sitters [27]. In the weighted setting, each vertex has a non-negative weight and the task is to minimize the weighted sum of latencies. The problem can be solved efficiently on unweighted trees and paths [1, 17, 25]. The first approximation algorithm for this problem was devised by Blum et al. [12] who gave a 144-approximation for general graphs and an 8-approximation for weighted trees. Goemans and Kleinberg [20] improved the approximation ratio for general graphs to 21.55 and the one for weighted trees to 3.59. In particular, they show that a β-approximation for the rooted k-MST problem of finding a shortest tree containing a given root and $k-1$ further vertices implies an approximation ratio of 3.59β for the traveling repairperson problem. Thus, the improved k-MST approximations of $\beta = 3$ by Garg [18], of $\beta = 2.5$ by Arya and Ramesh [8], of $\beta = 2 + \varepsilon$ by Arora and Karakostas [7], and of $\beta = 2$ by Garg [19] immediately yield better approximations of 10.77, 8.98, $7.18 + \varepsilon$, and 7.18, respectively. In addition, the work of Arora [5] implies an improved approximation ratio of $3.59 + \varepsilon$ for the Euclidean case. Archer et al. [4] showed that the approximation ratio of $7.18 + \varepsilon$ can be obtained with fewer calls to the k-MST subroutine. Chaudhuri et al. [15] improved the approximation ratio for general graphs to match the ratio of 3.59 for weighted trees. Archer and Blasiak [3] further improved the approximation ratio for weighted trees to 3.03. Arora and Karakostas [6] gave a quasi-polynomial-time approximation scheme (QPTAS) both for weighted trees and for Euclidean instances. Sitters [28] gave a polynomial-time approximation scheme (PTAS) for Euclidean instances, weighted trees, and planar graphs.

The expanding search problem has been shown to be NP-hard by Averbakh and Pereira [9]. Alpern and Lidbetter [2] proposed an algorithm for the expanding search problem on weighted trees. The first approximation algorithm was devised by Hermans et al. [23] who gave an 8-approximation. The approximation ratio was improved by Griesbach et al. [22] to $2\mathrm{e} \approx 5.44$.

Farhadi et al. [16] study the L_p-TSP, where the objective is to minimize the p-norm of the vector of visit times; this problem interpolates between the traveling repairperson problem for $p = 1$ and the path variant of TSP for $p \to \infty$ and corresponds to our case of $\alpha = 1$. They claimed to have a universal 8-approximation that is valid for all p simultaneously. If correct, this would improve over a 16-approximation by Golovin et al. [21]. Farhadi et al. [16] further claimed a 5.65-approximation for $p = 2$. However, we believe that both their results have a

substantial gap. Their algorithms rely on the ability to compute good k-trees for all values $k \in [n]$; Lemma 3.1 in their paper cites Chaudhuri et al. [15] for the claim that this can be done in polynomial time. However, this is not what Chaudhuri et al. [15] show. They only show "how to obtain such k-trees for some values of k" and "that it actually suffices to use the few k-trees that we found" [15, p. 3]. The algorithms of Farhadi et al. [16], on the other hand, crucially require good k-trees for *all* values of k to be computable in polynomial time. It seems to be an open problem whether this can be done. A positive answer to this open problem appears to require new techniques, as Garg [19, p. 1] writes that "we cannot argue that the cost of the tree picked is at most the cost of the best k-stroll. As was shown in [15] such an argument can be made for certain values of k by exploiting the same slack in the Goemans-Williamson argument". Our algorithms for $p > 1$ avoid this issue by computing 2-approximate k-MSTs for all values of k instead of good k-trees; the former can be done with the algorithm of Garg [19]. This is exactly why we incur an additional loss of a factor of 2. The discussion of Garg cited above makes it plausible that this additional factor of 2 cannot be avoided with current techniques. This route was also taken by Golovin et al. [21], who use 2-approximate k-MSTs for all values of k instead of good k-trees. It is interesting to note that our approximation guarantees for any $p \geq 1$ and $\alpha \in [0, 1]$ are strictly below 16 and approach this value when $\alpha = 1$ and $p \to \infty$.

Norm-based interpolation also appears in ordered optimization problems such as ordered k-median, which interpolates between k-median and k-center [13]. In scheduling and load balancing, one often minimizes the L_p-norm of the machine-load vector, which similarly interpolates between average-load objectives and makespan minimization; see, e.g., the work of Awerbuch et al. [10] and subsequent work on all-norm and minimum-norm load balancing [11, 14, 24]. While these problems differ from ours, they illustrate the role of p-norm objectives as a natural way to interpolate between sum-type and bottleneck-type criteria.

2 Preliminaries

Let $G = (V, E)$ be an undirected graph with $|V| = n + 1$ and a designated start vertex s and let $\alpha \in [0, 1]$ be the discount factor. Each edge $e \in E$ has a non-negative cost $c_e \in \mathbb{N}$. We assume that $c_e > 0$ for every edge incident to s since otherwise these edges can be contracted. We call a sequence of edges $\pi = (e_1, \ldots, e_k)$ a *path* if for all $1 \leq i < k$ the end vertex of e_i and the start vertex of e_{i+1} coincide and the sequence starts in s. If the path also ends in s, we call it a *tour*. The set of all tours is denoted by Π. For two paths $\pi = (e_1, \ldots, e_k)$ and $\pi' = (e'_1, \ldots, e'_l)$ where the end vertex of π coincides with the start vertex of π', we write $\pi + \pi' = (e_1, \ldots, e_k, e'_1, \ldots, e'_l)$ for the concatenation of those two paths.

For a sequence of edges π, we define the *α-cost* $c_\alpha(\pi)$ of π as the sum of all edges in π, where for the second and further traversals of an edge e its cost c_e is multiplied by α. We call a sequence π a *tree* if the set of edges in π spans a tree in G that contains s. Since a tree contains no edge more than once, the α-cost of a tree is independent of α, and we simply write $c(\pi)$. The following lemma states the simple fact that every tree can be transformed into a tour by increasing the α-cost by at most a factor of $1 + \alpha$. We state it here for future reference; its proof can be found in the full version of the paper.

▶ **Proposition 5.** *For a tree T, there exists a tour $\pi(T)$ that visits all vertices in T and has α-cost at most $c_\alpha(\pi(T)) \leq (1 + \alpha)c(T)$.*

For a vertex $v \in V$ visited by a tour $\pi \in \Pi$, we denote by π_v the prefix of π until v is visited for the first time. The *α-latency* $C_{\alpha,v}(\pi)$ of vertex v in π is defined as $C_{\alpha,v}(\pi) := c_\alpha(\pi_v)$ where we set $C_{\alpha,v}(\pi) = \infty$ if v is not visited by π at all. Note that $C_{\alpha,s}(\pi) = 0$. The *total*

α-*latency* $C_\alpha(\pi)$ of π is then defined as $C_\alpha(\pi) \coloneqq \sum_{v \in V} C_{\alpha,v}(\pi)$. In particular, we have $C_\alpha(\pi) = \infty$ if there is a vertex $v \in V$ that is never visited by π. The set of feasible solutions for the *discounted graph search problem* is the set Π. Further, a tour $\pi^* \in \Pi$ is optimal for the discounted graph search problem with $\alpha \in [0,1]$ if $C_\alpha(\pi^*) \leq C_\alpha(\pi)$ for all tours $\pi \in \Pi$.

A k-*tree*, k-*path*, or k-*tour* is a tree, path, or tour, respectively, that contains s and visits at least $k+1$ distinct vertices of V. For a k-tour $\pi \in \Pi$, we denote by π_k the prefix of π until the k-th distinct vertex of $V \setminus \{s\}$ is visited for the first time. A k-path π^* is *optimal* with respect to α if $c_\alpha(\pi^*) \leq c_\alpha(\pi)$ for all k-paths π. If α is clear from context, we simply say that π^* is optimal. Further, a k-tree T is called *good* if its cost is at most $c(T) \leq \frac{2}{1+\alpha} c_\alpha(\pi^*)$, where π^* is an optimal k-path.

3 Algorithms for the 1-Norm of α-Latencies

Recall that $\varrho(\alpha) = 2\frac{\alpha}{(1+\alpha)W(\alpha/\mathrm{e})}$ when $\alpha \in (0,1]$ and $\varrho(0) = 2\mathrm{e}$. We prove the following result.

▶ **Theorem 2.** *For $p = 1$ there is a polynomial-time $\varrho_1(\alpha)$-approximation algorithm for the discounted graph search problem.*

The intuitive idea behind the algorithm is to concatenate a specific subset of *good trees*. We construct an initial set of good trees in Section 3.1 using an algorithm by Chaudhuri et al. [15]. They introduced this algorithm for the computation of good k-trees for a specific subset of values of k and in the special case of $\alpha = 1$. A more thorough analysis of their approach yields that the obtained trees are indeed good trees for arbitrary choices of $\alpha \in [0,1]$. Since the algorithm does not return good k-trees for all values of $k \in [n]_0$, we use so-called phantom trees for the remaining values of k; the details of this construction can be found in the full version of the paper. Next, we introduce the concatenating algorithm in Section 3.2, which takes as input a set of good trees and returns a feasible solution to the discounted graph search problem. More precisely, it constructs an auxiliary graph H whose vertices correspond to the good trees. Within this auxiliary graph, the algorithm computes a shortest path and concatenates the corresponding trees to the desired tour. The algorithm is thus well-defined only if the input contains only real trees. We temporarily ignore this constraint and show in Section 3.3 that, under this relaxation, the returned (phantom) tour has an approximation guarantee of $\varrho_1(\alpha)$. The analysis builds on the construction of a randomized path in the auxiliary graph that visits exponentially growing trees. Then, we show that the same guarantee can be obtained by a path that visits only real trees. This allows us to restrict the input to good real trees while maintaining the approximation guarantee. Combining these results yields a well-defined algorithm that returns the desired solution. The running-time analysis then concludes the proof of Theorem 2.

3.1 Finding Good Trees

To obtain good k-trees, we use an algorithm by Chaudhuri et al. [15]. They study the pathwise search problem, i.e., the discounted graph search problem with $p = \alpha = 1$, for which they introduce a primal–dual algorithm that computes good k-trees for a subset of values of k. With a more thorough analysis, we can show that these trees are indeed good trees for all choices of $\alpha \in [0,1]$.

A subtle issue is that the primal–dual procedure is not monotone in the vertex-budget parameter. In contrast to what is sometimes assumed in related Lagrangian approaches for k-MST [7], increasing the parameter need not produce a larger tree, even before the final pruning step. This is because the parameter can change the order in which moats merge and become inactive. An explicit example can be found in the full version of the paper.

A detailed explanation of how the framework of Chaudhuri et al. [15] needs to be adapted to compute good k-trees for all values of $k \in [n]$ can be found in the full version of the paper. For this purpose, it is important to distinguish between values of k for which a good k-tree can be computed and those for which this is not the case. In the latter case, we define a phantom tree, which is not an actual tree but a placeholder whose costs are interpolated from the costs of the closest two real k-trees. We later argue that these phantom trees are not used by our approximation algorithm, so their inclusion as placeholders does not introduce any issues down the line.

The main result needed here is the following lemma; its proof can be found in the full version of the paper.

▶ **Lemma 6.** *There is a polynomial-time algorithm that computes a set $\mathcal{T}$ containing, for each value $k \in [n]_0$, a real or phantom tree $T_k \in \mathcal{T}$. Each such T_k is a good k-tree.*

3.2 The Concatenating Algorithm

We introduce the *concatenating algorithm*, which takes as input a set of good k-trees, selects a subset of these, and concatenates them to obtain a solution for the discounted graph search problem. To this end, let $\mathcal{I}$ be a set of good k-trees for a subset of values $k \in [n]_0$ and let $I \subseteq [n]_0$ be such that $k \in I$ if and only if $\mathcal{I}$ contains a good k-tree denoted by T_k. Then the concatenating algorithm with input $\mathcal{I}$ is defined as follows:

1. Construct a directed auxiliary graph $H = (V_H, A_H)$ with vertices $V_H = I$, edges $A_H = \{(i,j) : i < j\}$, and edge lengths $\ell_{i,j} = \big[(1+\alpha)n - \alpha j - i\big] c(T_j)$.
2. Compute a shortest 0–n-path $P^* = (n_0, n_1, \dots, n_l)$ with $n_0 = 0$ and $n_l = n$ in H.
3. Start with the empty sequence $\pi_{\text{ALG}} = (\cdot)$.
   For each phase $j = 1, \dots, l$, construct the tour $\pi(T_{n_j})$ according to Proposition 5. Let π_{f} and π_{b} be the tour obtained from traversing the sequence $\pi(T_{n_j})$ in forward or backward direction, respectively. Let $V_j \coloneqq V_{n_j} \setminus \big(\bigcup_{i=1}^{j-1} V_{n_i}\big)$ be the set of vertices that are contained in T_{n_j} but in no previous tree T_{n_i} for $1 \le i < j$. Let $\pi_{\min} \in \{\pi_{\text{f}}, \pi_{\text{b}}\}$ be such that $\sum_{v \in V_j} C_{\alpha,v}(\pi_{\text{ALG}} + \pi_{\min})$ is minimized. Set $\pi_{\text{ALG}} \leftarrow \pi_{\text{ALG}} + \pi_{\min}$.

Note that the concatenating algorithm is only well-defined under the following two assumptions. First, the input must contain a good 0-tree and a good n-tree. Second, all trees $T_{n_0}, \dots, T_{n_l}$ on the shortest path must be real trees, because otherwise Step 3 is not well defined. The second constraint is trivially fulfilled if the input $\mathcal{I}$ only contains real trees.

3.3 The Concatenating Algorithm with Phantom Trees

We want to apply the concatenating algorithm to the set $\mathcal{T}$ of good trees whose existence is guaranteed by Lemma 6. However, this set may contain phantom trees, so the concatenating algorithm is not necessarily well-defined on this input. We ignore this issue for now by assuming that all phantom trees are real trees and can therefore be transformed into tours. Under this assumption, we analyze the approximation ratio of the resulting tour π_{ALG} and then show how to obtain the same guarantee when restricting to real trees.

To this end, let $\mathcal{T}$ be the set of good k-trees whose existence is guaranteed by Lemma 6. Note that $\mathcal{T}$ contains a good (real or phantom) k-tree *for all* values of $k \in [n]_0$ and that the trees T_0 and T_n are real trees. Before applying the concatenating algorithm to $\mathcal{T}$, we slightly adjust the cost of the phantom trees $\mathcal{P} \subset \mathcal{T}$. More precisely, for a phantom tree $T_k \in \mathcal{P}$, let $k_l < k$ be maximal and $k < k_r$ be minimal such that $T_{k_l}, T_{k_r} \in \mathcal{T}$ are two real trees. We redefine the cost of T_k to
