- Additionally, unate distributions, which we define shortly, form a broad and natural family of probability distributions. For example, every unate function f induces a unate distribution (the uniform distribution over $f^{-1}(1)$), and the class of unate functions includes families such as halfspaces and read-once decision lists, which need not be monotone. Beyond this connection to functions, every product distribution over $\{\pm 1\}^n$ is unate.

Finally, as this work demonstrates, unate distributions pose challenges that cannot be addressed by simply reducing to the monotone setting. Even for basic tasks such as uniformity testing, the sample complexity changes, and more broadly, new ideas are required to design and analyze optimal testers for this richer class of distributions.

1.1 Our Results

We start by formally defining unate distributions over $\{\pm 1\}^n$:

▶ **Definition 1.** *A distribution $\mathcal{D}$ over $\{\pm 1\}^n$ is* unate *if there exists $\sigma \in \{\pm 1\}^n$ such that $\mathcal{D}(x \oplus \sigma)$ is a monotone probability mass function, where $\oplus$ denotes coordinate-wise multiplication.*

[1] Formally, a distribution $\mathcal{D}$ over $\{\pm 1\}^n$ is *monotone* if its probability mass function $\mathcal{D} : \{\pm 1\}^n \to [0, 1]$ is monotone, i.e., $\mathcal{D}(x) \leq \mathcal{D}(y)$ whenever $x_i \leq y_i$ for all $i \in [n]$.

Unate distributions immediately inherit many of the algorithmic challenges and lower bounds known from the monotone distribution setting. This includes, for example, the exponential sample lower bounds for tasks such as entropy estimation and independence testing [51]. In this work, we give efficient algorithms as well as lower bounds for two basic problems:

- Uniformity testing of unate distributions; and
- Testing unateness of an unknown distribution in the *subcube conditional model* introduced by Canonne, Ron, and Servedio [20] and Chakraborty, Fischer, Goldhirsh, and Matsliah [24].

In the subcube conditional model for distributions over $\{\pm 1\}^n$, an algorithm can query $\mathcal{D}$ with a subcube $\rho \in \{\pm 1, *\}^n$ and receive an independent sample $\boldsymbol{x} \sim \mathcal{D}$ conditioned on $\boldsymbol{x}_i = \rho_i$ for all i where $\rho_i \neq *$. This model provides a distributional analogue of the "membership query" from learning theory and property testing of Boolean functions, and has received considerable attention in recent years.

We note that for both of the problems we consider, an easy argument using the Chernoff bound together with a union bound over all $\sigma \in \{\pm 1\}^n$ (cf. Definition 1) allow us to reduce to the corresponding problems for monotone distributions with a multiplicative $O(n)$ sample/subcube query overhead. Our main algorithmic results improve on this naive approach for each task; we defer a technical overview of our results to Section 1.2 and survey related work in Section 1.3.

1.1.1 Uniformity Testing of Unate Distributions

Throughout, we write $\mathcal{U} = \mathcal{U}_n$ for the uniform distribution over $\{\pm 1\}^n$. Our first result gives an efficient uniformity tester for high-dimensional distributions under the promise of unateness:

▶ **Theorem 2.** *Let $\varepsilon \in (0,1)$. There is an algorithm,* `Unate-Uniformity` *(Algorithm 1) which, given i.i.d. sample access to an unknown unate distribution $\mathcal{D}$ over $\{\pm 1\}^n$, draws $\widetilde{O}(n^{3/2}/\varepsilon^2)$ samples and has the following performance guarantee:*

- *If $\mathcal{D} = \mathcal{U}$, then it outputs "accept" with probability $9/10$.*
- *If $\mathrm{d_{TV}}(\mathcal{D},\mathcal{U}) \geq \varepsilon$, then it outputs "reject" with probability $9/10$.*

Furthermore, it runs in $\widetilde{O}(n^{5/2}/\varepsilon^2)$ time.

Here $\mathrm{d_{TV}}(\cdot)$ refers to the total variation or statistical distance (Section 2.2). This result should be contrasted with the $\widetilde{O}(n/\varepsilon^2)$ bound for uniformity testing of monotone distributions due to Rubinfeld and Servedio [51].[2] At a high level, moving from monotone to unate distributions introduces an unknown orientation vector σ (cf. Definition 1); any naive strategy that first learns σ and then runs the [51] tester provably incurs an $\Omega(n^2)$ sample overhead. Our algorithm bypasses this bottleneck by never learning σ explicitly. Instead, we introduce a weak-orientation learning framework whose errors are provably weakly correlated across coordinates. This allows a small average bias to be amplified into a global signal using only $\widetilde{O}(n^{3/2})$ samples. We believe this structural result on limited correlations among marginals of unate distributions is of independent interest. We complement Theorem 2 with a matching lower bound:

[2] See also Adamaszek, Czumaj, and Sohler [2] who improved the sample complexity to $O(n/\varepsilon^2)$.

▶ **Theorem 3.** *Let $\mathcal{A}$ be any algorithm which, given i.i.d. sample access to an unknown distribution $\mathcal{D}$, has the performance guarantee from Theorem 2 with $\varepsilon = 1 - n^{-10}$. Then $\mathcal{A}$ must draw $\Omega(n^{3/2}/\log^2 n)$ samples from $\mathcal{D}$.*

Our proof of Theorem 3 extends the "monotone decomposition method" of Rubinfeld and Servedio [51] to the setting of unate distributions; see Section 1.2 for more details.

▶ Remark 4. One might hope that the additional power of the subcube conditional model could yield improved bounds for uniformity testing of unate distributions. Recall that uniformity testing of *arbitrary* distributions can be done using $\widetilde{O}(\sqrt{n})$ subcube queries [16]. Unfortunately, it turns out that the additional structure of unateness cannot beat this baseline: Chakrabarty, Chen, Ristic, Seshadhri, and Waingarten [21] have recently shown that even the easier problem of testing uniformity of monotone distributions in the subcube model already requires $\widetilde{\Omega}(\sqrt{n})$ queries.

1.1.2 Testing Unateness of Distributions

We now turn to the problem of testing whether an unknown distribution over $\{\pm 1\}^n$ is itself unate. In the standard access model where one receives i.i.d. samples from the unknown distribution being tester, this task is intractable: even for the simpler case of monotonicity, classical "birthday paradox" arguments imply that exponential-in-n sample complexity is unavoidable [4, 52]. It is therefore necessary to consider stronger access models to obtain meaningful algorithms.

Motivated by this, Chakrabarty, Chen, Ristic, Seshadhri, and Waingarten [21] studied monotonicity testing in the subcube conditional model, where the tester can query samples conditioned on arbitrary coordinate restrictions. Building on their results, we give an efficient algorithm for testing unateness in the same model.

▶ **Theorem 5.** *Let $\varepsilon \in (0, 1)$. There is an algorithm,* `Subcube-Unate` *(Algorithm 2) which, given subcube query access to an unknown distribution $\mathcal{D}$ over $\{\pm 1\}^n$, makes $\widetilde{O}(n^{3/2}/\varepsilon^2)$ queries and has the following performance guarantee:*

- *If $\mathcal{D}$ is unate, it outputs "accept" with probability at least $2/3$.*
- *If $\mathcal{D}$ is ε-far in TV distance from every unate distribution on $\{\pm 1\}^n$, then it outputs "reject" with probability at least $2/3$.*

We note that the algorithm of Theorem 5 also works in the weaker *coordinate oracle* model of Blanca et al. [13] where queries are only made on one-dimensional subcubes. We complement Theorem 5 with the following lower bound:

▶ **Theorem 6.** *There exists a constant $\varepsilon_0 > 0$ such that the following holds: If an algorithm tests whether an unknown distribution $\mathcal{D}$ over $\{\pm 1\}^n$ is unate or ε_0-far from unate by drawing Q_1 samples from $\mathcal{D}$ and making Q_2 (possibly adaptive) subcube queries on subcubes of dimensions $\leq d$, we have*

$$Q_1 + 2^d Q_2 \geq \Omega(n^{2/3}/\log^3 n).$$

We note that all prior lower bounds in the subcube model are based on product distributions as hard instances. Since every product distribution is trivially unate, these techniques cannot be applied to this setting. To the best of our knowledge, ours is the first lower bound that breaks this barrier; we return to this point in Section 1.4.

1.2 Main Ideas

We give a brief technical overview of our results. Although both of our upper bounds end up with the same asymptotic sample complexity of $\widetilde{O}(n^{3/2}/\varepsilon^2)$, that the ideas underlying each of them are quite different.

1.2.1 Testing Uniformity of Unate Distributions

Upper Bound. A natural first attempt is to adapt the Rubinfeld–Servedio [51] uniformity tester for monotone distributions to the unate setting. The idea would be to first learn the hidden "orientation vector" $\sigma^* \in \{\pm 1\}^n$ (cf. Definition 1) such that the reoriented distribution $\mathcal{D}^{\sigma^*}$, where $\boldsymbol{x} \sim \mathcal{D}^{\sigma^*}$ is obtained by drawing $\boldsymbol{y} \sim \mathcal{D}$ and setting $\boldsymbol{x}_i = \sigma_i^* \cdot \boldsymbol{y}_i$, is monotone. Since total variation distance is preserved under bijections, $\mathrm{d_{TV}}(\mathcal{D},\mathcal{U}) = \mathrm{d_{TV}}(\mathcal{D}^{\sigma^*},\mathcal{U})$. Thus, if σ^* were known, one could directly apply the $O(n/\varepsilon^2)$-sample uniformity tester of [51, 2].

However, exactly recovering σ^* can be prohibitively expensive. Consider, for example, a product distribution where each coordinate has mean $\pm\Theta(1/n)$. Such a distribution is $\Omega(1)$-far from uniform, but distinguishing $\mathbf{E}[x_i] = 0$ from $\mathbf{E}[x_i] = \pm\Theta(1/n)$ for each coordinate requires $\Omega(n^2)$ samples by Chernoff bounds. This naive approach of fully learning the orientation thus fails to give the desired sample complexity of $\widetilde{O}(n^{3/2})$.

Our algorithm circumvents this barrier by avoiding the need to learn σ^* exactly. Instead, we estimate a weakly correlated proxy for σ^* using only $\widetilde{O}(n^{3/2}/\varepsilon^2)$ samples. The key technical step (Lemma 11; which may be of independent interest) shows that for unate distributions, the coordinate-wise sign estimates cannot exhibit strong correlations: indeed, their covariances decay at rate $O(1/\sqrt{m})$ after m samples. This weak dependence is sufficient to amplify a small average bias across coordinates into a global signal, allowing us to test uniformity with $\widetilde{O}(n^{3/2})$ samples.

Lower Bound. The matching lower bound for uniformity testing is proved in the full version [45].

1.2.2 Testing Unate Distributions via Subcube Queries

Upper Bound. For the task of testing whether an unknown distribution is itself unate, we work in the *subcube conditional model*, following the recent work of Chakrabarty et al. [21]. At a high level, our algorithm adapts the classical *edge tester* for Boolean unateness [38] to the distributional setting. The central tool is a structural lemma of [21], based on a real-valued "directed" generalization of an isoperimetric inequality due to Talagrand [53], which controls the "edge bias" of monotone distributions. We refer the reader to Lemma 14 for a precise statement. Using this lemma, we show that if $\mathcal{D}$ is ε-far from unate, then there exists some coordinate i that simultaneously witnesses both "monotone" and "anti-monotone" violations. This can then be detected by making $\widetilde{O}(n^{3/2})$ subcube edge queries; the analysis requires an elementary but careful calculation.

Lower Bound. The lower bound for unateness testing in the subcube model is proved in the full version [45].

1.3 Related Work

Monotonicity of Boolean functions is among the most extensively studied properties in sublinear algorithms; we will not attempt to survey the very large body of results here and instead refer the reader to the comprehensive discussion from [21]. The problem of unateness

testing of Boolean functions was introduced alongside that of monotonicity testing in [38], and a sequence of works [38, 42, 23, 31, 32, 30] have pinned down its exact query complexity: $\widetilde{\Theta}(n^{2/3})$ queries are both necessary and sufficient to test unateness of Boolean functions.

A number of natural distribution testing tasks have exponential sample complexity in high-dimensional settings. This includes uniformity testing over $\{\pm 1\}^n$; see the surveys [15, 18] for more discussion on this. In order to overcome these lower bounds, many works either make structural assumptions on the distribution being tested, or assume stronger access models to the distribution. Examples of the former include monotonicity [51, 2], Bayesian networks [17, 35], Markov random fields [34, 8], various classes of structured truncations [40, 36, 37]; see also Section 7 of [15].

The subcube conditioning model, introduced by [20, 24, 10], takes the other route of assuming stronger access to the distribution being tested. This model has received much attention in recent years [16, 27, 47, 28, 3, 13, 21], and has also found applications beyond distribution testing to problems in learning theory [27, 12]. There has also been a nascent line of work on using the subcube conditioning model to make high-dimensional distribution testing practical [46, 49].

The works most relevant to our results are [51] and [21]. Rubinfeld and Servedio [51] establish an essentially tight bound of $\widetilde{\Theta}(n)$ samples for the problem of testing uniformity of an unknown monotone distribution, whereas Charkabarty et al. [21] give $\widetilde{\Theta}(n)$-query upper and lower bounds for testing monotonicity of an unknown distribution in the subcube model. Both our results – for uniformity testing as well as unateness testing – rely on ingredients going into the analyses of [51, 21] respectively.

1.4 Discussion

Our results raise a number of intriguing questions for further study; we highlight two compelling directions below.

Lower Bounds for Unateness Testing with Subcube Queries. Recall that Theorem 6 gives a $\widetilde{\Omega}(n^{2/3})$ query lower bound against algorithms that make $O(1)$-dimensional subcube queries. At present, all known lower-bounds in the subcube conditional model [16, 27, 21] construct hard instances that are product distributions, which are amenable to moment-matching techniques [27, 21]. However, since product distributions are automatically unate, none of these techniques can be lifted the unateness setting. Improving on Theorem 6 is thus likely to lead to new insights and techniques for proving lower bounds in the subcube conditional model.

***k*-Monotone Distributions.** Finally, one can consider distributional analogues of other structural generalizations of monotonicity. A natural candidate is the class of *k-monotone distributions*, where the distribution's mass function changes direction at most k times along any monotone path from -1^n to 1^n. The class of k-monotone functions has already been studied in the Boolean function setting [39, 19, 33], and k-monotone distributions could provide another structured setting for distribution testing beyond monotonicity.

2 Preliminaries

We use boldfaced letters such as (e.g. $\boldsymbol{x} \sim \{\pm 1\}^n$) to denote random variables. Unless explicitly stated otherwise, all probabilities and expectations will be with respect to the uniform distribution. Throughout, we will write $\mathcal{U}_n$ for the uniform distribution over $\{\pm 1\}^n$ and when the dimension n is clear from context we will simply write $\mathcal{U}$ instead.

For a distribution $\mathcal{D}$, it will be convenient to write $\mathcal{D}^{\otimes m}$ for the distribution of m independent draws from $\mathcal{D}$. We will use the following notation throughout:

▶ **Notation 7.** *Given a distribution $\mathcal{D}$ over $\{\pm 1\}^n$ and $\sigma \in \{\pm 1\}^n$, we write $\mathcal{D}^\sigma$ for the distribution over $\{\pm 1\}^n$ where a draw $\boldsymbol{x} \sim \mathcal{D}^\sigma$ is obtained by first drawing $\boldsymbol{y} \sim \mathcal{D}$ and then setting $\boldsymbol{x}_i \coloneqq \sigma_i \cdot \boldsymbol{y}_i$ for $i \in [n]$.*

2.1 The Berry–Esseen Theorem

We will write $N(0, I_d)$ for the d-dimensional standard Gaussian distribution, where I_d denotes the $d \times d$ identity matrix. We recall the (multi-dimensional) Berry–Esseen theorem (which will be used to prove Lemma 11):

▶ **Theorem 8** (Theorem 1.1 of [7]). *Let $\boldsymbol{X}_1, \ldots, \boldsymbol{X}_m$ be i.i.d. random vectors in $\mathbb{R}^d$ distributed as $\boldsymbol{X}$ where $\mathbf{E}[\boldsymbol{X}] = 0$ and $\mathbf{E}[\boldsymbol{X}\boldsymbol{X}^\top] = I_d$. Then for any convex set $A \subseteq \mathbb{R}^d$, we have*

$$\left| \mathbf{Pr}\left[\frac{\sum_{i=1}^m \boldsymbol{X}_i}{\sqrt{m}} \in A \right] - \mathbf{Pr}[\boldsymbol{G} \in A] \right| \leq O(1) \cdot \frac{d^{1/4}}{\sqrt{m}} \cdot \mathbf{E}\left[\|\boldsymbol{X}\|^3 \right].$$

where $\boldsymbol{G} \sim N(0, I_d)$.

2.2 Distance Metrics Between Probability Distributions

We will identify a distribution $\mathcal{D}$ over a discrete domain Ω with its density function $\mathcal{D} : \Omega \to [0, 1]$. Recall that for two distributions $\mathcal{D}_1$, $\mathcal{D}_2$ over a discrete domain Ω, the *total variation* (or *statistical*) distance between $\mathcal{D}_1$ and $\mathcal{D}_2$ is

$$\mathrm{d}_{\mathrm{TV}}(\mathcal{D}_1, \mathcal{D}_2) = \frac{1}{2} \sum_{x \in \Omega} \left| \mathcal{D}_1(x) - \mathcal{D}_2(x) \right|.$$

We will frequently make use of the fact that total variation distance is invariant under bijections.

We also recall the *Kullback–Leibler (KL)* and χ^2-divergences:

$$\mathrm{d}_{\mathrm{KL}}(\mathcal{D}_1, \mathcal{D}_2) = \sum_{x \in \Omega} \mathcal{D}_1(x) \log \frac{\mathcal{D}_1(x)}{\mathcal{D}_2(x)} \qquad \text{and} \qquad \mathrm{d}_{\chi^2}(\mathcal{D}_1, \mathcal{D}_2) = \sum_{x \in \Omega} \frac{\left(\mathcal{D}_1(x) - \mathcal{D}_2(x)\right)^2}{\mathcal{D}_2(x)}$$

respectively. The following relationships are standard:

$$\mathrm{d}_{\mathrm{TV}}(\mathcal{D}_1, \mathcal{D}_2) \leq \sqrt{\frac{1}{2} \mathrm{d}_{\mathrm{KL}}(\mathcal{D}_1, \mathcal{D}_2)} \leq \sqrt{\frac{1}{2} \log\left(1 + \mathrm{d}_{\chi^2}(\mathcal{D}_1, \mathcal{D}_2)\right)}. \tag{1}$$

We will use the following version of the data processing inequality:

▶ **Fact 9.** *Let $\boldsymbol{X}_1$, $\boldsymbol{X}_2$ be random variables over the same domain. For any (possibly randomized) algorithm $\mathcal{A}$, we have $\mathrm{d}_{\mathrm{TV}}\big(\mathcal{A}(\boldsymbol{X}_1), \mathcal{A}(\boldsymbol{X}_2)\big) \leq \mathrm{d}_{\mathrm{TV}}(\boldsymbol{X}_1, \boldsymbol{X}_2)$.*

3 Testing Uniformity of Unate Distributions

We will prove Theorems 2 and 3 in this section, starting with the former.

3.1 Upper Bound

We first recall the principal technical lemma of [51]'s uniformity tester for monotone distributions:

▶ **Lemma 10** (Corollary 6 of [51]). *If $\mathcal{D}$ is a monotone distribution over $\{\pm 1\}^n$ that is ε-far from uniform, then*

$$\mathop{\mathbf{E}}_{\boldsymbol{x}\sim\mathcal{D}}\left[\sum_{i=1}^{n}\boldsymbol{x}_i\right] \geq \varepsilon\,.$$

We now turn to our uniformity tester for unate distributions. First, note that if $\mathcal{D}$ is a unate distribution, then there exists some $\sigma^* \in \{\pm 1\}^n$ such that $\mathcal{D}^{\sigma^*}$ is a monotone distribution. In particular, note that we may take $\sigma_i^* = \mathrm{sign}(\mathbf{E}_{\boldsymbol{x}\sim\mathcal{D}}[\boldsymbol{x}_i])$. This suggests a natural algorithm: estimate σ^* by drawing m samples $\boldsymbol{x}^{(1)}, \boldsymbol{x}^{(2)}, \ldots, \boldsymbol{x}^{(m)}$ from $\mathcal{D}$ and setting

$$\boldsymbol{\sigma}_i := \mathrm{sign}\left(\sum_{j=1}^{m}\boldsymbol{x}_i^{(j)}\right),$$

and then run the [51] uniformity tester on the monotone distribution $\mathcal{D}^{\boldsymbol{\sigma}}$. Indeed, since

$$\mathrm{d}_{\mathrm{TV}}(\mathcal{D}^{\boldsymbol{\sigma}},\mathcal{U}) = \mathrm{d}_{\mathrm{TV}}(\mathcal{D}^{\boldsymbol{\sigma}},\mathcal{U}^{\boldsymbol{\sigma}}) = \mathrm{d}_{\mathrm{TV}}(\mathcal{D},\mathcal{U}),$$

replacing $\mathcal{D}$ with $\mathcal{D}^{\boldsymbol{\sigma}}$ preserves the uniformity (or distance from uniformity) of the distribution.

However, learning the whole sign vector σ^* can be too expensive. In particular, while Lemma 10 ensures that $\sum_{i=1}^{n}\mathbf{E}[\boldsymbol{x}_i]$ is large, it gives no guarantee on the magnitude of each individual $\mathbf{E}[\boldsymbol{x}_i]$. In particular, note that distinguishing $\mathbf{E}[\boldsymbol{x}_i] = 0$ (which corresponds to the uniform distribution) from $\mathbf{E}[\boldsymbol{x}_i] = \pm\Theta(1/n)$ requires $\Theta(n^2)$ samples per coordinate by standard Chernoff lower bounds. We bypass this obstacle by not insisting on the exact orientation and instead *weakly* learning the sign vector σ^*.

3.1.1 Warm-Up: A Sub-Quadratic Tester in a Special Case

As a warm-up, we show how to obtain a sub-quadratic tester in the hard instance just described above, where naively learning σ^* requires $\Omega(n^2)$ queries. It will be convenient to write

$$\mu_i := \mathop{\mathbf{E}}_{\boldsymbol{x}\sim\mathcal{D}}[\boldsymbol{x}_i]\,.$$

We make one simplifying assumption for now: $\mu_i = \frac{1}{n}$ holds for every $i \in [n]$, i.e., the unate distribution $\mathcal{D}$ is in fact monotone, and each coordinate has the same bias of $\Theta(1/n)$ towards $+1$.

Let $p > 0$ be a parameter that we will set later. By the assumption that $\mu_i = \frac{1}{n}$, it can be verified that $m = \Theta(n^2p^2)$ samples suffice for the "orientation step" to produce random signs $\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_n \in \{\pm 1\}$ with the promise that

$$\mathbf{E}[\boldsymbol{\sigma}_i] \geq p \text{ for all } i \in [n]\,.$$

Equivalently, we correctly deduce that $\sigma_i^* = +1$ with probability $1/2 + \Omega(p)$, which is slightly better than a random guess.

Writing $\boldsymbol{X} \coloneqq \frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\sigma}_i \in [-1,1]$, note that $\mathbf{E}[\boldsymbol{X}] \geq p$. Applying Markov's inequality to the non-negative random variable $1 - \boldsymbol{X}$ gives

$$\mathbf{Pr}\left[\boldsymbol{X} \leq \frac{p}{2}\right] = \mathbf{Pr}\left[1 - \boldsymbol{X} \geq 1 - \frac{p}{2}\right] \leq \frac{\mathbf{E}\left[1-\boldsymbol{X}\right]}{1-\frac{p}{2}} \leq \frac{1-p}{1-\frac{p}{2}} \leq 1 - \Omega(p)\,.$$

In other words, the event $\frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\sigma}_i \geq \frac{p}{2}$ holds with probability $\Omega(p)$. Repeating this "orientation step" independently $O(1/p)$ times ensures that with constant probability, at least one draw satisfies $\boldsymbol{X} \geq p/2$. Then, we note that, conditioning on the realization of $\boldsymbol{\sigma} \in \{\pm 1\}^n$, the $\boldsymbol{\sigma}$-weighted Hamming weight $\sum_{i=1}^{n} \boldsymbol{\sigma}_i \boldsymbol{x}_i$ for $\boldsymbol{x} \sim \mathcal{D}$ has an expectation of exactly

$$\sum_{i=1}^{n} \boldsymbol{\sigma}_i \cdot \mathop{\mathbf{E}}_{\boldsymbol{x}\sim\mathcal{D}}\left[\boldsymbol{x}_i\right] = \sum_{i=1}^{n} \boldsymbol{\sigma}_i \cdot \mu_i = \frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\sigma}_i.$$

Therefore, by estimating $\frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\sigma}_i$ to an additive error of $O(p)$ using $\widetilde{O}(n/p^2)$ additional samples, we obtain a tester with sample complexity (modulo polylogarithmic factors)

$$\frac{1}{p} \cdot n^2 p^2 + \frac{n}{p^2}. \tag{2}$$

Setting $p = n^{-1/3}$ gives a sample complexity of $\widetilde{O}(n^{5/3})$, which already improves upon the easy $\widetilde{O}(n^2)$ bound (cf. Section 1.1).

3.1.2 Main Technical Lemma

Recall from the warm-up that the sign estimates $\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2, \ldots, \boldsymbol{\sigma}_n$ satisfy $\mathbf{E}\left[\boldsymbol{\sigma}_i\right] \geq p$, which implies

$$\mathop{\mathbf{Pr}}_{\boldsymbol{\sigma}}\left[\frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\sigma}_i \geq \Omega(p)\right] \geq \Omega(p)\,.$$

Now, note that if we were able to replace the R.H.S. above with $\Omega(1)$ instead of $\Omega(p)$, then this stronger lower bound would imply that $O(1)$ independent sign estimates would suffice for "catching" the $\Omega(p)$ bias. Then, the sample complexity (up to polylogarithmic factors) would be $n^2p^2 + \frac{n}{p^2}$ (cf. Equation (2)), which reduces to $\widetilde{O}(n^{3/2})$ if we set $p = n^{-1/4}$.

We first note that the property $\mathbf{E}\left[\boldsymbol{\sigma}_i\right] \geq p$ alone does not imply the desired high-probability bound, namely,

$$\mathbf{Pr}\left[\frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\sigma}_i \geq \Omega(p)\right] \geq \Omega(1).$$

Suppose for the sake of simplicity that n is even, and imagine that $\boldsymbol{\sigma} \in \{\pm 1\}^n$ is drawn from the following distribution:

- With probability p, $\boldsymbol{\sigma} = (+1, +1, \ldots, +1)$.
- With the remaining probability $1-p$, $\boldsymbol{\sigma}$ is chosen as a uniformly random permutation of $n/2$ copies of $+1$ and $n/2$ copies of -1.

It can be easily verified that the above distribution satisfies $\mathbf{E}\left[\boldsymbol{\sigma}_i\right] = p$, yet $\frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\sigma}_i > 0$ only holds with probability p.

Therefore, the crux is to show that the $\boldsymbol{\sigma}_i$'s cannot be too correlated (as in the example above). Concretely, proving the following will suffice for our purposes:

Algorithm 1 The `Unate-Uniformity` algorithm.

Input: Access to i.i.d. samples from unate $\mathcal{D}$, distance parameter $\varepsilon \in (0,1)$

Output: "Accept" or "reject"

`Unate-Uniformity`$(\mathcal{D}, \varepsilon)$:

1. Repeat the following $O(1)$ times:
   a. Draw $m_1 := \Theta\left(\frac{n^{3/2}}{\varepsilon^2}\right)$ samples $\boldsymbol{x}^{(1)}, \ldots, \boldsymbol{x}^{(m_1)} \sim \mathcal{D}$.
   b. Compute $\boldsymbol{\sigma} \in \{\pm 1\}^n$ where for $i \in [n]$ we have

$$\boldsymbol{\sigma}_i := \operatorname{sign}\left(\sum_{j=1}^{m_1} \boldsymbol{x}_i^{(j)}\right) \in \{\pm 1\}\,.$$

   c. Draw $m_2 := \Theta\left(\frac{n^{3/2}}{\varepsilon^2} \log\left(\frac{n}{\varepsilon}\right)\right)$ samples $\boldsymbol{y}^{(1)}, \ldots, \boldsymbol{y}^{(m_2)} \sim \mathcal{D}$.
   d. For each $j \in [m_2]$, let $\boldsymbol{w}_j := \sum_{i=1}^n \boldsymbol{\sigma}_i \cdot \boldsymbol{y}_i^{(j)}$ denote the $\boldsymbol{\sigma}$-weighted Hamming weight of $\boldsymbol{y}^{(j)}$.
   e. If $|\boldsymbol{w}_j| \geq \Theta(\sqrt{n \log(n/\varepsilon)})$ holds for any $j \in [m_2]$, halt and output "reject."
   f. If $\frac{1}{m_2} \sum_{j=1}^{m_2} \boldsymbol{w}_j \geq \Theta(\varepsilon/n^{1/4})$, then halt and output "reject."
2. If the algorithm has not rejected yet, output "accept."

▶ **Lemma 11.** *Suppose $\mathcal{D}$ is a unate distribution on $\{\pm 1\}^n$. Suppose $\boldsymbol{x}^{(1)}, \ldots \boldsymbol{x}^{(m)} \sim \mathcal{D}$ and let*

$$\boldsymbol{\sigma}_i := \operatorname{sign}\left(\sum_{j=1}^{m} \boldsymbol{x}_i^{(j)}\right).$$

For any $1 \leq i < j \leq n$, it holds that

$$|\operatorname{\mathbf{Cov}}[\boldsymbol{\sigma}_i, \boldsymbol{\sigma}_j]| = O\left(\frac{1}{\sqrt{m}}\right).$$

It is readily verified that Lemma 11 fails for non-unate distributions: consider, for example, the two-point distribution $\mathcal{D}(+1^n) = \mathcal{D}(-1^n) = 0.5$. We defer the proof of Lemma 11 to Section 3.1.4, and first show why it implies the correctness of Algorithm 1.

3.1.3 Proof of Theorem 2

We will require the following lemma due to Qiao and Valiant [50]:

▶ **Lemma 12** (Lemma B.2 of [50])**.** *Suppose $k \in \mathbb{N}$ and $\delta \in (0, 1/15\sqrt{k})$. Let P and Q be two distributions on the same support with $\mathrm{d}_{\mathrm{TV}}(P, Q) \geq \delta$. Then*

$$\mathrm{d}_{\mathrm{TV}}(P^{\otimes k}, Q^{\otimes k}) \geq \frac{\delta\sqrt{k}}{15}\,.$$

Proof of Theorem 2. Note that the sample complexity and runtime are evident from Algorithm 1. Next, note that if $\mathcal{D} = \mathcal{U}$, then $\mathcal{D}^\sigma = \mathcal{U}$ for every $\sigma \in \{\pm 1\}^n$. It now follows from Theorem 4 of [51] that `Unate-Uniformity` will output "accept" with probability at least 9/10. In particular, note that in this case, Steps 1(c) through 1(f) of `Unate-Uniformity` are identical to the `TestUniform` algorithm of [51] run on $\mathcal{U}$.

We now show how Lemma 11 implies the soundness of `Unate-Uniformity`. Suppose that the unate distribution $\mathcal{D}$ is ε-far from uniform. As before, we write

$$\mu_i \coloneqq \mathop{\mathbf{E}}_{\boldsymbol{x}\sim\mathcal{D}}[\boldsymbol{x}_i]\,.$$

Since $\mathcal{D}$ is unate, it follows that there exists some $\sigma^* \in \{\pm 1\}^n$ such that $\mathcal{D}^{\sigma^*}$ is monotone. In particular, we can take $\sigma_i^* = \operatorname{sign}(\mu_i)$, and so we have $\sigma_i^*\mu_i = |\mu_i| \geq 0$. Since the TV distance is preserved under bijections, $\mathcal{D}^{\sigma^*}$ is also ε-far from uniform. Applying Lemma 10 to $\mathcal{D}^{\sigma^*}$ gives

$$\|\mu\|_1 = \sum_{i=1}^n \sigma_i^*\mu_i = \mathop{\mathbf{E}}_{\boldsymbol{x}\sim\mathcal{D}^{\sigma^*}}\left[\sum_{i=1}^n \boldsymbol{x}_i\right] \geq \varepsilon\,.$$

Recall that we use a sample of size $m_1 = \Theta(n^{3/2}/\varepsilon^2)$ in Step 1(a) and 1(b) to compute $\boldsymbol{\sigma}_1, \ldots, \boldsymbol{\sigma}_n \in \{\pm 1\}$. Set a threshold $\theta = \frac{\varepsilon}{100n}$. For every $i \in [n]$ that satisfies $|\mu_i| \geq \theta$, we will now show that

$$\mathbf{E}\left[\sigma_i^*\boldsymbol{\sigma}_i\right] \geq \Omega\left(\frac{\varepsilon}{n}\cdot\frac{n^{3/4}}{\varepsilon}\right) = \Omega(n^{-1/4})\,, \tag{3}$$

using Lemma 12. In more detail, let P be the distribution of $\sigma_i^*\boldsymbol{x}_i$ for $\boldsymbol{x}\sim\mathcal{D}$ and Q be $-P$, i.e. $\boldsymbol{y}\sim Q$ is obtained by drawing $\boldsymbol{y}'\sim P$ and setting $\boldsymbol{y} = -\boldsymbol{y}'$. Note that

$$\Pr_{\boldsymbol{y}\sim\mathcal{P}}[\boldsymbol{y}=+1] = \frac{1+|\mu_i|}{2} \qquad \text{and} \qquad \Pr_{\boldsymbol{y}\sim\mathcal{P}}[\boldsymbol{y}=-1] = \frac{1-|\mu_i|}{2}\,,$$

with swapped probabilities for Q. It follows that $\mathrm{d_{TV}}(P,Q) = |\mu_i| \geq \frac{\varepsilon}{100n}$; note also that

$$\frac{\varepsilon}{100n} \leq \frac{1}{15\sqrt{m_1}}$$

for appropriate choice of hidden constant in m_1. In particular, applying Lemma 12 gives

$$\mathrm{d_{TV}}(P^{\otimes m_1}, Q^{\otimes m_1}) \geq \Omega\left(\frac{\varepsilon}{n}\cdot\frac{n^{3/4}}{\varepsilon}\right) = \Omega(n^{-1/4})\,.$$

In order to establish Equation (3), it suffices to show that $\mathrm{d_{TV}}(P^{\otimes m_1}, Q^{\otimes m_1}) = \Theta(1)\cdot\mathbf{E}[\sigma_i^*\boldsymbol{\sigma}_i]$. Since P and Q are Bernoulli random variables, their likelihood ratio is monotone in the number of successes (i.e., $+1$ draws), and so by the Neyman–Pearson lemma, the TV-distance maximizing set is $\{\sum_\ell \boldsymbol{y}^{(\ell)} \geq 0\}$. We may assume that m_1 is odd (to avoid handling ties), and so we get

$$\begin{aligned}
\mathrm{d_{TV}}(P^{\otimes m_1}, Q^{\otimes m_1}) &= P^{\otimes m_1}\left(\sum_{\ell=1}^{m_1}\boldsymbol{y}^{(\ell)} \geq 0\right) - Q^{\otimes m_1}\left(\sum_{\ell=1}^{m_1}\boldsymbol{y}^{(\ell)} \geq 0\right) \\
&= P^{\otimes m_1}\left(\sum_{\ell=1}^{m_1}\boldsymbol{y}^{(\ell)} \geq 0\right) - P^{\otimes m_1}\left(\sum_{\ell=1}^{m_1}\boldsymbol{y}^{(\ell)} < 0\right) \qquad (4)\\
&= \mathbf{E}[\sigma_i^*\boldsymbol{\sigma}_i]\,,
\end{aligned}$$

from which Equation (3) follows readily. Note that Equation (4) relies on the fact that $P = -Q$. Finally, note also that the same argument shows that $\mathbf{E}\left[\sigma_i^*\boldsymbol{\sigma}_i\right] \geq 0$ for every $i \in [n]$, even if $|\mu_i| < \theta$.

Let $\boldsymbol{X} \coloneqq \sum_{i=1}^{n} \mu_i \cdot \boldsymbol{\sigma}_i = \sum_{i=1}^{n} |\mu_i| \cdot (\sigma_i^* \boldsymbol{\sigma}_i)$. We have

$$\mathbf{E}[\boldsymbol{X}] \geq \sum_{i \in [n]:|\mu_i| \geq \theta} |\mu_i| \cdot \mathbf{E}[\sigma_i^* \boldsymbol{\sigma}_i] \geq \Omega(n^{-1/4}) \cdot \sum_{i \in [n]:|\mu_i| \geq \theta} |\mu_i| = \Omega(n^{-1/4} \cdot \|\mu\|_1).$$

The first step above holds since both $|\mu_i|$ and $\mathbf{E}\left[\sigma_i^* \boldsymbol{\sigma}_i\right]$ are non-negative for every $i \in [n]$. The second step applies $|\mu_i| \geq \theta \implies \mathbf{E}\left[\sigma_i^* \boldsymbol{\sigma}_i\right] \geq \Omega(n^{-1/4})$. The third step holds since our choice of $\theta = \frac{\varepsilon}{100n}$ and the fact $\|\mu\|_1 \geq \varepsilon$ together imply

$$\sum_{i \in [n]:|\mu_i| \geq \theta} |\mu_i| \geq \sum_{i=1}^{n} |\mu_i| - n \cdot \theta = \|\mu\|_1 - \frac{\varepsilon}{100} \geq \Omega(\|\mu\|_1).$$

It remains to show that

$$\mathbf{Var}[\boldsymbol{X}] \leq O(n^{-1/2} \cdot \|\mu\|_1^2).$$

By Chebyshev's inequality, the variance bound above would imply that, with probability $\Omega(1)$,

$$\boldsymbol{X} \geq \mathbf{E}[\boldsymbol{X}] - O(\sqrt{\mathbf{Var}[\boldsymbol{X}]}) \geq \Omega(n^{-1/4} \cdot \|\mu\|_1) \geq \Omega(\varepsilon / n^{1/4}),$$

where the second step applies the following observations:

- $\mathbf{E}[\boldsymbol{X}] \geq \Omega(n^{-1/4} \cdot \|\mu\|_1)$, where the hidden constant in $\Omega(\cdot)$ is lower bounded by a universal constant when $m_1 = \Theta(n^{3/2}/\varepsilon^2)$ is sufficiently large.
- We will show that $\mathbf{Var}[\boldsymbol{X}] \leq O(n^{-1/2} \cdot \|\mu\|_1^2)$, where the hidden constant in $O(\cdot)$ goes to zero as the hidden constant in $m_1 = \Theta(n^{3/2}/\varepsilon^2)$ increases.
- Therefore, for some careful choice of m_1 in the algorithm, the difference $\mathbf{E}[\boldsymbol{X}] - O(\sqrt{\mathbf{Var}[\boldsymbol{X}]})$ is positive and on the order of $\Omega(n^{-1/4} \cdot \|\mu\|_1)$.

By a Chernoff bound, we can then catch this $\Omega(\varepsilon/n^{1/4})$ bias using $\widetilde{O}\left(\frac{n}{(\varepsilon/n^{1/4})^2}\right) = \widetilde{O}(n^{3/2}/\varepsilon^2)$ additional samples in Step 1(f) of the algorithm.

By Lemma 11, we have

$$\mathbf{Var}[\boldsymbol{X}] = \sum_{i=1}^{n} \mu_i^2 \mathbf{Var}[\boldsymbol{\sigma}_i] + 2 \sum_{1 \leq i < j \leq n} \mu_i \mu_j \mathbf{Cov}[\boldsymbol{\sigma}_i, \boldsymbol{\sigma}_j] \leq \sum_{i=1}^{n} \mu_i^2 \mathbf{Var}[\boldsymbol{\sigma}_i] + O(n^{-1/2}) \cdot \|\mu\|_1^2.$$

The second term above is exactly the desired upper bound. For the first term, we note that

$$\mathbf{Var}[\boldsymbol{\sigma}_i] = e^{-\Omega(m_1 \mu_i^2)},$$

so each term $\mu_i^2 \mathbf{Var}[\sigma_i]$ is at most $O(1/m_1)$. Recalling $m_1 = \Theta(n^{3/2}/\varepsilon^2)$ and $\|\mu\|_1 \geq \varepsilon$, we conclude that

$$\sum_{i=1}^{n} \mu_i^2 \mathbf{Var}[\boldsymbol{\sigma}_i] \leq O(n/m_1) = O(\varepsilon^2/\sqrt{n}) \leq O(n^{-1/2} \cdot \|\mu\|_1^2),$$

which proves the desired variance bound $\mathbf{Var}[\boldsymbol{X}] \leq O(n^{-1/2} \cdot \|\mu\|_1^2)$ and completes the proof. ◀

3.1.4 Proof of Lemma 11

Without loss of generality, we prove the lemma when the unate distribution $\mathcal{D}$ is monotone; the more general statement then follows from the observation that flipping the ith coordinate of $\mathcal{D}$ leads to a flip in the distribution of $\boldsymbol{\sigma}_i$, which preserves the magnitude of the covariances.

For $i \in [n]$, we define

$$\boldsymbol{S}_i := \sum_{\ell=1}^{m} \boldsymbol{x}_i^{(\ell)} \qquad \text{and} \qquad \mu_i := \mathop{\mathbf{E}}_{\boldsymbol{x}\sim\mathcal{D}}[\boldsymbol{x}_i]\,.$$

In particular, we have $\boldsymbol{\sigma}_i = \operatorname{sign}(\boldsymbol{S}_i) = 2\cdot\mathbf{1}\{\boldsymbol{S}_i \geq 0\} - 1$, and so

$$\mathbf{Cov}[\boldsymbol{\sigma}_i, \boldsymbol{\sigma}_j] = 4\big(\mathbf{Pr}[\boldsymbol{S}_i \geq 0, \boldsymbol{S}_j \geq 0] - \mathbf{Pr}[\boldsymbol{S}_i \geq 0]\,\mathbf{Pr}[\boldsymbol{S}_j \geq 0]\big)\,. \tag{5}$$

We will prove Lemma 11 with $i = 1$ and $j = 2$; that is, we will show that

$$\mathbf{Cov}[\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2] = O\left(\frac{1}{\sqrt{m}}\right).$$

Define

$$p_{00} := \mathop{\mathbf{Pr}}_{\boldsymbol{x}\sim\mathcal{D}}\left[(\boldsymbol{x}_1, \boldsymbol{x}_2) = (-1,-1)\right], \qquad p_{10} := \mathop{\mathbf{Pr}}_{\boldsymbol{x}\sim\mathcal{D}}\left[(\boldsymbol{x}_1, \boldsymbol{x}_2) = (+1,-1)\right],$$
$$p_{01} := \mathop{\mathbf{Pr}}_{\boldsymbol{x}\sim\mathcal{D}}\left[(\boldsymbol{x}_1, \boldsymbol{x}_2) = (-1,+1)\right], \qquad p_{11} := \mathop{\mathbf{Pr}}_{\boldsymbol{x}\sim\mathcal{D}}\left[(\boldsymbol{x}_1, \boldsymbol{x}_2) = (+1,+1)\right].$$

Thanks to monotonicity of $\mathcal{D}$, we have $p_{00} \leq p_{10} \leq p_{11}$ and $p_{00} \leq p_{01} \leq p_{11}$. It also follows that $\mu_1 = 1 - 2(p_{00} + p_{01}) \geq 0$ and $\mu_2 = 1 - 2(p_{00} + p_{10}) \geq 0$. The proof considers two cases depending on the value of $\mu_1 + \mu_2$:

Case 1: $\mu_1 + \mu_2 > 1/2$

We record the following easy bound on $\mathbf{Cov}[\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2]$:

$$\big|\mathbf{Cov}[\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2]\big| \leq 4\min\left\{\mathbf{Pr}\left[\boldsymbol{S}_1 < 0\right], \mathbf{Pr}\left[\boldsymbol{S}_2 < 0\right]\right\}. \tag{6}$$

Assuming Equation (6), a direct application of the Hoeffding bound gives

$$\mathbf{Pr}[\boldsymbol{S}_i < 0] \leq e^{-m\mu_i^2/2}\,, \qquad \text{and so} \qquad |\,\mathbf{Cov}(s_1, s_2)| \leq 4e^{-m/32} \ll O\left(\frac{1}{\sqrt{m}}\right),$$

where we make use of the fact that $\min\{\mu_1, \mu_2\} \geq 1/4$ by the assumption $\mu_1 + \mu_2 > 1/2$.

We now justify Equation (6). It will be convenient to write

$$A := \mathbf{Pr}[\boldsymbol{S}_1 \geq 0, \boldsymbol{S}_2 \geq 0]\,, \qquad B := \mathbf{Pr}[\boldsymbol{S}_1 \geq 0]\,, \qquad \text{and} \qquad C = \mathbf{Pr}[\boldsymbol{S}_2 \geq 0]\,.$$

Note that $\mathbf{E}[\boldsymbol{\sigma}_1] = 2B - 1$ and $\mathbf{E}[\boldsymbol{\sigma}_2] = 2C - 1$. Writing $D := 1 + A - B - C$, it is readily checked that $D = \mathbf{Pr}[\boldsymbol{S}_1 < 0, \boldsymbol{S}_2 < 0]$. It follows from Equation (5) that $\mathbf{Cov}[\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2] = 4(A - BC)$. In particular, we have

$$\frac{1}{4}\big|\mathbf{Cov}[\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2]\big| = |A - BC|\,.$$

Now,

- If $A \geq BC$, then $A - BC \leq C(1 - B) \leq 1 - B$.
- If $A < BC$, then $BC - A \leq C - (B + C - 1) = 1 - B$, since $D \geq 0$ gives $A \geq B + C - 1$.

It follows that $|\,\mathbf{Cov}[\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2]| \leq 4(1 - B) = 4\,\mathbf{Pr}[\boldsymbol{S}_1 < 0]$. By symmetry, the same holds with B and C swapped, which yields Equation (6).

Case 2: $\mu_1 + \mu_2 \le 1/2$

In this case, we will control $\mathbf{Cov}(\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2)$ via a Gaussian approximation to the sums $\boldsymbol{S}_1$ and $\boldsymbol{S}_2$. First, let $\kappa := \mathbf{Cov}[\boldsymbol{x}_1, \boldsymbol{x}_2]$ for $\boldsymbol{x} \sim \mathcal{D}$. Note that $\kappa = p_{00} + p_{11} - p_{01} - p_{10} - \mu_1\mu_2$.

We will first control the covariance of the Gaussian approximation. Consider the standardized random vector

$$\boldsymbol{T} = (\boldsymbol{T}_1, \boldsymbol{T}_2) := \frac{1}{\sqrt{m}}(\boldsymbol{S}_1 - m\mu_1, \boldsymbol{S}_2 - m\mu_2) \qquad \text{and let} \qquad \Sigma := \begin{pmatrix} \lambda_1^2 & \kappa \\ \kappa & \lambda_2^2 \end{pmatrix}$$

where $\lambda_i^2 = 1 - \mu_i^2$. We will sometimes write $\mu = (\mu_1, \mu_2)$. Finally, let ρ be the correlation between $\boldsymbol{T}_1$ and $\boldsymbol{T}_2$, that is,

$$\rho := \frac{\kappa}{\lambda_1\lambda_2}\,.$$

Note that by the central limit theorem, $\boldsymbol{T} \to N(0, \Sigma)$ (in distribution) as $m \to \infty$. Following Equation (5), the Gaussian approximation of the correlation is

$$\mathbf{Cov}_{\approx} := 4\Big(\mathbf{Pr}\left[\boldsymbol{Z}_1 \ge -\sqrt{m}\mu_1, \boldsymbol{Z}_2 \ge -\sqrt{m}\mu_1\right] - \mathbf{Pr}\left[\boldsymbol{Z}_1 \ge -\sqrt{m}\mu_1\right]\mathbf{Pr}\left[\boldsymbol{Z}_2 \ge -\sqrt{m}\mu_2\right]\Big).$$

Note that $\mathbf{Cov}_{\approx} = \mathbf{Cov}[\boldsymbol{\tau}_1, \boldsymbol{\tau}_2]$ where $\boldsymbol{\tau}_i = \mathrm{sign}(\boldsymbol{Z}_i - \sqrt{m}\mu_i)$. Next, we will show that $\mathbf{Cov}_{\approx} = O(m^{-1/2})$ via known estimates for computing bi-variate normal probabilities. In particular, applying Equation 3.6 of [48] gives

$$\begin{aligned}
|\,\mathbf{Cov}_{\approx}\,| &= 4\left|\frac{1}{2\pi}\int_0^{\rho}\frac{1}{\sqrt{1-z^2}}\exp\Big(-\frac{1}{2}\frac{(\sqrt{m}\frac{\mu_1}{\lambda_1})^2 + (\sqrt{m}\frac{\mu_2}{\lambda_2})^2 - 2(\sqrt{m}\frac{\mu_1}{\lambda_1})(\sqrt{m}\frac{\mu_2}{\lambda_2})z}{1-z^2}\Big)\,dz\right| \\
&\le \frac{2}{\pi}\int_0^{|\rho|}\frac{1}{\sqrt{1-z^2}}\exp\Big(-\frac{m}{2}\left(\frac{(\frac{\mu_1}{\lambda_1} - \frac{\mu_2}{\lambda_2})^2}{1-z^2} + \frac{2\frac{\mu_1}{\lambda_1}\frac{\mu_2}{\lambda_2}}{1+z}\right)\Big)\,dz \qquad (7) \\
&\le \frac{2}{\pi}\int_0^{|\rho|}\frac{1}{\sqrt{1-z^2}}\exp\Big(-\frac{m}{8}(\frac{\mu_1}{\lambda_1} + \frac{\mu_2}{\lambda_2})^2\Big)\,dz \qquad (8) \\
&\le \frac{2}{\pi}\sin^{-1}|\rho|\exp\Big(-\frac{m}{8}(\mu_1+\mu_2)^2\Big) \\
&\le |\rho|\exp\Big(-\frac{m}{8}(\mu_1+\mu_2)^2\Big)\,, \qquad (9)
\end{aligned}$$

where Equation (7) relies on the fact that the integrand is larger on the positive z side, Equation (8) uses

$$\frac{(\frac{\mu_1}{\lambda_1} - \frac{\mu_2}{\lambda_2})^2}{1-z^2} + \frac{2\frac{\mu_1}{\lambda_1}\frac{\mu_2}{\lambda_2}}{1+z} \ge (\frac{\mu_1}{\lambda_1} - \frac{\mu_2}{\lambda_2})^2 + \frac{\mu_1}{\lambda_1}\frac{\mu_2}{\lambda_2} = \frac{1}{4}(\frac{\mu_1}{\lambda_1} + \frac{\mu_2}{\lambda_2})^2 + \frac{3}{4}(\frac{\mu_1}{\lambda_1} - \frac{\mu_2}{\lambda_2})^2\,,$$

and Equation (9) relies on $\lambda_i \le 1$ and $\sin^{-1}(\theta) \le \frac{\pi\theta}{2}$ for $\theta \ge 0$.

We record the following lemma:

▶ **Lemma 13.** *For monotone distributions, if $\mu_1 + \mu_2 \le \frac{1}{2}$, then $|\rho| \le \mu_1 + \mu_2$.*

Proof. Parametrize the probabilities of the monotone distribution as

$$p_{00} = a, \quad p_{01} = a + b, \quad p_{10} = a + c, \quad p_{11} = a + d.$$

Then $\mu_1 = d + c - b$, $\mu_2 = d + b - c$, so $\mu_1 + \mu_2 = 2d$ implies $d \leq \frac{1}{4}$. Now

$$\begin{aligned}
|\rho| &= \frac{|(d-b-c) - (d+c-b)(d+b-c)|}{\sqrt{(1-\mu_1^2)(1-\mu_2^2)}} \\
&\leq \frac{2}{\sqrt{3}} \left|(d-b-c) + ((b-c)^2 - d^2)\right| && (10) \\
&\leq \frac{2}{\sqrt{3}}(d + d^2) && (11) \\
&= 2d \cdot \frac{1+d}{\sqrt{3}} \leq 2d = \mu_1 + \mu_2
\end{aligned}$$

where in Equation (10) we use that $(1-\mu_1^2)(1-\mu_2^2) \geq \frac{3}{4}$, and in Equation (11) we note that $|d - b - c| \leq d$ and $|b - c| \leq d$. ◀

Combining Equation (9) with Lemma 13, we get

$$|\operatorname{\mathbf{Cov}}_{\approx}| \leq (\mu_1 + \mu_2) \exp\left(-\frac{m}{8}(\mu_1 + \mu_2)^2\right) = O\left(\frac{1}{\sqrt{m}}\right). \tag{12}$$

Next, we will control the error in the Gaussian approximation to $\mathbf{Cov}[\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2]$ itself by applying the multivariate Berry-Eseeen central limit theorem (cf. Theorem 8). It is readily verified using Equation (5) and the triangle inequality that

$$\frac{1}{4}\left(\mathbf{Cov}[\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2] - \mathbf{Cov}_{\approx}\right) \leq \sum_{i=1}^{3} |\alpha_i - \beta_i|$$

where

$$\alpha_1 = \mathbf{Pr}[\boldsymbol{S}_1 \geq 0, \boldsymbol{S}_2 \geq 0], \quad \alpha_2 = \mathbf{Pr}[\boldsymbol{S}_1 \geq 0], \quad \alpha_3 = \mathbf{Pr}[\boldsymbol{S}_2 \geq 0],$$

$$\beta_1 = \mathbf{Pr}\left[\boldsymbol{Z}_1 \geq -\sqrt{m}\mu_1, \boldsymbol{Z}_2 \geq -\sqrt{m}\mu_2\right], \quad \beta_2 = \mathbf{Pr}\left[\boldsymbol{Z}_1 \geq -\sqrt{m}\mu_1\right], \quad \beta_3 = \mathbf{Pr}\left[\boldsymbol{Z}_2 \geq -\sqrt{m}\mu_2\right].$$

Theorem 8 combined with the fact that both $\mu_1, \mu_2 \leq 1/2$ immediately gives $|\alpha_2 - \beta_2|$, $|\alpha_3 - \beta_3| = O(m^{-1/2})$. In more detail, Theorem 8 gives

$$|\alpha_2 - \beta_2| = O\left(\frac{1}{\sqrt{m}} \cdot \frac{[|\boldsymbol{S}_1 - \mu_1|^3]}{\mathbf{E}[(\boldsymbol{S}_1 - \mu_1)^2]^{3/2}}\right) = O\left(\frac{1}{\sqrt{m}} \cdot \frac{(1+\mu_1)^3]}{(1-\mu_1^2)^{3/2}}\right) \leq O\left(\frac{1}{\sqrt{m}}\right).$$

An identical argument gives the same bound for $|\alpha_3 - \beta_3|$. Finally, in order to show that $|\alpha_1 - \beta_1| = O(m^{-1/2})$ using Theorem 8, it suffices to establish that $\mathbf{E}[\|\Sigma^{-1/2}(\boldsymbol{S} - \mu)\|_2^3] = O(1)$, where $\boldsymbol{S} = (\boldsymbol{S}_1, \boldsymbol{S}_2)$. To see this, first note that

$$\Sigma^{-1/2} = \frac{1}{2}\begin{bmatrix} \alpha & \beta \\ \beta & \alpha \end{bmatrix}\begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix}^{-1}$$

where $\alpha = \frac{1}{\sqrt{1+\rho}} + \frac{1}{\sqrt{1-\rho}}$ and $\beta = \frac{1}{\sqrt{1+\rho}} - \frac{1}{\sqrt{1-\rho}}$. Now,

$$\begin{aligned}
\|\Sigma^{-1/2}(\boldsymbol{S}-\mu)\|_2^2 &= \frac{1}{4}\left((\alpha\lambda_1^{-1}(\boldsymbol{S}_1-\mu_1)+\beta\lambda_2^{-1}(\boldsymbol{S}_2-\mu_2))^2+(\beta\lambda_1^{-1}(\boldsymbol{S}_1-\mu_1)+\alpha\lambda_2^{-1}(\boldsymbol{S}_2-\mu_2))^2\right)\\
&= \frac{1}{1-\rho^2}\left(\lambda_1^{-2}(\boldsymbol{S}_1-\mu_1)^2+\lambda_2^{-2}(\boldsymbol{S}_2-\mu_2)^2-\rho\lambda_1^{-1}\lambda_2^{-1}(\boldsymbol{S}_1-\mu_1)(\boldsymbol{S}_2-\mu_2)\right) \qquad (13)\\
&\le \frac{4}{1-\rho^2}\left(\lambda_1^{-2}+\lambda_2^{-2}+\rho\lambda_1^{-1}\lambda_2^{-1}\right) \qquad (14)\\
&= 4\cdot\frac{2-(\mu_1^2+\mu_2^2)+\kappa}{(1-\mu_1^2)(1-\mu_2^2)-\kappa^2}\\
&\le 4\cdot\frac{2-\frac{1}{2}+\frac{1}{4}}{\frac{3}{4}-\left(\frac{4}{9}\right)^2} < 16, \qquad (15)
\end{aligned}$$

where in Equation (13) we note that $\alpha^2+\beta^2=\frac{4}{1-\rho^2}$ and $2\alpha\beta=-\frac{4\rho}{1-\rho^2}$, in Equation (14) we use $|X_i-\mu_i|\le 2$, and in Equation (15) we recall $(1-\mu_1^2)(1-\mu_2^2)\ge\frac{3}{4}$ and $-\frac{4}{9}\le\kappa\le\frac{1}{4}$. The result follows immediately. ◀

3.2 Lower Bound

Turning to lower bounds for uniformity testing of unate distribution, we will establish the following:

▶ **Theorem 3.** *Let $\mathcal{A}$ be any algorithm which, given i.i.d. sample access to an unknown distribution $\mathcal{D}$, has the performance guarantee from Theorem 2 with $\varepsilon = 1-n^{-10}$. Then $\mathcal{A}$ must draw $\Omega(n^{3/2}/\log^2 n)$ samples from $\mathcal{D}$.*

In particular, Theorem 3 implies that the algorithm from Section 3.1 has essentially optimal sample complexity. The proof is deferred to the full version [45].

4 Testing Unateness with Subcube Conditioning

We now turn to the proofs of Theorems 5 and 6, starting with the former.

4.1 Upper Bound

We start by recalling Theorem 5:

▶ **Theorem 5.** *Let $\varepsilon\in(0,1)$. There is an algorithm,* `Subcube-Unate` *(Algorithm 2) which, given subcube query access to an unknown distribution $\mathcal{D}$ over $\{\pm1\}^n$, makes $\widetilde{O}(n^{3/2}/\varepsilon^2)$ queries and has the following performance guarantee:*

- *If $\mathcal{D}$ is unate, it outputs "accept" with probability at least $2/3$.*
- *If $\mathcal{D}$ is ε-far in TV distance from every unate distribution on $\{\pm1\}^n$, then it outputs "reject" with probability at least $2/3$.*

4.1.1 Preliminaries from [21]

Chakrabarty, Chen, Ristic, Seshadhri, and Waingarten [21] gave an $\widetilde{O}(n/\varepsilon^2)$-query algorithm for monotonicity testing of a distribution over $\{\pm1\}^n$ in the subcube conditional model. Our $\widetilde{O}(n^{3/2}/\varepsilon^2)$-query algorithm for unateness testing will rely on their principal technical lemma, which we state after introducing some relevant notation.

For any $x \in \{\pm 1\}^n$ and $i \in [n]$, we define

$$\delta_{x,i} \coloneqq \frac{\mathcal{D}(x^{i\to -1}) - \mathcal{D}(x^{i\to +1})}{\mathcal{D}(x^{i\to -1}) + \mathcal{D}(x^{i\to +1})} \in [-1,1]$$

as the bias on the edge $\{x, x^{\oplus i}\}$. Note that if $\mathcal{D}$ is monotone, we always have $\delta_{x,i} \le 0$, so a positive $\delta_{x,i}$ witnesses a violation of monotonicity.

Central to the analysis in [21] is the following lemma, which is implicit in the proof of [21, Lemma 2.3]. For $x \in \mathbb{R}$, we write $(x)_+ \coloneqq \max\{x, 0\}$.

▶ **Lemma 14** ([21]). *For any $\mathcal{D}$ that is ε-far from monotone, there exists a positive integer $w \le O(\log(n/\varepsilon))$ such that*

$$\mathop{\mathbf{Pr}}_{\substack{\boldsymbol{x}\sim\mathcal{D}\\ \boldsymbol{i}\sim[n]}}\left[(\delta_{\boldsymbol{x},\boldsymbol{i}})_+^2 \ge 2^{-w}\right] \ge \widetilde{\Omega}\left(\frac{2^w\cdot\varepsilon^2}{n}\right).$$

The proof of Lemma 14 relies on a real-valued "directed" isoperimetric inequality proved in [21]. In particular, it follows from Lemma 14 that if we draw a random $\boldsymbol{w} \le O(\log(n/\varepsilon))$ with probability $\boldsymbol{w} = w$ proportional to 2^{-w}, we have

$$\mathop{\mathbf{Pr}}_{\boldsymbol{w},\boldsymbol{x}\sim\mathcal{D},\boldsymbol{i}\sim[n]}\left[(\delta_{\boldsymbol{x},\boldsymbol{i}})_+^2 \ge 2^{-\boldsymbol{w}}\right] \ge \sum_{w=1}^{O(\log(n/\varepsilon))} 2^{-w}\cdot \mathop{\mathbf{Pr}}_{\substack{\boldsymbol{x}\sim\mathcal{D}\\ \boldsymbol{i}\sim[n]}}\left[(\delta_{\boldsymbol{x},\boldsymbol{i}})_+^2 \ge 2^{-w}\right] \ge \widetilde{\Omega}\left(\frac{\varepsilon^2}{n}\right). \tag{16}$$

Give the lemma above, the algorithm of [21] is natural: we simply sample $\widetilde{O}(n/\varepsilon^2)$ triples $(\boldsymbol{w},\boldsymbol{x},\boldsymbol{i})$, in the hope of finding at least one with $(\delta_{\boldsymbol{x},\boldsymbol{i}})_+^2 \ge 2^{-\boldsymbol{w}}$. For each triple, we make $\widetilde{O}(2^w)$ queries to the subcube (or edge) $\{x, x^{\oplus i}\}$ to check whether $(\delta_{x,i})_+^2 \ge 2^{-w}$ holds. If this holds for any triple, we reject distribution $\mathcal{D}$. Over the randomness in $\boldsymbol{w}$, we make $\sum_{w=1}^{O(\log(n/\varepsilon))} 2^{-w}\cdot\widetilde{O}(2^w) = \widetilde{O}(1)$ queries for each triple, so the overall query complexity is $\widetilde{O}(n/\varepsilon^2)$.

4.1.2 Proof of Theorem 5

We first introduce some additional notation before proving Theorem 5. Recall from Notation 7 that, for $\sigma \in \{\pm 1\}^n$, $\mathcal{D}^\sigma$ is the distribution of

$$\boldsymbol{x}^\sigma \coloneqq (\sigma_1\boldsymbol{x}_1, \sigma_2\boldsymbol{x}_2, \ldots, \sigma_n\boldsymbol{x}_n),$$

where $\boldsymbol{x} \sim \mathcal{D}$, i.e., $\mathcal{D}^\sigma$ is obtained from $\mathcal{D}$ by flipping the coordinates indexed by $\{i \in [n] : \sigma_i = -1\}$. Recall that, with respect to distribution $\mathcal{D}$, we defined

$$\delta_{x,i} \coloneqq \frac{\mathcal{D}(x^{i\to -1}) - \mathcal{D}(x^{i\to +1})}{\mathcal{D}(x^{i\to -1}) + \mathcal{D}(x^{i\to +1})}.$$

In the following, we will write $\delta_{x,i}^{\mathcal{D}}$ to avoid confusion and emphasize dependence on $\mathcal{D}$. While the next identity is notation-heavy, it states an intuitive fact: if $\mathcal{D}^\sigma$ has a bias on an edge adjacent to x along the ith direction, $\mathcal{D}$ should also have a bias at x^σ, albeit flipped by σ_i. More formally,

$$\begin{aligned}
\delta_{x,i}^{\mathcal{D}^\sigma} &= \frac{\mathcal{D}^\sigma(x^{i\to -1}) - \mathcal{D}^\sigma(x^{i\to +1})}{\mathcal{D}^\sigma(x^{i\to -1}) + \mathcal{D}^\sigma(x^{i\to +1})} \\
&= \frac{\mathcal{D}((x^{i\to -1})^\sigma) - \mathcal{D}((x^{i\to +1})^\sigma)}{\mathcal{D}((x^{i\to -1})^\sigma) + \mathcal{D}((x^{i\to +1})^\sigma)} && (\mathcal{D}^\sigma(x) = \mathcal{D}(x^\sigma)) \\
&= \frac{\sigma_i\cdot\left[\mathcal{D}((x^\sigma)^{i\to -1}) - \mathcal{D}((x^\sigma)^{i\to +1})\right]}{\mathcal{D}((x^\sigma)^{i\to -1}) + \mathcal{D}((x^\sigma)^{i\to +1})} \\
&= \sigma_i\cdot\delta_{x^\sigma,i}^{P}. && (17)
\end{aligned}$$

We now record a corollary of Lemma 14 which will be crucial to our analysis of Algorithm 2. Since $\mathcal{D}$ is ε-far from unate, for every sign pattern $\sigma \in \{\pm 1\}^n$, the distribution $\mathcal{D}^\sigma$ is ε-far from monotone. Applying Lemma 14 (or more precisely, Equation (16)) to $\mathcal{D}^\sigma$ then gives

$$\begin{aligned}\widetilde{\Omega}\left(\frac{\varepsilon^2}{n}\right) &\leq \mathop{\mathbf{Pr}}_{\boldsymbol{w},\boldsymbol{x}\sim\mathcal{D}^\sigma,\boldsymbol{i}\sim[n]}\left[(\delta^{\mathcal{D}^\sigma}_{\boldsymbol{x},\boldsymbol{i}})^2_+ \geq 2^{-\boldsymbol{w}}\right] \\ &= \mathop{\mathbf{Pr}}_{\boldsymbol{w},\boldsymbol{x}\sim\mathcal{D}^\sigma,\boldsymbol{i}\sim[n]}\left[(\sigma_i \cdot \delta^{\mathcal{D}}_{\boldsymbol{x}^\sigma,\boldsymbol{i}})^2_+ \geq 2^{-\boldsymbol{w}}\right] && \text{(Equation (17))} \\ &= \mathop{\mathbf{Pr}}_{\boldsymbol{w},\boldsymbol{x}\sim\mathcal{D},\boldsymbol{i}\sim[n]}\left[(\sigma_i \cdot \delta^{\mathcal{D}}_{\boldsymbol{x},\boldsymbol{i}})^2_+ \geq 2^{-\boldsymbol{w}}\right], && (18)\end{aligned}$$

where Equation (18) relies on the fact that for $\boldsymbol{x} \sim \mathcal{D}^\sigma$, the random variable $\boldsymbol{x}^\sigma$ is distributed as $\mathcal{D}$. We record this consequence of Lemma 14 for future use:

▶ **Corollary 15.** *Suppose $\mathcal{D}$ is ε-far from unate. Then for every $\sigma \in \{\pm 1\}^n$, we have*

$$\mathop{\mathbf{Pr}}_{\boldsymbol{w},\boldsymbol{x}\sim\mathcal{D},\boldsymbol{i}\sim[n]}\left[(\sigma_i \cdot \delta^{\mathcal{D}}_{\boldsymbol{x},\boldsymbol{i}})^2_+ \geq 2^{-\boldsymbol{w}}\right] \geq \widetilde{\Omega}\left(\frac{\varepsilon^2}{n}\right).$$

Corollary 15 suggests a natural test to detect distributions that are far from unate and forms the basis of Algorithm 2: iterating over each coordinate $i \in [n]$, we reject if there exist two pairs $(\boldsymbol{w}, \boldsymbol{x})$ and $(\boldsymbol{w}', \boldsymbol{x}')$ such that

$$(\delta^{\mathcal{D}}_{\boldsymbol{x},i})^2_+ \geq 2^{-\boldsymbol{w}} \quad \text{and} \quad (-\delta^{\mathcal{D}}_{\boldsymbol{x}',i})^2_+ \geq 2^{-\boldsymbol{w}'}. \tag{19}$$

Intuitively, the former condition rules out the possibility that $\mathcal{D}$ is monotone in direction i, and the latter rules out that $\mathcal{D}$ is anti-monotone in direction i. Note that if $\mathcal{D}$ is unate, then both conditions above can never hold simultaneously.

We now turn to the proof of Theorem 5:

Proof of Theorem 5. For a fixed triple $(i, \boldsymbol{x}, \boldsymbol{w})$, the expected number of conditional samples is

$$\sum_{t=1}^{\Theta(\log(n/\varepsilon))} \mathbf{Pr}[\boldsymbol{w} = t] \cdot T(t) = \sum_t \Theta(2^{-t}) \cdot \Theta(2^t \log(nk)) = \widetilde{O}(1).$$

We perform $\Theta(n \cdot k) = \widetilde{\Theta}(n^{3/2}/\varepsilon^2)$ triples, so the total query complexity is $\widetilde{O}(n^{3/2}/\varepsilon^2)$.

By Hoeffding's inequality,

$$\mathbf{Pr}\left[\left|\boldsymbol{\tau}_\ell - \delta^{\mathcal{D}}_{\boldsymbol{x},i}\right| \;\geq\; \frac{1}{8}\,2^{-\boldsymbol{w}/2}\right] \;\leq\; 2\exp\Big(-\tfrac{1}{2}\cdot(\frac{1}{8}\,2^{-\boldsymbol{w}/2})^2\,T(\boldsymbol{w})\Big) \;\leq\; \frac{\delta_{\mathrm{cmp}}}{6nk},$$

for a sufficiently large absolute constant in the definition of $T(\boldsymbol{w})$. Taking a union bound over all nk trials, with probability at least $1 - \delta_{\mathrm{cmp}}/6$ we have, simultaneously for all trials,

$$\boldsymbol{\tau}_\ell \in \Big[\delta^{\mathcal{D}}_{\boldsymbol{x},i} - \frac{1}{8}\,2^{-\boldsymbol{w}/2},\; \delta^{\mathcal{D}}_{\boldsymbol{x},i} + \frac{1}{8}\,2^{-\boldsymbol{w}/2}\Big]. \tag{20}$$

For the remainder of the argument, we condition on the event that Equation (20) holds for all trials.

Algorithm 2 The `Subcube-Unate` algorithm.

Input: Subcube query access to $\mathcal{D}$, distance parameter $\varepsilon \in (0,1)$

Output: "Accept" or "reject"

`Subcube-Unate`$(\mathcal{D}, \varepsilon)$:

1. Set $k := \widetilde{\Theta}\left(\frac{\sqrt{n}}{\varepsilon^2}\right)$ and repeat Step 2 $\Theta(1)$-times:
2. For $i \in [n]$:
   a. For $\ell \in [k]$:
      i. Sample $\boldsymbol{x} \sim \mathcal{D}$ and consider the restriction $\boldsymbol{\rho} \in \{\pm 1, *\}^n$ given by $\boldsymbol{\rho}_j = \boldsymbol{x}_j$ if $j \neq i$ and $\boldsymbol{\rho}_i = *$.
      ii. Draw $\boldsymbol{w} \in [\Theta(\log(n/\varepsilon))]$ where $\mathbf{Pr}[\boldsymbol{w} = t] \propto 2^{-t}$.
      iii. Query the conditional distribution $\mathcal{D}\,|_{\boldsymbol{\rho}}$ independently

$$T(\boldsymbol{w}) := \Theta(1) \cdot 2^{\boldsymbol{w}} \cdot \ln(12nk/\delta_{\mathrm{cmp}})$$

      times for $\delta_{\mathrm{cmp}} := n^{-3}$. Let $N_+^{(\ell)}$ and $N_-^{(\ell)}$ be the numbers of returns with coordinate i equal to $+1$ and -1, respectively ($\boldsymbol{N}_+^{(\ell)} + \boldsymbol{N}_-^{(\ell)} = T(\boldsymbol{w})$). Define the empirical edge bias

$$\boldsymbol{\tau}_\ell \;:=\; \frac{\boldsymbol{N}_-^{(\ell)} - \boldsymbol{N}_+^{(\ell)}}{\boldsymbol{N}_-^{(\ell)} + \boldsymbol{N}_+^{(\ell)}}\,, \qquad \text{and set} \;\; c_{\boldsymbol{w}} := \frac{2^{-\boldsymbol{w}/2}}{4}\,.$$

      Mark the trial ℓ as a *positive witness* if $\boldsymbol{\tau}_\ell \geq c_{\boldsymbol{w}}$, and as a *negative witness* if $\boldsymbol{\tau}_\ell < -c_{\boldsymbol{w}}$.
   b. If there exist $\ell_1, \ell_2 \in [k]$ such that ℓ_1 is a positive witness and ℓ_2 is a negative witness, then halt and output "reject."
3. If the algorithm has not rejected, output "accept."

Completeness. Conditioned on the above event, it is readily seen that `Subcube-Unate` has one-sided error. In particular, suppose $\mathcal{D}$ is a unate distribution. It follows that there exists $\sigma \in \{\pm 1\}^n$ such that $\mathcal{D}^\sigma$ is monotone. In particular, $\sigma_i \cdot \delta^{\mathcal{D}}_{x,i} \leq 0$ for all $x \in \{\pm 1\}^n$ and $i \in [n]$. Fix a coordinate $i \in [n]$ and suppose $\sigma_i = +1$. We have $\delta^{\mathcal{D}}_{\boldsymbol{x},i} \leq 0$ for every $\boldsymbol{x}$, and conditioned on Equation (20),

$$\boldsymbol{\tau}_\ell \leq \; \tfrac{1}{8}\, 2^{-\boldsymbol{w}/2} \;<\; c_{\boldsymbol{w}} = \frac{2^{-\boldsymbol{w}/2}}{4}\,,$$

so this trial cannot create a positive witness for coordinate i. An identical argument gives that if $\sigma_i = -1$, then the trial cannot create a negative witness for coordinate i. It follows that, conditioned on Equation (20), the algorithm will output "accept" with probability 1.

Soundness. We now turn to soundness of `Subcube-Unate`$(\mathcal{D}, \varepsilon)$. Suppose $\mathcal{D}$ is ε-far from every unate distribution, we will show that `Subcube-Unate`$(\mathcal{D}, \varepsilon)$ will output "reject" with probability at least 9/10. For $\boldsymbol{w}$ distributed as in Step 2(a).ii of Algorithm 2 and $i \in [n]$, let

$$q_i^+ := \mathop{\mathbf{Pr}}_{\boldsymbol{w},\boldsymbol{x}\sim\mathcal{D}}\left[(\delta^{\mathcal{D}}_{\boldsymbol{x},i})_+^2 \geq 2^{-\boldsymbol{w}}\right] \qquad \text{and} \qquad q_i^- := \mathop{\mathbf{Pr}}_{\boldsymbol{w},\boldsymbol{x}\sim\mathcal{D}}\left[(-\delta^{\mathcal{D}}_{\boldsymbol{x},i})_+^2 \geq 2^{-\boldsymbol{w}}\right]$$

be the probabilities that, over the randomness in $\boldsymbol{w}$ and $\boldsymbol{x}$, the pair $(\boldsymbol{w}, \boldsymbol{x})$ witnesses that the ith coordinate cannot be monotone and anti-monotone respectively. Corollary 15 directly implies that

$$m := \frac{1}{n}\sum_{i=1}^{n} m_i \geq \widetilde{\Omega}\left(\frac{\varepsilon^2}{n}\right), \qquad \text{where } m_i := \min\left\{q_i^+, q_i^-\right\}. \tag{21}$$

Let r_i be the probability that $\texttt{Subcube-Unate}(\mathcal{D}, \varepsilon)$ outputs "reject" in Step 2(b) on coordinate i. Thanks to independence, we have

$$\mathbf{Pr}\left[\texttt{Subcube-Unate}(\mathcal{D}, \varepsilon) \text{ outputs "accept"}\right] = \prod_{i=1}^{n}(1 - r_i) \leq \exp\left(-\sum_{i=1}^{n} r_i\right),$$

and so the remainder of the argument will establish that $\sum_{i=1}^{n} r_i = \Omega(1)$.

First, note that

$$r_i \geq \left(1 - (1 - q_i^+)^{k/2}\right)\left(1 - (1 - q_i^-)^{k/2}\right) \geq \left(1 - (1 - m_i)^{k/2}\right)^2, \tag{22}$$

where the first inequality holds because the probability of returning "reject" after k iterations of Steps 2(a).i–iii is at least the probability of detecting a positive witness among the first $k/2$ iterations and a negative witness among the last $k/2$ iterations. The following lemma will be useful:

▶ **Lemma 16.** *For $K \geq 1$, the function $f(x) = (1 - (1 - x)^K)^2$ is convex on the interval $(0, \ln(2)/K)$.*

Proof. We explicitly compute the first and second derivatives of the function f. Note that

$$f'(x) = 2K\Big(1 - (1 - x)^K\Big)(1 - x)^{K-1}.$$

Taking another derivative gives

$$\begin{aligned} f''(x) &= 2K^2(1 - x)^{2K-2} - 2K(K - 1)(1 - (1 - x)^K)(1 - x)^{K-2} \\ &= 2K(1 - x)^{K-2}((2K - 1)(1 - x)^K - (K - 1)). \end{aligned}$$

So it suffices to show

$$(2K - 1)\Big(1 - \tfrac{\ln 2}{K}\Big)^K \geq K - 1,$$

or equivalently $F(K) \geq 0$ where $F(x) := x\ln\Big(1 - \frac{\ln 2}{x}\Big) - \ln\Big(\frac{x-1}{2x-1}\Big)$. Since

$$\lim_{x \to +\infty} F(x) = -\ln 2 - \ln\tfrac{1}{2} = 0,$$

showing that $F'(x) < 0$ for all $x \in (1, +\infty)$ will complete the proof.

Note that

$$F'(x) = \ln\Big(1 - \frac{1}{x/\ln 2}\Big) + \frac{1}{x/\ln 2 - 1} - \frac{1}{(x-1)(2x-1)}.$$

Furthermore, the function $h(y) := \ln\Big(1 - \frac{1}{y}\Big) + \frac{1}{y-1}$ has derivative $h'(y) = -\frac{1}{y(y-1)^2}$, and is thus strictly decreasing on $(1, +\infty)$. If we could show that

$$h(x) = \ln\Big(1 - \frac{1}{x}\Big) + \frac{1}{x-1} \leq \frac{1}{(x-1)(2x-1)} \tag{23}$$

holds for all $x \in (1, +\infty)$, we would have the desired inequality

$$F'(x) = h(x/\ln 2) - \frac{1}{(x-1)(2x-1)} < h(x) - \frac{1}{(x-1)(2x-1)} \leq 0.$$

Equation (23) follows immediately from the well-known/readily verified inequality $2a \leq (2+a) \cdot \ln(1+a)$ for $a \geq 0$ by taking $a = (x-1)^{-1}$. ◀

Returning to the soundness of `Subcube-Unate`, note that if there exists a coordinate j with $m_j \geq \frac{2\ln 2}{k}$, then thanks to Equation (22) we have

$$r_j \geq (1-(1-m_j)^{k/2})^2 \geq \left(1 - \left(1 - \frac{\ln 2}{k/2}\right)^{k/2}\right)^2 \geq (1 - e^{-\ln 2})^2 = \frac{1}{4}.$$

Consequently, the amplification in Step 1 ensures that one of the $\Theta(1)$ independent runs will output "reject" with probability at least $9/10$.

On the other hand, suppose $m_i < \frac{2\ln 2}{k}$ for all $i \in [n]$. Thanks to Lemma 16 and Jensen's inequality, we then have

$$\sum_{i=1}^{n} r_i \geq \sum_{i=1}^{n} \left(1 - (1-m_i)^{k/2}\right)^2 \geq n\left(1 - (1-m)^{k/2}\right)^2.$$

It follows that $\sum_{i=1}^{n} r_i \geq 99/100$ from Equation (21) and our choice of k by an easy application of Bernoulli's inequality $(1+u)^r \geq 1 + ru$ for $r, u \geq 0$. ◀

4.2 Lower Bound

We prove the following lower bound for testing unateness of distributions in the subcube model, which applies to all testers that only make subcube queries on either the entire hypercube (to get an unconditional sample) or a small subcube.

▶ **Theorem 6.** *There exists a constant $\varepsilon_0 > 0$ such that the following holds: If an algorithm tests whether an unknown distribution $\mathcal{D}$ over $\{\pm 1\}^n$ is unate or ε_0-far from unate by drawing Q_1 samples from $\mathcal{D}$ and making Q_2 (possibly adaptive) subcube queries on subcubes of dimensions $\leq d$, we have*

$$Q_1 + 2^d Q_2 \geq \Omega(n^{2/3}/\log^3 n).$$

Recall that our tester for Theorem 5, like the monotonicity tester of [21], only makes subcube queries on edges (i.e., one-dimensional subcubes) in addition to drawing unconditional samples. In other words, our tester satisfies the precondition of Theorem 6 with $d = 1$. The theorem then implies that all such testers must make at least $\widetilde{\Omega}(n^{2/3})$ queries in total.

The proof is deferred to the full version [45].

Abstract

A central challenge in property testing is verifying algebraic structure with minimal access to data. A landmark result addressing this challenge, the linearity test of Blum, Luby, and Rubinfeld (JCSS '93), spurred a rich body of work on testing algebraic properties such as linearity and its generalizations to low-degree polynomials and group homomorphisms. However, classical tests for these properties assume unrestricted, noise-free access to the input function – an assumption that breaks down in adversarial or dynamic settings. To address this, Kalemaj, Raskhodnikova, and Varma (Theory of Computing '23) introduced the online manipulation model, where an adversary erases or corrupts query responses over time, based on the tester's past queries.

We initiate the study of *manipulation-resilient* testing for *group homomorphism* in this online model. Our main result is an *optimal* tester that makes $O(1/\varepsilon + \log t)$ queries, where ε is the distance parameter and t is the number of function values the adversary can erase or corrupt per query. Our result recovers the celebrated $O(1/\varepsilon)$ bound by Ben-Or, Coppersmith, Luby, and Rubinfeld (Random Struct. Algorithms '08) for homomorphism testing in the standard property testing model, albeit with a different tester. Our tester, Random Signs Test, *lifts* known manipulation-resilient linearity testers for $\mathbb{F}_2^n \to \mathbb{F}_2$ to general group domains and codomains by introducing more randomness: instead of verifying the homomorphism condition for a sum of random elements, it uses additions and subtractions of random elements, randomly selecting a sign for each element. We also obtain improved group-specific query bounds for key families of groups. Our results show that despite the challenges of online manipulation, group homomorphism – a fundamental algebraic property – is efficiently testable across a wide range of domains and codomains. Finally, we formalize a general framework for proving online resilience.

1 Introduction

Understanding how to verify algebraic structure with minimal access to data is a central question in *property testing*. A landmark result addressing this challenge is the linearity test of Blum, Luby, and Rubinfeld [15], which checks whether a given function is linear by querying it on two random inputs and their sum. This test and its variants sparked a rich line of work on testing algebraic properties of functions, including linearity [6, 21, 8], being a low-degree polynomial [5, 23, 22, 53, 51, 1, 3, 46, 33, 54, 56, 30, 14, 28, 52, 17, 32], and being a group homomorphism [15, 27, 11, 25, 7, 45, 26, 43], with deep connections to probabilistically-checkable proofs [2, 59, 29].

However, classical property testing, as defined by [53, 24], relies on the assumption of undisrupted query access to the input function – an assumption that may break down in dynamic environments or under adversarial or incomplete access to data. Many testers, especially for algebraic properties, use structured queries that can be vulnerable to online adversarial interference. To address this, Kalemaj, Raskhodnikova, and Varma [31] introduced the *online manipulation model,* where an adversary can erase or corrupt the input during the execution of the algorithm, based on prior queries. This framework has prompted the reexamination of classical testing problems under a new lens, seeking algorithms that remain correct and efficient despite adversarial interference.

In this work, we initiate the study of manipulation-resilient testing for group homomorphism, a fundamental property of functions between algebraic structures. Given finite groups $(G, +)$ and $(H, \oplus)$, and a function $f : G \to H$, the goal is to determine whether f is a *homomorphism*[1] – i.e., satisfies $f(x_1 + x_2) = f(x_1) \oplus f(x_2)$ for all $x_1, x_2 \in G$ – or is ε-far from every homomorphism.[2] The tester accesses the input function f by querying its values $f(x)$ on elements x of the group, but must contend with an *online adversary* that knows all queries made by the tester and can manipulate the data after answering each query. Two types of manipulation are considered: an *erasure*, where $f(x)$ is replaced by a special symbol $\perp$, and a *corruption*, where $f(x)$ is replaced by an arbitrary element of H. The rate of manipulations is controlled by a parameter t. Two types of adversaries have been studied: *fixed rate*, which can manipulate t values after every query is answered [31], and *budget-managing*, which accumulates a budget of t manipulations per query and may deploy them later at any point in the computation, after answering any query [10].

Linearity and low-degree testing are well understood in the online adversarial model. Linearity and quadraticity were among the first properties studied in this setting, with [31] proving a query lower bound of $\Omega(\log t)$ for testing linearity of functions $f : \mathbb{F}_2^n \to \mathbb{F}_2$. fThe linearity tester of [31] was improved by Ben-Eliezer, Kelman, Meir and Raskhodnikova [10], who achieved the optimal query complexity of $O(1/\varepsilon + \log t)$, and further refined by Arora, Kelman, and Meir [4] to handle the full range of the parameter t. For the related problem of direct sum testing, Westover, Yu and Zheng [60] achieve the same query complexity. For testing whether a function $f : \mathbb{F}_q^n \to \mathbb{F}_q$ has degree at most d, for fixed constants d, q and ε, a lower bound of $\Omega(\log^d t)$ on the query complexity was first shown by [10] for $q = 2$ and later by [36] whenever $q \geq d$, whereas the elegant tester of Minzer and Zheng [42] makes $\text{poly}(\log^d t)$ queries, and a recent refined tester and analysis yield the tight upper bound of $O(\log^d t)$ queries for this parameter regime [36].

[1] As noted in the Encyclopedia of Algorithms [50], the set of homomorphisms from G to H forms an error-correcting code, called the *homomorphism code*. When $G = \mathbb{F}_2^n$ and $H = \mathbb{F}_2$, this corresponds to the well-known Hadamard code. From this perspective, homomorphism testing is equivalent to testing membership in the corresponding code.

[2] We use additive notation for all group operations, even for non-abelian groups (as opposed to using $\cdot$ and $*$), as it enables compact summation notation (specifically, $\sum$ and $\bigoplus$) and leads to more concise and readable expressions.

While both lower bounds [31, 10] apply to the weakest model of online adversary (fixed-rate with erasures), the algorithms of [10, 4, 42, 60] are resilient even in the strongest model considered (budget-managing with corruptions).

These developments raise a natural question: Can one design testers resilient to online manipulations for the other natural generalization of linearity – namely, group homomorphism?[3] We answer this question affirmatively by designing testers that are resilient to the strongest type of online adversary in our framework – budget-managing with corruptions. Our main result is that homomorphism of functions $f : G \to H$ can be tested with $O(1/\varepsilon + \log t)$ queries in the presence of a t-online corruption adversary for all groups G and H. This bound is optimal: even without manipulations, $\Omega(1/\varepsilon)$ queries are required, and the $\Omega(\log t)$ lower bound of [31] holds for the special case $G = \mathbb{F}_2^n$ and $H = \mathbb{F}_2$.

Since the lower bound applies to specific groups G and H, a natural next question is whether some groups admit better testers. We obtain improved group-specific query bounds for many important families of groups. In particular, we design an online-manipulation-resilient homomorphism tester that makes $O(1/\varepsilon + E(G))$ queries, where $E(G)$ is the expected number of samples from G needed to generate G. This tester is optimal, for instance, when G is a cyclic, symmetric, alternating, or simple group. For vector spaces over finite fields of prime order, we obtain nearly tight bounds: when $G = \mathbb{F}_p^n$ and $H = \mathbb{F}_p^r$, homomorphism can be tested with $O(1/\varepsilon + \log_p t)$ queries, and we prove a matching $\Omega(\log_p t)$ lower bound for the case $r = 1$; when $H = \mathbb{F}_q^r$ where $q \neq p$, testing reduces to checking whether f is identically zero.

Our results demonstrate that group homomorphism – a fundamental algebraic property – admits efficient and manipulation-resilient testers across the board: we give a general optimal tester for all finite groups and complement it with sharper bounds for prominent families of domains and codomains.

1.1 Our results

Our main result is an *optimal* online-manipulations-resilient homomorphism tester of $f : G \to H$ for all groups G and H. As all our testers, it works in the strongest online adversary model considered: budget-managing with corruptions.

▶ **Theorem 1.1.** *There exists a constant $c > 0$ such that for all finite groups $(G, +)$ and $(H, \oplus)$, all $\varepsilon \in (0, 1)$ and $t \leq c \cdot \min\left\{\varepsilon^2, 1/\log^2 |G|\right\} \cdot |G|$, there exists an ε-tester for group homomorphism of functions of the form $f : G \to H$ that works in the presence of every budget-managing t-online erasure (or corruption) adversary and makes $O\left(\frac{1}{\varepsilon} + \log_2 t\right)$ queries. For erasures, the tester has 1-sided error.*

Our result recovers the celebrated $O(1/\varepsilon)$ bound by [15, 11] for testing homomorphism in the standard property testing model, albeit with a different tester. Our tester, which we call Random Signs Test, can be viewed as *lifting* the linearity testers developed by [31, 10, 4] for functions $f : \mathbb{F}_2^n \to \mathbb{F}_2$ to work for general groups G and H. As noted by [31], the original [15] tester breaks in the online manipulations model, and as we explain in Section 1.2, the known online-manipulation-resilient testers for the case $G = \mathbb{F}_2^n$ and $H = \mathbb{F}_2$ are not sound for general groups. Let $(G, +)$ be the domain group and $(H, \oplus)$ be the codomain group. For

[3] Importantly, efficient testability of a property $\mathcal{P}$ in the standard property testing model does not guarantee that $\mathcal{P}$ is testable with online adversary. For instance, [31] show that *sortedness* of integer sequences – despite having many efficient testers in the standard model [20, 19, 48, 13, 16, 49, 9] – is not testable even with a single online erasure per query, regardless of the number of queries.

the case without manipulations, our tester picks k points (for any even k) $x_1, \ldots, x_k$ from the domain group G and k signs $\sigma_1, \ldots, \sigma_k$ from $\{+, -\}^k$ uniformly and independently at random. Then it obtains an element $a = \sigma_1 x_1 + \cdots + \sigma_k x_k$, where $\sigma_i x_i$ denotes x_i when $\sigma_i = +$ and the inverse of x_i (in G) when $\sigma_i = -$. Finally, it queries f on $x_1, \ldots, x_k$, and a, and tests whether the homomorphism condition is satisfied for these elements, that is, whether $f(a) = \sigma_1 f(x_1) \oplus \cdots \oplus \sigma_k f(x_k)$, where $\sigma_i = -$ denotes the inverse in the group H. The manipulation-resilient version of the tester first samples a reserve of elements of G and then runs Random Signs Test with carefully selected k and elements $x_1, \ldots, x_k$ from the reserve. We provide a technical overview of the tester and its analysis in Section 1.2. Section 3 presents and analyzes Random Signs Test, and Section 5 – a manipulation-resilient version of Random Signs Test.

1.1.1 Group-specific homomorphism testing

Our first group-specific result, Theorem 1.3, gives a homomorphism tester with complexity expressed in terms of the parameter $E(G)$, defined next.

▶ **Definition 1.2** ([47]). *For all finite groups $(G, +)$, let $E(G)$ be the expected number of independent and uniform samples from G needed to obtain a generating set for G.*

This group-specific tester has an additional advantage of being *sample-based*, i.e., querying only independent and uniform elements of G. Its guarantees are given in Theorem 1.3 and proved in the full version.

▶ **Theorem 1.3** (Group-specific sample-based tester). *There exists a constant $c > 0$ such that for all finite groups $(G, +)$ and $(H, \oplus)$, all $\varepsilon \in (0, 1)$ and $t \leq c \cdot \min\left\{\varepsilon^2, 1/E(G)^2\right\} \cdot |G|$, there exists a sample-based ε-tester for group homomorphism of functions of the form $f : G \to H$ that works in the presence of every t-online erasure (or corruption) budget-managing adversary and makes $O(1/\varepsilon + E(G))$ queries. For erasures, the tester has 1-sided error.*

In the model without manipulations, Goldreich and Ron [25] gave a sample-based homomorphism tester with $O(1/\varepsilon + \log |G|)$ queries and showed this bound is tight for some groups G and H (in particular, $G = \mathbb{F}_2^n, H = \mathbb{F}_2$). The query bound in Theorem 1.3 improves on the bound in [25] for many natural groups and is tight when $E(G)$ is constant – e.g., for cyclic groups of prime order $\mathbb{Z}_p$, symmetric groups S_n and alternating groups A_n [18], and, more generally, finite simple groups [38]. This gives us the following corollary.

▶ **Corollary 1.4** (Homomorphism tester for simple groups). *There exists a constant $c > 0$ such that for all finite groups $(G, +)$ and $(H, \oplus)$, where G is a finite simple group, all $\varepsilon \in (0, 1)$ and all $t \leq c \cdot \varepsilon^2 |G|$, there exists a sample-based ε-tester for group homomorphism of functions of the form $f : G \to H$ that works in the presence of a t-online-erasure adversary and makes $\Theta(1/\varepsilon)$ queries.*

To improve the bound in [25] and prove Theorem 1.3, we analyze the subgroup generated by the sample S, rather than only partial sums that can be obtained from S, obtaining better group-specific bounds on the number of samples needed to properly learn the input homomorphism. Our analysis relies on work in group theory [18, 38, 47, 39, 40, 41] that relates $E(G)$ from Definition 1.2 to the size of the smallest set generating G and other structural parameters of the group.

Bounds for prime fields. Finally, we consider groups of the form $G = \mathbb{F}_p^n$ and $H = \mathbb{F}_q^r$, where p and q are primes and $n, r \in \mathbb{N}$. Our next result shows that if $p = q$, the query complexity is below the general bound of $O(1/\varepsilon + \log_2 t)$ from Theorem 1.1.

▶ **Theorem 1.5.** *There exists a constant $c > 0$ such that for all primes p, all $n, r \in \mathbb{N}$, all $\varepsilon \in (0,1)$ and $t \leq c \cdot \min\left\{\varepsilon^2, 1/n^2\right\} p^n$, there exists an ε-tester for homomorphism of functions of the form $f : \mathbb{F}_p^n \to \mathbb{F}_p^r$ that works in the presence of every t-online erasure (or corruption) budget-managing adversary and makes $O(1/\varepsilon + \log_p t)$ queries. For erasures, the tester has 1-sided error.*

Next we show that, when the range is $\mathbb{F}_p$ ($r = 1$), the bound in Theorem 1.5 is tight.

▶ **Theorem 1.6.** *For all primes p, there exists $n_0 \in \mathbb{N}$ such that for all $n \in \mathbb{N}, n \geq n_0$ and $\varepsilon \in (0, \frac{p-1}{2p}]$, every t-online erasure-resilient ε-tester for homomorphism of functions of the form $f : \mathbb{F}_p^n \to \mathbb{F}_p$ must make $\Omega(\log_p t)$ queries.*

We defer the proofs of Theorems 1.5 and 1.6 to the full version. Finally, we observe that the case when $p \neq q$ is easy.

▶ Remark 1.7. For all finite groups G and H such that the zero map is the only homomorphism from G to H (e.g., when $G = \mathbb{F}_p^n$ and $H = \mathbb{F}_q^r$, where p and q are distinct primes and $n, r \in \mathbb{N}$), testing if a function $f : G \to H$ is a homomorphism is equivalent to testing if f is identically zero and can be done with $\Theta(1/\varepsilon)$ queries, even in the presence of a t-online manipulation budget-managing adversary.

1.1.2 A general framework for resilience

Resilience to online manipulations creates a fundamental tension: a tester must make queries that are hard for the adversary to predict, yet these may not be the most informative ones. This perspective naturally interpolates between two familiar extremes in property testing: query-based testers, which optimize for information useful for the specified computational task but may be predictable, and sample-based testers, which query f on independent uniformly random elements of G and thus maximize unpredictability. Understanding how to balance these competing goals provides a new lens on property testing.

To formalize this perspective, we need a notion of unpredictability that captures this trade-off. A natural candidate is the notion of *fairness* of Goldreich and Ron [25], which constrains the marginal distribution of each query. A tester is *α-fair* if, at every step, no $x \in G$ is queried with probability more than α. They showed that if a property has an α-fair ε-tester that makes q queries with $\alpha = \Theta(|G|^{-1})$ and constant ε then it also has a sample-based tester (in a sense, a "completely fair" tester) with $|G|^{1-\frac{1}{q}}$ queries. This provides an intriguing trade-off between the number of queries and their predictability. However, fairness is ill-suited for resilience to online manipulations, as it does not account for dependencies between queries. For example, the [15] linearity test is completely fair – each query is uniformly random – yet, as observed by [31], it is vulnerable to online manipulations because its third query is fully determined by the first two. This suggests that marginal notions of unpredictability are insufficient.

The key ingredient in our framework for proving resilience is a new notion of *conditional* unpredictability for testers (Definition 4.2). Informally, a tester is (q, α, β)-unpredictable if, with probability at least $1 - \beta$, *each* of its q queries remains hard to predict even after conditioning on the previous queries. Formally, there exist parameters $\{\alpha_i, \beta_i\}_{i \in [q]}$ with $\sum_{i \in [q]} \alpha_i = \alpha$ and $\sum_{i \in [q]} \beta_i = \beta$ such that for each $i \in [q]$, with probability at least $1 - \beta_i$, the

conditional distribution of the ith query Q_i is α_i-flat, i.e., $\max_{x \in G} \Pr[Q_i = x \mid Q_1, \ldots, Q_{i-1}] \leq \alpha_i$. This sequential, conditional structure is reminiscent of Santha–Vazirani sources from the extractor literature [57].

We show that unpredictability directly yields resilience to online manipulations: regardless of the past manipulations, an unpredictable tester is unlikely to ever query a manipulated entry. In particular, a (q, α, β)-unpredictable tester queries a manipulated location with probability at most $\alpha T + \beta$, where T is the total number of manipulations over the entire execution (see Lemma 4.3). To prove our main results, we first establish soundness of a *core test*, modify it to get an *unpredictable core test* which has the same soundness as the core test along with sufficient unpredictability. To get our final testers, we then amplify the success probability of the unpredictable core test by repetition. We address some nuances of amplification in the online manipulation model – where accumulated manipulations can make later repetitions less reliable – and prove an amplification lemma that specifies the required parameters of the unpredictable core test and the number of repetitions.

1.2 Technical overview of the tester for general groups

The starting point for the classical homomorphism testers, as well as for manipulation-resilient linearity testers, is a core test (equivalently, a local characterization of a property). All core tests we discuss have perfect *completeness:* they always accept homomorphisms. In addition, they need to have good *soundness:* high enough rejection probability of inputs that are far from the desired property. For the standard model, good soundness suffices, since repeating the core test amplifies its rejection probability and yields the desired tester. For the online adversarial model, however, soundness alone is insufficient; the final tester must also be unpredictable enough to prevent the adversary from targeting its queries. As in [31], this is achieved by first building a reservoir of uniformly random queried elements, then using a final query to simulate the core test on a random subset of the reservoir, and finally repeating the resulting procedure as needed.

Our main technical contribution is the design and analysis of a new core test. While its full analysis with the reservoir requires additional ideas, we focus here on why a natural extension of the manipulation-resilient linearity test fails in our setting, how our test is constructed, and the key insights behind its correctness.

Before introducing our tester, we discuss why a natural generalization of online manipulation resilient testers from previous work fails to provide soundness. The $(k+1)$-point linearity test of [31] queries the input function f on k independent and uniformly random elements $x_1, \ldots, x_k$ and their sum $x_{k+1} := \sum_{i \in [k]} x_i$ and checks whether $\sum_{i \in [k]} f(x_i)$ equals $f(\sum_{i \in [k]} x_i)$. Let $(G, +)$ and $(H, \oplus)$ be finite groups and $f : G \to H$ be a function. A natural extension of the [31] test to the homomorphism property is to check whether[4]

$$f(x_1) \oplus f(x_2) \oplus \cdots \oplus f(x_k) \stackrel{?}{=} f(x_1 + x_2 + \cdots + x_k). \tag{1}$$

If f is a homomorphism, then (1) holds for all tuples $(x_1, \ldots, x_k)$, but the converse is false: for $G = H = \mathbb{Z}_{k-1}$ (the additive cyclic group over $k-1$ elements) and any homomorphism $h : G \to H$, the shifted homomorphism function $f(x) = h(x) \oplus s$ with shift $s \in H$ also satisfies (1) for all tuples.[5] To resolve this issue, our homomorphism tester uses a more robust local characterization.

---

[4] We use compact notation to represent our sums: (1) can also be written as $\bigoplus_{i \in [k]} f(x_i) = f\left(\sum_{i \in [k]} x_i\right)$. In non-Abelian groups, the order matters. The terms in the sums are ordered according to the index: in increasing index order for $\sum_{i \in [k]} x_i$ or $\bigoplus_{i=1}^{k} y_i$, and in decreasing index order for $\sum_{i=k}^{1} x_i$.

[5] A similar phenomenon occurs for functions $f : \mathbb{F}_2^n \to \mathbb{F}_2$: the k-point tester with even k works for linearity, but odd k produces a test for *affinity* instead.

Next, we discuss our desired soundness guarantee and sketch a simple argument showing that many NO instances are rejected by the $(k+1)$-point test with sufficient probability. (The example above shows that this tester fails on functions that are really far from any homomorphism, but it turns out it works well for functions which are closer to a homomorphism). Let h_f be a closest homomorphism to f and ε_f be the distance from f to h_f. Define $\Delta_f := \{x \in G : f(x) \neq h_f(x)\}$ (so that $|\Delta_f| = \varepsilon_f \cdot |G|$). Since all tuples $(x_1, \ldots, x_k)$ satisfy modified (1) with f replaced by h_f, one could analyze for how many tuples (1) holds for f by comparing f and h_f on each tuple. The following "wishful thinking" argument is an easy assertion when ε_f is small enough, and was used before, e.g., for optimal analysis of low-degree testing over $\mathbb{F}_2$ [14].

Simple case: $\varepsilon_f < \frac{1}{2k}$. We view each point x_i (including the sum x_{k+1}) as a random variable, and ask whether $x_i \in \Delta_f$. Marginally, each x_i is distributed uniformly over G and so this occurs with probability ε_f for all $i \in [k+1]$. Intuitively, the points are "independent enough" so when $\varepsilon_f < \frac{1}{2k}$, w.h.p. at most one of them falls in Δ_f. If exactly one point does, then the tester rejects f (by cancellation rule on the group H). Formally, when $\varepsilon_f < \frac{1}{2k}$ the probability of exactly one x_i falling in Δ_f can be lower bounded by $k\varepsilon_f/2$ using the premise, pairwise independence of the points and inclusion-exclusion (Bonferroni inequality of order 2), as was done, e.g., in [14, 10] to analyze low-degree tests of polynomials over fields. By a union bound, the rejection probability is at most $k\varepsilon_f$ so the analysis above is optimal (up to a factor of 2) for inputs with small distance ε_f.

However, larger values of ε_f lead to more than a single point in Δ_f for a typical tuple, and the guaranteed pairwise independence is no longer enough. Luckily, the $k+1$ points used in (1) are in fact k-wise independent, which is a stronger guarantee for $k > 2$. We demonstrate how to leverage this fact, focusing on the case $H = \mathbb{F}_2$.

The elementary argument (for $\varepsilon_f < \frac{1}{8}$). Let p_m be the probability that m independent and uniformly random elements $z_1, \ldots, z_m \in G$ satisfy $\bigoplus_{i\in[m]} f(z_i) = \bigoplus_{i\in[m]} h_f(z_i)$. Let $\gamma_m = 1 - p_m$ be the probability of an inequality. By definition, $\gamma_1 = \varepsilon_f$. We utilize the k-wise independence by splitting the last point, $x_{k+1} = \sum_{i\in[k]} x_i$, from the rest and comparing the RHS and LHS of (1) with f to those with h_f where the equality holds. In particular, the event that the RHS of f and h_f agree but the LHS are different, leads to rejection of f. Then

$$\begin{aligned}
&\Pr_{x_1,\ldots,x_k\in G}\left[\bigoplus_{i\in[k]} f(x_i) \neq f\Big(\sum_{i\in[k]} x_i\Big)\right] \\
\geq &\Pr_{x_1,\ldots,x_k\in G}\left[\bigoplus_{i\in[k]} f(x_i) \neq \bigoplus_{i\in[k]} h_f(x_i) \ \wedge\ f\Big(\sum_{i\in[k]} x_i\Big) = h_f\Big(\sum_{i\in[k]} x_i\Big)\right] \\
\geq &\Pr\left[\bigoplus_{i\in[k]} f(x_i) \neq \bigoplus_{i\in[k]} h_f(x_i)\right] - \Pr\left[f\Big(\sum_{i\in[k]} x_i\Big) \neq h_f\Big(\sum_{i\in[k]} x_i\Big)\right] = \gamma_k - \gamma_1,
\end{aligned}$$

where the second inequality uses $\Pr[A \wedge B] \geq \Pr[A] - \Pr[\bar{B}]$ for two events A, B (where $\bar{B}$ is the complement of B). The equality is since $(x_1, \ldots, x_k)$ are i.i.d. samples taken uniformly at random from G.

From here on, the goal is to lower bound γ_k. To showcase the argument we restrict ourselves to $H = \mathbb{F}_2$ (which in particular captures linearity over $\mathbb{F}_2$), and discuss the extension later. Here, $f(x) - h_f(x) = 1$ if $x \in \Delta_f$, and otherwise $f(x) = h_f(x)$. That is, γ_k is the probability that there is an odd number of indices $i \in [k]$ for which $x_i \in \Delta_f$. Since these points are independent and each has probability ε_f to fall inside Δ_f, this equals to the

probability of a binomial random variable $Z \sim Bin(k, \varepsilon_f)$ being odd, which is known to equal $\frac{1-(1-2\varepsilon_f)^k}{2}$. This expression has a known lower bound of $\Omega(\min\{k\varepsilon_f, 1\})$, which absorbs the subtraction of $\gamma_1 = \varepsilon_f$ for any $\varepsilon_f \leq 1/8$ and completes the proof.[6]

To generalize this argument, note that $H = \mathbb{F}_2$ is essentially the worst-case scenario, as "coincidental cancellations" are most probable when $f(x) - h_f(x) \in \{0, 1\}$. In Section 3.1 we prove the claim for our modified tester, described shortly, and any codomain H, by analyzing an inductive recurrence directly on p_m (rather than $\gamma_m = 1 - p_m$).

The random signs test. We make the local characterization more robust by adding *signs*. We rely on the inverse operation, which exists in every group, and use $-x$ to express the addition of the inverse of x for both groups, G and H. Since every homomorphism satisfies $f(-x) = -f(x)$ for all $x \in G$, it respects not only summations of elements but signed summations as well. The corresponding tester is this: given a function $f : G \to H$, choose uniformly at random (and independently) a tuple $(x_1, \ldots, x_k, \sigma_1, \ldots, \sigma_k)$ consisting of k elements $x_1, \ldots, x_k \in G$, and k signs $\sigma_1, \ldots, \sigma_k \in \{+, -\}$. Finally, check whether

$$\bigoplus_{i\in[k]} \sigma_i f(x_i) \stackrel{?}{=} f(\sum_{i\in[k]} \sigma_i x_i). \tag{2}$$

As before, if f is a homomorphism, all tuples satisfy equation (2). The difference is that now, when k is even, the converse holds as well.[7] To analyze the soundness of Random Signs Test, we consider two cases. For $\varepsilon_f < 1/8$, the elementary argument (Lemma 3.2) suffices. To prove this tester rejects functions with $\varepsilon_f \geq 1/8$ (unlike the unmodified k-point tester), we show the contrapositive via a corrector argument based on that of [15, 11].

In the corrector method, a corrector function $g(x)$ is defined as the value satisfying the most instances of equation (2), where each instance corresponds to a signed tuple for which $\sum_{i\in[k]} \sigma_i x_i = x$. Differently put, each tuple of elements and signs that sum to x "votes" for a value it wishes $f(x)$ to be – then $g(x)$ is defined as the plurality of these votes. To prove soundness, one shows that if the test rejects f with probability $\mu \leq 1/10$, then two key assertions follow: (a) f is 2μ-close to g; (b) g is a homomorphism. The two assertions are proved in Lemmas 3.12 and 3.13, respectively, with the latter employing the probabilistic method. Both rely on an auxiliary step, Lemma 3.11, which shows that the choice of $g(a)$ as a plurality of votes, is in fact a strong majority of at least $1 - 2\mu$ of the votes, for every input $a \in G$.

We focus here on the proof of this step, which demonstrates the techniques of the full argument, and the role of random signs. The proof analyzes the collision probability – the probability that two signed tuples $(\sigma, x), (\tau, y)$ that sum to a vote for the same value for $f(a)$.

---

[6] We use $\frac{1-(1-2\varepsilon_f)^k}{2} = \Omega(\min\{k\varepsilon_f, 1\})$ with a specific constant, by applying [10, Lemma 3.1].

[7] Indeed, if f always satisfies equation (2), then given $x_1, x_2 \in G$ we use the tuple with elements x_1, x_2 and $x_j = 0$ for $j \geq 3$, and signs $\sigma_1 = \sigma_2 = ' + '$, and σ_j for $j \geq 3$ alternates between addition and subtraction. The $k - 2$ alterations of $+0, -0$ cancel out on the RHS, and similarly the alterations of $+f(0) - f(0)$ cancel out on the LHS (even if $f(0) \neq 0_H$), which asserts that $f(x_1) + f(x_2) = f(x_1 + x_2)$. This holds for any $x_1, x_2 \in G$, showing that f is a homomorphism.

By re-arranging, we get

$$\underbrace{\bigoplus_{i\in[2k]} \sigma_i f(x_i)}_{S_{\sigma,x}} = \underbrace{\bigoplus_{i\in[2k]} \tau_i f(y_i)}_{S_{\tau,y}} \iff$$

$$\underbrace{\bigoplus_{i=0}^{k-1} -\tau_{k-i} f(y_{k-i}) \oplus \bigoplus_{i\in[k]} \sigma_i f(x_i)}_{S_1} = \underbrace{\bigoplus_{i=k+1}^{2k} \tau_i f(y_i) \oplus \bigoplus_{i=0}^{k-1} -\sigma_{2k-i} f(x_{2k-i})}_{S_2}.$$

Crucially, the tuples underlying the sums S_1, S_2 are each a mix from (σ, x) and (τ, y) and we show that both have the distribution of the random sign test, but they sum (in G) to the same element, a'. Therefore $\Pr[S_{\sigma,x} \neq S_{\tau,y}] = \Pr[S_1 \neq S_2] \leq \Pr[S_1 \neq f(a') \vee S_2 \neq f(a')] \leq \Pr[S_1 \neq f(a')] + \Pr[S_2 \neq f(a')] = 2\mu$.

The necessity of random signs is apparent: without them, the sums $S_{\sigma,x}, S_{\tau,y}, S_1, S_2$ correspond to tuples with different sign vector, failing to relate the probability of this event to μ (the rejection probability of the test). By adding random signs, each element has a symmetric role in the test, which leaves the connection between test and equation even after one rearranges the elements, which is a delicate matter especially in non-abelian groups. Similar issues arise for odd k, as there is no way to split the two summations "down the middle". Both technical requirements appear to be tight: we have seen a choice for G, H where fixed signs (say, all are $+$) fail to characterize homomorphisms. Yet for $G = \mathbb{F}_2^n, H = \mathbb{F}_2$ the signs have no meaning ($x = -x$ always), and our test coincides with the simple k-point test, which requires an even value of k to test linearity (otherwise, it tests affinity).

1.3 Additional related work

Injecting more randomness vs. derandomization. A significant effort [59, 55, 29, 12, 58] went into reducing the number of random bits used by homomorphism tests. Interestingly, the online manipulation model presents a contrasting goal: increasing randomness to make future queries less predictable to the adversary. Indeed, Kelman, Linder and Raskhodnikova [34] show that for certain properties, testing in the online model requires exponentially more random bits than in the offline setting (even with erasures), despite comparable query complexity. This increased randomness requirement motivates the design of testers that are more *sample-based*, i.e., use uniformly random labeled samples in place of some arbitrary (potentially adaptive) queries. This trend aligns with learning-theoretic settings, where labeled samples are typically modeled as less costly than arbitrary queries.

Low-soundness regime. Our work focuses on the *high-soundness* regime (which relates to unique decoding), showing that if the input function f is accepted by the tester with high probability, then f is close to a homomorphism. In contrast, in the *low-soundness* regime, the goal is to show that small, yet non-trivial, acceptance probability by the tester implies the input function has a non-trivial structure resembling that of a homomorphism. Homomorphism testing in the low-soundness regime has been extensively studied. Only Khot and Mittal [37] use a k-point tester and their work is specific to linearity over the *biased* hypercube. Their tester chooses points according to Hamming weight rather than uniformly; it is unclear whether it is resilient to online manipulations, since the adversary can manipulate points that are more likely to be queried.

Concurrent work. Concurrently with our work, Mittal and Roy [44] presented a general framework for homomorphism testing in the low-soundness regime and applied it to various choices of domain group G and codomain group H. Specifically, for the case of vector spaces over prime fields, [44] presented a k-point test with random coefficients, identical to the test we design for the special case of such G, H (which appears on the full version). Curiously, the same algorithm is well-suited for both settings (for this specific choice of G and H): the low-soundness regime in the standard model and high soundness in the online manipulations model. The general version of their k-point test chooses a k-tuple from G according to a weight that, roughly, comes from the order of each of its elements in the group G. In contrast, our tester picks k-tuples uniformly at random for any choice of G and H to evade adversarial manipulations.

1.4 Open questions

Our main results are in a sense orthogonal: Theorem 1.1 applies to all finite groups G and H, regardless of their structure, precisely quantifying the dependence on t. In contrast, Theorem 1.3 shows that $E(G)$ samples, rather than $\log|G|$ samples, suffice to generate the entire domain group G and successfully apply the learn-and-test approach. Combining both aspects should yield stronger results in the online manipulation model, as in the case of finite fields (Theorem 1.5). More results of this flavor would be interesting, focusing on the following question: given a group G and $t \in \mathbb{N}$, how many random samples from G are required to generate w.h.p. a subgroup $G' \subseteq G$ of size $|G'|$ that exceeds t?

A different avenue is utilizing the structure of H and its *compatibility* to G, both for upper and lower bounds. As mentioned in Remark 1.7, H could reduce the complexity dramatically when it is incompatible with G. Is it possible to define a measure of compatibility that dictates the complexity of testing homomorphism from G to H? For lower bounds, could we find for each G a group H so that Theorem 1.3 is tight? One candidate would be $H = Aut(G)$, the group of automorphisms from G to G.

Organization. The rest of the paper is organized as follows. We begin in Section 2 with formal definitions of the problem and the online manipulation model. In Section 3, we introduce our core technical contribution, the Random Signs Test (Algorithm 1), and analyze its soundness in the standard (non-adversarial) model. In Section 4, we present the general framework for achieving online manipulation resilience, defining *unpredictable testers* and proving our general amplification lemma (Lemma 4.4). We then apply this framework in Section 5 to prove our main optimal bound for general groups (Theorem 1.1). Finally, our group-specific results, including the bounds for sample-based testers (Theorem 1.3) and for functions over prime fields (Theorems 1.5 and 1.6) are deferred to the full version.

2 Preliminaries

For two groups $(G,+)$ and $(H,\oplus)$, the function $h : G \to H$ is a group *homomorphism* if $h(x_1+x_2) = h(x_1) \oplus h(x_2)$ for all $x_1, x_2 \in G$. In non-Abelian groups, the order matters. The terms in the sums are ordered according to the index: in increasing index order for $\sum_{i\in[k]} x_i$ or $\bigoplus_{i=1}^{k} y_i$, and in decreasing index order for $\sum_{i=k}^{1} x_i$. The set of all group homomorphisms from G to H is denoted $\mathsf{HOM}(G,H)$. The (relative) Hamming *distance* between two functions $f, g : G \to H$ is $dist(f,g) := \Pr_{x\in G}[f(x) \neq g(x)]$. The *distance from* $f : G \to H$ *to a property* (i.e., a set) $\mathcal{P}$ of functions of the same form is $dist(f,\mathcal{P}) := \inf_{g\in\mathcal{P}} dist(f,g)$. For every function $f : G \to H$, let $\varepsilon_f := dist(f, \mathsf{HOM}(G,H))$. A function f is *ε-close to a homomorphism* if $\varepsilon_f \leq \varepsilon$ and is *ε-far from a homomorphism* otherwise.

▶ **Definition 2.1** (Online ε-tester [31, 10]). *Fix $\varepsilon \in (0,1)$. An online ε-tester $\mathcal{T}$ for a property $\mathcal{P}$ that works in the presence of a specified adversary (e.g., t-online erasure budget-managing) is given access to an input function f via oracle access to a related function f' that is initially equal to f and, after each query answered, may be modified by the adversary. For all adversarial strategies of the specified type,*

1. *if $f \in \mathcal{P}$, then $\mathcal{T}$ accepts with probability at least 2/3, and*
2. *if f is ε-far from $\mathcal{P}$, then $\mathcal{T}$ rejects with probability at least 2/3,*

where the probability is over the internal randomness of $\mathcal{T}$. If $\mathcal{T}$ works in the presence of an erasure (resp., corruption) adversary, we refer to it as an online-erasure-resilient (resp., online-corruption-resilient) tester. If $\mathcal{T}$ always accepts every function $f \in \mathcal{P}$, then $\mathcal{T}$ has 1-sided error. *If all queries of $\mathcal{T}$ are chosen uniformly and independently from the domain of f, then $\mathcal{T}$ is* sample-based.

3 Random Signs Test

In this section, we present our Random Signs Test (Algorithm 1) for testing group homomorphism. This test always accepts functions that are homomorphisms because it only rejects if a violation of the homomorphism property is found. We analyze the soundness of the test in Theorem 3.1.

Algorithm 1 Random Signs Test$_k$.

Parameters: $k \in \mathbb{N}$

Input: Query access to a function $f : G \to H$ where $(G, +)$ and $(H, \oplus)$ are finite groups.

1: Draw k independent and uniformly random elements $x_1, x_2, \ldots, x_k$ from G.
2: Draw k independent and uniformly random signs $\sigma_1, \ldots, \sigma_k$ from $\{+, -\}$.
3: Query $f(x_1), f(x_2), \ldots, f(x_k)$ and $f(a)$, where $a \leftarrow \sum_{i\in[k]} \sigma_i x_i$.
▷ $+b = b$ and $-b$ is the inverse of b for both $b \in G$ and $b \in H$.
4: **Reject** if $\bigoplus_{i\in[k]} \sigma_i f(x_i) \neq f(a)$; otherwise, **accept**.

▶ **Theorem 3.1.** *For all $k \in \mathbb{N}$, $\varepsilon \in (0,1)$, finite groups $(G, +)$ and $(H, \oplus)$, and functions $f : G \to H$ such that f is ε-far from being a homomorphism,*

$$\Pr\left[\text{Random Signs Test}_{2k} \text{ rejects}\right] \geq \min\left\{\frac{(2k-3)\cdot\varepsilon}{3}, \frac{1}{16}\right\}. \tag{3}$$

Recall that ε_f denotes the (relative) distance from f to $\mathsf{HOM}(G, H)$. We analyze the soundness of Random Signs Test for small ε_f in Section 3.1 and for large ε_f in Section 3.2. We put these two results together and complete the proof of Theorem 3.1 in Section 3.3.

3.1 Soundness analysis for small ε_f

In this section, we state and prove Lemma 3.2, establishing the soundness of Algorithm 1 for $\varepsilon_f < \frac{1}{8}$.

▶ **Lemma 3.2.** *For all $k \in \mathbb{N}$, finite groups $(G, +)$ and $(H, \oplus)$, and functions $f : G \to H$ with $\varepsilon_f < \frac{1}{8}$,*

$$\Pr\left[\text{Random Signs Test}_{k} \text{ rejects}\right] \geq \min\left\{\frac{(k-3)\cdot\varepsilon_f}{3}, \frac{1}{6}\right\}. \tag{4}$$

To prove Lemma 3.2, we introduce Fixed Test$_k$ (Algorithm 2) which uses a fixed sequence of k signs $\overline{\sigma} = (\sigma_1, \sigma_2, \ldots, \sigma_k)$, in contrast to the uniform and independent signs from $+, -$ used in Algorithm 1.

Algorithm 2 Fixed Test$_k(\overline{\sigma})$.

Parameters: $k \in \mathbb{N}$, sign sequence $\overline{\sigma} \in \{+,-\}^k$
Input: Query access to a function $f : G \to H$ where $(G,+)$ and $(H,\oplus)$ are finite groups.
1: Draw k independent and uniformly random elements $x_1, x_2, \ldots, x_k$ from G.
2: Query $f(x_1), f(x_2), \ldots, f(x_k)$ and $f(a)$, where $a \leftarrow \sum_{i\in[k]} \sigma_i x_i$.
3: **Reject** if $\bigoplus_{i\in[k]} \sigma_i f(x_i) \neq f(a)$; otherwise **accept**.

Note that Algorithm 2 with $\overline{\sigma}$ set to $+^k$ recovers the tester of [31].

▶ **Lemma 3.3.** *For all $k \in \mathbb{N}$, all sign sequences $\overline{\sigma} \in \{+,-\}^k$, finite groups $(G,+)$ and $(H,\oplus)$, and functions $f : G \to H$ with $\varepsilon_f < \frac{1}{8}$,*

$$\Pr\left[\text{Fixed Test}_k(\overline{\sigma}) \text{ rejects}\right] \geq \min\left\{\frac{(k-3)\cdot\varepsilon_f}{3}, \frac{1}{6}\right\}. \tag{5}$$

We prove Lemma 3.3 after showing that it implies Lemma 3.2.

Proof of Lemma 3.2 assuming Lemma 3.3. Random Signs Test$_k$ (Algorithm 1) chooses the signs $\overline{\sigma}$ independently and uniformly at random from $\{+,-\}^k$. Thus, the rejection probability of Random Signs Test$_k$ is the expected rejection probability of Fixed Test$_k(\overline{\sigma})$ for uniformly random $\overline{\sigma}$. ◀

Proof of Lemma 3.3. Fix a sign sequence $\overline{\sigma}$ in $\{+,-\}^k$. Let $g : G \to H$ be a closest homomorphism to f, i.e., $\Pr_{x\in G}[f(x) \neq g(x)] = \varepsilon_f$. Then Fixed Test$_k(\overline{\sigma})$ always accepts g, since for all $x_1, x_2, \ldots, x_k \in G$,

$$\bigoplus_{i\in[k]} \sigma_i g(x_i) = g\Big(\sum_{i\in[k]} \sigma_i x_i\Big). \tag{6}$$

The core of the analysis is to compare how Algorithm 2 behaves on f and g for each sample. One way Algorithm 2 can reject f is by selecting $x_1, \ldots, x_k$ such that the RHS of (6) remains unchanged when replacing g with f, but the LHS does not.

$$\Pr\left[\text{Fixed Test}_k(\overline{\sigma}) \text{ rejects}\right] \geq \Pr_{x_1,\ldots,x_k\in G}\Big[\bigoplus_{i\in[k]} \sigma_i f(x_i) \neq \bigoplus_{i\in[k]} \sigma_i g(x_i) \bigwedge f\Big(\sum_{i\in[k]} \sigma_i x_i\Big) = g\Big(\sum_{i\in[k]} \sigma_i x_i\Big)\Big]. \tag{7}$$

We consider the probabilities of the complements of the two events – on the LHS and the RHS of (7) – obtaining the complement of the event on the RHS by applying the De Morgan's law:

$$\begin{aligned}
&\Pr[\text{Fixed Test}_k(\overline{\sigma}) \text{ accepts}] \\
&\leq \Pr_{x_1,\ldots,x_k\in G}\Big[\bigoplus_{i\in[k]} \sigma_i f(x_i) = \bigoplus_{i\in[k]} \sigma_i g(x_i) \bigvee f\Big(\sum_{i\in[k]} \sigma_i x_i\Big) \neq g\Big(\sum_{i\in[k]} \sigma_i x_i\Big)\Big] \\
&\leq \Pr\Big[\bigoplus_{i\in[k]} \sigma_i f(x_i) = \bigoplus_{i\in[k]} \sigma_i g(x_i)\Big] + \Pr\Big[f\Big(\sum_{i\in[k]} \sigma_i x_i\Big) \neq g\Big(\sum_{i\in[k]} \sigma_i x_i\Big)\Big],
\end{aligned} \tag{8}$$

where (8) holds by a union bound. The second term of (8) is exactly ε_f, as $\sum_{i\in[k]}\sigma_i x_i$ is a uniformly random element from G. Let p_k denote the first term of (8) where the subscript k indicates the number of elements the probability is taken over.

We next use induction on k to prove the following. Let $k_0 = \lfloor 1/\varepsilon_f \rfloor$, then

$$p_k \le \begin{cases} 1 - k\varepsilon_f/e & \text{for } k \in [k_0]; \\ \max\{p_{k_0}, 1/2 + \varepsilon_f\} & \text{for } k > k_0. \end{cases}$$

▷ Claim 3.4 (Base Case). For all $k \le 1/\varepsilon_f$, we have $p_k \le 1 - k\varepsilon_f/e$.

▷ Claim 3.5 (Inductive Step). For all $k > 1$, we have $p_k \le \max\{p_{k-1}, 1/2 + \varepsilon_f\}$.

The proofs of Claim 3.4 and Claim 3.5 are deferred to the full version.

Note that $k_0 = \lfloor 1/\varepsilon_f \rfloor > 1/\varepsilon_f - 1$. Using Claim 3.4 we have $p_{k_0} \le 1 - k_0\varepsilon_f/e < 1 - (1-\varepsilon_f)/e$. If $\varepsilon_f \le 1/8$, then $p_{k_0} \le 0.7$. Using Claim 3.5 we have for all $k \ge k_0$, $p_k \le \max\{p_{k_0}, 1/2 + \varepsilon_f\} \le 0.7$ for $\varepsilon_f \le 1/8$. We complete the proof by noting that $\Pr[\textsf{Fixed Test}_k(\overline{\sigma}) \text{ accepts}] \le p_k + \varepsilon_f$ from (8). Thus, $\Pr[\textsf{Fixed Test}_k(\overline{\sigma}) \text{ rejects}] \ge (1 - p_k) - \varepsilon_f \ge \min\{k\varepsilon_f/e - \varepsilon_f, 0.3 - \varepsilon_f\} \ge \min\{(k-3)\varepsilon_f/3, 1/6\}$. ◀

3.2 Soundness analysis for large ε_f

In this section, we show that Random Signs Test used with *even* k provides soundness proportional to ε_f. Specifically, we prove the following lemma.

▶ **Lemma 3.6.** *For all $k \in \mathbb{N}$, finite groups $(G, +)$ and $(H, \oplus)$, and functions $f : G \to H$,*

$$\Pr[\textsf{Random Signs Test}_{2k} \textit{ rejects}] \ge \min\left\{\frac{\varepsilon_f}{2}, \frac{1}{10}\right\}. \tag{9}$$

For ease of notation, let us define $\mu := \Pr[\textsf{Random Signs Test}_{2k} \text{ rejects } f]$. Lemma 3.6 immediately follows from the following lemma.

▶ **Lemma 3.7.** *If $\mu < \frac{1}{10}$, then f is 2μ-close to a homomorphism.*

Before proving Lemma 3.7, we explain why it implies Lemma 3.6. By Lemma 3.7, if $\mu < 1/10$ then f is 2μ-close to some homomorphism. Since f has distance ε_f to $\textsf{HOM}(G, H)$, we get $2\mu \ge \varepsilon_f \implies \mu \ge \frac{\varepsilon_f}{2}$. Thus, $\mu \ge \min\left\{\frac{\varepsilon_f}{2}, \frac{1}{10}\right\}$. Next we prove Lemma 3.7.

Proof of Lemma 3.7. In the test, the distribution of the element a, as specified in Algorithm 2, Line 2, is uniform over all elements of G, since for each realization of the signs $\sigma_1, \ldots, \sigma_{2k}$ and $x_1, \ldots, x_{2k-1}$, there is a single choice of x_{2k} leading to each a. Define $\text{FIX}(a)$ to be the set of realizations for σ's and x's leading to a,

$$\text{FIX}(a) := \left\{(\sigma_1, \ldots, \sigma_{2k}, x_1, \ldots, x_{2k}) : \textstyle\sum_{i\in[2k]} \sigma_i x_i = a\right\}.$$

We use $(\overline{\sigma}, \overline{x})$ as a shorthand for $(\sigma_1, \ldots, \sigma_{2k}, x_1, \ldots, x_{2k})$. A random tuple from $\text{FIX}(a)$ is k-wise independent in the following sense.

▷ Claim 3.8. For all $a \in G$, all sets of indices $S \subseteq [2k]$ of size $|S| = k$, let $(\overline{\sigma}, \overline{x})$ be a uniformly random tuple from $\text{FIX}(a)$. Then

1. The vector $(\sigma_i, x_i)_{i\in S}$ is a uniformly distributed vector of k signs and k elements from G.
2. The partial sum $\sum_{i\in S} \sigma_i x_i$ is a uniformly distributed element in G.

Proof.

Part 1. Consider a tuple $(\sigma_i, x_i)_{i\in[2k]}$, not necessarily in $\mathrm{FIX}(a)$, and fix a partial assignment that gives values only to $(\sigma_i, x_i)_{i\in S}$. Now choose an index $j \in [2k] \setminus S$ and let (σ_j, x_j) be chosen uniformly at random. Fill up the remaining indices, (σ_i, x_i) for $i \in [2k] \setminus (S \cup \{j\})$ with arbitrary values. Since (σ_j, x_j) is chosen uniformly at random, the sum $\sum_{i=1}^{j} \sigma_i x_i$ is a uniformly random element in G. Also, for any group G, the function $x \to x + g$ is a bijection from G to G for all $g \in G$ (the same holds true for $g + x, x - g, -g + x$). Thus, the rest of the additions and subtractions (for $i = j + 1, \ldots, 2k$) are all bijections and therefore the entire sum $\sum_{i\in[2k]} \sigma_i x_i$ is also a uniformly random element of G. This means that exactly $1/|G|$ of the tuples with a particular partial assignment to $(\sigma_i, x_i)_{i\in S}$ are in fact in $\mathrm{FIX}(a)$. The same argument applies for any partial assignment of $(\sigma_i, x_i)_{i\in S}$, so each such partial assignment produces the exact same number of tuples in $\mathrm{FIX}(a)$.

Part 2. Consider the set F_z which consists of all assignments to $(\sigma_i, x_i)_{i\in S}$ for which $\sum_{i\in S} \sigma_i x_i = z$. Using similar arguments as in the proof of part 1, each set F_z has the same size, and the same number of ways to complete the assignment to a tuple in $\mathrm{FIX}(a)$. Thus, the number of tuples in $\mathrm{FIX}(a)$ for which $\sum_{i\in S} \sigma_i x_i = z$ is the same for each z. ◁

Consider tuples whose signed sums over either their left or right halves equal a fixed value. Define

$$\mathrm{LEFT}(z) := \left\{(\overline{\sigma}, \overline{x}) : \textstyle\sum_{i\in[k]} \sigma_i x_i = z\right\}, \quad \mathrm{RIGHT}(z) := \left\{(\overline{\sigma}, \overline{x}) : \textstyle\sum_{i\in[k]} \sigma_{k+i} x_{k+i} = z\right\}.$$

▶ **Corollary 3.9.** *Consider the sets $S_L = [k]$ and $S_R = [2k] \setminus [k]$. The following process produces a uniformly random tuple in FIX(a):*

1. *Draw a uniformly random element $z \in G$.*
2. *Draw a uniformly random tuple $(\overline{\sigma}^L, \overline{x}^L)$ from LEFT$(a - z)$ and take its "left" part, $(\overline{\sigma}^L, \overline{x}^L)_{i\in S_L}$*
3. *Draw a uniformly random tuple $(\overline{\sigma}^R, \overline{x}^R)$ from RIGHT(z) and take its "right" part, $(\overline{\sigma}^R, \overline{x}^R)_{i\in S_R}$*
4. *Return the tuple $(\overline{\sigma}, \overline{x})$ where $(\overline{\sigma}, \overline{x})_{i\in S_L} = (\overline{\sigma}^L, \overline{x}^L)_{i\in S_L}$ and $(\overline{\sigma}, \overline{x})_{i\in S_R} = (\overline{\sigma}^R, \overline{x}^R)_{i\in S_R}$*

Proof. By the second part of Claim 3.8, the number of tuples $(\sigma_1, \ldots, \sigma_{2k}, x_1, \ldots, x_{2k}) \in \mathrm{FIX}(a)$ such that their right part is in $\mathrm{RIGHT}(z)$ (that is, $\sum_{i\in[k]} \sigma_{k+i} x_{k+i} = z$) is the same for each z. The same holds for the $\mathrm{LEFT}(a - z)$. Since each tuple in $\mathrm{FIX}(a)$ has a unique such pair $(a - z, z)$, the process gives an equal probability for each tuple in $\mathrm{FIX}(a)$, concluding the proof. ◀

▶ **Definition 3.10** (Vote of $(\overline{\sigma}, \overline{x})$ for the value of a)**.** *For all $a \in G$ and $(\overline{\sigma}, \overline{x}) \in$ FIX(a), define $\bigoplus_{i\in[2k]} \sigma_i f(x_i)$ as the* vote of $(\overline{\sigma}, \overline{x})$ for the value of a.

Corrector. Define g to be the local corrector for f, that is, the value that has the most votes as defined in Definition 3.10:

$$g(a) := \mathrm{argmax}_{h\in H} \left\{\Pr_{(\overline{\sigma},\overline{x})\in \mathrm{FIX}(a)} \left[\textstyle\bigoplus_{i\in[2k]} \sigma_i f(x_i) = h\right]\right\} \text{ for all } a \in G.$$

Define the following probabilities, all relating to how close f is to being homomorphic:

$$\eta_a := \Pr_{(\overline{\sigma},\overline{x})\in \mathrm{FIX}(a)}\left[g(a) \neq \bigoplus_{i\in[2k]} \sigma_i f(x_i)\right] \quad \eta := max_a \eta_a \quad \delta := \Pr_{x\in G}\left[f(x) \neq g(x)\right]$$

We follow the standard self-correction paradigm introduced by [15, 11], by showing that if the test fails with a small probability (e.g., $\mu < 1/10$), then: (1) η is bounded; (2) $\delta \leq 2\mu$; and (3) g is a homomorphism. The last part (3) is evidently the harder one, although similar simpler arguments are used to prove (1). Altogether, they show that if the test fails with a small probability, then f is close to being a homomorphism (and in particular, the homomorphism g). By contrapositive, this proves a soundness guarantee for the tester.

We start by formally stating and proving the first assertion.

▶ **Lemma 3.11.** $\eta \leq 2\mu$.

Proof. It suffices to show that $\eta_a \leq 2\mu$ for each $a \in G$. Fix some a and consider two tuples $(\overline{\sigma},\overline{x}), (\overline{\tau},\overline{y})$ chosen independently and uniformly at random from $\mathrm{FIX}(a)$. We show that the probability of the event that the votes of $(\overline{\sigma},\overline{x})$ and $(\overline{\tau},\overline{y})$ for the value of a are equal is close to 1, which implies the most common vote among all tuples in $\mathrm{FIX}(a)$ occurs with probability close to 1. To check whether they give the same vote we manipulate both summations as follows: apply from the left side $-\tau_k f(y_k)\cdots-\tau_1 f(y_1)$ to cancel out the first k summands from the tuple $(\overline{\tau},\overline{y})$, and similarly from the right side for the last k summands of the other tuple. We get the following equivalence:

$$\underbrace{\bigoplus_{i\in[2k]} \sigma_i f(x_i)}_{S_{\sigma,x}} = \underbrace{\bigoplus_{i\in[2k]} \tau_i f(y_i)}_{S_{\tau,y}} \iff$$

$$\underbrace{\bigoplus_{i=0}^{k-1} -\tau_{k-i} f(y_{k-i}) \oplus \bigoplus_{i\in[k]} \sigma_i f(x_i)}_{S_1} = \underbrace{\bigoplus_{i=k+1}^{2k} \tau_i f(y_i) \oplus \bigoplus_{i=0}^{k-1} -\sigma_{2k-i} f(x_{2k-i})}_{S_2}.$$

Importantly, each of the new sums S_1, S_2 contains exactly k summands respectively from $(\overline{\sigma},\overline{x})$ and $(\overline{\tau},\overline{y})$, but with different signs. By Claim 3.8 and independence between $(\overline{\sigma},\overline{x})$ and $(\overline{\tau},\overline{y})$, the tuple of $2k$ signs and $2k$ elements used in S_1 is uniformly random (and similarly for S_2). Since the original tuples are taken from $\mathrm{FIX}(a)$, $\sum_{i\in[2k]} \sigma_i x_i = a = \sum_{i\in[2k]} \tau_i y_i$. By the same reasoning as before but with x_i, y_i instead of $f(x_i), f(y_i)$

$$\textstyle\sum_{i=0}^{k-1} -\tau_{k-i} y_{k-i} + \sum_{i\in[k]} \sigma_i x_i = \sum_{i=k+1}^{2k} \tau_i y_i + \sum_{i=0}^{k-1} -\sigma_{2k-i} x_{2k-i}.$$

Thus, the two tuples defining the sums or votes S_1, S_2 are both in $\mathrm{FIX}(a')$, for the same uniformly random element $a' \in G$. The event $\{S_1 \neq S_2\}$ implies that at least one of the votes did not agree with $f(a')$.

$$\Pr\left[S_1 \neq S_2\right] \leq \Pr\left[S_1 \neq f(a') \vee S_2 \neq f(a')\right] \leq \Pr\left[S_1 \neq f(a')\right] + \Pr\left[S_2 \neq f(a')\right] = 2\mu,$$

where the second inequality is by a union bound, and the last equality holds since both the probabilities are equal to the probability that the check in Line 4 of Algorithm 1 accepts, thus simulating our test. Indeed, $S_i \in \mathrm{FIX}(a')$ for $i = 1, 2$, where a' is a uniformly random element of G. We denote by p_h the probability that a correction using a random tuple $(\overline{\sigma},\overline{x}) \in \mathrm{FIX}(a)$ produces $h \in H$, then:

$$2\mu \geq \Pr\left[S_1 \neq S_2\right] = \Pr\left[S_{\sigma,x} \neq S_{\tau,y}\right] = \sum_{h\in H} p_h(1-p_h) = \sum_{h\in H} (p_h - p_h^2) = 1 - \sum_{h\in H} p_h^2.$$

By definition, $g(a) = \arg\max_{h \in H} p_h$ is the most common vote or correction outcome (ties broken arbitrarily). We have $1 - \eta_a = p_{g(a)} = p_{g(a)} \cdot \sum_{h \in H} p_h = \sum_{h \in H} p_h p_{g(a)} \geq \sum_{h \in H} p_h^2 \geq 1 - 2\mu$, which concludes the proof. ◀

The next simple lemma shows the second easy assertion as a corollary of the first.

▶ **Lemma 3.12.** *If $\mu < 1/10$, then $\delta \leq 2\mu$.*

Proof. For each element $a \in G$ we have high agreement for corrections, and in particular $\eta_a \leq 1/2$. Denote the set where f and g disagree by $\Delta := \{x \in G : f(x) \neq g(x)\}$, noting that $\delta = |\Delta| / |G|$. Then

$$\mu = \Pr_{\substack{a \in G \\ (\sigma,x) \in \mathrm{FIX}(a)}} \left[f(a) \neq \bigoplus_{i \in [2k]} \sigma_i f(x_i) \right] = \frac{1}{|G|} \sum_{a \in G} \Pr_{(\sigma,x) \in \mathrm{FIX}(a)} \left[f(a) \neq \bigoplus_{i \in [2k]} \sigma_i f(x_i) \right].$$

The latter expression is only reduced if we take a subset of (positive) summands, only those from $\Delta \subseteq G$. It further reduces if we replace each event of the sum differing from $f(a)$ with the subevent that it specifically equals $g(a)$ (this is indeed a subevent for any $a \in \Delta$). We get

$$\mu \geq \frac{1}{|G|} \sum_{a \in \Delta} \Pr_{(\sigma,x) \in \mathrm{FIX}(a)} \left[g(a) = \bigoplus_{i \in [2k]} \sigma_i f(x_i) \right] = \frac{1}{|G|} \sum_{a \in \Delta} (1 - \eta_a) \geq \frac{1}{|G|} \cdot |\Delta| \cdot \frac{1}{2} = \frac{\delta}{2},$$

where the last inequality uses $1 - \eta_a \geq 1/2$ for any $a \in \Delta$. This concludes the proof. ◀

The last assertion uses the probabilistic method and the accuracy of corrections shown above, to prove that g is a homomorphism.

▶ **Lemma 3.13.** *If $\mu < 1/10$, then g is a homomorphism.*

Proof. Given $a, b \in G$, we need to show that $g(a) \oplus g(b) = g(a + b)$. Consider the following process:

1. Draw a uniformly random $r \in G$.
2. Draw a uniformly random tuple $(\overline{\sigma}, \overline{x}) \in \mathrm{LEFT}(a - r) \bigcap \mathrm{RIGHT}(r)$.
3. Let CL be the set "cancelling left" whose left side cancels exactly the right side of the previous tuple, defined as, $CL := \{(\overline{\tau}, \overline{y}) : \forall i \in [k].(\tau_i, y_i) = (-\sigma_{2k+1-i}, x_{2k+1-i})\}$, and choose uniformly at random a tuple $(\overline{\tau}, \overline{y})$ from $CL \bigcap \mathrm{RIGHT}(r + b)$.

Applying Corollary 3.9 three times, note that $(\overline{\sigma}, \overline{x})$ is a uniformly random tuple in $\mathrm{FIX}(a)$, the tuple $(\overline{\tau}, \overline{y})$ is a uniformly random tuple in $\mathrm{FIX}(b)$. Furthermore, we define the tuple $(\overline{\phi}, \overline{z})$ that has the left side taken from $(\overline{\sigma}, \overline{x})$ and the right side taken from $(\overline{\tau}, \overline{y})$, that is $(\phi_i, z_i) = (\sigma_i, x_i)$ for $i \in [k]$ and $(\phi_i, z_i) = (\tau_i, y_i)$ for $i \in [2k] \setminus [k]$. Applying Corollary 3.9 again, we get that $(\overline{\phi}, \overline{z})$ is a uniformly random tuple from $\mathrm{FIX}(a + b)$. Hence, each of the following three equalities holds with probability at least $1 - \eta$:

$$g(a) = \bigoplus_{i \in [2k]} \sigma_i f(x_i) \qquad g(b) = \bigoplus_{i \in [2k]} \tau_i f(y_i) \qquad g(a+b) = \bigoplus_{i \in [2k]} \phi_i f(z_i)$$

Next, recall we specifically chose the left side of $(\overline{\tau}, \overline{y})$ to cancel out the right side of $(\overline{\sigma}, \overline{x})$. This cancellation also happens when applying the function f, since pairs of summands cancel each other from inside out. The following equality thus holds with probability 1:

$$\bigoplus_{i=k+1}^{2k} \sigma_i f(x_i) \oplus \bigoplus_{i \in [k]} \tau_i f(y_i) = \sigma_{k+1} f(x_{k+1}) \oplus \cdots \oplus \sigma_{2k} f(x_{2k}) \oplus \tau_1 f(y_1) \oplus \cdots \oplus \tau_k f(y_k) = e_H.$$

Over the random choice of tuples, the event that all 4 equalities above hold has probability at least $1-3\eta \geq 1-6\mu > 0$ (by applying Lemma 3.11, a union bound, and the premise $\mu < 1/6$). This event implies that $g(a) \oplus g(b) = g(a+b)$, which also occurs with positive probability. However, the last equality does not depend on the probability space, and therefore it must hold with probability 1. ◀

This completes the proof of Lemma 3.7. ◀

3.3 Completing the soundness analysis

Proof of Theorem 3.1. Since f is ε-far from being a homomorphism, $\varepsilon_f \geq \varepsilon$. When $\varepsilon_f \geq 1/8$, then by Lemma 3.6, we get $\Pr[\textsf{Random Signs Test}_{2k} \text{ rejects}] \geq \min\left\{\frac{\varepsilon_f}{2}, \frac{1}{10}\right\} \geq \frac{1}{16}$. On the other hand, if $\varepsilon_f < 1/8$, then by Lemma 3.2, $\Pr[\textsf{Random Signs Test}_{2k} \text{ rejects}] \geq \min\left\{\frac{(2k-3)\cdot\varepsilon_f}{3}, \frac{1}{6}\right\} \geq \min\left\{\frac{(2k-3)\cdot\varepsilon}{3}, \frac{1}{6}\right\}$. Combining the two cases, we get

$$\Pr[\textsf{Random Signs Test}_{2k} \text{ rejects}] \geq \min\left\{\frac{(2k-3)\cdot\varepsilon}{3}, \frac{1}{6}, \frac{1}{16}\right\} \geq \min\left\{\frac{(2k-3)\cdot\varepsilon}{3}, \frac{1}{16}\right\}. \quad ◀$$

4 General framework for online manipulation resilience

The previous section provides a sound *core test* for homomorphism. To make this core test resilient to online manipulations, we now introduce the general framework used to build our final testers. This framework, based on the concept of *unpredictability* and an amplification lemma, provides a general recipe for converting a core test with certain unpredictability properties, i.e., an *unpredictable core test*, to one robust to online manipulations. In subsequent sections, we show how to modify our core test into an unpredictable core test and then apply this framework to prove our main results.

4.1 Unpredictable test

We define flatness of a distribution, which can also be seen as a bound on its "min-entropy".[8]

▶ **Definition 4.1** (α-flat). *A distribution ν on domain D is α-flat if* $\max_{z\in D} \nu(z) \leq \alpha$.

The following definition, loosely speaking, requires that other than with probability β of "losing its unpredictability", a q-query test maintains "aggregated flatness" of α. Later in Lemma 4.4, we show that such a tester is resilient to online manipulations.

▶ **Definition 4.2** (Unpredictable tester). *A tester making q sequential queries $x_1, \ldots, x_q$ to a function $f : D \to R$ is* ***(q, α, β)-unpredictable*** *(in the standard model, without an adversary) if there exist nonnegative flatness parameters $(\alpha_1, \ldots, \alpha_q)$ and failure probabilities $(\beta_1, \ldots, \beta_q)$ satisfying the following two conditions.*

1. ***Sequential unpredictability:*** *For every input function $f : D \to R$, the following holds. For each $j \in [q]$, let ν_j be the probability distribution of the j-th query x_j conditioned on all the previous queries $(x_1, \ldots, x_{j-1})$. Then, for each $j \in [q]$, with probability at least $1-\beta_j$ (taken over the randomness of the previous $j-1$ queries), ν_j is α_j-flat:*

$$\Pr_{x_1,\ldots,x_{j-1}}[\nu_j \text{ is } \alpha_j\text{-flat}] \geq 1-\beta_j.$$

2. ***Aggregate parameters:*** *The sums of flatness parameters and of the failure probabilities are bounded, satisfying $\sum_{j\in[q]} \alpha_j \leq \alpha$ and $\sum_{j\in[q]} \beta_j \leq \beta$.*

[8] A distribution is α-flat if and only if its min-entropy is at least $\log(1/\alpha)$.

▶ **Lemma 4.3** (Encountering a manipulation). *Let $\mathcal{A}$ be an algorithm that runs r independent iterations of a (q, α, β)-unpredictable test. Fix an iteration $i \in [r]$, and let E_i be an event completely determined by the first $i-1$ iterations. Then, for all input functions f and t-online budget-managing adversarial strategies, the probability that a manipulation is encountered in iteration i, conditioned on the event E_i, is at most $\alpha qrt+\beta$. (Note that qrt is the manipulation budget for the entire algorithm.)*

Proof. Fix an adversarial strategy. Since $\mathcal{A}$ runs a (q, α, β)-unpredictable test, there exist flatness parameters $(\alpha_1, \ldots, \alpha_q)$ and error terms $(\beta_1, \ldots, \beta_q)$ satisfying the conditions in Definition 4.2. Let M_i be the event that a manipulation was encountered in iteration i. For all $j \in [q]$, let M_{ij} be the event that the j-th query of iteration i is to a manipulated point.

We now bound the probability $\Pr[M_{ij}|E_i]$ for a single i. To do this, consider the sample space of all execution histories of $\mathcal{A}$ up to iteration $i-1$. The event E_i is simply a collection of such histories. Fix a specific execution history h, which fixes all queries made by $\mathcal{A}$ and all manipulations made by the adversary in the previous $i-1$ iterations.

Let G_j be the good event that the distribution ν_j is α_j-flat. Then $\Pr[\overline{G_j}|h] \le \beta_j$. Suppose the event G_j occurred, and let $\mathcal{M}_j$ be the set of manipulated entries when query j is made. Then $|\mathcal{M}_j| \le qrt$. Thus, the probability of the event M_{ij} conditioned on G_j and h,

$$\Pr[M_{ij} \mid G_j, h] = \sum_{z \in \mathcal{M}_j} \Pr_{x_j \sim \nu_j}[x_j = z] \le \sum_{z \in \mathcal{M}_j} \alpha_j \le \alpha_j qrt.$$

The probability of the event M_{ij} conditioned on the history h is bounded by

$$\begin{aligned}\Pr[M_{ij} \mid h] &= \Pr[M_{ij} \mid G_j, h]\Pr[G_j \mid h] + \Pr[M_{ij} \mid \overline{G_j}, h]\Pr[\overline{G_j} \mid h] \\ &\le \Pr[M_{ij} \mid G_j, h] + \Pr[\overline{G_j} \mid h] \le \alpha_j qrt + \beta_j.\end{aligned}$$

By a union bound over the events M_{ij} for all $j \in [q]$, the probability of the event M_i conditioned on h is

$$\Pr[M_i \mid h] \le \sum_{j \in [q]} \Pr[M_{ij}|h] = \sum_{j \in [q]} \left(\alpha_j qrt + \beta_j\right) \le \alpha qrt + \beta.$$

Now, consider all execution histories that satisfy the event E_i.

$$\begin{aligned}\Pr[M_i \mid E_i]\Pr[E_i] = \Pr[M_i \cap E_i] &= \sum_{h \in E_i} \Pr[M_i \cap h] = \sum_{h \in E_i} \Pr[M_i|h]\Pr[h] \\ &\le (\alpha qrt + \beta) \cdot \sum_{h \in E_i} \Pr[h]\end{aligned}$$

$$\implies \Pr[M_i \mid E_i]\Pr[E_i] \le (\alpha qrt + \beta) \cdot \Pr[E_i] \implies \Pr[M_i \mid E_i] \le \alpha qrt + \beta. \qquad \blacktriangleleft$$

4.2 General amplification lemma

In this section, we prove a general amplification lemma. This result provides a recipe for converting an unpredictable core test into an online manipulation-resilient tester. Specifically, we show that if a (q, α, β)-unpredictable test satisfies a condition linking its soundness $p_{\mathsf{rej}}(\varepsilon)$ (probability of rejecting $f \notin \mathcal{P}$ as a function of ε) to its aggregate unpredictability parameters (α, β) and the adversary's manipulation rate t, then running the test $O(1/p_{\mathsf{rej}}(\varepsilon))$ times yields a new tester with a constant soundness guarantee against the adversary.

▶ **Lemma 4.4** (General Amplification for Online Resilience). *Let $\mathcal{P}$ be a property (a set of functions $f : D \to R$). Let $\mathcal{T}$ be a (q, α, β)-unpredictable, 1-sided error ε-test for property $\mathcal{P}$. Suppose $\mathcal{T}$ rejects all functions that are ε-far from $\mathcal{P}$ with probability at least $p_{\mathsf{rej}}(\varepsilon)$. Let $\mathcal{A}$ be the algorithm that runs $\lceil 3/p_{\mathsf{rej}}(\varepsilon)\rceil$ independent iterations of test $\mathcal{T}$ and accepts iff each iteration accepts or (in the case when manipulations are erasures) encounters an erasure. Algorithm $\mathcal{A}$ is an ε-tester for property $\mathcal{P}$ that works in the presence of every t-online manipulation budget-managing adversary if*

$$\alpha q t \cdot \left\lceil \frac{3}{p_{\mathsf{rej}}(\varepsilon)} \right\rceil + \beta \leq \frac{p_{\mathsf{rej}}(\varepsilon)}{12}. \tag{10}$$

Moreover, if the manipulations are erasures, then $\mathcal{A}$ has 1-sided error.

Proof. Let $r = \lceil 3/p_{\mathsf{rej}}(\varepsilon)\rceil$ be the number of iterations of the test $\mathcal{T}$ run by $\mathcal{A}$.

Completeness. Consider $f \in \mathcal{P}$. The tester $\mathcal{A}$ fails on f only if one of the iterations rejects. This can only happen because of a manipulation, since $\mathcal{T}$ has 1-sided error (it always accepts $f \in \mathcal{P}$ when there are no manipulations). For all $i \in [r]$, let E_i be the trivial event that includes the entire sample space. By Lemma 4.3 instantiated with this E_i and by (10), the probability $\mathcal{A}$ encounters a manipulation in any single iteration is at most

$$\alpha q r t + \beta = \alpha q t \left\lceil \frac{3}{p_{\mathsf{rej}}(\varepsilon)} \right\rceil + \beta \leq \frac{p_{\mathsf{rej}}(\varepsilon)}{12}.$$

By a union bound over all $r = \lceil \frac{3}{p_{\mathsf{rej}}(\varepsilon)} \rceil$ iterations, $\mathcal{A}$ encounters a manipulation with probability at most

$$\frac{p_{\mathsf{rej}}(\varepsilon)}{12} \cdot \left\lceil \frac{3}{p_{\mathsf{rej}}(\varepsilon)} \right\rceil \leq \frac{1}{3}.$$

Therefore, $\mathcal{A}$ errs with probability at most $\frac{1}{3}$. Moreover, when manipulations are erasures, $\mathcal{A}$ always accepts f because it is designed to accept in any iteration where it sees an erasure.

Soundness. Assume f is ε-far from $\mathcal{P}$. Let F be the event that the amplified tester $\mathcal{A}$ fails to reject f. For all iterations $i \in [r]$, let F_i be the event that $\mathcal{A}$ fails on iteration i. Then $F = \bigcap_{i\in[r]} F_i$. Therefore,

$$\Pr[F] = \prod_{i\in[r]} \Pr[F_i \mid F_1 \cap \cdots \cap F_{i-1}]. \tag{11}$$

Next we bound each term in the product in (11). For all $i \in [r]$, let A_i be the event that $\mathcal{T}$ accepts in iteration i, and M_i be the event that a manipulated entry is queried in iteration i. Fix an iteration $i \in [r]$. Then $F_i \subseteq A_i \cup M_i = (A_i \cap \overline{M_i}) \cup M_i$. By a union bound,

$$\Pr[F_i \mid F_1 \cap \cdots \cap F_{i-1}] \leq \Pr[(A_i \cap \overline{M_i}) \mid F_1 \cap \cdots \cap F_{i-1}] + \Pr[M_i \mid F_1 \cap \cdots \cap F_{i-1}]. \tag{12}$$

The first term on the RHS of (12) corresponds to the event when $\mathcal{A}$ encounters no manipulations in iteration i and the unpredictable core test $\mathcal{T}$ accepts. In this case, the view of the algorithm $\mathcal{A}$ is the same as if the function f was not manipulated and conditioning on any event determined by the initial $i-1$ iterations such as $F_1 \cap \cdots \cap F_{i-1}$ doesn't affect the probability of the event $A_i \cap \overline{M_i}$. Since the core test $\mathcal{T}$ rejects f with probability at least $p_{\mathsf{rej}}(\varepsilon)$, this implies $\Pr[(A_i \cap \overline{M_i}) \mid F_1 \cap \cdots \cap F_{i-1}] \leq 1 - p_{\mathsf{rej}}(\varepsilon)$. To bound the second term on the RHS of (12), we use Lemma 4.3 with $E_i = \bigcap_{j\in[i-1]} F_j$ and then (10):

$$\Pr[M_i \mid F_1 \cap \cdots \cap F_{i-1}] \leq \alpha q r t + \beta = \alpha q t \left\lceil \frac{3}{p_{\mathsf{rej}}(\varepsilon)} \right\rceil + \beta \leq \frac{p_{\mathsf{rej}}(\varepsilon)}{12}.$$

By (12), $\Pr[F_i \mid F_1 \cap \cdots \cap F_{i-1}] \le (1 - p_{\mathsf{rej}}(\varepsilon)) + \frac{p_{\mathsf{rej}}(\varepsilon)}{12} = 1 - \frac{11 p_{\mathsf{rej}}(\varepsilon)}{12}$. The above bound holds for all iterations $i \in [r]$. Thus, by (11),

$$\Pr[F] \le \prod_{i \in [r]} \left(1 - \frac{11 p_{\mathsf{rej}}(\varepsilon)}{12}\right) = \left(1 - \frac{11 p_{\mathsf{rej}}(\varepsilon)}{12}\right)^r.$$

Substituting $r = \lceil 3/p_{\mathsf{rej}}(\varepsilon) \rceil$, we know $r \ge 3/p_{\mathsf{rej}}(\varepsilon)$, thus

$$\Pr[F] \le \left(1 - \frac{11 p_{\mathsf{rej}}(\varepsilon)}{12}\right)^{3/p_{\mathsf{rej}}(\varepsilon)} \le e^{\frac{-11 p_{\mathsf{rej}}(\varepsilon)}{12} \cdot \frac{3}{p_{\mathsf{rej}}(\varepsilon)}} = \left(\frac{1}{e}\right)^{11/4} \le \frac{1}{3},$$

where the second inequality holds since $1 - x \le e^{-x}$ for all x. Thus, the failure probability of $\mathcal{A}$ is at most $1/3$, and $\mathcal{A}$ rejects f with probability at least $2/3$. ◀

5 Resilience to online manipulations for general groups

In this section, we prove Theorem 1.1 by lifting the linearity tester in [4], which is based on the manipulation-resilient tester of [10], and the sample-based tester of Goldreich and Ron [25]. Define a parameter $m := 4\lceil \log_2 t + 15/\varepsilon \rceil + 12$. Depending on the value of m, we invoke one of the two different algorithms against the t-online-erasure adversary. Following the case-based strategy of [4], when $2^m \le |G|^{1/4}$ we use Algorithm 4, a lift of the linearity tester of [10] to the general group setting. On the other hand, when $2^m > |G|^{1/4}$, we instead use the sample-based tester by [25]. We analyze the two cases separately. Our main contribution here is in the analysis of the distribution of the element y in Algorithm 3, where we need to handle random signs along with random elements for any group G, whereas previous work did not have to worry about the random signs.

Case 1: $2^m \le |G|^{1/4}$. In this case, we use Algorithm 4 which internally runs Algorithm 3 a constant number of times.

Algorithm 3 Unpredictable Random Signs Test.

Parameters: even $m \in \mathbb{N}$
Input: Query access to $f : G \to H$ where $(G, +)$ and $(H, \oplus)$ are finite groups.
1: Draw m independent and uniformly random elements $x_1, x_2, \ldots, x_m$ from G.
2: Query $f(x_1), f(x_2), \ldots, f(x_m)$.
3: Draw independent and uniformly random signs σ_j for all $j \in [m]$ from the set $\{+, -\}$.
4: Let S be a uniformly random subset of $[m]$ of size $m/2$.
5: Query $f(y)$ where $y \leftarrow \sum_{j \in S} \sigma_j x_j$
6: **Reject** if $\bigoplus_{j \in S} \sigma_j f(x_j) \ne f(y)$. ▷ This implies no erasures were encountered.
7: **Accept**.

Note that Algorithm 3 has the same completeness and soundness as $\mathsf{Random\ Signs\ Test}_{m/2}$. Moreover, Algorithm 3 is also unpredictable as stated in Lemma 5.1 whose proof we defer to the full version.

▶ **Lemma 5.1.** *Fix a finite group G. If $2^m \le |G|^{1/4}$, then Algorithm 3 with parameter m is*

$$\left(m + 1, \frac{m}{2^m} + \frac{1}{\binom{m}{m/2}}, \frac{1}{2^m}\right)\text{-unpredictable.}$$

Algorithm 4 Online Erasure-Resilient Random Signs Test.

Parameters: $\varepsilon \in (0,1)$, $t \in \mathbb{N}$.
Input: Query access to $f : G \to H$ via t-erasure oracle, where $(G,+)$ and $(H,\oplus)$ are finite groups.
1: Set $m = 4\lceil \log_2 t + 15/\varepsilon \rceil + 12$
2: **for** $i \in [48]$ **do**
3: Run Algorithm 3 with parameter m, independent randomness and query access to f.
4: **Reject** if Algorithm 3 rejects.
5: **Accept**.

Proof of Theorem 1.1 when $2^m \leq |G|^{1/4}$. Finally, we prove that Algorithm 4 satisfies Theorem 1.1 by an application of the general amplification for online resilience lemma (Lemma 4.4). The details are deferred to the full version. ◀

Case 2: $2^m > |G|^{1/4}$. In this case, we use the sample-based tester by Goldreich and Ron [25] and use a theorem by Arora, Kelman and Meir [4] about online-manipulation-resilience of sample-based testers to handle this case. The details are deferred to the full version.

Abstract

Locality-sensitive hashing (LSH) has found widespread use as a fundamental primitive, particularly to accelerate nearest neighbor search. An LSH scheme for a similarity function $S : \mathcal{X} \times \mathcal{X} \to [0, 1]$ is a distribution over hash functions on $\mathcal{X}$ with the property that the probability of collision of any two elements $x, y \in \mathcal{X}$ is exactly equal to $S(x, y)$. However, not all similarity functions admit exact LSH schemes. The notion of LSH distortion measures how multiplicatively close a similarity function is to having an LSH scheme.

In this work, we study the LSH distortion of the Ulam and Cayley similarities, which are popular similarity measures on permutations of n elements. We show that the Ulam similarity admits a sublinear LSH distortion of $O(n/\sqrt{\log n})$; we also prove a lower bound of $\Omega(n^{0.12})$ on the best LSH distortion achievable. On the other hand, we show that the LSH distortion of the Cayley similarity is $\Theta(n)$.

1 Introduction

Locality-sensitive hashing (LSH) is an important tool for processing high dimensional data [4, 5, 13, 12]. Classic examples of LSH include minHash for the Jaccard similarity [4, 5], simHash for the cosine similarity [6], and sampling hash for the Hamming similarity [12]. LSH has been extensively used for solving (approximate) nearest-neighbor search [1] and similarity search [11, 16, 20]; see `https://www.mit.edu/~andoni/LSH/` for more pointers on classical results.

LSH is a way to represent a similarity S – which in the context of this paper is a bi-variate, reflexive, symmetric function – by a distribution over partitions. These partitions correspond to the pre-images of hash functions, so that two entities are considered similar by a hash function if they both hash to the same value. In other words, an LSH family $\mathcal{H}$ induces a *collision kernel* of the form $S(x, y) = \Pr_{h\sim\mathcal{H}}[h(x) = h(y)]$, for entities x, y in the universe.

Such collision kernels have to satisfy two constraints: they have unit diagonals (capturing reflexivity) and are a convex combination of equivalence-relation matrices (capturing hashing to the same value). Hence, it turns out that many natural and useful similarity measures do not admit an LSH. An interesting line of work studies which similarities have an LSH. Charikar [6] identified a necessary condition for a similarity to admit an LSH: the corresponding distance function (which is often one minus the similarity) must be a metric and must be isometrically embeddable into ℓ_1.

To circumvent this, Chierichetti et al. [9] introduced the notion of LSH distortion, which answers the question: how much is a non-LSHable similarity S multiplicatively close to an LSHable similarity?

Formally, given a similarity S that does not admit an LSH, is there another similarity S' that has an LSH and satisfies:

$$\forall x, y: \quad \frac{1}{\Delta} \cdot S(x, y) \leq S'(x, y) \leq S(x, y)? \tag{1}$$

We call the optimal Δ in (1) the *LSH distortion* of S.

In their paper, Chierichetti et al. showed tight LSH distortion bounds for several set similarities. Note that, since we are considering multiplicative approximations over **similarities**, and we wish to achieve them using collision kernels, the LSH distortion of a similarity can differ significantly from its metric counterpart, and known results for metric distortion do not transfer to this setting.

Our contributions

In this work, we study the LSH distortion of two natural similarities derived from popular metrics on permutations. The first is the normalized Ulam similarity, which measures the length of the longest common subsequence between two permutations. The second is the Cayley similarity, which is the normalized number of cycles in the relative permutation (its distance counterpart is number of transpositions needed to turn one permutation into another).

Our main results are the following:

- We show that the Ulam similarity has sublinear LSH distortion. In particular, we show that it can be approximated by a similarity that has an LSH, with distortion $O(n/\sqrt{\log n})$ (Theorem 5),
- We also show a lower bound of $\Omega(n^{0.12})$ on the LSH distortion of the Ulam similarity (Theorem 10),
- In contrast, we show that the Cayley similarity has an $\Omega(n)$ lower bound on its LSH distortion (Theorem 19), matching a simple $O(n)$ upper bound (Theorem 18).

Techniques

The proof of the upper bound for the Ulam similarity is based on computing a suitable measure of correlation between the given permutation and a random permutation. The collision probability of our scheme depends on how well the input permutations are correlated with a random one. Showing that the collision probability is upper bounded by $\mathrm{LCS}(\cdot, \cdot)/n$ is relatively easy. On the other hand, showing it is also lower bounded by the LCS (up to sublinear distortion) is more challenging.

For the lower bounds on the distortion, we crucially utilize the PSDness of the collision kernel (Lemma 4). The lower bound for the Ulam similarity is based on first constructing a small set of permutations on an 8-element universe that has an LSH distortion of at least 9/7, and then amplifying its cardinality to work for a universe of arbitrarily large size, by using the wreath product on permutations.

The lower bound for the Cayley similarity is based on representation theory, and uses both the fact that every bi-invariant PSD kernel on $\mathbb{S}_n$ can be written as a convex combination of normalized characters, as well as Roichman's character-ratio estimates applied to derangements. The distortion lower bound is obtained by constructing two derangements that share the high-order terms of this decomposition and hence must have close collision probabilities with the identity permutation, but have vastly different Cayley similarities (linear vs constant) to it.

Related work

For permutation metrics, the Ulam metric has been extensively studied through its connection to edit distance and longest common subsequences. Charikar and Krauthgamer [8] proved that the Ulam metric embeds into ℓ_1 with $O(\log n)$ distortion; Andoni and Krauthgamer [3] later proved that embeddings of the Ulam metric into ℓ_1 requires a near-tight distortion of $\Omega(\log n/\log\log n)$. Andoni et al. [2] bypassed the ℓ_1 barrier by embedding Ulam distance with constant distortion into an iterated product metric. Charikar et al. [7] obtained an $O(\log n)$ distortion randomized embedding of Ulam into Hamming space that also carries alignment information. Note that all these previous results are for the Ulam metric; to the best of our knowledge, the corresponding question of Ulam similarity has not been considered in the literature.

Unlike Ulam, the Cayley metric is not hard to embed into ℓ_1. Our work can be viewed as a hardness result for LSHability of the Cayley similarity.

Outline

We begin, in Section 2, by introducing some basic notation. In Section 3, we review the definition of LSH distortion and introduce in detail the central problems of the paper. In Section 4, we provide our $O(n/\sqrt{\log n})$ upper bound on the LSH distortion for the Ulam similarity. We then give a $\Omega(n^{0.12})$ lower bound in Section 5. In Section 6, we give a simple $O(n)$ upper bound on the distortion of the Cayley similarity, that we complement with a matching lower bound in Section 7.

In the appendix of the full version of the paper, we also review some background on the representation theory of $\mathbb{S}_n$, which we rely on for our proofs in Section 7.

2 Notation

Permutations

For a positive integer n, let $[n] := \{1, \ldots, n\}$. Let $\mathbb{S}_n$ be the set of all permutations of $[n]$. We denote by id the *identity* permutation. For a permutation $\pi \in \mathbb{S}_n$ we will sometimes use the one-line notation and sometimes the cycle decomposition.[1] For a permutation

[1] For example, for the permutation $\pi : [5] \to [5]$ such that $\pi(1) = 3$, $\pi(2) = 5$, $\pi(3) = 1$, $\pi(4) = 2$, $\pi(5) = 4$; the one-line representation is $(3, 5, 1, 2, 4)$ and the cycle decomposition is $(1\ 3)(2\ 5\ 4)$.

$\pi \in \mathbb{S}_n$ we denote with $c(\pi)$ the number of *cycles* in its cycle decomposition. Note that $c(\pi) = c(\pi^{-1}) = c(\sigma\pi\sigma^{-1})$ for any $\sigma \in \mathbb{S}_n$. For $\pi \in \mathbb{S}_n$, $a, b \in [n]$ we write $a <_\pi b$ to indicate that a comes before b in the one-line representation of π (alternatively that $\pi^{-1}(a) < \pi^{-1}(b)$). We write $a \leq_\pi b$ to indicate that either $a = b$ or $a <_\pi b$. For $\pi, \sigma \in \mathbb{S}_n$ we denote with $\mathrm{LCS}(\pi, \sigma)$ the length of the *longest common subsequence* between the one-line representations of π and σ. For $\pi \in \mathbb{S}_n$, we denote with $\mathrm{fix}(\pi)$ the number of *fixed points* of π and with $\mathrm{cycle}_2(\pi)$ the number of cycles of length *two* in the cycle decomposition of π. We also let $\mathrm{supp}(\pi) = n - \mathrm{fix}(\pi)$.

Partitions and Compositions

Recall that, for any positive integer n, a partition $\lambda = (\lambda_1, \ldots, \lambda_r)$ of n is a finite sequence of non-increasing positive integers that sum to n. We write $\lambda \vdash n$ to indicate that λ is a partition of n. We denote by (1^n) the partition $(1, \ldots, 1)$ containing n 1s. Given a partition $\lambda = (\lambda_1, \ldots, \lambda_r) \vdash n$ its *transpose* partition (sometimes also called the *conjugate* partition) is the partition $\lambda' \vdash n$ defined by $\lambda' = (\lambda'_1, \ldots, \lambda'_{\lambda_1})$, where:

$$\forall i \in [\lambda_1] : \lambda'_i = \max\{k \mid \lambda_k \geq i\}.$$

A *composition* of n is an ordered partition of n, i.e., an integer vector $\mu = (\mu_1, \ldots, \mu_\ell)$ such that $\mu_i \geq 0$ for every $i \in [\ell]$ and $\sum_{i \in [\ell]} \mu_i = n$.

Matrices

A symmetric matrix $M \in \mathbb{R}^{n \times n}$ is *positive semidefinite* (PSD, written $M \succeq 0$) if for all $x \in \mathbb{R}^n$, we have:

$$x^T M x \geq 0.$$

The *trace* operator is the function that takes in a square matrix $M \in \mathbb{R}^{n \times n}$ and returns $\mathrm{tr}(M) = \sum_{i \in [n]} M(i, i)$. Given two square matrices X, Y, we denote by $\mathrm{diag}(X, Y)$ the block matrix:

$$\mathrm{diag}(X, Y) = \begin{pmatrix} X & \mathbf{0} \\ \mathbf{0} & Y, \end{pmatrix}$$

where $\mathbf{0}$ is the all-zeros matrix.

3 Similarities, LSH, and Distortion

▶ **Definition 1** (Similarity). *Given a set $\mathcal{X}$, a* similarity *(or* similarity function*) on $\mathcal{X}$ is a function $S : \mathcal{X} \times \mathcal{X} \to [0, 1]$, satisfying:*
(a) Reflexivity: *$S(x, x) = 1$ for all $x \in \mathcal{X}$,*
(b) Symmetry: *$S(x, y) = S(y, x)$ for all $x, y \in \mathcal{X}$.*
A similarity space *is simply a pair $(\mathcal{X}, S)$, where $\mathcal{X}$ is a set, and S is a similarity function on $\mathcal{X}$.*

Given a similarity space, it is natural to ask whether one can find a small representation for elements of $\mathcal{X}$ that preserve the values of $S(\cdot, \cdot)$. A natural approach to obtaining this is locality-sensitive hashing, which aims to construct randomized embeddings of $\mathcal{X}$ into discrete (0-1) similarity spaces that preserve $S(\cdot, \cdot)$ in expectation. We recall the key definition here.

▶ **Definition 2** (Locality-Sensitive Hashing (LSH)). *A* locality-sensitive hashing (LSH) *scheme for a similarity space* $(\mathcal{X}, S)$ *is a distribution* $\mathcal{H}$ *over functions from* $\mathcal{X}$ *into some finite set* $\mathcal{Y}$ *with the property that:*

$$\Pr_{h\sim\mathcal{H}}[h(x) = h(y)] = S(x, y),$$

for all $x, y \in \mathcal{X}$.

We say that a similarity function S is *LSHable* if it admits an LSH scheme.

Chierichetti et al. [9] give a notion of distortion for similarity functions, quantifying the degree to which non-LSHable similarities are far from being LSHable. We recall the key definitions.

▶ **Definition 3** ([9]). *We say a distribution* $\mathcal{H}$ *over functions from* $\mathcal{X}$ *to some finite set* $\mathcal{Y}$ Δ-approximates *the space* $(\mathcal{X}, S)$*, if:*

$$\frac{1}{\Delta} \cdot S(x, y) \leq \Pr_{h\sim\mathcal{H}}[h(x) = h(y)] \leq S(x, y),$$

for all $x, y \in \mathcal{X}$*. The LSH* distortion *(or simply distortion) of a similarity space* $(\mathcal{X}, \mathcal{S})$ *is the smallest* $\Delta \geq 1$ *such that there exists a distribution* $\mathcal{H}$ *that* Δ*-approximates* $(\mathcal{X}, S)$.

A simple argument shows that the distortion of a similarity space $(\mathcal{X}, S)$ could be characterized as the smallest $\Delta \geq 1$ such that there exists an LSHable similarity function $S' : \mathcal{X} \times \mathcal{X} \to [0, 1]$ with the property that:

$$\frac{1}{\Delta} \cdot S(x, y) \leq S'(x, y) \leq S(x, y), \tag{2}$$

for all $x, y \in \mathcal{X}$.

The focus of this work is the distortion of two similarity spaces in which $\mathcal{X}$ is the symmetric group $\mathbb{S}_n$: the Ulam similarity and the Cayley similarity.

Ulam Similarity

The *Ulam distance* between two permutations $\pi, \sigma \in \mathbb{S}_n$ is defined as

$$\mathrm{d}^{\mathrm{U}}(\pi, \sigma) := n - \mathrm{LCS}(\pi, \sigma),$$

We define the (normalized) *Ulam similarity* in a natural way:

$$\mathrm{S}^{\mathrm{U}}(\pi, \sigma) = 1 - \frac{n - \mathrm{LCS}(\pi, \sigma)}{n} = \frac{\mathrm{LCS}(\pi, \sigma)}{n}.$$

Cayley Similarity

The *Cayley distance* between two permutations $\pi, \sigma \in \mathbb{S}_n$ is defined as the minimum number of (not necessarily adjacent) transpositions required to transform one permutation into the other, and it is also equivalent to $\mathrm{d}^{\mathrm{C}}(\pi, \sigma) := n - c(\pi^{-1}\sigma) = n - c(\pi\sigma^{-1})$ (see, e.g., [10, page 118]). We define a notion of (normalized) *Cayley similarity* in a natural way:

$$\mathrm{S}^{\mathrm{C}}(\pi, \sigma) = 1 - \frac{\mathrm{d}^{\mathrm{C}}(\pi, \sigma)}{n} = \frac{c(\pi^{-1}\sigma)}{n}.$$

Positive Semi-Definiteness

In order to prove lower bounds on the achievable distortion, we will use the following result. Let $\mathcal{H}$ be a probability distribution over functions from a finite domain $\mathcal{X}$ into a finite range $\mathcal{Y}$. Fixing any ordering of the elements of $\mathcal{X}$, we define the matrix $P_{\mathcal{H}} \in \mathbb{R}^{|\mathcal{X}|\times|\mathcal{X}|}$ such that:

$$P_{\mathcal{H}}(x_1, x_2) := \Pr_{h\sim\mathcal{H}}\left[h(x_1) = h(x_2)\right],$$

for $x_1, x_2 \in \mathcal{X}$.

We now show that this matrix is always PSD.

▶ **Lemma 4.** *For any distribution $\mathcal{H}$ over functions from $\mathcal{X}$ to $\mathcal{Y}$, where $\mathcal{X}$ and $\mathcal{Y}$ are finite sets, the matrix $P_{\mathcal{H}}$ is PSD. That is, for all $\{w_x\}_{x\in\mathcal{X}} \in \mathbb{R}^{|\mathcal{X}|}$, we have:*

$$\sum_{x_1\in\mathcal{X}}\sum_{x_2\in\mathcal{X}} w_{x_1} w_{x_2} P_{\mathcal{H}}(x_1, x_2) \geq 0.$$

Proof. Note that for any $x_1, x_2 \in \mathcal{X}$,

$$P(x_1, x_2) = \Pr_{h\sim\mathcal{H}}[h(x_1) = h(x_2)] = \mathop{\mathbb{E}}_{h\sim\mathcal{H}}\left[\mathbf{1}_{[h(x_1)=h(x_2)]}\right],$$

where $\mathbf{1}_{[.]}$ is the indicator function, and hence:

$$\begin{aligned}\sum_{x_1\in\mathcal{X}}\sum_{x_2\in\mathcal{X}} w_x w_y P(x_1, x_2) &= \sum_{x_1\in\mathcal{X}}\sum_{x_2\in\mathcal{X}} w_x w_y \mathop{\mathbb{E}}_{h\sim\mathcal{H}}\left[\mathbf{1}_{[h(x_1)=h(x_2)]}\right] \\ &= \mathop{\mathbb{E}}_{h\sim\mathcal{H}}\left[\sum_{x_1\in\mathcal{X}}\sum_{x_2\in\mathcal{X}} w_{x_1} w_{x_2} \mathbf{1}_{[h(x_1)=h(x_2)]}\right].\end{aligned}$$

Now, for a fixed $h : \mathcal{X} \to \mathcal{Y}$, we show that the inner sum is non-negative, which in turns completes the proof. We have:

$$\sum_{x_1\in\mathcal{X}}\sum_{x_2\in\mathcal{X}} w_{x_1} w_{x_2} \mathbf{1}_{[h(x_1)=h(x_2)]} = \sum_{y\in\mathcal{Y}}\sum_{\substack{x_1\in\mathcal{X}:\\ h(x_1)=y}}\sum_{\substack{x_2\in\mathcal{X}:\\ h(x_2)=y}} w_{x_1} w_{x_2} = \sum_{y\in\mathcal{Y}}\left(\sum_{\substack{x\in\mathcal{X}:\\ h(x)=y}} w_x\right)^2 \geq 0. \quad ◀$$

4 Upper Bound for Ulam Similarity

In this section, we prove the following result:

▶ **Theorem 5.** *The LSH distortion of $(\mathbb{S}_n, \mathrm{S^U})$ is $O(n/\sqrt{\log n})$.*

For two permutations $\tau, \pi \in \mathbb{S}_n$ and $z \in [n]$, define:

$$\mathrm{Rec}_{\tau,z}(\pi) := \{a \in [n] \mid z \leq_\pi a \text{ and } b <_\tau a \text{ for all } b \text{ such that } z \leq_\pi b <_\pi a\}.$$

Intuitively, $\mathrm{Rec}_{\tau,z}(\pi)$ is the set of new record maxima according to τ obtained while scanning the one-line representation of π starting from z.

For $\tau, \pi \in \mathbb{S}_n$, $a, z \in [n]$ define:

$$h_{\tau,z,a}(\pi) := \begin{cases} 1 & \text{if } a \in \mathrm{Rec}_{\tau,z}(\pi), \\ \pi & \text{otherwise.}\end{cases}$$

Let $\mathcal{H}$ be the uniform distribution over the set of functions: $\{h_{\tau,z,a} \mid \tau \in \mathbb{S}_n, z \in [n], a \in [n]\}$. Recall that for $\pi, \sigma \in \mathbb{S}_n$:

$$P_{\mathcal{H}}(\pi,\sigma) := \Pr_{h_{\tau,z,a}\sim\mathcal{H}}[h_{\tau,z,a}(\pi) = h_{\tau,z,a}(\sigma)].$$

We will show that: $O(\sqrt{\log n}/n) \cdot \mathrm{S}^{\mathrm{U}}(\pi,\sigma) \le P_{\mathcal{H}}(\pi,\sigma) \le \mathrm{S}^{\mathrm{U}}(\pi,\sigma)$.

▶ **Lemma 6.** *For $\pi, \sigma \in \mathbb{S}_n$, $\pi \neq \sigma$, it holds that:*

$$P_{\mathcal{H}}(\pi,\sigma) = \frac{1}{n} \cdot \mathop{\mathbb{E}}_{\tau,z}\left[\left|\operatorname{Rec}_{\tau,z}(\pi) \cap \operatorname{Rec}_{\tau,z}(\sigma)\right|\right].$$

Proof. Note that for $\pi \neq \sigma$, we have that $h_{\tau,z,a}(\pi) = h_{\tau,z,a}(\sigma)$ if and only if $a \in \operatorname{Rec}_{\tau,z}(\pi) \cap \operatorname{Rec}_{\tau,z}(\sigma)$. Conditioned on the choice of τ and z, there are n possible values for a and only $\left|\operatorname{Rec}_{\tau,z}(\pi) \cap \operatorname{Rec}_{\tau,z}(\sigma)\right|$ of them make the hashes of π and σ equal. This concludes the proof. ◀

▶ **Lemma 7.** *For any $\tau, \pi, \sigma \in \mathbb{S}_n$ and $z \in [n]$, it holds that:*

$$1 \le \left|\operatorname{Rec}_{\tau,z}(\pi) \cap \operatorname{Rec}_{\tau,z}(\sigma)\right| \le \mathrm{LCS}(\pi,\sigma).$$

Proof. Since $z \in \operatorname{Rec}_{\tau,z}(\pi) \cap \operatorname{Rec}_{\tau,z}(\sigma)$, the set $\operatorname{Rec}_{\tau,z}(\pi) \cap \operatorname{Rec}_{\tau,z}(\sigma)$ is always non-empty, proving the first inequality.

We now show the second inequality. If there is only one element in the intersection, the result is trivially true, since $\mathrm{LCS}(\pi,\sigma) \ge 1$ for any $\pi, \sigma \in \mathbb{S}_n$. Otherwise, consider any distinct $x, y \in \operatorname{Rec}_{\tau,z}(\pi) \cap \operatorname{Rec}_{\tau,z}(\sigma)$. Suppose without loss of generality that $x <_\pi y$. By definition of $\operatorname{Rec}_{\tau,z}(\pi)$, since y is observed after x in the one-line representation of π, it must hold that $x <_\tau y$. Moreover, we have $x <_\sigma y$, for otherwise we would have $x >_\tau y$, leading to a contradiction.

Therefore, if we let $\operatorname{Rec}_{\tau,z}(\pi) \cap \operatorname{Rec}_{\tau,z}(\sigma) = r_1 <_\pi \cdots <_\pi r_t$, we also have $r_1 <_\sigma \cdots <_\sigma r_t$, meaning that $r_1, \ldots, r_t$ is a common subsequence of π and σ, and therefore $t \le \mathrm{LCS}(\pi,\sigma)$. ◀

Fixed π, σ such that $\mathrm{LCS}(\pi,\sigma) \ge 2$, define $L := \mathrm{LCS}(\pi,\sigma)$ and let $C = (c_1, \ldots, c_L)$ be a longest common subsequence. For $1 \le i < j \le L$, define the intervals:

$$I^{\pi}_{i,j} := \{x \in [n] \mid c_i \le_\pi x \le_\pi c_j\}, \quad \text{and} \quad I^{\sigma}_{i,j} := \{x \in [n] \mid c_i \le_\sigma x \le_\sigma c_j\}.$$

Define also $W_{i,j} := |I^{\pi}_{i,j} \cup I^{\sigma}_{i,j}|$.

▶ **Lemma 8.** *For any $\pi, \sigma \in \mathbb{S}_n$ such that $L := \mathrm{LCS}(\pi,\sigma) \ge 2$, it holds that:*

$$P_{\mathcal{H}}(\pi,\sigma) \ge \frac{1}{n^2} \cdot \sum_{1\le i<j\le L} \frac{1}{W_{i,j}}.$$

Proof. Consider the case $\pi \neq \sigma$, otherwise the result is trivial, since the right-hand side is always less than 1. For $\tau \in \mathbb{S}_n$, and $1 \le i < j \le L$, suppose that:

$$c_j \ge_\tau x \quad \text{for all } x \in I^{\pi}_{i,j} \cup I^{\sigma}_{i,j}.$$

Under this assumption, it holds that: $c_j \in \operatorname{Rec}_{\tau,c_i}(\pi) \cap \operatorname{Rec}_{\tau,c_i}(\sigma)$. Indeed, we have that c_j is the maximum (according to τ) of all indices $I^{\pi}_{i,j}$ between c_i and c_j in the one-line representation of π and therefore it will be added to $\operatorname{Rec}_{\tau,z}(\pi)$ when starting from $z = c_i$ (and the same argument holds for σ).

By Lemma 6 and the remark above, we have:

$$\begin{aligned}
P_{\mathcal{H}}(\pi,\sigma) &= \frac{1}{n}\cdot \mathop{\mathbb{E}}_{\tau,z}\left[\left|\operatorname{Rec}_{\tau,z}(\pi)\cap\operatorname{Rec}_{\tau,z}(\sigma)\right|\right] \\
&\geq \frac{1}{n}\cdot\sum_{i=1}^{L-1}\Pr[z=c_i]\cdot\mathop{\mathbb{E}}_{\tau}\left[\left|\operatorname{Rec}_{\tau,z}(\pi)\cap\operatorname{Rec}_{\tau,z}(\sigma)\right|\,\middle|\, z=c_i\right] \\
&= \frac{1}{n}\cdot\sum_{i=1}^{L-1}\frac{1}{n}\cdot\sum_{j=1}^{n}\Pr_{\tau}[j\in\operatorname{Rec}_{\tau,c_i}(\pi)\cap\operatorname{Rec}_{\tau,c_i}(\sigma)] \\
&\geq \frac{1}{n^2}\sum_{i=1}^{L-1}\sum_{j=i+1}^{L}\Pr_{\tau}[c_j\in\operatorname{Rec}_{\tau,c_i}(\pi)\cap\operatorname{Rec}_{\tau,c_i}(\sigma)] \\
&\geq \frac{1}{n^2}\sum_{i=1}^{L-1}\sum_{j=i+1}^{L}\Pr_{\tau}\left[c_j\geq_{\tau} x \text{ for all } x\in I^{\pi}_{i,j}\cup I^{\sigma}_{i,j}\right] \\
&= \frac{1}{n^2}\sum_{i=1}^{L-1}\sum_{j=i+1}^{L}\frac{1}{W_{i,j}},
\end{aligned}$$

where the last inequality follows from the remark above and the last equality uses that for a uniform at random $\tau\in\mathbb{S}_n$, the element ranked highest among $I^{\pi}_{i,j}\cup I^{\sigma}_{i,j}$ is chosen uniformly at random among its elements. ◀

▶ **Lemma 9.** *For any $\pi,\sigma\in\mathbb{S}_n$ such that $L:=\operatorname{LCS}(\pi,\sigma)\geq 4$, it holds that:*

$$\sum_{1\leq i<j\leq L}\frac{1}{W_{i,j}}\geq\frac{L^2\ln L}{32n}.$$

Proof. For $1<t\leq L$, define:

$$w_t:=\left|I^{\pi}_{t-1,t}\right|+\left|I^{\sigma}_{t-1,t}\right|.$$

For $1\leq i<L$ and $1\leq d\leq L-i$, define $S_{i,d}:=\sum_{t=i+1}^{i+d}w_t$. Note that, for $1\leq i<j\leq L$, we have:

$$W_{i,j}\leq|I^{\pi}_{i,j}|+|I^{\sigma}_{i,j}|\leq\sum_{t=i+1}^{j}w_t=S_{i,(j-i)}. \tag{3}$$

Therefore, we have:

$$\sum_{1\leq i<j\leq L}\frac{1}{W_{i,j}}=\sum_{i=1}^{L-1}\sum_{j=i+1}^{L}\frac{1}{W_{i,j}}\overset{(3)}{\geq}\sum_{i=1}^{L-1}\sum_{j=i+1}^{L}\frac{1}{S_{i,(j-i)}}=\sum_{i=1}^{L-1}\sum_{d=1}^{L-i}\frac{1}{S_{i,d}}=\sum_{d=1}^{L-1}\sum_{i=1}^{L-d}\frac{1}{S_{i,d}}. \tag{4}$$

For a fixed $1\leq d<L$, by the Cauchy–Schwarz inequality, we have:

$$\left(\sum_{i=1}^{L-d}\frac{1}{S_{i,d}}\right)\cdot\left(\sum_{i=1}^{L-d}S_{i,d}\right)\geq\left(\sum_{i=1}^{L-d}\sqrt{\frac{1}{S_{i,d}}}\cdot\sqrt{S_{i,d}}\right)^2=(L-d)^2. \tag{5}$$

Note that each element of $[n]$ can be counted at most twice in w_t and it can appear in at most two w_t's, therefore:

$$\sum_{t=2}^{L}w_t\leq 4n.$$

Moreover, each w_t can appear in at most d distinct $S_{i,d}$ for $i \in \{1, \ldots, L-d\}$, giving:

$$\sum_{i=1}^{L-d} S_{i,d} \leq d \sum_{t=2}^{L} w_t \leq 4 \cdot d \cdot n.$$

Combining this inequality with (5) gives:

$$\sum_{i=1}^{L-d} \frac{1}{S_{i,d}} \geq \frac{(L-d)^2}{\sum_{i=1}^{L-d} S_{i,d}} \geq \frac{(L-d)^2}{4 \cdot d \cdot n}.$$

Plugging this inequality into (4) we obtain:

$$\sum_{1 \leq i < j \leq L} \frac{1}{W_{i,j}} \geq \sum_{d=1}^{L-1} \frac{(L-d)^2}{4 \cdot d \cdot n} \geq \sum_{d=1}^{\lfloor L/2 \rfloor} \frac{(L-d)^2}{4 \cdot d \cdot n} \geq \frac{L^2}{16n} \sum_{d=1}^{\lfloor L/2 \rfloor} \frac{1}{d} \geq \frac{L^2 \ln L}{32n},$$

where the last inequality uses that for $L \geq 4$:

$$\sum_{d=1}^{\lfloor L/2 \rfloor} \frac{1}{d} \geq \ln(\lfloor L/2 \rfloor + 1) \geq \ln\left(\sqrt{L}\right) = \frac{\ln L}{2}.$$ ◀

We are now ready to prove the main result of this section:

Proof of Theorem 5. It is sufficient to show that for each $\pi, \sigma \in \mathbb{S}_n$ it holds that:

$$\Theta(\sqrt{\log n}/n) \cdot \mathrm{S}^{\mathrm{U}}(\pi, \sigma) \leq P_{\mathcal{H}}(\pi, \sigma) \leq \mathrm{S}^{\mathrm{U}}(\pi, \sigma).$$

Note that if $\pi = \sigma$ then $P_{\mathcal{H}}(\pi, \sigma) = \mathrm{S}^{\mathrm{U}}(\pi, \sigma) = 1$. Therefore, consider the case where $\pi \neq \sigma$. By combining Lemma 6 and Lemma 7 we have:

$$\frac{1}{n} \leq P_{\mathcal{H}}(\pi, \sigma) \leq \frac{\mathrm{LCS}(\pi, \sigma)}{n} = \mathrm{S}^{\mathrm{U}}(\pi, \sigma). \tag{6}$$

Therefore, we only have to prove $P_{\mathcal{H}}(\pi, \sigma) \geq \Omega(\sqrt{\log n}/n) \cdot \mathrm{S}^{\mathrm{U}}(\pi, \sigma)$ to conclude the proof. Consider first the case where $\mathrm{LCS}(\pi, \sigma) \leq 3$. In this case we have:

$$P_{\mathcal{H}}(\pi, \sigma) \geq \frac{1}{n} \geq \frac{1}{3} \cdot \frac{\mathrm{LCS}(\pi, \sigma)}{n} = \frac{1}{3} \cdot \mathrm{S}^{\mathrm{U}}(\pi, \sigma).$$

Consider now the case $\mathrm{LCS}(\pi, \sigma) \geq 4$ and denote $L := \mathrm{LCS}(\pi, \sigma)$. By combining Lemma 8 and Lemma 9 we obtain:

$$P_{\mathcal{H}}(\pi, \sigma) \geq \frac{L^2 \ln L}{32 \cdot n^3} = \frac{L \ln L}{32 \cdot n^2} \cdot \mathrm{S}^{\mathrm{U}}(\pi, \sigma). \tag{7}$$

By (6) we also have:

$$P_{\mathcal{H}}(\pi, \sigma) \geq \frac{1}{L} \cdot \mathrm{S}^{\mathrm{U}}(\pi, \sigma). \tag{8}$$

We split the case $\mathrm{LCS}(\pi, \sigma) \geq 4$ in two sub-cases. Suppose first that $\mathrm{LCS}(\pi, \sigma) \leq \frac{n}{\sqrt{\ln n}}$. Then, (8) gives: $P_{\mathcal{H}}(\pi, \sigma) \geq \sqrt{\ln n}/n \cdot \mathrm{S}^{\mathrm{U}}(\pi, \sigma)$. Suppose instead that $\mathrm{LCS}(\pi, \sigma) > \frac{n}{\sqrt{\ln n}}$. Then, by (7) we have:

$$P_{\mathcal{H}}(\pi, \sigma) \geq \frac{\frac{n}{\sqrt{\ln n}} \ln\left(\frac{n}{\sqrt{\ln n}}\right)}{32n^2} \cdot \mathrm{S}^{\mathrm{U}}(\pi, \sigma) = \left(\frac{\ln n - \frac{1}{2} \ln \ln n}{32 \cdot \sqrt{\ln n} \cdot n}\right) \cdot \mathrm{S}^{\mathrm{U}}(\pi, \sigma) \geq \frac{\sqrt{\ln n}}{64 \cdot n} \cdot \mathrm{S}^{\mathrm{U}}(\pi, \sigma),$$

where we used that $\frac{\ln n}{2} \geq \frac{\ln \ln n}{2}$ for $n \geq 3$. ◀

5 Lower Bound for Ulam Similarity

In this section, we prove the following result.

▶ **Theorem 10.** *Let n be any integer of the form 8^{2^k}, for integer $k \geq 0$. The LSH distortion of $(\mathbb{S}_n, \mathrm{S^U})$ is $\Omega(n^\delta)$, where $\delta \geq 0.12$.*

At a high level, we obtain a lower bound on the LSH distortion by starting with a small instance that exhibits constant distortion, and then iteratively amplifying it to handle larger values of n. In each step, both the distortion bound and the permutation domain grow quadratically. Our base case has $n = 8$, therefore our construction produces instances for any n of the form 8^{2^k}, where k is a non-negative integer. The main tool enabling this amplification is the wreath product.

For any two subsets $A, B \subseteq \mathbb{S}_n$, we define the similarity matrix $M_{A,B} \in \mathbb{R}^{|A|\times|B|}$ by $M_{A,B}(\pi, \sigma) = \mathrm{S^U}(\pi, \sigma)$ for any $\pi \in A$ and $\sigma \in B$. For simplicity, when A and B are the same, we will adopt a lighter notation, and denote by M_A the matrix $M_{A,A}$. We note that the matrix $M_{(A\cup B)}$ has a simple block structure:

$$M_{(A\cup B)} = \begin{pmatrix} M_A & M_{A,B} \\ M_{B,A} & M_B \end{pmatrix},$$

where we fixed an ordering in which the permutations in A come before those in B.

▶ **Definition 11** (Witness). *For $n > 0$, let $A, B \subseteq \mathbb{S}_n$ be disjoint subsets such that $|A| = |B|$ and $M_A = M_B$. Let $W \in \mathbb{R}^{(|A|+|B|)\times(|A|+|B|)}$ be a PSD block matrix such that:*

$$W = \begin{pmatrix} U & -V \\ -V^T & U \end{pmatrix} \succeq 0,$$

where $U, V \in \mathbb{R}^{|A|\times|A|}$ are entry-wise non-negative symmetric matrices such that $\mathrm{tr}(U \cdot M_A) \neq 0$. We call the triple (A, B, W) a witness *of size n and we define its value to be:*

$$\nu(A, B, W) := \frac{\mathrm{tr}(V \cdot M_{A,B})}{\mathrm{tr}(U \cdot M_A)}.$$

We now show that the existence of a witness implies a lower bound to the LSH distortion for Ulam similarity on $\mathbb{S}_n$.

▶ **Lemma 12.** *Let (A, B, W) be a witness of size n (Definition 11). Then, the LSH distortion for Ulam similarity space $(\mathbb{S}_n, \mathrm{S^U})$ is at least the value of the witness, $\nu(A, B, W)$, even when restricted only to permutations in $A \cup B \subseteq \mathbb{S}_n$.*

Proof. Consider any distribution $\mathcal{H}$ over functions on $\mathbb{S}_n$ which Δ-approximates $(A \cup B, \mathrm{S^U})$ for $\Delta \geq 1$. For every $\pi, \sigma \in A \cup B$ we have:

$$\frac{M_{A\cup B}(\pi, \sigma)}{\Delta} = \frac{\mathrm{S^U}(\pi, \sigma)}{\Delta} \leq P_{\mathcal{H}}(\pi, \sigma) \leq \mathrm{S^U}(\pi, \sigma) = M_{A\cup B}(\pi, \sigma). \tag{9}$$

Note that, having fixed an ordering of the elements of $A \cup B$ that puts the elements of A before the elements of B, $P_{\mathcal{H}}$ gets naturally divided into four square blocks:

$$P_{\mathcal{H}} = \begin{pmatrix} P_A & P_{A,B} \\ P_{B,A} & P_B \end{pmatrix}.$$

By Lemma 4, $P_{\mathcal{H}} \succeq 0$ and $W \succeq 0$, we have $\mathrm{tr}(WP_{\mathcal{H}}) \geq 0$. Expanding blockwise, and using $V^T = V$ and $P_{B,A}^T = P_{A,B}$, we have:

$$\mathrm{tr}(UP_A) + \mathrm{tr}(UP_B) - 2\mathrm{tr}(VP_{A,B}) \geq 0.$$

Note that, by Equation (9), $P_{\mathcal{H}}(\pi,\sigma) \leq M_{A\cup B}(\pi,\sigma)$ and $P_{\mathcal{H}}(\pi,\sigma) \geq (1/\Delta)\cdot M_{A\cup B}(\pi,\sigma)$ for all π,σ. Therefore, we have:

$$\mathrm{tr}(U\cdot M_A) + \mathrm{tr}(U\cdot M_B) \geq \frac{2}{\Delta}\cdot \mathrm{tr}(V\cdot M_{A,B}).$$

Since $M_A = M_B$, we have $\mathrm{tr}(U\cdot M_A) = \mathrm{tr}(U\cdot M_B)$. Hence,

$$\Delta \geq \frac{\mathrm{tr}(V\cdot M_{A,B})}{\mathrm{tr}(U\cdot M_A)} = \nu(A,B,W). \qquad \blacktriangleleft$$

For permutations $\pi,\sigma \in \mathbb{S}_n$ the *wreath product* $\pi \wr \sigma \in \mathbb{S}_{n^2}$ is defined as follows. The elements of $[n^2]$ are partitioned into n blocks where the ith block, $i \in [n]$, contains elements $\Sigma_i := \{(i-1)\cdot n+1,\ldots,i\cdot n\}$. The resulting permutation $\pi\wr\sigma$ is obtained by permuting the elements in each block with the inner permutation σ and then permuting the blocks with the outer permutation π. For two sets $A,B \subseteq \mathbb{S}_n$, we define $A \wr B := \{\pi\wr\sigma \mid \pi\in A, \sigma\in B\}$. We use the following key property of the wreath product for amplification:

▶ **Lemma 13.** *For any $\pi,\sigma,\tau_1,\tau_2 \in \mathbb{S}_n$ we have:*

$$\mathrm{LCS}(\pi\wr\sigma, \tau_1\wr\tau_2) = \mathrm{LCS}(\pi,\tau_1)\cdot\mathrm{LCS}(\sigma,\tau_2).$$

Proof. In the permutation $\pi\wr\sigma$, the blocks appear in the order given by π, and within every block the elements appear in the order given by σ; similarly for $\tau_1\wr\tau_2$.

We first prove that $\mathrm{LCS}(\pi\wr\sigma,\tau_1\wr\tau_2) \leq \mathrm{LCS}(\pi,\tau_1)\cdot\mathrm{LCS}(\sigma,\tau_2)$. Let Z be any common subsequence of $\pi\wr\sigma$ and $\tau_1\wr\tau_2$. Since the alphabets Σ_i are pairwise disjoint, an element from a block Σ_i can only be matched with the same element from the same block Σ_i. Therefore, if we track the sequence of block indices that contribute at least one matched element to Z, then this is a common subsequence of the outer permutations π and τ_1; thus, the number of contributing blocks is at most $\mathrm{LCS}(\pi,\tau_1)$.

Let Σ_i be any contributing block. The matched elements of Z in this block is a common subsequence of the ordering of Σ_i inside $\pi\wr\sigma$ and the ordering of Σ_i inside $\tau_1\wr\tau_2$. These two internal orderings are σ and τ_2, relabeled with the alphabet Σ_i; therefore, this block contributes at most $\mathrm{LCS}(\sigma,\tau_2)$ matched elements. Summing over all contributing blocks, we obtain $\mathrm{LCS}(\pi\wr\sigma,\tau_1\wr\tau_2) \leq \mathrm{LCS}(\pi,\tau_1)\cdot\mathrm{LCS}(\sigma,\tau_2)$.

We now show $\mathrm{LCS}(\pi\wr\sigma,\tau_1\wr\tau_2) \geq \mathrm{LCS}(\pi,\tau_1)\cdot\mathrm{LCS}(\sigma,\tau_2)$. Consider an optimal common subsequence of the outer permutations π and τ_1, consisting of $\mathrm{LCS}(\pi,\tau_1)$ block indices. For each such matched block Σ_i, consider an optimal common subsequence of the inner permutations σ and τ_2, relabeled using Σ_i. Since the block indices appear in the same relative order in both π and τ_1, concatenating these common subsequences over the chosen blocks yields a valid common subsequence of $\pi\wr\sigma$ and $\tau_1\wr\tau_2$ of length $\mathrm{LCS}(\pi,\tau_1)\cdot\mathrm{LCS}(\sigma,\tau_2)$. $\blacktriangleleft$

We now show how to use the wreath product to amplify the size of the witness. We will make use of the *Kronecker product*. We recall that for two matrices $X \in \mathbb{R}^{n\times m}$ and $Y \in \mathbb{R}^{s\times t}$, the Kronecker product $X\otimes Y \in \mathbb{R}^{ns\times mt}$ is the following block matrix:

$$X\otimes Y = \begin{pmatrix} x_{11}\cdot Y & \ldots & x_{1m}\cdot Y \\ \vdots & \ddots & \vdots \\ x_{n1}\cdot Y & \ldots & x_{nm}\cdot Y \end{pmatrix}.$$

▶ **Lemma 14.** *Consider any disjoint sets $A, B \subseteq \mathbb{S}_n$ with $|A| = |B|$. Let $A' = A \wr A$ and $B' = B \wr B$. Then, we have:*

$$M_{(A' \cup B')} = \begin{pmatrix} M_A \otimes M_A & M_{A,B} \otimes M_{A,B} \\ M_{B,A} \otimes M_{B,A} & M_B \otimes M_B \end{pmatrix}.$$

Proof. Let $\pi, \sigma \in A' \cup B'$ and suppose that $\pi = \pi_1 \wr \pi_2$, $\sigma = \sigma_1 \wr \sigma_2$. By Lemma 13,

$$\begin{aligned} M_{(A' \cup B')}(\pi, \sigma) &= \frac{\mathrm{LCS}(\pi, \sigma)}{n^2} = \frac{\mathrm{LCS}(\pi_1, \sigma_1)}{n} \cdot \frac{\mathrm{LCS}(\pi_2, \sigma_2)}{n} \\ &= M_{(A \cup B)}(\pi_1, \sigma_1) \cdot M_{(A \cup B)}(\pi_2, \sigma_2). \end{aligned}$$

Then, by considering the ordering over A' obtained by the ordering of A when we consider first the outer permutation and then the inner permutation (and similarly for B'), we have that each entry of the matrix is equivalent to the Kronecker product. ◀

▶ **Lemma 15.** *Let (A, B, W) be a witness of size n. Let $A' = A \wr A$, $B' = B \wr B$, and:*

$$W' = \begin{pmatrix} U \otimes U & -(V \otimes V) \\ -(V^T \otimes V^T) & U \otimes U \end{pmatrix}.$$

Then, (A', B', W') is a witness of size n^2 and $\nu(A', B', W') \geq \nu(A, B, W)^2$.

Proof. Note that $U \otimes U$ and $V \otimes V$ are non-negative and symmetric. Moreover, since $W \succeq 0$, we have that $W \otimes W \succeq 0$. Define:

$$W'' = \begin{pmatrix} U \otimes U & V \otimes V \\ V^T \otimes V^T & U \otimes U \end{pmatrix}.$$

Since W'' is a principal sub-matrix of $W \otimes W$, we have that $W'' \succeq 0$. Observe now that $W' = \mathrm{diag}(I, -I) \cdot W'' \cdot \mathrm{diag}(I, -I)$, and therefore $W' \succeq 0$ since for any matrix $X \succeq 0$ and any matrix Y, $YXY^T \succeq 0$. Moreover, by Lemma 14 and since $M_A = M_B$, we also have $M_{A'} = M_{B'}$. Then, (A', B', W') is a valid witness of size n^2. We now compute its value.

For matrices A, B, C, D it holds that $\mathrm{tr}((A \otimes B)(C \otimes D)) = \mathrm{tr}(AC) \cdot \mathrm{tr}(BD)$. By using this property, and by Lemma 14, we have:

$$\begin{aligned} \mathrm{tr}((V \otimes V) \cdot M_{A',B'}) &= \mathrm{tr}((V \otimes V) \cdot (M_{A,B} \otimes M_{A,B})) = \mathrm{tr}(V \cdot M_{A,B})^2, \text{ and} \\ \mathrm{tr}((U \otimes U) \cdot M_{A'}) &= \mathrm{tr}((U \otimes U) \cdot (M_A \otimes M_A)) = \mathrm{tr}(U \cdot M_A)^2. \end{aligned}$$

Note that since $\mathrm{tr}(U \cdot M_A) \neq 0$, $\mathrm{tr}((U \otimes U) M_{A'}) \neq 0$. Then:

$$\nu(A', B', W') = \frac{\mathrm{tr}((V \otimes V) \cdot M_{A',B'})}{\mathrm{tr}((U \otimes U) \cdot M_{A'})} = \left(\frac{\mathrm{tr}(V \cdot M_{A,B})}{\mathrm{tr}(U \cdot M_A)} \right)^2 = \nu(A, B, W)^2. \qquad \blacktriangleleft$$

We now provide our starting instance.

▶ **Proposition 16.** *There exists a witness (A_0, B_0, W_0) of size 8 and value $\geq 9/7$.*

Proof. Let $A_0 = \{A_1, \ldots, A_4\}$ and $B_0 = \{B_1, \ldots, B_4\}$, where $\tau = (1\,2\,7\,8)(3\,6\,5\,4) = (2, 7, 6, 3, 4, 5, 8, 1)$ and $B_i = \tau A_i$:

$$\begin{aligned} A_1 &= (1, 2, 3, 4, 5, 6, 7, 8), & B_1 &= (2, 7, 6, 3, 4, 5, 8, 1), \\ A_2 &= (4, 3, 2, 1, 8, 7, 6, 5), & B_2 &= (3, 6, 7, 2, 1, 8, 5, 4), \\ A_3 &= (6, 5, 8, 7, 2, 1, 4, 3), & B_3 &= (5, 4, 1, 8, 7, 2, 3, 6), \\ A_4 &= (7, 8, 5, 6, 3, 4, 1, 2), & B_4 &= (8, 1, 4, 5, 6, 3, 2, 7). \end{aligned}$$

Since B_0 is obtained from A_0 by relabeling, we have $M_{A_0} = M_{B_0}$. A direct computation gives

$$M_{A_0} = \frac{1}{8}\begin{pmatrix} 8 & 2 & 2 & 2 \\ 2 & 8 & 2 & 2 \\ 2 & 2 & 8 & 2 \\ 2 & 2 & 2 & 8 \end{pmatrix}, \qquad M_{A_0,B_0} = \frac{1}{8}\begin{pmatrix} 5 & 4 & 4 & 5 \\ 4 & 5 & 5 & 4 \\ 4 & 5 & 5 & 4 \\ 5 & 4 & 4 & 5 \end{pmatrix}.$$

The matrix W_0 for this instance is given by $U = V = J_4$ (where J_4 is the all-ones 4×4 matrix). First,

$$W = \begin{pmatrix} U & -V \\ -V^T & U \end{pmatrix} = \begin{pmatrix} J_4 & -J_4 \\ -J_4 & J_4 \end{pmatrix} = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} \otimes J_4 \succeq 0.$$

Next, it is easy to calculate

$$\mathrm{tr}(V \cdot M_{A_0,B_0}) = \frac{1}{8}(18 \cdot 4) = 9, \qquad \mathrm{tr}(U \cdot M_{A_0}) = \frac{1}{8}(14 \cdot 4) = 7.$$

Hence, $\nu(A_0, B_0, W_0) = 9/7$. ◀

▶ **Lemma 17.** *There exists a constant $\delta > 0$ such that, for any $n_0 > 0$, there exists $n \geq n_0$ such that the LSH distortion of the Ulam similarity S^{U} on $\mathbb{S}_n$ is at least $\Omega(n^\delta)$.*

Proof. Let $\Delta_0 = 9/7$ and $m = 8$. Let k be the smallest integer such that $m^{2^k} \geq n_0$, we set $n = m^{2^k}$. Note that $k = \log_2 \log_m(n)$.

Starting from the witness of Proposition 16 and applying Lemma 15 k times we obtain a witness of size $m^{2^k} = n$ and value $\geq \Delta_0^{2^k}$. By Lemma 12, this implies that the LSH distortion on $\mathbb{S}_n$ is at least:

$$\Delta_0^{2^k} = \Delta_0^{\log_m(n)} = n^{\log_m \Delta_0} \geq n^{0.120856} = \Omega(n^\delta),$$

for $\delta = 0.12$. ◀

Note that Lemma 17 directly implies Theorem 10. The proof is elementary.

6 Upper Bound for Cayley Similarity

In this section, we show that the LSH distortion for Cayley similarity is no more than n.

▶ **Theorem 18.** *The LSH distortion of $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$ is at most n.*

Proof. Let $\mathcal{H}$ be the uniform at random distribution over the functions $h : \mathbb{S}_n \to [n]$. Clearly, for each $\pi, \sigma \in \mathbb{S}_n$, $\pi \neq \sigma$:

$$\Pr_{h \sim \mathcal{H}}[h(\pi) = h(\sigma)] = \frac{1}{n}.$$

Since $\frac{1}{n} \leq \mathrm{S}^{\mathrm{C}}(\pi, \sigma) \leq 1$ for all $\pi, \sigma \in \mathbb{S}_n$, we have:

$$\frac{1}{n} \cdot \mathrm{S}^{\mathrm{C}}(\pi, \sigma) \leq \Pr_{h \sim \mathcal{H}}[h(\pi) = h(\sigma)] \leq \mathrm{S}^{\mathrm{C}}(\pi, \sigma).$$ ◀

7 Lower Bound for Cayley Similarity

In this section, we show the following result:

▶ **Theorem 19.** *The LSH distortion of* $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$ *is* $\Omega(n)$.

The proof will rely on some standard results in the representation theory of $\mathbb{S}_n$. For convenience, we review these standard results in the appendix of the full version of the paper (see also, e.g., [19, 14, 17]).

We begin with the following definition:

▶ **Definition 20** (Bi-invariance). *We say that a function* $f : \mathbb{S}_n \times \mathbb{S}_n \to \mathbb{R}$ *is* bi-invariant *if:*

$$f(\pi, \sigma) = f(\tau_1 \pi \tau_2, \tau_1 \sigma \tau_2),$$

for any $\pi, \sigma, \tau_1, \tau_2 \in \mathbb{S}_n$. *We say a bi-invariant function is a* bi-invariant PSD kernel *if, in addition, it satisfies:*

$$\sum_{\pi,\sigma \in \mathbb{S}_n} a_\sigma a_\pi f(\pi, \sigma) \geq 0,$$

for every $a \in \mathbb{R}^{\mathbb{S}_n}$. *We also require that* $f(\mathrm{id}, \mathrm{id}) = 1$ *for* f *to be a PSD kernel.*

Recall that a *class function* on $\mathbb{S}_n$ is a function that is constant on each conjugacy class of $\mathbb{S}_n$. We recall the following property of bi-invariant functions. (Note that equivalent results are known in the literature, and hold for more general groups – see, e.g., [14, Chapter 4.5] – but we include a proof anyway for completeness.)

▶ **Lemma 21.** *A function* $f : \mathbb{S}_n \times \mathbb{S}_n \to \mathbb{R}$ *is bi-invariant if and only if there exists a class function* $g : \mathbb{S}_n \to \mathbb{R}$ *such that:*

$$f(\sigma, \pi) = g(\sigma \pi^{-1}),$$

for every $\sigma, \pi \in \mathbb{S}_n$.

Proof. Let $f : \mathbb{S}_n \times \mathbb{S}_n \to \mathbb{R}$ be a bi-invariant function. Define $g : \mathbb{S}_n \to \mathbb{R}$ as:

$$g(\pi) := f(\pi, \mathrm{id}).$$

Then we have:

$$f(\pi, \sigma) = f(\pi\sigma^{-1}, \sigma\sigma^{-1}) = f(\pi\sigma^{-1}, \mathrm{id}) = g(\pi\sigma^{-1})$$

for any $\pi, \sigma \in \mathbb{S}_n$. Moreover, g is a class function, since, for any $\pi, \sigma \in \mathbb{S}_n$:

$$g(\sigma\pi\sigma^{-1}) = f(\sigma\pi\sigma^{-1}, \mathrm{id}) = f(\pi, \sigma^{-1}\sigma) = f(\pi, \mathrm{id}) = g(\pi),$$

where the second equality follows from the bi-invariance of f.

On the other hand, suppose that $f : \mathbb{S}_n \times \mathbb{S}_n \to \mathbb{R}$ is a function such that $f(\pi, \sigma) = g(\pi\sigma^{-1})$ for some class function g, then, for any $\pi, \sigma, \tau \in \mathbb{S}_n$:

$$f(\pi\tau, \sigma\tau) = g(\pi\tau\tau^{-1}\sigma^{-1}) = g(\pi\sigma^{-1}) = f(\pi, \sigma),$$

and:

$$f(\tau\pi, \tau\sigma) = g(\tau\pi\sigma^{-1}\tau^{-1}) = g(\pi\sigma^{-1}) = f(\pi, \sigma),$$

where the second equality uses the fact that g is a class function. Hence f is bi-invariant. ◀

A crucial property of the Cayley similarity is that it is bi-invariant, as we now show.

▶ **Lemma 22.** $\mathrm{S}^{\mathrm{C}}(\cdot,\cdot)$ *is bi-invariant.*

Proof. We have that, for any choice of π and σ, $\mathrm{S}^{\mathrm{C}}(\pi,\sigma) = \frac{c(\pi\sigma^{-1})}{n}$. Since any two conjugate permutations have the same cycle type, the function $\pi \mapsto \frac{c(\pi)}{n}$ is a class function, and the result follows from Lemma 21. ◀

▶ **Definition 23** (Bi-invariant Distribution over Functions)**.** *We will say that a distribution $\mathcal{H}$ over functions from $\mathbb{S}_n$ into some set $\mathcal{Y}$ is* bi-invariant *if the function $P_{\mathcal{H}}(\cdot,\cdot)$ is bi-invariant.*

We now show that when studying the minimum achievable distortion for $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$, any LSH family can be assumed to be bi-invariant.

▶ **Lemma 24.** *Suppose there exists a distribution $\mathcal{H}$ over functions from $\mathbb{S}_n$ into a finite set $\mathcal{Y}$ that Δ-approximates $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$, then there exists a bi-invariant distribution $\mathcal{H}'$ that Δ-approximates $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$.*

Proof. We construct $\mathcal{H}'$ by pre-composing the elements of $\mathcal{H}$ with random left and right permutations: define a function $h' \sim \mathcal{H}'$ as $h'(\pi) = h(\alpha\pi\beta)$, where h is drawn from $\mathcal{H}$ and α, β are drawn uniformly and independently from $\mathbb{S}_n$. We first show that $\mathcal{H}'$ Δ-approximates $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$. For every choice of $\pi, \sigma \in \mathbb{S}_n$, we have:

$$\begin{aligned}\Pr_{h'\sim\mathcal{H}'}[h'(\pi) = h'(\sigma)] &= \mathop{\mathbb{E}}_{\alpha,\beta\sim\mathbb{S}_n}\left[\Pr_{h\sim\mathcal{H}}[h(\alpha\pi\beta) = h(\alpha\sigma\beta)]\right] \\ &\leq \mathop{\mathbb{E}}_{\alpha,\beta\sim\mathbb{S}_n}\left[\mathrm{S}^{\mathrm{C}}(\alpha\pi\beta, \alpha\sigma\beta)\right] \\ &\overset{\text{Lemma 22}}{=} \mathop{\mathbb{E}}_{\alpha,\beta\sim\mathbb{S}_n}\left[\mathrm{S}^{\mathrm{C}}(\pi,\sigma)\right] = \mathrm{S}^{\mathrm{C}}(\pi,\sigma),\end{aligned}$$

where the first inequality uses that $\mathcal{H}$ Δ-approximates $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$. Similarly:

$$\begin{aligned}\Pr_{h'\sim\mathcal{H}'}[h'(\pi) = h'(\sigma)] &= \mathop{\mathbb{E}}_{\alpha,\beta\sim\mathbb{S}_n}\left[\Pr_{h\sim\mathcal{H}}[h(\alpha\pi\beta) = h(\alpha\sigma\beta)]\right] \\ &\geq \mathop{\mathbb{E}}_{\alpha,\beta\sim\mathbb{S}_n}\left[\frac{1}{\Delta}\cdot\mathrm{S}^{\mathrm{C}}(\alpha\pi\beta, \alpha\sigma\beta)\right] \\ &\overset{\text{Lemma 22}}{=} \mathop{\mathbb{E}}_{\alpha,\beta\sim\mathbb{S}_n}\left[\frac{1}{\Delta}\cdot\mathrm{S}^{\mathrm{C}}(\pi,\sigma)\right] = \frac{1}{\Delta}\mathrm{S}^{\mathrm{C}}(\pi,\sigma),\end{aligned}$$

Showing that indeed $\mathcal{H}'$ Δ-approximates $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$. Finally, we verify that $P_{\mathcal{H}'}$ is bi-invariant. For any $\pi, \sigma \in \mathbb{S}_n$ and any left multiplier τ_1 and right multiplier τ_2:

$$P_{\mathcal{H}'}(\tau_1\pi\tau_2, \tau_1\sigma\tau_2) = \mathbb{E}_{\alpha,\beta\sim\mathbb{S}_n}[P_{\mathcal{H}}(\alpha\tau_1\pi\tau_2\beta, \alpha\tau_1\sigma\tau_2\beta)].$$

Because α and β are drawn uniformly from the group, the products $\alpha' = \alpha\tau_1$ and $\beta' = \tau_2\beta$ are also uniformly distributed. Thus, the expectation is identical to $\mathbb{E}_{\alpha',\beta'}[P_{\mathcal{H}}(\alpha'\pi\beta', \alpha'\sigma\beta')] = P_{\mathcal{H}'}(\pi,\sigma)$, completing the proof. ◀

Note also that, by Lemma 4, $P_{\mathcal{H}'}$ is PSD and it is therefore a bi-invariant PSD kernel.

Recall that each partition $\lambda \vdash n$ is associated with a distinct irreducible representation S^λ of $\mathbb{S}_n$, we denote by $\chi_\lambda : \mathbb{S}_n \to \mathbb{C}$ its character, and by $d_\lambda \in \mathbb{N}$ its dimension.

▶ **Lemma 25.** *Any bi-invariant PSD kernel P on $\mathbb{S}_n$ can be written as a convex combination of normalized characters of irreducible representations of $\mathbb{S}_n$ as follows:*

$$\forall \sigma, \pi \in \mathbb{S}_n : \quad P(\sigma, \pi) = \sum_{\lambda : \lambda \vdash n} w_\lambda \frac{\chi_\lambda(\sigma\pi^{-1})}{d_\lambda},$$

where $w_\lambda \geq 0$ and $\sum_\lambda w_\lambda = 1$.

Proof. Let $\phi : \mathbb{S}_n \to \mathbb{R}$ be the class function satisfying:

$$\phi(\sigma\pi^{-1}) = P(\sigma, \pi),$$

the existence of which is guaranteed by Lemma 21. By a result of Kondor [14, Corollary 4.5.5[2]], since ϕ is PSD, we have:

$$\phi = \sum_{\lambda \vdash n} a_\lambda \cdot \chi_\lambda, \tag{10}$$

for some choice of $\{a_\lambda\}_{\lambda \vdash n}$, where each $a_\lambda \in \mathbb{R}_{\geq 0}$.

In particular:

$$1 = P(\mathrm{id}, \mathrm{id}) = \phi(\mathrm{id}) = \sum_{\lambda \vdash n} a_\lambda \cdot \chi_\lambda(\mathrm{id}) = \sum_{\lambda \vdash n} a_\lambda \cdot d_\lambda,$$

where we use that $\chi_\lambda(\mathrm{id}) = d_\lambda$. Letting $w_\lambda := a_\lambda \cdot d_\lambda$, together with Equation (10) completes the proof. ◀

For our asymptotic bounds, it is necessary to isolate the trivial representation (n), where $\chi_{(n)}(\cdot) = 1$ and $d_{(n)} = 1$ and the sign representation (1^n), where $\chi_{(1^n)}(\sigma) = \mathrm{sgn}(\sigma)$ and $d_{(1^n)} = 1$. Thus, it is helpful to write

$$P(\mathrm{id}, \sigma) = w_0 + w_{\mathrm{sgn}} \cdot \mathrm{sgn}(\sigma) + \sum_{\lambda \neq (n), (1^n)} w_\lambda \frac{\chi_\lambda(\sigma)}{d_\lambda}. \tag{11}$$

For a permutation $\sigma \in \mathbb{S}_n$, the *fixed-point* count is defined as $\mathrm{fix}(\sigma) = |\{i \in [n] \mid \sigma(i) = i\}|$, i.e., the number of length-1 cycles. A *derangement* is a permutation σ that moves all elements, i.e., $\mathrm{fix}(\sigma) = 0$. For any $\sigma \in \mathbb{S}_n$, we also define the value $\mathrm{supp}(\sigma)$ as $n - \mathrm{fix}(\sigma)$. We recall the following result.

▶ **Theorem 26** ([18])**.** *There exist absolute constants $\varphi > 0$ and $0 < q < 1$ such that for any partition $\lambda = (\lambda_1, \ldots, \lambda_k) \vdash n$, any $n \geq 4$ and any permutation $\sigma \in \mathbb{S}_n$:*

$$\left| \frac{\chi_\lambda(\sigma)}{d_\lambda} \right| \leq \left(\max \left\{ \frac{\lambda_1}{n}, \frac{k}{n}, q \right\} \right)^{\varphi \cdot \mathrm{supp}(\sigma)}.$$

Theorem 26 allows us to prove the following.

▶ **Lemma 27.** *There exist absolute constants $\varphi > 0$ and $0 < q < 1$ such that for any $n \geq 4$, any partition $\lambda = (\lambda_1, \lambda_2, \ldots, \lambda_k) \vdash n$, and any derangement $\sigma \in \mathbb{S}_n$,*

$$\left| \frac{\chi_\lambda(\sigma)}{d_\lambda} \right| \leq e^{-\varphi \cdot \alpha},$$

where $\alpha = \min\{n - \lambda_1, n - k, (1 - q)n\}$.

[2] We remark that Kondor's result is stated in terms of what he refers to as "Positive Definite" kernels, which are, in reality, positive semidefinite kernels, as he himself explains earlier in the thesis.

Proof. Since σ is a derangement, $\mathrm{fix}(\sigma) = 0$; therefore $\mathrm{supp}(\sigma) = n - \mathrm{fix}(\sigma) = n$. Furthermore, from the definition of α, we have:

$$\max\left\{\frac{\lambda_1}{n}, \frac{k}{n}, q\right\} = 1 - \frac{\alpha}{n}.$$

Substituting these into the bound from Theorem 26 yields:

$$\left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right| \leq \left(1 - \frac{\alpha}{n}\right)^{\varphi n} \leq e^{-\varphi\cdot\alpha}.$$ ◀

▶ **Lemma 28** (Theorem 1.2 (i) from [15], paraphrased)**.** *For any derangement $\sigma \in \mathbb{S}_n$ and any partition $\lambda \vdash n$:*

$$\left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right| \leq \frac{1}{d_\lambda^{1/2-o(1)}}.$$

▶ **Lemma 29.** *For any partition $\lambda = (\lambda_1, \ldots, \lambda_k) \vdash n$ with $\lambda_1 \geq \frac{11}{12}\cdot n$, it holds that: $d_\lambda \geq \left(\frac{n}{2(n-\lambda_1)}\right)^{n-\lambda_1}$*

Proof. Let $\gamma = n - \lambda_1$. By the hook length formula (see the appendix of the full version of the paper), we have:

$$\begin{aligned}
d_\lambda = \frac{n!}{\prod h(i,j)} &\geq \frac{n!}{(n-2\gamma)!\cdot n^\gamma\cdot\gamma^\gamma} \\
&= \frac{n\cdots(n-2\gamma+1)}{n^\gamma\gamma^\gamma} \\
&= \frac{n}{n}\cdots\frac{n-\gamma+1}{n}\cdot\frac{(n-\gamma)\cdots(n-2\gamma+1)}{\gamma^\gamma} \\
&\geq \left(\frac{n-\gamma+1}{n}\right)^\gamma\cdot\left(\frac{n-2\gamma+1}{\gamma}\right)^\gamma \\
&\geq \left(\frac{n^2-6\cdot n\cdot\gamma}{\gamma\cdot n}\right)^\gamma \\
&= \left(\frac{n}{\gamma}-6\right)^\gamma \\
&= \left(\frac{n}{\gamma}\left(1-\frac{6\gamma}{n}\right)\right)^\gamma \\
&\geq \left(\frac{n}{2\gamma}\right)^\gamma,
\end{aligned}$$

where the last inequality used the fact that $\gamma \leq \frac{n}{12}$. ◀

▶ **Lemma 30.** *Consider any sufficiently large n, any derangement $\sigma \in \mathbb{S}_n$, and let P be a bi-invariant PSD kernel. Let:*

$$P(\tau,\pi) = \sum_{\lambda\vdash n} w_\lambda \frac{\chi_\lambda(\tau\pi^{-1})}{d_\lambda},$$

be the decomposition guaranteed by Lemma 25, then:

$$\left|\sum_{\substack{\lambda\vdash n\\ \lambda\neq(n),(1^n)}} w_\lambda\frac{\chi_\lambda(\sigma)}{d_\lambda}\right| \leq \frac{C}{n},$$

for some constant C.

Proof. We have:

$$\left|\sum_{\substack{\lambda\vdash n\\ \lambda\neq(n),(1^n)}} w_\lambda \frac{\chi_\lambda(\sigma)}{d_\lambda}\right| \leq \max_{\substack{\lambda\vdash n\\ \lambda\neq(n),(1^n)}} \left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right| \sum_{\substack{\lambda\vdash n\\ \lambda\neq(n),(1^n)}} w_\lambda \leq \max_{\substack{\lambda\vdash n\\ \lambda\neq(n),(1^n)}} \left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right|,$$

where we first apply Hölder's inequality on ℓ_∞ and ℓ_1 and then we use the fact that $\sum_{\lambda\vdash n} w_\lambda = 1$, as well as the non-negativity of the w_λs. We now give an upper bound for the right-hand side. Let φ and q be the constants given by Lemma 27. Let $\lambda = (\lambda_1, \ldots, \lambda_k) \vdash n$, and let $\alpha = \min\{n-\lambda_1, n-k, (1-q)n\}$. Since $\lambda \neq (n), (1^n)$, we have $\min\{n-\lambda_1, n-k\} \geq 1$. We obtain an upper bound by considering five possible cases for the value of α.

Case 1: $\alpha = (1-q)n$. Using Lemma 27, we have:

$$\left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right| \leq e^{-\varphi\cdot\alpha} = e^{-\Theta(n)} = o\left(\frac{1}{n}\right).$$

For the rest of the proof we will assume that $\alpha = n - \lambda_1 \geq 1$. This is without loss of generality, since, for any partition that does not satisfy this condition (i.e., for which $\alpha = n - k$), its transpose partition does satisfy it, and the values of $\left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right|$ are the same for the two partitions.

Case 2: $\alpha \geq \frac{1}{\varphi}\ln n$. Using Lemma 27 we have:

$$\left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right| \leq e^{-\varphi\cdot\alpha} \leq \frac{1}{n}.$$

Case 3: $3 \leq \alpha < \frac{1}{\varphi}\ln n$. Using Lemma 28 and Lemma 29 and recalling that $\alpha = n - \lambda_1$, and that therefore $\lambda_1 = n - \alpha > n - \frac{1}{\varphi}\ln n \geq \frac{11}{12}n$ for sufficiently large n, we obtain:

$$\left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right| \leq \left(\frac{1}{d_\lambda}\right)^{1/2-o(1)} \leq \left(\frac{2\alpha}{n}\right)^{\alpha\left(\frac{1}{2}-o(1)\right)} \leq \left(\frac{(2/\varphi)\cdot\ln(n)}{n}\right)^{3/2-o(1)} = O\left(\frac{1}{n}\right),$$

where we use that $\alpha \geq 3$ and $\alpha < O(\log n)$.

Case 4: $\alpha = 1$. In this case, the only partition is $\lambda = (n-1, 1)$, corresponding to the standard representation, which has dimension $n-1$. Its character is known to satisfy $\chi_\lambda(\pi) = \mathrm{fix}(\pi) - 1$ (See [19, Example 2.3.8]). Since σ is a derangement, $\mathrm{fix}(\sigma) = 0$, and the character $\chi_\lambda(\sigma) = -1$. We then have:

$$\left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right| = \left|\frac{-1}{n-1}\right| = O\left(\frac{1}{n}\right).$$

Case 5: $\alpha = 2$. In this case, the only two partitions are $\lambda = (n-2, 2)$ and $\mu = (n-2, 1, 1)$. By (19) in Example 32 in the appendix of the full version of the paper, we can write the character of the permutation module $M^{(n-2,2)}$ as the sum of irreducible characters as follows:

$$\chi_{M^{(n-2,2)}} = \chi_{(n-2,2)} + \chi_{(n-1,1)} + \chi_{(n)}.$$

By equation (17) in the appendix of the full version of the paper, this equation becomes:

$$\mathrm{cycle}_2(\pi) + \binom{\mathrm{fix}(\pi)}{2} = \chi_{(n-2,2)}(\pi) + \mathrm{fix}(\pi) - 1 + 1,$$

for all $\pi \in \mathbb{S}_n$, where $\text{cycle}_2(\pi)$ is the number of length-two cycles in the cycle decomposition of π. And hence:

$$\chi_{(n-2,2)}(\pi) = \text{cycle}_2(\pi) + \binom{\text{fix}(\pi)}{2} - \text{fix}(\pi),$$

for all $\pi \in \mathbb{S}_n$.
Similarly, by Equation (20) in Example 32 in the appendix of the full version of the paper, we can write the character of the permutation module $M^{(n-2,1,1)}$ as:

$$\chi_{M^{(n-2,1,1)}} = \chi_{(n-2,1,1)} + \chi_{(n-2,2)} + 2\chi_{(n-1,1)} + \chi_{(n)}.$$

By Equation (18) in that same appendix, this equation becomes:

$$\text{fix}(\pi)(\text{fix}(\pi) - 1) = \chi_{(n-2,1,1)} + \chi_{(n-2,2)} + 2(\text{fix}(\pi) - 1) + 1$$

for all $\pi \in \mathbb{S}_n$, which gives:

$$\chi_{(n-2,1,1)} = 1 - \text{cycle}_2(\pi) + \frac{\text{fix}(\pi)(\text{fix}(\pi) - 3)}{2}$$

for all $\pi \in \mathbb{S}_n$. Since σ is a derangement and $\text{fix}(\sigma) = 0$, we have:

$$\chi_{(n-2,2)}(\sigma) = \text{cycle}_2(\sigma),$$

and:

$$\chi_{(n-2,1,1)}(\sigma) = 1 - \text{cycle}_2(\sigma).$$

By Example 21 in the appendix of the full version of the paper: $d_\lambda = n(n-3)/2$ and $d_\mu = (n-1)(n-2)/2$. Putting things together, we have that:

$$\left|\frac{\chi_\lambda(\sigma)}{d_\lambda}\right| = \frac{2 \cdot \text{cycle}_2(\sigma)}{n(n-3)} \leq \frac{n}{n(n-3)} = \frac{1}{n-3} = O\left(\frac{1}{n}\right),$$

and:

$$\left|\frac{\chi_\mu(\sigma)}{d_\mu}\right| = \frac{2 \cdot (\text{cycle}_2(\sigma) - 1)}{(n-1)(n-2)} \leq \frac{n}{(n-1)(n-2)} = O\left(\frac{1}{n}\right).$$

This completes the proof of Lemma 30. ◀

We can now complete the proof of Theorem 19.

Proof of Theorem 19. Let $n \geq 6$ be a large enough integer so that Lemma 30 holds. Let $\mathcal{H}$ be a distribution that Δ-approximates $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$. Without loss of generality, by Lemma 24, we can assume that $P_{\mathcal{H}}$ is a bi-invariant PSD kernel.

We let σ^* be a derangement with $\Theta(n)$ cycles and π^* be a derangement with $O(1)$ cycles and having the same sign as σ^*. We explicitly define these permutations expressing them in their cycle decomposition. If n is even, we let:

$$\sigma^* := \prod_{i=1}^{n/2} (2i-1, 2i),$$

and observe that $c(\sigma^*) = n/2$. If instead n is odd, we define:

$$\sigma^* := (1,2,3) \prod_{i=2}^{\frac{n-1}{2}} (2i, 2i+1),$$

and observe that $c(\sigma^*) = (n-1)/2$ and σ^* can be decomposed in $(n+1)/2$ transpositions. Now, if n is even and $\operatorname{sgn}(\sigma^*) = 1$ or if n is odd and $\operatorname{sgn}(\sigma^*) = -1$, we define:

$$\pi^* = (1, 2, \ldots, n-3)(n-2, n-1, n),$$

and note that $\operatorname{sgn}(\pi^*) = \operatorname{sgn}(\sigma^*)$ since it can be decomposed into $n-2$ transpositions. If instead n is even and $\operatorname{sgn}(\sigma^*) = -1$ or if n is odd and $\operatorname{sgn}(\sigma^*) = 1$, we define:

$$\pi^* = (1, 2, \ldots, n),$$

and note that $\operatorname{sgn}(\pi^*) = \operatorname{sgn}(\sigma^*)$ since it can be decomposed into $n-1$ transpositions.

Observe that, since $n \geq 6$:

$$\mathrm{S}^{\mathrm{C}}(\mathrm{id}, \sigma^*) \geq \frac{(n-1)/2}{n} \geq \frac{1}{3} \qquad \text{and} \qquad \mathrm{S}^{\mathrm{C}}(\mathrm{id}, \pi^*) \leq \frac{2}{n}.$$

Since $\mathcal{H}$ Δ-approximates $(\mathbb{S}_n, \mathrm{S}^{\mathrm{C}})$, we have:

$$P_{\mathcal{H}}(\mathrm{id}, \pi^*) \leq \mathrm{S}^{\mathrm{C}}(\mathrm{id}, \pi^*) \leq \frac{2}{n}.$$

Plugging this into (11), and letting C be the constant in the statement of Lemma 30:

$$w_0 + w_{\mathrm{sgn}} - \frac{C}{n} \overset{\text{Lemma 30}}{\leq} w_0 + w_{\mathrm{sgn}} \cdot \operatorname{sgn}(\pi^*) + \sum_{\substack{\lambda \vdash n \\ \lambda \neq (n), (1^n)}} w_\lambda \frac{\chi_\lambda(\pi^*)}{d_\lambda} \overset{(11)}{=} P_{\mathcal{H}}(\mathrm{id}, \pi^*) \leq \frac{2}{n},$$

giving:

$$w_0 + w_{\mathrm{sgn}} \leq \frac{2 + C}{n}. \tag{12}$$

Again applying Equation (11) and Lemma 30, we have:

$$P_{\mathcal{H}}(\mathrm{id}, \sigma^*) \overset{(11),\text{Lemma 30}}{\leq} w_0 + w_{\mathrm{sgn}} + \frac{C}{n} \overset{(12)}{\leq} \frac{2 + 2C}{n}.$$

On the other hand:

$$P_{\mathcal{H}}(\mathrm{id}, \sigma^*) \geq \frac{1}{\Delta} \mathrm{S}^{\mathrm{C}}(\mathrm{id}, \sigma^*) = \frac{1}{3\Delta}.$$

Combining the last two equations yields:

$$\Delta \geq \frac{n}{6(1 + C)},$$

completing the proof. ◀

8 Conclusions and Open Questions

Our work shows that the Ulam similarity enjoys sublinear LSH distortion whereas the Cayley similarity does not. An obvious open problem is to close the glaring yet tantalizing gap between the upper bound $(n/\sqrt{\log n})$ and the lower bound $(\Omega(n^{0.12}))$ for the Ulam similarity; our current belief is that the correct LSH distortion bound is $\tilde{\Theta}(\sqrt{n})$. Improving the base case (Proposition 16) is a natural direction, though there are computational limitations to finding a larger and better base instance. While it seems possible to improve our upper bound to $\tilde{O}(n/\log n)$, going beyond this to $\tilde{O}(n^{1-\Omega(1)})$ might require an entirely new approach. Extending our results to other permutation similarities such as reversal is another interesting direction; our current lower bound techniques seem inadequate for the block reversal similarity, for which we conjecture an $\Omega(n)$ lower bound.

LLM Usage

The Ulam upper bound was obtained after weeks of interaction with and help from an LLM; the LLM-generated proof was hand-verified and somewhat simplified. The solver for the base case of the Ulam lower bound was written by an LLM; the instance itself was hand-verified. The high-level approach of using representation theory, in particular, Roichman's Theorem and derangements, to obtain the Cayley lower bound was suggested by an LLM (after the initial attempts to extend Ulam lower bound proof approach to Cayley failed). All the final proofs were written and verified by the authors.

Abstract

Buhrman, Patro, and Speelman [11] presented a framework of conjectures that together form a quantum analogue of the strong exponential-time hypothesis and its variants. They called it the QSETH framework. In this paper, using a notion of quantum natural proofs (built from natural proofs introduced by Razborov and Rudich), we show how part of the QSETH conjecture that requires properties to be "compression oblivious" can in many cases be replaced by assuming the existence of quantum-secure pseudorandom functions, a standard hardness assumption. Combined with techniques from Fourier analysis of Boolean functions, we show that properties such as PARITY and MAJORITY are compression oblivious for certain circuit class Λ if subexponentially secure quantum pseudorandom functions exist in Λ, answering an open question in [11].

1 Introduction

A well-studied problem in complexity theory is CNFSAT, the problem of whether a formula, input in conjunctive normal form, has a satisfying assignment. Not only is there no polynomial time known for CNFSAT, there is also no known algorithm that significantly improves over the brute-force method of checking all 2^n assignments. Impagliazzo, Paturi and Zane in [23, 24] conjectured that determining whether an input CNF formula is satisfiable or not cannot be done in time $O(2^{n(1-\varepsilon)})$ for any constant $\varepsilon > 0$. They called it *Strong Exponential-Time Hypothesis* (SETH). As a consequence, SETH-based lower bounds were shown for many computational problems; for example, see [31, 8, 21].

Variants of classical SETH

Subsequent works also explored alternate directions in which the strong exponential-time hypothesis can be weakened and thereby made more plausible. For, e.g.,

1. The *satisfiability* problem is studied for other (more general) succinct representations of Boolean functions such as BPSAT or `Circuit`SAT - the problem of whether a polynomial-size branching program or a polynomial-size circuit has a satisfying assignment. Furthermore, respective hardness conjectures for these satisfiability problems, namely NCSETH and `Circuit`SETH (under the name "`Circuit`SAT form of SETH") have also been discussed together with their implications [2, 30].
2. Another direction of study that has made SETH more plausible is by computing more complicated properties of the formula. For example, counting the number of satisfying assignments and computing whether the number of satisfying assignments is even or odd is captured by #SETH and $\oplus$SETH, respectively; see [17] for example.

Unfortunately, neither SETH nor NCSETH or `Circuit`SETH, hold relative to *quantum* computation, as using Grover's algorithm for unstructured search [19] it is possible to solve the respective satisfiability problems in $O(2^{n/2})$ time - leading to conjectured lower bounds of complexity $\Omega(2^{n/2})$. While these lower bounds have interesting consequences (as shown by [1, 11]), in the quantum case, generalizing the properties to be computed (as suggested in Item 2) is a way to come up with variants of the hypothesis that enable stronger bounds: for many of such tasks it is likely that the quadratic quantum speedup, as given by Grover's algorithm, no longer exists. In fact, motivated by this exact observation, Buhrman, Patro, and Speelman [11] introduced a framework of Quantum Strong Exponential-Time Hypotheses (QSETH) as quantum analogues to SETH, with a striking feature that allows one to technically unify quantum analogues of SETH, $\oplus$SETH, #SETH, NCSETH, $\oplus$NCSETH, etc., all under one umbrella conjecture.

The QSETH framework

Buhrman *et al.* consider the problem in which one is given a formula or a circuit representation of a Boolean function $f : \{0,1\}^n \to \{0,1\}$ and is asked whether a property $\mathrm{P} : \{0,1\}^{2^n} \to \{0,1\}$ on its truth table[1] evaluates to 1. They conjectured that when the circuit representation is *obfuscated* enough (that is, the description of the circuit provides no advantages over treating the circuit as a black-box with query access to its truth table), then for *most*

[1] Truth table of a formula/circuit ϕ on n variables, denoted by $\mathtt{tt}(\phi)$, is a 2^n bit string derived in the following way $\mathtt{tt}(\phi) = \bigcirc_{a\in\{0,1\}^n} \phi(a)$; the symbol $\circ$ denotes concatenation.

properties P (that are "compression oblivious" with respect to the representation), the time taken to compute P on the truth table of poly(n)-sized circuits is lower bounded by $\mathsf{Q}(\mathrm{P})$, i.e., the 1/3-bounded error quantum query complexity of P, on all bit strings of length 2^n.

Note that there are two requirements to using the QSETH framework. Firstly, the input formula or circuit must be "obfuscated enough" - as we already saw this translates to saying that knowing the description of the input must not help towards computing P any more than just having query access to the truth table of the input. The second requirement (which is the main topic of discussion of this paper) is that the property P itself must be "compression oblivious" - a notion introduced in [11] that we discuss next.

Compression-oblivious properties

Buhrman *et al.* defined this notion to capture properties whose *query complexity* on all strings is a lower bound for the *time complexity* to compute the property even for inputs that are "compressible" as a truth table of small formulas (or circuits). This notion is useful (to their framework) because if the formula (or circuit) is obfuscated enough then one can use the quantum query lower bound of such a property to conjecture a time lower bound of computing that property on a small formula (or circuit).[2] Therefore, before using their framework, one has to be convinced that the property is indeed compression-oblivious with respect to the circuit representation considered. They give various results to initiate the study of the set of compression-oblivious languages; see Section 2.3 in [11]. For example, they show the following.

- For simple properties, such as OR, AND, they were able to prove that these are compression-oblivious for polynomial-size AC^0_2 circuits.
- They gave an example of a property that is *not* compression oblivious for polynomial-sized circuits (or any smaller class of representations).[3]
- For more complicated properties, such as PARITY or MAJORITY, they show that proving compression-obliviousness would separate P from PSPACE; see Theorem 9 in [11]. Their result indicates that *unconditionally* proving compression-obliviousness for a complicated property is hard. One way around this would be to directly *conjecture* the compression-obliviousness of such properties, which was the choice of [11]. However, it would be desirable to put this on more solid ground.

[2] Here is an example to illustrate why obfuscation is important. Consider the OR property. The quantum query complexity of OR when restricted to truth tables of small CNF or DNF formulas defined on n input variables is $\Omega(\sqrt{N})$ where $N = 2^n$ - let us denote this statement by $(\star)$. Furthermore, the structure of CNF formulas are not known to help in computing OR more efficiently than $O(\sqrt{N})$. Therefore, we can use the same lower bound from $(\star)$ to conjecture the lower bound of $\Omega(\sqrt{N})$ for CNFSAT in the quantum setting. However, DNF formulas are not obfuscated enough for OR as we can compute OR in poly(n) time when input formulas are DNFs. This means we cannot use the query lower bound of $\sqrt{N}$ from $(\star)$ for the DNFs as we do in the case of CNF formulas.

[3] Consider the following property (Example 7 in [11]), defined on some string $z \in \{0,1\}^{2^n}$, which we view as the truth table of a formula or circuit:

$$\mathrm{P}_{\mathtt{large}-c}(z) = \textsc{parity}(z) \wedge [\text{there exists no circuit } C \text{ of size less than } 2^{n/100} \text{ s.t. } z = \mathtt{tt}(C)].$$

We use $\mathtt{tt}(C)$ to denote the truth table of C. Because most strings are not a truth table of a small circuit, the query complexity of this property is close to the query complexity of PARITY, i.e., $\mathsf{Q}(\mathrm{P}_{\mathtt{large}-c}) = \Omega(2^n)$. Nevertheless, the property is always 0 when restricted to truth tables of small circuits, and therefore trivial to compute. Therefore, $\mathrm{P}_{\mathtt{large}-c}$ is not compression oblivious for polynomial-sized circuits (or any smaller class of representations).

One might ask – *why is the notion of compression-oblivious properties useful for the QSETH framework when it is hard to prove results about this notion for many properties?*

Towards answering this question, consider the $\oplus$QSETH hypothesis - implicitly stated and discussed in [11] and explicitly stated in [14, 12]. It says,

▶ **Conjecture 1** (Conjecture 8.9 in [12]). *For each constant $\delta > 0$, there exists $c > 0$ such that there is no bounded-error quantum algorithm that solves $\oplus$CNFSAT (even restricted to formulas with at most $c \cdot n^2$ clauses) in $O(2^{n(1-\delta)})$ time.*

One can go about refuting this conjecture in two (immediate) ways.

1. Either one could use the description of the input formulas to help deduce PARITY of the truth table corresponding to this formula (which would mean that the CNF formula is not obfuscated enough and one could use the structure of the formula towards computing PARITY more efficiently), or
2. One could use the fact that the set of truth tables on which PARITY is to be computed is "not too big" (as the number of polynomial length formulas are not too many) and potentially use this information to speed up the computation quantumly.

While both approaches seem like good starting points, the likelihood of Item 1 not working out is probably for the same reason why $\oplus$SETH is not refuted yet. Which brings us to Item 2. There is a stark contrast between the possible speedups that quantum can offer over classical computation. For example, there exists a quantum *query* algorithm that can compute *any* property in $\widetilde{O}(\sqrt{N})$ many queries, when the input is promised to be the N-length truth table of a small formula [4, 5, 25]; such an algorithm is impossible in the classical setting. Although efficient in the number of queries, the algorithm itself is not *time* efficient. But the existence of this algorithm (in contrast to the lack of one in the classical setting) does alert us that query complexity cannot naively be used to lower bound time complexity in our setting, without taking care. (The results of the current work will indicate that such a fast algorithm is unlikely to refute $\oplus$QSETH via Item 2.)

As pointed out by Buhrman *et al.* [11], the proof barrier does not allow one to (easily) prove compression-obliviousness of properties such as PARITY or MAJORITY. It is therefore natural to ask if there are other reasons why certain properties, say PARITY for example, should be compression oblivious. The authors leave the following open question:

"What complexity-theoretic assumptions are needed to show that, e.g., the PARITY property, is compression oblivious?"

It is precisely this question we answer in this paper. While our answer doesn't give us a way around *conjecturing* the compression obliviousness of these properties, it gives strong evidence supporting the conjecture and the use of the QSETH framework.

1.1 Main idea: arguing compression obliviousness via quantum natural proofs

Following is the answer to the question asked earlier.

▶ **Theorem 2** (Informal restatement of Theorem 34). *The properties PARITY and MAJORITY are compression oblivious for a circuit class* M *unless there are no quantum-secure* M*-constructible* PRF*s (of a particular type).*[4]

In fact, we conclude the same for a larger class of properties (which includes PARITY and MAJORITY). The details are mentioned in the statement of Theorem 34.

[4] For us, the logical statements "A implies B", "if A then B" and "$\neg A$ unless B" are all equivalent.

1.1.1 Natural proofs by Razborov and Rudich

To prove our results, we use the notion of *natural proofs* introduced by Razborov and Rudich [28]. Consider a Boolean function defined on other Boolean functions, or equivalently defined on their truth tables. Razborov and Rudich called a property (of Boolean functions) *natural* if it satisfies certain "constructivity" and "largeness" conditions. Roughly speaking, for their proof, the constructivity condition requires that the property is decidable in $\text{poly}(n)$ time when the 2^n-sized truth table of an n-input Boolean function is given as input. The largeness condition requires that the property holds for a sufficiently large fraction of the set of all Boolean functions. Moreover, they say a property is useful against a complexity class Λ if every sequence of Boolean functions having the property (infinitely often) defines a language outside of Λ. A *natural proof* is a proof that establishes that a certain language lies outside of Λ. This can be formally defined as (following the notation of Chow [16]),

▶ **Definition 3** (Υ-natural property with density δ, Definition 3 in [16]). *Let Υ be a complexity class and let $\delta := (\delta_n)_{n\in\mathbb{N}}$ denote a sequence of positive real numbers. A property $D := (D_n)_{n\in\mathbb{N}}$ is Υ-natural with density $\delta := (\delta_n)_{n\in\mathbb{N}}$ if the following statements hold:*

1. *largeness: $\exists n', \forall n > n'$, $|D_n| \geq 2^{2^n} \cdot \delta_n$, and*
2. *constructivity: the problem of determining whether a Boolean function $f_n \in D_n$, when given as input the truth table of f_n on n variables, is decidable in Υ.*

Note that the largeness is captured by the density function $(\delta_n)_{n\in\mathbb{N}}$ and constructivity is captured by the complexity class Υ. Additionally, this Υ-natural property is useful against a complexity class Λ if the following statement is satisfied.

▶ **Definition 4** (Useful property, Definition 4 in [16]). *Let Λ denote a complexity class. A property $D := (D_n)$ is useful against complexity class Λ if $\forall (f_n)$, we have $(f_n) \notin \Lambda$ whenever (f_n) is a sequence of Boolean functions satisfying $f_n \in D_n$ for infinitely many n.*

Using these definitions, Razborov and Rudich prove the following.

▶ **Theorem 5** (Main theorem of Razborov and Rudich as stated in [16]). *If there exists a 2^{k^ε}-hard pseudorandom generator in $\mathsf{SIZE}(k^c)$, then there is no P/poly-constructible natural property with density $1/2^{n^d}$ that is useful against the complexity class $\mathsf{SIZE}(n^e)$ whenever $e > 1 + cd/\varepsilon$.*

Broadly speaking, their proof idea is to use the *algorithm* that computes the P/poly-natural property of density ($\delta_n = \frac{1}{2^{n^d}}$) that is useful against $\mathsf{SIZE}(n^e)$ (if such a property exists) as a *distinguisher* to distinguish truth tables of functions with $\text{poly}(n)$-size circuits from truth tables of truly random functions. As this algorithm computes a natural property of density (δ_n), this means the distinguisher (which is the algorithm itself) can now distinguish a δ_n fraction of truly random functions. As δ_n here is quite large (for all n), this translates to a statistical test with a significant advantage to distinguish pseudorandom functions from truly random (n-input) functions. This in turn breaks the assumption about the existence of pseudorandom generators.

1.1.2 Technical overview

We use techniques similar to those of Razborov and Rudich to relate compression obliviousness of PARITY (and MAJORITY) with the existence of quantum-secure pseudorandom functions. We divide our contributions into two broad categories: a part that uses natural proofs, and a part that uses techniques from Fourier analysis of Boolean functions.

Part 1: quantum natural proofs

We use the term *quantum natural proofs* to mean that the proof relies on natural properties computable within a complexity class that captures quantum computation; equivalently, Υ in Definition 3 is a quantum complexity class. In our case, it is sufficient to consider Υ to be BQTIME(`linear`). Let $\mathrm{P} = (\mathrm{P}_n)_{n\in\mathbb{N}}$ be the property whose compression obliviousness, with respect to M, we want to study. Additionally, suppose that P satisfies the following two conditions.

- The property P is computable in DTIME(N); where N is the length of the input.
- For all $S \subseteq \{0,1\}^N$ of size $|S| \geq 2^N\left(1-\frac{1}{N^2}\right)$, the $\mathsf{Q}(\mathrm{P}_n|_S)$, i.e., the quantum query complexity to compute P on strings in set S, is $\Omega(N)$.

We can show that P has to be compression oblivious with respect to M unless a type of quantum secure pseudorandom functions doesn't exist.

Towards contradiction, let us assume that P is *not* compression oblivious for M. This means there exists a quantum algorithm that computes P on truth tables of functions corresponding to M in $N^{1-\alpha}$ time for some constant $\alpha > 0$. Let $\mathcal{A}$ denote this algorithm. Without loss of generality, let us assume $\mathcal{A}$ is a 1/10-bounded-error quantum algorithm. Let $\mathcal{B}$ denote the algorithm that computes P in DTIME(N) as promised earlier. Using $\mathcal{A}$ and $\mathcal{B}$, we now construct an algorithm $\mathcal{D}$ that, on all inputs z, does the following:

1. Run $\mathcal{A}$ on z for $M = O(1)$ many times and note the outputs.
2. Run $\mathcal{B}$ on z once.
3. `ACCEPT` if over M runs of $\mathcal{A}$ on input z the number of times $\mathcal{A}(z) = \mathcal{B}(z)$ is *at most* $\frac{8}{10}\cdot M$, otherwise `REJECT`. (We need the success probability of $\mathcal{D}$ to be at least 2/3 therefore choosing $M = O(1)$ suffices.)

Let z be a Boolean string of length $N = 2^n$. Let D_n denote the set of N-bit strings that $\mathcal{D}$ accepts with at least 2/3 success probability. It is easy to see that $\mathcal{D}$ rejects strings for which $\mathcal{A}$ correctly computes P (i.e., with success probability 9/10). Recall that, correctness of $\mathcal{A}$ is only promised for strings that are truth tables of functions having poly(n)-size circuits. There is no guarantee on how $\mathcal{A}$ behaves outside of this promise. But, we do know that P has a quantum query complexity of $\Omega(N)$ on all sets of size at least $2^N\left(1-\frac{1}{N^2}\right)$. As $\mathcal{A}$ is a strictly-sublinear time algorithm (hence, also a strictly-sublinear query algorithm), it can at best correctly compute P on at most $2^N\left(1-\frac{1}{N^2}\right)$ many strings outside of its promise. This, by construction, means $\mathcal{D}$ accepts at least $\frac{2^N}{N^2}$ many strings of length N and therefore D_n will contain these strings (or alternatively these functions). Now it is easy to see that $\mathcal{D}$ computes a natural property $(D_n)_{n\in\mathbb{N}}$, of density $(\delta_n = \frac{1}{2^{2n}})_{n\in\mathbb{N}}$, in $2\cdot 2^n$ quantum time. Moreover, this property $(D_n)_{n\in\mathbb{N}}$ is useful against complexity class M.

Once we have the natural property which is useful against M, we run a similar argument as done by Razborov and Rudich. As the algorithm $\mathcal{D}$ computes (D_n), it can distinguish truth tables of functions with small circuits (i.e., circuits of polylog(n)-depth and poly(n)-size or simply poly(n)-size) from truth tables of truly random functions with $\frac{1}{2^{2n}}$ advantage. But many believe that it is not possible to have quantum adversaries that are bounded by $2\cdot 2^n$ time and distinguish pseudorandom functions constructible in M with $\frac{1}{2^{2n}}$ advantage. Then it must be the case that P is compression oblivious for M.

Part 2: Fourier analysis of Boolean functions

As discussed above, our impossibility results hold for properties that are computable in DTIME(`linear`) and that have high quantum query complexity even when the computation is restricted to strings from sets of size $2^N(1-\frac{1}{N^2})$. Both PARITY and MAJORITY can be

computed in DTIME(`linear`). Moreover, using techniques from Fourier analysis, we are able to show that PARITY and MAJORITY also require $\Omega(N)$ many quantum queries on sets of size $2^N(1-\frac{1}{N^2})$. Therefore, proving Theorem 2.

1.2 Related work

- Chen *et al.* in [14] use the QSETH framework to conjecture quantum time lower bounds for variants of CNFSAT such as $\oplus$CNFSAT and #CNFSAT, etc and show lower bounds for several computational problems, such as variants of lattice problems, set-cover, hitting-set, etc., as implications.
- Arunachalam *et al.* in [7] also discuss the notion of quantum natural properties but they do so to relate learning algorithms and circuit lower bounds. As one of the results, they show that containment of the Minimum Circuit Size Problem (MCSP) in BQP implies new circuit lower bounds. This type of result was later extended by [15] to show that a few (more) quantum complexity classes can be separated if the Minimum Quantum Circuit Size Problem (MQCSP) is in BQP. Despite the overlap in topic, both of these works turn out to be complementary to the current work. We use the notion of quantum natural properties to strengthen Buhrman *et al.*'s QSETH framework by grounding assumptions in cryptography.
- Contrary to Razborov and Rudich's impossibility result, Chow [16] proves the existence of a natural proof useful to imply circuit lower bounds as a consequence of the Exponential-Time Hypothesis (ETH).

1.3 Discussion and open questions

In agreement with [11], we also believe that the notion of *compression-oblivious* properties is of independent interest. (See the blog post by Aviad Rubinstein also expressing interest [29].)

- There may be other connections with topics in meta-complexity theory (as the one we witness in this paper) or say, connections with obfuscation as suspected by Aviad Rubinstein [29] or connections with Kolmogorov complexity (as suggested by Harry Buhrman).
- Note that our results cannot be extended to show PARITY and MAJORITY are compression oblivious for AC^0 circuits. This is because AC^0-constructible pseudorandom functions are not secure against $2^{\mathrm{polylog}(n)}$-time adversaries [26]. Therefore, extending this result to PARITY or MAJORITY for AC^0_2-QSETH, i.e. CNF or DNF input, would be another step towards grounding the (necessary) assumption that such properties are compression oblivious.
- It is also worthwhile to study compression obliviousness of properties that don't meet the criteria discussed in our paper. There might be properties for which one may be able to construct natural proofs of slightly worse densities potentially implying some other complexity theoretic results as shown in [16].

On the other front, our proof technique also allows us to, in a rather black-box way, check if a particular property is likely to be compression-oblivious. One could plausibly extend our results to a larger set of functions that have a similar structure, e.g., a natural candidate would be to show an equivalent statement for symmetric functions with non-negligible mass on high-degree Fourier coefficients. It is very likely that there are in fact many properties of the type we discuss in this paper; one could use techniques similar to ones used in [3] to formally estimate the number of such properties.

1.4 Structure of the paper

In Section 2, we present useful definitions and notations. In Section 3, we formally define the QSETH framework. Our definitions omit an ambiguity from its original version presented in [11]. In Section 4, we prove our main result - the complexity-theoretic evidence for compression obliviousness of PARITY and MAJORITY. A few proofs useful for this section are moved to Appendix A. Additionally, in [13, Appendix A] in the full version of this paper, we reprove some of the earlier results about compression-oblivious properties that were given in [11]; we do this to convince the readers of the correctness of our proposed definition of the QSETH framework.

2 Preliminaries

Most of the definitions and notions presented in this section are taken from [6], and we restate them here for completeness and ease of reading.

2.1 Uniform models of computation

▶ **Definition 6** (Function and language recognition). *Let $f : \{0,1\}^* \to \{0,1\}$ be a Boolean function. The language corresponding to f is the set of strings L_f on which f evaluates to 1, i.e., $\forall x \in \{0,1\}^*$,*

$$x \in L_f \iff f(x) = 1.$$

Additionally, we say a Turing machine M decides *a language L_f if for all $x \in \{0,1\}^*$, whenever M is initialized to the start configuration on input x, the machine M halts with $f(x)$ written on its output tape.*

▶ **Definition 7** (DTIME, Definition 1.12 in [6]). *Let $T : \mathbb{N} \to \mathbb{N}$ be a function. A language L is in $DTIME(T(n))$ if there exists a Turing machine M, and there exists a constant c, such that $\forall n, \forall x \in \{0,1\}^n$, M on input x runs in $c \cdot T(n)$ steps and decides L.*

▶ **Definition 8** (BQTIME, adapting Definition 10.9 in [6]). *Let $f : \{0,1\}^* \to \{0,1\}$ and $T : \mathbb{N} \to \mathbb{N}$ be a function. We say f is computable in quantum $T(n)$-time, or (equivalently) say $L_f \in BQTIME(T(n))$, if there is a classical polynomial-time Turing machine that, for every $n \in \mathbb{N}$, on input $(1^n, 1^{T(n)})$ outputs the descriptions of a $T(n)$-size quantum circuit,[5] let us denote it by $F := (F_1, \ldots, F_{T(n)})$, such that for every $x \in \{0,1\}^n$, the output of the following process is $f(x)$ with probability at least $2/3$:*

1. *Initialize an m-qubit quantum state $|x\rangle |0^{m-n}\rangle$, where $m \leq T(n)$.*
2. *Apply one after the other $T(n)$ elementary quantum operations $F_1, \ldots, F_{T(n)}$ to the state.*[6]
3. *Measure the last qubit in the computational basis and output the measurement outcome.*

A language L_f corresponding to a Boolean function $f : \{0,1\}^* \to \{0,1\}$ is in BQP if there exists a polynomial p such that f is computable in quantum $p(n)$-time, or equivalently, $L_f \in \mathrm{BQTIME}(p(n))$.

---

[5] A few clarifications.
- A description of a T-size quantum circuit $F := (F_1, \ldots, F_T)$ is an ordered sequence of T elements, where $\forall i \in [T]$ each element $F_i = (G_i, w_i)$ specifies a quantum elementary gate $G_i \in \{\texttt{CNOT}\} \cup \{$ set of all 1-qubit operations $\}$ and the label(s) of the wire(s) w_i on which gate G_i will be applied.
- The action "applying an elementary quantum operation $F_i = (G_i, w_i)$" means applying the elementary gate G_i on wire specified by location(s) w_i.
- The size of the quantum circuit, on the other hand, is the number of elements in its description.

[6] See Footnote 5.

2.2 Non-uniform model of computation - Boolean circuits and circuit families

▶ **Definition 9** (Boolean circuits, Definition 6.1 in [6]). *For every $n \in \mathbb{N}$, an n-input, single-output Boolean circuit is a directed acyclic graph with n sources (i.e., vertices with no incoming edges but could have an unbounded number of outgoing edges) and one sink (i.e., vertex with no outgoing edges); let us denote the sink vertex by s. All non-source vertices are called gates and are labeled with one of $\wedge$, $\vee$ or $\neg$ (the logical operations AND, OR and NOT, respectively). The vertices labeled with $\wedge$ and $\vee$ have fan-in equal to 2 and those labeled with $\neg$ gate have fan-in 1. The source vertices are labeled with indices $i \in [n]$. We use $\texttt{label}(v)$ to denote the label of a vertex v. The circuit-size of C, denoted by $|\mathsf{C}|$, is the total number of vertices in it.*

If C is a Boolean circuit and $x \in \{0,1\}^n$ is some input, then the output of C on x, denoted by $\mathsf{C}(x)$, is defined in the natural way. More formally, for every vertex v of C we define a $\texttt{val}(v)$ as follows: if $\texttt{label}(v) = i$ then $\texttt{val}(v) = x_i$ and otherwise $\texttt{val}(v)$ is defined recursively by applying the logical operation of v labeled by $\texttt{label}(v)$ on the values of vertices connected to v. The output $\mathsf{C}(x)$ is the value of the sink vertex $\texttt{val}(s)$.

In any situation, if we require that the Boolean circuits are only allowed to have $\wedge$ and $\vee$ gates with fan-in 2, as opposed to these gates having unbounded fan-in, then we explicitly mention it.

▶ **Definition 10** (Circuit family and language recognition, Definition 6.2 in [6]). *Let $T : \mathbb{N} \to \mathbb{N}$ be a function. A $T(n)$-size* circuit family *is a sequence $\{C_n\}_{n\in\mathbb{N}}$ of Boolean circuits where for every n, C_n has n inputs and a single output and its circuit size $|C_n| \leq T(n)$.*

▶ **Definition 11** (SIZE). *Let $T : \mathbb{N} \to \mathbb{N}$ be a function. We say a language $L \in \mathsf{SIZE}(T)$ if there exists a $T(n)$-size circuit family $\{C_n\}_{n\in\mathbb{N}}$ such that $\forall n$, C_n consists of $\wedge$ and $\vee$ gates with fan-in 2 and $\neg$ gates of fan-in 1 and, moreover, $\forall x \in \{0,1\}^n, x \in L \iff C_n(x) = 1$.*

▶ **Definition 12** (Complexity class). *A complexity class is a set of languages.*

▶ **Definition 13** (Circuit family corresponding to a language). *Let L be a language (as in Definition 6). We say a family of circuits $\{C_n\}_{n\in\mathbb{N}}$ corresponds to language L, if $\forall n$, $\forall x \in \{0,1\}^n$, we have $x \in L \iff C_n(x) = 1$.*

▶ **Definition 14** (P/poly, Definition 6.5 in [6]). P/poly *is the class of languages that are decidable by polynomial-sized circuit families, or equivalently,* $\mathsf{P}/\mathrm{poly} = \cup_{c,d}\mathsf{SIZE}(c \cdot n^d) = \cup_{c,d}\mathsf{SIZE}_{c,d}$.

▶ **Definition 15** (AC^0_2, Adapting Definition 6.25 in [6]). *A language L is in AC^0_2 if there exists a polynomial $p : \mathbb{N} \to \mathbb{N}$ and there exists a $p(n)$-size circuit family $\{C_n\}_{n\in\mathbb{N}}$ corresponding to L where $\forall n$, circuit C_n uses $\neg$, $\wedge$ and $\vee$ gates, with latter two allowed to have unbounded fan-in, and has depth at most 2.*

▶ **Definition 16** (Type-O complexity class). *We say a complexity class is of* Type-O *if it is any of the following complexity classes:*

1. *For every $d \in \mathbb{N}$ and $k \in \mathbb{N}$, we include the class $\mathsf{AC}^0_{d,k}$; we say a language $L \in \mathsf{AC}^0_{d,k}$ if there exists a family of Boolean circuits $\{C_n\}_{n\in\mathbb{N}}$ corresponding to L such that $\forall n$, C_n uses $\neg$, $\wedge$ and $\vee$ gates, with latter two allowed to have unbounded fan-in, and has depth at most d and circuit size $|C_n| \leq n^k$.*

2. *For every $d \in \mathbb{N}$ and $k \in \mathbb{N}$, we include the class $\mathsf{NC}_{d,k}$; we say a language $L \in \mathsf{NC}_{d,k}$ if there exists a family of Boolean circuits $\{C_n\}_{n\in\mathbb{N}}$ corresponding to L such that $\forall n$, C_n has depth at most $\log^d n$ and circuit size $|C_n| \leq n^k$.*
3. *For every $d \in \mathbb{N}$ and $k \in \mathbb{N}$, we include the class $\mathsf{SIZE}_{d,k}$; we say a language $L \in \mathsf{SIZE}_{d,k}$ if there exists a family of Boolean circuits $\{C_n\}_{n\in\mathbb{N}}$ corresponding to L such that $\forall n$, C_n has circuit size $|C_n| \leq d \cdot n^k$.*

2.3 Truth tables of circuits, languages and a few other useful notations

A truth table is binary string capturing the outputs of a Boolean function. If a function is defined on n binary inputs then its corresponding truth table is a Boolean string in $\{0,1\}^{2^n}$. The notion of a truth table can also be extended to capture the membership of strings in a language by fixing the length of the strings. We formally define these notions as follows.

▶ **Definition 17** (Truth tables). *For any $n \in \mathbb{N}$, let $f_n : \{0,1\}^n \to \{0,1\}$ be a Boolean function. Then the truth table of f_n, denoted by $\mathtt{tt}(f_n)$, is a 2^n-length binary string constructed in the following way:*

$$\mathtt{tt}(f_n) = \bigcirc_{a\in\{0,1\}^n} f_n(a).$$

Here $f_n(a)$ denotes the output f_n on input a. And for the concatenation, the strings $a \in \{0,1\}^n$ are taken in lexicographic order.

For a language $L \subseteq \{0,1\}^*$ the notion of truth table is as follows: for any $n \in \mathbb{N}$, the truth table of L at n, denoted by $\mathtt{tt}(L,n)$, is a 2^n-length binary vector that can be obtained by concatenating the outputs $b_a := [a \in L]$ for all $a \in \{0,1\}^n$ taken in lexicographic order.

Other useful notations

Let n be an integer. Let $f_n : \{0,1\}^n \to \{0,1\}$ be a Boolean function on n input variables.

- We use F_n to denote the set of *all* Boolean functions defined on n input variables; We represent $F_n = \{\mathtt{tt}(f_n) \mid f_n \text{ is a Boolean function on } n \text{ variables}\}$ as the set of truth tables of all functions $f_n : \{0,1\}^n \to \{0,1\}$, implying $F_n = \{0,1\}^{2^n}$ and $|F_n| = 2^{2^n}$. We also use $N = 2^n$.
- We overload the notation of $\mathtt{tt}(\cdot)$ on sets of Boolean functions to denote the following: if S is a set of Boolean functions on n variables then $\mathtt{tt}(S) = \{\mathtt{tt}(f_n) \mid f_n \in S\}$.
- Let Λ be a complexity class. Let $L \in \Lambda$. Furthermore, let $f_n : 0,1^n \to \{0,1\}$ be a Boolean function such that $\mathtt{tt}(f_n) = \mathtt{tt}(L,n)$ then we say f_n *is a sub-element of* Λ.
- We sometimes also overload the notation of $\mathtt{tt}(\cdot)$ on complexity classes to denote the following: if Λ is a complexity class then $\mathtt{tt}(\Lambda,n) = \{\mathtt{tt}(f_n) \mid f_n \text{ sub-element in } \Lambda\}$ or equivalently $\mathtt{tt}(\Lambda,n) = \{\mathtt{tt}(L,n) \mid L \in \Lambda\}$. Furthermore, we use $\mathtt{tt}(\Lambda) = \bigcup_{n\in\mathbb{N}} \mathtt{tt}(\Lambda,n)$.

3 The QSETH framework

3.1 Definitions

▶ **Definition 18** (Property). *A Boolean property (or just property) is a sequence $P := (P_n)_{n\in\mathbb{N}}$ where each P_n is a set of Boolean functions defined on n variables.*

Alternatively, one can view P_n as a set of 2^n-length Boolean strings that are truth tables of functions $f_n \in \mathrm{P}_n$, or equivalently view it as a function $\mathrm{P}_n : \{0,1\}^{2^n} \to \{0,1\}$ such that $\mathrm{P}_n(\mathtt{tt}(f_n)) = 1$ if and only if $f_n \in \mathrm{P}_n$; see Definition 17 for the definition of a truth table. Also note that it is possible for a property P to be *partial*. In such a case, for every n, there could be some functions f_n for which we don't care whether or not they belong to P_n.[7]

[7] For example, both the properties $\mathrm{PP}_{\mathrm{edit}}$ and $\mathrm{PP}_{\mathrm{lcs}}$ considered in [11] are partial.

Quantum query complexity of P

The (bounded-error) quantum query complexity is defined only in a non-uniform setting; therefore, we define this notion for P_n for every $n \in \mathbb{N}$. A quantum query algorithm $\mathcal{B}$ for $\mathrm{P}_n : \{0,1\}^{2^n} \to \{0,1\}$, on an input $x \in \{0,1\}^{2^n}$ begins in a fixed initial state $|\psi_0\rangle$, applies a sequence of unitaries $U_0, O_x, U_1, O_x, \ldots, U_T$, and performs a measurement whose outcome is denoted by z. Here, the initial state $|\psi_0\rangle$ and the unitaries $U_0, U_1, \ldots, U_T$ are independent of the input x. The unitary O_x represents the "query" operation, and maps $|i\rangle\,|b\rangle$ to $|i\rangle\,|b + x_i \bmod 2\rangle$ for all $i \in [2^n] - 1$. We say that $\mathcal{B}$ is a 1/3-bounded-error algorithm computing P_n if for all x in the domain of P_n, the success probability of outputting $z = \mathrm{P}_n(x)$ is at least 2/3. Let $\mathrm{cost}(\mathcal{B})$ denote the number of queries $\mathcal{B}$ makes to O_x throughout the algorithm. The 1/3-bounded-error quantum query complexity of P_n, denoted by $\mathsf{Q}_{1/3}(\mathrm{P}_n)$, is defined as $\mathsf{Q}_{1/3}(\mathrm{P}_n) = \min\{\mathrm{cost}(\mathcal{B}) : \mathcal{B} \text{ computes } \mathrm{P}_n \text{ with error probability } \leq 1/3\}$.[8]

Algorithms computing a property P in black-/white-box setting

We say a (bounded-error quantum) algorithm $\mathcal{A}$ computes a property P (as in Definition 18) in the *black-box* setting if for all $n \in \mathbb{N}$, for all f_n given its truth table as input, i.e., a 2^n-length Boolean string, $\mathcal{A}$ makes (quantum) queries to this input and (with success probability at least 2/3) determines whether or not $f_n \in \mathrm{P}_n$. An algorithm computing P in the *white-box* setting gets a circuit description of f_n, which is possibly a more succinct description of f_n's truth table, and the algorithm has to determine whether or not $f_n \in \mathrm{P}_n$. We emphasize that, in both the black-/white-box setting, we care about the *time* that algorithm $\mathcal{A}$ takes when deciding whether or not $f_n \in \mathrm{P}_n$.

We now present the definition of compression-oblivious properties. In simple terms, these are the properties whose quantum query complexity is a lower bound for the time complexity to compute the property even for inputs that are "compressible" as a truth table of small formulas (or circuits). Formally,

▶ **Definition 19** ($\Gamma_{d,k}$-compression-oblivious properties). *Let $d, k \in \mathbb{N}$. Let $\Gamma_{d,k}$ denote a* Type-O *complexity class as stated in Definition 16 parameterized by d and k. We say a property P is* $\Gamma_{d,k}$-compression-oblivious*, denoted by $P \in \mathcal{CO}(\Gamma_{d,k})$, if for every constant $\delta > 0$, for every quantum algorithm $\mathcal{A}$ that computes P in the **black-box** setting, $\forall n' \in \mathbb{N}, \exists n \geq n'$ and $\exists$ a set $L = \{L^1, L^2, \ldots\} \subseteq \Gamma_{d,k}$ of "hard languages", such that $\forall$ circuit families $\{C^1_{n''}\}_{n'' \in \mathbb{N}}$ corresponding to L^1, $\forall$ circuit families $\{C^2_{n''}\}_{n'' \in \mathbb{N}}$ corresponding to L^2, ..., the algorithm $\mathcal{A}$ uses at least $\mathsf{Q}_{1/3}(P_n)^{1-\delta}$ quantum time on at least one of the inputs in $\{C^i_n\}_{i \in [|L|]}$.*[9]

▶ **Definition 20** (compression-oblivious properties w.r.t. AC^0_2, NC, P/poly). *We say a property $P : \{0,1\}^* \to \{0,1\}$ is*

1. $P \in \mathcal{CO}(\mathsf{AC}^0_2)$ *if $d = 2$ and $\exists k \in \mathbb{N}$ such that $P \in \mathcal{CO}(\mathsf{AC}^0_{d,k})$,*
2. $P \in \mathcal{CO}(\mathsf{AC}^0)$ *if $\exists d \in \mathbb{N}, \exists k \in \mathbb{N}$ such that $P \in \mathcal{CO}(\mathsf{AC}^0_{d,k})$,*
3. $P \in \mathcal{CO}(\mathsf{NC})$ *if $\exists d \in \mathbb{N}, \exists k \in \mathbb{N}$ such that $P \in \mathcal{CO}(\mathsf{NC}_{d,k})$, and*
4. $P \in \mathcal{CO}(\mathrm{P/poly})$ *if $\exists d \in \mathbb{N}, \exists k \in \mathbb{N}$ such that $P \in \mathcal{CO}(\mathsf{SIZE}_{d,k})$.*

[8] Note that if $\textsc{parity} := (\textsc{parity}_n)_{n \in \mathbb{N}}$ is the property we are considering, under our definition of $\textsc{parity}_n$ the value of $\mathsf{Q}(\textsc{parity}_n)$ is equal to $\Omega(2^n)$ and not $\Omega(n)$. For the property $\mathrm{OR} := (\mathrm{OR}_n)_{n \in \mathbb{N}}$ then $Q(\mathrm{OR}_n) = \Omega(2^{\frac{n}{2}})$.

[9] While the idea of compression-oblivious properties can be easily expressed informally, describing the notion formally requires discussing intricate details to bridge the connections between uniform (e.g., algorithm $\mathcal{A}$ computing P) and non-uniform models of computations (e.g., query complexity $\mathsf{Q}(\mathrm{P}_n)$).

The original definition of compression-oblivious properties, as presented in Section 2.2 of [11], does not clearly enforce a unique ordering of the quantifiers, which can potentially lead to undesirable consequences. Hence, we make the effort of presenting a more formal definition of Γ-compression-oblivious properties in Definitions 19 and 20 (with the approval of the authors [11]).

Having formally defined Γ-compression-oblivious properties for all $\Gamma \in \{\mathsf{AC}^0_2, \mathsf{AC}^0, \mathsf{NC}, \mathsf{P/poly}\}$ we now state the Γ-QSETH conjecture. Earlier in this section, we discussed the difference between computing a Boolean property in a black-box setting versus computing the same property in a white-box setting. The compression-oblivious properties are those properties for which its corresponding quantum query complexity lower bounds the time complexity in the *black-box* setting. For such properties, Buhrman *et al.* conjectured that the time complexity of computing these properties in the *white-box* setting is as bad as it is in the black-box setting. This assumes that the succinct description of the Boolean functions doesn't help in computing the properties more efficiently. (This is similar to the *Black-Box Hypothesis (BBH)* stated in [22].) More formally,

▶ **Conjecture 21** (Γ-QSETH, a more formal presentation of Conjecture 5 in [11])**.** *Let* $\Gamma \in \{\mathsf{AC}^0_2, \mathsf{AC}^0, \mathsf{NC}, \mathsf{P/poly}\}$ *be a complexity class (as in Definition 12). Let* P *be a* Γ-compression-oblivious *property. The* Γ*-QSETH conjecture states that* $\exists d, \exists k \in \mathbb{N}$*, such that for every constant* $\delta > 0$*, for every quantum algorithm* $\mathcal{A}$ *that computes* P *in the* ***white-box*** *setting,* $\forall n' \in \mathbb{N}, \exists n \geq n'$*,* $\exists$ *a set* $L = \{L^1, L^2, \ldots\} \subseteq \Gamma_{d,k}$*,* $\forall$ *circuit families* $\{C^1_{n''}\}_{n'' \in \mathbb{N}}$ *corresponding to* L^1*,* $\forall$ *circuit families* $\{C^2_{n''}\}_{n'' \in \mathbb{N}}$ *corresponding to* L^2*, ..., the algorithm* $\mathcal{A}$ *uses at least* $\mathsf{Q}_{1/3}(P_n)^{1-\delta}$ *quantum time on at least one of the inputs in* $\{C^i_n\}_{i \in [|L|]}$*. Note that* $\Gamma_{d,k}$ *is a* Type-O *complexity class corresponding to* Γ*.*

3.2 Relevance

Note that a basic version of the QSETH conjecture and its implications has already been discussed in complementary works [1, 11], and other variants of QSETH are discussed more recently in [14] and in Chen's PhD thesis [12]. For example,

▶ **Conjecture 22** (Basic-QSETH, Conjecture 8.3 in [12])**.** *For each constant* $\delta > 0$*, there exists* $c > 0$ *such that there is no bounded-error quantum algorithm that solves CNFSAT (even restricted to formulas with at most* cn^2 *many clauses) in* $O(2^{\frac{n(1-\delta)}{2}})$ *time.*

▶ **Conjecture 23** (⊕QSETH, Conjecture 8.9 in [12])**.** *For each constant* $\delta > 0$*, there exists* $c > 0$ *such that there is no bounded-error quantum algorithm that solves* $\oplus$*CNFSAT (even restricted to formulas with at most* cn^2 *many clauses) in* $O(2^{n(1-\delta)})$ *time.*

▶ **Conjecture 24** (#QSETH, Conjecture 8.8 in [12])**.** *For each constant* $\delta > 0$*, there exists* $c > 0$ *such that there is no bounded-error quantum algorithm that solves #CNFSAT (even restricted to formulas with at most* cn^2 *many clauses) in* $O(2^{n(1-\delta)})$ *time.*

We are able to get these conjectures as a corollary to our QSETH framework. More precisely,

▶ **Corollary 25.** *The* AC^0_2*-QSETH implies Conjecture 22. Additionally, if we assume that* $\textsc{parity} \in \mathcal{CO}(\mathsf{AC}^0_2)$ *then* AC^0_2*-QSETH implies Conjectures 23 and 24.*

Proof. The proof of $\mathrm{OR} \in \mathcal{CO}(\mathsf{AC}^0_2)$ was first given in [11] (we also present the proof in the full version of this paper). Thereafter, setting $d = 2$ and $k = 3$ for AC^0_2-QSETH conjecture implies Conjectures 22–24. ◀

Therefore, all the QSETH-based lower bounds presented in Chen's PhD thesis [12] immediately follow from our QSETH framework.

4 When certain properties are not P/poly-compression-oblivious

In this section, we show that it is reasonable to conjecture that there exist $d', k' \in \mathbb{N}$ and $d'', k'' \in \mathbb{N}$ for which properties such as PARITY and MAJORITY are $\mathsf{SIZE}_{d',k'}$-compression-oblivious and $\mathsf{SIZE}_{d'',k''}$-compression-oblivious, respectively. We do so by relating this conjecture to topics in circuit complexity and pseudorandomness. In fact, we are able to show similar consequences for properties that satisfy certain constraints. PARITY and MAJORITY happen to be such properties.

Following the notation about natural proofs from [28] and [16], we now define the following.

▶ **Definition 26** (Υ-natural property with density δ). *Let Υ be a complexity class (as in Definition 12) and let $\delta := (\delta_n)_{n\in\mathbb{N}}$ denote a sequence of positive real numbers. A property $D := (D_n)_{n\in\mathbb{N}}$ (as in Definition 18) is Υ-natural with density $\delta := (\delta_n)_{n\in\mathbb{N}}$ if the following statements hold:*

1. *largeness: $\exists n', \forall n > n'$, $|D_n| \geq 2^{2^n} \cdot \delta_n$, and*
2. *constructivity: the problem of determining whether a Boolean function $f_n \in D_n$, when given as input the truth table of f_n on n variables, is decidable in Υ, which in more formal terms translates to saying $L_D \in \Upsilon$ where $L_D := \bigcup_{n\in\mathbb{N}}\{\mathtt{tt}(f_n) \mid f_n \in D_n\}$.*

▶ **Definition 27** (Quasi-useful property, Definition 5 in [16]). [10] *Let Λ denotes a complexity class. A property $D := (D_n)$, or equivalently the corresponding language $L_D := \bigcup_{n\in\mathbb{N}}\{\mathtt{tt}(g_n) \mid g_n \in D_n\}$, is quasi-useful against complexity class Λ if $\forall(f_n)$, we have $(f_n) \notin \Lambda$ whenever (f_n) is sequence of Boolean functions satisfying $f_n \in D_n$ for all sufficiently large n.*

Our goal is to realize the chain of arguments as illustrated in Figure 1.

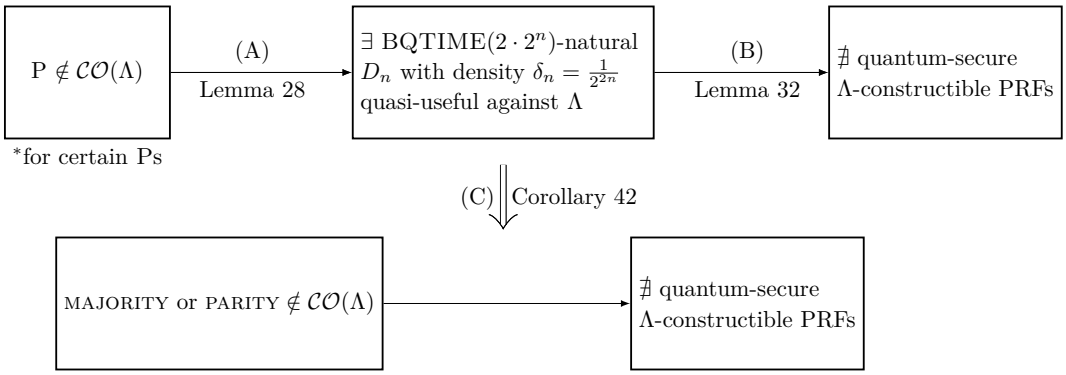

Figure 1 Chain of arguments presented in this section. We discuss the implications when a certain class of properties P are not Λ-compression-oblivious in links (A) and (B). In link (C) we show that MAJORITY and PARITY belong to this class of properties.

[10] Note that Razborov and Rudich use the notion of *useful* property which is defined for infinitely many n. However, for our results the notion of *quasi-useful* property (defined for all sufficiently large n) makes more sense so we use this instead.

Realising link (A)

The proof idea is as follows. Let $\Lambda = \mathsf{SIZE}_{d,k}$. Our choice of d, k will be clear later. If PARITY $\notin \mathcal{CO}(\Lambda)$ (or say MAJORITY $\notin \mathcal{CO}(\Lambda)$ may be for another choice of d, k) then (from the definition of compression-oblivious properties) there exists a quantum algorithm that computes the PARITY (or MAJORITY) of truth tables of circuits C that are sub-elements of Λ in time sublinear in the size of the input $\mathtt{tt}(C)$. Using this algorithm and the linear time deterministic algorithm to compute PARITY (or MAJORITY) on all strings of length $|\mathtt{tt}(C)|$, we will construct a BQTIME($\mathtt{linear}$)-natural property that is quasi-useful against complexity class Λ. Interestingly enough, the idea also generalizes to other simple properties that satisfy certain requirements; we formalize that in the statement of Lemma 28.

▶ **Lemma 28.** *Let $d, k \in \mathbb{N}$ and $\Lambda = \mathsf{SIZE}_{d,k}$. If a property $P : \{0,1\}^* \to \{0,1\}$, or alternatively denoted as $(P_n)_{n\in\mathbb{N}}$ (as in Definition 18), satisfies the following conditions:*

1. *$P \notin \mathcal{CO}(\Lambda)$,*
2. *P on inputs of length N is computable in $DTIME(N)$, which more formally means $L_P := \bigcup_{n\in\mathbb{N}}\{\mathtt{tt}(f_n) \mid f_n \in P_n\} \in DTIME(N)$, and*
3. *$\forall S \subseteq \{0,1\}^N$ of size $|S| \geq 2^N(1 - \frac{1}{N^2})$, any 1/3-bounded-error quantum query algorithm that computes $P_{\log N}$ on each $x \in S$ requires $\Omega(N)$ queries,*

then there exists a $BQTIME(2 \cdot N)$-natural property (D_n) with density $\delta_n = \frac{1}{N^2}$ and this natural property is quasi-useful against complexity class Λ.

Proof. Let $d, k \in \mathbb{N}$ and let $\Lambda = \mathsf{SIZE}_{d,k}$. From Definition 19 we say, $\mathrm{P} \notin \mathcal{CO}(\Lambda)$ if and only if $\exists \delta > 0$, $\exists$ algorithm $\mathcal{A}$ computing property P such that $\exists n' \in \mathbb{N}$ and $\forall n \geq n'$, $\forall L = \{L^1, L^2, \ldots\} \subseteq \Lambda$, $\mathcal{A}$ uses at most $Q_{1/3}(\mathrm{P}_n)^{1-\delta}$ quantum time on all inputs in $\{\mathtt{tt}(L^i, n)\}_{i\in[|L|]}$.

Then, let $n \geq n'$, let $N = 2^n$ and let L be the largest subset of Λ, i.e., the set Λ itself, $\mathcal{A}$ computes the property in at most $Q_{1/3}(\mathrm{P}_n)^{1-\delta}$ time for all binary strings in $\mathtt{tt}(\Lambda) = \{\mathtt{tt}(L^i, n)\}_{i\in[|L|]}$. Furthermore, we have $|\mathtt{tt}(\Lambda)| \leq 2^{d' \cdot n^k}$ for some $d' > d$; this is because all the languages $L^i \in \Lambda$ which means for every L^i there must exist a circuit family $\{C^i_n\}_{n\in\mathbb{N}}$ with $|C_n| \leq d \cdot n^k$ and the number of such circuits is at most $2^{d' \cdot n^k}$ which means the number of *unique* 2^n-length truth tables that Λ can hold is at most $2^{d' \cdot n^k}$. W.l.o.g., let us assume that $\mathcal{A}$ computes P with success probability at least 9/10 (as we can boost the probability of success by running the 1/3-bounded-error algorithm $\mathcal{A}$ and then take majority voting). For all $n > n'$, for all $x \in \mathtt{tt}(\Lambda, n)$, the algorithm $\mathcal{A}$ computes $\mathrm{P}(x)$ in $\mathsf{Q}_{1/10}(\mathrm{P}_{\log|x|})^{1-\delta} \leq |x|^{1-\delta}$ time for some constant $\delta > 0$.

In addition, let $\mathcal{B}$ denote a deterministic (quantum or classical) algorithm that computes P on all $y \in \{0,1\}^*$ in $\Theta(|y|)$ time – upper and lower bound follow from Item 2 and Item 3 of the theorem statement, respectively. Using $\mathcal{A}$ and $\mathcal{B}$ we now construct Algorithm $\mathcal{D}$ that on an input $z \in \{0,1\}^N$ does the following:

1. Run $\mathcal{A}$ on z for $M = O(1)$ times and note the outputs.
2. Run $\mathcal{B}$ on z once.
3. `Accept` if over M runs of $\mathcal{A}$ on input z the number of times $\mathcal{A}(z) = \mathcal{B}(z)$ is *at most* $\frac{8}{10} \cdot M$, otherwise `reject`. We need the success probability of $\mathcal{D}$ to be at least 2/3 therefore choosing $M = O(1)$ suffices.

Notice that Algorithm $\mathcal{D}$ (with high probability) computes a property that is quasi-useful (Definition 27) against complexity class Λ. This is true because $\mathcal{B}(z) = \mathrm{P}(z)$ for all z and whenever $z \in \mathtt{tt}(\Lambda)$ the $\Pr[\mathcal{A}(z) = \mathrm{P}(z)] \geq 0.9$, which means the outputs $\mathcal{A}(z)$ and $\mathcal{B}(z)$ are equal more than 9/10 of the M times. Therefore, if $z \in \mathtt{tt}(\Lambda)$ then $\mathcal{D}$ rejects z.

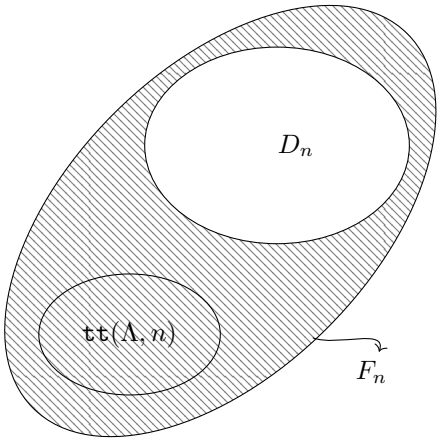

Figure 2 A pictorial representation of the fraction of 2^n-length strings that the algorithm $\mathcal{D}$ accepts. Recall that F_n denotes the full set $\{0,1\}^{2^n}$; hence, $|F_n| = 2^{2^n}$. The set $\mathtt{tt}(\Lambda, n)$ denotes the set of strings $\{\mathtt{tt}(L, n) \mid L \in \Lambda\}$. Algorithm $\mathcal{A}$ is guaranteed to accept all strings from $\mathtt{tt}(\Lambda, n)$ with success probability at least 9/10 and no guarantee whatsoever on strings in $F_n \setminus \mathtt{tt}(\Lambda, n)$. The set D_n denotes the set of 2^n-length strings that Algorithm $\mathcal{D}$ accepts.

What is left is to argue that Algorithm $\mathcal{D}$ computes a BQTIME$(2 \cdot N)$-natural property that satisfies both the *largeness* and *contructivity* conditions as mentioned in Definition 26. Let $z \in F_n$ and let $D_n = \{z \mid |z| = 2^n$ and Algorithm $\mathcal{D}$ accepts $z\}$.

- Algorithm $\mathcal{D}$ on any z of size $N = 2^n$ can in at most $2 \cdot N$ quantum time decide whether or not $z \in D_n$; hence satisfying the *constructivity* condition.
- We argue about the largeness condition of $|D_n| \geq 2^N \cdot \delta_n$ for $\delta_n = \frac{1}{N^2}$ in the following way. Consider the set F_n, i.e., the set of truth tables of all Boolean functions defined on n input variables. For a string $z \in F_n$, the algorithm $\mathcal{D}$ rejects z only if $\Pr[\mathcal{A}(z) = \mathrm{P}(z)] > 8/10$. In other words, $\mathcal{D}$ rejects z whenever $z \in F_n \setminus D_n$; see Figure 2. The runtime of Algorithm $\mathcal{A}$ on N-length inputs is $O(N^{1-\beta})$ time (for a constant $\beta > 0$), and we know from Item 3 in the statement of the theorem that $\mathcal{A}$ cannot compute P correctly (with success probability greater than 2/3) on sets bigger than $2^N(1 - \frac{1}{N^2})$. Hence, $|F_n \setminus D_n| \leq 2^N \cdot (1 - \frac{1}{N^2})$, which means $|D_n| \geq \frac{2^N}{N^2}$.

This concludes the proof of *Lemma* 28. ◀

Realising link (B)

We will now show the cryptographic implications when properties like PARITY and MAJORITY are not compression-oblivious. In link (A) we showed that, if either of these properties is not compression-oblivious with respect to complexity class $\Lambda = \mathsf{SIZE}_{d,k}$ for some constants $d, k \in \mathbb{N}$, then we can construct a BQTIME$(2 \cdot 2^n)$-natural property useful against Λ. Any quantum algorithm computing this natural property can now be used to distinguish pseudorandom functions constructible in $\Lambda = \mathsf{SIZE}_{d,k}$ from truly random functions. However, such linear-time (linear in the length of the truth table of the functions) quantum distinguishers are not believed to exist. Therefore, it is plausible that a quantum algorithm computing this natural property in the specified time does not exist.

Let us recall the standard definition of pseudorandom functions [18].

▶ **Definition 29** (Keyspace). *Let $K : \mathbb{N} \to \mathbb{N}$ be a function. A key space $\mathcal{K}$ generated by the function K is a set of sets defined as $\mathcal{K} = \{\{0,1\}^{K(n)}\}_{n\in\mathbb{N}}$ and we use $\mathcal{K}(n)$ to denote the set $\{0,1\}^{K(n)}$.*

Note that, for our results, the function K is always chosen to be a polynomial.

▶ **Definition 30** (Pseudorandom functions (PRFs)).
A set $F = \{ f_k : \{0,1\}^n \to \{0,1\} \}_{n\in\mathbb{N},k\in\mathcal{K}(n),}$ is called a family of pseudorandom functions with key space $\mathcal{K}$ generated by function K if for all probabilistic polynomial time (p.p.t.) adversary A, there is a negligible function ε such that for all $n \in \mathbb{N}$,

$$|\Pr_k[A^{f_k(\cdot)}(1^n) = 1] - \Pr_{\mathsf{TR}}[A^{\mathsf{TR}(\cdot)}(1^n) = 1]| < \eta(n),$$

where the probability is also over the random string used by A, TR denotes a truly random function from $\{0,1\}^n$ to $\{0,1\}$.

*Sometimes we may strengthen or weaken the definition by letting the adversary's running time be $T(n)$-bounded, and letting the distinguishing probability to be less than some specific function $\eta(n)$. In this case, we call it a (K,T,η)-*PRF*. Additionally, if the family F, which can be interpreted as a families of circuits, corresponds to languages in Λ, then we call it as Λ-constructible (K,T,η)-*PRF*s.*

Pseudorandom functions can also be defined against quantum adversaries making (classical or) quantum queries; see [32] for example. Formally stated as follows.

▶ **Definition 31** (Quantum-secure PRFs). *A set $F = \{ f_k : \{0,1\}^n \to \{0,1\} \}_{k\in\mathcal{K}(n),n\in\mathbb{N}}$ is called a family of quantum-secure pseudorandom functions with key space $\mathcal{K}$ generated by a function K if for all polynomial time (polynomial in the length of its input) quantum adversary A making quantum queries, there is a negligible function ε such that for all $n \in \mathbb{N}$,*

$$|\Pr_k[A^{f_k(\cdot)}(1^n) = 1] - \Pr_{\mathsf{TR}}[A^{\mathsf{TR}(\cdot)}(1^n) = 1]| < \eta(n),$$

where the probability is also over the random string used by A, TR denotes a truly random function from $\{0,1\}^n$ to $\{0,1\}$.

Sometimes (just as we do for PRF*s) we may strengthen or weaken the definition by letting the adversary's running time be $T(n)$-bounded, and letting the distinguishing probability governed by some other function $\eta(n)$. In this case, we denote them by (K,T,η)-quantum-secure-*PRF*s. Additionally, if the family F, which can be interpreted as a families of circuits, correspond to languages in Λ, then we call it as Λ-constructible (K,T,η)-quantum-secure-*PRF*s.*

Using this notion of quantum-secure pseudorandom functions, we are able to prove the following.

▶ **Lemma 32.** *Let $d,k \in \mathbb{N}$. If there exists a $BQTIME(2\cdot 2^n)$-natural property of density $\delta_n \geq \frac{1}{2^{2n}}$ that is quasi-useful against the complexity class $\Lambda = \mathsf{SIZE}_{d,k}$ then there doesn't exist any Λ-constructible $(d\cdot n^k, 2\cdot 2^n, \frac{1}{2^{2n}})$-quantum-secure-*PRF*; the size of the truth table of function f_n is 2^n.*

Proof. Let $N = 2^n$ be the length of the truth table of functions on n variables. Let P be a BQTIME$(2\cdot N)$-natural property of density $\delta_n \geq \frac{1}{2^{2n}}$ that is quasi-useful against the complexity class $\mathsf{SIZE}_{d,k}$. Let $\mathcal{C}$ be the algorithm that computes this property P. Because $\mathcal{C}$ computes P, for any (sufficiently large) value of n the following statements hold.

- Algorithm $\mathcal{C}$ rejects z whenever z is a string from $\mathtt{tt}(\mathsf{SIZE}_{d,k}, n)$; this is because P is quasi-useful against $\mathsf{SIZE}_{d,k}$.
- There are at least $\frac{1}{2^{2n}} \cdot 2^{2^n}$ number of functions in F_n that $\mathcal{C}$ accepts; this is because the P has density $\delta_n \geq \frac{1}{2^{2n}}$.
- Furthermore, $\mathcal{C}$ runs in $\mathrm{BQTIME}(2 \cdot 2^n)$.

Combining these observations we can see that

$$|\Pr[\mathcal{C}(x) = 1] - \Pr[\mathcal{C}(y) = 1]| \geq \frac{1}{2^{2n}}$$

when x is chosen at random from $\mathtt{tt}(\mathsf{SIZE}_{d,k}, n)$ and y is chosen at random from F_n. This means $\mathcal{C}$, despite being an algorithm running in $\mathrm{BQTIME}(2 \cdot N)$ time, can distinguish $\mathsf{SIZE}_{d,k}$-constructible pseudorandom functions from the set of all random functions. Hence, showing that $\mathsf{SIZE}_{d,k}$-constructible $(d \cdot n^k, 2 \cdot 2^n, \frac{1}{2^{2n}})$-quantum-secure-PRFs do not exist. ◀

We could also state our assumption about the existence of quantum-secure PRFs as a conjecture.

▶ **Conjecture 33.** *There exists $d, k \in \mathbb{N}$ for which $\mathsf{SIZE}_{d,k}$-constructible $(d \cdot n^k, 2 \cdot 2^n, \frac{1}{2^{2n}})$-quantum-secure-PRFs exist.*

Using Lemma 28 and Lemma 32 we can now claim the following statement.

▶ **Theorem 34.** *Let $P : \{0,1\}^* \to \{0,1\}$ be the Boolean property satisfying Items 2 and 3 stated in Lemma 28. Then property $P \in \mathcal{CO}(\mathsf{P/poly})$ unless Conjecture 33 is false.*

Proof. If $\mathrm{P} \notin \mathcal{CO}(\mathsf{P/poly})$ then $\forall d, \forall k \in \mathbb{N}$ we have $\mathrm{P} \notin \mathcal{CO}(\mathsf{SIZE}_{d,k})$; see Definition 20. For every value of d, k we will then be able to construct a $\mathrm{BQTIME}(2 \cdot 2^n)$-natural property that will be quasi-useful against $\mathsf{SIZE}_{d,k}$. This means for all values of d, k we will no longer have $\mathsf{SIZE}_{d,k}$-constructible $(d \cdot n^k, 2 \cdot 2^n, \frac{1}{2^{2n}})$-quantum-secure-PRFs. Hence, falsifying Conjecture 33. ◀

▶ Remark 35. Although not explicitly used in this paper, we would also like to mention that under the assumption that the learning with errors (LWE) conjecture holds against quantum algorithms, there exist quantum-secure PRFs evaluatable by NC^2 circuits (NC^1 if we assume the quantum hardness of RingLWE) [9]. This suggests that under the quantum hardness of LWE (resp. RingLWE), PARITY and MAJORITY are compression obliviousness with respect to the complexity class NC^2 (resp. NC^1).

▶ Remark 36 (Strengthening Conjecture 33 with OWFs). First, recall the definition of one-way functions.

▶ Definition 37 (One-way functions (OWFs)). *A function $g : \{0,1\}^* \to \{0,1\}^*$ is called a (T, η)-one-way function if there is a polynomial p such that for all adversary A running in time T, for all $n \in \mathbb{N}$,*

$$\Pr_{x \leftarrow \{0,1\}^{p(n)}}[A(1^n, g(x)) = x' \text{ such that } g(x') = g(x)] < \eta(n).$$

For example, when $T = 2^n$, we can set the length of the domain and range to be $p(n) = n^2$, therefore a $T = 2^n$ adversary will not trivially break such an OWF.

It is known [20, 18] that (K, T, η)-PRF exists if $(\mathrm{poly}(T), \mathrm{poly}(\eta))$-one-way function exists. Furthermore, the same result holds against quantum adversaries even if the adversary for the PRF is allowed to make superposition queries [32]. Therefore, we can say that

$(2^n, 2^{-\omega(n)})-$PRF against quantum adversaries exists as long as $(\text{poly}(2^n), \text{poly}(2^{-\omega(n)}))$-one-way function against quantum adversaries exists. Therefore, the following conjecture implies Conjecture 33.

▶ Conjecture 38. *Quantum secure* $(\text{poly}(2^n), \text{poly}(2^{-\omega(n)}))$*-one-way functions exist.*

Realising implication (C)

Earlier in this section we discussed that the arguments presented work for properties that satisfy Items 1–3 in the statement of Lemma 28. For properties like PARITY or MAJORITY it is trivial to see that they admit a linear time (quantum and classical) deterministic algorithm. However, it is not immediately clear if the query complexity of computing these properties is "high" on sets $S \subset F_n$ that are not the full set F_n but still are relatively "large". Using techniques from Fourier analysis of Boolean properties, we can show that this is indeed the case with PARITY and MAJORITY. In fact, we are able to say something more. More precisely, we show that the following statement holds.

▶ **Lemma 39.** *Let N be an integer and let $S \in \{0,1\}^N$ be a subset of size $s \geq 2^N\left(1 - \frac{1}{N^2}\right)$. Let $P : \{0,1\}^N \to \{-1,1\}$ be a Boolean property with $Q(P) = \Omega(N)$ and the N-degree Fourier coefficient $|\hat{P}([N])| \geq \sqrt{\frac{1}{2N}}$.*[11] *Then every quantum algorithm that, with error probability $\varepsilon \leq \frac{1}{2\cdot N^2}$, computes P on each $x \in S$ uses $\Omega(N)$ queries.*

Proof. Suppose there exists a T-query algorithm, let us denote by $\mathcal{A}_S$, to compute property P on all $x \in S$ with worst-case error probability $\varepsilon \leq \frac{1}{2\cdot N^2}$. W.l.o.g, we can assume that the output of $\mathcal{A}_S$ is in $\{-1,1\}$. Let $R(x)$ denote the probability that $\mathcal{A}_S$ outputs -1; then we can immediately see that $\forall x \in S$,

$$(1 - 2R(x)) \cdot \mathrm{P}(x) \geq (1 - 2\varepsilon).^{12} \tag{1}$$

We will now estimate the degree of the polynomial $R(x)$. Observe that $\deg(R(x)) = \deg(1 - 2R(x))$. Let $Q(x) = (1 - 2R(x))$ and let $\varepsilon' = (1 - 2\varepsilon)$. Let the Fourier expansions of $Q(x) = \sum_{B\subseteq[N]} \hat{\mathrm{Q}}(B)\chi_B(x)$ and $\mathrm{P}(x) = \sum_{B\subseteq[N]} \hat{\mathrm{P}}(B)\chi_B(x)$, respectively.

Towards a contradiction, suppose that $\deg(Q(x)) < N$ then $\hat{\mathrm{Q}}([N]) = 0$, which implies

$$\begin{aligned}\left(\sum_{B\in 2^{[N]}} \hat{\mathrm{Q}}(B)\cdot\hat{\mathrm{P}}(B)\right)^2 &\overset{(1)}{=} \left(\sum_{B\in 2^{[N]}\setminus[N]} \hat{\mathrm{Q}}(B)\cdot\hat{\mathrm{P}}(B)\right)^2 \\ &\overset{(2)}{\leq} \left(\sum_{B\in 2^{[N]}\setminus[N]} \hat{\mathrm{Q}}(B)^2\right)\cdot\left(\sum_{B\in 2^{[N]}\setminus[N]} \hat{\mathrm{P}}(B)^2\right) \\ &\overset{(3)}{\leq} 1 - \frac{1}{2N};\end{aligned}$$

[11] Note that we use these constants so that Lemma 39 can be almost directly used for PARITY and MAJORITY. However, one can modify these constants to accommodate other properties as well.

[12] Since $R(x)$ is the probability that $\mathcal{A}_S$ outputs -1 and since the error probability of the algorithm is at most ε, we know that (a) if $x \in P^{-1}(-1)$, then $R(x) \geq 1 - \varepsilon$, and (b) if $x \in P^{-1}(1)$, then $R(x) \leq \varepsilon$. If this is the case (a), we obtain $(1 - 2R(x)) \cdot P(x) = (1 - 2R(x)) \cdot (-1) \geq 1 - 2\varepsilon$. Moreover, even in case (b), we obtain $(1 - 2R(x)) \cdot P(x) = (1 - 2R(x)) \cdot (+1) \geq (1 - 2\varepsilon)$. Hence Equation 1 holds.

(1) using the assumption that $\hat{\mathrm{Q}}([N]) = 0$, (2) is argued using Cauchy-Schwarz inequality and (3) comes by using Parseval's theorem (on Boolean output and bounded functions). However, from Equation 1 we have that $\forall x \in S, Q(x) \cdot \mathrm{P}(x) \geq \varepsilon'$ which means

$$\begin{aligned}
\left(\sum_{B\in 2^{[N]}} \hat{\mathrm{Q}}(B)\cdot\hat{\mathrm{P}}(B)\right)^2 &= \left(\frac{1}{2^N}\sum_{x\in\{0,1\}^N} Q(x)\cdot \mathrm{P}(x)\right)^2 \\
&= \frac{1}{2^N}\left(\sum_{x\in S} Q(x)\cdot\mathrm{P}(x) + \sum_{x\in\{0,1\}^N\setminus S} Q(x)\cdot\mathrm{P}(x)\right)^2 \\
&\geq \left(\varepsilon'\cdot\frac{|S|}{2^N} + \frac{1}{2^N}\sum_{x\in\{0,1\}^N\setminus S} Q(x)\cdot\mathrm{P}(x)\right)^2 \\
&\geq \left(\varepsilon'\cdot\frac{|S|}{2^N} - \frac{2^N-|S|}{2^N}\right)^2 \\
&\geq \left(\left(1-\frac{1}{N^2}\right)\cdot\frac{|S|}{2^N} - \frac{2^N-|S|}{2^N}\right)^2 \\
&\geq \left(1-\frac{3}{N^2}\right)^2 \\
&> 1-\frac{6}{N^2},
\end{aligned}$$

leading to a contradiction; therefore, $\deg(Q(x)) = \deg(R(x)) = N$; using polynomial method [10] this implies $T = \Omega(N)$. ◀

Having stated Lemma 39 we can now immediately prove similar query lower bounds for PARITY and a *variant* of MAJORITY as their N-degree Fourier coefficients are 1 and at least $\sqrt{\frac{2}{\pi N}}$, respectively [27]. Moreover, this kind of result can be extended to show similar lower bounds for all Boolean properties P that have a non-negligible Fourier-mass of high degree coefficients. In fact, for PARITY we can show that similar lower bounds hold even on smaller sets as well. Also, we can prove such query lower bounds for MAJORITY and *st*-MAJORITY. More precisely,

▷ Claim 40 (see Lemma 43 in Appendix A for proof). Let $S \in \{0,1\}^N$ be a subset of size $s \geq 0.8\cdot 2^N$. Every quantum algorithm that, with success probability at least $\geq 2/3$, computes PARITY on each $x \in S$ uses $\Omega(N)$ queries.

and,

▷ Claim 41 (see Lemma 48 in Appendix A for proof). Let $S \in \{0,1\}^N$ be a subset of size $s \geq 2^N\left(1-\frac{1}{2\cdot N^2}\right)$. Every quantum algorithm that, with success probability $(1-\varepsilon) \geq (1-\frac{1}{2\cdot N^2})$, computes MAJORITY (*st*-MAJORITY) on each $x \in S$ uses $\Omega(N)$ queries.

The result proved in Lemma 28 when combined with the results stated in Claims 40 and 41 along with Theorem 34 lead us to the following result.

▶ **Corollary 42.** *Let $\Lambda = \mathsf{P/poly}$ be the complexity class. The properties PARITY $\in \mathcal{CO}(\Lambda)$, MAJORITY $\in \mathcal{CO}(\Lambda)$ and st-MAJORITY $\in \mathcal{CO}(\Lambda)$ unless Conjecture 33 is false.*

A Proofs of Claim 40 and Claim 41

▶ **Lemma 43.** *Let $S \in \{0,1\}^N$ be a subset of size $s \geq 0.8 \cdot 2^N$. Every quantum algorithm that, with success probability at least $\geq 2/3$, computes* PARITY *on each $x \in S$ uses $\Omega(N)$ queries.*

Proof. Suppose there exists a T-query bounded-error quantum algorithm $\mathcal{A}_S$ to compute parity on each $x \in S$ with worst-case error probability $\leq 1/3$. Here, without loss of generality, we assume the output of $\mathcal{A}_S$ is $\in \{-1, 1\}$, where 1 means odd parity and -1 means even parity. Let $P(x)$ be the polynomial that represents $\mathcal{A}_S$'s probability of outputting -1 on input x. Since $\mathcal{A}_S$ has worst-case error probability at most $1/3$ on each $x \in S$, we can immediately see $(1-2P(x)) \cdot (-1)^{|x|} \geq 1/3$ for every $x \in S$, where $|x|$ denotes the Hamming weight of x.

Observe that $\deg(P(x)) = \deg(1-2P(x))$ and $\mathbb{E}_{x\in\{0,1\}^N}[(1-2P(x))(-1)^{|x|}]$ is the Fourier coefficient of the degree-N term of $(1-2P(x))$. We obtain

$$\begin{aligned}\mathbb{E}_{x\in\{0,1\}^N}[(1-2P(x))(-1)^{|x|}] =& \frac{1}{2^N}\Big(\sum_{x\in S}[(1-2P(x))(-1)^{|x|}] + \sum_{x\in\{0,1\}^N\setminus S}[(1-2P(x))(-1)^{|x|}]\Big)\\ \geq& \frac{1}{2^N}\cdot\big(s/3 - (2^N - s)\big) > 0,\end{aligned}$$

implying that $\deg(P(x)) \geq N$. Then by polynomial method [10], [13] we immediately obtain $T \geq N/2$. ◀

▶ **Lemma 44** (Theorem 5.19 in [27])**.** *Let N be an odd integer and let odd-*MAJORITY *: $\{0,1\}^N \to \{0,1\}$ be defined as*

$$\textit{odd-MAJORITY}(x) = \begin{cases} 1, & \text{if } |x| > \frac{N}{2},\\ 0, & \text{otherwise,}\end{cases}$$

*where $|x| = |\{i \mid i \in [N] \text{ and } x_i = 1\}|$. If the Fourier expansion of odd-*MAJORITY *is*

$$\textit{odd-MAJORITY}(x) = \sum_{B\subseteq\{0,1\}^N} \widehat{\textit{ODD-MAJ}}(B)\chi_B(x),$$

where $\chi_B(x) = (-1)^{x.B}$, then $\widehat{\textit{ODD-MAJ}}(B) = 0$ whenever $|B| == 0 \mod 2$ and for $|B| = N$ we have

$$\widehat{\textit{ODD-MAJ}}(B)^2 = \frac{4}{4^N}\binom{N-1}{\frac{N-1}{2}}^2 \geq \frac{6}{\pi(3N-1)} > \frac{2}{\pi N}.$$

▶ **Lemma 45.** *Let N be an odd integer and let $S \in \{0,1\}^N$ be a subset of size $s \geq 2^N\left(1 - \frac{1}{N^2}\right)$. Every quantum algorithm that, with error probability $\varepsilon \leq \frac{1}{2\cdot N^2}$, computes odd-*MAJORITY *on each $x \in S$ uses $\Omega(N)$ queries.*

Proof. The absolute value of the N-degree Fourier coefficient for *odd-*MAJORITY is at least $\sqrt{\frac{2}{\pi N}}$ using Lemma 39 gives us the required proof. ◀

[13] By the polynomial method we know if the amplitudes of the final state are degree-N polynomials of x then we need to make at least $T \geq N/2$ queries.

▶ **Lemma 46.** *Let N be an even integer and let $S \in \{0,1\}^N$ be a subset of size $s \geq 2^N(1-\frac{1}{2\cdot N^2})$. Every quantum algorithm that, with error probability $\varepsilon \leq \frac{1}{2\cdot N^2}$, computes* MAJORITY *on each $x \in S$ uses $\Omega(N)$ queries.*

We embed the *odd*-MAJORITY into the MAJORITY and then argue lower bound for MAJORITY for sets of size at least $2^N(1-\frac{1}{2\cdot N^2})$ using the result obtained in Lemma 45.

Proof. Towards contradiction, let us assume that there is a set $B \subseteq \{0,1\}^N$ of size $b \geq 2^N(1-\frac{1}{2\cdot N^2})$ that uses at most $N^{0.999}$ queries to compute MAJORITY on all strings $y \in B$. The set $B = \{B_0 \bigcirc 0\} \sqcup \{B_1 \bigcirc 1\}$ can be viewed as two disjoint sets of strings ending with 0 and 1, respectively. Clearly $|B_1| \leq 2^{N-1}$ and by our assumption we have $|B| \geq 2^N(1-\frac{1}{2N^2})$, therefore, $|B_0| = |B| - |B_1| \geq 2^N(\frac{1}{2} - \frac{1}{2\cdot N^2})$. Set $S' = B_0$. The set S' is a subset of strings of N'-length strings where $N' = N-1$ and moreover N' is odd. Therefore, in terms of N' we have $|B_0| \geq 2^{N'+1}(\frac{1}{2} - \frac{1}{2\cdot(N'+1)^2}) = 2^{N'} - \frac{2^{N'}}{\frac{2}{2}\cdot(N'+1)^2} > 2^{N'}(1-\frac{1}{N'^2})$. As $S' = B_0$, computing MAJORITY on strings in $B_0 \bigcirc 0$ (or equivalently $S' \bigcirc 0$) would be equivalent to computing *odd*-MAJORITY on N'-length strings in S' of size $|S'| \geq 2^{N'}(1-\frac{1}{N'^2})$. But we know from Lemma 45 a sublinear query algorithm is not possible for these set sizes. Hence, proved. ◀

We can give query lower bound for *st*-MAJORITY by just setting $S' = B_1$ and running the same arguments mentioned in the proof of Lemma 46. Giving the following result for *st*-MAJORITY.

▶ **Lemma 47.** *Let N be an even integer and let $S \in \{0,1\}^N$ be a subset of size $s \geq 2^N(1-\frac{1}{2\cdot N^2})$. Every quantum algorithm that, with error probability $\varepsilon \leq \frac{1}{2\cdot N^2}$, computes st-MAJORITY on each $x \in S$ uses $\Omega(N)$ queries.*

When N is odd, all the three definitions of MAJORITY, *st*-MAJORITY and *odd*-MAJORITY are equivalent. Therefore, combining Lemmas 45–47 we get the following.

▶ **Lemma 48.** *Let $S \in \{0,1\}^N$ be a subset of size $s \geq 2^N\left(1-\frac{1}{2\cdot N^2}\right)$. Every quantum algorithm that, with success probability $(1-\varepsilon) \geq (1-\frac{1}{2\cdot N^2})$, computes MAJORITY (st-MAJORITY) on each $x \in S$ uses $\Omega(N)$ queries.*

Locality of Curve-Decoding and Improved Proximity Gaps

Abstract

Proximity gaps are a property of error correcting codes that arise in the study of Interactive Oracle Proofs (IOPs) and Succinct Non-interactive Arguments of Zero Knowledge (SNARKs). Informally, we say that a code $C \subset \Sigma^n$ exhibits a *proximity gap* (with respect to degree-ℓ curves) if for any degree-ℓ curve $u(x) \in \Sigma^n$, either *every* point on $u(x)$ is close to C, or else *most* of them are far from C.

Recent work [16] has established near-optimal proximity gaps for many families of codes, including subspace design codes, as well as random ensembles like random linear codes, Reed-Solomon codes with random evaluation points, and Gallager's ensemble of LDPC codes. However, the parameters for these latter randomized ensembles are worse than the parameters for subspace design codes, and degrade as the degree ℓ increases.

In this work, we obtain improved proximity gaps for random ensembles of codes, including random linear codes, Reed-Solomon codes with random evaluation points, and Gallager's ensemble. Quantitatively, our results for these random ensembles match the results that [16] attained for subspace design codes. In fact, our techniques are a black-box transference from subspace design codes: Any progress on subspace design codes will automatically lead to analogous progress for these random ensembles.

To obtain our results, we extend the Local Coordinate-wise Linear (LCL) property framework developed in [9, 27] to a *row-span constrained* version. This allows us to cast *curve-decodability* – a property that implies proximity gaps – directly as an (row-span constrained) LCL property, and make use of that machinery. In contrast, because curve-decodability is not obviously a (vanilla) LCL property, prior work had worked with a proxy property instead, leading to the aforementioned parameter losses. In addition, we extend the framework to also show an equivalence theorem for Gallager's ensemble of random LDPC codes and random linear codes for our row-span constrained LCL properties.

1 Introduction

Proximity gaps are a property of error correcting codes that arise in the study of Interactive Oracle Proofs (IOPs) and Succinct Non-interactive Arguments of Zero Knowledge (SNARKs), both of which are relevant for blockchains and related technologies. Let $\mathbb{F}$ be a finite field, and let Σ be a vector space over $\mathbb{F}$. An $\mathbb{F}$-*additive code* C (with alphabet Σ and block length n) is an $\mathbb{F}$-linear subspace $C \subset \Sigma^n$. Informally, we say that C exhibits a *proximity gap* (for degree-ℓ curves, which is the focus of this paper) if the following holds. For any degree-ℓ curve $u(x) = \sum_{i=0}^{\ell} u_i x^i$ in Σ^n given by $u_0, \ldots, u_\ell \in \Sigma^n$ and $x \in \mathbb{F}$, either *every* point $u(\alpha)$ on the curve is close to C, or else a $1-\varepsilon$ fraction of the points on the curve are far from C. Formally, we have the following definition. Below, $\Delta(x,y) := \frac{1}{n}\sum_{i=1}^{n} \mathbf{1}[x_i \neq y_i]$ is the (relative) Hamming distance between $x, y \in \Sigma^n$, and $\Delta(x, C) := \min_{y \in C} \Delta(x,y)$ for code C.

▶ **Definition 1** (Proximity Gaps (PG)). *An $\mathbb{F}$-additive code $C \subset \Sigma^n$ is said to have $(\ell, \delta, \varepsilon, \gamma)$ proximity gap if for all $u_0, u_1, \cdots, u_\ell \in \Sigma^n$, and for all $\delta' \leq \delta$,*

$$\mathbb{P}_{\alpha \in \mathbb{F}}\left(\Delta\left(\sum_{j=0}^{\ell} u_j \alpha^j, C\right) \leq \delta'\right) > \varepsilon \implies \forall \alpha \in \mathbb{F},\ \Delta\left(\sum_{j=0}^{\ell} u_j \alpha^j, C\right) \leq \frac{\delta'}{1-\gamma}\ .$$

When $\gamma = 0$, we say that C has an $(\ell, \delta, \varepsilon)$ proximity gap.

Proximity gaps, especially for *Reed-Solomon (RS) Codes*,[1] have been a hot topic lately, with the Ethereum Foundation offering $1M in prizes for resolving (or disproving) conjectures related to proximity gaps for RS codes [14]. See [2] for a recent survey on proximity gaps and problems relevant to the proximity prize.

Until recently, the best proximity gap guarantees required $\delta < 1 - \sqrt{R}$, where $R = \frac{\log_{|\Sigma|} |C|}{n}$ is the *rate* of the code $C \subset \Sigma^n$. In recent work [16], Guruswami and Goyal established near-optimal proximity gaps – with δ approaching $1 - R$ – for several families of codes. For *Folded Reed-Solomon Codes, Multiplicity Codes*,[2] and more generally any *Subspace Design Code* (Definition 15), they established $(\ell, \delta, \varepsilon)$ proximity gaps with $\delta = 1 - R - 2\eta$ for any $\eta > 0$, provided that

$$\varepsilon q \geq \frac{n\ell}{\eta} + O\left(\frac{\ell^2}{\eta^3}\right), \tag{1}$$

[1] Reed-Solomon codes are a classical family of codes based on low-degree polynomials. Given fixed distinct evaluation points $\alpha_1, \ldots, \alpha_n \in \mathbb{F}_q =: \Sigma$, the corresponding Reed-Solomon code $C \subset \Sigma^n$ of length n and dimension $k \leq n$ is given by $C = \{(f(\alpha_1), \ldots, f(\alpha_n)) : f \in \mathbb{F}_q[x], \deg(f) < k\}$.

[2] Informally, a *folded Reed-Solomon code* is obtained by "folding" (aka, bundling symbols together) an RS code $C \in \mathbb{F}_q^n$ to obtain a code $C' \in (\mathbb{F}_q^m)^{n/m}$. A (univariate) *multiplicity code* is similar to an RS code, except each symbol contains not just $f(\alpha_i)$, but also $f^{(j)}(\alpha_i)$ for $j = 1, 2, \ldots, m-1$, where $f^{(j)}$ denotes the j'th (Hasse) derivative. In either case, the alphabet size increases from q to q^m. By a result of [20], both are special cases of Subspace Design Codes, defined in Definition 15.

where q is the size of the base field. Thus, the left-hand side εq is a bound on the number of points on the curve $u(x)$ that can still be close to C, in the case that not all q points are. We'd like for this bound to be as small as possible.

Via a framework from [9, 27] that establishes a connection between random linear codes and subspace design codes, the work [16] extended their results for subspace design codes to several random ensembles of codes, including random linear codes, Reed-Solomon codes with random evaluation points, and Gallager's ensemble of random LDPC codes. However, some parameters degraded in this extension: The final result that [16] established for these random ensembles was $(\ell, \delta, \varepsilon)$ proximity gaps with $\delta = 1 - R - 2\eta$, provided that

$$\varepsilon q \geq \frac{n\ell(1-R)}{\eta} + \left(\frac{\ell}{\eta^2}\right)^{O(\ell)}. \tag{2}$$

When ℓ is large, on the order of $\Omega(\log n)$, the error term $(\ell/\eta^2)^{O(\ell)}$ in (2) swamps the main term, and the requirement on εq quickly becomes large. This leaves us with the question of whether a bound like (1) is achievable for these random ensembles of codes. This question has practical as well as theoretical motivations: Larger values of ℓ can occur in practice, for example in WHIR [3]; random ensembles of codes are also practically interesting, for example in Blaze [10] or Bolt [19];[3] and understanding RS codes with random evaluation points may deepen our understanding of explicit RS codes, relevant to the proximity prize [14].

1.1 Our Contributions

Our main contribution is to improve the bound (2) for random ensembles of codes to match the bound (1) that was already established for subspace design codes. We establish these improved bounds for random linear codes, RS codes with random evaluation points, and Gallager's ensemble of LDPC codes. See Definitions 5–7 for formal definitions of these codes.

▶ **Theorem 2** (Informal). *Fix any $\ell \in \mathbb{N}$ and $\eta > 0$. Let $C \in \mathbb{F}_q^n$ be a random linear code, random Reed-Solomon code, or random LDPC code*[4] *Then, with probability at least $2/3$ over the choice of C, C has $(\ell, 1 - R - 2\eta, \varepsilon)$ proximity gaps (with respect to degree-ℓ curves), provided that*

$$\varepsilon q \geq \frac{n\ell(1-R)}{\eta} + O\left(\frac{\ell^2}{\eta^3}\right). \tag{3}$$

In fact, our results establish not just proximity gaps, but also stronger notions known as *Correlated Agreement* (CA, Definition 8) and *Mutual Correlated Agreement* (MCA, Definition 9); see the full version for the full statements [18].

Our framework, discussed more below in Section 1.2, is a black-box transference method from subspace design codes. Thus, any future improvements for subspace design codes will immediately lead to an analogous improvement in Theorem 2.

In order to establish our results, we generalize the *Local Coordinate-wise Linear* (LCL) framework of [27] to a new "row-constrained" version of the framework, described below. We hope that this generalization may find other applications going forward.

[3] In more detail, Blaze considers a random ensemble of *RAA* codes, which use random permutations to decide the parity checks. Bolt uses *Gallager's ensemble* of LDPC codes, which we also study in this paper.

[4] Technically, the result for random LDPC codes requires the leading term $n\ell(1-R)/\eta$ to be slightly larger; see full version for details.

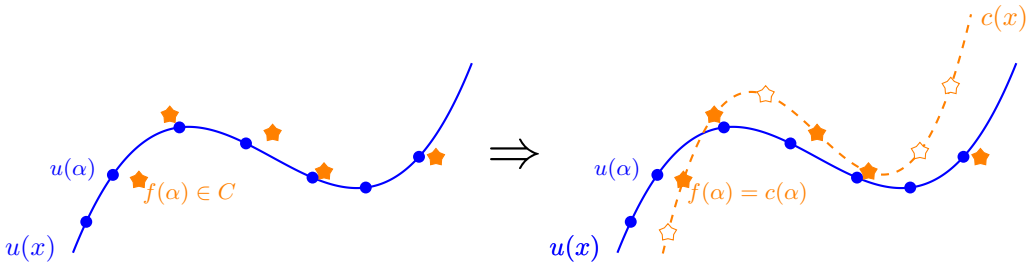

Figure 1 Depiction of curve decodability (Definition 10). The orange stars represent $f(\alpha) \in C$ for $\alpha \in A$, and the blue dots represent $u(\alpha) \in \Sigma^n$ for $\alpha \in \mathbb{F}_q$, where $u(x)$ is a degree-ℓ curve. Informally, a code $C \subseteq \Sigma^n$ is (ℓ, δ, a, b)-curve-decodable if the following holds: If there are at least a orange stars δ-close to distinct blue dots, then at least b of those orange stars lie on a degree-ℓ curve $c(x)$. In the picture, $a = 5$, and $b = 4$.

▶ Remark 3. [27] showed an equivalence for LCL properties between random linear and random Reed-Solomon codes; we state its row-span constrained extension here. The analogous statement for Gallager's ensemble, based on [28], is recorded in Section 3.3.3; the proofs and LDPC-specific details appear in the full version [18].

1.2 Techniques: Curve-Decoding as a Row-Span Constrained LCL Property

Following [16], we study *curve-decoding*. For the rest of this discussion, assume for simplicity that the alphabet Σ is equal to $\mathbb{F}_q$, so C is a linear subspace of $\mathbb{F}_q^n$.

Informally, such a code C is (ℓ, δ, a, b) *curve-decodable* if, for any degree-ℓ curve $u(x) = \sum_{i=0}^{\ell} u_i x^i$ with $u_i \in \Sigma^n$, the following holds. Suppose that there is a set $A \subset \mathbb{F}_q$ of size a so that $u(\alpha)$ is δ-close to some codeword $f(\alpha) \in C$ for all $\alpha \in A$. Then, there should be a "codeword curve" $c(x) = \sum_{i=0}^{\ell} c_i x^i$, where $c_i \in C \subset \Sigma^n$, so that $f(\alpha) = c(\alpha)$ for at least b values of $\alpha \in A$. See Definition 10 for a formal definition; the property is illustrated in Figure 1.

The work [16] showed that curve-decodability is a sufficient condition to establish proximity gaps (as well as stronger notions like correlated agreement and mutual correlated agreement); see Theorem 12 and Theorem 13. They then established that subspace design codes have curve-decodability (Theorem 18), which led to their results about subspace design codes.

Our work comes in the next step. To obtain their results for random ensembles of codes, [16] applied a framework of [9, 27]. This framework roughly shows that any *Local Coordinate-wise Linear (LCL)* property that is satisfied by subspace design codes is also satisfied by these random ensembles. We will explain what LCL properties are in a moment, but the main challenge with this approach is that "being curve-decodable" is in fact *not* (or, not obviously) an LCL property. To get around this, [16] defined another property, which they called $\bigvee$*-decoding*, which *is* captured by the LCL framework. Then existing results imply that the random ensembles of codes are just as $\bigvee$-decodable as subspace design codes, and translating back to curve-decoding gives the final result. Unfortunately, going through $\bigvee$-decoding results in a loss in parameters, degrading (1) to (2). We avoid this loss by *extending* the LCL framework to apply directly to curve-decoding.

The LCL Framework. Before explaining our extension, we first explain the LCL framework of [27]. Intuitively, an r-local LCL property is one defined by the exclusion of r-sized bad sets of codewords. For example, the property of "having good distance" might be defined by the

exclusion of all pairs ($r = 2$) of codewords that agree in too many places. The LCL framework allows for any definition of "bad" that can be captured by a family $\mathcal{F}$ of coordinate-wise linear relationships.

In more detail, let $C \subset \mathbb{F}_q^n$ be a linear code, and consider a set of r distinct "bad" codewords, stacked together to form the columns of a matrix $M \in \mathbb{F}_q^{n \times r}$. Let $\mathcal{F}$ be a family of *profiles* $\mathbf{V} = (V_1, \ldots, V_n)$, where each $V_i \in \mathcal{L}(\mathbb{F}_q^r)$. (Here, $\mathcal{L}(W)$ denotes the collection of subspaces of W.) In the LCL framework, the "badness" of a matrix M is captured by the following criterion: There is some $\mathbf{V} = (V_1, \ldots, V_n) \in \mathcal{F}$ so that for all $i \in [n]$, the i'th row of M is contained in V_i.

Thus, an LCL property defined by $\mathcal{F}$ is the property of *avoiding* all "bad" matrices M that satisfy the constraints given by some $\mathbf{V} \in \mathcal{F}$ (we say that C *avoids* M if the column span of M is not contained in C). See Definition 20 for a formal definition.

Capturing Curve-Decoding and the Approach of [16]. The LCL framework captures many familiar properties, for example distance, list-decoding, and list-recovery. Unfortunately, it does not seem to capture curve-decoding. To see why, let us consider two approaches.

For the first – and probably most natural – approach, suppose that we have a bad example for (ℓ, δ, a, b) curve-decoding. That is, suppose we have a set $A \subset \mathbb{F}_q$ of size a, a degree-ℓ curve $u(x) \in \mathbb{F}_q^n$, and a function $f : \mathbb{F}_q \to C$ so that $\Delta(u(\alpha), f(\alpha)) \leq \delta$ for all $\alpha \in A$; but suppose that there is *no* degree-ℓ "codeword curve" $c(x) = \sum_{i=0}^{\ell} c_i x^i$ for $c_i \in C$ that passes through at least b of the $f(\alpha)$.

We will attempt to construct a "witness" matrix $M \in \mathbb{F}_q^{n \times A}$ whose columns are $f(\alpha)$ for all $\alpha \in A$. In order to certify this as a bad example, we should be able to come up with some LCL profile $\mathbf{V} = (V_1, \ldots, V_n)$ that "explains" the badness of the example. There are two properties that make a "bad example" bad:

(A) Each of the $f(\alpha)$ (the columns of M) agree in many coordinates with some ambient curve $u(x)$ of degree ℓ.

(B) No b columns of M themselves lie on the same degree-ℓ curve.

Item (A) can be captured with an a-local profile $\mathbf{V} = (V_1, \ldots, V_n)$. Indeed, let $A_i = \{\alpha \in A : u(\alpha)_i = f(\alpha)_i\}$, and then define V_i to be the subspace of all $y \in \mathbb{F}_q^A$ so that y (when viewed as a function $y : A \to \mathbb{F}_q$) agrees with some degree-ℓ polynomial on A_i. Then consider the class $\mathcal{F}$ of all profiles $\mathbf{V}$ generated this way (over all appropriate choices of A_i). Item (A) holds if and only if C contains some $\mathbf{V} \in \mathcal{F}$.

However, it is not clear how to capture item (B) with the LCL framework, as (B) is a more global property of the matrix, not easily captured with coordinate-wise constraints. Thus, another approach seems needed.

As a second possible approach, we describe what [16] did, and briefly explain why it incurs an exponential loss in the parameter ℓ. The idea is to consider first the special case that $b = \ell + 2$. Given a bad example for curve-decoding, consider a much larger "witness" matrix $M \in \mathbb{F}_q^{n \times r}$ for $r = \binom{a}{\ell+1}$, as follows. The columns of M now correspond to subsets $S \in \binom{A}{\ell+1}$, and the columns correspond to polynomials $g_S(x)$ defined by interpolating through the points $(\alpha, f(\alpha))$ for all $\alpha \in S$. It turns out that if $b = \ell + 2$, then all of these polynomials must be distinct: Otherwise, if $g_S = g_{S'}$ for some $S \neq S'$, then this gives a degree-ℓ curve passing through at least $|S \cup S'| \geq \ell + 2 = b$ of the codewords $f(\alpha)$, contradicting the badness of this example. Then, if $\mathbb{F}_q$ is large enough, there is some β so that $\left\{g_S(\beta) \in C : S \in \binom{A}{\ell+1}\right\}$ are also all distinct, and these can be the columns of M. However, this requires us to take $\ell = b + 2$; otherwise, we can't be guaranteed that the columns are distinct, which is required by the LCL framework. The insight of [16] was to essentially transform the general-ℓ case

to the $\ell = b + 2$ case via a new property called $\bigvee$-decoding; but this came at a cost of an exponential dependence on ℓ. (We emphasize that the exponential loss comes from the transformation to the $b = \ell + 2$ case, not the larger size of the witness matrix, although we will be able to overcome both issues in this work.)

Our Approach: Row-span Constrained LCL Properties. Instead of trying to manipulate curve-decodability to fit into an LCL property, we extend the definition of an LCL property. That is, we return to the first, more straightforward, attempt above. Recall that the first property (A) – that each column of M is close to some degree-ℓ curve $u(x)$ –is easily captured by an a-local LCL profile. The harder part is dealing with item (B), that no b columns of M should themselves lie on a degree-ℓ curve. This is a global constraint on the matrix M, and thus is not immediately amenable to the coordinate-wise framework of [27].

In order to capture item (B), we introduce a *row-span* constraint. One example of such a constraint was already present in prior works [9, 27]. Indeed, that framework requires that the columns of the witness matrix M be distinct, which turns out to be equivalent to the property that the row-span U of M does not have any identically equal coordinates (that is, there should not be any $i \neq j$ so that $u_j = u_i$ for all $u \in U$). Thus, [9, 27] restricted the row-span of their witness matrices M to the set $\mathcal{L}_{\text{dist}}(\mathbb{F}_q^r)$ of *distinct* subspaces U, those without any identically equal coordinates.

Our observation is that item (B) can also be captured in this way. In Lemma 50 and Corollary 51, we show that item (B) is equivalent to the following: For any $B \in \binom{A}{b}$, there is some u in the row-span U of M so that $u|_B$ does *not* agree with any degree-ℓ curve $p : B \to \mathbb{F}_q$. We define a subspace U with this property to be (ℓ, A, b) *curve-free* (Definition 49). Thus, in addition to an a-local LCL profile $\mathbf{V}$ to enforce the condition (A), we also have a condition on the row-span – namely that the row-span U of M should be (ℓ, A, b) curve free – to enforce condition (B).

Formally, we implement this by defining the set $\mathcal{F}$ to be a set of *pairs* $(\mathbf{V}, U)$, where $\mathbf{V}$ is an r-local profile, and $U \subset \mathbb{F}_q^r$ is a subspace. Then a witness matrix M with columns in C is "bad" if there is some $(\mathbf{V}, U) \in \mathcal{F}$ so that the i-th row of M is contained in V_i for all i; and additionally the row-span of M is contained in U. We say that C *avoids* $\mathcal{F}$ if there is no such witness matrix.

Putting it Together. In order to implement the ideas above, we first re-derive the LCL framework and the connections in [9, 27] in the row-span constrained setting. We do this in Section 3. To do so, in Section 3, we introduces row-span constrained LCL profiles and states the corresponding threshold and transfer theorems for random linear, random Reed–Solomon, random LDPC, and subspace-design codes. In particular, Theorems 34 and 45 and Corollaries 37 and 48 identify the relevant threshold rate and its transfer to subspace-design codes.

Next, in Section 4, we characterize *not* being (ℓ, δ, a, b) curve-decoding as a row-span constrained a-local LCL property, as described above. The local profile records the agreement of the nearby codewords with an ambient degree-ℓ curve (property (A)), while the row-span constraint records the absence of a degree-ℓ codeword curve through any b nearby codewords (property (B)). This is stated formally in Theorem 52 and Corollary 53.

Finally, we apply our row-span constrained LCL theory to curve-decoding and to three random ensembles of codes – random linear codes, RS codes with random evaluation points, and Gallager's ensemble of LDPC codes – to prove Theorem 2. To recap, we know from [16] that subspace design codes satisfy curve-decodability; we have shown in Section 3 that

random ensembles of codes behave similarly to subspace design codes for any *row-span constrained* LCL property; and we have shown in Section 4 that curve-decodability is such a property. Therefore random ensembles of codes exhibit good curve-decodability as well. Section 5 states the resulting proximity-gap, CA, and MCA guarantees for the three random ensembles.

Due to space constraints, we omit some proofs and calculations; the reader can find these in the full version of this paper [18].

1.3 Related Works

Proximity Gaps. Proximity gaps (and related notions, including correlated agreement and mutual correlated agreement) arise naturally in the study of interactive protocols. The goal in these settings is to test whether or not *every* vector in a set – say, a line or a curve – is close to a code C. If that code exhibits a proximity gap, then it suffices to choose a random vector in that set and use its distance from the code as a proxy for the minimum distance to C over the whole set. This connection was observed in [29], and since then a long line of work has been devoted to improving the parameters [1, 3, 6–8, 16] and establishing limitations [5, 12, 13, 26]. See the recent survey [2] for an overview of the work on proximity gaps and related notions. Prior to the work of [16], the best known proximity gap results required $\delta < 1 - \sqrt{R}$, corresponding to the *Johnson radius* in list-decoding. As discussed above, the work [16] improved this to allow δ to approach $1 - R$, the best trade-off possible. However, as noted earlier, the results can still be improved, notably in how small the parameter ε can be. The current best results for explicit codes – including folded RS codes, multiplicity codes, and all subspace design codes – follow from [16] and work under the condition given by (1). In this work we improve their results for random ensembles of codes from (2) to (1).

Local properties and subspace design codes. A recent line of work [21, 22, 27, 28] has shown that a wide variety of random ensembles of codes – including random linear codes, random LDPC codes, and Reed-Solomon codes with random evaluation points – all behave similarly with respect to "local" properties: properties that are characterized by the exclusion of small bad sets. The paper [27] introduced the LCL framework discussed above, and [9] connected this to another line of work on *subspace design codes*. The study of subspace design codes implicitly began with the introduction of Folded Reed-Solomon codes [23]. Over nearly two decades, it was observed that a key property of these codes, as well as of univariate multiplicity codes, is that they satisfy a *subspace design property* [20], which has been leveraged and generalized in subsequent works [4, 9, 11, 17, 25, 30, 31]. Notably, [11] showed that *any* such subspace design codes enjoy optimal list-decodability. The work [9] then connected this line of work to the LCL framework discussed above, showing that in fact the same thresholds are achieved by subspace design codes. The work [16] leveraged this connection to study curve-decoding, and we do the same in this work.

1.4 Discussion and Open Problems

We conclude this section with a few open questions.

- Our approach can automatically turn any improvements for subspace design codes into analogous improvements for random ensembles of codes. Thus, the natural open question is to further improve the trade-offs between ε, q, ℓ and η for subspace design codes.

- Our results imply that Reed-Solomon codes with random evaluation points attain near-optimal proximity gaps, even for large ℓ. While it is known that there exist Reed-Solomon codes that do *not* achieve optimal proximity gaps [5, 12, 13, 26], it is not known which choices of evaluation points are "good." Can we identify explicit Reed-Solomon codes with near-optimal proximity gaps? This question is related to the open problem of identifying explicit Reed-Solomon codes that achieve near-optimal list-decoding.
- We hope that our techniques will be useful beyond the present application. Are there other natural properties that can be captured with the row-span constrained LCL framework, but not with the original LCL framework?

2 Preliminaries

We begin by introducing the basic coding-theoretic definitions we will be using. For any two vectors x, y in Σ^n where Σ is some alphabet, we define the fractional Hamming distance $\Delta(x,y) = \frac{1}{n}|\{i \in [n] : x_i \neq y_i\}|$ to be the fraction of coordinates where they differ. For a set $S \subset \Sigma^n$, we define $\Delta(x,S) = \min_{y \in S} \Delta(x,y)$ to be the fractional distance of x to its closest vector in S. Throughout this paper, all distances are taken to be fractional unless stated otherwise.

The two fundamental quantities associated with a code are its rate and distance. For a code $C \subset \Sigma^n$, we define its (relative) distance as $\delta(C) = \min_{x,y \in C, x \neq y} \Delta(x,y)$. Moreover, its rate $R(C)$ is defined as $R(C) = \frac{1}{n}\log_{|\Sigma|}|C|$.

In this paper, we will focus on additive codes over a finite field, defined as follows:

▶ **Definition 4** (Additive codes). *Let $\mathbb{F}$ be a finite field and let $\Sigma = \mathbb{F}^s$ for some positive integer s. A code $C \subset \Sigma^n$ is said to be $\mathbb{F}$-additive (or just additive when the field $\mathbb{F}$ is clear from context) if C is an $\mathbb{F}$-linear subspace of Σ^n.*

We focus on three families of random codes; the first is a random linear code.

▶ **Definition 5** (Random Linear Code (RLC) and Random $\mathbb{F}_q$-Additive Code). *A random linear code $C \subset \mathbb{F}_q^n$ of rate R is given by taking $C = \{(\mathsf{Enc}_1(x), \cdots, \mathsf{Enc}_n(x)) \mid x \in \mathbb{F}_q^{Rn}\}$ where $\mathsf{Enc}_i : \mathbb{F}_q^{Rn} \to \mathbb{F}_q$ are independent uniformly random linear maps.* [5] *More generally, a random $\mathbb{F}_q$-additive code $C \subset (\mathbb{F}_q^s)^n$ of rate R is given by taking $C = \{(\mathsf{Enc}_1(x), \ldots, \mathsf{Enc}_n(x)) \mid x \in \mathbb{F}_q^{Rsn}\}$ where $\mathsf{Enc}_i : \mathbb{F}_q^{Rsn} \to \mathbb{F}_q^s$ are independent uniformly random linear maps.*

The next family is a random Reed-Solomon code, which is just a Reed-Solomon code where the evaluation points are chosen uniformly at random.

▶ **Definition 6** (Random Reed-Solomon Code (RRS)). *A Reed-Solomon code over a field $\mathbb{F}_q$ with evaluation points $\alpha_1, \cdots, \alpha_n$ is defined as follows*

$$\mathsf{RS}_{\mathbb{F}_q}(\alpha_1, \ldots, \alpha_n, k) = \{(f(\alpha_1), \ldots, f(\alpha_n)) \mid f \in \mathbb{F}_q[X], \deg f < k\}$$

A random Reed-Solomon code of rate R is one in which $k = Rn$ and α_i are independent uniformly random elements of $\mathbb{F}_q$.

[5] Note that, defined this way, there is some small chance that the rate $\log_q |C|/n$ of a random linear code may not actually be R, if there are too many linear dependencies between the maps Enc_i. However, it is more convenient to work with i.i.d. encoding maps, and the probability of the rate not being R is negligible, so anything that holds with high probability for this model also holds with high probability for other models of random linear codes, for example the model where one chooses C to be a uniformly random subspace of dimension Rn, or the model where C is the kernel of a random matrix in $\mathbb{F}_q^{(1-R)n \times n}$. See, e.g., [27, Appendix A].

Finally, we introduce our last family of codes, random Low-Density Parity-Check (LDPC) codes. In this paper, by "random LDPC codes" we mean *Gallager's ensemble* of random LDPC codes [15]. In general, a rate R, s-sparse LDPC code can be described as follows: Pick a bipartite graph $G = (L \sqcup R, E)$ with $|L| = n$, $|R| = (1-R)n$ and right degree s. Each edge $e \in E$ has a weight $w_e \in \mathbb{F}_q$, the code C is given as follows:

$$C = \Big\{ c \in \mathbb{F}_q^L : \sum_{u \in N(v)} w_{(u,v)} c_u = 0 \text{ for all } v \in R \Big\}.$$

Above, $N(v)$ denotes the neighborhood of v in G.

To define a random LDPC code, we thus just need to describe the underlying bipartite graph and the edge weights w_e. Gallager's ensemble [15] defines an ensemble of random graphs (and hence random LDPC codes) as follows.[6]

▶ **Definition 7** (Random Low Density Parity Check Code (RLDPC)). *Let $t = (1-R)s$, and let $G_i = (V, W_i, E_i)$ for $i = 1, \cdots, t$ be uniformly random $(1, s)$ regular bipartite graphs with a shared left vertex set and disjoint right vertex sets W_i of size n/s. The graph G is then defined as $\bigsqcup_i G_i$; that is, $G = (V, W, E)$, where $W = \bigsqcup_i W_i$ and $E = \bigsqcup_i E_i$. The edge weights w_e are sampled as independent uniformly random elements of $\mathbb{F}_q^*$. A* Random LDPC Code *C of rate R is then the LDPC code derived from G and the weights $\{w_e\}$, as described above.*

2.1 Proximity Gaps and (Mutual) Correlated Agreement

Proximity Gaps are related to two stronger notions, *Correlated Agreement* (CA) and *Mutual Correlated Agreement* (MCA). Our results actually establish both CA and MCA as well as proximity gaps.

Informally, we say that a code C has $(\ell, \delta, \varepsilon, \gamma)$-correlated agreement if, for all degree-ℓ curves $u(x) = \sum_{i=0}^{\ell} u_i x^i$ with $u_i \in \Sigma^n$, the following holds: Either at most an ε fraction of the points on $u(x)$ are δ-close to C; or there is some "codeword curve" $c(x) = \sum_{i=0}^{\ell} c_i x^i$ with $c_i \in C$ so that $u(x)$ agrees identically with $c(x)$ on a set $S \subset [n]$ of at least $\delta n/(1-\gamma)$ coordinates. Formally, we have the following definition.

▶ **Definition 8** (Correlated Agreement (CA)). *An $\mathbb{F}$-additive code $C \subset \Sigma^n$ is said to have $(\ell, \delta, \varepsilon, \gamma)$ correlated agreement if for all $u_0, u_1, \cdots, u_\ell \in \Sigma^n$ and $\delta' \le \delta$*

$$\mathbb{P}_{\alpha \in \mathbb{F}}\Big[\Delta\big(\sum_{j=0}^{\ell} u_j \alpha^j, C\big) \le \delta'\Big] > \varepsilon \implies \exists c_0, c_1, \cdots c_\ell \in C : \Big|\Big\{ i : \bigvee_{j=0}^{\ell} c_{j,i} \neq u_{j,i} \Big\}\Big| \le \frac{\delta' n}{1-\gamma}.$$

In particular, CA implies that for all $\alpha \in \mathbb{F}$, we have that $\Delta\Big(\sum_{j=0}^{\ell} u_j \alpha^j, \sum_{j=0}^{\ell} c_j \alpha^j\Big) \le \delta'/(1-\gamma)$. Thus, $(\ell, \delta, \varepsilon, \gamma)$ correlated agreement implies an $(\ell, \delta, \varepsilon, \gamma)$proximity gap.

Next, we define Mutual Correlated Agreement (MCA). Informally, we say that an $\mathbb{F}$-additive code C has $(\ell, \delta, \varepsilon)$ MCA if for all degree-ℓ curves $u(x)$ in Σ^n, the following holds. For all sets $S \subset [n]$ of size at least $(1-\delta)n$, and for at least an $1-\varepsilon$ fraction of $\alpha \in \mathbb{F}$, if there is some $c \in C$ that agrees with $u(\alpha)$ on S, then there is some "codeword curve" $c(x) = \sum_{i=0}^{\ell} c_i x^i$ for $c_i \in C$ so that $c(x)$ and $u(x)$ agree identically on S. Formally, we have the following definition, which captures the contrapositive of the intuition above.

[6] Technically, this way of generalizing to larger alphabets is slightly different than [15]. Our definition coincides with [15] for $q = 2$; for larger q, [15] chooses weights w_e to all be 1, while we choose them uniformly in $\mathbb{F}_q^*$; this matches the ensemble studied in [28].

▶ **Definition 9** (Mutual Correlated Agreement (MCA)). *An $\mathbb{F}$-additive code $C \subset \Sigma^n$ is said to have $(\ell, \delta, \varepsilon)$ mutual correlated agreement if for all $u_0, u_1, \cdots, u_\ell \in \Sigma^n$ and $\delta' \leq \delta$*

$$\mathbb{P}_{\alpha \in \mathbb{F}}\left(\exists S \subset [n], c \in C, j \in \{0,1,\ldots,\ell\} : |S| \geq (1-\delta')n, c_{|S} = \sum_{j=0}^{\ell} \alpha^j u_{j|S}, c'_{|S} \neq u_{j|S} \forall c' \in C \right) \leq \varepsilon.$$

We note that $(\ell, \delta, \varepsilon)$ MCA implies $(\ell, \delta, \varepsilon, \gamma = 0)$ CA and hence $(\ell, \delta, \varepsilon, \gamma = 0)$ PG. Indeed, suppose that C satisfies MCA, and suppose there is some codeword $c \in C$ that is δ'-close to $u(x)$ on at least εq points, call them $A \subset \mathbb{F}$. MCA implies that there is a set $B \subset \mathbb{F}$ of size at least $(1-\varepsilon)q$ so that the event inside the $\mathbb{P}_\alpha[\cdot]$ statement holds. Then there must be at least one point $\alpha \in A \cap B$. Letting $S \subset [n]$ be the set of coordinates (of size at least $(1-\delta')n$) on which $u(\alpha)$ agrees with c, we conclude from the definition of MCA that there is some "codeword curve" $c(x)$ so that $c(x)$ and $u(x)$ identically agree on S, establishing CA.

Finally, we formally define curve-decodability, which we informally defined in Section 1 (see Figure 1). The following definition was given in [16], and the case of $\ell = 1$ was independently defined in [24] as *collinearity of proximates*. We adopt the convention from [16].

▶ **Definition 10** (Curve-Decodability). *An additive code $C \subset \Sigma^n$ is (ℓ, δ, a, b) curve-decodable if for every $u_0, u_1, \cdots, u_\ell \in \Sigma^n$, all functions $f : \mathbb{F}_q \to C$, whenever the set $A = \left\{\alpha \in \mathbb{F} : \Delta\left(\sum_{j=0}^{\ell} u_j \alpha^j, f(\alpha)\right) \leq \delta\right\}$ has at least a elements, there exist $c_0, c_1, \cdots, c_\ell \in C$ such that $\left|\left\{\alpha \in A : f(\alpha) = \sum_{j=0}^{\ell} c_j \alpha^j\right\}\right| \geq b$.*

The work [16] showed a transformation to boost results about the curve-decodability of a code assuming that the underlying code is also list-decodable.

▶ **Theorem 11** ([16, Theorem 3.6]). *Suppose an $\mathbb{F}_q$-additive code $C \subset (\mathbb{F}_q^s)^n$ is $\left(\delta\left(1+\frac{\ell}{b-\ell}\right), L\right)$-list-decodable and (ℓ, δ, a, b)-curve-decodable. Then C is also $(\ell, \delta, (T-1)L + a, T)$ curve-decodable for any T.*

The key motivation to define curve-decodability is due to the following implication for correlated and mutual correlated agreement.

▶ **Theorem 12** (Correlated agreement from curve-decodability, [16, Theorem 3.4]). *Let $C \subset \Sigma^n$ be an $\mathbb{F}_q$-additive code. Let $\ell, t > \ell, a \in \mathbb{N}$ and $\delta \in (0,1)$. Suppose that $\mathcal{C}$ is (ℓ, δ, a, t) curve-decodable. Then C has $(\ell, \delta, a/q, \ell/t)$ correlated agreement.*

▶ **Theorem 13** (Mutual correlated agreement from curve-decodability, [16, Theorem 3.5]). *Let $C \subset \Sigma^n$ be an $\mathbb{F}_q$-additive code. Let $\ell, a \in \mathbb{N}$ and $\delta \in (0,1)$. Suppose that $\mathcal{C}$ is $(\ell, \delta, a, \ell n + 1)$ curve-decodable. Then C has $(\ell, \delta, a/q)$ mutual correlated agreement.*

▶ **Corollary 14.** *If an $\mathbb{F}_q$-additive code $C \subset (\mathbb{F}_q^s)^n$ is $\left(\delta\left(1+\frac{\ell}{b-\ell}\right), L\right)$-list-decodable and (ℓ, δ, a, b)-curve-decodable, then C has:*

1. *for any $t \geq 1$, $(\ell, \delta, (t-1)L + a, t)$ curve-decodability,*
2. *for any $m > 1$, $\left(\ell, \delta, \frac{\ell m L + a}{q}, \frac{1}{m}\right)$ correlated agreement and proximity gap,*
3. *$(\ell, \delta, \frac{\ell n L + a}{q})$ mutual correlated agreement.*

Enabled by the above reductions, to prove an additive code C has correlated agreement, it suffices to prove list-decodability and curve-decodability of the code. In this work, and related works, we always work in the regimes where the codes in consideration are already known to be list-decodable with good parameters. Thus, the key innovation lies in establishing curve-decodability.

2.2 Subspace-Design Codes

We introduce notation and results from [16] that we will use.

▶ **Definition 15** (Subspace-Design Code). *For any function $\tau : \mathbb{N} \to \mathbb{R}_{\leq 1}$, an $\mathbb{F}_q$-additive code $C \subset (\mathbb{F}_q^s)^n$ is said to be a τ-subspace design code if for every $r \in \mathbb{N}$, and every $\mathbb{F}_q$-linear subspace A of C of dimension at most r, $\frac{1}{n}\sum_{i=1}^{n} \dim A_i \leq \dim(A) \cdot \tau(r)$, where $A_i = \{a \in A \mid a_i = 0\}$.*

▶ **Definition 16.** *For an additive code $C \subset \left(\mathbb{F}_q^s\right)^n$ and dimension r, let*

$$\sigma(r) := \max\left\{\mathbb{E}_{i\in[n]}\left[\frac{\dim V_i}{\dim V}\right] : V \subset C, \dim V = r\right\} \tag{4}$$

where $V_i = \{x \in V : x_i = 0\}$. In the message space with encoding maps $\mathrm{Enc}_i : \mathbb{F}_q^k \to \mathbb{F}_q^s$, we have

$$\sigma(r) := \max\left\{\mathbb{E}_{i\in[n]}\left[\frac{\dim(A \cap \ker(\mathrm{Enc}_i))}{\dim A}\right] : A \subset \mathbb{F}_q^k, \dim A = r\right\} \tag{5}$$

Following the notation of [16], we can define the monotone envelope $\tau(r) := \max\{\sigma(1), \ldots, \sigma(r)\}$. Observe that with this choice, C is by definition a τ-subspace design code.

▶ Remark 17 (Comparison to [9]). The paper [9] uses slightly different language; they say that C is *r-subspace designable if*, for every $d \in [r]$, $\sigma(d) \leq R + \frac{1}{nd}$. We recall that $\sigma(r) \geq R - r/sn$ always. Thus, having the subspace design property with "good" parameters means that we should have $\tau(d) \leq R + \eta$ for some "small" $\eta > 0$. [9] proved that random $\mathbb{F}_q$-additive codes $C \subset (\mathbb{F}_q^s)^n$ are r-subspace designable whenever $s = \Omega(rn)$.

Finally, we state a theorem from [16] which shows that any subspace-design code is curve-decodable.

▶ **Theorem 18** ([16, Theorem 4.7]). *Fix any integers a, ℓ and $\eta > 0$, and let $d = \lceil(\ell + 1)/\eta\rceil$. Then for any τ-subspace design code $C \subset (\mathbb{F}_q^s)^n$, C is $\left(\ell, 1 - \tau(d) - \eta, a, \frac{\eta a}{d+\eta}\right)$-curve-decodable.*

3 Row-span Constrained Local Properties

3.1 Generalizing Local Profiles

We begin by introducing some notation from [9, 27], and explaining how we generalize it to our row-span constrained versions. As described in Section 1.2, a *local profile* gives a set of coordinate-wise linear constraints that a "bad" witness matrix M might satisfy. This section states the threshold and transfer results needed later; their proofs appear in the full version [18].

▶ **Definition 19** (r-Local Profile, [27]). *Let $\mathbb{F}_q$ be a finite field of q elements and let n and r be positive integers. A tuple $\mathbf{V} = (V_1, \cdots, V_n) \in \mathcal{L}(\mathbb{F}_q^r)^n$ is called a r-local profile.*

Next, we define what it means for a code to *contain* a local profile (with a particular row-span).

▶ **Definition 20** (Containing a local profile, [27]). *A code $C \subset \mathbb{F}_q^n$ is said to* contain *a local profile $\mathbf{V}$ with span $U \in \mathcal{L}(\mathbb{F}_q^r)$ (often written "C* contains *$(\mathbf{V}, U)$") if there exists an $M \in \mathbb{F}_q^{n\times r}$ such that:*

- *each column of M is contained in C;*
- *the i-th row of M is contained in V_i; and*
- *the row-span of M is U.*

We call such an M a witness matrix*, and columns of M* witness columns*.*

In [27], an LCL property is given by a collection $\mathcal{F}$ of r-local profiles $\mathbf{V}$. Our key generalization is to also record the corresponding row-spans in the family. That is, $\mathcal{F}$ is no longer a collection of profiles $\mathbf{V}$; now it is a collection of *pairs* $(\mathbf{V}, U)$, where U constrains the row-span of a witness matrix.

▶ **Definition 21** (Row-span Constrained LCL Property)**.** *A* row-span constrained r-local LCL family $\mathcal{F}$ *is a collection of* r-local pairs $(\mathbf{V}, U)$ *where* $\mathbf{V} = (V_1, \ldots, V_n) \in \mathcal{L}(\mathbb{F}_q^r)^n$ *is an r-local profile and* $U \in \mathcal{L}(\mathbb{F}_q^r)$ *is the row-span constraint of the witness matrix.*

A code C contains *$\mathcal{F}$ if it contains some pair $(\mathbf{V}, U) \in \mathcal{F}$. It* avoids *$\mathcal{F}$ otherwise. We say that the* row-span constrained r-local property *given by $\mathcal{F}$ is the property of* avoiding *$\mathcal{F}$.*[7]

▶ Remark 22. Definition 21 generalizes the definition of an LCL property in [27], in the sense that they restrict the columns of their witness matrices M to be distinct; as they observe, this is the same as restricting the row-span of the witness matrices to lie in $\mathcal{L}_{\text{dist}}(\mathbb{F}_q^r)$, where $\mathcal{L}_{\text{dist}}(\mathbb{F}_q^r)$ denotes all subspaces U of $\mathbb{F}_q^r$ so that no two distinct coordinates $i, j \in [r]$ are identically equal on U.

Next, we define what it means for an $\mathbb{F}_q$-additive code to contain $(\mathbf{V}, U)$.

▶ **Definition 23** (Folded containment)**.** *Let $C \subset (\mathbb{F}_q^s)^n$ be an $\mathbb{F}_q$-additive code. For an r-local profile $\mathbf{V} = (V_1, \ldots, V_n) \in (\mathcal{L}(\mathbb{F}_q))^n$, define the* duplicated profile $\mathbf{V}^{\otimes s} \in (\mathcal{L}(\mathbb{F}_q))^{sn}$ *by*

$$V^{\otimes s}_{(i,j)} = V_i \tag{6}$$

for any $i \in [n]$ and $j \in [s]$. We say that C contains $(\mathbf{V}, U)$ if the "unfolded" version $C \subset \mathbb{F}_q^{sn}$ contains $(\mathbf{V}^{\otimes s}, U)$. Here, by the "unfolded code," we mean to embed $(\mathbb{F}_q^s)^n$ in $\mathbb{F}_q^{sn}$ in the natural way.

For a family $\mathcal{F}$ of pairs, define $\mathcal{F}^{\otimes s} = \{(\mathbf{V}^{\otimes s}, U) : (\mathbf{V}, U) \in \mathcal{F}\}$. Thus the $\mathbb{F}_q$-additive code $C \subset (\mathbb{F}_q^s)^n$ contains $\mathcal{F}$ if and only if the "unfolded" version $C \subset \mathbb{F}_q^{sn}$ contains $\mathcal{F}^{\otimes s}$.

▶ Remark 24. Note that $\mathcal{F}^{\otimes s}$ does not encode the same property as $\mathcal{F}$ applied to unfolded codes. For example, proximity is not preserved: being far as an $\mathbb{F}_q$-additive code over $\Sigma = \mathbb{F}_q^s$ does not mean it is far when we unfold, since we can change one coordinate per block of s. The onus is on the property proving step, to show for any additive code, the desired property profiles take the form (6) for every s.

Now, we define the potential function and the threshold of row-span constrained r-local LCL properties identically as [27], up to slightly modified notational conventions and normalization by n. We emphasize that these definitions are code-independent.

▶ **Definition 25** (Potential and Threshold, [27])**.** *For an r-local pair $(\mathbf{V}, U)$, and a real number R, define the* potential function

$$\phi_{\mathbf{V}}(U, R) \coloneqq (R-1)\dim U + \mathbb{E}_{i \in [n]} \dim(U \cap V_i). \tag{7}$$

[7] We note that other sources, like [27], define an r-local property to be the property of *containing* $\mathcal{F}$. Since we are concerned with the property of avoiding a family $\mathcal{F}$, we define it this way.

For $W \subsetneq U$, define

$$R_{\mathbf{V}}(U, W) \coloneqq 1 - \mathbb{E}_{i\in[n]}\left[\frac{\dim(U \cap V_i) - \dim(W \cap V_i)}{\dim U - \dim W}\right]. \tag{8}$$

Define threshold *of the r-local pair $(\mathbf{V}, U)$ as*

$$R_{\mathbf{V}}(U) \coloneqq \max_{W\subsetneq U} R_{\mathbf{V}}(U, W). \tag{9}$$

For a row-span constrained r-local LCL property, define

$$R_{\mathcal{F}} \coloneqq \min_{(\mathbf{V},U)\in\mathcal{F}} R_{\mathbf{V}}(U). \tag{10}$$

The only difference between the definition above and that in [27] is the fact that the minimum in (10) is over profile-subspace pairs $(\mathbf{V}, U) \in \mathcal{F}$ rather than over profiles $\mathbf{V} \in \mathcal{F}$.

Next, we unpack the definitions to interpret the threshold as a root of the potential function.

▶ **Lemma 26** (Threshold interpretation). *For every r-local profile $\mathbf{V}$, $W \subsetneq U \in \mathcal{L}(\mathbb{F}_q^r)$, and $R \in \mathbb{R}$,*

$$\phi_{\mathbf{V}}(U, R) - \phi_{\mathbf{V}}(W, R) = (\dim U - \dim W)(R - R_{\mathbf{V}}(U, W)). \tag{11}$$

Let $\mathcal{F}$ be a row-span constrained r-local LCL family and let $\eta \geq 0$. We observe that

1. *If $R \leq R_{\mathcal{F}} - \eta$, then for every $(\mathbf{V}, U) \in \mathcal{F}$ there exists $W \subsetneq U$ such that $\phi_{\mathbf{V}}(U, R) - \phi_{\mathbf{V}}(W, R) \leq -\eta$.*
2. *If $R \geq R_{\mathcal{F}} + \eta$, then there exists $(\mathbf{V}, U) \in \mathcal{F}$ such that for every $W \subsetneq U$, $\phi_{\mathbf{V}}(U, R) - \phi_{\mathbf{V}}(W, R) \geq \eta$.*

We also see that by our definition of profile containment for additive (rather than linear) codes, the threshold rate R_V is preserved for profiles taking tensor form in (6) as s changes. Intuitively, this is because $(U, \mathbf{V}, W)$ are all independent of s, so potential function $\phi_{\mathbf{V}^{\otimes s}}(U, R) = \phi_{\mathbf{V}}(U, R)$. Then, $R_{\mathbf{V}^{\otimes s}}(U, W)$ is simply its root. We verify this directly.

▶ **Proposition 27.** *Let $(\mathbf{V}, U)$ be any r-local pair on plain codes in $\mathbb{F}_q^n$ and let $W \subsetneq U$. Then, for every $s \in \mathbb{N}$, $R_{V^{\otimes s}}(U, W) = R_V(U, W)$. Consequently, for any row-span constrained local LCL family, $R_{\mathcal{F}} = R_{\mathcal{F}^{\otimes s}}$ is independent of s.*

3.2 Behavior Under Quotients

We next record how local profile containment behaves under quotient maps. Again, omitted proofs can be found in [18].

▶ Remark 28 (Comparison to [17]). In [17], the spaces V_i, U can lie in an arbitrary vector space over $\mathbb{F}_q$. In contrast, our definition of r-local pairs require $V_i, U \subset \mathbb{F}_q^r$ and is thus more concrete. However, this is at the expense of a less elegant quotient behavior: since our profiles are coordinate-dependent, a quotient by $W \subsetneq U$ is implemented by choosing a surjective linear map $\pi : \mathbb{F}_q^r \to \mathbb{F}_q^{r'}$ where $\ker \pi = W$. This is the same as quotienting by W and choosing coordinates on the quotient.

▶ **Definition 29** (Quotient profile). *Let $\mathbf{V} = (V_1, \ldots, V_n)$ be an r-local pair and let $\pi : \mathbb{F}_q^r \to \mathbb{F}_q^{r'}$ be a surjective linear map, so $r' \leq r$. Define the r'-local profile $\pi\mathbf{V} \coloneqq (\pi V_1, \ldots, \pi V_n)$. For an r-local pair $(\mathbf{V}, U)$ and surjective linear map π, if $W = \ker \pi \subsetneq U \subset \mathbb{F}_q^r$, then we say $(\pi\mathbf{V}, \pi U)$ is a quotient pair of $(\mathbf{V}, U)$. Then, the condition $W \subsetneq U$ is equivalent to $\pi U \neq 0$.*

While the locality is changed in a quotient pair which in particular means it is no longer in $\mathcal{F}$, we will see next that the potential, threshold, and code-containment are well-behaved.

▶ **Lemma 30** (Quotient Containment). *Suppose code C contains r-local pair $(\mathbf{V}, U)$ and $\pi : \mathbb{F}_q^r \to \mathbb{F}_q^{r'}$ is a surjective linear map such that $\pi U \neq 0$. Then, C contains $(\pi\mathbf{V}, \pi U)$.*

We remark that this definition of code containment works for all folding s.

▶ **Lemma 31** (Quotient Potential). *Let $\pi : \mathbb{F}_q^r \to \mathbb{F}_q^{r'}$ be a surjective linear map with kernel $W \subsetneq U \in \mathcal{L}(\mathbb{F}_q^r)$. Then, for any $R \in \mathbb{R}$, $\phi_{\pi\mathbf{V}}(\pi U, R) = \phi_{\mathbf{V}}(U, R) - \phi_{\mathbf{V}}(W, R)$.*

Finally, we present a useful corollary of the low-rate code profile containment via the quotient characterization. We emphasize that this is code-independent, and reduces the low-rate directions of the threshold proofs of various codes into simple code-specific counting.

▶ **Lemma 32** (Maximal Quotient). *If C contains an r-local pair $(\mathbf{V}, U)$ and $R \leq R_{\mathbf{V}}(U) - \eta$ for some $R, \eta \geq 0$, then there exists a surjective linear map $\pi : \mathbb{F}_q^r \to \mathbb{F}_q^{r'}$ such that*

- *$W \coloneqq \ker \pi \subsetneq U$,*
- *C contains r'-local pair $(\pi\mathbf{V}, \pi U)$,*
- *$\phi_{\pi\mathbf{V}}(\pi U, R) \leq -\eta \dim \pi U$.*

Moreover, we can choose π such that $\phi_{\pi\mathbf{V}}(U', R) \leq -\eta \dim U'$ for all nonzero subspaces $U' \subset \pi U$.

3.3 Thresholds for Random Ensembles of Codes

In this subsection, we state fixed-pair and family-level threshold results for the random ensembles considered here; omitted proofs can be found in [18]. The quantity $R_{\mathbf{V}}(U)$ is the fixed-pair threshold, and a union bound over pairs gives the corresponding statement for a row-span constrained LCL family $\mathcal{F}$.

3.3.1 Random Linear Codes

▶ **Lemma 33.** *Let $(\mathbf{V}, U)$ be an r-local pair, let $\mathcal{M}_{\mathbf{V}}(U)$ be the set of matrices $M \in \mathbb{F}_q^{n \times r}$ with row-span U that satisfy $\mathbf{V}$, and let $\mathcal{M}^{\star}_{\mathbf{V}}(U)$ be those with row-span contained in U. For any $R \in \mathbb{R}$, $|\mathcal{M}_{\mathbf{V}}(U)| \leq |\mathcal{M}^{\star}_{\mathbf{V}}(U)| = q^{n((1-R)\cdot \dim U + \phi_{\mathbf{V}}(U,R))}$.*

▶ **Theorem 34** (Fixed-Pair Random Linear Code Threshold). *Let $(\mathbf{V}, U)$ be an r-local pair and let $C \subset \mathbb{F}_q^n$ be a random linear code of rate R.*

1. *If $R \leq R_{\mathbf{V}}(U) - \eta$ for some $\eta > 0$, then $\mathbb{P}(C \text{ contains } (\mathbf{V}, U)) \leq q^{-\eta n}$.*
2. *If $R \geq R_{\mathbf{V}}(U) + \eta$ for some $\eta > 0$, then $\mathbb{P}(C \text{ contains } (\mathbf{V}, U)) \geq 1 - q^{r^2 - \eta n}$.*

The low-rate direction (1) will essentially follow from Lemma 32 and a few simple lemmas that we state first.

▶ **Lemma 35** ([27, Lemma 4.1]). *If $C \subset \mathbb{F}_q^n$ is an RLC of rate R, then for any $M \in \mathbb{F}_q^{n \times r}$*

$$\mathbb{P}(M_{\star j} \subset C \,\forall\, j \in [r]) = q^{(R-1)n \cdot \mathrm{rank}(M)} \tag{12}$$

The idea behind Lemma 35 is to view C as the kernel of $(1-R)n$ many linear constraints in $\mathbb{F}_q^n$ which column-span of M needs to satisfy. Each of $\mathrm{rank}(M)$ basis vectors satisfies them with probability $q^{-(1-R)n}$. We note that this is the only RLC-specific ingredient we use.

Combining with Lemma 33, we obtain the following corollary, which intuitively explains why $\phi_{\mathbf{V}}(U, R)$ characterizes the containment of $(\mathbf{V}, U)$ in a random linear code of rate C.

▶ **Corollary 36.** *The expected number of witnesses matrices M for the containment of an r-local pair $(\mathbf{V}, U)$ in a random linear code C with rate $R \in [0,1]$ is at most $q^{n\phi_{\mathbf{V}}(U,R)}$.*

With these lemmas, we deduce Theorem 34.

Proof of Theorem 34. For the low-rate case (1), if C contains $(\mathbf{V}, U)$, then by Lemma 32, there is a surjective linear map $\pi = \pi_{(\mathbf{V},U)} : \mathbb{F}_q^r \to \mathbb{F}_q^{r'}$ such that C contains $(\pi\mathbf{V}, \pi U)$ and $\phi_{\pi\mathbf{V}}(\pi U, R) \le -\eta$. By a union bound and Corollary 36,

$$\mathbb{P}(C \text{ contains } (\mathbf{V}, U)) \le \mathbb{P}(C \text{ contains } (\pi\mathbf{V}, \pi U)) \le q^{n\phi_{\pi\mathbf{V}}(\pi U, R)} \le q^{-\eta n}. \tag{13}$$

For the high-rate case (2), we know that $R \ge R_{\mathbf{V}}(U, W) + \eta$ for every $W \subsetneq U$. Then, $\phi_{\mathbf{V}}(U, R) \ge \phi_{\mathbf{V}}(W, R) + \eta$ for all $W \subsetneq U$. Let random variable X_W be the number of witnesses matrices M for the containment by C of an r-local pair $(\mathbf{V}, W)$. By Corollary 36, we know that

$$\mathbb{E}[X_W] \le q^{n\phi_{\mathbf{V}}(W,R)} \tag{14}$$

Now, let us fix any code C of rate $R \in [0,1]$ and consider matrices $\mathcal{M}^{\star}_{\mathbf{V}}(U)$ that satisfies $\mathbf{V}$ and has row-span contained in U. By Lemma 33, we know that

$$|\mathcal{M}^{\star}_{\mathbf{V}}(U)| = q^{n((1-R)\cdot \dim U + \phi_{\mathbf{V}}(U,R))}. \tag{15}$$

Now, for any realization of C, requiring each column of M to lie in C imposes at most $(1-R)n \dim U$ independent constraints, since C has codimension $(1-R)n$ and the row-span is contained in U. Therefore, the number of $M \in \mathcal{M}^{\star}_{\mathbf{V}}(U)$ contained in C is

$$\sum_{W \in \mathcal{L}(U)} X_W \ge |\mathcal{M}^{\star}_{\mathbf{V}}(U)| q^{(R-1)n \dim U} = q^{n\phi_{\mathbf{V}}(U,R)} \tag{16}$$

deterministically for every realization C. Now, C contains $(\mathbf{V}, U)$ if and only if $X_U > 0$, so

$$\begin{aligned}
\mathbb{P}(C \text{ does not contain } (\mathbf{V}, U)) &= \mathbb{P}(X_U = 0) \\
&\le \mathbb{P}\left(\sum_{W \subsetneq U} X_W \ge q^{n\phi_{\mathbf{V}}(U,R)} \right) \\
&\le \frac{\sum_{W \subsetneq U} \mathbb{E}[X_W]}{q^{n\phi_{\mathbf{V}}(U,R)}} \\
&\le \sum_{W \subsetneq U} q^{n\phi_{\mathbf{V}}(W,R) - n\phi_{\mathbf{V}}(U,R)} \\
&\le |\mathcal{L}(U)| q^{-\eta n}
\end{aligned} \tag{17}$$

where we apply Markov's inequality and (14). Now, the conclusion follows $|\mathcal{L}(U)| \le q^{r^2}$. ◀

We now lift Theorem 34 to the whole row-span constrained LCL family $\mathcal{F}$.

▶ **Corollary 37** (Random Linear Code Threshold)**.** *Let $\mathcal{F}$ be a row-span constrained r-local property and let $C \subset \mathbb{F}_q^n$ be a random linear code of rate R.*

1. *If $R \le R_{\mathcal{F}} - \eta$ for some $\eta > 0$, then $\mathbb{P}(C \text{ contains } \mathcal{F}) \le |\mathcal{F}| q^{-\eta n}$.*
2. *If $R \ge R_{\mathcal{F}} + \eta$ for some $\eta > 0$, then $\mathbb{P}(C \text{ contains } \mathcal{F}) \ge 1 - q^{r^2 - \eta n}$.*

Therefore, when $|\mathcal{F}| = q^{o(n)}$[8], we know that $R_{\mathcal{F}}$ is the threshold for RLCs for large n and q: RLCs of rate less than $R_{\mathcal{F}}$ avoid $\mathcal{F}$ with high probability; RLCs of rate greater than $R_{\mathcal{F}}$ contain $\mathcal{F}$ with high probability.

[8] Some previous literature, e.g. [27], call such $\mathcal{F}$ *reasonable*

3.3.2 Random Reed-Solomon Codes

We next record the analogue of the low-rate local threshold Corollary 37(1) for random Reed-Solomon code: if the rate is below the threshold of a row-span constrained LCL family, the random Reed-Solomon code is unlikely to contain the family. We use the following result from [27] as a black box.

▶ **Lemma 38** ([27, Proposition 6.1]). *Let $n \le q$ with q a prime power, and let $r \in \mathbb{N}$. Let $\mathbf{V} = (V_1, \cdots, V_n)$ be an r-local profile, $U \in \mathcal{L}(\mathbb{F}_q^r)$, and let $0 \le R \le 1$ such that for all $U' \in \mathcal{L}(U)$, $\phi_{\mathbf{V}}(U', R) \le -\varepsilon \cdot \dim U'$. Then, with probability taken over uniformly random $\alpha_1, \ldots, \alpha_n \in \mathbb{F}_q$, we have*

$$\mathbb{P}\big(C = \mathsf{RS}_{\mathbb{F}_q}(\alpha_1, \ldots, \alpha_n, k) \text{ contains } V \text{ with span } U \neq \{0\}\big) \le (2^r - 1)\left(\frac{(4r)^{4r} k}{\varepsilon q}\right)^{\varepsilon n / 2r}.$$

▶ **Corollary 39** (Random Reed-Solomon Code Threshold: Low Rate Direction). *Let $\mathcal{F}$ be a row-span constrained r-local property and let $C \subset \mathbb{F}_q^n$ be a random Reed-Solomon code of rate R. If $R \le R_{\mathcal{F}} - \eta$ for some $\eta > 0$, then*

$$\mathbb{P}(C \text{ contains } \mathcal{F}) \le |\mathcal{F}|(2^r - 1)\left(\frac{(4r)^{4r} R n}{\eta q}\right)^{\eta n / 2r} \tag{18}$$

3.3.3 Random LDPCs (Gallager's Ensemble)

We next record the analogue of the low-rate local threshold Corollary 37(1) and Corollary 39 for random LDPC codes drawn from Gallager's Ensemble (Definition 7).

There is one important difference from random linear codes. For RLCs, the probability that a fixed matrix M is contained in the code is exactly $q^{(R-1)n \operatorname{rank}(M)}$ by Lemma 35. For LDPC codes C, this exact identity is false. Instead, [28] proves that, after conditioning on the usual good-distance event defined for $C = \mathsf{RLDPC}(n, q, s, R)$ as

$$\mathsf{Good} := \left\{\Delta(C) \ge \frac{1}{2} h_q^{-1}(1 - R)\right\}, \tag{19}$$

then C contains any fixed matrix with essentially the same probability as a random linear code, up to a factor $q^{\varepsilon n}$. This is the only LDPC-specific input we need.

We first recall the lemma from [28] saying that Good happens with high probability.

▶ **Lemma 40** ([28, Theorem 2.14]). *For any finite field $\mathbb{F}_q$ and $R \in [0, 1 - 1/q)$, there exists $s_0 = s_0(R, q)$ such that for every $s > s_0$, with probability over $C = \mathsf{RLDPC}(n, q, s, R)$, we have $\mathbb{P}(\mathsf{Good}) := \mathbb{P}\big(\Delta(C) \ge \frac{1}{2} h_q^{-1}(1 - R)\big) \ge 1 - o_{n\to\infty}(1)$.*

The next lemma is the fixed-pair containment estimate for row-span constrained local profiles. This lemma follows [28]; we restate it in our framework and refer to the full version [18] for the proof.

▶ **Lemma 41** (RLDPCs containing local profiles). *For any $\varepsilon, R \in (0, 1)$, positive integer r, finite field $\mathbb{F}_q$, there exists an $s_0 = s_0(\varepsilon, r, R, q)$ such that the following holds for all odd $s > s_0$ and sufficiently large n. Let $\mathbf{V} = (V_1, \ldots, V_n)$ be an r-local profile and let $U \in \mathcal{L}(\mathbb{F}_q^r)$. For $C = \mathsf{RLDPC}(n, q, s, R)$, $\mathbb{P}(C \text{ contains } (\mathbf{V}, U) | \mathsf{Good}) \le q^{n\phi_{\mathbf{V}}(U,R) + \varepsilon n}$, where $\mathsf{Good} := \big\{\Delta(C) \ge \frac{1}{2} h_q^{-1}(1 - R)\big\}$.*

The LDPC threshold statement differs from its RLC analogue only by conditioning on the good-distance event Good and by the additional $q^{\eta n/2}$ slack from Lemma 41. The complete derivation appears in the full version [18].

▶ **Theorem 42** (Fixed-Pair Random LDPC Threshold). *Let $(\mathbf{V}, U)$ be an r-local pair and let $C = \mathsf{RLDPC}(n, q, s, R)$ be a random LDPC code from Gallager's ensemble. Define the event* $\mathsf{Good} := \left\{\Delta(C) \geq \frac{1}{2} h_q^{-1}(1-R)\right\}$.

For every $R, \eta \in (0,1)$, positive integer r, and finite field $\mathbb{F}_q$, there exists $s_0 = s_0(\eta, r, R, q)$ such that for every odd $s > s_0$, the following holds for all sufficiently large n:

1. *If $R \leq R_{\mathbf{V}}(U) - \eta$, then $\mathbb{P}(C \text{ contains } (\mathbf{V}, U) | \mathsf{Good}) \leq q^{-\eta n/2}$, and so*

$$\mathbb{P}(C \text{ contains } (\mathbf{V}, U)) \leq q^{-\eta n/2} + o_{n\to\infty}(1). \tag{20}$$

2. *If $R \geq R_{\mathbf{V}}(U) + \eta$, then $\mathbb{P}(C \text{ contains } (\mathbf{V}, U) | \mathsf{Good}) \geq 1 - q^{r^2 - \eta n/2}$, and so*

$$\mathbb{P}(C \text{ contains } (\mathbf{V}, U)) \geq 1 - q^{r^2 - \eta n/2} - o_{n\to\infty}(1). \tag{21}$$

▶ Remark 43. Only part (1) of Theorem 42 is needed later; part (2) is recorded for completeness, and the proofs of both parts appear in the full version [18].

This should not be confused with a converse to the local-property transfer theorem for RLDPC codes ([28, Theorem 1.9]), which is false at that level of generality, as observed in [28]; our argument uses the additional linear coordinate-wise profile structure of row-span constrained LCL properties.

As before, the corresponding family-level statement is the following.

▶ **Corollary 44** (Random LDPC Code Threshold). *Let $\mathcal{F}$ be a row-span constrained r-local property and let $C = \mathsf{RLDPC}(n, q, s, R)$ be a random LDPC code from Gallager's ensemble (Definition 7). For every $R, \eta \in (0,1)$, positive integer r, and finite field $\mathbb{F}_q$, there exists $s_0 = s_0(\eta, r, R, q)$ such that for every odd $s > s_0$, the following holds for all sufficiently large n:*

1. *If $R \leq R_{\mathcal{F}} - \eta$, then $\mathbb{P}(C \text{ contains } \mathcal{F}) \leq |\mathcal{F}| q^{-\eta n/2} + o_{n\to\infty}(1)$*
2. *If $R \geq R_{\mathcal{F}} + \eta$, then $\mathbb{P}(C \text{ contains } \mathcal{F}) \geq 1 - q^{r^2 - \eta n/2} - o_{n\to\infty}(1)$*

3.4 Threshold for Subspace Design Codes

Informally, for ordinary r-local properties where every row-span $U \in \mathcal{L}_{\text{dist}}(\mathbb{F}_q^r)$ is permitted for each profile $\mathbf{V}$, [9, Theorems 3.1, 4.2] shows that the threshold of containing $\mathbf{V}$ is dictated by $\tau(r)$ versus $R_{\mathbf{V}}$. For good subspace design codes, like folded Reed-Solomon codes, we have $\tau(r) \approx R$, which means that good subspace design codes and random linear codes share the same threshold.

We generalize these results to row-span constrained local properties. We emphasize that the transfer works at the level of any pair $(\mathbf{V}, U)$ via the following theorem.

▶ **Theorem 45** (Fixed-Pair Subspace Design Code Threshold). *Let $(\mathbf{V}, U)$ be an r-local pair.*

1. *Let $C \subset (\mathbb{F}_q^s)^n$ be an additive τ-subspace design code. If $\tau(r) < R_{\mathbf{V}}(U)$, then C does not contain $(\mathbf{V}, U)$.*
2. *For any $\eta > 0$, there exists a τ-subspace design additive code $C \subset (\mathbb{F}_q^s)^n$ with $\tau(r) \leq R_{\mathbf{V}}(U) + \eta$ that contains $(\mathbf{V}, U)$.*

The statement (1) in Theorem 45 essentially follows from Lemma 32 and the subspace design condition.

Proof of Theorem 45(1). Suppose $\tau(r) \leq R_{\mathbf{V}}(U) - \eta$, then by Lemma 32 there exists surjective linear map $\pi : \mathbb{F}_q^r \to \mathbb{F}_q^{r'}$ such that $\phi_{\pi\mathbf{V}}(\pi U, \tau(r)) < 0$ and C contains $(\pi\mathbf{V}, \pi U)$. The latter implies the existence of a witness matrix M. Let the columns of the witness matrix M for $(\pi\mathbf{V}, \pi U)$ be $c_j = \text{Enc}(a_j)$ and define the message subspace $A := \text{span}(a_j)$. Since the encoder is injective and the witness matrix has row-span πU, $d := \dim A = \dim(\pi U)$.

For each coordinate $i \in [n]$, the image $\mathrm{Enc}_i(A) \subset \mathbb{F}_q^s$ is the column span of the i-th "block" of the witness matrix. The rows of that block lie in $\pi U \cap \pi V_i$, hence

$$\dim(\pi U \cap \pi V_i) \geq \dim \mathrm{Enc}_i(A) = \dim A - \dim(A \cap \ker(\mathrm{Enc}_i)). \tag{22}$$

where the equality follows from rank-nullity. Averaging over i and applying the subspace design condition Definition 15 with $d = \dim A \leq r$, we obtain that

$$d - \mathbb{E}_{i\in[n]} \dim(\pi U \cap \pi V_i) \leq \mathbb{E}_{i\in[n]} \dim(A \cap \ker(\mathrm{Enc}_i)) \leq \tau(r)d. \tag{23}$$

Rearranging gives $\phi_{\pi\mathbf{V}}(\pi U, \tau(r)) \geq 0$, a contradiction. Thus, C does not contain $(\mathbf{V}, U)$. ◀

For the statement (2) in Theorem 45, we use the following theorem from [9] that shows RLCs are good subspace design codes when viewed as an $\mathbb{F}_q$-additive code with alphabet $\mathbb{F}_q^s$.

▶ **Theorem 46** ([9, Theorem 4.1]). *Fix any $\eta > 0$. A random $\mathbb{F}_q$-additive code $C \subset (\mathbb{F}_q^s)^n$ with rate $R = k/sn$ satisfies*

$$\mathbb{P}(\tau(r) \leq R + \eta) \geq 1 - rq^{-\eta srn + 3(r^2+1)n}. \tag{24}$$

Proof of Theorem 45(2). Fix $\eta > 0$ and let $R = R_{\mathbf{V}}(U) + \eta/2$. For sufficiently large s, we know by Theorem 46 that, for a random $\mathbb{F}_q$-additive code $C \subset (\mathbb{F}_q^s)^n$ of rate R,

$$\mathbb{P}\Big(\tau(r) \leq R_{\mathbf{V}}(U) + \eta = R + \frac{\eta}{2}\Big) \geq 1 - o_{s\to\infty}(1), \tag{25}$$

On the other hand, $R = R_{\mathbf{V}}(U) + \eta/2 = R_{\mathbf{V}^{\otimes s}}(U) + \eta/2$ by Proposition 27. By Theorem 34,

$$\mathbb{P}(C \text{ contains } (\mathbf{V}, U)) = \mathbb{P}(\text{unfolded } C \text{ contains } (\mathbf{V}^{\otimes s}, U)) \geq 1 - q^{r^2 - \eta sn/2} = 1 - o_{s\to\infty}(1). \tag{26}$$

Therefore, we can pick sufficiently large s such that with probability $2/3$, C contains $(\mathbf{V}, U)$ and is a τ-subspace design code with $\tau(r) \leq R_{\mathbf{V}}(U) + \eta$. This proves (2). ◀

▶ Remark 47. Compared to [9, Theorem 4.2], we take the subspace design parameter d in $\tau(d)$ to be $d = r$ for simplicity.

We can obtain analogous threshold statements for $R_{\mathcal{F}}$ by taking the minimum over $\mathcal{F}$.

▶ **Corollary 48** (Subspace Design Code Threshold). *Let $\mathcal{F}$ be any row-span constrained r-local LCL family. Then*

1. *Let $C \subset (\mathbb{F}_q^s)^n$ be an additive τ-subspace design code. If $\tau(r) < R_{\mathcal{F}}$, then C avoids $\mathcal{F}$.*
2. *For any $\eta > 0$, there exists a τ-subspace design additive code $C \subset (\mathbb{F}_q^s)^n$ with $\tau(r) \leq R_{\mathcal{F}} + \eta$ that contains $\mathcal{F}$.*

4 Curve-Decoding as a Row-Span Constrained LCL Property

Recall the definition of curve-decoding:

▶ **Definition 10** (Curve-Decodability). *An additive code $C \subset \Sigma^n$ is (ℓ, δ, a, b) curve-decodable if for every $u_0, u_1, \cdots, u_\ell \in \Sigma^n$, all functions $f : \mathbb{F}_q \to C$, whenever the set $A = \Big\{\alpha \in \mathbb{F} : \Delta\big(\sum_{j=0}^{\ell} u_j \alpha^j, f(\alpha)\big) \leq \delta\Big\}$ has at least a elements, there exist $c_0, c_1, \cdots, c_\ell \in C$ such that $\Big|\Big\{\alpha \in A : f(\alpha) = \sum_{j=0}^{\ell} c_j \alpha^j\Big\}\Big| \geq b$.*

As observed in [16] and discussed in Section 1.2, curve-decoding does not seem to fit immediately into the LCL framework. This section states its exact casting as a *row-span constrained* LCL property and refers to the full version [18] for the proof. Before we describe the correct row-span constraint, we define the degree-ℓ Reed-Solomon evaluation subspace on B by

$$\mathrm{RS}_\ell(B) \coloneqq \{(p(\alpha))_{\alpha\in B} : p \in \mathbb{F}_q[x],\ \deg p \le \ell\} \subset \mathbb{F}_q^B.$$

Thus $\mathrm{RS}_\ell(B)$ is the space of scalar degree-ℓ evaluation patterns on the parameter set B.

▶ **Definition 49** (Curve-free Subspaces). *Let $A \subset \mathbb{F}_q$. A subspace $U \in \mathcal{L}(\mathbb{F}_q^A)$ is (ℓ, A, b)* curve-free *if $\pi_B(U) \not\subset \mathrm{RS}_\ell(B)$ for every $B \in \binom{A}{b}$, where $\pi_B : \mathbb{F}_q^A \to \mathbb{F}_q^B$ denote coordinate restriction to B.*

For this definition to be non-trivial, we assume $\ell + 1 \le b \le |A|$. Now, we observe the following lemma, which translates (ℓ, A, b) curve-freeness of the row-span of a matrix to the condition that no b columns lie on a degree-ℓ curve; see [18] for the proof.

▶ **Lemma 50.** *Let $B \subset A \subset \mathbb{F}_q$ and let N be a positive integer.*[9] *Fix a matrix $M \in \mathbb{F}_q^{N\times A}$ with row-span $U \in \mathcal{L}(\mathbb{F}_q^A)$. Then, $\pi_B(U) \subset \mathrm{RS}_\ell(B)$ if and only if there exists a degree-ℓ curve $g : \mathbb{F}_q \to \mathbb{F}_q^N$ such that $g(\alpha) = M_{\star\alpha}$ for every $\alpha \in B$.*

Observe that latter condition is exactly the kind of codeword condition we wish to impose on columns of witness matrices for the failure of (ℓ, δ, a, b) curve-decoding. Lemma 50 gives an equivalent row-span constraint. We make this more formal below.

▶ **Corollary 51.** *Let $A \subset \mathbb{F}_q$ and let $M \in \mathbb{F}_q^{N\times A}$ be a matrix with row-span U whose columns lie in a linear code $C \subset \mathbb{F}_q^N$. If $\ell < b \le |A|$, then U is (ℓ, A, b) curve-free if and only if no b columns of M lie on a degree-ℓ "codeword curve." (That is, if and only if there is no curve $c(x) = \sum_{i=0}^{\ell} c_i x^i$ for $c_i \in C$ and no set $B \in \binom{A}{b}$ so that $c(\alpha) = M_{\star\alpha}$ for all $\alpha \in B$.)*

We now cast curve-decoding as a row-span constrained LCL property, thereby bypassing the notion of $\bigvee$-decodability from [16], and the parameter losses that arose from it.

▶ **Theorem 52** (Locality of curve-decoding). *Let $\ell, a, b \in \mathbb{N}$ with $\ell + 1 \le b \le a \le q$ and let $\delta \in (0, 1)$. Then there exists a row-span constrained a-LCL family $\mathcal{F}$ with $|\mathcal{F}| \le q^{a+a^2} 2^{an}$ such that every $\mathbb{F}_q$-additive code C is not (ℓ, δ, a, b) curve-decodable if and only if C contains $\mathcal{F}$.*

Proof. Fix indexing sets $A \in \binom{\mathbb{F}_q}{a}$ and $I_\alpha \subset [n]$ with $|I_\alpha| \ge (1-\delta)n$ for each $\alpha \in A$. For each choice of $A, \{I_\alpha\}_{\alpha\in A}$, we will define an r-local profile $\mathbf{V} = \mathbf{V}(A, \{I_\alpha\}_{\alpha\in A}) = (V_1, \ldots, V_n)$ as follows. For each $i \in [n]$, let $A_i \coloneqq \{\alpha \in A : i \in I_\alpha\}$. Define

$$V_i \coloneqq \left\{y \in \mathbb{F}_q^A : (y_\alpha)_{\alpha\in A_i} \in \mathrm{RS}_\ell(A_i)\right\}. \tag{27}$$

Equivalently, $y \in V_i$ if there exists a polynomial $p \in \mathbb{F}_q[x]$ of degree at most ℓ such that $p(\alpha) = y_\alpha$ for every $\alpha \in A_i$. This is clearly a linear subspace of $\mathbb{F}_q^A$. Now define

$$\mathcal{F} \coloneqq \left\{(\mathbf{V}(A, \{I_\alpha\}_{\alpha\in A}), U) : A \in \binom{\mathbb{F}_q}{a},\ I_\alpha \in \binom{[n]}{\ge (1-\delta)n},\ U \in \mathcal{L}(\mathbb{F}_q^A) \text{ is } (\ell, A, b) \text{ curve-free}\right\}. \tag{28}$$

We show the bound on the size of $\mathcal{F}$: There are $\binom{q}{a} \le q^a$ choices for A, at most 2^n choices for each $I_\alpha \subset [n]$, and the number of choices of U is at most $|\mathcal{L}(\mathbb{F}_q^a)| \le q^{a^2}$.

Next, we prove that not being curve-decodable is equivalent to containing $\mathcal{F}$.

[9] Think of N as either the block length $N = n$ of a linear code $C \subset \mathbb{F}_q^n$; or the block length $N = sn$ of an "unfolded" $\mathbb{F}_q$-additive code $C \subset (\mathbb{F}_q^s)^n$, thought of as $C \subset \mathbb{F}_q^{sn}$.

Not curve-decodable ⇒ Contains $\mathcal{F}$. If $C \subset (\mathbb{F}_q^s)^n$ is not (ℓ, δ, a, b) curve-decodable, then there exists $A \in \binom{\mathbb{F}_q}{a}$, a degree-$\ell$ curve $u : \mathbb{F}_q \to (\mathbb{F}_q^s)^n$, and codewords $f(\alpha) \in C$ such that $\Delta(u(\alpha), f(\alpha)) \leq \delta$ for every $\alpha \in A$, but no degree-ℓ codeword curve passes through $f(\alpha)$ for b-many of α. For $\alpha \in A$, define the agreement set $I_\alpha \coloneqq \{i \in [n] : u(\alpha)_i = f(\alpha)_i\}$, so $|I_\alpha| \geq (1-\delta)n$. Form the matrix $M \in \mathbb{F}_q^{sn \times A}$ with columns $M_{\star\alpha} = f(\alpha) \in C$. Index the rows by $[n] \times [s]$ and let U be the row-span of M.

We check the local profile constraints. For any $(i, j) \in [n] \times [s]$, the corresponding row $M_{ij,\star} = (f(\alpha)_{ij})_{\alpha \in A}$. Since $f(\alpha)_{ij} = u(\alpha)_{ij}$ whenever $i \in I_\alpha$, we observe that $M_{ij,\star}$ agrees with a polynomial $x \mapsto u(x)_{ij}$ of degree at most ℓ on A_i, so $M_{ij,\star} \in V_i$ by the definition of V_i in (27).

By assumption, no b of the columns $f(\alpha)$ lie on a degree-ℓ codeword curve. By Corollary 51, the row-span U is (A, ℓ, b) curve-free. Hence M witnesses that C contains $(\mathbf{V}(A, \{I_\alpha\}_{\alpha \in A}), U) \in \mathcal{F}$.

Contains $\mathcal{F}$ ⇒ Not curve-decodable. Suppose C contains the a-local pair $(\mathbf{V}(A, \{I_\alpha\}_{\alpha \in A}), U)$ via witness matrix $M \in \mathbb{F}_q^{sn \times A}$. Let the columns of M be $f(\alpha) \in C$ for $\alpha \in A$.

We construct a degree-ℓ curve close to these codewords. For $(i, j) \in [n] \times [s]$ the row $M_{ij,\star}$ lies in V_i, so by definition (27) of V_i, there exists a polynomial u_{ij} of degree at most ℓ such that $u_{ij}(\alpha) = f(\alpha)_{ij}$ for every $\alpha \in A_i \coloneqq \{\alpha \in A : i \in I_\alpha\}$. Collecting these polynomials over all (i, j) defines a degree-ℓ curve $u : \mathbb{F}_q \to (\mathbb{F}_q^s)^n$. For each $\alpha \in A$, if $i \in I_\alpha$ so $\alpha \in A_i$, then $u_{ij}(\alpha) = f(\alpha)_{ij}$ for every $j \in [s]$. Hence, $u(\alpha)_i = f(\alpha)_i$ for all $i \in I_\alpha$. For every $\alpha \in A$, $|I_\alpha| \geq (1-\delta)n$, so $\Delta(u(\alpha), f(\alpha)) \leq \delta$.

Finally, since U is (A, ℓ, b) curve-free, Corollary 51 implies that no b of the columns $f(\alpha)$ lie on a degree-ℓ codeword curve. Together, u and $f(\alpha)$ witness that C is not (ℓ, δ, a, b) curve-decodable. ◀

We can plug in specific choices of parameters from Theorem 18 for which subspace design codes are curve-decodable, thereby obtaining a lower bound on the threshold rate via Corollary 48.

▶ **Corollary 53.** *Let $\delta, \eta \in (0, 1)$ and integers $\ell, a, b \in \mathbb{N}$ such that*

$$d \coloneqq \left\lceil \frac{\ell + 1}{\eta} \right\rceil \leq a \quad \text{and} \quad b \leq \frac{\eta a}{d + \eta}. \tag{29}$$

Let $\mathcal{F}$ be the row-span constrained a-local LCL family from Theorem 52, so avoiding $\mathcal{F}$ is equivalent to being (ℓ, δ, a, b) curve-decodable. Then, $R_{\mathcal{F}} \geq 1 - \delta - \eta$. Additionally, $|\mathcal{F}| \leq q^{a+a^2} 2^{an}$.

We conclude with a specialization for the common choice of curve-decoding parameters.

▶ **Corollary 54.** *Let $\ell \in \mathbb{N}$ and $\delta, \eta \in (0, 1)$. Define $a, b, d \in \mathbb{N}$ by*

$$d \coloneqq \left\lceil \frac{\ell + 1}{\eta} \right\rceil, \qquad b \coloneqq \left\lceil \frac{4\ell}{\eta} + \ell \right\rceil, \qquad a \coloneqq \left\lceil \frac{100\ell^2}{\eta^3} \right\rceil. \tag{30}$$

Let $\mathcal{F}$ be the row-span constrained a-local LCL family from Theorem 52, so avoiding $\mathcal{F}$ is equivalent to being (ℓ, δ, a, b) curve-decodable. Then $R_{\mathcal{F}} \geq 1 - \delta - \eta$ and $|\mathcal{F}| \leq q^{a+a^2} 2^{an}$.

5 Improved Proximity Gaps

Finally, we establish proximity gaps (as well as CA and MCA) for three ensembles of codes. For each ensemble, we use Corollary 54 to prove curve-decodability, then we combine this with list-decodability via Corollary 14. We record the final statements below, and refer the reader to [18] for proofs. We begin with a statement for random linear codes.

▶ **Theorem 55** (PG, CA, and MCA for Random Linear Codes). *Let $\ell \in \mathbb{N}$ and $\eta, \delta \in (0,1)$. Let $C \subset \mathbb{F}_q^n$ be a random linear code of rate $R \le 1 - \delta - 2\eta$. If $q \ge \exp(\Omega(\ell^2/\eta^4))$ and $n \ge \Omega(\ell^4/\eta^7)$, then with high probability:*

1. *For every $T \ge 1$, C is curve-decodable with parameters $\left(\ell, \delta, (T-1)\left\lceil \frac{1-R}{\eta} \right\rceil + O\left(\frac{\ell^2}{\eta^3}\right), T\right)$.*
2. *For every $m > 1$, C has correlated agreement, and hence proximity gap, with parameters $\left(\ell, \delta, \frac{\ell m \lceil (1-R)/\eta \rceil + O(\ell^2/\eta^3)}{q}, \frac{1}{m}\right)$.*
3. *C has mutual correlated agreement with parameters $\left(\ell, \delta, \frac{\ell n \lceil (1-R)/\eta \rceil + O(\ell^2/\eta^3)}{q}\right)$.*

Next, we state our main result for Random Reed-Solomon Codes.

▶ **Theorem 56** (PG, CA, and MCA for Random Reed-Solomon Codes). *Let $\ell \in \mathbb{N}$ and $\eta, \delta \in (0,1)$. Let $C \subset \mathbb{F}_q^n$ be a random Reed-Solomon code of rate $R \le 1 - \delta - 2\eta$. If $q \ge n \cdot \exp(\Omega(\ell^4/\eta^7))$ and $n \ge \Omega(\ell^4/\eta^7)$, then with high probability:*

1. *For every $T \ge 1$, C is curve-decodable with parameters $\left(\ell, \delta, (T-1)\left\lceil \frac{1-R}{\eta} \right\rceil + O\left(\frac{\ell^2}{\eta^3}\right), T\right)$.*
2. *For every $m > 1$, C has correlated agreement, and hence proximity gap, with parameters $\left(\ell, \delta, \frac{\ell m \lceil (1-R)/\eta \rceil + O(\ell^2/\eta^3)}{q}, \frac{1}{m}\right)$.*
3. *C has mutual correlated agreement with parameters $\left(\ell, \delta, \frac{\ell n \lceil (1-R)/\eta \rceil + O(\ell^2/\eta^3)}{q}\right)$.*

Finally, we state our result for random LDPC codes.

▶ **Theorem 57** (PG, CA, and MCA for Random LDPC Codes). *Let $\ell \in \mathbb{N}$ and $\eta, \delta \in (0,1)$. There exists $s_0 = s_0(\ell, \eta, \delta, q)$ such that the following holds for every odd $s > s_0$. Let $C = \mathsf{RLDPC}(n, q, s, R)$ be a random LDPC code from Gallager's ensemble with rate $R \le 1 - \delta - 2\eta$. If $q \ge \exp(\Omega(\ell^2/\eta^4))$ and n is sufficiently large, then with high probability:*

1. *For every $T \ge 1$, C is curve-decodable with parameters $\left(\ell, \delta, (T-1)\left\lceil \frac{2(1-R)}{\eta} \right\rceil + O\left(\frac{\ell^2}{\eta^3}\right), T\right)$.*
2. *For every $m > 1$, C has correlated agreement, and hence proximity gap, with parameters $\left(\ell, \delta, \frac{\ell m \lceil 2(1-R)/\eta \rceil + O(\ell^2/\eta^3)}{q}, \frac{1}{m}\right)$.*
3. *C has mutual correlated agreement with parameters $\left(\ell, \delta, \frac{\ell n \lceil 2(1-R)/\eta \rceil + O(\ell^2/\eta^3)}{q}\right)$.*

Abstract

We consider the problems of *learning* and *testing* real-valued convex functions over Gaussian space. Despite the extensive study of function convexity across mathematics, statistics, and computer science, its learnability and testability have largely been examined only in discrete or restricted settings – typically with respect to the Hamming distance, which is ill-suited for real-valued functions.

In contrast, we study these problems in high dimensions under the standard Gaussian measure, assuming sample access to the function and a mild smoothness condition, namely Lipschitzness. A smoothness assumption is natural and, in fact, necessary even in one dimension: without it, convexity cannot be inferred from finitely many samples. As our main results, we give:

- Learning Convex Functions: An agnostic proper learning algorithm for Lipschitz convex functions that achieves error ε using $n^{O(1/\varepsilon^2)}$ samples, together with a complementary lower bound of $n^{\mathrm{poly}(1/\varepsilon)}$ samples in the *correlational statistical query (CSQ)* model.
- Testing Convex Functions: A tolerant (two-sided) tester for convexity of Lipschitz functions with the same sample complexity (as a corollary of our learning result), and a one-sided tester (which never rejects convex functions) using $O(\sqrt{n}/\varepsilon)^n$ samples.

1 Introduction

Few mathematical ideas are as pervasive or as powerful as convexity: recall that a function $f : \mathbb{R}^n \to \mathbb{R}$ is *convex* if for every $x, y \in \mathbb{R}^n$ and $\lambda \in [0, 1]$, we have $f(\lambda x + (1 - \lambda)y) \leq \lambda f(x) + (1 - \lambda)f(y)$. The mathematics of convex functions has been intensively studied for over a century, and continues to be central to a number of theoretical and applied disciplines ranging from mathematical analysis to machine learning [68, 15]. Within mathematical programming, for example, convexity of the objective function often governs computational tractability; to quote Rockafellar [69], "the great watershed in optimization isn't between linearity and nonlinearity, but convexity and non-convexity."

This centrality of convexity motivates the following basic questions, which form the focus of this work:

How many samples are needed to *learn* a convex function?

How many samples are needed to *test* if a function $f : \mathbb{R}^n \to \mathbb{R}$ is essentially convex?

We study each of these questions through the lens of theoretical computer science, viewing the former as a problem in *learning theory* [48] and the latter in *property testing* [36, 7]. For these problems to be well-defined, we must first specify a distance metric between functions on $\mathbb{R}^n$. Throughout this work, we employ the $L^2(\gamma)$ distance where $\gamma = \gamma_n$ denotes the measure corresponding to the n-dimensional standard Gaussian distribution $N(0, I_n)$.

Unsurprisingly, given their fundamental nature, both problems have been studied previously:

- There is work in statistics [72, 40, 41, 61, 32] that deals with optimal rates for convex regression where the perspective is that the dimension is fixed, and the number of samples is very large (could be more than exponential) and the question is to study the error rate as the number of samples goes to infinity. This is different than the standard perspective in learning theory where we are interested to more exactly quantify the number of samples needed as a function of the dimension.
- Turning to the problem of *testing* convexity, prior work has largely concerned discrete or highly constrained settings. Much of this literature [65, 6, 63, 5, 4, 54] focuses on testing functions over finite domains or ranges under the Hamming distance, reflecting the field's early connections to complexity theory [13, 71]. A few works such as [6] extend this line of work to real-valued functions under L^p metrics, but still assume bounded range and full query access.

We refer the reader to Section 1.2 for a detailed discussion of related work on both testing and learning convex functions.

In this work, we study both *agnostic proper learning* and *(tolerant) testing* of convexity in high dimensions, in the statistically natural setting where one only has access to *samples* labeled by an unknown function f. The query-access model used extensively in property testing, while natural and powerful for applications to complexity theory [13, 71], is ill-suited to statistical problems. By contrast, sample-based access is the standard framework in settings such as empirical risk minimization, convex regression, and stochastic optimization, where functions are observed only through (possibly noisy) random samples rather than arbitrary queries [67, 51, 44, 14, 73, 39].

Before proceeding, we note that some smoothness assumption is essential for both problems: without any regularity, convexity cannot be meaningfully inferred from finitely many samples, even in one dimension. Accordingly, we restrict attention to *Lipschitz* functions – a natural and mild assumption also adopted in prior work on convex regression [61].

1.1 Our Results

We begin by introducing notation that will be used throughout the paper. Given a function $f \in L^2(\gamma)$, we will write $\mathrm{d}^L_{\mathrm{conv}}(f)$ for the $L^2(\gamma)$ distance of f to its nearest convex L-Lipschitz function. More formally,

$$\mathrm{d}^L_{\mathrm{conv}}(f) := \inf_{\substack{g:\mathbb{R}^n\to\mathbb{R} \\ g \text{ convex, } L\text{-Lipschitz}}} \|f-g\|_{L^2(\gamma)}\,,$$

where

$$\|f-g\|_{L^2(\gamma)} := \mathop{\mathbf{E}}_{\boldsymbol{x}\sim N(0,I_n)}\left[(f(\boldsymbol{x})-g(\boldsymbol{x}))^2\right]^{1/2}.$$

The $L^2(\gamma)$ metric is a standard choice in learning theory, property testing, and derandomization (see, for example, [52, 60, 78, 43, 53, 20, 22, 28, 23, 49, 26, 27], among many others).

Although we focus on learning and testing convex functions over Gaussian space, all of our techniques and results extend naturally to functions over $[0,1]^n$ under the uniform measure. We adopt the Gaussian setting as it is a more canonical model for studying real valued learning and testing problems.

1.1.1 Agnostic Proper Learning and Sample-Based Testing of Convex Functions

We construct an agnostic proper learning algorithm for Lipschitz convex functions with the following guarantees:

▶ **Theorem 1** (Agnostic proper learning of Lipschitz convex functions). *Let $\varepsilon, L > 0$ and suppose $f:\mathbb{R}^n\to\mathbb{R}$ is a L-Lipschitz function. There exists an algorithm which, given i.i.d. access to labeled samples $(\boldsymbol{x}, f(\boldsymbol{x}))$ where $\boldsymbol{x}\sim N(0,I_n)$, draws $n^{O(L^2/\varepsilon^2)}$ samples, runs in time $\exp(\widetilde{O}(nL^2/\varepsilon^2))$, and outputs a function $g\in L^2(\gamma)$ such that*

$$\|f-g\|_{L^2(\gamma)} \le \mathrm{d}^L_{\mathrm{conv}}(f)+\varepsilon\,.$$

Additionally, the function g is convex and L-Lipschitz.

Note that our learning algorithm is agnostic in the sense that it produces a nearly optimal (convex) hypothesis even if the input function f is arbitrarily far from convex, as long as it satisfies the Lipschitz condition.

Using the proof of the Theorem above and the "testing-via-learning" paradigm [37], we obtain a *tolerant* testing algorithm for Lipschitz convex functions:

▶ **Theorem 2** (Tolerant two-sided testing of Lipschitz convex functions). *Let $\varepsilon, \varepsilon_0, L \ge 0$ and suppose $f:\mathbb{R}^n\to\mathbb{R}$ is L-Lipschitz. There is an algorithm which, given i.i.d. labeled samples $(\boldsymbol{x}, f(\boldsymbol{x}))$ where $\boldsymbol{x}\sim N(0,I_n)$, draws $n^{O(L^2/\varepsilon^2)}$ samples, runs in time $\exp(\widetilde{O}(nL^2/\varepsilon^2))$, and has the following performance guarantee:*

- *If $\mathrm{d}^L_{\mathrm{conv}}(f)\le\varepsilon_0$, then it outputs "accept" with probability $9/10$;*
- *If $\mathrm{d}^L_{\mathrm{conv}}(f)\ge\varepsilon+\varepsilon_0$, then it outputs "reject" with probability $9/10$.*

In particular, setting $\varepsilon_0 = 0$ shows that for every fixed $\varepsilon > 0$, there exists an (essentially) $\exp(n)$-time algorithm that distinguishes Lipschitz convex functions from those that are ε-far (in $L^2(\gamma)$) from all Lipschitz convex functions. The "testing-via-learning" approach underlies

the best known sample-based testing algorithms for several other function classes including convex subsets of $\mathbb{R}^n$ [52, 20], monotone Boolean functions [17, 56, 58], and k-monotone Boolean functions [8].

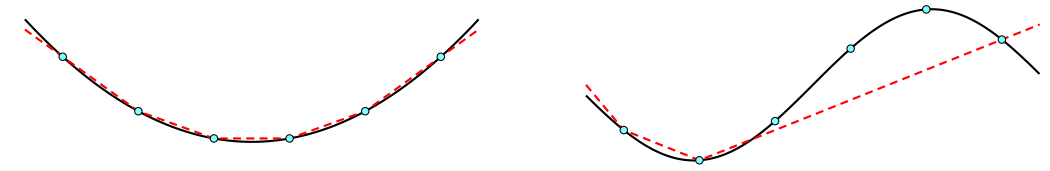
Our proof of Theorem 1 proceeds in two steps:

1. **Low-Degree Approximation.** We begin with a standard observation (see, for example, Theorem 4.1 of [2] or alternatively [46, 23]) that every L-Lipschitz function over Gaussian space is well-approximated in L_2 by a $O(L^2)$-degree polynomial. This allows us to learn such an approximation $\widetilde{f}$ from random samples via polynomial regression.
2. **Convex Regression.** We then *convexify* the learned polynomial $\widetilde{f}$ by projecting it onto the space of convex functions via convex regression [61]. This step is essential to obtain a *proper* learner – one whose output lies within the target class of convex L-Lipschitz functions. For our tolerant testing result, this is essential: the "testing via learning" reduction requires the learner to be proper.

Although the first step is conceptually straightforward, it has an independent implication:

> Any $O(1)$-Lipschitz function $f : \mathbb{R}^n \to \mathbb{R}$ can be learned – and hence tested – from $n^{O(1/\varepsilon^2)}$ random samples in an information-theoretic sense.

Note, however, that this guarantee is purely information-theoretic and does not yield a computationally efficient learning algorithm for the function class. In general, however, fitting a function from the target class to the observed samples may be computationally intractable. The main conceptual contribution of Theorem 1 is that we may combine standard low-degree learning with tools specific to convexity to obtain a *proper* learning algorithm.



Accordingly, the second step above introduces the main technical challenge: ensuring that the projection onto convex functions can be performed in finite (albeit exponential) time while preserving the $L^2(\gamma)$ error bound. Using queries to the learned low-degree approximation $\widetilde{f}$ on a sufficiently fine grid, we learn via convex regression a function $\widetilde{g}$ (namely a supremum of affine functions) which approximates $\widetilde{f}$ well on a discrete grid. Following [61], quadratic constraints in the convex regression ensure that $\widetilde{g}$ is L-Lipschitz. However, convex regression says nothing about the quality of the approximation over (continuous) Gaussian space, and the low-degree $\widetilde{f}$ need not inherit the Lipschitz behavior of f. To bridge this gap, we draw on Hermite analysis to show that the low-degree approximation $\widetilde{f}$ is L'-Lipschitz for some $L' \gg L$ over a large box in $\mathbb{R}^n$, where both L' and the size of the box can be controlled in terms of n, L and ε. This lets us recover an $L^2(\gamma)$ approximation guarantee for the convex $\widetilde{g}$ against the original target function f.

1.1.2 Lower Bounds for Learning Convex Functions

We complement this upper bound with corresponding *lower bounds* for learning convex functions. In the information-theoretic setting, we show that learning an arbitrary linear function to constant accuracy requires $\Omega(n)$ queries, not just samples; see the full version. We further strengthen this by proving a quantitatively sharper bound for algorithms in the *correlational statistical query* (CSQ) model:

▶ **Theorem 3** (CSQ lower bound; informal, see full version)**.** *Suppose algorithm A, given access to L-Lipschitz function $f : \mathbb{R}^n \to \mathbb{R}$ via correlational statistical queries, outputs a function $g \in L^2(\gamma)$ satisfying $\|f - g\|_{L^2(\gamma)} \le \mathrm{d}^L_{\mathrm{conv}}(f) + \varepsilon$. Then A requires $n^{\mathrm{poly}(L/\varepsilon)}$ correlational statistical queries with tolerance $n^{-\mathrm{poly}(L/\varepsilon)}$.*

CSQ algorithms only have access to the input f via approximate inner product queries of the form $\mathbf{E}_{\boldsymbol{z}\sim N(0,I_n)}[f(\boldsymbol{z})h(\boldsymbol{z})]$, for query h chosen by the algorithm; we formally define the CSQ model in the full version. This model captures, for example, gradient descent

(a) (b)

Figure 1 One-dimensional illustration of the empirical convex envelope (red, dashed) of (a) a convex function and (b) a far-from-convex function, with respect to the sampled points shown in cyan. (See Definition 19 for a precise definition).

with respect to squared loss, and the algorithm attaining our $n^{O(L^2/\varepsilon^2)}$ upper bound from Theorem 1 via low-degree approximation is a CSQ algorithm. Thus, Theorem 3 poses a barrier to improving upon the low-degree learning approach: any agnostic learning algorithm that fits the CSQ model, even if it uses properties of convex functions to do something more sophisticated than low-degree approximation, must use $n^{\mathrm{poly}(L/\varepsilon)}$ statistical queries.

Our proof relies on the construction of a large family $\mathcal{F}$ of functions with low pairwise-correlation, which is the standard approach for showing *weak learning* lower bounds in the CSQ model [12, 75, 33]. Additionally, we require each function in $\mathcal{F}$ to be non-trivially correlated with a convex Lipschitz function – namely a "projected ReLU", which is a function of the form $x \mapsto \mathrm{ReLU}(\langle x, u\rangle)$ for some $u \in \mathbb{S}^{n-1}$. This implies that an agnostic learning algorithm for convex functions gives a weak learner for $\mathcal{F}$, and yields our CSQ lower bound.

Our construction and proof strategy are inspired by and leverage the results of [30], who showed an $n^{\mathrm{poly}(1/\varepsilon)}$ lower bound for agnostically learning ReLUs under the Gaussian distribution using statistical queries. While one might hope to immediately conclude the same lower bound for agnostically learning convex functions in our model (since ReLUs are convex), the key difference is that in our setting the input must be Lipschitz, whereas [30] build their hard family of inputs from Boolean functions. We adapt their construction to our purposes via careful application of the Ornstein-Uhlenbeck noise operator P_t, which satisfies a few crucial properties for our application:

- It takes bounded functions into Lipschitz ones, so that from a hard input $f : \mathbb{R}^n \to \{\pm 1\}$, we may obtain a hard Lipschitz input $P_t f$.
- It satisfies the self-adjointness property $\langle P_t f, g\rangle = \langle f, P_t g\rangle$, which allows us to map the approximation quality of a learned hypothesis g for the Lipschitz input $P_t f$ into the approximation quality of hypothesis $P_t g$ for the hard input f.
- Lipschitz functions are stable under noise in the sense that $\|P_t f - f\|_2^2 = O(t)$, which informally implies that most of the "signal" in the reduction survives our application of noise.

1.1.3 One-Sided Testing of Lipschitz Convex Functions

Our final result is a *one-sided* testing algorithm for Lipschitz convex functions – that is, an algorithm which never rejects a Lipschitz convex function. In general, there can be dramatic separations between the complexity of one-sided and two-sided testing (cf. [37, §1.5]), and in particular, testing by learning is not a suitable approach to one-sided testing. Therefore, this goal requires us to exploit the properties of convex and Lipschitz functions in a different way. Our result is:

▶ **Theorem 4** (One-sided testing of Lipschitz convex functions). *Let $f : \mathbb{R}^n \to \mathbb{R}$ be L-Lipschitz, and let $\varepsilon \geq 0$. There is an algorithm, One-Sided-Tester (Algorithm 1), which, given access to i.i.d. labeled samples $(\boldsymbol{x}, f(\boldsymbol{x}))$ where $\boldsymbol{x} \sim N(0, I_n)$, makes $O(\sqrt{n}L/\varepsilon)^n$ draws, runs in time $(nL/\varepsilon)^{O(n)}$, and has the following performance guarantee:*

- *If f is convex, then One-Sided-Tester outputs "accept" with probability 1;*
- *If $\mathrm{d}^L_{\mathrm{conv}}(f) \geq \varepsilon$, then One-Sided-Tester outputs "reject" with probability $9/10$.*

Our tester operates by constructing an *empirical convex envelope* (cf. Definition 19) of the sampled function values, which can be viewed as the function analogue of the convex hull of a collection of points. Given random samples $(\boldsymbol{x}_i, f(\boldsymbol{x}_i))$, the tester checks whether f coincides with its empirical convex envelope at these points. If f is convex, this always holds; conversely, we show that if f is L-Lipschitz and ε-far from convex, then with sufficiently many samples the test will detect a violation with high probability. See Figure 1 for an illustration of the empirical convex envelope.

In particular, our analysis implies an associated *agnostic learning guarantee in $L^\infty(\gamma)$*: we show that when the input function f is an L-Lipschitz convex function, the empirical convex envelope learned by One-Sided-Tester uniformly approximates the convex envelope of f over all but an exponentially-small fraction of Gaussian space. Thus, the algorithm may also be viewed as a form of *uniform convex regression*.

1.2 Related Work

We briefly situate our results within the broader work on learning and testing convexity.

Learning Convex Functions

As discussed earlier, the statistical perspective for *convex regression* is interested in the error rate as the number of samples goes to infinity for fixed dimensions. This falls under the broader umbrella of *shape-constrained regression*. We refer the interested reader to [72, 40, 41, 61, 32] and the references therein for further background. By contrast, our results address the more general problem of *agnostic proper learning* from i.i.d. samples, with the goal of establishing PAC-style sample-complexity bounds rather than asymptotic error rates.

We note that low-degree approximation of Lipschitz functions over Gaussian space has been used a few times in the past; see, for example, [2, 46, 23]. Such approximations also are the source of $n^{\mathrm{poly}(1/\varepsilon)}$ sample-complexity bounds appearing in several agnostic learning problems beyond convexity, e.g., in the context of learning halfspaces [31, 57]. However, with the exception of [2], most of these works focus on Boolean-valued function classes rather than real-valued ones.

Approximation Theory

As indicated earlier in Section 1.1, our upper bounds for convexity testing follow from semi-agnostic learning algorithms for convex functions under the Gaussian L_2 distance. Related problems have been studied in approximation theory, both in the low-dimensional setting [74, 70] as well as in high-dimensions [45], with exponential-in-n sample lower bounds known for deterministic approximation under L^p distance [45].

More broadly, classical results in convex approximation typically focus on deterministic settings, approximating a convex function by piecewise-linear or polynomial surrogates and bounding the error in terms of smoothness or curvature (see, e.g., [29, 45]). Our setting differs in that we consider randomized, sample-based approximation under a fixed measure, leading to dimension-dependent but probabilistic guarantees.

Testing Convexity over Discrete Domains

The computational problem of recognizing convexity of quartic polynomials is known to be NP-hard [1]. (Deciding convexity of polynomials of odd-degree or quadratics is trivial, making degree 4 the first interesting case.) See [1] and the references therein for a history of the computational problem of recognizing *exact* convexity of functions. The relaxed problem of recognizing *approximate* convexity of functions has primarily been considered in the discrete setting. The study of testing convexity of functions $f : [N] \to \mathbb{R}$ under the Hamming distance was initiated by Parnas, Ron, and Rubinfeld [64], where convexity is defined as non-negativity of a discrete second-derivative. Their was later extended by Ben-Eliezer [5], who obtained improved quantitative bounds; by Pallavoor, Raskhodnikova, and Verma [63], who gave an improved bound parametrized by the size of the range of the function being tested; by Blais, Raskhodnikova, and Yaroslavtsev [11], who gave lower bounds on testing convexity of real-valued functions over the hypergrid $[N]^d$; and by Belovs, Blais, and Bommireddi [4], who gave upper and lower bounds on the number of queries required to test convexity of real-valued functions over various discrete domains including the discrete line, the "stripe" $[3] \times N$, and the hypergrid $[N]^d$. These results, however, do not have any bearing on this work due to differences in domain and choice of distance metric.

L^p Testing of Convexity

The work most closely related to ours is that of Berman, Raskhodnikova, and Yaroslavtsev [6], who study L^p testing of convexity of an unknown $f : [0,1]^n \to [0,1]$ where $[0,1]^n$ is endowed with the uniform measure. They provide tight bounds in the one-dimensional setting and exponential-in-n bounds for the high-dimensional case (see Corollary B.3 of [6]). Our results, in contrast, apply specifically to Lipschitz functions $f : \mathbb{R}^n \to \mathbb{R}$, giving polynomial-in-$n$ complexity algorithms for every fixed choice of the distance parameter ε. (We remark that our exponential-in-n algorithm from Theorem 4 has the additional property of being a tester with one-sided error, which does not follow from a black-box application of testing-by-learning.)

Although one might hope to relate the two settings, this connection does not appear to be straightforward. The two frameworks are best viewed as complementary: ours imposes regularity assumptions that enable polynomial dependence on n, whereas [6] addresses unrestricted (i.e., possibly highly irregular) albeit bounded functions at exponential cost. Indeed, assuming Lipschitzness or bounded gradient is the standard regularity condition in convex analysis, optimization, and high-dimensional learning, and thus provides a more natural setting for analytic property testing.

Testing Set Convexity

A different line of research considers testing convexity of high-dimensional sets (i.e., Boolean-valued indicator functions of subsets of $\mathbb{R}^n$). Rademacher and Vempala [66] established exponential-in-n upper bounds for testing set convexity under the Lebesgue measure; they also gave a strong lower bound against a simple "line" tester for convexity. The [66] lower bound was subsequently strengthened by Blais and Bommireddi [10]. For testing set convexity under the Gaussian measure, the best-known upper bound follows from the agnostic learning algorithm for convex sets due to Klivans, O'Donnell, and Servedio [52].

Strong lower bounds for sample-based testing under the Gaussian measure were established by Chen, Freilich, Servedio, and Sun [20], and the first lower bounds in the query model were obtained recently by Chen, De, Nadimpalli, Servedio, and Waingarten [21]. While our work shares conceptual and technical similarities with [52, 20, 21], there does not appear to be a

reduction or formal connection between the two settings. In particular, natural attempts to reduce testing convexity of functions to testing convexity of sets (such as mapping a function to its epigraph) fail to preserve the relevant distance measures, so neither problem appears to subsume the other.

Finally, beyond the Gaussian setting, the work of Black, Blais, and Harms [9] also considers consider testing and learning convex subsets of the ternary hypercube $\{0, \pm 1\}^n$.

1.3 Discussion

As evidenced above, convexity is a powerful and pervasive principle whose associated computational problems are notoriously challenging and enjoy long lines of study from a plethora of perspectives. We view the present work as a first step in posing and investigating the problems of learning and testing convex functions in the continuous setting from the perspective of learning theory and property testing. Our results establish that these problems are computationally feasible, albeit not at present with efficient algorithms, and suggest barriers to be tackled for overcoming this limitation: any agnostic learning algorithm with truly $\mathrm{poly}(n)$ sample complexity, beating the low-degree learning bound from Theorem 1, must not be a CSQ algorithm (Theorem 3); and any algorithm (for learning or testing) with subexponential running time must bypass the grid-based approaches of Theorems 1 and 4.

We conclude with a number of open directions suggested by our work.

Analogy with Boolean Monotonicity

Convexity is formally connected to the monotonicity of the gradient: in one dimension, a function is convex if and only if its derivative is monotone, and more generally, convexity corresponds to the monotonicity of the gradient map. This connection suggests a natural analogy between convexity and monotonicity, and one might hope that insights from the rich body of work on learning and testing monotone Boolean functions can inform the study of convex function learning and testing.

For *learning*, our results may at first appear considerably stronger than existing bounds for learning monotone Boolean functions. (Recall that the sample complexity of agnostically learning monotone Boolean functions over $\{0,1\}^n$ is $2^{\widetilde{O}(\sqrt{n})}$ [17].) However, this stems from the $O(1)$-Lipschitz assumption in our setting, which has no meaningful analog in the Boolean function setting. While all Boolean functions are technically $O(1)$-Lipschitz, the underlying metric geometry differs between the Boolean setting and Gaussian space: in the Boolean space (see, for example, [55]), the typical L_1 (Hamming) distance between points in dimension n is of order n while in the Gaussian space the typical distance is of order $\sqrt{n}$. So, at least in some sense, our polynomial agnostic learning algorithm does correspond to the results for learning monotone functions with $2^{\Theta(\sqrt{n})}$ samples.

As for *testing*, in the Boolean setting the analogous quantity to $\mathrm{d}_{\mathrm{conv}}$ is the *distance to monotonicity* $\mathrm{d}_{\mathrm{mon}}$, which has been extensively investigated in a rich line of work on monotonicity testing [38, 18, 50]. Classical Boolean monotonicity testers rely on upper bounds on $\mathrm{d}_{\mathrm{mon}}$ in terms of the *directed edge boundary*, and these structural relationships can be viewed as strengthenings of the classical edge-isoperimetric inequalities on the hypercube [59, 76].

This analogy raises a natural question: can $\mathrm{d}_{\mathrm{conv}}$ likewise give rise to structural inequalities that quantify the "non-convexity" of real-valued functions? Motivated by the role of the directed edge boundary in monotonicity testing, the following question suggests itself:

▶ **Question 5.** *Given an L-Lipschitz function $f : \mathbb{R}^n \to \mathbb{R}$, is*

$$\mathrm{d}_{\mathrm{conv}}(f) \leq \mathrm{poly}(n) \cdot \mathop{\mathbf{E}}_{\boldsymbol{x} \sim N(0,I_n)} \left[\left\| \nabla^2_- f(\boldsymbol{x}) \right\|_{\mathrm{op}} \right]$$

where $\nabla^2_- f(\boldsymbol{x})$ is the negative-definite part of $\nabla^2 f(\boldsymbol{x})$?

If true, such an inequality would likely imply a convexity tester based on random samples of (or queries simulating) the Hessian of f, mirroring how monotonicity testers – both in discrete and continuous settings – leverage local gradient information [50, 34]. Beyond its algorithmic implications, this inequality would also be of intrinsic geometric interest, as it would relate a *global* measure of non-convexity (namely, $\mathrm{d}_{\mathrm{conv}}(f)$) to *local* curvature data through the Hessian.

As a step toward understanding $\mathrm{d}_{\mathrm{conv}}$, we establish in the full version a quantitative relationship between $\mathrm{d}_{\mathrm{conv}}(f)$ and the negative degree-2 Hermite coefficients of f, which yields a lower bound on $\mathrm{d}_{\mathrm{conv}}(f)$ in terms of their magnitude.

We note that an independent line of work has identified an unexpected but powerful analogy between monotone Boolean functions and *convex subsets of Gaussian space* [24, 28, 25, 26, 27]. It is natural to ask which aspects of this correspondence extend further to the setting of convex functions over Gaussian space. As a first step in this direction, we note that [24] establishes a quantitative sharpening of Hu's correlation inequality for symmetric convex sets [47], in the spirit of Talagrand's quantitative correlation inequality [77].

Testing Lower Bounds

Since we are concerned with functions $f : \mathbb{R}^n \to \mathbb{R}$ whose outputs are real-valued, standard information-theoretic approaches to proving lower bounds become infeasible. A basic but significant obstacle – shared with many real-valued testing problems – is that each sample reveals a real number $f(x)$, which, at least naively, may contain an arbitrarily large amount of information. Presently, there is no general framework for establishing lower bounds for testing convexity of real-valued functions, even in the purely sample-based setting.

Therefore, we pose the following two questions on the true sample complexity of testing convexity of Lipschitz functions in the two-sided and one-sided error regimes. For two-sided testing, it is conceivable – again in analogy with monotonicity testing – that some polynomial dependence on n is unavoidable. We ask:

▶ **Question 6.** *Does testing convexity of 1-Lipschitz functions under the Gaussian distribution (with two-sided error) require $n^{\Omega(1)}$ samples? What if arbitrary queries are allowed?*

Even for one-sided testing algorithms, we currently lack any nontrivial lower bounds on the sample complexity of testing convexity. It is instructive to recall how an exponential lower bound is obtained for the analogous problem in the setting of *set* convexity [20]. In particular, Lemma 29 of [20] establishes that for sufficiently small constant c, if 2^{cn} points are drawn independently from $N(0, I_n)$, then with high probability no point lies in the convex hull of the others. Consequently, such a draw of samples is consistent with the indicator function of a convex set, and a one-sided sample-based tester cannot detect any violation of convexity.

The difficulty in our setting is that a sample with no witnessed violation of convexity need not be *consistent* with any L-Lipschitz function that is convex. In particular, a naive interpolation through the sampled points may fail to be $O(L)$-Lipschitz. Thus, it is not immediate that a one-sided tester must accept unless the sample explicitly contains a convexity violation. This leads to the following question:

▶ **Question 7.** *Is there a tester for convexity of* 1*-Lipschitz functions under the Gaussian distribution with one-sided error and sample complexity that is sub-exponential in* n*?*

Sample vs. Runtime Gaps

We note that while Theorem 1 achieves a sample complexity of $n^{O(1/\varepsilon^2)}$, its runtime remains exponential in n. An analogous gap long persisted for properly learning monotone Boolean functions from samples: the best-known sample complexity was $2^{\widetilde{O}(\sqrt{n})}$, whereas the best runtime was $2^{O(n)}$. Recent work by [56, 58] closed this gap, giving a $2^{\widetilde{O}(\sqrt{n})}$-time agnostic proper learner. It is natural to ask whether a similarly efficient proper learning algorithm exists for convex functions, potentially closing the gap between information-theoretic and computational efficiency in our setting as well.

Lower Bounds in the Full SQ Model

Our $n^{\mathrm{poly}(L/\varepsilon)}$ lower bound from Theorem 3 applies to correlational statistical query (CSQ) algorithms, a setting that already captures the algorithm attaining our $n^{O(L^2/\varepsilon^2)}$ upper bound. Recall that CSQ algorithms only have access to the input f via approximate inner product queries of the form $\mathbf{E}_{\boldsymbol{z}\sim N(0,I_n)}[f(\boldsymbol{z})h(\boldsymbol{z})]$. In contrast, the full SQ model allows approximate oracle access to $\mathbf{E}_{\boldsymbol{z}\sim N(0,I_n)}[q(\boldsymbol{z}, f(\boldsymbol{z}))]$ for general query functions $q(x, y)$.

In the (distribution-specific) setting of *Boolean* functions, the CSQ model is equivalent to the full SQ model [16], because SQ queries to Boolean functions may be simulated using correlational queries. However, the same is not true in the real-valued setting, where there exist separations between the CSQ and SQ models, for example for the problem of ReLU regression [42]. Indeed, proving lower bounds against SQ algorithms in the real-valued setting is a notoriously challenging problem; see [35, 19] and the discussion therein. We leave as an open question whether our $n^{\mathrm{poly}(L/\varepsilon)}$ CSQ lower bound can be extended to the full SQ model, or whether our problem witnesses a separation between these models.

Organization

In the rest of this paper, we outline the proofs of our main upper bound results – Theorems 1, 2, and 4. We defer proofs of technical lemmas and our lower bounds to the full version.

2 Preliminaries

We use boldfaced letters – such as $\boldsymbol{x}, \boldsymbol{f}, \boldsymbol{A}$ – to denote random variables (which may be real-valued, vector-valued, function-valued, or set-valued; the intended type will be clear from the context). We write $\boldsymbol{x} \sim \mathcal{D}$ to indicate that the random variable $\boldsymbol{x}$ is distributed according to the probability distribution $\mathcal{D}$. Throughout, $\mathbb{S}^{n-1} := \{x \in \mathbb{R}^n : \|x\|_2 = 1\}$ will denote the unit sphere in $\mathbb{R}^n$. We will write $B_p(r) \subseteq \mathbb{R}^n$ for the ℓ_p-ball of radius r, i.e.,

$$B_p(r) := \{x \in \mathbb{R}^n : \|x\|_p \leq r\}.$$

Hermite Analysis over Gaussian Space

Our notation and terminology follow Chapter 11 of [62]. We say that an n-dimensional *multi-index* is a tuple $\alpha \in \mathbb{N}^n$, and we define $|\alpha| := \sum_{i=1}^n \alpha_i$.

For $n \in \mathbb{N}_{>0}$, we write $L^2(\gamma_n)$ to denote the space of functions $f : \mathbb{R}^n \to \mathbb{R}$ that have finite second moment under the Gaussian distribution, i.e., $f \in L^2(\gamma_n)$ if

$$\|f\|^2_{L^2(\gamma_n)} := \mathop{\mathbf{E}}_{\boldsymbol{z} \sim N(0,I_n)} \left[f(\boldsymbol{z})^2\right] < \infty \,.$$

When the dimension n is clear from context, we will write $\gamma = \gamma_n$ instead. We view $L^2(\gamma)$ as an inner product space with

$$\langle f, g \rangle_{L^2(\gamma)} := \mathop{\mathbf{E}}_{\boldsymbol{z} \sim N(0,I_n)} [f(\boldsymbol{z}) g(\boldsymbol{z})] \,.$$

We will sometimes write $\langle f, g \rangle = \langle f, g \rangle_{L^2(\gamma)}$ for notational convenience. We recall the Hermite basis for $L^2(\gamma_1)$:

▶ **Definition 8** (Hermite basis). *The* Hermite polynomials $(h_j)_{j \in \mathbb{N}}$ *are the univariate polynomials defined as*

$$h_j(x) = \frac{(-1)^j}{\sqrt{j!}} \exp\left(\frac{x^2}{2}\right) \cdot \frac{d^j}{dx^j} \exp\left(-\frac{x^2}{2}\right).$$

In particular, we have

$$h_2(x) := \frac{x^2 - 1}{\sqrt{2}} \,. \tag{1}$$

The following fact is standard:

▶ **Fact 9** (Proposition 11.33 of [62]). *The Hermite polynomials $(h_j)_{j \in \mathbb{N}}$ form a complete, orthonormal basis for $L^2(\gamma_1)$. For $n > 1$ the collection of n-variate polynomials given by $(h_\alpha)_{\alpha \in \mathbb{N}^n}$ where*

$$h_\alpha(x) := \prod_{i=1}^{n} h_{\alpha_i}(x)$$

forms a complete, orthonormal basis for $L^2(\gamma_n)$.

Given a function $f \in L^2(\gamma)$ and $\alpha \in \mathbb{N}^n$, we define its *Hermite coefficient on* α as $\widehat{f}(\alpha) = \langle f, h_\alpha \rangle$. It follows that $f : \mathbb{R}^n \to \mathbb{R}$ can be uniquely expressed as

$$f = \sum_{\alpha \in \mathbb{N}^n} \widehat{f}(\alpha) h_\alpha$$

with the equality holding in $L^2(\gamma)$; we will refer to this expansion as the *Hermite expansion* of f. One can check that Parseval's and Plancharel's identities hold in this setting:

$$\langle f, f \rangle = \sum_{\alpha \in \mathbb{N}^n} \widehat{f}(\alpha)^2 \qquad \text{and} \qquad \langle f, g \rangle = \sum_{\alpha \in \mathbb{N}^n} \widehat{f}(\alpha) \widehat{g}(\alpha).$$

We recall the Gaussian Poincaré inequality (see, e.g., [3]):

▶ **Proposition 10.** *Suppose $f \in L^2(\gamma)$ is differentiable. Then*

$$\mathop{\mathbf{Var}}_{\boldsymbol{x} \sim N(0,I_n)} [f(\boldsymbol{x})] \leq \mathop{\mathbf{E}}_{\boldsymbol{x} \sim N(0,I_n)} \left[\|f(\boldsymbol{x})\|_2^2\right] .$$

3 Agnostic Proper Learning and Two-Sided Sample-Based Testing

Write $\mathcal{C}(L)$ for the class of convex, L-Lipschitz functions:

$$\mathcal{C}(L) := \{f : \mathbb{R}^n \to \mathbb{R} : f \text{ is } L\text{-Lipschitz and convex}\}.$$

Recall our notation for the L_2 distance to the set of convex L-Lipschitz functions, which we may now write as

$$\mathrm{d}^L_{\mathrm{conv}}(f) = \inf_{g \in \mathcal{C}(L)} \|f - g\|_{L^2(\gamma)}.$$

By convention, given a function $f : \mathbb{R}^n \to \mathbb{R}$, by "sample from f" we mean a sample of the form $(\boldsymbol{x}, f(\boldsymbol{x}))$ where $\boldsymbol{x} \sim N(0, I_n)$. The main result in this section is the following.

▶ **Theorem 1** (Agnostic proper learning of Lipschitz convex functions). *Let $\varepsilon, L > 0$ and suppose $f : \mathbb{R}^n \to \mathbb{R}$ is a L-Lipschitz function. There exists an algorithm which, given i.i.d. access to labeled samples $(\boldsymbol{x}, f(\boldsymbol{x}))$ where $\boldsymbol{x} \sim N(0, I_n)$, draws $n^{O(L^2/\varepsilon^2)}$ samples, runs in time $\exp(\widetilde{O}(nL^2/\varepsilon^2))$, and outputs a function $g \in L^2(\gamma)$ such that*

$$\|f - g\|_{L^2(\gamma)} \le \mathrm{d}^L_{\mathrm{conv}}(f) + \varepsilon.$$

Additionally, the function g is convex and L-Lipschitz.

Combining the agnostic proper learning algorithm with a distance estimation step, we obtain a sample-based tolerant tester for Lipschitz convex functions:

▶ **Theorem 2** (Tolerant two-sided testing of Lipschitz convex functions). *Let $\varepsilon, \varepsilon_0, L \ge 0$ and suppose $f : \mathbb{R}^n \to \mathbb{R}$ is L-Lipschitz. There is an algorithm which, given i.i.d. labeled samples $(\boldsymbol{x}, f(\boldsymbol{x}))$ where $\boldsymbol{x} \sim N(0, I_n)$, draws $n^{O(L^2/\varepsilon^2)}$ samples, runs in time $\exp(\widetilde{O}(nL^2/\varepsilon^2))$, and has the following performance guarantee:*

- *If $\mathrm{d}^L_{\mathrm{conv}}(f) \le \varepsilon_0$, then it outputs "accept" with probability $9/10$;*
- *If $\mathrm{d}^L_{\mathrm{conv}}(f) \ge \varepsilon + \varepsilon_0$, then it outputs "reject" with probability $9/10$.*

Proof. Note that

$$\mathrm{d}^L_{\mathrm{conv}}(f)^2 \le \mathbf{Var}[f] \le \mathbf{E}\left[\|\nabla f\|^2\right] \le L^2$$

by the Poincaré inequality (Proposition 10), the fact that f is L-Lipschitz, and the fact that constant functions are convex. Hence we may assume that $\varepsilon \le L$, since otherwise the tester can immediately accept.

On input $f : \mathbb{R}^n \to \mathbb{R}$, the tester uses the learning algorithm from Theorem 1 to learn a function $g \in \mathcal{C}(L)$ satisfying $\|f - g\|_2 \le \mathrm{d}^L_{\mathrm{conv}}(f) + \varepsilon/4$ with probability at least $2/3$; assume henceforth that this event occurs. It then takes $m = O(L^4/\varepsilon^4)$ samples $(\boldsymbol{x}_i, f(\boldsymbol{x}_i))$, and accepts if and only if

$$\boldsymbol{Y} := \frac{1}{m}\sum_{i=1}^{m}(f(\boldsymbol{x}_i) - g(\boldsymbol{x}_i))^2 \le \left(\varepsilon_0 + \frac{\varepsilon}{2}\right)^2.$$

The sample and time complexity claims are immediate, and we now prove correctness. Let $h := f - g$, so that $\mathbf{E}[\boldsymbol{Y}] = \mathbf{E}[h^2] = \|f - g\|^2_{L^2(\gamma)}$ and $\mathbf{Var}[\boldsymbol{Y}] = \frac{1}{m}\mathbf{Var}[h^2]$. Define the centered function $\bar{h} := h - \mathbf{E}[h]$. Then $\bar{h}$ is centered and $2L$-Lipschitz, and hence sub-Gaussian with sub-Gaussian norm $O(L)$. Then

$$\mathbf{Var}[h^2] = \mathbf{Var}[(\bar{h} + \mathbf{E}[h])^2] = \mathbf{Var}[\bar{h}^2 + 2\,\mathbf{E}[h]\bar{h}] \le 2\,\mathbf{Var}[\bar{h}^2] + 2 \cdot \mathbf{E}[h]^2\,\mathbf{Var}[\bar{h}].$$

By the sub-Gaussianity of $\bar{h}$, we have $\mathbf{Var}[\bar{h}^2] = O(L^4)$ and $\mathbf{Var}[\bar{h}] = O(L^2)$. Moreover, we have

$$\mathbf{E}[h]^2 \le \mathbf{E}[h^2] = \|f-g\|_{L^2(\gamma)}^2 \le \left(\mathrm{d}_{\mathrm{conv}}^L(f) + \frac{\varepsilon}{4}\right)^2 \le 2\mathrm{d}_{\mathrm{conv}}^L(f)^2 + \varepsilon^2 \le O(L^2)\,.$$

We conclude that $\mathbf{Var}[h^2] \le O(L^4)$. By Chebyshev's inequality,

$$\mathbf{Pr}\left[\left|\boldsymbol{Y} - \|f-g\|_{L^2(\gamma)}^2\right| \ge \frac{\varepsilon^2}{16}\right] \le \frac{\frac{1}{m}\cdot O(L^4)}{\varepsilon^4/256} \le \frac{1}{10}\,,$$

for suitable choice of $m = O(L^4/\varepsilon^4)$. Suppose $\left|\boldsymbol{Y} - \|f-g\|_{L^2(\gamma)}^2\right| \le \varepsilon^2/16$. Then if $\mathrm{d}_{\mathrm{conv}}^L(f) \le \varepsilon_0$, we obtain

$$\boldsymbol{Y} \le \|f-g\|_{L^2(\gamma)}^2 + \frac{\varepsilon^2}{16} \le \left(\|f-g\|_{L^2(\gamma)} + \frac{\varepsilon}{4}\right)^2 \le \left(\mathrm{d}_{\mathrm{conv}}^L(f) + \frac{\varepsilon}{2}\right)^2 \le \left(\varepsilon_0 + \frac{\varepsilon}{2}\right)^2,$$

and the tester accepts. On the other hand, suppose $\mathrm{d}_{\mathrm{conv}}^L(f) > \varepsilon_0 + \varepsilon$. Then, recalling that g is a convex, L-Lipschitz function, we obtain

$$\begin{aligned}\boldsymbol{Y} &\ge \|f-g\|_{L^2(\gamma)}^2 - \frac{\varepsilon^2}{16} > (\varepsilon_0+\varepsilon)^2 - \frac{\varepsilon^2}{16} = \varepsilon_0^2 + 2\varepsilon_0\varepsilon + \frac{15\varepsilon^2}{16} \\ &> \varepsilon_0^2 + 2\varepsilon_0\cdot\frac{3\varepsilon}{4} + \left(\frac{3\varepsilon}{4}\right)^2 = \left(\varepsilon_0 + \frac{3\varepsilon}{4}\right)^2,\end{aligned}$$

and the tester rejects. By a union bound, the tester correctly accepts/rejects except with probability at most $\frac{2}{3} + \frac{1}{10} < \frac{1}{2}$, which may be made as small as desired by a standard majority vote. ◀

Proof of the Main Result

We require the following lemmas, whose proofs we defer to the full version. The first lemma says that a Lipschitz function is well-approximated by its low-degree Hermite expansion. This fact has been observed before, e.g. in [2, 46] for domain $[0,1]^n$; here we give a Gaussian version. Recall the notation $f^{\le d} := \sum_{|\alpha|\le d}\widehat{f}(\alpha)h_\alpha$ for the degree-d Hermite expansion of f.

▶ **Lemma 11** (Lipschitz functions are approximately low-degree). *Let $L, \varepsilon > 0$, let $f : \mathbb{R}^n \to \mathbb{R}$ be L-Lipschitz, and let $d := \lceil L^2/\varepsilon^2 \rceil$. Then $\|f - f^{\le d}\|_{L^2(\gamma)} \le \varepsilon$.*

Additionally, we now give upper bounds on the number of samples required to approximately learn the low-degree Hermite coefficients of a Lipschitz function. We assume for simplicity that f has expectation bounded by some constant (this assumption is not essential, and the general case is recovered in the proof of Theorem 1).

▶ **Lemma 12** (Learning a single Hermite coefficient). *Let $L, \xi > 0$, $\delta \in (0,1)$, $\alpha \in \mathbb{N}^n$, and let $f : \mathbb{R}^n \to \mathbb{R}$ be L-Lipschitz and satisfy $|\mathbf{E}[f]| \le O(1)$. Then*

$$O\left(\frac{L^2 3^{|\alpha|}}{\xi^2}\log\left(\frac{1}{\delta}\right)\right) \text{ samples from } f$$

suffice to compute an estimate $\widetilde{\boldsymbol{f}}(\alpha)$ satisfying $\left|\widetilde{\boldsymbol{f}}(\alpha) - \widehat{f}(\alpha)\right| \le \xi$ with probability at least $1-\delta$. The running time is polynomial in the number of samples.

We have the following immediate consequence:

▶ **Corollary 13** (Learning a low-degree expansion). *Let $L, \varepsilon > 0$, $\delta \in (0,1)$, $d \in \mathbb{N}$, and let $f : \mathbb{R}^n \to \mathbb{R}$ be L-Lipschitz and satisfy $|\mathbf{E}[f]| \le O(1)$. Then*

$$O\left(\frac{L^2 n^{2.01d}}{\varepsilon^2} \log\left(\frac{1}{\delta}\right)\right) \text{ samples from } f$$

suffice to obtain coefficient estimates $\widetilde{\boldsymbol{f}}(\alpha)$, for all $\alpha \in \mathbb{N}^n$ with $|\alpha| \le d$, such that the function $\boldsymbol{f} := \sum_{|\alpha| \le d} \widetilde{\boldsymbol{f}}(\alpha) h_\alpha$ satisfies $\|f^{\le d} - \boldsymbol{f}\|_{L^2(\gamma)} \le \varepsilon$ with probability at least $1 - \delta$. The running time is polynomial in the number of samples.

We will require a simple a priori upper bound on the Lipschitz constant of the low-degree approximation above in terms of distance to the origin:

▶ **Lemma 14** (Lipschitz constant of low-degree polynomials). *Let $f : \mathbb{R}^n \to \mathbb{R}$ be a degree-d polynomial. Then for all $x \in \mathbb{R}^n$, we have*

$$\|\nabla f(x)\|_2 \le \|f\|_{L^2(\gamma)} d^{d+\frac{1}{2}} n^{d/2} (1 + |x|)^d .$$

The next lemma says that, given *query* access to a Lipschitz function g which is close to some convex Lipschitz function over a ball, we may learn (via convex regression) a good convex approximation to g using a finite number of queries. We will apply this result to an approximation $\boldsymbol{f}$ of the low-degree restriction $f^{\le d}$ over the restriction of the Gaussian measure to a sufficiently large ball. It is convenient to work with the centered radius-r ℓ^∞-ball $B_\infty(r)$, i.e. an axis-aligned hypercube.

▶ Remark 15. This number of queries used for the convex regression is exponential in n; however, we make these queries to the learned approximation $\boldsymbol{f}$ rather than the input function f, so we pay this cost in the running time but not in the sample complexity.

▶ **Lemma 16** (Learning a Lipschitz convex approximation). *Let $r > 0$, and let μ be the probability measure γ conditioned to $B_\infty(r)$. There exists an algorithm which, given parameters $L, L', \varepsilon > 0$, with $L' \ge L$, and query access to some L'-Lipschitz function $g : B_\infty(r) \to \mathbb{R}$, makes $(L' r \sqrt{n}/\varepsilon)^{O(n)}$ queries to g and outputs a function $\widetilde{g} \in \mathcal{C}(L)$ that is a nearly optimal convex approximation of g over $B_\infty(r)$ with respect to L-Lipschitz functions, in the following sense: for all convex, L-Lipschitz $h : B_\infty(r) \to \mathbb{R}$, we have*

$$\|\widetilde{g} - g\|_{L^2(B_\infty(r),\mu)} \le \|h - g\|_{L^2(B_\infty(r),\mu)} + \varepsilon.$$

The running time is polynomial in the number of queries.

To translate back and forth between full Gaussian space and its restriction to an ℓ^∞-ball, while approximately preserving the distance between Lipschitz functions, we use the following lemma.

▶ **Lemma 17** (Restricting Gaussian space to a box). *There exists a universal constant $C > 0$ such that the following holds. Let $L, \tau \ge 1$, $\varepsilon \in (0, L)$, and let $r := C\sqrt{\log(nL\tau/\varepsilon)}$. Let μ be probability measure γ conditioned to $B_\infty(r)$. Then for all L-Lipschitz functions $f, g : \mathbb{R}^n \to \mathbb{R}$ such that $|f(x^*) - g(x^*)| \le \tau$ for some $x^* \in B_\infty(r)$, we have*

$$\left| \|f - g\|_{L^2(\gamma)} - \|f - g\|_{L^2(B_\infty(r),\mu)} \right| \le \varepsilon .$$

▶ Remark 18. The condition that $|f(x) - g(x)| \le \tau$ for some $x \in B_\infty(r)$ in Lemma 17 holds in particular if $\|f - g\|_2 \le \tau/2$, since otherwise the choice of radius r is large enough to yield (say) $\|f - g\|_2 \ge 3\tau/4$, a contradiction.

Equipped with these results, we may prove Theorem 1.

Proof of Theorem 1. We first claim that we may assume without loss of generality that $|\mathbf{E}[f]| \le \varepsilon/100$. Indeed, the algorithm may first compute an approximation $\bar{\boldsymbol{f}}$ of $\mathbf{E}[f]$ up to $\varepsilon/100$ additive error using $O(L^2/\varepsilon^2)$ samples (by Chebyshev's inequality, since $\mathbf{Var}[f] \le \mathbf{E}[\|\nabla f\|_2^2] \le L^2$ by Proposition 10, and the Lipschitz assumption), then proceed with the modified input function $f - \bar{\boldsymbol{f}}$ and shift the final output again by $\bar{\boldsymbol{f}}$.

We may also assume that $L \ge 1$ (by rescaling the input and ε if necessary) and that $\varepsilon < \frac{100}{99}L$ (otherwise, we get $\|f\|_{L^2(\gamma)} \le \|f - \mathbf{E}[f]\|_{L^2(\gamma)} + |\mathbf{E}[f]| \le L + \varepsilon/100 \le \varepsilon$ by the triangle and Poincaré inequalities, and we may immediately output the constant zero function).

Let $\varepsilon' := \varepsilon/8$ and $d := \lceil (L/\varepsilon')^2 \rceil$. The algorithm first uses

$$O\left(\frac{L^2 n^{2.01d}}{\varepsilon^2}\right) = n^{O(L^2/\varepsilon^2)} \text{ samples from } f$$

to learn, via Corollary 13, a degree-d approximation $\boldsymbol{f}$ satisfying $\|f^{\le d} - \boldsymbol{f}\|_{L^2(\gamma)} \le \varepsilon'$ with probability at least $2/3$; assume henceforth that this event occurs. By Lemma 11 and the triangle inequality, we have $\|f - \boldsymbol{f}\|_{L^2(\gamma)} \le 2\varepsilon'$. Note that $\boldsymbol{f}$ satisfies $\|\boldsymbol{f}\|_{L^2(\gamma)} \le \|f\|_{L^2(\gamma)} + 2\varepsilon' \le L + \varepsilon/100 + 2\varepsilon' \le 2L$.

Let $r = \Theta\left(\frac{L}{\varepsilon}\sqrt{\log(nL/\varepsilon)}\right)$ be large enough to ensure that, when we set

$$L' := 2L(2ndr)^{2d} \ge \|\boldsymbol{f}\|_{L^2(\gamma)}(2ndr)^{2d} \ge \|\boldsymbol{f}\|_{L^2(\gamma)} d^{d+\frac{1}{2}} n^{d/2}(1 + r\sqrt{n})^d$$

as the upper bound on the Lipschitz constant of $\boldsymbol{f}$ over $B_\infty(r)$ via Lemma 14, we obtain

$$r \ge C'\sqrt{\log(nL'/\varepsilon)}$$

for sufficiently large choice of absolute constant $C' > 0$ so that, by Lemma 17, ball $B_\infty(r)$ gives an ε'-approximation for the distance between $\boldsymbol{f}$ and L-Lipschitz functions g for parameter $\tau = 6L$. (One may check that it is possible to choose r satisfying this.)

Let $\widetilde{g} \in \mathcal{C}(L)$ be the function produced by Lemma 16 with input $g = \boldsymbol{f}$, the choice of r above, and parameters L, L' and ε'. Note that the number of queries to $\boldsymbol{f}$, and thus the running time of this step, is

$$(L'r\sqrt{n}/\varepsilon)^{O(n)} = (Lndr/\varepsilon)^{O(dn)} = (nL/\varepsilon)^{O(nL^2/\varepsilon^2)} = \exp(\widetilde{O}(nL^2/\varepsilon^2))\,.$$

We claim that $\widetilde{g}$ satisfies the guarantee of Theorem 1. We already have that $\widetilde{g} \in \mathcal{C}(L)$, so it remains to show that $\|\widetilde{g} - f\|_{L^2(\gamma)} \le \mathrm{d}^L_{\mathrm{conv}}(f) + \varepsilon$. Let $h \in \mathcal{C}(L)$ be any function satisfying $\|f - h\|_{L^2(\gamma)} \le L$ (which exists because f is L-close to the constant $|\mathbf{E}[f]|$ function by the Poincaré inequality), so that $\|\boldsymbol{f} - h\|_{L^2(\gamma)} \le L + 2\varepsilon' \le 2L$. We have

$$\begin{aligned}
\|\widetilde{g} - f\|_{L^2(\gamma)} &\le \|\widetilde{g} - \boldsymbol{f}\|_{L^2(\gamma)} + \|\boldsymbol{f} - f\|_{L^2(\gamma)} \\
&\le \|\widetilde{g} - \boldsymbol{f}\|_{L^2(B_\infty(r),\mu)} + 3\varepsilon' && \text{(Lemma 17, see below)} \\
&\le \|h - \boldsymbol{f}\|_{L^2(B_\infty(r),\mu)} + 4\varepsilon' && \text{(Lemma 16)} \\
&\le \|h - \boldsymbol{f}\|_{L^2(\gamma)} + 5\varepsilon' && \text{(Lemma 17 via Remark 18)} \\
&\le \|h - f\|_{L^2(\gamma)} + \|f - \boldsymbol{f}\|_{L^2(\gamma)} + 5\varepsilon' \\
&\le \|h - f\|_{L^2(\gamma)} + 7\varepsilon'\,.
\end{aligned}$$

To justify the first use of Lemma 17, we claim that $\widetilde{g}$ satisfies $|\widetilde{g}(x) - \boldsymbol{f}(x)| \leq 6L = \tau$ at some point $x \in B_\infty(r)$. Indeed, note that the function h satisfies (by Lemma 17 via Remark 18) $\|h - \boldsymbol{f}\|_{L^2(B_\infty(r),\mu)} \leq \|h - \boldsymbol{f}\|_{L^2(\gamma)} + \varepsilon' \leq 3L$; hence, if we had $|\widetilde{g}(x) - \boldsymbol{f}(x)| > 6L$ for all $x \in B_\infty(r)$, we would obtain $\|\widetilde{g} - \boldsymbol{f}\|_{L^2(B_\infty(r),\mu)} > 6L > \|h - \boldsymbol{f}\|_{L^2(B_\infty(r),\mu)} + \varepsilon'$, contradicting Lemma 16.

Since the above holds for all $h \in \mathcal{C}(L)$ sufficiently close to f, we obtain $\|\widetilde{g} - f\|_{L^2(\gamma)} \leq \mathrm{d}^L_{\mathrm{conv}}(f) + \varepsilon$ as desired. ◀

4 One-Sided Sample-Based Testing

We now turn to convexity testing algorithms with *one-sided* error, i.e., algorithms that never incorrectly reject a convex function. Our main result here is the following:

▶ **Theorem 4** (One-sided testing of Lipschitz convex functions). *Let $f : \mathbb{R}^n \to \mathbb{R}$ be L-Lipschitz, and let $\varepsilon \geq 0$. There is an algorithm, One-Sided-Tester (Algorithm 1), which, given access to i.i.d. labeled samples $(\boldsymbol{x}, f(\boldsymbol{x}))$ where $\boldsymbol{x} \sim N(0, I_n)$, makes $O(\sqrt{n}L/\varepsilon)^n$ draws, runs in time $(nL/\varepsilon)^{O(n)}$, and has the following performance guarantee:*

- *If f is convex, then One-Sided-Tester outputs "accept" with probability 1;*
- *If $\mathrm{d}^L_{\mathrm{conv}}(f) \geq \varepsilon$, then One-Sided-Tester outputs "reject" with probability 9/10.*

Note that in contrast to our upper bound for standard testing (Theorem 2), our sample complexity is exponentially worse.

Our one-sided testing algorithm proceeds by constructing an empirical *convex envelope* of the function using labeled samples. We will ensure by design that when f is convex, its empirical convex envelope is close (in an $L^\infty(\gamma)$ sense) to f. On the other hand, when f is far from convex, it will be far from its empirical convex envelope, which will be revealed by the samples. The strong $L^\infty(\gamma)$ guarantee of the convex envelope may be contrasted with our two-sided tester from Theorem 2, which also proceeds via learning but rather in $L^2(\gamma)$ sense (which is a weaker guarantee that more precisely matches our target metric for testing).

4.1 The Empirical Convex Envelope

We will require the following definition:

▶ **Definition 19** (Empirical convex envelope). *For a function $f : \mathbb{R}^n \to \mathbb{R}$ and m points $Y = \{y_1, y_2, \ldots, y_m\} \subset \mathbb{R}^n$, we define the* empirical convex envelope *of f with respect to Y as the function $\overline{f_Y} : \mathbb{R}^n \to \mathbb{R}$ defined by*

$$\overline{f_Y}(x) := \sup\left\{\langle p, x\rangle + a : p \in \mathbb{R}^n, a \in \mathbb{R}, \|p\|_2 \leq L, \langle p, y\rangle + a \leq f(y) \text{ for all } y \in Y\right\}.$$

Informally, $\overline{f_Y}$ is the "largest" convex function that is below f on all the sampled points $y \in Y$. We record two immediate properties of the empirical convex envelope for future use:

▶ **Lemma 20.** *Suppose $f : \mathbb{R}^n \to \mathbb{R}$ is L-Lipschitz, and let $Y = \{y_1, \ldots, y_m\} \subseteq \mathbb{R}^n$. Let $\overline{f_Y} : \mathbb{R}^n \to \mathbb{R}$ be the empirical convex envelope of f with respect to Y.*

1. *The empirical convex envelope $\overline{f_Y}$ is convex and L-Lipschitz.*
2. *Furthermore, if f is itself convex, then for all $y \in Y$, $\overline{f_Y}(y) = f(y)$.*

Proof. Note that convexity of $\overline{f_Y}$ is immediate from Definition 19 since the supremum of affine functions is convex. Additionally, the constraint that $\|p\|_2 \leq L$ ensures that $\overline{f_Y}$ is L-Lipschitz. Together, these imply the first item.

We now turn to the second item. Since $\overline{f_Y}(y_j) \leq f(y_j)$ for all $y_j \in Y$ by construction, it remains to show that $f(y_j) \leq \overline{f_Y}(y_j)$ for $y_j \in Y$. This is readily seen to hold by taking $p = \nabla f(y_j)$ and $a = f(y_j)$. Since f is L-Lipschitz, and by Rademacher's theorem Lipschitz functions are differentiable almost everywhere, it follows that $\|\nabla f(y_j)\|_2 \leq L$. Since $\overline{f_Y}(y_j)$ is a supremum over all feasible p and a, it follows that $\overline{f_Y}(y_j) \geq f(y_j)$. ◀

Next, we note that the empirical convex envelope $\overline{f_Y}$ can be computed on an input $x \in \mathbb{R}^n$ by the quadratically constrained convex program CECE (short for "compute empirical convex envelope") given in Figure 2.

▶ **Lemma 21.** *Let $f : \mathbb{R}^n \to \mathbb{R}$ be L-Lipschitz, and let $Y = \{y_1, \ldots, y_m\} \subseteq \mathbb{R}^n$. Let $\overline{f_Y} : \mathbb{R}^n \to \mathbb{R}$ be the empirical convex envelope of f with respect to Y. Then for each $x \in \mathbb{R}^n$, the program CECE(x) is feasible and satisfies CECE$(x) = \overline{f_Y}(x)$. Additionally, CECE(x) runs in time* $\mathrm{poly}(m, n)$.

Here, we are assuming the real-valued model of computation, where infinite-length real-valued computations can be achieved with one unit operation. However, our results work equally well in the bounded-bit model, where we use and assume finite bits of precision, with some minor (and routine) modifications to the analysis.

Proof. Note that the quadratic program in Figure 2 coincides with the definition of the empirical convex envelope from Definition 19, and so correctness holds. (Feasibility can be verified by taking $p = 0$ and a small enough, since the set Y is finite.) The runtime is also immediate via standard guarantees for solving convex programs [15]. ◀

$$
\begin{array}{ll}
\text{maximize} & \langle p, x \rangle + a \\
\text{subject to} & p \in \mathbb{R}^n, a \in \mathbb{R} \\
& \|p\|_2 \leq L \\
& \langle p, y \rangle + a \leq f(y) \quad \forall y \in Y
\end{array}
$$

Figure 2 The quadratic program CECE(x) which takes as input a collection of samples $Y = \{y_1, \ldots, y_m\}$ labeled by an L-Lipschitz function f.

4.2 Algorithm 1 and Technical Results

We now formally describe our one-sided convexity testing algorithm, One-Sided-Tester(cf. Algorithm 1). We also record some useful lemmas before proving Theorem 4. For the remainder of this section, we set $d := \frac{\varepsilon}{8L}$, where ε, L are as in Theorem 4.

The first lemma shows that the distance from f to its convex envelope $\overline{f_Y}$ can be well-approximated by considering only the points in the set Y.

▶ **Lemma 22.** *Let $Y = \{y_1, y_2, \ldots, y_m\}$ be a set of points in $\mathbb{R}^n$. Let $f : \mathbb{R}^n \to \mathbb{R}$ be a L-Lipschitz function and let $\overline{f_Y}$ be its empirical convex envelope with respect to Y. Then for all $x \in \mathbb{R}^n$, we have*

$$|\overline{f_Y}(x) - f(x)| \leq \min_{y \in Y} \left\{ \left|\overline{f_Y}(y) - f(y)\right| + 2L\|x - y\|_2 \right\}.$$

Algorithm 1 A one-sided testing algorithm for Lipschitz convex functions.

Input: Access to i.i.d. labeled samples $(\boldsymbol{x}, f(\boldsymbol{x}))$ where f is L-Lipschitz, $\varepsilon \geq 0$

Output: "Accept" or "reject"

One-Sided-Tester:

1. Set
$$t_1 := \left(\frac{cL\sqrt{n}}{\varepsilon}\right)^n$$
for a universal constant c, and draw t_1 samples $(\boldsymbol{x}^{(1)}, f(\boldsymbol{x}^{(1)})), \ldots, (\boldsymbol{x}^{(t_1)}, f(\boldsymbol{x}^{(t_1)}))$. Let $\boldsymbol{Y} := \{\boldsymbol{x}^{(1)}, \ldots, \boldsymbol{x}^{(t_1)}\}$.
2. Let $\mathcal{P}$ be a partition of $B_2(1.1\sqrt{n})$ into at most $(3nL/\varepsilon)^n$ (solid) hypercubes of side length $\ell = \lceil \varepsilon/(4L\sqrt{n}) \rceil$. For each hypercube $C \in \mathcal{P}$, check if there exists $\boldsymbol{x}^{(i)} \in C$; if not, halt and return "accept."
3. If $f(\boldsymbol{x}^{(j)}) \neq \mathrm{CECE}(\boldsymbol{x}^{(j)})$ for any $j \in [t_1]$, then halt and return "reject." Otherwise, return "accept."

Proof. Fix $x \in \mathbb{R}^n$. For each $y \in Y$, we have

$$\begin{aligned} |\overline{f_Y}(x) - f(x)| &\leq |\overline{f_Y}(x) - \overline{f_Y}(y)| + |\overline{f_Y}(y) - f(y)| + |f(x) - f(y)| && \text{(triangle inequality)} \\ &\leq |\overline{f_Y}(y) - f(y)| + 2L \cdot \|x - y\|_2 && (f, \overline{f_Y} \text{ are } L\text{-Lipschitz}) \end{aligned}$$

as desired. ◀

The following lemma shows that with high probability, a draw of roughly $\exp(n \log n)$ samples from $N(0, I_n)$ will be sufficiently "dense" in $B_2(1.1\sqrt{n})$, which will help us bound the error term in Lemma 22. The proof computes a lower bound of the Gaussian density inside $B_2(1.1\sqrt{n})$, and then uses a union bound to show that, with high constant probability, each small cube in a partition of $B_2(1.1\sqrt{n})$ contains at least one sample.

▶ **Lemma 23.** *Let t_1 be as in Algorithm 1, and suppose $\boldsymbol{x}^{(1)}, \ldots, \boldsymbol{x}^{(t_1)} \sim N(0, I_n)$ are i.i.d. draws. Then with probability 0.99, for all $x \in B_2(1.1\sqrt{n})$ we have*

$$\min_{i \in [t_1]} \|x - \boldsymbol{x}^{(i)}\| \leq d\,.$$

Proof. Note that $B_2(1.1\sqrt{n}) \subseteq B_\infty(1.1\sqrt{n})$. Partition $B_\infty(1.1\sqrt{n})$ into a hypergrid of at most $(1.1\sqrt{n}\ell^{-1})^n \leq \left(3nd^{-1}\right)^n$ (hyper)cubes, each of side length $\ell := \lceil d/\sqrt{n} \rceil$. Suppose for every cube in the grid there exists a point $y \in Y$ in the cube. Then note that

$$\min_{y \in Y} \|x - y\|_2 \leq \ell \cdot \sqrt{n} \leq d$$

thanks to our choice of ℓ.

Thus, in order to establish Lemma 23, it suffices to show that after drawing t_1 samples, with probability at least 9/10, every cube in the hypergrid contains at least one sample. We will show this by taking a union bound over the $(3nd^{-1})^n$ cubes in the hypergrid.

In this argument, it will be necessary to consider the cube in the hypergrid with minimal Gaussian measure. Note that the maximum ℓ_2 norm of any point in the hypergrid is at most $(1.1 + \ell)\sqrt{n}$. Therefore for all $x \in B_\infty(1.1\sqrt{n})$, we have

$$\frac{\exp\left(-||x||_2^2/2\right)}{(2\pi)^{n/2}} \geq \frac{\exp\left(-(1.1+\ell)^2/(2n)\right)}{(2\pi)^{n/2}} = \frac{1}{(2\pi)^{n/2}} \cdot \exp\left(-\left(1.1 + \frac{\varepsilon}{(4L\sqrt{n})}\right)^2 \cdot \frac{1}{2n}\right).$$

Since the Lebesgue measure of any cube is ℓ^n, the minimum Gaussian measure of any of the cubes in our hypergrid is at least

$$\alpha := \frac{1}{(2\pi)^{n/2}} \cdot \exp\left(-\left(1.1 + \frac{\varepsilon}{(4L\sqrt{n})}\right)^2 \cdot \frac{1}{2n}\right) \cdot \ell^n \,.$$

The probability that t_1 independent draws from $N(0, I_n)$ all fail to land in this cube is

$$(1-\alpha)^{t_1} \leq \exp(-\alpha t_1) \,.$$

Applying a union bound, it follows that the probability that there exists a cube in the hypergrid not containing any sample is at most

$$\exp(-\alpha t_1) \cdot 2^{O(n \log(1.1n/d)} \,,$$

and it is readily verified that this is at most 0.01 for our choice of t_1 and ℓ, for some universal constant c. ◀

Finally, the next lemma shows that, under the density condition above, if f and $\overline{f_Y}$ agree on all points in Y then they are close in $L^2(\gamma)$.

▶ **Lemma 24.** *Suppose $f : \mathbb{R}^n \to \mathbb{R}$ is an L-Lipschiz function and $Y = \{y_1, y_2, \ldots, y_m\}$ is a set of points in $\mathbb{R}^n$ such that for all $x \in B(1.1\sqrt{n})$, there exists $i \in [m]$ such that $\|x - y_i\|_2 \leq d$, for $d = \varepsilon/(8L)$. Let $\overline{f_Y}$ be the empirical convex envelope of f with respect to Y. If $f(y_i) = \overline{f_Y}(y_i)$ for all $i \in [m]$, then $\left\|f - \overline{f_Y}\right\|_{L^2(\gamma)} \leq \varepsilon/2$.*

Proof. We decompose $\left\|f - \overline{f_Y}\right\|^2_{L^2(\gamma)}$ into the regions inside and outside $B_2(1.1\sqrt{n})$ and apply Lemma 22:

$$\begin{aligned}
&\left\|f - \overline{f_Y}\right\|^2_{L^2(\gamma)} \\
&= \mathop{\mathbf{E}}_{\boldsymbol{x}\sim N(0,I_n)}\left[\left|f(\boldsymbol{x}) - \overline{f_Y}(\boldsymbol{x})\right|^2\right] \\
&\leq \mathop{\mathbf{E}}_{\boldsymbol{x}\sim N(0,I_n)}\left[\left|f(\boldsymbol{x}) - \overline{f_Y}(\boldsymbol{x})\right|^2 \,\middle|\, \|\boldsymbol{x}\|_2 \leq 1.1\sqrt{n}\right] \\
&\quad + \mathop{\mathbf{E}}_{\boldsymbol{x}\sim N(0,I_n)}\left[\left|f(\boldsymbol{x}) - \overline{f_Y}(\boldsymbol{x})\right|^2 \,\middle|\, \|\boldsymbol{x}\|_2 > 1.1\sqrt{n}\right] \cdot \mathbf{Pr}\left[\|\boldsymbol{x}\|_2 > 1.1\sqrt{n}\right] \\
&\leq (2Ld)^2 + (2L)^2 \mathop{\mathbf{E}}_{\boldsymbol{x}\sim N(0,I_n)}\left[\min_{y\in Y} \|\boldsymbol{x} - y\|_2^2 \mid \|\boldsymbol{x}\|_2 > 1.1\sqrt{n}\right] \cdot \mathop{\mathbf{Pr}}_{\boldsymbol{x}\sim N(0,I_n)}\left[\|\boldsymbol{x}\|_2 > 1.1\sqrt{n}\right] \\
&= (2Ld)^2 + (2L)^2 \cdot \mathrm{poly}(n)\exp(-\Omega(n)) \\
&= \varepsilon^2/16 + o(1) \,,
\end{aligned}$$

which is less than $\varepsilon^2/4$ for large enough n. ◀

4.3 Proof of Theorem 4

Proof. First, note that the sample complexity of One-Sided-Tester is $O\left(\sqrt{n}L/\varepsilon\right)^n$ as desired. We establish correctness as well as the runtime bound below, starting with the former.

Correctness. We first show that if f is L-Lipschitz and convex, then One-Sided-Tester accepts with probability 1. Indeed, Algorithm 1 only outputs "reject" when $f(y) \neq \mathrm{CECE}(y)$ for some $y \in Y$, which cannot happen by Lemmas 20 and 21.

For soundness, suppose that $\mathrm{d}^L_{\mathrm{conv}}(f) \geq \varepsilon$, so that in particular $\left\|f - \overline{f_Y}\right\|_{L^2(\gamma)} \geq \varepsilon$. Suppose the algorithm samples a set Y of points in $\mathbb{R}^n$ such that for all $x \in B_2(1.1\sqrt{n})$, there exists $y \in Y$ such that $\|x - y\|_2 \leq d$, for $d = \varepsilon/(8L)$; by Lemma 23 this occurs with probability at least 0.99. In this case the algorithm rejects, because it would only accept if we had $f(y) = \mathrm{CECE}(y)$ for every $y \in Y$; since $\mathrm{CECE}(y) = \overline{f_Y}(y)$ for each $y \in Y$ by Lemma 21, this would imply via Lemma 24 that $\left\|f - \overline{f_Y}\right\|_{L^2(\gamma)} \leq \varepsilon/2$, a contradiction. Therefore the algorithm rejects with probability at least 0.99.

Runtime. Note that Step 1 takes time t_1 and Step 2 takes time

$$|\mathcal{P}| \cdot t_1 = (3nL/\varepsilon)^n \cdot \left(\frac{50L\sqrt{n}}{\varepsilon}\right)^n .$$

Finally, Step 3 requires time $\mathrm{poly}(n, t_1)$ by Lemma 21. It follows that Algorithm 1 uses time $(nL/\varepsilon)^{O(n)}$. ◀

Mixing and Cutoff for the Systematic Scan Dynamics of the Mean-Field Ferromagnetic Potts Model

Abstract

We study the mixing time of the systematic scan dynamics for the q-state ferromagnetic Potts model on the n-vertex complete graph, known as the mean-field model. This Markov chain updates vertices sequentially according to a fixed predetermined order, in contrast to the Glauber dynamics which updates a uniformly random vertex at each step. Systematic scan dynamics are attractive in practice as they often demonstrate strong empirical performance. However, their theoretical analysis remains far less developed than that of the Glauber dynamics.

We take a step toward addressing this imbalance by showing that for every $q \geq 2$ and $\beta < \beta_s$, where β_s is the metastability threshold associated with the onset of slow mixing for the Glauber dynamics, the systematic scan dynamics for the ferromagnetic mean-field Potts model mixes in $\Theta(\log n)$ scans or, equivalently, in $\Theta(n \log n)$ single site updates. We in fact prove a sharper result; namely, that there exists a constant $c(\beta, q) > 0$ such that the mixing time is $c(\beta, q) \log n + \Theta(1)$, which implies that the Markov chain exhibits the cutoff phenomenon, with the total variation distance to the stationary distribution dropping abruptly from nearly 1 to nearly 0 within a narrow $\Theta(1)$ time window. This result is tight in β as well since the dynamics mixes exponentially slowly for $\beta > \beta_s$. To the best of our knowledge, this is the first general cutoff result for the systematic scan dynamics in the context of spin systems. The result may also be of independent interest in the theory of Markov chains, since the systematic scan dynamics is both global and non-reversible, two settings in which cutoff remains poorly understood.

1 Introduction

Sampling high-dimensional probability distributions is an important task in science and engineering. It is, for example, a prevalent problem when running simulations in statistical physics or when solving inference problems in machine learning. As such, there is an array of sophisticated algorithms and heuristics to generate samples from these distributions. One of the most classical and powerful approaches is *Gibbs Sampling*, which iteratively updates one variable at a time conditioned on the values of all other variables.

There are two standard strategies for deciding which variable to update in each step: (i) the Glauber dynamics, where the variable to be updated is chosen uniformly at random, and (ii) systematic scan dynamics, where variables are updated according to a predetermined ordering. In practice, systematic scan dynamics offer several computational advantages over

the Glauber dynamics, as they are often amenable to parallelization, can exhibit improved memory locality and thus reduce data-access overhead, and require fewer random bits [29]. Despite these practical advantages, most theoretical analyses focus on the Glauber dynamics, which have historically proven more mathematically tractable, leaving the convergence theory for systematic scan dynamics significantly less developed.

The number of variable updates required to reach stationarity can differ significantly between the Glauber and systematic scan dynamics, sometimes up to polynomial factors in n [21, 27]. For example, even in the trivial case of n independent variables, the systematic scan mixes in exactly n updates, whereas the Glauber dynamics requires $\frac{1}{2}n\log n$ updates. When combined with the implementation benefits noted above, such differences in convergence rates can make the systematic scan dynamics a particularly attractive update strategy.

In this paper, we take a step toward a better theoretical understanding of the systematic scan dynamics by studying them in the context of the *ferromagnetic mean-field Potts model*, a classical spin system model central in statistical physics, theoretical computer science, machine learning, and probability theory. In this model, each variable in $V = \{1, \dots, n\}$ can take a value from $Q = \{1, ..., q\}$. The Gibbs or Boltzmann distribution assigns to each configuration $\sigma \in \Sigma_n = Q^V$ a probability given by:

$$\mu(\sigma) = \frac{1}{Z_{\beta,n}} \exp\left\{\frac{\beta}{n} \sum_{\{u,v\}\subseteq V} \mathbf{1}\big(\sigma(u) = \sigma(v)\big)\right\},$$

where $\sigma(u)$ is the value (or spin) assigned to vertex u in the configuration σ, and $Z_{\beta,n}$ is the normalization constant or partition function. The parameter β captures the strength of the interaction between the variables and is proportional to the inverse temperature in statistical physics applications. The $q = 2$ case corresponds to the classical Ising model. The Potts model can be defined on any graph by taking the summation in the definition over the edges of the graph instead of over pairs of vertices; the mean-field setting considered here corresponds to the complete graph on n vertices.

For concreteness, we consider the standard variant of the systematic scan dynamics in which site updates are given by the *heat-bath* update, i.e., they are performed according to the conditional distribution at each update site induced by the configuration on the remaining vertices. Formally, if vertex v is to be updated in a configuration σ, then v is assigned a new spin sampled from $\mu(\cdot \mid \sigma(V \setminus \{v\}))$. This is a non-reversible ergodic Markov chain with state space Σ_n that converges to μ. We measure rates of convergence to μ in terms of the *mixing time*, which is the most standard notion of speed of convergence for a Markov chain. It is defined as the number of steps until the dynamics is close in total variation distance to μ starting from any initial configuration. Formally, if P denotes the transition matrix of the chain, for $\varepsilon \in (0, 1)$, the ε-mixing time is given by

$$T_{\mathrm{mix}}(\varepsilon) = \min\left\{t \in \mathbb{Z}_{\geq 0} : \max_{\sigma\in\Sigma_n} \left\|P^t(\sigma, \cdot) - \mu\right\|_{\mathrm{TV}} \leq \varepsilon\right\}.$$

By convention, the mixing time is taken to be $T_{\mathrm{mix}} = T_{\mathrm{mix}}(1/4)$.

A more refined notion of convergence, when present, is the cutoff phenomenon. A Markov chain exhibits *cutoff* when there is a sharp drop in the total variation distance from close to 1 to close to 0 in an interval of time of smaller order than its mixing time; which is called the *cutoff window*. More precisely, we say that there is cutoff if as $n \to \infty$, for any fixed $\varepsilon \in (0, 1)$

$$T_{\mathrm{mix}}(\varepsilon) - T_{\mathrm{mix}}(1 - \varepsilon) = o(T_{\mathrm{mix}}). \tag{1}$$

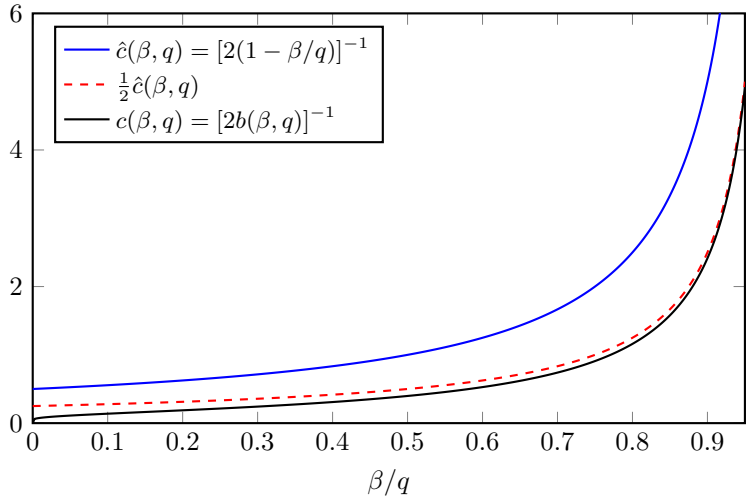

Figure 1 Comparison of mixing times of Glauber (blue curve) and systematic scan dynamics (black curve).

The mixing time and cutoff of the Glauber dynamics for the mean-field ferromagnetic Potts model is by now very well-understood. In the case of the Ising model (the $q = 2$ case) at $\beta < 2$, the Glauber dynamics mixes in $\frac{1}{2(1-\beta/2)} n \log n$ steps with an $O(n)$ cutoff window. The mixing time is $\Theta(n^{3/2})$ at $\beta = 2$ and exponential in n when $\beta > 2$ [13, 12, 23]. For $q \geq 3$, the model exhibits a first-order phase transition and the dynamics undergoes a slowdown at $\beta_s = \beta_s(q)$, which is the spinodal point marking the onset of metastability. Specifically, when $\beta < \beta_s$ the mixing time is $\frac{1}{2(1-\beta/q)} n \log n$ with an $O(n)$ cutoff window. At $\beta = \beta_s$ the dynamics mixes in $\Theta(n^{4/3})$ and no longer exhibits cutoff, and the mixing time is again exponential in n for $\beta > \beta_s$ [10].

In contrast with this fairly complete convergence picture for the mean-field Glauber dynamics, much less is known for systematic scan dynamics, with the best known mixing time bound being $O(n^2 \log n)$ for $\beta < \beta_s$. We provide here the first sharp analysis of the mixing time of the systematic scan dynamics for the mean-field ferromagnetic Potts model, valid for all scan orderings and for all inverse temperatures $\beta < \beta_s$.

▶ **Theorem 1.** *For $q \geq 2$, $\beta < \beta_s$, there exists a constant $c(\beta, q) > 0$ such that the systematic scan dynamics for the mean-field ferromagnetic Potts model exhibits cutoff at mixing time $T_{mix} = c(\beta, q) \log(n) + \Theta(1)$.*

For n large, the leading constant $c(\beta, q)$ corresponds to $\frac{1}{2b(\beta,q)}$ where $b = b(\beta, q)$ is the root of the equation $\beta(1 - e^{-b})/(qb) = e^{-b}$; see Section 4 for additional details. Figure 1 shows a plot of the constant $c(\beta, q)$ as a function of β/q and compares it to the leading constant $\hat{c}(\beta, q) = \frac{1}{2(1-\beta/q)}$ for the mixing time of the Glauber dynamics, revealing at least a twofold speedup. This is consistent with the folklore conjecture that the systematic scan dynamics exhibits such a speedup in several settings.

We note that Theorem 1 is tight in β, since, as mentioned, the Glauber dynamics mixes exponentially slowly for $\beta > \beta_s$ and known mixing time comparison results (see, e.g., [17, Theorem 1.2]) imply that so does the systematic scan. At $\beta = \beta_s$, based on the known behavior of the Glauber dynamics, we conjecture that the systematic scan dynamics mixes $\Theta(n^c)$ for some $c < 1$ without cutoff.

To better contextualize Theorem 1, we briefly comment on prior work on mixing times for the systematic scan dynamics on spin systems. There is a line of work that seeks to compare the convergence rates of Glauber and systematic scan dynamics. This is done with varying degrees of generality in [2, 17, 14, 11, 8, 9, 19]. In parallel, there is work establishing fast mixing for the systematic scan dynamics under model parameter and graph-structural conditions [15, 20, 16], or under monotonicity assumptions [7, 3, 26]. We note that the recent advances in Markov chain mixing via spectral independence have not yet yielded major new results for this dynamics; see [1] for initial progress. This body of work demonstrates sustained interest on the systematic scan dynamics while also underscoring the significant analytical challenges they present, with many questions that are well understood for the Glauber dynamics remaining unresolved in this setting.

Turning to cutoff, results like Theorem 1 are rarer still. To the best of our knowledge, our work provides the first cutoff result for the systematic scan dynamics in the context of spin systems. The cutoff result in [22] for the Ising model considers a Markov chain inspired by systematic scan but that is effectively quite different since in each step, $k = o(n^{1/3})$ vertices are chosen uniformly random and updated according to a random permutation. More generally, the systematic scan dynamics is a global, non-reversible Markov chain, and both features introduce substantial additional analytical challenges. Indeed, the only other cutoff result for a global Markov chain for spin systems we are aware of is the recent work [6] on the Swendsen-Wang dynamics, while the study of the cutoff phenomenon for non-reversible Markov chains is only in its early stages [25].

Proof Sketch

For the rest of the paper, we assume $\beta < \beta_s$, $q \geq 2$ and n to be asymptotically large. We refer to the vertex updates of the dynamics as *site updates*, and n consecutive vertex updates are called a *full-scan*. A step of the systematic scan dynamics Markov chain corresponds to a full-scan starting from the first vertex in the ordering. It will be convenient to index the site updates, and thus we use σ_t for the configuration after the t-th site update and σ_{kn} for the configuration after the k-th step of the chain.

We will show that for any fixed $\varepsilon \in (0,1)$, there exists a $\kappa(\varepsilon)$ independent of n such that

$$c(\beta,q)\log n - \kappa(\varepsilon) \leq T_{\mathrm{mix}}(\varepsilon) \leq c(\beta,q)\log n + \kappa(\varepsilon). \tag{2}$$

From this, Theorem 1 follows immediately; in particular, this inequality implies (1).

To establish the upper bound on $T_{\mathrm{mix}}(\varepsilon)$ we utilize a multiphase *coupling*, and in that sense, it is reminiscent of the other Markov chain analysis in the mean-field setting [18, 4, 6, 10]. A coupling considers two copies, $\{\sigma_t\}_{t\geq 0}$ and $\{\tilde{\sigma}_t\}_{t\geq 0}$, of the systematic scan dynamics starting from two arbitrary initial configurations σ_0 and $\tilde{\sigma}_0$, respectively. Each copy evolves according to the transition matrix P, but the moves of the two copies can be arbitrarily correlated. The ε-coupling time $T_{\mathrm{coup}}(\varepsilon)$ is the minimum number of full-scans T such that $\Pr[\sigma_{Tn} \neq \tilde{\sigma}_{Tn}] \leq \varepsilon$. A standard result says that $T_{\mathrm{mix}}(\varepsilon) \leq T_{\mathrm{coup}}(\varepsilon)$; for additional details see [24].

To describe the three main phases of our coupling we introduce some useful notation first. For a configuration $\sigma \in \Sigma_n$, let $\alpha(\sigma)$ denote the q-dimensional vector with coordinates

$$\alpha_i(\sigma) = \frac{1}{n}\sum_{j=1}^{n} \mathbf{1}(\sigma(j) = i).$$

We call $\alpha(\sigma)$ the proportions vector of σ. We let $\hat{e} = \big(1/q, \ldots, 1/q\big)$ denote the q-dimensional equiproportions vector that corresponds to the configuration with exactly the same number of vertices assigned each spin (ignoring rounding issues).

The main phases of our coupling are the following:

Phase 1: From arbitrary initial configurations σ_0 and $\tilde{\sigma}_0$, run two copies $\{\sigma_t\}$ and $\{\tilde{\sigma}_t\}$ independently for an initial *burn-in* period of $T = O(1)$ scans. After this initial burn-in, we show that both copies are such that $\|\alpha(\sigma_{Tn}) - \hat{e}\|_\infty \leq \rho$ and $\|\alpha(\tilde{\sigma}_{Tn}) - \hat{e}\|_\infty \leq \rho$ with probability $1 - o(1)$, for any desired constant $\rho > 0$. In addition, we show that both copies have "good spread" of their spins with respect to the ordering of the systematic scan dynamics.

Phase 2: We can then couple the evolution of the two instances of Markov chain so that after $c(\beta, q) \log n + O(1)$ additional scans: the Hamming distance between the two configurations is $O(\sqrt{n})$ and the ℓ_2 distance between their respective proportions vector and $\hat{e}$ is also $O(1/\sqrt{n})$.

Phase 3: Finally, we couple one final scan in a way that guarantees that the processes coalesce with at least the desired ε probability.

We provide additional details about **Phase 1** next. Let $e_i \in \mathbb{R}^q_{\geq 0}$ be the indicator vector with value 1 in the i-th coordinate and 0 elsewhere. We capture the notion of closeness to $\hat{e}$ with "good spread" by considering for each $\rho > 0$ the set of configurations

$$\Sigma_n^\rho = \left\{\sigma \in \Sigma_n : \left\|\hat{e} - \frac{1}{i}\sum_{j=n-i+1}^{n} e_{\sigma(j)}\right\|_\infty \leq \rho \quad \forall\, i \in \mathbb{N} \cap (n^{3/4}, n]\right\}.$$

Observe that $\sigma_t \in \Sigma_n^\rho$ implies not only that $\|\alpha(\sigma_t) - \hat{e}\|_\infty \leq \rho$, but also that as we perform site updates to generate σ_{t+n}, the intermediate configurations are also balanced. To see this, note that when updating σ_j for $j \in [t, t+n]$, the fact that $\sigma_t \in \Sigma_n^\rho$ ensures that the partial configuration in the vertices $v_{j+1-t}, \ldots, v_n$ is also balanced; in addition, the partial configuration in $v_1, \ldots, v_{j-t-1}$ we can guarantee to be balanced since it was just updated. (The $n^{3/4}$ gives a required slack to make such statement possible; note, for example, that a single vertex cannot be balanced.)

This more fine grained notion of closeness to $\hat{e}$ marks a clear distinction between the Glauber and systematic scan analyses. In the former, given a proportions vector α, the dynamics is oblivious to the specific spin assignment to vertices (i.e., from $\alpha(\sigma_{t-1})$ we can generate $\alpha(\sigma_t)$); as such, the speed of convergence of the Markov chain is governed by its ℓ_∞ closeness to $\hat{e}$. However, this is not the case for systematic scan, since this Markov chain updates vertices in a fixed order and thus depends on the specific assignment of spins to vertices along the scan order (not only on the spin counts). We are therefore required to establish this stronger notion of closeness to $\hat{e}$. We show that the following holds after **Phase 1**.

▶ **Lemma 2.** *For any fixed $\rho > 0$, there exist constants $c > 0$ and $k \in \mathbb{Z}_+$ depending only on β, q, and ρ such that*

$$\Pr\left[\sigma_{kn} \notin \Sigma_n^\rho\right] \leq 2qke^{-c\sqrt{n}}. \tag{3}$$

Moreover, if $\sigma_0 \in \Sigma_n^\rho$, for any $\hat{k} \in \mathbb{Z}_+$ we have

$$\Pr\left[\max_{1 \leq i \leq n} \left\|\alpha(\sigma_{(\hat{k}-1)n+i}) - \hat{e}\right\|_\infty > q\rho\right] \leq 2q\hat{k}e^{-c\sqrt{n}}. \tag{4}$$

We note that (3) establishes that the chain enters the set Σ_n^ρ after a constant number of scans with high probability, whereas (4) shows that once the chain enters Σ_n^ρ, it will remain also with high probability. To prove (3), we show that the proportions vector has drift

towards the $\hat{e}$. More precisely, we analyze the evolution of fraction of vertices in a spin class by decomposing into a drift and a fluctuation component. The drift component of each coordinate is then bounded by a one-dimensional recursive function that iterates towards its fixed point $1/q$. For every fixed constant $\rho > 0$ (independent of n), the recursive function enters the interval $[1/q, 1/q + \rho]$ after a constant number of iterations. To analyze the fluctuation component of the process, we show first that it is a supermartingale, and then we use the Doob decomposition to split it into a predictable non-increasing process and a martingale, with the martingale fluctuations controlled via a concentration of its maximum over an interval; more precisely, via a Maximal-Azuma inequality, a tailored version of which we establish here.

The proof of (4) follows from a similar argument. Once the proportions vector is close to $\hat{e}$ and the configuration has a good spread, the drift helps the process to remain close to $\hat{e}$. Then, the corresponding martingale estimate gives the desired high probability statement. The proof of Lemma 2 is fleshed out in Section 2.

In **Phase 2**, we couple the systematic scan dynamics using the optimal single site coupling; i.e., the coupling that maximizes the probability of agreement between the two copies of the chain at the update site conditional on the configuration off the site. We are able to establish that the Hamming distance d_H between the two chains drops from $O(n)$ to $O(\sqrt{n})$ in $O(\log n)$ steps, and that at the same time, the distance of the spin fraction from $\hat{e}$ drops from $O(1)$ to $O(1/\sqrt{n})$.

▶ **Lemma 3.** *Let $\rho > 0$ small enough and $\sigma_0, \tilde{\sigma}_0 \in \Sigma_n^\rho$. Then, for any fixed constants $C, \varepsilon > 0$, there exist an integer $k = k(\beta, q, C, \varepsilon)$ such that with probability at least ε for $T = c(\beta, q)\log(n) + k$ we have $d_H(\sigma_{Tn}, \tilde{\sigma}_{Tn}) \leq C\sqrt{n}$.*

To establish this lemma we show that for two copies of the systematic scan Markov chain with starting configurations in Σ_n^ρ, their Hamming distance exhibits an almost uniform geometric decay. To establish this, we show that the distances between the proportions vectors of the copies and $\hat{e}$ contract at exactly same geometric rate. Identifying these matching contraction rates determines the number of steps required for the Hamming distance to reach the desired scale (i.e., $O(\sqrt{n})$) and determines the leading constant $c(\beta, q)$ in the mixing time. The full proof of Lemma 3 is given in Sections 3, 4, and 5.

For **Phase 3** of the coupling we show that the relative entropy between the distribution of σ_{t+n} and $\tilde{\sigma}_{t+n}$ can be bounded in terms of the square of the Hamming distance between σ_t and $\tilde{\sigma}_t$. Then, since we start the phase from two configurations within $O(\sqrt{n})$ Hamming distance, Pinsker's inequality allows to conclude the following.

▶ **Lemma 4.** *There exists a coupling such that for any $\varepsilon > 0$ there is a constant $C = C(\varepsilon, \beta, q)$ such that for $\sigma_0, \tilde{\sigma}_0 \in \Sigma_n$ with $d_H(\sigma_0, \tilde{\sigma}_0) \leq C\sqrt{n}$, we have $\Pr\left[\sigma_n \neq \tilde{\sigma}_n\right] \leq \varepsilon$.*

The proof of Lemma 4 is deferred to the full version of the paper [5]. We can now provide the proof of the mixing time upper bound in Theorem 1.

Proof of Theorem 1 (upper bound). We show that $T_{\text{mix}}(\varepsilon) \leq c(\beta, q)\log n + \kappa(\varepsilon)$ for any $\varepsilon \in (0, 1)$ and a suitable κ independent of n. By Lemma 2, for any $\rho > 0$ there exists $\kappa_1 = \kappa_1(\beta, q, \rho)$ such that $\sigma_{\kappa_1 n}, \tilde{\sigma}_{\kappa_1 n} \in \Sigma_n^\rho$ with probability at least $1 - \varepsilon/3$. Conditioning on $\sigma_{\kappa_1 n}, \tilde{\sigma}_{\kappa_1 n} \in \Sigma_n^\rho$ and choosing ρ small enough, Lemma 3 implies that we can couple the the two copies of the chain so that for any fixed $C > 0$ there exists $\kappa_2 = \kappa_2(\beta, q, C, \varepsilon)$ such that after $T_2 = c(\beta, q)n\log n + \kappa_2 n + \kappa_1 n$ site updates we have that

$$\Pr\left[d_H(\sigma_{T_2}, \tilde{\sigma}_{T_2}) \leq C\sqrt{n}\right] \geq 1 - \varepsilon/3.$$

For the last phase, Lemma 4 implies that $\sigma_{T_2+n} = \tilde{\sigma}_{T_2+n}$ with probability at least $1 - \varepsilon/3$ for small enough C. So at $T = T_2 + n$ we obtain $\Pr[\sigma_T \neq \tilde{\sigma}_T] \leq \frac{\varepsilon}{3} + \frac{\varepsilon}{3} + \frac{\varepsilon}{3} = \varepsilon$. ◀

To establish the mixing time lower-bound in (2), we use the fact that the distribution μ is well-concentrated around the equiproportion vector $\hat{e}$. Therefore, if the event $\{\|\alpha(\sigma_{kn})-\hat{e}\|_2 > C/\sqrt{n}\}$ has a significant probability for a sufficiently large constant $C > 0$, the systematic scan dynamics chain cannot be mixed after k steps. Using our precise understanding of the rate of contraction towards $\hat{e}$ established in the analysis of **Phase 2**, and standard concentration inequalities, we prove that for any $C > 0$ and any $\varepsilon \in (0,1)$, there exists κ independent of n such that after $c(\beta,q)\log n - \kappa(\varepsilon, C)$ steps $\Pr[\|\alpha(\sigma_t)-\hat{e}\|_2 > C/\sqrt{n}] > 1-\varepsilon$ where for any fixed ε the function $\kappa(\varepsilon,\cdot)$ is increasing. The lower bound proof is provided in the full version of the paper [5].

2 Independent Burn-in

Our aim in this section is to analyze the **Phase 1** of our coupling and establish Lemma 2. We analyze the evolution of the number of vertices with a given spin (say spin 1 for concreteness) by decomposing this one-dimensional stochastic process into a mostly predictable component determined by a drift function and a fluctuation component that is controlled via martingale concentration bounds.

2.1 Drift analysis

Consider the drift function $G_\beta : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ given by

$$G_\beta(x) = \frac{e^{\beta x}}{e^{\beta x} + (q-1)e^{\beta\frac{1-x}{q-1}}}.$$

This function approximates the probability that a single-site update chooses spin 1 in a configuration that has xn vertices assigned spin 1 and all other $q-1$ spins distributed equally among the remaining $(1-x)n$ vertices. The correspondence is not exact in part because the spin of the selected vertex is taken into consideration; to account for this correction we define

$$G_{\beta,n}(x) = G_\beta(x) + \beta/n.$$

For $q \geq 2$, the spinodal point β_s can be defined in terms of the drift function G_β:

$$\beta_s = \sup\left\{\beta > 0 : G_\beta(x) - x \neq 0 \quad \forall x \in (1/q, 1)\right\};$$

see [10] for additional details.

We use the function G_β to control the evolution of the one-dimensional process corresponding to fraction of vertices assigned spin 1. To formalize this, let J_t be the random variable corresponding to the spin chosen in the t-th site update and let $X_t = \mathbf{1}(J_t = 1)$. We use the convention that for $-n < t \leq 0$, X_t indicates whether the $(t+n)$-th vertex in the initial configuration σ_0 has spin 1. We define $Y_t^{(\ell)}$ as the average of the X_i's for the last ℓ updates:

$$Y_t^{(\ell)} = \frac{1}{\ell}\sum_{i=t-\ell+1}^{t} X_i. \tag{5}$$

Observe that $Y_t^{(n)} = \alpha_1(\sigma_t)$; to simplify the notation we set $Y_t = Y_t^{(n)}$. We decompose the process $Y_t^{(\ell)}$ into the sum of a drift and a fluctuation component as follows. For all $t \geq \ell$ and $1 \leq \ell \leq n$:

$$Y_t^{(\ell)} = \frac{1}{\ell}\sum_{j=t-\ell+1}^{t} G_{\beta,n}(Y_{j-1}) + \frac{1}{\ell}\sum_{j=t-\ell+1}^{t}\left(X_j - G_{\beta,n}(Y_{j-1})\right),$$

and rewrite the fluctuation term as

$$D_t^{(\ell)} = \sum_{j=t-\ell+1}^{t} \big(X_j - G_{\beta,n}(Y_{j-1})\big), \tag{6}$$

so that

$$Y_t^{(\ell)} = \frac{1}{\ell} D_t^{(\ell)} + \frac{1}{\ell} \sum_{j=t-\ell+1}^{t} G_{\beta,n}(Y_{j-1}).$$

Our first lemma shows that under the assumption that the random fluctuations are small in aggregate over all intervals between kn and $(k+1)n$, then $\max_{n^{3/4}<i\le n} Y_{kn}^{(i)}$ has a contraction given by the function $G_{\beta,n}$ up to a small correction.

▶ **Lemma 5.** *Suppose that for some integer $k \ge 0$, a fixed constant $a \in (1/q, 1]$, and a sufficiently small $\varepsilon > 0$ that satisfies $G_{\beta,n}(a) + 2\varepsilon < a$, we have $\max_{n^{3/4}<i\le n} Y_{kn}^{(i)} \le a$, and $\max_{1\le i\le j\le n} D_{kn+j}^{(i)} < \varepsilon n^{3/4}$. Then,*

$$\max_{n^{3/4}<i\le n} Y_{(k+1)n}^{(i)} \le 2\varepsilon + G_{\beta,n}(a).$$

Moreover, $\max_{1\le i\le n} Y_{kn+i} \le a + \frac{1}{n^{1/4}}$.

Proof. We start by rewriting $Y_{kn+\ell}$ using (5) and (6) as

$$\begin{aligned}
Y_{kn+\ell} &= \frac{1}{n} \sum_{i=(kn+\ell)-n+1}^{kn} X_i + \frac{1}{n} \sum_{i=kn+1}^{kn+\ell} X_i \\
&= \frac{1}{n} \sum_{i=kn-(n-\ell)+1}^{kn} X_i + \frac{1}{n} \sum_{i=kn+1}^{kn+\ell} \Big(X_i - G_{\beta,n}(Y_{i-1})\Big) + \frac{1}{n} \sum_{i=kn+1}^{kn+\ell} G_{\beta,n}(Y_{i-1}) \\
&= \frac{(n-\ell)}{n} Y_{kn}^{(n-\ell)} + \frac{1}{n} D_{kn+\ell}^{(\ell)} + \frac{\ell}{n} \frac{1}{\ell} \sum_{i=kn+1}^{kn+\ell} G_{\beta,n}(Y_{i-1}) \\
&= \frac{1}{n} D_{kn+\ell}^{(\ell)} + \frac{1}{n} \bigg((n-\ell) Y_{kn}^{(n-\ell)} + \ell \Big(\frac{1}{\ell} \sum_{i=kn+1}^{kn+\ell} G_{\beta,n}(Y_{i-1}) \Big) \bigg).
\end{aligned} \tag{7}$$

We show first via induction on ℓ that

$$Y_{kn+\ell} \le a + \frac{1}{n^{1/4}}. \tag{8}$$

for all $\ell = 1, \dots, n$. This ensures that $Y_{kn+\ell}$ does not deviate much from its initial upper bound of a on the process. Conditioned on this, we can establish the desired contraction $\max_{n^{3/4}<i\le n} Y_{(k+1)n}^{(i)} \le 2\varepsilon + G_{\beta,n}(a)$.

For $\ell = 1$, under the assumptions of the lemma, and using the fact that $G_{\beta,n}$ is a monotonically increasing function, we obtain from (7)

$$Y_{kn+1} < \frac{\varepsilon n^{3/4}}{n} + \frac{1}{n}\big((n-1)a + G_{\beta,n}(a)\big) \le \frac{\varepsilon}{n^{1/4}} + a.$$

For the induction step we consider two cases. First assume that (8) holds for all $\ell \in \{1, \dots, \ell_1 - 1\}$ for some $\ell_1 \in \{1, \dots, n - n^{3/4} - 1\}$. From (7), the monotonicity of $G_{\beta,n}$, the lemma assumptions, and the inductive hypothesis, we get

$$\begin{aligned} Y_{kn+\ell_1} &= \frac{1}{n} D^{(\ell_1)}_{kn+\ell_1} + \frac{1}{n}\Big((n-\ell_1)Y^{(n-\ell_1)}_{kn} + \ell_1\Big(\frac{1}{\ell_1}\sum_{i=kn+1}^{kn+\ell_1} G_{\beta,n}(Y_{i-1})\Big)\Big) \\ &< \frac{\varepsilon}{n^{1/4}} + \frac{1}{n}\Big((n-\ell_1)a + \ell_1 G_{\beta,n}\Big(a + \frac{1}{n^{1/4}}\Big)\Big). \end{aligned}$$

Now, by the mean value theorem, since the derivative of $G_{\beta,n}$ is bounded in the interval $\big[a, a + \frac{1}{n^{1/4}}\big]$, we have $G_{\beta,n}(a + \frac{1}{n^{1/4}}) = G_{\beta,n}(a) + O(\frac{1}{n^{1/4}}) \le a - \varepsilon$ for large enough n. Then,

$$\begin{aligned} Y_{kn+\ell_1} &\le \frac{\varepsilon}{n^{1/4}} + \frac{1}{n}\Big((n-\ell_1)a + \ell_1(a-\varepsilon)\Big) \\ &\le \frac{\varepsilon}{n^{1/4}} + \frac{1}{n}\big(na - \ell_1\varepsilon\big) = a + \frac{\varepsilon}{n^{1/4}} - \frac{\ell_1}{n}\varepsilon \le a + \frac{1}{n^{1/4}}. \end{aligned}$$

Thus, the claim holds for all $1 \le \ell < n - n^{3/4}$. For the remaining range, let us assume that the claim holds for all $\ell \in \{1, \dots, \ell_2 - 1\}$ for some $\ell_2 \in \{n - n^{3/4} - 1, \dots, n\}$. Then, similarly

$$\begin{aligned} Y_{kn+\ell_2} &= \frac{1}{n} D^{(\ell_2)}_{kn+\ell_2} + \frac{1}{n}\Big((n-\ell_2)Y^{(n-\ell_2)}_{kn} + \ell_2\Big(\frac{1}{\ell_2}\sum_{i=kn+1}^{kn+\ell_2} G_{\beta,n}(Y_{i-1})\Big)\Big) \\ &< \frac{\varepsilon}{n^{1/4}} + \frac{1}{n}\Big(n - \ell_2 + \ell_2 G_{\beta,n}\Big(a + \frac{1}{n^{1/4}}\Big)\Big) \\ &\le \frac{\varepsilon}{n^{1/4}} + \frac{1}{n}\Big((n^{3/4}+1) + n(a-\varepsilon)\Big) = a - \varepsilon + \frac{\varepsilon}{n^{1/4}} + \frac{1}{n^{1/4}} + \frac{1}{n} \le a, \end{aligned}$$

and thus (8) follows.

To establish that $\max_{n^{3/4} < i \le n} Y^{(i)}_{(k+1)n} \le 2\varepsilon + G_{\beta,n}(a)$, observe that the lemma assumptions and (8) imply for all $\ell \in \{n^{3/4} + 1, \dots, n\}$,

$$\begin{aligned} Y^{(\ell)}_{(k+1)n} &= \frac{1}{\ell} D^{(\ell)}_{(k+1)n} + \frac{1}{\ell}\sum_{j=(k+1)n-\ell+1}^{(k+1)n} G_{\beta,n}(Y_{j-1}) \\ &< \frac{\varepsilon n^{3/4}}{\ell} + \frac{1}{\ell}\sum_{j=(k+1)n-\ell+1}^{(k+1)n} G_{\beta,n}\Big(a + \frac{1}{n^{1/4}}\Big) \le 2\varepsilon + G_{\beta,n}(a), \end{aligned}$$

which proves our claim. ◀

2.2 Fluctuation analysis

Our goal now is to bound the fluctuations $D^{(\ell)}_t$ of the $Y^{(\ell)}_t$ process. For this, consider the process

$$M_t = \sum_{i=1}^{t} (X_i - G_{\beta,n}(Y_{i-1}));$$

observe that $D^{(\ell)}_t = M_t - M_{t-\ell}$. We establish first that the process M_t is a supermartingale.

▶ **Lemma 6.** *$\{M_t\}_{t>0}$ is a supermartingale.*

The proof of this lemma is provided in Section 2.4. We bound the maximum supermartingale difference $M_i - M_j$ over a time interval using a Maximal-Azuma inequality. We use a small variation of a version of this type inequality that appears in [28]. A proof is provided in the full version of the paper [5] for completeness.

▶ **Lemma 7.** *Let $\{Z_t\}_{t\geq 1}$ be a bounded discrete-time supermartingale. Suppose there exists $R \in \mathbb{R}_+$ such that $|Z_{t+1} - Z_t| \leq R$ for all integer $t \geq 1$. Then, for any positive integers t_1, t_2 such that $1 \leq t_1 < t_2$ and $d > 0$ we have*

$$\Pr\left[\max_{t_1 \leq i < j \leq t_2} Z_j - Z_i > d\right] \leq 2e^{-\frac{d^2}{32(t_2-t_1)R^2}}.$$

2.3 Combining drift and fluctuation analysis

The next ingredient of the proof is to argue that repeated applications of Lemma 5 decrease the distance to equiproportionality. For this, we introduce the function $G^{\varepsilon}_{\beta,n} : \mathbb{Z}_+ \to \mathbb{R}_+$ defined recursively by setting $G^{\varepsilon}_{\beta,n}(1) = 1 - \varepsilon$, and for all integer $k \geq 2$:

$$G^{\varepsilon}_{\beta,n}(k) = G_{\beta,n}\left(G^{\varepsilon}_{\beta,n}(k-1) + \varepsilon\right). \tag{9}$$

The function $G^{\varepsilon}_{\beta,n}(k)$ is monotonically decreasing with k and for any $\rho > 0$, it enters the interval $[1/q, 1/q + \rho]$ after constant number of recursive steps. The latter is established in the following lemma which is proved in the full version of the paper [5].

▶ **Lemma 8.** *For any fixed $\rho > 0$, there exist constants $k \in \mathbb{Z}_+$ and $\varepsilon > 0$ such that $G^{\varepsilon}_{\beta,n}(k) + \varepsilon < \frac{1}{q} + \rho$.*

We use the recursive function $G^{\varepsilon}_{\beta,n}$ to probabilistically bound the process $Y^{(\ell)}_{kn}$.

▶ **Lemma 9.** *For any integer $k > 0$ and sufficiently small $\varepsilon > 0$, we have*

$$\Pr\left[\max_{n^{3/4} < i \leq n} Y^{(i)}_{kn} > G^{\varepsilon}_{\beta,n}(k) + \varepsilon\right] \leq 2ke^{-\frac{\varepsilon^2\sqrt{n}}{128}}.$$

Proof. Consider the events

$$A_k = \left\{\max_{n^{3/4} < i \leq n} Y^{(i)}_{kn} \leq G^{\varepsilon}_{\beta,n}(k) + \varepsilon\right\}, \text{ and}$$
$$B_k = \left\{\max_{1 \leq i \leq j \leq n} D^{(i)}_{(k-1)n+j} \leq \frac{\varepsilon n^{3/4}}{2}\right\}.$$

For $k > 1$ we have

$$\Pr[\overline{A}_k] \leq \Pr\left[\overline{A}_k \mid A_{k-1}\right] + \Pr[\overline{A}_{k-1}] \leq \Pr[\overline{A}_1] + \sum_{\ell=2}^{k} \Pr\left[\overline{A}_\ell \mid A_{\ell-1}\right]. \tag{10}$$

Since

$$\Pr[\overline{A}_1] = \Pr\left[\max_{n^{3/4} < i \leq n} Y^{(i)}_{n} > G^{\varepsilon}_{\beta,n}(1) + \varepsilon\right] = \Pr\left[\max_{n^{3/4} < i \leq n} Y^{(i)}_{n} > 1\right] = 0,$$

it suffices to prove that

$$\Pr[\overline{A_\ell} \mid A_{\ell-1}] \leq 2e^{-\frac{\varepsilon^2\sqrt{n}}{128}},$$

for all $\ell \in \{2, \dots, k\}$. For any such ℓ, using the definition of $G^{\varepsilon}_{\beta,n}$ in (9) and taking $a = G^{\varepsilon}_{\beta,n}(\ell-1)+\varepsilon$, we obtain from Lemma 5 that $A_{\ell-1} \cap B_\ell \subseteq A_\ell$ and thus $\overline{A}_\ell \subseteq \overline{A}_{\ell-1} \cup \overline{B}_\ell$. Then,

$$\begin{aligned}\Pr\left[\overline{A}_\ell \mid A_{\ell-1}\right] &\le \Pr\left[\overline{A}_{\ell-1} \cup \overline{B}_\ell \mid A_{\ell-1}\right] \le \Pr\left[\overline{B}_\ell \mid A_{\ell-1}\right] \\ &= \Pr\left[\max_{1\le i\le j\le n} M_{(\ell-1)n+j} - M_{(\ell-1)n+j-i} > \frac{\varepsilon n^{3/4}}{2} \,\middle|\, A_{\ell-1}\right]. \end{aligned} \tag{11}$$

We consider the following subset of configurations,

$$\Sigma^a_{n,1} = \Big\{\sigma \in \Sigma_n : \frac{1}{i}\sum_{j=n-i+1}^{n} \mathbf{1}\big(\sigma(j)=1\big) \le a \quad \forall i \in \mathbb{N} \cap (n^{3/4}, n]\Big\}.$$

It is easy to verify that $A_{\ell-1} = \{\sigma_{(\ell-1)n} \in \Sigma^a_{n,1}\}$. We rewrite (11) as

$$\begin{aligned}&\Pr\left[\overline{A}_\ell \mid A_{\ell-1}\right] \\ &\le \Pr\left[\max_{1\le i\le j\le n} M_{(\ell-1)n+j} - M_{(\ell-1)n+j-i} > \frac{\varepsilon n^{3/4}}{2} \,\middle|\, A_{\ell-1}\right] \\ &\le \max_{\sigma\in\Sigma^a_{n,1}} \Pr\left[\max_{1\le i\le j\le n} M_{(\ell-1)n+j} - M_{(\ell-1)n+j-i} > \frac{\varepsilon n^{3/4}}{2} \,\middle|\, \sigma_{(\ell-1)n} = \sigma\right].\end{aligned}$$

By the Markov property and Lemma 6, $\{M_t\}_{t\ge(\ell-1)n}$ conditioned on $\sigma_{(\ell-1)n}$ is a supermartingale with $|M_{t+1} - M_t| \le 1$. Lemma 7 implies that

$$\Pr\left[\overline{A}_\ell \mid A_{\ell-1}\right] \le 2e^{-\frac{(\varepsilon n^{3/4})^2}{128n}} = 2e^{-\frac{\varepsilon^2\sqrt{n}}{128}},$$

which yields the result. ◀

We are now ready to prove Lemma 2.

Proof of Lemma 2. By Lemma 8 and 9, for any $\hat{\rho} > 0$, there exist an integer k and $\varepsilon > 0$ such that

$$\Pr\left[\max_{n^{3/4}<i\le n} Y^{(i)}_{kn} > \frac{1}{q} + \hat{\rho}\right] \le 2ke^{-\frac{\varepsilon^2\sqrt{n}}{128}}.$$

Recall that $Y^{(i)}_{kn}$ denotes the fraction of vertices assigned the spin 1, but this bound holds by symmetry for all spins in Q. So, setting

$$\Sigma^{\rho+}_n = \Big\{\sigma \in \Sigma_n : \frac{1}{i}\sum_{j=n-i+1}^{n} \mathbf{1}\big(\sigma(j)=\kappa\big) \le \frac{1}{q} + \rho \quad \forall i \in \mathbb{N} \cap (n^{3/4}, n] \text{ and } \forall \kappa \in Q\Big\},$$

a union bound over the spins implies

$$\Pr\left[\sigma_{kn} \notin \Sigma^{\hat{\rho}q}_n\right] \le \Pr\left[\sigma_{kn} \notin \Sigma^{\hat{\rho}+}_n\right] \le q \Pr\left[\max_{n^{3/4}<i\le n} Y^{(i)}_{kn} > \frac{1}{q} + \hat{\rho}\right] \le 2qke^{-\frac{\varepsilon^2\sqrt{n}}{128}};$$

taking $\rho = \hat{\rho}q$ establishes (3).

To prove (4), observe that the initial configuration $\sigma_0 \in \Sigma^{\rho}_n \subseteq \Sigma^{\rho+}_n$. Then, as in (10), for any integer $k > 0$

$$\Pr\left[\sigma_{kn} \notin \Sigma^{\rho+}_n\right] \le \sum_{\ell=0}^{k-1} \Pr\left[\sigma_{(\ell+1)n} \notin \Sigma^{\rho+}_n \mid \sigma_{\ell n} \in \Sigma^{\rho+}_n\right].$$

Given that $\sigma_{\ell n} \in \Sigma_n^{\rho+}$, the configuration at the next step can leave the set $\Sigma_n^{\rho+}$ only if the fluctuation is large. In particular, we obtain from Lemma 5 and a union bound over the spins that

$$\Pr\left[\sigma_{kn} \notin \Sigma_n^{\rho+}\right] \le q \sum_{\ell=0}^{k-1} \Pr\left[\max_{1\le j'<j\le n} M_{\ell n+j} - M_{\ell n+j-j'} > \frac{\varepsilon n^{3/4}}{2} \,\middle|\, \sigma_{\ell n} \in \Sigma_n^{\rho+}\right].$$

Recall that $\{M_t\}_{t\ge \ell n}$ is a supermartingale (see Lemma 6), and thus the Maximal-Azuma inequality in Lemma 7 yields that

$$\Pr\left[\sigma_{kn} \notin \Sigma_n^{\rho+}\right] \le 2qke^{-\frac{(\varepsilon n^{3/4})^2}{128n}} = 2qke^{-\frac{\varepsilon^2\sqrt{n}}{128}}.$$

Using this bound, we obtain for any integer $\hat{k} > 0$

$$\begin{aligned}
&\Pr\left[\max_{1\le i\le n} \left\|\alpha(\sigma_{(\hat{k}-1)n+i}) - \hat{e}\right\|_\infty > \rho q\right] \\
&\le \Pr\left[\max_{1\le i\le n} \left\| \alpha(\sigma_{(\hat{k}-1)n+i}) - \hat{e}\right\|_\infty > \rho q \;\middle|\; \sigma_{(\hat{k}-1)n} \in \Sigma_n^{\rho+}\right] + \Pr\left[\sigma_{(\hat{k}-1)n} \notin \Sigma_n^{\rho+}\right] \\
&\le q \Pr\left[\max_{1\le i\le n} \alpha_1\big(\sigma_{(\hat{k}-1)n+i}\big) - 1/q > \rho + \frac{1}{n^{1/4}} \;\middle|\; \sigma_{(\hat{k}-1)n} \in \Sigma_n^{\rho+}\right] + 2q(\hat{k}-1)e^{-\frac{\varepsilon^2\sqrt{n}}{128}} \\
&\le q \max_{\sigma\in\Sigma_n^{\rho+}} \Pr\left[\max_{1\le i\le n} \alpha_1\big(\sigma_{(\hat{k}-1)n+i}\big) - 1/q > \rho + \frac{1}{n^{1/4}} \;\middle|\; \sigma_{(\hat{k}-1)n} = \sigma\right] + 2q(\hat{k}-1)e^{-\frac{\varepsilon^2\sqrt{n}}{128}},
\end{aligned} \tag{12}$$

where the second inequality is obtained by taking union bound over each spin. We consider the following events,

$$\begin{aligned}
E_{\hat{k}} &= \left\{\max_{n^{3/4}<i\le n} Y^{(i)}_{(\hat{k}-1)n} \le \frac{1}{q} + \rho\right\}, \\
B_{\hat{k}} &= \left\{\max_{1\le i\le j\le n} D^{(i)}_{(\hat{k}-1)n+j} < \frac{\varepsilon n^{3/4}}{2}\right\}, \text{ and} \\
C_{\hat{k}} &= \left\{\max_{1\le i\le n} Y_{(\hat{k}-1)n+i} \le \frac{1}{q} + \rho + \frac{1}{n^{1/4}}\right\}.
\end{aligned}$$

Lemma 5 implies that $\overline{C}_{\hat{k}} \subseteq \overline{E}_{\hat{k}} \cup \overline{B}_{\hat{k}}$. We recall that $D_t^\ell = M_t - M_{t-\ell}$ for any positive integer t and integer ℓ such that $1 \le \ell \le \min\{t, n\}$. Using the fact $\left\{\sigma_{(\hat{k}-1)n} \in \Sigma_n^{\rho+}\right\} \subseteq \overline{E}_{\hat{k}}$, we obtain for any $\sigma \in \Sigma_n^{\rho+}$

$$\begin{aligned}
&\Pr\left[\max_{1\le i\le n} \alpha_1\big(\sigma_{(\hat{k}-1)n+i}\big) - 1/q > \rho + \frac{1}{n^{1/4}} \;\middle|\; \sigma_{(\hat{k}-1)n} = \sigma\right] = \Pr\left[\overline{C}_{\hat{k}} \,\middle|\, \sigma_{(\hat{k}-1)n} = \sigma\right] \\
&\quad\le \Pr\left[\overline{E}_{\hat{k}} \,\middle|\, \sigma_{(\hat{k}-1)n} = \sigma\right] + \Pr\left[\overline{B}_{\hat{k}} \,\middle|\, \sigma_{(\hat{k}-1)n} = \sigma\right] \\
&\quad\le \Pr\left[\max_{1\le i<j\le n} M_{(\hat{k}-1)n+j} - M_{(\hat{k}-1)n+j-i} > \frac{\varepsilon n^{3/4}}{2} \Big| \sigma_{(\hat{k}-1)n} = \sigma\right] \\
&\quad\le 2e^{-\frac{\varepsilon^2\sqrt{n}}{128}},
\end{aligned}$$

where we apply Lemmas 6 and 7 in the last inequality. Plugging this bound into (12) yields the result. ◀

2.4 Proofs of auxiliary Facts

In this section, we complete the proof of Lemma 2 by providing the proofs of Lemmas 6 and 8. Let us introduce some notation first. Let

$$\mathcal{S}_q = \Big\{x \in \mathbb{R}^q_{\geq 0} : \sum_{i=1}^{q} x_i = 1\Big\},$$

$$\tilde{\mathcal{S}}_q = \Big\{x \in \mathbb{R}^q_{\geq 0} : \sum_{i=1}^{q} x_i = 1 - \frac{1}{n}\Big\}, \text{ and}$$

$$\mathcal{S}'_q = \Big\{x \in \mathbb{R}^q_{+} : \sum_{j=1}^{q} x_j = 1 \text{ and } x_i \geq \frac{1}{e^{\beta} + (q-1)} \quad \forall i \in Q\Big\}.$$

We define the function $g_\beta : \mathcal{S}_q \cup \tilde{\mathcal{S}}_q \to \mathcal{S}'_q$, as $g_\beta(s) = \big(g^1_\beta(s), \cdots, g^q_\beta(s)\big)$ where

$$g^j_\beta(s) = \frac{e^{\beta s_j}}{\sum_{i=1}^{q} e^{\beta s_i}}.$$

For $i, j \in Q$, let $g^{i\to j}_\beta : \mathcal{S}_q \to \mathcal{S}'_q$ be given by

$$g^{i\to j}_\beta(s) = g^j_\beta\Big(s - \frac{1}{n}e_i\Big),$$

where recall that $e_i \in \{0,1\}^q$ is the indicator vector with 1 in the i-th coordinate and 0 elsewhere. This function corresponds to the probability that a site update flips the vertex from spin i to j from configuration with proportion vector s. We establish the following inequality involving $g^{i\to j}_\beta$ and $G_{\beta,n}$; its proof is given in the full version of the paper [5].

▶ **Lemma 10.** *For $s \in \mathcal{S}_q$ and $i, j \in Q$, we have*

$$g^{i\to j}_\beta(s) \leq g^j_\beta(s) + \frac{\beta}{n} \leq G_{\beta,n}(s_j).$$

We can now provide the proof of Lemma 6.

Proof of Lemma 6. Let $t \geq 1$ be a integer and let j be the spin of the vertex to be update updated at time $t+1$. Then,

$$\begin{aligned}\mathbb{E}[M_{t+1} - M_t|\mathcal{F}_t] &= \mathbb{E}[X_{t+1} - G_{\beta,n}(Y_t)|\mathcal{F}_t] = \mathbb{E}[X_{t+1}|\mathcal{F}_t] - G_{\beta,n}(Y_t)\\ &= g^{j\to 1}_\beta\big(\alpha(\sigma_t)\big) - G_{\beta,n}(Y_t) \leq 0,\end{aligned}$$

where the last inequality follows from Lemma 10. ◀

3 Spin fraction analysis

In this section, we begin our analysis of Phase 2 of the coupling. In particular, we analyze rate of convergence of the systematic scan to a $O(1/\sqrt{n})$ neighborhood of $\hat{e}$ from a configuration $\sigma_0 \in \Sigma^\rho_n$. We start with the following bounds for the function g^ℓ_β which follow from its Taylor expansion; their proofs are provided in the full version of the paper [5].

▶ **Lemma 11.** *For any $\ell \in Q$ and $s, \tilde{s} \in \mathcal{S}_q$,*

(i) *$\exists\ R : \mathcal{S}_q \to \mathbb{R}$ such that $g^\ell_\beta(s) = \frac{1}{q} + \frac{\beta}{q}\Big(s_\ell - \frac{1}{q}\Big) + R(s)$ and $|R(s)| \leq 3q\beta^2\|s - \hat{e}\|_2^2$;*

(ii) *$\big\|g_\beta(s) - g_\beta(\tilde{s})\big\|_1 = \frac{\beta}{q}\big\|s - \tilde{s}\big\|_1 + \|s - \tilde{s}\|_1\Big\{O\big(\|s - \hat{e}\|_1 + \|\tilde{s} - \hat{e}\|_1\big)\Big\}$.*

Now, for a vector $X = (X_1, \dots, X_q) \in \mathbb{R}^q$, let

$$\mathrm{Var}(X) = \mathbb{E}\big[\|X - \mathbb{E}X\|_2^2\big] = \sum_{i=1}^{q} \mathbb{E}\big[\big(X_i - \mathbb{E}X_i\big)^2\big] = \sum_{i=1}^{q} \mathrm{Var}(X_i).$$

We prove the following bound on the variance of the q-dimensional process $\alpha(\sigma_t)$, assuming that $\sigma_0 \in \Sigma_n^\rho$; its proof is provided in the full version of the paper [5].

▶ **Lemma 12.** *There exists a constant $\rho = \rho(\beta, q) > 0$ such that for all $0 \le t \le n\sqrt{n}$ and $\sigma_0 \in \Sigma_n^\rho$, we have $\mathrm{Var}\big(\alpha(\sigma_t)\big) = O\big(1/n\big)$.*

We also require a tight control on the following recurrence; its analysis is fleshed out in Section 4.

▶ **Lemma 13.** *Let $\{x_t = (x_t^{(1)}, \dots, x_t^{(q)})\}_{t \ge 0}$ be a sequence of vectors in $\mathbb{R}^q_{\ge 0}$ such that for all $j \in Q$ and $t \ge n$, we have the recursion*

$$x_t^{(j)} = \frac{\beta}{nq} \sum_{i=t-n}^{t-1} x_i^{(j)} + \frac{C}{n} \sum_{i=t-n}^{t-1} \|x_i\|_2^2 + \frac{C}{n},$$

where C is a positive constant. Then, if for all $i \in \{0, \dots, n-1\}$ and all $j \in Q$, we have $|x_i^{(j)}| \le \rho$ for a small enough constant $\rho > 0$, then there exists constant $\hat{C} > 0$ such that $\|x_t\|_2^2 \le \hat{C}\rho^2\gamma_n^{2t} + \hat{C}/n$, where γ_n is the unique positive real root of the equation $\sum_{i=1}^{n} \gamma_n^{-i} = nq/\beta$.

We combine the three lemmas above to obtain the correct rate of contraction towards $\hat{e}$ of the proportions vector under the systematic scan dynamics. Let

$$u_t = \begin{cases} e_{J_t} & \text{if } t \ge 1 \\ e_{\sigma_0(n+t)} & \text{if } -n < t \le 0, \end{cases}$$

where recall that J_t denotes the random variable corresponding to the spin chosen in the t-th site update. With this notation, we have

$$\alpha(\sigma_t) = \frac{1}{n} \sum_{i=t-n+1}^{t} u_i. \tag{13}$$

▶ **Lemma 14.** *Let γ_n be the unique positive real root of the equation $\sum_{i=1}^{n} \gamma_n^{-i} = nq/\beta$. Then, for all integer $t \ge 0$ such that $t \le n\sqrt{n}$ there exist constants $\rho = \rho(\beta, q)$ and $C = C(\rho, \beta, q)$ such that for any $\sigma_0 \in \Sigma_n^\rho$*

$$\mathbb{E}\big[\|\alpha(\sigma_t) - \hat{e}\|_2^2\big] \le C\rho^2\gamma_n^{2t} + \frac{C}{n}.$$

Proof. We let $t_m = t_m(t) = \max\{1, t - n + 1\}$. From (13), for all $t \ge 0$ and $\ell \in Q$, we have

$$\alpha_\ell(\sigma_t) = \frac{1}{n} \sum_{i=t-n+1}^{0} \mathbf{1}\big(\sigma_0(n+i) = \ell\big) + \frac{1}{n} \sum_{i=t_m}^{t} \mathbf{1}\big(J_i = \ell\big),$$

and thus

$$\begin{aligned} \mathbb{E}\big[\alpha_\ell(\sigma_t)\big] &= \frac{1}{n} \sum_{i=t-n+1}^{0} \mathbf{1}\big(\sigma_0(n+i) = \ell\big) + \frac{1}{n} \sum_{i=t_m}^{t} \mathbb{E}\big[\mathbf{1}(J_i = \ell)\big] \\ &= \frac{1}{n} \sum_{i=t-n+1}^{0} \mathbf{1}\big(\sigma_0(n+i) = \ell\big) + \frac{1}{n} \sum_{i=t_m}^{t} \mathbb{E}\Big[g_\beta^\ell\Big(\alpha(\sigma_{i-1}) - \frac{1}{n}u_{i-n}\Big)\Big]. \end{aligned} \tag{14}$$

From Lemmas 10 and 11(i), we obtain

$$\begin{aligned}\mathbb{E}\Big[g_\beta^\ell\Big(\alpha(\sigma_{i-1})-\frac{1}{n}u_{i-n}\Big)\Big] \le& \frac{\beta}{n}+\mathbb{E}\Big[g_\beta^\ell(\alpha(\sigma_{i-1}))\Big]\\ \le& \frac{\beta}{n}+\frac{1}{q}+\frac{\beta}{q}\mathbb{E}\Big[\alpha_\ell(\sigma_{i-1})-\frac{1}{q}\Big]+3q\beta^2\mathbb{E}\big[\|\alpha(\sigma_i)-\hat{e}\|_2^2\big]\\ \le& \frac{\beta}{n}+3q\beta^2\mathrm{Var}\big(\alpha(\sigma_i)\big)+\frac{1}{q}+\frac{\beta}{q}\mathbb{E}\Big[\alpha_\ell(\sigma_{i-1})-\frac{1}{q}\Big]\\ &+3q\beta^2\big\|\mathbb{E}[\alpha(\sigma_i)-\hat{e}]\big\|_2^2.\end{aligned}$$

By Lemma 12, there exists a constant $C_1 > 0$ such that the following holds for all $t \in \{0,\cdots,n\sqrt{n}\}$

$$\mathbb{E}\Big[g_\beta^\ell\Big(\alpha(\sigma_{i-1})-\frac{1}{n}u_{i-n}\Big)\Big] \le \frac{C_1}{n}+\frac{1}{q}+\frac{\beta}{q}\mathbb{E}\Big[\alpha_\ell(\sigma_{i-1})-\frac{1}{q}\Big]+3q\beta^2\big\|\mathbb{E}[\alpha(\sigma_i)-\hat{e}]\big\|_2^2.$$

Plugging the above inequality into (14)

$$\begin{aligned}\mathbb{E}\big[\alpha_\ell(\sigma_t)\big] \le& \frac{C_1}{n}+\frac{1}{n}\sum_{i=t-n+1}^{0}\Big[\mathbf{1}\big(\sigma_0(n+i)=\ell\big)\Big]\\ &+\frac{t-t_m+1}{nq}+\frac{1}{n}\sum_{i=t_m}^{t}\frac{\beta}{q}\mathbb{E}\Big[\alpha_\ell(\sigma_{i-1})-\frac{1}{q}\Big]+\frac{3q\beta^2}{n}\sum_{i=t_m}^{t}\big\|\mathbb{E}[\alpha(\sigma_{i-1})-\hat{e}]\big\|_2^2,\end{aligned}$$

and subtracting $1/q$ from both sides yields,

$$\begin{aligned}\mathbb{E}\Big[\alpha_\ell(\sigma_t)-\frac{1}{q}\Big] \le& \frac{C_1}{n}+\frac{1}{n}\sum_{i=t-n+1}^{0}\Big[\mathbf{1}\big(\sigma_0(n+i)=\ell\big)-\frac{1}{q}\Big]\\ &+\frac{1}{n}\sum_{i=t_m}^{t}\frac{\beta}{q}\mathbb{E}\Big[\alpha_\ell(\sigma_{i-1})-\frac{1}{q}\Big]+\frac{3q\beta^2}{n}\sum_{i=t_m}^{t}\big\|\mathbb{E}[\alpha(\sigma_{i-1})-\hat{e}]\big\|_2^2. \qquad (15)\end{aligned}$$

Let $\{x_t\}_{t\ge 0}$ be a sequence of vectors in $\mathbb{R}^q$ such that for all $j \in Q$ and $t \ge n$, we have the recursion

$$x_t^{(j)} = \frac{\beta}{nq}\sum_{i=t-n}^{t-1}x_i^{(j)}+\frac{C_2}{n}\sum_{i=t-n}^{t-1}\|x_i\|_2^2+\frac{C_2}{n}.$$

where $C_2 = \max\{C_1, 3q\beta^2\}$. For all $i \in \{0,\dots,n-1\}$ and all $j \in Q$, $x_i^{(j)} = 2\rho$. We prove by induction on t that for every $\ell \in Q$ and $t \in \{0,\cdots,n\sqrt{n}\}$, the following holds

$$\Big|\mathbb{E}\Big[\alpha_\ell(\sigma_t)-\frac{1}{q}\Big]\Big| \le x_t^{(\ell)}. \qquad (16)$$

For $t = 0$, the claim trivially holds since $\sigma_0 \in \Sigma_n^\rho$ and therefore $|\alpha_\ell(\sigma_0)-1/q| \le \rho < 2\rho$. We consider three cases for the inductive step. We assume first that the claim holds for all $t \in \{1,\cdots,\kappa-1\}$ for some $\kappa \in \{1,\cdots,n-n^{3/4}-1\}$. For $t = \kappa$, we obtain from (15) and the triangle inequality that

$$\begin{aligned}\Big|\mathbb{E}\Big[\alpha_\ell(\sigma_t)-\frac{1}{q}\Big]\Big| \le& \frac{C_1}{n}+\frac{1}{n}\Big|\sum_{i=t-n+1}^{0}\Big[\mathbf{1}\big(\sigma_0(n+i)=\ell\big)-\frac{1}{q}\Big]\Big|\\ &+\frac{\beta}{nq}\sum_{i=t_m}^{t}\Big|\mathbb{E}\Big[\alpha_\ell(\sigma_{i-1})-\frac{1}{q}\Big]\Big|+\frac{3q\beta^2}{n}\sum_{i=t_m}^{t}\big\|\mathbb{E}[\alpha(\sigma_{i-1})-\hat{e}]\big\|_2^2.\end{aligned}$$

Since $\sigma_0 \in \Sigma_n^\rho$, we observe that $\left|\sum_{i=t-n+1}^{0}\left[\mathbf{1}\big(\sigma_0(n+i)=\ell\big)-\frac{1}{q}\right]\right| \le (n-t)\rho$, using the inductive hypothesis to bound the second and third sums we obtain

$$\begin{aligned}\left|\mathbb{E}\Big[\alpha_\ell(\sigma_t)-\frac{1}{q}\Big]\right| &\le \frac{C_1}{n}+\frac{(n-t)\rho}{n}+\frac{\beta}{nq}(2t\rho)+\frac{12q\beta^2}{n}\big(tq\rho^2\big)\\ &= \frac{C_1}{n}+\rho\Big[1+\frac{t}{n}\Big(\big(2\beta/q\big)-1+12q^2\beta^2\rho\Big)\Big].\end{aligned}$$

Set $1-\beta/q=\delta$ so that $2\beta/q-1=1-2\delta$ (recall that $\beta/q<1$). Since $12q^2\beta^2$ is a fixed constant, we can choose ρ small enough so that $12q^2\beta^2\rho<\delta$. Plugging these into the above inequality:

$$\left|\mathbb{E}\Big[\alpha_\ell(\sigma_t)-\frac{1}{q}\Big]\right| \le \frac{C_1}{n}+\rho\Big[1+(1-\delta)\Big] = 2\rho+\Big(\frac{C_1}{n}+-\rho\delta\Big) \le 2\rho \le x_t^{(\ell)}$$

provided n is large enough. For the second case, let us assume that the claim holds for all $t\in\{1,\cdots,\kappa-1\}$ for some $\kappa\in\{n-n^{3/4},\cdots,n-1\}$. For $t=\kappa$:

$$\begin{aligned}\left|\mathbb{E}\Big[\alpha_\ell(\sigma_t)-\frac{1}{q}\Big]\right| &\le \frac{C_1}{n}+\frac{n^{3/4}}{n}+\frac{2\beta t\rho}{nq}+\frac{12q^2\beta^2t\rho^2}{n} \le \frac{C_1}{n}+\frac{1}{n^{1/4}}+\rho\Big(\frac{2\beta}{q}+12q^2\beta^2\rho\Big)\\ &\le 2\rho+\Big(\frac{C_1}{n}+\frac{1}{n^{1/4}}-\rho\delta\Big) \le 2\rho \le x_t^{(\ell)}.\end{aligned}$$

For the third case, We assume that the claim holds for all $t\in\{0,\cdots,\kappa-1\}$ for some $\kappa\in\{n,\cdots,n\sqrt{n}\}$. For $t=\kappa$,

$$\begin{aligned}\left|\mathbb{E}\Big[\alpha_\ell(\sigma_t)-\frac{1}{q}\Big]\right| &\le \frac{C_1}{n}+\frac{\beta}{qn}\left|\sum_{i=t-n}^{t-1}\frac{\beta}{q}\mathbb{E}\Big[\alpha_\ell(\sigma_i)-\frac{1}{q}\Big]\right|+\frac{3q\beta^2}{n}\sum_{i=t-n}^{t-1}\big\|\mathbb{E}[\alpha(\sigma_i)-\hat{e}]\big\|_2^2\\ &\le \frac{C_2}{n}+\frac{\beta}{qn}\sum_{i=t-n}^{t-1}x_i^{(\ell)}+\frac{C_2}{n}\sum_{i=t-n}^{t-1}\|x_i\|_2^2 = x_t^{(\ell)},\end{aligned}$$

which proves the claim (16). Using the Lemma 13, we show that the following holds for some constant $C_3>0$

$$\Big\|\mathbb{E}\big[\alpha(\sigma_t)-\hat{e}\big]\Big\|_2^2 \le \|x_t\|_2^2 \le C_3\rho^2\gamma_n^{2t}+\frac{C_3}{n}.$$

Using Lemma 12 and the above equation, we prove this lemma. ◀

4 Recursion

In this section, we prove Lemma 13. For integer $n\ge 1$, we define $\gamma_n\in(0,1)$ as the unique positive root of

$$\frac{\beta}{nq}\sum_{i=1}^{n}\gamma_n^{-i}=1. \tag{17}$$

The left hand side of this equation is continuously decreasing in $\gamma_n\in(0,\infty)$, and it is $\frac{\beta}{q}$ when evaluated at $\gamma_n=1$. For $\gamma_n=\beta/q$, the left hand side is

$$\frac{\beta}{nq}\sum_{i=1}^{n}\Big(\frac{q}{\beta}\Big)^i=\frac{1}{n}\sum_{i=1}^{n}\Big(1+\frac{q}{\beta}+\cdots+\frac{q^{n-1}}{\beta^{n-1}}\Big)>1,$$

where the last inequality follows from $\frac{\beta}{q}<1$. There is indeed a unique positive solution for (17) in $(\beta/q,1)$.

We will show that the unique positive solution of (17) will be asymptotically approximated by $1 - b/n$ where b is the positive real root of the following equation

$$\frac{\beta(1-e^{-b})}{qb} - e^{-b} = 0, \tag{18}$$

while b does not have an elementary closed form, it can be expressed as

$$b = -\frac{\beta}{q} - W_{-1}\left(-\frac{\beta}{q}\exp\left(-\beta/q\right)\right),$$

where W_{-1} is the negative branch of the Lambert W function. Formally, for real numbers x and y, the equation $ye^y = x$ has real roots for y if $-\frac{1}{e} \leq x < 0$ and one of its real roots is $W_{-1}(x)$. We establish the following approximation for the root of (17); its proof is provided in the full version [5].

▶ **Lemma 15.** *Let $\hat{\gamma}_n = 1 - b/n$. Then, $|\gamma_n - \hat{\gamma}_n| = O(n^{-2})$ and for every $t \in [0, \ldots, n\sqrt{n}]$, we have $e^{-bt/n}/2 \leq \gamma_n^t \leq 2e^{-bt/n}$.*

A direct consequence of Lemma 15 is that

$$\sum_{i=0}^{\infty} \gamma_n^i = \Theta(n), \quad \text{and} \tag{19}$$

$$\gamma_n^j = \Theta(1) \text{ for all } 0 \leq j \leq n. \tag{20}$$

We use γ_n to bound the recurrence in the following lemma, which we later use to prove Lemma 13.

▶ **Lemma 16.** *Let $\{b_t\}_{t\geq n}$ be a sequence of nonnegative real numbers and define $\{d_t\}_{t\geq 0}$ as*

$$d_t = \begin{cases} 0 & \text{for } 0 \leq t < n, \\ b_t + \frac{\beta}{nq}\sum_{i=t-n}^{t-1} d_i & \text{for } t \geq n. \end{cases}$$

Then, there exists a constant $C \geq 1$ such that for all $t \geq n$, we have $d_t \leq b_t + \frac{C\gamma_n^t}{n}\sum_{i=n}^{t} b_i\gamma_n^{-i}$.

The proof of this lemma is deferred to the full version of the paper [5]. We are now ready to provide the proof of Lemma 13.

Proof of Lemma 13. Fix $k \in Q$ and consider the sequence $\{y_t\}_{t\geq 0}$ defined as $y_i = x_i^{(k)}$ for $i \in \{0, \ldots, n-1\}$ and $y_t = \frac{1}{n}\frac{\beta}{q}\sum_{i=t-n}^{t-1} y_i$ when $t \geq n$. Let $d_t = x_t^{(k)} - y_t$ for all $t \geq 0$. Observe that $d_t = 0$ for all $0 \leq t < n$. For $t \geq n$, we have

$$\begin{aligned} d_t = x_t^{(k)} - y_t &= \frac{\beta}{nq}\sum_{i=t-n}^{t-1}\left(x_i^{(k)} - y_i\right) + \frac{C}{n}\sum_{i=t-n}^{t-1}\|x_i\|_2^2 + \frac{C}{n} \\ &= \frac{\beta}{nq}\sum_{i=t-n}^{t-1} d_i + \frac{C}{n}\sum_{i=t-n}^{t-1}\|x_i\|_2^2 + \frac{C}{n} = b_t + \frac{\beta}{nq}\sum_{i=t-n}^{t-1} d_i, \end{aligned}$$

where we let $b_t = \frac{C}{n}\sum_{i=t-n}^{t-1}\|x_i\|_2^2 + \frac{C}{n}$ for all $t \geq n$. From Lemma 16, there exists $C_1 > 1$ such that the following holds for all $t \geq n$

$$d_t \leq b_t + \frac{C_1\gamma_n^t}{n}\sum_{i=n}^{t}\gamma_n^{-i}b_i.$$

For convenience, we choose the constant C_1 large enough such that also $\gamma_n^{-n} \leq C_1$ and

$$\sum_{i=0}^{\infty} \gamma_n^i \leq C_1 n; \tag{21}$$

see (20) and (19). We expand d_t as follows

$$d_t \leq \frac{C}{n} \sum_{i=t-n}^{t-1} \|x_i\|_2^2 + \frac{C}{n} + \frac{CC_1\gamma_n^t}{n^2} \sum_{i=n}^{t} \gamma_n^{-i} \sum_{j=i-n}^{i-1} \|x_j\|_2^2 + \frac{CC_1}{n^2} \sum_{i=n}^{t} \gamma_n^{t-i}.$$

From (21), we see $\sum_{i=n}^{t} \gamma_n^{t-i} \leq C_1 n$ and plugging this in the above bound, we obtain

$$\begin{aligned} d_t &\leq \frac{C}{n} \sum_{i=t-n}^{t-1} \|x_i\|_2^2 + \frac{C}{n} + \frac{CC_1\gamma_n^t}{n^2} \sum_{i=n}^{t} \gamma_n^{-i} \sum_{j=i-n}^{i-1} \|x_j\|_2^2 + \frac{CC_1^2}{n} \\ &\leq \frac{2CC_1^2}{n} + \frac{C}{n} \sum_{i=t-n}^{t-1} \|x_i\|_2^2 + \frac{CC_1\gamma_n^t}{n^2} \sum_{i=n}^{t} \gamma_n^{-i} \sum_{j=i-n}^{i-1} \|x_j\|_2^2 \end{aligned} \tag{22}$$

where we use the fact that $C + CC_1^2 \leq 2CC_1^2$. Observe also that

$$\begin{aligned} \sum_{i=n}^{t} \gamma_n^{-i} \sum_{j=i-n}^{i-1} \|x_j\|_2^2 &= \sum_{j=0}^{n-1} \gamma_n^{j-n} \sum_{i=n}^{t} \gamma_n^{-(i+j-n)} \|x_{i+j-n}\|_2^2 \\ &\leq \gamma_n^{-n} \sum_{j=0}^{n-1} \sum_{i=n}^{t} \gamma_n^{-(i+j-n)} \|x_{i+j-n}\|_2^2 \leq nC_1 \sum_{i=0}^{t-1} \gamma_n^{-i} \|x_i\|_2^2, \end{aligned} \tag{23}$$

where the last inequality follows from $\gamma_n^{-n} \leq C_1$. Plugging (23) into (22), we obtain

$$\begin{aligned} d_t &\leq \frac{2CC_1^2}{n} + \frac{C}{n} \sum_{i=t-n}^{t-1} \|x_i\|_2^2 + \frac{CC_1^2}{n} \gamma_n^t \sum_{i=0}^{t-1} \gamma_n^{-i} \|x_i\|_2^2 \\ &\leq \frac{2CC_1^2}{n} + \frac{C\gamma_n^{-n}}{n} \sum_{i=t-n}^{t-1} \gamma_n^{t-i} \|x_i\|_2^2 + \frac{CC_1^2}{n} \gamma_n^t \sum_{i=0}^{t-1} \gamma_n^{-i} \|x_i\|_2^2 \\ &\leq \frac{2CC_1^2}{n} + \frac{C(C_1+1)C_1}{n} \gamma_n^t \sum_{i=0}^{t-1} \gamma_n^{-i} \|x_i\|_2^2 \leq \frac{2CC_1^2}{n} + \frac{2CC_1^2}{n} \gamma_n^t \sum_{i=0}^{t-1} \gamma_n^{-i} \|x_i\|_2^2. \end{aligned} \tag{24}$$

We show next by induction on t that the following holds for all $t \geq 0$

$$y_t \leq C_1 \rho \gamma_n^t. \tag{25}$$

For all $0 \leq t < n$, we have $C_1\rho\gamma_n^t \geq \rho\gamma_n^{-n}\gamma_n^t = \rho\gamma_n^{t-n} \geq \rho \geq y_t$. Therefore, the base case holds. We assume that the claim holds for all $t < \ell$ where $\ell \geq n$. For $t = \ell$,

$$y_t = \frac{\beta}{nq} \sum_{i=t-n}^{t-1} y_i \leq \frac{\beta}{nq} \sum_{i=t-n}^{t-1} C_1\rho\gamma_n^i = C_1\rho \frac{\beta}{nq} \sum_{i=t-n}^{t-1} \gamma_n^i = C_1\rho\gamma_n^t \frac{\beta}{nq} \sum_{i=0}^{n-1} \gamma_n^{i-n} = C_1\rho\gamma_n^t,$$

which proves the claim in (25). Now, we show the following using induction

$$\|x_t\|_2^2 < 4C_1^2 q\rho^2\gamma_n^{2t} + \frac{4C_1^2 q}{n}. \tag{26}$$

We obtain the following for all t such that $0 \le t < n$,

$$4C_1^2 q\rho^2\gamma_n^{2t} + \frac{4C_1^2 q}{n} \ge 4C_1^2 q\rho^2\gamma_n^{2n} \ge 4\gamma_n^{-2n} q\rho^2\gamma_n^{2n} \ge 4q\rho^2 \ge \|x_t\|_2^2$$

Therefore, the base case holds. We assume that the claim holds for all $t < \ell$ where $\ell \ge n$. For $t = \ell$, we obtain the following from (25) and (24),

$$|x_t^{(k)}| \le |y_t| + |d_t| \le C_1\rho\gamma_n^t + \frac{2CC_1^2\gamma_n^t}{n}\sum_{i=0}^{t-1}\gamma_n^{-i}\|x_i\|_2^2 + \frac{2CC_1^2}{n}. \tag{27}$$

The induction hypothesis then implies that

$$\begin{aligned}\gamma_n^t\sum_{i=0}^{t-1}\gamma_n^{-i}\|x_i\|_2^2 &\le \gamma_n^t\sum_{i=0}^{t-1}\gamma_n^{-i}\Big(4C_1^2 q\rho^2\gamma_n^{2i} + \frac{4C_1^2 q}{n}\Big) \le 4C_1^2 q\gamma_n^t\sum_{i=0}^{t-1}\gamma_n^{-i}\big(\rho^2\gamma_n^{2i} + 1/n\big)\\ &\le 4C_1^2 q\Big(\rho^2\gamma_n^t\sum_{i=0}^{t-1}\gamma_n^i + \frac{1}{n}\sum_{i=0}^{t-1}\gamma_n^{t-i}\Big) \le 4C_1^2 q\big(\rho^2\gamma_n^t C_1 n + C_1\big)\end{aligned}$$

We then plug the above bound into (27) to obtain

$$\begin{aligned}|x_t^{(k)}| &\le C_1\rho\gamma_n^t + \frac{2CC_1^2}{n}\Big(4C_1^2 q\big(\rho^2\gamma_n^t C_1 n + C_1\big)\Big) + \frac{2CC_1^2}{n}\\ &\le C_1\rho\gamma_n^t + 8CC_1^5\rho^2 q\gamma_n^t + \frac{8CC_1^5 q + 2CC_1^2}{n}\\ &\le \rho\gamma_n^t C_1\big(1 + 8CC_1^4\rho q\big) + \frac{8CC_1^5 q + 2CC_1^2}{n}.\end{aligned}$$

Let $C_2 = C_1\big(1+8CC_1^4\rho q\big)$ and $C_3 = 8CC_1^5 q + 2CC_1^2$ for ease of notation. Since k is arbitrary, the above inequality holds for all coordinates in Q, hence,

$$\|x_t\|_2^2 \le 2q\rho^2\gamma_n^{2t}C_2^2 + \frac{2qC_3^2}{n^2},$$

where we use the fact that $(w+z)^2 \le 2w^2 + 2z^2$ for $w, z \in \mathbb{R}$. We want to show $2q\rho^2\gamma_n^{2t}C_2^2 + \frac{2qC_3^2}{n^2} \le 4C_1^2 q\rho^2\gamma_n^{2t} + \frac{4C_1^2 q}{n}$ by equating the coefficients of γ_n^{2t} and $1/n$. Comparing the coefficient of γ_n^{2t}, we show $C_2 \le \sqrt{2}C_1$ or equivalently, $1 + 8CC_1^4\rho q \le \sqrt{2}$. We choose $\rho > 0$ small enough to make the above inequality true. Moreover, $2qC_3^2/n \le 4C_1^2 q$ holds trivially. Therefore, we proved our claim (26), hence choosing $\hat{C} = 4C_1^2 q$ proves the lemma. ◀

5 Contraction of Hamming Distance

Our goal in this section is to establish Lemma 3 which ensures that **Phase 2** of our coupling succeeds with the desired ε probability. We use the following lemma to upper bound expectation of Hamming distance; its proof is deferred to the full version of the paper [5].

▶ **Lemma 17.** *Let $\{x_t\}_{t\ge 0}$ be a sequence of positive real numbers, such that $x_t \le n$ for $t < n$, and for $t \ge n$ we have $x_t = \frac{\beta}{nq}\sum_{i=t-n}^{t-1} x_i + C\sum_{i=t-n}^{t-1}\gamma_n^{2i} + C$, where $C > 0$ is a constant. Then, there exists a constant $\hat{C} > 0$ such that for all $t \ge 0$ $x_t \le \hat{C}n\gamma_n^t + \hat{C}$.*

We are now ready to provide the proof of Lemma 3.

Proof of Lemma 3. We couple two instances using the optimal single site coupling for two copies of the dynamics. Formally, we define a distribution $\nu_{\sigma,v}$ on Q such that $\nu_{\sigma,v}(j) = g_\beta^j\big(\alpha(\sigma) - \frac{1}{n}e_{\sigma(v)}\big)$ where $\sigma \in \Sigma_n$, $j \in Q$ and $v \in V$. From a pair of configurations σ_{t-1} and $\tilde{\sigma}_{t-1}$, we couple the t-th site update as follows:

1. Let $v = \big(t \bmod n\big) + 1$ be the vertex to be updated.
2. Draw spins J_t and $\tilde{J}_t$ from an optimal coupling of the distribution $\nu_{\sigma_{t-1},v}$ and $\nu_{\tilde{\sigma}_{t-1},v}$ respectively.
3. Set $\sigma_t(v) = J_t$ and $\tilde{\sigma}_t(v) = \tilde{J}_t$ leaving all other vertices unchanged.

We show next that under the optimal site coupling, there exists a constant $C_1 > 0$ such that $\forall\ t \geq n$, $\mathbb{E}[d_H(\sigma_t, \tilde{\sigma}_t)]$ is at most

$$C_1 + \frac{\beta}{nq} \sum_{i=t-n}^{t-1} \mathbb{E}[d_H(\sigma_i, \tilde{\sigma}_i)] + C_1 \sum_{i=t-n}^{t-1} \Big(\mathbb{E}\big[\|\alpha(\sigma_i) - \hat{e}\|_2^2\big] + \mathbb{E}\big[\|\alpha(\tilde{\sigma}_i) - \hat{e}\|_2^2\big] \Big). \tag{28}$$

The Hamming distance between two copies after t site updates for $t \geq n$ is $d_H(\sigma_t, \tilde{\sigma}_t) = \sum_{i=t-n+1}^{t} \mathbf{1}\left(J_i \neq \tilde{J}_i\right)$. Taking expectations on both sides we obtain for all $t \geq n$ that

$$\begin{aligned} \mathbb{E}\left[d_H(\sigma_t, \tilde{\sigma}_t)\right] = \sum_{i=t-n+1}^{t} \mathbb{E}\left[\mathbf{1}\left(J_i \neq \tilde{J}_i\right)\right] &= \sum_{i=t-n+1}^{t} \mathbb{E}\left[\mathbb{E}\left[\mathbf{1}\big(J_i \neq \tilde{J}_i\big)\big|\mathcal{F}_{i-1}\right]\right] \\ &= \sum_{i=t-n+1}^{t} \mathbb{E}\left[\Pr\left[J_i \neq \tilde{J}_i \Big| \mathcal{F}_{i-1}\right]\right]. \end{aligned} \tag{29}$$

Since we are optimally coupling each co-ordinate, the following holds,

$$\Pr\left[J_i \neq \tilde{J}_i \mid \mathcal{F}_{i-1}\right] = \frac{1}{2}\Big\| g_\beta\Big(\alpha(\sigma_i) - \frac{1}{n} e_{I_i}\Big) - g_\beta\Big(\alpha(\tilde{\sigma}_i) - \frac{1}{n} e_{\tilde{I}_i}\Big)\Big\|_1. \tag{30}$$

For any $I, \tilde{I} \in Q$, we have

$$\begin{aligned} \Big\| g_\beta(s - \frac{1}{n} e_I) - g_\beta(\tilde{s} - \frac{1}{n} e_{\tilde{I}})\Big\|_1 &= \|g_\beta(s) - g_\beta(\tilde{s})\|_1 + \frac{2q^2\beta}{n} \\ &\leq \frac{\beta}{q}\|s - \tilde{s}\|_1 + O\big((\|s - \hat{e}\|_1 + \|\tilde{s} - \hat{e}\|_1)^2\big) + \frac{2q^2\beta}{n} \\ &\leq \frac{\beta}{q}\|s - \tilde{s}\|_1 + O\big(\|s - \hat{e}\|_2^2 + \|\tilde{s} - \hat{e}\|_2^2\big) + \frac{2q^2\beta}{n}, \end{aligned} \tag{31}$$

where the first inequality follows from Lemma 11(ii) and the fact that $\|s - \tilde{s}\|_1 \leq \|s - \hat{e}\|_1 + \|\tilde{s} - \hat{e}\|_1$. Since, the total variation distance computes the optimal distance of the spin fractions between two copies, this lower bounds the fraction of the Hamming distance. Therefore, we use the identity $\frac{1}{n} d_H(\sigma_t, \tilde{\sigma}_t) \geq \frac{1}{2}\|\alpha(\sigma_t) - \alpha(\tilde{\sigma}_t)\|_1$, (31), and (30) to deduce that for some constant $C_2 > 2q^2/\beta$

$$\Pr\left[J_i \neq \tilde{J}_i \mid \mathcal{F}_{i-1}\right] \leq \frac{\beta}{nq} d_H(\sigma_i, \tilde{\sigma}_i) + C_2\big(\|\alpha(\sigma_i) - \hat{e}\|_2^2 + \|\alpha(\tilde{\sigma}_i) - \hat{e}\|_2^2\big) + \frac{C_2}{n}.$$

Plugging the above equation in (29), we prove (28). Using Lemma 14 into (28), there exists a constant $C_3 > 0$ such that for any $t \geq n$,

$$\mathbb{E}\big[d_H(\sigma_t, \tilde{\sigma}_t)\big] \leq \frac{\beta}{nq} \sum_{i=t-n}^{t-1} \mathbb{E}[d_H(\sigma_i, \tilde{\sigma}_i)] + 2C_1C_3 \sum_{i=t-n}^{t-1} \gamma_n^{2i} + (2C_1C_3 + C_1).$$

Using the Lemma 17, we get that for some constant $C_4 > 0$, $\mathbb{E}\big[d_H(\sigma_t, \tilde{\sigma}_t)\big] = C_4 n \gamma_n^t + C_4$, and the result follows from Lemma 15 and Markov's inequality. ◀

Lifting Polynomial Complexity Measures Using Error-Correcting Codes

Ivan Hu
University of Wisconsin-Madison, WI, USA

Dieter van Melkebeek
University of Wisconsin-Madison, WI, USA

Abstract

We describe a method that lifts an arbitrary polynomial f with sparsity s to a polynomial that requires a read-once oblivious algebraic program of width s for every variable order. To do so, we introduce a technique for constructing a gadget based on erasure codes over finite fields, where each variable in f is substituted with a monomial that encodes a codeword into the exponents of the monomial. Our construction represents the first use of error-correcting codes in the context of lifting. As an application, we consider factor complexity, which studies how much the complexity of a polynomial can increase under factorization. Our result allows us to lift any gap in sparsity to the same gap in width in a generic manner.

1 Introduction

The concept of lifting involves taking a function that is hard for some computational model and transforming it in some fixed manner into a different function, such that this new function is guaranteed to be hard for a stronger computational model. Lifting has proven to be a useful concept in establishing lower bounds for several computational models [26, 15, 8], proof systems [9, 30, 7, 14, 20], as well as in communication complexity [16, 17, 24, 10]. Lifting is generally done with *gadgets*, which substitute each variable in the function with an expression in some new variables. In our setting, we consider lifting in terms of the complexity of polynomials in algebraic models of computation.

We consider two measures of complexity for a polynomial f. The first notion is *sparsity*, which is simply the number of monomials needed to write f as a linear combination of those monomials. The second notion is the minimum width needed to compute f with a *read-once oblivious algebraic branching program* (roABP), which is an algebraic analogue of read-once branching programs in the Boolean setting. The model is heavily studied in contexts such as polynomial identity testing [27, 13, 12, 1, 19, 18, 6] and algebraic lower bounds [25, 2, 23]. A structural feature of roABPs is that they read variables in a particular order, and the complexity of an roABP can vary depending on this variable order. Still, roABP width is always less than or equal to the sparsity no matter the variable order, making it a stronger complexity measure.

Results. An efficient gadget for lifting a high sparsity polynomial to a polynomial requiring high roABP width has been constructed before [14, 20, 3], but only for certain variable orders for the roABP. An "intriguing question" raised in [3] is whether there is such a construction that produces a polynomial requiring high roABP width for *all* variable orders. In this work, we answer the question in the affirmative.

▶ **Theorem 1** (main result). *There exists an explicit gadget $\mathcal{G} : \mathbb{F}[x_1, \ldots, x_n] \to \mathbb{F}[y_1, \ldots, y_{2n}]$ such that for any polynomial $f(x_1, \ldots, x_n)$ of degree d and sparsity s, $\mathcal{G}(f)$ has degree $O(nd(n+d))$, sparsity s, and requires* roABP *width s in every variable order.*

Lifting results in the algebraic setting have consequences for closure properties, in particular for factor complexity: Given a polynomial f that is efficiently computable in some model, are all of the factors of f efficiently computable in the same model? A long line of work has established positive answers for reasonably strong models of algebraic computation, starting with general algebraic circuits [22], and later branching programs [29], formulas and constant-depth circuits [5], among others. However, in the weaker model of sparsity, there exists an explicit family of polynomials with a quasi-polynomial gap between the complexity of f and a factor of f [31] over any fixed field, and one with an exponential gap with specific conditions on the underlying fields [4]. The quasi-polynomial gap for sparsity was transformed into a quasi-polynomial gap for roABPs in [3] by exploiting the specific structure of the family. With our general lifting technique, any gap in factor complexity for sparsity generically translates into the same gap for roABPs.

Technique. The algebraic setting presents new opportunities for gadgets beyond the Boolean setting. For one thing, any Boolean function can be expressed as a multilinear polynomial over $\mathbb{F}_2$, but polynomials in general can have monomials with degrees that are arbitrarily large nonnegative integers. This allows us to encode information into the exponents of a monomial.

Our main idea is to use "codeword monomials" to replace each variable of the original polynomial f. More specifically, our gadget $\mathcal{G}$ substitutes each variable x_i with a monomial in new variables $y_1, \ldots, y_\ell$. A monomial $x_1^{d_1} \cdots x_n^{d_n}$ in f can be thought of as a vector $[d_1, \ldots, d_n] \in \mathbb{Z}^n$. The effect of the gadget can be interpreted as a linear map from $\mathbb{Z}^n \to \mathbb{Z}^\ell$ acting on each monomial of f. Our gadget essentially is a linear error-correcting code $E_p : \mathbb{F}_p^n \to \mathbb{F}_p^\ell$ for some sufficiently large prime p, where the elements of $\mathbb{F}_p$ are interpreted as elements of $\mathbb{Z}$ to serve as exponents.

How do we ensure that the sparsity of f becomes a lower bound for the roABP width of $\mathcal{G}(f)$ in every variable order? We use the well-known characterization of roABP width for a fixed variable order as the maximum rank of its coefficient matrices. Each coefficient matrix consists of the coefficients of the monomials of f up to the degree of f, arranged in a particular way. The injectivity of E guarantees that each monomial of f is mapped to a distinct monomial of $\mathcal{G}(f)$. By choosing E judiciously, we additionally ensure that for at least one of the coefficient matrices of $\mathcal{G}(f)$ in every order, the entries corresponding to those distinct monomials have distinct row indices and distinct column indices. Thus, if f has exactly s monomials, the s nonzero entries of this coefficient matrix are spread over distinct rows and distinct columns, which ensures that the matrix rank is s. As E_p is independent of the variable order, this yields a polynomial $\mathcal{G}(f)$ that requires roABP width at least s in every possible variable order.

We show that an erasure code E_p with appropriate parameters achieves our goal. The structure of the various coefficient matrices of $\mathcal{G}(f)$ depends on a partition of the variables $\{y_1, \ldots, y_\ell\}$ into two disjoint sets U and V. The row of the entry controlled by a given

monomial $\overline{m}$ is determined by the U-variables in $\overline{m}$, while the column is determined by the V-variables. With an erasure code gadget that can handle $|V|$ erasures, any $\overline{m}$ produced by $\mathcal{G}$ can be uniquely recovered from just knowing the U-variables. The effect is that no two nonzero entries share the same row. By swapping the roles of U and V, a similar property follows for columns instead of rows. An error-correcting code $E_p : \mathbb{F}_p^n \to \mathbb{F}_p^\ell$ that can handle erasures of up to half its output length ℓ has both properties for $|U| = |V| = \ell/2$. Reed-Solomon codes can handle the required number of erasures with $\ell = 2n$.

Organization. We start with the required background in Section 2, develop our results from first principles in Section 3, and end in Section 4 with directions for further research.

2 Preliminaries

We review elements of coding theory and the notions of polynomial sparsity and roABP's. As a warm-up, we also include a proof of the known gadget that works for restricted orders only. Throughout the paper, we use the notation $[n] = \{1, \ldots, n\}$ for positive integers n.

2.1 Codes

For a prime p, let $\mathbb{F}_p$ be the finite field of order p. For positive integers k, ℓ, a *linear error-correcting code* over $\mathbb{F}_p$ of dimension k and length ℓ is an injective linear map $E_p : \mathbb{F}_p^k \to \mathbb{F}_p^\ell$. We write $C \doteq E_p(\mathbb{F}_p^k)$ to denote the set of *codewords* of E_p. We say that E_p can *handle* e *erasures* if deleting up to e positions in a codeword of E_p still leaves enough information to retrieve the codeword. In symbols, for any two codewords $\mathbf{c}, \mathbf{c}' \in C$, and any subset of indices $I \subseteq [\ell]$ with $|I| \geq \ell - e$, we have that if $\mathbf{c}|_I = \mathbf{c}'|_I$, then $\mathbf{c} = \mathbf{c}'$.

We recall the properties of the classical Reed-Solomon code that we need. For completeness, we include the construction and proof.

▶ **Lemma 2** (Reed-Solomon, [28]). *For any positive integers k, e and prime $p \geq k + e$, there exists a linear code E_p over $\mathbb{F}_p$ with dimension k and length $k + e$ that can handle e erasures.*

Proof. Let $\alpha_1, \ldots, \alpha_{k+e}$ be fixed distinct elements in $\mathbb{F}_p$. For any vector $\mathbf{u} = \begin{bmatrix} u_1 & \ldots & u_k \end{bmatrix}$ in $\mathbb{F}_p^k$, define $f_{\mathbf{u}}(x) \in \mathbb{F}_p[x]$ to be the degree $k-1$ univariate polynomial

$$f_{\mathbf{u}}(x) = u_1 + u_2 x + \cdots + u_k x^{k-1}.$$

We define E as follows:

$$E_p(\mathbf{u}) = \begin{bmatrix} f_{\mathbf{u}}(\alpha_1) & \ldots & f_{\mathbf{u}}(\alpha_{k+e}) \end{bmatrix}.$$

We now show that E_p can handle e erasures. Let $I = \{i_1, \ldots, i_k\} \subseteq [k+e]$ be a set of $(k+e) - e = k$ indices. Suppose there are two codewords $\mathbf{c} = E_p(\mathbf{u})$, $\mathbf{c}' = E_p(\mathbf{u}')$ such that $\mathbf{c}|_I = \mathbf{c}'|_I$. Then for $j \in [k]$, we have that $f_{\mathbf{u}}(\alpha_{i_j}) = f_{\mathbf{u}'}(\alpha_{i_j})$. In other words, $f_{\mathbf{u}}$ and $f_{\mathbf{u}'}$ are degree $k-1$ polynomials that are equal at k distinct values. This implies that $f_{\mathbf{u}} = f_{\mathbf{u}'}$, meaning $\mathbf{c} = \mathbf{c}'$. ◀

Any element of $\mathbb{F}_p$ can be interpreted as an integer in $[0, p-1]$. For a linear code $E_p : \mathbb{F}_p^k \to \mathbb{F}_p^\ell$, we write the function $\widetilde{E}_p : \mathbb{F}_p^k \to \mathbb{Z}^\ell$ by interpreting the outputs of E_p as integers in this manner. Note that $\widetilde{E}_p$ is not a linear map, but if $E_p(\mathbf{u}) = \sum_{i=1}^s c_i E_p(\mathbf{v}_i)$, then $\widetilde{E}_p(\mathbf{u}) \equiv \sum_{i=1}^s c_i \widetilde{E}_p(\mathbf{v}_i) \bmod p$. Also, we abuse notation to allow vectors in $\mathbb{Z}^k$ as arguments to E_p and $\widetilde{E}_p$ by taking the entries modulo p.

2.2 Polynomials

Let $\mathbb{F}$ be a field (which may be unrelated to $\mathbb{F}_p$), and let $X = \{x_1, \ldots, x_n\}$ be a set of variables. A *monomial* $\overline{m}$ in X is a product of not necessarily distinct variables in X. For a subset $U \subseteq X$, define $\overline{m}_U$ to be the monomial produced by taking $\overline{m}$ and only including the variables in U (equivalently, setting $x_i = 1$ for $x_i \notin U$).

We can write a monomial uniquely as $\overline{m} = x_1^{d_1} \cdots x_n^{d_n}$, where $d_1, \ldots, d_n \geq 0$ are integers. We call the vector $[d_1, \ldots, d_n]$ the *degree vector* of $\overline{m}$. We refer to $\max_i(d_i)$ as the *individual degree* of $\overline{m}$, and to $\deg(\overline{m}) = \sum_i d_i$ as the *(total) degree* of $\overline{m}$. The individual and total degrees of a polynomial are defined as the maximum of the respective degrees of its monomials.

▶ **Definition 3** (sparsity). *For a polynomial $f \in \mathbb{F}[X]$, the sparsity of f is the number of terms used when f is written as a linear combination of monomials in X.*

2.3 Read-once oblivious algebraic branching programs

A *read-once oblivious algebraic branching program* (roABP) consists of a directed graph with $n+1$ layers labeled $0, 1, \ldots, n$. Layer 0 contains a source vertex s, layer n contains a sink vertex t, and each edge goes from a layer $i-1$ to layer i, for $i = 1, \ldots, n$. The other parameters are a set of n variables $x_1, \ldots, x_n$ and a variable order, which is a permutation $\pi : [n] \to [n]$. Each edge from layer $i-1$ to i is labeled with a univariate polynomial in $x_{\pi(i)}$. For every path γ from s to t, let the weight $\mathrm{wt}(\gamma)$ be the product of all the labels of the edges in γ. The polynomial f computed by the roABP is given by the sum of all the path weights from s to t:

$$f \doteq \sum_{\gamma : s \rightsquigarrow t} \mathrm{wt}(\gamma).$$

An roABP computes f only if both sides in the above equality are identical as polynomials in $\mathbb{F}[X]$, as opposed to just having the equality holding upon evaluation on all points in $\mathbb{F}^n$. If $|\mathbb{F}| > \deg(f)$, both notions are equivalent.

The *depth* of an roABP is the number of edge layers in the graph, i.e., n. The *width* of an roABP is equal to the maximum number of vertices in any layer. The *size* of an roABP is the total number of vertices in the graph. The primary measure of complexity of an roABP is width, since the depth is simply the number of variables, and the size is bounded by the product of width and depth.

▶ **Definition 4** (roABP width). *For a polynomial $f \in \mathbb{F}[X]$ and permutation $\pi : [n] \to [n]$, $\mathsf{roABP\text{-}width}_\pi(f)$ denotes the minimum width of any* roABP *of variable order π that computes f. $\mathsf{roABP\text{-}width}(f)$ denotes the minimum value of $\mathsf{roABP\text{-}width}_\pi(f)$ over all variable orders π.*

In our work, we do not directly use this definition to determine roABP width. Instead, we use a well-known characterization by Nisan [25] for non-commutative ABPs, extended to roABPs in [11, Lemma 4.5.8]. It expresses $\mathsf{roABP\text{-}width}_\pi(f)$ in terms of the ranks of its coefficient matrices.

▶ **Definition 5** (coefficient matrix). *Consider a partition $X \doteq U \sqcup V$. For a polynomial $f \in \mathbb{F}[X]$, we define a matrix $\mathrm{CMat}_{U,V}(f)$ as follows. The rows are indexed by monomials $\overline{m}_U$ over U, and the columns are indexed by monomials $\overline{m}_V$ over V. The entry of $\mathrm{CMat}_{U,V}(f)$ indexed by $(\overline{m}_U, \overline{m}_V)$ is the coefficient of $\overline{m}_U \overline{m}_V$ in f.*

Since we are only considering monomials of degree at most $\deg(f)$, we can assume that the dimensions of $\mathrm{CMat}_{U,V}(f)$ are finite.

▶ **Lemma 6** (roABP width characterization). *Let $f \in \mathbb{F}[X]$ be a polynomial, and let $\pi : [n] \to [n]$ be a variable order. For each $i \in \{0, \ldots, n\}$, let $U_i = \{x_{\pi(1)}, \ldots, x_{\pi(i)}\}$ and $V_i = \{x_{\pi(i+1)}, \ldots, x_{\pi(n)}\}$ be a partition of X. Then*

$$\mathsf{roABP\text{-}width}_\pi(f) = \max_{i \in \{0,\ldots,n\}} \operatorname{rank}(\mathrm{CMat}_{U_i,V_i}(f)).$$

roABP width is a stronger measure of complexity than sparsity. Specifically, any polynomial f with sparsity s satisfies $\mathsf{roABP\text{-}width}(f) \leq s$. To see this, one can construct an roABP with s disjoint paths or use Lemma 6 to see that any coefficient matrix has at most s nonzero entries, and thus has rank at most s.

The roABP width of a polynomial can vary wildly based on the variable order π. For example, consider the polynomial $f = \prod_{i=1}^{n}(x_i + y_i)$. If the variables are read in the order $x_1, y_1, \ldots, x_n, y_n$, then $\mathsf{roABP\text{-}width}_\pi(f) = 2$, while if the variables are read in the order $x_1, \ldots, x_n, y_1, \ldots, y_n$, then $\mathsf{roABP\text{-}width}_\pi(f) = 2^n$.

2.4 Lifting from sparsity to fixed-order roABP width

As a warm-up, we present a well-known gadget for lifting from sparsity to roABP width with respect to particular variable orders. Our gadget does not rely on it, but the construction was used in [14, 20, 3].

▶ **Proposition 7.** *There exists an explicit gadget $\mathcal{G} : \mathbb{F}[x_1, \ldots, x_n] \to \mathbb{F}[y_1, \ldots, y_n, z_1, \ldots, z_n]$ such that for any polynomial $f \in \mathbb{F}[x_1, \ldots, x_n]$ of total degree d and sparsity s, $\mathcal{G}_0(f)$ has the same individual degree at f, total degree $2d$, and $\mathsf{roABP\text{-}width}_\pi$ equal to s for every variable order π where the variables $y_1, \ldots, y_n$ are read before the variables $z_1, \ldots, z_n$.*

Proof. We define $\mathcal{G}(x_i) = y_i z_i$ for each $i \in [n]$, and write $g = \mathcal{G}(f)$. The individual degree of y_i and z_i in g are the same as the individual degree of x_i in f. The total degree of every monomial doubles, so $\deg(g) = 2d$.

For the roABP width, partition the variables $\{y_1, \ldots, y_n, z_1, \ldots, z_n\}$ into $Y = \{y_1, \ldots, y_n\}$, $Z = \{z_1, \ldots, z_n\}$. Notice that for any monomial $\overline{m}$ appearing in g, $\overline{m}_Y$ uniquely determines $\overline{m}_Z$ and vice versa, since $\overline{m}_Y$ and $\overline{m}_Z$ have the same degree vectors. Therefore, $\mathrm{CMat}_{Y,Z}(g)$ is a matrix with at most one nonzero entry in each row and column, and the number of nonzero entries is s. So $\operatorname{rank}(\mathrm{CMat}_{Y,Z}(g)) = s$ and Lemma 6 implies $\mathsf{roABP\text{-}width}_\pi(g) \geq s$. To see that $\mathsf{roABP\text{-}width}_\pi(g) \leq s$, notice that $\mathcal{G}$ maps monomials to monomials and thus g has sparsity at most s. ◀

3 Results

In this section we present our main result and its consequences for factor complexity.

3.1 Main result

Earlier gadgets for lifting from sparsity to roABP width either only work for restricted orders or require structural properties of the polynomials being lifted. We remedy these shortcomings and develop a gadget that works for every order and every polynomial.

Let $X = \{x_1, \ldots, x_n\}$, $Y = \{y_1, \ldots, y_{2n}\}$ be sets of variables. We define the gadget $\mathcal{G} : \mathbb{F}[X] \to \mathbb{F}[Y]$ for Theorem 1 as follows. For a prime $p > 2n$, let $E_p : \mathbb{F}_p^n \to \mathbb{F}_p^{2n}$ be a linear error-correcting code that can handle n erasures. Such a code exists by virtue of Lemma 2. Let $\widetilde{E}_p : \mathbb{F}_p^n \to \mathbb{Z}^{2n}$ be the corresponding integer-valued function. We write $\mathbf{e}_1, \ldots, \mathbf{e}_n \in \mathbb{F}_p^n$ as the standard basis vectors. We define $\mathcal{G}_p$ to perform the following substitution on a variable x_i.

$$\mathcal{G}_p(x_i) = \prod_{j=1}^{2n} y_j^{\widetilde{E}_p(\mathbf{e}_i)_j}. \tag{1}$$

Notice that if $\overline{m}$ is a monomial in X, then $\mathcal{G}_p(\overline{m})$ is a monomial in Y. The erasure capability of E allows us to prove the following structural lemma.

▶ **Lemma 8.** *Let n, d be positive integers, and $p > \max(2n, d)$ a prime. Let $Y \doteq U \sqcup V$ be any partition such that $|U| = |V| = n$. Let $\overline{m}_1, \overline{m}_2$ be monomials of individual degree at most d in X. If $\overline{m}_1 \neq \overline{m}_2$, then $\mathcal{G}_p(\overline{m}_1)_U \neq \mathcal{G}_p(\overline{m}_2)_U$ and $\mathcal{G}_p(\overline{m}_1)_V \neq \mathcal{G}_p(\overline{m}_2)_V$.*

Proof. The condition that $p > 2n$ ensures that the gadget $\mathcal{G}_p$ is well-defined.

Let $\overline{m}$ be a monomial in X with degree vector $\mathbf{d} = [d_1, \ldots, d_n]$. Since $d_1 E_p(\mathbf{e}_1) + \cdots + d_n E_p(\mathbf{e}_n) = E_p(\mathbf{d})$, we have that $d_1 \widetilde{E}_p(\mathbf{e}_1) + \cdots + d_n \widetilde{E}_p(\mathbf{e}_n) \equiv \widetilde{E}_p(\mathbf{d}) \bmod p$. In other words, there exist integers $q_1, \ldots, q_{2n}$ such that

$$\mathcal{G}_p(\overline{m}) = \prod_{j=1}^{2n} y_j^{d_1 \widetilde{E}_p(\mathbf{e}_1)_j + \cdots + d_n \widetilde{E}_p(\mathbf{e}_n)_j} = \prod_{j=1}^{2n} y_j^{\widetilde{E}_p(\mathbf{d})_j + pq_j}.$$

Armed with this fact, let $\overline{m}_1, \overline{m}_2$ be monomials of degree at most d in X. Suppose $\overline{m}_1, \overline{m}_2$ have degree vectors $\mathbf{d}_1$, $\mathbf{d}_2$, respectively. Furthermore, suppose that for $U = \{y_{i_1}, \ldots, y_{i_n}\} \subseteq Y$, we have that $\mathcal{G}_p(\overline{m}_1)_U = \mathcal{G}_p(\overline{m}_2)_U$. In other words, the powers of the U-variables in $\mathcal{G}_p(\overline{m}_1)$ and $\mathcal{G}_p(\overline{m}_2)$ agree. This means that, for $j \in [n]$, $\widetilde{E}_p(\mathbf{d}_1)_{i_j} \equiv \widetilde{E}_p(\mathbf{d}_2)_{i_j} \bmod p$, or $E_p(\mathbf{d}_1)_{i_j} = E_p(\mathbf{d}_2)_{i_j}$. So, $E_p(\mathbf{d}_1)$ and $E_p(\mathbf{d}_2)$ agree on at least n indices. Because E_p has output length $2n$ and can handle n erasures, we have that $\mathbf{d}_1 \equiv \mathbf{d}_2 \bmod p$. Since $p > d$ and each entry of $\mathbf{d}_1, \mathbf{d}_2$ is at most d, we have that $\mathbf{d}_1 = \mathbf{d}_2$. Therefore, if $\mathcal{G}_p(\overline{m}_1)_U = \mathcal{G}_p(\overline{m}_2)_U$, then $\overline{m}_1 = \overline{m}_2$.

We can conclude that if $\overline{m}_1 \neq \overline{m}_2$, then $\mathcal{G}_p(\overline{m}_1)_U \neq \mathcal{G}_p(\overline{m}_2)_U$. By the same reasoning, we can see that $\mathcal{G}_p(\overline{m}_1)_V \neq \mathcal{G}_p(\overline{m}_2)_V$. ◀

Now we show that our gadget $\mathcal{G}_p$ satisfies the conditions of Theorem 1. In fact, we prove a refined statement with Theorem 9 that considers the individual degree of each variable.

▶ **Theorem 9** (refined main result). *There exists an explicit gadget $\mathcal{G} : \mathbb{F}[x_1, \ldots, x_n] \to \mathbb{F}[y_1, \ldots, y_{2n}]$ such that for any polynomial $f(x_1, \ldots, x_n)$ of degree d and sparsity s, $\mathcal{G}(f)$ has individual degree $O(d(n+d))$ in each variable, sparsity s, and* roABP-width$(\mathcal{G}(f)) = s$.

Proof. Let $m \doteq \max(2n, d) + 1$. By Bertrand's postulate, there always exists a prime $p \in [m, 2m]$. We show that $\mathcal{G} \doteq \mathcal{G}_p$ satisfies the conditions of the theorem.

Write $g = \mathcal{G}(f)$. First, we prove the degree bound. Since $\widetilde{E}_p(\mathbf{e}_i)_j < p \leq 2m$ for any $i \in [n]$, $j \in [2n]$, $\mathcal{G}(x_i)$ is a monomial in Y of individual degree less than $2m$. As each monomial in f contains at most d occurrences of variables (counting multiplicities), after replacing each x_i by $\mathcal{G}(x_i)$, the resulting monomials have individual degree less than $md = O(d(n+d))$.

Now we show the lower bound on roABP width. Let $\pi : [2n] \to [2n]$ be any variable order on Y. Let $U = \{y_{\pi(1)}, \ldots, y_{\pi(n)}\}$ and $V = \{y_{\pi(n+1)}, \ldots, y_{\pi(2n)}\}$. We reason about the structure of the coefficient matrix $\mathrm{CMat}_{U,V}(g)$. Since f has sparsity s, we can write it as a linear combination of s monomials: $f = \sum_{i=1}^{s} c_i \overline{m}_i$ for some $c_i \neq 0$. We have

$$\mathcal{G}(f) = \sum_{i=1}^{s} c_i \mathcal{G}(\overline{m}_i) = \sum_{i=1}^{s} c_i \mathcal{G}(\overline{m}_i)_U \mathcal{G}(\overline{m}_i)_V.$$

By Lemma 8, all monomials in the sets $\{\mathcal{G}(\overline{m}_1)_U,\ldots,\mathcal{G}(\overline{m}_s)_U\}$ and $\{\mathcal{G}(\overline{m}_1)_V,\ldots,\mathcal{G}(\overline{m}_s)_V\}$ are distinct. Thus, for $i \in [s]$, the entry $(\mathcal{G}(\overline{m}_i)_U, \mathcal{G}(\overline{m}_i)_V)$ of $\mathrm{CMat}_{U,V}(g)$ is nonzero, all other entries of $\mathrm{CMat}_{U,V}(g)$ are zero, and no two of the s nonzero entries share a row or column. This implies that $\mathrm{rank}(\mathrm{CMat}_{U,V}(g)) \geq s$, and by Lemma 6, this implies that $\mathsf{roABP\text{-}width}_\pi(g) \geq s$. Since π was arbitrary, we have that $\mathsf{roABP\text{-}width}(g) \geq s$.

Finally, since $\mathcal{G}$ maps monomials to monomials, g still has sparsity s, so there exists an roABP of width s computing g, no matter the variable order. Therefore, $\mathsf{roABP\text{-}width}(g) = s$. ◀

3.2 Application to factor complexity

We now establish the consequences for factor complexity that we mentioned in the introduction. They immediately follow from our main result and two well-known gaps for sparsity.

Over any field, the following gap in sparsity was established in [31].

▶ **Fact 10.** For all fields $\mathbb{F}$ and positive integers n and d, there exists a degree-nd polynomial $f(x_1,\ldots,x_n)$ of sparsity 2^n that has a factor $g(x_1,\ldots,x_n)$ of sparsity d^n. Specifically,

$$f = \prod_{i=1}^{n}(x_i^d - 1) \text{ and } g = \prod_{i=1}^{n}(1 + x_i + x_i^2 + \cdots + x_i^{d-1}).$$

Over a field of nonzero characteristic d, the identity $(x_1 + \cdots + x_n)^d = x_1^d + \cdots + x_n^d$ yields the following gap (see, e.g., [4, Example 4.7]).

▶ **Fact 11.** Suppose $d = \mathrm{char}(\mathbb{F}) \neq 0$. For all positive integers n, there exists a degree-d polynomial $f(x_1,\ldots,x_n)$ of sparsity n that has a factor $g(x_1,\ldots,x_n)$ of sparsity $\binom{n+d-2}{d-1}$. Specifically,

$$f = x_1^d + \cdots + x_n^d \text{ and } g = (x_1 + \cdots + x_n)^{d-1}.$$

Notice that by the multinomial theorem and the fact that d is prime, every monomial of degree up to $d-1$ occurs in g with a nonzero coefficient modulo d.

By lifting Fact 10 and Fact 11 using our main result, we obtain the following results for roABP width.

▶ **Corollary 12.** *Let $\mathbb{F}$ be a field and n a positive integer.*

(a) *For every positive integer d, there exists a degree-$O(d^2n^3)$ polynomial $F(y_1,\ldots,y_{2n})$ such that $\mathsf{roABP\text{-}width}(F)=2^n$, and F has a factor $G(y_1,\ldots,y_{2n})$ such that $\mathsf{roABP\text{-}width}(G) = d^n$.*

(b) *If $\mathrm{char}(\mathbb{F}) = d \neq 0$, then there exists a degree-$O(nd(n+d))$ polynomial $F(y_1,\ldots,y_{2n})$ such that $\mathsf{roABP\text{-}width}(F) = n$, and F has a factor $G(y_1,\ldots,y_{2n})$ such that $\mathsf{roABP\text{-}width}(G) = \binom{n+d-2}{d-1}$.*

Proof. Since $\mathcal{G}$ is a substitution, if g is a factor of f, then $G \doteq \mathcal{G}(g)$ is a factor of $F \doteq \mathcal{G}(f)$. Apply Theorem 1 to Fact 10 and Fact 11. Respectively, we obtain $\mathsf{roABP\text{-}width}(F) = 2^n$ and $\mathsf{roABP\text{-}width}(G) = d^n$, and $w \doteq \mathsf{roABP\text{-}width}(F) = n$ and $\mathsf{roABP\text{-}width}(G) = \binom{n+d-2}{d-1}$. ◀

Note that for fixed d, the width gap in part (a) of Corollary 12 goes from $w = 2^n$ to $d^n = w^{\Omega(\log d)}$, and in part (b) from $w = n$ to $\binom{n+d-2}{d-1} = w^{\Omega(d)}$. By instead setting $d = n$, we obtain an explicit family of polynomials with a quasi-polynomial gap $w \mapsto w^{\Omega(\log w)}$ in case (a), and an exponential gap $w \mapsto \binom{2w-2}{w-1} = \Theta(2^{2w}/\sqrt{w})$ in case (b).

In comparison to the approach in [3], our technique has the advantage of exactly preserving the complexity measure, while [3] weakens the complexity of the factor slightly. Furthermore, we can apply our methods to any family of polynomials, while [3] requires specific conditions on the family. On the other hand, [3] has the advantage that the degree of the polynomial increases by a constant factor, while our gadget increases the degree by a factor of $O(n(n+d))$.

4 Further research

Error-correcting codes have been helpful in many contexts. We exhibit their first use in the context of lifting and manage to solve an open problem in lifting raised by [3]. Can our technique be applied to other lifting results, as well? For example, does it yield generic lifting lower bounds for roABPs in the context of algebraic proof systems such as fragments of the Ideal Proof System (IPS)? Previous works in this area [14, 20, 21] established lower bounds for specific instances of roABP-IPS. An interesting open question is to construct a gadget that takes a generic hard instance for a weaker fragment of IPS and lifts it to an instance that is hard for roABP-IPS.

On a more technical level, in comparison to other examples of lifting like [3], the gadget in our work increases the degree of the polynomial by a relatively large factor, polynomial in the original degree d and number of variables n. Could one construct a more efficient gadget that lifts sparsity to roABP width? For example, can one construct a gadget that only uses multilinear codeword monomials?

In the context of factor gap complexity, for degree-d polynomials of sparsity s, the best known gaps are essentially the ones given in Section 3.2, namely that a factor can have sparsity $s^{\Omega(\log d)}$ over any field and $s^{\Omega(d)}$ over fields with nonzero characteristic d. [4] showed an upper bound of $s^{O(d^2 \log n)}$ for the sparsity of any factor over any field, where n is the number of variables. Can one construct examples that achieve larger gaps in sparsity and therefore, by our main result, in roABPs width? Alternatively, can one find larger gaps in roABPs width independent of any results on sparsity?

Abstract

In this paper we initiate the study of *property testing of weighted computational networks viewed as computational devices*. Our goal is to design property testing algorithms that for a given computational network with oracle access to the weights of the network, accept (with probability at least $\frac{2}{3}$) any network that computes a certain function (or a function with a certain property) and reject (with probability at least $\frac{2}{3}$) any network that is *far* from computing the function (or any function with the given property). We parameterize the notion of being far and want to reject networks that are (ε, δ)-*far*, which means that one needs to change an ε-fraction of the description of the network to obtain a network that computes a function that differs in at most a δ-fraction of inputs from the desired function (or any function with a given property).

To exemplify our framework, we present a case study involving simple neural Boolean networks with ReLU activation function. As a highlight, we demonstrate that for such networks, any near-constant function is testable in query complexity independent of the network's size. We also show that a similar result cannot be achieved in a natural generalization of the distribution-free model to our setting, and also in a related vanilla testing model. While the analysis of neural Boolean networks with ReLU activation function is rigorous and technically demanding, we consider it a testament to the robustness of our framework and the depth of our findings.

1 Introduction

Since its development in the late 90s [46, 29], the area of *property testing* has emerged as an important area of modern theoretical computer science. It considers the relaxation of classical decision problems by distinguishing inputs that belong to a given set (have a given property $\mathcal{P}$) from those that are *"far"* from any input that belongs to the set (are *far* from having property $\mathcal{P}$). In its most classical setting (see, e.g., survey expositions in [28, 9]), a property $\mathcal{P}$ is a collection of objects (binary strings, graphs, etc), and being *"far"* is measured by the Hamming distance, namely, in how many places of its representation should an input object

be changed so as to have the property $\mathcal{P}$. As a useful and powerful way of relaxation of the classical decision problems, property testing has found numerous applications and established itself as a significant topic in the study of function properties, graph properties, and beyond. Examples include testing properties of functions such as being a low degree polynomial, being monotone, depending on a specified number of attributes, testing properties of graphs such as being bipartite and being triangle-free, testing properties of strings, and testing properties of geometric objects and visual images such as being well-clustered and being convex (for a more complete picture, see, e.g., [28, 9, 16, 18, 45] and the references therein). Furthermore, property testing is in the center of recent advances in *sublinear algorithms*, as property testing algorithms are frequently "superfast" and rely on inspecting small portions of objects and making the evaluation based on such an inspection.

In property testing one assumes an indirect access to the input and its representation that is provided by an *oracle*; e.g., one can query the value of a function on a *specific input*, or the existence of a *specific edge* of a graph. The *complexity of the tester* is the number of queries to the oracle.

In this paper, *we study property testing in the context of complex computational devices* (e.g., *computational networks*). We consider a setting in which one wants to study functions that are represented in an indirect way (e.g., as circuits or computational networks, or via complicated algebraic expressions) by computational devices used to determine the value of the functions. One may think about functions that are given *implicitly*, and in order to compute f one has to perform a possibly non-trivial computation on the input. For example, we may have a computational network that *computes* a function $f : \mathbb{R}^n \to \{0,1\}$; or we may have a function $f : \{0,1\}^n \to \mathbb{R}^r$ defined by a matrix $A \in \mathbb{R}^{r\times n}$ as $f(x) := Ax$, or $f : \{0,1\}^n \to \{0,1\}^r$ defined as[1] $f(x) := \mathrm{sgn}(\mathrm{ReLU}(Ax))$.

Our goal is to determine whether a given computational device computes a function having a given property or if it is *far* from any computational device computing function with a given property. For example, if for a matrix $A \in \mathbb{R}^{r\times n}$ we have $f(x) := Ax$, then, informally, we would call the "device" *Ax far from having property $\mathcal{P}$* if there is no matrix $A^* \in \mathbb{R}^{r\times n}$ that differs from A only in a small fraction of its entries (i.e., $\|A^* - A\|_0$ is small) such that function $f^*(x) := A^*x$ has the property $\mathcal{P}$. Furthermore, to make our study more general and applicable, we will allow to enhance our definition to devices that err on a small number of inputs.

Observe that while our model can be seen as a special case of the classical property testing framework (see, e.g., references to a similar setting in [28, Chapter 1]), the approach presented in our paper offers a different perspective than that most frequently studied: *our framework focuses on the computational device* – and its analysis should depend on specific parameters of the device rather than on the inputs or the function f. We want to determine if one has to make many changes in the device's representations in order to compute some function having desirable property $\mathcal{P}$, or only a small number of changes suffices. And so, for example, if for a matrix $A \in \mathbb{R}^{r\times n}$ we define $f(x) := Ax$ or $f(x) := \mathrm{sgn}(\mathrm{ReLU}(Ax))$ for any $x \in \mathbb{R}^n$, then it is natural to define the oracle to access individual entries from A (rather than to allow queries to the value of $f(x)$ for any specific input x).

[1] We use standard **ReLU** and **signum** functions to ensure that f has range $\{0,1\}^r$; recall that $\mathrm{ReLU}(z) := \max\{z, 0\}$ and $\mathrm{sgn}(z) := 1$ if $z > 0$, $\mathrm{sgn}(0) := 0$, $\mathrm{sgn}(z) := -1$ if $z < 0$. For vectors, the operations are for each coordinate. (Note that the use of these standard definitions make the combination $\mathrm{sgn}(\mathrm{ReLU}(\cdot))$ *not* redundant: $\mathrm{sgn}(\mathrm{ReLU}(Ax)) \not\equiv \mathrm{sgn}(Ax)$ for matrices A containing *negative* values – as it is the case for matrices and vectors studied in our paper.)

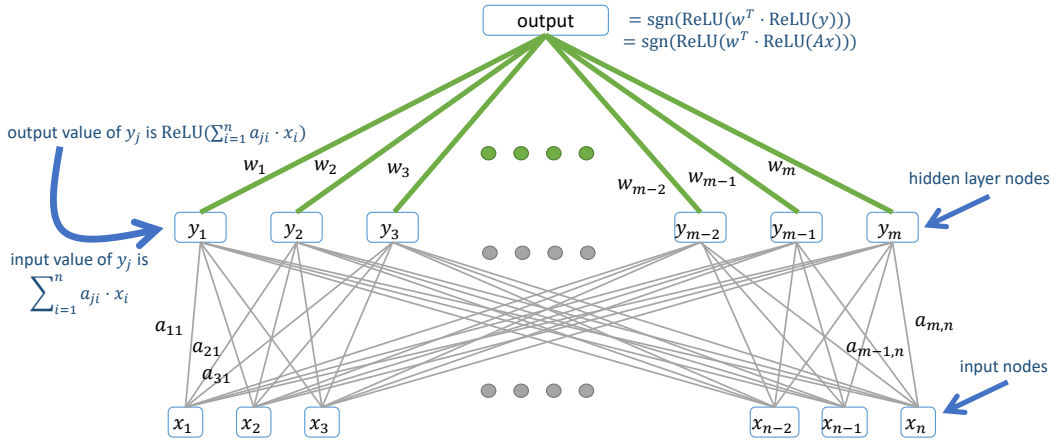

Figure 1 A ReLU network with n input nodes with inputs $x_1, \ldots, x_n$, a single hidden layer with m hidden layer nodes with values $y_1, \ldots, y_m$, and one output node. Every input node $x_i \in \{0,1\}$ is connected to every hidden layer node y_j by an edge with real weight $a_{ji} \in [-1,1]$ and every hidden layer node y_j is connected to the output node by an edge of real weight $w_j \in [-1,1]$. The value of node y_j is $\sum_{i=1}^n a_{ji}x_i$, which after applying the ReLU activation function gives $\mathrm{ReLU}(\sum_{i=1}^n a_{ji}x_i)$. The Boolean function computed by the network is equal to $\mathrm{sgn}\left(\mathrm{ReLU}\left(\sum_{j=1}^m \left(w_j \cdot \mathrm{ReLU}(\sum_{i=1}^n a_{ji}x_i)\right)\right)\right) \equiv \mathrm{sgn}\left(\mathrm{ReLU}(w^T \cdot \mathrm{ReLU}(Ax))\right)$. A more general ReLU network with multiple inputs, multiple outputs, and multiple layers is depicted on Figure 2.

Case study: Testing basic neural ReLU networks. Our setting is very open-ended, and in order to make our study more concrete, we will consider our framework for a specific example of complex computational networks. Our goal is to take a representative example of computational networks that is generic and simple, yet complex enough to go beyond the study relying on random sampling. We will study an example of the most basic yet highly non-trivial *neural ReLU networks* seen as computational devices from *the point of view of property testing*. Consider a trained feedforward network and view it as a circuit that receives an input vector $x \in \{0,1\}^n$ and computes some output. In the most basic case of the network with one output, one hidden layer, and the ReLU activation function (see also Figure 1), when a network is interpreted as a binary classifier, for a vector $w \in [-1,1]^m$ and matrix $A \in [-1,1]^{m \times n}$ it computes a Boolean function of the form

$$f(x) := \mathrm{sgn}\left(\mathrm{ReLU}(w^T \cdot \mathrm{ReLU}(Ax))\right).$$

(Our setting can be naturally extended to the study of more complex neural networks (functions) with *multiple outputs* and *multiple hidden layers*, where for matrices $W_0, \ldots, W_\ell$ with $W_i \in [-1,1]^{m_{i+1} \times m_i}$, we compute a function $f : \{0,1\}^{m_0} \to \{0,1\}^{m_{\ell+1}}$ defined as $f(x) := \mathrm{sgn}(\mathrm{ReLU}(W_\ell \cdot \ \ldots \ \cdot \mathrm{ReLU}(W_1 \cdot \mathrm{ReLU}(W_0 \cdot \mathrm{ReLU}(x))) \ldots))$, see Section 3.4.)

In order to facilitate our analysis in the property testing framework, we will consider property testing algorithms that are given the oracle access to the weights of the network[2] and the objective is to accept networks that compute functions that have a certain property of interest and reject networks that compute functions that are far from having that property for almost all inputs.

[2] Which for networks with one output and one hidden layer, is to query for the entries of A and w.

Our motivation. Our study is motivated by the modeling of computational networks in the framework of property testing, and to instantiate our framework in the context of basic neural networks. Taking the point of view of property testing and complexity theory, our goal is to obtain a better understanding of the relation between the (local) structure of a computational network and the function it computes. Our motivation stems from the fact that property testing has been a successful tool to reveal relations between the local structure of an object (here, a computational device) and its global properties that can provide combinatorial insights about the structure of an object. Examples of such insights include the characterization of property testing for dense graphs and its relation to the regularity lemma [1, 3], the relation of property testing of hyperfinite graphs to the theory of amenable groups [23, 39], or the line of research that started with testing connectivity [30] and then studied sublinear algorithms for approximating MST cost [13, 15, 17] and whose structural findings formed a building block in finding the currently fastest approximation algorithms for low dimensional MST approximation [4].

To showcase the versatility and power of our framework, we study *networks that are simple*, yet whose *computational properties are complex*. The reliance on *non-linear ReLU operators* is not only something that makes neural deep networks so powerful, but this also makes their study challenging (observe that, say, for $f(x) := Ax$, simple random sampling of entries of matrix A would provide sufficient information to understand many properties of such function; the non-linear ReLU operators make the study and the analysis more complex and interesting). Feedforward neural networks, as those studied in the simplest form in our paper, form a fundamental part of modern deep networks [34] such as transformers and the attention mechanism [49], which in turn are the main building block of large language models such as ChatGPT [43]. Unfortunately, despite their relatively simple setting, we still lack a good understanding of the computation process of these networks, leading to serious questions on the trust and transparency of the underlying learning algorithms. Therefore, even though *our main focus is on the complexity study*, we hope that the lens of property testing will contribute to a better understanding of the relation between the network structure and the computed function or properties of that function. Since the analysis of property testing algorithms relies on establishing close links between the object's local structure and the tested property, we believe that the study of simple yet fundamental models of ReLU networks may provide a new insight into such networks. Additionally, the basic notion of a relaxed decision problem in property testing has some appealing properties in the context of understanding neural networks: Typically, we would like a neural network to be robust to small changes in the network, as otherwise there is a higher risk of adversarial attacks [48]. Furthermore, during network training, *dropout* [47] is often used to improve generalization, i.e., a random fraction of input nodes is dropped during training for each training example.

1.1 Overview of our results

In this paper, we *introduce a property testing model for computational networks* through a study of *basic neural networks*. We first focus on a simple network structure: a fully connected feedforward network with the ReLU activation function, one hidden layer, and one output node (see Figure 1 and Definition 1). Later, we generalize our model to a more complex setting with multiple hidden layers and multiple output nodes (see Section 2.1 and Figure 2). We view the network as an *arithmetic circuit* that computes a Boolean function. Our objective is to design property testing algorithms that sample weights of the network and accept, if the network computes a function with a specific property, and reject, if the network is (ε, δ)-far from computing any function with the property, by which we mean that one has to change more than an ε-fraction of the network to obtain a function that differs from the target functions on less than a δ-fraction of the inputs.

An important contribution of this paper is *introduction of a model that allows a non-trivial study of computational networks (e.g., neural networks) from the lens of property testing.*

Next, we provide a *comprehensive study of our model*, focusing on the example of the constant 0 and the OR-function, for which we design constant-complexity property testers. Further, we consider other natural variants of our model for which we provide super-constant lower bounds demonstrating their complexity limitations. This shows that our model introduces a useful notion of being far that leads to interesting questions and results from the algorithmic and complexity perspective. Our results extend beyond the 0/OR-functions and we give some positive results showing the testability of some Boolean functions and classes of functions.

Our *main technical contributions* are (see Section 3 for more details):

(1) study of our model on the problem of *testing some very simple yet fundamental functions*,
(2) study of limitations of possibility of extending our results to a *distribution-free model*,
(3) *first steps towards understanding of constant time testable properties* in our model,
(4) extending the model to *more complex networks with multiple outputs and layers.*

In the following, after reviewing related work, we introduce our property testing model in detail. Then, in Section 3, we summarize our results and provide a technical overview. Due to space constraints, we omit the full technical details for the claims made in Section 3. However, to illustrate our analytical approach, Section 4 provides a complete proof of one key result. All remaining proofs and a comprehensive analysis are deferred to the full version [19].

1.2 Related work

Property testing. Since its development in the late 90s [46, 29], the area of property testing has emerged as an important area of modern theoretical computer science, see surveys in [9, 28, 44]. Although a close relationship between property testing and properties of functions, and in the context of learning has been known since the beginning of the area (these topics were explored as early as in [46, 29]), *the setting presented in this paper has received little attention.* The classical framework of testing properties of functions typically assumes an oracle access to the functions and/or the inputs rather than a computational device, see [9, 28]. (For example, most function property testers assume oracle access to the values of a given function on a specific input, and typically, graph testers assume access to the edges of the input graph.) Similarly, one normally studies networks in the context of their combinatorial properties rather than by analyzing "functions" they compute. The only work that we are aware of that considers a model similar to ours is the analysis of testing mixing property of Markov chains by Batu et al. [7]. We are not aware of any property testing work for basic logical or arithmetic circuits (even a related testing satisfiability in [2] uses a different setting), though some works on testing branching programs [25, 38] or whether a function can be represented by a small/shallow circuit/branching program [22, 24, 42], are of similar flavor. Other related works include property testing of some matrix properties (e.g., [5], where testing the rank of a matrix A has implications for some properties of Ax), but these works use a different setting, rely on linear operators, and do not apply to non-linear operators like those studied in our paper.

Neural networks. The complexity of neural networks has received significant attention in the past. In particular, threshold circuits have been studied as a model of computation and for corresponding complexity class TC^0 we know $\mathsf{AC}^0 \subsetneq \mathsf{TC}^0 \subseteq \mathsf{NC}^1$ [50]. The problem of verifying whether there exist weights such that an input circuit computes an input Boolean

function (threshold circuit loading) is known to be NP-complete [33], even when the circuit is restricted to three neurons [11]. For more details on the computational complexity of networks, see, e.g., [40].

In general, feedforward networks (acyclic networks) are universal approximators when viewed as computing a continuous function, i.e., they can arbitrarily well approximate any Borel-measurable function between finite dimensional spaces provided a sufficient number of neurons (nodes) in the hidden layer exist [32]. Furthermore, width-bounded networks (but generally with a large number of layers) are universal approximators [35]. The VC-dimension of neural networks with linear threshold gates has been studied and there is an upper bound of $O(m \log m)$ where m is the number of linear threshold gates [8]. These results imply bounds on the number of samples required to train the network. However, for our setting they do not seem to be directly relevant since one cannot evaluate a training example without querying the whole network.

In a related study, [20] investigated the problem of deciding if a neural network with real inputs is monotone and [37] considered monotone neural networks.

There has been extensive research on the computational complexity of training constant depth ReLU networks. It is known that even for a single ReLU unit, the problem of finding weights minimizing the squared error of a given training set is hard to approximate [27, 36, 21] (cf. [12] for a slightly different proof/result). Further results show that even for a single neuron, the training problem parameterized by the dimension d of the training data is $W[1]$-hard and there is a $n^{\Omega(d)}$ conditional lower bound assuming the exponential time hypothesis [26]. Studies have also explored learning linear combinations of ReLUs from Gaussian distributions (e.g., an algorithm for a constant number of ReLU units has been recently developed in [14]).

2 Property testing model

We begin our study with a feedforward network with one hidden layer and ReLU activation function. The network (see Figure 1) is fully connected between the layers, and has n input nodes labeled $\{1, \ldots, n\}$, a hidden layer with m nodes labeled $\{1, \ldots, m\}$, and one output node. (We later generalize our model to multiple hidden layers and output nodes, see Section 3.4.) We associate a *binary vector* $x = (x_1, \ldots, x_n)$ with the input nodes, so that input node i has value x_i. Between the input nodes and the hidden layer there is a *complete bipartite graph with real edge weights* from $[-1, 1]$. We define a_{ij} to be the weight between input node i and node j of the hidden layer. The *value of an input node is* x_i. The *value computed at a hidden layer node* j *is* $\sum_i a_{ji} x_i$. Thus, we can write the values at the hidden layer by a matrix multiplication Ax for an $m \times n$ matrix A. To the values at the hidden layer, we apply the *ReLU activation function*, which is defined as $\mathrm{ReLU}(y) := \max\{0, y\}$. For a vector $y = (y_1, \ldots, y_m)^T$, we define $\mathrm{ReLU}(y)$ to be $\mathrm{ReLU}(y) := (\mathrm{ReLU}(y_1), \ldots, \mathrm{ReLU}(y_m))^T$. We can now write the output of the hidden layer nodes as $\mathrm{ReLU}(Ax)$. Between the hidden layer and the output node there is a complete bipartite graph with real weights from $[-1, 1]$. Let w_j denote the weight of the edge connecting hidden layer node j to the output node. If $z = \mathrm{ReLU}(Ax)$ is the vector of hidden layer outputs, then $w^T z$ is the *value of output node*, where $w = (w_1, \ldots, w_m)^T$. Thus, on input $x \in \{0, 1\}^n$ the value at the output node is $w^T \cdot \mathrm{ReLU}(Ax)$. For further intuition, we refer the reader to Figure 1.

ReLU network as a binary classifier. We interpret the network as a *binary classifier*: the network assigns each input vector to one of two classes, defined as 0 and 1. If the value at the output node is at most 0 we assign class 0, if it is larger than 0 we assign class 1. In this paper

we focus on the setting when $x \in \{0,1\}^n$ is a binary vector. Thus, we view the neural network as a function $f : \{0,1\}^n \to \{0,1\}$ that computes 1 if the output value of the network is greater than 0, and 0 if the output value is at most 0. We write[3] $f(x) = \mathrm{sgn}(\mathrm{ReLU}(w^T \cdot \mathrm{ReLU}(Ax)))$. For a given input $x \in \{0,1\}^n$, we call $f(x)$ the *output of the network*.

Our goal is to understand how the local structure of the network is related to the function f or to properties of that function. We will address this question by studying the function from a *property testing* point of view. This leads us to the following definition.

▶ **Definition 1 (ReLU network with *one hidden layer* and *single output*).** *A ReLU network with n input nodes, m hidden layer nodes, and one output node is a pair (A, w), where $A \in [-1,1]^{m \times n}$ and $w \in [-1,1]^m$. The binary function $f : \{0,1\}^n \to \{0,1\}$ computed by the ReLU network (A, w) is defined as*

$$f(x) := \mathrm{sgn}(\mathrm{ReLU}(w^T \cdot \mathrm{ReLU}(Ax))).$$

2.1 Property testing: ReLU networks with *one hidden layer/one output*

We introduce a new property testing model for computational networks on an example of neural ReLU networks. We view (see Figure 1) the network as a weighted graph $G = (V, E)$, where $V = I \cup H \cup O$ with I being the set of *input nodes*, H the set of *hidden layer nodes*, and O the set of *output nodes* (frequently $|O| = 1$). The nodes in I, H and O are labelled from 1 to $|I|, |H|$ and $|O|$, respectively. Furthermore, E contains all edges between I and H, and between H and O. The edges between I and H are also referred to as *first layer edges* and the edges from H to O as *second layer edges*. We assume that we have *query access to the edge weights*: we can specify nodes number i in I and number j from H, and query the value a_{ij} of that edge in $O(1)$ time. Similarly, we can access the entries of w by specifying the corresponding hidden layer node.

Our objective is to design (randomized) sampling algorithms that decide whether a given neural network has a certain property or is far away from the property. To achieve this goal, we must first define a distance measure of neural networks. We view the network as a weighted graph and use the (relative) edit distance. However, since we want to take into consideration that there is a different number of edges on each layer, *for two networks (A_1, w_1) and (A_2, w_2)* with n input nodes, m hidden layer nodes, and one output node, we *define their distance* as $\max\left\{\frac{\|A_1 - A_2\|_0}{mn}, \frac{\|w_1 - w_2\|_0}{m}\right\}$, where we use the standard notation $\|\cdot\|_0$ to denote the number of non-zero entries in a matrix/vector.

In this paper, we view neural networks as computing Boolean functions and study the question whether a neural network computes a function that has a certain *property*. We begin with the study of networks that compute a specific function. Since there are often many networks that compute the same function, the question of whether a given network computes a certain function may be viewed as testing whether an input has a certain specific property in standard property testing.

Given a function $f : \{0,1\}^n \to \{0,1\}$, a *property tester* is an algorithm with query access to the weights of a network (with n input nodes and m hidden layer nodes) that accepts with probability at least $\frac{2}{3}$ every network that computes f and rejects with probability at least $\frac{2}{3}$

[3] Note: the outer ReLU is *not redundant* in $\mathrm{sgn}(\mathrm{ReLU}(\cdot))$ because the argument $w^T \cdot \mathrm{ReLU}(Ax)$ can be negative, in which case $\mathrm{sgn}(\cdot)$ would return $-1 \notin \{0,1\}$; see also the discussion in footnote 1.

every network that is *far* from computing f, where we parameterize the notion of being far with parameters ε, δ. Parameter ε refers to the distance between the networks and δ refers to the distance between the computed function with respect to the uniform distribution[4].

The model. Let us recall the notion of *property of Boolean functions*, which is any family $\mathcal{P} = \bigcup_{n\in\mathbb{N}} \mathcal{P}_n$, where $\mathcal{P}_n$ is a set of Boolean functions $f : \{0,1\}^n \to \{0,1\}$.

▶ **Definition 2 (ReLU network far from a property of functions).** *Let (A, w) be a ReLU network with n input nodes and m hidden layer nodes. (A, w) is called* ***(ε, δ)-close to computing a function $f : \{0,1\}^n \to \{0,1\}$ with property $\mathcal{P} = \bigcup_{n\in\mathbb{N}} \mathcal{P}_n$****, if one can change the matrix A in at most εnm places and the weight vector w in at most εm places to obtain a ReLU network that computes a function g, such that there exists a function $f \in \mathcal{P}_n$ for which $\Pr[g(x) \neq f(x)] \leq \delta$, where x is chosen uniformly at random from $\{0,1\}^n$. If (A, w) is not (ε, δ)-close to computing f with property $\mathcal{P}$ then we say that it is* ***(ε, δ)-far from computing f with property $\mathcal{P}$****.*

If $|\mathcal{P}_n| = 1$ and $f \in \mathcal{P}_n$, then in Definition 2 we say that a *network is (ε, δ)-close/far from computing f.*

▶ Remark 3. It might seem highly undesirable that the notion of (ε, δ)-distance employed in this paper does not satisfy the triangle inequality. However, our model is a natural relaxation of the model with $\delta = 0$, which is exactly the standard model of property testing with a property $\mathcal{P}$ being the set of networks computing a given function (like the 0-function) [28]. *It is an inherent feature of property testing that the distance to a property/function often does not satisfy the triangle inequality*: Just as two graphs G and H being close to 3-colorable does not imply that G and H are close to each other, or two networks close to computing the 0-function are not necessarily close.

▶ **Definition 4.** *A property $\mathcal{P} = \bigcup_{n\in\mathbb{N}} \mathcal{P}_n$ of Boolean functions is* ***testable*** *(for ReLU networks)* ***with query complexity $q(\varepsilon, \delta, n, m)$****, if for every $n, m \in \mathbb{N}$, every $\varepsilon \in (0,1)$, and every $\delta \in (0,1)$ there exists an algorithm that receives parameters $n, m, \varepsilon, \delta$ as input and is given query access to an arbitrary ReLU network with n input nodes, m hidden layer nodes and one output node, and that*

- *queries the ReLU network in at most $q(\varepsilon, \delta, n, m)$ many places,*
- *accepts with probability at least $\frac{2}{3}$ every network that computes a function from $\mathcal{P}_n$, and*
- *rejects with probability at least $\frac{2}{3}$ every network that computes a function (ε, δ)-far from $\mathcal{P}$.*

If the function q depends only on ε and δ, then we just say that the property $\mathcal{P}$ is ***testable****.*[5]

A tester that accepts every function from $\mathcal{P}$ with probability 1 is called ***one-sided tester****.*

---

[4] While distance to a property is often parameterized using only the parameter ε, a relaxation with another parameter has been studied before. In fact, a very similar model has been used in [7] to test if a Markov chain is mixing. Similarly to our problem, the graph/Markov chain can be seen as a computational model parameterized in terms of ε and δ, where ε refers to the edit distance of the Markov chain and δ to the ℓ_1-distance between the t-step distributions. We believe that a similar relaxation is useful in our case as the relation between the network and the function is rather complex, and we have little hope to obtain results without this second parameter δ.

[5] In property testing, traditionally (cf. [9, 28]), the ultimate goal of the analysis is to *obtain testers whose query complexity is independent of the input size*, depending only on ε, δ. Testers with query complexity $o(mn)$ are of interest, but often not as the main objective. The importance of having the query complexity independent of ε and δ is especially amplified in our setting: if we query the ReLU network in $q(\varepsilon, \delta, n, m)$ many places, then normally the tester will be computing the function on the subnetwork determined by the tested edges *for all* 2^n *inputs*. However, the number of *relevant* input bits is always upper bounded by $q(\varepsilon, \delta, n, m)$ (since only input bits adjacent to the queried edges impact the function computed), and therefore if the query complexity is independent of the input size, then the number of inputs to be considered is at most $2^{q(\varepsilon,\delta)}$, which is independent on n and m. Hence, *testers with query complexity independent of n and m have their running time independent of n and m* too.

3 Technical overview

We initiate the study of property testing of computational networks on an example of neural networks. Below we presented a detailed discussion of our findings and of the technical challenges involved in our analysis. Due to space constraints, we omit the full technical details for the claims made here. All remaining proofs and a comprehensive analysis are deferred to the full version [19], except for one key result proven in Section 4.

3.1 Studying variants of the model on a simple function

We begin with the study of the constant 0-function (the same results are true for the OR function) in our basic model of feedforward *networks with ReLU activation function, one hidden layer, and single output*. We start by showing that the constant 0-function is testable in such model. This is the case even though, as we can easily show, the problem of verifying if the network computes the constant 0-function is NP-hard (note that if we had no ReLU we could simply compute $w^T A$ and check whether $w^T A$ has positive entries; so here ReLU makes the problem more difficult); see [19] for a formal proof. Our result is summarized in the following theorem (for a proof of part (1), see Section 4; for a proof of part (2) see [19]):

▶ **Theorem 5.** *Let (A, w) be a ReLU network with n input nodes, m hidden layer nodes, and a single output. Let $\delta \geq e^{-n/16}$, $\frac{1}{m} < \varepsilon < \frac{1}{2}$, and $0 < \lambda < \frac{1}{2}$.*

(1) *There is a tester that queries $O(\frac{\ln^2(1/\varepsilon\lambda)}{\varepsilon^6})$ entries from A and w, and (i) accepts with probability at least $\geq 1-\lambda$, if the ReLU network (A, w) computes the constant 0-function, and (ii) rejects with probability at least $1-\lambda$, if (A, w) is (ε, δ)-far from computing the constant 0-function.*

(2) *There is a tester that queries $O(\frac{\ln^2(1/\varepsilon\lambda)}{\varepsilon^6})$ entries from A and w, and (i) accepts with probability at least $1-\lambda$, if the ReLU network (A, w) computes the OR-function, and (ii) rejects with probability at least $1-\lambda$, if (A, w) is (ε, δ)-far from computing the OR-function.*

The query complexity of our tester does not depend on δ and we only require $\delta \geq e^{-\Omega(n)}$. *Assuming that n and m are polynomially related, one could also remove this dependence* by introducing a factor $\mathrm{polylog}(1/\delta)$ in the complexity, since for $\delta < e^{-n/16}$ we can read the whole network.

Observe that the *query complexity of our tester in Theorem 5 is independent of the network size*. Further, for constant ε and λ, the query complexity of our tester is $O(1)$.

Our property tester for the constant 0-function samples a subset of $\mathrm{poly}(1/\varepsilon)\cdot\mathrm{polylog}(1/\lambda)$ input and hidden layer nodes and evaluates whether the induced network with a *suitable bias* at the output node computes the constant 0-function. While this approach seems natural, the analysis and *its use of the bias* is non-standard.

The first step of our analysis shows that if the network is (ε, δ)-far from computing the constant 0-function then there is an input $x_0 \in \{0,1\}^n$ on which the network outputs value $\Omega(\varepsilon nm)$. Then, we show that sampling a constant number of hidden layer nodes approximates the scaled output value for this particular x_0 with sufficient accuracy, giving the scaled output value $\Omega(\varepsilon nm)$. In the next step, we show that we can sample a constant number of input nodes and approximate the value at the sampled hidden layer nodes so that the value at the output node is positive. Combining all the steps yields that if the network is (ε, δ)-far then our tester rejects with sufficient probability.

In order to show that the algorithm accepts a network computing the constant 0-function, we will argue that for all inputs $x \in \{0,1\}^n$ the sampled network computes the constant 0-function. For that, we take a different view and consider the sample from the input nodes

as being fixed. We then observe that restricting our network to the sampled input nodes can also be done by restricting the input to vectors $x \in \{0,1\}^n$ that are 0 for all input nodes that do not belong to the sample. This allow us to interpret our sampling approach as only sampling from the hidden layer. Hence, we can apply a concentration bound and take a union bound over all choices of input vectors that are zero on the nodes not in the sample. We also observe that while the analysis considers n-dimensional input vectors we know that these are 0 except for the sampled input nodes. Thus, in order to compute the output value we only need to query edges between sampled nodes.

Comparison to a vanilla testing algorithm. The above result implies that a network far from computing the 0-function (or from computing the OR-function) already exhibits this property across most of its small subnetworks. While this may not seem to be too surprising in the first place, it turns out to be a useful addition to a *vanilla testing algorithm* that *samples inputs uniformly at random* and *evaluates the network on these inputs*. This vanilla testing algorithm is arguably the most natural and routinely used approach to test the functionality of neural networks. In fact, it corresponds to the most *standard setting in property testing of functions* [28, 9] in which *the oracle allows to query the value of the network on a given input* x, rather than to query the network's weights. In our paper (see [19], we demonstrate the versatility of our property testing model and show that there are networks that *can be recognized as* (ε,δ)*-far* (for constant ε and exponentially small δ) from computing the 0-function *by our tester*, but the *vanilla tester in expectation requires an exponential in* n *number of samples* in order to find an input that does not evaluate to 0.

▶ **Theorem 6.** *Let* $n \in \mathbb{N}$, $0 < \varepsilon < \frac{1}{1000}$, $\delta < 2^{-(16\sqrt{\varepsilon}n+1)}$, *and* $\sqrt{\varepsilon}n$ *be integral.*

(1) *There is a ReLU network* (A_L, w_L) *with* n *hidden layer nodes and* n *input nodes such that with probability at most* $e^{-10\sqrt{\varepsilon}n/8}$, *a vector* x *chosen uniformly at random from* $\{0,1\}^n$ *satisfies* $w_L^T \cdot \mathrm{ReLU}(A_L x) > 0$.

(2) *The ReLU network* (A_L, w_L) *is* (ε,δ)*-far from computing the constant* 0*-function.*

Testing with one-sided error. We also consider the testability of the constant 0-function and the OR-function with *one-sided error*. We design a tester with one-sided error and query complexity of $\widetilde{O}(m/\varepsilon^2)$. The one-sided error property tester samples a subset of $O(\log m/\varepsilon^2)$ input nodes S and rejects only if there exists an input that is zero on all nodes outside of S and that evaluates to 1 or 0, respectively. If such an input is found, then it is a counter-example to computing the constant 0-function (or the OR-function, respectively) and the algorithm can reject.

Next, we give a near matching lower bound: any tester (for any constant ε) for the constant 0-function (or for the OR-function) that has one-sided error has query complexity of $\Omega(m)$. The lower bound follows from the fact that if too few weights are known, one can always "complete" the network to enforce it to compute the constant 0-function. Thus, the tester always accepts, but there are inputs that are (ε,δ)-far from computing the 0-function.

▶ **Theorem 7.**

(1) *Let* (A,w) *be a ReLU network with* n *input nodes and* m *hidden layer nodes. Let* $e^{-n/16} \leq \delta < 1$, $\frac{1}{m} < \varepsilon < \frac{1}{2}$ *and* $0 < \lambda < \frac{1}{2}$. *There is a tester that queries* $O(\frac{m \cdot \ln(m/\lambda)}{\varepsilon^2})$ *entries from* A *and* w *and always accepts, if the ReLU network* (A,w) *computes the constant* 0*-function, and rejects with probability at least* $1-\lambda$, *if the ReLU network* (A,w) *is* (ε,δ)*-far from computing the constant* 0*-function. Furthermore, the same result holds for the OR-function.*

(2) *Any tester for the constant* 0*-function (or for the OR-function) that has one-sided error has query complexity of* $\Omega(m)$.

Why testing of the 0-function? We consider the constant 0- and the OR-functions to be representative for natural, simple, yet rich, and highly non-trivial functions in our setting. Furthermore, note that for functions f and g, $f \equiv g$ iff the network $\mathrm{ReLU}(f-g)+\mathrm{ReLU}(g-f)$ computes the 0 function, and therefore testing the 0-function is closely related to the question of two networks computing the same output values for all inputs. Other related problems that might be in reach are dictatorship and juntas (which look like essentially equivalent to 0-testing, but they are not).

3.2 Lower bound in a *distribution-free model* (or on the model's choice)

It is natural to try to extend our framework to a *distribution-free model* (see, e.g., [29, Section 2], [28, Chapter 12.4]), where the notion of being (ε, δ)-far from a property defines the farness with respect to the second parameter δ in terms of *arbitrary distribution*. In the distribution-free model the distance between Boolean functions is measured with respect to an unknown distribution rather than the uniform distribution, as in our model considered above. It is also assumed that a property tester has sample access to this distribution. In our case, we will assume *query access to bits of the sample* since our goal is to be sublinear in the input size n or even to have a constant query complexity. While the study of this model is very tempting, unfortunately, we show a *lower bound that for any constant $c < 1$, rules out $O(n^c)$-time testers even for the constant* 0 *function*:

▶ **Theorem 8.** *For every constant $k > 1$, every property tester for the constant* 0*-function in the distribution-free model has a query complexity of $\Omega(n^{1-1/k})$.*

We will sketch here the main idea of the proof for $k = 2$ (where for purpose of exposition we use different constants than in the general proof, see [19]). We define two distributions $\mathcal{D}_1$ and $\mathcal{D}_2$ on pairs of a network and an input distribution such that the networks from the first distribution are (whp.) computing the constant 0-function and such that the pairs of network and input distribution $\mathcal{D}_I$ from the second distribution are (whp.) (ε, δ)-far from computing the constant 0-function with respect to $\mathcal{D}_I$.

For $\mathcal{D}_1$ the network will (whp.) compute the constant 0-function, so the underlying distribution is not relevant. To construct the network we partition the hidden layer nodes into sets N and P such that the nodes in N are connected to the output by edges of weight -1 and the nodes in P by edges of weight 1. In the first layer, the edges to nodes from N are 1 with probability $\frac{2}{3}$ and -1, otherwise, and the edges to nodes from P are 1 with probability $\frac{1}{2}$. Ignoring the effect of the ReLU it is not too hard to see that the network will evaluate (whp.) to 0 on any fixed input and one can apply a union bound to show that this holds also for all inputs. As we show in the proof, this intuition still holds under the ReLU function.

Networks from $\mathcal{D}_2$ are similar, except that there is a random matching of input nodes and the connections to the nodes from P are sampled for one node of the matching pair and copied for the other. This implies that with probability $\frac{1}{2}$ the pair of nodes contributes 2 to the hidden layer node, while the expected contribution to N is $\frac{8}{9}$ (here the edge weights are sampled independently and the matched pair of input nodes contributes only if both first layer edges are 1, which happens with probability $\frac{4}{9}$ and the contribution is 2). Thus, for any matching pair the expected contribution to the output is linear in the size of the hidden layer. We now define the unknown input distribution to be the uniform distribution on the pairs of matched inputs. The network is far from computing the 0-function since "fixing" one of the $\Omega(n)$ matched pairs requires $\Omega(m)$ changes in the network.

Finally, we observe that distinguishing between the two distributions is expensive as the answers to the queries are identically distributed as long as no matched pair is queried. Having access to samples from the distribution does not help as it is impossible to "find"

input bits that are 1. Since the matching of input bits is random, we prove that one needs $\Omega(\sqrt{n})$ samples to find a matching pair. We formalize this intuition and parameterize it by replacing pairs of inputs by k-sets, where the first $k-1$ inputs are chosen randomly with probability $\frac{1}{2}$ to be 1 (and -1, otherwise) and the last one is 1, if there is an odd number of 1s among the first $k-1$. We then modify our construction to get a lower bound for any k. The lower bound is one of our main technical contributions, relying on a novel controlling of the expectation of ReLU of sums of binomially distributed random variables.

3.3 First steps towards a classification of testable properties?

Our next goal is to try to understand *which properties of ReLU networks are testable*. Our first result shows that some classes of functions, *symmetric Boolean functions* or *monotone Boolean functions* have trivial testers (that always accept). We prove this by showing that every network is close to computing the constant 0 function or is close to the OR-function (with ε, δ not too small).[6]

▶ **Theorem 9.** *Let (A, w) be a ReLU network with n input nodes, m hidden layer nodes, and a single output. Let $0 < \delta \leq \frac{1}{2}$ and $\max\{\frac{1}{m}, 2\sqrt{\log(2/\delta)/n}\} \leq \varepsilon$. Then (A, w) is (ε, δ)-close to computing the constant 0-function or it is (ε, δ)-close to computing the OR-function.*

The proof first argues that the value at the output (before we apply sgn and ReLU) typically deviates from its expectation by at most $O(\sqrt{nm})$. Then we show that we can modify the network in an ε-fraction of its inputs and increase (or decrease) the expected value at the output bit by more than $\frac{1}{2}\varepsilon mn$. These two facts can be shown to yield Theorem 9.

Note that the property of monotone functions includes both the 0-function *and* the OR-function. Thus an immediate consequence of Theorem 9 is that *monotonicity has a trivial tester* that always accepts if $\varepsilon \geq \max\{\frac{1}{m}, 2\sqrt{\log(2/\delta)/n}\}$, and reads the whole input if $\varepsilon < \max\{\frac{1}{m}, 2\sqrt{\log(2/\delta)/n}\}$. When n and m are polynomially related, the query complexity of the tester is $\mathrm{poly}(1/\varepsilon) \cdot \mathrm{polylog}(1/\delta)$.

Finally, we study *monotone properties* (which are different objects than monotone functions). A property $\mathcal{P}$ is *monotone*, if it is closed under flipping bits in the truth table of any function having the property $\mathcal{P}$ from 0 to 1. One can think of monotone properties as being defined by the set of minimal functions under the operation of flipping zeros to ones. We call such a set a *generator*.

We show that every monotone property is testable with query complexity logarithmically on the size of the generator (we assume that the algorithm gets the generator as input; this assumption is justified as this depends on the property only). We prove the following result.

▶ **Theorem 10.** *Let $\frac{1}{m} < \varepsilon < 1$, $2e^{-n/16} \leq \delta \leq 1$. Let $\mathcal{P} = \bigcup_n \mathcal{P}_n$ be an $f(n)$-generatible monotone property with generator $G = \bigcup_n G_n$ with $|G_n| \leq f(n)$ for all n. There is a property tester with query access to a ReLU network $\mathcal{N}$ with n input nodes and m hidden layer nodes that (i) accepts with probability at least $1-\lambda$, if $\mathcal{N}$ computes a function in $\mathcal{P}$, (ii) rejects with probability at least $1-\lambda$, if $\mathcal{N}$ is (ε, δ)-far from computing a function in $\mathcal{P}$. The tester has query complexity $O(\ln(\frac{f(n)}{\delta\varepsilon\lambda})/(\delta\varepsilon^4))$.*

[6] We would like to stress that if two networks are close to computing a given function, then *they are not necessarily* pairwise close to each other (cf. Remark 3). Similarly, notice that while the closeness result in Theorem 9 may on the first glance seem to be unnatural, similar and even stronger claims are known in various scenarios in property testing. For example, in the classical dense graph model (see [28]), for $\varepsilon > \frac{1}{n}$, every graph is *both*, ε-close to be connected and ε-close to be disconnected (every graph on n vertices can be made connected using at most n edge changes, and can be made disconnected using at most n edge changes). Therefore, the fact that in our property testing framework all properties are close to computing the constant 0-function or close to computing the OR-function, does not mean that testing of these two properties is trivial, nor it shows that the framework considered here is unnatural.

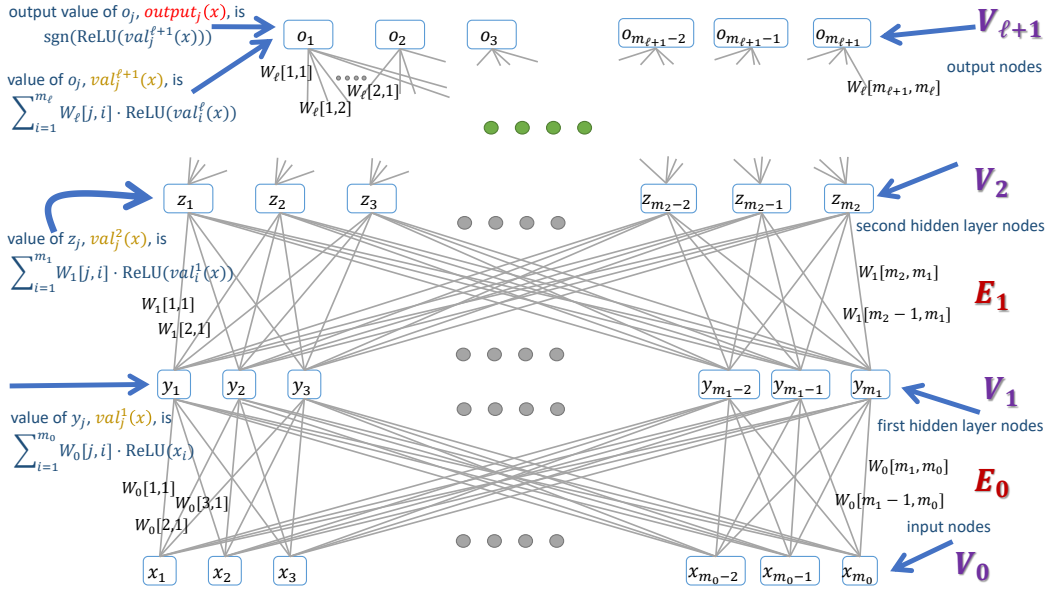

Figure 2 A general ReLU network with multiple inputs, multiple outputs, and multiple layers, extending the network depicted on Figure 1. ReLU network $(W_0, \ldots, W_\ell)$ has $\ell + 2$ layers:

- layer zero V_0 containing m_0 *input nodes*,
- ℓ *hidden layers* $1, \ldots, \ell$, with layer $1 \le k \le \ell$ containing m_k nodes V_k, and
- layer $(\ell + 1)$ containing $m_{\ell+1}$ *output nodes* $V_{\ell+1}$.

Weights: The network has *weighted edges* connecting pairs of consecutive layers. For every $0 \le k \le \ell$ and for every $1 \le i \le m_k$ and $1 \le j \le m_{k+1}$, there is an edge with weight $W_k[j,i] \in [-1,1]$ connecting the i-th node at layer k with the j-th node at layer $k+1$.
Values: For a given input $x = (x_1, \ldots, x_{m_0})^T \in \{0,1\}^{m_0}$, for any node j at layer 0, the *value* of that node $\mathrm{val}_j^0(x) = x_j$ (which is also the j-th row of $f_0(x)$). For any node j at layer $1 \le k \le \ell + 1$, the *value* of that node is $\mathrm{val}_j^k(x) = \sum_{i=1}^{m_{k-1}} W_{k-1}[j,i] \cdot \mathrm{ReLU}(\mathrm{val}_i^{k-1}(x))$; notice that this is the j-th row of $f_k(x)$.
Output: For any node j at layer $\ell + 1$ (i.e., for the j-th output node), the binary *output* computed by that node equals $\mathrm{output}_j(x) = \mathrm{sgn}(\mathrm{ReLU}(\mathrm{val}_j^{\ell+1}(x)))$; notice that this is the j-th row of $f(x)$.

3.4 Extension to ReLU networks with *multiple hidden layers/outputs*

For simplicity of presentation, we focused here mainly on the model for ReLU networks only with one output and one hidden layer. Our study, however, can be naturally extended to ReLU networks with multiple outputs and multiple hidden layers (see also Figure 2).

▶ **Definition 11 (ReLU networks with multiple hidden layers and multiple outputs).** *A ReLU network with n input nodes, $\ell \ge 1$ hidden layers with $m_1, \ldots, m_\ell$ hidden layer nodes each, and r output nodes is a tuple $(W_0, W_1, \ldots, W_\ell)$, where $W_i \in [-1,1]^{m_{i+1} \times m_i}$ for every $0 \le i \le \ell$, with $m_0 = n$ and $m_{\ell+1} = r$. The function $f : \{0,1\}^n \to \{0,1\}^r$ computed by a ReLU network $(W_0, \ldots, W_\ell)$ is defined recursively as $f(x) := \mathrm{sgn}(\mathrm{ReLU}(f_{\ell+1}(x)))$,*

$$f_i(x) := \begin{cases} W_{i-1} \cdot \mathrm{ReLU}(f_{i-1}(x)) & \text{if } 1 \le i \le \ell + 1, \\ x & \text{if } i = 0. \end{cases}$$

Observe that unfolding the recurrence in Definition 11 gives a non-recursive version of the value $f(x)$ computed by the network (in a form resembling Definition 1) is

$$f(x) := \mathrm{sgn}(\mathrm{ReLU}(W_\ell \cdot \ \ldots \ \cdot \mathrm{ReLU}(W_2 \cdot \mathrm{ReLU}(W_1 \cdot \mathrm{ReLU}(W_0 \cdot \mathrm{ReLU}(x)))) \ldots)).$$

One can also easily extend Definitions 2 and 4 to ReLU networks with multiple hidden layers and multiple outputs (for more details, see the full version of the paper [19]).

We can extend our framework to more complex neural networks and demonstrate that our methodology can be applied to a natural generalization of our setting allowing *multiple outputs* and *multiple hidden layers*. We show the applicability of our techniques by extending the approach for testing the constant 0- and the OR-function to testing near-constant functions in ReLU networks with multiple hidden layers and outputs: testing for $f(x) = \mathrm{sgn}(\mathrm{ReLU}(W_\ell \cdot \ \ldots \ \cdot \mathrm{ReLU}(W_0 \cdot \mathrm{ReLU}(x)) \ldots))$, where $W_i \in [-1,1]^{m_{i+1} \times m_i}$ and $x \in \{0,1\}^{m_0}$.

We begin with the analysis of ReLU networks with multiple outputs and *one hidden layer*. Before we proceed, let us introduce the notion of *near-constant functions* with multiple outputs[7], which are constant functions on every input x except $x = \mathbf{0}$. We first present a general reduction to single layer networks. The following theorem, central for our analysis, demonstrates that if a ReLU network with r outputs is (ε, δ)-far from computing near-constant function $\mathbf{b}$, then for at least an $\frac{\varepsilon}{2}$-fraction of the output bits i, the ReLU network restricted to the output node i is (ε', δ')-far from computing an appropriate near-constant function, where $\delta' \sim \delta/r$ and $\varepsilon' = \varepsilon^2/1025$.

▶ **Theorem 12.** *Let $\mathcal{N}$ be a ReLU network (A, W) with n input nodes, m hidden layer nodes, and r output nodes. Let $e^{-n/16} \leq \delta < 1$ and $16 \cdot \sqrt{\frac{\ln(2m)}{m}} \leq \varepsilon < \frac{1}{2}$. Let $\mathbf{b} = (\mathfrak{b}_1, \ldots, \mathfrak{b}_r) \in \{0,1\}^r$. If $\mathcal{N}$ is (ε, δ)-far from computing a near-constant function $\mathbf{b}$ then there are more than $\frac{1}{2}\varepsilon r$ output nodes such that for any such output node i, the ReLU network $\mathcal{N}$ restricted to the output node i is $(\frac{\varepsilon^2}{1025}, \frac{\delta - e^{-n/16}}{r})$-far from computing near-constant function $\mathfrak{b}_i$.*

One can then combine Theorems 5 and 12 to obtain the following theorem for testing near-constant functions in ReLU networks with *multiple outputs and one hidden layer*.

▶ **Theorem 13.** *Let $\mathcal{N}$ be a ReLU network (A, W) with n input nodes, m hidden layer nodes, and r output nodes. Let $\mathbf{b} \in \{0,1\}^r$, $(r+1)e^{-n/16} \leq \delta < 1$, and $c \cdot \sqrt{\ln(2m)/m} < \varepsilon < \frac{1}{2}$ for a sufficiently large constant c. There is a property tester that queries $O(\frac{\ln^2(1/\varepsilon\lambda)}{\varepsilon^{13}})$ entries from A and W and*

- *accepts with probability at least $\frac{2}{3}$, if $\mathcal{N}$ computes near-constant function $\mathbf{b}$, and*
- *rejects with probability at least $\frac{2}{3}$, if $\mathcal{N}$ is (ε, δ)-far from computing near-constant function $\mathbf{b}$.*

Observe that the *query complexity of our tester in Theorem 13 is independent of the network size*. Further, for constant ε and λ, the query complexity is $O(1)$, and similarly as in Theorem 5, one could remove the dependency for δ by introducing a small factor term in the query complexity.

Our analysis so far has studied the model of ReLU networks with a single hidden layer. We can extend our analysis of this setting to allow *multiple hidden layers*. A simplified claim is as follows.

[7] We need this notion to exclude trivial cases; notice that since for any ReLU network $f(\mathbf{0}) = \mathbf{0}$ (and so there is no ReLU network with $\forall_x f(x) = 1$), we consider only *near-constant functions*.

▶ **Theorem 14.** *Let* $0 < \lambda < \frac{1}{\ell+1}$, $\frac{1}{n} < \varepsilon < \frac{1}{2}$, *and* $\delta \geq e^{-n/16} + e^{-(\varepsilon/2)^{\ell} n/(342(\ell+1)^2)}$. *Let* $\mathcal{N}$ *be a ReLU network* $(W_0, \ldots, W_\ell)$ *with* n *input nodes,* $\ell \geq 1$ *hidden layers with* n *hidden layer nodes each, and a single output node. Further, suppose that* $n \geq 171 \cdot (\ell+1)^2 \cdot (2/\varepsilon)^{2\ell} \cdot (\ln(2/\delta) + \ell \ln n)$. *Assuming that* ℓ *is constant, there is a tester that queries* $\Theta(\varepsilon^{-8\ell} \cdot \ln^4(1/\lambda\varepsilon))$ *entries from* $W_0, \ldots, W_\ell$, *and*

- **(i)** *rejects with probability at least* $1 - \lambda$, *if* $\mathcal{N}$ *is* (ε, δ)*-far from computing the constant* 0*-function,*
- **(ii)** *accepts with probability at least* $1 - \lambda$, *if* $\mathcal{N}$ *computes the constant* 0*-function.*

The approach used in the proof of Theorem 14 follows the method presented in the analysis of a single hidden layer, but the need of dealing with multiple layers makes the analysis significantly more complex. The approach relies on two steps of the analysis, first proving part (i) about ReLU networks that are (ε, δ)-far from computing the constant 0-function and then part (ii) about ReLU networks that compute the constant 0-function.

The analysis of part (i) is in four steps. We first show that the use of randomly sampled nodes in each layer of the network results in a modified ReLU network that, after scaling, for any fixed input returns the value close to the value returned by the original network. Next, we extend this claim to show that there is always a modified ReLU network that, after scaling, for all but a small fraction of the inputs, returns the value close to the value returned by the original network. We then study ReLU networks $(W_0, \ldots, W_\ell)$ that are (ε, δ)-far from computing the constant 0-function. In that case, we first show that there is always an input $x_0 \in \{0,1\}^{m_0}$ on which the (ε, δ)-far network returns a value which is (sufficiently) large. Then, using the result that the sampled network approximates the output of the original network, we will argue that if $(W_0, \ldots, W_\ell)$ is (ε, δ)-far from computing the constant 0-function then randomly sampled network on input x_0 returns a (sufficiently) large.

The study of part (ii) relies on a similar approach as that in part (i). We use the fact that the sampled network computes a function which on a fixed input is (after scaling) close to the original function on that input, and hence that value cannot be too large. An important difference with part (i) is that one must prove the claim to *hold for all inputs*, making the arguments more complex (the straightforward arguments would require the size of the sample to depend on m_0).

A consequence of Theorem 14 is that it gives a tester with query complexity $1/\mathrm{poly}(\varepsilon)$ for any constant number of layers. Furthermore, as in our study for one hidden layer, essentially identical analysis as for the constant 0-function can be applied to test the OR-function.

Finally, we can extend the analysis above (Theorems 13 and 14) to networks with *multiple hidden layers* and *multiple outputs*. As in Theorem 13 (for ReLU networks with a single hidden layer and multiple outputs) the proof of the following theorem relies on a reduction of the problem to testing a near-constant function to testing the 0- and the OR-function.

▶ **Theorem 15** (Testing a near-constant function)**.** *Let* $\mathcal{N}$ *be a ReLU network* $(W_0, \ldots, W_\ell)$ *with* m_0 *input nodes,* $\ell \geq 1$ *hidden layers with* $m_1, \ldots, m_\ell$ *hidden layer nodes each, and* $m_{\ell+1} \geq 2$ *output nodes. Let* $0 < \lambda < \frac{1}{\ell+1}$, $2\sqrt[\ell]{\frac{17(\ell+1)}{\max_{0 \leq k \leq \ell}\{m_k\}}} < \varepsilon < \frac{1}{2}$, *and* $\delta \geq 2m_{\ell+1}(\xi + e^{-m_0/16})$. *Let* $\mathbf{b} \in \{0,1\}^{m_{\ell+1}}$ *and* $c = c(\ell)$ *be a sufficiently large positive constant. Suppose that for an arbitrary parameter* $0 < \xi < \frac{1}{\ell+1}$ *it holds that* $m_k \geq c \cdot (2/\varepsilon)^{2\ell^2} \cdot \ln(\frac{1}{\xi} \prod_{i=1}^{\ell} m_i)$ *for every* $0 \leq k \leq \ell$. *If* ℓ *is constant then there is a tester that queries* $\Theta(\varepsilon^{-(8\ell^2+1)} \cdot \ln^4(1/\lambda\varepsilon))$ *entries from* $W_0, \ldots, W_\ell$, *and*

- *accepts with probability at least* $1 - \lambda$, *if* $\mathcal{N}$ *computes near-constant function* $\mathbf{b}$, *and*
- *rejects with probability at least* $1 - \lambda$, *if* $\mathcal{N}$ *is* (ε, δ)*-far from computing near-constant function* $\mathbf{b}$.

As with our earlier results in Section 3.4, the *query complexity of our tester in Theorem 15 is independent of the network size*, and it is $O(1)$ for constant ε, λ, ℓ, and $m_{\ell+1}$.

4 Testing constant 0-function in ReLU networks with one hidden layer

To give readers a flavor of our analysis, we present here our analysis of ReLU networks with one hidden layer and a single output – Theorem 5 (1), deferring the study of other claims and of more complex neural networks with multiple outputs and multiple hidden layers to the full version of our paper [19]. We consider the simplest function, the **constant 0-function** $f_n^{(0)} : \{0,1\}^n \to \{0,1\}$ defined as $f_n^{(0)}(x) = 0$ for all $x \in \{0,1\}^n$, and study it from a property testing point of view. We define $P_n = \{f_n^{(0)}\}$ and the property $\Pi^{(0)} = \bigcup_{n\in\mathbb{N}} P_n$. Our objective is to design a property tester for $\Pi^{(0)}$.

While one can show (see [19]) that it is hard to decide if a given ReLU network computes the constant 0-function or not, in this section we prove that a *relaxed* version of the problem, namely, that of *(property) testing* whether a given ReLU network computes the constant 0-function, has significantly lower complexity. Below we prove the first part of Theorem 5 and show that property $\Pi^{(0)}$ is testable for ReLU networks with one hidden layer.

Testing 0-function. Our property testing algorithm AllZeroTester$(\varepsilon, \lambda, n, m)$ below works by focusing its attention on a small "subnetwork" induced by randomly sampled nodes. The algorithm samples a subset of $\text{poly}(1/\varepsilon) \cdot \ln(1/\lambda)$ nodes from the input layer and from the hidden layer. Then, we scale the weights of all edges between the sampled input and the sampled hidden layer nodes by a factor of $\frac{n}{s}$ and all edges from sampled hidden layer nodes to the output node by $\frac{m}{t}$. We then introduce a *bias* $b = -\frac{1}{16}\varepsilon nm$ to the output node, i.e., we subtract $\frac{1}{16}\varepsilon nm$ before pplying the ReLU function. For the resulting network we check if it computes the constant 0-function. If this is the case, we accept; otherwise, we reject.

Algorithm 1 AllZeroTester$(\varepsilon, \lambda, n, m)$.

1 Sample $s = \lceil \frac{2^{20}}{\varepsilon^2} \cdot \ln(1/\varepsilon\lambda) \rceil$ nodes from the input layer and $t = \lceil \frac{2^{30}}{\varepsilon^4} \cdot \ln(1/\varepsilon\lambda) \rceil$ nodes from the hidden layer uniformly at random without replacement.
2 Let $S \in \mathbb{N}_0^{n\times n}$ and $T \in \mathbb{N}_0^{m\times m}$ be the corresponding sampling matrices.
3 **if** there is $x \in \{0,1\}^n$ with $\frac{nm}{st} \cdot w^T \cdot \text{ReLU}(TASx) - \frac{1}{16}\varepsilon nm > 0$ **then reject**;
4 **else accept**.

In the following, we use matrix notation and write S and T for sampling matrices that select s and t input/hidden layer nodes at random. That is, S is an $n \times n$ diagonal matrix whose diagonal entries (i,i) are equal to 1 iff x_i is in the sample set (and is 0 otherwise), and T is an $m \times m$ diagonal matrix whose diagonal entries (j,j) are equal to 1 iff hidden layer node j is in the second sample set (and is 0 otherwise). With this notation we can describe our algorithm as follows (we did not optimize constants and assume $\varepsilon \in (\frac{1}{m}, \frac{1}{2}), \lambda \in (0, \frac{1}{2})$).

Let us first observe that the query complexity of AllZeroTester is $(s+1)\cdot t = \Theta(st)$, and hence the query complexity is as stated. Indeed, after sampling s input nodes and t nodes from the hidden layer, the diagonal matrices S and T have s and t non-zero entries, respectively. Therefore TAS can be computed by querying only $s \cdot t$ entries from matrix A and it will have at most t non-zero rows and at most s non-zero columns. Hence, in order to compute $TASx$ one has to consider only s bits from $\{0,1\}^n$, and to compute $\frac{nm}{st} \cdot w^T \cdot \text{ReLU}(TASx)$ one has to consider only t entries from w^T.

Properties of the output. Next, we will study the properties of the output. First, notice that our sampling network without a bias would compute

$$\text{sgn}\left(\text{ReLU}\left(\frac{m}{t} \cdot w^T \cdot T \cdot \text{ReLU}\left(\frac{n}{s} \cdot ASx\right)\right)\right).$$

Since the ReLU function is positive homogeneous, T is a fixed matrix with non-negative entries after the sampling, $\frac{n}{s} > 0$, and $\frac{m}{t} > 0$, we have that

$$\operatorname{sgn}\left(\operatorname{ReLU}\left(\frac{m}{t}\cdot w^T\cdot T\cdot \operatorname{ReLU}\left(\frac{n}{s}\cdot ASx\right)\right)\right) = \operatorname{sgn}\left(\operatorname{ReLU}\left(\frac{nm}{st}\cdot w^T\cdot \operatorname{ReLU}(TASx)\right)\right).$$

Introducing in AllZeroTester the bias to the output node leads to a network computing

$$\operatorname{sgn}\left(\operatorname{ReLU}\left(\frac{nm}{st}\cdot w^T\cdot \operatorname{ReLU}(TASx) - \frac{1}{16}\varepsilon nm\right)\right)$$

and we notice that one can drop sgn and the outer ReLU, if we check whether the computed value is greater than 0.

4.1 One hidden layer: If (ε, δ)-far then there is a bad input

To analyze the correctness of AllZeroTester, we first present our structural lemma.

▶ **Lemma 16.** *Let $\delta \geq e^{-n/16}$ and $\frac{1}{m} < \varepsilon < \frac{1}{2}$. Let (A, w) be a ReLU network with n input nodes and m hidden layer nodes. If (A, w) is (ε, δ)-far from computing the constant 0-function then there exists an input $x \in \{0,1\}^n$ such that $w^T \cdot \operatorname{ReLU}(Ax) > \frac{1}{8}\varepsilon mn$.*

Proof. The proof of Lemma 16 is by contradiction: we will assume that for every input x the output value is at most $\frac{1}{8}\varepsilon nm$ and then we will show that the ReLU network is (ε, δ)-close to computing the constant 0-function; this would imply contradiction.

First, suppose that there are less than $\lfloor \varepsilon m \rfloor$ positively weighted edges connecting the hidden layer to the output node. Then we set all of them to 0 and the resulting network computes the constant 0-function. Thus the network is (ε, δ)-close, which is a contradiction.

Otherwise, suppose that there are at least $\lfloor \varepsilon m \rfloor$ positively weighted edges connecting the hidden layer to the output node. Select an arbitrary subset E of $\lfloor \varepsilon m \rfloor$ positively weighted edges and let U denote the set of hidden layer nodes incident to the edges from E. Let E' be the subset of first layer edges connecting input nodes to the nodes from U. Notice that $|E| = |U| = \lfloor \varepsilon m \rfloor$ and $|E'| = n \cdot |U| = \lfloor \varepsilon m \rfloor n$. Now we modify the weights of $|E| = \lfloor \varepsilon m \rfloor$ edges between the hidden layer nodes and the output, and $|E'| = \lfloor \varepsilon m \rfloor n$ edges between input nodes and hidden layer nodes: we assign weight -1 to every edge from E and weight 1 to every edge from E'.

Observe that originally, before the modifications, every hidden layer node in U had a non-negative contribution to the output. After the modifications, every hidden layer node from U contributes $-k$ to the output node, where k is the number of 1s in the input vector x, i.e., $k = \|x\|_1$. Thus all nodes from U contribute $-|U| \cdot \|x\|_1 = -\lfloor \varepsilon m \rfloor \cdot \|x\|_1$, and the changes of the weights of the edges incident to U *reduce the output value* by at least $\lfloor \varepsilon m \rfloor \cdot \|x\|_1$.

Next, let us consider a random input vector $x \in \{0,1\}^n$. Using Chernoff bounds, with probability at least $1 - e^{-n/16} \geq 1 - \delta$, we have $\|x\|_1 > \frac{1}{4}n$. Conditioned on this event, after modifying the weights in the network, the sum of inputs to the output node is *reduced* by at least $\frac{1}{4}n \cdot \lfloor \varepsilon m \rfloor \geq \frac{1}{8}\varepsilon nm$ for our range of parameters. However, we have assumed that for every input x the output value is at most $\frac{1}{8}\varepsilon nm$, and thus the network computes the constant 0-function. Hence, we modified an ε-fraction of the network's edge weights and obtained a function that disagrees with the constant 0-function only on inputs with $\|x\|_0 \leq n/4$, which is at most a δ-fraction of all inputs. This is a contradiction to the assumption that the network is (ε, δ)-far from that function. ◀

4.2 One hidden layer: Random sampling concentration

Next, we consider the impact of the random sampling matrices S and T on the output value of a ReLU network for any fixed x (and hence, for x whose existence is argued in Lemma 16).

▶ **Lemma 17.** *Let $w \in [-1,1]^m$, $A \in [-1,1]^{m\times n}$. Let S, T be sampling matrices corresponding to samples of size $t \geq \frac{2048\ln(4/\lambda)}{\varepsilon^2}$ and $s \geq \frac{2048\ln(4t/\lambda)}{\varepsilon^2}$. Then for any fixed $x \in \{0,1\}^n$*

$$\Pr\left[\left|\frac{mn}{st}\cdot w^T\cdot \mathrm{ReLU}(TASx) - w^T\cdot\mathrm{ReLU}(Ax)\right| > \tfrac{1}{16}\varepsilon nm\right] \leq \lambda\ .$$

Proof. Fix an arbitrary $x \in \{0,1\}^n$. We first show that

$$\Pr\left[\left|\frac{m}{t}\cdot w^T\cdot T\cdot \mathrm{ReLU}(Ax) - w^T\cdot\mathrm{ReLU}(Ax)\right| > \tfrac{1}{32}\varepsilon nm\right] \leq \tfrac{1}{2}\lambda\ . \tag{1}$$

Observe that $w^T\cdot T\cdot\mathrm{ReLU}(Ax)$ is the sum of t entries in $w\odot\mathrm{ReLU}(Ax)$ (here $\odot$ denotes the Hadamard product) sampled uniformly without replacement. Next, we notice that $\mathbf{E}[w^T\cdot T\cdot\mathrm{ReLU}(Ax)] = \frac{t}{m}\cdot w^T\cdot\mathrm{ReLU}(Ax)$. Rescaling by $\frac{1}{n}$ ensures that the entries in $w\odot\mathrm{ReLU}(Ax)$ are in $[-1,1]$ and so we can apply Hoeffding bounds [31] (note that the Hoeffding bound also holds for sampling without replacement [6, Proposition 1.2]) to show

$$\Pr\left[\left|\frac{1}{n}w^T T\,\mathrm{ReLU}(Ax) - \frac{t}{mn}w^T\,\mathrm{ReLU}(Ax)\right| > \tfrac{1}{32}\varepsilon t\right] =$$
$$\Pr\left[\left|\frac{1}{n}w^T T\,\mathrm{ReLU}(Ax) - \mathbf{E}\left[\frac{1}{n}w^T\cdot T\cdot\mathrm{ReLU}(Ax)\right]\right| > \tfrac{1}{32}\varepsilon t\right] \leq 2e^{-2\varepsilon^2(t/32)^2/(4t)} \leq \tfrac{1}{2}\lambda$$

for our choice of $t \geq \frac{2048\ln(4/\lambda)}{\varepsilon^2}$. Multiplying both sides with $\frac{mn}{t}$ proves inequality (1).

We can view the sampling process as first sampling t nodes from the hidden layer and then s nodes from the input layer. Thus, we can condition on T being fixed and assume that the s nodes from the input layer are sampled uniformly at random. We will now prove:

$$\Pr\left[\left|\frac{mn}{ts}\cdot w^T\cdot\mathrm{ReLU}(TASx) - \frac{m}{t}w^T\cdot T\cdot\mathrm{ReLU}(Ax)\right| > \tfrac{1}{32}\varepsilon nm\ \middle|\ T\right] \leq \tfrac{1}{2}\lambda\ . \tag{2}$$

Let a_i be the i-th row of matrix A. The value $a_i\cdot x$ is the value at the i-th hidden layer node before applying ReLU. We may view a_iSx as the sum of s random entries from $a_i\odot x$. Since these entries are from $[-1,1]$ and $\mathbf{E}[a_iSx] = \frac{s}{n}\cdot a_i\cdot x$, Hoeffding's bound implies that

$$\Pr\left[\left|a_iSx - \frac{s}{n}\cdot a_ix\right| > \varepsilon s/32\right] \leq 2e^{-2\varepsilon^2(s/32)^2/(4s)} \leq \frac{\lambda}{2t},$$

where the last inequality follows from our assumption that $s \geq \frac{2024\ln(4t/\lambda)}{\varepsilon^2}$.

Now we observe that for $w_i \in [-1,1]$ we have

$$\left|w_i\cdot\left(\mathrm{ReLU}(a_iSx) - \mathrm{ReLU}\left(\frac{s}{n}a_ix\right)\right)\right| \leq \left|w_i\cdot\left(a_iSx - \frac{s}{n}a_ix\right)\right| \leq \left|a_iSx - \frac{s}{n}a_ix\right|.$$

Following our arguments above, for each of the rows we can bound the contribution of the edge with weight w_i that connects the i-th hidden layer node to the output node to get

$$\Pr\left[\left|w_i\cdot\left(\mathrm{ReLU}(a_iSx) - \mathrm{ReLU}\left(\frac{s}{n}\cdot a_ix\right)\right)\right| > \frac{1}{32}\varepsilon s\right] \leq 2e^{-2\varepsilon^2/(s/32)^2/(4s)} \leq \frac{\lambda}{2t}.$$

Next, we observe that TA equals A in exactly t rows (the sampled rows) and is 0 otherwise. Taking a union bound over the contribution of these t rows and observing that for the remaining rows the product with Sx is 0 for every S, we obtain

$$\Pr\left[\left|w^T\cdot\mathrm{ReLU}(TASx) - \frac{s}{n}\cdot w^T\cdot\mathrm{ReLU}(TAx)\right| > \frac{1}{32}\varepsilon st\ \middle|\ T\right] \leq \frac{\lambda}{2}.$$

Multiplying with $\frac{mn}{st}$ and observing that $\mathrm{ReLU}(TAx) = T \cdot \mathrm{ReLU}(Ax)$ (since ReLU is positively homogeneous), we obtain (2):

$$\Pr\left[\left|\frac{mn}{st} \cdot w^T \cdot \mathrm{ReLU}(TASx) - \frac{m}{t} \cdot w^T \cdot T \cdot \mathrm{ReLU}(Ax)\right| > \varepsilon mn/32 \;\middle|\; T\right] \leq \frac{\lambda}{2}.$$

Next observe that inequalities (1) and (2) are simultaneously satisfied with probability at least $1 - \lambda$. Thus, the lemma follows from

$$\begin{aligned}
&\left|\frac{mn}{st} \cdot w^T \cdot \mathrm{ReLU}(TASx) - w^T \cdot \mathrm{ReLU}(Ax)\right| \leq \\
&\leq \left|\frac{mn}{st} w^T \,\mathrm{ReLU}(TASx) - \frac{m}{t} w^T T \,\mathrm{ReLU}(Ax)\right| + \left|\frac{m}{t} w^T T \,\mathrm{ReLU}(Ax) - w^T \,\mathrm{ReLU}(Ax)\right| \\
&\leq \frac{1}{16}\varepsilon mn
\end{aligned}$$

with probability at least $1 - \lambda$. ◀

4.3 One hidden layer: If (ε, δ)-far then we reject

Our next lemma incorporates Lemmas 16 and 17 to summarize the analysis of our testers for ReLU networks that are (ε, δ)-far from computing the constant 0-function.

▶ **Lemma 18.** *Let $\delta \geq e^{-n/16}$, $\frac{1}{m} < \varepsilon < \frac{1}{2}$, and $0 < \lambda < \frac{1}{2}$. Let (A, w) be a ReLU network with n input nodes and m hidden layer nodes. If (A, w) is (ε, δ)-far from computing the constant 0-function then algorithm* AllZeroTester *rejects with probability at least $1 - \lambda$.*

Proof. By Lemma 16, since (A, w) is (ε, δ)-far from computing the constant 0-function, there exists an $x_0 \in \{0,1\}^n$ such that $w^T \cdot \mathrm{ReLU}(Ax_0) > \frac{1}{8}\varepsilon mn$. Next, by Lemma 17, with probability at least $1 - \lambda$ (over the random choice of S and T in the algorithm) we have

$$\left|\frac{mn}{st} \cdot w^T \cdot \mathrm{ReLU}(TASx_0) - w^T \cdot \mathrm{ReLU}(Ax_0)\right| \leq \frac{1}{16}\varepsilon nm \ .$$

This implies that with probability $1 - \lambda$ we obtain

$$\frac{mn}{st} \cdot w^T \cdot \mathrm{ReLU}(TASx_0) - \frac{1}{16}\varepsilon mn > 0,$$

and so AllZeroTester rejects with probability at least $1 - \lambda$. This concludes the proof. ◀

4.4 One hidden layer: If network computes 0 then we accept

Our final lemma of this section summarizes the second part of the analysis of AllZeroTester for ReLU networks and deals with the networks that correctly compute the 0-function.

▶ **Lemma 19.** *Let (A, w) be a ReLU network with n input nodes and m hidden layer nodes. Let S, T be sampling matrices corresponding to samples of size $t \geq \frac{512 \ln(2^{s+1}/\lambda)}{\varepsilon^2}$ and $s \geq 1$. If (A, w) computes the constant 0-function then with probability at least $1 - \lambda$ (over the random choice of S and T as defined by the algorithm), for all $x \in \{0,1\}^n$*

$$\frac{nm}{st} \cdot w^T \cdot \mathrm{ReLU}(TASx) - \frac{1}{16}\varepsilon nm < 0,$$

and so algorithm AllZeroTester *accepts.*

Proof. Let (A, w) be a ReLU network that computes the constant 0-function. Let I_S be the set of indices of the s nodes sampled by our algorithm from the input layer and let $X_S = \{x = (x_1, \ldots, x_n)^T \in \{0,1\}^n : x_i = 0, \forall i \notin S\}$ be the set of different inputs to the sampled network. In what follows, we will condition on the choice of S being fixed. Then

$$\frac{nm}{st} \cdot w^T \cdot \mathrm{ReLU}(TASx) - \frac{1}{16}\varepsilon nm < 0$$

holds for all $x \in \{0,1\}^n$ if and only if this inequality holds for all $x \in X_S$. Therefore, in what follows we will show that the output value of a fixed $x \in X_S$ will be approximated with high probability and then we will apply a union bound over all $x \in X_S$ to conclude the analysis.

Let x be an arbitrary fixed vector from X_S. Observe that $\frac{1}{s} \cdot w^T \cdot \mathrm{ReLU}(ASx)$ is an m-dimensional vector with entries from $[-1, 1]$. We know that $w^T \mathrm{ReLU}(ASx) \leq 0$ since the network computes the constant 0-function. Since ReLU is positively homogeneous we can move T out of the ReLU function. The fact that T is a sampling matrix and that $w^T \mathrm{ReLU}(ASx) \leq 0$ yields

$$\mathbf{E}\left[\frac{1}{s} \cdot w^T \cdot T \cdot \mathrm{ReLU}(ASx) \;\middle|\; S\right] \leq 0. \tag{3}$$

Then, applying Hoeffding bound gives us

$$\Pr\left[\left|\frac{1}{s} \cdot w^T \cdot T \cdot \mathrm{ReLU}(ASx) - \mathbf{E}\left[\frac{1}{s} \cdot w^T \cdot T \cdot \mathrm{ReLU}(ASx)\right]\right| \geq \frac{1}{16}\varepsilon t \;\middle|\; S\right] \leq 2e^{\frac{-2(\varepsilon t/16)^2}{4t}},$$

which is upper bounded by $\frac{\lambda}{2^s}$ for our choice of t, since $t \geq \frac{512 \ln(2^{s+1}/\lambda)}{\varepsilon^2}$. By the union bound over the $|X_S| = 2^s$ vectors in X_S, this implies the following inequality for all $x \in \{0,1\}^n$:

$$\Pr\left[\left|\frac{mn}{st} \cdot w^T \cdot T \cdot \mathrm{ReLU}(ASx) - \mathbf{E}\left[\frac{nm}{st} \cdot w^T \cdot T \cdot \mathrm{ReLU}(ASx)\right]\right| \geq \frac{1}{16}\varepsilon nm\right] \leq \lambda.$$

Lemma 19 follows from inequality (3) and the fact that in the algorithm we are subtracting $\frac{1}{16}\varepsilon nm$ from the result by taking a union bound over the $|X_S| = 2^s$ vectors in X_S. ◀

4.5 One hidden layer: Completing the proof of Theorem 5 (1)

Now Theorem 5 (1) follows immediately from Lemmas 18 and 19 and from our analysis of the query complexity after the description of AllZeroTester on page 16. ◀

5 Conclusions

In this paper, we introduce a property testing model to study computational networks used as computational devices and illustrate our setting on a case study of simple ReLU neural networks. We believe that the property testing model developed in this paper establishes a novel and useful theoretical framework for the study of testing algorithms and offers a new and interesting viewpoint with a potential of advancing our understanding of the structure of neural networks (and, in general, of computational networks). While, due to space constraints, we have omitted full technical details behind the claims made in Section 3, we refer the reader for the proofs and a comprehensive analysis to the full version of this paper [19].

In the context of neural networks, given our poor understanding of the computational processes in modern deep networks (leading to serious questions on the trust and transparency of the underlying learning algorithms), we hope that the lens of property testing as developed in the framework considered in this paper will contribute to a better understanding of the relation of the network structure and the computed function or properties of that function.

Indeed, since the analysis of property testing algorithms relies on establishing close links between the object's local structure and the tested property, we believe the study of simple yet fundamental models of ReLU networks may provide a new insight into such networks.

Although our paper makes the first step in the analysis of ReLU networks in the context of property testing, there is still a large number of open questions (from the property testing point of view) regarding such networks, including, among others, the following:

- What is the query complexity of testing dictatorship and juntas (see [10] for a survey on testing juntas)?
- Classify the constant time testable properties with one- and two-sided error.
- Study tolerant testing [41] in our model.
- Extend the results to inputs over the reals.

These are just a small number of immediate questions one can ask about our model. We believe that there is a wide variety of interesting questions and are confident to see further research in this direction.

Abstract

We construct an explicit distribution $\mathbf{D}$ over $\{0,1\}^N$ that exhibits an essentially optimal separation between adaptive and non-adaptive cell-probe sampling. The distribution can be sampled exactly when each output bit is allowed two adaptive probes to an arbitrarily long sequence of independent uniform symbols from $[N]$. In contrast, any non-adaptive sampler requires $\widetilde{\Omega}(N)$ non-adaptive cell probes to generate a distribution with total variation distance less than $1-o(1)$ from $\mathbf{D}$. This provides a 2-vs-$\widetilde{\Omega}(N)$ separation for sampling with adaptive versus non-adaptive cell probes, improving upon the 2-vs-$\widetilde{\Omega}(\log N)$ separation of Yu and Zhan (ITCS '24) and the $(\log N)^{O(1)}$-vs-$N^{\Omega(1)}$ separation of Alekseev, Göös, Myasnikov, Riazanov, and Sokolov (STOC '26).

1 Introduction

In recent years, the family of computational tasks involving *sampling* has received increased attention, particularly from a complexity-theoretic viewpoint. Broadly, the goal is to take uniform randomness as input and produce samples from some target distribution. Sampling has connections and applications to many other areas of complexity including data structure lower bounds [12, 11, 2, 14, 5, 15, 16, 10, 1], quantum-classical separations [3, 10, 9], randomness extractors [7, 13, 5, 4], and more.

One may study the complexity of sampling tasks in various computational models (e.g., circuits, branching programs, bounded-space Turing machines) and with a variety of randomness sources, but in this work we focus on the *cell-probe* model with uniformly random inputs. In this setting the sampler has query access to arbitrarily many independent

samples drawn uniformly from $[N] := \{1, 2, \ldots, N\}$, and outputs are determined by arbitrary functions depending on some subset of inputs queried, i.e., our sampler corresponds to some function $f\colon [N]^m \to \{0,1\}^N$, and we consider the distribution on $\{0,1\}^N$ which results from evaluating f on uniformly random input. We write $f(\mathbf{U}_{[N]}^m)$ to denote this distribution where $\mathbf{U}_{[N]}^m$ is the uniform distribution on $[N]^m$. We say that f is d-local if every output bit is a function of at most d input symbols; that is, it can be computed with at most d non-adaptive cell probes.

We also consider an adaptive version of this model wherein the sampler can perform intermediate computations with later queries depending on the results of earlier ones. Indeed, the focus of this work is on understanding the relative power of adaptivity for sampling tasks in this model:

How much can adaptive queries help to sample in the cell-probe model?

The challenge of exhibiting a distribution which requires asymptotically fewer adaptive queries than non-adaptive queries was raised by Viola in [14] and reiterated in [15]. He suggested the following candidate distribution $\mathbf{D}_V$ on $[N]^N$. Fix some integer $k = N^{1-\Omega(1)}$, and sample a string $r \in [N]^k$ uniformly at random. Each output symbol x_i of $\mathbf{D}_V$ is determined by independently and uniformly sampling an index $j \in [k]$ and setting $x_i = r_j$. It is easy to see that two adaptive probes are sufficient to sample from this distribution (assuming $k|N$), but a separation was not known until Yu and Zhan [16] proved that $\Omega(\log N/\log\log N)$ non-adaptive probes are necessary to sample from $\mathbf{D}_V$ (even approximately).

More recently, Alekseev, Göös, Myasnikov, Riazanov, and Sokolov [1] showed that sampling a uniform random permutation in $[N]^N$ also gives a separation between adaptive and non-adaptive cell-probe samplers. They proved that $N^{\Omega(1)}$ non-adaptive probes are required, while Czumaj [6] showed that $O(\log^2 N)$ adaptive probes suffice to get polynomially small distance. Alekseev et al. [1] also showed that $(\log N)^{\Omega(1)}$ adaptive probes are necessary, and highlighted obtaining an $O(1)$-vs-$N^{\Omega(1)}$ separation as an interesting open question. Weaker lower bounds on the number of non-adaptive probes required to sample permutations had been shown earlier in [14, 16].

In this work, we give an essentially optimal $O(1)$-vs-$\widetilde{\Omega}(N)$ separation.

▶ **Theorem 1.** *For any $\varepsilon > 0$ and infinitely many N, there exists an explicit distribution $\mathbf{D}_1$ over $\{0,1\}^N$ which can be sampled exactly by two adaptive probes to independent uniform symbols from $[N]$, yet for any $(N^{1-\varepsilon})$-local function $f\colon [N]^m \to \{0,1\}^N$, we have*

$$\left\| f(\mathbf{U}_{[N]}^m) - \mathbf{D}_1 \right\|_{\mathsf{TV}} \geq 1 - \exp(-N^{\Omega_\varepsilon(1)}). \tag{1}$$

Similarly, there exists a constant $c > 0$ such that for infinitely many N, there exists an explicit distribution $\mathbf{D}_2$ over $\{0,1\}^N$ which can be sampled exactly by two adaptive probes to independent uniform symbols from $[N]$, yet for any $(N/\log^c N)$-local function $g\colon [N]^m \to \{0,1\}^N$, we have

$$\left\| g(\mathbf{U}_{[N]}^m) - \mathbf{D}_2 \right\|_{\mathsf{TV}} \geq 1 - \exp(-\Omega(\log^2 N)). \tag{2}$$

▶ Remark 2. These results are essentially the best possible in several ways.

- Any adaptive sampler which only makes one cell probe (per output bit) is trivially equivalent to a non-adaptive sampler, so at least two probes are necessary for a separation.
- The error in (1) cannot be appreciably improved, since any distribution over $\{0,1\}^N$ can be approximated to distance $1 - e^{-\Omega(N)}$ by a point mass (which needs no locality to generate).

- The locality in (2) cannot be appreciably improved, since a $\Theta(N/\log N)$-local sampler can use the probed cells as a shared seed with $2^{\Theta(N)}$ possible values to approximate any distribution over $\{0,1\}^N$ with exponentially small error (see, e.g., [12, Lemma 5.2]).
- The alphabet size s of the random symbols must be large for such a separation to hold. If s were smaller than any polynomial in N, then any sampler making $d = O(1)$ adaptive probes could be simulated by one making $s^{O(d)} \ll N^{\Omega(1)}$ non-adaptive probes by considering all possible queried inputs.

The distributions in Theorem 1 are instantiations of the following distribution with different choices of parameters.

▶ **Definition 3** (Distribution $\mathbf{D}_{n,\ell}$). *Let $n \geq 2$ be a power of two, and let $\ell \geq 1$ be an integer. We define $\mathbf{D}_{n,\ell}$ to be the distribution over $(\mathbf{i}^{(1)}, \ldots, \mathbf{i}^{(\ell)}, \mathbf{x}, \mathbf{y}^{(1)}, \ldots, \mathbf{y}^{(\ell)}) \in \{0,1\}^{\ell\log(n)+(\ell+1)n}$, where each $\mathbf{i}^{(j)}$ is independently uniform over $\{0,1\}^{\log(n)}$ (viewed as an element of $[n]$), $\mathbf{x}$ is uniform over $\{0,1\}^n$, and $\mathbf{y}^{(j)}_k = \mathbf{x}_{k+\mathbf{i}^{(j)} \bmod n}$ for all $j \in [\ell]$ and $k \in [n]$.*

Note that $\mathbf{D}_{n,\ell}$ is similar in spirit to the aforementioned distribution $\mathbf{D}_V$, but with a more explicit indexing structure. In $\mathbf{D}_V$, each output samples a private index $j \in [k]$ and outputs r_j. This produces clusters of coordinates which must take the same value, although the output itself does not reveal which coordinates belong to which cluster. Our method instead explicitly produces many random groups of $\ell + 1$ outputs that must correlate and encodes which clusters those must be in the index portion of the output.

As with $\mathbf{D}_V$, the distribution $\mathbf{D}_{n,\ell}$ can be sampled with two adaptive cell probes.

▷ Claim 4. Let n, ℓ be as in Definition 3, and let N be a (positive) integer multiple of $2n$. Then $\mathbf{D}_{n,\ell}$ can be sampled exactly by two adaptive probes to independent uniform symbols from $[N]$.

Proof. Let the first $\ell + n$ random input symbols be $S_1, \ldots, S_\ell, R_1, \ldots, R_n \in [N]$. For each $j \in [\ell]$, use S_j to generate the shift $\mathbf{i}^{(j)}$ using some balanced mapping from $[N] \to [n]$. Similarly for each $k \in [n]$, use R_k to generate the bit $\mathbf{x}_k$ using some balanced mapping from $[N] \to \{0,1\}$. (Since $(2n)|N$, both mappings exist.) To produce $\mathbf{y}^{(j)}_k$, first probe S_j to learn the shift $\mathbf{i}^{(j)}$, then probe $R_{k+\mathbf{i}^{(j)} \bmod n}$ and output the corresponding bit. ◁

Our main technical result is the following lower bound, which shows that $\mathbf{D}_{n,\ell}$ is hard to sample non-adaptively.

▶ **Theorem 5.** *Let $m \geq d \geq 1$, $\ell \geq 1$, and $n, N \geq 2$ be integers where n is a power of two. Additionally, let $f\colon [N]^m \to \{0,1\}^{\ell\log(n)+(\ell+1)n}$ be a d-local function, and let $\mathbf{D}_{n,\ell}$ be the distribution in Definition 3. Then $f(\mathbf{U}^m_{[N]})$ and $\mathbf{D}_{n,\ell}$ have total variation distance at least*

$$1 - \exp\left(-\Omega\left(\frac{n}{\ell^2 d \log N}\right)\right) - d\left(\frac{\Theta(d\log N)}{n}\right)^{\ell} - \exp\left(d\ell\log(n)\log(N) - \Omega(n)\right).$$

Taking Theorem 5 as a black-box, we can immediately derive Theorem 1.

Proof of Theorem 1 (assuming Theorem 5). Both $\mathbf{D}_1$ and $\mathbf{D}_2$ will be chosen to be padded versions of $\mathbf{D}_{n,\ell}$ (for different values of ℓ), where $n \geq 2$ is a power of 2, $\ell \geq 1$ is an integer, and $N = 4\ell n$. Note that under these conditions, Claim 4 guarantees we can exactly sample $\mathbf{D}_{n,\ell}$ with two adaptive cell probes, so the same must also be true when the distribution is padded with zeros.

In the case of $\mathbf{D}_1$, we set $\delta = 3\varepsilon/4$, $\ell = \lfloor n^{\delta/3} \rfloor$, and $d = \lceil n^{1-\delta} \rceil$. Then Theorem 5 implies that for any d-local $f\colon [N]^m \to \{0,1\}^{\ell \log n + (\ell+1)n}$, we have

$$\left\| f(\mathbf{U}_{[N]}^m) - \mathbf{D}_{n,\ell} \right\|_{\mathsf{TV}} \geq 1 - \exp(-\widetilde{\Omega}(n^{\delta/3})) \geq 1 - \exp(-\Omega(N^{\varepsilon/6}))$$

for large enough n. Since $d \geq N^{1-\varepsilon}$ and $\mathbf{D}_{n,\ell}$ is a projection of $\mathbf{D}_1$, the desired lower bound for $\mathbf{D}_1$ follows. Similarly in the case of $\mathbf{D}_2$, we set $\ell = \lfloor \log^2 n \rfloor$ and $d = \lceil n/\log^7 n \rceil$. Then for any d-local g, we have

$$\left\| g(\mathbf{U}_{[N]}^m) - \mathbf{D}_{n,\ell} \right\|_{\mathsf{TV}} \geq 1 - \exp(-\Omega(\log^2 n)) \geq 1 - \exp(-\Omega(\log^2 N))$$

for large enough n. Using $d \geq N/\log^{10} N$, we obtain the desired lower bound for $\mathbf{D}_2$. ◀

We will prove Theorem 5 in Section 3 after setting up some preliminary material in the subsequent section.

2 Preliminaries

In this section, we review some basic notation, terminology, and standard results. For a positive integer n, we use $[n]$ to denote the set $\{1, 2, \ldots, n\}$. All logarithms given in the paper are base 2. The indicator function is denoted by $\mathbb{1}(\cdot)$.

Asymptotics

We use the standard $\Omega(\cdot), O(\cdot), \Theta(\cdot)$ asymptotic notation to hide universal positive constants. Occasionally, we will use subscripts to indicate an unspecified dependence on a particular parameter (e.g., $\Omega_\varepsilon(1)$). Additionally, we write $\widetilde{\Omega}(\cdot)$ to suppress polylogarithmic factors.

Cell-Probe Samplers

We study sampling in the cell-probe model. A sampler is given access to an arbitrarily long sequence of independent random cells, each uniformly distributed over $[N]$, and produces an output in $\{0,1\}^n$ according to probes made to the random cells. The complexity of the sampler is the maximum number of cells queried in order to produce any single output bit.

A central distinction is whether these probes are adaptive. In an adaptive sampler, the location of a later probe may depend on the values observed in earlier probes. In a non-adaptive sampler, all probe locations for a given output bit are fixed in advance. In the non-adaptive setting, this cost is often called the *locality* of the sampler. Thus, a function $f\colon [N]^m \to \{0,1\}^n$ is said to be d-local if each output bit of f depends on at most d input cells.

Probability

We use bold letters to denote probability distributions and random variables. We reserve $\mathbf{U}_{[n]}$ for the uniform distribution over $[n]$. For an event $\mathcal{E}$, we define $\mathbf{X}(\mathcal{E})$ to be the probability mass assigned to $\mathcal{E}$ by $\mathbf{X}$. For a function f, we use $f(\mathbf{X})$ to denote the output distribution of $f(\mathbf{x})$ on randomly drawn $\mathbf{x} \sim \mathbf{X}$.

Given a distribution $\mathbf{X}$ and positive integer t, we use $\mathbf{X}^t$ to denote the t-fold product distribution $\mathbf{X} \times \cdots \times \mathbf{X}$. If s is a finite set, we write $\mathbf{X}^s$ to emphasize that the coordinates of $\mathbf{X}^{|s|}$ are indexed by s. We refer to $\mathbf{X}$ as a mixture if it can be written as a convex combination

of other distributions. That is, there exist $c_1, \dots, c_k \in [0,1]$ with $\sum_i c_i = 1$ and distributions $\mathbf{X}_1, \dots, \mathbf{X}_k$ such that $\mathbf{X}(\mathcal{E}) = \sum_{i=1}^k c_i \cdot \mathbf{X}_i(\mathcal{E})$ for every event $\mathcal{E}$. Occasionally, we write this more concisely as $\mathbf{X} = \sum_{i=1}^k c_i \mathbf{X}_i$. We measure the similarity of two (discrete) distributions $\mathbf{P}$ and $\mathbf{Q}$ by the *total variation (TV) distance*

$$\|\mathbf{P} - \mathbf{Q}\|_{\mathsf{TV}} = \max_{\text{event } \mathcal{E}} \mathbf{P}(\mathcal{E}) - \mathbf{Q}(\mathcal{E}) = \frac{1}{2} \sum_x |\mathbf{P}(x) - \mathbf{Q}(x)| \,.$$

We say $\mathbf{P}$ is ε-*close* to $\mathbf{Q}$ if $\|\mathbf{P} - \mathbf{Q}\|_{\mathsf{TV}} \le \varepsilon$, and ε-*far* otherwise.

Concentration Inequalities

We will need the following standard concentration inequality.

▶ **Lemma 6** (Chernoff). *Let $\mathbf{X}_1, \dots, \mathbf{X}_n$ be independent indicator random variables with $\mathbf{Pr}[\mathbf{X}_i = 1] \ge p$ for all i. Then for any $\delta \in (0,1)$, we have*

$$\mathbf{Pr}\left[\sum_i \mathbf{X}_i \le (1-\delta)pn\right] \le \exp\left(-\Omega(\delta^2 pn)\right).$$

We will also require a variant of Lemma 6 in which the random variables are only partially independent. There are a plethora of standard results giving concentration under these weaker conditions (e.g., McDiarmid's or Azuma's inequalities). For our purposes, a lesser-known inequality derived from Shearer's lemma (from information theory) by Gavinsky, Lovett, Saks, and Srinivasan [8] appears to provide the best bounds. A collection of random variables $\mathbf{X}_1, \dots, \mathbf{X}_n$ is said to be a *read-k family* if they are functions of independent random variables $\mathbf{Y}_1, \dots, \mathbf{Y}_m$, where each $\mathbf{Y}_j$ influences at most k of the $\mathbf{X}_i$'s. The following is essentially [8, Theorem 1.1].

▶ **Lemma 7** (Read-k Chernoff). *Let $\mathbf{X}_1, \dots, \mathbf{X}_n$ be a read-k family of indicator random variables with $\mathbf{Pr}[\mathbf{X}_i = 1] \ge p$ for all i. Then for any $\delta \in (0,1)$, we have*

$$\mathbf{Pr}\left[\sum_i \mathbf{X}_i \le (1-\delta)pn\right] \le \exp\left(-\Omega\left(\frac{\delta^2 pn}{k}\right)\right).$$

3 Proof of Theorem 5

In this section, we prove Theorem 5, restated below for the reader's convenience.

▶ **Theorem 5.** *Let $m \ge d \ge 1$, $\ell \ge 1$, and $n, N \ge 2$ be integers where n is a power of two. Additionally, let $f\colon [N]^m \to \{0,1\}^{\ell \log(n) + (\ell+1)n}$ be a d-local function, and let $\mathbf{D}_{n,\ell}$ be the distribution in Definition 3. Then $f(\mathbf{U}^m_{[N]})$ and $\mathbf{D}_{n,\ell}$ have total variation distance at least*

$$1 - \exp\left(-\Omega\left(\frac{n}{\ell^2 d \log N}\right)\right) - d\left(\frac{\Theta(d \log N)}{n}\right)^{\ell} - \exp\left(d\ell \log(n) \log(N) - \Omega(n)\right).$$

At a high level, the proof reduces to a setting in which many groups of output bits that are forced to be equal under $\mathbf{D}_{n,\ell}$ do not share a common input cell. For each such group, this absence of a shared input creates a dichotomy: either the sampler produces unequal bits with noticeable probability, immediately violating the defining constraints of $\mathbf{D}_{n,\ell}$, or the entire group is biased toward one fixed constant value. If the latter occurs for many groups, then the sampler places too much mass on outputs where many coordinates simultaneously

take prescribed values, an event that is exponentially unlikely under $\mathbf{D}_{n,\ell}$. Thus in either case the sampler is far from the target distribution. We now proceed to the details.

For clarity, we will write $\mathbf{U}$ for $\mathbf{U}_{[N]}$ and $\mathbf{D}$ for $\mathbf{D}_{n,\ell}$. It will also be convenient to discuss the indices in the output of $f(\mathbf{U}^m)$ in a similar fashion to the definition of $\mathbf{D}$ (in Definition 3). That is, we will abuse notation and often use (say) $\mathbf{i}^{(1)}$ for the first $\log n$ bits of $f(\mathbf{U}^m)$. It will be evident from context which distribution (i.e., $f(\mathbf{U}^m)$ or $\mathbf{D}$) the random variables $\mathbf{i}^{(j)}, \mathbf{x}, \mathbf{y}^{(j)}$ are being taken from.

Let $t > 0$ be a threshold parameter (eventually taken to be $\Theta(\ell d \log N)$), and let $S \subseteq [m]$ be the set of input symbols to the sampler f that either affect more than t output bits or affect one of the first $\ell \log n$ outputs (corresponding to $\mathbf{i}^{(1)}, \ldots, \mathbf{i}^{(\ell)}$). Observe that $s := |S| \leq d\ell \log(n) + d(\ell+1)n/t$. By conditioning on the values that the symbols in S take, we can express $f(\mathbf{U}^m)$ as the mixture

$$f(\mathbf{U}^m) = \sum_{\rho \in [N]^S} \frac{1}{N^s} \cdot f(\mathbf{U}^{[m]\setminus S}, \rho).$$

Below, we will write the distribution $f(\mathbf{U}^{[m]\setminus S}, \rho)$ more concisely as $\mathbf{F}_\rho$. Observe that any such conditioning ρ fixes the value of the shift vector $\mathbf{i}(\rho) := (\mathbf{i}^{(1)}(\rho), \ldots, \mathbf{i}^{(\ell)}(\rho))$, where $\mathbf{i}^{(j)}(\rho)$ is the value of $\mathbf{i}^{(j)}$ after conditioning on ρ, and it guarantees that every unfixed input cell affects at most t output bits. We will use these properties to show that for certain restrictions ρ, the distribution $\mathbf{F}_\rho$ is far from $\mathbf{D}$ conditioned on their shift vectors being equal. Then, we amalgamate the behavior of these conditional distributions to obtain our final distance bound.

In order for $f(\mathbf{U}^m)$ to approximate $\mathbf{D}$, there must be clusters of $k := \ell + 1$ output bits which all take the same value. More precisely, for each shift vector $i \in (\{0,1\}^{\log n})^\ell$ and $u \in [n]$, define the equality block $B_u(i) = (\mathbf{x}_u, \mathbf{y}^{(1)}_{u-i^{(1)}}, \ldots, \mathbf{y}^{(\ell)}_{u-i^{(\ell)}})$. Call such an i *bad* if at least $n/4$ of the equality blocks have some unfixed input cell $c \notin S$ which affects every bit in the block (and *good* otherwise); if a block has such an input symbol, we say the block is *covered*.

▷ Claim 8. The fraction of bad $i \in (\{0,1\}^{\log n})^\ell$ is at most $4d\left(\frac{t}{\ell n}\right)^\ell$.

Proof. For each unfixed input cell $c \notin S$, define $A_{x,c} \subseteq [n]$ to be the set of $\mathbf{x}$ coordinates affected by c. Similarly, for all $j \in [\ell]$ define $A_{j,c} \subseteq [n]$ to be the set of $\mathbf{y}^{(j)}$ coordinates affected by c. Observe that $\sum_j |A_{j,c}| \leq t$, and that a block $B_u(i)$ is covered by a cell c only if $u \in A_{x,c}$ and $u - i^{(j)} \in A_{j,c}$ for all j. In a uniformly sampled $\mathbf{i}$, each $\mathbf{i}^{(j)}$ is chosen independently and uniformly at random from $\{0,1\}^{\log n}$, so the probability that $u - \mathbf{i}^{(j)} \in A_{j,c}$ is $|A_{j,c}|/n$. Thus,

$$\begin{aligned}
\mathop{\mathbb{E}}_{\mathbf{i}\in(\{0,1\}^{\log n})^\ell}[\#\text{ blocks covered}] &\leq \sum_{c\notin S} \mathop{\mathbb{E}}_{\mathbf{i}\in(\{0,1\}^{\log n})^\ell}[\#\text{ blocks covered by } c] \\
&= \sum_{c\notin S} \sum_{u\in A_{x,c}} \prod_{j=1}^{\ell} \frac{|A_{j,c}|}{n} && \text{(since } \mathbf{i}^{(j)}\text{'s independent)} \\
&\leq \sum_{c\notin S} |A_{x,c}| \left(\frac{\sum_j |A_{j,c}|}{n\ell}\right)^\ell && \text{(by AM-GM inequality)} \\
&\leq \left(\sum_{c\notin S} |A_{x,c}|\right) \cdot \left(\frac{t}{n\ell}\right)^\ell && \text{(by def'n of } S\text{)} \\
&\leq dn \left(\frac{t}{n\ell}\right)^\ell. && \text{(since } \mathbf{x} \text{ affected by} \leq dn \text{ inputs)}
\end{aligned}$$

Applying Markov's inequality concludes the proof. ◁

By Claim 8, we can primarily focus our attention on the case of good i's, where we have many uncovered blocks. We will show that the lack of correlation within the bits of such a block causes behavior which does not occur in the target distribution. Below, we view $\mathbf{Z}$ as the marginal distribution of $\mathbf{F}_\rho$ onto an uncovered block.

▷ Claim 9. Let $\mathbf{Z}$ be the marginal distribution over some $k \geq 2$ output bits. If no input cell affects every bit in $\mathbf{Z}$, then either

1. $\mathbf{Pr}[\mathbf{Z} \notin \{0^k, 1^k\}] \geq 1/(100k)$, or
2. $\mathbf{Pr}[\mathbf{Z} = z] \geq 2/3$ for some fixed $z \in \{0^k, 1^k\}$.

Proof. Arbitrarily partition the input cells into sets $I_1, \ldots, I_k$ where the cells in I_j do not affect the j-th output bit of $\mathbf{Z}$. We proceed by a hybrid argument. Consider two independent random inputs $\mathbf{A}, \mathbf{B}$. We define the sequence of inputs

$$\mathbf{A} = \mathbf{C}^{(0)}, \mathbf{C}^{(1)}, \ldots, \mathbf{C}^{(k)} = \mathbf{B},$$

where $\mathbf{C}^{(j)}$ has the input symbols in $I_1 \cup \cdots \cup I_j$ taken from $\mathbf{B}$ and the rest from $\mathbf{A}$. We also define $\mathbf{Z}^{(j)}$ to be the value of $\mathbf{Z}$ on input $\mathbf{C}^{(j)}$, and observe that each $\mathbf{Z}^{(j)}$ has the same marginal distribution as $\mathbf{Z}$. Moreover, let $\delta = \mathbf{Pr}[\mathbf{Z} \notin \{0^k, 1^k\}]$, $p_0 = \mathbf{Pr}[\mathbf{Z} = 0^k]$, and $p_1 = \mathbf{Pr}[\mathbf{Z} = 1^k]$.

Whenever $\mathbf{Z}^{(0)} = 0^k$ and $\mathbf{Z}^{(k)} = 1^k$ (or vice-versa), there must exist some $\mathbf{Z}^{(j)} \notin \{0^k, 1^k\}$. Indeed, any two consecutive outputs $\mathbf{Z}^{(j-1)}, \mathbf{Z}^{(j)}$ agree on their j-th bit, since the cells in I_j do not affect it. Thus, we cannot transition directly from 0^k to 1^k, so if the sequence contains both strings, then it must also contain some other output. This implies $2p_0p_1 \leq (k+1)\delta$. Assume by contradiction that $\delta < 1/(100k)$ and $p_0, p_1 < 2/3$. Then $\min(p_0, p_1) > 1 - \frac{1}{100k} - \frac{2}{3} \geq \frac{1}{4}$, so

$$\frac{1}{8} \leq 2\left(\frac{1}{4}\right)^2 < \frac{k+1}{100k} \leq \frac{1}{100} + \frac{1}{100k} \leq \frac{1}{8} - \frac{11}{100},$$

a contradiction. ◁

Fix a conditioning ρ such that $\mathbf{i}(\rho)$ is good. That is, at least $3n/4$ blocks $B_u(\mathbf{i}(\rho))$ are uncovered. We break into cases depending on which conclusion of Claim 9 is satisfied by most of these blocks. Below, let $n' = 3n/8$.

Case 1: Most blocks satisfy (1)

Let $B_1, \ldots, B_{n'}$ be blocks satisfying (1). While they are not fully independent, one would expect their behavior to resemble that of independent random variables, since each unfixed input cell only affects a small number of blocks.[1] More formally, we have that the indicator random variables $\{\mathbb{1}(B_j \notin \{0^k, 1^k\})\}_j$ form a read-t family, so Lemma 7 implies

$$\mathop{\mathbf{Pr}}_{\mathbf{F}_\rho}\left[\sum_{j=1}^{n'} \mathbb{1}(B_j \notin \{0^k, 1^k\}) \geq \frac{n'}{200k}\right] \geq 1 - \exp\left(-\Omega\left(\frac{n}{kt}\right)\right).$$

For comparison, this event never occurs under $\mathbf{D}$ conditioned on its shift vector being $\mathbf{i}(\rho)$.

[1] A greedy construction allows us to find $\Omega(n/dt)$ actually independent blocks, but pursuing this line of analysis gives worse bounds.

Case 2: Most blocks satisfy (2)

Let $B_1, \dots, B_{n'}$ be blocks satisfying (2), where their most common values are $b_1, \dots, b_{n'}$, respectively. Again applying Lemma 7, we have

$$\Pr_{\mathbf{F}_\rho}\left[\sum_{j=1}^{n'} \mathbb{1}(B_j = b_j) \geq \frac{7n'}{12}\right] \geq 1 - \exp\left(-\Omega\left(\frac{n}{t}\right)\right).$$

For comparison, $\sum_{j=1}^{n'} \mathbb{1}(B_j = b_j)$ is distributed like the binomial $\mathsf{Bin}(n', 1/2)$ under $\mathbf{D}$ conditioned on its shift vector being $\mathbf{i}(\rho)$, so this event occurs with probability at most $e^{-\Omega(n)}$ by Lemma 6.

In either case, there exists an event $\mathcal{E}_\rho$ which occurs with probability at least $1 - e^{-\Omega\left(\frac{n}{kt}\right)}$ under $\mathbf{F}_\rho$, but probability at most $e^{-\Omega(n)}$ under $\mathbf{D}$ conditioned on its shift vector. We now define the global event $\mathcal{E}$ witnessing the TV distance between $f(\mathbf{U}^m)$ and $\mathbf{D}$ to be

$$\mathcal{E} = \{\text{bad } \mathbf{i}\} \cup \bigcup_{\rho\,:\,\mathbf{i}(\rho) \text{ is good}} (\mathbf{i} = \mathbf{i}(\rho) \text{ and } \mathcal{E}_\rho).$$

Under $f(\mathbf{U}^m)$, each conditioning $\rho \in [N]^S$ produces a shift vector $\mathbf{i}(\rho)$. If $\mathbf{i}(\rho)$ is bad, then the output automatically lies in $\mathcal{E}$, and if $\mathbf{i}(\rho)$ is good, then we have already shown it lies in $\mathcal{E}$ with probability at least $1 - e^{-\Omega\left(\frac{n}{kt}\right)}$. To analyze the probability under $\mathbf{D}$, we apply a union bound to find that

$$\begin{aligned}\Pr_{\mathbf{D}}[\mathcal{E}] &\leq \Pr_{\mathbf{D}}[\mathbf{i} \text{ is bad}] + \sum_{\rho\,:\,\mathbf{i}(\rho) \text{ is good}} \Pr_{\mathbf{D}}\left[\mathcal{E}_\rho \,|\, \mathbf{i} = \mathbf{i}(\rho)\right] \\ &\leq 4d\left(\frac{t}{\ell n}\right)^\ell + N^s \exp(-\Omega(n)). \qquad \text{(by Claim 8)}\end{aligned}$$

Hence,

$$\|f(\mathbf{U}^m) - \mathbf{D}\|_{\mathsf{TV}} \geq 1 - \exp\left(-\Omega\left(\frac{n}{(\ell+1)t}\right)\right) - 4d\left(\frac{t}{\ell n}\right)^\ell - N^s \exp(-\Omega(n)).$$

Setting $t = \Theta(\ell d \log N)$ with a sufficiently large implicit constant gives $s \leq d\ell \log(n) + O(n/\log N)$, where $O(n/\log N)$ has a sufficiently small implicit constant, so we find the distance between $f(\mathbf{U}^m)$ and $\mathbf{D}$ is at least

$$1 - \exp\left(-\Omega\left(\frac{n}{\ell^2 d \log N}\right)\right) - d\left(\frac{\Theta(d \log N)}{n}\right)^\ell - \exp\left(d\ell \log(n) \log(N) - \Omega(n)\right).$$

This concludes the proof of Theorem 5.

Abstract

Recent work gave near-linear time algorithms for list decoding Folded Reed–Solomon codes and univariate multiplicity codes up to capacity in their natural parameter regimes. Unlike most known list decoding algorithms, these techniques appeared inherently tied to list decoding, and it was unclear whether they could be extended to list recovery in near-linear time.

In this work, we resolve this question by giving $\widetilde{O}(n)$-time algorithms for list recovery of Folded Reed–Solomon codes and univariate multiplicity codes up to capacity, where n is the block length. Our algorithms build on the lattice-based framework of the prior work, augmented with a new technical ingredient: the construction of suitably structured lattices over the univariate polynomial ring that capture the list recovery problem for these codes.

1 Introduction

An error-correcting code $\mathcal{C} \subseteq \Sigma^n$ is said to be (η, L) list decodable if every Hamming ball of radius ηn in Σ^n contains at most L codewords of $\mathcal{C}$. When $\eta < \delta/2$, where δ is the minimum distance of the code, we are in the unique decoding regime, in which at most one codeword lies in such a ball. List decoding is of fundamental interest both from a combinatorial perspective, where one studies tradeoffs between parameters such as η, L, δ, and the rate of the code, and from an algorithmic perspective, where the goal is to design efficient decoding algorithms for increasingly large values of η. Since Sudan's breakthrough work showing that Reed–Solomon

codes can be efficiently list decoded beyond the unique decoding radius [19], there has been substantial progress in our understanding of list decoding, culminating in explicit codes that achieve list decoding capacity with constant list size [9, 8, 10, 14, 15, 17, 5, 11] and, in several cases, near-linear time decoding algorithms [6, 2, 18]. Beyond coding theory, list decoding has deep and fruitful connections to complexity theory and pseudorandomness, including randomness extraction and hardness amplification [21].

Our focus in this paper is on the related notion of *list recovery*. A code $\mathcal{C} \subseteq \Sigma^n$ is said to be (η, ℓ, L) list recoverable if for all subsets $E_1, \ldots, E_n \subseteq \Sigma$ with $|E_i| \leq \ell$, there are at most L codewords $c \in \mathcal{C}$ such that $c_i \notin E_i$ for at most ηn coordinates $i \in [n]$. Clearly, the case $\ell = 1$ recovers the definition of list decoding. List recovery has attracted considerable attention both because of its close connection to list decoding and because of its numerous applications, including the construction of pseudorandom objects such as extractors and expanders, cryptographic constructions, and algorithmic problems such as group testing and compressed sensing. We refer the reader to the survey of Resch and Venkitesh [16] and the lecture notes of Wootters [23] for further background.

A notable feature of many list decoding algorithms is that they naturally extend to the more general setting of list recovery. This phenomenon holds for the classical Sudan and Guruswami–Sudan algorithms for Reed–Solomon codes [19, 9], for algorithms achieving capacity for Folded Reed–Solomon (FRS) and (univariate and multivariate) multiplicity codes [8, 10, 14, 15, 3, 4], as well as for recent results on expander-based codes approaching list decoding capacity [11, 18, 12]. Consequently, one might expect fast list decoding algorithms to extend automatically to fast list recovery.

A central direction in the study of list decoding and list recovery is the design of near-linear time algorithms. This includes both the construction of codes admitting such fast decoding algorithms and the development of efficient algorithms for several well-studied and natural code families. A key milestone in this direction is the work of Alekhnovich [1], which gave a near-linear time algorithm for list decoding (and list recovery) Reed–Solomon codes up to the Johnson radius. Alekhnovich's algorithm can be viewed as a fast implementation of the Guruswami–Sudan algorithm that exploits natural connections between polynomial interpolation-based decoding algorithms and lattices over the univariate polynomial ring. More recently, a lattice-based framework building on these ideas was used to obtain near-linear time list decoding algorithms up to capacity for FRS codes and univariate multiplicity codes [6]. In addition, this work developed fast algorithms for solving certain families of differential and functional equations that arise naturally in this context.

Perhaps surprisingly, the techniques underlying these near-linear time list decoding results do not appear to extend directly to the setting of list recovery. This obstruction already arises for $\ell = 2$, and stands in contrast to the behavior of most known list decoding algorithms. In this work, we show that this limitation can in fact be overcome[1].

Informally, our main result gives a near-linear time algorithm for list recovery up to capacity. In the standard parameter regime for univariate multiplicity codes, where the list-size parameter ℓ, the error parameter ε, and the multiplicity parameter s are treated as constants, the running time of our algorithm is $\widetilde{O}(n)$.

More formally, we prove the following theorem.

▶ **Theorem 1** (main result for multiplicity codes). *For every $\varepsilon > 0$ and $\ell \in \mathbb{N}$, there exists $s_0 = \Theta(\ell/\varepsilon^2) \in \mathbb{N}$ such that for all $s > s_0$, degree parameter k, block length n, and fields $\mathbb{F}$ of characteristic zero or characteristic greater than k, satisfying $k < ns$, the following holds.*

[1] In this paper we focus on univariate multiplicity codes. We believe our results extend to FRS codes and defer that case to the full version.

There is a randomized algorithm that, given a set $S \subseteq \mathbb{F}$ of size n and sets $E_\alpha \subseteq \mathbb{F}^s$ with $|E_\alpha| \le \ell$ for each $\alpha \in S$, takes

$$O\Big(n \cdot \mathsf{poly}\Big(s, \ell, \log n, (\ell/\varepsilon)^{\frac{1+\log \ell}{\varepsilon}}\Big)\Big)$$

field operations and with high probability outputs all univariate polynomials $f(X) \in \mathbb{F}[X]$ of degree less than k such that for at least $(\frac{k}{sn} + \varepsilon)$ fraction of $\alpha \in S$,

$$(f(\alpha), f^{(1)}(\alpha), \ldots, f^{(s-1)}(\alpha)) \in E_\alpha.$$

1.1 An overview of the proof

We give a high-level overview of the proof, focusing on the list-recovery problem for univariate multiplicity codes. Our algorithm follows the same two-step structure as prior near-linear time list-decoding algorithms, but the interpolation step requires a fundamentally new construction.

The input to the list-recovery problem consists of a set $S \subseteq \mathbb{F}$ of size n, where each $\alpha \in S$ is associated with a list $\{\beta(\alpha)_j\}_{j\in[\ell]}$ of s-tuples in $\mathbb{F}^s$. As in the list-decoding setting, we refer to this input as the received word.

We begin by recalling the structure of the near-linear time list-decoding algorithm of [6], which is a fast implementation of the algorithm of Guruswami and Wang [10]. This algorithm has two main components:

- **Interpolation via a differential equation.** One constructs, for an appropriately chosen parameter $m = \Theta(\sqrt{s})$, a nonzero polynomial $Q(X, Y_0, \ldots, Y_m) = \widetilde{Q}(X) + \sum_i Q_i(X)Y_i$, linear in the Y-variables and of bounded degree, such that every polynomial f whose encoding agrees sufficiently with the received word satisfies the differential equation:

  $$Q(X, f(X), f^{(1)}(X), \ldots, f^{(m)}(X)) \equiv 0.$$

- **Solving the differential equation.** The solution space of this linear differential equation is an affine space of dimension at most m. A near-linear time algorithm computes a basis for this space, followed by a pruning step [15, 20] to recover the constant-sized list of close enough codewords.

The fast list-recovery algorithm in this paper follows the same high-level outline. This is consistent with the polynomial-time list-recovery algorithm of Guruswami and Wang [10], where the list-decoding and list-recovery procedures are structurally identical, differing only in parameter settings.

To extend the results of [6] to the list-recovery setting, we use the fast differential equation solver from [6] as is. The main new ingredient is in the first step: constructing an appropriate differential equation in near-linear time.

We briefly recall the relevant interpolation framework from [6]. In the list-decoding setting, each $\alpha \in S$ is associated with a unique received vector $\beta(\alpha)$. The algorithm constructs in near-linear time univariate polynomials $A_0(X), A_1(X), \ldots, A_m(X)$ satisfying $(A_i)^{(j)}(\alpha) = \beta(\alpha)^{(i+j)}$ for all $\alpha \in S$, $i \in [m], j \in [s-m]$. One then considers the $\mathbb{F}[X]$-module (lattice) of polynomials in $X, Y_0, \ldots, Y_m$ generated by

$$\{\, Y_i - A_i(X) : i \in [m] \,\} \;\cup\; \left\{ \prod_{\alpha \in S} (X - \alpha)^{s-m} \right\}. \tag{1}$$

This lattice has the property that any nonzero element of this lattice of sufficiently small degree yields a polynomial $Q(X, Y_0, \ldots, Y_m) = \widetilde{Q}(X) + \sum_i Q_i(X)Y_i$ such that every polynomial f whose encoding agrees with the received word on sufficiently many α's satisfies

$$Q(X, f, f^{(1)}, \ldots, f^{(m)}) \equiv 0.$$

In [6], existence of such a "short" nonzero lattice element is proved via an analogue of Minkowski's theorem, and it is found in near-linear time using Alekhnovich's algorithm for shortest vectors (with respect to the degree norm) in polynomial lattices. The "short" guarantee here matches that [10] achieve via variable and constraint counting.

The difficulty in moving to list recovery is that each α now comes with ℓ candidate vectors $\beta(\alpha)_1, \ldots, \beta(\alpha)_\ell$, so the received word is no longer a function $\alpha \mapsto \beta(\alpha)$. In particular, the definition of the polynomials A_i above breaks down. A natural attempt is to arbitrarily "split" the input into ℓ received words in the list-decoding sense: for $t \in [\ell]$, let $r_t = (\alpha, \beta(\alpha)_t)_{\alpha \in S}$, and construct the corresponding polynomials $A_{t,0}, \ldots, A_{t,m}$. One could then try to work with the lattice generated by products such as $\prod_{t=1}^{\ell}(Y_j - A_{t,j}(X))$ (over $\mathbb{F}[X]$), thereby capturing the disjunction "Y_j matches one of the ℓ possibilities." However, this immediately leads to polynomials Q with Y-degree ℓ, and hence to nonlinear differential equations. This is the main obstacle. Even if one could find such a low-degree Q in near-linear time, it is unclear how to solve the resulting nonlinear differential equation and recover all close codewords efficiently: the solution set need not be an affine subspace, and the linear-algebraic techniques of [6] do not apply. While high Y-degree interpolation is standard in other contexts (e.g., [19, 9, 1, 14, 13]), we do not know how to make this approach work here[2].

Motivated by this, it is natural to insist on keeping Q *linear* in the Y-variables even in the list-recovery setting. Guruswami and Wang show that this can be done in polynomial time. Our main technical contribution is to show that it can in fact be done in near-linear time: we construct a carefully structured lattice over $\mathbb{F}[X]$ whose generators are linear in $Y_0, \ldots, Y_m$, and whose short nonzero vectors correspond precisely to linear differential equations that *capture* all close codewords. In the list-decoding setting the received word is a function $\alpha \mapsto \beta(\alpha)$ leading to an almost-diagonal basis of the form (1) for the resulting $(m+1)$-dimensional lattice. In list recovery, the received word no longer has such a functional structure and hence one cannot expect the resulting lattice to admit a similar simple basis. What we show is the next best thing: there exists a lattice whose basis has a structured almost-triangular form, which is sufficient for computing short nonzero vectors efficiently and for deriving the required linear differential equation. The basis we obtain has the following form.

$$\begin{aligned}
&\prod_{\alpha \in S}(X - \alpha)^{s-m}, && \\
&Y_i \cdot \prod_{\alpha \in S}(X - \alpha)^{s-m}, && \forall i, \text{ such that } 0 \le i \le \ell - 2 \\
&\widetilde{C_i}(X) + \sum_{r=0}^{i-1} Y_r \cdot C_{i,r}(X) + Y_i \cdot \prod_{\alpha \in S}(X - \alpha)^{\ell-1}, && \forall i, \text{ such that } \ell - 1 \le i \le m
\end{aligned}$$

for some polynomials $\widetilde{C_i}, C_{i,r} \in \mathbb{F}[X]$ for $\ell - 1 \le i \le m$ and $0 \le r \le i - 1$. The proof that such a basis exists is considerably involved. We first show that such an almost-triangular

[2] Note that the Guruswami–Sudan list-decoding algorithm, and Alekhnovich's near-linear time implementation thereof, already employ a Y-degree larger than one; consequently, Alekhnovich's approach readily extends to list recovery.

basis exists for each $\alpha \in S$ and then combine the almost-triangular bases for the different α to obtain the basis of the above type using the Chinese remainder theorem. See Section 3 for details.

Organization

The rest of this paper is organized as follows. Section 2 introduces univariate multiplicity codes and the subroutines used in the lattice construction. Section 3 gives the fast lattice construction and the resulting differential equation. Setting up this lattice is the key novelty of the paper. Section 4 describes the list-extraction procedure from the differential equation, completing the proof of Theorem 1.

2 Preliminaries

2.1 Notation

- We work in some fixed finite field $\mathbb{F}$.
- For a natural number N, we will use $[N]$ to refer to the set $\{0, 1, 2, \ldots, N-1\}$.
- We use $\mathbf{0}_k$ to denote the k-length zero vector. We may drop the subscript if the length is clear from context.

2.2 Univariate multiplicity codes

We recall the formal definition of the univariate multiplicity code.

▶ **Definition 2** (Multiplicity codes). *Let n, k, s be positive integers satisfying $k < ns$, $\mathbb{F}$ be a field of characteristic zero or at least s and size at least n, and let $S = \{\alpha_1, \alpha_2, \ldots, \alpha_n\}$ be a set of n distinct elements of $\mathbb{F}$. Then, the univariate multiplicity code with multiplicity parameter s and degree parameter k is defined as follows.*

The alphabet of the code is $E = \mathbb{F}^s$ and the block length is $n = |S|$, where the coordinates of a codeword are indexed by $\alpha \in S$. The message space is the set of all univariate polynomials of degree less than k in $\mathbb{F}[x]$. The encoding of such a message $f \in \mathbb{F}[x]$, denoted by $\mathsf{Mult}_s(f) \in E^S$ is defined as

$$\mathsf{Mult}_s(f)|_\alpha := \left(f(\alpha), f^{(1)}(\alpha), \ldots, f^{(s-1)}(\alpha)\right),$$

where $f^{(j)}(\alpha)$ is the evaluation of the jth-order derivative[3] of f on the input α. The rate of this code is k/ns while the distance is $1 - (k-1)/ns$.

In the list-recovery setting, the received word R assigns to every evaluation point $\alpha \in S$ a collection of tuples $\beta(\alpha)_j = (\beta(\alpha)_j^{(0)}, \beta(\alpha)_j^{(1)}, \ldots, \beta(\alpha)_j^{(s-1)})$ for every $j \in [\ell]$. In words $\beta(\alpha)_j^{(i)}$ is the jth option for the ith derivative of the message polynomial at α. Agreement is with respect to inclusion in this list; that is, $\mathsf{Mult}(f)$ agrees with R on point α if there exists $j \in [\ell]$ such that $(f(\alpha), f^{(1)}(\alpha), \ldots, f^{(s-1)}(\alpha)) = \beta(\alpha)_j = (\beta(\alpha)_j^{(0)}, \beta(\alpha)_j^{(1)}, \ldots, \beta(\alpha)_j^{(s-1)})$.

Our goal is to carry out list recovery from an agreement fraction of $k/ns + \varepsilon$, for a given parameter ε.

[3] This definition in terms of (standard) derivatives requires the characteristic of the field to be 0 or at least k. All known capacity-achieving list-decoding results for univariate multiplicity codes require large characteristic (previous works [14, 10, 15, 6] as well as our work). For this reason as well as ease of presentation, we work with standard derivatives.

2.3 Polynomial operators and lattices

We recall below the τ operator, used in [10, 13], and [6].

▶ **Definition 3** (Tau operator). *Let $s \in \mathbb{N}$ be a parameter. Then, for every m such that $0 \leq m < s$, the function τ is an $\mathbb{F}$-linear map from the set of polynomials in $\mathbb{F}[X, Y_0, Y_1, \ldots, Y_m]$ with $\mathbf{Y}$-degree 1 to the set of polynomials in $\mathbb{F}[X, Y_0, Y_1, \ldots, Y_{m+1}]$ with $\mathbf{Y}$-degree 1 and is defined as follows.*

$$\tau\left(\widetilde{Q}(X) + \sum_{i=0}^{m} Q_i(X) \cdot Y_i\right) := \widetilde{Q}^{(1)}(X) + \sum_{i=0}^{m} \left(Q_i^{(1)}(X) \cdot Y_i + Q_i(X) \cdot Y_{i+1}\right).$$

For an integer $i \leq (s-m-1)$, we use $\tau^{(i)}$ to denote the linear map from $\mathbb{F}[X, Y_0, Y_1, \ldots, Y_m]$ to $\mathbb{F}[X, Y_0, Y_1, \ldots, Y_{m+i}]$ obtained by applying the operator τ iteratively i times.

The operator is defined this way so that

$$\frac{d}{dX} Q(X, f(X), f^{(1)}(X), \ldots, f^{(m)}(X)) = \tau Q(X, f(X), f^{(1)}(X), \ldots, f^{(m+1)})(X).$$

It will be convenient to view polynomials in $\mathbb{F}[X, Y_0, \ldots, Y_{m+i}]$ for $i \leq s-m-1$ as polynomials in $\mathbb{F}[X, Y_0, \ldots, Y_{s-1}]$. Thus, when evaluating a polynomial $R \in \mathbb{F}[X, Y_0, \ldots, Y_{m+i-1}]$ at the point $(\alpha, \beta) \in \mathbb{F}^{s+1}$, $R(\alpha, \beta)$ refers to $R(\alpha, \beta_{[m+i]}) = R(\alpha, \beta_0, \ldots, \beta_{m+i-1})$.

We will extensively use the following simple property of the τ operator.

▶ **Proposition 4.** *Let α be a field element and $\beta = (\beta_0, \ldots, \beta_i, \ldots, \beta_{s-1}) \in \mathbb{F}^s$. Then, for any integer j with $1 \leq j \leq s - m$,*

$$\tau^{(j)}[(X - \alpha)Q](\alpha, \beta) = j\tau^{(j-1)}(Q)(\alpha, \beta).$$

Proof. We prove this by induction on j. When $j = 1$, the left-hand side is $\tau[(X - \alpha)Q](\alpha, \beta)$. From the definition, this equals $[(X - \alpha)\tau Q + Q](\alpha, \beta)$. (This can be checked term by term.) The first term $(X - \alpha)\tau Q$ is zero when evaluated at (α, β) leaving $Q(\alpha, \beta)$ as required.

For the induction step, observe similarly that

$$\begin{aligned}
\tau^{(j)}[(X - \alpha)Q] &= \tau^{(j-1)}\tau[(X - \alpha)Q] \\
&= \tau^{(j-1)}[(X - \alpha)\tau Q + Q] \\
&= \tau^{(j-1)}[(X - \alpha)\tau Q] + \tau^{(j-1)}Q
\end{aligned}$$

Evaluating at (α, β), by the induction hypothesis,

$$\begin{aligned}
\tau^{(j-1)}[(X - \alpha)\tau Q](\alpha, \beta) + \tau^{(j-1)}Q(\alpha, \beta) &= (j-1)\tau^{j-2}[\tau Q](\alpha, \beta) + \tau^{(j-1)}Q(\alpha, \beta) \\
&= (j-1)\tau^{(j-1)}Q(\alpha, \beta) + \tau^{(j-1)}Q(\alpha, \beta) \\
&= j\tau^{(j-1)}Q(\alpha, \beta). \qquad \blacktriangleleft
\end{aligned}$$

We now define lattices and state the version of Minkowski's theorem for polynomial lattices.

▶ **Definition 5** (polynomial lattice). *Let $\mathcal{B} = \{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_N\}$ be a set of m-dimensional vectors of polynomials, that is, $\mathbf{v}_i \in \mathbb{F}[X]^m$ for all i. The* lattice *$\mathcal{L}_\mathcal{B}$ generated by this set over the ring $\mathbb{F}[X]$ is the set of all linear combinations*

$$\mathcal{L}_\mathcal{B} := \{f_i\mathbf{v}_1 + f_2\mathbf{v}_2 + \cdots + f_N\mathbf{v}_N \colon f_i \in \mathbb{F}[X]\}.$$

A basis *of a lattice is a set $\mathcal{B}$ of vectors of polynomials such that $\mathcal{B}$ generates the lattice in the sense of the above definition and the vectors in $\mathcal{B}$ are linearly independent over the field $\mathbb{F}(X)$ of rational functions over $\mathbb{F}$. A basis B can be viewed as an $m \times \ell$ matrix (the ℓ basis vectors written side by side as columns).*

For a full-rank lattice (i.e., when $\ell = m$), the determinant of a basis $\mathcal{B}$ refers to the determinant of this matrix Since this quantity is independent of the choice of basis, it is also referred to as the determinant of the lattice, denoted by $\det \mathcal{L}$.

Let $\beta = (\beta(1), \beta(2), \ldots, \beta(m)) \in \mathbb{F}[X]^m$ be a vector of polynomials. We define the max-degree norm as follows $\beta := \max_{j \in [m]} \deg \beta(j)$.

▶ **Theorem 6** (polynomial version of Minkowski's theorem)**.** *Let $\mathcal{L}$ be an m-dimensional polynomial lattice. Then, there is a nonzero vector $\mathbf{v}$ in the lattice $\mathcal{L}$ satisfying*

$$\deg \mathbf{v} \leq \frac{1}{m} \deg \det \mathcal{L}$$

where $\deg \mathbf{v}$ is the max-degree norm and $\det \mathcal{L}$ is the determinant of the lattice basis.

A proof can be found in [6].

▶ **Theorem 7** ([1, Theorem 2.1],[7, Theorem 9])**.** *Let B be a set of N vectors of dimension m. Let d be the maximal degree of the polynomials which are entries of the vectors in B. Then, there is an algorithm* `ShortVector` *that finds the shortest vector in $\mathcal{L}_B$, the lattice generated by B, in time $\widetilde{O}(d(N+m)^\omega)$ where ω is the exponent in the complexity of matrix multiplication.*

Here "shortest vector" is in the max-degree norm. See [6] for details.

We will also use the following off-the-shelf subroutines for fast Hermite interpolation and polynomial Chinese remainders.

▶ **Theorem 8** ([22, Algorithm 10.22])**.** *Let $m_1(X), m_2(X), \ldots, m_r(X)$ be univariate polynomials in $\mathbb{F}[x]$ with pairwise GCD equal to 1. Let $v_1(X), v_2(X), \ldots, v_r(X) \in \mathbb{F}[X]$ such that $\deg v_i < \deg m_i$ for all $i \in [r]$. Then, we can find the unique polynomial $f(X) \in \mathbb{F}[X]$ of degree less than $d = \sum_i \deg m_i$ such that $f \equiv v_i \mod m_i$ for all $i \in [r]$, in time $O(d \mathsf{poly} \log(d))$.*

3 Fast construction of differential equation

As in Guruswami–Wang, our first step is to construct an "explanation" polynomial for the received word. In this section, we show that this can be done in near-linear time. Below is the main theorem for this section.

▶ **Theorem 9.** *Let $R = \left(\alpha, \beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)}\right)_{\alpha \in S, j \in [\ell]}$ be a received word and let $m \leq s-1$ be a parameter.*

Then, for $D \leq n\ell(s-m)/m + n\ell$, there exists a nonzero polynomial $Q(X, Y_0, Y_1, \ldots, Y_m)$ of the form $Q = \widetilde{Q}(X) + \sum_i Q_i(X) \cdot Y_i$ of X-degree at most D with the following property: if $f(X) \in \mathbb{F}_{<k}[X]$ is such that for at least $(D+k)/(s-m)$ values of $\alpha \in S$, we have

$$\left(f(\alpha), f^{(1)}(\alpha), \ldots, f^{(s-1)}(\alpha)\right) = \left(\beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)}\right)$$

for some $j \in [\ell]$, then,

$$Q\left(X, f(X), f^{(1)}(X), \ldots, f^{(m)}(X)\right) \equiv 0. \tag{2}$$

Furthermore, there is a deterministic algorithm that takes as input R and returns Q as a list of coefficients that carries out $\widetilde{O}(n\mathsf{poly}(s+m+\ell))$ field operations – specifically, $\widetilde{O}(n[\ell(s-m)^2+m^2(s-m)+(s-m)m^\omega])$.

A natural way to ensure that the polynomial Q satisfies (2), is to ensure that for each $\alpha \in S$, we have the following conditions

$$\tau^{(t)}(Q)\left(\alpha, \beta_j^0, \beta_j^1, \ldots, \beta_j^{m+t}\right) = 0, \qquad \forall t \in [s-m],\ j \in [\ell]. \tag{3}$$

This will ensure that every close enough codeword satisfies (2) (see Lemma 14 for exact details). We will refer to these conditions as the "τ-conditions". The set of polynomials Q satisfying (3) are closed under addition and multiplication by a polynomial in $\mathbb{F}[X]$. In other words, they form a $\mathbb{F}[X]$-module (or equivalently a lattice with entries from the univariate ring $\mathbb{F}[X]$). Here, it will be convenient to view the polynomial $Q = \widetilde{Q}(X) + \sum_i Q_i(X)\cdot Y_i$ as an $(m+2)$-dimensional vector of the form $(\widetilde{Q}, Q_0, Q_1, \ldots, Q_m) \in \mathbb{F}[X]^{m+2}$ where the first component $\widetilde{Q}$ is the Y-free part of Q and the subsequent components are the coefficients of $Y_0, Y_1, \ldots, Y_m$ respectively. To prove Theorem 9, we will first construct a structured basis for this lattice and then use Minkowski's theorem to show that there exists a short vector in this lattice. The following proposition gives this structured basis for a sub-lattice of the lattice of polynomials satisfying the "τ-conditions".

▶ **Proposition 10.** *Let ℓ be the list size and $R = \left(\alpha, \beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)}\right)_{\alpha\in S, j\in[\ell]}$ be the received word and let $m \le s-1$ be a parameter.*

Then, there exist $m+2$ polynomials in $\mathbb{F}[X, Y_0, \ldots, Y_m]$ satisfying the τ-conditions (3) *for all $\alpha \in S$ of the following type*

$$\begin{aligned}
\widetilde{\mathbf{B}} &= \prod_{\alpha\in S}(X-\alpha)^{s-m}, \\
\mathbf{B}_i &= Y_i \cdot \prod_{\alpha\in S}(X-\alpha)^{s-m}, && \forall i,\ \text{such that } 0 \le i \le \ell-2 \\
\mathbf{B}_i &= \widetilde{C_i}(X) + \sum_{r=0}^{i-1} Y_r \cdot C_{i,r}(X) + Y_i \cdot \prod_{\alpha\in S}(X-\alpha)^{\ell-1}, && \forall i,\ \text{such that } \ell-1 \le i \le m.
\end{aligned}$$

for some polynomials $\widetilde{C_i}, C_{i,r} \in \mathbb{F}[X]$ for $\ell-1 \le i \le m$ and $0 \le r \le i-1$. Furthermore, there is a deterministic algorithm that takes as input R and returns these $(m+2)$-polynomials carrying out $\widetilde{O}(n[\ell(s-m)^2+m^2(s-m)])$ field operations.

The analogue of Proposition 10 in the list-decoding case was easier to obtain since the conditions for all the evaluation points (i.e., $\alpha \in S$) are identical. However, this is not the case when the list size ℓ is more than 1. In order to address this, we first show that a version of Proposition 10 can be proved for each $\alpha \in S$ and then combine these different bases for the different α into a single basis that works for all the α. The following proposition is the version of Proposition 10 for a single $\alpha \in S$ (which is proved in Section 3.1).

▶ **Proposition 11.** *Let $\alpha \in S$ and ℓ be the list size and let $m \le s-1$ be a parameter.*

Given ℓ possible evaluations (i.e., $\left(\beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)}\right)$ for each $j \in [\ell]$) at the point α, there exist $m+2$ polynomials in $\mathbb{F}[X, Y_0, \ldots, Y_m]$ satisfying the τ-conditions (3) *for this specific $\alpha \in S$ of the following type*

$$\begin{aligned}
\widetilde{\mathbf{B}}_\alpha &= (X-\alpha)^{s-m}, \\
\mathbf{B}_{\alpha,i} &= Y_i \cdot (X-\alpha)^{s-m}, && \forall i, \text{ such that } 0 \le i \le \ell-2 \\
\mathbf{B}_{\alpha,i} &= \widetilde{C_i}(X) + \sum_{r=0}^{i-1} Y_r \cdot C_{i,r}(X) + Y_i \cdot (X-\alpha)^{\ell-1}, && \forall i, \text{ such that } \ell-1 \le i \le m.
\end{aligned}$$

for some polynomials $\widetilde{C_i}, C_{i,r} \in \mathbb{F}[X]$ *for* $\ell-1 \le i \le m$ *and* $0 \le r \le i-1$. *Furthermore, there is a deterministic algorithm that takes as input* $\left(\beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)}\right)_{j\in[\ell]}$ *and returns these* $(m+2)$ *polynomials, carrying out* $\widetilde{O}(\ell(s-m)^2)$ *field operations.*

We then show in Section 3.2 that the bases for two disjoint sets U, V of evaluation points (i.e., $U, V \subseteq S$) can be combined into a basis for the set $W = U \cup V$ in time approximately $\widetilde{O}(\max(|U|, |V|))$. We use this procedure recursively over the bases constructed via Proposition 11 for each $\alpha \in S$ to obtain a basis that works simultaneously for all $\alpha \in S$ to yield Proposition 10.

3.1 Construction of basis for a single evaluation point

In this section, we will fix an evaluation point $\alpha \in S$ and construct a set of $m+2$ linearly independent polynomials (over the ring $\mathbb{F}[X]$) as specified in Proposition 11. More precisely, we want to show that there exist $m+2$ polynomials of the following type that satisfy the τ-conditions for α. Since α will be fixed throughout this section, we will drop α from the subscript to declutter the notation.

$$\begin{aligned}
\widetilde{\mathbf{B}} &= (X-\alpha)^{s-m}, \\
\mathbf{B}_i &= Y_i \cdot (X-\alpha)^{s-m}, && \forall i, \text{ such that } 0 \le i \le \ell-2 \\
\mathbf{B}_i &= \widetilde{C_i}(X) + \sum_{r=0}^{i-1} Y_r \cdot C_{i,r}(X) + Y_i \cdot (X-\alpha)^{\ell-1}, && \forall i, \text{ such that } \ell-1 \le i \le m.
\end{aligned}$$

for some polynomials $\widetilde{C_i}, C_{i,r} \in \mathbb{F}[X]$ for $\ell-1 \le i \le m$ and $0 \le r \le i-1$.

To this end, given a polynomial $\mathbf{B}$ of the above form and any $\beta = (\beta^{(0)}, \beta^{(1)}, \ldots, \beta^{(s-1)})$ we will find it convenient to use the following notation for the vector in $\mathbb{F}^{s-m}$ composed of evaluations of iterated τ-operator of the polynomial $\mathbf{B}$ at the point (α, β):

$$\tau(\mathbf{B}, \beta) := \tau^{(<s-m)}(\mathbf{B})(\alpha,\beta) = \begin{bmatrix} \mathbf{B}(\alpha,\beta) \\ \tau(\mathbf{B})(\alpha,\beta) \\ \tau^{(2)}(\mathbf{B})(\alpha,\beta) \\ \vdots \\ \tau^{(s-m-1)}(\mathbf{B})(\alpha,\beta) \end{bmatrix}.$$

The linearity of the τ operator shows that the function $\tau(\cdot,\cdot)$ is linear in its first argument.

Proof of Proposition 11. In the notation defined above, we want to show that $\tau(\mathbf{B}, \beta) = \mathbf{0}_{s-m}$ for all $\beta \in \{\beta_j : j \in [\ell]\}$ and each $\mathbf{B} \in \{\widetilde{\mathbf{B}}, \mathbf{B}_0, \mathbf{B}_1, \ldots, \mathbf{B}_m\}$. Clearly, this is true when $\mathbf{B} \in \{\widetilde{\mathbf{B}}, \mathbf{B}_0, \mathbf{B}_1, \ldots, \mathbf{B}_{\ell-2}\}$. In the rest of the proof, we will construct polynomials $\widetilde{C_i}, C_{i,r} \in \mathbb{F}[X]$, such that this is also true for the polynomials $\mathbf{B} = \{\mathbf{B}_{\ell-1}, \mathbf{B}_\ell, \ldots, \mathbf{B}_m\}$. We will prove this by induction on ℓ, the list size.

Base case $\ell = 1$: This is the list-decoding setting, where we have only β in the list corresponding to α, namely $\beta_0 = (\beta_0^{(0)}, \beta_0^{(1)}, \ldots, \beta_0^{(s-1)})$. The proof in this case is similar to the corresponding step in [6], which is obtained by Hermite interpolation. For each $0 \le i \le m$, we define the polynomial $\widetilde{C_i}$ to be the unique $(s-m-1)$-degree polynomial in $\mathbb{F}[X]$ such that for all $j \in [s-m]$, we have

$$\widetilde{C_i}^{(j)}(\alpha) = -\beta_0^{(i+j)}.$$

The remaining $C_{i,r}(X)$ are set to zero for all $0 \le i \le m$ and $r \in [i]$. In other words, the ith polynomial $\mathbf{B}_i := Y_i + \widetilde{C}_i(X)$ for $\ell - 1 = 0 \le i \le m$. $\mathbf{B}_i$ clearly satisfies the τ-conditions (3) for α.

Induction step $\ell \ge 2$: By induction, let us assume that for the first $(\ell-1)$ list elements $\beta_j, j \in [\ell-1]$, we have polynomials $\mathbf{B}'_i$ satisfying the τ-conditions for α, namely $\tau(\mathbf{B}'_i, \beta_j) = \mathbf{0}$ for all i such that $\ell - 2 \le i \le m$ and $j \in [\ell-1]$. We now need to construct polynomials $\mathbf{B}_i$ for $\ell - 1 \le i \le m$ such that $\tau(\mathbf{B}_i, \beta_j) = \mathbf{0}$ for all i such that $\ell - 1 \le i \le m$ and $j \in [\ell]$. Note that the number of polynomials to be constructed in the ℓ-case is one less than the $(\ell-1)$-case while the number of β's for which we need $\tau(\mathbf{B}_i, \beta_j) = \mathbf{0}$ is one more.

Fix an i such that $\ell - 1 \le i \le m$. We will construct the polynomial $\mathbf{B}_i$ from the polynomial $\mathbf{B}'_{i-1}$. Consider the polynomial $\mathbf{B}''_i := \tau\left((X-\alpha)\cdot \mathbf{B}_{i-1}\right)$. Clearly, this polynomial is of the required form $Y_i \cdot (X-\alpha)^{\ell-1} + \sum_{r\in[i]} Y_r \cdot C_{i,r}(X) + \widetilde{C}_i(X)$. By Proposition 4, we have that $\tau(\mathbf{B}''_i, \beta_j) = \mathbf{0}$ for all $j \in [\ell-1]$. Now, if $\tau(\mathbf{B}''_i, \beta_{\ell-1})$ is also $\mathbf{0}$, we can set $\mathbf{B}_i := \mathbf{B}''_i$ and be done.

Suppose $\tau(\mathbf{B}''_i, \beta_{\ell-1}) \neq \mathbf{0}$. Then, let $r_* \in [s-m]$ be the least r such that $\tau^{(<r)}(\mathbf{B}''_i)(\alpha, \beta_{\ell-1}) = \mathbf{0}_r$ but $\tau^{(r)}(\mathbf{B}''_i)(\alpha, \beta_{\ell-1}) \neq 0$. By Proposition 4, definition of $\mathbf{B}''_i$ and the fact that $s-m$ is less than the characteristic of $\mathbb{F}$, we also have $\tau^{(<r_*)}(\mathbf{B}'_{i-1})(\alpha, \beta_{\ell-1}) = \mathbf{0}_{r_*}$ but $\tau^{(r_*)}(\mathbf{B}'_{i-1})(\alpha, \beta_{\ell-1}) \neq 0$. Let us consider the $(s-m-r_*)$ polynomials $\{(X-\alpha)^t \cdot \mathbf{B}'_{i-1} \colon t \in [s-m-r_*]\}$. The t-th polynomial in this set, namely $(X-\alpha)^t \cdot \mathbf{B}'_{i-1}$ satisfies $\tau^{(<r_*+t)}((X-\alpha)^t \cdot \mathbf{B}'_{i-1})(\alpha, \beta_{\ell-1}) = \mathbf{0}_{r_*+t}$ but $\tau^{(r_*+t)}((X-\alpha)^t \cdot \mathbf{B}'_{i-1})(\alpha, \beta_{\ell-1}) \neq 0$. Hence, the $(s-m-r_*)$ vectors $\{\tau\left((X-\alpha)^t \cdot \mathbf{B}'_{i-1}, \beta_{\ell-1}\right) : t \in [s-m-r_*]\}$ form a basis for the space of all vectors in $\mathbb{F}^{s-m}$ which are zero in the first r_* coordinates. This space contains the vector $\tau(\mathbf{B}''_i, \beta_{\ell-1})$ and hence there exist scalars $c_t \in \mathbb{F}$ for $t \in [s-m-r_*]$ such that

$$\tau(\mathbf{B}''_i, \beta_{\ell-1}) = \sum_{t\in[s-m-r_*]} c_t \cdot \tau((X-\alpha)^t \cdot \mathbf{B}'_{i-1}, \beta_{\ell-1}).$$

We can now set

$$\mathbf{B}_i := \mathbf{B}''_i - \sum_{t\in[s-m-r_*]} c_t \cdot (X-\alpha)^t \cdot \mathbf{B}'_{i-1}.$$

By choice of the scalars c_t, we have that $\tau(\mathbf{B}_i, \beta_{\ell-1}) = \mathbf{0}$. Since $\tau(\mathbf{B}''_i, \beta_j) = \mathbf{0}$ and $\tau(\mathbf{B}'_{i-1}, \beta_j) = \mathbf{0}$ for all $j \in [\ell-1]$, we also have that $\tau(\mathbf{B}_i, \beta_j) = \mathbf{0}$ for all $j \in [\ell-1]$. Combining, we have that $\tau(\mathbf{B}_i, \beta_j) = \mathbf{0}$ for all $j \in [\ell]$.

It can be seen that $\mathbf{B}_i$ is of the required form $Y_i \cdot (X-\alpha)^{\ell-1} + \sum_{r\in[i]} Y_r \cdot C_{i,r}(X) + \widetilde{C}_i(X)$ since $\mathbf{B}''_i$ is of this form and each of the polynomials $(X-\alpha)^t \cdot \mathbf{B}'_{i-1}$ are of the form $\sum_{r\in[i]} Y_r \cdot C_{i,r}(X) + \widetilde{C}_i(X)$.

We turn to the time complexity. For each list element, we may have to solve a system of equations to find the scalars $\{c_t\}$. Observe that this is a triangular system in at most $s-m$ variables, and hence can be solved with $O(s-m)^2$ operations; giving an overall total of $\widetilde{O}(\ell(s-m)^2)$ operations. This concludes the proof of the proposition. ◀

3.2 Combining the bases

In the previous section, we constructed a structured basis for each $\alpha \in S$. In this section, we will show how to combine these bases recursively to obtain a single basis that works for all $\alpha \in S$. To this end, we begin by showing a general procedure to combine the bases of two $\mathbb{F}[X]$-modules to generate the basis for a related $\mathbb{F}[X]$-module.

Let S be the set of evaluation points. For each $\alpha \in S$, let $p_\alpha(X)$ be an associated monic polynomial of degree at most $(s-m)$ such that for any two distinct $\alpha, \beta \in S$, we have $\gcd(p_\alpha, p_\beta) = 1$. We will be setting $p_\alpha(X) = (X-\alpha)^{s-m}$ for multiplicity codes.

Let $\mathcal{U}, \mathcal{V}$ be two disjoint non-empty subsets of S. Define the polynomials

$$P_{\mathcal{U}}(X) := \prod_{\alpha \in \mathcal{U}} p_\alpha(X), \qquad P_{\mathcal{V}}(X) := \prod_{\alpha \in \mathcal{V}} p_\alpha(X).$$

Observe that since $\mathcal{U} \cap \mathcal{V} = \emptyset$, we have $\gcd(P_{\mathcal{U}}, P_{\mathcal{V}}) = 1$.

Let $\mathcal{M}_{\mathcal{U}}, \mathcal{M}_{\mathcal{V}}$ be two $(m+2)$-dimensional $\mathbb{F}[X]$-modules[4] with lower-triangular bases $\mathcal{B}_{\mathcal{U}} = \{\widetilde{\mathbf{U}}, \mathbf{U}_0, \mathbf{U}_1, \ldots, \mathbf{U}_m\}$ and $\mathcal{B}_{\mathcal{V}} = \{\widetilde{\mathbf{V}}, \mathbf{V}_0, \mathbf{V}_1, \ldots, \mathbf{V}_m\}$ respectively of the following type:

$$\widetilde{\mathbf{U}} = \widetilde{U}(X), \qquad \widetilde{\mathbf{V}} = \widetilde{V}(X)$$
$$\mathbf{U}_i = \widetilde{U_i}(X) + \sum_{r=0}^{i} Y_r \cdot U_{i,r}(X), \qquad \mathbf{V}_i = \widetilde{V_i}(X) + \sum_{r=0}^{i} Y_r \cdot V_{i,r}(X), \qquad \forall 0 \le i \le m$$

Furthermore, suppose these bases $\mathcal{B}_{\mathcal{U}}, \mathcal{B}_{\mathcal{V}}$ behave "nicely" with their respective polynomials $P_{\mathcal{U}}, P_{\mathcal{V}}$ in the following sense: the diagonal elements $\widetilde{U}, U_{i,i}, i \in [m]$ are nonzero factors of the polynomial $P_{\mathcal{U}}$ and similarly $\widetilde{V}, V_{i,i}, i \in [m]$ are nonzero factors of the polynomial $P_{\mathcal{V}}$.

Let $\mathcal{W} = \mathcal{U} \cup \mathcal{V}$ and $P_{\mathcal{W}} = P_{\mathcal{U}} \cdot P_{\mathcal{V}}$ be the associated polynomial with the set $\mathcal{W}$. We can construct a lower-triangular basis $\mathcal{B}_{\mathcal{W}} = \{\widetilde{\mathbf{W}}, \mathbf{W}_0, \mathbf{W}_1, \ldots, \mathbf{W}_m\}$ which behaves "nicely" with the polynomial $P_{\mathcal{W}}$ as follows:

$$\widetilde{\mathbf{W}} = \widetilde{W}(X)$$
$$\mathbf{W}_i = \widetilde{W_i}(X) + \sum_{r=0}^{i} Y_r \cdot W_{i,r}(X), \qquad \forall 0 \le i \le m$$

where the diagonal elements are given by $\widetilde{W} = \widetilde{U} \cdot \widetilde{V}$ and $W_{i,i} = U_{i,i} \cdot V_{i,i}, 0 \le i \le m$ and the non-diagonal elements $W_{i,r}(X), r \in [i]$ are the unique polynomials (by the Chinese remainder theorem) such that

$$W_{i,r} \equiv U_{i,r} \cdot V_{i,i} \mod P_{\mathcal{U}},$$
$$W_{i,r} \equiv V_{i,r} \cdot U_{i,i} \mod P_{\mathcal{V}}.$$

This basis satisfies that $\mathbf{W}_i \equiv V_{i,i}(X) \cdot \mathbf{U}_i \bmod P_{\mathcal{U}}$ and symmetrically, $\mathbf{W}_i \equiv U_{i,i}(X) \cdot \mathbf{V}_i \bmod P_{\mathcal{V}}$.

Let $\mathcal{M}_{\mathcal{W}}$ be the $\mathbb{F}[X]$-module generated by this basis $\mathcal{B}_{\mathcal{W}}$. This basis satisfies the following property.

[4] Here, we identify the polynomial $\widetilde{Q} + \sum_{i \in [m]} Y_i \cdot Q_i(X)$ with the $(m+2)$-dimensional vector $(\widetilde{Q}, Q_0, Q_1, \ldots, Q_m)$

▷ Claim 12. If $\mathbf{H} = \widetilde{H}(X) + \sum_{i\in[m]} Y_i \cdot H_i(X)$ or equivalently $(\widetilde{H}, H_0, H_1, \ldots, H_m)$ satisfies $\mathbf{H} \bmod P_{\mathcal{U}} \in \mathcal{M}_{\mathcal{U}}$ and $\mathbf{H} \bmod P_{\mathcal{V}} \in \mathcal{M}_{\mathcal{V}}$, then $\mathbf{H} \bmod P_{\mathcal{W}} \in \mathcal{M}_{\mathcal{W}}$.

Proof. Since $\mathbf{H} \bmod P_{\mathcal{U}} \in \mathcal{M}_{\mathcal{U}}$ and $\mathbf{H} \bmod P_{\mathcal{V}} \in \mathcal{M}_{\mathcal{V}}$, we have polynomials $\widetilde{A}, \widetilde{B}, A_i, B_i, 0 \le i \le m$ such that

$$\mathbf{H} \bmod P_{\mathcal{U}} = \widetilde{A}(X) \cdot \widetilde{\mathbf{U}} + \sum_{i=0}^{m} A_i(X) \cdot \mathbf{U}_i,$$
$$\mathbf{H} \bmod P_{\mathcal{V}} = \widetilde{B}(X) \cdot \widetilde{\mathbf{V}} + \sum_{i=0}^{m} B_i(X) \cdot \mathbf{V}_i.$$

Define polynomials

$$\widetilde{C}(X) := \widetilde{U}^{-1} \cdot P_{\mathcal{U}}^{-1} \cdot \widetilde{B} \bmod P_{\mathcal{V}}, \qquad \widetilde{D}(X) := \widetilde{V}^{-1} \cdot P_{\mathcal{V}}^{-1} \cdot \widetilde{A} \bmod P_{\mathcal{U}}$$
$$C_i(X) := U_{i,i}(X)^{-1} \cdot P_{\mathcal{U}}^{-1} \cdot B_i \bmod P_{\mathcal{V}}, \quad D_i(X) := V_{i,i}^{-1} \cdot P_{\mathcal{V}}^{-1} \cdot A_i \bmod P_{\mathcal{U}}, \quad i \in [m]$$

We claim that

$$\mathbf{H} = [\widetilde{C} \cdot P_{\mathcal{U}} + \widetilde{D} \cdot P_{\mathcal{V}}]\widetilde{\mathbf{W}} + \sum_{i=0}^{m} [C_i \cdot P_{\mathcal{U}} + D_i \cdot P_{\mathcal{V}}]\mathbf{W}_i \bmod P_{\mathcal{U}} P_{\mathcal{V}}.$$

Indeed, observe the right-hand side mod $P_{\mathcal{U}}$. All the terms involving $P_{\mathcal{U}}$ vanish, leaving $\widetilde{D} \cdot P_{\mathcal{V}} \cdot \widetilde{\mathbf{W}} + \sum_{i=0}^{m} D_i \cdot P_{\mathcal{V}} \cdot \mathbf{W}_i$. Simplifying using the definition of $\mathbf{W}$, we have $\widetilde{A} \cdot \widetilde{\mathbf{U}} + \sum_{i\in[m]} A_i \cdot \mathbf{U}_i$, which is $\mathbf{H} \bmod P_{\mathcal{U}}$. The case mod $P_{\mathcal{V}}$ is symmetric and the equivalence follows from the Chinese remainder theorem. ◁

For the specific setting of multiplicity codes, the polynomial $p_\alpha(X)$ will be $(X-\alpha)^{s-m}$. For any subset $\mathcal{U} \subseteq S$ of the evaluation points, we will say that the basis $\mathcal{B}_{\mathcal{U}} = \{\widetilde{\mathbf{U}}, \mathbf{U}_0, \ldots, \mathbf{U}_m\}$ is $\mathcal{U}$-good, if the following two properties are satisfied.

1. The diagonal elements of the basis satisfy

$$\widetilde{U}(X) := \prod_{\alpha\in\mathcal{U}} (X-\alpha)^{s-m},$$
$$U_{i,i}(X) := \prod_{\alpha\in\mathcal{U}} (X-\alpha)^{s-m}, \qquad 0 \le i \le \ell - 2$$
$$U_{i,i}(X) := \prod_{\alpha\in\mathcal{U}} (X-\alpha)^{\ell-1}, \qquad \ell - 1 \le i \le m$$

   where ℓ is the list size.
2. Every basis element $\mathbf{U} \in \mathcal{B}_{\mathcal{U}}$ satisfies the τ-conditions (3) for every $\alpha \in \mathcal{U}$.

Clearly, the basis generated by Proposition 11 when $\mathcal{U} = \{\alpha\}$ is a singleton set is $\{\alpha\}$-good. The following claim shows that if $\mathcal{B}_{\mathcal{U}}, \mathcal{B}_{\mathcal{V}}$ are both good, so is $\mathcal{B}_{\mathcal{W}}$.

▷ Claim 13. Let $\mathcal{U}, \mathcal{V} \subseteq S$ be two disjoint non-empty subsets of the set of evaluation points S. If $\mathcal{B}_{\mathcal{U}}$ is $\mathcal{U}$-good and $\mathcal{B}_{\mathcal{V}}$ is $\mathcal{V}$-good, then $\mathcal{B}_{\mathcal{W}}$ is $\mathcal{W}$-good.

Furthermore, there is a deterministic algorithm that when given the bases $\mathcal{B}_{\mathcal{U}}$ and $\mathcal{B}_{\mathcal{V}}$ outputs the basis $\mathcal{B}_{\mathcal{W}}$, carrying out $\widetilde{O}(\max\{|\mathcal{U}|, |\mathcal{V}|\}m^2(s-m))$ field operations.

Proof. Item 1 follows from how the diagonal elements of the basis $\mathcal{B}_{\mathcal{W}}$ are defined. The runtime bound follows from the time required for the Chinese remainder theorem (Theorem 8): for the $O(m^2)$ off-diagonal elements $W_{i,r}$, we carry out a CRT of polynomials of degree at most $\max\{|\mathcal{U}|, |\mathcal{V}|\}(s-m)$.

We now prove Item 2. Let $\mathbf{W} \in \mathcal{B}_{\mathcal{W}}$. If $\mathbf{W} = \widetilde{\mathbf{W}}$, then $\mathbf{W} = \widetilde{\mathbf{V}} \cdot \widetilde{\mathbf{U}} = \prod_{\alpha \in \mathcal{W}} (X - \alpha)^{s-m}$ and hence satisfies the τ-conditions for all $\alpha \in \mathcal{W}$. Suppose $\mathbf{W} = \mathbf{W}_i$ for some $0 \leq i \leq m$. Let $\alpha \in \mathcal{W}$. Suppose $\alpha \in \mathcal{U}$. By definition of $\mathbf{W}_i$, we have $\mathbf{W}_i \equiv V_{i,i} \cdot \mathbf{U}_i \bmod P_{\mathcal{U}}$ and is hence of the form $V_{i,i} \cdot \mathbf{U}_i + \prod_{\alpha \in \mathcal{U}} (X - \alpha)^{s-m} \cdot \mathbf{H}$ for some polynomial $\mathbf{H} = \widetilde{H} + \sum_{i=0}^{m} Y_i \cdot H_i(X)$. Since $\mathcal{B}_{\mathcal{U}}$ is $\mathcal{U}$-good, $\mathbf{U}_i$ satisfies the τ-conditions with respect to α. Hence, so does $V_{i,i} \cdot \mathbf{U}_i$ and $\mathbf{W}_i$. The case when $\alpha \in \mathcal{V}$ is similar. ◁

We are now ready to prove Proposition 10.

Proof of Proposition 10. Let $\mathcal{B}_S := \{\widetilde{\mathbf{B}}, \mathbf{B}_0, \mathbf{B}_1, \ldots, \mathbf{B}_m\}$ be obtained by the following process: Divide S into two halves $\mathcal{U}$ and $\mathcal{V}$, and recursively compute bases $\mathcal{B}_{\mathcal{U}}$ and $\mathcal{B}_{\mathcal{V}}$ for them, and then combine them as indicated earlier in this section. For a singleton set, we use the basis given by Proposition 11.

It follows from Claim 13, that since the bases for the singleton sets are good, so are all the bases that are recursively constructed. Thus, the basis $\mathcal{B}_S$ has all the properties mentioned in Proposition 10. The only thing left to be verified is the running time.

As for the running time, let $T(n)$ be the running time where n is the size of the set S. We split it into two instances of size $n/2$, each of which can be solved in time $T(n/2)$. Claim 13 states that the bases for the two instances can be combined in time $\widetilde{O}(nm^2(s-m))$. Finally, Proposition 11 states that the base case when the set is a single point requires time $\widetilde{O}(\ell(s-m)^2)$. Putting all this together, we have $T(n) = 2T(n/2) + \widetilde{O}(nm^2(s-m))$ and $T(1) = \widetilde{O}(\ell(s-m)^2)$. Solving, we get $T(n) = \widetilde{O}(n[\ell(s-m)^2 + m^2(s-m)])$. ◀

3.3 Proof of Theorem 9

Before we prove the main theorem of the section, we have to connect the τ-conditions to the desired property, of close enough codewords satisfying the differential equation.

▶ **Lemma 14.** *Let $Q(X, Y_0, Y_1, \ldots, Y_m) \in \mathcal{M}_S$ have X-degree at most $D \leq n\ell(s-m)/m + n\ell$ and Y_i-degree at most 1 for every Y_i. Let $f(X) \in \mathbb{F}_{<k}[X]$ be such that for $(D+k)/(s-m)$ values of $\alpha \in S$, $(f(\alpha), f^{(1)}(\alpha), \ldots, f^{(s-1)}(\alpha)) = (\beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)})$ for some $j \in [\ell]$. Then, $Q(X, f(X), f^{(1)}(X), \ldots, f^{(m)}(X)) \equiv 0$.*

Proof. Let $P(X) = Q(X, f(X), f^{(1)}(X), \ldots, f^{(s-1)}(X))$. Since f has degree less than k and Q is linear in the Y-variables, $P(X)$ has degree less than $D + k$. The definition of the τ operator is set up such that $\tau^{(i)}(Q)(X, f(X), f^{(1)}(X), \ldots, f^{(s-1)}(X)) = \frac{d^i P}{dX^i}$. This combined with Proposition 10 implies that for an agreement point α,

$$\frac{d^i P}{dX^i}(\alpha) = [\tau^{(i)}(Q)](\alpha, f(\alpha), f^{(1)}(\alpha), \ldots, f^{(s-1)}(\alpha)) = \tau^{(i)}(Q)(\alpha, \beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)}) = 0$$

for any $i \in [s-m]$. That is, at these points, P vanishes with multiplicity at least $(s-m)$. Therefore, if the number of such agreements is at least $(D+k)/(s-m)$, P must be identically zero. ◀

We are now ready to prove the main theorem of the section.

Proof of Theorem 9. We will take Q to be a polynomial in the $\mathbb{F}[X]$-span of the polynomials $\widetilde{\mathbf{B}}, \mathbf{B}_0, \mathbf{B}_1, \ldots, \mathbf{B}_m$ given by Proposition 10. Since each of them satisfies the τ-conditions, as given by the proposition, so will Q. In addition, Q will have the form $Q = \widetilde{Q}(X) + \sum_i Q_i(X) \cdot Y_i$, inherited from the basis polynomials.

We now have to bound the degree of the coefficients. Following our previous notation, let $\mathcal{M}_S$ be span$\{\widetilde{\mathbf{B}}, \mathbf{B}_0, \mathbf{B}_1, \ldots, \mathbf{B}_m\}$. By Theorem 6, $\mathcal{M}_S$ contains a polynomial of degree at most $(\deg \det \mathcal{M}_S)/(m+2)$. Because of the lower triangular structure, to find $\deg \det \mathcal{M}_S$, we need only multiply the degrees of the terms on the diagonal.

The first ℓ terms on the diagonal are $\prod_{\alpha \in S}(X-\alpha)^{s-m}$, and the remaining $m+2-\ell$ are $\prod_{\alpha \in S}(X-\alpha)^{\ell-1}$. This gives $\deg \det \mathcal{M}_S = n\ell(s-m) + (m+2-\ell)n(\ell-1) \leq n\ell(s-m) + n(m+2)\ell$. Applying the Minkowski statement gives the required bound.

The close enough codewords statement is given by Lemma 14. This gives all the required properties of Q.

The running time is the time to construct the basis followed by the time to find a short vector in the lattice. From Proposition 10 and Theorem 7, we get a running time bound of $\widetilde{O}(n[\ell(s-m)^2 + m^2(s-m) + (s-m)m^\omega])$. ◀

4 List-recovery algorithm for multiplicity codes

Having constructed the differential equation, we now have to solve it in near-linear time. We use off-the-shelf subroutines for this. We recall the relevant algorithms before analyzing the overall list-recovery algorithm.

4.1 Fast algorithms for solving differential equations

We will invoke the following algorithms for solving differential equations from [6]. (Their paper also contains an analogous result for functional equations, for FRS codes.)

▶ **Theorem 15** ([6, Theorem 1.6]). *Let $\mathbb{F}$ be a finite field of characteristic greater than d or zero, and let*

$$Q(X, Y_0, \ldots, Y_m) = \widetilde{Q}(X) + \sum_{i=0}^{m} Q_i(X) \cdot Y_i$$

be a nonzero polynomial with X-degree at most D. Then, the set of polynomials $f(X) \in \mathbb{F}[X]$ of degree at most d that satisfy

$$Q\left(X, f, f^{(1)} \ldots, f^{(m)}\right) \equiv 0$$

is contained in an affine space of dimension at most m.

Furthermore, there is a deterministic algorithm `FastDESolver` *that when given Q as an input via its coefficient vector, and the parameter d, performs at most $\widetilde{O}((D+d)m^4)$ field operations and outputs a basis for this affine space.*

▶ Remark 16. The [6, Theorem 1.6] paper presents a complexity of $\widetilde{O}((D+d)\mathsf{poly}(m))$. On closer examination, their recursion contains a factor of at most m^4 as they solve for m different basis elements separately and each is solved using [6, Algorithm 1]. The time complexity for this step is analyzed in [6, Lemma 5.8] which their analysis shows has a dependence of at most $O(m^3)$.

These algorithms output a subspace containing the codewords. We use the "Prune" subroutine introduced by [15], which was simplified by [20], to obtain the codewords. The list-size bounds we present below are due to [20].

▶ **Theorem 17** ([15, Lemma 3.1], [20, Theorem 4.5]). *For every $\varepsilon > 0, \ell \in \mathbb{N}$, all integers $s > \frac{16\ell}{\varepsilon^2}$, degree parameter k, block length n and field $\mathbb{F}$ of characteristic zero or greater than k, the following is true.*

Define

$$L(\delta, \varepsilon, \ell, r) = \left(\frac{\ell}{\varepsilon}\right)^{O(\frac{1+\log(\ell)}{\varepsilon})} .$$

Then, for any $\gamma > 0$, there is a randomized algorithm `Prune` *that when given as input sets $S \subseteq \mathbb{F}$ and $E_\alpha \subseteq \mathbb{F}^s$, with $|E_\alpha| \leq \ell$ for every $\alpha \in S$ and $|S| = n$, and a basis for an affine space $\mathcal{A}$ of dimension at most $4\ell/\varepsilon$, outputs*

$$\mathcal{L} = \{f(X) \in \mathbb{F}_{<k}[X] \cap \mathcal{A} \mid |\{\alpha \in S \mid (f(\alpha), f^{(1)}(\alpha), \cdots, f^{(s-1)}(\alpha)) \in E_\alpha\}| > (R+\varepsilon)n\}$$

with probability at least $1-\gamma$ in time $\widetilde{O}(n)\mathsf{poly}(\log q, s, L(\delta, \varepsilon, \ell, r), \log(1/\gamma))$ and it is guaranteed that

$$|\mathcal{L}| \leq L(\delta, \varepsilon, \ell, r) .$$

4.2 Algorithm and proof of main theorem

The final algorithm proceeds in 3 steps: finding the differential equation, solving it, and pruning. Before restating and proving the main theorem, we state separately here the combination of the first two steps, as the time complexity in those parts is our main contribution.

▶ **Theorem 18.** *For all integers $\ell, m, s \in \mathbb{N}$ with $m < s$, degree parameter k, block length n and field $\mathbb{F}$ of characteristic zero or greater than k, the following is true.*

There is a deterministic algorithm that, when given as input sets $S \subseteq \mathbb{F}$ and $E_\alpha \subseteq \mathbb{F}^s$ with $|E_\alpha| \leq \ell$ for every $\alpha \in S$ and $|S| = n$, runs in time $O(n \log|\mathbb{F}|(\ell(s^2 + sm^3) + \frac{k}{n}m^4)\mathsf{polylog}(n, s, \log\log|\mathbb{F}|))$ and outputs the basis of an affine space $\mathcal{A} \subseteq \mathbb{F}[X]$ of dimension at most m such that $\mathcal{A}$ contains all polynomials $f(X)$ of degree less than k such that for at least $(\frac{n\ell+k}{n(s-m)} + \frac{\ell}{m})$ fraction of $\alpha \in S$,

$$(f(\alpha), \cdots, f^{(s-1)}(\alpha)) \in E_\alpha .$$

Proof. We begin by describing the algorithm.

Input: $R = \{(\alpha_i, \beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)})\}_{i\in[n], j\in[\ell]}, k \in \mathbb{Z}$

Task: Return the basis of an affine space $\mathcal{A}$ of dimension at most m containing all $f \in \mathbb{F}_{<k}[X]$ such that for $n\ell/m + (n\ell+k)/(s-m)$ values of i,

$$(f(\alpha_i), f^{(1)}(\alpha_i), \ldots, f^{(s-1)}(\alpha_i)) = (\beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)})$$

for some $j \in [\ell]$.

1. Construct a multivariate polynomial Q as per Theorem 9.
2. Solve the resulting differential equation using the algorithm in Theorem 15, to obtain an affine space A containing all the codewords.

Observe that by Theorem 9, we can construct a multivariate polynomial $Q(X, Y_0, \cdots, Y_m)$ of the form $Q = \widetilde{Q}(X) + \sum_i Q_i(X) \cdot Y_i$ of X-degree at most $D \leq \frac{n\ell(s-m)}{m} + n\ell$ with the following property: if $f(X) \in \mathbb{F}_{<k}[X]$ is such that for at least $\frac{1}{s-m}\left(\frac{n\ell(s-m)}{m} + n\ell + k\right) = \frac{n\ell}{m} + \frac{n\ell+k}{s-m}$ values of $\alpha \in S$, we have

$$(f(\alpha), \cdots, f^{(s-1)}(\alpha)) \in E_\alpha ,$$

then,

$$Q(X, f(X), f^{(1)}(X), \cdots, f^{(m)}(X)) \equiv 0$$

in time $\widetilde{O}(n\ell((s-m)^2 + (s-m)m^\omega))$ which is within our time complexity.

Now, Theorem 15 outputs the basis of the affine space of dimension at most m of the polynomials of degree $< k$ which are solutions of the above differential equation in time $\widetilde{O}((D+k)m^4)$. Substituting $D \leq \frac{n\ell(s-m)}{m} + n\ell$, the time complexity is within the claimed range. ◀

We are finally ready to prove the main theorem. We first recall the theorem statement.

▶ **Theorem 1** (main result for multiplicity codes). *For every $\varepsilon > 0$ and $\ell \in \mathbb{N}$, there exists $s_0 = \Theta(\ell/\varepsilon^2) \in \mathbb{N}$ such that for all $s > s_0$, degree parameter k, block length n, and fields $\mathbb{F}$ of characteristic zero or characteristic greater than k, satisfying $k < ns$, the following holds. There is a randomized algorithm that, given a set $S \subseteq \mathbb{F}$ of size n and sets $E_\alpha \subseteq \mathbb{F}^s$ with $|E_\alpha| \leq \ell$ for each $\alpha \in S$, takes*

$$O\Big(n \cdot \mathsf{poly}\Big(s, \ell, \log n, (\ell/\varepsilon)^{\frac{1+\log \ell}{\varepsilon}}\Big)\Big)$$

field operations and with high probability outputs all univariate polynomials $f(X) \in \mathbb{F}[X]$ of degree less than k such that for at least $(\frac{k}{sn} + \varepsilon)$ fraction of $\alpha \in S$,

$$(f(\alpha), f^{(1)}(\alpha), \ldots, f^{(s-1)}(\alpha)) \in E_\alpha.$$

Proof. We will first set the parameters. Recall that the agreement fraction for which Theorem 9 works is

$$\frac{n\ell + k}{n(s-m)} + \frac{\ell}{m}.$$

The rate R is k/ns. For the above to approximately equal $R + \varepsilon$, we set $s_0 = 16\ell/\varepsilon^2 + \frac{4\ell}{\varepsilon}$ and $m = 4\ell/\varepsilon$ with $s > s_0$. Thus,

$$\frac{n\ell + k}{n(s-m)} + \frac{\ell}{m} \leq \frac{\ell}{(s-m)} + \frac{k}{n(s-m)} + \frac{\varepsilon}{2} \leq \frac{\varepsilon^2}{16} + \frac{\varepsilon}{4} + R \cdot \left(\frac{s}{s-m}\right) \leq R + \frac{\varepsilon \cdot R}{4} + \frac{\varepsilon}{4} + \frac{\varepsilon^2}{16}$$

Since $\varepsilon \leq 1 - R$ and thus $\varepsilon^2 \leq \varepsilon(1-R)$, we get that

$$\frac{n\ell + k}{n(s-m)} + \frac{\ell}{m} < R + \varepsilon/2.$$

The algorithm is given below.

Input: $R = \{(\alpha_i, \beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)})\}_{i \in [n], j \in [\ell]}, k \in \mathbb{Z}$

Task: Return all $f \in \mathbb{F}_{<k}[X]$ such that for $n\ell/m + (n\ell + k)/(s-m)$ values of i,

$$(f(\alpha_i), f^{(1)}(\alpha_i), \ldots, f^{(s-1)}(\alpha_i)) = (\beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)})$$

for some $j \in [\ell]$.

1. Find an affine space of dimension at most m which contains all the required codewords using Theorem 18.
2. Using the algorithm in Theorem 17, obtain a list $\mathcal{L}$ of codewords and return it.

Let f be a polynomial such that for $n\ell/m + (n\ell + k)/(s-m)$ values of i,

$$(f(\alpha_i), f^{(1)}(\alpha_i), \ldots, f^{(s-1)}(\alpha_i)) = (\beta_j^{(0)}, \beta_j^{(1)}, \ldots, \beta_j^{(s-1)})$$

for some $j \in [\ell]$. By Theorem 18, f is contained in the output affine space. The algorithm in Theorem 17 finds f with high probability.

We saw in Theorem 18 that step 1 can be done in $\widetilde{O}(n\mathsf{poly}(s + m + \ell))$ time. Combining with the runtime of Theorem 17, we get a runtime of $\widetilde{O}\left(n\mathsf{poly}(s, \ell, (\ell/\varepsilon)^{\frac{1+\log \ell}{\varepsilon}})\right)$. ◀

Abstract

We study the algorithmic tractability of finding large independent sets in dense random hypergraphs. In the sparse regime, much of the natural algorithms can be formulated within either the local or the low-degree polynomial (LDP) framework, and a rich literature has subsequently identified nearly sharp algorithmic thresholds within these classes by exploiting their stability. In the dense setting, however, the algorithmic paradigms are fundamentally different: they are online and thus need not be stable. Perhaps more crucially, even for the classical Erdős–Rényi random graph $G(n,p)$, LDPs are conjectured to fail in the "easy" regime accessible to online algorithms, thereby challenging their viability for dense models.

Our focus is on two models: (i) finding large independent sets in dense r-uniform Erdős–Rényi hypergraphs, where each size-r hyperedge is present independently with probability p, and (ii) the more challenging problem of finding large γ-balanced independent sets in dense r-uniform r-partite hypergraphs, where the vertex set is the disjoint union $V_1 \sqcup \cdots \sqcup V_r$ with $|V_i| = n$ for all i, each hyperedge in $V_1 \times \cdots \times V_r$ is present independently with probability p, and the i-th coordinate of $\gamma \in \mathbb{Q}^r$ specifies the proportion of vertices from V_i in the independent set. For both models, we pinpoint the size of the largest independent set and design online algorithms that achieve a multiplicative approximation factor of $r^{1/(r-1)}$ in the uniform and $(\max_i \gamma_i)^{-1/(r-1)}$ in the r-partite model. Furthermore, we establish matching algorithmic lower bounds, showing that these computational gaps are *sharp*: no online algorithms can breach these gaps.

Our results provide a detailed landscape for dense hypergraphs, thereby completing the picture for dense models in a manner parallel to the sparse counterparts developed recently. Our main technical contribution is twofold: a novel *staged and bucketed greedy* algorithm and a stopping-time argument tailored to the hypergraph and multipartite structure for algorithmic hardness, both of which may be of independent interest. The algorithms and proof techniques in the dense regime differ substantially from those in the sparse, yet the resulting computational gaps are remarkably analogous, pointing to a form of universality. More conceptually, our results corroborate a hypothesis from statistical mechanics linking glassy equilibrium to computational hardness: optimization problems become far more intricate in the presence of global constraints.

1 Introduction

In this paper, we study the statistical and algorithmic landscape of large independent sets in two hypergraph models: (i) the r-uniform Erdős–Rényi hypergraph $H_r(n,p)$, where each size-r subset of $[n] \coloneqq \{1,\dots,n\}$ is present independently with probability p, and (ii) the r-uniform r-partite hypergraph $H(r,n,p)$, whose vertex set is partitioned into r parts $V_1,\dots,V_r$, each of size n, where each edge in $V_1 \times \cdots \times V_r$ is present independently with probability p. Our focus is on the *dense* regime in which p is a constant (as $n \to \infty$). While the landscape for sparse random hypergraphs has been characterized in detail recently [21], the dense regime has remained elusive and requires different techniques. We examine large independent sets in $H_r(n,p)$ and large *balanced* independent sets in $H(r,n,p)$, where the selected vertices are required to be distributed across the r parts according to a prescribed vector $\gamma \in \mathbb{Q}_+^r$. For both models, we pinpoint the largest possible size – referred to as the *statistical threshold*, design polynomial-time algorithms that provably outputs a large independent set, and establish sharp algorithmic lower bounds. Taken together, our results reveal *statistical-computational gaps* analogous to those in the sparse regime, thereby pointing to a form of universality.

Establishing sharp results for dense hypergraphs requires new technical ingredients. To this end, we introduce a novel *staged and bucketed greedy* algorithm tailored to hypergraphs and design a geometrical barrier, equipped with a carefully chosen stopping time, to establish tight algorithmic lower bounds. Informally, the *staged and bucketed* greedy procedure is divided into r stages where in each stage, the algorithm populates the independent set from an "unexhausted" part until a certain target capacity is reached, and then locks that part. As for our algorithmic barrier, it is adapted to the multipartite structure and global balancedness constraint; specifically, it tracks the first time at which the independent set contains sufficiently many vertices from every part of the partition. See Section 1.3 for a more detailed overview. We expect these new tools to be of independent interest for understanding algorithmic tractability in hypergraph models and beyond.

Our algorithmic viewpoint is *online*: vertices are exposed sequentially, and upon the arrival of a vertex v, the algorithm learns the status of hyperedges involving v together with previously exposed vertices, and must irrevocably decide whether to include v in its output. As we explain below, online algorithms are central in the dense setting, where they capture the only known class of polynomial-time algorithms. This stands in stark contrast to the sparse setting, where the predominant algorithmic frameworks are markedly different, see Section 1.1.

We emphasize that, while approximating the largest independent set to within a factor of $n^{1-\epsilon}$ is already NP-hard in the worst-case [38, 47], the average-case picture is substantially richer. For the Erdős–Rényi random graph $G(n,\frac{1}{2})$, the independence number – size of the largest independent set – is approximately $2\log_2 n$, whereas the online greedy algorithm reaches $\log_2 n$, both with high probability (whp) as $n \to \infty$ [11, 37, 54, 55]. In his seminal 1976 work [46], Karp challenged the community to design an efficient algorithm that reaches $(1+\epsilon)\log_2 n$ (whp) for some $\epsilon > 0$, or to prove that this is impossible (modulo a complexity-theoretic assumption such as $P \neq NP$). Nearly five decades later, this question remains open

and is widely regarded as a cornerstone of average-case complexity and random graph theory. It has inspired several major developments – such as Jerrum's introduction of the *planted clique* problem [44], and a substantial literature has since uncovered analogous "factor-2 gaps" across a broad range of random graphs models.[1] For an overview of such gaps in random graphs and beyond, see the surveys [29, 30, 34, 7, 63, 27].

1.1 Comparison between Online Algorithms and Low-Degree Polynomials

There is by now a substantial literature on algorithmic phase transitions for the largest independent set problem in sparse random graphs (including the classical Erdős–Rényi model as well as bipartite and multipartite analogues), where nearly sharp lower bounds have been established for local algorithms and low-degree polynomials (LDPs) [35, 60, 62, 59, 21, 31]. In the sparse regime, this framework is particularly natural: local neighborhoods remain small and approximately tree-like, and several natural algorithms can be formulated within either the local or low-degree framework [62, 59, 21, 31].

▶ Remark 1. We note that in the low-degree setting, the local tree-like property is essential to control the variance of certain quantities. We discuss this further in relation to our work below.

The dense regime, however, is fundamentally different. Even for the classical Erdős–Rényi graph $G(n,p)$ with constant p, it is likely that the online greedy algorithm cannot be implemented as an LDP. An informal justification for this is through a certain *invariant*: while LDPs enjoy input stability [62, 31, 59], the online greedy algorithm is shown to be unstable [32], thus unlikely to be implemented as an LDP. The current state of affairs is in fact more subtle. A remarkable conjecture put forth in a recent AIM workshop [1] suggests that LDPs fail even in the "easy" regime:

▶ **Conjecture 2.** *In $G(n,\frac{1}{2})$, no degree-$o(\log^2 n)$ polynomial can find an independent set of size $0.9\log_2 n$.*

Accordingly, while LDPs provide an important proxy for efficient algorithms in sparse random graphs, their viability in the dense setting, even for the classical Erdős–Rényi random graph $G(n,p)$ with constant p, is questionable.[2] If true, Conjecture 2 would show that LDPs are actually not viable for dense random graphs. A relatively weaker variant of this conjecture was proven in the aforementioned workshop [1]. This motivates the study of online algorithms in the dense regime.

▶ Remark 3. The online greedy algorithm is in fact relevant well beyond the dense setting. Indeed, in the intermediate regime where $p = o(1)$ and $np \to \infty$, the independence number of $G(n,p)$ is $(2+o(1))\log(np)/p$, whereas the greedy algorithm finds an independent set of size $(1+o(1))\log(np)/p$, both whp [10, 28, 25]. The same phenomenon persists in the sparse regime: in the double limit $n \to \infty$ followed by $d \to \infty$, the independence number of $G(n,d/n)$ is $(2+o_d(1))n\log d/d$, while greedy reaches $(1+o_d(1))n\log d/d$ [13]. Thus, throughout dense, intermediate, and sparse regimes, the online greedy yields 1/2-approximation to the optimum (at the level of the leading-order terms).

[1] Importantly, Karp's original conjecture regarding "factor-2 gaps" was formulated for the dense regime, while much of the recent effort has been focused on the sparse setting.

[2] Degree-$o(\log^2 n)$ polynomials are used as a proxy for polynomial-time algorithms; see [40, 51, 63].

Lower bounds for computational intractability of finding large independent sets in $G(n,p)$ within the framework of online algorithms had remained elusive, emerging only very recently [32].[3] At a technical level, they required substantial refinements of the machinery based on the Overlap Gap Property (see below for details). These results were recently extended to the balanced independent set problem in dense bipartite random graphs [19]. As we detail below, the largest balanced independent set problem in bipartite models closely resemble their classical Erdős–Rényi counterparts (even though the unconstrained independent set problem in bipartite random graphs is polynomial-time solvable via a max-flow reduction). As such, a variant of Conjecture 2 plausibly holds for bipartite models – this was in fact put forth in [19, Conjecture 1.6].

Bipartite Random Graphs. For the large balanced independent set problem in sparse random bipartite graphs, Perkins and Wang [59] obtained sharp algorithmic results within both the local and LDP frameworks. Their algorithm arises from bipartiteness, but the sparsity is crucial in placing it into the local or LDP framework – their analysis breaks down in the absence of sparsity. They explicitly note that, since sparse random graphs are locally tree-like, the performance of local algorithms is determined, to first order, by evaluation on a Galton-Watson tree. The same is true also in the bipartite case. More specifically, the analysis of the local algorithm uses the fact that for sparse random graphs, the neighborhoods are asymptotically tree-like and hence can be approximated by a Galton-Watson tree, which they leverage to control certain acceptance probabilities and to bound neighborhood sizes; see [59, Section 2.1]. As for the low-degree analysis, one must control the variance of a certain LDP, for which it is essential to control the size of certain neighborhoods. In [59, Section 2.2], this is handled precisely through a Poisson approximation, which unfortunately holds only in the sparse regime and is no longer valid for the dense setting.

For these reasons, results of [59] for sparse bipartite graphs do not extend to the dense setting. In a dense bipartite graph, even a depth-1 neighborhood already contains $\Theta(n)$ vertices (along with substantial dependencies), so the local limit argument based on Galton-Watson approximation disappears. Consequently, if one tries to adapt the algorithmic framework of [59], the resulting polynomial will unfortunately have a large variance, breaking down the analysis. As for the balanced independent set problem in sparse random multipartite hypergraphs, recent work of Dhawan and Wang [21] devised LDP algorithms, for which the analysis does not transfer to dense regime either.

For these models, the main source of hardness is not multipartiteness per se, but rather the *balancedness* constraint. More broadly, once one imposes a global constraint such as balancedness, the resulting optimization problem becomes substantially more delicate.[4] In particular, the largest balanced independent set problem in dense bipartite or multipartite random graphs is much closer in flavor to the classical largest independent set problem in dense $G(n,p)$ than to the unconstrained independent set problem on bipartite graphs. In light of this, online algorithms offer a natural algorithmic framework in the dense regime, across both the Erdős–Rényi and multipartite settings, whereas the viability of the low-degree framework (or local algorithms) is presently much less clear.[5]

[3] We note, however, that lower bounds for LDPs appeared earlier in [43, 62].

[4] In the language of statistical mechanics, a global constraint such as balancedness is expected to induce "glassy equilibrium" and lead to computational hardness [58, 56, 59, 34]; this has been rigorously verified for certain models, see, e.g., [22, 23].

[5] For related reasons, online algorithms also play an important role in other optimization problems such as coloring over dense random graphs; see [49].

Extension to Hypergraphs and Multipartite Models. The higher uniformity ($r \geq 3$), the multipartite structure, and the balancedness constraint collectively make the rigorous study of random hypergraph models substantially more delicate. To address these challenges, we develop new technical ideas both on the algorithmic side and for establishing sharp algorithmic hardness. These ideas contribute to the technical toolkit for dense random structures, which has only recently begun to emerge; we expect them to be broadly useful for hypergraph models and beyond.

▶ Remark 4. While it is well-established that the independence number of various pseudorandom graph classes attains the computational threshold – a line of inquiry originating with Shearer's foundational work on K_3-free graphs from 1983 [61] and expanding into a robust body of literature [18, 6, 48, 15] – an analogous result for pseudorandom hypergraphs was entirely absent from the literature until the recent work of Dhawan, Methuku, and Vo [20]. There are, however, several earlier results that match the growth rate [4, 26, 16].

These results suggest that finding large independent sets in hypergraphs is inherently harder than the graph case, further motivating the study of hypergraphs.

For a detailed technical overview, see Section 1.3. A summary of our contributions is in order.

1.2 Summary of Main Results

We now provide informal versions of our main results. Recall the descriptions of our models: the first is the dense r-uniform Erdős–Rényi hypergraph $H_r(n,p)$, where each r-element subset of $[n] \coloneqq \{1,\dots,n\}$ is present independently with probability p; the second is the dense r-uniform r-partite hypergraph $H(r,n,p)$, where the vertex set is partitioned into r parts $V_1,\dots,V_r$ of size n and each r-tuple from $V_1 \times \cdots \times V_r$ is included independently with probability p.

For $b \coloneqq \frac{1}{1-p}$ and $\gamma \coloneqq (\gamma_1,\dots,\gamma_r) \in \mathbb{Q}_+^r$ with $\sum_i \gamma_i = 1$, define

$$\alpha_{\mathtt{r}}^{\mathrm{STAT}} \coloneqq (r! \log_b n)^{\frac{1}{r-1}} \qquad \text{and} \qquad \alpha_{\mathtt{r\text{-}bal}}^{\mathrm{STAT}} \coloneqq \left(\frac{\log_b n}{\prod_{i=1}^r \gamma_i}\right)^{\frac{1}{r-1}}.$$

Throughout this paper, we focus on constant p, $p = \Theta(1)$ (as $n \to \infty$). We ignore all floor/ceiling operators for simplicity with the understanding that this has no effect on our arguments.

Our first result pins down the size of the largest (γ-balanced) independent set.

▶ **Theorem 5.** *For $H_r(n,p)$, the largest independent set has size $(1 \pm o(1))\,\alpha_{\mathtt{r}}^{\mathrm{STAT}}$ whp. Likewise, for $H(r,n,p)$, the largest γ-balanced independent set has size $(1 \pm o(1))\,\alpha_{\mathtt{r\text{-}bal}}^{\mathrm{STAT}}$ whp.*

Theorem 5 identifies $\alpha_{\mathtt{r}}^{\mathrm{STAT}}$ and $\alpha_{\mathtt{r\text{-}bal}}^{\mathrm{STAT}}$ as the *statistical threshold* for independent sets in $H_r(n,p)$ and γ-balanced independent sets in $H(r,n,p)$, respectively. The proof of Theorem 5 is based on the second moment method and is, therefore, non-constructive. This naturally leads to an algorithmic question: can we efficiently find large independent sets in $H_r(n,p)$ or large γ-balanced independent sets in $H(r,n,p)$? To address this question, we let

$$\alpha_{\mathtt{r}}^{\mathrm{COMP}} \coloneqq ((r-1)! \log_b n)^{\frac{1}{r-1}} \qquad \text{and} \qquad \alpha_{\mathtt{r\text{-}bal}}^{\mathrm{COMP}} \coloneqq \left(\frac{\log_b n}{\prod_{i=1}^r \gamma_i} \max_{1 \leq i \leq r} \gamma_i\right)^{\frac{1}{r-1}}.$$

Our next result establishes that the thresholds $\alpha_{\mathtt{r\text{-}bal}}^{\mathrm{COMP}}$ and $\alpha_{\mathtt{r}}^{\mathrm{COMP}}$ are achievable in polynomial time via an online algorithm.

▶ **Theorem 6.** *For $H_r(n,p)$, there is an online algorithm which finds, for any $\epsilon > 0$, an independent set of size $(1-\epsilon)\alpha_r^{\mathrm{COMP}}$ whp. Likewise, for $H(r,n,p)$, there is an online algorithm which finds, for any $\epsilon > 0$, a γ-balanced independent set of size $(1-\epsilon)\alpha_{r\text{-}bal}^{\mathrm{COMP}}$ whp.*

We now compare the statistical thresholds with the algorithmically achievable values. For the dense r-uniform hypergraph $H_r(n,p)$, there is a factor-$r^{1/(r-1)}$ gap between the two, which recovers the well-known "factor-2 gap" for the special case $r = 2$. As for $H(r,n,p)$, the gap is of the order $(\max_{1\le i\le r}\gamma_i)^{-1/(r-1)}$. (Note that for $\gamma_1 = \cdots = \gamma_r = 1/r$, the gaps in both cases are identical.)

Are there fundamental computational barriers in these models? Our final result addresses this question and yields sharp algorithmic lower bounds, suggesting that the barriers above are not spurious and likely inherent.

▶ **Theorem 7.** *For $H_r(n,p)$ and any $\epsilon > 0$, no online algorithm finds an independent set of size $(1+\epsilon)\alpha_r^{\mathrm{COMP}}$ with probability $o(1)$. Likewise, for $H(r,n,p)$ and any $\epsilon > 0$, no online algorithm finds a γ-balanced independent set of size $(1+\epsilon)\alpha_{r\text{-}bal}^{\mathrm{COMP}}$ with probability $o(1)$.*

Note that aside from onlineness, there is no restriction on the algorithms ruled out by Theorem 7. In particular, so long as the algorithm is online, we impose no restrictions on its runtime. Importantly, Theorem 7 rules out algorithms succeeding even with a vanishing probability $o(1)$. In relevant literature, this is known as *strong hardness*; see [43] as well as [32, 19].

▶ Remark 8. More explicitly, the $o(1)$ guarantee is of the form $\exp(-\Omega(\alpha_r^{\mathrm{COMP}}\log n))$ for $H_r(n,p)$ and of form $\exp(-\Omega(\alpha_{r\text{-}bal}^{\mathrm{COMP}}\log n))$ for $H(r,n,p)$. Both of these guarantees are essentially optimal, since the probability that a randomly chosen subset with size reaching the computational threshold is independent in $H_r(n,p)$ (or a γ-balanced independent set in $H(r,n,p)$) is of the same order.

Taken together, Theorems 6 and 7 sharply characterize the performance of online algorithms in dense r-uniform hypergraphs and dense r-partite hypergraphs, suggesting an inherent computational barrier, precisely at α_r^{COMP} and $\alpha_{r\text{-}bal}^{\mathrm{COMP}}$. Our result recovers the analogous computational gaps present for $r = 2$, generalizing them to $r > 2$, thus pointing towards a certain universality.[6]

▶ Remark 9. Note that for $H_r(n,p)$, the computational gap is of the order $r^{1/(r-1)}$, which vanishes as $r \to \infty$. Likewise, the same conclusion also holds for $H(r,n,p)$, using the fact $\max_i \gamma_i \ge 1/r$. Thus, the computational problem gets "easier" when the sizes of the hyperedges become large.

▶ Remark 10. As discussed below, we introduce a novel variant of the greedy algorithm – staged and bucketed greedy – together with a carefully designed stopping time that accounts for both the multipartite structure and the balancedness constraint. Both ingredients are crucial for addressing hypergraphs and multipartite structures, and for moving beyond the classical $G(n,p)$ and bipartite setting. In this sense, our results substantially generalize several existing results in the literature. Indeed, for $H_r(n,p)$ with $r = 2$, we recover both Karp's algorithmic result [46] as well as the lower bound of [32]. Likewise, for $H(r,n,p)$, our results with $r = 2$ recover the full set of results in [19].

[6] We remark that such a universality arises also in the context of sparse random graphs, see [59, 21, 62].

1.3 Proof Overview

Our proofs for $H_r(n,p)$ and $H(r,n,p)$ follow a consistent three-part strategy: identifying the statistical threshold, demonstrating achievability via online algorithms, and applying OGP to establish matching algorithmic lower bounds. We focus first on $H_r(n,p)$ to clarify the underlying mechanics. We then discuss the technical innovations required for the more complex $H(r,n,p)$ setting, including the *staged and bucketed* greedy procedure and a new stopping time argument, both of which account for the multipartite structure and the global balancedness requirement.

The statistical threshold is established via the second moment method [5]. As for the algorithms, our approach is through an online greedy algorithm. To the best of our knowledge, ours is the first work to analyze the greedy independent set procedure on Erdős–Rényi hypergraphs for $r \geq 3$.

Our impossibility result is positioned in a body of work initiated by Gamarnik and Sudan [35], who investigated local algorithms for independent sets in sparse random graphs using the Overlap Gap Property (OGP); see below for a background. This property yields a dichotomy: the intersection of two "large" independent sets must be either significantly large or very small, creating a forbidden "gap" in overlap sizes. They demonstrated that a successful local algorithm could be leveraged to produce independent sets that violate this OGP. While this approach was refined by Rahman and Virág [60] and extended by Wein [62] to LDPs, these methods fail in dense settings. For dense random graphs, LDPs – and local algorithms, which can be implemented as LDPs – are conjectured to fail; see Conjecture 2. By contrast, the only known algorithmic frameworks that achieve large independent sets in this regime are online. The arguments of [62, 60] crucially rely on algorithmic stability, whereas online algorithms are known to be unstable [32]. Thus, the dense setting calls for substantially different techniques.

In a recent development, Gamarnik, Kızıldağ, and Warnke [32] introduced an OGP-based framework tailored for the online setting. This approach is inherently algorithm-dependent: it utilizes a stopping time to monitor output size, together with interpolation paths that evolve temporally as the algorithm progresses. It yielded sharp lower bounds within online algorithms for the classical Erdős–Rényi random graph $G(n,p)$. Extending these techniques to higher uniformities and multipartite models under a global balancedness constraint turns out to be substantially more challenging, due to additional technical hurdles that are absent in $G(n,p)$ (discussed below). Among other technical contributions, we introduce a new stopping-time argument tailored specifically to hypergraphs, which may be of independent interest. Taken together, our techniques allow us to complete the picture for hypergraph models: while the sparse regime was recently addressed by Dhawan and Wang [21], the dense regime had remained open, which is our focus.

Formally, we construct a family of correlated random hypergraphs that remain identical until a specific random stopping time, after which they evolve independently. Executing the algorithm on these correlated instances yields a collection of candidate independent sets with rigid structural constraints – most notably, they must coincide on all vertices revealed prior to the stopping time. We define these configurations as "forbidden tuples" and prove they are absent from the correlated random hypergraphs with high probability. Since a successful online algorithm would necessarily imply the existence of such tuples, this contradiction establishes our lower bound.

We next extend our analysis to the $H(r,n,p)$ model. Although the statistical threshold is determined via a second-moment argument, the γ-balancedness, a global constraint, adds substantial technical complexity. As for developing an online algorithm, the primary hurdle

in this model is the global nature of the balancedness requirement, which must be maintained throughout the construction. To address this, we introduce a *staged and bucketed* greedy algorithm. The procedure is partitioned into r distinct stages; in each stage, the algorithm populates the independent set using vertices from "unexhausted" parts until some such part reaches its target capacity and is "locked." By controlling acceptance probabilities and bounding failure events via careful estimates, we prove that this algorithm yields a γ-balanced independent set of size $(1-\epsilon)\alpha^{\text{COMP}}_{\texttt{r-bal}}$ with high probability.

The derivation of the impossibility result for $H(r,n,p)$ is substantially more involved. The main difficulties stem from two sources: (i) the multipartite nature of $H(r,n,p)$, together with the permutation invariance of the parts in the partition, and (ii) the γ-balancedness constraint, which imposes prescribed cardinality requirements on the intersections of the independent set with the r parts. Among other technical ideas, we introduce a novel stopping time that accounts for both issues simultaneously. Specifically, we stop when the independent set contains sufficiently many vertices from all parts of the partition (by contrast, the stopping time for $H_r(n,p)$ is triggered once the algorithm's output reaches a prescribed size threshold).

Background on OGP. As mentioned earlier, our algorithmic lower bound is based on the OGP framework pioneered by Gamarnik and Sudan [35, 36] (and termed in [33]). The OGP is among the most powerful techniques for identifying computationally hard phases of random optimization problems – i.e., those in which the objective function is random. Its origins lie in earlier works on random CSPs, where the apparent hard phases were observed to exhibit striking geometric phase transitions [3, 2, 57]. The OGP framework systematically converts such geometric features of the solution landscape into formal algorithmic lower bounds; see [29, 32] for surveys on the method.

We now describe the OGP in greater detail for random graphs – the context in which it was originally introduced. For the sparse Erdős–Rényi model $G(n,\frac{d}{n})$, the work of Gamarnik and Sudan [35, 36] established that independent sets of size greater than $(1+1/\sqrt{2})n\frac{\log d}{d}$ must either substantially overlap or be nearly disjoint.[7] As a consequence, they rigorously ruled out local algorithms at this threshold, thereby refuting a well-known conjecture by Hatami, Lovász, and Szegedy [39], widely believed at the time. A subsequent work by Rahman and Virág [60] extended this threshold down to $n\frac{\log d}{d}$ by analyzing the overlap patterns of many independent sets, below which polynomial-time algorithms are known [52]. This approach, now known as the multi OGP (m-OGP), has since proved instrumental in obtaining sharp algorithmic lower bounds in a variety of other models. In the context of random graphs, hardness at the $(1+1/\sqrt{2})n\frac{\log d}{d}$ threshold was later extended to LDPs [31], and sharp lower bounds for LDPs were subsequently obtained in [62] using an asymmetric variant of the m-OGP. Still more delicate refinements of the m-OGP were required in other models, such as random k-SAT [12] and spin glasses [41, 42, 43]. For the latter, this led to the branching OGP, an especially powerful variant organized around an ultrametric tree of solutions. Even more recently, novel variants of the OGP tailored for online algorithms – which need not be stable – have begun to emerge [32, 19].

A summary of our contributions along with potential future directions of inquiry are now in order.

[7] For sparse random graphs, the relevant asymptotic regime is the double limit $n\to\infty$ followed by $d\to\infty$.

1.4 Summary and Open Problems

In this work, we consider the computational hardness of finding large (γ-balanced) independent sets in random hypergraphs. We focus on online algorithms, one of the most natural algorithmic frameworks containing Karp's original algorithm for $G(n,p)$, which motivated his celebrated conjecture regarding statistical-computational gaps for independent sets in $G(n,p)$. Our results imply a computational gap of a multiplicative factor of $r^{1/(r-1)}$ for independent sets in $H_r(n,p)$ and a gap of a multiplicative factor of $(\max_i \gamma_i)^{-1/(r-1)}$ for γ-balanced independent sets in $H(r,n,p)$ with respect to online algorithms; these gaps match those shown for LDPs in the sparse regime [21].

We conclude this introduction with a description of potential future directions of inquiry.

Future Queries. The setting of [32] permits querying a limited set of *future edges* – edges incident to vertices not yet seen – at each step. That is, the decision at time t is based not only on the edges revealed so far, but also on a restricted set of such future edges. In this augmented model, [32] prove both lower bounds and algorithmic guarantees for independent sets in graphs: specifically, they show that algorithms with modest access to future information can in fact exceed the $(1+\epsilon)\log_b n$ threshold, albeit using quasi-polynomial time. Similarly, [19] prove analogous results for γ-balanced independent sets in Erdős–Rényi bipartite graphs.

This naturally raises the following question: can algorithms with limited future information outperform the $(1+\epsilon)\alpha_{\mathtt{r}}^{\mathrm{COMP}}$ threshold for $H_r(n,p)$ and the $(1+\epsilon)\alpha_{\mathtt{r\text{-}bal}}^{\mathrm{COMP}}$ threshold for $H(r,n,p)$? We conjecture that the answer is yes:

▶ **Conjecture 11.** *Let E be the set of all future edges ever revealed to the algorithm and denote by $\binom{\mathcal{A}(G)}{r}$ the set of all r-edges whose vertices are contained in the output $\mathcal{A}(G)$.*

1. *For any $\epsilon > 0$ and $r \in \mathbb{N}$, there exists a constant $c_{\epsilon,r} > 0$ and an online algorithm $\mathcal{A}$ that finds an independent set of size at least $(1+\epsilon)\alpha_r^{\mathrm{COMP}}$ whp in $H_r(n,p)$, provided*

$$\left|E \cap \binom{\mathcal{A}(G)}{r}\right| \le c_{\epsilon,r}\Big(\log_b(np)\Big)^{\frac{r}{r-1}}.$$

2. *For any $\epsilon > 0$ and $r \in \mathbb{N}$, there exists a constant $c_{\epsilon,r} > 0$ and an online algorithm $\mathcal{A}$ that finds a γ-balanced independent set of size at least $(1+\epsilon)\alpha_{r\text{-}bal}^{\mathrm{COMP}}$ whp in $H(r,n,p)$, provided*

$$\left|E \cap \binom{\mathcal{A}(G)}{r}\right| \le c_{\epsilon,r}\Big(\log_b(np)\Big)^{\frac{r}{r-1}}.$$

▶ Remark 12. Due to r-uniformity, the amount of future information required to surpass the computational threshold is $O\left(\log^{\frac{r}{r-1}} n\right)$. For $r = 2$, this is the same scaling arising in [32, 19].

β-Independent Sets. For an integer $1 \le \beta \le r-1$, a β-independent set in a hypergraph $H = (V,E)$ is a set $I \subseteq V$ such that $|e \cap I| \le \beta$ for each $e \in E(H)$. These structures interpolate between the notions of *strong* and *weak* independent sets – the cases $\beta = 1$ and $\beta = r-1$ (note that $\beta = r-1$ corresponds to the usual notion of independent sets). While strong and weak independent sets have been heavily studied in the literature (both in the random and deterministic settings [50, 26, 16, 4, 14]), β-independent sets for $1 < \beta < r-1$ are not as well understood.

Regarding $H_r(n,p)$, the statistical threshold was determined by [50] in the sparse regime.[8] A curious feature of these structures is that the online greedy algorithm is not guaranteed to construct a β-independent set. To see this, consider an instance $H \sim H_r(n,p)$ and suppose, for example, at step t we have constructed an independent set I_t thus far. At this point, we do not know the structure of the subhypergraph $H' \coloneqq H[I_t \cup \{v_{t+1}, \dots, v_n\}]$. In particular, while I_t is a β-independent set in $H[\{v_1, \dots, v_t\}]$, it may not be one in H'. Generalizing our results on $H_r(n,p)$ – and, indeed, those of [21] in the sparse regime – to $\beta < r-1$ is an interesting direction.

Distance-k Independent Sets. In a similar flavor, a distance-k independent set in a graph $G=(V,E)$ is a set $I \subseteq V$ such that the vertices in I are pairwise of distance at least $k+1$; equivalently, it is an independent set in G^k (note that one recovers the usual notion of independent sets for $k=1$). As above, the greedy algorithm is not guaranteed to construct a distance-k independent set in a graph G.

Very recently, the growth rate of the statistical threshold for the distance-k independence number was determined for $G(n,p)$ [24]. They do not pin down the leading constant factor and raise it as an open problem (see the discussion after [24, Conjecture 8]). In the deterministic setting, there are a number of results for special graph classes, most notably for line graphs [45, 8, 53]. We remark that the problem is trivial for random graphs when $p \geq \sqrt{\frac{2\log n}{n}}$ and $k \geq 2$ as such graphs have diameter 2 [9]. It would be interesting to investigate the problem in the sparse regime.

▶ **Question 13.** *Are there statistical–computational gaps for the maximum distance-k independent set problem when $p = o\left(\sqrt{\frac{2\log n}{n}}\right)$ and $k \geq 2$?*

QMA Lower Bounds for Batch Verification via Approximate Degree

Mark Bun

Abstract

We study batch verification in QMA query and communication complexity, where the goal is to understand how the resources needed to verify m copies of a Boolean function f depend on m. We give a general technique for proving lower bounds on the witness-query tradeoff needed to batch verify a function f in terms of its approximate degree. Applying this technique to an explicit family of DNF formulas f, we show that attempting to save even a constant factor on the witness length of the baseline approach to batch verifying f necessitates a large polynomial increase in the query cost. We also obtain new lower bounds on the QMA query complexity of read-once CNF formulas and on the surjectivity and k-element distinctness functions. Our lower bounds also lift to give communication analogs of these results.

1 Introduction

A powerful but untrusted server wants to convince a computationally constrained client that it has correctly performed a large list of computations that were delegated to it. It can do so by proving to the client the veracity of m statements $x_1, \ldots, x_m$. As communication is costly, the proof must be as short as possible. If the statements are instances of an NP (or more generally for this work, QMA) language, a baseline strategy is to send as a proof witnesses $w_1, \ldots, w_m$ for all of the statements – the client can then verify each statement individually. Both the communication and the client's computational cost in this strategy are m times the cost for a single statement. For what statements is it possible to do better? What tradeoffs are achievable between communication and computation?

This *batch verification* problem has generated exciting research in complexity theory and cryptography. Highly communication-efficient interactive proofs are known for batch verifying UP statements (i.e., NP statements with unique witnesses) [34, 35, 36], while a connection between batch verification and statistical witness indistinguishability [6] suggests extending such a result to all of NP may be impossible. Zero-knowledge batch verification protocols are known for problems admitting non-interactive statistical zero-knowledge proofs [25, 26, 31, 27]. Under cryptographic assumptions, computationally sound noninteractive batch arguments are known for all of NP [23, 16, 15, 18, 42, 22]; recent work has even constructed succinct interactive (classical) batch arguments for QMA [20]. In cryptography, the study of batch verification of NP statements has led to new constructions of succinct non-interactive arguments (SNARGs) [15, 24] and non-interactive zero-knowledge arguments (NIZKs) [14] for more expressive classes and from weaker assumptions. Finally, [32] recently initiated a study of quantum witness indistinguishable proofs and showed that they are implied by quantum batch proofs.

In this work, we study the batch verification problem for quantum Merlin-Arthur (QMA) proofs in the query and communication models. These models abstract computation to settings where techniques are available for proving strong lower bounds, yet which shed both conceptual and technical light on the corresponding Turing machine model. In the QMA *query* or *black-box* model, hereafter denoted by $\mathrm{QMA}^{\mathrm{dt}}$, a quantum verifier (the resource-bounded mortal "Arthur") wishes to evaluate a known function $f : \{-1,1\}^n \to \{-1,1\}$ on an input $x \in \{-1,1\}^n$.[1] He receives a witness consisting of w qubits from a prover (the all-powerful wizard "Merlin"), and is allowed to make q queries to x in quantum superposition. The protocol is correct if (1) whenever $f(x) = -1$ (i.e., x is a "true" input), there exists a witness that causes the verifier to accept with probability at least $2/3$, and (2) whenever $f(x) = 1$ (i.e., x is a "false" input), every witness causes the verifier to reject with probability at least $2/3$. The cost of such a protocol is the sum $w + q$ of the witness length and the number of verifier queries, though we are also interested in understanding the tradeoff between these parameters. The QMA query complexity of a Boolean function f, denoted $\mathsf{QMA}^{\mathsf{dt}}(f)$, is the least cost of a protocol computing f.

The batch verification problem for QMA query complexity can thus be stated as follows: under what conditions on f does the function $(\mathsf{AND}_m \circ f^m)(x_1, \ldots, x_m) := f(x_1) \wedge \cdots \wedge f(x_m)$ have low $\mathrm{QMA}^{\mathrm{dt}}$ complexity? But what should "low" mean here? In the quantum setting, Grover's search algorithm gives a way to "batch compute" all functions with bounded-error algorithms: when f has a bounded-error quantum query protocol (i.e., one that does not make use of a witness) with query cost q, Grover search implies that $\mathsf{AND}_m \circ f^m$ has a bounded-error quantum query protocol with cost only $O(\sqrt{m} \cdot q)$ [21]. This methodology extends to $\mathrm{QMA}^{\mathrm{dt}}$ protocols. If f admits a $\mathrm{QMA}^{\mathrm{dt}}$ protocol with witness length w_f and query complexity q, one can compute $\mathsf{AND}_m \circ f^m$ by taking as witness all m individual witnesses (for a total witness length of $w = m \cdot w_f$) and using Grover search to verify all m copies using $O(\sqrt{m} \cdot q)$ queries. Our batch verification problem thus becomes: for what functions f can one beat this baseline protocol for $\mathsf{AND}_m \circ f^m$ that uses Grover search to verify all m individual witnesses?

Our first main result establishes a strong limitation on batching even when f is highly structured and admits an efficient NP query protocol.

[1] The notation $\mathrm{QMA}^{\mathrm{dt}}$ alludes to yet another view of query algorithms as generalizations of decision trees. Here and throughout the paper we identify -1 with "true" and 1 with "false."

▶ **Theorem 1** (Informal). *For every $\delta > 0$ there is an explicitly given polynomial-size, constant-width DNF $f : \{-1,1\}^n \to \{-1,1\}$ such that every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$, $m = n^{O(1)}$, with witness length $w \le cm \log n$ for a suitable constant $c \in (0,1)$ must make at least $\widetilde{\Omega}(n^{1-\delta}\sqrt{m/w})$ queries.*

One can interpret this result as follows. Since the function f is computed by a polynomial-size, constant-width DNF, it admits an NP query protocol with witness length $O(\log n)$ and $O(1)$ queries. The baseline strategy for verifying $\mathsf{AND}_m \circ f^m$ thus entails a proof with witness length $O(m \log n)$ and uses $O(\sqrt{m})$ queries. Theorem 1 shows that if one seeks to beat this baseline using a protocol with witness length just a constant factor smaller than this $O(m \log n)$, then the requisite query complexity jumps to $\Omega(n^{1-\delta})$, which is $\Omega(m)$ whenever $m = O(n^{1-\delta})$.

We prove Theorem 1 by proving a more general connection between the $\mathrm{QMA}^{\mathrm{dt}}$ complexity of batch verifying f with the *approximate degree* of f. The ε-approximate degree of f, denoted $\mathrm{adeg}_\varepsilon(f)$, is the minimum degree of a real-valued polynomial that approximates f point-wise to additive error ε. Approximate degree is an extensively studied measure, and has many connections to randomized and quantum query and communication complexity (see, e.g., [13]). In particular, Beals et al. [5] showed that the acceptance probability of every q-query quantum algorithm can be written as a degree-$2q$ polynomial in its input, and hence the ε-error quantum query complexity of a function f is always at least half of its ε-approximate degree.

We show that lower bounds on the ε-approximate degree of f for various settings of ε yield witness-query tradeoffs for $\mathrm{QMA}^{\mathrm{dt}}$ batch verifying f.

▶ **Theorem 2** (Informal). *Let $f : \{-1,1\}^n \to \{-1,1\}$ be a function.*

1. *If $\mathrm{adeg}_{1-1/m}(f) > d$ then every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length $w = O(m)$ requires $\Omega(d\sqrt{m/w})$ queries.*
2. *If $\mathrm{adeg}_{1/3}(f) > d$ then every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length at most m requires $\Omega(d)$ queries.*

As we discuss below, previous work derived $\mathrm{QMA}^{\mathrm{dt}}$ lower bounds from more stringent variants of approximate degree lower bounds. However, to our knowledge, ours is the first to draw a direct connection between $\mathrm{QMA}^{\mathrm{dt}}$ complexity and the standard notion of approximate degree.

As an illustrative example, let f be the complement of the element distinctness function on n bits (defined in Section 2.1), which is known to have approximate degree $\tilde{\Omega}(n^{2/3})$ [3, 4]. At the same time, f admits a $\mathrm{QMA}^{\mathrm{dt}}$ protocol with witness length $O(\log n)$ and query complexity $O(\sqrt{\log n})$: the witness consists of the location of a collision, and the verifier uses Grover search to check the collision. So the naïve batching strategy achieves witness length $O(m \log n)$ and query complexity $O(\sqrt{m \log n})$. Item 2 of Theorem 2 shows that any protocol improving on this witness length by even an $O(\log n)$ factor must have its query complexity jump to $\widetilde{\Omega}(n^{2/3})$, which is significantly larger for any $m \ll n^{4/3}$. Item 1 of the theorem gives more fine-grained tradeoffs when one can obtain lower bounds on the approximate degree of f to *large* error. Similar tradeoffs apply to other functions that admit efficient $\mathrm{QMA}^{\mathrm{dt}}$ protocols such as DNFs and the complement of the surjectivity function.

Beyond the intrinsic interest of the batch verification problem, Theorem 2 also serves as a valuable technical tool for understanding the $\mathrm{QMA}^{\mathrm{dt}}$ complexity of specific functions that have been central to the study of quantum query complexity. Sherstov and Thaler [41] used $\mathrm{QMA}^{\mathrm{dt}}$ lower bounds on functions of the form $\mathsf{AND}_m \circ f^m$ to give the sharpest known lower bounds for the influential element distinctness and permutation testing problems. For

technical reasons elaborated on below, their method falls short of applying to closely related functions, such as the two-level AND-OR tree, the k-element distinctness function, and the surjectivity function. Our framework for proving batch verification lower bounds bypasses the limitations from prior work, allowing us to prove the following lower bounds for these functions.

▶ **Theorem 3.** *Let* SURJ_n *denote the surjectivity function on* n *bits and* $k\mathsf{ED}_n$ *the* k*-element distinctness function on* n *bits.*

1. $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{AND}_{n^{1/3}} \circ \mathsf{OR}_{n^{2/3}}^{n^{1/3}}) = \Omega(n^{1/3})$.
2. $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{SURJ}_n) = \widetilde{\Omega}(n^{3/7})$.
3. $\mathsf{QMA}^{\mathsf{dt}}(k\mathsf{ED}_n) = \widetilde{\Omega}(n^{\frac{3k-1}{7k-1}})$.

The best lower bounds that followed straightforwardly from prior work were $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{AND}_{n^{1/3}} \circ \mathsf{OR}_{n^{2/3}}^{n^{1/3}}) = \Omega(n^{1/6})$, $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{SURJ}_n) = \widetilde{\Omega}(n^{1/4})$ and $\mathsf{QMA}^{\mathsf{dt}}(k\mathsf{ED}_n) \geq \mathsf{QMA}^{\mathsf{dt}}(\mathsf{ED}_n) = \widetilde{\Omega}(n^{2/5})$.

1.1 Technical Overview

Our main results follow from a general result (Corollaries 12 and 13, which formalize Theorem 2) showing that $\mathsf{AND}_m \circ f^m$ has high $\mathrm{QMA}^{\mathrm{dt}}$ complexity whenever f has high *approximate degree*.

Suppose there is a QMA protocol for a function F using witness length w and q queries. The in-place amplification technique of Marriott and Watrous [30] gives rise to a protocol for F with improved error 2^{-8w} using witness length w and $O(qw)$ queries. Replacing the witness in this protocol with the maximally mixed state yields a witness-free quantum query protocol for F, and hence an approximating polynomial p with the following properties:

$$F(x) = -1 \implies -2^{8w} \leq p(x) \leq -1,$$
$$F(x) = 1 \implies 1 - 2^{-8w} \leq p(x) \leq 1.$$

That is, p very tightly approximates F on its false inputs, but (roughly) subject to having the right sign behavior, can become exponentially large on true inputs. Thus, in order to prove a lower bound on the QMA query complexity of F, it suffices to rule out low-degree approximating polynomials p of this form. Up to this point, this lower bound method, which is inspired by the complexity class containment $\mathsf{QMA} \subseteq \mathsf{SBQP}$, is well-established for proving QMA query complexity lower bounds [1, 2, 41, 17]. We refer to such an approximating polynomial p as an "SBQP approximation" to F.

Prior work proved degree lower bounds for SBQP approximations by relating it to other better-studied notions of polynomial approximation, including ε-approximate degree in the "large error" regime where $\varepsilon \approx 1 - 2^{-w}$, threshold degree, and vanishing error one-sided approximate degree. We depart from prior work by studying SBQP approximations more directly. We do this using the method of dual polynomials, whereby one proves approximability lower bounds by constructing dual solutions to a linear program capturing the approximation problem. We introduce a notion of "relaxed SBQP duals" to capture feasible solutions in this dual space that are relatively clean to construct and reason about. A relaxed SBQP dual for a function F is a real-valued function Φ that is ε-correlated with F for some $\varepsilon \geq 2^{-8w}$, orthogonal to all low degree polynomials, and which has "almost one-sided error" in the sense that the total weight it places on $\{x : F(x) = -1 \wedge \Phi(x) > 0\}$ is at most $2^{-8w}\varepsilon$. The proof of our general theorem proceeds by showing that whenever f has high approximate degree, we can construct an appropriate relaxed SBQP dual for the function $\mathsf{AND}_m \circ f^m$. The connection outlined above, in turn, implies our $\mathrm{QMA}^{\mathrm{dt}}$ tradeoffs.

To construct this relaxed SBQP dual, we appeal to the fact that the high approximate degrees of AND_m and f are themselves witnessed by dual objects ψ and φ, respectively. Building on a construction of Sherstov [38], we show how to combine ψ and φ to produce a new dual witness to the high SBQP degree of the composed function $F = \mathsf{AND}_m \circ f^m$. Note that Sherstov's original construction was tailored to showing only that F has high approximate degree. Since we need a stronger SBQP degree lower bound, our analysis needs to first take advantage of the fact that ψ actually witnesses the high *one-sided* approximate degree of AND_m. That is, it rules out one-sided approximations which tightly approximate AND_m on false inputs, but may be arbitrarily unbounded on true inputs. This manifests in the dual witness ψ as the property that it places zero weight on the set $\{x : \mathsf{AND}_m(x) = -1 \wedge \psi(x) > 0\}$. Second, our analysis needs to keep tighter track of how errors on the "true" side of F accumulate to show that it has the required almost one-sided error.

With Theorem 2 established, Theorem 1 follows by taking the f to be an explicit, constant-width, polynomial-size DNF with approximate degree $\Omega(n^{1-\delta})$ as constructed by Sherstov [40]. We obtain the results in Theorem 3 by building on the ideas of Sherstov and Thaler [41]. For every parameter m, the functions $k\mathsf{ED}_n$ and SURJ_n contain, as subfunctions, $\mathsf{AND}_m \circ (k\mathsf{ED}_{n/m})^m$ and $\mathsf{AND}_m \circ \mathsf{SURJ}^m_{n/m}$, respectively. We can thus invoke our general theorem on these subfunctions for appropriate choices of m that balance the final witness length and query costs in our lower bound.

The reason why Sherstov and Thaler could use this insight to prove lower bounds for element distinctness and permutation testing, but not for k-element distinctness or surjectivity, owes to a gap between the type of polynomial approximation lower bounds they could prove on functions of the form $\mathsf{AND}_m \circ f^m$ and the type they identified as yielding SBQP approximation lower bounds. Specifically, they showed a lower bound on the vanishing-error approximate degree $\widetilde{\deg}_\varepsilon(\mathsf{AND}_m \circ f^m)$, but needed to invoke a stronger lower bound on the *one-sided* vanishing-error approximate degree $\widetilde{\deg}^-_\varepsilon(\mathsf{AND}_m \circ f^m)$ to rule out SBQP approximations. For some functions with special structure, including AND, element distinctness, and permutation testing, ordinary approximate degree and one-sided approximate degree fortuitously coincide, and hence vanishing-error approximate degree lower bounds imply $\mathrm{QMA}^{\mathrm{dt}}$ lower bounds. But such a coincidence is not (yet) known for k-distinctness or surjectivity, and false for other simple functions such as the two-level AND-OR tree. By working directly with SBQP approximations via our relaxed SBQP duals, we can prove $\mathrm{QMA}^{\mathrm{dt}}$ lower bounds for arbitrary composed functions $\mathsf{AND}_m \circ f^m$, regardless of whether ordinary and one-sided approximate degree agree.

1.2 Lifting to QMA Communication Lower Bounds

In the QMA *communication* model, denoted by $\mathrm{QMA}^{\mathrm{cc}}$, Alice holds an input $x \in \{-1,1\}^n$, Bob holds an input $y \in \{-1,1\}^n$, and they wish to compute a joint function $f : \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$ of their inputs. Bob receives a witness of w qubits from the prover and the parties have unlimited access to shared entanglement. They wish to minimize the amount of communication between them (including the witness) required to compute $f(x,y)$. The success criterion, cost of a protocol, and $\mathrm{QMA}^{\mathrm{cc}}$ complexity of a function f are defined analogously to the query model.

Sherstov's pattern matrix method [37] shows how to generically "lift" an approximate degree lower bound for a function f to a communication lower bound for a related function $G := f \circ g^n$, where g is a certain constant-sized two-party gadget. By adapting the pattern matrix method to show how to lift SBQP degree lower bounds to QMA communication lower

bounds, we establish QMA lower bounds for communication analogs of the batch verification problems we study. Our analysis builds closely on prior generalizations of the pattern matrix method lifting one-sided approximate degree to (multiparty) MA communication [19, 40] and to QMA communication [28], but the formulation of the statement that is most useful to us appears to be new. We defer these results to the full version of this paper [8].

1.3 Open Questions

- Is the witness-query tradeoff given by Theorem 2 tight? That is, can one find a function f such that for every $w = O(m)$, $\mathsf{AND}_m \circ f^m$ admits a $\mathrm{QMA}^{\mathrm{dt}}$ protocol with witness length w and query complexity $O(\mathrm{adeg}_{1-1/m}(f) \cdot \sqrt{m/w})$?
- Our $\mathrm{QMA}^{\mathrm{dt}}$ batch verification lower bounds depend on approximate degree lower bounds for the base function f. Recall that approximate degree is a lower bound on the quantum query complexity of f, but can be much smaller. Can one obtain similar batch verification lower bounds starting from arbitrary quantum query lower bounds on f?
- How tight are the $\mathrm{QMA}^{\mathrm{dt}}$ lower bounds in Theorem 3? Can our ideas be used to obtain improved $\mathrm{QMA}^{\mathrm{dt}}$ lower bounds for element distinctness and permutation testing?

2 Preliminaries

We let $\mathbb{N} = \{1, 2, \ldots\}$ denote the set of natural numbers and $\mathbb{R}$ denote the set of real numbers. We write $[n]$ for the set $\{1, 2, \ldots, n\}$.

We identify the Boolean values "true" and "false" with -1 and 1 respectively. The functions $\mathsf{OR}_n : \{-1,1\}^n \to \{-1,1\}$ and $\mathsf{AND}_n : \{-1,1\}^n \to \{-1,1\}$ are the usual functions $\mathsf{OR}_n(x) = \bigvee_{i=1}^n x_i$ and $\mathsf{AND}_n(x) = \bigwedge_{i=1}^n x_i$. The Hamming weight of a string $x \in \{-1,1\}^n$, denoted $|x|$, is the number of indices i such that $x_i = -1$. A function f is said to be computable by a *disjunctive normal form (DNF)* formula of size s and width w if there exist $S_1, S_2, \ldots, S_s \subseteq [n]$ with cardinality w such that $f(x) = \bigvee_{i \in [s]} \bigwedge_{j \in S_i} x_j$. The conjunctions $\bigwedge_{j \in S_i} x_j$ are called *terms*.

We use the following standard real-valued functions. We use $\exp_k$ to denote the base-k exponential, i.e., $\exp_k(x) = k^x$. The base-2 logarithm is denoted by $\log(\cdot)$. For any predicate P, $\mathbb{1}[P(x)]$ equals 1 if $P(x)$ is true and 0 otherwise. The notation $|x|$ represents the absolute value, Hamming weight, or cardinality of x depending on if x is a real number, binary string, or set respectively.

For real valued functions f and g with the same finite support X, we use the usual notation for the ℓ_1 norm and inner product.

$$\|f\|_1 = \sum_{x \in X} |f(x)|$$
$$\langle f, g \rangle = \sum_{x \in X} f(x) g(x)$$

We often refer to the inner product $\langle f, g \rangle$ as the *correlation* between f and g. The function f is *balanced* if $\sum_{x \in X} f(x) = 0$.

We use superscripts to denote the direct product of a function with itself: for every $f : X \to Y$ and $m \in \mathbb{N}$, $f^m : X^m \to Y^m$ is the function $f^m(x_1, \ldots, x_m) = (f(x_1), \ldots, f(x_m))$. The symbol $\circ$ is used for function composition, so that $(f \circ g)(x) = f(g(x))$. Consequently, for every $g : X \to Y$ and $f : Y^m \to Z$, $f \circ g^m$ denotes the "block composition" of f and g: $(f \circ g^m)(x_1, \ldots, x_m) = f(g(x_1), \ldots, g(x_m))$.

For any set S, we use 2^S to denote the set of all subsets of S. For every $T \subseteq [n]$, we denote by $\chi_T : \{-1,1\}^n \to \{-1,1\}$ the Fourier character $\chi_T(x) = \prod_{i \in T} x_i$. We recall that for every function $f : \{-1,1\}^n \to \mathbb{R}$ there exists a unique function $\widehat{f} : 2^{[n]} \to \mathbb{R}$ called the *Fourier transform* of f such that for all x,

$$f(x) = \sum_{T \subseteq [n]} \widehat{f}(T)\chi_T(x).$$

Furthermore, this unique function is given by

$$\widehat{f}(T) = 2^{-n} \sum_{x \in \{-1,1\}^n} f(x)\chi_T(x).$$

2.1 Polynomial approximation

We say that a polynomial p *ε-approximates* a function $f : \{-1,1\}^n \to \{-1,1\}$ if for all $x \in \{-1,1\}^n$, $|f(x) - p(x)| \leq \varepsilon$. The *$\varepsilon$-approximate degree*, denoted $\mathrm{adeg}_\varepsilon(f)$, of f is the minimum degree of a polynomial that ε-approximates f. A polynomial p *ε-one-sided approximates* f if the following conditions hold.

1. For every $x \in f^{-1}(-1)$, we have $p(x) \in (-\infty, -1 + \varepsilon]$.
2. For every $x \in f^{-1}(1)$, we have $p(x) \in [1 - \varepsilon, 1 + \varepsilon]$.

The *ε-one-sided approximate degree* of f, denoted $\mathrm{adeg}^-_\varepsilon(f)$, is the minimum degree of a polynomial that ε-one-sided approximates f. One can also define a complementary notion of one-sided approximation where the approximating polynomial must tightly approximate true inputs and is allowed to be arbitrarily positive on false inputs, though we do not consider that notion or its associated one-sided approximate degree measure in this paper. For both one-sided and regular approximate degree, when ε is not specified, we assume that $\varepsilon = 1/3$.

We recall the standard dual formulation of approximate degree.

▶ **Theorem 4** ([37, 11]). *Let $f : \{-1,1\}^n \to \{-1,1\}$ be a Boolean function. Let $d \geq 1$ be an integer and $\varepsilon > 0$ be a real number. Then $\mathrm{adeg}_\varepsilon(f) > d$ if and only if there exists a function $\psi : \{-1,1\}^n \to \mathbb{R}$ such that*

1. *$\langle f, \psi \rangle \geq \varepsilon$,*
2. *$\|\psi\|_1 = 1$, and*
3. *for every $T \subseteq [n]$ with $|T| \leq d$, $\langle \psi, \chi_T \rangle = 0$.*

Furthermore, $\mathrm{adeg}^-_\varepsilon(f) > d$ if and only if there exists a function ψ that satisfies the conditions above and has the additional property that for all x such that $f(x) = -1$, $\psi(x) \leq 0$.

The function ψ is called a *dual polynomial* for the lower bound $\mathrm{adeg}_\varepsilon(f) > d$ or $\mathrm{adeg}^-_\varepsilon(f) > d$ (depending on whether it has the additional property). Condition 3 is often referred to as ψ having "pure high degree at least d."

Sherstov showed that there exist functions computable by polynomial-size, constant-width DNF formulas that have near-maximal approximate degree.

▶ **Theorem 5** ([40]). *For all constants $\delta > 0$ and $c \geq 1$, for every $n \in \mathbb{N}$, there is an explicit function $f_n : \{-1,1\}^n \to \{-1,1\}$ computable by a polynomial-size, constant-width DNF such that $\mathrm{adeg}_{1-1/n^c}(f_n) = \Omega(n^{1-\delta})$.*

"Explicit" here means that there is a uniform algorithm that, given n, prints out a description of f_n in time polynomial in n.

The *surjectivity* function $\mathsf{SURJ}_{N,R} : \{-1,1\}^{N \log R} \to \{-1,1\}$ interprets its input as a list of N numbers in $[R]$ and evaluates to true if and only if every element of $[R]$ appears in the list at least once. As a default we let $n = N \log R$ and $R = N/2$. We write SURJ_n for $\mathsf{SURJ}_{N,R}$ with the default setting of parameters. Bun, Kothari, and Thaler [9] showed that the approximate degree of SURJ_n is $\widetilde{\Omega}(n^{3/4})$.

The *element distinctness* problem $\mathsf{ED}_{N,R} : \{-1,1\}^{N \log R} \to \{-1,1\}$ interprets its input as a list of N numbers in $[R]$ and evaluates to true if and only if no element appears more than once. The canonical setting of parameters is $N = R$, as the function is trivially false when $N > R$ and it was shown by Ambainis [4] that the ε-approximate degree of $\mathsf{ED}_{N,R}$ is the same for all $N \leq R$. Aaronson and Shi [3] showed that $\mathrm{adeg}(\mathsf{ED}_n) = \widetilde{\Theta}(n^{2/3})$ when R is large compared to N. The aforementioned result of Ambainis extended their bounds to our setting of parameters.

The *k-element distinctness* problem $k\mathsf{ED}_{N,R} : \{-1,1\}^{N \log R} \to \{-1,1\}$ is a generalization of element distinctness that evaluates to true if and only if no range element appears k or more times. We use the same canonical setting of parameters as for element distinctness: $k\mathsf{ED}_n = k\mathsf{ED}_{N,N}$ where $n = N \log N$. Mande, Thaler, and Zhu [29] showed that $\mathrm{adeg}(k\mathsf{ED}_n) = \widetilde{\Omega}(n^{3/4 - 1/(4k)})$.

Finally, for our lower bound on the $\mathrm{QMA}^{\mathrm{dt}}$ complexity of the two-level AND-OR tree we will need the lower bound $\mathrm{adeg}(\mathsf{AND}_m \circ \mathsf{OR}_n) = \Omega(\sqrt{mn})$, proved by Bun and Thaler [10] and Sherstov [39].

2.2 Quantum Merlin-Arthur protocols

Let $f : \{-1,1\}^n \to \{-1,1\}$ be a function. A *QMA query protocol* for f with witness length w, query complexity q, completeness error ε_1, and soundness error ε_2, is a quantum oracle algorithm A such that

1. For all $x \in f^{-1}(-1)$ there exists an w-qubit "witness" $|\psi\rangle$ such that $\Pr_A[A^x(|\psi\rangle) = -1] \geq 1 - \varepsilon_1$;
2. For all $x \in f^{-1}(1)$, for every w-qubit state $|\psi\rangle$, $\Pr_A[A^x(|\psi\rangle) = -1] \leq \varepsilon_2$; and
3. For all x and w, $A^x(w)$ makes at most q queries to the input x.

The algorithm A is often referred to as a *verifier*. If a protocol has completeness (resp. soundness) error 0, we say that it has perfect correctness (resp. soundness). When the completeness and/or soundness errors are not specified, we set them to the default value 1/3. The QMA query complexity of f, denoted $\mathsf{QMA}^{\mathsf{dt}}(f)$, is the minimum $w + q$ such that there exists a QMA query protocol for f with witness length w and query complexity q.

QMA communication complexity is defined analogously. A QMA communication protocol for a two-party function $f : X \times Y \to \{-1,1\}$ with witness length w, communication cost c, completeness error ε_1, and soundness error ε_2 is a two-party quantum communication protocol (A, B) with access to shared entanglement such that for all inputs (x, y) and w-qubit states $|\psi\rangle$, the execution $[A(x), B(y, |\psi\rangle)]$ involves at most c qubits of communication and satisfies completeness and soundness conditions analogous to the query case. For a more formal definition of this setting we refer the reader to [33]. The QMA communication complexity of f, denoted $\mathsf{QMA}^{\mathsf{cc}}(f)$ is the minimum $w + c$ such that there exists a QMA communication protocol for f with witness length w and communication cost c.

In models with classical witnesses (such as MA or QCMA), one can reduce completeness and soundness errors by repeatedly executing the verifier and outputting the majority output. This does not work for protocols where the witness is a quantum state, since executing the verifier might alter the witness state. Nevertheless, Marriott and Watrous showed that one

can, in fact, reduce the completeness and soundness errors for QMA protocols. The proof of this theorem can be adapted to achieve the same error reduction in the QMA communication setting.

▶ **Theorem 6** ([30]). *Let $f : \{-1,1\}^n \to \{-1,1\}$ be a function. Suppose there exists a $q(n)$-query quantum algorithm Q, numbers $a(n), b(n) \in [0,1]$, and $w(n), p(n) \leq \mathsf{poly}(n)$ such that*

1. *for all $x \in f^{-1}(-1)$ there exists a $w(n)$-qubit state $|\psi\rangle$ such that $\Pr_Q[Q^x(|\psi\rangle)$ accepts$] \geq a(n)$,*
2. *for all $x \in f^{-1}(1)$, for all $w(n)$-qubit states $|\psi\rangle$, $\Pr_Q[Q^x(|\psi\rangle)$ accepts$] \leq b(n)$, and*
3. *$a(n) - b(n) \geq 1/p(n)$.*

Then for every $r(n) \leq \mathsf{poly}(n)$ there exists a $\mathrm{QMA}^{\mathrm{dt}}$ protocol for f with completeness and soundness error $2^{-r(n)}$, witness length $w(n)$, and query complexity $O(q(n) \cdot r(n) \cdot p(n)^2)$.

2.3 Linear algebra

Our results on communication complexity require some standard concepts from matrix analysis which we recall here. Unless otherwise specified, all matrices we consider are over the field of real numbers. We use the notation $[A_{x,y}]_{x\in X, y\in Y}$ to refer to a $|X| \times |Y|$ matrix A whose rows and columns are indexed by elements of X and Y respectively and whose entries are $A_{x,y}$. For any two matrices $[A_{x,y}]_{x\in X,y\in Y}$ and $[B_{x,y}]_{x\in X,y\in Y}$, the inner product of A and B is defined as

$$\langle A, B\rangle = \sum_{x\in X, y\in Y} A_{x,y}B_{x,y}.$$

The singular values of an $m \times n$ matrix A are denoted by $\sigma_1(A) \geq \sigma_2(A) \geq \cdots \geq \sigma_{\min\{m,n\}}(A) \geq 0$. We recall four standard notions of matrix norm.

$$\|A\|_1 = \sum_{x,y} |A_{x,y}| \qquad \text{(The } L_1 \text{ norm)}$$

$$\|A\| = \max_i \sigma_i(A) \qquad \text{(The spectral norm)}$$

$$\|A\|_\Sigma = \sum_i \sigma_i(A) \qquad \text{(The trace norm)}$$

$$\|A\|_F = \sqrt{\sum_i \sigma_i(A)^2} \qquad \text{(The Frobenius norm)}$$

We will use the following well-known identities. For all compatible real matrices A and B,

$$\|AB\|_\Sigma \leq \|A\|_F \|B\|_F, \text{ and}$$
$$\langle A, B\rangle \leq \|A\|_\Sigma \|B\|.$$

3 SBQP Lower Bounds from High Approximate Degree

In this section we show that if a function f has high large-error approximate degree, then $\mathsf{AND}_m \circ f^m$ has high SBQP cost. We start by defining a notion of SBQP cost in terms of polynomial approximations and deriving a corresponding dual notion for it.

▶ **Definition 7.** *A polynomial (M,ε)-SBQP-approximates $f : \{-1,1\}^n \to \{-1,1\}$ if for all $x \in \{-1,1\}^n$,*

1. *if $f(x) = -1$ then $-M - 1 - \varepsilon \leq p(x) \leq -1 + \varepsilon$, and*
2. *if $f(x) = 1$ then $1 - \varepsilon \leq p(x) \leq 1 + \varepsilon$.*

▶ **Lemma 8.** *For all $f : \{-1,1\}^n \to \{-1,1\}$ and $M^*, \varepsilon, d \geq 0$, if there exists a function $\varphi : \{-1,1\}^n \to \mathbb{R}$ with the following properties, then there does not exist a polynomial of degree at most d that (M^*, ε)-SBQP-approximates f.*

1. $\langle \varphi, f \rangle \geq 2\varepsilon$,
2. $\|\varphi\|_1 \leq 1$,
3. *for all $S \subseteq [n]$ such that $|S| \leq d$, $\langle \varphi, \chi_S \rangle = 0$,*
4. $\sum_{x : f(x) = -1, \varphi(x) > 0} \varphi(x) \leq \varepsilon / M^*$.

Proof. Let $f : \{-1,1\}^n \to \{-1,1\}$ be arbitrary. Fix any $\varepsilon \geq 0$. The smallest M such that there exists a degree-d (M, ε)-SBQP-approximation to f is given by the following linear program.

$$\begin{aligned} \min_{\substack{M \\ p \text{ of deg } < d}} \quad & M & \\ \text{s.t.} \quad & p(x) \geq f(x) - \varepsilon & \forall x \in f^{-1}(1) \\ & p(x) + M \geq f(x) - \varepsilon & \forall x \in f^{-1}(-1) \\ & -p(x) \geq -f(x) - \varepsilon & \forall x \in \{-1,1\}^n \\ & M \geq 0 & \end{aligned}$$

The dual of this linear program is the following.

$$\begin{aligned} \max_{\psi^+, \psi^- : \{-1,1\}^n \to \mathbb{R}} \quad & \sum_{x \in \{-1,1\}^n} (\psi^+(x) - \psi^-(x)) f(x) - \varepsilon \sum_{x \in \{-1,1\}^n} (\psi^+(x) + \psi^-(x)) & \\ \text{s.t.} \quad & \left\langle \psi^+ - \psi^-, \chi_S \right\rangle = 0 & \forall S \subseteq [n], |S| \leq d \\ & \sum_{x : f(x) = -1} \psi^+(x) \leq 1 & \\ & \psi^-, \psi^+ \geq 0 & \end{aligned}$$

By a standard transformation (which appears, e.g., in the derivation of the dual formulation of approximate degree), any optimal solution to the dual program can be turned into one where ψ^+ and ψ^- have disjoint support. Thus, we can set $\psi = \psi^+ - \psi^-$ to get the following equivalent dual linear program.

$$\begin{aligned} \max_{\psi : \{-1,1\}^n \to \mathbb{R}} \quad & \langle \psi, f \rangle - \varepsilon \|\psi\|_1 & \\ \text{s.t.} \quad & \langle \psi, \chi_S \rangle = 0 & \forall S \subseteq [n], |S| \leq d \\ & \sum_{x : f(x) = -1, \psi(x) > 0} \psi(x) \leq 1 & \end{aligned}$$

By weak duality, to show that f does not admit an (M^*, ε)-SBQP-approximation it is sufficient to show that the dual program has objective at least M^*. Suppose we have a φ as in the theorem statement. Consider $\psi = M^* \varphi / \varepsilon$. This ψ satisfies the first constraint of the dual since φ has pure high degree at least d. It satisfies the second constraint since $\sum_{x : f(x) = -1, \psi(x) > 0} \psi(x) = \frac{M^*}{\varepsilon} \sum_{x : f(x) = -1, \varphi(x) > 0} \varphi(x) \leq 1$. Finally, the objective attained by ψ is $\frac{M^*}{\varepsilon} \langle \varphi, f \rangle - \varepsilon \cdot \frac{M^*}{\varepsilon} \|\varphi\|_1 \geq 2M^* - M^* = M^*$. ◀

Functions that satisfy the conditions in Lemma 8 are central to our proofs. We call a φ that has those properties with respect to a function f and parameters M, ε, and d a *relaxed (M, ε, d)-SBQP dual to f*. The word "relaxed" refers to the fact that while the existence of

φ is sufficient for a lower bound on the degree of an (M, ε)-SBQP approximation, it might not be necessary. This is because the proof of Lemma 8 loses tightness when it replaces ψ, which is obtained via LP duality, by the weaker (but easier to reason about) object φ. Just as SBQP approximations are natural restrictions of one-sided approximations (allowing large but bounded error on one side), property 4 of the dual is a natural relaxation of the one-sidedness property of adeg^- duals described in Theorem 4. We use relaxed SBQP duals to prove that if a function f has high approximate degree, then all SBQP approximations to $\mathsf{AND}_m \circ f^m$ must have high degree. To do so, we use the following well-known fact about the vanishing-error one-sided approximate degree of the AND function.

▶ **Theorem 9** ([7]). *There exist universal constants δ_{AND} and δ'_{AND} such that for every $\gamma \in [2^{-m}, 1/3]$, $\delta_{\mathsf{AND}}\sqrt{m\log(1/\gamma)} < \mathrm{adeg}^-_\gamma(\mathsf{AND}_m) \leq \delta'_{\mathsf{AND}}\sqrt{m\log(1/\gamma)}$.*

Strictly speaking, [7] only implies $\mathrm{adeg}_\gamma(\mathsf{AND}_m) = \Theta(\sqrt{m\log(1/\gamma)})$, but it is easy to see that one-sidedness is without loss of generality for the AND function. (This observation goes back to Gavinsky and Sherstov [19].) Suppose $\mathrm{adeg}_\gamma(\mathsf{AND}_m) > d \geq 1$, and let ψ be a dual witness to that lower bound guaranteed by Theorem 4. Since ψ has pure high degree at least 1, we get that $0 = \langle \psi, 1\rangle = \psi(-\mathbf{1}_m) + \sum_{z \neq -\mathbf{1}_m} \psi(z)$. That ψ has correlation at least γ with AND_m combined with the fact that $-\mathbf{1}_m$ is the only -1 instance of AND_m gives us $\gamma \leq \langle \psi, \mathsf{AND}_m\rangle = -\psi(-\mathbf{1}_m) + \sum_{z \neq -\mathbf{1}_m} \psi(z)$. Combining the two equations yields $\psi(-\mathbf{1}_m) \leq -\gamma/2 < 0$, which means ψ is a witness for $\mathrm{adeg}^-_\gamma(\mathsf{AND}_m) > d$. The other ingredient in our construction is the following polynomial p_k.

▶ **Lemma 10** ([38]). *Let k be an even number in $[m-1]$, and define $p_k : [-1,1]^m \to \mathbb{R}$ as the unique degree-k multilinear polynomial such that for all $z \in \{-1,1\}^m$,*

$$p_k(z) = \prod_{i=1}^{k}(|z| - i).$$

Then $p_k(z) \geq 0$ for all $z \in [-1,1]^m$ and for every $\eta \in [0,1)$,

$$\mathop{\mathbb{E}}_{z\sim\Pi(\eta)}[p_k(z)] \leq p_k(\mathbf{1}_m)(1-\eta)^m\left\{1 + \frac{\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1}\right\},$$

where $\Pi(\eta)$ is the distribution on $\{-1,1\}^m$ where each coordinate is -1 with probability η and 1 with probability $1-\eta$.

We now prove our main connection between approximate degree and SBQP degree. Our proof works by way of constructing a relaxed SBQP dual for $\mathsf{AND}_m \circ f^m$ from (1) a dual witness for the vanishing-error one-sided approximate degree of AND, (2) a dual for the assumed approximate degree lower bound on f, and (3) the polynomials p_k. The construction itself is a renormalized special case of the dual constructed in [38, Theorem 6.1]. Consequently, the correlation, ℓ_1 norm, and pure high degree analyses for the dual follow from the corresponding analyses in that work. Additionally, to get an SBQP dual, we need to show that the dual construction does not place too much mass on "true" inputs that it misclassifies. We do so by taking advantage of the fact that the dual for AND is one-sided and keeping tighter track of how errors on misclassified "true" inputs accumulate.

▶ **Theorem 11.** *Let n be a function of m, and let $\{f : \{-1,1\}^{n(m)} \to \{-1,1\}\}_{m\in\mathbb{N}}$ be a family of functions. Let $\gamma \in [2^{-m}, 1/3]$, $\varepsilon > 0$, $M > 0$, and $k \in \mathbb{N}$ be such that k is even and*

$$\varepsilon \leq \frac{\gamma}{2} - \frac{\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1} \text{ and} \tag{1}$$

$$\frac{\varepsilon}{M} \geq \frac{\eta^{k+1}}{2(1-\eta)^m}\binom{m}{k+1}. \tag{2}$$

If $\mathrm{adeg}_{1-\eta}(f) > d \geq 1$ then for sufficiently large m, every (M,ε)-SBQP approximation to $F = \mathsf{AND}_m \circ f^m$ has degree $\Omega(d \cdot (\delta_{\mathsf{AND}}\sqrt{m\log(1/\gamma)} - k))$.

Proof. Fix n, $\eta \in (0,1]$, $f : \{-1,1\}^n \to \{-1,1\}$, $d \geq 1$, and suppose $\mathrm{adeg}_{1-\eta}(f) > d$. Suppose γ, ε, M, and k are such that equations 1 and 2 hold. By Lemma 8, it suffices to construct a relaxed $(M, \varepsilon, \Omega(d \cdot (\delta_{\mathsf{AND}}\sqrt{m\log(1/\gamma)} - k)))$-SBQP dual Φ to F.

By Theorems 4 and 9 there is a dual witness $\psi : \{-1,1\}^m \to \mathbb{R}$ for $\mathrm{adeg}^-_\gamma(\mathsf{AND}_m) \geq \delta_{\mathsf{AND}}\sqrt{m\log(1/\gamma)}$. Similarly, there is a dual $\varphi : \{-1,1\}^n \to \mathbb{R}$ witnessing $\mathrm{adeg}_{1-\eta}(f)$. Let $\widetilde{\mu}$ be the distribution on $\{-1,1\}^n$ with probability mass function $\widetilde{\mu}(y) = |\varphi(y)|$, and let μ be a distribution consisting of m independent samples from $\widetilde{\mu}$. For every $z \in \{-1,1\}^m$ define μ_z to be μ conditioned on $(\ldots, \operatorname{sgn}\varphi(x_i), \ldots) = z$.

Note that $\mathbb{E}_{y\sim\widetilde{\mu}}[\operatorname{sgn}\varphi(y)] = \sum_{y\in\{-1,1\}^n} |\varphi(y)| \operatorname{sgn}\varphi(y) = \langle\varphi, \chi_\emptyset\rangle$. Since φ has pure high degree $d \geq 1$, $\langle\varphi,\chi_\emptyset\rangle = 0$ and so $\Pr_{y\sim\widetilde{\mu}}[\varphi(y) > 0] = \Pr_{y\sim\widetilde{\mu}}[\varphi(y) < 0]$. In other words, if $y \sim \widetilde{\mu}$, then $\operatorname{sgn}\varphi(y)$ is a uniformly random bit. Consequently, if $x \sim \mu$, then $(\ldots, \operatorname{sgn}\varphi(x_i), \ldots)$ is uniformly distributed over $\{-1,1\}^m$.

Since φ is a dual for $\mathrm{adeg}_{1-\eta}(f) > d$, $\langle\varphi, f\rangle \geq 1-\eta$. Thus $1-\eta \leq \sum_{y\in\{-1,1\}^n} f(y)\varphi(y) = \mathbb{E}_{y\sim\widetilde{\mu}}[f(y)\operatorname{sgn}\varphi(y)]$. Notice that for all y, $\frac{1-f(y)\operatorname{sgn}\varphi(y)}{2}$ is equal to 1 if $\operatorname{sgn}\varphi(y) \neq f(y)$ and 0 otherwise. Thus

$$\Pr_{y\sim\mu}[\operatorname{sgn}\varphi(y) \neq f(y)] = \mathop{\mathbb{E}}_{y\sim\widetilde{\mu}}\left[\frac{1-f(y)\operatorname{sgn}\varphi(y)}{2}\right] \leq \frac{\eta}{2}.$$

Now define

$$\eta^+ = \Pr_{y\sim\mu}[f(y) \neq \operatorname{sgn}\varphi(y) \mid \varphi(y) > 0],$$
$$\eta^- = \Pr_{y\sim\mu}[f(y) \neq \operatorname{sgn}\varphi(y) \mid \varphi(y) < 0],$$

and $\alpha : \{-1,1\}^n \to [-1,1]$ as

$$\alpha(y) = \begin{cases} \frac{1-2\eta+\eta^-}{1-\eta^-} & \text{if } f(y) = \operatorname{sgn}\varphi(y) = -1 \\ \frac{1-2\eta+\eta^+}{1-\eta^+} & \text{if } f(y) = \operatorname{sgn}\varphi(y) = 1 \\ -1 & \text{otherwise.} \end{cases}$$

The range of α is $[-1,1]$ because $\max\{\eta^+,\eta^-\} \leq \eta$, which holds since $1-\eta \leq 2\Pr_{y\sim\widetilde{\mu}}[\operatorname{sgn}\varphi(y) \neq f(y)] = \frac{1}{2}(1-2\eta^+) + \frac{1}{2}(1-2\eta^-)$. For $x \in (\{-1,1\}^n)^m$, we write $\alpha^m(x)$ to mean $(\ldots, \alpha(x_i), \ldots)$. Note that for $z \in \{-1,1\}^m$ and $i \in [m]$, $\mathbb{E}_{x\sim\mu_z}[\alpha(x_i)] = 1-2\eta$.

We are now ready to present the dual. Let $p_k : [-1,1]^m \to [0,\infty)$ be the degree-k multilinear polynomial given by Lemma 10. Our relaxed SBQP dual $\Phi : (\{-1,1\}^n)^m \to \mathbb{R}$ is defined as

$$\Phi(x_1,\ldots,x_m) = \frac{2^m}{p_k(\ldots,1-2\eta,\ldots)} \cdot \psi(\ldots,\operatorname{sgn}\varphi(x_i),\ldots) \cdot p_k(\alpha^m(x)) \prod_{i=1}^m |\varphi(x_i)|.$$

As we now describe, the required correlation, ℓ_1 norm, and pure high degree properties follow from the corresponding claims in [38]. First, [38, Claim 6.3] tells us that

$$\langle F, \Phi \rangle \geq \gamma - \frac{2\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1} \geq 2\varepsilon,$$

where the last inequality applies Eq. 1. That $\|\Phi\|_1 = 1$ follows from [38, Claim 6.2]. Finally, [38, Eq. 6.7] and the fact that ψ has pure high degree at least $\delta_{\mathsf{AND}}\sqrt{m\log(1/\gamma)}$ implies that Φ has pure high degree $\Omega(d \cdot (\delta_{\mathsf{AND}}\sqrt{m\log(1/\gamma)} - k))$.

It remains to show that Φ does not place too much mass on -1 instances that it "misclassifies." Notice that the only term in the definition of Φ that is not non-negative is $\psi(\ldots, \operatorname{sgn}\varphi(x_i), \ldots)$. For convenience, let $\beta = p_k(\ldots, 1-2\eta, \ldots)$. We can write the error on -1 instances as

$$\begin{aligned}
&\sum_{x:F(x)=-1,\Phi(x)>0} \Phi(x) = \sum_{x\in(\{-1,1\}^n)^m} \Phi(x)\cdot \mathbb{1}[F(x)=-1 \wedge \Phi(x)>0] \\
&= \frac{2^m}{\beta} \sum_{x\in(\{-1,1\}^n)^m} \psi(\ldots,\operatorname{sgn}\varphi(x_i),\ldots)\cdot p_k(\alpha^m(x_i))\cdot \mathbb{1}[F(x)=-1\wedge\Phi(x)>0]\prod_{i=1}^m |\varphi(x_i)| \\
&= \frac{2^m}{\beta} \mathop{\mathbb{E}}_{x\sim\mu}\left[\psi(\ldots,\operatorname{sgn}\varphi(x_i),\ldots)\cdot p_k(\alpha^m(x))\cdot \mathbb{1}[F(x)=-1\wedge\Phi(x)>0]\right] \\
&= \frac{1}{\beta} \sum_{z\in\{-1,1\}^m} \mathop{\mathbb{E}}_{x\sim\mu_z}\left[\psi(z)\cdot p_k(\alpha^m(x))\cdot \mathbb{1}[F(x)=-1\wedge\psi(z)>0]\right] \\
&= \frac{1}{\beta} \sum_{z:\psi(z)>0} \psi(z) \mathop{\mathbb{E}}_{x\sim\mu_z}\left[p_k(\alpha^m(x))\cdot \mathbb{1}[F(x)=-1]\right]. \qquad (3)
\end{aligned}$$

The second-to-last equality holds since $\Pr_{x\sim\mu}[(\ldots,\operatorname{sgn}\varphi(x_i),\ldots)=z] = 2^{-m}$. Fix z. By multilinearity of p_k, $\mathbb{E}_{x\sim\mu_z}[p_k(\alpha^m(x))] = \beta$. Thus,

$$\begin{aligned}
&\left|\mathop{\mathbb{E}}_{x\sim\mu_z}\left[p_k(\alpha^m(x))\cdot\mathbb{1}[F(x)=-1]\right] - \beta\cdot\mathbb{1}[\mathsf{AND}_m(z)=-1]\right| \\
&\qquad = \left|\mathop{\mathbb{E}}_{x\sim\mu_z}\left[p_k(\alpha^m(x))\cdot\mathbb{1}[F(x)=-1] - p_k(\alpha^m(x))\cdot\mathbb{1}[\mathsf{AND}_m(z)=-1]\right]\right| \\
&\qquad \leq \mathop{\mathbb{E}}_{x\sim\mu_z}\left[\,|p_k(\alpha^m(x))|\cdot\left|\mathbb{1}[F(x)=-1] - \mathbb{1}[\mathsf{AND}_m(z)=-1]\right|\right].
\end{aligned}$$

Recall that $F(x) = \mathsf{AND}_m(\ldots, f(x_i), \ldots)$. So $|\mathbb{1}[F(x)=-1] - \mathbb{1}[\mathsf{AND}_m(z)=-1]|$ is 1 when exactly one of $(\ldots, f(x_i), \ldots)$ and z is equal to $-\mathbf{1}_m$ and 0 otherwise. By the non-negativity of p_k on inputs in $[-1,1]^m$, it follows that

$$\begin{aligned}
&\left|\mathop{\mathbb{E}}_{x\sim\mu_z}\left[p_k(\alpha^m(x))\cdot\mathbb{1}[F(x)=-1]\right] - \beta\cdot\mathbb{1}[\mathsf{AND}_m(z)=-1]\right| \\
&\qquad \leq \mathop{\mathbb{E}}_{x\sim\mu_z}\left[p_k(\alpha^m(x))\cdot\mathbb{1}[(\ldots,f(x_i),\ldots)\neq z]\right] \\
&\qquad = \mathop{\mathbb{E}}_{x\sim\mu_z}\left[p_k(\alpha^m(x))\cdot\big(1-\mathbb{1}[(\ldots,f(x_i),\ldots)=z]\big)\right] \\
&\qquad = \beta - \mathop{\mathbb{E}}_{x\sim\mu_z}\left[p_k(\alpha^m(x))\cdot\mathbb{1}[(\ldots,f(x_i),\ldots)=z]\right].
\end{aligned}$$

Now [38, Eq. 6.8] shows that

$$\mathop{\mathbb{E}}_{x\sim\mu_z}\left[p_k(\alpha^m(x))\cdot\mathbb{1}[(\ldots,f(x_i),\ldots)=z]\right] \geq (1-\eta)^m p_k(\mathbf{1}_m),$$

which means

$$\left| \mathop{\mathbb{E}}_{x\sim\mu_z} \left[p_k(\alpha^m(x)) \cdot \mathbb{1}[F(x) = -1] \right] - \beta \cdot \mathbb{1}[\mathsf{AND}_m(z) = -1] \right| \leq \beta - (1-\eta)^m p_k(\mathbf{1}_m).$$

Combining this bound with Eq. 3, we get

$$\begin{aligned} \sum_{x:F(x)=-1,\Phi(x)>0} \Phi(x) &\leq \frac{1}{\beta} \sum_{z:\psi(z)>0} \psi(z)\big(\beta \cdot \mathbb{1}[\mathsf{AND}_m(z) = -1] + \beta - (1-\eta)^m p_k(\mathbf{1}_m)\big) \\ &= \left(\sum_{z:\psi(z)>0} \psi(z) \right) \left(1 - \frac{(1-\eta)^m p_k(\mathbf{1}_m)}{\beta} \right) \\ &= \frac{1}{2} \left(1 - \frac{(1-\eta)^m p_k(\mathbf{1}_m)}{\beta} \right). \end{aligned}$$

The second-to-last equality uses the one-sidedness of ψ: whenever $\mathsf{AND}_m(z) = -1$, $\psi(z) < 0$. The last equality uses the fact that ψ is balanced.

Now let Π be a distribution on $\{-1,1\}^m$ where each coordinate is an independent, uniformly random element of $\{-1,1\}$. Then by multilinearity, $\mathbb{E}_{z\sim\Pi}[p_k(z)] = \beta$. By Lemma 10,

$$\begin{aligned} \frac{(1-\eta)^m p_k(\mathbf{1}_m)}{\beta} &\geq \left(1 + \frac{\eta^{k+1}}{(1-\eta)^m} \binom{m}{k+1} \right)^{-1} \\ &\geq 1 - \frac{\eta^{k+1}}{(1-\eta)^m} \binom{m}{k+1}. \end{aligned}$$

Plugging this back in and using Eq. 2,

$$\sum_{x:F(x)=-1,\Phi(x)>0} \Phi(x) \leq \frac{\eta^{k+1}}{2(1-\eta)^m} \binom{m}{k+1} \leq \frac{\varepsilon}{M}.$$ ◀

The ensuing corollaries apply Theorem 11 with specific parameters to obtain more "user-friendly" connections between the approximate degree of f and the SBQP degree of $\mathsf{AND}_m \circ f^m$.

▶ **Corollary 12.** *Let n be a function of m, and let $\{f : \{-1,1\}^{n(m)} \to \{-1,1\}\}_{m\in\mathbb{N}}$ be a family of functions. Let $c > 0$ be a constant, $d \geq 1$, and $\varepsilon \in [2^{-m-2}, 1/12]$ such that either $c \geq 1$ or $\varepsilon = 2^{-\Omega(m)}$. If $\widetilde{\deg}_{1-\frac{1}{m^c}}(f) > d$, then there exists a constant $\tau > 0$ such that for sufficiently large m, every (M,ε)-SBQP approximation to $F = \mathsf{AND}_m \circ f^m$ with $M \leq \varepsilon 2^{\tau\sqrt{m\log(1/\varepsilon)}\log m}$ must have degree $\Omega(d\sqrt{m\log(1/\varepsilon)})$. The constant τ depends only on c when $c \geq 1$, and on c as well as the constant in the Ω when $c \in (0,1)$ but $\varepsilon = 2^{-\Omega(m)}$.*

Proof. Let n, f, c, d, and ε be as in the corollary statement. Let $\tau > 0$ be a constant to be set later in this proof. We apply Theorem 11 with

$$\begin{aligned} \eta &= \frac{1}{m^c}, \\ \gamma &= 4\varepsilon, \\ M &= \varepsilon 2^{\tau\sqrt{m\log(1/\varepsilon)}\log m}, \text{ and} \\ k &= \text{the least even number greater than } \frac{\delta_{\mathsf{AND}}\sqrt{m\log(1/\gamma)}}{2}. \end{aligned}$$

This will imply that every (M,ε)-SBQP approximation to $\mathsf{AND}_m \circ f^m$ has degree at least $\Omega(d \cdot (\delta_{\mathsf{AND}}\sqrt{m\log(1/\gamma)} - k)) = \Omega(d\sqrt{m\log(1/\varepsilon)})$. The lower bound extends to smaller M immediately since an (M',ε)-SBQP approximation with $M' < M$ is also an (M,ε)-SBQP approximation.

We now get an upper bound on the quantity $\frac{\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1}$, which will allow us to show that the premises of Theorem 11 are satisfied. First, suppose $c \geq 1$. We have $(1-\eta)^m = ((1-1/m^c)^{m^c})^{m^{1-c}}$. For large m, this is at least $(1/2e)^{m^{1-c}} \geq 1/2e$. By Theorem 9 there is a universal constant C such that $k \geq C\sqrt{m\log(1/\gamma)}$. We have

$$\frac{\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1} \leq 2e \cdot m^{-c\,(k+1)} \cdot m^{k+1} = 2em^{-(c-1)(k+1)} = 2^{-\Omega(k\log m)}.$$

The last bound holds because $c \geq 1$ and hence $m^{-(c-1)(k+1)} = 2^{-\Omega(k\log m)}$.

Now suppose $c \in (0,1)$ but $\varepsilon = 2^{-\Omega(m)}$. Since $\gamma = 4\varepsilon$, there is a constant $C_1 \in (0,1]$ such that $\gamma = 2^{-C_1 m}$. Also, $k+1 \leq C_2 m$ for an appropriate constant $C_2 \in (0,1)$ that depends on δ_{AND} and C_1. Using Stirling's approximation,

$$\begin{aligned}
\frac{\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1} &\leq \frac{m^{-c\,(k+1)}}{(1-m^{-c})^m}\left(\frac{me}{k+1}\right)^{k+1} \\
&= \frac{(m^c)^{m-(k+1)}}{(m^c-1)^m}\left(\frac{e}{C_2}\right)^{C_2 m} \\
&= \exp_2\left((1-C_2)cm\log m - m\log(m^c-1) + C_2 m\log(e/C_2)\right) \\
&= 2^{-\Omega(m\log m)} = 2^{-\Omega(k\log m)},
\end{aligned}$$

where the last bound holds since for large m, $(1-C_2)cm\log m < m\log(m^c+1)$.

Thus in either case, it follows from $k \geq \frac{\delta_{\mathsf{AND}}}{2}\sqrt{m\log(1/\gamma)}$ that for sufficiently large m, $\frac{\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1} \leq \gamma/4$. Thus $\frac{\gamma}{2} - \frac{\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1} \geq \frac{\gamma}{4} = \varepsilon$, which establishes Eq. 1.

Eq. 2 holds similarly. Since $k \geq \frac{\delta_{\mathsf{AND}}}{2}\sqrt{m\log(1/\gamma)} \geq C_3\sqrt{m\log(1/\varepsilon)}$ (for an appropriate universal constant C_3), there exists τ' such that

$$\frac{\eta^{k+1}}{2(1-\eta)^m}\binom{m}{k+1} \leq 2^{-\tau' C_3\sqrt{m\log(1/\varepsilon)}\log m}.$$

Setting $\tau = \tau' \cdot C_3$, this quantity is at most ε/M. ◀

▶ **Corollary 13.** *Let n be a function of m, and let $\{f : \{-1,1\}^{n(m)} \to \{-1,1\}\}_{m\in\mathbb{N}}$ be a family of functions. If $\mathrm{adeg}_{1/3}(f) > d \geq 1$, then for sufficiently large m, every $(2^{m-1}, 2^{-m-2})$-SBQP approximation to $F = \mathsf{AND}_m \circ f^m$ must have degree $\Omega(dm)$.*

Proof. By standard error reduction techniques (see, e.g., [13, Section 3.4]), it is possible to transform any degree-k 0.99-approximation to f into a degree-$O(k)$ 1/3-approximation to f. Thus it suffices to prove the corollary assuming $\mathrm{adeg}_{0.99}(f) > d \geq 1$; the corollary as stated follows with at the cost of a constant factor in the degree lower bound.

We use the well-known fact that $\mathrm{adeg}^{-}_{2^{-m}}(\mathsf{AND}_m) \geq m$ (note the absence of a constant factor); the dual witness justifying this is simply the normalized parity function on m bits. Let $f : \{-1,1\}^n \to \{-1,1\}$ be such that $\mathrm{adeg}_{0.99}(f) > d \geq 1$. We apply Theorem 11 with

$$\eta = \frac{1}{100},$$
$$\gamma = 2^{-m},$$
$$\varepsilon = 2^{-m-2},$$
$$M = 2^{m-1}, \text{ and}$$
$$k = \frac{m}{2} - 1.^{2}$$

By Stirling's approximation,

$$\begin{aligned}\frac{\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1} &\le \frac{1}{100^{k+1}} \cdot \frac{100^m}{99^m} \cdot \left(\frac{me}{k+1}\right)^{k+1} \\ &= \frac{100^{m/2}}{99^m} \cdot (2e)^{m/2} && (k+1 = m/2) \\ &= \left(\frac{\sqrt{200e}}{99}\right)^m \le 2^{-2m}. && (\sqrt{200e}/99 \le 1/4)\end{aligned}$$

Thus for large m,

$$\frac{\gamma}{2} - \frac{\eta^{k+1}}{(1-\eta)^m}\binom{m}{k+1} \ge 2^{-m-1} - 2^{-2m} \ge 2^{-m-2} = \varepsilon \text{ and}$$
$$\frac{\eta^{k+1}}{2(1-\eta)^m}\binom{m}{k+1} \le 2^{-2m-1} = \frac{\varepsilon}{M},$$

satisfying the premises of Theorem 11. ◀

4 QMA^{dt} Lower Bounds

In this section, we apply Corollaries 12 and 13 to obtain various QMA^{dt} lower bounds. Our proofs rely on the following connection between QMA^{dt} protocols and SBQP approximations.

▶ **Lemma 14.** *If $f : \{-1,1\}^n \to \{-1,1\}$ has a* QMA^{dt} *protocol with witness length w and query complexity q, then for every $\varepsilon > 0$ there is an $O(q \cdot \max\{w, \log(1/\varepsilon)\})$-degree polynomial that $(2^{w+2}, \varepsilon)$-SBQP approximates f.*

Proof. Suppose f has a QMA^{dt} protocol with witness length w and query complexity q. Fix $\varepsilon > 0$, and let $\nu = \min\{\frac{\varepsilon}{2}, 2^{-2w}\}$. By Theorem 6, there is a QMA^{dt} protocol P for f with completeness and soundness error at most ν, witness length w, and query complexity $O(q \log(1/\nu))$. Let Q be the witness-free protocol that simulates P with the maximally mixed state as the witness and accepts if and only if P outputs -1. By soundness of P, whenever $f(x) = 1$, $\Pr_Q[Q^x \text{ accepts}] \le \nu$. On the other hand, on inputs where $f(x) = -1$, the probability that Q accepts is at least $(1-\nu)2^{-w} \ge (1-2^{-2w})2^{-w} \ge 2^{-w-1}$.

Let $\widetilde{p}$ be the $O(q \log(1/\nu))$-degree polynomial computing the acceptance probability of Q. Define $p = 1 - 2 \cdot 2^{w+1}\widetilde{p}$. The degree of p is $O(q \log(1/\nu)) = O(q \cdot \max\{w, \log(1/\varepsilon)\})$.

1. If $f(x) = -1$ then $2^{w+1}\widetilde{p}(x) \in [1, 2^{w+1}]$ and so $p(x) \in [1 - 2^{w+2}, -1] \subset [-2^{w+2} - 1 - \varepsilon, -1 + \varepsilon]$.
2. If $f(x) = 1$ then $2^{w+1}\widetilde{p}(x) \in [0, \nu]$ and so $p(x) \in [1 - 2\nu, 1] \subset [1 - \varepsilon, 1 + \varepsilon]$. ◀

[2] We assume for simplicity of exposition that k is an even natural number. The case where $m/2 - 1$ is not an even number follows by setting k to the least even number greater than $m/2 - 1$.

4.1 The QMA^{dt} Complexity of Batch Verification

Our first lower bound exhibits a smooth tradeoff between witness length and query complexity of batch verifying functions with high large-error approximate degree.

▶ **Theorem 15.** *Let n be a function of m, and $\{f : \{-1,1\}^{n(m)} \to \{-1,1\}\}_{m\in\mathbb{N}}$ be an arbitrary family of functions. For all sufficiently large m, if $\mathrm{adeg}_{1-1/m}(f) > d \geq 1$ then every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length $w = O(m)$ requires $\Omega(d\sqrt{m/w})$ queries.*

Proof. Fix $n(m)$ and $f : \{-1,1\}^{n(m)} \to \{-1,1\}$. Assume $\mathrm{adeg}_{1-1/m}(f) > d \geq 1$. Suppose there is a $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length $w = O(m)$ and query complexity q. We assume that $w \geq \log(12)$; the case where $w < \log(12)$ follows immediately with a smaller constant in the Ω. Let $\varepsilon = \max\{2^{-w}, 2^{-m-2}\} \in [2^{-m-2}, 1/12]$. The premises of Corollary 12 are satisfied with $c = 1$. Thus, by Corollary 12, there exists a constant τ such that every (M,ε)-SBQP approximation to $\mathsf{AND}_m \circ f^m$ with $M \leq \varepsilon 2^{\tau\sqrt{m\log(1/\varepsilon)\log m}}$ has degree $\Omega(d\sqrt{m\log(1/\varepsilon)})$.

By Lemma 14, there is a degree-$O(qw)$ polynomial p that $(2^{w+2},\varepsilon)$-SBQP approximates $\mathsf{AND}_m \circ f^m$. Since $\log(1/\varepsilon) = \Omega(w)$, we have $\tau\sqrt{m\log(1/\varepsilon)}\log m = \Omega(\sqrt{mw}\log m)$. Thus for large m, $2^{w+2} \leq \varepsilon 2^{\tau\sqrt{m\log(1/\varepsilon)\log m}}$. So $O(qw) = \deg(p) = \Omega(d\cdot\sqrt{m\log(1/\varepsilon)}) = \Omega(d\sqrt{mw})$. Rearranging yields the desired lower bound. ◀

Observe that the proof of Theorem 15 can actually tolerate witness lengths all the way up to $\tau' m\log m$ for some fixed constant $\tau' \in (0,1)$. Roughly speaking, it shows that whenever $w \leq \tau' m\log m$, any $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length w must have query complexity at least $\Omega(\mathrm{adeg}_{1-1/m}(f)\sqrt{m/w})$. Combining this observation with Theorem 5 we show that even a constant-factor improvement in witness length over the trivial protocol for batch verifying DNFs incurs a large increase in query complexity.

▶ **Corollary 16.** *For all sufficiently large n and all $\delta > 0$ there exists an explicitly given function $f : \{-1,1\}^n \to \{-1,1\}$ computable by a polynomial-size, constant-width DNF and a constant $k \in \mathbb{N}$ such that for all $m = n^{O(1)} \leq n$, the following hold.*

1. *There is a $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length $km\log n$ and query complexity $O(k\sqrt{m})$.*
2. *There is a constant $\tau' \in (0,1)$ such that every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length at most $\tau' m\log n$ must have query complexity $\min\{\Omega(n^{1-\delta}\sqrt{m/w}), \Omega(n^{1-\delta}m/w)\}$.*

Proof. By Theorem 5 for every n and $\delta > 0$ there exists an explicitly given function $f : \{-1,1\}^n \to \{-1,1\}$ computable by a polynomial-size, constant-width DNF such that $\mathrm{adeg}_{1-1/n}(f) > n^{1-\delta}$. Let $k \in \mathbb{N}$ be a constant such that the DNF computing f has width at most k and size a most n^k. Henceforth we refer to f and the DNF computing it interchangeably. Let $m = n^a$ for some constant $a \in (0,1]$. Consider the following $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$.

1. The witness consists of indices $i_1, i_2, \ldots, i_m \in ([n^k])^m$ such that the i_jth term in the jth copy of f is satisfied.
2. The verifier, given query access to x and the witness $(i_1, i_2, \ldots, i_m)$ uses Grover's search algorithm to look for $j \in [m]$ such that the i_jth term of the jth copy of f is not satisfied.
3. If such an index is found, the verifier rejects. Else, it accepts.

If $(\mathsf{AND}_m \circ f^m)(x) = -1$ then the verifier, given the honest witness, will not find an unsatisfied term among those indicated by the witness. Thus the protocol has perfect completeness. If $(\mathsf{AND}_m \circ f^m)(x) = 1$ then there must be some j such that the jth copy of f is not satisfied.

It follows that none of the terms of f are satisfied in that copy, and so given any witness $(i_1, i_2, \ldots, i_m)$ the i_jth term of the jth copy of f will not be satisfied. By properties of Grover search, the verifier finds that index and rejects with probability $2/3$. Thus the protocol is sound. The witness length of the protocol is at most $km \log n$ since each term requires $k \log n$ bits to describe. Whether or not each term is satisfied can be computed exactly with k queries. One can thus implement the search over these checks with $O(k\sqrt{m})$ queries using standard techniques (see, e.g., [21]). This proves the upper bound.

The lower bound holds due to the proof of Theorem 15. Since $m \leq n$, $\widetilde{\deg}_{1-1/m}(f) \geq \widetilde{\deg}_{1-1/n}(f) > n^{1-\delta}$. For convenience, let $d = n^{1-\delta}$. Setting $\varepsilon = \max\{2^{-w}, 2^{-m-2}\}$, we can apply Corollary 12 as in the proof of Theorem 15. This yields a constant τ such that every (M, ε)-SBQP approximation to $\mathsf{AND}_m \circ f^m$ with $M \leq \varepsilon 2^{\tau\sqrt{m \log(1/\varepsilon)} \log m}$ must have degree $\Omega(d\sqrt{m \log(1/\varepsilon)}) = \Omega(d\sqrt{m \cdot \min\{m, w\}})$. Due to our setting of ε and m, there exists a constant $\tau'' > 0$ such that the degree lower bound holds for all (M, ε)-SBQP approximations with $M \leq 2^{\tau'' a\sqrt{m \cdot \min\{m-w\}} \log n}$. Set $\tau' = \tau'' a/2$. Suppose there is a $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length $w \leq \tau' m \log n$. Then by Lemma 14 there is a $(2^{w+2}, \varepsilon)$-SBQP approximation to $\mathsf{AND}_m \circ f^m$ with degree $O(q \min\{w, \max\{w, m\}\}) = O(qw)$. Combining the upper and lower bounds, $q = \Omega(d\sqrt{m \cdot \min\{m, w\}}/w) = \min\{\Omega(d\sqrt{m/w}), \Omega(dm/w)\}$. ◀

Our techniques also allow us to get query complexity lower bounds for batch verifying f from lower bounds on $\widetilde{\deg}_{1-1/m^c}(f)$ for arbitrarily small constants $c > 0$ and on $\widetilde{\deg}_{1/3}(f)$.

▶ **Theorem 17.** *Let n be a function of m and let $\{f : \{-1,1\}^{n(m)} \to \{-1,1\}\}_{m \in \mathbb{N}}$ be an arbitrary family of functions. The following statements hold for all sufficiently large m.*

1. *For every $c > 0$, if $\widetilde{\deg}_{1-1/m^c}(f) > d \geq 1$ then every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length at most $O(m)$ requires $\Omega(d)$ queries.*
2. *If $\widetilde{\deg}_{1/3}(f) > d \geq 1$ then every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length at most $m - 3$ requires $\Omega(d)$ queries.*

Proof.

(Part 1). Fix $c > 0$ and $f : \{-1,1\}^{n(m)} \to \{-1,1\}$. Assume $\widetilde{\deg}_{1-1/m^c}(f) > d \geq 1$, and suppose there is a $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length $w = O(m)$ and query complexity q. Assume that $w \geq \log(12)$; the complementary case follows immediately. Let $\varepsilon = 2^{-m-2}$. By Corollary 12 there is a constant τ that depends only on c such that every (M, ε)-SBQP approximation to $\mathsf{AND}_m \circ f^m$ with $M \leq \varepsilon 2^{\tau\sqrt{m \log(1/\varepsilon)} \log m}$ must have degree $\Omega(d\sqrt{m \log(1/\varepsilon)}) = \Omega(dm)$.

By Lemma 14 there is a degree-$O(qm)$ polynomial that $(2^{w+2}, \varepsilon)$-SBQP approximates $\mathsf{AND}_m \circ f^m$. We have $\varepsilon 2^{\tau\sqrt{m \log(1/\varepsilon)} \log m} = 2^{\Omega(m \log m)} \geq 2^{O(m)} = 2^{w+2}$. So we must have $O(qm) = \deg(p) = \Omega(dm)$, which implies $q = \Omega(d)$ as claimed.

(Part 2). Suppose $\widetilde{\deg}_{1/3}(f) > d \geq 1$, and suppose there is a $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ f^m$ with witness length $w \leq m - 3$ and query complexity q. By Corollary 13, for sufficiently large m, every $(M, 2^{-m-2})$-SBQP approximation with $M \leq 2^{m-1}$ must have degree $\Omega(dm)$. By Lemma 14 there is a degree-$O(qm)$ polynomial that $(2^{w+2}, 2^{-m-2})$-SBQP approximation to $\mathsf{AND}_m \circ f^m$. Since $w \leq m - 3$, $2^{w+2} \leq 2^{m-1}$. The query lower bound follows. ◀

4.2 $\mathrm{QMA}^{\mathrm{dt}}$ Lower Bounds for Natural Functions

Some functions have the property that they contain as sub-functions the problem of batch verifying smaller copies of themselves. For such functions, a lower bound on the $\mathrm{QMA}^{\mathrm{dt}}$ complexity of batch verification immediately implies a lower bound on the $\mathrm{QMA}^{\mathrm{dt}}$ complexity

of the functions themselves. In this subsection, we use this insight along with Theorem 17 to get $\mathrm{QMA}^{\mathrm{dt}}$ lower bounds for element distinctness, surjectivity, and k-distinctness. Our lower bounds make use of the observation by Sherstov and Thaler [41] that the surjectivity and k-element distinctness functions contain the batch verification problem for smaller instances of themselves as a subfunction.

▶ **Theorem 18.**

1. $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{AND}_m \circ \mathsf{OR}_n^m) = \Omega((mn)^{1/3})$. *Consequently,* $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{AND}_{n^{1/3}} \circ \mathsf{OR}_{n^{2/3}}^{n^{1/3}}) = \Omega(n^{1/3})$.
2. $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{SURJ}_n) = \widetilde{\Omega}(n^{3/7})$.
3. $\mathsf{QMA}^{\mathsf{dt}}(k\mathsf{ED}_n) = \widetilde{\Omega}(n^{\frac{3k-1}{7k-1}})$.

Before presenting the proof of our lower bounds, we briefly mention lower bounds that follow directly from prior work. For $\mathsf{AND}_{n^{1/3}} \circ \mathsf{OR}_{n^{2/3}}^{n^{1/3}}$, the best known lower bound is $\Omega(n^{1/6})$, which follows – via the connection between $\mathrm{QMA}^{\mathrm{dt}}$ complexity and threshold degree in [17] – from the fact that the threshold degree of $\mathsf{AND}_{n^{1/3}} \circ \mathsf{OR}_{n^{2/3}}^{n^{1/3}}$ is $\Omega(n^{1/3})$. For SURJ_n, the best known lower bound is $\widetilde{\Omega}(n^{1/4})$, due to a threshold degree lower bound of $\widetilde{\Omega}(\sqrt{n})$ [12]. Finally, for $k\mathsf{ED}_n$, we have $\mathsf{QMA}^{\mathsf{dt}}(k\mathsf{ED}_n) \geq \mathsf{QMA}^{\mathsf{dt}}(\mathsf{ED}_n) = \widetilde{\Omega}(n^{2/5})$, which was proved implicitly in [41].

Proof of Theorem 18.

(Part 1). Note that for every m' that divides m, $\mathsf{AND}_m \circ \mathsf{OR}_n^m = \mathsf{AND}_{m'} \circ (\mathsf{AND}_{m/m'} \circ \mathsf{OR}_n^{m/m'})^{m'}$. By a lower bound from Section 2, $\mathrm{adeg}(\mathsf{AND}_{m/m'} \circ \mathsf{OR}_n^{m/m'}) = \Omega(\sqrt{mn/m'})$. By Theorem 17, every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_{m'} \circ (\mathsf{AND}_{m/m'} \circ \mathsf{OR}_n^{m/m'})^{m'}$ with witness length at most $m' - 3$ must have query complexity $\Omega(\sqrt{mn/m'})$. Setting $m' = (mn)^{1/3}$, we get that every $\mathrm{QMA}^{\mathrm{dt}}$ protocol or $\mathsf{AND}_m \circ \mathsf{OR}_n^m$ either has witness length at least $(mn)^{1/3} - 3$ or query complexity $\Omega(\sqrt{mn/(mn)^{1/3}}) = \Omega((mn)^{1/3})$, which means $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{AND}_m \circ \mathsf{OR}_n^m) = \Omega((mn)^{1/3})$.

(Part 2). Set $R = N/2$ as is typical. Observe that for all m that divide $N/2$, $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{SURJ}_{N,R}) \geq \mathsf{QMA}^{\mathsf{dt}}(\mathsf{AND}_m \circ \mathsf{SURJ}_{N/m,R/m}^m)$. This is due to the fact that evaluating $\mathsf{AND}_m \circ \mathsf{SURJ}_{N/m,R/m}^m$ amounts to evaluating whether m different lists of numbers from $[R/m]$ each contain every $r \in [R/m]$. One way to do this is to, for all $i \in [m]$, add $(i-1)R/m$ to each number in the ith list, concatenate all the lists, and then evaluate $\mathsf{SURJ}_{N,R}$ on the concatenated list. It follows that any $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{SURJ}_{N,R}$ can be used to solve $\mathsf{AND}_m \circ \mathsf{SURJ}_{N/m,R/m}^m$ with no additional cost. Recall that $\mathrm{adeg}(\mathsf{SURJ}_{N/m,R/m}) = \widetilde{\Omega}((N/m)^{3/4})$. By Theorem 17, every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ \mathsf{SURJ}_{N/m,R/m}^m$ with witness length at most $m - 3$ must have query complexity $\widetilde{\Omega}((N/m)^{3/4})$. Setting $m = N^{3/7}$, every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ \mathsf{SURJ}_{N/m,R/m}^m$ must either have witness length at least $N^{3/7} - 3$ or query complexity at $\widetilde{\Omega}(N^{3/7})$. Hence $\mathsf{QMA}^{\mathsf{dt}}(\mathsf{SURJ}_n) = \widetilde{\Omega}(N^{3/7})$, which is $\widetilde{\Omega}(n^{3/7})$.

(Part 3). Like in the case of surjectivity, $\mathsf{QMA}^{\mathsf{dt}}(k\mathsf{ED}_{N,N}) \geq \mathsf{QMA}^{\mathsf{dt}}(\mathsf{AND}_m \circ k\mathsf{ED}_{N/m,N/m}^m)$. When one shifts the input to $\mathsf{AND}_m \circ k\mathsf{ED}_{N/m,N/m}^m$ as in part 2, the shifted input is a "yes" instance of $k\mathsf{ED}_{N,N}$ if and only if the original instance is a "yes" instance of $\mathsf{AND}_m \circ k\mathsf{ED}_{N/m,N/m}^m$. Recall that $\mathrm{adeg}(k\mathsf{ED}_{N/m,N/m}) = \widetilde{\Omega}((N/m)^{3/4-1/(4k)})$. So Theorem 17 tells us that every $\mathrm{QMA}^{\mathrm{dt}}$ protocol for $\mathsf{AND}_m \circ k\mathsf{ED}_{N/m,N/m}^m$ with witness length at most $m - 3$ must have query complexity $\widetilde{\Omega}((N/m)^{3/4-1/(4k)})$. Setting $m = n^{\frac{3k-1}{7k-1}}$ yields the desired lower bound. ◀

Good Locally Testable Codes with Small Alphabet and Small Query Size

Abstract

Ben-Sasson, Goldreich and Sudan [3] showed that a binary error correcting code admitting a 2-query tester cannot be good, i.e., it cannot have both linear distance and constant rate. They also showed that there are no good codes if the alphabet is a finite field $\mathbb{F}$, the code is $\mathbb{F}$-linear, and the 2-query tester is $\mathbb{F}$-linear. We show that those are essentially the only limitations on the existence of good locally testable codes (LTCs). That is, there are good 2-query LTCs on any alphabet with more than 2 letters, and good 3-query LTCs with a binary alphabet. Similarly, there are good 3-query $\mathbb{F}$-linear LTCs, and for every $\mathbb{F}$-vector space V of dimension greater than 1, there are good 2-query LTCs with alphabet V whose tester is $\mathbb{F}$-linear. This completely solves, for every $q \geq 2$ and alphabet (resp. $\mathbb{F}$-vector space) Σ, the question of whether there is a good q-query LTC (resp. $\mathbb{F}$-LTC) with alphabet Σ. Our proof builds on the recent good 2-query $\mathbb{F}$-LTCs of the first author and Kaufman [11], by establishing a general method for reducing the alphabet size of a good low-query LTC.

1 Introduction

Throughout, Σ is a (finite) alphabet and $\mathbb{F}$ is a finite field. We let $C \subseteq \Sigma^n$ be an error correcting code, which we think of as ranging in an infinite family of codes with block length tending to infinity. The normalized Hamming distance in Σ^n is denoted $\delta(\cdot,\cdot)$. We recall other relevant coding theory terminology in Section 2.

Informally, the code $C \subseteq \Sigma^n$ is said to be a locally testable code (LTC) if it admits a randomized algorithm – called a *tester* – that can estimate with high probability whether a word $w \in \Sigma^n$ is far from C or not by reading only a constant number of letters from w. Formally, we require the tester for C to read at most q letters from w, accept all words in C, and reject every $w \in \Sigma^n - C$ with probability at least $\mu \cdot \delta(w, C)$ for some $\mu > 0$. Here, q and μ are independent of n and w. When we wish to specify the implicit constants q and μ, we will say that $C \subseteq \Sigma^n$ is a q-query LTC with soundness μ. Also, if not indicated otherwise, we assume that any tester is *non-adaptive*, i.e., it decides which positions to read from the input word before reading them.

The notion of an LTC arose in the 1990s from the many works on the developing theories of *property testing* and *probabilistically checkable proofs* (PCPs). It first appeared in print in [13, Dfn. 9] in a more lax version, in which the requirement that T rejects every $w \in \Sigma^n$ with probability at least $\mu \cdot \delta(w, C)$ was imposed only for words that are $\Omega(1)$-far from C. Such a codes are known as *weak LTCs*. The definition of LTCs which we use here, known as *strong LTCs*, originates from [15, Dfn. 2.2], which intitiated the systematic study of LTCs as objects of independent interest. See [14] for a more detailed history of how LTCs emerged.

Since their introduction, it was not clear whether there are LTCs that are also *good codes*, i.e., LTCs whose relative distance and rate is bounded away from 0; see [14, Open Problem 2], for example. Indeed, Ben-Sasson, Goldreich and Sudan [3] showed that there are no good 2-query LTCs on a binary alphabet, and no $\mathbb{F}$-linear 2-query LTCs. (Here, an LTC is said to be $\mathbb{F}$-linear if its alphabet is $\mathbb{F}$ and its tester checks $\mathbb{F}$-linear constraints.) Further limitations on 2-query LTCs and 3-query LTCs appeared in [6, 18]. See also [4]. Roughly at the same time, a series of works including [23, 8, 5, 25, 19, 16] established the existence of "almost" good LTCs (both weak and strong), e.g., LTCs with rate $\mathrm{poly}(\log n)^{-1}$ and constant relative distance, or good codes admitting a tester reading $(\log n)^{O(\log \log n)}$ letters. The existence of good LTCs was finally settled by Dinur–Evra–Livne–Lubotzky–Mozes [9] and Panteleev–Kalachev [22] (independently), who showed that good $\mathbb{F}$-linear LTCs (with large query size) do exist. Shortly after, the first author and Kaufman [11] (see also [12]) showed that there are also good 2-query LTCs (with a large alphabet). The latter codes are $\mathbb{F}$-LTCs, meaning that their alphabet is an $\mathbb{F}$-vector space, and their tester checks $\mathbb{F}$-linear constraints.

Main Results

In this work, we completely resolve the question of what are the integers $q \geq 2$ and alphabets Σ for which there exists a good q-query LTC (resp. $\mathbb{F}$-LTC) with alphabet Σ.

▶ **Theorem 1.** *Let $q \geq 2$ be an integer and let Σ be an alphabet.*

(i) *There exists a good q-query LTC with alphabet Σ if and only if $(q, |\Sigma|) \neq (2, 2)$.*

(ii) *Suppose Σ is an $\mathbb{F}$-vector space. Then there exists a good q-query $\mathbb{F}$-LTC with alphabet Σ if and only if $(q, \dim \Sigma) \neq (2, 1)$.*

Note that the non-existence statements of Theorem 1 were established by Ben-Sasson, Goldreich and Sudan [3]. Theorem 1 therefore says that the restrictions on the existence of good LTCs (resp. $\mathbb{F}$-LTCs) from [3] are actually the only restrictions.

We prove the existence part of Theorem 1 by introducing an alphabet reduction method for LTCs and applying it to the good 2-query $\mathbb{F}$-LTCs of [12, Thms. 9.7, 9.8] (see also [11, Cor. 7.2] where the construction is given for $\mathbb{F} = \mathbb{F}_2$). This is the content of the following two theorems, which together with [12, Thms. 9.7, 9.8] and [3] imply Theorem 1.

▶ **Theorem 2.** *If there exists a good 2-query LTC with a possibly adaptive tester on some alphabet Σ, then there exist*

(i) *a good 2-query LTC with alphabet Δ for every Δ having more than 2 letters, and*

(ii) *a good 3-query LTC with a binary alphabet.*

▶ **Theorem 3.** *If there exists a good 2-query $\mathbb{F}$-LTC, then there exist*

(i) *a good 2-query $\mathbb{F}$-LTC with alphabet Δ for every $\mathbb{F}$-vector space Δ with $\dim \Delta \geq 2$, and*

(ii) *a good 3-query $\mathbb{F}$-linear LTC.*

In both Theorem 2 and Theorem 3, the relative distance, rate and soundness of the LTCs promised by the theorem are at least proportional to the corresponding parameters of the given LTC. In Theorem 3, all the parameters are diminished by a factor that is at most polynomial in $|\Sigma|$, while in Theorem 2, that factor is at most exponential in $|\Sigma|$; see Theorems 28 and 29. However, if the LTC given in Theorem 2 is an $\mathbb{F}_2$-LTC, then the relative distance, rate and soundness are diminished only by a factor polynomial in $|\Sigma|$; see Theorem 30. If the randomness complexity of the given LTC's tester is $r(n)$ (a function of the block length n), then the randomness complexity of the promised LTC's tester is $\max\{r(n), \log_2 n\} + O(1)$; see Remark 32.

Analogous statements hold for q-query LTCs. Again, see Theorems 28 and 29.

We hope that our alphabet reduction results will find other uses.

▶ Remark 4. Some methods for reducing the number of queries of a good LTC are also known. Specifically, by [12, Thm. 3.11, Prop. 3.6], if there exists a good q-query LTC satisfying some assumptions (which are satisfied by the good LTCs of [9]) on alphabet Σ, then there exists a good 2-query LTC with alphabet $\Sigma' \subseteq \Sigma^q$. A different construction of this kind, which also needs assumptions on the LTC, appears in [25, Cor. 3.4]. It is further known that the existence of a good *weak* $\mathbb{F}$-linear LTC implies the existence of a good weak 3-query $\mathbb{F}$-linear LTC [6, Thm. A.1]. We do not know if there is a query complexity reduction method that works for a general good LTC.

Proof Idea

Our alphabet reduction method for LTCs (Theorems 2 and 3) is simple in nature and consists of concatenating[2] the given 2-query LTC $C \subseteq \Sigma^n$ with a special code $D \subseteq \Delta^k$ (which remains fixed as n grows) and showing that the concatenated code $C \circ D \subseteq \Delta^{nk}$ is also a good 2-query LTC. While concatenation is a well-known method for reducing a good code's alphabet size, it usually fails to preserve the property of being a 2-query LTC. The novelty of our approach is in showing that the inner code $D \subseteq \Delta^k$ (and the identification of Σ with D) can be chosen so that the property of being a 2-query LTC will persist.

Let us now explain in more detail how our concatenation approach works in the context of Theorem 2(i). To begin, let us first see why $C \circ D \subseteq \Delta^{nk}$ is in general not a 2-query LTC. Let T denote the 2-query tester of C, and choose some encoding function $f : \Sigma \to D \subseteq \Delta^k$. Then each codeword of $C \circ D$ has the form

$$f(w_1)f(w_2)\cdots f(w_n) \in \Delta^{nk}$$

for some $w \in C$. Let $u \in \Delta^{nk}$ and write $u = u_1 u_2 \cdots u_n$ with $u_1, \ldots, u_n \in \Delta^k$. A natural way to test whether u is in $C \circ D$ would be to try one of the following:

(1) Check that $u_i \in D$ for some $i \in [n]$;

(2) Emulate the tester T of C: run T to get two coordinates $i, j \in [n]$ to read, find the letters $a, b \in \Sigma$ satisfying $f(a) = u_i$, $f(b) = u_j$ (or reject if there are no such a, b), and return what T would have returned upon reading a and b in positions i and j.

A naive implementation of (1) and (2) requires making k or $2k$ queries to u, so the 2-query testability is seemingly lost.

[2] Concatenation of codes is recalled in Section 3.

We solve the large number of queries in (1) by requiring that $D \subseteq \Delta^k$ is defined by 2-letter constraints. Then, instead of checking whether $u_i \in D$, we check whether u_i satisfies a random 2-letter constraint. (Note that since $D \subseteq \Delta^k$ remains fixed as n grows, we do not need the stronger assumption that $D \subseteq \Delta^k$ is included in a family of codes that is a 2-query LTC.)

Reducing the number of queries in (2) is possible under special assumptions on T and f. Given a random seed s for T, denote by $i_s, j_s \in [n]$ the coordinates queried by T, and by $T^s(w)$ the output of T on $w \in \Sigma^n$ when given the seed s. What we need from T and f is that for every s, there are coordinates $i', j' \in [k]$ (depending on s) such that one can determine $T^s(w)$ – which depends only on w_{i_s} and w_{j_s} – from the i'-th letter of $f(w_{i_s})$ and the j'-th letter of $f(w_{j_s})$. In other words, writing $f_{i'} : \Sigma \to \Delta$ for the i'-th coordinate of f (so that $f(a) = (f_1(a), \ldots, f_k(a))$), we want to be able to determine $T^s(w)$ from $f_{i'}(w_{i_s})$ and $f_{j'}(w_{j_s})$ for some i', j' depending on s. When this holds for every seed s, we say that T is *f-compatible*; see Section 4 for details. Provided that T is f-compatible, we can emulate the action of T^s on $u = u_1 \cdots u_n$ by reading just two letters from u, namely, $(u_{i_s})_{i'}$ and $(u_{j_s})_{j'}$, and thus perform (2) using only 2 queries.

We show in Theorem 8 that if $D \subseteq \Delta^k$ is defined by 2-letter constraints and T is f-compatible, then the concatenated code $C \circ D$ is indeed a 2-query LTC. With this at hand, we need to find a code $D \subseteq \Delta^k$ and an encoding function $f : \Sigma \to D$ such that (i) T is f-compatible, and (ii) $D \subseteq \Sigma^k$ is defined by 2-letter constraints.

The code $D \subseteq \Delta^k$ that we choose for the task is a generalization of the *long code* of [2, §3]. Formally, letting $f_1, \ldots, f_k$ denote *all* the functions from Σ to Δ (so that $k = |\Delta|^{|\Sigma|}$), we choose D to be the code $L(\Sigma, \Delta) := \{(f_1(a), \ldots, f_k(a)) \mid a \in \Sigma\} \subseteq \Delta^k$ and take $f : \Sigma \to D$ to be the obvious encoding $f(a) = (f_1(a), \ldots, f_k(a))$. We call $L(\Sigma, \Delta)$ a *generalized long code*; the usual long code is the special case where $\Sigma = \{0,1\}^t$ and $\Delta = \{0,1\}$. The rationale behind this choice of D is that having any function $g : \Sigma \to \Delta$ in the collection $\{f_i\}_{i=1,\ldots,k}$ helps in securing that T is f-compatible. (This is still not enough to guarantee f-compatibility, and we solve this below.) The drawback of choosing D to be $L(\Sigma, \Delta)$ is that it *a priori* it does not fulfill the requirement of being defined by 2-letter constraints. We prove this nontrivial statement in Theorem 17 under the assumption $|\Delta| \geq 3$ (the hardest case is $|\Delta| = 3$). By contrast, the "usual" long code $L(\{0,1\}^t, \{0,1\})$ is *not* defined by 2-letter constraints; see Remark 20.

In order to finish, it remains to check that the tester T is f-compatible. We show in Proposition 23 that the f-compatibility of T is equivalent to another condition called *Δ-separability*. While this condition fails in general, we show in Theorem 26 that T can be replaced with a Δ-separable 2-query tester with soundness that is proportional to that of T. Conveniently, this replacement is also the usual trick to turn an adaptive tester into a nonadaptive tester, so we can also treat non-adaptive 2-query testers. After that replacement, we can finally conclude that the concatenated code $C \circ D \subseteq \Delta^{nk}$ is a 2-query LTC.

The proof of Theorem 3(i) follows a similar path except that we define $D \subseteq \Delta^k$ by choosing $f_1, \ldots, f_k$ to be all the $\mathbb{F}$-linear functions from Σ to Δ. This gives rise to what we call a *generalized Hadamard code*; see § 5.2. Similarly to the generalized long code, it can be defined by 2-letter constraints if and only if $\dim \Delta \geq 2$ (Theorem 16).

▶ Remark 5. Passing from $C \subseteq \Sigma^n$ to $C \circ D \subseteq \Delta^{nk}$ as described above scales down the soundness by a constant factor depending on Σ and D. There are three sources for this scale-down.

The first is the soundness of the 2-query tester for D (cf. (1) above) – we use the naive lower bound $\frac{1}{R}$ where R is the number of 2-letter constraints defining D; for the generalized long code this factor is $|\Delta|^{-O(|\Sigma|)}$. This can probably be improved significantly. That is,

when $|\Delta| \geq 3$, we expect that the generalized long code $L(\Sigma, \Delta) \subseteq \Delta^{|\Delta|^{|\Sigma|}}$ should have a 2-query tester with soundness that is *independent of* $|\Sigma|$. Similarly, in the linear case, we expect the generalized Hadamard code (§ 5.2) to have the same property when $\dim \Delta \geq 2$. We pose this as a problem.

The second source for loosing on the soundness is the block length k of $D \subseteq \Delta^k$. This $\frac{1}{k}$ factor comes up in the analysis of the tester of $C \circ D$, and is forced in situations in which the coordinates $i', j' \in [k]$ from the definition of f-compatibility (which are determined by the random seed of T) are very unevenly distributed. See Remark 9 for details and possible ways one might overcome it (which were not pursued in this work).

The final cause for loosing on the soundness is the replacement of T by a Δ-separable tester. In more detail, in the non-linear case, the trick is to first guess what are the two letters that will be read by T, and apply T only if these letters are actually encountered (otherwise accept the word). This multiplies the soundness by a factor of $|\Sigma|^{-2}$. We do not know how to avoid this factor in general. However, in the linear case, T is morally close to being Δ-separable (it is always Δ^m-separable for $m = \lceil \frac{2 \dim \Sigma}{\dim \Delta} \rceil$), and one can use a different trick which reduces the soundness by a factor of $O(\log |\Sigma|)$.

Relation to Other Works on Alphabet Reduction

Concatenation with the "ordinary" long code and Hadamard code was used in the literature for alphabet reduction in the construction of PCPs and 2-query LTCs. For example, in [8, §§7–8], resp. [20, §6.4], this technique is used to construct non-linear, resp. linear, weak 2-query LTCs having linear distance and inverse-polylogarithmic rate. The same method was pushed further in [25] to construct (strong) $\mathbb{F}_2$-linear 3-query LTCs (with a binary alphabet) and $\mathbb{F}_2$-LTCs with an 8-letter alphabet having similar distance and rate.

In a nutshell, the idea of these alphabet reductions is to encode both the letters and the constraints of the code; this is different from our approach which encodes only the letters. To explain this, let us describe an oversimplified version of the alphabet reduction of [8]: We start with a code $C \subseteq \Sigma^n$ having a 2-query tester T. Choose some embedding of Σ in $\{0,1\}^t$ and use it to view words in Σ^n as strings of tn bits. Think of T as checking at random one of (say) R 2-letter constraints which define $C \subseteq \Sigma^n$. Since $\Sigma \subseteq \{0,1\}^t$, every such constraint is a circuit on $2t$ bits. Now construct a new code $C' \subseteq \{0,1\}^N$ by modifying the codewords $w \in C$ as follows. First, view w as a tn-bit string using that $\Sigma \subseteq \{0,1\}^t$. Then, for each of the R constraints defining C, attach to w the long-code encoding of the $2t$ bits participating in that constraint.[3] This results in a string of $N = tn + 2^{2^{2t}} R$ bits, and we take C' to be the collection of all such strings. Since the long-code encoding of $2t$ bits includes the evaluation of any circuit on those bits, if $w' \in \{0,1\}^N$ is obtained from some $w \in \Sigma^n$ by the above procedure, then we can emulate the action of T on w by reading just 1 bit from w'. The long code[4] has two additional relevant properties. First, it has a 3-query tester. Second, it has a 2-local decodability property – if $y \in \{0,1\}^{2^{2^{2t}}}$ is close to the encoding of some $x \in \{0,1\}^{2t}$, then there is a randomized algorithm which can determine x_i with high probability by reading just 2 letters from y.[5] Using these properties and other mild assumptions, it can be shown that $C' \subseteq \{0,1\}^N$ has a 3-query tester with soundness

[3] This is a little different from [8, §7], where a certain puncturing of the long code is used.
[4] More precisely, its puncturing that is used in [8, §7].
[5] The algorithm: choose uniformly at random two functions $f, g : \{0,1\}^{2t} \to \{0,1\}$ such that $f + g$ is the i-th coordinate function $e_i : \{0,1\}^{2t} \to \{0,1\}$, and return $y_f + y_g$. See [8, Thm. 7.1] for a precise statement. See [20, Lem. 6.21] for a corresponding statement for the Hadamard code.

that is proportional to that of T. Briefly, the idea is that given $u \in \{0,1\}^N$, we can detect if u is very corrupted in its last $2^{2^{2t}}R$ bits (the long-code encoding of the constraints) using the 3-query tester of the long code. If that is not the case, then we can use the 2-local decodability property of the long code to check if the last $2^{2^{2t}}R$ bits of u are consistent with the first tn bits (this requires querying $2+1=3$ bits from u). When they are almost consistent, meaning that u is very close to a word coming from some $w \in \Sigma^n$, we can emulate T on w.

There are two reasons why we cannot use this alphabet reduction approach to prove our main results. First, the above construction increases the block length by $O(R)$, where $\log_2 R$ is the randomness complexity of T, while leaving the message length the same. Therefore, applying it to a good LTC would result in a good LTC only if $R = O(n)$, equiv. the randomness complexity of T is $\log n + O(1)$. By contrast, our alphabet reduction method (Theorems 2 and 3) makes no assumptions on the randomness complexity. Second, the alphabet reduction just described (loosely) relies on the fact that the long code (resp. Hadamard code) is 2-locally decodable, which is one reason why the resulting tester needs to query $2+1=3$ letters (the other reason is that the long code's tester queries 3 letters). If we were to use this approach to get a 2-query LTC, we would need to replace the long code with a 1-locally decodable code, and there are no such useful codes. That said, it seems likely that applying the alphabet reduction of [8], [20], [25] to a good 2-query LTC (or even any good LTC) whose tester has randomness complexity $\log_2(n) + O(1)$, e.g., those of [11] (or [9], [22]), would result in a good 3-query LTC on a binary alphabet.

Finally, in terms of soundness, the alphabet reduction of [8], etc. is more economical than ours as it decreases the soundness by a constant factor (independent of $|\Sigma|$); see Remark 5 for what causes the soundness loss in our alphabet reduction. As for rate and distance, our alphabet reduction reduces the rate by a smaller factor than that of *op. cit.*, and both alphabet reductions reduce the distance by a constant factor independent of $|\Sigma|$.

Organization

The paper is organized as follows: Section 2 is preliminary and recalls necessary definitions and facts about codes and testers. In Section 3, we recall concatenation of codes. In Section 4, we prove a theorem giving sufficient conditions for the concatentation of two codes to be a q-query LTC. The inner codes to which this result will be applied – the generalized long code and the generalized Hadamard code – are presented in Section 5. In that section, it is also shown that these codes are defined by 2-letter constraints. Section 6 is concerned with showing that one can replace the tester of any LTC by another tester to which our result about concatenation of LTCs can be applied. Finally, in Section 7, all previous results are combined to prove Theorems 2 and 3.

2 Preliminaries

2.1 General Conventions

Throughout this paper, $\mathbb{F}$ is a finite field, and $[n]$ denotes the set $\{1,\dots,n\}$. Vector spaces are over $\mathbb{F}$ and are assumed to be finite-dimensional. (Unlike some other texts, the letter q will be reserved for the number of queries performed by a tester and will *not* denote the size of $\mathbb{F}$.) An alphabet is a finite set with at least two elements.

Recall that a distribution on a countable set X is a collection of non-negative real numbers $p = (p_x)_{x \in X}$ adding up to 1; the number p_x is the probability of drawing x when sampling an element from X according to p. We write $x \sim p$ to indicate that $x \in X$ is chosen at random accroding to the distribution p. For a finite set X, we write $x \sim X$ to denote that x is chosen from X uniformly at random.

2.2 Error Correcting Codes

Let Σ be an alphabet and $n \in \mathbb{N}$. We write Σ^n for the set of n-letter words in the alphabet Σ, and unless indicated otherwise, write w_i for the i-th letter of a word $w \in \Sigma^n$. As usual, the normalized Hamming distance on Σ^n, denoted $\delta(\cdot,\cdot)$, is given by $\delta(u,v) = \frac{1}{n} \cdot \#\{i \in \{1,\dots,n\} : u_i \neq v_i\}$ for all $u, v \in \Sigma^n$.

In this work, an *error correcting code*, or a *code* for short, with alphabet Σ and block length n is a nonempty subset $C \subseteq \Sigma^n$. Recall that the *relative distance* of $C \subseteq \Sigma^n$ is

$$\delta(C) := \min\{\delta(u,v) \,|\, u, v \in C,\, u \neq v\}$$

and its *rate* is

$$r(C) := \frac{\log_{|\Sigma|} |C|}{n}.$$

We say that C has relative distance δ (resp. rate r) when $\delta(C) \geq \delta$ (resp. $r(C) \geq r$) and add the word "exactly" to indicate that equality holds.

It is common to think of a code $C \subseteq \Sigma^n$ as ranging in a *family of codes*, i.e., a sequence of codes $\{C_i \subseteq \Sigma^{n_i}\}_{i \in \mathbb{N}}$ with n_i tending to ∞. Recall that the family $\{C_i \subseteq \Sigma^{n_i}\}_{i \in \mathbb{N}}$ is said to be a *good code* if there are $r, \delta > 0$ such that $r(C_i) \geq r$ and $\delta(C_i) \geq \delta$ for all i. In this case, we also say that the family $\{C_i \subseteq \Sigma^{n_i}\}_{i \in \mathbb{N}}$ has relative distance δ and rate r.

2.3 Testers

Let $q \in \mathbb{N}$. Recall that a *q-query tester*, or a *q-tester* for short, for a code $C \subseteq \Sigma^n$ is a randomized algorithm T which, given oracle access to some $w \in \Sigma^n$, reads at most q letters from w and returns 1 – meaning "accept" – or 0 – meaning "reject" – subject to the requirement that any $w \in C$ is accepted. The tester T is said to have soundness μ ($\mu \geq 0$) if

$$\Pr(T(w) = 0) \geq \mu\, \delta(w, C) \qquad \forall w \in \Sigma^n.$$

The tester T is called *non-adaptive* if it does not use information from previous queries to w to determine which position to read next.

Unless explicitly indicated, we always assume that testers are non-adaptive.

Observe that in order to specify a (non-adaptive) q-tester for $C \subseteq \Sigma^n$, it is enough to give the following data: a finite set I, a probability distribution $p = (p_i)_{i \in I}$ on I, a q-tuple $(a_1^{(i)}, \dots, a_q^{(i)}) \in [n]^q$ for each $i \in I$, and a function $T^{(i)} : \Sigma^q \to \{0,1\}$ for every $i \in I$. The corresponding tester T then works as follows: Given $w \in \Sigma^n$, choose $i \in I$ according to the distribution p, read the letters in positions $a_1^{(i)}, \dots, a_q^{(i)}$ from w and return $T^{(i)}(w_{a_1^{(i)}}, \dots, w_{a_q^{(i)}})$. We write this simply as

$$T = (T^{(i)}, (a_1^{(i)}, \dots, a_q^{(i)}), p_i)_{i \in I}.$$

A code $C \subseteq \Sigma^n$ is said to be *defined by q-letter constraints* if it has a q-query tester with positive soundness. This is equivalent to saying that there is a list of constraints on words in Σ^n, each involving q or less letters, such that C is the set of words in Σ^n satisfying all those constraints.

A family of codes $\{C_i \subseteq \Sigma^{n_i}\}_{i\in\mathbb{N}}$ is called a *q-query locally testable code* (q-query LTC) if there is $\mu > 0$ such that each code in the family admits a q-tester with soundness μ. In this case, we also say that the q-query LTC $\{C_i \subseteq \Sigma^{n_i}\}_{i\in\mathbb{N}}$ has soundness μ. A *locally testable code* (LTC) is a family of codes that is a q-query LTC for some $q \in \mathbb{N}$.

2.4 Linear Codes

Let $\mathbb{F}$ be a finite field, and suppose that the alphabet Σ is also an $\mathbb{F}$-vector space (hence $\Sigma \neq 0$). A code $C \subseteq \Sigma^n$ is said to be an *$\mathbb{F}$-code* if C is a subspace of Σ^n. An *$\mathbb{F}$-linear code* is an $\mathbb{F}$-code with alphabet $\mathbb{F}$.

Let C be an $\mathbb{F}$-code. We say that a q-tester $T = (T^{(i)}, (a_1^{(i)}, \ldots, a_q^{(i)}), p_i)_{i\in I}$ is *$\mathbb{F}$-linear* if for each $i \in I$, there is a linear subspace $V_i \subseteq \Sigma^q$ such that

$$T^{(i)}(u) = \begin{cases} 1 & u \in V_i \\ 0 & u \notin V_i \end{cases}$$

for all $u \in \Sigma^q$. For example, when $\Sigma = \mathbb{F}$ and V_i has codimension 1 in Σ^q, the test $T^{(i)}$ merely checks that the input $w \in \mathbb{F}^n$ satisfies a single homogeneous linear equation involving at most q of the coordinates.

Any q-tester for an $\mathbb{F}$-code can be replaced by an $\mathbb{F}$-linear q-query tester having soundness greater than or equal to the soundness of the original tester.

A *q-query $\mathbb{F}$-LTC* (resp. *$\mathbb{F}$-linear LTC*) is a family of $\mathbb{F}$-codes (resp. $\mathbb{F}$-linear codes) for which there is $\mu > 0$ such that each code in the family admits an $\mathbb{F}$-linear q-tester with soundness μ.

3 Concatenation of Codes

We proceed by recalling concatenation of codes, setting notation along the way. Let $C \subseteq \Sigma^n$ be a code with alphabet Σ, let Δ be another alphabet, and let $f : \Sigma \to \Delta^k$ be an injective function with image D. We think of D as a code inside Δ^k and of $f : \Sigma \to D \subseteq \Delta^k$ as its encoding function. Recall that the *concatenated code* $C \circ D \subseteq \Delta^{kn}$ is obtained by encoding the letters of each codeword in C using the code D. Formally,

$$C \circ D := \{f(w_1) \cdots f(w_n) \,|\, w \in C\} \subseteq \Delta^{kn}.$$

The codes C and D are often called the *outer code* and *inner code*, respectively. When the encoding map f is not clear from the context, we shall write $C \circ_f D$ for $C \circ D$. For more details, see [24, Chp. 12] or [17, §10.1], for instance.

Note that if C is an $\mathbb{F}$-code, Δ is an $\mathbb{F}$-vector space and $f : \Sigma \to \Delta^k$ is $\mathbb{F}$-linear, then $C \circ D$ is an $\mathbb{F}$-code. When $\Delta = \mathbb{F}$, the code $C \circ D$ is moreover $\mathbb{F}$-linear.

The behavior of the relative distance and rate of $C \circ D$ is well-known and summarized in the following proposition.

▶ **Proposition 6.** *With notation as above, we have*

$$\delta(C \circ D) \geq \delta(C)\delta(D) \qquad \text{and} \qquad r(C \circ D) = r(C)r(D).$$

In applications of concatenation in this paper, the outer code C will range over a family of codes $\{C_i \subseteq \Sigma^{n_i}\}_{i\in\mathbb{N}}$, while the inner code $D \subseteq \Delta^k$ will remain fixed. Then, by Proposition 6, the family $\{C_i \circ_f D \subseteq \Sigma^{kn_i}\}_{i\in\mathbb{N}}$ will be a good code as long as $\{C_i \subseteq \Sigma^{n_i}\}_{i\in\mathbb{N}}$ is a good code; this holds no matter how poor the relative distance and rate of D are.

4 Concatenation of Codes with Testers

In general, the concatenation of codes admitting q-testers with positive soundness does not share the same property. However, in this section, we will show that under certain assumptions, this is indeed the case.

▶ **Definition 7.** *Let $C \subseteq \Sigma^n$ be a code, let $T = (T^{(i)}, (a_1^{(i)}, \dots, a_q^{(i)}), p_i)_{i \in I}$ be a q-tester for C (see § 2.3), and let $f : \Sigma \to \Delta^k$ be an injective function. We denote the j-coordinate of f as $f_j : \Sigma \to \Delta$. We say that T is* f-compatible *if for every $i \in I$, there are $b_1, \dots, b_q \in [k]$ and a function $g : \Delta^q \to \{0,1\}$ such that for every $w_1, \dots, w_q \in \Sigma$,*

$$T^{(i)}(w_1, \dots, w_q) = g(f_{b_1}(w_1), \dots, f_{b_q}(w_q)).$$

In the other words, we can compute $T^{(i)}(w_1, \dots, w_q)$ by reading q letters from the word $f(w_1) \cdots f(w_q)$ in Δ^{qk}.

▶ **Theorem 8.** *Let $C \subseteq \Sigma^n$ be a code admitting a q_C-tester T_C with soundness $\mu_C > 0$. Let $f : \Sigma \to \Delta^k$ be an injective function such that the code $D := \mathrm{im}(f) \subseteq \Delta^k$ has a q_D-tester T_D with soundness $\mu_D > 0$. Suppose further that T_C is f-compatible. Then the concatenated code $E := C \circ_f D \subseteq \Delta^{nk}$ admits a $\max\{q_C, q_D\}$-tester T_E with soundness*

$$\frac{\mu_C \mu_D}{qk + \mu_C + \mu_D}.$$

Proof. We abbreviate q_C to q and write $T = T_C = (T^{(i)}, (a_1^{(i)}, \dots, a_q^{(i)}), p_i)_{i \in I}$. Given $i \in I$, denote the $b_1, \dots, b_q \in [k]$ and the function $g : \Delta^q \to \{0,1\}$ promised by Definition 7 by $b_1^{(i)}, \dots, b_q^{(i)} \in [k]$ and $g^{(i)} : \Delta^q \to \{0,1\}$.

Fix some distribution $\rho = (\rho_1, \rho_2, \rho_3)$ on the set $\{1,2,3\}$; we will specify ρ at the end. Using ρ, we define a tester T_E for $E \subseteq \Delta^{nk}$ as follows: Given $u \in \Delta^{nk}$, write $u = u_1 \cdots u_n$ with $u_1, \dots, u_n \in \Delta^k$. Then choose $x \in \{1,2,3\}$ according to the distribution ρ and perform routine (x) from the following list.

(1) Choose $\ell \in [n]$ uniformly at random and return $T_D(u_\ell)$ (q_D letters are read from u).

(2) Choose $i \in I$ according to $p = (p_i)_{i \in I}$ and return $g^{(i)}\left((u_{a_1^{(i)}})_{b_1^{(i)}}, \dots, (u_{a_q^{(i)}})_{b_q^{(i)}}\right)$ (q_C letters are read from u).

(3) Choose $i \in I$ according to $p = (p_i)_{i \in I}$, choose $\ell \in [q_C]$ uniformly at random and return $T_D(u_{a_\ell^{(i)}})$ (q_D letters are read from u).

The rationale behind (1) and (2) was explained in the introduction. Routine (3) is included in order to deal with situations where $a_1^{(i)}, \dots, a_q^{(i)}$ are very unevenly distributed; otherwise it is subsumed by routine (1).

It is straightforward to see that T_E accepts every word in E. It remains to prove that it has the claimed soundness.

Let $u \in \Delta^{nk}$ and write $\varepsilon := \delta(u, E)$. Then

$$\Pr(T(u) = 0) = \sum_{x=1}^{3} \rho_x \cdot \Pr(T(u) = 0 \,|\, (x) \text{ is executed}).$$

We will bound the three summands on the right hand side from below. To that end, we think of D^n as a subset of Δ^{nk} and define the following words in Δ^{nk}:

- u' is an element of D^n with minimal distance from u.
- u'' is an element of E with minimal distance from u'.

We further let $w' \in \Sigma^n$ denote the word satisfying $f^n(w') = u'$. Obseve that

$$\varepsilon = \delta(u, E) \le \delta(u, u'') \le \delta(u, u') + \delta(u', u''). \tag{4.1}$$

Now, since T_D has soundness μ_D, we have

$$\begin{aligned}\Pr(T_E(u) = 0 \,|\, (1) \text{ is exec.}) &= \Pr_{\ell\sim[n]}\left(T_D(u_\ell) = 0\right) \ge \frac{1}{n}\sum_{\ell=1}^{n} \mu_D\, \delta_{\Delta^k}(u_\ell, D) \\ &= \mu_D\, \delta_{\Delta^{nk}}(u, D^n) = \mu_D\, \delta(u, u').\end{aligned}$$

Next, denote by R the probability that $u_{a_t^{(i)}} \in D$ for all $t = 1, \dots, q$ (equivalently, $u_{a_t^{(i)}} = u'_{a_t^{(i)}}$ for $t = 1, \dots, q$) when $i \in I$ is chosen according to the distribution p. Then

$$\begin{aligned}\Pr(T_E(u) = 0 \,|\, (2) \text{ is exec.}) &= \Pr_{i\sim p}\left[g^{(i)}\left((u_{a_1^{(i)}})_{b_1^{(i)}}, \dots, (u_{a_q^{(i)}})_{b_q^{(i)}}\right) = 0\right] \\ &\ge \Pr_{i\sim p}\left[g^{(i)}\left((u_{a_1^{(i)}})_{b_1^{(i)}}, \dots, (u_{a_q^{(i)}})_{b_q^{(i)}}\right) = 0 \text{ and } u_{a_t^{(i)}} = u'_{a_t^{(i)}}\ \forall t \in [q]\right] \\ &= \Pr_{i\sim p}\left[g^{(i)}\left((u'_{a_1^{(i)}})_{b_1^{(i)}}, \dots, (u'_{a_q^{(i)}})_{b_q^{(i)}}\right) = 0 \text{ and } u_{a_t^{(i)}} = u'_{a_t^{(i)}}\ \forall t \in [q]\right] \\ &\ge \Pr_{i\sim p}\left[T^{(i)}(w'_{a_1^{(i)}}, \dots, w'_{a_q^{(i)}}) = 0\right] - \Pr_{i\sim p}\left[\exists t \in [q] \,:\, u_{a_t^{(i)}} \ne u'_{a_t^{(i)}}\right] \\ &\ge \mu_C\, \delta(w', C) - (1 - R) \\ &\ge \mu_C\, \delta(u', E) - (1 - R) = \mu_C\, \delta(u', u'') - (1 - R),\end{aligned}$$

while

$$\begin{aligned}\Pr(T_E(u) = 0 \,|\, (3) \text{ is exec.}) &= \Pr_{i\sim p, \ell\sim[q]}(T_D(u_{a_\ell^{(i)}}) = 0) \\ &\ge (1 - R) \cdot \Pr_{i\sim p, \ell\sim[q]}\left[T_D(u_{a_\ell^{(i)}}) = 0 \,\middle|\, u_{a_\ell^{(i)}} \notin D \text{ for some } \ell\right] \\ &\ge (1 - R) \cdot \frac{1}{q} \cdot \frac{\mu_D}{k}\end{aligned}$$

Here, the second-to-last inequality holds since $u_{a_\ell^{(i)}} \notin D$ implies $\delta_{\Delta^k}(u_{a_\ell^{(i)}}, D) \ge \frac{1}{k}$.

Putting everything together gives

$$\begin{aligned}\Pr(T_E(u) = 0) &\ge \rho_1 \cdot \delta(u, u')\mu_D + \rho_2 \cdot (\mu_C\, \delta(u', u'') - (1 - R)) + \rho_3 \cdot (1 - R)\frac{\mu_D}{qk} \\ &= \rho_1\mu_D\delta(u, u') + \rho_2\mu_C\, \delta(u', u'') + (1 - R)\left(-\rho_2 + \rho_3 \cdot \frac{\mu_D}{qk}\right) =: (\star)\end{aligned}$$

Suppose that ρ is chosen so that $\rho_2 \le \frac{\mu_D}{qk}\rho_3$. Then by (4.1), we have

$$(\star) \ge \rho_1\mu_D\delta(u, u') + \rho_2\mu_C\, \delta(u', u'') \ge \varepsilon \cdot \min\{\rho_1\mu_D, \rho_2\mu_C\}.$$

Subject to the requirements $\rho_1 + \rho_2 + \rho_3 = 1$ and $\rho_2 \le \frac{\mu_D}{qk}\rho_3$, the right hand side is maximized for

$$\rho_1 = \frac{\mu_C}{\mu_C + \mu_D + qk}, \quad \rho_2 = \frac{\mu_D}{\mu_C + \mu_D + qk}, \quad \rho_3 = \frac{qk}{\mu_C + \mu_D + qk},$$

in which case it evaluates to $\frac{\mu_C\mu_D}{\mu_C + \mu_D + qk} \cdot \varepsilon$. This is what we want. ◀

▶ Remark 9. Without additional assumptions in Theorem 8, the tester T_E described in its proof cannot have soundness larger than $\Omega(\frac{1}{k})$. The reason is that we make no assumption

on the distribution of the coordinates $b_1^{(i)}, \ldots, b_q^{(i)} \in [k]$ from Definition 7 as $i \in I$ distributes according to p. For example, consider an extreme situation in which $b_1^{(i)} = \cdots = b_q^{(i)} = 1$ for all $i \in I$ and $\delta(D) > \frac{1}{k}$. Start with a word $w' \in \Sigma^n$ that is δ-far from C, let $w \in C$ be the closest word to w', and let $u = f(w_i) \cdots f(w_n)$ and $u'_i = f(w'_i) \cdots f(w'_n)$. Then, for every $i \in [n]$ such that $w_i \neq w'_i$, replace the $(ki+1)$-letter of u' with the corresponding letter in u; denote the resulting word by u''. Now, the word u'' satisfies $\delta(u'', C \circ D) \geq \delta(u', C \circ D) - \delta(u'', u') \geq \delta \cdot (\delta(D) - \frac{1}{k}) = \Omega(\delta)$. However, when we attempt to emulate T_C on u'' (routine (2) above), we cannot distinguish between u and u''. Thus, the only way we could detect that u'' is not in $C \circ D$ is by applying the tester of D to one of the k-letter blocks of u'' (routines (1) or (3)). Regardless of how this block is chosen, it differs by only one letter from a word in D, and so we are only guaranteed to succeed with probability $\mu_D \cdot \frac{1}{k}$ or less. It follows that T_E rejects u'' with probability $O(\frac{1}{k})$, while u'' is $\Omega(\delta)$-far from $C \circ D$.

One can overcome the $\Omega(\frac{1}{k})$ limitation by requiring that for every $t \in [q]$, the position $k(a_t^{(i)} - 1) + b_t^{(i)}$ distributes nearly uniformly in $[nk]$ when $i \sim p$. This requires imposing additional assumptions on T, f, D. We omit the details because these assumptions are not guaranteed in the situations in which we apply Theorem 8.

Another approach to bypass this limitation is to take into advantage the fact that in routine (3) above, we only need to check that the block $u_{a_t^{(i)}}$ was not corrupted *in position* $b_t^{(i)}$. Calling $T_D(u_{a_t^{(i)}})$ is wasteful since it does not use this information. To use it, however, we need D to be equipped with a "local tester" able to detect with high probability whether a given word is far from D *or corrupted in a given position*. Such local testers were not considered in the literature, and are out of the scope of this work.

Theorem 8 implies in particular that if $C \subseteq \Sigma^n$ admits a q-tester with soundness $\mu > 0$ and if Δ is an alphabet containing Σ, then the code $C \subseteq \Delta^n$ (i.e., C thought of as a code in Δ^n) has a q-tester with soundness $\frac{\mu}{q+1+\mu}$ (take $f : \Sigma \to \Delta^1$ to be the embedding of Σ in Δ). In this case, however, there is a tester with larger soundness.

▶ **Proposition 10.** *Let $C \subseteq \Sigma^n$ be a code admitting a q-tester T with soundness $\mu > 0$, and let Δ be an alphabet containing Σ. Then $C \subseteq \Delta^n$ admits a tester T' with soundness $\frac{\mu}{\mu+1}$.*

Proof. Write $T = (T^{(i)}, (a_1^{(i)}, \ldots, a_q^{(i)}), p_i)_{i \in I}$. Fix $\rho_1, \rho_2 > 0$ with $\rho_1 + \rho_2 = 1$ and consider the following tester T' for $C \subseteq \Delta^n$: Given $u \in \Delta^n$, choose $x \in \{1, 2\}$ according to the distribution (ρ_1, ρ_2) and perform routine (x) from the following:

(1) Choose $\ell \in [n]$ uniformly at random and accept u if and only if $u_\ell \in \Sigma$.

(2) Choose $i \in I$ according to p. Read $u_{a_1^{(i)}}, \ldots, u_{a_q^{(i)}}$. If one of these letters is not in Σ, then reject u. Otherwise, return $T^{(i)}(u_{a_1^{(i)}}, \ldots, u_{a_q^{(i)}})$.

As in the proof of Theorem 8, to show that T' has the claimed soundness, let $u' \in \Sigma^n$ be a word with minimal distance from u, and let $u'' \in C$ be a word with minimal distance from u'. Then

$$\delta(u, u') + \delta(u', u'') \geq \delta(u, C) =: \varepsilon.$$

Moreover, $\Pr(T'(u) = 0 \,|\, (1) \text{ exec.}) = \delta(u, u')$. Next, as in the proof of Theorem 8, writing R for the probability that $u_{a_1^{(i)}}, \ldots, u_{a_q^{(i)}} \in \Sigma$ when $i \in I$ distributes according to p, we have

$$\begin{aligned}\Pr(T'(u) = 0 \,|\, (2) \text{ is exec.}) &= (1-R) \\ &\quad + \Pr_{i\sim p}\left[T^{(i)}(u_{a_1^{(i)}}, \ldots, u_{a_q^{(i)}}) = 0 \text{ and } u_{a_1^{(i)}}, \ldots, u_{a_q^{(i)}} \in \Sigma\right] \\ &\geq (1-R) + [\mu\,\delta(u', C) - (1-R)] \geq \mu\,\delta(u', u'').\end{aligned}$$

It follows that

$$\Pr(T'(u) = 0) \geq \rho_1\,\delta(u, u') + \rho_2\mu\,\delta(u', u'') \geq \min\{\rho_1, \rho_2\mu\}\varepsilon.$$

Taking $\rho_1 = \frac{\mu}{\mu+1}$ and $\rho_2 = \frac{1}{\mu+1}$ completes the proof of proposition. ◀

▶ Remark 11. In Theorem 8, if Σ and Δ are $\mathbb{F}$-vector spaces, $f : \Sigma \to \Delta$ is $\mathbb{F}$-linear, and the code C is an $\mathbb{F}$-code, then $E = C \circ D \subseteq \Delta^{nk}$ is also an $\mathbb{F}$-code. Moreover, it is clear from the proof that if the testers T_C and T_D are $\mathbb{F}$-linear, then so is the tester T_E of E.

Similarly, in Proposition 10, if Σ and Δ are $\mathbb{F}$-vector spaces such that Σ is a subspace of Δ and T is $\mathbb{F}$-linear, then so is the tester T' for $C \subseteq \Delta^n$.

5 The Generalized Hadamard Code and the Generalized Long Code

In this section, we introduce two types of codes generalizing the (linear) Hadamard code and the (non-linear) long code, respectively. They will ultimately serve as the inner code when we apply Theorem 8, and to that end, we will show that they can be defined using 2-letter constraints. This stands in contrast to the original Hadamard code and long code which, as we also show, cannot be defined by 2-letter constraints.

5.1 A General Construction

We begin with a general construction which is natural in the context of Theorem 8. Let S be a finite set, let Δ be an alphabet and let $f_1, \ldots, f_n : S \to \Delta$ be some functions. We associate with S, Δ and the collection $\{f_i\}_{i=1}^n$ the code

$$D(\{f_i\}_{i=1}^n) := \{(f_1(s), \ldots, f_n(s)) \,|\, s \in S\} \subseteq \Delta^n.$$

If we further define $f : S \to \Delta^n$ by $f(s) = (f_1(s), \ldots, f_n(s))$ and assume that f is injective, then this recovers the setting of Theorem 8. In fact, every code $D \subseteq \Delta^n$ equipped with an encoding function $f : S \to D$ is of the form $D(\{f_i\}_{i=1}^n)$, but the point of our construction is to build a code in Δ^n from functions $f_1, \ldots, f_n : S \to \Delta$ rather than doing the opposite.

The construction recovers two well-known codes. When $S = \{0,1\}^k$, $\Delta = \{0,1\}$ and $f_1, \ldots, f_n$ consist of all the functions from S to $\{0,1\}$ (so that $n = 2^{2^k}$), the code C is known as the *long code*, e.g., see [2, §3]. Next, when $S = V$ with V an $\mathbb{F}$-vector space, $\Delta = \mathbb{F}$ and $f_1, \ldots, f_n$ are all the $\mathbb{F}$-linear functions from V to $\mathbb{F}$ (so that $n = |V|$), the code C is (up to equivalence) the $|\mathbb{F}|$-ary *Hadamard code* associated to the vector space V, e.g., see [17, Exercise 2.22] (we also recall the definition in § 5.2).

We now introduce a q-tester for $D(\{f_i\}_{i=1}^n)$. To that end, we say that a collection of functions $f_1, \ldots, f_q : S \to \Delta$ is *dependent* if

$$\mathrm{im}(f_1 \times \cdots \times f_q) = \{(f_1(s), \ldots, f_q(s)) \,|\, s \in S\} \subsetneq \Delta^q.$$

Informally, this means that knowing (say) the values of $f_1, \ldots, f_{q-1}$ on some input $s \in S$ gives some information on the value of f_q on that input, even without knowing what s is. (Note that it is possible for a single function f_1 to be dependent, namely, if its image is strictly smaller than Δ.) With this at hand, we introduce:

▶ **Definition 12** (q-dependence tester)**.** *With notation as a above, given a word $w \in \Delta^n$, the* q-dependence tester *for $D(\{f_i\}_{i=1}^n)$ chooses uniformly at random a tuple $(i_1, \ldots, i_q) \in [n]^q$ such that $f_{i_1}, \ldots, f_{i_q}$ are dependent, and accepts w if and only if $(w_{i_1}, \ldots, w_{i_q}) \in \mathrm{im}(f_{i_1} \times \cdots \times f_{i_q})$.*

If the q-dependence tester has positive soundness, then this soundness is at least n^{-q}.

▶ **Example 13.** To demonstrate how the q-dependence tester works, suppose for simplicity that $\Delta = \mathbb{F}$, and let $w \in \Delta^k$ be a word that is always accepted by the 3-dependence tester. We claim that if f_i, f_j, f_k satisfy $f_i + f_j = f_k$, then we must have $w_i + w_j = w_k$. Indeed, this is forced by the fact that $\mathrm{im}(f_i \times f_j \times f_k) \subseteq \{(\alpha, \beta, \alpha+\beta) \,|\, \alpha, \beta \in \mathbb{F}\}$. Similarly, if $f_i = \alpha f_j$ for some $\alpha \in \mathbb{F}$, then $w_i = \alpha w_j$, because for any $k \in [n]$, $\mathrm{im}(f_i, f_j, f_k) \subseteq \{(\beta, \alpha\beta, \gamma) \,|\, \beta, \gamma \in \mathbb{F}\}$ (f_k was added artificially to f_i and f_j to make a dependent triple of functions). More generally, for a general Δ, if there is a function $g : \Delta \times \Delta \to \Delta$ such that $g \circ (f_i, f_j) = f_k$ (i.e. $g(f_i(s), f_j(s)) = f_k(s)$ for all $s \in S$), then $g(w_i, w_j) = w_k$.

The following useful property of the q-dependence tester will be used freely in the sequel.

▶ **Proposition 14.** *With notation as above, the code $D(\{f_i\}_{i=1}^n) \subseteq \Delta^n$ is defined by q-letter constraints (i.e., it has a q-tester with positive soundness) if and only if its q-dependence tester has positive soundness.*

Proof. The "if" direction is clear, so we treat the "only if" direction. Write $D := D(\{f_i\}_{i=1}^n)$ and let $T = (T^{(i)}, (a_1^{(i)}, \ldots, a_q^{(i)}), p_i)_{i \in I}$ be a q-tester for D having positive soundness. Let $w \in \Delta^n - D$. It is enough to prove that w fails the q-dependence test with some positive probability. Since T has positive soundness, there is $i \in I$ such that $T^{(i)}(w_{a_1^{(i)}}, \ldots, w_{a_q^{(i)}}) = 0$. Since T accepts all words in D, we must also have $T^{(i)}(f_{a_1^{(i)}}(s), \ldots, f_{a_q^{(i)}}(s)) = 1$ for all $s \in S$. Consequently, $(w_{a_1^{(i)}}, \ldots, w_{a_q^{(i)}}) \notin \mathrm{im}(f_{a_1^{(i)}} \times \cdots \times f_{a_q^{(i)}})$. This means that $f_{a_1^{(i)}}, \ldots, f_{a_q^{(i)}}$ are dependent and that w will be rejected if the q-dependence test chooses these functions. ◀

5.2 The Generalized Hadamard Code

Keeping the notation above, suppose that both S and Δ are $\mathbb{F}$-vector spaces. We write V in place of S to denote that. Let $f_1, \ldots, f_n$ enumerate all the $\mathbb{F}$-linear functions from V to Δ (so that $n = |\mathbb{F}|^{\dim V \cdot \dim \Delta} = |\Delta|^{\dim V} = |V|^{\dim \Delta}$). The *generalized Hadamard code* associated to V and Δ is defined to be

$$H(V, \Delta) := D(\{f_i\}_{i=1}^n) = \{(f_1(v), \ldots, f_n(v)) \,|\, v \in V\} \subseteq \Delta^n.$$

It easy to see that $H(V, \Delta) \subseteq \Delta^n$ is an $\mathbb{F}$-code of relative distance $1 - \frac{1}{|\Delta|}$ and rate $\frac{\log_{|\Delta|} |V|}{|\Delta|^{\dim V}} = \frac{\dim V}{\dim \Delta \cdot |\Delta|^{\dim V}} = \frac{\log_{|\Delta|} n}{n \dim \Delta}$.

▶ Remark 15. Recall that the Hadamard code associated to an $\mathbb{F}$-vector space V is $\mathrm{Hom}_{\mathbb{F}}(V, \mathbb{F})$ – the set of linear functions from V to $\mathbb{F}$ – viewed as a subset of $\mathbb{F}^V$, i.e., all functions from V to $\mathbb{F}$. More concretely, writing $v_1, \ldots, v_n$ for the vectors in V, the Hadamard code of V is

$$H' = \{(f(v_1), \ldots, f(v_n)) \,|\, f : V \to \mathbb{F} \text{ is linear}\} \subseteq \mathbb{F}^n.$$

This code is in fact equivalent to $H(V, \mathbb{F})$, which is the reason why we call $H(V, \Delta)$ a generalized Hadamard code. Indeed, let V^* denote the dual vector space of V. Then $f_1, \ldots, f_n$ are the vectors of V^*. Since every linear map g from V^* to $\mathbb{F}$ admits a unique $v \in V$ such that $g(f) = f(v)$ for all $f \in V^*$, the code H' is just $H(V^*, \mathbb{F})$. Choosing an isomorphism $V \to V^*$ then gives an equivalence between H' and H.

It is well-known that the code $H(V,\mathbb{F})$ is 3-testable. Indeed, it is equivalent to the ordinary Hadamard code $\mathrm{Hom}_{\mathbb{F}}(V,\mathbb{F}) \subseteq \mathbb{F}^V$, which is defined by 3-letter constraints, namely,

$$\mathrm{Hom}_{\mathbb{F}}(V,\mathbb{F}) = \{f : V \to \mathbb{F} \,:\, f(x+y) = f(x) + f(y) \text{ and } f(\alpha x) = \alpha f(x) \text{ for all } x, y \in V,\ \alpha \in \mathbb{F}\}.$$

Tracing this back to $H(V,\mathbb{F}) \subseteq \mathbb{F}^n$ ($n = |V|$) shows that a word $w \in \mathbb{F}^n$ is in $H(V,\mathbb{F})$ if and only if

(1) $w_i = w_j + w_k$ for all $i,j,k \in [n]$ such that $f_i = f_j + f_k$ and

(2) $w_i = \alpha w_j$ for all $i,j \in [n]$ and $\alpha \in \mathbb{F}$ such that $f_i = \alpha f_j$.

Consequently, the 3-dependence tester of $H(V,\mathbb{F})$ has positive soundness (cf. Example 13). (In fact, for some fields $\mathbb{F}$, e.g. $\mathbb{F}_2$, the Hadamard code is known to have 3-testers with soundness that is independent of V; see [7], [1] and the many followup works.) On the other hand, it is not difficult to see that the 2-dependence tester for $H(V,\mathbb{F})$ has soundness 0 if $\dim V > 1$; the reason is that a pair of $\mathbb{F}$-linear functions $f, g : V \to \mathbb{F}$ is dependent if and only if they are proportional. As a result, $H(V,\mathbb{F})$ is not defined by 2-letter constraints (Proposition 14). By contrast, we now show that $H(V,\Delta)$ is defined by 2-letter constraints when $\dim \Delta \geq 2$.

▶ **Theorem 16.** *Let Δ be a vector space of dimension > 1 and let V be any vector space. Then the 2-dependence tester (Definition 12) for the code $H(V,\Delta) \subseteq \Delta^n$ has positive soundness (depending on n).*

Proof. We may assume without loss of generality that $\Delta = \mathbb{F}^m$ for some $m > 1$. Given functions $g_1, \ldots, g_r \in \mathrm{Hom}_{\mathbb{F}}(V,\mathbb{F})$ ($r \leq m$), we denote by $(g_1, \ldots, g_r, \vec{0})$ the function from V to $\Delta = \mathbb{F}^m$ sending $v \in V$ to $(g_1(v), \ldots, g_r(v), 0, \ldots, 0) \in \mathbb{F}^m = \Delta$. Let $g_1, \ldots, g_t$ enumerate all the linear functions from V to $\mathbb{F}$ ($t = |V|$). We may assume that $f_1, \ldots, f_n$ are numbered so that $f_i = (g_i, \vec{0})$ whenever $1 \leq i \leq t$.

Let $w \in \Delta^n$ be a word that is always accepted by the 2-dependence tester of $H(V,\Delta)$. We need to show that $w \in H(V,\Delta)$.

Since $\mathrm{im}(f_1), \ldots, \mathrm{im}(f_t) \subseteq \mathbb{F} \times \{0\}^{m-1}$ and w passes the 2-dependence test, we must have $w_1, \ldots, w_t \in \mathbb{F} \times \{0\}^{m-1}$. Thus, for each $i \in [t]$, we can write $w_i = (u_i, 0, \ldots, 0)$ with $u_i \in \mathbb{F}$.

Let $u = u_1 \cdots u_t$. We claim that $u \in D(\{g_i\}_{i=1}^t) = H(V,\mathbb{F})$. As we noted earlier, in order to show this, it is enough to check that for all $i,j,k \in [t]$ with $g_i + g_j = g_k$ (equiv. $f_i + f_j = f_k$), we have $u_i + u_j = u_k$, and for all $i,j \in [t]$ and $\alpha \in \mathbb{F}$ with $g_i = \alpha g_j$ (equiv. $f_i = \alpha f_j$), we have $u_i = \alpha u_j$. The second statement holds because w passes the 2-dependence test, so we only need to establish the first. There is $\ell \in [n]$ such that $f_\ell = (g_i, g_j, \vec{0})$. Then $\mathrm{im}(f_i \times f_\ell) \subseteq \{((\alpha,0,\ldots,0),(\alpha,\beta,0,\ldots,0)) \,|\, \alpha,\beta \in \mathbb{F}\}$, and so our assumption on w implies that w_ℓ has the form $(u_i, *, 0, \ldots, 0)$. Repeating this argument with f_j in place of f_i gives $w_\ell = (u_i, u_j, 0, \ldots, 0)$. Now, since $\mathrm{im}(f_k \times f_\ell) \subseteq \{((\alpha+\beta,0,\ldots,0),(\alpha,\beta,0,\ldots,0)) \,|\, \alpha,\beta \in \mathbb{F}\}$, we must have $u_k = u_i + u_j$, which is what we want. We conclude that $u \in H(V,\mathbb{F})$.

Let $v \in V$ be a vector such that $u_i = g_i(v)$ for all $i \in [t]$. We finish the proof by showing that $w_i = f_i(v)$ for all $i \in [n]$. Let $i \in [n]$. Then there are $i_1, \ldots, i_m \in [t]$ such that $f_i = (g_{i_1}, \ldots, g_{i_m})$. Now, for every $\ell \in [m]$, the dependence between f_i and f_{i_ℓ} implies that the ℓ-th component of $w_i \in \mathbb{F}^m$ is $u_{i_\ell} = g_{i_\ell}(v)$. As this holds for every ℓ, it follows that $w_i = (g_{i_1}(v), \ldots, g_{i_m}(v)) = f_i(v)$, as required. ◀

5.3 The Generalized Long Code

Returning to the general setting of § 5.1, let $f_1, \ldots, f_n$ denote all functions from S to Δ (so that $n = |\Delta|^{|S|}$). We call

$$L(S, \Delta) := D(\{f_i\}_{i=1}^n) = \{(f_1(s), \ldots, f_n(s)) \,|\, s \in S\} \subseteq \Delta^n$$

the *generalized long code* associated to S and Δ. This code has relative distance $1 - \frac{1}{|\Delta|}$ and rate $\frac{\log_{|\Delta|} |S|}{|\Delta|^{|S|}} = \frac{\log_{|\Delta|} \log_{|\Delta|} n}{n}$. As we noted earlier, this is a generalization of the *long code*, which arises as the special case where $S = \{0,1\}^k$ and $\Delta = \{0,1\}$.

We will show in Remark 20 that $L(S, \Delta)$ cannot be defined by 2-letter constraints when $|\Delta| = 2$. However, it turns out that it can be defined by 2-letter constraints when $|\Delta| > 2$.

▶ **Theorem 17.** *Let S be a set and let Δ be an alphabet with more than 2 letters. Then the 2-dependence tester of the generalized long code $L(S, \Delta) \subseteq \Delta^n$ has positive soundness (depending on n).*

In order to prove the theorem, we first note that $L(S, \{0,1\})$ has a 3-tester with positive soundness.

▶ **Proposition 18.** *With notation as above, suppose that $\Delta = \mathbb{F}_2$ and the functions $f_1, \ldots, f_n$ from S to Δ are numbered so that f_1 is the function sending every element of S to 1. Then a word $w \in \mathbb{F}_2^n$ is in $L(S, \Delta)$ if and only if*
(1) *$w_i + w_j = w_k$ (in $\mathbb{F}_2$) for every $i, j, k \in [n]$ such that $f_i + f_j = f_k$,*
(2) *$w_i \cdot w_j = w_k$ for every $i, j, k \in [n]$ such that $f_i \cdot f_j = f_k$, and*
(3) *$w_1 = 1$.*
In particular, $L(S, \mathbb{F}_2)$ is defined by 3-letter constraints.

Proof. This is well-known for $S = \{0,1\}^k$ [2, Prp. 3.2]. For the general case, see the extended version of this paper [10, Prp. 5.7]. ◀

We shall also need the following key lemma.

▶ **Lemma 19.** *Let $g_1, \ldots, g_t : S \to \{0,1\}$ be distinct functions. For every $i, j \in [t]$, let $g_{i,j}$ and $g'_{i,j}$ denote the functions from S to $\{0,1,2\}$ defined as follows:*

$$g_{i,j}(s) = \begin{cases} 0 & f_i(s) = 0 \\ 1 & f_i(s) = 1 \wedge f_j(s) = 0 \\ 2 & f_i(s) = 1 \wedge f_j(s) = 1 \end{cases} \qquad g'_{i,j}(s) = \begin{cases} 1 & f_i(s) = 1 \\ 0 & f_i(s) = 0 \wedge f_j(s) = 1 \\ 2 & f_i(s) = 0 \wedge f_j(s) = 0 \end{cases}$$

Let $f_1, \ldots, f_n : S \to \{0,1,2\}$ enumerate the functions in $\{g_i, g_{i,j}, g'_{i,j} \,|\, i, j \in [t]\}$. If the code $D' := D(\{g_i\}_{i=1}^t) \subseteq \{0,1\}^t$ is defined by 3-letter constraints, then $D := D(\{f_j\}_{j=1}^n) \subseteq \{0,1,2\}^n$ is defined by 2-letter constraints.

Proof. We may assume that $f_1, \ldots, f_n$ are numbered so that $f_i = g_i$ when $i \in [t]$.

Suppose $w \in \{0,1,2\}^n$ always passes the 2-dependence test of D. We need to show that $w \in D$. We begin by noting that since $\mathrm{im}(f_i) \subseteq \{0,1\}$ for all $i \in [t]$, we must have $w_i \in \{0,1\}$ for $i \in [t]$.

Next, fix $i, j \in [t]$ and let $k, \ell \in [n]$ be the numbers for which $f_k = g_{i,j}$ and $f_\ell = g'_{i,j}$. Observe that $f_i = g_i$ and $f_k = g_{i,j}$ are dependent, and $f_j = g_j$ and $f_k = g_{i,j}$ are dependent. These dependencies and our assumption on w imply that (i) $w_k = 0$ if and only if $w_i = 0$, (ii) if $w_k = 1$, then $w_j = 0$, and (iii) if $w_k = 2$, then $w_j = 1$. This means that

$$w_k = \begin{cases} 0 & w_i = 0 \\ 1 & w_i = 1 \wedge w_j = 0 \\ 2 & w_i = 1 \wedge w_j = 1. \end{cases} \tag{5.1}$$

Arguing similarly with ℓ in place of k gives

$$w_\ell = \begin{cases} 1 & w_i = 1 \\ 0 & w_i = 0 \wedge w_j = 1 \\ 2 & w_i = 0 \wedge w_j = 0. \end{cases} \tag{5.2}$$

At this point, if we could show that $w' := w_1 \cdots w_t$ is in D', then we could conclude that $w \in D$. Indeed, if it were the case that $w' \in D'$, then there would be an $s \in S$ such that $w_i = g_i(s) = f_i(s)$ for all $i \in [t]$. Since for every $p \in [n] - [t]$, the function f_p is either $g_{i,j}$ or $g'_{i,j}$ for some $i, j \in [t]$, by the previous paragraph, we would have that w_p is $g_{i,j}(s)$ or $g'_{i,j}(s)$, respectively, and consequently $w_p = f_p(s)$.

Suppose for the sake of contradiction that $w' \notin D'$. By assumption, D' admits a 3-tester $T = (T^{(u)}, (a_u, b_u, c_u), p_u)_{u \in U}$ with positive soundness. Then there is some $u \in U$ such that $T^{(u)}(w_{a_u}, w_{b_u}, w_{c_u}) = 0$. Write $(i, j, p) = (a_u, b_u, c_u)$ and $(x_1, x_2, x_3) = (w_{a_u}, w_{b_u}, w_{c_u})$. By the pigeonhole principle, at least two of x_1, x_2, x_3 are equal. We reorder (a_u, b_u, c_u) to have $x_1 = x_2$. Suppose that $x_1 = x_2 = 1$. The fact that $T^{(u)}(v_i, v_j, v_p) = 1$ for all $v \in D'$ while $T^{(u)}(x_1, x_2, x_3) = 0$ means that

$$\mathrm{im}(f_i \times f_j \times f_p) \subseteq \{0,1\}^3 - \{(x_1, x_2, x_3)\} = \{0,1\}^3 - \{(1,1,x_3)\}.$$

As a result, $\mathrm{im}(g_{i,j} \times f_p) \subseteq \{0,1,2\} \times \{0,1\} - \{(2, x_3)\}$. Writing $g_{i,j} = f_k$ with $k \in [n]$, this means that f_k and f_p are dependent (as functions from S to $\{0,1,2\}$), and thus $(w_k, w_p) \in \{0,1,2\} \times \{0,1\} - \{(2, x_3)\}$. However, since $w_i = x_1 = 1$ and $w_j = x_2 = 1$, we have $w_k = 2$ by (5.1), and since $w_p = x_3$, it follows that $(w_k, w_p) = (2, x_3)$, a contradiction to our earlier conclusion. Similarly, when $x_1 = x_2 = 0$, we reach a contradiction using (5.2). As all possibilities lead to contradiction, our assumption $w' \notin D'$ must have been false. This completes the proof. ◀

We are now ready to prove Theorem 17.

Proof of Theorem 17. We may assume without loss of generality that $\{0,1,2\} \subseteq \Delta$ and that the functions $f_1, \ldots, f_n : S \to \Delta$ are numbered so that $f_1, \ldots, f_t$ ($t = 2^{|S|}$) are all the functions from S to $\{0,1\}$.

Suppose that $w \in \Delta^n$ always passes the 2-dependence test. We need to show that $w \in L(S, \Delta)$.

We begin by showing that the exists $s \in S$ such that $w_i = f_i(s)$ for all $i \in [t]$. To that end, let $g_i = f_i$ for $i \in [t]$, and for all $i, j \in [t]$, define $g_{i,j}, g'_{i,j} : S \to \{0,1,2\}$ as in Lemma 19. We may assume that there is $m \in \{t, \ldots, n\}$ such that $f_1, \ldots, f_m$ enumerate all the functions in the set $\{g_i, g_{i,j}, g'_{i,j} \mid i, j \in [t]\}$. Now, since w passes the 2-dependence, and since $\mathrm{im}(f_i) \subseteq \{0,1,2\}$ for all $i \in [m]$, we have $w_i \in \{0,1,2\}$ for all $i \in [m]$. We may therefore think of $w' := w_1 \cdots w_m$ as a word in $\{0,1,2\}^m$. Our assumption on w implies that w' also passes the 2-dependence test for the code $D(\{f_i\}_{i=1}^m)$, so by Lemma 19 and Proposition 18 (applied to $D(\{f_i\}_{i=1}^t) = L(S, \{0,1\})$), we have $w' \in D(\{f_i\}_{i=1}^m)$. This means in particular that there is $s \in S$ such that $w_i = f_i(s)$ for all $i \in [t]$ (and even for all $i \in [m]$).

We finish by showing that $w_i = f_i(s)$ for all $i \in [n]$. Fix some $i \in [n]$. For every $a \in \Delta$, let $g_a : \Delta \to \{0,1\}$ be the function mapping a to 1 and all other elements of Δ to 0. There is some $j \in [t]$ such that $f_j = g_a \circ f_i$. The dependency between f_i and f_j and our assumption on w now imply that $w_j = g_a(w_i)$ (cf. Example 13). Since $w_j = f_j(s)$, we get that $g_a(w_i) = f_j(s) = g_a(f_i(s))$. By the definition of g_a, this means that $w_i = a$ if and only if $f_i(s) = a$. As this holds for every $a \in \Delta$, we conclude that $w_i = f_i(s)$. ◀

▶ Remark 20. By contrast to Theorem 17, the code $L(S, \{0,1\}) \subseteq \{0,1\}^n$ ($n = 2^{|S|}$) is not defined by 2-letter constaints when $|S| > 2$. To show this, it is enough to exhibit a word $w \in \{0,1\}^n$ that always passes the 2-dependence test and is not in $L(S, \{0,1\})$. Fix distinct $x_1, x_2, x_3 \in S$ and define the word $w \in \{0,1\}^n$ by $w_i = \mathrm{maj}(f_i(x_1), f_i(x_2), f_i(x_3))$ for all $i \in [n]$, where $\mathrm{maj}(-)$ is the majority function. The word w is not in $L(S, \{0,1\})$ because for every $s \in S$, there is $i \in [n]$ such that $f_i(s) \neq \mathrm{maj}(f_i(x_1), f_i(x_2), f_i(x_3)) = w_i$.

Let us now show that w always passes the 2-dependence test. Suppose that $f_i, f_j : S \to \{0,1\}$ are dependent. We need to show that $(w_i, w_j) \neq (a, b)$ for every $(a, b) \in \{0,1\}^2 - \mathrm{im}(f_i \times f_j)$. Fix such (a, b). If $w_i \neq a$, then it is clear that $(w_i, w_j) \neq (a, b)$. On the other hand, if $w_i = a$, then $\mathrm{maj}(f_i(x_1), f_i(x_2), f_i(x_3)) = a$, and so at least 2 of $f_i(x_1), f_i(x_2), f_i(x_3)$ equal a. Since $(a, b) \notin \mathrm{im}(f_i \times f_j)$, at least 2 of $f_j(x_1), f_j(x_2), f_j(x_3)$ are different from b. This means that $w_j \neq b$ and again we get $(w_i, w_j) \neq (a, b)$, as required.

When $|S| = 2$, the long code $L(S, \{0,1\})$ is $\{0101, 0011\} \subseteq \{0,1\}^4$ (up to equivalence), and it is easy to see that it is defined by 2-letter constaints.

6 Separable Testers

In order to apply Theorem 8 and change the alphabet of an LTC from Σ to Δ, we need to have a suitable function $f : \Sigma \to \Delta^k$ such that the tester T of our code is f-compatible (Definition 7). In this section, we give a necessary and sufficient condition on T to be compatible with *some* f, and moreover show that every tester can be replaced with one that satisfies our condition and has proportional soundness.

▶ **Definition 21.** *Let $C \subseteq \Sigma^n$ be a code and let $T = (T^{(i)}, (a_1^{(i)}, \ldots, a_q^{(i)}), p_i)_{i \in I}$ be a q-tester for C. Let Δ be another alphabet. We say that the tester T is* Δ-separable *if for every $i \in I$, there are functions $g_1, \ldots, g_q : \Sigma \to \Delta$ such that $T^{(i)} : \Sigma^q \to \{0,1\}$ factors via the function $g_1 \times \cdots \times g_q : \Sigma^q \to \Delta^q$, i.e., there is $g : \Delta^q \to \{0,1\}$ such that $T^{(i)} = g \circ (g_1 \times \cdots \times g_q)$.*

When C is an $\mathbb{F}$-code, T is $\mathbb{F}$-linear, and Δ is an $\mathbb{F}$-vector space, we say that T is linearly Δ-separable *if $g_1, \ldots, g_q$ can be taken to be $\mathbb{F}$-linear maps.*

▶ **Example 22.** Suppose that $C \subseteq \Sigma^n$ is an $\mathbb{F}$-code and $T = (T^{(i)}, (a_1^{(i)}, \ldots, a_q^{(i)}), p_i)_{i \in I}$ is q-tester such that each $T^{(i)}$ checks a single linear constraint involving at most q letters. Then T is linearly $\mathbb{F}$-separable. Indeed, by assumption, for every $i \in I$, there is a linear map $\varphi_i : \Sigma^q \to \mathbb{F}$ such that for every $w \in \Sigma^q$, we have $T^{(i)}(w) = 1$ if and only if $\varphi_i(w) = 0$. For such φ_i, there are linear functionals $g_1, \ldots, g_q : \Sigma \to \mathbb{F}$ such that $\varphi_i(w) = g_1(w_1) + \cdots + g_q(w_q)$. In particular, we can determine from $g_1(w_1), \ldots, g_q(w_q)$ the value of $T^{(i)}(w)$, meaning that $T^{(i)}$ factors via $g_1 \times \cdots \times g_q : \Sigma^q \to \mathbb{F}^q$.

We now show that Δ-separability is a necessary and sufficient condition for a tester T to be f-compatible with some $f : \Sigma \to \Delta^k$.

▶ **Proposition 23.** *Let $C \subseteq \Sigma^n$ be a code, let T be a q-tester for C, and let Δ be another alphabet.*

- **(i)** *If there is a function $f : \Sigma \to \Delta^k$ such that T is f-compatible, then T is Δ-separable.*
- **(ii)** *If T is Δ-separable, then there is $k \in \mathbb{N}$ and an injective function $f : \Sigma \to \Delta^k$ such that T is f-compatible. In fact, f can be constructed as follows: Let $k = |\Delta^\Sigma|$, let $f_1, \ldots, f_k$ be all the functions from Σ to Δ, and take $f(w) = (f_1(w), \ldots, f_k(w))$.*

Proof. Write $T = (T^{(i)}, (a_1^{(i)}, \dots, a_q^{(i)}), p_i)_{i \in I}$.

(i) For $j \in [k]$, let $f_j : \Sigma \to \Delta$ denote the j-th component of f. Let $i \in I$. Our assumption that T is f-compatible means that there exist a function $g : \Delta^q \to \{0,1\}$ and $b_1, \dots, b_q \in [k]$ such that for every $w_1, \dots, w_q \in \Sigma$, we have $T^{(i)}(w_1, \dots, w_q) = g(f_{b_1}(w_1), \dots, f_{b_q}(w_q))$. This is equivalent to saying that $T^{(i)} = g \circ (f_{b_1} \times \cdots \times f_{b_q})$, so $T^{(i)}$ factors via $f_{b_1} \times \cdots \times f_{b_q} : \Sigma^q \to \Delta^q$, and we have shown that T is Δ-separable.

(ii) Define f as in the statement. We need to show that T is f-compatible. Let $i \in I$. Then there are functions $g_1, \dots, g_q : \Sigma \to \Delta$ and a function $g : \Delta^q \to \{0,1\}$ such that $g \circ (g_1 \times \cdots \times g_q) = T^{(i)}$. By the construction of f, there are $b_1, \dots, b_q \in [k]$ such that $g_\ell = f_{b_\ell}$ for all $\ell \in [q]$. Then $g \circ (f_{b_1} \times \cdots \times f_{b_q}) = T^{(i)}$, or rather, $T^{(i)}(w_1, \dots, w_q) = g(f_{b_1}(w_1), \dots, f_{b_q}(w_q))$ for all $w \in \Sigma^q$. This is exactly what we need to show. ◀

▶ **Proposition 24.** *Let $C \subseteq \Sigma^n$ be an $\mathbb{F}$-code, let T be an $\mathbb{F}$-linear q-tester for T, and let Δ be a nonzero $\mathbb{F}$-vector space.*

(i) *If there is an $\mathbb{F}$-linear function $f : \Sigma \to \Delta^k$ such that T is f-compatible, then T is linearly Δ-separable.*

(ii) *If T is linearly Δ-separable, then there is $k \in \mathbb{N}$ and an injective function $f : \Sigma \to \Delta^k$ such that T is f-compatible. In fact, f can be constructed as follows: Let $k = |\operatorname{Hom}_{\mathbb{F}}(\Sigma, \Delta)|$, let $f_1, \dots, f_k$ be all the linear functions from Σ to Δ, and take $f(w) = (f_1(w), \dots, f_k(w))$.*

Proof. This is completely analogous to the proof of Proposition 23. ◀

▶ Remark 25. In Proposition 23(ii), the image of $f : \Sigma \to \Delta^k$ is the generalized long code $L(\Sigma, \Delta)$ of § 5.3. In Proposition 24(ii), the image of $f : \Sigma \to \Delta^k$ is the generalized Hadamard code $H(\Sigma, \Delta)$ of § 5.2.

Next, we show that every code admitting a q-tester also admits a Δ-separable q-tester with soundness that is proportional to that of the original tester. In particular, when given an LTC, we can always assume that its tester is Δ-separable.

▶ **Theorem 26.** *Let $C \subseteq \Sigma^n$ be a code, let T be a possibly adaptive q-tester for C with soundness $\mu > 0$, and let Δ be another alphabet. Then C admits a Δ-separable tester T' with soundness $\frac{\mu}{|\Sigma|^q}$.*

This proof is a mild modification of a standard trick to turn T into a non-adaptive q-tester. The idea is to guess what will be the q letters that the adaptive tester T would see. Based on this guess, we can determine which coordinates T would read, and then read letters in those positions. If the letters did match our guess, we return what T would return, and if our guess was wrong, we accept the word.

Proof. Let I be the set of random seeds for T (say, $I = \{0,1\}^r$ if T flips r coins). We define a non-adaptive tester T' as follows: Given $w \in \Sigma^n$, choose $u = (u_1, \dots, u_q) \in \Sigma^q$ and $i \in I$ uniformly at random. Let $a_1^{(i,u)}, \dots, a_q^{(i,u)}$ be the coordinates that T would have read on the seed i if the letters it would query in these positions were $u_1, u_2, \dots$, and let c be the output of T in that situation. Now query $w_{a_1^{(i,u)}}, \dots, w_{a_q^{(i,u)}}$. If this sequence is different from $u_1, \dots, u_q$, then w is accepted. Otherwise, T' returns c.

It is straightforward to see that $\Pr(T'(w)=0) \geq \frac{1}{|\Sigma^q|}\Pr(T(w)=0)$, so T' has soundness $\frac{\mu}{|\Sigma|^q}$. It remains to show that T' is Δ-separable. To that end, note that

$$T' = \left(T^{(i,u)}, (a_1^{(i,u)}, \ldots, a_q^{(i,u)}), \tfrac{1}{|I|\cdot|\Sigma|^q}\right)_{(i,u)\in I\times\Sigma^q},$$

where $T^{(i,u)} : \Sigma^q \to \{0,1\}$ a function that returns 1 for every $u' \in \Sigma^q - \{u\}$ and for u returns what T would have returned on the random seed i if it would read the letters $u_1, u_2, \ldots$ in positions $a_1^{(i,u)}, a_2^{(i,u)}, \ldots$.

Fix $(i,u) \in I \times \Sigma^q$. We need to show that $T^{(i,u)} = g \circ (g_1 \times \cdots \times g_q)$ for some $g_1, \ldots, g_q : \Sigma \to \Delta$ and $g : \Delta^q \to \{0,1\}$. Without loss of generality, we may assume that $0, 1 \in \Delta$. If $T^{(i,u)}(u) = 1$, then $T^{(i,u)}$ is identically 1 and we can take $g_1, \ldots, g_q, g$ to be the functions which map everything to 1. Otherwise, $T^{(i,u)}(u) = 0$ and $T^{(i,u)}(w) = 1$ for all $w \in \Sigma^q - \{u\}$. In this case, define $g_\ell : \Sigma \to \Delta$ by

$$g_\ell(w) = \begin{cases} 0 & w_\ell = u_\ell \\ 1 & w_\ell \neq u_\ell \end{cases}$$

and let $g : \Delta^q \to \{0,1\}$ be the function which maps $(0,\ldots,0)$ to 0 and all other elements to 1. It is straightforward to check that $T^{(i,u)} = g \circ (g_1 \times \cdots \times g_q)$, so T' is indeed Δ-separable. ◀

▶ **Theorem 27.** *Let $C \subseteq \Sigma^n$ be an $\mathbb{F}$-code, let T be an $\mathbb{F}$-linear q-tester for C with soundness $\mu > 0$, and let Δ be a nonzero $\mathbb{F}$-vector space. Then C admits a linearly Δ-separable tester T' with soundness $\left\lceil \frac{q \dim \Sigma}{\dim \Delta} \right\rceil^{-1} \mu$.*

Proof. Write $T = (T^{(i)}, (a_1^{(i)}, \ldots, a_q^{(i)}), p_i)_{i\in I}$ and put $m = \lceil \frac{q\dim\Sigma}{\dim\Delta} \rceil$. Then for every $i \in I$, there is a subspace $V_i \subseteq \Sigma^q$ such that $T^{(i)}(u) = 1$ if and only if $u \in V_i$ ($u \in \Sigma^q$). By the definition of m, we have $\dim \Delta^m = m \dim \Delta \geq \dim \Sigma^q$. Thus, there is a linear map $h_i : \Sigma^q \to \Delta^m$ with kernel V_i. For $j \in [m]$, denote by $h_{ij} : \Sigma^q \to \Delta$ the j-th component of h_i.

We now define an $\mathbb{F}$-linear q-tester T' as follows: Given $w \in \Sigma^n$, choose $i \in I$ according to p and $j \in [m]$ uniformly at random, and accept w if and only if $h_{ij}(w_{a_1^{(i)}}, \ldots, w_{a_q^{(i)}}) = 0$. It is clear that T' accepts every $w \in C$. Moreover, since $V_i = \ker h_i = \bigcap_{j=1}^m \ker h_{ij}$, whenever $T^{(i)}(w_{a_1^{(i)}}, \ldots, w_{a_q^{(i)}}) = 0$, there is at least one $j \in [m]$ such that $h_{ij}(w_{a_1^{(i)}}, \ldots, w_{a_q^{(i)}}) \neq 0$. This means that $\Pr(T'(w)=0) \geq \frac{1}{m}\Pr(T(w)=0)$, so T' has soundness $\frac{\mu}{m}$.

It remains to show that T' is linearly Δ-separable. To that end, observe that

$$T' = (T^{(i,j)}, (a_1^{(i,j)}, \ldots, a_q^{(i,j)}), p_{(i,j)})_{(i,j)\in I\times[m]},$$

where $p_{(i,j)} := \frac{p_i}{m}$, $a_\ell^{(i,j)} := a_\ell^{(i)}$ ($i \in I$, $j \in [m]$, $\ell \in [q]$), and $T^{(i,j)}(u)$ ($u \in \Sigma^q$) is defined to be 1 if $u \in \ker h_{ij}$ and 0 otherwise. Fix some $i \in I$ and $j \in [m]$. Then there are linear maps $g_1, \ldots, g_q : \Sigma \to \Delta$ such that $h_{ij}(u) = g_1(u_1) + \cdots + g_q(u_q)$ for all $u \in \Sigma^q$. This means that we can recover $T^{(i,j)}(u)$ from $g_1(u_1), \ldots, g_q(u_q)$, so $T^{(i,j)}$ factors via $g_1 \times \cdots \times g_q : \Sigma^q \to \Delta^q$. ◀

7 Alphabet Reduction for Good LTCs

We finally put the results of the previous sections together to prove our alphabet reduction results for good LTCs.

We begin with results about $\mathbb{F}$-codes. Theorem 3 is an immediate consequence of the following theorem applied with $(q,c) = (2,2)$ and $(q,c) = (3,1)$.

▶ **Theorem 28.** *Let $q \geq 2$ be an integer and let Δ be an $\mathbb{F}$-vector space of dimension $d > 0$. We further fix an auxiliary parameter $c \in \{1, \dots, d\}$ and require that $q \geq 3$ if $c = 1$. Suppose that $C \subseteq \Sigma^n$ is an $\mathbb{F}$-code with relative distance δ and rate r admitting an $\mathbb{F}$-linear q-query tester T with soundness $\mu > 0$. Then there exists an $\mathbb{F}$-code $C' \subseteq \Delta^{|\Sigma|^c n}$ with relative distance $(1 - |\mathbb{F}|^{-c})\delta$ and rate $\frac{1}{d} \cdot \frac{\dim \Sigma}{|\Sigma|^c} \cdot r$ admitting an $\mathbb{F}$-linear q-query tester T' with soundness*

$$\frac{c\mu\nu}{(q \dim \Sigma + c)(q|\Sigma|^c + \nu) + c\mu(1+\nu)},$$

where ν is the largest possible soundness of a q-query tester for the generalized Hadamard code $H(\Sigma, \mathbb{F}^c)$ (see § 5.2). Moreover, $\nu \geq |\Sigma|^{-2c}$ if $c > 1$ and $\nu \geq |\Sigma|^{-3}$ if $c = 1$.

Our requirement about q implies that the theorem cannot be applied with 1-dimensional Δ and $q = 2$.

Note that increasing the auxiliary parameter c decreases the rate of C', and also the ratio between the block-lengths of C and C'. On the other hand, we expect that increasing c would increase ν, and thus the soundness of T'. In particular, we believe that ν is much larger than the naive lower bound provided in the theorem. For example, when $q = 3$ and $c = 1$, we have $\nu \geq \frac{1}{6}$ by [20, Lem. B.2]; see also [21, Thm. 4.8] which shows that ν is close to 1 when $c = 1$.

Proof. Fix a c-dimensional subspace $\Delta' \subseteq \Delta$. By Theorem 27, we may assume that T is Δ'-separable at the cost of reducing the soundness from μ to $\mu' := \frac{c}{q \dim \Sigma + c}\mu$ (note that $\lceil \frac{q \dim \Sigma}{c} \rceil^{-1} \geq (\frac{q \dim \Sigma}{c} + 1)^{-1} = \frac{c}{q \dim \Sigma + c}$). Now, by Proposition 24(ii), there is an $\mathbb{F}$-linear injective function $f : \Sigma \to (\Delta')^k$ such that T is f-compatible. Moreover, by Remark 25, $D := \mathrm{im}(f)$ is the generalized Hadamard code $H(\Sigma, \Delta')$, and so $k = |\Sigma|^c$. By the definition of ν, the code $D \subseteq (\Delta')^k$ admits an $\mathbb{F}$-linear q-tester with soundness ν. Moreover, since $q \geq 2$ when $c > 1$ (resp. $q \geq 3$ with $c = 1$), ν is greater than or equal to the soundness of the 2-dependence (resp. 3-dependence) tester for $H(\Sigma, \Delta')$. The latter is positive by Theorem 16 (resp. the discussion in § 5.2), so $\nu \geq k^{-2} = |\Sigma|^{-2c}$ (resp. $\nu \geq k^{-3} = |\Sigma|^{-3}$).

Consider the code $C'' := C \circ_f D \subseteq (\Delta')^{kn}$. By Proposition 6, it has relative distance $\delta(H(\Sigma, \Delta'))\delta(C) = (1 - |\Delta'|^{-1})\delta$ and rate $r(H(\Sigma, \Delta'))r(C) = \frac{r \dim \Sigma}{c|\Sigma|^c}$, and by Theorem 8, it has an $\mathbb{F}$-linear q-tester with soundness

$$\mu'' := \frac{\mu'\nu}{qk + \mu' + \nu} = \frac{c\mu\nu}{(q \dim \Sigma + c)(q|\Sigma|^c + \nu) + c\mu}.$$

Finally, we take C' to be C'' viewed as a code with alphabet Δ (instead of Δ'). This multiplies the rate by $\frac{\dim \Delta'}{\dim \Delta} = \frac{c}{d}$, has no effect on the relative distance, and by Proposition 10, C' still admits an $\mathbb{F}$-linear q-tester with soundness $\frac{\mu''}{\mu'' + 1} = \frac{c\mu\nu}{(q \dim \Sigma + c)(q|\Sigma|^c + \nu) + c\mu(1+\nu)}$. ◀

Theorem 2 follows by applying following theorem with $(q, c) = (2, 3)$ and $(q, c) = (3, 2)$.

▶ **Theorem 29.** *Let $q \geq 2$ be an integer and let Δ be an alphabet with d elements. We further fix an auxiliary parameter $c \in \{2, \dots, d\}$ and require that $q \geq 3$ if $c = 2$. Suppose that $C \subseteq \Sigma^n$ is a code with relative distance δ and rate r admitting a possibly adaptive q-query tester T with soundness $\mu > 0$. Then there exists a code $C' \subseteq \Delta^{c^{|\Sigma|} n}$ with relative distance $(1 - c^{-1})\delta$ and rate $\frac{\log_d |\Sigma|}{c^{|\Sigma|}} \cdot r$ admitting a q-query tester T' with soundness*

$$\frac{\mu\nu}{|\Sigma|^q(qc^{|\Sigma|} + \nu) + \mu(\nu + 1)},$$

where ν is the largest possible soundness of a q-query tester for the generalized long code $L(\Sigma, \{1, \dots, c\})$ (see § 5.3). Moreover, $\nu \geq c^{-2|\Sigma|}$ if $c > 2$ and $\nu \geq 2^{-3|\Sigma|}$ if $c = 2$.

Our requirement about q implies that the theorem cannot be applied when $q = 2$ and $|\Delta| = 2$. As in Theorem 28, the parameter c allows a trade-off between code-theoretic properties of C' and the soundness of the tester T', where again, we believe that ν is much larger than the naive bounds given in the theorem.

Proof. The proof strategy is similar to that of proving Theorem 28.

Let Δ' be a subset of Δ having c elements. We use Theorem 26 to replace T with a Δ'-separable tester with soundness $\mu' := \frac{\mu}{|\Sigma|^q}$. By Proposition 23(ii), there is an injective function $f : \Sigma \to (\Delta')^k$ such that T is f-compatible, and by Remark 25, it can be chosen so that $D := \mathrm{im}(f)$ is the generalized long code $L(\Sigma, \Delta')$. In particular, $k = c^{|\Sigma|}$. By Theorem 17 (resp. Proposition 18), when $c > 2$ (resp. $c = 2$), the 2-dependence (resp. 3-dependence) for D has positive soundness. As a result, when $c > 2$ (resp. $c = 2$), D has a q-tester with soundness $\nu \geq k^{-2}$ (resp. $\nu \geq k^{-3}$).

The proof is finished as in Theorem 28 by taking C' to be the code $C \circ_f D \subseteq (\Delta')^{kn}$ and viewing it as a code inside Δ^{kn}. ◀

Next, we note that the parameters of the code C' and the tester T' promised by Theorem 29 can be improved if C is assumed to be an $\mathbb{F}_2$-code and T is $\mathbb{F}_2$-linear. This is the content of the following theorem, which we state only in the case $|\Delta| = 3$ for simplicity.

▶ **Theorem 30.** *Suppose that $C \subseteq \Sigma^n$ is an $\mathbb{F}_2$-code with relative distance δ and rate r admitting an $\mathbb{F}_2$-linear q-query tester T with soundness $\mu > 0$. Then there exists a code $C' \subseteq \{0,1,2\}^{(2|\Sigma|^2+|\Sigma|)n}$ with relative distance $\frac{\delta}{2|\Sigma|^2+|\Sigma|}$ and rate $\frac{\log_3 |\Sigma|}{2|\Sigma|^2+|\Sigma|} \cdot r$ admitting a q-query tester T' with soundness*

$$\frac{\mu\nu}{q \dim \Sigma \cdot (2q|\Sigma|^2 + q|\Sigma| + \nu) + \mu},$$

where $\nu \geq (2|\Sigma|^2 + |\Sigma|)^{-2}$ is the maximal possible soundness of a 2-query tester for a certain code $D \subseteq \{0,1,2\}^{2|\Sigma|^2+|\Sigma|}$ specified in the proof.

We will need the following lemma, whose straightforward proof may be found in the extended version of this paper [10, Lem. 7.4].

▶ **Lemma 31.** *Let $C \subseteq \Sigma^n$ be a code with a q-tester T. Let Δ be an alphabet and let Δ' be another alphabet containing Δ. Let $f_1, \ldots, f_k : \Sigma \to \Delta$ and let $f'_1, \ldots, f'_{k'} : \Sigma \to \Delta'$. Define $f : \Sigma \to \Delta^k$ by $f(a) = (f_1(a), \ldots, f_k(a))$ and define $f' : \Sigma \to (\Delta')^{k'}$ similarly. Suppose that for every $i \in [k]$, there is $i' \in [k']$ such that $f'_{i'} = f_i$ as functions from Σ to Δ'. If T is f-compatible, then it is f'-compatible.*

Proof of Theorem 30. By Theorem 27, we may replace T with a linearly $\mathbb{F}_2$-separable tester at the cost of reducing the soundness to $\mu' := \frac{\mu}{q \dim \Sigma}$.

Let $g_1, \ldots, g_t$ be all the linear $\mathbb{F}_2$-functions from Σ to $\mathbb{F}_2$ (so $t = |\Sigma|$), and let $g : \Sigma \to \{0,1\}^t$ be defined by $g(a) = (g_1(a), \ldots, g_t(a))$. By Proposition 24(ii), T is g-compatible. Now define $f_1, \ldots, f_\ell : \Sigma \to \{0,1,2\}$ as in Lemma 19 (with ℓ in place of n). By construction, $\ell \leq t + 2t^2 =: k$, and if $\ell < t + 2t^2$ we define $f_{\ell+1}, \ldots, f_k : \Sigma \to \{0,1,2\}$ to be identically 0. Now define $f : \Sigma \to \{0,1,2\}^k$ similarly to g. By Lemma 31, T is also f-compatible.

Put $D = D(\{f_i\}_{i=1}^k) \subseteq \{0,1,2\}^k$ and let $C' = C \circ_f D \subseteq \{0,1,2\}^{kn}$. By Lemma 19, $D \subseteq \{0,1,2\}^k$ has a 2-query tester with soundness $k^{-2} = (t + 2t^2)^{-2}$, so $\nu \geq (t + 2t^2)^{-2}$. Furthermore, by Theorem 8, $C' \subseteq \{0,1,2\}^{kn}$ has a 2-query tester with soundness

$$\frac{\mu'\nu}{qk + \mu' + \nu} = \frac{\mu\nu}{q \dim \Sigma \cdot (2q|\Sigma|^2 + q|\Sigma| + \nu) + \mu}.$$

To finish, note that by Proposition 6, $\delta(C') \geq \delta(D)\delta(C) \geq \frac{\delta}{k}$ and $r(C') = r(D)r(C) = \frac{\log_3 |\Sigma|}{k} \cdot r$. ◀

▶ Remark 32. By tracing the proofs of Theorems 28, 29, 30, one sees that if the tester T of C has randomness complexity R, then the promised tester T' for C' has randomness complexity $\max\{R, \log_2 n\} + O(1)$, where the $O(1)$-factor depends on μ, $|\Sigma|$, $|\Delta|$.

Parallel Sampling from the Ising p-Spin Model

Abstract

We study the parallel complexity of sampling from the high-temperature Ising mixed p-spin Gibbs measure, a canonical instance of a mean-field spin glass on the hypercube $\{\pm 1\}^n$. We propose two different algorithms for this problem, corresponding to two different regimes of accuracy.

Our first algorithm is a parallel implementation of a Markov chain known as block dynamics, combined with an approximate rejection sampling step that uses an Ising model in a novel way as a proposal distribution to approximate the quadratic interaction terms of the p-spin Hamiltonian. For any $\varepsilon > 0$, this algorithm runs in $n^{1/3}\mathrm{polylog}(n/\varepsilon)$ parallel time with $\mathrm{poly}(n/\varepsilon)$ work, and outputs a sample whose law is ε-close to the p-spin measure in total variation distance.

Our second algorithm uses Picard iterations to parallelize the Algorithmic Stochastic Localization (ASL) process of El Alaoui, Montanari, and Sellke (2025), and for any $\varepsilon > \varepsilon_n$, takes $\mathrm{polylog}(n/\varepsilon)$ parallel time and $\mathrm{poly}(n/\varepsilon)$ work to produce a sample that is ε-close to the p-spin measure in the normalized 2-Wasserstein metric. Here, $\varepsilon_n > 0$ is a threshold that goes to 0 as $n \to \infty$. Our result constitutes a doubly exponential improvement in the ε dependence of the runtime and an exponential improvement in the ε dependence of the total work when compared to naïve ASL, whose runtime scales as $\exp(\mathrm{poly}(1/\varepsilon))$.

1 Introduction

Efficient sampling from a probability distribution which is specified only up to an unknown normalizing constant is a central algorithmic problem across computer science, statistical physics, and machine learning. Generally, given a finite state space Ω and a Hamiltonian $H : \Omega \to \mathbb{R}$, the target distribution is a Gibbs measure of the following form:

$$\mu(x) = \frac{1}{Z}\exp(H(x)), \qquad Z = \sum_{x\in\Omega}\exp(H(x)) \tag{1}$$

where the normalizing constant Z, also known as the partition function, is unknown and typically hard to compute. This setting includes classical problems in approximate counting [32] and randomized algorithms such as approximating the volume of convex bodies [15] and approximating matrix permanents [31], Markov-chain Monte Carlo methods in statistical physics [41], and posterior sampling in high-dimensional statistical models.

Our work studies the problem of sampling from the Gibbs measure of the Ising mixed p-spin model, which is a Gibbs measure on the hypercube $\{\pm 1\}^n$ whose Hamiltonian is a random polynomial with Gaussian coefficients.

$$H(x) = \sum_{p=2}^{P} \frac{\beta_p \sqrt{p!}}{n^{\frac{p-1}{2}}} \cdot \sum_{J \subseteq [n], |J|=p} G_J \prod_{k \in J} x_k + \langle x, h \rangle, \qquad \mu(x) = \frac{1}{Z} \exp(H(x)) \tag{2}$$

Here, $P \geq 2$ is an integer, the disorder $G_J \overset{i.i.d}{\sim} \mathcal{N}(0,1)$ for every choice of J, and h is an arbitrary external field independent of G. The p-spin Hamiltonian can be equivalently characterized as a Gaussian process on $\{\pm 1\}^n$ with $\mathbb{E}_G[H(x)] = \langle h, x \rangle$ and $\mathrm{Cov}[H(x)H(y)] = N\xi(\langle x,y \rangle / N)$, where $\xi(t) = \sum_{p=2}^{P} \beta_p^2 t^p$ denotes the mixture function. The mixed p-spin model is a canonical instance of a mean-field spin glass, which plays a central role in several areas of probability, mathematical physics, and average-case complexity [37, 46, 40, 38]. Notable special cases include the pure p-spin model where only one β_p is nonzero, and the Sherrington-Kirkpatrick (SK) model where $P = 2$.

We consider the problem of approximate sampling from the p-spin Gibbs measure in the quenched setting, where the disorder G is sampled once and then fixed, and the algorithm is tasked with approximately sampling from μ given random access to the disorder coefficients (which can be stored with $\mathrm{poly}(n)$ memory). Given an error parameter $\varepsilon > 0$, the goal is to design an algorithm that runs in time $\mathrm{poly}(n, 1/\varepsilon)$ for any realization of G, and produces an output distributed as $\hat{\mu}$ such that $\mathrm{dist}(\hat{\mu}, \mu) \leq \varepsilon$ for typical realizations of G. Here, dist denotes any appropriate metric between probability distributions.

Under this setting, [1] and [7] analyze Glauber dynamics [27], a canonical Markov chain for sampling from discrete distributions, which, at every step, resamples a randomly chosen coordinate according to its conditional marginal, while fixing the remaining coordinates. The authors identify a high-temperature regime for the p-spin model under which Glauber dynamics efficiently samples from μ. Specifically, they show that when $\sum_{p=2}^{P} \beta_p \sqrt{p^3 \ln(p)} \leq C$ for some small enough $C = \Theta(1)$, Glauber dynamics takes $O(n \ln(n/\varepsilon))$ time to output a sample distributed as $\hat{\mu}$ satisfying $d_{\mathrm{TV}}(\hat{\mu}, \mu) \leq \varepsilon$ with high probability over the randomness of G. Since the error parameter $\varepsilon > 0$ can be made as small as desired, we refer to such a guarantee as a *High Accuracy Guarantee*.

In another line of work, [19] propose a different approximate sampler for the p-spin model with a zero external field (i.e., $h = 0$ in Equation (2)) based on an approximate discretization of an Itô diffusion process known as Eldan's stochastic localization [20]. Their algorithm, named Algorithmic Stochastic Localization (ASL), offers a weaker sampling guarantee, albeit supporting a broader range of temperatures than that covered by the high-temperature condition defined above. Concretely, there exists an error threshold $\varepsilon_n = o_n(1)$ such that for any $\varepsilon > \varepsilon_n$, ASL runs in time $O(\mathrm{poly}(n) \exp(\mathrm{poly}(1/\varepsilon)))$ and with high probability over G, approximately samples from μ up to error ε in the normalized 2-Wasserstein metric. In other words, the output $\hat{x}$ of their algorithm can be coupled with some $x^\star \sim \mu$ such that $n^{-1}\,\mathbb{E}[\|\hat{x} - x^\star\|] \leq \varepsilon^2$. We call such a guarantee a *Low Accuracy Guarantee* for two key reasons. Firstly, for a fixed problem instance, the accuracy of ASL can only be certified above a threshold $\varepsilon > \varepsilon_n$. Secondly, their guarantees are presented in the normalized 2-Wasserstein metric, which is strictly weaker than the total variation metric for the range of ε tolerated by their algorithm.

A common drawback of both algorithms considered above is that they are inherently sequential. Indeed, Glauber dynamics sequentially updates one coordinate after another in a random order, while Algorithmic Stochastic Localization discretizes the trajectory of a continuous Markov process, which naturally evolves in a sequential fashion. Consequently, these algorithms fail to utilize the full potential of modern hardware, which is generally capable of massive parallelism, both in terms of parallel computation and parallel memory access. This motivates the central problem of our work:

Can we design an efficient approximate sampling algorithm for the Ising p-spin model that can take advantage of parallel hardware?

Specifically, we consider the problem of sampling from the p-spin Gibbs measure in the PRAM model of computation, where the algorithm is allowed to query the disorder G in multiple rounds, with each round comprising polynomially many synchronous queries that are executed in parallel. Given an error tolerance $\varepsilon > 0$, our goal is to design an algorithm that approximately samples from μ up to error ε in some suitable metric for typical realizations of G, while also optimizing for two criteria: *Parallel Runtime* or *Round Complexity*, which denotes the number of rounds of parallel queries made to G, and *Work*, which denotes the total number of queries made to G. Ideally, for every realization of G, we want the parallel runtime to scale at most sublinearly in n and ε^{-1}, and the work to scale at most polynomially in n and ε^{-1}.

Compared to the complexity of sequential sampling, the theory of parallel sampling for mean-field spin glasses is far less developed. To our knowledge, the only prior parallel algorithm for sampling from the p-spin Gibbs measure is the work of [34], which considers the p-spin model in the high-temperature regime and achieves a high-accuracy guarantee with a parallel runtime of $O(\sqrt{n} \cdot \mathrm{polylog}(n/\varepsilon))$ and $O(\mathrm{poly}(n/\varepsilon))$ work. Beyond this, for the special case of the high-temperature SK model (i.e., $P = 2$ and $\beta_2 < 1/4$), [11] show that the Restricted Gaussian Dynamics algorithm of [12] is a high-accuracy approximate parallel sampler with parallel runtime $O(\mathrm{polylog}(n/\varepsilon))$ and $O(\mathrm{poly}(n/\varepsilon))$ work.

1.1 Our Contributions

In this work, we develop two different algorithms for parallel sampling from the Ising mixed p-spin Gibbs measure. The first is a high-accuracy algorithm which samples from the p-spin model up to ε total variation error in $O(n^{1/3}\mathrm{polylog}(n/\varepsilon))$ parallel time and $O(\mathrm{poly}(n, \log(n/\varepsilon)))$ work. To our knowledge, this constitutes an improvement both in terms of parallel runtime and work compared to the previous best known result of [34], which exhibits a parallel runtime of $O(\sqrt{n}\mathrm{polylog}(n/\varepsilon))$ with $O(\mathrm{poly}(n/\varepsilon))$ work.

▶ **Theorem 1** (High-Accuracy Parallel p-spin Sampler, Informal Version of Theorem 7)**.** *Let μ denote the Ising p-spin Gibbs measure as defined in Equation (2). Assume the model is in the high-temperature regime, i.e., $\sum_{p=2}^{P} \beta_p \sqrt{p^3 \ln(p)} \le C$ for some $C = \Theta(1)$. Then, there exists a parallel sampling algorithm (Algorithm 1) satisfying the following for any $\varepsilon > 0$.*

- *The algorithm runs in parallel time $\widetilde{O}(n^{1/3} \ln(1/\varepsilon))$ with $O(\mathrm{poly}(n, \log(n/\varepsilon)))$ work.*
- *With probability at least $1 - \exp(-cn)$ over the randomness of the disorder G, the algorithm outputs $\hat{x} \sim \hat{\mu}$ such that $d_{\mathrm{TV}}(\hat{\mu}, \mu) \le \varepsilon$.*

Our second algorithm obtains a low-accuracy approximate sampling guarantee in the normalized 2-Wasserstein metric, and enjoys a parallel runtime of $O(\mathrm{polylog}(n/\varepsilon))$ with $O(\mathrm{poly}(n/\varepsilon))$ work. This significantly improves upon the $O(\mathrm{poly}(n) \cdot \exp(\mathrm{poly}(1/\varepsilon)))$ runtime of [19] and constitutes the first parallel algorithm for sampling from the p-spin model with $\mathrm{polylog}(n/\varepsilon)$ parallel runtime in any metric.

▶ **Theorem 2** (Low-Accuracy Parallel p-spin Sampler, Informal Version of Theorem 16)**.** *Let μ denote the Ising p-spin Gibbs measure as defined in Equation (2) with $h = 0$. Assume the model is in the high-temperature regime, i.e., $\sum_{p=2}^{P} \beta_p \sqrt{p^3 \ln(p)} \le C$ for some $C = \Theta(1)$. Then, there exists an $\varepsilon_n > 0$ such that $\varepsilon_n \to 0$ as $n \to \infty$, and a parallel sampling algorithm (Algorithm 4) which satisfies the following for any $\varepsilon > \varepsilon_n$:*

- *The algorithm runs in parallel time $O(\mathrm{polylog}(n/\varepsilon))$ with $O(\mathrm{poly}(n/\varepsilon))$ work.*
- *With probability at least $1 - o(1)$ over the randomness of the disorder G, the output $\hat{x}$ of the algorithm can be coupled to some $x^\star \sim \mu$ such that $n^{-1}\,\mathbb{E}[\|\hat{x} - x^\star\|^2] \le \varepsilon^2$.*

For the special case of the SK model, our low-accuracy algorithm satisfies the above guarantee for $\beta_2 \leq 0.375$. To the best of our knowledge, this constitutes the only parallel sampler for the SK model running in $O(\mathrm{polylog}(n/\varepsilon))$ time with $O(\mathrm{poly}(n/\varepsilon))$ work in this regime of inverse temperatures.

1.2 Related Work

1.2.1 Sampling from mean-field spin glasses

For the Sherrington–Kirkpatrick model ($P = 2$), classical mixing criteria such as Dobrushin's condition [14] imply $\widetilde{O}(n^2)$ mixing time of Glauber dynamics only up to the vanishing window $\beta_2 = O(n^{-1/2})$. This falls short of the dimension-free β_2 regime predicted in the statistical physics literature and leads to algorithmically unsatisfactory guarantees. The first major breakthrough was the work of [21] which used stochastic localization to prove that Glauber dynamics mixes in $\widetilde{O}(n^2)$ time up to $\beta_2 < 1/4$. The mixing time was subsequently sharpened to $\widetilde{O}(n)$ by [6] and [12], and the range of β_2 was improved to $\beta_2 < 0.295$ by [8]. For the Ising p-spin model, [1] proved an $\widetilde{O}(n^2)$ mixing time for Glauber dynamics in the high-temperature regime $\sum_{2\leq p\leq P} \beta_p \sqrt{p^3 \ln(p)} = O(1)$. The mixing time was later improved to $\widetilde{O}(n)$ by [7].

In a different direction, [17] (see also [10]) introduced Algorithmic Stochastic Localization (ASL) for the SK model with zero external field. For any $\varepsilon > \varepsilon_n$ for a fixed $\varepsilon_n = o_n(1)$, their algorithm runs in time $O(\mathrm{poly}(n)\exp(\mathrm{poly}(1/\varepsilon)))$ and obtains a low-accuracy guarantee: sampling up to ε-error in the normalized 2-Wasserstein distance. Their algorithm works up to $\beta_2 < 1$, which is conjectured to be the sharp threshold up to which the SK model admits a polynomial-time approximate sampler. Their framework was later extended to the Ising p-spin model in [19], obtaining a similar low-accuracy guarantee but covering a broader range of temperatures than that of [1] and [7].

There also exists a parallel line of work on the spherical p-spin model, where the Gibbs measure μ is supported on the sphere $\{x \in \mathbb{R}^n \mid \|x\|^2 = n\}$, a setting that is often more analytically tractable than the hypercube. In the high-temperature regime, [26] proved that a continuous-time diffusion process known as Langevin dynamics samples from the spherical p-spin model in total variation in $\widetilde{O}(1)$ time. Beyond the high-temperature regime considered in [26], the recent breakthrough of [30] designed an improved version of ASL for the spherical p-spin model with zero external field that samples up to $o(1)$ error in total variation in $O(\mathrm{poly}(n))$ time beyond the high-temperature regime considered by [26]. Building upon their techniques, [29] proved that continuous-time annealed Langevin dynamics samples up to total variation error $\exp(-\Omega(n^{-1/5}))$ in $O(\mathrm{poly}(n))$ time beyond the high-temperature regime.

1.2.2 Parallel sampling

Parallel sampling has been a longstanding topic of interest in theoretical computer science, and more recently, in machine learning, where diffusion-based generative models are often deployed on massively parallel hardware [33, 44, 28]. In theoretical computer science, the problem dates back to at least [39], who developed an RNC algorithm (i.e., running in $O(\mathrm{polylog}(n))$ parallel time on a PRAM with $O(\mathrm{poly}(n))$ work) for finding a perfect matching, and asked whether one can also sample a uniform random perfect matching in parallel; this remains a major open problem to date.

Recent works study parallel sampling assuming access to global counting oracles. One such model is the weighted counting oracle, where one has access to the log Laplace transform $L(w) = \ln \mathbb{E}_\mu[\exp(\langle w, x\rangle)]$. A weaker model is the unweighted counting oracle, which returns

conditional marginals $\mathbb{P}_{X\sim\mu}[X_i = a \mid X_S = \omega_S]$ for $S \subseteq [n]$, $i \notin S$, $a \in \{\pm 1\}$, and $\omega_S \in \{\pm 1\}^S$. Such models are of interest for several combinatorial distributions such as spanning trees, Eulerian tours, planar perfect matchings, and determinantal point processes, where such oracles can be implemented on a PRAM in $O(\text{polylog}(n))$ time and $O(\text{poly}(n))$ work [13]. Assuming access to weighted counting oracles, [5, 3] obtained RNC samplers for distributions satisfying $\|\nabla^2 L(w)\|_{\text{op}} = O(1)$. For more general distributions that do not satisfy such a regularity condition, [28] developed an algorithm running in $\widetilde{O}(n^{2/3})$ parallel time with polynomial work. The parallel runtime was later improved to $\widetilde{O}(\sqrt{n})$ by [2]. In the weaker unweighted counting model, [4] developed an $O(n^{2/3})$ time parallel sampler with $O(\text{poly}(n))$ work. The parallel runtime was later improved to $O(\sqrt{n})$ by [2].

Contrary to the above, our work falls under the more challenging local oracle setting, where one has to design a parallel sampler for a Gibbs measure given access to its Hamiltonian. This constitutes a far weaker form of access compared to the global counting oracles described above. In fact, the problem of computing a counting oracle of a Gibbs measure given its Hamiltonian is NP-hard in the worst case [25], and highly nontrivial even for specialized Hamiltonians like the SK model. In this setting, [23, 36] develop RNC samplers for Ising models satisfying a Dobrushin-type condition. For mean-field spin glass models, this only covers a vanishing window of temperatures, e.g., $\beta_2 = O(n^{-1/2})$ for the SK model. More recently, [11] show that the Restricted Gaussian Dynamics algorithm of [12] is an RNC sampler for the SK model. For general Ising p-spin models, much less is known. To our knowledge, the only parallel sampler in this setting prior to our work is [34], which runs in $\widetilde{O}(\sqrt{n})$ parallel time with polynomial work.

1.3 Overview of Our Techniques

Algorithm 1 s-Glauber Dynamics with Parallel Rejection Sampling.

Sample $X^{(0)}$ from $\mu_0 \propto e^{\langle h,x\rangle}$
for $t = 0, \ldots, T-1$ **do**
  Sample $S \sim \text{Uniform}\binom{[n]}{s}$
  $X_S^{(t+1)} \leftarrow \textsc{ParallelRejectionSampler}(S, X_{\overline{S}}^{(t)}, \varepsilon/10T)$ *(see Algorithm 2)*
  $X_{\overline{S}}^{(t+1)} \leftarrow X_{\overline{S}}^{(t)}$
return $X^{(T)}$

1.3.1 High Accuracy Sampler

Motivated by the prior work of [34], our high-accuracy sampler for the p-spin model, stated in Algorithm 1, is a computationally efficient implementation of a Markov chain called s-Glauber dynamics (also known as s-block dynamics), whose kernel $P_s(X^{(t)}, \cdot)$ is defined as follows:

1. Sample S uniformly at random from all subsets of $[n]$ of size s.
2. Sample $X^{(t+1)}$ from the posterior $\mu\left(X^{(t+1)} \;\middle|\; X_S^{(t+1)} = X_S^{(t)}\right)$

The above Markov chain is reversible with respect to μ and, for $s = 1$, it corresponds to Glauber dynamics, a canonical sampling algorithm for discrete spaces. When μ is the p-spin Gibbs measure at high temperature, s-Glauber dynamics is known to exhibit a mixing time of $\widetilde{O}(n/s)$ [7, 34]. Although this mixing time improves upon increasing s, the computational complexity of implementing each step of s-Glauber dynamics worsens significantly as s grows.

Algorithm 2 Approximate Parallel Rejection Sampling with an Ising Proposal (ParallelRejectionSampler).

Input: S, pinning τ on $\overline{S}$, $\varepsilon_{\text{step}}$

Set $y = X_S$ and decompose the conditional Hamiltonian $H_{S,\tau}(y) = H(y, \tau)$ on S as follows

$$H(y) = \langle b_{S,\tau}, y\rangle + \frac{1}{2}\, y^\top A_{S,\tau} y + R_{S,\tau}(y).$$

Set the rejection parameter $\bar{c} = \Theta(1)$, $L = \Theta(\bar{c}\ln(1/\varepsilon_{\text{step}}))$, $\varepsilon_{\text{RGD}} = \Theta(\varepsilon_{\text{step}}/L)$, $\eta = \Theta(1)$, and $\delta = \Theta(\varepsilon_{\text{step}})$

$\hat{h} = \textsc{CenteringExternalField}(A_{S,\tau}, b_{S,\tau}, R_{S,\tau}, \eta, \delta)$ *(see Algorithm 6)*

for $\ell = 1$ **to** L **do In Parallel**

- $U_\ell, V_\ell \overset{\text{iid}}{\sim} \text{RGD}\Big(A_{S,\tau},\, b_{S,\tau} + \hat{h},\, \varepsilon_{\text{RGD}}\Big)$
- $W_\ell \sim \mathsf{Uniform}[0,1]$
- Accept U_ℓ if $W_\ell \le \min\big\{1, \bar{c}^{-1}\exp(\psi(U_\ell) - \psi(V_\ell))\big\}$ where $\psi(y) = R_{S,\tau}(y) - \Big\langle \hat{h}, y \Big\rangle$

return *the first accepted sample; declare FAILURE otherwise*

Indeed, a naïve implementation of the posterior sampling step (i.e., Step 2 above) takes $O(2^s)$ time, which is computationally prohibitive, and completely negates the potential benefits of any mixing time improvements for $s > 1$.

To circumvent this, our Algorithm 1 replaces the posterior sampling step in s-Glauber dynamics with an approximate rejection sampler (Algorithm 2), whose proposal distribution is a carefully chosen Ising model. The idea of using rejection sampling in the posterior sampling step also appears in the work of [34], which approximates the posterior sampling step with a product proposal. While this enables computational efficiency (as product measures can be sampled in $O(1)$ parallel time), their rejection sampling procedure fails to correctly approximate the posterior when $s = \omega(\sqrt{n})$, and obtains a parallel runtime of $\widetilde{O}(n^{1/2})$. In contrast, the choice of our Ising proposal, which serves as the key technical innovation underlying our parallel speedup, can be made to approximate the posterior to arbitrary accuracy as long as $s = O(n^{2/3})$, leading to an improved parallel runtime of $\widetilde{O}(n^{1/3})$.

To motivate the construction of our Ising proposal, we observe that the conditional posterior distribution $\mu_{S,\tau}(y) \coloneqq \mu(x_S = y \mid x_{\bar{S}} = \tau) \propto \exp(H_{S,\tau}(y))$ is also a p-spin Gibbs measure whose Hamiltonian, $H_{S,\tau}(y) = H(x)$ for $x_S = y$ and $x_{\bar{S}} = \tau$, is obtained by restricting H to the coordinates in S and pinning the coordinates in $\bar{S}$ according to τ. $H_{S,\tau}$ is then a polynomial of the underlying disorder G, and admits the following decomposition:

$$H_{S,\tau}(y) = \langle b_{S,\tau}, y\rangle + \frac{1}{2}\langle y, A_{S,\tau} y\rangle + R_{S,\tau}(y) \tag{3}$$

where $b_{S,\tau}$, $A_{S,\tau}$, and $R_{S,\tau}$ depend on G. Motivated by this decomposition, our rejection sampler uses a proposal distribution $\pi_{S,\tau}$ such that $\ln \pi_{S,\tau}$ serves as a quadratic approximation to $H_{S,\tau}$, i.e., $\pi_{S,\tau}(x) \propto \exp\Big(\frac{1}{2}\langle y, A_{S,\tau} y\rangle + \Big\langle b_{S,\tau} + \hat{h}, y\Big\rangle\Big)$[1]. The performance and accuracy of our algorithm are governed by two key problems: 1. How easily can we sample from the proposal? 2. How well does our rejection sampler approximate the posterior? Below, we discuss how we address each of these questions in our proof of Theorem 1.

[1] As explained in Section 3.2, the nonzero external field $\hat{h}$ *centers* our rejection sampling proposal, leading to improved accuracy.

Analyzing the parallel complexity of our algorithm is a delicate problem due to the choice of our proposal distribution. Indeed, sampling from an Ising model is in itself a nontrivial problem, which can even be NP-hard in the worst case [45, 24]. To resolve this, we use the concentration properties of the p-spin Hamiltonian to prove that sampling from $\pi_{S,\tau}$ is computationally tractable. In particular, the Hamiltonian of $\pi_{S,\tau}$ satisfies a spectral condition which ensures that a Markov chain known as Restricted Gaussian Dynamics (or RGD, see Algorithm 3) approximately samples from $\pi_{S,\tau}$ in total variation, with $\widetilde{O}(1)$ mixing time [12]. Moreover, each step of RGD can be implemented in $\widetilde{O}(1)$ parallel time with $O(\mathrm{poly}(n))$ work [11]. Thus, to ensure parallel efficiency, our rejection sampler uses approximate samples from the proposal distribution, drawn via $\widetilde{O}(1)$ parallel calls to RGD, thereby implying an $\widetilde{O}(1)$ parallel runtime for Algorithm 2, which in turn leads to an $\widetilde{O}(n/s)$ parallel runtime for Algorithm 1.

Algorithm 3 Restricted Gaussian Dynamics (RGD) [12, 11].

Input: symmetric interaction matrix $J \in \mathbb{R}^{m\times m}$, external field $h \in \mathbb{R}^m$, tolerance ε
Output: Sample X satisfying $d_{\mathsf{TV}}(\mathsf{Law}(X), \nu_{J,h}) \le \epsilon$ where
$\nu_{J,h}(x) \propto \exp(\frac{1}{2}\langle x, Jx\rangle + \langle h, x\rangle)$
Initialize $X^{(0)} \in \{\pm 1\}^m$ arbitrarily
Set $T = \Theta(\log(m/\epsilon))$
for $t = 1, \dots, T$ **do**
  Sample $y \sim \mathcal{N}(X^{(t)}, J^{-1})$
  Sample $X^{(t)}$ from the product measure $p(x) \propto \exp(\langle x, h + Jy\rangle)$
return $X^{(T)}$

Finally, the optimal choice of s is determined by the approximation error of our rejection sampler. There are two main sources of this error, namely, the approximate sampling error of RGD (which can be controlled to arbitrary precision without sacrificing algorithmic efficiency), and the error due to mismatch between the proposal $\pi_{S,\tau}$ and the conditional posterior $\mu_{S,\tau}$, which is governed by the log-density $\psi(y) = \ln \frac{\mathrm{d}\mu_{S,\tau}}{\mathrm{d}\pi_{S,\tau}}(y)$. We show that this error can be controlled by proving exponential tail bounds on ψ under $\pi_{S,\tau}$, which we establish via the concentration properties of the p-spin Hamiltonian and the isoperimetric properties of the proposal, and conclude that Algorithm 2 uniformly approximates the posterior sampling step of s-Glauber dynamics for $s \le O(n^{2/3})$, leading to an overall runtime of $\widetilde{O}(n^{1/3})$ for Algorithm 1.

1.3.2 Low Accuracy Sampler

Adapting the framework of [17, 19], our low-accuracy parallel sampler, presented in Algorithm 4, is based on Eldan's Stochastic Localization (SL) [20], which we briefly introduce. For any probability measure μ supported on $\{\pm 1\}^n$, the associated SL process $(y_t)_{t\ge 0}$ is defined by the following stochastic differential equation on $\mathbb{R}^n$.

$$\mathrm{d}y_t = m(y_t)\,\mathrm{d}t + \mathrm{d}B_t, \quad y_0 = 0, \qquad m(y) = \frac{\mathbb{E}_{x\sim\mu}[x\cdot\exp(\langle y, x\rangle)]}{\mathbb{E}_{x\sim\mu}[\exp(\langle y, x\rangle)]} \tag{4}$$

Here, $(B_t)_{t\ge 0}$ denotes the standard Brownian motion on $\mathbb{R}^n$, and $m(y)$ corresponds to the mean of the exponential tilt of the measure μ, which we call the tilted mean. A key property of SL is that $t^{-1}y_t$ is marginally distributed as $x^\star + \zeta_t$ where $x^\star \sim \mu$ and

$\zeta_t \sim \mathcal{N}(0, t^{-1}I)$. Intuitively, $t^{-1}y_t$ is approximately distributed as μ for large enough t, and thus, a suitable discretization of Equation (4), such as the Euler discretization below, can be used to approximately sample from μ.

$$\widetilde{y}_{(k+1)h} = \widetilde{y}_{kh} + hm(\widetilde{y}_{kh}) + (B_{(k+1)h} - B_{kh}),\ 0 \le k < K, \qquad y_0 = 0 \tag{5}$$

Being the Euler discretization of a continuous Markov process, the discrete dynamical system specified by Equation (5) naturally evolves in a sequential fashion, and thus, naively simulating K steps requires $\Theta(K)$ calls to an oracle for the tilted mean m, even on a PRAM. To circumvent this, we employ a parallelization technique based on the concept of Picard iteration, a classical technique for proving the existence and uniqueness of ODE solutions [42], which was later used algorithmically by [3] to develop parallel algorithms for sampling from continuous log-concave densities in $\mathbb{R}^n$. The key idea behind Picard iteration is to view the trajectory defined by Equation (5) as the solution to the following fixed point problem defined by an operator $\mathcal{T} : \mathbb{R}^{n\times K} \to \mathbb{R}^{n\times K}$ over discrete trajectories:

$$\mathcal{T}(z) \coloneqq z'; \qquad z'_{kh} = h\sum_{i=0}^{k-1} m(z_{ih}) \ + B_{kh}\ \forall\ k \in [K], \qquad z'_0 = 0 \tag{6}$$

By unrolling the recurrence, one can observe that the trajectory defined by Equation (5) is a fixed point of the operator $\mathcal{T}$, i.e., $\mathcal{T}(\widetilde{y}) = \widetilde{y}$. Consequently, the discretized SL process can be approximated via the following fixed point iteration over discrete trajectories, which we call Picard iteration.

$$\widetilde{y}^{(r)}_{kh} = h\sum_{i=0}^{k-1} m(\widetilde{y}^{(r-1)}_{ih}) + B_{kh},\ \forall\ k \in [K], \qquad \widetilde{y}^{(r)}_0 = 0 \tag{7}$$

Algorithm 4 Picard Algorithmic Stochastic Localization.

Input : Parallel depth R, steps K, step size h, parameters $(\eta, K_{\mathrm{AMP}}, K_{\mathrm{NGD}})$
$B_0 \leftarrow 0$
for $k \leftarrow 0$ **to** $K-1$ **do In Parallel**
  $B_{(k+1)h} \leftarrow B_{kh} + \varepsilon_k$, where $\varepsilon_k \sim \mathcal{N}(0, hI)$
  $\hat{y}^{(0)}_{kh} \leftarrow 0$
for $r \leftarrow 1$ **to** R **do**
  $\hat{y}^{(r)}_0 \leftarrow 0$
  for $k \leftarrow 0$ **to** $K-1$ **do In Parallel**
    $\hat{m}\big(\hat{y}^{(r-1)}_{kh}\big) \leftarrow \text{TAP-AMP}\big(\hat{y}^{(r-1)}_{kh}, \eta, q_\star(kh), K_{\mathrm{AMP}}, K_{\mathrm{NGD}}\big)$
      (see Algorithm 5) and Equation (18)
  for $k \leftarrow 1$ **to** K **do In Parallel**
    $\hat{y}^{(r)}_{kh} \leftarrow h\sum_{j=0}^{k-1} \hat{m}\big(\hat{y}^{(r-1)}_{jh}\big) + B_{kh}$
Output : $\hat{x} \leftarrow \mathrm{sign}\big(\hat{y}^{(R)}_{Kh}\big)$

The key algorithmic benefit of this reformulation lies in its inherent parallelizability, albeit at the cost of introducing some mild approximation error. Indeed, Equation (7) turns the problem of sequentially evaluating the recurrence in Equation (5) into a highly parallelizable fixed point computation over the whole trajectory: given access to a parallel oracle for the tilted mean m, each Picard iteration can be implemented efficiently in parallel across all time

points. In particular, at depth r, $(\widetilde{y}_{kh}^{(r-1)})_{k\in[K]}$ can be computed simultaneously in one parallel oracle call, after which the cumulative drift terms in Equation (7) can be computed via parallel prefix sums in $O(\log(k))$ time and $O(k)$ work. However, to guarantee the effectiveness of this approach as a parallel sampler, one needs to quantify how well the Picard iterate $\widetilde{y}^{(R)}$ approximates its limiting trajectory $\widetilde{y}$. To this end, one can show (see Lemma 6) that Lipschitzness of the tilted mean (which can be guaranteed in the high-temperature regime) suffices to ensure that the Picard iterates converge to the discretized SL process exponentially fast. In particular, $R = \widetilde{\Theta}(Kh)$ iterations suffice to approximate the discrete SL trajectory in Equation (5) to arbitrary accuracy.

The key challenge in algorithmically implementing the Picard iteration in Equation (7) arises from the approximate computation of the tilted mean m, which is highly nontrivial and is known to be NP-hard even for worst-case Hamiltonians [25]. To circumvent this, we make use of the TAP-AMP algorithm of [18] (Algorithm 5), which constructs an estimator $\hat{m}$ of the tilted mean for points along the continuous SL trajectory. This results in the following inexact fixed point iteration, which we call Picard Algorithmic Stochastic Localization (Algorithm 4).

$$\hat{y}_{kh}^{(r)} = h\sum_{i=0}^{k-1}\hat{m}(\hat{y}_{ih}^{(r-1)}) + B_{kh},\ \forall\ k\in[K],\quad \hat{y}_0^{(r)} = 0 \tag{8}$$

While standard perturbation-based analyses of inexact fixed point iterations rely on uniformly controlling the deviation between the ideal and the inexact iterates, such a strategy is not applicable to Equation (8) due to the absence of uniform guarantees on the estimation error of $\hat{m}$. In fact, the current best known analysis of the tilted mean estimator can certify only a very weak error bound of the form $\|\hat{m}(y_t) - m(y_t)\|^2 \le n\varepsilon_n^2$ for points along the continuous SL trajectory. Here, ε_n is a fixed error threshold which converges to 0 as $n\to\infty$. This subtle distinction constitutes a major obstacle in our analysis since the Picard trajectories at low depth (i.e., low values of r) are expected to deviate significantly from the continuous SL trajectory. Consequently, the currently available guarantees are insufficient for controlling $\|\hat{m}(\hat{y}_{kh}^{(r)}) - m(\hat{y}_{kh}^{(r)})\|$.

To circumvent this obstacle, we depart from the standard perturbation-based analysis of inexact fixed point iteration, and instead analyze Equation (8) directly. In particular, we prove that in the high-temperature regime, the tilted mean estimator $\hat{m}(y)$ itself is uniformly $O(1)$-Lipschitz. Hence, the inexact Picard iteration in Equation (8) converges exponentially fast to the discrete process $\hat{y}_{(k+1)h} = \hat{y}_{kh} + h\hat{m}(y_{kh}) + (B_{(k+1)h} - B_{kh})$ in $R = \widetilde{O}(Kh)$ iterations. We then prove a sign rounding stability guarantee for the limiting discrete trajectory $\hat{y}$, and show that for any $\varepsilon \ge \varepsilon_n$, the distribution of $\mathrm{sign}(\hat{y}_{Kh}^{(R)}/Kh)$ approximates the p-spin measure μ up to ε error in normalized 2-Wasserstein distance whenever $Kh = O(\log(n/\varepsilon))$ and $h = O(\mathrm{poly}(1/\varepsilon))$. Since the K iterations are executed in parallel in each round, Algorithm 4 exhibits a parallel runtime of $O(\mathrm{polylog}(n/\varepsilon))$ with $O(\mathrm{poly}(n/\varepsilon))$ work. Compared to the $O(\mathrm{poly}(n)\exp(\mathrm{poly}(1/\varepsilon)))$ runtime of Algorithmic Stochastic Localization, this constitutes a doubly exponential improvement in runtime and an exponential improvement in work in terms of ε.

2 Preliminaries

2.1 Notation

For differentiable functions $g:\mathbb{R}^d\to\mathbb{R}$, we use ∇g and $\nabla^2 g$ to denote their Euclidean gradient and Hessian, respectively. For functions $f:\{\pm1\}^m\to\mathbb{R}$, we define the discrete partial derivative, and the associated discrete gradient and discrete Hessian as follows:

Algorithm 5 AMP Algorithm for Tilted Mean Estimation (TAP-AMP) [19, Algorithm 1].

Input : Iterations $K_{\mathrm{AMP}}, K_{\mathrm{NGD}}$, step size η, overlap parameter q

$\hat{m}^{-1} \leftarrow 0$, $z^0 \leftarrow 0$

for $k \leftarrow 0$ **to** $K_{\mathrm{AMP}} - 1$ **do**

$\hat{m}^k \leftarrow \tanh(z^k)$

$\hat{q}_k \leftarrow \frac{1}{n}\sum_{i=1}^n \tanh^2(z_{i,k})$

$b_k \leftarrow (1-\hat{q}_k)\,\xi''(\hat{q}_k)$

$z^{k+1} \leftarrow \beta \nabla H(\hat{m}^k) + y - b_k \hat{m}^{k-1}$

$u^0 \leftarrow z^{K_{\mathrm{AMP}}}$, $\hat{m}^{+,0} \leftarrow \hat{m}^{K_{\mathrm{AMP}}}$

for $k \leftarrow 0$ **to** $K_{\mathrm{NGD}} - 1$ **do**

$u^{k+1} \leftarrow u^k - \eta \nabla \hat{\mathcal{F}}_{\mathrm{TAP}}(\hat{m}^{+,k}; y, q)$ *(see Equation (22))*

$\hat{m}^{+,k+1} \leftarrow \tanh(u^{k+1})$

Output : $\hat{m}^{+,K_{\mathrm{NGD}}}$

$$\partial_i f(x) = \frac{1}{2}\cdot[f(x_{\neg i}\ ;\ x_i = +1) - f(x_{\neg i}\ ;\ x_i = -1)],$$
$$(\nabla f(x))_i = \partial_i f(x), \qquad (\nabla^2 f(x))_{ij} = \partial_i \partial_j f(x) \tag{9}$$

For any two distributions μ and ν we use $d_{\mathsf{TV}}(\mu,\nu)$ to denote their total variation distance. When μ and ν are distributions on $\mathbb{R}^d$, we use $W_2(\mu,\nu)$ to denote their Euclidean 2-Wasserstein distance and $W_{2,d}(\mu,\nu) = d^{-1/2}W_2(\mu,\nu)$ to denote its normalized variant. Throughout, we use H and μ to denote the Ising p-spin Hamiltonian and its associated Gibbs measure as defined in Equation (2). We use $\xi(t) = \sum_{p=2}^P \beta_p^2 t^p$ to denote its mixture function. We also define the coefficients $\mathfrak{C}(\beta)$ and $\mathfrak{D}(\beta)$ as follows:

$$\mathfrak{C}(\beta) \coloneqq \sum_{p=2}^P \beta_p \sqrt{p^3 \ln(p)}\ ; \qquad \mathfrak{D}(\beta) \coloneqq \sum_{p=2}^P \beta_p \sqrt{2^p p^3 \ln(p)} \tag{10}$$

2.2 Stochastic Localization

Let μ denote any arbitrary measure on $\mathbb{R}^n$ with a finite second moment. Stochastic localization, introduced by [20], denotes the following diffusion process:

$$\mathrm{d}y_t = m(y_t,t)\,\mathrm{d}t + \mathrm{d}B_t, \qquad y_0 = 0$$
$$m(y,t) = \mathbb{E}_{x\sim\mu,\zeta\sim\mathcal{N}(0,1)}\left[x \;\middle|\; tx + \sqrt{t}\zeta = y\right] \tag{11}$$

Stochastic localization exhibits several interesting properties that have found innumerable applications in areas such as convex geometry and the analysis of Markov chains [35, 21, 12]. Among these, the following property, which appears in [16], will be of particular importance to us.

▶ **Theorem 3** (Equivalent Characterization of SL [16]). *Let $(y_t)_{t\geq 0}$ denote the stochastic localization process associated with the measure μ, as defined in Equation (11). Then, there exists an $x^\star \sim \mu$ and a standard Brownian motion $(W_t)_{t\geq 0}$ such that for any $t \geq 0$, $y_t = tx^\star + W_t$. Consequently, the marginal law of $t^{-1}y_t$ is equal to that of $x^\star + \zeta_t$ where $\zeta_t \sim \mathcal{N}(0, t^{-1}I)$.*

The following lemmas, which follow from Theorem 3, are vital for analyzing the rounding scheme used in Algorithm 4.

▶ **Lemma 4** (Rounding SL for the hypercube). *Let μ be a measure supported on $\{\pm 1\}^n$, and let $(y_t)_{t\geq 0}$ denote the associated SL process. For any $T > 0$, define $\hat{x}_T = \mathrm{sign}(T^{-1}y_T)$. Then, $W_{2,n}^2(\mathsf{Law}(\hat{x}_T), \mu) \leq 8\exp(-T/2)$.*

▶ **Lemma 5** (Stability of SL Rounding). *Let μ be a distribution on $\{\pm 1\}^n$, and let $(y_t)_{t\geq 0}$ denote the associated SL process. For any $T > 0$, let $\hat{z}_T$ be a random variable satisfying $W_2^2(\hat{z}_T, T^{-1}y_T) \leq n\Delta^2$. Then,*

$$W_{2,n}^2\big(\mathrm{sign}(\hat{z}_T), \mathrm{sign}(T^{-1}y_T)\big) \leq 8e^{-T/8} + 16\Delta^2. \tag{12}$$

2.3 Picard Iteration

Consider a discrete-time dynamical system $(x_{kh})_{0\leq k\leq K}$ on $\mathbb{R}^n$ defined by the following iteration:

$$x_{(k+1)h} = x_{kh} + hf(kh, x_{kh}) + g(kh), \qquad k \in \{0, \ldots, K-1\} \tag{13}$$

where $h > 0$ denotes the step-size and $T = Kh$ denotes the time horizon, and the functions f and g can potentially be random. We observe that solving the difference equation above is an inherently sequential task. Concretely, given an initialization x_0 and access to an oracle for computing f and g, computing the trajectory $(x_{kh})_{0\leq k\leq K}$ requires $\Theta(K)$ oracle calls.

The key idea in Picard iteration is to view the entire trajectory $(x_{kh})_{0\leq k\leq K}$ as the fixed point of a trajectory-level iteration in $\mathbb{R}^{n\times K}$ such that, given access to a *parallel oracle* for computing f and g, each round of this trajectory-level iteration can be computed in $\Theta(1)$ oracle calls. To begin, we unroll the recurrence in Equation (13) and observe that the solution $(x_{kh})_{0\leq k\leq K}$ satisfies the following:

$$x_{kh} = x_0 + \sum_{j=0}^{k-1} \left(hf(jh, x_{jh}) + g(jh)\right), \qquad 0 \leq k \leq K \tag{14}$$

The Picard iteration associated with Equation (13) is the following sequence of trajectories $(x_{kh}^{(r)})_{0\leq k\leq K},\ r \in \mathbb{N}$.

$$x_{kh}^{(r+1)} = x_0 + \sum_{j=0}^{k-1} \left(hf(jh, x_{jh}^{(r)}) + g(jh)\right) \tag{15}$$

We make two key observations regarding the above trajectory sequence:

- The solution x_{kh} to Equation (13) is a fixed point of Equation (15). Indeed, setting $x_{kh}^{(r)} = x_{kh}$ for every k and using Equation (14), we conclude that $x_{kh}^{(r+1)} = x_{kh}$.
- Each round of the iteration in Equation (15) can be computed using $\Theta(1)$ calls to a parallel oracle for computing f and g. Indeed, the values of $g(jh),\ 0 \leq j < K$ can be precomputed using one parallel oracle call, and in each round, the values of $f(jh, x_{jh}^{(r)}),\ 0 \leq j < K$ can be computed via one call to a parallel oracle to f.

The parallel efficiency of Picard iteration then depends on how fast the sequence of trajectories in Picard iteration converges to its fixed point trajectory. Below, we prove that Picard iteration exhibits an exponential convergence rate whenever $f(t, x)$ is uniformly L-Lipschitz in x.

▶ **Lemma 6** (Exponential convergence of Picard iteration under Lipschitzness). *Let $(x_{kh})_{0\le k\le K}$ denote the solution to Equation (13), where $T = Kh$, and let $(x_{kh}^{(r)})_{0\le k\le K,\ r\ge 0}$ denote the associated Picard iteration as defined in Equation (15). Suppose $f(t,\cdot)$ is uniformly L-Lipschitz in x and define $M = \max_{0\le k\le K}\|x_{kh}^{(0)} - x_{kh}\|$. Then, for any $r \ge 0$ and $0 \le k \le K$,*

$$\|x_{kh}^{(r)} - x_{kh}\| \le \frac{(khL)^r}{r!}\cdot M. \tag{16}$$

In particular, $R = \max\{e^2 LT, \ln(M/\varepsilon)\}$ Picard iterations suffice to ensure the following:

$$\max_{k\in\{0,\dots,K\}} \|x_{kh}^{(R)} - x_{kh}\| \le \varepsilon. \tag{17}$$

2.4 TAP Free Energy and the Tilted Mean Estimator

The construction of the tilted mean estimator (Algorithm 5) of El Alaoui, Montanari, and Sellke [19] is motivated by a deep structural property of the p-spin model: The mean of the tilted Gibbs measure at high temperature is an approximate stationary point of the Thouless–Anderson–Palmer (TAP) free energy [47, 37, 46], which we briefly introduce below.

Recall that the mixture function of the p-spin model is defined as $\xi(t) = \sum_{p=2}^{P}\beta_p^2 t^p$. For any $t \ge 0$, the asymptotic overlap $q^\star(t)$ is defined as follows:

$$q_{k+1}(t) = \mathbb{E}_{W\sim N(0,1)}\left[\tanh\left(t + \xi'(q_k) + W\sqrt{\xi'(q_k)+t}\right)\right], \quad q_k(t) = 0, \quad q^\star(t) = \lim_{k\to\infty} q_k(t) \tag{18}$$

Since $q_k(t)$ is independent of G, computable to high accuracy via a one-dimensional Gaussian integral, and approaches the limit $q^\star(t)$ exponentially fast, we assume, for simplicity, that $q^\star(t)$ is known exactly for $t = kh, k \in [K]$.

The TAP free energy associated with the p-spin Hamiltonian in Equation (2) is defined as follows:

$$\mathcal{F}_{\mathrm{TAP}}(m, y) = -H(m) - \langle y, m\rangle - \sum_{i=1}^{n} h(m_i) - \mathrm{ONS}(Q(m)) \tag{19}$$

$$\mathrm{ONS}(q) = \frac{n}{2}\left[\xi(1) - \xi(Q) - (1-Q)\xi'(Q)\right] \tag{20}$$

$$Q(m) = n^{-1}\|m\|^2, \qquad h(m) = -\frac{1+m}{2}\ln\left(\frac{1+m}{2}\right) - \frac{1-m}{2}\ln\left(\frac{1-m}{2}\right) \tag{21}$$

For the sake of tractability, El Alaoui, Montanari, and Sellke [19] also define an approximate version of the TAP free energy which replaces the $\mathrm{ONS}(Q(m))$ term by a quadratic approximation.

$$\hat{\mathcal{F}}_{\mathrm{TAP}}(m\,; y, q) = -H(m) - \langle y, m\rangle - \sum_{i=1}^{n} h(m_i) - \mathrm{ONS}(q) - \mathrm{ONS}'(q)(Q(m) - q) + \frac{n\Gamma}{8}(Q(m) - q)^2 \tag{22}$$

where q is set to be the asymptotic overlap $q^\star(t)$ for $t = kh$, and $\Gamma = \Theta(1)$ is a tunable parameter depending only on ξ. [19] show that the mean of the tilted Gibbs measure continues to be an approximate stationary point of $\hat{\mathcal{F}}_{\mathrm{TAP}}$. The tilted mean estimator in Algorithm 5 then works in two phases. The first phase runs a series of AMP updates to compute an approximate stationary point $\hat{m}^{K_{\mathrm{AMP}}}$ for $\hat{\mathcal{F}}_{\mathrm{TAP}}$ around which it is locally strongly convex. The second stage exploits this local strong convexity to refine the AMP estimate via natural gradient descent.

3 High Accuracy Parallel Sampler for the p-Spin Model

In this section, we analyze Algorithm 1 and prove the following Theorem.

▶ **Theorem 7** (Analysis of Algorithm 1). *For any $\varepsilon > 0$, the output $X^{(T)}$ of Algorithm 1 run with $s = \Theta(n^{2/3}\log(n/\varepsilon)^{-2/3})$ and $T = \Theta(n^{1/3}\log(n/\varepsilon)^{5/3})$ satisfies $d_{\mathsf{TV}}(\mathsf{Law}(X^{(T)}), \mu) \le \varepsilon$ with probability at least $1 - e^{-cn}$. Moreover, Algorithm 1 has a parallel runtime of $O(n^{1/3}\mathrm{polylog}(n/\varepsilon))$ with $O(\mathrm{poly}(n, \log(n/\varepsilon)))$ work.*

We describe the key technical ideas of our proof below, and refer the readers to the full version of our paper for complete proofs.

3.1 Bounds on the Hamiltonian of the Conditional Posterior

Consider any arbitrary $S \in \binom{[n]}{s}$. For any $x \in \{\pm 1\}^n$, let $x = (y, \tau)$ where $y = x_S$ denotes the block spins in S and $\tau = x_{\bar{S}}$ denotes the pinning outside S. Then the conditional distribution $\mu_{S,\tau}(y) = \mu(y \mid x_{\bar{S}} = \tau)$ of the spins in S satisfies $\mu_{S,\tau}(y) \propto \exp(H_{S,\tau}(y))$ where:

$$H_{S,\tau}(y) = \langle b_{S,\tau}, y\rangle + \tfrac{1}{2}\langle y, A_{S,\tau}y\rangle + R_{S,\tau}(y) \tag{23}$$

Here, $A_{S,\tau}$ is a symmetric matrix with zero diagonals with:

$$(A_{S,\tau})_{ij} = \sum_{p=2}^{P} \frac{\beta_p\sqrt{p!}}{n^{\frac{p-1}{2}}} \sum_{K\subseteq\bar{S},|K|=p-2} G_{K\cup\{i,j\}}\tau^K, \qquad i,j \in S,\ i \ne j \tag{24}$$

The remainder term is given by

$$R_{S,\tau}(y) = \sum_{p=3}^{P} \frac{\beta_p\sqrt{p!}}{n^{(p-1)/2}} \sum_{\substack{J\subseteq[n],|J|=p,\\ |J\cap S|\ge 3}} G_J\ y^{J\cap S}\ \tau^{J\cap\bar{S}} \tag{25}$$

As discussed earlier, each step of s-Glauber dynamics requires sampling from $\mu_{S,\tau}$, which can be computationally expensive. We address this via a parallelized implementation of rejection sampling in Algorithm 2 where $\mu_{S,\tau}(y)$ is approximated by an Ising model of the form $\pi_{S,\tau}(y) \propto \exp(\frac{1}{2}\langle y, A_{S,\tau}y\rangle + \left\langle b_{S,\tau} + \hat{h}, y\right\rangle)$, where $\hat{h}$ is an external field that satisfies $\hat{h} \approx \mathbb{E}_{y\sim\pi_{S,\tau}}[\nabla R_{S,\tau}(y)]$.

To ensure the parallel efficiency of Algorithm 2, we generate approximate samples from the Ising proposal $\pi_{S,\tau}$ using Restricted Gaussian Dynamics (Algorithm 3). To this end, the following theorem uses the concentration properties of the p-spin Hamiltonian to prove that $\|A_{S,\tau}\|_{\mathsf{op}} \le 1/4$ holds with high probability uniformly over all choices of S and τ whenever $s = O(n^{2/3})$. Consequently, Algorithm 3 can approximately sample from the proposal in $\widetilde{O}(1)$ parallel time.

▶ **Theorem 8** (Uniform Operator Norm Bound for Ising Proposal). *There exists a numerical constant $C > 0$ such that for $\mathfrak{C}(\beta) \le C$ and $s = o(n)$, the following holds with probability at least $1 - \exp(-cn)$:*

$$\|A_{S,\tau}\|_{\mathsf{op}} \le \frac{1}{4}, \qquad \forall\ S \in \binom{[n]}{s},\ \tau \in \{\pm 1\}^{\bar{S}} \tag{26}$$

Naturally, the success probability of our rejection sampling procedure is governed by how well the Ising proposal $\pi_{S,\tau}$ approximates the conditional distribution $\mu_{S,\tau}$, or, in other words,

how large the influence of the remainder term $R_{S,\tau}$ is. We quantify this via a uniform bound on the discrete Hessian of $R_{S,\tau}$, which follows from the concentration properties of the p-spin Hamiltonian and a careful combinatorial bookkeeping.

▶ **Theorem 9** (Uniform Bound on Hessian of Remainder Term). *There exists a numerical constant $C > 0$ such that for $\mathfrak{C}(\beta) \le C$, the following holds with probability at least $1 - \exp(-cn)$ whenever $\Omega(\sqrt{n}) \le s \le o(n)$*

$$\|\nabla^2 R_{S,\tau}(y)\|_F^2 \le \frac{C_1 \mathfrak{C}(\beta)^2 s^3}{n^2}, \qquad \forall\ S \in \binom{[n]}{s},\ (y,\tau) \in \{\pm 1\}^n \tag{27}$$

3.2 Analysis of Parallel Rejection Sampling

In this section, we shall establish the accuracy and parallel efficiency of Algorithm 2. Henceforth, we condition on the event $\mathcal{E}$ that the bounds in Theorem 8 and Theorem 9 hold uniformly over all S and τ.

▶ **Theorem 10** (Analysis of Parallel Rejection Sampler). *For any $S \in \binom{[n]}{s}$ and $\tau \in \{\pm 1\}^{\overline{S}}$, let $\tilde{\mu}_{S,\tau}$ denote the law of the sample output by Algorithm 2. Conditioned on the event $\mathcal{E}$, the following holds whenever $s = \Theta(n^{2/3})$:*

$$d_{\mathsf{TV}}(\tilde{\mu}_{S,\tau}, \mu_{S,\tau}) \le \varepsilon_{\mathrm{step}} \qquad \forall S \in \binom{[n]}{s},\ \tau \in \{\pm 1\}^{\overline{S}}. \tag{28}$$

Moreover, Algorithm 2 has parallel runtime $O(\mathrm{polylog}(n/\varepsilon_{\mathrm{step}}))$ with $O(\mathrm{poly}(n, \log(1/\varepsilon_{\mathrm{step}})))$ work.

The proof of Theorem 10, whose complete proof is relegated to the full version, involves several technical components, the first of which is an accuracy guarantee for the approximate rejection sampling step in Algorithm 2. This result appears as Lemma 4.4 in Lee [34] and Lemma 2 in [22].

▶ **Lemma 11** (Accuracy of Rejection Sampling). *Let P and Q be probability measures satisfying $\frac{dP}{dQ}(y) \propto e^{\psi(y)}$. Let $Y, Z \overset{\text{iid}}{\sim} Q$, and define $R = \exp(\psi(Y) - \psi(Z))$. Consider the following rejection sampling procedure: Draw $U \sim \mathsf{Uniform}[0,1]$ and accept Y if $U \le \min\{1, R/c\}$ for some $c \ge 1$. Let $\tilde{P}$ denote the law of the accepted sample and assume $\psi(Y) - \psi(Z)$ exhibits subexponential tails of the form $\mathbb{P}[\psi(Y) - \psi(Z) \ge t] \le a\exp(-bt)$ for $b > 1$. Then, $d_{\mathsf{TV}}\left(P, \tilde{P}\right) \le \frac{a}{b-1} \cdot c^{-(b-1)}$*

In Algorithm 2, (X, Z) corresponds to (U_ℓ, V_ℓ), both of which are approximately distributed as $\pi_{S,\tau}$ (modulo the negligible sampling error of Algorithm 3, which we ignore for now). Since $\frac{d\mu_{S,\tau}}{d\pi_{S,\tau}}(y) \propto e^{\psi(y)}$, where $\psi(y) = R_{S,\tau}(y) - \langle \hat{h}, y\rangle$, Lemma 11 suggests that we can bound the TV error of Algorithm 2 by controlling the sampling error of Algorithm 3 and proving a subexponential tail bound for $|\psi(\widetilde{U}) - \psi(\widetilde{V})|$, where $\widetilde{U}, \widetilde{V} \overset{\text{iid}}{\sim} \pi_{S,\tau}$, or equivalently, for $|\psi(Y) - \mathbb{E}[\psi(Y)]|$ under $Y \sim \pi_{S,\tau}$. By Theorem 8 and [34, Theorem 4.1], $\pi_{S,\tau}$ satisfies approximate tensorization of entropy with high probability. The work of [43] then implies the following concentration bound:

$$\mathbb{P}_{Y \sim \pi_{S,\tau}}\left[|\psi(Y) - \mathbb{E}_{\pi_{S,\tau}}[\psi(Y)]|\right] \le 2\exp\left(-c\min\left\{\frac{t^2}{\mathbb{E}_{\pi_{S,\tau}}[\|\nabla\psi\|^2]}, \frac{t}{\max\limits_{y\in\{\pm1\}^S}\|\nabla^2\psi(y)\|_F}\right\}\right) \tag{29}$$

Algorithm 6 Centering External Field.

Input: $A_{S,\tau}$, $b_{S,\tau}$, $R_{S,\tau}$, accuracy $\eta > 0$, failure probability $\delta \in (0,1)$
Set iterations $T = \Theta(\log(n/\eta))$ and sample size $K = \Theta\big(s\eta^{-2}\log(sT/\delta)\big)$
Initialize $z_0 \leftarrow 0$
for $t = 0, \ldots, T-1$ **do**
  for $i = 1, \ldots, K$ **do** In parallel
    $U_i^{(t)} \sim \mathrm{RGD}(A_{S,\tau}, b_{S,\tau} + z_t, \delta/100KT)$
  $z_{t+1} = \frac{1}{K}\sum_{i=1}^{K} \nabla R_{S,\tau}(U_i^{(t)})$
return $\hat{h}_{S,\tau} = z_T$

Since $\|\nabla^2\psi(y)\|_F^2 = \|\nabla^2 R_{S,\tau}(y)\|_F \lesssim \mathfrak{C}(\beta)\cdot\frac{s^3}{n^2}$ holds whp uniformly for any S, τ and y by Theorem 9. Hence, setting $s = \Theta(n^{2/3})$ and $\mathfrak{C}(\beta)$ sufficiently small, $\max_{y\in\{\pm1\}^S} \|\nabla^2\psi(y)\|_F \le \delta$ for any $\delta = O(1)$. To control $\mathbb{E}_{\pi_{S,\tau}}[\|\nabla\psi\|^2]$, we note that:

$$\mathbb{E}_{\pi_{S,\tau}}[\|\nabla\psi\|^2] = \| \hat{h} - \mathbb{E}_{\pi_{S,\tau}}[\nabla R_{S,\tau}] \|^2 + \mathbb{E}_{\pi_{S,\tau}}\left[\| \nabla R_{S,\tau} - \mathbb{E}[\nabla R_{S,\tau}] \|^2\right] \tag{30}$$

Using the Poincare Inequality for $\pi_{S,\tau}$ and Theorem 9, the second term in Equation (30) can be made $O(\delta^2)$ for any $\delta = O(1)$ by setting $s = \Theta(n^{2/3})$ and $\mathfrak{C}(\beta)$ sufficiently small. The centering field $\hat{h}$ must be chosen so as to make the first term $\|\hat{h} - \mathbb{E}_{\pi_{S,\tau}}[\nabla R_{S,\tau}]\|^2$ as small as possible. Since $\pi_{S,\tau} = \nu_{A_{S,\tau}, b_{S,\tau}+\hat{h}}$ where $\nu_{J,v}(y) \propto \exp(\frac{1}{2}\langle y, Jy\rangle + \langle v, y\rangle)$, the optimal choice of $\hat{h}$ is given by the solution to the following fixed point problem:

$$h = \mathbb{E}_{\nu_{A_{S,\tau},\, h+b_{S,\tau}}}[\nabla R_{S,\tau}]. \tag{31}$$

As we shall demonstrate, Equation (31) admits a unique solution which can be efficiently approximated by an inexact fixed point iteration, namely Algorithm 6, which replaces the expectation in Equation (31) by an empirical average over approximate samples drawn via RGD. In particular, we prove the following guarantee.

▶ **Theorem 12** (Analysis of Algorithm 6). *Conditioned on the event $\mathcal{E}$, the output $\hat{h}$ of Algorithm 6 satisfies $\|\hat{h} - \mathbb{E}_{\pi_{S,\tau}}[\nabla R_{S,\tau}]\| \le \eta$ with probability at least $1-\delta$. Moreover, Algorithm 6 runs in $O(\mathrm{polylog}(n, \eta^{-1}, \delta^{-1}))$ parallel time with $O\big(\mathrm{poly}(\frac{n}{\eta}, \ln(1/\delta))\big)$ work.*

The proof of Theorem 10, which is presented in our full version, then follows by combining Theorem 12 and Lemma 11

3.3 Proof of Theorem 7

Proof. Let $\mu_t = \mathsf{Law}(X^{(t)})$. Since $\mu_0(x) \propto \exp(\langle h, x\rangle)$, by Lemma 5.5 of [34],

$$\mathbb{P}\big[D_{\mathsf{KL}}(\mu_0 \,||\, \mu) \le Cn\big] \ge 1 - \exp(-cn). \tag{32}$$

Let $\mathcal{G} = \mathcal{E} \cap \big\{D_{\mathsf{KL}}(\mu_0 \,||\, \mu) \le Cn\big\}$. Then, $\mathbb{P}[\mathcal{G}] \ge 1 - e^{-cn}$, and henceforth, we condition on $\mathcal{G}$.

Let P_s and $\widetilde{P}_s$ denote the Markov kernel for s-Glauber dynamics and the Markov chain in Algorithm 1 respectively. By Theorem 10, for $s = \Theta((\frac{n}{\log(n/\varepsilon)})^{2/3})$,

$$\max_{x\in\{\pm1\}^n} d_{\mathsf{TV}}\big(P_s(x,\cdot), \widetilde{P}_s(x,\cdot)\big) \le \varepsilon_{\mathrm{step}} = \tfrac{\varepsilon}{10T}. \tag{33}$$

Hence,

$$d_{\mathsf{TV}}\left(\mu_T, \mu_0 P_s^T\right) \le T\varepsilon_{\text{step}} \le \tfrac{\varepsilon}{10}. \tag{34}$$

By [7, Theorem 6], the following holds with probability $1 - e^{-cn}$:

$$D_{\mathsf{KL}}\left(\mu_0 P_s^T \mid\mid \mu\right) \le \exp\left(-\tfrac{csT}{n}\right) Cn \le \exp\left(-\frac{cT}{n^{1/3}\log(n/\varepsilon)^{2/3}}\right) Cn. \tag{35}$$

Setting $T = \Theta(n^{1/3}\log(n/\varepsilon)^{5/3})$, applying Pinsker's inequality and taking appropriate union bounds, we conclude that the following holds with probability at least $1 - \exp(-cn)$:

$$d_{\mathsf{TV}}(\mu_T, \mu) \le d_{\mathsf{TV}}\left(\mu_T, \mu_0 P_s^T\right) + d_{\mathsf{TV}}\left(\mu_0 P_s^T, \mu\right) \le \tfrac{\varepsilon}{10} + \tfrac{\varepsilon}{2} \le \varepsilon. \tag{36}$$

To compute the parallel runtime, note that Algorithm 1 makes T calls to Algorithm 2 each of which has parallel runtime $O(\mathsf{polylog}(n/\varepsilon))$ with $O(\mathsf{poly}(n/\varepsilon))$ processors as per Theorem 10. Hence, Algorithm 1 exhibits a parallel runtime of $O(n^{1/3}\mathsf{polylog}(n/\varepsilon))$ with $O(\mathsf{poly}(n/\varepsilon))$ processors. ◀

4 Low Accuracy Parallel Sampler for the p-Spin Model

In this section, we key technical ideas of our proof below and refer the readers to the full version of our paper for complete proofs. We prove that Picard Algorithmic Stochastic Localization (Algorithm 4) samples from the mixed p-spin model with Wasserstein guarantees.

We first illustrate our results for the SK model. The TAP-AMP mean-estimation algorithm for the SK model (Algorithm 7) is slightly different from that for the mixed p-spin model, but it uses the same AMP iterations followed by NGD iterations. We prove that the TAP-AMP algorithms proposed in prior work for computing mean approximations in the SK and mixed p-spin models, Algorithm 7 and Algorithm 5, are Lipschitz with respect to the external field and $\widetilde{O}(1)$ parallel computable. This enables us to apply Picard iteration to the steps of algorithmic stochastic localization Equation (8), yielding a parallel speedup.

For the rest of the section, we first present an improved parameter dependence for algorithmic stochastic localization in Section 4.1. Then, using the improved parameters, we prove the parallelization result for algorithmic stochastic localization in Section 4.2, relying on the following two results:

- The TAP-AMP mean approximations are executable in $\widetilde{O}(1)$ parallel time (Section 4.3).
- The TAP-AMP mean approximations are Lipschitz (Section 4.4).

4.1 Sign Rounding for Algorithmic Stochastic Localization

El Alaoui, Montanari, and Sellke [17, 19] provide Wasserstein guarantees for algorithmic stochastic localization using TAP fixed points as mean approximations. Their analysis controls the propagation of the mean-estimation error along the discretized stochastic localization trajectory. They obtain an ε upper bound in normalized Wasserstein distance between the output of the sampling algorithm and the target distribution by using $\exp(\mathrm{poly}(1/\varepsilon))$ discrete steps to run the stochastic localization up to a time horizon $\mathrm{poly}(1/\varepsilon)$.

▶ **Proposition 13.** *For $\varepsilon_n < \varepsilon$, El Alaoui, Montanari, and Sellke [17, 19] provide algorithmic stochastic localization for a time horizon* $\mathrm{poly}(1/\varepsilon)$ *with* $\exp(\mathrm{poly}(1/\varepsilon))$ *discretization steps.*

In this work, in addition to the Picard parallelization and Lipschitz analysis, we improve the dependence of the discretization step size and the time horizon in stochastic localization on the parameter ε by analyzing sign rounding for algorithmic stochastic localization.

▶ **Theorem 14.** *For any n, there exists a value ε_n such that, for any $\varepsilon > \varepsilon_n$ and any high-temperature mixed p-spin model with Hamiltonian H_n and no external field, there is an algorithm based on algorithmic stochastic localization using TAP-AMP mean approximations (Algorithm 7 and Algorithm 5) whose output is within ε of the target distribution in normalized Wasserstein distance with probability $1 - o(1)$ over the disorder.*

Moreover, the algorithmic stochastic localization procedure uses a discretization step of size δ and time horizon t satisfying

$$\delta = \mathrm{poly}(\varepsilon), \qquad t = O(\log(1/\varepsilon)).$$

The output of the algorithm is generated by sign rounding, namely $\mathrm{sign}(\hat{y}_t)$, where $\hat{y}_t$ is the output of the discrete algorithmic stochastic localization process at time t. Furthermore, if y_t denotes the true stochastic localization process, then

$$W_{2,n}(y_t, \hat{y}_t) \le O(\varepsilon).$$

4.2 Parallel Time Analysis of Algorithm 4

In this section, we analyze the parallelization result for algorithmic stochastic localization using Picard iteration. The Picard iterations produce a trajectory that is close, in Wasserstein distance, to the true solution of the discrete stochastic localization process using the TAP-AMP mean approximation. This discrete process is itself close to the true continuous-time stochastic localization process by Theorem 14. Therefore, by the triangle inequality for Wasserstein distance, the input to the rounding step is close to the output of the true stochastic localization process.

We present our results for the SK model and the mixed p-spin model separately. For the SK model, the Gibbs measure is defined by

$$\mu_A(x) \propto \exp\left(\frac{\beta}{2}\langle x, Ax\rangle\right),$$

where $A \sim \mathrm{GOE}(n)$. Here $\mathrm{GOE}(n)$ denotes the distribution over symmetric matrices whose entries are Gaussian with variance of order $1/n$. Although the proof structure is nearly the same, we separate the two cases because, for the SK model, we obtain a parallel sampling algorithm in a temperature regime not covered by previous parallel algorithms. The analysis for the SK model yields the threshold $\beta_0 \approx 0.3753$ for Lipschitzness and parallelization, improving on the $\beta < 1/4$ threshold at which the previous $\mathrm{polylog}(n)$-depth algorithm for sampling from the SK model applies [11]. However, unlike the algorithm of Chen, Liu, Yin, and Zhang [11], our low-accuracy algorithm cannot achieve arbitrarily small error.

▶ **Theorem 15** (SK Model Parallelization)**.** *For any $\varepsilon \ge \varepsilon_n$ and inverse temperature $\beta < \beta_0 \approx 0.3753$, there exist parameters (Theorem 14)*

$$\eta, K_{\mathrm{AMP}}, K_{\mathrm{NGD}} = \mathrm{polylog}(n/\varepsilon), \quad K = \mathrm{poly}(1/\varepsilon), \quad \delta = \mathrm{poly}(\varepsilon), \quad t = K\delta = O(\log(1/\varepsilon))$$

such that the following holds. Let $R = O(\frac{\log^2(1/\varepsilon)}{\beta_0 - \beta})$, and execute Algorithm 4 on a Hamiltonian of the form $H_n(x) = x^\top Ax$ using TAP-AMP (Algorithm 7) as the approximate mean function $\hat{m}$ with parameters $(\eta, K_{\mathrm{AMP}}, K_{\mathrm{NGD}}, K, \delta)$.

Then Algorithm 4 outputs a random point $\mathbf{x}^{\mathrm{alg}} \in \{-1, +1\}^n$ with law $\mu_{\mathbf{A}}^{\mathrm{alg}}$ such that, with probability $1 - o(1)$ over $\mathbf{A} \sim \mathrm{GOE}(n)$,

$$W_{2,n}(\mu_{\mathbf{A}}^{\mathrm{alg}}, \mu_{\mathbf{A}}) \le O(\varepsilon).$$

The parallel runtime of the algorithm is $\mathrm{poly}(\log(n/\varepsilon))$, and its total work is $\mathrm{poly}(n/\varepsilon)$.

▶ **Theorem 16** (p-spin Model Parallelization). *For any $\varepsilon \geq \varepsilon_n$ and temperature coefficients $\{\beta_p\}_{p\geq 2}$ satisfying*

$$\mathfrak{C}(\beta) \coloneqq \sum_{p=2}^{P} \beta_p \sqrt{p^3 \ln(p)} < \gamma_0 \qquad \mathfrak{D}(\beta) = \sum_{p=2}^{P} \beta_p \sqrt{2^p p^3 \ln(p)} < \infty$$

there exist parameters (Theorem 14)

$$\eta, K_{\mathrm{AMP}}, K_{\mathrm{NGD}}, K = \mathrm{poly}(1/\varepsilon), \qquad \delta = \mathrm{poly}(\varepsilon), \qquad t = K\delta = O(\log(1/\varepsilon)),$$

such that the following holds. Let $R = O_{\mathfrak{C}(\beta)}\big(\log^2(1/\varepsilon)\big)$ be the number of Picard iterations. Given query access to the p-spin Hamiltonian as defined in Equation (2), Algorithm 4, run with parameters $(\eta, K_{\mathrm{AMP}}, K_{\mathrm{NGD}}, K, \delta)$, outputs a random point $\mathbf{x}^{\mathrm{alg}} \in \{-1, +1\}^n$ with law $\mu_{H_n}^{\mathrm{alg}}$ such that, with probability $1 - o(1)$ over the Gaussian coefficients $\{g_J\}_{J\subseteq[n]}$,

$$W_{2,n}(\mu_{H_n}^{\mathrm{alg}}, \mu_{H_n}) \leq O(\varepsilon).$$

Here, ε is the error incurred by the sequential algorithm in Theorem 14, while $\mathrm{poly}(\varepsilon)$ is the additional error incurred by replacing the sequential updates with Picard iteration.

The parallel runtime of the algorithm is $\mathrm{poly}(\log(n/\varepsilon))$ and its total work is $\mathrm{poly}(n, 1/\varepsilon)$.

4.3 TAP-AMP in $\mathrm{polylog}(n)$ Parallel Time

The TAP-AMP mean-approximations can be computed in $\mathrm{polylog}(n/\varepsilon)$ parallel depth. The TAP-AMP algorithms Algorithm 7 and Algorithm 5 consist of AMP iterations followed by NGD iterations. Each individual AMP or NGD iteration is computable in parallel with depth $O(\log n)$; thus, it suffices to prove $\widetilde{O}(1)$ bounds on the numbers of AMP and NGD iterations. Since this proof is rather involved and does not affect the rest of the argument, we give only a brief sketch here; the complete details appear in the full version of this paper.

▶ **Proposition 17.** *The mean-approximation algorithms Algorithm 7 and Algorithm 5 are computable with parallel depth $\mathrm{polylog}(n/\varepsilon)$, given query access to the mixed p-spin Hamiltonian and the parameter choices specified in Theorem 14 for attaining normalized Wasserstein error ε.*

4.4 Lipschitz Property of the TAP-AMP Mean Approximation for the SK Model

In this section, we prove that, for the SK model at high temperature $\beta < \beta_0 \approx 0.3753$, the TAP-AMP algorithm (Algorithm 7) for mean approximation is $O\Big(\frac{1}{\beta_0 - \beta}\Big)$-Lipschitz with respect to the tilt parameter, or external field, with high probability. We provide an analogous result for the mixed p-spin model in the full version of this paper.

Algorithm 7 Mean of the Tilted Ising Measure [17].

Input: Data $A \in \mathbb{R}^{n\times n}$, $y \in \mathbb{R}^n$, parameters $\beta, \eta > 0$, $q \in (0,1)$, iteration numbers $K_{\mathrm{AMP}}, K_{\mathrm{NGD}}$

$m_{-1} = z_0 = 0$

for $k = 0, \dots, K_{AMP} - 1$ **do**

  $m_k = \tanh(z_k), \quad b_k = \frac{\beta^2}{n}\sum_{i=1}^n (1 - \tanh^2((z_k)_i))$

  $z_{k+1} = \beta A m_k + y - b_k m_{k-1}$

$u^0 = z_{K_{\mathrm{AMP}}}$

for $k = 0, \dots, K_{NGD} - 1$ **do**

  $u_{k+1} = u_k - \eta \cdot \nabla \hat{\mathcal{F}}_{\mathrm{TAP}}(m_k^+; y, q)$

  $m_{k+1}^+ = \tanh(u_{k+1})$

return $m^+_{K_{\mathrm{NGD}}}$

Algorithm 7 consists of two phases: it first uses AMP iterations attempting to get close to the fixed point of the TAP iteration, and then it uses an NGD algorithm to close the gap to the fixed point as much as needed. Here, we will take a closer look at the two phases of Algorithm 7.

4.4.1 Phase 1: AMP phase

In the first phase, initialize $m_{-1} = 0$ and $z_0 = 0$. For $k = 0, 1, \dots, K_{\mathrm{AMP}} - 1$, set $m_k = \tanh(z_k)$ and $b_k = \frac{\beta^2}{n}\sum_{i\in[n]} \operatorname{sech}^2\big((z_k)_i\big)$, then update

$$z_{k+1} = \beta A m_k + y - b_k\, m_{k-1}. \tag{37}$$

4.4.2 Phase 2: NGD phase on TAP free energy

Initialize $u_0 := z_{K_{\mathrm{AMP}}}$. For $t = 0, 1, \dots, K_{\mathrm{NGD}} - 1$, set $m_t^+ = \tanh(u_t)$ and update

$$u_{t+1} = u_t - \eta\, \nabla_m \hat{\mathcal{F}}_{\mathrm{TAP}}(m_t^+; y, q). \tag{38}$$

The algorithm outputs $\hat{m}(A, y) := m^+_{K_{\mathrm{NGD}}} = \tanh(u_{K_{\mathrm{NGD}}})$.

▶ **Definition 18.** *For a given external field $y \in \mathbb{R}^n$ and interaction matrix $A \in \mathbb{R}^{n\times n}$, let $\hat{m}_{(K_{AMP}, K_{NGD})}(A, y)$ be the output of the algorithm after running the AMP iteration for K_{AMP} steps and then running NGD for K_{NGD} steps. We refer to $\hat{m}(y)$ as the tilted-mean computation for the external field y whenever A, K_{AMP}, and K_{NGD} are clear from the context.*

Our goal in this section is to find the temperature $\beta(A) = \beta(\|A\|_{\mathrm{op}})$ such that, for any two tilts y and $\widetilde{y}$, the TAP fixed point of the Ising model with interaction matrix A and temperature β satisfies

$$\|\hat{m}_{(K_{\mathrm{AMP}}, K_{\mathrm{NGD}})}(A, y) - \hat{m}_{(K_{\mathrm{AMP}}, K_{\mathrm{NGD}})}(A, \widetilde{y})\| \le \frac{\gamma(A)}{\beta(A) - \beta}\|y - \widetilde{y}\|.$$

▶ **Theorem 19** (Lipschitzness of AMP phase). *Assume $\gamma(A, \beta) := \beta\,\|A\|_{\mathrm{op}} + (1 + \frac{4}{3\sqrt{3}})\beta^2 < 1$. Then for all $k \ge 0$,*

$$\|\Delta z_k\| \le \frac{1}{1-\gamma}\,\|\Delta y\|, \qquad \|\Delta m_k\| \le \frac{1}{1-\gamma}\,\|\Delta y\|.$$

Lipschitzness of the full AMP+NGD algorithm for the SK model

We have proved so far that after an arbitrary number of iterations, $\|\Delta m_k\|$ is upper bounded by $\frac{1}{1-\gamma(A,\beta)}\|\Delta y\|$. Now, we prove that applying NGD after AMP preserves the same bound for the difference of the mean estimates. For convenience, and to avoid overloading the notation m_k from the AMP phase, we analyze the NGD step in the variables u_i defined by $m = \tanh(u)$ (equivalently $u = \operatorname{atanh}(m)$ component-wise).

▶ **Theorem 20** (TAP Lipschitz property)**.** *Assume* $\gamma(A,\beta) = \beta\|A\|_{\mathrm{op}} + (1+\frac{4}{3\sqrt{3}})\beta^2 < 1$ *and* $q \in (0,1)$*. Let* $0 < \eta \le 1$*. Then for every* $t \ge 0$*,*

$$\|\hat{m}(A,y) - \hat{m}(A,\widetilde{y})\| \le \frac{1}{1-\gamma(A,\beta)}\|y-\widetilde{y}\|.$$

▶ Remark 21. The key stability requirement for AMP and NGD iterations is

$$\gamma(A,\beta) = \beta\|A\|_{\mathrm{op}} + (1+\frac{4}{3\sqrt{3}})\beta^2 < 1.$$

In random matrix settings (e.g. $A \sim \mathrm{GOE}(n)$), one typically has $\|A\|_{\mathrm{op}} = 2 + o(1)$ with high probability, so any sufficiently small β ensuring $\gamma(2,\beta) < 1$ implies that the TAP-AMP mean approximation is $\frac{1}{1-\gamma(2,\beta)-c}$-Lipschitz with high probability for every sufficiently small constant c.

▶ **Corollary 22.** *Fix* $\varepsilon > 0$*. If the SK inverse temperature* β *is at most* $\beta_0 - \varepsilon$*, where* $\beta_0 \approx 0.3753$ *is the positive root of the equation*

$$\gamma(2,\beta) = 2\beta + (1+\frac{4}{3\sqrt{3}})\beta^2 = 1,$$

then the tilted-mean computation in Algorithm 7 is $O(\frac{1}{\varepsilon})$*-Lipschitz for the SK model with high probability.*

Proof. We know that $\|A\|_{\mathrm{op}}$ is concentrated around 2, and the probability that it exceeds $2+\varepsilon/\beta_0$ is $e^{-\Omega_\varepsilon(n)}$ [9]. Recall that β_0 is the positive solution of the equation $2x+(1+\frac{4}{3\sqrt{3}})x^2 = 1$. Thus, we only need to show that the parameter $\gamma = \beta\|A\|_{\mathrm{op}} + (1+\frac{4}{3\sqrt{3}})\beta^2 \le 1 - \Omega(\varepsilon)$ with high probability.

$$\begin{aligned}\beta\|A\|_{\mathrm{op}} + (1+\frac{4}{3\sqrt{3}})\beta^2 &\le \beta(2+\varepsilon/\beta_0) + (1+\frac{4}{3\sqrt{3}})\beta^2\\ &\le \varepsilon + 2\beta + (1+\frac{4}{3\sqrt{3}})\beta^2\\ &\le -\varepsilon + 2\beta_0 + (1+\frac{4}{3\sqrt{3}})\beta_0^2 = 1-\varepsilon\end{aligned}$$

Since $\mathrm{P}\{\|A\|_{\mathrm{op}} > 2+\varepsilon/\beta_0\} \le e^{-\Omega_\varepsilon(n)}$, the tilted-mean computation is $O(\frac{1}{\varepsilon})$-Lipschitz with high probability if $\beta \le \beta_0 - \varepsilon$. ◀

Abstract

The quantum query complexity of subgraph-containment problems, which ask whether a given subgraph H is present in an input graph G, has been the subject of considerable study. This interest stems not only from the natural and well-motivated formulation of these problems, but also from a flurry of novel quantum algorithmic techniques that were developed specifically to solve them. Notably, even for relatively simple subgraphs, such as paths and cycles, a complete understanding of their query complexities remains elusive.

In this work, we consider several variants of path- and cycle-containment problems in the adjacency matrix model, where we search for paths or cycles of constant length $k \in O(1)$. We compare the settings where the graphs are directed or undirected, where the goal is to detect or find the existence of a path/cycle, and where the path/cycle we're looking for has length exactly k, or at most k. We also consider several promise versions of these problems, where we know beforehand that the input graph has a certain structure. We characterize the relative difficulty of these variants of the path- and cycle-containment problems, by relating them to one another using randomized reductions, and grouping them into several equivalence classes.

When we restrict our attention to path-containment problems, this implies a dichotomy result. Some of the path-containment problems can be solved using a linear number of queries, and all the others are equivalent to one another (and additionally to several cycle-containment problems as well) under randomized reductions and up to constant multiplicative overhead. For the latter equivalence class, we prove a novel quantum-walk-based algorithm that achieves query complexity $\widetilde{O}(n^{3/2-\alpha_k})$, where $\alpha_k \in \Theta(c^{-k})$ and $c = \sqrt{3+\sqrt{17}}/2 \approx 1.33$, beating the previous best upper bound $O(n^{3/2})$ on its query complexity. We also provide a conditional lower bound based on the graph-collision problem, which implies that this equivalence class does not admit linear-query quantum algorithms unless graph collision admits an $O(\sqrt{n})$ query algorithm.

1 Introduction

The subgraph containment problem asks whether a given (undirected) subgraph H is contained in an (undirected) input graph G. In this work, we consider subgraphs H of constant size that are known ahead of time, and input graphs G consisting of n vertices that we can access through adjacency-matrix queries. Now, we wish to decide whether the subgraph H is present in the input graph G, while making a minimal number of queries to the adjacency matrix of G. We denote this problem concisely by $\texttt{Subgraph}^H$, and the minimal number of queries to the input required to solve it is known as its query complexity. We also consider a restricted version of this problem where we select several vertices $v_1, \ldots, v_m$ from H and additionally require that these vertices get mapped to predetermined positions $s_1, \ldots, s_m$ in G. Under this restriction, we then ask whether H is present in G, and we denote the resulting problem by $\texttt{Subgraph}^H_{v_1,\ldots,v_m}$.

In the randomized setting, we decide which edges to query by a (classical) randomized algorithm, and we require the resulting algorithm to output the correct answer with probability at least $2/3$. The randomized query complexity of the unrestricted subgraph containment problem, denoted by $\mathsf{R}(\texttt{Subgraph}^H)$, satisfies $\Theta(n^2)$ for any non-empty graph H. Moreover, it is not hard to show that the restricted problems are classified into three distinct classes, where the randomized query complexities $\mathsf{R}(\texttt{Subgraph}^H_{v_1,\ldots,v_m})$ are $\Theta(1)$, $\Theta(n)$ and $\Theta(n^2)$, respectively.

In contrast, in the quantum setting, we can query the adjacency matrix coherently in superposition, and we aim to give a quantum algorithm whose final measurement outputs the right answer with probability at least $2/3$. The corresponding quantum query complexities, denoted by $\mathsf{Q}(\texttt{Subgraph}^H)$ for the unrestricted problem, and $\mathsf{Q}(\texttt{Subgraph}^H_{v_1,\ldots,v_m})$ for the restricted problem, seem to have a much richer structure than their classical counterparts. This is the focus of this work.

The study of the constant-size subgraph-containment problem in the quantum setting was pioneered by Magniez, Szegedy and Santha [24], who built on a quantum walk algorithm by Ambainis [2] to show that the existence of any subgraph H consisting of k vertices can be detected using $\widetilde{O}(n^{2-2/k})$ queries. This result was subsequently independently improved by Zhu [28], and Lee, Magniez and Santha [21], resulting in the current state-of-the-art complexity for general subgraphs H through the following learning-graph-based result.

▶ **Theorem 1** ([21, Theorem 4.4]). *Let H be an undirected graph with $k \geq 3$ vertices, m edges, and minimum vertex-degree $d \geq 1$, where $k, m, d \in O(1)$. Then, $\mathsf{Q}(\texttt{Subgraph}^H) \in O\left(n^{2-2/k-t}\right)$, where*

$$t = \max\left\{\frac{k^2 - 2(m+1)}{k(k+1)(m+1)}, \frac{2k-d-3}{k(d+1)(m-d+2)}\right\}.$$

Even though this result gives a non-trivial upper bound on the query complexity for the subgraph containment problem for any subgraph H, it is not expected that this bound is optimal in general. Indeed, for several specific families of subgraphs, we know better bounds than those provided by Lee, Magniez and Santha. Examples of such subgraph families include the line graphs with k edges (L_k) and cycle graphs with k edges (C_k), for which we refer to the subgraph-containment problems as $\texttt{Path}^{=k} := \texttt{Subgraph}^{L_k}$ and $\texttt{Cycle}^{=k} := \texttt{Subgraph}^{C_k}$, respectively.

The path-containment problem was pioneered by Childs and Kothari [14], who showed that it can be solved using $\widetilde{O}(n^{3/2-1/\lceil k/2\rceil})$ quantum queries. This was later improved by Belovs and Reichardt [6] to $\mathsf{Q}(\texttt{Path}^{=k}) \in \Theta(n)$, for all $k \in O(1)$. Their algorithm involves

reducing this problem to the promise problem, which we denote by $\texttt{PromPath}^{\leq k}_{s,t}$, where two vertices s and t are fixed, and the task is to distinguish between the existence of a path between s and t of length at most k, and no path between s and t at all. They used a span-program approach to show that $\mathsf{Q}(\texttt{PromPath}^{\leq k}_{s,t}) \in O(n\sqrt{k})$, even for non-constant k.

Despite Belovs's and Reichardt's remarkable progress on the path-containment problem, subsequent efforts to generalize their techniques were unsuccessful. Specifically, all attempts to solve the path-containment problem in the directed setting, or a version of their promise problem where one is required to not just detect the existence of a path, but actually output it, have not resulted in linear-query algorithms. In this work, we argue why these efforts are unlikely to work, with the following reasoning containing two parts. First, we show that all these directed and finding versions of the path-containment problem are equivalent up to randomized reductions (Section 3), and then we show a conditional quantum query lower bound for all these problems based on the graph-collision problem (Section 6). Since it is considered unlikely that we can make progress on the graph-collision problem with the current techniques, we conclude it's unlikely that we can make progress on these generalizations of Belovs's and Reichardt's work with the current techniques as well.

On the topic of cycle-containment problems, the problem of detecting 3-cycles (more commonly known as the triangle-detection problem) has played a central role in the literature on quantum query complexity. The study of this problem gave rise to many novel quantum algorithmic frameworks, and has been improved multiple times since it was first considered in [9]. Currently, the best-known algorithm is by Carette, Laurière and Magniez [11], who removed the log-factors from the algorithm by Le Gall [20].

▶ **Theorem 2** ([20, 11]). $\mathsf{Q}(\texttt{Cycle}^{=3}) \in O(n^{5/4})$.

The more general constant-length cycle-finding problem was also considered by Childs and Kothari [14], who showed the following improved upper bounds for even values of k.

▶ **Theorem 3** ([14, Theorem 4.11,4.12]). *Let $4 \leq k \in \mathbb{N}$ be even. Then,* $\mathsf{Q}(\texttt{Cycle}^{=k}) \in \widetilde{O}\left(n^{\frac{3}{2}-\frac{k-2}{k(k+2)}}\right)$. *Moreover,* $\mathsf{Q}(\texttt{Cycle}^{=4}) \in \widetilde{O}(n^{5/4})$.

Finally, Cade, Montanaro and Belovs [10] considered a promise version of the cycle-containment problem, where they fix a vertex s in the input graph, and then distinguish between graphs with a cycle of length at most k passing through s and graphs with no cycles at all. Much like the promise path problem, they present an algorithm making $O(n\sqrt{k})$ queries, even for non-constant values of k.

As in the path-containment setting, all attempts to generalize the above results to the directed setting proved to be futile. Moreover, generalizing the promise version of the problem considered by Cade, Montanaro and Belovs to the finding setting, where one additionally has to output the cycle, proved elusive as well. In this work, we connect the cycle-containment problems rigorously to the path-containment problems through randomized reductions, explaining in a similar fashion why these generalization efforts are unlikely to succeed.

From the lower-bound perspective, progress is hampered by the *certificate barrier* [27, 26], which states that lower bounds obtained through the non-negative-weighted adversary bound are upper bounded by the geometric average of the worst-case positive and negative certificate sizes. For all subgraph containment problems where the subgraph H is of constant size, the positive certificate sizes are of constant size as well, and therefore the best possible lower bound on the quantum query complexity we can obtain through the non-negative-weighted adversary bound is, up to constants, equal to $\sqrt{n^2 \cdot 1} = n$.

Even though there are other methods available for proving lower bounds on quantum query complexity, like the polynomial method [4], and the general adversary bound [17], applying these techniques to the subgraph containment problem has so far not been fruitful. As such,

proving any unconditional super-linear lower bound on the quantum query complexity for any subgraph containment problem is a major open problem in this area that has been open for about two decades.

Despite (or perhaps because of) these barriers, alternative progress was made by Balodis and Iraids [3] in showing a conditional lower bound for the triangle-detection problem, based on the hardness of the graph-collision problem. This problem is parametrized by a graph G on n vertices, which is completely known ahead of time. The input to the problem is a bit sting x that we have query access to, where each bit of x is associated with a distinct vertex of G. The graph collision problem on G asks whether there exists an edge in G for which both endpoints are labeled by a 1 in x. We refer to this problem as $\mathtt{GC}_G$, and we write $\mathsf{Q}(\mathtt{GC}_n)$ for the maximum of $\mathsf{Q}(\mathtt{GC}_G)$, over all graphs G on n vertices.

The best generic algorithm for this problem was given by Magniez, Szegedy and Santha [24, Theorem 3], which is essentially based on the algorithm of Ambainis [2] and has query complexity $\mathsf{Q}(\mathtt{GC}_n) \in O(n^{2/3})$. This complexity is believed by some in the community to be optimal. However, the best-known lower bound is only $\mathsf{Q}(\mathtt{GC}_n) \in \Omega(\sqrt{n})$, where further progress is again impeded by the certificate barrier.

Balodis and Iraids embedded the OR of n instances of the graph-collision problem into a single instance of the triangle-detection problem on $3n$ vertices. In doing so, they prove a conditional lower bound on the family of cycle-containment problems.

▶ **Theorem 4** ([3, Theorem 1]). $\mathsf{Q}(\mathtt{Cycle}^{=3}) \in \Omega(\sqrt{n} \cdot \mathsf{Q}(\mathtt{GC}_n))$.

This result implies a plausible path toward lower bounding the query complexity of the triangle-detection problem. Indeed, any lower bound $\omega(\sqrt{n})$ for the graph-collision problem would immediately imply a super-linear lower bound $\omega(n)$ for the triangle-detection problem.

In this work, we provide similar graph-collision-based conditional lower bounds for the families of path- and cycle-containment problems. This solidifies the role of the graph-collision problem in the landscape of subgraph-containment problems, as a non-trivial lower bound for graph-collision would imply non-trivial lower bounds for both cycle- and path-containment problems.

1.1 Contributions

In this work, we provide a rigorous study of the different variants of subgraph-containment problems, with a specific focus on path- and cycle-containment problems. We present a number of simpler *observations* based on prior work that help paint the landscape of these problems, and we obtain three *main results* that improve our understanding of their query complexities.

For the general constant-size subgraph-containment problem, we consider relations between the undirected and the directed setting, as well as between their detection and finding versions. Even though it is not explicitly analyzed by Lee, Magniez and Santha, we make the simple observation that their learning-graph-based approach readily generalizes to the directed setting.

▶ **Observation 5** (Informal version of Proposition 25). *Theorem 1 holds too whenever the subgraph H and the input graph are directed.*

Next, we also observe that for non-promise subgraph-containment problems, detection and finding are equivalent up to randomized reductions and constant multiplicative overhead.

▶ **Observation 6** (Informal version of Lemma 23). *For any (directed/undirected) subgraph H, the quantum query complexities of the finding and detection versions of the non-promise (possibly restricted) subgraph-containment problem with subgraph H are equal up to a multiplicative constant.*

We note that the above only holds for non-promise problems, i.e., where all graphs are valid inputs to the problem. That is, one can only have separations between the detection and finding versions of a subgraph-containment problem in a setting where the input satisfied some promise known a priori. Indeed, in such promise settings, there are several graph problems where the finding and detection versions seem to be very much distinct. For instance, there is a quantum algorithm that makes polylogarithmic queries to output the (first bit of the) EXIT vertex in the Welded tree graph [12], while outputting an ENTRANCE-to-EXIT path in this graph takes polynomially many queries for a certain natural class of quantum algorithms [13]. Moreover, as we will see, the promise problem $\texttt{PromFindPath}^{=k}_{s,t}$ would be polynomially harder than $\texttt{PromPath}^{=k}_{s,t}$ assuming graph collision is harder than its trivial lower bound.

We also show that there is a generic randomized reduction from the undirected version of a subgraph-containment problem to the directed one.

▶ **Observation 7** (Informal version of Lemma 24). *Every directed subgraph-containment problem is at least as hard (in terms of randomized/quantum query complexity) as its undirected counterpart.*

Next, we focus specifically on the path- and cycle-containment problems. For these problems, we consider the restricted and unrestricted versions of the problem, where in the restricted versions, we fix the start and end vertices s and t for the path-containment problem, and a single vertex s on the cycle for the cycle-finding problem. We also consider the directed versions of these problems, and the finding versions where we ask to output the path or cycle. Finally, we consider versions where we search for a path or cycle of length exactly k, or at most k. We denote the directed and finding versions with the keywords `Dir` and `Find`, we attach a superscript $= k$ or $\leq k$ to indicate the length constraint, and we supply a subscript s or s, t for the restricted versions. Thus, for instance, the problem $\texttt{FindDirPath}^{=k}_{s,t}$ is the finding version of the directed path-finding problem between s and t, of length exactly k.

Akin to Belovs and Reichardt [6], and Cade et al. [10], we also consider promise versions of this problem. In the restricted path problem, i.e., where we fix the start and end vertex s and t, the promise version satisfies that a path of the required length exists between s and t, or s and t are not connected at all. Similarly, in the restricted cycle-finding problem through a vertex s, either a cycle through s exists with the required length, or no cycle through s exists at all. We note that this promise is weaker than the promise considered in Cade et al. [10], and so our algorithmic results for this problem are stronger. Finally, for the unrestricted cycle-finding problem, we also consider a promise version, where either a cycle exists of the required length, or there exists no cycle at all (i.e., the graph is a forest). These problems are indicated with the `Prom` keyword, i.e., $\texttt{PromDirCycle}^{\leq k}_{s}$ is the promise problem of detecting a directed cycle through s of length at most k.[1]

Our first observation in this direction is that every `PromFind`-version of these problems requires the same number of queries as the corresponding `Find`-version.

[1] Note that we don't consider a promise version of the unrestricted path-containment problem, because we don't see a meaningful way of defining it.

▶ **Observation 8** (Informal version of Lemmas 28 and 38)**.** *Let* P *be a (restricted/unrestricted, directed/undirected) path- or cycle-containment problem, with length constraint* $= k$ *or* $\leq k$ *with* $k \in O(1)$*. Then, the finding version of* P *is equivalent to the promise-finding version of* P*, up to randomized reductions and multiplicative constants.*

Observations 6 and 8 show that for all path- and cycle-containment problems P, we have that P, FindP and PromFindP are equivalent up to randomized reductions and multiplicative constants. As such, these three problems fall in the same equivalence class, and it suffices to restrict our attention to P and PromP in what follows.

Now, we arrive at the first main result of this work. We classify all remaining path- and cycle-containment problems into several equivalence classes via randomized reductions between them. We aid the reader by providing a graphical overview of these reductions in Figure 1, and we obtain the following classification.

▶ **Main result 9.** *The unrestricted and undirected path-containment problem, and the undirected promise versions of the path- and cycle-containment problems admit linear-query quantum algorithms. All other path-containment problems are equivalent, and all other cycle-containment problems can be classified into at most 5 equivalence classes. See Figure 1.*

For some reductions we use the color-coding technique, introduced by Alon, Yuster and Zwick [1]. The idea is to assign distinct colors to the vertices of the path/cycle graph L_k/C_k, and then to randomly assign these colors to the vertices of the input graph G. Next, we only keep an edge in G if the colors of the two vertices it connects are associated to two vertices in the path/cycle graph that are connected by an edge too. The resulting color-coded graph becomes a layered graph in the path-containment case, and a layered cycle graph in the cycle-containment case, as displayed in Figure 2. With at least constant probability, a path/cycle in the original graph gets mapped to a path/cycle in the layered graph that straddles across all the layers.

To show relations between the various subgraph-containment problems, we cleverly make subtle modifications to the input graphs, oftentimes combined with the aforementioned color-coding technique. For instance, we can insert layers into a layered graph to show that one can find short paths using an algorithm that finds longer paths. Similarly, we can merge the vertices s and t into a single vertex s to convert an st-path containment problem into a cycle-containment problem through the vertex s, and similarly we can separate a vertex s into two vertices s and t to prove a reduction in the reverse direction.

All these conversions, however, are subject to subtle caveats. For instance, in a layered cycle graph with k layers, a cycle of length k is guaranteed to go through all layers whenever k is odd, whereas when k is even it can exist between two consecutive layers. Similarly, when we merge two vertices s and t into a single vertex s, a cycle through s in the resulting graph does not necessarily imply that the original graph contains an st-path. We obtain our classification, i.e., Main result 9, by carefully checking which reductions can be made to work despite these caveats. Since we don't expect Figure 1 to collapse to a single island, we don't expect these subtleties to be artifacts of the techniques used, but rather highlight the fundamental relations between these problems.

The overview of reductions presented in Figure 1 reveals some interesting relations. For instance, it shows that one can reduce the $\texttt{DirCycle}_s^{\leq k}$-problem to the $\texttt{Cycle}_s^{\leq k}$-problem, through a series of reductions that involve the $\texttt{DirCycle}_s^{=k}$- and $\texttt{Cycle}_s^{=k}$-problems. We remark here that making this connection without going through the intermediate steps is not immediate, since it's not clear how one can remove directions in a layered graph while preventing the introduction of new cycles. This highlights the benefit of this classification effort, as it uncovers relations between problems that would otherwise not be easily obtained.

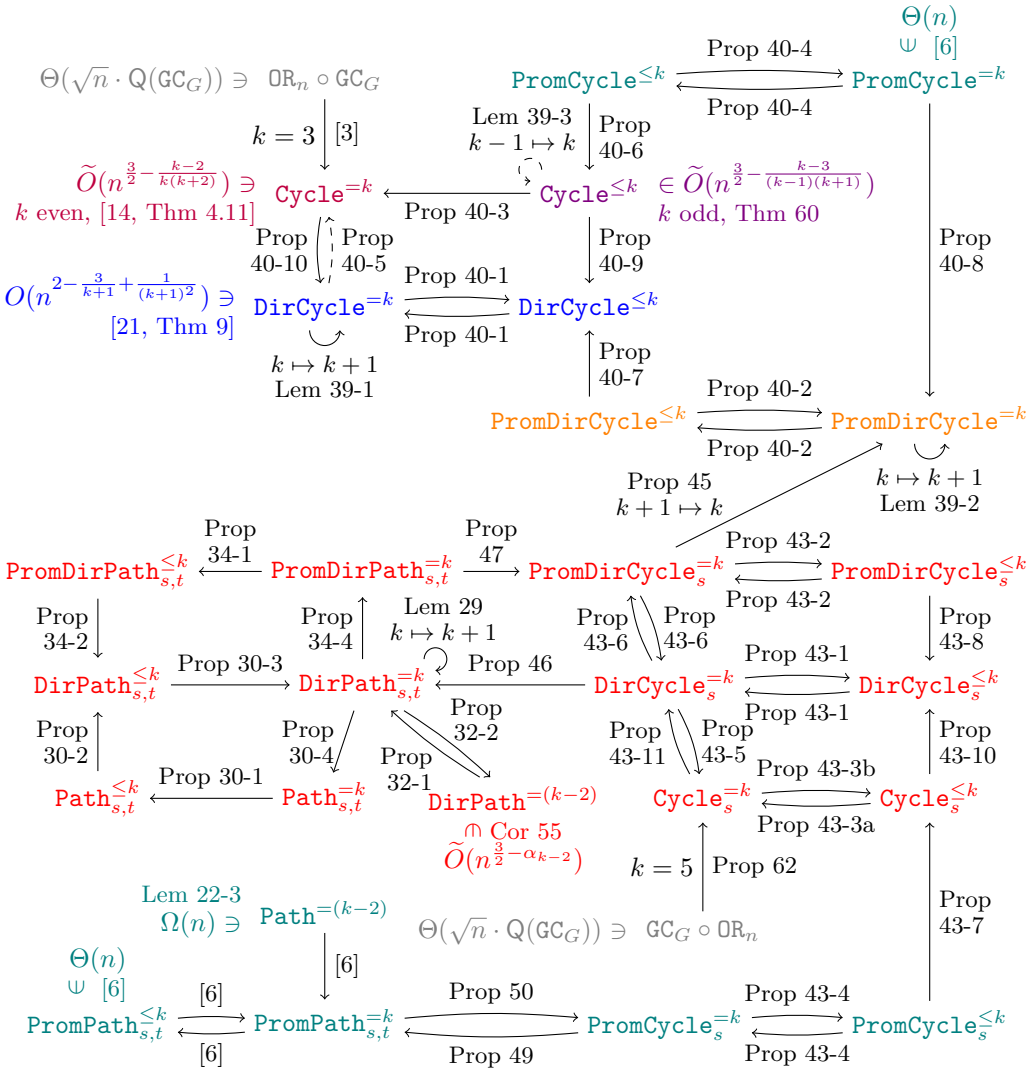

Figure 1 Randomized reductions between problems for $k \geq 3$. The dashed connections hold only for odd values of k. For the graph-collision problems, we can take any graph G with n vertices. All problems' randomized query complexities are $\Theta(n^2)$. All complexity bounds stated in the figure are upper and lower bounds on the quantum query complexity. In the upper bound for $\mathsf{Q}(\mathtt{DirPath}^{=(k-2)})$, $\alpha_k \in \Theta(c^{-k})$, with $c \approx 1.33$. If two problems have the same color, they have the same quantum query complexity up to constants.

Next, the classification of path- and cycle-finding problems displayed in Figure 1 motivates the search for new quantum algorithms and query lower bounds for problems in these equivalence classes specifically. For instance, the $\mathtt{DirPath}^{=k}$-problem is part of an equivalence class containing 12 other path- and cycle-containment problems, hence an improved algorithm for this problem immediately provides an algorithm for all the others as well. Moreover, this equivalence class includes all directed versions of the path problems, as well as the finding versions of the promise-path problems, i.e., exactly the problems for which generalizing Belovs's and Reichardt's span-program-based construction failed.

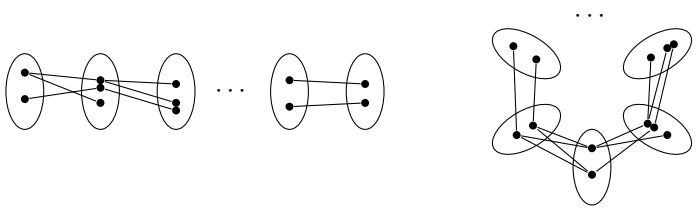

Figure 2 A layered graph (left) and a layered cycle graph (right). These can be obtained from general graphs using the color-coding technique, where a path of length k (resp. cycle of length k) is preserved with constant probability.

Our main algorithmic result is a novel quantum-walk-based algorithm for this $\texttt{DirPath}^{=k}$-problem, and hence for all problems in the equivalence class highlighted in red in Figure 1. The best previously-known algorithm for any of the problems in this equivalence class is an algorithm that finds the shortest path between s and t, if it exists, and thereby solves the $\texttt{Path}_{s,t}^{\leq k}$-problem. This algorithm was originally developed by Dürr et al. [16], making $\widetilde{O}(n^{3/2})$ queries, and the log-factors were subsequently removed by a series of works culminating in a paper by Lin and Lin [22, Theorem 13]. We note that Beigi and Taghavi also developed $O(n^{3/2})$-query algorithms for the $\texttt{Cycle}_s^{=k}$ and $\texttt{Cycle}_s^{\leq k}$-problems [5, Proposition 9.iv-v]. Our result provides an improved algorithm for all these problems.

▶ **Main result 10** (Corollary 55). *Let $5 \leq k \in \mathbb{N}$. Then, $\mathsf{Q}(\texttt{DirPath}^{=k}) \in \widetilde{O}(n^{3/2-\alpha_k})$, where $\alpha_k \in \Theta(c^{-k})$ as $k \to \infty$, with $c = \sqrt{3+\sqrt{17}}/2 \approx 1.33$.*

The main algorithmic idea is to reduce the directed-path-detection problem of length k to the same problem with length $k-2$. To that end, we employ the MNRS-framework [23] to search for vertices that have at least one incoming edge, and those that have at least one outgoing edge. Then, it remains to find a pair of such vertices that has a path of length $k-2$ between them, which we then solve recursively. This results in a nested quantum-walk construction, where we optimize the parameters of the quantum-walk framework to minimize the resulting query complexity. The resulting minimization problem involves solving a recurrence relation, whose solution yields an exponent that satisfies $3/2 - \Theta(c^{-k})$ for large values of k.

We additionally provide an improved algorithm for the $\texttt{Cycle}^{\leq k}$-problem, which is also displayed in Figure 1. A slight modification of Childs and Kothari [14] yields the following result.

▶ **Observation 11** (Theorem 60). *Let $5 \leq k \in \mathbb{N}$ be an odd integer. Then, $\mathsf{Q}(\texttt{Cycle}^{\leq k}) \in \widetilde{O}(n^{\frac{3}{2}-\frac{k-5}{(k-1)(k+3)}})$.*

Finally, we focus on the lower bounds. Our main result in this direction is relating the cycle-finding problem through a particular vertex s to the graph-collision problem. In particular, through the reductions highlighted in Figure 1, we emphasize that this result also provides a conditional lower bound on the $\texttt{DirPath}^{=k}$-problem, and consequently on all path-containment problems that are in the same equivalence class.

▶ **Main result 12** (Proposition 62). *Let $5 \leq k \in \mathbb{N}$ be an odd integer. Then, $\mathsf{Q}(\texttt{Cycle}_s^{\leq k}) \in \Omega(\sqrt{n} \cdot \mathsf{Q}(\texttt{GC}_n))$.*

Even though the resulting lower bound is identical to the lower bound derived by Balodis and Iraids for the triangle-detection problem, the underlying construction is profoundly different. Whereas Balodis and Iraids embed n instances of the graph-collision problem into a

single instance of triangle-detection, we embed a single instance of the graph-collision problem composed with the OR-function into a single instance of the 5-cycle-detection problem through a fixed vertex s. In other words, Balodis and Iraids prove $\mathsf{Q}(\texttt{Cycle}^{=3}) \in \Omega(\mathsf{Q}(\texttt{OR}_n \circ \texttt{GC}_n))$, whereas we prove that $\mathsf{Q}(\texttt{Cycle}_s^{=5}) \in \Omega(\mathsf{Q}(\texttt{GC}_n \circ \texttt{OR}_n))$, where $\texttt{OR}_n$ is the boolean functions encoding the OR-function on n bits.

Finally, we remark that combining all our results provides conditional separations between the $\texttt{Path}^{=k}$ and $\texttt{DirPath}^{=k}$ problems, the $\texttt{PromDirPath}_{s,t}^{=k}$ and $\texttt{PromPath}_{s,t}^{=k}$ problems, and the $\texttt{PromFindPath}_{s,t}^{=k}$ and $\texttt{PromPath}_{s,t}^{=k}$ problems. Indeed, any non-trivial lower bound on the graph-collision problem implies a query separation between each pair of these problems. This in particular suggests that Belovs's and Reichardt's span-program-based approach can likely not be generalized to either the directed or finding settings, and, as such, that the undirected promise problems are indeed likely to be much easier than their directed and non-promise counterparts.

2 Preliminaries

2.1 Notation

Let $\mathbb{N} = \{1, 2, \ldots\}$ be the set of all positive integers, and $\mathbb{N}_0 = \mathbb{N} \cup \{0\}$. For any integer $n \in \mathbb{N}$, we define $[n] \coloneqq \{1, \ldots, n\}$ and $[n]_0 \coloneqq \{0, 1, \ldots, n\}$.

Let $g : \mathbb{R} \supseteq D_g \to \mathbb{R}_{\geq 0}$. We define $O(g)$ to be the set of functions $f : D_g \supseteq D_f \to \mathbb{C}$ such that there exist $C, M > 0$ such that for all $x \in D_f$, $x > M \Rightarrow |f(x)| \leq C \cdot g(x)$. Similarly, we define $\widetilde{O}(g)$ to be the set of functions $f : D_g \supseteq D_f \to \mathbb{C}$ such that there exist $C, M, k > 0$ such that for all $x \in D_f$, $x > M \Rightarrow |f(x)| \leq C \cdot g(x) \cdot \log^k(g(x))$. We define $\Omega(g)$ and $\widetilde{\Omega}(g)$ analogously, but with the conditions being $|f(x)| \geq C \cdot g(x)$ and $|f(x)| \geq C \cdot g(x)/\log^k(g(x))$, respectively. Finally, we write $\Theta(g) := O(g) \cap \Omega(g)$, and $\widetilde{\Theta}(g) := \widetilde{O}(g) \cap \widetilde{\Omega}(g)$.

We denote undirected graphs by $G = (V, E)$, where every edge $\{v, w\} = e \in E$ is a set of two vertices, with $v, w \in V$. Similarly, we denote directed graphs by $G = (V, A)$, where every arc $(v, w) = a \in A$ is an ordered pair of vertices, with $v, w \in V$. If $V' \subseteq V$, then $G - V'$ denotes the graph G with all vertices from V' and their adjacent edges removed. All (undirected/directed) graphs considered in this work are simple, i.e., there are no duplicate edges and arcs. However, in the directed setting, we do allow for both arcs in opposite directions to exist simultaneously between two vertices.

We consider the adjacency-matrix model, where any algorithm can make queries to the entries of the adjacency matrix of an input graph G. Equivalently, for an undirected graph, the algorithm can supply a set of two vertices to an oracle, that outputs whether an edge exists between the two, and similarly in the directed setting the algorithm can ask whether an arc exists between two vertices from an ordered pair. In the randomized setting, the algorithm can employ randomness to select which vertices to query. In the quantum setting, the vertex pairs can be queried coherently in superposition, e.g., for an undirected graph $G = (V, E)$, the oracle behaves as a unitary O_G that acts as

$$O_G : |v, w\rangle\,|b\rangle \mapsto |v, w\rangle\,|b \oplus [\{v, w\} \in E]\rangle\,, \qquad \forall v, w \in V, b \in \{0, 1\}.$$

We refer the reader to a quantum computing textbook for more details on the quantum computational model, e.g., [25]. The randomized and quantum query complexities of a given problem are the minimal numbers of queries required to solve the problem in these respective computational models.

Finally, we use regular expressions to denote sets of problems. That end, for two expressions $\texttt{A}$ and $\texttt{B}$, we write $(\texttt{A}|\texttt{B})$ to denote the set of expressions $\{\texttt{A}, \texttt{B}\}$. We use this in combination with concatenation, i.e., $\texttt{A}(\texttt{B}|\texttt{C})$ denotes the set $\{\texttt{AB}, \texttt{AC}\}$. In particular, some of the expressions can be empty, i.e., $(|\texttt{A})\texttt{B}$ denotes the set $\{\texttt{B}, \texttt{AB}\}$.

2.2 Subroutines

We begin with a quantum subroutine that approximates the hamming weight of a Boolean string with a an error parameter ϵ.

▶ **Theorem 13** (Approximate quantum counting [8, Theorem 15]). *Let $f : \{0,1\}^n \to \{0,1\}$ and $\epsilon \in (0,1]$. Let $t = |f^{-1}(1)|$. Then, there is a quantum algorithm that outputs $\tilde{t}$ such that $|t - \tilde{t}| \leq \epsilon t$ with probability at least $1 - \delta$ using $O\left(\frac{1}{\epsilon}\sqrt{n/t}\log\frac{1}{\delta}\right)$ queries to f.*

We will mainly need to use the approximate counting algorithm for approximating the number of edges in a graph and approximating the degree of a vertex. For that reason, we will need the following corollaries.

▶ **Corollary 14** ([14, Corollary 4.1]). *Let $A : \{0,1\}^{\binom{n}{2}} \to \{0,1\}$ be an adjacency matrix representation of an undirected graph G, $\epsilon \in (0,1]$ be a constant and $\overline{m}$ be an integer. Then, there is a quantum algorithm ApproxEdgeCount that accepts G if the number of edges $|E(G)| = |A|$ in G are at least $(1+\epsilon)\overline{m}$ and rejects G if $|E(G)|$ is at most $(1-\epsilon)\overline{m}$ with probability at least $1 - \delta$ using $O\left(\frac{1}{\epsilon}\sqrt{n^2/\overline{m}}\log\frac{1}{\delta}\right)$ queries to A.*

▶ **Corollary 15.** *Let $A : \{0,1\}^{\binom{n}{2}} \to \{0,1\}$ be an adjacency matrix representation of an undirected graph G, v be a vertex in G, $\epsilon \in (0,1]$ be a constant and $\overline{d}$ be an integer. Then, there is a quantum algorithm ApproxDegreeCount that accepts (G, v) if the degree $\deg(v)$ of v in G are at least $(1+\epsilon)\overline{d}$ and rejects G if $\deg(v)$ is at most $(1-\epsilon)\overline{d}$ with probability at least $1 - \delta$ using $O\left(\frac{1}{\epsilon}\sqrt{n/\overline{d}}\log\frac{1}{\delta}\right)$ queries to A.*

We will also need a subroutine that retrieves all the marked elements of a function.

▶ **Lemma 16** ([14, Lemma 4.1]). *Let $f : [n] \mapsto \{0,1\}$ and $t = |f^{-1}(1)|$. Then, there is a quantum algorithm that computes $f^{-1}(1)$ using $O(\sqrt{n(t+1)})$ queries to f.*

The following lemma relates the query complexity of problems that can be related by a randomized reduction with one-sided error.

▶ **Lemma 17.** *Let P and P' be arbitrary decision problems. Let G be an instance of P and let G' be obtained from G via an efficient randomized reduction, i.e., each query to G' can be made using $O(1)$ queries to G. Suppose that if G is a YES instance of P, then G' is a YES instance of P' with probability at least $p \in \Omega(1)$, and if G is a NO instance of P, then G' is a NO instance of P' with probability 1. Then, for $\mathsf{M} \in \{\mathsf{R}, \mathsf{Q}\}$, we have $\mathsf{M}(\mathsf{P}) \in O(\mathsf{M}(\mathsf{P}'))$.*

Proof. Let $\mathcal{A}$ be the optimal (randomized/quantum) algorithm for the problem P'. We first construct a new algorithm $\mathcal{B}$ with majority voting, where we run $\mathcal{A}$ on the same input a total of $\Theta(\log(1/p))$ times, so that it decides between YES and NO inputs with probability at least $1 - p/4$.

Now, we run the algorithm $\mathcal{B}$ on an instance G' generated through the randomized reduction. Then, if G is a positive input, this procedure will succeed with probability at least $p(1 - p/4) > 3p/4$, whereas if G is a negative input, this procedure will succeed with probability at most $p/4$. Thus, by running this procedure a total of $\Theta(1/p)$ times, we can distinguish between these two cases with high probability. As such, the total number of calls to $\mathcal{A}$ is $\Theta((1/p)\log(1/p))$, which is constant as $p \in \Omega(1)$. Thus, $\mathsf{M}(\mathsf{P}) \in O(\mathsf{M}(\mathsf{P}'))$, for $\mathsf{M} \in \{\mathsf{Q}, \mathsf{R}\}$. ◀

▶ Remark 18. Note that, to be able to argue sub-quadratic quantum query bounds for graph problems on n vertices through randomized reductions, these reductions must be query-efficient. In the reductions we use throughout this work, we express the edge set of the new graph in terms of the edge set of the original graph, such that checking a specific edge in the new graph requires $O(1)$ queries to the edge set of the original graph, unless explicitly stated otherwise.

2.3 Quantum walks

Throughout this paper, we will be making use of the MNRS-framework for quantum walks, developed by Magniez, Nayak, Rolland and Santha [23]. We recall their result here.

▶ **Theorem 19** ([23, Theorem 3]). *Let P be a reversible ergodic Markov chain over a state space V, with spectral gap δ. Let $M \subseteq V$ be a marked subset, such that if $M \neq \varnothing$, then $\mathbb{P}_{v\sim\pi}[v \in M] \geq \varepsilon > 0$, where π is the stationary distribution of P. Let S be such that the number of queries required to prepare a q-sample of $|\pi\rangle$ up to norm-error at most δ is $\widetilde{O}(\mathsf{S}\text{polylog}(1/\delta))$. Similarly, let U be such that the number of queries required to prepare a q-sample over the neighbors of a given vertex $v \in V$ with norm-error at most δ is $\widetilde{O}(\mathsf{U}\text{polylog}(1/\delta))$. Finally, let C be the number of queries required to check whether a given state $v \in V$ is marked, with high probability. Then, we can decide whether M is empty or non-empty with a total number of queries that satisfies*

$$\widetilde{O}\left(\mathsf{S} + \frac{1}{\sqrt{\varepsilon}}\left(\frac{1}{\sqrt{\delta}}\mathsf{U} + \mathsf{C}\right)\right).$$

On several occasions, we will recursively use this construction, which is known as a nested quantum walk. This has been considered ample times in previous works, for instance [14, 19]. These constructions typically suffer from polylogarithmic overhead, but recent work has shown that this can be avoided in certain settings [18, 15]. We leave using these more recent techniques to remove the polylogarithmic overhead from our algorithms for future work.

3 Reductions between subgraph containment problems

We start by formally introducing the different versions of the subgraph-containment problems we consider in this work.

▶ **Definition 20** (Subgraph containment). *We define several computational problems.*

1. *Let $H = (V_H, E_H)$ be a known undirected graph, and suppose we have access to an undirected graph $G = (V, E)$ through adjacency-matrix queries. Let $m \in \mathbb{N}_0$, $v_1, \ldots, v_m \in V_H$ and $s_1, \ldots, s_m \in V$ all distinct. The subgraph containment problem asks whether there exists an injection $\varphi : V_H \to V$, such that $\varphi : v_j \mapsto s_j$, for all $j \in [m]$, and such that the induced map $\varphi' : \binom{V_H}{2} \to \binom{V}{2}$ acting as $\{v, w\} \mapsto \{\varphi(v), \varphi(w)\}$ satisfies $\varphi'(E_H) \subseteq E$. The resulting boolean function, that evaluates to 1 if and only if such an injection exists, is denoted by*

$$\texttt{Subgraph}^{H,v_1,\ldots,v_m}_{V,s_1,\ldots,s_m} : \{0,1\}^{\binom{V}{2}} \to \{0,1\},$$

and we use the following shorthand notation for the sequence of boolean functions

$$\texttt{Subgraph}^{H}_{v_1,\ldots,v_m} := (\texttt{Subgraph}^{H,v_1,\ldots,v_m}_{[n],1,\ldots,m})_{n=1}^{\infty}.$$

Whenever $m = 0$, we refer to the subgraph containment problem as unrestricted, in which case the boolean function is simply denoted by $\texttt{Subgraph}^{H}_{V}$, and the sequence of boolean functions by $\texttt{Subgraph}^{H}$. On the other hand, when $m \geq 1$, we say that the problem is restricted.

2. *We define the restricted and unrestricted subgraph containment problems analogously for directed graphs, i.e., if $H = (V_H, A_H)$ is a directed graph and we have adjacency-matrix-query access to a directed graph $G = (V, A)$, we define the boolean function* $\texttt{Subgraph}_V^H : \{0,1\}^{\{(v,w):v,w\in V:v\neq w\}} \to \{0,1\}$*, and similarly in the restricted setting.*
3. *Finally, we define finding versions of these problems, which ask to output* 0 *if the subgraph H is not contained in G, and the injective map φ otherwise. Formally, in the undirected unrestricted setting, this is a relation* $\texttt{FindSubgraph}_V^H \subseteq \{0,1\}^{\binom{V}{2}} \times (\{0\} \cup \{\varphi : V_H \to V \text{ injective}\})$*, and similarly for the restricted and directed settings.*

We can now phrase many graph problems formally as subgraph containment problems. For instance, if we let H be an undirected cycle on three vertices, then the sequence of boolean functions $\texttt{Subgraph}^H$ represents the triangle finding problem, where we have the bounds $\mathsf{Q}(\texttt{Subgraph}^H) \in O(n^{5/4}) \cap \Omega(n)$ [20, 11].

In this work, we restrict our attention to subgraph-containment problems where the subgraph is of constant size. In this setting, we can prove several elementary structural properties of these problems. The proofs of these properties are available in the full version of the paper.

▶ **Lemma 21.** *Let H be a graph of constant size, $m \in \mathbb{N}_0$ and $v_1, \dots, v_m \in V_H$. Suppose that $H_1, \dots, H_\ell$ are the connected components of H, and we write $i_1^{\ell'}, \dots, i_{m_{\ell'}}^{\ell'} \in [m]$ such that $v_{i_1^{\ell'}}, \dots, v_{i_{m_{\ell'}}^{\ell'}}$ are the vertices from $v_1, \dots, v_m$ that are contained in $H_{\ell'}$, for all $\ell' \in [\ell]$. Then, for $\mathsf{M} \in \{\mathsf{Q}, \mathsf{R}\}$, we have*

$$\mathsf{M}\left(\texttt{Subgraph}^H_{v_1,\dots,v_m}\right) \in \Theta\left(\max_{\ell'\in[\ell]}\left\{\mathsf{M}\left(\texttt{Subgraph}^{H_{\ell'}}_{v_{i_1^{\ell'}},\dots,v_{i_{m_{\ell'}}^{\ell'}}}\right)\right\}\right).$$

The above lemma informs us that we can without loss of generality focus on the case where H is connected. Next, we provide a full classification of these problems in the randomized setting, and a similar partial classification in the quantum setting. This lemma is folklore (see for instance [6, Proposition 4] for the third item), but we provide a formal statement and proof here for completeness.

▶ **Lemma 22.** *Let H be a connected non-empty graph of constant size, and let $m \in \mathbb{N}_0$ with $v_1, \dots, v_m \in V_H$. Then,*

1. *If $\{v_1, \dots, v_m\} = V_H$, then $\mathsf{Q}(\texttt{Subgraph}^H_{v_1,\dots,v_m}) \in \Theta(1)$ and $\mathsf{R}(\texttt{Subgraph}^H_{v_1,\dots,v_m}) \in \Theta(1)$.*
2. *If $H - \{v_1, \dots, v_m\}$ contains just isolated vertices, then $\mathsf{Q}(\texttt{Subgraph}^H_{v_1,\dots,v_m}) \in \Theta(\sqrt{n})$ and $\mathsf{R}(\texttt{Subgraph}^H_{v_1,\dots,v_m}) \in \Theta(n)$.*
3. *If $H - \{v_1, \dots, v_m\}$ contains an edge, then $\mathsf{Q}(\texttt{Subgraph}^H_{v_1,\dots,v_m}) \in \Omega(n)$ and we have $\mathsf{R}(\texttt{Subgraph}^H_{v_1,\dots,v_m}) \in \Theta(n^2)$.*

Note that the above lemma completely characterizes the randomized query complexity of all detection versions of undirected subgraph containment problems. The simplicity of this characterization is in stark contrast with the quantum setting, where such a characterization seems elusive.

Next, we provide some generic reductions between the detection and finding versions of the subgraph containment problems, and between the undirected and directed versions.

▶ **Lemma 23.** *Let H be a connected non-empty graph of constant size, $m \in \mathbb{N}_0$, and $v_1, \dots, v_m \in V_H$. Then, for $\mathsf{M} \in \{\mathsf{Q}, \mathsf{R}\}$, we have the characterization $\mathsf{M}(\texttt{Subgraph}^H_{v_1,\dots,v_m}) \in \Theta(\mathsf{M}(\texttt{FindSubgraph}^H_{v_1,\dots,v_m}))$.*

▶ **Lemma 24.** *Let H be a connected non-empty undirected graph of constant size, $m \in \mathbb{N}_0$, and $v_1, \ldots, v_m \in V_H$. Let $\vec{H}$ be the same graph as H, but then with arcs pointed in arbitrary directions. Then, for $\mathsf{M} \in \{\mathsf{Q}, \mathsf{R}\}$, we have $\mathsf{M}(\mathtt{Subgraph}^{H}_{v_1,\ldots,v_m}) \in O(\mathsf{M}(\mathtt{Subgraph}^{\vec{H}}_{v_1,\ldots v_m}))$.*

We note that the above lemmas also completely characterize the randomized query complexity for all directed and finding subgraph containment problems. We spend the rest of the document investigating the quantum counterparts of these results in more detail.

Finally, we recall that Theorem 1, as proved by Lee, Magniez and Santha, strictly speaking only holds for undirected subgraph-containment problems. However, we argue that their learning-graph-based algorithm also works in the directed setting, with the same complexity.

▶ **Proposition 25.** *Let $H = (V, A)$ be a directed graph, and let $H' = (V, E')$ be its undirected counterpart, i.e., $\{v, w\} \in E'$ if and only if $(v, w) \in A$ or $(w, v) \in A$. Then, $\mathsf{Q}(\mathtt{Subgraph}^{H})$ is upper bounded by the expression in Theorem 1 applied to H'.*

3.1 Path-containment reductions

We introduce shorthand notations for the subgraph-containment problems where the subgraph is a line graph. We refer to these as path-containment problems.

▶ **Definition 26** (Path-containment problems)**.** *Let $k \in \mathbb{N}$.*

1. *Let L_k be the undirected line graph with k edges, with the endpoint vertices labeled by s and t. We define $\mathtt{Path}^{=k} := \mathtt{Subgraph}^{L_k}$, and $\mathtt{Path}^{=k}_{s,t} := \mathtt{Subgraph}^{L_k}_{s,t}$.*
2. *Let L'_k be the directed version of L_k, where the edges are all pointing from s to t. We define $\mathtt{DirPath}^{=k} := \mathtt{Subgraph}^{L'_k}$, and $\mathtt{DirPath}^{=k}_{s,t} := \mathtt{Subgraph}^{L'_k}_{s,t}$.*

Finally, for $\mathtt{P} \in (|\mathtt{Dir})\mathtt{Path}_{(|s,t)}$, we write

$$\mathtt{P}^{\leq k} := \bigvee_{\ell=1}^{k} \mathtt{P}^{=\ell}.$$

We also consider the finding versions of these problems, denoted by $\mathtt{FindP}$ for all $\mathtt{P} \in (|\mathtt{Dir})\mathtt{Path}^{(=k|\leq k)}_{(|s,t)}$. In the $(\leq k)$-problems, it suffices to output a path for any of the subproblems $\mathtt{P}^{=\ell}$, with $\ell \in \{1, \ldots, k\}$.

We also consider promise versions of the path-containment problems.

▶ **Definition 27** (Promise path-containment problems)**.** *Let $k \in \mathbb{N}$.*

1. *The $\mathtt{PromPath}^{(=k|\leq k)}_{s,t}$-problem is the $\mathtt{Path}^{(=k|\leq k)}_{s,t}$-problem, restricted to inputs that satisfy the promise that if s and t are connected, then there exists a path of length exactly, or at most, k between s and t, respectively.*
2. *The $\mathtt{PromDirPath}^{(=k|\leq k)}_{s,t}$-problem is the $\mathtt{DirPath}^{(=k|\leq k)}_{s,t}$-problem, restricted to inputs that satisfy the promise that if s and t are connected by a directed path from s to t, then there exists a directed path of length exactly, or at most, k from s to t, respectively.*

The finding versions of these problems, $\mathtt{PromFindPath}^{(=k|\leq k)}_{s,t}$ and $\mathtt{PromFindDirPath}^{(=k|\leq k)}_{s,t}$ respectively, are the finding problems under the same restriction.

Formally speaking the promise path-containment problems are also boolean functions, but on a restricted domain. As such, they are partial booelan functions, rather than total ones.

We start by showing some elementary reductions between the promise and non-promise versions of the path-containment problems. The proofs are available in the full version of the paper.

▶ **Lemma 28.** *Let* $\mathtt{P} \in (|\mathtt{Dir})\mathtt{Path}_{s,t}^{(=k|\leq k)}$.
1. *We have* $\mathsf{Q}(\mathtt{PromP}) \in O(\mathsf{Q}(\mathtt{P}))$.
2. *We have* $\mathsf{Q}(\mathtt{FindP}) \in \Theta(\mathsf{Q}(\mathtt{PromFindP}))$.

Through Lemmas 23 and 28, we conclude that the `Find` and `PromFind` versions of the path-containment problems considered above all have the same query complexity up to constants as the non-promise detection version of the problem. Thus, to understand the relative hardness of the path-containment problems introduced above, we will ignore the `Find` and `PromFind` versions in what follows. We provide a graphical overview of the remaining problems in Figure 3, with arrows representing the reductions we prove in the remainder of this section.

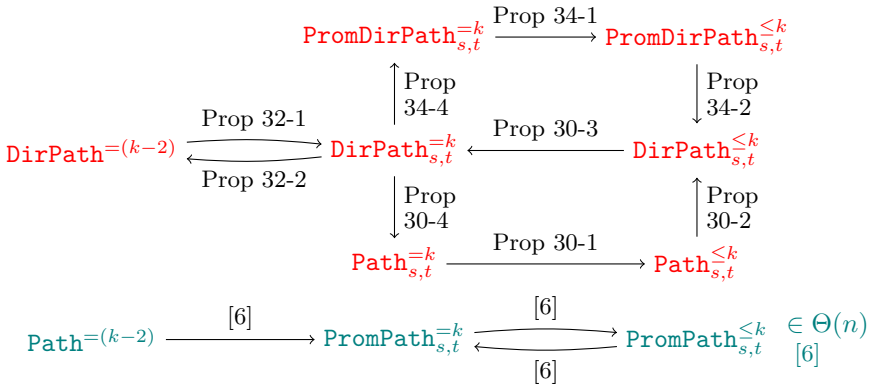

Figure 3 Randomized reductions between path-containment problems. All the green problems can be solved in linear number of queries, and all the red problems are equivalent under randomized reductions and constant multiplicative overhead.

If we set $k = 1$, or $k = 2$ then the problems $(|\mathtt{Dir})\mathtt{Path}_{s,t}^{(=k|\leq k)}$ are instances of the first and second classes derived in Lemma 22, respectively. Thus, whenever we set $k = 1$ or $k = 2$, we already understand the exact query complexity of the problems in Figure 3, and so we assume without loss of generality that $k \geq 3$.

For the $\mathtt{PromPath}_{s,t}^{\leq k}$-problem, Belovs and Reichardt [6] proved that it can be solved using $O(n\sqrt{k})$ queries, which is simply $O(n)$ when k is constant. They also realize that the $\mathtt{PromPath}_{s,t}^{=k}$-problem has a stronger promise, and so there is a generic reduction from this problem to the $\leq k$-version. Moreover, they provide a randomized reduction from the $\mathtt{Path}^{=(k-2)}$-problem to the $\mathtt{PromPath}_{s,t}^{=k}$-problem [6, Page 2]. This means that these three problems have linear query complexity, i.e., their query complexity is $\Theta(n)$ for $k \geq 3$.

We now prove that all the other path-containment problems form an equivalence class, i.e., they have the same query complexity up to a constant. We then prove a new quantum algorithm that solves all the problems from this equivalence class in Section 4.

We begin with showing monotonicity of $\mathsf{Q}(\mathtt{DirPath}_{s,t}^{\leq k})$ in terms of k. From our results later in this section, this monotonicity result also follows for all the problems in the same equivalence class as $\mathtt{DirPath}_{s,t}^{\leq k}$. All proofs are available in the full version of the paper.

▶ **Lemma 29.** *Let* $3 \leq \ell \leq k \in \mathbb{N}$. *Then,* $\mathsf{Q}(\mathtt{DirPath}_{s,t}^{=\ell}) \in O(\mathsf{Q}(\mathtt{DirPath}_{s,t}^{=k}))$.

▶ **Proposition 30.** *Let* $3 \leq k \in \mathbb{N}$. *Then,*
1. $\mathsf{Q}(\mathtt{Path}_{s,t}^{=k}) \in O(\mathsf{Q}(\mathtt{Path}_{s,t}^{\leq k}))$;
2. $\mathsf{Q}(\mathtt{Path}_{s,t}^{\leq k}) \in O(\mathsf{Q}(\mathtt{DirPath}_{s,t}^{\leq k}))$;
3. $\mathsf{Q}(\mathtt{DirPath}_{s,t}^{\leq k})) \in O(\mathsf{Q}(\mathtt{DirPath}_{s,t}^{=k}))$;
4. $\mathsf{Q}(\mathtt{DirPath}_{s,t}^{=k})) \in O(\mathsf{Q}(\mathtt{Path}_{s,t}^{=k}))$.

An immediate corollary of the above theorem is as follows.

▶ **Corollary 31.** *Let $3 \leq k \in \mathbb{N}$. Then, all the problems in $(|\mathtt{Dir})\mathtt{Path}_{s,t}^{(=k|\leq k)}$ have the same, up to constants, quantum query complexity.*

▶ **Proposition 32.** *Let $k \in \mathbb{N}$. Then,*
1. $\mathsf{Q}(\mathtt{DirPath}^{=k}) \in O(\mathsf{Q}(\mathtt{DirPath}_{s,t}^{=k+2}))$;
2. *For $k \geq 3$, $\mathsf{Q}(\mathtt{DirPath}_{s,t}^{=k}) \in O(\mathsf{Q}(\mathtt{DirPath}^{=k-2}))$.*

▶ **Corollary 33.** *Let $3 \leq k \in \mathbb{N}$. Then, the problems in $\mathtt{DirPath}_{s,t}^{=k}$ and $\mathtt{DirPath}^{=k-2}$ have the same, up to constants, quantum query complexity.*

▶ **Proposition 34.** *Let $3 \leq k \in \mathbb{N}$. Then,*
1. $\mathsf{Q}(\mathtt{PromDirPath}_{s,t}^{=k}) \in O(\mathsf{Q}(\mathtt{PromDirPath}_{s,t}^{\leq k}))$;
2. $\mathsf{Q}(\mathtt{PromDirPath}_{s,t}^{\leq k}) \in O(\mathsf{Q}(\mathtt{DirPath}_{s,t}^{\leq k}))$;
3. $\mathsf{Q}(\mathtt{DirPath}_{s,t}^{\leq k})) \in O(\mathsf{Q}(\mathtt{DirPath}_{s,t}^{=k}))$;
4. $\mathsf{Q}(\mathtt{DirPath}_{s,t}^{=k})) \in O(\mathsf{Q}(\mathtt{PromDirPath}_{s,t}^{=k}))$.

An immediate corollary of the above theorem is as follows.

▶ **Corollary 35.** *Let $3 \leq k \in \mathbb{N}$. Then, all the problems in $(|\mathtt{Prom})\mathtt{DirPath}_{s,t}^{(=k|\leq k)}$ have the same, up to constants, quantum query complexity.*

3.2 Cycle-containment reductions

We now introduce cycle-containment problems.

▶ **Definition 36** (Cycle-containment problems)**.** *Let $3 \leq k \in \mathbb{N}$.*
1. *Let C_k be the undirected cycle graph with k edges, and let s be any vertex on the cycle. Then, $\mathtt{Cycle}^{=k} := \mathtt{Subgraph}^{C_k}$ and $\mathtt{Cycle}_s^{=k} := \mathtt{Subgraph}_s^{C_k}$.*
2. *Let C'_k be the directed cycle graph with k arcs all pointing in the same direction, and let s be any vertex on the cycle. Then, $\mathtt{DirCycle}^{=k} := \mathtt{Subgraph}^{C'_k}$ and $\mathtt{DirCycle}_s^{=k} := \mathtt{Subgraph}_s^{C'_k}$.*

We also consider versions of the problem where we are looking for cycles of length at most k, i.e., for all $\mathtt{P} \in (|\mathtt{Dir})\mathtt{Cycle}_{(|s)}$, we write

$$\mathtt{P}^{\leq k} = \bigvee_{\ell=3}^{k} \mathtt{P}^{=k}.$$

Finally, we also consider the finding versions of these problems. That is, for all $\mathtt{P} \in (|\mathtt{Dir})\mathtt{Cycle}_{(|s)}^{(=k|\leq k)}$, we consider $\mathtt{FindP}$ where the task is to output the cycle. For the $(\leq k)$-problem, outputting a cycle of any length $3 \leq \ell \leq k$ suffices.

For simplicity, we only consider cycles of length at least 3. Technically, one can also have a "cycle" of length 2 in the directed setting, if two arcs in opposite directions are present between two vertices, but we will refrain from calling these cycles in this work.

We also consider promise problems of these problems.

▶ **Definition 37** (Promise cycle-containment problems)**.** *Let $3 \leq k \in \mathbb{N}$.*
1. *The $\mathtt{PromCycle}^{(=k|\leq k)}$ problem is the $\mathtt{Cycle}^{(=k|\leq k)}$-problem, restricted to inputs where if there exists any cycle in the graph, there must be at least one cycle of length exactly, or at most, k, respectively.*

2. *The* $\texttt{PromDirCycle}^{(=k|\leq k)}$ *problem is the* $\texttt{DirCycle}^{(=k|\leq k)}$*-problem, restricted to inputs where if there exists any directed cycle in the graph, there must be at least one directed cycle of length exactly, or at most,* k*, respectively.*
3. *The* $\texttt{PromCycle}_s^{(=k|\leq k)}$ *problem is the* $\texttt{Cycle}_s^{(=k|\leq k)}$*-problem, restricted to inputs where if there exists any cycle in the graph that passes through* s*, there must be at least one cycle of length exactly, or at most,* k*, respectively, that passes through* s*.*
4. *The* $\texttt{PromDirCycle}_s^{(=k|\leq k)}$ *problem is the* $\texttt{DirCycle}_s^{(=k|\leq k)}$*-problem, restricted to inputs where if there exists any directed cycle in the graph that passes through* s*, there must be at least one directed cycle of length exactly, or at most,* k*, respectively, that passes through* s*.*

We consider the finding versions of these problems as well, which are defined to be the finding problems under the same restrictions on the input, denoted by $\texttt{PromFind}(|\texttt{Dir})\texttt{Cycle}_{(|s)}^{(=k|\leq k)}$*.*

We note here that the same reductions hold between the promise and non-promise versions of the cycle-containment problems as in the path case.

▶ **Lemma 38.** *Let* $3 \leq k \in \mathbb{N}$*, and* $\texttt{P} \in (|\texttt{Dir})\texttt{Cycle}_{(|s)}^{(=k|\leq k)}$*.*
1. *We have* $\mathsf{Q}(\texttt{PromP}) \in O(\mathsf{Q}(\texttt{P}))$*.*
2. *We have* $\mathsf{Q}(\texttt{FindP}) \in \Theta(\mathsf{Q}(\texttt{PromFindP}))$*.*

Similar to the path-containment setting, the above lemma informs us that we don't need to consider the finding versions of the cycle-containment problems, since they are always equivalent to the non-promise detection versions up to randomized reductions. Thus, for all $\texttt{P} \in (|\texttt{Dir})\texttt{Cycle}_{(|s)}^{(=k|\leq k)}$, we only consider the problems $\texttt{P}$ and $\texttt{PromP}$ in the remainder of this section.

We now prove several randomized reductions between these problems, and we give a concise graphical overview of them in Figure 4.

For the following problems we can show that the quantum query complexity is monotonically increasing in k. The proofs are available in the full version of the paper.

▶ **Lemma 39.** *Let* $3 \leq \ell \leq k \in \mathbb{N}$*. Then,*
1. $\mathsf{Q}(\texttt{DirCycle}^{=\ell}) \in O(\mathsf{Q}(\texttt{DirCycle}^{=k}))$*;*
2. $\mathsf{Q}(\texttt{PromDirCycle}^{=\ell}) \in O(\mathsf{Q}(\texttt{PromDirCycle}^{=k}))$*;*
3. $\mathsf{Q}(\texttt{Cycle}^{\leq(k-1)}) \in O(\mathsf{Q}(\texttt{Cycle}^{\leq k}))$ *whenever* k *is an odd integer.*

The same monotonicity relations hold for $\texttt{P}_s$ *where* $\texttt{P} \in \{\texttt{DirCycle}, \texttt{PromDirCycle}, \texttt{Cycle}\}$*.*

We will now prove a few cycle-containment reductions as illustrated in Figure 4.

▶ **Proposition 40.** *Let* $3 \leq k \in \mathbb{N}$ *be a constant. Then,*
1. $\mathsf{Q}(\texttt{DirCycle}^{=k}) \in \Theta(\mathsf{Q}(\texttt{DirCycle}^{\leq k}))$*;*
2. $\mathsf{Q}(\texttt{PromDirCycle}^{\leq k}) \in \Theta(\mathsf{Q}(\texttt{PromDirCycle}^{=k}))$*;*
3. $\mathsf{Q}(\texttt{Cycle}^{\leq k}) \in O(\mathsf{Q}(\texttt{Cycle}^{=k}))$*;*
4. $\mathsf{Q}(\texttt{PromCycle}^{=k}) \in \Theta(\mathsf{Q}(\texttt{PromCycle}^{\leq k}))$*;*
5. $\mathsf{Q}(\texttt{DirCycle}^{=k}) \in O(\mathsf{Q}(\texttt{Cycle}^{=k}))$ *whenever* k *is an odd integer;*
6. $\mathsf{Q}(\texttt{PromCycle}^{\leq k}) \in O(\mathsf{Q}(\texttt{Cycle}^{\leq k}))$*;*
7. $\mathsf{Q}(\texttt{PromDirCycle}^{\leq k}) \in O(\mathsf{Q}(\texttt{DirCycle}^{\leq k})))$*;*
8. $\mathsf{Q}(\texttt{PromCycle}^{=k}) \in O(\mathsf{Q}(\texttt{PromDirCycle}^{=k}))$*;*
9. $\mathsf{Q}(\texttt{Cycle}^{\leq k}) \in O(\mathsf{Q}(\texttt{DirCycle}^{\leq k}))$*;*
10. $\mathsf{Q}(\texttt{Cycle}^{=k}) \in O(\mathsf{Q}(\texttt{DirCycle}^{=k}))$*.*

▶ **Theorem 41** (Implicit in [6, Theorem 8])**.** *Let* $3 \leq k \in \mathbb{N}$ *be a constant. Then, there exists a* $O(n)$*-query quantum algorithm that, given a simple graph* G *with* n *vertices, accepts if* G *contains a cycle of length* k *and rejects if* G *is a forest, except with error probability at most* $1/3$*.*

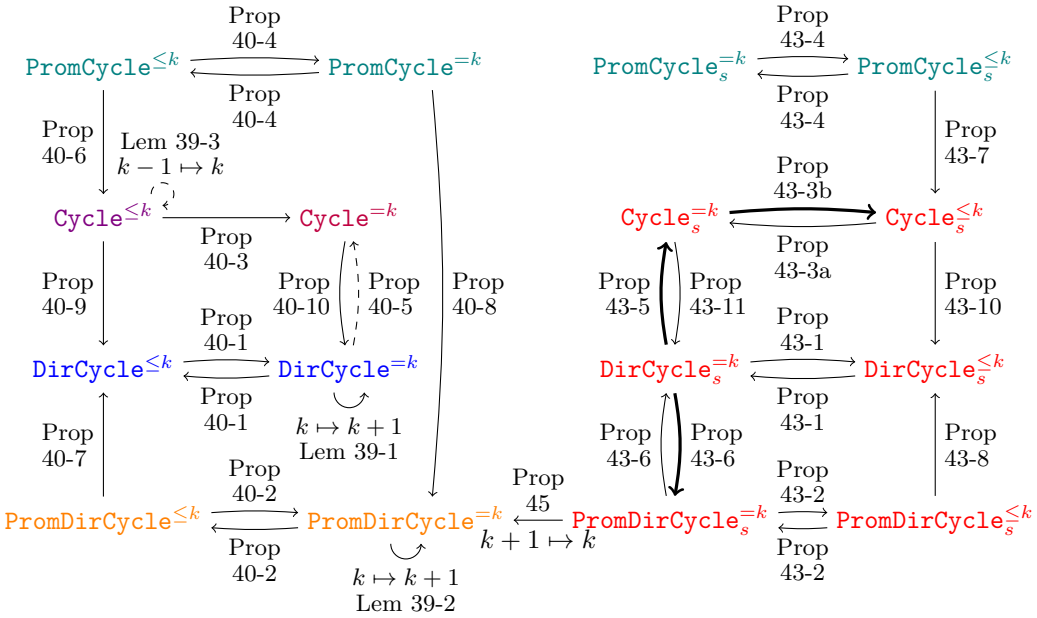

Figure 4 Pictorial representation of the randomized reductions we prove in this section, for $k \geq 3$. The dashed connections only hold for odd values of k. Problems depicted in the same color have the same quantum query complexity up to constants. Note that the connections represented in bold only exist in the restricted cycle-containment version of the problem, i.e., the corresponding result cannot be obtained in the left-hand side of the picture using the same techniques.

Combining Item 4 of Proposition 40 and Theorem 41 we conclude the following.

▶ **Corollary 42.** *Let $3 \leq k \in \mathbb{N}$ be a constant. Then,* $\mathsf{Q}(\texttt{PromCycle}^{=k|\leq k}) \in \Theta(n)$.

We will now present a few other cycle-containment reductions where the cycles are required to pass through a specific vertex, let us denote by s, given as input. For these reductions we will use color-coding and layer insertion techniques as done earlier, but we will use the color-coding version that passes through s. It is interesting to note that for some of these problems we are able to prove stronger relation in contrast to its counterparts that don't have this additional requirement of the subgraph containing s. For example, Items 3b and 5 in Proposition 43 are to name a few. See Figure 4 for an illustrative and comparative summary of the results.

▶ **Proposition 43.** *Let $3 \leq k \in \mathbb{N}$ be a constant. Then,*

1. $\mathsf{Q}(\texttt{DirCycle}_s^{=k}) \in \Theta(\mathsf{Q}(\texttt{DirCycle}_s^{\leq k}))$;
2. $\mathsf{Q}(\texttt{PromDirCycle}_s^{\leq k}) \in \Theta(\mathsf{Q}(\texttt{PromDirCycle}_s^{=k}))$;
3. **a.** $\mathsf{Q}(\texttt{Cycle}_s^{\leq k}) \in O(\mathsf{Q}(\texttt{Cycle}_s^{=k}))$;
   b. $\mathsf{Q}(\texttt{Cycle}_s^{=k}) \in O(\mathsf{Q}(\texttt{Cycle}_s^{\leq k}))$;
4. $\mathsf{Q}(\texttt{PromCycle}_s^{=k}) \in \Theta(\mathsf{Q}(\texttt{PromCycle}_s^{\leq k}))$;
5. $\mathsf{Q}(\texttt{DirCycle}_s^{=k}) \in O(\mathsf{Q}(\texttt{Cycle}_s^{=k}))$;
6. $\mathsf{Q}(\texttt{PromDirCycle}_s^{=k}) \in \Theta(\mathsf{Q}(\texttt{DirCycle}_s^{=k}))$;
7. $\mathsf{Q}(\texttt{PromCycle}_s^{\leq k}) \in O(\mathsf{Q}(\texttt{Cycle}_s^{\leq k}))$;
8. $\mathsf{Q}(\texttt{PromDirCycle}_s^{\leq k}) \in O(\mathsf{Q}(\texttt{DirCycle}_s^{\leq k}))$;
9. $\mathsf{Q}(\texttt{PromCycle}_s^{=k}) \in O(\mathsf{Q}(\texttt{PromDirCycle}_s^{=k}))$;
10. $\mathsf{Q}(\texttt{Cycle}_s^{\leq k}) \in O(\mathsf{Q}(\texttt{DirCycle}_s^{\leq k}))$;
11. $\mathsf{Q}(\texttt{Cycle}_s^{=k}) \in O(\mathsf{Q}(\texttt{DirCycle}_s^{=k}))$.

Consequently, we get the following.

▶ **Corollary 44.** *Let $3 \leq k \in \mathbb{N}$. Then, all the problems in* $(|\texttt{Prom})\texttt{DirCycle}_s^{(=k|\leq k)}$ *have the same, up to constants, quantum query complexity.*

Finally, we prove a connection between the restricted and unrestricted version of the cycle-containment problems.

▶ **Proposition 45.** *Let $3 \leq k \in \mathbb{N}$ be a constant. Then, we have* $\mathsf{Q}(\texttt{PromDirCycle}_s^{=(k+1)}) \in O(\mathsf{Q}(\texttt{PromDirCycle}_s^{=k}))$.

3.3 Path-cycle-containment reductions

In this subsection, we present reductions between path and cycle problems (in both directions) to further refine the classification established in Sections 3.1 and 3.2 for path and cycle problems, respectively. All the proofs are available in the full version of the paper.

▶ **Proposition 46.** *Let $3 \leq k \in \mathbb{N}$ be a constant. Then,* $\mathsf{Q}(\texttt{DirCycle}_s^{=k}) \in O(\mathsf{Q}(\texttt{DirPath}_{s,t}^{=k}))$.

▶ **Proposition 47.** *Let $3 \leq k \in \mathbb{N}$ be a constant. Then, we have* $\mathsf{Q}(\texttt{PromDirPath}_{s,t}^{=k}) \in O(\mathsf{Q}(\texttt{PromDirCycle}_s^{=k}))$.

Using Corollary 35 from Section 3.1, Corollary 44 from Section 3.2 and Propositions 46 and 47 we conclude the following.

▶ **Corollary 48.** *Let $3 \leq k \in \mathbb{N}$ be a constant. Then, the path problems* $(|\texttt{Prom})\texttt{DirPath}_{s,t}^{(=k|\leq k)}$ *and the cycle problems* $(|\texttt{Prom})\texttt{DirCycle}_s^{(=k|\leq k)}$ *have the same, up to constants, quantum query complexity.*

▶ **Proposition 49.** *Let $3 \leq k \in \mathbb{N}$ be constant. Then,* $\mathsf{Q}(\texttt{PromCycle}_s^{=k}) \in O(\mathsf{Q}(\texttt{PromPath}_{s,t}^{=k}))$.

▶ **Proposition 50.** *Let $3 \leq k \in \mathbb{N}$ be constant. Then,* $\mathsf{Q}(\texttt{PromPath}_{s,t}^{=k}) \in O(\mathsf{Q}(\texttt{PromCycle}_s^{=k}))$.

As $\texttt{PromPath}_{s,t}^{=k}$ is known to have quantum query complexity of $\Theta(n)$ (see Figure 3), using Item 4 of Proposition 43 and Propositions 49 and 50 we can conclude the following:

▶ **Corollary 51.** *Let $3 \leq k \in \mathbb{N}$ be a constant. Then,* $\mathsf{Q}(\texttt{PromCycle}_s^{(=k|\leq k)}) \in \Theta(n)$.

4 Length-k directed path-detection algorithm

In this section, we consider the subgraph containment problem $\texttt{DirPath}^{=k}$, and we develop a novel algorithm for this problem. This implies a query upper bound for all of the problems displayed in red in Figure 1.

We start by employing the color-coding technique, introduced by Alon, Yuster and Zwick [1], to partition the graph into $k+1$ subsets. All proofs are available in the full version of the paper.

▶ **Lemma 52.** *Let $k, n \in \mathbb{N}$, and let $G = (V, A)$ be a directed graph with $|V| = n$ and $k \in O(1)$. Let $V_0 \sqcup \cdots \sqcup V_k \subseteq V$ be a random partition of V such that $|V_j| \in \Theta(n/k)$. We define $G' = (V, A')$, where $A' = A_1 \sqcup \cdots \sqcup A_k$, with $A_j = \{(v, w) \in A : v \in V_{j-1}, w \in V_j\}$. Now, if $\texttt{DirPath}^{=k}(G) = 0$, then $\texttt{DirPath}^{=k}(G') = 0$. On the other hand, if $\texttt{DirPath}^{=k}(G) = 1$, then $\mathbb{P}_{G'}[\texttt{DirPath}^{=k}(G') = 1] \in \Omega(1)$, where the probability distribution is over the randomization in the procedure that constructs G'.*

We can combine the previous theorem with Lemma 17, so without loss of generality we can consider the color-coded version of the problem, i.e., where the graph's vertices are already partitioned into $k+1$ disjoint sets and where we're looking for a path that traverses all the way from one end to the other, as displayed in Figure 5. To optimize the parameters in the recursion, we consider a version this problem where the first and last layer have a smaller size than all the intermediate layers, and setting $r \in \Theta(n)$ recovers the problem considered in Lemma 52.

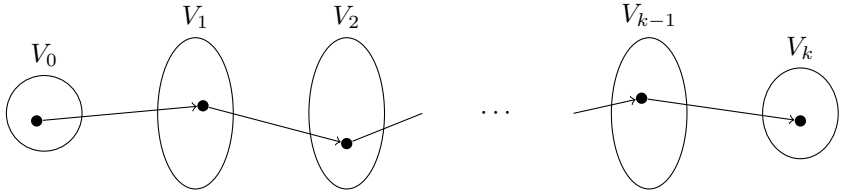

Figure 5 The layered-path problem. Every set V_j for $j \in [k-1]$ represents a set of $\Theta(n)$ vertices, and the first and last layer might have a different size, say $|V_0| = |V_k| = r$. We are looking for a directed path that traverses all the layers from V_0 to V_k.

We now provide a recursive nested walk construction that finds such a layered path, if it exists.

▶ **Lemma 53.** *Let $k, n, r \in \mathbb{N}$, with $3 \leq k \in O(1)$ and $r \leq n$. Let $n/2 \geq s \in \mathbb{N}$, and suppose that we can solve the layered path-finding problem with length $k-2$ and first and last layer size s with $C_{n,s}^{(k-2)}$ queries. Then, we can solve the layered path-finding problem with complexity $C_{n,r}^{(k)}$, satisfying*

$$C_{n,r}^{(k)} \in \widetilde{O}\left(s\sqrt{r} + \left(\frac{n}{s}\right)\left(\sqrt{sr} + C_{n,s}^{(k-2)}\right)\right).$$

Now that we have described the recursive algorithm, we should work out what the resulting number of queries becomes, for a given value of $k \in O(1)$. This is the objective of the following lemma.

▶ **Lemma 54.** *Let $\alpha_r \in [0,1]$. For all $k \in \mathbb{N}$, let $\alpha_{k,r}$ be defined by the recurrence relation*

$$\alpha_{k+2,r} := \min_{\alpha_s \in [0,1]} \max\left\{\alpha_s + \frac{1}{2}\alpha_r, 1 - \frac{1}{2}\alpha_s + \frac{1}{2}\alpha_r, 1 - \alpha_s + \alpha_{k,s}\right\},$$

with $\alpha_{1,r} = \alpha_r$, and $\alpha_{2,r} = \frac{1}{2} + \frac{1}{2}\alpha_r$. Next, let $n \in \mathbb{N}$, and $r \in \Theta(n^{\alpha_r})$. Then, we can solve the layered-path problem with first and last layer size r with a number of queries that satisfies $C_{n,r}^{(k)} \in \widetilde{O}(n^{\alpha_{k,r}})$. Moreover, the solution to the recurrence relation satisfies $\alpha_{k,n} \in 3/2 - \Theta(c^{-k})$ with $c \approx 1.33$.

Putting everything together, we now obtain the following result.

▶ **Corollary 55.** $\mathrm{Q}(\texttt{DirPath}^{=k}) \in \widetilde{O}(n^{\frac{3}{2}-\alpha_k})$, *where $\alpha_k \in \Omega(c^{-k})$ as $k \to \infty$, with $c = \sqrt{3+\sqrt{17}}/2 \approx 1.33$.*

We compute the resulting query complexity for the first few values of k for good measure.

5 Length-$\leq k$ cycle-detection algorithm

In this section, we modify the approach developed in [14], to obtain a novel quantum algorithm for the $\texttt{Cycle}^{\leq k}$-problem, whenever k is odd. The core result that we are using is the following theorem.

Table 1 The query complexity of $\mathsf{Q}(\texttt{DirPath}^{=k})$ for the first few values of k.

k	1	2	3	4	5	6	7
$\mathsf{Q}(\texttt{DirPath}^{=k})$	$\widetilde{O}(n)$	$\widetilde{O}(n)$	$\widetilde{O}(n^{7/6})$	$\widetilde{O}(n^{7/6})$	$\widetilde{O}(n^{23/18})$	$\widetilde{O}(n^{29/22})$	$\widetilde{O}(n^{91/66})$

▶ **Theorem 56** ([14, Theorem 4.7]). *Let $\mathcal{P}$ be the property that an n-vertex graph either has more than $\overline{m}$ edges, where $\overline{m} \in \Omega(n)$, or contains a given subgraph H. Let H' be the graph obtained by deleting all degree-1 vertices of H that are not part of an isolated edge. Then $\mathsf{Q}(\mathcal{P}) \in \widetilde{O}(\sqrt{\overline{m}}n^{1-\frac{1}{vc(H')+1}})$, where $vc(H')$ denotes the vertex cover of H', i.e., the minimum number of vertices in H' required to cover all edges.*

Applying this to k-cycles, we get the following corollary.

▶ **Corollary 57.** *Let $k \geq 3$. Let $\mathcal{P}$ be the property that an n-vertex graph either has more than $\overline{m}$ edges, where $\overline{m} \in \Omega(n)$, or contains a k-cycle. Then, there is a quantum algorithm that computes $\mathcal{P}$ using $\widetilde{O}(\sqrt{\overline{m}}n^{1-\frac{1}{\lceil k/2 \rceil+1}})$ queries.*

We modify the algorithm attaining the result in Theorem 56 (and Corollary 57) to get a slight improvement for the case when k is odd (making a stronger assumption on $\overline{m}$ which will also be satisfied for our applications). The proof is available in the full version of the paper.

▶ **Theorem 58.** *Let $k \geq 3$. Let $\mathcal{P}$ be the property that an n-vertex graph either has more than $\overline{m}$ edges, where $\overline{m} \in \Omega(n^{1+1/(\ell+1)})$ and $\ell = \lfloor k/2 \rfloor$, or contains a k-cycle. Then, there is a quantum algorithm SparseCycle that computes $\mathcal{P}$ using $\widetilde{O}(\sqrt{\overline{m}}n^{1-\frac{1}{\ell+1}})$ queries.*

Now, we can combine this construction with a combinatorial result by Bondy and Simonovits [7], that connects the non-existence of an even-length cycle of a given length to a sparsity condition on the graph.

▶ **Theorem 59** ([7]). *Let G be a graph on n vertices. For any $\ell \geq 2$, if $|E(G)| > 100\ell n^{1+1/\ell}$ then G contains $\mathcal{C}_{2\ell}$ as a subgraph.*

Combining the previous two results now gives us our algorithm that solves the $\texttt{Cycle}^{\leq k}$-problem. The proof is available in the full version of the paper.

▶ **Theorem 60.** *Let $k \geq 4$. Then, $\mathsf{Q}(\texttt{Cycle}^{\leq k}) \in \widetilde{O}(n^{\frac{3}{2}-\gamma(k)})$, where*

$$\gamma(k) = \begin{cases} \frac{k-2}{k(k+2)}, & \text{if } k \text{ is even,} \\ \frac{k-3}{(k-1)(k+1)}, & \text{if } k \text{ is odd.} \end{cases}$$

Finally, we summarize the best-known upper bounds on the query complexities for $\texttt{Cycle}^{=k}$ and $\texttt{Cycle}^{\leq k}$ in Figure 6. We observe that for all k, the $\texttt{Cycle}^{\leq k}$-problem can be solved in $o(n^{3/2})$ queries, whereas for the $\texttt{Cycle}^{=k}$-problem, we can only make that statement for even values of k. It would be a very interesting direction of future research to establish whether the $\texttt{Cycle}^{=k}$-problem for odd values of k can be solved in $\widetilde{O}(n^{3/2})$ queries as well.

We also observe that the expressions we obtain for general values of k do not recover the best-known upper bounds for the cases where $k = 3$ and $k = 4$. This suggests that for higher values of k, the upper bounds we know for these cycle-containment problems are likely not tight. We think it's a very nice future direction of research to improve these algorithms.

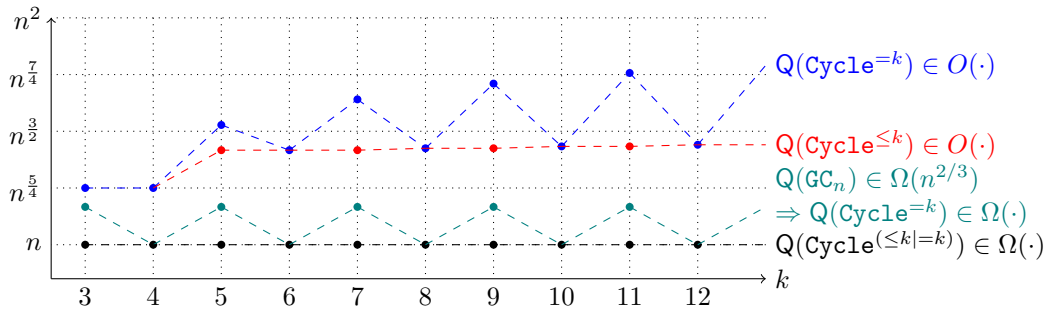

Figure 6 The best-known upper bounds on the query complexity of the $\texttt{Cycle}^{=k}$-problem (shown in blue) and the $\texttt{Cycle}^{\leq k}$-problem (shown in red). The black vertices represent the best-known unconditional lower bounds on both problems, and the green dots represent the best-known conditional lower bounds on the $\texttt{Cycle}^{=k}$-problem, conditional on $\mathsf{Q}(\texttt{GC}_n) \in \Omega(n^{2/3})$.

6 Conditional lower bounds based on graph collision

In this final section, we prove a novel super-linear conditional lower bound on the query complexities of several problems in Figure 1. Our lower bounds will be based on the graph-collision problem, introduced in [24, Section 4.2].

▶ **Definition 61** (Graph collision problem [24, Section 4.2]). *Let $G = (V, E)$ be an undirected graph. We consider the boolean function $\texttt{GC}_G = \texttt{GraphCollision}_G : \{0,1\}^V \to \{0,1\}$, which evaluates to 1 on input $x \in \{0,1\}^V$ if and only if there exists an edge $vw \in E$, such that $x_v = x_w = 1$. This is the graph collision problem on G. For all $n \in \mathbb{N}$,*

$$\mathsf{Q}(\texttt{GC}_n) := \max_{\substack{G=(V,E)\\|V|=n}} \mathsf{Q}(\texttt{GC}_G).$$

Balodis and Iraids [3] showed that the quantum query complexity of triangle finding is related to the graph collision problem, which gives us a conditional lower bound on several of the equivalence classes displayed in Figure 1. We modify Balodis's and Iraids's approach to give the same lower bound to the cycle-finding problem through a vertex s. The proof is available in the full version of the paper.

▶ **Proposition 62.** $\mathsf{Q}(\texttt{Cycle}_s^{=5}) \in \Omega(\sqrt{n} \cdot \mathsf{Q}(\texttt{GC}_n))$.

Abstract

The optimal sample complexity of testing if an n-vertex graph has an independent set of size ρn, or is ε-far from having an independent set of size ρn, was established to be $\widetilde{O}(\rho^3/\varepsilon^2)$, in a notable result by Blais and Seth (SICOMP 2025). In contrast, for q-uniform hypergraphs, there is a significant gap between the best known upper and lower bounds, and there has been no progress on the problem for the last two decades. In this work, we prove a new upper bound of $\widetilde{O}\left(\frac{q\rho^{2q-3}}{\varepsilon^2(q-2)!^2}\right)$ on the sample complexity of testing the ρ-independent set property. The previous best known upper bound was $\widetilde{O}\left(\frac{2^q q!\rho^{2q}}{\varepsilon^3}\right)$, due to Langberg (RANDOM 2004). This establishes the optimal dependence on ε and gives an exponential improvement in the dependence on q. We prove our result via a new application of the hypergraph container method.

1 Introduction

Graph and hypergraph property testing address the question of when one can distinguish between the case that a (hyper)graph has some property and the case that it is *far* from having the property, by inspecting only a small fraction of the input (hyper)graph. In this work we study the classic problem of testing whether a hypergraph has a large independent set in the dense hypergraph model. We say that a q-uniform hypergraph H on n vertices has the ρ-independent set property if H has an independent set I of size ρn, and H is considered to be ε-far from having a ρn independent set if at least εn^q edges must be removed from H to obtain a hypergraph with an independent set of size ρn.

An ε-*tester* for ρ-independence is a bounded error randomized algorithm that takes a random sample $S \subseteq V$ of vertices, inspects $H[S]$, and, if H has a ρn independent set, accepts with probability at least δ, and if H is ε-far from having a ρn independent set, accepts with

probability at most γ, for some positive constants $\delta > \gamma$.[2] The sample size $|S|$ is known as the sample complexity of the tester, and the sample complexity of testing the ρn independent set property is the minimum sample complexity of any such ε-tester for the property.

Independent set testing on graphs (when $q = 2$) is one of the classic graph properties which was studied by Goldreich, Goldwasser and Ron when they introduced the notion of graph property testing [6]. They showed that it is possible to ε-test the ρ-independent set property in graphs with sample complexity $\widetilde{O}(\rho/\varepsilon^4)$. Feige, Langberg and Schechtman later improved the bound to $\widetilde{O}(\rho^4/\varepsilon^3)$ [5]. The problem of finding the optimal sample complexity in graphs remained open for nearly 20 years until a recent work by Blais and Seth improved the bound to $\widetilde{O}(\rho^3/\varepsilon^2)$ by introducing a new connection between property testing and the graph container method [4]. The result by Blais and Seth is optimal up to logarithmic (in $1/\varepsilon$) factors based on a lower bound in [5].

Finding the optimal sample complexity of ρ-independent set testing in q-uniform hypergraphs remains open. Generalizing the results of [5], Langberg showed that there is an ε-tester for ρ-independent set testing in hypergraphs with sample complexity of $\widetilde{O}\left(\frac{2^q q! \rho^{2q}}{\varepsilon^3}\right)$ [8]. Additionally, Langberg gave a lower bound on the sample complexity of $\widetilde{\Omega}\left(\frac{\rho^{2q-1}}{(q!)^2\varepsilon^2}\right)$. This leaves the natural open question: what is the optimal dependence on ε for the sample complexity of testing ρ-independent sets in q-uniform hypergraphs? Further, there is also an exponential gap in the q dependence between the upper and lower bounds. It's worth noting that even though the upper bound has a ρ^{2q} in the numerator and the lower bound has a ρ^{2q-1} in the numerator, the problem is only non-trivial when $\varepsilon < \frac{\rho^q}{q!}$ and so the lower bound is strictly smaller than the upper bound.

1.1 Our Results

We give a new upper bound on the sample complexity of testing the ρ-independent set property in hypergraphs.

▶ **Theorem 1.** *The sample complexity for testing the ρ-independent set property is $\widetilde{O}\left(\frac{q\rho^{2q-3}}{\varepsilon^2(q-2)!^2}\right)$.*

Our analysis achieves the optimal dependence on ε, matching the lower bound of Langberg, while also improving the dependence on q exponentially compared to previous results.

There is a gap between our upper bound and the lower bound of Langberg of roughly $\frac{\rho^2}{q^5}$. We note that the lower bound result of Langberg can be improved slightly to $\frac{\rho^{2q-1}}{((q-1)!)^2\varepsilon^2}$ using the same proof approach (see Appendix A), and so this reduces the gap between upper and lower bounds to roughly $\frac{\rho^2}{q^3}$. Achieving the optimal ρ dependence remains an open problem, however we show in Remark 7 that our analysis cannot be tightened to achieve the optimal ρ-dependence.

We note that, while our bound applies for any q, in the regime that q is non-constant, there is an alternate distance measure. We could instead say a q-uniform hypergraph is γ-far from having a ρn independent set if at least $\gamma\binom{n}{q}$ edges must be modified to make the hypergraph have the property, similar to what was studied by [3] for satisfiability testing. Observe that $\gamma\binom{n}{q} \approx \frac{\gamma}{q!}n^q$, and so if a hypergraph is γ-far from having a ρn independent set

[2] The standard success acceptance probabilities are $\delta = 2/3$ and $\gamma = 1/3$, but so long as $\delta > \gamma$ the probabilities can be boosted to $2/3$ and $1/3$ by standard error reduction techniques. We note that if $\delta = 1$ the tester is called a one-sided error tester, and otherwise it's called a two-sided error tester.

under this alternate distance measure then it is $\varepsilon \approx \frac{\gamma}{q!}$-far in the distance measure we use in this paper. Using Theorem 1 with this change of variable we get an upper bound of roughly $\frac{q^5\rho^{2q-3}}{\gamma^2}$ for testing ρ-independence under this alternate notion of distance.

1.2 Overview of Techniques

To prove Theorem 1 we analyze the natural testing algorithm that takes a random sample $S \subseteq V$ of vertices and accepts if and only if $H[S]$ contains an independent set of size $\rho|S|$. This is a two-sided error tester, which is necessary for any tester for the ρ-independent property, as it is not a semihereditary property [1]. As is common for property testing algorithms, the main challenge is showing that the tester rejects hypergraphs that are ε-far from having a ρn independent set with high probability.

The main tool in our analysis is a new application of the hypergraph container method. Blais and Seth first applied the graph container method to analyze property testers for the ρ-independent set and k-colorability properties on graphs [4]. They further used the hypergraph container method to analyze the sample complexity for the satisfiability problem and hypergraph coloring [3]. We adapt their hypergraph container method algorithm to analyze the sample complexity of ρ-independence testing in hypergraphs. We first briefly describe the container method and the approach used by Blais and Seth for graphs, and then discuss the main challenges with adapting the container method to analyzing testers for the ρ-independent set property on hypergraphs.

1.2.1 The Container Method

The container method is a tool for characterizing independent sets in graphs with specific structure, commonly regular or nearly regular graphs. While in general a graph on n vertices may have up to 2^n independent sets, the container method can be used to show that for a graph G satisfying some specific structure, there is a relatively small collection of containers, where each container is a subset of vertices and each container is relatively small, such that every independent set is a subset of a container.

The natural way to construct the collection of containers is with a container generating algorithm, first used by Kleitman and Winston [7], which works as follows. Given a graph $G = (V, E)$ and an independent set $I \subseteq V$, the goal of the container generating algorithm is to find a small fingerprint $F \subseteq I$ that can be used to construct a small container $C \subseteq V$ such that $I \subseteq C$. In graphs, the natural approach is an iterative greedy approach that first initializes the candidate container to V, and in each step adds a vertex $v \in I$ to the fingerprint which has highest degree in the current container candidate set. Then, all the neighbours of v are removed from the current container because they cannot be in the independent set. Further, any vertex with degree higher than v in the current container can be removed as well because they also cannot be in the independent set (otherwise they would have been selected to the fingerprint). The container generating procedure stops once the container is sufficiently small. This procedure is run on every independent set to construct the collection, however, since each constructed fingerprint corresponds to a unique container, and each fingerprint is relatively small, then there are a small number of containers (corresponding to the total number of possible fingerprints).

1.2.2 Overview of Blais–Seth Approach

Blais and Seth showed that the container method applies very naturally to graphs that are ε-far from having a ρn independent set [4]. They showed that when G is ε-far from having a ρn independent set, there is a collection of containers, where each container is a subset of

vertices, such that every independent set is a subset of a container. They show that each container is small (strictly smaller than ρn) and that there are not too many of them (at most roughly $n^{1/\varepsilon}$).

Blais and Seth then use this collection of containers to analyze the natural testing algorithm that takes a random sample $S \subseteq V$ of vertices and checks if $G[S]$ has an independent set of size $\rho|S|$. In particular, when G is ε-far from having a ρn independent set, they use the collection of containers to upper bound the probability that $G[S]$ has a $\rho|S|$ independent set as follows. By the container statement, since every independent set is a subset of a container, $G[S]$ only has a $\rho|S|$ independent set if at least $\rho|S|$ vertices of S are drawn from a specific container. The probability that $\rho|S|$ vertices are drawn from a specific container can be upper bounded by a Chernoff bound, and then using a union bound they upper bound the probability that $\rho|S|$ vertices are drawn from any container, thereby upper bounding the probability that $G[S]$ has a $\rho|S|$ independent set.

In order to get the optimal bound for ρn independent set testing, Blais and Seth are crucially able to show that there is a trade off in the container and fingerprint size. In particular, they show that large containers have small fingerprints and vice versa. A key step in their proof is an argument that roughly says the following: given a graph $G = (V, E)$ that is ε-far from having an independent set and some independent set I, if the container generating procedure ends up at a very large (and sparse) container $C \subseteq V$, then either $|E(C, V \setminus C)|$ is relatively large, or $G[V \setminus C]$ is very dense. They show that in either case a large number of vertices would be removed from the container in a single step, and, further, this holds at every step of the container procedure. Since many vertices are removed in each step of the procedure then the procedure must terminate in a relatively small number of steps, resulting in a relatively small fingerprint.

1.2.3 First Challenge with Adapting to the Hypergraph Problem

One immediate challenge for hypergraphs is that the container generating procedure is not as simple as in the graph case. In graphs, selecting a fingerprint vertex to be the vertex in I with highest degree in the current container works very well because if $v \in I$ then the neighbours of v must not in the independent set and so can immediately be removed from the current container. However, even for 3-uniform hypergraphs this does not work: if $v \in I$ then vertices that share an edge with v may still be in the independent set.

We address this challenge using a similar approach as used by Blais and Seth in their follow-up work on testing satisfiability [3], and also in hypergraph container method literature (see [2, 10] for example). In particular, in each iteration of our container generating procedure, we have an inner loop which takes q-edges and turns them into $(q-1)$-edges, and repeats on the corresponding $(q-1)$-uniform hypergraph. For example, in the 3-uniform hypergraph case, if $v \in I$ then for any pair $\{u, w\}$ for which $\{v, u, w\}$ is an edge in H, at most one of u or w can be in I. So, after selecting a vertex $v \in I$ to the fingerprint, the container procedure will construct a graph (i.e. a 2-uniform hypergraph) where the edges are all pairs $\{u, w\}$ such that $\{v, u, w\}$ is an edge in H. The procedure then can operate on the graph as before by selecting another vertex in I and removing neighbours (see Section 2 for more details).

1.2.4 Second Challenge with Adapting to the Hypergraph Problem

The second key challenge in adapting the Blais–Seth approach to get nearly tight bounds for hypergraph ρ-independent set testing is that the argument about the trade off between the container and fingerprint size cannot be generalized directly to hypergraphs. As mentioned

above, they show that given a graph G that is ε-far from having an independent set and some independent set I, if the container procedure ends up at a very large (and sparse) container C, then either $E(C, V \setminus C)$ is relatively large, or $G[V \setminus C]$ is very dense. This step of the proof does not generalize naturally to hypergraphs because the edges between C and $V \setminus C$ can now take many forms (i.e. i endpoints in C and $(q-i)$ endpoints in $V \setminus C$ for any $1 \leq i \leq q-1$). In fact, using a standard hypergraph container generating procedure to analyze a tester for ρ-independent set would result in a sample complexity that is larger than our upper bound by at least roughly $1/\rho^q$ (see Remark 8 for an example to demonstrate this).

In order to get our tighter upper bound on the sample complexity we change the hypergraph container procedure following ideas from [3]. Instead of selecting a vertex with highest degree in the hypergraph to the fingerprint, we select a vertex to the fingerprint with highest degree in some specific ρn-subhypergraph. Then the inner loop focuses on this specific ρn-subhypergraph. We note that Blais and Seth [3] use a similar approach in the hypergraph container method by focusing on a smaller n-vertex subhypergraph in a kn-vertex graph for their CSP hypergraph construction.

We note that once we make this change to the container procedure, the proof approach is similar to that used by Blais and Seth to study k-colorability and satisfiability [3]. Roughly speaking the proof goes by contradiction. Given a hypergraph H that is ε-far from having a large independent set, and an independent set I, we assume that for all steps of the procedure the container is larger than desired. We prove a proposition which shows that the max degree in the container decreases in each step, and use this to reconstruct a ρn-subhypergraph that demonstrates that H is not ε-far from having a ρn independent set, a contradiction. Since we reconstruct a subhypergraph of size ρn to prove the contrapositive, we obtain a tighter bound by considering the maximum q-degree of a vertex in any ρn-induced subhypergraph in the container.

2 New Container Lemma

In this section, we prove a new container lemma for hypergraphs, which will be used in Section 3 to prove our upper bound $\widetilde{O}\left(\frac{q\rho^{2q-3}}{\varepsilon^2(q-2)!^2}\right)$ on the sample complexity. We start by describing our hypergraph container procedure and formalizing some basic properties of the fingerprints and the containers which is then used to prove the new container lemma for q-uniform hypergraphs. We note that Blais and Seth [3] use similar ideas to prove their upper bound on the sample complexity of CSP.

We defer the proof for the lower bound $\Omega\left(\frac{\rho^{2q-1}}{\varepsilon^2(q-1)!^2}\right)$ using the construction by Langberg [8] to Appendix A.

2.1 The Container Method

Our hypergraph container algorithm builds on the work of Kleitman and Winston [7] and of Sapozhenko [9]. The key idea behind the container method is to identify a small set of vertices called the *fingerprint* vertices which uniquely identify its *containers* (upto a predefined ordering of vertices) for an input independent set I in a q-uniform hypergraph $H = (V, E)$. We denote the fingerprint and container at t^{th} iteration of the algorithm as $F_t(I)$ and $C_t(F_t(I))$ respectively. We may use the shorthand notation F_t and $C_t(F_t)$ when the underlying independent set is clear from the context.

The algorithm (see Algorithm 1) starts with initializing the entire vertex set as the container C_0 and an empty set of vertices as the fingerprint F_0. We add vertices to the fingerprint and remove vertices from its corresponding container as the algorithm progresses. At t^{th} iteration, the algorithm chooses the vertex v_t from the container C_{t-1} as the vertex in the input independent set $I \subseteq V$ with the maximum q-degree in any ρn-induced subhypergraph of the container C_{t-1} and $\mathcal{D}_{t,q}$ as the corresponding subhypergraph. We break ties by giving higher precedence to lower ranked vertices in the ordering π. We save all the vertices which have higher q-degree than the chosen vertex v_t in any ρn induced subhypergraph induced by vertices in the container C_{t-1} to the set X_q. We then focus on this ρn induced hypergraph to choose the next $(q-1)$ fingerprint vertices. We initialize the fingerprint for the current iteration F^* as F_{t-1} at the start of the inner loop.

For each ℓth (as ℓ goes from $q-1$ to 1) iteration of the inner loop, note that $\mathcal{D}_{t,\ell+1}$ is an $(\ell+1)$-uniform hypergraph with at most $\rho n - (q-(\ell+1))$ vertices. We choose the next fingerprint vertex $v_{t,\ell}$ from $I \setminus F^*$ as the vertex with the maximum $(\ell+1)$-degree in $\mathcal{D}_{t,\ell+1}$ and add it to F^*. Note that we define $\deg_{\mathcal{D}_{t,\ell+1}}(v)$ for a vertex $v \notin \mathcal{D}_{t,\ell+1}$ as zero. We then construct $\mathcal{D}_{t,\ell}$ by removing $v_{t,\ell}$ from the vertex set of $\mathcal{D}_{t,\ell+1}$ and using the edges in $\mathcal{D}_{t,\ell+1}$ incident to $v_{t,\ell}$ minus the vertex $v_{t,\ell}$. We also save the vertices with higher $(\ell+1)$-degree than the current fingerprint vertex $v_{t,\ell}$ in the current hypergraph $\mathcal{D}_{t,\ell+1}$ to the set X_ℓ to be removed later. Note that these vertices cannot be a part of the independent set otherwise they would have been chosen in the fingerprint before the current vertex. We then construct the container set for the next iteration C_t by removing all sets X_ℓ, all vertices with a 1-edge $V[\mathcal{D}_{t,1}]$, and all the new fingerprint vertices $v_{t,\ell}$ from C_{t-1}.

By construction of the algorithm, the fingerprints and containers satisfy

$$F_0 \subseteq F_1 \subseteq F_2 \cdots \subseteq F_{|I|/(q-1)} \subseteq I,$$
$$I \subseteq C_t(F_t) \cup F_t \text{ and } C_{|I|/(q-1)} \subseteq C_{|I|/(q-1)-1} \cdots \subseteq C_0 = V$$

We now prove some important properties of the containers that we use later in our proof to compute an upper bound on the sample complexity of ρ-independent set testing.

▶ **Proposition 2** (Uniqueness of Containers). *For any hypergraph $H = (V, E)$ with a predefined ordering of vertices π, any independent set I in H, and any t, the fingerprint $F_t(I)$ and container $C_t(I)$ of I satisfy*

$$C_t\big(F_t(I)\big) = C_t(I).$$

Proof. For $t \leq \frac{|I|}{q-1}$, the algorithm chooses the same fingerprint vertices in the same order for $F_t(I)$ and I in the first $t-1$ rounds of the algorithm, breaking ties based on the given ordering of vertices π, hence the vertices removed from the container are also identical, i.e., $C_t\big(F_t(I)\big) = C_t(I)$. For $t > \frac{|I|}{q-1}$, $F_t(I) = I$, hence the inequality is satisfied. ◀

We prove another important property of any ℓ-uniform hypergraph which we refer as the standard averaging bound [3].

▶ **Proposition 3** (Standard Averaging Bound). *Let $H = (V, E)$ be an ℓ-uniform hypergraph with $\ell \geq 2$. Then there are at least $\frac{\ell|E|-d|V|}{\binom{|V|-1}{\ell-1}-d} > \frac{\ell|E|-d|V|}{\binom{|V|-1}{\ell-1}}$ vertices in H whose degree is larger than d.*

Algorithm 1 Fingerprint & Container Generator.

Input: A q-uniform hypergraph $H = (V, E)$, a parameter $\rho < 1$, an ordering of vertices π, and an independent set $I \subseteq V$

Initialize $F_0 \leftarrow \emptyset$ and $C_0 \leftarrow V(H)$;

for $t = 1, 2, \ldots, |I|/(q-1)$ **do**

`// Choose` v_t `as the vertex with maximum` q`-degree in any` ρn `induced subhypergraph of` C_{t-1} `and` $\mathcal{D}_{t,q}$ `as the corresponding` ρn `induced subhypergraph. We break ties by giving higher precedence to lower ranked vertices in the ordering` π`.`

$$(v_t, \mathcal{D}_{t,q}) = \underset{v \in I \cap C_{t-1}, D \subseteq C_{t-1}, |D| \leq \rho n}{\arg\max} \deg_D(v) \ ;$$

`// Keep track of all vertices with higher` q`-degree than` v_t `in any` ρn `induced subhypergraph of` C_{t-1} `to remove later`

$X_q \leftarrow \{w \in V[C_t] : \deg^{\leq \rho n}_{C_{t-1}}(w) > \deg^{\leq \rho n}_{C_{t-1}}(v_t)\}$;

`// Initialize the fingerprint for the current iteration`

$F^* \leftarrow F_{t-1}$

for $\ell = q-1, \ldots, 1$ **do**

$v_{t,\ell} \leftarrow$ the vertex in $I \setminus F^*$ with largest $(\ell+1)$ degree in $\mathcal{D}_{t,\ell+1}$;

$F^* \leftarrow F^* \cup v_{t,\ell}$

`// Keep track of all vertices with higher` $(\ell+1)$`-degree than` $v_{t,\ell}$ `in` $\mathcal{D}_{t,\ell+1}$ `to remove later`

$X_\ell \leftarrow \{w \in V[\mathcal{D}_{t,\ell+1}] : \deg_{\mathcal{D}_{t,\ell+1}}(w) > \deg_{\mathcal{D}_{t,\ell+1}}(v_{t,\ell})\}$;

`// Construct` $D_{t,\ell}$ `using vertices of` $D_{t,\ell+1}$ `minus` $v_{t,\ell}$ `and edges incident on` $v_{t,\ell}$

$V[\mathcal{D}_{t,\ell}] \leftarrow V[\mathcal{D}_{t,\ell+1}] \setminus \{v_{t,\ell}\}$;

$E[\mathcal{D}_{t,\ell}] \leftarrow \{e \setminus \{v_{t,\ell}\} : e \in E[\mathcal{D}_{t,\ell+1}] \text{ and } v_{t,\ell} \in e\}$;

end

`// Add` $v_{t,q-1}, \ldots, v_{t,1}$ `to the fingerprint`

$F_t \leftarrow F^*$;

`// Update container set by removing all sets` X_ℓ`, all vertices with a 1-edge, and the new fingerprint vertices`

$C_t \leftarrow C_{t-1} \setminus (\bigcup_{\ell=1}^{q} X_\ell \cup \{v \in C_{t-1} : \{v\} \in E[\mathcal{D}_{t,1}]\} \cup \{v_{t,1}, \ldots, v_{t,q-1}\})$;

end

return $F_1, \ldots, F_{|I|/(q-1)}$ *and* $C_1, \ldots, C_{|I|/(q-1)}$

Proof. Let S be the set of vertices with degree larger than d.

The vertices in S have degree at most $\binom{|V|-1}{\ell-1}$. The remaining $|V| - |S|$ vertices have degree at most d. Since the total number of edges is $1/\ell$ times the sum of degrees, the total number of edges $|E|$ is less than or equal to

$$\frac{1}{\ell}\left(|S|\binom{|V|-1}{\ell-1} + (|V| - |S|)d\right).$$

Rearranging the terms we see that

$$\left(|S|\left[\binom{|V|-1}{\ell-1} - d\right]\right) \geq \ell|E| - d|V|$$

which gives us the desired inequality. ◀

We can now find an upper bound on the maximum q-degree in any ρn-induced subhypergraph of $H[C_t]$.

▶ **Proposition 4** (Maximum Degree Bound). *Let $H = (V, E)$ be a q-uniform hypergraph with $|V| = n$, let I be an independent set in H, and let $t \leq \frac{|I|}{q-1}$. Then the maximum q-degree of every $(\leq \rho n)$-subhypergraph of $H[C_t]$ is at most*

$$\frac{2(q-1)}{\rho t}\binom{\rho n - 1}{q-1}.$$

Proof. Fix any $t \leq \frac{|I|}{q-1}$. Since the containers satisfy $V = C_0 \supseteq C_1 \supseteq \cdots \supseteq C_t$, we have

$$n \geq |C_0| - |C_t| = \sum_{i=1}^{t}\big(|C_{i-1}| - |C_i|\big) = \sum_{i=1}^{t}|C_{i-1} \setminus C_i|.$$

Hence, there exists an index $j \in [t]$ such that $|C_{j-1} \setminus C_j| \leq \frac{n}{t}$.

▷ Claim 5. For each step of the inner loop, $1 \leq \ell \leq q-1$ in the jth iteration, the number of ℓ-edges in $\mathcal{D}_{j,\ell}$ is at most

$$\frac{2\ell}{\rho t}\binom{\rho n - (q-\ell)}{\ell} \tag{1}$$

Proof. We argue by induction on ℓ.

Base case: (ℓ_0 = smallest value of ℓ such that $E[\mathcal{D}_{j,\ell+1}] > 0$)
We observe that $\ell_0 = 1$ or $E[\mathcal{D}_{j,\ell_0}] = 0$ in this case.[3]

(i) $\ell_0 = 1$*:* The vertices corresponding to 1-edges in $\mathcal{D}_{j,1}$ are removed when forming C_j, so their number is at most $|C_{j-1} \setminus C_j| \leq \frac{n}{t}$. Since $q = o(\rho n)$ [4], we have

$$\frac{n}{t} \leq \frac{2}{\rho t}(\rho n - q + 1),$$

so the claim holds for $\ell_0 = 1$.

(ii) $E[\mathcal{D}_{j,\ell_0}] = 0$*:* The claim trivially holds since $E[\mathcal{D}_{j,\ell_0}] = 0 < \frac{2\ell}{\rho t}\binom{\rho n-(q-\ell)}{\ell}$ for any value of ℓ.

Inductive step: Assume Equation (1) holds for $\ell - 1$ where $1 \leq \ell \leq q-2$. Suppose, for contradiction,

$$|E[\mathcal{D}_{j,\ell}]| > \frac{2\ell}{\rho t}\binom{\rho n - (q-\ell)}{\ell}$$

By induction, we have $|E[\mathcal{D}_{j,\ell-1}]| \leq \frac{2(\ell-1)}{\rho t}\binom{\rho n-(q-(\ell-1))}{\ell-1}$, hence $\deg_{\mathcal{D}_{j,\ell-1}}(v_{j,\ell-1}) \leq \frac{2(\ell-1)}{\rho t}\binom{\rho n-(q-\ell)-1}{\ell-1}$.

---

[3] We require $E[\mathcal{D}_{j,\ell_0}] = 0$ as a base case to handle the case that a vertex outside of $\mathcal{D}_{j,\ell+1}$ is added to the fingerprint, because when that happens $|V[\mathcal{D}_{j,\ell}]|$ does not shrink by one, and so the proof in the inductive step does apply as is. As such a vertex is selected then $E[\mathcal{D}_{j,\ell-1}]$ becomes 0.

[4] We observe that the sample complexity bound of Theorem 1 holds trivially when $q = \Omega(\rho n)$. Notice that the number of vertices is $O\left(\frac{q}{\rho}\right)$ in this case so the sample complexity is $O\left(\frac{q}{\rho}\right) < O\left(\frac{1}{\varepsilon}\right)$. We remind the reader that the problem is non-trivial only when $\varepsilon < \frac{\rho^q}{q!}$. We can therefore assume $q = o(\rho n)$ for the remainder of this paper.

Therefore, by the standard averaging bound (Proposition 3) with $d = (\ell-1)\frac{|E|}{|V|}$,

$$\frac{|E[\mathcal{D}_{j,\ell}]|}{\binom{|V[\mathcal{D}_{j,\ell}]|-1}{\ell-1}} > \frac{\frac{2\ell}{\rho t}\binom{\rho n-(q-\ell)}{\ell}}{\binom{\rho n-(q-\ell)-1}{\ell-1}} = \frac{2}{\rho t}\big(\rho n-(q-\ell)\big) > \frac{n}{t}$$

where we have used the fact that $|V[\mathcal{D}_{j,\ell}]| \le \rho n-(q-\ell)$.

Hence there are more than n/t vertices in some ρn-induced subhypergraph of $\mathcal{D}_{j,\ell}$ with degree exceeding

$$(\ell-1)\,\frac{|E[\mathcal{D}_{j,\ell}]|}{|V[\mathcal{D}_{j,\ell}]|} > (\ell-1)\cdot\frac{\frac{2\ell}{\rho t}\binom{\rho n-(q-\ell)}{\ell}}{\rho n-(q-\ell)} = \frac{2(\ell-1)}{\rho t}\binom{\rho n-(q-\ell)-1}{\ell-1}$$

All such vertices are removed from C_j (since they have higher degree than $v_{j,\ell}$), implying $|C_{j-1}\setminus C_j| > n/t$, a contradiction. This completes the induction and the proof of the claim. ◁

Why the claim implies the proposition: We consider the jth iteration of the algorithm. Taking $\ell = q-1$, the number of $(q-1)$-edges in $\mathcal{D}_{j,q-1}$ is at most $\frac{2(q-1)}{\rho t}\binom{\rho n-1}{q-1}$. Therefore, the fingerprint vertex $v_{j,q-1}$ or v_j has q-degree at most $\frac{2(q-1)}{\rho t}\binom{\rho n-1}{q-1}$ in any $(\le \rho n)$-induced subgraph of $H[C_{j-1}]$. All vertices exceeding this degree in some $(\le \rho n)$-subgraph of $H[C_{j-1}]$ are excluded from C_j, so the maximum q-degree in any $(\le \rho n)$-subgraph of $H[C_j]$ is at most $\frac{2(q-1)}{\rho t}\binom{\rho n-1}{q-1}$. Since $C_t \subseteq C_j$, the same bound holds for every $(\le \rho n)$-subgraph of $H[C_t]$. ◀

2.2 Proof of the New Container Lemma

We can now prove the new container lemma which essentially states that the container size is "small" (as defined in the lemma) for some small value of t independent of the hypergraph size n when the input hypergraph is ε-far from ρn independent set. We prove the contrapositive, i.e., we construct a ρn-induced subhypergraph which is not ε-far from ρ-independent set property if the container size is "large" for all values of t.

▶ **Lemma 6** (New Container Lemma). *Let $H=(V,E)$ be a q-uniform hypergraph on n vertices that is ε-far from ρ-independent set property. Then, for any independent set I in H, there exists an index $t \le \frac{8\rho^{q-1}}{\varepsilon(q-1)!}$ such that the size of the tth container of I satisfies*

$$|C_t| \le \left(\rho - t\cdot\frac{\varepsilon(q-2)!}{4\rho^{q-2}\ln(\rho^{q-1}/\left(\varepsilon(q-1)!\right))}\right)n$$

Proof. We prove the contrapositive. Let $t_1 = \frac{8\rho^{q-1}}{\varepsilon(q-1)!}$. Suppose that for all $t \le t_1$, the size of the tth container $C_t(I)$ satisfies

$$|C_t(I)| > \left(\rho - t\cdot\frac{\varepsilon(q-2)!}{4\rho^{q-2}\ln(\rho^{q-1}/(\varepsilon(q-1)!))}\right)n \tag{2}$$

We will show that there is some ρn induced subhypergraph with $< \varepsilon n^q$ edges showing that H is not ε-far from ρ-independent set property.

We start with the container $C_{t_1}(I)$ to construct the set of vertices S and the corresponding induced subhypergraph $H[S]$. Add vertices one at a time from the previous containers $C_t(I)$ (in decreasing order of t) until the size of the set reaches ρn. Note that we can choose

any set of ρn vertices from $C_{t_1}(I)$ if the size of the container is greater than ρn. Let V_t denote the set of vertices in container $(t-1)$ but not in container t in this set S, i.e., $V_t = \{v : v \in S \text{ and } v \in C_{t-1} \backslash C_t\}$ and let t_0 be the smallest value of t for which $|V_t| > 0$.

We now prove the claim. Since $|S| \leq \rho n$, Proposition 4 implies that the maximum q-degree in any ρn induced subhypergraph of $H[C_{t_1}(I)]$ is at most

$$\frac{\frac{2(q-1)}{\rho}\binom{\rho n-1}{q-1}}{\frac{8\rho^{q-1}}{\varepsilon(q-1)!}} \leq \frac{\varepsilon q!}{4\rho^q}\binom{\rho n-1}{q-1}$$

Hence, any $(\leq \rho n)$-induced subhypergraph of $H[C_{t_1}(I)]$ has at most $\frac{\varepsilon q!}{4\rho^q}\binom{\rho n}{q}$ q-edges.

When $|C_{t_1}| \geq \rho n$, then the total number of edges is at most

$$\frac{\varepsilon q!}{4\rho^q}\binom{\rho n}{q} < \frac{\varepsilon q!}{\rho^q}\frac{(\rho n)^q}{q!} < \varepsilon n^q,$$

therefore $H[S]$ is not ε-far from ρn independent set.

Now we consider the case when $|C_{t_1}| < \rho n$. By Proposition 4, each $v \in V_t$ contributes at most

$$\frac{2(q-1)}{\rho(t-1)}\binom{\rho n-1}{q-1}$$

additional edges (or $\binom{\rho n-1}{q-1}$ if $t=1$), since v lies in $C_{t-1}(I)$.

Therefore, the total number of edges is at most

$$\frac{\varepsilon q!}{4\rho^q}\binom{\rho n}{q} + |V_1| \cdot \binom{\rho n-1}{q-1} + \sum_{t=2}^{t_1} |V_t| \cdot \frac{2(q-1)}{\rho(t-1)}\binom{\rho n-1}{q-1} \tag{3}$$

For any $t_0 \leq t \leq t_1$, the set $\bigcup_{j=1}^{t} V_j$ corresponds to the vertices not appearing in $C_t(I)$, and so Equation (2) implies

$$\sum_{j=1}^{t} |V_j| \leq \rho n - |C_t| < \frac{t\varepsilon n(q-2)!}{4\rho^{q-2}\ln(\rho^{q-1}/(\varepsilon(q-1)!))}$$

In the sum (3), the contribution from $|V_t|$ decreases as t increases, so the sum is maximized when all $|V_t| = \frac{\varepsilon n(q-2)!}{4\rho^{q-2}\ln(\rho^{q-1}/\varepsilon(q-1)!)}$. Substituting into (3), we obtain

$$\begin{aligned}
&\frac{\varepsilon q!}{4\rho^q}\binom{\rho n}{q} + \frac{\varepsilon n(q-2)!}{4\rho^{q-2}\ln(\rho^{q-1}/(\varepsilon(q-1)!))}\binom{\rho n-1}{q-1} \\
&\qquad + \frac{\varepsilon n(q-2)!}{4\rho^{q-2}\ln(\rho^{q-1}/(\varepsilon(q-1)!))} \sum_{t=2}^{\frac{8\rho^{q-1}}{\varepsilon(q-1)!}} \frac{2(q-1)}{\rho(t-1)}\binom{\rho n-1}{q-1} \\
&< \frac{\varepsilon q!}{4\rho^q}\binom{\rho n}{q} + \frac{\varepsilon q!}{4(q-1)\rho^{q-1}\ln(\rho^{q-1}/(\varepsilon(q-1)!))}\binom{\rho n}{q} \\
&\qquad + \frac{2\varepsilon q!}{4\rho^q\ln(\rho^{q-1}/(\varepsilon(q-1)!))} \sum_{t=2}^{\frac{8\rho^{q-1}}{\varepsilon(q-1)!}} \frac{1}{(t-1)}\binom{\rho n}{q} \\
&< \frac{\varepsilon q!}{\rho^q}\binom{\rho n}{q}\left(\frac{1}{4} + \frac{\rho}{4(q-1)\ln(\rho^{q-1}/(\varepsilon(q-1)!))} + \frac{1}{2\ln(\rho^{q-1}/(\varepsilon(q-1)!))} \sum_{t=2}^{\frac{8\rho^{q-1}}{\varepsilon(q-1)!}} \frac{1}{t-1}\right) \\
&< \frac{\varepsilon q!}{\rho^q}\binom{\rho n}{q} < \frac{\varepsilon}{\rho^q}(\rho n)^q < \varepsilon n^q,
\end{aligned}$$

where the final inequality uses the upper bound $H(m) \leq \ln(m) + 1$ on the harmonic series and the assumption that ε is less than a sufficiently large constant, i.e., $\varepsilon < e^{-8}\frac{\rho^{q-1}}{(q-1)!}$ (which can be made without loss of generality as we can always choose a smaller value of ε' for the tester such that $e^{-8}\varepsilon < \varepsilon' < \varepsilon$ which gives us the same sample complexity). Note that $\varepsilon < \frac{\rho^q}{q!} < \frac{\rho^{q-1}}{(q-1)!}$ since the graph is ε-far from ρ-independent set property.

This completes the proof. ◀

▶ Remark 7. There exists a q-uniform hypergraph H that is ε-far from having a ρn independent set and an independent set I for which Lemma 6 is nearly tight in the ρ-dependence. Consider the same example from the lower bound of Langberg [8], and re-analyzed in Appendix A, which is a hypergraph H formed by planting an independent set I of size $\left(\rho - \frac{4(q-1)!\varepsilon}{\rho^{q-1}}\right)n$ in a complete q-uniform hypergraph. See Appendix A for a justification that this hypergraph is ε-far from having a ρn independent set.

We claim that for all t we have that $|C_t(I)| \geq \left(\rho - \frac{16(q-1)!\varepsilon t}{\rho^{q-2}}\right)n$, which demonstrates that Lemma 6 is roughly tight in the ρ dependence. To show this, first consider the case that $t \leq \frac{1}{2\rho}$. Observe that for the first $\frac{1}{2\rho}$ iterations of the outer loop of the container procedure, exactly ρn vertices are removed from the container in each iteration. This is because no vertices will be removed due to having larger degree in a ρn subhypergraph (every vertex has full degree in some ρn subhypergraph). Hence, $|C_t(I)| \geq \rho n$ for all $t \leq \frac{1}{2\rho}$.

Next consider the case that $t > \frac{1}{2\rho}$. Recall that at every step t of the container procedure we have that $I \subseteq C_t(I) \cup F_t(I)$, and so $|C_t(I)| \geq |I \setminus F_t(I)| \geq \left(\rho - \frac{8(q-1)!\varepsilon}{\rho^{q-1}}\right)n$, where we are assuming that $|F_t(I)|$ is sufficiently small. Hence, for $t > \frac{1}{2\rho}$, we find that $|C_t(I)| \geq \left(\rho - \frac{16(q-1)!\varepsilon t}{\rho^{q-2}}\right)n$, completing the proof of the claim.

▶ Remark 8. It is not possible to achieve our bound in Lemma 6 and Theorem 1 using a standard hypergraph container procedure. In particular, a standard hypergraph container procedure run on a q-uniform hypergraph $H = (V, E)$ and independent set I would initialize a container to V and run in iterations. In each iteration it would run an inner loop that selects a vertex v in the independent set with highest degree in the hypergraph on the current container, then look at the $(q-1)$-uniform hypergraph formed by all edges incident to v, and so on until reaching the 1-uniform hypergraph. This is in stark contrast to the algorithm described in Section 2.1 that selects vertices with highest degree in some ρn subhypergraph. We argue that this natural hypergraph procedure is not useful for proving our bounds via an example described below.

Similar to the the lower bound of Langberg [8] and re-analyzed in Appendix A, start by planting a large independent set I of size $\left(\rho - \frac{8(q-1)!\varepsilon}{\rho^{q-1}}\right)n$ in an n-vertex hypergraph. Between I and $V \setminus I$ add all possible edges with $q-1$ endpoints in I and 1 endpoint in $V \setminus I$. The hypergraph $H[V \setminus I]$ is going to be a random hypergraph with edge density $\rho^{q-2} \cdot (q-1)$ so that the vertices in $V \setminus I$ have degree less than roughly $\rho^{q-2}(q-1) \cdot \binom{n}{q} \cdot \frac{q}{n} \leq \frac{\rho^{q-2}n^{q-1}}{(q-2)!}$, which is roughly the degree of vertices in I. Finally, select a small subset $I' \subset I$ of size roughly q/ρ^{q-2} and remove all edges in the hypergraph with at least one endpoint in I'. Instead, for each $v \in I'$ select $2\frac{\rho^{q-2}}{(q-2)!}n^{q-1}$ random $(q-1)$ tuples from $V \setminus v$ and add an edge containing v and those $q-1$ vertices. Crucially we want the vertices in I' to have highest degree in the hypergraph, but whose degree is similar to the vertices in I.

It is not hard to show that H is ε-far from having a ρn independent set with high probability (over the randomness of the edges added in the hypergraph), assuming that ε is sufficiently small compared to ρ. Further, we claim that running the standard hypergraph

container procedure above would take at least roughly $\frac{1}{\rho^{q-2}}$ steps to get a desirable container. This is because the vertices in I' have highest degree and so they are selected in each step of the procedure until they have all been selected. Since the edges of vertices in I' are randomly placed throughout the hypergraph with density roughly $2(q-1)\rho^{q-2}$, the standard hypergraph container procedure removes roughly $2(q-1)\rho^{q-2}n$ vertices in each step of the outer loop. Hence it will take at least roughly $1/\rho^{q-2}$ steps until $|C_t(I)| < \rho n$.

Comparing with our hypergraph procedure given in Section 2.1 on this hypergraph construction, since at every step t of the container procedure we have that $I \subseteq C_t(I) \cup F_t(I)$, then $|C_t(I)| \gtrsim \left(\rho - \frac{8(q-1)!\varepsilon}{\rho^{q-1}}\right) n$. Hence, the t given in Lemma 6 is at most $\frac{32(q-1)\ln(1/\varepsilon)}{\rho}$, and so the number of steps required by a standard hypergraph is larger than the number of steps given in Lemma 6 by a factor of at least $1/\rho^{\Theta(q)}$.

3 Upper Bound on Sample Complexity

The proof of the theorem uses the following form of Chernoff's bound for hypergeometric distributions [4].

▶ **Lemma 9** (Chernoff's bound). *Let X be drawn from the hypergeometric distribution $H(N, K, m)$, where m elements are drawn without replacement from a population of N elements, K of which are marked. Let X denote the number of marked elements drawn. Then for any $\vartheta \geq \mathbb{E}[X]$,*

$$\Pr\left[X \geq \vartheta\right] \leq \exp\left(-\frac{(\vartheta - \mathbb{E}[X])^2}{\vartheta + \mathbb{E}[X]}\right).$$

▶ **Theorem 1.** *The sample complexity for testing the ρ-independent set property is $\widetilde{O}\left(\frac{q\rho^{2q-3}}{\varepsilon^2(q-2)!^2}\right)$.*

Proof. Let S be a random set of $s = c \cdot \frac{q\rho^{2q-3}}{\varepsilon^2(q-2)!^2} \ln^3\left(\frac{\rho^{q-1}}{\varepsilon(q-1)!}\right)$ vertices drawn uniformly at random from V without replacement, where c is a large enough constant. We ignore the integer rounding issues in the rest of the proof as they do not affect the asymptotics of the final result. The ε-tester checks if the induced subhypergraph $H[S]$ contains an independent size of ρs, if yes, the tester accepts and rejects otherwise.

If G contains a ρn independent set, then S contains at least ρs vertices from this independent set with probability at least $1/2$, since the number of such vertices follows a hypergeometric distribution, and the median of this distribution is at least ρs.

In the remainder of the proof we upper bound the probability that S contains a ρs-independent set when G is ε-far from containing a ρn-independent set. For the rest of the argument, let us call a container C_t small when its cardinality is bounded by $|C_t| \leq \left(\rho - t \cdot \frac{\varepsilon(q-2)!}{4\rho^{q-2}\ln(\rho^{q-1}/(\varepsilon(q-1)!))}\right) n$, the expression in the lemma above.

Let us denote the vertices of the sampled set S as $u_1, u_2, \ldots, u_s$. First observe that, by Lemma 6, for every independent set I of size ρs in S, there is a $t \leq \frac{8\rho^{q-1}}{\varepsilon(q-1)!}$ and a fingerprint $F_t \subseteq I$ of size $(q-1)t$ that defines a small container $C_t(F_t)$ such that $I \subseteq C_t(F_t) \cup F_t$. Hence, the probability that S contains an independent set of size at least ρs is at most the probability that there exists some $t \leq \frac{8\rho^{q-1}}{\varepsilon(q-1)!}$ such that S contains a set of $t' = (q-1)t$ vertices that form the fingerprint F_t of a small container C_t, and S contains at least $\rho s - t'$ other vertices from C_t. We now upper bound this probability.

For any t' distinct indices $i_1, i_2, \ldots, i_{t'} \in [s]$, consider the event where the vertices $u_{i_1}, \ldots, u_{i_{t'}}$ form the fingerprint F_t of a small container C_t. Let X denote the number of vertices among the other $s - t'$ sampled vertices that belong to C_t. By the bound on the size of small containers, the expected value of X is

$$\begin{aligned} E[X] &\leq \left(\rho - t \cdot \frac{\varepsilon(q-2)!}{4\rho^{q-2}\ln(\rho^{q-1}/(\varepsilon(q-1)!))}\right)(s-t') \\ &< \rho s - \frac{t\varepsilon s(q-2)!}{4\rho^{q-2}\ln(\rho^{q-1}/(\varepsilon(q-1)!))} \\ &\leq \rho s - t' - \frac{t\varepsilon s(q-2)!}{8\rho^{q-2}\ln(\rho^{q-1}/(\varepsilon(q-1)!))}, \end{aligned}$$

where the last inequality uses the fact that $s = c \cdot \frac{q\rho^{2q-3}}{\varepsilon^2(q-2)!^2}\ln^3\left(\frac{\rho^{q-1}}{\varepsilon(q-1)!}\right)$ for a large enough constant c and that the problem is non-trivial only when $\varepsilon < \frac{\rho^q}{q!}$.

By the Chernoff bound (Lemma 9), the probability that we draw at least $\rho s - t'$ vertices from C_t in the final $s - t'$ vertices drawn to form S is

$$\begin{aligned} \Pr[X \geq \rho s - t'] &\leq \exp\left(-\frac{(\rho s - t' - E[X])^2}{\rho s - t' + E[X]}\right) \\ &\leq \exp\left(-\frac{1}{2\rho s}\frac{t^2\varepsilon^2 s^2(q-2)!^2}{64\rho^{2q-4}\ln^2(\rho^{q-1}/(\varepsilon(q-1)!))}\right) \\ &\leq \exp\left(-\frac{t^2\varepsilon^2(q-2)!^2 s}{128\rho^{2q-3}\ln^2(\rho^{q-1}/(\varepsilon(q-1)!))}\right). \end{aligned}$$

Therefore, by applying a union bound over all possible choices of t' indices from $[s]$, the probability that any set of at most $\frac{8\rho^{q-1}}{\varepsilon(q-2)!}$ vertices in S form the fingerprint of a small container from which we sample at least $\rho s - t'$ vertices in S is at most

$$\begin{aligned} &\sum_{t'}\binom{s}{t'}\exp\left(-\frac{t'^2\varepsilon^2 s}{128(q-1)^2\rho^{2q-3}\ln^2(\rho^{q-1}/(\varepsilon(q-1)!))}\right) \\ &\leq \sum_{t}\exp\left((q-1)t\ln s - \frac{t^2\varepsilon^2(q-2)!^2 s}{128\rho^{2q-3}\ln^2(\rho^{q-1}/(\varepsilon(q-1)!))}\right) \\ &< \frac{1}{3} \end{aligned}$$

where the first inequality uses the upper bound $\binom{s}{t'} \leq s^{t'}$, and the last inequality again uses the fact that $s = c \cdot \frac{q\rho^{2q-3}}{\varepsilon^2(q-2)!^2}\ln^3\left(\frac{\rho^{q-1}}{\varepsilon(q-1)!}\right)$ for a large enough constant c. Hence, the probability that S contains an independent set of size at least ρs is less than $1/3$. ◀

A Lower Bound on Sample Complexity

We prove a lower bound for the sample complexity of ρ-independent set testing using the construction by Langberg [8].

▶ **Proposition 10.** *Let n be a sufficiently large constant. Let $\rho > 0$ and $\varepsilon > 0$ satisfy the following conditions:*

- $\varepsilon \ll \dfrac{\rho^q}{2q!}$,
- $\dfrac{\rho^{2q-1}}{\varepsilon^2} \ll n$,
- $q^2 \ll \rho n$,

Then there exists a hypergraph H on n vertices such that H is ε-far from ρ-independent set property, and with probability at least $e^{-1/2}$, a random subhypergraph H of size

$$s = \frac{\rho^{2q-1}}{8\left((q-1)!\right)^2 \varepsilon^2}$$

contains an independent set of size ρs.

Proof. Consider the q-uniform hypergraph $H = (V, E)$ defined as follows:

i) $|V| = n$,

ii) V is partitioned into two disjoint sets A and $V \setminus A$, where

$$|A| = \left(1 - \frac{4(q-1)!\varepsilon}{\rho^q}\right)\rho n,$$

iii) the edge set E consists of all q-subsets of V except those fully contained in A (i.e., A is an independent set).

We first show that H is ε-far from ρ-independent set property, i.e., every subset of vertices of size ρn induces a subhypergraph with at least εn^q edges.

Consider any subset $S \subseteq V$ of size ρn. We define $\delta := \frac{4(q-1)!\varepsilon}{\rho^q}$ so $|A| = (1-\delta)\rho n$.

Thus,

$$\begin{aligned}
|E(S)| &\geq \binom{\rho n}{q} - \binom{(1-\delta)\,\rho n}{q} \\
&\geq \frac{(\rho n - q)^q}{q!} - \frac{((1-\delta)\rho n)^q}{q!} \\
&\geq \frac{(\rho n)^q}{q!}\left[\left(1 - \frac{q}{\rho n}\right)^q - (1-\delta)^q\right] \\
&\geq \frac{(\rho n)^q}{q!}\left[\left(1 - \frac{q^2}{\rho n}\right) - \left(1 - \frac{\delta q}{2}\right)\right] \qquad (*) \\
&\geq \frac{(\rho n)^q}{q!}\left[\left(\frac{\delta q}{2} - \frac{q^2}{\rho n}\right)\right] \\
&\geq \frac{(\rho n)^q}{q!}\frac{\delta q}{4}
\end{aligned}$$

where (*) follows from $(1-a)^x \geq 1 - ax$ and $(1-a)^x \leq e^{-ax} \leq (1 - \frac{ax}{2})$ when $ax < 1$ using Taylor's expansions and the last inequality follows when $q < \frac{\delta \rho n}{4}$.

Substituting $\delta = \frac{4(q-1)!\varepsilon}{\rho^q}$ gives $|E(S)| \geq \varepsilon n^q$.

Now we consider a sample of $s = \frac{\rho^{2q-1}}{8((q-1)!)^2\varepsilon^2}$ vertices chosen randomly from the hypergraph H. We define $X := |S \cap A| = \sum_{v \in A} \mathbf{1}_{\{v \in S\}}$. Then X follows a hypergeometric distribution with parameters $(n, |A|, s)$, and mean $\mu = \frac{|A|}{n} \cdot s = \left(1 - \frac{4(q-1)!\varepsilon}{\rho^q}\right)\rho s$.

Thus, using the Central Limit Theorem, we obtain that for sufficiently large n,

$$\Pr\left[|S \cap A| > \left(1 - \frac{4(q-1)!\varepsilon}{\rho^q}\right)\rho s + \sqrt{\rho s} = \rho s\right] \geq \Pr[N(0,1) > 3/2] \geq \frac{1}{20}$$

Therefore, the chosen sample has an independent set of size ρs with some constant positive probability and the sample size $s = \frac{\rho^{2q-1}}{8((q-1)!)^2\varepsilon^2}$ gives a lower bound for testing ρn independent set. ◀

Toward a KKL Theorem for Any HDX

Max Hopkins
Institute for Advanced Study, Princeton, NJ, USA

Abstract

The KKL Theorem, a seminal result in boolean function analysis, characterizes the structure of low-influence (non-expanding) functions on the hypercube. While recent years have seen breakthrough results across a variety of areas relying on analogs of the KKL Theorem *beyond the cube* (e.g. on product spaces, Grassmann graphs), further progress has been inhibited by our poor understanding of the phenomenon across more general domains. Motivated in this context, Bafna, Hopkins, Kaufman, and Lovett (STOC 2022) and Gur, Lifshitz, and Liu (STOC 2022) proved a generalized KKL-type Theorem for spectral high dimensional expanders (HDX). Their results, however, remain highly restricted due to strong quantitative expansion requirements on the underlying complex.

In this work, we introduce a simple local-to-global method for analyzing low influence functions on simplicial complexes. Using this method we prove a local-to-global KKL-type Theorem: any simplicial complex whose links satisfy a KKL-Theorem also satisfies such a result globally. Building on Gotlib and Kaufman (RANDOM 2023), we also prove a weaker dimension-dependent KKL-type Theorem for simplicial complexes with *any non-trivial (two-sided) expansion*. As concrete applications of our framework, we give the first characterization of non-expanding functions on "combinatorial" HDX such as dense clique complexes and a corresponding Kruskal-Katona Theorem, as well as a small-set expansion theorem for the Ramanujan Complexes of Lubotzky, Samuels, and Vishne (EJC '05).

1 Introduction

In 1988, Kahn, Kalai, and Linial [51] proved the KKL Theorem: a characterization of low influence (non-expanding) functions[1] on the hypercube that revolutionized the field of boolean function analysis. In recent years, variants of the KKL Theorem *beyond the cube*, including on products [13, 70, 38, 36, 46, 56, 63], Lie groups [30], and the Grassmann [62, 29] have become a powerful tool across a surprisingly broad array of areas, leading, e.g., to the theory of sharp thresholds [37], multiple breakthroughs in PCP theory [62, 61, 27, 26, 10, 60, 66], new streaming lower bounds [32], and to progress on longstanding problems in group theory and combinatorics [30, 58, 57, 59, 43]. Despite its broad importance our understanding of KKL-type theorems on general spaces remains poor, standing as a barrier to further progress on key problems such as the unique games conjecture [10].

Toward this end, a series of works over the past several years [55, 19, 6, 7, 44, 39, 47] developed a new framework for unifying our understanding of Fourier analysis and KKL-type Theorems beyond the cube: *spectral high dimensional expanders* (HDX). HDX are

[1] Informally, a low-influence function on the hypercube is one which has low expected probability of changing value under a random coordinate flip.

a generalization of expanders to hypergraphs and ranked posets that have seen a recent explosion of application within theoretical computer science [55, 19, 6, 7, 44, 39, 25, 18, 53, 2, 24, 48, 11, 5, 3, 4, 16, 15, 14, 33, 50, 64, 12, 23, 68, 28, 21, 20, 8, 9, 49, 45, 22]. In particular, Bafna, Hopkins, Kaufman, and Lovett [6, 7], Gur, Lifshitz, and Liu [44], and Hopkins [47] proved a KKL-Type Theorem for certain spectral high dimensional expanders stating that any low influence function must be *local*, highly concentrated in some restriction of the hypergraph. Unfortunately, these results only hold for the regime of *near-perfect* expansion, a strong requirement satisfied only by a few families of sparse hypergraphs [65, 54, 17].

In this work, we develop simple local-to-global machinery for analyzing low influence functions on hypergraphs allowing us to remove these requirements in certain well-studied settings. We prove two main results: a KKL-Type Theorem for simplicial complexes whose links (local restrictions) themselves satisfy such a bound such as quotients of the affine building [65] (the so-called Ramanujan complexes), and a weaker (dimension-dependent) KKL-type Theorem for simplicial complexes with *any* non-trivial (two-sided) spectral high dimensional expansion allowing us to give the first non-trivial characterization of low influence functions on product-based HDX [40] and dense clique complexes. We also derive Kruskal-Katona theorems for these objects, a broadly used set of results in extremal combinatorics bounding the lower shadow of a set system.

Our work builds on a growing body of Fourier analytic tools for high dimensional expanders [55, 19, 6, 7, 44, 39, 18, 2, 42] and relies in particular on a decomposition theorem of Gotlib and Kaufman (GK) [42]. We make two main technical contributions in this line. First, we show for any hypergraph X whose *negative* local spectra is bounded away from -1, "global" functions on X (i.e. functions not concentrated in any local component) have bounded projection onto low levels of the GK-decomposition. Second, we consider an *inductive* approach for bounding expansion through a new "function-dependent" variant of Garland's Lemma, a way to write the expansion of f as an expectation across local parts of the complex where, unlike prior such methods, the underlying distribution may depend on the function f in question. In a similar vein, our local-to-global theorem for (global) small-set expansion combines this latter Garland method with Fourier analytic properties of a localized noise operator to derive global expansion bounds.

2 Background

2.1 High Dimensional Expanders

We focus on weighted *pure simplicial complexes* (X, Π) where

$$X = X(0) \cup \ldots \cup X(d)$$

for $X(d) \subset \binom{n}{d}$ an arbitrary d-uniform hypergraph and $X(i) \subset \binom{n}{i}$ given by downward closure, and

$$\Pi = (\pi_0, \ldots, \pi_d)$$

for π_d an arbitrary distribution over $X(d)$ and π_i given by selecting a uniformly random i-set from $\tau \sim \pi_d$.

Our bounds will depend on the now standard notion of high dimensional expansion which bounds the behavior of local neighborhoods of X called *links*. For every face $\tau \in X(i)$, the link of τ is given by:

$$X_\tau \coloneqq \{\sigma \setminus \tau \in X : \tau \subseteq \sigma \in X\}$$

Given a function $f : X(k) \to \mathbb{R}$, its localization $f|_\tau : X_\tau(k - |\tau|) \to \mathbb{R}$ is $f_\tau(\sigma) = f(\tau \cup \sigma)$.

Denote the normalized adjacency matrix of the graph underlying X_τ by A_τ, and for $0 \le j \le d-2$ denote the worst-case spectral parameters of j-links by

$$\gamma_j \coloneqq \max_{\tau \in X(j)} \{\lambda_2(A_\tau)\}, \qquad \gamma_j^{(-)} \coloneqq \min_{\tau \in X(j)} \{\lambda_{\min}(A_\tau)\}.$$

A complex is called *strongly connected* if every $\gamma_j < 1$, a (one-sided) *local-spectral expander* if every γ_j is bounded away from 1 [52, 67, 25], and a (two-sided) local-spectral expander if every $\gamma_j^{(-)}$ is additionally bounded away from -1.

2.2 Influence and the Down-Up Walk

As in the seminal work of KKL, we are interested in characterizing the structure of boolean functions $C_k(X, \mathbb{F}_2) \coloneqq \{f : X(k) \to \{0,1\}\}$ with low total influence. In our setting it will be convenient to use an equivalent definition (up to normalization) concerning the expansion of a celebrated random walk on complexes called the *lower* or *down-up* walk. The lower walk at level k, denoted N_k^1, moves between k-faces of the complex via a shared $(k-1)$-face, removing a vertex uniformly at random and re-sampling from the appropriate conditional distribution on the remaining $(k-1)$-face. The *edge expansion* of a set $S \subset X(k)$ with respect to the lower walk is the expected probability of leaving S in a single step, or equivalently:

$$\Phi(S) = 1 - \frac{\langle N_k^1 1_S, 1_S \rangle}{\langle 1_S, 1_S \rangle}.$$

It is not hard to see that expansion, which can also be written as $\frac{\langle 1_S, L 1_S \rangle}{\langle 1_S, 1_S \rangle}$ for the "Laplacian Operator" L, is equivalent to standard notions of influence up to normalization (see full version for details), so we will focus on this notion throughout instead.

2.3 Small-Set Expansion and the Noise Operator

The small-set expansion theorem is a classical and closely related result to the KKL theorem [1, 51]. In its standard form, it states that small sets on the noisy cube expand near perfectly. To prove an analog result beyond the cube, we need to define a corresponding notion of the noise operator T_ρ on simplicial complexes. A natural generalization is to consider the walk on k-faces of X which fixes each vertex with probability ρ, and re-samples the remaining vertices. Formally, we may express this operator as a convex combination of "longer" down-up walks

$$T_\rho \coloneqq \sum_{i=0}^{k} \binom{k}{i} (1-\rho)^{k-i} \rho^i N_k^{k-i},$$

where N_k^j moves between k-faces via a shared $(k-j)$-face. Note this recovers the standard operator when X is a product space (see [7]). We will always write expansion with respect to the noise operator at Φ_{T_ρ}, and write just Φ for the down-up walk. Finally, it will sometimes be useful to reference the opposite variant of the lower walks, the "upper" walks $\widehat{N}_k^i$, which moves between k-faces via a shared $(k+i)$-face.

3 Results

We are now ready to more formally cover our results. We split the subsection into two parts: structure theorems for low-influence functions on arbitrary HDX, and a local-to-global small-set expansion theorem.

3.1 A Structure Theorem for Low Influence Functions

The canonical examples of low influence (non-expanding) sets on simplicial complexes are *links*.[2] Our goal is to show these are the *only* such examples. To this end, we call a function f (ε, i)-global if it is uncorrelated with i-links:

$$\forall \tau \in X(i) : \mathop{\mathbb{E}}_{X_\tau}[f_\tau] \leq \mathbb{E}[f] + \varepsilon.$$

We prove that global functions indeed expand, where the quantitative parameters depend on the underlying local-spectral expansion of the complex.

▶ **Theorem 1** (Expansion of Global Functions). *Let (X, Π) be a k-dimensional simplicial complex and $f : X(k) \to \mathbb{R}$ any (ε, i)-global boolean function. Then*

$$\Phi(f) \geq \frac{1 - \mathbb{E}[f]}{k - i} \prod_{j=i}^{k-2} (1 - \gamma_j) - c_{k,i,\gamma}\varepsilon.$$

where $c_{k,i,\gamma} \leq (k - i + 1)\left(\frac{1}{k-i}\prod_{j=i}^{k-2}(1-\gamma_j) - \frac{1}{k-i+1}\prod_{j=i-1}^{k-2}(1-\gamma_j)\right)\left(1 + (k-i)\gamma_{i-1}^{(-)}\right)^{-1}$

For many regimes of interest, e.g. when either γ_{k-2} or $|\gamma_{k-2}^{(-)}|$ is less than roughly $\frac{1}{k}$, $c_{\gamma,k,i} \leq O(1)$ is an *absolute constant*, with no dependence on dimension. In such cases the contrapositive of Theorem 1 states *any non-expanding function has constant density in some link*. We discuss the relation of this bound to prior literature further in Section 5. It remains an interesting open problem whether the expression is tight, or could be improved to match the expansion profile known under stronger expansion guarantees.

As applications of Theorem 1, we give the first structure theorems for simpler combinatorial constructions of high dimensional expanders. We'll start by looking at one of the most classical constructions of simplicial complexes: *clique-complexes*. Given a graph $G = (V, E)$, the k-dimensional clique-complex $K_{G,k}$ is the complex induced by taking the uniform distribution over k-cliques of G. Using Theorem 1, we give the first non-trivial characterization of non-expanding sets on (dense) clique-complexes.

▶ **Corollary 2** (Expansion in Clique-Complexes). *Fix $k \in \mathbb{N}$ and let $G = (V, E)$ be any graph with minimum degree at least $\Delta_{min} \geq \frac{2k-2}{2k-1}|V|$. Then the expansion of any (ε, i)-global boolean function f on the k-dimensional clique-complex $K_{G,k}$ is at least:*

$$\Phi(f) \geq (1 - \mathbb{E}[f])\frac{(i+1)}{k(k-i)} - O(\varepsilon)$$

While Corollary 2 is non-trivial in any dimension, it is strongest in low dimensions. For instance, an interesting implication for 3-clique (triangle) complexes is that any function of triangles with expansion worse than $1/3$ must have a dense vertex.

▶ **Corollary 3** (Low Influence Functions on Triangle Complexes). *Let $G = (V, E)$ be any graph of minimum degree at least $\Delta_{min} \geq \frac{5}{6}|V|$ and $S \subset K_{G,3}(3)$ any set with expansion*

$$\Phi(S) \leq \frac{1}{3} - \delta.$$

Then there exists a vertex $v \in G$ such that S contains at least a $\frac{\delta}{2}$-fraction of the triangles touching v.

[2] Note here we really mean the set of k-faces including some fixed i-face, sometimes called a star (rather than removing the common face as in the formal definition of a link).

Of course, clique-complexes arising from dense graphs are themselves dense objects. A major selling points of prior work was the ability to characterize low-influence functions on several families of *sparse* complexes. While our work cannot match the quantitative strength of these results, it does lead to new insight on the structure of functions on simpler constructions of bounded-degree HDX with quantitatively weaker parameters. In particular, we consider (cutoffs of) the elementary combinatorial HDX of Golowich [40], which tensors a bounded-degree expander G with the complete complex to give a weak bounded-degree two-sided HDX.

▶ **Corollary 4** (Expansion in Combinatorial HDX). *Let X be a $2k$-dimensional "product-HDX" of any graph G and $\Delta_{4k}(2k)$, and $f \in C_k$ any (ε, i)-global boolean function. Then*

$$\Phi(f) \geq \frac{(1-\mathbb{E}[f])i}{(k-1)(k-i)} - O(\varepsilon)$$

As for the case of clique-complexes, this is especially powerful in low dimensions. For concreteness, we again look at the first non-trivial setting of $k = 3$.

▶ **Corollary 5** (Low Influence Functions on Combinatorial HDX). *Let X be a 3-dimensional "product-HDX" of any graph G and $\Delta_n(6)$, and $S \subset X(3)$ be any subset of triangles with expansion at most*

$$\Phi(S) \leq \frac{1}{4} - \delta.$$

Then there exists a vertex $v \in X(1)$ such that S contains a $\Omega(\delta)$ fraction of triangles including the vertex v.

Finally, we note that as an immediate corollary of Theorem 1 we also get a "Kruskal-Katona" type theorem in all the above settings. Kruskal-Katona is a seminal and broadly used result in extremal combinatorics which given a set $S \subset X(k)$, lower bounds the number of $(k-1)$-faces that sit inside S, called its "lower shadow" and denoted ∂S.

▶ **Corollary 6** (Kruskal-Katona for Weak HDX). *Let (X, Π) be a k-dimensional simplicial complex and $S \subset X(k)$ any (ε, i)-global set. Then*

$$\mathbb{E}[\partial S] \geq \mathbb{E}[S]\left(1 + \frac{1-\mathbb{E}[S]}{k-i}\prod_{j=i}^{k-2}(1-\gamma_j) - c_{k,i,\gamma}\varepsilon.\right)$$

where $c_{k,i,\gamma} \leq (k-i+1)\left(\frac{1}{k-i}\prod_{j=i}^{k-2}(1-\gamma_j) - \frac{1}{k-i+1}\prod_{j=i-1}^{k-2}(1-\gamma_j)\right)\left(1+(k-i)\gamma_{i-1}^{(-)}\right)^{-1}$

3.2 Small-Set Expansion

Similar to the setting of the lower walk, links also provide a canonical family of non-expanding sets for the noise operator on simplicial complexes. In this setting, it is typical [56, 44, 7] to use a slightly stronger notion of global functions we'll call "(ε, i)-strongly global", which simply assumes f is sparse on every link:

$$\forall \tau \in X(i) : \mathop{\mathbb{E}}_{X_\tau}[f_\tau] \leq \varepsilon.$$

BHKL [7], GLL [44], and Hopkins [47] prove small-set expansion for strongly global functions on two-sided and one-sided partite HDX with very strong quantitative expansion.[3] While these properties are satisfied by some constructions (e.g. [55]), some variants of the seminal *Ramanujan complexes* (quotients of the affine building) of Lubotzky, Samuels, and Vishne [65] actually fail these conditions.

On the other hand, these complexes exhibit nice *local* structure. In particular, for large enough fields, their links are quantitatively strong partite HDX, and therefore satisfy a small-set expansion theorem. This raises a natural question: is any complex X whose links satisfy global small-set expansion itself a global small-set expander? We answer this question in the affirmative.

▶ **Theorem 7** (Local-to-Global SSE). *Let X be a complex such that $\forall v \in X(1)$:*

1. *Any $(\varepsilon, i-1)$-strongly global function f on X_v has expansion*

$$\Phi_{T_\rho}(f) \geq \phi(\varepsilon, k, i)$$

2. *X_v is a γ-two-sided or γ-one-sided partite HDX*

Then any (ε, i)-global boolean function f has expansion at least

$$\Phi_{T_\rho}(f) \geq \phi(\varepsilon, k, i) - 2^{O(k)}\gamma - 2^{-\Omega(k)}.$$

We note the requirement that links of X are HDX can be removed up to worsened dependence in the dimensional error term (see the full version). The inverse exponential error above is essentially negligible, since any function with respect to the noise operator has non-expansion at least inverse exponential in k.

As an immediate corollary, we prove the Ramanujan complexes are global small-set expanders.

▶ **Corollary 8** (Ramanujan Complexes are Global SSEs). *Let $f \in C_k$ be an (ε, i)-strongly global boolean function on a Ramanujan complex of [65] with $2^{-\Omega(k)}$ one-sided local-spectral expansion. The expansion of f is at least*

$$\Phi_{T_\rho}(f) \geq 1 - \rho^i - O_i(\varepsilon) - 2^{-\Omega(k)}.$$

4 Techniques

We sketch the proofs of Theorem 1 and Theorem 7, starting with the former. The formal versions and proofs of all results are deferred to the full version of the paper.

4.1 Proof Overview of Theorem 1

Our general approach to prove global sets expand is broken into three core components. The first is a new function-dependent variant of "Garland's Lemma", a classical method of breaking global functions into local components over the complex. In particular, we show the expansion of a function f with respect to the lower walks can be written as an expectation of its expansion over links of X.

[3] In particular, they require local-spectral expansion to be inverse exponential in the dimension.

▶ **Lemma 9** (Garland's Lemma for Expansion). *Let (X, Π) be a weighted, pure simplicial complex and $f \in C_k$ any function on k-faces. Then for all $i \leq k$ and $j \leq k - i$:*

$$\Phi(f) = \mathop{\mathbb{E}}_{\tau \sim \pi_j^f}[\Phi_{X_\tau}(f|_\tau)], \tag{1}$$

where $f|_\tau(\sigma) = f(\tau \cup \sigma)$ is the localization of f to the link of τ, and π_j^f is some f-dependent distribution over j-faces of X.

We remark that to the authors' knowledge, this is the first variant of Garland's lemma where the expectation is over a *function-dependent* distribution, rather than simply over the complex distribution π_j, which is necessary for our setting.

The second core component is a variant of the GK's decomposition theorem [42] for the lower walk.

▶ **Theorem 10** (GK-Decomposition). *Let (X, Π) be a k-dimensional simplicial complex. Then for any $f \in C_k$ there is an orthogonal decomposition $f = \sum_{i=0}^{k} f_i$ such that:*

$$\langle N_1^k f, f\rangle \leq \mathbb{E}[f]^2 + \sum_{i=1}^{k-1}\left(1 - \frac{1}{k-i+1}\prod_{j=i-1}^{k-2}(1-\gamma_j)\right)\langle f, f_i\rangle.$$

Finally, the third main component is a "level-1 inequality" showing any $(\varepsilon, 1)$-global function has low projection onto the first level of the GK-decomposition.

▶ **Proposition 11** (Level-1 Inequality). *Let (X, Π) be a k-dimensional complex and f any $(\varepsilon, 1)$-global boolean function $f \in C_k$. Then*

$$\langle f, f_1\rangle \leq \frac{k}{1 + \gamma_0^{(-)}(k-1)}\varepsilon.$$

We remark that this is a corollary of a more general level i inequality that scales with the minimum non-zero eigenvalue of the upper walks (see full version). One could instead apply this directly with the GK decomposition, but the resulting dependence on ε is worse than can be achieved by combining these with Garland's method.

Given these three components, Theorem 1 follows from a careful induction. We first prove the statement directly for $(\varepsilon, 1)$-global functions using the GK-Decomposition and Level-1 inequality. For general i, we use Garland's lemma to reduce to $i = 1$ inside links of X, writing the expansion as $\Phi(f) = \mathbb{E}_{\tau \sim \pi_{i-1}^f}[\Phi_\tau(f|_\tau)]$, and observe that the localization $f|_\tau$ of a (ε, i) global function is itself $(\varepsilon - \delta_\tau, 1)$ global for some $|\delta_\tau| \leq \varepsilon$. Applying the statement for 1-global functions inside the expectation (carefully handling dependence on $\mathbb{E}_{\tau \sim \pi_{i-1}^f}[\delta_\tau]$) then gives the claimed bound.

4.2 Proof Overview of Theorem 7

The first main component of our low influence characterization, Lemma 9, already shows that expansion of the lower walk exhibits local-to-global behavior. The proof of Theorem 7 would follow immediately if the same form of localization were to hold for the noise operator. Unfortunately, while the lemma may be extended to lower walks of arbitrary length, such a statement does not hold directly for the noise operator.

To see why, recall the noise operator is a convex combination of lower walks $T_\rho = \sum_{i=0}^{k} B_k^\rho(i) N_k^{k-i}$ where $B_k^\rho(i) = \binom{k}{i}(1-\rho)^{k-i}\rho^i$. Since expansion is linear, for any function f we can write

$$\Phi_{T_\rho}(f) = \sum_{i=0}^{k} B_k^\rho(i) \Phi_{N_k^{k-i}}(f).$$

Localizing T_ρ naively hits two main issues. First, a walk N_k^i can only be appropriately localized to j-links when $j \le k-i$ (otherwise the walk goes below the level of the link, and cannot be captured at this level of locality). Second, the *coefficients* of T_ρ, which are binomially distributed, depend on dimension and therefore do not localize correctly. In particular, after localizing "permissible" lower walks in the sum, we'd get:

$$\Phi_{T_\rho}(f) = \sum_{i=0}^{j-1} B_k^\rho(i) \Phi_{N_k^i}(f) + \mathbb{E}_{\tau \sim \pi_j^f}\left[\sum_{i=j}^{k} B_k^\rho(i) \Phi_{N_{k-j}^{k-i}}(f|_\tau).\right]$$

To correspond to the local noise operator on the right-hand side, we'd instead need the corresponding coefficients to be $B_{k-j}^\rho(i)$, the binomial distribution on $k-j$ trials, not k trials as in the original instance. A first approach to solving these issues is to define a "shifted" noise operator over the original space that simply throws out the lefthand sum, which is negligible, and replaces the remaining coefficients with $B_{k-j}^\rho(i)$ over the original space. One can then argue that the expansion with respect to the shifted operator "localizes correctly" (allowing us to apply local SSE), and is moreover close to the expansion of the original noise operator. Unfortunately, this procedure results in error scaling with the TV-distance between Binomial distributions on k and $k-j$ trials. This costs $\mathrm{poly}(k^{-1})$ additive error, and therefore does not give the desired global SSE theorem.

To fix this issue, we instead make the stronger assumption that links of X are good two-sided or partite one-sided high dimensional expanders, a property satisfied by our main motivating example (the Ramanujan complexes). This allows us to appeal to the theory of Fourier analysis developed in [19, 6, 7, 44], which shows one may decompose expansion with respect to the lower walks as

$$\Phi_{N_k^i}(f) \approx \frac{1}{\langle f, f\rangle} \sum_{\ell=0}^{k} \lambda(N_k^i)\langle f_\ell, f_\ell\rangle$$

for some decomposition $f = \sum_{i=0}^{k} f_i$ and approximate eigenvalues $\lambda(N_k^i)$. With this in mind, instead of shifting the noise operator, we can decompose the localized expansion in the Fourier basis as

$$\Phi_{T_\rho}(f) \lesssim \sum_{i=0}^{j-1} B_k^\rho(i) + \mathop{\mathbb{E}}_{\tau \sim \pi_j^f}\left[\frac{1}{\langle f|_\tau, f|_\tau\rangle} \sum_{i=j}^{k} B_k^\rho(i) \sum_{\ell=0}^{k-j} \lambda_\ell(N_{k-j}^{k-i}|_\tau)\langle (f|_\tau)_\ell, (f|_\tau)_\ell\rangle\right]$$

Finally for each fixed ℓ, we show its corresponding coefficient in the above sum is at most ρ^ℓ, the (approximate) eigenvalue of the local noise operator itself [7, 44]. This allows us to write the desired localized inequality

$$\Phi_{T_\rho}(f) \lesssim \sum_{i=0}^{j-1} B_k^\rho(i) + \mathop{\mathbb{E}}_{\tau \sim \pi_j^f}\left[\Phi_{T_\rho}(f|_\tau)\right]$$

which may finally be bounded by the local SSE theorem using the fact that any j-restriction $f|_\tau$ of an (ε, i)-strongly global function is $(2\varepsilon, i-j)$-strongly global. The error in this analysis scales only with the cost of cutting off small i (the first term) and the approximation error of the Fourier decomposition. For constant j, the former is at most $\exp(-k)$, while the latter is $2^{O(k)}\gamma$ when j-links are γ-HDX. Thus for complexes with sufficiently expanding links, we get an SSE theorem with negligible additive error as desired.

5 Discussion and Related Work

We close the extended abstract with a more in-depth comparison with prior work and a natural open problem such comparisons raise. At a high level, our work fits into a long line of research examining the structure of low-influence functions beyond the hypercube, starting not long after the KKL Theorem itself with the study of product spaces and the p-biased cube [13, 70, 38, 36, 46, 56] and more recently in extended settings such as the slice [60], multi-slice [35, 69], symmetric group [34], Grassmannian [62, 31], high dimensional expanders [6, 7, 44, 39, 42], and Lie groups [30]. We rely heavily on the Fourier analytic machinery initiated by Dikstein, Dinur, Filmus, and Harsha [19], and Kaufman and Oppenheim [55], and further extended by Bafna, Hopkins, Kaufman, and Lovett [6, 7], Gur Lifshitz, and Liu [44], Hopkins [47], and Gotlib and Kaufman [42].

Concretely, several bounds are known for the expansion of global sets with respect to the lower walk. In the regime of strong (inverse exponential) quantitative expansion, BHKL [6] prove any (ε, i)-global function has expansion at least

$$\Phi(f) \gtrsim (1-\mathbb{E}[f])\frac{i+1}{k} - \binom{k}{i}\varepsilon.$$

This is tight when $\varepsilon \ll \frac{1}{\binom{k}{i}}$, and mimics the structure one would expect to see on general k-fold product spaces. For strongly global functions, BHKL [7], GLL [44], and Hopkins [47] improve the ε-dependence to be *independent of dimension*:

$$\Phi(f) \gtrsim (1-\mathbb{E}[f])\frac{i+1}{k} - 2^{O(i)}\varepsilon.$$

In the regime of weak high dimensional expansion, the only known bound for global functions is due to Gotlib and Kaufman [41], who show that on any *one-sided* HDX:

$$\Phi(f) \geq (1-\mathbb{E}[f])\frac{1}{k-i}\prod_{j=i}^{k-2}(1-\gamma_j) + |X(k)|\varepsilon.$$

Unlike the prior bounds, however, this is only really meaningful when $\varepsilon \approx 0$, a non-trivial but extremely strong notion of globalness that does not lead to meaningful structural characterizations.

In some sense our bound, Theorem 1, sits between the latter two. it has the beneficial properties of the latter in that it holds for global functions and under arbitrary (two-sided) local-spectral expansion, and of the former in that the dependence on ε is typically constant. On the other hand, due to being obtained through an inductive approach, it also inherits the main term of Gotlib-Kaufman [42], scaling with $\frac{1}{k-i}$ instead of $\frac{i+1}{k}$. When i and k are large, the former dependence is substantially worse.

At a technical level, this difference in main term stems from the fact that our "advantage" for i-global functions, like in Gotlib-Kaufman [42], comes from the second eigenvalue of the lower walk inside i-links of X, which scales as $1-\frac{1}{k-i+1}\prod_{j=i-1}^{k-2}(1-\gamma_j)$. On the other hand,

on very strong HDX, the advantage of i-global functions comes from the ith approximate eigenvalue of the global lower walk on X itself, which scales with $1 - \frac{i}{k}$. It is natural to conjecture the "correct" dependence sits between these two bounds, as $1 - \frac{i}{k} \prod_{j=i-1}^{k-2} (1 - \gamma_j)$, closer to the type of bound known for the second eigenvalue from [3]. Unfortunately, both the techniques of this paper and Fourier analytic techniques from prior work (which typically incur exponential error) seem far from proving such a bound.

Improved Local Computation of Edge Orientation

Reut Levi

Reichman University, Herzliya, Israel

Abstract

In this paper, we study the problem of orienting the edges of a graph G so that every vertex has bounded out-degree in the *local computation algorithms (LCA)* model, as defined by Rubinfeld et al. (ICS 2011). More specifically, given a query $e \in E$ our algorithm returns the orientation of e such that with high constant probability (namely, at least 0.9) the out-degree of each vertex is bounded by r where r is a parameter. We provide such an upper bound for any $r = \Omega(arb(G) \cdot \log n)$ where $arb(G)$ denotes the arboricity of G (we note that such orientation exists only when $r = \Omega(arb(G))$). Our query complexity is $\tilde{O}(n \cdot arb(G)/r^2)$ in the worst case and $O(1)$ on expectation (over the vertices and the randomness of the algorithm). This generalizes the upper bound by Mitrović–Rubinfeld–Singhal (ESA 2024) that provided a similar upper bound only when $r = \Omega((arb(G)^2 \cdot n))^{1/3}$.

For $r = \Omega(arb(G) \cdot \log n)$, our algorithm also improves their weaker upper bound of $\tilde{O}(n/r)$ queries for the special case where the input graph is a tree (whose arboricity is 1).

Our algorithm assigns each vertex a *level* derived from locally sampled neighborhoods combined through a staggered multi-scale recursion, inspired by the recent arboricity-approximation framework of Dai–Ghaffari–Portmann (FOCS 2025). The main novelty of our approach is that it reconstructs levels consistently across the graph while simultaneously respecting the out-degree bound and maintaining locality of computation.

1 Introduction

Orienting graph edges while satisfying degree constraints has broad algorithmic applications. From a structural perspective, bounded out-degree orientations capture the sparsity of a graph via its degeneracy and arboricity, and play a key role in graph coloring and subgraph enumeration algorithms [4, 13].

Due to this fact, low-out-degree orientation has been extensively studied in the dynamic, distributed, and massively parallel settings (see e.g. [10, 17, 9, 7, 3]).

In many local settings, a standard approach is to simulate a distributed peeling-type process that, for a graph G of arboricity $\alpha = arb(G)$, yields an orientation with maximum out-degree at most $\alpha(2 + \epsilon)$ in $O(\log n)$ iterations.

Mitrović, Rubinfeld, and Singhal [14] initiated the study of computing bounded out-degree edge orientations in the LCA model. They showed that directly simulating the peeling approach via standard LCA transformations can require $\Omega(n)$ probes per query. They also proved a lower bound of $\Omega(\sqrt{n}/r)$ probes per query for producing an r-out-degree orientation, even when the input graph is a forest (i.e., when $\alpha = 1$).

On the algorithmic side, they gave sublinear-probe LCAs for forests and for general graphs. For general graphs, however, their approach requires $r = \Omega\big((\alpha^2 n)^{1/3}\big)$, and for this range they provide a randomized LCA that computes an r-orientation using $\tilde{O}(\max\{\alpha n/r^2, 1\})$ probes per query. Their approach is based on a degree-threshold decomposition together with randomized sampling of the immediate neighborhood of a vertex, rather than on recursively reconstructing a global peeling process.

As a result, their work leaves a gap both in probe complexity and in the range of parameters for which sublinear algorithms are known. In this paper, we address the latter gap, up to logarithmic factors, by providing an LCA with the same probe complexity for all $r = \Omega(\alpha \log n)$. Since r must be at least $\Omega(\alpha)$, this extends the best known upper bound essentially down to the smallest range currently compatible with the sampling requirements of the approach.

1.1 The problem of r-orientation and the peeling process

A natural *global* approach for achieving almost optimal out-degree is the *peeling process*. This process proceeds in iterations. In each iteration, i, all vertices whose *current* degree is at most $(2+\epsilon)\alpha$ are removed from the graphs. These vertices will be called the i-th layer. The process repeats until no vertices remain. Edges are then oriented from earlier to later layers, and arbitrarily within each layer, resulting in a maximum out-degree of $(2+\epsilon)\alpha$ after $O(\log n)$ phases. However, when simulated in the LCA model using the standard Parnas–Ron simulation argument, peeling requires $\Omega(n)$ probes per query, and is therefore not sublinear [15].

In a pair of papers studying the problem of approximating the arboricity of a graph, the authors nevertheless manage to locally simulate a peeling process. In particular, both the algorithm of Eden, Mossel, and Ron [6] and that of Dai, Ghaffari, and Portmann [5] employ a local *simulation of a peeling process*. However, in both cases the simulation does not reconstruct the order in which vertices are peeled. Moreover, the local views produced by the simulation do not correspond to any consistent global peeling sequence.

EMR [6]: pruning-based simulation

In this paper, Eden, Mossel, and Ron [6] introduced a local recursive procedure designed to estimate whether a global peeling process removes a vertex v by the i-th iteration. To keep query complexity manageable, the algorithm prunes branches of the recursion that are expected to be costly. While their analysis shows that this pruning does not significantly distort the simulation's outcome, the procedure has a key limitation for our purposes: it does not recover the actual peeling iteration, but only provides an upper bound. More critically, the local views generated by the simulation do not correspond to any coherent global peeling order. Specifically, on query v, the algorithm attempts to peel a sample consisting of a $\Theta(1/\alpha)$-fraction of the neighbors of v, while *pruning* those predicted to trigger deep recursion. This technique controls the expected recursion depth and yields an $O(\log^2 n)$-approximation using $\tilde{O}(n/\alpha)$ probes. However, the resulting simulation should be viewed only as an approximation of the ideal peeling process. In particular, the local

simulation used for one vertex may correspond to one approximate peeling process, while the simulation for another vertex may correspond to a different approximate peeling process. As a result, the algorithm does not recover the actual peeling iterations and does not define a globally consistent peeling order, which requires a different approach in our setting.

DGP [5]: staggered multi-copy simulation

In their recent work, Dai, Ghaffari, and Portmann [5] propose a procedure that estimates whether a vertex would be peeled in a global peeling process. Their method samples a set of vertices and, for each one, simulates a peeling process to determine if it gets removed – but crucially, it does not recover the iteration in which the vertex is peeled. To manage query complexity, they avoid pruning and instead run multiple simulations in parallel, each with a different pace. Their key insight is that if the graph has low arboricity then with high probability, one of these simulations will terminate quickly and return an answer. Moreover, they design a clever scheduling scheme that ensures the algorithm reaches this efficient simulation without incurring a significant overhead in queries.

However, this approach has a fundamental limitation for our purposes: each simulation uses independent randomness, which is essential for their analysis but prevents the results from aligning with any consistent global peeling order. In particular, the different simulations do not correspond to different executions of the same ideal peeling process, but rather to different approximate local simulations of peeling. Consequently, the depth of the first recursive exploration that terminates successfully should not be interpreted as the actual peeling level of the vertex.

To illustrate this, consider two adjacent vertices u and v, where u is peeled before v in the ideal peeling process. Due to the independent randomness used in the local simulations, it may happen that the recursive exploration rooted at u encounters several bad samples and only terminates after many recursive levels, while the exploration rooted at v quickly encounters a good sample and terminates much earlier. Thus, the local recursion depth may suggest that u belongs to a later layer than v, even though the ideal peeling order is the opposite. Since these local simulations are generated independently, there is no globally consistent peeling order that they collectively realize.

Moreover, the algorithm only determines whether a vertex is peeled – not when. This lack of global coherence motivates the need for a different strategy in our orientation setting.

1.2 Our result

We present a new local computation algorithm for r-orientation in general graphs. Given a query access to an input graph $G = (V, E)$ of arboricity α and a parameter $r = \Omega(\alpha \log n)$, the algorithm answers each edge-orientation query using $O\left(\frac{\alpha n \log^2 n}{r^2}\right)$ probes, and with high constant probability produces an orientation of maximum out-degree r. In particular, we prove the following theorem.

▶ **Theorem 1** (LCA for bounded out-degree orientation). *Let $G = (V, E)$ be an n-vertex graph of arboricity $\alpha = arb(G)$, given through adjacency-list probe access. Let r be a parameter satisfying $r \geq C\alpha \log n$ for a sufficiently large universal constant C. Then there exists a randomized LCA which, on query an edge $\{u, v\} \in E$, returns an orientation of this edge such that, with high constant probability over the random tape, all answers are consistent with a single orientation of G whose maximum out-degree is at most r. The probe complexity per edge query is $O\left(\frac{\alpha n \log^2 n}{r^2}\right)$.*

To compare the parameter ranges, consider the case $\alpha = O(1)$. The previous upper bound of Mitrović, Rubinfeld, and Singhal [14] achieves probe complexity $\tilde{O}(n\alpha/r^2)$, but only for $r = \Omega(n^{1/3})$. Our result achieves the same asymptotic upper bound for every $r = \Omega(\log n)$. In particular, for $r = n^{1/4}$, which is outside the range of the previous general-graph algorithm, our LCA uses $O(n^{1/2} \log^2 n)$ probes per query and produces an orientation of maximum out-degree $n^{1/4}$. Moreover, in this regime the lower bound of Mitrović, Rubinfeld, and Singhal [14] is already $\Omega(n^{1/4})$, even for trees, which are in some sense the simplest constant-arboricity graphs. Thus, the improvement in the range of r is meaningful even in parameter regimes where the probe complexity remains strongly sublinear.

1.3 Description of our algorithm

At a high level, our LCA consists of three components. The first assigns each vertex a level by locally simulating a peeling process. The second answers an edge query $\{u, v\}$ by comparing the levels of u and v, orienting the edge from the lower-level endpoint to the higher-level endpoint (breaking ties according to vertex IDs). The third component implements a single local simulation step of the peeling process.

We begin with the intuition behind the local simulation. Consider the ideal peeling process in which, at every iteration, all vertices of degree at most $\Theta(\alpha)$ are removed. A vertex belongs to layer t if it is removed during the t-th iteration. Observe that if one could recursively follow only neighbors belonging to strictly lower layers, then any recursive exploration rooted at a vertex in layer t would have depth at most t.

However, the algorithm does not know the layers in advance. Instead, for each vertex v and iteration t, the algorithm generates random samples of the neighbors of v, where each neighbor is included independently with probability $\Theta(\log n/r)$. Intuitively, if many neighbors of v belong to lower layers, then with constant probability, a sampled set contains only such neighbors. In this case, recursively exploring the sampled neighbors simulates progress toward lower peeling layers.

A single local simulation step proceeds as follows. Initially, the algorithm queries the degree of v. If the degree is at most $\Theta(\alpha)$, the the first peeling layer. Otherwise, the algorithm recursively explores sampled neighbors while decreasing the iteration counter. The recursion terminates if the iteration counter reaches zero, if a low-degree vertex is encountered, or if the total number of probes exceeds the target budget $\tilde{O}(n\alpha/r^2)$.

One difficulty is that a random sample may contain neighbors that do not belong to lower layers, causing the recursive exploration to continue for much longer than the ideal peeling depth. As a mental experiment, we first assume that this does not happen, and explain why the query complexity can be bounded under this assumption. We then explain how this assumption can be removed using the staggered scheduling technique of Dai, Ghaffari, and Portmann [5]. Finally, we explain why introducing the structure of iterations is necessary in order to obtain a globally coherent solution.

Step 1: Assuming one good sample per vertex

To provide intuition for the query bound, let us first consider an idealized setting in which every vertex v is associated with a single *good* sample, namely a sample containing only neighbors that belong to strictly lower peeling layers than v. For the moment, we ignore the staggered scheduling and assume that the algorithm recursively explores only this single sample.

A natural way to analyze the query complexity would be to bound the size of the recursive exploration tree rooted at every vertex. Instead, we reverse the perspective and ask the following question: for a fixed vertex u, how much does u contribute to the recursive trees rooted at other vertices?

Since samples are good, every recursive call moves to a strictly lower peeling layer. Thus every root-to-node trajectory in the recursive exploration corresponds to a directed path in the graph, where edges are directed from higher layers to lower layers. By the peeling property, every vertex has out-degree at most 3α in this directed graph.

Fix a vertex u. Every time u appears in the recursive tree of another vertex, there must exist a sampled directed path leading to u. The expected number of sampled directed paths of length j ending at u is at most $(3\alpha)^j p^j = (3\alpha p)^j$, because there are at most $(3\alpha)^j$ directed paths of length j leading to u, and each such path survives in the recursive exploration with probability p^j. Therefore, the expected total contribution of u to all recursive trees is at most $1 + \sum_{j\geq 1}(3\alpha p)^j$.

Since $p = \Theta(\log n/r)$ and $r = x\alpha$, we have $3\alpha p = \tilde{O}(1/x)$. For sufficiently large x, this geometric series is bounded by $1 + \tilde{O}(1/x)$.

Summing over all vertices, the expected total additional recursive work is therefore $\tilde{O}(n/x)$. Consequently, by Markov's inequality, only a small number of vertices can have recursive explorations whose size exceeds the probe budget. These vertices are the overflow vertices. Since the overflow threshold is set to $\tilde{O}(n\alpha/r^2)$, the expected total work bound implies that, with constant probability, the number of overflow vertices is at most $O(r)$, and the constants are chosen so that it is at most $r/2$.

Step 2: Why staggered scheduling is needed

The discussion above assumed that every sample is good. In reality, however, a random sample is good only with constant probability. Thus, in order to find a good sample, the algorithm performs $O(\log n)$ independent sampling trials for every vertex.

A naive implementation would recursively explore all these trials, increasing the query complexity by an additional logarithmic factor *at every* recursive level. Instead, following Dai, Ghaffari, and Portmann [5], we evaluate these trials according to a staggered schedule.

The key idea is that trial i is slowed down by a factor 2^i, namely it is advanced only once every 2^i scheduling steps. Since each trial is good with constant probability, the index of the first good trial is geometrically distributed. Consequently, although there are $O(\log n)$ possible trials, the expected amount of work invested before reaching the first good one remains bounded by a convergent geometric sum. Intuitively, the algorithm tries many possible recursive explorations, while paying essentially only for the first successful one.

As a result, the accounting argument from the idealized setting still applies, up to a constant-factor overhead in expectation.

Step 3: Why iterations are needed

The discussion above explains why the recursive explorations remain small in expectation. We now turn to the correctness argument, namely why the resulting levels induce an orientation in which every vertex has at most r neighbors whose level is greater than or equal to its own.

The key point is that the algorithm should mimic the ideal peeling process. Suppose that a vertex v still has many neighbors that were not peeled after t iterations of the ideal process. Then we would like to conclude that v itself should also survive iteration $t + 1$. Intuitively, this follows because every sample of v is likely to contain at least one neighbor that survived iteration t, preventing the recursive exploration from terminating too early.

For this argument to hold, however, the randomness used to determine whether a neighbor survives iteration t must be independent of the randomness used when evaluating v in iteration $t+1$. Otherwise, the events become circularly dependent: the randomness used to decide whether u survives could simultaneously influence whether v observes u, destroying the inductive peeling argument.

For this reason, the algorithm uses different random samples for different iterations. Intuitively, iteration t determines which vertices survive after t rounds of peeling, while iteration $t+1$ uses fresh randomness to test whether a vertex still has many neighbors that survived iteration t. This separation between iterations is what allows us to argue inductively that vertices with many surviving neighbors cannot themselves be peeled too early.

This should be contrasted with the approach of Dai, Ghaffari, and Portmann [5], where independent recursive simulations are used only to decide whether a vertex is peeled. Since those simulations are not meant to define a common level assignment, they may use fresh randomness across recursive calls. In our setting, however, the randomness associated with each vertex and each iteration is fixed globally and reused across all recursive calls and all edge queries. This is crucial for ensuring that the local computations are consistent with one global level assignment.

1.4 Why the DGP batching technique does not remove the $\log n$ Gap

Dai, Ghaffari, and Portmann [5] strengthened the staggered scheduling framework by introducing *batches* of parallel recursive simulations. Each batch contains many independent recursive calls, and a vertex is considered peeled once a majority of the recursive calls in some batch terminate. The role of these batches is to amplify correctness in the high-arboricity case: if a vertex belongs to a dense core, then with high probability most recursive calls do not terminate, preventing the vertex from being mistakenly declared peelable. This amplification allows them to obtain a constant-factor approximation.

In our setting, however, this batching mechanism does not seem useful. First, the arboricity bound is already given, and thus we do not need to distinguish between low- and high-arboricity graphs. More importantly, the logarithmic gap between r and α does not stem from the probability amplification aspect of the recursion, but rather from the need to detect surviving neighbors with high probability in every iteration.

Specifically, to ensure the out-degree bound, if a vertex has many neighbors that survived previous iterations, then its samples in the next iteration must hit one of these surviving neighbors with high probability. This requires $p = \Omega(\log n/r)$. At the same time, the query complexity analysis requires the branching factor to remain bounded, namely that αp is bounded away from one. Together, these conditions imply $r = \Omega(\alpha \log n)$. Since the batching mechanism amplifies correctness but does not reduce the sampling probability p, it does not seem to improve the parameter range in our orientation application.

1.5 Related Work

Local Computation Algorithms (LCAs) answer *local* queries about a global solution using a sublinear number of input probes per query, and the answers over all queries are consistent with one global solution [16, 1].

By now, a wide range of results have been established within the LCA model, including maximal independent set [16], graph coloring [8], approximate maximum matching [12], and minor-free graph partitioning [11]. Edge orientations [14] are among the more recent additions to this growing body of work. In particular Mitrović, Rubinfeld, and Singhal [14] obtained the following results.

- *Lower bound.* Any (possibly randomized) LCA that outputs an r-orientation with success probability at least 0.9 must make $\Omega(n^{1/2}/r)$ probes in the worst case, even on forests ($\alpha = 1$) and even when allowed adjacency-list, adjacency-matrix, or degree queries.
- *Upper bounds for general graphs.* When $r \geq 10(\alpha^2 n)^{1/3}$, they obtain probe complexity $\tilde{O}(\max\{\alpha n/r^2, 1\})$.
- *General forests.* When the graph is a forest they obtain an upper bound of $\tilde{O}(n/r)$ queries for any r.
- *Bounded-degree forests.* For forests of maximum degree Δ they provide an LCA with probe complexity $\Delta\, n^{\,1-\log_\Delta r+o(1)}$.

2 Preliminaries

Let $G = (V, E)$ be a simple graph on $n = |V|$ vertices. For $S \subseteq V$ we denote by $E(S)$ the set of edges with both endpoints in S, and by $G[S]$ the induced subgraph on S. The degree of a vertex v is denoted $d(v)$.

▶ **Definition 2** (Arboricity). *The* arboricity *of G, denoted α, is the smallest integer k for which E can be partitioned into k forests. Equivalently,*

$$\alpha = \max_{S \subseteq V,\, |S| \geq 2} \left\lceil \frac{|E(S)|}{|S| - 1} \right\rceil .$$

Graph access model. We assume adjacency-list probe access to the input graph $G = (V, E)$ where $V = [n]$. Specifically, the probe $\texttt{neighbor}(v, i)$ returns the i-th neighbor or $\perp$ if it has less than i neighbors. We also use degree probes, where $\texttt{degree}(v)$ returns the degree of v.

The complexity of the LCA is mainly measured by the number of probes (query complexity), running time per query, and the amount of randomness used.

▶ **Definition 3** (Local Computation Algorithm (LCA) - [16]). *Let $\mathcal{P}$ be a computational problem where, given an input x of size n, the goal is to compute a valid solution $y \in F(x)$. A randomized algorithm $\mathcal{A}$ is a* ***(t, s, δ)-local computation algorithm*** *for $\mathcal{P}$ if, when given probe access to input x and random tape r (the random tape r is fixed once and reused across all queries):*

1. ***Query Handling:*** *For any query q_i (representing a specific part of the solution), $\mathcal{A}(q_i, x, r)$ returns a partial answer y_{q_i}.*
2. ***Sublinear Complexity:*** *The probe complexity per query is sublinear in n.*
3. ***Consistency:*** *The algorithm is* consistent *with a single global valid solution $y \in F(x)$. That is, for any sequence of queries $q_1, q_2, \ldots, q_m$, the algorithm produces an output sequence $y_{q_1}, y_{q_2}, \ldots, y_{q_m}$ that matches the values in y at those locations.*
4. ***Correctness:*** *For all x, with probability at least $2/3$ (over the random tape r) [1], the algorithm answers all queries consistently with a valid solution.*

2.1 r-Orientation in the LCA model

An LCA for the problem of r-orientation receives queries of the form "what is the orientation of edge $\{u, v\}$?" and must answer with either $u \to v$ or $v \to u$, using a number of probes that is sublinear in n, while ensuring that all such answers are consistent with a single global orientation whose maximum out-degree is at most r.

[1] Alternatively, one may require high success probability, namely, $1 - 1/n^c$, for any constant c (without changing the asymptotic complexity of the algorithm).

2.2 A Structural Ordering for α-Arboricity Graphs

Our analysis relies on a fixed acyclic orientation as described next.

▶ **Definition 4** (Ideal Peeling Layers). *Let $G = (V, E)$ be a graph, and let $G_0 = G$. For every integer $k \geq 1$, define recursively*

$$L_k^* := \{ v \in V(G_{k-1}) \mid d_{G_{k-1}}(v) \leq 3\alpha \},$$

and let

$$G_k := G\Big[V \setminus \bigcup_{i=1}^{k} L_i^*\Big]$$

be the subgraph induced by the vertices that remain after removing the first k layers.

For each vertex $v \in V$, define $\ell(v)$ to be the unique index k such that $v \in L_k^*$.

This peeling-based partition originates in the work of Barenboim and Elkin [2].

▶ **Lemma 5** (Structural Depth Bound). *The ideal peeling process terminates in $L = O(\log n)$ levels.*

Proof. Consider any subgraph $H \subseteq G$. Since G has arboricity α, $|E(H)| \leq \alpha|V(H)|$. By the Handshaking Lemma, $\sum_{v \in V(H)} d_H(v) \leq 2\alpha|V(H)|$. Let $S \subseteq V(H)$ be the set of vertices with $d_H(v) > 3\alpha$. Then $3\alpha|S| < \sum d_H(v) \leq 2\alpha|V(H)|$, implying $|S| < \frac{2}{3}|V(H)|$. Thus, each level removes at least $1/3$ of the remaining vertices, leading to $O(\log n)$ levels. ◀

▶ **Definition 6** (Good sample). *Fix a vertex v and a sampled neighbor set $S \subseteq N(v)$. We say that S is* good *(with respect to the peeling layers) if every vertex $u \in S$ belongs to a strictly lower level than v, i.e., $\ell(u) < \ell(v)$ for all $u \in S$.*

The structural levels are introduced purely for the purpose of analysis and are never accessed by the algorithm. Assume that each vertex initially possesses a good sample. Starting from a vertex v, we consider a recursive process that follows sampled (good) neighbors until it reaches a terminal vertex, defined as a vertex of degree at most 3α. Lemma 5 implies that the recursion depth of this process is bounded by $O(\log n)$. The depth of this recursion allows us to bound the number of iterations of our algorithm as we shall see next.

Our algorithm proceeds in $\Theta(\log n)$ iterations. In order to describe it we introduce several objects and definitions that will be used throughout the algorithm and its analysis.

Notation and Setup

For every vertex $v \in V$ and every iteration t, we use a different set of sampled neighbors. These samples are fixed implicitly by the algorithm's randomness and are used to guide the recursive exploration of the neighborhood of v at different paces during the level computation. We define these sets next.

2.2.1 Per-Iteration Samples

In this subsection, we describe how the samples associated with each vertex and iteration are generated. The parameters introduced here will be used throughout the paper.

Fix an arboricity α, an orientation target $r = x\alpha$ where $x = \Omega(\log n)$, and a bound on the number of iterations $T \stackrel{\text{def}}{=} \Theta(\log n)$.

For every vertex $v \in V$ and every iteration $t \in [T]$, the algorithm associates with v a collection of $\ell \stackrel{\text{def}}{=} \Theta(\log n)$ independent random neighbor samples

$$S_{v,1}^{(t)}, S_{v,2}^{(t)}, \ldots, S_{v,\ell}^{(t)} \subseteq N(v).$$

Each sample $S_{v,i}^{(t)}$ is generated by including every neighbor $u \in N(v)$ independently with probability $p \stackrel{\text{def}}{=} c \cdot \frac{\log n}{r}$, where c is a constant whose precise choice will be dictated by the inequalities appearing later in the proof.

Implementation details

Our analysis focuses on query complexity. By Lemma 2.3 of Dai, Ghaffari, and Portmann [5], the samples $S_{v,1}^{(t)}, \ldots, S_{v,\ell}^{(t)}$ can be generated in expected time proportional to their size. Consequently, the running time of our algorithm matches its query complexity up to constant factors.

The generation occurs according to the following schedule.

2.2.2 Per-Iteration Staggered Scheduling

Fix an iteration $t \in [T]$. We next describe the execution of iteration t of the algorithm which is essentially a staggered generation of the samples defined above.

Iteration t proceeds in steps $y = 1, 2, \ldots$ Let $i(y)$ denote the (unique) index of the bit that flips from 0 to 1 when incrementing $y - 1$ to y in binary. Equivalently, $i(y)$ is the index of the least significant 1 bit in the binary representation of y.

Scheduling rule

At time step y, the algorithm advances the generation of the sample $S_{v,i}^{(t)}$, where $i = i(y)$. Once the sample $S_{v,i}^{(t)}$ has been fully generated, the algorithm recursively processes its vertices using the same scheduling rule with the number of iterations decreased by 1. Thus, we obtain the following.

Execution frequency

The generation of $S_{v,i}^{(t)}$ and its recursion advance exactly at steps y satisfying

$$y \equiv 2^{i-1} \pmod{2^i}.$$

Therefore, over the first y steps, this advancement occurs $\Theta\left(\frac{y}{2^i}\right)$ times. Since each advancement accounts for 2^i underlying steps, the total processing time is obtained by multiplying the number of advancements by 2^i.

3 The algorithm for r-Orientation

Our LCA is organized into three procedures: Orient answers an edge query using the two endpoint levels; ComputeLevel tries iterations $t = 1, \ldots, T$ and returns the first successful one; and ComputeLevelIter implements a single iteration.

Algorithm 1 Orient(u, v): LCA for edge orientation.

Require: An undirected edge $\{u, v\}$
$a \leftarrow$ ComputeLevel(u)
$b \leftarrow$ ComputeLevel(v)
if $a < b$ **then**
    return $u \to v$
else if $b < a$ **then**
    return $v \to u$
else
    return orientation by vertex IDs
end if

The procedure ComputeLevel(v) determines the smallest iteration t in which v can be resolved within the probe budget by invoking ComputeLevelIter$(v, t, \cdot)$ for increasing t.

Algorithm 2 ComputeLevel(v).

Require: Vertex v
Ensure: $\ell(v) \in \{1, \ldots, L\} \cup \{\infty\}$
if $d(v) \leq 3\alpha$ **then**
    return 1
end if
for $t \leftarrow 1$ **to** T **do**
    $q \leftarrow 0$ ▷ local probes used in iteration t
    if ComputeLevelIter$(v, t, q) =$ **true then**
        return t
    end if
end for
return ∞

At iteration t, ComputeLevelIter explores sampled neighbors of v using the staggered schedule, and returns **true** iff it certifies that the sampled recursive exploration starting from v terminates without exceeding the local probe budget $B \stackrel{\text{def}}{=} \Theta(\alpha n \log n / r^2)$. More concretely, a sampled set is considered successful if all recursive calls made on vertices in that set return **true**. If a recursive call returns **false**, then this particular sampled set is discarded; however, the entire iteration does not necessarily fail, since the staggered schedule may still find another sampled set whose recursive calls all succeed. The iteration fails only if no sampled set succeeds before the budget is exceeded.

3.1 Analysis

In the analysis of our algorithm we use the following notion of processing time.

▶ **Definition 7** (Processing-time). *For a vertex v and an iteration $t \geq 1$, define* $\mathrm{Proc}_t(v)$ *recursively as*

$$\mathrm{Proc}_t(v) := \begin{cases} 1, & \text{if } d(v) \leq 3\alpha, \\ 1 + \min\limits_{i \in [\ell]} \left\{ 2^i \cdot \left(|S_{v,i}^{(t)}| + \sum\limits_{u \in S_{v,i}^{(t)}} \mathrm{Proc}_{t-1}(u) \right) \right\}, & \text{if } d(v) > 3\alpha. \end{cases}$$

and set $\mathrm{Proc}_0(v) := 1$ *for all* v.

Algorithm 3 ComputeLevelIter(v, t, q).

Require: Vertex v, iteration t, global counter q
Ensure: **true** iff iteration t succeeds for v

$q \leftarrow q + 1$
if $q > B$ **then**
  return false
end if
if $d(v) \leq 3\alpha$ **then**
  return true
end if
if $t = 0$ **then**
  return false
end if
Initialize the recursive processing of $S_{v,1}^{(t)}, \ldots, S_{v,\ell}^{(t)}$.
for each scheduling step $y = 1, 2, \ldots$ while $q \leq B$ **do**
  $i \leftarrow i(y)$
  Continue processing the vertices of $S_{v,i}^{(t)}$.
  For the next unprocessed vertex $u \in S_{v,i}^{(t)}$, invoke ComputeLevelIter$(u, t-1, q)$.
  if the recursive call returns **false then**
    Discard the sample $S_{v,i}^{(t)}$.
  else if all vertices of $S_{v,i}^{(t)}$ have been processed **then**
    return true
  end if
end for
return false

The factor 2^i appears because sample $S_{v,i}^{(t)}$ is advanced only once every 2^i scheduling steps. Thus, if the evaluation of this sample requires Q units of local work, then the global schedule spends $O(2^i Q)$ steps before this evaluation completes. This is why the processing time takes a minimum over terms of the form $2^i(\cdot)$.

By construction, $\mathrm{Proc}_t(v)$ upper bounds the number of probes used to evaluate iteration t rooted at v under the staggered schedule. For a fixed sample index i, recursively processing its sampled neighbors costs $\sum_{u \in S_{v,i}^{(t)}} \mathrm{Proc}_{t-1}(u)$, and the execution frequency contributes a multiplicative $\Theta(2^i)$ factor, giving the term $2^i(\cdot)$. Since the schedule runs all indices in parallel and stops when the first completes, we take the minimum over $i \in [\ell]$.

By Algorithm 2, the level of a vertex v is defined as follows.

▶ **Definition 8** (Level). *The level of a vertex v, $level(v)$ is defined to be the minimum $t \in T$ such that the processing time of* ComputeLevelIter$(v, t, \cdot)$ *is less than B, or ∞ if such t does not exist. In the latter case we call v and* overflow vertex.

3.1.1 Total expected work per iteration

In this subsection, we bound the expected total work per iteration, summed over all vertices, when excluding from the count the initial degree query performed for each vertex.

▷ Claim 9. For every $t \leq T$, $\mathbb{E}\left[\sum_{v \in V}(\mathrm{Proc}_t(v) - 1)\right] = O((n \log n)/x)$.

Proof. Recall that $p = c \cdot \frac{\log n}{r}$. Thus, for $r \geq 100c\alpha \log n$ it is bounded from above by $\frac{1}{100 \cdot \alpha}$. In each sample $S_{v,i}^{(t)}$, every neighbor of v is included independently with probability p.

Call a sample $S_{v,i}^{(t)}$ *good* if all sampled neighbors belong to strictly lower ideal peeling layers than v, i.e., $\ell(u) < \ell(v)$ for all $u \in S_{v,i}^{(t)}$ (Definitions 4 and 6). Since each vertex has at most 3α neighbors whose layer index is not strictly smaller than its own, we have

$$\Pr\left[S_{v,i}^{(t)} \text{ is good}\right] = (1-p)^{L_{\geq t}} \geq (1-p)^{3\alpha} \geq e^{-3/100} \geq 0.97.$$

Hence each sample is good with probability at least 0.97 and bad with probability at most 0.03. Let $i^\star$ be the index of the first good sample. Then

$$\Pr[i^\star = i] \leq (0.03)^{i-1} = q^{\,i-1}, \qquad q := 0.03.$$

Condition on the event that $i^\star = i$. By the definition of $\mathrm{Proc}_t(v)$, we have

$$\mathbb{E}[\mathrm{Proc}_t(v) - 1] \leq \sum_{i=1}^{\ell} \Pr[i^\star = i] \cdot 2^i \cdot \mathbb{E}\left[|S_{v,i}^{(t)}| + \sum_{u \in S_{v,i}^{(t)}} \mathrm{Proc}_{t-1}(u) \;\middle|\; i^\star = i \right].$$

Using the bound $\Pr[i^\star = i] \leq q^{\,i-1}$, this implies

$$\mathbb{E}[\mathrm{Proc}_t(v) - 1] \leq \sum_{i=1}^{\ell} q^{\,i-1} \cdot 2^i \, \mathbb{E}\left[\sum_{u \in S_{v,i}^{(t)}} |S_{v,i}^{(t)}| + \mathrm{Proc}_{t-1}(u) \;\middle|\; i^\star = i \right]. \tag{1}$$

Conditioned on the event that $S_{v,i}^{(t)}$ is a good sample, only neighbors u in strictly lower ideal layers than v can appear. Each such neighbor is included independently with probability p, so by linearity of expectation,

$$\mathbb{E}\left[|S_{v,i}^{(t)}| + \sum_{u \in S_{v,i}^{(t)}} \mathrm{Proc}_{t-1}(u) \;\middle|\; i^\star = i \right] = \sum_{\substack{u \in N(v) \\ \ell(u) < \ell(v)}} p \,(1 + \mathbb{E}[\mathrm{Proc}_{t-1}(u)]).$$

Plugging into (1) yields

$$\mathbb{E}[\mathrm{Proc}_t(v) - 1] \leq \sum_{i=1}^{\ell} q^{\,i-1} 2^i \sum_{\substack{u \in N(v) \\ \ell(u) < \ell(v)}} p\,(1 + \mathbb{E}[\mathrm{Proc}_{t-1}(u)]). \tag{2}$$

The geometric factors satisfy

$$\sum_{i=1}^{\ell} q^{\,i-1} 2^i \leq 2 \sum_{i=1}^{\infty} (2q)^{i-1} = \frac{2}{1-2q} = \frac{2}{1-0.06} < 3.$$

Therefore,

$$\mathbb{E}[\mathrm{Proc}_t(v) - 1] \leq 3 \sum_{\substack{u \in N(v) \\ \ell(u) < \ell(v)}} p\,(1 + \mathbb{E}[\mathrm{Proc}_{t-1}(u)]). \tag{3}$$

Summing (3) over all vertices v and rearranging gives

$$\sum_{v\in V}\mathbb{E}[\mathrm{Proc}_t(v)-1]\le 3p\sum_{u\in V}(1+\mathbb{E}[\mathrm{Proc}_{t-1}(u)])\cdot\left|v\in N(u):\ell(v)>\ell(u)\right|. \tag{4}$$

By the ideal peeling layers property, for every vertex u there are at most 3α neighbors v with $\ell(v)\ge\ell(u)$. Hence,

$$\sum_{v\in V}\mathbb{E}[\mathrm{Proc}_t(v)-1]\le 9\alpha p\sum_{u\in V}(1+\mathbb{E}[\mathrm{Proc}_{t-1}(u)])=9\alpha p\left(2|V|+\sum_{u\in V}\mathbb{E}[\mathrm{Proc}_{t-1}(u)-1]\right) \tag{5}$$

Let $R_t\stackrel{\text{def}}{=}\sum_{v\in V}\mathbb{E}[\mathrm{Proc}_t(v)-1]$. Then (5) implies

$$R_t\le 9\alpha p\left(2|V|+R_{t-1}\right).$$

Since $R_0=\sum_{v\in V}\mathbb{E}[\mathrm{Proc}_0(v)-1]=0$, and from the fact that $9\alpha p<0.5$ and that $9\alpha p=O((\log n)/x)$ it follows by induction that $R_t=O((n\log n)/x)$, as claimed ◁

▷ Claim 10. With high constant probability, the number of overflow vertices is at most $r/2$.

Proof. Observe that R_t is the expected total number of queries required to execute iteration t on *all* vertices, excluding only the first degree query performed on the starting vertex. By Claim 9,

$$\mathbb{E}\left[\sum_{v\in V}(\mathrm{Proc}_t(v)-1)\right]\le c_1(n\log n)/x,$$

where c_1 is a constant. Let

$$Z_t=\left|\left\{v\in V:\mathrm{Proc}_t(v)-1\ge c_2\cdot\frac{n\alpha\log n}{r^2}\right\}\right|,$$

where c_2 is a sufficiently large constant (the conditions it must satisfy will become apparent in the remainder of the proof). Then

$$Z_t\cdot c_2\frac{n\alpha}{r^2}\le\sum_{v\in V}(\mathrm{Proc}_t(v)-1).$$

Taking expectations,

$$\mathbb{E}[Z_t]\le\frac{c_1(n\log n)/x}{c_2\alpha n\log n/r^2}=O\left(\frac{c_1 r}{c_2}\right),$$

where we used $x=r/\alpha$. Choosing c_2 sufficiently large gives

$$\mathbb{E}[Z_t]\le\frac{r}{20}.$$

Therefore, by Markov's inequality,

$$\Pr\left[Z_t>\frac{r}{2}\right]\le\frac{\mathbb{E}[Z_t]}{r/2}\le\frac{1}{10}.$$

Thus, with high constant probability, at most $r/2$ vertices require at least $c_2\cdot\alpha n\log n/r^2$ additional queries, as claimed. ◁

3.2 Bounding the out-degree

▷ Claim 11. With high constant probability (over the randomness of the algorithm) the out-degree of every vertex is r.

Proof. Fix an iteration t, and consider only the randomness required by the algorithm for executing iterations $1, \ldots, t$, namely the sets $\{S_{v,i}^{(j)}\}_{j\in[t],\, i\in[\ell],\, v\in V}$. Let $U_{\leq t}$ denote the set of vertices that were unsuccessful in all iterations in $[t]$.

Let $v \in V$ be a vertex such that $|N(v) \cap U_{\leq t}| \geq r/2$. Fix an index $i \in [\ell]$. The probability that none of the vertices in $N(v) \cap U_{\leq t}$ belongs to $S_{v,i}^{(t)}$ is at most

$$(1-p)^{r/2} \leq e^{-pr/2} \leq 1/n^{c/2} \leq 1/n^2,$$

where the last inequality holds for an appropriate setting of c in the definition of p. By a union bound over all vertices v and all indices i, it follows that, with high probability, for every v and i, if $|N(v) \cap U_{\leq t}| \geq r/2$, then at least one vertex in $N(v) \cap U_{\leq t}$ belongs to $S_{v,i}^{(t+1)}$.

Consequently, it holds that $level(v) \geq t+1$ (note that a vertex v can be successful in iteration $t+1$ only if there exists $i \in [\ell]$ such that all vertices in $S_{v,i}^{(t+1)}$ were successful in one of the iterations in $[t]$ (this is a necessary but not a sufficient condition since the query budget is divided between the different procedures). We conclude that, with high probability, every vertex has at most $r/2$ neighbors whose level is greater than or equal to its own, excluding overflow vertices. Since w.h.c.p. the number of overflow vertices is bounded by $r/2$, this concludes the proof. ◁

We now prove Theorem 1.

Proof of Theorem 1. The claim on the query complexity follows from the construction as the probe complexity per edge query is $O\left(\frac{\alpha n \log^2 n}{r^2}\right)$, where the additional $\log n$ factor comes from trying $T = \Theta(\log n)$ iterations, and each iteration is stopped after budget $B = \Theta(\alpha n \log n / r^2)$. The claim on the success probability of the algorithm follows from Claim 11. ◀

Abstract

Estimating the second frequency moment (F_2) of an underlying frequency vector is a fundamental problem in the streaming model. While recent work by Braverman and Zamir [STOC 2025] resolved the space complexity for constant failure probability in the insertion-only model, the optimal dependence on the failure parameter δ remained open.

We close this gap by proving a tight high-probability lower bound of $\Omega\left(\frac{1}{\varepsilon^2}\log\frac{1}{\delta}\log\frac{\varepsilon\sqrt{n}}{\log(1/\delta)}\right)$ for $(1\pm\varepsilon)$-approximate F_2 estimation. The key challenge is the failure of prior multi-scale direct sum arguments under noise sensitivity. We introduce a noise-robust communication primitive, *Exam Mostly Set Disjointness*, and prove an $\Omega\left(\frac{m}{t}\log\frac{1}{\delta}\right)$ one-way lower bound. Embedding this into a multi-scale reduction yields the correct $\log(1/\delta)$ dependence.

We also give two complementary algorithms under natural structure assumptions. For streams with frequency bound B, we design a subsampling method using continuous F_0 tracking that replaces a $\log(n)$ factor with $\mathrm{polylog}(B)$. For k-sparse streams, we develop a two-stage sketch using approximate Morris counters, replacing $\log n$ with $\log k$ and achieving a further $\log\log m$ dependence on stream length.

1 Introduction

The emergence of large-scale data applications has made streaming algorithms a fundamental framework for space-efficient computation. Such applications routinely generate massive datasets arising from sources such as social networks, web search systems, network monitoring, and distributed sensor platforms. A central problem in this model is the estimation of frequency moments. Here, elements from a universe $[n] := \{1, 2, \ldots, n\}$ arrive one by one in a stream, implicitly defining a frequency vector f, where $f_i \in \mathbb{N}$ denotes the number of occurrences of each element $i \in [n]$. We typically denote the stream length by m and assume that $n = \mathrm{poly}(m)$. The goal is to output, with high probability, a $(1\pm\varepsilon)$-approximation to

the p-th frequency moment of the stream, $F_p := \sum_{x \in U} f_x^p$, using space sublinear in both m and n. Since the seminal work of Alon, Matias, and Szegedy [2], the frequency moments problem has been closely studied for more than two decades [11, 3, 29, 18, 17, 25, 22, 21, 12, 9, 8, 6, 10, 13, 31, 32, 4, 19, 33, 15, 16, 26].

The second frequency moment ($p = 2$) is a fundamental quantity in data stream analysis. This statistic, commonly referred to as the repeat rate or surprise index, appears in a range of settings including database query optimization [1], approximate histogram maintenance [14], machine learning [28, 30], and network traffic anomaly detection [24], among others. In addition to these applications, F_2 provides a measure of skew or homogeneity in a dataset, which is important for performance optimization in database systems. In distributed and parallel computation, it is used to assess load imbalance and to guide how data should be partitioned across processors. It also informs other streaming tasks; for instance, some hybrid algorithms for estimating the number of distinct elements (F_0) rely on F_2 to decide which sampling strategy to apply. Exactly computing F_2 in a streaming setting requires storing all frequency counts, which leads to $\Omega(n)$ space usage and becomes impractical for large inputs. This has driven the development of streaming algorithms that maintain compact summaries of the data and produce accurate estimates in a single pass. Formally, the goal of the F_2 estimation problem is to compute a $(1 \pm \varepsilon)$-approximation with probability at least $1 - \delta$ while minimizing space. The classical AMS sketch of Alon, Matias, and Szegedy [2] achieves this using $O\left(\frac{1}{\varepsilon^2} \log \frac{1}{\delta} \log n\right)$ bits of space for a universe of size n. Despite extensive progress, the best known lower bound until 2025, due to Woodruff [29], was $\Omega\left(\frac{1}{\varepsilon^2} + \log n\right)$. Finally, a recent breakthrough by Braverman and Zamir [7] closed this gap for the case of constant failure probability δ in the insertion-only model, proving a tight lower bound of $\Omega(\frac{1}{\varepsilon^2} \log(n\varepsilon^2))$ space. When ε is not too small, e.g., $\varepsilon > n^{-1/2+c}$ for $c > 0$, this matches the AMS upper bound of $O\left(\frac{1}{\varepsilon^2} \log n\right)$. For smaller ε, [7] also provided a modified algorithm matching their lower bound. However, while the complexity in terms of n and ε was resolved, the optimal dependence on the failure probability δ remains an open question.

Our main result closes this gap by establishing a matching lower bound on the space complexity of F_2 estimation as a function of the failure probability δ, thereby resolving the dependence on δ in the insertion-only streaming model:

▶ **Theorem 1.** *Let $\mathcal{A}$ be a streaming algorithm that, for any data stream of length polynomial in n over a universe of size n, computes an estimate $\hat{F}_2$ such that $\Pr[|\hat{F}_2 - F_2| \le \varepsilon F_2] \ge 1 - \delta$. For $\varepsilon\sqrt{n} \ge \log \frac{1}{\delta}$, the space used by $\mathcal{A}$ is at least $\Omega\left(\log\left(\frac{\varepsilon\sqrt{n}}{\log \frac{1}{\delta}}\right) \frac{1}{\varepsilon^2} \log\left(\frac{1}{\delta}\right)\right)$.*

Beyond the main lower bound, our techniques yield additional results at both the communication and algorithmic levels. At the core of our approach is a new communication primitive called Exam Mostly Set Disjointness (EMostlyDISJ). In this problem, t players hold sets with a total size parameter m, and a referee holds a target element. The players' sets are promised to be either κ-almost disjoint (meaning the total number of repeated occurrences of elements across the sets is at most κ) or to have a unique element common to at least a constant fraction of the sets. The referee must decide whether the latter case holds and the common element matches their target.

▶ **Theorem 2** (EMostlyDISJ lower bound)**.** *Any one-way communication protocol for the t-player EMostlyDISJ problem with failure probability at most δ requires $\Omega\left(\frac{m}{t} \log \frac{1}{\delta}\right)$ communication when the almost-disjointness parameter is $\kappa = O\left(\log \frac{1}{\delta}\right)$. (Informal, see Corollary 24.)*

We then use this lower bound as a core primitive in our reduction framework, together with a multi-scale embedding argument, to obtain the streaming lower bound above. On the algorithmic side, we identify structured regimes where faster algorithms are possible.

▶ **Theorem 3** (Bounded-frequency streams). *Let $x \in \mathbb{Z}^n_{\geq 0}$ be the frequency vector of an insertion-only stream of length m. Suppose that $0 \leq x_i \leq B$ for all $i \in [n]$. Then there exists a streaming algorithm that, with probability at least $1-\delta$, computes a $(1\pm\varepsilon)$-approximation to $\|x\|_2^2$ using space (in bits) $O\left(\frac{1}{\varepsilon^2}\log^2\frac{B}{\varepsilon}\log\frac{1}{\delta}\left(\log B+\log\frac{1}{\varepsilon}\right)\right)+O\left(\log\frac{n}{\delta}\right)$.*

▶ **Theorem 4** (Sparse streams). *Let $x \in \mathbb{Z}^n_{\geq 0}$ be the frequency vector of an insertion-only stream of length m. Suppose that $\|x\|_0 \leq k$. Then there exists a streaming algorithm that, with probability at least $1-\delta$, computes a $(1\pm\varepsilon)$-approximation to $\|x\|_2^2$ using space (in bits) $O\left(\frac{1}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\left(\log\frac{k}{\varepsilon}+\log\log m\right)+\log n\cdot\log\frac{1}{\delta}\right)$.*

Together, these results provide a refined picture of the complexity of F_2 estimation, capturing both its limitations in the general case and improved guarantees under natural structural assumptions.

2 Background and Technical Overview

Proving strong streaming space lower bounds via communication complexity often encounters a known barrier: traditional reductions struggle to amplify the hardness of a single communication problem to achieve the logarithmic factors (e.g., $\log n$) required for F_2 estimation. A recent breakthrough by Braverman and Zamir [7] overcame this barrier by introducing a novel multi-scale direct sum argument applied directly at the streaming level, built on top of a specialized communication model.

The Braverman-Zamir Approach and Exam Set Disjointness. At the core of their lower bound is the *Exam Set Disjointness* (EDISJ) problem. In this communication game, t players each hold a set of items, and a referee holds a single target element y. The players communicate sequentially, eventually sending a message to the referee, who must determine if y is the *unique* intersection of all the players' sets. This "exam" model is crucial because it forces the players to communicate enough information to verify a specific intersection, rather than merely detecting whether any intersection exists. They showed that solving EDISJ requires $\Omega(m/t)$ communication, where m is the total size of the sets.

To lift this communication bound to the streaming setting, Braverman and Zamir embed multiple instances of EDISJ into a single stream. These instances encode games with varying numbers of players (e.g., $2, 4, 8, \ldots$, up to roughly $\varepsilon\sqrt{n}$) and are interleaved at different "scales" or "levels." Because these instances share parts of the stream, they are dependent, and standard direct sum theorems do not apply. Instead, they developed a clever information-theoretic argument to show that a streaming algorithm must effectively solve all these dependent instances simultaneously. At any arbitrary point j in the stream, an algorithm needs information about the "past" relevant to each scale. For a level l (corresponding to 2^l players), the algorithm must remember information about the preceding $n/2^l$ elements of the stream to solve the EDISJ instance at that scale. They demonstrated that these different-scaled pasts are sufficiently disjoint that the required information adds up. Summing the $\Omega(1/\varepsilon^2)$ cost across each of the $\Theta(\log(n\varepsilon^2))$ scales yields their final $\Omega(\frac{1}{\varepsilon^2}\log n)$ space bound.

The Barrier to Optimal Error Dependence. While this multi-scale argument elegantly resolves the space complexity in terms of n and ε, it fails to capture the optimal dependence on the failure probability δ. The limitation stems directly from the EDISJ problem itself: the standard Set Disjointness problem, and its exam variant, are highly sensitive to noise. Because

the YES instance relies on a single, perfect intersection, an algorithm that is permitted to fail with probability δ might simply miss this unique intersection without paying the full information cost. Consequently, EDISJ cannot yield the robust $\log(1/\delta)$ communication lower bounds necessary for stronger high-probability streaming guarantees.

Our Contributions: Exam Mostly Set Disjointness. To achieve tight dependence on δ, we adapt the Braverman-Zamir framework by replacing EDISJ with a new, noise-robust communication primitive that we call *Exam Mostly Set Disjointness* (EMostlyDISJ). This problem is a synthesis of the Exam Set Disjointness problem from [7] and the Mostly Set Disjointness problem introduced by Kamath et al. [20].

Instead of demanding perfect disjointness, EMostlyDISJ relaxes the conditions to make the problem strictly harder for algorithms prone to error. By distinguishing between sets being almost disjoint (few intersections) and having an element common to a large fraction of the sets, the problem becomes robust to failure probabilities.

▶ **Definition 5** (Exam Mostly Set Disjointness (EMostlyDISJ)). *The setup involves t players and one referee. Let U be a universe of size $|U|$. The inputs are sets $S_1, \ldots, S_t \subseteq U$ for the players and an element $j \in U$ for the referee. The input sets are promised to be either (i) κ-almost disjoint (the total number of repeated occurrences of elements across the sets is at most κ) or (ii) to have a unique element $j_0 \in U$ that is common to at least ct of the sets for some constant $c \in (0, 1)$, and the remaining elements across the sets are κ-almost-disjoint. The communication is one-way from player i to player $i + 1$, and finally to the referee. With failure probability at most δ, the referee must decide if the input is an instance of case (ii) and the intersecting element j_0 is equal to its element j.*

We prove that this game requires $\Omega\left(\frac{m}{t}\log\frac{1}{\delta}\right)$ communication when the almost-disjointness parameter is bounded by $M = O\left(\log\frac{1}{\delta}\right)$.

Putting it Together: The Multi-Scale Reduction. With the robust communication bound in hand, we plug EMostlyDISJ directly into the multi-scale direct sum framework. In our reduction, the stream is divided into blocks corresponding to players, and elements are grouped into "super-items" of size $d = \Theta(\frac{\varepsilon^2 n}{t^2})$. If a super-item is repeated among a constant fraction of the players (the "Yes" case of EMostlyDISJ), the F_2 moment of the stream increases significantly compared to the "No" case, where items are repeated at most M times. By embedding these robust EMostlyDISJ instances across multiple scales (different values of t) and applying the direct sum argument over the disjoint "pasts," the robust $\log(1/\delta)$ communication costs naturally accumulate at every valid level of the stream, culminating in our complete and tight space lower bound for F_2 estimation.

Bounded-frequency streams. We consider two classes of insertion-only streams for which the general space lower bound above does not apply. By exploiting structural assumptions about the data, we show that it is possible to beat the lower bound with more space-efficient algorithms. The first class is streams with entries bounded by B, i.e., the maximum frequency of any element is $x_i \leq B$. The main observation is that when B is small, we obtain a good estimate of $F_2(x)$ by subsampling entries from the support of x. We implement this by applying a pairwise independent hash function to filter the stream down to an expected effective dimension of roughly $K = O(\frac{B^2}{\varepsilon^2})$. Because the frequencies are strictly bounded by B, the variance of this sampling-based estimator remains well-controlled. This subsampling reduces the size of the vector dramatically. When we apply the classical AMS sketch of [2]

purely to this restricted substream, the counters accumulate much smaller values (bounded by $O(BK)$). This drastically lowers the bit complexity per entry, effectively reducing the dominant multiplicative space dependence on $\log n$ down to roughly $\log B$.

There are several complications in following the outlined procedure in a single-pass streaming model. In particular, the optimal subsampling rate needs to depend inversely on the total support size (F_0), which we do not have access to at the start of the stream and grows dynamically. To handle this, we use a continuous F_0 tracker to estimate the sparsity at all points in time. As the stream progresses and our F_0 estimate crosses power-of-two thresholds, we dynamically spawn new sets of sketches tuned to progressively smaller sampling rates. By maintaining only a small active window of parallel instances (specifically, $O(\log(B/\varepsilon))$ instances) at any given time and discarding older ones, we successfully isolate a sketch with the correct sampling scale for the suffix of the stream, while bounding the error accumulated from the prefix.

Sparse streams. We also consider sparse streams, where the underlying frequency vector has at most k non-zero entries (i.e., $\|x\|_0 \leq k$). For this setting, our strategy utilizes a two-stage dimensionality reduction tailored specifically for sparse vectors. First, we hash the massive n-dimensional universe items into $M = \Theta(k/\varepsilon^2)$ random buckets. Because the underlying vector is guaranteed to be k-sparse, mapping the non-zero elements into this number of buckets results in very few collisions. This ensures that the F_2 moment of the resulting compressed, low-dimensional vector closely preserves the original F_2 moment up to a $(1 \pm \varepsilon/4)$ factor. We then compose this with an AMS sketch applied directly to the resulting compressed vector. To aggressively optimize the space and further remove lingering logarithmic dependencies on the stream length m, we do not store the entries of the AMS sketch exactly. The AMS sketch relies on linear combinations with random ± 1 signs, so we conceptually decompose each sketch counter into separate positive and negative updates. We then use Morris Counters [27] to separately estimate the positive and negative contributions to each bucket. The key to the error analysis relies on the structure of sparse vectors: by the Cauchy-Schwarz inequality, any k-sparse stream of length m satisfies $F_2 \geq m^2/k$. By tuning the Morris counters to operate with an error parameter of $\varepsilon' = O(\varepsilon/k)$, the additive error introduced by the approximate counting is tightly bounded, ensuring it is small enough to be absorbed into the overall $(1 \pm \varepsilon)$ multiplicative error. This layered approach roughly allows us to replace the heavy $\log n$ dependence with $\log k$ (alongside a deeply sub-logarithmic $\log \log m$ factor), where k is the sparsity.

3 Preliminaries

In this section, we formally define the fundamental concepts, models, and tools used throughout the paper. We review key concepts from information theory and communication complexity, and briefly describe the standard probability bounds and sketching algorithms utilized in our upper bounds.

3.1 Information Theory

Our space lower bounds rely heavily on information-theoretic measures to quantify how much the internal memory of a streaming algorithm "knows" about the input stream. We use standard concepts from Shannon information theory. All logarithms are taken to base 2. Let X, Y, and Z be discrete random variables.

▶ **Definition 6** (Entropy and Conditional Entropy). *The Shannon entropy of X, which measures its expected uncertainty or information content, is defined as $H(X) := \sum_{x \in \mathrm{supp}(X)} \Pr[X = x] \log\left(\frac{1}{\Pr[X=x]}\right)$. The conditional entropy of X given Y is the expected remaining uncertainty of X after Y is observed, $H(X|Y) := \sum_{y \in \mathrm{supp}(Y)} \Pr[Y = y] H(X \mid Y = y) = H(X,Y) - H(Y)$. A fundamental property of entropy is that conditioning cannot increase uncertainty: $H(X|Y) \leq H(X)$, with equality holding if and only if X and Y are completely independent.*

▶ **Definition 7** (Mutual Information). *The mutual information between X and Y quantifies the amount of information that observing Y reveals about X (and vice versa), $I(X;Y) := H(X) - H(X|Y) = H(Y) - H(Y|X)$. By definition, mutual information is symmetric and non-negative: $I(X;Y) \geq 0$. The mutual information between X and Y conditioned on a third variable Z is defined as $I(X;Y \mid Z) := H(X|Z) - H(X|Y,Z)$.*

▶ **Lemma 8** (Chain Rules). *Information-theoretic quantities can be decomposed over sequences of random variables using chain rules. For a sequence of random variables $X_1, X_2, \ldots, X_k$, and letting $X_{<i}$ denote the prefix $(X_1, \ldots, X_{i-1})$:*

- ***Chain Rule for Entropy:*** $H(X_1, \ldots, X_k \mid Y) = \sum_{i=1}^{k} H(X_i \mid X_{<i}, Y)$.
- ***Chain Rule for Mutual Information:*** $I(X_1, \ldots, X_k; Y \mid Z) = \sum_{i=1}^{k} I(X_i; Y \mid X_{<i}, Z)$.

▶ **Lemma 9** (Data Processing Inequality). *If X, Y, and Z form a Markov chain $X \to Y \to Z$ (meaning Z is conditionally independent of X given Y), then algorithmic post-processing cannot generate new information: $I(X;Z) \leq I(X;Y)$.*

Because a streaming algorithm's memory state is a function of the stream prefix and internal randomness, the data processing inequality is commonly used to bound the information the algorithm retains about the original input stream.

3.2 Communication Complexity and Information Cost

To lower bound the space complexity of a streaming algorithm, we rely on reductions from multi-party communication games.

▶ **Definition 10** (The Multi-Party One-Way Model). *In the t-player one-way communication model, t players $P_1, P_2, \ldots, P_t$ receive respective inputs $X_1, X_2, \ldots, X_t$ drawn from a joint probability distribution μ. A referee may also receive an independent input y. The players collaborate to compute a joint function $f(X_1, \ldots, X_t, y)$ or solve a decision problem.*

The communication flows strictly one-way: player P_1 computes a message based on their input X_1 and sends it to P_2. Then, P_2 computes a message based on X_2 and the message from P_1, sending it to P_3, and so on. The final player P_t sends a message to the referee, who must output the correct answer.

▶ **Definition 11** (Protocols and Transcripts). *A randomized protocol Π governs the players' message generation. Players may utilize local private randomness as well as a shared* public randomness *string R, which is visible to all participants without incurring communication costs. The* transcript *of the protocol, denoted $\Pi(X)$ (or simply Π), is the concatenation of all messages sent over the channel. The* communication cost *of Π is the worst-case bit-length of its transcript.*

▶ **Definition 12** (Conditional Information Cost). *While traditional communication complexity bounds the raw bit-length of the transcript,* information complexity *measures the actual amount of information the transcript reveals about the inputs. For a protocol* Π *running on inputs* $X \sim \mu$ *and utilizing public randomness* R*, the* conditional information cost *is defined as the mutual information between the inputs and the transcript, conditioned on the public randomness,* $I_\mu(X_1, \ldots, X_t; \Pi \mid R)$*. By Shannon's source coding theorem, the expected communication cost of a protocol is always lower-bounded by its information cost:* $\mathbb{E}[|\Pi|] \geq I_\mu(X; \Pi \mid R)$.

Reduction to streaming space. A streaming algorithm $\mathcal{A}$ evaluated on a stream naturally induces a one-way communication protocol. By partitioning the stream into t contiguous blocks assigned to t players, Player i simulates $\mathcal{A}$ on their block and passes the resulting memory state $\mathcal{M}$ as their message to Player $i+1$. Thus, proving a lower bound on the information cost of a distributed game strictly lower bounds the space complexity of any streaming algorithm capable of solving that game.

3.3 Algorithmic Primitives and Probabilistic Tools

In our upper bound constructions, we utilize the following standard sketching tools and probability structures:

▶ **Lemma 13** (Concentration Inequalities). *We frequently apply standard probability tail bounds to control algorithm failure rates:*

- ***Markov's Inequality:*** *For any non-negative random variable* X *and* $a > 0$, $\Pr[X \geq a] \leq \frac{\mathbb{E}[X]}{a}$.
- ***Chernoff Bound:*** *For a sum of independent indicator variables* $X = \sum_{i=1}^{k} X_i$*, the probability of a large relative deviation is bounded exponentially. For any* $\delta > 0$, $\Pr[X \geq (1+\delta)\mathbb{E}[X]] \leq \exp\left(-\frac{\delta^2 \mathbb{E}[X]}{2+\delta}\right)$ *and* $\Pr[X \leq (1-\delta)\mathbb{E}[X]] \leq \exp\left(-\frac{\delta^2 \mathbb{E}[X]}{2}\right)$.

▶ **Definition 14** (k-wise Independent Hash Functions). *A family of hash functions* $\mathcal{H} = \{h : [n] \to [M]\}$ *is* k-wise independent *if, for any* k *distinct elements* $x_1, \ldots, x_k \in [n]$ *and any target values* $y_1, \ldots, y_k \in [M]$*, a function* h *chosen uniformly at random from* $\mathcal{H}$ *satisfies* $\Pr[h(x_1) = y_1 \wedge \ldots \wedge h(x_k) = y_k] = \frac{1}{M^k}$*. Storing such a function requires only* $O(k \log(\max(n, M)))$ *bits, which provides highly memory-efficient pseudo-randomness. We utilize pairwise (*2*-wise) and* 4*-wise independent hash functions in our sketches.*

▶ **Theorem 15** (AMS Sketch). *[2] There exists a streaming algorithm that uses* $O\left(\frac{1}{\varepsilon^2} \log n\right)$ *bits of space and outputs a* $(1+\varepsilon)$*-approximation to the* F_2 *moment with constant probability.*

We remark that the AMS algorithm utilizes a 4-wise independent hash function $\sigma : [n] \to \{-1, 1\}$ and maintains a linear counter $Z = \sum_{j=1}^{m} \sigma(a_j) = \sum_{i=1}^{n} \sigma(i) f_i$, whose square Z^2 serves as an unbiased estimator for F_2 with bounded variance.

▶ **Theorem 16** (Morris Counters). *[27] There exists a streaming algorithm that outputs a constant-factor approximation to the count of size* n *with constant probability, using* $O(\log \log n)$ *bits of space.*

To track a count up to N, a Morris counter explicitly stores a logarithmic value c (requiring only $O(\log \log N)$ bits). To update the counter, c is incremented with probability 2^{-c}, giving an unbiased estimator for the true count.

▶ **Theorem 17** (F_0 Estimators). *[23, 5] There exists a streaming algorithm that uses $O\left(\frac{1}{\varepsilon^2}\log\frac{1}{\delta}+\log n\right)$ bits of space and with constant probability, outputs a $(1+\varepsilon)$-approximation to the F_0 moment at all points in the stream.*

4 Insertion-Only Lower Bounds for F_2 Estimation

We present a strengthened space lower bound for the problem of F_2 estimation in the insertion-only model, incorporating the optimal dependence on the failure probability δ. The proof strategy closely follows the multi-scale framework introduced by [7], but replaces their underlying communication problem with a robust variant that accounts for error probability.

▶ **Theorem 1.** *Let $\mathcal{A}$ be a streaming algorithm that, for any data stream of length polynomial in n over a universe of size n, computes an estimate $\hat{F}_2$ such that $\Pr[|\hat{F}_2 - F_2| \le \varepsilon F_2] \ge 1-\delta$. For $\varepsilon\sqrt{n} \ge \log\frac{1}{\delta}$, the space used by $\mathcal{A}$ is at least $\Omega\left(\log\left(\frac{\varepsilon\sqrt{n}}{\log\frac{1}{\delta}}\right)\frac{1}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\right)$.*

We utilize standard concepts from information theory. For a communication protocol Π with inputs X drawn from a distribution μ and public randomness R, the conditional information cost is the mutual information $I(X;\Pi(X)|R)$ between the input and the protocol transcript, conditioned on the public randomness. The communication cost of any protocol is an upper bound on its information cost. For a streaming algorithm processing a random stream X, we analyze the information $I(X;\mathcal{M})$ that the memory state $\mathcal{M}$ contains about the stream.

4.1 The Exam Mostly Set Disjointness Problem

The core of the streaming space lower bound in [7] relies on a communication game called "Exam Set Disjointness" (EDISJ). However, EDISJ is highly sensitive to noise; a protocol can fail to identify a unique intersecting element by simply making an error on a single critical coordinate. Consequently, it cannot yield the robust $\Omega(\log(1/\delta))$ information cost bounds required to establish optimal dependencies on the failure probability δ. To overcome this limitation, we introduce a noise-robust variant inspired by the "Mostly Set Disjointness" problem introduced by Kamath et al. [20]. We first define a technical relaxation of disjointness that permits a bounded amount of noise in the sets.

▶ **Definition 18** (κ-Almost-Disjointness). *A collection of sets $S_1,\dots,S_t \subseteq U$ is said to be κ-almost-disjoint if the total number of non-unique element memberships is at most κ. Formally, the number of pairs (i,x) where x appears in S_i and at least one other set S_j is bounded by κ, $\left|\{(i,x)\in[t]\times U : x\in S_i \text{ and } x\in S_j \text{ for some } j\neq i\}\right| \le \kappa$.*

With this relaxation, we define our core communication primitive.

▶ **Definition 19** (Exam Mostly Set Disjointness (EMostlyDISJ)). *The setup involves t players and one referee. Let U be a universe of items. The inputs are sets $S_1,\dots,S_t \subseteq U$ for the players and an element $j\in U$ for the referee. The input sets are promised to satisfy exactly one of two conditions:*

- ***NO Instance:*** *The sets $S_1,\dots,S_t$ are globally κ-almost-disjoint.*
- ***YES Instance:*** *There is a unique element $j_0\in U$ that is common to at least ct of the sets for some constant $c\in(0,1)$, and the remaining elements across the sets are κ-almost-disjoint.*

The communication is one-way from player 1 to player t, and finally to the referee. With failure probability at most δ, the referee must decide if the input is a YES instance and the heavily intersecting element j_0 is exactly equal to the referee's target element j.

4.1.1 The One-Bit Problem: $F_{ct,t}$

To establish the information complexity of EMostlyDISJ, we reduce it to a primitive one-bit problem, much like how standard Set Disjointness reduces to the multi-party AND function.

In the $F_{ct,t}$ problem, each of the t players receives a single bit $Y_i \in \{0,1\}$. Their goal is to distinguish between two cases regarding the Hamming weight of the joint input vector $Y = (Y_1, \ldots, Y_t)$: a NO instance where the Hamming weight is at most 1, and a YES instance where the Hamming weight is at least ct.

We analyze the information cost of this problem with respect to a hard distribution ν over NO instances, adapting the approach of [20]. By bounding the information revealed on NO instances, we can embed many instances of this problem into a continuous stream.

▶ **Definition 20** (Hard Distribution ν). *Let R be a public random variable drawn uniformly from the player indices $[t] = \{1, 2, \ldots, t\}$. The distribution ν over the joint inputs $Y \in \{0,1\}^t$ is defined conditionally based on R: if $R = i$, the input Y is the all-zeros vector 0^t with probability $1/2$, and the standard basis vector e_i (where only the i-th coordinate is 1) with probability $1/2$.*

▶ **Lemma 21** (Conditional Information Cost on ν, adapted from [20]). *Let Π be a one-way communication protocol that solves $F_{ct,t}$ with failure probability at most δ. Let the inputs Y be drawn from the distribution ν. The conditional information cost of the protocol with respect to ν is lower-bounded by $I_\nu(Y; \Pi \mid R) \geq \Omega\left(\min\left(1, \frac{1}{t}\log\left(\frac{1}{\delta}\right)\right)\right)$.*

Proof. Assume without loss of generality that $\delta \leq 1/4$. Lemma 3.7 of [20] establishes a constant lower bound for protocols with sufficiently small error. Specifically, if a protocol has a failure probability δ' that satisfies $t \leq c' \log(1/(2e\delta'))$ for some absolute constant c', then its conditional information cost is bounded below by a constant $I_\nu(Y; \Pi \mid R, C) \geq \Omega(1)$, where C represents the public randomness. If the base protocol's failure probability δ already satisfies this condition ($t \leq c' \log(1/(2e\delta))$), then no amplification is needed. The lower bound is $\Omega(1)$ directly. To handle arbitrary failure probabilities δ, we use an information-theoretic amplification argument. Suppose we have a base protocol Π that fails with probability δ. We construct a boosted protocol Π' by executing Π independently r times using independent private randomness and independent public coins $C_1, \ldots, C_r$, and having the referee output the majority vote of the results. By a standard Chernoff bound, the failure probability of the boosted protocol Π' is bounded by $\delta' \leq (4\delta)^{r/2}$.

We choose the number of repetitions to be $r = \Theta\left(\frac{t}{\log(1/\delta)}\right)$. This ensures that the amplified error δ' is driven down precisely to the threshold required by the condition from [20]. The transcript of the boosted protocol Π' simply consists of r independent transcripts from the base protocol, denoted $(\Pi^1, \ldots, \Pi^r)$. By applying the established lower bound for the small-error regime, we know the information cost of Π' is bounded below by a constant $\Omega(1) \leq I_\nu(\Pi^1, \ldots, \Pi^r; Y \mid R)$. We now decompose this joint information using the chain rule for mutual information, $\Omega(1) \leq \sum_{i=1}^{r} I_\nu(\Pi^i; Y \mid R, C_1, \ldots, C_r, \Pi^{<i})$, where $\Pi^{<i}$ denotes the sequence of transcripts from the first $i-1$ repetitions. By an averaging argument, there must exist at least one index $i \in \{1, \ldots, r\}$ that contributes at least the average amount of information to the sum, $I_\nu(\Pi^i; Y \mid R, C_1, \ldots, C_r, \Pi^{<i}) \geq \frac{\Omega(1)}{r} = \Omega\left(\frac{1}{t}\log\frac{1}{\delta}\right)$. Finally, we decouple this term from the transcripts of the previous repetitions. By expanding the conditional mutual information into Shannon entropies, we have:

$$\begin{aligned} I_\nu(\Pi^i; Y \mid R, C_1, \ldots, C_r, \Pi^{<i}) &= H(\Pi^i \mid R, C_1, \ldots, C_r, \Pi^{<i}) - H(\Pi^i \mid R, C_1, \ldots, C_r, \Pi^{<i}, Y) \\ &\leq H(\Pi^i \mid R, C_i, \Pi^{<i}) - H(\Pi^i \mid R, C_i, Y). \end{aligned}$$

The last inequality holds because the transcripts of separate repetitions are generated using independent private randomness and public coins; thus, conditioned on the exact inputs Y, public randomness C_i and the selector R, Π^i is entirely independent of the previous transcripts $\Pi^{<i}$ and other public coins. Next, we use the fundamental property that conditioning reduces entropy, which implies $H(\Pi^i \mid R, C_i, \Pi^{<i}) \leq H(\Pi^i \mid R, C_i)$. Substituting this upper bound into our equation yields $I_\nu(\Pi^i; Y \mid R, C_1, \ldots, C_r, \Pi^{<i}) \leq H(\Pi^i \mid R, C_i) - H(\Pi^i \mid R, C_i, Y) = I_\nu(\Pi^i; Y \mid R, C_i)$. Because Π^i is identical in distribution to a single invocation of our original protocol Π utilizing public coins C, we conclude that the conditional information cost of the base protocol itself satisfies $I_\nu(\Pi; Y \mid R, C) \geq \Omega\left(\frac{1}{t} \log \frac{1}{\delta}\right)$. This completes the proof. ◀

4.1.2 From Hard Distribution to Product Distribution

To embed instances of the EMostlyDISJ communication game into a continuous streaming algorithm lower bound, we must transition from the artificially correlated hard distribution ν to a fully independent product distribution. We define μ_p as the product distribution over $\{0,1\}^t$ where each bit Y_i is set to 1 independently with probability p. Because data stream elements appear independently, simulating the stream naturally generates inputs drawn from μ_p. The following lemma, adapting a crucial technique from [7], establishes that the information cost lower bound holds even under this independent product distribution, scaling proportionately with p.

▶ **Lemma 22** (Adapted from Lemma 4.4 of [7]). *Let Π be a communication protocol for $F_{ct,t}$ with failure probability at most δ. Let $p < 1/t$. For the independent product distribution μ_p, the information cost of the protocol is lower-bounded by $I_{\mu_p}(Y; \Pi) \geq \Omega\left(p \cdot \min\left(t, \log\left(\frac{1}{\delta}\right)\right)\right)$.*

Proof. We shall define a probabilistic coupling between the product distribution μ_p and the hard distribution ν. We achieve this by introducing an auxiliary indicator variable $D \in \{0,1\}$ that acts as a filter, where conditioning on $D = 1$ forces $Y \sim \mu_p$ to perfectly emulate $Y \sim \nu$.

Step 1: Bounding probabilities under μ_p. First, we evaluate the probabilities of the critical NO instances (the all-zeros vector 0^t and the standard basis vectors e_i) under the product distribution μ_p. Since $p < 1/t$, the probability of observing the all-zeros vector is bounded below by a constant $\mu_p(0^t) = (1-p)^t \geq \left(1 - \frac{1}{t}\right)^t \geq \frac{1}{4}$ (for $t \geq 2$). Similarly, the probability of observing any specific standard basis vector e_i is $\mu_p(e_i) = p(1-p)^{t-1} \geq p\left(1 - \frac{1}{t}\right)^{t-1} \geq \frac{p}{e} \geq \frac{p}{4}$.

Step 2: Constructing the coupling variable D. Recall that under the marginalized hard distribution ν, the probabilities are $\nu(0^t) = 1/2$ and $\nu(e_i) = 1/(2t)$. Because the probabilities of these events under μ_p strictly dominate their relative frequencies under ν (up to a scaling factor), we define a boolean random variable D as a function of $Y \sim \mu_p$ so that:
1. Conditioned on $D = 1$, the distribution of Y is exactly the marginal distribution of ν.
2. The probability of the coupling succeeding is maximized: $\Pr[D = 1] = \Theta(p \cdot t)$.
By Bayes' theorem, ensuring $(Y \mid D = 1) \sim \nu$ requires setting the conditional probabilities as $\Pr[D = 1 \mid Y = y] = \frac{\nu(y) \Pr[D=1]}{\mu_p(y)}$. This is a valid probability assignment as long as the ratio on the right-hand side never exceeds 1. For $y = 0^t$, the ratio $\nu(0^t)/\mu_p(0^t)$ is upper bounded by $(1/2)/(1/4) = 2$. For $y = e_i$, the ratio $\nu(e_i)/\mu_p(e_i)$ is upper bounded by $(1/(2t))/(p/4) = 2/(pt)$. Thus by setting $\Pr[D = 1] = pt/2$, it follows that all conditional probabilities are contained in $[0,1]$ (since $p < 1/t$, the probability for 0^t evaluates to $pt < 1$, and for e_i evaluates to a constant), confirming that $\Pr[D = 1] = \Theta(p \cdot t)$. For all other vectors $y \notin \{0^t, e_1, \ldots, e_t\}$, we simply set $\Pr[D = 1 \mid Y = y] = 0$.

Because D is generated solely based on the realized value of Y, the variables form a Markov chain $D \to Y \to \Pi$. This implies that, conditioned on Y, the protocol transcript Π is entirely independent of D, yielding $I_{\mu_p}(D; \Pi \mid Y, C) = 0$.

Step 3: Chain rule expansion for D. We now use the chain rule for mutual information to relate the information cost under μ_p to the cost conditioned on the coupling success. We expand the joint mutual information $I_{\mu_p}(Y, D; \Pi)$ in two different ways:

$$\begin{aligned} I_{\mu_p}(Y; \Pi \mid C) &= I_{\mu_p}(Y, D; \Pi \mid C) - I_{\mu_p}(D; \Pi \mid Y, C) \\ &= I_{\mu_p}(Y, D; \Pi \mid C) \quad \text{(by the Markov property)} \\ &= I_{\mu_p}(D; \Pi \mid C) + I_{\mu_p}(Y; \Pi \mid D, C) \end{aligned}$$

By the non-negativity of mutual information, $I_{\mu_p}(D; \Pi \mid C) \geq 0$. Thus, we can expand the conditional mutual information over the states of D:

$$\begin{aligned} I_{\mu_p}(Y; \Pi \mid C) &\geq I_{\mu_p}(Y; \Pi \mid D, C) \\ &= \Pr[D = 0] I_{\mu_p}(Y; \Pi \mid D = 0, C) + \Pr[D = 1] I_{\mu_p}(Y; \Pi \mid D = 1, C) \\ &\geq \Pr[D = 1] I_{\mu_p}(Y; \Pi \mid D = 1, C). \end{aligned}$$

Because the distribution of Y conditioned on $D = 1$ is exactly ν, the information cost in this branch is precisely $I_\nu(Y; \Pi \mid C)$. Substituting $\Pr[D = 1] = \Theta(p \cdot t)$, we have $I_{\mu_p}(Y; \Pi \mid C) \geq \Theta(p \cdot t) \cdot I_\nu(Y; \Pi \mid C)$.

Step 4: Chain rule expansion for R. We now have a bound in terms of the unconditional information cost $I_\nu(Y; \Pi \mid C)$. However, our base lower bound from Lemma 21 bounds the *conditional* information cost $I_\nu(Y; \Pi \mid R, C)$. To bridge this gap, we observe the relationship between Y and the public randomness R under ν. If $Y = e_i$, the chosen index must be $R = i$. If $Y = 0^t$, R is uniformly distributed in $[t]$. Therefore, R can be viewed as a randomized function of Y. Consequently, $R \to Y \to \Pi$ forms another Markov chain, meaning R provides no additional information about the transcript Π once Y and C are known. Thus, $I_\nu(R; \Pi \mid Y, C) = 0$. Applying the chain rule again:

$$\begin{aligned} I_\nu(Y; \Pi \mid C) &= I_\nu(Y, R; \Pi \mid C) - I_\nu(R; \Pi \mid Y, C) = I_\nu(Y, R; \Pi \mid C) \\ &= I_\nu(R; \Pi \mid C) + I_\nu(Y; \Pi \mid R, C) \geq I_\nu(Y; \Pi \mid R, C). \end{aligned}$$

Step 5: Putting it all together. We concatenate the inequalities derived in Step 3 and Step 4, and substitute the conditional lower bound from Lemma 21:

$$\begin{aligned} I_{\mu_p}(Y; \Pi \mid C) &\geq \Theta(p \cdot t) \cdot I_\nu(Y; \Pi \mid R, C) \geq \Theta(p \cdot t) \cdot \Omega\left(\min\left(1, \frac{1}{t} \log \frac{1}{\delta}\right)\right) \\ &= \Omega\left(p \cdot \min\left(t, \log \frac{1}{\delta}\right)\right). \end{aligned}$$

This establishes the required information cost bound for the independent product distribution. ◀

4.1.3 Direct Sum for EMostlyDISJ

We now apply an information-theoretic direct sum argument, following the framework of Braverman and Zamir [7], to lift the $\Omega(p \log(1/\delta))$ lower bound from the independent 1-bit $F_{ct,t}$ instances to the full EMostlyDISJ problem. Let m be the total set size parameter across all players. To suppress spurious collisions and simulate disjointness, we assume the abstract universe U is exceptionally large, specifically $|U| \geq m^4$. We set the independent inclusion probability for our product distribution to $p = m/(2t|U|)$. Before executing the direct sum, we must guarantee that sampling sets independently under μ_p naturally generates inputs that satisfy the NO instance promise of EMostlyDISJ: namely, that the resulting sets are κ-almost-disjoint with overwhelmingly high probability.

▶ **Proposition 23.** *Let U be a universe of size $|U| \geq m^4$. Suppose t players construct sets $S_1, \ldots, S_t$ such that each S_i is chosen uniformly and independently at random from all subsets of U of size exactly m/t. With probability at least $1 - \delta$, the resulting collection of sets is κ-almost-disjoint, where $\kappa = O(\log(1/\delta))$.*

Proof. We upper bound the probability of having too many non-disjoint coordinates, which we call an *overlap* and occurs when an element $u \in U$ is chosen by two or more players. Because each of the t players draws a set of size exactly m/t, the total number of slots draws across all players is exactly m. For κ slots out of the m total slots to be non-unique, they must form at least $\kappa/2$ colliding pairs. We construct a union bound over all possible ways this could occur:

1. There are $\binom{m}{\kappa}$ ways to select which κ specific slots will be involved in the collisions.
2. For each of these κ slots, we must specify a collision partner from the m total slots, giving at most m^κ possible partner assignments.
3. Forming these partner assignments forces at least $\kappa/2$ equality constraints between the slots. We upper bound the probability of satisfying a specific set of $\kappa/2$ equalities. The total number of valid ways to assign elements to the m slots, drawing s items without replacement for each of the t players, is exactly $\left(\frac{|U|!}{(|U|-s)!}\right)^t \geq (|U|-s)^m$. The number of assignments satisfying the $\kappa/2$ equalities is at most $|U|^{m-\kappa/2}$, because the equalities group the m slots into at most $m - \kappa/2$ connected components, and each component can take at most $|U|$ values. Thus, the probability of satisfying a specific set of $\kappa/2$ equalities is at most $\frac{|U|^{m-\kappa/2}}{(|U|-s)^m} = \frac{1}{|U|^{\kappa/2}} \left(\frac{|U|}{|U|-s}\right)^m$. Since $|U| \geq m^4$ and $s \leq m$, we have $\left(\frac{|U|}{|U|-s}\right)^m = \left(1 + \frac{s}{|U|-s}\right)^m \leq e^{sm/(|U|-s)}$. Since $|U| - s \geq m^4 - m \geq m^2$, the exponent is at most $sm/(|U|-s) \leq m^2/m^2 = 1$. Therefore, the probability of satisfying any specific set of $\kappa/2$ equality constraints is at most $e/|U|^{\kappa/2}$.

Multiplying these factors together, the probability of observing at least κ overlaps is upper bounded by $\binom{m}{\kappa} m^\kappa \frac{e}{|U|^{\kappa/2}} \leq e \left(\frac{em}{\kappa}\right)^\kappa \left(\frac{m^2}{|U|}\right)^{\kappa/2} = e \left(\frac{em^2}{\kappa\sqrt{|U|}}\right)^\kappa$. Substituting our universe size assumption $|U| \geq m^4$ implies $\sqrt{|U|} \geq m^2$. Thus, the probability is at most $e \left(\frac{e}{\kappa}\right)^\kappa$. By setting $\kappa = C \log(1/\delta)$ for a sufficiently large constant C, it follows that the probability is at most $O(\delta)$. Thus, the uniformly sampled fixed-size sets are globally κ-almost-disjoint with probability at least $1 - \delta$. ◀

With the promise condition satisfied, we establish the final communication lower bound by synthesizing $|U|$ parallel games.

▶ **Corollary 24.** *Let $\kappa = O(\log(1/\delta))$ and assume $t = \Omega\left(\log \frac{1}{\delta}\right)$ and $te^{-m/(6t)} \leq \delta$. Let Π be a one-way communication protocol of worst-case transcript length C_Π, utilizing public coins C, that solves the t-party EMostlyDISJ problem with failure probability at most $O(\delta)$, total set size parameter m, almost-disjointness parameter κ, and universe size $|U| \geq m^4$. Let $\beta := \Pr[F = 1] \leq te^{-m/(6t)}$ be the abort probability. The conditional information cost of the protocol satisfies $I_\mu(\Pi; X' \mid C) \geq \frac{\Omega\left(\frac{m}{t}\log\left(\frac{1}{\delta}\right)\right) - h_2(\beta) - \beta(C_\Pi+1)}{1-\beta}$, where h_2 is the binary entropy function.*

Proof. We employ the direct sum reduction formalized in Section 4.2 of [7]. We consider $|U|$ parallel, independent instances of the 1-bit problem $F_{ct,t}$. Let the input matrix $Y \in \{0,1\}^{t\times|U|}$ consist of columns Y^j drawn i.i.d. from the product distribution μ_p, where $p = m/(2t|U|)$.

We construct a protocol Π' that solves these parallel instances by simulating the EMostlyDISJ protocol Π. Each player i locally constructs a preliminary set $S'_i = \{j \in U : Y_i^j = 1\}$. Because $Y_i^j \sim \text{Bern}(p)$, the expected size of this set is $\mathbb{E}[|S'_i|] = p|U| = m/(2t)$.

If any player's set size exceeds double its expectation ($|S'_i| > m/t$), the reduction immediately aborts and declares a failure (Event F). Otherwise, player i pads S'_i up to a size of exactly m/t using dummy elements drawn uniformly at random without replacement from the unselected elements of the common universe $U \setminus S'_i$. Let $X' = (S_1, \ldots, S_t)$ be the resulting collection of padded sets. The players then execute $\Pi(X')$.

Step 1: Bounding failure and error. By a standard Chernoff bound, the probability that a single player's set exceeds m/t is at most $e^{-m/(6t)}$. By a union bound over all t players, the probability of the failure event F is bounded by $\beta := \Pr[F = 1] \leq te^{-m/(6t)}$. By adjusting constants appropriately in our parameter assumptions, $\beta \leq \delta$. Provided F does not occur, Lemma 4.6 of [7] guarantees that the resulting compound protocol Π' correctly solves the embedded instances with high probability. The total error probability of Π' is upper bounded by $O(\delta)$. Crucially, because the initial Bernoulli process treats all elements of U symmetrically, padding uniformly from the unselected elements guarantees that the resulting set S_i is distributed uniformly over all subsets of U of size m/t. Because the players pad independently, conditioned on $F = 0$, the collection X' matches the distribution μ of independent, uniform fixed-size subsets. Because the universe size is $|U| \geq m^4$, Proposition 23 applies directly to the padded sets X'. Thus, with probability at least $1 - \delta$, the constructed sets satisfy the κ-almost-disjointness promise.

Step 2: Direct sum over independent instances. Because the columns Y^j are drawn completely independently under μ_p, the mutual information between the full matrix Y and the transcript Π' decomposes linearly via the super-additivity of independent inputs $I(Y;\Pi') \geq \sum_{j\in U} I(Y^j;\Pi')$. Applying our 1-bit lower bound from Lemma 22 to each instance, we aggregate the information $I(Y;\Pi') \geq |U| \cdot \Omega\left(p\log\left(\frac{1}{\delta}\right)\right) = |U| \cdot \Omega\left(\frac{m}{2t|U|}\log\left(\frac{1}{\delta}\right)\right) = \Omega\left(\frac{m}{t}\log\left(\frac{1}{\delta}\right)\right)$.

Step 3: Relating to the original protocol. Finally, we must relate the unconditional information cost $I(Y;\Pi')$ of the simulated inputs back to the actual conditional information cost $I_\mu(\Pi; X') = I(\Pi'; X' \mid F = 0)$ of the base protocol operating on the padded sets.

Conditioned on $F = 0$, the symmetric random padding from the common universe U ensures the padded sets match the distribution μ of independent uniform fixed-size subsets. Moreover, conditioned on X', $F = 0$, and the public coins C, the transcript is generated only from X' and the protocol's private coins. Hence, $Y \to X' \to \Pi'$ is a Markov chain,

which implies by the data processing inequality $I(Y;\Pi' \mid F=0,C) \le I(X';\Pi' \mid F=0,C) = I_\mu(\Pi;X' \mid C)$. We expand the mutual information $I(Y;\Pi' \mid C)$ using the chain rule over the abort indicator F:

$$\begin{aligned} I(Y;\Pi' \mid C) &\le I(Y;\Pi',F \mid C) = I(Y;F \mid C) + I(Y;\Pi' \mid F,C) \\ &\le h_2(\beta) + (1-\beta)I(Y;\Pi' \mid F=0,C) + \beta I(Y;\Pi' \mid F=1,C). \end{aligned}$$

Let C_Π be the worst-case bit length of the transcript of Π. Even on an abort ($F=1$), we can pad the compound transcript to length $C_\Pi+1$. Thus, the conditional mutual information $I(Y;\Pi' \mid F=1)$ is upper bounded by $C_\Pi+1$. Substituting these bounds into our expansion, we have $I(Y;\Pi' \mid C) \le h_2(\beta) + (1-\beta)I_\mu(\Pi;X' \mid C) + \beta(C_\Pi+1)$. Rearranging the terms to isolate $I_\mu(\Pi;X')$, we have $I_\mu(\Pi;X' \mid C) \ge \frac{I(Y;\Pi'|C) - h_2(\beta) - \beta(C_\Pi+1)}{1-\beta}$. Substituting the main term $I(Y;\Pi' \mid C) \ge \Omega\left(\frac{m}{t}\log\left(\frac{1}{\delta}\right)\right)$ from Step 2, we obtain the lower bound $I_\mu(\Pi;X' \mid C) \ge \frac{\Omega\left(\frac{m}{t}\log\left(\frac{1}{\delta}\right)\right) - h_2(\beta) - \beta(C_\Pi+1)}{1-\beta}$. This concludes the direct sum. ◀

4.2 F_2 Estimation Lower Bound via Multi-Scale Reduction

We now employ the multi-scale reduction framework of [7] (Section 5) using EMostlyDISJ as the building block.

4.2.1 Reduction from EMostlyDISJ to F_2

We first generalize the reduction in Section 5.1 of [7] to EMostlyDISJ and allow for flexible parameters t. Note that this section describes the construction for a *single level* (i.e., a single instance of the game played with exactly t players); in the next section, we will embed multiple such levels simultaneously. Fix n,ε. Let $2 \le t \le \varepsilon\sqrt{n}/2$. Define the super-element size $d := \lfloor \frac{\varepsilon^2 n}{4t^2} \rfloor \ge 1$. We reduce from a single instance of EMostlyDISJ$_t$. The abstract universe of items for this game is instantiated as U^d (where each abstract item is a super-element, defined as a d-tuple of distinct elements from a base stream universe U). The total set size parameter m from the previous section (which bounds the total number of abstract items distributed across all players' sets) is set to $m = \lfloor n/(4d) \rfloor = \Theta(t^2/\varepsilon^2)$. We set the almost-disjointness parameter to $\kappa = O(\log(1/\delta))$.

Given an instance $X = (S_1,\dots,S_t,x) \in (U^d)^t \times U^d$, we construct a stream $s(X)$ of base items from U. This implicitly defines a frequency vector $v \in \mathbb{N}^{|U|}$, where each coordinate v_u records the exact number of times base item $u \in U$ appears in the stream. First, we concatenate the elements of the players' sets S_i: each super-element is "unzipped" and its d distinct constituent base elements from U are written to the stream. Since there are at most m super-elements across all players, this contributes $md \le n/4$ base items to the stream. Finally, we append the referee's target super-element x by writing its d base elements repeatedly $k = \lceil t/\varepsilon \rceil$ times. Because $k = \lceil t/\varepsilon \rceil$ and $d \le \frac{\varepsilon^2 n}{4t^2}$, we have $dk \approx \frac{\varepsilon n}{4t} \le n/4$. The total stream length is upper bounded by $md + dk \le n/4 + n/4 \le n$.

▶ **Definition 25** (ζ-Base-Separation). *A stream built from an instance X is ζ-base-separated if the number of non-unique base-element memberships arising from coordinates of distinct abstract items is at most ζ.*

▶ **Lemma 26** (Adapted from Lemma 5.2 of [7]). *If $t \ge C_1 \log\frac{1}{\delta}$ and $\kappa \le C_2 \log\frac{1}{\delta}$ for sufficiently large constants $C_1 > C_2$, and the stream is ζ-base separated for $\zeta \le C_2 \log\frac{1}{\delta}$, then a $(1 \pm \Theta(\varepsilon))$-approximation to $F_2(s(X))$ solves any valid instance X of EMostlyDISJ$_t$ where the total number of base element collisions is at most κ.*

Proof. We analyze the gap in the second frequency moment $F_2(v) = \sum_{u \in U} v_u^2$ between YES and NO instances. For simplicity, we assume $c = 1/2$ and $\gamma \leq \kappa$. Let F_{bg} denote the F_2 contribution from the background base items (all items not belonging to the referee's target x or the heavy element j_0). By assumption, the total number of base element collisions is at most κ. Because the m super-elements contribute $md \leq n/4$ base items, then we have $F_{bg} \leq d(\kappa+1)^2 + n/4 \leq n/4 + \mathcal{O}(d\kappa^2)$. We now distinguish the YES instance from two logically distinct NO instances.

In the first NO case, the input sets are κ-almost disjoint, and the referee's target x is repeated $k = \lceil t/\varepsilon \rceil$ times. The target x appears at most κ times among the players. Including additional collisions, the d coordinates of the target reach a frequency of at most $k + 2\kappa$. Hence, we have $F_2(\mathrm{NO}_1) \leq F_{bg} + d(k+2\kappa)^2 \leq n/4 + dk^2 + O(dk\kappa + d\kappa^2)$.

In the second NO case, there is a heavy element j_0 appearing $t/2$ times, but the referee's target is a different element x appearing k times. Because x and j_0 are distinct super-elements, their base coordinates are completely disjoint except for the additional collisions, which occur at most κ times. Thus, the d coordinates of j_0 have frequency at most $t/2 + \kappa$, and the d coordinates of x have frequency at most $k + \kappa$. Hence, we have $F_2(\mathrm{NO}_2) \leq F_{bg} + d(t/2+\kappa)^2 + d(k+\kappa)^2 \leq n/4 + d\left(\frac{t^2}{4} + k^2\right) + O(dt\kappa + dk\kappa + d\kappa^2)$.

In a YES instance, the heavy element j_0 is exactly the referee's target x. The d target coordinates appear at least $t/2$ times from the players and k times from the referee, reaching a frequency of $t/2+k$. Then we have $F_2(\mathrm{YES}) \geq F'_{bg} + d\cdot(t/2+k)^2 \geq n/4 - d(t/2) + d\cdot(t/2+k)^2$. Here, $F'_{bg} \geq n/4 - d(t/2)$ accounts for the target items being removed from the background calculation, assuming the total size of the players' sets is exactly m.

Observe that the F_2 moment for the NO instance is maximized in Case 2, and so the additive gap between the YES case and the NO case is at least:

$$\begin{aligned}
\Delta F_2 &= F_2(\mathrm{YES}) - F_2(\mathrm{NO}_2) \\
&\geq d \cdot [(t/2+k)^2 - (t/2+\kappa)^2 - (k+\kappa)^2] - O(dt\kappa + dk\kappa + d\kappa^2) - dt/2 \\
&= d \cdot [(t/2)^2 + tk + k^2 - (t/2)^2 - t\kappa - \kappa^2 - k^2 - 2k\kappa - \kappa^2] - O(dt\kappa + dk\kappa + d\kappa^2) - dt/2 \\
&= d \cdot [tk - O(t\kappa) - O(k\kappa) - O(\kappa^2) - O(t)].
\end{aligned}$$

Substituting $k = \lceil t/\varepsilon \rceil$ and $d = \lfloor \varepsilon^2 n/(4t^2) \rfloor$, we have $\Delta F_2 \geq \frac{\varepsilon^2 n}{4t^2} \cdot \left[\frac{t^2}{\varepsilon} - O\left(\frac{\kappa t}{\varepsilon}\right)\right]$. The dominant term is $\frac{\varepsilon^2 n}{4t^2} \cdot \frac{t^2}{\varepsilon} = \frac{\varepsilon n}{4}$. The subtracted negative terms are negligible, since $t^2/\varepsilon \gg \kappa t/\varepsilon$ for $t \geq C_1 \log \frac{1}{\delta}$ and $\kappa \leq C_2 \log \frac{1}{\delta}$ for sufficiently large constants $C_1 > C_2$. We also need $t^2/\varepsilon \gg t^2$, which holds for $\varepsilon < 1$. If $t \geq C \log(1/\delta)$, the additive gap remains $\Delta F_2 = \Omega(\varepsilon n)$.

To establish that this additive gap translates to a strict $(1+\Omega(\varepsilon))$-multiplicative factor, we bound the maximum value of $F_2(\mathrm{NO}_2)$. By our parameter choices, the referee's isolated squared contribution is $dk^2 \approx \left(\frac{\varepsilon^2 n}{4t^2}\right)\frac{t^2}{\varepsilon^2} = \Theta(n)$. Since $F_{bg} \leq n/4 + O(\kappa^2)$, it follows that $F_2(\mathrm{NO}_2) \leq n/4 + \Theta(n) + o(n) = \Theta(n)$. Since the baseline is $F_2(\mathrm{NO}_2) = \Theta(n)$ and the additive gap is $\Delta F_2 = \Omega(\varepsilon n)$, the multiplicative ratio between the instances is $\frac{F_2(\mathrm{YES})}{F_2(\mathrm{NO}_2)} \geq \frac{F_2(\mathrm{NO}_2)+\Omega(\varepsilon n)}{F_2(\mathrm{NO}_2)} = 1 + \Omega\left(\frac{\varepsilon n}{n}\right) = 1 + \Omega(\varepsilon)$. Because the YES and NO cases differ by a $(1+\Omega(\varepsilon))$-multiplicative factor, any streaming algorithm providing a $(1 \pm c\varepsilon)$-relative approximation to F_2 (for a sufficiently small constant c) will successfully distinguish between the two cases, solving the single-level EMostlyDISJ$_t(X)$ instance. ◀

A streaming algorithm $\mathcal{A}$ for F_2 naturally induces a communication protocol Π for EMostlyDISJ$_t$, where player i simulates $\mathcal{A}$ on their part of the stream and passes the memory state to player $i+1$. The total communication is $t \cdot \mathrm{Space}(\mathcal{A})$.

4.2.2 The Multi-Scale Construction and Direct Sum

We now employ the multi-scale reduction framework of [7] (Section 5.2). We define levels l, where $t_l = 2^l$, and conceptually embed an instance of EMostlyDISJ$_{t_l}$ at each level.

We define a range of "good" levels. A level l is good if t_l satisfies the necessary conditions for both the F_2 reduction and the communication lower bound:

1. $t_l \leq \varepsilon\sqrt{n}/2$ (Ensures the super-element size $d_l \geq 1$).
2. $t_l \geq C\log(1/\delta)$ (Ensures the F_2 gap is distinguishable, Lemma 26).
3. $\delta \geq t_l e^{-m_l/(6t_l)}$ (Condition for Corollary 24). Since $m_l/t_l = \Theta(t_l/\varepsilon^2)$, this requires $t_l/\varepsilon^2 \geq \Omega(\log(t_l/\delta))$.

The number of good levels L is approximately $\log_2(\varepsilon\sqrt{n}) - \log_2(C'\max(1,\varepsilon^2)\log(1/\delta))$. Assuming standard parameter regimes where ε is small, this yields $L = \Omega(\log(\frac{\varepsilon\sqrt{n}}{\log(1/\delta)}))$. A naïve concatenation of these instances would result in a stream of length $\omega(n\log n)$, which would artificially inflate the space bounds. To embed these instances without increasing the total stream length beyond n, the construction interleaves them implicitly within a single continuous stream. The information cost is analyzed over a stream drawn from a distribution $\mathcal{E}$, where n base elements are chosen uniformly and independently from U.

To upper bound element repetitions across instances, we set the base universe size to $|U| = n^3$. Let $\mathcal{E}_{coll}$ be the event that there are fewer than $\kappa = C_1\log\frac{1}{\delta}$ collisions in the entire stream of length n. Note that since the expected number of collisions is $\mu \leq \binom{n}{2}/n^3 < \frac{1}{2n}$, then by standard tail bounds, the probability of κ or more collisions is at most $O(\delta)$. Hence, for the remainder of the section, we condition on the event $\mathcal{E}_{coll}$. Now, because the stream consists of independent random variables, it can be analyzed at multiple scales simultaneously. For any level l, partitioning the stream into contiguous blocks of size n/t_l to form d_l-tuples naturally generates a valid NO instance for the t_l-player EMostlyDISJ game. However, before bounding the information measure, we must reconcile a subtle distributional difference between the multiscale stream and the communication game of Corollary 24. The communication inputs X' are fixed-size sets drawn *without replacement* from the universe U^{d_l}, whereas the continuous multiscale stream generates d_l-tuples *with replacement*.

▶ **Lemma 27** (Distributional Coupling). *Let $\mathcal{D}_{stream}$ be the distribution of a single active stream block at level l, consisting of m_l abstract d_l-tuples drawn i.i.d. with replacement from U^{d_l}. Let $\mathcal{D}_{game}$ be the exact communication distribution from Corollary 24, which generates sets without replacement. For any streaming algorithm's memory state M processing the stream $X \sim \mathcal{D}_{stream}$, the mutual information satisfies $I(X;M) \geq \left(1-\frac{1}{n}\right)\cdot I(X_{game};M)$, where $X_{game} \sim \mathcal{D}_{game}$.*

Proof. Let E be the event that the sequence of m_l items drawn from U^{d_l} contains no duplicate tuples within each player. Conditioned on E, a sequence drawn i.i.d. with replacement is identical to a uniform sequence drawn without replacement. Thus, $(X \mid E) \sim \mathcal{D}_{\text{game}}$. Because we set the base universe size to $|U| \geq n^3$ and $d_l \geq 1$, the abstract universe size is $|U^{d_l}| = |U|^{d_l} \geq n^3$. The total number of abstract items drawn across all t_l players in the instance is $m_l \leq n$. Hence, the probability of drawing a duplicate is at most $\Pr[\neg E] \leq \frac{m_l^2}{2|U^{d_l}|} \leq \frac{n^2}{2n^3} \leq \frac{1}{2n} \leq \frac{1}{n}$. To lower bound the information cost, we use the chain rule for mutual information. Let I_E be the binary indicator of event E. Expanding $I(X, I_E; M)$ in two ways, we have $I(X;M) + I(I_E;M \mid X) = I(I_E;M) + I(X;M \mid I_E)$. Since I_E is a deterministic function of X, we have $H(I_E \mid X) = 0$ and hence $I(I_E;M \mid X) = 0$. Since mutual information is non-negative, $I(I_E;M) \geq 0$. Thus $I(X;M) \geq I(X;M \mid I_E)$. Expanding the conditional mutual information over the states of I_E, $I(X;M \mid I_E) =$

$\Pr[E] \cdot I(X; M \mid E) + \Pr[\neg E] \cdot I(X; M \mid \neg E) \geq \Pr[E] \cdot I(X; M \mid E)$. Conditioned on E, the input is distributed as $\mathcal{D}_{\text{game}}$ and the memory state is produced by the same algorithm, so the joint law of (X, M) given E equals that of (X_{game}, M); hence $I(X; M \mid E) = I(X_{\text{game}}; M)$. Substituting $\Pr[E] \geq 1 - 1/n$ gives the desired claim. ◀

We use the information measures defined by [7]. Let X be the random stream and M_j the memory state of the algorithm after processing index j.

▶ **Definition 28** (Definition 5.6 of [7]). *For level l, with $t_l = 2^l$, define the information measure $I_l := \sum_{j=1}^{n} I\left(X_{(j-\frac{n}{2^l}, j-\frac{n}{2^{l+1}})}; M_j \mid M_{j-\frac{n}{2^l}}\right)$.*

This measure sums over all time steps j to capture the total information the algorithm must retain about the past stream segments relevant to scale l.

▶ **Lemma 29** (Adapted from Lemma 5.7 of [7]). *Let S be the worst-case space (in bits) of the streaming algorithm. For each good level l, the information measure I_l satisfies $I_l \geq \Omega\left(\frac{n}{\varepsilon^2} \log \frac{1}{\delta}\right) - O(n\beta_l S) - O\left(\frac{n}{t_l} h_2(\beta_l)\right)$.*

Proof. Following the structure of Lemma 5.7 in [7], we lower bound I_l by tracking the number of independent instances of EMostlyDISJ_{t_l} that can be embedded within the stream. For a fixed level l, simulating a single instance of the game requires t_l players sequentially passing the memory state of the streaming algorithm, corresponding to t_l stream blocks of length n/t_l. Because the streaming algorithm uses at most S bits of space, the induced communication protocol has a worst-case transcript length $C_{\Pi_l} \leq t_l S$. Evaluating this instance requires examining the sequence of memory states M_j spaced at intervals of exactly n/t_l. However, this sequence of memory states need not begin at index 1. Because the stream elements are drawn independently, shifting the starting index of these intervals yields disjoint set of indices j defining I_l, and thus independent communication games. Since this starting offset can be shifted exactly n/t_l times before the blocks begin to overlap, [7] identified $\Omega(n/t_l)$ disjoint sequences of indices $j_1, \ldots, j_{t_l}$ that serve as independent parallel transcripts for the EMostlyDISJ_{t_l} instances at that level. By Corollary 24 (and noting $1/(1-\beta_l) \leq O(1)$ since $\beta_l \leq \delta \leq 1/2$), the conditional information cost to solve one such instance is $\Omega(\frac{m_l}{t_l} \log(1/\delta)) - O(\beta_l C_{\Pi_l}) - O(h_2(\beta_l))$. Substituting $m_l = \Theta(t_l^2/\varepsilon^2)$ from our parameter choice and $C_{\Pi_l} \leq t_l S$, the cost per instance becomes $\Omega(\frac{t_l}{\varepsilon^2} \log(1/\delta)) - O(\beta_l t_l S) - O(h_2(\beta_l))$.

To lower bound the information cost of a single embedded instance, we apply the conditioning argument required by Lemma 27. Let $X \sim \mathcal{D}_{\text{stream}}$ be the stream instance. The coupling guarantees $I(X; \Pi) \geq \left(1 - \frac{1}{n}\right) \cdot I(X_{\text{game}}; \Pi)$. Because the streaming algorithm guarantees a failure probability of at most δ on *any* valid input sequence, it fails on the communication game on the conditional distribution X_{game} with probability less than δ. Thus, Corollary 24 applies directly to $I(X_{\text{game}}; \Pi)$, so that $I(X_{\text{game}}; \Pi) \geq \Omega\left(\frac{m_l}{t_l} \log \frac{1}{\delta}\right) - O(\beta_l C_{\Pi_l}) - O(h_2(\beta_l))$. Substituting $m_l = \Theta(t_l^2/\varepsilon^2)$ and $C_{\Pi_l} \leq t_l S$, the expected information cost per instance under $\mathcal{D}_{\text{stream}}$ is lower bounded by $\left(1 - \frac{1}{n}\right)\left[\Omega\left(\frac{t_l}{\varepsilon^2} \log \frac{1}{\delta}\right) - O(\beta_l t_l S) - O(h_2(\beta_l))\right]$.

Now, using Lemma 3.2 of [7] (a chain rule for streaming mutual information), the total information cost I_l is lower bounded by the sum of the costs of these independent interleaved instances. Therefore:

$$
\begin{aligned}
I_l &\geq (\text{Number of independent instances}) \times (\text{Information cost per instance}) \\
&\geq \Omega\left(\frac{n}{t_l}\right) \times \left[\Omega\left(\frac{t_l}{\varepsilon^2} \log \frac{1}{\delta}\right) - O(\beta_l t_l S) - O(h_2(\beta_l))\right] \\
&= \Omega\left(\frac{n}{\varepsilon^2} \log \frac{1}{\delta}\right) - O(n\beta_l S) - O\left(\frac{n}{t_l} h_2(\beta_l)\right).
\end{aligned}
$$

Observe that the dependence on t_l cancels out in the main term. This gives a uniform lower bound on the required information cost across all good levels, independent of the number of players involved at scale l. ◀

The final step is the innovative direct sum argument over dependent instances developed by [7]. They define the average information stored by the algorithm:

▶ **Definition 30** (Definition 5.9 of [7]). $\bar{I} := \frac{1}{n}\sum_{j=1}^{n} I(X_{<j}; M_j)$.

They prove that the information measures I_ℓ from different scales essentially add up, even though the underlying problems are dependent.

▶ **Lemma 31** (Lemma 5.10 of [7]). $\bar{I} \geq \frac{1}{n}\sum_{\ell \in Good} I_\ell$.

Proof. This follows from Lemma 5.8 of [7], which uses the chain rule to show that for any j, $I(X_{<j}; M_j)$ is lower bounded by the sum over ℓ of the information M_j has about the specific past segment relevant to level ℓ, conditioned on the memory state corresponding to the beginning of that segment. This relies on the observation that these past segments are disjoint for different ℓ. Summing over j and reordering yields the result. ◀

Proof of Theorem 1. Let S be the space required by the algorithm. This space is at least the maximum information stored, which is at least the average information $\bar{I}$ (Observation 3.1 in [7]), so $S \geq \bar{I}$. By combining Lemma 29 and Lemma 31:

$$S \geq \bar{I} \geq \frac{1}{n}\sum_{\ell \in \text{Good}} I_\ell \geq \frac{1}{n}\sum_{\ell \in \text{Good}} \left[\Omega\left(\frac{n}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\right) - O(n\beta_\ell S) - O\left(\frac{n}{t_\ell}h_2(\beta_\ell)\right)\right]$$

$$= (\text{Number of Good Levels}) \cdot \Omega\left(\frac{1}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\right) - S\sum_{\ell \in \text{Good}} O(\beta_\ell) - \sum_{\ell \in \text{Good}} O\left(\frac{h_2(\beta_\ell)}{t_\ell}\right).$$

The number of good levels is $L = \Omega(\log(\frac{\varepsilon\sqrt{n}}{\log(1/\delta)}))$. Observe that the abort probabilities $\beta_\ell \leq t_\ell e^{-m_\ell/(6t_\ell)}$ decay exponentially across the dyadic levels since $m_\ell/t_\ell = \Theta(t_\ell/\varepsilon^2)$. Thus, by choosing constants appropriately, we ensure that the aggregated defect sum is bounded by a fraction: $\sum_{\ell \in \text{Good}} O(\beta_\ell) \leq 1/2$. The entropy penalty sum is similarly upper bounded by a negligible constant $O(1)$. Substituting these bounds into our inequality yields $S \geq \Omega\left(\log\left(\frac{\varepsilon\sqrt{n}}{\log\frac{1}{\delta}}\right)\frac{1}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\right) - \frac{1}{2}S - O(1)$. Thus, we conclude $S \geq \Omega\left(\log\left(\frac{\varepsilon\sqrt{n}}{\log\frac{1}{\delta}}\right)\frac{1}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\right)$. ◀

5 Improved Algorithms

5.1 Bounded Frequencies

We present an ℓ_2-estimation algorithm for insertion-only streams where the frequencies are bounded by B. The goal is to achieve a space complexity where the dependence on B is only logarithmic, and the dependence on n is also logarithmic, independent of $1/\varepsilon^2$.

▶ **Theorem 32.** *Let $x \in \mathbb{Z}^n_{\geq 0}$ be the frequency vector of an insertion-only stream of length m. Suppose that $0 \leq x_i \leq B$ for all $i \in [n]$. Then there exists a streaming algorithm that, with probability at least $1-\delta$, computes a $(1\pm\varepsilon)$-approximation to $\|x\|_2^2$ using space (in bits) $O\left(\frac{1}{\varepsilon^2}\log^2\frac{B}{\varepsilon}\log\frac{1}{\delta}\left(\log B + \log\frac{1}{\varepsilon}\right)\right) + O\left(\log\frac{n}{\delta}\right)$.*

Proof. The strategy is to use subsampling to reduce the effective dimension of the problem to a size that depends polynomially on B and $\frac{1}{\varepsilon}$, but only logarithmically on n. Then, we apply an efficient ℓ_2 estimator on this reduced stream. We use pairwise independent hash

functions $h : [n] \to [2^L]$ (where $L = O(\log n)$). We define levels of sampling based on the number of trailing zeros in the hash value $h(i)$. Let $z(i)$ be the number of trailing zeros of $h(i)$. We aim to find a sampling level ℓ such that the expected number of distinct items i with $z(i) \geq \ell$ is approximately K, where $K = \Theta\left(\frac{B^2}{\varepsilon^2}\right)$, independent of δ.

We first utilize a continuous F_0 tracking algorithm [23] to estimate the total number of distinct elements F_0. By setting the failure probability of the F_0 estimator to $\delta/\log n$, we may assume that it yields a constant-factor approximation to F_0 at all times throughout the stream. Let $F_{0,t}$ be the number of non-zero entries at time t of the stream, and let $\hat{F}_{0,t}$ be the corresponding estimator. We first describe a two-pass version of our algorithm, and then explain how to extend it to a single pass.

A two-pass algorithm. On the first pass, we compute the final estimate $\hat{F}_0$. We choose the sampling level ℓ such that $2^\ell \approx \hat{F}_0/K$. This ensures that the expected number of items surviving the sampling is within a constant factor of K. Let S be the set of surviving coordinates: $S = \{i \in [n] \mid z(i) \geq \ell\}$. The expected size of S is roughly $F_0/2^\ell \approx K$.

We define the natural inverse-probability estimator based on the sampled set S, so that $Y = 2^\ell \sum_{i \in S} x_i^2 = \frac{1}{p} \sum_{i \in S} x_i^2$, where $p = 2^{-\ell}$. Since Y is a standard sampling estimator and elements are sampled pairwise independently, its expectation is $\mathbb{E}[Y] = \|x\|_2^2$, and its variance is upper bounded by $\mathrm{Var}(Y) \leq \frac{1-p}{p} \sum_{i=1}^n x_i^4 \leq \frac{1}{p}\|x\|_4^4$. Since the frequencies are upper bounded by B ($x_i \leq B$), we have $\|x\|_4^4 \leq B^2\|x\|_2^2$, which implies $\mathrm{Var}(Y) \leq \frac{B^2}{p}\|x\|_2^2$.

To achieve our $(1 \pm \varepsilon)$ guarantee, Chebyshev's inequality implies that it suffices to have $\mathrm{Var}(Y) \leq \varepsilon^2\|x\|_2^4$. This holds if $p \geq \Omega\left(\frac{B^2}{\varepsilon^2\|x\|_2^2}\right)$. Since all non-zero entries are at least 1, $\|x\|_2^2 \geq F_0$. Therefore, it suffices to set $p \geq \Omega\left(\frac{B^2}{\varepsilon^2 F_0}\right)$. Our choice of ℓ, which ensures $p \approx K/\hat{F}_0$, guarantees this condition when the constants are set appropriately. Thus, a single sampling instance gives a $(1 \pm \varepsilon)$-approximation with constant probability, e.g., $7/8$. Finally, to achieve the required $1 - \delta$ success probability, confidence bound, we utilize the standard median-of-means technique, taking the median of $T = \Theta(\log(1/\delta))$ independent instances.

Implementation and space complexity. We do not explicitly store the sampled set S_r for each independent instance r. Instead, for each of the T independent instances, we observe that the stream restricted to the coordinates in S_r is itself a valid sparse stream. To avoid paying a logarithmic dependence on n for the sketch hash seeds, we apply dimensionality reduction. Let $M = \Theta(K^2)$. We draw a pairwise independent hash function $g_r : [n] \to [M]$. Because the expected support size of the restricted stream is K, hashing into $M = \Theta(K^2)$ buckets yields zero collisions with high constant probability. Let $y^{(r)}$ be this compressed vector. When a stream update (i, Δ) arrives, we evaluate $h_r(i)$ to check if $z_r(i) \geq \ell$. If so, we pass the update to a standard AMS sketch [2] tracking $x|_{S_r}$. Because $K = \Theta(B^2/\varepsilon^2)$ is independent of δ, the expected ℓ_1 norm of each restricted substream $x|_S$ is at most $BK = \Theta(B^3/\varepsilon^2)$. By standard concentration bounds, the maximum ℓ_1 norm is $O(BK)$ with high probability. Thus, the bit complexity for a single counter is at most $\log(BK) = O(\log B + \log(1/\varepsilon))$. Each of the $T = \Theta(\log(1/\delta))$ independent instances maintains an AMS sketch with $O(1/\varepsilon^2)$ counters, operating on the reduced domain $[M]$. Thus, each of the $O(1/\varepsilon^2)$ hash functions uses $O(\log M) = O(\log K) = O(\log B + \log(1/\varepsilon))$ bits to store. Hence, the overall space required for the AMS sketches is $O\left(\frac{1}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\left(\log B + \log\frac{1}{\varepsilon}\right)\right)$. We also need a constant-factor approximation to determine our sampling probability, through a continuous monitoring F_0 algorithm that uses an additive $O\left(\log\frac{n}{\delta}\right)$ bits, c.f., Theorem 17.

Extension to a single pass. To extend this to a single pass, one could run $O(\log n)$ instances of the above two-pass algorithm in parallel, using every possible power-of-two sampling rate p. At the end of the stream, we would query $\hat{F}_0$ and output the estimate from the instance that used the correct value of p. However, this would increase the overall space by an undesired $\log n$ factor.

To avoid this overhead, we utilize our continuous F_0 tracker. Let $t_0 < t_1 < \dots$ be the timestamps at which the F_0 estimate crosses consecutive powers of two, meaning $\hat{F}_{0,t_i} \geq 2^i$. Let $N = \lceil \log(B^2/\varepsilon^2) \rceil$. At each milestone t_i, we initialize a new group of $N+1$ instances of our sketch, which consists of the $T = \Theta(\log(1/\delta))$ independent instances necessary for the median-of-means aggregation. These $N+1$ instances use sampling probabilities p calibrated for future F_0 scales of $2^0\hat{F}_{0,t_i}, 2^1\hat{F}_{0,t_i}, \dots, 2^N\hat{F}_{0,t_i}$. Crucially, we do not store every sketch indefinitely. We maintain only the sketch groups generated at the $N+1$ most recent milestones (from t_i down to t_{i-N}). Any older sketches are permanently discarded. Consequently, we maintain at most $O(N^2) = O(\log^2(B/\varepsilon))$ active sketches at any point in time.

At the end of the stream, we examine the earliest remaining group of non-discarded sketches. Among the N sketches in this group, we select the one that used the correct sampling rate p corresponding to our final F_0 estimate. This selected sketch guarantees a $(1 \pm \varepsilon)$-approximation to F_2, but only for the *suffix* of the stream processed after the sketch was initialized. Let x_2 be the frequency vector corresponding to this suffix, and let x_1 be the discarded prefix, so that $x = x_1 + x_2$. Because we retained sketches stretching back $N = \lceil \log(B^2/\varepsilon^2) \rceil$ epochs, the support size of the unsketched prefix x_1 satisfies $\|x_1\|_0 \leq 2^{-N}\|x\|_0 \leq \frac{\varepsilon^2}{B^2}\|x\|_0$. Exploiting the bounded-frequency assumption ($x_i \leq B$) and the fact that all non-zero entries are at least 1 (so $\|x\|_0 \leq \|x\|_2^2$), we can bound the ℓ_2 norm of the prefix $\|x_1\|_2^2 \leq B^2\|x_1\|_0 \leq B^2\left(\frac{\varepsilon^2}{B^2}\|x\|_0\right) = \varepsilon^2\|x\|_0 \leq \varepsilon^2\|x\|_2^2$. Taking the square root yields $\|x_1\|_2 \leq \varepsilon\|x\|_2$. By the triangle inequality, the difference between the full norm $\|x\|_2$ and the estimated suffix norm $\|x_2\|_2$ is at most $\|x_1\|_2 \leq \varepsilon\|x\|_2$. Adjusting ε by a constant factor ensures a strict $(1\pm\varepsilon)$-approximation for the final estimate. The total space complexity is dominated by the F_0 tracker plus the $O(\log^2(B/\varepsilon))$ active epoch states, where each state maintains $T = \Theta(\log(1/\delta))$ independent AMS instances. Multiplying the space complexity for each instance by these factors gives the final desired bound. ◀

5.2 Sparse Streams

We present an ℓ_2-estimation algorithm for insertion-only streams where the frequency vector x is k-sparse, meaning it has at most k non-zero entries (i.e., $\|x\|_0 \leq k$). This algorithm achieves a space complexity where k and the stream length m appear only inside logarithmic factors. The core idea is to first use hashing to reduce the dimensionality of x. We then apply the standard AMS sketch to the resulting compressed vector. To aggressively optimize the space required per counter, we do not maintain the exact sketch counters. Instead, we conceptually split each counter into positive and negative increments and maintain them approximately using Morris counters.

▶ **Theorem 33.** *Let $x \in \mathbb{Z}^n_{\geq 0}$ be the frequency vector of an insertion-only stream of length m. Suppose that $\|x\|_0 \leq k$. Then there exists a streaming algorithm that, with probability at least $1-\delta$, computes a $(1 \pm \varepsilon)$-approximation to $\|x\|_2^2$ using space (in bits) $O\left(\frac{1}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\left(\log\frac{k}{\varepsilon} + \log\log m\right) + \log n \cdot \log\frac{1}{\delta}\right)$.*

Proof. The strategy involves a two-stage process: dimensionality reduction tailored specifically for sparse vectors, followed by an AMS sketch where the underlying counters are maintained approximately using Morris counters [27].

Dimensionality reduction via hashing. We first reduce the dimension by hashing the coordinates of x into a much smaller set of random buckets. We draw $T = \Theta(\log(1/\delta))$ independent pairwise independent hash functions $h_r : [n] \to [M]$, where $M = \lceil Ck/\varepsilon^2 \rceil$ for a sufficiently large constant C. For each independent instance $r \in [T]$, we define the reduced vector $y^{(r)} \in \mathbb{R}^M$, where $y^{(r)}_j = \sum_{i:h_r(i)=j} x_i$. Since x is k-sparse, the expected ℓ_2^2 error introduced by collisions in a single instance is at most $\|x\|_1^2/M \le k\|x\|_2^2/M$. By Markov's inequality, a single hash preserves $\|y^{(r)}\|_2^2 = (1 \pm \varepsilon/4)\|x\|_2^2$ with constant probability. Taking the median across the T independent instances amplifies this probability to the desired $1 - \delta$.

AMS Sketch with Morris Counters. For each of the T instances, we apply an AMS sketch to the lower-dimensional vector $y^{(r)}$ using $R = \Theta(1/\varepsilon^2)$ estimators. We conceptually decompose each exact AMS counter into its positive and negative accumulating parts, i.e., $A_{r,w} = A^+_{r,w} - A^-_{r,w}$. Notice that the total accumulated mass across both parts is precisely the ℓ_1 norm of x: $A^+_{r,w} + A^-_{r,w} = \|x\|_1 = m$. To avoid the space overhead of storing these counters exactly, we maintain them approximately. We instantiate two unbiased Generalized Morris counters for each index (r, w), one for $A^+_{r,w}$ and one for $A^-_{r,w}$, and each with variance $\gamma = \Theta(\varepsilon^2/k^2)$. Let $\hat{A}^+_{r,w}$ and $\hat{A}^-_{r,w}$ be their respective estimates. Our approximate counter is then $\hat{A}_{r,w} = \hat{A}^+_{r,w} - \hat{A}^-_{r,w}$, which remains unbiased, i.e., $\mathbb{E}[\hat{A}_{r,w}] = A_{r,w}$. Thus, the variance of the approximate counter is at most $\mathrm{Var}(\hat{A}_{r,w}) = \mathrm{Var}(\hat{A}^+_{r,w}) + \mathrm{Var}(\hat{A}^-_{r,w}) \le \gamma(A^+_{r,w})^2 + \gamma(A^-_{r,w})^2 \le \gamma m^2$.

Error analysis. Let $\hat{Y}'_r$ be the AMS estimator computed using these approximate counters for a single instance r, i.e., averaging $R = \Theta(1/\varepsilon^2)$ squared approximate counters $\hat{A}^2_{r,w}$ across $w \in [R]$. Because the Morris counters are unbiased, the expected value of a squared approximate counter $\hat{A}^2_{r,w}$ includes the true squared signal plus the variance, i.e., $\mathbb{E}[\hat{A}^2_{r,w}] = A^2_{r,w} + \mathrm{Var}(\hat{A}_{r,w})$. Thus, the expected bias introduced to the final estimator by the approximate counters is at most $\mathrm{Var}(\hat{A}_{r,w}) \le \gamma m^2 \le O(\varepsilon^2 m^2/k^2)$. Because x is k-sparse and $\|x\|_1 = m$, then $\|x\|_2^2 \ge m^2/k$, so that the bias is at most $O(\varepsilon^2/k) \cdot \|x\|_2^2$.

Similarly, we bound the variance of the overall estimator. Let $E = \hat{A}_{r,w} - A_{r,w}$ be the error of the Morris counter. Expanding the squared counter, we have $\hat{A}^2_{r,w} = (A_{r,w} + E)^2 = A^2_{r,w} + 2A_{r,w}E + E^2$. Since $A^2_{r,w} = O(m^2)$ and $\mathrm{Var}(E) \le \gamma m^2$, then the variance is at most $O(\gamma m^4)$. Averaging over the $R = \Theta(1/\varepsilon^2)$ and applying the above argument, it follows that the variance is at most $O(\varepsilon^4\|x\|_2^4) \ll \varepsilon^2\|x\|_2^4$. Thus Chebyshev's inequality, each instance outputs a $(1 \pm \varepsilon/2)$ approximation to $\|y^{(r)}\|_2^2$ with constant probability. By taking the median of $O(\log 1/\delta)$ instances, we can boost the success probability to $1 - \delta$.

Space Complexity. A Generalized Morris counter tracking up to m with variance parameter $\gamma = \Theta(\varepsilon^2/k^2)$ uses $O(\log(1/\gamma) + \log\log m) = O(\log(k/\varepsilon) + \log\log m)$ bits. Maintaining $2RT = O(\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$ such counters thus uses space $O\left(\frac{1}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\left(\log\frac{k}{\varepsilon} + \log\log m\right)\right)$. Additionally, the T initial pairwise independent hash functions $h_r : [n] \to [M]$ require $O(\log(1/\delta)\log n)$ additional bits of space. Similarly, the AMS hash functions σ require $O(\log M) = O(\log(k/\varepsilon))$ bits to generate. Altogether, the space complexity is $O\left(\frac{1}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\left(\log\frac{k}{\varepsilon} + \log\log m\right) + \log n \cdot \log\frac{1}{\delta}\right)$. ◀

Approximate Cauchy-Schwarz Inequality and Improved Bounds for Sherali-Adams Refutation of Semirandom CSPs

Abstract

We formulate an *approximate Cauchy-Schwarz* inequality and show that it is satisfied by solutions to the Sherali-Adams linear programming hierarchy (interpreted as "pseudo-distributions"). As a consequence, we resolve a question left open by the work of O'Donnell and Schramm [13] that they had explicitly attributed to the lack of such an inequality.

A Cauchy-Schwarz inequality is *exactly* satisfied by pseudo-distributions satisfying the constraints of the *sum-of-squares* semidefinite programming hierarchy and already has scores of applications. However, the proof there requires *global* positive semidefiniteness. Our approximate version, on the other hand, relies only on *local* positive semidefiniteness satisfied by the Sherali-Adams pseudo-distributions. Our formulation loses an additive error that scales with the L1 norm of the coefficients of the constituent polynomials, and this loss is asymptotically tight. Our proof is elementary and relies on a simple sampling argument.

As an application, we resolve a question left open in the work of O'Donnell and Schramm that gives a trade-off between constraint density and the Sherali-Adams degree for refuting random constraint satisfaction problems. Specifically, for odd arity CSPs, we show that the constraint density requirement for a given degree can be improved by a polynomial factor in n. Along the way, we observe that by a simple extension, the results in their work extend to a more general semirandom setting.

1 Introduction

A degree d sum-of-squares (SoS) pseudo-distribution on $\{-1,1\}^n$ is a signed measure $D : \{-1,1\}^n \to \mathbb{R}$ such that the associated pseudo-expectation functional defined for any $f : \{-1,1\}^n \to \mathbb{R}$ by $\widetilde{\mathbb{E}}_D[f] = \sum_x D(x)f(x)$ satisfies 1) $\widetilde{\mathbb{E}}_D[1] = 1$ and 2) $\widetilde{\mathbb{E}}_D[f^2] \geqslant 0$ for every polynomial f of degree $\leqslant d/2$. Such pseudo-distributions are equivalent to feasible points for SDPs from the SoS semidefinite programming hierarchy. Degree d SoS pseudo-distributions are equivalent to *pseudo-moment matrices* – matrices M indexed by subsets of $[n]$ of size $\leqslant d/2$ whose entry at (S,T) is given by $\widetilde{\mathbb{E}}_D[\prod_{i \in S \Delta T} x_i]$. Pseudo-moment matrices are themselves in one-to-one correspondence with the set of all positive semidefinite matrices that satisfy some natural linear constraints[1]. The SoS semidefinite programming

[1] These constraints encode that $M(S,T)$ depends only on $S\Delta T$ and the diagonals of M are 1.

hierarchy, at a high level, can be thought of as solving (in $n^{O(d)}$ time) the problem of finding a pseudo-expectation (equivalently, a pseudo-moment matrix) satisfying some additional linear constraints.

The analysis of algorithms (see the survey [7]) based on the SoS hierarchy requires reasoning about the pseudo-expectations of various polynomials arising in a given problem. Such analyses often rely on generalizing natural analytic inequalities that hold for expectations (w.r.t. probability distributions) to pseudo-expectations (w.r.t. pseudo-distributions). Indeed, the power of the pseudo-expectation view of SoS solutions comes largely from being able to "guess" true inequalities for pseudo-distributions by analogy with actual probability distributions.

The Cauchy-Schwarz Inequality

Perhaps the most fundamental of such general analytic inequalities is the Cauchy-Schwarz inequality:

$$\widetilde{\mathbb{E}}_D[fg] \leqslant \widetilde{\mathbb{E}}_D[f^2]^{1/2}\widetilde{\mathbb{E}}_D[g^2]^{1/2},$$

which is satisfied whenever D is a degree d pseudo-distribution and f, g are polynomials of degree $\leqslant d/2$. The Cauchy-Schwarz inequality appears in scores of applications of the sum-of-squares hierarchy, especially in executing the *proofs-to-algorithms* paradigm in algorithm design. The proof (and indeed, the truth) of the inequality relies on the positive semidefiniteness constraint that is often viewed as a *global* constraint on the pseudo-moments.

Such global positive semidefiniteness constraints are not satisfied by solutions to the weaker *Sherali-Adams* linear-programming hierarchy. An R-local Sherali-Adams solution can also be viewed as a degree $2R$ pseudo-distribution $D : \{-1,1\}^n \to \mathbb{R}$ with the key difference that the associated pseudo-expectation only satisfies a *local* version of (2). More precisely:

▶ **Definition 1.1** (R-local pseudo-distributions and pseudo-expectation)**.** *An R-local pseudo-distribution over the n-dimensional Boolean hypercube is a function $D : \{-1,1\}^n \to \mathbb{R}$ such that the associated pseudo-expectation defined by $\widetilde{\mathbb{E}}_D[f] := \sum_{x\in\{-1,1\}^n} D(x)f(x)$ satisfies:*

1. $\widetilde{\mathbb{E}}[1] = 1$,
2. *For every pointwise non-negative $f : \{-1,1\}^n \to \mathbb{R}$ such that f depends on only $\leqslant R$ out of n possible inputs, we have: $\widetilde{\mathbb{E}}[f] \geqslant 0$.*

Equivalently, for every non-negative function f that depends only on $\leqslant R$ variables, $\widetilde{\mathbb{E}}[f] \geqslant 0$. The corresponding pseudo-moment matrices now satisfy *local* positive semidefiniteness constraints – every principal submatrix that corresponds to pseudo-moments of any set of at most R variables is positive semidefinite. However, the matrix as a whole may not be PSD! This weakening allows encoding the constraints of a degree-d Sherali-Adams pseudo-expectation as an $n^{O(d)}$-size *linear* (as opposed to a semidefinite) program. The weakening to only satisfying local constraints comes at a cost. Results like the Cauchy-Schwarz inequality no longer hold, provably (see Theorem 2.2)!

Our goal in this work is to formulate an approximate version of the Cauchy-Schwarz inequality that can hold for Sherali-Adams pseudo-distributions. Before diving into our formulation, let us discuss our main motivation:

Sherali-Adams vs Sum-of-Squares

How does the power of the Sherali-Adams linear programming hierarchy compare with that of the SoS SDP hierarchy? On the one hand, lower bounds for constraint satisfaction problems such as Max-Cut [4] show that degree 2 SoS SDPs [9] can achieve drastically better

approximation ratios even as Sherali-Adams LPs of n^{ε}-degree fail to appreciably beat simply returning a uniformly random assignment. On the other hand, O'Donnell and Schramm [13] and the follow-up work due to Hopkins, Schramm, and Trevisan [11] show that degree n^c (for fixed $c < 1$) Sherali-Adams LPs can qualitatively match the performance of SDPs for Max-Cut! Perhaps more strikingly, they show that $O(1/\varepsilon)$-degree Sherali-Adams LPs (thus, in polynomial time!) can strongly refute (i.e., certify an upper bound of $1/2 + \varepsilon$ on the normalized value of) random k-XOR instances with $m \geqslant n^{k/2+\varepsilon}$ constraints **for even k**. This matches, up to n^{ε} factors for an arbitrarily small ε, the best-known refutation algorithms based on spectral methods [2, 3, 6].

The case of odd k

For random k-XOR refutation when k is odd, O'Donnell and Schramm prove a weaker bound of $m \geqslant n^{\lceil k/2 \rceil + \varepsilon}$ for the same guarantee that is off of the optimal $n^{k/2}$ by a fixed (i.e., that does not improve as $\varepsilon \to 0$) polynomial factor in n . This is because the argument in [13] essentially treats an odd k-XOR formula as a $(k+1)$-XOR and then applies their result for even arity XOR.

As an aside, such a gap between the case of even and odd ks has been a fixture in this line of work. The case of odd k, for which the above bound appears suboptimal, has indeed proved to be more difficult to tackle in all previous analyses [5, 2, 1, 12, 10] even with more powerful classes of spectral methods.

In the work of O'Donnell and Schramm [13], the polynomial factor "discrepancy" can be blamed on the lack of a Cauchy-Schwarz inequality for Sherali-Adams pseudo-distributions. Indeed, the authors themselves remark (see footnote on page 4): "*This is because we do not know how to relate the Sherali–Adams value of the objective function to its square (local versions of the Cauchy-Schwarz argument result in a loss). Such a relation would allow us to apply our techniques immediately to prove that Sherali Adams matches the SOS and spectral performance for odd as well as even k.*"

Our Results

In this work, we prove an approximate Cauchy-Schwarz inequality that holds for Sherali-Adams pseudo-distributions (so a "local" version as in the above quote) but with an additive loss that becomes negligible as the locality/degree of the Sherali-Adams LP increases. As an application, we get the right conjectured bound for refuting random k-XOR formulas for odd k. Along the way, we also observe a natural generalization of the ideas of [13] to the problem of semirandom k-XOR refutation where the set of tuples participating in constraints is arbitrary (i.e., worst-case) while the "right hand sides" are chosen independently at random.

Let us begin with our approximate Cauchy-Schwarz inequality. For any functions f, g, of $x = (x_1, x_2, \ldots, x_n)$ and any distribution D over x, $\mathbb{E}_{x\sim D}[f(x)g(x)] \leqslant \mathbb{E}[f(x)^2]^{1/2}\mathbb{E}[g(x)^2]^{1/2}$. The proof crucially relies on the positive semidefiniteness of the *moment* matrix of the pseudo-distribution. It provably does not hold for Sherali-Adams pseudo-distributions that only satisfy *local* positive semidefiniteness. Indeed, in Section 2.1, we observe the following seemingly drastic failure of the Cauchy-Schwarz inequality.

▶ **Theorem 1.2** (Sherali-Adams Cannot Satisfy Cauchy-Schwarz Exactly, see Theorem 2.2)**.** *For any R and $n \gg R$, there exists an R-local Sherali-Adams pseudo-distribution on $\{-1, 1\}^n$ such that for the linear polynomial $p(x) = \sum_i x_i$, we have: $\widetilde{\mathbb{E}}_D[p(x)^2] = 0$, and, $\widetilde{\mathbb{E}}_D[p] \geqslant (1 - o_R(1))\frac{n}{\sqrt{R-1}}$.*

Despite this failure, we show that there is a natural way to formulate a correct, approximate Cauchy-Schwarz inequality. To the best of our knowledge, such an approximate formulation has not appeared in prior works. Notice that the above counter-example rules out an approximate Cauchy-Schwarz inequality with a *multiplicative* error. Our formulation has a bound on the *additive* error instead.

▶ **Theorem 1.3** (Approximate Cauchy-Schwarz Inequality). *Let $f, g : \{-1,1\}^n \to \mathbb{R}$ be polynomials of degree $\leqslant d$. Let $\|f\|_1, \|g\|_1$ be the L1 norms of the coefficients of f, g, respectively. Then, for every R-local pseudo-distribution $\mathcal{D}$ on $\{-1,1\}^n$ and any positive integers s, t such that $d(s+t) \leqslant R$, we have:*

$$\left|\widetilde{\mathbb{E}}[fg]\right| \leqslant \sqrt{(1-\frac{1}{s})\widetilde{\mathbb{E}}[f^2] + \frac{1}{s}\|f\|_1^2}\sqrt{(1-\frac{1}{t})\widetilde{\mathbb{E}}[g^2] + \frac{1}{t}\|g\|_1^2}.$$

▶ Remark 1.4. Note that $\|f\|_1$ and $\|g\|_1$ are basis dependent quantities. This is to be expected as Sherali-Adams (unlike sum-of-squares) is not basis independent. Next, our bounds are written in the $\{\pm 1\}$ basis. They can, of course, be transformed into the $\{0,1\}$ basis, but the quantities appearing will change. Finally, we present the inequality with s, t as independent parameters (as opposed to setting them both to be $R/2$, say) since we anticipate that in applications, $\|f\|_1, \|g\|_1$ could be different and the freedom to modulate s, t accordingly may lead to better bounds.

As we observe in Section 2.1, Theorem 1.2 shows that the formulation we prove in Theorem 1.3 is tight down to the exact constant as $n/R \to \infty$.

Applications

We apply Approximate Cauchy-Schwarz to prove tight bounds for CSP refutation.

▶ **Theorem 1.5** (Sherali-Adams Refutation of Random and Semirandom k-XOR; see Theorems 3.4 and 4.2). *Suppose we have a random or semirandom k-XOR instance on n variables with $n^{k/2+\delta}$ expected (in the random case) or total (in the semirandom case) constraints. Then with high probability, there exists some $R = O_{\varepsilon,\delta,k}(1)$ such that for all R-local Sherali-Adams pseudodistributions D on $\{-1,1\}^n$, we have $\widetilde{\mathbb{E}}_D \psi(x) \leqslant 2\varepsilon|\mathcal{H}|$.*

In the case of odd k, we use our approximate Cauchy-Schwarz lemma to show that the standard spectral certificate used to refute random odd k-XOR instances in [2] implies a Sherali-Adams refutation, which allows us to refute with just $n^{k/2+\delta}$ constraints. In addition, we show that we can refute semirandom k-XOR in Sherali-Adams, matching the SOS algorithms from [1]. This was previously unknown for both even and odd k.

2 Sherali-Adams Proof of an Approximate Cauchy-Schwarz Inequality

In this section, we show that Sherali-Adams pseudo-distributions satisfy a natural approximate Cauchy-Schwarz inequality. In the next section, we will see how this inequality helps linear-programming-based refutations of random constraint satisfaction problems.

Let us formulate the approximate Cauchy-Schwarz inequality:

▶ **Theorem 2.1** (Approximate Cauchy-Schwarz Inequality). *Let $f, g : \{-1,1\}^n \to \mathbb{R}$ be polynomials of degree $\leqslant d$. Let $\|f\|_1, \|g\|_1$ be the L1 norms of the coefficients of f, g respectively when written in the standard monomial basis over $\{-1,1\}^n$. Then, for every R-local pseudo-distribution $\mathcal{D}$ on $\{-1,1\}^n$, and any positive integers s, t such that $d(s+t) \leqslant R$, we have:*

$$\left|\widetilde{\mathbb{E}}[fg]\right| \leqslant \sqrt{(1-\frac{1}{s})\widetilde{\mathbb{E}}[f^2] + \frac{1}{s}\|f\|_1^2}\sqrt{(1-\frac{1}{t})\widetilde{\mathbb{E}}[g^2] + \frac{1}{t}\|g\|_1^2}.$$

Our proof is based on a simple sampling scheme that allows us to write f and g as averages over *local* functions with some additive "sampling" error.

Proof. We present the proof for $d = 1$. The case of larger d is the same but, unlike below, where we "sample" monomials of degree 1, we sample monomials of degree $\leqslant d$ instead.

Let $f(x) = a_0 + \sum_{i \leqslant n} a_i x_i$ and $g(x) = b_0 + \sum_i b_i x_i$. We will assume that $0 < \|f\|_1 = \sum_i |a_i|$ and $0 < \|g\|_1 = \sum_i |b_i|$ (if either of these quantities is 0 then there is nothing to prove).

Let us sample an unbiased estimator for f. Define a distribution p on $\{0, 1, 2, \cdots, n\}$ by setting $p_i = \frac{|a_i|}{\|f\|_1}$. For each $i \in \{0, 1, 2, \cdots, n\}$, let $\chi_i(x) = x_i$ if $i > 0$ and $\chi_0(x) = 1$. Draw $i_1, i_2, \ldots, i_s$ independently from p and define:

$$F = \frac{1}{s}\sum_{\ell=1}^{s} \frac{a_{i_\ell}}{p_{i_\ell}}\chi_{i_\ell}(x).$$

Then, clearly, F depends on at most s variables. Further, $\mathbb{E}[F] = f$, where the expectation is with respect to p. Similarly, construct G from g using t samples.

Now, let $\mathcal{D}$ be any R-local pseudo-distribution on $x_1, x_2, \ldots, x_n \in \{\pm 1\}$. Since F and G are s, t-local respectively and $s + t \leqslant R$, we must have:

$$|\widetilde{\mathbb{E}}_D[FG]| \leqslant \widetilde{\mathbb{E}}_D[F^2]^{1/2}\widetilde{\mathbb{E}}_D[G^2]^{1/2}. \tag{1}$$

Now, since F and G are sampled independently, we also have:

$$\mathbb{E}_{\text{sampling}}\widetilde{\mathbb{E}}[FG] = \widetilde{\mathbb{E}}[fg].$$

Thus, using (1), taking expectations with respect to the sampling process and applying Jensen's inequality for the expectation of the square root function gives

$$\left|\widetilde{\mathbb{E}}[fg]\right| \leqslant \mathbb{E}_{\text{sampling}}\widetilde{\mathbb{E}}_{\mathcal{D}}[F^2]^{1/2}\widetilde{\mathbb{E}}_{\mathcal{D}}[G^2]^{1/2} \leqslant \sqrt{(\mathbb{E}_{\text{sampling}}\widetilde{\mathbb{E}}_{\mathcal{D}}[F^2])}\sqrt{\mathbb{E}_{\text{sampling}}\widetilde{\mathbb{E}}_{\mathcal{D}}[G^2]}. \tag{2}$$

We will now finish the proof by computing the RHS. Let $X_\ell = \frac{a_{i_\ell}}{p_{i_\ell}}\chi_{i_\ell}(x)$, so $F = \frac{1}{s}\sum_{\ell=1}^{s} X_\ell$.

For two distinct samples $\ell \neq m$, we have:

$$\mathbb{E}_{i_\ell, i_m}[\widetilde{\mathbb{E}}[X_\ell X_m]] = \widetilde{\mathbb{E}}[f^2].$$

On the other hand, when $\ell = m$, we have:

$$\mathbb{E}_{i_\ell}[\widetilde{\mathbb{E}}[X_\ell^2]] = \sum_i \frac{a_i^2}{p_i} = (\sum_i |a_i|)^2 = \|f\|_1^2.$$

Thus,

$$\mathbb{E}_{\mathsf{sampling}}[\widetilde{\mathbb{E}}[F^2]] = \frac{s(s-1)}{s^2}\widetilde{\mathbb{E}}[f^2] + \frac{s}{s^2}\|f\|_1^2 = (1-1/s)\widetilde{\mathbb{E}}[f^2] + \frac{\|f\|_1^2}{s}.$$

A similar argument for G gives:

$$\mathbb{E}_{\mathsf{sampling}}[\widetilde{\mathbb{E}}[G^2]] = (1-1/t)\widetilde{\mathbb{E}}[g^2] + \frac{\|g\|_1^2}{t}.$$

Plugging back in (2) finishes the proof. ◀

2.1 A Matching Lower Bound

In this section, we prove that the additive error appearing in our approximate Cauchy-Schwarz inequality is necessary and, in fact, that our bound is quantitatively optimal.

▶ **Theorem 2.2.** *Let R, n be such that $n/R \to \infty$. Then, there exists an R-local Sherali-Adams pseudo-distribution on $\{-1,1\}^n$ such that for the linear polynomial $p(x) = \sum_i x_i$, we have: $\widetilde{\mathbb{E}}_D[p(x)^2] = 0$, and,*

$$\widetilde{\mathbb{E}}_D[p] \geqslant (1 - O(1/R + R/n))\frac{n}{\sqrt{R-1}}.$$

▶ Remark 2.3. Applying Theorem 2.1 with $f = p$, $g = 1$, $s = R-1$ and $t = 1$ gives $\widetilde{\mathbb{E}}_D[p] \leqslant n/\sqrt{R-1}$. Thus, the additive error in Theorem 2.1 is asymptotically tight with the correct leading constant. Notice also that this example rules out an approximate Cauchy-Schwarz inequality with any finite *multiplicative* error.

Proof. We will define the pseudo-distribution D by describing a local distribution on every collection T of R variables. The local distributions will be permutation-invariant on T and thus, the marginal distribution on any $T' \subseteq T$ will depend only on $|T'|$. Thus, in particular, local consistency holds: for any $T' \subseteq T_1 \cap T_2$ for two different sets of size R each, the marginal of the local distributions on T_1 and T_2 on T' agree. This implies immediately the existence of an R-local Sherali-Adams pseudo-distribution with pseudo-moments agreeing with the local distributions we will construct.

For every $T \subseteq [n]$ of size exactly R, let $Y_T = \sum_{i \in T} x_i$. We will sample Y_T from a distribution on $[-R, R]$ and then set the constituent x_is to be uniform conditioned on satisfying $\sum_i x_i$ being equal to the sampled value of Y_T. This will ensure permutation-invariance that we desire immediately.

What remains to be described is the specific distribution to sample the random variable Y_T on $[-R, R]$. We will choose this carefully to have prescribed first and second moments (which will govern $\widetilde{\mathbb{E}}_D[p]$ and $\widetilde{\mathbb{E}}_D[p^2]$ respectively).

Let $A = \frac{R(n-R)}{n-1}$. This will be our prescribed 2nd moment for Y_T. Notice that $A = R(1 - O(R/n))$ and $\sqrt{A} = \sqrt{R}(1 - O(R/n))$. Choose a to be the largest positive integer in $\{-R, -R+2, \cdots, R-2, R\}$ such that $a \leqslant \sqrt{A}$. Set $b = a + 2$. Choose θ so that $(1-\theta)a^2 + \theta b^2 = A$, that is, set $\theta = \frac{A - a^2}{b^2 - a^2}$. Observe that since $a^2 \leqslant A \leqslant b^2$, $\theta \in [0, 1]$.

Now, consider the following distribution for Y_T. With probability $1 - \theta$, output a, with probability θ, output b. Choose $x_T \in \{-1, 1\}^T$ to be uniform over all assignments satisfying $\sum_i x_i = Y_T$.

Let's compute $\widetilde{\mathbb{E}}_D[x_i x_j]$ for $i \neq j$. Observe that $Y_T^2 = R + 2\sum_{i<j, i,j \in T} x_i x_j$. Since $\mathbb{E}[Y_T^2] = A$, we must have $\widetilde{\mathbb{E}}_D[x_i x_j] = \frac{(A-R)}{R(R-1)} = -\frac{1}{n-1}$. Thus, $\widetilde{\mathbb{E}}_D[p^2] = 0$.

Next, a simple computation gives $\widetilde{\mathbb{E}}_D[x_i] = 1/R\widetilde{\mathbb{E}}_D[Y_T] = 1/R[(1-\theta)a + \theta b] = \frac{1}{\sqrt{R}}(1 - O(1/R + R/n))$.

Thus, $\widetilde{\mathbb{E}}_D[p] = (1 - O(1/R + R/n))\frac{n}{\sqrt{R}} = (1 - O(1/R + R/n))\frac{n}{\sqrt{R-1}}$. ◀

3 Refuting Random k-XOR

In this section, we will show that Sherali-Adams can refute random k-XOR instances, which we define below, as an application of approximate Cauchy-Schwarz.

▶ **Definition 3.1.** *Let $k \geqslant 2$ be an integer. We say that ψ is a random k-XOR instance with pn^k expected clauses if for all $U \in [n]^k$, we add U to $\mathcal{H}$ with probability p and sample an independent Rademacher (± 1) sign b_U. Then we write $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$, where $x^U \coloneqq \prod_{i\in U} x_i$.*

▶ Remark 3.2. Notice that if an $\frac{1}{2} + \gamma$ fraction of constraints are satisfied, i.e. we have $b_U \cdot x^U = 1$ for $\frac{1}{2} + \gamma$ fraction of $U \in \mathcal{H}$, then $\psi(x) = 2\gamma|\mathcal{H}|$. Therefore, certifying that we cannot satisfy a large fraction of constraints is equivalent to certifying an upper bound on $\psi(x)$.

We also define the following notation that we will use:

▶ **Definition 3.3.** *Let $\psi = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a k-XOR instance with clause set $\mathcal{H}$. For all $U \notin \mathcal{H}$, we let $b_U = 0$. Define $\mathcal{H}_i \coloneqq \{C \in \mathcal{H} : C_k = i\}$ be the subset of clauses in $\mathcal{H}$ whose last coordinate is i.*

We will prove the following theorem:

▶ **Theorem 3.4.** *Let k be an odd integer and $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a random k-XOR instance with $n^{k/2+\delta}$ expected constraints. Suppose we have $2^{O(k)} \log^3 n \leqslant n^{\delta/2}$. Then for all $\Omega(1) = \gamma \leqslant 1/2$, there exists some $R = O_{\gamma,\delta,k}(1)$ such that every R-local pseudodistribution $\mathcal{D}$ satisfies $\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(x) \leqslant 2\gamma|\mathcal{H}|$.*

▶ Remark 3.5. Using a standard Fourier analytic reduction, we can generalize this result to general k-CSPs.

The state-of-the-art refutation algorithms for random (and semirandom) k-XOR instances are based on spectral certificates. Informally, the idea is to show that the "value" polynomial of any k-XOR instance (the polynomial that computes the advantage over $1/2$ of an assignment) can be upper bounded at every x by a quadratic form of a certain matrix built from the instance. One then establishes that when the input instance is random (or semirandom) with appropriately many constraints, then, the spectral norm of this matrix is small. We will call a matrix satisfying sufficient conditions for obtaining a Sherali-Adams refutations a spectral certificate.

▶ **Definition 3.6** (Spectral Certificates)**.** *Let k be an odd integer and $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a k-XOR instance. Define $A(\psi)$ to be a $n^{k-1} \times n^{k-1}$ matrix defined as follows: For all $(S_1, T_1) \neq (S_2, T_2) \in [n]^{(k-1)/2} \times [n]^{(k-1)/2}$, we have*

$$A(\psi)_{(S_1,S_2),(T_1,T_2)} \coloneqq \sum_{i\in[n]} b_{S_1T_1i}b_{S_2T_2i} + b_{T_1S_1i}b_{T_2S_2i}\,,$$

and $A(\psi)_{(S_1,S_1),(S_2,S_2)} = 0$. *We call* $A(\psi)$ *a* δ-spectral certificate for $\mathcal{H}$ *if*

$$\|A(\psi)\| \leqslant n^{-\delta} \left(\min_{(S_1,S_2)} \left\|A(\psi)_{(S_1,S_2)}\right\|_1 \right) .$$

We let $D(\psi)_{S_1,S_2} \coloneqq \|A_{S_1,S_2}\|_1$ *and write* $D(\psi) \coloneqq \operatorname{diag}(\{D(\psi)_{S_1,S_2}\})$. *Observe that*

$$x^{\odot(k-1)} A(\psi) x^{\odot(k-1)} = 2 \sum_i \sum_{U \neq U' \in \mathcal{H}_i} b_U b_{U'} x^U x^{U'} .$$

With high probability over the choice of ψ, the matrix $A(\psi)$ is a spectral certificate. The proof of this is simple and follows from the work of [2], and is deferred to the appendix.

▶ **Lemma 3.7.** *Suppose* ψ *is a random* k*-XOR instance with* $n^{k/2+\delta}$ *constraints such that* $2^{O(k)} \log^3 n \leqslant n^{\delta/2}$. *Then* $A(\psi)$ *is a* $\frac{\delta}{2}$*-spectral certificate for* ψ *with high probability.*

One can view the main idea of O'Donnell and Schramm's work as showing (under appropriate conditions) that spectral bounds on certifying matrices such as above can be proven using the Sherali-Adams linear program. We will abstract their analysis into the following lemma:

▶ **Lemma 3.8** (Abstracting out [13])**.** *Let* A *be a symmetric matrix with integer entries with rows and columns indexed by* t*-tuples of* $[n]$*, and let* D *be its degree matrix. Let* $\pi_* = \frac{1}{\sum_{S,T} |A_{S,T}|} \min_S \|A_S\|_1$, $\rho(\cdot)$ *denote the spectral radius of a matrix, and* $\eta > \min(\pi_*^{-1/2}, \rho(D^{-1}A))$. *Take* $\ell \coloneqq \left\lceil \frac{1}{4} \frac{\log(\eta^2 \pi_*)}{\log(\rho(D^{-1}A)/\eta)} \right\rceil$ *and* $p \coloneqq \lceil (\frac{2}{5\eta})^{2\ell} \rceil$. *Then for* $R(A) \coloneqq tp\ell + t$*, any* R*-local pseudoexpectation* $\mathcal{D}$ *on* $x_1, \cdots, x_n$ *satisfies*

$$\left| \widetilde{\mathbb{E}}_{\mathcal{D}} (x^{\odot t})^\top A x^{\odot t} \right| \leqslant \eta \sum_{S,T} |A_{S,T}|,$$

where $x^{\odot t}$ *is the* n^t*-dimensional vector whose entries are indexed by* t*-tuples of* $[n]$ *and are equal to the product of the corresponding entries.*

▶ **Lemma 3.9.** *Let* k *be an odd integer and* $\psi(x) = \sum_{U \in \mathcal{H}} b_U \cdot x^U$ *be a* k*-XOR instance such that* $|\mathcal{H}| \geqslant \frac{36n}{\gamma^2}$ *and* $|\mathcal{H}_i| \leqslant \frac{|\mathcal{H}|}{n}(1+\gamma)$ *for all* i. *Suppose that* $A(\psi)$ *is a* δ*-spectral certificate for* ψ. *Then for all* $\Omega(1) = \gamma \leqslant \frac{1}{2}$, $R = O_{\gamma,\delta,k}(1)$*-rounds of Sherali-Adams can certify that* $\psi(x) \leqslant 2\gamma|\mathcal{H}|$*; in other words, for all* R*-local pseudodistributions* $\mathcal{D}$, $|\widetilde{\mathbb{E}}_{\mathcal{D}} \psi(x)| \leqslant 2\gamma|\mathcal{H}|$.

Proof. Let $\psi_i = \sum_{U \in \mathcal{H}_i} b_U x^U$, $R \coloneqq \max\{R(A(\psi)), \frac{10k(1+\gamma)^2}{\gamma^2}\} = O_{\gamma,\delta,k}(1)$, where $R(A(\psi))$ is the quantity from Lemma 3.8 when $\eta = \gamma^2$, and $\widetilde{\mathbb{E}}$ be any R-local pseudodistribution. A δ-spectral certificate $A(\psi)$ satisfies $\rho(D^{-1}(\psi)A(\psi)) \leqslant n^{-\delta}$ (recall that $\rho(\cdot)$ is the spectral radius of a matrix) and therefore by Lemma 3.8,

$$\begin{aligned} \widetilde{\mathbb{E}} \sum_i \psi_i^2(x) &= \widetilde{\mathbb{E}} \sum_{U \in \mathcal{H}} b_U^2 + \frac{1}{2} \widetilde{\mathbb{E}} x^{\odot(k-1)} A(\psi) x^{\odot(k-1)} \\ &\leqslant |\mathcal{H}| + \frac{\gamma^2}{2} \sum_i |\mathcal{H}_i|(|\mathcal{H}_i| - 1) \leqslant |\mathcal{H}| + \frac{\gamma^2}{2} \frac{|\mathcal{H}|^2}{n} (1+\gamma)^2 , \end{aligned}$$

so by Theorem 2.1, we have for $s \geqslant \frac{9(1+\gamma)^2}{\gamma^2}$,

$$\left|\widetilde{\mathbb{E}}\psi(x)\right| = \left|\widetilde{\mathbb{E}}\sum_i \psi_i(x)\right| \leqslant \sum_i \sqrt{\left(1-\frac{1}{s}\right)\widetilde{\mathbb{E}}\psi_i^2 + \frac{1}{s}\|\psi_i\|_1^2}$$
$$\leqslant \sqrt{n\left(\left(1-\frac{1}{s}\right)\sum_i \widetilde{\mathbb{E}}\psi_i^2 + \frac{1}{s}\sum_i |\mathcal{H}_i|^2\right)}$$
$$\leqslant \sqrt{n|\mathcal{H}|} + \gamma(1+\gamma)|\mathcal{H}| + \frac{|\mathcal{H}|}{\sqrt{s}}(1+\gamma) \leqslant 2\gamma|\mathcal{H}|\,. \quad \blacktriangleleft$$

Proof of Theorem 3.4. For random k-XOR, Chernoff bounds imply that $|\mathcal{H}_i| \leqslant \frac{|\mathcal{H}|}{n}(1+\gamma)$ for all i with high probability. Then the result follows directly from Lemma 3.7 and Lemma 3.9. $\blacktriangleleft$

4 Refuting Semirandom k-XOR

In this section, we show that Sherali-Adams can refute semirandom instances of k-XOR.

▶ **Definition 4.1.** *Let k be an integer and $\mathcal{H} \subseteq [n]^k$. We say that ψ is a semirandom k-XOR instance with clause set $\mathcal{H}$ if for $U \in \mathcal{H}$, we sample an independent Rademacher (± 1) sign b_U and write $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$.*

▶ **Theorem 4.2.** *Let k be an integer. $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a semirandom k-XOR instance with clause set $\mathcal{H}$ such that $|\mathcal{H}| = n^{k/2+\delta}$ total constraints. Suppose we have $\gamma \geqslant n^{-\delta/4}4\sqrt{15}$ and $16384k^4\log^3 n \leqslant n^{\delta/18}$. Then for all $\Omega(1) = \gamma \leqslant 1/2$, with high probability, there exists some $R = O_{\gamma,\delta,k}(1)$ such that every R-local pseudodistribution $\mathcal{D}$ satisfies $\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(x) \leqslant 2\gamma|\mathcal{H}|$.*

For semirandom odd k-XOR, the $\mathcal{H}_i$ can be much larger than $\frac{|\mathcal{H}|}{n}$, in which case we need to partition large $\mathcal{H}_i$ into smaller sets to ensure the matrix $A(\psi)$ does not have too many nonzero entries. In addition, we can no longer guarantee that $A(\psi)$ is a spectral certificate with high probability. We thus define a notion of a regular partition and a refined notion of a spectral certificate that allows us to delete a negligible fraction of rows and columns of the matrix.

▶ **Definition 4.3.** *For all $\mathcal{H}_1 \sqcup \cdots \sqcup \mathcal{H}_n$, Let $\mathcal{H} \subseteq [n]^k$. We call a partition $P \coloneqq \bigsqcup_i P_i \coloneqq \bigsqcup_i \bigsqcup_{j\in[p_i]} \mathcal{H}_i^{(j)}$ of the $\mathcal{H}_i$s* regular *if it has a total of at most $2n$ parts and $|\mathcal{H}_i^{(j)}| \leqslant \frac{|\mathcal{H}|}{n}$ for all i, j.*

▶ **Definition 4.4** ((γ,δ)-Spectral Certificates)**.** *Let k be an odd integer and $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a k-XOR instance with clause set $\mathcal{H}$. Suppose we have a partition $P_i \coloneqq \sqcup_{j\in[p_i]}\mathcal{H}_i^{(j)}$ of each $\mathcal{H}_i$, and let $P = (P_1, \cdots, P_n)$. Define $A'_P(\psi)$ to be a $n^{k-1} \times n^{k-1}$ matrix defined as follows: For all $(S_1, T_1) \neq (S_2, T_2) \in [n]^{(k-1)/2} \times [n]^{(k-1)/2}$, we have*

$$A'_P(\psi)_{(S_1,S_2),(T_1,T_2)} \coloneqq \sum_{i\in[n]}\sum_{j\in[p_i]} b_{S_1T_1i}b_{S_2T_2i} \cdot \mathbf{1}\{S_1T_1i, S_2T_2i \in \mathcal{H}_i^{(j)}\}$$
$$+ b_{T_1S_1i}b_{T_2S_2i} \cdot \mathbf{1}\{T_1S_1i, T_2S_2i \in \mathcal{H}_i^{(j)}\}\,,$$

*and $A'_P(\psi)_{(S_1,S_1),(S_2,S_2)} = 0$. Let $A(\psi)$ be a principal submatrix of $A'_P(\psi)$, and define $D(\psi)_{S_1,S_2} \coloneqq \|A_{S_1,S_2}\|_1$ and write $D(\psi) \coloneqq \operatorname{diag}(\{D(\psi)_{S_1,S_2}\})$. We call $A(\psi)$ a (γ,δ)-*spectral certificate of ψ with respect to P *if the following hold:*

- *$A(\psi)$ can be formed by removing a collection of rows of $A'_P(\psi)$ and their corresponding columns whose ℓ_1 norms sum to at most $\frac{\gamma^2}{2}\sum_{i\in[n]}\sum_{j\in[p_i]}|\mathcal{H}_i^{(j)}|(|\mathcal{H}_i^{(j)}|-1)$,*
- *$\rho(D^{-1}(\psi)A(\psi)) \leqslant n^{-\delta/2}$, where $\rho(\cdot)$ denotes the spectral radius of a matrix.*

Observe that (abusing notation and treating $A(\psi)$ as a $n^{k-1}\times n^{k-1}$ matrix where the removed rows are replaced by zeros), we have

$$x^{\odot(k-1)}A'_P(\psi)x^{\odot(k-1)} = 2\sum_i \sum_{j\in[p_i]} \sum_{U\neq U'\in\mathcal{H}_i^{(j)}} b_U b_{U'} x^U x^{U'},$$

and

$$x^{\odot(k-1)}\left(A'_P(\psi)-A(\psi)\right)x^{\odot(k-1)} \leqslant \frac{\gamma^2}{2}\sum_{S_1,S_2}|A'_P(\psi)_{S_1,S_2}|.$$

▶ **Definition 4.5.** *Let k be an integer and $\psi(x)=\sum_{U\in\mathcal{H}} b_U\cdot x^U$ be a k-XOR instance with clause set $\mathcal{H}$. Then we define $\psi^{\mathbf{1}}(x) \coloneqq \sum_{U\in\mathcal{H}} x^U$ to be the k-XOR instance with the same constraints but all ones on the RHS.*

▶ Remark 4.6. Note that any entry $A'_P(\psi)_{(S_1,S_2),(T_1,T_2)}$ is the sum of $A'_P(\psi^{\mathbf{1}})_{(S_1,S_2),(T_1,T_2)}$ independent Rademacher random variables. In particular, if $A'_P(\psi^{\mathbf{1}})_{(S_1,S_2),(T_1,T_2)}\neq 0$, then $A'_P(\psi)_{(S_1,S_2),(T_1,T_2)}=0$ with probability at most $\frac{1}{2}$.

We will show that the existence of a (γ,δ)-spectral certificate of ψ implies that Sherali-Adams admits a refutation of ψ.

▶ **Lemma 4.7.** *Let k be an odd integer and $\psi(x)=\sum_{U\in\mathcal{H}} b_U\cdot x^U$ be a semirandom k-XOR instance. Suppose that there exists a (γ,δ)-spectral certificate for ψ with respect to a regular partition P of all $\mathcal{H}_i$. Then if $\gamma\leqslant\frac{1}{2}$ and $|\mathcal{H}|\geqslant\frac{4n}{\gamma^2}$, then $R=O_{\gamma,\delta,k}(1)$-rounds of Sherali-Adams can certify that $\psi(x)\leqslant 2\gamma|\mathcal{H}|$; in other words, for all R-local pseudodistributions $\mathcal{D}$, $|\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(x)|\leqslant 2\gamma|\mathcal{H}|$.*

Proof of Lemma 4.7. Let $\psi_{ij}=\sum_{U\in\mathcal{H}_i^{(j)}} b_U x^U$ and $A(\psi)$ be a (γ,δ)-spectral certificate of ψ. Let $R\coloneqq\max\{R(A(\psi)),\frac{5k}{\gamma^2}\}=O_{\gamma,\delta,k}(1)$, where $R(A(\psi))$ is the quantity from Lemma 3.8 when $\eta=\frac{\gamma^2}{2}$, and $\widetilde{\mathbb{E}}$ be an R-local pseudodistribution. Then $\rho(D^{-1}(\psi)A(\psi))\leqslant n^{-\delta/2}$ and thus by Lemma 3.8,

$$\begin{aligned}
\widetilde{\mathbb{E}}\sum_i\sum_{j\in[p_i]}\psi_{ij}^2(x) &= \widetilde{\mathbb{E}}\sum_{U\in\mathcal{H}} b_U^2 + \frac{1}{2}\widetilde{\mathbb{E}}x^{\odot(k-1)}A'(\psi)x^{\odot(k-1)}\\
&\leqslant |\mathcal{H}| + \frac{1}{2}\widetilde{\mathbb{E}}x^{\odot(k-1)}A(\psi)x^{\odot(k-1)} + \frac{1}{2}\widetilde{\mathbb{E}}x^{\odot(k-1)}(A'(\psi)-A(\psi))x^{\odot(k-1)}\\
&\leqslant |\mathcal{H}| + \left(\frac{\gamma^2}{2}+\frac{\gamma^2}{4}\right)\sum_i\sum_{j\in[p_i]}|\mathcal{H}_i^{(j)}|(|\mathcal{H}_i^{(j)}|-1)\\
&\leqslant |\mathcal{H}| + \frac{3\gamma^2}{4}\frac{|\mathcal{H}|^2}{n},
\end{aligned}$$

where the last line uses the fact that our partition is regular and therefore each $\mathcal{H}_i^{(j)}$ has size at most $\frac{|\mathcal{H}|}{n}$. Thus by Theorem 2.1, since P has at most $2n$ parts, we have, for $s\geqslant\frac{4}{\gamma^2}$,

$$\left|\widetilde{\mathbb{E}}\psi\right| = \left|\widetilde{\mathbb{E}}\sum_i \sum_{j\in[p_i]} \psi_{ij}(x)\right| \leqslant \sum_i \sum_{j\in[p_i]} \sqrt{\left(1-\frac{1}{s}\right)\widetilde{\mathbb{E}}\psi_{ij}^2 + \frac{1}{s}\left\|\psi_{ij}\right\|_1^2}$$
$$\leqslant \sqrt{2n\left(\left(1-\frac{1}{s}\right)\sum_i\sum_{j\in[p_i]}\widetilde{\mathbb{E}}\psi_{ij}^2 + \frac{|\mathcal{H}_i|^2}{sn}\right)}$$
$$\leqslant \sqrt{2n|\mathcal{H}| + 3\gamma^2|\mathcal{H}|^2 + \frac{2|\mathcal{H}|^2}{s}} \leqslant 2\gamma|\mathcal{H}|\,. \qquad \blacktriangleleft$$

Finally, we note that given sufficient regularity conditions on $\mathcal{H}$, there exists a spectral certificate of ψ with high probability.

▶ **Lemma 4.8.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a semirandom k-XOR instance with constraint set $\mathcal{H} \subseteq [n]^k$ such that $|\mathcal{H}| = n^{k/2+\delta}$ and let P be a regular partition of the $\mathcal{H}_i$s. Suppose $\mathcal{H}$ has the following properties:*

- *For all $S \in [n]^{(k-1)/2}$, $i \in [n]$, there are at most $n^{\delta/2}$ total clauses of the form STi or TSi in $\mathcal{H}$.*
- *For all $S_1T_1 \in [n]^{(k-1)/2} \times [n]^{(k-1)/2}$, there are at most $n^{\delta/2}$ total clauses of the form $S_1T_1i \in \mathcal{H}$.*

Suppose that $\gamma \geqslant n^{-\delta/4}\sqrt{60}$ and $16384k^4\log^3 n \leqslant n^{\delta/18}$. Then with high probability, there exists a $(\gamma, \delta/9)$-spectral certificate of ψ with respect to P.

We defer the proof of this lemma to Section 4.3.

4.1 Refuting induced 2-XOR instances

Unlike the random case, a semirandom XOR instance ψ does not necessarily have a spectral certificate: when large groups of variables occur together in a large number of clauses, the spectral norm of $A'(\psi)$ can be large and making it sufficiently small requires pruning a large (possible almost all) of the rows. Instead, we can partition our set of clauses $\mathcal{H}$ into two subparts $\mathcal{H}'$ and $\mathcal{H}''$, where for $\mathcal{H}'$ is the "approximately regular" part where we can construct the aforementioned spectral certificate, and for the second part $\mathcal{H}''$, we instead construct a 2-XOR instance that we can refute using Sherali-Adams. At a high level, this resembles the approach of [1], however, their method for refuting the 2-XOR instance for $\mathcal{H}''$ relies on bounding the value of the instance by an infinity-to-1 norm and using the fact that SOS can recognize Grothendieck's inequality. This is not known for Sherali-Adams, so we must handle this case differently.

We define the notion of an induced 2-XOR instance below. This is a 2-XOR instance formed by splitting each clause U of a k-XOR instance into two parts $S \sqcup T$, defining a variable y_S and y_T for each of the two parts, and replacing the k-XOR constraint $b_U x^U$ with the 2-XOR constraint $b_U y_S y_T$. Formally, we have a bijective map between our clause $U \in \mathcal{H}$ and the partition (S,T), and using the transformation $y_S = \prod_{i\in S} x_i$, for all x, there exists y such that $\phi(y) = \psi(x)$.

▶ **Definition 4.9.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a semirandom k-XOR instance with constraint set $\mathcal{H} \subseteq [n]^k$. We call a 2-XOR instance ϕ an* f-induced 2-XOR instance *of ψ if each of its variables y_S is indexed by some $S \subseteq [n]^{\leqslant k}$ and there exists a set $\mathcal{B} = \mathcal{B}(\phi)$ of pairs of variables (S,T) and a bijection $f : \mathcal{B} \to \mathcal{H}$ such that ST is a permutation of $f(S,T)$ and ϕ can be written as*

$$\phi = \sum_{(S,T)\in\mathcal{B}} b_{f(S,T)} y_S y_T\,,$$

Let $d^{\phi}(S) = |\{U \in \mathcal{H} : f^{-1}(U) \ni S\}|$ denote the number of times the variable y_S appears in the above expression for ϕ, which we call the degree *of S in ϕ. Then we define the weighted adjacency matrix $A'(\phi)$ of ϕ with rows and columns indexed by variables of ϕ:*

$$(A'(\phi))_{S,T} = b_{f(S,T)}\mathbf{1}\{(S,T) \in \mathcal{B}\} + b_{f(T,S)}\mathbf{1}\{(T,S) \in \mathcal{B}\}\,.$$

Let $A(\phi)$ be a principal submatrix of $A'(\phi)$ and let $D(\phi)$ be the degree matrix of $A(\phi)$. We call $A(\phi)$ an induced (γ,δ)-spectral certificate for ψ *if the following hold:*

- *$A(\phi)$ can be formed by deleting rows of $A'(\phi)$ and their corresponding columns whose ℓ_1 norms sum to at most $\gamma \sum_{S,T} |A'(\phi)_{S,T}|$,*
- *$\rho(D^{-1}(\phi)A(\phi)) \leqslant n^{-\delta}$.*

A Sherali-Adams refutation of an induced 2-XOR instance of ψ implies a refutation of ψ itself, which we prove in the appendix.

▶ **Lemma 4.10.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a k-XOR instance with constraint set $\mathcal{H} \subseteq [n]^k$ and ϕ be an f-induced 2-XOR instance of ψ. Suppose that for all R-local pseudodistributions $\mathcal{D}'$, we have $|\widetilde{\mathbb{E}}_{\mathcal{D}'}\phi(y)| \leqslant 2\gamma|\mathcal{H}|$. Then for all kR-local pseudodistributions $\mathcal{D}$, we have $|\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(x)| \leqslant 2\gamma|\mathcal{H}|$.*

Using this, we prove that Sherali-Adams can refute XOR instances with an induced spectral certificate.

▶ **Lemma 4.11.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a k-XOR instance and suppose there exists an induced (γ,δ)-spectral certificate for ψ. Then $R = O_{\gamma,\delta,k}(1)$-rounds of Sherali-Adams can certify that $\psi(x) \leqslant 2\gamma|\mathcal{H}|$; in other words, for all R-local pseudodistributions $\mathcal{D}$, $|\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(x)| \leqslant 2\gamma|\mathcal{H}|$.*

Proof. Let ϕ be an f-induced 2-XOR instance of ψ and $A(\phi)$ be a corresponding induced (γ,δ)-spectral certificate. Let $R \coloneqq k \cdot R(A(\phi))$, where $R(A(\phi))$ is the quantity from Lemma 3.8 where $\eta = \gamma$, and let $\mathcal{D}$ be any $R = O_{\gamma,\delta,k}(1)$-local pseudodistribution. Since $\rho(D^{-1}(\phi)A(\phi)) \leqslant n^{-\delta}$, by Lemma 3.8, for any $R(A(\phi))$-local pseudodistribution $\mathcal{D}'$, we have

$$\begin{aligned}
|\widetilde{\mathbb{E}}_{\mathcal{D}'}\phi(y)| &= \frac{1}{2}\left|\widetilde{\mathbb{E}}y^\top A'(\phi)y\right| \\
&= \frac{1}{2}\left|\widetilde{\mathbb{E}}y^\top A(\phi)y\right| + \frac{1}{2}\left|\widetilde{\mathbb{E}}y^T(A'(\phi)-A(\phi))y\right| \\
&\leqslant \gamma|\mathcal{H}| + \gamma|\mathcal{H}| = 2\gamma|\mathcal{H}|\,,
\end{aligned}$$

so $\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(x) \leqslant 2\gamma|\mathcal{H}|$ by Lemma 4.10. ◀

Furthermore, induced 2-XOR instances without too many variables admit an induced spectral certificate for its parent instance, which we show in Section 4.3.

▶ **Lemma 4.12.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a semirandom k-XOR instance with constraint set $\mathcal{H} \subseteq [n]^k$ and ϕ be an f-induced 2-XOR instance of ψ with variable set $\mathcal{S}$ such that $|\mathcal{S}| \leqslant n^{-\delta}|\mathcal{H}|$. If $\gamma \geqslant n^{-\delta/2}$ and $4\sqrt{k\log n} \leqslant n^{\delta/20}$, then with high probability, there exists an induced $(\gamma, \frac{\delta}{5})$-spectral certificate for ψ with respect to $(\mathcal{B}, f)$.*

4.2 Proof of Theorem 4.2

Here we prove the main result of this section.

Proof of Theorem 4.2. First, suppose that k is even. For all $U = ST \in \mathcal{H}$, where $S, T \in [n]^{k/2}$ define $f(S,T) := U$. Construct the f-induced 2-XOR instance ϕ of ψ. Then we have at most $n^{k/2} = n^{-\delta}|\mathcal{H}|$ total variables, so by Lemma 4.12, there exists an induced $(\gamma, \frac{\delta}{5})$-spectral certificate for ψ with respect to f. Thus by Lemma 4.11, there exists some $R = O_{\gamma,\delta,k}(1)$ such that for all R-local pseudodistributions $\mathcal{D}$, we have $|\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(x)| \leqslant 2\gamma|\mathcal{H}|$.

Now suppose that k is odd. We construct a partition $\mathcal{H} = \mathcal{H}' \sqcup \mathcal{H}'' \sqcup \mathcal{H}'''$ as follows:

1. While there exists some $S \in [n]^{(k-1)/2}$ and $i \in [n]$ such that there are more than $n^{\delta/2}$ total clauses of the form STi or TSi in $\mathcal{H}$, move all STi and TSi to a new hypergraph $\mathcal{H}'$.
2. Afterwards, while there exist some $(S,T) \in [n]^{(k-1)/2} \times [n]^{(k-1)/2}$ such that there are more than $n^{\delta/2}$ total clauses of the form $STi \in \mathcal{H}$, move all such STi from $\mathcal{H}$ to a new hypergraph $\mathcal{H}''$.
3. Let $\mathcal{H}'''$ consist of the remaining clauses.

Now, consider $\mathcal{H}'$. If $|\mathcal{H}'| \leqslant \frac{\gamma}{2}|\mathcal{H}|$, then $\psi(\mathcal{H}') \leqslant \frac{\gamma}{2}|\mathcal{H}|$ trivially. Otherwise, each edge $STi \in \mathcal{H}'$ consists of one part $(S,i) \in [n]^{(k-1)/2} \times [n]$ and one part $T \in [n]^{(k-1)/2}$. By construction, we have at most $n^{k/2+\delta/2}$ different (S,i) that occur in $\mathcal{H}'$, since each must occur in at least $n^{\delta/2}$ tuples for it to be added to $\mathcal{H}'$, and there are at most $n^{(k-1)/2}$ total T. Thus, when we use these clauses to construct an induced 2-XOR instance (letting $f((S,i),T) = STi$ if (S,i) was the heavy part and $f(S,(T,i)) = STi$ if (T,i) was the heavy part), we will have $\leqslant n^{k/2+\delta/2} + n^{(k-1)/2} \leqslant n^{-\delta/3}|\mathcal{H}'|$ total variables. Thus by Lemma 4.12, there exists an induced $(\frac{\gamma}{2}, \frac{\delta}{15})$-spectral certificate for $\psi(\mathcal{H}')$, so by Lemma 4.11 there exists some $R' = O_{\gamma/2,\delta/15,k}(1) = O_{\gamma,\delta,k}(1)$ such that for all R'-local pseudodistributions $\mathcal{D}'$, we have $\widetilde{\mathbb{E}}_{\mathcal{D}'}\psi(\mathcal{H}') \leqslant \gamma|\mathcal{H}'|$.

Similarly for $\mathcal{H}''$ either $|\mathcal{H}''| \leqslant \frac{\gamma}{2}|\mathcal{H}|$ and thus $\psi(\mathcal{H}'') \leqslant \frac{\gamma}{2}|\mathcal{H}|$, or we can construct an induced 2-XOR instance whose variables are $ST \in [n]^{k-1}$ which occur together in at least $n^{\delta/2}$ clauses and $i \in [n]$. Therefore we will have $\leqslant n^{k/2+\delta/2} + n \leqslant n^{-\delta/3}|\mathcal{H}''|$ total variables, so like before there exists an induced $(\frac{\gamma}{2}, \frac{\delta}{15})$-spectral certificate for $\psi(\mathcal{H}'')$ so for all R'-local pseudodistributions $\mathcal{D}'$, we have $\widetilde{\mathbb{E}}_{\mathcal{D}'}\psi(\mathcal{H}'') \leqslant \gamma|\mathcal{H}''|$.

Finally, for $\mathcal{H}'''$, if $|\mathcal{H}'''| \leqslant \frac{\gamma}{2}|\mathcal{H}|$, then $\psi(\mathcal{H}''') \leqslant \frac{\gamma}{2}|\mathcal{H}|$. Otherwise, construct a regular partition P of $\mathcal{H}'''$ by taking each $\mathcal{H}'''_i$ of size larger than $\frac{|\mathcal{H}'''|}{n}$ and repeatedly peeling off $\frac{|\mathcal{H}'''|}{n}$ at a time. Then $\mathcal{H}'''$ satisfies the conditions of Lemma 4.8 so there exists a $(\frac{\gamma}{2}, \frac{\delta}{9})$-spectral certificate for $\psi(\mathcal{H}''')$. Thus by Lemma 4.7, there exists some $R''' = O_{\gamma/2,\delta/9,k}(1) = O_{\gamma,\delta,k}(1)$ such that for all R'''-local pseudodistributions $\mathcal{D}'$, we have $\widetilde{\mathbb{E}}_{\mathcal{D}'}\psi(\mathcal{H}''') \leqslant \gamma|\mathcal{H}'''|$.

Combining the above and letting $R := \max(R', R''')$, for all R-local pseudodistributions $\mathcal{D}$, we have

$$\begin{aligned}\left|\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(x)\right| &\leqslant \left|\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(\mathcal{H}')(x)\right| + \left|\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(\mathcal{H}'')(x)\right| + \left|\widetilde{\mathbb{E}}_{\mathcal{D}}\psi(\mathcal{H}''')(x)\right| \\ &\leqslant \frac{\gamma}{2}|\mathcal{H}| + \frac{\gamma}{2}|\mathcal{H}| + \gamma(|\mathcal{H}'| + |\mathcal{H}''| + |\mathcal{H}'''|) \\ &\leqslant 2\gamma|\mathcal{H}|\,.\end{aligned}$$

◀

4.3 Existence of spectral certificates

Here we prove Lemma 4.8 and Lemma 4.12. We use the following result, which we defer to the appendix, in the proof of Lemma 4.8.

▶ **Lemma 4.13.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a semirandom k-XOR instance with constraint set $\mathcal{H} \subseteq [n]^k$ such that $|\mathcal{H}| = n^{k/2+\delta}$ and let P be a regular partition of the $\mathcal{H}_i$s. Suppose $\mathcal{H}$ has the following properties:*

- *For all $S \in [n]^{(k-1)/2}$, $i \in [n]$, there are at most $n^{\delta/2}$ total clauses of the form STi or TSi in $\mathcal{H}$.*
- *For all $S_1T_1 \in [n]^{(k-1)/2} \times [n]^{(k-1)/2}$, there are at most $n^{\delta/2}$ total clauses of the form $S_1T_1i \in \mathcal{H}$.*

Then with high probability, there exists a principal submatrix $A(\psi)$ of $A'(\psi)$ such that all of the following hold:

- *The deleted rows and columns of $A'(\psi)$ have ℓ_1 norms summing to at most*

$$30n^{-\delta/2} \sum_{i\in[n]} \sum_{j\in[p_i]} |\mathcal{H}_i^{(j)}|(|\mathcal{H}_i^{(j)}| - 1)\,.$$

- *Each row of $A(\psi)$ has at least n^δ nonzero entries.*
- *Each row of $A(\psi)$ has at least $\frac{1}{3}$ as many nonzero entries as the corresponding row of $A(\psi^{\mathbf{1}})$, where we recall that $A'(\psi^{\mathbf{1}})$ is the matrix defined with the same $\mathcal{H}$ as ψ but with all b_Us equal to 1.*
- *Each entry of $A(\psi)$ has absolute value at most $4kn^{\delta/4}\sqrt{\log n}$.*

▶ **Lemma 4.8.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a semirandom k-XOR instance with constraint set $\mathcal{H} \subseteq [n]^k$ such that $|\mathcal{H}| = n^{k/2+\delta}$ and let P be a regular partition of the $\mathcal{H}_i$s. Suppose $\mathcal{H}$ has the following properties:*

- *For all $S \in [n]^{(k-1)/2}$, $i \in [n]$, there are at most $n^{\delta/2}$ total clauses of the form STi or TSi in $\mathcal{H}$.*
- *For all $S_1T_1 \in [n]^{(k-1)/2} \times [n]^{(k-1)/2}$, there are at most $n^{\delta/2}$ total clauses of the form $S_1T_1i \in \mathcal{H}$.*

Suppose that $\gamma \geqslant n^{-\delta/4}\sqrt{60}$ and $16384k^4 \log^3 n \leqslant n^{\delta/18}$. Then with high probability, there exists a $(\gamma, \delta/9)$-spectral certificate of ψ with respect to P.

Proof. Let $A(\psi)$ be the principal submatrix of $A'(\psi)$ given by Lemma 4.13. Since $\gamma \geqslant \sqrt{60}n^{-\delta/4}$, it satisfies the first condition of a (γ, δ)-spectral certificate with high probability. Now we prove the second condition. Let $D(\psi)$ be the degree matrix of $A(\psi)$, $D(\psi^{\mathbf{1}})$ be the degree matrix of $A(\psi^{\mathbf{1}})$, and $M(\psi)$ be the degree matrix of the support matrix of $A(\psi^{\mathbf{1}})$, i.e. a diagonal entry of $M(\psi)$ is the number of nonzero entries in the corresponding row of $A(\psi^{\mathbf{1}})$.

Note that we have $M(\psi) \leqslant 3D(\psi)$ entrywise. Define $\Gamma \coloneqq M(\psi)^{-1/2}A(\psi)M(\psi)^{-1/2}$, so we have

$$\rho(D(\psi)^{-1}A(\psi)) \leqslant 3\rho(M(\psi)^{-1}A(\psi)) = 3\rho(\Gamma) \leqslant 3\,\|\Gamma\|\,.$$

We start by upper bounding $\mathbb{E}\mathrm{tr}(\Gamma^\ell) = \mathbb{E}\mathrm{tr}((M^{-1}(\psi)A(\psi))^\ell)$ for even ℓ by analyzing closed length-ℓ walks $V_1 \mapsto V_2 \mapsto \cdots \mapsto V_\ell \mapsto V_1$ in the weighted multigraph whose vertices are variables of ψ corresponding to the weighted signed adjacency matrix $M^{-1}(\psi)A(\psi)$. Note that for any edge between two vertices $V_j = (S_1, S_2)$ and $V_{j+1} = (T_1, T_2)$, there exists some i such that either both $S_1T_1i, S_2T_2i \in \mathcal{H}$ or both $T_1S_1i, T_2S_2i \in \mathcal{H}$. Since each $U \in \mathcal{H}$ comes with an independent Rademacher sign ξ_U, if some clause $U \in \mathcal{H}$ appears only once as one of the two clauses inducing an edge in our walk, then the expected value of the walk is 0. Therefore, in a walk with a nonzero contribution to the expected trace, each clause which induces an edge must occur at least twice.

Then we can define an encoding of any closed walk $V_1 \mapsto V_2 \mapsto \cdots \mapsto V_\ell \mapsto V_1$ by first choosing a variable $V_j = (S_1, S_2)$, of which there are at most n^{k-1} choices, then choosing $b \in \{0,1\}^\ell$ such that b_j is the indicator that both of the two tuples which induce the edge from V_j to V_{j+1} have not induced a previous step in the walk. Since each edge must occur at least twice, we note that $b_j = 0$ for at least $\frac{\ell}{2}$ values of j.

At each step j, we choose the next step of the walk based on the value of b_j: At $V_j = (S_1, S_2)$, if $b_j = 1$, we simply pick an arbitrary neighbor of V_j, while if $b_j = 0$, there are at most $2j \leqslant 2\ell$ possible $U \in \mathcal{H}$ to choose from which have induced a previous step in the walk. Therefore, when $b_j = 1$, there are at most $D(\psi)(V_j)$ possible choices, so $\sum_{V_{j+1} \in N_1(V_j)} \frac{1}{M(\psi)(V_j)} \leqslant \frac{D(\psi)(V_j)}{M(\psi)(V_j)} \leqslant 4kn^{\delta/4}\sqrt{\log n}$. When $b_j = 0$, without loss of generality, suppose the tuple we pick is of the form $S_1 T_1 i \in \mathcal{H}$ for some $i \in [n]$. Then the second tuple inducing this edge must be of the form $(S_2, T_2, i) \in \mathcal{H}_i^{(j)}$ for some $i \in [n], j \in [p_i]$, and there are at most $n^{\delta/2}$ total choices for that, so $\sum_{V_{j+1} \in N_0(V_j)} \frac{1}{M(\psi)(V_j)} \leqslant \frac{2\ell n^{\delta/2}}{n^\delta} \leqslant 2\ell n^{-\delta/2}$, since $M(\psi)(V_j) \geqslant n^\delta$. Thus we get

$$\begin{aligned}
\mathbb{E}\mathrm{tr}(\Gamma^\ell) &\leqslant \sum_{b \in \{0,1\}^\ell} \sum_{V_1 \in [n]^{k-1}} \frac{1}{M(\psi)(V_1)} \sum_{S_2 \in N_{b_1}(S_1)} \frac{1}{M(\psi)(S_2)} \\
&\qquad \cdots \sum_{S_\ell \in N_{b_{\ell-1}}(S_{\ell-1})} \frac{\mathbf{1}\{S_1 \in N_{b_\ell}(S_\ell)\}}{M(\psi)(S_\ell)} \\
&\leqslant 2^\ell n^{k-1} (4kn^{\delta/4}\sqrt{\log n} \cdot 2\ell n^{-\delta/2})^{\ell/2} \\
&= 2^\ell n^{k-1} (2\sqrt{2k\ell}(\log n)^{1/4} n^{-\delta/8})^\ell \,.
\end{aligned}$$

Therefore, we set $\ell = 2\left\lceil \frac{k \log n}{2} \right\rceil$ so by Markov's inequality, we have

$$\Pr\left[\|\Gamma\| \geqslant n^{-\delta/9} \geqslant 8\sqrt{2}kn^{-\delta/8}\log^{3/4} n\right] \leqslant \frac{\mathbb{E}\mathrm{tr}(\Gamma^\ell)}{(8\sqrt{2}kn^{-\delta/8}\log^{3/4} n)^\ell} = \frac{1}{\mathrm{poly}(n^k)} \,. \qquad \blacktriangleleft$$

▶ **Lemma 4.12.** *Let $\psi(x) = \sum_{U \in \mathcal{H}} b_U \cdot x^U$ be a semirandom k-XOR instance with constraint set $\mathcal{H} \subseteq [n]^k$ and ϕ be an f-induced 2-XOR instance of ψ with variable set $\mathcal{S}$ such that $|\mathcal{S}| \leqslant n^{-\delta}|\mathcal{H}|$. If $\gamma \geqslant n^{-\delta/2}$ and $4\sqrt{k \log n} \leqslant n^{\delta/20}$, then with high probability, there exists an induced $(\gamma, \frac{\delta}{5})$-spectral certificate for ψ with respect to $(\mathcal{B}, f)$.*

Proof. While $A'(\phi)$ contains a row with at most $n^{\delta/2}$ entries, delete that row and its corresponding column, and let $A(\phi)$ be the result. Then note that the deleted rows contain at most $|\mathcal{S}|n^{\delta/2} \leqslant n^{-\delta/2}|\mathcal{H}|$ entries. Now let $D(\phi)$ be the degree matrix of $A(\phi)$, and note that all diagonal entries of $D(\phi)$ are at least $n^{\delta/2}$. Define $\Gamma = D(\phi)^{-1/2} A(\phi) D(\phi)^{-1/2}$, and note that $\rho(D(\phi)^{-1}A(\phi)) = \rho(\Gamma) \leqslant \|\Gamma\|$. We start by upper bounding $\mathbb{E}\mathrm{tr}(\Gamma^\ell) = \mathbb{E}\mathrm{tr}((D^{-1}(\phi)A(\phi))^\ell)$ by analyzing closed even length-ℓ walks $S_1 \mapsto S_2 \mapsto \cdots \mapsto S_\ell \mapsto S_1$ in the weighted graph whose vertices are variables of ϕ which corresponds to the weighted signed adjacency matrix $(D^{-1}(\phi)A(\phi)$. Note that there exists an edge between two vertices S_i, S_{i+1} if either $f(S_i, S_{i+1}) \in \mathcal{H}$ or $f(S_{i+1}, S_i) \in \mathcal{H}$. Since each $U \in \mathcal{H}$ comes with an independent Rademacher sign ξ_U, if some unordered tuple (S, T) appears only once as an edge of the walk, then the expected value of the walk is 0. Therefore, each edge in a walk with a nonzero contribution to the expected trace must occur at least twice. Then we can define an encoding of any closed walk $S_1 \mapsto S_2 \mapsto \cdots \mapsto S_\ell \mapsto S_1$ by first choosing a variable S_1, of which there are $|[n]^{k-1}| < n^k$ choices, then choosing $b \in \{0,1\}^\ell$ such that b_i is the indicator that the ith edge of the walk has not occurred in a previous step. Since each edge must occur at least twice, we note that $b_i = 0$ for at least $\frac{\ell}{2}$ values of i.

At each step i, we choose the next step of the walk based on the value of b_i: At S_{i-1}, if $b_i = 1$, we simply pick an arbitrary neighbor of S_{i-1}, while if $b_i = 0$, we pick some S_i such that the edge (S_{i-1}, S_i) has occurred previously. Then, when $b_i = 1$, there are at most $D(\phi)(S_{i-1})$ possible choices, so $\sum_{S_i \in N_1(S_{i-1})} 1/D(\phi)(S_{i-1}) \leqslant 1$. When $b_i = 0$, there are at most $i - 1 \leqslant \ell$ previous edges to choose from, so $\sum_{S_i \in N_0(S_{i-1})} 1/D(\phi)(S_{i-1}) \leqslant \ell n^{-\delta/2}$. Combining the above, we get

$$\begin{aligned}\mathbb{E}\mathrm{tr}(\Gamma^\ell) &\leqslant \sum_{b \in \{0,1\}^\ell} \sum_{S_1 \in \mathcal{S}} \frac{1}{D(\phi)(S_1)} \sum_{S_2 \in N_{b_1}(S_1)} \frac{1}{D(\phi)(S_2)} \cdots \sum_{S_\ell \in N_{b_{\ell-1}}(S_{\ell-1})} \frac{\mathbf{1}\{S_1 \in N_{b_\ell}(S_\ell)\}}{D(\phi)(S_\ell)} \\ &\leqslant 2^\ell n^k (\ell n^{-\delta/2})^{\ell/2} \,.\end{aligned}$$

Therefore, we set $\ell = 2\left\lceil \frac{3k \log_2 n}{4} \right\rceil$ so by Markov's inequality, we have

$$\Pr\left[\|\Gamma\| \geqslant n^{-\delta/5} \geqslant 4n^{-\delta/4}\sqrt{k \log_2 n}\right] \leqslant \frac{\mathbb{E}\mathrm{tr}(\Gamma^\ell)}{(4n^{-\delta/4}\sqrt{k \log_2 n})^\ell} = \frac{1}{\mathrm{poly}(n^k)} \,. \qquad \blacktriangleleft$$

A Proofs of auxiliary statements

In this section, we fill in the proofs of Lemma 3.7 and Lemma 3.8. The proofs here are all reformulations of ideas in prior works [2, 13] and are included here for completeness.

A.1 Auxiliary statements for random k-XOR

We show that with high probability, the matrix $A(\psi)$ defined in Definition 3.6 is a spectral certificate.

▶ **Lemma 3.7.** *Suppose ψ is a random k-XOR instance with $n^{k/2+\delta}$ constraints such that $2^{O(k)}\log^3 n \leqslant n^{\delta/2}$. Then $A(\psi)$ is a $\frac{\delta}{2}$-spectral certificate for ψ with high probability.*

This follows directly from the following two statements.

▶ **Fact A.1** ([2, Lemma A.5])**.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a k-XOR instance with $n^{k/2+\delta}$ expected constraints. Then with high probability, $\|A(\psi)\| \leqslant 2^{O(k)} n^{\delta}\log^3 n$.*

▶ **Proposition A.2.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a k-XOR instance with $n^{k/2+\delta}$ expected constraints. Then with probability $1 - 1/\mathrm{poly}(n)$, we have $\min_{(S_1,S_2)} \left\|A(\psi)_{(S_1,S_2)}\right\|_1 \geqslant \min\left(\frac{n^{2\delta}}{4}, \frac{n}{6}\right)$.*

Proof. First, suppose that $\delta < \frac{1}{2}$. Note that each $U \in [n]^k$ is included in $\mathcal{H}$ independently with probability $p = n^{-k/2+\delta}$. For all $S \in [n]^{(k-1)/2}$ and $i \in [n]$, the number of $(STi) \in \mathcal{H}$ is Binomial$(n^{(k-1)/2}, n^{-k/2+\delta})$. Then this is nonzero with probability $1-(1-n^{-k/2+\delta})^{n^{(k-1)/2}} \geqslant 1 - e^{-n^{\delta-1/2}} \geqslant n^{\delta-1/2}(1-o(1))$. Recall the notation $\psi^{\mathbf{1}}$ from Definition 4.5, and note that for any $(S_1,S_2) \in [n]^{(k-1)/2}\times[n]^{(k-1)/2}$, $A(\psi^{\mathbf{1}})_{(S_1,S_2)}$ has a total of $\sum_{i\in[n]} \mathbf{1}\{\exists S_1 Ti \in \mathcal{H}\}\mathbf{1}\{\exists S_2 Ti\in\mathcal{H}\}$ nonzero entries, which is Binomial with mean $n^{2\delta}(1-o(1))$ when $S_1 \neq S_2$ or mean $n^{\frac{1}{2}+\delta}(1-o(1)) \geqslant n^{2\delta}$ when $S_1 = S_2$, and thus it has at least $n^{2\delta}/2$ nonzero entries by Chernoff with probability $1-\exp(-\Omega(n^{2\delta}))$. Recall that if an entry of $A(\psi^{\mathbf{1}})$ is nonzero, then the corresponding entry of $A(\psi)$ is nonzero with probability at least $\frac{1}{2}$ (see Remark 4.6), so $A(\psi)_{(S_1,S_2)}$ has at least $n^{2\delta}/4$ nonzero entries with probability $1-\exp(-\Omega(n^{2\delta}))$. The result thus holds simultaneously for all $(S_1,S_2)\in[n]^{(k-1)/2}\times[n]^{(k-1)/2}$ by a union bound.

Now suppose that $\delta \geqslant \frac{1}{2}$. Then following the $\delta < \frac{1}{2}$ case, the number of $(STi) \in \mathcal{H}$ is nonzero with probability at least $1-(1-n^{-k/2+\frac{1}{2}})^{n^{(k-1)/2}} \geqslant 1-\frac{1}{e}-o(1)$. Then $\sum_{i\in[n]}\mathbf{1}\{\exists S_1 Ti\in\mathcal{H}\}\mathbf{1}\{\exists S_2 Ti\in\mathcal{H}\}$ is Binomial with mean at least $(1-\frac{1}{e}-o(1))^2 n$, and thus $A(\psi^{\mathbf{1}})_{(S_1,S_2)}$ has at least $n/3$ nonzero entries with probability $1-\exp(-\Omega(n))$ by Chernoff, and thus $A(\psi)_{(S_1,S_2)}$ has at least $n/6$ nonzero entries with probability $1-\exp(-\Omega(n))$, and as before this holds simultaneously for all (S_1,S_2) by a union bound. ◀

▶ **Lemma 3.8** (Abstracting out [13]). *Let A be a symmetric matrix with integer entries with rows and columns indexed by t-tuples of $[n]$, and let D be its degree matrix. Let $\pi_* = \frac{1}{\sum_{S,T}|A_{S,T}|}\min_S \|A_S\|_1$, $\rho(\cdot)$ denote the spectral radius of a matrix, and $\eta > \min(\pi_*^{-1/2}, \rho(D^{-1}A))$. Take $\ell \coloneqq \left\lceil \frac{1}{4}\frac{\log(\eta^2\pi_*)}{\log(\rho(D^{-1}A)/\eta)} \right\rceil$ and $p \coloneqq \lceil (\frac{2}{5\eta})^{2\ell} \rceil$. Then for $R(A) \coloneqq tp\ell + t$, any R-local pseudoexpectation $\mathcal{D}$ on $x_1, \cdots, x_n$ satisfies*

$$\left| \widetilde{\mathbb{E}}_{\mathcal{D}} (x^{\odot t})^\top A x^{\odot t} \right| \leqslant \eta \sum_{S,T} |A_{S,T}|,$$

where $x^{\odot t}$ is the n^t-dimensional vector whose entries are indexed by t-tuples of $[n]$ and are equal to the product of the corresponding entries.

We utilize the following reparameterization of results from [13]:

▶ **Fact A.3** ([13, Theorem 3.6, Corollary 3.7]). *Let $G = (V, E)$ be a multigraph with signs b_{uv} for all $uv \in E$ and signed transition operator $\overline{K}$. Suppose we have $\pi_* = \min_{v \in V} \frac{\deg(v)}{2|E|}$. Given $\gamma > \min(\pi_*^{-1/2}, \rho(\overline{K}))$, take $\ell = \left\lceil \frac{1}{4}\frac{\log(\gamma^2\pi_*)}{\log(\rho(\overline{K})/\gamma)} \right\rceil$, and take $k = \lceil (\frac{2}{5\gamma})^{2\ell} \rceil$. Then for $R = k\ell + 1$, it holds that R-local degree-2 SOS can deduce that for all $x \in \{\pm 1\}^V$,*

$$-\gamma \leqslant \frac{1}{|E|} \sum_{uv \in E} b_{uv} x_u x_v \leqslant \gamma\,.$$

Proof of Lemma 3.8. For all $S \subseteq [n]^t$, define a variable y_S. Define an R-local pseudoexpectation $\mathcal{D}'$ over the y_Ss by setting, for $r \leqslant R$,

$$\widetilde{\mathbb{E}}_{\mathcal{D}'}[y_{S_1} y_{S_2} \cdots y_{S_r}] \coloneqq \widetilde{\mathbb{E}}_{\mathcal{D}} \prod_{i \in S_1} x_i \prod_{i \in S_2} x_i \cdots \prod_{i \in S_r} x_i\,.$$

Applying Fact A.3 with $\eta = \gamma$, we see that $\widetilde{\mathbb{E}}_{\mathcal{D}'} \sum_{S,T} y_S y_T A_{S,T} \leqslant \eta \sum_{S,T} |A_{S,T}|$, and therefore

$$\begin{aligned}\widetilde{\mathbb{E}}_{\mathcal{D}} (x^{\odot t})^\top A x^{\odot t} &= \sum_{S,T} A_{S,T} \widetilde{\mathbb{E}}_{\mathcal{D}} \prod_{i \in S} x_i \prod_{i \in T} x_i \\ &= \widetilde{\mathbb{E}}_{\mathcal{D}'} \sum_{S,T} A_{S,T} y_S y_T \leqslant \eta \sum_{S,T} |A_{S,T}|\,.\end{aligned}$$ ◀

A.2 Auxiliary statements for semirandom k-XOR

▶ **Lemma 4.10.** *Let $\psi(x) = \sum_{U \in \mathcal{H}} b_U \cdot x^U$ be a k-XOR instance with constraint set $\mathcal{H} \subseteq [n]^k$ and ϕ be an f-induced 2-XOR instance of ψ. Suppose that for all R-local pseudodistributions $\mathcal{D}'$, we have $|\widetilde{\mathbb{E}}_{\mathcal{D}'} \phi(y)| \leqslant 2\gamma|\mathcal{H}|$. Then for all kR-local pseudodistributions $\mathcal{D}$, we have $|\widetilde{\mathbb{E}}_{\mathcal{D}} \psi(x)| \leqslant 2\gamma|\mathcal{H}|$.*

Proof. Let $\mathcal{D}$ be a kR-local pseudodistribution over variables $x_1, \cdots, x_n$. Letting $\mathcal{S}$ be the variable set of ϕ, define an R-local pseudodistribution $\mathcal{D}'$ over variables y_S of ϕ by setting, for $r \leqslant R$,

$$\widetilde{\mathbb{E}}_{\mathcal{D}'}[y_{S_1} y_{S_2} \cdots y_{S_r}] \coloneqq \widetilde{\mathbb{E}}_{\mathcal{D}} \prod_{i \in S_1} x_i \prod_{i \in S_2} x_i \cdots \prod_{i \in S_r} x_i\,.$$

Then we have

$$\widetilde{\mathbb{E}}_{\mathcal{D}} \psi(x) = \widetilde{\mathbb{E}}_{\mathcal{D}} \sum_{(S,T) \in \mathcal{B}} b_{f(S,T)} \prod_{i \in S} x_i \prod_{i \in T} x_i = \widetilde{\mathbb{E}}_{\mathcal{D}'} \sum_{(S,T) \in \mathcal{B}} b_{f(S,T)} y_S y_T = \widetilde{\mathbb{E}}_{\mathcal{D}'} \phi(y) \leqslant 2\gamma|\mathcal{H}|\,.$$ ◀

▶ **Lemma 4.13.** *Let $\psi(x) = \sum_{U\in\mathcal{H}} b_U \cdot x^U$ be a semirandom k-XOR instance with constraint set $\mathcal{H} \subseteq [n]^k$ such that $|\mathcal{H}| = n^{k/2+\delta}$ and let P be a regular partition of the $\mathcal{H}_i$s. Suppose $\mathcal{H}$ has the following properties:*

- *For all $S \in [n]^{(k-1)/2}$, $i \in [n]$, there are at most $n^{\delta/2}$ total clauses of the form STi or TSi in $\mathcal{H}$.*
- *For all $S_1T_1 \in [n]^{(k-1)/2} \times [n]^{(k-1)/2}$, there are at most $n^{\delta/2}$ total clauses of the form $S_1T_1i \in \mathcal{H}$.*

Then with high probability, there exists a principal submatrix $A(\psi)$ of $A'(\psi)$ such that all of the following hold:

- *The deleted rows and columns of $A'(\psi)$ have ℓ_1 norms summing to at most*

$$30n^{-\delta/2} \sum_{i\in[n]} \sum_{j\in[p_i]} |\mathcal{H}_i^{(j)}|(|\mathcal{H}_i^{(j)}| - 1)\,.$$

- *Each row of $A(\psi)$ has at least n^δ nonzero entries.*
- *Each row of $A(\psi)$ has at least $\frac{1}{3}$ as many nonzero entries as the corresponding row of $A(\psi^{\mathbf{1}})$, where we recall that $A'(\psi^{\mathbf{1}})$ is the matrix defined with the same $\mathcal{H}$ as ψ but with all b_Us equal to 1.*
- *Each entry of $A(\psi)$ has absolute value at most $4kn^{\delta/4}\sqrt{\log n}$.*

We use the following concentration result for dependent indicators.

▶ **Fact A.4** (Chernoff Bound for Weakly Dependent Random Variables). *[8] Suppose we have a set S of independent random variables and indicator random variables $Y_1, \cdots, Y_r$ with mean μ, such that each Y_i is a function of some $T_i \subseteq S$ and no $s \in S$ is contained in more than k total T_i's. Then for any $\varepsilon > 0$, we have*

$$\Pr[Y_1 + \cdots + Y_r \notin (\mu \pm \varepsilon)r] \leqslant 2e^{-2\varepsilon^2 r/k}\,.$$

Proof of Lemma 4.13. Note that since P has at most $2n$ parts, the total ℓ_1 norm of $A'(\psi^{\mathbf{1}})$ is $\sum_i \sum_{j\in[p_i]} \binom{|\mathcal{H}_i^{(j)}|}{2} \geqslant 2n \cdot \frac{1}{2}\left(\frac{|\mathcal{H}|}{2n}\right)^2 (1-o(1)) \geqslant \frac{1}{5}n^{k-1+2\delta}$. Also, since for all $(S_1,S_2),(T_1,T_2)$, there are at most $n^{\delta/2}$ total i such that $S_1T_1i \in \mathcal{H}$ or $S_2T_2i \in \mathcal{H}$, there are at most $n^{\delta/2}$ pairs of clauses that contribute to each entry of $A'(\psi)$; in other words, every entry of $A'(\psi^{\mathbf{1}})$ is at most $n^{\delta/2}$. Consider an arbitrary entry $(S_1,S_2),(T_1,T_2)$. We note that $A(\psi)_{(S_1,S_2),(T_1,T_2)}$ is the sum of $A(\psi^{\mathbf{1}})_{(S_1,S_2),(T_1,T_2)}$ products of independent Rademacher random variables, all of which are distinct, and thus it is also the sum of independent Rademachers, so $A(\psi)_{(S_1,S_2),(T_1,T_2)} \leqslant 4k\sqrt{A(\psi^{\mathbf{1}})_{(S_1,S_2),(T_1,T_2)}\log n} \leqslant 4kn^{\delta/4}\sqrt{\log n}$ with probability $1 - \frac{1}{n^{2k}}$ and thus it holds for all n^{2k-2} entries with probability $\geqslant 1 - 1/n^2$.

Now, while there exists some row of $A'(\psi^{\mathbf{1}})$ indexed by (S_1,S_2) whose total sum is less than $3n^{3\delta/2}$, delete that row and its corresponding column. Then the sum of the elements of $A'(\psi^{\mathbf{1}})$ we delete is at most $2 \cdot 3n^{k-1+3\delta/2} \leqslant 30n^{-\delta/2}\sum_{i\in[n]}\sum_{j\in[p_i]}|\mathcal{H}_i^{(j)}|(|\mathcal{H}_i^{(j)}|-1)$, and first condition then follows from the fact that the ℓ_1 norm of rows in $A'(\psi)$ is upper bounded by the sum of the corresponding row in $A'(\psi^{\mathbf{1}})$. Let $A(\psi)$ and $A(\psi^{\mathbf{1}})$ be the matrices after the deletion step.

Now consider a surviving row indexed by some (S_1,S_2), whose ℓ_1 norm is at least $3n^{3\delta/2}$. Since every entry of $A(\psi^{\mathbf{1}})$ is at most $n^{\delta/2}$, there are at least $3n^\delta$ nonzero entries in the row indexed by (S_1,S_2), each of which are indexed by some (T_1,T_2). Recall that if an entry $A(\psi^{\mathbf{1}})_{(S_1,S_2),(T_1,T_2)}$ is nonzero, then $A(\psi)_{(S_1,S_2),(T_1,T_2)}$ is nonzero with probability at least $\frac{1}{2}$ (Remark 4.6). Furthermore, each entry in row (S_1,S_2) of $A(\psi)$ depends on variables of the form b_{S_1Ti} and b_{S_2Ti}. Note that anytime some b_{S_1Ti} appears in row (S_1,S_2), it must be multiplied with some $b_{S_2T'i}$ (in which case it corresponds to the (T,T') entry of that

row). However, we are given that there are at most $n^{\delta/2}$ total $S_2T'i \in \mathcal{H}$, and thus b_{S_1Ti} appears in at most $n^{\delta/2}$ entries in row (S_1, S_2). Therefore, the family of indicators of entries in row (S_1, S_2) being nonzero is read-$n^{\delta/2}$ with respect to the b_Us, and thus after coupling to a family of indicators which occur with probability $\frac{1}{2}$, by Fact A.4, with probability $1 - \exp(-\Omega(n^{\delta/2}))$, the number of nonzero entries in row (S_1, S_2) of $A(\psi)$ is at least $\frac{1}{3}$ the number of nonzero entries in row (S_1, S_2) of $A(\psi^{\mathbf{1}})$, which is at least n^{δ}. Union bounding over all $\leqslant n^{k-1}$ rows of $A'(\psi)$ gives the desired result. ◀

Local Algorithms and the Failure of Log-Depth Quantum Advantage on Sparse Random CSPs

Abstract

We construct and analyze a message-passing algorithm for random constraint satisfaction problems (CSPs) at large clause density, generalizing work of El Alaoui, Montanari, and Sellke for Maximum Cut [3] through a connection between random CSPs and mean-field Ising spin glasses [1, 55]. For CSPs with even predicates, the algorithm asymptotically solves a stochastic optimal control problem dual to an extended Parisi variational principle. This gives an optimal fraction of satisfied constraints among algorithms obstructed by the branching overlap gap property of Huang and Sellke [50], notably including the Quantum Approximate Optimization Algorithm and all quantum circuits on a bounded-degree architecture of up to $\epsilon \cdot \log n$ depth [24].

1 Introduction

Today's quantum computers are starting to show signs of advantage over classical machines. Many people are seeking to use this technology in a practical application as soon as possible. One such area is combinatorial optimization: even though the problems are NP-hard, optimization has incredible value to the contemporary world. This industry is also eager to experiment with quantum computers, perhaps because rigorous worst-case analysis is not always relevant.

The most popular quantum protocol for classical optimization is the *Quantum Approximate Optimization Algorithm* (QAOA), proposed in [34]. Given an optimization problem, the protocol associates a qubit to each variable, and evolves a quantum state to a near-ground state of the problem, depending on choice of hyperparameters. The QAOA has also sparked the interest of theorists, characterizing the protocol's performance on canonical problems, and debating whether it is any more powerful than existing classical algorithms (e.g. [9, 45, 11]).

One key property of the QAOA is its *locality*: at each layer of the algorithm, a qubit interacts only with qubits associated with adjacent variables in the optimization problem. Locality is known to limit the QAOA up to logarithmic circuit depth when the optimization problem is *sparse* [32, 33]. This limitation is due to a phenomenon known as the *overlap gap property* (OGP), a type of clustering behavior of near-optimal solutions [44]. Notably, this is an *average-case* property of many random optimization problems. Recent formulations of the OGP have led to quantitative obstructions for broad families of algorithms, both quantum and classical [21, 24, 50].

In this work, we show that *with high probability* over a large family of sparse optimization problems, there is an *optimal* algorithm among those obstructed by the OGP. Furthermore, this algorithm is *classical*, so there can be no quantum advantage by the QAOA up to logarithmic depth. In fact, this no-go result extends to logarithmic-depth quantum circuits on fixed, bounded-degree architectures, such as the *brickwork* circuits [18] used in random circuit sampling [15]. This is the strongest *average-case* result known to the authors regarding quantum advantage in classical optimization.

Our algorithm is related to the theory of *message-passing* used in random inference problems [13], and inspired by rich connections to statistical physics models such as the mean-field spin glass [82]. The parameters of the algorithm are chosen by solving a stochastic control problem dual to a problem determining the quantitative barrier of the OGP, as pioneered in [1, 50]. In particular, our algorithm extends work of [3], and uses a sparse-to-dense connection observed in e.g. [26, 55]. The performance of the algorithm, like that of [68, 1, 3, 79], is dependent on a technical condition (Assumption 1) which we explain in the text.

1.1 Background

We study Constraint Satisfaction Problems (CSPs). A CSP instance consists of n variables and a set of constraints associated with a *predicate* $f : \{\pm 1\}^r \to \{0, 1\}$.

▶ **Definition 1** (Instance of a random CSP)**.** *Consider a function $f : \{\pm 1\}^r \to \{0, 1\}$. Fix a constant $\alpha > 0$. A* random CSP instance $\mathcal{I}$ *over n variables $\{x_i\}_{i\in[n]}$ and $m = \alpha \cdot n$ clauses is generated by the following procedure: For each $i = 1, \dots, m$, draw $i_1, \dots, i_r$ uniformly i.i.d from $[n]$, draw r random signs $\epsilon_{i_1}, \dots, \epsilon_{i_r}$ uniformly i.i.d from $\{\pm 1\}$, and add the constraint e to $E(\mathcal{I})$, where e describes the clause $f_e(x_e) \stackrel{\text{def}}{=} f(\epsilon_{i_1} x_{i_1}, \dots, \epsilon_{i_r} x_{i_r})$. A clause is satisfied if it evaluates to* 1.

We denote this random model as $\mathsf{CSP}_f(\alpha)$. We are interested in the best *satisfying fraction* (i.e. largest fraction of clauses satisfied by some assignment in $\{\pm 1\}^n$) an algorithm can achieve as $n \to \infty$ when α is a very large constant, i.e. so that instances of $\mathsf{CSP}_f(\alpha)$ are typically unsatisfiable. This value is related to the rich literature of *mean-field Ising spin glasses*. We summarize some relevant results, especially drawing on [1, 3, 55]. Let $\mathscr{U}$ denote the following set of functions:

$$\mathscr{U} \stackrel{\text{def}}{=} \left\{ \mu : [0, 1) \to \mathbb{R}_{\geq 0} : \mu \text{ is non-decreasing, right-continuous, and } \int_0^1 \mu(t)\, dt < \infty \right\}.$$

Given a univariate polynomial $\xi : \mathbb{R} \to \mathbb{R}$ with non-negative coefficients, define the functional $\mathsf{P}_\xi : \mathscr{U} \to \mathbb{R}$ given by

$$\mathsf{P}_\xi(\mu) \stackrel{\text{def}}{=} \Phi^\mu(0, 0) - \frac{1}{2} \cdot \int_0^1 \xi''(t) \cdot t \cdot \mu(t)\, dt\,,$$

where $\Phi^\mu : [0, 1) \times \mathbb{R} \to \mathbb{R}$ is a solution of the following partial differential equation:[1]

$$\begin{aligned} &\Phi^\mu_t(t, x) = -\frac{\xi''(t)}{2} \cdot \left(\Phi^\mu_{xx}(t, x) + \mu(t) \cdot \left(\Phi^\mu_x(t, x) \right)^2 \right) && \forall t \in [0, 1), \forall x \in \mathbb{R}\,, \\ &\Phi^\mu(1, x) = |x| && \forall x \in \mathbb{R}\,. \end{aligned} \tag{1.1}$$

P_ξ is known as the Parisi functional, while Equation (1.1) are known as the Parisi equations [73]. Let the infimum of P_ξ be defined as $\mathsf{OPT}_\xi \stackrel{\text{def}}{=} \inf_{\mu\in\mathscr{U}} \mathsf{P}_\xi(\mu)$.

[1] For the multivariable function $\Phi^\mu(t, x)$, we use subscripts to denote partial derivatives.

▶ **Theorem 2** ([6, 53]). *Consider any polynomial ξ with non-negative coefficients. Then OPT_ξ is achieved by some unique $\mu \in \mathcal{U}$.*

Surprisingly, the maximum satisfying fraction of a typical instance $\mathcal{I} \sim \mathsf{CSP}_f(\alpha)$ is related to OPT_ξ:

▶ **Theorem 3** ([55, Corollary 1.2], building on [73, 85, 70, 71, 26, 80, 72]). *Consider $\mathcal{I} \sim \mathsf{CSP}_f(\alpha)$. With high probability as $n \to \infty$, the maximum satisfying fraction of $\mathcal{I}$ is*[2]

$$\mathbb{E}[f] + \frac{\mathsf{OPT}_\xi}{\sqrt{\alpha}} + o_\alpha\left(\frac{1}{\sqrt{\alpha}}\right),$$

where $\xi(s) \stackrel{\text{def}}{=} \sum_{j=1}^{r} \|f^{=j}\|^2 s^j$, and $\|f^{=j}\|^2$ is the Fourier weight of f at degree j.

We also know that some algorithms are quantitatively obstructed due to the geometry of the solution space.

▶ **Definition 4** (Overlap-concentrated algorithm, [50, Definition 2.1]). *A deterministic algorithm $\mathcal{A}$ is* overlap-concentrated *with respect to a random family of problems $\mathcal{F}$ if the following is true for every $t \in [0,1]$ and constant $\delta > 0$: Draw two instances $\mathcal{I}_1, \mathcal{I}_2 \sim \mathcal{F}$ that are t-correlated.*[3] *Let $\mathcal{A}(\mathcal{I})$ be the assignment in $\{\pm 1\}^n$ that $\mathcal{A}$ generates on instance $\mathcal{I}$. Then the event*

$$\frac{1}{n}\left|\langle \mathcal{A}(\mathcal{I}_1), \mathcal{A}(\mathcal{I}_2)\rangle - \mathop{\mathbb{E}}_{\mathcal{I}_1,\mathcal{I}_2}[\langle \mathcal{A}(\mathcal{I}_1), \mathcal{A}(\mathcal{I}_2)\rangle]\right| \le \delta \tag{1.2}$$

occurs with high probability over choice of $\mathcal{I}_1, \mathcal{I}_2$.

For example, *local* algorithms in the factors of i.i.d. model and certain quantum circuits up to logarithmic depth [55] are overlap-concentrated on $\mathsf{CSP}_f(\alpha)$. A randomized algorithm is overlap-concentrated if the w.h.p. statement and the expectation in Equation (1.2) also vary over the algorithm's internal randomness.

We briefly explain the intuition of why Definition 4 prevents algorithms from succeeding on certain optimization problems; see [40] for more detail. Suppose the optimal assignments are *clustered*; i.e. they are "needles in the haystack". Then random instances will have "needles" in random locations in the solution space. But for $t \in [0,1]$, consider instances $\mathcal{I}_2(t)$ that are t-correlated with the initial instance $\mathcal{I}_1$. If the algorithm $\mathcal{A}$ is successful, the correlation $\frac{1}{n}\mathbb{E}_{\mathcal{I}_2(t)}[\langle \mathcal{A}(\mathcal{I}_1), \mathcal{A}(\mathcal{I}_2(t))\rangle]$ measures the correlation of these "needles" (i.e. good assignments), and so it varies smoothly from 0 to 1 as t goes from 0 to 1. The *overlap-concentrated* property is a bound on the variance of this quantity, meaning that with high probability over $\{\mathcal{I}_2(t)\}_{t\in[0,1]}$, the quantity $\frac{1}{n}\langle \mathcal{A}(\mathcal{I}_1), \mathcal{A}(\mathcal{I}_2(t))\rangle$ varies smoothly with t from 0 to 1. But this is not possible on problems that exhibit an *overlap gap property* (OGP)[4] across pairs of instances; so $\mathcal{A}$ cannot be successful at locating the "needles" or good assignments.

There is an emerging literature generalizing the *overlap gap property* with increasingly strong quantitative obstructions [44, 21, 43, 50]. We use the *branching OGP* of [50], which gives the strongest quantitative bounds of algorithms known on spin glasses and random CSPs [55].

---

[2] Following [26], we use $o_x(g(x))$ to mean the value is at most some function $\kappa(n,x)$ satisfying $\frac{\kappa(n,x)}{g(x)} \to 0$ as $n \to \infty$, then $x \to \infty$.

[3] Instances $\mathcal{I}_1, \mathcal{I}_2$ are t-correlated if a t fraction of constraints are identical, and the rest are independent; see also [55, Definition 6.1].

[4] An *overlap gap property* exists when an inner product, for example $\frac{1}{n}\langle \mathcal{A}(\mathcal{I}_1), \mathcal{A}(\mathcal{I}_2)\rangle$, is forbidden to take values within a certain range $[a,b]$.

Given a polynomial ξ with non-negative coefficients, let $\mathscr{L}_\xi$ denote the following set of functions:

$$\mathscr{L}_\xi \stackrel{\text{def}}{=} \left\{ \mu : [0,1) \to \mathbb{R}_{\geq 0} : \mu \text{ is right-continuous, } \|\xi''\mu\|_{\mathrm{TV}[0,t]} < \infty \ \forall t \in [0,1), \text{ and } \int_0^1 \xi''(t)\mu(t)\,dt < \infty \right\}.$$

Here, $\mathrm{TV}[a,b]$ over an interval $[a,b]$ is the total variance over partitions:

$$\|f\|_{\mathrm{TV}[a,b]} \stackrel{\text{def}}{=} \sup_n \sup_{a \leq t_0 < \cdots < t_n \leq b} \sum_{i \in [n]} |f(t_i) - f(t_{i-1})|\,.$$

Furthermore, the definition of P_ξ over $\mathscr{U}$ can be naturally extended to $\mathscr{L}_\xi$, with infimum

$$\mathsf{ALG}_\xi \stackrel{\text{def}}{=} \inf_{\mu \in \mathscr{L}_\xi} \mathsf{P}_\xi(\mu)\,. \tag{1.3}$$

Since $\mathscr{L}_\xi \supseteq \mathscr{U}$, we have $\mathsf{ALG}_\xi \leq \mathsf{OPT}_\xi$. It turns out that all *overlap-concentrated* algorithms over $\mathsf{CSP}_f(\alpha)$ are with high probability obstructed to some ALG_ξ:

▶ **Theorem 5** ([55, Corollary 6.10])**.** *Choose any* even *predicate f. For all $\epsilon > 0$ there is $\alpha_0 > 0$ such that the following is true: For all $\alpha \geq \alpha_0$, for every* overlap-concentrated *algorithm $\mathcal{A}$ over $\mathsf{CSP}_f(\alpha)$, and with high probability over instances $\mathcal{I} \sim \mathsf{CSP}_f(\alpha)$ as $n \to \infty$, $\mathcal{A}$ returns an assignment to $\mathcal{I}$ with satisfying fraction* at most

$$\mathbb{E}[f] + \frac{\mathsf{ALG}_\xi + \epsilon}{\sqrt{\alpha}}\,,$$

where $\xi(s) \stackrel{\text{def}}{=} \sum_{j=1}^r \|f^{=j}\|^2 s^j$, and $\|f^{=j}\|^2$ is the Fourier weight of f at degree j.

Note that if $\mathsf{ALG}_\xi \neq \mathsf{OPT}_\xi$, then these *overlap-concentrated* algorithms are obstructed from reaching the optimal solution for typical instances of $\mathsf{CSP}_f(\alpha)$.

1.2 Statement of results

The main result of our work is that there is an *optimal* algorithm among *overlap-concentrated* algorithms over $\mathsf{CSP}_f(\alpha)$, subject to a technical condition. This matches analogous results for Ising spin glasses [1], and for multi-species spherical spin glasses [84, 48].

▶ **Assumption 1** (Proposed in [79, Remark 1.7])**.** *For any polynomial ξ with non-negative coefficients and where $\xi''(0) \neq 0$,*[5] *ALG_ξ is achieved by some $\mu_* \in \mathscr{L}_\xi$. That is, the minimizer of Equation* (1.3) *exists.*

We include Assumption 1 because our algorithm uses the minimizer μ_*. As noted in [1, journal version, Remark 2.4], Assumption 1 should not have a major impact on the algorithm's performance, since by an informal continuity argument, using a near-minimizer $\widetilde{\mu}_* \in \mathscr{L}_\xi$ instead of μ_* incurs negligible error. We further discuss this in Section 5.

▶ **Theorem 6.** *Suppose Assumption 1 holds. Choose any predicate f without linear-weight terms; i.e. $\|f^{=1}\|^2 = 0$. For all $\epsilon > 0$ there is $\alpha_0 > 0$ such that the following is true: For all $\alpha \geq \alpha_0$, there exists a* randomized *algorithm $\mathcal{A}$ such that $\mathcal{A}$ is* overlap-concentrated *over $\mathsf{CSP}_f(\alpha)$, and with high probability over* both *instances $\mathcal{I} \sim \mathsf{CSP}_f(\alpha)$ and internal randomness of $\mathcal{A}$ as $n \to \infty$, $\mathcal{A}$ returns an assignment to $\mathcal{I}$ with satisfying fraction* at least

$$\mathbb{E}[f] + \frac{\mathsf{ALG}_\xi - \epsilon}{\sqrt{\alpha}}\,,$$

where $\xi(s) \stackrel{\text{def}}{=} \sum_{j=1}^r \|f^{=j}\|^2 s^j$, and $\|f^{=j}\|^2$ is the Fourier weight of f at degree j.

[5] It is shown in [79] that ALG_ξ is not achieved by any $\mu \in \mathscr{L}_\xi$ when $\xi''(0) = 0$. See also Remark 14.

This is analogous to work of [1], which proves a similar result for mean-field spin glasses. This also extends the algorithm of [3], which studies Maximum Cut on random regular graphs. In fact, all of these algorithms are related to the Approximate Message Passing (AMP) framework, popularized by the results of [13]; see [7] for a recent survey. It was suspected that such an algorithm could be written down for $\mathsf{CSP}_f(\alpha)$ [55, 41].

One immediate impact of this result is in quantum computing. In the gate-based circuit model, many quantum circuits are *overlap-concentrated* for instances of $\mathsf{CSP}_f(\alpha)$ of depth up to $c \cdot \log n$ for some c [24]. This work implies that such quantum circuits, even up to $c \cdot \log n$ depth, cannot outperform classical algorithms on typical instances of a random CSP.

▶ **Corollary 7** (Failure of quantum advantage). *Suppose Assumption 1 holds. Choose any* even *predicate* f. *For all* $\epsilon > 0$ *there exist* $\alpha_0 > 0$ *and* $c : \mathbb{R}^{>0} \to \mathbb{R}^{>0}$ *such that the following is true: For all* $\alpha \geq \alpha_0$, *and with high probability over instances* $\mathcal{I} \sim \mathsf{CSP}_f(\alpha)$ *as* $n \to \infty$, no quantum circuit *with depth up to* $c(\alpha) \cdot \log n$ *that applies 2-local gates on a fixed, bounded-degree architecture can produce an assignment with satisfying fraction that outperforms classical algorithms by more than* $\frac{\epsilon}{\sqrt{\alpha}}$.

Even until now, the promise of quantum advantage for optimization problems has been unclear. Multiple times, improved analyses of the Quantum Approximate Optimization Algorithm (QAOA) [34] suggesting a such an advantage [35, 88, 77, 11] led to better classical algorithms [9, 45, 63, 8, 3]. This work shows that for the QAOA and many other quantum circuits up to logarithmic depth, there can be *no quantum advantage* on random CSPs with even predicates of sufficiently large clause density. Note that unlike related work on the QAOA [32, 12, 4], this rules out quantum advantage *regardless* of the presence of overlap gap phenomena.

We remark on the technical condition of *even predicates*. This can likely be removed with two steps. First, the obstruction of *overlap-concentrated* algorithms only applies to *even* predicates. New techniques to prove OGPs for spherical spin glasses [47] can possibly be ported to all Ising spin glasses; these results would immediately transfer to random instances of $\mathsf{CSP}_f(\alpha)$ via [55]. Second, the algorithm we analyze applies when predicates have no linear-weight terms; adjustments taken in [79] will likely generalize this algorithm. These steps would extend Corollary 7 to all predicates f.

Previous works noting limitations of logarithmic-depth quantum algorithms on sparse random optimization problems [32, 33, 24] also rely on the concept of *overlap gap property*. As in [1, 48], this work shows the existence of a family of random optimization problems with an *optimal* algorithm up to the OGP barrier. All of the optimal algorithms are classical, which hints that quantum algorithms that cannot pass the OGP barrier offer no additional power for classical optimization in general.

1.3 Proof overview

Our proof builds on a number of other works, especially [68, 1, 3]. We outline the proof here. Due to the page limit, some proofs in this paper are deferred to the full version.

In Section 2, we define our model of CSP and describe the algorithm. Instead of $\mathsf{CSP}_f(\alpha)$, we run the algorithm on a CSP whose associated constraint hypergraph is locally a regular *hypertree*.[6] This algorithm runs in *iterations*, where on each iteration, every vertex recomputes its value using information from adjacent vertices; we parameterize this algorithm by the functions (two per *iteration number*) that recompute each vertex's value.

[6] In the hypergraph, the variables are vertices and the constraints are hyperedges.

Table 1 List of important terms used in the analysis of message-passing algorithms for mean-field spin glasses and random CSPs. Terms in the first row asymptotically approach independent Gaussians after applying state evolution, and so constitute the *Brownian motion* (up to normalization) in the stochastic picture.

Term	**[68]**	**[1]**	**[3]**	**(our work)**
Brownian motion (asymptotically independent)	u	Δ	u	u
sum of Brownian motions	–	z	–	w
nonlinearity controller	x	x	x	x
value of spin	z	$m = f(\dots)$	z	z

We can already study the performance of the parameterized algorithm, analyzing how information propagates locally through the hypertree. In Section 3, we generalize a set of σ-algebras from [3] to describe this behavior. This allows us to analyze the correlation of a variable from the algorithm with any other variable from a particular σ-algebra. With these tools in hand, we simplify the expected performance of the parameterized algorithm, deferring some detailed calculations to the full version of this paper.

We then show how the algorithm, with the right choice of parameters, solves a stochastic optimal control problem that is dual to the minimization problem in Equation (1.3).

1. First, we show that with high probability as $\alpha \to \infty$, the intermediate values in the algorithm are asymptotically *Gaussian*. We prove this in Section 4 with an argument known as *state evolution*. Notably, this argument works for sparse models (as in [3]), and for message-passing on hypergraphs, where some values are products of Gaussians. This allows us to study quantities in the algorithm output as *discrete* stochastic processes.
2. Then, we take the number of iterations to a very large constant while proportionally decreasing the step size. Under this process, each discrete stochastic process asymptotically approximates a *continuous* stochastic process. In Section 5, we show how to choose the optimal parameters. We also show that rounding the algorithm's output to a value in $\{\pm 1\}^n$ does not meaningfully affect its performance.

This work extends [3] in a spiritually similar way that [1] extends [68]; roughly, we extend from graphs to *hypergraphs*. This requires more involved calculations and in some cases new arguments. For example, we require a more complicated proof of state evolution, since the messages in our algorithm are not Gaussian at fixed degree. Furthermore, our proof of rounding is new, since we cannot rely on spectral statistics of random *graphs*. Finally, our analysis uses an additional symmetry we call *index-regularity* (defined in Section 2) which, to the best of our knowledge, does not come up in prior work. We show that enforcing this symmetry has negligible effect (proof deferred to the full version of the paper) and use this symmetry to simplify some of our analysis.

There are a number of quantities to keep track of. We annotate the important symbols in Table 1. Following notation in [3], we typically use lowercase for a quantity in the algorithm (e.g. $u^{\ell}_{i\to a}$), uppercase with step size δ for a *discrete* stochastic process (e.g. U^{δ}_{ℓ}), and uppercase with time t for a *continuous* stochastic process (e.g. U_t).

1.4 Related work

Approximate Message Passing. Approximate Message Passing (AMP) is an algorithmic framework used to design locally computable, iterative methods for a variety of high-dimensional statistical inference and recovery tasks [61, 76, 67, 64, 10]. Many of the ideas

motivating AMP originate from the study of *belief propagation*, an iterative method rediscovered multiple times in different scientific contexts; see [65, 58] for a broader history. AMP was first introduced in the context of compressed sensing and signal recovery [29, 57], partly inspired by the use of structured priors in decoding low-density parity check codes [75, 69]. In spin glass theory, AMP is synonymous with computing the fixed points of a certain Thouless–Anderson–Palmer (TAP) free energy functional [87, 59, 90, 22, 23]. In fact, our algorithm is inspired by similar connections between the TAP equations and belief propagation [66, 65].

A beneficial feature of AMP is that one can rigorously analyze the asymptotic behavior of statistics in the framework. This is typically done through the use of *state evolution* statements [14, 13]: laws of large numbers which dictate the behavior of such statistics when the dimension in the problem approaches infinity. This has been subsequently used to compute approximate ground states of both Ising and spherical mean-field spin glasses [68, 1, 47], as well as Max-Cut on random sparse graphs [3, 19]. See the surveys of [38, 7] for further discussion on AMP and its variants. See also [78, 52, 54] for connections to the sum-of-squares hierarchy.

Ising spin glasses and CSPs. Although mean-field spin glasses with Ising spins were proposed as mathematical models of materials [82], their connection to combinatorial optimization has been observed for some time [39, 66]. More recently, a correspondence has emerged between Ising spin glasses and sparse random CSPs at large enough clause density; this started with relating the supremum of the two models [26, 80, 72]. This supremum was calculated using a novel heuristic argument known as "replica symmetry breaking" [73], and proven to be correct in [85, 70] (see also [71]). Moreover, the duality preserves a phenomenon known as *overlap gap* [44], a generalization of solution clustering that obstructs certain algorithms; see [21, 43, 42, 24, 50, 55, 49], and the expositions of [40, 46]. Notably, a strong version of overlap gap phenomena [50, 47, 48] is connected to the message-passing algorithms of [68, 1, 3], and this work. Other topics at the intersection of spin glasses and CSPs include approximating partition functions (e.g. [83]), sampling from Gibbs measures (e.g. [2, 51]), and computing thresholds for random CSPs (e.g. [27, 28]).

Quantum algorithms for classical optimization. Recent demonstrations of quantum advantage (e.g. [5, 91]) have led to increased excitement around using contemporary (i.e. NISQ [74]) quantum computers for a practically relevant problem. Although classical optimization is such a problem, quantum algorithms here are not proven to have any benefit over classical algorithms. The most popular proposal is the Quantum Approximate Optimization Algorithm (QAOA) [34]. Earlier suggestions of quantum advantage with the QAOA [35, 88, 77, 89] led to better classical algorithms [9, 45, 63, 8]; note that all of these comparisons were for very small circuit depth. Recently, [36, 11, 12] find an expression for the performance of the QAOA on spin glasses and sparse CSPs at any constant depth. For some problems, this is competitive with known classical algorithms; see [37, 16].

The QAOA is a *local* algorithm. It was noted that this feature can limit its performance [32, 33]. The authors in [24] unify definitions of quantum and classical local algorithms to show that the QAOA is obstructed by overlap gap phenomena on sparse problems. Because of this, [3] rules out quantum advantage through $\epsilon \cdot \log n$-depth QAOA on random regular Max-Cut instances of large degree (up to Assumption 1); our work generalizes this fact to CSPs with even predicates. Regardless of theory, there are many recent demonstrations of the QAOA on state-of-the-art quantum computing systems; see for example [31, 81, 62]. It is also known that the QAOA can solve satisfiability faster than brute force [17]; see also [25] for a related

protocol with a more-than-quadratic improvement. Some quantum algorithms for machine learning are known to provide no quantum advantage [86]. Very recently, [56] proposed a quantum algorithm for classical optimization, but we do not yet know if it gives a quantum advantage.

2 Local algorithms for sparse CSPs

A CSP instance has an implicit *directed* hypergraph, with variables as vertices and constraints as hyperedges.

▶ **Definition 8** (Directed hypergraph of a CSP)**.** *Consider a r-uniform CSP instance $\mathcal{I}$ with n variables and constraints $E(\mathcal{I})$, where each constraint $e \in E(\mathcal{I})$ involves r (ordered) variables in $[n]$. Then $\mathcal{I}$ is associated with the directed hypergraph with vertices $[n]$ and hyperedges $E(\mathcal{I})$; i.e. $G([n], E(\mathcal{I}))$.*

We consider a hyperedge *directed* when the involved vertices are ordered. For example, if constraint e involves vertices $\{v_1, v_2, v_3\}$ in order $[2, 3, 1]$, then the associated directed hyperedge is $[v_2, v_3, v_1]$. We denote this ordered list as ∂e. We often refer to the CSP instance by its hypergraph. The instance is fully specified by its hypergraph, the CSP function f, and the (ordered) randomness $[\epsilon_{e_1}, \ldots, \epsilon_{e_r}]$ on each constraint $e \in E(\mathcal{I})$. For each variable i, we use ∂i to denote the set of constraints i participates in.

The *factor graph* of a hypergraph $G(V, E)$ is a bipartite graph of order $|V| + |E|$, with edges between each hyperedge $e \in E$ and each vertex in ∂e. For more information on the factor graph formalism, see [60]. Let $\mathsf{B}_i(\ell)$ be the induced subgraph of G given by the ℓ-local neighborhood around vertex $i \in V$.[7]

▶ **Definition 9.** *A finite hypergraph $G(V, E)$ is (ℓ, ϵ)-*locally treelike *if the factor graph of $\mathsf{B}_i(\ell + 1)$ is isomorphic to a tree for at least $(1 - \epsilon) \cdot n$ vertices $i \in V$.*

This definition is a generalization of locally treelike graphs used in [3]; see Figure 1 for an illustration.

Every *message-passing* algorithm is contained in the model of local algorithms presented in [24]. In this model, the value associated with each variable is uniquely determined by its local neighborhood.

▶ **Definition 10** (Generic p-local algorithms, [24, Definition 3.1])**.** *Consider a randomized algorithm $\mathcal{A}$ that inputs a r-uniform hypergraph $G(V, E)$ and outputs a label in an alphabet Σ to each vertex in the graph, i.e. $\mathcal{A}(G) \in \Sigma^V$. Then $\mathcal{A}$ is* generic p-local *if for any set $S \subseteq V$, the following conditions hold:*

1. (Local distribution determination) *The joint marginal distribution of $(\mathcal{A}(G)_v)_{v \in S}$ is identical to that of $(\mathcal{A}(G')_v)_{v \in S}$, where $G' = \bigcup_{v \in S} \mathsf{B}_v(p)$.*
2. (Local independence) *$\mathcal{A}(G)_v$ is statistically independent of $\mathcal{A}(G)_{v'}$ over all vertices $v' \notin \mathsf{B}_v(2p)$.*

This model also includes the Quantum Approximate Optimization Algorithm [34] on typical instances of $\mathsf{CSP}_f(\alpha)$. In fact, any depth-p quantum circuit with a fixed architecture of bounded degree can be seen as generic p-local by including the architecture in the input hypergraph. [24] proves that for all $p \leq c(\alpha) \cdot \log n$, generic p-local algorithms are overlap-concentrated over instances of $\mathsf{CSP}_f(\alpha)$ with high probability as $n \to \infty$.

[7] Note that we define distance as the number of *hypergraph vertices* in the shortest path; vertices that share a hyperedge are distance 1 apart.

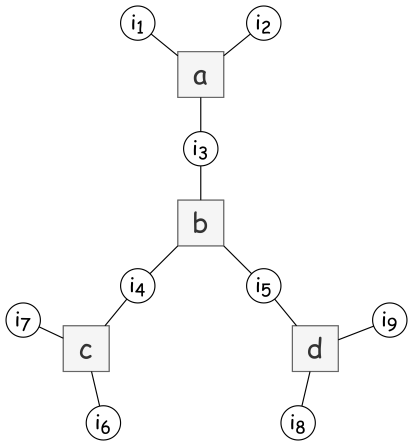

Figure 1 Factor graph of the hypergraph with vertices $\{i_1, \ldots, i_9\}$ and hyperedges $\{a, b, c, d\}$. Note that this hypergraph is locally treelike.

In our analysis, we make some convenient modifications to the input. First, since our algorithm is local and the instances are locally treelike on all but a negligible fraction of vertices[8], we analyze the algorithm on an instance which is locally a *hypertree*, i.e. a hypergraph whose factor graph is a tree. We also make the hypergraph *regular*, by embedding our instance of $\mathsf{CSP}_f(\alpha)$ in a locally treelike d-regular instance with $d = r \cdot \alpha + o_\alpha(1)$.

On hypergraphs, we need one additional property, which we call *index-regular*. Here, we mean that for each $\iota \in [r]$, each variable is used in *index* ι of a constraint the same number of times.

▶ **Definition 11** (d-index-regular CSP). *Consider a (r-uniform) CSP instance $\mathcal{I}$ with n variables and constraints $E(\mathcal{I})$, such that each constraint $e \in E(\mathcal{I})$ has associated variables $\partial e = [v_{e,1}, \ldots, v_{e,r}]$. Then $\mathcal{I}$ is* d-index-regular *if every variable $v \in [n]$ is involved in d constraints, and moreover, for each $\iota \in [r]$, v is the ιth-indexed variable in exactly $\frac{d}{r}$ constraints.*

We describe our choice of algorithm in Figure 2. This involves some notation we describe here. A function that depends on zero inputs is a constant; i.e. $A_i^0 = F_0$ and $A_{i\to a}^0 = F_{\to,0}$. For any scalar quantity that depends on vertex, a bolded version represents a vector quantity. For example, given $\partial a = [i_1, \ldots, i_r]$, $\boldsymbol{z}_{\partial a \to a}^\ell$ is the *ordered* list $[z_{i_1\to a}^\ell, \ldots, z_{i_r\to a}^\ell]$, and $\boldsymbol{z}_{\partial a}^\ell$ is the *ordered* list $[z_{i_1}^\ell, \ldots, z_{i_r}^\ell]$. Similarly, $\boldsymbol{z}^L$ is the vector in $\mathbb{R}^V$ such that $\left(\boldsymbol{z}^L\right)_i = z_i^L$.

[8] In particular, for any finite ℓ, with high probability our instances are (ℓ, ϵ)-locally treelike for some ϵ, where $\epsilon \to 0$ as $n \to \infty$.

Input: The timestep $\delta > 0$, and a d-index-regular hypergraph with girth at least $2L+2$, where $L = \lfloor \frac{1}{\delta} \rfloor$.
Parameters: The CSP function $f : \{\pm 1\}^r \to \{0,1\}$, constant $K > 0$, and nonlinearities

$$\big\{F_{\to,\ell} : \mathbb{R}^\ell \to [-K,K]\big\}_{\ell=0,\dots,L-1} \qquad \big\{F_\ell : \mathbb{R}^\ell \to [-K,K]\big\}_{\ell=0,\dots,L-1}$$

Algorithm:

1. Initialize the following:
   a. $z_i^0 \sim \mathcal{N}(0,\delta)$ for all $i \in V$ and $z_{i\to a}^0 = z_i^0$ for all $i \in \partial a$ and $a \in E$.
   b. $w_i^0 = 0$ for all $i \in V$ and $w_{i\to a}^0 = 0$ for all $i \in \partial a$ and $a \in E$.
2. For each iteration $\ell = 0, \dots, L-1$:
   a. Let $A_{i\to a}^\ell = F_{\to,\ell}\big(u_{i\to a}^1, \dots, u_{i\to a}^\ell\big)$, and let $A_i^\ell = F_\ell\big(u_i^1, \dots, u_i^\ell\big)$.
   b. For each factor $a \in E$ and involved variable $i \in \partial a$, compute:

$$w_{i\to a}^{\ell+1} = \frac{1}{\sqrt{d-1}} \cdot \sum_{b \in \partial i \setminus a} \mathsf{D}_{i;b} f(\boldsymbol{z}_{\partial b \to b}^\ell)$$
$$u_{i\to a}^{\ell+1} = w_{i\to a}^{\ell+1} - w_{i\to a}^\ell$$
$$z_{i\to a}^{\ell+1} = z_{i\to a}^0 + \sum_{s=1}^{\ell+1} A_{i\to a}^{s-1} \cdot u_{i\to a}^s$$

   c. For each variable $i \in V$, compute:

$$w_i^{\ell+1} = \frac{1}{\sqrt{d}} \cdot \sum_{b \in \partial i} \mathsf{D}_{i;b} f(\boldsymbol{z}_{\partial b \to b}^\ell)$$
$$u_i^{\ell+1} = w_i^{\ell+1} - w_i^\ell$$
$$z_i^{\ell+1} = z_i^0 + \sum_{s=1}^{\ell+1} A_i^{s-1} \cdot u_i^s$$

Output: For every $i \in V$, output 1 with probability p_i and -1 with probability $1-p_i$, where $p_i = \begin{cases} 1 & \text{if } z_i^L \geq 1, \\ \frac{1+z_i^L}{2} & \text{if } |z_i^L| < 1, \\ 0 & \text{if } z_i^L \leq -1. \end{cases}$

Figure 2 Description of the message-passing algorithm.

Our analysis makes extensive use of the partial derivative operator. For any factor a and variable $j \in \partial a$, let $\mathsf{D}_{j;a} f$ be the partial derivative of f at the *coordinate* ι such that j is the ιth coordinate of ∂a. For example, if $\partial a = [k,i,j]$ and $f(x_1,x_2,x_3) = x_1x_2 + x_2x_3$, then $\mathsf{D}_{k;a} f(x_1,x_2,x_3) = x_2$ and $\mathsf{D}_{i;a} f(x_1,x_2,x_3) = x_1 + x_3$. Note the following:

▶ Remark 12. Since the domain of f is $\{\pm 1\}^r$, f has a representation as a multilinear polynomial. As a result, for all factors b and variables $i \in \partial b$, $\mathsf{D}_{i;b} f$ is independent of the entry with the same coordinate as i in ∂b.

We additionally require the nonlinearities to satisfy the following two properties:

▶ **Property 1** (Similar node and node-to-factor evolution). *For every $\ell \geq 0$, variable i, factor $a \in \partial i$, and $m \in \mathbb{N}$, we have $\mathbb{E}[|A_i^\ell - A_{i\to a}^\ell|^m] = O_d(\frac{1}{d^{m/2}})$.*

▶ **Property 2** (Normalization of second moment). *For every $\ell \geq 0$, variable i, and factor $a \in \partial i$, we have $\mathbb{E}[(A_i^\ell)^2] = \mathbb{E}[(A_{i\to a}^\ell)^2] = \frac{\delta}{\nu_{\ell+1}}$, where $\nu_\ell \stackrel{\text{def}}{=} \frac{\xi'(\ell\delta) - \xi'((\ell-1)\delta)}{r}$, and ξ is defined as in Theorem 6.*

In Section 5, we show how to choose the nonlinearities based on Equation (1.1), and show that our choice indeed satisfies Property 1 and Property 2.

▶ Remark 13. Our analysis of the algorithm above holds even if the CSP predicate depends on factor a, so long as the absolute value of each Fourier component is fixed (this implies that all f_a are associated with the same ξ). For example, this implies that the algorithm achieves the same value for *every* choice of signs $\{\epsilon_{i,\iota}\}_{i\in[n],\iota\in[r]}$ in Definition 1.

▶ Remark 14. If $\|f^{=2}\| = 0$, the associated ξ does not satisfy $\xi''(0) \neq 0$ as in Assumption 1. We handle this case via the following argument. First, it can be shown that ALG_ξ is continuous in each coefficient of ξ using an explicit form of the Parisi functional and the fact that $\mathsf{ALG}_\xi \geq 0$ [1, Proposition 4.1]. Then, we can add a small quadratic term to f, and run the algorithm on the perturbed instance. The error produced by this perturbation may be absorbed in the ϵ of Theorem 6.

3 Independence claims

Given random variables $\{X_1, \ldots, X_k\}$, let $\sigma(X_1, \ldots, X_k) = \sigma(\{X_1, \ldots, X_k\})$ be the *σ-algebra* generated by $\{X_1, \ldots, X_k\}$. For an introduction to σ-algebra and related concepts, see for example [30].

Consider the algorithm in Figure 2. For every $0 \leq \ell \leq L$,[9] variable v, and factor $a \in \partial v$, we'll reuse the notation $\mathsf{B}_v(\ell)$ as the set of *nodes* of distance[10] at most ℓ from v in the corresponding hypergraph. We define the set $\mathsf{B}_{v\to a}(\ell)$ as the set of nodes of distance at most ℓ from v, *excluding* nodes that reach v through the factor a. We define

$$\mathcal{G}_v^\ell \stackrel{\text{def}}{=} \sigma\left(\{z_i^0 \mid i \in \mathsf{B}_v(\ell)\}\right), \qquad \mathcal{G}_{v\to a}^\ell \stackrel{\text{def}}{=} \sigma\left(\{z_i^0 \mid i \in \mathsf{B}_{v\to a}(\ell)\}\right).$$

Intuitively, these $\mathcal{G}_v^\ell$ algebras are the random variables determined by the initial Gaussian variables in the radius-ℓ neighborhood around v; here, ℓ is a *distance*. We formalize a series of information-theoretic claims using these σ-algebras, similar to [3, Lemma 2.2]. See also an illustration in Figure 3.

The first fact about independence informally says that node-to-factor messages never use information on "the other side" of the factor; once information goes across a, it never comes back.

▶ **Lemma 15.** *For every $0 \leq \ell_1, \ell_2 \leq L$, distinct variables i, j, and factors $a \in \partial i, b \in \partial j$, if every path of length at most $2L$ from i to j goes through a and b, then $\mathcal{G}_{i\to a}^{\ell_1}$ and $\mathcal{G}_{j\to b}^{\ell_2}$ are independent.*

[9] Recall that because the instance has girth at least $2L+2$, all local neighborhoods of radius up to L are treelike.

[10] Once again, we consider *distance* of i and j as the number of *nodes* required to pass from i to j; the factors are not counted.

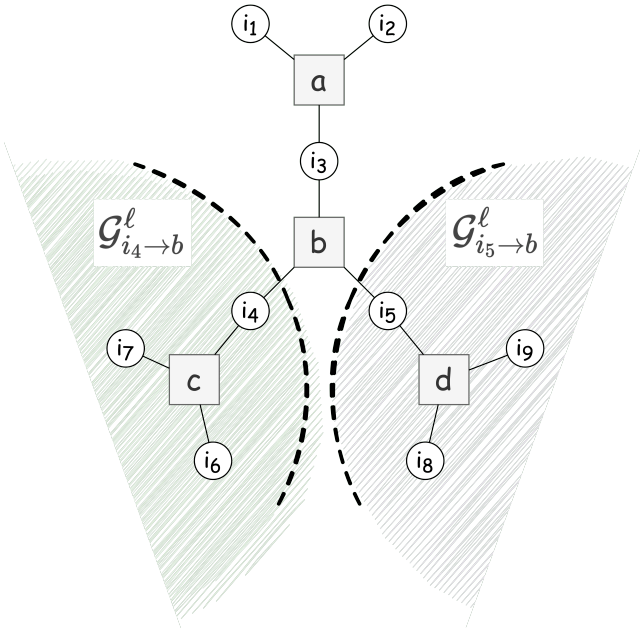

Figure 3 An illustration of σ-algebras on the hypertree. Since the path from i_4 to i_5 goes through factor b, $\mathcal{G}^{\ell}_{i_4\to b}$ and $\mathcal{G}^{\ell}_{i_5\to b}$ are independent by Lemma 15. In addition, $\mathcal{G}^{\ell+1}_{i_3\to a} = \sigma\left(\mathcal{G}^{0}_{i_3} \bigcup \mathcal{G}^{\ell}_{i_4\to b} \bigcup \mathcal{G}^{\ell}_{i_5\to b}\right)$ by Lemma 16.

Lemma 15 holds even if the factors are the same, i.e. $a = b$. We refer to this case as Lemma 15 *around* factor a.

The next fact concerns the geometry of local neighborhoods. It allows us to decompose each σ-algebra into σ-algebras with distance reduced by one, which is handy for induction.

▶ **Lemma 16.** *For every $1 \le \ell \le L$, variable i, and factor $a \in \partial i$, we have*

$$\mathcal{G}^{\ell}_{i} = \sigma\left(\mathcal{G}^{\ell}_{i\to a} \cup \left(\bigcup_{j\in\partial a\setminus i} \mathcal{G}^{\ell-1}_{j\to a}\right)\right), \qquad \mathcal{G}^{\ell}_{i\to a} = \sigma\left(\mathcal{G}^{0}_{i} \cup \left(\bigcup_{b\in\partial i\setminus a}\ \bigcup_{v\in\partial b\setminus i} \mathcal{G}^{\ell-1}_{v\to b}\right)\right).$$

The next statement sorts quantities appearing in the algorithm (Figure 2) into appropriate σ-algebras. It proves the intuition that messages at iteration number ℓ are determined by the local neighborhood of distance at most ℓ:

▶ **Lemma 17.** *For every $1 \le \ell \le L$, variable i, and factor a, we have $u^{\ell}_{i\to a}, w^{\ell}_{i\to a}, z^{\ell}_{i\to a} \in \mathcal{G}^{\ell}_{i\to a}$ and $u^{\ell}_{i}, w^{\ell}_{i}, z^{\ell}_{i} \in \mathcal{G}^{\ell}_{i}$.*

Lemma 17 implies that the ℓth node message at variable i is determined by the initial Gaussian variables in the radius-ℓ neighborhood around i. Note that the node-to-factor message $u^{\ell}_{i\to a}$ is *not* influenced by Gaussians at nodes that pass through a to reach i.

Next, we prove that messages at node i and iteration number $\ell+1$ are uncorrelated with the initial Gaussians in the radius-ℓ neighborhood around i. Put another way, the "extra randomness" at distance $\ell+1$ removes any correlation with $\mathcal{G}^{\ell}_{i}$. To do this, we show that the messages $\{u^{\ell}_{j\to b}\}_{j\in\partial b\setminus i}$ are uncorrelated with each other, conditioned on $\mathcal{G}^{\ell}_{i}$.[11]

[11] This is subtle. Although $\{u^{\ell}_{j\to b}\}_{j\in\partial b\setminus i}$ are independent by Lemma 15 around factor b, independence does not imply *conditional* independence.

▶ **Lemma 18.** *Choose any variable i, factor $b \in \partial i$, and $1 \le \ell \le L$. Choose also $s_j \ge 0$ for every $j \in \partial b \backslash i$. Then*

$$\mathbb{E}\left[\prod_{j\in\partial b\backslash i}(u^{\ell}_{j\to b})^{s_j}\;\middle|\;\mathcal{G}^{\ell}_i\right] = \prod_{j\in\partial b\backslash i}\mathbb{E}\left[(u^{\ell}_{j\to b})^{s_j}\;\middle|\;\mathcal{G}^{\ell}_i\right].$$

▶ **Lemma 19.** *Choose any variable i, factor $a \in \partial i$, and $0 \le \ell \le L-1$. Then $\mathbb{E}\left[u^{\ell+1}_{i\to a}\mid \mathcal{G}^{\ell}_i\right] = 0$ and $\mathbb{E}\left[u^{\ell+1}_{i}\mid \mathcal{G}^{\ell}_i\right] = 0$.*

▶ **Corollary 20.** *Fix any variable i, factor $b \in \partial i$, and $0 \le \ell \le L$. Then $\mathbb{E}\left[\mathsf{D}_{i;b}f(\boldsymbol{z}^{\ell}_{\partial b\to b}) \mid \mathcal{G}^{\ell}_i\right] = \mathsf{D}_{i;b}f(\boldsymbol{z}^{\ell-1}_{\partial b\to b})$ if $\ell \ge 1$ and 0 otherwise.*

3.1 Simplifying the main sum

What is the average value achieved by the algorithm? By linearity, we can look at the value of any factor a; i.e. $\mathbb{E}[f(\boldsymbol{z}^{L}_{\partial a})]$. Note that $\mathbb{E}[f(\boldsymbol{z}^{0}_{\partial a})] = f(0,\dots,0) = \mathbb{E}[f]$, and

$$\begin{aligned}\mathbb{E}[f(\boldsymbol{z}^{L}_{\partial a})] &= \mathbb{E}[f(\boldsymbol{z}^{0}_{\partial a})] + \sum_{\ell=0}^{L-1}\left(\mathbb{E}[f(\boldsymbol{z}^{\ell+1}_{\partial a})] - \mathbb{E}[f(\boldsymbol{z}^{\ell}_{\partial a})]\right)\\ &= \mathbb{E}[f] + \sum_{\ell=0}^{L-1}\left(\mathbb{E}[f(\boldsymbol{z}^{\ell+1}_{\partial a})] - \mathbb{E}[f(\boldsymbol{z}^{\ell}_{\partial a})]\right).\end{aligned}$$

It suffices to compute the difference $\mathbb{E}[f(\boldsymbol{z}^{\ell+1}_{\partial a})] - \mathbb{E}[f(\boldsymbol{z}^{\ell}_{\partial a})]$ for every $0 \le \ell \le L-1$. We use the Fourier expansion of f to express this as a sum of differences of monomials.

First, we simplify terms of the form $u_i^{s_i}Y_i^{s_i-1}\prod_{v\in\partial a\backslash i}Y_v^{s_v}$, which we encounter along the way. This relies on the following consequence of the monotone class theorem:

▶ **Lemma 21** (e.g. [30, Theorem 5.2.2], [3, Lemma 2.3])**.** *Let $\{\mathcal{F}_1,\dots,\mathcal{F}_m,\mathcal{A}\}$ be a set of σ-algebras so that $\mathcal{F} \stackrel{\text{def}}{=} \sigma(\mathcal{F}_1,\dots,\mathcal{F}_m) \subseteq \mathcal{A}$. Choose a random variable $X \in \mathcal{A}$,[12] and suppose for any $Y_1 \in \mathcal{F}_1,\dots,Y_m \in \mathcal{F}_m$, $\mathbb{E}[XY_1\dots Y_m] = 0$ when the expectation exists. Then $\mathbb{E}[XY] = 0$ (when the expectation exists) for every $Y \in \mathcal{F}$.*

As a result, to show an expectation is zero, we may replace a variable in σ-algebra $\mathcal{F}$ with a product of variables from σ-algebras that cover $\mathcal{F}$.

▶ **Lemma 22** (Generalization of [3, Lemma 2.5])**.** *Choose factor a, integers $s_v \ge 0$ for $v \in \partial a$, and let $Y_v^{s_v} \in \mathcal{G}_v^{s_v}$. Let $i \in \partial a$ be such that $s_i + 1 \ge s_v$ for all $v \in \partial a$. Then*

$$\mathbb{E}\left[u_i^{s_i+1}\prod_{v\in\partial a}Y_v^{s_v}\right] = \frac{1}{\sqrt{d}}\,\mathbb{E}\left[\left(\mathsf{D}_{i;a}f(\boldsymbol{z}^{s_i}_{\partial a\to a}) - \mathbb{1}_{[s_i\ge 1]}\mathsf{D}_{i;a}f(\boldsymbol{z}^{s_i-1}_{\partial a\to a})\right)\prod_{v\in\partial a}Y_v^{s_v}\right],$$

where $\mathbb{1}_{[x\ge y]} = 1$ if $x \ge y$ and 0 otherwise.

▶ **Proposition 23.** *Fix $0 \le \ell \le L-1$, factor a, and $S \subseteq \partial a$. Then*

$$\mathbb{E}\left[\prod_{j\in S}z_j^{\ell+1}\right] - \mathbb{E}\left[\prod_{j\in S}z_j^{\ell}\right] = \sum_{i\in S}\mathbb{E}\left[A_i^{\ell}u_i^{\ell+1}\cdot\prod_{j\in S\backslash i}z_j^{\ell}\right] + O_d\left(\frac{1}{d}\right). \tag{3.1}$$

[12] $X \in \mathcal{A}$ means that $\sigma(X) \subseteq \mathcal{A}$.

▶ **Corollary 24.** *Choose $0 \le \ell \le L-1$ and factor a. Then*

$$\mathbb{E}\left[f(\boldsymbol{z}_{\partial a}^{\ell+1})\right] - \mathbb{E}\left[f(\boldsymbol{z}_{\partial a}^{\ell})\right] = \sum_{i \in \partial a} \mathbb{E}\left[A_i^\ell u_i^{\ell+1} \cdot \mathsf{D}_{i;a} f(\boldsymbol{z}_{\partial a}^{\ell})\right] + O_d\left(\frac{1}{d}\right).$$

We simplify this expression further, assuming the algorithm's node and node-to-factor nonlinearities are similar (Property 1). We choose nonlinearities exhibiting this property in Section 5.

▶ **Proposition 25.** *Assume Property 1. Let $0 \le \ell \le L-1$, a be a factor, and $i \in \partial a$. Then*

$$\frac{1}{\alpha n}\sum_{a \in E}\left(\mathbb{E}\left[f(\boldsymbol{z}_{\partial a}^{\ell+1})\right] - \mathbb{E}\left[f(\boldsymbol{z}_{\partial a}^{\ell})\right]\right) = \frac{r}{\sqrt{d}} \cdot \frac{1}{n}\sum_{i \in V} \mathbb{E}\left[A_i^\ell (u_i^{\ell+1})^2\right] + O_d\left(\frac{1}{d}\right).$$

By these propositions, we get the following:

▶ **Theorem 26.** *Assume Property 1. Fix a constant $L \ge 1$. Then*

$$\frac{1}{\alpha n}\sum_{a \in E} \mathbb{E}\left[f(\boldsymbol{z}_{\partial a}^{L})\right] = \mathbb{E}[f] + \frac{r}{\sqrt{d}} \cdot \sum_{\ell=0}^{L-1}\left(\frac{1}{n}\sum_{i \in V} \mathbb{E}\left[A_i^\ell (u_i^{\ell+1})^2\right]\right) + O_d\left(\frac{1}{d}\right).$$

4 State evolution for message-passing on hypergraphs

So far, we've shown that the value of the algorithm takes a simple form (i.e. Theorem 26). From here, we prove a *state evolution* statement: with some weak conditions on the nonlinearities (Property 2), we analyze the asymptotic behavior of statistics of the algorithm. State evolution as applied to AMP first appeared in [13]; this was inspired by a proof in a paper computing the fixed points of the TAP equations for the Sherrington–Kirkpatrick model [14]. Since then, state evolution has been used in AMP algorithms applied to a variety of tasks; see for example [38].

Here, we consider functions of the messages $\{u_{i\to a}^\ell\}_{\ell \in [L]}$ (or $\{u_i^\ell\}_{\ell \in [L]}$) that are *pseudo-Lipschitz*:

▶ **Definition 27.** *Fix $s > 0$. We say that a given function $\psi : \mathbb{R}^s \to \mathbb{R}$ is* pseudo-Lipschitz *if there exists a constant $C > 0$ such that*

$$|\psi(\boldsymbol{x}) - \psi(\boldsymbol{y})| \le C \cdot \left(1 + \|\boldsymbol{x}\| + \|\boldsymbol{y}\|\right) \cdot \|\boldsymbol{x} - \boldsymbol{y}\|,$$

for every $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^s$.

As $d \to \infty$, the expected value of a pseudo-Lipschitz function ψ with messages $\{u_{i\to a}^\ell\}_{\ell \in [L]}$ (or $\{u_i^\ell\}_{\ell \in [L]}$) as input approaches the expected value of ψ with independent Gaussians as input.

▶ **Definition 28.** *For any predicate $f : \{\pm 1\}^r \to \{0,1\}$, let ξ be defined as in Theorem 6. For any $\ell \ge 1$, define the quantity*[13]

$$\nu_\ell \stackrel{\text{def}}{=} \frac{\xi'(\ell\delta) - \xi'((\ell-1)\delta)}{r}.$$

[13] Note this is the same parameter ν_ℓ in Property 2.

▶ **Theorem 29.** *Assume Property 2. Then for any pseudo-Lipschitz function $\psi : \mathbb{R}^\ell \to \mathbb{R}$, variable i, factor $a \in \partial i$, $1 \le \ell \le L$, we have*

$$\mathbb{E}\left[\psi(u^1_{i\to a}, \dots, u^\ell_{i\to a})\right] = \mathbb{E}\left[\psi(U_1, \dots, U_\ell)\right] + o_d(1)\,, \tag{4.1}$$

$$\mathbb{E}\left[\psi(u^1_{i}, \dots, u^\ell_{i})\right] = \mathbb{E}\left[\psi(U_1, \dots, U_\ell)\right] + o_d(1)\,, \tag{4.2}$$

where $U_s \sim \mathcal{N}(0, \nu_s)$ independently.

Theorem 29 is inspired by the state evolution statement in [3]. These statements are for *sparse* problems, and so do not require a correction term to ensure variables remain Gaussian (often named the *Onsager correction*). In [3], the messages $\{u^\ell_{i\to a}\}_{\ell\in[L]}$ are Gaussian even at fixed degree! In our algorithm, this is not the case for arbitrary predicates f; we must take additional care showing that these quantities are close to Gaussian.

We defer the proof of Theorem 29 to the full version of the paper. As a quick overview of the proof, we first establish that given Property 2, $u^\ell_{i\to a}$ is *close* to the Gaussian $\mathcal{N}(0, \nu_\ell)$ when $d \to \infty$, independently of $\mathcal{G}_i^{\ell-1}$. Then, we show that pseudo-Lipschitz functions are smooth enough so that an input $u^\ell_{i\to a}$ may be exchanged with an independent Gaussian input, and use this argument inductively to finish the proof.

Given Theorem 29, we may convert each spin $\{z_i^\ell\}_{0\le\ell\le L}$ to a certain *Gaussian process*. In Section 5, we do exactly this, and choose the nonlinearities $\{A_i^\ell\}_{0\le\ell\le L}$ to maximize the expression in Theorem 26 (subject to $|z_i^L| \le 1$).

5 Choosing the nonlinearities

We now design the nonlinearities to maximize Theorem 26. In light of Section 4, we consider the stochastic optimal control problem of [1]. Define $\xi(s) \stackrel{\text{def}}{=} \sum_{j=1}^r \|f^{=j}\|^2 s^j$. Consider any $\mu \in \mathscr{L}_\xi$, and Φ^μ chosen as in Equation (1.1). Define the stochastic differential equation[14]

$$\mathrm{d}X_t = \xi''(t)\mu(t)\Phi^\mu_x(t, X_t)\mathrm{d}t + \sqrt{\xi''(t)}\mathrm{d}B_t\,, \quad X_0 = 0\,, \tag{5.1}$$

along with associated martingale

$$Z_t = \int_0^t \sqrt{\xi''(s)}\Phi^\mu_{xx}(s, X_s)\mathrm{d}B_s\,. \tag{5.2}$$

We now crucially use Assumption 1. Let $\mu_* \in \mathscr{L}$ be the minimizer of Equation (1.3).

▶ **Lemma 30** ([1, Theorem 3])**.** *Suppose Assumption 1 holds. Then for every $\epsilon > 0$, there exists $\eta > 0$ such that*

$$\int_0^{1-\eta} \xi''(t)\,\mathbb{E}[\Phi^{\mu_*}_{xx}(t, X_t)]\mathrm{d}t \ge \mathsf{ALG}_\xi - \epsilon\,.$$

For mean-field spin glasses, Parisi predicted that the minimizer of $\inf_{\mu\in\mathscr{U}} \mathsf{P}_\xi(\mu)$ led to the correct description of the ground state. While this was true, uniqueness (Theorem 2) required a stochastic representation of the minimization problem. Later, [68, 1] formulated an algorithm whose optimal value can be written as a stochastic optimal control problem dual to Equation (1.3). Surprisingly, the study of overlap gap phenomena is also linked to Equation (1.3) [50, 55], so this algorithm is optimal among a broad family.[15]

[14] Here, $(B_t)_{t\ge0}$ is standard Brownian motion.
[15] This is the family of *overlap-concentrated* algorithms; see Definition 4.

In a sense, the optimal message-passing algorithm updates its local information in a way concordant with the Parisi minimizer μ_*, *assuming* that μ_* exists. Nonetheless, even if Assumption 1 is false, we informally argue that this algorithm succeeds. Since Φ^μ_x and Φ^μ_{xx} are continuous in μ (e.g., [20, Theorem 4]), using a near-minimizer $\widetilde{\mu}_*$ of Equation (1.3) changes the value in Lemma 30 by a negligible amount, which can be absorbed into the choice of ϵ. Furthermore, $\widetilde{\mu}_*$ can be precomputed, since finding $\widetilde{\mu}_*$ is a task required only once per *CSP predicate* f, not once per run of the algorithm. Mathematizing this argument, however, is a valuable open problem; see [1, Section 6].

In this section, we prove that the algorithm achieves a value affine to Lemma 30 after taking two sets of limits.

5.1 A finite difference equation

Consider discrete versions of Equations (5.1) and (5.2). Choose $\delta > 0$, and consider independent *standard* Gaussians $\{B_1, B_2, \dots\}$. Then consider the finite difference

$$X^\delta_{\ell+1} - X^\delta_\ell = \xi''(\delta\ell)\mu_*(\delta\ell)\Phi^{\mu_*}_x(\delta\ell, X^\delta_\ell)\cdot\delta + \sqrt{\xi'(\delta(\ell+1)) - \xi'(\delta\ell)}\cdot B_{\ell+1} \qquad X^\delta_0 = 0\,, \tag{5.3}$$

$$Z^\delta_{\ell+1} - Z^\delta_\ell = \sqrt{\xi'(\delta(\ell+1)) - \xi'(\delta\ell)}\cdot\Phi^{\mu_*}_{xx}(\delta\ell, X^\delta_\ell)\cdot B_{\ell+1} \qquad Z^\delta_0 = 0\,. \tag{5.4}$$

The variables are named suggestively. By Section 4, the messages $u^\ell_{i\to a}, u^\ell_i$ behave as independent Gaussians as $d\to\infty$, which we use to imitate B_ℓ above. To this end, we define the sequences

$$x^{\ell+1}_i = x^\ell_i + \xi''(\delta\ell)\mu_*(\delta\ell)\Phi^{\mu_*}_x(\delta\ell, x^\ell_i)\cdot\delta + \sqrt{r}\cdot u^{\ell+1}_i \qquad x^0_i = 0\,,$$
$$x^{\ell+1}_{i\to a} = x^\ell_{i\to a} + \xi''(\delta\ell)\mu_*(\delta\ell)\Phi^{\mu_*}_x(\delta\ell, x^\ell_{i\to a})\cdot\delta + \sqrt{r}\cdot u^{\ell+1}_{i\to a} \qquad x^0_{i\to a} = 0\,.$$

We show that in the limit $d\to\infty$, the messages $\{u^\ell_i, u^\ell_{i\to a}\}$ behave as stochastic input to Equations (5.3) and (5.4). Note that $\Phi^\mu_x(t,x)$ and $\Phi^\mu_{xx}(t,x)$ are Lipschitz in x, since all x-derivatives are of $\Phi^\mu_x(t,x)$ are bounded:

▶ **Lemma 31** ([1, Lemma 6.4])**.** *For every $\mu\in\mathscr{L}$, $\epsilon>0$, and $j\ge 2$, there exists $K = K(\mu,j,\epsilon) > 0$ such that the jth derivative in x of Φ^μ is within $[-K,K]$ for all $t\in[0,1-\epsilon]$ and $x\in\mathbb{R}$. In other words, $|\frac{\partial^j}{\partial x^j}\Phi^\mu(t,x)|\le K$ for all $t\in[0,1-\epsilon]$ and $x\in\mathbb{R}$.*

By induction and using Lemma 31, x^ℓ_i and $\Phi^{\mu_*}_{xx}(t,x^\ell_i)$, and $x^\ell_{i\to a}$ and $\Phi^{\mu_*}_{xx}(t,x^\ell_{i\to a})$ are Lipschitz in the messages $\{u^s_i\}_{s\le\ell}$ and $\{u^s_{i\to a}\}_{s\le\ell}$, respectively. So we can apply Theorem 29:

▶ **Proposition 32.** *Assume Property 2. Choose $1\le\ell\le L$ and any variable i. Then for every integer $k\ge 1$, we have*

$$\mathbb{E}[\Phi^{\mu_*}_{xx}(\delta\ell, x^\ell_i)^k] = \mathbb{E}[\Phi^{\mu_*}_{xx}(\delta\ell, X^\delta_\ell)^k] + o_d(1)\,.$$

We now choose the nonlinearities:

$$A^\ell_i = \Phi^{\mu_*}_{xx}(\delta\ell, x^\ell_i)\cdot\sqrt{\frac{\delta}{\nu_{\ell+1}\cdot\mathbb{E}[\Phi^{\mu_*}_{xx}(t,x^\ell_i)^2]}}\,, \tag{5.5}$$

$$A^\ell_{i\to a} = \Phi^{\mu_*}_{xx}(\delta\ell, x^\ell_{i\to a})\cdot\sqrt{\frac{\delta}{\nu_{\ell+1}\cdot\mathbb{E}[\Phi^{\mu_*}_{xx}(t,x^\ell_{i\to a})^2]}}\,. \tag{5.6}$$

These nonlinearities behave as we promised earlier. First of all, by Lemma 31, the nonlinearities are uniformly bounded for all d (presumed in Figure 2). Furthermore, by construction, the second moment of the nonlinearities satisfy Property 2. Finally, the nonlinearities do satisfy Property 1:

▶ **Proposition 33.** *Equations* (5.5) *and* (5.6) *satisfy Property 1. That is, for every* $m \in \mathbb{N}$, *we have* $\mathbb{E}[|A_i^\ell - A_{i\to a}^\ell|^m] = O_d(\frac{1}{d^{m/2}})$.

Note that with this choice of nonlinearities, the value of the spin $\boldsymbol{z}^\ell$ differs slightly from Equation (5.4) in the large degree limit. By Figure 2, the spin value evolves as

$$\widetilde{Z}_{\ell+1}^\delta - \widetilde{Z}_\ell^\delta = B_{\ell+1} \cdot \frac{\sqrt{\delta} \cdot \Phi_{xx}^{\mu_*}(\delta\ell, X_\ell^\delta)}{\sqrt{\mathbb{E}[\Phi_{xx}^{\mu_*}(\delta\ell, X_\ell^\delta)^2]}}, \quad \widetilde{Z}_0^\delta \sim N(0, \delta)\,.$$

However, the difference between Z_ℓ^δ and $\widetilde{Z}_\ell^\delta$ is inconsequential for small enough δ:

▶ **Proposition 34** ([1, Equation 5.7])**.** *Suppose Assumption 1 holds. Then there exist* $\delta_0, C > 0$ *such that for every* $\delta < \delta_0$ *and* $\ell < \frac{1}{\delta}$, *we have*

$$\left| \frac{\xi'((\ell+1)\delta) - \xi'(\ell\delta)}{\delta} \cdot \mathbb{E}[\Phi_{xx}^{\mu_*}(\delta\ell, X_\ell^\delta)^2] - 1 \right| \le C\sqrt{\delta}\,.$$

5.2 Achieving the extended Parisi value

Here we show that Theorem 26 achieves a value affine to ALG_ξ, the infimum of a Parisi minimization problem. First, note that the expectation $\mathbb{E}[A_i^\ell(u_i^{\ell+1})^2]$ can be simplified at large degree:

▶ **Proposition 35.** *For every variable* i *and* $0 \le \ell \le L-1$, *we have*

$$\left|\mathbb{E}\left[A_i^\ell(u_i^{\ell+1})^2\right] - \nu_{\ell+1} \cdot \mathbb{E}\left[A_i^\ell\right]\right| = O_d\left(\frac{1}{\sqrt{d}}\right).$$

After the large degree limit, we take a second limit sending the timestep to 0; i.e. $\delta \to 0$ or $\frac{1}{\delta} \to \infty$. As a result, the finite difference describing $x_i^\ell, x_{i\to a}^\ell$ converges to Equation (5.1), and the finite difference describing $z_i^\ell, z_{i\to a}^\ell$ converges to Equation (5.2). We bound the error when making this approximation, using a statement from [1]:[16]

▶ **Proposition 36** ([1, Proposition 5.3], see also [3, Proposition 4.8])**.** *Suppose Assumption 1 holds. Then there exists a coupling between* $(X_t, Z_t)_{t\ge 0}$ *and* $(X_\ell^\delta, \widetilde{Z}_\ell^\delta)_{\ell\in\mathbb{N}}$ *and a constant* $C > 0$ *such that for every small enough* δ *and* $\ell \le \frac{1}{\delta}$, *we have* $\mathbb{E}[|X_{\delta\ell} - X_\ell^\delta|^2] \le C\delta$ *and* $\mathbb{E}[|Z_{\delta\ell} - \widetilde{Z}_\ell^\delta|^2] \le C\delta$.

We are now in a position to simplify Theorem 26:

▶ **Theorem 37.** *Suppose Assumption 1 holds. Then for all* $\epsilon > 0$, *there exist* $d_0 \in \mathbb{N}$ *and* $\delta_0 > 0$ *such that for all* $d \ge d_0$ *and* $0 < \delta \le \delta_0$,

$$\frac{1}{\alpha n}\sum_{a\in E}\mathbb{E}\left[f(\boldsymbol{z}_{\partial a}^L)\right] \ge \mathbb{E}[f] + \frac{\mathsf{ALG}_\xi - \epsilon}{\sqrt{\alpha}}\,.$$

[16] The curious reader may refer to Table 1 to convert between the notation here and in [1].

Proof. Recall that $\alpha = \frac{d}{r}$ is the clause density. By Theorem 26 and Proposition 35, we have

$$\frac{1}{\alpha n}\sum_{a\in E}\mathbb{E}\left[f(\boldsymbol{z}^L_{\partial a})\right] = \mathbb{E}[f] + \frac{r}{\sqrt{d}}\cdot\sum_{\ell=0}^{L-1}\left(\frac{1}{n}\sum_{i\in V}\nu_{\ell+1}\cdot\mathbb{E}\left[A_i^\ell\right]\right) + O_d\left(\frac{1}{d}\right).$$

Let $\Delta_{\ell,i} \stackrel{\text{def}}{=} \nu_{\ell+1}\cdot\mathbb{E}[A_i^\ell]$. At large enough d, Proposition 32 and Proposition 34 imply the following for all i:[17]

$$\Delta_{\ell,i} = \nu_{\ell+1}\cdot\mathbb{E}[\Phi^{\mu_*}_{xx}(\delta\ell, X^\delta_\ell)]\cdot\sqrt{r}(1+O_{\frac{1}{\delta}}(\sqrt{\delta})) + o_d(1).$$

By definition of $\nu_{\ell+1}$,

$$\Delta_{\ell,i} = \frac{\xi'(\delta(\ell+1))-\xi'(\delta\ell)}{\sqrt{r}}\cdot\mathbb{E}[\Phi^{\mu_*}_{xx}(\delta\ell, X^\delta_\ell)]\cdot(1+O_{\frac{1}{\delta}}(\sqrt{\delta})) + o_d(1).$$

By Proposition 36 and Lipschitzness of $\Phi^{\mu_*}_{xx}(t,x)$ in x, using the continuous $X_{\delta\ell}$ introduces multiplicative error:

$$\Delta_{\ell,i} = \frac{\xi'(\delta(\ell+1))-\xi'(\delta\ell)}{\sqrt{r}}\cdot\mathbb{E}[\Phi^{\mu_*}_{xx}(\delta\ell, X_{\delta\ell})]\cdot(1+O_{\frac{1}{\delta}}(\sqrt{\delta}))^2 + o_d(1).$$

Putting it all together,

$$\begin{aligned}
&\frac{1}{\alpha n}\sum_{a\in E}\mathbb{E}\left[f(\boldsymbol{z}^L_{\partial a})\right]\\
&= \mathbb{E}[f] + \frac{r}{\sqrt{d}}\cdot\sum_{\ell=0}^{L-1}\left(\frac{1}{n}\sum_{i\in V}\Delta_{\ell,i}\right) + O_d\left(\frac{1}{d}\right)\\
&= \mathbb{E}[f] + \sqrt{\frac{r}{d}}\cdot\sum_{\ell=0}^{L-1}(\xi'(\delta(\ell+1))-\xi'(\delta\ell))\cdot\mathbb{E}[\Phi^{\mu_*}_{xx}(\delta\ell, X_{\delta\ell})]\cdot(1+O_{\frac{1}{\delta}}(\sqrt{\delta}))^2 + o_d\left(\frac{1}{\sqrt{d}}\right)\\
&= \mathbb{E}[f] + \frac{1}{\sqrt{\alpha}}\cdot\sum_{\ell=0}^{L-1}(\xi'(\delta(\ell+1))-\xi'(\delta\ell))\cdot\mathbb{E}[\Phi^{\mu_*}_{xx}(\delta\ell, X_{\delta\ell})]\cdot(1+o_{\frac{1}{\delta}}(1)) + o_d\left(\frac{1}{\sqrt{d}}\right).
\end{aligned}$$

Applying Lemma 30 with large enough d and small enough δ proves the result. ◀

5.3 Rounding

We have nearly achieved our objective. However, the entries of $\boldsymbol{z}^L$ are *continuous*, not in $\{\pm 1\}$. We account for this by *rounding* each entry of $\boldsymbol{z}^L$ without significant impact to the value of the algorithm.

Let $\mathrm{trnc}:\mathbb{R}\to[-1,1]$ be the truncation function, defined by

$$\mathrm{trnc}(x) = \begin{cases} -1 & \text{if } x < -1,\\ x & \text{if } -1 \le x \le 1,\\ 1 & \text{if } x > 1.\end{cases}$$

We use a randomized rounding procedure R that acts independently on each vertex i: it outputs $+1$ at vertex i with probability $\frac{1+\mathrm{trnc}(z_i^L)}{2}$, and -1 with probability $\frac{1-\mathrm{trnc}(z_i^L)}{2}$. The

[17] Note that an error bound in Proposition 32 could improve the scaling beyond $o_d(1)$.

average value of the algorithm is unchanged when replacing $\mathrm{trnc}(\boldsymbol{z}^L)$ with $R(\boldsymbol{z}^L)$.[18] This is because averaging over the randomness in R, we have for every set $S \subseteq V$,

$$\mathbb{E}\left[\prod_{i\in S} R(z_i^L)\right] = \prod_{i\in S} \mathrm{trnc}(z_i^L)\,.$$

We also compare the average value of the algorithm when replacing $\boldsymbol{z}^L$ with $\mathrm{trnc}(\boldsymbol{z}^L)$; i.e. the average value of $\mathbb{E}[f(\mathrm{trnc}(\boldsymbol{z}_{\partial a}^L))] - \mathbb{E}[f(\boldsymbol{z}_{\partial a}^L)]$ across factors a. Intuitively, trnc has no effect because each entry of $\boldsymbol{z}^L$ is almost surely bounded by 1 after taking the limits $d \to \infty$ and $\delta \to 0$:

▶ **Lemma 38** ([1, Lemma 6.2 and 6.5]). *Suppose Assumption 1 holds with minimizer $\mu_* \in \mathscr{L}$, and consider the martingale Z_t in Equation (5.2) corresponding to μ_*. Then for all $t \in [0,1]$, $|Z_t| \le 1$ almost surely.*

For each factor a, the difference $\mathbb{E}[f(\mathrm{trnc}(\boldsymbol{z}_{\partial a}^L))] - \mathbb{E}[f(\boldsymbol{z}_{\partial a}^L)]$ can be split into at most 2^r terms of the form

$$\mathbb{E}\left[\left(\prod_{i\in S}\mathrm{trnc}(z_i^L)\right) - \left(\prod_{i\in S} z_i^L\right)\right],$$

for some set $S \subseteq \partial a$ where $|S| \ge 2$ (since f has no linear terms). We show that each of these terms is at most $\delta \cdot O_d(\frac{1}{\sqrt{d}})$, where δ is the timestep of the algorithm.

Arbitrarily *order* the elements of set S; then the above term can be written as

$$\begin{aligned}&\mathbb{E}\left[\left(\prod_{i\in S}\mathrm{trnc}(z_i^L)\right) - \left(\prod_{i\in S} z_i^L\right)\right]\\ &= \sum_{\kappa=1}^{|S|}\mathbb{E}\left[\left(\prod_{\iota=1}^{\kappa-1}\mathrm{trnc}(z_{S[\iota]}^L)\right)\left(\mathrm{trnc}(z_{S[\kappa]}) - z_{S[\kappa]}\right)\left(\prod_{\iota=\kappa+1}^{|S|} z_{S[\iota]}^L\right)\right].\end{aligned}$$

We show that the average value of such terms across factors a is negligible with d as $n \to \infty$.

▶ **Proposition 39.** *For every integer $L \ge 1$, clause a, and disjoint subsets $T_1, T_2 \subseteq \partial a$ such that $T_1 \cup T_2 \ne \varnothing$, we have*

$$\mathbb{E}\left[\left(\Big(\prod_{i\in T_1} z_i^L\Big)\prod_{i\in T_2}\mathrm{trnc}(z_i^L) - \Big(\prod_{i\in T_1} z_{i\to a}^L\Big)\prod_{i\in T_2}\mathrm{trnc}(z_{i\to a}^L)\right)^2\right] = O_d\left(\frac{1}{d}\right).$$

▶ **Proposition 40.** *Fix an integer $L \ge 1$ and variable i. For each $a \in \partial i$, fix disjoint subsets $T_{1,a}, T_{2,a} \subseteq \partial a \backslash i$ with $T_{1,a} \cup T_{2,a} \ne \varnothing$. Then*

$$\left|\mathbb{E}\left[(z_i^L - \mathrm{trnc}(z_i^L))\cdot\frac{1}{d}\sum_{a\in\partial i}\prod_{j\in T_{1,a}} z_j^L \prod_{j\in T_{2,a}}\mathrm{trnc}(z_j^L)\right]\right| = O_d\left(\frac{\mathbb{E}[(z_i^L - \mathrm{trnc}(z_i^L))^2]^{1/2}}{\sqrt{d}}\right).$$

Although this is enough to show that the difference

$$\frac{1}{\alpha n}\sum_{a\in E}\left(\mathbb{E}[f(\mathrm{trnc}(\boldsymbol{z}_{\partial a}^L))] - \mathbb{E}[f(\boldsymbol{z}_{\partial a}^L)]\right) = O_d(\tfrac{1}{\sqrt{d}}),$$

we want this quantity to be negligible even among terms of size $O_d(\frac{1}{\sqrt{d}})$. We show this as the timestep δ also goes to 0.

[18] For convenience, we use the notation $\mathrm{trnc}(\boldsymbol{z}^L)$ or $R(\boldsymbol{z}^L)$ to apply trnc or R entrywise on $\boldsymbol{z}^L$.

▶ **Proposition 41.** *Suppose Assumption 1 holds. Then for every integer $L \geq 1$, there is a C such that*

$$\frac{1}{n}\sum_{i\in V}\mathbb{E}[(z_i^L - \mathrm{trnc}(z_i^L))^2] \leq C\delta + o_d(1)\,.$$

Proof. Consider the pseudo-Lipschitz function $\psi(x) \stackrel{\text{def}}{=} (x - \mathrm{trnc}(x))^2$. By Theorem 29,

$$\mathbb{E}[\psi(z_i^L)] = \mathbb{E}[\psi(\widetilde{Z}_L^\delta)] + o_d(1)\,.$$

We consider the behavior as δ goes to zero. Since ψ is bounded by a quadratic function,

$$\mathbb{E}[\psi(\widetilde{Z}_L^\delta)] \leq \mathbb{E}[|\psi(Z_{\delta L})|] + \mathbb{E}[|\widetilde{Z}_L^\delta - Z_{\delta L}|^2]\,.$$

The first term is zero by Lemma 38. The statement follows by Proposition 36. ◀

We combine these statements with Theorem 37 to achieve our goal:

▶ **Theorem 42.** *Suppose Assumption 1 holds. Fix a factor a. Then for all $\epsilon > 0$, there exist $d_0 \in \mathbb{N}$ and $\delta_0 > 0$ such that for all $d \geq d_0$ and $0 < \delta \leq \delta_0$,*

$$\frac{1}{\alpha n}\sum_{a\in E}\mathbb{E}\left[f(R(\boldsymbol{z}_{\partial a}^L))\right] \geq \mathbb{E}[f] + \frac{\mathsf{ALG}_\xi - \epsilon}{\sqrt{\alpha}}\,.$$

We conclude this section by showing the value of the algorithm *concentrates* around its mean. This implies that the algorithm is not only good on average, but it finds a good solution with high probability as $n \to \infty$.

▶ **Proposition 43** (Generalization of [3, Lemma 4.10])**.** *Fix a integer $L \geq 1$. Then there exists a constant C such that for all $t \geq 0$,*

$$\mathbb{P}\left(\left|\frac{1}{\alpha n}\sum_{a\in E}\left(f(R(\boldsymbol{z}_{\partial a}^L)) - \mathbb{E}[f(R(\boldsymbol{z}_{\partial a}^L))]\right)\right| \geq t\right) \leq Ce^{-nt^2/(2C)}\,.$$

Proof. Partition the nodes of the graph G into $C = C(L)$ sets $\{W_1, \dots, W_C\}$ such that any two nodes $i, j \in W_q$ have distance at least $2L + 3$. Then the value $\sum_{a\in E}\left(f(R(\boldsymbol{z}_{\partial a}^L)) - \mathbb{E}[f]\right)$ can be split into C sums as in

$$\Delta \stackrel{\text{def}}{=} \sum_{a\in E}\left(f(R(\boldsymbol{z}_{\partial a}^L)) - \mathbb{E}[f]\right) = \frac{1}{r}\sum_{i\in V}R(z_i^L)\sum_{a\in\partial i}\mathsf{D}_{i;a}f(R(\boldsymbol{z}_{\partial a}^L)) = \frac{1}{r}\sum_{\iota=1}^{C}\Delta_\iota\,,$$

where $\Delta_\iota \stackrel{\text{def}}{=} \sum_{i\in W_\iota}R(z_i^L)\sum_{a\in\partial i}\mathsf{D}_{i;a}f(R(\boldsymbol{z}_{\partial a}^L))$. By a union bound, $\mathbb{P}((\Delta - \mathbb{E}[\Delta]) \geq t\alpha n) \leq \sum_{\iota=1}^{C}\mathbb{P}((\Delta_\iota - \mathbb{E}[\Delta_\iota]) \geq tdn/C)$. Since each Δ_ι is a sum of up to n independent variables each bounded by d, this probability is at most $C\exp\left(-\frac{(tdn/C)^2}{8nd^2}\right) = C\exp\left(-\frac{nt^2}{8C^2}\right)$. ◀

6 Open questions

The first challenge is to either prove Assumption 1, or mathematize the continuity argument that using a near-minimizer $\widetilde{\mu}_* \in \mathscr{L}_\xi$ in the algorithm incurs negligible error. This would address the chief concern of Corollary 7.

As mentioned before, our algorithm assumes the CSP predicate f has no linear terms; e.g. f cannot represent k-SAT. We expect that a preprocessing step fixes this issue, similar to [79]'s improvement to [1].

Current techniques obstructing overlap-concentrated algorithms [50, 55] are restricted to *even* Ising spin glasses and CSP predicates f. However, a recent technique [47] on spherical spin glasses seems to circumvent this issue. Applying this technique to Ising spin glasses could lead to obstructions beyond even models, which automatically transfer to $\mathsf{CSP}_f(\alpha)$ by [55]. We suspect that message-passing is optimal among *overlap-concentrated* algorithms for *all* Ising spin glasses and CSP predicates f.

Furthermore, this work deepens a curious connection between $\mathsf{CSP}_f(\alpha)$ and Ising spin glasses [26, 55]. For example, this algorithm and the one in [1] are very similar, and achieve the same performance up to affine shift. In fact, the same is true for the QAOA for any constant depth and choice of hyperparameters [11, 12]! (This is known for monomial predicates f but likely extends to all predicates.) Perhaps there is a way to characterize the equivalence in energy landscape that explains why some algorithms "can't see the difference" between the two models. This equivalence extends beyond overlap gap phenomena, which are defined only at near-optimal energies.

It seems that understanding optimal algorithms for $\mathsf{CSP}_f(\alpha)$ without asymptotics in α requires new techniques.
